ABSTRACT: Selenium (Se) biofortification of barley is a suitable strategy to increase the Se concentration in grain. In the present paper, the suitability of this Se-biofortified grain for making Se-enriched beer is analyzed. The aim of the present study was to evaluate the effect of different Se fertilizer doses (0, 10, and 20 g of Se ha^{-1}) and forms (sodium selenate or sodium selenite) on the Se loss during the malting and brewing processes and Se speciation in grain, malt, wort, and beer. Samples were analyzed using inductively coupled plasma−mass spectrometry (ICP−MS) and high-performance liquid chromatography (HPLC)−ICP−MS for total Se and speciation. Mashing−lautering was the process with the greatest Se loss (83.8%). After malting and brewing, only 7.3% of the initial Se was retained in beer, mainly in selenite form. Even so, the fertilizer application of sodium selenate at 20 g ha^{-1} increased the total Se concentration almost 6-fold in the final beer in comparison to the use of grain derived from unfertilized barley. The present paper provides evidence that the use of Se-biofortified barley grain as a raw material to produce Se-enriched beer is possible, and the results are comparable to other methods in terms of efficiency.

KEYWORDS: *selenium, speciation, beer, brewing, HPLC−ICP−MS*

INTRODUCTION

Selenium (Se) is an essential trace element for humans and animals. An adequate Se intake has beneficial effects in humans, such as prevention of several cancers, benefits in immune system,[1] and some protection against the aging process and cardiovascular diseases.[2] According to Elmadfa,[3] the European recommended dietary allowance (RDA) of Se for humans is about 55 μg of Se day^{-1}, slightly lower than the current Se intake recommendation of 1 μg of Se kg^{-1} of body weight day^{-1} reported by the Committee on the Medical Aspects of Food Policy (COMA).[4] According to Roman Viñas et al.,[5] there is an inadequate intake of Se in more than 20% of the European population. In this context, the Se intake should be increased to reach the recommended values. Several strategies to remedy Se deficiency have been tried. Because yeast (*Saccharomyces cerevisiae* Meyen ex E. C. Hansen) has been shown to accumulate and transform inorganic Se to organo-Se compounds,[6] Se-enriched yeast supplements have been widely used.[7] Another strategy to remedy the Se-deficient intake is the use of Se-enriched common dietary foodstuff obtained by means of Se biofortification of crops.[8] Cereals constitute a major source of Se because they are consumed in large amounts in many human diets. Among cereals, two-rowed barley (*Hordeum vulgare* L. ssp. *distichum*) is one of the most ancient and widely distributed crops. Currently, about two-thirds of barley crops are used for animal feed, approximately one-third for malting and about 2% for human food directly. Spain produces annually more than 8 million tons of barley grain, and annual consumption is approximately 78 kg of beer per capita.[9]

Two-rowed barley has already demonstrated to be a suitable candidate to be included in Se biofortification programs under Mediterranean conditions.[10] However, that study was focused on the Se accumulation in the grain, but very scarce information is found regarding the effect of the biofortification in the final Se concentration in beer after the manufacturing process. At this regard, only a study carried out in Australia by Gibson et al.[11] has been found to deal with the use of Se-enriched barley grain by crop biofortification to obtain Se-enriched beer. However, in that study, the fertilizer application rates were much higher than those recommended in the literature for barley[10] and only total Se by inductively coupled plasma−mass spectrometry (ICP−MS) was analyzed, without analyzing the chemical forms of this Se. Other authors[12,13] proposed a different approach to increase the Se concentration in beer and other beverages, such as white wine. This procedure consisted of adding sodium selenite during the beer-making process directly to the fermentation medium to use the capacity of yeast to accumulate and biotransform Se. Finally, Gibson et al.[11] also proposed the Se biofortification of the grain during the malting process. In that case, the inorganic form of Se (especially sodium selenate) was added to the water used in the germination stage of the grain.

To obtain precise information about the Se benefit, it is important to know not only the amount of Se in beer but also the chemical forms in which Se is presented. According to Thiry et al.,[14] the organic Se forms, such as SeMet (selenomethionine), are the most efficient in the long term to prevent Se deficiency. Conversely, inorganic Se forms give a more rapid response to an acute shortage of Se, but they have a higher risk of becoming toxic in the long term. Several authors[15,16] have found differences in Se bioavailability in

Table 1. Percentage (Mean ± Standard Error) of Total ICP Selenium Loss, Related to the Total Se Remaining from the Previous Process, in Each Partial Process (Malting, Mashing−Lautering, and Fermentation−Maturation) and in the Whole Malting−Brewing Process, in Relation to the Dose and Form of Se in the Fertilizer[a]

treatment	malting	mashing−lautering	fermentation−maturation	whole brewing
0 g ha^{-1}	1.8 ± 2.5	76.8 ± 11.6	54.3 ± 18.0	88.6 ± 4.2
10 g of Se ha^{-1} selenate	11.9 ± 9.8	84.5 ± 0.6	58.0 ± 8.2	94.2 ± 1.5
20 g of Se ha^{-1} selenate	5.5 ± 7.7	84.6 ± 2.1	55.9 ± 2.4	93.6 ± 1.1
10 g of Se ha^{-1} selenite	3.3 ± 4.6	85.8 ± 2.4	45.4 ± 8.7	92.4 ± 0.6
20 g of Se ha^{-1} selenite	2.9 ± 3.2	87.2 ± 0.3	58.3 ± 5.0	94.8 ± 0.6
% average	5.1 ± 2.0 C	83.8 ± 8.8 A	54.4 ± 3.0 B	

[a]Letters indicate significant ($p < 0.05$) differences in the Se losses between the different brewing processes according to ANOVA and Fisher's LSD test. For each process, the one-way ANOVA on the effect of the treatment on the Se loss showed no significant effect ($p > 0.05$).

relation to different food sources, being higher in wheat (83%) than in garlic (78%), fish (56%), or mushrooms (5%). It is also important to distinguish between absorption, availability, and activity. While most dietary selenium is absorbed efficiently, the retention of organic forms for further bioactivity is higher than that of inorganic forms.[17] The U.S. Food and Nutrition Board Report[18] suggested that more than 90% of SeMet is absorbed; SeCys (selenocysteine) appears to be absorbed very well; although almost 100% of selenate is absorbed, a significant fraction is lost in the urine; and although 50% of selenite is absorbed, it shows better retention than selenate in the organism. It is already known that SeMet is the predominant form of selenium (56−83%) in the grain of many cereals, while other selenocompounds occur in smaller proportions (selenate, 12−19%; selenocysteine, 4−12%; Se-methyl-selenocysteine, 1−4%; and others, 4−26%).[19] However, to our knowledge, how Se fertilization affects such speciation in the barley grain and how the manufacturing process affects such speciation have not yet been studied.

Therefore, to advance the study of the two-rowed barley as a product able to increase the available Se levels in the organism and also to test beer as a "functional food", the aim of the present study was (1) to evaluate the effect of different Se doses and Se fertilizer forms on the total Se losses during the manufacturing processes (malting and brewing) and (2) to evaluate the influence of those Se doses and Se forms on the chemical speciation of Se accumulated in the different products derived from the manufacturing process (grain, malt, wort, and beer).

MATERIALS AND METHODS

Samples and Malting and Brewing Process. The barley grain used for malting and brewing in the present study was obtained from a previous Se biofortification field experiment.[10] The experiment had been conducted in the growing season 2011/2012, in Badajoz, southern Spain, on a Xerofluvents soil under rainfed Mediterranean conditions. The experiment was designed as a split plot arrangement with four repetitions, including two forms of Se [sodium selenate (Na_2SeO_4) and sodium selenite (Na_2SeO_3)], one per plot, and within the plot, three application doses (0, 10, and 20 g of Se ha^{-1} diluted in 3 L of water) were randomly distributed. The crop area for each treatment was 15 m^2 (3 × 5 m). Barley grain was harvested in early June. A more detailed description of the experiment is described by Rodrigo et al.[10]

Malting and brewing were carried out in our lab according to the guidelines by local brewers. Five barley grain samples (600 g), one per treatment obtained by mixing the four repetitions, were taken. Malt was obtained by germinating the barley seeds (20 °C, 100% humidity) in an incubator (GER-700, RADIBER, S.A., Barcelona) until the sprout reached $^2/_3$ of the seed size (after approximately 30 h), then air-dried for 24 h at room temperature, and kilning at 55 °C in an oven for a further 24 h. Roots were manually removed to obtain clean malt that was milled in a corundum mill (WolfgangMOC, Germany).

Brewing consisted of the following main processes: mashing, lautering, fermentation, and maturation. The mashing process was performed in 2 L of distilled water per sample for 1 h at 54 °C, followed by 1 h at 67 °C. For lautering, wort was separated from spent grains with a laboratory sieve and then boiled for 90 min. After boiling, wort was quickly cooled and filtered. For fermentation, 2 g of dried *S. cerevisae* yeast (SaftBrew T-58, Fermentis, Lesaffre Group, France) was added to wort. After a 9 day fermentation period, yeast was removed from the container bottom, and the resulting beer was left to mature for 20 days. Aliquots of grain, malt, wort, and beer were taken at the end of each process to evaluate the Se losses during malting, mashing−lautering, and fermentation−maturation.

Measurement of Total Se with ICP−MS and Se Speciation with High-Performance Liquid Chromatography (HPLC)−ICP−MS and Data Presentation. For each sample of each fraction (grain, malt, wort, and beer), total Se was determined by ICP−MS (Agilent 7500ce, Agilent Technologies, Palo Alto, CA) operating in the hydrogen gas mode. This analytical method was developed by the Elemental and Molecular Analysis Service of the University of Extremadura (Spain). Previously 1 g per sample was digested with ultrapure concentrated nitric acid (2 mL) and 30% (w/v) hydrogen peroxide (2 mL) using a closed-vessel microwave digestion protocol (Mars X, CEM Corp., Matthews, NC) and diluted to 25 mL with ultrapurified water.[20] Sample vessels were thoroughly washed with acid before use. For quality assurance, a blank and a standard (tomato leaf material, NIST 1573a) were included in each batch of samples. All of the results were reported on a dry weight basis.

Speciation was carried out by HPLC−ICP−MS following proteolytic digestion with protease and lipase[21] using an Agilent 1050 HPLC pump and a Hamilton PRPX100 250 × 4 mm column (Cole-Parmer, London, U.K.). It was performed following the methodology proposed by Li et al.[22] This method was slightly modified in the present study using 40 mM NH_4NO_3 instead of 50 mM NH_4NO_3 in the mobile phase, because it was found to be more effective. ICP−MS monitored m/z 78 and 80, with hydrogen flow into the octopole reaction cell of 4 mL min^{-1}. Peak areas for quoted species were measured, percentage value for a particular peak calculated relative to the total area under the chromatogram, and compared to the total Se content. Percentages of each fraction, selenomethionine (SeMet), selenite, selenate, oxidized selenomethionine (SeMetO), and others (unknown fraction), were calculated in each step of the brewing process. Three replicates from every fraction (grain, malt, wort, and beer) of the 10 g ha^{-1} sodium selenate treatment were analyzed to assess technical repeatability.

Statistical Analysis. In each manufacturing process (malting, mashing−lautering, and fermentation−maturation) as well as in the whole malting and brewing process, the effect of the fertilizer treatment (0, sodium selenate at a dose of 10 and 20 g ha^{-1}, and sodium selenite at a dose of 10 and 20 g ha^{-1}) and the manufacturing process (malting, mashing−lautering, and fermentation−maturation) on the percentage losses of total Se (determined by ICP−MS) was statistically analyzed by two-way analysis of variance (ANOVA) and multiple comparison tests [Fisher's least significant difference (LSD)

[a]Se species are presented as a percentage of total Se HPLC. In the total ICP Se column, mean ± standard error values are presented. Letters indicate significant ($p < 0.05$) differences among treatments for each product fraction according to ANOVA and Fisher's LSD test. Technical repeatability of the HPLC measurements was determined for the 10 g of Se ha^{-1} sodium selenate samples in each product fraction and expressed as the average ± standard error.

test]. The same effect of the fertilizer treatment was also analyzed by one-way ANOVA and LSD test on the total Se (determined by ICP–MS) accumulated in each product fraction (grain, malt, wort, and beer) obtained during the malting and brewing processes.

RESULTS

The two-way ANOVA performed to evaluate the effect of the fertilizer treatment and the manufacturing process on the losses of total Se resulting from the different malting and brewing processes showed a significant effect of the process [degrees of freedom (df) = 2; F statistic (F) = 284.42; $p < 0.001$] but not of the treatment (df = 4; F = 1.03; p = 0.426) nor the interaction (df = 8; F = 0.58; p = 0.781). For this reason, the multiple comparison test between the three different processes was carried out with the pooled data of the different treatments. The highest Se losses (obtained by ICP–MS) occurred significantly during the mashing–lautering processes, with a loss of 83.8% on average (Table 1). Although significantly lower, important Se losses were also observed during fermentation–maturation, with a loss percentage of 54.4%, in relation to the Se remaining after mashing–lautering. During the malting process, only 5.1% of Se was lost. On average, during the whole malting and brewing process, the loss of total ICP Se was 92.7%. As the ANOVA showed, similar Se loss patterns were observed in the different Se fertilization treatments used during barley cultivation (Table 1).

The fertilization treatment also significantly affected the total ICP–MS Se obtained in the different product fractions (grain, malt, wort, and beer) derived from the manufacturing process (Table 2). In the grain, the fertilization treatment significantly increased the Se concentration in comparison to controls. Sodium selenate was the most effective fertilizer form in boosting Se in the grain, and the higher fertilizer dose gave the highest Se accumulation in the grain (Table 2). With regard to malt, the pattern was similar, although no differences were found between the two doses of sodium selenite. In the wort, which had much lower Se concentrations than grain because of the already mentioned losses during the malting and mashing–lautering processes, fertilization with sodium selenate was the only treatment that significantly increased the Se concentration but no difference between doses. In the final beer, again the application of sodium selenate as a Se fertilizer was the only form able to increase the total Se in the manufactured product. A clear effect of the dose was observed, with the highest dose giving the highest Se concentration (Table 2).

On the basis of the Se speciation analysis (one example of a malt sample is given in Figure 1), the results obtained are shown in Table 2. The technical repeatability of the procedure, which can be observed in the total Se (HPLC) column in Table 2, can be considered adequate, because the relative standard error was less than 10% (n = 3) in almost all of the cases. Only

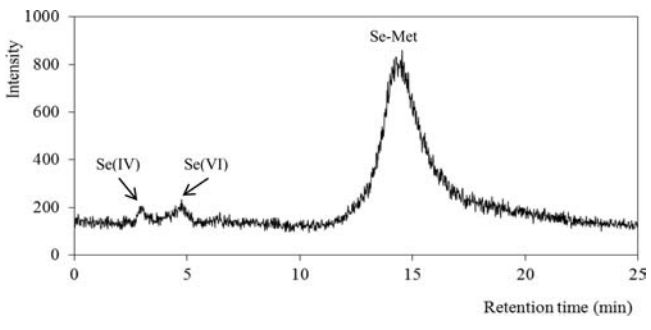

Figure 1. Se species of a malt sample separated by anion-exchange–HPLC–ICP–MS. The chromatogram was monitored at Se m/z 78.

dx.doi.org/10.1021/jf500793t | J. Agric. Food Chem. 2014, 62, 5948–5953

in the case of malt, it was a little bit higher (around 13%). In the grain, Se was mainly accumulated as SeMet, regardless of the chemical Se form used in the crop fertilization, although SeMet concentrations were higher when sodium selenate was used (on average 90.6%) in comparison to sodium selenite (on average 70.9%) and controls (on average 59.0%). The dose had a positive effect on the SeMet concentration in grain, only when Se was applied as sodium selenite but not when Se was applied as sodium selenate. In grain, selenite was also recorded, especially when Se was applied as sodium selenite (on average 29.2%). No other Se species were detected in the grain. In the control grain, the pattern was quite similar to that observed for the lower dose of selenite fertilizer, although the percentage of selenite was a little higher in detriment of the percentage SeMet. According to the results, the malting process did not have any substantial effect on the distribution pattern of the different Se species proportions (Table 2). In this case, a very small percentage of SeMetO (a SeMet oxidation product) was observed, and several unknown Se species occurred when the sodium selenate fertilizer was used, which slightly decreased the percentage of SeMet.

Important changes took place after the mashing–lautering process. In wort derived from non-Se-enriched barley and barley fertilized with sodium selenite, regardless of the dose, only the selenite form was detected. In wort from barley fertilized with sodium selenate, the proportion of SeMet was also substantially reduced but around 60% of SeMet was still recorded in these samples. This progressive removal of the SeMet fraction was completed after the fermentation–maturation processes. In almost all of the cases, Se measured in beer was in the selenite form. Only when barley was fertilized with the highest dose of sodium selenate, 37.0% of Se detected was unknown and the rest was in the selenite form.

DISCUSSION

The Se loss recorded in the present paper during the malting process (around 5% on average) was lower than the approximately 12–20% obtained by Gibson et al.[11] in their study dealing with the use of barley grain biofortified with Se during malting and brewing. Those authors determined that the amount of Se lost in this process was very similar to the amount of Se recorded in the rootlets. Therefore, the removal of rootlets from malt might explain in a high percentage the Se loss during this process. If the germination step had been stopped before in our study, then the rootlets should be smaller, and consequently, they might contain a lower amount of Se, which might explain the differences between both studies. However, not all of the Se loss during this process can be explained with the removal of rootlets. The rest of the Se loss observed during the malting process could be explained by Se phytovolatilization in the germination step. Grant et al.[23] found that plants transform the different Se forms during their metabolic activity. During germination and root development, part of Se contained in grain, mainly in the form of SeMet, may be transformed to selenomethylmethionine (SeMMet), which is the principal precursor of the volatile compound, dimethylselenide (DMSe). However, the slightly smaller proportion of SeMet that we found after malting might be explained in part by the transformation and volatilization hypothesis explained above but could also be a consequence of the transformation of SeMet to SeMetO, because easy oxidation of SeMet has already been demonstrated.[13] Even so, in our study carried out on barley, most Se recorded in grain and malt after biofortification has been found to be in the SeMet form, similar to findings in the grain of bread-making wheat,[24] hard wheat,[25] rice,[22] and chickpea.[26]

The highest loss of total Se was clearly produced during the mashing and lautering (a Se loss of around 85% on average). This Se loss was higher than that found in the same process in the already mentioned study by Gibson et al.[11] In that study, the Se loss was dependent upon the capacity of the pilot brew used. They used 20 and 500 L pilot breweries, which produced Se losses during mashing–lautering of about 71.5 and 64%, respectively. Therefore, taken into account that there appears to be a link between beer capacity (or brewing scale) and Se loss, the lab scale (in 2 L volumes) used in the present paper might explain the higher Se loss found in our study. With regard to the Se speciation analysis during this process, most SeMet was removed from the Se fraction. The cause could be thought to be the degradation of this compound because of the high temperatures during boiling. However, Poblaciones et al.[25] reported minimal SeMet losses after boiling in Se-enriched pasta. Thus, SeMet could be considered thermostable. Therefore, the most likely explanation for this loss would be that Se was strongly bound to the spent grain, and only a proportion of the most water-soluble compounds, such as selenite,[22] was able to pass to the wort. However, when the initial concentration of SeMet in the malt was high (more than 300 μg kg^{-1}), as occurred in the case of sodium selenate fertilization, not all SeMet was lost in the spent grain and approximately $^{1}/_{18}$ and $^{1}/_{25}$ of SeMet remained in the wort. Further experiments analyzing the Se concentration and the Se species contained in the spent grain should be performed to confirm this hypothesis.

Finally, during the fermentation–maturation process, a large proportion of total Se was also lost (around 54% on average). Yeast (*S. cerevisiae*) has been shown to accumulate Se in high concentrations.[27,28] This fact may explain the strong reduction in the total Se recorded in our study after this process removed the yeast from the fermented and matured wort. Thus, after malting and brewing, only around 7.3% (range of 5.2–11.4%) of the total Se contained in grain was maintained in the final beer. This proportion was only a little bit lower than 10.3 and 15.6% obtained by Gibson at al.[11] in the 20 and 500 L pilot breweries, respectively. Therefore, the quite similar results obtained in the two studies carried out in different conditions might reflect they are highly consistent, regardless of the conditions used. The Se concentration of the control beer was in line with that obtained for commercial beer, because in the Mediterranean area, it has been reported[13] to range between 9.2 and 17.2 μg kg^{-1}.

In the final beer obtained in the present study, no SeMet was found; instead, most Se was obtained in the selenite form. This lack of SeMet is a negative aspect of the use of Se-biofortified barley to obtain selenized beer because it is known that the bioavailability of Se organic forms is much higher than that of inorganic forms.[17] Nevertheless, it has been shown above that a large percentage of Se (around 37%) was in unknown forms in beer produced from barley fertilized with the largest dose of sodium selenate. In addition, when the total Se obtained by ICP–MS is compared to that obtained by HPLC–ICP–MS, it can be observed that there was a great amount of Se that was not considered in the speciation analysis because of accuracy limitations in the procedure. Further studies including more advanced techniques may allow for the identification of these fractions, the unknown fraction, and that not included in the

speciation analyses. At least, it would be very interesting to know if these fractions are in organic or inorganic forms to know accurately the bioavailability of the Se remaining in beer.

In addition to the approach to making Se-enriched beer through Se-biofortified barley indicated in the present study and that by Gibson et al.,[11] other authors[13] have proposed to add sodium selenite directly to wort during the brewing process, expecting biotransformation of selenite to organic selenium compounds by yeast. The same methodology was also used to obtain other Se-enriched beverages, such as white wine.[12] A variant of this method was also proposed by Gibson et al.[11] consisting of adding the inorganic form of Se in the water used for germination during malting. A comparison between these two approaches could be of great interest for farmers and beer manufacturers to establish their effectiveness, suitability, and convenience. Technically, both approaches reported a similar Se loss derived from the fermentation−maturation process (the only common in both methodologies), for example, 45−58% in our study and 40−57% in the study by Sánchez-Martinez et al.[13] In both approaches, the SeMet concentration reported in the final beer once removed yeast was either negligible or very low (1−2%). With regard to easiness and cost of the method, the brewer should choose one of the two following options, which correspond with each approach: to pay a little bit more money to farmers for Se-enriched barley (the method proposed in the present paper) or to introduce an additional step during the manufacturing process to include selenite/selenate in the wort or water for malting. The second option presents a high initial investment. It is true that it could be compensated in the long term if Se-enriched beer can be sold at higher prices than normal beer, but meanwhile, this investment is at risk to be lost. Conversely, the first option allows for examining the market trend year to year and, consequently, paying farmers for Se-enriched barley according to that trend. On the other hand, it is important to take into account that adding selenium during the beer-making process may be interpreted as the addition of an ingredient, and this may have a negative connotation to food health authorities and beer consumers.

For farmers, the application of Se would be very cheap because they can use the conventional fertilizer applications and incorporate Se at the same time. The cost of the product is also very cheap, around 4 € ha^{-1} (at a dose of 20 g ha^{-1}), easy to be compensated if beer manufacturers pay more for this Se-enriched product. The main weakness of the approach proposed in the present paper is the apparently low proportion of Se (ranging between 5.2 and 11.4% of the total Se contained in grain) remaining in the final beer after malting and brewing. Even so, Se biofortification provided barley grain able to produce beer with a much higher Se concentration than that obtained from non-Se-enriched barley. Beer produced with barley fertilized with sodium selenate at a dose of 20 g ha^{-1}, showed total ICP Se concentrations almost 6 times higher than beer produced with non-Se-fertilized barley. Gibson et al.[11] considered that 1 L of beer made from malt with a initial concentration of 2.2 mg of Se kg^{-1} would provide a male with over 100% of his recommended daily intake of Se. In our study, the maximum Se concentration in malt was 1076 μg kg^{-1}, obtained with a fertilizer application of sodium selenate at 20 g ha^{-1}. However, the biofortification of barley with sodium selenate in the same area at a dose of 40 g ha^{-1} has produced according to Rodrigo et al.[10] a Se concentration in grain of almost 2400 μg kg^{-1}, a concentration very close to that given by Gibson et al.[11] considering the Se loss during malting.

In following the methodology indicated in the present paper, it is also important to note that several Se-rich byproducts, generated during the brewing process, could be used as an important Se source. For example, spent grain, which includes approximately 25−30% of the malt weight, is an important byproduct from brewing that is commonly used for animal feed.[29] Therefore, considering that most Se, especially SeMet, might be bound in the spent grain, it could become a high-quality and an excellent feeding product for animals, able to remedy Se deficiencies and avoid their consequences for animal health and fertility.[30] Finally, it is also important to note that grain yield and quality parameters of grain were not affected by Se fertilization.[10] This is an important point, because it would be impossible to successfully implement a potential biofortification program if farmers obtained lower income gains as a consequence of Se application.

In conclusion, this paper provides an alternative approach to the already described methods to obtain Se-enriched beer, in our case through the use of Se-biofortified barley grain as raw material. Although after malting and brewing, only 7.3% of the initial total Se was retained in the beer, the use of grain from barley fertilized with sodium selenate at 20 g ha^{-1} increased the final Se concentration in grain almost 6-fold. Selenium was mainly lost during the mashing−lautering process because most Se seemed to be bound to the spent grain, which could be used consequently to prevent Se deficiency in the animal feeding. The present paper provides evidence that the use of Se-biofortified barley grain as a raw material to produce Se-enriched beer is possible, and the results are comparable to other methods in terms of efficiency. The final decision by farmers or brewers about the suitability of its use should be taken based on the importance of the positive or negative aspects of the different methods in each particular case and balancing investment risk and profitability according to the market preferences.

ABSTRACT: Denaturation of the protein matrix during heat treatment of duck *foie gras* was studied in relationship to the amount of fat loss during cooking. A low fat loss group was compared with a high fat loss group by histochemistry, FT-IR, and synchrotron UV microspectroscopy combination to characterize their protein matrix at different scales. After cooking, the high fat loss group showed higher densification of its matrix, higher ultraviolet tyrosine autofluorescence, and an infrared shift of the amide I band. These results revealed a higher level of protein denaturation and aggregation during cooking in high fat loss than in low fat loss *foie gras*. In addition, the fluorescence and infrared responses of the raw tissue revealed differences according to the level of fat losses after cooking. These findings highlight the importance of the supramolecular state of the protein matrix in determining the fat loss of *foie gras*.

INTRODUCTION

In some birds such as palmipeds in which the liver is the main site of de novo lipogenesis, nonpathological steatosis can be triggered by dietary carbohydrates. This ability is used to produce *foie gras*, a coveted product highly appreciated for its flavor and sensorial qualities. Usually, ducks or geese are reared and overfed in standardized conditions. Immediately after slaughter, the *foie gras* is removed, trimmed, and seasoned before cooking. However, even under these standardized conditions, quality is uneven. Despite the controlled cooking conditions, fat loss ranges from 2% to 50%, with a marked impact on technological yield and organoleptic qualities. A study suggested that lipid and fatty acid characteristics are not closely related to fat loss during cooking.[1] However, a recent ultrastructural analysis showed that lipid staining intensity was linked to fat loss during cooking, thus suggesting a role of the composition of the lipid droplets in this effect.[2]

The protein component, though minor in amount, seems to play a major role in the molecular mechanisms underlying fat loss during cooking. Enzymes involved in redox processes are over-represented in livers with high fat loss during cooking;[3] this finding was interpreted as precocity in the steatosis stage. An extracellular matrix of hepatocytes forms the support tissue of cells. The integrity of this matrix is probably important for the structural support of lipid-filled hepatocytes. A proteomic study performed on duck livers showed that during postmortem storage, the proteolytic pattern was linked to fat loss during cooking.[4] A variation in the molecular composition of this matrix could affect its mechanical resistance during cooking and thereby modulate lipid retention. Cooking causes thermal denaturation of proteins[5] with consequent changes in the morphology of the protein components.[2] Using electron microscopy, these last authors found a coagulation of protein matrix that was difficult to quantify. New imaging tools allow a quantitative approach to the local chemical changes in composition and molecular structure, offering an opportunity to establish links between such changes and fat loss during cooking. This is the case of microspectroscopy tools consisting of an optical microscope coupled to a spectrometer. The microscope allows one to select an area of interest in the histological tissue section, and the spectrometer allows spectral acquisition in the same area. Results from different spectral acquisition modalities provide additional informations. From a series of spectral acquisition, it is possible to edit spectral maps of the region of interest. The image is multimodal when spectra come from different wavelength ranges such as infrared, visible, or UV.

Analysis of infrared spectra yields information on the molecular structure with a spatial resolution of 10 μm.[6] Synchrotron deep ultraviolet (DUV) fluorescence spectra provide knowledge of chemical composition with a spatial resolution that may reach 300 nm.[7,8] The simultaneous approaches of located microspectroscopy and histochemistry are therefore well-suited to characterize cellular morphology and molecular

(E) Toluidine Blue staining highlighting the proteins in blue. (F) Histofluorescence of the Nile Red probe. Proteins in black; lipids in red. (G) Deep UV spectral image of the 290−375 nm emission band, assigned to the protein. The difference between the spatial resolution of FT-IR microspectroscopy (25 μm; B,C) and UV fluorescence microspectroscopy (1 μm; G) does not allow for a comparison of images at the same intensity. The UV spectrofluorescence imaging confirms protein histological identification without staining.

structures of targeted areas on the same tissue section. A recent study conducted by FT-IR microspectroscopy characterized the effect of heating on the secondary structure of muscle proteins previously identified by immunohistofluorescence.[9] The spatial resolution was reduced from about 25 to 6 μm by the use of a synchrotron source. In addition, the combination of FT-IR and UV fluorescence microspectroscopies allowed a fine in situ characterization of liver steatosis in human subjects.[10]

Considering the fat loss of *foie gras*, we suspected that slight differences in the molecular structure of the protein matrix could affect its mechanical resistance during cooking and thereby modulate lipid retention. So, our objectives were to characterize the in situ protein molecular structure changes of *foie gras* during cooking in order to find lipid loss markers and to acquire knowledge on the molecular mechanism involved in fat loss variability. Therefore, we conducted a multimodal imaging study combined with histological and spectroscopy analyses to characterize the thermal denaturation of *foie gras* proteins and to elucidate the molecular mechanisms underlying fat loss during cooking.

MATERIALS AND METHODS

Animals, *Foie Gras* Processing, and Sample Collection. Animals and samples were from an experiment that has been described in previous articles.[2,4] Briefly, 120 male mule ducks (*Cairina moschata* × *Anas platyrhynchos*) were reared with access to free range until age 13 weeks in a poultry house under natural conditions of light and temperature at the Agricultural College of Périgueux (EPLEFPA, 24, France). The ducks were then overfed in individual cages for 12 days by dispensing a soaked corn mixture (42% grain, 58% flour) twice a day. Ducks were slaughtered at the experimental slaughterhouse of the Agricultural College of Périgueux, 10 h after their last meal. The birds were electrically stunned head-only using scissor tongs and bled by ventral cutting of neck vessels within 10 s after the stun. After 5 min of bleeding, the carcasses were scalded and plucked.

The experiments described here fully comply with the legislation on research involving animal subjects in the European Communities Council Directive of November 24, 1986 (86/609/EEC). The investigators were

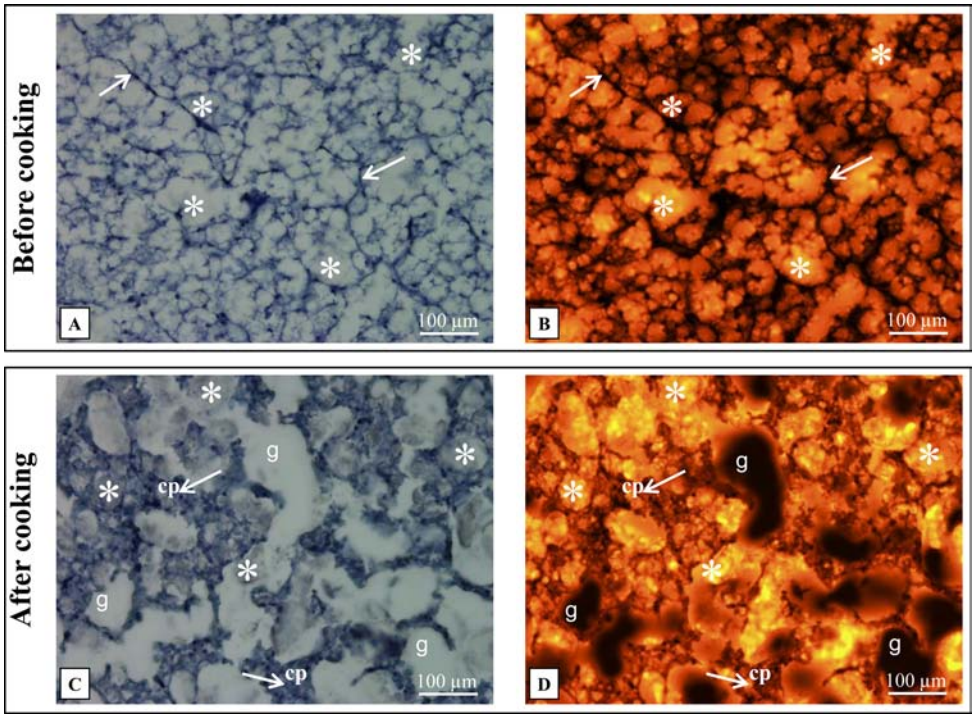

Figure 2. Cooking effect on *foie gras* tissue structure. Protein matrix (arrows) revealed by Toluidine Blue staining appeared thin before cooking (A) and thick after cooking (C) owing to coagulated proteins (cp). Lipids were stained with Nile Red fluorescent dye and were surrounded by the matrix, which appeared black before cooking (B) and fluorescent after cooking (D). Before cooking, the lipid droplets (stars) were small and spherical (B); after cooking, they were large and had lost their spherical shape (D). After cooking, gaps (g) are seen on the tissue sections (C and D).

certified by the French government authority to conduct these experiments (agreement no. 31-11.43.501).

At the end of the slaughter process, 20 min after bleeding, livers were removed from the carcasses and weighed. About 1 cm^3 was excised from each liver and frozen in cooled isopentane (−160 °C) chilled with liquid nitrogen (−196 °C). Samples were stored at −80 °C until use.

Livers were chilled on ice for 6 h and trimmed of their main blood vessels. Each *foie gras* was then transversally divided into three parts including its two lobes. In the middle part of each lobe, a slice of approximately 200 g was excised and placed in a closed glass jar. Salt (12 g/kg) and pepper (2 g/kg) were added, and the jars were left for 1 h in water in an autoclave ("Brouillon Process", Sainte-Bazeille, France) at 85 °C under a pressure of 0.8 bar. Temperature was controlled in the water and in two control jars equipped with temperature sensors. After 30 min of chilling (circulating cool water), the jars were stored at 4 °C for two months until opened for estimation of technological yield. The jars were opened, and the surface fat exuded during cooking was carefully removed from the liver. The technological yield was evaluated by the expression of fat loss during cooking as a percentage of initial liver weight: technological yield = (cooked liver weight trimmed of all visible fat/raw liver weight) × 100.

Among the 120 livers collected, 25 with similar lipid contents following Folch analysis[11] were selected for histological analysis, 13 with low cooking fat loss or high technological yield (89.9% ± 0.8%, mean ± SEM) and 12 with high cooking fat loss or low technological yield (68.3% ± 1.3%). Given the 96 h synchrotron beam time allocation, microspectroscopy analyses were performed on eight livers from the 25 selected, four livers with high technological yield (90.8% ± 1.6%) and four livers with low technological yield (67.0% ± 1.1%). About 1 cm^3 of cooked *foie gras* was cryofixed in cooled isopentane chilled with liquid nitrogen in the same way as that for raw *foie gras* and stored at −80 °C until use.

Tissue Section Preparation. Sections (10 µm thick) cut using a cryostat (Microm, HM 560) at −20 °C were collected on glass slides for histology and on infrared transparent BaF_2 windows for UV and IR microspectroscopy. Sections for both histology and microspectroscopy were dried and stored for several hours to several days at −20 °C until use.

Histochemistry. Slides were immersed in a 1% Toluidine Blue (EMS Company, Hatfield, PA 19440, USA) solution maintained at 4 °C for 10 min to contrast the nonlipidic matrix. Two washes of 1 min and one wash of 2 min were then performed in ultrapure water. After 1 h of drying, the same sections were stained with Nile Red fluorescent dye (Sigma-Aldrich corporation, St Louis, Missouri, USA) to reveal the lipids. Slides were incubated in a Nile Red solution (90 µg/mL in 75% glycerol) for 30 min in the dark at 4 °C. After three washes of 5 min in PBS buffer and one in ultrapure water, the slides were dried and stored at 4 °C in the dark until acquisition.

Image Acquisition and Image Analysis. Histological examination and image acquisitions were performed using an Olympus BX61 transmission bright field/fluorescence microscope coupled to a high-resolution digital acquisition kit (Olympus DP 71 digital camera and Olympus CellF software). Digital images were successively acquired on the same optical field in bright field and fluorescence mode (550 nm excitation and 570 nm emission). Proteins appeared in blue and lipids fluoresced in orange. Twenty-five images of each acquisition condition were acquired at 200× magnification on the same histological section.

For image analysis, the ×200-magnified Toluidine Blue stained section images were quantitatively analyzed with the open source ImageJ image processing software (http://rsbweb.nih.gov/ij) using exactly the same acquisition settings for all images. Each RGB-colored image was separated into its three monochromatic components (i.e., red, green, and blue) to keep only the green component of the image, which provided the best contrast between protein and lipid components. Protein matrix was extracted after thresholding segmentation of the gray levels, and its relative area was estimated by pixel counting of the region relative to the whole field-of-view area. The number of pixels stained was counted for each region of interest, in bright field acquisition mode, before and after cooking, and was expressed as a percentage of stained matrix per field. The protein matrix densification index, defined as the ratio of the percentage of stained matrix per field after to that before cooking, was calculated.

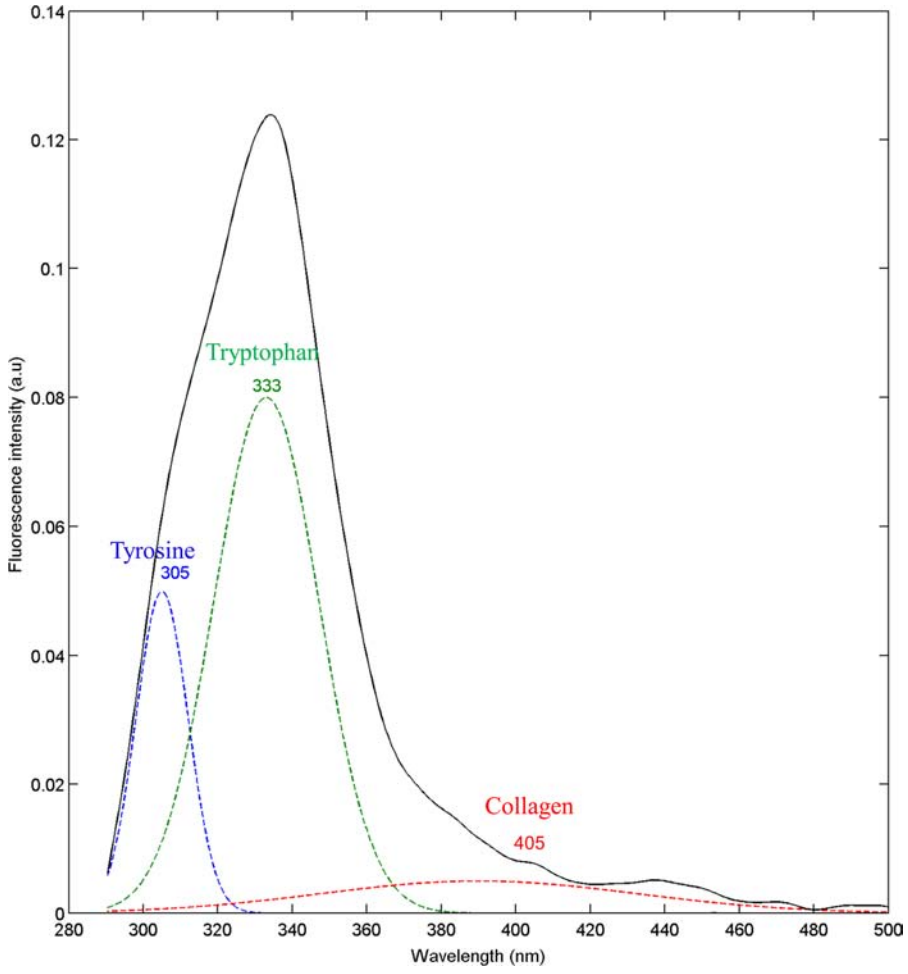

Figure 3. Representative UV fluorescence deconvoluted spectra of duck *foie gras*. Deconvolution of a UV spectrum of duck *foie gras* showing the autofluorescence bands assigned to Tyrosine (305 nm), tryptophan (333 nm), and to a lesser degree collagen (405 nm).

Lipid proportion was determined on the black and white images of Nile Red fluorescence. The same approach was used to extract lipid droplets. In each field of view, the total area of lipid droplets was estimated by its pixel count. A conversion factor was applied to express the measured surface areas in μm^2. The densification index was calculated as the ratio of percentage of matrix stained after/before cooking within each fat loss group.

Microspectroscopies Spectra Acquisitions. Synchrotron DUV microspectroscopy was performed on the DISCO beamline of the SOLEIL synchrotron radiation facility (Saint-Aubin, France).[7,8] DUV monochromatized light (typically between 270 and 330 nm) was used to excite tissue sections through a 40× ultrafluar immersion objective (Zeiss, Germany). The emission spectra were acquired from 290 to 539 nm and recorded with a 0.1 nm spectral resolution. The fluorescence spectrum from each excited pixel was recorded. Rastering of the sample allows the recording of a chosen map of interest. Mapping of 50 × 50 μm^2 was performed with 1 μm spatial resolution and a 3 s acquisition time per spectrum. Among all of the spectra acquired, 100 were selected for their high 335 nm peak intensity, characteristic of the protein target (tryptophan fluorescence).

FT-IR spectra acquisitions were performed on a Nicolet iN10 MX microscope (Thermo Scientific), using the internal (globar) infrared source, available at the SMIS beamline (Synchrotron SOLEIL, Saint-Aubin, France). Spectra were acquired on whole sections of each sample with a spectral resolution of 8 cm^{-1}. All spectra were recorded in transmission mode. The microscope comprises a motorized sample stage and a liquid nitrogen cooled array detector. A 15× Schwarzschild objective (NA = 0.5) was used, and all spectra were recorded in the mid-IR region from 4000 to 800 cm^{-1}. The spectra were saved in absorbance format using OMNIC software (Thermo Scientific).

Processing of Spectra. To study the chemical variations of interest, all of the spectra underwent data preprocessing before multivariate analysis. Autofluorescence spectra were spike- and noise-filtered using an in-house program written in MATLAB, version 7.3 (The MathWorks, Natick, MA), and images of each individual fluorescent component were produced. The Unscrambler software (v9.8, Camo Software AS, Norway) was used to perform a baseline adjustment to zero and to apply unit vector normalization.

Data processing of IR spectra was performed using the Unscrambler software (v9.8, Camo Software AS, Norway). An extended multiplicative signal correction (EMSC) was used as a flexible method for correcting artifacts in spectra by removing physical light scattering effects from chemical light absorbance effects.[12] The reference spectrum representative of the data set was calculated as the average of all spectra. The EMSC model was calculated over the 1700−1560 cm^{-1} range. On the basis of the 9-point Savitzky-Golay smoothing and using a third polynomial degree, the second derivative was first applied, and the calculated EMSC model was used to obtain the EMSC corrected spectra.

Statistical Analysis. Numerical variables of histology (protein matrix area) were expressed as the mean ± standard error of the mean (SEM). Variance analysis and mean comparisons were performed using one-way variance analysis and the Student−Newman−Keuls test under the general linear model procedure of the Statistical Analysis System software (Statistical Analysis Systems Institute Inc. SAS/STAT User's Guide, release 6.03, SAS Institute Inc., Cary, NC, 1988).

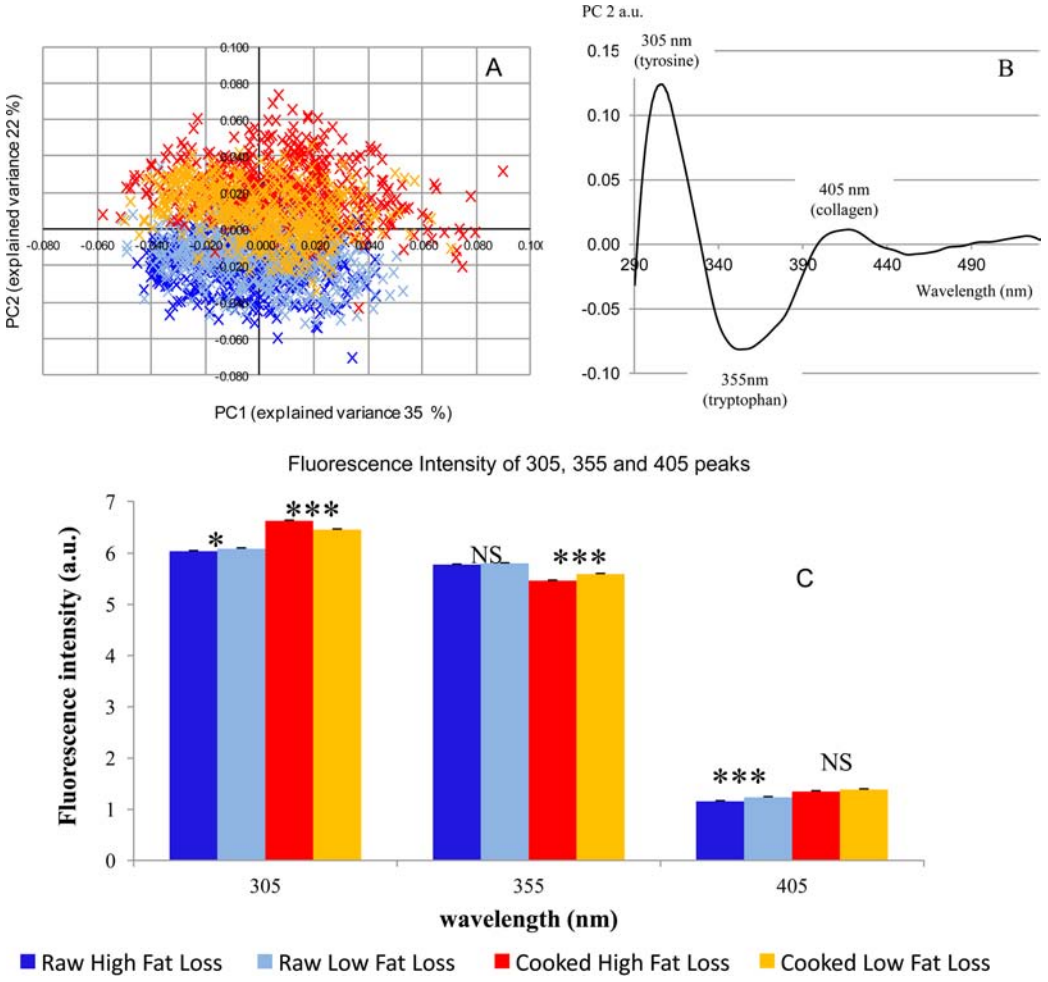

Figure 4. Synchrotron deep UV microspectroscopy comparison between raw and cooked *foie gras* within low and high fat loss groups. Dark blue, raw high fat loss; light blue, raw low fat loss; red, cooked high fat loss; and orange, cooked low fat loss. (A) Score plot of principal component analysis from the 290-510 nm fluorescence spectra. (B) PC2 loadings. (C) Autofluorescence intensity of 305, 355, and 405 nm bands. PCA score plots show that the groups separate along PC2. Compared to raw *foie gras*, cooked ones show higher fluorescence intensity at 305 and 405 nm wavelengths (assigned to tyrosine and collagen, respectively; $p < 0.001$) and lower fluorescence at 355 nm (assigned to the hydrophilic shift of tryptophan; $p < 0.001$). As shown in C, both the high and low fat loss groups are significantly different for raw *foie gras* at 305 and 405 nm and for cooked ones at 305 and 355 nm. NS: not significant; *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$. PC: principal component.

Processed spectra were analyzed by principal component analysis (PCA) using the Unscrambler software (v9.8, Camo Software AS, Norway). PCA was applied as an unsupervised approach to handle this new set of data and reveal variances or combinations of variables among this large multivariate data set. For this study, the infrared and fluorescence spectral domains were in the ranges 1700−1560 cm^{-1} and 290−530 nm, respectively. The number of possible components was always left sufficiently high (7). After analysis, the family label of each spectrum was revealed, and the first two components were plotted. The mean characteristic spectrum of each group was also plotted to relate the separation to spectral features. Score plots were used to show similarity maps allowing comparison of spectra regardless of sample categories. Loading plots derived from lists and second principal component X-loading plots were used to reveal and identify characteristic vibrational absorption bands.

RESULTS AND DISCUSSION

Complementarities of Imaging Modalities. The complementarity of the different imaging modalities used in this study is illustrated in Figure 1. The infrared maps of the spectral region 1600−1700 cm^{-1} allowed one to identify the protein matrix on the whole tissue section but with much lower spatial resolution than with fluorescence spectra imaging and histochemistry. A deep UV spectral image of the 290−375 nm emission band, which is assigned to proteins, evidences the protein matrix according to histology.

***Foie Gras* Ultrastructure.** The histological sample preparation performed in this study was used here on *foie gras* for the first time. Cryofixation followed by double staining with Toluidine Blue and the Nile Red fluorescent probe allowed the colocation of the lipid droplets and nonlipid matrix, composed mainly of protein. Previous histological studies of *foie gras* were carried out after fixation with formalin followed by organic solvent dehydration and inclusion in paraffin.[13,14] However, in this type of sample preparation, lipid esters are not fixed by formalin but are eluted by an organic solvent during dehydration.[15] In our study, cryo-fixation allowed lipid preservation in the tissue section, and the high contrast of the protein matrix facilitated its density measurement by image analysis. The *foie gras* ultrastructure study included characterizing the nonlipid structure (taken as protein) around the lipid droplets.

Before cooking, the protein matrix located around the lipid droplets (Figure 2A) was thin, and lipid droplets appeared

dx.doi.org/10.1021/jf5009605 | J. Agric. Food Chem. 2014, 62, 5954−5962

small (3.8 ± 0.7 μm^2) and spherical (Figure 2B) as already described for duck *foie gras* from a semithin section embedded in epoxy resin.[2] In fluorescence mode, the protein matrix was not visible, underlining the specificity of Nile Red fluorescent dye for lipids in raw *foie gras*.

After cooking, lipid droplets were larger (9.0 ± 3.6 μm^2) and had lost their spherical shape (Figure 2 D), probably because of the merging of droplets under heat treatment, as previously shown by Théron et al.[2]

The protein matrix appeared thicker than that before cooking (Figure 2C). These findings were consistent with results obtained on cooked meat.[16] Heating leads to protein aggregation through protein thermal denaturation[5,9,16] and protein oxidation[17] that can form disulfide and bityrosine bonds. Such protein aggregations probably explain the protein matrix structural changes. Also, in contrast to the raw *foie gras*, the protein matrix of cooked *foie gras* expressed fluorescence because of the affinity of Nile Red dye for protein aggregates.[17,18] These authors highlighted in situ protein aggregation on histological sections of cooked meat by detecting the Nile Red fluorescence dye fixed on protein aggregates formed during heating.

The protein matrix densification index, defined as the ratio of the percentage of stained matrix per field after to before cooking, was 1.55 ± 0.04 and 1.35 ± 0.02 ($p < 0.05$) in the high and low fat loss groups, respectively. These results evidence the link between the level of fat loss during cooking and the densification of the protein matrix, i.e., protein denaturation and aggregation.

Cooking Effects on the Protein Matrix Fluorescence Spectroscopy Response. The high brightness and high spatial resolution provided by the DISCO synchrotron beamline allowed the protein matrix to be characterized on an ultrastructural scale on raw and cooked *foie gras*. The UV spectra of duck *foie gras* (Figure 3) showed a marked peak at 333 nm assigned to the autofluorescence of tryptophan,[10,19] with a shoulder at 305 nm characteristic of tyrosine.[19] The band at 405 nm that could be assigned to collagen was not as well-defined as in human pathologic fibrosis studies.[10] This result is not surprising since *foie gras* is not the result of a disease, unlike human steatosis, which causes liver fibrosis. Figure 4A,B presents the score and loadings plots of the principal component analysis performed on UV spectra from the four groups: before and after cooking in low and high fat loss groups. The loadings show that cooking was characterized by peaks at 305, 355, and 405 nm. Cooking resulted in an increase in fluorescence intensity ($p < 0.001$) at 305 nm (tyrosine) and 405 nm (collagen), while fluorescence intensity decreased at 355 nm ($p < 0.001$); regardless of the fat loss during cooking.

The discriminatory effect of cooking at 355 nm could be due to a shift in the tryptophan peak as a consequence of changes in protein hydrophobicity[20] or to its partial degradation. Indeed, a decrease in tryptophan was still observed after meat cooking.[21] This amino acid can be oxidized in 5- and 7-hydroxytryptophan[22] or reacted with other molecules to form heterocyclic aromatic amines (HAAs).[23]

In Figure 4C, compared to raw *foie gras*, we observed an increase of fluorescence intensity of tyrosine in cooked *foie gras*. Thermal denaturation tends to move the hydrophobic amino acids to the external parts of proteins,[17,24] and tyrosine can be considered predominantly hydrophobic as its hydroxyl residue is not ionized at the pH of *foie gras* (about 6).[25] The hydrogen bond environment is known to affect the fluorescence intensity of a molecule.[26] In the present case, heating led to the cleavage of many hydrogen bonds, which probably helped to increase the fluorescence yield of tyrosine. The greater accessibility of the excitation radiation to well-exposed tyrosine residues, together with their lower molecular interactions, may explain this increase in tyrosine autofluorescence intensity.

In addition, heating causes melting and peroxidation of lipids, which are particularly abundant in *foie gras*. Aldehyde compounds from lipid peroxidation react with proteins and increase the fluorescence intensity of cooked meat.[27] This effect could be transposed to *foie gras*, where lipid movement during cooking could influence autofluorescence parameters of molecules in their vicinity. Before cooking, compared with high fat loss *foie gras*, we observed in low fat loss *foie gras*, a slight but significant increase in the fluorescence intensity at 305 nm assigned to tyrosine ($p < 0.05$) and at 405 nm that could be assigned to collagen ($p < 0.001$) (Figure 4 C). These results suggest that tyrosine and collagen autofluorescence of raw *foie gras* could be used to predict fat loss during cooking. Significant differences were observed after cooking on emission fluorescence between low and high fat loss groups. The low fat loss group showed a decrease in fluorescence at 305 nm ($p < 0.001$) and an increase at 355 nm ($p < 0.001$). This finding reflects different changes in the protein matrix structure and/or composition during cooking, related to fat loss level.

Cooking Effects on Protein Matrix Infrared Spectroscopy Response. FT-IR microspectroscopy was applied on the tissue sections to characterize the secondary structure of proteins in situ. The global profile obtained from FT-IR spectra (Figure 5) was similar to that observed on human nonalcoholic steatosis liver samples.[28] The spectrum shows major peaks at 3000−3060, 2800−3000, 1710−1780, and 1475−1710 cm^{-1} assigned to C = C, CH3-CH2, C = 0, and amide (I and II) bands of proteins, respectively.[28] The 1600−1700 cm^{-1} spectral range, was used to characterize the molecular structure of proteins.[29] A close-up of this part of the spectrum shows a peak at 1658 cm^{-1} reflecting α-helix structure.[29] Cooked samples

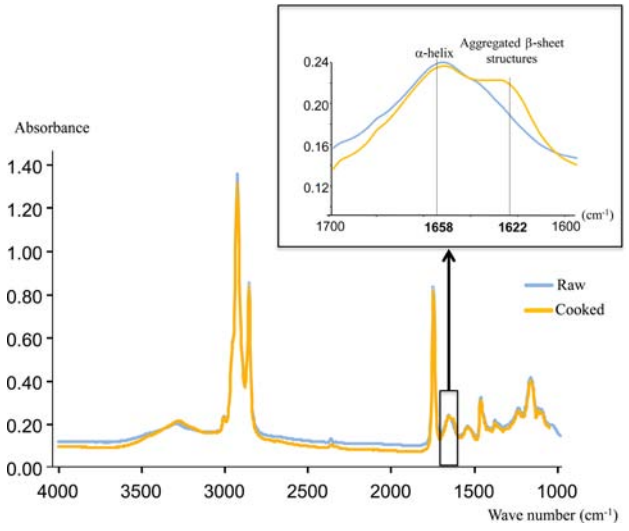

Figure 5. Mean infrared spectra of raw and cooked *foie gras*. The 1600-1700 cm^{-1} spectral range, which corresponds to the amide I band of protein, was used to characterize molecular structure. A close-up of this part of the spectrum shows that the cooked samples have a shoulder at 1622 cm^{-1}, assigned to aggregated β-sheet structures.

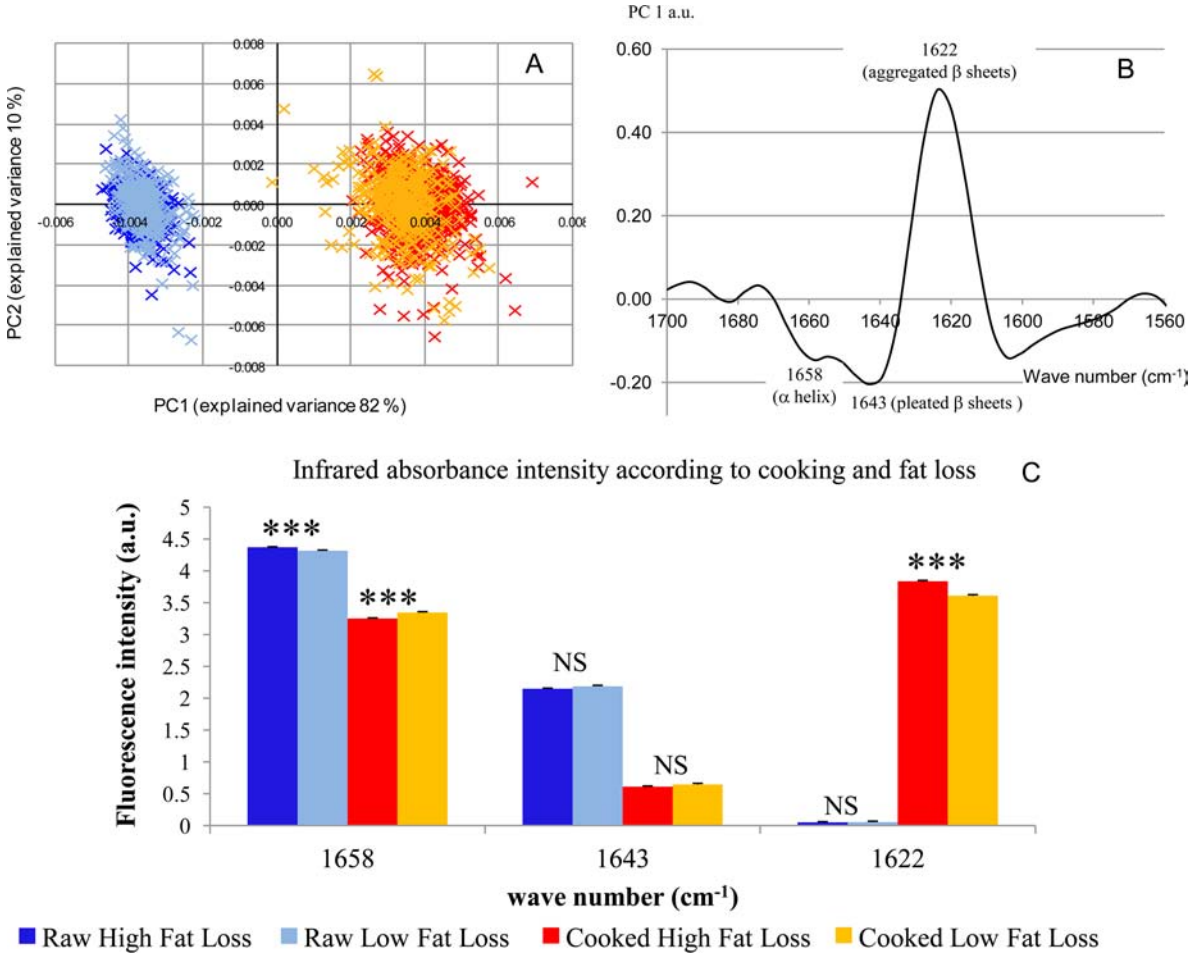

Figure 6. Infrared microspectroscopy comparison between raw and cooked *foie gras* within low and high fat loss groups. Dark blue, raw high fat loss; light blue, raw low fat loss; red, cooked high fat loss; orange, cooked low fat loss. (A) Score plot of principal component analysis from the 1558–1700 cm^{-1} band infrared spectra. (B) PC1 loadings. (C) Infrared response of 1658, 1643, and 1622 cm^{-1} bands. PCA score plots show that the groups separate along PC1. Compared to raw *foie gras*, cooked ones show lower infrared absorbance intensities at 1658 and 1643 cm^{-1} (attributed to α-helix and antiparallel β sheets structures, respectively; $p < 0.001$) and higher response at the 1622 cm^{-1} band assigned to aggregated β sheet structure ($p < 0.001$). From the ANOVA analysis, shown in C, the two fat loss groups (high and low) are significantly different for raw *foie gras* at 1658 cm^{-1} and for cooked ones at 1658 and 1622 cm^{-1}. NS, not significant; *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$. PC: principal component.

have a shoulder at 1622 cm^{-1}, assigned to aggregated β-sheet structures.[29]

Multivariate statistical analysis (Figure 6A,B) separated cooked samples from raw samples on the amide 1 band of proteins. This finding results in the changes in the secondary structure of proteins during heating characterized by changes in spectral bands at 1658, 1643, and 1622 cm^{-1}, as shown by PC1 loadings (Figure 6B) and the close-up of the amide 1 band (Figure 5). These bands are assigned to the α-helical structures, pleated (parallel/antiparallel) β-sheet structure, and aggregated β-sheet structure, respectively.[29−31] Compared with raw *foie gras*, after cooking, the peak heights at 1658 and 1643 cm^{-1} decreased by about 25% and 75%, respectively, while the peak height at 1622 cm^{-1} was increased by seven times (Figure 6).

These results agree with those of Kirschner et al.[32] and Astruc et al.[9] showing a decrease in α-helix and pleated β-sheet structures and an increase in aggregated β-sheet structures of skeletal muscle proteins subjected to heating. The decrease in native secondary structure of protein (α-helix and pleated β-sheet structures) associated with an increase of aggregated β-sheet structure is an illustration of the thermal denaturation of proteins.

The level of α-helix structure was slightly lower in the raw low fat loss group than in the raw high fat loss group, but the difference was highly significant ($p < 0.001$; Figure 6C). This finding could be linked to the lower content of heat shock proteins (HSP) in low fat loss *foie gras*,[3] which protects proteins against denaturation.

After cooking, the level of α-helix structures was higher, and the aggregated β-sheet structures were lower in the low fat loss group. Thus, the *foie gras* that was most sensitive to thermal denaturation of proteins also displayed lower lipid retention after cooking. It seems that the thermostability of proteins that maintain the structural integrity of hepatocytes is involved in the retention of lipid droplets during cooking.

The variability in protein thermal denaturation between high and low fat loss groups could also come from differences in the proportion of thermostable protein in the *foie gras* protein matrix. Indeed, FT-IR microspectroscopy does not allow for characterizing a specific single protein but does allow all proteins probed by the beam, i.e., a set of colocalized proteins. However, each protein has a specific thermal stability.[5] We have recently shown that myofibrillar proteins of muscle begin to denature at 40 °C, whereas elastin is thermostable up to at least

dx.doi.org/10.1021/jf5009605 | J. Agric. Food Chem. 2014, 62, 5954−5962

80 °C.[9] In the case of *foie gras*, the lower thermal denaturation of overall matrix proteins from low fat loss *foie gras* could be explained by a higher proportion of thermostable proteins.

Coupling morphological, multimodal imaging methods and spectroscopies enabled us to characterize the structure of *foie gras* at mesoscopic, ultrastructural, and supramolecular scales. The coagulation of heated proteins observed by histology is the result of their aggregation at the molecular scale after their thermal denaturation, which was characterized by microspectroscopy. Our results link the evolution of the protein matrix to the level of fat loss during cooking. Each of the three methods (histology, infrared microspectroscopy, and fluorescence microspectroscopy) showed that a reduced thermal change in *foie gras* proteins promotes better lipid retention and thereby enhances the technological quality of *foie gras*.

ABSTRACT: Technological properties and structural characteristics of proteins and lipids, using Raman spectroscopy, of frankfurters formulated with olive oil bulking agents as animal fat replacers were examined during chilling storage. Frankfurters reformulated with oil bulking agents showed lower ($P < 0.05$) processing loss and higher ($P < 0.05$) hardness and chewiness. Purge loss during chilling storage was relatively low, demonstrating a good water retention in the products. β-Sheet structures were enhanced by the use of olive oil bulking agents, and this effect was more pronounced in samples containing inulin. Reformulated frankfurters contained the least turns ($P < 0.05$). A significant decrease of β-sheets and an increase of turns were observed after 85 days of chilled storage. The lowest ($P < 0.05$) values of $I\nu_sCH_2/I\nu_{as}CH_2$ were recorded in frankfurters reformulated with oil bulking agents, which suggests more lipid acyl chain disorder. Structural characteristics were correlated to processing losses, hardness, and chewiness.

KEYWORDS: *lipid, protein, olive oil bulking agent, frankfurter, texture, processing loss, structure, Raman spectroscopy*

INTRODUCTION

Frankfurters are very popular, frequently consumed meat products. However, they are increasingly being associated with negative aspects relating to health. In order to minimize this negative aspect, frankfurters have been reformulated to improve their lipid composition by reducing fat content and/or replacing the animal fat present in the product with alternative fat whose characteristics are more in line with health recommendations.[1] In this context various strategies have been devised to incorporate these fats in meat products, for instance in liquid and solid forms, encapsulated, or as oil-in-water emulsions.[1] Our group has developed solid animal fat replacers such as oil bulking agents based on polysaccharide gels, which have been used in the formulation of meat batters.[2,3] The potential of a konjac matrix containing healthy oils to improve fat content in meat products has also been evaluated.[4−7] To properly develop this type of meat product, it is especially useful to look at reformulation processes that affect technological properties (water and fat binding properties, color, texture, etc.). It has been reported that food processing can potentially alter the structure of food proteins either as the result of intended unit operations or as a consequence of the physicochemical environment a protein encounters during processing.[8] In particular, the use of certain reformulation strategies based on replacement of animal fat in the development of healthier lipid meat products could alter both the structural properties of their main components (proteins, lipids, etc.) and technological properties of the final product. An understanding of the interactions that occur between meat proteins and other ingredients is vital for product quality and the development of new processed meat products.[9] The interactions of meat proteins with the other ingredients can significantly affect the properties of the end product, since many of these have a close bearing on the adequate formation of a protein network. Supplementary information relating to the structure/function relationship would clarify the mechanisms that act on them and help determine criteria for adjusting these. It would also aid to find conditions for certified aspects relating to processing and composition and their impact on technological properties of a complex meat system.

Raman spectroscopy can provide comprehensive structural information to highlight this structure/function relationship. Raman spectroscopy provides a means to approach the structure,[10−16] and particularly the interactions among the different components (protein, lipids, etc.) of these types of healthier-lipid meat products, modified by the addition of animal fat replacers as oil bulking agents. Studies have demonstrated that Raman spectroscopy is a useful tool for directly determining the changes occurring in lipids and proteins of meat batters due to the incorporation of various types of lipids.[2,17] These studies identify associations between the protein and lipid structure data obtained using Raman spectroscopy and the technological properties of the product such as texture and water binding.[2,17]

The primary objective of this work was to determine technological properties (processing loss, purge loss, and texture) and structural characteristics of protein and lipids, using Raman spectroscopy, of frankfurters formulated with olive oil bulking agents, as animal fat replacer. These bulking agents are based on the combination of olive oil, water, a cold set binding agent (alginate), and polysaccharides (inulin or

ACS Publications © 2014 American Chemical Society

dextrin). Technological and structural properties were also evaluated as affected by chilling storage (85 days at 2 °C). The secondary objective was to examine the possible relationship between the technological properties and the protein and lipid structures of these frankfurters. A fuller understanding of this relationship could throw more light on the role of oil bulking agents in a meat matrix, which could be useful in optimizing the quality of frankfurters to which they are added.

MATERIALS AND METHODS

Materials. Ingredients used for preparation of oil bulking agents as fat replacers included the following: olive oil (13% SFA, 79% MUFA, and 8% PUFA) (Carbonell Virgen Extra, SOS Cuétara SA, Madrid, Spain); sodium alginate (90% carbohydrates) (Tradissimo, TRADES S.A., Barcelona Spain); calcium sulfate (Panreac Química, S.A. Madrid, Spain); tetra-sodium pyrophosphate anhydrous (STP) (Manuel Riesgo, S.A. Madrid, Spain); inulin consisting mainly of chicory inulin (>90% inulin) with a molecular weight of 1650 g/mol (TRADES S.A., Barcelona Spain); and white maize dextrin (molecular weight average approximate between 10 and 20 glucose molecule per polymer) (CARGILL S.L.U., CTS Rubi, Barcelona, Spain).

Fresh post-rigor pork (mixture of musculus *biceps femoris*, musculus *semimembranosus*, musculus *semitendinosus*, musculus *gracilis*, and musculus *adductor*) and pork backfat used for the preparation of frankfurters were obtained from a local meat market. The meat was trimmed of fat and connective tissue, and the pork fat was passed through a grinder with a 0.4 mm plate. Lots of approximately 1 kg were vacuum packed, frozen, and stored at −20 °C until use, which took place within 2 weeks.

Other ingredients and additives used were sodium chloride (Panreac Química S.A., Barcelona, Spain), sodium nitrite (Fulka Chemie GmbH, Buchs, Germany), and flavoring (Gewürzmüller, GmbH, Münchingen, Germany).

Preparation of Olive Oil Bulking Agents. Two different types of olive oil bulking agents were considered:[3] a combination of olive oil with sodium alginate, $CaSO_4$, STP, and dextrin, named A/D, or inulin, named A/I. These samples were prepared by mixing sodium alginate (1%), $CaSO_4$ (1%), STP (0.75%), and dextrin (2.25%) or inulin (2.25%) with water (40%) in a homogenizer (Thermomix TM 31, Vorwerk España M.S.L., S.C., Madrid) to prepare A/D or A/I respectively. The mixtures were prepared at 1500 rpm for 20 s. Olive oil (55%) was gradually added to this mixture with the homogenizer running (1500 rpm). Samples of each type were placed in metal molds under pressure to compact them and avoid air bubbles, and stored in a chilling room at 2 °C for 24 h until analysis. Each type of oil bulking agent was prepared in duplicate using two metal molds for each type of sample. These oil bulking agents were used as pork backfat replacers in the formulation of the frankfurters.

Preparation of Frankfurters. Frankfurters were prepared following the procedure previously reported.[7] Six different products were prepared as reported in Table 1: control normal fat (NFF-PF) and low fat (LFF-PF) frankfurter formulated with meat and pork backfat (PF); four reformulated samples in which the pork backfat was replaced by an equal amount of oil bulking agent A/D or A/I to formulate normal (NFF-A/D, NFF-A/I) and low (LFF-A/D, LFF-A/I) fat frankfurters. For frankfurter preparation a Stephan Universal Machine UM5 (Stephan u. Söhne GmbH and Co., Hameln, Germany) was used at 2 °C.

The meat batter was stuffed into 20 mm diameter Nojax cellulose casings (Viscase S.A., Bagnold Cedex, France), hand-linked, and heat processed in an Eller smokehouse (model Unimatic 1000, Micro 40, Eller, Merano, Italy). After that, the frankfurters were cooled (at room temperature), vacuum-packed in plastic bags (Cryovac BB3050), stored at 2 °C (±1 °C), and analyzed periodically (days 1, 45, and 85).

Proximate Analysis. Moisture and ash contents of the frankfurters were determined[18] in triplicate. Protein content was measured in triplicate with a LECO FP-2000 Nitrogen Determinator (Leco Corporation, St Joseph, MI, USA). Fat content was evaluated in triplicate.[19]

Table 1. Formulation (%) of Frankfurters[a]

			olive oil bulking agent[c]		
samples[b]	meat	pork backfat	A/D	A/I	water
NFF-PF	63.0	21.0			13.2

[a]Additives added to all samples: 2.0 g/100 g NaCl; 0.30 g/100 g sodium tripolyphosphate; 0.012 g/100 g sodium nitrite; 0.5 g/100 g flavoring. [b]Frankfurter: normal fat (NF-) and low fat (LF-) frankfurter (F) formulated with pork backfat (NFF-PF and LFF-PF) or olive oil bulking agent containing dextrin (NFF-A/D and LFF-A/D) or inulin (NFF-A/I and LFF-A/I) as a fat replacer. [c]Olive oil bulking agent formulated with a combination of olive oil, water, sodium alginate, $CaSO_4$, sodium pyrophosphate, and dextrin (A/D) or inulin (A/I).

Energy values were estimated from both protein and carbohydrate content (×4.1 kcal/g) and fat content (×9.1 kcal/g).[6]

Processing Loss and Purge loss. Processing loss of frankfurters (expressed as % of initial sample weight) occurring after heat processing and chilling overnight at 2 °C was calculated in quadruplicate.

Three vacuum packs per formulation were used to determine purge loss during chilling storage for each storage time. After the frankfurters were removed from the package, the surface exudate (tiny drops) was wiped off with paper towels and the frankfurters were weighed again. The purge loss was calculated by weight difference and expressed as a percentage of the initial weight.

Texture Profile Analysis. Texture profile analysis (TPA) was performed in a TA.XTplus Texture Analyzer (Texture Technologies Corp., Scarsdale, NY, USA). Cylindrical cores (diameter = 20 mm, height = 20 mm) from each frankfurter formulation were axially compressed to 40% of their original height[20] with an aluminum cylinder probe P/25. Six replicates were performed for each frankfurter formulation. Force−time deformation curves were obtained with a 5 kg load cell, applied at a crosshead speed of 1 mm/s. Attributes were calculated as follows: hardness (Hd) = peak force (N) required for first compression; cohesiveness (Ch) = ratio of active work done under the second compression curve to that done under the first compression curve (dimensionless); springiness (Sp) = distance (mm) the sample recovers after the first compression; chewiness (Cw): Hd × Ch × Sp (N × mm). Measurement of samples was carried out at room temperature.

FT-Raman Spectroscopic Analysis. Various Raman spectra were measured and used as reference: spectra of heated homogenized raw meat, heated pork backfat, and heated olive oil bulking agent (A/I and A/D). Heating of these samples was performed in a water bath at 70 °C for 30 min (similar conditions to preparation of frankfurters). These Raman spectra were used to appropriately subtract their respective contribution in the spectra of frankfurters analyzed.

Spectra of frankfurters formulated according to Table 1 (NFF-PF, LFF-PF, NFF-A/D, LFF-A/D, NFF-A/I, and LFF-A/I) were also measured.

Portions (approximately 5 g) of the different samples were measured directly without previous treatment. These portions of samples were transferred to quartz cuvettes (ST-1/Q/10) (Teknokroma, Barcelona, Spain), which were filled to reach 1 cm sample length. For each sample 1500 scans were recorded. This procedure was carried out in triplicate. Measurements were performed on three samples from each formulation. Spectra were excited with the 1064 nm Nd:YAG laser line and recorded on a Bruker RFS 100/S FT-spectrometer. The scattered radiation was collected at 180° to the source, and frequency-dependent scattering of the Raman spectra was corrected by multiplying point by point with (ν_{laser}/ν).[4] The influence of the

[b]Frankfurter: normal fat (NF-) and low fat (LF-) frankfurter (F) formulated with pork backfat (NFF-PF and LFF-PF) or olive oil bulking agent containing dextrin (NFF-A/D and LFF-A/D) or inulin (NFF-A/I and LFF-A/I) as a fat replacer.

optics on the spectrometer was eliminated by means of Opus 2.2 software Raman correction command (Bruker, Karlsruhe, Germany). Raman spectra were resolved at 4 cm^{-1} resolution with a liquid nitrogen cooled Ge detector. The samples were illuminated by laser power at 300 mW, and the frequencies cited are accurate to ±0.1 cm^{-1}. Analysis of the ratios of the intensities of the Stokes and anti-Stokes Raman bands of the same frequency showed that there was no sample heating by using this laser power.

Spectroscopic Data Analysis To Determine Secondary Protein Structure. The secondary protein structure of meat proteins was determined as follows. First, the water spectrum was subtracted from the spectra following the same criteria as described previously.[21,22] In order to eliminate any spectral influence of lipids in the spectral region characteristic of proteins (800−1800 cm^{-1}), the corresponding spectrum of the heated oil bulking agent (A/D or A/I) was subtracted from the reformulated frankfurters (NFF-A/D, NFF-A/I, LFF-A/D, or LFF-A/I) by zeroing the bending =CH band located close to 1267 cm^{-1}, which is attributed to lipid molecules.[2,23] Similarly, the heated pork backfat spectrum was subtracted from the control (all pork backfat) frankfurters (NFF-PF or LFF-PF) following the same criteria.

The Phe ν-ring band located near 1003 cm^{-1} was used as an internal standard to normalize the spectra as it has been reported to be insensitive to the microenvironment.[13−15] The visible bands were assigned to vibrational modes of peptide backbone or amino acid side chains by comparing Raman spectra of model polypeptides or monographs of Raman spectra of proteins.[13−15] The intensity values of Raman bands from various atomic groups were determined after spectral normalization. Protein secondary structures were determined as percentages of α-helix, β-sheet, turns, and unordered conformations using a parametric method.[21] This method permits the determination of the quantitative secondary structure of proteins by using parameters of the Raman amide I band.[21]

Spectroscopic Data Analysis To Determine Lipid Structure. In order to eliminate any spectral influence of water in the samples in the spectral region 2800−3000 cm^{-1}, the spectral contribution of water was subtracted from the sample spectra.[2,21] The water-free spectra of the samples were then appropriately subtracted using the heated raw meat spectrum, based on elimination of the Phe ν-ring band by means of a subtraction factor so that the intensity of this Raman band near 1003 cm^{-1} is not visible. In this way, spectral influence of protein was eliminated.

Raman spectra were processed using Opus 2.2 (Bruker, Karlsruhe, Germany) and Grams/AI version 9.1 (Thermo Electron Corporation, USA) software. For intensity measurements, baselines were considered as straight lines drawn tangentially between the intensity minima occurring on either side of each band.

Statistical Analysis. One-way analyses of variance (ANOVA) to evaluate the statistical significance ($P < 0.05$) of the effect of formulation and two-way ANOVA as a function of formulation and storage time were performed using SPSS 13.0 (SPSS Inc., Chicago, IL, USA). Least squares differences were used for comparison of mean values among formulations and Tukey's HSD test to identify significant differences ($P < 0.05$) between formulations and storage times. In addition, Pearson product moment correlation (R) was performed to determine the relationships between technological properties (processing loss and texture parameters) and Raman spectroscopy data. These correlation coefficients range between −1 and +1 and measure the strength of the linear relationship between the variables. In this statistical analysis P-value tests the statistical significance of the estimated correlations. P-values below 0.05 indicate statistically significant nonzero correlations at the 95% confidence level. This statistical analysis was carried out using Statgraphics Plus version 5.0. Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Proximate Analysis, Processing Loss, and Purge Loss. Proximate analysis of samples (Table 2) was in agreement with the target composition (Table 1). Protein content was similar ($P > 0.05$) in all frankfurters. Low fat frankfurters showed the highest moisture values according to formulation (Table 2). Ash contents varied between 2.79 and 4.42%. All animal fat samples (NFF-PF and LFF-PF) contained the lowest proportion of ash. These results are consistent with the composition of the components used in the preparation of oil bulking agents, which provide higher ($P < 0.05$) ash values in reformulated samples. Fat content ranged between 20.38% and 9.59% (Table 2), and the highest ($P < 0.05$) values were recorded in normal fat frankfurters (NFF-PF, NFF-A/D, and NFF-A/I).

The energy content of the oil bulking agent used to replace pork backfat was about 514 kcal/100 g, while the energy content of the pork backfat was around 810 kcal/100 g. This implies that if this oil bulking agent were used as animal fat replacer in the formulation of meat products, their energy content could be reduced by about 36.5%. In addition, frankfurters formulated with this oil bulking agent, which contain 55% olive oil, included around 13.5 g of olive oil per 100 g of product. These observations indicate that given the nature and composition of the lipid components of the olive oil included in the bulking agent, this approach could also be adopted to improve the fatty acid profiles of meat products.

Processing loss of frankfurters ranged from 12.9 to 22.6% (Table 2). The values of processing loss were highest ($P < 0.05$) in LFF-PF, which was also the sample with the most added water (Table 1). Reported values of processing loss in frankfurters normally oscillate between 10 and 20%.[7,24,25] Samples reformulated with oil bulking agents, both normal (NFF-A/D, NFF-A/I) and low (LFF-A/D and LFF-A/I) fat, showed significantly less processing loss than their respective counterparts (NFF-PF or LFF-PF) formulated with all pork backfat (Table 2). Processing losses were lowest ($P < 0.05$) in normal fat frankfurters prepared with A/D and A/I as pork backfat replacers (NFF-A/D and NFF-A/I), significantly more so in NFF-A/I. In these reformulated frankfurters with the added olive oil bulking agent, these agents encapsulated parts of the water and fat in the product, so that less was released during processing (Table 2). In previous assays cooking loss was found

Table 3. Textural Profile Analysis (TPA) Parameters (Hardness, Springiness, Cohesiveness, Chewiness) of Frankfurters[a] during Chilling Storage[b]

[a]Frankfurter: normal fat (NF-) and low fat (LF-) frankfurter (F) formulated with pork backfat (NFF-PF and LFF-PF) or olive oil bulking agent containing dextrin (NFF-A/D and LFF-A/D) or inulin (NFF-A/I and LFF-A/I) as a fat replacer. [b]Means ± standard deviation. Different letters in the same column indicate significant differences ($P < 0.05$), and different numbers in the same row indicate significant differences ($P < 0.05$).

to be lower in meat batters where fat was replaced by polysaccharide matrices containing olive oil than in samples made with all pork backfat.[2] Similar behavior has been found in other products such as low fat pork batters formulated with animal fat replacers based on polysaccharides such as konjac gel.[26]

Purge loss is associated with unwanted purge accumulation in the packaged product during storage. This accumulation is undesirable for both commercial and microbiological reasons. Results showed that purge loss levels over storage were relatively low (ranging from 0.5 to 1.5%) and similar to those reported by other authors.[7,24,25] This fact was associated with appropriate stability during storage in terms of fat and water binding properties of the new meat derivate. The good stability found was independent of the formulation.

Texture Profile Analysis (TPA). Both types of formulation and chilling storage significantly influenced textural properties. Samples with normal fat content (NFF-PF, NFF-A/D, and NFF-A/I) presented the highest ($P < 0.05$) hardness and chewiness (Table 3). All frankfurters reformulated with oil bulking agents showed the highest ($P < 0.05$) springiness, while there was no significant difference in cohesiveness between samples. This difference in textural properties would appear to be due to two factors, the differences in fat and moisture content, and incorporation of an oil bulking agent as animal fat replacer. In normal fat frankfurters an increase in fat content and a decrease in water (Table 2) will raise the "effective" concentration of the protein that acts to form the gel/emulsion matrix. An increase in protein concentration generally entails the formation of a denser and more compact protein matrix,[27,28] a structure associated with harder products in normal fat samples (Table 3). The incorporation of fat replacers also seems to have affected the texture. Reformulated frankfurters containing a fat replacer, irrespective of fat content, produced stronger structures with higher ($P < 0.05$) hardness and chewiness values (Table 3). Given similar compositions (and the same fat level), the differences in hardness and chewiness were presumably attributable to the bulking agent, which should facilitate the formation of a gel/emulsion matrix in the samples, so that samples should be harder/firmer. Previous results indicated that meat products reformulated using fat replacers based on a mixed konjac/gellan gum gel,[29] oil in a konjac glucomannan matrix,[7] or pre-emulsified oils were more firm than those formulated with pork backfat.[17,24,25,30,31]

In general, the TPA parameters were affected ($P < 0.05$) by chilling storage (Table 3). However, no clear relationship was identified between these changes in texture during storage and the type of sample (Table 3). Results showed a significant decrease of hardness and chewiness and an increase ($P < 0.05$) of cohesiveness and springiness in all samples during chilling storage (Table 3). Previous studies have detected similar texture behavior in frankfurters formulated with emulsified oils as fat replacers.[25]

FT-Raman Spectroscopic Analysis. *Protein Structure.* Figure 1 shows representative Raman spectra in the 950−1800 cm^{-1} region from normal fat frankfurters (NFF-PF, NFF-A/D, and NFF-A/I), following elimination of the spectral influence of water and lipids (see Materials and Methods).

Amide III Band. This Raman band includes C−N stretching and N−H in-plane bending vibrations of the peptide bond.

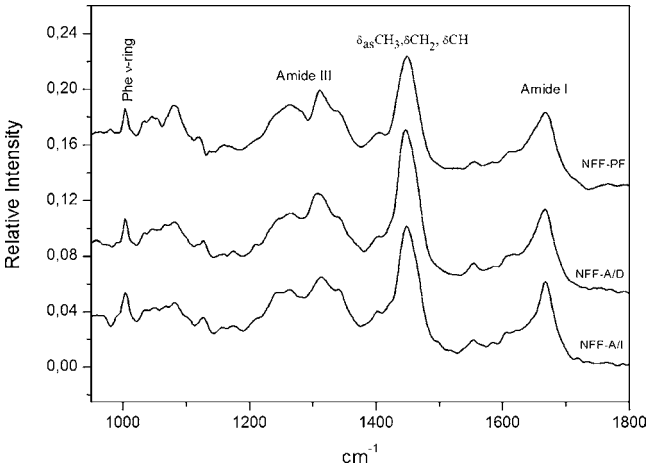

Figure 1. Raman spectra in the 950−1800 cm^1 region from the normal fat frankfurters with pork backfat (NFF-PF) or olive oil bulking agent containing alginate (A) and dextrin (NFF-A/D) or inulin (NFF-A/I) as a fat replacer.

Contributions from Cα−C stretching and C═O in-plane bending[13−15] were also detected (Figure 1). The amide III band provides information about the secondary structure of proteins. The amide III band in the spectra comprises a complex pattern of bands in the 1225−1350 cm^{-1} range (Figure 1) and for that reason is difficult to interpret.

Amide I Band. Figure 1 shows the amide I band, which offers valuable information about protein secondary structure.[13−15] The amide I band comprises mainly C═O stretching and, to a lesser extent, N−H in-plane bending of peptide groups.[13−15] In all spectra the amide I band was analyzed to elucidate the structural changes occurring in the meat protein due to the use of an olive oil bulking agent as pork backfat replacer. Figure 2 shows the amide I region (1620−1720 cm^{-1}) from the different frankfurters in detail. The alterations of frequency and intensity in this band revealed mainly changes in the secondary structure of meat proteins and variations in local environments. The highest frequency values were recorded in normal fat frankfurter when compared with the low fat one, both in control and in reformulated samples (NFF-PF, NFF-A/D, and NFF-A/I) (Figure 2). Some frequency upshifting from 1667.8 to 1668.3 cm^{-1} was detected, particularly in normal fat samples containing the oil bulking agent with inulin (Figure 2). This result may be related to increased β-sheet structure content in the meat protein in NFF-A/I. When the amide I bands of LFF-PF and reformulated frankfurters (LFF-A/D and LFF-AI) were compared, shifts of the frequency maximum from 1665.7 to 1666.1 cm^{-1} in LFF-A/D and from 1665.7 to 1667.2 cm^{-1} in LFF-A/I (Figure 2) were observed. These frequency upshifts are related to increased β-sheet structure content in the meat protein due to the use of a pork backfat replacer in the low fat frankfurters. As in the case of normal fat frankfurters, this effect was more pronounced in samples where the oil bulking agent contained inulin.

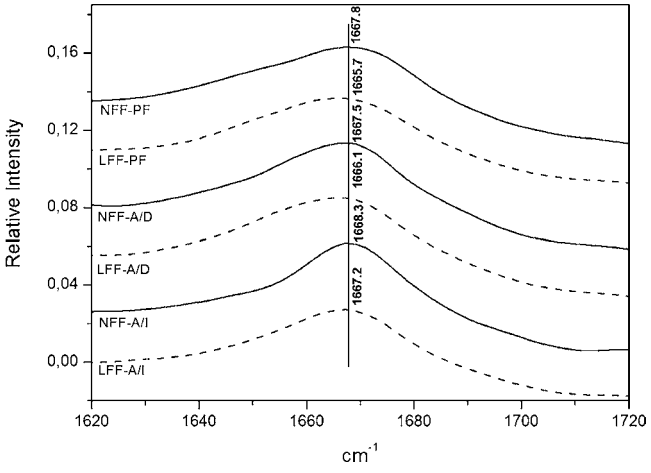

Figure 2. Raman spectra in the 1620−1720 cm^{-1} region from frankfurters formulated as normal fat (NFF-) and low fat (LFF-) formulated with pork backfat (NFF-PF and LFF-PF) or olive oil bulking agent containing alginate (A) and dextrin (NFF-A/D and LFF-A/D) or inulin (NFF-A/I and LFF-A/I) as a fat replacer.

Quantitative Percentages of Secondary Structure. In depth examination of amide I spectra profiles offered quantitative information about the percentages of secondary structure in the different frankfurters (Table 4). In general, values of α-helix content were lowest ($P < 0.05$) in normal fat frankfurters. Quantitative results of protein secondary structure confirm that β-sheet content was higher ($P < 0.05$) in normal than in low fat frankfurters, either control or reformulated. Among the normal fat frankfurters, β-sheet content was higher ($P < 0.05$) in samples reformulated with oil bulking agents as fat replacers (NFF-A/D and NFF-A/I) and highest ($P < 0.05$) of all in the sample with inulin in the oil bulking agent (NFF-A/I) (Table 4). Similar results were found when only low fat frankfurters were compared. β-Sheet content was significantly higher in LFF-A/D and LFF-A/I, with the highest values ($P < 0.05$) in the samples containing inulin in the oil bulking agent. These structural results were consistent with previous studies indicating that the use of animal fat replacers like olive oil bulking agents in meat batters, or oil-in-water emulsions in frankfurters, produces an increase in β-sheet structure.[2,32,33] The presence of aggregated intermolecular β-sheets in frankfurters has been associated with the formation of a compact network imparting more firmness.[2,17,32,33] These findings are consistent with our results (Tables 3 and 4). The formation of intermolecular β-sheets may result from the self-aggregation of the proteins. Studies of FT-Raman indicated the effect of modified celluloses, pectins, and NaCl on the secondary structure of gluten proteins. In general, a decrease in α-helix conformation and an increase in less ordered structures were observed with the addition of hydrocolloids.[34] It has been reported that certain systems based on mixes of milk proteins such as whey protein concentrate and sodium alginate were distinguished by a tendency to protein aggregation.[35] Interactions among muscle proteins and hydrocolloids, reflected in an enhancement of hydrogen bonding, have been suggested.[36]

The structural results show that, regardless of fat content, turn content was lowest ($P < 0.05$) in reformulated frankfurter, while differences among samples in term of unordered structure were nonsignificant.

Table 4 shows a decrease ($P < 0.05$) in β-sheet structure, in general accompanied by an increase in turn content at 85 days of chilled storage, while the rest of the protein secondary structure parameters (α-helix and unordered) remained constant throughout storage.

Relationship between Protein Structure and Technological Properties. Results showed that reformulation-induced changes in the secondary structure of meat protein were

[a]Means ± standard deviation. Different letters in the same column indicate significant differences ($P < 0.05$). [b]Frankfurter: normal fat (NF-) and low fat (LF-) frankfurter (F) formulated with pork backfat (NFF-PF and LFF-PF) or olive oil bulking agent containing dextrin (NFF-A/D and LFF-A/D) or inulin (NFF-A/I and LFF-A/I) as a fat replacer.

accompanied by changes in processing loss and texture. Thus, a correlation was found between processing loss and β-sheet ($R = -0.81$, $P < 0.0005$) and turn ($R = 0.74$, $P < 0.0005$) content. These correlations seem to indicate that in these types of meat products processing loss could be due to a specific meat protein structure in terms of β-sheet and turn content.

In addition, the results showed a positive correlation between β-sheet structure and hardness ($R = 0.77$, $P < 0.05$) and chewiness ($R = 0.92$, $P < 0.005$). There was also a negative correlation between turn and hardness ($R = -0.86$, $P < 0.005$) and chewiness ($R = -0.92$, $P < 0.005$). These findings indicate that reformulation-induced modifications in protein secondary structure could affect textural properties of the final meat product. Previous studies have reported a similar correlation between β-sheet content and hardness in frankfurters prepared with an olive oil-in-water emulsion.[32,33] Similarly, a positive correlation has been reported between β-sheet structures and textural behavior in meat products prepared with different lipids (pork fat, soybean oil, and dairy butter).[17] In particular, meat batters reformulated with soybean presented greater hardness, springiness, cohesiveness, chewiness, and resilience than meat batters made with pork fat or butter. These specific textural properties were accompanied by an increase of β-sheet structures.[17] This is consistent with the observation of increases of hardness associated with increases in β-sheet and turn structure in meat systems to which cold-set binding systems such as transglutaminase or fibrinogen/thrombin from porcine blood plasma have been added.[37,38]

Lipid Structure. In the Raman spectra obtained after removing the water and protein spectral contribution (see Materials and Methods), the 2800−3025 cm^{-1} region was studied to elucidate the lipid structure (Figure 3). This region contained bands that are characteristic of symmetric and asymmetric C−H stretching vibrations of methyl and methylene groups in aliphatic molecules.[23,39] There were prominent bands: a CH_2 asymmetric stretching band at 2897 cm^{-1}, a CH_3 symmetric stretching band at 2931 cm^{-1}, and a

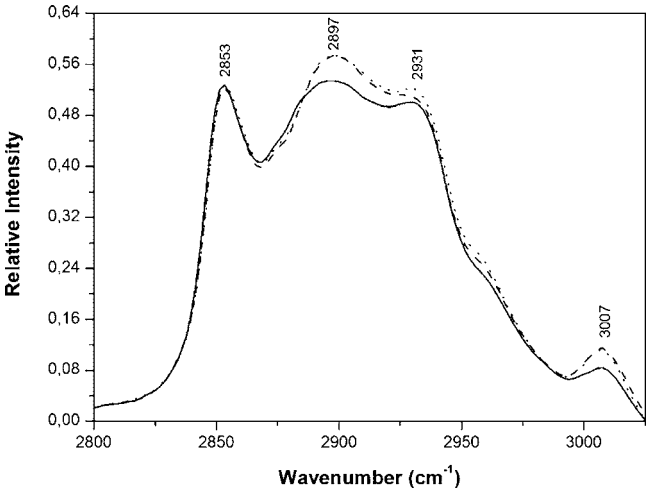

Figure 3. Raman spectra in the 2800−3025 cm^{-1} region from the low fat frankfurters with pork backfat (LFF-PF) (solid line) or olive oil bulking agent containing alginate (A) and dextrin (LFF-A/D) (dashed line) or inulin (LFF-A/I) (dotted line) as a fat replacer.

CH_2 symmetric stretching motion near 2853 cm^{-1} (Figure 3). Another Raman band at 3007 cm^{-1} attributable to *cis*-olefinic group =C−H stretching vibration is clearly visible.

Intensity Ratios $I\nu_sCH_2/I\nu_{as}CH_2$ and $I\nu_{as}CH_2/I\nu_sCH_3$. It has been reported that the peak height intensity ratios $I\nu_sCH_2/I\nu_{as}CH_2$ (I_{2850}/I_{2880}) and $I\nu_{as}CH_2/I\nu_sCH_3$ (I_{2880}/I_{2935}) are valuable references for gauging lipid packing effects and determining relative order/disorder of the intermolecular lipid chain.[40] In particular, the $I\nu_sCH_2/I\nu_{as}CH_2$ index reflects primarily interchain interactions whereas the $I\nu_{as}CH_2/I\nu_sCH_3$ intensity ratio evaluates effects resulting from modifications in intrachain trans/gauche isomerization superimposed on the chain−chain interactions. Intensity ratio $I\nu_{as}CH_2/I\nu_sCH_3$ was similar ($P < 0.05$) for all samples (Table 5). However, the intensity ratio values $I\nu_sCH_2/I\nu_{as}CH_2$ were lowest ($P < 0.05$) in frankfurter reformulated with olive oil bulking agent as pork backfat replacer (Table 4). These significant differences indicate that there was more lipid acyl chain disorder in frankfurters containing oil bulking agents than in samples made with animal fat, regardless of the fat content. There are a number of mechanisms that may explain fat stabilization in gel/emulsion meat products like frankfurters.[41] An "emulsion theory" has been proposed to the effect that a thin layer of myofibrillar proteins forms around the fat globules. The hypothesis assumes that this is accompanied by physical entrapment so that fat globules are stabilized within a gelled protein matrix.[41] On that assumption, the higher lipid chain disorder observed in frankfurters formulated with an oil bulking agent could be due to the fact that in reformulated samples more meat protein chains can be inserted between the acyl chains of the olive oil bulking agent than in control normal and low fat frankfurters containing pork backfat. This would imply more lipid−protein interactions in the reformulated products, which in turn implies more lipid acyl chain disorder (Table 4). Similar behavior has been found in meat batters in which oil bulking agents containing polysaccharide gels were used as fat replacers.[2] In general, $I\nu_sCH_2/I\nu_{as}CH_2$ and $I\nu_{as}CH_2/I\nu_sCH_3$ were not significantly affected by chilling storage (Table 4).

Relationship between Lipid Structure and Technological Properties. The possible relationship between lipid structure and processing loss and texture was also evaluated. Results showed that the observed changes in lipid structure due to the use of an olive oil bulking agent as pork backfat replacer were accompanied by changes in processing loss and textural properties of frankfurters. Thus, a positive significant correlation ($R = 0.80$; $P < 0.05$) was found between processing loss and intensity ratios $I\nu_sCH_2/I\nu_{as}CH_2$ related to lipid acyl chain order/disorder. This correlation suggests that disordering in oil acyl chains or lipid−protein interaction as a result of reformulation could affect the water and fat binding properties of the final meat product. In addition, order/disorder of lipid acyl chain correlated negatively or inversely with hardness ($R = -0.73$, $P < 0.005$) and chewiness ($R = -0.81$, $P < 0.05$).

The reformulation strategy employed could be used to reduce the energy content and improve the fat content of frankfurters. The implications of this study are that technological and structural characteristics of proteins and lipids were affected by the incorporation in frankfurters of olive oil bulking agent based on polysaccharides and cold-set binding agent like alginate as animal fat replacers. This reformulation process reduced processing loss while increasing hardness and chewiness of the frankfurters. The behavior of samples during chilling storage in terms of the technological properties considered was similar in all products regardless of the formulation.

Raman spectroscopy provided useful information on secondary protein structures in terms of enrichment of β-sheet structure, which was more pronounced in frankfurters containing inulin in the oil bulking agent. The high presence of aggregated intermolecular β-sheets in frankfurters suggests the formation of a denser network producing greater hardness. In addition a reduction in turn content was observed in response to reformulation.

In relation to how lipid structure was affected by this reformulation process, we should stress that it caused increased lipid acyl chain disorder, which involved more lipid−protein interactions when an oil bulking agent was used as a pork backfat replacer.

This study presented further advances in terms of how these reformulation processes influence the structures of the principal component proteins and lipids in these meat products, and how this affects the technological properties of the final meat product. This information can be helpful in improving these conditions and hence could be valuable for the development and formulation of healthier-lipid meat products. In addition, these correlations could be decisive for understand the

implications of both protein and lipid interactions in specific functional or technological properties such as texture or processing loss, which are very important for the acceptance of consumer.

ABSTRACT: The aim of the current research was to examine the influence of nitric oxide (NO) on calpain activation, protein proteolysis, and oxidation in post-mortem pork. Five longissimus muscles were removed from carcass after slaughter, and samples were incubated with water, nitric oxide synthase (NOS) inhibitor, or NO donor for 24 h at 4 °C. The samples were taken out and then stored under 4 °C for 1, 4, and 7 d. Results showed that autolysis of μ-calpain increased by incubation with NOS inhibitor after storage for 1 d ($P < 0.05$). Degradation of titin and nebulin increased by treatment of NOS inhibitor among three treatments ($P < 0.05$). Higher levels of protein oxidation were observed after samples incubated with NO donor than treatment of NOS inhibitor ($P < 0.05$). These data indicated that NO could participate in regulating calpain activation and its proteolysis activity during post-mortem aging.

KEYWORDS: *nitric oxide, calpain, post-mortem proteolysis, protein oxidation*

INTRODUCTION

Protein *S*-nitrosylation, which is the thiol site of protein cysteine modified by a nitric oxide (NO) group, has many functions in diverse biological processes. However, whether NO and protein *S*-nitrosylation could affect meat quality during post-mortem aging remains to be unknown. Few studies have shown that fresh meat quality could be affected by the level of NO preslaughter[1] or postslaughter.[2,3] Changed meat quality might have a relationship with the modification of calpain by nitric oxide. However, no studies have focused on the influences of NO and protein *S*-nitrosylation on calpain activation and its proteolysis activity of pork during post-mortem aging.

It is well-known that early post-mortem biochemical and biophysical processes, especially protein degradation, could contribute to the variation of water-holding capacity and tenderness of pork. Many proteins that are involved in meat quality have been shown to be susceptible substrates of the cysteine protease calpain. Among the calpain system, μ-calpain is the main protease for the protein proteolysis during post-mortem aging.[4] The 80 kDa catalytic subunit of μ-calpain contains four domains in which the catalytic domain II contains an active cysteine residue at position 115.[5] Because μ-calpain has an active cysteine residue, it is very sensitive to oxidation and nitrosylation modification. The disulfide bond, which was formed between Cys108 and Cys115 within domain II of μ-calpain, was shown to inhibit its activity and autolysis upon exposure to an oxidating environment.[6] The activity of μ-calpain was changed slightly after treatment with nitric oxide enhancer under neutral pH. However, it turned out that 80% of its activity could be inhibited when the pH was shifted to 5.5.[7] This is particularly important, because pH declines from near neutral pH in living muscle to approximately 5.3−5.7 in normal pork.[8]

NO is generated when arginine is converted to citrulline with the catalysis of nitric oxide synthase (NOS). Brannan and Decker[9] investigated the NOS activity in post-mortem muscle and found that the pork diaphragm still showed NOS activity after 24 h aging. The activity of NOS was stable when the pH was in the range from 4.5 to 7.4, indicating that the generation of nitric oxide could not be influenced by post-mortem pH decline in skeletal muscle after slaughter. However, no study has been aimed to examine the influence of NO on protein modification in post-mortem pork by managing NOS activity. The objective of the current experiment was to examine the role of NO and NO-induced protein *S*-nitrosylation in regulating μ-calpain, its proteolytic activity, and protein oxidation during post-mortem storage.

MATERIALS AND METHODS

Samples and Treatment. Five 6-month-old crossbred pigs with live weight 100 ± 10 kg were slaughtered at Sushi Meat Co. in Huaian of Jiangsu Province. The longissimus muscle was removed from porcine carcasses after slaughter and then randomly dissected into small pieces (0.2 g/piece). The samples were randomly divided into one of three groups: control group containing deionized distilled water, NOS inhibitor group containing 0.1 M Nw-nito-L-arginine methyl ester hydrochloride (L-NAME, Sigma, MO), or NO donor group containing 1 mM diethylenetriamine/nitric oxide adduct (DETA/NO, Sigma, MO). DETA/NO is a NO generating agent. The ratio of meat and solution (w/v) was 1:1. The samples were kept for 24 h at 4 °C. After incubation, the samples were taken out from the solution and stored for 1, 4, or 7 d at 4 °C under vacuum package. The samples were kept at −80 °C for further analysis.

Sarcoplasmic Protein Extraction. Sarcoplasmic protein from the samples was prepared at 4 °C as in the description of Veiseth et al.[10] Ground muscle from the samples was homogenized with polytron (IKA T25 digital ultraturrox Made in IKA, German) twice at 15 000 rpm for 15 s. 0.5 g of the samples was homogenized with 6 volumes (w/v) of

solutions containing 10 mM EDTA, 100 mM Tris-HCl, and 0.1% β-mercaptoethanol (MCE) (v/v) (pH 8.3). After centrifugation under 4 °C at the speed of 15 000*g* for 30 min, the collected supernatant was utilized for concentration measurement using BCA Protein Assay Kit (Thermo, RD, U.S.). The concentration was adjusted to 6.4 mg/mL with ddH_2O. The samples were mixed with tracking dye buffer (30 mM Tris-HCl, 20% glycerol [v/v], 3% SDS [w/v], 3 mM EDTA, and 0.003% pyronin-Y [w/v], pH 8.0) with the ratio of 2:1 (v/v). Final protein concentration for gel sample was 4 mg/mL with 6.25% MCE. The samples of the sarcoplasmic protein were heated at 50 °C (20 min) and were kept in frozen storage.

Myofibrillar Protein Preparation. Myofibrillar proteins were extracted using the method of Etlinger et al.[11] One gram samples were homogenized with 7.5 mL of PRB solution that consisted of 2 mM $Na_4P_2O_7$, 1 mM NaN_3, 2 mM $MgCl_2$, 2 mM EGTA, 1 mM dithiothreitol (DTT), 100 mM KCl, and 10 mM Tris-maleate (pH 6.8). The homogenate of the samples was centrifuged at the speed of 1000*g* for 10 min. Precipitates then were collected for seven washes with 7.5 volumes of LSB buffer (same as PRB without pyrophosphate), and the condition was the same as above. After being suspended in EDTA (5 mM) and Tris-HCL (10 mM), myofibrils were vortex mixed, removed using eppendorf, and mixed with the treatment buffer (20% glycerol [v/v], 125 mM Tris-HCl, 4% SDS [w/v], pH 6.8). The myofibril was heated at 50 °C for 0.5 hour, and then the supernatant was obtained for protein concentration analysis using the BCA Protein Assay Kit (Thermo, RD, U.S.) after centrifugation for 30 min at the speed of 16 000*g*. The final concentration for SDS-PAGE was 3.5 mg/mL by mixing the samples with treatment buffer (same as above with 0.001% bromophenol blue and 10% MCE). Samples for SDS-PAGE were kept at 50 °C (20 min) and then at −80 °C.

Gel System. For determination of μ-calpain autolysis, a 10% polyacrylamide separating gel (0.05% ammonium peroxodisulfate (APS) [w/v], *N*,*N*-bis-methylene acrylamide:acrylamide = 1:100 [w/w], 0.1% SDS [w/v], 0.05% *N*,*N*,*N*,*N*′-tetramethylethyl-enediamine (TEMED) [v/v], 1.5 M Tris-HCl) was used. Stacking gel was 4% polyacrylamide gel that contained 0.075% APS [w/v], *N*,*N*-bis-methylene acrylamide:acrylamide = 1:100 [w/w], 0.1% SDS [w/v], 0.125% TEMED [v/v], and 0.5 M Tris-HCl. Degradation of titin and nebulin was detected by 5% polyacrylamide successive gel (pH 8.0, 2 mM EDTA, *N*,*N*-bis-methylene acrylamide:acrylamide = 1:100, 0.1% SDS, 0.067% TEMED, 0.1% APS, 1.5 M Tris-HCl).

SDS-PAGE and Western Blotting. Sixty micrograms of proteins was loaded per well for calpain autolysis. Sixteen micrograms of sarcoplasmic proteins was used for SDS-PAGE. A constant voltage of 120 V was set for all gels until the samples were at the bottom of the gels. Seventy micrograms of samples was loaded for titin and nebulin, and a constant current was set as 5 mA for each gel. Bio-Rad Mini-Protean II system (Bio-Rad, CA) was used to run gels for 18 h.[12] By following electrophoresis, the 10% gels for SDS-PAGE of sarcoplasmic proteins were stained using 7% glacial acetic acid [v/v], 40% ethanol [v/v] with 0.1% coomassie brilliant blue R-250 [w/v]. The proteins of calpain were then moved to polyvinylidene difluoride (PVDF) membranes at 4 °C (90 V, 1.5 h). The membranes were then blocked at room temperature with gentle agitation for 90 min in 5% nonfat dry milk, which was dissolved in PBST (100 mM sodium chloride, 20 mM sodium dihydrogen orthophosphate, 80 mM disodium hydrogen orthophosphate, and 0.1% (v/v) polyoxyethylene sorbitan monolaurate (Tween-20)). After blocking, the membranes with calpain proteins were put in PBST containing primary antibody (MA3-940, Aynity Bioreagents, CO) for 13 h at 4 °C. The dilution for the primary antibody was 1:10 000. The membranes were taken out from the cold room, washed 30 min (6 min per wash) using PBST, and then incubated with the second antibody (1:5000, goat antimouse) for 90 min followed by washing in PBST for another 30 min. After reacting with ECL reagent for 5 min, the blots were scanned with ImageQuant LAS4000[13] (GE, CT).

Semi Quantification of Targeted Proteins. Quantity One (Bio-Rad, U.S.) was the major software for analysis of the intensity of proteins. An approximately 2400 kDa band was a main indicator for the degradation of titin. Autolysis of μ-calpain was indicated by the intact calpain intensity of an approximately 80 kDa band and autolyzed 76 kDa band.

Carbonyl Content. The content of protein carbonyl was detected using the method of Lund et al.[14] with slight changes. Ground muscle from the sample was homogenized using a Ploytron (IKA T25 digital ultraturrox Made in IKA, German) at a speed of 18 000 rpm for 30 s (15 s × 2). One gram of muscle was homogenized in 10 volume of pyrophosphate buffer (w/v) containing 100 mM KCl, 2.0 mM $Na_4P_2O_7$, 10 mM tris-maleate, 2.0 mM EGTA, and 2.0 mM $MgCl_2$ (pH 7.4). Four milliliter solutions were removed from homogenate for two tubes equally. The samples were precipitated twice with 20% trichloroacetic acid (TCA, 2 mL) and followed by centrifugation at the speed of 12 000*g* (5 min). The 10 mM 2,4-dinitrophenylhydrazine (DNPH, 2 mL) in 2 M HCl or 2.0 M HCl (control) was reacted with pellets for 30 min at 25 °C. The samples were precipitated with the same solution, and the centrifugation condition was the same as described above. To eliminate the impact of the unreacted DNPH, the precipitates were washed with 10 mM HCl (5 mL) dissolved in ethanol-ethyl acetate (v/v = 1:1, three times). The absorbance was detected by a spectrophotometer (Shimadzu, Japan) at 370 nm after pellets reacted with guanidine hydrochloride (6.0 M, 2 mL), which was dissolved in 20 mM potassium hydrogen phosphate, pH 2.3) overnight under 4 °C. The amount of nanomolar DNPH in per milligram protein was the carbonyl content (nmol/mg).

Free Protein Thiol Groups. The amount of free thiol groups in protein was measured according to the method of Ellman.[15] The

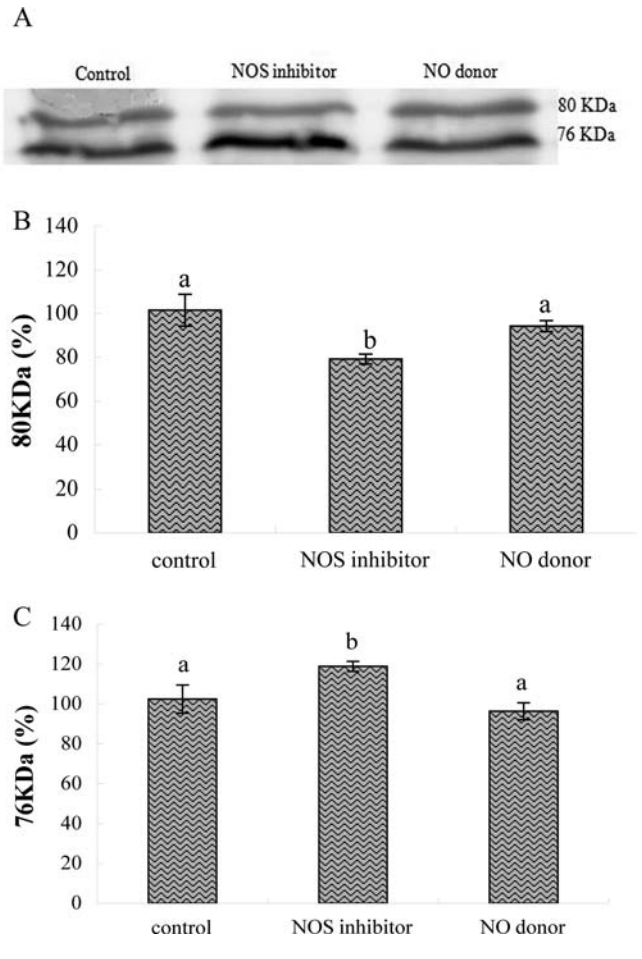

Figure 1. (A) Western blotting of μ-calpain. (B) Intensity of 80 kDa products of μ-calpain. (C) Intensity of 76 kDa products of μ-calpain. Ratios were calculated as the blot intensity of the μ-calpain fragment in each gel over the intensity of μ-calpain at 1 d control (100%). Vertical bars are mean ± SE (n = 5). Values with different letters show significant difference between treatments at $P < 0.05$.

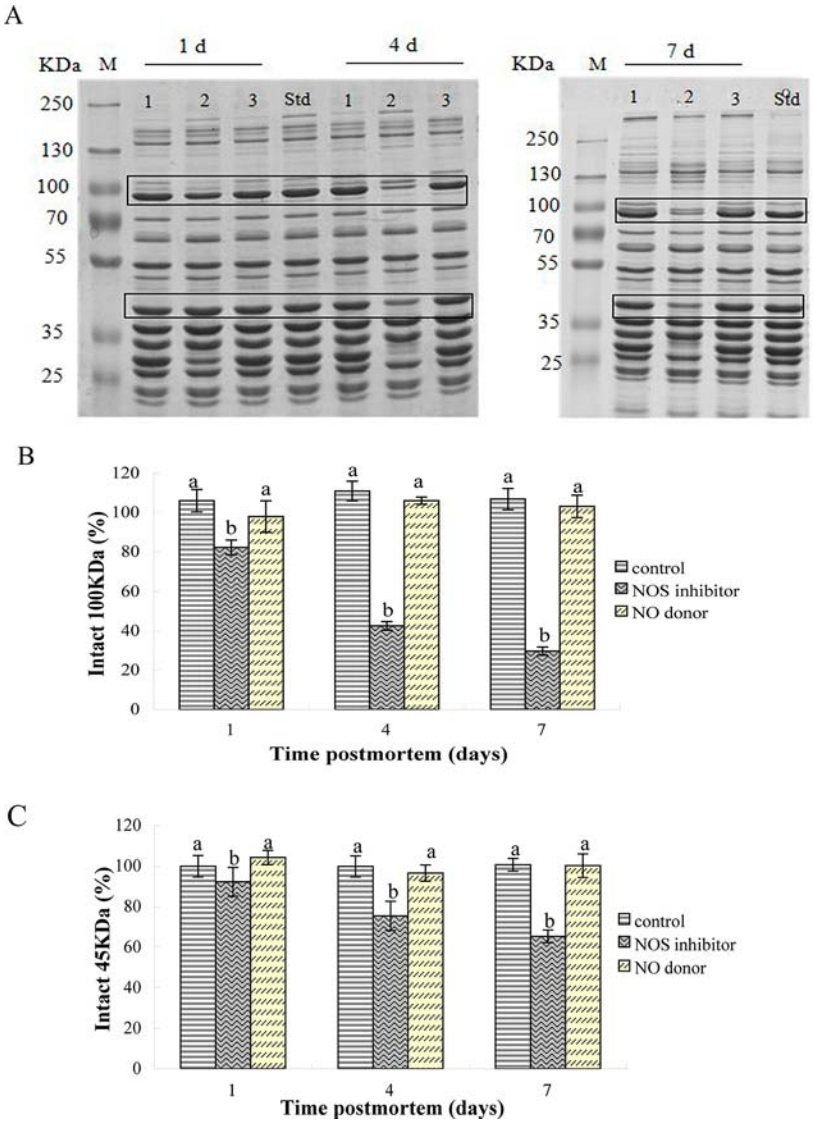

Figure 2. (A) 10% SDS-PAGE of sarcoplasmic proteins. 1, 2, and 3 represent control, NOS inhibitor group, and NO donor group, respectively. (B) The intensity of 100 kDa protein. (C) The intensity of 45 kDa protein. Ratios were calculated as intensity of the intact 100 and 45 kDa bands in each sample over intensity of 100 and 45 kDa bands at 1 d control (std). Values with different letters show significant difference between treatments at $P < 0.05$.

myofibril was dissolved in a solution containing 0.6 M NaCl, 50 mM Na_2HPO_4, and 50 mM NaH_2PO_4. Next, 0.5 mL of dissolved myofibril was added to 4 mL of Tris-Gly (86 mM Tris, 4 mM EDTA, 90 mM glycine, pH 8.0) and 0.4 mL of Ellman's reagent (Tris-Gly with 10 mM DTNB). The sample was vortex mixed, then incubated in 25 ± 1 °C for 1 h followed by centrifugation for 5 min at the speed of 12 000*g*. Free thiol groups were measured at 412 nm and calculated as nmol/mg protein.

Statistical Analysis. For statistical analysis, the version of SAS 9.2 was used. There were five replications in each group analyzed by ANOVA-one-way analysis of variance. The Bonferroni *t* test was used to analyze the difference among individual means, and the significant difference between treatments was considered at $P < 0.05$.

RESULTS AND DISCUSSION

***μ*-Calpain.** During the transformation of muscle to meat, *μ*-calpain plays a key role in proteolysis of some structural proteins.[16] The activation of *μ*-calpain has a close relationship with its autolysis. Because the autolysis from 80 to 76 kDa product had significance in early post-mortem muscle,[17] the intact 80 kDa band and the autolyzed 76 kDa band of calpain were investigated using Western blotting to examine the influence of L-NAME and DETA/NO treatment on calpain activation. The NOS inhibitor-treated group had less 80 kDa ($P < 0.05$, Figure 1B) and more 76 kDa products ($P < 0.05$, Figure 1C) as compared to control and NO donor group, suggesting that NO might inhibit the autolysis of *μ*-calpain. However, no significant differences were shown between control and NO donor group. Zhang, Lonergan, and Huff-lonergan[18] found that the rate of *μ*-calpain autolysis was slowed when it was first exposed to *S*-nitrosoglutathione before calcium at both pH 6.5 and pH 7.5, which was evidenced by more 80 and 78 kDa products and less 76 kDa products as compared to control group. Interestingly, endogenous purified *μ*-calpain was shown to be nitrosylated, and part of this nitrosylation could be reversed by DTT incubation. Koh and Tidball[19] used a NO enhancer, sodium nitroprussiate (SNP), to react with ionophore-treated cells. SNP pretreatment significantly reduced the degradation of talin and vinculin, indicating that NO might exert a negative influence on the activity of *μ*-calpain. Furthermore,

dx.doi.org/10.1021/jf501332d | J. Agric. Food Chem. 2014, 62, 5972−5977

calpain-mediated proteolysis could be reduced by modification with *S*-nitrosylation. Reduced *S*-nitrosylation of calpain during aging corresponded to the increased activity of calpain to cleave some proteins.[20]

Instead of μ-calpain, previous studies have shown that NO could inhibit other cysteine protease including papain, mammalian caspases, and cathepsins.[21] According to these studies, the activity of calpain was inhibited by NO through removal of the negative feedback by L-NAME at early stage post-mortem resulting in increased autolysis. However, the behind mechanism about the NO on the autolysis procedure of μ-calpain during post-mortem aging remains unknown and needs to be further studied.

Sarcoplasmic Protein. Sarcoplasmic proteins with molecular weights of about 100 and 45 kDa from NOS inhibitor group decreased during aging, and the differences were significant as compared to control and NO donor group ($P < 0.05$, Figure 2B and C). The sarcoplasmic protein of 100 kDa was tentatively considered as phosphorylase, while the protein of 45 kDa was believed as creatine kinase.[22,23] Creatine kinase is functionally coupled to enzymes and transport systems that participated in energy production and utilization,[24] and the enzyme of phosphorylase participates in glycogenolysis. Post-mortem degradation of creatine kinase has been observed in several studies.[25,26] Increased post-mortem glycolysis, evidenced by lower muscle glycogen and increased lactate concentration, was shown by inhibiting nitric oxide release preslaughter in ovine muscle.[1] *S*-Nitrosylation of kinase or phosphatase through a single Cys residue could have an inhibitory effect on its activity. In addition, *S*-nitrosylation could inhibit kinases directly through the suppression of kinase activity or by modulating the interaction of kinase and its substrate.[27] Further studies need to be conducted to investigate the mechanism of how NO and *S*-nitrosylation affects the enzymes during post-mortem storage.

Titin and Nebulin. Titin is the largest protein found in mammalian. One terminal end (C) of titin overlaps with M-line and the other terminal (N) overlaps with Z-line;[28] thus titin crosses one-half of a whole sarcomere. A major degradation product (T_2), which migrates at approximately 2400 kDa by using SDS-PAGE, could be observed when the intact titin is degraded. Nebulin, another mega-protein with MW 600−900 kDa, forms the fourth filament system in muscle.[29] The degradation of titin and nebulin could irreversibly cause myofibril fragmentation and also the integrity of muscle and result in improved tenderness.

The degradation product (T_2) of titin was not significantly different after 1 d of refrigerated storage ($P > 0.05$, Figure 3B), while significant difference was observed after 4 and 7 d by treatment with NOS inhibitor and water, and also by incubation with NOS inhibitor and NO donor ($P < 0.05$, Figure 3B). Lower levels of T_2 were observed by treatment of NOS inhibitor. Interestingly, another titin degradation product migrated below T_2 in NOS inhibitor group, which was reported in a previous study.[30] Although we could not analyze nebulin quantitatively, apparent differences could be observed from Figure 3A. The intact nebulin could not be detected from NOS inhibitor group after refrigerated storage of 1, 4, and 7 d. However, intact nebulin still could be observed by treatment of water and DETA/NO after storage of 4 and 7 d. Because titin and nebulin are susceptible substrates for μ-calpain, the increased activation of μ-calpain in NOS inhibitor group could result in a high degree of degradation.

The degradation of titin and nebulin is known to be associated with improved tenderness and increased water holding capacity.[31] Cottrell et al.[1] injected 30 mg/kg L-NAME into the ovine before slaughter and found the shear force of longissimus lumborum was significantly reduced. More importantly, the improved tenderness was independent of color parameters, pH decline, water holding capacity, or sarcomere length. Zhang et al.[2] incubated the broiler chicken meat with water, NO enhancer, and NOS inhibitor immediately after slaughter. The water holding capacity was lowered by treatment of incubation with *S*-nitrosoglutathione (a NO enhancer) after storage.

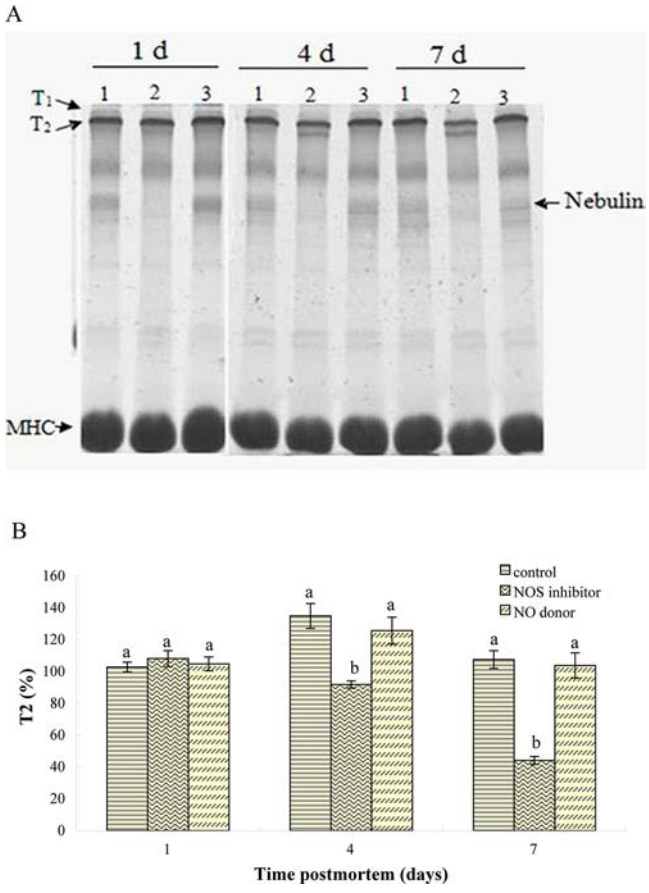

Figure 3. (A) SDS-PAGE (5%) showing degradation of titin and nebulin. 1, 2, and 3 represent control, NOS inhibitor group, and NO donor group, respectively. T_1 = intact titin, T_2 = large degradation of intact titin, MHC = myosin heavy chain. (B) The intensity of T_2. Ratios were calculated as intensity of 2400 kDa band in each sample over intensity of 2400 kDa band at 1 d control. Values with different letters show significant difference between treatments at $P < 0.05$.

Carbonyl Content. The carbonyl content by treatment with NO donor was higher than those in NOS inhibitor samples after storage of 1, 4, and 7 d ($P < 0.05$, Figure 4). No significant differences were observed by treatment with water and NOS inhibitor and by incubation with water and NO donor ($P > 0.05$, Figure 4). This indicated high content of nitric oxide might result in high levels of protein oxidation in post-mortem pork. Zhang et al.[2] injected the breast muscle with water, NOS inhibitor, or NO enhancer immediately after slaughter, and they reported similar results that the content of carbonyl by treatment of NO enhancer was improved. In that study, the higher content of carbonyl could not be the result of cross-reactions of protein oxidation products and lipid oxidation products because lipid oxidation just showed a significant difference after 7 d storage. The production of NO and superoxide ($O_2^{\bullet-}$) in muscle could contribute to the formation of peroxynitrite ($ONOO^-$). Protein thiols could be modified by peroxynitrite, whereas this modification cannot result in carbonyl

dx.doi.org/10.1021/jf501332d | J. Agric. Food Chem. 2014, 62, 5972−5977

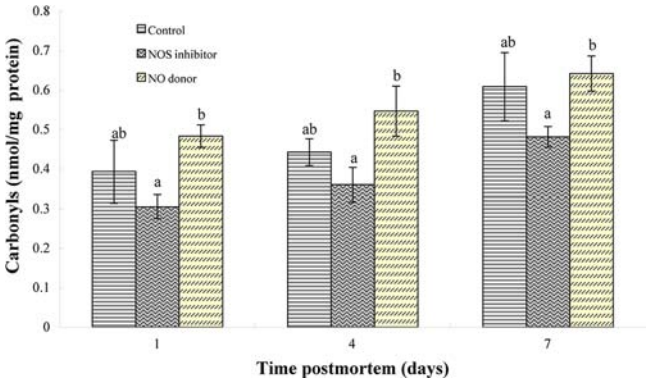

Figure 4. Carbonyl content. Vertical bars are mean ± SE (n = 5). Values with different letters show significant difference between treatments at $P < 0.05$.

formation.[32] A possible explanation could be that the NO donor group presented high levels of nitric oxide, and this might exert a high oxidative environment as compared to control and NOS inhibitor group. Antioxidant ability would decrease in pork samples during refrigerated storage and thus increased the content of the carbonyl group in the NO enhancer group.

Free Protein Thiol Group. The thiol content by incubation with NOS inhibitor was higher than the content in the other two groups after post-mortem storage of 1 and 4 d ($P < 0.05$, Figure 5). However, no significant difference was

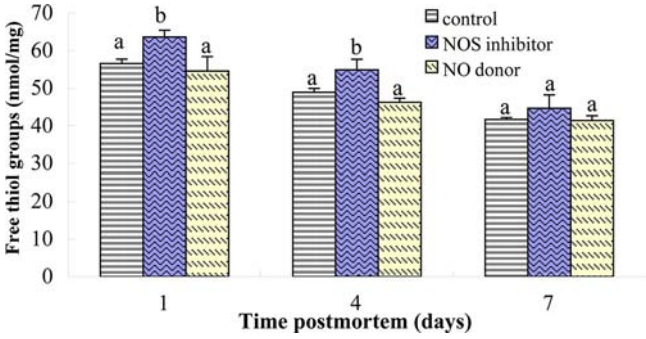

Figure 5. Free protein thiol group. Values with different letters show significant difference between treatments at $P < 0.05$ (n = 5).

shown by treatments with water and NO donor at 1 and 4 d. No significant difference was observed for free protein thiol content among three groups after refrigerated storage of 7 d ($P > 0.05$, Figure 5). Because of the decreased antioxidant system during refrigerated storage, NO could react with superoxide ($O_2^{\bullet-}$) in muscle, thus promoting the formation of peroxynitrite ($ONOO^-$). Peroxynitrite is a potent oxidant that mediates oxidation of both nonprotein and protein sulfhydryls. Besides, other reactive compounds derived from peroxynitrite ($ONOO^-$) could have a negative influence on the antioxidant capability during long-term storage.[9] Through inhibition of NOS activity at early stage post-mortem, less NO could be produced in the NOS inhibitor group than the other two groups, thus resulting in high levels of free thiol content after 1 and 4 d of storage.

Formation and Reduction of Furan in Maillard Reaction Model Systems Consisting of Various Sugars/Amino Acids/Furan Precursors

Heera Cho and Kwang-Geun Lee*

Department of Food Science and Biotechnology, Dongguk University—Seoul, 30, Pildong-ro-1-gil, Jung-gu, Seoul 100-715, Republic of Korea

ABSTRACT: To investigate the effect of the temperature on the formation of furan, various furan models were conducted at 90, 121, and 150 °C. A total 15 models, including alanine (ALA), serine (SER), ribose (RIB), RIB/ALA, RIB/SER, glucose (GLU), GLU/ALA, GLU/SER, sucrose (SUC), SUC/ALA, SUC/SER, furoic acid (FUR), GLU/FUR, acetaldehyde (ACET), and GLU/ACET, were prepared. The maximum level of furan was detected in the GLU/SER and GLU/ALA models at a molar ratio of 0.5:0.5. The formation of furan was proportional to the temperature in all models. The RIB/SER model generated the greatest amount of furan among the 11 models ranging from 2.1 to 4931.9 ng mL^{-1} under all temperature conditions. Among the precursor models, the FUR model formed the greatest amount of furan ranging from 1058.2 to 13 927.9 ng mL^{-1} at all temperatures.

KEYWORDS: *model system, furan, Maillard reaction HS-SPME, GC−MS*

INTRODUCTION

Furan (C_4H_4O) is a heterocyclic and highly volatile compound with a boiling point of 31.4 °C. Furan has received attention since 1995 because it was classified as "possibly carcinogenic to humans" by the International Agency for Research on Cancer.[1] Data have shown furan induces liver and kidney toxicity in rats and mice.[2,3] The Food and Drug Administration (FDA) announced that furan was present in a large number of thermally processed foods.[4] High amounts of furan have been detected in a variety of foods and beverages, including coffee, canned fish and vegetables, jarred source, fruit and vegetable juices, and bakery products.[5,6]

Furan is generated in food from multiple routes. Many researchers have reported that primary sources, such as sugars, amino acids, ascorbic acid, and polyunsaturated fatty acids, generate furan through thermal degradation, the Maillard reaction, and oxidation.[7,8] In particular, the Maillard reaction between the carbonyl groups of sugars and the amino groups of amino acids are regarded as major pathways of furan formation. Yaylayan proposed a pathway of furan formation with sugars and amino acids.[7] On the basis of this pathway, the degree of furan formation was evaluated using various heating sources. Ribose (RIB) as pentose, glucose (GLU) as hexose, and sucrose (SUC) as a disaccharide were chosen to determine the effect on the number of carbons. Serine (SER) and alanine (ALA) were used as amino group donors. In this study, single and binary primary source models were used. Single and binary models refer to one and two substrates, respectively. For example, a GLU or SER model is a single model and GLU/SER or GLU/ALA models are binary models. In this study, to determine the optimal molar ratio of a binary model, the concentration of furan of the GLU/SER and GLU/ALA models was compared at various molar ratios.

There are many precursors for furan formation, and they have occasionally been used as food additives. To confirm the effect of various precursors on furan formation, the heating process of the model including sugars, amino acids, and precursors was carried out in the same manner. Among furan precursors, we chose acetaldehyde (ACET) and 2-furoic acid, which are classified as edible synthetic flavoring substances.[9,10]

Several factors influence the formation of furan. Many studies have demonstrated that furan is formed in model systems during various heating processes.[7] Fan et al. reported that the heating time, temperature, and pH affect the formation of furan in food.[11−13] The aim of this study was to investigate the effect of the temperature and various ingredients in furan formation models. Each model was heated at 90, 121, and 150 °C. Eleven and four furan models were selected for clarification of the effect of the temperature and precursors on furan formation, respectively.

MATERIALS AND METHODS

Chemicals. L-ALA, D-SER, D-RIB, D-GLU, D-SUC, 2-furoic acid (FUR), and ACET were provided by Sigma-Aldrich Chemical (St. Louis, MO). Water and methanol were obtained from J.T. Baker (Phillipsburg, NJ).

Furan (+99%, purity) and d_4-furan (>99 atom % D) were purchased from Sigma-Aldrich. Stock solutions of furan and d_4-furan were prepared weekly by dissolving standard solutions in cold methanol at a concentration of 100 μg mL^{-1}. The stock solutions were further diluted in cold water to give a working solution with a concentration of 1 μg mL^{-1}. The stock and working solutions were stored in headspace vials closed with silicone−polytetrafluoroethylene (PTFE) septa and aluminum seals (Supelco, Bellefonte, PA) at 4 °C until analysis.

Method Validation for the Furan Analysis. The furan analytical method was validated using linearity, limit of detection (LOD), limit of quantification (LOQ), and repeatability. The calibration curve was drawn using the ratio of the area of furan versus the area of d_4-furan). A 10 μL aliquot of internal standard (1 μg mL^{-1}) was spiked in 10 mL

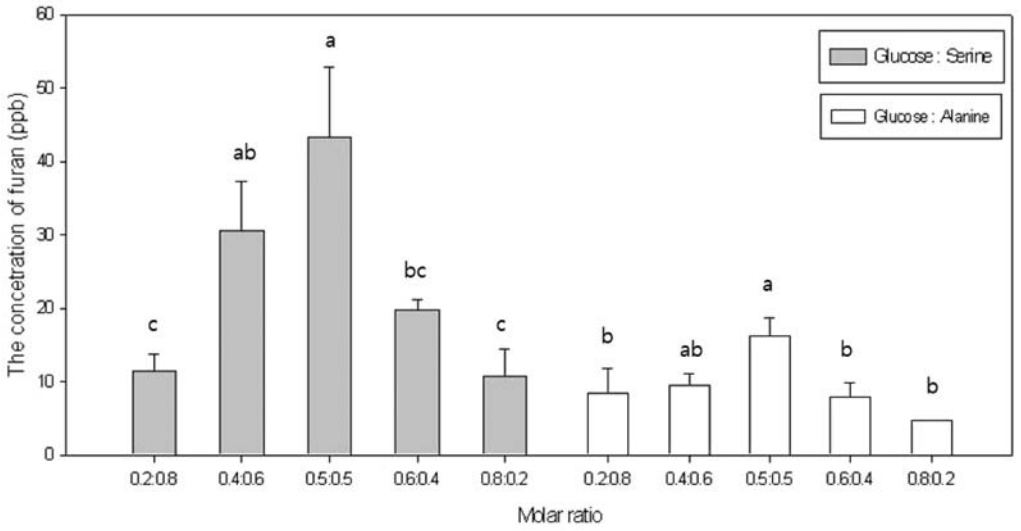

Figure 1. Effect of the molar ratio of amino acid to sugar on the furan formation. Within same figure, lower case alphabetical letters indicate spastically differences ($p < 0.05$, Duncan's multiple range test).

of water in a 20 mL headspace vial with a syringe to prepare the calibration curve. Seven different amounts (5, 10, 20, 50, 100, 500, and 1000 μL) of furan (1 μg mL^{-1}) were spiked into the vial. All experiments were performed at <4 °C to minimize furan loss.

Linearity was expressed as the correlation coefficient (r^2). LOD and LOQ were determined by the standard deviation (SD) of the response and the slope. LOD was calculated from the equation $3.3\sigma/S$, and LOQ was calculated from equation $10\sigma/S$, where σ is the SD of the response and S is the slope of the calibration curve. The SD, σ, is the SD of the blank in this study. The blank sample was analyzed 7 times.

Three concentrations (1, 5, and 10 ng mL^{-1}) of sample were analyzed to evaluate repeatability. Each concentration was investigated 5 times. Repeatability was presented as relative standard deviation (RSD, %).

Effect of the Molar Ratio of Amino Acid to Sugar on Furan Formation. GLU/SER and GLU/ALA models were selected to determine the effect of the sugar/amino acid molar ratio on furan formation. The two models (GLU/SER and GLU/ALA) were prepared by mixing both compounds at the following molar ratios in a headspace vial: 0.2:0.8, 0.4:0.6, 0.5:0.5, 0.6:0.4, and 0.8:0.2. Subsequently, 10 mL of water was added to the vial, and the solution was homogenized with a vortex machine (Scientific Industries, Bohemia, NY). The vial was heated at 121 °C for 25 min in a drying oven (OF-22, JEIO Tech., Daejeon, Korea). Immediately after heating, the sample was cooled in an ice box at <4 °C for a minimum of 30 min. Then, d_4-furan was spiked into a 20 mL vial with a syringe. After injection of 10 μL of d_4-furan (1 μg mL^{-1}), the fiber of a solid-phase microextraction (SPME) was injected into the headspace vial. All analyses were performed in triplicate.

Effect of the Heating Temperature on Furan Formation. Experiments were conducted at 90, 121, and 150 °C to identify the effect of the heating temperature on furan formation. The 11 models, including amino acid and sugar, were selected. The models were ALA, SER, RIB, RIB/ALA, RIB/SER, GLU, GLU/ALA, GLU/SER, SUC, SUC/ALA, and SUC/SER. A single compound (0.5 M) or a binary mixture (0.5:0.5 molar ratio) was transferred to a 20 mL headspace vial. After vortexing for 30 s, the samples were heated in a drying oven at 90, 121, and 150 °C for 25 min. Furan was then analyzed as described above.

Effect of Adding Various Precursors on Furan Formation. FUR, GLU/FUR, ACET, and GLU/ACET models were selected to investigate the effect of adding a direct precursor on furan formation. Each compound (0.5 M) was added to a 20 mL headspace vial and diluted with 10 mL of water. After vortexing for 30 s, the samples were heated in a drying oven at 90, 121, and 150 °C for 25 min. Furan was then analyzed as described above.

Analysis of Furan Using SPME–Gas Chromatography–Mass Spectrometry (GC–MS). A SPME fiber was pushed through a vial septum. The fiber was pushed out of the housing and exposed to the headspace (1.5 cm in depth) of the vial. Extraction was carried out at 50 °C for 20 min using a heating block. After extraction, the fiber was pulled into the housing and the SPME device was removed from the vial and inserted into the injection port of a gas chromatograph for thermal desorption analysis (4 cm in depth). The fiber was desorbed for 5 min at 230 °C to eliminate any residual volatile compounds.

The SPME fiber was a 75 μm Carboxen–polydimethylsiloxane (CAR–PDMS, Supleco, Bellefonte, PA) fiber. The extraction was carried out at 50 °C for 20 min on a heating block, and desorption was carried out at 230 °C for 5 min. GC–MS analyses were performed with an Agilent Technologies 6890 N GC system coupled with an Agilent Technologies 5975 mass selective detector (Palo Alto, CA) equipped with a HP-PLOT Q capillary column (HP-PLOT Q, 15 m × 0.32 mm inner diameter, 20 μm film thickness, J&W Scientific, Folsom, CA). Operational conditions were as follows: carrier gas, high-purity helium (99.999%); flow rate, 1 mL min^{-1}; and injector temperature, 230 °C. The oven temperature was programmed from 50 °C (held for 5 min) to 230 °C (held for 2 min). The mass spectrometer was operated in electron impact ionization mode (70 eV) and selected ion monitoring mode. The m/z (mass/charge) of 68 for furan and m/z of 72 for d_4-furan were used as quantification ions, and the m/z of 39 for furan and 42 for d_4-furan were used as confirmation ions.

Measurement of Ultraviolet (UV) Absorbance in Each Model System. A total of 1 mL of each sample was transferred to a cuvette. The absorbance of each sample was measured with a UV spectrometer (UV-1800, Shimadzu, Tokyo, Japan). The wavelength was set to 420 nm. Water was used as the control. All experiments were repeated 3 times.

Statistical Analysis. Results are presented as the mean ± SD. Data were analyzed by one-way analysis of variance (ANOVA), and multiple comparisons were performed with Duncan's test. The SAS 9.3 program was used for the statistical analysis (SAS Institute, Cary, NC). Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Method Validation for the Analysis of Furan and the Effect of the Sugar to Amino Acid Molar Ratio on Furan Formation. Satisfactory linearity was obtained with 0.997 correlation coefficient values. The LOD was 0.04 ng mL^{-1}, and the LOQ was 0.14 ng mL^{-1}. These LOD and LOQ values were

similar to those of a previous study.[5] RSD values for 1, 5, and 10 ng mL^{-1} were 9.33, 13.01, and 13.10%, respectively.

Figure 1 shows the effect of the molar ratio on furan formation in the GLU/SER and GLU/ALA models. Five molar ratios were selected for each model. The greatest amount of furan was formed at a molar ratio of 0.5:0.5 in both the GLU/SER and GLU/ALA models with 43.26 and 16.16 ng mL^{-1}, respectively. The molar ratio of 0.5:0.5 was selected as the optimal molar ratio for the sugar and amino acid binary models throughout this study.

Effect of the Heating Temperature on Furan Formation. All models were prepared by heating at 90, 121, and 150 °C to investigate the effect of the heating temperature on furan formation. The furan concentrations produced at 90, 121, and 150 °C are presented in Figures 2−4, respectively.

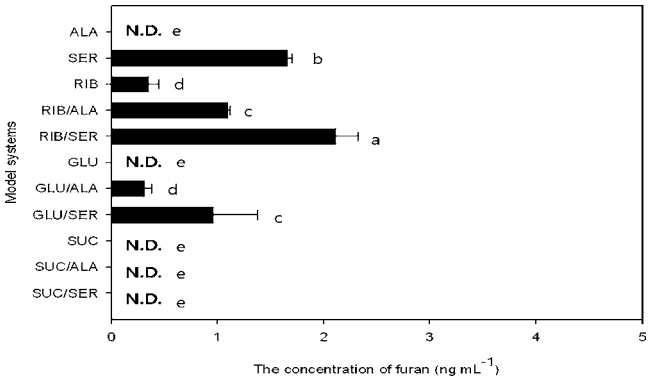

Figure 2. Concentration of furan in various model systems at 90 °C. Within same figure, lower case alphabetical letters indicate spastically differences (p < 0.05, Duncan's multiple range test). N.D.: Not detected.

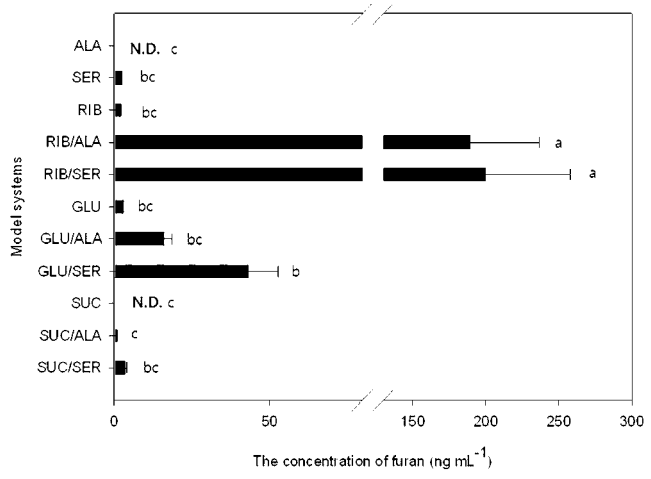

Figure 3. Concentration of furan in various model systems at 121 °C. Within same figure, lower case alphabetical letters indicate spastically differences (p < 0.05, Duncan's multiple range test). N.D.: Not detected.

The furan concentration was below the LOD in the ALA and SUC models at all temperatures. Furan formation ranged from not detectable to 8.5 ng mL^{-1} in the GLU model. Furan was not detected in any of the sugar single models at 90 °C, except for the RIB model. Although the RIB model generated furan (0.3 ng mL^{-1}) at 90 °C, no significant difference was observed in the GLU or SUC models. Furan was detected in the RIB model at concentrations of 1.9 and 44.9 ng mL^{-1} after heating at 121 and 150 °C, respectively. However, no significant difference with the GLU or SUC models was found.

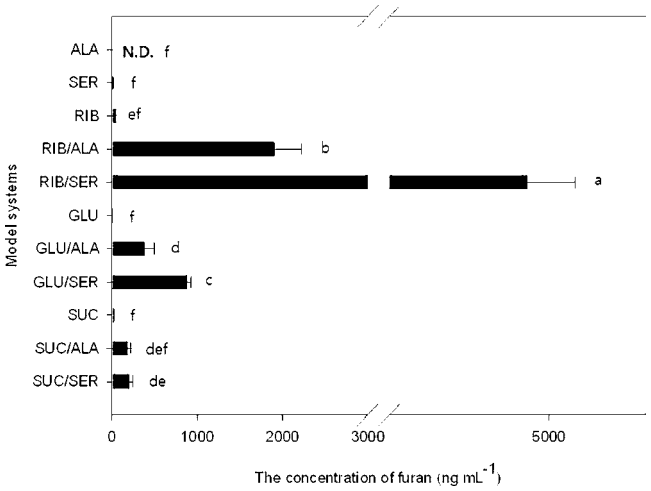

Figure 4. Concentration of furan in various model systems at 150 °C. Within same figure, lower case alphabetical letters indicate spastically differences (p < 0.05, Duncan's multiple range test). N.D.: Not detected.

SER formed furan at concentrations of 1.66−9.07 ng mL^{-1} at all temperatures; however, ALA produced no furan. Locas and Yaylayan explained the pathway of furan formation from sugars and amino acids.[14] Sugars and amino acids form ACET and glycolaldehyde by deamination and decarboxylation to produce furan. A previous study suggested the formation of furan from the aldol condensation reaction between ACET and glycolaldehyde.[14] Locas and Yaylayan reported that certain amino acids, such as SER, form ACET and glycoladehyde and eventually form furan. However, most amino acids, such as aspartic acid, ALA, and threonine, only generate ACET. These amino acids need a reducing sugar to generate glycoladehyde and eventually form furan.[14]

In contrast with the single model, the binary models, including an amino acid and sugar, produced more furan. For example, the RIB/SER model generated the greatest amount of furan ranging from 2.1 to 4931.9 ng mL^{-1} at all temperatures among the 11 models, followed by the RIB/ALA model (1.1−1901.3 ng mL^{-1}). Furan formation increased at higher temperatures for all model systems. For example, after heating at 150 °C, a significant increase in furan formation was observed in the RIB/SER model compared to heating at 90 °C (2347% increase). These results indicate that the temperature provides the main contribution to furan formation.

Effect of Various Precursors on Furan Formation. Four models were prepared to determine the effect of the precursor on furan formation. Figure 5 shows the furan concentration in these models. The FUR model formed the greatest amount ranging from 1058.2 to 13 927.9 ng mL^{-1} at all temperatures. The GLU/FUR model produced furan ranging from 628.1 to 9936.2 ng mL^{-1}. The formation of furan ranged from 647.9 to 834.2 ng mL^{-1} and from 600.1 to 742.9 ng mL^{-1} in the ACET and GLU/ACET models. However, no significant difference was observed between the ACET and GLU/ACET models.

The models including precursors generated more furan than the models including an amino acid and sugar. Amino acids and sugars undergo hydrolysis and elimination followed by decarboxylation, and they eventually form deoxyaldoltetrose.[15]

dx.doi.org/10.1021/jf501619e | J. Agric. Food Chem. 2014, 62, 5978−5982

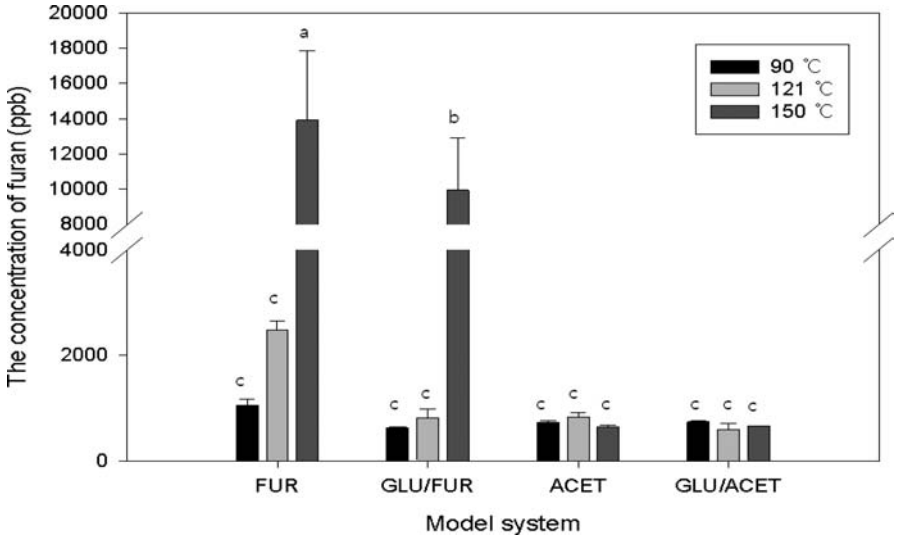

Figure 5. Concentration of furan in the model including precursors of furan. Within same figure, lower case alphabetical letters indicate spastically differences ($p < 0.05$, Duncan's multiple range test).

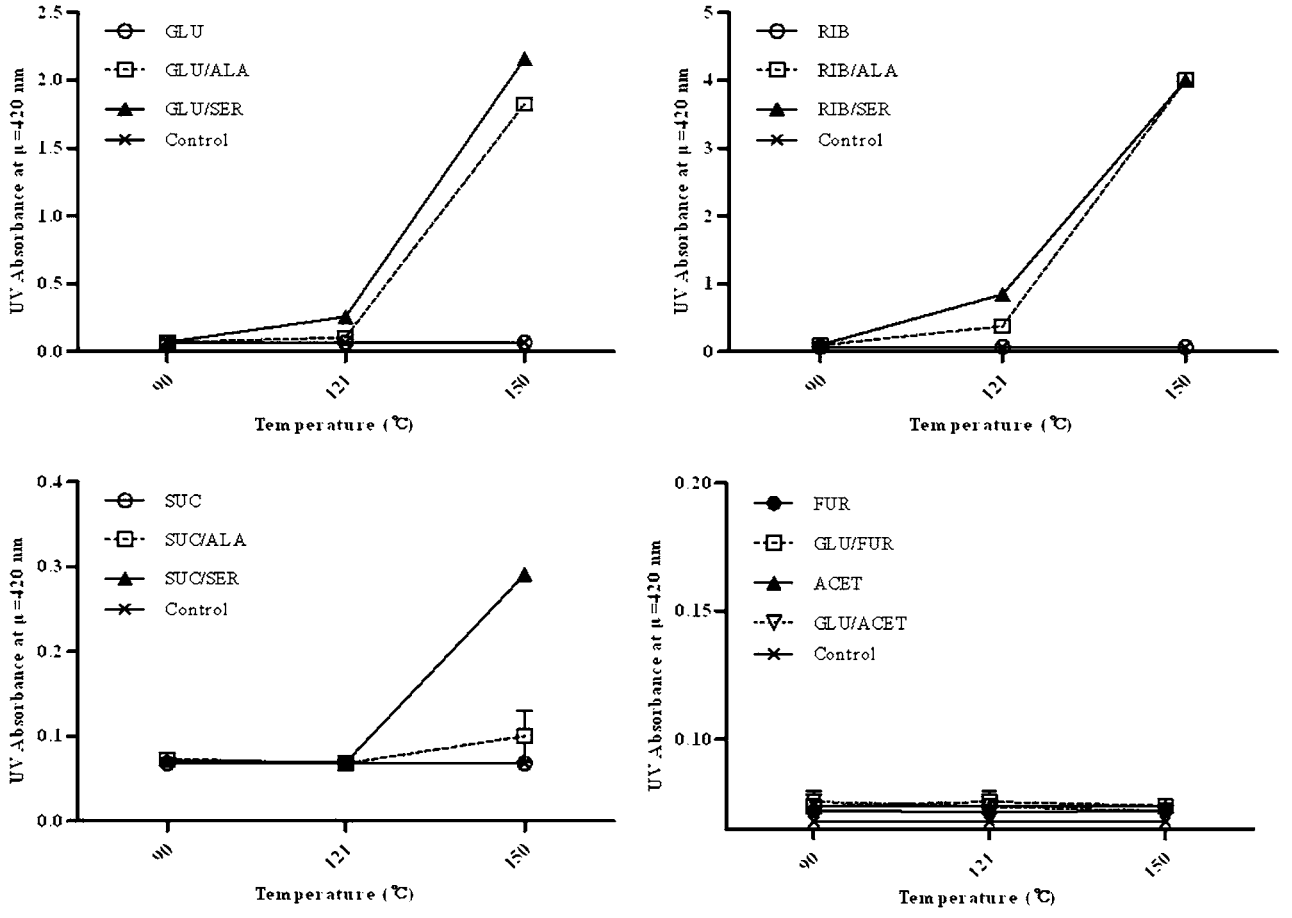

Figure 6. UV absorbance of the solution prepared in various models.

Deoxytaldoltetrose yields FUR and finally forms furan. However, FUR, which is a direct precursor of furan, can be produced only by decarboxylation and heating. These results explain why the FUR model formed furan at the greatest amount. FUR and ACET are used as food additives. However, FUR and ACET may potentially cause more furan formation during thermal processing.

Measurement of UV Absorbance in Each Model System. UV absorbance at 420 nm is often used to indicate the final products of the Maillard reaction, whereas UV absorbance at 294 nm is used to assess intermediate Maillard reaction products.[16] In the present study, changes in UV absorbance at 420 nm were investigated to identify the effects of the temperature on the Maillard reaction. Figure 6 shows the

dx.doi.org/10.1021/jf501619e | J. Agric. Food Chem. 2014, 62, 5978−5982

intensity of absorbance at 420 nm in the amino acid and sugar model systems. The intensity of absorbance in the RIB/SER model which had the greatest concentration of furan increased from 0.1 to 4.0 as the temperature increased. However, the intensity of the SUC model, which had the smallest concentration of furan, did not change. These results indicate that the Maillard reaction and formation of furan were promoted as the temperature increased. In contrast with the intensity of the Maillard reaction model, the intensity of models including furan precursors remained unchanged as the temperature increased. It was similar to the absorbance of the control. From these results, it was assumed that the models including precursors had different routes to produce furan during the Maillard reaction.

In summary, the effect of the sugar/amino acid molar ratio, heating temperature, and addition of precursor on furan formation was investigated. SPME−GC−MS was used to analyze furan production. The LOD and LOQ were 0.04 and 0.14 ng mL^{-1}, respectively. Repeatability by the RSD was 9.33−13.10%. Experiments were carried out at various molar ratios to investigate the effect of the molar ratio on furan formation, and the molar ratio of 0.5:0.5 was the optimal molar ratio for the binary model. Three heating temperatures and 11 binary models were selected to determine the effect of the heating temperature and type of sugar and amino acid. As the temperature increased, the formation of furan increased in all Maillard binary reaction models. Among the 11 models, the RIB/SER model generated the greatest amount of furan (2.10, 199.61, and 4931.97 ng mL^{-1} at 90, 121, and 150 °C, respectively). The FUR model formed the greatest amount of furan in an experiment to identify the effect of adding precursors on furan formation (1058.2−13 927.9 ng mL^{-1}) at all temperatures. In a future study, real food systems to form furan will be prepared and the furan level will be analyzed in the system.

ABSTRACT: Insoluble calcium phosphate particles, such as hydroxyapatite (HA), are often used in calcium-fortified milks as they are considered to be chemically unreactive. However, this study showed that there was an interaction between the casein micelles in milk and HA particles. The caseins in milk were shown to bind to the HA particles, with the relative proportions of bound β-casein, α_S-casein, and κ-casein different from the proportions of the individual caseins present in milk. Transmission electron microscopy showed no evidence of intact casein micelles on the surface of the HA particles, which suggested that the casein micelles dissociated either before or during binding. The HA particles behaved as ion chelators, with the ability to bind the ions contained in the milk serum phase. Consequently, the depletion of the serum minerals disrupted the milk mineral equilibrium, resulting in dissociation of the casein micelles in milk.

KEYWORDS: *milk, caseins, casein micelle, calcium phosphate, hydroxyapatite, adsorption*

INTRODUCTION

Calcium fortification is a growing trend in the food industry, especially for milk and dairy products. However, fortifying milk with calcium can be a challenge, especially if the product has to be heat treated. When soluble calcium salts are added to milk, the ionic calcium modifies the mineral equilibrium of the milk. Consequently, the physicochemical characteristics of the casein micelles are modified and their heat stability decreases.[1] Therefore, insoluble calcium phosphate particles such as hydroxyapatite (HA) or calcium carbonate, rather than soluble salts, are often used for the calcium fortification of milk. When HA particles were added to cow's milk or soy milk, they were reported not to modify the ionic calcium content or the pH of the milk and, therefore, did not affect the heat stability of the casein micelles when the milk was sterilized.[2−4] They are therefore considered to be unreactive when added to milk. However, it is known that proteins can interact with HA particles, for example, in chromatographic columns or nanoceramic materials.[5,6] HA particles are not homogeneously charged. Proteins can adsorb to both positive and negative adsorbing sites that are expressed at the surface of HA particles.

The negative sites are formed by oxygen atoms associated with phosphate and are called P-sites. Positively charged groups of proteins, such as amino groups, can adsorb to P-sites.[7] The positively charged sites, called C-sites, are formed by calcium ions in the crystal lattice. C-sites can complex specifically with negatively charged groups of proteins, such as carboxyl or phosphoserine groups.[7] As milk proteins are negatively charged at the natural pH of milk, they can adsorb to the C-sites of HA, as has been reported in several previous studies. For example, Reynolds and Wong[8] showed that, at pH 7, all of the main milk proteins (α_{S1}-casein, β-casein, κ-casein, β-lactoglobulin, and α-lactalbumin) adsorb onto HA disks and cause them to acquire an overall negative charge. In our previous work,[9] we showed that caseins from sodium caseinate (SC) adsorb onto HA particles, resulting in negatively charged particles and providing an electrosteric stabilization to the particles.

Whey proteins from whey protein isolate (WPI) are also able to bind to HA particles but to a lesser extent than the caseins.[9] They are believed to bind to HA particles through their carboxyl groups, whereas the caseins in SC are considered to bind more strongly onto HA particles through both their carboxyl groups and their phosphoserine groups. SC is a mixture of the natural caseins contained in milk, without the calcium and phosphate, which are removed from the micelles during processing and are replaced by sodium.[10] Therefore, in SC, the casein molecules reassociate randomly and their phosphoserine groups are available for binding to the calcium of HA particles. In milk, however, the phosphoserine groups of the caseins are involved in the casein micelle structure and are already bound to the colloidal calcium phosphate (CCP).[11] Therefore, if exogenous HA particles are added to milk, it is not certain whether the caseins in the micelles will be able to bind to the HA particles. Also, about 20% of the protein in milk is whey proteins, and these may also bind to HA particles.

The salt composition of milk is likely to affect the adsorption of proteins onto HA particles, as the binding of proteins has been shown to depend on the mineral composition of the suspending medium.[12,13] Potential-determining ions can change the surface charge of the HA particles, thereby affecting the amount of protein that can bind to them. For example, calcium ions have been shown to give a positive charge to the surface of HA, and this enhances protein adsorption by increasing the number of sites available for protein binding through their carboxyl and phosphoserine groups.[14] Preliminary experiments (unpublished data) showed that the adsorption of both caseins and whey proteins decreased in simulated milk ultrafiltrate (SMUF), and this was attributed to the binding of phosphate or citrate ions from the milk serum, which competed with the negatively charged groups of the

proteins for adsorption. As milk contains free calcium, phosphate, and citrate ions, it is likely that these ions will adsorb onto HA particles. If the ions in milk bind to the HA surface, the mineral equilibrium of the milk serum phase could be disrupted, potentially affecting the integrity of the casein micelles.[15]

As HA particles are often added to milk for calcium fortification, it is important to understand the interactions that could take place between the milk proteins, the milk minerals, and the HA particles and whether they are likely to cause any instability in the products. Therefore, the objective of this research was to investigate whether or not the casein micelles and whey proteins contained in skim milk (SM) adsorbed onto HA particles when HA was added. The binding of casein micelles onto HA particles was investigated using both SM and whey-protein-depleted skim milk (WPD-SM). Transmission electron microscopy (TEM) was used to check whether or not casein micelles could be observed at the surface of the HA particles. To check whether the milk mineral equilibrium was affected by the addition of HA particles, increasing levels of HA particles were added to SMUF and SM and the soluble minerals were quantified. SM was also dialyzed against SMUF or against SMUF containing HA particles to check whether the presence of HA particles caused disruption of the casein micelles when casein micelles and HA particles were separated.

EXPERIMENTAL PROCEDURES

Materials. Fresh SM was obtained from a local supermarket and was used to prepare the WPD-SM. Low-heat skim milk powder (SMP) was obtained from Fonterra Co-operative Group Ltd., New Zealand. The protein content of the SMP was 33% (w/w). Food grade HA powder was purchased from Budenheim (TCP 53-83, Budenheim, Germany). The median diameter $d_{(0.5)}$ was found to be 4.5 μm. The specific surface area of the powder was determined according to the Brunauer–Emmett–Teller (BET) method and was reported to be 65 m^2/g. SMUF was prepared according to the method of Jenness and Koops,[16] and the pH was adjusted to 6.67. All of the chemicals used were of analytical grade and were obtained from Sigma-Aldrich unless otherwise specified.

Preparation of WPD-SM. WPD-SM was prepared using a bench-scale microfiltration (MF) membrane unit (Amicon hollow fiber membrane, H1P30-43, pore size = 0.1 μm). This membrane unit allows the passage of the two main whey proteins (β-lactoglobulin and α-lactalbumin), the lactose, and the serum-phase minerals to the MF permeate, but retains the casein micelles. Fresh SM (1.3 L) was run through the membrane. The volume of the MF permeate was monitored and an equivalent volume of SMUF containing 5% (w/w) lactose was added back to the milk. Seven successive rinses with SMUF were necessary to obtain a final WPD-SM containing only ~5% of the initial whey proteins. The WPD-SM was then spray-dried using a Yamato Pulvis spray-dryer (model GB-22, Yamato Scientific Co., Tokyo, Japan), and the powder obtained was stored in an airtight container in a refrigerator until needed. The protein content of the WPD-SM powder was measured using the Kjeldahl method and was found to be 31% (w/w).

Adsorption Experiment. Stock solutions (10% (w/w) total solids (TS) on a powder basis, corresponding to 3.3% (w/w) total protein) of WPD-SM and SM, were reconstituted from WPD-SM powder and SMP in Milli-Q water. The solutions were stirred for at least 1 h and were left overnight at 4 °C to equilibrate.

The stock solutions were centrifuged at low speed (3000*g* for 2 min) prior to the adsorption experiment. A small pellet of casein micelles was centrifuged down at this speed (variable amount between 5 and 10% of the total casein micelles). The supernatants were carefully poured out and used for further experiments.

Ranges of WPD-SM and SM solutions at different concentrations (0.15–2.8% (w/w) total protein) were prepared by diluting appropriate volumes of the WPD-SM and SM stock solutions in SMUF. As protein adsorption varies with ionic strength, pH, and mineral composition, SMUF was used to prepare successive dilutions of the WPD-SM and SM solutions so that the casein micelles were suspended in a solution of similar pH, ionic strength, and mineral composition, for all samples. A constant weight of the WPD-SM or SM solutions (0.95 g) of various protein concentrations (0.15–2.8% (w/w)) was added to Eppendorf tubes containing the same amount of HA powder (50 mg).

The suspensions were stirred for 2 h at room temperature (approximately 20 °C), as preliminary experiments had shown that equilibrium was reached after 2 h of adsorption. The suspensions were then centrifuged (3000*g* for 2 min) to separate the HA particles from the WPD-SM and SM solutions. Preliminary work (unpublished data) had established that, under these conditions, <5% (w/w) of the HA particles remained in suspension after centrifugation; this did not affect the results. The supernatants (referred to in this paper as the adsorption supernatants) were kept aside for further analysis. The adsorption experiments were repeated at least twice.

Analysis of the Unabsorbed Protein Contained in the Adsorption Supernatant. *Determination of Surface Protein Concentration and Composition by SDS-PAGE.* The concentration of unadsorbed protein contained in the adsorption supernatants was determined as a percentage of that in the initial WPD-SM or SM sample, using microfluidic chip sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), as described by Anema,[17] and conventional SDS-PAGE, as described by Tercinier et al.[9] The amount of adsorbed protein (in mg of protein/m^2 of HA surface available) was calculated by difference between the amount of protein in the initial WPD-SM or SM solution and that in the supernatant, as described by Tercinier et al.[9] No correction was applied for the small portion of casein micelles that were centrifuged down during the centrifugation of HA particles, as it could not be measured precisely and was different for all samples prepared at different initial concentrations. However, it was estimated to be always <5% of the total unadsorbed caseins and did not have a significant effect on the calculation of the amount of adsorbed protein.

Nonmicellar Casein Content. Nonmicellar caseins were defined as those that did not sediment from the adsorption supernatants during centrifugation at 21000*g* and 25 °C for 60 min using a bench centrifuge (centrifuge 5417R, Eppendorf AG, Hamburg, Germany). The serum containing the nonmicellar caseins was carefully removed from the pellet (containing the casein micelles), and the protein content was determined by microfluidic chip SDS-PAGE and was expressed as a percentage of the protein content in the adsorption supernatants.

Casein Micelle Diameter Measurement. Dynamic light scattering (DLS) was performed using a Malvern Zetasizer Nano ZS instrument (Malvern Instruments, Malvern, Worcestershire, UK) to determine the hydrodynamic diameter (D_h) of the casein micelles. The samples were diluted in SMUF (25 μL of sample in 5 mL of SMUF), and 1 mL was transferred to a plastic cuvette and placed in the instrument; the automatic attenuator setting was used, and the temperature of the cell was maintained at 20 °C for the duration of the experiments. Measurements of the dynamics of the scattered light were collected at a scattering angle of 173°. Average diffusion coefficients were determined according to the method of cumulants and were translated into average particle hydrodynamic diameters using the Stokes–Einstein relationship for spheres.

Transmission Electron Microscopy. Three selected samples were prepared for TEM observation: WPD-SM, HA particles suspended in water, and 50 mg of HA particles suspended in 0.9 mL of WPD-SM. The general TEM method was similar to the method used by McKenna et al.[18] The WPD-SM solution was pipetted into agarose tubes, and the ends of the tubes were sealed with agarose. The suspensions of HA particles in water and in WPD-SM were mixed with warm 3% low-temperature-gelling agarose at a ratio of 1:1. This solution was poured onto a microscope slide, was allowed to set, and was chopped into 1 mm^3 cubes. Agarose-embedded tubes and cubes were put into bijoux bottles containing 3% glutaraldehyde in 0.2 M

dx.doi.org/10.1021/jf5018143 | J. Agric. Food Chem. 2014, 62, 5983–5992

sodium cacodylate buffer and were left at 5 °C for 24 h. The glutaraldehyde was rinsed twice with 0.2 M sodium cacodylate buffer over 2 h. The agarose-embedded samples were then placed in 1% osmium tetroxide overnight at 5 °C. The samples were placed in 1% uranyl acetate for 30 min and then rinsed twice with distilled water before dehydration. The dehydration process consisted of successive rinses of the samples carried out at 5 °C in 25% acetone for 15 min and in 50, 70, and 90% acetone for 30 min each, followed by 100% acetone (three changes over 90 min). The acetone was then replaced by embedding resin (Procure 812), and the bottles were placed on a rotator for 36 h. The cubes (for samples containing HA particles) and the tubes (for samples containing only WPD-SM) were then placed into an embedding capsule containing resin and baked at 60 °C for 48 h. The embedded samples were then sectioned to a thickness of 90 nm using a Reichert Ultracut microtome (Reichert-Jung, Heidelburg, Germany). These sections were mounted on 3 mm copper grids and stained with lead citrate before examination in a Philips TEM 201C transmission electron microscope (Philips, Eindhoven, The Netherlands) at an accelerating voltage of 60 kV.

Dialysis Experiment. A dialysis experiment was carried out using 10% TS (w/w) SM. A 5% TS (w/w) SM solution was prepared by diluting the 10% TS SM in SMUF. These SM solutions are referred to as 10%-SM and 5%-SM in this paper. Samples of the 5%-SM and 10%-SM (10 mL) were placed in dialysis bags (MEMBRA-CEL MC25-16 × 100 CLR) and dialyzed overnight at room temperature against SMUF (control) or SMUF containing 10% HA particles. The SM samples were removed from the dialysis bags, their visual turbidity was assessed by taking photographs, and the samples were analyzed for hydrodynamic diameters of casein micelle and nonmicellar casein content.

Mineral Concentrations. Total calcium was measured by inductively coupled plasma−atomic emission spectrometry. The ionic calcium concentration was measured using a Radiometer (Copenhagen, Denmark) type F2112 Ca calcium-specific electrode paired with an Orion (Beverly, MA, USA) Sure-Flow model 90-02 Ag/AgCl double-junction electrode with 0.08 M KCl in the outer electrode chamber. The standards used were $CaCl_2$ solutions (1−5 mM) in 0.08 M KCl. Inorganic phosphate (PO_4^{3-}) was determined by automated colorimetric analysis using a Technicon Auto-Analyzer. The samples were pumped through a segmented flow injection system, and inorganic phosphate was determined by using a procedure involving measurement of the absorption at 420 nm of a complex formed by orthophosphate ions and a phosphate color reagent, containing ammonium molybdate and ammonium metavanadate. Citrate was measured by an enzymatic method, involving successive enzymatic reactions with citrate lyase, malate dehydrogenase, lactate dehydrogenase, and $NADH/H^+$. After the enzymatic reactions, the concentration of $NADH/H^+$, which was stoichiometric with the concentration of citric acid, was determined by measuring the absorbance at 365 nm.

Statistical Analysis. *t* tests and analysis of variance (ANOVA) tests were carried out using Minitab software (Minitab version 16, Minitab, Inc., State College, PA, USA) to determine the significance of the differences. Significance was established at $P < 0.05$.

RESULTS AND DISCUSSION

Adsorption of Caseins and Whey Proteins. The adsorption studies were carried out by adding a constant amount of HA to WPD-SM or SM solutions of different protein concentration (0.15−2.8% (w/w)). After 2 h of stirring, the HA was separated from the WPD-SM or SM solutions by centrifugation, and the supernatants (referred to as the adsorption supernatants) were analyzed for protein composition and concentration using SDS-PAGE. The adsorbed protein concentration was calculated as the difference between the total protein concentration and the unadsorbed protein concentration in each sample.

Figure 1 shows the unadsorbed protein concentration measured in the adsorption supernatants and the amount of

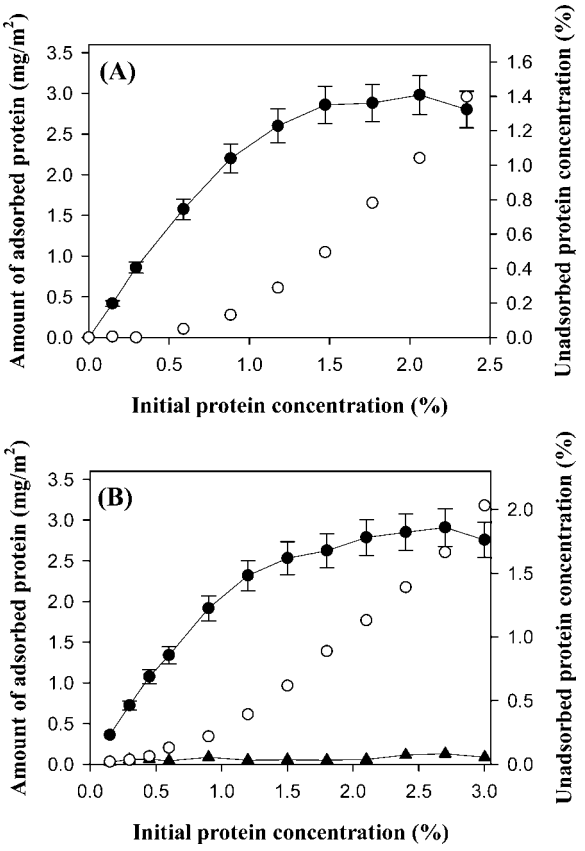

Figure 1. Amount of (●) caseins and (▲) whey proteins adsorbed onto HA particles (mg/m²) and (○) unadsorbed protein concentration (% (w/w)) as a function of initial protein concentration: (A) WPD-SM; (B) SM. Fifty milligrams of HA particles was added in 0.95 mL of WPD-SM and SM; the total surface area of HA was 3.25m². Results are means of duplicates or triplicates with error bars for the standard deviation.

adsorbed proteins on the surface of the HA particles as a function of the initial protein concentration for both WPD-SM (Figure 1A) and SM (Figure 1B). For both WPD-SM and SM, at low initial protein concentration (<0.5%), the amount of protein that remained in the supernatants (i.e., the unadsorbed protein) was very low. As the initial protein concentration increased, the amount of unadsorbed protein increased considerably. For both systems, the amount of adsorbed caseins increased gradually until it reached a plateau value, corresponding to a maximum protein coverage of the surface of the HA particles. For HA particles mixed with WPD-SM, the surface casein concentration increased gradually with the initial protein concentration up to about 1.5% (w/w, total protein) and reached a maximum value of ∼2.9 mg/m². For HA particles mixed with SM, the amount of adsorbed casein increased with the initial protein concentration up to about 2% (w/w, total protein) and reached a maximum value of ∼2.8 mg/m² (Figure 1B). These results clearly showed that the caseins from WPD-SM and SM adsorbed at the surface of HA particles, to similar maximum amounts of ∼2.9 mg/m². In contrast, the maximum amount of whey proteins from SM that bound to HA particles was ∼0.1 mg/m², which was negligible, as it represented only ∼3% of the total protein bound (Figure 1B).

Both caseins and whey proteins have been shown to bind to HA at pH ∼7, when adsorption studies are carried out in water or buffer.[8,9] As both caseins and whey proteins carry a net

dx.doi.org/10.1021/jf5018143 | J. Agric. Food Chem. 2014, 62, 5983−5992

negative charge at the milk pH, they mostly adsorb onto HA particles via an interaction between their negatively charged groups (carboxyl groups for the whey proteins, and both carboxyl and phosphoserine groups for the caseins) and the calcium sites (C-sites) on HA particles.[5−7] However, as the interactions between the C-sites and phosphoserine groups are stronger than those between the C-sites and carboxyl groups, caseins bind to HA to a greater extent than whey proteins.[9] As the phosphoserine groups of the caseins are grouped in clusters, the caseins probably also carry more anchor points to bind to the C-sites on HA particles than the whey proteins, which would partly explain the higher surface load for caseins compared with whey proteins.[19,20]

Also, in a milk environment, there is competition for binding between the milk ions and the milk proteins. Our previous work (unpublished data) on the binding of both caseins from SC and whey proteins from WPI in SMUF showed that the whey proteins from WPI could bind to HA particles only at a very low level (~0.5 mg/m^2), as they had to compete for binding with the divalent milk anions, mostly phosphate and citrate present in SMUF. However, as the interactions between caseins and HA are stronger, caseins could compete better with the milk ions for binding and more casein was bound (~2.4 mg/m^2). Negligible whey protein binding was therefore expected when HA particles were added to SM, and this is what was observed (Figure 1). Devold et al.[21] showed that, at the milk pH, only caseins were able to bind to the HA in tooth enamel and there was no whey protein binding.

The caseins in SC are in a nonmicellar form and can be present as individual molecules or small aggregates,[22] whereas the caseins in WDP-SM and SM are associated together to form casein micelles. The Langmuir model is often used in studies on the adsorption of protein onto HA, to compare the adsorption characteristics of different types of protein.[23−25] The Langmuir model was therefore fitted to the adsorption data obtained in this study for WPD-SM and SM and for SC in water and SMUF (unpublished data), to compare the adsorption characteristics of the caseins from SC, WPD-SM, and SM. The Langmuir model quantifies the amount of protein adsorbed onto HA as a function of the protein concentration once equilibrium has been reached (in this case, the unadsorbed protein concentration) at a given temperature. This model assumes that the proteins bind to a series of distinct empty sites on the HA surface. The surface is assumed to be energetically homogeneous, and the model allows only a monolayer coverage. The Langmuir model is given by eq 1

$$\frac{m_{abs}}{S} = q_m \times \frac{K[P]}{1 + K[P]} \quad (1)$$

where m_{abs}/S is the amount of protein bound to the surface expressed in mg/m^2, [P] is the concentration of protein at equilibrium (g/100 g), q_m is the maximum monolayer surface coverage (mg/m^2), and K is the Langmuir affinity constant and is dimensionless.

The Langmuir isotherm curves for casein adsorption onto HA for the adsorption experiments carried out with WPD-SM and SM are given in Figure 2. Table 1 gives the calculated Langmuir constants for each of the isotherms and for the adsorption data of SC onto HA in water and in SMUF. The maximum surface protein concentrations obtained for both WPD-SM and SM experiments (Figure 1) (3.0 and 2.7 mg/m^2, respectively) were not different from the maximum adsorption value obtained for SC in water (2.9 mg/m^2, $P < 0.05$) and were only slightly higher than the maximum adsorption value for SC in SMUF (2.4 mg/m^2).

Table 1. Parameters for the Adsorption of Caseins from WPD-SM, SM, and SC in Water and in SMUF, Calculated According to the Langmuir Model[a]

casein source	affinity constant, K	max surface coverage, q_m (mg/m^2)
WPD-SM	24.5ab ± 9	3.0a ± 0.02
SM	31.5a ± 7.1	2.7ab ± 0.15
SC in water	13.7b ± 4.8	2.9a ± 0.2
SC in SMUF	31.5a ± 3.6	2.4b ± 0.01

[a]Means with different letters differ significantly ($P < 0.05$; vertical comparison).

In food emulsion systems, casein micelles have been shown to bind as intact micelles onto oil droplets.[26,27] The surface protein concentration for casein-micelle-coated droplets has been reported to be much higher than that for SC-coated droplets,[27,28] with usually 2 or 3 times more adsorbed protein for casein micelles than for SC. As casein micelles are larger than SC aggregates, they form a thicker layer at the surface of the oil droplets so that the protein surface load is higher. The fact that the maximum amount of casein adsorbed onto HA was similar for WPD-SM, SM and SC in SMUF (Table 1) could indicate that casein micelles do not bind as intact micelles to HA particles. The affinity constant of the Langmuir model characterizes the initial slope of the adsorption isotherms and indicates a high affinity of protein for HA.[24] There was a variability of the affinity constants in this study (Table 1), as a small variation in the first points of the adsorption isotherms (Figure 2) can lead to a high variation of the slope and, therefore, of the affinity constant. However, it is interesting to

dx.doi.org/10.1021/jf5018143 | J. Agric. Food Chem. 2014, 62, 5983−5992

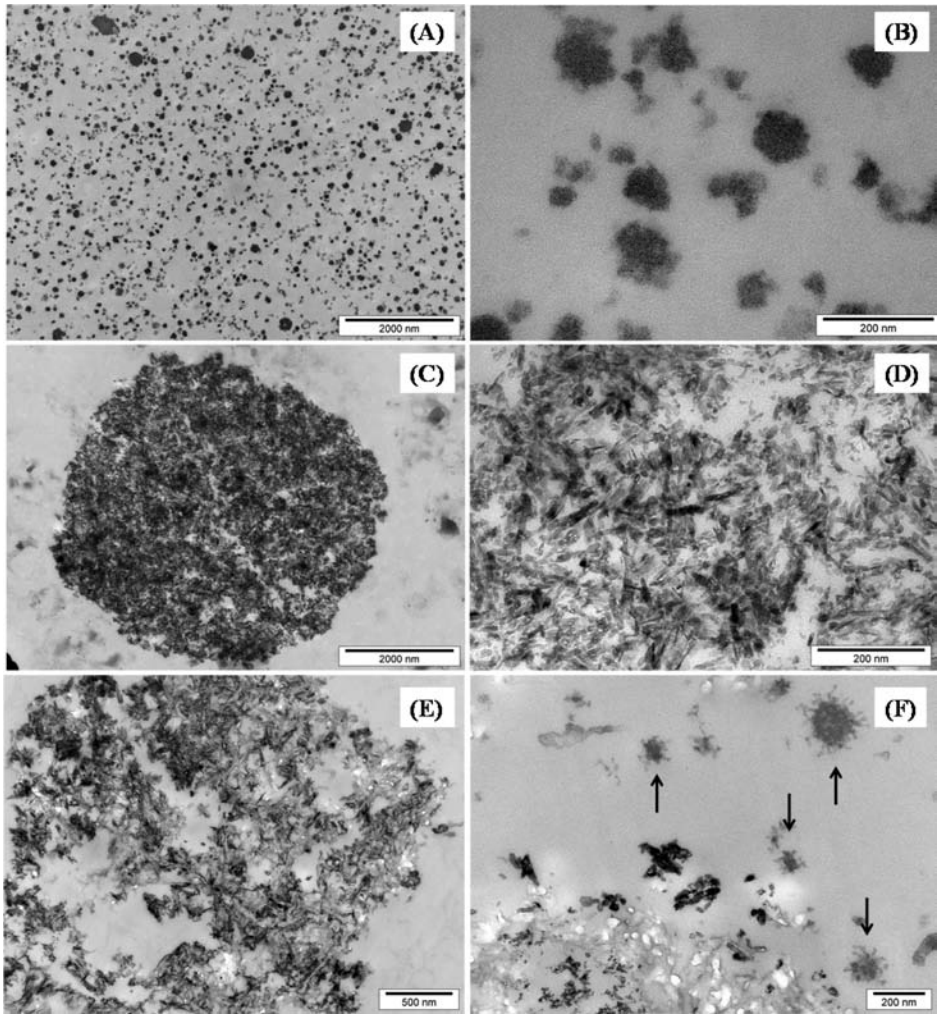

Figure 3. TEM micrographs obtained from (A, B) WPD-SM solution reconstituted from WPD-SMP in water (10% (w/w)); (C, D) suspension of HA particles in SMUF; (E, F) suspension of HA particles in WPD-SM solution, corresponding to a stage of adsorption at which the maximum amount of adsorbed protein was reached. The arrows show the remaining unbound casein micelles in the suspending phase.

note that the mean affinity constants were similar for the casein adsorption experiments carried out on SC in SMUF, WDP-SM, and SM binding to HA (Table 1). This suggests that the adsorption mechanisms and the affinity of HA for micellar and nonmicellar forms of caseins in a milk environment are somewhat similar.

Transmission Electron Microscopy. TEM was carried out to examine the structure of the adsorbed caseins at the surface of the HA particles. Panels A and B of Figure 3 show TEM images from a solution of WPD-SM. The casein micelles in WPD-SM appear to be dark spherical aggregates, to be well dispersed, and to have diameters ranging from ∼30 to 150 nm, consistent with the images of casein micelles observed in previous studies.[29−31] Panels C and D of Figure 3 show TEM images of the HA powder used in this study. It consists of particles of ∼4 μm average diameter. However, these particles are made of elementary nanometer-sized rod-like particles (Figure 3D) that aggregate together into micrometer-sized particles, as has been observed previously.[32,33]

Panels E and F of Figure 3 show images of the HA particles suspended in WPD-SM. As the particles had been stirred for 2 h in the WPD-SM before preparation for TEM, the caseins had adsorbed to the HA particles. The HA particles had an appearance similar to that of the HA particles in the control (Figure 3C). No casein micelles could be seen on the surfaces of the particles (Figure 3E,F). It was therefore hypothesized that the caseins did not adsorb as intact micelles, but as small aggregates and/or individual molecules, which would be too small to be observed with TEM. The unadsorbed casein micelles could still be seen in the suspending phase around the particles, as shown by the arrows in Figure 3F. These unadsorbed micelles had a hairy and disorganized appearance compared with the control (Figure 3A,B), which may have been because they were partly dissociated in the presence of HA particles.

Analysis of Unadsorbed Caseins. The initial adsorption measurements and TEM observations led to the hypothesis that casein micelles did not bind to HA particles as intact micelles, possibly because the micelles dissociated either before or shortly after binding. To verify this hypothesis, the supernatants containing the unadsorbed proteins were analyzed for casein content, particle size, and protein composition.

The supernatants were centrifuged at 21000*g* and 25 °C for 60 min; the pellet contained micellar caseins, whereas the nonmicellar caseins stayed in the serum phase. This serum phase was analyzed for protein content using microfluidic chip SDS-PAGE. Figure 4 shows the distribution of the unadsorbed caseins between micellar and nonmicellar forms (Figure 4A)

dx.doi.org/10.1021/jf5018143 | J. Agric. Food Chem. 2014, 62, 5983−5992

and their size (Figure 4B) as a function of the initial protein concentration.

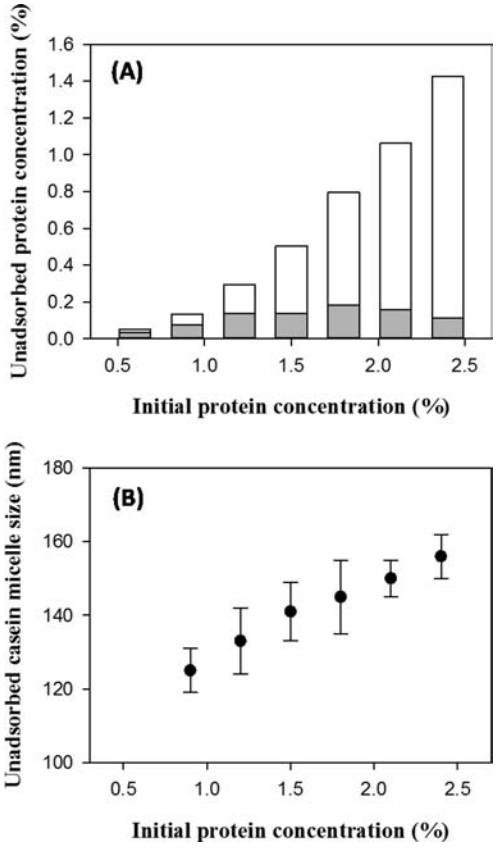

Figure 4. (A) Distribution of unadsorbed caseins between (white bar) micellar and (gray bar) nonmicellar forms and (B) diameters of unadsorbed caseins. Error bars represent standard deviation.

At low initial protein concentration, more than half of the unadsorbed caseins were in a nonmicellar form. For example, when the HA particles were prepared with WPD-SM containing 0.9% protein, 0.08% of the unadsorbed protein was nonmicellar (Figure 4A), which represented ∼57% of the unadsorbed proteins (total 0.14%). As the initial protein concentration increased, the proportion of nonmicellar casein in the unadsorbed protein decreased, reaching approximately 5% when HA particles were prepared with WPD-SM containing 2.4% protein (0.08% of 1.4% unadsorbed protein), which was close to the level of nonmicellar casein in the initial WPD-SM solutions (∼3% nonmicellar casein, data not shown).

At low initial protein concentration, the average diameter of the unadsorbed casein particles was about ∼122 nm (Figure 4B). As the initial protein concentration increased, the diameter increased, until it reached ∼155 nm, which was close to the size of the casein micelle in the initial WPD-SM solutions (160 nm).

Figure 5 shows the protein composition of the unadsorbed proteins as a function of the initial protein concentration. For the adsorption experiments carried out with WPD-SM containing <1% (w/w) protein, the ratio of unadsorbed κ-casein to unadsorbed α_S- and β-caseins was considerably greater than in the original WPD-SM (the composition of the original WPD-SM is indicated by the lines in Figure 5 and was α_S-casein 50%, β-casein 38%, and κ-casein 12%, based on the theoretical

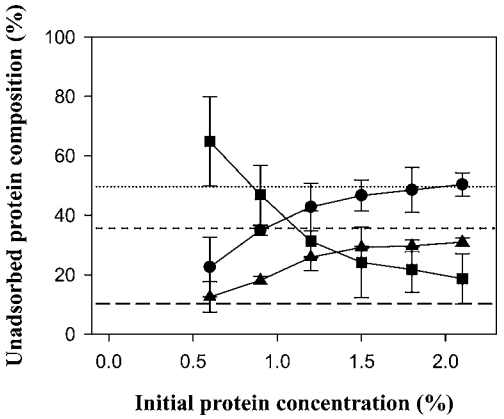

Figure 5. Composition of the supernatants containing the unadsorbed protein after adsorption of WPD-SM onto HA particles as a function of the initial protein concentration: (●) α_S-casein (α_{S1} + α_{S2}); (▲) β-casein; (■) κ-casein. The lines indicate the composition of the original WPD-SM in (dotted line) α_S-casein (α_{S1} + α_{S2}), (short dashed line) β-casein, and (long dashed line) κ-casein. Error bars represent standard deviation.

proportions of the individual proteins in SM[10]). For example, when HA particles were mixed with WPD-SM containing 0.6% protein, ∼60% of the unadsorbed protein was κ-casein, which is substantially higher than the proportion found in milk (12%). The ratio of unadsorbed α_S-casein to unadsorbed β-casein remained approximately constant. As the initial protein concentration in the SM increased, the relative proportions of the three unadsorbed individual caseins gradually approached the initial WPD-SM composition as more and more unadsorbed protein accumulated in the supernatant.

Analysis of the unadsorbed proteins showed that the proportions of micellar casein in the unadsorbed casein fraction (Figure 4A), the casein micelle size (Figure 4B), and the protein composition (Figure 5) were not constant across the range of initial protein concentrations studied. The unadsorbed caseins obtained at low initial protein concentrations contained a higher proportion of κ-casein, contained a higher proportion of nonmicellar casein, and were of a smaller size compared with the unadsorbed caseins obtained at high initial protein concentration. This confirmed that the caseins were not bound to the HA particles as intact micelles and that the casein micelle structure was disrupted by the addition of HA particles. However, it was not possible to determine whether the casein micelles dissociated first and then the liberated caseins bound to HA or casein micelles adsorbed as intact micelles and then dissociated, allowing only the strongly bound caseins to remain on the HA particle surface. However, as there was no change in the proportions of the different caseins adsorbed onto the HA particles as a function of time, from 1 min to 3 h (data not shown), it is believed that the caseins first dissociated from the micelles and then bound independently. However, further experiments would be needed to confirm this hypothesis.

The amounts of the individual proteins adsorbed onto HA were calculated from the composition of the unadsorbed protein and the original protein composition of the WPD-SM (Figure 6). When the initial protein concentration was varied from 0 to 2.5%, the amounts of adsorbed α_S-casein, β-casein, and κ-casein increased gradually until they reached maxima of ∼1.5, 1.3, and 0.15 mg/m^2, respectively. The maximum amount of bound κ-casein represented only ∼5% of the total bound

dx.doi.org/10.1021/jf5018143 | J. Agric. Food Chem. 2014, 62, 5983−5992

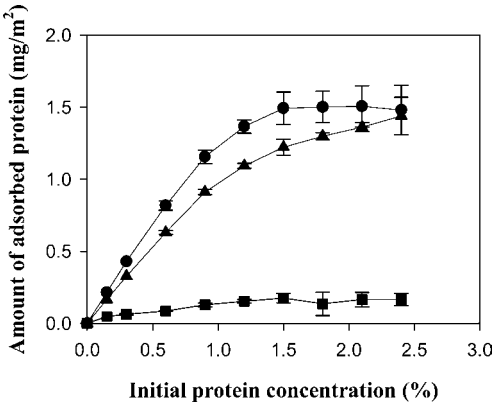

Figure 6. Estimated amount of adsorbed caseins (mg/m^2) on HA particles as a function of initial protein concentration of WPD-SM: (●) α_S-casein (α_{S1} + α_{S2}); (▲) β-casein; (■) κ-casein. Error bars represent standard deviation.

protein (0.15 mg/m^2 of 2.9 mg/m^2), even though the original WPD-SM contained ∼12% κ-casein. This confirms that α_S-casein and β-casein are preferentially adsorbed over κ-casein.

The preference for α_S- and β-caseins binding to HA has been shown previously and has been attributed to the high content of phosphoserine residues in both α_S- and β-caseins, compared with κ-casein.[9] Caseins adsorb mainly through their phosphoserine residues, which bind to calcium on the HA particles. α_{S1}-Casein, α_{S2}-casein, and β-casein contain 7−9, 10−13, and 5 phosphoserine residues, respectively, whereas κ-casein contains only 1 phosphoserine residue.[34] As α_S- and β-caseins carry more residues that can bind to the C-sites on HA particles, they can bind to a greater extent. As the casein micelles are probably disrupted by the addition of HA particles, the phosphoserine groups of α_S- and β-caseins must become available to bind to HA particles.

It has been shown previously that both α_S- and β-caseins contain specific phosphopeptides with a high ability to bind to calcium phosphate.[35−37] They contain similar calcium phosphate binding motifs, made of a sequence of amino acids containing three phosphoserine residues followed by two glutamic acid residues.[38] These casein-derived phosphopeptides (CPP) have been produced and purified by enzymatic digestion and have been bound to amorphous calcium phosphate (ACP) to form complexes (CPP−ACP).[39,40] It is probably the same motif of amino acids as involved in the CPP−ACP complexes that are involved in the binding of α_{S1}-casein, α_{S2}-casein, and β-casein to HA particles.

Mechanism of Casein Micelle Dissociation by HA Particles. This study has shown that the addition of HA particles to WPD-SM and SM causes dissociation of casein micelles into individual casein or casein aggregates that then bind to the HA particles. However, it is not known why the addition of HA particles causes the dissociation of the casein micelles. To further investigate the mechanism, a dialysis experiment and mineral quantification were carried out.

Dialysis Experiments. 10%-SM and 5%-SM were dialyzed overnight against SMUF (controls) or SMUF containing HA particles to ascertain whether the presence of HA particles caused the dissociation of the casein micelles when not in direct contact.

When removed from the dialysis bags, the 10%-SM and 5%-SM dialyzed against SMUF containing HA particles (cuvettes B and D, respectively, in Figure 7) were less turbid than their

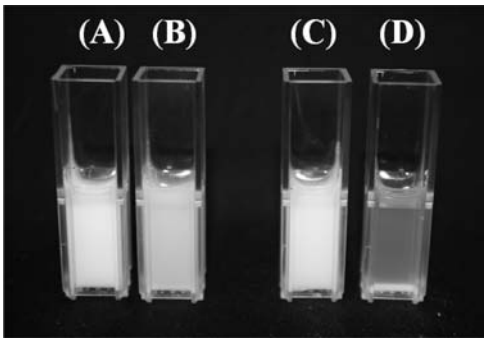

Figure 7. Visual turbidity of SM samples after dialysis against SMUF or against SMUF containing 10% (w/w) HA particles: (A) 10%-SM dialyzed against SMUF; (B) 10%-SM dialyzed against SMUF containing 10% (w/w) HA particles; (C) 5%-SM dialyzed against SMUF; (D) 5%-SM dialyzed against SMUF containing 10% (w/w) HA particles.

respective controls dialyzed against SMUF (cuvettes A and C, respectively, in Figure 7). For the lower concentration of SM (5%-SM), the sample dialyzed against SMUF containing HA particles was almost transparent, indicating that almost all of the casein micelles had dissociated. This shows that the casein micelles in the milks dialyzed against HA particles dissociated during the dialysis process, even though they were not in direct contact with the particles. This was confirmed by measurement of the nonmicellar casein content and the casein micelle diameter of the dialyzed milks (Table 2). The casein micelle diameter of the control SM was ∼230 nm for both 10%-SM and 5%-SM, and both milks contained <5% nonmicellar caseins, which was similar to the original nondialyzed SM. This shows that the milks dialyzed against SMUF were stable during dialysis. The 10%-SM and 5%-SM dialyzed against SMUF containing HA particles contained 73 and 94% nonmicellar caseins, respectively. The casein micelle diameter of 10%-SM dialyzed against SMUF containing HA particles was 165 nm; that of 5%-SM treated identically could not be measured by the Zetasizer because the sample did not show the required turbidity.

Table 2. Nonmicellar Casein Content and Casein Micelle Diameter of the Dialyzed Milks

sample	nonmicellar caseins (%)	casein micelle diameter (nm)
10%-SM		
dialyzed against SMUF	3	230
dialyzed against HA in SMUF	73	165
5%-SM		
dialyzed against SMUF	5	227
dialyzed against HA in SMUF	94	N/A[a]

[a]N/A, not applicable.

Mineral Quantification. The observations that HA caused the casein micelles to dissociate even when not in direct contact (Figure 7) led to the hypothesis that HA particles were able to draw out some of the minerals contained in SMUF, which would cause the casein micelles to dissociate. It has been shown previously that calcium, phosphate, and citrate ions can adsorb to HA.[12,41] The ions contained in SMUF must have adsorbed

dx.doi.org/10.1021/jf5018143 | J. Agric. Food Chem. 2014, 62, 5983−5992

onto HA particles, disrupting the salt balance in the SMUF. This hypothesis was tested by adding different amounts of HA particles (from 0 to 18% (w/w)) into SMUF and SM and then measuring ionic calcium, total calcium, and inorganic phosphate.

Figure 8 shows the variation in the ionic calcium concentration when HA particles at different concentrations

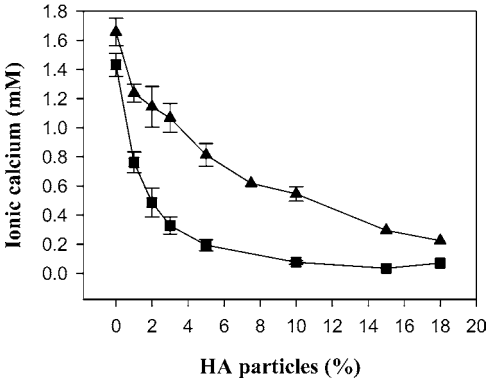

Figure 8. Effect of addition of HA particles in (■) SMUF and in (▲) SM on ionic calcium concentration. Error bars represent standard deviation.

(from 0 to 18% (w/w)) were added to SMUF or to SM. The SM and SMUF contained ∼1.7 and ∼1.45 mM ionic calcium, respectively, which was in accordance with the values reported in the literature.[42−44] As more HA particles were added to both SMUF and SM, the ionic calcium concentration decreased, with the decrease being more pronounced in SMUF. The addition of 10% (w/w) HA particles led to ionic calcium concentrations of ∼0.1 mM in SMUF and ∼0.55 mM in SM, which represented losses of 93 and 68% of the initial ionic calcium, respectively. The decrease in ionic calcium on the addition of HA particles indicates that ionic calcium binds to these particles. As ionic calcium binds to HA particles, CCP must be released from the casein micelles to compensate for the loss of ionic calcium in the serum, thereby explaining the smaller decrease in ionic calcium for SM than for SMUF. The binding of ionic calcium onto the HA particles was a relatively fast process; the ionic calcium concentration reached a stable level in <5 min (data not shown).

A mineral analysis was also carried out on SMUF and SM samples after the HA particles had been removed from the solution by centrifugation. As HA particles were added to SM at increasing concentration from 0 to 18% (w/w), the concentrations of total calcium, citrate, and inorganic phosphate decreased (Figure 9A). The initial SM contained ∼21.5 mmol/kg inorganic phosphate, ∼28.5 mmol/kg calcium, and ∼11 mmol/kg citrate, which are consistent with the values reported previously for SM.[15] On the addition of 18% HA particles to SM, the calcium concentration in the SM decreased by ∼93%, from 28.5 to 2.2 mmol/kg, the inorganic phosphate concentration decreased by ∼68%, from 21.6 to 6.8 mmol/kg, and the citrate concentration decreased by ∼74%, from 11 to 2.85 mmol/kg. Part of the decrease was probably because the calcium, phosphate, and citrate that were contained in the casein micelles before they dissociated and adsorbed on the HA particles sedimented out with the HA particles during centrifugation. However, CCP contains only ∼50% of the total inorganic phosphate, ∼70% of the total calcium, and ∼20% of the total citrate contained in milk. As the percentage decreases in calcium, phosphate, and citrate on the addition of 18% HA particles to SM were higher than the percentage of the corresponding mineral in CCP, calcium, phosphate, and citrate ions must have bound to HA particles, depleting the milk serum in these ions.

This was confirmed by the mineral analysis results when HA particles were added to SMUF (Figure 9B). On the addition of 15% HA particles to SMUF, the total calcium concentration decreased by ∼95%, from 8.7 to 0.5 mmol/kg, the inorganic phosphate concentration decreased by ∼53%, from 11.6 to 5.5 mmol/kg, and the citrate concentration decreased by ∼77%, from 9.8 to 2.3 mmol/kg. The decrease in calcium was faster and more pronounced than the decreases in phosphate and citrate, probably because phosphate and citrate have to compete for the same binding sites on the HA surface (positive sites, C-sites), whereas only calcium ions can bind to the negative sites (P-sites), and because more P-sites than C-sites are expressed on the surface of HA at pH ∼7, as shown by a negative zeta-potential of ∼ −9 mV (data not shown).

The disruption effect of HA on the integrity of the casein micelle and on the milk mineral equilibrium can also be explained by taking into account the thermodynamic aspects of calcium phosphate growth and sequestration. In milk, calcium and phosphate are sequestered in the form of calcium phosphate nanoclusters inside the casein micelle.[45] The phosphoserine groups of the caseins are bound to the calcium phosphate nanoclusters inside the micelles, keeping the calcium phosphate in a thermodynamically metastable state in which its precipitation and further growth are prevented.[46,47] However, when HA particles are added to milk, it is possible that the

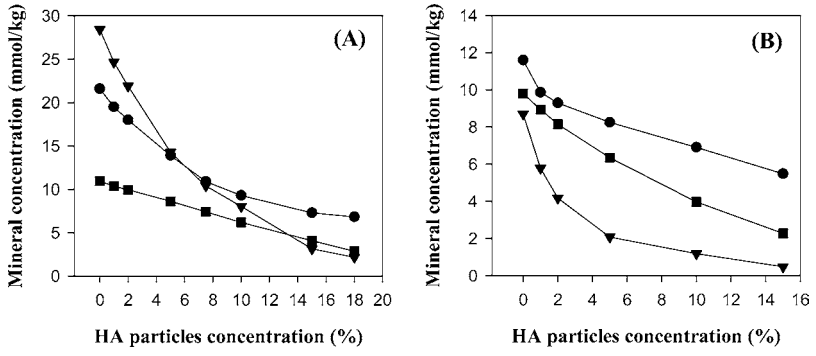

Figure 9. Effect of addition of HA particles in (A) SM and (B) SMUF on (▼) total calcium, (■) total citrate, and (●) inorganic phosphate concentrations. HA particles were removed from the solution by centrifugation before the measurements.

dx.doi.org/10.1021/jf5018143 | J. Agric. Food Chem. 2014, 62, 5983−5992

most stable form of calcium phosphate (HA) grows at the expense of the least stable form (calcium phosphate sequestered in the casein micelles). The calcium phosphate inside the casein micelles would therefore be released to contribute to the growth of the HA particles, leading to micelle dissociation. The process of calcium phosphate growth is generally very slow. However, the HA particles used in this study may have provided a very large surface of initially crystallized HA that would allow a fast crystallization of calcium phosphate from the minerals that were drawn out of the milk serum onto the HA particles.[48]

In conclusion, this study showed the existence of interactions between casein micelles and HA particles. The addition of HA particles to SM causes the dissociation of the casein micelles and the binding of the individual caseins to the particles. This dissociation of the casein micelles is a consequence of calcium, phosphate, and probably citrate ions contained in the milk serum binding to the surface of the HA particles. Consequently, CCP of casein micelle is drawn out of the micelles, and the structure of the casein micelles is disrupted. Therefore, the phosphoserine groups of α_S- and β-caseins become available to bind to HA particles. Both α_S- and β-caseins were preferentially bound compared with κ-casein, and this was attributed to the higher content of phosphoserine residues of both α_S- and β-caseins. The results of this study indicate that the addition of hydroxyapatite particles to milk may compromise the stability of the milk by disrupting the equilibrium of the milk minerals and dissociating the casein micelles.

Supporting Information

ABSTRACT: Worldwide, many different grains are infected by various fungi that may produce trichothecene mycotoxins. Fungi that produce trichothecenes, as well as the trichothecenes themselves, are potential problems for public health. On the other hand, trichothecenes possess multiple biological activities. Reduced toxicity may result in their applications in the pharmaceutical field. Two new trichothecenes along with seven known trichothecenes were isolated from an endophyte of the herb plant *Ajuga decumbens*. Their structures were deduced from 1D and 2D NMR data. The results of MTT assays revealed that new trichothecene 2′,3′-epoxymyrothecine A, **1**, and myrothecine A, **3**, exhibited much lower toxicity compared to other trichothecenes. New trichothecene 2′,3′-epoxymyrothecine A, **1**, could induce phosphorylation of JNK (c-Jun N-terminal protein kinase) protein and the PARP (poly ADP-ribose polymerase) cleavage, and eventually induce apoptosis in cancer cells. These results point out the possibility for application of trichothecenes as chemotherapeutic agent.

KEYWORDS: *trichothecenes, endophyte, mycotoxin, chemotherapeutic agent*

INTRODUCTION

Trichothecenes are a large family of chemically related mycotoxins produced by various species of *Fusarium*, *Myrothecium*, *Trichoderma*, *Trichothecium*, *Cephalosporium*, *Verticimonosporium*, and *Stachybotrys*.[1] These mycotoxins are produced in *Fusarium*-infested grains such as corn, wheat, and barley, and ingestion of contaminated grain can result in a variety of symptoms including diarrhea, hemorrhaging, and feed refusal.[2] Potentially hazardous concentrations of the trichothecene mycotoxins can occur naturally in moldy grains, cereals, and agricultural products.[3] They can be found worldwide in cereal grains and in animal feed and human food produced from contaminated grains, which creates a food safety risk.[1]

Trichothecenes can enter human and animal food chains through breakfast cereals, bakery products, snack foods, beer, and compound feeds made from small grains and maize.[4] These mycotoxins are characterized by a tricyclic 12,13-epoxytrichothec-9-ene (trichothecene) ring structure. They can be classified into two different types: simple or nonmacrocyclic trichothecenes, and macrocyclic trichothecenes. The simple or nonmacrocyclic trichothecenes can be divided further into two subgroups based on the presence or absence of a carbonyl function at C-8.[5] Type B trichothecenes have a keto function at C-8, while type A trichothecenes have a hydrogen, hydroxyl, or ester function at C-8.[2] Simple trichothecenes including type A and type B have variations at four sites (C-3, C-4, C-7, and C-15) and are subdivided into epoxy types and de-epoxy types, which are structural analogues bearing an ethylene group, which has not been epoxidized, and they may be biosynthetic intermediates on the pathway to corresponding epoxidized derivatives.[6] Type A trichothecenes are generally more toxic to animals. The naturally occurring macrocyclic trichothecenes are classified as verrucarins (mainly C27 compounds) and roridins (mainly C29 metabolites). They are characterized by a family of sesquiterpenols with a diacyl residue anchored at the 4β and 15 positions.

Among these trichothecenes, a number have been demonstrated to play a substantial role in malaria therapy,[7] immunomodulation,[8] and cancer prevention.[9] The inhibitory effect of trichothecene mycotoxins on rapidly dividing cells was the basis for their evaluation as antitumor chemotherapy drugs during the late 1970s and early 1980s.[10] They are cytotoxic to most eukaryotic cells and inhibit protein synthesis in a variety of eukaryotic cells.[11] Higher efficacy and lower toxicity trichothecenes might have significant potential for use as a chemotherapeutic agent in cancer treatment. Because of their multiple functions, the trichothecene mycotoxins have become a frequent research subject in the fields of medicine, agriculture, animal breeding, food safety, and toxicology.[12]

From an endophyte of the herb *Ajuga decumbens*, two new and seven known trichothecenes were isolated. Their structures were elucidated by spectroscopic methods, and cytotoxicity structure−activity relationships were investigated.

MATERIALS AND METHODS

General Experimental Procedures. NMR spectra were taken on a Avance III-600 NMR spectrometer (Bruker BioSpin International AG, Zurich, Switzerland) with TMS as an internal standard. HR-FT-MS data were acquired using an Apex Ultra 7.0 FT-MS (Bruker Corp., Billerica, MA, USA). Optical rotations were obtained on a PerkinElmer 341 automatic polarimeter (Waltham, MA, USA) with $CHCl_3$ as the solvent. IR spectra were recorded on a Nicolet Avatar 330 FT IR spectrometer (Thermo Electron Corp., Madison, WI, USA). Sephadex

LH-20 (40−70 μm) (Amersham Pharmacia Biotech AB, Uppsala, Sweden), silica gel (200−300 mesh) (Qingdao Marine Chemical, Inc., Qingdao, China), and Lichroprep reversed-phase RP-18 silica gel (40−63 μm) (Merck, Darmstadt, Germany) were used for column chromatography. TLC was carried out using glass-precoated silica gel GF254 (Qingdao Marine Chemical, Inc., Qingdao, China) and visualized under UV light or by spraying with vanillin ethanol reagent, which contains H_2SO_4. The cell culture medium, Dulbecco's modified Eagle's medium (DMEM; high glucose, without sodium pyruvate, HyClone), and fetal bovine serum (FBS, HyClone) were purchased from HyClone Laboratories Inc. (Logan, UT, USA). Acrylamide/bis-acrylamide solution (30%; 29:1) was purchased from Bio-Rad Laboratories, Inc. (Hercules, CA, USA). Protein content was tested using a BCA kit (Thermo Fisher Scientific, Waltham, MA, USA). Anti-poly(ADP-ribose) polymerase-1 (PARP-1), anti-β-actin mouse antibody, horseradish peroxidase (HRP)-labeled anti-rabbit/mouse IgG (H + L), and dimethyl sulfoxide (DMSO) were obtained from Sigma-Aldrich Corp. (St. Louis, MO, USA). Cytochrome *c* was purchased from Beyotime Institute of Biotechnology (Jiangsu, China). DAPI (4′,6′-diamidino-2-phenylindole) was purchased from Pierce (Rockford, IL, USA).

Fungal Material. The fungus was isolated from current-year root of *Ajuga decumbens* collected from Fuzhou, Fujian, China. A BLAST search result showed that the internal transcribed spaces (ITS) sequence of this fungus was highly homologous (100% percent similarity) to that of *Myrothecium roridum* (E-1069), indicating that this fungus belongs to this genus.

Fermentation and Extraction. The strain was cultivated at 28 °C with 5 L of PDA (potato dextrose agar) media for 16 d. After fermentation, the culture medium was chopped and extracted with ethyl acetate/methanol (80:20) at room temperature overnight. The combined organic layer was concentrated under vacuum until 4.1 g of residue was obtained.

Isolation and Spectral Data. The crude extract (4.1 g) was separated into 18 fractions (fraction 1 to fraction 18) by column chromatography on RP-18 silica gel (100 g, 36 mm × 230 mm), eluted by methanol/H_2O (30:70, 50:50, 70:30, and 100:0, 1 L for each gradient, 100 mL per collection bottle). Fraction 1 (0.2315 g, fraction volume: 200 mL); fraction 2 (0.0380 g, fraction volume: 100 mL); fraction 3 (0.0611 g, fraction volume: 300 mL); fraction 4 (0.1080 g, fraction volume: 400 mL); fraction 5 (0.0431 g, fraction volume: 100 mL); fraction 6 (0.0836 g, fraction volume: 200 mL); fraction 7 (0.0386 g, fraction volume: 100 mL); fraction 8 (0.1195 g, fraction volume: 300 mL); fraction 9 (0.0674 g, fraction volume: 100 mL); fraction 10 (1.4100 g, fraction volume: 200 mL); fraction 11 (0.0745 g, fraction volume: 200 mL); fraction 12 (0.1649 g, fraction volume: 100 mL); fraction 13 (0.0476 g, fraction volume: 100 mL); fraction 14 (0.1802 g, fraction volume: 300 mL); fraction 15 (0.6822 g, fraction volume: 100 mL); fraction 16 (0.7478 g, fraction volume: 100 mL); fraction 17 (0.1352 g, fraction volume: 100 mL); and fraction 18 (0.0390 g, fraction volume: 400 mL).

Fraction 4 (108 mg) was separated using the Sephadex LH-20 (elution with 100% methanol, 25 mm × 1000 mm, 100 g, 400 mL) to give three subfractions (fraction 4-a to fraction 4-c). Fraction 4-a (0.0784 g, fraction volume: 15 mL) was separated by column chromatography on silica gel (2.35 g, 10 mm × 250 mm, elution with chloroform, 600 mL) to afford compound **1** (19.9 mg).

Fraction 6 (83.6 mg) was chromatographed on normal phase silica gel (2.51 g, 10 mm × 250 mm) and eluted with chloroform (120 mL) to yield compound **3** (9.0 mg, fraction volume: 30 mL).

Fraction 9 (67.4 mg) was purified using the Sephadex LH-20 (25 mm × 1000 mm, 100 g) column, eluted with methanol (300 mL), and two subfractions (fraction 9-a, 39.6 mg, and fraction 9-b, 20.4 mg) were obtained. Compound **9** (4.9 mg) was obtained from fraction 9-a eluted with petroleum ether−EtOAc [5:1(60 mL), 4:1 (100 mL), 3:1 (80 mL), 2:1 (60 mL), 1.5:1 (150 mL), 1:1 (100 mL), v/v] on column chromatography over normal phase silica gel (1.5 g, 10 mm × 250 mm).

Fraction 10 (1.41 g) was subjected to the Sephadex LH-20 (180 g) (25 mm × 1800 mm, elution with 100% methanol, 800 mL), and two fractions (fraction 10-a, 36.6 mg, and fraction 10-b, 841 mg) were collected. Fraction 10-b (841 mg) was fractionated on a silica gel column (8.4 g, 20 mm × 350 mm) eluted with petroleum ether−EtOAc of increasing polarity [4:1 (200 mL), 3:1 (240 mL), 2.5:1 (280 mL), 2:1 (90 mL), 1:1 (200 mL), v/v] to give compound **5** (4 mg, fraction volume: 10 mL), compound **6** (25.7 mg, fraction volume: 20 mL), and compound **2** (3.9 mg, fraction volume: 60 mL).

Fraction 11 (74.5 mg) was chromatographed on the Sephadex LH-20 (25 mm × 1000 mm, 100 g) and eluted with methanol (400 mL). Two fractions (fraction 11-a, 26 mg, and fraction 11-b, 43 mg) were made. Fraction 11-a (26 mg) was isolated with column chromatography over normal-phase silica gel [1.0 g, 8 mm × 250 mm, eluted with chloroform−methanol, v/v, 200:1 (100.5 mL)] to afford comopund **4** (6.8 mg).

Fraction 13 (47.6 mg) was purified by normal phase silica gel column chromatography (1.5 g, 10 mm × 250 mm), eluted with petroleum ether−chloroform [4:1 (100 mL), 3:1 (80 mL), 2:1 (90 mL), 1:1 (100 mL), 1:2 (80 mL), v/v], and compound **7** (4.1 mg, fraction volume: 35 mL) was obtained.

Fraction 14 (180.2 mg) was further subjected to the Sephadex LH20 (180 g, 25 mm × 1800 mm) column, eluted with methanol (600 mL). Subfraction 14-a (15.3 mg, fraction volume: 20 mL) was purified using a normal phase silica gel column [0.5 g, 8 mm × 250 mm, eluted with chloroform−methanol (100:1, v/v, 400 mL)] to yield compound **8** (3.0 mg, fraction volume: 10 mL).

2′,3′-Epoxymyrothecine A, 1: white powder; $[\alpha]_D^{20}$ +12.8 (*c* 0.525, chloroform); IR (KBr) ν_{max} 3428, 2920, 2850, 1745, 1711, 1461, 1383, 1181, 1098, 1058, 1023, 754 cm^{-1}; ^1H and ^{13}C NMR data shown in Table 1; HR-FT-MS, *m*/*z* 541.2045 $[M + Na]^+$ (calculated for $C_{27}H_{34}O_{10}Na$, 541.2146).

13′,14′-Hydroxymytoxin B, 2: white powder; $[\alpha]_D^{20}$ +60 (*c* 0.1, chloroform); IR (KBr) ν_{max} 3348, 2921, 2851, 1720, 1712, 1658, 1461, 1441, 1383, 1085, 1180 cm^{-1}; ^1H and ^{13}C NMR data shown in Table 1; HR-FT-MS, *m*/*z* 569.2361 $[M + Na]^+$ (calculated for $C_{29}H_{38}O_{10}Na$, 569.2465).

Cleaved-PARP and JNK Protein Phosphorylation Western Blotting. HepG2 (hepatocellular carcinoma, ATCC) cells were exposed to 5-Fu (5-fluorouracil) (20 and 50 μM) and compounds **1**−**9** at concentrations of **1** (50 μM), **2** (50 nM), **3** (50 μM), **4** (5 nM), **5** (50 nM), **6** (50 nM), 7 (50 nM), **8** (50 nM) and **9** (1 μM) for 8 h.

HepG2, A549 (human lung adenocarcinoma, ATCC) and MCF-7 (human breast adenocarcinoma, ATCC) cells were exposed to 2′,3′-epoxymyrothecine A, **1**, at concentrations of 0, 20, 50, and 100 μM for 8 h. HepG2 cells were treated with 20 μM **1** for different periods of time (0, 2, 4, and 8 h) respectively. After the treatment, cells were lysed with prepared lysis buffer with a WH-3 vortex machine (Shanghai Qingpu-Huxi Instruments Factory, Shanghai, China). For Western blot analysis, an amount of 25 μL of the protein sample containing 40 μg of protein was separated by 8% SDS−polyacrylamide gel electrophoresis and transferred to nitrocellulose membranes (Millipore, Bedford, MA, USA). The level of protein expression was determined using specific primary antibodies, PARP and β-actin, followed by rabbit/mouse HRP-conjugated secondary antibodies.

Cytotoxicity Assay. In vitro cytotoxicity of isolated compounds was evaluated by an MTT assay. Briefly, four different cancer cells [HepG2, MCF-7, A549, and SMMC-7721 (human hepatocellular carcinoma, Type Culture Collection of the Chinese Academy of Sciences, Shanghai, China)] were plated at 3000 cells/well in a 96-well plate and treated with the different concentrations of the isolated compounds for 48 h. Three independent experiments were performed and the results shown as the percentage of cell inhibition ratio.

Immunofluorescence Analysis of Cytochrome *c*. HepG2 cells were seeded onto glass coverslips and treated with compounds for 12 h. Cells were fixed with 4% paraformaldehyde in PBS for 20 min and permeabilized with 0.2% Triton X-100 in PBS for 10 min at room temperature. The cells were washed twice with PBS and blocked with 5% BSA in PBS for 30 min at room temperature. After washing, the cells were incubated with anti-cytochrome *c* (diluted 1:500 in PBS + 1% BSA) overnight at 4 °C. The cells were then washed twice in PBS

and detected by anti-mouse IgG conjugated with Cy3 (1:1000) at room temperature for 30 min. Cells were costained with DAPI to visualize nuclei. The images were taken using LSM-510 confocal laser scanning microscope system (Carl Zeiss, Oberkochen, Germany).

To investigate whether these compounds may induce the mitochondrial release of cytochrome *c*, we performed immunofluorescence analysis of cytochrome *c* in HepG2 cells treated with 5-Fu (50 μM), **1** (50 μM), **3** (50 μM), **5** (50 nM), **6** (50 nM), and **8** (50 nM) for 12 h, and observed that they can induce a diffuse cytosolic staining of cytochrome *c*.

Flow Cytometry for Cell Cycle Distribution. HepG2 cells (50% confluent) were synchronized by serum starvation for 24 h and treated with 5-Fu (50 μM), compound **1** (50 μM), **2** (50 nM), **3** (50 μM), **4** (5 nM), **5**−**8** (50 nM), and **9** (1 μM) in complete medium for 12 h. The cells were washed with cold PBS and centrifuged at 1000 rpm for 5 min. 70% ethanol was employed to fix the cells overnight at 4 °C. The cells were incubated using PBS with RNase (10 μg/mL) (Tiangen, Beijing, China) for 30 min, stained with propidium iodide (50 μg/mL) at room temperature for 30 min, and determined by FAC Plus flow cytometry (Beckman Coulter, Miami, FL, USA). The DNA histograms were further analyzed through the WinMDI 2.9 software program (Scripps Institute, La Jolla, CA, USA).

RESULTS AND DISCUSSION

Structure Elucidation. 2′,3′-Epoxymyrothecine A, **1**, was isolated as a white powder. The molecular formular was established as $C_{27}H_{34}O_{10}$. The ^{1}H and ^{13}C NMR spectra of **1** were similar to those of myrothecine A,[13] except for the presence of signals [δ_H 3.53 (1H, S, H-2′), δ_C 56.3 (C-2′), δ_C 65.3 (C-3′), δ_H 4.61 (1H, dd, J = 2.3, 10.6 Hz, H-7′), δ_C 108.5 (C-7′), δ_C 151.3 (C-6′)] and the absence of signals [δ_H 5.78 (1H, brs, H-2′), δ_C 117.3 (C-2′), δ_C 154.1 (C-3′), δ_H 1.96, 1.65 (2H, m, H-7′), δ_C 29.5 (C-7′), δ_C 87.3 (C-6′), δ_C 213.0 (C-13′), δ_H 2.30 (1H, s, H-14′), δ_C 28.7 (C-14′)] observed in the NMR spectra of myrothecine A due to the epoxidation between C-2′ and C-3′ in myrothecine A, **3**, the double bond of C-6′ and C-7′, and the absence of an acetyl group that was connected to C-6′ in myrothecine A. The HMBC correlations from proton δ_H 4.21 (2H, m, H-15) to C-1′ (δ_C 167.6), C-5 (δ_C 50.8), and C-7 (δ_C 27.6) revealed the linkage between C-15 and C-1′ via an oxygen bridge. The HMBC correlations from proton δ_H 4.01 (1H, d, J = 4.3 Hz, H-2) to C-13 (δ_C 39.9), C-5 (δ_C 50.8), and C-11 (δ_C 69.3) revealed the oxygen bridge between C-2 and C-11. The HMBC correlations from proton δ_H 5.43 (1H, dd, J = 2.6, 7.9 Hz, H-4) to C-12 (δ_C 76.6), C-2 (δ_C 80.8), and C-11′ (δ_C 164.9) revealed the ester linkage between C-4 and C-11′. The HMBC correlations from proton δ_H 4.24 (2H, m, H-5′) to C-3′ (δ_C 65.3) and C-6′ (δ_C 151.3) revealed the oxygen bridge linkage between C-5′ (δ_C 66.9) and C-6′. Other key HMBC correlations are shown in Figure 2. Therefore, the planar structure of compound **1** was determined. Moreover, the relative configuration of **1** was given by its nuclear Overhauser effect spectroscopy (NOESY) NMR spectrum which displayed the cross peaks of δ_H 4.01 (1H, d, J = 4.3 Hz, H-2) with δ_H 5.43 (1H, dd, J = 2.6, 7.9 Hz, H-4), δ_H 4.01 (1H, d, J = 4.3 Hz, H-2) with δ_H 2.21 (1H, m, H-10), δ_H 3.56 (1H, s, H-11) with δ_H 2.21 (1H, m, H-10), and δ_H 1.25 (3H, s, H-16) with δ_H 1.16 (3H, s, H-14).

13′,14′-Hydroxymytoxin B (**2**) was isolated as a white powder. The molecular weight and formula ($C_{29}H_{38}O_{10}$) were determined from the HR-FT mass spectrum ($C_{29}H_{38}O_{10}Na$) and the ^{13}C NMR data. The ^{1}H and ^{13}C NMR spectra of **2** were nearly identical to those of 14′-hydroxymytoxin B (**5**),[5] except for the presence of signals [δ_H 4.06 (1H, d, J = 2.6 Hz, H-13′), δ_C 75.8 (C-13′)] ascribable to a hydroxymethylene group and the absence of a signal at δ_C 214.1 (C-13′), observed in the NMR spectra of 14′-hydroxymytoxin B due to the 13′ carbonyl group. HMBC correlations from proton δ_H 4.33 (1H, m, H-15) to C-7 (δ_C 20.9), C-6 (δ_C 42.9), C-11′ (δ_C 68.7), and C-1′ (δ_C 166.4) revealed the ester linkage between C-15 and C-1′. The HMBC correlations from proton δ_H 3.16 (1H, m, H-2) to C-13 (δ_C 79.1) and C-11 (δ_C 67.9) revealed the oxygen bridge between C-2 and C-11. The HMBC correlations from proton δ_H 5.80 (1H, dd, J = 3.5, 8.1 Hz, H-4) to C-12 (δ_C 65.6), C-2 (δ_C 47.6), and C-11′ (δ_C 165.8) revealed the ester linkage between C-4 and C-11′. Other key HMBC correlations are shown in Figure 2. Therefore, the structure of 2 was deduced to be the 13′-hydroxy derivative of 14′-hydroxymytoxin B. The relative configurations of **2** were determined by the analysis of the NOESY spectrum which displayed the nuclear Overhauser effect (NOE) correlations of δ_H 5.45 (1H, d, J = 4.6 Hz, H-10) with δ_H 3.62 (1H, d, J = 5.2 Hz, H-11), δ_H 5.45 (1H, d, J = 4.6 Hz, H-10) with δ_H 1.73 (3H, s, H-16), δ_H 5.74 (1H, s,

H-2′) with δ_H 0.81 (3H, s, H-14), δ_H 5.74 (1H, s, H-2′) with δ_H 3.85 (1H, s, H-12′), and δ_H 0.81 (3H, s, H-14) with δ_H 3.62 (1H, d, J = 5.2 Hz, H-11).

Two new trichothecenes, 2′,3′-epoxymyrothecine A, **1**, and 13′,14′-hydroxymytoxin B, **2**, along with seven known trichothecenes, myrothecine A, **3**,[12] myrotoxin A, **4**,[13] 14′-hydroxymytoxin B, **5**,[5] vertisporin, **6**,[14] mytoxin C, **7**,[15] roridin E, **8**,[16] and 12′-hydroxyroridin E, **9**,[17] were isolated from an endophyte of the herb *Ajuga decumbens*; their structures are shown in Figure 1.

Since *Fusarium* and other related fungi that produce trichothecenes infect various agricultural products, especially important crops, they have been associated with intoxication of humans and animals all over the world. Trichothecenes are a well-known major class of mycotoxins. Many new macrocyclic trichothecenes have been isolated from different fungi possessing cytotoxic,[9] immunomodulation,[18] antimicrobial,[19] and phytotoxic[20] properties.

MTT assays were used to evaluate these trichothecenes' toxicity. 2′,3′-Epoxymyrothecine A, **1**, and myrothecine A, **3**, exhibited more than 1000-fold less toxicity than other trichothecenes (Table 2). The 12,13-epoxy ring is the most important structural feature leading to the remarkable differences in toxicity. A promising target for preharvest detoxification is the epoxide group located at C-12. 2′,3′-Epoxymyrothecine A, **1**, and myrothecine A, **3**, do not have an epoxy ring at C-12 and C-13. This variation can lead to

9	2.08 ± 0.71 μM	1.25 ± 0.11 μM	1.26 ± 0.08 μM	6.56 ± 4.15 μM

different trichothecene structures that result in differences in toxicity. 2′,3′-Epoxymyrothecine A, **1**, and myrothecine A, **3**, exhibited much lower toxicity compared to those trichothecenes which possess a 12,13-epoxy ring (Table 2). PARP-1 is a nuclear protein that has important roles in the maintenance of genomic integrity.[21] Cleavage of PARP-1 by caspases is considered to be a hallmark of apoptosis.[22,23] The PARP-cleavage activity of nine trichothecenes in HepG2 cells was tested (Figure 3). With the exception of trichothecenes **2**, **4**, **7**, and **9**, the other trichothecenes could induce PARP-cleavage in HepG2 cells (Figure 3). The results revealed that 2′,3′-epoxymyrothecine A, **1**, myrothecine A, **3**, 14′-hydroxymytoxin B, **5**, vertisporin, **6**, and roridin E, **8**, could induce apoptosis in HepG2 cells (Figure 3).

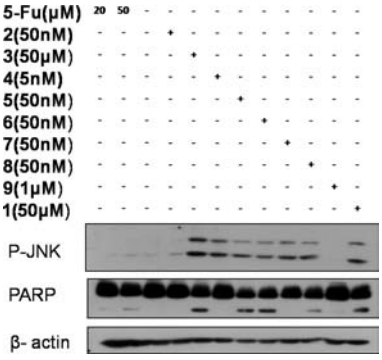

Figure 3. PARP-cleavage and phosphorylation of JNK protein in treated HepG2 cells. Cells were treated with 5-Fu (20 and 50 μM), **1** (50 μM), **2** (50 nM), **3** (50 μM), **4** (5 nM), **5**-**8** (50 nM), and **9** (1 μM) for 8 h.

Cytochrome *c* has been identified as an important mediator in apoptotic pathways.[24] The release of mitochondrial cytochrome *c* into the cytoplasm stimulates apoptosis and is commonly used as an indicator of the apoptotic process in the cell.[25] In order to confirm the apoptosis activity of these trichothecenes, cytochrome *c* releasing assays were carried out. The results confirmed that 2′,3′-epoxymyrothecine A, **1**, myrothecine A, **3**, 14′-hydroxymytoxin B, **5**, vertisporin, **6**, and roridin E, **8**, could promote the cytochrome *c* release from the mitochondria and subsequently cause apoptosis in HepG2 cells (Figure 4).

Cell cycle regulation in the G1 phase has attracted a great deal of attention as a promising target for the research and treatment of cancer. Many of the important genes associated with G1 regulation have been shown to play a key role in proliferation, differentiation and oncogenic transformation, and programmed cell death (apoptosis).[26] Cell cycle arrest experiments were carried out. Nine trichothecenes could induce the G1 cell cycle arrest in HepG2 cells (Figure 5). 2′,3′-Epoxymyrothecine A, **1**, and myrotoxin A, **4**, exhibited significant effects of G1 cell cycle arrest in HepG2, nearly 20% greater than the control (Figure 5). In structure comparions of these two trichothecenes to other trichothecenes, the most obvious difference was the substitution at C-6′. There was no substituent at C-6′ in these two trichothecenes (2′,3′-epoxymyrothecine A and myrotoxin A), whereas the other trichothecenes had a substitution group at C-6′. Therefore, this difference should be important for the G1 cell cycle arrest activity of trichothecenes.

Cells are continuously exposed to a variety of environmental stresses and have to decide "to live or die" depending on the types and strength of stress. Among the many signaling pathways that respond to stress, mitogen-activated protein kinase (MAPK) family members are crucial for the maintenance of cells.[27] Three subfamilies of MAPKs have been identified: c-Jun N-terminal kinases (JNKs), extracellular signal-regulated kinases (ERKs), and p38-MAPKs. It has been shown that ERKs are important for cell survival, whereas JNKs were deemed stress-responsive and thus involved in apoptosis.[27] JNK was discovered almost 20 years ago as the protein kinase responsible for phosphorylating c-Jun at Ser-63 and Ser-73.[28] JNKs belong to the family of mitogen-activated protein kinases (MAPK) that are responsive to a variety of environmental stimuli.[29,30] JNKs (also known as stress-activated protein kinases; SAPKs) are ubiquitously expressed, and the JNK stress pathways participate in many different intracellular signaling pathways that control a spectrum of cellular processes, including cell growth, differentiation, transformation, or apoptosis.[31−37]

Transient JNK activation promotes cell survival, while prolonged JNK activation induces cellular apoptosis.[38] In order to explain the structure−activity relationships of these trichothecenes, the PARP-cleavage and phosphorylation of JNK protein activities were carried out in HepG2 cells. With the exception of trichothecenes **2**, **4**, **7**, and **9**, all of the other trichothecenes could induce PARP-cleavage in HepG2 cells (Figure 3). Also, with the exception of trichothecenes **2** and **9**, all of the other trichothecenes could induce phosphorylation of JNK protein in HepG2 cells (Figure 3). Trichothecenes **1** and **3**, in which the epoxy ring typically located at C-12 and C-13 was absent and the olefinic bond, which is typically located at C-9 and C-10, was substituted with a hydroxy group, could induce PARP-cleavage and phosphorylation of JNK protein in HepG2 cells (Figure 3). These results indicated that the epoxy ring at C-12 and hydroxy substitution at C-9 were important for PARP-cleavage and phosphorylation of JNK protein in HepG2 cells. This conclusion can be further confirmed by the comparison of **1** and **4**. The epoxy ring at C-12 of **4** was open in **1**, and the olefinic bond at C-9 of **4** was substituted with a hydroxy group in **1**. For trichothecenes **1**, **4**, and **7**, the epoxy ring at C-12 and the hydroxy substitution at C-9 were absent in trichothecenes **4** and **7**. Among these three trichothecenes, the epoxy ring located at C-2′ and C-3′ did not play an important role in PARP-cleavage and phosphorylation of the JNK protein in HepG2 cells (Figure 3). For trichothecenes **2**, **5**, and **6**, the substituent group located at C-6′ was the major cause for the activities in HepG2 cells. In other two trichothecenes, **2** and **5**, no ring system existed at C-6′. In a comparison of these two trichothecenes, the only difference between them was that the

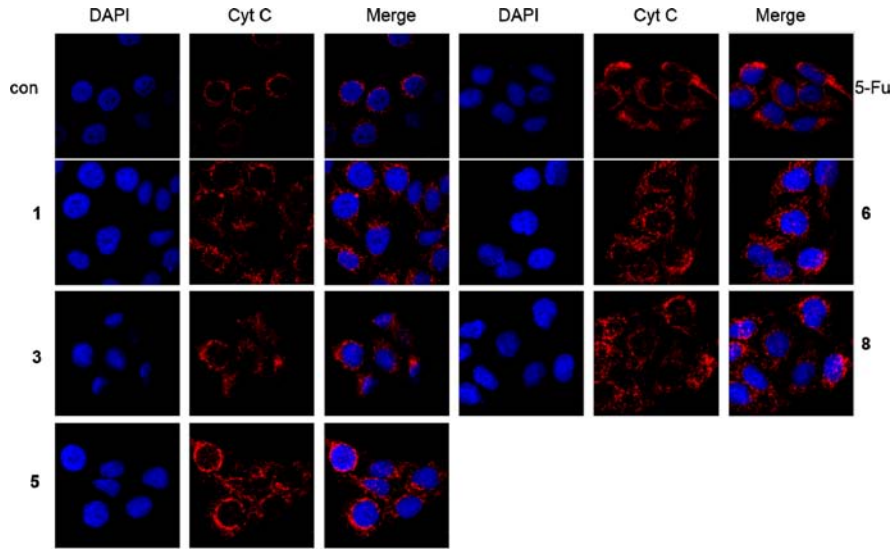

Figure 4. Trichothecene-induced release of cytochrome *c* in the HepG2 cell line. Cells were treated with 5-Fu (50 μM), **1** (50 μM), **3** (50 μM), **5** (50 nM), **6** (50 nM), and **8** (50 nM) for 12 h.

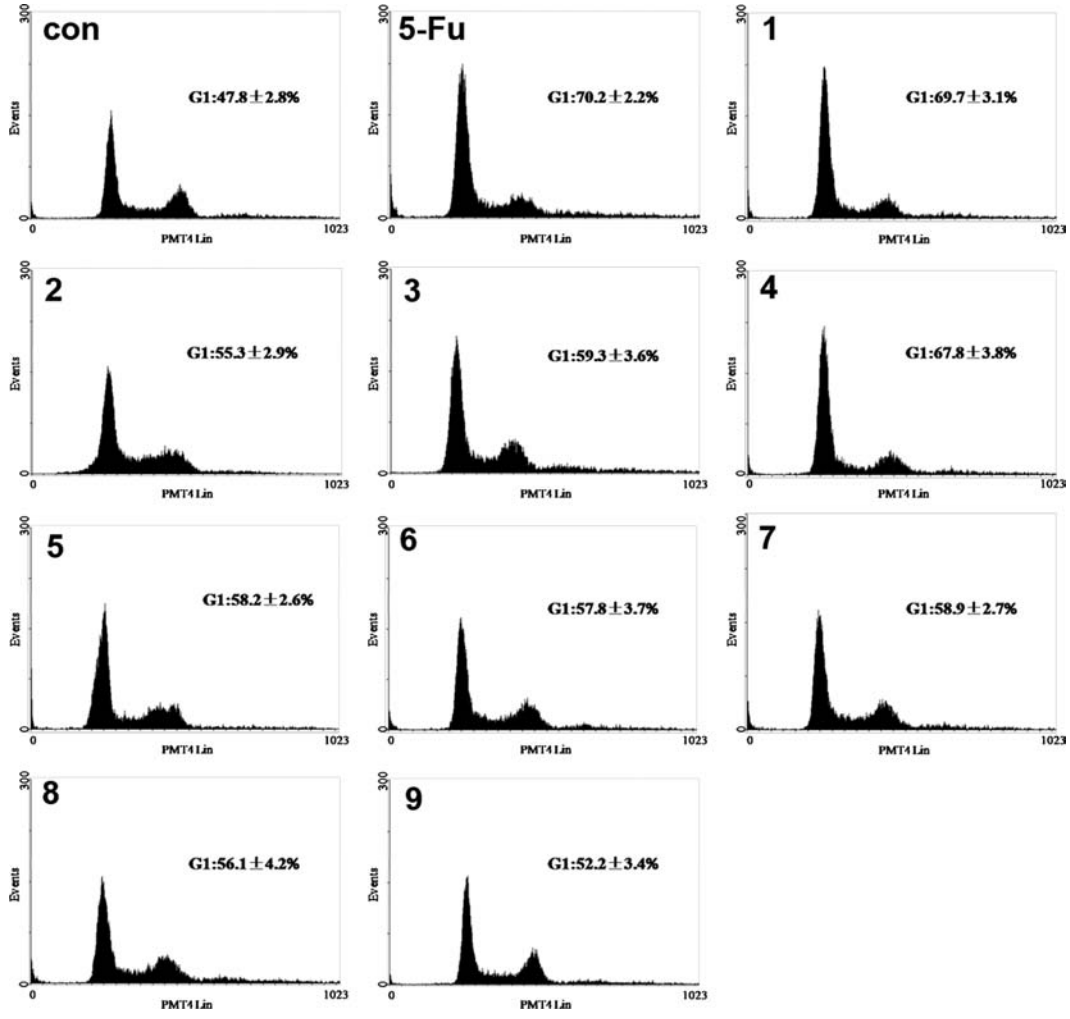

Figure 5. Trichothecene-induced G1 cell cycle arrest in the HepG2 cell line. Cells were treated with 5-Fu (50 μM), compounds **1** (50 μM), **2** (50 nM), **3** (50 μM), **4** (5 nM), **5**-**8** (50 nM), and **9** (1 μM) for 12 h).

hydroxy group located at C-13′ of **2** became a keto group in **5**. These results revealed that the keto group located at C-13′ was an important site for their activity in HepG2 cells (Figure 3).

For trichothecenes **8** and **9**, the only difference between them was the hydroxy group at C-12′. Roridin E, **8**, exhibited far stronger cytotoxicity than its derivative 12′-hydroxyroridin

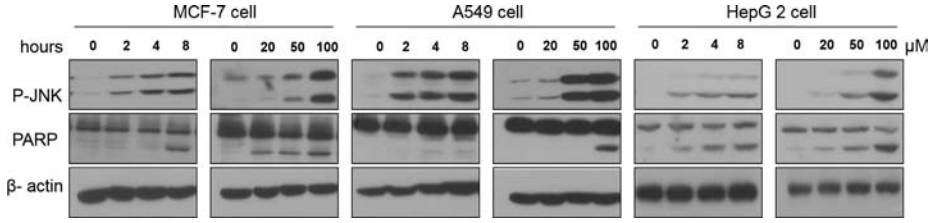

Figure 6. PARP-cleavage and protein JKN phosphorylation in treated MCF-7 cells, A549 cells, and HepG2 cells. Cells were incubated at concentration 50 μM of compound **1** for 0, 2, 4, and 8 h, respectively, or at concentrations 0, 20, 50, and 100 μM of compound **1** for 8 h.

E, **9**, and 12′-hydroxyroridin E, **9**, which exhibited no activity on PARP-cleavage and phosphorylation of JNK protein in HepG2 cells (Figure 3). These results indicated that hydroxy group substitution at C-12′ was vital for PARP-cleavage and phosphorylation of JNK protein in HepG2 cells.

2′,3′-Epoxymyrothecine A could induce the PARP-cleavage in a time- and dose-dependent manner in HepG2 and MCF-7 cells (Figure 6). Compared to HepG2 cells, 2′,3′-epoxymyrothecine A exhibited clear PARP-cleavage only after 8 h in MCF-7 cells, and the dose-dependency was much weaker (Figure 6). 2′,3′-Epoxymyrothecine A did not exhibit the same time-dependent effect on the PARP-cleavage in A549 cells. When A549 cells were treated with 2′,3′-epoxymyrothecine A (50 μM) for 8 h, the PARP-cleavage was unclear (Figure 6). For the dose-dependent experiment, 2′,3′-epoxymyrothecine A did not showed any PARP-cleavage activity until the concentration increased to 100 μM (Figure 6). All these results revealed that 2′,3′-epoxymyrothecine A showed much better apoptosis activity in HepG2 cells compared to A549 and MCF-7 cells.

2′,3′-Epoxymyrothecine A can induce phosphorylation of JNK protein in a time- and dose-dependent manner in HepG2 and MCF-7 cells (Figure 6). There were no significant differences of phosphorylation of JNK protein when A549 cells were treated with 50 μM 2′,3′-epoxymyrothecine A for 2, 4, and 8 h. In terms of dose-dependent manner, it seems that 50 μM 2′,3′-epoxymyrothecine A would achieve the plateau (Figure 6). From the perspective of JNK phosphorylation, 2′,3′-epoxymyrothecine A was more suitable for the treatment of HepG2 and MCF-7 cells. Based on these results, we can conclude that 2′,3′-epoxymyrothecine A can induce the G1 cell cycle arrest, phosphorylation of JNK protein, and the PARP-cleavage in a time- and dose-dependent manner, promote the cytochrome *c* release from the mitochondria, and eventually induce apoptosis in HepG2 liver cancer cells.

All these results indicated that a small change in trichothecenes could dramatically reduce the toxicity and still retain the apoptosis inducing activity in human cancer cells. These data provide a pilot study for future exploitation of the applicability of trichothecenes in cancer chemotherapy.

ABSTRACT: The purpose of this study was to investigate the intake, excretion, and tissue accumulation of carboxymethyl-lysine (CML), after feeding rats a diet containing advanced glycation end products (AGEs) from a glucose−lysine (GL) model system. Rats were distributed into two groups and assigned to a control diet or a diet including 3% heated GL (GL diet) for three months. Feces and urine were collected over the last week. After sacrifice, serum was obtained and some organs were removed for CML analysis. The percentage of fecal CML was 2.5-fold higher in the animals fed the GL diet (33.2 vs 76.5% for control and GL group), whereby total recovery was 91.8% compared with a level of 54.6% in the animals fed the control chow, evidencing the importance of the chemical form and the net quantity of dietary CML on its elimination. We suggest that dietary dicarbonyl compounds from GL diet or dietary CML itself are responsible for CML accumulation in hearts and tendons. The most significant result of the present study is that the regular consumption of dietary AGEs in healthy individuals promotes CML accumulation in some organs.

KEYWORDS: *advanced glycation end products, carboxymethyl-lysine, bone, heart, tendon*

INTRODUCTION

Advanced glycation end products (AGEs) are compounds formed by the nonenzymatic reaction between reducing sugars and free amino groups in proteins, lipids, or nucleic acids, called the Maillard reaction. This reaction takes place during thermal processing of food by techniques such as frying, baking, or roasting and is responsible for the formation of characteristic flavors, colors, and tastes that are desirable to the consumer.[1] On the other hand, the formation of AGEs could lead to a decrease in the nutritional value of the food due to the destruction of vitamins,[2] loss of essential amino acids, or lower protein digestibility.[3,4]

AGEs may also be generated in biological systems by the reaction of α-dicarbonyl compounds with amino groups of endogenous proteins which accumulate in some tissues or are present in the systemic circulation and play a physiopathological role in cases of metabolic and degenerative disorders.[5] In addition to endogenous synthesis, food can provide a significant amount of AGEs, since glycation derivatives are widely consumed as part of the human diet.[6,7] AGEs are thought to be absorbed in the process of digestion, increasing the circulating level and being deposited in different tissues and organs.[8]

Carboxymethyl-lysine (CML) is one of the best characterized AGEs and is frequently used as a marker of glycation product formation in food and in vivo.[9] Several authors have correlated the CML accumulation in plasma and in different tissues with the progression of diabetes and with the acceleration of the aging process.[10,11] However, to date, its absorption, metabolism, and elimination have been only partially elucidated.[12] A direct correlation between the intake of CML and its elimination in feces and urine has been established in several studies. Thus, in the assay of Birlouez-Aragon et al.[13] carried out in humans, the urinary excretion of CML increased by 40% after the consumption of a diet rich in this compound compared with a low-AGE diet; moreover, its presence in plasma was 7% higher. Delgado-Andrade et al.[12] corroborated a higher CML elimination in feces when human volunteers consumed a diet containing large quantities of AGEs. However, the urinary excretion was weakly correlated, probably because renal excretion may be saturated or limited, exceeding the kidney's detoxification capacity. Renal clearance saturation has also been described in a rat study by Alamir et al.[14] after the intake of a diet based on crushed extruded biscuits rich in CML.

Derivatives from the glucose−lysine model system are frequently used to study diverse aspects of AGE effects. Their advantage is that they are easy to produce under laboratory conditions, and the results obtained after in vivo trials are often simpler and more easily interpreted. AGEs from lysine are commonly present in food, since this amino acid is very sensitive to thermal treatment and highly reactive in the Maillard reaction.[15]

The aim of the present study is to investigate CML intake and excretion after feeding rats a diet containing AGEs from a heated glucose−lysine model system. The main originality of

[a]Values are means ± SE (n = 6). Different letters within a column indicate significant differences between groups ($p < 0.05$).

this work is the seeking of possible target organs for the CML deposit in the organism of healthy subjects. For that reason, total CML in different tissues and the protein-bound fraction in serum were measured.

MATERIALS AND METHODS

Chemicals. All the chemical products and solvents for all the analyses were of the highest grade available and acquired from Sigma (Sigma-Aldrich, St. Louis, MO) and Merck (Darmstadt, Germany). CML and (D_2)-CML were provided by PolyPeptide Laboratories France SAS (Strasbourg, France).

Sample Preparation. Glucose (Merck, Darmstadt, Germany) and lysine (Sigma Chemical, St. Louis, MO., USA) were used to prepare the sample. Equimolar mixtures of glucose−lysine−HCl (GL) (40% moisture) were heated in open receptacles in an oven (Selecta 2000210; Barcelona, Spain) at 150 °C for 90 min to obtain the GL sample. This procedure tried to simulate usual home cooking. After heating, the reaction was stopped by cooling in an ice bath and the products were then removed, frozen, lyophilized, and stored at 4 °C as described by Delgado-Andrade et al.[16] until required for preparing the diets.

Preparation of Diets. The AIN-93G purified diet for laboratory rodents (Dyets Inc., Bethlehem, PA) was used as the control diet. The GL sample was added to the AIN-93G diet to reach a final concentration of 3%. This diet was termed GL. The individual analysis of the GL diet revealed no modification of the overall nutrient composition, compared with the control diet (AIN-93G). The mean ± SD nutrient content of the diets was as follows: moisture (%) 8.14 ± 0.08; protein (g/kg) 176.6 ± 3.1; fat (g/kg) 78.1 ± 0.9; and ashes (%) 2.55 ± 0.13.

The higher Maillard reaction product (MRP) content in the GL diet with respect to the control one was confirmed by analyzing the furosine and hydroxymethylfurfural (HMF) contents and total MRP associated fluorescence as described in previous publications.[17,18] The data obtained for furosine (mean ± SD) were as follows: 28.8 ± 0.5 and 1787.08 ± 7.31 mg/kg diet for control and GL diets, respectively. The results for HMF (mean ± SD) were as follows: 0.44 ± 0.06 and 5.15 ± 0.08 mg/kg diet for control and GL diets, respectively. In the case of total MRP associated fluorescence (mean ± SD), they were as follows: 1.1 ± 0.1 and 10.3 ± 0.1 × 10^5 fluorescence units/g diet for control and GL diets, respectively.

Biological Assays. Twenty-four weanling Wistar rats weighing 39.76 ± 0.85 g (mean ± SE) were used in the study. They were randomly distributed into two groups (12 animals per group), and each group was assigned to one of the dietary treatments. The animals were individually housed in metabolic cages in an environmentally controlled room under standard conditions (temperature: 20−22 °C with a 12 h light−dark cycle and 55−70% humidity). The rats had ad libitum access to their diets and demineralized water (Milli-Q Ultrapure Water System, Millipore Corps., Bedford, MA, USA).

The experiment involved a preliminary 81-day period during which solid food intake and body weight changes were monitored weekly, followed by a 7-day period in which feces and urine from each animal were collected daily and stored separately as a 1-week pool. The feces were weighed, lyophilized, powdered, and then homogenized. The urine was collected in 0.5% HCl (v/v), filtered (Whatman Filter Paper No. 40, ashless, Whatman, England), and diluted to an appropriate volume. On day 88, after an overnight fast, the animals were anesthetized with sodium pentobarbital (5 mg per 100 g of body weight) (Abbott Laboratories, Granada, Spain) and terminal exsanguination was performed by a cannulation of the carotid artery. Blood was drawn to obtain serum. Hearts, the right pelvic bones, and the tail tendons were removed, weighed, and frozen at −80 °C until CML analysis.

All management and experimental procedures carried out in this study were in strict accordance with the current European regulations (86/609 E.E.C.) regarding laboratory animals. The Bioethics Committee for Animal Experimentation at our institution (EEZ-CSIC) approved the study protocol.

Sample Preparation for CML Analysis. For CML determination, feces, urines, and hearts were lyophilized and powdered, while diets, serum, and tail tendons were directly processed. Bones were powdered and homogenized. In all samples, an equivalent to 10 mg of proteins was weighed to perform the CML determination. In the case of serum, a step prior to the acid hydrolysis was carried out for protein precipitation using trichloroacetic acid. Therefore, in this last case only protein-bound CML was quantified. The total content of CML (free and protein-bound) was measured in all other samples.

Analytical Techniques. The CML and lysine analysis in extracts of diets, feces, urine, serum, hearts, and bones were performed at the Institut Polytechnique LaSalle Beauvais. All the extractions were done in triplicate and analysis was done in duplicate, when possible, using the method recently developed by Niquet-Léridon and Tessier.[19] Each sample was treated with sodium borohydride to stabilize the Amadori products and to prevent their conversion into CML during the acid hydrolysis. A quantity of reduced sample, equivalent to 10 mg of protein, was dissolved in 5 mL of 6 M HCl and incubated at 110 °C for 20 h. Three hundred microliters of each acid hydrolysate was dried under vacuum and reconstituted in 300 μL of internal standard containing 0.15 μg of (D_2)-CML and 12.5 μg of ($^{15}N_2$)-lysine (dissolved in 20 mM nonafluoropentanoic acid (NFPA)) prior to analysis by LC−MS/MS. The use of internal standards which are isotopes of CML and lysine, respectively, increases the precision and the accuracy of the measurements compared with previous studies.[13] Liquid chromatography coupled to linear ion trap tandem mass spectrometry was used for the analysis of CML. The following instrumentation and criteria were used: Surveyor HPLC system coupled to an LTQ mass spectrometer working in its tandem operation mode (ThermoFisher Scientific, Courtaboeuf, France); thermostat, 10 °C; column Hypercarb, 100 mm × 2.1 mm, 5 μm with a guard column Hypercarb, 10 mm × 2.1 mm, 5 μm; injection volume, 10 μL; flow rate, 0.2 mL/min; mobile phase, 20 mM NFPA in a water−acetonitrile gradient (linear increase of acetonitrile from 0 to 50% over 20 min), electrospray ionization in positive mode; multiple reaction monitoring with the specific transitions m/z 205.0/130.0 and m/z 207.0/130.0 for CML and (D_2)-CML, respectively, with a normalized collision energy of 37% to achieve optimum fragmentations of the parent ions. Lysine and its isotope were detected with the specific transitions m/z 147.0/130.0 and m/z 149.0/131.0, respectively.

The CML and lysine analysis for tail tendons were carried out at Case Western Reserve University (Cleveland, OH). CML and lysine were determined in acid hydrolysates of processed collagen tendon samples and derivatized as its trifluoroacetyl methyl esters by selected ion monitoring gas chromatography GC/MS as previously described by Sell et al.[20]

Statistical Analysis. After checking the normal distribution of data, they were statistically tested with a Student's unpaired t test to compare means that showed a significant variation ($p < 0.05$). Analyses

were performed using Statgraphics Plus, version 5.1, 2001. Evaluation of the relationship between the different variables was carried out by computing the relevant correlation coefficient (Pearson's linear correlation) at the $P < 0.05$ confidence level.

RESULTS AND DISCUSSION

CML Intake and Excretion. The total CML content in the diets (mean ± SD) was 2.18 ± 0.03 and 12.5 ± 0.24 μg/g for the control and GL diets, respectively. As expected, the GL diet had a significantly higher CML content ($P < 0.05$). However, the control diet presented a basal CML content that was probably formed during storage of the diet or of its individual ingredients or even during their production.[21] However, due to the higher proportion of CML in the GL diet, the animals submitted to this diet had a much higher daily exposure to CML than the control group (Table 1). Previous assays conducted by our research group in designing AGE-rich diets for rats, using bread crust as a glycoprotein source, have also recorded significant amounts of CML in these animals and a subsequent higher CML intake, compared with the control diet.[22]

As a result of the high CML intake, fecal excretion was increased in the GL group, and CML intake and its elimination were highly correlated ($r = 0.981$, $p < 0.001$) (Figure 1), which is consistent with what other authors have described previously.[14,23,24] Despite the high proportion of CML eliminated in the feces after consumption of the GL diet (>75%) compared with the control diet (33%), its possible net absorption could be higher than in the control animals due to the great CML exposure of this diet (Table 1). The CML included in the GL diet and originated from a glucose−lysine model system is more likely present as a free adduct although other forms could exist (Table 1).

The animals in the GL group eliminated significantly more urinary CML than did those in the control group (Table 1). As before, this difference was related to the amount of CML consumed by each group; this is corroborated by the strong correlation between CML intake and its urinary elimination ($r = 0.943$, $p < 0.001$) (Figure 1). Previous studies have also reported CML intake to be significantly correlated with its urinary elimination, both in humans[13] and in rats.[14,23] However, the findings obtained by our research group working with AGEs derived from bread crust did not reflect any relationship between these parameters.[22] The lack of concordance between the two assays might be related to the form of CML preferentially ingested in each case. Whereas in the present assay free forms of CML were predominant in the GL diet, in our previous experiment bread crust was used as the source of glycoproteins, and in this latter case protein-bound CML forms would predominate. However, it is worthy to note that Alamir et al.[14] used a protein-bound CML source in their study and found a good correlation between dietary CML and its urinary excretion. Lastly, it must be also noticed that the excretion rate of urinary CML in the rats of the present assay was much higher than that recorded for humans in the ICARE study.[13] This fact points out strong differences between rats and human species with special relevance for CML metabolism.

The intake of free CML, a more absorbable form than the protein-bound compounds, could elevate the circulating CML and thus explain the high net renal clearance of CML in the GL diet (Table 1), which is corroborated by the existence of an important direct relationship between CML intake and its urinary elimination.

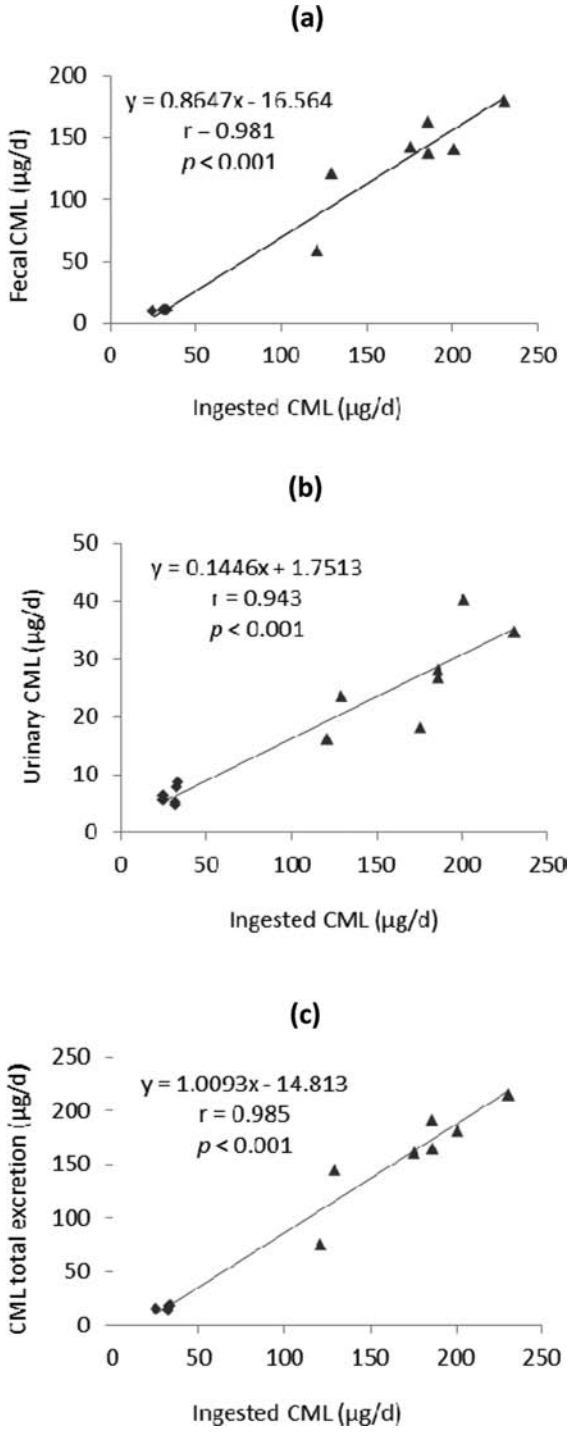

Figure 1. Relationship between CML intake (μg/day) and either fecal CML (a), urinary CML (b), or total excretion (c). $p < 0.05$ indicates the existence of a significant correlation (◆, control group; ▲, GL group).

With respect to the total percentage of CML excreted, the control group rats recovered approximately 50% while those in the GL group recovered 92% (Table 1). Results similar to those for our control group have been observed in other studies working with CML from food. Thus, Delgado-Andrade et al.[12] reported recovery rates of 45−50% in human volunteers, and Somoza et al.[25] found that 50% of the CML ingested was excreted in the feces and urine. Probably, the high difference between the recovery in the human studies and that from the

dx.doi.org/10.1021/jf501005n | J. Agric. Food Chem. 2014, 62, 6001−6006

GL group was mainly due to the great difference in the CML fecal elimination. Focused exclusively in the rate of total CML recovery, its high value in the GL group, once again, highlights the importance of the form of ingested CML (free or linked to a protein backbone) as well as the level of the oral dose of CML. Food-derived CML has a different chemical form and molecular weight to CML obtained from a model system. Available information regarding AGE absorption indicates that its absorption strongly depends on whether these compounds are present in protein-bound form or not. Low molecular weight AGEs may be relatively quickly absorbed, metabolized, and excreted; however, high molecular weight AGEs may remain relatively nonabsorbed due to insufficient degradation by gastrointestinal enzymes.[26]

The results obtained in the present paper for total CML recovery in the GL group (92%) are in line with the recovery described for pyrraline by Foerster and Henle.[27] However, unlike the CML, pyrraline was almost entirely absorbed from foods and, after its metabolic transit, was eliminated rapidly and almost completely in the urine, with only slight metabolism within the body.

CML in Plasma and Tissues. As has been observed previously, diets rich in AGEs can increase levels of circulating CML in serum.[25] Several authors have described a significant positive correlation between dietary intake of AGEs and CML concentrations in the blood.[28,29] In the present assay, the protein-bound CML in serum was measured and no differences were found between the GL group and the control group (Figure 2). Recent studies have described stability in protein-bound CML in serum after the consumption of diets rich in this AGE,[14,30] which is consistent with the results of the present work.[12] In the study by Alamir et al.,[14] in which rats were fed a diet based on crushed extruded biscuits, the protein-bound CML level in plasma did not vary, but the free fraction increased with consumption of this diet. In the light of these data it could be hypothesized that free CML is more affected by dietary exposure than protein-bound fraction, and this fact could be used to know the real index of the CML obtained from the diet. Unfortunately, this measurement could not be obtained in the present study.

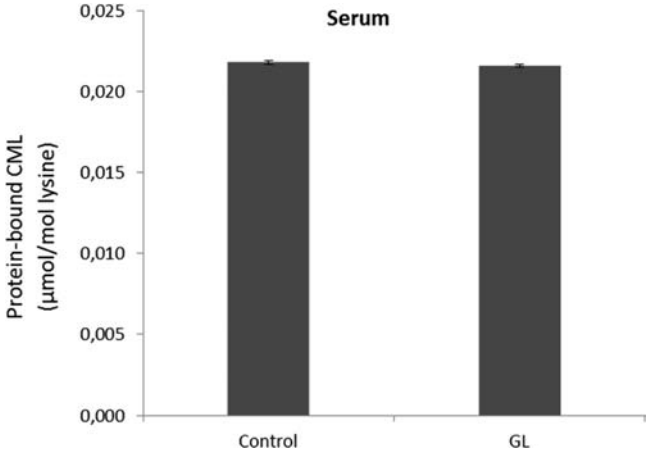

Figure 2. Protein-bound CML in serum expressed as μmol/mol lysine (mean ± SE, $n = 6$). No significant differences were found between the groups ($p > 0.05$).

A significant increase in tissue CML concentration has been observed under pathological conditions such as diabetes.[11] Although the accumulation of CML in the kidney, skin, and blood vessels in diabetic subjects is well established,[31] its accumulation in the heart has yet to be completely elucidated. Subsequent studies suggested that an increase in CML levels in cardiac tissue could play an important role in the pathogenesis of heart disease.[32,33] Moreover, our research group recently showed that after rats were fed an AGE-enriched diet elaborated from bread crust, the total CML level in cardiac tissue increased.[22] In the present assay, consumption of the GL diet significantly raised the total concentration of CML in the heart, in comparison with the animals given the control diet (Figure 3) ($p = 0.035$). In this respect, it should be noted that the remaining blood was not completely removed from the heart prior to the CML analysis, and so some contribution to the final CML content in the heart cannot be excluded. However, taking into account that no modifications were

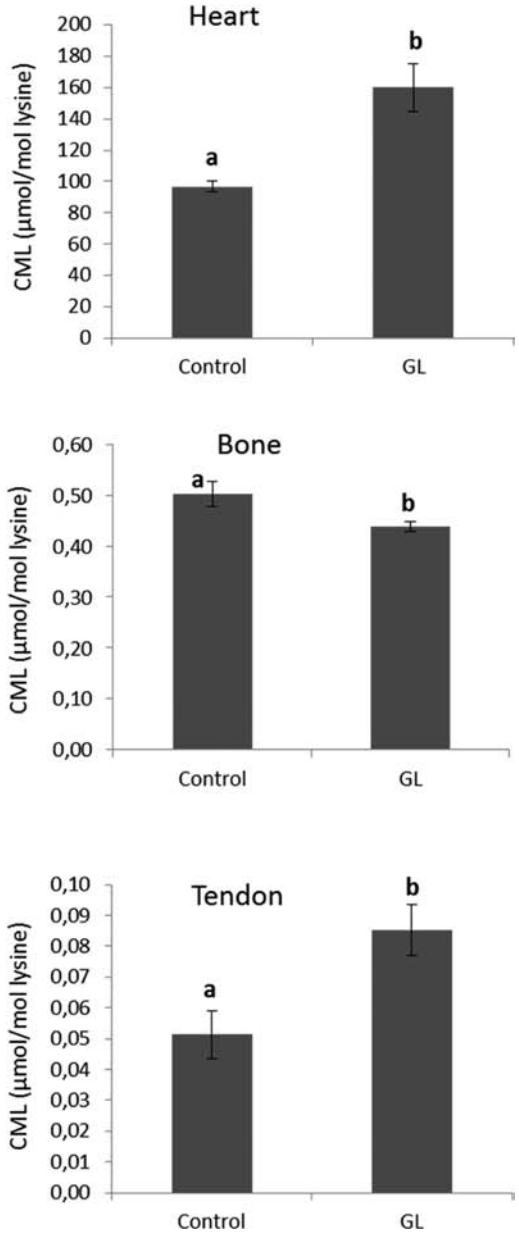

Figure 3. CML in heart, bone, and tail tendon (μmol/mol lysine) (mean ± SE, $n = 6$). Different letters indicate significant differences between the groups ($p < 0.05$).

dx.doi.org/10.1021/jf501005n | J. Agric. Food Chem. 2014, 62, 6001−6006

detected in the protein-bound CML of the plasma (which could be more representative of the endogenous CML), its accumulation in the heart could have a dietary origin. Supporting this hypothesis, a correlation between the daily intake of CML and its accumulation in the heart ($r = 0.785$; $p = 0.003$) was detected. But in any case, the in situ CML formation from dietary dicarbonyl compounds must be also considered due to the elevated recovery rate of the compound in urine and feces. The effect of a high dietary AGEs intake in increasing the heart AGEs content has been previously established.[34]

With respect to the concentration of CML in the bones, the GL group presented a significantly lower CML content than the control group. However, in the case of the tail tendons, total CML was significantly increased when the animals consumed the GL diet (Figure 3). This fact could be due to the tendon collagen being more susceptible to glycation than is bone collagen.[35] It has been reported that the mineral phase of bone provides some protection against glycation.[36] The high CML accumulation could also be explained by the lower turnover of collagen type I in the tendons and other connective tissues, such as cartilage or ligaments;[37] the turnover of this type of collagen in bones is faster, and this, too, could be significant in the lesser accumulation of AGEs. CML in the tendons might come from the direct deposition of ingested CML, and/or from absorbed dicarbonyl compounds, which could act as promoters for the in vivo formation of CML. Several authors have described the accumulation of AGEs in the bones[38] as well as in the tendons[39] under conditions of diabetes or aging,[40] but further studies are necessary to clarify the question of CML deposit or its formation by dietary exposure.

In summary, the results of the present study, together with those of previous work by our research group, underline the importance of the chemical form of dietary CML in its fecal and urinary excretion. The simpler forms of the compound in the diet increase its possible absorption, with a subsequent high renal clearance in comparison with the intake of the protein-bound CML. In view of the high rate of CML recovery observed in the GL group, we believe that, in addition to dietary CML, dietary dicarbonyl compounds could be partly responsible for CML accumulation in the heart. In parallel, those products could also be involved in the increased amount of CML in the tail tendons but not in the bones, due to the greater turnover of its collagen. Possibly the most significant result of the present study is the demonstration that the uninterrupted consumption of dietary AGEs promotes CML accumulations in the target tissues of healthy individuals, a fact which could have pathophysiological implications especially in the elderly population.

Partially Hydrolyzed Bamboo (*Phyllostachys heterocycla*) As a Porous Bioadsorbent for the Removal of Pb(II) from Aqueous Mixtures

Xiao-kun OuYang,* Ru-Na Jin, Le-Ping Yang, Zheng-Shun Wen, Li-Ye Yang, Yang-Guang Wang,* and Chong-Yu Wang

School of Food and Pharmacy, Zhejiang Ocean University, Zhoushan 316022, P. R. China

Supporting Information

ABSTRACT: A novel porous succinylated bioadsorbent was prepared by the partial enzymatic hydrolysis of bamboo (*Phyllostachys heterocycla*) and its subsequent modification with succinic anhydride. Pb(II) removal from solutions that also contained sodium chloride and an amino acid was investigated using the bioadsorbent. Enzymatic hydrolysis increased the number of accessible hydroxyl groups and surface area of the raw bamboo, and created many pores within the material. The porous succinylated bioadsorbent exhibited high efficiency for Pb(II) binding. The sodium chloride content significantly decreased the Pb(II) adsorption capacity, whereas a minor effect was observed in the presence of arginine. The experimental data could be accurately described by a pseudo-second-order kinetics model, and the adsorption proceeded via an ion exchange mechanism. Even in a solution containing sodium chloride and arginine, the maximum adsorption capacity of Pb(II) by the porous succinylated bioadsorbent was 99.5 mg/g at 303 K.

KEYWORDS: *partial enzymatic hydrolysis, porous biomass, Pb(II), arginine, sodium chloride, Phyllostachys heterocycla*

INTRODUCTION

Pb(II) is widely used in many industries despite its toxicity to humans.[1] Large volumes of contaminated wastewater are discharged into the oceans, where lead accumulates[2] and has the potential to move up the food chain through marine organisms.[3] Previous reports have revealed the contamination of some saltwater fish with Pb(II).[4,5] As a common practice, byproducts of the marine fish−processing industry are hydrolyzed to produce other products,[6,7] and China has set a hygienic limit on Pb(II) in aquatic protein hydrolysates.[8] A survey reported by Ip et al.[9] showed that the concentration of Pb(II) in edible fish muscle varied from 0.04 to 30.7 mg/kg. The Pb(II) concentrations in marine fish byproducts such as the liver and viscera are reportedly higher than that in muscles;[10] therefore, marine protein hydrolysates prepared from such byproducts may be contaminated with relatively high levels of Pb(II) residues. Thus, it is necessary and urgent to remove Pb(II) from marine protein hydrolysate solutions before the byproducts are used in the manufacture of other products.

Traditional methods[11] for the removal of heavy metal ions from aqueous solutions include coagulation, chemical precipitation, and chemical oxidation/reduction. However, these methods may introduce new pollutants or generate toxic products. Another method preferred for the removal of heavy metals from aqueous solutions is adsorption,[12] with activated carbon[13] being an effective adsorbent. However, the high cost of the adsorbent limits its application. Ion exchange resins[14] are also effective adsorbents; however, they may generate toxic pollutants during the adsorption process.[15] Therefore, from a food safety viewpoint, there is a demand for green adsorbents. Plant wastes[12] that can be used as bioadsorbents for the removal of Pb(II) residues from aqueous solutions are readily available, and many studies have reported their use.[12,16] However, raw plant waste is efficient only at high ion concentrations and in the absence of salts and amino acids. Marine protein hydrolysate solutions may contain high concentrations of amino acids[17] and salts.[7] Competition between heavy metal ions, sodium chloride,[18] and amino acids may dramatically affect the adsorption capacity of the adsorbent. Thus, there is demand for a bioadsorbent capable of high-efficiency Pb(II) adsorption in the presence of high concentrations of amino acids and salts.

The functional groups in a lignocellulosic biomass material are a key factor in its ability to adsorb heavy metal ions from solution,[12] and many efforts have been made to increase the number of these accessible functional groups.[19] Carboxylic acid functionalities are effective for binding metal ions[20] and can be introduced by the chemical modification of hydroxyl groups in the lignocellulosic biomass. The degree of biomass modification (e.g., by succinylation) is determined by the number of accessible hydroxyl groups. An adsorbent's structure has a significant influence on its metal ion adsorption abilities. For example, compactness reduces the accessibility and restricts the diffusion of metal ions into the interior of the biomass. If the compact lignocellulosic cell wall could be disrupted to some extent, the number of accessible functional groups would be increased and metal ion adsorption would take place in both the exterior and interior of the biomass. Zhong et al.[20] employed a new strategy to prepare a porous succinylated biopolymer by dissolving biomass in an ionic liquid. However, ionic liquid residues in the biomass have the potential to contaminate the solution, and previous reports[21] indicate that

ACS Publications © 2014 American Chemical Society

ionic liquids also exhibit human toxicity. Thus, from a food safety viewpoint, a new strategy for the preparation of porous succinylated bioadsorbents with a high degree of efficiency and safety must be developed.

Enhancing the efficiency of enzymatic hydrolysis for the conversion of lignocellulosic biomass into sugars[22] to produce biofuel is quite difficult. However, natural biomass can be partially degraded by enzymatic hydrolysis: holes and cracks can be created within the material, thus increasing the accessible surface area and numbers of pores and hydroxyl groups in the biomass.

In this study, a porous succinylated bioadsorbent, prepared from lignocellulosic biomass by partial enzymatic hydrolysis coupled with a succinylation reaction, was used to remove lead ions from an aqueous solution in the presence of high concentrations of salts and amino acids. The adsorption behaviors of Pb(II) on the bioadsorbent were investigated under different experimental conditions. This study will help to ensure the safety of downstream products prepared from marine protein hydrolysates.

MATERIALS AND METHODS

Materials. Bamboo (*Phyllostachys heterocycla*) was collected in the summer of 2013 from a bamboo handicraft factory in AnJi City (Zhejiang province, China). A standard solution of Pb(II) (lead nitrate) was purchased from the National Analysis Center for Iron and Steel (Beijing, China). Cellulase was purchased from the Aladdin Reagent Co., Ltd. (Shanghai, China), with an enzyme activity of 10000 U/g. All other chemicals were of analytical grade. A stock solution of Pb(II) was prepared by diluting the standard solution with double-distilled water.

Preparation of Porous Succinylated Bioadsorbent. The collected bamboos were crushed into pieces, boiled in distilled water for 1 h to remove dust and soluble impurities, and thoroughly washed with distilled water until the supernatant was free of color and turbidity. The obtained materials were dried in an air oven for 24 h at 80 °C, and then ground and sieved to obtain <150 μm particles. The solids were subjected to successive ultrasonic treatments in 1 M hydrochloric acid and 1 M sodium hydroxide for 3 h. The solutions were filtered and the residues were washed with distilled water repeatedly until the washings were pH 7.0. The resulting powders were completely dried in an air oven at 80 °C for 48 h to obtain raw bamboo powder (RBP, mean size 99.6 μm). A portion of the RBP (10 g) was treated with cellulase (0.4 g, 4 g of enzyme/100 g of dry RBP) in acetic acid buffer solution (400 mL, pH 5.0) in a conical flask with a stopper, which was placed in a water bath shaker maintained at 50 °C and shaken at 150 rpm for 24 h. After this hydrolysis, the samples were placed in boiling water for 15 min to deactivate the enzyme. The mixture was centrifuged at 5000 rpm for 10 min. The solids were collected, washed three times with acetone until the washings were free of turbidity, and dried in air in an 80 °C oven for 48 h to obtain enzymatically hydrolyzed bamboo (EHP, mean size 110.9 μm). A portion of the EHP (5 g) was treated with succinic anhydride (10 g) in pyridine (120 mL) at reflux for 1 h. The resulting material was thoroughly washed with ethanol and dried in air in an 80 °C oven for 4 h. The material was then treated with saturated $NaHCO_3$ solution for 1 h and washed with double-distilled water and ethanol (95%). Finally, it was dried in an air oven at 80 °C to obtain the succinylated bamboo powder (SBP). A second succinylated bamboo powder was prepared by the reaction of RBP with succinic anhydride under similar succinylation conditions. This succinylated raw bamboo powder was called RSP. The prepared adsorbents were stored in a desiccator. Scanning electron microscopy (SEM) and Fourier transform infrared spectroscopy (FTIR) were used to characterize the bioadsorbents. FTIR analysis of RBP, EHP, and SBP was performed on a Thermo Nicolet 6700 spectrometer using KBr pellets. X-ray photoelectron spectroscopy (XPS) analysis was performed on AXIS ULTRA^{DLD} spectrometer (Kratos, England). SEM analysis of the materials was performed on a Philips XL30 ESEM (FEI Company, Germany) after coating of the samples with a thin layer of gold. The surface zeta potentials of the adsorbents were measured using Zetasizer 2000 (Malvern, United Kingdom). The particle size of the adsorbents was measured using a S3500 Microtrac Particle Size Analyzer (Microtrac Inc., USA).

Degree of Succinylation. The concentration of carboxylic acid functional groups per gram of bioadsorbent was determined by reverse-titration.[20] Briefly, the prepared bioadsorbent (100 mg) was mixed with NaOH solution (100 mL, 0.01 M) for 1 h while stirring. Thereafter, the materials were separated by filtration, and three aliquots of the obtained solution were titrated with aqueous HCl solution (0.01 M) by using phenolphthalein as an indicator. The concentration of the carboxylic acid functional groups was calculated using eq 1,

$$C_{COOH} = \frac{C_1V_1 - 5C_2V_2}{m} \quad (1)$$

where C_1 is the concentration (mol/L) and V_1 is the volume (L) of the NaOH solution; C_2 is the concentration (mol/L) and V_2 is the volume (L) of the HCl solution used in the titration of excess unreacted NaOH; and m is the mass of the bioadsorbent (g).

Preparation of Reagent Solutions. Aqueous solutions containing different concentrations of Pb(II) (5−100 mg/L), arginine (0−50 mg/mL), and sodium chloride (0−8 mg/mL) were prepared for use in the batch experiments.

Adsorption Experiments. Adsorption experiments were investigated in batch mode. Unless otherwise stated, these batch studies were conducted at pH 5.0 with an initial Pb(II) concentration of 50 mg/L and a contact time of 240 min, at 303 K. Except for the adsorbent dosage studies, all other experiments were performed by mixing aqueous Pb(II) solution (50 mL) with dry bioadsorbent (0.05 g). The initial pH of each Pb(II) solution was adjusted with 0.01 M HNO_3 or 0.01 M NaOH solution. The adsorbent/Pb(II) solution mixtures were shaken in a thermostatic shaker bath (GFL 1092 shaker) at 150 rpm at various temperatures for different contact times. At the end of the experiments, the solutions were centrifuged at 5000 rpm for 10 min to separate the bioadsorbents. Pb(II) concentrations before and after adsorption in the solutions were determined using an inductively coupled plasma (ICP) spectrometer (Prodigy XP, Teledyne Technologies Corp., USA). All experiments were performed in triplicate, and the average values were used in the data analysis. Data were analyzed using EXCEL 2003 (Microsoft).

The effect of pH on the adsorption capacity q_e of the adsorbents was investigated in the range 2.0−6.0. In these experiments, the Pb(II) concentration was 50 mg/L. The equilibrium absorption amount of Pb(II) absorbed on the adsorbent was calculated using eq 2,

$$q_e = \frac{(C_o - C_e)V}{m} \quad (2)$$

where q_e is the adsorption capacity of the adsorbent (mg/g), C_o is the initial concentration of Pb(II) (mg/L), C_e is the equilibrium Pb(II) concentration in solution (mg/L), m is the mass of adsorbent used (g), and V is the volume of Pb(II) solution (L).

To investigate the adsorption performance of EHP, SBP, and RSP, experiments were conducted by mixing aqueous Pb(II) solution (50 mL) with the dry bioadsorbent (0.05 g). This group of experiments was conducted under standard batch mode conditions.

Kinetics experiments were carried out with a series of different initial Pb(II) concentrations (5, 10, 20, 50, and 100 mg/L). The adsorption capacity of the adsorbents at any time was calculated using eq 3,

$$q_t = \frac{(C_o - C_t)V}{m} \quad (3)$$

where q_t (mg/g) is the adsorption capacity of Pb(II) on the adsorbent at any time t, and C_t (mg/L) is the Pb(II) concentration in solution at any time t.

To study the effect of temperature, isothermal experiments were conducted at 293, 298, 303, and 308 K. In this group of experiments, the initial Pb(II) concentration was varied from 5 to 100 mg/L. The effects of arginine (0−50 mg/mL) and sodium chloride (0−8 mg/mL) concentration, adsorbent dosage (0.05−0.25 g), and contact time (10−720 min) were also investigated.

Desorption Experiments. For the desorption study, batch experiments were conducted by mixing aqueous Pb(II) solution (50 mL, 50 mg/mL) with SBP (0.05 g) in the presence of sodium chloride (4 mg/mL) and arginine (20 mg/mL). The mixtures of the adsorbent and Pb(II) solutions were shaken in a thermostatic shaker bath at 150 rpm and 303 K for 240 min. After the attainment of equilibrium, the Pb(II)-loaded SBP was separated from the solution by centrifugation and washed three times with distilled water (50 mL) to remove unabsorbed Pb(II). Subsequently, the bioadsorbents were mixed with 0.1 M HCl (50 mL) and shaken for 240 min at 303 K. The solution was centrifuged at 5000 rpm for 10 min to collect the adsorbent and washed three times with distilled water. The obtained solids were dried in an air oven at 80 °C and reused for batch desorption studies. The adsorption and desorption experiments were performed over five cycles. The desorption efficiency was calculated using eq 4.

$$\text{desorption efficiency} = \frac{\text{amount of Pb (II) desorbed}}{\text{amount of Pb(II) adsorbed}} \times 100\% \quad (4)$$

RESULTS AND DISCUSSION

FTIR Analysis. The FTIR spectra of the adsorbents were obtained over the wavenumber range 400−4000 cm^{-1} with a resolution of 4 cm^{-1}. Figure 1 shows the FTIR spectra of (a) Pb(II)-loaded SBP, (b) as-prepared SBP, (c) EHP, (d) RSP, and (e) RBP. In the figure, the absorption at 3350 cm^{-1} may be attributed to hydroxyl group stretching vibrations.[23] In spectra b and d, the peak intensity at 3350 cm^{-1} decreases significantly, indicating that hydroxyl groups are involved in the succinylation reaction. The absorption at 2920 cm^{-1} is dominated by the stretching of the $-CH_2$ group.[24] As compared with spectrum e, the strong adsorptions at 1720 cm^{-1} in the spectra of SBP (spectrum b) and RSP (spectrum d)—attributable to carbonyl groups[24]—indicate the successful introduction of the succinyl groups. The peak intensity at 1720 cm^{-1} in SBP is stronger than that in RSP, suggesting that the enzymatically hydrolyzed biomass greatly favors the succinylation reaction. The peaks observed at 1590 cm^{-1} and between 1420 and 1360 cm^{-1} (spectra b and e) correspond to asymmetric and symmetric stretches of carboxylate ions.[20] The peaks at 1160 cm^{-1} belong to the C−O−C groups in the ester and carboxylic acid groups, and the band at 1030 cm^{-1} corresponds to C−O stretching.[20] As illustrated in Figure 1, the intensities of some peaks changes. In comparing spectra a and b, the peak intensities at 3350 cm^{-1} and 1720 cm^{-1} and between 1590 and 1160 dramatically decrease after Pb(II) loading, indicating that hydroxyl and carboxyl groups are involved in adsorption; these groups may be important in the adsorption of Pb(II) on SBP.

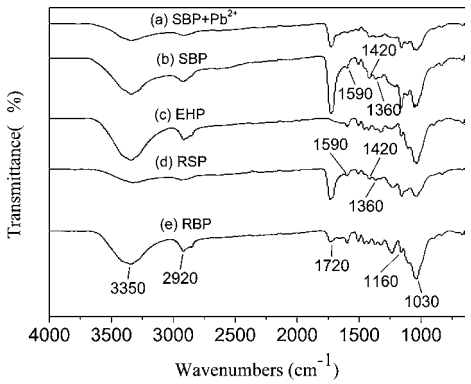

Figure 1. FTIR spectra of (a) Pb(II)-loaded porous succinylated bamboo, (b) porous succinylated bamboo, RBP; (c) partial enzymatically hydrolyzed bamboo, EHP; (d) succinylated bamboo prepared from raw bamboo material, RSP; and (e) raw bamboo material, RBP. The adsorption conditions were pH 5.0; contact time, 240 min; Pb(II) concentration, 50 mg/L; sodium chloride concentration, 4 mg/mL; arginine concentration, 20 mg/mL; adsorbent dosage, 0.05 g; and temperature, 303 K.

XPS analysis. XPS was used to characterize the changes in the main functional groups of SBP upon exposure to Pb(II) solution. From the XPS wide-scan spectra in Figure S1 (Supporting Information), distinct peaks for carbon and oxygen in both SBP and Pb(II)-loaded SBP were observed, as well as a peak due to sodium in SBP. After Pb(II) adsorption, the sodium peak disappeared and peaks for Pb(II) were observed in the Pb(II)-loaded SBP. It is evident that Pb(II) was bound to SBP through ion exchange. Figure 2 shows the C 1s region of the high-resolution XPS spectra of SBP before (a) and after (b) Pb(II) adsorption. The C 1s spectra can be deconvoluted into four peaks which can be assigned to C−C (aromatic), C−O (alcohol), O−C−O (ether), and O−C═O (carboxyl or ester) groups.[25] After Pb(II) adsorption, the binding energies of O−C and O−C═O shift from 286.3 and 289.0 eV to 286.2 and 288.8 eV, respectively. The changes in the C−O and O−C═O binding energies indicate that they are involved in the adsorption of Pb(II) onto the adsorbent.[26] In the XPS spectrum of Pb 4f (shown in Figure 2c), the peak observed at 139.0 eV, which corresponds to the characteristic binding energies of lead carbonate and lead oxalate compounds,[27,28] also indicates that Pb(II) is bound on SBP through hydroxyl and carboxyl groups. The results obtained above are consistent with the FTIR analysis.

Scanning Electron Microscopy (SEM) Analysis. Representative SEM micrographs of RBP, RSP, EHP, and SBP are given in Figure 3. Although RBP (Figure 3A) has a smooth and compact surface, after it is subjected to chemical modification with succinic anhydride, the resultant RSP (Figure 3B) has a rough surface morphology. The surface structure of EHP (Figure 3C) is significantly changed, with many observable pores and a rough surface, suggesting that enzymatic hydrolysis can create a porous structure in the RBP. By comparison with RBP, many cracks appeared on the surface of EHP, suggesting that surface area was increased after enzymatic hydrolysis. These changes should greatly favor subsequent chemical modification with succinic anhydride. Hence, the porous succinylated bioadsorbent, SBP (Figure 3D), with an enlarged surface area and considerable number of pores as well as COO^- groups was successfully prepared from enzymatically hydrolyzed bamboo. These structural changes in SBP will provide more binding sites for Pb(II) loading, as will the enhanced porosity, which will allow adsorption on both the exterior and interior of the bioadsorbent. As a result, the succinylated bioadsorbent will possess high adsorption efficiency.

Effect of Enzymatic Hydrolysis Modification on Pb(II) Uptake. Succinylated biomass has been used for the adsorption of heavy ion metals from solutions, and has exhibited excellent performance.[20] Carboxylic acid groups, which actively bind metal ions, can be introduced in the

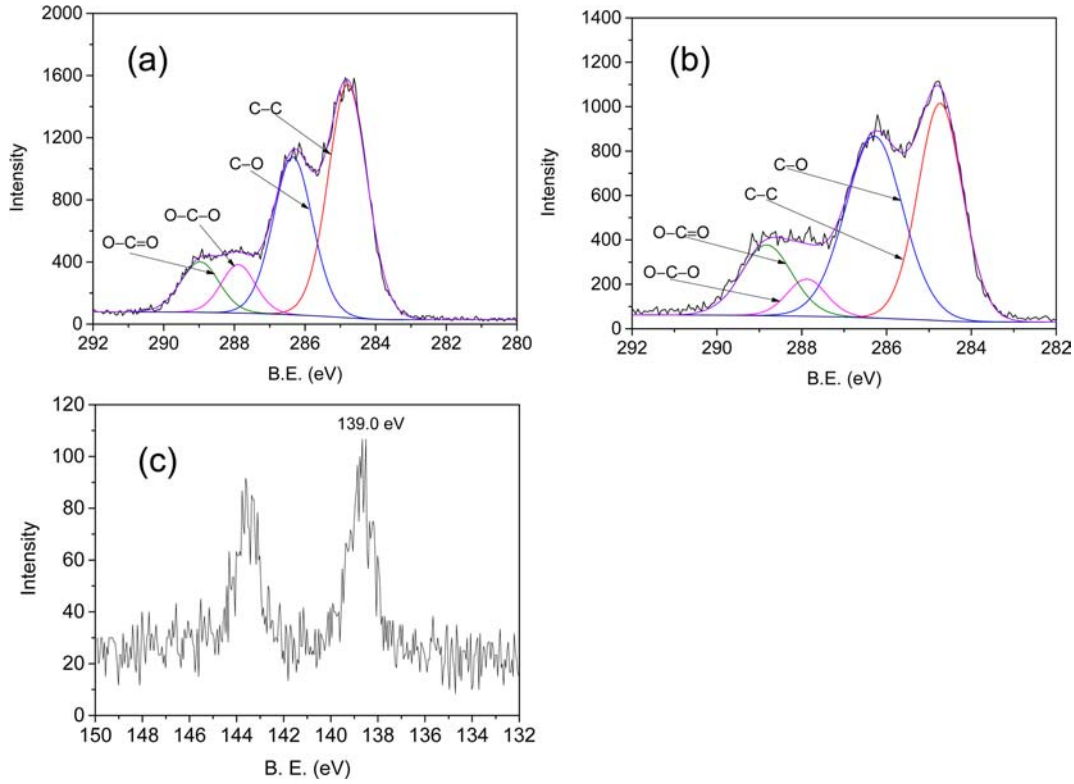

Figure 2. High-resolution of C 1s spectra of SBP (a), Pb(II)-loaded SBP (b), and Pb 4f spectrum on SBP (c). The adsorption conditions were pH 5.0; Pb(II) concentration, 50 mg/L; sodium chloride concentration, 4 mg/mL; arginine concentration, 20 mg/mL; adsorbent dosage, 0.05 g; and temperature, 303 K.

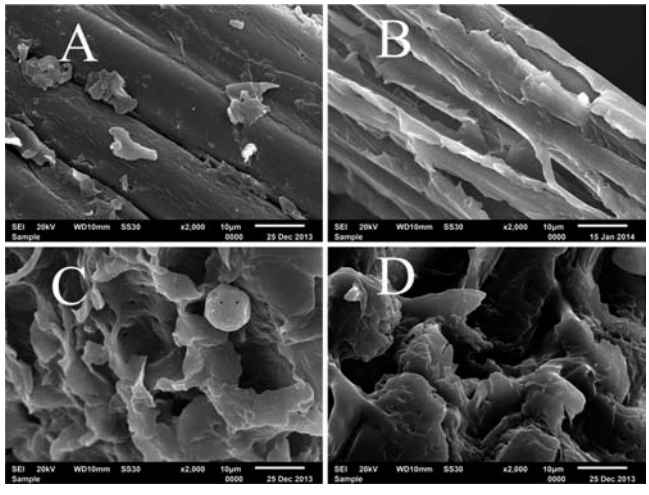

Figure 3. SEM images of adsorbents: (A) ground bamboo raw material, RBP; (B) RSP; (C) EHP (enzyme-to-bamboo ratio = 4:100 (g/g)); and (D) SBP.

biomass through the reaction of hydroxyl groups and succinic anhydride.[27,29] Hence, the degree of succinylation of the biomass largely depends on the number of accessible hydroxyl groups and the surface area. As mentioned above, enzymatic hydrolysis can create many pores within the bioadsorbent and roughen its surface. Enzyme treatment can dramatically affect the number of accessible hydroxyl groups and the biomass surface area, consequently influencing the carboxylic acid content introduced. Therefore, the effect of the enzyme-to-bamboo ratio on the introduction of carboxylic acid content to the bioadsorbent was investigated. The results are shown in Figure 4A. When the enzyme-to-bamboo ratio increased from 1:100 to 4:100 (g/g), the carboxylic acid content increased from 5.24 to 5.62 mmol/g, whereas the carboxylic acid content decreased gradually from 5.62 to 4.81 mmol/g when the enzyme-to-bamboo ratio increased from 4:100 to 24:100 (g/g). Hence, an enzyme-to-bamboo ratio of 4:100 (g/g) was selected to prepare the porous bamboo (EHP). This effect may be due to destruction of the RBP structure under higher enzymatic loads, resulting in a decreasing number of pores in the material. Consequently, the number of accessible hydroxyl groups would decrease, leading to a lower degree of succinylation. The carboxylic acid content of RSP is 5.06 mmol/g, suggesting that it may exhibit a higher q_e for Pb(II). A comparison of Pb(II) adsorption by RBP, EHP, SBP, and RSP (shown in Figure 4B) reveals a lower q_e toward Pb(II) for RSP (18.64 mg/g) than SBP (34.83 mg/g), and a higher q_e for EHP (24.44 mg/g) than RBP (12.97 mg/g). The higher q_e of SBP for Pb(II) over EHP suggests that the succinylated biomass adsorbs Pb(II) better than biomass without chemical modification. These results suggest that both the carboxylic acids and porous structure are important for higher q_e. In the other batch experiments, SBP was used as the bioadsorbent.

Effect of Pb(II) Solution pH on Uptake. Marine proteins are hydrolyzed in the pH range 3−11.[7,30] However, lead ions in solution will precipitate as lead hydroxides at pH values over 7.0.[31] To ensure the availability of Pb(II) in solution, therefore, in this group of experiments, the influence of the initial pH of the Pb(II) solution on the adsorption of lead ions by SBP was studied in the pH range 2−6. As illustrated in Figure 5A, the q_e increased slowly with pH, from 2.25 mg/g at pH 2.0 to 5.25 mg/g at pH 3.0, while a rapid increase in q_e occurred in the pH range from 3.5 (9.67 mg/g) to 6.0 (40.23 mg/g). As the pH

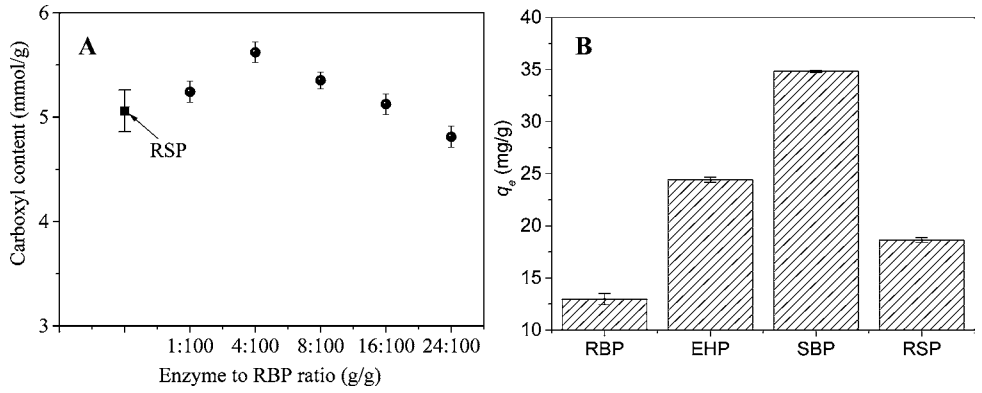

Figure 4. Effects of enzymatic hydrolysis modifications on Pb(II) uptake: (A) effect of enzyme-to-RBP ratio on carboxyl content in bioadsorbent; (B) effect of different adsorbents on the adsorption capacity q_e of Pb(II). The adsorption conditions were pH 5.0; contact time, 240 min; Pb(II) concentration, 50 mg/L; sodium chloride concentration, 4 mg/mL; arginine concentration, 20 mg/mL; adsorbent dosage, 0.05 g; and temperature, 303 K.

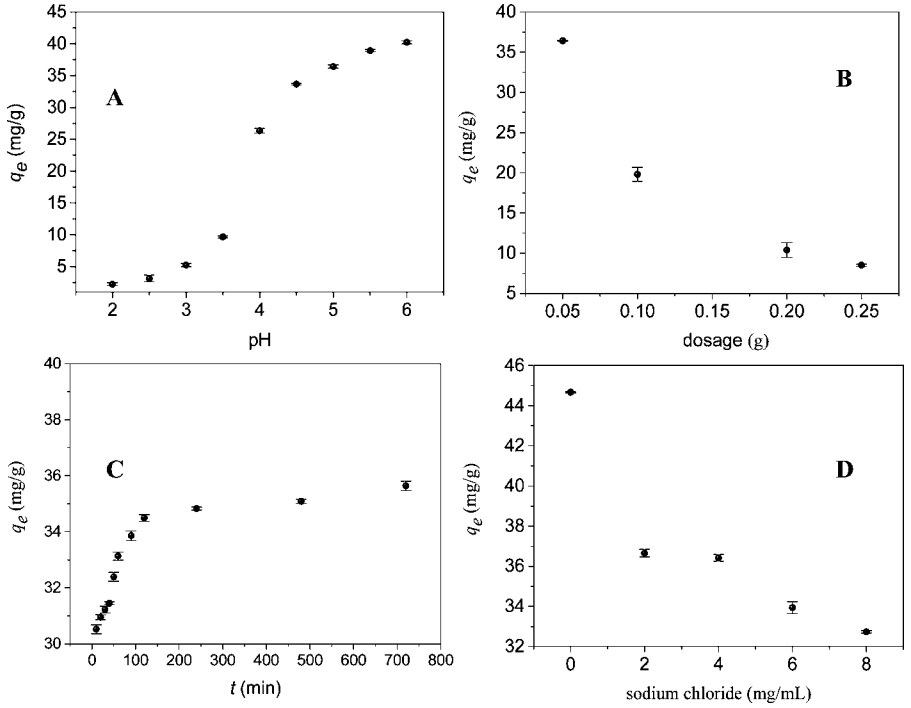

Figure 5. Effects of experimental conditions on Pb(II) adsorption by SBP: (A) pH, (B) adsorbent dose, (C) contact time, and (D) sodium chloride concentration. Studies were conducted at pH 5.0; initial Pb(II) concentration, 50 mg/L; contact time, 240 min; adsorbent dosage, 0.05 g; and temperature, 303 K, unless otherwise stated.

increases (3.5 to 6), the proton competition and electrostatic repulsion effects decrease, and the carboxylic acid groups become deprotonated (COO^-) and easily attract Pb(II); hence, the q_e significantly improves. Thus, it can be concluded that Pb(II) adsorption onto SBP mainly involves electrostatic interactions between Pb(II) and negatively charged carboxylate groups, and the adsorption process is an ion exchange mechanism.[20] Therefore, the rest of the batch experiments were conducted at pH 5.

Effect of Dosage and Contact Time on Pb(II) Uptake. The effect of SBP dosage on the equilibrium q_e of Pb(II) was investigated in the range 0.05−0.25 g, and the results are shown in Figure 5B. It can be found that q_e decreases from 36.42 to 8.51 mg/g as the dosage increases from 0.05 to 0.25 g. Similar results were observed in previous studies.[32] The reason for this phenomenon is likely to be adsorption sites remaining unsaturated during the adsorption process.[33] Another reason may be due to aggregation resulting from high adsorbent concentration.[34] This propensity can be assessed through the zeta potential, which is a measure of the electrokinetic potential in a colloidal system and of its stability.[35] The zeta potentials of SBP at concentrations of 1−5 mg/mL were measured to study the stability of the adsorbent. As can be seen from Figure S2 (Supporting Information), all the SBP zeta potentials are negative, but decrease from −29.55 to −10.1 mV as the adsorbent concentration increases from 1 to 5 mg/mL. The adsorbent surface becomes less negatively charged, thereby reducing the repulsive interactions between the particles and resulting in their aggregation.[35] Such aggregation would lead to a decrease in the total surface area of the adsorbent.

The effect of contact time (10−720 min) on the q_e of Pb(II) by SBP is shown in Figure 5C. Pb(II) adsorption on SBP is

dx.doi.org/10.1021/jf5015846 | J. Agric. Food Chem. 2014, 62, 6007−6015

rapid from 10 to 120 min, and the q_e increases continuously with increasing contact time within the first 120 min, increasing from 30.5 to 34.5 mg/g. Thereafter, the q_e increases slowly with contact time, increasing from 120 to 240 min. The rapid absorption behavior up to 120 min may be due to the abundance of vacant sites initially available for Pb(II) loading.[36] With increasing contact time, most of the SBP functional groups participate in the adsorption of Pb(II), reaching equilibrium. As illustrated in Figure 5C, there is no noticeable change in adsorption capacity after 240 min, thus ensuring that equilibrium is attained. Based on the data obtained in these batch experiments, 240 min was selected as the equilibrium time.

Effect of Sodium Chloride and Amino Acids on Pb(II) Uptake. Normally, marine protein hydrolysate contains high concentrations of sodium chloride.[7] The presence of sodium chloride leads to high ionic strength in the solution, which may significantly affect metal-ion adsorption on the bioadsorbent.[18] Hence, the effects of ionic strength on Pb(II) adsorption by SBP were examined by varying the concentration of sodium chloride from 0 to 8 mg/mL. The initial Pb(II) and arginine concentrations used in this study were 50 mg/L and 20 mg/mL, respectively. As can be seen from Figure 5D, increasing the sodium chloride concentration led to a decrease in Pb(II) adsorption on SBP; as the salt concentration increased from 0 to 8 mg/mL, the q_e decreased from 44.67 to 32 mg/g. The q_e sharply decreased at low sodium chloride concentrations (0−2 mg/mL). This can be explained by the formation of outer-sphere complexes, since Na^+ can compete with Pb(II) adsorbed on the outer-sphere sorption−active sites at a higher ionic strength.[18] Furthermore, the activity coefficients of Pb(II) would decrease with the increasing ionic strength induced by sodium chloride,[37] which limits Pb(II) ion transfer to the adsorbent surfaces. The surface charge of the adsorbent can also be changed by the increased ionic strength,[38] which should decrease the electrostatic force of attraction. A slight salt effect on Pb(II) adsorption by SBP was observed with sodium chloride concentrations from 2 to 4 mg/mL. According to the theory by Hayes,[39] Pb(II) adsorption by SBP at elevated NaCl concentrations (2−4 mg/mL) may take place by the formation of inner-sphere complexes, suggesting that Na^+ would not have competed for the inner-sphere sorption sites. A decreasing trend in the adsorption capacities can be found as sodium chloride concentrations increase from 4 to 8 mg/mL. Here, Na^+ may compete with Pb(II) adsorbed on both the inner- and outer-sphere sorption sites and thus reduce adsorption of the lead ions.

In addition to salts, marine protein hydrolysate contains abundant amino acids[17] that may affect Pb(II) adsorption. In this group of experiments, the effect of the amino acid arginine on the adsorption process was investigated at concentrations of 0−50 mg/mL. The initial Pb(II) and sodium chloride concentrations used in this study were 50 mg/L and 4 mg/mL, respectively. As illustrated in Figure 6, the equilibrium q_e of SBP decreased from 42.18 to 36.68 mg/g as the arginine concentration increased from 0 to 20 mg/mL. Thereafter, there was no obvious variation in q_e with the arginine concentration increasing from 20 to 50 mg/mL; a plateau value (approximately 35.5 mg/g) was observed after the concentration reached 20 mg/mL. These results indicate that amino acids affect the adsorption of Pb(II) on SBP to some extent. This adsorption behavior suggests that interactions do occur between the amino acids and adsorbents, indicating that

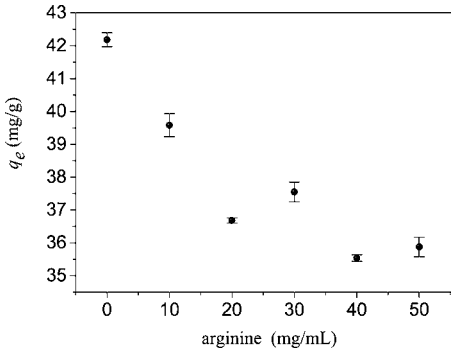

Figure 6. Effect of arginine concentration on Pb(II) adsorption by SBP. The adsorption conditions were pH 5.0; Pb(II) concentration, 50 mg/L; sodium chloride concentration, 4 mg/mL; contact time, 240 min; adsorbent dosage, 0.05 g; and temperature, 303 K.

amino acids could compete with lead ions for the adsorption sites of the bioadsorbents, and therefore, decrease the adsorption capacity.

Adsorption Kinetics Studies. Adsorption kinetics is very important for the design of adsorption systems. Therefore, the adsorption kinetics data for Pb(II) adsorption by SBP at different initial Pb(II) concentrations were fitted by applying pseudo-first-order and pseudo-second-order models, shown herein as eqs 5 and 6, respectively,[40]

$$\ln(q_e - q_t) = \ln q_e - k_1 t \tag{5}$$

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^{\,2}} + \frac{t}{q_e} \tag{6}$$

where k_1 is the pseudo-first-order rate constant (min^{-1}), and k_2 is the pseudo-second-order rate constant of adsorption (g mg^{-1} min^{-1}). The values of $\ln(q_e - q_t)$ are calculated from the kinetics experimental data. The models are examined by linear plots of $\ln(q_e - q_t)$ versus t and (t/q) versus t, respectively. The models' characteristic parameters and regression coefficients are listed in Table 1. By comparing the two kinetics models, the

correlation coefficient values (R^2 > 0.999) calculated by the pseudo-second-order model at different initial Pb(II) concentrations are higher than those of the pseudo-first-order model, and the experimental $q_{e,exp}$ values agree with the calculated $q_{e,cal}$ values from the pseudo-second-order model. This suggests that the experimental data fits the pseudo-second-order model better than the pseudo-first-order model, and the rate is

dx.doi.org/10.1021/jf5015846 | J. Agric. Food Chem. 2014, 62, 6007−6015

proportional to the square of the number of unoccupied binding sites.[41] Hence, the adsorption of Pb(II) by SBP is dominated by chemisorption. The interactions may occur between the COO^- groups and the Pb(II) ions,[20] which means that the adsorption mechanism of SBP is ion exchange. This is consistent with the results of the analysis of the effects of sodium chloride.

Adsorption Isotherm Studies. Equilibrium adsorption isotherms are important to determine the mechanism of the adsorption systems. Hence, the Langmuir and Freundlich isotherm models were used to describe the adsorption process, and the corresponding adsorption isotherms were plotted. The Langmuir and Freundlich isotherms are expressed as eqs 7 and 8, respectively,

$$\frac{C_e}{q_e} = \frac{1}{bq_{max}} + \frac{C_e}{q_{max}} \quad (7)$$

$$\ln q_e = \ln K_f + \frac{1}{n} \ln C_e \quad (8)$$

where q_{max} is the maximum sorption capacity, and C_e and q_e have the same meanings as noted previously. In the Langmuir equation, b is the Langmuir constant, which can be determined from the intercept of the linear plot of experimental data of C_e/q_e versus C_e (shown in Figure S3, see the Supporting Information). In the Freundlich equation, K_f and $1/n$ are empirical constants that can be determined from the intercept and slope of the linear plot of ln q_e versus ln C_e (shown in Figure S4, see the Supporting Information).

Based on eqs 7 and 8, the values of the isotherm constants were obtained and are presented in Table 2. The Langmuir and Freundlich isotherms show no obvious difference in the adsorption of Pb(II) by SBP. Normally, the Langmuir isotherm assumes that the adsorption process only occurs at specific homogeneous sites within the adsorbent surface, with a uniform distribution of energy levels. It can be concluded that the adsorption process is monolayer in nature, based on the Langmuir isotherm.[42] However, the Freundlich isotherm supposes that the adsorption occurs at heterogeneous sites with a nonuniform distribution of energy levels. The Freundlich isotherm describes reversible adsorption and is not restricted to the formation of a monolayer.[43] These results suggests that the behavior of Pb(II) adsorption on SBP is complex due to the presence of sodium chloride and arginine.

Table 2. Isotherm Parameters for the Adsorption of Pb(II) on SBP at Different Temperatures

R^2	0.995	0.995	0.994	0.996

R_L is a dimensionless constant referred to as a separation factor or equilibrium parameter, which can be used to describe the essential feature of the Langmuir isotherm. It is expressed as $R_L = 1/(1 + bC_o)$,[44] where C_o is the highest initial Pb(II) concentration. It is possible to predict whether an adsorption system is favorable by its R_L value.[44] As can be seen from Table 2, the R_L values are all between 0 and 1 at different temperatures, indicating that the adsorption of Pb(II) by SBP is favorable.

Effect of Temperature. The effect of temperature on Pb(II) adsorption by SBP was studied at four temperatures (293, 298, 303, and 308 K) and different initial Pb(II) concentrations (5−100 mg L^{-1}). The thermodynamic parameters can be calculated by eq 9,

$$\Delta G = -RT \ln \frac{q_e}{C_e} = -RT\left(-\frac{\Delta H}{RT} + \frac{\Delta S}{R}\right) \quad (9)$$

where R is the universal gas constant (8.314 J mol K^{-1}), and T is the absolute temperature (K). Changes in enthalpy (ΔH) and entropy (ΔS) can be calculated from the slope and intercept of the linear plot of $\ln(q_e/C_e)$ versus $1/T$. The changes in Gibbs free energy (ΔG), ΔH, and ΔS are given in Table 3. The negative ΔG values confirm the feasibility and spontaneous nature of the absorption of Pb(II) by SBP. Moreover, the decrease in the values of ΔG with increasing temperature suggests that adsorption is more favorable at higher temperatures.[45] The positive value of ΔH indicates the endothermic nature of the process. The positive values of ΔS indicate that there is an increase in the randomness at the solid/solution interface during Pb(II) adsorption by SBP. Normally, the values of ΔG for physisorption are between −20 and 0 kJ mol^{-1} and between −40 and −80 kJ mol^{-1} for chemisorption.[44] In this study, the ΔG values are not within either of these ranges, which indicates that Pb(II) adsorption by SBP is dominated by an ion exchange mechanism.

Desorption Studies. From an economic viewpoint, it is necessary to reuse adsorbents. As can be observed from Figure 7, no noticeable losses were observed in the adsorption capacity or desorption efficiency of SBP as the number of cycles increased. Even after five cycles of adsorption−desorption, the desorption efficiency of SBP was more than 91.2%. These results reveal that SBP can be reused without significant change in its adsorption performance.

Table 3. Thermodynamic Parameters for the Adsorption of Pb(II) Adsorption on SBP

	ΔG (kJ mol^{-1}) at temp (K)					
Pb(II) concn (mg L^{-1})	293	298	303	313.2	ΔH ($kJmol^{-1}$)	ΔS (J mol^{-1} K^{-1})
5	−19.26	−19.73	−20.31	−20.98	14.37	114.53
10	−19.35	−19.83	−20.31	−20.75	8.10	93.65

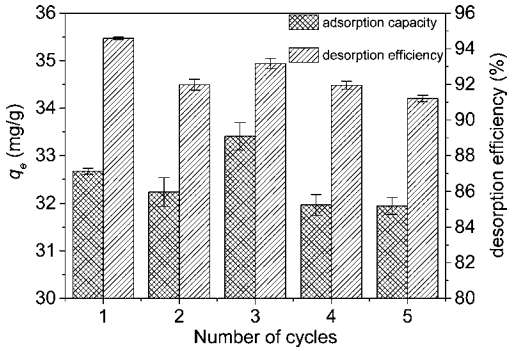

Figure 7. Adsorption−desorption studies of Pb(II) adsorption by SBP. The adsorption conditions were pH 5.0; contact time, 240 min; Pb(II) concentration, 50 mg/L; sodium chloride concentration, 4 mg/mL; arginine concentration, 20 mg/mL; adsorbent dosage, 0.05 g; and temperature 303 K.

In conclusion, enzymatic hydrolysis can be used as a new strategy for the preparation of porous bioadsorbents from biomass. Bamboo was subjected to enzymatic hydrolysis to increase its porosity, and then modified with succinic anhydride to obtain a porous succinylated bioadsorbent. Both the porous structure and the carboxylic acid content were found to significantly influence the adsorption capacity of the bioadsorbent. The carboxylate groups were found to be the main sites for Pb(II) binding. A pseudo-second-order kinetics model was a good fit for the SBP adsorption kinetics, and equilibrium data could be fitted well to the Langmuir isotherm. The adsorption isotherms and thermodynamic parameters suggested that the Pb(II) adsorption on SBP is favorable. SBP could be regenerated and high desorption efficiencies were obtained over five adsorption−desorption cycles. Sodium chloride content significantly affected Pb(II) adsorption by SBP. However, even in the presence of high concentrations of sodium chloride and arginine, the porous succinylated bioadsorbent showed high efficiency for Pb(II) binding, and the maximum adsorption capacity of Pb(II) was higher than 99 mg/g at different temperatures.

ABSTRACT: Rice is an important route of arsenic (As) exposure to humans, especially populations with rice-based diets. Human health risk of As varies greatly with rice variety and country of origin. The purpose of the present study was to determine total and speciated As in Australian-grown and imported rice on sale in Australia to assess their health risk to consumers. The total As (tAs) concentrations in Australian-grown organic brown, medium grain brown, and organic white rice were 438 ± 23, 287 ± 03, and 283 ± 18 μg kg^{-1} dry weight (d wt), respectively. In Bangladeshi, Indian, Pakistani, and Thai rice imported and on sale in Australia, tAs concentrations were 56 ± 05, 92 ± 10, 82 ± 06 and 172 ± 24 μg kg^{-1}, respectively. Asian rice contained mainly inorganic As (iAs; 86−99%), whereas 18−26% of the tAs in Australian-grown rice was dimethylarsinic acid (DMA). Relatively higher concentrations of tAs in Australian-grown rice than that in imported rice of Asian origin suggest that Australian-grown rice may be a health risk for the consumers. It was estimated that Australian-grown organic brown rice can contribute up to 98% of the FAO/WHO recommended maximum tolerable daily intake limit of iAs (2.1 μg kg^{-1} body wt day^{-1}) for Asian immigrants. However, other Australian consumers including European immigrants are unlikely to be at risk to As from rice diets due to their lower rice consumption rates than that of Asian immigrants. The risk assessment showed that imported rice on sale in Australia was likely to pose a lower health risk to consumers than Australian-grown rice.

KEYWORDS: *arsenic speciation, rice, dietary intake, risk assessment, human health*

INTRODUCTION

Elevated concentrations of arsenic (As) in groundwater pose major health problems for the people of Bangladesh, West Bengal (India), and several other countries of Southeast (SE) Asia.[1−4] Arsenic-contaminated groundwater is used in South and SE Asian countries not only for drinking purposes but also for agricultural irrigation to grow crops such as rice and other food crops.[5,6] Increasing levels of As in agricultural soils are due to irrigation with contaminated groundwater, and its uptake in rice and other food crops has become a real health issue in this region.[5,7,8] Chronic effects of As toxicity to humans have been reported from many Asian countries through widespread water and crop contamination.[3] Around 200 million people in South and SE Asia are estimated to be exposed to As contamination from water and foods.[9] The recent incidence, where thousands of people are dying of arsenicosis and millions are potentially at risk, has led to renewed interest in As contamination worldwide.[10]

Arsenic pollution is also considered an important environmental issue in Australia;[11] however, the health risks of As to the Australian people from foods have not been fully determined. Whereas many of the emerging As problems in the Asian region are due to mobilization of As originating from natural processes, those recorded in Australia include contributions from both natural processes and anthropogenic activities associated with the use of arsenical pesticides, herbicides, sheep dip, atmospheric deposition, mining activities, waste disposal, and timber treatment processes.[12] Mining activities have contributed to the contamination of soil and water in Western Australia and Victoria; however, other anthropogenic activities such as agriculture, forestry, and a variety of industrial processes have also contaminated soil and water on a localized scale.[11]

The most significant concern related to human health risks from As toxicity is worldwide food-chain transfer with the expansion of the global food trade, as millions more people are potentially exposed to increased concentrations of As in imported food in situations where local As contamination does not occur. A study showed that rice imported into the United Kingdom (UK) from Bangladesh contained high concentrations of As.[13] These findings suggest that with supermarkets now sourcing their rice worldwide, As poisoning has potentially become a global problem exposing millions of

consumers in countries not significantly affected by As-contaminated groundwater. Thus, As in rice and the associated possible risks to human health can no longer be considered just a regional issue, but an important global issue.

Australia is a multicultural country with significant numbers of immigrants from a range of countries including Asia and Europe. Rice is the staple food for a large number of Asian people living in Australia. Asian immigrants in Australia generally have strong preferences for rice imported from Asian countries, notably Bangladesh, West Bengal (India), Cambodia, and Vietnam. Because high concentrations of As in rice from As-endemic Asian countries have been reported,[8] rice on sale in Australia imported from these countries could be an important source of dietary As exposure for Australian consumers, particularly the Asian immigrants who are normally high consumers of rice. The objective of this study was to determine total and speciated As concentrations in Australian-grown and imported rice on sale in Australia from Asian countries with significant As contamination issues, particularly Bangladesh and India, to establish whether average Australians and Asian immigrants are likely to be at risk of As exposure via their rice diets. The forms of As present in rice were measured to predict the degree of As toxicity from this food source. The dietary contributions of Australian-grown and imported rice on sale in Australia to the maximum tolerable daily intake (MTDI) of total and inorganic As for Australian consumers (average Australian, and Asian and European immigrants) were also estimated on the basis of rice consumption rates and body weights.

MATERIALS AND METHODS

Chemicals and Reagents. All reagents were of analytical grade. Milli-Q (MQ) water (Milli-Q Plus system, Millipore, Bedford, MA, USA) was used throughout. Nitric acid (70%) and trifluoroacetic acid (TFA) were obtained from Mallinckrodt Chemicals, USA, and BDH Chemicals, UK, respectively. Sodium arsenite ($NaAsO_2$), monosodium arsenate ($Na_2HAsO_4{\cdot}7H_2O$), and monomethylarsonate ($CH_3AsNa_2O_3$) were obtained from Sigma Chemicals, and dimethylarsinate ($(CH_3)_2AsO(OH)$) was from Chem Service Inc. Phosphate buffer (30 mM, pH 5.6) was prepared from ammonium dihydrogen orthophosphate (Ajax Chemicals, Australia), and the pH was adjusted by adding ammonium hydroxide (Biolab, Australia). The buffer solution was filtered through a 0.22 μm nylon membrane before use.

Sample Collection and Preparation. Twenty-one samples representing 7 Australian-grown rice varieties and 51 samples of 17 different varieties of imported rice on sale in Australia were purchased from Australian and Asian shops in Sydney, Australia, during the month of January 2012. The samples were washed with tap water (three times) followed by deionized water (twice). The samples were then homogenized by grinding with a glass mortar and dried in an oven at 65 °C for 48 h before digestion for analysis.

Total As and As Speciation Analysis. Total As in the samples was determined following the method of Rahman et al.[4] Briefly, dried and ground samples (0.5 g) were each weighed into a digestion tube, and 5 mL of concentrated nitric acid (70%) was added and allowed to equilibrate overnight at room temperature. Then the tubes were placed on a digestion block (A. I. Scientific Block Digestion System AIM 500), and the temperature was increased from 75 to 140 °C over 8 h. Following digestion, tubes were removed, and after cooling, the samples were diluted to 20 mL with MQ water. Prior to analysis, all samples were filtered through 0.45 μm pore size filter paper (Whatman no. 41). The TFA extraction technique was used to determine As species in rice samples.[14]

An Agilent 7500c (Agilent Technologies, Tokyo, Japan) inductively coupled plasma mass spectrometer (ICP-MS) was used for the determination of total As (tAs) and As speciation. An Agilent 1100 liquid chromatography unit (Agilent, Tokyo, Japan) equipped with a guard column and a Hamilton PRP-1000 separation column (250 × 4.1 mm) was used for the determination of As species in the samples. The samples were injected using an 1100 autosampler (injection volume was 50 μL). The mobile phase contained 30 mM $NH_4H_2PO_4$ at pH 5.6, and the flow-rate was 1.0 mL min^{-1}. The details of the instrumental conditions for As speciation were described elsewhere.[15,16] All results in this paper are expressed on a dry weight (dw) basis.

Analysis of Standard Reference Materials (SRMs) and QC/QA. The analytical procedure was validated by analyzing certified standard reference material (SRM) of rice flour (SRM 1568a) from the National Institute of Standard and Technology (NIST), USA. The certified value of tAs in the SRM sample was 0.263 ± 0.012 μg g^{-1}, whereas the measured value was 0.290 ± 0.03 μg g^{-1}, indicating a recovery value of 110%. A reagent blank was also included in each batch of sample digestion and analysis to check the precision of the method. The detection limits for tAs and speciated As were evaluated by the analysis of solution matrix and determined to be 0.01 μg L^{-1} for tAs, 0.3 μg L^{-1} for As^V, 0.1 μg L^{-1} for As^{III} and dimethylarsinic acid (DMA), and 0.2 μg L^{-1} for methylarsonic acid (MMA). The precisions of five replicate determinations were 2.7, 1.5, 1.7, and 2.4% for As^V, As^{III}, DMA, and MMA, respectively.

There is no certified material currently available for As speciation in rice. In the present study, we used an established and published extraction method for As speciation in rice grain using 2 M TFA.[14] To validate the accuracy of our method and instrumental performance of As speciation analysis in rice grain sample, we analyzed As species in rice SRM (NIST 1568a) using the extraction procedures of 2 M TFA in a previous study, and the results were compared with those published by others.[17] Our results on As speciation in NIST SRM rice sample were consistent with those of other studies.

Dietary Exposure Estimates. According to the FAO/WHO,[18] three basic approaches can be used to determine the dietary intake of chemical contaminants from foods: (i) total diet study, (ii) duplicate diet method, and (iii) diary study. These approaches combine the concentration of specific contaminants in food with individual consumption rate. In the present study, the total diet study approach was used to determine the dietary intake of As from Australian-grown and imported rice on sale in Australia according to the equation

$$DI_{As} = C_{tAs\ or\ iAs} \times CR_{rice} \quad (1)$$

where DI_{As} is the dietary intake of As (μg $person^{-1}$ day^{-1}), C_{tAs} is the tAs concentration (μg kg^{-1}), C_{iAs} is the iAs concentration (μg kg^{-1}), and CR_{rice} is the rice consumption rate (kg $person^{-1}$ day^{-1}).

The health risk of total and inorganic As exposure from rice diet was estimated according to the equation

$$DE_{As} = DI_{tAs\ or\ As} \div BW_{av\ ind} \quad (2)$$

where DE_{As} is the dietary exposure (μg kg^{-1} body weight day^{-1}), DI_{tAs} is the dietary intake of tAs (μg $person^{-1}$ day^{-1}), DI_{iAs} is the dietary intake of iAs (μg $person^{-1}$ day^{-1}), and $BW_{av\ ind}$ is the average individual body weight of the consumers.

Total dietary intake and health risk of tAs and As species were estimated for three major consumer groups in Australia: (i) average Australian, (ii) Asian immigrants, and (iii) European immigrants. These consumer groups were selected because they represent the major populations in the country who consume rice on a regular basis. As the body weights and rice consumption rates of Asian and European immigrants living in Australia are not available, the dietary intake and health risk of As were estimated based on average body weights and rice consumption rates of Asian and European adults as reported by Walpole et al.[19] and Wailes and Chavez.[19]

RESULTS AND DISCUSSION

Total As Content in Australian-Grown and Imported Rice. The mean and range of tAs concentrations in Australian-grown rice were 270 and 188−438 μg kg^{-1}, respectively. The highest tAs was found in organic brown rice (438 ± 23 μg

Table 1. Concentrations of Total and Speciated Arsenic (Micrograms per Kilogram Dry Weight) in Australian-Grown and Imported Rice on Sale in Local Markets in Sydney, Australia[a]

[a]Arsenic speciation was analyzed only in selected rice samples. –, As speciation data are not available for these rice varieties; dl, detection limit (0.01 $\mu g\ L^{-1}$ in solution matrix.

kg^{-1}) followed by medium-grain brown rice (287 ± 03 $\mu g\ kg^{-1}$) and organic white rice (283 ± 18 $\mu g\ kg^{-1}$). Total As concentrations in Australian-grown rice were higher than in imported rice on sale in Australia, except Italian Arborio rice (Table 1). In previous studies, Williams et al.[7] found tAs of 20–40 $\mu g\ kg^{-1}$ in Australian rice, with a mean of 30 $\mu g\ kg^{-1}$ ($n = 5$), whereas Juhasz et al.[20] reported 189 ± 18 $\mu g\ kg^{-1}$ in Australian long-grain white rice, which are both lower than the results of the present study for all rice varieties. It is notable that tAs concentration in Australian-grown organic brown rice exceeded the FAO/WHO recommended maximum permissible limit of 300 $\mu g\ kg^{-1}$.[21]

Although brown rice is generally considered healthier due to a higher fiber and nutrient content, the present study showed that it contains significantly higher concentrations of tAs than white rice (Table 1). Meharg et al.[22] also reported that brown rice contained more As than polished white rice. This is due to a higher As concentration in the outer layer (rice bran), which is removed in the polishing process to produce white rice, than in the inner layer of rice.[23] Why As concentration in the outer layer is higher than in inner layer is unclear. It is likely that the outer layer of rice bran acts as translocation barrier to As that prevents As movement into the inner layers.[23]

In a recent study, Jackson et al.[24] found tAs ranging from 2.2 to 12.6 $\mu g\ kg^{-1}$ in different infant formulas purchased from supermarkets in Hanover (Germany) and New Hampshire (USA). Another study by Vela and Heitkemper[25] reported 12–17 $\mu g\ kg^{-1}$ tAs in infant formulas and 63–320 $\mu g\ kg^{-1}$ tAs in rice-based cereals. Thus, not only the organic brown rice but also infant formulas and other foods manufactured from this rice can be sources of dietary As for both children and adults.[26−28] As brown rice and rice bran are the main ingredients in many of the previously tested baby and toddler food products (e.g., organic rice milk, organic rice syrup), high concentrations of tAs in Australian-grown organic brown rice, as found in the present study, could be of concern for babies eating significant quantities of such products in Australia.

Arsenic concentrations in long- and medium-grain Arborio rice of Italian origin were 547 ± 24 and 253 ± 10 μg kg^{-1}, respectively, which are comparable to tAs concentrations in some of the Australian-grown rice varieties (Table 1). The present study also showed that the tAs concentration in long-grain Arborio rice was about double that in medium-grain Arborio rice of Italian origin on sale in Australia (Table 1). Several market basket surveys have also reported tAs concentrations in different rice varieties of European origin.[7,20,29] Williams et al.[7] reported tAs concentrations as 220 ± 10 and 190 ± 30 μg kg^{-1} in medium-grain risotto and brown rice of Italian origin, respectively, and 170 ± 10 μg kg^{-1} in paella rice of Spanish origin. D'Amato et al.[30] reported 211 ± 7 μg kg^{-1} tAs in Italian origin Arborio rice. In a more recent study, Meharg et al.[29] reported tAs concentrations of 200 μg kg^{-1} (range = 50−820 μg kg^{-1}; n = 76) in Spanish rice, 280 μg kg^{-1} (range = 90−560 μg kg^{-1}; n = 33) in French rice, and 150 μg kg^{-1} (range = 70−330 μg kg^{-1}; n = 38) in Italian rice. The tAs concentration in medium-grain Arborio rice of Italian origin on sale in Australia (253 ± 10 μg kg^{-1}), as found in the present study, is similar to that in medium-grain risotto rice (220 ± 10 μg kg^{-1}) as reported by Williams et al.[7] The tAs concentration in medium-grain Arborio rice of Italian origin (547 ± 24 μg kg^{-1}), as found in the present study, is also comparable to the highest value in rice of French origin (560 μg kg^{-1}) as reported by Meharg et al.[29]

It is notable that in the present study, tAs concentrations in different rice varieties of Asian origin were lower than in Australian and Italian rice varieties on sale in Australia (Table 1). Among the Asian rices, tAs concentration in Thai rice was highest (mean = 172 μg kg^{-1}; range = 159−196 μg kg^{-1}) followed by Indian, Pakistani, and Bangladeshi rice (range = 38−108 μg kg^{-1}). Williams et al.[31] reported 110 ± 0.01 μg kg^{-1} of tAs in Thai rice, whereas in a later study, Williams et al.[7] found mean tAs to be 100 μg kg^{-1} with a range from 60 to 140 μg kg^{-1} in Thai rice. The tAs concentration in Thai rice, as found in the present study, was comparable to that reported by Meharg et al.[29] but higher than that reported by Williams et al.[7,31]

High concentrations of tAs in Indian (West Bengal) and Bangladeshi rice varieties cultivated in As-endemic areas (range = 150−1840 μg kg^{-1}) have been reported in many previous studies.[4,7,8,31] In the present study, the mean tAs concentrations in Indian and Pakistani rice on sale in Australia were 92 μg kg^{-1} (range = 77−108 μg kg^{-1}) and 82 μg kg^{-1} (range = 73−88 μg kg^{-1}), respectively (Table 1). Long- and medium-grain basmati rice is mainly imported into Australia from India and Pakistan. Williams et al.[31] reported tAs concentration in white basmati rice collected from Indian supermarkets as 50 μg kg^{-1} with a range of 30−80 μg kg^{-1}, which is comparable to that in Indian and Pakistani basmati rice used in the present study (Table 1). Indian basmati rice is mainly produced in the states of Haryana, Jammu, Kashmir, Himanchal Pradesh, Punjab, Delhi, Uttarakhand, and western Uttar Pradesh, where As contamination has not been reported to be extensive. Arsenic contamination is not wide spread in Pakistan either. Thus, it is consistent that tAs concentrations in Indian and Pakistani basmati rice on sale in Australia were found to be lower than those reported in rice of the As-contaminated Indian state of West Bengal (70−310 μg kg^{-1},[29] 110−440 μg kg^{-1},[32] and 30−480 μg kg^{-1}[33]).

As Speciation in Rice. Numerous studies have been conducted to determine As speciation in different varieties of Asian, European, and U.S. rice; however, little is known about As speciation in Australian-grown rice. In the present study, As speciation (inorganic and methylated As species) in 4 Australian-grown rice varieties (of 7) and 7 rice varieties (of 17) imported into Australia from Italy, Bangladesh, India, Pakistan, and Thailand was determined to estimate health risks of As exposure to Australian consumers from their rice diet. The results are presented in Table 1.

In the present study, the average iAs [As(III) + As(V)] and DMA in Australian-grown rice (except sushi rice) were found to be about 58−63 and 18−26% of the tAs, respectively (Table 1). In a previous study, Juhasz et al.[20] reported that the fractions of inorganic and organic As species were 86 and 14% of the tAs, respectively, in Australian Quest rice (a variety launched in 2003; it has a shorter growing cycle, making it more water efficient) grown in a greenhouse. Smith et al.[34] found As(III) and DMA as the major As species in Australian Quest rice grain. Notably, DMA was found to comprise 85−94% of the tAs concentration in the grain.

In the present study, iAs and DMA in Italian Arborio rice comprised 49 and 20% of the tAs, respectively (Table 1). Williams et al.[31] reported that 26−40% of the tAs in Italian rice was methylated species. D'Amato et al.[30] reported 31% of the tAs to be organic in Italian Arborio rice, which is slightly higher than that in the same rice of the present study. The iAs content in Asian rice on sale in Australia (86−99% of the tAs) is similar to that reported by Juhasz et al.[20] Australian-grown sushi rice contained only iAs representing 94% of the tAs and is comparable to As in Asian rice on sale in Australia (Table 1). With the exception for U.S. rice, iAs has been reported to be the main species (10−90% of the tAs) in most rice from other countries.[8] A small amount of the tAs has been found to be DMA, with a trace amount of MMA in some rice samples.[35] MMA was not detected in any rice samples used in the present study.

The present study reported As speciation (inorganic and methylated As) in field-grown Australian rice bought from the supermarket, for the first time. Although Juhasz et al.[20] determined As speciation in greenhouse-grown Australian rice, their As speciation data may not represent the rice that people consume regularly and, therefore, may not be true results of As speciation in Australian rice. A market basket survey of As speciation in U.S. rice showed that methylarsenic species (almost entirely as DMA) was the major species (36−65% of the tAs;[31]). Methylated As species have also been reported to be 10−15% in Chinese rice,[36] 12% in Indian rice,[31] and 11−43% in Bangladeshi rice.[36] In the present study, methylated As in Australian-grown rice was much higher than that in Asian rice on sale in Australia, but lower than that in U.S. rice, as reported in a previous study by Williams et al.[31]

Among the Australian-grown rice varieties, the highest concentration of DMA was found in organic brown rice (115 ± 02 μg kg^{-1}), which was ∼26% of the tAs. The concentration of iAs in this rice variety was 276 ± 25 μg kg^{-1}, which was ∼63% of the tAs (Table 1). Meharg et al.[22] reported mean concentrations of inorganic and organic As (mainly DMA with trace amounts of MMA) in U.S. brown rice as 170 and 140 μg kg^{-1}, which were about 45 and 28% of the tAs, respectively. The concentration of iAs in Australian-grown brown rice was higher than that in U.S. origin brown rice. As the speciation methodology for As remains technically challenging, the reason for the differences in iAs and DMA in Australian-grown and U.S. rice may lie in the high proportion of As where the species could not be determined. Additionally, rice types, varieties, and

Table 2. Estimated Dietary Intake of Total, Inorganic, and Methylated Arsenic Species (Micrograms per Person per Day) by Average Australian Consumers Including Asian and European Immigrants from Their Rice Diet Based on Rice Consumption Rates of 0.046, 0.016, and 0.44 kg Day^{-1} by Average Australian and European and Asian Adult Immigrants, Respectively[39] [a]

[a] –, As speciation data are not available for these varieties.

sources of contamination may also be associated with the differences in iAs and methylated As ratios in rice as reported in several previous studies.[8] The variations in As speciation in rice have been suggested to reflect the source of As contamination, rice growing condition, the role of rhizosphere/soil microbial activity, and As uptake ability of the rice cultivars.[8,37] In Asian As-endemic countries, inorganic As-rich underground irrigation water is the main source of As contamination, and the agro-ecological condition of rice cultivation also favors iAs uptake by rice plants. On the other hand, arsenical pesticides consist of monosodium methanearsonate, disodium methanearsonate, calcium acid methanearsonate, and cacodylic acid, the main source of As for U.S. rice.[38] However, mining and arsenical pesticides, the sources of As in Australian paddy soils, have not been fully identified.

Dietary Intake of As from Rice Diet. Australians, who have been consuming locally grown rice and that imported from Bangladesh and other As-affected Asian countries, are likely to be unaware of the possible health risk of As from their rice diet. In the present study, dietary intake of As from Australian-grown and imported rice on sale in Australia was determined to establish whether Australian consumers, particularly the Asian immigrants who normally consume high amounts of rice (0.44 kg person^{-1} day^{-1} [39]), are likely to be at risk of As exposure from the rice in their diet. Australia is a multicultural country, and rice consumption rates in Australia differ substantially between the immigrants of different countries. In general, Asian people consume more rice than Australian and European people.[39] Per capita rice consumption data for different nationalities[39] have been used for the

dx.doi.org/10.1021/jf501077w | J. Agric. Food Chem. 2014, 62, 6016−6024

calculation of rice consumption rates by Bangladeshi, Cambodian, Laotian, and Vietnamese as the highest (between 0.59 and 80 kg person^{-1} day^{-1}), with an average of 0.44 kg person^{-1} day^{-1}. In contrast, average rice consumption rates by Australians and Europeans were 0.046 and 0.016 kg person^{-1} day^{-1}, respectively. On the basis of these data, we have estimated the daily dietary intake of total and speciated As from rice diet by the Australian consumers, particularly Asian and European immigrants (Table 2), for the assessment of health risk of As exposure from rice diet.

The results clearly show that the Asian immigrants in Australia are at higher risk of As exposure from their rice diet (77.72 and 68.42 μg of total and inorganic As person^{-1} day^{-1}, respectively) than the average Australian and European immigrants (2.83 and 2.49 μg of total and inorganic As person^{-1} day^{-1}, respectively) (Figure 1). This was due to the differences in rice consumption rates by Australian, Asian, and European people as reported by Wailes and Chavez.[39] It was estimated that an Asian immigrant in Australia may be exposed to 118.80, 40.48, 176.00, 36.08, and 75.68 μg of tAs day^{-1} from Australian, Indian, Italian, Pakistani, and Thai rice on sale in Australia, respectively. In contrast, the European immigrants may be exposed to 4.32, 1.47, 6.40, 1.31, and 2.75 μg of tAs day^{-1} from Australian, Indian, Italian, Pakistani, and Thai rice on sale in Australia, respectively (Table 2). Australian organic brown rice and Italian Arborio rice were the highest contributors of daily dietary total (192.72 and 240.68 μg person^{-1}, respectively) and inorganic (121.44 and 119.24 μg person^{-1}, respectively) As for Asian immigrants in Australia. In addition to inorganic As, Australian and Italian rices also contribute dietary intake of methylated As (mainly DMA) for Australian consumers. However, because organic As is far less toxic than iAs,[40] dietary intake of methylated As species from rice diet may not be a health issue for Australian consumers.

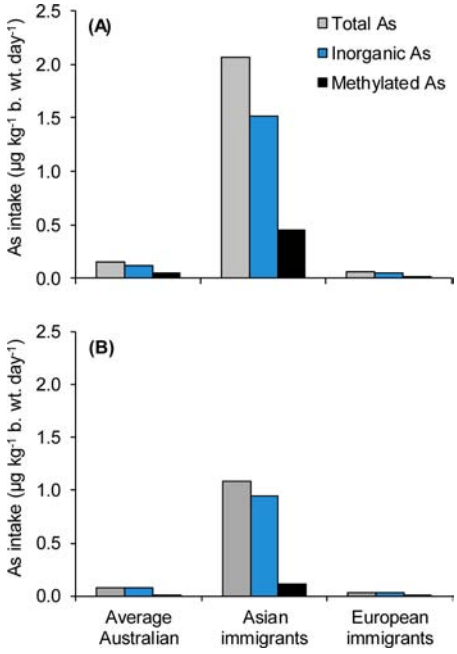

Figure 1. Estimated daily dietary intake of total, inorganic, and methylated As speciation by three consumer groups (average Australian and Asian and European immigrants) from Australian-grown (A) and imported (B) rice on sale in Australia.

The MTDI of tAs, as set by the FAO/WHO in 1967 and unrevised in 1989, is 50 μg kg^{-1} body weight (b wt).[41] For inorganic As, a provisional MTDI of 2.1 μg kg^{-1} b wt has also been set by the FAO/WHO for humans because of the higher toxicity of iAs than organic As species.[42,43] According to the Australian Bureau of Statistics,[44] on average, Australian adult men and women weigh 85.9 and 71.1 kg, respectively, with an average of 78.5 kg irrespective of gender. On the basis of these data, it was estimated that Australian-grown rice alone may contribute an average of 0.16 and 0.12 μg of total and inorganic As kg^{-1} b wt day^{-1} for Australian consumers, respectively (Figure 1A). Among all rice samples studied, Australian organic brown rice was found to be the highest contributor of tAs to MTDI (0.26 μg kg^{-1} b wt day^{-1}, which is about 0.51% of the MTDI) for Australian consumers, followed by Italian Arborio rice (0.23 μg kg^{-1} b wt day^{-1}; 0.64% of MTDI), Thai rice (0.10 μg kg^{-1} b wt day^{-1}; 0.20% of MTDI), and Indian and Pakistani basmati rice (0.05 μg kg^{-1} b wt day^{-1}; 0.10% of MTDI) (Table 3). These amounts are far less than the FAO/WHO recommended MTDI of total, suggesting that Australian consumers may not be at health risk of As exposure from their rice diet alone. On average, a European adult weighs 70.8 kg[19] and consumes 0.016 kg rice day^{-1}.[39] On the basis of these data, the estimated intakes of total and inorganic As were 2.83 and 2.49 μg day^{-1} for European immigrant in Australia (Table 2), which contribute 0.08 and 1.70% to the MTDI of total and inorganic As, respectively. Thus, the European immigrants are unlikely to have a health risk of As exposure from their rice diet alone.

The average body weight of an Asian adult is 57.7 kg,[19] and the rice consumption rate is 0.44 kg day^{-1}.[34,39] On the basis of these data, Australian-grown rice may contribute an average of 2.06 μg of tAs kg^{-1} b wt day^{-1} for an Asian immigrant (Figure 1A), which represents about 4% of the MTDI of tAs. Australian-grown organic brown rice alone may contribute 3.34 μg of tAs kg^{-1} b wt day^{-1} (about 7% of MTDI) for Asian immigrants, which is the highest among all rice varieties on sale in Australia, followed by Italian Arborio rice (3.05 μg kg^{-1} b wt day^{-1}; about 6% of MTDI), Thai rice (1.31 μg kg^{-1} b wt day^{-1}; about 2.6% of MTDI), and Indian and Pakistani basmati rice (0.63−0.70 μg kg^{-1} b wt day^{-1}; about 1.3−1.4% of MTDI) (Table 3). On average, the contribution of Australian-grown rice to daily dietary intake of total and inorganic As was higher than that of Asian rice for all Australian consumers (Figure 1). It is notable that Australian-grown organic brown rice and Italian Arborio rice were found to be the highest contributors of MTDI of iAs (2.07−2.10 μg kg^{-1} b wt day^{-1}, which is about 98−100% of MTDI) recommended by the FAO/WHO (2.1 μg kg^{-1} b wt day^{-1}[42,43]) for Asian immigrants in Australia (Table 3). Other Australian-grown rice varieties and Thai rice may also be significant sources of iAs (up to 65% of MTDI) for Asian immigrants.

The results indicate that Asian immigrants in Australia who regularly consume Australian-grown rice, particularly brown rice, and imported Italian Arborio rice may be at high health risk of iAs exposure. Several previous studies also reported high health risk of iAs to Asian populations from their rice-based diet.[31,45−47] However, the present study showed that Bangladeshi aromatic rice and Indian and Pakistani basmati rice on sale in Australia contribute very low amounts of total and inorganic As to the MTDI (Table 3), and hence, these imported rices may be safer than Australian-grown rice for the high rice-consuming Asian immigrants living in Australia. In a

Table 3. Dietary Intake of Total, Inorganic, and Methylated Arsenic Species (Micrograms per Kilogram Body Weight per Day) by Average Australian Consumers from Australian-Grown and Imported Rice on Sale in Australia Calculated Considering (i) Concentrations of Total and Speciated As in Rice of the Present Study, (ii) Body Weights of 78.5, 70.8, and 57.5 kg for Average Australian, and European and Asian Adult Immigrants, Respectively,[19] and (iii) Rice Consumption Rates of 0.046, 0.016, and 0.44 kg Day^{-1}for Average Australian, and European and Asian Adult Immigrants, Respectively[39]

[a]Dietary intake of inorganic and methylated As species and percent contribution of rice diet to maximum tolerable daily intake (MTDI) of inorganic As were calculated considering (i) the concentrations of inorganic and methylated As species in rice grains, (ii) body weights of 78.5, 70.8, and 57.5 kg for average Australian, and European and Asian adult immigrants, respectively,[19] (iii) rice consumption rates of 0.046, 0.016, and 0.44 kg day^{-1} for average Australian, and European and Asian adult immigrants, respectively,[39] and (iv) bioavailability factors of 0.33 and 98.6 for organic and inorganic As species, respectively.[20].

recent evaluation conducted by the Joint FAO/WHO Expert Committee on Food Additives,[21] the provisional MTDI of iAs in rice has been withdrawn and is no longer valid as the iAs lower limit of the benchmark dose for a 0.5% increased the incidence of lung cancer. This was determined from epidemiological studies to be 3.0 μg kg^{-1} b wt day^{-1} (2−7 μg kg^{-1} based on the range of estimated total dietary exposure) using a range of assumptions to estimate total dietary exposure to iAs from drinking water and food.[48]

Bioaccessibility and bioavailability of As in rice are two important factors that have substantial influence on As toxicity to humans. The bioaccessibility and bioavailability of As in food mainly depend on the As speciation, and toxic iAs species are readily assimilated into the bloodstream.[5] Therefore, human health risk of iAs is greater than that of organic As species. Laparra et al.[49] investigated the bioavailability and bioaccessibility of iAs in cooked rice to assess the potential toxicological risk of this species to humans using the Caco-2 cell model. The results showed that iAs concentration in the bioaccessible fraction of cooked rice was 0.8−3.10 μg g^{-1} d wt, which suggests that a large proportion of iAs present in the cooked rice (63−100%) could be available for intestinal absorption. In another study, Juhasz et al.[20] investigated the bioavailability of As species in rice using the swine animal model to determine its significance for human health risk. The absolute bioavailability of iAs was found to be the highest [98.6% for iAs, which is the average of 103.9 and 92.5% for As(III) and As(V), respectively] followed by DMA (33.3%) and MMA (16.7%).[20]

On the basis of the As speciation data of the present study (Table 1) and bioavailability of As species as reported by Juhasz et al.,[20] dietary intake of inorganic and methylated As species and percent contribution to MTDI of iAs from Australian-grown and imported rice on sale in Australia were estimated (Table 4). Results showed that dietary intake of iAs from rice diet did not differ for total and bioavailable fractions of iAs in rice. However, dietary intake of methylated As differed substantially for total and bioavailable fractions of iAs in rice. The consumption of Australian-grown rice was estimated to contribute 4.5−7.6% (average = 5.5%) of the MTDI of iAs for Australian consumers, 59−98% (average = 71%) for Asian immigrants in Australia, and 1.8−3.0% (average = 2.1%) for European immigrants when the bioavailability of iAs (98.6%) was considered (Table 4). These values were slightly lower than those calculated without considering the bioavailability of the As species. Italian Arborio rice imported into Australia was estimated to contribute 7.5, 97, and 2.9% of the MTDI of iAs for average Australian, and Asian and European immigrants, respectively. In contrast, on average, the consumption of imported Asian rice on sale in Australia was estimated to contribute 0.5−4.6% (average = 2.8%) of the MTDI of iAs for average Australian consumers, 6.8−60.2% (average = 35.8%) for Asian immigrants, and 0.2−1.8% (average = 1.1%) for European immigrants when the bioavailability of iAs (98.6%) was considered (Table 4). The results showed that, if only the total concentration of iAs in rice is considered for assessing the human health risk of As from rice diet, the calculation may not reflect the real risk. Therefore, the bioavailability of As species should be taken into account to estimate dietary intake, MTDI, and human health risk of As.

Only small-grain aromatic rice is imported into Australia from Bangladesh in which tAs concentrations ranged between 38 and 73 μg kg^{-1}. This concentration is lower than the FAO/WHO recommended safe level (300 μg kg^{-1} [21]). Rice from other Asian countries such as India, Pakistan, and Thailand also contain tAs lower than the FAO/WHO recommended maximum level. However, the tAs concentration in Australian-grown organic brown rice exceeds the FAO/WHO recommended level, and because a significant fraction (about 63%) of tAs in this rice was inorganic As, Australian organic brown rice may be a matter of human health concern, especially for infants who eat cereals and formulas manufactured from organic brown rice and rice bran and for adults who regularly eat organic brown rice. Asian people consume much higher amounts of rice than those of other origins,[39] and therefore, regular consumption of high As-containing brown rice over an extended period may cause adverse health effects for Asian immigrants in Australia. The present study showed that compared to Australian-grown brown rice, Pakistani and Indian basmati rice and Thai rice may be safer for the Australian consumers, especially for high rice consuming Asian immigrants.

Antibacterial, Antiviral, and Antifungal Properties of Wines and Winery Byproducts in Relation to Their Flavonoid Content

Mendel Friedman*

Western Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture, Albany, California 94710, United States

ABSTRACT: Grapes produce organic compounds that may be involved in the defense of the plants against invading phytopathogens. These metabolites include numerous phenolic compounds that are also active against human pathogens. Grapes are used to produce a variety of wines, grape juices, and raisins. Grape pomace, seeds, and skins, the remains of the grapes that are a byproduct of winemaking, also contain numerous bioactive compounds that differ from those found in grapes and wines. This overview surveys and interprets our present knowledge of the activities of wines and winery byproducts and some of their bioactive components against foodborne (*Bacillus cereus, Campylobacter jejuni, Escherichia coli, Listeria monocytogenes, Salmonella enterica, Staphylococcus aureus, Yersinia enterocolitica, Vibrio cholerae, Vibrio vulnificus*), medical (*Helicobacter pylori, Klebsiella pneumoniae*), and oral pathogenic bacteria, viruses (adeno, cytomegalo, hepatitis, noro, rota), fungi (*Candida albicans, Botrytis cinerea*), parasites (*Eimeria tenella, Trichomonas vaginalis*), and microbial toxins (ochratoxin A, Shiga toxin) in culture, in vivo, and in/on food (beef, chicken, frankfurters, hot dogs, lettuce, oysters, peppers, pork, sausages, soup, spinach) in relation to composition and sensory properties. Also covered are antimicrobial wine marinades, antioxidative and immunostimulating aspects, and adverse effects associated with wine consumption. The collated information and suggested research needs might facilitate and guide further studies needed to optimize the use of wines and byproducts to help improve microbial food safety and prevent or treat animal and human infections.

KEYWORDS: *adverse effects, antibacterial, antibiotic properties, antifungal, antiinflammatory effects, antioxidative effects, antiviral, flavonoids, food, grape pomace, grape seeds, grape skins, grapevine leaves and stems, human infections, immunostimulating effects, microbial food safety, microbial toxins, oral bacteria, parasites, pathogens, research needs, sensory properties, wine, wine byproducts, wine compostion, wine marinades*

INTRODUCTION

Grapes are the second largest fruit crop in the world after oranges. According to the Food and Agricultural Organization of the United Nations, >67 million tons of grapes is produced annually worldwide, with the United States contributing about 10% to the total.[1] Wines are classified into major groups, table wines with an alcohol content <14% and dessert wines produced from grapes high in sugar and low in acid content.[2] During the production of wines, up to 40% of the grapes ends up as byproducts.[3] Winery byproducts including grape pomace, seeds, skins, stems, and leaves are rich sources of inexpensive antioxidative phenolic compounds.[4−6] Numerous studies have demonstrated that these compounds exhibit health-promoting effects associated with cardioprotective, neuroprotective, and other health benefits.[7−13] The present paper seems to be the first review on the antimicrobial properties of wines and winery byproducts.

The literature indicates that the concentrations of the byproducts vary widely among the different grape cultivars from which they are derived. Because biological activities and health benefits may depend on both the total amounts and the specific amounts of highly bioactive phenolic compounds present in the byproducts, there is a need to relate the beneficial effects to the composition of the wines and byproducts.

Food safety researchers, regulatory agencies, microbiologists, virologists, epidemiologists, nutritionists, pharmacists, physicians, and the general public have been increasingly concerned about the growing number of foodborne illnesses caused by some pathogens. Antibiotic resistance of some pathogens associated with foodborne illness caused by the overconsumption of medicinal antibiotics seems to exacerbate these effects. There has been increasing interest in developing novel plant-derived safe antimicrobial compounds, including those present in grapes and grape products.

The main objective of this review is to unify and interpret widely scattered information on reported studies on the inhibitory effects of bioactive grape-derived polyphenolic compounds against pathogenic bacteria, viruses, and fungi in vitro and in/on food. The cited findings and suggested research outlined below may facilitate and guide further needed studies to optimize the use of wines and grape-derived products to improve microbial food safety and to protect animals and humans against infectious diseases.

POLYPHENOLIC COMPOUNDS IN GRAPES, WINES, AND WINERY BYPRODUCTS

In general, the phenolic composition of grapes may be influenced by variety, vineyard, micro- and macroclimate,

viticultural practice, and winemaking techniques. To help provide a scientific rationale for the antibiotic properties, we will first provide brief summaries on the composition, sensory properties, and immunostimulating, antioxidative, and adverse aspects of wines.

Wines. The extraordinarily large number of structurally different wine flavonoids is illustrated in randomly selected recent studies.[14−16] Two review papers on structures of wine flavonoids by He et al.[17,18] list 25 free anthocyanin glycosides, 25 anthocyanin diglycosides, and 63 anthocyanin-derived pigments (pyranoanthocyanins), along with molecular and fragment ion mass spectral peaks and UV−vis absorption maxima for most of these compounds. Selected compositional aspects described below further demonstrate the presence of different classes and amounts of polyphenolic compounds in wines originally synthesized in grapes and numerous new ones formed during winemaking.

New Zealand Pinot noir and Pinot Meunier wines contain the following polyphenol compounds: (a) anthocyanins—cyanidin-3-glucoside, delphinidin-3-glcoside, malvidin-3-glucoside, peonidin-3-glucoside, petunidin-3-glucoside, and vitisin, with total depending on extraction solvent and ranging from 6.01 to 17.35 malvidin equivalents/g extracts; (b) flavanols—catechin, epicatechin, epicatechin gallate, procyanidin A, and procyanidin B; (c) flavonols—quercetin and quercetin methylglucoside; and (d) a nonflavonoid—gallic acid.[17] The procyanidin content of polymeric phenolic isolates from Pinot noir wine during fermentation varied from 27 to 54%.[18,19]

The analysis of wines by HPLC and LC-DAD/ESI-MS revealed the presence of the following classes of bioactive compounds in wines: (a) phenolic acids—caffeic, gallic, protocatechuic, 4-hydroxybenzoic, and syringic; (b) flavonoids—(+)-catechin, catechin dimer, (−)-epicatechin, epicatechin gallate trimer, procyanidin B1, procyanidin B2, quercetin-3-*O*-rhamnoside, *trans*-polydatin, and *trans*-resveratrol; and (c) total phenolic content of 327.6 gallic acid equivalents (GAE)/g extract.[20] A related study reported a TPC of 628 mg GAE/g in grape seed extracts originating from Turkish grapes.[21,22]

An Australian study found that the proximity of eucalyptus trees to grapevines can directly influence the concentration of the aroma compound 1,8-cineole present in the corresponding red wines, and a fermentation study showed that the amount of rotundone in red wine can be influenced by grapevine leaves and stems in the ferment.[23]

Statistical instruments based on artificial neural networks (ANN) can be used to predict relationships between the total phenolic, flavonoid, anthocyanin, and tannin levels and antioxidative activity and wine variety and authenticity.[24]

Using wine model solutions, Sousa et al.[25] demonstrated interactions between deoxyanthocyanidin (oaklins), catechin−pyrilium compounds formed in red wines aged in oak barrels, and copigment molecules that form new wine ingredients. Related studies reported that (a) postharvest treatment of grapes with ethylene before vinification affected wine composition[26] and (b) exposure of grapevine cv. Tempranillo fruit-bearing cuttings to UV-B radiation induced changes in the profiles of flavonoids and amino acids.[27]

Grape Pomaces. About 20% of the grape remains as pomace—peel (skins), seeds, and stems—after wine production.[28] Pomaces that are largely used as soil conditioners or as fertilizers contain significant quantities of phenolic compounds that are not extracted into the wines. A high-phenolic grape pomace residue that consists of skin and seeds after the winemaking fermentation process can be analyzed. Several chemical and biological methods have been used to determine antioxidant and antimicrobial properties of grape seed and skin extracts, including quantitative analysis of phytochemicals by HPLC and GC-MS, measuring antioxidant activities, determining total antioxidant capacity, and measuring antimicrobial activity using the agar well diffusion method.

The described approaches could serve as a model for the in vitro evaluation of grape products. The review by Fontana et al.[29] on grape pomace lists 25 reported solid−liquid extraction and 28 HPLC detection methods for the characterization of different classes of phenolic compounds in the extracts. The authors suggest that future studies should focus on simplified extraction methods and nontoxic solvents that meet generally accepted as safe (GRAS) requirements. The distribution of *p*-coumaric, ellagic, gallic, protocatechuic, syringic, and vanillic acids, (−)-epicatechin, myricetin, kaemferol, and quercetin of grape pomace extracts (GPE) from a mixture of Chilean grapes depended on the nature of the solvent used for the extraction.[30]

The pomace contains the following antioxidative polyphenolic categories: phenolic acids, flavonoids, lignans, and stilbenes.[31] The Brazilian investigators report that GPE also contains chlorogenic acid, *trans*-resveratrol, and rutin and that the total phenolic content (TPC) of seeds (213−1652 mg/of catechin equivalents (CE)/g is greater than that in the skins (66−184 CE/g).

Another detailed LC-MS study of 14 pomace samples originating from red wines showed (a) the presence of 13 anthocyanins, 12 phenolic acids, and 15 anthoxanthins and stilbenes; (b) the total anthocyanin content of peel separated from five grape pomaces from two vintages ranged from 2744 to 131,868 mg/kg DM, or a 48-fold variation from lowest to highest value, with malvidin-3-*O*-glucoside being the predominant anthocyanin followed by peonidin-3-*O*-glucoside; (c) the content of phenolic acids was much lower than that of anthocyanins and varied significantly among samples of different vintages, with caftaric acid being the predominant compound in all samples; (d) with the exception of the 3-flavan-3-ols in the seeds that ranged up to several grams per kilogram of dry matter, anthoxanthins and stilbenes were minor components; and (e) aside from lack of anthocyanins,there were no major differences in total, but there were differences among individual phenolic compounds among pomaces from red and white grapes.[28] The TPC of pomace extracts from five Turkish grape cultivars ranged from 6.63 to 20.1 mg/g.[32,33] Levels of 19 individual phenolic compounds in the extracts ranged from 0.0031 mg/g for *trans*- resveratrol to 50.83 mg/g for (+)-catechin.

An evaluation of Moroccan Cabernet Sauvignon, Merlot, and Syrah red wine fractions against four Gram-positive bacteria, nine Gram-negative bacteria, two yeasts, and four molds showed that the Cabernet Sauvignon wine, as well as fractions with the highest monomeric anthocyanin content, were the most active, suggesting that these compounds largely contribute to the antimicrobial effects associated with wine components.[34]

The high phenolic content of grape pomace is due to the fact that some of these bioactive compounds are poorly extracted into the wine during the vinification process. Environmental factors, such as climate and soil, and grape variety also influence the composition of the pomaces.[35]

These results indicate that studies on bioactivities of grape pomace, skins, and seeds need to take into account composi-

tional differences among the test substances. For example, juicemaking pomace from Cabernet Sauvignon wine is a better source of anthocyanins for use in functional foods than winemaking pomace.[36,37]

Grape Seeds. Grape seed extracts derived from whole grape seeds are a rich source of bioactive flavonoids such as resveratrol, oligomeric procyanidins, and linoleic acid. Microencapsulation has the potential to reduce the astringency and bitterness of grape seed extracts for use as a functional food.[38] An HPLC analysis of fatfree grape seeds extracted with acetone/water/acetic acid (90:9.5:0.5) showed the following contribution of nine procyanidins to the total (in %): monomers, 48; dimers, 16.5; trimers, 10.8; tetramers, 8.1; pentamers, 5.3; hexamers, 3.2; heptamers, 2.7; octamers, 3.0; and nonamers, 1.5.[39,40]

Analysis by HPLC and LC-DAD/ESI-MS revealed the presence of the following classes of bioactive compounds in the seeds from pomace: (a) phenolic acids—caffeic, gallic, protocatechuic, 4-hydroxybenzoic, and syringic; (b) flavonoids—(+)-catechin, catechin dimer, (−)-epicatechin, epicatechin gallate trimer, procyanidin B1, procyanidin B2, quercetin-3-*O*-rhamnoside, *trans*-polydatin, and *trans*-resveratrol; and (c) total phenolic content of 327.6 gallic acid equivalents (GAE)/g extract.[41] A related study reported a total phenolic content of 628 mg GAE/g in grape seed extracts originating from Turkey.[20]

Analysis of grape seeds and pomaces derived from six French grape varieties showed that the highest total phenolic content of 44.5 GAE/g dry wt was present in Alicante seeds compared with 31.6 GAE/g dry wt for pomace.[42] Additional studies showed pomaces also contained significant amounts of proanthocyanidins and anthocyanin glycosides and that seeds had the highest antioxidant capacity. Related studies found that (a) the percentage of prodelphinidins in the seed and skin extracts of two Croatian grape cultivars was negatively correlated with the bitterness (astringency) intensity of the skins[43] and (b) a grape seed proanthocyanidin extract improved the psychological and physical symptoms and reduced blood pressure in middle-aged menopausal women.[44]

Grapevine Stems and Leaves. The following selected results indicate that grape stems and leaves are additional sources of bioactive phenolic compounds. Püssa et al.[45] reported that grapevine *Vitis vinifera* stems contained *trans*-resveratrol and derivatives, flavan-3-ols, and phenolic acid glucosides. A factorial design and response surface method used to assess the extractability of phenolic compounds from the stems of three grape varieties followed by GC-MS analysis showed the presence of the following compounds: caffeic acid, flavanols, and derivatives, dehydroflavanols, and flavonols.[46] An evaluation of byproducts from 10 different grape varieties showed that stems from Callet, Syrah, Premsal Blanc, Parellada, and Mano Negro varieties contained the highest total phenolic and total proanthocyanidin content and showed the greatest antioxidant capacity; that Chardonnay and Merlot stems showed the lowest values; that no significant differences were apparent among stems from red or white varieties; and that the stems from the Callet variety are an especially rich source of polyphenols.[47] Results from a study on copigmentation effects of pomace, skins, seeds, and stem extracts suggest the possibility of reusing the byproducts to improve the biological value and color properties of red wines.[48] Grape stem extracts inhibited the growth of breast, colon, renal, and thyroid cancer cells,[49] suggesting that stem phenolics might also inhibit microbial cells.

Grapevine *V. vinifera* leaves contained flavonols, flavones, and stilbenes.[50] Flavonols slow the infection of grapevine leaves by *Plasmopara viticola* phytopathogens.[51] The total phenolic content of leaves from organically and conventionally grown *Vitis labrusca* plants was similar, but the organic leaves contained 10 times more resveratrol than did the conventional leaves.[52] Whether grapevine leaves can serve as an inexpensive source of bioactive phenolic compounds merits study.

SENSORY PROPERTIES OF WINES IN RELATION TO COMPOSITION

Because sensory properties of wines affect consumption and bioactivity, we present here summaries of selected studies on the relationship between composition and sensory properties such as astringency, bitterness, bouquet, color, flavor, and taste.[53−57]

An investigation of the sensory, olfactory, and hedonic properties of Italian wines showed that Italian students liked about equally wines prepared from grapes grown organically and conventionally and that 61% of respondents were willing to pay more for organically produced wines.[58] A study designed to define the relationship between phenolic composition and color of wines produced by 55 different grape samples found that the average ratios between wine and grape phenolics ranged from 0.25 and 7.9 for the different phenolic compounds, that individual wine phenolics correlated with several wine phenolics, and that there was a high correlation between predicted and measured total wine color ($r = 0.958$), suggesting that it is possible to predict the color and quality of fresh wines from grape measurements.[59] Ethyl phenylacetate, phenylacetic acid, and γ-decalactone were found to be key aroma compounds in sour rotten wines at levels above those found in controls, suggesting that rot infection affects sensory properties of Portuguese wines.[60,61] Measurements of the phenolic composition of grapes and wines from two maturity stages and two maturation times showed that (a) grape anthocyanin increased during ripening, (b) procyanidin content of wine decreased with extraction and maceration time, (c) wine made from riper grapes contained higher tannin levels, and (d) the color of the French wines was related to the content of anthocyanins and anthocyanin−tannin adducts, suggesting that sensory quality is linked to grape quality at harvest.[62,63] Storage of sweet red wines in the bottle for a year caused degradation of monomeric anthocyanins, with most of them being lost between 6 and 9 months, the appearance of stable oligomeric and polymeric pyranoanthocyanin and methylmethine-mediated condensation products, hydrolysis of glycosylated flavonols to aglycones, and retention of antioxidative and sensory properties.[55] By contrast, increasing storage temperature seems to reduce the antioxidative properties of California wines, especially Cabernet Sauvignon and other Chardonnay varieties.[64,65] Analysis of 67 red French wines showed that 3-methyl-2,4-nonadione is a good marker for defining quantitative changes in the oxidative potential.[66]

Related recent studies on the relationship between composition and sensory properties include (a) analytical characterization of red wines by aroma wheels;[67,68] (b) apparent relationships between starter cultures, sensory and chemical attributes, and consumer acceptance of South African wines;[67,68] (c) changes in composition and organoleptic properties of wines stored in wooden barrels;[43,69] (d) the

sensory quality of Cabernet wines related to grape quality at harvest and to anthocyanin, proanthocyanidins, and grape volatiles;[54,63,70,71] and (e) the greater impact of large-sized, water-soluble tannins on wine astringency and bitterness of Cabernet Sauvignon wines relative to smaller-sized hydrophobic, highly pigmented tannins.[72,73] Additional studies on sensory aspects include those by Vidal et al.,[74] Malherbe et al.,[75] Bindon et al.,[53] Schmidtke et al.,[76] Villamor and Ross,[77] and Ugliano.[78]

The cited studies suggest that grape composition, wine-making practices, and storage conditions significantly affect sensory and presumably health-promoting properties of wines. It is not known to what extent, if any, these complex relationships might also affect antimicrobial properties.

BIOMARKERS OF BIOACTIVITIES

Here, we will briefly highlight some of the biomarkers that have been reported to be related to the beneficial effects of wine compounds at the molecular and cellular levels that might be related to bioactivities of wines and wine compounds.

Immunomodulating and Anti-inflammatory Properties. Italian red wine induced the release of nitric oxide and both anti-inflammatory and pro-inflammatory cytokines in healthy human blood mononuclear cells, leading to the maintenance of the immune host; removal of the polyphenols from red wine abrogated these effects.[79] Exposure of macrophages stimulated by bacterial lipopolysaccharide to malvidin, the most abundant polyphenolic compound in red wine, induced a series of cellular and signaling events that protect cells against inflammation-mediated chronic diseases, suggesting that malvidin significantly contributes to the anti-inflammatory and antioxidant effects of red wine.[80,81] A human study with 67 high cardiovascular risk male volunteers found that the phenolic content of red wines may modulate leukocyte adhesion molecules and that ethanol polyphenols of red wine may modulate soluble inflammatory mediators in high-risk patients, suggesting that both ethanol and non-alcoholic compounds contribute to the anti-inflammatory effects.[82] On the basis of a review of the literature on the anti-inflammatory properties of flavonoids from different sources in humans, Peluso et al.[83] suggest the need for placebo-controlled trials to identify bioactive flavonoids in the anti-inflammatory effect of plant foods, including wines.

On the basis of the mechanism that seems to govern the anti-inflammatory action of a red wine extract, Nunes et al.[84] suggest that the wine extract may represent a simple and inexpensive therapeutic strategy against intestinal inflammation. This suggestion is supported by the observation that a grape seed extract enhances the chemotherapy of colon cancer in rats by the drug 5-fluorouracil by decreasing the severity of inflammation-related mucositis of the cancer cells.[85] Because macrophage cells associated with the immune system seem to have a strong affinity for pathogenic bacteria, and natural compounds protected mice against lethal effects of *Salmonella* via immunostimulation,[86−89] expectations are that wine flavonoids might exhibit similar in vivo antibiotic effects.

Antioxidative Properties. As illustrated by the following selected recent studies, the antioxidative properties of wine compounds seem to be paramount in neutralizing adverse effects of reactive oxygen species (ROS, free radicals) that induce oxidative stress in tissues that contributes to the cause of chronic diseases. Free radicals are highly reactive, short-lived molecules that can react with and damage essential structural proteins, enzymes, and DNA. Such damage has the potential to cause cancer, atherosclerosis, and cardiovascular and other diseases. Wine flavonoids have the potential to reduce such undesirable molecular events because the high-energy, highly reactive free electron on DNA is transformed to a less reactive and thus less damaging radical. Wine antioxidants inhibit the activation of the oxidative stress-related transcription nuclear factor κB (NF-κB) that participates in the regulation of inflammatory responses.[90]

A study of the effect of acute and chronic consumption by 19 obese men of red wine or dealcoholized red wine showed that consumption of moderate, but not high, amounts of red wine acutely increased plasma total antioxidant capacity (TEAC) and suppressed NF-κB activation, whereas chronic red wine, but not dealcoholized red wine, consumption increased oxidative lipid damage.[91] Romanian scientists found that mathematical modeling of red wines from different grape varieties showed that 57% of the observed variance in antioxidant capacity is linearly related to the age of the wines[92] and that neural networks can be used to predict antioxidant activities and classification of wines.[93] A Canadian study found that red wine intake by 12 healthy human volunteers induced a marked increase in salivary radical-scavenging activity within 30 min followed by a plateau up to 240 min, suggesting that the wine greatly improved the salivary antioxidant status.[94] An Australian study found that warmer climate wines had lower in vitro antioxidant capacity values but retained good ex vivo bioavailability compared to cool climate wines, suggesting the need for further studies of the effect of soil composition on the polyphenolic content.[95] A Slovakian in vitro interaction study of three red wine polyphenols and their mixtures found that the antioxidant activity of individual polyphenols is not a constant value in the presence of other polyphenols, suggesting that the antioxidant quality of individual polyphenols differs markedly when tested separately and in mixtures, presumably because interactions can cause additive, antagonistic, and synergistic effects.[96] The authors suggest the need for in vivo studies, where interactions among compounds always take place in a mixture. It is also worth noting that wine antioxidative properties seem to be influenced differently by each polyphenolic compound[97] and that the antioxidant potential of GSEs is 20- and 50-fold greater than those of vitamins C and E.[98] We do not know whether antioxidative properties of wine flavonoids correlate with antibiotic effects.

POSSIBLE ADVERSE EFFECTS OF WINES

To balance the largely beneficial properties of wines, here, we briefly mention some possible adverse effects of wine components.

Alcohol. Moderate consumption (one or two glasses per day) of red wines with an alcohol content of 12−13% has been associated with numerous health benefits mentioned earlier. Both alcohol and polyphenolic compounds of wine seem to contribute to these beneficial effects. To what extent, if any, excess consumption of wine might adversely affect human health merits study.

Biogenic Amines. Wine contains a class of compounds called biogenic amines naturally present in grapes and/or produced by amino acid transaminase induced transamination of aldehydes by decarboxylation of amino acids by microbial enzymes. Because the biogenic amines are reported to cause various symptoms in susceptible humans associated with allergic reaction,[99−101] there is an interest in their content in

different wine varieties. For example, the analysis of 67 Italian wines showed that red wines contained 19.3 mg/L total biogenic amines, rose wines, 9.2 mg/L, and white wines, 7.67 mg/L, with histamine, tyramine, and cadaverine as the most representative amines.[102]

Catecholamines. Bioactive compounds from wines and other foods can occasionally inhibit cytosolic sulfotransferases (SULTs) that catalyze the sulfonation (metabolism) of catecholamines (dopamine, epinephrine), resulting in increased plasma levels of these bioactive compounds that can trigger migraine headache, increased blood pressure, and atrial fibrillation.[103]

D-Amino Acids. Low levels of D-amino acids (D-Ala, D-Glu, and D-Lys) are produced by *Saccharomyces cerevisiae* and *Oenococcus oeni* during fermentation of wine.[104] Another study[105] found that the concentrations of D-amino amino acids relative to the corresponding L-enantiomers ranged for white wines from 0.4 to 3.9% D-Ala, from 0.9 to 8.3% D-Asx, and from 0.5 to 8.9% D-Glx; in red wines, from 2.9 to 10.6% D-Ala, from 2.2 to 10.9% D-Asx, and from 3.9 to 7.4% D-Glx. Storage times of bottled wines up to 24 years did not correlate with D-amino acid content. Studies on the nutrition and safety of D-amino acids reported that D-Lys is not bioavailable as a source of L-Lys and that certain D-amino amino acids inhibited the growth of mice.[106,107]

Homocysteine. Analysis of 32 different wines showed that the average homocysteine content, an amino acid that is linked to cardiovascular disease[106,108] and to macular edema and neuropathy in patients with type 2 diabetes,[109] was 10.31 and 6.11 μM and in red and white wines, respectively.[110]

Ochratoxin A. The possible human carcinogen ochratoxin A produced by *Aspergillus* and *Penicillium* fungal species[111] was found to be present in about 50% of all evaluated wines at levels that are generally lower than the European Union (EU) regulatory level of 2 μg/L.[112−117]

Sulfites. Sulfites added to wines as antimicrobial preservatives to extend shelf life may aggravate symptoms of allergic asthma.[8,118,119] Wine labels suggest that susceptible individuals need to be aware of the possible adverse effects of wines.

With the above brief overview of wine composition, sensory properties, bioactivities, and possible adverse effects as background, reported studies on the antimicrobial, antiviral, and antifungal potential of wines and wine byproducts, in culture, in vivo, and on/in food will now be described.

■ ANTIBACTERIAL PROPERTIES

Wines. This section presents brief overviews of reported studies on the growth inhibition of bacteria that can cause human illness. The individual pathogens are listed alphabetically followed by studies that cover multiple pathogens. General comments concerning pathogenicity are based on information listed in a book on foodborne pathogens[120] and in *The Merck Manual of Diagnosis and Therapy*.[121]

Bacillus cereus. This foodborne pathogen causes vomiting and diarrhea. A study on wine-induced inactivation of *B. cereus* found that (a) wine inactivated *B. cereus* cultures to undetectable levels in <10 s, (b) wine diluted with water was less effective, (c) *B. cereus* spores were highly resistant to inactivation, (d) wine organic acids strongly inhibited vegetative cells, (e) wine phenolic compounds were inactive, and (f) the addition of wine to a simulated intestine resulted in a reduction of the total number of vegetative cells and spores.[122] It can be suggested that these results show that drinking wine with a meal or consumption as a marinade might reduce the viable *B. cereus* organisms, thus lowering the toxic potential of this pathogen. A related study reported that tea catechins and theaflavins and whole teas exhibited exceptionally high activity against *B. cereus*.[123]

Campylobacter jejuni. This pathogen causes the gastrointestinal infection in humans called campylobacteriosis. A kinetic study on the inactivation of *C. jejuni* showed that (a) a Portuguese red wine rapidly inactivated the foodborne pathogen within 30 s, (b) ethanol and organic acid (malic, tartaric) wine fractions acted synergistically with an efficacy similar to that of wine itself, and (c) wine enhanced the anti-*Campylobacter* effect of a food- and gastric fluid-containing model stomach, suggesting that concurrent ingestion of wine with food might help prevent campylobacteriosis.[124] Related studies reported that *C. jejuni* was about 100 times more susceptible to inhibition by plant essential oils, oil compounds, and phenolic acids than three other foodborne pathogens.[125,126]

Listeria innocua. A study of the bactericidal effect of nonpathogenic *L. innocua* as a substitute for the pathogenic *L. monocytogenes* in a food matrix in a stomach model under simulated acid gastric conditions found that (a) red wine induced a 3−4 log CFU reduction of the initial pathogen count in <2 h, (b) the combination of ethanol and malic and tartaric acids was less effective than wine, and (c) the kinetics of the bactericidal effect of white wine differed from that of red wine, showing that the antimicrobial effects of wines depend on composition.[127] These results imply that ingestion of wine with food may reduce the *Listeria* level in the alimentary tract.

Pseudomonas savastanoi pv phaseolicola. This phytopathogen, the cause of halo bean blight, was inhibited by Hungarian red wines and, to a less extent, by white wines, with the inhibition directly related to the phenolic content of the wines.[128]

Wine Components. Wines are multicomponent solutions. Wine properties and components that have been reported to possess antimicrobial properties include acid pH (~3.00), alcohol (~12%), sulfur dioxide (sulfite), organic acids (caftaric, lactic), and numerous polyphenolic compounds. A factorial design study on the susceptibilities of *E. coli* O157:H7 and *S. aureus* to 20 min exposure to four of these factors[129] revealed the importance of pH, titratable acidity, and ethanol, but not total sulfur dioxide, in predicting inactivation, suggesting that lowering the pH would likely enhance the efficacy of the other parameters. The paramount role of phenolic compounds in inhibiting bacteria was not evaluated.

A study of the contribution of polyphenolic content, pH, ethanol content, and other components to the observed antimicrobial effects of Croatian wines against *E. coli* and *S. enterica* found the following order of activities: wine > phenol-stripped wine > dealcoholized wine > ethanol at low pH > low pH > ethanol, suggesting the antimicrobial efficacy of wine cannot be attributed to a specific component.[130] The average TPC of these wines (in mg GAE/L) was 3204; flavonoids, 2941; nonflavonoids, 262.6; catechins, 726.6. Anthocyanins were found at 239.7 mg M-3-G/L, and resveratrol was found at 2.00 mg/L.

A study of three Argentinean wine varieties found that (a) the TPC content of the Cabernet Sauvignon wine (2300 mg/L GAE) was lower than those of Malbec (2522 mg/L GAE) and Merlot (2704 mg/L GAE) varieties; (b) the relative antimicrobial activities against *E. coli* and *L. monocytogenes* in a meat model treated with 100 and 200 mg/L of isolated

phenolic compounds paralleled the phenolic content of the wines; and (c) the polyphenol effect was ethanol-independent, suggesting that phenolic content governs activity and the need to produce new wine varieties with high polyphenolic content.[131]

Wine Varieties. A study of the antimicrobial effects of three Argentinean wines with different phenolic contents against multiple organisms showed that *E. coli* was the most sensitive bacterium to Merlot wine and that clarified wines, prepared by exposure of red wines to charcoal to remove phenolic compounds, were inactive.[132]

A study of the composition and antioxidative and antimicrobial effect of six Serbian wines prepared from different grape varieties against nine different pathogenic bacteria showed that the contents of two wine flavonoids, quercetin and quercetin-3-glucoside, can be used as biochemical markers for antioxidative and antimicrobial bioactivities.[133]

An evaluation of Moroccan Cabernet Sauvignon, Merlot, and Syrah red wine fractions against four Gram-positive bacteria, nine Gram-negative bacteria, two yeasts, and four molds showed that the Cabernet Sauvignon wine, as well as fractions with the highest monomeric anthocyanin content, were the most active, suggesting that these compounds largely contribute to the antimicrobial effects associated with wine components.[34]

Winery Byproducts. An analytical and antimicrobial study of the polyphenolic profile of GSEs from seven red and seven white Croatian grape varieties showed that (a) the total phenols, flavonoids, catechins, flavanols, and individual polyphenols [(+)-catechin, (−)-epicatechin, epicatechin gallate, procyanidins B1 and B2, quercetin glucoside, resveratrol monomers, piceid, and astringin] was variety dependent; (b) the TPC (>70 mg/g DM) of red skins of red cultivars were much higher in phenolic content than the skins from white cultivars (>20 mg); (b) antioxidative properties were related to polyphenolic content; (c) the average content of highly bioactive *trans*-resveratrol of 0.29 mg/kg of fresh berry wt was lower than the corresponding value of 0.59 mg/kg of fresh berry wt in the extracts from the red varieties; (d) the corresponding values for *cis*-resveratrol were 0.30 and 0.80 mg/kg of fresh berry wt, respectively; (e) minimum inhibitory concentration (MIC) values against multiple organisms (Gram-positive *B. cereus* and *S. aureus* and Gram-negative *C. jejuni*, *E. coli*, and *Salmonella infantis*) ranged from 0.014 to 0.59 mg GAE/mL; and (f) MICs of white cultivars against *E. coli* and *Salmonella*, the most frequent causes of foodborne infections, were the lowest (highest activity).[134]

Resveratrol. Although present in small amounts in wine, resveratrol is probably the most widely studied flavonoid.[135−137] This phytoalexin phenolic compound is reported to inhibit the growth of microbial species (*S. aureus*, *Enterococcus faecalis*, and *Pseudomonas aeruginosa*) as well as several pathogenic fungal dermatophytes that cause skin infections,[138] to inhibit biofilm formation of *E. coli* O157:H7 and *P. aeruginosa*,[139,140] and *V. cholerae*,[141] to reduce the growth rates of numerous animal-associated bacteria in culture,[142] and to exhibit cytotoxicity against *T. vaginalis*, the cause of the sexually transmitted disease trichomoniasis.[143] It seems that resveratrol exhibits antimicrobial, antiparasitic, and anti-inflammatory properties that have the potential to benefit microbial food safety and human infections.

4-Hydroxytyrosol. We previously reported that this olive compound inhibited both the growth of foodborne pathogens and the biological activity of a bacterial toxin.[111,144,145] Because 30 Spanish red wines contained an average of 0.074 mg/L of 4-hydroxytyrosol,[146,147] the compound probably contributes to the antimicrobial properties of wines.

Gut Microbiota. A study of the effect of the consumption of Spanish Merlot red and dealcoholized red wines by 10 healthy volunteers for 4 weeks showed (a) a significantly increased number of native gut bacteria and (b) decreased blood pressure and cholesterol, triglyceride, and C-reactive plasma levels. The results of this in vivo study suggest that a moderate consumption of red wine can inhibit nonbeneficial bacteria from the human microbiota and stimulate the growth of probiotic bifidobacteria.[148] A related study found large interindividual differences in microbial metabolites in human feces following the consumption of red wine and dealcoholized red wine, suggesting differences in gut microbial composition among evaluated subjects.[149] These investigators also analyzed by HPLC the total and individual polyphenolic profile of the two wines. Dealcoholized red wine had the same composition of polyphenolic compounds as red wine, with respective TPC values of 733 and 798 GAE. Individual polyphenolic compounds consisted of six anthocyanins, three flavonols, four stilbenes, six flavan-3-ols, two hydroxybenzoic acids, four hydroxycinnamic acids, and tyrosol.

Wine Marinades. Here, we briefly describe the reported protection of wine marinades against adverse effects of foodborne pathogens and spoilage organisms on meat products.[150−156]

We developed a series of antimicrobial wine marinade recipes each consisting of red or white wine extracts of oregano leaves with added garlic juice and oregano oil, against *B. cereus*, *E. coli* O157:H7, *L. monocytogenes*, and *S. enterica*.[157] The results showed that (a) activities increased with incubation temperatures in the order 37 °C > 21 °C > 4 °C, (b) storage for up to 2 months did not affect activities against *Salmonella*, (c) combinations of antimicrobials in wine exhibited additive antimicrobial effects, and (d) polyphenolic compounds isolated by chromatography separation from red wine exhibited exceptional activity at nanogram levels against two strains of *B. cereus*. The cited beneficial effects seem to have stimulated interest in defining the efficacy of wine marinades against contaminated meat products outlined below.

The populations of *Carnobacterium maltaromaticum*, *L. monocytogenes*, *Brochothrix thermosphacta*, and *C. jejuni* bacteria were reduced by ∼1.5, 2, 3, and 6 log CFU, respectively, on contaminated pork meat submerged into Spanish red wine for 15 min followed by storage at 4 °C for 3 days.[151] Except for *C. maltaromaticum*, ultrasound treatment with red wine acted synergistically against the pathogens, suggesting that marinating can be used to enhance the taste, texture, and safety of pork meat counts (7 log CFU/mL) and low counts (3 logs CFU/mL) of *C. jejuni*. The bacteria were completely inactivated in both white and red wines. Immersion of poultry meat contaminated with this pathogen in both wine marinades was less effective in reducing the microbial levels.[152]

Immersion of contaminated beef fillets in Greek red wine or wine supplemented with 0.3% thyme oil for 12 h significantly reduced the levels of acid-adapted and -nonadapted *S. enterica* Typhimurium compared to nonmarinated control samples by 2.0 and 1.9 log CFU/g, respectively, during storage for 19 days at 5 °C.[155] The addition of thyme oil to the wine seems to increase the antimicrobial effect of marinades, suggesting the marinating can be used to extend the shelf life of meats.

Greek red wine with and without 0.5% oregano oil induced reduced levels of *S. enterica* and *L. monocytogenes* on contaminated beef pieces after storage at 5 °C for 18 h by 2.1 and 3.4 log CFU/cm^2.[156] Because the addition of oregano oil enhanced the antimicrobial activity and no changes in heat resistance were apparent during storage of the beef samples, wine marinating can enhance both safety and shelf life. Marinating with soy sauce or red wine marinades can control oxidation and microbial spoilage of raw beef, suggesting that marinating can extend the shelf life of meat.[158]

A wine-based marinade with added garlic powder or juice and a starter culture of *Lactobacillus sakei* induced loss of viability of *L. monocytogenes* and *Salmonella* spp. in a Portuguese dry sausage made from wine-marinated pork.[156] A related study optimized the drying conditions to protect the sausage against *Salmonella*, *Listeria*, and *S. aureus*.[159]

As described in detail elsewhere, there is a need to reduce both pathogens and heat-induced potentially carcinogenic heterocyclic amines in cooked meat products.[160,161] Wine marinades without and with added herbs used as meat flavoring (garlic, ginger, thyme, rosemary, and red chilli peppers) reduced the formation of heterocyclic amines in pan-fried beef.[162] Additional studies found no correlation between the marinade-induced antioxidant activities and individual or total heterocyclic amine formation.[162] Related studies on the reduction of amine formation by wine-fried chicken breast are described by Brusquest et al.[163] The concurrent reduction of both pathogens and heterocyclic amines by wine marinades with added herbs merits study.

Brannan found that 0.1% GSE inhibited the intensity of musty and rancid odor and rancid flavor, but caused color darkening, on ground chicken breast and thigh during refrigerated storage, suggesting that the seed extract may be an effective antioxidant in precooked chicken products.[164]

Grape Seed Extracts. This section presents brief overviews of reported studies on the inhibition of growth and/or destruction of pathogenic microorganisms by GSEs.

Brochothrix thermofacta. GSE incorporated into pea starch films with pork loins infected with the psychotrophic spoilage organism *B. thermofacta* reduced the bacterial growth on surface-inoculated pork loins by 1.3 log CFU/mL after 4 days of incubation at 4 °C.[20] Additional studies showed that GSE films also inhibited the growth of the following pathogens: *S. aureus*, *E. faecalis*, *E. faecium*, and *L. monocytogenes*. The authors suggest that biodegradable and edible GSE antimicrobial films have the potential to improve meat quality and extend shelf life.

Cronobacter sakazakii. *C. sakazakii* is a Gram-negative, anaerobic bacterium of the family Enterobacteriaceae reported to cause infection in adults and children, especially infants.[165] Freshly prepared red muscadine grape juices induced a 6 log reduction of *C. sakazakii* after a 2 h incubation at 37 °C, suggesting that red muscadine juice could inhibit the pathogen in baby food.[166]

Escherichia coli O157:H7. *E. coli* O157:H7 is a foodborne, toxin-producing enteropathogen responsible for hemorrhagic colitis, bloody diarrhea, and hemolytic uremic syndrome. Here, we will briefly review reported activities of grape-derived products against this organism.

A study on the effect of fresh and processed muscadine red grape juices against a 5 log cocktail of cells of *E. coli* O157:H7 incubated for 4 h at 37 °C showed that polar fractions containing malic, tartaric, and tannic acids showed strong antimicrobial activity and that synthetic tannic acid showed the highest activity.[167] These results indicate that muscadine juice can be used as an active antimicrobial ingredient against these pathogens in nonalcoholic beverages. A related study by the same investigators[168] found that water-soluble muscadine GSE prepared from the purple cultivar Ison and the bronze cultivar Carlos exhibited strong antimicrobial activity against a cocktail of three strains of *E. coli* O157:H7 and that heat treatment of both extracts increased antimicrobial activity, possibly because of increased acidity, tartaric acid, and individual and total phenolic content. These results suggest that water-soluble muscadine seed extracts could serve as natural preservatives in beverages.

Electrostatic spraying of GSE onto contaminated lettuce and spinach samples with GSE alone and in combination with lactic, malic, or tartaric acids reduced *E. coli* levels on spinach up to 4.0 log CFU/g and on spinach up 2.8 log CFU/g during the 14 day storage, suggesting that electrospraying technology could help lower risks due to pathogen contamination of fresh produce.[169]

Commercial grape seed and grape pomace extracts inhibited antitoxin properties of the Shiga toxins Stx1 and Stx2 produced by *E. coli* O157:H7 bacteria.[170] Because red and white wines and phenolic compounds isolated by chromatography from red wine exhibited strong antimicrobial activities against *E. coli* and other pathogens,[123] it would be of interest to find out whether the wine compounds can concurrently or consecutively inactivate the foodborne pathogens and the toxins produced by the pathogens. We previously reviewed the inactivation of food-related microbial, fungal, and plant toxins by natural compounds.[111,123,144]

Helicobacter pylori. *H. pylori*, a Gram-negative organism that has adapted to thrive in the acid conditions of the digestive tract, causes gastritis, peptic ulcers, and adenocarcinoma. To help overcome multidrug resistance, Brown et al.[171] evaluated the efficacy of muscadine grape skin and two polyphenolic constituents against *H. pylori*. They found that (a) grape skin and quercetin inhibited *H. pylori* infection in mice; (b) quercetin and resveratrol reduced the bacterial counts of the pathogen with MIC values of 256 and 128 μg/mL, respectively; (c) grape skin extracts were more effective than the two constituents; and (d) the inhibitions were dose dependent and pH independent.[172] The observed anti-*H. pylori* effects suggest that the extracts and components might be used in a diet-based approach for the prevention and/or treatment of *H. pylori* infection. A related study found that a comparison of the inhibition of *H. pylori* by grape seed, skin, and seed plus skin extracts of two grape varieties showed that the highest observed zone of inhibition was with the seed extracts, with MIC and minimum bactericidal concentration (BMC) values of 2048 μg/mL of the extracts of both varieties.[172,173]

Klebsiella pneumoniae. *K. pneumoniae* causes lung and urinary infections that occur mainly in hospital patients with diminished resistance. Because some isolates are resistant to medical antibiotics, there is a need for new antimicrobials to overcome infections associated with this pathogen. Ethanol extracts of grape seeds were found to be more effective in inhibiting *K. pneumoniae* than were grape skin extracts, suggesting a potential value for the seed extract against human infections.[174] These authors also found that the seed extract was also active against *E. faecalis* and *E. coli*.

Listeria monocytogenes. *L. monocytogenes* is a Gram-positive foodborne bacterial pathogen that causes human listeriosis, with symptoms ranging from headaches to

bacteremia, septicemia, encephalitis, and meningitis and a mortality rate of about 20−30%.[175] We now will record efforts to inactivate the pathogen with grape products.

Grape juice and skin extracts from black table grapes strongly inhibited multiple *L. monocytogenes* species but did not inhibit *B. cereus*, *Salmonella* Menston, *E. coli*, *S. aureus*, or *Y. enterocolitica* pathogens.[176] Fractionation of the extracts showed that the antilisterial activity was highest in the polymeric phenolic fractions, that activity of the red-pigmented fractions was pH dependent, and that the unpigmented polymeric phenolics from the seed showed pH-independent activity. The observed reduction was striking, from ∼log CFU7 to undetectable levels after 10 min. Evidently, both pigmented and unpigmented phenolic compounds from grapes were bioactive against *Listeria*, but apparently not against the other mentioned pathogens.

Chardonnay and black raspberry seed flour extracts at 165 and 160 μg seed flour equivalents/mL inhibited the growth of *L. monocytogenes* and *E. coli* with zero survival rates under the test conditions. These results and compositional and antioxidant activities suggest that the seed flours have the potential to serve as natural food preservatives for improving food stability, quality, and safety, and consumer acceptance.[177]

Dipping of surface-inoculated (log 6 CFU/g) turkey frankfurters into soy protein film-forming solutions without and with antimicrobials (1% GSE plus nisin, 10000 IU/mL) resulted in 2.8 log CFU reduction of *L. monocytogenes* after storage for 28 days at 4 or 10 °C, suggesting that the antilisterial activity of the combination was greater than that observed with the individual antimicrobials and that the use of antimicrobial films may enhance the microbial safety of meat products.[178] Because the combination of antimicrobials caused a much higher 9 log cycle reduction in culture, it seems that antimicrobial results in the absence of food do not predict the efficacy in a meat matrix.

Dipping contaminated turkey frankfurters with 1% GSE plus nisin (6400 IU/mL) reduced the *L. monocytogenes* population from ∼log 7 CFU/g to undetectable levels after storage at 4 or 10 °C for 21 days, suggesting that the combination can improve the antimicrobial efficacy against this pathogen in refrigerated ready-to-eat (RTE) meat and poultry storage.[179] A related study[180] found that soy protein edible films containing GSE, nisin, and EDTA were more effective in inhibiting the growth of *L. monocytogenes* (reduction of 2.9 log CFU/mL) than *E. coli* (1.8 log reduction) or *Salmonella* Typhimurium (0.6 log reduction), suggesting that the susceptibility of the pathogens to inhibition is not uniform.

Dipping turkey frankfurters contaminated with *L. monocytogenes*, *E. coli* O157:H7, or *Salmonella* Typhimurium (∼6 log CFU/g) into a whey protein isolate coating incorporated with GSE (0.5%) and nisin (6000 IU/g) followed by storage for 28 days at 4 °C reduced the bacterial population by 2.3, 4.6, and 1.0 log cycles, respectively, confirming that antimicrobial protein coatings can be used to inhibit foodborne pathogens in meat.[181]

Grape seed and stem extracts from the red Greek grape variety Mandilaria containing high concentrations of flavan-3-ols and derivatives represent a source of potent antilisterial compounds with low MIC values of 0.26−0.34. The extracts have the potential to serve as food additives to prevent the growth of *L. monocytogenes*.[182]

The addition of tartaric acid and grape seed and green tea extracts added to chicken marinades significantly reduced *L. monocytogenes* in vacuum-marinated irradiated chicken breast meat without affecting consumer acceptance of the product, suggesting that the combination of the plant formulations with levels of irradiation below the maximum allowed could contribute to the prevention of contamination by *Listeria*.[183]

Chitosan films impregnated with GSE inhibited *L. monocytogenes* as well as aerobic mesophiles and lactic acid bacteria on sausages during refrigerated storage, suggesting that the antimicrobial chitosan films could extend the shelf life of sausages.[184,185]

Maximum growth inhibition (∼2.0 log CFU/g) of *L. monocytogenes* was observed in chicken and turkey hot dogs treated with combinations of potassium lactate and sodium diacetate with green tea and grape seed extracts. The antilisterial effect was enhanced by heat treatment of the hot dogs, suggesting that the extracts can partially replace the chemical preservatives and enhance the antilisterial activities.[186]

Staphylococcus aureus. *S. aureus* is a Gram-positive, aerobic, toxin-producing foodborne pathogen that can also contaminate the skin, lung, heart, and other organs.

A total ethanol grape extract prepared by the percolation method of whole grapes inhibited *S. aureus*, suggesting that the extract represents a natural antibacterial for possible treatment of local skin infections.[187]

Pomace, seed, and skin extracts from New Zealand Pinot noir grapes were more effective against *S. aureus* bacteria than extracts from Pinot Meunier grapes, suggesting that extraction solvent, fraction, and grape variety significantly influence antimicrobial properties. A weak but significant relationship was observed between TPC and antimicrobial effects (r = 0.58).[17] A screening assay showed that bioactive polyphenols from pomace concentrated onto a protein-rich matrix inhibited the proliferation of *S. aureus* bacteria on the skin.[188]

Vibrio cholerae. *V. cholerae* produces a cholera toxin that causes watery diarrhea of cholera, an often fatal disease.[111] Two grape extracts sold as nutritional supplements inhibited the cholera toxin, as well as the heat-labile Shiga toxin produced by *E. coli* in cultured cells and intestinal loops by blocking toxin binding to the cell surface.[189,190] These results suggest that grape extracts could help ameliorate cholera in humans.

Vibrio vulnificus/Vibrio parahemolyticus. *V. vulnificus*, a Gram-negative foodborne bacterium present in estuarine environments where oysters are harvested, has a 40−50% fatality rate. Dipping of oysters contaminated with *V. vulnificus* in solutions of GSE (500 mg/mL), citric acid (300 mg/mL), or lactic acid (150 mg/mL) reduced the pathogens to levels lower than control samples during refrigerated storage for 20 days.[191]

The MIC value of *V. parahemolyticus* in artificially inoculated oysters dipped in GSE solutions was 10 mg/mL; a solution of 500 mg/mL of GSE reduced the population below detection level.[191]

Multiple Pathogens. An in vitro study showed that GSE was more effective in inhibiting Gram-positive bacteria (*S. aureus*, *L. innocua*, and *B. thermosphacta*) than Gram-negative ones (*E. coli*, *P. aeruginosa*, and *S. enterica*), suggesting that GSE can inhibit the most frequent causes of foodborne bacterial infections in developed countries.[174,192,193] A Turkish study found that GSEs completely inhibited Gram-positive (*B. cereus*, *B. coagulans*, *B. subtilis*, and *S. aureus*) and, less so, Gram-negative (*E. coli* and *P. aeruginosa*) bacteria.[194]

GSE with a high total phenolic content (628 mg GAE/g) inhibited the growth of the following spoilage and pathogenic bacteria: *Aeromonas hydrophila*, *Bacillus brevis*, *B. cereus*, *Bacillus*

megaterium, *Bacillus subtilis*, *Enterobacter aerogenes*, *E. faecalis*, *E. coli*, *K. pneumoniae*, *L. monocytogenes*, *Mycobacterium smegmatis*, *Proteus vulgaris*, *P. aeruginosa*, and *S. aureus*.[21,22] It seems that GSE with a high polyphenolic content can act as a broad-spectrum antibiotic in food contaminated with multiple pathogens.

Grape Pomace Extracts. Pomace extracts (5 and 10% concentration) from five Turkish grape varieties inhibited pathogenic (*S. aureus*, coliforms, Enterobacteriaceae, Enterococci, and *Salmonella*) as well as spoilage organisms (lactobacilli, lactococci, lipolytic bacteria, Micrococaceae, and proteolytic and psychotrophic bacteria) in beef patties, suggesting that the extracts could serve as antimicrobial agents that can prevent the deterioration of meat products.[32,195]

Pomaces from Pinot noir and Merlot Oregon grapes with TPC of 21.2−76.7 GAE/g DM, anthocyanin content of 0.35−0.76 mg Mal-3-glu/g DM, total flavonoid content (TFC) of 30.2−106.1 mg CE/g DM, and dietary fiber content of 57−63% of total dry matter (DM) showed higher activity against *L. innocua* than against *E. coli*.[196] The pomace extracts were more active against the bacteria than the skin extracts. All samples lost significant amounts of bioactive compounds during 16 weeks of storage, with freeze-dried samples retaining higher amounts of TPC than samples stored at ambient temperatures or 40 °C. The authors suggest that the two pomaces could be used as functional food ingredients that can promote human health.

An evaluation of the antimicrobial efficacy of grape pomace powder and pomace extracts from Turkish grape varieties showed that a 10% concentration of the powder completely inhibited *S. aureus* in vegetable soup at the end of 120 h and that this pathogen was more susceptible to inhibition than *E. coli*.[197] The same authors also analyzed the data by an adaptive neuro fuzzy inference system (ANFIS), an artificial neural network (ANN), and multiple linear regression (MLR) models to predict antibacterial effects of the two pathogens in the soup.

Supercritical fluid pomace extracts from Brazilian grapes were more effective against Gram-positive bacteria (*S. aureus* and *B. cereus*) than against Gram-negative ones (*P. aeruginosa* and *E. coli*).[41] Seed and skin extracts from grape winery byproducts of the Portuguese Arinto variety showed higher antimicrobial activity against five bacteria and yeast species (*E. coli*, *Salmonella* Poona, *B. cereus*, *S. cerevisiae*, and *C. albicans*) than did some of the individual components, suggesting that the extracts can both protect against the adverse effects of contaminated food and be used to prevent or treat animal and human infectious diseases.[198]

Pomace extract-based polysaccharide films induced ∼5 log reduction in bacterial activity against *E. coli* and up to a 3.0 log reduction against *L. innocua* on a Petri dish at the end of a 24 h test compared to the control, suggesting the need to evaluate the films for applicability to contaminated food.[20,199]

We evaluated the relative bactericidal activities of 10 presumed health-promoting food-based powders (neutraceuticals) and, for comparison, selected known components against the following foodborne pathogens: *E. coli* O157:H7, *S. enterica*, *L. monocytogenes*, and *S. aureus*.[144] The relative activities were evaluated using quantitative bactericidal activity (BA_{50} value, defined as the percentage of the sample in the assay mixture that resulted in a 50% decrease in colony-forming units). The BA_{50} values were determined by fitting the data to a sigmoidal curve by regression analysis using concentration−antimicrobial response data. Antimicrobial activity is indicated by a low BA_{50} value, meaning less material is needed to kill 50% of the bacteria. Olive pomace, olive juice powder, and oregano leaves were active against all four pathogens, suggesting that they behave as broad-spectrum antimicrobials. All powders exhibited strong antimicrobial activity against *S. aureus*. The following powders showed exceptionally high activity against *S. aureus* (as indicated by the low BA_{50} values shown in parentheses): apple skin extract (0.002%); olive pomace (0.008%); and GSE (0.016%). *Listeria* bacteria were also highly susceptible to apple skin extract (0.007%). The most active substances provide candidates for the evaluation of antimicrobial effectiveness in human foods and animal feeds.

■ ORAL PATHOGENIC BACTERIA

Several studies describe anticariogenic/cariostatic effects of grape products. These include the following observations. Phenolic extracts with highly variable anthocyanin and flavan-3-ol contents prepared from several red wine grape varieties and their fermented byproduct of winemaking (pomace) were highly effective against virulence traits of the dental pathogen *Streptococcus mutans*, suggesting their potential value against dental disease.[200−204] A study on bacterial adherence to enamel in the oral cavity of six human subjects revealed that rinses with red wine and teas induced up to a 66% reduction of adherent bacteria compared to controls, suggesting that these beverages might contribute to the prevention of biofilm-induced diseases in the oral cavity.[205]

A red wine GSE reduced plaque area on bovine teeth in an artificial mouth by 40% compared to the control. This value was, however, lower than corresponding reductions of 84.0 and 87.5%, respectively, observed with *Salvia officinalis* and *Rosmarinus officinalis* plant extracts.[206] An evaluation of the antibacterial activities of wine phenolic compounds and GSEs against potential respiratory pathogens present in the oral cavity that contribute to the formation of dental plaque showed that (a) gallic acid and ethyl gallate had the highest activity, (b) two commercial GSEs were more active than the phenolic compounds, and (c) Gram-positive bacteria (*E. faecalis*, *S. aureus*, and *Streptococcus pneumoniae*) were more susceptible to inactivation than Gram-negative bacteria (*Moraxella catarrhalis* and *P. aerations*).[207] Red wine alone and with added GSE inhibited oral microbiota in a five-species biofilm model of supragingival plaque.[208] These observations suggest the need to evaluate the germ-killing efficacy of wine compounds in oral rinses and chewing gums.

■ ANTIVIRAL ACTIVITIES

Viral contamination of food and infection of animals and humans is a major cause of numerous diseases. The mechanism of antiviral action of plant polyphenolic compounds is based on their abilities to act as antioxidants, to inhibit essential enzymes, to disrupt cell membranes, to prevent viral binding and penetration into cells, and to trigger the host cell self-defense mechanism.[209] Here, we present a brief overview of reported studies on the antiviral activities of grape products against pathogenic viruses.

Adenovirus. A polyphenol-based grape extract from Portuguese white-winemaking byproducts and resveratrol reduced adenovirus-5 production by 4.5 and 6.5 log ($TCID_{50}$/mL). In contrast to resveratrol, the extract irreversibly inhibited the replication of the adenovirus, suggesting its potential value as an antiviral agent.[210]

Cytomegalovirus. The wine polyphenolic compound resveratrol reduced human cytomegalovirus DNA replication to undetectable levels by blockage of epidermal growth factor receptor activation in human embryonic fibroblasts.[211]

Hepatitis Viruses and Virus Surrogates. A study of the effect of commercial GSE on human enteric virus surrogates and hepatitis A virus evaluated the infectivity of the virus exposed to GSE concentrations of 0.5, 1, and 2 mg/mL for 2 h at room temperature or 37 °C.[212,213] At high titer (~log 7 PFU/mL), the infectivity was reduced by up to 4.61 log PFU in a dose-dependent manner, suggesting that GSE has the potential to be used by the food industry as an inexpensive novel natural broad-spectrum antiviral alternative to reduce viral contamination and enhance food safety and quality.

Noroviruses. The foodborne norovirus causes gastroenteritis and diarrhea in humans. An examination of the effect of GSE against the human norovirus by a plaque and other bioassays for murine norovirus found that GSE at 0.2 and 2 mg/mL reduced the infectivity by >3 log PFU/mL of the murine virus and the binding of the human norovirus to salivary human histo-blood group antigen receptors.[213−215] The observed 1.5−2 log PFU/mL reduction in the murine virus titer following addition of 2 mg of GSE/mL to sanitized water in the washing bath of fresh-cut lettuce suggests the potential value of the treatment to reduce the viral burden of leafy greens. The mechanism of the antiviral effect seems to involve denaturation of the viral capsid protein.

GSE was also effective against these viruses on contaminated produce.[215] Thus, treatment of lettuce and jalapeno peppers (25−30 g) inoculated with human norovirus surrogates (feline calicivirus and murine norovirus) or hepatitis A virus with 0.25, 0.5, 1 mg/mL GSE or water for 30 s−5 min reduced the viral counts from ~7 log PFU/mL to 2.33, 2.58, and 2.71 log PFU on lettuce and to 2.20, 2.74, and 3.05 log PFU on peppers after 1 min at all three concentrations, respectively. The authors suggest that GSE should be considered for use as part of hurdle approaches that combine GSE with other antiviral treatments for foodborne virus reduction on produce.

Rotaviruses. Exposure of rotaviruses, the most common cause of severe diarrhea in children, to grape and cranberry juices and proanthocyanidins resulted in a loss of viral infectivity after 5 min via blockage of viral antigenic determinants caused by modification of viral integrity at physiological pH, suggesting that the fruit juices may help protect against viral-induced diarrheas.[216,217] A related study by Ko et al.[218] reported that an orally administered alcohol-free Cabernet Sauvignon red wine extract inhibited diarrhea in a neonatal mouse model of rotaviral infection, but did not prevent watery stools in the mice administered cholera toxin.[219,220]

Nair et al.[221] found that the flavonoid constituents of GSE seem to exert antiviral effects by inducing Th1-derived cytokine γ-interferon (IFN-γ) by peripheral mononuclear cells, suggesting that the beneficial immunostimulatory effect of GSE may be mediated through induction of IFN-γ.[222]

ANTIFUNGAL EFFECTS

***Botrytis cinerea* and Other Phytopathogens.** GPE fractions extracted with methanol or ethanol from a mixture of Chilean grape varieties exhibited in vitro antifungal activity against the phytopathogenic fungus *B. cinerea* that damages grapevines, resulting in extensive economic losses, suggesting that the pomace can provide a low-cost fungicide to help overcome this problem. Related studies reported that pomaces from other grape varieties inhibited the growth of *Zygosaccharomyces rouxii* and *Zygosaccharomyces bailii*[32,195] and that GPE from three Chilean grape varieties showed a large inhibitory effect on mycelia growth of *B. cinerea* with an IC_{50} value of 50 ppm.[30,35]

***Candida albicans* and Other Human Fungal Pathogens.** GPE from Brazilian Merlot grapes exhibited moderate activity against three fungal species (*C. albicans*, *Candida krusei*, and *Candida parapsilosis*), with MIC values ranging from 500 to 1000 μg/mL.[41] GSE acted synergistically with the medicinal antibiotic amphotericin B against *C. albicans*, the most common cause of fungal disease in humans, suggesting that the combination with 75% less antibiotic merits use in human fungal infections.[223−225] The authors suggest that synergism of natural compounds such as GSE with medicinal antibiotics has the potential to benefit the fight against human infectious diseases. Phenolic red and white wine extracts also inhibit *C. albicans*.[226]

MISCELLANEOUS ASPECTS

Anticoccidiosis Activity. GSE from grapes and other plant extracts significantly decreased adverse effects in broiler chickens infected with the parasitic organisms (*E. tenella*, *E. maxima*, and *E. acervulina*) that cause coccidiosis, a poultry disease that results in large economic losses.[227,228] The protection involved decreased mortality and improved feed conversion ratio (FCR), suggesting that antioxidant-containing plant extracts may be of benefit in the management of coccidiosis. A related study reported that a 0.1% GSE inhibited the intensity of musty and rancid odor and rancid flavor in chicken breast compared with control patties, suggesting that the extract may be an effective antioxidant in precooked chicken breast.[164,229]

Caenorhabditis elegans. Pomace flavanols and flavonols (122.75 and 23.11 mg/100 g dry pomace) from Zalema grapes seem to be responsible for the increased survival of *C. elegans* worms exposed to thermally induced oxidative stress.[230]

RESEARCH NEEDS AND OUTLOOK

In addition to the research needs mentioned earlier, future studies need to address the following food and medical aspects of the properties of wines and wine flavonoids. In this context the term "flavonoid" represents wines, grape pomace, seed, and skin extracts and their flavonoids.

- Determine whether the antibiotic activities of flavonoids and wines in vitro can be duplicated in vivo, especially in humans.
- Determine the relationship between wine consumption and lower risk of infection in humans. Will frequent consumption of red wine or flavonoids protect against infection and/or ameliorate the severity of infectious disease in humans?
- Determine how bioactivities of flavonoids vary, depending on whether they are tested or consumed in the free state or as part of a mixture or a food.
- Determine whether flavonoid metabolites formed after absorption into the circulation by animals and humans possess antimicrobial properties.
- Define additive or synergistic effects of mixtures of wine flavonoids with other plant antimicrobials, including plant essential oils, apple, and olive compounds, and

seashell-derived chitosans. Combinations of food ingredients that act synergistically will lessen amounts needed to design effective antimicrobial food formulations. They will be safer and affect flavor and taste less than individual compounds.

- Evaluate the effectiveness of wines and flavonoids against antibiotic resistant foodborne and medical pathogens, a largely unexplored area.[231−234]
- Determine whether flavonoids can additively or synergistically enhance antibiotic properties of medicinal antibiotics.
- Determine whether wine flavonoids can protect against bacterial infection through stimulation of the immune system.[88,89,235]
- Determine antibacterial, antiviral, antifungal, and antitoxin efficacies of wines and flavonoids in various contaminated foods including leafy greens, fruits and fruit juices, vegetables, dairy, meat, poultry, and seafood products.
- Develop methods to simultaneously reduce both pathogens and carcinogenic heterocyclic amine levels in processed meat products.
- Develop flavonoid-containing edible antimicrobial films and coatings to protect food against contamination by pathogens.
- Determine whether flavonoids can prevent biofilm formation by bacteria on contaminated food.
- Determine whether the flavonoid content of wines and byproducts can predict antibiotic activities.
- Determine whether molecular modeling of flavonoid structure−cell membrane interactions can be used to explain the antibiotic mechanisms of structurally different flavonoids.[236−238]
- Encourage growers to produce grapes with a high content of bioactive compounds.

In summary, because grape phenolic phytonutrients are considered to be generally accepted as safe, the cited and proposed studies will provide numerous benefits. The most active compounds could be used to protect liquid and solid foods against contamination by pathogenic and spoilage microorganisms and microbial toxins as well as therapeutically to treat animal and human infections. The grape pomace, seed, and skin extracts have the potential to provide inexpensive sources of compounds for use against a broad range of diseases. These byproducts will also provide a source of income to grape growers and wine producers. Growers will be encouraged to produce grapes with high levels of bioactive compounds.

Supporting Information

ABSTRACT: Copper (Cu) compounds are widely used as antibacterial/antifungal agents for protecting food crops. Prolonged use of Cu biocides would lead to undesirable Cu levels in agricultural soil. In the absence of a suitable alternative, prudent use of Cu biocides is required. This paper reports for the first time a composite material of sol−gel silica host matrix loaded with mixed-valence Cu as an alternative to conventional biocides. In this composite material, Cu is present in different oxidation states. The hydrophilic silica matrix serves as a water-dispersible delivery vehicle for antimicrobial Cu. It is hypothesized that a mixed-valence Cu system, specifically enriched with Cu(0) and Cu(I), will exhibit enhanced antimicrobial efficacy over traditional Cu(II) compounds. Materials were characterized by high-resolution transmission electron microscopy and X-ray photoelectron spectroscopy for the determination of particle size, morphology, crystallinity, and Cu oxidation states. Antimicrobial studies against *Xanthomonas alfalfae* and *Escherichia coli* (minimum inhibitory concentration) showed improved efficacy in MV-CuSiNG treatment compared to CuSiNG and other controls. Phytotoxicity studies performed (in *Vinca* sp. and Hamlin orange) under greenhouse conditions showed that the newly prepared nanocomposite is safe for plants, demonstrating potential usefulness of the material in agricultural biocides.

KEYWORDS: *copper, silica, antimicrobial, mixed-valence, agricultural biocide*

INTRODUCTION

In modern agriculture, copper (Cu)-based biocides are widely used for crop protection. Cu exhibits antimicrobial properties only at higher concentration (>50 μM),[1] as it is an essential micronutrient in many organisms including plants and animals.[2] Therefore, to achieve adequate protection, aggressive use of Cu is necessary, requiring multiple applications in one crop season.[3,4] For example, in the citrus industry, spraying Cu bactericides/fungicides is considered a standard measure for protection against a number of citrus diseases including citrus canker, scab, melanose, etc. In a season, running from March through October, Cu biocides are applied 5−15 times in citrus groves.[3] Extensive and continuous use of Cu-based biocides in agricultural field over years has caused undesirable accumulation of Cu in fertile soil, raising a huge environmental concern of Cu toxicity.[5−8] A serious concern for the citrus industry is the citrus canker disease caused by *Xanthomonas citri* subsp. *citri*. Studies conducted on *X. citri* subsp. *citri* and *Xanthomonas alfalfae* subsp. *citrumelonis* have revealed the development of Cu resistance.[9] Although there is no suitable alternative to Cu available to date, there is a strong need to improve the antimicrobial efficacy of the existing Cu-based biocides. Commercially available Cu compounds that are used in agriculture are primarily insoluble Cu(II) compounds such as basic copper(II) sulfate, copper(II) hydroxide, and copper(II) oxychloride.[4] Insoluble Cu(I) oxide and a mixed system containing both Cu(II) and Zn(II) are also available. All of these Cu-based products are traditional Cu compounds with known composition.[10]

Multiple mechanisms have been proposed to understand the biocidal activity of Cu, which has been correlated with its oxidation states, metallic (0), +1, and +2.[11] Cu(II) has been connected with a rapid decline in cell membrane integrity and specific binding for DNA, leading to cross-linking between strands and eventual denaturation.[2,12] Higher antimicrobial potency of Cu(I) over Cu(II) has been reported.[13−15] It has been suggested that Cu(I) is responsible for protein inactivation via its ability to strongly interact with thiol (−SH) groups of protein molecules.[16] It is also reported that Cu(I) is effective in producing reactive oxygen species via the Haber−Weiss reaction, leading to degradation of biomolecules.[17] Although the antimicrobial mechanism of Cu in its zero valence state (i.e., metallic Cu) is yet not fully understood, it has been suggested that metallic Cu surfaces such as Cu alloy based materials cause a rapid change in cell membrane potential, leading to damage in membrane integrity.[18,19] Release of ionic Cu from metallic Cu surfaces has been also suggested as a reason behind its antimicrobial effect.[19] Overall, Cu(I) and metallic Cu are shown to possess higher antimicrobial potency than the Cu(II) state.[1,13−15,18] To the best of our knowledge, there is no mixed-valence composite Cu system containing Cu(0), Cu(+1), and Cu(+2) reported to date.

In this paper, our objective is to design and synthesize a novel mixed-valence composite Cu system and study the role of mixed-valence Cu on overall antimicrobial efficacy. Amorphous silica is used as an inert environmentally friendly host matrix for embedding Cu in its mixed-valence states in this work. Our working hypothesis was that a mixed-valence copper system containing Cu(0), Cu(+1), and Cu(+2) will have an improved antimicrobial efficacy over a Cu(II)-only containing system. The goal is to improve overall Cu antimicrobial efficacy, which could potentially reduce the total amount of Cu biocide released into the environment.

EXPERIMENTAL PROCEDURES

Materials. All reagents used in synthesis and studies were purchased from commercial vendors and utilized without any further purification: tetraethylorthosilicate (TEOS, Gelest Inc.), copper(II) sulfate pentahydrate (CQ Concepts, Ringwood, IL, USA), concentrated hydrochloric acid (Fisher Scientific, USA), sodium borohydride (Sigma-Aldrich), neocuproine (Acros), ethylenediaminetetraacetic acid (EDTA) (Amresco, USA), Hyclone phosphate-buffered saline (PBS) (Fisher Scientific, USA), deionized (DI) water (Nanopure; Barnstead model D11911). Kocide 3000, a product of DuPont, was received as a gift from Dr. Jim Graham (Citrus Research and Education Center, Lake Alfred, FL, USA). Luria–Bertani (LB) broth and agar and nutrient broth and agar as well as Muller Hinton 2 (MH2) broth and agar were purchased from Fluka. Alamar blue dye was purchased from Life Technologies, Grand Island, NY, USA. *Escherichia coli* strain ATCC 35218 was obtained from the microbiology laboratory at the University of Central Florida, and *X. alfalfae* strain F1 ATCC 49120 was purchased from ATCC (U.S. Department of Agriculture permit P526P-12-04060). A cuprous ion efflux mutant of *E. coli*, *copA1(del)::kan* DW3110 CGSC#7968, was obtained from The Coli Genetic Stock Center (CGSC) at Yale University.

Synthesis of Composite Mixed-Valence Copper-Loaded Silica Nanogel (MV-CuSiNG). MV-CuSiNG was synthesized in two steps. In step 1, a water-soluble composite copper(II)-loaded silica nanogel (CuSiNG) was synthesized. The CuSiNG material was then converted to MV-CuSiNG material in step 2 using a reducing agent. Synthesis of CuSiNG material was done following a published protocol.[20] Briefly, 1.87 g of copper(II) sulfate pentahydrate was added to a mixture of 330 μL of 1% hydrochloric acid and 110 mL of deionized (DI) water. Then the solution was magnetically stirred for 30 min to ensure complete dissolution of copper sulfate crystals. Next, 778 μL of tetraethylorthosilicate (TEOS) was added a drop at time to the acidified copper sulfate solution, and stirring was continued for 24 h. The resulting composite CuSiNG solution was transparent, and the pH of the solution was measured to be 4. The CuSiNG nanocomposite loaded with Cu(II) was further converted to a mixed-valence Cu system by the treatment of sodium borohydride (a strong reducing agent). Briefly, about 183.3 mg of sodium borohydride was added directly to the CuSiNG solution, and the mixture was stirred for 1 h. The resulting mixture was then centrifuged at 10000 rpm for 10 min to remove residue. The supernatant containing the soluble form of MV-CuSiNG nanogel was used for further studies. The residue containing unreacted reagent was discarded. The pH of the MV-CuSiNG nanogel solution was 4 as measured by a pH-meter (Mettler, Toledo, OH, USA).

Nanogel Characterization. Nanogels, both CuSiNG and MV-CuSiNG, were characterized using high-resolution transmission electron microscopy (HRTEM, FEI Tecnai F30), X-ray photoelectron spectroscopy (XPS, Physical Electronics 5400 ESCA), UV–vis spectroscopy (Varian Cary 300), and atomic absorption spectroscopy (AAS, PerkinElmer AAnalyst 400 AA spectrometer).

HRTEM sample preparation was carried out by dipping carbon-filmed gold grids (400 square mesh) into the solution of nanogels followed by vacuum drying at room temperature overnight. Electron beam intensity of 100 kV was used for HRTEM. The HRTEM samples were analyzed at the Advanced Materials and Processing Center, Materials Characterization Facility (AMPAC-MCF) at the University of Central Florida. For XPS studies, 10 mL of each nanogel was lyophilized using a LabConco FreeZone 4.5 Liter Freeze-Dryer (model 7750020). AAS analysis was done by comparing nanogel samples with a series of copper standards. Samples for AAS were prepared by extracting Cu from lyophilized nanogel powder using saturated EDTA solution. EDTA strongly chelates with Cu and forms a water-soluble Cu–EDTA complex. The nanogel residue after EDTA treatment was also analyzed by AAS to confirm complete release of Cu from the nanogel material.

Copper(I) content within CuSiNG materials was observed using 2,9-dimethyl-1,10-phenanthroline (neocuproine, N_c assay) with UV–vis spectroscopy. Nc is a copper(I)-specific chelator, soluble in methanol and chloroform. The Cu(I)–Nc complex has a characteristic absorption band maxima at around 455 nm.[21,22] The Nc assay was done in a methanol–water mixed solvent. One milliliter of N_c solution (1 mg/mL) in methanol was combined with 1 mL of CuSiNG material solution (1 mg/mL). The resulting mixture was then stirred for 48 h using a stir plate. UV–vis absorption spectrum of the mixture was then recorded in the wavelength range between 350 and 550 nm.

Antimicrobial Studies. The antimicrobial properties of MV-CuSiNG and CuSiNG with control samples were investigated using a battery of standard microbiological techniques including minimum inhibitory concentration (MIC) and a bacterial growth inhibition assay using turbidity. Samples were tested against Gram-negative *Xanthomonas alfalfae* subsp. *citrumelonis* strain F1 (*X. alfalfae* F1, ATCC 49120, a nonpathogenic surrogate of citrus canker), Gram-negative *Escherichia coli* (ATCC 35218) and an *E. coli* efflux pump mutant *E. coli copA1(del)::kan*. The *E. coli* mutant was used to ascertain whether Cu(I) played a large role in Cu toxicity. The gene *copA* is known to be responsible for the development of Cu(I) efflux pumps. CopA translocates Cu(I) from the cytoplasm to periplasm when the Cu(I) concentration in cytoplasm reaches high levels.[23] *E. coli* and *E. coli copA1(del)::kan* were subcultured and maintained using LB agar and broth, whereas *X. alfalfae* was subcultured and maintained using nutrient agar and broth. Culturing and testing of *X. alfalfae* were done at 28 °C, whereas *E. coli* and *E. coli copA1(del)::kan* cultures and tests were conducted at 37 °C. All antimicrobial studies were conducted using LB and MH2 agar and broth with bacterial concentrations of 0.5 McFarland standard (10^8 CFU/mL). Kocide 3000 ("insoluble Cu" compound), copper sulfate ("soluble Cu" compound), and cuprous chloride ("insoluble Cu(I)" compound) were positive controls for growth inhibition, whereas silica nanogel (no Cu loaded) acted as the negative control. All test materials were standardized to a metallic Cu concentration of 3000 μg/mL before antimicrobial studies.

Determination of Minimum Inhibitory Concentration (MIC). The MIC values of MV-CuSiNG and CuSiNG with controls were determined along with those of Kocide 3000, copper sulfate, and cuprous chloride with equivalent Cu concentrations. MIC was carried out using broth microdilution in accordance with the guidelines of the Clinical and Laboratory Standards Institute (CLSI).[24] The accuracy of the MIC determination was improved by adding 5 μL of Alamar blue dye per 100 μL well volume and observing color changes (blue to pink for live organisms). This reduced an error produced from the cloudiness of the nanomaterial and control materials with broth.

Bacterial Alamar Blue Assay. The bacterial growth inhibition studies for the MV-CuSiNG and CuSiNG with controls were conducted using an Alamar blue assay with a microplate reader.[25] Briefly, different volumes of MV-CuSiNG and controls (5, 10, 15, 20, and 25 μL) were prepared in sterile MH2 or LB broth in separate wells within a 96-well flat-bottom, polystyrene microplate. Uniform growth potential was ensured by each well containing an equal amount of broth and equal final volumes (200 μL). Each well contained ~10^5 CFU/mL of bacteria. Appropriate "blank" wells were prepared containing no bacteria to compare with samples to determine bacterial growth. Microplates were incubated at the appropriate temperature for each bacterial species on a shaker at 200 rpm for 20–24 h. After incubation, 10 μL/well of Alamar blue dye was added to each well followed by further incubation. After 60 min of incubation, the absorbances of each well at both 570 and 600 nm were measured.

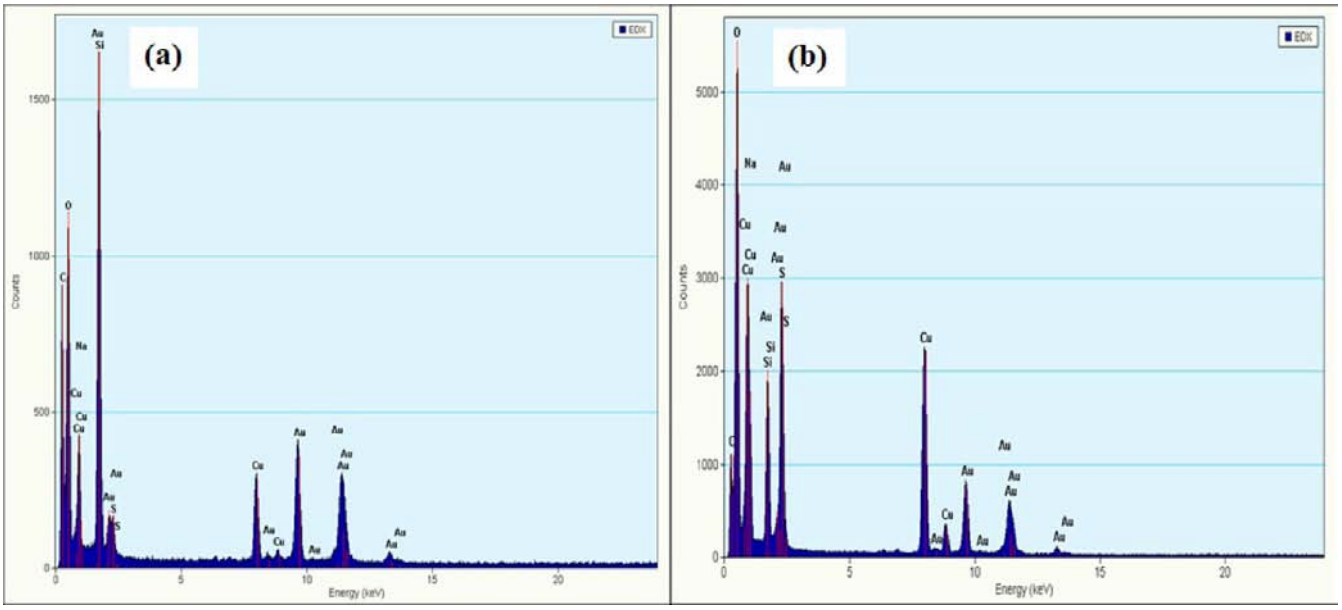

Figure 1. Energy-dispersive X-ray spectroscopy (EDX) for elemental analysis of (a) CuSiNG and (b) MV-CuSiNG during HRTEM.

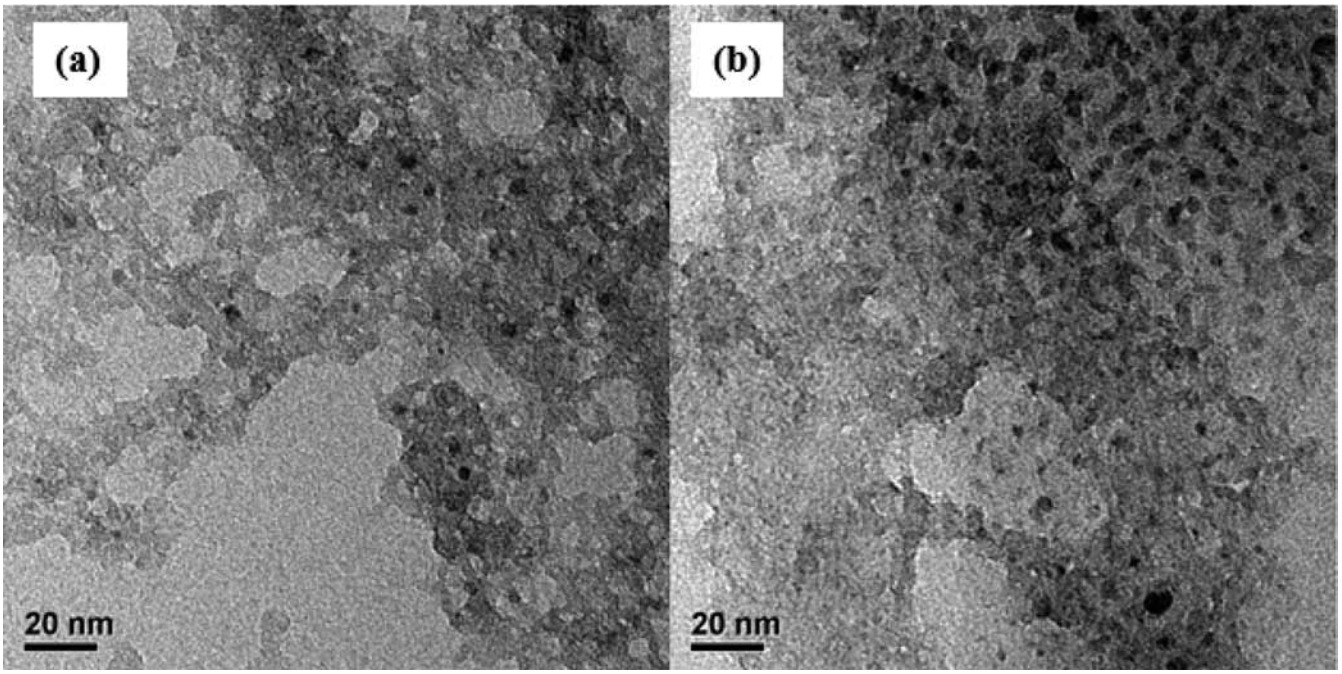

Figure 2. HRTEM image of (a) CuSiNG and (b) MV-CuSiNG at lower magnification with well-distributed material with light and dark contrast.

Wells containing sterile media with material controls and Alamar blue served as negative controls. Alamar blue assays for each bacterial strain were conducted at least three times to verify the results for reproducibility.

The percentage reduction of the dye was calculated by using the following formula as supplied by the manufacturer:

$$\frac{(\varepsilon_{ox})\lambda_2 A_{\lambda_1} - (\varepsilon_{ox})\lambda_1 A_{\lambda_2}}{(\varepsilon_{red})\lambda_1 A'\lambda_2 - (\varepsilon_{red})\lambda_2 A'_{\lambda_1}} \times 100$$

ε_{ox} is the molar extinction coefficient of Alamar blue oxidized form (blue), ε_{red} is the molar extinction coefficient of Alamar blue reduced form (pink), A is the absorbance of test wells, A' is the absorbance of negative control well, λ_1 = 570 nm, and λ_2= 600 nm.

Bacterial Viability Assay. The bactericidal activities of MV-CuSiNG and CuSiNG with controls were determined by colony-forming unit (CFU) assay. The copper concentration (225 μg/mL) that produced a significant decrease in viability over the lower concentration (150 μg/mL) as observed in the Alamar blue assay was used to perform the CFU assay. Treatment of bacteria with nanomaterial was carried out following the same procedure as described in the Alamar blue assay. After 24 h of nanomaterial treatment with the bacteria, each sample was serially diluted in 1× PBS and plated on LB or MH2 agar. After overnight incubation at species-appropriate temperatures, individual colonies were counted.

Phytotoxicity Studies. Phytotoxicity studies of MV-CuSiNG and CuSiNG with controls were carried out to observe potential plant tissue damage. Studies were conducted using *Vinca* sp., an annual ornamental plant purchased from a local Home Depot, and Hamlin orange, a citrus species purchased from Lukas Nursery in Oviedo, FL, USA. Ornamental species such as *Vinca* sp. and citrus were used to see if they exhibit differences in their levels of tolerance to oxidative stress,

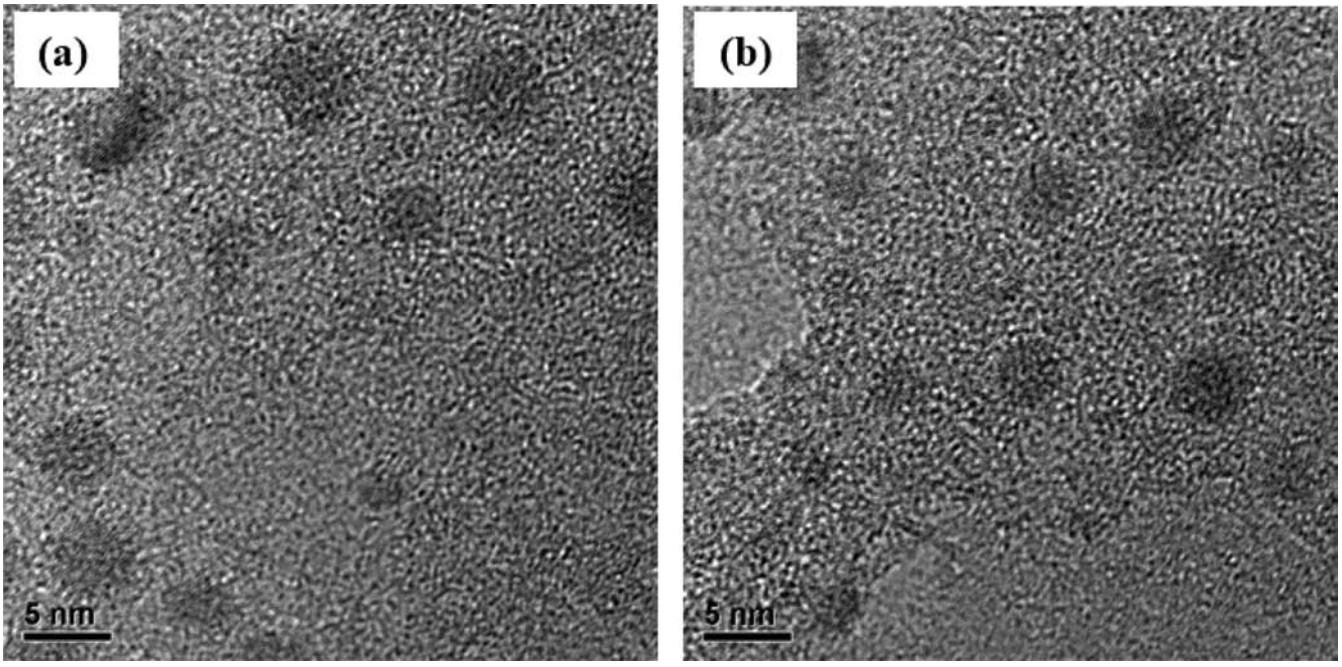

Figure 3. HRTEM image of (a) CuSiNG and (b) MV-CuSiNG at higher magnification with scattered dark contrast confirming presence of electron-rich material.

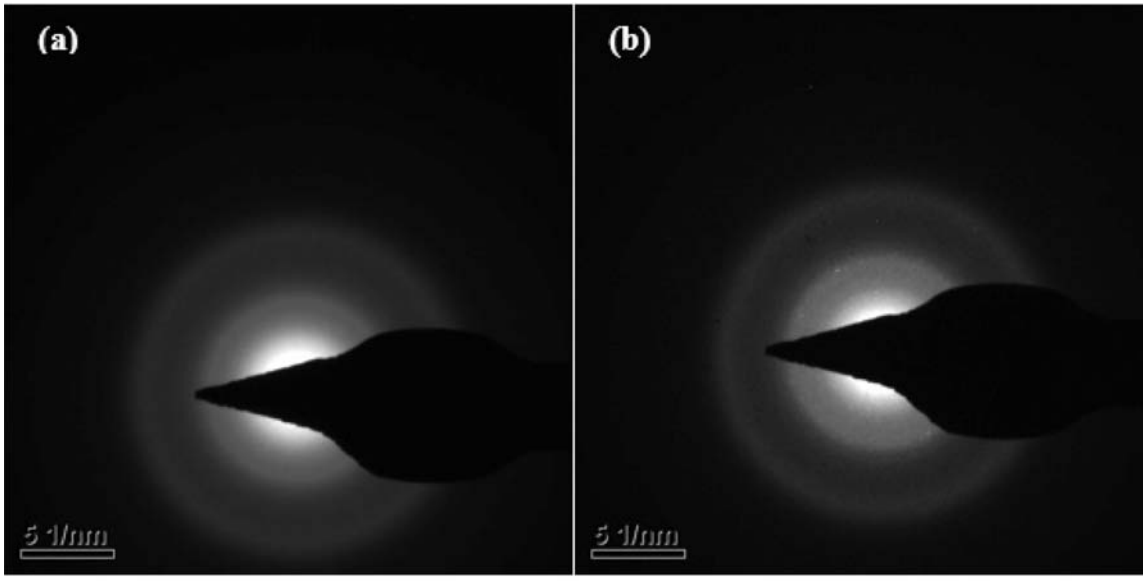

Figure 4. Selected area electron diffraction (SAED) image during HRTEM of (a) CuSiNG and (b) MV-CuSiNG.

thus giving a fair idea of how toxic or useful the agricultural material can be. Studies were carried out in a polyvinyl chloride (PVC) cold frame "mini greenhouse" covered in shade cloth and equipped with an Acurite temperature and humidity sensor purchased from Home Depot. Plants were purchased and placed in the greenhouse for at least 24 h prior to application of the formulation, allowing for acclimatization. Weather and conditions were monitored to ensure that plants were sprayed only on appropriate days for phytotoxicity (temperature > 80 °F, humidity 60−80%). CuSiNG and MV-CuSiNG were applied, along with Kocide 3000 ("insoluble Cu" compound), copper sulfate ("soluble Cu(II)" compound), cuprous chloride ("insoluble Cu(I)"), and SiNG (negative control containing no copper) used for comparisons. Formulations were sprayed at concentrations of 90, 450, and 900 ppm of metallic Cu at 8:00 a.m. before temperatures became too high, and observations were taken at 24, 48, and 72 h postspray application.

RESULTS AND DISCUSSION

Copper-loaded silica nanogel (CuSiNG) was successfully synthesized using an acid-catalyzed sol−gel method. CuSiNG was then converted to a mixed Cu valence state by using a reducing agent, sodium borohydride. Both the CuSiNG and MV-CuSiNG materials appeared as blue transparent solution and were stable for at least 12 months (Supporting Information Figure S1(a,b)). Copper loading within CuSiNG materials were confirmed from AAS measurements with Cu concentrations of ∼4300 μg/mL in both CuSiNG and MV-CuSiNG. AAS studies confirmed that the unreacted residue portion of the MV-CuSiNG material did not contain Cu.

HRTEM studies confirmed the state of dispersion and crystallinity of the nanogel materials. Energy-dispersive X-ray

nm size crystalline material. Average lattice spacing between crystal planes was calculated. Values were determined as ~1.87, ~2.32, ~2.47, and ~3.02 Å to reveal Cu crystallites of cupric oxide[26] and cuprous oxide[26] in CuSiNG, whereas MV-CuSiNG possessed values of ~2.32, ~3.02, ~2.47, and ~2.09 Å, revealing cupric oxide,[26] cuprous oxide,[26] and metallic Cu[26] (Figure 3) . HRTEM selected area electron diffraction (SAED) measurements of CuSiNG and MV-CuSiNG showed a diffused diffraction pattern, suggesting the amorphous nature of the silica-rich matrix of the nanogel material (Figure 4).

Copper valence states were analyzed using XPS. Survey spectra were collected for CuSiNG and MV-CuSiNG materials. Characteristic XPS elemental signatures confirmed the presence of Cu, Si, S, O, C, and Cl (Supporting Information Figures S2 and S3). Detailed investigation of XPS spectra of Cu within CuSiNG and MV-CuSiNG was carried out to identify the Cu compounds and Cu valence states (Figure 5). Curve fitting and referencing through the National Institute for Science and Technology (NIST) XPS database indicated that $CuSO_4$,[27] $CuCl_2$,[28] CuO,[29] and Cu_2O[30] were found in CuSiNG, whereas $CuSO_4$,[27] CuO,[29] Cu_2O,[30] and metallic Cu[31] were found in MV-CuSiNG material. Nc assay was used to confirm the presence of Cu(I) in CuSiNG and MV-CuSiNG materials and its relative abundance. Nc is specific to Cu(I) only. The Cu(I)−Nc complex shows an absorption maximum around ~455 nm.[21,22] It was observed that Nc alone, methanol, Cu(II)SO_4, Cu(I)Cl, CuSiNG, and MV-CuSiNG do not absorb light at ~455 nm. Strongest 455 nm Nc−Cu(I) specific absorption for Nc−CuCl (positive control), moderate to high absorption for Nc−MV-CuSiNG, and low (insignificant) absorption for Nc−

CuSiNG were observed (Figure 6). Metallic Cu content was kept equal in each of these samples before exposure to Nc. XPS and HRTEM results support that Cu(0), Cu(I), and Cu(+2) are present in MV-CuSiNG material, whereas small amounts of Cu(I) and mostly Cu(+2) are present in CuSiNG material. The percentage of Cu_2O found within MV-CuSiNG was higher than that of CuSiNG, confirming higher Cu(I) content in MV-CuSiNG material. Cu(I) is increased in MV-CuSiNG, whereas CuSiNG primarily contains Cu(+2) as confirmed by the Nc assay. Therefore, the Nc assay clearly indicated that MV-CuSiNG had higher Cu(I) content in comparison to CuSiNG. This assay complements results from HRTEM and XPS studies and clearly supports the fact that Cu(I) content in MV-CuSiNG is increased after sodium borohydride reduction of CuSiNG material. HRTEM suggests that sodium borohydride further reduced some Cu(I) to Cu(0), indicated by the presence of metallic Cu crystallites.

Various antimicrobial assays were performed to measure the effectiveness of MV-CuSiNG and CuSiNG along with appropriate controls at inhibiting bacterial growth and/or causing bacterial cell death. Alamar blue assays were performed on *X. alfalfae* (Figure 7), *E. coli* (Figure 8), and *E. coli copA1(del)::kan* (Figure 9). Alamar blue dye is a colorimetric dye that is converted from an oxidized blue form to a reduced pink form by live cells. It is a semiquantitative assay that helps screen materials and can give an indication of antimicrobial effectiveness. The bacterial viability assay reported in CFU/mL was conducted to give a clear and quantitative measure of effectiveness of the MV-CuSiNG nanocomposite (Figure 10). MV-CuSiNG exhibited improved antimicrobial efficacy over CuSiNG material and controls, whereas CuSiNG composite material performed comparably to controls against all bacteria.

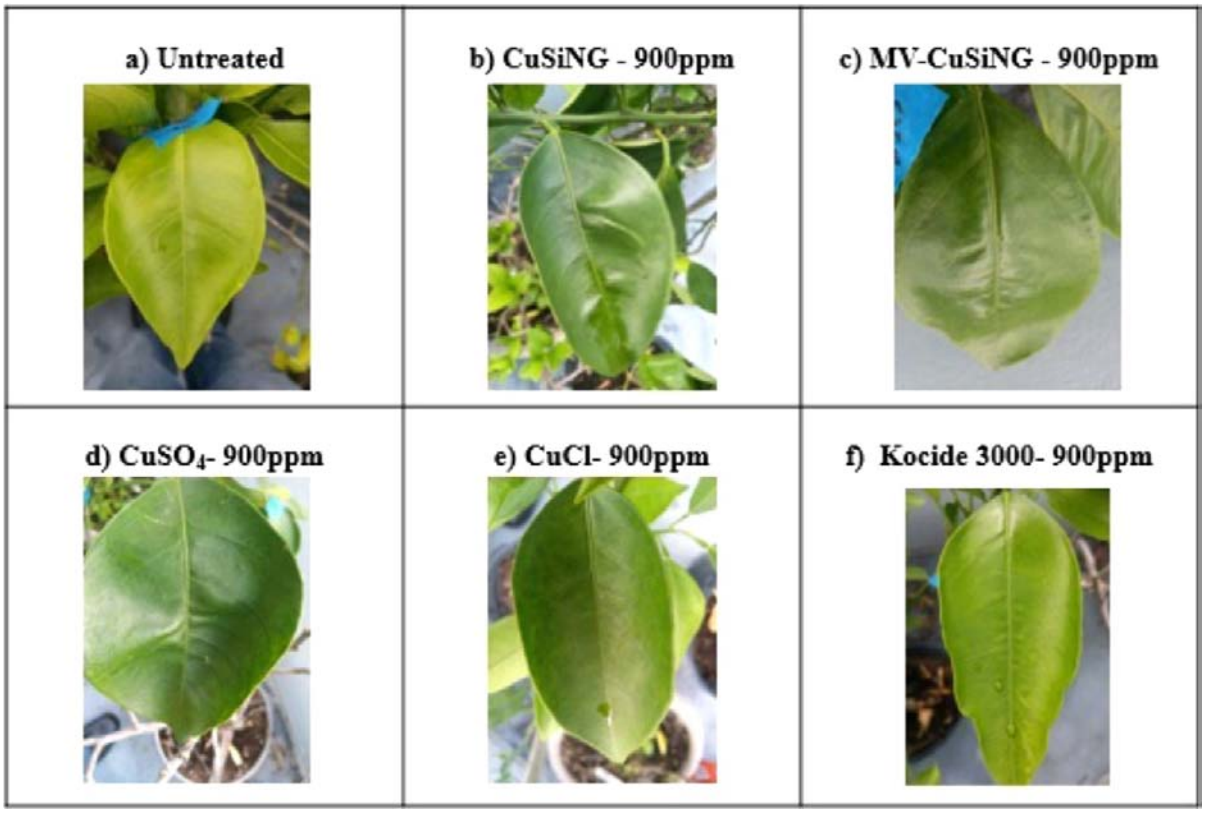

Figure 12. Images of Hamlin orange 72 h after application of CuSiNG materials and controls at a Cu concentration of 900 ppm.

The gene *copA* is responsible for limited Cu resistance within *E. coli*. It is responsible for Cu(I) efflux pumps, which transport Cu(I) ions from the cytoplasm to the periplasm to prevent Cu(I) accumulation.[23] *E. coli copA1(del)::kan* was far more susceptible to the MV-CuSiNG material than regular *E. coli*. Both MV-CuSiNG and CuSiNG along with CuCl materials performed better than the other controls against the *E. coli* mutant. This confirms the separate mechanism of Cu(I) toxicity. Improved efficacy of the mixed-valence Cu system has been correlated to the increased number of growth inhibition pathways in comparison to the Cu(II)-rich system. *E. coli copA1(del)::kan* was far more susceptible to the MV-CuSiNG material than regular *E. coli*, confirming the significant role of Cu(I) in growth inhibition. The high antimicrobial potency of Cu(I) was validated using the *E. coli copA1(del)::kan* model system (with no Cu(I) efflux pump) and MV-CuSiNG nanogel material enriched with Cu(I). MIC results reinforced and confirmed that the MV-CuSiNG formula was more efficient than Cu(II) only systems, exhibiting improved antimicrobial efficacy in *X. alfalfae*, *E. coli*, and *E. coli copA1(del)::kan* (Table 1).

Plant tissue damage potential (phytotoxicity) of MV-CuSiNG and CuSiNG with controls was tested on Hamlin orange and *Vinca* sp. *Vinca* sp. is highly susceptible to Cu phytotoxicity and therefore used as a model plant. *Vinca* sp. exhibited moderate to high levels of plant tissue damage when exposed to copper-containing agents including CuSiNG and MV-CuSiNG materials. Plant tissue damage was seen for all other copper formulations with the exception of Kocide 3000. All formulations showed no damage at 90 ppm but caused moderate to serious damage at 900 ppm (Table 2 and Figure 11). Hamlin orange was also tested as a model for citrus species. Hamlin orange exhibited strong tolerance to Cu-induced phytotoxicity even at the highest (900 ppm) metallic Cu concentrations for all formulations after 3 days (Table 3 and Figure 12). Phytotoxicty was absent in Hamlin orange, whereas it occurred in higher Cu concentrations in *Vinca* sp. for MV-CuSiNG material and controls. This could be attributed to residual copper ions present in the formulations. Copper hydroxide is the active Cu compound in Kocide 3000, and it is water-insoluble. Availability of Cu ions in Kocide 3000 is therefore very limited. As a result, Kocide 3000 exhibited no sign of phytotoxicity to *Vinca* sp. and Hamlin orange. These results indicate that MV-CuSiNG material requires further development before it can be used for protection of ornamental plant species, but in its current state it is very suitable for use in citrus crop protection.

We have successfully tested the hypothesis that a MV Cu system containing Cu in 0, +1, and +2 will exhibit improved antimicrobial potency relative to Cu(II) systems. Sodium borohydride (a model reducing agent) may not be a suitable reagent for large-scale production of MV-CuSiNG for agricultural applications; however, MV-CuSiNG material can be scaled up by using a mixture of Cu(I)- and Cu(II)-containing starting materials. We are currently characterizing such MV-CuSiNG materials and evaluating their antimicrobial efficacy. We will report our results in subsequent publications.

Identification of Pheromone Synergists for *Rhynchophorus ferrugineus* Trapping Systems from *Phoenix canariensis* Palm Volatiles

Sandra Vacas,* María Abad-Payá, Jaime Primo, and Vicente Navarro-Llopis

Centro de Ecología Química Agrícola, Instituto Agroforestal del Mediterráneo, Universitat Politècnica de València, edificio 6C, 5ª planta, Cmno. de Vera s/n, 46022 Valencia, Spain

ABSTRACT: Trapping systems for the red palm weevil, *Rhynchophorus ferrugineus* Olivier, rely on the use of natural plant odor sources to boost the attractiveness of the aggregation pheromone. The identification of the key odorants involved in attraction is essential in the development of a synthetic pheromone synergist to replace the nonstandardized use of plant material in traps. Canary Islands date palms (*Phoenix canariensis*) have become preferred hosts for *R. ferrugineus* in Europe; thus, the volatile profile of different *P. canariensis* plant materials, including healthy and infested tissues, is investigated in the present work by means of solid phase microextraction (SPME-GC-MS), aimed to identify pheromone synergists. The electroantennography (EAG) response of the compounds identified was recorded, as well as the preliminary field response of several EAG-active compounds. The so-called "palm esters" (ethyl acetate, ethyl propionate, ethyl butyrate, and propyl butyrate) elicit the strongest EAG responses but performed poorly in the field. Mixtures of esters and alcohols give evidence of better performance, but release rates need further optimization.

KEYWORDS: *red palm weevil, Rhynchophorus ferrugineus (Coleoptera: Curculionidae), ferrugineol, kairomone, host attractants, Phoenix canariensis (Arecales: Arecaceae), Canary Islands date palm, SPME*

INTRODUCTION

Integrated pest management strategies play an important role in controlling the red palm weevil, *Rhynchophorus ferrugineus* (Olivier) (Coleoptera: Curculionidae), given this pest's concealed nature and its exceptional colonization capability. Larvae are the most destructive stage of this weevil as they penetrate deep into the stem, damage its internal tissues, disrupt nutrient transport, and even lead to tree collapse and death.[1] Red palm weevil was first described to attack coconut palms, but it has been reported to affect 30 palm species belonging to 17 different genera.[2−4] Since *R. ferrugineus* invaded the Mediterranean Basin and reached southern Europe in 1993,[5] it has become the most damaging pest for Canary Islands date palms [*Phoenix canariensis* (hort. ex Chabaud) (Arecales: Arecaceae)].[6−8] In the past 20 years in Europe, *R. ferrugineus* has demonstrated a strong preference for *P. canariensis* compared with other palm species such as *Phoenix dactylifera* L. or *Washingtonia* spp. In our region (the east coast of Spain), local government institutions have reported this preference on the basis of inspections made of thousands of palm trees. By way of example, 16% of a total of 2699 *P. canariensis* in the city of Valencia (eastern Spain) were infested during 2011−2012, whereas only 0.7% of a total 5925 *P. dactylifera* specimens were infested.[9] Moreover, the red palm weevil seems to prefer male to female Canary Islands palms. According to the Detection and Eradication Campaign developed by the regional Valencian government, 76.2% of the infested *P. canariensis* were male specimens, taking into account that the sex ratio in this area is ca. 60:40 (males/females) (data provided by Conselleria de Agricultura, Peixca i Alimentació, Generalitat Valenciana). The same was observed in the city of Valencia, where 74.7% of the attacked *P. canariensis* were males and 18.5% were females, with 6.8% undetermined.[9]

Generally, attack is detected only after the palm has been seriously damaged; thus, most efforts are made to develop methods that detect early stages of infestations, such as visual inspection, sniffing dogs,[10,11] and acoustic[12−14] and thermal detection.[15] Preventive and curative procedures have been investigated and proposed as control methods, which include chemical control[16−20] and biological control with entomopathogenic organisms, nematodes,[21−23] and fungi.[24,25] However, trapping systems through mass trapping play an important role for both detection and control purposes. This system does not create resistances, but allows population monitoring and helps enhance the efficacy of other control methods to reduce weevil populations and the number of insecticide applications. The introduction of pheromone-based trapping systems was possible thanks to the discovery of the red palm weevil aggregation pheromone component 4-methyl-5-nonanol (ferrugineol).[26] In general, male-produced aggregation pheromones for palm weevil consist of 8−10 carbon, methyl-branched secondary alcohols.[27] However, the attractant power of these pheromones tends to be weak in the traps deployed in the field, and the presence of synergistic plant tissues or other food attractants is required.[28−30] Unfortunately, this is a nonstandardized, costly, and cumbersome practice because the plant material needs to be replaced frequently to maintain the attractant level.

[a]Attractant contained in Picusan traps: ph, aggregation pheromone dispenser (Ferosan RF); esters mix, (ethyl acetate + ethyl propionate + ethyl butyrate + propyl butyrate); EtAc, ethyl acetate; EtOH, ethanol; alcohol mix, (ethanol + 3-methyl-1-butanol); phenyl-EtOH, 2-phenylethanol. [b]Reference attractant employed for the main comparison: ph, aggregation pheromone; complete bait, molasses (10%) + water (2 L) + plant material (*P. canariensis* stem pieces).

Adult female weevils are attracted to and oviposit in healthy, stressed, or damaged palms[31] as they are attracted by a range of stimuli. However, attractiveness for weevils is generally boosted by the fermentation volatiles emanating from wounds or those resulting from infestation.[27,32] Ethyl esters are common volatile constituents in fermenting palm oils, sap, and plant tissues.[27,29,30] Many of these esters elicit significant electrophysiological responses in palm weevil species. Currently, however, they still prove less effective than the plant material used in traps when employed alone or combined.

This work investigates the volatile profile of different *P. canariensis* plant materials, including healthy and infested tissues, by means of solid phase microextraction (SPME), with a view to identifying pheromone synergists for red palm weevil. For this purpose, both the electroantennography (EAG) response of the identified volatiles and the preliminary field response of the most EAG-active compounds were recorded.

MATERIALS AND METHODS

Plant Material. Different *P. canariensis* palm materials were sampled for volatile collection and compound identification: (1) freshly cut petiole and rachis pieces of nonsprayed female and male *P. canariensis* palm leaves; (2) fresh healthy meristem stem tissues; (3) male inflorescence, including rachis and flowers; (4) infested stem tissues, upon which weevil larvae were feeding; (5) leaf pieces fermented in a 10% sugar water solution under field conditions; and (6) fermented stem pieces from the traps of the monitoring system deployed in Elche (Alicante, eastern Spain), which were also baited with a 10% molasses water solution. Fermented materials were collected when they still displayed attractant activity (1 or 2 weeks old).

Volatile Collection. The three replicates of each experimental case were simultaneously collected by SPME using Supelco SPME holders equipped with a polydimethylsiloxane/divinylbenzene fiber (PDMS/DVB), film thickness = 100 μm (Supelco Inc., Bellefonte, PA, USA). SPME fibers were conditioned before volatile sampling in a GC injector at 250 °C for 10 min under a 20 mL/min helium flow rate.

Each sample was placed inside a 1.3 L glass chamber with a screw-top polytetrafluoroethylene (PTFE)−silicone septum cap (Supelco Inc.) in the middle. Chambers were connected to the outlet of an air compressor (Jun-air Intl. A/S, Norresundby, Denmark) coupled with an AZ 2020 air purifier system (Claind Srl, Lenno, Italy) to provide ultrapure air (amount of total hydrocarbons <0.1 ppm). Before each chamber, an ELL-FLOW digital flowmeter (Bronkhorst High-Tech BV, Ruurlo, The Netherlands) was installed to run an air flow of 20 mL/min during sampling. Under these conditions, SPME needles were inserted through the septa, and fibers were exposed to each sample for the required period (3 h for the affected and fermented samples; 20 h for the green material) at 26 ± 1 °C. Then, fibers were removed and inserted into the GC injection port to desorb volatiles.

Detection and Identification of Volatiles. SPME fibers were thermally desorbed into the GC injection port, set at 250 °C for 1 min, and operated in the splitless mode. The extracted volatiles were analyzed by gas chromatography coupled with mass spectrometry (GC-MS) using a Clarus 600 GC-MS (PerkinElmer Inc., Wellesley, MA, USA). The column used was a 30 m × 0.25 mm i.d., 0.25 μm, ZB-5MS fused silica capillary column (Phenomenex Inc., Torrance, CA, USA). The oven was held at 40 °C for 3 min and then programmed at 3 °C/min to 60 °C, followed by 6 °C/min to 160 °C; when reached, temperature was raised to 260 °C at 12 °C/min and maintained at 260 °C for 5 min. Helium was used as the carrier gas with a flow rate of 1.2 mL/min. Detection was performed in the EI mode (ionization energy, 70 eV; source temperature, 180 °C), and spectra acquisition was done in the scanning mode (mass range m/z 35−400). Chromatograms and spectra were recorded with GC-MS Turbomass software version 5.4 (PerkinElmer Inc.).

Compounds were identified by comparing their retention times and mass spectra with those of pure standards (confirmed identification). They were all purchased from Sigma-Aldrich Química SA (Madrid, Spain), and their purity was ≥98−99% by GC-MS except for β-myrcene (≥90%); limonene, α-copaene, and aromadendrene (>90%, sum of enantiomers); ocimene and farnesene (90%, mixture of isomers); β-caryophyllene (≥80%); and 3-hydroxy-2-butanone (>96%). Unfortunately, it was not possible to obtain the commercial standards of some compounds, so their identification was tentative and based on high-probability matches (>80%) according to the NIST MS Search routine (NIST Mass Spectral Search Program for the NIST \EPA\NIH Mass Spectral Library, version 2.0, build 4/2005).

Electrophysiological Antennal Activity. Once identified, the electroantennographic response triggered by the compounds was

Table 2. Compounds Detected in the Different *P. canariensis* Samples

[a]Means of three replicates. [b]RT, retention time (min) on ZB-5 column (30 m × 0.25 mm i.d. × 0.25 μm; Phenomenex Inc., Torrance, CA, USA). [c]Identification of the compound: C, confirmed with commercial standard; T, tentative with spectra and high probability matches (>80%) according to NIST mass spectral database.

dx.doi.org/10.1021/jf502663y | J. Agric. Food Chem. 2014, 62, 6053−6064

evaluated with a Syntech IDAC 2 acquisition controller and a Syntech CS-55 stimulus controller (Ockenfels Syntech GmbH, Kirchzarten, Germany), whereas GC-EAD 32 (v 4.3) software was employed for data acquisition. The EAG tests for each compound had seven replicates per sex, with each antenna belonging to seven different weevils. Individuals were collected from the field, maintained at 26 ± 2 °C under photoperiod conditions (10 h light and 14 h dark), and fed apples. Antennae were removed from living insects, cut off as close as possible to their base with fine-point stainless steel entomology scissors, whereas the club remained unaltered. After excision, the antenna was placed immediately on a fork holder, the flat tips of which had been previously covered with a small bead of Spectra 360 electrode gel (Parker Laboratories Inc., Fairfield, NJ, USA). The holder was then mounted in an EAG probe type PRG-2 (Syntech) to be connected directly to the IDAC-2 system. Test and control samples were prepared in hexane solution, and 1 μL aliquots were applied to filter paper strips. The solvent was allowed to evaporate for 30 s before the strip was placed into a disposable Pasteur pipet. The olfactory stimulus (1 s duration) was delivered into a continuous humidified charcoal-filtered air stream (400 mL/min) toward the antenna, after placing the pipet tip into the hole of the tube carrying the air stream. Each antenna was stimulated successively with the solvent, the positive reference (1 μg of ferrugineol), and no more than four different test compounds (1 μg). Stimuli were applied at 3 min intervals. To eliminate the variability of the response due to the different antennae conditions, the EAG test results are provided as the ratio: mV_C/mV_F, where C is the response for each compound and F is the response of the reference stimulus, which was 1 μg of ferrugineol in all cases.

Preliminary Field Tests. The compounds that triggered the most significant electrophysiological responses were included in the preliminary field tests to study the weevils' actual response under field conditions, using Picusan traps (Sansan Prodesing SL, Náquera, Valencia, Spain), the bases of which were filled with water.[33] All of the trials were designed as randomized block assays and were carried out in different locations in the Valencian community (on the Spanish eastern coast): Godelleta, Manises, Valencia, and Elche. The revision of catches and rotation of traps were performed on a weekly basis. In all of the trials, the traps within each block were separated by at least 30 m and the distance between blocks was at least 100 m.

The different attractants compared are detailed in Table 1, which also includes the number of blocks in each trial and the dates when the tests were conducted. The aggregation pheromone (ph) dispenser employed in all cases was Ferosan RF (Sansan Prodesing SL), loaded with 1 g of ferrugineol. Mixtures of compounds were formulated in low-density polyethylene vials to obtain controlled release rates. The gravimetric method was employed to assess the amount of active ingredients released in relation to the aging time. In parallel to the field trials, three corresponding dispensers of each type were aged under the same field conditions inside the same type of trap. These dispensers were weighed weekly in the laboratory on a precision balance. The weight differences over a period were referred to as the active mixture released from the dispenser. To obtain the mean emission level for each dispenser, recorded weights were fitted to linear regression models, $y = a + bx$, where y is the weight of the dispenser and x is the corresponding aging days. The resulting mean release rates refer to the mixtures released from the polyethylene vials. In addition, several samples of aged dispensers were also analyzed by gas chromatography (GC-FID) to check the proportions at which ethyl acetate and ethanol were emitted in the mixtures tested in trial 5.

The number of weevils captured with each experimental attractant was compared with that obtained in the traps baited only with ferrugineol (ph) or with the complete bait employed in the Valencian community red palm weevil monitoring network, which is composed of water, 10% molasses solution, and *P. canariensis* palm stem pieces.

The number of males, females, or total weevils recorded during each trapping period was divided by the number of days between dates to calculate the weevils per trap and day index (WTD). Log (WTD+1) transformation was applied to normalize the errors distribution prior to the analysis of variance (ANOVA), followed by LSD test (at $P < 0.05$). The Statgraphics Centurion XVI package was employed to perform the statistical analysis (Statpoint Technologies Inc., Warranton, VA, USA).

RESULTS AND DISCUSSION

Overview of Detected Compounds. Table 2 reports the 122 compounds detected in the different *P. canariensis* palm samples. Of these, 81 were confirmed with commercial standards and 32 were tentatively identified (most of them being sesquiterpenes with no available standards).

The main constituents of the palm leaf volatile samples were identified as cyclosativene, α-copaene, and δ-cadinene which, all together, assumed ∼70% of the total chromatogram area. Terpene hydrocarbons (mostly monoterpenes $C_{10}H_{16}$ and sesquiterpenes $C_{15}H_{24}$) are the largest group of airborne natural products emitted by vegetation and are responsible for both floral and fruity aromas and a mild, wood-like odor.[34] The remaining compounds detected in palm leaves were other terpenes, except for ∼5%, which comprised alkanes, aldehydes, and 2,6-dimethylnaphthalene (probably a contaminant from the aeration system). The volatile profiles of the female and male *P. canariensis* palm leaves were not significantly different if compared to the reported qualitative and relative composition (Table 2); only decanal and α-terpinolene were not detected in the male profile. Consequently, the volatile profile does not seem to explain the greater susceptibility of male palms observed in the field. Thus, other physical factors could affect the oviposition preferences of females or make larvae's feeding habits difficult.

Benzoates, such as ethyl and methyl benzoate, were the main constituents of the healthy tissue volatile profile (∼99% of the total chromatogram area), which are reported to confer floral and fruity odors.[35,36] As expected, male inflorescence presented traces of several aldehydes (0.5%), which are commonly found in essential oils and contribute to their favorable odors (citrusy, floral, and green aromas).[37] Several alkanes were also detected (2.4%), but sesquiterpenes were the main constituents. Unfortunately, it was not possible to identify the most abundant compound (45.1%), but the mass spectrum suggests a sesquiterpene structure [m/z 91 (50), 105 (45), 119 (100), 131 (40), 132 (50), 145 (38), 159 (25), 187 (21), 202 (12)] with a molecular weight of 202. Nonetheless, some GC-EAD coupled tests performed with SPME replicates of these samples did not evidence any electrophysiological activity for this unidentified compound (data not shown).

The volatile profile of the palm material dramatically changes when tissues are either affected by the pest or subjected to fermentation processes in traps; then esters, acids, alcohols, and ketones are the main constituents of the volatile profile of this plant material (Table 2). Short-chain fatty acids (acetic, propanoic, butanoic, etc.), associated with off-flavors, are the main products of the fermentative microorganisms responsible for anaerobic plant fiber degradation. A substantial part of many arthropods' diet consists of plant-derived polymers, such as lignin, hemicellulose, and cellulose,[38] which is the case for *R. ferrugineus* larvae. After egg hatching, larvae bore galleries into the palm and leave a frass, composed of excrements and plant debris with a high water content. The production of CO_2, 3-hydroxy-2-butanone (acetoin), ethanol, and ethyl lactate, among others, is associated with the bacterial community present in the frass.[39] In general, the relative distribution of the volatiles in degraded samples can be determined by several factors during fermentation, including microorganism species and/or strain, fermentation temperature, nutrient availability,

[a]Relative response: ratio = (mV compound)/(mV ferrugineol). [b]Means of seven replicates for each sex.

pH, unsaturated fatty acid levels, etc.[40−42] The formation of fatty acid ethyl esters and acetate esters confers floral and fruity sensory properties. Fatty acid esters (such as ethyl butyrate, ethyl hexanoate, and ethyl octanoate) result from the ethanolysis of acylCoA, which is produced during fatty acid synthesis or degradation. Acetate esters (such as butyl acetate, isoamyl acetate, hexyl acetate, and phenethyl acetate) are formed from the reaction of acetylCoA with the alcohols that result from the degradation of amino acids, carbohydrates, and lipids.[40,43] Biodegradation of lignin from plant tissues by rot fungi and bacteria can also generate the phenolic compounds detected (guaiacol, *p*-methylguaiacol, etc.),[44] which are associated with smoky or spicy trait.[45]

Electrophysiological Antennal Activity. Seventy-four compounds were tested for EAG responses (Table 3). The largest number of significant responses was elicited by the esters identified in the degraded samples for both male and female weevils, followed by alcohols and ketones. Propyl butyrate, ethyl propionate, ethyl butyrate, ethyl 2-methylbutyrate, ethyl valerate, and 3-hydroxy-2-butanone (acetoin) elicited the most significant responses, which were comparable to the reference ferrugineol (ratio ≥1) for males, whereas 2-phenylethanol, ethyl propionate, ethyl acetate, and acetoin

were the most active for females. The palm esters (ethyl propionate, ethyl acetate, ethyl butyrate, etc.) that elicited significant antennal responses have already been reported by Gries et al.[29] for *R. phoenicis* L., *R. palmarum* L., *R. cruentatus* (Fabricius), *R. ferrugineus*, *R. vulneratus* (Panz.), and *R. bilineatus* (Montrouzier). Later, while testing the antennal responses of several palm esters (ethyl acetate, ethyl butyrate, ethyl isobutyrate, and ethyl lactate), Guarino et al.[46] reported that ethyl propionate was the ester that elicited the strongest response for *R. ferrugineus* and for both females and males. Aldehydes and terpene hydrocarbons, these being characteristic compounds of inflorescence and palm leaves, elicited only intermediate responses in our tests.

Preliminary Field Activity. Nevertheless, the EAG tests do not provide conclusive ideas about the attractiveness and potential of each compound as semiochemical under field conditions. Indeed, the mechanisms responsible for EAG and field activity are different, and possible correlations between them should be considered with caution, as should the possible synergistic effects of blends for single compounds. For example, Giblin-Davis et al.[47] reported the attraction of *R. cruentatus* to some fermentation products. Yet, whereas isopropyl acetate elicited a major EAG response but not significant attractiveness in traps, ethanol elicited a minor relative EAG response, but proved attractive in the field when combined with the pheromone cruentol. This scenario coincides with the main findings of our preliminary field tests. In trial 1 (Figure 1A), when traps were baited with a mixture of the most EAG-active esters (ethyl acetate, ethyl propionate, ethyl butyrate, and propyl butyrate), the attractant power of the traps did not significantly differ from that of the traps baited only with pheromone for female, male, and total weevil catches (the significance of the factors is provided in Table 4 for the ANOVA performed using the data collected per sex and for total catches). Thus, the addition of these esters, in the proportion and at the emission level employed (Table 5), did not significantly improve weevil catches. The same was observed when ferrugineol was combined with acetoin or with esters and acetoin (Figure 1A and Table 4), these being the compounds that elicited the strongest EAG responses.

Whereas the combination of esters and ketones did not offer any advantage if compared to using the aggregation pheromone alone, the total weevil catches significantly increased when the ethyl acetate ester was combined with ethanol (Figure 1B), which was due mainly to the significant female captures obtained (trial 2) (Table 4). The total weevil catches almost doubled with this kairomonal mixture. When a second alcohol (3-methyl-1-butanol) was added to the mixture (alcohol mix in Figure 1B), catches did not significantly improve with regard to ethyl acetate + ethanol, suggesting that addition of this alcohol is irrelevant, at least under our particular test conditions (trial 2) (Table 5).

Although 2-phenylethanol elicited a strong antennal response for female *R. ferrugineus*, no synergistic effect was observed when it was added to traps in combination with ethyl acetate in trial 3 (Figure 1C and Table 4), whereas the combination (ethyl acetate + ethanol) still achieved significantly larger female, male, and total catches. The same was observed in Elche for trial 4 (Figure 1D and Table 4). Whereas the female catches obtained in traps baited with 2-phenylethanol combined with ethyl acetate did not significantly differ from those baited with only pheromone, the results obtained with ethyl acetate + ethanol + 3-methyl-1-butanol were significantly

[a]Release profile studies by gravimetric method; linear model fittings (R^2) are also provided.

mixture did not substantially differ from that obtained with the complete bait (water + molasses + palm material + pheromone). Nevertheless, as found in trial 2, the activity of this synthetic mixture was due to ethyl acetate + ethanol, and the addition of 3-methyl-1-butanol did not improve efficacy.

Although ethyl acetate + alcohol mix in trial 4 performed significantly better than pheromone alone for the total weevil catches, the mixture did not reach the level of catches obtained with the complete bait, which was due mainly to the lack of differences in male catches (Figure 1D). Nevertheless, the data on the increased female catches offered promising results. Trial 5 was conducted in an attempt to adjust the proportion of the kairomonal active ingredients by testing 1:3 and 3:1 blends (v/v) of ethyl acetate/ethanol (Table 1). The results showed that the efficacy of Picusan traps baited with pheromone and the 1:3 ethyl acetate/ethanol blend did not significantly differ from those baited with the complete bait for the female, male, and total weevil catches (Figure 1E and Table 5). Although the mixture may still be incomplete, or need dose/proportion adjustments, the results suggest that it is possible to develop a synthetic kairomone to avoid the use of plant material to boost trap attractiveness.

The literature provides no conclusive results about currently employed synthetic kairomones having efficacy equal to or better than fermenting plant material for any *Rhynchophorus* sp. Ethyl acetate and several other esters were tested with cruentol to trap *R. cruentatus* in the field, but the efficacy was significantly poorer than that of fermenting sugar cane.[47] For *R. phoenicis*, ethyl propionate combined with phoenicol improved the efficacy of phoenicol + ethyl acetate, but it was still less effective than freshly cut oil palm tissues.[29] Rochat et al.[30] reported field trappings of *R. palmarum* with synthetic plant odors as compared to sugar cane. Despite not being significantly different, the complex synthetic blend ethyl acetate + ethanol + base fermentation odors + coconut volatiles (28 compounds) was 82% efficient if compared to sugar cane, but was better than the 1:1 ethyl acetate/ethanol blend, which can accomplish 50% efficacy compared to sugar cane. We found that this blend was synergistic for *R. ferrugineus*, as it increased weevil catches by 2 times as compared to aggregation pheromone alone (Figure 1B). Moreover, the 1:3 ethyl acetate/ethanol blend achieved 76% efficacy if compared to the total weevil catches obtained with the natural kairomone employed in Spain (palm stem + molasses), as found in trial 5. The GC-FID analysis of the aged dispenser samples demonstrated that the mixture was emitted in a 2:3 ratio (ethyl acetate/ethanol).

Many studies have shown that the addition of ethyl acetate to traps emitting aggregation pheromones (with or without food bait) increases attraction for *R. ferrugineus* adults.[48−50] Attraction of ethyl acetate + pheromone is sufficiently good if compared to pheromone + food bait (fermented date fruits) in

Oman.[50] Nevertheless, whether any of these combinations improves the efficacy of aggregation pheromone alone was not shown. Yet the results of our trial 5 (Figure 1E) reveal that the attraction of ethyl acetate + pheromone was significantly poorer than that of pheromone + food bait (palm stem pieces + molasses). This different result might be due to a greater efficacy of palm tissues + molasses if compared to date fruits as food baits, which highlights the importance of developing a synthetic kairomone to replace the use of nonstandardized food baits, which can provide diverse efficacy.

The results of the present study show the good field performance of ethyl acetate combined with ethanol, but further trials are required to optimize release rates. Designing dispensers that optimize the release rate of each compound can improve the results obtained in these trials. These findings can provide us with an inexpensive synthetic kairomone that is capable of avoiding trap servicing every 2 weeks, which would be a clear advantage for red palm weevil mass trapping and detection strategies.

Glucose Positions Affect the Phloem Mobility of Glucose−Fipronil Conjugates

Zhiwei Lei,[†] Jie Wang,[†] Genlin Mao, Yingjie Wen, Yuxin Tian, Huawei Wu, Yufeng Li, and Hanhong Xu*

State Key Laboratory for Conservation and Utilization of Subtropical Agro-bioresources, and Key Laboratory of Natural Pesticide and Chemical Biology, Ministry of Education, South China Agricultural University, Guangzhou, Guangdong 510642, People's Republic of China

Supporting Information

ABSTRACT: In our previous work, a glucose−fipronil (GTF) conjugate at the C-1 position was synthesized via click chemistry and a glucose moiety converted a non-phloem-mobile insecticide fipronil into a moderately phloem-mobile insecticide. In the present paper, fipronil was introduced into the C-2, C-3, C-4, and C-6 positions of glucose via click chemistry to obtain four new conjugates and to evaluate the effects of the different glucose isomers on phloem mobility. The phloem mobility of the four new synthetic conjugates and GTF was tested using the *Ricinus* seedling system. The results confirmed that conjugation of glucose at different positions has a significant influence on the phloem mobility of GTF conjugates.

KEYWORDS: *phloem mobility, glucosyl conjugates, click chemistry, glycosyl azides, glucose positions*

INTRODUCTION

The phloem is one of the two long-distance transport pathways in plants.[1] The phloem mobility of pesticides is an essential requirement that contributes positively to its efficacy.[2] Pesticides with good phloem mobility can have an efficacious function in controlling hidden and soil-dwelling pests[3] because these pesticides can be distributed along with the nutrients via the phloem to pest-damaged sites.[4] In addition, the agricultural sector needs novel pesticides that have sufficient phloem mobility in plants because of their evolved resistance, environmental regulations, and economic considerations.[5] For modern synthetic insecticides, the most effective mode of transport in plants is via the xylem, and only a few phloem-mobile insecticides are available. An efficient and economical strategy to develop novel systemic pesticides has been mentioned, in which the structure of the parent compounds is modified by adding endogenous carboxylic acid, amino acid, and hexose derivatives.[2,3,6,7] For example, ε-(2,4-dichlorophenoxyacetyl)-L-Lys, a conjugate of an α-amino acid and an auxenic herbicide, exhibits high phloem mobility in broad bean (*Vicia faba*).[7] IPGN, a novel fluorescent conjugate containing glucose, could enter *Ricinus communis* phloem.[8]

Our research team focuses on exploring the possibility of glycosylation to develop new phloem-mobile pesticides. *N*-[3-Cyano-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)-sulfinyl]-1*H*-pyrazol-5-yl]-1-(β-D-glucopyranosyl)-1*H*-1,2,3-triazole-4-methanamine (GTF) has been synthesized, and a systemicity test demonstrated that the glucose core confers phloem mobility to fipronil.[9] To fully understand the function of the sugar core in the phloem-mobile molecule, a series of monosaccharide−fipronil conjugates were synthesized in our further study. Phloem mobility tests in castor bean seedlings indicated that the hydroxyl of the monosaccharide has a significant effect on the phloem mobility of the conjugates.[10]

Glucosyl derivatives, which are conjugated at different carbons of glucose, have different properties. For example, the new glucosyl dopamine conjugates substituted at C-6 of the sugar were more potent inhibitors of glucose transport compared to C-1- and C-3-substituted derivatives.[11] (7-Nitrobenz-2-oxa-1,3-diazol-4-yl)-amine (NBD) replaced at C-6 of the sugar cannot be phosphorylated by hexokinase, but NBD substituted at C-2 can be metabolized to 2-NBDG-6-phosphate.[12] In addition, several different (C-2, C-3, C-4, and C-6) natural glucosides are found in nature.[13] Therefore, biological properties of the glucosides have a correlation with different positions of glucose.

All of the monosaccharide−fipronil conjugates were linked at C-1 of the monosaccharide,[8,9] which gives rise to consider if parent compounds linking different positions of the glucose may have different phloem mobilities. In the present work, four novel glucosyl conjugates were designed and synthesized by linking the fipronil to C-2, C-3, C-4, and C-6 of glucose via click chemistry to study the effects of the different positions of glucose on phloem mobility.

MATERIALS AND METHODS

General Information for Synthesis. Melting points were determined on a FP62 digital micro melting point apparatus. Nuclear magnetic resonance (NMR) spectra were obtained on a Bruker AV-600 instrument. Deuterated solvents were obtained from Cambridge Isotope Laboratories (Andover, MA). CD_3OD and $CDCl_3$ solvent peaks (3.31 and 7.26 ppm for ^1H and 49.0 and 77.0 ppm for ^{13}C, respectively) were used as internal chemical shift references. The mass spectra (MS) of new compounds were obtained by a Waters ZQ 4000 with electronspray ionization (ESI) or a Bruker maXis 4G ESI-Q-TOF mass spectrometer. Data were reported as m/z. Silica gel was used for column chromatography. Reagents and anhydrous solvents were used as purchased without further purification.

Plant Materials. Castor bean seeds (*R. communis*) No. 9, obtained from the Agricultural Science Academy of Zibo, Shandong, China, were sown and grown as previously described.[6] Six-day-old seedlings (the hypocotyl at about 20 mm in length) were relatively selected for further experiments.

Table 1. Properties of the Tested Compounds[a]

properties	GTF	2-GTF	3-GTF	4-GTF	5-GTF
MW	680.37	680.37	680.37	680.37	680.37
log K_{ow}	2.06	1.11	1.42	1.41	1.58
pK_a	12.8 ± 0.7	11.9 ± 0.7	12.0 ± 0.7	12.0 ± 0.7	12.1 ± 0.7
HBD	5	5	5	5	5
HBA	13	13	13	13	13

[a]The physicochemical properties of tested compounds were predicted by ACD Laboratories Percepta program, version 14.0. Log K_{ow} and pK_a values were classic values. 2-GTF, 3-GTF, 4-GTF, and 6-GTF mean that fipronil was conjugated at the C-2, C-3, C-4, and C-6 positions of glucose, respectively. All values (MW, HBD, and HBA) are the same for the different compounds.

Membrane Potential Measurements. Plasma membrane potential of the protoplasts of *R. communis* cotyledons was performed with flow cytometric analysis using a fluorescent membrane potential indicator dye bis(1,3-dibutylbarbituric acid)-trimethine oxonol [DiBAC4(3)]. The protoplasts were incubated with buffer solution without (control) or with the five glucosyl fipronil conjugates at 100 μM concentration for 5 h, and then the protoplast suspension was co-incubated with 3 μM DiBAC4(3) for 30 min at 28 °C prior to flow cytometric analysis.

Phloem Sap Collection and Analysis. The seedlings with 6 days of development were prepared for phloem sap collection. The phloem sap was collected from the upper part of the hypocotyl, which was similar to that recently described.[6,14] The cotyledons were removed from endosperm carefully without bending or crushing the cotyledons. The cotyledons were incubated in buffered solution supplemented with 100 μM glucosyl fipronil conjugtes. After 1 h of preincubation, the hypocotyl was severed in the hook region for phloem exudation. Phloem sap was collected from the upper part of the hypocotyl at a 1 h interval for 5 h and was stored at 4 °C until analysis.[15]

The collected phloem sap, diluted with pure water [1:4 (v/v) phloem sap/H_2O], was quantified by an Agilent 1100 HPLC system. Separations were made with a C8 reversed-phase column (5 μm, 250 × 4.6 mm inner diameter, Agilent Co.) at 30 °C. The injection was 10 μL, and the flow rate was 1 mL/min. The elution system consisted of acetonitrile and water (50:50, v/v). The conjugates detected in the phloem sap were further identified using ultra-performance liquid chromatography–mass spectrometry (UPLC–MS, Waters, Milford, MA). Samples were separated using an ACQUITY UPLC BEH C18 column (1.7 μm, 2.1 × 100 mm, Waters). The parameters were similar to our previously reported method.[16]

Physicochemical Properties. The physicochemical properties [molecular weight (MW), ionization constant in aqueous solution (pK_a), octanol/water partitioning coefficient (log K_{ow}), number of hydrogen bond donors (HBDs), and number of hydrogen bond acceptors (HBAs)] of different positions of glucose conjugates were predicted using ACD LogD suite version 14.0 software (Table 1).

*Synthesis of 1,3,4,6-Tetra-O-acetyl-2-azido-2-deoxy-β-D-glucoside (**2a**) (Scheme 1).* 2-Azido-2-deoxy-D-glucose (205 mg, 1 mmol) was dissolved in pyridine (5 mL), and then acetic anhydride (Ac_2O, 3 mL) was added with catalytic dimethylaminopyridine (DMAP, 6.1 mg, 0.05 mmol). After the solvents were stirred for 12 h at room temperature, they were removed under reduced pressure and the residue was diluted with CH_2Cl_2. The solution was washed with 1 M HCl and saturated $NaHCO_3$ solution, dried with $MgSO_4$, concentrated under reduced pressure, and purified by column chromatography (1:1 ethyl acetate/hexane) to obtain compound **2a**. White power; yield, 78%; melting point (mp), 80.4 °C; ^{1}H NMR (600 MHz, $CDCl_3$) δ, 5.54 (d, J = 8.6 Hz, 1H, H-1), 5.08 (t, J = 9.6 Hz, 1H, H-4), 5.03 (t, J = 9.6 Hz, 1H, H-3), 4.29 (dd, J = 12.5 and 4.5 Hz, 1H, H-6-a), 4.07 (dd, J = 12.5 and 2.1 Hz, 1H, H-6-b), 3.80 (ddd, J = 9.8, 4.5, and 2.2 Hz, 1H, H-5), 3.65 (dd, J = 9.9 and 8.6 Hz, 1H, H-2); ^{13}C NMR (150 MHz, $CDCl_3$) δ, 170.6, 69.8, 169.7, 168.6, 92.6, 72.8, 72.8, 67.9, 62.7, 61.5, 21.0, 20.8, 20.7, 20.6; MS–ESI [M + Na]$^+$, 396.1.

*Synthesis of 1,2,4,6-Tetra-O-acetyl-3-azido-3-deoxy-D-glucoside (Anomers α/β = 1:1) (**3a**).* A solution of 1,2:5,6-di-*O*-isopropylidene-3-azido-3-deoxy-α-D-glucofuranose (2 g, 7 mmol) in 80% CF_3COOH (10 mL) was stirred at room temperature for 3 h. Evaporation of the solvent afforded 3-azido-3-deoxy-D-glucose without further purification. The crude 3-azido-3-deoxy-D-glucose was per-acetylated according to the procedure of compound **2a** to obtain compound **3a**. α anomer: syrup; yield, 35%; ^{1}H NMR ($CDCl_3$, 600 MHz) δ, 6.25 (d, J = 3.6 Hz, 1H, H-1), 4.98 (t, J = 10.1 Hz, 1H, H-4), 4.90 (dd, J = 10.6 and 3.5 Hz, 1H, H-2), 4.17 (dd, J = 12.0 and 4.6 Hz, 1H, H-6-a), 4.05–3.99 (m, 1H, H-6-b), 3.93 (t, J = 10.3 Hz, 1H, H-3), 3.75 (m, H-5), 2.15–2.03 (4 s, 12H, $COCH_3$); ^{13}C NMR ($CDCl_3$, 150 MHz) δ, 171.0, 169.7, 168.6, 87.8, 73.2, 69.9, 69.8, 61.5, 60.5, 21.1, 20.9, 20.8, 20.8. β anomer: syrup; yield, 35%; ^{1}H ($CDCl_3$, 600 MHz) δ, 5.63 (d, J = 8.2 Hz, 1H, H-1), 4.99 (dd, J = 10.1 and 8.2 Hz, 1H, H-2), 4.18 (dd, J = 12.0 and 4.6 Hz, 1H, H-6-a), 4.04–3.96 (m, 3H), 3.66 (t, J = 10.1 Hz, 1H, H-3), 2.15–2.03 (4s, 12H, $COCH_3$); ^{13}C ($CDCl_3$, 150 MHz) δ, 171.0, 169.7, 168.6, 91.3, 69.6, 67.4, 66.0, 64.4, 61.5, 21.1, 21.0, 20.9, 20.8; MS–ESI [M + Na]$^+$, 396.1.

*Synthesis of 1,2,3,6-Tetra-O-acetyl-4-azido-4-deoxy-α-D-glucoside (**4a**).* To a solution of methyl 4-azido-4-deoxy-α-D-glucopyranoside (2 g, 9.13 mmol) in glacial acetic acid (10 mL) and acetic anhydride (10 mL) was added concentrated sulfuric acid (2 mL) dropwise with stirring. The solution was left at room temperature for 48 h. Then, 6.13 g of sodium acetate was added to neutralize the sulfuric acid, and chloroform (100 mL) was added. The mixture was pour into ice–water. The chloroform layer was washed with aqueous $NaHCO_3$ and aqueous NaCl, dried, and evaporated to dryness *in vacuo*. The brown oil was purified by column chromatography (1:1 ethyl acetate/hexane) to obtain compound **4a**. Syrup; yield, 68%; ^{1}H NMR (600 MHz, $CDCl_3$) δ, 6.12 (d, J = 3.6 Hz, 1H, H-1), 5.31 (t, J = 10.0 Hz, 1H, H-3), 4.88 (dd, J = 10.2 and 3.7 Hz, 1H, H-2), 4.18 (dd, J = 12.4 and 1.8 Hz, 1H, H-6-a), 4.12 (dd, J = 12.4 and 3.9 Hz, 1H, H-6-b), 3.80–3.72 (m, 1H, H-5), 3.58 (t, J = 10.2 Hz, 1H, H-4), 2.01 (s, 3H, $COCH_3$), 1.97 (s, 3H, $COCH_3$), 1.96 (s, 3H, $COCH_3$), 1.85 (s, 3H, $COCH_3$); ^{13}C (150 MHz, $CDCl_3$) δ, 170.1, 169.5, 169.4, 168.5, 88.8, 70.1, 69.9, 69.0, 62.1, 59.6, 20.5, 20.4, 20.3, 20.1; MS–ESI [M + Na]$^+$, 396.1.

*Synthesis of 1,2,3,4-Tetra-O-acetyl-6-azido-6-deoxy-D-glucopyranose (**6a**).* 1,2,3,4-Tetra-*O*-acetyl-6-*O*-*p*-tolylsulfonyl-D-glucopyranose[17] (7 g, 13.95 mmol) and sodium azide (5.0 g, 154 mmol) dissolved in dry *N*,*N*-dimethylformamide (DMF) (50 mL) were stirred at 50 °C for 4 h and then at room temperature for 16 h. The mixture was poured onto icy water and extracted with ether (4 × 50 mL). The organic extracts were washed twice with water and then dried over calcium chloride. After evaporation to dryness, 1,2,3,4-tetra-*O*-acetyl-6-azido-6-deoxy-α-D-glucopyranose (**6a**) was obtained (2.03 g). Needle solid; yield, 39%; mp, 146.2 °C; ^{1}H NMR (600 MHz, $CDCl_3$) δ, 6.33 (d, J = 3.7 Hz, 1H, H-1), 5.44 (t, J = 9.9 Hz, 1H, H-3), 5.09 (t-like, J = 9.6 Hz, 1H, H-4), 5.07 (dd, J = 10.3 and 3.7 Hz, H-2), 4.06 (m, 1H, H-5), 3.38 (dd, J = 13.5 and 2.7 Hz, 1H, H-6-a), 3.28 (dd, J = 13.5 and 5.5 Hz, 1H, H-6-b), 2.17 (s, 3H, $COCH_3$), 2.03 (s, 3H, $COCH_3$), 2.01 (s, 3H, $COCH_3$), 2.00 (s, 3H, $COCH_3$); ^{13}C NMR (150 MHz, $CDCl_3$) δ, 170.3, 169.7, 169.5, 168.8, 88.9, 70.8, 69.7, 69.3, 69.1, 50.8, 20.9, 20.7, 20.7, 20.5; MS–ESI [M + Na]$^+$, 396.1.

General Procedure for Synthesis of the Conjugates 2-GTF, 3-GTF, 4-GTF, and 6-GTF (Scheme 2). Fipronil–alkyne (474 mg, 1 mmol) was added to a vigorously stirred suspension of azide-containing glucoses (373 mg, 1 mmol) in 3 mL of *tert*-butyl alcohol. The reaction was initiated by the addition of a solution of $CuSO_4{\cdot}5H_2O$ (100 mg, 0.4 mmol) and sodium ascorbate (173 mg, 0.8 mmol) in distilled water (3 mL). The deep yellow suspension was stirred vigorously at 50 °C for 3 h. Distilled water (10 mL) was added, and the aqueous layer was

extracted with chloroform (10 mL × 3). The combined organic extracts were washed with aqueous sodium hydrogen carbonate and brine, dried with sodium sulfate, filtered, and evaporated *in vacuo*. The crude compound was added to a solution of sodium methoxide in dry methanol (0.05 M, 15 mL). The resultant solution was stirred for 30 min at room temperature. The mixture was neutralized with Amberlite IR 120 (H^+) resin and filtered, and the filtrate was then evaporated. The residues were purified by column chromatography (9:1 CH_2Cl_2/MeOH) to obtain the glucosyl fipronil conjugates.

RESULTS AND DISCUSSION

Various strategies for increasing the phloem mobility of pesticides have been considered. A feasible strategy is the use of endogenous transporter proteins to carry pesticides. In this work, D-glucose was chosen as a vector for several reasons. First, it is the most abundant and important monosaccharide in nature. Second, it could be transported by various monosaccharide transporters and their homologues through diverse plant species.[18] Third, D-glucose confers moderate phloem mobility to the non-phloem-mobile insecticide fipronil, as presented in our previous paper.[9,16] In the present work, to evaluate the effects of the different positions of glucose on phloem mobility, four novel GTF conjugates, namely, 2-GTF, 3-GTF, 4-GTF, and 6-GTF, were synthesized via click chemistry based on the synthetic method of GTF.[9] All of the novel structures were confirmed via ^{1}H and ^{13}C NMR spectroscopy and ESI mass spectrometry.

dx.doi.org/10.1021/jf5010429 | J. Agric. Food Chem. 2014, 62, 6065−6071

Synthesis of Azido-Containing Acetylglucoses (Scheme 1). 2,3,4,6-Tetra-*O*-acetyl-1-azido-1-deoxy-D-glucoside (**1a**) was prepared from glucose pentaacetate in the presence of azidotrimethylsilane and $SnCl_4$ (Scheme 1A).[19] Glucosamine hydrochloride was transformed into 2-azido-2-deoxy-D-glucose by diazo transfer from triflyl azide (TfN_3). 2-Azido-2-deoxy-D-glucose was subsequently acetylated using acetic anhydride with catalytic DMAP in pyridine to yield 1,3,4,6-tetra-*O*-acetyl-2-azido-2-deoxy-D-glucose (**2a**) (Scheme 1B).[20] The introduction of nitrogen at C-3 of glucose required a double inversion of the configuration. Thus, the usual oxidation/reduction sequence led to the fomation of diacetone allose, which was then converted to azide via a triflation/azide displacement sequence.[21] Treatment of furanose diacetonide with aqueous trifluoroacetic acid was followed by the complete acetylation of the crude products via treatment with acetic anhydride and pyridine, and pyranose acetates were produced as 1,2,4,6-tetra-*O*-acetyl-3-azido-3-deoxy-D-glucosise (**3a**)[22] (Scheme 1C). Methyl α-D-galactopyranoside (1 equiv) was benzoylated by benzoyl chloride (3.5 equiv) in pyridine to link selectively to methyl 2,3,6-tri-*O*-benzoyl-α-D-galactopyranoside because the axial C-4 hydroxyl in the favored conformation has a lower reactivity than C-2, C-3, and C-6.[23] Methyl 2,3,6-tri-*O*-benzoyl-α-D-galactopyranoside was then sulfonated by trifluoromethanesulfonic anhydride. The displacement of the trifluoromethanesulfonate by sodium azide in dimethylformamide gave a good yield of methyl 4-azido-2,3,6-tri-*O*-benzoyl-4-deoxy-α-D-glucopyranoside in syrup form.[24] The debenzoylation of methyl 2,3,6-tri-*O*-benzoyl-4-azido-4-deoxy-α-D-glucopy-ranoside with sodium methoxide resulted in crystalline methyl 4-azido-4-deoxy-α-D-glucopyranoside, which was subsequently peracetylated to obtain a syrupy 1,2,3,6-tetra-*O*-acetyl-4-azido-4-deoxy-α-D-glucose (**4a**). 1,2,3,4-Tetraacetyl-6-*O*-*p*-tolylsulfonyl-D-glucopyranose was prepared from D-glucose as previously described.[17] Conventional azidation in the presence of dimethylformamide resulted in the formation of 1,2,3,4-tetra-*O*-acetyl-6-azido-6-deoxy-D-glucopyranose (**6a**).[25]

Synthesis and Characterization of GTF Conjugates. The synthetic method of GTF conjugates was proposed by Yang et al.[9] To prepare these conjugates via click chemistry, tetraacetylglucosides containing the azide group were synthesized according to the same method mentioned above (Scheme 1). Propargyl was introduced into fipronil according to a previous method by Yang et al.[9] as a coupling partner. In Scheme 2, the $CuSO_4{\cdot}5H_2O$/ascorbate click reaction system was explored to prepare the acetyl glucose-containing fipronil conjugates, which were O-deacetylated via the Zemplén procedure to obtain the target products.

The ^{1}H NMR spectra of these compounds are complicated because fipronil has an asymmetrical sulfoxide and forms two enantiomers.[26,27] In addition, the α,β configuration of the glucosyl group also exists. Their configurations were confirmed on the basis of a chemical shift, coupling constants, and band shape of H-1. For example, the NMR signals of product 2-GTF were immediately measured after the dissolution of the glucosyl conjugates in denatured methanol. A one-proton doublet was observed at 5.28 and $J_{1,2}$ = 3.2 Hz. These results indicate that the substance was in the α-D-pyranose anomer form. The second doublet, observed at 5.11 and $J_{1,2}$ = 7.3 Hz, was assigned to H-1 of the β-D-pyranose anomer. The characteristic peaks at 8.00 in the ^{1}H NMR spectra and the peaks at 127.9 and 123.5 in the ^{13}C NMR spectra appeared after reaction. These results demonstrate that 1,2,3-triazole was produced and the target conjugate was obtained. The analysis via ESI−MS spectroscopy showed a specific peak at m/z 702.0135 $[M + Na]^+$, from which the MW was estimated at 702.0140 $[M + Na]^+$. From these results, the synthesized product was identified as 2-GTF.

Phloem Mobility. The castor bean seedling system is an ideal biological model to evaluate the phloem systemicity of xenobiotics because of its thin and highly permeable cuticle, which facilitates molecule diffusion to and within the cotyledon apoplast system.[28] The system was adopted to test the phloem mobility of GTF, 2-GTF, 3-GTF, 4-GTF, and 6-GTF. As presented in a previous study,[9] the plasma membrane potential of the conjugates was measured via flow cytometric analysis with DiBAC4(3) as the fluorescent dye indicator.[29] In comparison to the control sample, the relative fluorescence data did not have any remarkable changes during the treatment period (Figure 1).

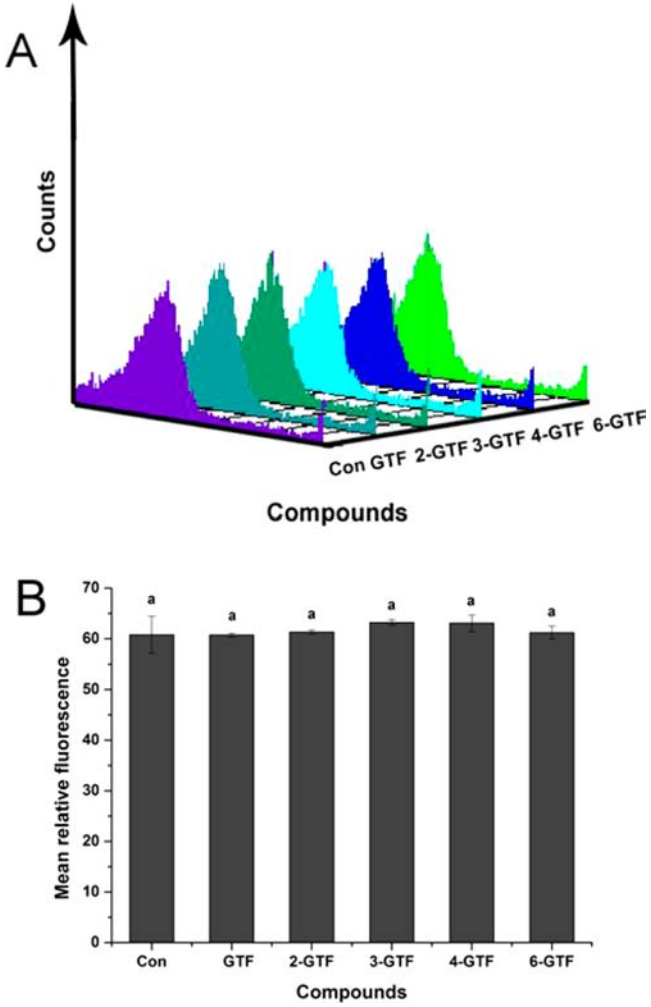

Figure 1. Plasma membrane potential in the protoplasts of *R. communis* cotyledons after 6 h of treatment. (A) Fluorescent intensity histogram marked DiBAC4(3) of the treatment of tested compounds and the control (Con). (B) Relative fluorescence of the treatment of tested compounds and the control (Con). The protoplasts were suspended in a buffered solution at pH 5.5 with or without (control) tested compounds (100 μM) for 5 h. The protoplasts were analyzed by flow cytometry for DiBAC4(3) fluorescence. The data [mean ± standard error (SE); n = 3] within a column are not significantly different, as shown by the Kruskal−Wallis test ($p > 0.05$).

The results indicate that the five conjugates have no depolarizing effects on the transmembrane potential. Therefore, the five

dx.doi.org/10.1021/jf5010429 | J. Agric. Food Chem. 2014, 62, 6065−6071

conjugates were not phytotoxic in the phloem mobility test during the 5 h experimental period.

After a 5 h incubation (including the 1 h pre-incubation period), the conjugates were clearly detected in the phloem sap. The phloem sap determination results indicate that the five conjugates (GTF, 2-GTF, 3-GTF, 4-GTF, and 6-GTF) all exhibited moderate phloem mobility in *Ricinus* seedlings (Figure 2). The GTF conjugates in the phloem sap were further

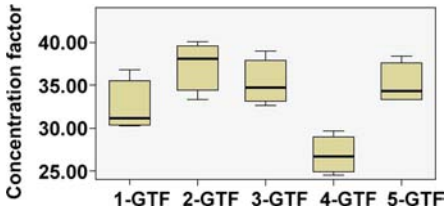

Figure 2. Phloem exudation collection of 4 sets of 12 castor bean seedlings for each conjugate at 5 h (mean ± SE). The Kruskal–Wallis tests at a 5% probability level were used to determine statistical differences among treatments ($p < 0.05$).

identified with UPLC–MS (see the figure in the Supporting Information). The UPLC–MS results indicated that the fipronil parent molecule was not detected in the phloem sap.

The "rule of five", which is widely adopted in the pharmaceutical industry, can also be used to predict the diffusion of endogenous molecules or xenobiotics through plant and animal membranes.[30] According to this rule, the passive absorption of small molecules is more likely to occur when their MW, log*P*, number of hydrogen bond donors, and number of hydrogen bond acceptors are less than 500 Da, 5, 5, and 10, respectively. Given the physical properties of the five conjugates (Table 1), their diffusion through the membranes should be very low. Models based on the physicochemical properties of pesticides are widely used to predict their phloem mobility. The Kleier model is widely used to predict the phloem systemicity of a compound based on the physicochemical properties (pK_a and log K_{ow}) of xenobiotics.[14,16,28] According to Kleier's prediction model, the physical properties of the five conjugates (Table 1) in terms of log K_{ow} and pK_a are found in non-mobile areas (Figure 3). In general, based on the "rule of five" and the Kleier prediction model, the five conjugates should have a low diffusion through the membrane and no phloem mobility should be observed. However, the experimental results of the phloem sap analysis violated the "rule of five" and the Kleier model. Specific carrier processes were probably involved in the phloem transport, as demonstrated in the phloem transport of GTF in *Ricinus* seedlings, which involves an active carrier-mediated mechanism that effectively contributes to GTF phloem loading.[16]

Among these conjugates, the analysis result showed that linking the fipronil to C-2, C-3, C-4, and C-6 of glucose affected phloem mobility of GTF conjugates. The concentrations of GTF, 2-GTF, 3-GTF, 4-GTF, and 6-GTF in phloem sap were 32.35 ± 1.51, 37.37 ± 1.44, 35.25 ± 1.32, 26.87 ± 1.07, and 35.10 ± 1.19 μM, respectively (Figure 2). In a previous work, sugar transporters have been shown to transport many glucose derivatives and glucose conjugates across the membrane. 2-NBDG is incorporated into mammalian cells through glucose transporters in a time-, concentration-, and temperature-dependent manner.[31] The uptake of IPNG into tobacco cells involves an active transport process.[32] Specifically, GTF can be mediated by sugar carrier systems during its phloem loading. The glucose conjugates (2-GTF, 3-GTF, 4-GTF, and 6-GTF) are isomers of GTF and

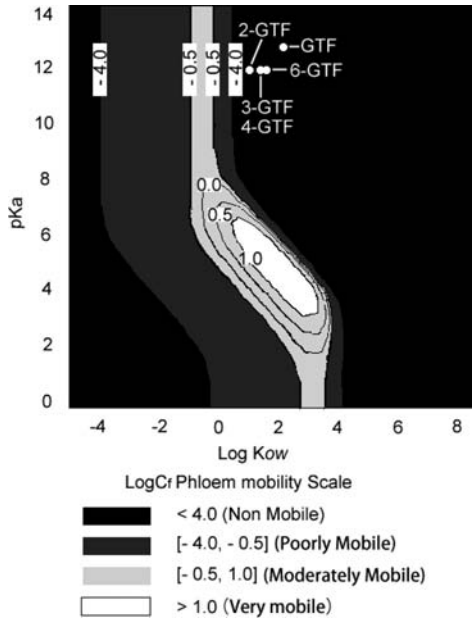

Figure 3. Prediction of phloem mobility of tested compounds (GTF, 2-GTF, 3-GTF, 4-GTF, and 6-GTF) using the Kleier map (log C_f as a function of log K_{ow} and pK_a) according to Kleier;[3,5] plant parameters are for a short plant.[3] Log K_{ow} and pK_a were calculated by the ACD Laboratories Percepta program, version 14.0, and log K_{ow} and pK_a values were classic values.

have very similar properties with each other (Table 1). Therefore, we speculate that sugar carrier systems are involved in the phloem loading of 2-GTF, 3-GTF, 4-GTF, and 6-GTF. Moreover, glucosyl derivatives, which are conjugated at different carbons of glucose, have a significant influence on affinities for sugar carriers. Among the O-methylsulfonyl derivatives of D-glucose, mesylation at C-4 and C-6 of glucose resulted in a slightly diminished affinity for the GLUT1, whereas mesylation at C-3 led to the complete loss of affinity.[33] Therefore, their phloem mobility difference of glucosyl conjugates might be caused by their different affinities for sugar carriers.

In conclusion, four new conjugates containing both fipronil and glucose moieties were synthesized via click chemistry. The phloem mobility tests in the 5 h experimental period demonstrated that the conjugates could enter into the phloem and exhibit moderate phloem mobility without being degraded. Results show that the phloem mobility was closely related to the position of the glucose. Crop protection and production technology have given increasing attention to the effective transport of pesticides through the phloem. Therefore, understanding the influence of the positions of glucose on phloem mobility provides a foundation for synthesis of excellent phloem-mobile sugar pesticides.

Design, Synthesis, and Biological Evaluation of Various α-Substituted Benzylpyrroles Based on the Structures of Insecticidal Chlorfenapyr and Natural Pyrrolomycins

Qiaoqiao Ma, Yuxiu Liu,* Pengxiang Zhang, Yongqiang Li, Lixia Xiong, and Qingmin Wang*

State Key Laboratory of Elemento-Organic Chemistry, Research Institute of Elemento-Organic Chemistry, Collaborative Innovation Center of Chemical Science and Engineering (Tianjin), Nankai University, Tianjin 300071, People's Republic of China

ABSTRACT: On the basis of the structures of chlorfenapyr and dioxapyrrolomycin, a series of 2-benzylpyrroles with a hydroxyl, an alkyloxy, an acyloxy, an alkylsulfanyl, or an oxime moiety at the α-position of benzyl were designed and synthesized. Their insecticidal, acaricidal, and fungicidal activities were extensively investigated. The structure−activity relationship showed that benzylpyrroles bearing shorter α-alkyloxy groups gave better activities against most of the insect species; the alkylation of pyrrole usually gave increased activity. Among all compounds, (4-bromo-2-(α-(2,2,2-trifluoroethoxy)-4-chlorobenzyl)-1-(ethoxymethyl)-5-(trifluoromethyl)-1*H*-pyrrole-3-carbonitrile) (**5′j**) exhibited the most outstanding insecticidal activities against oriental armyworm (IC_{50} = 10 mg L^{-1}), diamondback moth (0.07 mg L^{-1}), corn borer (50 mg L^{-1}), and mosquito (0.04 mg L^{-1}), which are very close to those of chlorfenapyr (**5**, 0.08, <25, and <0.025 mg L^{-1}, respectively). In addition, some compounds also exhibited a broad or selective fungicidal spectrum.

KEYWORDS: *chlorfenapyr, dioxapyrrolomycin, 2-benzylpyrrole, insecticidal activity, acaricidal activity, fungicidal activity*

INTRODUCTION

Using natural products as lead compounds to develop new pesticides with a novel structure and mechanism is one of the most effective drug design methods.[1,2] Dioxapyrrolomycin (Figure 1), isolated from the metabolites of the microorganism *Streptomyces* by the American Cyanamid Co. in 1987, is the first chiral pyrrole toxin found to have insecticidal, acaricidal, and fungicidal activities.[3] Chlorfenapyr is such a commercial arylpyrrole insecticide/acaricide optimized from dioxapyrrolomycin.[4−7] In fact, after chemical structure modification, chlorfenapyr has obvious changes in the skeleton compared with dioxapyrrolomycin. First, there is a carbon atom between the benzene ring and pyrrole ring in dioxapyrrolomycin, whereas in chlorfenapyr the benzene ring and pyrrole ring are directly connected. Second, the substituents on both the benzene ring and pyrrole ring of the two compounds are significantly different. Third, chlorfenapyr has an ethoxymethyl group on the pyrrole N, which is a necessary structural modification to solve the tough problem that the chlorfenapyr parent compound (**1**) has an intolerable phytotoxicity to the plants applied.[7]

Though dioxapyrrolomycin and chlorfenapyr have some differences in their skeletons, their insecticidal mechanisms are the same. Both dioxapyrrolomycin and the chlorfenapyr parent compound (**1**), acting as uncouplers of oxidative phosphorylation,[8] can uncouple respiratory electron transport in mitochondria and hinder ADP conversion to ATP.[9] Chlorfenapyr, as a precursor pesticide, shows same effect because it could be converted to **1** inside the insect body.[8] Thus, we speculated that when we retain all the substituents on the benzene and pyrrole rings of **1** but insert a methylene group between the two rings (compound **2**, Figure 1), such an alteration in the structure would not change the insecticidal mechanism and insecticidal/acaricidal activity, and the mentioned compound may also likely keep the fungicidal activity. To our delight, compound **2** and its N-alkylation product **3** were synthesized and found to have considerable insecticidal and/or acaricidal activity.[10]

Dioxapyrrolomycin contains a dioxane moiety in the structure; from another point of view, there is an oxygen-containing substituent on the methylene between the benzene ring and pyrrole ring. The presence of oxygen is thought to provide the possibility for the molecule to form a hydrogen bond with the target in the respiratory electron transport chain and therefore to give improved biological activity. Thus, in this paper, choosing compound **2** as the skeleton structure, we designed and synthesized a series of compounds with a hydroxyl group (**4**) and various alkyloxy groups (**5**) on the methylene and investigated the influence of different substituents on the insecticidal, acaricidal, and fungicidal activities; we also synthesized (α-(acyloxy)benzyl)pyrroles **6**, α-sulfanyl compounds **7**, and α-oxime ether compounds **8** to test their bioactivity. For (α-(alkyloxy)benzyl)pyrroles **5** with higher insecticidal activity, we further introduced an ethoxymethyl group onto the nitrogen atom of the pyrrole ring to get **5′** to compare the resulting changes in biological activity (Scheme 1). Herein, we present the synthesis and variety of bioactivities of the compounds mentioned above in detail. The structure−activity relationships are also discussed.

MATERIALS AND METHODS

Instruments. ^{1}H NMR and ^{13}C NMR spectra were obtained at 400 MHz using a Bruker AV400 spectrometer in $CDCl_3$ or DMSO-d_6

solution with tetramethylsilane as the internal standard. Chemical shift values (δ) are given in parts per million. In the ^{13}C NMR data, four peaks in one set of parentheses means that they are assigned to one carbon which is split by three adjacent F atoms. HRMS data were obtained on an FTICR-MS instrument (Ionspec 7.0 T). The melting points were determined on an X-4 binocular microscope melting point apparatus and are uncorrected. The yields were not optimized.

4-Bromo-2-(α-hydroxyl-4-chlorobenzyl)-5-(trifluoromethyl)-1*H*-pyrrole-3-carbonitrile (4). Method 1: A solution of **2** (0.50 g, 1.38 mmol) in dichloromethane (180 mL) was heated to reflux until all solid was dissolved. After this solution was cooled to room temperature, a solution of freshly distilled sulfonyl chloride (0.23 g, 1.70 mmol) in dichloromethane (10 mL) was added, and the reaction mixture was stirred at room temperature for 12 h. Saturated sodium bicarbonate aqueous solution (100 mL) was added, and the mixture was stirred for another 0.5 h. The organic layer was separated and washed with water and brine, dried over anhydrous magnesium sulfate, and concentrated to give **4** as a white solid (0.49 g, 90%): mp 158−159 °C; ^1H NMR (400 MHz, $CDCl_3$) δ 9.38 (s, 1H), 7.39 (d, J = 8.4 Hz, 2H), 7.35 (d, J = 8.4 Hz, 2H), 6.00 (s, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 142.8, 137.6, 135.6, 129.6, 128.0, (123.6, 120.9, 118.2, 115.6), (119.2, 118.8, 118.4, 118.0), 112.5, 101.7, 95.9, 69.0; HRMS (ESI) m/z calcd for $C_{13}H_6BrClF_3N_2O$ $(M - H)^-$ 376.9315, found 376.9310.

Method 2: To a solution of **2** (0.50 g, 1.38 mmol) in a mixed solvent of dichloromethane (50 mL) and DMF (5 mL) was added freshly distilled sulfonyl chloride (0.46 g, 3.40 mmol) in dichloromethane (10 mL), and the reaction mixture was stirred at room temperature for 12 h. Then water (100 mL) was added to the mixture, and the resulting mixture was stirred for another 0.5 h. The organic layer was separated and washed with water and brine, dried over anhydrous magnesium sulfate, and concentrated to give 4-bromo-2-(4-chlorobenzoyl)-5-(trifluoromethyl)-1*H*-pyrrole-3-carbonitrile (**10**) as a white solid (0.49 g, 94%): ^1H NMR (400 MHz, $CDCl_3$) δ 11.19 (s, 1H), 7.84 (d, J = 8.4 Hz, 2H), 7.55 (d, J = 8.4 Hz, 2H); HRMS (ESI) m/z calcd for $C_{13}H_3BrClF_3N_2O$ $(M - H)^-$ 374.9153, found 374.9153.

To a solution of **10** (1.0 g, 2.65 mmol) in THF (30 mL) was added $NaBH_4$ (0.15 g, 3.95 mmol), and the reaction mixture was stirred at room temperature for 12 h. The mixture was quenched with water, the solvent evaporated, and then the mixture extracted with dichloromethane. The organic layer was separated, washed with water and brine, dried over anhydrous magnesium sulfate, filtered, and then concentrated. The residue was purified by silica gel using petroleum ether/ethyl acetate as the eluent to give **4** as a white solid (0.50 g, 50%).

4-Bromo-2-(α-chloro-4-chlorobenzyl)-5-(trifluoromethyl)-1*H*-pyrrole-3-carbonitrile (9). Method 1: A solution of **2** (0.50 g, 1.38 mmol) in dichloromethane (180 mL) was heated to reflux until all solid was dissolved. After this solution was cooled to room temperature, a solution of freshly distilled sulfonyl chloride (0.23 g, 1.70 mmol) in dichloromethane (10 mL) was added, and the reaction mixture was stirred at room temperature for 12 h. Then the mixture was successively washed with water (3 × 100 mL) and brine, dried over anhydrous magnesium sulfate, an dconcentrated to give **9** as a white solid (0.51 g, 92%): mp 120−122 °C; ^1H NMR (400 MHz, $CDCl_3$) δ 9.23 (s, 1H), 7.42 (d, J = 8.4 Hz, 2H), 7.35 (d, J = 8.4 Hz, 2H), 6.20 (s, 1H).

Method 2: To a solution of **4** (0.50 g, 1.32 mmol) in dichloromethane (40 mL) was added freshly distilled sulfonyl chloride (0.46 g, 3.40 mmol) in dichloromethane (10 mL), and the reaction mixture was refluxed for 8 h. Then the mixture was successively

dx.doi.org/10.1021/jf501377t | J. Agric. Food Chem. 2014, 62, 6072−6081

washed with water (3 × 100 mL) and brine, dried over anhydrous magnesium sulfate, and concentrated to give **9** (0.47 g, 90%).

Synthesis of (α-Alkoxybenzyl)pyrrole (5). General Procedure. To a solution of the corresponding alcohol (4.5 mmol) in THF (40 mL) was added NaH (0.10 g, 4.1 mmol). After the mixture was refluxed for 1.5 h, crude **9** (0.60 g, 1.51 mmol) was added, and the mixture was refluxed for another 3 h. After the solvent was evaporated, the residue was dissolved in dichloromethane (50 mL), washed with water (3 × 25 mL) and brine, dried over anhydrous magnesium sulfate, and then concentrated. The crude was purified by silica gel using petroleum ether/ethyl acetate (10:1) as the eluent to give **5** as a white solid.

*Data for 4-bromo-2-(α-methoxy-4-chlorobenzyl)-5-(trifluoromethyl)-1H-pyrrole-3-carbonitrile (**5a**):* yield 63%; white solid; mp 51−53 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 9.28 (s, 1H), 7.40 (d, J = 8.4 Hz, 2H), 7.31 (d, J = 8.4 Hz, 2H), 5.40 (s, 1H), 3.40 (s, 3H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 141.1, 134.4, 130.1, 128.4, 127.5, (122.6, 119.9, 117.2, 114.5), (118.5, 118.1, 117.7, 117.3), 111.4, 100.3, 95.2, 76.3, 56.2; HRMS (ESI) m/z calcd for $C_{14}H_{13}BrClF_3N_3O$ $(M + NH_4)^+$ 409.9877, found 409.9867.

*Data for 4-bromo-2-(α-ethoxy-4-chlorobenzyl)-5-(trifluoromethyl)-1H-pyrrole-3-carbonitrile (**5b**):* yield 80%; white solid; mp 118−119 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 9.15 (s, 1H), 7.40 (d, J = 8.0 Hz, 2H), 7.32 (d, J = 8.0 Hz, 2H), 5.52 (s, 1H), 3.60−3.48 (m, 2H), 1.28 (t, J = 6.8 Hz, 3H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 141.5, 135.0, 134.1, 128.3, 127.4, 111.5, 100.3, 95.1, 74.4, 64.3, 14.0; HRMS (ESI) m/z calcd for $C_{15}H_{15}BrClF_3N_3O$ $(M + NH_4)^+$ 424.0034, found 424.0040.

*Data for 4-bromo-2-(α-propoxy-4-chlorobenzyl)-5-(trifluoromethyl)-1H-pyrrole-3-carbonitrile (**5c**):* yield 65%; yellow oil; ^{1}H NMR (400 MHz, $CDCl_3$) δ 9.23 (s, 1H), 7.39 (d, J = 8.4 Hz, 2H), 7.31 (d, J = 8.4 Hz, 2H), 5.50 (s, 1H), 3.45 (t, J = 6.4 Hz, 2H), 1.74−1.55 (m, 2H), 0.94 (t, J = 7.6 Hz, 3H); HRMS (ESI) m/z calcd for $C_{16}H_{17}BrClF_3N_3O$ $(M + NH_4)^+$ 438.0190, found 438.0193.

Alternative Method for 5b. To a solution of **9** (0.55 g, 1.38 mmol) in ethanol (40 mL) was added sodium bicarbonate (0.35 g, 4.15 mmol), and the mixture was refluxed for 1 h. After the solvent was evaporated, the residue was dissolved in ethyl acetate (50 mL),

washed with water (3 × 25 mL) and brine, dried over anhydrous magnesium sulfate, and concentrated to give **5b** as a white solid (0.52 g, 93%).

4-Bromo-2-(α-ethoxy-4-chlorobenzyl)-1-(ethoxymethyl)-5-(trifluoromethyl)-1*H*-pyrrole-3-carbonitrile (5′b). To a stirred solution of **5b** (0.40 g, 1.24 mmol) in THF (20 mL) under an ice−salt bath was added sodium hydride (0.12 g, 6.19 mmol) in batches. After the mixture was stirred at room temperature for 10 min, chloromethyl ethyl ether (0.35 g, 3.71 mmol) was added, and the mixture was refluxed for 2.5 h. Then the solvent was removed by evaporation, and the residue was redissolved in ethyl acetate, successively washed with water and brine, dried over sodium sulfate, and concentrated give **5′b** as a white solid (0.50 g, 85%): mp 61−63 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.36 (d, J = 8.4 Hz, 2H), 7.29 (d, J = 8.4 Hz, 2H), 5.77 (s, 1H), 5.27 (d, J = 10.4 Hz, 1H), 5.18 (d, J = 10.4 Hz, 1H), 3.63 (q, J = 6.8 Hz, 2H), 3.25 (hept, J = 6.8 Hz, 2H), 1.32 (t, J = 6.8 Hz, 3H), 1.06 (t, J = 6.8 Hz, 3H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 142.7, 135.3, 133.5, 128.0, 126.6, (122.8, 120.7, 117.4, 114.7), (120.7, 120.4, 120.0, 119.6), 111.9, 101.9, 101.9, 99.0, 74.8, 73.9, 65.0, 63.4, 13.9, 13.5; HRMS (ESI) m/z calcd for $C_{18}H_{21}BrClF_3N_3O_2$ $(M + NH_4)^+$ 482.0452, found 482.0448.

4-Bromo-1-(ethoxymethyl)-2-(α-(2,2,2-trifluoroethoxy)-4-chlorobenzyl)-5-(trifluoromethyl)-1*H*-pyrrole-3-carbonitrile (5′j). The synthetic procedure was according to that of **5′b** using **5j** as the starting material: yield 90%; colorless oil; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.31 (d, J = 8.4 Hz, 2H), 7.24 (d, J = 8.4 Hz, 2H), 5.89 (s, 1H), 5.21 (d, J = 10.4 Hz, 1H), 5.10 (d, J = 10.4 Hz, 1H), 3.87 (q, J = 8.4 Hz, 2H), 3.25 (q, J = 6.8 Hz, 2H), 1.00 (t, J = 6.8 Hz, 3H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 140.5, 134.5, 133.2, 128.4, 127.1, (126.7, 123.9, 121.1, 118.3), (122.7, 120.0, 117.4, 114.7), (121.2, 120.8, 120.5, 120.1), 111.4, 102.2, 99.4, 75.2, 74.9, (66.2, 65.9, 65.5, 65.2), 63.7, 13.4; HRMS (ESI) m/z calcd for $C_{18}H_{18}BrClF_6N_3O_2$ $(M + NH_4)^+$ 536.0170, found 536.0163.

(4-Bromo-3-cyano-5-(trifluoromethyl)-1*H*-pyrrol-2-yl)(4-chlorophenyl)methyl Isobutyrate (6). To a solution of sodium isobutyrate (0.28 g, 2.51 mmol) in dichloromethane (40 mL) was added the appropriate amount of molecular sieves, and the mixture was refluxed for 0.5 h. After compound **9** (0.50 g, 1.26 mmol) was added, the mixture was refluxed for another 1.5 h. Then the molecular sieves were filtrated, and the filtrate was washed with water (3 × 25 mL) and brine, dried over anhydrous magnesium sulfate, and then concentrated. The crude was purified by silica gel using petroleum ether/ethyl acetate (5:1) as the eluent to give **6** as a white solid: yield 71%; mp 101−102 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 9.61 (s, 1H), 7.40 (d, J = 8.4 Hz, 1H), 7.35 (d, J = 8.4 Hz, 1H), 6.89 (s, 1H), 2.76 (hept, J = 7.0 Hz, 1H), 1.25 (d, J = 4.0 Hz, 3H), 1.23 (d, J = 4.0 Hz, 3H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 176.5, 139.3, 135.7, 133.9, 129.6, 128.1, (123.4, 120.7, 118.0, 115.4), (120.2, 119.8, 119.4, 119.0), 112.1, 102.1, 97.7, 69.1, 34.1, 18.9, 18.6; HRMS (ESI) m/z calcd for $C_{17}H_{17}BrClF_3N_3O_2$ $(M + NH_4)^+$ 466.0139, found 466.0147.

Synthesis of (α-(Alkylsulfanyl)benzyl)pyrroles 7 and Benzylpyrrole α-Oxime Ethers 8. The synthetic procedures were according to that of **5** using compound **9** and 1.5−2 equiv of the corresponding alkanethiol or oxime as the starting material.

*Data for 4-bromo-2-(α-(ethylthio)-4-chlorobenzyl)-5-(trifluoromethyl)-1H-pyrrole-3-carbonitrile (**7a**):* yield 90%; pale yellow solid; mp 46−48 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 9.50 (s, 1H), 7.34 (d, J = 8.4 Hz, 2H), 7.25 (d, J = 8.4 Hz, 2H), 5.32 (s, 1H), 2.64−2.28 (m, 2H), 1.28 (t, J = 7.6 Hz, 3H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 140.4, 134.5, 133.6, 128.5, 127.9, (122.4, 119.8, 117.1, 114.4), (118.7, 118.3, 117.9, 117.5), 111.4, 100.3, 100.3, 97.1, 44.0, 25.9, 13.2; HRMS (ESI) m/z calcd for $C_{15}H_{10}BrClF_3N_2S$ $(M - H)^-$ 420.9394, found 420.9395.

4-Bromo-2-(α-(2,2,2-trifluoroethoxy)-4-chlorobenzyl))-5-(tris(2,2,2-trifluoroethoxy)methyl)-1*H*-pyrrole-3-carbonitrile (11). To a solution of **9** (0.05 g, 0.13 mmol) in trifluoroethanol (15 mL) was added sodium bicarbonate (0.10 g, 0.94 mmol), and the mixture was refluxed for 5 h. After the solvent was evaporated, the residue was dissolved in dichloromethane (25 mL), washed with water (3 × 25 mL) and brine, dried over anhydrous magnesium sulfate, and then concentrated to give **11** as a white solid (0.08 g, 90%): ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.37 (d, J = 8.4 Hz,2H), 7.26 (d, J = 8.4 Hz, 2H), 5.60 (s, 1H), 3.93 (q, J = 8.0 Hz, 6H), 3.80 (q, J = 8.0 Hz, 2H).

Biological Assay. All bioassays were performed on representative test organisms reared in the laboratory. Each bioassay was replicated three times at 25 ± 1 °C for the statistical requirements. Mortalities were evaluated according to a percentage scale of 0−100%, in which 0% indicates no activity and 100% indicates total kill. When the mortality of the blank control was less than 5%, the test result was directly used. However, if the mortality of the blank control was less than 20%, the test result was corrected by means of $V = ((X - Y)/X) \times 100$ (V = value of the corrected mortality, X = livability of the blank control, and Y = livability of the treated organisms). To calculate IC_{50}, at least two mortalities at different concentrations had to be lower than 50%. The IC_{50} was taken from a graph plotting mortality (y-axis) against compound concentration (x-axis); the IC_{50} value is the concentration where the mortality crosses 50%.

Stock solutions of each test compound were prepared in dimethylformamide at a concentration of 600 or 200 mg L^{-1} and then diluted to the required concentration (100, 50, 25, 10, 5, 2, 1, 0.5, 0.25, 0.1, 0.05, 0.025, and 0.01 mg L^{-1}) with water containing 0.1% TW-20 (a type of emulsifier).

Insecticidal Activity. *Insecticidal Activities against Oriental Armyworm (Mythimna separata), Diamondback Moth (Plutella xylostella), Cotton Bollworm (Helicoverpa armigera), Corn Borer (Ostrinia nubilalis), Beet Armyworm (Spodoptera exigua), and Bean Aphid (Aphis craccivora).* The leaf-dip method was used. Leaf disks (5 cm × 3 cm) were cut from fresh cabbage leaves (or other leaves) and then dipped into the test solution for 3 s. After air-drying, the treated leaf disks were placed individually into vertical tubes (or Petri dishes), and the disks were infested with 10 larvae (for example, 2nd-instar diamondback moth larvae). The mortalities were evaluated 3 days after treatment.

[a]Concentration of the tested compounds. The units are milligrams per liter. [b]A dash means not tested. [c]The assay was conducted at a concentration of 600 mg L^{-1}.

Insecticidal Activities against Mosquito (Culex pipiens pallens). Twenty 4th-instar mosquito larvae were put into 10 mL of the test solution. The mortalities were evaluated 8 days after treatment.

Acaricidal Activity Assay. The detailed assay method against the eggs, larvae, and adults of the spider mite (*Tetranychus cinnabarinus*) was described in the literature.[10]

Fungicidal Activity Assay. In vitro assay: The compounds were evaluated in mycelial growth tests in artificial media against 10 phytopathogens, *Fusarium oxysporium*, *Cercospora arachidicola* Hori, *Physalospora piricola*, *Alternaria solani*, *Fusarium graminearum*, *Phytophthora infestans*, *Sclerotinia sclerotiorum*, *Botrytis cinerea*, *Rhizoctonia solani*, and *Phytophthora capsici*, at rate of 50 mg L^{-1}.

In vivo assay: The compounds were evaluated in leaf-piece assays at a rate of 200 mg L^{-1} for *Corynespora cassiicola* and *B. cinerea* on cucumber, *Blumeria graminis* f. sp. *tritici* on wheat, *S. sclerotiorum* on oilseed rape, *R. solani* on rice, and *Phytophthora* on pepper.

[a]The data in blue mean good to excellent activity, and the data in pink mean moderate activity. [b]The concentrations were set as 600, 200, 100, 50, 25, 10, and 5 mg L^{-1} for calculation of IC_{50}. In the rectangular coordinate system, a line was drawn with concentration as the abscissa and mortality rate as the ordinate. The IC_{50} value was roughly read from the straight line that connected the two concentrations that gave mortality rates of just more and just less than 50%. Other IC_{50} values were calculated in the same way. [c]The concentrations were set as 600, 200, 100, 10, 1, 0.1, and 0.01 mg L^{-1} for calculation of IC_{50}. [d]The concentrations were set as 5, 2, 1, 0.5, 0.25, 0.1, 0.05, 0.025, and 0.01 mg L^{-1} for calculation of IC_{50}.

The detailed assay method was described in the literature.[10]

RESULTS AND DISCUSSION

Synthesis. Benzylpyrrole **2**, prepared according to our previous method,[10] was reacted with 1.3 equiv of sulfonyl dichloride to obtain *α*-monochlorinated benzylpyrrole **9**. As a key intermediate, **9** was treated with different nucleophiles such as sodium bicarbonate aqueous solution, sodium alkoxide, sodium carboxylate, thiol sodium salt, or oxime sodium salt to afford **4**, **5**, **6**, 7, or **8**, respectively (Scheme 1). **5** was further allowed to react with chloromethyl ethyl ether to obtain N-substituted compound **5′**. (*α*-(Aryloxy)benzyl)pyrroles or more (*α*-(acyloxy)benzyl)pyrroles were to be synthesized, but they were too unstable during the workup.

Note that, due to the poor solubility of **2** in dichloromethane, the preparation of intermediate **9** required a lot of solvent (0.50 g of **2** requires about 180 mL of warm dichloromethane), and adding dimethylformamide to increase the solubility was only to find an increased amount of *α*,*α*-dichlorinated benzylpyrrole. During the multiple repeated tests, it was also found that the amount of sulfonyl dichloride had to be changed depending on the degree of solvent dryness and even the humidity of the air because insufficient sulfonyl dichloride resulted in incomplete reaction, while excess sulfonyl dichloride produced more *α*,*α*-dichlorinated benzylpyrrole, and both circumstances made the reaction systems complicated. Therefore, preparing **9** directly from **2** was not always the quickest and the most convenient method. The preparation of **9** was then adopted as an alternative route (Scheme 1, route with purple arrows). **2** was first transformed to dichlorinated benzylpyrrole by using excess sulfonyl dichloride (3 equiv) in a mixed solvent of dichloromethane and dimethylformamide (0.5 g of **2** in 50 mL of dichloromethane and 5 mL of DMF) and after hydrolysis gave benzoylpyrrole **10**. Then **10** was reduced by $NaBH_4$ to (*α*-hydroxybenzyl)pyrrole **4**. Finally, **4** was treated with 1.3 equiv of sulfonyl dichloride to obtain *α*-monochlorinated benzylpyrrole **9**. This route needs three steps from compound **2**, **4** had much better solubility than **2**, and the chlorination step was not

[a]The data in blue mean good to excellent activity. Concentration of tested compounds. The units are milligrams per liter. [b]A dash means not tested.

so uncontrollable; thus, the purity of crude **9** prepared from **4** was better than that from **2**, which made the following nucleophilic substitution step clearer and the product easier to purify. Another thing to remember is that compound **9** is sensitive to alkaline aqueous solution, so whether it was prepared from **2** or **4**, during the workup the reaction mixture should be washed with sufficient water to remove excess sulfonyl dichloride but not with sodium bicarbonate aqueous solution.

Here we also mention some other experimental phenomena we encountered. (α-Alkoxybenzyl)pyrroles **5** were generally prepared from **9** and the corresponding sodium alkoxide, which were prepared in advance. Accidentally, we found (α-ethoxybenzyl)pyrrole **5b** also formed when **9** was refluxed in ethanol in the presence of sodium bicarbonate. The simpler procedure was then expected to be applied to other alcohols. However, when **9** was refluxed in trifluoroethanol, orthoester **11** was unexpectedly separated in high yield. In the structure of **11** not only the α-chloro atom but also the three fluorine atoms in the trifluoromethyl group on the pyrrole ring were replaced by trifluoroethoxyl (Scheme 2). The formation of the orthoester was thought to be via the repeated ion-participating F^- elimination and nucleophilic addition/rearomatization courses, which had been elucidated in detail in our previously published paper.[11] It seemed that an alcoholic solvent, a high reaction temperature (at least higher than the boiling point of dichloromethane), and a large excess amount of sodium bicarbonate jointly promoted the formation of the orthoester.

Bioactivity. The α-substituted benzylpyrroles were designed from insecticidal/acaricidal chlorfenapyr and dioxapyrrolomycin, so their insecticidal, acaricidal, and fungicidal activities were all assayed.

Insecticidal Activity. Table 1 shows the data of insecticidal activity against the larvae of oriental armyworm (*M. separata*), diamondback moth (*P. xylostella*), cotton bollworm (*H. armigera*), corn borer (*O. nubilalis*), beet armyworm (*Sp. exigua*), bean aphid (*A. craccivora*), and mosquito. Chlorfenapyr is included as a control.

As shown in Table 1, at 600 mg L^{-1}, most of the compounds exhibited 100% mortality against oriental armyworm, diamondback moth, and mosquito, and half of them gave 100% mortality against cotton bollworm and corn borer. However, for beet armyworm and bean aphid, no compounds gave the desired activity. Therefore, against those five species, the insecticidal activities at lower concentrations were determined, and the IC_{50} (the concentration of compounds resulting in 50% mortality) values of each species were roughly calculated (Table 2).

Table 2 shows clear structure−activity relationships for each insect species. For oriental armyworm, α-H-substituted (**2**), α-hydroxy-substituted (**4**), α-chloro-substituted (**9**), and most α-alkyloxy-substituted (**5a−n**) benzyl pyrroles gave moderate to

[a]The data in blue mean good to excellent activity. FO = *F. oxysporium*, CH = *C. arachidicola* Hori, PP = *Phys. piricola*, AS = *Al. solani*, FG = *F. graminearum*, PI = *Phyt. infestans*, SS = *S. sclerotiorum*, BC = *B. cinerea*, RS = *R. solani*, and PC = *Phyt. capsici*. [b]A dash means not tested.

excellent activity, except those bearing long or hindered alkyl groups such as **5e** (X = OBu-*n*), **5f** (X = OHex-*n*), **5h** (X = OHex-*c*), and **5l** (X = $OCH(CF_3)_2$). Compound **6** bearing an isobutyryloxy group at the α-position of benzylpyrrole also gave poor activity due to both steric and stereoelectronic effects. The α-alkylsulfanyl compounds **7a** and **7b** had structure−activity relationships different from those of α-alkyloxy compounds, as **7b** (X = SBu-*t*) had a more hindered substituent than **7a** (X = SEt) but exhibited much higher activity. Data for oxime ethers **8a−c** showed that an electron-withdrawing group played a significant role in the activity, as **8a** (4-$NO_2C_6H_4CH{=}NO$) gave much better activity than **8b** (X = 4-$Me_2NC_6H_4CH{=}$NO). In comparing *N*-ethoxymethyl compounds **3**, **5′b**, and **5′j** with corresponding NH compounds **2**, **5b**, and **5j**, the two types of structures did not show significant differences in the activity against oriental armyworm.

For diamondback moth, the compounds showed structure−activity relationships very similar to those for oriental armyworm. Benzylpyrroles with a shorter alkyloxy group at the α-position also gave better activity, with **5b** (X = OEt), **5i** (X = $OCH_2C{\equiv}CH$), **5j** (X = OCH_2CF_3), **5′j** (X = OCH_2CF_3), and **5k** (X = OCH_2CCl_3) having the lowest IC_{50} values (<0.1 mg L^{-1}), close to that of chlorfenapyr (0.08 mg L^{-1}).

The structure−activity relationships for cotton bollworm and corn borer were very similar to each other. However, neither of them had insecticidal ability comparable to that of chlorfenapyr.

For mosquito, most of the benzylpyrroles bearing shorter or longer α-alkyloxy groups (**5**) gave moderate to excellent activity, but the activity rule was not so distinct. The compounds with an oxime ether moiety (**8a−c**) also showed good activity. Notably, compounds **3**, **5′b**, and **5′j** with an ethoxymethyl group at the nitrogen of pyrrole all exhibited higher activity than their corresponding parent compounds **2**, **5b**, and **5j**, and the IC_{50} values for **5′b** and **5′j** (0.07 and 0.04 mg L^{-1}, respectively) were close to that of chlorfenapyr (0.025 mg L^{-1}).

Overall, benzylpyrroles bearing shorter α-alkyloxy groups gave better activities against most of the insect species. The alkylation of pyrrole usually gave increased activity. Among all the compounds, **5b** (X = OEt), **5i** (X = $OCH_2C{\equiv}CH$), **5j** (X = OCH_2CF_3), **5′j** (X = OCH_2CF_3), and **5k** (X = OCH_2CCl_3)

[a]The data in blue mean good to excellent activity. SS = *S. sclerotiorum*, RS = *R. solani*, BG = *Bl. graminis*; CC: *Co. cassiicola*; PH: *Phytophthora*; BC = *B. cinerea*. [b]A dash means not tested.

exhibited excellent insecticidal activity against both oriental armyworm and diamondback moth; **5′j** also showed an eminent insecticidal effect against corn borer and mosquito.

Acaricidal Activity. Table 3 shows that few compounds exhibited satisfactory acarcidal activity; only compounds **3**, **9**, **5b**, **5i**, **5j**, and **5n** maintained certain mortality at a concentration of 100 mg L^{-1} against spider mite adults, larvae, and/or eggs, and none of them were comparable to chlorfenapyr. An interesting discovery is that though **5′b** and **5′j** had much lower activity than their parent products **5b** and **5j**, compound **3** gave much higher acarcidal activity than its parent product **2**.

Another thing to note is that no serious phytotoxicity was observed during the insecticidal and acaricidal assays; even those compounds without an ethoxymethyl group on the pyrrole N, such as compounds **2** and **5**, did not cause distinct harm to the leaves of the test plants at different concentrations.

Fungicidal Activity. The compounds were designed according to the structure of fungicidal dioxapyrrolomycin, so their fungicidal activities were also assayed to see if they could maintain fungicidal activity. The compounds were first evaluated in mycelial growth tests in artificial media against 10 species of phytopathogens at a rate of 50 mg L^{-1}. As shown in Table 4, most of the designed (α-(alkyloxy)benzyl)pyrroles **5** and α-alkylsulfanyl compounds **7** gave more than 80% inhibition against *Phys. piricola* (PP) and *S. sclerotiorum* (SS). **5a** (X = OMe) had the broadest fungicidal spectrum, with more than 80% inhibition against eight kinds of fungi. **5b** (X = OEt), **5d** (X = OPr-*i*), **5j** (X = OCH_2CF_3), **5k** (X = OCH_2CCl_3), and **5m** (X = $O(CH_2)_3Cl$) also gave broad fungicidal activity against at least five kinds of fungi.

Selected compounds were also tested for their fungicidal activity in vivo at 200 mg L^{-1}. Azoxystrobin, carbendazim, thiram, and dimethomorph were respectively used as contrast compounds for different fungi (Table 5). At the test concentration, most compounds exhibit certain fungicidal activity; especially **5a**, **5d**, **5g**, **6**, and **7a** gave better and broader fungicidal activity against at least three kinds of fungi. In contrast, **5m** showed some selectivity; it inhibited 87% of *Phytophthora*, which was very close to the value for dimethomorph. Thus, this kind of compound can be used as a lead compound for further fungicide research and development.

dx.doi.org/10.1021/jf501377t | J. Agric. Food Chem. 2014, 62, 6072−6081

In summary, on the basis of the structures of chlorfenapyr and dioxapyrrolomycin, a series of 2-benzylpyrroles with a hydroxyl, an alkyloxy, an acyloxy, an alkylsulfanyl, or an oxime moiety at the α-position of benzyl were designed and synthesized. The structure−activity relationships showed that benzylpyrroles bearing shorter α-alkyloxy groups gave better activities against most of the insect species; the alkylation of pyrrole usually gave increased activity. Several compounds were identified with excellent insecticidal and/or fungicidal activities, and the structure−activity relationship should be useful for future new active compound design and development.

Quantitative Analysis of Neonicotinoid Insecticide Residues in Foods: Implication for Dietary Exposures

Mei Chen,[†] Lin Tao,[†] John McLean,[§] and Chensheng Lu*[,†]

[†]Department of Environmental Health, Harvard School of Public Health, 665 Huntington Avenue, Boston, Massachusetts 02115, United States

[§]Consultant Entomologist, Gisborne 4010, New Zealand

ABSTRACT: This study quantitatively measured neonicotinoids in various foods that are common to human consumption. All fruit and vegetable samples (except nectarine and tomato) and 90% of honey samples were detected positive for at least one neonicotinoid; 72% of fruits, 45% of vegetables, and 50% of honey samples contained at least two different neonicotinoids in one sample, with imidacloprid having the highest detection rate among all samples. All pollen samples from New Zealand contained multiple neonicotinoids, and five of seven pollens from Massachusetts detected positive for imidacloprid. These results show the prevalence of low-level neonicotinoid residues in fruits, vegetables, and honey that are readily available in the market for human consumption and in the environment where honeybees forage. In light of new reports of toxicological effects in mammals, the results strengthen the importance of assessing dietary neonicotinoid intakes and the potential human health effects.

KEYWORDS: *neonicotinoid insecticides, dietary exposure, pollen, honey*

INTRODUCTION

A growing body of research shows that fruits and vegetables are critical to promoting good health. Fruits and vegetables are major contributors of nutrients, such as folate, magnesium, dietary fiber, and vitamins A, C, and K, and essential for disease prevention. Diets rich in fruits and vegetables also help adults and children to achieve and maintain a healthy weight.[1] However, because of the wide usage of pesticides in agriculture, diet also becomes an important source of exposure to pesticides. Although relatively unknown to the public, neonicotinoids are the most commonly used insecticides in the world, which include acetamiprid, clothianidin, dinotefuran, imidacloprid, nitenpyram, thiacloprid, and thiamethoxam. Additionally, flonicamid has been categorized as a neonicotinoid insecticide,[2] although the mode of action is different from that of other neonicotinoids.[3] These insecticides act as nicotinic acetylcholine receptor (nAChR) agonists, which cause insect paralysis to death. Advantages of neonicotinoids in pest control, including a broad spectrum of insecticidal activity, high receptor specificity for insects relative to mammals, and versatility in application methods, have led to the replacement of organophosphates, carbamates, and synthetic pyrethroids.[4] They are now registered globally in more than 120 countries and extensively used in seed treatment (such as seed dressing or film coating) and soil treatment (by broadcast application, mechanical incorporation, soil drench, or soil injection) and are also directly applied to plant foliage for crop protection.[5,6] Additionally, neonicotinoids have been used as insect control on pets or companion animals, such as termite and flea control.[4,7]

Because of neonicotinoids' wide uses and their extreme toxicity to bees, neonicotinoids have been implicated in causing the steep decline of the global honeybee population and specifically colony collapse disorder (CCD).[8,9] Neonicotinoids are systemic insecticides and water-soluble, which means that they have superb plant-systemic activity.[4] When applied into the soil or as seed treatment, they are taken up by the roots and translocated through the entire plant.[10,11] Residue studies have detected low levels of neonicotinoids in the pollen of treated crops[10−12] and substantially high levels of resides in corn grown from imidacloprid-treated corn seeds.[13] When applied to the top surface of leaves and fruits, they penetrate into the plant tissues and afford long-term protection from piercing−sucking insects.[4] For example, substantial portions of thiacloprid and clothianidin residues and radiolabeled neonicotinoids were found to penetrate in and beyond the outer flesh regions of apples 24 h after topical application.[14,15] In another study, thiamethoxam and acetamiprid were detected in cherry leaves and the fruit's interior tissue 14 days after application.[16] Translocation of neonicotinoids into plant tissues (after either foliar application or seed/soil treatment) may potentially be subject to human consumption and subsequently dietary intake.

To estimate dietary exposure to neonicotinoids in humans, it is important to monitor neonicotinoid residues in and on foods that people consume. Although the U.S. Department of Agriculture (USDA) publishes Pesticide Data Program (PDP) reports annually, usually fewer than 15 fresh fruits and vegetables are included each year. Nevertheless, imidacloprid, the most commonly used insecticide in the world, had been detected in 81% of sweet bell peppers, 81% of broccoli, and 53% of grapes, as reported by the USDA PDP.[17] Imidacloprid is not only widely detectable in fruits and vegetables but also absorbed with high efficiency, as shown in a human intestinal cell model.[18] Imidacloprid and acetamiprid have also shown excitatory effects on cultured cerebellar neurons from neonatal

rats, suggesting possible neurotoxicity in developing mammalian brains.[19] These results raise the concerns of potential health risks from chronic exposure to consumers by dietary intake of residues with food. Because half-lives for most neonicotinoids in aerobic soil can range from months to years,[20] neonicotinoids can become persistent in the environment for several years after repeated applications. Consequently, the persistence of neonicotinoids in soil would have created a reservoir of residues for plant to take up over a long period of time and, therefore, contaminate crops for human consumption. In addition, because of their systemic characteristics, neonicotinoids often occur as residues in the plant flesh and could not be washed off easily.

To the best of our knowledge, this is the first study aiming to demonstrate the presence of neonicotinoids in foods that people commonly consume. Only specific neonicotinoids (such as imidacloprid) in fruits and vegetables have been monitored and reported.[21,22] Most data on neonicotinoid residues in fruits and vegetables were from brief reports of the application of the newly developed analytical methods. In addition, in most of these brief reports, only up to six neonicotinoids were simultaneously monitored,[22−28] and eight neonicotinoids were monitored in only one study and in one commodity.[2] In recent years, the QuEChERS (quick, easy, cheap, effective, rugged, and safe) sample preparation procedure has been widely used for extraction of a wide variety of pesticides from various food matrices.[29−31] In this study, we used a sensitive and modified LC-MS/MS method along with the QuEChERS procedure to simultaneously measure eight neonicotinoid residues in various foods incluing fruits, vegetables, and honey and in pollen.[30] The results provided an initial assessment of the potential dietary exposure of neonicotinoids and will contribute to future epidemiological research linking neonicotinoid insecticide exposure to potential human health effects.

EXPERIMENTAL PROCEDURES

Materials. Acetamiprid, flonicamid, thiacloprid, thiamethoxam, and nitenpyram standard solutions were purchased from Accustandard (New Haven, CT, USA) with purity ≥99.7%. Imidacloprid and clothianidin were purchased from Sigma-Aldrich (St. Louis, MO, USA) with purity of 99.9%. Dinotefuran was purchased from Chem Service (West Chester, PA, USA) with purity of 99.2%. The isotope-labeled internal standards (IS) for imidacloprid-d_4 (99.2%), clothianidin-d_3 (98.9%), and thiamethoxam-d_3 (99.8%) were purchased from C/D/N Isotopes, Inc. (Quebec, Canada). LC-MS/MS grade formic acid and ammonium formate were purchased from Sigma-Aldrich. HPLC grade reagents, including acetonitrile and water, were purchased from J. T. Baker (Center Valley, PA, USA). Vial (1.5 mL with 0.2 μm nylon filter) were purchased from VWR international (Radnor, PA, USA). QuEChERS extraction salt packages, which include 4 g of $MgSO_4$, 1 g of NaCl, 1 g of sodium citrate, and 500 mg of of disodium citrate sesquihydrate in each salt pack, and 2 mL of QuEChERS dispersive SPE containing 50 mg of PSA + 50 mg of C18 + 150 mg of $MgSO_4$ or 50 mg of PSA + 50 mg of graphitized carbon black (GCB) + 150 mg of $MgSO_4$ or 25 mg of PSA + 7.5 mg of GCB + 150 mg of $MgSO_4$ ceramic homogenizer were purchased from Agilent Technologies (Santa Clara, CA, USA).

Liquid Chromatography−Mass Spectrometry (LC-MS/MS) Instrumentation. The HPLC system consists of a Shimadzu LC SCL-10AVP solvent delivery unit, an online solvent degasser, a gradient mixer, and a system controller (Shimadzu Scientific, Columbia, MD, USA), coupled with a CTC-PAL autosampler (LEAP Technologies, Carrboro, NC, USA) for injecting samples. The mass spectrometer is an API 4000 LC-MS/MS system (AB SCIEX, Framingham, MA, USA) equipped with a Turbo V IonSpray ionization source. The ShaQer 1500 from SPEX SamplePrep (Metuchen, NJ, USA) was used for mixing samples in the QuEChERS extraction procedure.

LC-MS/MS Conditions. Neonicotinoids in pollen and honey were analyzed by the LC-MS/MS method that was developed previously for pollen and high-fructose corn syrup (HFCS) samples.[30] Analysis of neonicotinoids in fruits and vegetables was conducted by using the modified method for pollen and HFCS. Briefly, the chromatographic separation was performed on a YMC ODS-AQ column (100 mm × 2.1 mm, 3 μm particle size, YMC, Allentown, PA, USA) with the mobile phase, consisting of water with 5 mM ammonium formate and 0.1% formic acid (mobile phase A) and acetonitrile/water (95:5 v/v) with 5 mm ammonium formate and 0.1% formic acid (mobile phase B), running gradient at 170 μL/min in 11 min for each analysis. The mobile phase gradient was as follows: 0% B for 1.3 min; linearly increased to 100% B from 1.3.0 to 2.3 min, and then maintained at 100% B from 2.3 to 7.5 min, back to 0% B from 7.5 to 8.0 min, and maintained at this proportion from 8.0 to 11.0 min. Injection volume into the LC-MS/MS is 10 μL. The mass spectrometer equipped with an electrospray was operated in the positive ionization mode with multiple reaction monitoring (MRM). The mass/charge (m/z) ratios monitored were 223/126, 250/169, 203/129, 230/203, 256/209, 271/225, 253/126, and 292/211 for acetamiprid, clothianidin, dinotefuran, flonicamid, imidacloprid, nitenpyram, thiacloprid, and thiamethoxam, respectively. A second transition was used for each analyte for identification purposes. The m/z of the internal standards (IS) of imidacloprid-d_4, clothianidine-d_3, and thiamethoxam-d_3 were 260/213, 253/172, and 294/214, respectively. The quantification of neonicotinoids was made from matrix-matched standard calibration curves using peak-area ratio of analyte versus IS. The calibration curves were constructed using weighted ($1/x$) linear least-squares regression. A calibration standard curve and two concentrations of QCs (QC low and QC high) in duplicate were incorporated into each analytical run. The QCs provide the basis for accepting or rejecting the run (within 20% of accuracy and precision).

Sample Collection. Twenty-nine fresh fruit and vegetable samples were purchased from several neighborhood grocery stores in Boston in 2012. Honey samples were collected directly from hives located in urban and suburban areas in Massachusetts (n = 3) or purchased from a local grocery store in Boston (n = 5) and from a store in Israel in 2012 (n = 2). Six pollen samples from New Zealand were collected by using pollen collectors set out under three hives located near a kiwifruit orchard during peak flowing for 2 days in 2011. The pollen samples were then separated into kiwifruit pollen and others (nonkiwifruit) pollen on the basis of the color of the pollen pellets. Another seven pollen samples were collected from hives located in seven different locations in the central Massachusetts area in July 2012.

Sample Preparation. *Calibration and QC Samples.* A prior analysis of neonicotinoid-free pollen, honey, and organic fruits and vegetable samples, which were used as blank matrix samples, was performed and confirmed to have no contamination of neonicotinoids. These blank samples were used for calibration, QCs, and blanks for the analysis. In addition, as a background check for any possible interference, blank matrix samples were also injected immediately after high-level standards to check the carry-over of the instrument. No carry-over was observed during the analysis. All calibration, QCs, and blanks were generated in 2 g blank matrix for pollen, 5 g for honey, and 10 g for fruits/vegetables. Calibration curves for eight neonicotinoids at seven levels ranging from 0.1 to 100 ng/g (except 0.1−50 ng/g for honey) were prepared by adding aliquots of intermediate standard solutions (preparation steps can be found in the previous study[30]) to blank sample matrix. The QC samples at two concentration levels, 5 (QCL) and 50 ng/g (QCH) (except 2 (QCL) and 40 ng/g (QCH) for honey), were prepared the same way as the blank sample matrix. The standards and QCs were stored at −20 °C.

Food Samples. The fruit and vegetable samples were washed under cold water for 15 s and allowed to drain for at least 2 min on paper toweling. Oranges were peeled, and the rinds of pumpkin and watermelon were removed. Anything that would not normally be consumed, such as apple core, pepper core, orange seeds, and the leafy tops of strawberries, were also removed. Then the samples were

chopped into small pieces and blended in a Magic Bullet until a homogeneous paste was achieved. If the sample was homogenized in portions, all portions were mixed together in a clean container to ensure an evenly mixed sample.

The overall sample preparation procedure is shown in Figure 1. The sample extraction procedures for fruits and vegetables were modified from the method that we developed previously for pollen and HFCS samples, and the procedure for honey samples was the same as that for HFCS.[30] Ten grams of homogenized fruit and vegetable samples was weighed in a 50 mL centrifuge tube, and 10 mL of acetonitrile and 20 μL of IS solutions were added. For calibration standard and QCs, 10 g of homogenized organic samples was fortified with appropriate levels of working standard solutions. Double-blanks and blanks were also prepared in parallel with and without IS added, respectively. The tube was subsequently shaken for 30 s in a ShaQer at 1500 strokes per minute. Then one pack of QuEChERS salt and one ceramic homogenizer were added. An additional 5 mL of *n*-hexane was added to all olive samples. The tubes were shaken vigorously for 40 s in the shaker and centrifuged for 4 min at 4000*g*. One milliliter from the acetonitrile layer was transferred to a 2 mL QuEChERS dispersive SPE vial. Pollen, honey, and olive samples were added to d-SPE vials containing 50 mg of PSA, 50 mg of C18, and 150 mg of $MgSO_4$; spinach sample was added to d-SPE containing 50 mg of PSA, 50 mg of GCB, and 150 mg of $MgSO_4$; and all the rest of the fruits and vegetables were added to d-SPE containing 25 mg of PSA, 7.5 mg of GCB, and 150 mg of $MgSO_4$. The next d-SPE extraction, sample drying, and transfer steps were the same as presented before.[30]

RESULTS AND DISCUSSION

In this study, we analyzed various types of fruits, including oil fruits, stone fruits, pome fruits, citrus fruits, and berries, and vegetables, including leafy vegetables and root vegetables, as well as honey and pollen. Table 1 shows the performance of this method including the limit of quantification (LOQ) and the average recoveries (and the variations) of eight neonicotinoids in various sample matrices. LOQ was calculated as 10 times the signal-to-noise ratio of the quantitative ion transition in the matrix and was 0.1 ng/g for neonicotinoids in pollen, honey, fruits, and vegetables with the exceptions of 0.5 ng/g for flonicamid and 0.5 ng/g for nitenpyram in pollen and dinotefuran in honey. A sample was considered positive when residue levels were above the LOQ. As shown in Table 2, all fruit and vegetable samples in our study tested positive for one or more neonicotinoids, except nectarine and tomato. Five neonicotinoids, including clothianidin, dinotefuran, flonicamid, imidacloprid, and thiamethoxam, were detected in both fruits and vegetables; however, acetamiprid and thiacloprid were found only in fruits. Nitenpyram was the only neonicotinoid that is not detectable in any fruit or vegetable samples. Imidacloprid not only was detected with the highest concentration in a green pepper sample (7.2 ng/g), but also was the most frequently detected neonicotinoid in both fruits and vegetables with the overall detection rate of 70%. The results in Table 2 show that not only are neonicotinoids widely found in fruits and vegetables but also multiple neonicotinoids are often detected in a single sample, especially in apples. Seventy-two percent of fruits and 45% of vegetables were found to have multiple neonicotinoids. These percentages included 5 of 8 apples, which were detected with three different neonicotinoids, and 6 of 10 fruits and 5 of 11 vegetables were positive for two neonicotinoids. Because most commercially available products do not contain multiple neonicotinoids as the active ingredients, except for clothianidin, which could be the breakdown product of thiamethoxam, this result indicates that these fruit and vegetable plants were likely treated multiple times during their lifespan with different neonicotinoids or absorbed neonicotinoid residues accumulated in the soil. The persistence of neonicotinoids in aerobic soil is highly likely due

to the accumulation of repeated applications of neonicotinoids, especially ones with long half-lives.[20]

In addition to fruits and vegetables, we analyzed 10 domestic and foreign honey samples collected from urban, suburban, and rural areas. Table 3 shows that five neonicotinoids, including acetamiprid, clothianidin, imidacloprid, nitenpyram, and thiamethoxam, were found in these honey samples. Similar to fruits and vegetables, imidacloprid was found in 9 of 10 honey samples, including 2 organic honey samples purchased from a local grocery store. The highest concentration of imidacloprid of 1.3 ng/g was found in a domestic organic honey sample. The USDA organic regulations allowed residues of prohibited pesticides up to 5% of the tolerance set by the U.S. Environmental Protection Agency (EPA) in organic products, but there are no defined tolerances for most neonicotinoids (including imidacloprid) in honey.[32] Five honey samples contained multiple neonicotinoids, including two organic honey samples. Only one honey sample collected from a hive located in the rural area was free from neonicotinoid contamination. The high frequency of detections of neon-

icotinoids, especially imidacloprid, in these samples indicates the wide usage of neonicotinoids in the environment where honeybees often foraged.

We also tested 13 pollen samples; 7 of them were from central Massachusetts and 6 from New Zealand. As shown in Table 4, imidacloprid continued to be the most commonly detected neonicotinoid with a detection frequency of 77% in all 13 pollen samples. Among the seven pollen samples from Massachusetts, the five that tested positive were collected from central Massachusetts within the so-called "quarantine area", where trees were injected with imidacloprid to combat the Asian Longhorn beetle problem in 2011–2012. The other two pollen samples containing no neonicotinoids were collected outside the "quarantine area", where neonicotinoid uses have not been observed or reported. The degree of neonicotinoid contamination in pollen samples collected in New Zealand is more extensive than that of samples collected from central Massachusetts areas, as shown in Table 4. All six samples contained multiple neonicotinoids, and five of those six samples contained three neonicotinoids. It is also noticeable that

nonkiwifruit (others) pollen samples contained higher concentrations of imidacloprid and clothianidin than kiwifruit pollen. Those nonkiwifruit pollen samples were likely from nearby dandelion, clover, and other weed flowers, on the basis of the color of the pollen pellets. Because kiwifruit has little nectar, honeybees need to forage widely (as far as 2 km) to get their nectar feed for energy. In this search, bees could pick up other pollens containing higher levels of neonicotinoids around the kiwifruit orchard than the pollen of kiwifruit; therefore, higher levels of neonicotinoids showed up in these "others" pollen. This finding is consistent with the systemic property of neonicotinoids because upon application (such as spray), neonicotinoid residues can penetrate and translocate through the plant/weed, including nectar and pollen, located near the adjacent area. Because pollen is honeybees' main source of protein and neonicotinoids have been linked to CCD,[8,9] the widespread presence of neonicotinoids in these pollen samples could pose a potential threat to the survival of honeybees.

In addition, neonicotinoids, such as imidacloprid, clothianidin, and thiacloprid, have often been used as soil treatment for insect controls because of their long half-lives in aerobic soil (half-lives for imidacloprid and clothianidin are 26−229 and 148−1155 days, respectively) and water solubility.[6,20,33] A recent study has shown that clothianidin was found in both soil and dandelion flowers grown adjacent to a clothianidin-treated agriculture area.[34] Another study has shown that untreated sunflowers grown in fields previously treated with imidacloprid a year ago can still take up imidacloprid from the soil.[35] Therefore, some neonicotinoids can become persistent for several years and accumulated in the environment after repetitive applications and, therefore, cause concern for prolonged exposure.

This result from pollen samples is consistent with that from the fruit and vegetable samples in this study because most of these types of fruits and vegetables testing positive were pollinated by honeybees. Our study also raises the concern of pollen contaminated with neonicotinoids because not only is pollen the primary protein source for honeybees but also it could be readily available for human exposure via inhalation as well.

Table 5 shows the summary results of neonicotinoid residues detected in all samples that were analyzed in this study. Both imidacloprid and clothianidin were found in all four types of foods followed by thiamethoxam (three types of foods); acetamiprid, dinotefuran, flonicamid, and thiacloprid (two types of food); and nitenpyram (in only one honey sample). Results from this study were generally consistent with what have reported by the USDA PDP during 2004−2011 (Table 6). Consistent with having the highest frequency of detection among all neonicotinoids in samples that we analyzed, imidacloprid was found in seven of eight apple samples in this study, as well as in apples/applesauce/apple juice samples reported by PDP from 2004 to 2010 (Table 6). Along with imidacloprid, apples/applesauce/apple juice have the highest detection frequency of acetamiprid in almost every year from 2004 to 2010, although the frequency of detection for acetamiprid has gradually decreased from 100% in 2004 to approximately 30% in 2007. Similarly, apple, applesauce, or apple juice has consistently been the commodity with the highest frequency of detection for thiacloprid every year from 2004 to 2010 and has an increasing trend of use from 4.7% in 2007 to 9% in 2009 to 12.6% in 2010. Although clothianidin was not detectable in apples or apple juice in PDP from 2007 to 2009, clothianidin was found in three of eight apples in the current study conducted in 2012. Consistent with results from PDP, the current study has confirmed the wide use of imidacloprid, clothianidin, acetamiprid, flonicamid, and thiacloprid on apples, ranging from 38 to 88%. Unfortunately, we were not able to continue monitoring the trend of neonicotinoid residues in apples because they were not included in PDP after 2010. We found a higher frequency of detection of imidacloprid than USDA PDP reported primarily because we used a more sensitive analytical method with lower LOQs for all neonicotinoids in this study than those used by USDA PDP with a limit of detection ≥1 ng/g. Smaller sample sizes in our study could be another reason for higher frequency of detection; however, the commodities testing positive in our study matched the commodities reported by PDP. For instance, the highest concentration of thiamethoxam detected in our study was from a cucumber sample (13.2 ng/g), and cucumber was found with the highest detection rate of 12% in 2009 and an even higher rate of 16% in 2010 by PDP. The highest concentration of dinotefuran in our study was found in a cantaloupe sample, which was also reported by PDP in 2010 and 2011 with the highest detection rates of 15 and 12%, respectively.

This study has demonstrated the widespread presence of neonicotinoids in foods that people commonly consume and in pollen and honey that honeybees bring back to hives from the environment. Although those levels were low, studies have suggested a link to adverse health effects in honeybees as the results of sublethal exposure to neonicotinoids.[8,36,37] Neonicotinoid insecticides are known to selectively target insects' nicotinic acetylcholine receptors (nAChRs) and therefore were previously thought to pose less toxicity in mammals. However, a growing amount of evidence has shown that neonicotinoids are capable of directly activating and/or modulating the activation of mammalian nAChRs. Both in vitro and in vivo studies have shown that imidacloprid can change the membrane properties of mouse neurons,[38] significantly impair sensorimotor performance, and elevate glial fibrillary acidic protein expression in the motor cortex and hippocampus of neonatal rats after in utero exposure to a single sublethal dose.[39] Most mammalian adverse toxic effects of neonicotinoids are associated with their action on binding to the $\alpha4\beta2$ nAChR subtype.[40] In an in vitro study, imidacloprid and other neonicotinoids have been shown to directly activate and modulate human $\alpha4\beta2$ nAChR subtypes.[41] The $\alpha4\beta2$ nAChR subtype is the most prominent nAChR subtype in the mammalian brain, with the highest density of receptors in the

thalamus.[42] The $\alpha4\beta2$ nAChR is involved in various brain functions, such as cognition, memory, and behavior. There is strong evidence for a role of $\alpha4\beta2$ nAChR and alteration of the receptor density in CNS disorders, such as Alzheimer's disease, Parkinson's disease, schizophrenia, and depression.[43,44] In the developing brain (such as perinatal stage), $\alpha4\beta2$ nAChR subtypes have been implicated in neuronal proliferation, apoptosis, migration, differentiation, synapse formation, and neural-circuit formation.[45,46] It is likely that neonicotinoids could affect these processes when activating nAChRs. In addition, absorption studies using the human intestinal cell line have shown that neonicotinoids can be absorbed by active transportation.[18,47] Neonicotinoids and some of their metabolites are also shown to be able to pass through the blood–brain barrier in mice, and some metabolites having enhanced potency to nAChR are even more toxic than their parent compounds.[48] Therefore, there is an inevitable question if neonicotinoids could pose potential health risks to humans as well.

In conclusion, this is the first paper to document the widespread presence of neonicotinoid residues in fruits, vegetables, and honey that are readily available in the market for human consumption. We also reported neonicotinoid residues in pollen collected by honeybees in areas where neonicotinoids are known to be used, and the variation of neonicotinoid levels in pollen likely reflects the amount of neonicotinoids applied. It is important to note here that although all neonicotinoid residues reported in this study were below the maximum residue levels, or tolerances, established by the EPA, the determination of these tolerances is based on the best field practice and studies conducted in test animals exposed at acute and chronic toxic levels, and therefore does not take into sufficient account the protection of human health from long-term low-dose exposure. In light of the extensive use of neonicotinoids on fruit and vegetable crops and their widespread presence in foods along with new information on the toxicological effects of neonicotinoids in mammals, it is therefore warranted to conduct epidemiological studies to assess dietary neonicotinoid intakes in humans and the health effects.

ABSTRACT: Lignin amount and subunit composition were analyzed from stems and leaf sheaths of timothy (*Phleum pratense* L.) clones of different in vitro digestibility. Lignin concentration in stems and leaf sheaths was higher in clones of low digestibility than those of high digestibility. No change in lignin concentration occurred in stems as digestibility decreased. Intriguingly, the lignin concentration was lower and the syringyl/guaiacyl (S/G) ratio was higher in stems compared to leaf sheaths at all developmental stages studied. The developmental-associated decrease in digestibility correlated with the increase in S units in lignin in stems and leaf sheaths and in the amounts of *p*-coumaric acid and ferulic acid residues in the cell wall of stems. Yields of copper oxidation products increased in stems during maturation indicating qualitative changes in the lignin structure. This correlated strongly with the developmentally linked decrease in digestibility. The information obtained is valuable for breeding and for DNA marker development.

KEYWORDS: *cell wall, digestibility, ferulic acid, lignin amount, lignin subunit composition, lignin linkage structure, timothy*

INTRODUCTION

Grass silage is an important source of metabolizable energy for milk and beef production in many countries, particularly in the temperate and cool zones of Europe and North America.[1] The main goal in forage production is to obtain high herbage mass that is of high nutritive value and digestibility. Plant cell wall polysaccharides cellulose and hemicellulose are of great importance for the energy content of silage. In grasses, lignin, a phenolic component in the cell wall, increases with increasing maturity, as the need for structural strength increases during stem elongation. This is accompanied by a decrease in digestibility.[2] Lignin provides rigidity and structural support to the cell wall polysaccharides, and it also excludes water from the wall. In grasses and cereals, cell walls of several parenchymatous cell layers in the cortex thicken and lignify during stem development, i.e., a sclerenchyma ring develops.[3−5]

In grasses and cereals lignin is composed of guaiacyl (G), syringyl (S), and *p*-hydroxyphenyl (H) units originating from coniferyl alcohol, sinapyl alcohol, and *p*-coumaryl alcohol, respectively.[6] In addition, cell walls of grasses contain hydroxycinnamic acids (*p*-coumaric and ferulic acid).[7−10] The monolignol biosynthetic pathway leading to lignin precursors is well-known.[11,12] Each gene of the pathway has been individually down-regulated, and the effects on plant growth, lignin amount, and composition have been assayed. Down-regulation of certain genes in the pathway has led to reduced lignin content and/or change in lignin composition and improved digestibility, for example, in cultivars of maize (*Zea mays*) and alfalfa (*Medicago sativa*).[2,11]

Accumulation of lignin reduces digestibility of cell wall polysaccharides as lignin makes them inaccessible to rumenal enzymes that would normally digest them. Di- and oligoferulate cross-links between ferulic acid units ester-linked to arabinoxylans and linkages between ferulates/di- and oligoferulates and lignin further impede enzymatic degradation of cell wall polysaccharides.[2,6,7,13,14] Several studies have shown that there is a negative relationship between the amount of lignin and digestion.[4,15−17] The effect of lignin subunit composition on digestibility, however, remains unclear. In many forage crops both the lignin content and its S/G ratio increase during development.[4,16] In the case of alfalfa, no clear relationship was shown between in vitro digestibility and the S/G ratio.[16] In addition, in maize, artificially produced lignins had similar inhibitory effects on cell wall degradation independently of their monolignol composition.[18] In maize plants the lignin interunit linkage pattern (with uncondensed *β*-O-4 units correlating with low cell wall digestibility) and S units acylated with *p*-coumaric acid had a greater impact on cell wall degradability than lignin subunit composition.[19]

Whereas much is known about the relationship between lignification and digestibility in other major forage grass species,[4,15,17] in the case of timothy (*Phleum pratense* L.) there is relatively little information about this relationship. Timothy is the most important perennial forage grass grown for silage and hay production in Scandinavia[20] and is also widely grown in other cool and humid regions in Europe, Asia, and North America.[21] Earlier studies have shown that both total and

acid-insoluble lignin increase during the development of timothy tillers.[15] Increase in acid-insoluble lignin, expressed as a percentage of total lignin, was more closely related to decreasing in vitro digestibility than that in total lignin. The increased portion of acid-insoluble lignin in total lignin suggests that the quality of lignin changed during plant maturation.[15] In addition, by using histochemical stains and biochemical tests, Stafford observed that the lignin in xylem vessels of timothy is different from that in the subepidermal sclerenchyma which develops later.[3] It is known that S units become more abundant in lignin at later developmental stages,[4,18] a phenomenon also detected by Quicke and Bentley as an increase in methoxyl groups in total lignin.[15]

Because the digestibility of grass is crucial in ruminant production, the biological processes controlling the digestibility of harvested forage are therefore of great importance. Changes of digestibility in the stem fraction (true stem and leaf sheath) of cool-season grasses during plant development are much larger than in leaf blades.[22−24] Furthermore, the contribution of the stem fraction to yield formation of harvested grass is high.[24,25] Therefore, in this study we focused on lignification in the stem fraction.

The aims of the present study were to compare different analytical methods to quantitate lignin in timothy and to evaluate how the lignin amount and the subunit composition affect the organic matter (OM) digestibility in timothy clones selected for either high or low OM digestibility. It is well-known that the developmental stage of the tiller and the leaf to stem (which includes leaf sheath) ratio affect both the lignin component and the digestibility of timothy.[26,27] Therefore, these factors were taken into account in the sampling procedure. In addition we carried out the lignin analyses of leaf sheaths and stems separately, as the leaf sheaths are botanically part of the leaf though typically analyzed within the stem fraction.[22,24,26,27]

MATERIALS AND METHODS

Plant Material. For comparing several methods for quantitative lignin analyses cultivar (cv.) Tammisto II was used (expt I; collected in 2008). In order to explore the role of lignin in determining the in vitro organic matter digestibility (IVOMD) of different genotypes, timothy clones that were characterized as having either low or high digestibility were used (expt II; years 2011−2012). The clones originated from the breeding material of Boreal Plant Breeding Ltd. (Jokioinen, Finland). Based on the results of a previous experiment, six clones were selected for each of the low- and the high-digestibility groups. The selection was done by taking account of the stem proportion of each clone in order to avoid selection for leafiness only.[23] Three clones were selected from each of the two groups for this study. Clones 50, 51, and 85 represented the high-IVOMD group, whereas clones 41 and 84, together with cv. Grindstad, represented the low-IVOMD group. The cultivar Grindstad was chosen as a control because it is a high-yielding variety that has a relatively low IVOMD value when cut at the same date as the other cultivars based on the Finnish cultivar testing system.[28] The sampling dates and corresponding weather parameters are presented in Table 1.

The plant material was cultivated on a coarse loamy soil (Aquic Cryorthent) at the Maaninka Research Station of MTT Agrifood Research Finland, Maaninka, Finland (63°08′ N, 27°19′ E). The clones were propagated vegetatively, and cv. Grindstad and cv. Tammisto II were propagated from seeds. The clonal tillers and cv. Grindstad were grown individually in cardboard boxes (3 cm × 3 cm) in commercial garden peat (Kekkilä White 630 W; Kekkilä Ltd., Vantaa, Finland) in an unheated greenhouse and planted on Sept. 27 and 28, 2010 in 10 cm × 12.5 cm grids on the field in microplots of 50 cm × 100 cm. The plots were fertilized with N 100, P 15, and K 25 kg ha^{-1} for the first cut and N 100, P 0, and K 35 kg ha^{-1} for the second cut. Cultivar Tammisto II was sown on May 26, 2005 in plots of 12 m^2 in the field, and the plots were fertilized for the first cut in year 2008 with N 90, P 13.5, and K 22.5 kg ha^{-1}. In 2011 fertilization was at the same rates as applied to the clone microplots. The dates of fertilizer application are given in Table 1. Both 2008 and 2011 were the third grass year for cv. Tammisto II plots.

The experimental layout of the clonal plots was a randomized block design with four replicates. Due to the limited amount of plant material, the tillers collected from blocks 1 and 2 were used for lignin analyses, and the tillers from the blocks 3 and 4 were used for IVOMD analysis. There were no blocks for cv. Tammisto II samples.

The tillers were collected at three developmental stages according to Simon and Park[29] (stage 45, boot swollen; stage 56, three-fourths of the inflorescence emerged; stage 58, base of the inflorescence just visible). The sampling time corresponded to the time of spring harvesting, except in 2008 when fully mature generative plants were collected for lignin quantitative analyses. Tillers were harvested by cutting with a razor blade immediately above the soil, and the height to the uppermost ligule was measured after which the leaves, leaf sheaths, stems, and heads were separated. For chemical analyses, leaf sheaths and stems of six tillers collected from the same block were separately pooled and stored at −20 °C until dried. Two sets of pooled samples (i.e., biological replicates) were collected from blocks 1 and 2.

At the same time, 18−25 tillers of each clone at developmental stages 45 and 58 (see preceding descriptions) were collected for IVOMD analysis from blocks 3 and 4. These tillers were pooled due to a limited amount of plant material. Leaves and heads were removed, and stems and leaf sheaths were kept together and dried in a forced draft oven at 60 °C (approximately 40 h). Dry weights were determined and the proportions of the dry matter per tiller calculated. In order to determine the organ portions in each clone at the developmental stages studied, leaves, leaf sheaths, stems, and heads were separated from 10 (stages 45 and 56) or 30 tillers (stage 58) in year 2012. Fractions were dried at 60 °C (approximately 40 h) and

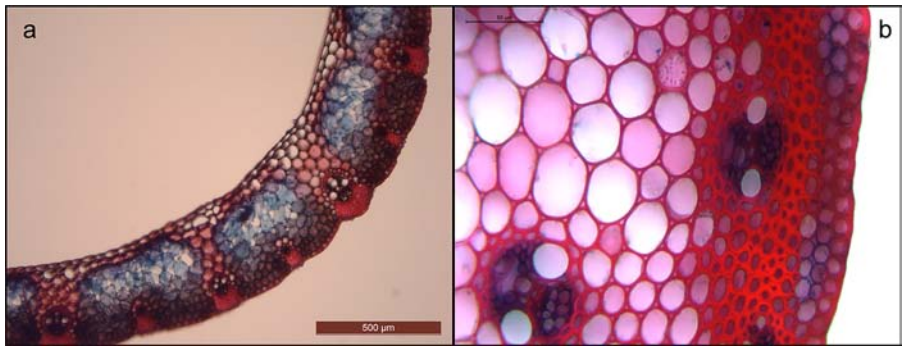

Figure 1. Cross-section of a timothy (a) leaf sheath and (b) stem stained with Alcian blue-Safranin O staining.

weighed. The proportions of leaf sheath and stem were determined by using dry weights.

Microscopy. The lignification stage of the tillers at each developmental stage was studied by microscopy. A sample (1 cm) was taken from the middle of the second lowest internode and fixed in a formalin (2%, v/v)−acetic acid (5%, v/v)−ethanol (63%, v/v) mixture (FAA). Hand-made or paraffin-embedded sections were made, and the developmental stage was observed after Alcian blue−Safranin O staining.[5]

Chemical Analyses. For lignin analyses plant material was dried in an oven at 60 °C and milled to a fine powder with a Retch ball mill (Retsch MM400, Haan, Germany; 50 mL grinding jars with one ball; stems, 4 × 30 s; leaf sheaths, (1−)2 × 30 s; frequency, 30 s^{-1}). To prevent warming of the samples during the milling, the grinding jars were cooled on carbon dioxide ice between samples. The extractive-free alcohol-insoluble residue (AIR) was obtained by extracting the powder for 8 times with 70% (v/v) ethanol in a water bath sonicator (25−30 °C; 30 min incubation in each extraction, with regular mixing) followed by 3 times with acetone. The tubes were centrifuged (4000 rpm, 10 min, at room temperature) before the solvent change. AIR was dried overnight at 60 °C and stored in firmly closed tubes in the dark at room temperature.

Since different quantitative methods for lignin determination are known to give different results,[30] we compared several methods by using AIR of cv. Tammisto II as a material (stems only, leaf sheaths removed). Permanganate lignin[31] was assayed in the MTT laboratory, and acid detergent lignin (ADL) by using the Foss Tecator Fibertec System M 1020 hot extractor and Fibertec System 1021 cold extractor, as described in Ordior Application Note AN 304, Ordior Application Sud Note ASN 3430 (AOAC-973.18) and USDA Forage Analyses Procedures, July 1993. Acid dioxane lignin was prepared as described.[32] Klason lignin was analyzed with a method commonly utilized by the Finnish Forest Research Institute.[33] For Klason lignin, the plant powder was sequentially extracted in a Soxhlet apparatus with acetone, ethanol, and water, 6 h each. The total nitrogen content of the Klason lignin was determined using a Leco CHN-1000 analyzer (St. Joseph, MI, USA), and the protein content calculated using the equation 6.25 × N%.[34]

Lignin content of timothy clones (stems and leaf sheaths separately; two pooled biological replicates) was analyzed with an acetyl bromide (AcBr) method[35] with modifications. Corresponding cv. Tammisto II samples of known Klason lignin content were used as standards. Briefly, 5 mg of AIR was transferred into a glass tube with a Teflon-coated lid. A 5 mL aliquot of AcBr reagent (20% AcBr (v/v) in glacial acetic acid without perchloric acid)[35] was added and the sample incubated at 50 °C for 3 h 15 min with regular mixing. The reaction was stopped in a −20 °C freezer for 15 min. An aliquot of 1.0 mL was transferred into a 10 mL volumetric flask containing 1 mL of 2 M NaOH and 2.4 mL of glacial acetic acid. After careful mixing, 0.1 mL of 7.5 M hydroxylamine−HCl was added. The volume was filled to 10 mL with acetic acid, and the absorbance at 280 nm was read with a Shimadzu UV-2401 spectrophotometer (Shimadzu Corp., Kyoto, Japan) against a blank that had been treated similarly to the samples.

Lignin subunit composition and *p*-hydroxycinnamic acid content in the cell wall of stems and leaf sheaths were studied by an alkaline cupric (II) oxidation method (CuO)[36] with modifications using AIR as a starting material. Oxidations were performed using a microwave digestion system MSD-2000 and a liquid phase hydrolysis accessory set (CEM Corp., Matthews, NC, USA). The gas chromatography−mass spectroscopy (GC-MS) detection of trimethylsilyl derivatives of CuO oxidation products was made using a HP 6890/HP 5972 (Hewlett-Packard, Palo Alto, CA, USA) equipped with a HP-5MS column (30 m; 0.25 mm i.d.; film thickness, 0.25 µm). The concentrations of individual compounds were calculated using response factors of commercially available standards. The internal standard, cinnamic acid, was added into the reaction vessel before microwave-assisted CuO treatment of samples. The method is time-consuming, and therefore the analysis was restricted to samples of one pooled biological replicate. Lignin subunit content was calculated as the percent of the corresponding total yield of CuO oxidation products, whereas *p*-coumaric acid and ferulic acid content was calculated as µmol g^{-1} AIR.

Digestibility Values. IVOMD (g kg^{-1} OM (cellulase))[37] with calculation of the results as described in Huhtanen et al.[38]), ash (g kg^{-1} dry matter (DM)), and neutral detergent fiber (NDF, g kg^{-1} DM) were assayed from the same clonal material (stems and leaf sheaths together) for the developmental stages 45 and 58 in the MTT laboratory. IVOMD was also determined separately for stems and leaf sheaths of clones at developmental stage 58 collected in 2012. Digestibility value (*D* value; g kg^{-1} DM) was calculated by (1000 − ash) × (IVOMD × 1000^{-1}).

Statistical Analyses. In order to study the relationship between measured IVOMD and the parameters obtained from lignin analyses, the lignin parameters were first calculated to correspond the same plant organs as the IVOMD analyses; i.e., we calculated weighted means for the whole stem (which includes leaf sheath; subsequently referred to as stem + leaf sheath) using original values of true stems and leaf sheaths separately, and their corresponding organic proportions that were determined in 2012 from the same plots. The generated weighted means for stem + leaf sheath were subjected to analysis of variance together with the original separate values for leaf sheath and stems.

Analysis of variance was performed using a mixed model with a residual maximum likelihood (REML) estimation method. In the model, the phenological stage, digestibility group, and their interaction were fixed effects, while clones were considered as a random effect. In the case of AcBr analyses with two biological replicates, the replicate was a random effect and the fixed effects were phenological stage and clone. Stage × clone interaction was not significant for any of the AcBr parameters, so it was not included in the model. The difference between digestibility groups was determined using contrast. The same model without a random effect was also used for the proportion of leaf sheaths and stems as there were no replicates. Pairwise comparisons between phenological stages were assessed by Tukey's test in all models. The MIXED procedure of SAS software (version 9.2; SAS Institute Inc., Cary, NC, USA).[39] The statistical dependences between IVOMD and other parameters were determined by Spearman's rank

correlation coefficient (r_s) using the CORR procedure of SAS software. Usage of r_s does not require the assumption of normality. Statistical significance was postulated at the 0.05 level of probability.

RESULTS AND DISCUSSION

Timothy clones of different in vitro digestibility were analyzed for lignin amount and subunit composition to evaluate their effects on digestibility. We separated leaf sheaths from stems before the analyses to assay the lignin in both organs separately. Timothy has a regular veining pattern in the leaf sheath that is an important support-giving structure for developing grass stems with intercalary meristems. Each vascular strand in the leaf sheath is accompanied by highly lignified sclerenchyma cells toward the adaxial epidermis (Figure 1a). The central area of the leaf sheath contains large, thin-walled cells that probably store water and are important for turgor-driven adjustment of the leaf sheath around the stem. In stems, xylem vessels in the vascular strands lignify first, followed by the sclerenchyma cells in and around the vascular strands (data not shown). The cell walls of the outer cortex cell layers also thicken and lignify during further development (Figure 1b).

Lignin Quantitative Analyses. Results obtained with various lignin quantitative methods differed (Figure 2), which is in accordance with a previous report.[30] Klason lignin and AcBr lignin (with acid dioxane standard) methods gave 3.5−6 times higher lignin concentrations than ADL, permanganate lignin, and acid dioxane lignin methods. Of the methods used, the ADL and Klason methods are gravimetric methods where cell wall carbohydrates are hydrolyzed with concentrated sulfuric acid, after which the residue that represents nonsoluble lignin is weighed. The acid-soluble part of the lignin is assayed from the solution and taken into account in the Klason estimate. The ADL procedure, which is based on the preparation of acid detergent fiber (ADF), however, underestimates the lignin content in grasses as a considerable amount of lignin (50% or more) is acid-soluble.[30] The S lignin, especially, is more soluble than other types of lignin during sulfuric acid hydrolysis.[32]

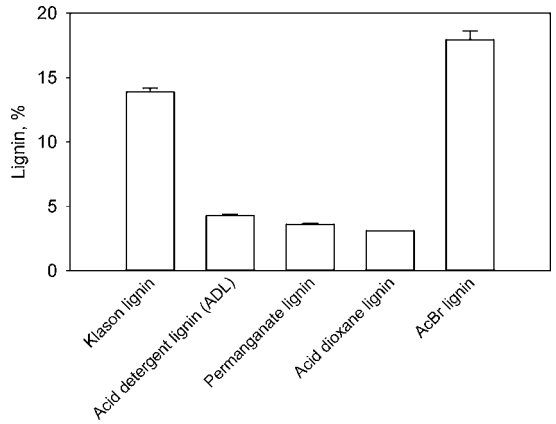

Figure 2. Lignin concentration (%) in stems of cv. Tammisto II as assayed by using several quantitative methods. AcBr = acetyl bromide. Error bars are standard errors of the means.

Timothy leaf sheaths were observed to contain more lignin than was present in stems. This occurred at all developmental stages studied, as calculated per mass unit of AIR, and was the case with AcBr lignin (Table 2) and Klason lignin (data not shown). The organ proportions (Table 2) were used to calculate the lignin concentration in stem + leaf sheath. Surprisingly, the phenological stage did not have any effect on the lignin concentration in AIR of stems, whereas that in AIR of leaf sheaths increased during development (Table 2). As the proportion of leaf sheaths decreased during development, however, the phenological stage had no effect on the calculated lignin concentration in AIR of stem + leaf sheath. The digestibility groups did not differ in the proportion of leaf sheaths but clones of low digestibility had higher lignin concentration both in AIR of stems and in AIR of leaf sheaths, and thus, also in the AIR of stem + leaf sheath (Table 2). This correlated negatively with IVOMD (Table 3). There were also some differences between individual clones in the lignin concentrations and also in the proportions of leaf sheaths (Table 2). The proportion of leaf sheaths did not, however, correlate with the IVOMD of the whole stem (stem that includes the leaf sheath; Table 3). The fact that the organ proportions were not determined in the same year as the samples for chemical analyses were collected may, however, weaken the relationship between plant organ proportions and chemical analyses.

Lignin Subunit Composition and Hydroxycinnamic Acids. Relatively mild oxidation with CuO induces cleavage of β-O-4 ether bonds in lignin;[36] thus, the subunit composition observed with this method originates from these noncondensed linkages. In timothy the abundance of S units in lignin increased during tiller development in both digestibility groups (Tables 4−6), correlating with the decrease in digestibility (Figure 3a; Table 3). In stems the S/G ratio was higher than in leaf sheaths at all developmental stages studied, suggesting that, in the case of timothy, the lignin subunit composition differs between stems and leaf sheaths (Tables 4 and 5). A similar difference in S/G ratio has been observed in leaf sheaths and stems of maize.[40] Interestingly, the relative increase in S units during development was higher in leaf sheaths than in stems of timothy. S units are able to form C−C bonds at the 8-position (β−β pinoresinol type structures), but they are unable to form C−C bonds in the 5-position due to methoxylation. Thus, an increase in S units observed during development suggests that the linkage structure in lignin changed. This conclusion is supported by the increased yields of CuO oxidation products obtained in stems at later developmental stages (Table 4) indicative of an increase in noncondensed β-O-4 bonds. There was, however, no developmental-related change in the yields of CuO oxidation products in leaf sheaths (Table 5) when both the lignin concentration (Table 2) and the proportion of S units increased. This indicates qualitative changes in lignin structure and possible cross-linking with carbohydrates.[40] The lower yields of CuO oxidation products obtained at earlier developmental stages from stems that contain higher relative proportions of S units than leaf sheaths, however, suggest that early in true-stem development the amount of β-O-4 linkages in stem lignin is less than in leaf-sheath lignin, but that during stem development S units are preferentially incorporated in these noncondensed linkages in stem lignin (Tables 4 and 5). Clones of low digestibility resulted in higher yields of CuO oxidation products in stem + leaf sheath than those of high digestibility (Table 6); furthermore, the increase in the yields CuO oxidation products strongly correlated with the decrease in digestibility during development (Figure 3b; Table 3).

Gramineous plants contain *p*-hydroxycinnamic acid residues esterified to arabinoxylan in the cell wall.[7,9,40] Ferulates can also be ether-linked to lignin. The ester-linked units can be released by saponification at room temperature whereas those residues

that are etherified to lignin can be released by high-temperature alkali treatment.[7] While being esterified to carbohydrates and etherified to lignin, ferulates make bridges between carbohydrates and lignin; these enhance the mechanical properties of the lignified cell walls and also contribute to digestibility decrease.[9,14] Ferulic and *p*-coumaric acid contents were higher in timothy stems than in leaf sheaths (Tables 4 and 5). The amount of ferulic acid in timothy cell walls increased during development in stems, and thus in stem + leaf sheath (Tables 4−6), correlating negatively with digestibility (Figure 3d; Table 3). This observation suggests that ferulates were continuously incorporated into the cell wall of stems leading to formation of di- and oligoferulate bridges as well as carbohydrate−lignin complexes.[14] Also, *p*-coumarate is associated with lignins, mainly esterified to S units.[14,41] In timothy, the level of cell wall-located *p*-coumaric acid rose slightly (ca. 1.1 times) in stems during development when S units increased (Table 4), suggesting that *p*-coumarates were at least partly coupled to S units. In leaf sheaths, however, no change in *p*-coumarate or ferulate concentration occurred during maturation (Table 5). This observation is interesting as ferulate cross-linking often correlates with reduced digestibility.[9,14] In maize, the concentrations of both ferulate esters and ferulate ethers increase between immature and mature (silage stage maturity) samples in both stems and leaf sheaths.[40] We do not know whether there are differences in the CuO procedure in the effectiveness of releasing of the hydroxycinnamic acids from the AIR of leaf sheaths and stems. However, none of the methods presently used in lignin analyses gives the absolute amounts of lignin subunits. The observation that the CuO method used in the present study gave repeatable results with different plant organs (leaf sheaths and stems, respectively) justifies making comparisons between these organs and the developmental stages. The results indicate that the ferulic acid content alone, and the cross-linking to arabinoxylans do not explain the differences observed in the digestibility of stems and leaf sheaths. A pronounced difference exists in cell wall-located *p*-coumarates in stems of timothy, a C3 plant, and maize, a C4 plant, because in maize stem the amount of *p*-coumarate esters increase by 2.6-fold during maturation,[40] whereas in maize leaf sheaths the situation is similar to that of timothy (1.2-fold increase in maize; no change in timothy). *p*-Coumarates in lignin are known to exist as terminal pendant groups; thus, the growth of the lignin polymer is restricted after incorporation of *p*-coumarylated S units.[6]

Digestibility Values. The effect of the phenological stage was evident for tiller dry weight, stem height, NDF, IVOMD, and *D* value of the stem (including leaf sheath) in the clonal material (Table 7). The clones of the high-digestibility group had lower NDF and higher IVOMD and *D* values. The differences between digestibility groups in IVOMD and *D* value were more evident at the later development stage 58 than at the earlier stage 45. Surprisingly, similar interaction (stage × group) was not found in the lignin subunit composition analysis (Table 6). In general the measured NDF values of the stem fraction were similar to those of early and late maturing timothy cultivars[22] and logically higher than determined for the total DM yield of timothy.[27] Furthermore, the observed IVOMD in stems including leaf sheaths were markedly higher than in the results given by Nissinen and co-workers[24] even for stage 58 tillers of the low-digestibility group. The NDF concentration and stem height correlated strongly with the decrease in IVOMD (Table 3) referring to the role of fiber fraction (NDF) as mechanical support needed for higher stems.

There were clear differences in the lignin concentration and its subunit composition in stems and leaf sheaths of timothy clones. Unfortunately, in the IVOMD analyses these plant parts were not separated. When IVOMD was analyzed separately in stems and leaf sheaths for the clonal material collected in the following year (2012) from the same plots at stage 58, the leaf sheaths had lower digestibility (663 vs 650 g kg^{-1} DM, P = 0.020) and higher ADL lignin concentration (53 vs 62 g kg^{-1} DM, P = 0.020) than stems. Similarly, in cv. Tammisto II collected in 2011, the leaf sheaths had lower digestibility than stems (data not shown). This is probably due to higher lignin concentration in leaf sheaths than in stems. However, the yields of CuO oxidation products obtained from leaf sheaths at all developmental stages studied were approximately at the same level as in stems at stage 58, when digestibility had already decreased (Tables 4, 5, and 7). This finding suggests that lignin linkage structure in leaf sheaths is not optimal for digestion even at an early development stage.

Summary. Lignin concentration in cell walls of timothy is the factor that explains the digestibility difference between clones of low and high digestibility. The developmental-associated decrease in digestibility correlates with the change in lignin subunit composition, and especially with the change in lignin linkage structure as shown by the increase in the yields of CuO oxidation products indicative of noncondensed β-O-4 linkages. In addition, the increase in the content of cell wall-located hydroxycinnamates contributes to the digestibility decrease during maturation. The difference in the lignin amount and the subunit composition between stems and leaf sheaths is interesting, as leaf sheaths have lower digestibility than stems. This is probably due to the fact that leaf sheaths contain more lignin than stems, but the lignin linkage structure may also contribute to this. Interestingly, there are less cell wall-bound hydroxycinnamic acids in leaf sheaths compared with stems. Considering that leaf sheaths, which consist of ca. one-third of the whole stem (stem including leaf sheath), are less digestible than stems, some goals in the future breeding efforts of timothy could include a reduction of the leaf-sheath proportion in the yield or a targeted lowering of the lignin concentration in leaf sheaths to the level of that in stems. It should be noted, however, that cell wall composition (lignin among other factors) in leaf sheaths is important in resistance

ABSTRACT: In this paper, a rapid and effective HPLC method, using tetraazacalix[2]arene[2]triazine-modified silica gel (NCSi) as solid-phase extraction (SPE) sorbent, was developed for the purification and determination of trace acrylamide in starchy foodstuffs. The main influence factors of SPE including amount of NCSi sorbent, sample flow rate, and volume and composition of washing solution were investigated and evaluated in the sample pretreatment step. The optimized purification effect was achieved at the sample flow rate of 3 mL/min with 100 mg of NCSi and 2 mL of washing solution (water, 100%). The HPLC separation was carried out on a C18 column (250 × 4.6 mm i.d., 5 μm) with a mobile phase of methanol/water (10:90, v/v). The linear range of the calibration curve was 4−4000 ng/mL with s correlation coefficient of >0.9999. The intraday and interday RSDs (n = 5) of peak areas of acrylamide were 0.22 and 0.90% and the intraday and interday RSDs (n = 5) of retention times were 0.50 and 1.63%, respectively. In addition, overall recoveries through the extraction and NCSi-SPE purification ranged from 73.13 to 98%. Compared with the commercial SPE sorbents, NCSi featured excellent selectivity to retain polar and nonpolar interferences in the sample matrices. The improved method was simple, rapid, accurate, and promising for the determination of trace acrylamide in starchy foods with a complex matrix.

KEYWORDS: *tetraazacalix[2]arene[2]triazine-modified silica gel, SPE purification, HPLC, acrylamide, starchy foodstuffs*

INTRODUCTION

Acrylamide, a colorless and odorless crystalline powder, is known to be formed by the Maillard reaction during heating of starchy foodstuffs. In April 2002, the Swedish National Food Administration (NFA) and researchers from Stockholm University found high acrylamide levels in carbohydrate-rich foodstuffs fried/baked at high temperatures.[1] In recent years, research on acrylamide in different matrices has attracted extensive attention due to its demonstrated neurotoxicity, genotoxicity, and potential human carcinogenicity.[2]

In past years, a number of chromatographic methods have been developed to determine acrylamide such as gas chromatography (GC) with derivatization and high-performance liquid chromatography (HPLC) without derivatization.[3,4] Nowadays, most analytical methods are based on GC-MS and LC-MS/MS,[5−20] which appear to be acknowledged as the most useful and authoritative methods for the quantification of acrylamide in complex matrices. However, both GC-MS and LC-MS are high-cost and cannot be easily adopted by nonspecialized laboratories. On the contrary, HPLC with UV detection possesses the advantages of simplicity, lower cost, and strong maneuverability compared to MS techniques. Meanwhile, it is noteworthy that the matrix effect is a serious problem in the trace analysis of acrylamide in complex matrices such as chips and coffee,[7,12,13] which make quantification and identification difficult. Therefore, removal of the matrix effect and sample pretreatment are of great importance in trace analysis.

For the cleanup of acrylamide from complex samples, accelerated solvent extraction (ASE), liquid−liquid extraction (LLE), and solid-phase extraction (SPE), alone or in combination with other purification steps, were conducted by many laboratories. ASE and LLE with conventional organic solvent are time-consuming and labor-intensive. Furthermore, they can easily lead to loss of acrylamide in the scavenging process and require large amounts of toxic solvents. To overcome these shortcomings, SPE has been developed and applied in the cleanup of acrylamide in coffee and coffee products,[21,22] potato chips,[23] and so on. As acrylamide is a small, polar, and hydrophilic molecule, a large amount of matrix interferences tends to be extracted simultaneously with acrylamide, which makes it difficult for analysis using a single conventional SPE method employing reversed-phase (RP) or ion-exchange sorbents. With the aim of solving this problem, multiple retention mechanism cleanup procedures were developed. However, most of them consist of the combination of several SPE cartridges. Bortolomeazzi et al.[21] used a single SPE column consisting of 0.5 g of an in-house-prepared mixture of C18, strong cation (SCX), and anion exchange (SAX) sorbents in the ratio 2/1.5/1.5 (w/w/w) to extract and clean up roasted coffee samples.[24] Becalski et al. used a combination of three different cartridges including Oasis MAX (mixed mode

anion exchange), Oasis MCX (mixed-mode cation exchange), and ENVI-Carb (graphitized carbon) to treat various samples (potato fries, potato chips, crispbread, instant coffee, coffee beans, cocoa, chocolate, and peanut butter). A similar combination of SPE cartridges consisting of Bond Elut C18, Bond Elut Jr-PSA (anion exchange), and Bond Elut Accucat was chosen for cleanup samples.[24] However, these different SPE combination modes make the purification process cumbersome and expensive and even lead to loss of acrylamide in the cleanup process. Therefore, it is necessary to design a novel SPE sorbent with a multiple retention mechanism for the cleanup of acrylamide from complex sample matrices.

Calixarenes, following cyclodextrins and crown ethers, are considered to be a typical representative of the third generation of host supramolecules. They consist of phenol units linked via methylene bridges and can also form inclusion complexes like other host supramolecules. There are a number of selective factors in the configuration of calixarenes such as cavity size, conformation, and substituents. Since Glennon and his co-workers reported the application of calixarenes as the stationary phase, it has attracted extensive attention.[25−27] Our group has been comitted to the research of calixarene stationary phases for many years,[28−31] and a novel multi-interaction and mixed-mode stationary phase based on tetraazacalix[2]arene[2]-triazine modified silica gel (NCS, Figure 1) has been synthesized in our laboratory in 2012.[32] Being different from conventional calixarenes in which the aromatic rings are linked by methylene units, tetraazacalix[2]arene[2]triazine assembles aromatic rings by −NH− and adopts a 1,3-alternate conformation with two benzene rings nearly face-to-face parallel and two triazine rings tending to an edge-to-edge orientation in the solid phase. Our previous work indicated that the NCS exhibited high selectivity toward various compounds under different conditions with different mechanisms including hydrophobicity, $\pi-\pi$ stacking, hydrogen-bonding, inclusion, and anion-exchange interactions. A nNumber of compounds, including polycyclic aromatic hydrocarbons, nitrobenzene, organic bases, phenols, and inorganic anions, have been well separated on the NCS stationary phase.[33] Recently, a NCSi (tetraazacalix[2]arene[2]triazine functionalized silica) SPE sorbent (Figure 2)[34] was prepared utilizing preparation procedures similar to the NCS stationary phases in our laboratory. Because of the existence of multi-interaction, it is of great application value for purification or concentration trace analyte in a complex matrix. Furthermore, it has been successfully used for the extraction tobacco-specific *N*-nitrosamines, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol, and a metabolite of 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone in rabbit plasma.[35]

In the present work, a novel multiple retention mechanism sorbent (NCSi) was used with the aim of developing a rapid and reliable sample preparation procedure for the determination of acrylamide in starchy foodstuffs. All of the main factors were optimized, and the results obtained by using the developed HPLC method based on NCSi SPE indicated that it is more suitable for the determination of acrylamide in the complex matrices.

MATERIALS AND METHODS

Chemicals, Materials, and Solutions. Tetraazacalix[2]arene[2]-triazine was synthesized in accordance with the previously published procedures.[32,36] 3-Aminopropyltriethoxysilane was purchased from

dx.doi.org/10.1021/jf501569q | J. Agric. Food Chem. 2014, 62, 6100−6107

Jingchun Chemical Reagent Co., Ltd. (Shanghai, China). Acrylamide (>99%) was purchased from Research Institute of Fine Chemical Industry (Tianjin, China). HPLC grade methanol (MeOH), *n*-hexane, ethyl alcohol, and acetonitrile were provided by Fisher (Fair Lawn, NJ, USA). Deionized water was purified by a Milli-Q system from Millipore (Bedford, MA, USA). The polypropylene column tube and 20 μm PTFE sieve plates used for SPE were bought from DIKMA (Beijing, China). Commercially available MCX, MAX, HLB, and C18 cartridges (100 mg/3 mL) were obtained from Waters (Milford, MA, USA).

Standard acrylamide was dissolved in water at a concentration of 40 μg/mL and stored at 4 °C as stock solutions. Five standard solutions at different concentration (4, 16, 40, 160, 400m and 4000 ng/mL) were prepared by diluting the standard stock solution with mobile phase.

Instruments and Measurement. The comparison of retention behaviors of acrylamide on NCS and octadecyl silane (ODS) stationary phases and all determinations were carried out on an Agilent 1260 (Agilent, USA) consisting of a G1311C quaternary pump with a vacuum degasser, a G13116A temperature-controlled column oven, a G1329B autosampler, and a G1314F VWD UV detector. A Flash EA 1112 elemental analyzer and a Bruker Vector 22 IR spectrograph were used for characterization of the NCSi SPE sorbent. A centrifuge (Zhongda Instrument Plant, Jiangsu, China) was used for centrifugal separation. A Vortex mixer (Shanghai jingke industrial LTD, Shanghai, China) was used for mixing solutions. A rotary evaporator was used for enrichment (Yarong, Shanghai, China). The HPLC separations were performed on an Ultimate XB-C18 column (250 × 4.6 mm i.d., 5 μm) with a solution of MeOH/water (10:90, v/v) at 0.5 mL/min. The wavelength was 200 nm, the injection volume was 20 μL, and the oven temperature was 30 °C. Under these chromatographic conditions, acrylamide and the food components in the tested samples were all baseline separated and eluted. Each separation and/or determination was performed in triplicate.

Synthesis of NCSi SPE Sorbent. As illustrated in Figure 2, NCSi sorbent was prepared by a two-step modification process as previously described.[32] First, aminopropyltriethoxyl-bonded silica gel (APS) was obtained. In the second step, APS was reacted with an excess of tetraazacalix[2]arene[2]triazine in anhydrous dimethylformamide (DMF) at 130 °C under nitrogen atmosphere. Different from the previous work, the spherical silica had a particle diameter of 40−60 μm instead of the previous 5 μm. The surface area is 500 m^2/g.

Retention Behaviors of Acrylamide on the NCS Stationary Phase. The retention behaviors were investigated on the previously studied NCS column (150 × 4.6 mm, 5 μm) and another four commercial columns (Agilent ZORBAX SB-C18, Waters XBridge Shield RP18, Ultimate XB-C18, and Hypersil ODS2) to evaluate the interactions between the NCS stationary phase and acrylamide. All tests were conducted at the same chromatographic conditions.

Sample Preparation. *Homogenization, Extraction, and Enrichment Process.* All samples (fried potato chips, rice crust, instant noodles, biscuit) were purchased from the local supermarket. Dry samples were ground, mesh size 1 mm. One gram of homogenized samples was weighed and put into 15 mL centrifuge tubes in triplicate. To each centrifuge tube was added 10 mL of acetonitrile followed by 30 s of vortexing to extract the target acrylamide. All of the centrifuge tubes were centrifuged for 5 min at 4000 rpm. Then the clear supernatant was transferred into a glass tube, this process was repeated, and the two clear supernatants were combined. About 20 mL of extraction solution was rotary evaporated to near 3 mL after the addition of 2 mL of water under vacuum at 30 °C.

SPE Cleanup. In this paper, a new purification procedure based on a novel homemade NCSi SPE sorbent is proposed for the analysis of acrylamide. The procedure consists of an acetonitrile extraction, centrifugation, and cleanup using homemade SPE cartridges. This method was compared with four different commercial SPE cartridges (C18, HLB, MAX, and MCX) with different interaction mechanisms to establish the best conditions for the determination of acrylamide in food products.

To investigate the availability of the NCSi SPE for the cleanup of acrylamide in complex matrix, 100 mg of NCSi sorbent was packed into a 3 mL SPE cartridge. The concentrated extracting solution (Sample Preparation) was passed through the five kinds of SPE cartridges, which had been preconditioned with 5 mL of MeOH and 5 mL of water, at the rate of 3 mL/min, and collected into a glass tube. The cartridges were then eluted with 2 mL of water and collected into the same glass tube, making the final volume approximately 5 mL. The 5 mL of collected aqueous solution was filtered through a 0.22 μm nylon filter (Agilent, USA) prior to HPLC analysis. All tests were performed in triplicate.

Recovery Test. The extraction and purification were validated by recovery investigation. We spiked test samples at three concentration levels of 40, 400, and 4000 ng/g by adding acrylamide to blank samples or real samples. Then, the recoveries were determined by HPLC method after the spiked test samples were treated by extraction and SPE cleanup procedures.

RESULTS AND DISCUSSION

Characterization of NCSi SPE Sorbent. In IR spectra of NCSi (Figure 3), the bands at 2937 and 2888 cm^{-1} are assigned

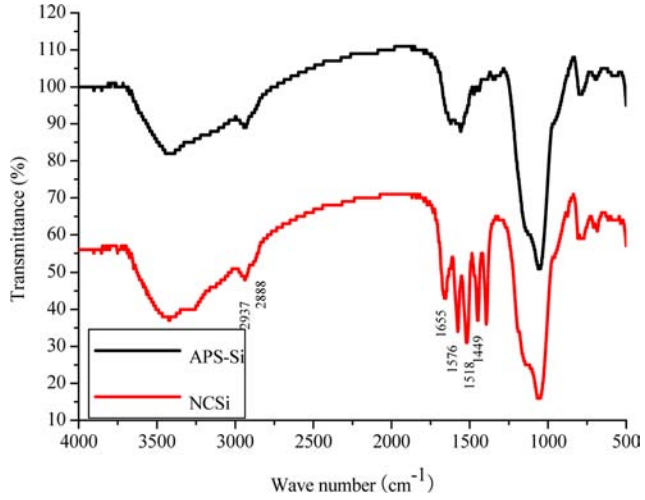

Figure 3. IR spectra of APS and NCSi sorbent.

to the stretching vibration of $-CH_2-$ groups. The characteristic absorption bands of the benzene rings appearing at 1449, 1518, and 1576 cm^{-1} confirmed that the macrocycle ligand was successfully immobilized on silica gel. Elemental analysis showed (Table 1) the bonding amount of tetraazacalix[2]-arene[2]triazine on NCSi sorbent was about 200 μmol/g.

SPE Optimization for Trace Acrylamide with the NCSi Sorbent. In this section, the main influence factors (amount of sorbent, flow rate of sample, composition and volume of washing solution) on the SPE recoveries (n = 3) of acrylamide

are evaluated in detail to obtain the optimal purification conditions.

The sorbent amount in the SPE cartridge is closely correlated with the purification effect. In this section, the influence of NCSi amount on the acrylamide's extraction was studied with the amount ranging from 50 to 250 mg. As shown in Figure 4,

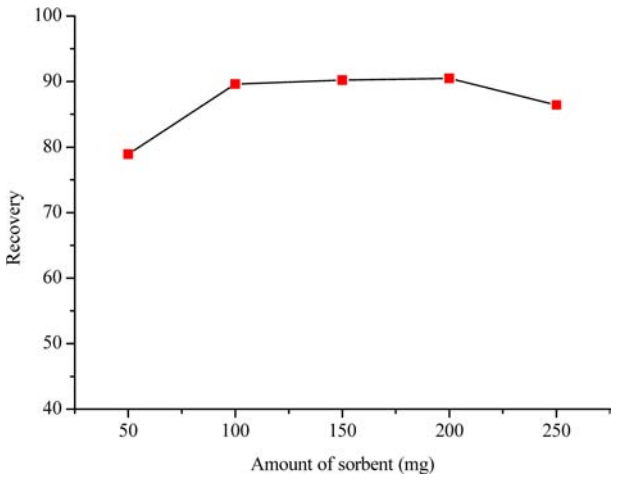

Figure 4. Recovery efficiency with different amounts of NCSi sorbent.

it is easily found that 100 mg of NCSi sorbent was enough to achieve satisfactory extraction and purification efficiency compared with 150 or 200 mg of NCSi sorbent. Thus, the optimal amount of sorbent was 100 mg.

As is known, the flow rate of the sample is another critical factor that not only affects the purification effect of analytes but also controls the sample pretreatment time. In this section, flow rates ranging from 1 to 5 mL/min were investigated, and it was found that 3 mL/min was the optimal flow rate to provide higher extraction recovery (Figure 5).

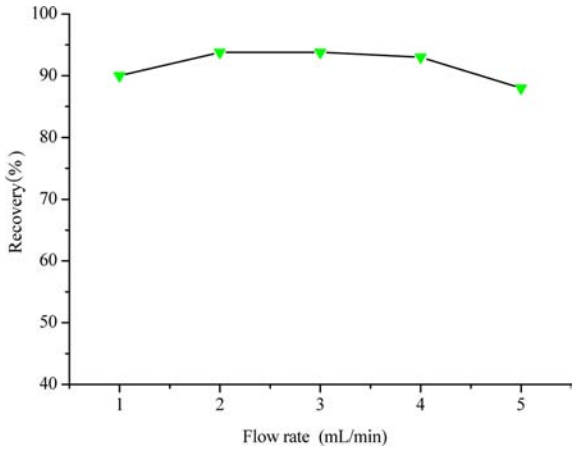

Figure 5. Recovery efficiency with different flow rates of sample.

A proper washing solvent is of great importance to reduce interfering substances and improve the recovery. Thus, the influence of the composition and volume of the washing solution on the purification of trace acrylamide (1 mL of working aqueous solution, 40 ng/mL) was studied. Different concentrations of MeOH solution (MeOH/water, v/v) at a constant volume (2 mL) were investigated. It was found that the recoveries showed no significant difference with the concentration of MeOH increasing from 0 to 20%; however, the interfering substances in the real samples increased along with the increasing proportion of MeOH. Meanwhile, a high concentration of MeOH may also result in loss of the target compounds. Therefore, a 100% water solution was selected as the optimal washing solution composition. For the selection of washing solution volume, various volumes (0.5−5 mL) of water solution were applied for the NCSi SPE process. The results display that the recoveries of acrylamide increased with the rise of the water solution volume from 0.5 to 2 mL. When the volume of water solution was >2 mL, the recoveries of acrylamide remained almost constant while the interference increased. As a result, 2 mL of water solution was chosen as the washing solution in this study.

Comparison of SPE Cleanup by NCSi Sorbent and Commercial Sorbents (MCX, MAX, HLB, and C18). *Comparison of SPE Cleanup by NCSi Sorbent and Commercial Sorbents.* Concentrated extracting solution of 1 g of blank cookies (Sample Preparation) was passed through NCSi and four kinds of commercial SPE cartridges (MCX, MAX, HLB, and C18) possessing the same specifications as the homemade NCSi SPE cartridge according to the SPE cleanup procedures as previous described, respectively. About 5 mL of purged aqueous solution was collected in the five glass tubes (Figure 6), respectively. As shown in Figure 6, it was found that

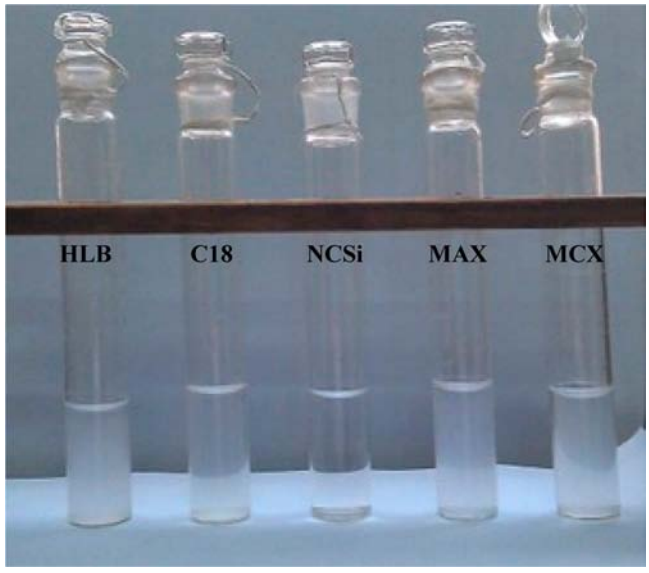

Figure 6. Turbidity comparison of the purged liquors from NCSi and four commercial SPE cartridges.

the type of sorbent used played an important role on the purification efficiency: the purged liquor from NCSi is obviously clearer than those from the other four kinds of commercial SPE cartridges. The purged liquor from NCSi was clear, but the purged liquors from C18 and HLB showed a little turbidity and the liquors from MAX and MCX were a milky white. These results imply that the fat and weak polar matrices could coelute out together with acrylamide during the purification of real samples through MCX, MAX, HLB, and C18 SPE cartridges. Therefore, NCSi SPE was selected as optimal for the extraction and purification of acrylamide in the actual samples.

To further evaluate the purification capacity of NCSi SPE sorbent, the above purged liquors from MCX and NCSi were

dx.doi.org/10.1021/jf501569q | J. Agric. Food Chem. 2014, 62, 6100−6107

defatted with hexane as described in the literature,[37,38] respectively. The defatting procedures are described as follows: add 15 mL of *n*-hexane to the 5 mL of purged liquor, then vortex for 30 s, allow to stand, and remove the upper hexane to get rid of lipid. The remaining liquids were clear, and 5 μL of liquid was injected for HPLC separation. As expected, it was found that the chromatograms of the defatted and non-defatted liquors from NCSi showed no difference, and they were similar to the chromatogram of the defatted liquor from the MCX SPE cartridge (Figure 7). These results prove that NCSi SPE could omit the defatting step and reduce acrylamide loss during the purification process.

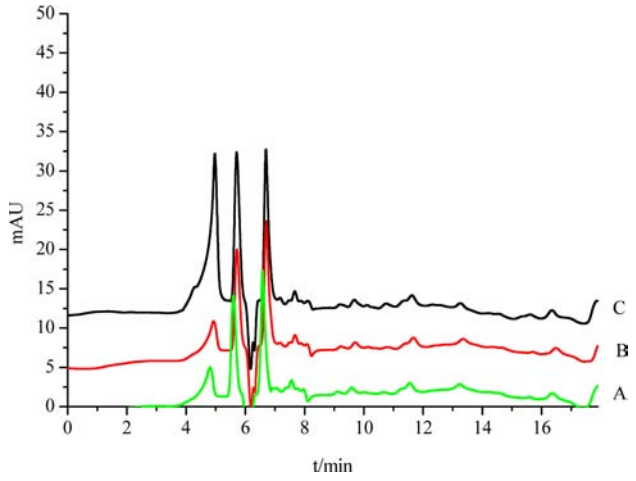

Figure 7. Chromatograms of purged liquors from MCX and NCSi with and without defatting steps in blank cookies. Conditions: column, Ultimate XB-C18 (250 × 4.6 mm i.d., 5 μm); mobile phase, MeOH/water (10:90, v/v); flow rate, 0.5 mL/min; detection wavelength, 200 nm; injection volume, 20 μL; column temperature, 30 °C. Chromatograms: (A) NCSi defatted; (B) NCSi without defatting; (C) MCX defatted.

Moreover, comparison of SPE purification efficiency between NCSi SPE and commercially available C18, HLB, MAX, and MCX SPE was carried out to further demonstrate the suitability of NCSi SPE for real samples. The sample cookies spiked at 40 ng/g acrylamide were performed under the extraction and SPE cleanup procedures. The 20 μL of purged liquor from NCSi and defatted liquor from the other four SPE sorbents was injected to perform HPLC separations. Their chromatograms are shown in Figure 8. The target peak of acrylamide by NCSi SPE cleanup showed more symmetry and higher UV response than those of the other commercially SPE cartridges, which makes the determination of trace acrylamide in complex matrix more accurate and sensitive. The NCSi sorbent exhibited high selectivity toward various interference and coprecipitation compounds with different mechanisms including hydrophobic, $\pi-\pi$ stacking, hydrogen-bonding, inclusion, and anion-exchange interactions. The proteins and carbohydrates were retained on NCSi depending on hydrogen-bonding and anion-exchange interactions, whereas fat and nonpolar matrices were held on the basis of hydrophobic interactions. For acrylamide, there is a weak hydrogen-bonding interaction with NCSi, which leads to its being weakly retained on NCSi.

Optimization of the Chromatographic Conditions. The chromatographic separation of acrylamide was performed by reverse-phase liquid chromatography using NCS and four

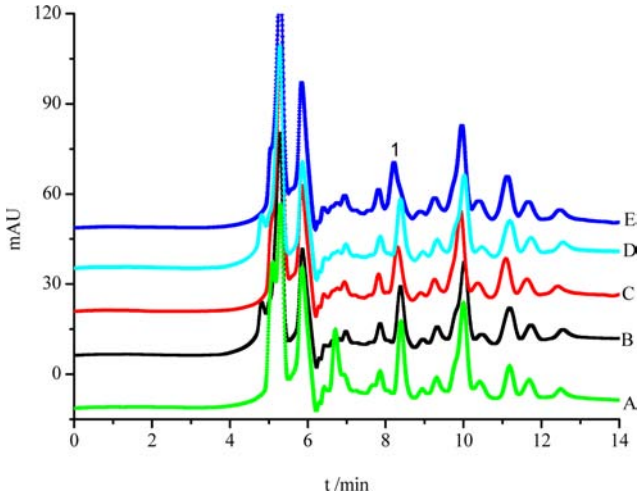

Figure 8. Chromatogram comparison of purged liquors from (A) NCSi without defatting step and from (B) C18, (C) HLB, (D) MAX, and (E) MCX with defatting steps. Conditions were as for Figure 7. Peak: 1, acrylamide.

different chromatographic columns. The retention properties of acrylamide are described in Table 2. From Table 2, NCS and

Table 2. Retention Properties of Acrylamide on Different Chromatographic Columns[a]

chromatographic column	retention time (min)	symmetrical factor	half-peak width
NCS (150 × 4.6 mm, 5 μm)	6.183	0.826	0.2542
Agilent ZORBAX SB-C18 (150 × 4.6 mm, 5 μm)	4.253	0.563	0.2442
Waters XBridge Shield RP18 (250 × 4.6 mm, 5 μm)	7.054	0.745	0.1239
Hypersil ODS2 (250 × 4.6 mm, 5 μm)	7.465	0.672	0.1653
Ultimate XB-C18 (250 × 4.6 mm, 5 μm)	8.487	0.929	0.1672

[a]Chromatographic conditions are given under Instruments and Measurement.

Ultimate XB-C18 provided better symmetry than the other columns, and Ultimate XB-C18 possessed higher theoretical plates than the others. Therefore, Ultimate XB-C18 (250 × 4.6 mm, 5 μm) was selected as the optimal column for the separation and determination of acrylamide in the real samples. However, it is noteworthy that the retention of acrylamide on the NCS column was a little bit stronger than those on the other ODS columns. Obviously, triazine rings and nitrogen bridges on the NCS stationary phase played an important role in acrylamide's retention. This result again displays that weak hydrogen bonding interaction exists between acrylamide and NCS.

We also carried out the HPLC separation of acrylamide with different mobile phases at different flow rates (detection wavelength at 200 nm). Chromatograms are shown in Figure 9. From Figure 9A,C,D, the retention time of acrylamide gradually reduced with the increase of MeOH content in the mobile phase from 5 to 15% at a flow rate of 0.5 mL/min. From Figure 9B,C,E, the retention time of acrylamide gradually decreases with the increase of flow rate from 0.4 to 0.6 mL/min with the mobile phase of 10% MeOH. Their retention times, peak areas, and theoretical plates were calculated and are presented in

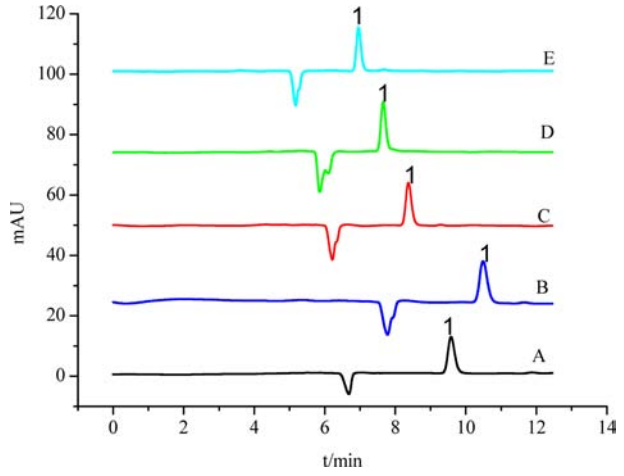

Figure 9. Chromatograms of acrylamide with different mobile phases and flow rates. Conditions: (A) methanol/water (5:95, v/v), 0.5 mL/min; (B) methanol/water (10:90, v/v), 0.4 mL/min; (C) methanol/water (10:90, v/v), 0.5 mL/min; (D) methanol/water (15:85, v/v), 0.5 mL/min; (E) methanol/water (10:90, v/v), 0.6 mL/min; others as for Figure 7. Peak: 1, acrylamide.

Table 3. As can be seen from Table 3, along with the increase of flow rate, both the retention time and peak area decrease. When

Table 3. Retention Time, Peak Areas, and Theoretical Plates of Acrylamide with Different Chromatographic Conditions[a]

chromatographic conditions	retention time (min)	peak area	theoretical plates (plates/m)
(A) methanol–water (5:95, v/v), 0.5 mL/min	9.58	166.6	32004.57
(B) methanol–water (10:90, v/v), 0.4 mL/min	10.492	207.2	31330.94
(C) methanol–water (10:90, v/v), 0.5 mL/min	8.373	166.1	34315.10
(D) methanol–water (15:85, v/v), 0.5 mL/min	7.659	178	34307.81
(E) methanol–water (10:90, v/v), 0.6 mL/min	6.959	136.7	35955.18

[a]Other chromatographic conditions are given underInstruments and Measurement.

5.0% methanol was invoked as the mobile phase at a flow rate of 0.6 mL/min, the peak area reduced 23.2% compared with 0.5 mL/min. The flow rate of 0.4 mL/min shows the largest response, but it also holds the disadvantage of longer retention time and solvent cost. With the retention time, peak area, and theoretical plate taken into consideration, a 10% v/v methanol mobile phase and 0.5 mL/min flow rate were chosen as optimal conditions for our HPLC-UV analysis of acrylamide in the samples.

Linear Regression Equation, LOD and LOQ of the Method. Method validation such as recovery, linearity, correlation coefficients, LODs, and LOQs were measured. The calibration curve was constructed by plotting peak area (y) versus the corresponding concentration of acrylamide (x, ng/mL) and its linear regression equation was obtained as follows:

$$y = 0.4357x + 0.2648 \ (n = 5, r^2 = 0.9999)$$

The results showed that good linearity was achieved in the range of 4–4000 ng/mL for acrylamide with a correlation coefficient of 0.9999. The limits of detection (LOD) and quantification (LOQ) of this method were determined with signal/noise ratios of 3 and 10, respectively. The LOD and LOQ were about 5 and 20 ng/g at a detection wavelength of 200 nm, respectively. This LOD or LOQ was low compared to those of published works by GC-MS[6] and LC-MS.[39,40] The intraday and interday RSDs (n = 5) of peak areas (400 ng/mL) were 0.22 and 0.90% and the intraday and interday RSDs (n = 5) of retention time were 0.50 and 1.63%, respectively.

Recovery and Application to Real Samples. The recovery investigations were carried out in accordance with the previous description. The standard acrylamide solutions at three levels (40, 400, and 4000 ng/mL) were added to real samples including potato chips, cookies, fried steamed buns, and rice crust. Then, the original samples and spiked samples were extracted, cleaned up by NCSi sorbent, and separated by HPLC. Typical chromatograms of potato chips are shown in Figure 10. The contents and recoveries of acrylamide were

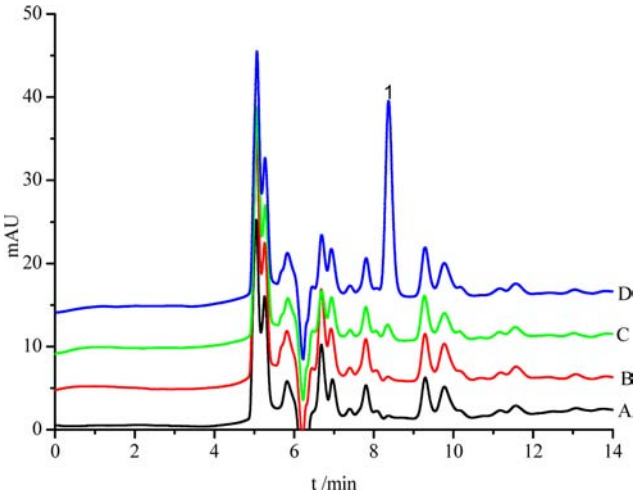

Figure 10. Chromatograms of potato chips and spiked potato chips. Chromatograms: (A) potato chips; (B) potato chips spiked at 40 ng/g; (C) potato chips spiked at 400 ng/g; (D) potato chips spiked at 4000 ng/g. Conditions were as for Figure 7. Peak: 1, acrylamide.

determined and are shown in Table 4. It can be seen from Table 4 that their recoveries ranged from 73.13 to 98%, indicating that the developed HPLC method based on NCSi SPE cleanup possessed high accuracy. The contents of acrylamide in these foods ranged from 13 to 28 ng/g; these values were much lower than the maximum residue limits (MRLs) recommended by the European Commission.[41] These foods can be safely consumed. From the results above, it is concluded that the present SPE method based on NCSi sorbent is more suitable for the determination of acrylamide in samples with a complex matrix.

In conclusion, an HPLC method based on NCSi-SPE cleanup has been successfully employed for the purification and determination of acrylamide in potato chip, cookie, fried steamed bun, and rice crust samples with complex matrices. The NCSi-SPE method enables a more efficient purification of acrylamide from a complex matrix due to its multi-interaction ability. The multi-interaction ability can selectively keep the main interferences (such as carbohydrates and proteins) from passing through NCSi while allowing acrylamide pass without any obstacle. The SPE procedure is simple and easy to operate; furthermore, NCSi-SPE offers higher accuracy for the determination of acrylamide in a complex matrix. The proposed

ABSTRACT: Plant-derived polyphenols have been shown to influence bone turnover and bone properties in the estrogen-depleted state. We used a crossover design in ovariectomized rats (n = 16 rats for each diet) to investigate the effect of supplementation of two doses each of blueberry, plum, grape, grape seed extract, and resveratrol on bone. We tested the aglycon and glucoside forms of genistein to quantify differences in efficacy on bone calcium retention. Rats were given an intravenous dose of ^{45}Ca to prelabel bone, and bone calcium retention was assessed by urinary excretion of ^{45}Ca:Ca ratio during an intervention period compared with nonintervention. Genistein aglycon increased bone calcium retention significantly ($p < 0.05$) more than the glucoside (22% vs 13%, respectively). Plum extract (0.45% w/w total dietary polyphenols) and resveratrol (0.2% w/w total dietary polyphenols) were also effective, increasing bone calcium retention by 20% ($p = 0.0153$) and 14% ($p = 0.0012$), respectively. Several polyphenolic-rich diets improved bone calcium retention.

KEYWORDS: *genistein aglycon, genistein glucoside, bone calcium retention, bone resorption, plant-derived polyphenols*

INTRODUCTION

Various plant sources of polyphenolic compounds have been studied for their ability to prevent postmenopausal bone loss associated with estrogen deficiency. The link between soy consumption in the Asian diet and reduced fracture risk[1] has sparked many studies examining soy isoflavones and postmenopausal bone health. More recently, plum, blueberry, and grape products have also been implicated in preventing postmenopausal bone loss due to their polyphenolic components.[2−6]

In Western countries, soy is not consumed as often or in sufficient quantities to match the soy consumed in Asia, where beneficial effects to bone have been observed. In addition, soy in Western countries is typically consumed as an ingredient or in supplemental form that contains extracted isoflavones from soy rather than in whole soy foods.[7] The ability of soy isoflavones to attenuate bone resorption in an estrogen deficient state remains controversial.[8] Discrepancies have been attributed to a number of factors including an individual's ability to convert daidzein to equol, the effect of food matrix on bioavailability of isoflavones compared with extracted isoflavones, and specific isoflavone composition. In foods, isoflavones exist as glycosides and require cleavage of the sugar moiety in the gut to be absorbed in the intestine.[9] Although there have been contrary reports of bioavailability of glycoside compared with aglycon forms of genistein,[10,11] there is interest in comparing glycoside to aglycon forms for bone health as the aglycon form was used in various studies that have demonstrated a strong bone preserving effect in postmenopausal women.[12−15] The presence of the sugar moiety may have an influence on where the isoflavone is absorbed in the gut and how the isoflavone is subsequently conjugated inside the body.

Isoflavones and other phenolics have demonstrated estrogenic activity[16,17] and are being investigated for their biological effect on the estrogen-depleted state. Depletion of estrogen results in a marked increase in osteoclastogenesis, causing bone resorption. During this postmenopausal period, bone formation lags behind resorption, and net bone loss ensues.[18]

There is emerging evidence to suggest that certain fruits, vegetables, and other dietary compounds found in the Western diet may be protective to bone, especially from prune, grape products, and blueberries.[19−21] Grape seed extract has also shown promise in maintaining bone health as supplementation with grape seed extract was able to recover bone lost while on a calcium deficient diet in rats.[22] Dried plum is one of the most extensively studied botanicals for its role in bone health because of a potentially anabolic effect in bone. Dried plum was very effective in protecting bone in ovariectomized (OVX) rats when compared with the effect of intermittent teriparatide (parathyroid hormone 1−34) administration, which is the most effective anabolic drug therapy currently available for osteoporosis treatment.[3] Plum, as a daily supplement of 100 g/d dried plum for one year, was able to increase bone mineral density (BMD) in the spine and ulna of postmenopausal women compared with those who were supplemented with an equal amount of dried apple.[23] While these extracts appear to be diverse, they are rich sources of specific polyphenol forms

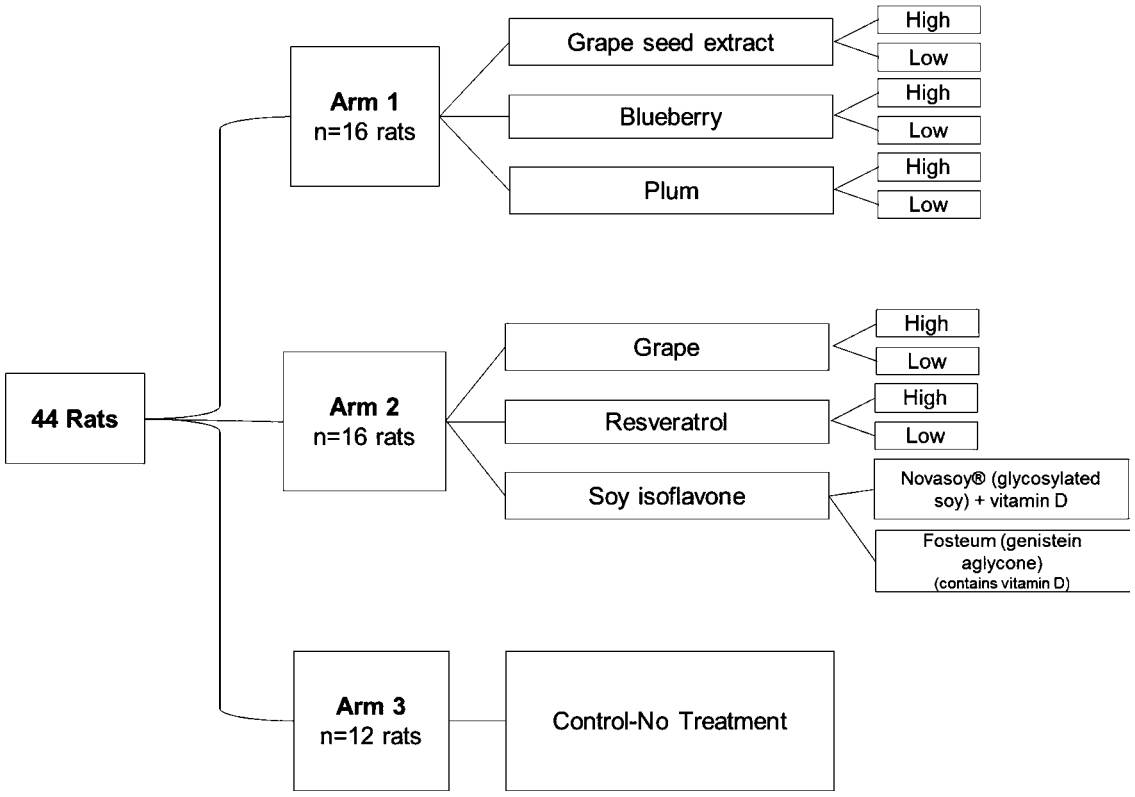

Figure 1. Study design. Forty-four rats were designated into one of three study arms. Rats in arm 1 (n = 16) received blueberry and plum fruit powder and grape seed extract to compare the effect of polyphenols in the whole fruit. Rats in arm 2 (n = 16) received whole fruit polyphenols from grape to compare against the isolated resveratrol polyphenols. Rats in arm 2 were also given genistein in the aglycon form and glycosylated soy to determine the effect of conjugation. Rats in arm 3 (n = 12) were not given a dietary botanical to establish an unperturbed excretion of ^{45}Ca excretion.

including quercetin, anthocyanins, proanthocyanidins, hydroxycinnamates, and resveratrol, which can be classified as possible bioactive agents responsible for observed bone health benefits associated with these foods. For example, resveratrol, found in grape products, extracts, and supplements, increased bone formation markers and decreased expression of receptor activator of nuclear factor kappa-B (RANK) in human primary monocytes,[21] showing potential to alter osteoclastogenesis.

Although the bioactive foods and ingredients described above have been shown to benefit bone by traditional measures of bone density and material properties, these approaches require chronic feeding and terminal measures. This has largely prevented comparisons among multiple diets and dose response effects. The aims of this study were to directly compare botanical sources and to study the effective dose of extracts to increase bone calcium retention in OVX rats using a novel technology that does not require sacrifice and evaluates responses quickly so that multiple comparisons can be efficiently tested. This involves prelabeling bones with ^{45}Ca as we have done previously with ^{41}Ca in human studies[24,25] as a means of screening botanical extracts for their ability to improve bone calcium retention. By injecting rats with ^{45}Ca, allowing the isotope to incorporate into bone, and quantifying the amount of ^{45}Ca in urine, a direct measure of net calcium tracer lost from bone is obtained. The long half-life of ^{45}Ca (163 days) allows multiple diets to be compared using a crossover design in the same rat, providing greater power to detect differences among diets. This method allows for screening of numerous diets on a relatively small number of rats during a short time period.

The method for determining bone calcium retention was derived from a well-established protocol using another bone seeking tracer, ^{3}H-tetracycline,[19,26−28] and adapted by us for calcium tracers in rats[29−31] and humans.[32] ^{3}H-tetracycline was the tracer of choice initially because it was assumed that it assessed only bone resorption from prelabeled bones in rats because it attaches tightly to hydroxyapatite and was slow to release.[33−35] However, we showed through kinetic modeling of both ^{3}H-tetracycline and calcium tracers that both isotopes leave bone during bone resorption and can re-enter bone during bone formation. Our findings suggest that these two tracers give comparable values and that net bone calcium retention is a more accurate description of what is being measured with bone seeking tracers.[30] Mühlbauer and Fleish[36] evolved the method to use daily measures of urinary ^{3}H-tetracycline from prelabeled bone of young rats given multiple injections of the tracer in order to continuously monitor bone resorption through 10-day diet periods and 10-day washout periods using a crossover design. We established that older OVX rats and a single isotope administration could be used in a study that evaluated effects of time of stabilization to OVX and time from dose on tracer behavior.[31] We further validated urinary tracer excretion against bone disappearance of the tracer[31] and adequacy of 10-day diet and washout periods.[29] Quantifying the urinary tracer appearance of a bone label enables rapid screening and multiple comparisons of efficacy of diets designed to improve bone calcium retention.

We hypothesized that both source and dose effects would be observed through testing high and low doses of various extracts from grape seed, grape, and blueberry, as well as plum powder,

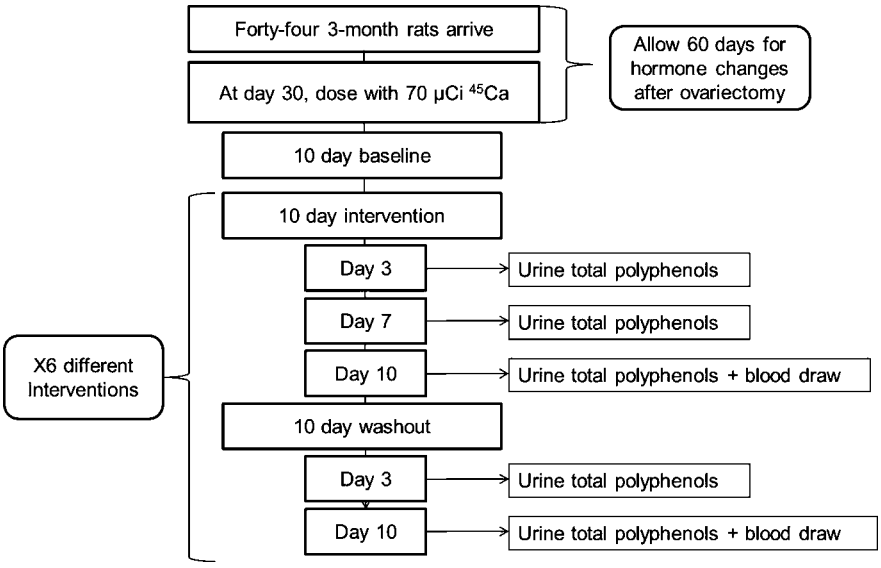

Figure 2. Study timeline for arrival of ovariectomized (OVX) rats, dosing with ^{45}Ca, and urine and blood collection pattern.

and resveratrol. We also used this screening method to determine whether genistein in an aglycon form is more effective at increasing bone calcium retention than its glucoside counterpart.

MATERIALS AND METHODS

Chemicals. A retrospective analysis of phenolic compounds from grape, blueberry, and plum extract was conducted after the conclusion of the study. Extracts were stored at −80 °C, reconstituted in 2% formic acid in ddH_2O at ∼1 mg/mL, and analyzed for key phenolic components by LC−MS as described by Song et al.[37]

Rats. Forty-four OVX Sprague Dawley rats (3 month old) were shipped from Harlan (Indianapolis, IN) and given approximately 30 days to acclimate to their environment, and to stabilize hormone changes post-OVX, while being fed AIN93-M polyphenol-free diet (soybean oil was replaced with corn oil) and distilled water ad libitum. The rats were housed individually in a humidity- and temperature-controlled room with a 12 h light and 12 h dark cycle. Food intake was monitored twice weekly, and body weight was recorded weekly. All procedures performed on rats were approved by and in compliance with the standards set by Purdue University's Animal Care and Use Committee.

Study Design. The study design (Figure 1) was a randomized, crossover intervention trial to evaluate 12 different polyphenolic-containing diets on bone turnover. The rats were randomized into one of three groups: (1) 16 rats received six diets of plum, blueberry, and grape seed extract at two doses, (2) 16 rats received six diets of grape extract and resveratrol at two doses each, and Novasoy (glycosylated soy) and Fosteum (genistein aglycon) at a single dose, and (3) 12 rats received no treatment to establish unperturbed ^{45}Ca excretion over time to verify that the regression lines computed from the nondiet periods were not confounded by diets for both calcium retention and the biomarker of bone turnover. Within each arm, the diets were randomized by polyphenolic source and then by dose.

The rats were injected with 70 μCi of ^{45}Ca in saline via a tail vein catheter approximately 30 days after arrival, moved to metabolic cages, and allowed 29 days for the isotope to be eliminated from soft tissues and fully incorporated into bone. Urine was collected for 24 h twice weekly during this equilibration period. The metabolic cages contained screens that prevented food debris and feces from contaminating the urine; the cages were cleaned once every 3 days throughout the duration of the experiment. Following the equilibration period, a baseline level of urinary tracer excretion was assessed during an initial 10 day baseline period (Figure 2), which was followed by a 10 day intervention and 10 day washout period. For each diet, there was n = 16 rats with 10 days of 24 h urine samples for each rat. The intervention and washout collections were repeated for 6 total intervention/washout cycles, and the total duration of the study was 189 days. Throughout the baseline, intervention, and washout, urine was collected for 24 h for 10 days during the intervention and 6 days during the washout. Urine was analyzed as a 24 h sample and was not pooled over multiple days. Food intake and body weight were monitored every 5 days. Blood was taken at the end of each diet and washout via the saphenous vein, and serum was stored at −80 °C to assay for bone-specific alkaline phosphatase. The urine collected at the end of each intervention and washout period was stabilized with 1% ascorbic acid at a 4:1 ratio immediately after the 24 h collection period, stored at −80 °C, and used to assay for total polyphenols and cross-linked N-telopeptides of type I collagen (NTx). Rats were killed using an excess of CO_2.

Diets. All diets were formulated to be isocaloric and to have approximately equal macronutrient, vitamin, and mineral content. The AIN93-M polyphenol-free diet[38] (Table 1) was used as a basal diet with the replacement of soybean oil with corn oil to prevent confounding from residual isoflavones. A higher amount of corn starch than in the original AIN93-M diet was used to facilitate the incorporation of up to 25% fruit powder, while maintaining the ability to pellet the diets. Research Diets, Inc. (New Brunswick, NJ),

Table 1. Modified AIN93-M Diet

ingredient	gm/kg
casein	140
L-cystine	1.8
corn starch[a]	495.692
maltodextrin[a]	125
sucrose	100
cellulose	50
corn oil[b]	40
tert-butylhydroquinone	0.008
mineral mix[c]	35
vitamin mix	10
choline bitartrate	2.5

[a]Modified from AIN93-M diet to enable pelleting while replacing up to 25% of corn starch with fruit powders. [b]Soybean oil in AIN93-M diet replaced with corn oil to avoid residual soy isoflavone interaction. [c]Mineral mix contains phosphorus at 3000 mg/kg diet and calcium at 5000 mg/kg diet.

dry blended the extracts and fruit powders into the basal diet prior to pelleting the diets. Each extract or fruit powder was added to the diet to create two doses of varying polyphenolic content and stored at −20 °C. The diets were formulated based on the goal of delivering 0.2% and 1% w/w total polyphenols for each extract where possible (Table 2). The total polyphenol content in the extracts was determined using the Folin−Ciocalteu method;[39] however, levels of resveratrol and soy isoflavones were added based on the manufacturers' specified levels of resveratrol and total isoflavones, respectively.

Table 2. Botanical and Total Polyphenol Composition in Modified AIN93-M Diet

botanical (% total polyphenols in extract)	exptl dose	% w/w diet	
		product	total polyphenols
grape seed extract (82.7)	high	1.2	1
	low	0.25	0.2
plum[a] (2.22)	high	20	0.45
	low	9	0.2
blueberry[b] (1.65)	high	25	0.4
	low	9	0.15
grape (32.8)	high	3	1
	low	0.6	0.2
resveratrol (99.9)	high	0.2	0.2
	low	0.1	0.1
genistein aglycon (6.67)	aglycon	0.6	0.04
glycosylated soy[c] (40.0)	glucoside	0.1	0.04

[a]Corn starch and cellulose in the AIN93-M diet were replaced by carbohydrates and fiber from plum powder. [b]Corn starch in the modified AIN93-M diet was replaced with maltodextrin from blueberry powder. [c]Additional 2960 IU of vitamin D/kg diet to match Fosteum (genistein aglycon).

We could achieve this goal with grape seed extract (Sensient, Indianapolis, IN) and grape skin extract (Sensient, Indianapolis, IN), which were both formulated to deliver 0.2% and 1% w/w total dietary polyphenols in the low and high doses, respectively. The blueberry and plum powder had lower phenolic content; therefore, these were added to the diet at levels that have been shown to be effective in bone.[3−6] The blueberry powder (Sensient, Indianapolis, IN) was added at levels of 9% and 25% w/w in the diet (delivering 0.15% and 0.40% w/w total dietary polyphenols, respectively) and plum powder (donated by the California Dried Plum Board, Los Altos, CA) was added at 9% and 20% w/w diet to deliver 0.20% and 0.45% w/w total dietary polyphenols, respectively. The added carbohydrates from the blueberry and plum powders were balanced by removing corn starch from the diet formula. Additionally, cellulose was removed to balance the added fiber in the plum powder. Resveratrol and isoflavones were added at lower levels than the fruit powders and extracts because they are isolated components rather than a complex botanical matrix. Resveratrol (Chromadex, Inc., Irvine, CA) was added at 0.1% and 0.2% w/w total dietary polyphenols. Novasoy (Archer Daniels Midland Company, Decatur, IL), which contains genistein glycoside plus other isoflavones, and Fosteum (Primus Pharmaceuticals, Inc., Scottsdale, AZ), which is genistein aglycon, were added to the diet to deliver an equivalent amount of total isoflavone content (0.04% w/w total dietary polyphenols) and to be consistent with the range of doses published in similar studies.[40,41] The diets delivered 5000 mg/kg diet calcium and 5000 mg/kg diet total phosphorus. Vitamin D was added to the Novasoy (glycosylated soy) diet at 2960 IU/kg diet to match the vitamin D present in the Fosteum supplement.

^{45}Ca and Total Calcium in Urine. Urine was centrifuged at 3500 rpm for 10 min at 4 °C, decanted, and diluted to the nearest 0.5 mL with ultrapure water; the total volume was recorded. Scintillation vials were prepared with 15 mL of Ecolite(+) (MP Biomedicals LLC., Solon, OH) and 1 mL of urine, and ^{45}Ca was measured on a Beckman LS 6500 scintillation counter (Beckman Instruments, Inc., Fullerton, CA). The ^{45}Ca values were corrected for decay and were reported as a percentage of original dose. Urinary total calcium was determined by vortexing, diluting, and analyzing urine samples on the atomic absorption spectrometer, AAnalyst 300 (PerkinElmer Instruments, Waltham, MA). For each 24 h urine sample of each rat, the ratio of percent dose ^{45}Ca to milligrams of total calcium was determined as the ^{45}Ca:Ca ratio. ^{45}Ca:Ca excretion during intervention was compared with ^{45}Ca:Ca excretion during nonintervention periods to determine percent bone calcium retention due to dietary polyphenols.

Biochemical Markers of Bone Turnover. Urine from day 10 of each intervention and washout period was stored at −80 °C for cross-linked N-telopeptides of type I collagen (NTx) analysis. Urine NTx was assayed in triplicate using an enzyme-linked immunosorbent assay (ELISA) from Wampole Laboratories R, Inc. (Princeton, NJ). The microtiter plate in the kit was precoated with an antibody specific to NTx. Samples and standards were added, followed by a series of reagents designed to produce a color change in the wells containing NTx. Bound NTx was analyzed spectrophotometrically at a wavelength of 450 nm, and concentration of NTx was determined by comparison to a standard curve.

Blood was taken at the end of each botanical diet period and washout period, and serum bone alkaline phosphatase was assayed using an ELISA from MyBioSource (San Diego, Ca). Serum samples were diluted 2-fold with saline and added to the wells of a microtiter plate that were precoated with an antibody specific to bone alkaline phosphatase. A series of reagents were added to produce a color change in the wells that contained bone alkaline phosphatase. Bone alkaline phosphatase was analyzed spectrophotometrically at 450 nm, and the concentration of bone alkaline phosphatase was determined by comparison to a standard curve.

Total Polyphenol Analysis. To confirm the dose dependent increase in polyphenol absorption from diets, urinary total polyphenols were quantified following solid phase extraction based on a modification of methods as described by Medina-Remón et al.[42] Briefly, urine samples were diluted to approximately 1 mL using a 50 mM sodium phosphate buffer (pH = 3.0). Strata-X polymeric reversed phase extraction tubes (Phenomenex Inc., Torrance, CA) were used for solid phase extraction. The tubes were initially washed with 3 mL of methanol, followed by 6 mL of phosphate buffer. The entire urine sample was applied to the column and washed with 6 mL of phosphate buffer, followed by 6 mL of 5% methanol. The samples were eluted with 6 mL of methanol, dried, and resolubilized with ethanol. Samples were then pipetted in triplicate onto a 96-well plate, along with gallic acid (Sigma-Aldrich, St. Louis, MO) in ethanol to create a standard curve, and an ethanol blank. The Folin−Ciocalteu reagent (2 N, Sigma-Aldrich, St. Louis, MO) was diluted to 0.2 N and added to the plate, and then samples were incubated for 7 min at room temperature. An equal amount of 7% sodium bicarbonate solution was added to the reaction, and the plate was incubated for 30 min prior to being analyzed by a spectrophotometer at 750 nm. Total polyphenols of the urine samples were calculated from the gallic acid standard curve and were reported as gallic acid equivalents.

Statistical Analysis. The ^{45}Ca:Ca ratio was transformed using the natural logarithm to correct for skewedness. For each rat, a simple linear regression model was fit through all of the nonintervention periods (baseline and washout data points) creating a regression line as illustrated in Figure 3A and Figure 3B. During the intervention period, a predicted value from the regression line for each observation of each rat was determined using the model described. The predicted value for each observation was subtracted from the experimental value measured during the botanical diet period, and the mean of differences was taken for that botanical diet of that rat. The means from each dietary intervention were averaged across all rats, and 95% confidence intervals were calculated. The values were exponentiated and reported in the original scale as percent improvement in calcium retention compared with baseline.

The data for food intake, weight change, feeding efficiency ratio, body weight, and total polyphenols were normal and were analyzed without transformation. Means and standard deviations were calculated for these variables, a repeated measures analysis of variance

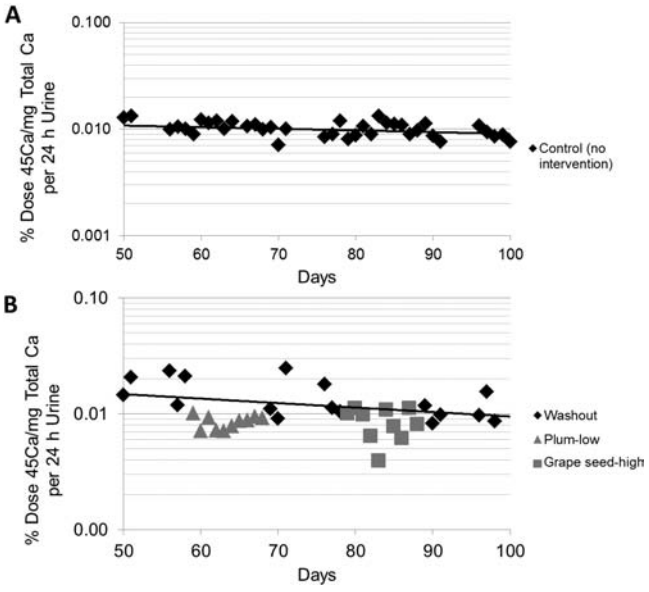

Figure 3. Plot of days vs ^{45}Ca:Ca ratio for (A) a control rat that did not receive a botanical diet and (B) two botanical diet periods and washout periods in one rat. Each data point represents a single 24 h urine collection. Different diets are indicated by different symbols. A regression line was fit through all of the nonintervention periods, which include baseline and washout data points. During the botanical diet periods, the residual was determined by finding the difference between the predicted value from the regression line and the experimental value.

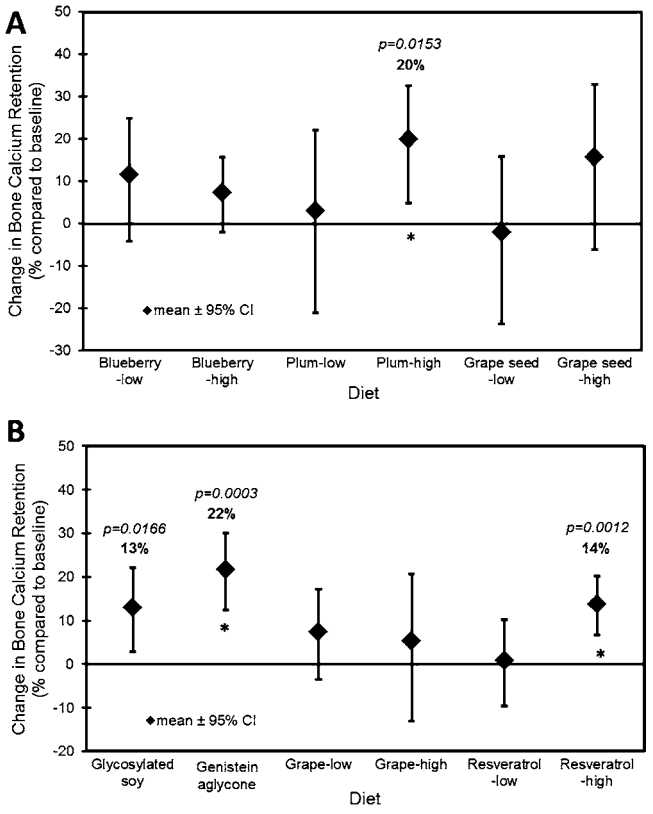

Figure 4. Effect of dietary botanicals on bone calcium retention in ovariectomized (OVX) rats (n = 16 rats per diet) was reported as mean ± 95% confidence intervals for (A) arm 1 and (B) arm 2. A value of "0" represents no change from the regression line computed from nonintervention periods. A confidence interval that excludes "0" indicates a significant change from the regression line at α = 0.05. The * indicates significant difference (p < 0.05) between high and corresponding low dose of the same dietary botanical as determined by a t test. For soy, the * indicates significant difference (p < 0.05) between genistein aglycon and glycosylated soy.

(ANOVA) was performed, and differences were determined by contrasts between high and low doses within each extract, and between genistein aglycon and glycosylated soy. t tests were performed for food intake, body weight, weight change, and feeding efficiency ratio to determine differences between control and botanical diets with a Bonferroni correction to adjust for multiple comparisons of means.

For each rat, NTx values were transformed to correct for skewedness using the natural logarithm. Subsequently, the difference in NTx between intervention and washout was determined for each botanical diet as change in NTx. The means and 95% confidence intervals of the differences were taken for each diet. A repeated measures ANOVA was performed followed by contrasts to determine differences between high and low doses of each diet, and between genistein aglycon and glycosylated soy. The means for each diet were transformed back to the original scale and reported as a ratio with 95% confidence interval. SAS software (version 9.3 SAS Institute, Cary, NC) was used for all analyses.

RESULTS

Bone Calcium Retention. Percent change in bone calcium retention was determined by finding the difference between the ^{45}Ca:Ca ratio excreted during the botanical diet compared with the residual line of all control diet periods. The urinary ^{45}Ca:Ca ratio of the control rats in arm 3 (Figure 1) verified that the regression line was not altered by diets in similarly aging rats (Figure 3A). The ratio of percent dose of ^{45}Ca to milligrams of Ca in the 24 h urine samples and residuals for two diets for one rat in arm 1 is shown in Figure 3B. Using this method, bone calcium retention was significantly improved due to dietary intervention with glycosylated soy (13%; p = 0.0166), genistein aglycon (22%; p = 0.0003), resveratrol-high (14%; p = 0.0012), and plum-high (20%; p = 0.0153) compared with baseline (Figures 4A and 4B). The genistein aglycon supplement, Fosteum, increased bone calcium retention 2-fold compared to glycosidic mixed isoflavone supplement, Novasoy (p < 0.05). The high dose of plum (0.45%) and resveratrol (0.2%) improved bone calcium retention compared with the lower doses (p < 0.05).

Food Intake and Body Weight. There was no significant difference in body weight between high and low doses of any botanical diet intervention despite some differences in the contributing factors (Table 3). In arm 1, plum-low increased the food intake, feeding efficiency ratio, and weight change compared with the plum-high diet (p < 0.0001). Blueberry-low increased the feeding efficiency ratio and weight change compared with the blueberry-high diet (p = 0.05). In arm 2, grape-low and resveratrol-high decreased the feeding efficiency ratio compared with control (p < 0.05), and glycosylated soy, grape-low, and resveratrol-high diets decreased the weight change of rats compared to those on the control diet (p < 0.05). There was a weak, but significant, positive correlation between change in body weight and net bone calcium retention (r = 0.21; p = 0.002); however, change in body weight was not correlated with NTx (p = 0.69).

Analysis of Extracts. Analysis of key phenolic compounds in grape, blueberry, and plum extracts highlighted some compositional differences between the different extracts (Table 4). The most prominent constituents in the plum

acetylated malvidins		7.72	
total polyphenols[c]	22.2	328	16.5

[a]Phenolic compounds were tested in duplicate using LC−MS[41] to assay for key compounds. [b]Resveratrol contained 295.12 mg resveratrol/g sample and grape seed extract contained 827 mg/g total polyphenols as determined using the Folin−Ciocalteu[38] method. Grape seed extract was unavailable for analysis using LC−MS. [c]Total polyphenols were determined through the Folin−Ciocalteu method.[38]

extract were chlorogenic acids (11.62 mg/g extract 3-0-caffeoylquinic and 21.75 mg/g extract other forms of caffeoylquinic), which were also notably higher than the content found in grape (3.28 mg/g extract chlorogenic acids) and blueberry (5.04 mg/g extract total chlorogenic acids). Grape and blueberry were both characterized as being higher in anthocyanins (54.7 mg/g extract and 44.41 mg/g extract total anthocyanins, respectively) compared with plum (0.5 mg/g extract total anthocyanins); however, grape had a greater amount of gallic acid compared with blueberry (11.85 mg/g extract compared with 0.45 mg/g extract, respectively), and blueberry contained a higher level of chlorogenic acids than grape (5.04 mg/g extract compared with 3.28 mg/g extract, respectively). Grape extract did not contain resveratrol, but did have other stilbene derivatives (9.16 mg/g extract).

Biochemical Markers of Bone Turnover. Grape seed extract-high ($p = 0.0056$) and grape-high ($p = 0.004$) dietary interventions reduced NTx compared with each corresponding baseline period (Figure 5A and Figure 5B). Resveratrol-low significantly increased NTx compared with the corresponding baseline period ($p = 0.0039$). Blueberry, plum, soy, grape seed extract, grape-low, and resveratrol-high diets did not produce a significant change in NTx.

The aglycon soy diet significantly increased serum bone alkaline phosphatase compared with baseline ($p = 0.03$, data not shown); however, none of the other diets impacted bone alkaline phosphatase.

Urine Total Polyphenols. There was a significant dose response of urinary total polyphenols in blueberry ($p = 0.005$) and grape seed extract ($p < 0.0001$) interventions of arm 1 and grape ($p = 0.0002$) dietary intervention of arm 2 rats (Figure 6A and Figure 6B). There was no difference in total polyphenols between glycosylated soy and genistein aglycon ($p = 0.27$).

DISCUSSION

In this crossover intervention trial in OVX rats, we identified that although both isoflavone-containing diets were effective at increasing bone calcium retention, the aglycon form of genistein was significantly more effective than the glucoside. In addition, we demonstrated that higher levels of resveratrol and plum (0.20% and 0.45% total polyphenols, respectively) increased bone calcium retention.

dx.doi.org/10.1021/jf403310q | J. Agric. Food Chem. 2014, 62, 6108−6117

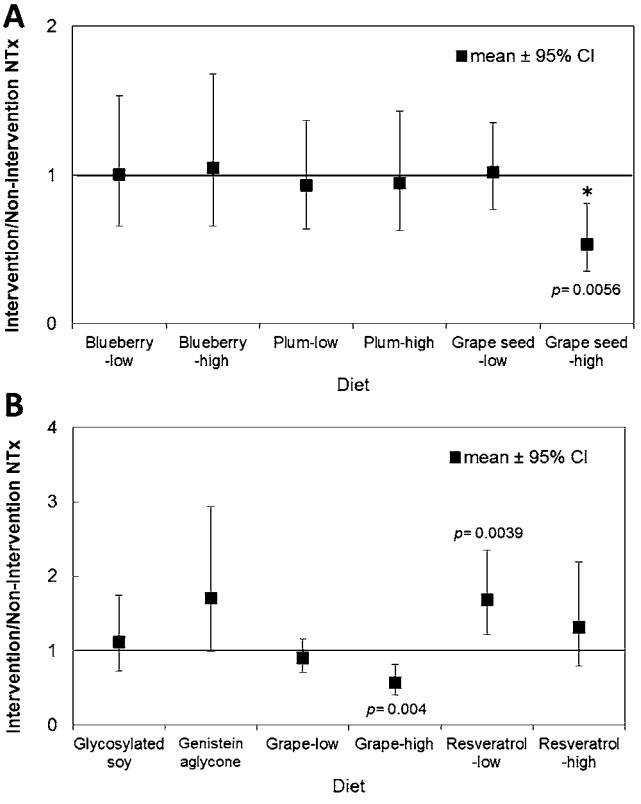

Figure 5. Effect of dietary botanicals on urinary NTx in ovariectomized (OVX) rats was reported as mean ± 95% confidence interval. A value of "1" represents no change from the regression line computed from nonintervention periods. A confidence interval that excludes "1" indicates a significant change from the regression line at α = 0.05. Contrasts were performed after ANOVA. For blueberry (n = 15 for low; n = 16 for high), plum (n = 15 for low; n = 14 for high), and grape seed extract (n = 14 for low; n = 15 for high) diets (A) * indicates a significant ($p < 0.05$) difference between NTx values during the low and corresponding high doses of the same diet. For soy (n = 14 for genistein aglycon; n = 15 for glycosylated soy), grape extract (n = 16 for low and high), and resveratrol (n = 16 for low and high) (B) there was a trend for NTx to be lower during the grape-high diet compared with the grape-low diet (p = 0.078). NTx, urinary collagen type 1 cross-linked N-telopeptide.

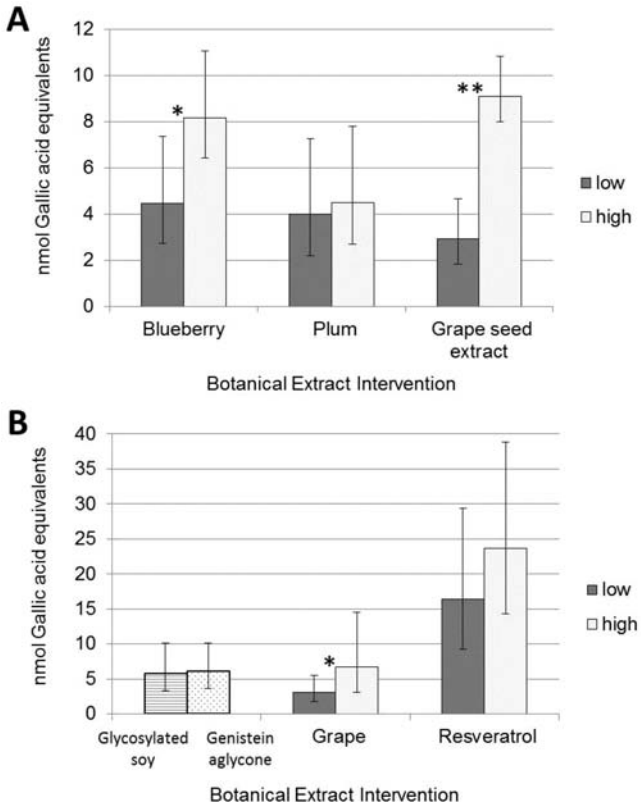

Figure 6. Effect of dietary botanicals on urinary total polyphenols in 24 h urine of ovariectomized (OVX) rats (n = 16 rats per diet). Values are reported as mean ± standard deviation with contrasts performed to detect differences between means. For blueberry, plum, and grape seed extract diets (A) * and ** indicate low is significantly different from high at p = 0.005 and $p < 0.0001$, respectively. All arm 1 diets were significantly different from baseline at p = 0.0015. For soy, grape, and resveratrol diets (B) * indicates that low is significantly different from high at p = 0.0002. There was a trend for total polyphenols during low to be different from high during the resveratrol-high diet with p = 0.06. All arm 2 diets were significantly different from baseline at $p < 0.0001$.

Dietary aglycon soy elicited an improvement to bone calcium retention that was approximately double the response from a diet with glycosylated soy (22% for aglycon soy compared with 13% for glycosylated soy), which supported our hypothesis that the aglycon form of genistein is more effective than the glucoside when tested on an equivalent mass basis of total polyphenols. We did not observe a difference in urinary total polyphenols between genistein aglycon and glycosylated soy, which supports that the glycosylated soy and genistein aglycon diets were formulated to have equivalent isoflavone content. We are first to directly compare soy aglycon to glucoside for effect on bone in an estrogen-depleted rodent model. Through this direct comparison, we were able to demonstrate that the aglycon form of genistein was more effective than glycosylated soy in increasing bone calcium retention.

Cleavage of the sugar moiety is believed to be required for genistin (glycosylated) to be effectively absorbed in the intestine,[9] but absorption of genistein (aglycon) occurs readily[11] and as early in the digestive process as in the stomach.[43] After the glucoside is hydrolyzed and absorbed in the gut, it is conjugated to mostly glucuronic acid by both intestinal and hepatic enzymes. Consumption of the aglycon form of genistein has the potential to lead to a higher presence of unconjugated genistein in the blood due to enhanced uptake in the gut and some absorption in the stomach. This is biologically important because unconjugated genistein has been shown to bind more strongly to estrogen receptor-β than its glucuronide metabolites,[16] demonstrating the potential for a more estrogenic effect on bone. We were able to demonstrate the enhanced efficacy of the aglycon form of genistein on bone in an estrogen-depleted rodent model. Future research should directly compare the metabolites produced from consumption of aglycon and glycoside soy to more closely link this mechanism to the increase in bone calcium retention from the aglycon form of soy.

Estrogen in bone works primarily by decreasing the production of inflammatory cytokines (interleukin (IL)-1, IL-6, and RANKL and M-CSF (macrophage colony stimulating factor)) in osteoblasts and precursor cells to regulate osteoclast activity.[44,45] A drop in estrogen leads to a prominent increase in osteoclast activity, which greatly increases bone resorption with a lag in subsequent bone formation.[18] Although the estrogenic activity of phytoestrogens such as isoflavones has been shown to elicit an antiresorptive response on bone,[24] we observed that

dx.doi.org/10.1021/jf403310q | J. Agric. Food Chem. 2014, 62, 6108−6117

genistein aglycon increased bone calcium retention, consistent with bone formation. This is evidenced by an increase in BAP, which is a marker of bone turnover and often an indicator of an anabolic effect to bone. Our finding suggests that the ability of isoflavones to reduce net bone loss works by stimulating the anabolic bone building effect to counter the increase in resorption caused by loss of estrogen, rather than by mitigating bone resorption only. Urinary calcium tracer excretion is specific to bone mineral balance and more precise than biochemical markers of bone turnover.

Our finding that short-term supplementation of dried plum at 20% w/w diet, delivering 0.45% w/w total dietary polyphenols (plum-high), to OVX rats resulted in a 20% increase in bone calcium retention was similar to the 15% increase in bone tracer retention observed by Mühlbauer et al. using a similar method in OVX rats with a lower percentage (8% w/w diet) of dried prune extract for 10 days.[19] The effects we observed on bone calcium retention from plum is also consistent with doses reported in the literature to be protective to bone in OVX rats, i.e., 15% and 25%.[3−5,46,47] In postmenopausal women, plum supplemented at 100 g/d prevented bone loss and increased BMD;[23,47] the control diet of 100 g/d dried apples also protected bone from loss, but to a lesser degree than dried plum supplementation.[23] This level of dried plum intake would be equivalent to the 25% w/w diet given to rodents and similar to the 20% w/w diet given in this study, assuming that food intake in women totals approximately 400 g/d on a dry weight basis.

We did not find a significant effect on bone with diets of blueberry, grape seed extract, or grape extract in OVX rats. Evaluation of the phenolic profiles of these extracts reveals that chlorogenic acids are more prominent in plum compared to the other extracts. Both chlorogenic acid[48] and dried plum powder[49] have been found to have an inhibitory effect on the RANKL pathway involved in osteoclastogenesis. However, we did not observe a decrease in NTx, a marker of bone resorption, with dietary supplementation with dried plum.

Previous work demonstrated that blueberry at 5% w/w diet prevented the loss of whole-body BMD in OVX rats.[50] Additionally, blueberry at 10% w/w diet fed to prepubertal[6,51] rats prevented bone loss later in life; the suggested mechanism was that phenolic acids found in blueberry promoted osteoblast differentiation. Although sera phenolic acid derivatives were described,[6] the phenolic profile of the blueberry extract was not reported. The lack of effect observed in our study could potentially be attributed to differences in blueberry phenolic profile and concentration of phenolic compounds in the extract. While abundant in anthocyanins, blueberry had lower levels of chlorogenic acids compared with the plum powder, which may have impacted the efficacy of the blueberry diet.

Grape seed extract when given with calcium was shown to have a protective effect on bone in adult and growing intact rats when given immediately following a low calcium diet.[2,22] We tested grape seed extract in an estrogen-depleted rodent model and did not find an effect on bone. Catechins, the most abundant polyphenols present in grape seed extract,[52] have been shown to have estrogenic activity,[53,54] and there is evidence to suggest that catechins from green tea have a role in preventing postmenopausal bone loss.[55,56] however, the binding affinity of different catechins to estrogen receptor-β should be investigated further as this receptor more directly impacts bone.

We did not see an effect of grape extract (0.2−1% w/w total polyphenols in diet) on bone calcium retention; however, we did find that resveratrol-high, which delivered 0.2% dry matter as total polyphenols in the diet, increased bone calcium retention by 14%. Mühlbauer et al.[19] fed rats 8% w/w diet red wine residue and observed a reduction in bone resorption; however, the measured total polyphenols and resveratrol content were not reported. Despite anthocyanins and gallic acid being more prominent in grape than the other extracts, our analysis of the phenolic profile of grape extract showed an absence of resveratrol, a compound which has been proven to have estrogenic activity[17] and was effective as an isolated compound in our study. Further analysis comparing grape extracts with varying levels of resveratrol should be tested to determine if efficacy is due primarily to resveratrol.

Total polyphenols were significantly higher during the botanical interventions than during baseline and washout periods, suggesting that polyphenols were absorbed and cleared into urine from test diets. Total polyphenols were not significantly different during the washout compared with baseline, which suggests clearance of prior diet in the system and no carryover effect.

Biochemical markers of bone turnover were not always consistent with bone calcium retention response to diets. Grape seed extract-high and grape-high supplementation decreased NTx without a change in bone calcium retention. Resveratrol-low induced an increase in NTx, but had no significant effect on bone calcium retention. The increase in bone calcium retention for glycosylated soy, aglycon soy, plum-high, and resveratrol-high failed to lower NTx or increase bone alkaline phosphatase.

In our crossover study with OVX rats, dietary plum, resveratrol, genistein glucoside, and genistein aglycon increased bone calcium retention by 13−22%. To our knowledge we are the first to directly compare and report the enhanced effect of genistein aglycon on bone. Additionally, we confirmed efficacy of dried plum on bone and highlighted chlorogenic acids as the group of phenolic compounds contributing to increased bone calcium retention. Although we did not observe a bone protective effect with a resveratrol-devoid grape extract, we did observe a strong bone protective effect with resveratrol, which suggests that resveratrol may be the active component in other grape products that have been shown to have bone protective effects. Future studies could extend this work by evaluating the effect of specific classes of botanical polyphenolics on bone strength measures.

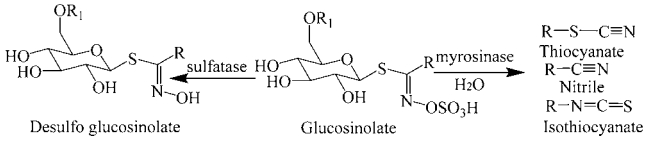
ABSTRACT: An UHPLC-PDA-ESI/HRMS^n profiling method was used to identify the glucosinolates and flavonoids of *Rorippa indica* (Cruciferae), a wild vegetable and Chinese herb used to treat cough, diarrhea, and rheumatoid arthritis. Thirty-three glucosinolates, more than 40 flavonol glycosides, and 18 other phenolic and common organic compounds were identified. The glucosinolates and polyphenols were separated by UHPLC. High-resolution deprotonated molecules provided high accuracy mass values that were used to determine formulas and provide putative identification of the glucosinolates and flavonoids. The fragments from multistage mass spectrometry were used to elucidate the structures. The concentrations of the main components were based on UV peak areas and molar relative response factors with a single calibration standard. This study found this plant to be a rich source for glucosinolates, containing 24 new glucosinolates, including 14 glucosylated glucosinolates that were previously unidentified.

KEYWORDS: *glucosinolates, flavonol glycosides, Rorippa indica (Cruciferae), Chinese wild vegetable, Chinese herb, UHPLC-PDA-ESI/HRMS^n, compound identification, main compound quantification*

INTRODUCTION

Glucosinolates (GSs) are sulfur- and nitrogen-containing secondary metabolites found in cruciferous plants. A central carbon is connected to a thioglucose, to a sulfate via a nitrogen atom, and to a side chain (R) (Figure 1). The side chain determines whether the glucosinolate is defined as aliphatic (straight- or branched-chain alkyl, alkenyl, and oxo-, hydroxyl forms), aromatic, or indole. Many glucosinolates also contain one or two more sulfur atoms in the side chain to form another sulfur-containing unit, such as methyl-thio- (−S−), methyl-sulfinyl- (−SO−), methyl- or benzyl-sulfonyl- (−SO_2−), mercapto- (HS−), glucosyl-disulfanyl (−S−S−), and cysteinyl-thio- [HOOC−CH(NH_2)−CH_2−S−]. The glucosinolates and their enzyme-hydrolyzed products (thiocyanates, isothiocyanates, and nitriles) have shown important human health benefits, especially with respect to cancer prevention. Thus, many studies have been carried out on the isolation and structural elucidation of glucosinolates and their hydrolyzed products with respect to their biological activities and distribution in the plant kingdom.[1−7]



The identification code, name, and R and R_1 groups of the glucosinolates

GS-1 to GS-3 : R=9-(methylsulfonyl)nonyl (straight and branch chain, R_1=H

GS-32: R=8-methylthiooctyl, R_1=Glc; R1=H: deoxyglucohirsutin in RS)
GS-33: R=7-(methylsulfinyl)heptyl, R_1=Glc

Figure 1. Structures of the glucosinolates of *Rorippa indica*.

To date, approximately 200 glucosinolates have been reported in plants. An electronic database of the structures, formulas, and accurate masses of 200 knownn and a further 180 predictedn GSs has been established.[8] Desulfoglucosinolates, glucosinolate-related nitriles, and isothiocyanates (Figure 1) formed by the loss of SO_3 or other functional groups through the action of sulfatase and myrosinase have been isolated from plants.[9,10] Glucosinolates, widely distributed in many plants of the Cruciferae family, have also been found in plants from other familiesn although at significantly reduced levels. The glucosinolate profiles of many foods derived from cruciferous plants have been studied qualitatively and quantitatively to

establish their dietary intake and relationship to health outcomes in biological, epidemiological, and clinical studies.[1−28]

The fragmentation patterns of glucosinolates have been studied using multistage mass spectrometry (MS^n), primarily in the negative ionization mode. High-performance liquid chromatography and MS^n with electrospray ionization (HPLC-ESI/MS^n) has been widely used to identify the intact glucosinolate components of plants.[8,11−18] Most glucosinolates have an ultraviolet (UV) absorbance maximum wavelength (λ_{max}) between 219 and 228 nm. They can be quantified directly from the UV absorbance at 225 nm when they are well separated.[8,14,19,20] However, in most cases, quantification has been based on absorbance of the desulfoglucosinolates following sulfatase hydrolysis. Quantification is based on calibration with a single compound and predetermined relative response factors (RRFs).[8,20−26]

Rorippa indica (Linn.) Hiern. is a perennial plant of the Cruciferae family that is widely distributed throughout the world. Its fresh spear-shaped leaves and tender seedlings are

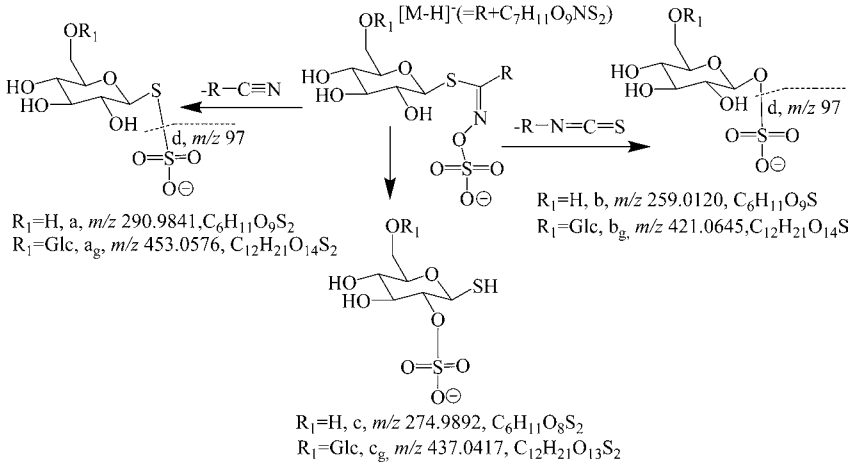

Figure 3. Molecular and typical fragments for the glucosinolates in *Rorippa indica*.

used as a healthy food, and the whole plant is used as an animal feed in China. The dried whole plant material is used as a Chinese traditional herb with purported diuretic, anti-inflammatory, antifever, and anticough properties and to help with blood circulation and rheumatoid arthritis.[27] Some glucosinolates have been reported in *R. indica* and several other *Rorippa* plants.[4,28] Ronifore (9-methylsulfonylnonyl nitrile) and its related amide (rorifamide) were isolated as the anticough components of *Rorippa montana*.[27,29] Fifteen isothiocyanates and desulfoglucosinolates were isolated from the roots of *Rorippa* plants, and several flavonol glycosides, phenolic acids, and derivatives, and other organic compounds have been reported.[9,28−30] This paper presents a comprehensive study of the glucosinolate and polyphenolic components of *R. indica*.

Phenolic compounds are widely distributed in plant-derived foods, whereas the glucosinolates are among the biologically active components of Cruciferous plants. Both types of compounds are known to have many potential benefits to human health. As a part of our project to systematically identify and quantify these compounds, both standardized HPLC-PDA-ESI/MS and UHPLC-PDA-ESI/HRMS^n methods were developed to identify and quantify the phenolics using their molar relative response factors (MRRFs) for UV absorbance.[31−33] In this study, the UHPLC-PDA-ESI/HRMS^n method was used to analyze the phenolic and glucosinolate profiles of *R. indica* and led to the identification of 33 glucosinolates, including 24 for the first time, and more than 40 flavonol glycosides. This study found that *R. indica* was a rich plant source for glucosinolates on the basis of its structural variety and total concentration of glucosinolates.[4,5,8]

MATERIALS AND METHODS

Standards and Other Chemicals. Glucocheirolin potassium salt [3-(methylsulfonyl)propyl glucosinolate-K, MW = 439 + 39 Da], rutin $3H_2O$ (MW = 610 + 54 Da), quercetin, kaempferol, and isorhamnetin were obtained from Chromadex, Inc. (Irvine, CA, USA). Formic acid, hydrochloric acid (~37%), HPLC grade methanol, and acetonitrile were purchased from VWR International, Inc. (Clarksburg, MD, USA). HPLC grade water was prepared from distilled water using a Milli-Q system (Millipore Lab., Bedford, MA, USA).

Standard Solutions. The stock standard solution consisted of dried rutin (1.27 mg) [34] and glucocheriolin-K (1.43 mg) in 10.0 mL of methanol/water (60:40, v/v). The stock solution was prepared at three concentrations (1, 1/2, and 1/4) to provide a range of signals suitable for the quantification of the main glucosinolates and phenolics of this sample. Each of the solutions (2 μL) was injected in triplicate, and the relative standard deviation (RSD) for each peak was <5.0%. The three standards provided a linear calibration curve for estimating the concentration of the main compounds of the extract.[31,32]

Plant Materials and Extracts. The dried *R. indica* plant materials were purchased by the Longjin Pharmaceutical Co., Ltd., from local herb stores in Chongqing, China. The plant materials were ground into powders and passed through 60 mesh sieves prior to extraction. The ground powder (200 mg) was extracted with 5.0 mL of methanol/water (60:40, v/v) using an FS30 ultrasonic sonicator (Fisher Scientific, Pittsburgh, PA, USA) for 60 min at room temperature. The slurry mixture was centrifuged at 2500 rpm for 15 min (IEC Clinical Centrifuge, Damon/IEC Division, Needham, MA, USA), and the supernatant (4.000 mL) was filtered through a 17 mm (0.45 μm) PVDF syringe filter (VWR Scientific, Seattle, WA, USA). Two microliters of the extract was injected in triplicate into the HPLC for analysis.[31−33]

Acidic Hydrolyzed Extracts. The filtered extracts (0.50 mL) were mixed with concentrated HCl (37%, 0.1 mL) and heated in a capped tube at 85 °C for 2 h. Then, 0.4 mL of methanol was added to the mixture, and the solution was sonicated for 10 min. The solution was refiltered prior to HPLC injection.[31]

UHPLC-PDA-ESI/HRMS^n Conditions. The UHPLC-DAD-ESI/HRMS-MS^n system used consisted of an LTQ Orbitrap XL mass spectrometer with an Accela 1250 binary Pump, a PAL HTC Accela TMO autosampler, a diode array detector (DAD) (ThermoScientific, San Jose, CA, USA), and a G1316A column compartment (Agilent, Palo Alto, CA, USA). The separation was carried out on an UHPLC column (200 mm × 2.1 mm i.d., Hypersil Gold AQ RP- C18, 1.9 μm) (ThermoScientific) with an HPLC/UHPLC precolumn filter (Ultra-Shield Analytical Scientific Instruments, Richmond, CA, USA) at a flow rate of 0.3 mL/min. The mobile phase consisted of a combination of A (0.1% formic acid in water, v/v) and B (0.1% formic acid in acetonitrile, v/v). The linear gradient was from 4 to 20% B (v/v) at 40 min, to 35% B at 60 min, to 100% B at 61 min, and held at 100% B to 65 min.[32] The PDA recorded spectra from 200 to 700 nm, and peak intensities at 225 and 354 nm were used for the quantification of the main glucosinolates and flavonoids, respectively.[33]

The MS was operated in the negative ionization mode using the following conditions: sheath gas at 70 (arbitrary units), auxiliary and sweep gas at 15 (arbitrary units), spray voltage at 4.8 kV, capillary temperature at 300 °C, capillary voltage at 15 V, and tube lens at 70 V. The scan range was from m/z 100 to 1500 with a resolution of 15000, FTMS AGC target at 2e5, FT-MS/MS AGC target at 1e5, isolation width of m/z 1.5, and maximum ion injection time of 500 ms. High-accuracy ion mass values were determined for all primary ions (i.e., the deprotonated molecular ions). The most intense ion was selected for the data-dependent scan to provide MS^2−MS^5 product ions with a normalized collision energy at 35% (CID).[33] The product ions were

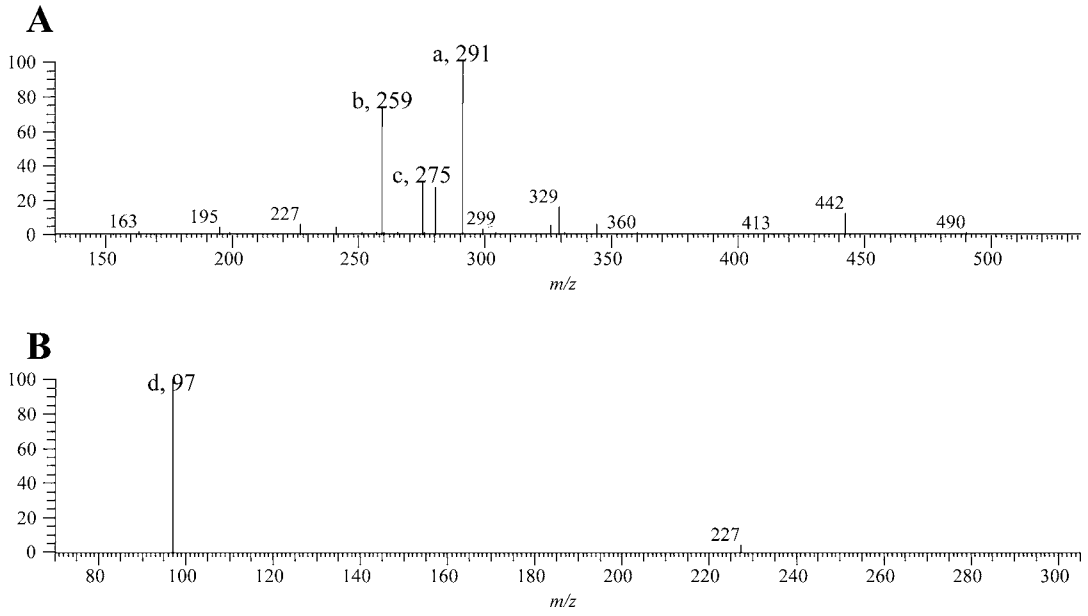

Figure 4. MS^2 (A) and MS^3 (B) spectra of 9-(methylsulfonyl)nonylglucosinolate (GS-1).

determined with nominal mass accuracy. An additional separate data-dependent scan with high-energy collisional dissociation (HCD) at 75% was also carried out for high-accuracy measurement of some of the MS^n ions with the resolution of 7500.

RESULTS AND DISCUSSION

Identification of Glucosinolates. Thirty-three glucosinolates were detected in the plant extract. Figure 1 lists the identification codes, putative identification, retention times (recorded on the TIC chromatogram), deprotonated molecule high-resolution mass, formula, error between the experimental and calculated values, and main and important fragments from MS^2, MS^3, and MS^4 fragmentations for each peak. The listing is in order of molecular weight. The TIC and PDA (at 225 nm) chromatograms are shown in Figure 2. Thirty-three of the compounds were putatively identified, and nine compounds could not be identified.

The main glucosinolates of this plant consisted of methylsulfonyl straight alkyl chain compounds ($CH_3S(O)_2(CH_2)_n$) (Figure 1). The most concentrated glucosinolate (GS-1) had TIC and UV peaks with retention times (t_R) at 18.88 and 18.83 min (Figure 2), UV λ_{max} at 225 nm, and a $[M - H]^-$ of 522.1134 Da for $C_{17}H_{32}O_{11}NS_3$ (calcd 522.1129 Da, with the error of −1.72 ppm) for 9-(methylsulfonyl)-nonylglucosinolate (GS-1). The assignment of this compound as 9-(methylsulfonyl)nonyl glucosinolate (GS-1) was based on the fact that the hydrolyzed products, desulfoglucosinolate, isothiocynate, and nitrile (rofifone), had been previously isolated from this plant.[9,27,28] Furthermore, the authors in China isolated the related nitrile from the same plant material and confirmed the structure by nuclear magnetic resonance.

GS-1 had major MS^2 fragments at m/z 291 (100%, $[C_6H_{11}O_9S_2]^-$), 275 (28%, $[C_6H_{11}O_8S_2]^-$), and 259 (73%, $[C_6H_{11}O_9S]^-$), ions a, c, and b in Figures 3 and 4A. MS^3 had a major fragment at m/z 97 (100%, $[HSO_4]^-$), ion d in Figure 4B. The compositions for ions a, c, and b were confirmed by the experimentally determined masses of 290.9842 (error −2.7 ppm), 274.9890 (error −3.9 ppm), and 259.0117 (error −4.8 ppm, Figure 3), respectively, from the additional data-dependent scan with activation in HCD.

Figure 3 illustrates the fragmentation pathway leading to the four product ions through the loss of RCN and RNCS groups. Some glucosinolates, such as 4-methoxyglucobrassin, glucobrassicin, 3′-hydroxyglucoisatisin, glucoisatinsin, and sinalbin, were reported to present an MS^2 fragment (b, 291 Da) with a relative intensity of 6−61%.[13,14,22] These diagnostic ions fully supported the identification of this compound as a glucosinolate.

Two minor peaks (GS-2 and GS-3, t_R = 10.39 and 21.00 min) had the same high-resolution deprotonated molecular ion masses as GS-1 and similar MS^2 and MS^3 fragments. Thus, they were determined to be isomers of GS-1. Most likely, the R groups are isomeric.

Three glucosinolates, GS4, GS-5, and GS-6, are analogues of GS-1 and identified as 7-methylsulfonylheptyl- (t_R = 6.67 min, $[M - H]^-$ = 494.0823 Da), 8-(methylsulfonyl)octyl- (t_R = 12.24 min, $[M - H]^-$ = 508.0978 Da), and 10-methylsulfonyldecylglucosinolates (t_R = 27.25 min, $[M - H]^-$ = 536.1301 Da), respectively. Their mass differences arise from the numbers of CH_2 units. Their retention times correlate with increasing mass, suggesting that the R groups are straight chains and the increasing number results in increased retention times as the polarity decreases. These data also confirmed the identification of these compounds as glucosinolates.

Four other glucosinolates (GS-7−GS-10) containing methylsulfinyl ($CH_3SO(CH_2)_n$) were detected. They were putatively identified as 8-(methylsulfinyl)octyl- (t_R = 11.39 time, $[M - H]^-$ = 492.1031 Da), 9-(methylsulfinyl)nonyl- (t_R = 17.66 and 18.71 min, $[M - H]^-$ close to 506.1189 Da, two isomers, GS-8 and GS-9), and 10-(methylsulfinyl)decyl glucosinolates (t_R = 25.28 min, $[M - H]^-$ = 520.1347 Da), respectively. All of them showed the same diagnostic fragments, confirming them as glucosinolates, and their elution time increased with increasing numbers of CH_2 units.

GS-11 (t_R = 11.85 min) contained an indole function and was putatively identified as 4-methoxyindol-3-ylmethylglucosinolate on the basis of its high-resolution mass value of 477.0635 Da. This compound showed the same fragmentation behavior observed above. Eight of the above glucosinolates (GS-1, GS-4,

dx.doi.org/10.1021/jf405538d | J. Agric. Food Chem. 2014, 62, 6118−6129

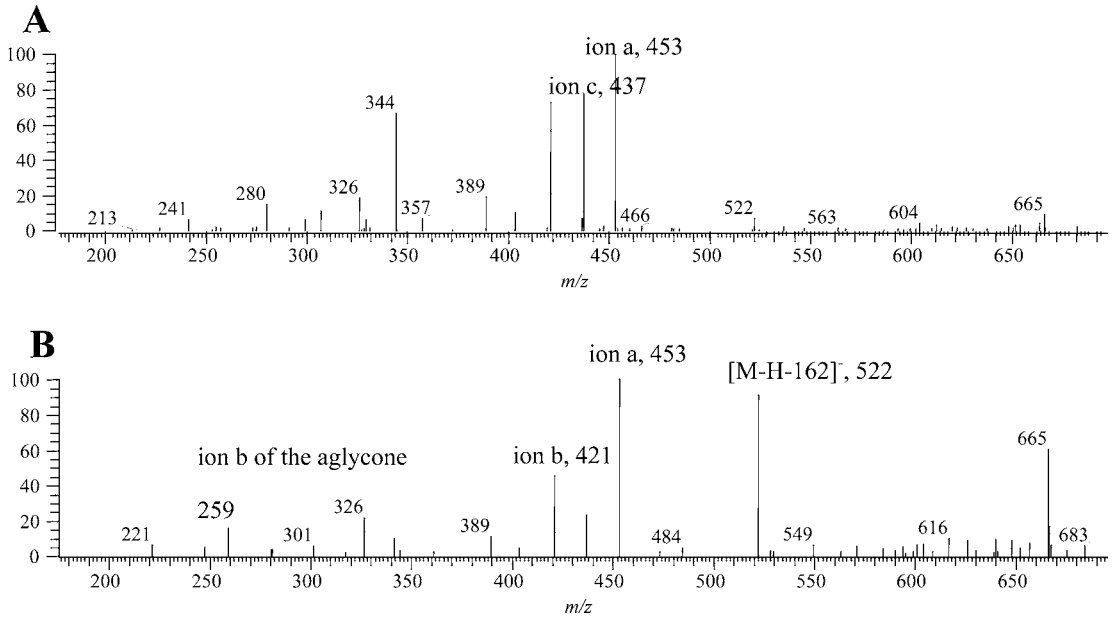

Figure 5. MS^2 spectra of the glucosides (A, GS-19; and B, GS-22) of 9-(methylsulfonyl)nonylglucosinolate.

GS-5, GS-6, GS-7, GS-8, GS-10, and GS-11) were previously reported, and GS-7, GS-8, and GS-11 were found in *Rorippa* plants.[4] Furthermore, the desulfoglucosinolates and/or isothiocyanates of the above glucosinolates (except GS-4) were previously isolated from the roots of this plant.[9] However, compounds GS-2, GS-3, and GS-9 were not known glucosinolates.[4−8]

The remaining 21 peaks were putatively identified as glucosinolates and will be discussed in detail. GS-12 (t_R = 33.33 min, $[M - H]^-$ = 488.1622 Da) had a deprotonated molecular ion of $C_{18}H_{34}O_{10}NS_2$ (error 0.49 ppm) and showed the classic glucosinolate MS^2 fragments at *m/z* 259 (100%), 275 (44%), and 291 (33%). After subtraction of ion b (*m/z* 259, $C_6H_{11}O_9S$) or ion a (*m/z* 291, $C_6H_{11}O_9S_2$) from the deprotonated molecule (Figure 3), the masses for R-NCS or R-CN were obtained. Each showed a formula for R = HO−$(CH_2)_{11}$, that is, $C_{11}H_{23}O$, the same as that obtained directly from R = $C_{18}H_{34}O_{10}NS_2$ − $C_7H_{11}O_9NS_2$ (Figure 3). In this way, the structures for the glucosinolates can be figured out easily. Thus, this compound was putatively identified as hydroxyundecyl glucosinolate. This glucosinolate was not among the predicted 180 new glucosinolates in the electronic database of Clarke because the number of CH_2 groups (*n*) is 11 and 10 was the largest considered in the prediction set.[8]

Two groups of the isomeric alkyl glucosinolates were observed. The first group (GS-13−GS-16) contained four isomers (t_R = 5.41, 6.47, 7.74, and 10.55 min, $[M - H]^-$ = 538.1081 Da). They showed product ions of *m/z* 291, 275, 259, and 97 and were identified as 9-(methylsulfonyl)-hydroxynonylglucosinolates. They had one more hydroxyl group than that of related 9-(methylsulfonyl)-nonylglucosinolate (GS-1) and its isomers (GS-2 and GS-3). The second group (GS-17 and GS-18) consisted of two isomers (t_R = 10.97 and 13.34 min, $[M - H]^-$ = 552.1236 Da). They showed the same diagnostic GS fragments and were putatively identified as 10-methylsulfonylhydroxydecylglucosinolates and to be the hydroxyl derivatives of 10-methylsulfonyldecylglucosinolate (GS-6) and its isomers. The R groups for the isomers can be determined in the same manner as described previously for GS-12. Among them, GS-13 and GS-17 (with suggested straight chains for the R group) were among the predicted 180 new glucosinolates in the electronic database of Clarke with code numbers 245 and 246, respectively.[8]

Four minor peaks (GS-19−GS-22) had different retention times (t_R = 17.68, 16.08, 16.84, and 20.92 min) but a similar mass ($[M - H]^-$ = 684.1658−684.1663 Da) corresponding to a formula of $C_{23}H_{42}O_{16}NS_3$ (errors less than −2.0 ppm). GS-19 had major MS^2 fragments at *m/z* 522 (77%, $[M - H] - 162$, loss of glucosyl), 453 (100%, 291 + 162, ion a_g, the "$_g$" means the fragment contained a glucosyl, $C_6H_{10}O_5$, Figure 3), 437 (23%, 275 + 162, ion c_g), 421 (94%, 259 + 162, ion b_g, Figure 3), and 259 (14%, ion b) (Figures 4 and 5 and Table 1). The detection of ions a, b, and c plus a glucosyl is reasonable, and $[M - H]^-$ = 421.0670 (error of 3.0 ppm) for ion b confirmed its composition as $C_{12}H_{21}O_{14}S$. Thus, the data suggest that these compounds are the glucosides of 9-(methylsulfonyl)nonyl glucosinolate (the glucoside of GS-1).

GS-20, GS-21, and GS-22 also showed the typical glucosinolate glucoside fragments at *m/z* 453, 437, and 421 (Figures 3 and 5 and Table 1). On the basis of both of the high-resolution mass values and the presence of the gluocosinolate glucoside characteristic fragments, they were identified as the glucosides of 9-(methylsulfonyl)nonylglucosinolates (the glucosides of GS-1−GS-3). Because there was no hydroxyl function on the R group, this glucosyl was most likely connected to the thioglucoside and most likely at the 6-position as that for a monoacylated glucosinolate.[6,7]

Similarly, four other compounds (GS-23−GS-26) were recognized as the glucosides of glucosinolates on the basis of the fact that they presented the same diagnostic fragments at *m/z* 453, 437, and 421. GS-23 (t_R = 22.55 min, $[M - H]^-$ = 654.1554 Da, $C_{22}H_{40}O_{15}NS_3$, error less than −2 ppm) was putatively identified as a glucoside of 9-(methylsulfinyl)-nonylglucosinolate (the glucoside of GS-8). GS-24−GS-26 (t_R = 23.37, 24.29, and 28.18 min, $[M - H]^-$ = 698.1915 Da, $C_{24}H_{44}O_{16}NS_3$, error −1.8 ppm) were putatively identified as the glucosides of 10-methylsulfonyldecylglucosinolates (the glucosides of GS-6 and its isomers).

[a]GS, glucosinolate.

One pair of isomers, GS-27 and GS-28 (t_R = 16.43 and 18.58 min, $[M - H]^-$ = 668.1712 Da, $C_{23}H_{42}O_{15}NS_3$, error −1.5 ppm) were putatively identified as glucosides of 9-(methylsulfinyl)nonylglucosinolate (the glucosides of GS-5 or its isomer). GS-29 (t_R = 22.79 min, $[M - H]^-$ = 682.1868 Da, $C_{23}H_{44}O_{15}NS_3$, error −1.5 ppm) was thought to be the glucoside of 10-(methylsulfinyl)decylglucosinolate (the glucosides of GS-10 or its isomer). The base MS^2 fragments (m/z 604 for GS-27 and GS-28 and m/z 618 for GS-29) showed a loss of 64 Da (loss of $CH_3 - SO - H$), indicating that these glucosinolates contained a methylsulfinyl ($CH_3{-}SO^-$) group in the side chain.[17,18] Both GS-27and GS-28 had MS^3 spectra containing the diagnostic gucosinolate glucoside fragments at m/z 453 (25 and 28%, respectively), 437 (100 and 56%), and 421 (both 100%) to confirm their identification. Similar fragments were not observed for GS-29. However, the MS^2 signal was very weak.

Four other compounds (GS-30−GS-33) also appeared to be analogues of the glucosides of glucosinolates on the basis of their masses and formulas. GS-30 (t_R = 28.07 min, $[M - H]^-$ = 622.1290 Da, $C_{21}H_{36}O_{14}NS_3$, error −0.5 ppm) might be the glucoside of methylthioethenylpentenyl (CH_3—S—C═C-$(CH_2)_5$) or an isomer of methylthioheptenyl. The aglycone with a methylthioethenylpentenyl group is among the 180 predicted new glucosinolates (no. 204) in the electronic database of Clarke.[8]

GS-31 and GS-32 (t_R = 22.16 and 21.15 min) have the same nominal masses, but have different high-accuracy masses. GS-31 ($[M - H]^-$ = 638.1245 Da, $C_{21}H_{36}O_{15}NS_3$, error −1.2 ppm) was putatively identified as the glucoside of 7-methylthio-3-oxoheptylglucosinolate or 7-methylsulfinylheptenylglucosinolate. GS-32 ($[M - H]^-$ = 638.1608 Da, $C_{22}H_{40}O_{14}NS_3$, error −1.3 ppm) might be the glucoside of 8-methylthiooctylglucosinolate.

GS-33 (t_R = 16.51 min, $[M - H]^-$ = 640.1403 Da, $C_{21}H_{38}O_{15}NS_3$, error −0.9 ppm) might be the glucoside of 7-(methylsulfinyl)heptyl glucosinolate. Instead of showing the typical glucosinolate glucoside fragment described above, three of them (GS-31−GS-33) had base MS^2 or MS^3 fragments at m/z 391 like GS-23. Consequently, the lack of definitive MS^2 fragments made it impossible to develop a molecular formula for this ion. The putative formula offered in Table 1 was based primarily on the close match of the experimentally measured high-resolution masses with calculated values. The aglycones of these three glucosides were known glucosinolates, but not detected in this plant.

The 14 glucosinolate glucosides mentioned above have not been previously reported in any other plants. They represent a new family of glucosinolates with a glucosyl connected to the thioglucosyl group. All of the observed MS^n fragments could be related to the structural elements of the glucosinolate skeleton. For examples, ions a, b, c, and d and thioglucosyl (m/z 195), as well as fragments obtained from further losses of oxygen, sulfur, or parts of the glucosyl were observed. However, not enough fragments were obtained to determine the structure of the R groups.[8,11−25] Of course, the R groups for the glucosinolates were not very large (containing fewer than 12 carbon atoms for the aliphatic GSs), but they can be arranged in several different ways to form the isomers. For example, the aliphatic structure can be linear or branched, the oxygen atom can be found in the oxo (keto) or hydroxy form, and the alkenyl double bond can be located at different positions.[3−8] As a result, nuclear

magnetic resonance (NMR) analysis is still the most accurate way to identify GSs structurally.[6,7]

The major glucosinolates of *R. montana* had similar side chains and were well separated, allowing for the measurement of their peak areas at 225 nm (Figure 3). Their concentrations were calculated relative to glucocheirolin using MRRF values of 1.0, on the basis of previous reports that the side chains were similar and did not alter the absorption coefficient of the molecules.[8,14,19,20] The relative peak area ratios for GS-1, GS-8, GS-6, GS-5, and GS-10 were 100.0, 15.5, 9.6, 5.1, and 4.6, respectively. The corresponding concentrations for GS-1, GS-8, GS-6, GS-5, and GS-10 were 0.51, 0.079, 0.049, 0.026, and 0.024% on a dry weight basis, and their total contents was 0.69% or 690 mg/100 g of dried plant materials. GS-1 constituted approximately 71% of the total glucosinolate content.

Identification of Phenolic and Other Common Compounds. Table 2 presents the retention times (recorded on the TIC chromatograms), HR masses, and formulas for deprotonated molecules $[M - H]^-$, diagnostic MS^2, MS^3, MS^4, and MS^5 product ions, and putative identities of 44 flavonol glycoside, 18 phenolic, and other common compounds. The listing is in order of molecular weight. The typical TIC and PDA (at 354 nm) chromatograms are shown in Figure 2. The strategy for identifying phenolic compounds in food samples has been described previously.[31,33] In this study, only the glycosides of flavonols were observed, and most are reported for the first time.

Two tetrahydroxyflavone 3-*O*-rhamnosylhexosides (t_R = 28.22 and 26.52 min, $[M - H]^-$ = 593.1491) provided the largest peaks (F-1 and F-2 in Figure 2A) in chromatograms of the *R. indica* extract. They had UV band I maximum absorbances at 265 and 346 nm and base MS^2 and MS^3 fragments of *m/z* 447 (by loss of 146) and *m/z* 284 (the radical anion species of kaempferol from the loss of 162 + 1 rather than the ion at *m/z* 285), suggesting that they might be kaempferol glycosides containing a rhamnosylhexose. This radical anion had base MS^4 and MS^5 fragments of *m/z* 255 (100%) and 221(100%), which suggested that this flavonol was most likely to be kaempferol. This identification was confirmed by the fact that kaempferol was the tetrahydroxyflavone (by direct comparison with kaempferol standards) in the acidic hydrolyzed extract (chromatogram not shown). The close retention times of the flavonol glycoside suggested that they might be kaempferol 3-*O*-rhamnosylglucosides with the rhamnosyl at the 6-position of hexosyl (glucosyl or galactosyl).[33] Their high-resolution mass confirmed their putative identification.

Four other peaks with different retention times (t_R = 17.35, 21.04, 30.80, and 32.13 min) had high-resolution masses close to 593.1500 Da, and all had similar fragments, suggesting they were also kaempferol rhamnosylhexosides. However, they were all minor components of the plant and did not provide sufficient UV data or MS^n fragments to allow identification of a specific isomeric structure. Thus, their position of attachment to the flavone and the type of hexose were not completely identified.

Similarly, flavonoid F-3 (t_R = 24.61 min, $[M - H]^-$ = 609.1470 Da) had a MS^2 fragment at *m/z* 447 (loss of 162) and an MS^3 fragment at *m/z* 301 (loss of 146) and was putatively identified as quercetin 3-*O*-hexosylrhamnoside. Its isomers (t_R = 23.42 and 25.84 min) had MS^2 fragments at *m/z* 463 (loss of 146) and MS^3 fragments at *m/z* 301 (loss of 162), suggesting they were quercetin 3-rhamnosylhexosides. The isomer with t_R = 23.42 min was further identified as rutin by direct comparison with an authentic standard. Another isomer (t_R = 34.50 min) had a MS^2 fragment at *m/z* 301, and its sugar connection could not be determined. The MS^4 and MS^5 fragments for *m/z* 301 were 255 (22−27%), 179 (41−71%), 151 (100%), and 107 (100) and suggested the aglycone was quercetin. This was confirmed by the fact that the pentahydroxyflavone in the acidic hydrolyzed extract was identified as quercetin.

One flavonoid (t_R = 30.31 min, $[M - H]^-$ = 623.1611 Da) had a base MS^2 fragment at *m/z* 477, a base MS^3 fragment at *m/z* 314, and MS^4 and MS^5 ions at *m/z* 285 and 270 to suggest it was isorhamnetin 3-*O*-rhamnosylhexoside. Two rhamnosides and three hexosides of kaempferol were detected. At least one of the rhamnosides and hexosides might have the glycosyl at the 3-position of kaempferol. Another flavonoid (t_R = 33.59 min, $[M - H]^-$ = 577.1555 Da, $C_{27}H_{29}O_{14}$) had a base MS^2 fragment at *m/z* 431 and a base MS^3 fragment at *m/z* 285 to suggest it was kaempferol 3-*O*-rhamnosylrhamnoside.

Similarly, six flavonoids conjugated with three monosaccharides were putatively identified. The first two flavonoids (t_R = 34.46 and 33.19 min, $C_{32}H_{37}O_{18}$) showed one pentosyl more than that of kaempferol 3-*O*-rhamnosylrhamnoside. The first one (F-6) had a base MS^2 fragment at *m/z* 563 (loss of 146 Da) and a base MS^3 fragment at *m/z* 284 (loss of 278 Da, i.e., 146 + 132) to indicate it was kaempferol 3-*O*-rhamnosylpentosylrhamnoside. The second one (t_R = 33.19) was very similar to F-6 but had a base MS^2 fragment at *m/z* 447 (loss of 294 Da) for a dirhamnosylpentoside. Another three flavonoids (t_R = 34.46, 33.19, 24.73, 26.21, and 27.94 min, $C_{33}H_{39}O_{20}$) had base MS^2 fragments at *m/z* 609 Da (loss of 146 Da), a base MS^3 fragment at *m/z* 285 Da (loss of 324 Da), and a base MS^4 fragment at *m/z* 151, suggesting them to be isomers of kaempferol 3-*O*-rhamnosyldihexosides. The last flavonoid (t_R = 22.95 min $[M - H]^-$ = 771.1971 Da, $C_{33}H_{39}O_{21}$) had a base MS^2 fragment at *m/z* 625 (loss of 146 Da), indicating it might be quercetin 3-*O*-rhamnosyldihexoside.

Acylation of the flavonol glycosides was determined by mass difference. An increased mass close to 146.0366, 162.0315, 176.0471, or 206.0576 Da was diagnostic of the presence of a *p*-coumaroyl, caffeoyl, feruloyl, or sinapoyl group. For example, two kaempferol acylglyocosides (t_R = 37.65 and 39.03 min, $[M - H]^-$ close to 755.1826 Da, $C_{36}H_{35}O_{18}$) had a base MS^2 fragment at *m/z* 609 Da (calculated as 609.1460, with error of −0.177 ppm for $C_{27}H_{29}O_{16}$, from loss of 146.0366 Da, $C_9H_6O_2$ for coumaroyl, instead of loss of 146.0576 Da, $C_6H_{10}O_4$, rhamnosyl) and base $MS^{3,4}$ fragments (*m/z* 447, 285, 257, 241, 229, 151 Da) identifying them as kaempferol 3-*O*-*p*-coumaroyldihexosides. Similarly, three acylated flavonoids (t_R = 30.24, 42.70, and 46.66 min, $[M - H]^-$ close to 769.1975 Da, $C_{37}H_{37}O_{18}$) had base MS^2 fragments at *m/z* 575 (loss of around 194.0576 Da for $C_{10}H_{10}O_4$, ferulic acid) suggesting they were kaempferol 3-*O*- feruloylrhamnosylhexosides. In the same way, four acylated glycosides were putatively identified as the 3-*O*-caffoeyldihexoside (t_R = 31.67 min, $[M - H]^-$ = 771.1797 Da), the 3-*O*-sinapoyldihexoside (t_R = 41.60 min, $[M - H]^-$ = 831.1974 Da), the 3-*O*-hexoside-7-*O*-methoxybenzoyldihexoside (t_R = 33.57 min, $[M - H]^-$ = 921.2290 Da), and the 3-*O*-sinapoylhydroxyferuoyldihexoside-7-*O*-hexoside (t_R = 39.84 min, $[M - H]^-$ = 1185.2914 Da) of quercetin, respectively. In the same manner, the remaining ones were identified as two 3-*O*-sinapoylhexoside-7-*O*-rhamnosides (t_R = 42.40 and 46.26 min, $[M - H]^-$ close to 799.2093 Da), the 3-*O*-

[a]is, isorhamnetin; km, kaempferol; qn, quercetin. [b]Identified using in-house database.

hydroxybenzoyldihexoside-7-*O*-hexoside (t_R = 31.17 min, $[M - H]^-$ = 891.2185 Da), the 3- *O*-caffeoyldihexoside-7-*O*-rhamnoside (t_R = 32.85 min, $[M - H]^-$ = 917.2340 Da), the 3-*O*-feruloyldihexoside-7-*O*-rhamnosides (t_R = 34.95 and 38.95 min, $[M - H]^-$ = 931.2504 Da), two 3-*O*-sinapoyldihexoside-7-*O*-rhamnosides (t_R = 34.46 min, $[M - H]^-$ = 961.2604 Da), and the 3-*O*-acetylhexosylrhamnoside (t_R = 31.43 min, $[M - H]^-$ = 635.1605 Da) of kaempferol, respectively.

As mentioned in a previous publication, dried rutin (at 354 nm) was used as the quantification standard and the MRRF values of two main flavonoids were used to determine their concentrations.[31] Concentrations of approximately 0.05 and 0.01% (or 50 and 10 mg/100 g of plant material on dry weight basis) were obtained for flavonoids F1 and F2, respectively. The total flavonoid content of this plant is <0.10% because the remaining flavonols were present at very low concentrations and UV peaks were not detectable for absorbance measurements.

In addition to the flavonoids, 1 lignan (lariciresinol 4-*O*-*β*-D-glucopyranoside) and 18 other common compounds, including the glucosides of hydroxybenzoic and hydroxycinnamic acids and their derivatives (e.g., bound to sugar, quinic acid, and malic acid) and organic acids, were identified by comparison of the chromatographic and MS data with those in our in-house flavonoid database. Most of the common compounds have previously been detected in other plants analyzed in this laboratory.

The results of this study showed that *R. indica* is a rich source of glucosinolates.[1−5,8] These compounds were reasonably separated using the UHPLC conditions described here and identified by their high-accuracy mass measurement and multistage mass fragments. The UV absorbance of the major glucosinolates was used to compute their concentration. In summary, 33 glucosinolates, over 40 flavonoids, and more than 20 other phenolic and organic compounds were identified.

ABSTRACT: Dietary phytosterols have been successfully used for lowering cholesterol levels, which correlates with the fact that some phytosterols are able to act as liver X receptor (LXR) agonists. *Sargassum fusiforme* is an edible marine seaweed well-known for its antiatherosclerotic function in traditional Chinese medicine. In this study, seven phytosterols including fucosterol (**1**), saringosterol (**2**), 24-hydroperoxy-24-vinyl-cholesterol (**3**), 29-hydroperoxy-stigmasta-5,24(28)-dien-3β-ol (**4**), 24-methylene-cholesterol (**5**), 24-keto-cholesterol (**6**), and 5α,8α-epidioxyergosta-6,22-dien-3β-ol (**7**) were purified and evaluated for their actions on LXR-mediated transcription using a reporter assay. Among these phytosterols, **2** was the most potent compound in stimulating the transcriptional activities of LXRα by (3.81 ± 0.15)-fold and LXRβ by (14.40 ± 1.10)-fold, respectively. Two epimers of **2**, 24(*S*)-saringosterol (**2a**) and 24(*R*)-saringosterol (**2b**), were subsequently separated by semipreparative high-performance liquid chromatography. Interestingly, **2a** was more potent than **2b** in LXRβ-mediated transactivation ((3.50 ± 0.17)-fold vs (1.63 ± 0.12)-fold) compared with control. Consistently, **2a** induced higher expression levels of LXR target genes including key players in reverse cholesterol transport in six cell lines. These data along with molecular modeling suggested that **2a** acts as a selective LXRβ agonist and is a potent natural cholesterol-lowering agent. This study also demonstrated that phytosterols in *S. fusiforme* contributed to the well-known antiatherosclerotic function.

KEYWORDS: *Sargassum fusiforme, phytosterols, 24(S)-saringosterol, selective LXRβ agonist, cholesterol metabolism*

INTRODUCTION

Sargassum fusiforme (Harvey) Setchell, a member of the genus *Sargassum* of the Sargassaceae family, is a common edible marine seaweed in China, Japan, and Korea.[1−4] In China, the seaweed is called "Chang Shou Cai", which is translated to "antiaging vegetable" in English.[1] *S. fusiforme* has also been widely used in traditional Chinese medicine (TCM) for thousands of years for treating atherosclerosis, hyperlipidemia, hypertension, thyroid diseases, and cancer.[1,3,5] In addition, several other species in *Sargassum* (*S. pallidum*, *S. thunbergii*, *S. muticum*, *S. horneri*, *S. siliquastrum*, *S. hemiphyllum*, *S. vachellianum*) are used as TCM for treating cardiovascular disease (CVD).[3] The active components and the underlying molecular mechanism of the antiatherosclerotic function of *Sargassum* have not been systematically investigated.

Polysaccharides, fatty acids, phytosterols, phlorotannins, and meroterpenoids were the major components previously described in *Sargassum*.[1,3] Recent studies on the antiatherosclerotic constituents of *S. fusiforme* were focused on polysaccharides and their derivatives, whereas investigations on nonpolar components such as phytosterols have not been done.[6,7] It is well-known that phytosterols, such as β-sitosterol, campesterol, and stigmasterol from terrestrial plants, are able to reduce plasma low-density lipoprotein (LDL) cholesterol levels and have been shown to be safe for half a century.[8−13] Phytosterols are abundant in *Sargassum*; however, the functions of its phytosterols are barely reported.[1,3,5]

Phytosterols are structurally related to cholesterol. They cannot be synthesized by humans and, therefore, are always obtained from diet. β-Sitosterol, campesterol, and stigmasterol account for >95% of phytosterol dietary intake,[9] and are known as "terrestrial lipid-rich food". Dietary phytosterols decrease intestinal cholesterol absorption, resulting in a reduction of both LDL and total cholesterol concentrations in plasma.[9] It has been shown recently that some phytosterols may regulate gene expressions in the cholesterol metabolism pathway through liver X receptor (LXR) activation.[14,15]

LXRs are ligand-dependent nuclear receptors that play critical roles in cholesterol homeostasis, inflammation, and lipogenesis. Their putative association with human diseases makes them promising pharmacological targets.[16,17] Functioning as chief regulators of cholesterol homeostasis, LXRs, the sterol-responsive transcription factors, control cholesterol influx, transport, and efflux. Studies have shown that local activation of LXRs have beneficial effects on atherosclerosis.[18] LXRs have two isoforms (LXRα and LXRβ) with distinct tissue distributions.[17,19] It has been suggested that hepatic lipogenesis is mainly mediated through LXRα and that LXRβ mediates the antiatherogenic effects.

5		$C_{28}H_{46}O$	398	399 ([M+H]$^+$, 16), 397 ([M+H-2H]$^+$, 18), 395 ([M+H-4H]$^+$, 31), 381 ([M-H_2O+H]$^+$, 100)
6	O	$C_{27}H_{44}O_2$	400	401([M+H]$^+$, 18), 399 ([M+H-2H]$^+$, 12),397 ([M+H-4H]$^+$, 33), 383 ([M-H_2O+H]$^+$, 100)
7		$C_{28}H_{44}O_3$	428	429 ([M+H]$^+$, 67), 411 ([M-H_2O+H]$^+$, 100), 393 (50), 377 (35)

Endogenous LXR ligands are oxysterols.[15,20] Phytosterols found in *Sargassum* possess similar structures.[1,3,5] Could these analogues of oxysterols activate LXRs and be responsible for the observed antiatherosclerotic effects? Little evidence has been afforded until now except for fucosterol, which inhibits cholesterol absorption in rats and activates LXRs.[21] In the current study, seven phytosterols from *S. fusiforme* were purified and characterized by NMR and MS. These compounds

were then evaluated for their effects on LXR-mediated transactivation and target gene expression in six cell lines. Indeed, 24(*S*)-saringosterol, an analogue of oxysterols, acted as a selective LXRβ agonist. This study also demonstrated that phytosterols in *S. fusiforme* contributed to the well-known antiatherosclerotic function.

MATERIALS AND METHODS

Chemicals. Spectral grade solvents for spectroscopic measurements were obtained from Sigma-Aldrich. HPLC grade solvents were obtained from Merck Inc. (Merck KgaA, Darmstadt, Germany). All other solvents were of analytical grade (Yuwang Reagent Co., Shandong, China).

Cell culture materials such as Dulbecco's modified Eagle medium (DMEM), modified Eagle medium (MEM), fetal bovine serum (FBS), trypsin, glutamine, and penicillin/streptomycin (PES) were obtained from Gibco. Phorbol myristate acetate (PMA) and T0901317 were obtained from Sigma-Aldrich. Lipofectamine 2000 transfection reagent was obtained from Invitrogen. Dual-GloLuciferase Assay System was purchased from Promega. For RNA isolation, TRIzol reagent and M-MLV reverse transcriptase were obtained from Invitrogen. Regular PCR was performed with the TaKaRa Taq Kit (Takara). Power SYBR Green PCR Master Mix was purchased from Applied Biosystems.

General Experimental Procedures. NMR spectra were recorded on JEOL JNM-ECP 600 NMR spectrometers, using TMS as internal standard, and chemical shifts were recorded as δ values. APCI-MS analysis was performed on a Bruker amaZon SL mass spectrometer. High-performance liquid chromatography (HPLC) analysis was performed on an Agilent 1100 HPLC system coupled to a photodiode array detector with routine detection at 210 nm. The separation column (250 × 4.6 mm i.d., 5 μm) was prefilled with YMC ODS Pack-A, and a linear gradient of MeOH and H_2O was used. Semipreparative HPLC was performed on a Shimadzu LC-6AD using a C-18 column (YMC ODS Pack-A, 250 × 10 mm i.d., 5 μm; flow rate = 4.0 mL/min, UV detection at 210 nm). Silica gel (100−200 and 200−300 mesh; Qingdao Haiyang Chemical Co., Ltd., Qingdao, China), Sephadex LH-20 (GE Healthcare Bio-Sciences AB, Uppsala, Sweden) were used for column chromatography. Thin layer chromatography (TLC) silica gel GF_{254} plates (Yantai Zi Fu Chemical Co., Ltd., Yantai, China) were used for TLC analysis.

Plant Material. Fronds of *S. fusiforme* (Harvey) Setchell were collected from the Dongtou area in Zhejiang Provinice, China, in May 2012. The original seaweed was identified by Dr. Tao Liu (College of Marine Life Science, Ocean University of China), and a voucher specimen has been deposited at the School of Medicine and Pharmacy, Ocean University of China.

Isolation and Identification. Air-dried fronds of *S. fusiforme* (200 g) were powdered and repeatedly extracted with dichloromethane/methanol (1:2) three times to give a crude extract (12.4 g), which was fractionated by vacuum liquid chromatography over silica gel by gradient elution using dichloromethane/methanol to yield six fractions. The fourth fraction (CH_2Cl_2/MeOH 98:2, 1450 mg) was subsequently separated over Sephadex LH-20 with CH_2Cl_2/MeOH (1:1) followed by flash silica gel column chromatography with light petroleum/acetone (20:1 to 8:1) to achieve five subfractions. Compounds **1** (119 mg), **2** (60 mg), and **3** (7.6 mg) were crystallized as colorless needles from subfractions 1, 3, and 4, respectively. Subfraction 2 was further purified by semipreparative HPLC (MeOH/H_2O, 85:15) to afford compound **7** (3 mg). Subfraction 5 was further purified by semipreparative HPLC with MeOH/H_2O (85:15) to yield compounds **4** (4.1 mg), **5** (5 mg), and **6** (5.6 mg). The epimeric mixture **2** was separated into **2a** (2.4 mg) and **2b** (4.9 mg) by semipreparative HPLC (MeOH/acetonitrile/H_2O, 95:1:4).

Characterization of Purified Compounds. Fucosterol (**1**): colorless needles; APCI-MS data, see Table 1; ^{1}H NMR data, see Table 2.

Saringosterol (**2**): colorless needles; APCI-MS data, see Table 1; ^{1}H NMR data, see Table 2.

24(*S*)-Saringosterol (**2a**): colorless needles; APCI-MS data, see Table 1; ^{1}H NMR data, see Table 2.

24(*R*)-Saringosterol (**2b**): colorless needles; APCI-MS data, see Table 1; ^{1}H NMR data, see Table 2.

24-Hydroperoxy-24-vinyl-cholesterol (**3**): colorless needles; APCI-MS data, see Table 1; ^{1}H NMR data, see Table 2.

29-Hydroperoxy-stigmasta-5,24(28)-dien-3β-ol (**4**): colorless needles; APCI-MS data, see Table 1; ^{1}H NMR data, see Table 2.

24-Methylene-cholesterol (**5**): colorless needles; APCI-MS data, see Table 1; ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.35 (1H, br d, J = 5.2 Hz, H-6), 4.71 (1H, br s, H-28), 4.65 (1H, br s, H-28), 3.52 (1H, m, H-3), 1.02 (6H, d, J = 6.8 Hz, H-26 and H-27), 1.00 (3H, s, H-19), 0.95 (3H, d, J = 6.6 Hz, H-21), 0.68 (3H, s, H-18).

24-Keto-cholesterol (**6**): colorless needles; APCI-MS data, see Table 1; ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.35 (1H, br d, J = 3.5 Hz, H-6), 3.52 (1H, m, H-3), 2.61 (1H, m, H-25), 1.09 (6H, d, J = 6.9 Hz, H-26 and H-27), 1.00 (3H, s, H-19), 0.91 (3H, d, J = 6.5 Hz, H-21), 0.67 (3H, s, H-18).

5α,8α-Epidioxyergosta-6,22-dien-3β-ol (**7**): APCI-MS data, see Table 1; ^{1}H NMR (600 MHz, $CDCl_3$) δ 6.51 (1H, d, J = 8.6 Hz, H-6), 6.25 (1H, d, J = 8.5 Hz, H-7), 5.22 (1H, dd, J = 15.2, 7.7 Hz, H-22), 5.14 (1H, dd, J = 15.4, 8.6 Hz, H-23), 3.97 (3H, m, H-3), 1.00 (3H, d, J = 6.6 Hz, H-28), 0.88 (3H, s, H-19), 0.83 (3H, d, J = 6.8 Hz, H-27), 0.82 (3H, d, J = 6.7 Hz, H-26), 0.82 (3H, s, H-18).

Cell Culture. HEK293T, THP-1, HepG2, and Caco-2 cells were from ATCC. HEK293T and HepG2 cells were maintained in DMEM containing 10% heat-inactivated FBS and 1% PES. THP-1 cells were maintained in RPMI-1640 medium supplemented with 10% FBS and 1% PES. THP-1 cells were differentiated in the presence of PMA (50 ng/mL) for 72 h prior to treatment and RNA extraction. Caco-2 cells were maintained in MEM supplemented with 20% FBS and 1% PES. All cell lines were grown in 5% CO_2 at 37 °C. As for phytosterol treatment, cells were preincubated in a complete growth medium for 24 h and then were incubated for an additional 24 h in 2 mL of medium containing phytosterols (30 μM), T0901317 (20 μM), ethanol, or DMSO. Stock solutions of phytosterols were prepared in ethanol, whereas a stock solution of T0901317 (0.1 mM) was prepared in DMSO. Control cells were treated with the corresponding amount of ethanol (1%). Experiment was carried out in at least triplicate.

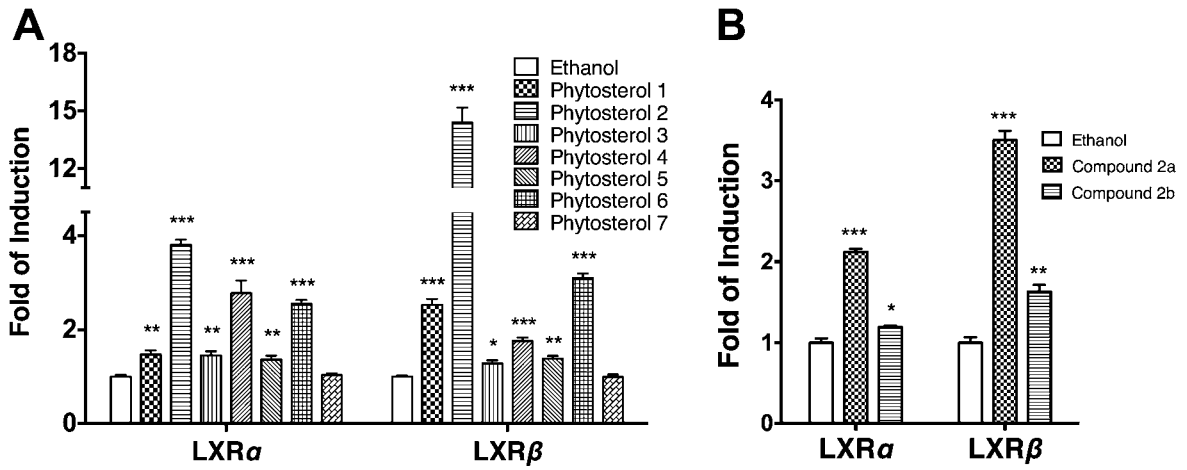

Figure 2. Effects of different phytosterols on LXR transcriptional activity. Luciferase assay was performed to compare the effects of phytosterols **1**-**7** (a and b), **2a** and **2b** (c and d), on LXR-mediated transcription. HEK-293T cells were transfected with expression plasmids pGal4-LXRα-LBD (a and c) or pGal4-LXRβ-LBD (b and d), together with reporter plasmid pTATA-LUC. Twelve hours after transfection, the cells were exposed to phytosterols **1**−**7** (30 μM), **2a** and **2b** (10 μM), or ethanol for 12 h. Data represent the means ± SEM ($n \geq 3$). (∗) $P < 0.05$, (∗∗) $P < 0.01$, and (∗∗∗) $P < 0.001$ versus control.

Transfection and Luciferase Assay. A dual-luciferase reporter assay system was utilized to examine the effect of phytosterols on the transactivation of LXRα/β. The vectors used in luciferase assays in the Gal4-LXR system include pGal4-LXRα/β-LBD (LBD, ligand-binding domain; amino acids 137−102 for LXRα and amino acids 209−468 for LXRβ, respectively), pTATA-LUC containing UAS element, and pRL-TK as control. A modified assay method was used in this study.[22] Briefly, HEK293T cells (1×10^5/mL) were plated in 48-well culture plates and then incubated in DMEM containing 10% FBS without antibiotics. After 24 h, cells were cotransfected with 0.075 μg/well of plasmid below: 0.05 μg of pTATA-luc, 0.005 μg of pRL-TK, and 0.02 μg of either pGal4-LXRα-LBD or pGal4-LXRβ-LBD, using Lipofectamine 2000 transfection reagent. Cells were cultured for 24 h post-transfection and then treated with phytosterols, T0901317, ethanol, or DMSO for an additional 12 h. After that, cells were lysed in 1× passive lysis buffer. The supernatant was assayed for Firefly luciferase activity and Renilla luciferase activity. Values were reported as relative Firefly luciferase to Renilla luciferase activity.

Quantitative RT-PCR. Total RNA was extracted with TRIzol reagent from THP-1, Caco-2, RAW264.7, HEK293T, and HepG2 cells, after treatment for 24 h with T0901317 and phytosterol or vehicle. After reverse transcription by M-MLV reverse transcriptase, regular PCR was performed with the TaKaRa Taq Kit. Quantitative real-time PCR was conducted with an ABI Prism 7500 sequence detection system, using Power SYBR Green PCR Master Mix according to the manufacturer's recommendations. Expression levels were normalized to those of glyceraldehyde 3-phosphate dehydrogenase or β-actin by the normalized expression (CT) method, according to the manufacturer's guidelines. The oligonucleotide primers for each target gene examined are as follows: h-ABCA1-F, ACCCACCCTATGAACAACATGA; h-ABCA1-R, GAGTCGGGTAACGGAAACAGG; h-ABCG1-F, ATTCAGGGACCTTTCCTATTCGG; h-ABCG1-R, CTCACCACTATTGAACTTCCCG; h-SREBF1-F, ACAGTGACTTCCCTGGCCTAT; h-SREBF1-R, GCATGGACGGGTACATCTTCAA.

Statistical Analysis. GraphPad Prism 5.0 was used for statistical analysis. All data are presented as the mean ± standard error of the mean (SEM). Statistical analysis was conducted using an unpaired two-tailed t test. $P < 0.05$ was considered to be statistically significant.

Molecular Modeling. Molecular docking analysis and visualization including other related work were performed with SYBYL-X 2.0 (Tripos Inc., St. Louis, MO, USA) running on Microsoft Windows 7. All of the ligand structures were drawn using the sketch tool in SYBYL-X with the default parameters. Then Gasteiger−Huckel charges were calculated and their geometric conformations minimized with the Tripos force field. The crystal structure of LXRβ with 24,25-epoxy-cholesterol (PDB ID 1P8D)[23] as ligand was used for docking study. Before docking, ligand and waters in the complex were removed, and the protein structure was standardized with the protein preparation processes in SYBYL-X.

RESULTS

Identification of Compounds. Phytosterols were isolated from the extract of *S. fusiforme*. On the basis of spectroscopic methods combined with comparison with the data of authentic compounds, they were identified as fucosterol (**1**),[24] saringosterol (**2**, as 1:1 mixture of epimers),[24] 24-hydroperoxy-24-vinyl-cholesterol (**3**),[25] 29-hydroperoxy-stigmasta-5,24(28)-dien-3β-ol (**4**),[25] 24-methylene-cholesterol (**5**),[25] 24-keto-cholesterol (**6**),[26] and 5α,8α-epidioxyergosta-6,22-dien-3β-ol (**7**).[27] Further separation of **2** offered 24(*S*)-saringosterol (**2a**)[28] and 24(*R*)-saringosterol (**2b**)[28] (Figure 1). Compounds **5**−**7** were isolated from *S. fusiforme* for the first time.

Effects of Compounds 1−7 on LXR Transcriptional Activity. Dual-luciferase reporter assay was utilized to investigate the effects of compounds **1**−**7** on LXR-mediated transcription. Consistent with a recent report by Dr. Hoang,[29] fucosterol (**1**) increased the transactional activity of both LXRα and LXRβ. Saringosterol (**2**) showed the strongest ability to activate LXRs compared with other active compounds **1**, **4**, and **6**, whereas **3**, **5**, and **7** exhibited little effects (Figure 2A). Our data demonstrated that various oxidized phytosterols had different abilities to activate LXRs, which was in agreement with the review on oxidized phytosterols by Hovenkamp.[20]

Saringosterol (**2**) at 30 μM increased the transcriptional activity of LXRα by (3.81 ± 0.15)-fold and that of LXRβ by (14.40 ± 1.10)-fold, indicating that **2** had a selective effect. Because **2** was a mixture of stereoisomers, 24(*S*)-saringosterol (**2a**) and 24(*R*)-saringosterol (**2b**) were separated and tested individually to clarify the influence of the orientation of 24-OH group on the LXR activation. With regard to the transcriptional activity of LXRα and LXRβ, **2a** was more potent than **2b** for LXRβ-mediated transactivation ((3.50 ± 0.17)-fold vs (1.63 ± 0.12)-fold) at 10 μM (Figure 2B). These results hinted that **2a** was a stronger LXR agonist than **2b**.

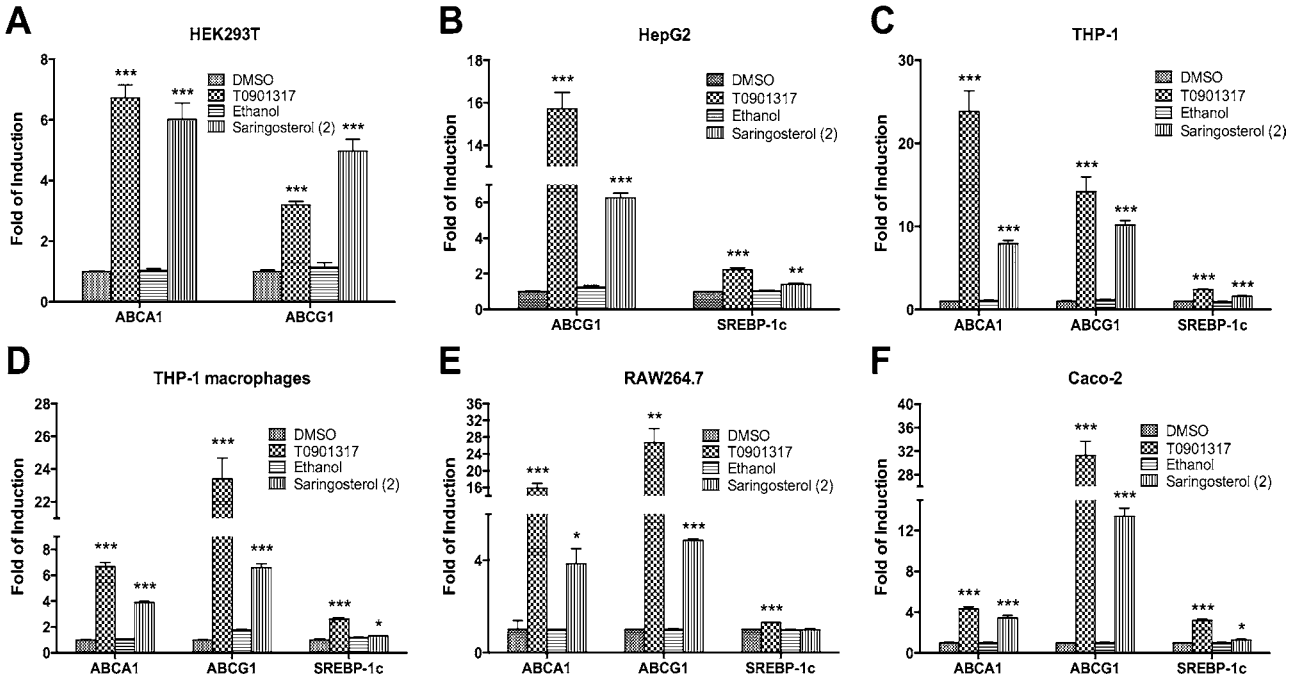

Figure 3. Effects of saringosterol (**2**) on LXR target genes expression in multiple cell types. The HEK293T (A), HepG2 (B), THP-1 monocytes (C), THP-1-derived macrophages (D), RAW264.7 (E), and intestinal Caco-2 (F) cells were cultured and then treated with **2** (30 μM), T0901317 (20 μM), or vehicle (DMSO, or ethanol) for 12 h. Total RNA was extracted and mRNA expression of ABCA1, ABCG1, and SREBP-1c was measured by qPCR. Data represent the means ± SEM ($n \geq 3$). (*) $P < 0.05$, (**) $P < 0.01$, and (***) $P < 0.001$ versus control.

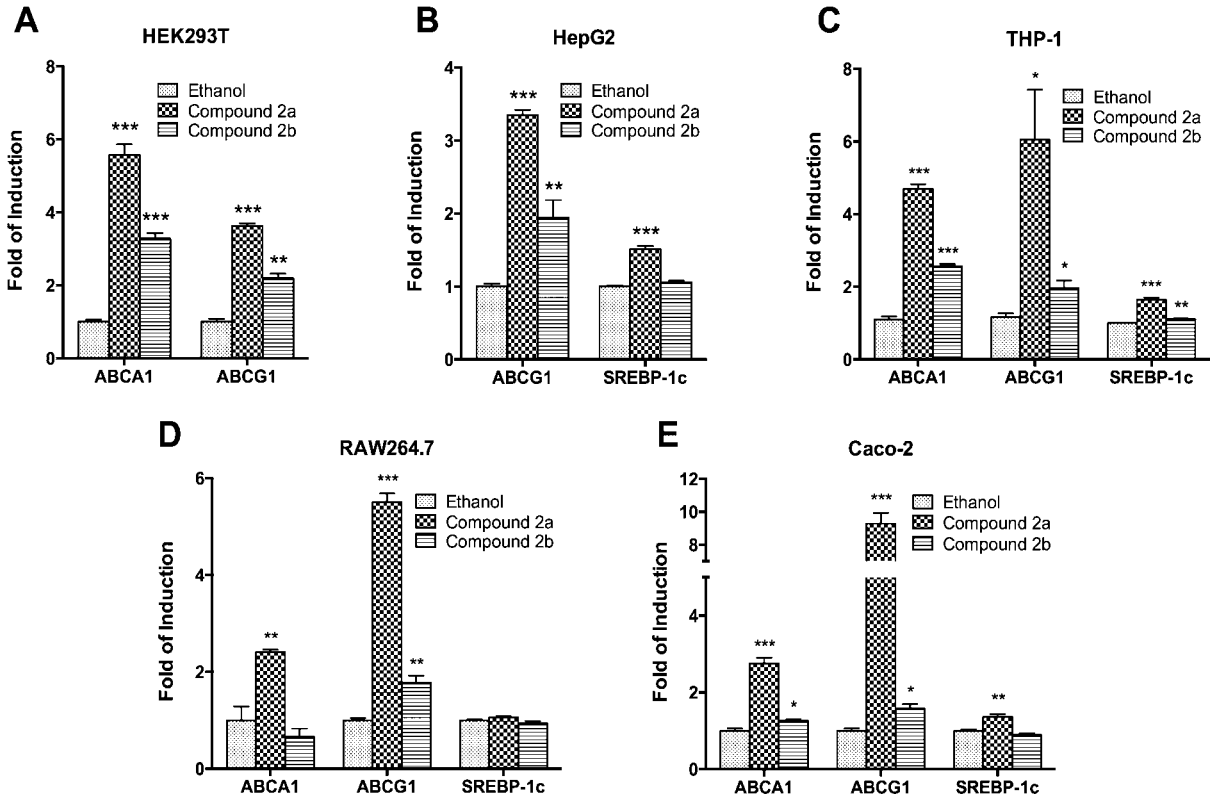

Figure 4. Induction of LXR-responsive genes by saringosterol isomers **2a** and **2b** in multiple cell types. The HEK293T (A), HepG2 (B), THP-1 monocytes (C), RAW264.7 (E), and intestinal Caco-2 (E) cells were treated with **2a** and **2b** (10 μM) or vehicle (ethanol) for 12 h. Total RNA was extracted, and mRNA expression of ABCA1, ABCG1, and SREBP-1c was measured by qPCR. Data represent the means ± SEM ($n \geq 3$). (*) $P < 0.05$, (**) $P < 0.01$, and (***) $P < 0.001$ versus control.

Effects of 2, 2a, and 2b on LXR Target Gene Expression in Multiple Cells Types. The regulation of LXR target genes by the epimer mixture **2** in different cell lines was examined subsequently. The LXR target gene expression in

dx.doi.org/10.1021/jf500083r | J. Agric. Food Chem. 2014, 62, 6130−6137

HEK293T cells was examined with real-time qRT-PCR. The mRNA expressions of two LXR target genes, ATP-binding cassette family transporter A1 (ABCA1) and ATP-binding cassette family transporter G1 (ABCG1),[17] were significantly increased by treatment with **2** (Figure 3A) as expected. The effects of **2** in HepG2 were also tested. The epimeric mixture **2** increased mRNA expression of ABCG1 and another LXR target gene, sterol regulatory element-binding protein-1c (SREBP-1c) (Figure 3B). In addition, **2** significantly enhanced the mRNA expression of ABCA1 and ABCG1 in THP-1 monocytes (Figure 3C), THP-1 derived macrophages (Figure 3D), RAW264.7 macrophages (Figure 3E), and Caco-2 cells (Figure 3F). Increased expression of SREBP-1c by **2** in THP-1, RAW264.7, Caco-2, and HepG2 cells was very limited compared to that of ABCA1 and ABCG1, but the increase was statistically significant (Figure 3B–F).

The abilities of compounds **2a** and **2b** to modulate LXR target gene expression in various cell lines were then compared. Consistent with the results obtained from luciferase assay, the induction fold of ABCA1 and ABCG1 by **2a** was greater than that of **2b** in HEK-293T cells (Figure 4A). Similarly, **2a** increased the mRNA expression of ABCG1 and SREBP-1c in HepG2 cells (Figure 4B). In agreement with the finding in luciferase assay, the mRNA expression of ABCA1 and ABCG1 was more sensitive to **2a** treatment as compared with **2b** in THP-1 monocytes and RAW264.7 macrophages (Figure 4C,D). A similar result was obtained in intestinal Caco-2 cells (Figure 4E). Consistent with the activity of **2**, the induction of SREBP-1c by **2a** was relatively small (Figure 4B–E). Thus, 24(*S*)-saringosterol (**2a**) was the major active component to stimulate LXR target gene expression.

24(*S*)-Saringosterol Acting As a Selective LXR*β* Agonist. Highest induction by the epimer mixture **2** was observed in the presence of LXR*β* (Figure 2A). This observation prompted us to test whether 24(*S*)-saringosterol (**2a**) was a selective LXR*β* agonist. To this end, dual luciferase assay using different doses of **2a** was performed. As shown in Figure 5, when the highest concentration of **2a** (40 *μ*M) was used, the LXR*β*-mediated transactivation increased 5-fold, whereas a <2-fold induction was seen for LXR*α*-mediated transactivation. Moreover, **2a** at a concentration lower than 5 *μ*M was still able to enhance LXR*β*-mediated transcription. In contrast, the transactivation of LXR*α* by **2a** was almost diminished when the concentration was lower than 5 *μ*M (Figure 5). These results clearly indicated that **2a** was a selective agonist for LXR*β*.

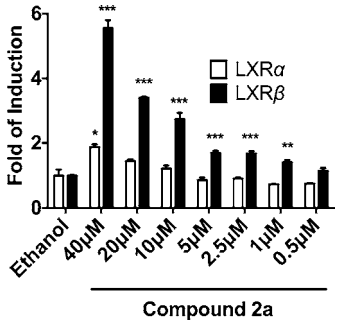

Figure 5. 24(*S*)-Saringosterol (**2a**) acts as a selective LXR*β* agonist. Luciferase assay were performed to compare the effect of compound **2a** on LXR*α*- and LXR*β*-mediated transcription. Compound **2a** at different concentrations was used as indicated.

A molecular docking approach was used to explore the interaction modes between the compounds and LXR*β*. After an energy minimization process, the lowest energy conformations of **2a** and **2b** were obtained, respectively (Figure 6). Both of the side chains of **2a** and **2b** were buried into the pocket, and the steroid nuclei were pushed outward. For **2a**, with a relatively higher docking scores, the hydroxyl group in C-3 position formed three hydrogen bonds with amino acid residues ARG319 and PHE329, which granted **2a** the binding affinity with LXR*β*. The equivalent hydroxyl group of **2b** formed only one hydrogen bond with amino acid residue GLU281. We inferred that the different docking modes of **2a** and **2b** were caused by the conformational difference in steroid nuclei A-ring, which showed an obvious difference after energy minimization. This result suggested that specific chirality is required in forming hydrogen bond indirectly. This observation agreed with the result of the luciferase assay and likely explained why **2a** showed better agonist activity than **2b**.

DISCUSSION

Phytosterols purified from *S. fusiforme* had more oxygen-containing groups than terrestrial plant phytosterols, especially on their side chain (Figure 1). Thus, marine phytosterols resembled the oxysterols, which are native LXR ligands, more than terrestrial plant phytosterols did. On the basis of this structural characteristic, we hypothesized that the marine phytosterols from *Sargassum* might be an excellent source for novel LXR agonist screening. As expected, phytosterols **2**, **4**, and **6** acted as LXR agonists, which could be correlated with their oxysterol-like structures, with **3** as an exception. Meanwhile, a peroxide bridge in steroid nucleus, such as in compound **7**, did not contribute to their effect on LXR-mediated transcription activation. Most importantly, our results indicated that 24(*S*)-saringosterol might be a selective LXR*β* agonist. Specific chiral configuration of C-24 position was a pivotal factor responsible for the activity, which was also supported by the molecular docking results. Further research is needed on the structure–activity relationship of *Sargassum* phytosterols, including natural or their synthetic analogues.

LXR*α* is highly expressed in the liver, adrenal gland, intestine, adipose tissue, macrophages, lung, and kidney, whereas LXR*β* is ubiquitously expressed.[29] LXR agonists stimulate reverse cholesterol transport and cholesterol excretion in the bile, but they can also activate lipogenesis at the same time. Lipogenesis could lead to hypertriglyceridemia and liver steatosis, which casts a shadow on the development of drugs based on LXR agonists.[30−32] Some studies have shown that it is the highly specific expression of LXR*α* in liver that causes hypertriglyceridemia.[29,31] Hence, selective LXR*β* activation could be a promising treatment for hypercholesteremia without side effects. Because natural selective LXR*β* agonists are rare, LXR*α*-null animals were usually used to test nonselective LXRs agonists on LXR*β* activation.[30,33] Thus, 24(*S*)-saringosterol would be a valuable agent to test if selective LXR*β* activation could be a promising way to treat hypercholesteremia.

ABCA1 and ABCG1 play important roles in atherosclerosis. Recent studies demonstrated that in humans, ABCA1 mutations can cause a severe HDL deficiency syndrome characterized by cholesterol deposition in tissue macrophages and prevalent atherosclerosis.[34] Similarly, ABCG1 has also been shown to have antiatherosclerotic activity in mice.[35] Here, our

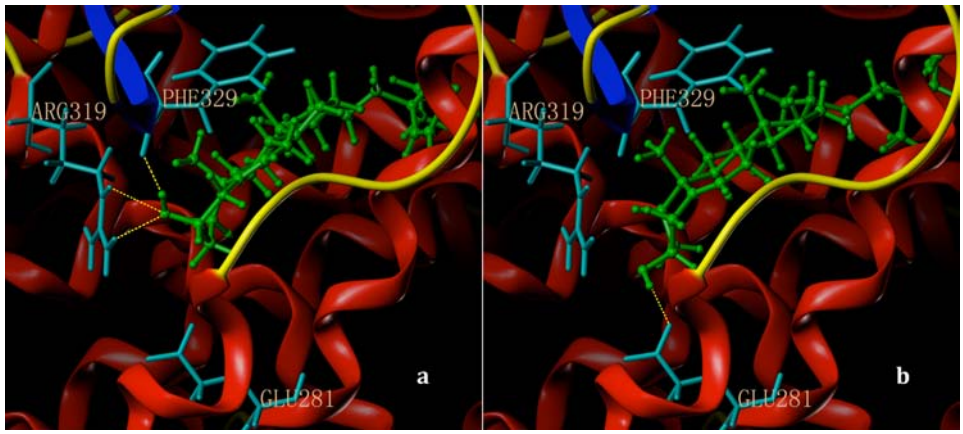

Figure 6. Predicted interaction modes of compounds **2a** and **2b** with LXRβ from molecular docking. Compounds **2a** (left) and **2b** (right) are shown as indicated. Only important residues (cyan) are shown for clarity. Hydrogen bonds are denoted by yellow dotted lines.

data indicated that compound **2a** might be a potential agent useful in treating atherosclerosis. In addition, SREBP-1c is responsible for lipogenesis in liver and may cause steatosis that develops in both leptin-deficient ob/ob mice and wild-type mice fed a lard-based high-fat diet.[36] In our study little effect of **2a** on the expression of SREBP-1c was seen in hepatocytes, implying that **2a**, not like other LXR agonists such as T0901317,[29,31,32] might not cause fatty liver.

Taken together, we investigated phytosterols from *S. fusiforme* and evaluated their effect on LXR-mediated transactivation and downstream target gene expression in various cell lines. On the basis of our findings, we concluded that 24(*S*)-saringosterol acted as a selective LXRβ agonist and is a potentially interesting natural cholesterol-lowering agent.

Supporting Information

ABSTRACT: A novel strain of *Pseudomonas monteilii*, PsF84, was isolated from tannery waste soil from Jajmau, Kanpur, India. 16S rRNA gene sequence phylogenetic analysis confirmed the taxonomic affiliation of PsF84 as *P. monteilii*. An antifungal volatile organic compound (VOC) active against hyphal growth of *Fusarium oxysporum* (CIMAP-IMI-357464) in vitro was isolated from strain PsF84 by using chromatographic techniques. The molecular formula of the antifungal VOC was deduced to be $C_{14}H_{22}O$ by EI-MS and 1D and 2D NMR spectral analysis. 2,4-Di-*tert*-butylphenol was found to be effective against an agriculturally important fungus, namely, *F. oxysporum*, in inhibiting spore germination and hyphal growth. Molecular docking analysis of 2,4-di-*tert*-butylphenol with β-tubulin further validated the potential of β-tubulin binding in *F. oxysporum*. Two residues of β-tubulin protein, HIS 118 and THR 117, showed hydrogen binding with ligand. To the authors' knowledge, this is the first report of antifungal VOC (2,4-di-*tert*-butylphenol) produced by *P. monteilii* PsF84 that can be a potent inhibitor of β-tubulin of *F. oxysporum*.

INTRODUCTION

Fungal phytopathogens pose serious problems worldwide in the cultivation of economically important plants, especially in subtropical and tropical regions.[1] However, excessive use of chemical fungicides in agriculture has led to deterioration of the environment, impairing human health and increasing development. Because of the worsening problems in fungal disease control, serious efforts are required to identify alternative methods for plant protection that are less dependent on chemicals and are more environment friendly. Biological control using microbes or organic products in agriculture systems has been proposed as an environment friendly disease management strategy.[2−5] For successful biocontrol, searching for beneficial microbes that can prevent plant pathogens is a critical first step. Microbial antagonist strains are capable of producing a wide range of soluble secondary metabolites, many of which are volatile organic compounds (VOCs) exhibiting strong inhibitory activity against plant pathogens, and have received much attention.[6,7] All microbial species produce a unique reproducible profile of VOCs under specific conditions.[8] These antagonists include bacteria, such as *Pseudomonas* spp., *Streptomyces* spp., and *Bacillus* spp.[6,9,10] Strains of *Pseudomonas* spp. have been reported to produce several VOCs, such as benzothiazole, cyclohexanol, *n*-decanal, dimethyl trisulfide, 2-etyhl-1-hexanol, and nonanal, which directly inhibit mycelial growth and spore germination of pathogenic fungi and could be a mechanism of biocontrol against some soilborne fungal disease.[11,12] VOCs belong to several chemical classes (aldehydes, alcohols, esters, lactones, butylphenol, terpenes, and sulfur compounds) and are characterized by low molecular weight and the ability to interact with olfactory receptors.[13] Antifungal VOCs produced by *Pseudomonas chlororaphis*, *Pseudomonas corrugata*, *Pseudomonas fluorescence*, and *Pseudomonas. aurantiaca* inhibited the growth and spore germination of *Sclerotinia sclerotiorum* in vitro.[11] VOCs produced by bacteria or fungi could be a mechanism of biocontrol against some soilborne fungal diseases.[7,14] Antifungal VOCs produced from microorganisms with novel structures have the potential to provide insight to agricultural researchers as to which compounds could be used as fungicides. The relationship between soil microorganisms and VOCs is still unclear, and many fungistatic compounds remain to be identified. Recognizing the hazards of fungicides and pesticides to man and the environment, many countries in the world today are considering biological control as the best alternative to chemical control of plant diseases and pests.[15] *F. oxysporum* is well represented among the communities of soilborne fungi, in every type of soil all over the world.[16] Some strains of *F. oxysporum* are pathogenic to plants and are difficult to control; however, biological methods may be a reliable alternative to chemical methods for controlling soilborne fungal growth. Studies using in silico approaches such as targeted protein have begun to shed light on the mechanisms underlying some of these processes and their role in spore germination inhibition.[17]

Microtubules composed of heterodimers of α-tubulin and β-tubulin, which are present in all eukaryotic cells, play important roles in various cellular processes such as cell signaling, cell motility, separation of the duplicated centrosomes, cell division, and mitosis.[18] In fungal cells mitosis takes place without nuclear envelope breakdown in many organisms; cytoplasmic microtubules break down upon entry into mitosis, and tubulin molecules are transported into the nucleoplasm to establish an internuclear spindle. Therefore, one would assume that the loss of microtubules should negatively affect the growth rate of spore germination.[19] Loss of cytoplasmic microtubules should negatively affect tip growth rate, and if they disappear completely during mitosis, one should expect a reduction in fungal growth.

Despite its important role, β-tubulin has not yet been well characterized either functionally or structurally in *F. oxysporum*. In this study, the structure of the β-tubulin protein was predicted in silico on the basis of sequence similarity with protein having known structure. The sequence of β-tubulin is consistent with a conserved domain of the tubulin FtsZ superfamily. This domain family includes alpha (α), beta (β), gamma (γ), delta (λ), and epsilon (δ) tubulins as well as FtsZ, all of which are involved in polymer formation. Tubulin is the major component of microtubules, but also exists as a heterodimer and a curved oligomer. FtsZ can polymerize into tubes, sheets, and rings in vitro and is ubiquitous in eubacteria, archaea, and chloroplasts. Cellular microtubules are known to play an essential role in nuclear division as components of the mitotic spindle, and dimeric tubulin is their primary component. A key property of tubulin is its ability to assemble into microtubules via interaction between polymerized α- and β-tubulin monomers (heterodimer) and to undergo disassembly at appropriate times in the cell cycle. In this study, we have characterized the antifungal VOC produced by strain PsF84, a potential biocontrol agent, highly active against *F. oxysporum*. We used various chromatographic techniques, 1D and 2D nuclear magnetic resonance (NMR) spectral analysis and gas chromatography−mass spectroscopy (GC-MS), to identify antifungal VOC. The sequence-based prediction of 3D structure of β-tubulin was predicted to analyze the properties and function of the protein. In addition, a molecular docking study of 2,4-di-*tert*-butylphenol with β-tubulin has been carried out to explore binding to this antifungal relevant protein target as a possible mechanism of the antifungal activity of volatile compounds.

MATERIALS AND METHODS

Chemicals. All of the chemicals and organic solvents used for vacuum liquid chromatography (VLC) were of analytical grade and purchased from Merck (Mumbai, India). For thin layer chromatography (TLC) precoated silica gel 60_{254} plates (20 × 20 cm, Merck) were used. Hexane, dichloromethane (DCM, GR), methanol (MeOH, GR), and *p*-dimethylaminobenzaldehyde were also purchased from Merck. The conventional fungicide bavistin (methyl benzimidazol-2-ylcarbamate) was purchased from Sigma-Aldrich.

General Experimental Conditions. ^{1}H and ^{13}C NMR spectra were recorded at 400 MHz (Avance, Bruker, Switzerland). The GC-MS analysis was carried out on a Perkin- Elmer SQ8 mass spectrometer instrument using a DB-5 column (30 m × 0.25 mm i.d., film thickness = 0.25 μm). The carrier gas was helium with a flow rate of 1 mL/min column head pressure; temperature was programmed from 60 to 240 °C at a rate of 3 °C/min with a final hold for 10 min. The injector (250 °C), transfer line, and ion-source temperature were 220 °C. Mass spectra were prepared in EI-mode with 70 eV ionization energy between 40 and 450 amu mass range and 0.35 s scan time. Characterization was carried out by computer matching of the mass spectra of the peak with the Wiley and NIST libraries mass spectral databases.

Collection of Samples and Isolation of Bacterial Strain PsF84. Soil samples were collected from the tannery waste polluted area of Jajmau, a Research center of CSIR−Central Leather Research Institute, Chennai, India, located at latitude 26° 42′ N and longitude 80° 41′ E in the Kanpur district of Uttar Pradesh, India, in November 2012 and were dried at ambient temperature. Isolation was carried out on Pseudomonas Isolation Agar (PIA) following the serial dilution technique of Hammond and Lambert.[20] Colonies were further purified and screened for fluorescence under UV light (366 nm). For long-term maintenance, strain PsF84 was preserved in nutrient broth containing 20% (v/v) glycerol at −80 °C.

Phenotypic Characterization of *P. monteilii* PsF84. Bacterial isolates were characterized for phenotypic and biochemical traits according to *Bergey's Manual of Determinative Bacteriology*.[21] Grams reaction was determined by using the KOH technique.[22] The presence of cytochrome oxidase was determined using 1% *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine dihydrochloride solution.[23] Catalase, levan formation, nitrate reduction, starch, casein, and gelatin liquefaction and growth at pH 5−7 and 4−42 °C were recorded following the methods described.[24] Substrate utilization profiles were tested using Hi-carbohydrate kits (Himedia Laboratories, Mumbai, India) according the instructions of the manufacturer.

16S rRNA Gene Amplification, Sequencing, and Phylogenetic Analysis. Isolation of genomic DNA, PCR amplification of 16S rRNA gene, and purification and sequencing of the PCR product were performed as previously described.[25] Phylogenetic molecular evolutionary analysis was conducted using MEGA version 5.05.[26] The nucleotide sequence of 16S rRNA was deposited as GenBank accession no. KC45055.

Extraction and Purification of Bioactive Volatile Compound. A single colony of *P. monteilii* PsF84 on a nutrient agar (NA agar) plate was transferred into 100 mL of modified pigment production medium (PPM) broth: peptone, 10.0 g; NaCl, 5.0 g; glycerol, 5.0 mL; and KNO_3, 1.0 g, in 1 L of distilled H_2O (pH 7.5). The PPM was used to recover antibiotics from the culture filtrate of strain PsF84. The fermentation was carried out in pigment production medium for 4 days at 28 °C on a rotary shaker at 150 rpm. The harvested broth (120 L) of *P. monteilii* strain PsF84 was centrifuged at 8000 rpm and the supernatant pooled. The culture filtrate (CF) was successively fractionated with hexane and dichloromethane (3 × 100 mL each).

Isolation and Characterization of Bioactive Constituent. The DCM extract (8 g) was subjected to Vacuum Liquid Chromatographic (VLC) separation over TLC grade silica gel H (250 g). Gradient elution of the VLC was carried out with mixtures of *n*-hexane, $CHCl_3$, and MeOH in increasing polarity as shown in the flowchart (Figure 1). A total of 125 fractions of 100 mL each were collected and pooled on the basis of their TLC (SiO_2) profile after spraying with Ehrlich reagent and heating the plate for 2 min at 100 °C.[27] The pooled fractions were marked as fractions 1−10 (F1), 4−7 (F2), 10−12 (F3), 13−16 (F4), 17−20 (F5), 21−25 (F6), 26−46 (F7), 47−115 (F8), and 116−125 (F9). Subfraction fraction 8 (F8) was further purified by preparative TLC [$CHCl_3$/MeOH (90:10)], which afforded a homogeneous compound **P1a** (75 mg). **P1a** was subjected to ^{1}H and ^{13}C NMR and GC-MS spectroscopic data as given below.

^{1}H NMR ($CDCl_3$) δ 7.34 (1H, d, J = 2.4 Hz, H-3), 7.11 (1H, dd, J = 8.2, 2.4 Hz, H-5) 6.63 (1H, d, J = 8.2 Hz, H-6), 1.46 (9H, s, H-9), 1.34 (9H, s, H-10); ^{13}C NMR δ 151.8 (C-1), 135.2 (C-2), 124.1 (C-3), 143.0 (C-4), 123.5 (C-5), 115.1 (C-6), 34.3 (C-7), 34.7 (C-8), 31.6 (C-9, 3 × CH_3), 29.7 (C-10, 3 × CH_3); GC-MS m/z 206 $[M]^+$, $C_{14}H_{22}O$.

In Vitro Disk Diffusion Assay against *F. oxysporum*. CF, DCM, F8, and **P1a** were subjected to evaluation of their antifungal activity in vitro against the wilt-causing pathogen, *F. oxysporum*, by using the standard agar disk diffusion technique of Kai et al.[28] A mycelial disk (5 mm), obtained from a 4-day-grown culture of *F. oxysporum*, was placed on one side of a 90 mm potato dextrose agar

dx.doi.org/10.1021/jf5001138 | J. Agric. Food Chem. 2014, 62, 6138−6146

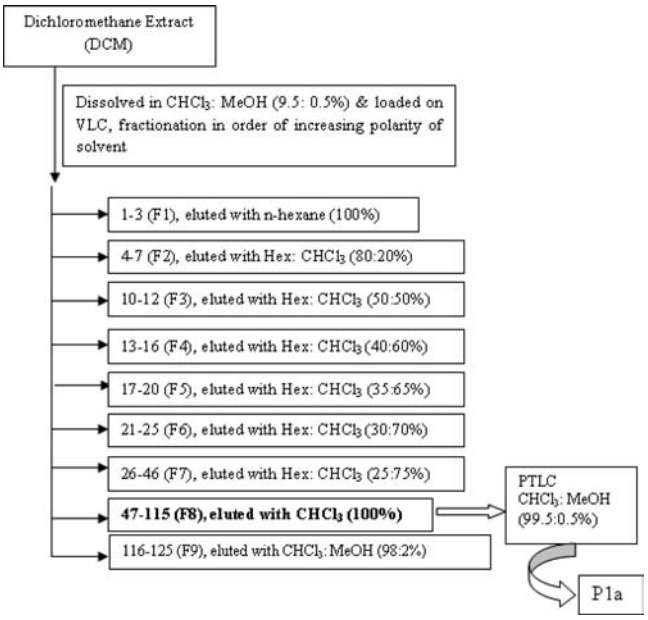

Figure 1. Schematic representation of vacuum liquid chromatography.

(PDA) medium containing Petri plate. The commercial fungicide bavistin (methyl benzimidazol-2-ylcarbamate), provided as technical grade material (Carbendazim 50% DF), was used to compare the antifungal activity in vitro. For evaluation of the antifungal activity of 2,4-di-*tert*-butylphenol and bavistin, both were dissolved in methanol and diluted with water containing Tween 20 (0.5 g/L; Himedia, India) to give concentrations of 1, 25, 50, 100, 200, and 500 μg/mL. Pure compound (2,4-di-*tert*-butylphenol) was applied on the paper disk and for the control set, and an equal volume of Tween 20 solution was also applied. The Petri dishes were sealed with sterile laboratory parafilm to avoid eventual evaporation of the volatile compound, and plates were incubated at 28 ± 2 °C for 72 h, measuring the size of growth inhibition in comparison to control plate. Each assay in these experiments was repeated three times, and the results (percent inhibition) were expressed as average values (± standard deviation).

Statistical Anlysis. Data from three independent replicate trials were subjected to analysis using one-way analysis of variance (ANOVA) techniques. The data are reported as the mean ± standard deviations, and significant differences between mean values were determined with Duncan's multiple-range tests (DMRT) performed by ASSISTAT software version 7.6 beta (2013) http://www.assistat.com. The significance of the data was analyzed at $p > 0.005$.

Effect of 2,4-Di-*tert*-butylphenol on Hyphal Morphology of *F. oxysporum*. To evaluate morphological changes with volatile compounds, fungal samples of *F. oxysporum* taken from areas showing inhibition levels were placed on the slides and were stained with lactophenol cotton blue (Fluka, Buchi, Switzerland). A sample from the control plate without volatile compound was also stained and observed under a light microscope (40× magnification) (Axio Scope A1, Zeiss, Germany).

Computational Analysis. Computational studies were carried out with different tools and software packages. The conserved domains were analyzed through a tool incorporated in a conserved domain database (http://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi).[29] Geno3d (http://geno3d-pbil.ibcp.fr) was used for structure prediction of the protein.[30] The spatial restraint (distances and dihedrals) satisfaction was performed for comparative protein structure modeling. The modeled protein was validated by PROCHECK for its stereochemical qualities through SAVES (Structure Analysis and Verification Server) (http://nihserver.mbi.ucla.edu/SAVES/).[31] The ProSA program was used to examine the validation of the model.[32] Protein visualization and superimposition were carried out using PyMol (http://www.pymol.org/). The secondary structure of tubulin protein was predicted by Polyview (http://polyview.cchmc.org/). Protein–ligand docking studies were carried out on the basis of the predicted structure of β- tubulin protein. Molecular docking calculations for 2,4-di-*tert*-butylphenol, considered as a ligand with β-tubulin, was undertaken using Autodock 4.2,[33] and different orientations of the ligands were searched and ranked on the basis of their energy scores. The RMSD threshold for multiple cluster poses was set at <1.00 Å. The docking algorithm was set at a maximum of 1500 iterations with a simple evolution population size of 50 and a minimum of 25 runs for the ligand.

RESULTS AND DISCUSSION

Isolation and Screening of Fluorescent Pseudomonas. Eight hundred fluorescent pseudomonas isolates were obtained on PIA from the tannery waste polluted soil samples, in which a unique fluorescent *Pseudomonas* strain, designated PsF84, was predominantly produced. The strain was further purified and maintained on Luria–Bertani (LB) slants at −20 °C for subsequent studies.

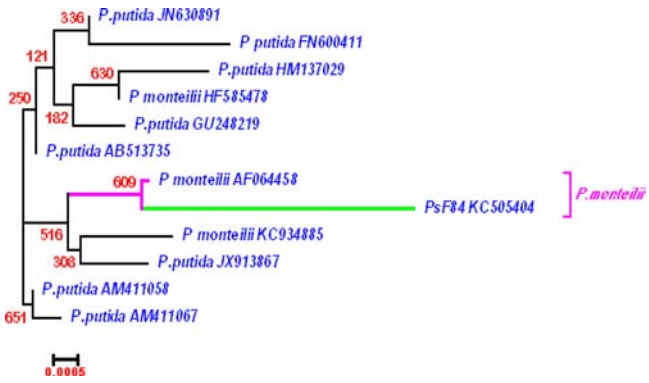

Figure 2. Phylogenetic tree based on 16S rRNA sequences, representing the relatedness among the *Pseudomonas monteilii* PsF84. Distance and clustering were performed by using the software package MEGA 5.05. Boot strap values based on 1000 replications are listed at the branching point. The sequence of the present study is dotted in red.

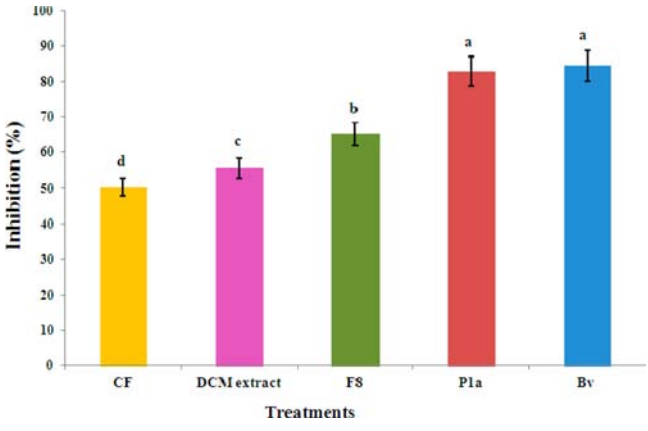

Figure 3. Antifungal activity of CF, culture filtrate; DCM, dichloromethane; F8, eighth fraction; P1a, 2,4-di-tert-butylphenol; Bv, Bavistin against *F. oxysporum*. Mean values followed by different letters are significantly different according to Duncan's multiple-range test ($P < 0.05$).

Identification of Bacterial Strain. PsF84 was found to be a Gram-negative, aerobic, motile, non-spore-forming bacterium. The strain grew at 15–37 °C but not at >40 °C. Growth was optimum at pH 5.5–10 but inhibited at pH <5.5. The strain

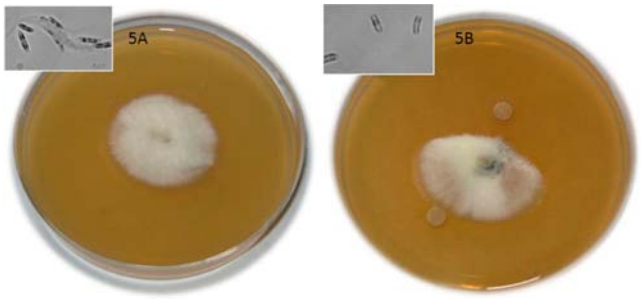

Figure 5. Antifungal activity of 2,4-di-*tert*-butylphenol against *Fusarium oxysporum*: (A) control showing normal growth; (B) potato dextrose plate containing filter disk loaded with 25 μg/mL of 2,4-di-*tert*-butylphenol showing growth inhibition.

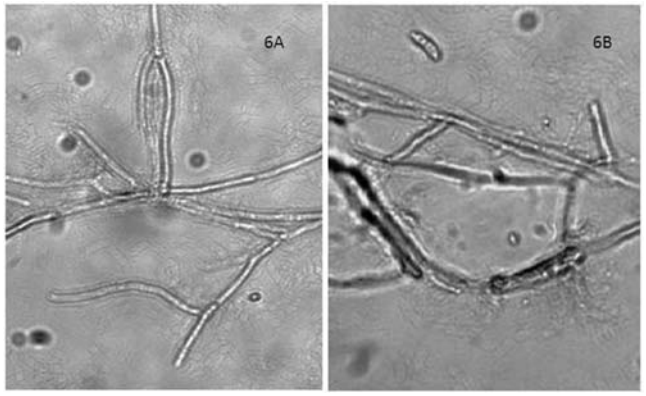

Figure 6. Microscopic examination of hyphal morphology of (A) *F. oxysporum* from PDA culture (40× magnification) and (B) effect of 2,4-di-*tert*-butylphenol showing deformed mycelia of *F. oxysporum* (40× magnification). Arrows indicate hyphal lysis.

tolerated well up to 7% NaCl in the basal medium. It utilized citrate and produced catalase and cytochrome oxidase. Nitrate reduction, urease, indole, levan, gelatin liquification, or hydrogen sulfides were not produced. Methyl red and Voges−Proskauer reactions were negative. PsF84 strain utilized L-arabinose, galactose, glucose, fructose, and xylose, but not mannitol, raffinose, salicin, sucrose, rhamanose, meso-inositol, and lactose.

16S rRNA Gene Amplification Sequencing and Phylogenetic Tree Analysis. The 16S rRNA sequence of starin PsF84 has been submitted to the GenBank database of NCBI (http://www.ncbi.nlm.nih.gov/) having the accession number KC45055. A phylogenetic tree is presented (Figure 2).

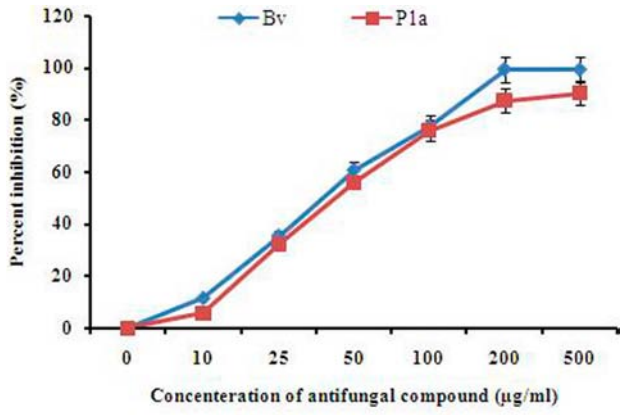

Figure 7. Antifungal spectrum of the metabolite 2,4-di-*tert*-butylphenol isolated from *P. monteilii* PsF84 against *F. oxysporum* under in vitro conditions (values are the mean of three replicates ± SD). Mean values followed by different letters are significantly different according to Duncan's multiple-range test ($P < 0.05$).

Activity-Guided Isolation and Characterization of Bioactive Constituents. The culture filtrate (CF) of *P. monteilii* PsF84 showed significant activity against *F. oxysporum* at 25 μg/mL (50.23 ± 1.48) (Figure 3), which prompted us to carry out activity-guided fractionation, isolation, and characterization of the bioactive compound. For this purpose, the CF was fractionated into *n*-hexane and DCM fractions, and both fractions were evaluated for their antifungal potential. The results showed that the DCM fraction was found to be most active at 25 μg/mL (55.46 ± 0.67) (Figure 3). Hence, the DCM fraction was subjected to chromatographic separation. Finally, the most active subfraction 8 (F8) at 25 μg/mL (65.23 ± 0.80) (Figure 3) was further purified by preparative TLC, which afforded a homogeneous compound, **P1a**. The ^{1}H NMR spectra of **P1a** showed the presence of a total 21 protons, of which 18 protons were present as six *tert*-methyls at δ 1.34 (9H, s, 3 × CH_3) and 1.46 (9H, s, 3 × CH_3). The remaining three protons were present in the downfield aromatic region at 6.63 (1H, d, J = 8.2 Hz), 7.11 (1H, dd, J = 8.2, 2.4 Hz), and 7.34 (1H, d, J = 2.4 Hz), suggesting that this compound is a trisubstituted aromatic compound. This was supported by its ^{13}C NMR spectra, which showed the presence of 10 carbon signals, of which six downfield carbon signals between 115.1and 151.8 ppm were in the aromatic region, whereas the remaining four carbon signals were in the upfield region between 29.7 and

34.7 ppm. Of six aromatic carbon signals, three were quaternary carbons (135.2, 143.0, and 151.8 ppm), suggesting that the aromatic substitutions were at these carbons. The most downfield quaternary carbon at 151.8 ppm indicated the presence of a phenolic OH group at this carbon in the molecule. Among the four upfield carbon signals, the two at 34.3 and 34.7 ppm were tertiary carbons and the remaining two at 29.7 and 31.6 ppm were methyl signals. This clearly suggested the presence of two *tert*-butyl substitutions on the two remaining quaternary carbons at 135.2 and 143.0 ppm in the aromatic ring. Finally, on the basis of the splitting patterns and coupling constants of the three aromatic protons, the structure of **P1a** was deduced as 2,4-di-*tert*-butylphenol. This was further confirmed from the GC-MS spectra of **P1a**, which showed a single peak at a retention time of 26.95 min with m/z 206, showing reverse and forward matching 915 and 890 for the 2,4-di-*tert*-butylphenol (Figure 4). Our results were in complete agreement with data reported by Yoon et al.[14] for **P1a**. To the best of our knowledge this is the first report of 2,4-di-*tert*-butylphenol in *P. monteilii* PsF84 (see ^{1}H and ^{13}C NMR and GC-MS spectra in the Supporting Information, Figure S1).

In Vitro Antifungal Activity of 2,4-Di-*tert*-butylphenol against *F. oxysporum*. Compound **P1a** inhibited the hyphal growth of *F. oxysporum* f. sp. (CIMAP-IMI-357464) (a soilborne pathogen causing vascular wilt/rot) under in vitro conditions at a concentration of 25 μg/mL (32.2 $\pm$ 1.2) (Figure 5). Nonvolatile antibiotics, including lipopeptides, have strong antifungal activities.[34−36] The light microscopic image of the treated *F. oxysporum* with 2,4-di-*tert*-butylphenol revealed a deformation of the fungal mycelia and growth inhibition (Figure 6). It is possible that application of 2,4-di-*tert*-butylphenol suppresses the assembly of spindle microtubules and disturbs the chromosomal alignment at the metaphase plate and microtubule−kinetochore interactions, causing chromatids loss, chromosome loss, or nondisjunction in target cells, which may reduce the mycelia growth and the germination of spores. A similar study reported on 2,4-di-*tert*-butylphenol to be an antifungal volatile compound from *Bacillus amyloliquefaciens* NJN-6 indicated that 2,4-di-*tert*-butylphenol strongly inhibited the growth of *F. oxysporum* f. sp. cubense.[37] The antifungal bioactive compound significantly inhibited the conidial suspension of *F. oxysporum* under in vitro conditions at a concentration of 100 μg/mL, whereas that of standard fungicide also exhibited inhibition action at the same level of 100 μg/mL, respectively (Figure 7). The result showed the effect of 2,4-di-*tert*-butylphenol on *F. oxysporum* occurred during spore germination, and it completely inhibited the germination of spores by preventing the emergence of a normal germ tube and led to abnormal branching and swelling of hyphae occurring after 72 h of incubation at 26 $\pm$ 2 °C. This compound has also been found in plant extracts or plant essential oils with antibacterial or antioxidant activities[14,38] because phenols had been described as antioxidants, growth regulators, or flavors.[39] Recently, an antifungal compound 2,4-di-*tert*-butylphenol isolated from *Flavobacterium johsoniae* strain GSE09 showed biocontrol activity against *Phytophthora capsici* in peppers.[40] The antifungal nature of the organic volatiles has been demonstrated in several pathogen systems, such as inhibition of hyphal extension and formation of arthrospore in

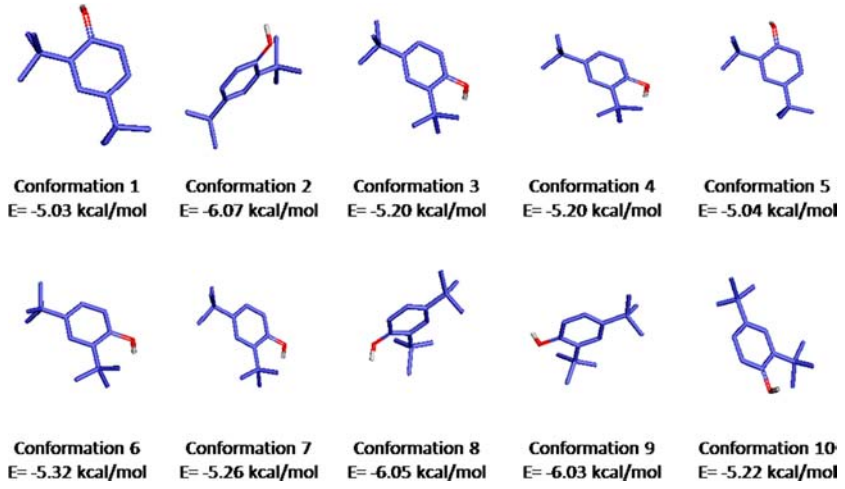

Figure 15. Low-energy and docked conformations of 2,4-di-*tert*-butylphenol.

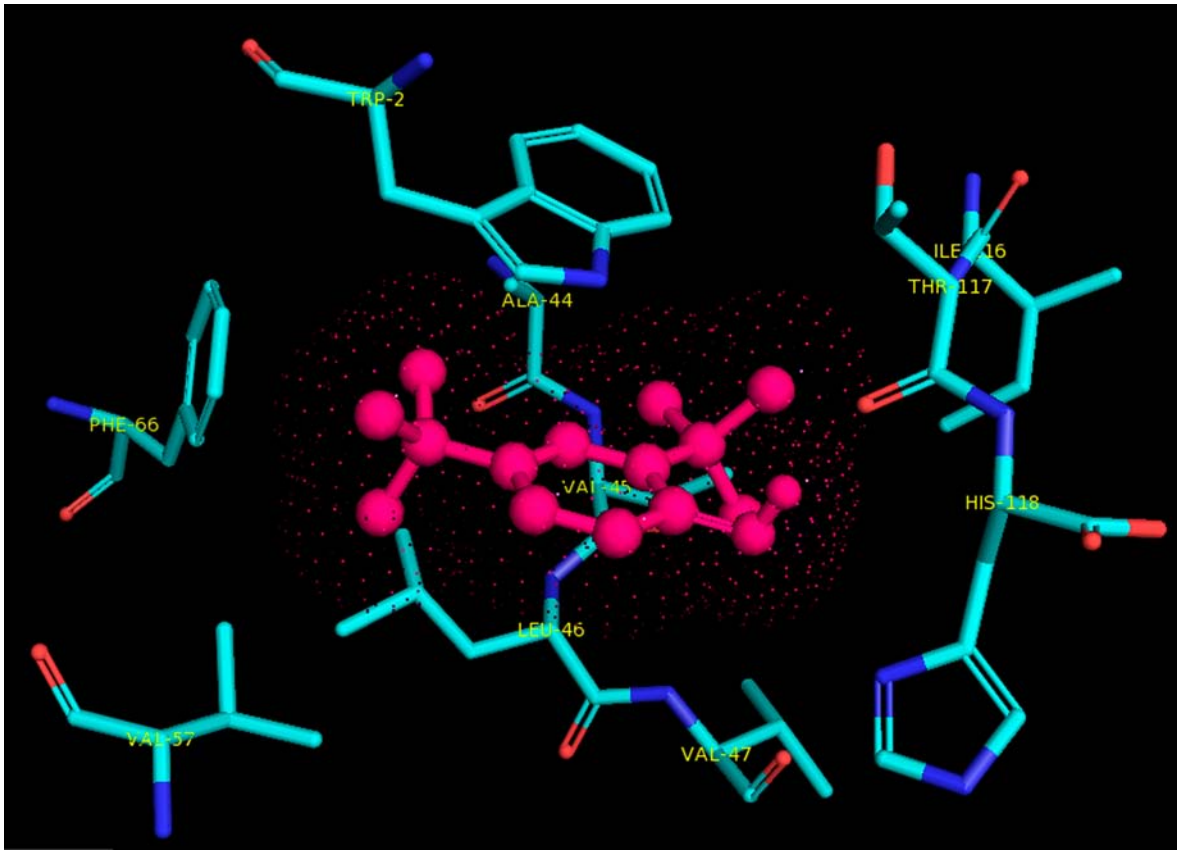

Figure 16. 2,4-Di-*tert*-butylphenol (pink) showing docking with active site residues (labeled in yellow).

Geotrichum candidum by trimethylamine,[41] inhibition of carpogenic germination of sclerotia of *S. sclerotiorum* in bean by allyl alcohol,[42] and control of root rot of tobacco by hydrogen cyanide produced by pseudomonads.[43] On the basis of the results from in vitro studies, 2,4-di-*tert*-butylphenol is assumed to play a major role in the inhibition of fungal growth and indicates that germination inhibition is one of the mechanisms by which a volatile compound (2,4-di-*tert*-butylphenol) might provide effective biocontrol activity against *F. oxysporum*.

Structure Prediction of β-Tubulin. The three-dimensional structure of 2,4-di-*tert*-butylphenol was retrieved from the pubchem database of NCBI (http://www.ncbi.nlm.nih.gov/) (Figure 8). The pubchem id of this compound is CID 7311. The protein sequence of β-tubulin of *F. oxysporum* was retrieved from the Genpept database of NCBI. The accession number of the sequence is AAU15035.1 and the length, 119 amino acids. The secondary structure of the sequence of *F. oxysporum* β-tubulin was assigned (Figure 9).

Model Building. The three-dimensional structure was predicted through homology modeling approach. The template for the prediction of structure was selected on the basis of identity with the sequence having known structure. The PDB blast search suggested *Ovis aries* tubulin protein crystal

dx.doi.org/10.1021/jf5001138 | J. Agric. Food Chem. 2014, 62, 6138−6146

structure at 2.22 Å resolution (PDB id 4DRX) for structure prediction. The selected protein is present in six chains. Of the six, chains B and D showed highest sequence similarity. The query and template identity and positives were 81 and 93% after pairwise alignment. The stretch 20−138 of the sequence of chains B and D showed alignment. The expected value and query coverage were 4e-74 and 99%, respectively. Multiple sequence alignment among β-tubulin sequence and B and D chains of template protein was performed to show the regions of identity (Figure 10). The percentage identity with chains A and C was 41% and with chains E and F was 32%. After finding the most appropriate template, three models were generated by Geno3D having their respective model energies. The model with lowest energy of −5050.22 kcal/mol was chosen as the best model and subjected to further analysis. The generated model was submitted to the PMDB database (http://mi.caspur.it/PMDB/main.php). The assigned PMDB id is PM0079294. Although the β-tubulin sequence showed highest identity with both chains B and D, the modeled structure was superimposed with chain D only (Figure 11).

Protein Model Validation. After modeling of the protein, several structure assessment methods including Ramachandran plot, *z* score, and energy plot were used to check the reliability of the 3D model. To validate the *F. oxysporum* β-tubulin model, a Ramachandran plot was drawn to analyze the stereochemical quality of the model by PROCHECK. It was found that the phi-psi angles of 71.1% of the residues were in the core regions, 25.8% in the additional allowed regions, 3.1% in generously allowed region, and no residues were in the disallowed regions (Figure 12). To determine the overall quality and measures of the deviation of the total energy of the structure, the ProSA program was used.[44] A *z* score of −4.52 of β-tubulin was in the acceptable range (−10 to 10) (Figure 13). A negative *z* score is good and depends on the length of the protein. The *z* score in this plot is displayed with a dark black point. The structure is displayed in two distinguishing regions, the dark blue and light blue representing NMR and X-ray, respectively. The energy plot analysis from the ProSA program showed that most of the residues of the protein were within the negative range of energy, indicating the stability of the protein (Figure 14).

Docking Analysis. The docking of ligand with modeled β-tubulin protein was performed by Autodock 4.2 using a genetic algorithm approach. Conformational analyses were carried out for 2,4-di-*tert*-butylphenol at the result of docking poses. Ten conformations were generated having different docking energies and numbers of hydrogen bonds (Figure 15). The docking energies were in the range from −5.86 to −6.40 kcal/mol. Conformation 4 was considered to be most suitable, binding with HIS 118 and THR 117 with two hydrogen bonds. Residues within a 5 Å radius of the ligand were selected as actively participating in binding (Figure 16). The following amino acid residues of β-tubulin played an active role in the interaction with ligand: PHE 66, VAL 57, TRP 2, ALA 44, VAL 45, LEU 46, VAL 47, ILE 116, HIS 118, and THR 117. The more negative value of the docking energy as well as the maximum number of hydrogen bonds showed strong and most favorable binding between protein and ligand molecules.

These findings are important as antifusarium activity of 2,4-di-*tert*-butylphenol from *P. monteilii* PsF84 significantly reduced the pathogen's mycelial growth and inhibited spore germination. It is assumed that 2,4-di-*tert*-butylphenol may be binding with β-tubulin in microtubules, inhibiting their proliferation and suppressing their dynamic instability as the microtubules are the cytoskeletal polymers in eukaryotic cells and thus play a vital role in many cellular functions.[18] Therefore, one would assume that the loss of microtubules should negatively affect the growth rate of spore germination and expect a reduction in fungal growth in vitro. Furthermore, docking results also supported that compound 2,4-di-*tert*-butylphenol is a potent inhibitor of *F. oxysporum*. These observations may be of great help in the QSAR-based design of fungicides from a very common, inexpensive, and nontoxic natural product, which is safe for humans, animals, and the environment. The current study may provide useful information regarding the antifungal activity of the bioactive compounds against the plant pathogenic fungi *F. oxysporum* from *P. monteilii* PsF84. We conclude that the *P. monteilii* strain PsF84 is a promising source of natural bioactive secondary metabolites, which may receive great benefit as potential sources in the agricultural and pharmacological industries. However, further evaluation of the effectiveness of 2,4-di-*tert*-butylphenol in vivo for disease control and formulations is required.

ABSTRACT: Greek oregano (*Origanum vulgare*), marjoram (*Origanum majorana*), rosemary (*Rosmarinus officinalis*), and Mexican oregano (*Lippia graveolens*) are concentrated sources of bioactive compounds. The aims were to characterize and examine extracts from greenhouse-grown or commercially purchased herbs for their ability to inhibit dipeptidyl peptidase IV (DPP-IV) and protein tyrosine phosphatase 1B (PTP1B), enzymes that play a role in insulin secretion and insulin signaling, respectively. Greenhouse herbs contained more polyphenols (302.7−430.1 μg of gallic acid equivalents/mg of dry weight of extract (DWE)) and flavonoids (370.1−661.4 μg of rutin equivalents/mg of DWE) compared to the equivalent commercial herbs. Greenhouse rosemary, Mexican oregano, and marjoram extracts were the best inhibitors of DPP-IV (IC_{50} = 16, 29, and 59 μM, respectively). Commercial rosemary, Mexican oregano, and marjoram were the best inhibitors of PTP1B (32.4−40.9% at 500 μM). The phytochemicals eriodictyol, naringenin, hispidulin, cirsimaritin, and carnosol were identified by LC−ESI-MS as being present in greenhouse-grown Mexican oregano and rosemary. Computational modeling indicated that hispidulin, carnosol, and eriodictyol would have the best binding affinities for DPP-IV. Biochemically, the best inhibitors of DPP-IV were cirsimaritin (IC_{50} = 0.43 ± 0.07 μM), hispidulin (IC_{50} = 0.49 ± 0.06 μM), and naringenin (IC_{50} = 2.5 ± 0.29 μM). Overall, herbs contain several flavonoids that inhibit DPP-IV and should be investigated further regarding their potential in diabetes management.

KEYWORDS: *hispidulin, marjoram, oregano, rosemary, type 2 diabetes mellitus, DPP-IV, PTP1B*

INTRODUCTION

Type 2 diabetes mellitus (T2DM) affects 8.3% of Americans and cost the United States $175 billion in 2012.[1] Currently, the only effective therapies for the management of T2DM are lifestyle intervention and treatment with pharmaceuticals; however, these approaches have poor adherence[2] and can be expensive to maintain.[1] Thus, there is a need to identify natural compounds that can aid in the management of this disease.

Plants produce bioactive compounds that inhibit the pharmaceutical targets related to T2DM, dipeptidyl peptidase IV (DPP-IV) and protein tyrosine phosphatase 1B (PTP1B).[3,4] DPP-IV is a serine protease responsible for the degradation of the insulinotropic incretin glucagon-like peptide 1 (GLP-1). Pharmaceutical inhibitors of this enzyme have successfully reduced hyperglycemia and hemoglobin A1C levels as a monotherapy and in combination with other antidiabetic agents.[5] PTP1B is a tyrosine phosphatase responsible for the reversal of insulin receptor autophosphorylation. Reducing the activity of this enzyme is hypothesized to prolong the insulin signaling cascade and thus increase insulin sensitivity.[6] A synthetic inhibitor of PTP1B reduced enzyme activity and plasma insulin levels in high-fat-diet-induced obese mice.[7]

A review of recent scientific publications on culinary herbs indicates that herbs from a traditional Mediterranean diet alleviate inflammation, hypertension, hyperlipidemia, and hyperglycemia in vivo.[8] Investigation of the hypoglycemic mechanisms showed that oregano (*Origanum vulgare*), marjoram (*Origanum majorana*), and rosemary (*Rosmarinus officinalis*) can inhibit α-glucosidase[9−11] and act as peroxisome proliferator-activated receptor γ (PPAR-γ) agonists in vitro;[12,13] however, there has been no investigation into the effect of these herbs on DPP-IV or PTP1B.

Mexican oregano (*Lippia graveolens*) is an herb from Latin cuisine that has traditional medicinal uses. In a comprehensive review of the traditional uses of 28 varieties of *Lippia* from around the world, only the use of *L. graveolens* had been reported as a therapy for diabetes.[14] Mexican oregano is also of specific interest in diabetes research because it contains one of the highest concentrations of flavonoids of all foods listed in the U.S. Deparment of Agriculture (USDA) database. Remarkably, there have been no studies examining its potential in diabetes management.

It is well-known that the concentration of phytochemicals such as polyphenols in plants can be impacted by growth conditions[15,16] and drying methods;[17] therefore, it is important to consider origin when examining the therapeutic potential of these herbs. Thus, the first aim of this study was to examine the differences in polyphenol concentration and antioxidant capacity of greenhouse-grown and commercial herbs and the ability of herb extracts from different sources to inhibit DPP-IV and PTP1B. Our second aim was to identify and quantify specific compounds responsible for DPP-IV inhibition in culinary herbs using bioassay-guided fractionation, LS−ESI-

MS, and HPLC. Our third aim was to examine these compounds for the ability to inhibit DPP-IV independently. To complement this work, computational modeling was used to provide insight into the theoretical enzyme−ligand interactions which identifies molecular targets for inhibition within the enzyme. Through these aims, we have systematically identified compounds that inhibit DPP-IV, an enzyme that plays a role in insulin secretion.

MATERIALS AND METHODS

Materials. Seeds for *O. majorana* and *O. vulgare* ssp. *hirtum* were purchased from Richter's Herbs (Goodwood, Ontario, Canada). Propagated cuttings of *L. graveolens* and *R. officinalis* were purchased from Companion Plants (Athens, OH). Commercial dry herbs were purchased at local grocery stores in the area of Urbana, IL. Fluorescein (S71283), *p*-nitrophenyl phosphate (≥98%, BP2534-1), and all solvents used in extraction, chromatography, and mass spectrometry were of HPLC grade and were purchased from Fisher Scientific (Pittsburgh, PA). Sitagliptin phosphate monohydrate (≥98%, S8576), sodium orthovanadate (≥90%, S6508), Trolox (97%, 238813), gallic acid (≥97.5%, G7384), rutin (≥94%, R5143), hispidulin (≥98%, SML0582), cirsimaritin (≥90%, SMB00174), naringenin (≥95%, N5893), rosmarinic acid (96%, 536954), porcine DPP-IV (D7052, EC 3.4.14.5), AAPH (97%, 440914), 2-aminoethyl diphenylborinate (D9754), and Folin−Ciocalteu phenol reagent (F9252) were purchased from Sigma Chemical Co. (St. Louis, MO). Carnosol (≥96%, 89800) was purchased from Cayman Chemical Co. (Ann Arbor, MI). Eriodictyol (95%, 20056) was purchased from Indofine Chemical Co. (Hillsburough, NJ). Human recombinant PTP1B (BML-SE332-0050, EC 3.1.3.48) was purchased from Enzo Life Sciences (Farmingdale, NY).

Greenhouse Herb and Extract Preparation. Fresh herbs were grown in the University of Illinois Plant Care Facility under greenhouse conditions (average temperature 24.0 ± 0.3 °C) between the months of March and June 2013 and were not exposed to any pesticides or fertilizers. After three months, leaves were removed from the plants, washed, frozen at −80 °C, and freeze-dried within 48 h using a Labconco Freezone 6L (Kansas City, MO) freeze-dryer with a collector temperature of −50 °C. The dried leaves were ground using a commercial coffee grinder and pulverized using a mortar and pestle until a fine powder developed. The powder was sifted through a 20 mesh sieve to remove any remaining large pieces of material. The herb powder was then extracted in an excess of 100% methanol using a Soxhlet exhaustive extraction apparatus for at least 24 h. The methanolic extract was filtered using no. 4 Whatman filter paper by gravity flow and concentrated by evaporation under a fume hood at room temperature overnight. An aliquot was removed and evaporated to near dryness (∼3 mL) using a Buchi rotoevaporator. After rotoevaporation, water was added, and the aliquot was freeze-dried to remove any residual water and methanol. The remaining methanolic extract was fractionated by flash chromatography.

Commercial Herb and Extract Preparation. Commercial dry herbs were ground into a fine powder using a commercial coffee grinder, pulverized with a mortar and pestle, and sifted. The herbs were then extracted in methanol at room temperature for 4 h, after which the extract was filtered using no. 4 Whatman filter paper by gravity flow, the methanol was reserved, and new methanol was added to the herbs for a second extract overnight at room temperature. After the extract was filtered once more, methanol from the 4 h extraction and that from the overnight extraction were pooled. Methanolic extract was evaporated to near dryness (∼3 mL) using a Buchi rotoevaporator (Newcastle, DE). After rotoevaporation, water was added, and the extracts were freeze-dried to remove any residual water and methanol.

Flash Chromatography and Fraction Preparation. Fractionation was performed using a Büchi Sepacore flash chromatography system (Newcastle, DE) with dual C-605 pump modules, a C-615 pump manager, a C-660 fraction collector, and a C-635 UV photometer, with SepacoreRecord chromatography software. The column used was a 40 × 150 mm flash column with approximately 90 g of preparative C18 reversed-phase bulk packing material (125 Å, 55−105 μm, Waters Corp., Milford, MA). The column was equilibrated with 20% methanol and 0.5% acetic acid in water for 10 min at a flow rate of 30 mL/min. After injection of the samples (20 mL), the column was developed with a binary gradient to 100% methanol over 45 min. The effluent was monitored at 280 nm, and fractions based on absorbance were collected in the fraction collector by the software program. Fractions containing each absorbance peak were then pooled. This procedure was repeated until all the extract was used. Fraction designations correspond to the following elution times (min): (Greek oregano) OA, 4−5; OB, 6−10; OC, 11−19; OD, 20−23; OE, 24−28; OF, 29−45; (Mexican oregano) LA, 4−5; LB, 6−10; LC, 11−13; LD, 14−17; LE, 18−20; LF, 21−25; LG, 26−28; LH, 29−31; LI, 32−45; (rosemary) RA, 4−6; RB, 7−15; RC, 16−22; RD, 23−26; RE, 27−30; RF, 31−32; RG, 33−35; RH, 36−39; RI, 40−45; (marjoram) MA, 4−6; MB, 7−13; MC, 14−19; MD, 20−21; ME, 22−23; MF, 24−25; MG, 26−27; MH, 28−45. The fraction pools were then concentrated by evaporation in the hood at room temperature, rotoevaporation, and then freeze-drying. The fraction extracts were then weighed and stored at −20 °C for future use.

Total Polyphenols. The total phenolic concentration was quantified on the basis of the principles introduced by Singleton and Rossi[18] adapted to a microassay. Samples (100 μg of extract/mL) or gallic acid standard and 1 N Folin−Ciocalteu phenol reagent were added to a 96-well flat-bottom plate and allowed to stand for 5 min before the addition of 20% Na_2CO_3. The mixture was allowed to stand for 10 min before the absorbance was read at 690 nm using a Synergy 2 multiwell plate reader (Biotek Instruments, Winooski, VT). The results are expressed as micrograms of gallic acid equivalents (GAE) per milligram of dry weight of extract (DWE) using a gallic acid standard curve: $y = 0.0195x + 0.0054$, $R^2 = 0.9997$.

Total Flavonoids. The total flavonoid concentration was quantified using an adaptation of the method used by Oohmah et al.[19] Briefly, 20 μL of sample (100 μg/mL) or rutin standard was added to a flat-bottom 96-well plate followed by the addition of 180 μL of distilled water. A solution of 2-aminoethyl diphenylborinate (10 mg/mL, 20 μL) was then added to each well, and the absorbance was read at 380 nm using a Synergy 2 multiwell plate reader (Biotek Instruments). The results are expressed as micrograms of rutin equivalents (RE) per milligram of DWE using a rutin standard curve: $y = 0.0028x + 0.0487$, $R^2 = 0.99$.

Oxygen Radical Absorbance Capacity. Antioxidant capacity was measured by the oxygen radical absorbance capacity (ORAC) assay previously described.[20] Trolox standard, blanks, or samples in assay buffer (75 mM phosphate buffer, pH 7.4) were added to the wells of a 96-well black-walled plate. Fluorescein (116.9 nM) was added to each well, and the plate was incubated at 37 °C for 15 min. AAPH (40 mM) was added to each well, and fluorescence was read at 485 and 582 nm every 2 min at sensitivity 60 at 37 °C using a Synergy2 multiwell plate reader (Biotek Instruments). The results are expressed as millimoles of Trolox equivalents (TE) per milligram of DWE.

DPP-IV Inhibition. DPP-IV inhibition was measured using the DPP-IV Glo protease assay (G8351, Promega, Madison, WI) following the manufacture's protocol. Briefly, 50 μL of DPP-IV Glo reagent was added to a white-walled 96-well plate containing 50 μL of blank, 40 μL of enzyme control, 40 μL of sample, 40 μL of positive control sitagliptin, or 40 μL of pure compounds. The samples were prepared in an assay buffer (100 mM Tris, 200 mM NaCl, 1 mM EDTA, pH 8.0) at a concentration of 100, 10, 1, or 0.1 μg of GAE/mL. A stock solution of sitagliptin was prepared by adding 10.48 mg of sitagliptin phosphate monohydrate to 10 mL of assay buffer, making a 2 mM solution which was then diluted to 10, 1, 0.1, and 0.01 μM. Pure compounds were prepared in assay buffer at a concentration of or 100, 10, 1, and 0.1 μM. The blank contained only assay buffer, while the enzyme control contained assay buffer and 10 μL of purified porcine DPP-IV enzyme (88% homology to the human enzyme)[21] at 0.075 U/nL. DPP-IV enzyme was also added to each sample. Luminescence was then measured after gentle mixing and incubation at 26 °C for 30 min

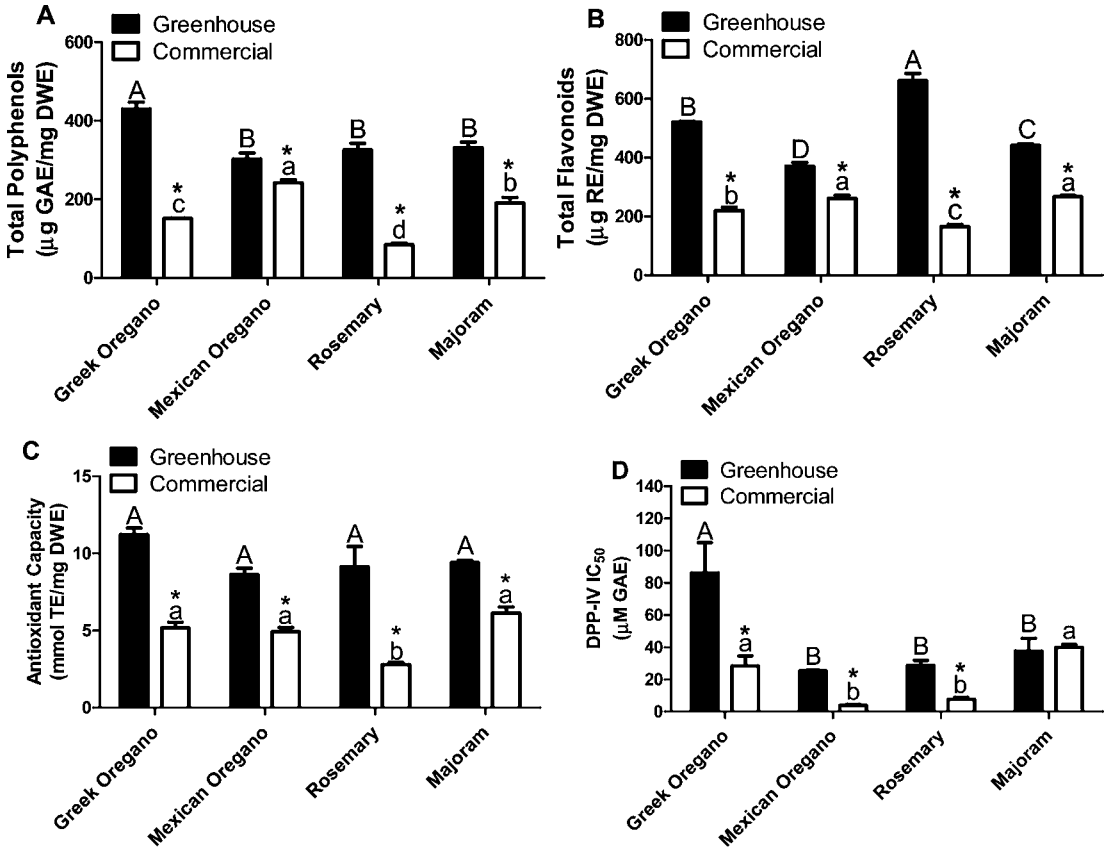

Figure 1. (A) Concentration of polyphenols, (B) concentration of flavonoids, (C) antioxidant capacity, and (D) DPP-IV IC_{50} for greenhouse and commercial herbs. The data represent the mean ± SEM from at least three independent studies done in triplicate. Capital letters indicate significant difference among greenhouse herbs. Lowercase letters indicate significant difference among commercial herbs. Asterisks indicate significant difference between greenhouse and commercial herbs. Significance is reported at $p < 0.05$. GAE = gallic acid equivalents, RE = rutin equivalents, and TE = Trolox equivalents.

using a Synergy2 multiwell plate reader (Biotek Instruments). Percent inhibition was calculated from the blank and enzyme control for each sample. IC_{50} was calculated from the quadratic formula generated from log(concentration) and percent inhibition, and the units were converted to micromolar.

PTP1B Inhibition. PTP1B inhibition was determined by analysis of *p*-nitrophenyl phosphate (*p*-NPP) degradation adapted from the methods of previous researchers.[22−24] Briefly, 50 μL of blank, 40 μL of enzyme control, 40 μL of sample, or 40 μL of positive control sodium orthovanadate was added to a flat-bottomed clear 96-well plate followed by the addition of 50 μL of *p*-NPP (10 mM). The samples and sodium orthovanadate were prepared in assay buffer (50 mm HEPES, 100 mm NaCl, 0.1% BSA, 1 mm DTT, pH 7.3) and contained 100, 10, 1, or 0.1 μg of GAE/mL on the basis of data obtained from the polyphenol analysis for the samples or 100, 10, 1, or 0.1 μM for sodium orthovanadate. The blank contained only assay buffer, while the enzyme control contained assay buffer and 10 μL of purified PTP1B enzyme (10 μg/mL). Purified PTP1B enzyme was also added to each sample. The plates were incubated at room temperature for 20 min, the reaction was terminated with the addition of 50 μL of 1.5 M NaOH, and the absorbance was read at 405 nm using a Synergy2 multiwell plate reader (Biotek Instruments). Each sample at each concentration was also run without enzyme in the same experiment to control for the inherent color present in each sample. Percent inhibition was calculated from the blank and enzyme control for each sample. IC_{50} was calculated from the quadratic formula generated from log(concentration) and percent inhibition, and the units were converted to micromolar.

LC−ESI-MS and HPLC Analysis. A turbo ion spray electrospray source and an Agilent 100 series HPLC system (G1379A degasser, G1357A binary capillary pump, G1389A autosampler, G1315B photodiode array detector, and G1316A column oven) running under Applied Biosystems Analyst 2.0 (build 1446) LC−MS software were utilized. The mass spectrometer was calibrated at least daily with a standard calibration mixture recommended by Applied Biosystems, and the signal detection was optimized as needed. The data were acquired in the MOF MS mode, negative. The MS parameters were as follows: accumulation time, 1 s; mass range, 200−1000 Da; source gas 1, 50 units; source gas 2, 35 units; curtain gas, 25 units; ion spray voltage, 4500; source heater, 400 °C; declustering potential 1, 80; focusing potential, 265; declustering potential 2, 15; ion release delay, 6; ion release width, 5. The column was a 3 mm × 150 mm Inertsil reversed-phase C-18, ODS-3, 3 μm column (Metachem, Torrance, CA). The initial solvent system was 20% methanol and 80% water with 0.25% formic acid at a flow rate of 0.25 mL/min. After injection (15 μL) the column was developed with a linear gradient to 100% methanol over 50 min. The column effluent was monitored at 280 nm in the PDA detector. The software package was set to collect mass data between 150 and 1000 amu.

Phenolic Compound Quantification by HPLC. HPLC analysis was conducted on a Shimadzu LC-20 HPLC system (LC-20AT quaternary pump, DGU-20A5 degasser, SIL-20A HT autosampler, and SPD M20A photodiode array detector) running under Shimadzu LCSolutions version 1.22 chromatography software (Columbia, MD). The column used was a 4.6 mm × 250 mm Inertsil ODS-3 reversed-phase C-18, 5 μm column from Varian. The initial conditions were 20% methanol and 80% water with 0.05 M phosphoric acid at a flow rate of 1 mL/min. The effluent was monitored at 280 nm. After injection of 25 μL, the column was held at the initial conditions for 2 min and then developed to 100% methanol in a linear gradient over 55 min. A standard curve based on nanomoles injected was prepared from rosmarinic acid, eriodictyol, naringenin, hispidulin, cirsimaritin, and

carnosol prepared at concentrations of 0.1, 0.2, 1, and 2 nmol/μL. The molar extinction coefficients for each standard were 1.702×10^{-3}, 1.375×10^{-3}, 1.686×10^{-3}, 1.254×10^{-3}, and 10.087×10^{-3} abs/nmol, respectively, and were used to quantify the concentrations of the compounds of interest.

Computational Modeling. Molecular files for the compounds tested were acquired from Chemical Book (www.chemicalbook.com). Structural hydrogens were added to the molecular files, and the CHARMm force field was applied using Accelrys Discovery Studio 3.5 Vizualizer (Discovery Studio 3.5, Accelrys Software Inc., San Diego, CA). The structure of DPP-IV was acquired from the Protein Data Bank (PDB ID 1X70, www.rcsb.org). Because DPP-IV exists as a homodimer in the crystal structure with sitagliptin and stabilizing water molecules, the ligands from the crystal structure, water molecules, and a monomer unit of DPP-IV were removed from PDB file 1X70 using Discovery Studio 3.5. Rotational bonds for each compound were assigned, and the amino acid TYR547 was made flexible in the DPP-IV structure using AutoDock Tools (version 1.5.6).[25] AutoDock Vina[26] search box parameters were determined using a rigid form of DPP-IV. The orientation of the search box was predetermined by AutoDock Tools; however, the dimensions in angstroms were changed to encapsulate DPP-IV as a whole (center $X = -8.425$, center $Y = 54.618$, center $Z = 33.543$, size $X = 68$, size $Y = 64$, size $Z = 78$). In a physiological system a ligand may have access to other regions of the enzyme beyond the catalytic site. Thus, the enzyme was encapsulated as a whole to model any potentially novel interactions between the ligands of interest and DPP-IV outside of its active site. A text configuration file was created detailing the search parameters, and the exhaustiveness of the search was set to 150. The exhaustiveness is proportional to the number of runs per search and was increased from the default setting of 8 to 150 due to the large search space used in this study, as such a low value may have given inconsistent results. Additionally, exhaustiveness was increased to 150 on the basis of the consistency of preliminary research modeling sitagliptin. The best binding conformation was determined by the lowest binding affinity (kcal/mol) of each computational docking for each compound tested. Interactions between the amino acids of DPP-IV and each compound were observed using Discovery Studio 3.5. AutoDock Vina provides the results based on the best docking conformation, which is given a root-mean-square deviation of zero. Since only the best docking conformation for each ligand was chosen, the root-mean-square deviations could not be compared.

Statistics. Data are expressed as the mean ± SEM of at least three replications. Statistical analysis was conducted using SAS Enterprise Guide (version 6.1, SAS Institute Inc., Cary, NC) and GraphPad Prism (version 5.02, GraphPad Software, Inc., San Diego, CA). One-way analysis of variance (ANOVA) with Tukey's post-test was used to evaluate the differences between group means. Regression analysis was used to evaluate associations between variables. Analyses were considered statistically significant at an α-level of $p < 0.05$.

RESULTS AND DISCUSSION

Characterization and Comparison of Greenhouse and Commercial Herbs. Figure 1A–C represents the total polyphenol concentration, total flavonoid concentration, and antioxidant capacity measured in greenhouse-grown and commercially available Greek oregano, Mexican oregano, rosemary, and marjoram. Greenhouse-grown herbs had significantly higher polyphenol concentrations (range 302.7–430.1 μg of GAE/mg of DWE), flavonoid concentrations (range 370.1–661.4 μg of RE/mg of DWE), and antioxidant capacity (range 8.62–11.22 mmol of TE/mg of DWE) compared to the commercially available products.

Of all greenhouse-grown herbs, extracts from Greek oregano contained the highest concentration of polyphenols (430.1 ± 17.1 μg of GAE/mg of DWE) and rosemary extract contained the highest concentration of flavonoids (661.4 ± 24.6 μg of RE/mg of DWE), while there was no statistical difference in antioxidant capacity among the extracts from the greenhouse grown herbs. Of all commercial herbs, Mexican oregano extract contained the highest concentration of polyphenols (241.5 ± 8.0 μg of GAE/mg of DWE) and Mexican oregano and marjoram extracts contained the highest concentration of flavonoids (260.9 ± 11.0 and 266.9 ± 3.8 μg of RE/mg of DWE). Rosemary extract had the lowest antioxidant capacity (2.8 ± 0.1 mmol of TE/mg of DWE) of the commercial herbs. There was a positive correlation ($R^2 = 0.70$, $P < 0.001$) between total polyphenol and total flavonoid concentrations, total polyphenol concentration and antioxidant capacity ($R^2 = 0.92$, $P < 0.001$), and total flavonoid and antioxidant capacity ($R^2 = 0.74$, $P < 0.01$) of the extracts.

Extraction in polar solvents results in a yield of approximately 15%.[27−30] Adjusting for extract yield, the total polyphenol concentration for the dry herbs ranged from 1266 mg of GAE/100 g of dry weight (DW) (commercial rosemary) to 6452 mg of GAE/100 g of DW (greenhouse Greek oregano). These values are consistent with those reported in the literature for culinary herbs.[31] The total flavonoid concentration ranged from 2474 mg/100 g of DW (commercial rosemary) to 9921 mg/100 g of DW (greenhouse rosemary), and the antioxidant capacity ranged from 41.9 mmol of TE/100 g of DW (commercial rosemary) to 168.3 mmol of TE/100 g of DW (greenhouse Greek oregano). These values are consistent with the reported antioxidant capacity of methanol extracts from culinary herbs.[32]

Previous reports indicated that field-grown herbs have significantly lower total polyphenol concentration and antioxidant capacity[16] than greenhouse-grown herbs. Drying temperatures can also negatively impact the total polyphenol concentration and antioxidant capacity.[17] Furthermore, the cultivar or plant origin can play an important role in dictating the concentrations of antioxidants.[32] All of the aforementioned factors may have contributed to the differences observed between greenhouse and commercial herbs.

DPP-IV and PTP1B Inhibition by Greenhouse and Commercial Herbs. Figure 1D indicates the concentration required to inhibit DPP-IV by 50%. Lower concentrations indicate a fraction is a more potent inhibitor. Among all greenhouse-grown herbs, rosemary (IC_{50} = 28.7 ± 3.1 μM), Mexican oregano (25.3 ± 0.3 μM), and marjoram (37.7 ± 7.9 μM) extracts were the most potent inhibitors of DPP-IV. For all commercially produced herbs, rosemary (6.5 ± 0.4 μM) and Mexican oregano (IC_{50} = 3.9 ± 0.6 μM) extracts were the most potent inhibitors of DPP-IV.

Commercial Greek oregano extract (28.4 ± 6.3 μM) was a better inhibitor of DPP-IV than greenhouse-grown Greek oregano extract (86.2 ± 18.8 μM), commercial Mexican oregano extract (3.9 ± 0.6 μM) was a better inhibitor of DPP-IV than greenhouse-grown Mexican oregano extract (25.3 ± 0.3 μM), and commercial rosemary extract (6.5 ± 0.4 μM) was a better inhibitor than greenhouse rosemary extract (28.7 ± 3.1 μM). There was no difference in DPP-IV inhibition between the extracts of commercially produced and greenhouse-grown sources for marjoram. The positive control sitagliptin had an IC_{50} of 0.05 ± 0.01 μM.

Percent inhibition of PTP1B by 500 μM herb extracts was measured from each greenhouse and commercial herb. Extracts from greenhouse herbs did not inhibit PTP1B; however, commercial Mexican oregano (37.3% ± 6.8%), rosemary (40.9% ± 7.2%), and marjoram (32.4% ± 17.5%) extracts inhibited PTP1B at this concentration (data not shown). The

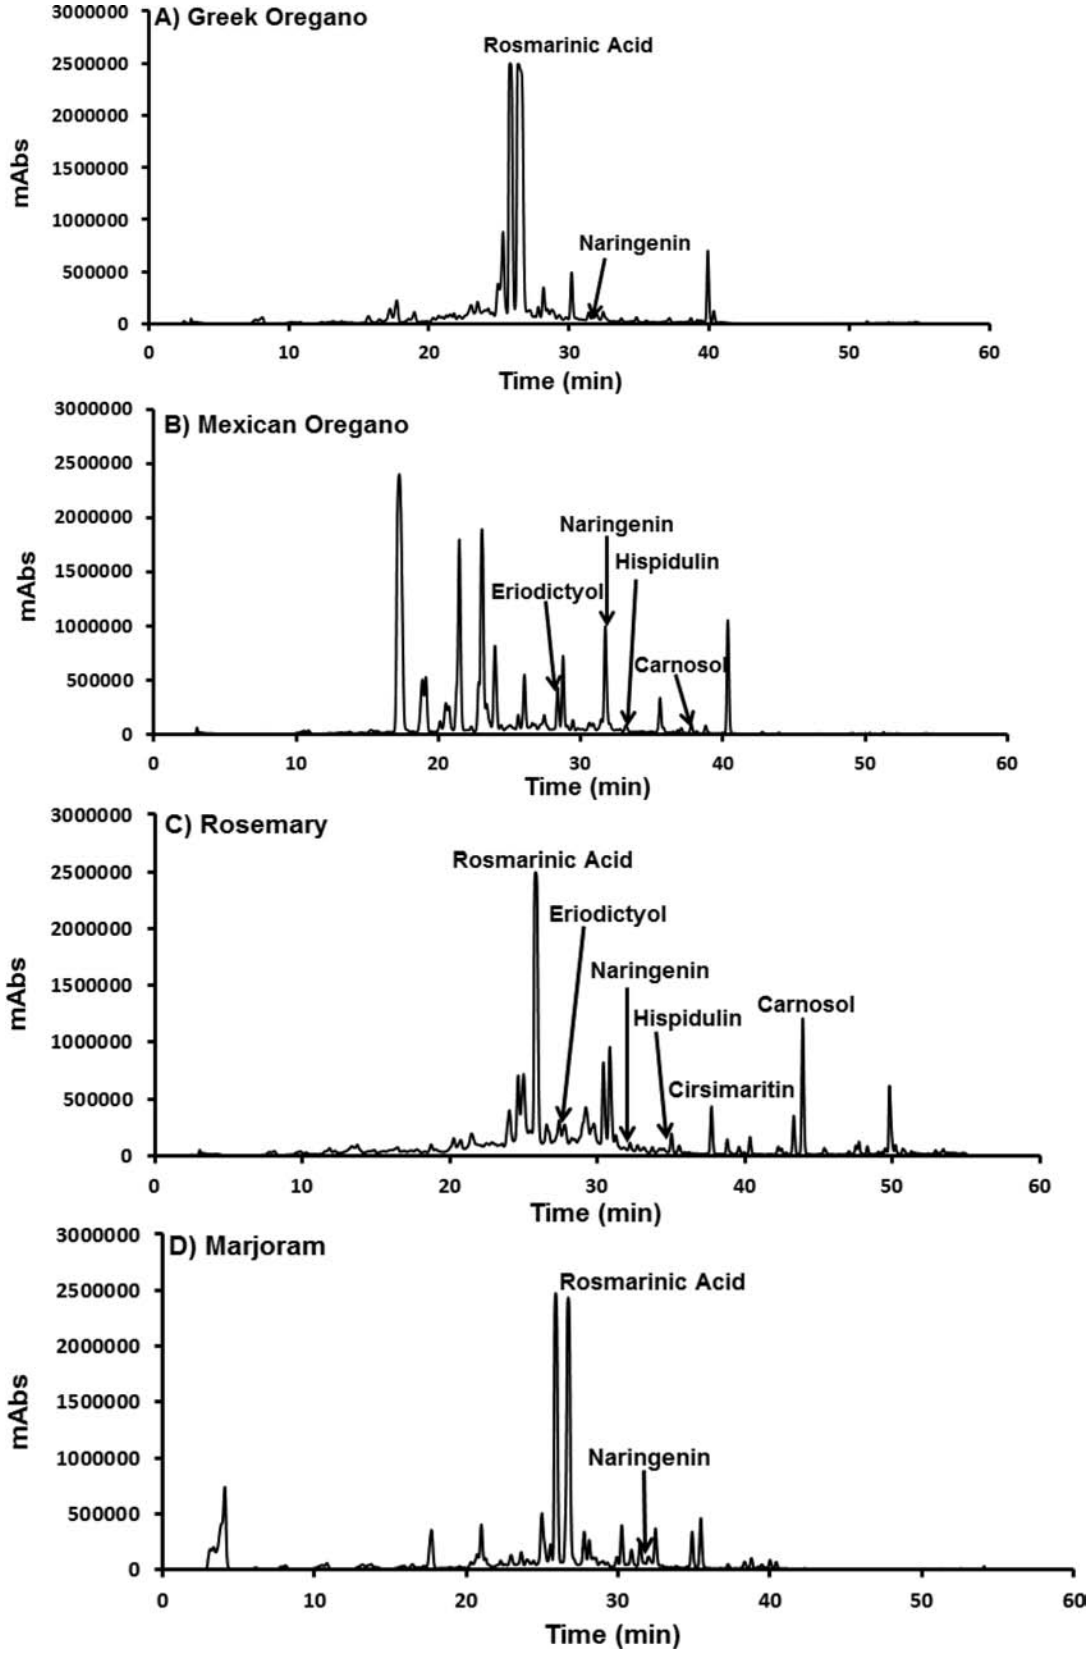

Figure 2. Representative HPLC chromatograms of the greenhouse-grown herbs. Positively identified compounds are indicated.

positive control sodium orthovanadate inhibited PTP1B by 100% at 500 μM and by 50% at 5.7 $\pm$ 2.7 μM. Comparison of the LC−ESI-MS chromatograms between commercial and greenhouse Greek oregano reveals many differences between the two in peak retention times and intensities (data not shown). We are currently performing further analysis to better understand the chemical differences in the composition of the commercial and greenhouse herb extracts.

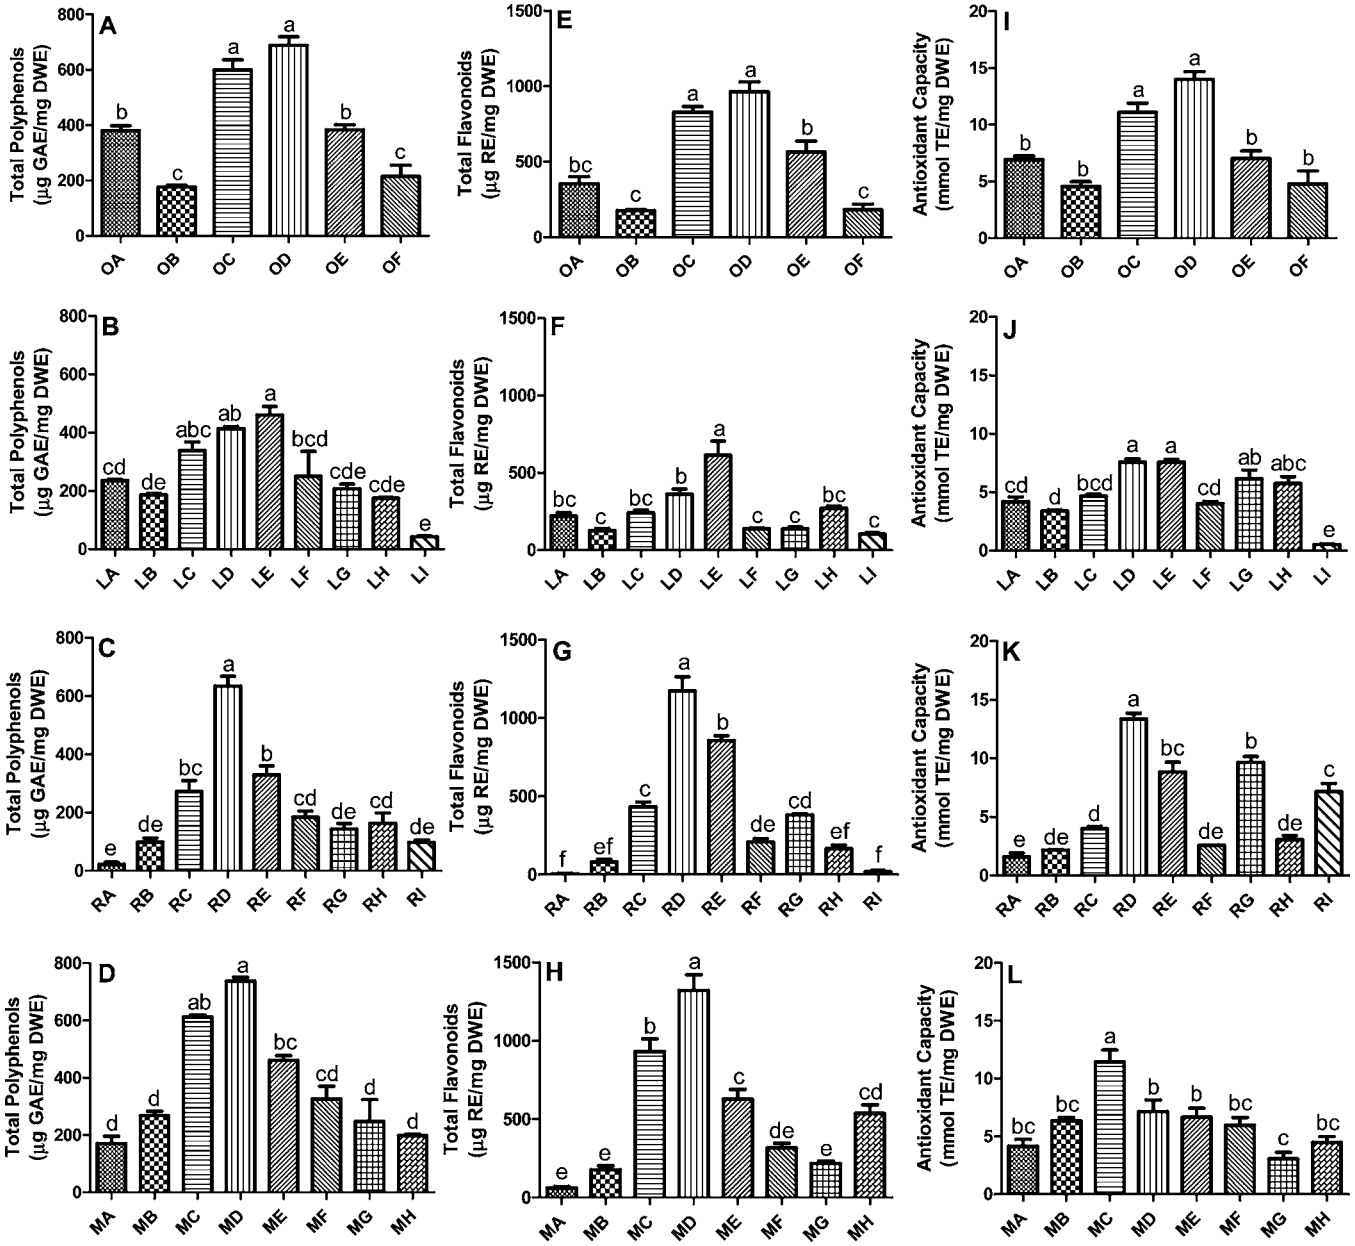

Figure 3. Total polyphenols (A–D), total flavonoids (E–H), and antioxidant capacity (I–L) for all fractions of greenhouse herbs: Greek oregano (A, E, I), Mexican oregano (B, F, J), rosemary (C, G, K), and marjoram (D, H, L). The data represent the mean ± SEM from at least three independent studies done in triplicate. Columns with differing letters are different with a significance of $p < 0.05$. GAE = gallic acid equivalents, RE = rutin equivalents, and TE = Trolox equivalents.

Jiang et al.[4] identified more than 200 natural compounds that were reported to inhibit PTP1B with IC_{50} < 100 μM; these included flavones, phenolic acids, and phenolic terpenoids. The natural compounds present in the herb extracts examined in this study did not inhibit PTP1B to the same extent. Jiang et al.[4] reported the values for pure compounds rather than whole extracts, and they reported natural compounds from a wide variety of sources such as plant roots, bark, and leaves as well as fungi and marine algae, and it is possible that the types of compounds that best inhibit PTP1B are not found in high concentrations in the leaves of culinary herbs.

Characterization of Fractions from Greenhouse Herbs. Figure 2 shows the comparative HPLC chromatograms of the greenhouse-grown herbs. Positively identified compounds are indicated. Figure 3 indicates the polyphenol concentration, flavonoid concentration, and antioxidant capacity of all fractions collected from each herb extract based on retention times using flash chromatography as indicated in the Materials and Methods. For Greek oregano (O), fractions C and D had the highest concentration of polyphenols and flavonoids and the highest antioxidant capacity. For Mexican oregano (L), fraction E had the highest of these three measurements, while, for rosemary (R), it was fraction D. For marjoram (M), fraction D had the highest concentration of polyphenols and flavonoids; however, fraction C had the highest antioxidant capacity. This could be due to the presence of nonphenolic antioxidants such as iridoid glycosides,[33] terpenoids, or saponins.[34]

DPP-IV and PTP1B Inhibition by Fractions from Greenhouse Herbs. Table 1 contains the IC_{50} values for

[a]The data represent the mean ± SEM from at least three independent studies done in triplicate. Values within a column followed by different letters are significant at $p < 0.05$. GAE = gallic acid equivalents, and IC_{50} = concentration required to inhibit enzyme activity by 50%. NI = no inhibition at 500 μM. NA = not applicable. Bold numbers indicate the most potent fractions.

DPP-IV for the fractions of each herb extract. From Mexican oregano, fractions LF, LG, LH, and LI were the most potent inhibitors of DPP-IV (IC_{50} range 0.8−19.0 μM), from rosemary, fraction RG was the most potent inhibitor of DPP-IV (IC_{50} = 0.4 ± 0.1 μM), from marjoram, fraction MH was the most potent inhibitor of DPP-IV (IC_{50} = 1.9 ± 0.4 μM), and from Greek oregano, fractions OE and OF were the most potent inhibitors of DPP-IV (IC_{50} range 20.3−23.3 μM). Fractions from these herbs also inhibited PTP1B. At 500 μM, the most potent inhibitors of PTP1B were fractions LH (97.5% ± 1.0%), RI (87.2% ± 2.9%), MH (77.7% ± 4.3%), and OE (77.4% ± 18.4%).

LC−EIS-MS Composition Analysis. To identify specific compounds from these herbs that inhibit DPP-IV, the most potent fractions were analyzed by LC−ESI-MS. Figure 4 shows representative chromatograms and a mass spectrum for rosemary fraction RG. Table 2 indicates which compounds were identified in the most potent fractions for Mexican oregano and rosemary. Eriodictyol, naringenin, hispidulin, and cirsimaritin have been previously identified in Mexican oregano.[35] Other compounds previously found in Mexican oregano that were tentatively identified but not confirmed due to lack of an analytical standard were sakuranetin or scutellarein[36,37] and desmethoxycentaureidin.[38] Rosmarinic acid, hispidulin, cirsimaritin, carnosol, and 7-methylrosmanol have been previously reported in rosemary.[39−43] Rosmarinic acid glucoside[44] and rosmanol isomers[39−42] were tentatively identified in rosemary fractions on the basis of comparison to the literature.

Concentrations of Purified Compounds. The concentrations of compounds identified through bioassay-guided fractionation were quantified using HPLC. Table 3 indicates the concentrations of the compounds in each herb.

Naringenin was quantified in all four species of culinary herbs, ranging from 0.15 mg/g of DW in Greek oregano and marjoram to 4.49 mg/g of DW in Mexican oregano. On the basis of the literature, Mexican oregano (3.72 mg/g of DW)[35] and Greek oregano (2.20 mg/g of DW)[45] concentrations are comparable to these results. There have yet to be reports on the concentration of naringenin aglycon in rosemary or marjoram; however, the concentration of naringenin glycoside has been reported to be 7.16 mg/g of DW[46] in rosemary. In other species of the same family, thyme (*Thymus vulgaris*) contains 0.64 mg/g of DW[47] naringenin glycoside, while the aglycon has been identified in savory (*Satureja cuneifolia*) and thyme (*Thymbra spicata*) at 0.30 and 0.23 mg/g of DW, respectively.[48] Cirsimaritin was also identified in all four culinary herbs in concentrations ranging from 0.05 mg/g of DW in marjoram to 1.10 mg/g of DW in rosemary. The cirsimaritin concentration has previously been reported in rosemary and Mexican oregano to be 0.08 mg/g of DW[49] and 0.68 mg/g of DW,[35] respectively, agreeing with the results of this study.

Eriodictyol was quantified at concentrations ranging from 0.30 ± 0.02 mg/g in marjoram to 1.38 ± 0.02 mg/g in Mexican oregano. Lin et al.[35] measured the range of concentrations of eriodictyol in three samples of Mexican oregano at 0.72−0.91 mg/g, and eriodictyol has been identified as being present in Greek oregano at a concentration of 0.4 mg/g by Agiomyrgianaki et al.[45] There have been no reports on the concentration of eriodictyol in rosemary and marjoram; however, eriodictyol has been identified in thyme,[47] indicating its presence in other species of the Lamiaceae family.

Rosmarinic acid was present in Greek oregano, rosemary, and marjoram extracts at concentrations that ranged from 16.87 mg/g of DW in rosemary to 28.77 mg/g of DW in Greek oregano. Almela et al.[40] report that methanol extract from rosemary contains 32.6 mg/g of DW rosmarinic acid, while

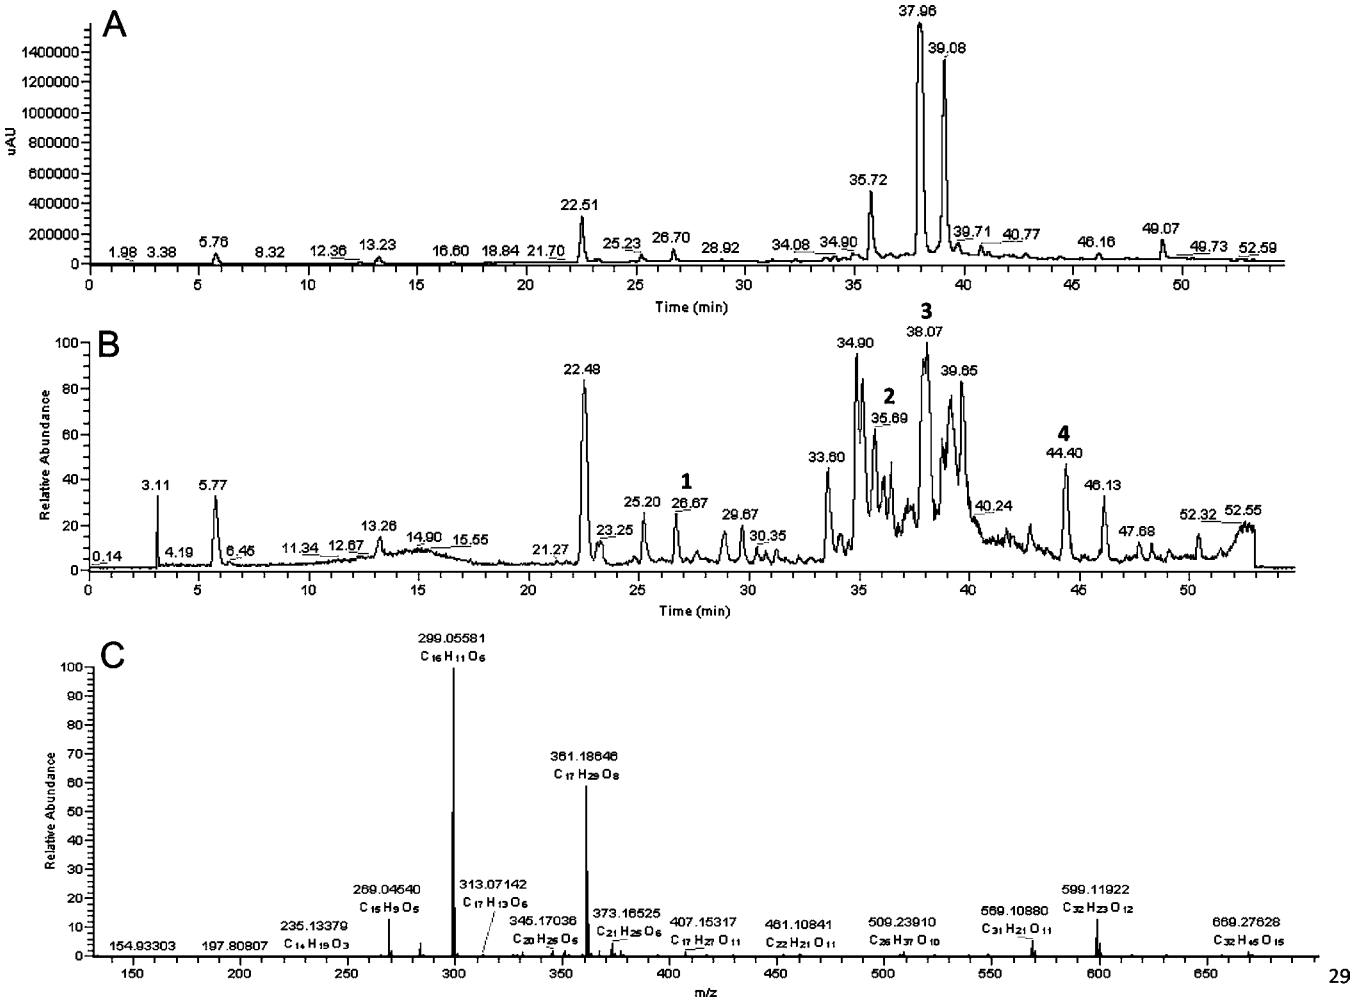

Figure 4. Representative chromatograms [(A) absorbance at 280 nm, (B) total ion current] and mass spectrum (C) from LC−ESI-MS for rosemary fraction RG: rosmarinic acid (**1**), hispidulin (**2**), cirsimaritin (**3**), carnosol (**4**).

Table 2. Composition As Determined by LC−ESI-MS of the Most Potent Fractions, Lowest DPP-IV IC_{50}, from Mexican Oregano and Rosemary

Mexican oregano				rosemary			
fraction	peak (t_R)	m/z	compound	fraction	peak (t_R)	m/z	compound
LF	28.48	287.06	eriodictyol	RF	32.64	345.17	rosmanol isomers[39−42]
	31.76	271.06	naringenin		38.63	520.14	rosmarinic acid 3-*O*-glucoside[44]

LI	40.24	329.03	desmethoxycentaureidin[38]		39.79	345.17	rosmanol isomers[39−42]
					44.51	329.18	carnosol
				RI	34.9	345.17	rosmanol isomers[39−42]
					44.40	329.18	carnosol

Shekarchi et al.[50] reported that ethanol extraction of Greek oregano yields a rosmarinic acid concentration of 25.0 mg/g of DW, concentrations which are comparable to those presented in this study.

Hispidulin was identified in Mexican oregano at 0.14 mg/g of DW and rosemary at 0.08 mg/g of DW. Previously, Mexican oregano has been reported to contain 1.00 mg/g of DW,[35] while rosemary has been reported to contain 0.02 mg/g of

dx.doi.org/10.1021/jf500639f | J. Agric. Food Chem. 2014, 62, 6147−6158

Table 3. Concentrations of Compounds (mg/g of DW) in Greek Oregano, Mexican Oregano, Rosemary, and Marjoram[a]

[a]The data represent the mean ± SEM from at least three independent extractions. Values within a column followed by different letters are significant at $p < 0.05$. ND = none detected. DW = dry weight.

Table 4. Binding Affinity and DPP-IV IC_{50} of the Compounds of Interest[a]

flavonoid	binding affinity (kcal/mol)	IC_{50} (μM)	functional group, location	fraction
hispidulin	−9.4	0.49 ± 0.1 b	OH, 4′, 5, 7; OCH_3, 6	LF, LG, LH, RG
eriodictyol	−8.9	10.9 ± 0.4 a	OH, 3′, 4′, 5, 7	LF
naringenin	−8.6	2.5 ± 0.3 b	OH, 4′, 5′, 7	LF, LG
cirsimaritin	−8.4	0.43 ± 0.07 b	OH, 4′, 5; OCH_3, 6, 7	LG, LH, RG, RH
other				
carnosol	−8.8	>100		LG, RG, RH, RI
rosmarinic acid	−7.8	14.1 ± 1.7 a		RG, MH
sitagliptin	−9.6	0.06 ± 0.03 b		control

[a]The data represent the mean ± SEM from at least three independent studies done in triplicate. Values within a column followed by different letters are significant at $p < 0.05$. Binding affinities were obtained through computational modeling. IC_{50} values were determined by biochemical assay.

DW[49] and 1.5 mg/g of DW[39] hispidulin. Carnosol was measured in all herbs; the highest concentration was 24.86 mg/g of DW in rosemary, which is similar to 21.5 mg/g of DW previously reported by Kontagianni et al.[39] While the values obtained in this study deviate some from the reported values, it is important to note that there is variation in the literature regarding the concentrations of secondary plant metabolites due to the differences in growth conditions, processing, and extraction.

DPP-IV Inhibition by Purified Compounds. Table 4 lists the IC_{50} of DPP-IV for the compounds of interest. Of the compounds identified, cirsimaritin (0.43 ± 0.07 μM), hispidulin (0.49 ± 0.1 μM), and naringenin (2.5 ± 0.3 μM) were the most potent inhibitors of DPP-IV. Eriodictyol (10.9 ± 0.4 μM) and rosmarinic acid (14.1 ± 1.7 μM) were also good inhibitors of DPP-IV. Carnosol was the least effective inhibitor, having an IC_{50} over 100 μM. These results are comparable to those published for flavonoids by Fan et al.,[3] where the IC_{50} values for luteolin, apigenin, and naringenin were 0.12, 0.14, and 0.24 μM, respectively.

Computational Modeling. Table 4 lists the calculated binding affinities between the compounds of interest and DPP-IV. Computational modeling indicates that hispidulin (−9.4 kcal/moL), eriodictyol (−8.9 kcal/mol), carnosol (−8.8 kcal/moL), and naringenin (−8.6 kcal/moL) have the most negative binding affinities for the DPP-IV enzyme, suggesting that they could easily bind to DPP-IV.

Figure 5A−E shows the theoretical ligand−amino acid interactions between DPP-IV and hispidulin, eriodictyol, naringenin, carnosol, and the pharmaceutical inhibitor sitagliptin. Hispidulin and eriodictyol interacted with amino acids in the catalytic region of DPP-IV.[51] The experimental conformation of sitagliptin was compared to the conformation of sitagliptin in the crystal structure of PDB file 1X70 through Discovery Studio 3.5 to validate the results of the computational model. Both conformations had 14 identical interactions and interacted with all three pockets of DPP-IV.

These flavonoids formed H-bonds to the amino acids Thr565 and Arg560. Hispidulin and naringenin formed H-bonds with Lys512, while only hispidulin formed an H-bond with Asn562. Figure 5F shows the relative positions of these flavonoids in the catalytic region of DPP-IV. The arrow in Figure 5G shows the location of the catalytic region relative to the whole enzyme.

Carnosol had electrostatic interactions with amino acids in the S1 and S2 pockets of DPP-IV and van der Waals interactions with the S3 pocket. The S1 pocket consists of the key catalytic amino acids Ser630, Asn710, and His740, the S2 pocket consists of Glu205 and Glu206, and the S3 pocket consists of Ser209, Phe357, and Arg358.[52] Sitagliptin interacted with all three pockets of DPP-IV and had the lowest binding affinity of all compounds tested (−9.6 kcal/mol), but does not interact with the catalytic region. Given that the best binding conformations of naringenin, hispidulin, and eriodictyol did not show interactions with the pockets of DPP-IV, these compounds may have synergistic effects with sitagliptin in the inhibition of DPP-IV.

Computational modeling of cirsimaritin (diagram not shown) revealed that this flavonoid also binds within the catalytic region and has several amino acid interactions in common with hispidulin, naringenin, and eriodictyol. In contrast to the computational modeling, carnosol was not a good inhibitor of DPP-IV. This could be due to the relatively weak electrostatic interactions predicted between carnosol and DPP-IV compared to the several hydrogen bonds predicted for the flavonoids. This may also be the result of competition between the substrate and carnosol for the binding pockets and access to the catalytic amino acids.

Our model was validated on the basis of the comparison of sitagliptin interactions between the crystal structure and experimental conformation. The two arrangements had most interactions in common and bonded to the active site in a similar manner. The experimental conformation and the crystal structure both have sitagliptin having electrostatic interactions with all the residues of the S1 and S2 pockets of DPP-IV, and both have interactions with the S3 pocket. The two arrangements deviated where the crystal structure has sitagliptin interacting electrostatically with Arg358 of DPP-IV while the

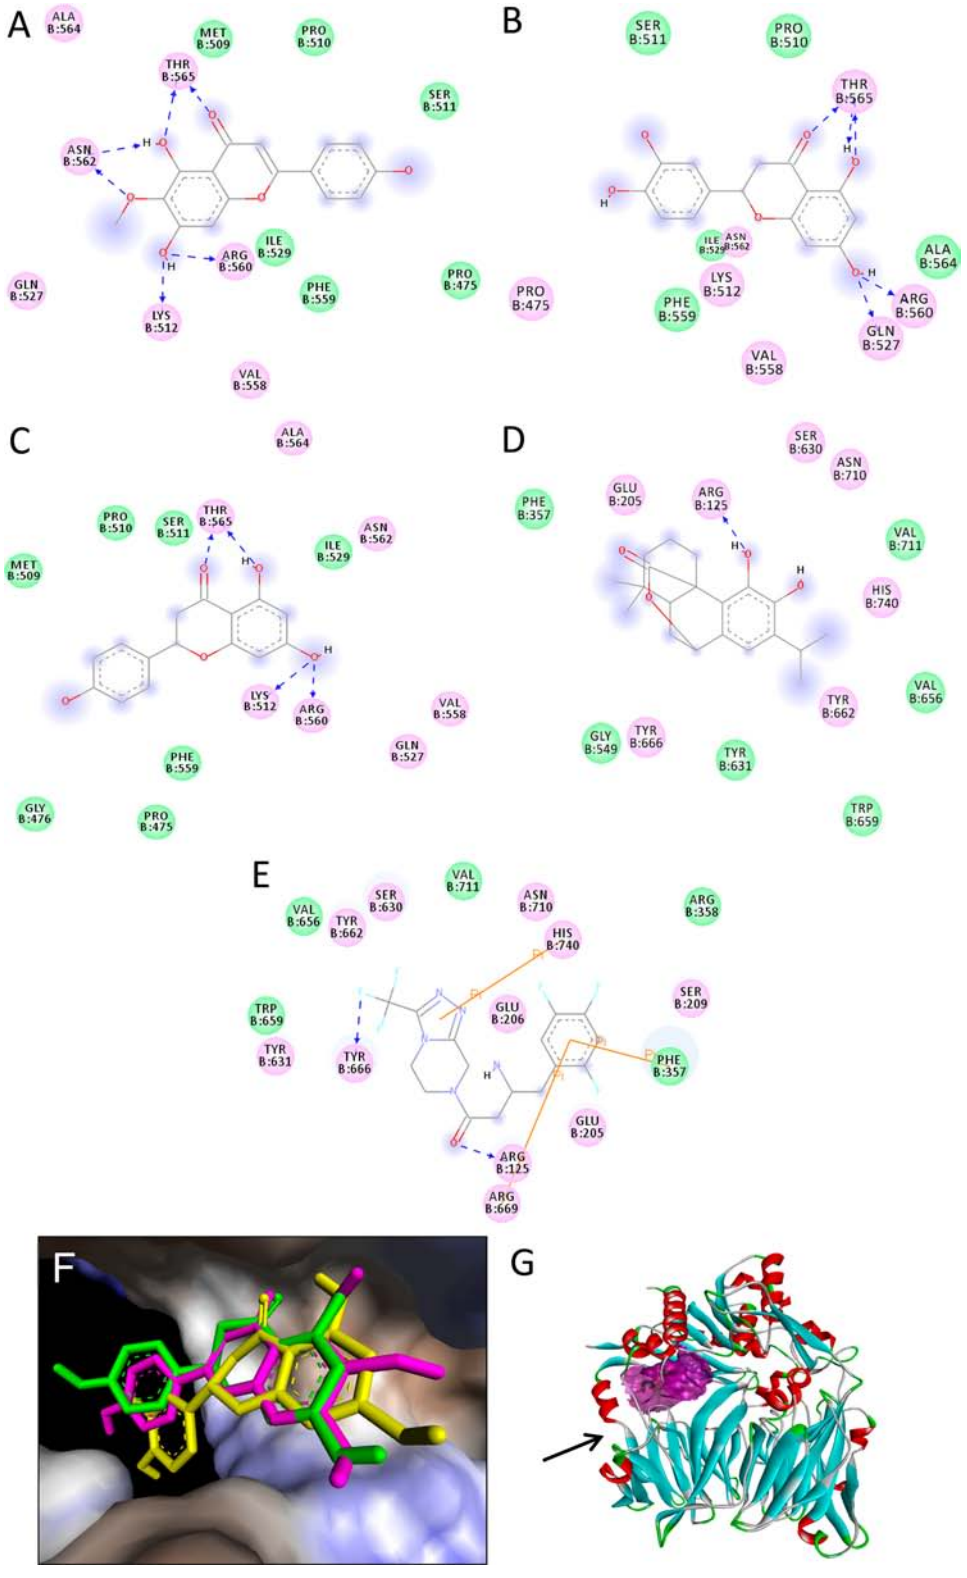

Figure 5. Computational amino acid–ligand interactions for (A) hispidulin, (B) eriodictyol, (C) naringenin, (D) carnosol, and (E) sitagliptin: electrostatic interactions (pink), van der Waals interactions (green), H-bonds (blue arrows), π-interactions (orange lines). (F) 3-D molecular docking of hispidulin (purple), eriodictyol (yellow), and naringenin (green) in DPP-IV. (G) Location of the catalytic pockets (arrow) relative to the region in which the flavonoids bind (purple).

experimental results have sitagliptin having only a van der Waals interaction with the same residue and the crystal structure has sitagliptin interacting with Val207 and Tyr547 while the experimental conformation does not. These deviations may be a result of the structure of sitagliptin being rotated in the final experimental conformation, rather than being planar as in the crystal structure. Furthermore, the experimental conformation for sitagliptin interactions with the

dx.doi.org/10.1021/jf500639f | J. Agric. Food Chem. 2014, 62, 6147–6158

S1, S2, and S3 subsites has been published by Nabeno et al.,[53] further validating this model.

Conclusion. In summary, extracts of greenhouse-grown herbs were a better source of flavonoids and polyphenols compared to commercially produced herbs; however, this did not impact the concentration required to inhibit DPP-IV. Commercially produced herbs inhibited PTP1B; however, this effect remained only in fractions of greenhouse-grown herbs. Extracts from rosemary and Mexican oregano were the most potent inhibitors of DPP-IV and contained the flavonoids cirsimaritin, hispidulin, and naringenin, which are potent inhibitors of DPP-IV independently. Future work in this area should focus on optimization of the growth and processing conditions for Mexican oregano and rosemary to increase their concentrations of these flavonoids. Overall, this research supports further investigation into the potential for rosemary and Mexican oregano and their flavonoids to be used in the management of T2DM.

Essential Oil Alloaromadendrene from Mixed-Type *Cinnamomum osmophloeum* Leaves Prolongs the Lifespan in *Caenorhabditis elegans*

Chan-Wei Yu,[†] Wen-Hsuan Li,[†] Fu-Lan Hsu,[‡] Pei-Ling Yen,[§] Shang-Tzen Chang,*[,§] and Vivian Hsiu-Chuan Liao*[,†]

[†]Department of Bioenvironmental Systems Engineering, and [§]Department of Forestry and Resource Conservation, National Taiwan University, Number 1 Roosevelt Road, Section 4, Taipei 106, Taiwan

[‡]Forest Chemistry Division, Taiwan Forestry Research Institute, 53 Nanhai Road, Taipei 100, Taiwan

ABSTRACT: *Cinnamomum osmophloeum* Kaneh. is an indigenous tree species in Taiwan. The present study investigates phytochemical characteristics, antioxidant activities, and longevity of the essential oils from the leaves of the mixed-type *C. osmophloeum* tree. We demonstrate that the essential oils from leaves of mixed-type *C. osmophloeum* exerted *in vivo* antioxidant activities on *Caenorhabditis elegans*. In addition, minor (alloaromadendrene, 5.0%) but not major chemical components from the leaves of mixed-type *C. osmophloeum* have a key role against juglone-induced oxidative stress in *C. elegans*. Additionally, alloaromadendrene not only acts protective against oxidative stress but also prolongs the lifespan of *C. elegans*. Moreover, mechanistic studies show that DAF-16 is required for alloaromadendrene-mediated oxidative stress resistance and longevity in *C. elegans*. The results in the present study indicate that the leaves of mixed-type *C. osmophloeum* and essential oil alloaromadendrene have the potential for use as a source for antioxidants or treatments to delay aging.

KEYWORDS: *Cinnamomum osmophloeum, alloaromadendrene, antioxidant, lifespan, Caenorhabditis elegans, FOXO transcription factor DAF-16*

INTRODUCTION

Essential oils are considered to be secondary metabolites and important for plant defense because they often possess antimicrobial properties.[1] Today, many essential oils of plants have gained attention for various types of bioactivity, such as antibacterial,[2] antiviral,[3] antifungal,[4] and antioxidant[5] actions. For these reasons, essential oils from natural plants are considered to be important alternative source of drugs and natural food preservatives.[6]

Cinnamomum osmophloeum Kaneh. is an indigenous tree species in Taiwan.[7] *C. osmophloeum* contains essential oils showing multiple biological activities, including antibacterial,[8] antifungal,[9] anti-inflammatory,[10] and *in vivo* antioxidant[11] activities. Other beneficial properties of the essential oils of *C. osmophloeum*, however, remain further explored. Among essential oils, aromadendrene is one of a group of naturally occurring sesquiterpenes structurally characterized by the fusion of a cyclopropane ring to a hydroazulene skeleton. Several studies have reported that aromadendrene has biological properties, including antifungal,[12] antiviral,[13] antibacterial,[14] antifeedant and repellent,[15] and cytotoxic[16] properties. However, most of the potential beneficial effects, including the antioxidant and anti-aging properties of aromadendrene have not yet been evaluated.

Aging research has rapidly gained increased scientific interest. The causes of aging remain largely unknown, although they are probably related to radical and mitochondrial activities.[17] An increase in stress resistance has been linked with an increase in longevity in a variety of organisms, including the nematode *Caenorhabditis elegans*.[18,19] *C. elegans* has become an informative and popular model for stress and aging studies because of its small size, relatively short life cycle, and well-defined genetic and environmental factors that influence lifespan.[20] The Forkhead box O (FOXO) transcription factors are evolutionarily conserved and have important roles in diverse cellular functions, including metabolism, cellular proliferation, defense against oxidative stress, and probably lifespan.[21] Therefore, the association between oxidative stress and FOXO is of particular interest as a result of the possible role of FOXO in controlling lifespan, because aging has been suggested to result from cumulative free-radical-induced cellular and organismal damage.[17,22]

Herein, we use *C. elegans* as an *in vivo* model to determine whether extracts and bioactive compounds from *C. osmophloeum* leaves could (1) enhance oxidative stress resistance and also trigger mechanisms that lead to a longer lifespan in a whole organism and, if so, (2) what potential mechanism is involved.

MATERIALS AND METHODS

Plant Material and Essential Oil Preparation. Leaves of *C. osmophloeum* were collected, and the species was identified as previously described.[23] Fresh leaves from a single plant were divided into three batches (200 g/batch) and then hydrodistilled in a Clevenger-type apparatus for 6 h, followed by determination of the

essential oil contents. The essential oils were stored in airtight containers prior to further analysis.

Gas Chromatography–Mass Spectrometry (GC–MS) and Gas Chromatography–Flame Ionization Detection (GC–FID) Analyses of Essential Oils. Essential oils were analyzed by a Trace GC Ultra (Thermo, Austin, TX) gas chromatograph coupled with a Polaris Q (Thermo) ion-trap mass spectrometer, equipped with a 30 m × 0.25 mm × 0.25 μm DB-5ms column (Agilent J&W Scientific, Santa Clara, CA). The mass spectrometer was operated in the electron-impact mode, with ionization energy of 70 eV. The oven temperature started at 60 °C for 1 min and then was programmed as follows: from 60 to 220 °C at 4 °C/min, held for 2 min, then increased to 250 °C at 20 °C/min, and held for 3 min. The injector temperature was 250 °C, and the flow rate of helium (the carrier gas) was 1.0 mL/min in a 1:10 split ratio. Samples were diluted (1.0 μL, 1:10^4, v/v, in ethyl acetate) and then manually injected in the split mode. Kovats indices were determined for all volatile constituents using a homologous series of C_9–C_{19} *n*-alkanes on the DB-5ms column. Quantification was determined by percentage peak area calculations using GC–FID, and the major constituents were identified by co-injection with standards (wherever possible) and confirmed by using the Wiley (version 7.0) and National Institute of Standards and Technology (NIST) version 2.0 GC–MS libraries and the Kovats indices provided in the literature.[24] The relative concentration of each compound was quantified by integrating the peak area of the chromatograms.

***C. elegans* Strains and Handling.** The nematodes used in this study were Bristol wild-type N2 and GR1307 *daf-16* (*mgDf50*). *C. elegans* strains and *Escherichia coli* OP50 were obtained from the *Caenorhabditis* Genetics Center (CGC), University of Minnesota, Minneapolis, MN. *C. elegans* were maintained and assayed (unless otherwise stated) at 20 °C on nematode growth medium (NGM) agar plates carrying a lawn of *E. coli* OP50. Phytochemicals were dissolved in dimethyl sulfoxide (DMSO). All chemicals in NGM plates and liquid are presented as the final concentrations.

***C. elegans* Oxidative Stress Assays.** Oxidative stress assays were performed essentially as previously described.[25] Briefly, synchronized L1 larvae were treated with chemical or 0.1% DMSO (Wako, Saitama, Japan) as the solvent control for 72 h, followed by 250 μM juglone (5-hydroxy-1,4-naphthoquinone) (Sigma, St. Louis, MO) exposure for 3 h,[11] and then scored for viability. The survival of nematodes was determined by touch-provoked movement as previously described.[19] At least three independent biological replicates were performed.

***C. elegans* Lifespan Assays.** *C. elegans* lifespan analyses were performed in the same manner for all treatments at 20 °C. Synchronized L1 larvae (wild-type N2 and *daf-16* mutant) were transferred to NGM plates in the absence or presence of 100 μM alloaromadendrene, and nematodes were allowed to develop to adulthood. Surviving and dead animals were counted daily (starting on the first day of adulthood) until all nematodes had died. Animals that did not move when gently prodded (with a platinum wire) were scored as dead. During the reproductive period, adult *C. elegans* was transferred to fresh NGM plates (in the absence or presence of 100 μM alloaromadendrene) every day during the progeny production period and then every other day thereafter. To examine antibacterial effects of alloaromadendrene, lifespan assays were performed with live and ultraviolet (UV)-killed *E. coli* OP50 according to Kaeberlein et al.[26] At least three independent biological replicates were performed.

Data Analysis. For the lifespan assay, animal survival was plotted using Kaplan–Meier survival curves and analyzed by log-rank test using GraphPad Prism (GraphPad Software, Inc., La Jolla, CA). Survival curves resulting in p values of < 0.05 relative to the untreated control were considered significantly different.

Statistical analysis was performed using SPSS Statistics 17.0 Software (SPSS, Inc., Chicago, IL). The results are presented as the mean ± standard error of the mean (SEM). The statistical significance of differences between the *C. elegans* populations was determined using one-way analysis of variation (ANOVA) and the least significant difference (LSD) post-hoc test. A two-factor analysis of variation (two-way ANOVA) was performed to determine significance and interactions between factors in the wild-type N2 lifespan assays. Differences were considered significant at $p < 0.05$ (see the figures).

RESULTS AND DISCUSSION

Chemical Constituents of the Essential Oils. Table 1 shows the main components and their relative contents of essential oils distilled from leaves of *C. osmophloeum*. The relative amounts of each component were determined by GC–FID analysis. At least 27 chemicals were identified, comprising about 78% of the total amount. The remaining was either unidentified or of very low amount. The major compounds were L-bornyl acetate (16.6%) with 95% purity, T-cadinol (14.2%) with > 95% purity, α-cadinol (8.8%) with > 95% purity, caryophyllene oxide (5.5%) with 95% purity, and alloaromadendrene (5.0%) with 97% purity (Table 1).

Table 1. Major Components from Mixed-Type *C. osmophloeum* Leaves

compound[a]	content (%)[a]	Kovats index[b]
L-bornyl acetate	16.6	1285
T-cadinol	14.2	1641
α-cadinol	8.8	1654
caryophyllene oxide	5.5	1581
alloaromadendrene	5.0	1461
coumarin	4.3	1433
cadalene	4.1	1671

[a]Compounds presented here are the main components (%) in the mixed-type essential oils from *C. osmophloeum* leaves according to a GC–MS analysis. [b]Kovats index relative to *n*-alkanes (C_9–C_{19}) on a DB-5ms column.

It has been suggested that the constituents and their relative contents of essential oils from the same plant species may vary because of ecological and plant growth factors.[27] On the basis of the differences in the chemical constituents of leaf essential oils, *C. osmophloeum* was classified into nine types: cassia, cinnamaldehyde, coumarin, linalool, eugenol, camphor, terpineol-4-ol, linalool-terpineol, and mixed-type.[28] On the basis of this classification, the indigenous *C. osmophloeum* tree, which was analyzed in this study, belongs to the mixed-type *C. osmophloeum* because of the lack of a dominant compound.

In light of the existence of chemical polymorphisms of leaf essential oils from various geographical indigenous cinnamon (*C. osmophloeum*),[29] chemical compositions in mixed-type *C. osmophloeum* were varied. However, it is difficult to predict or conclude the chemical compositions in mixed-type *C. osmophloeum* simply based on geographical or environmental factors. Therefore, it is of great concern to use the plant extract instead of pure compounds because of the possible variability of the components in the same plant group.

Extracts from the Leaves of Mixed-Type *C. osmophloeum* Enhance the Oxidative Stress Resistance in Wild-Type *C. elegans*. Our previous study showed that essential oils from leaves of cinnamaldehyde- and camphor-type *C. osmophloeum* trees exhibited antioxidant activities in *C. elegans*.[11] To investigate whether essential oils from the leaves of the mixed-type *C. osmophloeum* tree have protective effects against oxidative stress in *C. elegans*, wild-type N2 nematodes were pretreated with extracts immediately followed by exposure to juglone-induced oxidative stresses. Wild-type N2 synchronized L1 larvae were pretreated with 0, 1, 5, 10, and 20 μg/mL extracts and 0.1% DMSO as the solvent control for 72 h before being exposed to juglone (250 μM) and then were incubated for 3 h. Juglone was used as the oxidative stress generator because it is a redox-active quinone capable of intracellular redox cycling with superoxide radical $O_2^{\bullet -}$ production in *C. elegans*[30] and is commonly used to generate the intracellular oxidative stress in *C. elegans*.[25,31]

The results show that pretreatment with 5, 10, and 20 μg/mL extracts from the leaves of the mixed-type *C. osmophloeum* tree significantly increased the survival of *C. elegans* exposed to juglone-induced oxidative stress (Figure 1). It was observed that 5 μg/mL extract exerted the maximal effect, whereas higher concentrations (10 and 20 μg/mL) of extract did not further enhance the antioxidant resistance of the nematodes. The extract contains various chemical compounds that might exert different biological activities. In addition, it is possible that higher concentrations of extracts might be toxic, thereby reducing the antioxidant effects.

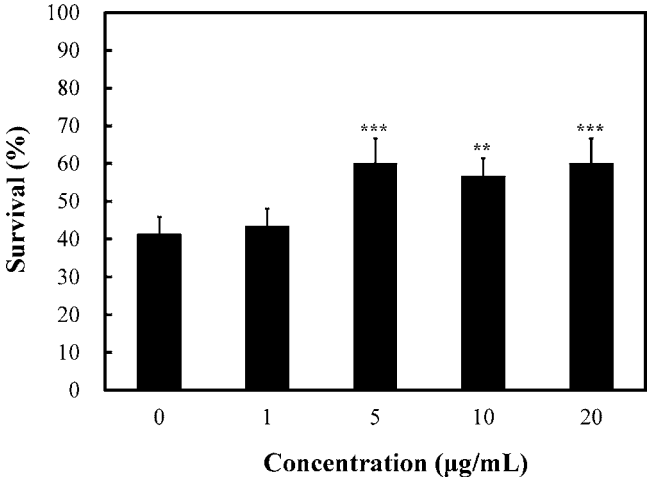

Figure 1. Essential oils from the leaves of mixed-type *C. osmophloeum* enhance the oxidative stress resistance of wild-type *C. elegans*. Synchronized wild-type L1 larvae were pretreated with 0, 1, 5, 10, and 20 μg/mL essential oils or 0.1% DMSO as the solvent control for 72 h. Adult worms were then immediately subjected to oxidative stress assays. Essential-oil-treated and untreated control adult nematodes were exposed to 250 μM juglone for 3 h and then scored for viability. At least three independent biological replicates were performed, and approximately 60−80 worms were scored in each experiment. Error bars represent the standard error, and differences compared to the control (0 μg/mL, 0.1% DMSO) were considered significant at (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ by one-way ANOVA and the LSD post-hoc test.

Alloaromadendrene Is the Key Compound That Contributes to the Oxidative Stress Resistance in *C. elegans*. We next examined which chemical constituents from the leaves of the mixed-type *C. osmophloeum* tree contributed to the observed oxidative stress resistance in Figure 1. Five major compounds (Figure 2A and Table 1), L-bornyl acetate, α-cadinol, T-cadinol, caryophyllene oxide, and alloaromadendrene, were selected for further oxidative stress resistance assays.

Initially, synchronized wild-type N2 L1 larvae were pretreated with 100 μM of each chemical and 0.1% DMSO (solvent control) for 72 h before juglone exposure. Except for alloaromadendrene, none of chemicals demonstrated significantly enhanced juglone-induced oxidative stress resistance in *C. elegans* (Figure 2B). Given that alloaromadendrene estimated at ∼5% in the extracts and as low as 5 μg/mL extracts from the leaves of mixed-type *C. osmophloeum* was able to protect *C. elegans* from juglone-induced oxidative stress, we tested levels of alloaromadendrene [molecular weight (MW) of 204.35] as low as 1.5 μM, which is approximately 0.3 μg of alloaromadendrene/mL of extracts. Figure 2C show that all examined concentrations of alloaromadendrene (1.5, 20, 100, and 200 μM) pretreatment produced a significant increase in the survival of nematodes exposed to juglone-induced oxidative stress (Figure 2C). This suggests that minor (alloaromadendrene, 5%) but not major chemical components in the extract might have played a key role in the observed oxidative stress resistance in Figure 1. This unexpected finding differed from *trans*-cinnamaldehyde and D-(+)-camphor, which represent the major compounds in the cinnamaldehyde- and camphor-type trees, respectively, and which exerted significant *in vivo* antioxidant activities against juglone-induced oxidative stress in *C. elegans*.[11]

Alloaromadendrene Prolongs the Lifespan of Wild-Type *C. elegans*. Aromadendrene is a member of a group of naturally occurring sesquiterpenes, and it has been shown to exhibit toxicity in a number of applications.[12−16] However, most of its potential beneficial effects remain largely unexplored. In addition, most of the biological activities of aromadendrene were examined in cell cultures or with *in vitro* systems and not with *in vivo* studies.

Stress resistance has been linked to an increase in lifespan in *C. elegans*.[18,19] Similarly, an increased lifespan has been shown to be closely associated with enhanced survival under conditions of oxidative stress or heat in *C. elegans*.[19] Moreover, oxidative stress has been shown to be a major determinant of the aging process.[32]

We evaluated whether alloaromadendrene has an effect on the lifespan of *C. elegans* by comparing the lifespan of untreated (control) and alloaromadendrene-treated wild-type N2 nematodes. Synchronized wild-type L1 larvae were transferred to alloaromadendrene-containing plates and exposed to alloaromadendrene throughout normal aging. In Figure 2C, because 100 μM alloaromadendrene exerted the most significantly oxidative stress resistance, 100 μM alloaromadendrene was chosen as the working concentration for further experiments.

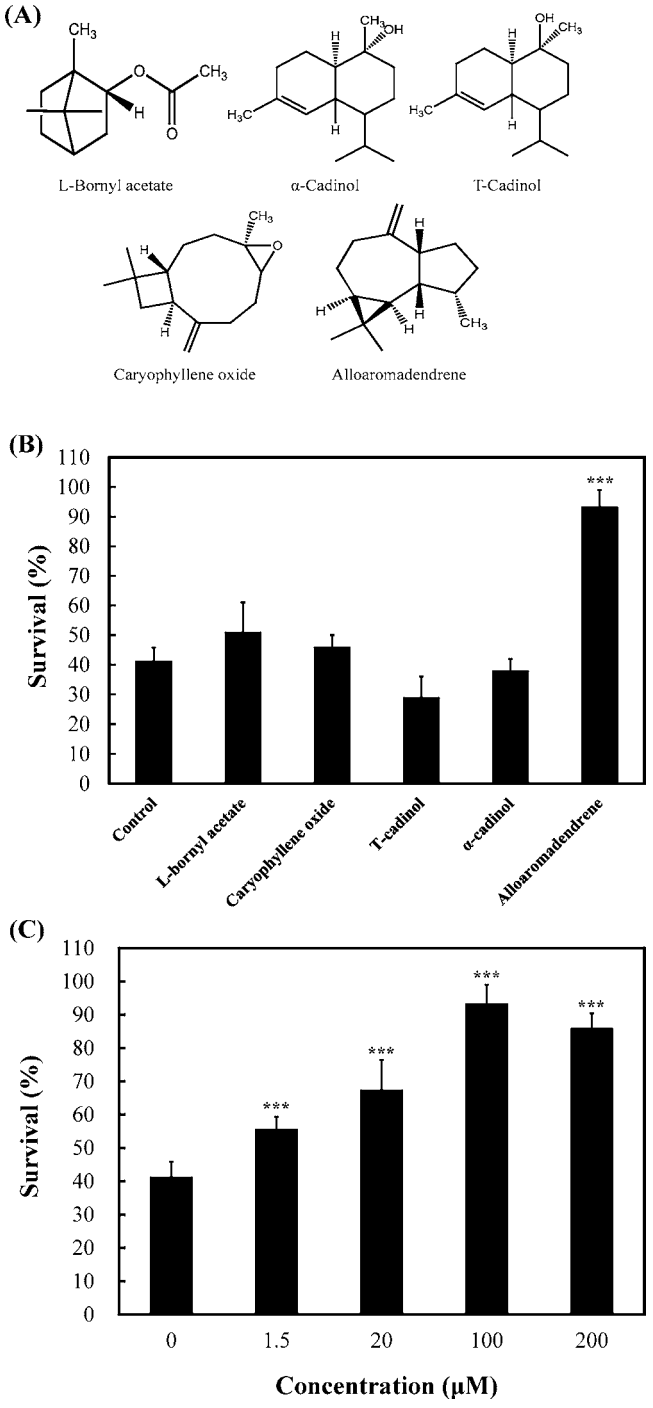

Figure 2. Effects of major compounds on the oxidative stress resistance in *C. elegans*. (A) Structure of five major compounds from leaves of *C. osmophloeum*. (B) Oxidative stress assays were performed as described in extracts, except that L1 larvae were pretreated with 100 μM L-bornyl acetate, α-cadinol, T-cadinol, caryophyllene oxide, and alloaromadendrene. (C) Oxidative stress assays were performed as described in extracts, except that L1 larvae were pretreated with 1.5, 20, 100, and 200 μM alloaromadendrene. At least three independent biological replicates were performed. Approximately 60–80 worms were scored in each experiment. Error bars represent the standard error, and differences compared to the control (0 μM, 0.1% DMSO) were considered significant at (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ by one-way ANOVA and the LSD post-hoc test.

The results showed that adult wild-type *C. elegans* fed with live *E. coli* OP50 and grown under our standard laboratory conditions at 20 °C have a mean lifespan of 12.0 ± 0.8 days, with a maximum lifespan of 18 days (age at death of the oldest animals) (Figure 3 and Table 2). On media containing 100 μM alloaromadendrene, the mean lifespan of wild-type animals was 13.4 ± 0.6 days, with a maximum lifespan of 20 days (log rank; $p = 0.047$; untreated versus treated) (Figure 3 and Table 2), indicating that alloaromadendrene is capable of extending the lifespan of wild-type *C. elegans*. This suggests that the observed delayed aging by alloaromadendrene might be due to its antioxidant activity in *C. elegans*.

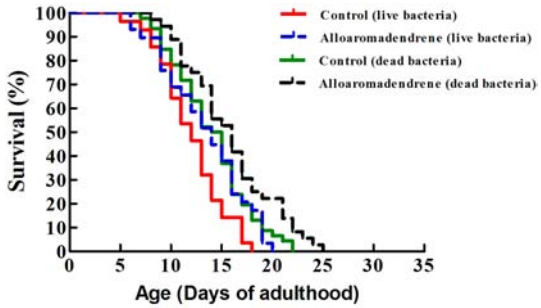

Figure 3. Alloaromadendrene prolongs the lifespan of wild-type *C. elegans*. Synchronized wild-type L1 larvae were incubated on NGM plates with dead or live *E. coli* OP50 in the absence (0 μM, 0.1% DMSO) or presence of alloaromadendrene (100 μM), and nematodes were allowed to develop to adulthood. Surviving and dead nematodes were counted daily until all nematodes had died. Survival curves are of the untreated control (0 μM, 0.1% DMSO) compared to alloaromadendrene-treated nematodes. Day 1 refers to the first day of adulthood. At least three independent biological replicates were performed. Approximately 60 worms were scored in each experiment. Statistical significance of the difference between the curves (treated versus untreated control) was demonstrated by the log-rank test using the Kaplan–Meier survival analysis. Differences at the $p < 0.05$ level were considered significantly different.

One factor contributing to late-age mortality in *C. elegans* is the adverse effect of proliferating bacteria that produce harmful metabolites.[33] To evaluate whether the lifespan extension by alloaromadendrene treatment was regulated by the inhibition of bacterial growth, nematodes were fed with UV-killed bacteria in the absence and presence of 100 μM alloaromadendrene. The results showed that UV-killed (non-proliferating) *E. coli* bacteria increased the mean lifespan from 12.0 ± 0.8 to 14.0 ± 0.3 days in the absence of alloaromadendrene, whereas exposure to 100 μM alloaromadendrene even further and significantly increased the lifespan to 16.1 ± 0.3 days (log rank; $p = 0.0265$; untreated versus treated) (Figure 3 and Table 2). We further performed a two-way ANOVA to determine significance and interaction between factors (with alloaromadendrene untreated versus treated and live versus dead bacteria as factors) in the wild-type N2 lifespan assays. Two-way ANOVA analysis showed that there is no statistically significant interaction between alloaromadendrene and the food source bacteria ($p = 0.663$), suggesting that the effect of alloaromadendrene on lifespan does not depend upon the bacterial load. Hence, the antibacterial property of alloaromadendrene is not an important factor for the lifespan extension. A summary of *C. elegans* lifespan data is present in Table 2.

Several studies have reported that *C. elegans* responds to various natural compounds with increased stress resistance and/or extended lifespan.[34,35] Although translation of lifespan extension from *C. elegans* to more complex organisms remains

Table 2. Lifespan of Alloaromadendrene Treatment on *C. elegans*

		median lifespan (day)	mean lifespan (day)	maximum lifespan (day)	log-rank test[a]
N2	control (live bacteria)	12	12.0 ± 0.8	18	$p = 0.047$[b] (untreated versus treated)
	alloaromadendrene (live bacteria)	14	13.4 ± 0.6	20	
	control (dead bacteria)	14.5	14.0 ± 0.3	22	$p = 0.0265$[b] (untreated versus treated)
	alloaromadendrene (dead bacteria)	16	16.1 ± 0.3	25	
daf-16	control (dead bacteria)	10	10.0 ± 0.7	17	$p = 0.9876$ (untreated versus treated)
	alloaromadendrene (dead bacteria)	9	9.8 ± 0.6	17	

[a]Statistical significance of the difference between the survival curves was demonstrated by the log-rank test using the Kaplan−Meier survival analysis. [b]$p < 0.05$.

to be elucidated, studies have shown that an increase in stress resistance has been linked with an increase in longevity in a variety of organisms, including the nematode *C. elegans*.[18,19] Moreover, several lines of experimental evidence suggest that drugs prolonging lifespan in *C. elegans* are very effective in the treatment of age-related diseases, such as cancer and neurodegenerative diseases.[36,37] Therefore, *C. elegans* provides a useful tool for identifying genes and compounds that can prolong lifespan in higher animals, perhaps including humans.

Alloaromadendrene Enhances Oxidative Stress Resistance and Longevity Depending upon DAF-16. One potential mechanism that might be involved in alloaromadendrene-mediated oxidative stress resistance and longevity was further explored. In *C. elegans*, many signaling pathways, including the insulin like/IGF-1, JNK, the sensory neurons signaling, and the germline signaling pathways, converge at the FOXO transcription factor DAF-16, which is the only FOXO in *C. elegans*.[38,39] DAF-16 integrates signals from multiple pathways and regulates its downstream target genes to control diverse cellular functions, including metabolism, stress resistance, and longevity.[38,39] Therefore, DAF-16 is regarded as a key regulator to enhance stress resistance and longevity in *C. elegans* and mammals.[38,39] Herein, to analyze the involvement of DAF-16 in alloaromadendrene-mediated oxidative stress resistance and longevity, we examined the loss of function of the *daf-16* mutant for its ability to resist oxidative stress and prolong lifespan during alloaromadendrene exposure. The premise of these experiments was that alloaromadendrene treatment would not increase oxidative stress resistance or extend lifespan in *daf-16* mutant nematodes.

Oxidative stress and lifespan assays for the *daf-16* mutant were performed essentially the same as those for wild-type nematodes. For the oxidative stress-resistance test, unlike wild-type N2 *C. elegans*, the survival of alloaromadendrene-treated (100 and 200 μM) *daf-16* mutants did not show a significant difference compared to untreated *daf-16* mutants (Figure 4A). This suggests that DAF-16 is required for alloaromadendrene-mediated oxidative stress resistance in *C. elegans*.

For lifespan assays, 100 μM alloaromadendrene-treated *daf-16* mutant nematodes did not exhibit a significant difference in lifespan in compared to that of untreated animals (log rank; $p = 0.9876$; Figure 4B and Table 2). The mean lifespans for both alloaromadendrene-treated and untreated *daf-16* mutant animals are 10.0 ± 0.7 and 9.8 ± 0.6 days, respectively, with a maximum lifespan of 17 days (Figure 4B and Table 2). This indicates that DAF-16 is required for alloaromadendrene-enhanced lifespan in *C. elegans*. Taken together, DAF-16 is required for alloaromadendrene-mediated oxidative stress resistance and longevity in *C. elegans*.

In conclusion, the results obtained from this study reveal that minor (alloaromadendrene, 5%) but not major chemical components from the leaves of mixed-type *C. osmophloeum* have key roles in oxidative stress resistance. We demonstrate that the essential oil alloaromadendrene not only acts protective against oxidative stress but also prolongs the lifespan of *C. elegans*. Additionally, DAF-16 is required for alloaromadendrene-mediated oxidative stress resistance and longevity in *C. elegans*. We show that alloaromadendrene can

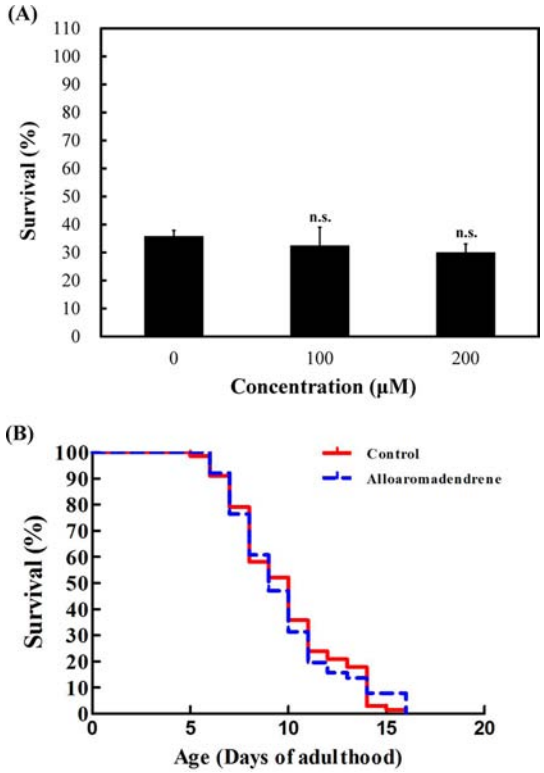

Figure 4. Alloaromadendrene enhances oxidative stress resistance and longevity depending upon DAF-16. Oxidative stress and lifespan assays for *daf-16* mutants were performed essentially the same as wild-type nematodes. (A) For oxidative stress assays, *daf-16* mutants were treated with 100 and 200 μM alloaromadendrene and at least three independent biological replicates were performed. Approximately 60−80 worms were scored in each experiment. Error bars represent the standard error, and differences compared to the control (0 μM, 0.1% DMSO) were considered significant at (∗) $p < 0.05$, (∗∗) $p < 0.01$, and (∗∗∗) $p < 0.001$ by one-way ANOVA and the LSD post-hoc test. n.s. = non-significant. (B) For lifespan assays, *daf-16* mutants were treated with 100 μM alloaromadendrene and at least three independent biological replicates were performed. Approximately 60 worms were scored in each experiment. Statistical significance of the difference between the curves (treated versus untreated control) was demonstrated by the log-rank test using the Kaplan−Meier survival analysis. Differences at the $p < 0.05$ level were considered statistically significant.

significantly prolong lifespan and enhance resistance to oxidative stress in a whole organism. Although further detailed investigations are needed, our results provide the first tantalizing insights on the alloaromadendrene function in longevity and antioxidative stress *in vivo*. The results in the present study indicate that alloaromadendrene has the potential for use as a source for antioxidants or treatments to delay aging.

Relationship between the Acyl Chain Length of Paradol Analogues and Their Antiobesity Activity following Oral Ingestion

Akinori Haratake, Daisuke Watase,* Shuichi Setoguchi, Kazuki Terada, Kazuhisa Matsunaga, and Jiro Takata

Laboratory of Drug Design and Drug Delivery, Faculty of Pharmaceutical Sciences, Fukuoka University, 8-19-1 Nanakuma, Jonan-ku, Fukuoka 814-0180, Japan

ABSTRACT: 6-Paradol is known to activate thermogenesis in brown adipose tissue (BAT), and paradol analogues with different acyl chain lengths possess different pungency thresholds. In this study, the influence of the acyl chain length on the antiobesity activity of the paradol analogues was investigated. The antiobesity activity of 6-paradol in mice fed a high-fat diet for 8 weeks was greater than that of dihydrocapsiate. A comparison of the antiobesity activities of zingerone and 6-paradol showed that the length of the acyl chain in the paradol analogue was important for strong activity. Furthermore, the antiobesity activities of 6-, 8-, and 12-paradol appeared to decrease in an acyl chain length-dependent manner. The mechanism of the antiobesity activity of 6-paradol was enhanced by increasing levels of energy metabolism in the BAT, as well as an increase in the expression of uncoupling proteins 1 via the activation of sympathetic nerve activity.

KEYWORDS: *antiobesity activity, paradol analogue, acyl chain, oral ingestion, uncoupling protein*

INTRODUCTION

Obesity and related health issues represent a significant threat to human health in an increasing number of countries.[1] Obesity is the outcome of a prolonged positive energy balance, which can be caused by reduced energy expenditure and/or excessive calorie intake. A negative energy balance is needed to produce weight loss and can be achieved by a reduction in calorie intake or increased energy expenditure. Several tools are available for the management of obesity, including caffeine, ephedrine, capsaicin, and green tea, and materials of this type have been proposed as parts of strategies for weight loss and weight maintenance because their intake can lead to an increase in energy and could therefore counteract the decrease in metabolic rate that occurs during weight loss.[2]

Brown adipose tissue (BAT) acts as a major defense mechanism against obesity in rodents and human infants, where it serves to increase energy expenditure through dissipation in the form of heat (thermogenesis).[3] BAT tends to be localized in the intrascapular and paraspinal regions, and the amount present in rodents and humans appears to decrease as they develop from the neonatal to adult stage.[4] Increases in thermogenesis in BAT occur in response to cold or calorie intake, whereas the ablation of BAT resulting from the use of a toxigene results in hyperphagia and obesity.[5] The protein responsible for thermogenesis in BAT is uncoupling protein (UCP)-1,[6−8] which is the major endogenous stimulator of thermogenesis, and β_3-adrenergic receptor stimulation induces UCP-1 expression.[7] Knockout of UCP-1 in mice leads to a decrease in oxygen consumption following treatment with a β_3-adrenergic receptor agonist and also leads to increased cold sensitivity.[9] Two other UCPs, UCP-2 and UCP-3, are more widely expressed than UCP-1 and appear to play important roles in mitochondrial function in a limited number of tissues. Although it was initially thought that UCP-2 and UCP-3 might also allow tissues such as skeletal muscle to undergo thermogenesis and energy expenditure,[10] subsequent studies revealed this speculation to be unfounded.[11,12] Furthermore, the results of a recent study revealed that UCP-3 does not play a role in any thermogenic process, although the results of the same study did indicate that novel UCPs were involved in attenuating the production of reactive oxygen species, particularly during fatty acid oxidation.[13] The results of another recent study, however, showed that UCP-3 was not required for fatty acid oxidation or fatty acid anion export, but that it was essential for adaptation to fasting, where it may be involved in mitigating the formation of reactive oxygen species.[14] Finally, the overexpression of UCP-3 in mice leads to decreased body mass despite higher food intake.[15] Although the role of UCP-3 is currently unclear, evidence from the literature strongly suggests that an increase in UCP-3 expression leads to a reduction in body mass.

In their recent review, Bonet et al.[16] reported that dietary changes and chemicals including specific nutrients were strongly associated with BAT. There have been several reports in the literature suggesting that the activity of BAT was activated with dietary methionine restriction, dietary leucine restriction, high-fat diet, fucoxanthin, salmon protein hydrolysate, n-3 fatty acids of marine origin, and resveratrol. Furthermore, thermogenesis can be modified by macronutrient content in the different types of fat.[17] It has also been reported that olive leaf extracts can exert beneficial antiobesity effects by regulating the expression of genes involved in adipogenesis and thermogenesis in the visceral adipose tissue of mice fed a high-fat diet.[18] Spices and their principal pungent components have been reported to provide several potential benefits to human

health, including antiobesity activity. Capsaicin, which is the major pungent component of hot red pepper,[19] has been reported to elevate body temperature,[20] stimulate the secretion of catecholamines,[21] promote energy expenditure,[22] and suppress body fat accumulation[23] in experimental animals. However, capsaicin is strongly pungent and neurotoxic,[24] and high capsaicin concentrations can be damaging to human health. Capsinoids (i.e., capsiate, dihydrocapsiate (Figure 1), and nordihydrocapsiate) are nonpungent analogues of capsaicin that are derived from CH-19 sweet pepper,[25] and have been shown to increase oxygen consumption and suppress body fat accumulation in mice to the same extent as capsaicin.[26,27] Capsaicin analogues bearing longer acyl chains than capsaicin, such as vanillyl tetradecanamide (C14) and vanillyl octadecanamide (C18), are not pungent, although some of these analogues do enhance the secretion of adrenaline from the adrenal medulla in rodents in the same way as capsaicin.[21,28] Vanillyl (*Z*)-9-octadecenamide (C18:1) possesses capsaicin-like biological and physiological properties without any noxious stimuli.[29]

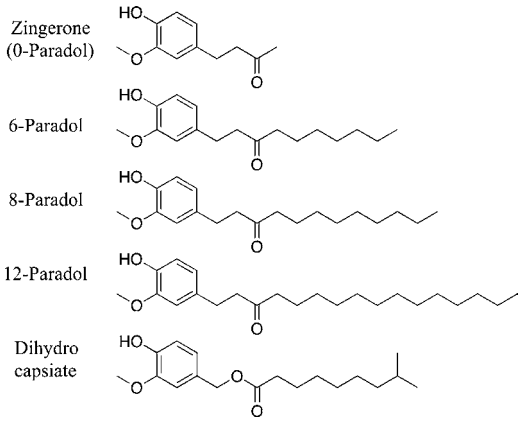

Figure 1. Structures of the paradol analogues and dihydrocapsiate tested for their antiobesity effects.

Paradols are a series of phenolic ketones that are structurally related to gingerols and shogaols.[30] Zingerone (Figure 1) is a 0-paradol of paradol analogues and is the major pungent component of ginger.[31] The oral administration of zingerone led to a significant reduction in the body weight and final parametrial adipose tissue weight in ovariectomized rats.[31] 6-Paradol (Figure 1) is the characteristic pungent component of the extract of the seeds of *Amomum melegueta* Roscoe (zingiberaceae), which are also known as grains of paradise, and is the only naturally occurring member of the paradol series to have been isolated to date exclusive of zingerone, although there are strong indications that other paradols also exist in nature.[30] Iwami et al.[32] recently demonstrated that an extract from the grains of paradise and 6-paradol activated thermogenesis in BAT, which could open up new avenues for the regulation of weight loss and weight maintenance. Furthermore, Sugita et al.[33] demonstrated that the oral ingestion of an extract of grains of paradise increased whole-body energy expenditure via the activation of BAT in human subjects. However, no studies have been reported in the literature to date pertaining to the antiobesity effects of 6-paradol following oral ingestion. Paradol analogues with different acyl chain lengths have been reported to have different pungency thresholds.[30] With this in mind, it was envisaged that the length of the acyl chains in different paradol analogues, which is related to their pungency strength, could also be related to the strength of their antiobesity effect following oral ingestion.

In this study, the antiobesity activities of high-fat diets containing 6-paradol or zingerone were compared in mice. Furthermore, the antiobesity activities of a series of paradol analogues bearing acyl chains of different lengths were evaluated following their oral ingestion, and the antiobesity mechanism of 6-paradol was investigated.

MATERIALS AND METHODS

Animals. Five-week-old C57BL/6J mice (male) were purchased from Clea Japan (Tokyo, Japan) and 5-week-old Sprague−Dawley rats (male) were purchased from Charles River Laboratories Japan (Kanagawa, Japan). The animals were housed in standard cages (345 × 403 × 177 mm) under controlled conditions (i.e., ambient temperature, 23 ± 2 °C; relative humidity, 60 ± 10%; 12 h light/dark cycle). The mice were given AIN-93 M (Oriental Yeast, Tokyo, Japan) and water ad libitum, whereas the rats received CE-2 (Clea Japan) and water ad libitum. All of the procedures used in the current study regarding the care and use of the animals were carried out on the basis of the regulations dictated by the Experimental Animal Care and Use Committee of Fukuoka University.

Chemicals. Zingerone was purchased from Givaudan (Dubendorf, Switzerland). 6-, 8-, and 12-paradol (Figure 1) were synthesized from the reactions of vanillin (Tokyo Chemical Industry, Tokyo, Japan) with 2-nonanone (Wako Pure Chemical Industries, Osaka, Japan), 2-undecanone (Wako Pure Chemical Industries), and 2-pentadecanone (Tokyo Chemical Industry), respectively, using the methods reported by Locksley and Rauney.[30] Dihydrocapsiate was synthesized from vanillyl alcohol (Tokyo Chemical Industry) and methyl nonanoate (Tokyo Chemical Industry) according to the method described by Kobata et al.[34] The compounds synthesized in this study were characterized by NMR spectrometry (JNM-A500, JEOL, Tokyo, Japan) at 500 MHz, and their purities were confirmed by element analysis (MICRO CORDER JM10, J-Science, Kyoto, Japan) with an absolute error of <0.3% between the theoretical and experimentally determined values. All of the other reagents used in the current study were purchased from Wako Pure Chemical Industries. AIN-93 M and the high-fat diet (HFD-60) were obtained from Oriental Yeast.

Comparison of the Antiobesity Effects following the Oral Ingestion of Zingerone and 6-Paradol. The mice were randomly divided into five groups of 10 at 8 weeks old, including one normal group and four experimental groups. The compositions of the experimental diets are shown in Table 1. The normal group was fed a normal diet of AIN-93 M for 8 weeks, whereas the four experimental groups were fed a high-fat diet with or without 0.1% by weight of zingerone, 6-paradol, or dihydrocapsiate for 8 weeks, with the latter serving as a positive control. The total food intake for each group was recorded five times a week, and the body weight of each mouse was recorded once a week. After 8 weeks on their diet, the mice were euthanized without suffering, and their inguinal subcutaneous fat, epididymal fat, perirenal fat, and interscapular BAT were collected. Each fat specimen was weighed, with the result expressed as milligram of wet weight (mean ± SE). Each BAT specimen was stored at −80 °C prior to being subjected to Western blotting for UCP-1.

Comparison of Antiobesity Effects following Oral Ingestion of 6-, 8-, or 12-Paradol. The mice were randomly divided into five groups of 10 at 8 weeks old. The compositions of the experimental diets are shown in Table 1. The normal group was fed a normal diet (AIN-93M) for 8 weeks, whereas the four experimental groups were fed a high-fat diet with or without 0.1% by weight of 6-, 8-, or 12-paradol for 8 weeks. Thereafter, the mice were subjected to the same protocol as that described above.

Expression of UCP-3 in Femoral Muscle following Oral Ingestion of 6-Paradol. The mice were randomly divided into three groups of 10 at 8 weeks old. The normal group was fed a normal diet (AIN-93M) for 8 weeks, whereas the two experimental groups were fed a high-fat diet with or without 0.1% by weight of 6-paradol for 8 weeks. Thereafter, the mice were subjected to the same protocol as that described above. After 8 weeks, the mice were sacrificed and their femoral muscles were collected and stored at −80 °C prior to being subjected to Western blotting for UCP-3.

Immunoblotting. Mitochondria were isolated using the method reported by Hong et al.[35] The protein contents were determined in triplicate using the Bradford method (Bradford reagent, Sigma-Aldrich, St. Louis, MO, USA). BAT and muscle protein (4 μg) samples were subjected to gel electrophoresis using sodium dodecyl sulfate 10% polyacrylamide mini-gels and electroblotted onto polyvinylidene difluoride. Blocked polyvinylidene difluoride (Blocking One, Nacalai Tesque, Kyoto, Japan; 4 °C, overnight) was probed with rabbit anti-UCP-1 polyclonal antibody (Abcam, Cambridge, MA, USA) at a dilution of 1:100000, as well as rabbit anti-UCP-3 polyclonal antibody (Abcam) at a dilution of 1:5000. Horseradish peroxidase-conjugated mouse anti-rabbit IgG antibody (Cell Signaling Technology, Beverly, MA, USA) was used as the secondary antibody at a dilution of 1:50000. Each incubation was performed for 1 h at room temperature, with the resulting immune complexes being detected with Immunostar LD (Wako Pure Chemical Industries) and a Western blot imaging system (FluorChemQ, Palo Alto, CA, USA). The expression levels of UCP-1 and -3 have been shown as the ratio of the level of expression on the high-fat diet to the level of expression observed on the normal diet (mean ± SE).

Pharmacokinetics. The pharmacokinetic properties of the paradol analogues and their metabolites were investigated following their oral administration to determine their active sites.

At 8 weeks old, the rats were fasted for 14 h prior to the oral administration of olive oil (1 mL) containing zingerone or 6-, 8-, or 12-paradol (10 mg/kg). Three rats in each group were anesthetized with isoflurane, and samples (300 μL) of their blood were collected from their jugular vein using a heparinized needle and syringe at 0 (before administration), 0.25, 0.5, 1, 3, 6, and 24 h after oral administration. The samples were centrifuged, and the resulting plasma was harvested and frozen at −80 °C prior to its analysis. The plasma (50 μL) was incubated at 37 °C for 1 h with 50 μL of β-glucuronidase. Each component was then collected by sequential extraction with 100 μL of methanol and 300 μL of *n*-hexane using a combination of vortexing and centrifugation. The hexane extract was then evaporated to dryness under a gentle stream of N_2 gas to give a residue, which was dissolved in methanol and analyzed using an API4000 QTRAP LC-MS/MS system (Applied Biosystems API4000, Life Technologies, Carlsbad, CA, USA) and a Prominence UFLC system (Shimadzu) equipped with a reversed-phase C18 column (Capcell PAK C18 UG120, 3 μm particle size, 100 × 2.0 mm, i.d., Shiseido). The MS detector was equipped with an electrospray ionization source. Mass spectral data were obtained by electrospray in the positive ion mode. Quantization analyses were performed using the multiple reaction monitoring mode with an external standard. The following pairs of ions were monitored with values of 195 (Q1) and 137 (Q3) for zingerone; 279 (Q1) and 137 (Q3) for 6-paradol; 307 (Q1) and 137 (Q3) for 8-paradol; and 363 (Q1) and 137 (Q3) for 12-paradol. The maximum concentration in the plasma (C_{max}) and the time to reach C_{max} (t_{max}) were recorded as observed. The area under the plasma concentration−time curve from 0 to 24 h (AUC_{0-24h}) and the mean residence time (MRT) were calculated using the moment method.[36,37]

Measurement of Lipolysis. Mice at 8 weeks old were fed a high-fat diet for 8 weeks. The mice were then sacrificed, and their epididymal adipose tissue was quickly collected. Isolated fat cells were obtained from the collected epididymal adipose tissue using the method of Rodbell.[38] The fat cells (40 μL packed volume) were incubated at 37 °C for 1 h in 160 μL of Hanks' buffer (pH 7.4) supplemented with 2.5% (w/v) bovine serum albumin (Rockland Immunochemicals, Gilbertsville, PA, USA), 6-paradol (concentration of 10^{-6}, 10^{-5}, or 10^{-4} M), and norepinephrine (NE, 0.1 μg/mL). The free fatty acids (FFAs) were extracted, and the amount of FFAs was determined using the method of Zapf et al.[39] The amounts of FFAs are shown as microquivalents released per milliliter of packed fat cells per hour (mean ± SE).

Statistical Analysis. All of the values have been expressed as the mean ± SE. Data were analyzed using Student's *t* test or Tukey's

Table 2. Food Intake and Body and Adipose Tissue Weights of the Mice Given Zingerone, 6-Paradol, and Dihydrocapsiate[a]

	diet groups

[a]Data are shown as the mean ± SE (n = 10). [b]$p < 0.05$. [c]$p < 0.01$ vs control. [d]$p < 0.01$ vs zingerone. [e]$p < 0.05$ vs 6-paradol, Tukey's multiple-range test.

multiple-range test, and differences were considered significant at $p < 0.05$.

RESULTS AND DISCUSSION

The antiobesity activities and UCP-1 expression levels in BAT were compared following oral ingestion of zingerone or 6-paradol. No differences were observed between the high-fat diet groups in terms of the food intake, which indicated that there were no differences in the energy intakes of the different groups (Table 2). Furthermore, the intake levels of zingerone, 6-paradol, and dihydrocapsiate were the same in each group (Table 2). Table 2 also shows the initial and final body weights for each group, as well as the adipose tissue weights. Significant differences were observed in the initial body weights of the 6-paradol and dihydrocapsiate groups compared with the control ($p < 0.05$ in both groups). The final body weight of the mice in the 6-paradol group was significantly lower than that of the control ($p < 0.01$). The dihydrocapsiate and zingerone groups did not show a significant difference in their final body weight compared with the control. The final body weights of the 6-paradol and dihydrocapsiate groups were significantly lower than that of the zingerone group ($p < 0.01$ and $p < 0.05$, respectively).

A comparison of the subcutaneous fat weights across the different groups revealed that the 6-paradol and dihydrocapsiate groups exhibit significantly lower weights than the control ($p < 0.01$ in both cases). In contrast, there was no significant difference between the subcutaneous fat weight of the zingerone group and the control, although there were significant differences between the zingerone group and the dihydrocapsiate and 6-paradol groups ($p < 0.05$ and $p < 0.01$, respectively). With regard to the epididymal fat weight, the 6-paradol group exhibited significantly lower levels of fat compared with those of the control and zingerone groups ($p < 0.01$ in both cases). The dihydrocapsiate group exhibited a significantly lower level of epididymal fat, which followed a similar tendency to that of the final body weight. With regard to the perirenal fat weight, the 6-paradol group exhibited significantly lower levels of fat compared with the control and zingerone groups ($p < 0.01$ in both cases). The dihydrocapsiate group exhibited a significantly lower level of perirenal fat weight compared with the zingerone group ($p < 0.05$).

The lowest overall body weight gain was observed in the 6-paradol group, followed by the dihydrocapsiate group, with the highest body weight gain being observed in the control group (Figure 2). Significant differences in body weight gain were observed between the control and 6-paradol groups from week 1 of the study, the control and dihydrocapsiate groups at weeks

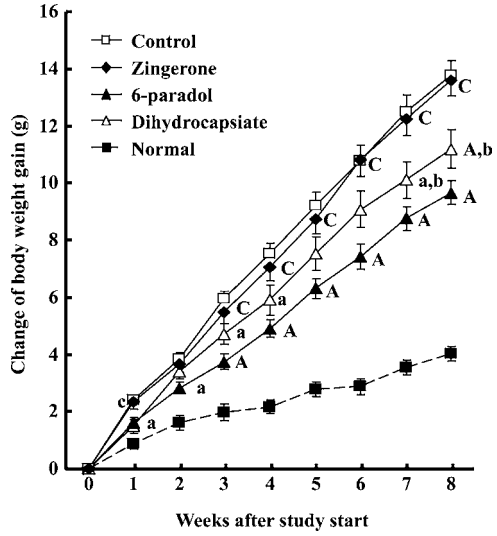

Figure 2. Changes in body weight gain following the oral ingestion of zingerone, 6-paradol, and dihydrocapsiate in mice. Normal group was fed AIN-93M, and the experimental groups were fed a high-fat diet with or without 0.1% (w/w) zingerone, 6-paradol, or dihydrocapsiate for 8 weeks. Data are shown as the mean ± SE (n = 10). There were significant difference between control and normal at all time points after the first week, $p < 0.01$, respectively, Student's t test. a, $p < 0.05$, and A, $p < 0.01$, versus control; b, $p < 0.05$ versus zingerone; c, $p < 0.05$, and C, $p < 0.01$, versus 6-paradol; Tukey's multiple-range test.

3, 4, and 7 of the study as well as at the end point of the study; the zingerone and dihydrocapsiate groups at week 7 as well as at the end point of the study, and the zingerone and 6-paradol groups from week 1 of the study, except at week 2.

Figure 3 shows changes in the expression levels of the UCP-1 protein in BAT mitochondria for all of the tested diets. The level of UCP-1 protein expression in the mice fed the high-fat diet with 6-paradol was about 2.6-fold greater than that found in the mice given the normal diet ($p < 0.01$). The level of UCP-1 expression in the dihydrocapsiate group (1.9-fold) was also significantly higher than that of the mice that received the normal diet ($p < 0.01$). These increases in the levels of UCP-1 expression in the control (1.4-fold) and zingerone (1.3-fold) groups were not significant relative to the normal diet. It has been reported that the level of UCP-1 expression in BAT increased significantly in mice fed a high-fat diet compared with a normal diet.[40] With this in mind, our current data were analyzed to identify any differences compared with the normal diet group. The results of this analysis revealed that the 6-paradol group had significantly higher levels of UCP-1 protein

dx.doi.org/10.1021/jf500873a | J. Agric. Food Chem. 2014, 62, 6166−6174

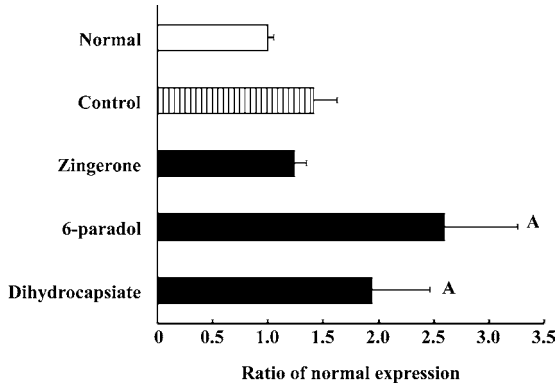

Figure 3. UCP-1 protein expression levels in murine interscapular brown adipose tissue following the oral ingestion of zingerone, 6-paradol, and dihydrocapsiate for 8 weeks. Data are shown as the mean ± SE (normal, n = 5, control; 6-paradol, n = 9, zingerone; dihydrocapsiate, n = 10). A, $p < 0.01$, versus normal; Tukey's multiple-range test.

expression compared with the normal diet group, whereas the levels of expression in the high-fat control group were similar to those of the control. Although there was no significant difference between the 6-paradol and control groups, it was concluded that the effect of 6-paradol was greater than that of the control. This result was similar to that of dihydrocapsiate, which was used as a positive control. The antiobesity activity of 6-paradol was found to be stronger than that of zingerone or dihydrocapsiate, with the latter used as a positive control. On the basis of these results, it was concluded that the length of the acyl chain of the paradol analogues was closely related to their antiobesity activity.

A separate experiment was then conducted to compare the antiobesity activities of 6-, 8-, and 12-paradol following their oral ingestion. Significant differences were observed in the food intake levels of the control group and the 8- and 12-paradol groups, and a similar difference was also observed between the 6- and 12-paradol groups (Table 3). These results indicated that the energy and intake levels of the test compounds were lower in the 8- and 12-paradol groups than they were in the control and 6-paradol groups. Although significant differences were observed in the food intake of the animals belonging to the high-fat diet groups, it was concluded that the antiobesity effects were limited, because both the calorie and test compound intake decreased. 6-Paradol was the most pungent of these compounds, followed sequentially by 8- and 12-paradol.[30] The latter two of these compounds may therefore have had an effect on appetite suppression, although their effects in this regard have not been clarified and further studies would be required.

Table 3 shows the initial and final body weights of the mice fed the different diets, as well as their adipose tissue weight. No differences were observed in the initial body weights of each high-fat diet group. The final body weight was lowest in the 6-paradol group, followed by the 12-paradol group, whereas the final body weight in the control group was found to be the highest of all of the groups tested. Significant differences were observed in body weight between the 6-paradol and control groups ($p < 0.01$) and between the control group and the 6-, 8-, and 12-paradol groups ($p < 0.01$, $p < 0.05$, and $p < 0.05$, respectively). The subcutaneous and epididymal fat weights were lowest in the 6-paradol group, followed by the 8- and 12-paradol groups, with the control group showing the highest subcutaneous and epididymal fat weights of all of the groups tested. Significant differences were also observed in the subcutaneous and epididymal fat weights between the control and 6-paradol groups ($p < 0.05$ and $p < 0.01$, respectively). In comparison to the 6-paradol group, the 8- and 12-paradol groups exhibited significantly higher epididymal fat weights ($p < 0.05$ and $p < 0.01$, respectively). The 6-paradol group showed the lowest level of perirenal fat weight of all the groups tested, followed by the 8-paradol and control groups, with the highest level of fat being observed in the 12-paradol group. A significant difference was also observed in the perirenal fat weights of the 6- and 12-paradol groups ($p < 0.05$).

The level of UCP-1 protein expression in mice fed the high-fat diet with 6-paradol was about 2.6-fold greater than that of the mice given the normal diet ($p < 0.05$, Figure 4). No significant differences were observed in the levels of UCP-1 protein expression between the control, 8-paradol (1.7-fold), and 12-paradol (1.5-fold) groups and the normal diet group. On the basis of these results, it was concluded that the antiobesity activities of the paradol analogues in this study were related to the length of their acyl chain, and 6-paradol was consequently identified as the most promising antiobesity candidate of all of the compounds tested.

It has been reported that the intragastric injection of 6-paradol in rats enhanced the efferent discharges of sympathetic nerves in a dose-dependent manner and also led to a significant increase in the tissue temperature of BAT.[32] A high caloric intake diet and a high-fat diet independent of caloric intake can both stimulate the sympathetic nervous system.[41−43] The activation of BAT by the sympathetic nervous system prevented the occurrence of obesity associated with a high-fat diet in rodents. Furthermore, capsaicin has been reported to activate

Table 3. Food Intake and Body and Adipose Tissue Weights of Mice for Paradol Analogues Study[a]

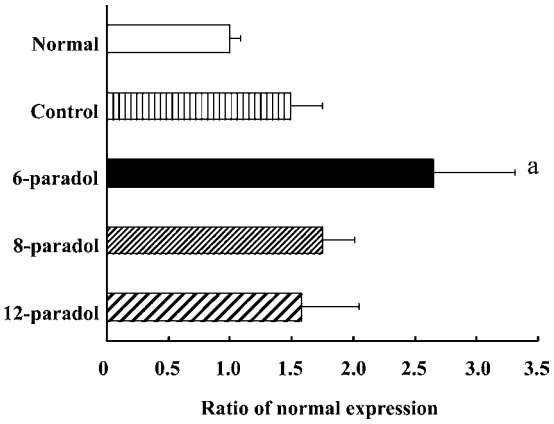

Figure 4. UCP-1 protein expression levels in murine interscapular brown adipose tissue following the oral ingestion of the paradol analogues for 8 weeks. Data are shown as the mean ± SE (n = 9). a, p < 0.05 versus normal; Tukey's multiple-range test.

the sympathetic nervous system.[44] On the basis of these findings, it was concluded that one of the possible mechanisms for the antiobesity effects of 6-paradol involved increased energy metabolism resulting from thermogenic activity in the BAT, as well as an increase in UCP-1 protein expression via the activation of the sympathetic nervous system.

Our understanding of white adipose tissue is currently changing with the realization that it is possible to induce the appearance of brown-like adipocytes in white adipose tissue depots and that these brown-like adipocytes are capable of expressing UCP-1 and activating uncoupled respiration in response to an appropriate stimulus. This process is referred to as the browning of white adipose tissue, and the brown-like cells that appear in white adipose tissue depots are known as brite or beige adipocytes.[45,46] Apart from browning, another manifestation of the metabolic plasticity of white adipose tissue that could be exploited in the context of the management of obesity and associated medical complications is the stimulation of mitochondrial oxidative capacity in a manner that is independent of UCP-1, but linked to the activation of a futile substrate cycle based on lipolysis of triacylglycerols and the re-esterification of the fatty acids in the adipocytes.[47] This approach would lead to increased energy expenditure and reduced adiposity while improving the deleterious conditions associated with mitochondrial dysfunction in white adipose tissue in obesity.[47,48] An increasing number of dietary and pharmacological agents capable of stimulating mitochondrial oxidative metabolism in white adipocytes are being reported in the literature as well as agents capable of modulating the browning of white fat, including UCP-1.[16] Capsaicin and capsinoids have been reported to induce the browning of white adipose tissue in rats fed a high-fat diet supplemented with these compounds.[49] Although the change in white adipose tissue has not been observed in this study, it remains likely that changes in the white adipose tissue were involved in the mechanism of the antiobesity activity of 6-paradol.

Figure 5 shows the mean concentrations of zingerone and 6-, 8-, and 12-paradol in the plasma following oral administration. Under the optimized conditions, linear relationships with good correlation coefficients (r = 0.999, n = 3, respectively) were observed between the peak area ratios and the concentrations of zingerone and 6-, 8-, and 12-paradol in the range of 10.0–1000.0 ng/mL. These experiments were performed using a

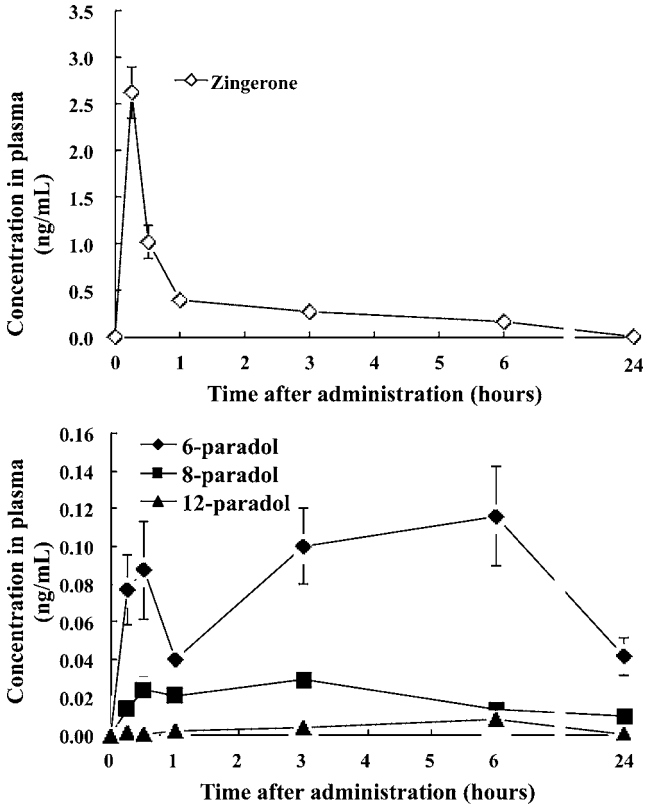

Figure 5. Mean plasma concentrations of the paradol analogues following their oral administration in rats. Rats were fasted for 14 h prior to the oral administration of olive oil (1 mL) containing zingerone or 6-, 8-, or 12-paradol (10 mg/kg). Data are shown as the mean ± SE (n = 3).

standard four-point series for each component. The limit of detection (LOD) and limit of quantitation (LOQ) were calculated according to the International Conference on Harmonization guidelines for the validation of analytical procedures based on the standard deviations of the responses and the slopes of the calibration curves. All four experiments were performed in triplicate and the results averaged to give LODs of 78.6, 0.551, 1.06, and 2.62 ng/mL and LOQs of 236, 1.65, 3.18, and 7.85 ng/mL for zingerone and 6-, 8-, and 12-paradol, respectively. In this study, the plasma concentrations of the tested compounds were determined from the sum of the concentration of the free compound and its glucuronide conjugate, because all of the compounds being tested for egestion were effectively metabolized to the corresponding glucuronides following their absorption. The pharmacokinetic parameters are summarized in Table 4. Zingerone was rapidly absorbed after oral administration, with C_{max} occurring at 0.25 h (t_{max}), whereas 6-, 8-, and 12-paradol were adsorbed at significantly slower rates. Furthermore, the C_{max} values of the paradols decreased as their acyl chain length increased and a significant difference was observed relative to zingerone (p < 0.01, respectively). The AUC_{0-24h} values also decreased as the acyl chain length of the paradols increased. The MRT of zingerone was the shortest of all of the compounds tested at 3.9 h, followed by 12- and 6-paradol, with that of 8-paradol being the longest at 9.5 h.

The water and lipid solubility properties of a drug compound are important factors for consideration in terms of the oral absorption of the material. The calculated logP (clogP) value of

Table 4. Pharmacokinetic Parameters for the Paradol Analogues following Their Oral Administration in Rats[a]

parameter	zingerone	6-paradol	8-paradol	12-paradol
C_{max} (ng/mL)	2624.8 ± 393.4	126 ± 33.9[b]	32.9 ± 8.2[b]	9.5 ± 2.2[b]
t_{max} (h)	0.25	6	3	6
AUC_{0-24h} (ng·h/mL)	4191.7 ± 1132.5	1948.4 ± 504.5[b]	344.5 ± 43.1[b]	112.5 ± 0.8[b,c]
MRT (h)	3.9 ± 0.9	8.8 ± 0.6[b]	9.5 ± 0.4[b]	6.7 ± 0.1[b,c,d]

[a]Data are the sum of intrinsic paradols and their glucuronides and are shown as the mean ± SE (n = 3). [b]$p < 0.01$ vs zingerone. [c]$p < 0.01$ vs 6-paradol. [d]$p < 0.01$ vs 8-paradol, Tukey's multiple-range test.

a compound can be used to provide an index of its lipid solubility. The clogP values of 6-, 8-, and 12-paradol were 4.7, 5.5, and 7.2, respectively, with the increase in the clogP value reflecting the increase in lipid solubility of the compounds. This increase in lipid solubility was attributed to the increase in the length of the acyl chains of the paradol analogues, which reduced their solubility in the intestinal lumen, leading to a decrease in their bioavailability. These results clearly indicate that 6-paradol was effectively absorbed into the enterocyte following oral ingestion and, therefore, suggested that the difference in the absorption properties were related to the different effects of the paradol analogues.

The effect of 6-paradol on norepinephrine-induced lipolysis is shown in Figure 6. The administration of NE at a concentration of 0.1 μg/mL led to a significant increase in the amount of FFAs released by fat cells ($p < 0.05$). In contrast, 6-paradol at a concentration in the range of 10^{-6}–10^{-4} M had no discernible effect on the release of FFAs from fat cells. It was previously reported that capsiate is readily broken down in the intestinal tract to yield vanillyl alcohol and a fatty acid,[50] indicating that the active sites for the antiobesity effect of orally administered capsiate were located in the digestive canal prior to the small intestine. The bioactivity of capsaicin has been attributed to an increase in the secretion of catecholamine from the adrenal medulla, which occurs through the activation of the sympathetic nervous system,[44] as well binding to and activating specific transient receptor potential channels within the gastrointestinal tract.[51] The capsaicin-dependent selective activation of transient receptor potential channels in the upper gastrointestinal tract has been shown to trigger the thermogenic reflex by activating vagal afferents to the brain, as well as sympathetic efferents innervating BAT.[51] Taken together, these results indicated that the active sites for the antiobesity activity of the orally ingested paradol analogues were located in the small intestine.

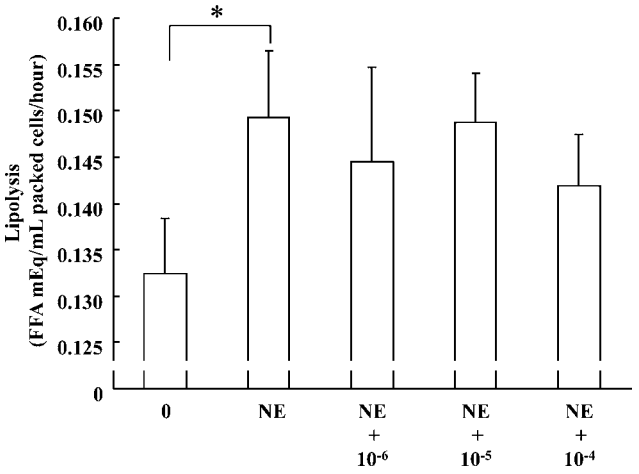

Figure 6. Effect of 6-paradol on lipolysis in fat cells derived from murine epididymal fat following oral ingestion of a high-fat diet for 8 weeks. Fat cells were incubated at 37 °C for 1 h with 6-paradol (10^{-6}, 10^{-5}, or 10^{-4} M) and/or norepinephrine (NE, 0.1 μg/mL). Data are shown as the mean ± SE (n = 4). (*) $p < 0.05$; Student's t test.

Although it has been reported that zingerone and 6-paradol possess similar levels of pungency,[30] the antiobesity activity of zingerone was found to be much lower than that of 6-paradol in the current study. It was reported in another study, however, that zingerone (170 mg/kg) exhibited pronounced antiobesity activity when it was administered to ovariectomized rats via a stomach tube.[31] The intake volumes of the compounds tested in the current study were in the range of 60–85 mg/kg/day. Furthermore, it was envisaged that the evanescent increase in the plasma concentration of zingerone observed as bioavailability would not occur in the present animals as a consequence of ingestion ad libitum. For this reason, it was considered that the intake of zingerone in the current study was too low to exhibit a significant antiobesity effect. Moreover, the results of the current study indicated that receptor related to the pungency of zingerone could be different from that of 6-paradol, although the precise nature of these receptors remains unclear at this stage, and further work would be needed to clarify any potential differences. The bioavailability of zingerone (AUC_{0-24h}) was found to be >2-fold greater than that of 6-paradol, and zingerone also had a faster absorption rate (t_{max}; Table 4; Figure 5). It has been reported that the accelerated effect of lipid decomposition led to a decrease in the adipose tissue weight of rats treated with zingerone via a stomach tube for 72 days.[31] However, 6-paradol did not have an effect on murine adiposities in the current study, as measured using the method of Han et al.[31] (Figure 6). Although the differences observed between zingerone and 6-paradol could be related to differences in the animal species studied,[31] it was speculated that they were most likely related to the active sites because of the differences in the physical properties of these compounds.

The level of UCP-3 expression in the femoral muscle following the oral ingestion of 6-paradol was also investigated. No differences were observed in the food intakes between the high-fat control and 6-paradol groups (Table 5). Table 4 also shows the initial and final body weights of the mice fed the different diets, as well as their adipose tissue weight. These data show that the final body weight of the 6-paradol group was significantly lower than that of the high-fat control group ($p < 0.01$). The amounts of subcutaneous, epididymal, and perirenal fat in the 6-paradol group were also significantly lower than those found in the high-fat control group ($p < 0.05$, $p < 0.01$, and $p < 0.05$, respectively).

Figure 7 shows the changes in the expression levels of UCP-3 protein in the femoral muscle mitochondria. The level of UCP-3 protein expression in mice fed the high-fat diet with 6-paradol was about 1.5-fold greater than that of those given the normal diet ($p < 0.05$). In contrast, the level of UCP-3 expression in

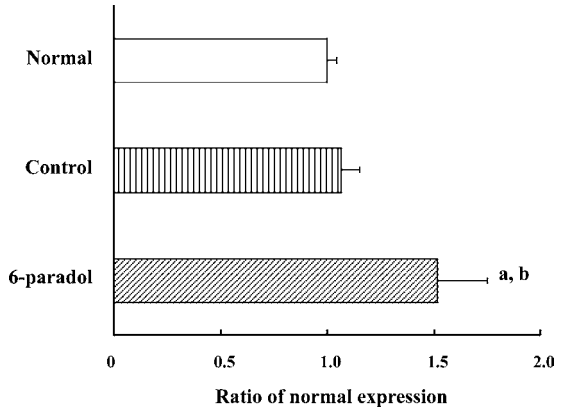

Figure 7. UCP-3 protein expression levels in murine femoral muscles following the oral ingestion of 6-paradol for 8 weeks. Data are shown as the mean ± SE (n = 9). a, $p < 0.05$ versus normal; b, $p < 0.05$ versus control; Tukey's multiple-range test.

the high-fat control group (1.1-fold) remained unchanged relative to the normal diet group, although it was significantly different from the 6-paradol diet group ($p < 0.05$). Although the role of UCP-3 remains unclear, it was concluded that the increase in UCP-3 expression was one of the mechanisms responsible for the antiobesity effects of 6-paradol.

In summary, the antiobesity activities of orally ingested paradols with different acyl chain lengths were investigated. The effect of 6-paradol was stronger than that of the positive control dihydrocapsiate. Our results also showed that the length of the acyl chain of the paradol analogues had a significant impact on the strength of their antiobesity activity. Furthermore, a comparison of the antiobesity activities of 6-, 8-, and 12-paradol revealed that the strength of their antiobesity activities was also related to the length of their acyl chain. On the basis of these results, it was concluded that the mechanisms of the antiobesity activity of 6-paradol involve increased energy metabolism in BAT, as well as an increase in UCP-1 protein expression, which occurred through the activation of the sympathetic nervous system.

Isolation of the Sapogenin from Defatted Seeds of *Camellia oleifera* and Its Neuroprotective Effects on Dopaminergic Neurons

Yong Ye,* Fei Fang, and Yue Li

Department of Pharmaceutical Engineering, School of Chemistry and Chemical Engineering, South China University of Technology, Guangzhou 510640, People's Republic of China

ABSTRACT: Sasanqua saponin is a major active compound in the defatted seeds of *Camellia oleifera* but is always discarded without effective utilization. The sapogenin from hydrolysis of sasanqua saponin was purified, and its amination derivative was investigated on its neuroprotective effects, which were evaluated by animal models of Parkinson disease in mice induced by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). The results showed that the sapogenin and its derivative increased dopamine content in striatum and tyrosine hydroxylase (TH) positive cells in substantia nigra and relieved inflammation and behavioral disorder, but the effect on movement was reversed by dopamine receptor antagonist haloperidol and was not intervened by adenosine receptor antagonist CGS 15943. Molecular simulation showed the interaction between dopamine receptor and the sapogenin or its derivative. It is proven that the sapogenin can protect dopamine neurons through antineuroinflammation and activation of dopamine receptor rather than adenosine receptor, and its amination improves the effects. This research provides the prospective prodrugs for Parkinson disease and a new medicinal application of sasanqua saponin.

KEYWORDS: *sasanqua saponin, amination, Camellia oleifera, neurodegeneration, Parkinson disease, dopaminergic neuron*

INTRODUCTION

Parkinson disease (PD) is a chronic neurodegenerative disease caused by extrapyramidal dysfunction, which is related to genetic factors, environmental factors, mitochondrial dysfunction, and so forth,[1] and is characterized with the loss of dopaminergic neurons in midbrain and the formation of Lewy body with the main component of α-synuclein.[2] Its clinical symptoms will appear since almost 50% of dopaminergic neurons located at substantia nigra compact (SNC) are lost and the concentration of dopamine in the striatum decreases to 80%,[3] including motor dysfunction of bradykinesia, tremor, rigidity, and gait disorders as well as movement unassociated symptoms such as the smell sense disorder, autonomic nerve dysfunction, depression, cognitive impairment, sleep disorders, and so forth. Currently, there is no perfect treatment for PD, and traditional treatment strategy is L-dopa replacement therapy. Although the clinical symptoms can be controlled, disease progression cannot be prevented. Moreover, long-term L-dopa treatment can lead to efficacy reduction and severe adverse effects, lowering the quality of patients' lives.[4] In recent years, medication therapy of PD has changed from direct dopamine supplement to multilevel therapy, aiming at reliving the symptoms and impeding the progression of the disease at the same time.[5] Natural medicines play an important role in therapy of PD.

Camellia oleifera, an edible oil plant, is mainly distributed in China, but the defatted seeds are discarded, leading to environmental pollution and waste of resource. Flavonoids, saponins, and polysaccharides are the main compounds in the defatted seeds of *C. oleifera*,[6] but flavonoids and polysaccharides are unstable in vivo and cannot take effect in the central system because it is difficult for them to pass through the blood brain barrier.[7,8] Sasanqua saponin is a safe compound with LD_{50} 4.5 g/kg and accumulation coefficient 5.3 in rats.[9] It has a stable block called sapogenin with a lot of pharmacological activities of antioxidation, anti-inflammation, immunomodulation, and antitumor,[10−12] and it may play a role in neuroprotection.

Saponin is one of the active ingredients in many herbs, and some have neuroprotective effects. It is found that ginsenoside Rg1 can reverse the changes of neurotransmitters caused by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP),[13] and ginsenoside Re has significant inhibition on apoptosis of nigra neurons in mouse caused by MPTP,[14] and gypenosides can cause neuroprotective effects through enhancing activity of antioxidative enzymes and inhibiting generation of hydroxyl radicals and lipid peroxide to reduce Glu-mediated oxidative nerve injury.[15] Unlike those saponins, sasanqua saponin from seeds of *C. oleifera* has a different structure of pentacyclic triterpenoids, whose main active block is sapogenin.[16] Our previous research proved the anti-inflammatory and analgesic activities of the sapogenin,[17] diclosing its central roles. The protective role of the sapogenin and its derivative on dopaminergic neurons is worth investigation.

MATERIALS AND METHODS

Materials. The defatted seeds of *Camellia oleifera* were collected from The Oil Factory in Meizhou of Guangdong province, China. Macroreticular resin AB-8 was purchased from Cangzhou Resin Company (Hebei, China). Reagents for synthesis were triphenyl chloromethane, triphenyl phosphine, and diethyl azodicarboxylate bought from J & K Scientific Ltd.

(Beijing, China). Drugs for animal tests were MPTP and CGS 15943 purchased from Sigma-Aldrich Company (St. Louis, MO, U.S.) and haloperidol from Shanghai Pharmaceutical Co. Ltd. (Shanghai, China). TNF-α, IL-1β, and tyrosine hydroxylase (TH) immunoassay kits were bought from Jiancheng Biotech. Co. (Nanjing, China). Other chemicals were purchased from Qianhui Reagent Company (Guangzhou, China).

Animals. The experiments were carried out on male Kunming mice of weight 30 ± 3 g. The animals were housed under conditions of 25 ± 2 °C, 50 ± 10% humidity with a 12 h light/dark cycle. Food and water were accessible ad libitum. The experiments were performed in accordance with the Chinese Guidelines for the use of laboratory animals, which conforms to the European Union Directive for the protection of experimental animals (2011/63/EU), and received approval (Permit No. 13910) from the Animal Experimentation Ethic Committee of South China University of Technology. All efforts were made to minimize animal suffering and to reduce the number of animals used.

Isolation of the Sapogenin. The seeds of *C. oleifera* were defatted with *n*-hexane in the Soxhlet apparatus for 8 h. One kilogram of the defatted seeds was extracted with 15 L of 70% (V/V) methanol aqueous solution under reflux at 80 °C for 2 h. The filtrate was vaporized to 5 L in reduced pressure, was flowed at 2 mL/min through the column (diameter 5 cm × height 30 cm) filled with macroreticular resin AB-8, and then was eluted by 2 L of 80% (V/V) ethanol aqueous solution. The eluent was added to 52 mL of hydrochloride acid and was refluxed at 80 °C for 5 h. The precipitate was collected and dissolved in 500 mL of 80% ethanol containing 25 g of sodium hydroxide and was refluxed for the second time at 80 °C for 5 h. The precipitate was collected and crystallized with diethyl ether and was dried in vacuum condition. Then, 82 g of the sapogenin was obtained. The scheme of extraction is illustrated in Figure 1.

Synthesis of Sapogenin Derivative. Fifty grams of the sapogenin was dissolved in 300 mL of pyridine, was mixed with triphenyl chloromethane (28.4 g), and was stirred at 50 °C for 8 h. Then, acetic anhydride (20.8 g) was added into the mixture and was stirred for 15 h. The solution was added to 4.7 mL of formic acid and was heated to 100−110 °C under reflux for 1 h and then was cooled to 20 °C. Five grams of ammonia, 0.5 g of triphenyl phosphine, and 0.5 g of diethyl azodicarboxylate were mixed into the solution, stirring for 9 h. Finally, 28 g of potassium carbonate was added, stirring for 1 h. Pyridine was distilled off under reduced pressure, and the soluble fractions in water and toluene were removed stepwise by 500 mL of water and toluene. The residue was dissolved in methanol to crystallize and was dried under vacuum condition. Twenty-six grams of the product was gained. The synthetic route is illustrated in Figure 2.

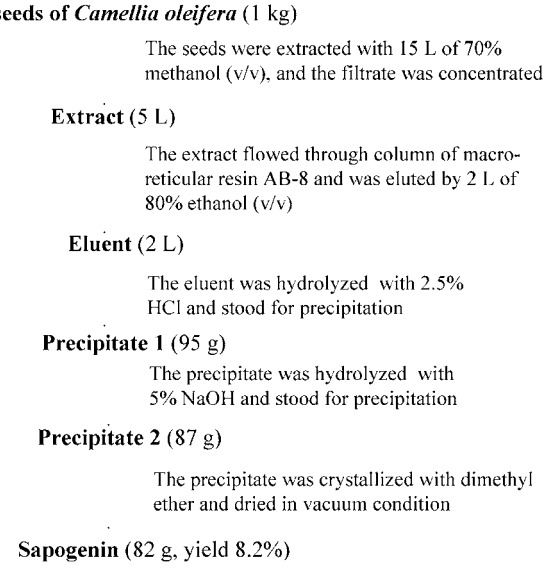

Figure 1. Scheme of sapogenin isolation from the defatted seeds of *Camellia oleifera*.

Structural Analysis. UV spectra analysis was carried out on UV-3010 ultraviolet spectrometer (Hitachi Company, Japan) scanning from 200 to 600 nm. IR spectra were measured on Nicolet 380 FT-IR spectrometer (Nicolet Apparatus Company, U.S.) with KBr tablets from 4000 to 400 cm^{-1} with resolution 2 cm^{-1}. Mass spectra were recorded on Bruker Esquire Hct Plus Mass spectrometer with electrospray ionization (ESI, Bruker Company, Germany) in m/z of cation model scanning from 150 to 1200 for 60 min. NMR spectra were determined on 400 MHz AM NMR (Bruker Company, Switzerland) in DMSO-d_6 operating at 101 MHz for ^{13}C NMR and at 400 MHz for ^{1}H NMR.

PD Model Induced by MPTP. The experiment was performed according to ref 18. Eighty mice were randomly divided into 10 groups of 8 mice for each: normal group, MPTP group, four medicated groups, and four antagonist groups. Medicated groups of mice were intragastricly administered once a day with the sapogenin and its derivative at 25 mg/kg (low dose) and 100 mg/kg (high dose), respectively, for 6 days; the antagonist groups received 1 mg/kg haloperidol or CGS 15 943 (intraperitoneal injection (i.p.)) plus a high dose of the sapogenin or the derivative (i.g.), and the other groups were fed with normal saline instead. Haloperidol, a dopamine receptor antagonist, can decrease dopamine neurotransmission in the striatum and can induce Parkinson disease-like symptoms in humans.[19] CGS 15943 is a competitive adenosine receptor antagonist and a behavioral stimulant in animals.[20] These drugs were used in this experiment to deduce whether the drugs took effect through the dopamine receptor pathway or through the adenosine receptor pathway. On the seventh day of administration, the mice except the normal group were intraperitoneally injected with 20 mg/kg MPTP once every 2 h for three consecutive times to prepare the PD mice model. The mice were reared for an additional 7 days and were decapitated after behavioral tests; the striatum of half the brain was quickly separated, and remain of the half was used to determine the levels of TNF-α and IL-1β with the ELISA method of the kit description. The other half of the brain was kept for immunohistochemical analysis. The striatum was homogenized in 1 mL 0.1 mol/L pH 7.4 PBS-EDTA buffer. The homogenate was centrifuged at 3000g for 10 min, and the content of dopamine (DA) in supernatant was measured by high-performance liquid chromatography-electron-capture detector (HPLC-ECD, Agilent Company, U.S.).[21] The operating conditions of HPLC were column, Diamonsil C18 (150 × 4.6 mm, 5 μm); mobile phase, 110 mM citrate buffer/100 mM EDTA/70 mM 1-octanesulfonate sodium solution and 20% (V/V) methanol; flow rate, 1 mL/min; temperature, 30 °C; and injection volume, 20 μL.

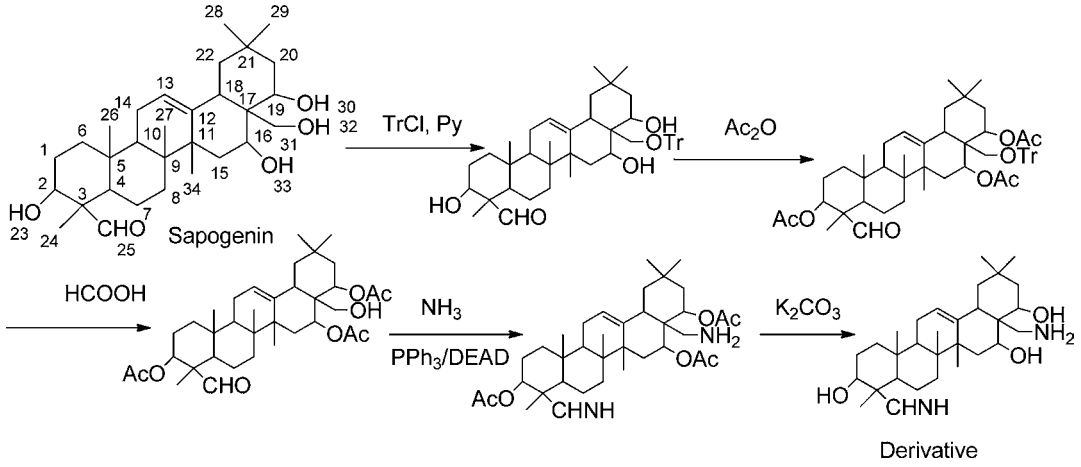

Figure 2. Synthetic route of the sapogenin derivative.

Behavioral Test. The locomotive activities of mice were monitored by a ZZ-6 spontaneous activity apparatus (Chengdu Taimeng Software Co., China). Moving counts were collected by computer with the infrared-sensitive motion-detection system. Each mouse was placed in the testing chamber for 10 min of adaptation, followed by a 10 min recording.[22] The rotarod test was used to detect the balance of mice. Mice were trained three times before the test, and the rotating speed was set to 15 r/min.[23] Latency to fall was calculated five times within 180 s. In the traction test, a horizontal metal rod with diameter of 1.5 mm was used as a hanging rod at a height of 30 cm from the ground. Latency to fall was recorded to evaluate their motor coordination.[24]

Assay of TH Expression. The test was carried out on the basis of the protocol.[25] The half brain of a mouse was sunk in paraformaldehyde solution (pH 7.4, 40 g/L) containing 300 g/L sucrose for 48 h and was cryostat sectioned to slices (60 mm thickness). Nigra slices were incubated in TH antibody with dilution of 1:5000, were stained by diaminobenzidine (DAB), and were mounted to slides for photograph and TH positive cell counting.

Simulation of Molecular Interaction. Molecular docking was simulated by Discovery Studio V2.5 software (Accelry Inc., CA, U.S.) in the following procedure.[26] Structural data of dopamine receptor was downloaded from Brookhaven Library.[27] The missing amino acids and hydrogens were supplemented, and excessive protein conformation was removed. Dopamine receptor was defined as the receptor, and the binding sites and coordinates were defined. A new plot window was opened to draw structures of the sapogenin and its derivative, to optimize 3D geometric structures, and to apply CHARMm force field to ensure correct bond length and bond angle in a state of energy stability.[28] CDOCKER Protocol was run to obtain binding parameters, which were used to evaluate the interaction. CDOCKER energy and CKOCKER interaction energy were two important parameters, and their absolute values were in accord with the affinity and action force between the receptor and the ligand.

Statistical Analysis. Data were expressed as mean ± standard deviation ($\bar{x} \pm s$) and were analyzed with SPSS13.0 software. Significant tests among the groups were based on one-way ANOVA and Student−Newman−Keuls (SNK) test.

RESULTS AND DISCUSSION

Structure of the Sapogenin and Its Derivative. Sasanqua saponin has certain antioxidative, anti-inflammatory, and analgesic effects, and the sapogenin from hydrolysis of the sasanqua saponin could increase cellular uptake and could promote its roles in vivo.[17] The amino group enhances the interaction of drugs with some receptors[29] and may be helpful to PD. Thus, the sapogenin was purified and was derived by amination in hydroxyl and aldehyde groups in order to improve its neuroprotective effects.

Table 1. Influence of the Sapogenin and Its Derivative on DA Content in Striatum of Mice Treated with MPTP ($\bar{x} \pm s$, $n = 8$)[a]

group	dose (mg/kg)	DA content (pmol)	TH^+ neurons number
normal saline		63.2 ± 8.1[b]	39.6 ± 8.1[b]
MPTP		23.4 ± 7.4	6.6 ± 3.7
sapogenin	25	30.4 ± 9.8	12.6 ± 5.8
sapogenin	100	40.9 ± 8.5[b]	35.8 ± 6.9[b]
derivative	25	33.2 ± 8.7	14.4 ± 8.0
derivative	100	42.8 ± 8.4[b]	36.2 ± 8.6[b]
DA antagonist/sapogenin	1/100	41.7 ± 6.2[b]	35.6 ± 5.8[b]
DA antagonist/derivative	1/100	42.7 ± 7.9[b]	36.4 ± 6.5[b]
adenosine antagonist/sapogenin	1/100	39.1 ± 4.6[b]	32.8 ± 6.6[b]
adenosine antagonist/derivative	1/100	41.3 ± 4.4[b]	34.2 ± 6.1[b]

[a]Mice were administered (i.g.) with sapogenin or derivative or were injected (i.p.) with haloperidol (dopamine antagonist) or CGS 15943 (adenosine antagonist) once a day for 6 days and then were injected (i.p.) with MPTP. Seven days later, striatum was taken for determination of dopamine by HPLC. TH positive neurons in nigra were counted under microscope in five visual fields (4 mm^2) for each of eight slices after immunostaining. [b]$p < 0.01$, compared with MPTP group.

The purified sapogenin was an amorphous powder and was insoluble in water, chloroform, petroleum ether, and dimethyl ether and was soluble in methanol, ethanol, acetone, and ethyl acetate. mp 251.2−251.7 °C. There was an absorption peak at 207 nm in UV spectra. IR spectra showed a smaller peak of hydroxyl groups at 3435 cm^{-1} and no characteristic absorption peak of α, β-unsaturated ester, and ether. In MS, m/z was 488 (M^+). ^1H NMR spectra had no Tig moiety signals but showed

dx.doi.org/10.1021/jf501166w | J. Agric. Food Chem. 2014, 62, 6175−6182

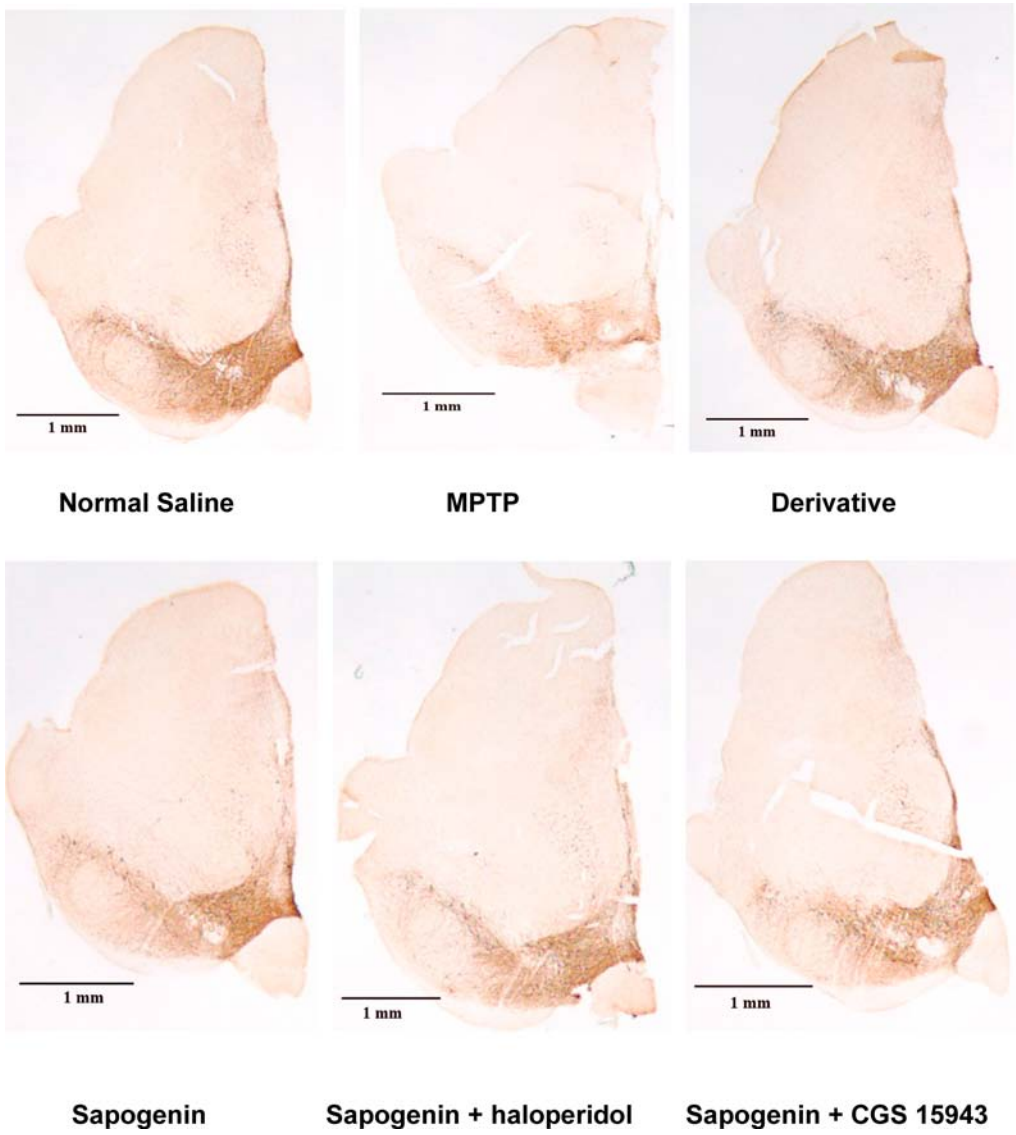

Figure 3. TH immunohistochemistry of substantia nigra sections in mice with different treatments. Sapogenin, 100 mg/kg, i.g.; derivative, 100 mg/kg, i.g.; MPTP, 20 mg/kg × 3 i.p.; haloperidol, 1 mg/kg, i.p.; CGS 15943, 1 mg/kg, i.p. Half brains were sectioned for determination of TH expression by immunohistochemistry. The photos were taken by camera in 50 times magnification.

one carbonyl (d 9.97, J = 12.48). ^{13}C NMR spectra had signals of one carbonyl carbon and two olefinic carbons. The signals in ^{13}C NMR spectra were assigned as follows: δ208.7 (C-25), 144.5 (C-12), 123.3 (C-13), 74.9 (C-2), 70.3 (C-19), 67.7 (C-16), 65.6 (C-31), 52.6 (C-3), 50.1 (C-4), 47.5 (10, 22), 45.9 (C-11, 20), 42.1 (C-17, 18), 38.4 (C-6, 9, 15), 36.1 (C-5, 8), 30.7 (C-21, C-28, 29), 27.1 (C-1), 24.9 (C-14, 34), 19.5 (C-7), 16.8 (C-24, 26, 27). Its property and structure are the same with camelliagenin ($C_{30}H_{48}O_5$) in the reference.[30]

The derivative of sapogenin had similar properties as the sapogenin. The maximum absorption peak was at 215 nm in UV spectra. IR spectra showed imino groups at 1640 cm^{-1}. MS: m/z 486 (M^+). There were signals of imino proton (d 9.61) and amino protons (d 2.71) in ^{1}H NMR spectra. ^{13}C NMR spectra also had no signal of carbonyl carbon. Its formula was speculated as $C_{30}H_{50}N_2O_3$. The structures of sapogenin and its derivative are shown in Figure 2.

Protection on Dopaminergic Neurons Damaged by MPTP. The MPTP model is one of the well-known animal models of PD and is used to appraise the neuroprotective effects of the sapogenin and its derivative. MPTP can cross the blood-brain barrier, transforms to 1-methyl-4-phenylpyridine radical with the oxidation of monoamine oxidase B, and then enters dopaminergic nerve cells and selectively destructs dopaminergic neurons, causing a significant reduction of dopamine neurotransmitters in neurons and behavioral changes.[31]

The result of animal tests showed that DA levels in striatum of mice treated by MPTP were significantly (p < 0.01) lower than the normal saline group, indicating that MPTP caused the damage of the dopaminergic neuron. However, mice fed with the sapogenin and its derivative increased the levels of DA in striatum, and especially, the high dose of the sapogenin and its derivative had significant effects (p < 0.01) on the increase of DA content. Mice treated with the dopamine receptor antagonist haloperidol and the adenosine receptor antagonist CGS 15943 also had higher DA levels in striatum (Table 1). This suggests that high doses of the sapogenin and its derivative can prevent dopaminergic neurons from damage induced by

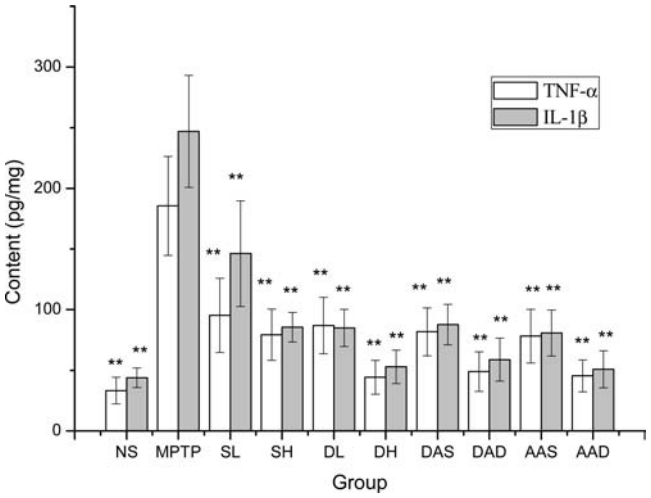

Figure 4. Levels of TNF-α and IL-1β in brain of mice in different treatments. The groups are normal (NS), MPTP (20 mg/kg × 3 i.p.), low dose of sapogenin (SL, 25 mg/kg, i.g.), high dose of sapogenin (SH, 100 mg/kg, i.g.), low dose of derivative (DL, 25 mg/kg, i.g.), high dose of derivative (DH, 100 mg/kg, i.g.), dopamine antagonist plus sapogenin (DAS, haloperidol 1 mg/kg i.p. and sapogenin 100 mg/kg i.g.), dopamine antagonist plus derivative (DAD, haloperidol 1 mg/kg i.p. and derivative 100 mg/kg i.g.), adenosine antagonist plus sapogenin (AAS, CGS15943 1 mg/kg i.p. and sapogenin 100 mg/kg i.g.), and adenosine antagonist plus derivative (AAD, CGS15943 1 mg/kg i.p. and derivative 100 mg/kg i.g.). Data are presented as mean ± standard deviation ($\bar{x} \pm s$, $n = 8$). **, $p < 0.01$, compared with MPTP group.

MPTP and that DA or adenosine receptor antagonist has no adverse effect on DA content.

Tyrosine hydroxylase (TH) is the key enzyme for dopamine synthesis in dopaminergic neurons, and its expression is lowered in substantia nigra of patients with Parkinson disease.[32] Immunostaining intensity of brain slices in immunohistochemistry can reflect the expression of TH. Compared with normal mice, MPTP treated mice had less staining in substantia nigra of brain slices, indicating that MPTP depressed the expression of TH. However, the intensity had no significant difference between normal control and high dose of the sapogenin or its derivative and between dopamine or adenosine receptor antagonist and sapogenin. This further proves that high dose of the sapogenin and its derivative has the protective effects on dopaminergic neurons and that the antagonists did not reduce the effects. The pictures are shown in Figure 3.

TH positive neurons were counted in five visual fields (4 mm^2) for each of eight slices, and the average cell number is listed in Table 1. Significant difference ($p < 0.01$) was found between MPTP group and high dose of sapogenin or its derivative but was not found between antagonist and no antagonist group, suggesting that the dopaminergic neurons' protection of the sapogenin and its derivative was not affected by dopamine or adenosine receptor antagonist.

Inhibition on the Inflammation in Brain. MPTP can induce neuroinflammation through an increase in the expression of TNF-α and IL-1β in the brain.[33] The anti-inflammatory effects of the sapogenin and its derivative on brain tissues were investigated. The results showed that TNF-α and IL-1β in mice brain of MPTP group were significantly ($p < 0.01$) increased but decreased in the groups treated with the sapogenin and its derivative. There was no significant difference

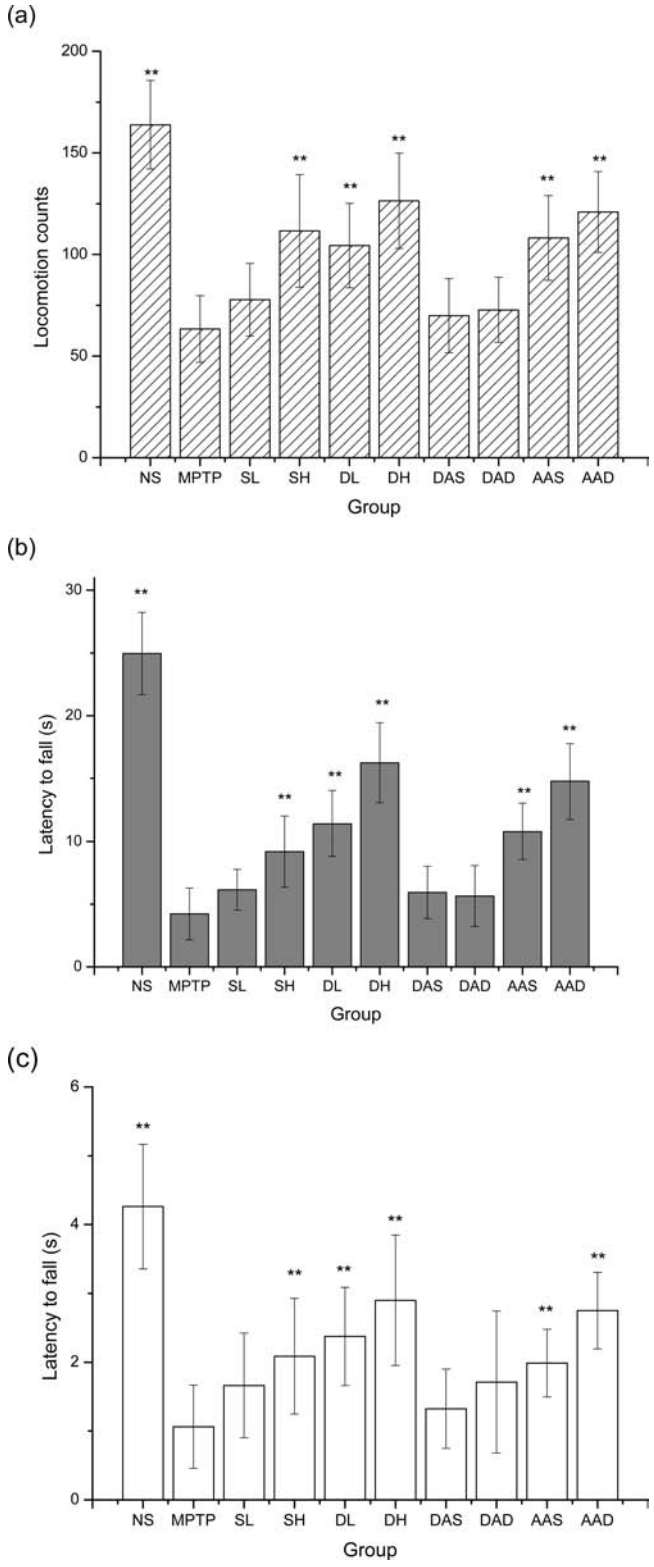

Figure 5. (a) Locomotive activity, (b) latency to fall by rotarod test, and (c) latency to fall by traction test in mice of different groups. The groups are NS (normal saline), MPTP (20 mg/kg × 3 i.p.), SL (low dose of sapogenin, 25 mg/kg), SH (high dose of sapogenin, 100 mg/kg), DL (low dose of derivative, 25 mg/kg), DH (high dose of derivative, 100 mg/kg), DAS (dopamine antagonist haloperidol 1 mg/kg plus sapogenin 100 mg/kg), DAD (dopamine antagonist haloperidol 1 mg/kg plus derivative 100 mg/kg), AAS (adenosine antagonist CGS 15943 1 mg/kg plus sapogenin 100 mg/kg), and AAD (adenosine antagonist CGS 15943 1 mg/kg plus derivative 100 mg/

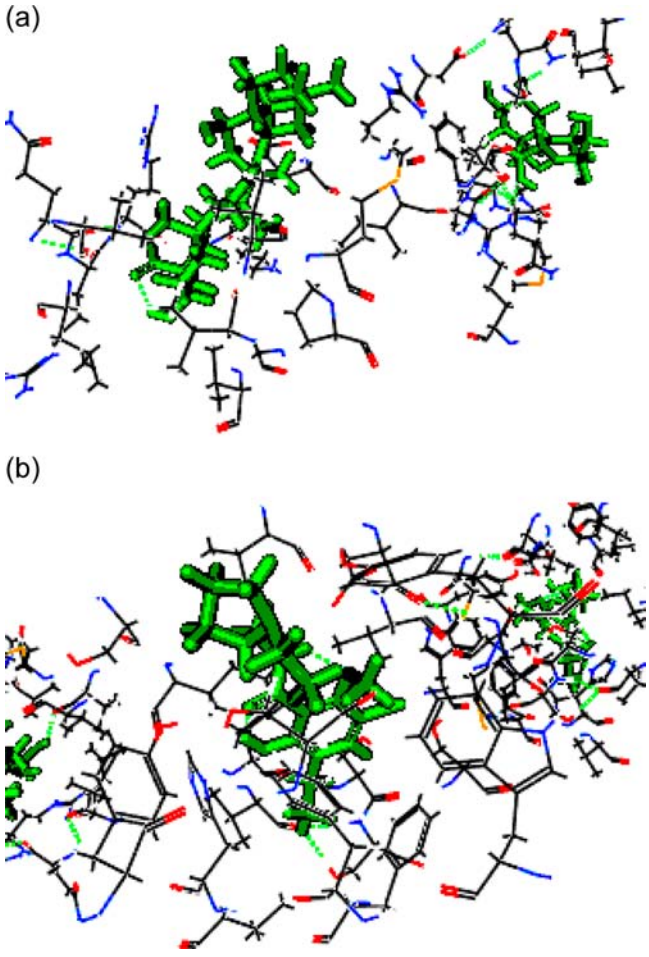

Figure 6. Group linkage of interaction of (a) the sapogenin and (b) its derivative with dopamine receptor.

between the group of derivative in high dose and normal group, suggesting that the derivative had better control of inflammation in brain. The antagonists had no significant effects on neuroinflammation. The results are illustrated in Figure 4.

TNF-α and IL-1β had obvious neurotoxicity on dopaminergic neurons.[34] High-level expression of TNF-α could induce great loss of dopaminergic neurons, accompanied by the proliferation of glial monocytes and macrophages.[35] TNF-α and IL-1β could also cause phosphorylation and degradation of IKK-β kinase, leading to translocation of NF-κB into the nucleus to promote expression of inflammatory genes.[36] This experiment shows that MPTP increases the expression of TNF-α and IL-1β in the brain, triggering inflammation and leading to neuron loss. The sapogenin and its derivative inhibit the expression of TNF-α and IL-1β in the mouse brain induced by MPTP and protect dopaminergic neurons in the brain from degeneration by antineuroinflammation.

Behavioral Improvement of PD Mice. PD patients not only have dopamine loss in striatum and substantia nigra of brain but also have a lot of motor dysfunction, which can be imitated by animal tests. Spontaneous activities of mice were determined by locomotion test, and the balances were measured by the rotarod test and the traction test. The results showed that MPTP significantly ($p < 0.01$) lessened the spontaneous activity and latency to fall, suggesting that it caused movement disorder and damaged the motion balance and coordination of mice. The locomotion counts and latency to fall were increased significantly ($p < 0.01$) after the administration of the sapogenin and its derivative but decreased after injection of haloperidol. This indicated that the sapogenin and its derivative improved the behavioral disorders induced by MPTP, but the effects were reversed by DA receptor antagonist. The derivative had better effects than the sapogenin on behavioral improvement. The results are shown in Figure 5.

The structures of sapogenin and its derivative are responsible for their effects on protection of dopaminergic neurons and behavior improvement. They do not have phenolic hydroxyl groups, and it is difficult for them to eliminate the MPTP radical. The neuroprotection contributes to their significant anti-inflammatory effects rather than to their antioxidant effect. They can relieve the motor dysfunction, and the effects are counteracted by dopamine receptor antagonist, indicating they might take effect by activating dopamine receptor rather than adenosine receptor, which is related to PD in many reports.[37] The amination of sapogenin shows better effects on amelioration of PD symptoms. It may be attributed to its stronger interaction with dopamine receptor.

Interaction with Dopamine Receptor. Molecular simulation is a good way to observe the interaction among groups. The protocol of semiflexible docking (CDOCKER) is proper for interaction of large molecule receptor and small molecule ligand. Major factors on binding stability of receptor and ligand are hydrophobicity and bonding force, which are calculated and judged by free energy. Docking simulation showed that both the sapogenin and its derivative could bind to the dopamine receptor. Each molecule successfully docked in five poses; the binding energy is shown in Table 2. The derivative had higher CDOCKER interactive energy and higher absolute value of CDOCKER energy than the sapogenin, suggesting that it is more powerful to bind to and interact with the dopamine receptor. The group linkage of the sapogenin and its derivative with dopamine receptor is shown in Figure 6, illustrating that one receptor can interact with many more derivatives. The

dx.doi.org/10.1021/jf501166w | J. Agric. Food Chem. 2014, 62, 6175−6182

interaction between the sapogenin or the derivative and the dopamine receptor contributes to their effects on behavioral improvement.

The sapogenin was isolated from the defatted seeds of *C. oleifera* and was used to synthesize a derivative by amination. By means of animal PD models induced by MPTP, it is found that the sapogenin and its derivative have significant effects on inhibition of DA loss, relieving motor deficits and protection of dopaminergic neurons. It is owing to their control of neuroinflammation in central tissues and interaction with dopamine receptor. The sapogenin and its derivative may become the prospective prodrugs for PD.

Although the MPTP animal model is widely used for PD therapeutic interventions, it has limitations and cannot produce sleep disturbances and cognitive deficits commonly seen in PD patients.[38] Because many factors are involved in PD including gene mutation, environmental impact, and so forth, the key mechanism of PD is still unknown. Therefore, other models such as transgenic animal model will be discussed in our next investigation so as to achieve the clinical application of the sapogenin and its derivative on PD.

ABSTRACT: The present study examined the impact of the supplementation of glutathione (GSH), γ-L-glutamyl-L-cysteinyl-glycine, on human blood GSH levels. Healthy human volunteers were orally supplemented with GSH (50 mg/kg body weight). Venous blood was collected from the cubital vein before and after ingestion. Plasma was mixed with 3 volumes of ethanol. The supernatant and precipitate were used for the deproteinized and protein fractions of plasma, respectively. Blood cell and plasma fractions were pretreated with 5% trichloroacetic acid−2% 2-mercaptoethanol to reduce the oxidized form of GSH and liberate protein-bound GSH. The 2-mercaptoethanol-pretreated GSH was determined by precolumn derivatization with 6-aminoquinolyl-*N*-hydroxy succinimidyl carbamate and liquid chromatography−tandem mass spectrometry. There was no significant difference in GSH contents in the deproteinized fraction of plasma and blood cell fraction after GSH ingestion. However, the GSH contents in the protein-bound fraction of plasma significantly ($P < 0.01$) increased from 60 to 120 min after GSH supplementation.

KEYWORDS: *glutathione, GSH, blood, supplementation, oral administration, human trial*

INTRODUCTION

Glutathione (GSH), γ-L-glutamyl-L-cysteinyl-glycine, is a ubiquitous compound found in humans, animals, plants, and microorganisms.[1] Within cells, GSH exists in both reduced and oxidized states. In healthy cells, the majority of GSH is present in the reduced form.[2] Most cells in the human body are capable of synthesizing GSH from glutamate, cysteine, and glycine. First, γ-glutamyl-cysteine is synthesized from L-glutamate and L-cysteine by γ-glutamyl-cysteine synthetase. Second, glycine is conjugated to the C-terminaus of γ-glutamyl-cysteine by GSH synthetase.[1,3]

GSH is a cofactor or substrate for GSH peroxidase and GSH *S*-transferase (GST), which are involved in very important antioxidant and detoxification systems, respectively.[4] The main function of GSH peroxidase is to reduce hydrogen peroxide to water and to reduce lipid hydroperoxides to their corresponding alcohols.[3,5] The reduced form of GSH, which is involved in these reactions as a cofactor, is converted to the oxidized form. Thus, the ratio of the oxidized form to the reduced form of GSH has been thought to reflect oxidative status in cells, organs, and individuals.[6] However, oxidized GSH is reduced by GSH reductase. The reduced form of nicotinamide adenine dinucleotide phosphate, which is a cofactor for GSH reductase, is supplied by the pentose phosphate pathway.[7] GST catalyzes the conjugation of reduced GSH to a wide variety of exogenous chemicals through a sulfhydryl group to make the compounds more soluble and to facilitate urinary excretion.[8,9]

Decreased GSH levels in cells have been demonstrated to increase the risks of diseases and poisoning.[1,10] GSH has therefore been used to treat chronic liver diseases and poisoning through intravenous injections.[11,12] In addition to intravenous injections of GSH, oral administration has been used for medical applications. Aside from medical applications, GSH has also been implicated in skin whitening. In vitro studies have revealed that GSH inhibits melanin synthesis in the reaction of tyrosinase and L-3,4-dihydroxyphenylalanine in a dose-dependent manner.[13,14] On the basis of these findings, GSH has been used as a supplement for skin whitening and improvement of liver function.

GSH supplementation has been prevalent worldwide. However, bioavailability and the metabolic fate of orally administered GSH have not been fully understood. It has been proposed that GSH is first degraded by γ-glutamyl transferase into γ-glutamyl-X (X = other amino acids) and cysteinyl-glycine. The cysteinyl-glycine is degraded into cysteine and glycine by peptidases.[6,15] Orally administered GSH could be degraded in this system. In addition, some human studies have demonstrated no significant increases in blood GSH levels in human volunteers after the oral administration of a relatively large dose of GSH.[16,17] These findings suggest that GSH supplementation has no impact on blood and organ GSH levels. However, GSH can potentially bind to proteins by disulfide bonds. Therefore, it is possible that orally administered GSH may be present and transported as a protein-bound form in the blood, and this has not been reported in previous studies.

The objective of the present study was to elucidate the impact of GSH supplementation on human blood GSH levels in the free and protein-bound forms.

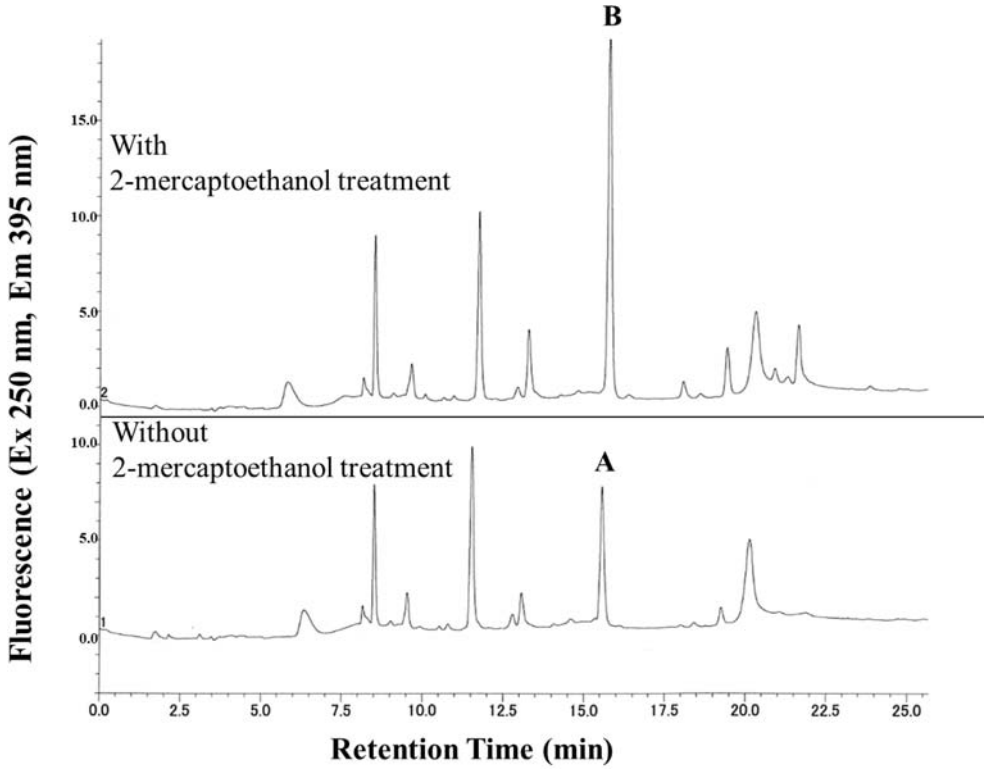

Figure 1. Elution profiles of the 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (AccQ) derivatives of 2-mercaptoethanol-pretreated or intact glutathione (GSH). Pretreated and intact GSH was dried in the presence of triethylamine (TEA) before derivatization with AccQ. Peaks marked A and B show GSH derivatives.

MATERIALS AND METHODS

Chemicals. The reduced form of L-glutathione was produced by fermentation with Torula yeast by KOHJIN Life Sciences, a subsidiary of Mitsubishi Corp. (Tokyo, Japan). This product has been qualified for Generally Recognized As Safe status by the U.S. Food and Drug Administration (U.S. FDA GRAS notified GRN000293). γ-L-Glutamyl-L-cysteine (γGlu-Cys) and L-cysteinyl-glycine (Cys-Gly) were obtained from Sigma-Aldrich (St. Louis, MO, USA). An amino acid labeling kit (AccQ Tag) that consisted of 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate reagent (AccQ), acetonitrile, and 0.2 mM sodium borate buffer, pH 8.8, was purchased from Waters (Milford, MA, USA). Acetonitrile [high-performance liquid chromatography (HPLC) grade], triethylamine (TEA), formic acid, trichloroacetic acid (TCA), and 2-mercaptoethanol were obtained from Wako Pure Chemicals (Osaka, Japan). All other reagents were of analytical grade or higher.

Clinical Study Design. The experimental protocol was submitted to and approved by the experimental ethical committees of Kyoto Prefectural University (KPU no. 63) and KOHJIN Life Sciences. The human studies were performed according to the Helsinki Declaration and were under the control of medical doctors. The potential risks of the ingestion of GSH and the objective of the present study were revealed to the volunteers. After careful reading of a consent form, all subjects signed it. Seven healthy male subjects (mean age ± standard deviation 39.8 ± 15.1 years) were fasted for 12 h before the experiment and given the reduced form of L-glutathione at 50 mg/kg body weight and 100 mL of water, which was the same dose as used in the previous study.[17] Approximately 10 mL of venous blood was collected in the presence of heparin from the cubital vein before and 15, 30, 60, 90, and 120 min after ingestion.

Preparation of Blood Samples. One milliliter of the blood was centrifuged at 3700*g* for 5 min to prepare the plasma and blood cell fractions. Four hundred microliters of the plasma was mixed with 1.2 mL of ethanol and then centrifuged at 3700*g* for 5 min. Then, the supernatant was collected. Aliquots of the supernatant (300 μL) were dried under vacuum and added to 100 μL of 5% TCA containing 2% 2-mercaptoethanol, and the mixture was allowed to stand for 30 min at room temperature and used as the deproteinized plasma fraction in the following experiments. The ethanol precipitate of the plasma was washed with 200 μL of 75% (v/v) ethanol and then mixed with 160 μL of 10% (w/v) TCA and stirred vigorously. To this suspension were added another 320 μL of 5% (w/v) TCA and 10 μL of 10% (v/v) 2-mercaptoethanol. The mixture was allowed to stand for 30 min at room temperature and then centrifuged at 14800*g* for 5 min. The supernatant was collected and used as the protein-bound plasma fraction. The blood cell from 1 mL of blood was mixed with 500 μL of 10% TCA and 1 mL of 5% TCA and stirred for 3 min. The supernatant was collected after centrifugation at 14800*g* for 5 min. Fifty microliters of the 5% TCA extract of the blood cell was mixed with 450 μL of 5% TCA containing 2% 2-mercaptoethanol and allowed to stand for 30 min at room temperature and used as the blood cell fraction.

The weights of the blood cell and plasma ethanol precipitate were determined before the addition of TCA solutions. The samples were stored at −80 °C until use.

Derivatization of GSH with the AccQ Reagent. The reduced form of GSH was dissolved in 10 mM HCl to result in 2.5 μmol/mL and used as a stock solution. Suitable amounts of the standard stock solution were dried under vacuum in a glass tube (50 mm × 6 mm i.d.) with a KLV-CC-105 centrifugal concentrator (Tomy, Tokyo, Japan). Fifty microliters of 5% TCA containing 2% 2-mercaptoethanol was added to the tube and allowed to stand for 30 min, and the solution was then dried under vacuum in a hydrolysis/derivatization vial with a resealable valve (Waters). Twenty microliters of an alkaline solution, which consisted of methanol, water, and TEA at a ratio of 7:1:2 (v/v), was added to the tube, and the mixture was then dried under vacuum to increase the pH for derivatization with AccQ. In some cases, this treatment was deleted from the protocol. The dried standards were resolved in 20 μL of 20 mM HCl, and 20 μL of AccQ reagent and 60 μL of borate buffer were added in the AccQ Tag Kit and reacted at 50 °C for 10 min. The resultant AccQ derivatives were

dx.doi.org/10.1021/jf501338z | J. Agric. Food Chem. 2014, 62, 6183−6189

diluted with 5 mM sodium phosphate buffer, pH 7.4, containing 10% (v/v) acetonitrile. The solutions were filtered through a 0.45 μm filter (column guard LCR4; Millipore, Billerica, MA, USA).

Fifty microliters of the plasma deproteinized and protein-bound fractions and blood cell fraction were also dried under vacuum in the presence of TEA and then derivatized with AccQ, as described above.

Isolation of the AccQ Derivatives. The AccQ derivatives of GSH with and without 5% TCA−2% 2-mercaptoethanol and TEA pretreatments were isolated by reversed phase HPLC (RP-HPLC) with an Inertsil ODS-3 (4.6 mm i.d. × 250 mm, GL Sciences, Tokyo, Japan). Elution was performed with a binary gradient system with 0.1% formic acid (solvent A) and 60% (v/v) acetonitrile (solvent B). The gradient profile was as follows: 0−1 min, 5−10% B; 1−10 min, 10−20% B; 10−25 min, 20−40% B; 25−30 min, 40−45% B; 30−35 min, 45−50% B; 35−40 min, 50−100% B; 40−45 min, 100% B; 45−45.1 min, 100−5% B; and 45.1−55 min, 5% B. The column was equilibrated with 5% B at 1 mL/min. The column was maintained at 45 °C, and elution was monitored by fluorescence at 395 nm that was excited at 250 nm.

Mass Spectrometry Analysis. The isolated AccQ derivatives of GSH were analyzed by electrospray ionization ion trap mass spectrometry (ESI-MS) with an LCQ (Thermo Fisher Scientific, Waltham, MA, USA). The sample was delivered to the ion source by a syringe pump at 3 μL/min. Detection was conducted in positive mode and optimized and processed by Xcalibur version 2.07 (Thermo Fisher Scientific).

Determination of GSH by Liquid Chromatography−Tandem Mass Spectrometry (LC-MS/MS). The concentrations of GSH, γGlu-Cys, and Cys-Gly in the blood samples were determined by precolumn derivatization with AccQ that was followed by an LC-MS/MS analysis with a Q-TRAP 3200 (AB SCIEX, Framingham, MA, USA). The AccQ derivative was prepared as described above and clarified by passing through a filter (0.45 μm column guard; Millipore). The samples (10 μL) were injected onto an Inertsil ODS-3 column (2.1 mm i.d. × 250 mm; GL Sciences), and a binary gradient elution was performed with 0.1% formic acid (solvent A) and 60% acetonitrile (solvent B) at a flow rate of 0.2 mL/min. The column was equilibrated with 100% solvent A, and the gradient profile was as follows: 0−15 min, 0−50% B; 15−20 min, 50−100% B; 20−24 min, 100% B; 24−24.1 min, 100−0% B; and 24.1−30 min, 0% B. The column was maintained at 40 °C throughout. The multireaction monitoring (MRM) condition was optimized in positive mode with Analyst version 4.2 (AB SCIEX) in autoselect mode.

Statistics. Differences between the means were evaluated by analyses of variance (ANOVA) that were followed by one-way ANOVAs with StatView 4.11 (Abacus Concepts, Berkeley, CA, USA). Significant differences between the groups were evaluated by Scheffe's post hoc test.

RESULTS

Structures of the AccQ Derivatives. The AccQ derivatives of GSH, which had been pretreated with or without the 5% TCA−2% 2-mercaptoethanol solution, were resolved by RP-HPLC. In both cases, the GSH was pretreated by TEA before derivatization with AccQ. As shown in Figure 1, several peaks of fluorescence were observed. When different amounts of GSH were derivatized, only the peaks marked A and B changed in a dose-dependent manner, which indicated that these peaks corresponded to AccQ−GSH derivatives and that the other ones were reagent peaks. The derivative that had been pretreated without 2-mercaptoethanol (A) showed a similar but slightly different retention time and a smaller peak area compared to the counterpart (B). These peaks were collected and subjected to an ESI-MS analysis. As shown in Figure 2A, the AccQ derivative without 2-mercaptoethanol pretreatment showed a main peak with a m/z of 477 (full scan). A zoom scan analysis revealed that the difference in m/z between the adjacent isotopes was 0.5, which indicated that the charge

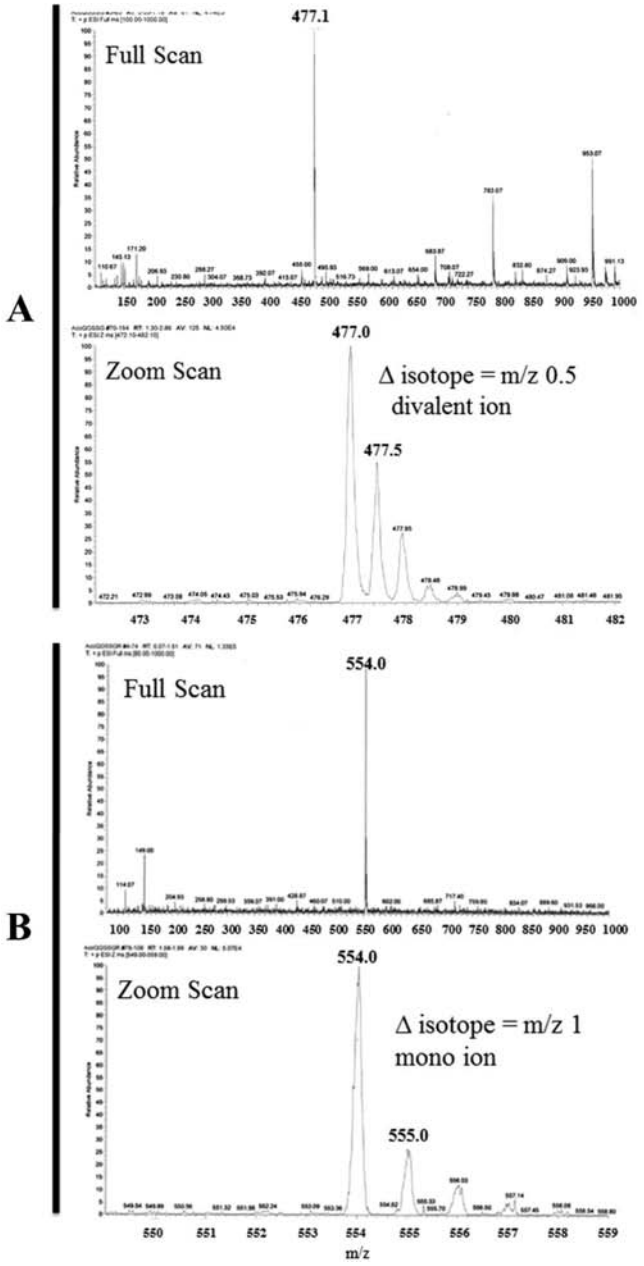

Figure 2. Mass spectrometry analyses of the GSH derivative that had been prepared without (A) and with (B) 2-mercaptoethanol pretreatment. Peaks marked A and B in Figure 1 were collected and analyzed by electrospray ionization (ESI) ion trap MS. The upper and lower panels represent full and zoom scan spectra, respectively.

number was 2. Assuming that this derivative had two protons, its molecular weight (x_1) can be calculated with the following formula: $(x_1 + 2)/2 = 477$, $x_1 = 952$. This value coincided with the molecular weight of the oxidized form of GSH that was coupled with two AccQ molecules through two amino groups, as shown in Figure 3A. However, the AccQ derivative with 2-mercaptoethanol pretreatment showed a main peak with a m/z of 554 (Figure 2B). The difference in m/z between the adjacent isotopes was 1.0. Then, its molecular weight (x_2) can be calculated as follows: $(x_2 + 1)/1 = 554$, $x_2 = 553$. This value did not coincide with the reduced form of AccQ-GSH that was conjugated through an amino group, but it corresponded to the AccQ−GSH−2-mercaptoethanol conjugate through an amino

dx.doi.org/10.1021/jf501338z | J. Agric. Food Chem. 2014, 62, 6183−6189

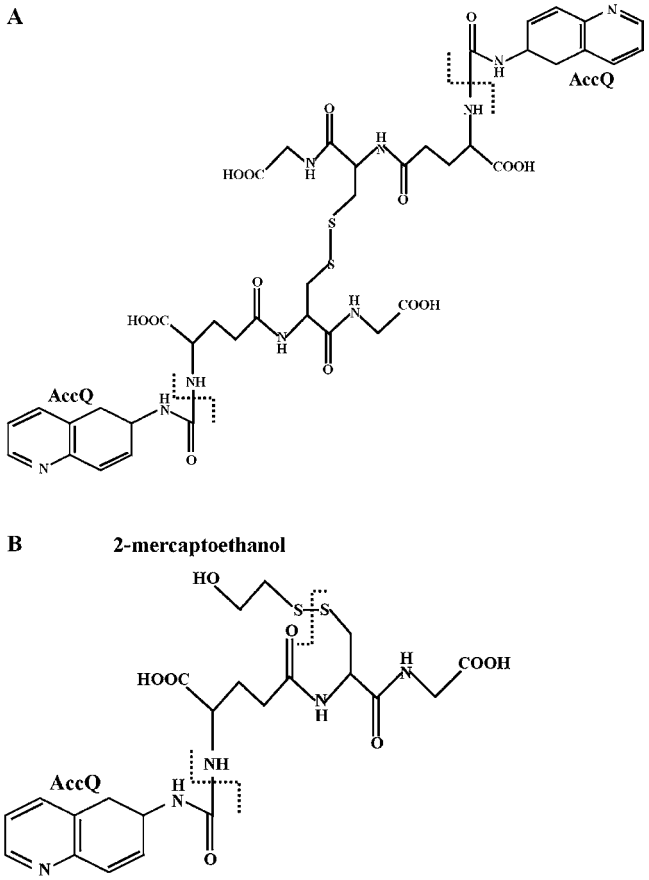

Figure 3. Estimated chemical structures of GSH derivatives that were prepared without (A) and with 2-mercaptoethanol pretreatment (B).

group and a sulfhydryl group, respectively, as shown in Figure 3B. The other peaks in Figure 1 could not be assigned to GSH derivatives, such as the AccQ−GSH conjugate with a free sulfhydryl group and the AccQ−GSH−AccQ conjugate through an amino and a sulfhydryl group. For preparation of these derivatives, the 5% TCA−2% 2-mercaptoethanol solution was removed by vacuum in the presence of TEA before reaction with the AccQ reagent. When this drying treatment with TEA was deleted, a similar chromatogram was obtained (Figure 4, upper) with a larger peak of the derivative (C) compared to the derivative with the drying treatment (A). The ESI-MS analysis of the derivative without the drying treatment with TEA (peak C) showed no significant peak of m/z 554, which was the protonated ion of the AccQ−GSH−2-mercaptoethanol conjugate (Figures 2B and 3B). However, two main peaks with m/z 171 and 249 were observed, and these corresponded to the AccQ fragment ion and the AccQ−2-mercaptoethanol protonated ion, respectively. These results indicated that the amino group of GSH was dissociated to the $-NH_3^+$ ion in the presence of a strong acid (TCA) and that it then could not react with the AccQ reagent. However, an excess amount of 2-mercaptoethanol reacted with AccQ through the sulfhydryl group under this condition. Therefore, the drying treatment with TEA was critical for the derivatization of GSH when the sample was pretreated with 5% TCA−2% 2-mercaptoethanol to liberate the protein-bound GSH.

On the basis of these findings, all of the blood samples were pretreated with 5% TCA−2% 2-mercaptoethanol, which was followed by the drying treatment with TEA before derivatization with AccQ for the determination of GSH by LC-MS/MS in the MRM mode. The fragment ions with the first and second high intensities (m/z 554.1 → 171.3 and m/z 554.1 → 145.2) were automatically selected.

Blood GSH Levels. Figure 5a shows the GSH contents in the deproteinized fraction of plasma before and after the ingestion of GSH. There was no significant difference in the GSH contents after the ingestion of GSH in this fraction. Much higher contents of GSH were contained in the blood cell fraction than in the deproteinized fraction of the plasma (Figure 5b). However, no significant difference was observed in the GSH contents in the blood cell fraction during the experimental period. However, the contents of GSH, γGlu-Cys, and Cys-Gly in the protein-bound fraction of plasma significantly increased 60−120 min after the supplementation of GSH (Figure 6). The protein-bound GSH and related compounds in plasma did not return to the initial level 2 h after supplementation.

DISCUSSION

GSH is present in high concentrations in liver and blood cells.[3,18] Generally, GSH concentrations have been determined in such samples with Ellman's reagent, which contains 5,5′-dithiobis(2-nitrobenzoic acid). To increase sensitivity, an enzyme recycling reaction using GSH reductase has been developed.[19,20] The GSH content in the blood cells, hepatic tissues, and other tissues has been determined with these methods. Allen et al. have reported that oral GSH supplementation did not improve blood cell GSH levels.[16] However, plasma GSH levels are lower (low μM levels) than those in blood cells. The plasma GSH levels have been determined by RP-HPLC with the precolumn derivatization of the sulfhydryl group or the enzyme recycling reaction method. Witschi et al. have observed no increase in plasma GSH levels after a single oral supplementation of GSH to healthy human volunteers at 0.15 mmol/kg body weight.[17] The present study confirmed these results (Figure 5). On the basis of these results, it has been suggested that the oral supplementation of GSH does not affect blood GSH levels.

It has been demonstrated that plasma proteins, including albumin, can bind to low molecular weight thiol compounds through a disulfide bond.[21,22] Therefore, there is the possibility that supplemented GSH may be transported as a conjugate of protein in the blood, and this has not been examined. In the present study, the effects of the supplementation of GSH on plasma protein-bound GSH levels were examined. To liberate GSH from protein conjugate, a reducing reagent is necessary. For this purpose, dithiothreitol has been frequently used,[23,24] but it is incompatible with the enzyme recycling reaction method. The dithiothreitol also reacts with labeling reagents for sulfhydryl and amino groups, which can interfere with the precolumn labeling reaction. In the present study, 2-mercaptoethanol was used to liberate GSH from the conjugates. The excess amount of 2-mercaptoethanol can be removed by vacuum in the presence of TEA. This drying treatment is, therefore, indispensable in the reaction between AccQ and an amino group of GSH. The final GSH derivative was double conjugated with AccQ and 2-mercaptoethanol through amino and sulfhydryl groups, respectively. As the final GSH derivative had no free sulfhydryl groups, it could not be oxidized to form a disulfide bond. A single GSH derivative was obtained, as shown by the MS analysis of the derivative peaks

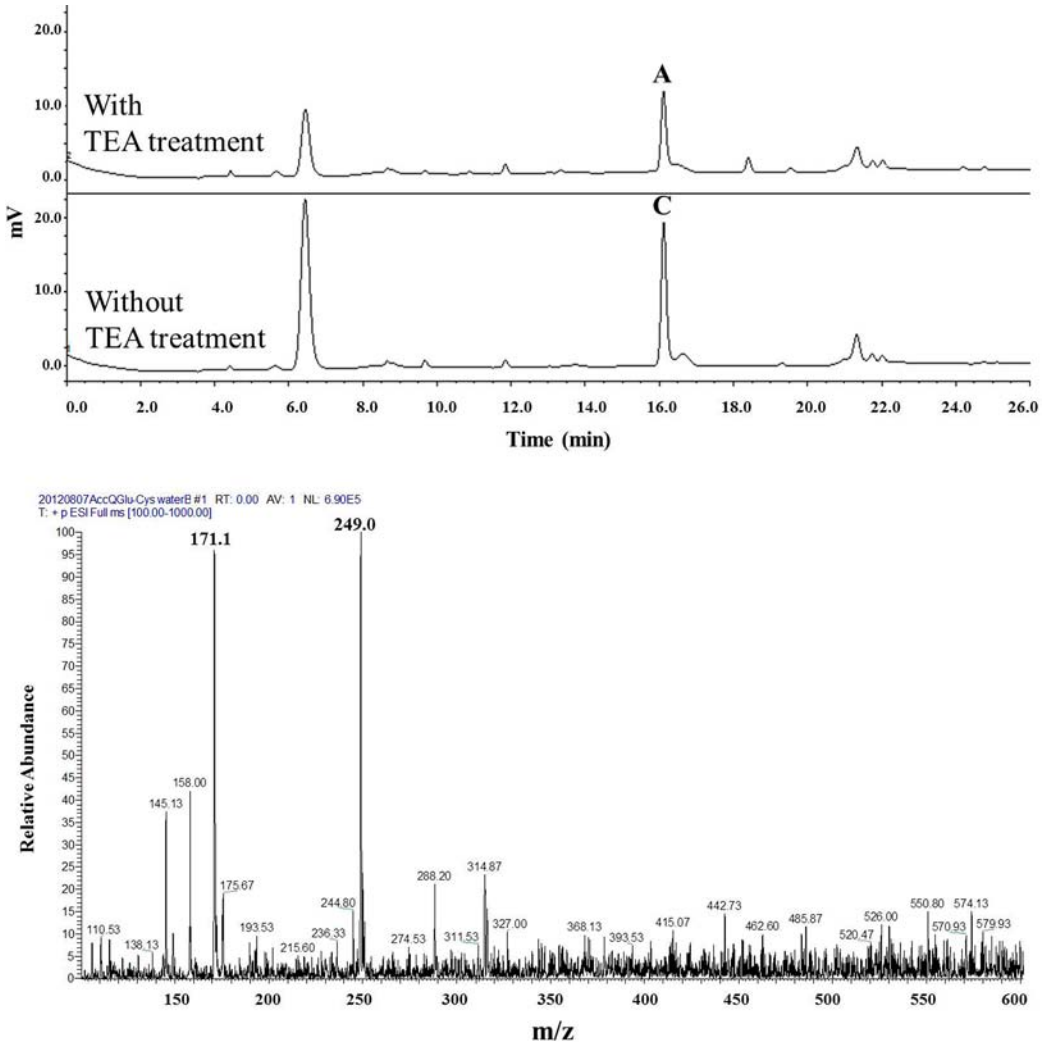

Figure 4. Effects of the drying pretreatment with TEA on the derivatization of 2-mercaptoethanol-pretreated GSH with AccQ: elution profiles of the derivatives with and without the TEA treatment (upper); ESI-MS analysis of the derivative without TEA treatment (lower).

(Figure 1). The GSH derivative could be resolved by RP-HPLC and detected by fluorescence. Other derivatives of thiol compounds, such as γGlu-Cy and Cys-Gly, however, show similar retention times (data not shown). These peaks may interfere with the determination of GSH by fluorescence detection.

Therefore, the MRM was used for the specific detection of the GSH and its fragment peptides (γGlu-Cys, Cys-Gly) by monitoring m/z 554 → 171.3 and m/z 554 → 145.2 (GSH), m/z 497 → 171.3 and m/z 497 → 145.2 (γGlu-Cys), and m/z 425 → 171.2 and m/z 425 → 116.1 (Cys-Gly), respectively, in the present study. By using this method, protein-bound GSH and its fragment peptides at a concentration of <1 μM in the plasma could be successfully determined.

Ikegaya et al. have demonstrated that cysteine and cysteinyl-glycine bind to human serum albumins through disulfide bonds, whereas no significant amount of GSH is bound to serum albumin that is obtained from human blood.[22] The present study also demonstrated that only a negligible amount of GSH was bound to plasma protein before the supplementation of GSH. However, the protein-bound GSH significantly (P < 0.01) increased from 60 to 120 min after the oral supplementation of GSH. This is the first report to demonstrate an increase in GSH in the human blood fraction by the oral supplementation of GSH. The protein-bound form GSH level in plasma after supplementation of GSH is much higher (>1000 times) than that of other food-derived peptides such as Val-Tyr[25] and Ile-Pro-Pro[26] but less than that of the food-derived collagen peptides in human blood.[27]

It has been thought that orally administered GSH is successively degraded to cysteinyl-glycine, cysteine, and glycine by γ-glutamyl-transferase and peptidase.[17,28,29] Cysteine could be used for GSH synthesis in cells. Increased levels of protein-bound GSH might be derived from the newly synthesized GSH. The present study also detected fragment peptide (Cys-Gly) and precursor peptide (γGlu-Cys) as protein-bound forms in human blood, which suggests some GSH is synthesized from degradation products of GSH.

However, an early study by Kubo that used ^{35}S-labeled GSH and paper electrophoresis has suggested that GSH could be directly absorbed from the small intestine into rat portal blood.[30] Therefore, there is a possibility that supplemented GSH is directly absorbed into human blood and bound to plasma protein. To solve these problems, further studies on the metabolic fate of supplemented GSH that use ^{13}C-labeled GSH are in progress. The procedure that was used in the present study for the determination of protein-bound GSH that was based on LC-MS/MS and precolumn label techniques can

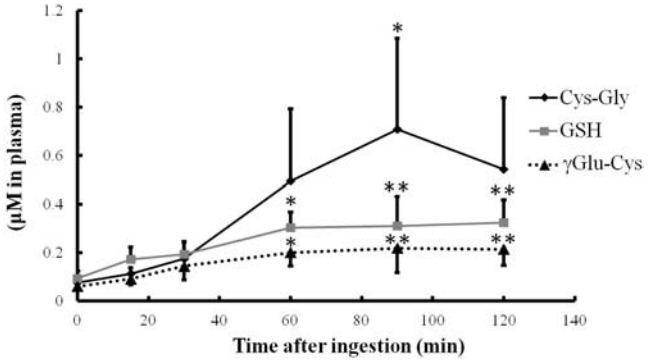

Figure 6. Contents of glutathione (GSH), γ-glutamyl-cysteine (γGlu-Cys), and cysteinyl-glycine (Cys-Gly) in the ethanol precipitate fraction of plasma after ingestion of GSH. (*, **) Significantly different from baseline P < 0.05 and 0.01, respectively, according to Scheffe's post hoc test.

distinguish food-derived (^{13}C-labeled) and endogenous GSH and their metabolites, such as γGlu-Cys, Cys-Gly, and cysteine, and this is a powerful tool for the elucidation of the absorption, metabolism, and transportation of food-derived GSH.

ABSTRACT: Olive leaves are rich in bioactive compounds, which are beneficial for humans. The objective of this work was to assess the influence of processing conditions (drying and extraction) of olive leaves on the extract's bioaccessibility. Thus, extracts obtained from dried olive leaves (hot air drying at 70 and 120 °C or freeze-drying) by means of conventional or ultrasound-assisted extraction were subjected to in vitro digestion. Antioxidant capacity, total phenolic content, and HPLC-DAD/MS/MS analysis were carried out during digestion. The dehydration treatment used for the olive leaves did not have a meaningful influence on bioaccessibility. The digestion process significantly ($p < 0.05$) affected the composition of the extracts. Oleuropein and verbascoside were quite resistant to gastric digestion but were largely degraded in the intestinal phase. Nevertheless, luteolin-7-*O*-glucoside was the most stable polyphenol during the in vitro simulation (43% bioaccessibility). Therefore, this compound may be taken into consideration in further studies that focus on the bioactivity of olive leaf extracts.

KEYWORDS: *Olea europaea, drying, in vitro digestion, antioxidant potential, byproduct*

INTRODUCTION

Although olives (*Olea europaea* L.) are cultivated in several parts of the world, the Mediterranean region is the major crop production area, accounting for about 98% of the world's olive cultivation.[1] Olive hydrophilic extracts contain a large number of phenolic compounds.[2] The most important source of these polyphenolic compounds is the olive fruit; however, they are also present in the leaves.[3] The most abundant polyphenols identified in olive leaf extracts have been oleuropein, hydroxytyrosol, verbascoside, apigenin-7-glucoside, and luteolin-7-glucoside.[4] These compounds confer bioactive properties on the olive leaf extracts, such as antioxidant,[4] antimicrobial,[5] and antitumor capacities.[6] Moreover, they are able to reduce the risk of coronary heart disease.[7]

Not only do olive leaves appear as a byproduct during oil processing in the olive oil industries (10% of the total weight of the olives), they are also a residue of olive tree pruning.[8] Despite the aforementioned bioactive potential of olive leaves, the large volumes generated of this byproduct have been traditionally used as animal feed.[9] The exploitation of olive leaves as a natural resource rich in antioxidant phenolic compounds would involve the valorization of this byproduct. However, it is essential to determine if the leaf processing (drying and extraction methods) used to obtain the extracts can affect not only the antioxidant potential but also the stability necessary for later applications. Hot air and freeze-drying are common dehydration techniques used in the food, chemical, and pharmaceutical industries. Nevertheless, although both methods reduce the water content of the raw material, improving the polyphenol extraction, the extracts obtained exhibit different compositions,[10] and their degree of stability could also vary. Moreover, the stability of extracts obtained by conventional maceration could also be different from those obtained by the use of new, emerging extraction technologies, such as ultrasound-assisted or supercritical CO_2 extraction. In the case of ultrasound (US), although its ability to speed the extraction process has already been stated, it is also well-known that it induces the formation of free radicals,[11] which even at low concentrations could affect extract behavior.

The aforementioned facts, together with the scarce amount of knowledge about the stability and behavior of olive leaf phenolic compounds under digestion conditions, open up a new line of research in the area of antioxidant extracts and their possible applications as natural remedies. Thus, to use the olive leaf polyphenols for the benefit of human health, it is important not only to extract and quantify these bioactive compounds but also to study their bioaccessibility. This term is defined as the amount of an ingested compound that is available for absorption in the gut after digestion.[12] Nowadays, there are two possible methods for the evaluation of the behavior of bioactive compounds during the digestive processes: in vivo and in vitro. On the one hand, in vivo methods simulate the digestion better, but are complex, expensive, and lengthy,[13] and the control of the process variables is complicated. On the other hand, in vitro digestion models simulate the release of compounds from the food matrix[14] and the gastrointestinal conditions, are relatively inexpensive, are technically simple,[13,15]

and allow for the accurate testing of several process variables. Moreover, considering that there exist some host-related factors, such as intestinal factors, gender, age, disorders, or physiological conditions which could influence bioaccessibility,[16] in vitro methods seem to be a suitable alternative to obtain proper simulation data. In fact, they are considered a proper alternative to animal experimentation by the European Directive on the protection of animals (2010/63/UE).[17]

Even so, the bioaccessibility study is a challenge because, apart from human factors, there are external, food, or processing factors that could affect bioactive compounds. Thus, there is ample evidence that the physical state of the matrix plays a key role in the release, mass transfer, accessibility, and biochemical stability of many food components.[18] Hence, nutrients located in natural cellular compartments or within assemblies produced during processing need to be released during digestion so they can be absorbed in the gut.[19] Therefore, removing the handicap of structural barriers could facilitate the extraction of the components and, consequently, it would improve their bioaccessibility. In this sense, obtaining extracts rich in bioactive compounds could be a suitable alternative.

The objective of this work was to assess the influence of the processing conditions (drying and extraction) of olive leaves on the bioaccessibility of the extracts. The study aims to evaluate not only the compositional but also the kinetic changes that take place in the extracts during in vitro gastrointestinal digestion.

MATERIALS AND METHODS

Olive Leaf Extracts. Olive leaf extracts were obtained from leaves (*O. europaea* var. Serrana) dried by following two different methods described in previous works:[10] hot air drying at 70 °C (HAD-70) and 120 °C (HAD-120) and freeze-drying using conventional freezing at −28 °C (FD).

The extraction of olive leaf phenolic compounds was carried out by using conventional[10] and US-assisted extraction.[20] Briefly, extractions were performed at 25 °C using milled olive leaves (Blixer 2, Robot Coupe USA, Inc., Jackson, MS, USA) and an 80:20 (v/v) ethanol/water solution as solvent (extracting medium). The ratio between the weight of olive leaves and the solvent volume used was different depending on the method: 0.125 and 0.031 g/mL for conventional and US-assisted extraction, respectively. In the ultrasonic experiments, the ultrasonic emitter, with a surface of 12.6 cm^2, was immersed 1 cm into the solution, and 100% electric power of the system (400 W) was supplied to the transducer. The extracts obtained were centrifuged for 10 min at 5000 rpm (Medifriger BL-S, J.P. Selecta, Barcelona, Spain), filtered (nylon filters of 0.45 μm), and stored in opaque vials at 4 °C until used. Thus, combining the drying (FD, HAD-70, and HAD-120) and the extraction methods (conventional or US-assisted), a total of four different extracts were obtained: FD, HAD-70, HAD-120, and HAD-120+US. At least three extraction replicates were made for each different processing condition.

Polyphenolic Standard Solutions. Standard solutions of the main polyphenols found in the olive leaf extracts were prepared in distilled water. Concentrations of the standard solutions were similar to the concentration (mg compounds/mL extract) of the polyphenols in the olive leaf extracts. The standard polyphenols used are described in the following sections.

In Vitro Digestion. In vitro digestion was simulated using a slightly modified version of previously described methods.[21,22] Ten grams of sample (olive leaf extract, polyphenolic standards solution, or blank) was diluted with distilled water (1:8, p/v) and acidified to pH 2.0 using 6 N HCl under vigorous stirring. The acidified sample was stirred for 15 min. Then, the pH value was checked and eventually corrected if necessary with 6 N HCl. The extract sample was then mixed with 3 mL of a solution (160 mg/mL) of pepsin from pig gastric mucosa (Sigma Chemical Co., 3.8 units/mg protein) in 0.1 N HCl. Subsequently, distilled water was added to reach a final volume of 100 mL. The mixture was stirred for 2 h at 37 °C. After gastric digestion, the pH of the digesta was increased to pH 5 with 0.9 M $NaHCO_3$, and 22.54 mL of pancreatin−bile solution (pancreatin 4 mg/mL, bile 25 mg/mL in 0.1 M $NaHCO_3$) was added. Then, to complete the intestinal digestion, the pH was increased to 7.0 with 0.1 M $NaHCO_3$, and the mixture was stirred for 2 h at 37 °C.

The digestion simulation was carried out in sealed containers protected from light and placed in an orbital incubator (Rotabit, J. P Selecta, Barcelona, Spain) at 120 rpm. To monitor the changes undergone by extracts during in vitro digestion, samples of 2 mL were taken at preset times (0, 1, 2, 3, and 4 h). All samples were immediately cooled and filtered (nylon filters of 0.45 μm), stored in opaque vials at 4 °C, and analyzed within 24 h. At least three digestion replicates were made for each different olive leaf extract.

Total Phenolic Content (TPC) Measurement. The phenolic content was determined by the Folin−Ciocalteu method.[23] Briefly, 100 μL of sample or blank was mixed with 200 μL of Folin−Ciocalteu's phenol reagent (Sigma-Aldrich, Madrid, Spain) and 2 mL of distilled water. After 3 min at 25 °C, 1 mL of Na_2CO_3 (Panreac, Barcelona, Spain) solution (Na_2CO_3/water 20:80, w/v) was added to the mixture. The reaction was kept in the dark at room temperature for 1 h. Finally, the absorbance was read at 765 nm using a spectrophotometer (Helios Gamma, Thermo Spectronic, Cambridge, UK). The measurements were carried out in triplicate, unless otherwise stated. The standard curve was previously prepared using solutions of a known concentration of gallic acid hydrate (Sigma-Aldrich) in water and ethanol/water (80:20, v/v). Results were expressed as milligrams of gallic acid (GAE) per gram of dry weight of olive leaves (g dw) or in the case of the standards as milligrams of gallic acid (GAE) per gram of compound.

Antioxidant Capacity (AC) Measurement. *Ferric Reducing Ability Power (FRAP).* The FRAP method, which is a simple method used to estimate the reduction of a ferric−tripyridyltriazine complex, was applied[24] with some modifications. Briefly, 900 μL of freshly prepared FRAP reagent was mixed with 30 μL of distilled water and 30 μL of test sample or blank and kept at 37 °C for 30 min. The FRAP reagent contained 2.5 mL of a 10 mM TPTZ (Fluka, Steinheim, Germany) solution in 40 mM HCl (Panreac, Barcelona, Spain) plus 2.5 mL of 20 mM $FeCl_3 \cdot 6H_2O$ (Panreac) and 2.5 mL of 0.3 M acetate buffer (Panreac), pH 3.6.[25] Readings at the maximum absorption level (595 nm) were taken using a spectrophotometer (Helios Gamma, Thermo Spectronic). Four replicates were made for each measurement. The antioxidant capacity was evaluated through a calibration curve, which was previously determined using water and ethanol solutions (ethanol/water 80:20, v/v) of known Trolox (Sigma-Aldrich) concentrations and expressed as milligrams of Trolox per gram of dry weight of olive leaves (g dw) or in the case of the standards as milligrams of Trolox per gram of compound.

Trolox Equivalent Antioxidant Capacity (TEAC). The TEAC method, which measures the reduction of the radical cation of ABTS by antioxidants, was performed.[26] Briefly, ABTS radical cation ($ABTS^{\bullet+}$) was produced by reacting ABTS (Sigma-Aldrich) stock solution with 2.45 mM potassium persulfate (final concentration) and allowing the mixture to stay in the dark at room temperature for 12−24 h before use. The $ABTS^{\bullet+}$ solution was diluted with distilled water until an absorbance value of 0.714 ± 0.02 at 734 nm was reached. For the photometric assay, the absorbance of 200 μL of the $ABTS^{\bullet+}$ solution or blank was measured (Spectrostar Omega, BMG Labtech, Offenburg, Germany). Afterward, 20 μL of the antioxidant extract or blank (water or ethanol/water 80:20, v/v) was added and, after 29 min at 734 nm, the final absorbance was measured (Spectrostar Omega, BMG Labtech). The antioxidant capacity was determined from the difference of absorbance, using a Trolox calibration curve (Sigma-Aldrich). Four replicates were made for each extract. The antioxidant capacity results were expressed as milligrams of Trolox per gram of dry weight of olive leaves (g dw) or in the case of the standards as milligrams of Trolox per gram of compound.

Table 1. Content (Milligrams per Gram Dry Weight) of the Main Identified Polyphenols and Antioxidant Activity of Olive Leaf Extracts

	initial extracts[a]			
extract characterization	HAD-70	HAD-120	FD	HAD-120+US
TPC (mg GAE/g dw)	42 ± 4 a	66 ± 3 b	33 ± 3 a	66 ± 9 b

Identification and Quantification of Polyphenols by HPLC-DAD/MS-MS. To identify and quantify the main polyphenols, olive leaf extracts were analyzed using an HPLC instrument (Agilent LC 1100 series; Agilent Technologies, Inc., Palo Alto, CA, USA) controlled by Chemstation software. The HPLC instrument was coupled to an Esquire 3000+ (Bruker Daltonics, GmbH, Bremen, Germany) mass spectrometer equipped with an ESI source and ion-trap mass analyzer and controlled by Esquire control and data analysis software. A Merck Lichrospher 100RP-18 (5 μm, 250 × 4 mm) column was used for analytical purposes.

Separation was carried out through a linear gradient method using 2.5% acetic acid (A) and acetonitrile (B), starting the sequence with 10% B and programming the gradient to obtain 20% B at 10 min, 40% B at 35 min, 100% B at 40 min, 100% B at 45 min, 10% B at 46 min, and 10% B at 50 min. For the LC-MS pump to perform accurately, 10% of organic solvent was premixed in the water phase. The flow rate was 1 mL/min, and the chromatograms were monitored at 240, 280, and 330 nm. Mass spectrometry operating conditions were optimized to achieve maximum sensitivity values. The ESI source was operated in negative mode to generate $[M - H]^-$ ions using the following conditions: desolvation temperature at 365 °C and vaporizer temperature at 400 °C; dry gas (nitrogen) and nebulizer were set at 12 L/min and 4.83 bar, respectively. The MS data were acquired as full scan mass spectra at m/z 50−1100 by using 200 ms for collection of the ions in the trap.

The main compounds were identified by HPLC-DAD analysis, comparing the retention time, UV spectra, and MS/MS data of the peaks in the samples with those of authentic standards or data reported in the literature. Only the main olive leaf polyphenols were quantified using commercial standards: oleuropein (Extrasynthese, Genay Cedex, France), luteolin-7-*O*-glucoside (Phytolab, Vestenbergsgreuth, Germany), and apigenin (Nutrafur, Murcia, Spain). A verbascoside standard (96.85%) purified from *Lippia citriodora* extract was kindly provided by Universidad Miguel Hernández (Elche, Spain). The quantitative evaluation of the compounds was performed with a calibration curve for each polyphenol, using ethanol (oleuropein) or methanol (verbascoside and luteolin) solutions of known concentration. The polyphenol concentrations were expressed as milligrams of polyphenol per gram of dry weight of olive leaves (g dw) or, in the case of the standards, as milligrams of compound per milliliter of initial solution.

Method accuracy for the determination of oleuropein, verbascoside, and luteolin-glucoside in samples was further assessed with recovery studies by spiking standard compounds into blank samples in triplicate. The linearity range of the responses was determined on seven concentration levels with three injections for each level. Calibration graphs for HPLC were recorded with sample amount ranging from 0.25 μg/mL to 0.25 mg/mL ($r^2 > 0.9999$). Quantitative evaluation of oleuropein, verbascoside, and luteolin-glucoside was performed by means of a six-point regression curve ($r^2 > 0.996$, 0.997, and 0.986, respectively) in a concentration range between 0.25 μg/mL and 10 mg/mL, using oleuropein, verbascoside, and luteolin-glucoside as reference external standard and evaluated by DAD signal. The limit of detection (LOD) was 0.10 μg/mL and the limit of quantification (LOQ), 0.25 μg/mL.

Statistical Analysis. Analysis of variance (ANOVA) was applied to determine the significant effects of in vitro digestion on extract composition taking a significance level of 95%. The statistical analysis was performed using Statgraphics-Plus software 5.1 (Statistical Graphics, Rockville, MD, USA).

RESULTS AND DISCUSSION

Initial Characterization of Olive Leaf Extracts. Previous studies have reported that the composition of olive leaf extracts is greatly influenced by processing conditions, namely, the drying and extraction. In such a way, a conventional extraction method[10] was used with leaves hot air-dried at 70 (HAD-70) and 120 °C (HAD-120) and freeze-dried (FD). Moreover, HAD-120 leaves were subjected to ultrasound-assisted extraction (HAD-120+US).[20]

As can be observed in Table 1, the TPC and AC of the extracts used were significantly ($p < 0.05$) influenced by the olive leaf drying technique, which confirms the previously reported results.[10] It is relevant to highlight that the HAD-120 and FD extracts showed the highest and lowest antioxidant potentials, respectively. With regard to the extraction method, ultrasonically assisted extraction provided extracts (HAD-120+US) with a bioactive content similar to that of the conventional procedure (HAD-120), as already reported.[20] Thus, although US did not involve a change in the initial polyphenolic composition of the extracts, the HAD-120+US extracts were included in the analysis due to the reported ability of US to promote the formation of free radicals.[27] These compounds, even at low concentrations, may induce compositional changes in the gastric/intestinal environment, a fact that has not been previously studied.

To gain insight into the differences in the antioxidant potential of olive leaf extracts, major polyphenolic compounds

peak	phenolic compound	mol mass (g/mol)	retention time (min)
1	caffeoyl	354.31	4.70
2	apigenin-6,8-diglucoside	594.52	9.41
3	verbascoside	624.6	13.85
4	luteolin-7-*O*-rutinoside	578.52	14.57
5	luteolin-7-*O*-glucoside	448.38	15.27
	luteolin-7-*O*-glucoside (isomer)	448.38	18.50
6	oleuropein-glucoside	702	16.45
7	apigenin-rutinoside	578.53	17.11
8	apigenin-7-*O*-glucoside	432.37	18.24
9	oleuropein	540.52	19.02
10	luteolin	286.24	25.50

were identified by HPLC-DAD/MS/MS (Figure 1 and Table 2). A similar phenolic profile was found in all of the extracts, with minor differences. However, significant ($p < 0.05$) differences were found (Table 1) for the concentration of the main polyphenols (verbascoside, oleuropein, luteolin-glucoside). In overall terms, the highest contents of these compounds were correlated with the highest levels of TPC and AC.

Influence of in Vitro Gastrointestinal Digestion on Antioxidant Potential. To simulate the stability of the main identified bioactive polyphenols, in vitro digestions of the olive leaf extracts and polyphenolic pure standards (oleuropein, verbascoside, and luteolin-glucoside) were carried out. During digestion, samples were taken at preset times (0, 1, 2, 3, and 4 h) and the TPC and AC determined.

A significant ($p < 0.05$) decrease in the TPC was observed for all extracts within the first hour of the gastric phase (Figure 2a), thereafter remaining practically constant for the rest of the intestinal digestion. This result indicates that a portion of the

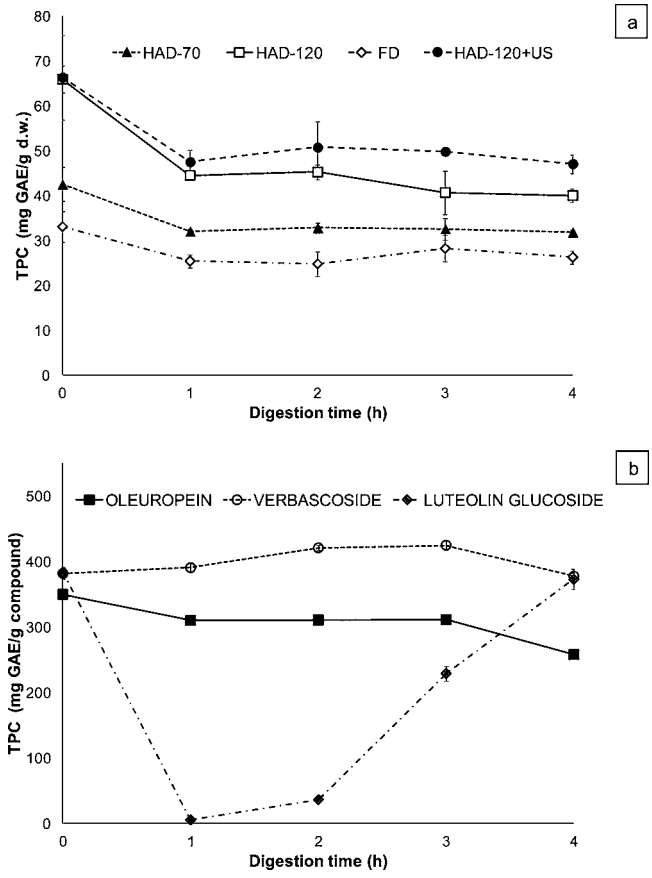

Figure 2. Kinetics of total phenolic content (TPC) during the in vitro digestion of olive leaf extracts (a) and standard compounds (b). Means ± standard deviation are plotted.

bioactive compounds may be degraded in the first steps of the digestion[28] due to the combined effect of the pH changes and

dx.doi.org/10.1021/jf501414h | J. Agric. Food Chem. 2014, 62, 6190−6198

the enzymatic activity, but a significant portion still reached the duodenum. Thus, after the gastric digestion (2 h), the TPC of HAD-120 extracts decreased by 31.4%, whereas the reduction in HAD-70 and FD extracts was smaller (22.9 and 25.1%, respectively). Grape bioaccessible polyphenols have been reported to behave differently during digestion.[29] Thus, after 2 h under gastric conditions, the TPC increased by 21.9% in the liquid fraction. These differences could be ascribed to the nature of the matrix being digested. The bioaccessibility study of grape polyphenols[29] was conducted in solid matrices (grapes); therefore, a release of polyphenols from the solid parts of the grape must take place during digestion. However, in our study, polyphenols were solubilized into the solution and, hence, directly exposed to gastric conditions from the beginning.

The kinetics showed that the intestinal phase, from 2 to 4 h, hardly influenced the TPC, because only slight changes were found (Figure 2a). The global balance of the TPC throughout the digestion showed a decrease of between 20.6% (FD) and 39.3% (HAD-120) when values were compared at 0 and 4 h. Although the HAD-120 extracts exhibited the highest TPC at the beginning of the digestion, they also showed a more significant decrease, indicating that these extracts were less resistant to gastrointestinal conditions. In contrast, FD and HAD-70 processed extracts were less affected by the digestion process.

On the other hand, when conventional and US extraction methods were compared, the US extracts exhibited a smaller reduction of TPC at the end of the in vitro digestion (29% for HAD-120+US and 39% for HAD-120). Consequently, the extraction method would have a significant influence ($p < 0.05$) on the TPC bioaccessibility; ultrasound application would be a good alternative to reduce olive leaf polyphenol extraction time[20] and ensure a better preservation of phenols during digestion.

To determine the contribution of the major compounds present in olive leaf to the TPC evolution under gastric digestion, their individual stability was studied (Figure 2b) by subjecting selected polyphenolic standard solutions to digestion and monitoring the TPC. The behavior observed during the digestion of the standard solutions was quite different compared to that of olive leaf extracts. Whereas oleuropein and verbascoside TPC values remained practically constant throughout the digestion process, the behavior of luteolin-glucoside standard solution was unexpected; that is, it dropped to a value of 0 after 1 h of digestion and increased to initial values after 4 h of digestion. The only reasonable explanation for this fact is that luteolin-glucoside shows a poor solubility or is complexed to proteins in the solutions for gastric digestion, so no TPC values were detected and its solubility recovered at the end of the intestinal digestion. This drop in the TPC of the luteolin-glucoside standard solution could contribute to the TPC reduction of the olive leaf extracts in the first hour of digestion (Figure 2).

The evolution of the AC of the extracts during digestion was determined by using two different methods, FRAP (Figure 3) and TEAC (Figure 4), which yielded different results. Whereas the TEAC kinetics of olive leaf extracts showed a behavior similar to that obtained for TPC (Figures 2a and 4a), the AC evolution measured by the FRAP method behaved totally differently (Figure 3a). The AC methods showed different trends, a fact that was also found in the case of in vitro tested

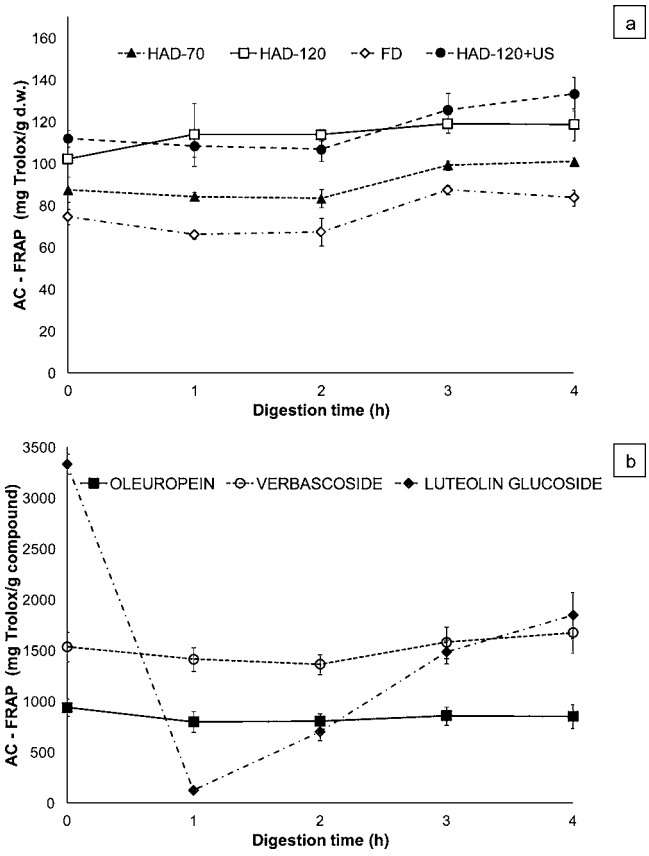

Figure 3. Kinetics of antioxidant capacity (AC) measured by FRAP method during the in vitro digestion of olive leaf extracts (a) and standard solution compounds (b). Means ± standard deviation are plotted.

wholegrain foods[30] and could be explained by the different chemical principles on which both AC methods are based.

The decrease in the TEAC values within the first hour of the extracts' digestion coincided with that observed for the TPC, and it may be related to the degradation of some compounds. We have reported that oleuropein is the major contributor to AC when measured by TEAC,[10] and it is also the most abundant compound in olive leaf extracts. The results of the evolution of the TEAC values for polyphenolic standard solutions under digestion (Figure 4b) also agree with this hypothesis, because the oleuropein and verbascoside TEAC values dropped dramatically after 1 h of digestion. Otherwise, the TEAC values for luteolin-glucoside recovered during intestinal digestion, coinciding with the behavior of the TPC and FRAP values during the same type of digestion (Figures 2b and 3b), indicating that this compound may resist the in vitro digestion process and may be considered for the subsequent intestinal absorption process. This negative impact of the digestion process on the TEAC values of the extracts has also been observed in the in vitro digestion of polyphenols deriving from extra virgin olive oils,[31] so the source of the compounds may not be the reason for this behavior.

However, although the FRAP values of olive leaf extracts remained almost constant during gastric digestion, despite the decrease in TPC and TEAC, a significant increase was observed during the intestinal digestion (Figure 3a). It has been reported that the reaction rates for the radical scavenging capacity of some flavonoids increase in correlation with their anionic

dx.doi.org/10.1021/jf501414h | J. Agric. Food Chem. 2014, 62, 6190−6198

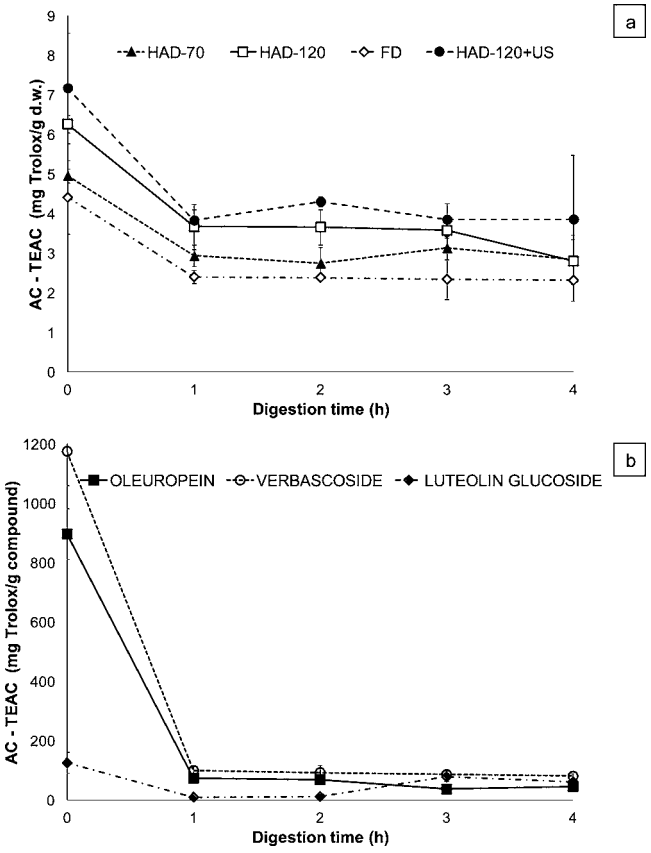

Figure 4. Kinetics of antioxidant capacity (AC) measured by TEAC method during the in vitro digestion of olive leaf extracts (a) and standard compounds (b). Means ± standard deviation are plotted.

character due to their higher electron-donating capacity. We postulate that at least luteolin may contribute to the greater capacity for reducing Fe^{3+} ions during the intestinal digestion process (Figures 3b, 3–4h) due to the fact that less protonation occurs at neutral pH.[32,33] We have previously reported that verbascoside and oleuropein are the main polyphenols contributing to the measurement of the FRAP values in the olive leaf extract.[10] This result would support the steady FRAP values of the extracts throughout the digestion (Figure 3a,b). However, although the luteolin-glucoside in the extracts is much less concentrated, its contribution to the final stages of the digestion process would be significant. Moreover, the formation of polyphenol derivatives during the digestion with enhanced AC, as well as potential synergistic effects among individual olive phenols, could contribute to keep the AC[34] measured by FRAP despite the observed reduction in the TPC.

In general terms, processing conditions did not largely affect the AC kinetic of the extracts during the in vitro digestion. However, as in the case of the TPC, both AC methods confirmed that the US extracts withstood the gastrointestinal digestion slightly better than the conventional extracts.

Considering that AC and TPC are global measurements of the extracts' antioxidant potential and taking into account that the polyphenolic composition may vary throughout the digestion, a more thorough characterization of the extracts was proposed during the digestion process. Hence, the HPLC-DAD/MS/MS was chosen as the most reliable alternative to understand how individual olive leaf polyphenols evolved during in vitro digestion.

Degradation Kinetics of the Individual Olive Leaf Polyphenols during in Vitro Digestion. With the aim of gaining insight into the stability of the major olive leaf polyphenols under gastric and intestinal conditions and to design strategies aimed at increasing their bioaccessibility in the gut, their contents were monitored during the in vitro digestion (0, 1, 2, 3, and 4 h) (Figure 5).

The content of the studied phenolic compounds underwent a significant ($p < 0.05$) decrease during the first hour of the gastric digestion. However, from 1 to 2 h the gastric conditions

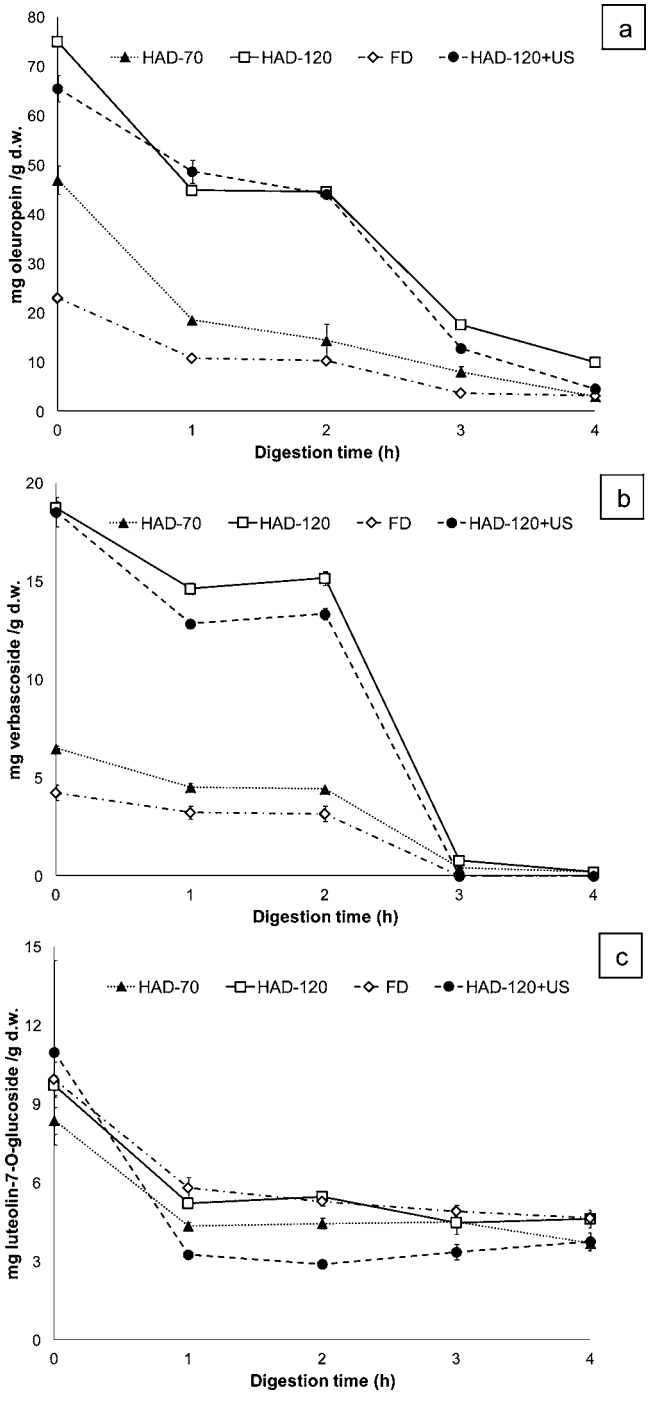

Figure 5. Kinetics of oleuropein (a), verbascoside (b), and luteolin-7-*O*-glucoside (c) content during the in vitro digestion of olive leaf extracts. Means ± standard deviation are plotted.

dx.doi.org/10.1021/jf501414h | J. Agric. Food Chem. 2014, 62, 6190–6198

did not promote significant changes in the polyphenol concentrations and the content of every compound was almost constant. Oleuropein degradations ranged from 26 to 61%, depending on the extract source (Figure 5a). The most resistant oleuropein was the one extracted from HAD-120 leaves by means of US-assisted extraction (HAD-120+US). As far as the verbascoside is concerned (Figure 5b), its degradation during the first hour under gastric conditions ranged from 22 to 31%. Thus, it could be stated that verbascoside was less affected during gastric incubation than oleuropein. The reduction in the luteolin-glucoside content after 1 h of digestion was around 45% for the extracts obtained by conventional extraction (Figure 5c). However, a significantly ($p < 0.05$) greater reduction (63%) was found in the US extract. Dietary polyphenols have been reported to enjoy a good degree of stability during gastric digestion,[28,35,36] including all of the major olive oil phenolics, such as tyrosol, hydroxytytrosol, and related secoiridoids.[13] Our results show that verbascoside is a little more resistant to gastric digestion than oleuropein and luteolin-glucoside.

The intestinal in vitro digestion hardly affected the luteolin-7-*O*-glucoside content (Figure 5c). However, the main part of the verbascoside degradation during in vitro simulation happened under intestinal conditions (Figure 5b), probably due to the fact that it is extremely susceptible at high pH.[37] As a consequence, the verbascoside practically disappeared, with its final content being close to 0 mg/g dw. Although the oleuropein reduction was less marked than that of verbascoside, the intestinal phase affected oleuropein more than the gastric period (Figure 5a). Thus, pancreatic enzymatic activity and alkaline pH contributed to a reduction in the bioaccessibility of oleuropein and verbascoside extracted from olive leaves, and both compounds almost disappeared from the medium. Some authors have also pointed to the possible interaction of pancreatic α-amylase and trypsin with phenolic compounds.[38] Therefore, the study of the degradation kinetics of polyphenols and the polyphenol−protein interactions would allow the bioaccessibility of these bioactive compounds to be improved through the design of pharmaceutical formulations aimed at increasing the amount of these compounds present at the site of intestinal absorption.

Cooked amaranth leaves have been reported to exhibit β-carotene bioaccessibility values of 18%.[39] Compared with this result, the percentage of bioaccessible luteolin-7-*O*-glucoside exhibited by olive leaf extracts was much higher, because 43 ± 6% of its initial content was recovered after digestion. However, only 10 ± 4% of oleuropein resisted the in vitro simulation, and most of the verbascoside practically disappeared in the extracts. Although oleuropein undergoes rapid hydrolysis under gastric conditions and it is rapidly degraded by the colonic microflora, leading to significant increases in the amount of tyrosol and hydroxytyrosol,[40,41] neither of these compounds was found in the HPLC-DAD/MS/MS analysis.

Another set of experiments was carried out to confirm if the stability of the compounds behaved in a similar manner when these were in the extract or in isolated form. Thus, oleuropein, verbascoside, and luteolin-glucoside standard solutions were subjected to complete digestions (Figure 6). Oleuropein and verbascoside solutions were quite resistant to gastric conditions and behaved similarly to the digestions of the extracts (Figure 6a,b). Thus, in both cases, the amount of these compounds at the end of the pancreatic digestion was almost negligible; therefore, their level of absorption must be even lower, as

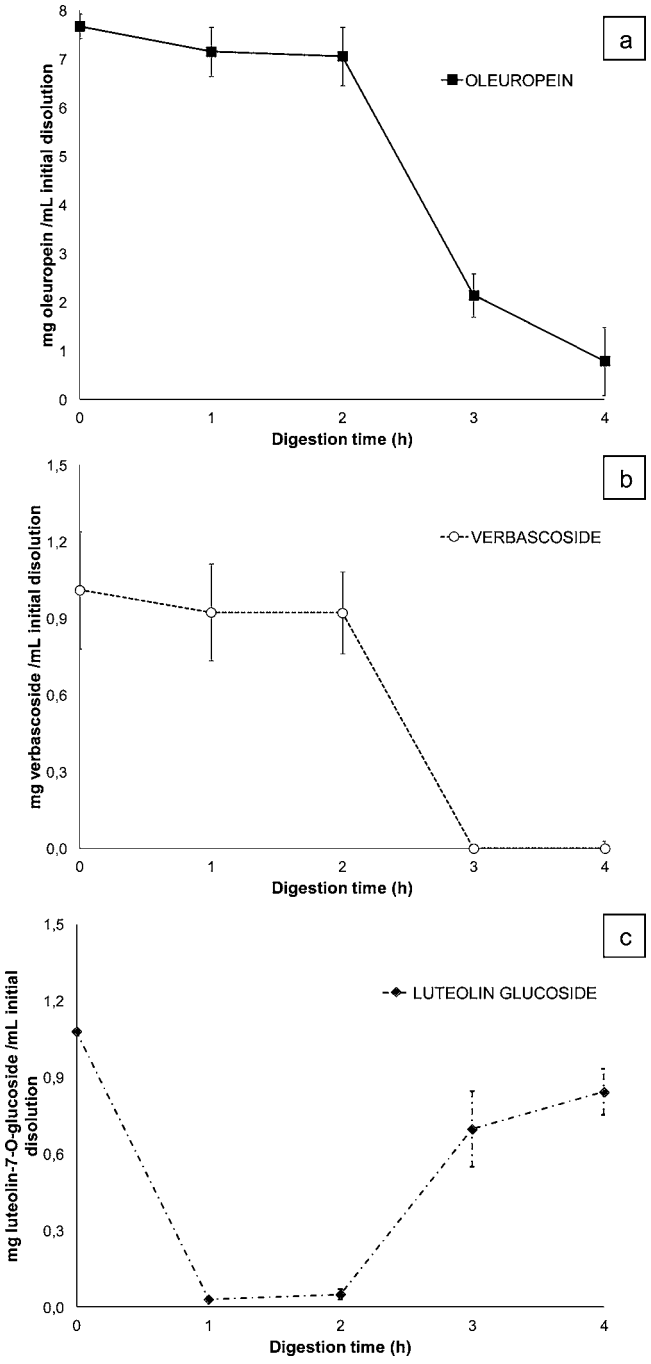

Figure 6. Kinetics of oleuropein (a), verbascoside (b), and luteolin-7-*O*-glucoside (c) content during the in vitro digestion of its standard solutions. Means ± standard deviation are plotted.

reported.[41,42] In contrast, isolated luteolin showed a completely different stability from that contained in the extract. Whereas the luteolin-glucoside in olive leaf extracts remained fairly stable after the first hour of digestion, it was not identified by HPLC in the standard solution during gastric digestion and was detected again during intestinal digestion, as shown in Figures 2b and 3b. As mentioned above, this effect could be due to the precipitation of this compound under acidic gastric conditions or its complexation with proteins under gastric conditions, a fact that may be enhanced when in pure form. Both digestions (Figures 5c and 6c) demonstrate the pancreatic−biliar resistance of luteolin.

dx.doi.org/10.1021/jf501414h | J. Agric. Food Chem. 2014, 62, 6190−6198

In conclusion, the degradation kinetics of the major bioactive compounds derived from olive leaf extracts was not dependent on the type of extract or source. Hence, neither the drying treatment of olive leaves nor the extraction method (conventional or US application) had a significant ($p < 0.05$) influence on oleuropein, verbacoside, and luteolin-7-*O*-glucoside behavior during in vitro digestion. The most relevant finding of our study is that the amounts of oleuropein and verbascoside at the end of the digestion processes are almost negligible, mainly due to their instability during intestinal digestion. Interestingly, luteolin-7-*O*-glucoside was fairly resistant to digestion and, therefore, must be considered as an interesting polyphenol for further absorption processes.

ABSTRACT: Non-invasive techniques are a key to study nutrition and structure interaction. Fourier transform infrared microspectroscopy coupled with a synchrotron radiation source (SR-IMS) is a rapid, non-invasive, and non-destructive bioanalytical technique. To understand internal structure changes in relation to nutrient availability in oil seed processing is vital to find optimal processing conditions. The objective of this study was to use a synchrotron-based bioanalytical technique SR-IMS as a non-invasive and non-destructive tool to study the effects of heat-processing methods and oil seed canola type on modeled protein structure based on spectral data within intact tissue that were randomly selected and quantify the relationship between the modeled protein structure and protein nutrient supply to ruminants. The results showed that the moisture heat-related processing significantly changed ($p < 0.05$) modeled protein structures compared to the raw canola (control) and those processing by dry heating. The moisture heating increased ($p < 0.05$) spectral intensities of amide I, amide II, α-helices, and β-sheets but decreased ($p < 0.05$) the ratio of modeled α-helices to β-sheet spectral intensity. There was no difference ($p > 0.05$) in the protein spectral profile between the raw and dry-heated canola tissue and between yellow- and brown-type canola tissue. The results indicated that different heat processing methods have different impacts on the protein inherent structure. The protein intrinsic structure in canola seed tissue was more sensitive and more response to the moisture heating in comparison to the dry heating. These changes are expected to be related to the nutritive value. However, the current study is based on limited samples, and more large-scale studies are needed to confirm our findings.

KEYWORDS: *protein structure, heat-induced processing, nutrient availability, yellow- and brown-type canola, synchrotron application, spectral modeling*

INTRODUCTION

Recently, it has been reported that using synchrotron radiation infrared microspectroscopy (SR-IMS) as a non-invasive and non-destructive tool for inherent molecular structure changes in different plant-based foods/seeds/feeds could be revealed within intact tissue at cellular and molecular levels.[1−3] The published results showed that the changes of protein, carbohydrate, and lipid molecular structure spectral profiles could be induced by bioethanol processing,[4] gene transformation,[5] and heating.[6,7] In these published studies, it was found that the inherent structure of the plant tissue within cellular or subcellular dimension could affect nutritive quality, fermentation, and degradation behavior. Different cultivars have different inherent structure characteristics. The relative percentage of protein secondary structure profiles may influence protein functionality and nutritive utilization. Different protein structure profiles affect the access of gastrointestinal digestive enzymes to the protein and subsequently affect digestibility.[8,9]

Oil seed canola is considered an important protein and energy source for animal and human food because of its high contents of both protein and oil. There are several different processing methods available for canola processing. To understand internal structure changes in relation to nutrient availability in canola processing is vital to find optimal processing conditions and prevent huge nutrient loss. However, any conventional "wet" chemical analytical method is unable to detect the structure changes within intact tissue after processing at cellular and molecular levels. In contrast to traditional "wet" chemical methods, which during processing for analysis often result in destruction of the intrinsic structures of feeds/seeds, to date, there has been little application of SR-IMS to study heat-induced molecular structure changes within intact tissue in different types of canola seeds with different processing methods in relation to digestive behavior and nutrient utilization.

The objectives of this study were to study the modeled protein structure changes (α-helices, β-sheets, and their ratio; amide I, amide II, and their ratios) induced by heat-related dry and moisture processing based on spectral data that were collected on the seed tissue and to investigate the relationship between protein structural changes (α-helix/β-sheet ratio) and protein chemical profiles, Cornell Net Carbohydrate and Protein System (CNCPS) protein fractions, truly digestible nutrients, energy value, *in situ* rumen degradation, and intestinal protein available in the raw (control) and heating of yellow- and brown-type canola seeds that were reported previously in a conventional

nutrition study. In addition, hierarchical cluster analysis and principal component analysis of the synchrotron-based spectral data from randomly selected seed tissue were performed to classify treatment difference. The hypothesis of this study was that the sensitivity and response of oil seed canola to heating differed in the nutrient availability between different heating methods and between yellow- and brown-type oil seed canola. These structural changes and differences are expected to be associated with nutritive values.

MATERIALS AND METHODS

Canola Varieties and Processing Methods: Moisture Heating and Dry Heating. Two different types of canola samples: yellow-seeded canola (*Bassica rapa*) and dark-brown-seeded canola (*Bassica nupus*) were used in a synchrotron-based modeled protein structure

study based on randomly selected seed tissues (spot samples). Each canola sample was previously heated by moisture (autoclave) and dry heating (Amsco Eagle SG-3031, Steris Corp., Mentor, OH) at the temperature of 120 °C for 1 h before nutrition and spectral studies. Control samples were kept raw. Heat-treated samples were subsequently cooled at room temperature. The detailed sampling structure, nutrient profiles, degradation kinetics, and metabolic characteristics of protein as well as Globar-source infrared (IR) spectroscopy work and functional group relationship to the nutrient value were reported previously.[7] In this study, we used the same samples for the synchrotron-based SR-IMS study to see what changes inside of the tissues after processing application and how these changes are related to nutritive values.

Canola Tissue and Synchrotron-Based IR Window Preparation. As reported before in synchrotron IR sample preparation methodology, the canola seed samples were cut into thin cross-sections (6 μm thickness) using a microtome. The cross-sections of the canola tissues were transformed to BaF2 windows (size of 13 × 1 mm disk) for transmission mode in SR-IMS work. Randomly selected five different seeds from each sample and randomly selected spot samples from each

(II) PCA: scatter plots of the first principal components (PC_1) versus the second principal components (PC_2). Protein fingerprint spectral region, ca. 1724−1487 cm^{-1}.

seed tissue were used to investigate the modeled protein structural features. Each seed tissue was collected around 40 spot spectral samples from a relative pure protein tissue area (which means with high amide I and II peaks) in the tissue between ca. 100 and 600 μm as detected by SR-IMS. More detailed methodology on synchrotron window preparation was described by Yu et al.[10]

Canadian Light Source (CLS) and Synchrotron-Based IR Microspectroscopy. The experiment was performed at the mid-IR station in the CLS with a SR-IMS station. "A Bruker Vertex 70v/S spectrometer with a Hyperion 3000 microscope is attached to the synchrotron, providing diffraction limited spatial resolution with a variety of experimental techniques available" (see the CLS website for the detailed facility description). The spectroscopic data were recorded using Fourier transform infrared (FTIR) spectroscopy equipped with IR microscopy. The bench was configured with a synchrotron light beamline. The spectra were collected in the mid-IR range of ca. 4000−800 cm^{-1} at a resolution of 4 cm^{-1} with 128 scans co-added. To obtain an ideal signal-to-noise ratio, the aperture setting was set in ca. 10 × 10 μm. Scanned visible images were obtained using a charge-coupled device (CCD) camera linked to the IR images.

Synchrotron Spectral Data Analysis. The spectral data of the canola tissues were collected, corrected for background spectrum, displayed in the absorbance mode, and analyzed using the Bruker-OPUS 6.5 and OMNIC 7.2 (Spectra Tech, Madison, WI). Figure 1 shows typical tissue spectra of spot samples. Protein amide I and II peak areas, amide I and II peak heights, modeled α-helix and β-sheet peak height intensities, and their ratios were determined. Chemical functional groups related to the protein structure were identified on the basis of band assignments published in the literature.[11,12] The analysis amide spectral region in this study was approximately ca. 1725−1487 cm^{-1} because this region is mainly related to protein biopolymer. The analysis of protein spectral regions of amide I and II in this study were ca. 1725−1577 cm^{-1} and ca. 1577−1487 cm^{-1}, respectively. For the modeled α-helix and β-sheet, the peak falls within the range of ca. 1650−1660 cm^{-1} and ca. 1620−1640 cm^{-1}, respectively. The ratio of the amide I and II peak areas, the ratio of the amide I and II peak heights, and the ratio of modeled α-helix and β-sheet peak heights were calculated on the basis of respective spectral absorbance intensity values. The ratio data were obtained by the height or area under one functional group band (e.g., amide I) divided by the height or area under another functional group band (e.g., amide II) at each pixel (spot sample), which represents the biological component ratio intensity and distribution in the tissue. Because the protein amide I component band was overlapped, a secondary derivative function was used to identify component bands for estimating the relative intensity of modeled protein secondary structures, such as modeled α-helices, β-sheets, and their ratios. The FTIR protein fingerprint data of canola tissue were analyzed by agglomerative hierarchical cluster analysis (CLA) and principal component analysis (PCA) using Statistica 8.0 software (StatSoft, Inc., Tulsa, OK) to classify and distinguish inherent protein structural differences among different types of canola seeds and then identify the main sources of variation within the protein amide I and II fingerprint spectra (ca. 1724−1487 cm^{-1}).[5,13]

Statistical Analysis. Statistical analysis between different types of canola seeds and different heat processing were performed using the mixed procedure of SAS.[14] Correlation analysis between protein structure α-helix and β-sheet and nutrient profile in raw and heated brown- and yellow-type canola were analyzed using the SAS. The normality tests were used with the univariate procedure of SAS with options of normal and plot. Treatment means were compared using Fisher's protected least significant difference test. For all statistical analysis, significant was declared at $p < 0.05$ and trends at $p \leq 0.10$.

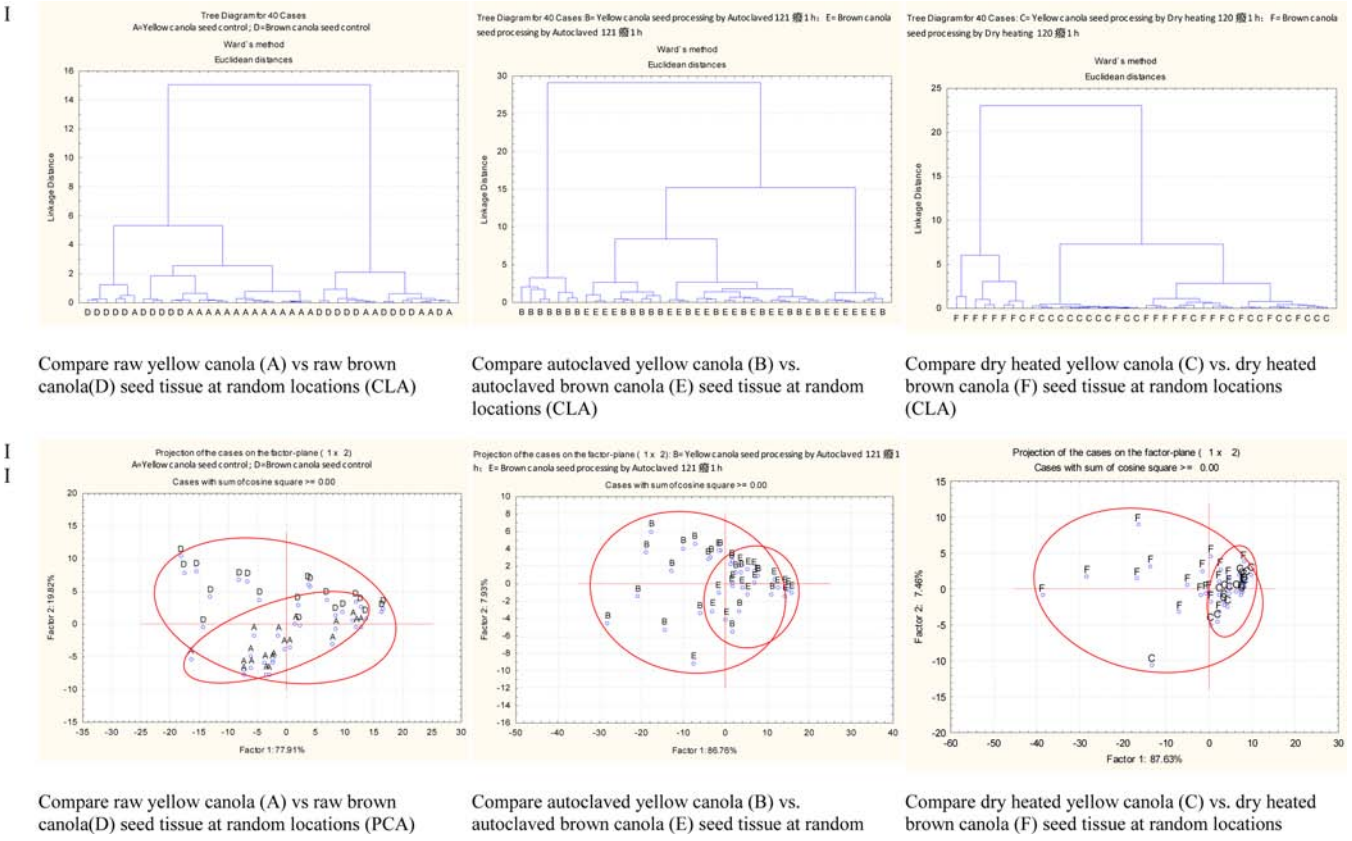

Figure 4. Multivariate spectral analyses of canola structures in the whole seed tissues at random locations using synchrotron-based FTIR microspectroscopy. Comparison of yellow- and brown-type canola and their heat treatments: A versus D, yellow- versus brown-type canola (control); B versus E, yellow- versus brown-type canola autoclaved at 121 °C for 1 h; and C versus F, yellow- versus brown-type canola dry heated at 120 °C for 1 h. (I) CLA: (1) protein fingerprint spectral region, ca. 1724−1487 cm^{-1}; (2) distance method, Euclidean; and (3) cluster method, Ward's algorithm. (II) PCA: scatter plots of the first principal components (PC_1) versus the second principal components (PC_2). Protein fingerprint spectral region, ca. 1724−1487 cm^{-1}.

RESULTS AND DISCUSSION

Effect of the Heat Treatment on the Physical Shape of Canola Seeds. The sensitivity of canola seeds to heating may differ among different heated treatments or between different types of canola. To investigate the physical−chemical changes, the entire images of raw (control) and heat treatments of canola seeds were scanned using the synchrotron-based SR-IMS equipped with a microscopy. From the images, it indicated that heat treatments may affect seed physical shape. Both yellow- and brown-type canola seeds were more sensitive to the moisture heat treatment because the physical shape had dramatic changes in terms of internal (the tissue swelled) or external (the seed coat split off) tissue. These results indicated that different processing methods had different impacts on physical structures and different types of seeds might have different sensitivity or response to different heat processing methods.

Effect of the Heat Treatment on Chemical Profiles, Protein Fractions, Digestible Nutrients, and *In Vitro* Intestinal Digestibility: Comparison of Raw (Control) versus Heat Treatments of Canola Seed, with a Summary of the Previous Study. Effects of heat treatments on chemical profiles, protein subfractions, digestible nutrient, and estimated intestinal digestibility of the raw and heat treatments of canola seed were reported by Samadi and Yu.[7] In summary, in the previous study, we found that moisture heating resulted in a significant increase in neutral detergent insoluble protein (NDIP), slowly degradable protein subfraction (PB_3), and estimated intestinal digestibility of rumen undegraded protein (dRUP, % of CP) but a decrease in soluble crude protein [SCP, % of crude protein (CP)], non-protein nitrogen (NPN, % of CP), protein PA fraction, rapidly degradable protein fraction (PB_1), and *in situ* dry matter (DM) and CP rumen degradation after 16 h of rumen incubation and resulted in increased more bypass protein and increased more protein availability in the small intestine. As a result, moisture heating greatly improved the nutrient value and the usage of canola seed in diets in dairy cattle. However, dry heating did not affect overall the content of chemicals and the degradability and availability of nutrient profiles. The results indicated that the sensitivity and response of canola seeds to heating differed between the moisture and dry heating. Moisture heating had a much greater effect on chemical and nutrient profiles than dry heating. To improved nutrient availability, moisture heating is a good potential method.[7] The data from the previous study were used in the following relationship study between the modeled protein structure and protein nutrient profiles and the protein utilization and availability.

Changes in Spectral Characteristics of Protein Induced by Heat-Related Processing, Revealed Using a Non-invasive Method (SR-IMS). The results of the structural spectral characteristics of protein between the raw and heat treatments of randomly selected canola seed tissue are presented in Table 1. The results showed that the heat-induced protein structure changes were able to be revealed and identified by the

[a]NDIP = 6.25 × neutral detergent insoluble nitrogen. [b]ADIP = 6.25 × acid detergent insoluble nitrogen. [c]Protein subfractions using CNCPS: PA, fraction of CP that is instantaneously solubilized at time zero; PB1, fraction of CP that is soluble in borate−phosphate buffer and precipitated with trichloroacetic acid; PB2, calculated as total CP minus the sum of fractions PA, PB1, PB3, and PC; PB3, calculated as the difference between the portions of total CP covered with NDF and ADF; and PC, fraction of CP recovered with ADF and considered to be undegradable. It contained protein associated with lignin and tannins and heat-damaged protein, such as the Millard reaction products.

non-invasive method (SR-IMS). In comparison to the raw, moisture heating significantly affected the spectral modeled protein structure profile and it increased ($p < 0.05$) amide I, amide II, modeled α-helices, and moldeled β-sheets while decreasing ($p < 0.05$) the ratio of modeled α-helices to modeled β-sheet; however, there was no change ($p > 0.05$) to the ratio of amide I/amide II. Similarly, dry heating did not change ($p > 0.05$) the protein structure spectral profiles, including amide I, amide II, modeled α-helices, and modeled β-sheets, as well as their ratios (both the modeled α-helix/modeled β-sheet ratio and the amide I/amide II ratio). The results in the present study were in agreement with our previous work using IR spectroscopy for soybean.[7] The moisture heating altered the inherent protein structures, subsequently, altered *in situ* rumen degradation of DM and CP, and further changed intestinal digestibility of rumen undegraded protein. However, dry heating did not change the molecular protein structures; thus, there were no differences in chemical characteristics and nutrient metabolic kinetics between dry heat treatment and the control. The change of the ratio of modeled α-helices/modeled β-sheets by moisture heating was reported by Doiron et al.[6] in Vimy flax. However, in their study, the ratio of modeled α-helices/modeled β-sheets of Vimy flaxseed was increased when the autoclaving temperature was increased from 40 to 60 min at 120 °C. The differences in the ratio of modeled α-helices/modeled β-sheets may be caused by heating processing conditions. These results indicated that different types of oil seeds (canola versus flaxseed versus soybean) had different sensitivities and responses to even the same heat processing. Generally, there was very little application of this novel advanced synchrotron radiation analytical technique to the study of internal structure changes in different plant-based feed samples with different heating methods for structure and nutrition interaction.

The protein structure spectral profiles between different types of canola seeds using the non-invasive method SR-IMS is presented in Table 1. The results showed that yellow-type canola was lower in the ratio of amide I/amide II than the dark-brown-type canola tissues that were randomly selected but there were no differences in amide I, amide II, modeled α-helices, modeled β-sheets, and the ratio of modeled α-helices/modeled β-sheets between yellow- and brown-type canola tissues.

Multivariate Spectral Analyses of Protein Spectral Profiles Using the Non-Invasive Method (SR-IMS): Comparison of the Control and Heat Treatments. The results of CLA and PCA of protein amide I and amide II spectra in the region of ca. 1724−1487 cm^{-1} obtained from different canola seed tissues with different heating are presented in Figures 2−4. From Figure 2, the results showed that yellow-type canola seed processing by moisture heating (B) was relatively different from the yellow-type canola seed processing by dry heating (C) and raw yellow-type canola seed (A), which could be discriminated into different clusters (CLA) and could be grouped into separate ellipses (PCA). However, the yellow-type canola seed processing by dry heating (C) and raw yellow-type canola seed (A) had similarities in their structure makeup, which could not be discriminated into different clusters (CLA) and could not be grouped into separate ellipses (PCA). However, the results showed that brown-type canola seed processed by moisture heating (E) was the same as the brown-type canola seed processed by dry heating (F) and raw brown-type canola seed (D) (Figure 3), which could not be discriminated into different clusters (CLA) and could not be grouped into separate ellipses (PCA). Likewise, the brown-type canola seed processed by dry heating (C) and raw brown-type canola seed (D) had similarities in their structure makeup, which could not be discriminated into different clusters (CLA) and could not be grouped into separate ellipses (PCA) (Figure 3). In Figure 4, it is again proven that there was no difference between yellow- and brown-type canola (both CLA and PCA) in vibrational pattern in amide I and II regions, which indicated that heating did not result in a significant impact on different types of canola seeds (yellow and brown). On the other side, maybe the heat condition in this study was not optimal and not enough to reveal the due changes or CLA and PCA are not sensitive enough to pick up subtle changes of the protein intrinsic structures.

Correlation between Protein Spectral Profiles and Protein Nutrient Profiles. Pearson correlations between protein secondary structure and chemical profiles, protein fractions, truly digestible nutrients, energy value, *in situ* rumen degradability, and intestinal protein availability in the control and heat treatments of canola seed tissues are presented Table 2. The results showed that the ratio of modeled α-helices/modeled β-sheets in the control and heat treatments had a strong negative correlation with NDIP ($R = -0.998$; $p < 0.05$), ADIP ($R =$

dx.doi.org/10.1021/jf501553g | J. Agric. Food Chem. 2014, 62, 6199−6205

−0.999; $p < 0.05$), and PB_3 ($R = -0.997$; $p < 0.05$). Our results are different from the flaxseed reported by Doiron et al.[6] The reason may also be different types of oil seeds (flaxseeds versus canola). The flaxseed results reported by Doiron et al.[6] were under the conditions of moisture heating at 120 °C from 20, 40, and 60 min. There was no significant correlation detected between the ratio of modeled α-helices/modeled β-sheets and other protein chemical and nutrient profiles. It needs to be mentioned that only moisture heating showed the significant effect on canola seed tissue but dry heating did not in this study. There is no published report on the protein spectral profile study on various feeds from other laboratories using our approaches. No comparison can be made. This is because previously we did not have an advanced non-invasive tool to detect molecular structure changes within intact tissue. Since the advanced synchrotron-based analytical technique has been developed, the structure spectral features can be revealed in relation to nutrient availability.

It was concluded that the effect of heating processing on the protein structure spectral profiles in canola seed tissues were detected using advanced the non-invasive method, synchrotron-radiation-based Fourier transform infrared microspectroscopy. Using moisture heat processing, the canola seeds were significantly changed in physical shape, protein structure spectral profile, protein nutrient profiles, utilization, and availability compared to the control and those processed by dry heating. The results partially supported our hypothesis that the sensitivity of canola seeds to heating methods differed between different types of canola seeds and the nutrient availability differed between different heating methods. Using an advanced synchrotron radiation technique, a non-invasive approach to evaluate protein quality could be further developed.

ABSTRACT: We established a simple, sensitive, and reproducible method to analyze the histamine and tyramine levels in Japanese soy sauce and its mash (called *moromi*) using hydrophilic interaction liquid chromatography with tandem mass spectrometry (HILIC–MS/MS). Histamine and tyramine quantification was performed using their stable isotopes for electrospray ionization–tandem mass spectrometry in the selected reaction monitoring mode. The sample pretreatment process was a simple, one-step liquid–liquid extraction. HILIC separation was performed with a gradient elution of aqueous ammonium formate and acetonitrile. Because of validation tests, the linearity, the accuracies, and precisions were sufficient. The limit of detection and the limit of quantification were 0.09 and 0.29 ppm for histamine and 0.13 and 0.42 ppm for tyramine, respectively. We successfully applied this method to histamine and tyramine determination in four kinds of commercial Japanese soy sauces and also in *moromi* samples during soy sauce production.

KEYWORDS: *histamine, tyramine, high-performance liquid chromatography, HILIC–MS/MS, soy sauce, moromi*

INTRODUCTION

Soy sauces are fermented condiments produced from soybeans, grain, brine, and *Aspergillus oryzae* or *Aspergillus sojae* molds. In the Japanese traditional soy sauce manufacturing process, the microbial fermentation occurs in soy sauce mash (commonly called *moromi*). Several aromatic components of soy sauces are generated during this process. Lactic acid is produced by halophilic lactic acid bacteria (*Tetragenococcus* spp., primarily *Tetragenococcus halophilus*) to acidify the *moromi*; alcoholic fermentation is subsequently caused by yeast (*Zygosaccharomyces rouxii*). Histamine (Him) and tyramine (Tym) are produced during the lactic acid fermentation in the mash by the *Tetragenococcus* spp. having histidine decarboxylase (HDC) and/or tyrosine decarboxylase (TDC) genes. The HDC gene is encoded on a 30-kb plasmid, and the plasmid can be transferred among *Tetragenococcus* bacteria, and the bacterium that acquire the transformable element become histamine-productive.[1] Excessive intake of Him and Tym can cause an allergy-like food poisoning.[2] Therefore, the maximum acceptable Him levels in foods has been established as less than 200 ppm in European Union (EU) countries, Switzerland, and Norway.[3−5] Although Him and Tym levels in foods have not yet been legally regulated in Japan, they will be regulated as in the EU in the near future. To manufacture soy sauces with low Him and/or Tym levels, it is necessary to use *Tetragenococcus* spp. without HDC and/or TDC genes during the lactic acid fermentation of the soy sauce mash. Therefore, a simple and sensitive monitoring method for Him and Tym during the production process of soy sauce is required.

Biogenic amines, including Him and Tym, analysis in foods by LC coupled in tandem with mass spectrometry (MS) using an ODS column[6−8] and a hydrophilic interaction liquid chromatography (HILIC) column[9−11] have been widely reported. In the HILIC mode, analytes interact with the hydrophilic stationary phase, and the elution is generated by the hydrophobic binary mobile phase, which uses water as a strong eluting solvent; therefore, polar substances such as Him and Tym are strongly retained to minimize the potential endogenous interferences and ion suppression. Unlike other food samples, however, soy sauces contain high concentrations of sodium chloride and many stained compounds such as melanoidins.[12] Time consuming pretreatments, such as ion-pair or cation-exchange solid-phase extraction, are required to remove these interfering compounds. Nevertheless, these pretreatments could not sufficiently prepare samples from soy sauce to be introduced into the mass spectrometer.

In this study, we established an HILIC–MS/MS method to analyze Him and Tym in soy sauces and their intermediates. This method enables highly selective Him and Tym detection,

and the sample pretreatment process has been simplified to a one-step liquid−liquid extraction (LLE). For Him and Tym quantification, the stable isotopes Him-d_4 and Tym-d_4 were used for the electrospray ionization−tandem mass spectrometry (ESI−MS/MS) in the selected reaction monitoring (SRM) mode. The developed method was validated with regard to linearity, sensitivity, precision, accuracy, and recovery. Furthermore, we successfully applied this method to sensitive and selective Him and Tym analysis in soy sauce and its *moromi* samples after lactic acid fermentation during soy sauce production.

MATERIAL AND METHODS

Reagents and Solutions. Deionized and distilled water purified using an Aquerius pwu-200 automatic water distillation apparatus (Advantec, Tokyo, Japan) was used to prepare all aqueous solutions. LC grade acetonitrile was purchased from Honeywell Burdick & Jackson (Muskegon, MI). Histamine dihydrochloride, tyramine hydrochloride, magnesium sulfate, and 1 M sodium hydroxide solution were purchased from Wako Pure Chemicals (Osaka, Japan). Histamine-d_4 sodium salt and tyramine-d_4 were purchased from Cambridge Isotope Laboratories (Andover, MA) and CDN Isotopes (Quebec, Canada), respectively. Other chemicals and solvents were of the highest purity available and were used as received. Individual stock solutions (1000 ppm) were prepared by dissolving 5 mg of each compound in 5 mL of water and stored in polypropylene test tubes at 4 °C. Various concentrations of standard working solutions were prepared daily by appropriate dilution with water just prior to use.

Sample Collection. Four kinds of Japanese soy sauces (*koikuchi*, *usukuchi*, *saishikomi*, and *tamari*)[13] were purchased from supermarkets in Shizuoka city (Japan). Two *moromi* samples after lactic acid fermentation with pH 4.68 and pH 5.04 were obtained from Shizuoka Kensan Shoyu K. K. (Yaizu, Shizuoka, Japan). In addition, an additional soy sauce mash was prepared as an example of lower contamination with Him and Tym after lactic acid fermentation by a *T. halophilus* 52−47C strain that was isolated from a soy sauce mash naturally fermented by a procedure previously described.[14] Polymerase chain reaction (PCR) was performed on the *T. halophilus* 52−47C strain in advance to confirm the absence of the genes HDC and TDC before starting the lactic acid fermentation of the soy sauce mash. PCR reactions were performed using primers of HmF (5′-TGTTTCGTATGACCGTGCGG-3′) and HmR (5′-CACCATTTTCGCCGGCAGTG-3′) for a partial 560 bp HDC gene[1] and using primers of TD5 (5′-CAAATGGAAGAAGAAGTAGG-3′) and TD2 (5′-ACATAGTCAACCATRTTGAA-3′) for a 1100 bp TDC gene.[15]

Instrumentation. Liquid chromatography was performed using a Shimadzu (Kyoto, Japan) Nexera system coupled with a Shimadzu LCMS 8040 triple quadrupole mass spectrometer with an ESI interface. Data acquisition was controlled using the LabSolution LCMS software ver. 5.53 (Shimadzu).

Chromatographic Conditions. The analytical column used was an Aeris HILIC column (2.1 mm i.d. × 150 mm, 5 μm, Phenomenex, Torrance, CA) maintained at 40 °C; the mobile phase consisted of 10 mM ammonium formate in water (solvent A) and a mixture of acetonitrile and 100 mM ammonium formate (9:1) (solvent B). The gradient profile was as follows: 85% solvent B at 0 min, 85% solvent B at 2.5 min, 50% solvent B at 4 min, 50% solvent B at 6 min, 85%

dx.doi.org/10.1021/jf500767p | J. Agric. Food Chem. 2014, 62, 6206−6211

solvent B at 6.01 min, and 85% solvent B at 12 min with a flow rate of 0.4 mL/min. The total run time was 12 min.

MS Conditions. The mass spectrometer was operated in the SRM mode using positive electrospray ionization. The parameters for the SRM analysis were as follows: drying N_2 gas flow at 15.0 L/min, nebulizing Ar gas flow at 2.0 L/min, desolvation line temperature at 250 °C, heat block temperature at 400 °C, interface voltage of 4.5 kV, and collision gas flow of 230 kPa. SRM transition of the precursor to product ions used for quantification were as follows: m/z 112.0 → 95.1 for Him, m/z 116.0 → 99.1 for Him-d_4, m/z 138.0 → 121.0 for Tym, and m/z 142.0 → 125.0 for Tym-d_4. The collision energy was 18 eV for Him and Him-d_4 and 14 eV for Tym and Tym-d_4.

Sample Preparation. A mixture of 100 ppm of Him-d_4 and Tym-d_4 (20 μL, for internal standard), 1 M sodium hydroxide (20 μL) and 100 mM magnesium sulfate (20 μL) were added to a 20-μL portion of each sample. After the addition of acetonitrile (320 μL), the solution was vigorously shaken for 1 min. An aliquot (20 μL) of the upper layer was transferred to another tube and then diluted 50 times with the initial mobile phase. The resulting solution (1 μL) was applied to the LC−MS/MS system.

Method Validation. To obtain the validation parameters, the peak areas were estimated by the LabSolution LCMS, and the baseline-to-baseline method was used for quantification. Him and Tym concentrations were calculated by the internal standard method. For quantitative analysis, calibration standard solutions (n = 6 each) with concentrations ranging from 0.5 to 500 ppm (0.5, 1, 5, 10, 50, 100, and 500 ppm) were prepared by diluting the stock solutions. The equations of the calibration curves were determined using least-squares linear prediction.

Precision of the assays was determined by the repeated measurement of four spiked samples at the lowest, low, middle, and high levels (0.5, 10, 100, and 500 ppm; n = 6). For intraday precision, these levels were analyzed six times each day, whereas for interday precision, specimens of the spiked samples at the same concentrations were analyzed twice per day for 6 days (n = 12). The spiked samples were pretreated and subsequently subjected to the HILIC−MS/MS. Him and Tym levels were determined from each calibration curve. Accuracy was defined as $F/(F_0 + A) \times 100$ (%), where F is the level of Him and Tym in the spiked sample, F_0 is the level of Him and Tym in the unspiked sample, and A is the spiked concentration.

RESULTS AND DISCUSSION

MS Analysis of Him and Tym. Figure 1 shows SRM chromatograms of the 100 ppm standard for Him and Tym and their MS spectra. We could observe ions regarding the major fragment ions at m/z = 138.0 → 121.0 (Tym), 142.0 → 125.0 (Tym-d_4), 112.0 → 95.0 (Him), and 116.0 → 99.0 (Him-d_4). The retention times of Tym, Tym-d_4, Him, and Him-d_4 were 1.6, 1.6, 5.4, and 5.4 min, respectively. Him and Him-d_4 as well as Tym and Tym-d_4 were eluted at almost the same retention times. Quantitative separation of Him and Tym was achieved within 6 min on the HILIC column at the given chromatographic conditions, and selective detection of Him and Tym was also achieved with the SRM mode.

Sample Pretreatment. Japanese soy sauces currently on the market are weakly acidic and contain approximately 16% sodium chloride. For the pretreatment process, soy sauce samples were alkalinized to a pH of ca. 10 by the addition of 1 M sodium hydroxide. These solutions were subsequently added to 100 mM magnesium sulfate and acetonitrile to form a bilayer. Water-soluble compounds, neutral and acidic amino acids, proteins, and melanoidins all remained in the aqueous layer. In contrast, positively charged, undissociated Him and Tym successfully partitioned into the acetonitrile phase.

Method Validation. Seven different concentrations in the range 0.5−500 ppm with six replicates were chosen to draw each calibration curve. The calibration curves for both Him and Tym were observed between the peak area and analyte concentration with good correlation coefficients (r^2 > 0.999).

Limit of detection (LOD) and limit of detection (LOQ) were determined from the signal-to-noise ratios of 3 and 10, respectively. LOD of Him and Tym was 0.09 and 0.13 ppm, respectively, LOQ of Him and Tym was 0.29 and 0.42 ppm, respectively. When analyzing the Him and Tym standard solution without the pretreatment process, 1000th of the above values were obtained as LOD and LOQ by the same HILIC−MS/MS system.

The results of precision and accuracy of intraday and interday assays are listed in Tables 1 and 2. The intraday assay precisions of Him and Tym were in the range 1.11−5.57% and 1.25−5.76%, respectively; the interassay precisions were in the range 1.76−7.17% and 4.66−9.72%, respectively. Accuracy of the method was determined by assessing the agreement between the observed and nominal concentrations of the analyzed samples. These values for Him and Tym were in the range 85.9−98.6% and 96.6−103.8%, respectively.

Recovery studies for the method were performed by spiking seven concentrations (0.5, 1, 5, 10, 50, 100, and 500 ppm) of Him and Tym into soy sauce samples. The recoveries were calculated from the slope of the calibration curve ratio of the peak areas of spiked soy sauce samples and those of standards

Table 1. Precision and Accuracy of Intra-day Assay for Him and Tym in Soy Sauce Samples (n = 6)

nominal concentration (ppm)	observed concentration (ppm)	precision[b] (%)	accuracy[c] (%)

[a] n = 12 (2 × 6 days). [b] Expressed as relative standard deviation. [c] Accuracy % = Average of observed concentration/(nominal concentration + concentration of QC sample) × 100.

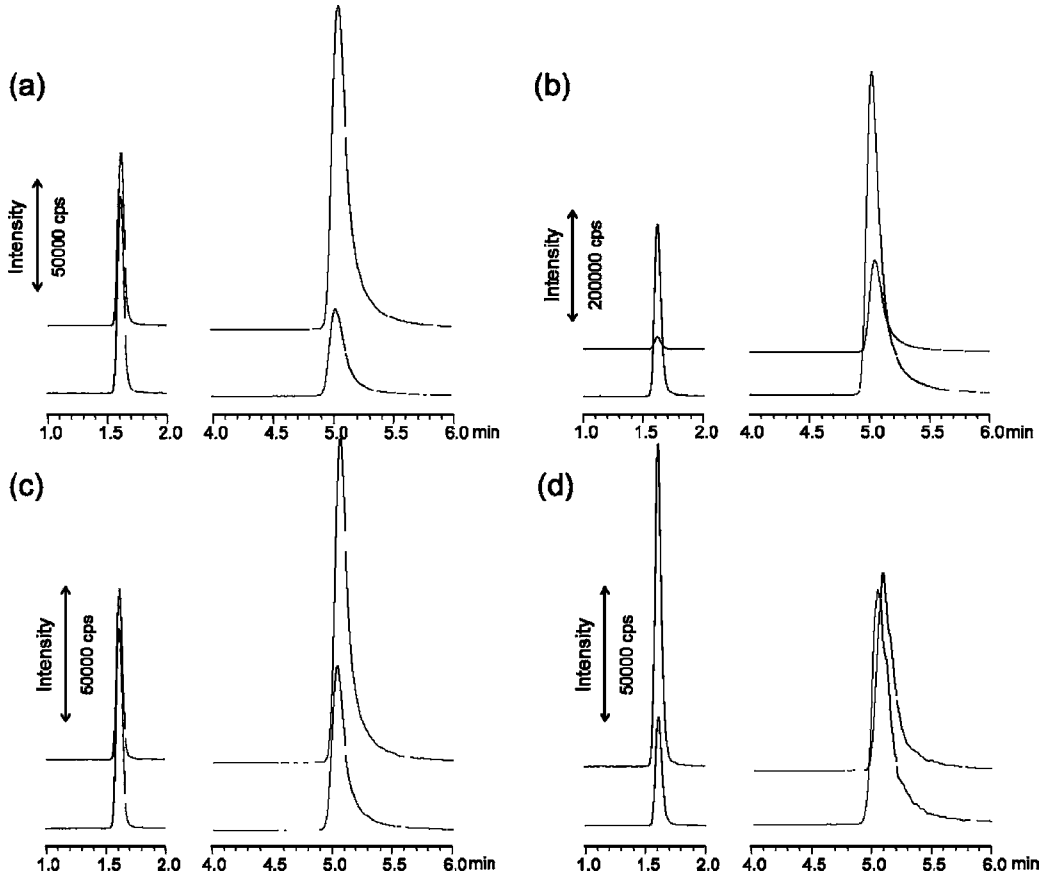

Figure 2. Typical SRM chromatograms obtained from commercially available Japanese soy sauces: (a) *koikuchi*, (b) *usukuchi* (10-fold diluted), (c) *saishikomi*, and (d) *tamari*. Upper, 100 ppm internal standards; lower, soy sauce samples.

(n = 3 each). Mean recoveries of Him and Tym were 47.7 and 59.9%, respectively.

Him and Tym Determination in Commercial Japanese Soy Sauces. This method was used for Him and Tym quantification in commercial Japanese soy sauces to investigate its applicability. Figure 2 shows typical SRM chromatograms of four kinds of commercial soy sauce samples: (a) *koikuchi*, (b) *usukuchi*, (c) *saishikomi*, and (d) *tamari*. The *koikuchi*, *usukuchi*, and *tamari*-type soy sauces are produced from *moromi*, which is fermented with rice malt and brine, whereas *nama shoyu* (raw soy sauce) is used in the production of the *saishikomi* soy sauce instead of brine. The *nama shoyu* is rich in color, taste, aroma, and nitrogen contents, and it may contain significant amounts of Him and Tym. Results of the Him and Tym levels obtained by the present method were summarized in Table 3. Him levels of the commercial soy sauce samples used were 1.2−775 (*koikuchi*), 1.9−364 (*usukuchi*), 46.2−173.9 (*saishikomi*), and 131 ppm (*tamari*). Tym levels of the above samples were 1.2−2040 (*koikuchi*), 4.3−1594 (*usukuchi*), 171−575 (*saishikomi*), and 336 ppm (*tamari*). Each sample was purchased from a different manufacturer; therefore, Him and Tym levels were significantly different because of differences in the manufacturers.

Him and Tym Analysis in *Moromi* Samples after Lactic Acid Fermentation. Figure 3 shows the SRM chromatograms of three *moromi* samples after lactic acid fermentation during the manufacturing process of *koikuchi* soy sauces. When the soy sauce mash was fermented at pH 4.68, 183.4 ppm of Him and 108.7 ppm Tym were detected (Figure 3a). When the mash was fermented at a slightly higher pH (5.04), 116.7 ppm of Him and 150.3 ppm Tym were observed (Figure 3b). Thus, lactic acid fermentations under different pHs appears to influence the production quantities of Him and Tym; this probably depends on the growth of contaminated *Tetragenococcus* spp. that contains HDC and TDC genes during the fermentation, although no significant difference was observed in the Him and Tym levels between the two pH samples.

We further analyzed Him and Tym levels in a soy sauce mash after lactic acid fermentation using a *T. halophilus* 52−47C strain that did not have HDC and TDC genes. Extremely low Him and Tym levels were detected (less than 8.29 and 14.3

Table 3. Him and Tym Contents in Commercial Japanese Soy Sauces

		concentration (ppm)	
sample no.	kind of soy sauce	Tym	Him

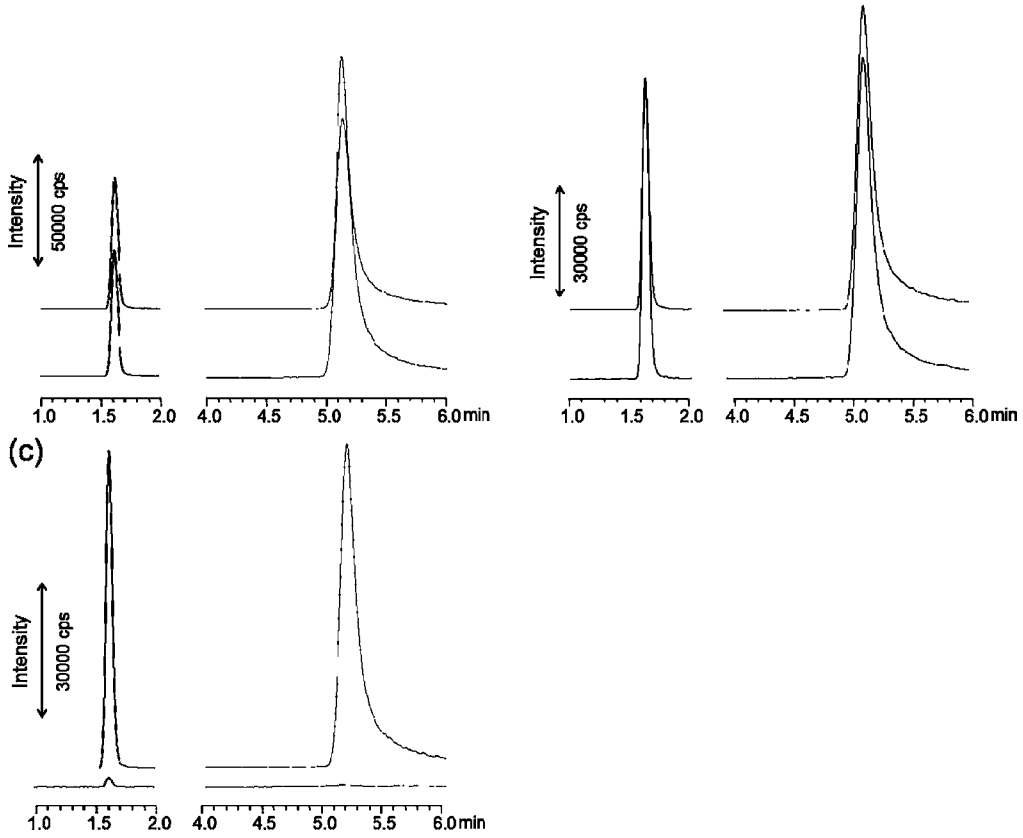

Figure 3. Chromatograms of three *moromi* samples after the lactic fermentation manufacturing process of *koikuchi* soy sauces. (a) Lactic acid fermentation at pH 4.68; (b) lactic acid fermentation at pH 5.04; (c) lactic acid fermentation using a *T. halophilus* 52−47C strain without HDC and TDC genes. Upper, 100 ppm internal standards; lower, *moromi* samples.

ppm, respectively) in the mash (Figure 3c), suggesting that *T. halophilus* without HDC and TDC genes available in lactic acid fermentation can be used to manufacture soy sauce with minimal Him and Tym contamination.

As mentioned above, our method would be useful for monitoring Him and Tym contaminations during the manufacturing of soy sauce.

CONCLUSION

This paper reports a simple and sensitive analysis method for Him and Tym in Japanese soy sauce and *moromi* samples. The total run time was satisfactorily short for the routine analyses. The sample pretreatment procedure was also simplified to a one-step LLE without concentration of the extract. In this procedure, solid-phase extraction cartridge was not necessary, and general-use reagents, which are magnesium sulfate, sodium hydroxide and acetonitrile, were only required for the LLE. Therefore, it would suppress the analytical cost and be useful in routine analyses. The developed method was validated and successfully applied for Him and Tym quantification in the four kinds of Japanese commercial soy sauces and *moromi* samples. The proposed method would be useful as a simple assay method for soy sauce manufacturers, quality control units in food companies, and related analytical laboratories. Our simple pretreatment procedure enabled the extraction of Him and Tym from high-salting and protein-containing matrices selectively and efficiently. In addition, the HILIC−MS/MS analysis provided simple and clean SRM chromatograms for Him and Tym with high sensitivity. Therefore, our proposed method would be applicable to Him and Tym analysis in various kinds of foods and beverages beside Japanese soy sauces, such as fish sauces, seafood, and lactic fermented foodstuffs.

ABSTRACT: The prevalence of fish allergy is rapidly increasing because of a growing fish consumption driven mainly by a positive image of the fish and health relationship. The purpose of this study was to characterize parvalbumin isotypes from grass carp (*Ctenopharyngodon idella*), one of the most frequently consumed freshwater fish in China. Three parvalbumin isotypes were purified using consecutive gel filtration and reverse-phase chromatography and denoted as PVI, PVII, and PVIII. The molecular weights of the isotypes were determined to be 11.968, 11.430, and 11.512 kDa, respectively. PVI showed 74% matched amino acids sequence with PV isotype 4a from *Danio rerio*, while PVII and PVIII showed 46% matched amino acids sequence with PV isotypes from *Hypophthalmichthys molitrix*. PVII is the dominant allergen, but it was liable to gastrointestinal enzymes as PVIII; however, PVI was resistant to pepsin digestion. A further study is to characterize the epitopes of PVII, the dominant allergen.

KEYWORDS: *parvalbumin isotypes, purification, characterization, IgG binding, IgE binding*

INTRODUCTION

Fish consumption has grown tremendously over the past several decades, driven mainly by a positive image of the fish and health relationship and as an alternative animal protein source over pork and beef.[1,2] Fish (including shellfish) allergies are common in both the western world and Asian countries, affecting 0.2−2.29% of the general population;[3] unlike other allergies, most of the children cannot outgrow fish allergy. Although fish allergies occur mainly via the gastrointestinal tract (eating fish), handling and inhalation of cooking vapors can also cause fish allergic reactions.[4,5] Fish allergies cause urticaria, rhino conjunctivitis, asthma, oral allergy syndrome, diarrhea, and even life-threatening anaphylaxis.[6]

Parvalbumin (PV), accounting for 90% of fish allergic reaction, was first identified as the major allergen in cod[7] and then from many different species.[8−10] As the major clinical cross-reactive fish allergen, PV is a subfamily of closely related three EF-hand calcium-binding proteins, with a molecular weight of 10−12 kDa and isoelectric points of 3.9−5.5.[11] PV is often subdivided into two distinct isoform lineages, α-PV and β-PV, with β-PV as the major allergen.[3] α-PV and β-PV consist of 109 and 108 amino acid residues, respectively. PV consisting of 110 amino acid residues was also reported in herring recently.[12] The pI value of α-PV is ∼5.0, while that of β-PV is more acidic, with an pI value ∼4.5.[13,14] The presence of isotypes with different levels of immunoglobulin G (IgG)- and immunoglobulin E (IgE)-binding capacities was reported in several kinds of fish species.[15−17] Cai et al. indicated that PVII (11.95 kDa) may be more allergenic than PVI (12.29 kDa) in red stingray.[15] However, two isotypes of PV with the same molecular weight (11.5 kDa) and similar IgG- and IgE-binding capacities but different isoelectric points (4.39 and 4.6, respectively) were reported from Alaska pollack.[16]

Grass carp (*Ctenopharyngodon idella*) is one of the most frequently consumed freshwater fish in China, with an annual harvest of 4.78 million metric tons in 2012.[18] There were reports about the main allergen in carp[9] and silver carp,[19] but PV from grass carp has not been characterized. Carp, grass carp, silver carp, and zebrafish are from the same family (Cyprinidae) but different genus. Liu et al. revealed that silver carp PV had 92.7 and 82.6% similarities with PVs from carp.[19] Therefore, it is important to investigate and characterize the main allergen in grass carp. The objectives of this study were to purify and characterize PV isotypes from grass carp, determine their IgG- and IgE-binding capacities, and compare their digestibility using a simulated gastrointestinal condition.

MATERIALS AND METHODS

Materials. Live grass carps were purchased from a local fish market (Beijing, China). After sacrifice, white muscle was collected and used for PV extraction. Human sera were purchased from Plasma Lab International (Everett, WA). According to the supplier, these patients were selected on the basis of their allergic symptoms, such as itchy mouth, hives, wheezing, swelling throat, and IgE levels, against codfish. The IgE levels were measured by the Thermo Fisher Scientific ImmunoCAP at levels of 68.4, 77.5, 84.4, and 44.7 kU/L for 17716 (female, age: 28), 21290 (male, age: 22), 21473 (female, age: 56), and 17485 (male, age: 38), respectively. Anti-grass carp PV sera from rabbit was prepared in the lab (China Agricultural University, China). Mouse anti-frog PV monoclonal antibody (PARV-19), *para*-nitrophenylphosphate (*p*-NPP) substrate solution, tetramethylbenzidine (TMB) substrate solution, anti-mouse IgG peroxidase-conjugated antibody produced in goat, anti-rabbit IgG peroxidase-conjugated antibody produced in goat, and anti-human IgE peroxidase-conjugated antibody produced in goat were from Sigma (St. Louis, MO). Molecular weight protein standard and 4−20% gel were purchased from Bio-Rad Laboratories,

Inc. (Hercules, CA). Trypsin used in gel digestion was purchased from Promega (Madison, WI). High-performance liquid chromatography (HPLC)-grade acetonitrile was from Acros Organics (Fair Lawn, NJ). Pepsin (from porcine gastric mucosa) and trypsin (from porcine pancreas) used in simulated gastrointestinal digestion were purchased from Sigma (St. Louis, MO).

Extraction and Purification of PV. For PV extraction, the white muscle was homogenized with three volumes of 20 mM Tris−HCl (pH 7.5). After centrifugation at 10000*g* for 20 min, the supernatant was incubated in a water bath at 95 °C for 30 min. The heated extract was subjected to gel filtration chromatography on a Superdex 75 column coupled with an ÄKTA explorer 10XT system (GE Healthcare, Uppsala, Sweden) and eluted with 0.15 M NaCl in 0.01 M phosphate buffer (pH 7.0). Fractions were collected every 7 min, and absorbance was measured at 220 and 280 nm. Cytochrome *c* from horse heart (molecular mass of 12.4 kDa) was run under the identical conditions as a standard. Fractions containing PV from gel filtration chromatography were further applied to a Waters XBridge C_{18} column (5 μm, 3.0 × 250 mm, Waters Corporation, Milford, MA) coupled with a guard column (40 × 10 mm, Waters Corporation, Milford, MA) attached with a Waters 600 HPLC system. Instrumental control and data collection were carried out by Empower, version 2. Samples were automatically injected by Waters 2707 autosampler at a volume of 25 μL. The column was eluted by two solvents, solvent A [HPLC-grade water containing 0.1% trifluoroacetic acid (TFA)] and solvent B (70% acetonitrile containing 0.1% TFA), at a flow rate of 0.5 mL/min using a gradient from 0 to 50% B within 5 min, to 50% B within 30 min, to 0% B over 5 min, and maintained for 10 min for the next injection. Fractions were collected every 0.5 min from 19 to 24 min, and elution was monitored by a Waters 2998 photodiode array at 220 nm. The fractions were concentrated by a vacuum rotary evaporator at 35 °C and then freeze-dried for further analysis.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS−PAGE). SDS−PAGE was performed with 4−20% gel (Bio-Rad) according to the method by Laemmli.[20] The load volume was 15 μL at a protein concentration of 2 mg mL^{-1}. SDS−PAGE was performed in a Mini-PROTEAN tetra cell at a constant voltage of 200 V. Protein bands were stained using Brilliant Blue R-250. After destaining, the gel was scanned in an Alpha Innotech gel scanner (Alpha Innotech Corp., San Leandro, CA) with FluorChem SP software.

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF-MS) Analysis of PV Isotypes. Molecular weight of the purified PV isotypes was analyzed by MALDI-TOF-MS according to the procedure of two-layer sample preparation.[21,22] For the first thin matrix layer, 0.7 μL of 10 mg mL^{-1} 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid) in 80% acetone/20% methanol (HPLC grade) (v/v) was loaded onto a clean MALDI target, and then the matrix layer was spread and dried immediately. A total of 2 μL of diluted PV isotype sample was mixed with 2 μL of saturated sinapinic acid in 50% acetonitrile/50% water (v/v). A total of 1 μL of treated sample was applied to the first layer of the matrix. After drying, 5 μL of water was added on top of the dry spot to desalt the sample, and after 10 s, the liquid was blown off by an air pulse; this was repeated 5 times. Each sample was applied to six spots. At least, three spots of each sample were analyzed. MALDI analysis was carried out on an Applied Biosystems Voyager Elite MALDI (Foster City, CA) time-of-flight mass spectrometer in a positive linear ion mode.

In-Gel Digestion of PV Isotypes and Liquid Chromatography (LC)−Tandem Mass Spectrometry (MS/MS) Analysis. Excised gel pieces containing PV isotypes were digested by trypsin, as Offengenden et al. described.[23] First, the protein in gel pieces were reduced with 10 mM dithiothreitol (DTT) and then alkylated with 50 mM iodoacetamide. After washing with 100 mM ammonium bicarbonate and acetonitrile, the gel pieces were dried in a SpeedVac. The dried gel pieces were digested by 0.8 μg of trypsin (20 ng μg^{-1} in 50 mM ammonium) at 37 °C. After overnight digestion, the peptides were extracted with 30 μL of 100 mM ammonium bicarbonate, followed by two steps of extraction with 30 μL of solution containing 5% formic acid and 50% acetonitrile in water. At last, the extracts were dried to about 15 μL in a SpeedVac. The sample after in-gel trypsin digestion was analyzed by a hybrid quadrupole orthogonal acceleration time-of-flight mass spectrometer, QToF Premier (Waters, Milford, MA), online connected to a Waters nanoAcquity ultrahigh-performance liquid chromatography (UPLC) system. A total of 5 μL of sample was loaded onto a nanoAcquity UPLC system with a peptide trap (180 μm × 20 mm, Symmetry C18 nanoAcquity column, Waters Corporation, Milford, MA) and a nano analytical column (75 μm × 100 mm, Atlantis dC18 nanoAcquity column, Waters Corporation, Milford, MA). A solution of 1% acetonitrile and 0.1% formic acid in water (solvent A) was used to flush the trap column at a flow rate of 10 μL min^{-1} for 3 min to desalt the trapped sample. Peptides were separated with a gradient of 1−65% solvent B (acetonitrile and 0.1% formic acid) over 35 min at a flow rate of 300 nL min^{-1}. The column was connected to a QToF Premier (Waters Corporation) for electrospray ionization−mass spectrometry (ESI−MS) and MS/MS analyses of the effluent. Then, analysis using the online search algorithm Mascot (Matrix Science) was carried out for peptide identification.

Preparation of Anti-grass Carp PV Antibodies in Rabbit. Anti-PV antibody was prepared from three female New Zealand rabbits by injection of purified PV from gel filtration chromatography, as described everywhere.[24] The first injection was 0.5 mL of PV solution (1 mg mL^{-1}) emulsified with an equal volume of Freund's complete adjuvant (Sigma, St. Louis, MO) to the hind leg muscle of a rabbit. After 2 weeks, 0.5 mL of PV solution (1 mg mL^{-1}) emulsified with an equal volume of incomplete Freund's complete adjuvant (Sigma, St. Louis, MO) was injected to the back muscle of a rabbit. After 2 weeks, the rabbits were injected with another 1 mL solution containing 2 mg of PV via the ear vein of a rabbit. After 1 week, the rabbit sera were collected and kept at −80 °C until use.

Indirect Enzyme-Linked Immunosorbent Assay (ELISA). IgG- and IgE-binding capacities of PVs from grass carp were analyzed by indirect ELISA using PARV-19, anti-grass carp PV produced in the sera of rabbits and fish allergic patients. Briefly, samples were coated on a 96-well high binding polystyrene plate and incubated at 4 °C overnight, and bovine serum albumin (BSA) was coated as the blank. After four steps of washing, 100 μL of phosphate-buffered saline (PBS) containing 0.1% Tween-20 and 1% BSA was added to each well to block the unoccupied space of the wells and incubated at 37 °C for 1 h. Then, 100 μL of antibodies was added to wells after four steps of washing. Four human serum diluted 1:10 with PBS contained 0.1% Tween-20 and 1% BSA. Mouse serum and rabbit serum were diluted 1:400 000 and 1:160 000 with the same dilution, respectively. After incubation at 37 °C for 1 h, 100 μL of the corresponding peroxidase-conjugated antibody produced in goat (anti-mouse IgG, anti-rabbit IgG, or anti-human IgE) was added to the plate after diluted 1:10 000 with PBS contained 0.1% Tween-20 and 1% BSA and incubated at 37 °C for 1 h. For anti-human IgE, the enzyme reactions was performed using *p*-NPP substrate solution at room temperature for 30 min and stopped by 3 mol L^{-1} sodium hydroxide, and the color that developed was measured by absorbance at 405 nm. For the anti-mouse IgG and anti-rabbit IgG, the enzyme reaction was performed using TMB substrate solution at 37 °C for 10 min, stopped by 2 mol L^{-1} sulfuric acid, and measured by absorbance at 450 nm.

Simulated Gastrointestinal Digestion. Simulated gastrointestinal digestion of purified PVs was performed according to a modified method by Majumder et al.[25] PVs were dispersed in 0.15 M KCl−HCl (pH 2.0) buffer at a concentration of 2 mg mL^{-1} and first digested with pepsin (E/S, 2%, w/w) at 37 °C for 1.5 h, and then the pH of the digest was raised to 7.4. Half of the pepsin digest was removed and heated in a 95 °C water bath for 15 min. The rest of the sample was further digested by trypsin (E/S, 2%, w/w) at 37 °C for 3 h and then was inactivated by heating the sample at 95 °C for 15 min. The digested samples were stored at −20 °C for further analysis.

Separation of Digested PV Isotypes by HPLC. The digested PV isotypes were applied to a Waters XBridge C_{18} column (5 μm, 3.0 × 250 mm, Waters Corporation, Milford, MA) coupled with a guard column (40 × 10 mm, Waters Corporation, Milford, MA) attached with a Waters 600 HPLC system for further separation. Instrumental control and data collection were carried out by Empower, version 2. Samples were automatically injected by a Waters 2707 autosampler at a volume of

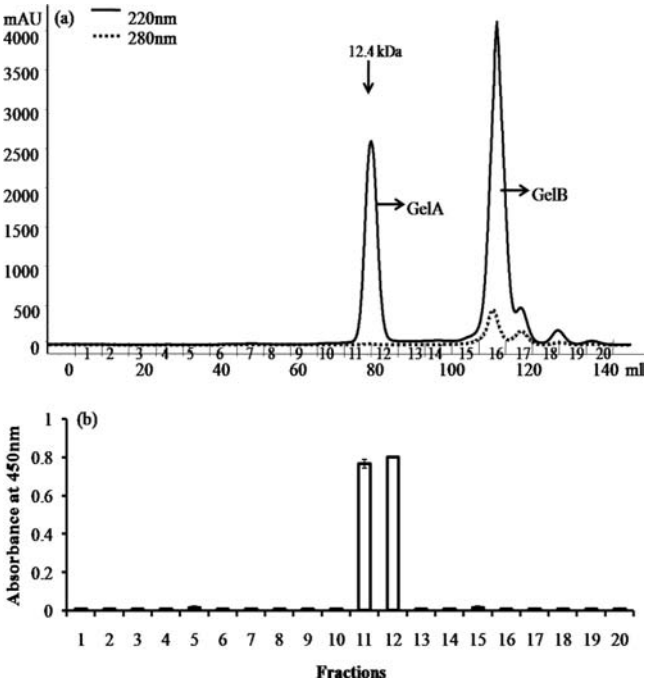

Figure 1. (a) Fractionation of PV, extracted from grass carp white muscle, by gel filtration chromatography on a Superdex 75 (1.6 × 60 cm) column. (b) IgG-binding capacity of fractions with mouse anti-frog PV monoclonal antibody (PARV-19). Data were expressed as the mean ± SD (n = 3).

25 μL. The column was eluted at a flow rate of 0.5 mL/min using a gradient consisting of solvent A (HPLC-grade water containing 0.1% TFA) and solvent B (70% acetonitrile containing 0.1% TFA) from 0 to 50% B within 5 min, to 50% B within 30 min, to 0% B over 5 min, and maintained for 10 min for the next injection. Fractions were collected every 1 min from 21 to 41 min, and elution was monitored by a Waters 2998 photodiode array at 220 nm. The fractions were concentrated by a vacuum rotary evaporator at 35 °C and then freeze-dried for further analysis.

Data Analysis. All sample determinations were performed in triplicate, and the results were expressed as the mean value ± standard deviation (SD). Analysis of variance (ANOVA) with Tukey's post-hoc test was used to determine statistical differences, and differences were considered significant with a p value of <0.05.

RESULTS AND DISCUSSION

Purification of PV Isotypes from Grass Carp White Muscle. PV extracted from grass carp was first purified by gel filtration chromatography, as shown in Figure 1a, where two major fractions, GelA and GelB, were collected. The GelA fraction displayed high binding capacity to PARV-19, whereas no binding activity was found in fraction GelB, indicating fraction GelA containing PV (Figure 1b). Furthermore, fraction GelA did not have absorbance at 280 nm because of the lack of Trp and Tyr residues in PV.[15,17] The retention time of fraction GelA was close to the protein standard, indicating that the molecular weight of fraction GelA was close to the molecular weight of the standard protein (12.4 kDa).

Fraction GelA was further purified by reverse-phase (RP)-HPLC. Three distinct peaks were collected and denoted as PVI, PVII, and PVIII (Figure 2a). PV samples were subjected to SDS–PAGE analysis (Figure 2b). GelA fraction revealed two bands, similar to the band of PVI, whereas PVII and III contain one band at a molecular weight of ~10 kDa. The presence of a lower molecular weight band in PVI was probably due to cross-contamination of PVII. Different isotypes of PV was previously reported in several fish species.[16,26] Hamada et al. purified two isotypes by reverse-phase HPLC from Janpanese flounder and Japanese eel but did not detect isotypes in red sea bream and skipjack.[27] Liu et al. purified three PV isotypes by DEAE-Sepharose chromatography and Superdex 75 gel filtration chromatography from silver carp with the molecular weights of 12, 11, and 14, respectively.[19]

Characterization of PV Isotypes. As shown in Figure 3, the molecular weights of PVI, PVII, and PVIII were 11.968, 11.430, and 11.516 kDa, respectively, which were in the range of PV molecular weight (10–12 kDa) as previously reported.[3] However, a 14 kDa isotype was recently reported in sea bream[17] and red sea bream.[28] The molecular weight of PVI was close to that of a PV isotype (11.954 kDa) in red stingray.[15] There are three small peaks that appeared in the MS spectrum of PVI as inserted, corresponding to the smaller band observed in Figure 2b of PVI, with the molecular weights of 11 430, 11 462, and 11 479 Da, respectively. The 11 430 kDa peak was the contamination of PV II, whereas the peak of 11 462 showed the same/similar molecular weight to isotypes of Atlantic cod, with the molecular weight of 11 462 Da[13] or 11 459 Da.[29] The peak

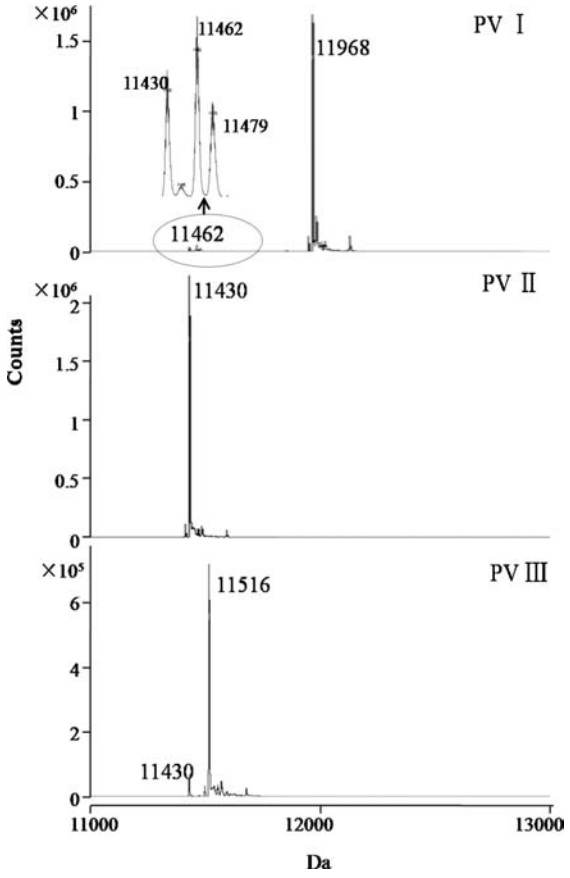

Figure 3. MALDI-TOF-MS analysis of molecular weights of PV isotypes.

of 11 479 Da showed a similar molecular weight to PV (11 487 Da) of carp.[9]

To characterize the sequences, three bands of PVI, PVII, and PVIII in Figure 2b were digested by trypsin and subjected to LC−MS/MS. As shown in Table 1, PVI showed 74% sequence coverage with the PV isoform 4a from *Danio rerio* (gil28194094), supporting that PVI was an isotype of PV. Perez-Gordo et al.[30] reported a 15 amino acid residue (DGKIGVDEFGAMIKA) of PV from Atlantic cod, which was considered as a major epitope of the protein. A 15 amino acid residue (DGKIGIDEFEALVHE) of PVI displayed 60% similarity with the major epitope of PV from Atlantic cod; it is to be determined if this epitope in PVI is the major epitope. PVII and PVIII showed 46% sequence coverage with PV isotypes from *Hypophthalmichthys molitrix* (gil209902357 and gil209902355). In addition, PVII and PVIII shared two epitopes, 51-65 (IDQDKSGFIEEDELK) and 89-103 (AG DSDGDGKIGVDEF). The 51-65 amino acid epitope was also reported in the PV isotype of crimson sea bream, Janpanese eel, carp, Atlantic salmon, cod, and horse mackerel.[17] The 89-103 amino acid epitope was identified in the PV isotype of cod, horse mackerel, and skipjack.[17] Therefore, these two epitopes are likely to be antigenic epitopes of PV.

IgG- and IgE-Binding Capacities of PV Isotypes. Absorbance of the immunosorbent assay was used to reflect the binding capacity of IgG or IgE. IgG-binding capacities with anti-frog and anti-grass carp PV antibodies increased dose-dependently at increasing concentrations of PVI, PVII, and PVIII, further supporting that the purified proteins are PV isotypes. PVI showed the highest IgG-binding capacity with anti-frog antibody (Figure 4a), whereas PVII displayed the highest IgG-binding capacity with anti-grass carp antibody (Figure 4b). The difference in IgG-binding capacities of fish PV with anti-frog PV antibody and anti-grass carp antibody was due to the difference in PV amino acid sequences between frog and grass carp PVs. Lee et al. also demonstrated that antibodies raised against fish and frog PVs displayed varying specificity for different fish species.[31]

The IgE-binding capacity of PV samples with sera from four allergic patients also increased dose-dependently with an increasing concentration of PVI, PVII, and PVIII, as shown in panels c−f of Figure 4. The PV isotypes were recognized as allergens by the sera of all four fish allergic patients. Three isotypes purified from pilchard PV and two isotypes from anchovy, yellowtail, and bake purified PVs were also reported to have an IgE-binding capacity with different sera of fish allergic patients.[32] When the coated protein concentration was 0.1 or 10 μg mL^{-1}, the IgE-binding capacity of the three isotypes showed no significant difference. At the coated protein concentration of 1 μg mL^{-1}, PVII showed the highest IgE-binding capacity, whereas PVIII showed the lowest IgE-binding capacity. Kuehn et al.[33] pointed out that, besides the difference in PV IgE epitopes in different fish species, variability in the PV content was likely to contribute to the variation in clinical reactivity to different fish species. In this study, PVII showed the highest content in grass carp PV (Figure 2a); therefore, PVII is the dominant allergen in PV isotypes. Cai et al. also reported that PVII from red stingray is more allergenic than PVI.[15] Guo et al. reported that the 14 kDa PV isotype showed lower antibody binding capacity than the 12 kDa PV isotype from crimson sea bream.[17]

Simulated Digestibility of the Three PV Isotypes. Normally, primary food allergens present strong resistance to gastrointestinal degradation and are therefore believed to sensitize via the gut,[34] and an incomplete digestion of dietary protein may cause an inappropriate immune response in the gut.[35] Therefore, digestibility of allergens is one major factor that might affect the allergenic potential of an allergen. The effect of pepsin and trypsin digestion on IgE-binding capacity is shown in Figure 5. In comparison to the IgE-binding capacity of PV isotypes in panels c–f of Figure 4, it was apparent that digestion significantly decreased the IgE-binding capacity of the digested PV isotypes. Untersmayr et al. also reported that peptic digestion of codfish PV could significantly reduce allergenic potency probably because of the generation of small fragments.[36] The absorbance of pepsin-digested PVI was higher than 0.1, while the absorbance of pepsin-digested PVII and PVIII was less than 0.05; although the IgE-binding capacity of PVI was further decreased by trypsin digestion, the IgE-binding capacity of trypsin-digested PVI was still higher than those of pepsin-digested PVII and PVIII. Our results implied that PVI was resistant to digestion or there are IgE-binding sites after pepsin and trypsin digestions. A number of food allergens were also claimed to be resistant to simulating gastrointestinal digestion.[37−39]

To determine if there was residual PV or there were new peptides generated from digestion that could contribute to IgE-binding capacity of peptic and tryptic digests, these two digests were further fractionated by PR-HPLC (Figure 6a). Peptic digestion showed residual PVI in the digest, but most of the residual PVI can be further digested by trypsin. For the peptic digestion, 20 fractions were collected from 21 to 41 min, and each fraction was subjected to an IgE-binding capacity assay. As shown in Figure 6b, the two fractions collected from 39 to 41 min showed the highest IgE-binding capacity, suggesting that the undigested

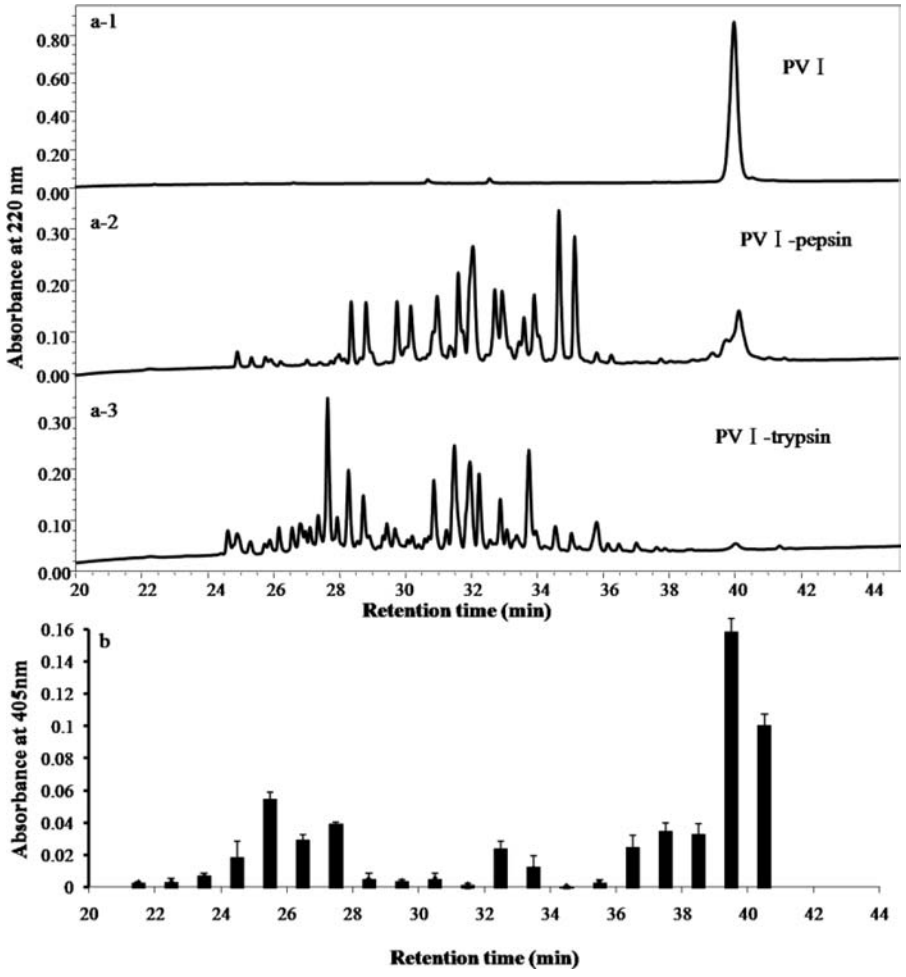

Figure 6. (a) Reverse-phase chromatogram of PVI and its pepsin and trypsin digests. (b) IgE-binding capacity of each fractions (collected every 1 min) from 21 to 41 min. Data were expressed as mean ± SD (n = 3).

PVI in the peptic digest was responsible for its IgE-binding capacity. RP-HPLC analysis was also perform on digested PVII and PVIII (data not shown), and almost all of the PVII and PVIII were digested by pepsin after 1.5 h. In summary, three PV isotypes were first purified from grass carp and identified by LC−MS/MS. These isotypes were different in molecular weight, amino acid sequence, IgG-binding capacity, IgE-binding capacity, and digestibility. PVII may be the main allergen but was liable to gastrointestinal enzymes, as well as PVIII; however, PVI was resistant to pepsin digestion.

Supporting Information

ABSTRACT: The objective of this study was to characterize the phenolic composition of Brazilian pepper (*Schinus terebinthifolius* Raddi) exocarp extract. Using UHPLC-DAD-MS/MS analysis, four anthocyanins, three biflavonoids, gallic acid, and two types of hydrolyzable tannins (galloyl glucoses, galloyl shikimic acids) were tentatively identified. The structure of the so far unknown 7-*O*-methylpelargonidin 3-*O*-*β*-D-galactopyranoside was elucidated by 2D NMR. Within the group of gallotannins, galloyl shikimic acids with uncommon degrees of galloylation (tetra- to hexagalloyl shikimic acids) were detected. Among the biflavonoids, I3′,II8-biapigenin (amentoflavone), I6,II8-biapigenin (agathisflavone), and II-2,3-dihydro-I3′,II8-biapigenin were identified, which have already been described for Anacardiaceae. From the results of the present study together with previous findings on the phenolic profile of other Anacardiaceae plants, it is concluded that 7-methoxylated flavonoids are a chemotaxonomic trait frequently found in this family.

KEYWORDS: *Anacardiaceae, biflavones, chemotaxonomy, galloyl glucose, galloyl shikimic acid, methylated anthocyanidins, NMR, Schinus terebinthifolius, tandem mass spectrometry, UHPLC*

INTRODUCTION

The Brazilian pepper tree (*Schinus terebinthifolius* Raddi) belongs to the Anacardiaceae family, which also encompasses economically relevant species such as mango (*Mangifera indica* L.), pistachio (*Pistacia vera* L.), and cashew nut (*Anacardium occidentale* L.) as well as plants of regional importance such as jocote (*Spondias purpurea* L.) and marula (*Sclerocarya birrea* (A. Rich) Hochst.).[1−4] The fruits of *S. terebinthifolius* are commonly used as a spice, either alone or in mixtures with pepper. *S. terebinthifolius*, which is indigenous to Brazil, has meanwhile spread to other countries and is even classified as an invasive species in Florida.[5,6] Its success in foreign habitats and the aggressive expansion of *S. terebinthifolius* suggest that this plant harbors phytochemicals which protect it from biotic stress. There is ample evidence for the presence of allelopathic antimicrobial compounds in various plant parts. Among these, phenolics presumably contribute to the biological activity observed.[6−8]

Although some information is available on the chemical composition of different parts of *S. terebinthifolius*,[9] detailed studies on the nature of phenolic compounds are scarce. Our previous investigations into the phytochemical profile of mango and jocote have revealed the presence of a broad spectrum of various types of phenolic compounds, such as phenolic acids, hydrolyzable tannins, and anthocyanins.[10−12] In mango peels, a novel anthocyanin, namely, 7-*O*-methylcyanidin 3-*O*-*β*-D-galactopyranoside, has been found.[11] Because of the chemotaxonomic relationship between *Mangifera indica*, *Spondias purpurea*, and *S. terebinthifolius*, we hypothesized that Brazilian pepper contains phenolic compounds of similar composition. Therefore, the objective of this work was to characterize the phenolic composition of the exocarp from *S. terebinthifolius* by UHPLC-DAD-MS/MS. The structure of a so far unknown anthocyanin was elucidated by NMR spectroscopy.

MATERIALS AND METHODS

Chemicals. All solvents and reagents were of analytical grade and were purchased from Roth (Karlsruhe, Germany), Sigma-Aldrich (Steinheim, Germany), and VWR (Darmstadt, Germany). Technical grade ethanol was obtained from Hofmann (Düsseldorf, Germany). Unless noted otherwise, deionized water was used throughout. All solvents used as UHPLC-MS eluents were of LC-MS grade and obtained from the following suppliers: Optigrade water was from Promochem (Wesel, Germany), acetonitrile was from Mallinckrodt Baker (Deventer, The Netherlands), and formic acid was from Fluka/Sigma-Aldrich. Amentoflavone (I3′,II8-biapigenin) was purchased from Extrasynthèse (Lyon, France); pelargonidin 3-*O*-glucoside and cyanidin 3-*O*-glucoside were from PhytoLab (Vestenbergsgreuth, Germany).

Sample Preparation and Extraction of Phenolic Compounds. Air-dried fruits from *S. terebinthifolius* Raddi were obtained from Fuchs (Dissen, Germany). Most of the phenolic compounds are located in the outer layer (exocarp), especially the red pigments, which have been characterized here for the first time. Thus, the extraction of phenolic compounds is more efficient and selective when the exocarp is extracted separately. Therefore, the exocarp was manually separated from the rest of the fruit and ground using a model S100 ball mill

(Retsch, Haan, Germany). Accelerated solvent extraction (ASE) was performed with a Dionex ASE 350 (Thermo Scientific, Idstein, Germany) system. The powdered exocarp (1.5 g) was mixed with diatomaceous earth (Thermo Scientific) and filled into 10 mL Dionex (ASE 350) stainless steel cells. For extraction, the cell was filled with extraction solvent (EtOH/water/acetic acid, 70:25:5, v/v/v), pressurized (1500 psi), and heated (to 160 °C). Then, the cell was rinsed with fresh extraction solvent (150% of the cell volume) and purged with a flow of nitrogen (100 psi, 60 s).

Purification of Anthocyanin Ac4. Because MS analysis was not sufficient for structure elucidation of anthocyanin Ac4, purification by SPE and preparative HPLC followed by structure elucidation by NMR spectroscopy was necessary. For this purpose, the extract obtained from ASE was evaporated in vacuo at 30 °C in a rotary evaporator (Büchi, Essen, Germany). After dilution with water (1:3, v/v), liquid−liquid extraction with ethyl acetate (1:1, v/v) was performed, followed by rotary evaporation of the aqueous phase. Subsequently, this fraction was purified[13] using a C18 (ec) SPE column (Macherey-Nagel, Düren, Germany). The solvents were removed from the eluate by evaporation and freeze-drying prior to storage in a vacuum desiccator.

For preparative HPLC, the lyophilisate was reconstituted (10 mg/mL) in acetonitrile/water/formic acid (18:80:2, v/v/v) and filtered through 0.2 μm Chromafil RC-20/15 MS filters (Macherey-Nagel).

The anthocyanins were separated on a semipreparative HPLC from Knauer (Berlin, Germany) consisting of a pump 1050, an autosampler 3950, a manager 5050, and a UV detector 2550. Using a reversed phase C18 column (Vertex, 250 × 16 mm Eurosphere II 100-5 C18, Knauer) with a C18 guard column (Vertex, 30 × 16 mm Eurospher 100-5 C18, Knauer), the compounds were eluted with 2.9% (v/v) formic acid in water (solvent A) and 2.9% (v/v) formic acid in acetonitrile (solvent B) at a constant flow rate of 6.0 mL/min. An isocratic separation with 18% of solvent B was performed for 20 min followed by conditioning and equilibration (0 min, 18% B; 4 min, 100% B; 8 min, 100% B; 10 min, 18% B; 20 min, 18% B). The injection volume was 500 μL. The peak recognition mode (500 nm, start/stop 70/100 AU) was used for collection of the anthocyanin fractions with a Foxy R1 fraction collector (Teledyne ISCO, Lincoln, NE, USA). During removal of the organic solvent and the following lyophilization, the fraction containing peak Ac4 was protected from light and temperatures above 30 °C. The lyophilisate was dissolved in deuterated methanol acidified with d_1-TFA (1%) for analysis by NMR spectroscopy. All samples were stored at −80 °C until further use.

UHPLC-DAD-MS/MS Analysis of Phenolic Compounds. For the analysis of phenolic compounds, an Acquity UPLC system (Waters, Milford, MA, USA) consisting of a binary pump (BSM), an autosampler (SM) cooled at 10 °C, a column oven (CM) set at 40 °C, a diode array detector (PDA) scanning from 190 to 500 nm, and an Acquity TQD triple-quadrupole mass spectrometer with an electrospray interface was used.

Anthocyanins were separated using an Acquity HSS-T3 RP18 column (150 mm × 2.1 mm; 1.8 μm particle size) from Waters with a guard column (5 mm × 2.1 mm). Eluent A was water/1% formic acid, and eluent B was acetonitrile/0.1% formic acid. The gradient program was as follows: 0 min, 0% B; 0.2 min, 5% B; 12 min, 16.9% B; 13 min, 98% B; 15 min, 98% B; 16 min, 5% B; 18 min, 5% B. The flow rate was 0.4 mL/min. The mass spectrometer was tuned using a solution of cyanidin 3-*O*-glucoside. The following parameters were used: capillary voltage, 1.6 kV; cone voltage, 32 V; extractor voltage, 3.0 V; RF voltage, 1.3 V; source temperature, 150 °C; desolvation temperature, 450 °C; cone gas (nitrogen) flow, 50 L/h; desolvation gas (nitrogen) flow, 800 L/h. The collision gas (argon) flow used in MS/MS experiments was 0.3 mL/min.

For the separation of nonanthocyanin phenolics, an Acquity BEH Shield RP18 column (150 mm × 2.1 mm, particle size = 1.7 μm) from Waters with a guard column (5 mm × 2.1 mm) was used. Eluent A was water/0.1% formic acid, and eluent B was acetonitrile/0.1% formic acid. The gradient program at a flow rate of 0.4 mL/min was as follows: 0 min, 2% B; 20 min, 60% B; 20.3 min, 100% B; 21.3 min, 100% B; 22 min, 2% B; 23.5 min, 2% B. The mass spectrometer was tuned using a solution of I3′,II8-biapigenin, resulting in the following parameters: capillary voltage, −1.0 kV; cone voltage, 25 V; extractor voltage, 2.0 V; RF voltage, 2.0 V; source temperature, 150 °C; desolvation temperature, 450 °C; cone gas (nitrogen) flow, 50 L/h; desolvation gas (nitrogen) flow, 800 L/h. Argon was used as the collision gas in tandem mass spectrometry experiments at a flow rate of 0.25 mL/min. The MS system was controlled by MassLynx 4.1 software.

The compounds were first detected using single MS scanning followed by fragment ion scans of the peaks showing major signals in the MS or UV−vis chromatogram. The UV−vis and mass spectra were used as a basis for structural assignments. To obtain more structural information about the anthocyanins, the cone voltage was set at 50 V for enhanced in-source fragmentation. The aglycones generated were then subjected to fragment ion scans. For the identification of gallic acid derivatives, fixed product ion scan (m/z 169) and neutral loss scans (152 u) were conducted. Furthermore, the cone voltage was set at 100 V, resulting in in-source fragmentation. The resulting fragment at m/z 169 was then used for fragment ion scan.

The exact masses of the glycosides and the corresponding aglycones were determined by HPLC-QToF-MS using a 6530 Accurate-Mass QToF mass spectrometer (Agilent, Waldbronn, Germany) connected to an Agilent 1260 series HPLC consisting of a degasser, binary pump, autosampler, and DAD. The mass spectrometer was used in positive ionization mode with the following settings: capillary voltage, 3000 V; fragmentor voltage, 200 V; and skimmer, 65 V. The separation was performed on a Kinetex C18 column (150 mm × 2.1 mm, 2.6 μm particle size) from Phenomenex (Aschaffenburg, Germany). The gradient program was as follows: 0 min, 0% B; 7 min, 5% B; 15 min, 15% B; 24 min, 50% B; 25 min, 100% B; 27 min, 100% B; 28 min, 0% B. Eluent A was 93% water, 5% acetonitrile, and 2% formic acid (v/v/v), and eluent B was 5% water, 93% acetonitrile, and 2% formic acid (v/v/v). The flow rate was 0.4 mL/min, and the column temperature was set to 40 °C.

NMR Spectroscopy. NMR experiments were carried out on a Bruker Avance DPX-300 spectrometer (Rheinstetten, Germany). The sample was dissolved in d_4-methanol (99.8% D, Deutero, Kastellaun, Germany) acidified with d_1-TFA (99.5% D, Sigma-Aldrich).

^{1}H NMR (300 MHz, CD_3OD wih CF_3COOD) δ 2.71 (d, H3″, 1H, J = 3.4 Hz), 3.83 (m, H6′, 1H), 3.86 (m, H5″, 1H), 3.99 (d, H4″, 1H, J = 3.4 Hz), 4.04 (m, H2″, 1H), 4.08 (s, H7a, 3H OCH_3), 5.34 (d, H1″, 1H, J = 7.5 Hz), 6.72 (s, H6, 1H), 7.09 (d, H3′ and H5′, 2H, J = 8.7 Hz), 7.25 (s, H8, 1H), 8.71 (d, H2′ and H6′, 2H, J = 8.7 Hz), 9.11 (s, H4, 1H); ^{13}C NMR (75 MHz CD_3OD wih CF_3COOD) δ 57.5 (C7a (OCH_3)), 62.4 (C6″), 70.1 (C4″), 72.4 (C2″), 74.1 (C3″), 77.8 (C5″), 92.9 (C8), 103.1 (C6), 104.3 (C1″), 114.4 (C4a), 117.9 (C3′ and C5′), 120.2 (C1′), 136.0 (C4), 136.2 (C2′ and C6′), 146.4 (C3), 157.2 (C8a), 158.4 (C5), 165.5 (C2), 167.1 (C4′), 170.7 (C7).

RESULTS AND DISCUSSION

Anthocyanins. The separation of phenolic compounds in exocarp extracts from *S. terebinthifolius* detectable at 500 nm is shown in Figure 1. Four peaks are designated Ac1, Ac2, Ac3, and Ac4, respectively.

Compound Ac1. Peak Ac1 showed a molecular ion at m/z 449 and a dominant fragment m/z 287 ($M^+ - 162$) in the MS^2 experiment, corresponding to a hexose attached to cyanidin. The standard of cyanidin 3-*O*-glucoside eluted later than Ac1. It is well-known that in reversed-phase chromatography, galactosides of a given aglycone elute prior to the glucosides.[14]

The product ion scan of the in-source fragment with m/z 287 of peak Ac1 gave rise to product ions at m/z 241, 213, 137, 121, and 109. Identical fragmentation was observed for the cyanidin reference (originating from cyanidin 3-*O*-glucoside). Because an authentic reference compound was not available, the identity of peak Ac1 was proven indirectly by analyzing extracts of mango (*Mangifera indica* L.) peels, chokeberry (*Aronia melanocarpa* [Michx.] Elliot) juice, and Cornelian cherry

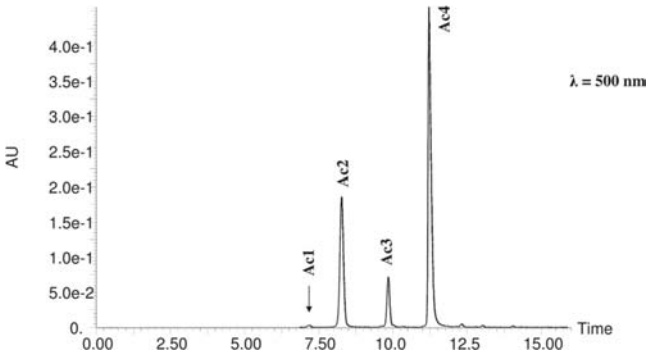

Figure 1. Separation of anthocyanins from Brazilian pepper exocarp extracts by UHPLC (detection wavelength = 500 nm). Ac1, cyanidin 3-*O*-galactoside; Ac2, pelargonidin 3-*O*-galactoside; Ac3, 7-*O*-methylcyanidin 3-*O*-galactoside; Ac4, 7-*O*-methylpelargonidin 3-*O*-galactoside.

(*Cornus mas* L.) fruit extracts. These plants have previously been demonstrated to contain cyanidin 3-*O*-galactoside.[15−18] By comparison of the retention time and the UV−vis and mass spectrometric data, compound Ac1 was identified as cyanidin 3-*O*-galactoside (Figure 2a).

Compound Ac2. Peak Ac2 showed a molecular ion at m/z 433 (M^+) and a dominant fragment at m/z 271 ($M^+ - 162$) in the MS^2 experiment, corresponding to a hexose attached to the pelargonidin aglycone. The standard of pelargonidin 3-*O*-glucoside eluted later than Ac2. As mentioned above, in reversed-phase chromatography, galactosides of a given aglycone elute prior to the glucosides.[14]

The product ion scan of the in-source fragment with m/z 271 of peak Ac2 gave rise to product ions at m/z 197, 169, 141, and 121, which matched the fragmentation of the pelargonidin 3-*O*-glucoside reference. Corresponding data have previously been reported in multistage mass spectrometric studies on black carrot anthocyanins.[15] A peak with the same retention time, UV−vis spectrum, and fragmentation pattern has been found in the above-mentioned extract from Cornelian cherry. Seeram and co-workers[16,17] had identified pelargonidin 3-*O*-galactoside in Cornelian cherry by NMR spectroscopy. On the basis of these findings, compound Ac2 was identified as pelargonidin 3-*O*-galactoside (Figure 2a).

Compound Ac3. The retention time of peak Ac3 matched that of the peonidin 3-*O*-glucoside standard. For both Ac3 and peonidin 3-*O*-glucoside, a molecular ion at m/z 463 (M^+) and a loss of 162 in MS/MS were obtained. In both cases, the product ion scan of the in-source fragment at m/z 301 showed three predominant product ions at m/z 301, 286, and 258, but several minor fragments were different (Table 1).

In mango peel extract, a compound with the same retention time, UV−vis spectrum, and fragmentation pattern as Ac3 has been described as 7-*O*-methylcyanidin 3-*O*-galactoside.[11] The fragmentation patterns of the in-source fragment with m/z 301 of Ac3 and the major anthocyanidin in a mango peel extract used in our study for comparison matched well, even regarding the minor fragments and the abundance of each fragment. On the basis of these data, compound Ac3 was identified as 7-*O*-methylcyanidin 3-*O*-galactoside (Figure 2a). Until recently, 7-*O*-methylcyanidin had been detected only in mango peels as its galactoside and in Madagascar rosy periwinkle (*Catharanthus roseus* (L.) G. Don) as its rhamnogalactoside.[18] However, a number of unusual anthocyanins including 7-*O*-methylcyanidin 3-*O*-galactoside have recently been identified in the fruits of Staghorn sumac (*Rhus typhina* L.).[19]

Compound Ac4. Prior to NMR analysis, compound Ac4 was isolated using SPE and semipreparative HPLC. These fractionation and purification processes were necessary because of the complex composition of the crude extract. The anthocyanins not only had to be concentrated, but some of the phenolic compounds, namely, hydrolyzable tannins, coeluted with the anthocyanins and therefore needed to be removed. The chromatographical purity of Ac4 was determined at 280 nm and was ≥96%.

The proton and carbon signals of Ac4 were attributed according to previously published data.[11,17,20] The ^{1}H NMR displays the typical AA′XX′ signal pattern with two doublets at δ 8.71, J = 8.6 Hz, and δ 7.06, J = 8.6 Hz, which is characteristic of a symmetric monosubstituted B-ring. The anomeric proton of the hexose moiety displays a doublet with a coupling constant of 7.5 Hz, confirming a β-glycosidic bond. The two A-ring protons exhibit two relatively broad singlets (δ 6.72 and 7.25), revealing a meta substitution. The H4 proton shows a typical high-field shifted singlet at δ 9.11. Besides the signals of the glycosyl moiety between δ 3.8 and 4.1, the spectrum includes a large singlet of a methyl group (δ 4.08). The identity of the galactosyl moiety may be deduced from the small coupling constant (J = 3.6 Hz) of the proton H4″ (δ 3.99), which is characteristic of an equatorial proton. The

[a]Nomenclature of the fragment ions according to Olivera et al.[47] Data of peonidin and the hypothetical 4′-*O*-methyl-pelargonidin are included for comparison. [b]*m*/*z* of observed product ions in bold face; relative abundance in parentheses.

corresponding proton in a glucose moiety would exhibit a larger coupling constant due to the larger dihedral angle to the adjacent protons.[21] Two-dimensional NMR experiments were conducted to determine the positions of the galactose moiety and the methyl group. HMBC correlations of both the methyl protons and the A ring protons H8 and H6 with the carbon at position C7 revealed that the methoxy group is located at C7. Furthermore, the 3-glycosidic bond was deduced from the correlation of the anomeric proton H1″ and the C4 carbon (Figure 3). The signal pattern of Ac4 is in agreement with the

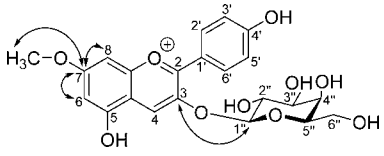

Figure 3. Structure of 7-*O*-methylpelargonidin 3-*O*-*β*-D-galactopyranoside identified in *Schinus terebinthifolius* Raddi exocarp. Arrows show important HMBC correlations.

data observed by Berardini et al.,[11] who isolated 7-*O*-methylcyanidin 3-*O*-*β*-D-galactopyranoside from mango peel. To our knowledge, 7-*O*-methylpelargonidin 3-*O*-*β*-D-galactopyranoside has not been described before.

Mass Spectrometric Considerations. Although the structure was elucidated by NMR spectroscopy, it is appropriate to discuss the mass spectrometric data of Ac4 together with those of Ac3 to confirm the proposed identity of Ac3 as 7-*O*-methylcyanidin 3-*O*-galactoside (Figure 2a). Compound Ac4 showed a molecular ion at *m*/*z* 447 (M^+) with a loss of 162 in the MS^2 experiment, resulting in a fragment with *m*/*z* 285 ($M^+ - 162$). The fragments of the aglycones match the theoretically possible fragments of 7-*O*-methylpelargonidin and also those of 4′-*O*-methylpelargonidin for Ac4 and 7-*O*-methylcyanidin or 4′- or 3′-*O*-methylcyanidin (peonidin) for Ac3 (Table 1).

Ac4 showed a molecular ion at *m*/*z* 447 (M^+) (exact mass of 447.12970) with a loss of 162 in the MS^2 experiment, resulting in a fragment with *m*/*z* 285 ($M^+ - 162$). The predominant fragments of the aglycones (formed by in-source fragmentation) at *m*/*z* 270 and 242 for Ac4 and at 286 and 258 for Ac3 correspond to the loss of a methyl group (M − 162 − 15) and of a CH_3CO moiety (M − 162 − 43), respectively (Table 1). The minor fragments may be used for the localization of the methyl moiety, but the fragments of the aglycones match the theoretically possible fragments of both conceivable structures 7-*O*-methylpelargonidin or 4′-*O*-methylpelargonidin for Ac4 and 7-*O*-methylcyanidin or 4′- or 3′-*O*-methylcyanidin (= peonidin) for Ac3.

Nevertheless, the 7-*O*-position of the methyl group on Ac4 can be deduced by comparison of the mass spectra of the aglycones of Ac3, Ac4, and the peonidin standard. Ac3 and peonidin are isomers and show partially the same fragments in the MS^2 spectra of the aglycones. The major fragments (*m*/*z* 286 and 258; loss of a methyl group (M − 162 − 15) and of a CH_3CO moiety (M − 162 − 43), respectively) match, whereas the minor fragments differ. Furthermore, the relative intensities of the major fragments and of the unfragmented aglycone (*m*/*z* 301) differ. These data indicate that the Ac3 aglycone is not peonidin and the methyl moiety is not attached at the 4′-*O* position.

The product ion scan of the in-source fragment with *m*/*z* 285 of peak Ac4 reveals a fragment pattern similar to that of Ac3, but Ac4 shows fragments that differ from those of Ac3 by 16 u. The relative intensities of all fragments match well considering the mass shift of 16 u, which is a clear indication of close structural similarity. The mass spectrometric data of Ac3 are consistent with those of 7-*O*-methylcyanidin 3-*O*-galactoside found in mango peel extract. Considering the pronounced similarity of the aglycone fragments of Ac3 and Ac4, it is convincing that also Ac4 has the methyl moiety at position 7-*O*. Additionally, it is observed that under the ionization and fragmentation conditions applied in this study, the positive charge of the aglycone fragments is always located on the B-ring and the $0,2B^+ - CO$ fragment, which would be of diagnostic value, is never detected (Table 1).

Chemotaxonomic Considerations. The occurrence of 7-*O*-methylated flavonoids in Brazilian pepper fruits is particularly remarkable in view of the results of previous investigations into the profile of flavonoids in members of the Anacardiaceae family. In mango peel extracts, 7-*O*-methylcyanidin 3-*O*-galactoside and cyanidin 3-*O*-galactoside have been described previously.[11] Mango peels have also been demonstrated to contain both quercetin 3-*O*-glycosides and 7-*O*-methylquercetin (rhamnetin) glycosides.[22,23] In peels of Costa Rican jocote fruits, several glycosides of quercetin and rhamnetin have also been found.[24] Interestingly, Kirby and colleagues detected 7-*O*-methyl derivatives of delphinidin and cyanidin, along with other unusual anthocyanins, in fruits of Staghorn sumac,[19] which is also a member of the Anacardiaceae family. However, the corresponding pelargonidin derivatives were not detected in the sumac fruits. Taking together these results, it becomes evident

that 7-methoxylated flavonoids, including anthocyanins, frequently occur in Anacardiaceae and might even be considered a chemotaxonomic trait of this family.

Gallotannins. Gallotannins often occur in complex mixtures, which renders their separation and characterization difficult. The separation by UHPLC of gallotannins and other phenolic compounds from Brazilian pepper exocarp is shown in Figure 4. The gallotannins were tentatively identified by their

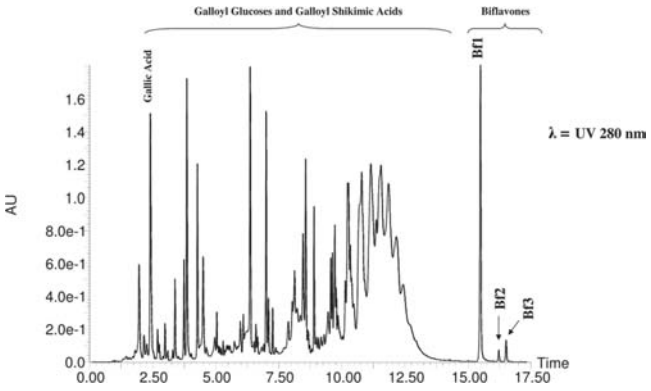

Figure 4. Separation of gallotannins (galloyl glucoses and galloyl shikimic acids) and biflavones by UHPLC (detection wavelength = 280 nm).

MS^2 spectra. There were a number of peaks showing a signal at the fixed product ion scan of m/z 169 and the neutral loss scan of 152 suggesting gallotannins. They gave rise to an in-source fragment at m/z 169 with the same product ion spectrum as gallic acid, confirming the galloyl moiety. These peaks were further examined. Two groups of compounds were distinguished: (1) Peaks showed mass differences of 152 between each other, starting at m/z 331 and ending at m/z 2155; this group was identified as mono- to tridecagalloyl glucoses (Supporting Information Tables S1 and S2). (2) Peaks showed mass differences of 152 between each other, starting at m/z 325 and ending at m/z 1085; this group was later tentatively identified as mono- to hexagalloyl shikimic acids (Supporting Information Tables S3 and S4).

In addition, gallic acid was identified by comparing retention time and mass spectrometric data with those of an authentic reference.

Galloyl Glucoses. Three peaks were detected with m/z 331 (at 2.7, 2.9, and 3.3 min) showing the same product ions differing in abundance (Supporting Information Tables S1 and S2) as reported by others for monogalloyl glucoses,[25−27] including fragments formed by the loss of water (313), the loss of hexose (169), and cross-ring fragmentation of the glucose (271, 241, 211). The loss of CO_2 was not observed for monogalloyl glucoses, indicating that the gallic acid moieties are attached to the sugar moiety via an ester linkage rather than an ether linkage.[27]

Five peaks were observed with m/z 483 (at 5.1, 5.4, 5.7, 5.8, and 6.1 min) showing the same product ions differing in abundance as reported by others for digalloyl glucoses.[25−27] The peaks with m/z 483 had the same product ions as monogalloyl glucose and an additional product ion with m/z 331. Furthermore, two of these peaks (eluting after 5.8 and 6.1 min) showed a product ion at m/z 439, corresponding to the loss of CO_2 and indicating at least one ether linkage between glucose and gallic acid. This series of peaks with m/z of 179 + ($n \times 152$) proceeded consistently until m/z 2155, that is, for n = 1−13.

Whereas there were three or five peaks with m/z 331 or 483, respectively, indicating several isomers of the mono- or digalloyl glucoses, the signals with m/z 635 and higher did not split into multiple peaks. It remains to be demonstrated whether this observation may be explained by coelution of isomers or by the absence of different isomers.

Starting from m/z 939 (n = 5), the doubly charged ion $[M - 2H]^{2-}$ was more abundant than the singly charged ion, resulting in a series of ions from m/z 469 to 1077 with m/z differences of 76. This behavior has already been described for galloyl glucoses.[28] In most cases, the fragment ions of the $[M - 2H]^{2-}$ precursor ions were interpreted also as doubly charged. Thus, this group was identified as mono- to tridecagalloyl glucoses. 1,2,3,4,6-*O*-Pentagalloylglucose has been reported to occur in *S. terebinthifolius*.[29] Although galloyl glucoses have been intensively investigated,[30] the presence of undeca-, dodeca- and tridecagalloyl glucose has only rarely been reported.[31,32]

Galloyl Shikimic Acids. Three peaks were detected with m/z 325 (at 3.4, 3.75, and 3.9 min) showing the same profile of product ions with dominant ions at m/z 169, 125 and 173 (Supporting Information Tables S3 and S4), as reported by others for monogalloyl shikimic acid.[33,34] The four peaks with m/z 477 (eluting after 6.7, 7.0, 7.6, and 7.75 min) showed the same product ions as monogalloyl shikimic acid and in two cases an additional product ion with m/z 325 corresponding to digalloyl shikimic acids. This series of peaks with m/z 173 + ($n \times 152$) proceeded consistently until m/z 1085, that is, for n = 1−6. The two heaviest compounds of this series with m/z 933 and 1085 showed equally abundant doubly charged ions $[M - 2H]^-$ with m/z 467 and 543, respectively. Thus, this group was tentatively identified as mono- to hexagalloyl shikimic acids. Monogalloyl,[35−37] digalloyl,[38,39] and trigalloyl[33,38] shikimic acids have been described before, whereas to our knowledge there is no literature precedent for the presence of tetra-, penta-, and hexagalloyl shikimic acids.

Biflavones. Three major peaks named Bf1, Bf2, and Bf3 were visible in the chromatogram recorded at 280 nm (Figure 4) in the time range from 15.0 to 17.5 min with UV absorption maxima close to 335 nm. Their UV and mass spectrometric data are shown in Table 2.

Compound Bf1. Compound Bf1 eluting at 15.6 min showed a UV spectrum similar to that of the I3′,II8-biapigenin standard, with the two maxima at 272 and 334 nm (I3′,II8-biapigenin, 269 and 335 nm). Identical fragments were found for Bf1 and the reference compound in the negative product ion scans. However, in the positive mode some differences are evident. In the mass spectrum of Bf1, m/z 387 and 153 are lacking and m/z 419 and 257 are present in significant intensity. The fragment at m/z 121 is about 4-fold more abundant in Bf1 than in I3′,II8-biapigenin. This fragmentation behavior can be explained by assuming the structure I6,II8-biapigenin.

In I6,II8-biapigenin, the C−C bond between the apigenin moieties links the two A-rings. Therefore, fissions of the C-ring leading to B^+ fragments form relatively light ions, for example, m/z 121 ($^{0,2}IB^+$ and $^{0,2}IIB^+$) and 163 ($^{0,4}IB^+$ and $^{0,4}IIB^+$). These ions are also formed from I3′,II8-biapigenin, but only when cleavage of part II occurs ($^{0,2}IIB^+$ and $^{0,4}IIB^+$). $^{1,3}IB^+$ fragmentation of I3′,II8-biapigenin yields a rather heavy ion (m/z 387) because part II is attached to the B-ring of part I. A fragment ion at m/z 387 is not observed in Bf1. The A^+

[a]Nomenclature of the fragment ions according to Zhang et al.[45] [b]In the case of Bf1 this ring fission in part I leads to the same fragment.

fragments of I6,II8-biapigenin always have the same m/z regardless of whether fission occurs in part I or II: m/z 421 ($^{1,3}IA^+$ and $^{1,3}IIA^+$) and m/z 377 ($^{0,4}IA^+$ and $^{0,4}IIA^+$). These ions are also formed from I3′,II8-biapigenin, but only when cleavage of part II occurs ($^{1,3}IIA^+$ and $^{0,4}IIA^+$). After $^{1,3}IA^+$ fragmentation of I3′,II8-biapigenin, an ion with m/z 153 is formed, which is not observed in Bf1. The fragment with m/z 257 in the mass spectrum of Bf1 can be explained by the two ring fissions $^{0,4}IA^+$ and $^{0,2}IIA^+$ if Bf1 is considered as I6,II8-biapigenin (Figure 2b).

Although the mass spectrometric data do not allow the distinction between 6,8-, 6,6- and 8,8-linkages, I6,II8-biapigenin (agathisflavone) confirms the structure, which has been described in *S. terebinthifolius*[9,40] as well as in other Anacardiaceae species (*Rhus* ssp.[41,42] and *Anacardium occidentale* (cashew)[43]).

Compound Bf2. Peak Bf2 eluting at 16.3 min with $[M - H]^-$ 539 shows UV maxima at 282 and 330 nm, which indicates the presence of a naringenin part. The MS^2 fragments in the positive ionization mode are in agreement with those of a II-2,3-dihydro-I3′,II8a biapigenin from *S. terebinthifolius*[44] and a 2,3-dihydro biapigenin from *Selaginella tamariscina*.[45] However, the mass spectrometric data do not allow the distinction between 3′,6- and 3′,8-linkages. We consider our findings as a confirmation of the II-2,3-dihydro-I3′,II8a biapigenin found by Skopp and Schwenker.[44] Therefore, peak Bf2 was tentatively identified as a II-2,3-dihydro-I3´,II8-biapigenin (I3',II8-naringeninyl-apigenin), Figure 2b).

Compound Bf3. Peak Bf3 eluting at 16.6 min with $[M - H]^-$ 537 shows the same retention time, UV spectrum, and MS fragments as the I3′,II8-biapigenin (amentoflavone) standard. The UV spectrum as well as MS^2 spectra in negative and positive mode are in agreement with published data of I3′,II8-biapigenin,[45,46] which has been described in *S. terebinthifolius*[44] as well as in other Anacardiaceae species (*Rhus* ssp.[41,42]). Therefore, peak Bf3 was identified as I3′,II8-biapigenin (Figure 2b).

In conclusion, this study contributes to the characterization of the phenolic compounds found in *S. terebinthifolius* fruits. The red pigments in the exocarp of *S. terebinthifolius* were characterized for the first time. Besides three anthocyanins, which are known from other Anacardiaceae, the novel anthocyanin 7-*O*-methylpelargonidin 3-*O*-*β*-D-galactopyranoside was identified. Furthermore, two groups of hydrolyzable tannins, namely, galloyl glucoses and galloyl shikimic acids, with partially uncommon degrees of galloylation and three biflavonoids were found.

The presence of 7-*O*-methylated anthocyanins confirms the assumed chemotaxonomic relationship to other Anacardiaceae

because 7-*O*-methylcyanidin 3-*O*-β-D-galactopyranoside was also found in mango and Staghorn sumac. These findings expand the knowledge about the phenolic profile of Anacardiaceae and enhance the chemotaxonomic understanding. Antimicrobial effects of extracts from leaves and bark of *S. terebinthifolius* have already been shown. Therefore, microbiological testing with exocarp extracts from *S. terebinthifolius* should be the focus of further investigations. The successful characterization of the phenolic profile facilitates the isolation and identification of promising antimicrobials and may thus enable the assignment of bioactivity to particular compounds. Thus, the present study provides a crucial basis for future research.

Comparative Analysis of Antioxidant Activity and Functional Components of the Ethanol Extract of Lotus (*Nelumbo nucifera*) from Various Growing Regions

Xu Zhao,[†] Jian Shen,[‡] Kyung Ja Chang,[†] and Sung Hoon Kim*[,‡]

[†]Department of Food and Nutrition, Inha University, Incheon 402-751, Korea

[‡]Department of Chemistry, Konkuk University, Seoul 143-701, Korea

Supporting Information

ABSTRACT: The variations in antioxidant activity and concentration of functional components in the ethanol extracts of lotus seeds and rhizomes based on the growing region and dryness were investigated. Free radical scavenging activity, total phenolic and flavonoid content, and concentration of several specific flavonoids and alkaloids in the ethanol extracts of lotus were measured. Antioxidant activity and its correlative total phenolic content varied characteristically depending on the growing region and dryness. High-perfomance liquid chromatography analysis showed that the ethanol extracts of lotus seeds from Vietnam (Ho Chi Minh City), raw rhizomes from Korea (Siheung), and dried rhizomes from Japan (Nigata) had the greatest specific flavonoid content. The ethanol extracts of seeds from China (Hubei), raw rhizomes from Japan (Nigata), and dried rhizomes from Korea (Siheung) had the greatest specific alkaloid content. Astragaline, rutin, isoquercetin, nuciferine, dauricine, isoliensinine, and neferine were identified in lotus rhizomes for the first time in this study.

KEYWORDS: *lotus (Nelumbo nucifera), seeds, rhizomes, ethanol extract, antioxidant, flavonoids, alkaloids*

INTRODUCTION

Lotus (*Nelumbo nucifera* Gaertn), a member of the Nymphaeaceae family, is an aquatic plant widely cultivated in Asia. Most parts of the lotus are utilized as the medicinal herbs in traditional medicine. Lotus seeds, rhizomes, leaves, and flowers are also food ingredients, especially in Korea, China, Indian, Japan, Vietnam, and Thailand. The important functional components of the lotus are flavonoids and alkaloids, and their physiological properties have been extensively reported. Flavonoids, a group of polyphenols in plants, are usually subdivided into anthoxanthins, flavanones, flavanonols, flavans, anthocyanidins, and isoflavonoids. The total flavonoid intake of an average American is ≈20 mg/day and for Japanese it is ≈63 mg/day in food originating from plants.[1] Flavonoids have been found to possess antiallergic,[2] anti-inflammatory,[3] antiviral,[4,5] antiproliferative,[6] anticarcinogenic,[7] and antioxidant[8] effects. Alkaloids, a group of compounds containing basic nitrogen atoms, are toxic to humans when consumed beyond a certain level. Previous studies have indicated that alkaloids possess antifibrotic,[9] sedative,[10] anti-HIV,[11] antioxidant, anti-inflammatory,[12] and antiobesity[13] properties.

Compared to the white lotus, which is distinguished by the color of the lotus flower, the red lotus is more commonly used as a food ingredient. The concentration of functional components differ in the red and white lotus.[14] The methanol extracts of different parts of the lotus also contain different concentrations of functional components.[15] Additionally, lotus leaves from different growing regions contain different concentrations of functional components and exert different levels of antioxidant effects.[16] Therefore, the concentration of functional components and antioxidant effect of the lotus varies with the lotus type and parts, as well as the geographic location where the lotus is grown. In addition, the concentration of functional components is also affected by the drying process.[17]

Recently, a lot of studies have been dedicated to the analysis of functional components of lotus leaves and embryos and their health-related properties. Lotus leaves and embryos are more commonly consumed as tea and medicines than as ingredients in meals. Lotus rhizomes, followed by lotus seeds, hold the largest market share as edible vegetables. Some previous studies indicated that lotus seeds and rhizomes possess antipyretic, antidiarrheal,[18] antidiabetic,[19] hepatoprotective,[20,21] anti-inflammatory,[12] and antioxidant[22,23] effects. Flavonoids (flavonols and flavanols) and several alkaloids (neferine, liensinine, isoliensinine, and nuciferine) in lotus seeds have been extensively studied.[24−27] However, only a few flavonoids such as catechin, quercetin, and gallocatechin and alkaloids from lotus rhizomes have been studied.[28−30] Therefore, determination of several specific flavonoid and alkaloid contents in lotus rhizomes and seeds may be valuable for the development of functional foods derived from the lotus.

In our preliminary studies, the ethanol extracts of lotus seeds and rhizomes showed an antiobesity effect.[31,32] The lipid components in the ethanol extracts of lotus seeds and rhizomes, which were analyzed by our group,[33] showed no antiobesity effect. Therefore, it was necessary to analyze the obesity-related functional components in the ethanol extracts of lotus seeds and rhizomes. In addition, the analysis of antioxidant activity and concentration of functional compounds, which vary with

[a]Two types of lotus were distinguished by the color of the lotus flower. [b]Dried lotus samples were purchased from different lotus farms and the Internet. [c]Raw lotus rhizomes were dried with a fan for 1 day in our laboratory.

the growing region and drying process, may play an important role in utilizing lotus extracts and developing functional foods. Therefore, in this study, we compared the antioxidant activity and concentration of several specific functional compounds in the ethanol extracts of dried lotus seeds and raw and dried lotus rhizomes from various growing regions.

MATERIALS AND METHODS

Materials and Chemicals. Lotus samples were purchased from various lotus farms and via the Internet in September 2012 (Table 1). Dried lotus seeds were procured from Korea (Muan), China (Guangzhou and Hubei), Vietnam (Ho Chi Minh City), and Thailand (Lamphun) (Figure 1A). Raw lotus rhizomes were procured from Korea (Siheung, Daegu, Haman, and Muan), and Japan (Nigata) and frozen in liquid nitrogen (Figure 1B). Dried lotus rhizomes were obtained from China (Guangxi) and Vietnam (Ho Chi Minh City). Each raw rhizome from various growing regions was subdivided into two parts: one part for direct extraction and the other for drying. For the preparation of dried lotus rhizomes, air was fan-blown on the samples for 1 day at room temperature. The water content of the dried samples was normally less than 5%. The photographs of dried lotus rhizomes are shown in Figure 1C. All lotus samples were stored at −20 °C until they were used.

Astragaline, rutin, isoquercetin, nuciferine, dauricine, isoliensinine, and neferine (≥98%) were obtained from Shenzhen Sungening Bio-Tech Co. Ltd. (Shengzhen, China). Gallic acid (≥98%), (+)-catechin (≥98%), Folin-Ciocalteu's phenol reagent, and 2,2-diphenyl-1-picrylhydrazyl (DPPH) were purchased from Sigma-Aldrich (St. Louis, MO, USA). AB-8 macroporous adsorption resin was purchased from Anhui Sanxing Resin Technology Co. Ltd. (Anhui, China).

Extraction of Lotus Seeds and Rhizomes. Each lotus sample (200 g) was blended with 70% ethanol solvent (1 L), extracted at 50 °C for 2 h and then filtered over a short pad of Celite. The filter cake was extracted with 70% ethanol three times (1 L × 3) at 50 °C for 2 h. The combined ethanol extract was evaporated to complete dryness under reduced pressure at 40 °C. The ethanol extract is referred to hereafter as LE. The crushed LE was continuously extracted with hexane (0.05 g of sample/(mL of hexane)) five times at room temperature for separating lipids and pigment components from the LE fractions. The combined hexane extract and residual fraction after hexane extraction were evaporated to dryness under reduced pressure at 40 °C. The hexane extract and residual fraction after hexane extraction from the LE fraction are respectively referred to hereafter as LEa and LEb. Each LE and LEb fraction was assayed to determine

DPPH radical scavenging activity and total phenolic and flavonoid content.

Determination of Free Radical Scavenging Activity. Free radical scavenging activity was assessed using a modified DPPH radical decoloration assay.[34] Various concentrations of samples (0−3.0 mg/mL, 0.6 mL) were reacted with a DPPH methanol solution (100 μmol/L, 5 mL) in the dark for 30 min. The absorbance was measured at 517 nm using a UV−vis spectrophotometer (Agilent Technologies, Santa Clara, CA, USA), and methanol without DPPH was used as the blank. The antioxidant activity of each sample was expressed as an EC_{50} value (the efficient concentration of the sample that decreases the initial DPPH radical formation by 50%), which was estimated using linear regression analysis. In this decoloration assay, higher EC_{50} value refers to a lower antioxidant activity.

Determination of Total Phenolic Content. The total phenolic content was analyzed using Folin-Ciocalteu assay.[34] The sample (5 mg/mL, 0.1 mL) was mixed with distilled water (2 mL) and Folin-Ciocalteu's phenol reagent (1 mL). After 5 min, a 20% aqueous sodium carbonate solution (5 mL) was added, and the mixture was incubated in the dark for 60 min. The absorbance was measured at 735 nm using a UV−vis spectrophotometer, and with distilled water was used as the blank. The total phenolic content was determined using gallic acid (0−0.8 mg/mL) as a calibration standard, and the results were expressed as milligrams of gallic acid equivalents (GAE) per gram of sample.

Determination of Total Flavonoid Content. Total flavonoid content was determined using a modified aluminum chloride coloration method.[34] Each sample (10 mg/mL, 0.6 mL) was mixed with distilled water (3.75 mL) and 5% aqueous sodium nitrite solution (0.225 mL). After 6 min, a 10% aqueous aluminum chloride solution (0.45 mL) was added, and the mixture was incubated for 5 min, after which a sodium hydroxide solution (1 mol/mL, 1.5 mL) and distilled water were added for a total volume of 7.5 mL. The absorbance was measured at 510 nm using a UV−vis spectrophotometer, and distilled water was used as the blank. Total flavonoid content was determined using catechin (0−0.8 mg/mL) as a calibration standard. The results were expressed as milligrams of catechin equivalents (CE) per gram of sample.

AB-8 Macroporous Adsorption Resin Column Chromatography. Each aliquot of the LEb fraction (1 g) was suspended in distilled water (10 mL) and centrifuged to the separate aqueous solution and precipitated fraction. The precipitated fraction was evaporated to complete dryness under reduced pressure. The aqueous solution was applied into an AB-8 macroporous adsorption resin column (190 mm × 30 mm i.d.) for 2 h and then eluted.[35] Elution was performed as follows: first, polar compounds such as amino acids and carbohydrates were eluted with distilled water (500 mL) at a flow rate of 3 mL/min; second, nonpolar compounds such as flavonoids and alkaloids were eluted with 95% ethanol (500 mL) at a flow rate of 5 mL/min; third, the rest of the compounds were eluted with 5% ammonia solution (300 mL) at a flow rate of 5 mL/min. Water and ammonia fractions eluted from the column are referred to hereafter as LEb-1 and LEb-3, respectively. The precipitated fraction of the LEb separated by centrifugation and the ethanol fraction eluted from the column were combined and designated as LEb-2. The LEb-1, LEb-2, and LEb-3 fractions were evaporated to dryness under reduced pressure. The LEb-2 fraction was analyzed by high-performance liquid chromatography (HPLC) to determine the concentration of specific flavonoids and alkaloids.

HPLC Analysis. Each LEb-2 fraction was dissolved in 50% aqueous methanol and filtered through a 0.45 μm filter. Analysis of flavonoids and alkaloids was performed by HPLC (Agilent Technologies 1200 series HPLC) using a Waters SYMMETRY C_{18} (T61421F) reverse-phase column (250 mm × 4.6 mm i.d., 5 μm particle size) with a column temperature of 30 °C. The flow rate was 1 mL/min, and the injection volume was 20 μL. For the flavonoid analysis, the mobile phase was composed of two solvents: 2% aqueous acetic acid solution (solvent A) and 0.5% aqueous acetic acid solution:acetonitrile (1:1, v/v, solvent B).[34] Gradient elution conditions were as follows: 0−10 min, 90% solvent A; 10−40 min, 90−60% solvent A; 40−55 min, 60−45% solvent A; 55−60 min, 45−20% solvent A; 60−65 min, 20−0% solvent A; 65−70 min, 0−50% solvent A; 70−75 min, 50−70% solvent A; and 75−80 min, 70−90% solvent A. Elution was monitored by UV detection at 270 and 350 nm. For the alkaloid analysis, the mobile phase was composed of two solvents: acetonitrile (solvent A) and 0.1% aqueous triethylamine solution (solvent B).[36] Gradient elution conditions were as follows: 0−15 min, 40−70% solvent A; 15−20 min, 70−100% solvent A; and 20−30 min, 100−40% solvent A. Elution was monitored by UV detection at 270 nm. The concentration of several specific flavonoids and alkaloids were calculated using the individual calibration curves.

Statistical Analysis. Statistical analysis was performed using SPSS version 17.0. Results from three independent experiments were used to calculate the mean ± SD values for each sample. Significant differences among dried seeds and raw or dried rhizomes were determined using the Student's *t* test and analysis of variance (ANOVA), respectively. Duncan's multiple range tests were performed when data differences were identified at $P < 0.05$ by ANOVA analysis. Pearson's correlation coefficient was used to analyze correlation between EC_{50} values and total phenolic and flavonoid content in the LE and LEb fractions.

RESULTS AND DISCUSSION

Descriptions of lotus samples, including growing region, lotus parts used, and storage conditions, are presented in Table 1. The growing regions in Korea, China, Japan, Vietnam, and Thailand represent the main lotus-producing and lotus-consumption areas in Asia. Since many factors such as oxidants and the presence of microorganisms can lower the quality of raw lotus, the shelf life of raw lotus is very short. A semidrying process is adopted for long-term storage and ease of transportation, although the drying process can increase the oxidative browning of some antioxidants, such as flavonoids, and reduce antioxidant capacity.[17] Dried lotus seeds and raw lotus rhizomes are commonly found in the market. In this study, raw lotus rhizomes from Korea (Siheung, Daegu, Haman, and Muan) and Japan (Nigata) were dried in order to compare the antioxidant effect and functional compound content of raw and dried rhizomes. The water content in raw lotus rhizomes was not statistically different (77.12%−81.60%, w/w).

In general, organic solvents such as ethyl acetate, *n*-butanol, and methanol are widely used to extract functional components from natural products. However, such solvents are toxic and harmful for humans. A previous report indicated that 70% alcoholic solvents (either ethanol or methanol) exhibit a higher extraction efficiency for flavonoids from lotus leaves than 100% alcoholic solvents.[37] Some of the hydrophilic functional compounds of lotus, such as certain alkaloids and polar phenolic content, are readily soluble in water and not organic solvents. Therefore, in this study, 70% aqueous ethanol was used as a nontoxic, safe, and highly efficient solvent to extract functional compounds from lotus seeds and rhizomes.

The variations in the extract yield are presented in Table 2. The large quantity of water in raw lotus samples is likely to result in a lower yield under similar extraction conditions. Accordingly, the yield of the LE fractions showed obvious variation between raw and dried lotus rhizomes (5.30%−34.85%, w/w), due to the variable water content and not the growing region. Lotus rhizomes are the richest in carbohydrates of all lotus parts studied, followed by the seeds.[38−40] The high water-absorbing capacity of carbohydrates may result in a higher yield than the actual yield of the LE fractions, especially from starch-rich lotus rhizomes. Residual ethanol, absorbed water, and other volatile compounds in the LE fraction were

14	96.62	5.53	2.69
15	95.89	5.92	1.88
16	87.77	9.42	3.93
17	89.23	6.94	3.16

[a]Yields (%) of the LEb-1, LEb-2, and LEb-3 fractions were calculated by LEb-1/LEb, LEb-2/LEb, and LEb-3/LEb, respectively. LEb-1, water fraction eluted from the AB-8 column; LEb-2, combined precipitated fraction of the LEb separated by centrifugation and the ethanol fraction eluted from the AB-8 column; LEb-3, ammonia fraction eluted from the AB-8 column.

eliminated by hexane extraction followed by vacuum drying. Therefore, the sum of the yields of LEa and LEb fractions was less than the yield of the LE fraction. The yields of the three fractions isolated by AB-8 macroporous resin column are shown in Table 3. Similarly, the total yield of all fractions, including the LEb-1, LEb-2, and LEb-3 fractions, appeared to be higher than 100% because the LEb-1 fraction contained most of the carbohydrates presented in the LE fraction.

DPPH radical scavenging activity varied significantly in the LE and LEb fractions of lotus seeds and rhizomes depending on the growing region and dryness (Table 4). The free radical scavenging activity was the highest in the LE fraction of lotus seeds from Vietnam and raw and dried rhizomes from Korea (Siheung). Phenolic compounds such as flavonoids are common plant antioxidants, and these are abundant in lotus seeds and rhizomes.[23,41] In this study, the total phenolic and flavonoid content differed significantly in the LE and LEb fractions of lotus seeds and rhizomes from different growing regions (Table 5). The total phenolic content was the highest in the LE fraction of lotus seeds from Vietnam and raw and dried rhizomes from Korea (Siheung). In addition, the total flavonoid content was the highest in the LE fraction of lotus seeds from Korea (Muan), raw rhizomes from Korea (Daegu), and dried rhizomes from Korea (Siheung). A previous report demonstrated that the polyphenolic content determined in apple cultivars was affected by the growing region.[42] Therefore, identical lotus parts may exhibit variations in antioxidant activity and total phenolic and flavonoid content depending on their growing region.

The EC_{50} values and total phenolic content, not total flavonoid content, in the LE and LEb fractions of most raw rhizomes obviously increased after drying. Compared with the results for dried rhizomes, the extraction efficiency for nonpolar phenolic compounds in raw rhizomes was lower because of the dilution of the ethanol solvent by the large water content in raw rhizomes. However, most of these nonpolar phenolic compounds (e.g., chlorogenic acid) exhibit low DPPH radical scavenging activity. The drying process led to an increase in oxidative browning, which in turn results in a decrease in antioxidant capacity.[17] Therefore, this may explain why the extracts of dried rhizomes exhibited a lower antioxidant activity than did raw rhizomes. In addition, DPPH radical scavenging capacity and total phenolic content were lower in oven-dried papaya than freeze-dried papaya because of the decomposition of functional compounds at high temperatures.[43] Dried brownish rhizomes purchased from China and Vietnam, which has been dried in a hot air oven, exhibited lower antioxidant activity and total phenolic content than other, less colored rhizomes dried under a fan in our laboratory. These results indicated that the drying process affects the antioxidant activity and total phenolic content of rhizome extract, not the total flavonoid content.

As for the lotus part, the DPPH radical scavenging activity of seeds was lower than that of rhizomes. In addition, the total phenolic content in the LE fraction of seeds was obviously lower than that of the rhizomes. However, the total flavonoid content in lotus seeds and rhizomes was similar. These results did not correspond with a previous report, which indicated that the extract of lotus seeds showed similar DPPH radical scavenging activity with rhizomes and had higher total phenolic and flavonoid content than rhizomes.[15] The ascorbic acid content in raw lotus seeds is under the detection limit,[40] but its concentration in raw rhizomes is 0.44 mg/g[39] and in dried rhizomes of Korea is from 15.5 to 22.5 mg/g.[44] Other than phenolic compounds, ascorbic acid is a well-known potent

[a]Data shown are mean ± standard deviation (SD) from SPSS; each data point was derived from three independent repetitions. LE, the ethanol extract; LEb, residual fraction after separating hexane fraction from the ethanol extract. Values with different letters within the column were significantly different ($P < 0.05$) as observed by Duncan's multiple range test for dried seeds and raw and dried rhizomes. Values with characters within raw and dried lotus rhizomes from the same growing region were significantly different as observed by the Student's t test (see P values in footnotes b, c, and d). [b]$P < 0.05$. [c]$P < 0.01$. [d]$P < 0.001$.

antioxidant, and its EC_{50} value of DPPH in this study was 5.79 μg/mL. Folin-Ciocalteu's phenol reagent is sensitive to not only phenolic compounds but also nonphenolic compounds such as vitamins and certain amino acids.[45] Studies in our laboratory showed that the Folin-Ciocalteu assay is very sensitive toward ascorbic acid while the aluminum chloride assay is not. In the Folin-Ciocalteu assay, 1 g of ascorbic acid shows 596.19 mg of GAE, but in the aluminum chloride assay, 1 g of ascorbic acid shows only 1.12 mg of CE. Therefore, the higher DPPH radical scavenging activity and total phenolic content may be attributed to a higher concentration of ascorbic acid in lotus rhizomes. In addition, the differences in the results between the current and previous study[15] may be due to potential differences in dryness and extraction conditions, which can affect the degree of oxidation and extraction efficiency of phenolic compounds and ascorbic acid.

Because the aluminum chloride coloration method is specific only for the analysis of anthoxanthins, including flavones and flavonols, estimation of total flavonoid content using this method likely underestimates the actual content.[46] In this study, similar total flavonoid content in lotus seeds and rhizomes indicated similarity in the concentration of anthoxanthins, not of other flavonoids.

Similar correlation coefficients were observed for DPPH radical scavenging activity and total phenolic and flavonoid content in the extracts of dried seeds and raw and dried rhizomes (Tables S1−S3, Supporting Information), respectively. The EC_{50} value significantly negatively correlated with the total phenolic content in lotus. A previous report also indicated that the total phenolic content in plant extracts significantly correlated with their free radical scavenging activity.[47] Therefore, our finding indicated that the total phenolic content in lotus extracts contributes to their antioxidant potential.

The HPLC analysis showed significant differences in the special flavonoids content for the LEb-2 fractions of dried lotus seeds and raw and dried rhizomes from various growing regions (Table 6). The highest concentrations of flavonoids identified in the LEb-2 fractions of lotus were as follows: catechin in seeds from Vietnam and raw and dried rhizomes from Japan; astragaline in seeds from China (Guangzhou), raw rhizomes from Korea (Muan), and dried rhizomes from Korea (Daegu); rutin in seeds from Vietnam, raw rhizomes from Japan, and dried rhizomes from China (Guangxi); and isoquercetin in seeds from Thailand, raw rhizomes from Korea (Siheung), and dried rhizomes from China (Guangxi). These results suggest that the variations in the concentration of special flavonoids in the LE fraction of lotus can be partly attributed to different growing conditions (e.g., weather and soil) and dryness. After drying, the concentration of catechin obviously increased and the concentration of other flavonoids obviously decreased in the LEb-2 fractions of rhizomes. A previous study showed that the concentration of special flavonoids such as catechin and isoquercetin in *Ziziphus jujuba* fruit was affected by the growing region, and the concentrations decreased after drying.[17]

Catechin in lotus embryos was determined by Geng et al.[48] A previous study showed that fresh seed coats from China (Wuhan) contained astragaline (7.2 mg/kg), rutin (11.8 mg/kg), and isoquercetin (55.8 mg/kg); while dried embryos contained rutin (4079.0 mg/kg) and isoquercetin (637.8 mg/kg).[24] However, in this study, the concentrations of astragaline, rutin, and isoquercetin (1.0−3.3 mg/kg, 81.7−166.5 mg/kg, and 17.8−36.1 mg/kg, respectively) were measured in dried lotus seeds, which included the seed coat, embryo, and endosperm. In dried lotus rhizomes from China (Hubei), the concentration of catechin was 25 mg/kg in rhizomes and 110 mg/kg in knots of rhizomes.[49] In this study, the concentration of catechin in dried rhizomes with knots varied from 13.2 to 133.7 mg/kg depending on the growing region and dryness. Lotus seeds that include the seed coat, embryo, and endosperm are rich in starch, lipids, and protein, and lotus rhizomes with knots contain more carbohydrates than isolated knots. This may be one of the reasons for the differences in specific flavonoid content between current and previous studies; the differences in the lotus-growing regions and analysis methods could also have contributed to the observed differences. Although many flavonoids found in lotus leaves and seeds have been previously reported,[24,34,49] the presence of astragaline, rutin, and isoquercetin in lotus rhizomes was first identified in this study. Because of the lower flavonoids contents in lotus rhizomes,[15] the levels of special flavonoids in rhizomes obtained from some growing regions were under the detection limit. In future studies, the unknown peaks in HPLC chromatograms are expected to be identified.

There were significant differences in alkaloid contents in the LEb-2 fraction of lotus seeds and raw and dried rhizomes from various growing regions (Table 7). After drying, the concentration of dauricine significantly increased and the concentration of neferine decreased in the LEb-2 fractions of rhizomes. The concentration of specific alkaloids in the LEb-2

Vietnam, raw rhizomes from Korea (Daegu), and dried rhizomes from Vietnam; and neferine in seeds from Vietnam, raw rhizomes from Japan, and dried rhizomes from Vietnam. These results suggested that the concentration of special alkaloids in the lotus extracts can vary depending on the growing region and dryness.

The presence of dauricine in lotus embryos was first reported in 1961.[51] In previous reports from China, the concentration of nuciferine in dried lotus embryos from Hubei was reported to be 10.2 mg/kg,[52] while the concentrations of isoliensinine and neferine in dried lotus embryos from Shanghai were reported as 2466.7 and 226.4 mg/kg, respectively.[26] These concentrations were different from those obtained in this study for nuciferine, isoliensinine, and neferine in dried lotus seeds (11.3−62.7, 18.8−217.2, and 93.7−312.4 mg/kg). These differences between current and previous studies may be attributed to the fact that we used whole lotus seeds containing endosperm rich in starch, lipids, and protein, and this may have affected the concentration of alkaloids. Moreover, the concentration of alkaloids in lotus seeds may vary depending on the growing region and analysis methods. In addition, the presence of dauricine, nuciferine, isoliensinine, and neferine in lotus rhizomes was first identified in this study. The concentrations of special alkaloids in rhizomes from some growing regions were under the detection limit because lotus rhizomes generally have lower levels of alkaloids. There were some unknown peaks in the HPLC chromatograms that need further analysis.

In conclusion, the antioxidant activity and total phenolic and flavonoid content in lotus seeds and rhizomes varied characteristically depending on the growing region and dryness. Total phenolic content in the LE fraction positively correlated with the antioxidant activity. In addition, the LE fractions of lotus seeds and rhizomes contained several specific flavonoids and alkaloids, and their concentrations also varied depending on the growing region and dryness. The HPLC analysis showed that the LE fractions of lotus seeds from Vietnam, raw rhizomes from Korea (Siheung), and dried rhizomes from Japan have the highest flavonoid content, and they were 2.25, 3.34, and 10.07 times more than the flavonoid content in samples with the lowest levels, that is, the seeds from China (Hubei), raw rhizomes from Korea (Haman), and dried rhizomes from Vietnam, respectively. However, the LE fractions of seeds from China (Hubei), raw rhizomes from Japan, and dried rhizomes from Korea (Siheung) had the highest alkaloid content. The HPLC analysis indicated that these samples contained 2.08, 6.15, and 6.41 times more alkaloid content than the samples with the lowest alkaloid levels which were the seeds and raw and dried rhizomes from Korea (Muan), respectively. Therefore, these results indicated that the conditions in the growing region may significantly affect the antioxidant activity and concentration of functional components in the extracts of lotus seeds and rhizomes. The antioxidant activity and concentration of functional components in rhizomes were also sensitive to dryness. Moreover, this study is the first to detect the presence of astragaline, rutin, isoquercetin, dauricine, nuciferine, isoliensinine, and neferine in lotus rhizomes and to provide novel data regarding these functional components. Therefore, the lotus part, i.e., seeds or rhizomes, obtained from different growing regions can be selected based on the antioxidant activity and concentration of functional components for specific applications as functional foods.

Supporting Information

ABSTRACT: Hazelnuts exhibit functional properties due to their content in fatty acids and phenolic compounds that could positively affect human health. The food industry requires precise traits for morphological, chemical, and physical kernel features so that some cultivars could be more suitable for specific industrial processing. In this study, agronomical and morphological features of 29 hazelnut cultivars were evaluated and a detailed structural characterization of kernel polyphenols was performed, confirming the presence of protocatechuic acid, flavan-3-ols such as catechin, procyanidin B2, six procyanidin oligomers, flavonols, and one dihydrochalcone in all the analyzed cultivars. In addition, an innovative methodology based on the MALDI-TOF mass spectrometric analysis of peptide/protein components extracted from kernels was developed for the authentication of the most valuable cultivars. The proposed method is rapid, simple, and reliable and holds the potential to be applied in quality control processes. These results could be useful in hazelnut cultivar evaluation and choice for growers, breeders, and food industry.

KEYWORDS: *European hazelnut, bioagronomical characterization, polyphenols, MALDI-TOF-MS, cultivar authentication*

INTRODUCTION

European hazelnut (*Corylus avellana* L.) is a diploid ($2n = 2x = 22$), monoecious, open pollinated tree. It has self-incompatibility, due to negative chemical interaction between pollen and style tissue, which enforces cross-pollination.[1]

Hazelnut kernels are rich in fats, proteins, and vitamins and play a relevant role in the agricultural market, mainly because of their use to provide flavor in dairy, bakery, confectionery, candy, and chocolate products. In fact, the aroma is considered to be among the primary determinants of nut quality and is improved by the roasting process. Therefore, the majority of the world hazelnut crop is roasted, thus developing a unique aroma that depends on the cultivar used and on the roasting conditions applied. The volatile profiles of fresh and roasted products were characterized by integrating sensory evaluation, nuclear magnetic resonance (NMR), high-resolution gas chromatography-olfactometry (HRGC-O), high-resolution gas chromatography-mass spectrometry (HRGC-MS), and two-dimensional gas chromatography-mass spectrometry.[2] More recently a new discipline, named sensomics, has been introduced that was aimed to perform a quantitative analysis of the entire set of aroma compounds of a given food, thus defining its sensometabolome. This methodology was applied to the analysis of odorant compounds in raw and roasted hazelnuts of different cultivars.[3,4]

European hazelnut is one of the most cultivated nut crops worldwide. This species spread from Asia Minor and Caucasus region to Europe and North Africa. Italian hazelnut production is 85.232 tons yearly for in-shell product.[5] Particularly, Campania, Lazio, Piemonte, and Sicilia account for 98% of the national production. About 90% of the world crop is sold as kernels and processed in the food industry (i.e., chocolates, bakery, dairy), and the remaining 10% is sold as in-shell product and consumed fresh, blanched, or roasted.[6] The food industry requires uniform high-quality nuts and precise morphological, chemical, and physical kernel characteristics, as well as absence of defects.[7,8] European hazelnut includes several cultivars, biotypes, and accessions, and many of these come from Europe and Turkey. These cultivars show a high level of genetic diversity for traits such as vigor, growth habits, suckering, nut size and shape, and shell thickness.[1] Cultivars more used in the food industry are Tonda Gentile delle Langhe, also named Tonda Gentile Trilobata, Tonda Gentile Romana, Tonda di Giffoni, S. Giovanni, Mortarella, and Riccia di Talanico, cultivated in Italy; Tombul, Sivri, Palaz, and Fosa, cultivated in Turkey; Negret and Pauetet produced in Spain. Among Italian cultivars, Tonda di Giffoni and Tonda Gentile delle Langhe gained the Protected Geographical Indication (PGI) European marks "Nocciola di Giffoni" and "Nocciola Piemonte", respectively. These cultivars are particularly appreciated for their agronomic traits such as resistance to pathogens and pests, round kernels of excellent quality, and consistent yields, and for their processing qualities such as

sweetness, low burnt aroma, and cooked bread aroma.[9,10] Other minor Italian cultivars such as Tonda Bianca, Tonda Rossa, Camponica, and Riccia di Talanico are mainly destined to be sold in shelled form as snacks for direct consumption (fresh consumption).[7,11] USA production, especially that from Oregon, is principally destined for fresh consumption and only recently has been directed to industrial use.[12]

Hazelnut consumption may have a positive influence on human health,[13,14] as kernels are rich in unsaturated fatty acids (i.e., oleic, palmitic, stearic, linoleic, and linolenic acids)[15] and in α-tocopherol (vitamin E) and polyphenols.[16,17] Furthermore, the presence of Fe, Zn, and Cu and a high K/Na ratio make hazelnut interesting for human diets, and especially for electrolyte balance.[17] The bioaccessibility of essential and toxic elements in hazelnut kernels has been also evaluated.[18]

In this context, the analysis of nut and kernel phenotypic traits and polyphenolic content could lead to define genotype specific features, providing information useful to growers, breeders, and the food industry for cultivar evaluation and choice. The agronomical and morphological features of 29 hazelnut cultivars originating from different geographical areas were characterized in this study. In addition, a comprehensive study of the phenolic composition of extracts from hazelnut kernels was conducted.

The authentication of different cultivars is also crucial in the definition of hazelnut quality. Traditional methods to identify hazelnut cultivars were based on phenotypic observations that may be affected by environmental and developmental factors, making cultivar differentiation difficult. Therefore, the development of innovative analytical methodologies that could suitably integrate well-established protocols for cultivar authentication is clearly desirable. DNA-typing methods such as random amplification of polymorphic DNA (RAPD), inter-simple sequence repeat (ISSR), restriction fragment length polymorphism (RFLP), amplification refractory mutation system (ARMS-PCR), and simple sequence repeat (SSR) were known to be useful for revealing genetic polymorphisms among different cultivars and accurately identifying hazelnut cultivars. However, these methods were laborious and time-consuming and were mainly applied on leaf material.[19−21]

Other approaches used for hazelnut cultivar identification were based on the analysis of volatile constituents and metabolites using chromatographic and/or spectroscopic techniques such as gas chromatography coupled to mass spectrometry (GC-MS)[22] and NMR[10,23] as well as on the analysis of trace elements such as lanthanides by means of inductively coupled plasma mass spectrometry (ICP-MS).[24] In addition, a few papers describe the application of molecular profiling strategies based on matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) in food science,[25,26] and novel methodologies have been developed for authentication and detection of fraud in different food matrices.[27,28] In this study, a similar approach has been developed, based on the MALDI-TOF-MS analysis of the peptide/protein fraction extracted from kernels, and, for the first time, has been applied to hazelnut cultivar authentication.

MATERIALS AND METHODS

Plant Material. Twenty-nine hazelnut cultivars originating from different geographical areas were used (Table 1). Three plants per cultivar were maintained in the same agronomical and pedoclimatical conditions, in the Fruit Tree Research Unit's collection field (CRA-FRC) located in Pignataro Maggiore (Caserta province, Italy). All plants were about seven years old.

Chemicals. High performance liquid chromatography (HPLC) grade methanol, HPLC grade acetonitrile, and formic acid were obtained from Merck (Darmstadt, Germany). HPLC grade *n*-hexane and chloroform were obtained from Carlo Erba (Milan, Italy). Protocatechuic acid, quercetin-3-*O*-rhamnoside (quercitrin), phloretin-2′-*O*-glucoside (phloridzin), myricetin, sodium carbonate, sinapinic acid, and ribonuclease A (Rnase A) and trifluoroacetic acid (TFA) were purchased from Sigma Chemical Company (St. Louis, MO, USA). (+)-Catechin, procyanidin B2, and myricetin-3-*O*-rhamnoside (myricitrin) were purchased from Extrasynthese (Genay, France). HPLC grade water (18.2 mΩ) was prepared using a Millipore Milli-Q purification system (Millipore Corp., Bedford, MA, USA).

Agronomical and Pomological Characterization. Agronomical and pomological traits were evaluated for each cultivar for three years (2010−2012), according to the guidelines provided by Bioversity International in the "Descriptor for Hazelnut".[29] The investigated plants were taken from the Fruit Tree Research Unit's collection field (Pignataro Maggiore-Caserta, Campania, South Italy). Nut samples from the selected cultivars were collected at the ripening time optimum for each cultivar, i.e., when nut falling, observed at maturity, occurred.[29] Nut samples were dried at 43 °C to prevent quality deterioration and rancidity, frozen with carbon dioxide to destroy insect pests, and stored according to good handling practices in clean, closed vials at room temperature. Twelve standard descriptors were evaluated.[29] Agronomical traits, such as growth habit, vigor, and suckering, were evaluated on three plants per cultivar. Pomological traits, such as nut shape, nut weight, kernel weight, and yield, were estimated on 50 nuts per cultivar for each year (Table 1). These characters were monitored following previously reported guidelines.[30,31] The percentage of pellicle removal was estimated after blanching kernels at 115 °C for 20 min and skin was removed by mechanical brushing.[32]

Sample Treatment and Polyphenol Extraction. Kernels (with skin) were ground with an electric blender, and, for each cultivar, 5 g of these samples was defatted three times with 10 mL of *n*-hexane, with the help of an ultrasonic bath, and then filtered through filter paper. The defatted samples were extracted with 15 mL of methanol in an ultrasonic bath for 60 min. Extracts were then dried in a rotary evaporator (LaboRota 4000/HB Efficient, Heidolph, Schwabach, Germany) and stored at −20 °C until analysis.

HPLC-UV Analysis. Extracts from different hazelnut cultivars were analyzed by HPLC-UV using a HP 1110 series HPLC (Agilent, Palo Alto, CA, USA) equipped with a binary pump (G-1312A) and a UV detector (G-1314A). Compounds were separated on an XBridge BEH C18 column (130 Å, 5 μm, 4.6 mm × 150 mm) (Waters, Milford, MA, USA) at a flow rate of 1 mL/min; solvent A was 0.1% formic acid, and solvent B was 0.1% formic acid in acetonitrile. After an 8 min hold at 2% solvent B, elution was performed according to the following conditions: from 2% (B) to 35% (B) in 42 min, from 35% (B) to 95% (B) in 2 min, followed by 10 min of maintenance. Extracts were reconstituted in HPLC solvent A prior to injection into the HPLC, and chromatograms were acquired at 280 nm. Standard curves for each polyphenol standard were prepared over a concentration range of 2.5−30 μg/mL with five different concentration levels and duplicate injections at each level. Peak area ratios between the areas of each polyphenol standard and those of myricetin, used as internal standard, were calculated and plotted against the corresponding standard concentration, using weighted linear regression to generate standard curves. All samples were prepared and analyzed in duplicate. Results were expressed as mg/kg of fresh weight (FW).

ESI-ITMS^n Analysis. Identification of phenolic compounds present in the different HPLC separated fractions was carried out by electrospray ionization multistage ion trap mass spectrometry (ESI-ITMS^n) using a Finnigan LCQ DECA XP Max ion trap mass spectrometer (Thermo Finnigan, San Jose, CA, USA) equipped with Xcalibur system manager data acquisition software (Thermo Finnigan, San Jose, CA, USA). Mass spectra were recorded from mass/charge (m/z) 50 to 1200 in negative ionization mode. The capillary voltage

[a] According to the "Descriptors for hazelnut (*Corylus avellana* L.)", Bioversity, FAO and CIHEAM. 2008. [b] Phenological and carpological traits were calculated from three-yearly data. The investigated plants were from the Fruit Tree Research Unit's collection field. [c] Early: < 02/28. Medium-early: 03/01−03/10. Intermediate: 03/11−03/20. Medium-late: 03/21−03/30. Late: >03/30.

was set at −10 V, the spray voltage was at 3.0 kV, and the tube lens offset was at −10 V. The capillary temperature was 275 °C. Data were acquired in MS, MS/MS, and MS^n scanning mode.

Statistical Analysis. Data were analyzed in the R environment,[33] using Packages FactoMineR,[34] ade4,[35] and ggplot2[36] (R version 3.1.0). R is a software environment for statistical computing and graphics that provides a wide variety of statistical (linear and nonlinear modeling, classical statistical tests, classification, clustering, etc.) and graphical techniques.[33] FactoMineR is a package dedicated to multivariate data analysis. The main feature of this package is the possibility to take into account different types of variables (quantitative or categorical), data structures, and supplementary information.[34] The ade4 package (Data Analysis functions to analyze Ecological and Environmental data in the framework of Euclidean Exploratory methods) is dedicated to multivariate analyses for the identification and the understanding of structures of ecological communities.[35] Finally, ggplot2 is a data visualization package for the statistical programming language R.[36]

Individual and total polyphenol content as well as nut shape (length/width) and kernel weight were used for cultivar ordination by clustering. Other traits (kernel yield, growth habit, plant vigor, plant suckering, and bud break) were introduced as supplementary variables. A range score was calculated in order to make comparable variables with different ranges and to focus on distributions. Range score values for $n(x)$ are obtained as the ratio between each value (x) minus the minimum and the difference between maximum and minimum: $[X - \min(x)]/[\max(x) - \min(x)]$ for x from 1 to n. Score distributions were summarized in quartiles for graphical presentation. Hierarchical clustering was performed on principal components using Euclidean distances with the complete-linkage method.

Extraction of the Protein Fraction. 0.06 g of ground kernels (with skin) was suspended in 0.8 mL of chloroform and vortexed for 5 min. 0.8 mL of 0.1% TFA, containing 1% protease inhibitor cocktail (Sigma, St. Louis, MO, USA), was added, and protein extraction was carried out for 5 min. The mixture was then centrifuged for 10 min at 13000 rpm, and the aqueous fraction was recovered. Protein concentration was determined using the Bradford method.[37]

MALDI-TOF-MS Analyses and Processing of Mass Spectra. Two separated aliquots (0.2 μg) of the protein extract were concentrated and desalted by solid phase extraction using μZipTipC18 tips (Millipore, Billerica, MA, USA). Tips were washed and equilibrated with 0.1% TFA and eluted in 1 μL of sinapinic acid (10 mg/mL in 0.1% TFA/acetonitrile (1:1 v:v), containing 1 pmol/μL of Rnase A) used as matrix for MALDI-TOF-MS analyses. Three spectra were acquired from each well, so that six mass spectra were generated for each sample.

MALDI-TOF-MS analyses were carried out on a Voyager DE PRO mass spectrometer (AB SCIEX, Foster City, CA, USA) operating in linear positive-ion mode. Mass spectra, acquired in the m/z range 3500−15000, were calibrated using the average peaks (doubly charged ion at m/z 6841 and singly charged ion at m/z 13682) originating from the internal standard Rnase A. Mass spectra were processed and transformed in a list containing the m/z values of all the signals and the corresponding intensity, using the DataExplorer 5.1 software (AB SCIEX).

Peak intensities were normalized by considering 100 the intensity of the most intense signal in the mass spectrum, and signals having intensity <2% were excluded from the peak list. For each cultivar, peak lists obtained from the six mass spectra were aligned along the m/z axis using the NEAPOLIS software developed in-house (www.bioinformatics.org/bioinfo-af-cnr/NEAPOLIS).[38] The threshold value to align signals was fixed to 1000 ppm, so that, among the aligned signals, the minimum and maximum m/z values differed for <1000 ppm. Signals present in at least four of the six replicate mass spectra were included in the mean peak list. This processing allowed calculating the mean m/z value and the corresponding mean intensity for each signal, leading to the mean peak list of each cultivar. Mean peak lists from all the hazelnut cultivars were further aligned by NEAPOLIS to obtain the total data set. Data processed by NEAPOLIS were subjected to a visual inspection to resolve any mass spectral ambiguities.

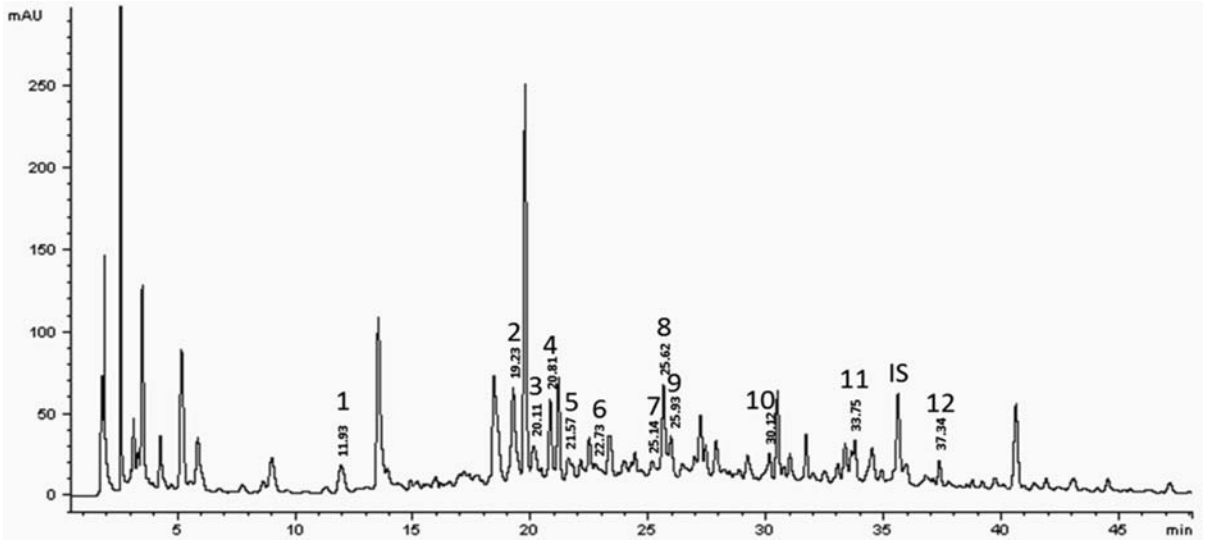

Figure 1. HPLC chromatogram of hazelnut extract (Grossal cultivar) recorded at 280 nm. Peaks are labeled according to Table 2

RESULTS AND DISCUSSION

Plants used in the present study (29 cultivars) were grown in the CRA-FRC collection field, and some of them were phenotypically and genetically characterized in previous studies.[1,39] In addition, as plants were grown in the same field, the effects of agronomical and pedoclimatical conditions on fruit characteristics were minimized and it could be assumed that the reported results are mainly related to differences in genetic traits of the cultivars.

Bioagronomical and Pomological Analysis. According to the guidelines provided by Bioversity, 12 agronomical and pomological traits were selected to describe the 29 hazelnut cultivars.[29−31] The selected traits represent well-defined characteristics of economic interest and, consequently, could act as target traits for selection by growers, breeders, and the food-processing industry. Agronomical and pomological traits are depicted in Table 1.

Significant differences among cultivars were observed for all the examined nut and kernel traits. Pellicle removal, one of the most important practices for nut quality preservation, was evaluated after roasting.[40] Percentage of pellicle removal ranged from 19.6% for Grifoll to 87.5% for Tonda di Giffoni. Other cultivars that showed good score for pellicle removal (value higher than 55%) were Avellana sp, Barcelona, Fructo Rubro, Montebello, Napoletana II, Riccia di Talanico, S. Maria del Gesù, Segorbe, Sivri, Tonda Romana, and Willamette. The most common shapes were short subcylindrical (24.14%) and subspherical (31.03%). The kernel yield ranged from 37.5% for Locale di Piazza Armerina to 50% for Tonda di Giffoni. Apolda, Barcelona, Fructo Rubro, Ghirara, Nocchione, Royal, Tonda di Giffoni, and Tonda Gentile Romana were characterized by higher nut weights, associated with kernel yield higher than 40% and lower than 50%, and Tonda di Giffoni showed the highest kernel yield (50%) (Table 1). In particular, Barcelona, Tonda di Giffoni, and Tonda Gentile Romana showed high kernel yield and subspheroidal nut shape, which are the most important traits required by the food-processing industry, as also reported by Cristofori et al.[41]

Identification and Quantification of Polyphenols and Their Correlation with Agronomical and Pomological Traits. The polyphenol fraction of each cultivar was analyzed by HPLC. The characterization of phenolic compounds was carried out by ESI-ITMS^n. Identification was achieved on the basis of pseudomolecular $[M - H]^-$ ions, together with the interpretation of their collision induced dissociation (CID) fragments. When authentic standards were available, identification was conducted by comparing retention times and MS^n fragmentation spectra with those of standards. Twelve compounds were characterized, and the classes of polyphenols detected were in agreement with those already reported in previous studies on phenolic composition of hazelnut.[42,43] As an example, the HPLC chromatogram of hazelnut extract (Grossal cultivar) recorded at 280 nm is shown in Figure 1 and the list of compounds identified in the polyphenol hazelnut extract of Grossal cultivar is reported in Table 2.

Table 2. List of Compounds Identified in Hazelnut Extract (Grossal Cultivar) Including Corresponding HPLC Retention Times, Quasi-Molecular Ions, and Fragment Ions

peak	t_R (min)	$[M - H]^-$ m/z	MS/MS ions m/z	identification
1	11.93	153	109	protocatechuic acid
2	19.23	577	451, 407, 289	procyanidin dimer (D1)
3	20.11	577	451, 407, 289	procyanidin dimer (D2)
4	20.81	865	577	procyanidin trimer (T1)
5	21.57	289	245	(+)-catechin
6	22.73	865	577	procyanidin trimer (T2)
7	25.14	577	451, 407, 289	procyanidin dimer (D3)
8	25.62	577	451, 407, 289	procyanidin B2
9	25.93	865	577	procyanidin trimer (T3)
10	30.12	463	317	myricetin-3-*O*-rhamnoside (myricitrin)
11	33.75	447	301	quercetin-3-*O*-rhamnoside (quercitrin)
12	37.34	435	273	phloretin-2′-*O*-glucoside (phloridzin)

Total and individual polyphenol content of each cultivar is summarized in Figure 2 and in Supplementary Table 1 in the Supporting Information. The total polyphenol content varied among the different cultivars and ranged from 84.80 ± 3.10 mg/kg of FW in Fructo Rubro to 32.29 ± 0.11 mg/kg of FW in Cosford. ESI-ITMS^n identification of individual phenolics in

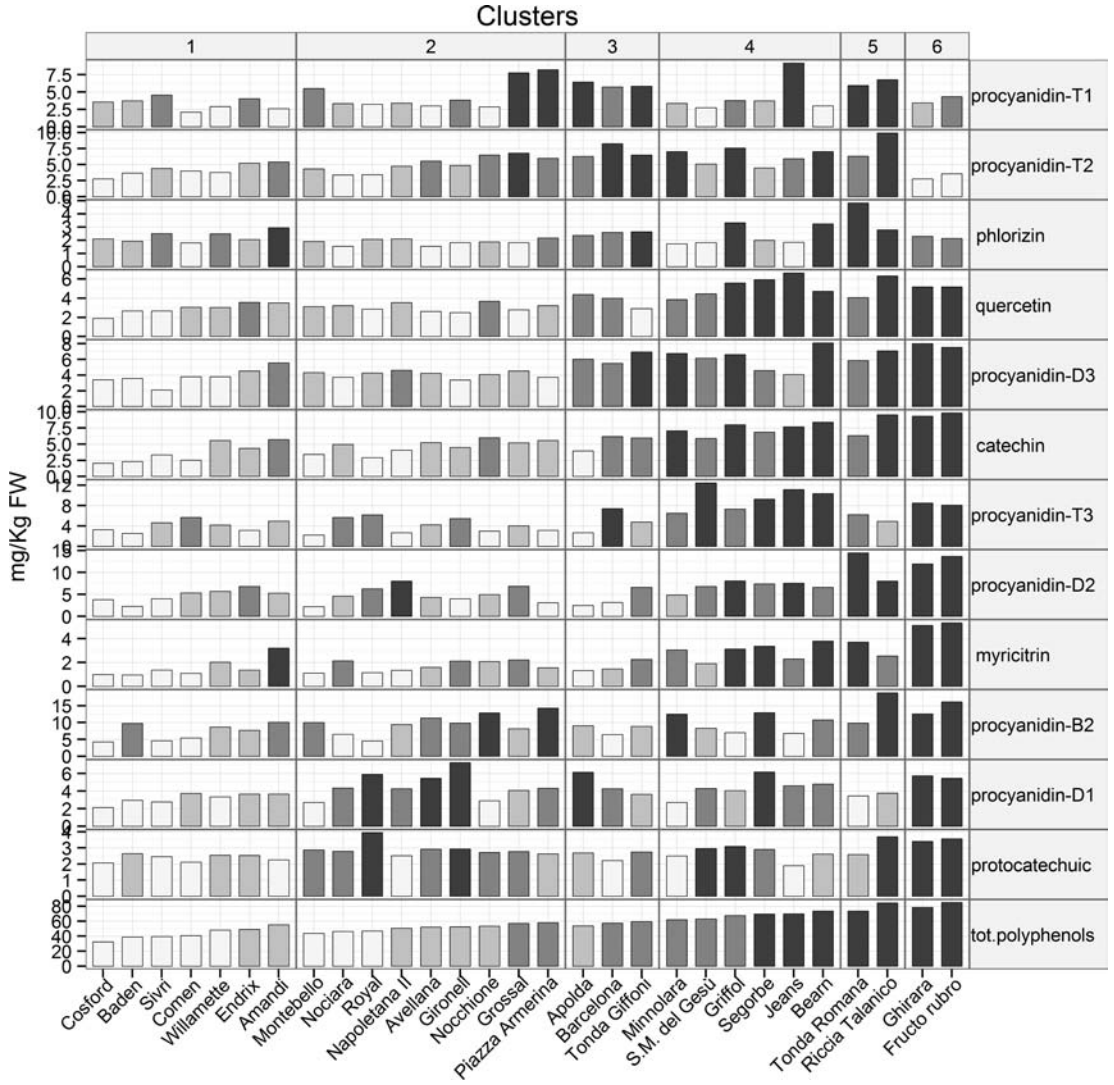

Figure 2. Medium score for total and individual polyphenolic content in kernels. Parameters are subdivided into four quartiles, depicted with different colors: white (lower quartile), light gray (second quartile), dark gray (third quartile), and black (upper quartile).

the different hazelnut extracts confirmed the presence of protocatechuic acid, flavan-3-ols such as catechin, procyanidin B2, six procyanidin oligomers (three other unidentified procyanidin dimers (indicated as D1, D2, D3), and three unidentified procyanidin trimers (indicated as T1, T2, T3)), flavonols (quercetin-3-*O*-rhamnoside and myricetin-3-*O*-rhamnoside), and one dihydrochalcone (phloretin-2-*O*-glucoside) in all the analyzed cultivars. Among the detected flavonols, quercetin-3-*O*-rhamnoside was present in highest content in whole kernels, ranging from 1.89 ± 0.04 mg/kg of FW in Cosford to 6.62 ± 0.42 mg/kg of FW in Jeans (Supplementary Table 1 in the Supporting Information).

Based on kernel polyphenolic content, cultivars were divided into six clusters, and this division reflected the clustering obtained by correlating the total polyphenolic content with the agronomical and pomological features (Figures 2 and 3).

Some agronomical and pomological features, such as kernel weight and yield, nut shape (as length/width ratio), plant vigor, suckering, bud break, and growth habit were summarized and correlated to total polyphenol content in kernels (Figure 3). A negative correlation between nut shape and kernel weight and yield was observed, and plant vigor and suckering were negatively correlated with kernel weight and yield. Tonda di Giffoni and Riccia di Talanico showed the higher kernel yield, while the higher total polyphenol content was registered in Riccia di Talanico, Tonda Gentile Romana, Fructo Rubro, and Ghirara (Figure 3, Supplementary Table 1 in the Supporting Information). Based on these features, cultivars can be divided into six clusters:

- Cluster 1 containing cultivars with small, elongated nuts and low polyphenol levels (Table 1, Figure 3). In this cluster Willamette was the most typical and Cosford was the most specific.
- Cluster 2 containing 9 of the 29 cultivars with high vigor, erect branches, low kernel yield, and low levels of procyanidin trimer (T3), phlorizin, procyanidin dimer (D3), and quercetin (Table 1, Figures 2 and 3, Supplementary Table 1 in the Supporting Information). In this cluster, Napoletana II was the most typical and Royal was the most specific.
- Cluster 3 including cultivars with round nuts and high kernel weight (Table 1, Figure 3). In this cluster Barcelona was the most typical, Apolda was the most

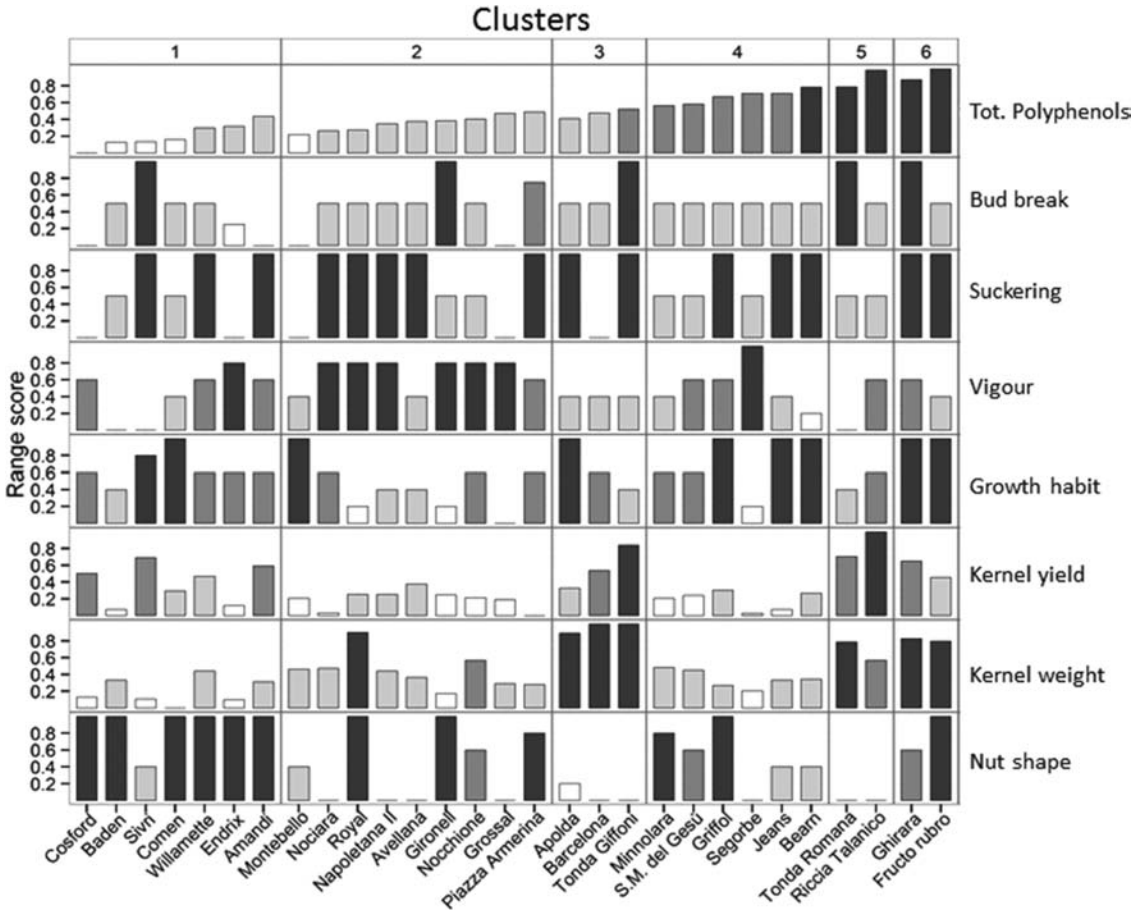

Figure 3. Medium score for morphological and pomological traits combined with total polyphenolic content in kernels. Parameters are subdivided into four quartiles, depicted with different colors: white (lower quartile), light gray (second quartile), dark gray (third quartile), and black (upper quartile).

specific, and Tonda di Giffoni showed the better combination of features of this cluster (Figure 3).

- Cluster 4 including cultivars whose nuts showed high levels of quercetin, catechin, and procyanidin trimer (T3) (Figure 2, Supplementary Table 1 in the Supporting Information). In this cluster, S. Maria del Gesù was the most typical and Jeans was the most specific.
- Cluster 5 containing two cultivars, Tonda Romana and Riccia di Talanico, that showed high kernel yield and high levels of phlorizin, procyanidin B2, procyanidin dimer (D2), and trimer (T2) (Figures 2 and 3, Supplementary Table 1 in the Supporting Information).
- Cluster 6 including two cultivars, Ghirara and Fructo Rubro, whose nuts showed the higher total polyphenol content and high levels of myricitrin, catechin, protocatehuic acid, procyanidin B2, and procyanidin dimers (D2) and (D3) (Figure 2, Supplementary Table 1 in the Supporting Information).

In order to better observe the relationship among traits of the hazelnut cultivars, a dendrogram based on Euclidean distances was constructed (Figure 4). Clustering cannot be related to geographical origin of cultivars. This is likely due to plant species domestication that resulted in a narrowing of the gene pool.[44] Two major clusters were recognized; about 67% of cultivars included in cluster 1 originated from Italy, while the others had different geographic origin (see Table 1). Cluster 2 was composed of European cultivars, excepted for Fructo

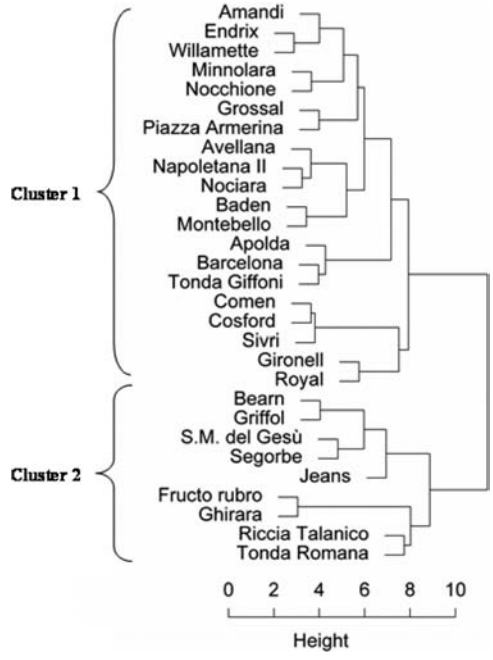

Figure 4. Dendrogram depicting the relationship among different *C. avellana* cultivars based on quantitative and qualitative features. Dendrogram was inferred using Euclidean distances with complete-linkage method.

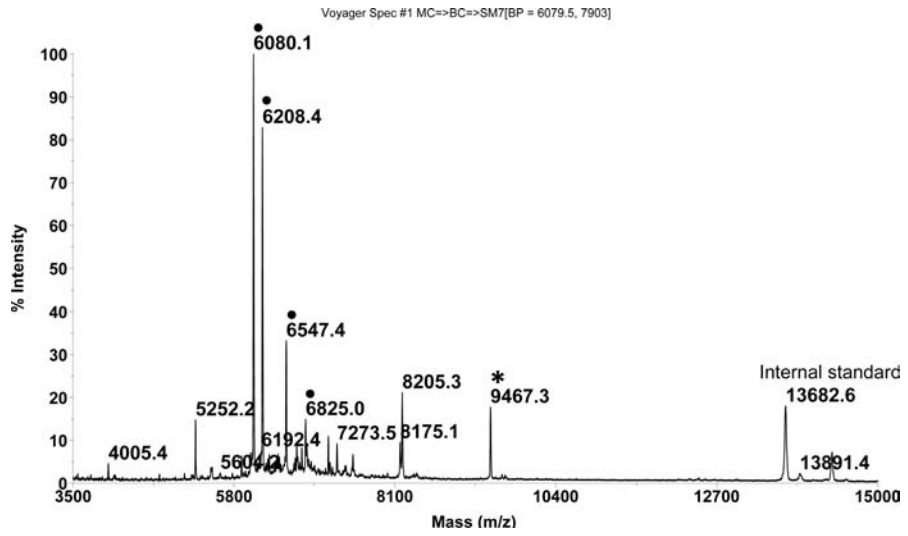

Figure 5. MALDI-TOF mass spectrum obtained from the analysis of the protein fraction extracted from kernels of the Tonda di Giffoni cultivar. The four signals present in the molecular profiles of all the cultivars are indicated by dots. The signal originating from the allergen Cor a 8 (nonspecific-lipid transfer protein) is indicated by an asterisk.

Rubro, a cultivar originating from Turkey (Figure 4). The two clusters reflected cultivar features such as kernel weight and yield, nut shape, and content of polyphenols. Cultivars included in cluster 2 showed higher content of polyphenols than those included in cluster 1, but lower kernel yield, except for Tonda Gentile Romana and Riccia di Talanico (Table 1, Figures 2, 3, and 4).

MALDI-TOF-MS Analyses and Processing of Mass Spectra. The present study was also aimed to develop an innovative strategy based on the MALDI-TOF-MS suitable for discriminating different hazelnut cultivars. The applicability of the method was ascertained by analyzing the 29 selected cultivars. Protein extracts from kernels were analyzed by MALDI-TOF-MS and mass spectra were acquired in the m/z range 3500−15000 in linear positive-ion mode, as no significant peaks were detected outside the selected m/z range (data not shown). The mass spectrum obtained from the analysis of Tonda di Giffoni is shown in Figure5.

The 29 mean peak lists were aligned by the NEAPOLIS software, and a data set that included about 270 m/z values and their corresponding mean intensity was thus generated. This data set highlighted a high variability in the molecular profile of different samples. To increase data reliability, m/z values having mean intensity less than 10% in all the cultivars were excluded from this data set. Unfortunately, only a few signals had intensity higher than 10% in the mean peak lists of Grossal and Willarmette. Therefore, these cultivars were not further included in this analysis.

Four intense signals in the m/z range 6000−7000 (m/z 6825.3, 6547.9, 6209.0, 6080.5) were present in the acquired molecular profiles, regardless of the cultivar (Supplementary Table 2 in the Supporting Information, Figure 5). Interestingly, these signals were absent in the mass spectra of protein extracts from walnuts, peanuts, and almonds (data not shown). Therefore, it could be suggested to consider this cluster as a specific signature of hazelnut presence in nut mixtures or in nut containing products.

Furthermore, a signal at m/z 9468.3 was present in the mean peak lists of 20 cultivars and it could be originated from the nonspecific-lipid transfer protein (ns-LTP), also called Cor a 8 (theoretical molecular weight 9468.0 Da), described as one of the predominant hazelnut allergens (Figure 5). Due to the presence of four disulfide bridges, the protein structure of ns-LTPs is particularly stable and resistant to proteolysis, harsh pH changes, or thermal treatments.[45] As these proteins are usually not affected by technological processes, they have been also proposed as biomarkers for in vitro diagnosis of potentially severe hazelnut allergy.[46]

The main goal of the molecular profiling analyses was to discriminate the analyzed cultivars. Specific signals among the ones having the highest mean intensity for at least one cultivar (>10%) were selected as putative biomarkers, thus leading to the data set of 35 signals reported in Supplementary Table 2 in the Supporting Information. Due to the high specificity of the acquired molecular profiles, the 27 different hazelnut cultivars could be unambiguously discriminated on the basis of specific biomarker patterns (presence and/or absence of m/z values). The obtained data could be also used for the identification of unknown samples.

In this context, in order to automate the authentication method, a four-step process that used the NEAPOLIS software was set up, as reported in the flowchart (Figure 6). At first, the mean peak list of a putative unknown sample should be aligned with a list containing the selected biomarkers of each cultivar of Group I using 500 ppm as threshold for aligning values (Sheet Group I in Supplementary File 1 in the Supporting Information) and 2 as the minimum number of aligned signals. This step would allow us to rapidly identify the unknown sample (if it is one of these 12 cultivars) on the basis of a biomarker pattern including from two to five signals, as indicated in Supplementary File 1 in the Supporting Information. In case the identification would not been achieved, as following steps, this process should be reiterated using the lists of Group II (that is defined based on the presence of the m/z value 3661, Sheet Group II in Supplementary File 1 in the Supporting Information), Group III (whose peculiar features were the absence of the m/z value 3661 and the presence of the m/z value 14345, Sheet Group III in Supplementary File 1 in the Supporting Information), Group IIIA (that included Nociara and Locale Piazza Armerina, Sheet Group IIIA in

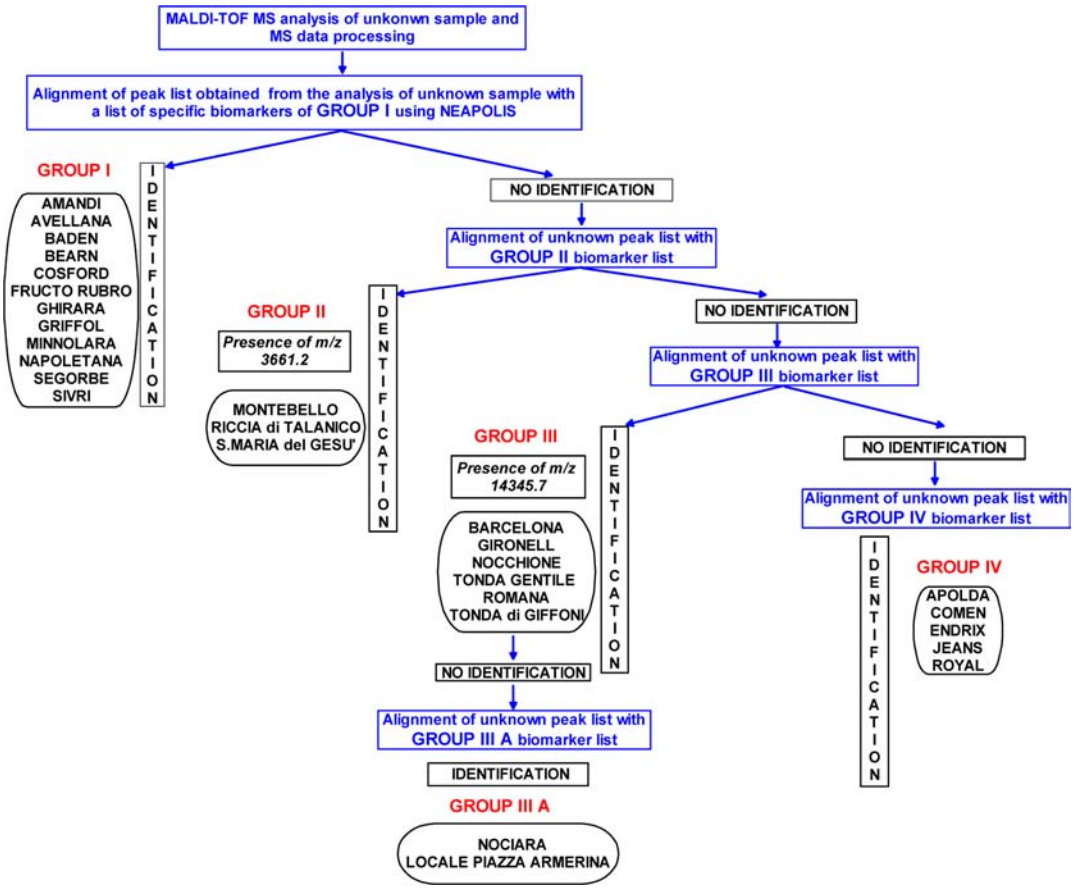

Figure 6. Flowchart of the four-step process developed in order to automate the authentication method based on the MALDI-TOF-MS molecular profiles of the different cultivars.

Supplementary File 1 in the Supporting Information), and Group IV (whose peculiar feature was the absence of the m/z values 3661 and 14345, Sheet Group IV in Supplementary File 1 in the Supporting Information). It is worth stressing that the biomarker data set could be easily updated as more mass spectrometric data on other cultivars will be gathered and bioinformatic tools could be further developed to simplify and speed the identification process.

In conclusion, although the analysis of a larger number of cultivars of different geographic origins could further validate the method, these results clearly highlight that the developed molecular profiling strategy is able to discriminate hazelnut cultivars and strongly suggest the applicability of the method to the analysis of other foods of plant origin. Furthermore, as the method is rapid, simple, and reliable, it holds the potential to be routinely applied in quality control processes.

Recombinant lipid transfer protein Cor a 8 from hazelnut: a new tool for in vitro diagnosis of potentially severe hazelnut allergy. *J. Allergy Clin. Immunol.* **2004**, *113*, 141−147.

Overcautionary and unsubstantiated precautionary labeling however unnecessarily limits the freedom of choice for allergic consumers in a given product range and can thus negatively affect their quality of life.[18]

It is therefore important to have reliable and sensitive methods at hand to accurately determine the allergenic residues' concentration and the resulting health hazard. Recent analytical approaches toward detecting lysozyme include chromatographic methods with either fluorescence or mass spectrometric detection,[19,20] DNA aptamer-based methods,[21] and competitive ELISA methods for use in wine[22] and cheese matrices.[23] Since all of these methods may be prone to severe matrix interactions,[24] a noncompetitive, indirect ELISA method to be specifically used in wine analysis was developed and validated.

Furthermore, in order to assess the contamination risk of the final product and to evaluate the possibilities for effective allergen management by technical measures, the lysozyme depletion efficiencies of an array of different filtration regimes and other enological procedures were compared. To gain knowledge about the fate of lysozyme throughout the wine making process, trial wines were treated with lysozyme, further processed according to the respective enological procedures, and successively analyzed for allergen content.

MATERIALS AND METHODS

Reagents and Materials. Antibodies were produced by immunizing rabbits with enological grade lysozyme by Eurogentecs (Seraing, Belgium) as described by Weber et al.[25]

Goat anti-rabbit antibody-horseradish peroxidase (HRP) conjugate was purchased from Dako (Glostrup, Denmark). 3,3′,5,5′-Tetramethylbenzidine (TMB) was purchased from Serva (Heidelberg, Germany). Analytical grade lysozyme, ovomucoid, and ovalbumin were purchased from Sigma (St. Louis, MO, USA), and enological grade lysozyme used for treatment of the wines was purchased from Begerow (Langenlonsheim, Germany). Further enological grade lysozyme qualities from several European producers were supplied by Oenoppia (Paris, France). Gradient grade acetonitrile for HPLC-F analysis was purchased from VWR (Radnor, PA, USA). Citric buffer, pH 4.0 (210 mM citric acid monohydrate, 300 mM potassium hydroxide), carbonate buffer, pH 9.6 (75 mM sodium carbonate, 175 mM sodium bicarbonate), Tris/Tween20 buffer, pH 9.6 (50 mM tris(hydroxymethyl)aminomethane, 150 mM sodium chloride, 0.5% Tween 20), and phosphate buffered saline (PBS)/Tween20, pH 7.4 (10 mM sodium phosphate monobasic monohydrate, 70 mM sodium phosphate dibasic, 150 mM sodium chloride, 0.5% Tween 20), for ELISA were prepared according to Weber et al.[25] All other chemicals were of analytical grade if not stated otherwise.

Wines. Wine fining and processing was performed at pilot scale size at the Geisenheim cellars using a Rheingau region Müller-Thurgau as white wine and a Nahe region Regent as red wine. Musts were inoculated with cultured yeast strains and kept in stainless steel tanks after vinification. The physicochemical characteristics of the wines are given in Table 1.

Treatment with enological grade lysozyme was carried out at the maximum permissible concentration of 0.5 g/L and, to mimic the case of a potential accidental overdose, at a double concentration of 1.0 g/L. Twenty-four hours after initial lysozyme treatment, the following filtration regimes and enological procedures were employed to evaluate their respective lysozyme depletion potentials:

- sheet filtration using SEITZ-K 200 200 × 200 mm filter sheets from Pall Corporation (Port Washington, NY, USA)
- membrane filtration using a Type 419A, grade B (beverage version) SEITZ-MEMBRAcart cartridge with 0.45 μm pore size from Pall Corporation (Port Washington, NY, USA)

Table 1. Analytical Characterization of the Trial Wines

	white wine (Müller-Thurgau)	red wine (Regent)
alcoholic strength by volume	90.7 g/L (11.5% vol)	97.2 g/L (12.3% vol)
total alcoholic strength	90.7 g/L (11.5% vol)	97.8 g/L (12.4% vol)
total dry extract	23.2 g/L	22.1 g/L
reduced extract	23.2 g/L	20.7 g/L
residual extract	8.8 g/L	8.5 g/L
reducing sugars	1.0 g/L	2.4 g/L
reducing sugars after inversion	1.0 g/L	2.4 g/L
pH value	3.5	3.6
total acidity	3.5 g/L	5.2 g/L
tartaric acid	1.7 g/L	2 g/L
lactic acid	1.4 g/L	1.8 g/L
malic acid	0.3 g/L	0.2 g/L
volatile acid	0.4 g/L	0.6 g/L
glycerol	6.6 g/L	8.5 g/L

- cross-flow filtration using a Sartoflow Compact system from Sartorius (Göttingen, Germany) at a flow of 15−20 m^3/h at a pressure of 2.5 bar
- precoat/alluviation filtration using fine diatomaceous earth (kieselguhr) from Pall Corporation (Port Washington, NY, USA) as filter aid
- centrifugation using a SB14 disk separator from GEA Westfalia (Oelde, Germany) at 7500 rounds per minute, separating 1500 L/h at a pressure of 3.5 bar
- flash-pasteurization at 72 °C for 20 s
- fining with the inorganic fining agent silica, using Klar-Sol 30 silica colloid from Erbslöh (Geisenheim, Germany) at a concentration of 0.5 mL/L
- fining with the inorganic fining agent bentonite using Aktivit bentonite from Erbslöh (Geisenheim, Germany) at a concentration of 2 g/L.

Immediately after secondary treatments, sterilizing filtration was performed on all wines, using SEITZ-EK 200 × 200 mm depth filter sheets from Pall Corporation (Port Washington, NY, USA), and wines were bottled into 0.7 L screw cap bottles. Samples were drawn after every production step and kept at 8 °C until analysis.

Electrophoresis and Immunoblotting. Electrophoresis and successive immunoblotting were carried out following the protocol laid down by Steinhoff et al.[26] Proteins were separated with precast NuPAGE Bis-Tris 12% gels and MOPS SDS running buffer from Invitrogen (Karlsruhe, Germany) after reduction with dithiothreitol (DTT) and lithium dodecyl sulfate (LDS). For unspecific detection of the separated proteins, silver staining was carried out as described by Heukeshoven and Dernick.[27]

For immunoblotting, proteins were transferred to a 2 mm nitrocellulose membrane from Whatman (Maidstone, U.K.) by semidry-Western blot and incubated overnight at room temperature with rabbit anti-lysozyme antibodies, diluted 1:20000 in Tris/Tween20 buffer, pH 9.6. Successively, the membranes were incubated with goat anti-rabbit antibody-HRP conjugate, diluted 1:20000 in Tris/Tween20 buffer, pH 9.6, and staining solution, as described by Steinhoff et al.[26]

ELISA. For ELISA analysis, analytical grade lysozyme stock solutions of 5000 mg/L were prepared in citric buffer, pH 4.0, and diluted with carbonate buffer, pH 9.6, to the respective calibration standard concentrations. Wine samples were diluted with carbonate buffer, pH 9.6, at least 1:10 or higher, if required to match the calibration range. For matrix calibration and determination of repeatability and recovery rates, untreated red and white wines were diluted 1:10 and spiked with ascending lysozyme concentrations to reach the corresponding calibration standard concentrations. Measurements were performed on two separate assays on 3 consecutive days (n = 6). For the determination of dilution linearity, wines were spiked

with 300 mg/L and diluted 1:30, 1:300, and 1:3000. For ELISA analysis of wines, 3 measurements from 2 discrete bottles of each sample were performed on 3 consecutive days (n = 6) and values confirmed by HPLC-F analysis. The measured lysozyme concentrations were calculated as % of the theoretical lysozyme concentrations. All measurements were carried out in triplicate by pipetting 3 × 200 μL per sample in Nunc MaxiSorb 96-well microplates (Thermo Fisher Scientific, Waltham, MA, USA) and leaving the plates for 16 h for incubation at 4 °C. All samples and calibration standards were prepared immediately before incubation, and stock solutions were prepared freshly at least every 5 days and kept at 4 °C.

After incubation, wells were washed three times with Tris/Tween20 buffer, pH 9.6, and blocked for 2 h with 300 μL of Tris/Tween20 buffer, pH 9.6, at room temperature under gentle agitation. After blocking, wells were washed three times with PBS/Tween20, pH 7.4, and 200 μL of rabbit anti-lysozyme antibodies diluted 1:10000 in PBS/Tween20, pH 7.4, was added to each well. After incubation for 1 h at room temperature under gentle agitation, wells were washed three times with PBS/Tween20, pH 7.4, and 200 μL of goat anti-rabbit antibody-HRP conjugate, diluted 1:2000 in PBS/Tween20, pH 7.4, was added to each well. Wells were left for incubation for 1 h at room temperature under gentle agitation again and washed three times with PBS/Tween20, pH 7.4, before rebuffering by washing three times with 300 μL of citric buffer, pH 4.0. All washing procedures were carried out using a Biotek Elx50 plate washer with 8-tube manifold (Biotek, Winooski, VT, USA).

For the detection step, HRP substrate solutions were prepared immediately before incubation as described by Holzhauser and Vieths,[28] resulting in a final organic solvent content of no more than 5%.

Incubation was started by adding 200 μL of substrate solution to each well, and color development was stopped by addition of 100 μL of stopping solution consisting of 2 M sulfuric acid after 2 min. Incubation times were intentionally kept short in order to minimize TMB autoxidation, especially with regard to the blanks and low concentration standards. Increased signal intensity deviations caused by autoxidation could otherwise augment detrimental effects on the assays sensitivity.

Photometric measurements were carried out on a Dynex MRX plate reader (Dynex, Chantilly, VA, USA) at 450 nm with a reference wavelength of 630 nm. Calculation of regression curves was accomplished using the nonweighted 4 parameter logistic regression logarithm of the SoftMax Pro v5.4 software (Molecular Devices, Sunnyvale, CA, USA).

HPLC-F. HPLC analysis was performed on a Agilent 1100 series HPLC equipped with a G1321A fluorescence detector (Agilent, Santa Clara, CA) using a Phenomenex Jupiter C4 column (250 × 4.6 mm), 5 μm particle size with 300 Å pore size (Phenomenex, Torrance, CA, USA), held at 36 °C. Mobile phase was a gradient of solvent A (0.1% formic acid in bidistilled water) and solvent B (acetonitrile). The gradient program started with 18% solvent B for the first 1.5 min, then a ramp toward 40% solvent B at minute 3 and back to 18% at minute 4.5, with a gradient flow of 2.5 mL/min. Total run time was 7 min, and lysozyme retention time was at 0.8 min. Fluorescence detection was performed at 280 nm excitation wavelength and 340 nm emission wavelength. Wine samples were diluted 1:1 with a mix of solvent A and solvent B (82/18, v/v) prior to analysis.

RESULTS AND DISCUSSION

Antibody Characterization and Lysozyme Preparation Characterization. By choosing enological grade lysozyme actually intended for enological application as sensitizing agent instead of highly purified analytical grade lysozyme, it was facilitated to raise antibodies that show specificity not only against intact lysozyme but also against partially denatured, modified, or fragmented lysozyme molecules potentially formed during production and handling of the enological product, which could still possess allergenic properties, but potentially exhibit different solubility or depletion resistance patterns than intact lysozyme.

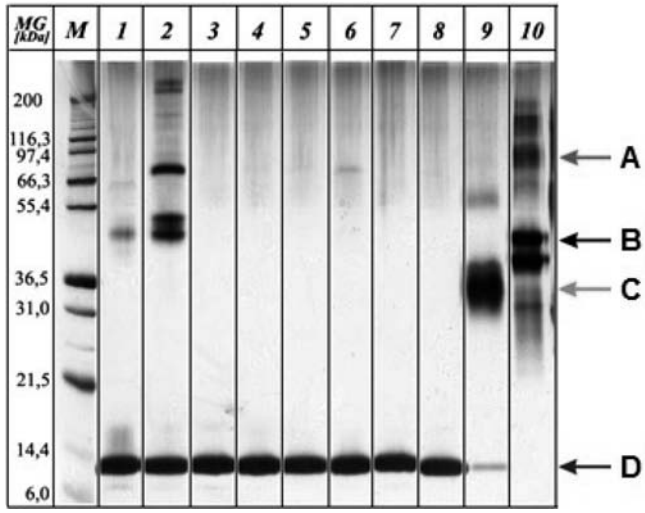

Figure 1. Antibody characterization, LDS−PAGE (M, molecular weight marker; 1−7, enological grade lysozyme preparations from different suppliers, with 7, enological grade lysozyme used for wine treatments; 8, analytical grade lysozyme; 9, analytical grade ovomucoid; 10, analytical grade ovalbumin; A, conalbumin (77−78 kDa); B, ovalbumin (42.7 kDa); C, ovomucoid (28 kDa); D, lysozyme (14.4 kDa)).

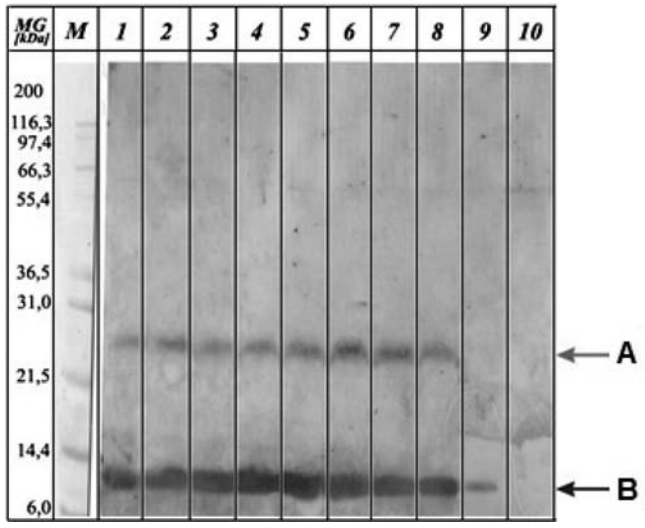

Figure 2. Antibody characterization, immunoblot (M, molecular weight marker; 1−7, enological grade lysozyme preparations from different suppliers, with 7, enological grade lysozyme used for wine treatments; 8, analytical grade lysozyme; 9, analytical grade ovomucoid; 10, analytical grade ovalbumin; A, unknown/artifact?; B, lysozyme (14.4 kDa)).

To show specific affinity and exclude potential cross-reactivities, antibodies were characterized by electrophoresis and immunoblotting of analytical grade lysozyme, enological grade lysozyme from different suppliers, and contiguous egg allergens ovomucoid and ovalbumin (Figures 1 and 2). It could be shown that the antibodies specifically detect lysozyme and show no cross-reactivity toward ovomucoid or ovalbumin (Figure 2, lanes 9 and 10). Furthermore, in all lysozyme preparations including analytical grade lysozyme, they are

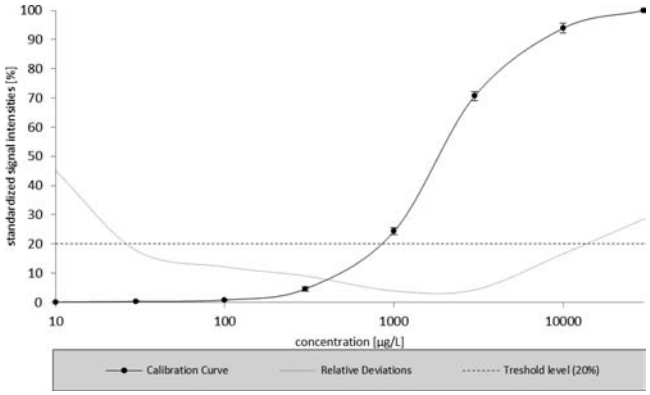

Figure 3. ELISA calibration curve and according precision profile.

Table 2. Statistical Characteristics of the Developed Indirect ELISA Method

LOD (blank + 3 × SD_{blank})	5 μg/L
LOD (blank + 3 × SD_{blank} < x − SD_x)	6 μg/L
LLOQ (blank + 10*SD_{blank})	10 μg/L
LLOQ (precision profile)	30 μg/L
ULOQ (precision profile)	10 mg/L
repeatability (n = 6)	5.2−14.7%
recovery rate	69.8−105.1%

Table 3. Performance Characteristics of HPLC-F Methods

	HPLC-F method as described	OIV-MA-AS315-14[30]
linearity range	5−400 mg/L	1−250 mg/L
correlation coeff	0.9998	0.9990
LOD	0.46 mg/L	0.18 mg/L
LOQ	1.38 mg/L	0.59 mg/L
repeatability (n = 5)		
buffer	0.98%	2.61%
white wine	1.78%	0.68%
red wine	2.54%	2.37%
recovery rate	94.4−101.3%	97.7−102.2%
retention time	0.8 min	25.5 min
total run time	7 min	40 min

capable of detecting an additional protein band of a higher molecular weight than native lysozyme (Figure 2, lanes 1−8, indicator A), possibly a lysozyme artifact or dimerized lysozyme. Since this protein has only been detected by immunoblotting and not by silver staining, specificity seems to be high and concentrations low. Immunostaining intensities suggest that the concentration is lowest in analytical grade lysozyme and may vary in enological grade lysozyme preparations, indicating a potential influence of the production protocol on its presence. Furthermore, residues of ovalbumin could be detected in some preparations (lanes 1, 2, and 6), but not in others. Low molecular weight lysozyme fragments could not be detected in either of the lysozyme preparations.

Development of the ELISA Method. Comparison of different enological grade lysozyme preparations showed a significant degree of variability in composition. In order to have a more reliably defined calibrator, calibration and validation of the ELISA method were carried out using analytical grade lysozyme. Signal response intensities of the analytical grade lysozyme used for calibration and the enological grade lysozyme used for treatments of the wines showed a correlation of 97.4−106.0% over the entire quantification range, averaging

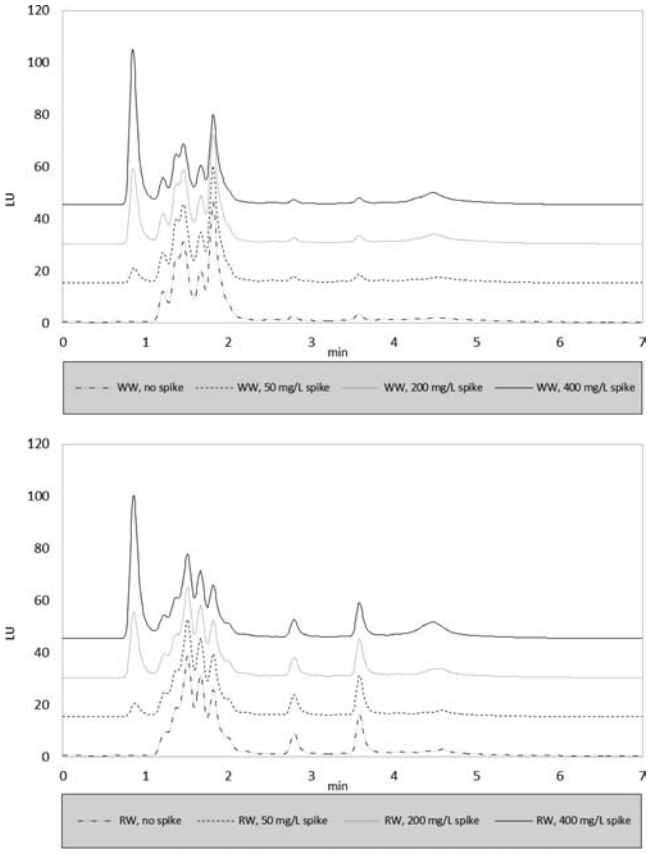

Figure 4. HPLC-F analysis of untreated white and red wines spiked with lysozyme.

101.1%. Therefore, signal responses of this enological grade lysozyme can be regarded as equivalent to the analytical grade lysozyme signal responses. In order to estimate the limit of detection (LOD) and limit of quantification (LOQ), it is a well-established approach to calculate the concentration value corresponding to the matrix blank signal plus a respective multiple (usually n = 3 for the LOD, n = 10 for the LOQ) of the standard deviation of the matrix blank signal. This approach is based on the presumption of homogeneity of variances over the complete calibration range and does not take into account the actual signal variations of the calibration standards. However, in an analytical system like an ELISA, relying on a cascade of interrelated principles for signal generation and amplification, a heteroscedastic distribution of signal deviations over the calibration range may be assumed, even more so when employing a calibration range covering multiple orders of magnitude. The relevance of this consideration for determining the LOD/LOQ is further enhanced by the nonlinear, logistic nature of the signal curve in an ELISA. With the decreasing slope on both ends of the curve, it becomes increasingly difficult to reliably distinguish between discrete calibration standard concentrations on the fringes of the calibration range. Depending on the calibration range, this may lead to the necessity to determine not only a lower but also an upper LOQ.

To account for these characteristics, an alternative approach toward establishing potentially more meaningful LOQs for ELISA methods has been pursued by employment of a precision profile as proposed by Ekins.[29] This approach aims to take both the steepness of the slope and the standard deviation of the matrix calibration standard signal over the

whole range of the calibration curve into consideration for determining a lower and an upper LOQ (LLOQ, ULOQ). Relative deviations of the calibration standard signal intensities are calculated by dividing the standard deviations of the calibration standard signals by the product of the calibration standard concentration and the steepness of the slope at the calibration standard concentration value in question. These relative deviations are plotted against a set threshold level that provides a cutoff value to warrant a defined quantitative significance of the signal read-out. Thus, the LLOQ and ULOQ are respectively considered the lowest and highest matrix calibration standard concentrations yielding a relative deviation below the threshold level. Figure 3 shows the calibration curve and the according precision profile.

Furthermore, for the estimation of an LOD taking both the standard deviation of the blank and the standard deviations of the calibration standards into account, the lowest calibration standard concentration for which the matrix blank signal plus 3-fold its standard deviation is smaller than the matrix calibration standard signal minus 3-fold its standard deviation is considered the LOD.

Table 2 summarizes the statistical characteristics of the ELISA with a relative deviation of 20% defined as the threshold value determining the LLOQ and ULOQ. The proposed alternative approaches toward establishing an LOD and LLOQ bring forth higher values than with the commonly applied method. This comes as no surprise, taking into consideration that these alternative approaches aim to address more elements of uncertainty than only the standard deviation of the blank. With regard to the presumed higher reliability of these values, however, this appears acceptable. Recovery rates for matrix calibration standards calculated on the calibration curves obtained from calibration standards in buffer were between 69.8 and 105.1% over the entire quantification range. Repeatability is reflected in the coefficients of variation ranging from 5.2 to 14.7% for n = 6. Dilution linearity for dilutions 1:30, 1:300, and 1:3000 was considered satisfying with recovery rates of 86.7−99.8%.

For analysis of the wines, ELISA results were confirmed by additional HPLC-F analysis. With a LOD < 0.5 mg/L (calculated as blank + 3 × SD_{blank}), linearity range from 5 to 400 mg/L, and correlation coefficient of 0.9998, the HPLC method shows good correlation with the statistical characteristics defined in the official OIV method for the measurement of lysozyme in wine by HPLC OIV-MA-AS315-14,[30] but with a total run time of 7 min as compared to 40 min in OIV-MA-

dx.doi.org/10.1021/jf405319j | J. Agric. Food Chem. 2014, 62, 6247−6253

AS315-14, it gives an almost 6-fold increase in sample throughput. Table 3 gives a brief comparison of the performance characteristics of the two methods. Chromatograms of untreated white and red wine spiked with ascending lysozyme concentrations are shown in Figure 4. Upon comparison, the congruency of the ELISA and the HPLC-F method was considered very satisfying. Lysozyme concentrations measured by HPLC-F in the spiked wines were on average 98% of the concentrations measured by ELISA.

Analysis of Wines and Comparison of Enological Procedures. For the assessment of the depletion efficiencies, the wines were subjected to the respective enological procedures and samples drawn directly after the procedure and after sterilizing filtration. As can be seen from Table 4, all enological procedures under scrutiny are capable of reducing the detectable lysozyme amount. However, except for bentonite fining, the detectable amounts are still very high. This shows that most of these procedures are not capable of satisfactorily reducing the lysozyme content and thus do not represent suitable tools for allergen depletion. This may at least in part be attributed to the good solubility and low molecular weight of lysozyme. For both red and white wines treated with 500 mg/L lysozyme, bentonite fining is effective enough to deplete the lysozyme amounts to levels below 100 mg/L. While the effect of sterilizing filtration on depletion efficiencies generally appears to be negligible, for bentonite-treated wines, this last filtration step serves to lower lysozyme levels below the LOD. Potentially, the remaining lysozyme adsorbs to bentonite particles still in suspension, forming aggregates big enough to be removed by sterilizing filtration. For wines treated with 1000 mg/L lysozyme, however, not even bentonite fining and successive sterilizing filtration proved sufficient for total depletion. This spotlights the general limitation of the capability of a given amount of bentonite to reduce a given amount of lysozyme present in wine. On the other hand, employed amounts of bentonite cannot be continuously increased, without severely affecting the sensory and organoleptic characteristics of the wine. Excessive use of bentonite may impair both the aroma profile and the color intensity of the wine, resulting in quality deterioration and thus economic loss. Differences in bentonite quality used for treatment of wines may effect different results regarding their respective potential to deplete lysozyme or to affect the overall quality and taste of the wine being treated.

Hence, it may be concluded that, depending on the production technique employed, lysozyme used as a microbial stabilizer in the wine making process may potentially be present in the final product at concentrations that could pose a thread toward sensitized individuals..

This is relevant information for winemakers intending to establish a good manufacturing practice guideline to be able to utilize lysozyme in their cellars and still provide wines free of allergenic residues. Since in the case of wine, the labeling of allergenic ingredients is only statutory if the wines were positively tested for allergenic residues, bentonite fining might offer a viable opportunity to enable lysozyme treatment of musts and wines, and still provide products that can safely be enjoyed by allergic individuals.

Overall, it can be concluded that allergen management of lysozyme in wine should always include analytical control for product safety. Regarding future developments, there are also intentions not to rely on dissolved lysozyme in the wine but rather to use lysozyme immobilized on supportive beads.[31] Uncertainties regarding the durability of the attachment of the lysozyme to the beads and the release rates encountered in commercial application would of course create sufficient necessity for sensitive lysozyme analysis of the final product just as if the wine was treated with the native enzyme and then subjected to filtration or other further processing.

including irrigation or public water needs. Much of this water is returned for use in agriculture or municipal uses downstream. For this reason thermoelectric power plants are located near rivers, lakes, or oceans. The power plant needs for water are vulnerable to fluctuating water supplies, and when water is not adequate, there is increased risk of environmental damage or forced shutdown if there is not sufficient water for cooling requirements.

The water demands for food production and processing are enormous. Agricultural crop irrigation accounts of 82% of all water withdrawals in the United States.[5] Irrigation directly competes with water uses such as power-plant cooling, municipal needs, and fossil fuel production and transportation. When we face drought conditions, irrigation restrictions are by state and county governments, which can negatively affect food production. Food production also can have an impact on water quality because of water runoff from agriculture, which contains fertilizers, pesticides, herbicides, and manure from agricultural production and wastewater from food-processing facilities. More efficient use of water, through drip irrigation and other conservation practices, is an ongoing need in agricultural.

Figure 1 illustrates the water withdrawals and water consumption in the United States. Electricity generation and irrigation account for the largest withdrawals of water in the United States. However, electricity generation returns most of the water withdrawn, whereas irrigation does not. This water use is critical for the production of agricultural commodities including both domestic needs and economically important exported agricultural products.[5] Major concerns exist as we see more areas of drought from global climate change (GCC). If we use irrigated biomass for energy production, our already limited water system becomes further strained. GCC estimates are that drier areas will become drier and wetter areas will become wetter. Therefore, water redistribution might be the biggest challenge for the future.

Increases in demand for food and energy have made clear the concerns about sufficient water availability. Renewable water resources throughout the world are used to various degrees for agriculture, industry, and domestic uses. In all cases agriculture is the largest user of water worldwide as summarized in Table 1. It is worth noting that Asia is the largest user of agricultural water, whereas Asia, North America, and Europe use similar amounts of water for industrial purposes. This supports the demand for more efficient use of water in agriculture and the need for plants that require less water for food or biofuel production.

Water is a key component in energy production; it is used in power generation, cooling thermal power plants, and the extraction, transportation, and processing of fuels. Water also is required for irrigation and for processing of biomass crops. Energy is also required for the collection, transport, treatment, and distribution of fresh potable water. Both fresh water and seawater are critically important for transportation of raw materials and products in most parts of the world.[7]

Continuing droughts and demands for irrigation to support food production are requiring greater reliance on underground water aquifers. To meet these needs, water wells must be drilled deeper and deeper. Energy is required for groundwater delivery. As we drill deeper for groundwater sources, more energy is required to bring the water to the surface. The need for current and expanding populations for clean water and sewage treatment will require energy to move water to the needed sites economically and without the addition of more environmental stress.

If desalination becomes economical, it could provide an important source of water at least in coastal areas. The technology for desalination of seawater and/or brackish water has improved significantly in the past 10 years; as a result, the capacity has grown rapidly. Cost remains a significant figure in desalination. The cost of desalinated water ranges from U.S. $0.50/m^3$ to U.S. $1.00/m^3$ depending on location. Recent developments including the increase of unit capacity, process design and materials, improved membrane technology, and hybrid systems are offering promise for decreased cost and reduced energy consumption in the desalination processes. The developments of low-energy desalination technologies, such as adsorption desalination, provide promise for low cost and energy demand in the future.[8,9]

The relative amounts of water used in the energy sectors differ among the various sectors. Table 2 provides a comparison of the amounts of water required to produce a million British thermal units (BTU) of energy. The data provide interesting comparisons of the amounts of water required for enhanced recovery techniques. It also must be kept in mind that currently it is difficult to recycle that water. The biofuels comparisons are important to consider, but it must be recognized that rainwater is not considered in the estimates.

Table 2. Average Water Consumption for Production of Transportation Fuels[10]

source	water for material recovery (gal/million BTU)	transformation (gal/million BTU)	total gal/million BTU
traditional oil	1.4	12.5	13.9
conventional natural gas	0	2	2
shale natural gas	12.5	2	14.5
oil sands	260	12.5	272.5
enhanced oil recovery (fracking)	1257	172	1429
irrigated corn (ethanol)	15750	9	15759
irrigated soy biodiesel	44500	9	44509

Traditional oil and gas production use less water than production from tar sands and fracturing. Developing agricultural-based bioenergy substitutes produces additional stress on water resources. The need for water posts a significant constraint on corn-based ethanol production in the United States. Water demand for ethanol fuel production ranges widely. For example, to produce a gallon of ethanol, from 995 to 2967 gal of water is required.[10] These differences are due to variations in climate and irrigation requirements. Switch grass requires from 1.9 to 9.8 gal of water per gallon of ethanol.[11] Gasoline production requirements range from 2.8 to 6.6 gal of water per gallon of gasoline.[12] In 2001, 707 million bushels of grain were used for ethanol production. By 2010, 5020 million bushels of corn were utilized for ethanol production. The 2010 figure represents about 40% of the 12447 bushels of corn produced.[5,13] To put water use and energy use in perspective, it requires about 2 million BTU to drive an automobile on a round trip from New York City to Washington, DC. Table 3 presents the amount of water necessary to produce the various fuels required for such a trip.

Table 3. Gallons of Water Consumed To Produce Fuel for a Round Trip Drive from New York City to Washington DC

fuel type	gal of water to produce fuel
natural gas (as on land)	5
shale natural gas	33
traditional oil	32
oil sands mining	616
irrigated corn (ethanol)	35616
irrigated soy	100591

Hydraulic fracturing, or "fracking," is used to extract gas and oil from rock formations where oil and gas are not normally accessible. However, after fractures are developed in the rock formations using horizontal drilling and high levels of hydraulic pressure, gas and oil can move through the fractures and become accessible. These more accessible oil and gas reserves can then be exploited by wells.[14] The Marcellus shale basin, one of the largest, extends from northern Georgia to New York. Various other formations are found in Texas, Oklahoma, Indiana, Michigan, Arkansas, Louisiana, and the Rockies.[15] Other areas of the country offer similar opportunities for oil and gas production, including North Dakota, Pennsylvania, Wyoming, and Montana[5,17] Fracking has resulted in the ability to recover vast new quantities of petroleum and natural gas, lowered energy costs, and improved energy independence for the United States. Production estimates for the Eagle Ford area in Texas are expected to reach 2−3 million barrels of oil per day by 2035. This would represent as much as 1.5−2% of current gasoline production from this single area. To accomplish this, water demand in the Eagle Ford region will increase 10-fold by 2020.[17]

It is anticipated that shale gas will make up 46% of the total energy supply of the United States by 2035. Fracking raises a major concern because of the volumes of water required and the risk of contamination of aquifers needed for food production and domestic drinking water needs. The average shale gas well requires 3−4 million gallons of water and will yield 800 million cubic feet of gas over the 7.5 year lifetime of a well.[15]

The large volumes of water required by the fracking process pose particular problems in semiarid areas where water tables are receding. This generates a competition with agricultural irrigation and domestic water needs.[16] In addition to the vast quantities of water required for fracking, the wastewater from fracking contains a variety of compounds that make it unsuitable for irrigation or domestic use. Fracking fluid contains hundreds of chemical compounds. Companies involved in fracking reported to a Congressional committee that up to 750 different chemicals are used and/or formed in the fracking process. They range from the innocuous such as sodium chloride, citric acid, coffee, and walnut hulls to toxic ones such as lead, benzene, and methanol. Twenty-nine known or possible carcinogens have been reported in fracking wastewater.[15]

A major challenge for the industry is to develop processes to clean this water enough that it can be used for other purposes, such as irrigation, potable water, or environmentally benign release to the environment. There is rising public concern about water competition where fracking is conducted in arid regions.[17]

Thermoelectric power consumption whether coal, oil, or gas requires cooling water, which comes from surface water.

Table 4. Cost and Environmental Factors for Electricity-Generating Technologies[26]

energy technology	av levelized cost of electricity ($/MWh)	median water withdrawal by cooling type (gal/MWh)	median water consumption by cooling type (gal/MWh)	CO_2 (lb/MWh)
existing technology				
conventional coal	62	531−36350	250−471	1886
natural gas combined cycle	57	253−11380	100−198	797
nuclear	59	1101−44350	269−672

wind, onshore	97		0	
wind, offshore	243		0	
solar thermal	312		8−1000	
photovoltaic	211		26	

Currently, cooling for thermoelectric power withdraws up to 75% of the surface water in some areas, however, much of it is returned for other uses.[18]

When greenhouse gases are sequestered, their cooling water demand could double because of the energy and water required for compressing the carbon dioxide.[19]

Water is very likely to become the most limiting resource in the nexus scenario. More work is needed to improve the efficiency of our water use, enhance our ability to provide clean water where needed, and purify wastewater from domestic use, energy production, and agriculture. We also need to continue development of drought- and heat-resistant crops.

■ ENERGY

The energy system, as defined by Hanlon et al.,[1] includes operations necessary to generate, transport, and distribute electricity and the steps required to produce and distribute fuels required for transportation and industry. Electrical energy is generated in a variety of power plants, which operate through the combustion of fossil fuels (coal or natural gas) or nuclear fission. These processes all generate heat, which is converted to steam, which turns turbines and ultimately generates electricity. Electricity is also generated from flowing water, wind, sunlight, and the Earth's heat (e.g., geothermal). Most electricity-generating facilities consume water either to process the raw materials used in the facility for fuel, to cool thermoelectric generation plants (fossil fuel and nuclear), or to generate the electricity itself (i.e., hydroelectric).

Thermal power plants require large amounts of water to remove excess heat. Up to 39% of all freshwater withdrawals in the United States are used for thermoelectric energy production. The needs for cooling water frequently are in competition with agriculture and municipal demands. If drought conditions increase as predicted with continuing GCC, some river flows will be very low in the summer, putting additional strain on power production and waterway transportation.[20]

In thermoelectric power plants in the United States, 1 kilowatt hour (kWh) of electricity requires the evaporation of about 2 U.S. gal (7.6 L) of water to eliminate waste heat from the process. In hydroelectric plants an average of 18 gal (68 L) of water is evaporated to generate 1 kWh of electricity. In practical terms, this means that 8−16 gal of water IS required to burn one 60 W light bulb for 12 h. This would mean that annually one incandescent light bulb would consume 3999−6300 gal of water. If it is assumed that the 111 million occupied housing units (U.S. Census Bureau 2005) burned one 60 W light bulb for 12 h a day for a year, it would require between 336 and 656 billion gallons of water use.[21]

Extraction and pumping water from ground and surface sources to sites of use requires electrical energy. The energy intensity of treatment required for different types of water source varies, depending on water sources. Fresh surface waters use energy mainly for pumping over long distances. Use of seawater adds the energy requirements for desalination. The energy required for residential end use water is very high relative to other parts of the water supply cycle. Processes such as heating water, washing clothes and dishes, and cooking all require intense energy input. Hot water usage is responsible for making end use the most energy-intensive stage of the water cycle.[22] Potable water must be pumped from its source (underground or surface) to the treatment plant, pretreated, and then pumped to consumers. In areas without adequate fresh water, it may be necessary to bring water from very long distances, making the energy footprint for this water extremely high.

Table 4 compares the cost of energy to the amount of water (withdrawals and consumption) and carbon dioxide emissions produced by various means of power generation. The data provide insight into the trade-offs of different means of energy production. Nuclear power has no carbon dioxide emissions but requires large amounts of cooling water. This water (like water for hydroelectric power generation) is suitable for reuse in agriculture or domestic use. Coal uses relatively modest amounts of water but generates high levels of carbon dioxide, which is a significant contributor to greenhouse gas and related global warming.

Southern California receives potable water from the Sacramento−San Joaquin Delta, which requires pumping water over hundreds of miles over low-lying mountains using 9200 kWh per million gallons.[23] In California the conveyance, storage, treatment, distribution, wastewater collection, and

discharge of water consumes 19% of the state's electricity, 30% of its natural gas, and 88 billion U.S. gallons (330,000,000 m^3) of diesel fuel annually. The River Network reports that the United States consumes at least 521 million megawatt-hours a year for water-related purposes, which is equivalent to 13% of the nation's electricity consumption.[24−26]

FOOD

From a global perspective food security would exist "when all people at all times have physical, social and economic access to sufficient, safe, nutritious food to meet dietary needs and food preferences".[27] Increases in demand for food and energy have made clear the concerns for sufficient water. Table 5 summarizes the amount of water required to bring selected foods to market. The water demand for animal protein foods is much higher than that for plant-based foods. This begs the question as to the sustainability of high animal protein production under ever-increasing population growth.

Table 5. Water Requirements for Food Commodities[27]

product	unit	equivalent water (m^3/unit)
cattle	head	4000
sheep and goats	head	500
fresh beef	kg	15
fresh lamb	kg	10
fresh poultry	kg	6
cereals	kg	1.5
citrus fruits	kg	1
palm oil	kg	2
pulses, roots, and tubers	kg	1

The production and processing of food are the largest users of fresh water, consuming an average of 70% of the human use of fresh water. Modern agriculture and food production requires large amounts of energy and also affects the water resources because of land degradation, changes in runoff, disruption of groundwater recharge, water quality, and availability of water and land for other purposes such as natural habitat. Modern agriculture, which is required to feed the current population, uses approximately 30% of total global energy. Fuels are required for land preparation, fertilizer production, irrigation and sowing, harvesting, transportation of crops, and processing and distribution of foods.[27]

All food production requires significant amounts of water. The quantities are determined by growing conditions and the nature of the food. Animal production, because of the inherent inefficiencies, utilizes relatively large amounts of water compared to cereals and pulses. Table 5 illustrates the range of water required to produce some basic agricultural commodities. To produce a kilogram of beef requires 15500 L of water, the same amount required to produce 12 kg of wheat or 118 kg of carrots. Making a hamburger requires >2400 L of water, not including the bun.

Table 6 contains the water requirements to produce some processed foods and fruits. This offers an interesting perspective on how much water is required for various foods. The values include production as well as processing requirements.

The Food and Agricultural Organization of the United Nations (FAO) projects that to feed the 9 billion people anticipated in 2050, global food production will need to rise by 70% and in the developing world will need to double. Currently we are not providing sufficient food to prevent global hunger. The FAO reports that in the past decade the number of chronically hungry people rose to one billion. The FAO estimated the number of people suffering from chronic hunger at 642 million in Asia and the Pacific, 265 million in sub-Saharan Africa, 53 million in Latin America and the Caribbean, and 42 million in the Near East and North Africa.[27]

Table 6. Water Requirements for Processed Foods[27]

product	quantity	equivalent water (L)
glass of beer	250 mL	75
glass of wine	125 mL	120
glass of milk	200 mL	200
glass of apple juice	200 mL	190
cup of coffee	125 mL	140
glass of orange juice	200 mL	170
cup of tea	250 mL	35
bag of chips	200 g	185
slice of bread	30 g	40
egg	40 g	135
slice of bread with cheese	30 g + 10 g	90
hamburger	150 g	2400
potato	100 g	25
tomato	70 g	13
apple	100 g	70
orange	100 g	50

The use of agricultural land for biofuels will further stress food production agriculture. The FAO projected that biofuel production by 2030 will require 35 million hectares of land, an area about the size of France and Spain combined. The projected 70% increase in food production is challenged by rising energy prices, depletion of aquifers available for water withdrawal, and the continuing loss of farmland to urbanization.

Energy conversion from solar energy to food products is inherently inefficient. Photosynthesis converts <2% of incoming solar radiation to biomass. Conversion of that biomass to food by feeding animals compounds the inefficiency, because only 5−10% of feed is converted to edible beef. Poultry is only slightly better with a 10−15% conversion. The United States expends approximately 10 units of fossil or other energy to recover one unit of food energy. To put this in perspective, a healthy male might expend 2500 kcal/day, which equates to 10000 BTU per day or 125 W.[28] If one extrapolates these numbers to the 9 billion mouths to feed in 40 years, energy for food production must be considered to be equally challenging to the water issues. In addition to developing more energy-efficient production practices from farm to fork, we also need to improve efficiency by reducing food waste. Wasted food not only does no good from a nutritional point of view, but requires energy to dispose of it. Table 7 summarizes estimated food wasted in the United States. Clearly reducing waste will

Table 7. Food Wasted in the United States[28]

food group	% ultimately wasted
grains	32
vegetables	25
fruit	23
tree nuts, peanuts	16
dairy	33
meat, poultry, fish	16
eggs	31

dx.doi.org/10.1021/jf501496r | J. Agric. Food Chem. 2014, 62, 6255−6262

ultimately improve sustainability and total food supply. However, we need to consider the entire food system, including the consumption and use of animals and the inherent inefficiencies of current animal food production.

In recent years there has been a growing interest in "eating local". Consuming locally produced foods reduces transportation and frequently addresses freshness and quality issues with produce. In some cases the locally produced products have a larger energy input than foods imported from miles away. For example, when marginal land is used, it may require more chemical input (fertilizers and pesticides), where yields per acre still remain much less.[28] Locally produced food is often labor-intensive and does not provide the efficiencies of large farming operations. It is an important niche in food production, but not likely to substantially affect food production for the 9 billion population of the future.

Establishing a model or simple measure of energy requirements to move food from farm to dinner plate is difficult because of the wide diversity of agriculture and the inherent variability of locale and climate. The cost of energy to produce food products can be extremely high, particularly when we consider production of animal protein foods.[29]

From Tables 8−10 it is clear that animal production is far less efficient than the production of corn. The efficiency also translates to other commodity crops. It is unlikely that we can convince meat-eating societies to switch to vegetarian diets in the near future. In addition, as low-consumption meat-eating societies become wealthier, it is likely that they will demand more meat protein in their diet. One approach would be to produce ground meat and sausage products that are blends of meat with pulse crops (dry beans and lentils). Pulse crops maintain protein levels, contribute fiber, and lower fat and cholesterol. Pulses are efficient crops to produce, requiring relative low levels of water and energy for production. Therefore, pulse/meat blends could provide energy-efficient and healthier options.

Table 8. Energy Use at Various Stages of Food Production[30]

use segment	energy use (quads[a])
farm fuel	1.0
farm chemicals	1.5
farm machinery	0.6
farm irrigation	0.5
processing	1.2
packaging	2.3
transportation	1.4
retail and commercial	2.5
residential	7.1

[a]A quad is 10^{15} BTU.

Table 9. Energy Required To Produce 1 lb of Various Foods[30]

food	energy (kWh) to produce 1 lb
corn	0.43
milk	0.75
apples	1.67
eggs	4
chicken	4.4
cheese	6.75
pork	12.6
beef	31.5

Table 10. Energy Efficiency of Various Foods Measured as Food Calories per Energy Used in Production[30]

food	cal/lb	energy efficiency (%)
corn	390	102
milk	291	45
cheese	1824	31
eggs	650	19
apples	216	15
chicken	573	15
pork	480	8.5
beef	1176	4.3

SOLUTIONS MUST BE SUSTAINABLE

The solutions to the water, energy, and food crisis must be carefully integrated to meet the needs to produce resources for the 9 billion inhabitants in the next 40 years. Without joint solutions the entire system will fail. Sustainable food production requires optimizing health, safety, quality, and consumer appeal of sufficient foods to sustain the growing world population. Agricultural food production has helped sustain this growth by increasing food production 20% from 1990 to 2010. If we are to meet the food needs of the anticipated population growth, this rate of increased production must continue for the next 25 years.[31] In addition to increasing population, improved nutrition and health care are extending life expectancy, further increasing the need for more high-quality food. These increases must continue in the face of limited energy supplies, limited water supplies, and increased global warming, which results in lower production using current practices.

To meet the growing need for food production, we must face the following considerations:

1 − production of more food on less desirable land using less water;
2 − decreasing energy required for production;
4 − sufficient water in the proper location at a low cost;
3 − increased globalization of best means to provide energy and water resources for food;
4 − globalization of compliance regulations.

Within the food system sustainability is regarded quite differently depending on the particular segment. For example, for food producers sustainability relates to land, water, and energy management. In addition to these macroconcerns, producers must consider fertilization and pest management, focusing on the sustainable environmental factors as well as energy resources for production of the chemicals. To help address these concerns, in recent years the U.S. Environmental Protection Agency (EPA) registration of new pesticides is now largely devoted to biorational or biopesticides, rather than further modification of synthetics from the 20th century.[32] This should help improve overall water quality by reducing residual agricultural chemicals. When food sustainability is considered from the food health and nutrition viewpoint, consumer health and nutrition are particularly important (e.g., vitamin, antioxidant, and mineral balance and avoiding undue levels of fats, carbohydrates, sodium, and synthetic additives).[33−37] Food processors' sustainability issues are focused on preserving and distributing foods, including maximizing shelf life for quality and safety.

dx.doi.org/10.1021/jf501496r | J. Agric. Food Chem. 2014, 62, 6255−6262

There is growing momentum demonstrating the benefits of new biopesticides, biofuels, and biobased products used in the production, processing, and distribution of foods.[38] Food processing results in the production of considerable waste, but much of the waste material could be recovered and used as an energy source as summarized in Table 7. Food waste needs to be minimized and value captured whenver possible. Capturing and using the energy from processing and food wastes through approaches such as anaerobic fermentation to biogas and recovering the energy as electricity would make use of biomass and result in net energy savings.[39]

The "9 Billion Problem" has implications for the way research, education, and outreaches are supported at the National Institute of Food and Agriculture (NIFA). The science, policies, and regulations must align with addressing the global challenges in a sustainable manner, including food security, hunger, food safety, health and nutrition, childhood obesity, energy, water, and climate change.

The nexus between food, water, energ,y and health is critical as to how we deploy resources to address the same because of the need to consider them collectively, rather than individually. The increase in population will contribute to escalating the scarcity of land, water, energy, and food.[40]

Addressing these complex issues will take a commitment to seeking collaborative efforts between federal and state agencies, private enterprise, and nongovernmental organizations. Investing in enabling sound science and policies that address these complex issues and investments in ensuring food security and sustainable bioenergy and water will be a significant part of NIFA's portfolio. NIFA along with other federal agencies including the National Science Foundation, the Department of Energy, and the Bureau of Land Management must continue to support the best and brightest scientists at academic institutions and in private and nongovernmental sectors to find innovative solutions to these challenges. By making the right investments in science, our expectation is that NIFA-supported reseach will enable the scientific community to make great discoveries that can be translated into innovations beneficial to the lives of the American people, and for that matter, globally.[40] For example, drought-resistant and heat-tolerant crops produced through biotechnology could help maintain or increase usable production land for commodity crops such as corn. The corn would lower food production costs and potentially provide feed for production of more animal protein for the growing population. Improving the feed efficiency for milk and meat production also provides challenging but potentially impactful means to provide desirable foods for the growing population.

The dilemma of food, energy, and water present us with a worldwide multidimensional problem that links resources, politics, and quality of life for all on the planet now and for the 9 billion that will inhabit the plant in the next 40 years.

IMPLICATIONS

We must adopt a nexus approach to deal with the relationships of food, energy, and water. None of these issues can be effectively resolved in isolation. Development of new technology in any of the sectors must consider the impact on the other sectors as well as the environment. Specifically, the development of a new energy or food crop must consider water use, energy consumption, and waste or byproduct production during the process. Government and international policy needs to be developed to ensure integrated implementation of technologies considering growing population stresses, the associated energy and food needs, and how these affect the environment and potential for global warming. We must avoid isolated silo approaches and consider broad effects of new technologies and their impact on the food, water, and energy systems. The nexus must involve individuals, policy makers, and thought leaders. As scientists we need to take leadership in communicating the issues clearly and bring forth new technologies that solve problems while also considering the broad implications of these new technologies.

In summary, it is critical that we develop environmentally sustainable sources of energy. The use of carbon-based energy sources needs to be restricted in favor of lower carbon emission sources including solar, wind, and nuclear energy. Water use and protection are major concerns. It is imperative that groundwater pollution be restricted and water used in processes such as fracking be purified to a degree that it can be used for agricultural or domestic applications. Agriculture is the largest user of water, and thus improved practices to minimize water use are needed. Biotechnology should continue to develop drought-tolerant crops for use throughout the world. With GCC the need for drought-tolerant crops will become even greater. With the potential problem of feeding 9 billion people in 40 years, we must seriously consider how much agricultural land should be used for biofuels. Land not suitable for agriculture can be used for crops such as switchgrass that may be viable alternatives for biofuel production. As part of this consideration, however, the impact on the local environment and the habitats of wildlife must be assessed. In addition, sugar cane could be a sustainable source for biofuels. The decreased consumption of sugar from antiobesity campaigns may result in increased sugarcane supplies at prices favorable for biofuels. A major concern is the sustainability of animal products. As discussed, animal production requires large amounts of water and energy compared to grain- and pulse-based products. It is important that we consider greater use of plant-based foods to meet long-term needs for the growing population.

The pressures on energy, water, and food for the growing population are being exacerbated by climate change. At the current pace of growth of food, water, and energy needs, the planet will not be able to provide sufficient resources to meet these demands. There is no one simple solution to resolve these complex issues. Additional investment is needed by government, universities, and industry to identify, fund, and develop integrated and sustainable solutions to address our current and future needs for food, energy, and water. Solutions must include environmentally benign approaches through continued research on sustainable processes. Alternative solutions that provide greener processes need to be encouraged with tax incentives. Assessments and metrics need to be based on long-term solutions that reflect their true impact.

herbicide, formulation, and related adjuvants; or the tank mix herbicide spray solution.[26] Vegetable oils have been used as adjuvant to increase the performance of sethoxydim,[27] but so far, they have received little attention on their effect on photosensitivity or photoquenching of sethoxydim. The purposes of this project were (i) to study the effects of vegetable oils on photodecomposition of sethoxydim, (ii) to assess the effect of vegetable oil viscosity on photodecomposition of sethoxydim, and (iii) to study the saturation status of vegetable oils on photodecomposition of sethoxydim.

MATERIALS AND METHODS

Chemicals and Vegetable Oils. Oils of soybean, cotton, canola, sesame (*Sesamum indicum* L.), castor (*Ricinus communis* L.), corn (*Zea mays* L.), sunflower (*Helianthus annuus* L.), and turnip (*Eruca sativa* L.) were extracted from grains via the mechanical extraction method.[28] Olive oil (*Olea europaea* L.) was extracted from fruit with the Decanter centrifugation (horizontal centrifuge rotating at 3 000 rpm) method.[29] The reference of fatty acid methyl esters in methylene chloride (ampule containing 10 mg/mL) was obtained from Supelco (grain fatty acid methyl ester mix 99−100%).The standard of sethoxydim [(RS)-(EZ)-2-[1-(ethoxyimino)butyl]-5-[2-(ethylthio)propyl]-3-hydroxycyclohex-2-enone] with 99.3% purity was supplied by BASF Ltd. (Limburgerhof, Germany). All solvents were of high-performance liquid chromatography (HPLC) and gas chromatography (GC) grade. N-Hexane and methanol were of chromatography grade (99.9% purity, Merck); potassium hydroxide (pellets/certified ACS) and sodium lauryl sulfate powder were purchased from Fisher Chemicals.

Sample Preparation. *Oil Composition.* To determine the chemical nature of fatty acid oils, 15 drops of each vegetable oil were added to 7 mL N-hexane plus 2 mL of potassium hydroxide in methanol (11.2% m/v). Then, four replications of the supplied compounds were shacked for 1 min and heated to 55 °C for 5 min until the solution was separated into two phases. The upper phase was desiccated with sodium lauryl sulfate and filtered to analyze with gas chromatography.

Herbicide Solution. A nonionic emulsifier, Citogate (100% alkylarylpolyglycol ether prepared from Zarnegaran Pars Company, Karaj, Iran) was added to the vegetable oils at 10% (v/v). This compound (90% vegetable oil +10% emulsifier) was added to the recommended rate of sethoxydim (375 g ai ha^{-1}) at 0.5% (v/v). Herbicide preparation solutions (100 mL) were placed into 250 mL Erlenmeyer flasks. Then they were shacked for a period of 1 h.

Oil Viscosity. A K100 tensiometer was used to determine the viscosity of vegetable oils with ring method. The measurement was determined via the buoyancy of the solid in the liquid and the weight difference of the solid in the air and in the liquid. The mass of the volume of liquid displaced by the measuring probe corresponds exactly to the difference in weight. If the viscosity of the measuring probe is known, then the viscosity of the liquid is obtained by differential weighting using the following equation

$$\rho_L = \rho_{MP}\frac{G_{MPA} - G_{MPL}}{G_{MPA}} \quad (1)$$

where ρ_L is the viscosity of the liquid; ρ_{MP} is the viscosity of the measuring probe; G_{MPA} is the weight of the measuring probe in air; and G_{MPL} is the weight of the measuring probe in liquid.

Photodecomposition Experiments. Irradiation experiments were carried out under sunlight at the College of Agriculture, Ferdowsi University of Mashhad, Mashhad, Iran, with latitude 36°, 17′, 44″ N, longitude 59°, 36′, 42″ E, and altitude of 985 m, on April 11, 2013 (mean temperature 30 °C, light intensity 16.407 MJ/M2/day, and UV index 8), from 11:10 a.m. to 3:10 p.m.

The experiment was conducted as completely randomized factorial design with three replications including nine vegetable oil and eight time course study. Time course study for each herbicide solution (with and without vegetable oil) was 0, 5, 10, 20, 30, 60, 120, and 240 min. After each interval, 15 mL of each solution was sampled and placed in an amber vial and immediately stored in a refrigerator (at 5 °C) until being used for HPLC analysis.

Analytical Equipment and Methods. *Gas Chromatography Mass Spectroscopy.* The fatty acid content was determined using gas chromatography Acme 6000 (Younglin, South Korea) equipped with a flame ionization detector and a CP-Sil 88 Wcot fused silica column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; Chrompack, Middleburg, Netherlands). The carrier gas was ultrahigh-purity helium; we used a 1:100 split mode and a flame-ionization detector. The GC oven temperature was maintained at 140 °C for 5 min, then ramped to 240 °C at the rate of 4 °C/min and maintained at 240 °C for 15 min. The flow rate of helium was 20 mL/min. The injector and detector temperatures were 250 and 280 °C, respectively. The volume of injected sample was 1 μL. Fatty acids were identified by matching their retention times with those of their relative standards.

High-Performance Liquid Chromatography. Photodecomposition kinetics was performed in an HPLC system (Shimadzu) coupled to a RF-10A_{XL} fluorescence detector (280 nm excitation and 425 nm emission), equipped with a pump (6000A). This HPLC system was furnished with a degassing tool (DGU-14A). The analytical column was a perfect sil target, C18column (5 μm particle size, 4.6 mm 250 mm, back pressure 5.7 MPa) with a octadecylsilane (ODS) precolumn (3−5 μm particle size). The mobile phase was methanol/water (80:20, v/v), degassed by placing in an ultrasonic bath (Camlab UK) before using them. For determining the kinetic parameters, an isocratic method of 80% methanol was applied. The flow rate was 1 mL min^{-1}; the injection volume was 20 μL. All samples were filtered through a 0.45 μm Millex filter (Millipore, HV-4, Beford, MA) before injecting into the chromatograph. The limit of detection by HPLC for sethoxydim was 0.01 ppm.

Data Processing. Quantitative analysis was performed using the standard curve method,[10] with the detection mode of full scan, setting up a standard curve of sethoxydim (peak height) at the concentration of 2, 4, 8, 16, 32, 81, 162, 324, 405, 810, 1215, and 1620 mg/L (Figure 1). A linear association was obtained ($y = 0.164x + 4.190$, $R^2 = 0.999$)

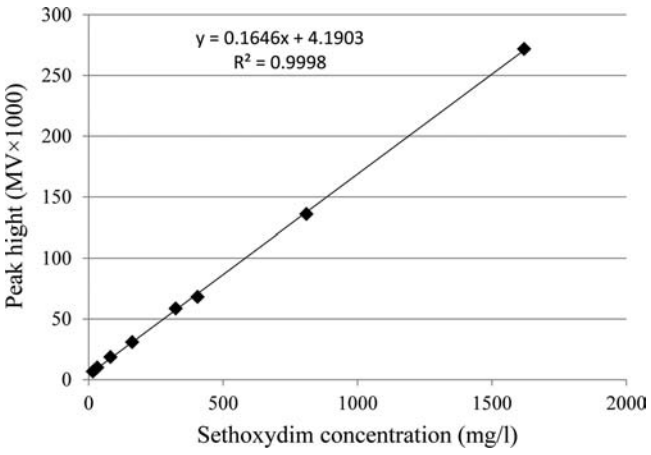

Figure 1. Standard curve of sethoxydim.

by peak height. The peak height was used as a model to determine the concentration of the other sample injection.

The constant rate of photodecomposition of sethoxydim (k) and half-life ($t_{1/2}$) were estimated by fitting the concentration of sethoxydim on eqs 1 and 2,

$$c_t = c_0\, e^{-kt} \quad (2)$$

where c_t is the herbicide concentration at irradiation time t, c_0 is the initial concentration, and k is the first-order rate constant. The half-life $t_{1/2}$ of sethoxydim was calculated using the following equation:

$$t_{1/2} = \frac{\ln 2}{k} \quad (3)$$

dx.doi.org/10.1021/jf501447x | J. Agric. Food Chem. 2014, 62, 6263−6268

Analysis of variance (ANOVA) was conducted to determine the differences between types of vegetable oils, at the 0.05 significance level. The results were analyzed using LSD statistical procedure (Sigma plot 11).

RESULTS AND DISCUSSION

Photodecomposition in the Presence of Vegetable Oils. Sethoxydim is a photochemicaly unstable herbicide (Figure 2). Under the irradiation experiment, in contrast light

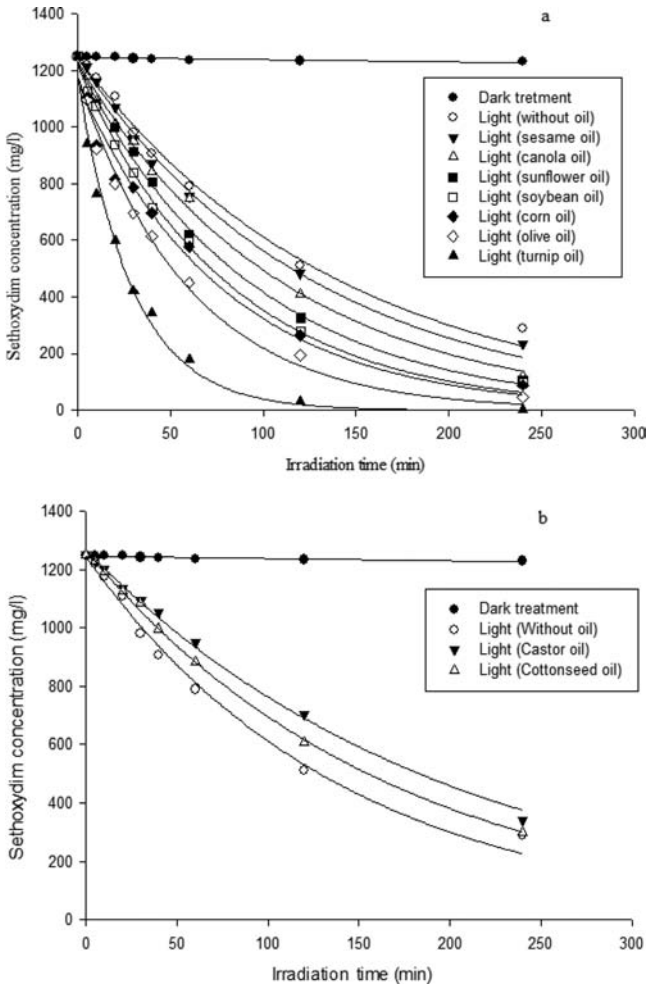

Figure 2. Photodecomposition rate of sethoxydim in the presence of vegetable oils: (a) decrease half-life and (b) increase half-life to compare without oil.

sethoxydim decomposed very fast, whereas the concentration of it remained constant in dark control experiments during the same irradiation time (Figure 2). The effects of vegetable oils on photodecomposition of sethoxydim are illustrated in Figure 2. Sethoxydim photodecomposition was enhanced in the presence of turnip, olive, corn, soybean, sunflower, canola, and sesame oils, and the photodecomposition values were considerably increased. However, in the presence of castor and cottonseed oils, photodecomposition of sethoxydim was retarded (Figure 2 and Table 1).

When turnip, olive, corn, soybean, sunflower, canola, and sesame oils were added to sethoxydim solution, the half-life of sethoxydim was decreased down to 4.74-, 2.38-, 1.81-, 1.75-, 1.52-, 1.28-, and 1.11-fold, respectively (a significant difference was observed between vegetable oils), compared to non-

Table 1. Kinetic Parameters of Sethoxydim Photolysis with Vegetable Oils under Natural Sunlight

vegetable oil	$k^{a,b}$ (10^{-3} min^{-1})	$t_{1/2}$ (min)	R^2

vegetable oil solution. The half-life of sethoxydim was increased in the presence of castor and cottonseed oils by 1.39- and 1.18-fold, respectively (a significant difference was observed between vegetable oils), compared to nonvegetable oil solution (Table 1). Among vegetable oils, turnip oil and castor oil had the highest photosensitivity and photoquenching impact on sethoxydim, respectively. An acceptable fit to the first-order kinetics reaction was obtained for the photodecomposition of sethoxydim in the presence of all vegetable oils over the irradiation time as indicated by the regression coefficient ranging from 0.97 to 0.99 (Table 1). Kinetic parameters of sethoxydim photolysis revealed that a significant difference among vegetable oils existed (Table 1).

Previous studies[3,4] provided the evidence for the early photodecomposition of the sethoxydim under synthetic light and sunlight conditions. This herbicide was highly sensitive to the light. Characteristics of the herbicide, formulation, and adjuvants added to their formulations affected the photodecomposition of sethoxydim. The disappearance of sethoxydim upon irradiation with sunlight largely depends on the presence of total organic carbon (TOC) in herbicide solution.[4] Harrison and Wax[25] reported that, with the addition of soybean oil to 2,4-D and haloxyfop, their photodecomposition effect increased.

According to Izadi-Darbandi et al.,[27] turnip oil alone did not have the phytotoxic potential on wild oat, whereas in combination with sethoxydim, the performance on fresh and dry weight of wild oat was increased by 4.13 and 5.85 times, respectively. These findings were also observed for olive, soybean, canola, and sesame oils. It may be concluded that not only does the application of turnip oil improve the performance of sethoxydim but also it may increase the amount of sethoxydim photodecomposition. Therefore, the use of proper vegetable oils with sethoxydim provides bilateral benefits: (i) an increase in performance and/or (ii) an increase in photodecomposition.

Vegetable Oils' Viscosities. The values of vegetable oils' viscosities are shown in Table 2. Our finding indicated a positive relationship between the half-life of sethoxydim in the presence of each vegetable oil and the viscosity of the vegetable oils (Figure 3). The half-life of sethoxydim was increased by increasing the viscosity with a determination coefficient (R^2) of 0.8951 ($y = 3369.6x - 3021.7$). When vegetable oils with high density were added to the sethoxydim solution, an increase in half-life of sethoxydim was observed as compared to adding vegetable oils with low density (Figure 3). In general, an

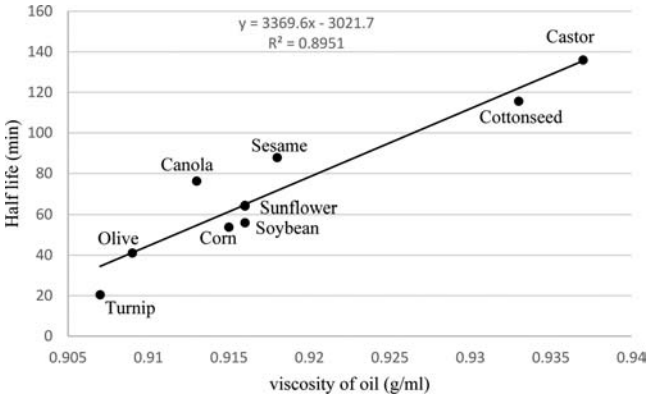

Figure 3. Relationship between viscosity of vegetable oils and half-life of sethoxydim.

increase in viscosity led to a high half-life of sethoxydim for all vegetable oils.

Apparently, enhancing vegetable oil viscosity depends on fatty acid chain length and degree of saturation. Theoretically, herbicides applied with a highly saturated vegetable oil could be too viscous for a good deposit of spray droplets on the leaf surface and reduced efficacy, especially when applied under cool conditions.[30] Beattie et al.[31] declared that, with the reduction of vegetable oils' viscosity and increasing solubility of the herbicide with methylation, the penetration of the herbicide solution within the plants increased. Therefore, decreasing the half-life of the aqueous solution of sethoxydim in the presence of vegetable oil with low viscosity will be compensated by fast penetration through the leaf surface. Izadi-Darbandi et al.[27] showed that sethoxydim performance for wild oat control was increased in the presence of turnip oil with low viscosity mainly due to fast penetration of the herbicide solution through the epicuticular wax layer.

Vegetable Oils' Fatty Acids Compositions. Fatty acids compositions of vegetable oils are summarized in Table 2. Equation 2 determined the k parameter and eq 3 determined the half-life ($t_{1/2}$) values of the sethoxydim in the presence of each vegetable oil (Table 1). Turnip oil and castor oil had the highest increasing and decreasing on the rate of sethoxydim photodecomposition, respectively (Table 1).

The reason for these differences may be attributed to differences in saturation status of fatty acids composition (Table 2). There was a negative relationship between monounsaturated (Figure 4a) and unsaturated/saturated fatty acids ratios (Figure 4b) with determination coefficient (R^2) of 0.73 and 0.85 half-life, respectively. Moreover, there was a positive relationship between the half-life of sethoxydim in the presence of each vegetable oil with saturation status of vegetable oils: saturated fatty acids (Figure 4c), polyunsaturated fatty acids (Figure 4d), palmitic acids (Figure 4e), and linoleic acids (Figure 4f) with coefficient determinations (R^2) of 0.86, 0.62, 0.75, and 0.60, respectively.

It means that the half-life was enhanced with increasing saturated fatty acids, polyunsaturated fatty acids, palmitic acid, or linoleic acids. Half-life was also reduced with increasing monounsaturated and unsaturated/saturated fatty acids ratio (Figure 4a and b). A correlation existed between the half-life of sethoxydim in the presence of each vegetable oil with the content of palmitic acid (C 16:0) and linoleic acid (C 18:2). A correlation between the half-life of stearic acid (C 18:0), palmitoleic acid (C 16:1), oleic acid (C18:1), and linolenic acid (C 18:3) of each vegetable oil was not observed.

The results indicated that the rate of photodecomposition of sethoxydim mainly depended on the kind of vegetable oil added to the sethoxydim solution. Adding vegetable oils with high unsaturated/saturated ratio increased the half-life of sethoxydim less than the low unsaturated/saturated ratio. Vegetable oils were ranked in the following order based on the decrease of half-life reduction, turnip oil > olive oil > corn oil > soybean oil > sunflower oil > canola oil > sesame oil, and based on the increase of half-life, castor oil > cottonseed oil compared with the sethoxydim solution without oil (Table 1)

In general, oil plants grown at high latitudes (cool conditions) have more unsaturated fatty acids than those grown in lower latitudes (warm conditions).[31] Therefore, to obtain accurate results in any given experiment, determination of oils' characteristics, such as the amount of fatty acids and viscosity, is indispensable. The large variation in the composition of vegetable oils imposes different effects on the modification of the herbicide efficacy. Izadi-Darbandi et al.[27] showed that, with increasing oleic acid (C 18:1) or decreasing palmitic acid volume, the relative potency of sethoxydim to control wild oat was decreased with coefficient of determination (R^2) of 0.80 and 0.76, respectively. They also reported that, with increasing unsaturated/saturated fatty acids ratio, the sethoxydim performance was decreased. On the basis of our results, this may be due to enhanced photodecomposition and decreased half-life of sethoxydim in the presence of vegetable oils with a high level of unsaturated fatty acids on the leaf surface but increasing through to the cuticular wax in the presence of vegetable oils with a high level of unsaturated fatty acids before photodecomposition, which improved herbicide performance.

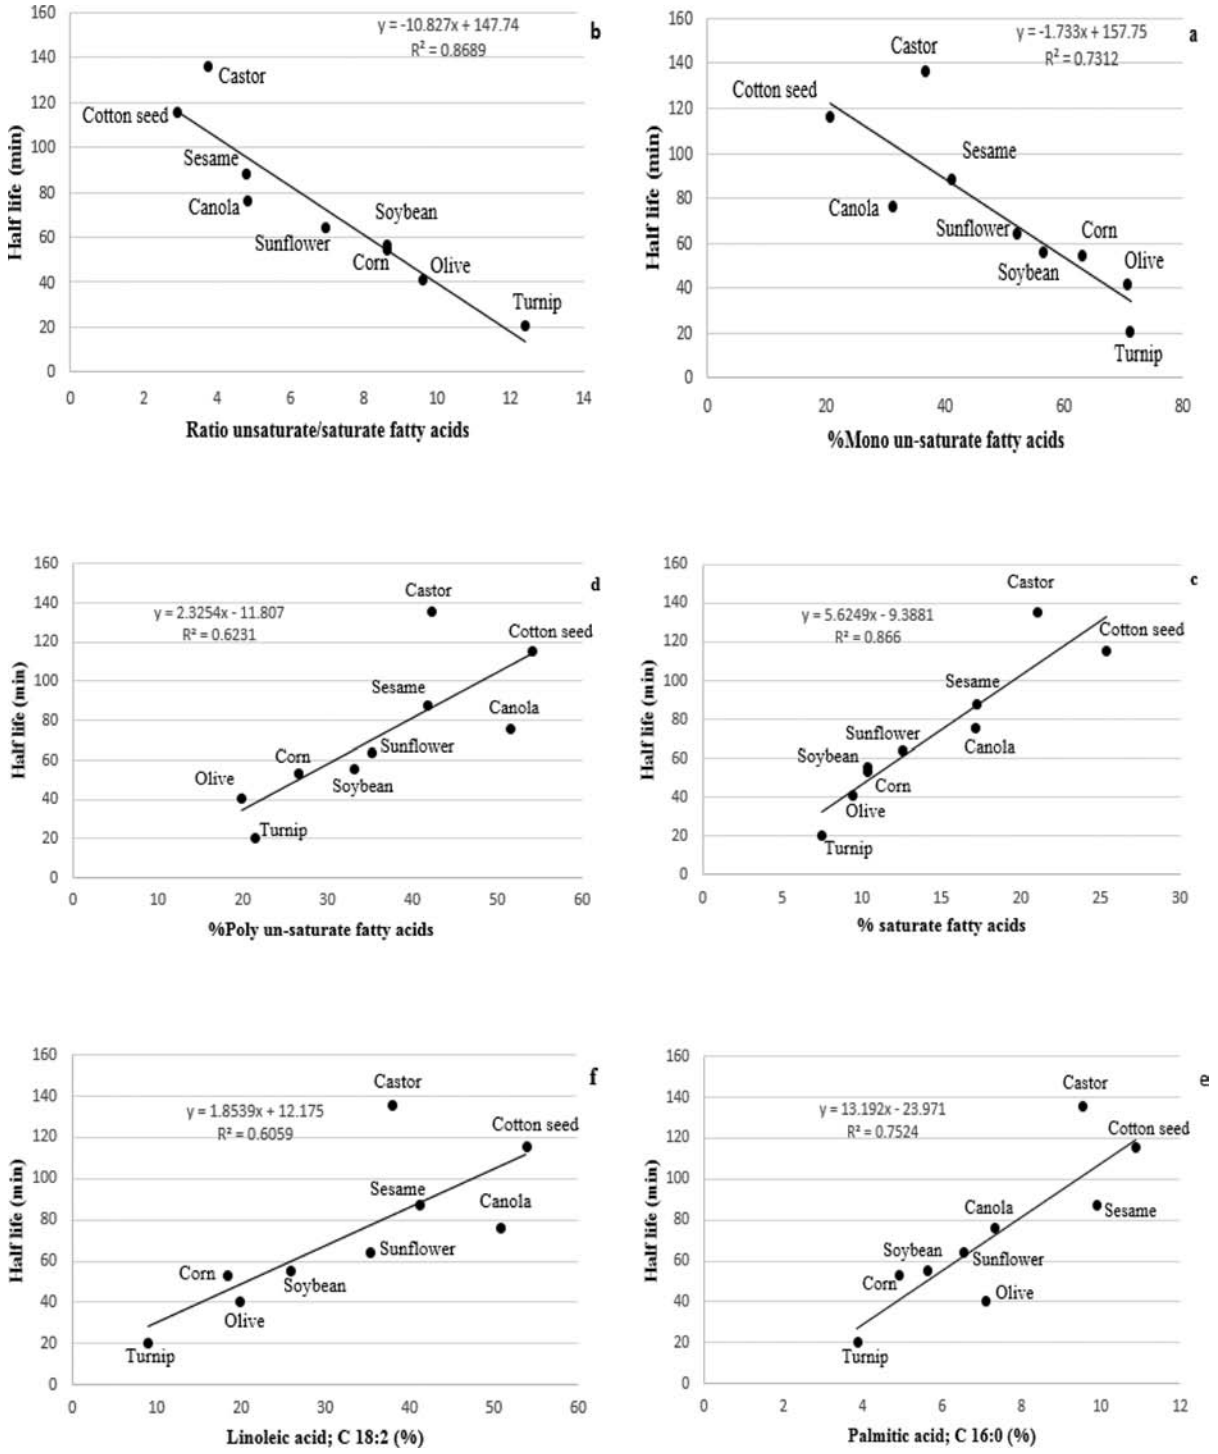

Figure 4. Relationship between half-life of sethoxydim plus vegetable oils in the presence of sunlight: (a) % monounsaturated fatty acids of vegetable oils; (b) ratio of unsaturated/saturated fatty acid; (c) saturated fatty acid; (d) % polyunsaturated fatty acids ratio of vegetable oils; (e) palmitic acid; and (f) linoleic acid.

Selecting the proper adjuvant is a key factor in weed management mainly because of reducing the dosage of herbicide. On the other hand, vegetable oils are less phytotoxic compared with mineral oils, and due to fast degradation,[32] they are a better choice for the environment. Therefore, the application of vegetable oil is a proper ecological method to enhance herbicide performance and decrease its dosage. Our results revealed that vegetable oils can enhance photodecomposition effects of the herbicide sethoxydim. Careful selection of adjuvants in formulation or tank mix is very important because it will alter photodecomposition of sethoxydim after spraying. The fatty acid compositions of vegetable oils are clearly effective in their impact on the photodecomposition of sethoxydim. Our findings also revealed that a negative correlation existed between quantities of monounsaturated or unsaturated/saturated fatty acids ratio with half-life. Moreover, there was a positive relationship between viscosity and saturate status with half-life. Therefore,

dx.doi.org/10.1021/jf501447x | J. Agric. Food Chem. 2014, 62, 6263−6268

the importance of viscosity and fatty acids composition of vegetable oils on the photodecomposition of sethoxydim was proved.

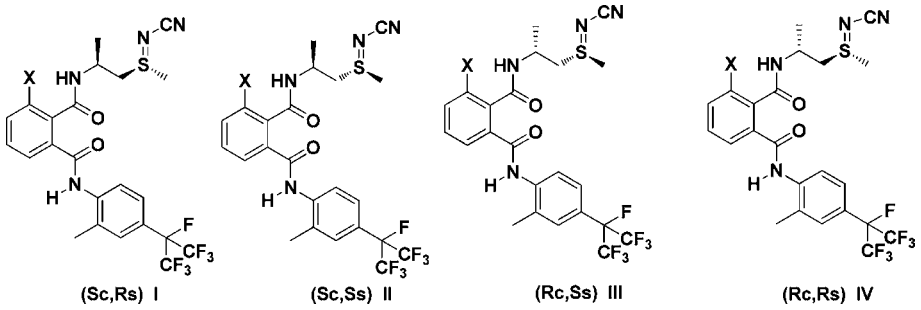

Figure 2.

field analysis (CoMFA) calculation was also undertaken. The structure−activity relationship (SAR) was concluded.

MATERIALS AND METHODS

Instruments and Materials. The melting points were determined on an X-4 binocular microscope melting point apparatus (Beijing Tech Instrument Co., Beijing, China) and are uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded at 300 MHz (Bruker AC-P 300 spectrometer) or 400 MHz (Bruker AV 400 spectrometer) in $CDCl_3$ or DMSO-d_6 solution with tetramethylsilane as internal standard, and chemical shift (δ) were recorded in parts per million. Elemental analyses were performed on a Vario EL elemental analyzer. HRMS data were obtained by Varian QFT-ESI. Optical rotations were measured with a PerkinElmer 341 polarimeter at 20 °C. GC-MS was recorded on HP 5973 MSD with 6890 GC flash chromatography with silica gel (200−300 mesh). All reagents were analytically pure. All solvents and liquid reagents were dried according to standard methods and distilled before use. Commercial insecticide flubendiamide was used only as contrast compound and synthesized according to the literature.[19] 3-Substituted anhydride compounds **4a**−**f**,[20,21] 2-methyl-4-(perfluoropropan-2-yl)aniline **6a**,[22] (*S*)-1-(methylthio)propan-2-amine **3**, and (*R*)-1-(methylthio)propan-2-amine **10**[23] were synthesized according to the methods reported in the cited literature.

Synthesis of Intermediate Compounds. Synthesis of 1-(methylthio)propan-2-amine **3**: pale yellow liquid; yield 57.8%; ^{1}H NMR (400 MHz, $CDCl_3$-d_6) δ 2.90 (dqd, J = 8.4, 6.3, 4.5 Hz, 1H, −CHNH$_2$), 2.42 (dd, J = 13.2, 4.4 Hz, 1H, −SCH$_2$−), 2.19 (dd, J = 13.2, 8.4 Hz, 1H, −SCH$_2$−), 1.95 (s, 3H, −SCH$_3$), 0.99 (d, J = 6.4 Hz, 3H, −C−CH$_3$).

(*S*)-1-(Methylthio)propan-2-amine **12**: $[\alpha]^{20}_D$ +30.13 (c = 53.7, $CHCl_3$).

(*R*)-1-(Methylthio)propan-2-amine **13**: $[\alpha]^{20}_D$ = −29.79 (c = 53.2, $CHCl_3$).

General Synthetic Procedure for Compounds ***7a*****−*****f*****.** These phthalamide derivatives were synthesized in moderate yield according to the method reported in the literature. The melting point and ^{1}H NMR data were consistent with the literature.[24]

(*S*)-N^1-(1-(Methylthio)propan-2-yl)-N^2-(3-(trifluoromethyl)-phenyl)phthalamide, **7f**: ^{1}H NMR (400 MHz, DMSO-d_6) δ 10.65 (s, 1H, Ar−NH), 8.36 (d, J = 7.7 Hz, 1H, −CNH), 8.22 (s, 1H, Ar−H), 7.90 (d, J = 7.1 Hz, 1H, Ar−H), 7.58 (m, 5H, Ar−H), 7.44 (d, J = 7.0 Hz, 1H, Ar−H), 4.08−3.98 (m, 1H, −N−CH), 2.66 (dd, J = 13.0, 6.3 Hz, 1H, −SCH$_2$), 2.54 (m, 1H, −SCH$_2$), 2.05 (s, 3H, −SCH$_3$), 1.19 (d, J = 6.3 Hz, 3H, −CCH$_3$).

General Synthetic Procedure for Compounds ***Ia*****−*****e*****,** ***IIa*****−*****e*****,** ***IIIa*****−*****d*****, and** ***IVa*****−*****d*****.** A mixture of 1.0 mmol of **7a**−**f** and 0.046 g (1.1 mmol) of cyanamide in 20 mL of acetonitrile was cooled below 0 °C. To this solution was added 0.322 g (1 mmol) of iodobenzene diacetate all at once. The reaction mixture was allowed to stir below 0 °C for 10 min and slowly warmed to room temperature over 1.5 h; the progress of the reaction was followed by TLC. Excess oxidant was destroyed by adding 5 mL of 2.5% aqueous sodium metabisulfite. The solution was washed with dilute hydrochloric acid, water, an aqueous sodium carbonate solution, and water, respectively, and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure, and the residue was purified by silica gel column chromagraphy.[25−28]

(*S*,*R*)-3-Iodo-N^2-(1-(*N*-cyano-*S*-methylsulfinimidoyl)propan-2-yl)-N^1-(2-methyl-4-(perfluoropropan-2-yl)phenyl)phthalamide, **Ia**: white solid; yield 70.3%; mp 116−119 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 9.95 (s, 1H, Ar−NH), 8.83 (d, J = 7.8 Hz, 1H, −CNH), 8.05 (d, J = 7.9 Hz, 1H, Ar−H), 7.79−7.75 (m, 2H, Ar−H), 7.54 (d, J = 7.3 Hz, 2H, Ar−H), 7.31 (t, J = 7.8 Hz, 1H, Ar−H), 4.24 (dt, J = 13.6, 6.8 Hz, 1H, −N−CH), 3.29 (dd, J = 12.7, 5.9 Hz, 1H, −SCH$_2$), 3.18 (dd, J = 7.9, 4.9 Hz, 1H, −SCH$_2$), 2.66 (s, 3H, −SCH$_3$), 2.36 (s, 3H, ArCH$_3$), 1.26 (d, J = 6.7 Hz, 3H, −CCH$_3$); ^{13}C NMR (101 MHz, DMSO-d_6) δ 167.68, 165.45, 141.54, 140.92, 139.25, 135.59, 133.63, 130.31, 127.38, 127.20, 125.79, 123.33, 121.80, 120.48, 95.32, 54.77, 41.27, 32.01, 18.67, 17.94. X-ray Diffraction. The crystal structure of compound **If** was determined, and X-ray intensity data were recorded on a Bruker SMART 1000 CCD diffraction meter using graphite monochromated Mo Kα radiation (λ = 0.71073 Å). All calculations were refined anisotropically. All hydrogen atoms were located from a difference Fourier map and were placed at calculated positions and were included in the refinements in the riding mode with isotropic thermal parameters.

Biological Assay. All bioassays were performed on representative test organisms reared in the laboratory. The bioassay was repeated at 25 ± 1 °C according to statistical requirements. Assessments were made on a dead/alive basis, and mortality rates were corrected using Abbott's formula.[29] Evaluations were based on a percentage scale of 0−100, in which 0 = no activity and 100 = total kill. The standard deviations of the tested biological values were ±5%. LC_{50} and LC_{95} values were calculated by probit analysis.[30]

Larvicidal Activity against Oriental Armyworm (*Mythimna separata* Walker). The larvicidal activity of the title compounds and commercial flubendiamide against oriental armyworm was tested according to the leaf-dip method using the reported procedure.[31] Leaf disks (about 5 cm) were cut from fresh corn leaves and were dipped into the test solution for 3−5 s. After drying, the treated leaf disks were placed individually into a glass-surface vessel (7 cm). Each dried treated leaf disk was infested with 10 third-instar oriental armyworm larvae. Percentage mortalities were evaluated 4 days after treatment. Leaves treated with acetone were provided as controls. Each treatment was performed three times. The larvicidal activities of **Ia**, **IIIa**, **Va**, and flubendiamide against oriental armyworm are listed in Table 2. The insecticidal activity is summarized in Table 3. LC_{50} values of compounds **Ia**,**b**, **IIa**,**b**, **IId**, **IIIa**,**b**, and **IVa**,**b** and flubendiamide against oriental armyworm are listed in Table 4.

Larvicidal Activity against Diamondback Moth (*Plutella xylostella* L.). The larvicidal activity of the title compounds and flubendiamide against diamondback moth was tested by the leaf-dip method using the reported procedure.[32,33] Leaf disks (5 cm × 3 cm) were cut from fresh cabbage leaves and then dipped into the test solution for 3 s. After air-drying, the treated leaf disks were placed individually into boxes (80 cm). Each dried treated leaf disk was infested with 30 second-instar diamondback moth larvae. Percentage mortalities were evaluated 3 days after treatment. Each treatment was performed three times. The insecticidal activity is summarized in Table 5.

RESULTS AND DISCUSSION

Synthesis. The method of oxidative imination based on a sulfide was followed to prepare these sulfilimines. Cyanogen amine was used as a nitrogen source, and hypervalent iodinane such as $PhI(OAc)_2$ was used as a mild oxidant. The reaction of the sulfide with cyanogen amine in the presence of $PhI(OAc)_2$ was carried out in 1,4-dioxane. The preferred reaction temperature ranged from −5 to 0 °C. *N*-Cyanosulfilimines were obtained in 95−99% yield with the ratio of diastereoselectivity 7:3. The title compounds were synthesized as shown in Scheme 1.

The title compounds have been characterized by melting point, ^{1}H NMR, ^{13}C NMR, elemental analyses (or high-resolution mass spectrometry), and optical polarimetry. All spectral and analytical data were consistent with the assigned structures. Physical parameters of each pair of enantiomers were alike, except with the opposite specific optical rotation signs. Compared with each diastereoisomer in **I** and **II**, the value of HRMS was the same, whereas differences were found in the melting points and proton signals of −NHCO− in the aliphatic amide moiety. As shown in Table 1, the melting point of isomer in **I** was approximately equal to or lower than that of the corresponding diastereoisomer in **II**. As for the proton signals of −NHCO− in the aliphatic amide moiety, the former was 0.14−0.16 ppm higher than the later, as well as in **III** and **IV**. Specific optical rotation values were negative (**I**), positive (**II**), positive (**III**), and negative (**IV**), respectively (Table 1). In ^{1}H NMR spectra of all title compounds, the proton signals of −NHCO− on the amide bridge were observed at δ 8.26−10.84 and 7.96−8.90 as a singlet or doublet, respectively. In all title compounds, the methyne proton appeared at δ 4.23−4.53 as a multiplet, and the methylene protons attached to the sulfur atom appeared at δ 3.52−4.16 and 2.97−3.89 as a couple of doublets due to respective chemical environment. Meanwhile, in the ^{1}H NMR of aliphatic amide moiety, methyl protons attached to tertiary carbon were observed as a doublet as well.

Crystal Structure Analysis. To identify the chiral characteristic of each isomer, the colorless crystal (0.20 mm × 0.10 mm × 0.10 mm) structure of compound **If** was obtained in DMSO, which was suitable for X-ray single-crystal diffraction as shown in Figure 3 with the following crystallographic

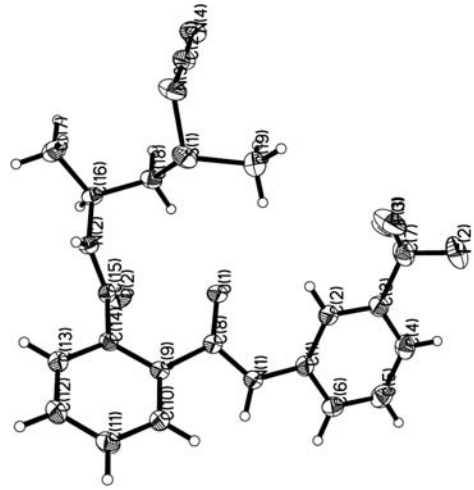

Figure 3. Crystal structure of compound **If**.

parameters: a = 5.0807(10) Å, b = 21.298 (4) Å, c = 19.011(4) Å, α = 90°, β = 90.17 (3)°, γ = 90°, V = 2057.1(7) Å^3, Z = 4, D_c = 1.409 mg m^{-3}, μ = 0.208 mm^{-1}, F (100) = 904, R = 0.0717, wR = 0.0908, final R factor = 4.37%, final wR factor = 7.98%, absolute structure parameter = 0.02 (7).

Structure−Activity Relationship (SAR). *Larvicidal Activity against Oriental Armyworm.* To explore the impact of carbon chirality on larvicidal activity, **Va** (the racemic compound of **Ia** and **IIIa**) was evaluated against oriental armyworm for its insecticidal activity. As shown in Table 2, **Va** displayed 60, 40, and 20% larvicidal activities at concentration of 0.5, 0.25, and 0.1 mg L^{-1}, respectively, which showed better activity than **IIIa** (0.5 mg L^{-1}, 20%) and weaker activity than **Ia** (0.1 mg L^{-1}, 60%). These observations clearly revealed that the Sc configuration of **Ia** improved the bioactivity greatly. Furthermore, carbon chirality resulted from the aliphatic amine, which can easily be derived from the obtained (L)-alanine.

The larvicidal activities of compounds **Ia−e**, **IIa−e**, **IIIa−d**, and **IVa−d** and flubendiamide against oriental armyworm are listed in Tables 3 and 4. Most compounds exhibited good to excellent activity against oriental armyworm. Generally, the sequence of each configuration's biological activity is (Sc, Ss) ≥ (Sc, Rs) ≫ (Rc, Ss) > (Rc, Rs). For example, **IId** (Sc, Ss) showed 60% insecticidal activity at 0.25 mg L^{-1} (0.5 mg L^{-1}, 100%), whereas **Id** (Sc, Rs) gave a death rate of 60% at only 1 mg L^{-1}. It is worth noting that the Sc configurations showed much better than Rc configurations. At a higher concentration of 10 mg L^{-1}, we can see that **IIId** (Rc, Ss) (50%) showed better activity than **IVd** (Rc, Rs) (30%). As seen for other substituents in the phthaloyl moiety, (Sc, Ss) **II** was most active followed by (Sc, Rs) **I** and (Rc, Ss) **III**, and the (Rc, Rs) **IV** was almost inactive. The results indicated that the improvement of insecticidal activity required a reasonable coordination of both carbon and sulfur chirality and that a probable synergistic effect was involved.

In comparison, Sc configurations (**Ia** vs **IIa**, **Ib** vs **IIb**, **Ie** vs **IIe**) and Rc configurations (**IIIb** vs **IVb**, **IIIc** vs **IVc**, **IIId** vs

IVb	$y = 1.2531 + 2.4626x$	0.9688	33.2304	154.6959
flubendiamide	$y = 7.4237 + 2.6428x$	0.9945	0.1230 (0.0958−0.1503)	0.5160 (0.3733−0.8966)

IVd), these diastereoisomers reached the same activity level. For example, **Ia** and **IIa** showed similar activity at 0.1 mg L^{-1}. **IIc** displayed 60% insecticidal activity at 0.25 mg L^{-1}, whereas **Ic** gave a death rate of only 60% at 1 mg L^{-1}, as did **Id** and **IId**. These observations showed that chiral sulfur had an influence on the larvicidal activity. However, carbon chirality influenced the activities more strongly than sulfur, as seen in comparison of compounds in Rs configurations such as **Ia** versus **IIIa**, **Ib** versus **IIIb**, **Ic** versus **IIIc**, and **Id** versus **IIId**) and in Ss configurations such as **IIa** versus **IVa**, **IIb** versus **IVb**, **IIc** versus **IVc**, and **IId** versus **IVd**.

As shown in Table 3, all compounds showed a mortality of 100% at 10 mg L^{-1}, except **IIIb−d**, **IVb**, **IVd**. Particularly (Sc, Rs) **Ia−e**, (Sc, Ss) **IIa−e**, (Rc, Ss) **VIIa**, and (Rc, Rs) **VIIIa** exhibited 100% larvicidal activities at 2.5 mg L^{-1}. **Ia** and **IIa** showed excellent activities comparable to that of flubendiamide. These results indicated that compounds with the iodine substituent in each configuration showed the best larvicidal activity, which was consistent with the previous study.[19] A Cl substituent as well as NO_2, Br, and F possessed inferior insecticidal activity against oriental armyworm.

From Table 4, it is worth noting that the LC_{50} values of **Ia** and **IIa** were 0.0504 and 0.0699 mg L^{-1}, respectively, lower than that of flubendiamide (0.1230 mg L^{-1}). In addition, the LC_{50} values of compounds **IIb**, **IId**, and **IIIa** were 0.4872, 0.2290, and 0.3744 mg L^{-1}, respectively.

Larvicidal Activity against Diamondback Moth. The larvicidal activities of compounds **Ib−e**, **IIa−e**, and **IVa** and flubendiamide against diamondback moth are listed in Table 5. Most compounds possessed excellent activities. In comparison

dx.doi.org/10.1021/jf501727k | J. Agric. Food Chem. 2014, 62, 6269−6277

Table 5. Insecticidal Activities of Compounds Ib−e, IIa−e, IVa, Va, Ve , and VIa−c and Flubendiamide against Diamondback Moth

	larvicidal activity (%) at							
compd	100 mg L^{-1}	10 mg L^{-1}	1 mg L^{-1}	10^{-1} mg L^{-1}	10^{-2} mg L^{-1}	10^{-3} mg L^{-1}	10^{-4} mg L^{-1}	10^{-5} mg L^{-1}

flubendiamide		100	100	100	100	50	0	

of Sc configurations **I** and **II**, the sequence of activity was (Sc, Ss) > (Sc, Rs), except in the case of **Ib** (10^{-2} mg L^{-1}, 90%), which displayed better activity than **IIb** (10^{-2} mg L^{-1}, 40%). For the pair of enantiomers, it is worth noting that **IIa** and **IVa** reached similar activity levels. We conclude that in these cases the sulfur chirality influenced the activities more greatly than carbon. When different substituents in the phthaloyl scaffold were compared, it was found that Br showed the best activity. **Ie** and **IIc**,**d** reached the same activity as flubendiamide. In particular, **IIe** gave higher activity than flubendiamide with a mortality of 40% at low 10^{-5} mg L^{-1}, whereas flubendiamide showed only 50% at 10^{-3} mg L^{-1}.

CoMFA Analysis by SYBYL. A brief CoMFA analysis for compounds **Ia**,**b**, **IIa**,**b**, **IId**, **IIIa**,**b**, and **IVa**,**b** was performed with SYBYL.[34] The conformations with minimum energy were calculated with Tripos force field and Gasteiger−Hukel charges in advance. The activity data were reported as pLC_{50}, and the negative logarithms of the LC_{50} data are in Table 2. Thus, a larger number of pLC_{50} indicates a higher activity. Details are shown in Figure 4.

From the results of CoMFA, the green area near the I substituent suggests a bulkier group is favorable, as Cl or F declines in larvicidal activity. The yellow area indicates a less bulky substituent enhances activity. It is worth noting that the chiral carbon atom is located near the yellow area, and chirality (Rc or Sc) causes a difference in the orientation of the methyl group, which is bulkier than H atom. Thus, the methyl groups with Rc configurations (**III** and **IV**) come closer to the yellow area and have a poorer activity than Sc configurations. Finally, the red area surrounding the CN group indicates more electronegativity is favorable here, whereas Rc configurations on chiral carbon atoms cause the CN group to stay out of the red area, which leads to a decrease in activity. This is in accordance with SARs described in this paper.

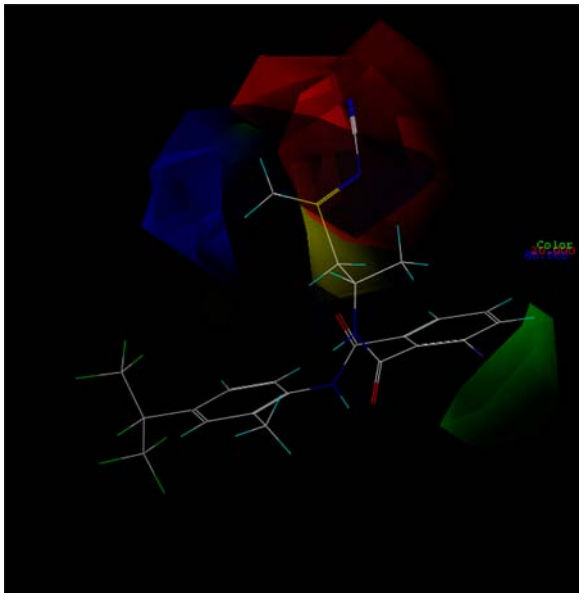

Figure 4. CoMFA results for **Ia**.

Partial least-squares analysis gives an excellent linear relationship between predicted and actual activities (R_2 = 1.000), which indicates a valid CoMFA model.

In summary, this is the first report of the novel optically active configuration incorporated into dicarboxamides containing *N*-cyano sulfiliminyl moieties. Four chiral series of novel phthalamide derivatives with sulfur-containing groups were designed, synthesized, and evaluated against oriental armyworm and diamondback moth for their insecticidal activities. All structures were characterized by ^{1}H NMR, ^{13}C NMR, and HRMS (or elemental analysis), and their relative absolute configurations were confirmed by optical polarimetry. For oriental armyworm, these stereoisomers exhibited different impacts on biological activity following the sequence (Sc, Ss) ≥ (Sc, Rs) ≫ (Rc, Ss) > (Rc, Rs); carbon chirality influenced the activities more strongly than sulfur. Compounds **Ia** and **IIa** reached activity as high as that of commercial flubendiamide, with LC_{50} values of 0.0504 and 0.0699 mg L^{-1}, respectively, lower than that of flubendiamide (0.1230 mg L^{-1}). For diamondback moth, the sequence of activity was (Sc, Ss) > (Sc, Rs), and the sulfur chirality influenced the activities greater to a greater extent than carbon. Compound **IIe** had an even higher activity than flubendiamide, whereas **Ie** and **Ic**,**d** reached the activity of the latter. The results indicated that the improvement of insecticidal activity required a reasonable coordination of both carbon and sulfur chirality. Probable synergistic influence was involved. CoMFA calculation indicated that stereoisomers with Sc configurations containing a strong electron-withdrawing group such as CN are important to retain their high activity. The *N*-cyano sulfiliminyl substituent was also essential for high larvicidal activity. Our research indicated that some of the title compounds could be potential candidates as ryanodine receptor activators.

NOTE ADDED AFTER ASAP PUBLICATION

In the third from last sentences of both the abstract and final paragraph of the text, the stereoisomer configuration has been corrected from Rs in the original publication of June 26, 2014, to Sc, as corrected on June 27, 2014.

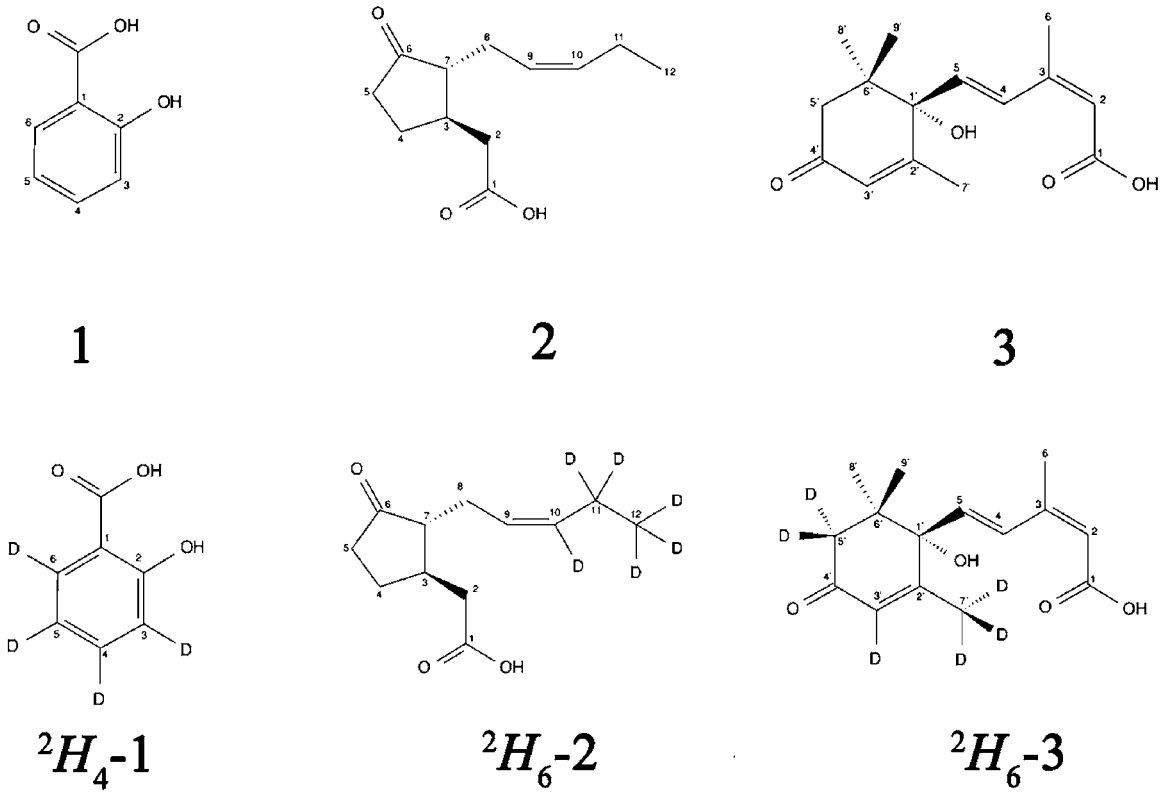

Figure 1. Chemical structures of salicylic acid (**1**), (−)-jasmonic acid (**2**), (±)-2-*cis*-4-*trans*-abscisic acid (**3**), and deuterium-labeled internal standards [$^2H_4$]-salicylic acid ($^2H_4$-**1**), [$^2H_6$]-(±)-jasmonic acid ($^2H_6$-**2**), and [$^2H_6$]-(+)-2-*cis*-4-*trans*-abscisic acid ($^2H_6$-**3**).

Sensitivity of these analytical approaches is often not sufficient to provide hormone content information on specific plant tissue in small samples. GC−MS is routinely applied for the multiplex analysis of various hormones in plant tissues.[19] However, the hydrophilic groups need to be derivatized to obtain the high analyte volatility for proper GC separation. Besides this relatively time-consuming step, another disadvantage is the need for at least 300 mg of fresh plant material to reach the dynamic range of the mass spectrometer even with the modern GC−MS approaches.[21] An elegant way to overcome the limitations of GC−MS is the use of reversed-phase high-performance liquid chromatography (RP-HPLC)−electrospray ionization (ESI)−MS. This technique offers a high separation efficiency and selectivity and minimal ESI matrix effects, and it ensures the sensitive detection of analytes without the need for derivatization.[22,23] Sensitivity is improved by tandem mass spectrometry (MS/MS) with triple quadrupole instruments operating in multiple reaction monitoring (MRM) mode by fast duty cycles and reduced chemical noise.[24] A rapid analysis of multiple hormones is possible through the relatively short dwell times typical for modern mass spectrometers.[25] In addition, the application of ultrahigh-performance liquid chromatography (UHPLC)[26] as well as solid-phase extraction (SPE)-based enrichment[27] may lead to the further improvement of sensitivity of phytohormone analysis.

The aim of this study was to develop a selective and sensitive analytical method for the simultaneous quantitation of (±)-2-*cis*-4-*trans*-abscisic acid (**3**), (−)-jasmonic acid (**2**), and salicylic acid (**1**) in rose leaves based on SPE purification and UHPLC−MS/MS analysis. [$^2H_4$]-salicylic acid ($^2H_4$-**1**), [$^2H_6$]-(±)-jasmonic acid ($^2H_6$-**2**), and [$^2H_6$]-(+)-2-*cis*-4-*trans*-abscisic acid ($^2H_6$-**3**) were used as internal standards (Figure 1). The method developed was validated according to Commission Decision 2002/657/EC.[28]

MATERIALS AND METHODS

Reagents and Chemicals. Analytical-reagent-grade chemicals were used. Water was HPLC-grade, generated by a Milli-Q gradient purification system (Millipore, Billerica, MA). Methanol (MeOH, LC−MS absolute) and acetic acid (99%, ULC−MS) were supplied by Biosolve B.V. (Biosolve B.V., Valkenswaard, Netherlands). Phytohormones **1**, **2**, and **3** and the deuterium-labeled internal standards $^2H_4$-**1**, $^2H_6$-**2**, and $^2H_6$-**3** were all purchased from OlChemIm (OlChemIm, Olomouc, Czech Republic).

Stock and Working Solution Preparation. Stock standard solutions (1 mg/mL) of compounds **1**, **2**, and **3** were prepared using methanol/water (75:25, v/v). Working standard solutions were prepared by dilution of the stock solution to obtain concentrations ranging between 0 and 60.0 μg/g for compound **3** and between 0 and 20.0 μg/g for compounds **1** and **2**.

Rose Leaf Samples and Sample Preparation. Rose plants were grown in the greenhouse of the Institute for Agricultural and Fisheries Research (ILVO, Melle, Belgium) and were subjected to standard cultural practices. The rose genotype used was a F1 hybrid of 'Yesterday' × *Rosa wichurana*. For the method development and validation, young (just unfolded) leaves were used. The collected rose leaves were free from any damage and were immediately frozen in liquid nitrogen to prevent enzymatic and thermal degradation of the phytohormones. They were stored at −80 °C until analysis. Prior to extraction, the leaf material was homogenized by removing the biggest veins and grinding with liquid nitrogen, using a mortar and pestle. In total, 20 mg of each homogenized sample was transferred to a 10 mL glass tube.

Extraction buffer containing the internal standard (IS) was prepared with final concentrations of 20 ng/mL $^2H_4$-**1**, 1 ng/mL $^2H_6$-**2**, and 400 ng/mL $^2H_6$-**3**.

[a]Product ion used in the screening program.

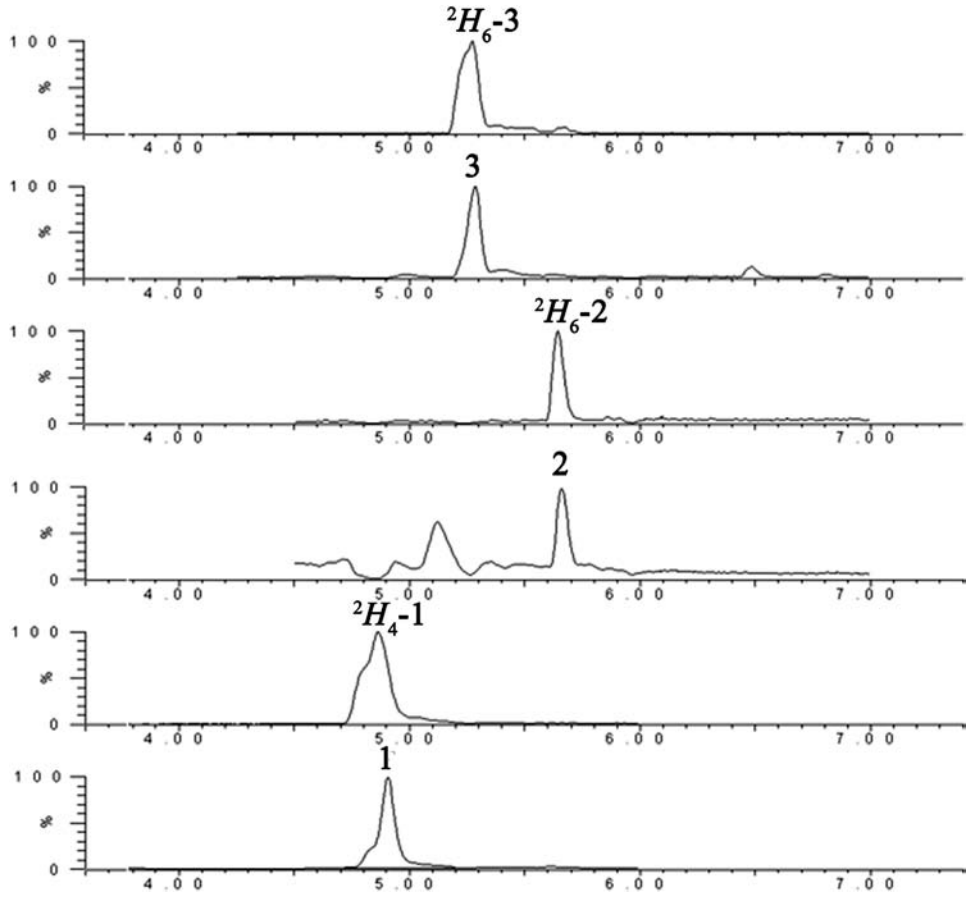

Figure 2. Representative total ion chromatograms (TIC) of the rose leaf matrices analyzed using the method developed (the concentrations of the peaks in the chromatogram correspond to endogenous concentrations, with the addition of 1.25 μg/g of compounds **1** and **2** and 3.75 μg/g of compound **3**, with the intensities of the signals at 4.26×10^6, 1.11×10^6, and 1.36×10^6, respectively).

Extraction was performed using 2 mL of methanol/water/acetic acid (10:89:1) for 16 h at 4 °C in the dark on an orbital shaker rotating at 210 rpm. The extract was filtered through a 0.22 μm Millex-GV filter (Millipore, Billerica, MA). Before loading 1 mL of this eluate onto Oasis MCX 1 cm^3 SPE cartridges (Waters, Milford, MA), these cartridges were first conditioned with 1 mL of methanol (100%), followed by 1 mL of water for equilibration. The acidic hormones bound onto the column were washed with 0.5 mL of H_2O and then eluted with a total of 1 mL of methanol (100%), applied in two consecutive steps of 0.5 mL each. Subsequently, the total eluate was evaporated to dryness using nitrogen gas at 35 °C, and the residues were redissolved in 0.5 mL of methanol/water (75:25, v/v). This extract was transferred to a microvial and stored at 4 °C prior to injection (10 μL) into the UHPLC−MS/MS system.

UHPLC−MS/MS Analyses. An Acquity UHPLC system coupled to a Xevo TQ-S triple quadrupole MS detector (Waters, Milford, MA) was used for analytical determination of the target compounds in the leaf samples. Chromatographic separation was achieved using a 100 × 2.1 mm inner diameter, 1.7 μm, Acquity UHPLC BEH C_{18} column (Waters, Milford, MA) at 30 °C. The mobile phase consisted of 0.3% acetic acid in water (A) and 0.3% acetic acid in methanol (B). The flow rate was set at 0.3 mL/min. The gradient was adapted from a previous report[29] as follows: 0 min, 2% B; 1.0−2.5 min, 2−40% B; 2.5−4.0 min, 40−50% B; 4.0−5.0 min, 50−80% B, held for 2.0 min; 7.0−7.1 min, 80−100% B, held for 0.9 min; and 8.0−11.0 min, 100−2% B.

The mass spectrometer operated in the ESI negative mode with MRM. Desolvation gas was set at 1000 L/h and a temperature of 600 °C. The MRM settings in the MS/MS function with corresponding

dx.doi.org/10.1021/jf5023884 | J. Agric. Food Chem. 2014, 62, 6278−6284

cone voltage and collision energy were optimized for each compound (Table 1). Data were acquired and processed using MassLynx, version 4.1 (Waters, Milford, MA). A standard mix at a concentration of 100 μg/g was prepared and injected into the LC−MS/MS system prior to each experiment to check the system sensitivity and reproducibility.

Method Validation. Because of the absence of specific guidelines for the analysis of phytohormones in plant tissue, the Commission Decision 2002/657/EC was used as a guideline for the validation of the extraction and detection method developed for compounds **1**, **2**, and **3**. Appropriate deuterium-labeled internal standards, $^2H_4$-**1**, $^2H_6$-**2**, and $^2H_6$-**3**, were used to correct the data obtained for the extraction of the corresponding phytohormones from rose leaf tissue. Matrix-matched calibration curves making use of these deuterium-labeled internal standards were used for quantitation. The validation parameters considered were specificity, linearity (R^2), matrix effect by signal suppression/enhancement (SSE), apparent recovery (R_A), repeatability through the relative standard deviation (RSD_r), intra-laboratory reproducibility [also through calculation of the relative standard deviation (RSD_R)], and the limits of decision (LOD) and quantitation (LOQ).

RESULTS AND DISCUSSION

Method Development. By infusion of pure standards into the UHPLC mass spectrometer, the analyte-dependent mass spectrometric parameters were optimized for both the precursor ion and product ions (Table 1). The shortest analysis time with good resolution and peak shapes was observed using the Acquity UHPLC BEH C_{18} column. The effect of the column temperature on analyte separation within the range of 25−45 °C was investigated, with the most optimal results obtained at 30 °C. Representative chromatograms for compounds **1**, **2**, and **3** in rose leaves are shown in Figure 2. The retention times of compounds **1**, **2**, and **3** were 4.86, 5.65, and 5.28 min, respectively.

After optimization of the LC−MS/MS conditions, a suitable extraction procedure for the three phytohormones **1**, **2**, and **3** from rose leaves was developed. Although the cleanup of raw extracts can theoretically be kept to a minimum when applying analytical methods as sensitive and specific as UHPLC−MS/MS, the "dilute-and-shoot" principle was not tested in this study. Given the complexity of the plant material considered and the yet to be proven long-term suitability of such methods without cleanup step(s) in terms of minimally polluting the MS equipment, we chose to test a SPE cleanup method. When searching for suitable SPE columns, several factors should be taken into account: the sample matrix, analyte-specific physicochemical properties, and the nature of the bonded phase. Besides enrichment, SPE-based procedures also provide a reduction in sample complexity and help to minimize the matrix effect by SSE. To select an appropriate SPE column capable of retaining the analytes of interest, which are characterized by different hydrophobicities and pK_a values, a screening experiment with five commercially available solid-phase materials was conducted using a standard mixture of the three hormones **1**, **2**, and **3**. In this experiment, Oasis mixed-mode ion-exchange chemistry MAX (strong anion exchanger), WAX (weak anion exchanger), MCX (strong cation exchanger), WCX (weak cation exchanger), and Oasis HLB (universal polymeric reversed-phase sorbent) were evaluated. For the three hormones **1**, **2**, and **3**, the average recovery percentage of three repetitions was determined. This experiment showed that the anion-exchange cartridges MAX and WAX can be used for the purification of compounds **2** and **3** but not for compound **1** because the latter is not retained by the stationary phase (data not shown). In contrast, cation-exchange cartridges MCX and WCX and the generic cartridge HLB retained all three phytohormones examined. Balcke et al.[30] developed a purification method similar to the method presented in this paper. They tested 11 types of SPE devices and found strong cation-exchange solid-phase material to give the best recovery results. Our findings are in agreement with these results and the choice of the MCX cartridge as the best SPE cartridge for the purification of the phytohormones **1**, **2**, and **3** from plant material. The method currently presented offers a more effective extraction protocol when compared to the method by Balcke et al.[30] The amount of leaf material used was reduced to 20 mg and combined with an easier analysis procedure. Furthermore, the method was tested on a woody plant. It is known that interference of secondary metabolites makes woody plants more recalcitrant.

At present, extraction with organic solvents is the most widely used method for plant hormones. Many procedures and solvents have been developed and used for plant hormone extraction.[29,30] The polarity of the extraction solvent is chosen to closely match that of the target compounds; thus, the ratio of organic solvent/water is defined according to the polarity of hormones. Nonpolar solvents, such as ether, are rarely used to extract plant hormones. Instead, methanol is the preferred solvent, allowing for efficient plant cell penetration during extraction.[31,32] Because methanol produced the best recoveries in preliminary experiments (data not shown), experiments were performed using methanol alone[30] and with different proportions of ultrapure water [methanol/water, 75:25;[20] methanol/water/formic acid, 75:20:5;[29] and methanol/water/acetic acid, 10:89:1[33]). The results obtained are summarized in Table 2. The extraction solvent methanol/water/acetic acid (10:89:1) resulted in the highest recovery for compound **1** and a good recovery for compounds **2** and **3**, whereas the other extraction solvents led to a significantly lower recovery of compound **1**. For the optimization of the extraction time, three situations were tested: 1, 2, and 16 h. These data indicated that 1 h of extraction was sufficient for the recovery of compound **3** (100%), but the recovery of compounds **1** and **2** was only 70%. An extraction of 2 h yielded a recovery of 100% for the phytohormones **2** and **3** and 83% for phytohormone **1**. After 16 h of extraction, the recovery of compound **1** was 100%. On the basis of these data and logistical issues, the analyzes were carried out after 16 h of extraction.

Table 2. Percentage of Recovery with Different Solvents and Solvent Combinations Used for Extraction of Salicylic Acid (1), (−)-Jasmonic Acid (2), and (±)-2-*cis*-4-*trans*-Abscisic Acid (3)

	phytohormone (% recovery)		
solvent	1	2	3
100% methanol	29	100	93
75:25% methanol/water	46	72	100
75:20:5% methanol/water/formic acid	42	78	78
10:89:1% methanol/water/acetic acid	100	68	98

Method Validation. *Specificity.* When pure phytohormone standards were injected separately, the obtained UHPLC−MS/MS signals clearly did not interfere with the traces of the other phytohormones, baseline separation of all analytes could be achieved, and no crosstalk between different mass ranges of the MRM experiment was observed.

3	3.75, 15, and 30	105	3	11	103	2	6	100	2	4	0.0075	0.015	+140

[a] n = 4 for first day of validation. For the second and third days, n = 6.

Linearity. Linearity was evaluated by preparing seven-point calibration curves in the matrix for the different phytohormones (in triplicate). The "blank" samples were fortified with concentrations ranging from 0.00 to 60.0 μg/g for compound **3** and from 0.00 to 20.0 μg/g for compounds **1** and **2**. Correlation coefficients (R^2) obtained for these compounds were all >0.99, which indicated good linearity within the considered concentration ranges.

Matrix Effect. SSE is common in LC−ESI−MS/MS because of competition of charge carriers between analytes and co-eluting compounds during the ionization process. Matrix effect (SSE), ionization suppression or enhancement, in liquid chromatography/electrospray ionization mass spectrometry (LC/ESI−MS) is caused by matrix components co-eluting with the analytes. The matrix effect is also highly variable from sample to sample, making it difficult to compensate. To determine possible matrix effects, calibration curves of spiked extracts (i.e., matrix-matched calibration curves) were compared to the corresponding calibration curves of the pure standards. These effects were expressed in terms of SSE and calculated as follows: SSE (%) = 100 × (slope of the matrix-matched standard/slope of the pure standard). The values of SSE shown in Table 3 indicate that all phytohormones considered suffered from signal enhancement (≥100%), with the most profound enhancement observed for compound **2** (202% SSE). The observed SSE emphasized the need to quantitate these analytes by means of matrix-matched calibration curves.

Recovery, Precision, LOD, and LOQ. Table 3 gives an overview of the percentage of apparent recovery (R_A), intraday precision (RSD_r), interday precision over three non-consecutive days (RSD_R), LOD (μg/g), and LOQ (μg/g) for each phytohormone. R_A percentages were within an acceptable range (80−110%). Intralaboratory reproducibility and repeatability were all considered acceptable according to Commission Decision 2002/657/EC ("performance criteria"). For the phytohormones, the LOD and LOQ were theoretically calculated on the basis of calibration curves in the matrix: LOD = 3(seb/slope) and LOQ = 6(seb/slope), with seb being the standard deviation on the intercept of the calibration curve with the y axis and slope being the slope of the calibration curve (Table 3). The LOD and LOQ for compounds **1**, **2**, and **3** were 0.00015 and 0.015 μg/g, 0.0075 and 0.018 μg/g, and 0.0089 and 0.00030 μg/g, respectively. In our method, LOD and LOQ values show that hormones can be analyzed at endogenous concentrations. One can conclude that the values for the LOD and LOQ obtained with the multi-phytohormones method developed in this study were below typical endogenous concentrations.[34]

Analysis of Leaf Samples. In this study, concentrations of compounds **1**, **2**, and **3** measured in leaves were 0.68 ± 0.014, 0.17 ± 0.009, and 0.65 ± 0.032 μg/g, respectively (n = 3). The resulting values agreed with the ranges found in previous studies.

Knowledge of the compound **3** concentration in leaves is of particular interest to understand plant responses to abiotic stresses. Compound **3** is involved in the adaptability toward drought, salinity, cold, and other environmental stresses. A recent study[35] in roses under dark/light conditions and moderate/high humidity indicated compound **3** leaf quantitation levels in rose leaves ranging from ca. 1.00 to ca. 5.00 μg/g using UHPLC−ESI−MS/MS. The data obtained by our method for compound **3** (0.4−0.9 μg/g) showed comparable results to those by Giday et al.,[36] but no data were shown in the latter study on the concentrations of compounds **1** and **2** in rose leaves.

Plant matrix complexity complicates the analysis of phytohormones. Accurate quantitation of amounts of these compounds depends upon a robust method. We have developed a highly specific protocol for simultaneous determination of compounds **1**, **2**, and **3** in rose leaf material. The method is a rapid, sensitive, and accurate way to simultaneously determine the amount of compounds **1**, **2**, and **3** in rose leaves based on SPE purification and UHPLC separation, coupled with MS detection in MRM mode. The procedure described allows for quantitation of endogenous plant hormones in plants, without the need of a derivatization step. The compounds studied are representative of three groups of acidic plant hormones with several important biological properties. This method offers the possibility to incorporate other plant hormones and related metabolites into one single analysis. The simultaneous determination of phytohormones could support scientific efforts in plant functional genomics and hormone signal transduction. Using matrix-matched calibration curves for quantitation, we worked with a woody plant species. We assume that the method is also applicable and improves the analysis of phytohormones proposed earlier[30] in other plant material (e.g., tomato, rice, etc.) as well.

(renal inflammation, tissue necrosis, and renal apoptosis).[10] In addition, the International Agency for Research on Cancer (IARC) has now classified nanosized TiO_2 as a potential carcinogen on the basis of the rate of incidence of respiratory tract cancer in rats after prolonged inhalation of TiO_2 dust particles.[11] This indicates the need to evaluate the possible carcinogenicity of nanosized TiO_2 following other exposure routes.

A Monte Carlo human exposure analysis indicated that U.S. adults are exposed to about 1 mg Ti/kg bw per day.[8] These authors indicate that in the assessed food and consumer products approximately 36% of the TiO_2 particles were <100 nm in one dimension. Although TiO_2 has been authorized as a food additive,[7] no recent risk assessment is available. In general, the risk assessment of oral exposure to nanoparticles is difficult because of a number of uncertainties and a general lack of data.[12] Specifically for TiO_2, knowledge about the particle sizes and size distribution of TiO_2 particles in E171, let alone food and consumer products containing E171, is limited. The European Commission adopted a recommendation for the definition of nanomaterials, Commission Recommendation 2011/696/EU, stating that a material is a nanomaterial if 50% or more of the particles in a number-based size distribution have one or more external dimension in the size range of 1−100 nm. In specific cases the number-based size distribution threshold of 50% may be replaced by a threshold between 1 and 50%.[13] Currently the recommendation is under review; the discussion is focused on the percentage of the number-based size distribution below the 100 nm to classify a material as nanomaterial. Yet no internationally agreed upon method to determine the number-based size distribution has been proposed. Therefore, we used a combination of analytical methods as suggested by Linsinger.[14]

In this study we aimed to provide more information on the number-based size distribution of food grade TiO_2 ingredients and their occurrence in consumer products because this is required to increase the reliability of the human food exposure studies as part of the risk assessment. We used a combination of methods for this: asymmetric flow field-flow fractionation online with inductively coupled plasma mass spectrometry (AF4-ICP-MS) and two methods that provide number-based size distributions, scanning electron microscopy (SEM) and single-particle ICP-MS (sp-ICP-MS). Comparable size distributions were found, indicating that these methods can reliably be used to enforce food labeling in line with the recommendation of the EU definition of nanomaterials.

EXPERIMENTAL PROCEDURES

Samples. In this study three types of samples were involved: first, several types of TiO_2 food additive E171; second, food products such as cakes, candy, and chewing gum; and last, personal care products such as toothpaste. In total seven E171 materials, all food grades and four labeled as E171, were received from suppliers in China, Germany, Italy, The Netherlands, and the United Kingdom and consisted of fine white powders. In total 24 food products and 3 personal care products were investigated. All of these products were purchased in 2012 from regular shops in The Netherlands. Because food labeling for titanium dioxide may be imprecise, 20 products that listed "E171", "TiO_2", or "titanium dioxide" on the package were selected, as well as 7 products without this labeling but with a typical white color. Samples were stored in a clean, dry, and dark location and analyzed before the expiration data.

Determination of Total Titanium Content. For the determination of the total titanium content of the TiO_2 materials, a suspension of these materials was prepared according to the method of Jensen.[15] In short, ca. 15 mg of bovine serum albumin (BSA) is dissolved and diluted in Milli-Q water to reach a final concentration of 10 mg/mL. This solution is filtered over a 0.2 μm pore size filter and diluted 20-fold with Milli-Q water to a final concentration of 0.5 mg/mL BSA. An accurately weighed sample of ca. 15 mg of finely powdered TiO_2 material is brought into a 30 mL vial. Then 30 μL of 96% ethanol is added and distributed equally over the TiO_2 material followed by 970 μL of the 0.5 mg/mL BSA solution. The mixture is shaken manually, another 5 mL of the 0.5 mg/mL BSA solution is added, and the final suspension is shaken manually to obtain a homogeneous suspension. While the sample vial is cooled in ice water, the suspension is sonicated with a Misonix XL-2000 sonicator with a CML-4 needle probe for 16 min at 22.5 kHz and 4 W power. The final suspension is used as such or after further dilution to the desired concentration with the 0.5 mg/mL BSA solution. Suspensions prepared in this way showed to be stable for at least 3 days. From each suspension a subsample was collected in a perfluoroalkoxy (PFA) digestion vial to which 8 mL of nitric acid (70% HNO_3) and 2 mL of hydrogen fluoride (50% HF) were added. For the determination of the total titanium content of the food and personal care products, the whole sample was cut into small pieces and ground, and a representative subsample was used for analysis. An analytical sample of ca. 0.5 g was collected from each sample and brought into a PFA digestion vial to which 6 mL of nitric acid (70% HNO_3), 2 mL of hydrofluoric acid (50% HF), and 2 mL of hydrogen peroxide (30% H_2O_2) were added. All samples were digested in a MARS microwave system for 50 min. The temperature program was as follows: at 1200 W power from 20 to 150 °C in 15 min, then to 180 °C in 15 min, and finally constant at 180 °C for 20 min. Following digestion and cooling to room temperature, Milli-Q water was added to a total volume of 50 mL. The extracts were shaken manually, diluted to 100 mL, and analyzed with a Thermo X series-2 ICP-MS equipped with an autosampler and a conical glass concentric nebulizer and operated at an RF power of 1400 W. Data acquisition was performed in the selected ion monitoring mode at m/z ratios of 48 and 49 that are characteristic for titanium. Quantification was based on ionic titanium standard diluted in the same acidic matrix. The recovery of the total Ti method was determined by spiking three products of different matrices in triplicate with known amounts of a TiO_2 reference material, NM-103.

Determination of the Size Distribution in TiO_2 Materials Using Electron Microscopy. To determine the size distribution of the titanium oxide nanoparticles in the TiO_2 materials, suspensions of these materials were studied using electron microscopy. TiO_2 suspensions (2.5 mg/mL) were filtered over an Anopore aluminum oxide filter with a pore size of 20 nm. The filters were mounted on aluminum specimen holders with double-sided adhesive carbon tape and were coated with a 5 nm layer of chromium using an Emitech K575X turbo sputter coater. The filters were analyzed with a high-resolution field emission gun scanning electron microscopy in combination with X-ray analysis (FEG-SEM/EDX). The microscope is a Tescan MIRA-LMH FEG-SEM at an accelerating voltage of 15 kV, working distance of 10 mm, spot size of 5 nm. The EDX spectrometer is a Bruker AXS spectrometer with a Quantax 800 workstation and an XFlash 4010 detector. The SEM is equipped with the Scandium SIS software package (Olympus Soft Imaging Solutions, Germany) for automated particle analysis. With this system the filter area is automatically inspected on a field-by-field basis. In each field of view particles are recognized using a preselected grayscale video threshold (detection threshold level) to discriminate between particles and filter background. The analysis is conducted using the backscattered electron (BE) mode. From each particle/cluster of particles the projected area equivalent diameter (dpa) is measured. Magnifications were chosen so that their measurable size ranges overlap slightly and cover the particle sizes of interest. To measure dpa values from 25 to 1600 nm, three magnifications of 10000×, 25000×, and 75000× were selected. These three magnifications cover eight size bins: 25−40, 40−65, 65−100, 100−160, 160−250, 250−400, 400−650, 650−1000, and 1000−1600 nm. Per size bin a minimum of 10 particles were measured, and in total approximately 1000 particles were measured

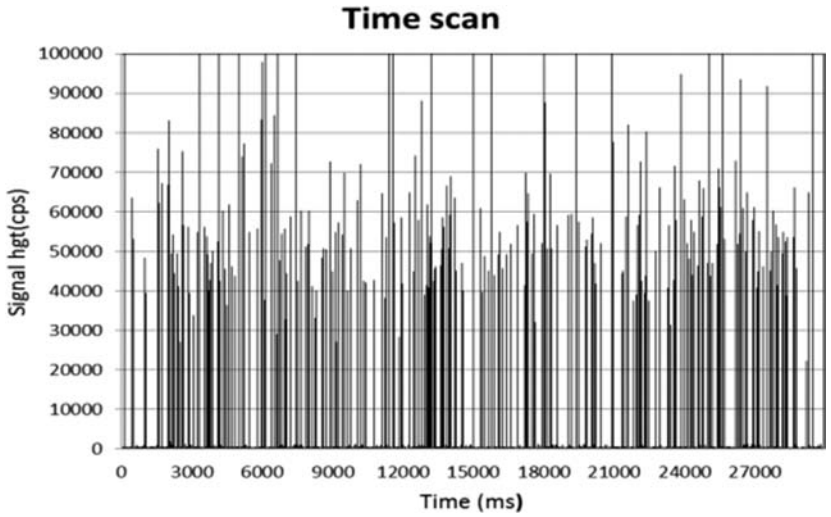

Figure 1. Single-particle ICPMS time scan of a diluted sample extract. Each peak represents one particle. The number of peaks is proportional to the particle concentration in the sample, whereas the peak height is proportional to the particle's diameter to the third power.

per sample. To ensure that there is no overlap of particles, the total loading of the filter with particles was always <10%. Per size bin the mean diameter and the 95% confidence interval are calculated on the basis of the Poisson distribution.

Quantification and Size Determination of TiO_2 Particles Using AF4-ICP-MS. For quantification and size determination of particulate TiO_2 in TiO_2 materials, a suspension of these materials was prepared as described before. For quantification and size determination of particulate TiO_2 in food and personal care products a representative subsample was prepared, and 0.5 g of this sample was brought into a 50 mL glass beaker together with 20 mL of hydrogen peroxide (30% H_2O_2). The content of the beaker was heated to about 100 °C and kept just below the boiling point of the H_2O_2 matrix. When most of the organic matrix is consumed, the content is evaporated until a residue of about 1 mL remains. The content is allowed to cool to room temperature and is diluted to 10 mL with the 0.5 mg/mL BSA solution. Prepared suspensions and extracts are analyzed with asymmetric flow field-flow fractionation (AF4) online coupled with ICP-MS. The AF4 consisted of a metal-free Wyatt Eclipse Dualtec separation system equipped with a 153 × 22 mm flow cell containing a Nadir regenerated cellulose separation membrane with a 10 kDa molecular weight cutoff and a spacer of 350 μm. The AF4 system was further coupled to an Agilent 1100 system with an autoinjector and a binary pump for eluent flow delivery and degassing. Prior to injection, samples were thoroughly mixed to ensure homogeneous distribution of suspended particles. The injection volume was 10 μL, and a 7 min focusing time was used. A constant cross-flow of 0.1 mL/min was applied, and the flow rate to the detector was kept at 0.5 mL/min. After 57 min, the cross-flow was reduced to 0 mL/min within 5 min and kept at 0 mL/min for 5 min to remove any residual particles from the separation channel. The outlet flow of the AF4 system passed through a UV detector and was directly coupled with the ICP-MS system for the selective determination of titanium. The ICP-MS system and settings were as described before. Because no well-characterized titanium oxide particles were available for calibration purposes, particle size calculation was based on FFF theory using the Boltzmann constant, the column temperature, the eluent viscosity, and the instrumental settings.[16,17] In short, the AF4 separation channel consists of an impermeable top block and a bottom block holding a semipermeable ultrafiltration membrane on top of a porous frit. The perpendicular field is caused by restricting the channel flow at the outlet. This restriction will force part of the carrier liquid to leave the channel through the bottom block, thus causing the cross-flow. Prior to elution, the analyte is concentrated at a position close to the injection port during a focusing step. Particle equilibrium heights above the membrane in AF4 depend on the diffusion coefficient of the particles and the applied cross-flow rate with larger particles being driven closer to the membrane. Retention times are dependent on the equilibrium height at which the particles travel in the parabolic flow profile of the channel flow and are expressed by

$$t_r = \frac{\pi \eta d \omega^2}{2kT} \times \frac{V_{cross}}{V_{channel}} \quad (1)$$

where t_r is the retention time of the analyte, η the viscosity of the eluent, d the hydrodynamic diameter of the particle, ω the channel thickness, k the Boltzmann constant, T the absolute temperature, V_{cross} the cross-flow rate, and $V_{channel}$ the channel flow rate. With this equation the particle's hydrodynamic diameter can be calculated directly from its retention time. This relationship was confirmed by calibration with polystyrene particles. Mass calibration of the ICP-MS was performed with one of the TiO_2 materials for which it was established that the TiO_2 content of this material was close to 100%.

Transformation of Mass-Based to Number-Based Size Distributions. The signal measured by ICP-MS in standard mode is a mass-based signal, and the size distribution determined with AF4-ICP-MS is thus also a mass-based distribution. The conversion of a mass- to a particle number-based distribution is carried out by placing the detected mass in size bins and calculating the number of particles as

$$N = \frac{M}{\rho \frac{4}{3}\pi (r \times 10^{-7})^3 \times 10^9} \quad (2)$$

where N is the number of particles, M is the mass detected in a certain particle size bin in ng, ρ is the density of the particle material in g/cm^3 (4.23 g/cm^3 was used for TiO_2), and r is the radius of the particle in that size bin in nm. The numbers are conversion factors to get the units right.

Size Determination of TiO_2 Particles Using Single-Particle ICP-MS. Single-particle ICP-MS is a relatively new approach for the detection and characterization of nanoparticles, and the principle has been described previously.[18−21] The ICP-MS instrument and settings used were as described before, only in this case data acquisition was done in the time-resolved analysis (TRA) mode. The dwell time was set at 3 ms with a typical acquisition time of 60 s per measurement. Because of the short dwell time, it is not possible to switch between different isotopes (switching itself takes ∼50 ms), and therefore only one titanium isotope, m/z 48, is monitored during measurement. Note that polyatomic interferences are possible, for example, $^{32}S^{16}O$ and $^{36}Ar^{12}C$, and also isobaric interference by ^{48}Ca. However, these interferences result in a continuous background, whereas TiO_2 particles will result in discontinuous signals (peaks) and can thus be distinguished from the background. Because only a part of the

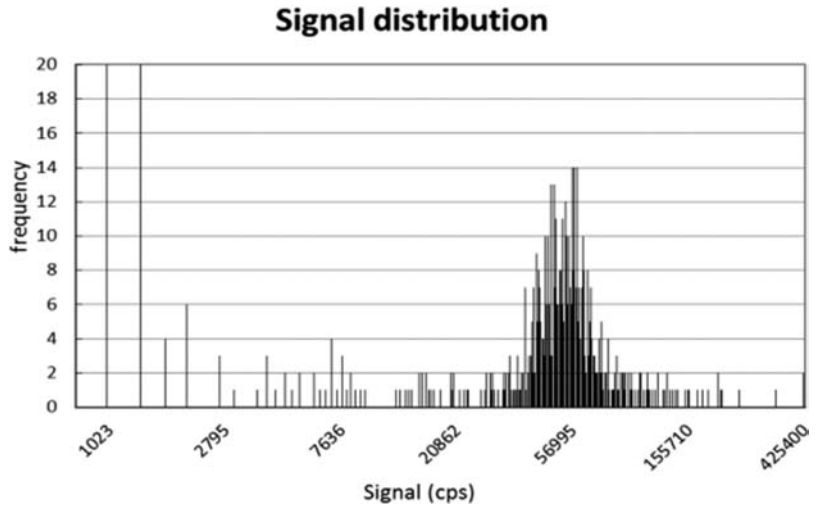

Figure 2. Signal distribution graph plotting the frequency of the ICP-MS response in data points as a function of the ICP-MS response. ICP-MS responses to the left of the minimum depict background and ions, those to the right the minimum particles.

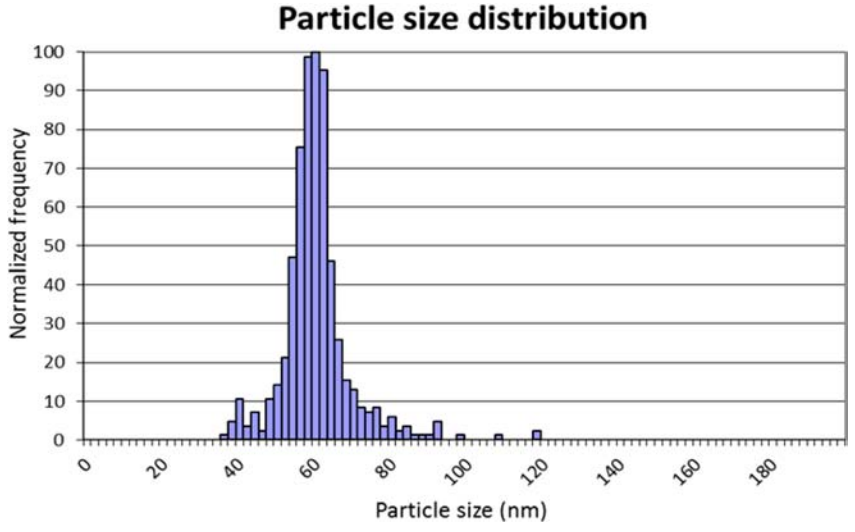

Figure 3. Typical example of a particle size distribution as produced by single-particle ICP-MS analysis.

nebulized droplets reaches the plasma, the nebulization efficiency needs to be known to determine the actual particle number concentration in the extract. The nebulization efficiency is determined by the analyses of a NIST material, SRM8013, a suspension of 60 nm gold nanoparticles in a citrate buffer, under the same instrumental conditions as the samples but monitoring m/z 197 for gold. The nebulization efficiency is calculated from the observed number of particles in the time scan and the particle flux into the ICP-MS system using eq 3. Single-particle data are transferred to and processed in Microsoft Excel for the calculation of particle sizes, particle size distributions, and particle concentrations. Acquiring data for 60 s at a dwell time of 3 ms results in 20000 data points consisting of background signals and signals with a much higher intensity originating from particles (Figure 1). These particle signals are isolated from the background by plotting a signal distribution, that is, the frequency with which a signal height occurs as a function of that signal height. This allows the determination of a cutoff point to separate particle signals from the background (Figure 2). From the number of the particle signals in the time scan and the nebulization efficiency determined previously with the gold nanoparticles, the particle number concentration in the diluted sample suspension is calculated as

$$C_p = \frac{N_p}{\eta_n} \times \frac{1000}{V} \quad (3)$$

where C_p = particle number concentration (L^{-1}), N_p = number of particles detected in the time scan (min^{-1}), η_n = nebulization efficiency, and V = sample input flow (mL/min). The same formula is used to calculate the nebulization efficiency after measurement of the 50 ng/L 60 nm gold nanoparticle suspension. In that case the particle number concentration C_p is known (50 ng/L of a 60 nm gold particle results in 2×10^7 particles/L) and the nebulization efficiency is calculated from the observed number of particles N_p in the time scan. From the intensity of the particle signals and the response factor calculated from a series of ionic titanium calibration standards that are analyzed under the same conditions, the mass of the individual particles is calculated as

$$m_p = \frac{I_p t_d}{RF_{ion}} \times \frac{V\eta_n}{60} \quad (4)$$

where m_p = particle mass (ng), I_p = particle signal intensity in the sample (cps), RF_{ion} = ICP-MS response factor from the calibration curve of the ionic titanium standards (cps/μg/L), t_d = dwell time (s), and V = sample flow (mL/min). To calculate the particle mass concentration in the diluted sample suspension, the masses of all

dx.doi.org/10.1021/jf5011885 | J. Agric. Food Chem. 2014, 62, 6285−6293

individual particles are summed and corrected for nebulization efficiency and sample flow:

$$C_m = \frac{\sum m_p}{\eta_n \times V \times 1000} \quad (5)$$

In eq 5 C_m = particle mass concentration (ng/L). Finally, the particle size, expressed as the particle's diameter (and assuming a spherical particle shape), is calculated for each particle as

$$d_p = \sqrt[3]{\frac{6m_p}{\pi\rho_p}} \times 10^4 \quad (6)$$

where d_p = particle diameter in the sample (nm) and ρ_p = particle density (g/mL). The individual particle sizes can be used to produce a size distribution graph (Figure 3). For all of these calculations a template in Microsoft Excel was produced and used throughout.

RESULTS AND DISCUSSION

We compared the size distributions of TiO_2 particles as determined with three different analytical approaches in three types of samples. First we characterized TiO_2 powders that, according to the manufacturers, are E171 food additives; second, we characterized food products (cakes, candy, and chewing gum); and, finally, personal care products (toothpaste) were examined.

Titanium Content and Particle Size Determination of TiO_2 Materials. *Total Titanium Content of TiO_2 Materials.* The total TiO_2 content of the E171 materials was determined as total titanium using HNO_3/HF digestion and ICP-MS analysis of the extracts followed by recalculation of results to titanium dioxide. The results show that the total TiO_2 content is in the range of 90−99% for five of the seven E171 materials and is 74 and 83% for the other two materials. Taking into account the measurement uncertainty of the total-Ti method (±6%) and the fact that these materials may contain some water, five of the seven E171 materials consist of pure TiO_2. It is known that some TiO_2 materials are coated with aluminum and silicon oxides or polymers to increase photostability and prevent aggregation.[22,23] Only the packaging of one of the two samples with a lower TiO_2 content declares that the material may contain aluminum hydroxide, amorphous silica, aluminum phosphate, and water. No further information about the chemical composition of these two TiO_2 materials was available.

Size Distributions of TiO_2 Materials Determined with SEM. The size distribution of the particles in the TiO_2 materials was determined by SEM. For this the materials were suspended in water and stabilized by BSA.[15] Representative SEM images of the TiO_2 materials are shown in Figure 4. The images on the left side in Figure 4 give a good picture of the large agglomerates that are encountered in the samples, whereas the images on the right side allow the estimation of the primary particle sizes. Detected particles were automatically counted using image analyses software and divided into size bins of 25−40, 40−65, 65−100, 100−160, 160−250, 250−400, 400−650, 650−1000, and 1000−1600 nm. The number percentage of the particles in each bin is then plotted against the mean particle size of the size bin to produce a number-based size distribution (Figure 4). In general, the size distributions of the seven TiO_2 materials are very alike and range from 30 to 600 nm, with the apex in all size distributions between 200 and 400 nm. About 10% of the particles have dimensions below 100 nm. The actual percentage of particles with at least one dimension <100 nm will be higher because the image analysis software determines an area equivalent diameter (diameter projected area; dpa) for the particles. As a consequence, particles with an aspect ratio different from 1 will be "averaged" into round particles, leading to an underestimation of the number of particles with one dimension <100 nm. From the image analysis it appears that for >80% of the particles, large and small, the aspect ratio is in the range of 0.8−1.2. As a consequence, it is expected that the underestimation of the number of particles with one dimension <100 nm is limited to 10−20%. That all materials appear to be more or less identical probably reflects the production process of this material. The most common production method for TiO_2 particles is the chloride process or the sulfate process.[24] In industrialized countries chloride processes appear to be favored over sulfate processes for environmental, economic, and qualitative reasons.[25] Therefore, there is a reasonable chance that all investigated TiO_2 materials are produced by the same process.

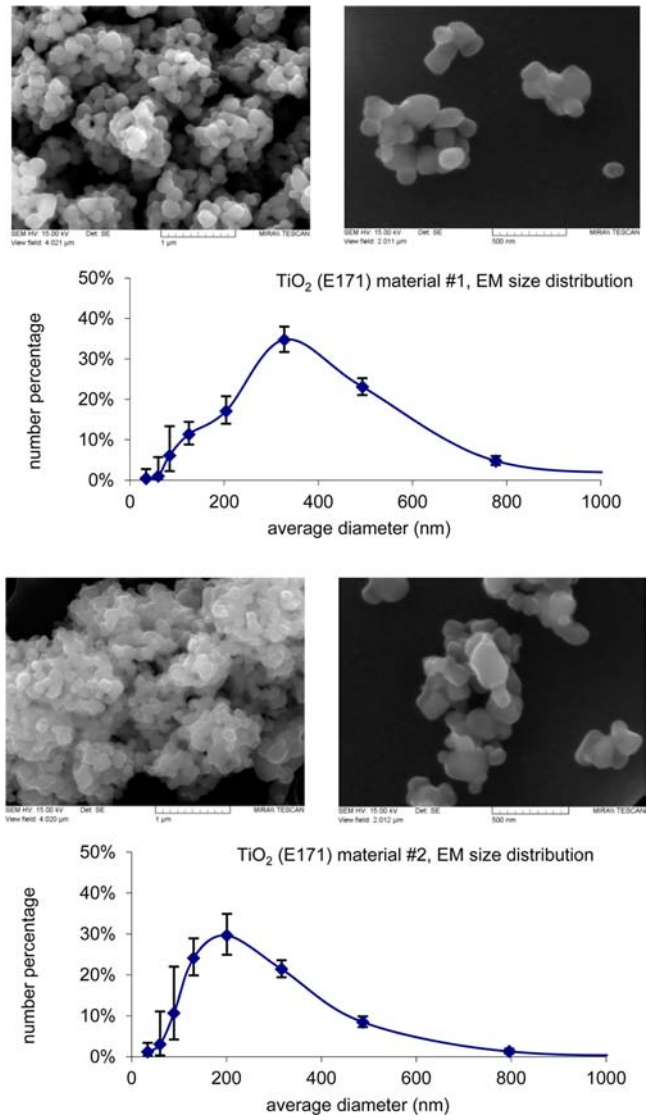

Figure 4. Representative SEM images of TiO_2 materials. The image on the left shows the agglomerates, whereas the image on the right shows the individual particles. The number-based size distributions produced by image analysis of the SEM images are shown below the SEM images (the error bars indicate the 95% confidence intervals of the number percentage in each particular size bin).

dx.doi.org/10.1021/jf5011885 | J. Agric. Food Chem. 2014, 62, 6285−6293

The smallest size bin used in our measurements was 25−40 nm. Particles in that size range could still be detected, identified, and counted by the image analysis software. TiO_2 particles <20 nm cannot be reliably identified and counted by the image analysis software. Manually, the operator can detect TiO_2 particles with diameters down to 10−20 nm in clean suspensions. However, manually detecting small particles is not a reasonable option because many fields have to be viewed to produce a reliable particle number. Thus, our measurements show that the lower size limit of detection for routine SEM analysis is around 20 nm for TiO_2 particles.

Size Distributions of TiO_2 Materials Determined with AF4-ICP-MS. Strictly speaking, AF4 is a separation technique and is not able to determine size, or a number-based size distribution. As there are no well-characterized TiO_2 particles of different sizes (i.e., reference materials for size calibration), we used a theoretical approach based on the well-established theory of flow field-flow fractionation for size calibration as explained under Experimental Procedures.

The result of the AF4-ICP-MS analysis is a chromatogram in which the signal height is a measure for the mass of titanium detected at a certain retention time. Following mass calibration this signal height is expressed as the mass of Ti or TiO_2, and with the time scale recalculated as a particle size scale based on an equation from flow field-flow fractionation theory described under Experimental Procedures, this results in a mass-based size distribution. However, to apply the EU definition for nanomaterials this mass-based distribution has to be transformed into a number-based distribution. Therefore, this mass-based size distribution is transformed into a number-based size distribution using the equation under Experimental Procedures and assuming that particles have a spherical shape. However, if the mass is converted into a number of particles, this number depends on particle size. If the mass remains constant, as shown in Figure 5, the number of particles increases strongly when

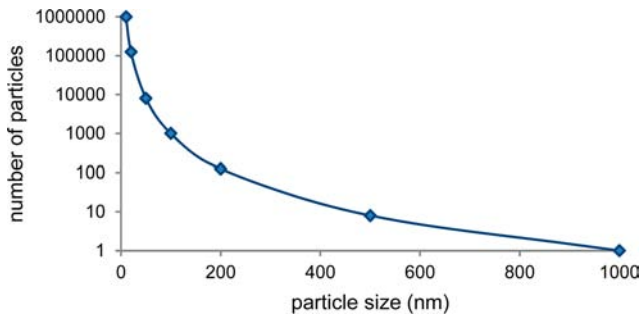

Figure 5. When the mass remains constant, the number of particles rapidly increases, especially at smaller particle sizes.

going to smaller particle (notice that the *y*-scale is a log scale), especially at small particle sizes, because particle size and mass are related by d^3 (see eq 6 under Experimental Procedures). This means that mass to number transformations have large conversion factors for small particles that easily lead to erroneous results. In practice, the beginning of chromatograms tends show small spikes, noise, nonparticle peaks or small electrical offsets. If these phenomena are also transformed from mass- to number-based, small particle sizes will completely and erroneously dominate the number-based distribution, resulting in a dramatic shift of the size distribution to smaller particle sizes. From the chromatograms in this study it was concluded that the smallest TiO_2 particle size that can be determined and reliably transformed from mass- to number-based distributions is around 20 nm.

Comparing the Measured Size Distributions of TiO_2 Materials. Conversion of the retention time into particle size and the mass-based distribution into a number-based distribution allows us to derive number-based size distributions for the TiO_2 materials. The AF4 size distribution of the materials for which the EM size distribution is shown in Figure 4 is shown in Figure 6. In general, the number-based size

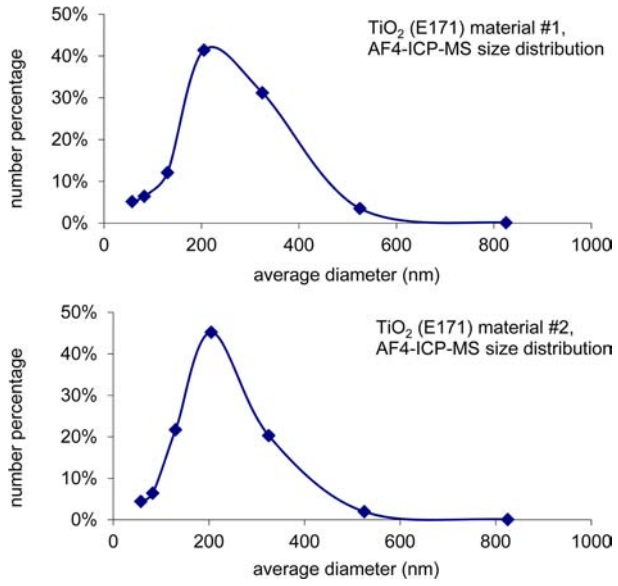

Figure 6. Number-based size distribution of two TiO_2 materials as determined with AF4-ICP-MS and after recalculation from mass-based to number-based.

distribution as determined by EM and AF4 shows two types of differences. First, the apex of the size distributions originating from AF4 generally is between 200 and 300 nm, whereas in EM size distributions it is between 200 and 400 nm. Second, the EM size distributions contain larger particles (diameter > 600 nm) than the AF4 size distributions. In AF4 large particles (diameter > 400 nm) may actually drop on, and roll over, the membrane surface at velocities that are higher than normal elution.[26] As a result these large particles elute at shorter retention times, thereby simulating smaller sized particles. In the number-based size distribution this will become visible as a shift to smaller particle sizes. As before, the percentage of particles with a size <100 nm is determined. In the AF4 analysis this ranges from 10 to 15% with an average of 12%. This is comparable with the 10% of particles with sizes below 100 nm that were found in the EM analyses.

Titanium Content and Size Distributions in Food and Personal Care Products. In addition to the TiO_2 materials, food and personal care products were also analyzed for total titanium content and with AF4-ICP-MS for titanium content as well as size distribution. An attempt was made to determine the size distribution of the TiO_2 particles in the extracts of these products with SEM. However, matrix constituents that were still present made it impossible to make a proper image analysis of the particle sizes. As an alternative, the extracts were analyzed using single-particle ICP-MS (sp-ICPMS) because this technique also produces a number-based size distribution. In total 24 food products and 3 personal care products were purchased in regular shops in The Netherlands. Products that

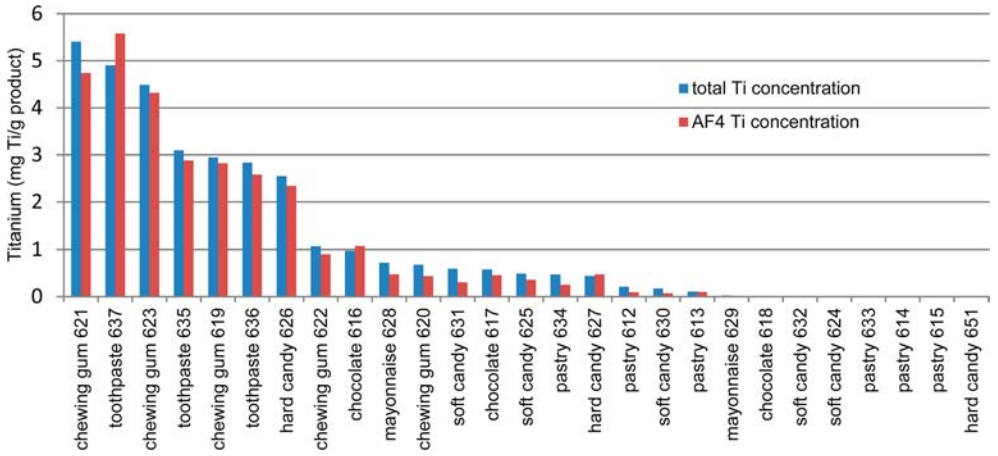

Figure 7. Total Ti content in food and personal care products determined with ICP-MS (blue, left-side bars) and the particle-based Ti content in the same products determined with AF4-ICP-MS analysis (red, right-side bars). The numbers after the product description refer to sample codes.

listed "E171" or "titanium dioxide" on the package, as well as a few products with a typical "white color", were selected for this study.

Total Titanium Content of Food and Personal Care Products. All 27 products were digested with a combination of HNO_3, HF, and H_2O_2, and the total Ti content was determined using ICP-MS. Total Ti recovery was determined by spiking three products of different matrices in triplicate with known amounts of a TiO_2 reference material NM-103. The total Ti recovery ranged from 92 to 109% with an average of 96 ± 6%. Method blanks showed only low amounts of titanium, that is, on average <2 μg of Ti, which corresponds to <0.005 mg Ti/g product. The quantification limit of the digestion and detection method was set to 0.01 mg Ti/g product. The total Ti content of the products ranges from 5.4 mg Ti/g product for a chewing gum to 0.01 mg Ti/g for a white-topped cookie. Four products had total Ti levels that were below the quantification limit of the method. The highest levels of total Ti are found in chewing gums and in toothpastes and the lowest in bakery products such as cookies and cupcakes (Figure 7). The results are comparable to the total Ti content in food items reported recently by Weir et al.[8]

Titanium Content of Food and Personal Care Products Determined by AF4-ICP-MS. All food and consumer products with a detectable amount of total Ti have been analyzed with AF4-ICP-MS for particle-based Ti content as well as the particle size distribution. For this purpose a separate sample preparation was set up using H_2O_2 to oxidize the sample matrix. The use of strong acids was avoided because these are not compatible with the AF4 analysis. H_2O_2 oxidation worked for all samples with the exception of the chewing gums, where debris of the guar gum remained. Because the TiO_2 particles are expected to be present in the outer, water-soluble coating of the chewing gum,[8] the removal of this debris probably does not influence the result. The time between sample preparation and measurement with AF4-ICP-MS was kept as short as possible and was no more than 4 h. After sonication of the sample extract, the extract was kept in constant movement on a roller bank until analysis. Prior to injection, the sample was thoroughly mixed to ensure homogeneous distribution of suspended particles. Because ions are removed in AF4 separation during the focusing of the analyte on the semipermeable membrane, mass calibration can be done only with a particle-based standard. In the absence of a reliable, well-characterized TiO_2 particle standard, one of the TiO_2 powders characterized as pure, 99% TiO_2, was used for this purpose. The particle-based Ti content of the food and personal care products as determined with AF4 and expressed as milligrams of Ti particle per gram of product is presented as the red, right-side, bars in Figure 7. The side-by-side comparison of the total Ti content and the particle-based Ti content as determined with AF4-ICP-MS in each product shows that they are comparable, certainly at Ti concentrations >0.5 mg Ti/g product. At lower concentration the results from the AF4 determination are generally lower than those from the total ICP-MS method. This can be explained by adsorption processes in the AF4 separation that become visible in the lower concentration range. Another reason may be that very large particles, aggregates, or agglomerates (>1600 nm) may be present in the samples and are lost in the AF4 determination. For products containing >0.5 mg Ti/g the results show that most of the total Ti originates from particles, that is, TiO_2 particles, and that no large amounts of titanium are unaccounted for in the AF4 analysis.

Number-Based Size Distributions in Food and Personal Care Products. Next to the particle-based Ti content of the samples, number-based size distributions were determined (Figure 8). From products containing <0.1 mg Ti/g product no reliable number-based size distributions could be produced. In general, the calculated number-based size distributions in food items and personal care products based on AF4-ICP-MS analysis are comparable with the number-based size distribution as determined for TiO_2 in E171 materials with EM. The apex of the size distribution was mostly found around 200 nm, which is in the size range of the primary particle sizes found with EM. The results indicate that a part of the TiO_2 particles have diameters below 100 nm. On a number-based basis the average percentage of particles with diameters <100 nm is around 8%, comparable with the 12 and 10% that were found for the number-based size distributions of TiO_2 in E171 with AF4-ICPMS and EM analyses.

Size Distributions Determined Using Single-Particle ICPMS. Because EM analysis was not feasible in products, sp-ICP-MS was used to determine a number-based size distribution of the TiO_2 particles in food and personal care products. The sample extracts that were used for the AF4 analysis were diluted 10000 times to get in the proper working range of the sp-ICP-MS method. Counting between 300 and

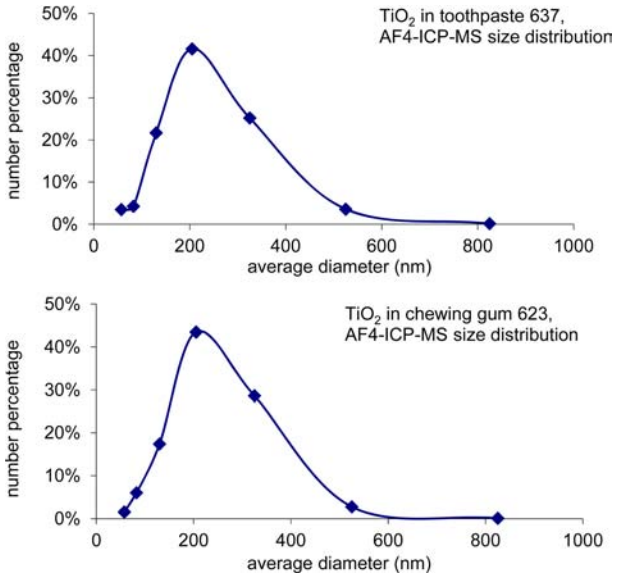

Figure 8. Number-based size distribution of the TiO_2 material in a toothpaste and chewing gum sample as determined with AF4-ICP-MS and after transformation of the mass-based to a number-based distribution.

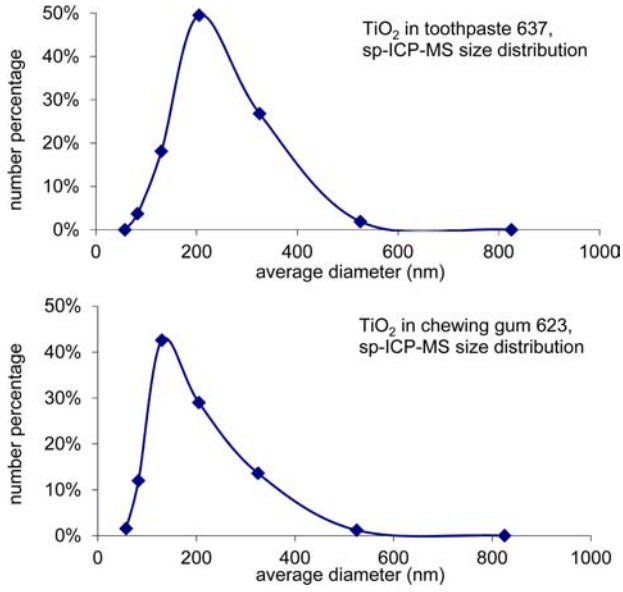

Figure 9. Number-based size distribution of the TiO_2 material in toothpaste as determined directly with sp-ICPMS.

3000 particle peaks in each time scan gives enough information to produce a reliable number-based size distribution. Whereas TiO_2 particles produce discontinuous signals (peaks) in sp-ICP-MS, small particle peaks will disappear in the background noise and can no longer be distinguished. Ti is measured at m/z 48 or 49, which is not that specific or sensitive, respectively. The presence of biatomic ions such as $^{32}S^{16}O$ and $^{36}Ar^{12}C$ and isobaric interference by ^{48}Ca result in a continuous background. This background noise for Ti measured at m/z 48 is substantially higher than that for silver (m/z 107) or gold (m/z 197), and therefore the minimum particle size that can be determined for titanium is also higher. Whereas for gold and silver 20 nm nanoparticles can be determined, the particle size detection limit for TiO_2 particles in the sp-ICP-MS method is 50 nm. The use of a collision cell did not improve the situation because not only the background noise but also the Ti particle peaks were reduced, resulting in no improvement of the signal/noise ratio.

Comparing the Measured Size Distributions of TiO_2 Materials. Compared to the calculated AF4-ICP-MS number-based size distribution (Figure 8), the measured sp-ICP-MS number-based size distributions (Figure 9) generally are shifted to the left, that is, toward smaller particle sizes, as illustrated by the results for chewing gum 623 in Figure 9. Nevertheless, the AF4-ICP-MS and sp-ICP-MS number-based size distributions of TiO_2 particles in the products are comparable. Furthermore, the distributions of the TiO_2 particles in the products are also comparable with the number-based size distributions of the TiO_2 (E171) materials as determined with AF4-ICP-MS and with EM. In all cases the apex of the size distribution is found around 200 nm within the size range of the primary particle sizes found with EM. The sp-ICP-MS results indicate that 5−10% of the TiO_2 particles have diameters below 100 nm. This is comparable to, or somewhat lower than, what was found in the EM and AF4-ICP-MS analysis and may in part be explained by the difference in the smallest particle that can be detected. For EM in the analysis of the TiO_2 materials the smallest TiO_2 particle that could be detected was around 20 nm; for AF4-ICP-MS in the analysis of TiO_2 materials and food and personal care products it was also around 20 nm, whereas in the sp-ICP-MS analysis of the food and personal care products the smallest detectable TiO_2 particle had a diameter of 50 nm.

These practical size detection limits for TiO_2 particles introduce a certain and perhaps significant bias because the size range between 1 and 20 nm is excluded. Whereas Figure 7 shows that >95% of the total titanium (mass-based) concentration is explained by TiO_2 particles >20 nm, if even only 1% of the total titanium (mass-based) concentration exists of TiO_2 particles <20 nm, this will change the determined number-based particle size distribution significantly. As a consequence, it is not clear whether TiO_2 in food products is a nanomaterial, and the results especially show the inability of current state of the art methods to support the EU recommendation for the definition of nanomaterials.

Potential for Consumer Exposure Assessment. In this study 7 TiO_2 materials, 24 food products, and 3 personal care products were studied for their titanium dioxide content and the number-based size distribution of TiO_2 particles therein. Three principally different methods have been used to determine the number-based size distribution of TiO_2 particles in E171 materials and food and personal care products. Comparable size distributions were found, and from these it was determined that 5−12% of the TiO_2 particles in these materials and products were <100 nm. These data are suitable to be used in an exposure study, further refining the exposure assessment by Weir et al. for the U.S. population.[8] Previously we assessed the SiO_2 content of food products[27] and subsequently assessed its fate during in vitro digestion.[28] There we concluded that the intestinal epithelium is exposed to nanoscale material. The fate of TiO_2 particles while in the human digestive tract is unknown and should be evaluated to allow a comparison with the existing oral toxicity studies using different forms of the TiO_2 NPs. Although the applied analytical methods showed practical size limits, all of these methods, and especially sp-ICP-MS, can be elegantly employed for further studies on the fate of food grade TiO_2 to bridge the

dx.doi.org/10.1021/jf5011885 | J. Agric. Food Chem. 2014, 62, 6285−6293

gap between our findings and recent oral toxicity studies to guarantee consumer safety.

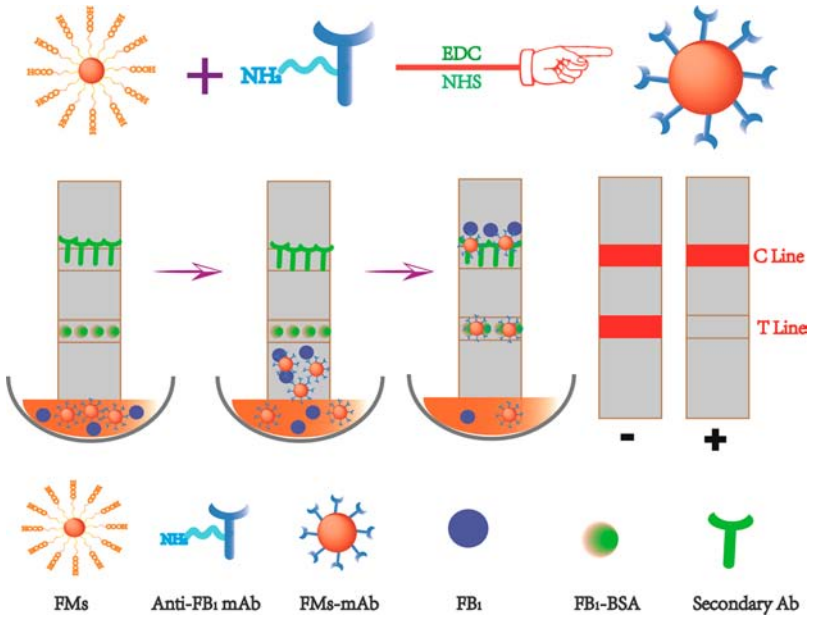

Figure 1. Fabrication process of the prepared FM−mAbs and the schematic illustration of the ICA. The ICA shows two lines on the vertical strip; the test line (T Line) is coated with coating antigen (FB_1-BSA), whereas the control line (C Line) is coated with secondary antibody that is specific to anti-FB_1 mAb.

(580/605, $\lambda_{ex}/\lambda_{em}$), 2% solids, were purchased from Invitrogen (Carlsbad, CA, USA). Bovine serum albumin (BSA), 1-ethyl-3-(3-(dimethylamino)propyl) carbodiimide hydrochloride (EDC), and 2-(*N*-morpholino)ethanesulfonic acid (MES) were purchased from Sigma-Aldrich (St. Louis, MO, USA). All other reagents were of analytical grade or better and were purchased from Beijing Reagent Corp. (Beijing, People's Republic of China). The nitrocellulose filter membrane (HF13520s25) was obtained from Millipore Corp. (Bedford, MA, USA). The sample pad (CH37K) and the absorbance pad (SB08) were supplied by Shanghai Liangxin Co., Ltd. (Shanghai, China). White opaque 96-well polystyrene microtiter plates were purchased from Costar, Inc. (Milpitas, CA, USA). The mAb 2D7 to FB_1 and the coating antigen were prepared previously and were purified using protein A prior to use.[22]

MES buffer was prepared as follows: 9.76 g of MES was dissolved in 1000 mL of purified water. The pH value of the MES buffer was adjusted by using 1 M NaOH.

Apparatus. The NanoDrop ND-1000 spectrophotometer was purchased from Gene Co., Ltd. (Hong Kong, People's Republic of China). The ZX1000 dispensing platform and the CM4000 guillotine cutting module used to prepare the ICA were purchased from BioDot, Inc. (Irvine, CA, USA). The ESE Quant LFR fluorescence reader was purchased from QIAGEN (Dusseldorf, Germany). The UV spectrometer was provided by Qiangyun Co. (Shanghai, People's Republic of China).

Preparation of FM-Labeled FB_1-mAbs. The FM−mAb conjugates were prepared as follows: anti-FB_1 mAb (7 μg) was dissolved in 1 mL of 50 mM MES (pH 6.5), and FMs (10 μL) were added dropwise. After 15 min, EDC (0.5 mg) was added and maintained on a shaker for 2 h at room temperature. The pH of the reaction mixture was adjusted to 6.5 using 1 M $NaHCO_3$. To quench the reaction, 100 μL of 0.1 M glycine was added and incubated for 30 min. The FM-labeled mAbs were obtained after centrifugation at 8076*g* for 15 min at room temperature to remove any unreacted mAbs. The pellets were resuspended in 100 μL of 0.05 M PBS containing 0.2% BSA and 0.4% poly(ethylene glycol). The suspension was dispersed and blended by supersonic vibration for 10 min and stored at 4 °C in the dark until use.

Fluorescence-Based ICA. Suspensions of 0.1 mg/mL FB_1-BSA and 1 mg/mL goat anti-mouse IgG were dispensed onto nitrocellulose filter membranes to produce the test (0.7 μL/cm) and control (0.9 μL/cm) lines, respectively. The membrane was dried for 2 h at 37 °C in an air oven. The sample pad was soaked in 0.01 M PBS (containing 0.05% Tween 20 and 0.05% sodium azide) and dried at 40 °C for 24 h. The absorbent pad was pasted onto the top side of the backing pad by overlapping a 2 mm section with the membrane. The sample pad was also pasted onto the other side of the backing pad by overlapping a 2 mm section with the membrane. Finally, the whole assembled plate was cut into 4 mm wide strips and stored under dry conditions at room temperature. A total of 120 μL of sample solution (or standard buffer) was transferred into a 96-well microtiter plate and homogenized with 2 μL of FM−mAbs at room temperature. After 5 min of shaking, the strip was added to the microwell to absorb the mixture. The capillary migration process lasted approximately 15 min, and the strip was then removed and fully dried for 5 min at 40 °C in an air oven prior to measuring the fluorescence signal. The results of the test and control lines were either qualitatively estimated by eye under a UV light or quantitatively measured by measuring the signal intensities using an ESE Quant lateral flow reader set at 580 and 605 nm for the excitation and emission wavelengths, respectively.

To test the specificity of the ICA for FB_2, FB_3, T-2 toxin, DON, ochratoxin A, zearalenone, and aflatoxin B_1, standard solutions of these mycotoxins with concentrations of 0.1, 0.5, 1, 1.5, 2.0, 4.0, and 10 ng/mL were prepared by diluting the corresponding stock solutions (1 mg/mL) with 0.01 M PBS. The following ICA experiments were carried out in the same way as mentioned above for FB_1. The cross-reactivity values were calculated according to the following equation:

$$[IC_{50}\ (FB_1,\ ng/mL)/IC_{50}\ (mycotoxins,\ ng/mL)] \times 100\%$$

Analysis of Maize Samples. Maize flour samples were provided by a local company in Belgium and stored at −20 °C. The concentration of mycotoxins was determined by HPLC-MS/MS, as previously described.[23] In spike and recovery studies, 10 g of FB_1-negative maize flour samples was spiked with FB_1, which was dissolved in methanol, with 500, 1000, and 1500 μg/kg. The samples were thoroughly mixed and then allowed to stand at room temperature overnight. Maize flour (1 g) was vigorously mixed and extracted with 20 mL of methanol/water (4:6, v/v) for 5 min before ultrasonic dispersion for 5 min and centrifugation at 8076*g* for 5 min. A total of 20 μL of supernatant was diluted with 980 μL of sample diluent prior to analysis by the ICA as described before.

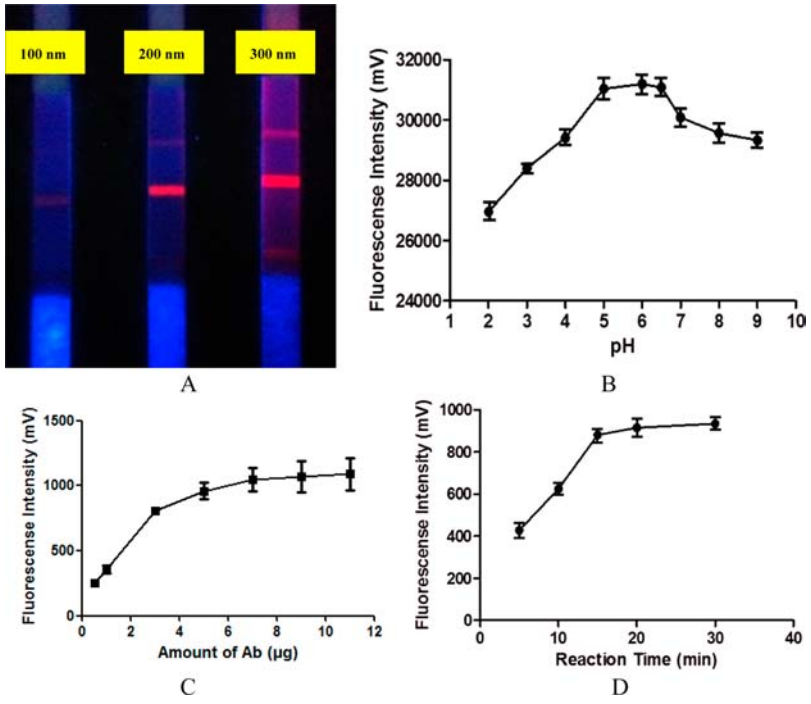

Figure 2. (A) Effect of the FM diameter on the fluorescence signal and mobility on the test line. (B) Effect of the pH on the fluorescence signals of FMs and FM−mAbs. The signals of FMs alone (pH values outside 5.0−6.5) and the signal of FM−mAb conjugates (pH values between 5.0 and 6.5) are shown. (C) Effect of the antibody loading amount on the fluorescence signal of FM−mAbs. (D) Effect of the immunoreaction time on the fluorescence signal in the ICA. Error bars = ±SD, n = 5.

RESULTS AND DISCUSSION

Detection Principle of the FM-Based ICA. In this study, the detector reagent consisted of anti-FB_1 mAb-functionalized FMs. The carboxyl groups of fluorescent microsphere were covalently coupled to the amino group of mAb in the presence of carbodiimide to ensure the stability of the detector (Figure 1). The detection principle of the FM-based ICA was based on the competitive binding between the FB_1-BSA (test line) and the mycotoxin FB_1 to combine with the limited mAbs on the fluorescence reporter. As shown in Figure 1, when FB_1 was present in the sample solution, the FB_1-FM−mAbs were formed in a microwell, diminishing the formation of FB_1-BSA−FM−mAbs at the test line, causing its fluorescence intensity to become weaker. Regardless of the presence of FB_1 in the sample, secondary antibody in the control line would bind to the anti-FB_1 mAbs ensuring the validity of the detection. According to the principle described above, the fluorescence intensity on the test line would be inversely proportional to FB_1 concentrations in the sample, which could be used for quantitation of FB_1 in samples. Quantitative analysis was realized by reading the fluorescence intensities of test line with a portable strip reader.

FM-Labeled mAbs. The activity of the FM−mAbs primarily guaranteed assay speed and sensitivity; thus, we first optimized the FM−mAb preparation conditions. Figure 2A shows the influence of the FM diameter on the fluorescence intensity of the test line. In the presence of 300 nm FMs, the signal generation was rather slow, and it took >30 min to accomplish the procedure. Although the 300 nm FMs produced strong signals, this duration is not appropriate for a rapid assay (Figure 2A). Besides, the significant residue of FM−mAb conjugates in the membrane pores could affect the accurate detection of the target (Figure 2A). It took <10 min to accomplish the procedure in the presence of 100 nm FMs; however, the signal response was very weak, as shown in Figure 2A, indicating that the small-diameter FMs were not appropriate for application with the ICA. The 200 nm FMs represented a compromise between speed and sensitivity in the assay and were selected for further experiments (Figure 2A).

The pH of the buffer has a great influence on the fluorescence of the FMs alone and on the FM−mAb conjugates, for example, through their dissolution and stability properties; therefore, the effect of several buffers with different pH values on these FM properties was evaluated. The fluorescence signal of FMs alone has been tested at pH values outside 5.0−6.5 and the signal of FM−mAb conjugates at pH values between 5.0 and 6.5 (Figure 2B). Thus, we evaluated the effect of buffers with pH values of 5.0, 6.0, and 6.5 on the performance of the FM−mAb conjugates. The FM−mAb conjugates clogged the membrane at pH values of 5.0 and 6.0. The pH 6.5 coupling buffer was thus selected as the most suitable condition for the subsequent experiments.

Figure 2C shows the results of the mAb loading onto the FMs. The fluorescence intensity of the FMs increased as increasing amounts of mAb were added onto the FMs until asymptotically approaching a maximum value. As the increase of intensity is very limited for amounts of added mAb above 7 μg (Figure 2C), this quantity has been selected as the most appropriate for an adequate signal sensitivity in the ICA.

One of the main characteristics of ICA is rapid detection, which is an important advantage over other immunoassays. A time−intensity curve was constructed by measuring the signal of the test line as a function of incubation time. The signal increased rapidly during the first 15 min, and the signal asymptotically reached a maximum for longer incubation time plateaued between 15 and 30 min (Figure 2D), indicating that the signal was already relatively stable for analysis at 15−30

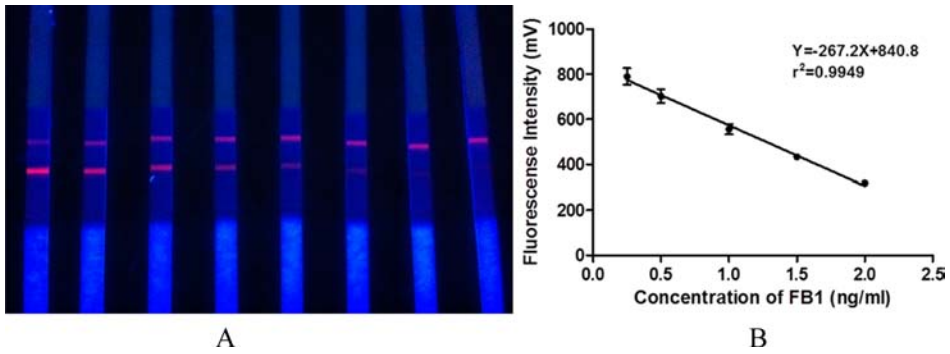

Figure 3. (A) Fluorescent image of the ICA acquired under UV light for 0, 0.25, 0.5, 1, 1.5, 2.0, 2.5, and 3 ng/mL FB_1 (from left to right). (B) Standard curve for quantitative detection by the fluorescence ICA. Error bars = ±SD, n = 5.

min. With consideration of finding the shortest time for an optimal detection, the best incubation time was considered as 15 min.

Analytical Performance of the ICA. The fluorescence ICA is based on competitive binding of the FB_1 in the samples and the FB_1-BSA immobilized on the test line to the FM−mAb conjugates flowing through the membrane. Analytical parameters of the ICA for FB_1 were obtained under the previously determined optimal conditions. Concentrations of FB_1 from 0 to 3.0 ng/mL were applied to the ICA, and the corresponding inhibition fluorescence intensity of the test line was observed under an ultraviolet light source or recorded by a fluorescence reader. As shown in Figure 3A, the red fluorescence intensity of the test line clearly decreased as the concentration of FB_1 increased. The fluorescence intensity was barely detectable at 2.5 ng/mL of FB_1; thus, 2.5 ng/mL FB_1 was considered the cutoff value for the assay (corresponding to 25 μg/kg in maize flour samples according to the extraction procedure used in the study). A calibration curve was generated using FB_1 in the range of 0.25−2.0 ng/mL (250−2000 μg/kg in maize flour samples) with an IC_{50} value of 1.32 ng/mL, as shown in Figure 3B (r^2 = 0.9949). The LOD for the quantitative detection was estimated from the concentration that corresponded to the blank test line value minus 3 times the standard deviation of the blank, which was calculated as 0.12 ng/mL (1.2 μg/kg in maize flour samples). This LOD is lower than that of the ELISA method employing the same immunoreagents (5.4 μg/kg in maize flour samples).[22]

The specificity of the ICA was determined by evaluating cross-reactivity with frequently occurring mycotoxins, including FB_2, FB_3, T-2 toxin, DON, ochratoxin A, zearalenone, and aflatoxin B_1. The ICA exhibited cross-reactivities with FB_2 and FB_3 of 1.5 and 67.3%, respectively, and negligible cross-reactivities with other mycotoxins (<1%).

Maize Sample Analysis. Results for the analytical recovery of FB_1 spiked to maize sample are given in Table 1. As observed in Table 1, the average recovery values (n = 5) ranged from 91.4 to 118.2% with CV values between 6.01 and 12.02%. Ten naturally contaminated maize samples were subjected to both the ICA and an HPLC-MS/MS method. The data obtained by the two methods were in good agreement (r^2 = 0.93), as shown in Table 2. The content of DON in the maize samples did not appear to affect the quantification of FB_1 in the maize samples by the ICA.

Table 1. Recoveries of FB_1 Added to Maize Flour Samples

added concn (μg/kg)	measured concn (μg/kg)	recovery (%)	CV[a] (%)
500	591	118.2	6.01
1000	914	91.4	6.82
1500	1527	101.8	12.02

Comparison with Colloidal Gold-Based ICA. ICA provides a simple, rapid, and robust technique for the screening detection of mycotoxins in cereals, and colloidal gold is the most frequently used reporter system. Shiu et al. developed an ICA for the detection of FB_1 in grain-based food and feed samples. This strip had a cutoff value of 5 ng/mL for FB_1.[24] Wang et al. also described an ICA for FB_1 and obtained a cutoff value of 1.0 μg/L.[25] A lateral flow dual immunoassay for the quantitative detection of zearalenone and FB_1 in corn and wheat samples was recently reported. The LODs were 5.23 ng/mL for FB_1 in the dual ICA format.[26] Anfossi et al. developed a quantitative ICA for simultaneous detection of both FB_1 and FB_2 in maize because the employed FB_1-antiserum provided a cross-reactivity of 97% to FB_2. The LOD of the quantitative ICA was 12 μg/L.[27] In the study, we employed FMs as a reporter to develop a fluorescence ICA for FB_1. Compared to the colloidal gold reporter, we found that the sensitivity of the fluorescence ICA is greater than or comparable to those of most currently available ICAs.

In conclusion, we demonstrated that FMs are a promising practical reporter for ICAs. The FM-based ICA for FB_1 was capable of detecting a minimum of 0.12 ng/mL FB_1 within 15 min. The assay was simple, rapid, and sensitive and provided not only qualitative results for rapid assessment but also quantitative results for the accurate determination of FB_1 in maize samples. Therefore, the FM-based ICA has great potential to improve detection sensitivity to enable more

dx.doi.org/10.1021/jf5017219 | J. Agric. Food Chem. 2014, 62, 6294−6298

sensitive and quantitative bioassays. The application of FMs can be easily extended to other contaminants by using the corresponding specific antibody.

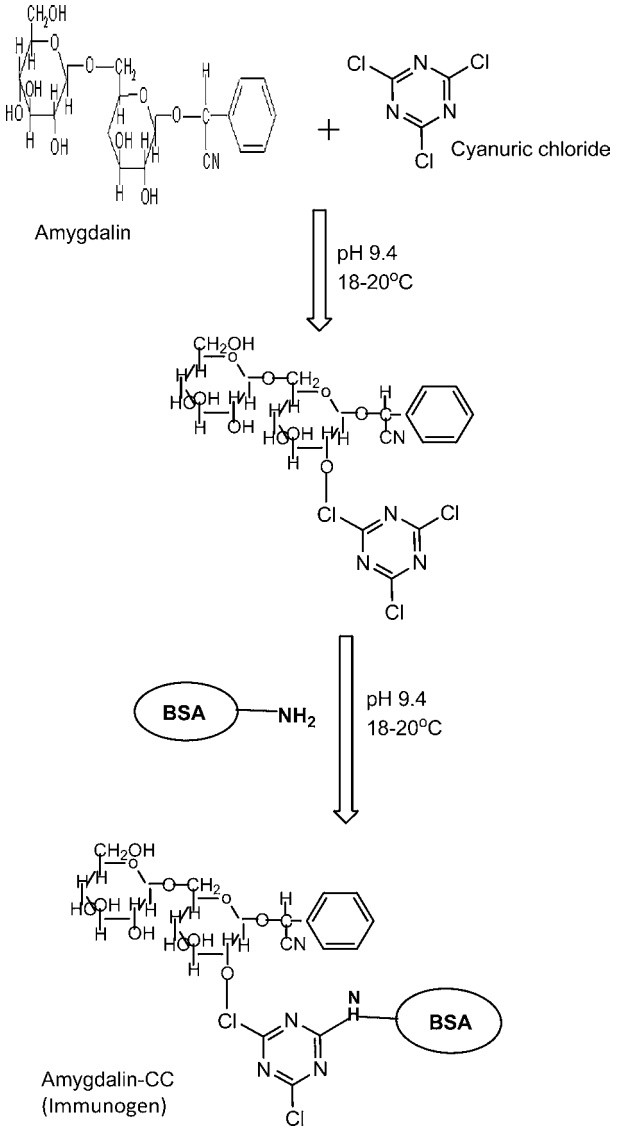

Figure 1. Structure of amygdalin and the synthetic approach to immunogen production.

food analysis for the determination of food contaminants and in the agrochemical industry for the detection of chemical residues in plants, water, and soil.[19−21] Different types of immunoassay techniques have been developed for the detection and quantification of hazardous compounds in foods. Quan et al.[22] developed a sensitive enhanced chemiluminescence enzyme-linked immunosorbent assay (ECL-ELISA) for the detection of fumonisin B_1 (FB_1) in foods and animal feeds. An ELISA developed by Pastor-Navarro et al.[23] was able to detect different tetracycline residues in honey. ELISA methods have also been developed for monitoring the levels of herbicides in water,[24] pesticides, and estrogenic compounds in agricultural products.[25,26] Antibodies against amygdalin have been described previously[27,28] but have not been fully characterized or used quantitatively. We describe the development, characterization, and application (for the first time) of an ELISA for the specific quantification of amygdalin in commercially available food products.

MATERIALS AND METHODS

Chemicals. Amygdalin, dhurrin, TMB (ready-to-use ELISA substrate), acetone, cyanuric chloride, Tween 20, gelatin, casein, and buffer salts were all purchased from the Sigma Chemical Co., Poole, Dorset, UK. Prunasin, mandelonitrile and linamarin were purchased from Santa Cruz Biotechnology, Dallas, TX, USA. 2,4,6-Trinitrobenzenesulfonic acid (TNBS; 5%, w/v) was obtained from VWR International Ltd., Leicestershire, UK. Keyhole limpet hemocyanin (KLH) was from Merck Chemicals Ltd., Nottingham, UK. Bovine serum albumin (BSA) was purchased from Fisher Scientific Ltd., Leicestershire, UK. Goat anti-rabbit IgG (H+L) horseradish peroxidase conjugate was obtained from Invitrogen Life Technology, Paisley, UK. Microtitration plates (96-well, MaxiSorp) were purchased from Nunc, Rosklide, Denmark. Microtitration plate washing was carried out using a Labsystem 4MK2 Wellwash (Labsystems, Uxbridge, UK), and the optical densities at 405 nm were recorded using a plate reader (ThermoFisher Scientific, Vantaa, Finland). Phosphate-buffered saline (PBS, 0.01 M, pH 5.5 and 7.4), phosphate-buffered saline (pH 7.4) containing 0.05% Tween 20 (PBST), sodium carbonate−bicarbonate buffer (0.05 M, pH 9.4 and 9.6) were used.

Food Samples. All fruits and processed products used in this study were purchased from local supermarkets in Leeds, UK. The products were toasted almond kernels (produced in the United States, packaged in the United Kingdom by Sainsbury's), EcoMil almond cocoa dessert (8% almond) produced in Spain, Tesco own-brand almond flour (produced in the United States, packaged in the United Kingdom by Tesco), Morrison's own-brand white marzipan (25% almond) produced in the United Kingdom, Sainsbury's own-brand apple juice (produced in the United Kingdom), Copella apple juice (hand-picked English apples, produced in the United Kingdom), Del Monte quality long life apple juice (100% concentrate), squashes, melons, and black cherries (from the United Kingdom), black plums (from Chile), yellow plums (from South Africa), apples (from Brazil), pears (from The Netherlands), courgettes and cucumbers (from Spain), peaches (from Argentina), and marrows (from Egypt). Three packs from different batches were purchased for each brand or product. All products were stored at 4 °C for 2 days after purchase and extracted as soon as possible.

Synthesis of Hapten−Protein Conjugates. The hapten−protein synthesis route is illustrated in Figure 1. Amygdalin was first activated with cyanuric chloride (CC) using a modification of the method of Abuknesha et al.[29] used for antibody−enzyme conjugations. CC (1 mg) was dissolved in acetone (1 mL), and 0.3 mL of the solution was measured into a glass vial. The content of the vial was allowed to evaporate. Amygdalin was activated by adding a solution of amygdalin (2.3 mg in 0.5 mL sodium carbonate−bicarbonate buffer, pH 9.4) to the CC residue. The mixture was stirred for 6 h at room temperature (20 ± 2 °C) to produce the activated hapten (amygdalin-CC). BSA (0.1 μmol, 6.6 mg in 0.5 mL sodium carbonate−bicarbonate buffer, pH 9.4) was added to the hapten, and the mixture was incubated overnight at 37 °C and then dialyzed for 6 h against 0.01 M phosphate buffer (pH 5.5). The resulting material (amygdalin−BSA conjugate, Figure 1) was freeze-dried to obtain a white powder. The conjugate was stored at −20 °C until use. The synthesized amygdalin−BSA conjugate was used as the immunogen. Amygdalin−KLH conjugate used for the immobilized phase of the ELISA was synthesized using the same method as for immunogen production.

Assessment of Hapten−Protein Conjugates. The ratios of coupled hapten to protein in the conjugates were assessed by both spectrophotometric and chemical methods.[130−] First, verification of conjugate synthesis and estimation of the number of moles of hapten conjugated per mole of protein were estimated by UV−visible spectrometry. Amygdalin (1 mg), BSA (1 mg), or amygdalin−BSA conjugate (1 mg) was dissolved in sodium carbonate−bicarbonate buffer (0.05 M, pH 9.6, 1 mL). Absorption over 200−400 nm was determined, and the number of moles of hapten in the conjugate was calculated using the maximum absorbance for amygdalin at 262 nm to calculate the molar extinction coefficient. The number of moles of conjugated hapten was calculated using $A = \varepsilon cl$.

Second, the trinitrobenzenesulfonic acid assay (TNBS; Habeeb[30]) was used to estimate the molar conjugation ratios of amygdalin−BSA and amygdalin−KLH conjugates. The method is based on the determination of available amino acid groups present in carrier protein before and after hapten conjugation following its reaction with TNBS. The end product of the reaction of TNBS produces trinitophenyl derivatives, which can be measured spectrophotometrically. The assay protocol used was as modified by Kemp and Morgan.[31] Carrier protein or conjugate (1 mg) was dissolved in 1 mL of 0.05 M sodium carbonate−bicarbonate buffer, pH 9.4. Standard curves for the proteins were constructed using a total volume of 200 μL in the wells of a microtitration plate. To each of the wells was added 50 μL of TNBS (0.1%) in carbonate buffer (4%). The plate was incubated for 2 h at 37 °C for color development, and the absorbance was read at 405 nm on a plate reader. The percentage substitution of amino acid in the carrier protein was used to estimate the conjugation ratio of hapten to carrier protein.

$$\%\ \text{substitution} \equiv \frac{\text{OD of carrier protein} - \text{OD of hapten−protein conjugate}}{\text{OD of carrier protein}} \times 100$$

Immunization Protocol and Polyclonal Antibody Production. Antibodies were raised by Covalab Ltd., Cambridge, UK. Two female New Zealand White rabbits (2−2.5 kg) were immunized with the immunogen (amygdalin−BSA conjugate) to generate polyclonal antibodies. The first injection consisted of the immunogen (50 μg in 0.5 mL of phosphate-buffered saline) emulsified with 0.5 mL of Freund's complete adjuvant and injected intradermally on multiple sites on the rabbits' back. The rabbits were further boosted by injecting intradermally the immunogen (50 μg) dissolved in 0.5 mL of Freund's incomplete adjuvant three times at 3 week intervals, with the final booster injection administered subcutaneously. The antisera were stored at −20 °C until use.

Enzyme-Linked Immunosorbent Assay. For determination of antibody titer, each well of the 96-well microtitration plate was coated with amygdalin−KLH overnight at 4 °C using 300 μL of a solution of conjugate dissolved in 0.05 M carbonate−bicarbonate buffer, pH 9.6. The plate was then washed three times with water and twice with 0.01 M PBST. Antibody titer was determined by incubating serial dilutions of antisera and preimmune sera in PBST (200 μL per well, in triplicate). The plate was incubated overnight at 4 °C, washed five times with PBST, and dried. A species-specific secondary antibody, goat anti-rabbit horseradish peroxidase IgG conjugate (diluted 1/1000 in PBST, v/v; 200 μL per well), was added. The plate was incubated at 37 °C for 2 h, washed and dried as before, and then TMB substrate (200 μL) was added to each well. The plate was further incubated for 30 min at 37 °C, and the reaction was stopped with sulfuric acid (2 M, 50 μL per well). The absorbance of each well was determined at 405 nm. The development of yellow color was proportional to the amount of antibody present. The mean absorbance values of triplicate determinations were plotted against antiserum dilutions.

For the indirect competitive ELISA (icELISA), standard curves were constructed with 100 μL of solution containing amygdalin standard (10 pg/well−10 μg/well) dispensed into appropriate wells of the coated plates prior to adding antibody (100 μL). The plate was then processed for the antibody titer curve determination. The limit of detection of the assay was estimated as the concentration that corresponds to the optical density at zero binding minus 3 times the standard deviation of the mean of zero binding.

To optimize the ELISA, the sensitivity of the immunoassay was improved by varying the antiserum dilution, the incubation time, and the concentration of the coating antigen and by using different protein buffers. The protein buffers that were evaluated were PBST containing 1% BSA, 1% gelatin, or 1% casein. Evaluation of the optimization process was based on the IC_{50} value and the coefficient of evaluation of the linear equation (R^2) as described by Qian et al.[32]

Cross-Reactions. The optimized assays were applied to cross-reactivity studies using standard solutions of amygdalin and other cyanogenic glycosides. The cross-reactivity of the antibody with some closely related cyanogenic glycosides such as prunasin, dhurrin, mandelonitrile, and linamarin was determined by icELISA. The specificity of the polyclonal antibody was determined using

$$\%\ \text{cross-reactivity (CR)} = (IC_{50}\ \text{of amygdalin}/IC_{50}\ \text{of analogue}) \times 100$$

Application of the icELISA to Quantification of Amygdalin in Commercially Available Food Products. The extraction method described previously[18] was used for the extraction of amygdalin from food samples. Solid samples (2 g) were ground in a blender (20 s; Moulinex Optiblend 2000, France), and 1 g was weighed into a round-bottom flask (500 mL). In the case of liquid samples, ethanol (50 mL) was added to the samples (10 mL) in a round-bottom flask, and the mixture was boiled under reflux for 100 min. The extracts were filtered (Whatman no. 1 filter paper) and transferred into plastic polypropylene tubes (50 mL). Ethanol was completely evaporated from the filtrate with a rotary evaporator (low boiling point, 35 °C, 7 mbar). Diethyl ether (10 mL) was added to the dried sample, and the mixture was vortexed (1 min) at room temperature (20 ± 2 °C) to precipitate amygdalin. The diethyl ether was allowed to evaporate overnight in a fume hood, and the extracted amygdalin was dissolved in 1% BSA−PBST (1 mL). The food extract (100 μL) was then incubated with antibody on a coated plate as previously described for setting up the standard curve. Quantification of amygdalin in the sample was by reference to standard curves. Samples were also analyzed by HPLC as described previously to show the correlation of the results from the two methods. The HPLC extraction method was, however, different from the ELISA method. In the HPLC method, extracted amygdalin was further purified by dissolving it in water followed by centrifugation (14000 rpm, 22 °C, 10 min) and filtration with 0.45 μm PTFE filters prior to HPLC analysis.

RESULTS AND DISCUSSION

Immunoassays are now widely used in quantitative analysis for agri-food components for their advantages of cost-effectiveness and simplicity, which arise directly from the affinity of the antibody interaction with its target. Surprisingly, perhaps, given that immunoassays can be used away from fully equipped laboratories to monitor food processing, only two previous papers have described antibody production against cyanogenic glycosides, both against amygdalin.[27,28] No antibody characterization was carried out and no assay validation reported, nor were any quantitative data provided. The present paper provides antibody characterization, assay validation, and quantitative data on commercially available food products.

Hapten Synthesis. Methods for the production of hapten−protein conjugates need to be efficient, carried out under mild conditions, and effective. To produce the amygdalin immunogen, we used a method previously used by Abuknesha et al.[29] to synthesize antibody−enzyme conjugates. Cyanuric chloride has reactivity toward hydroxyl groups under mild conditions, and the coupling method did not affect the structure of the target analyte (amygdalin). Figure 1 shows the synthetic scheme followed. To provide the immobilized phase of the assay, a KLH−amygdalin conjugate was produced using the same chemistry.

Estimation of Hapten−Protein Ratios. Amygdalin exhibited a UV maximum at 262 nm and BSA at 278 nm. The BSA−amygdalin conjugate had a peak at 278 nm and a significant shoulder at 262 nm. Similar results were seen with KLH. The magnitude of the 262 nm absorption was used to calculate hapten−protein ratios, which were found to be 23:1 and 19:1 for the BSA−amygdalin and KLH−amygdalin conjugates, respectively.

dx.doi.org/10.1021/jf501978d | J. Agric. Food Chem. 2014, 62, 6299−6305

Reaction of the proteins with TNBS generated standard curves at 405 nm. Theoretically, 59 lysine residues of BSA are available for coupling to hapten.[1] The percentage substitution of amygdalin calculated from the standard curves was 34.4%, giving a hapten−protein ratio for the immunogen of 20:1. The same procedure was employed for the KLH coating conjugate, and the ratio was calculated to be 17:1.

The hapten−protein ratios obtained for the BSA conjugate (23 and 20:1) and the coating conjugate (19 and 17:1) using the spectrophotometric and chemical methods were very close. This is an indication that the use of cyanuric chloride as a coupling agent for conjugate production was efficient and that the procedure merits wider utilization in the future. The hapten−protein ratios obtained in this study were in line with recommended ratios for good antibody production. Kemp and Morgan[31] reported that a conjugate with a high hapten−protein ratio is good as an immunogen, whereas the one with a low ratio may be desirable as a coating antigen. Hapten densities of 15−30 molecules per carrier protein were also reported to be good for the production of high antibody titers.[1]

Antibody Titer. The BSA−amygdalin conjugate was used in antibody production in rabbits. The presence of anti-amygdalin antibodies was observed through production of titer curves using KLH−amygdalin as the immobilized phase on microtitration plates. Antibody binding as measured by optical density was 2.1 at a dilution of 1:10000 (v/v) compared to that given by preimmune serum (0.03 at 1:10000). Even at dilutions of 1:100,000, the antisera showed significant binding above that of the preimmune serum. The antiamygdalin antiserum was used at a dilution of 1:30000 for subsequent experiments unless otherwise stated. For antihapten antisera, such a dilution is at the high end of what is achievable.

Optimization of the ELISA. The antibody dilution, incubation time, coating conjugate concentration, and use of protein buffers were each investigated for ELISA optimization (Table 1). Antibody dilution significantly influenced the sensitivity of the ELISA. A lower dilution (1:10000) of antibody resulted in higher IC_{50} (7 μg/well) than a 1:30000 dilution, which gave an IC_{50} of 0.80 μg mL^{-1}. When the antibody dilution was increased beyond 1:30000, the IC_{50} increased significantly. Consequently, an antibody dilution of 1:30000 in PBST was used throughout.

The incubation time for anti-amygdalin antibody and amygdalin on the microtitration plate was varied from 1 to 5 h (at 37 °C) and overnight at 4 °C. A higher IC_{50} (5.51 μg/mL) and lower R^2 (0.97) resulted from a 1 h incubation at 37 °C. As the incubation time increased, the IC_{50} decreased and R^2 values increased. Overnight incubation at 4 °C resulted in the lowest IC_{50} with $R^2 > 0.9$. Subsequent assays utilized an overnight incubation at 4 °C.

The concentration of the coating conjugate, KLH−amygdalin, strongly influenced ELISA performance. As the concentration of the coating conjugate was decreasing, the concentration of the free hapten (unconjugated amygdalin) was increasing. Consequently, an increase in the binding of the antibody to the unconjugated amygdalin was evidenced for coating conjugate concentrations of 0.01−0.05 μg mL^{-1}. The IC_{50} of the standard curve decreased with decreased coating conjugate concentration and the associated R^2 value increased. The assay was most sensitive with a coating conjugate concentration of 0.05 μg mL^{-1}. The assay sensitivity was good at this concentration (50 ng mL^{-1}), possibly because antibody bivalent binding was prevented at this lower concentration of conjugate.[31] A coating conjugate concentration of 0.05 μg mL^{-1} was used for subsequent assays.

Table 1. Effect of Antibody Dilution, Incubation Time, Coating Antigen Concentration, and Protein Buffers on ELISA Sensitivity

factor	IC_{50}[a] (μg/mL)	R^2 of linear equation
antibody dilution		
1:10000	7.00	0.96
1:20000	5.52	0.98
1:30000	0.80	0.99
1:40000	5.10	0.99
1:60000	8.91	0.99
incubation time (h)		
1	5.51	0.97
2	5.82	0.97
3	2.00	0.97
4	1.00	0.99
5	1.00	0.99
overnight	0.80	0.99
coating antigen concentration (μg/mL)		
0.01	0.08	0.90
0.05	0.39	0.99
0.1	0.75	0.98
1	0.80	0.99
protein buffers		
PBST	0.39	0.99
1% casein−PBST	0.81	0.98
1% gelatin−PBST	0.75	0.99
1% BSA−PBST	0.05	0.99

[a] IC_{50} = concentration of the analyte required for 50% inhibition of the antibody binding to the coating antigen.

The ELISA absorbance and sensitivity were greatly enhanced by using 1% (w/v) BSA−PBST as buffer. A significantly lower IC_{50} value was observed when 1% BSA−PBST was used as buffer compared to when PBST only or 1% casein−PBST or 1% gelatin−PBST was used as buffer. On the basis of the IC_{50} values, R^2 values and the ratios of the maximum and minimum absorbances for the amygdalin standard curves, 1% BSA−PBST was selected as the buffer for subsequent experiments.

Indirect Competitive ELISA. The optimized conditions were used to obtain an indirect competitive standard curve for amygdalin (Figure 2), represented by $Y = A_2 + (A_1 - A_2)/(1 + (x/x_0)_p)$, $R^2 = 0.9995$. The curve was fitted using OriginPro 8.6 software. The IC_{50} of the assay was estimated to be 50 ± 0.02 ng/mL with a detection limit of 200 ± 0.05 pg mL^{-1} (as determined by the concentration that corresponded to the optical density of zero binding reduced by 3 times the standard deviation of the mean zero binding). The working concentration range of the icELISA was 10 ng mL^{-1} (IC_{20}) and 1 μg mL^{-1} (IC_{80}). The detection limit of the ELISA reported here was significantly lower than previously reported limits using a polyclonal antibody (100 μg mL^{-1})[27] or a recombinant antibody (500 pg mL^{-1}).[28]

Cross-Reactivity. The specificity of the assay was investigated by testing the cross-reactivity of the antibody with other cyanogenic glycosides that are closely related to amygdalin. The results obtained (Table 2) showed that the antibody was very specific for amygdalin, with cross-reactions of 1.3% for prunasin, 0.1% for mandelonitrile, and <0.01% for linamarin and dhurrin. The differences in structure between amygdalin and prunasin occur at the point farthest from the

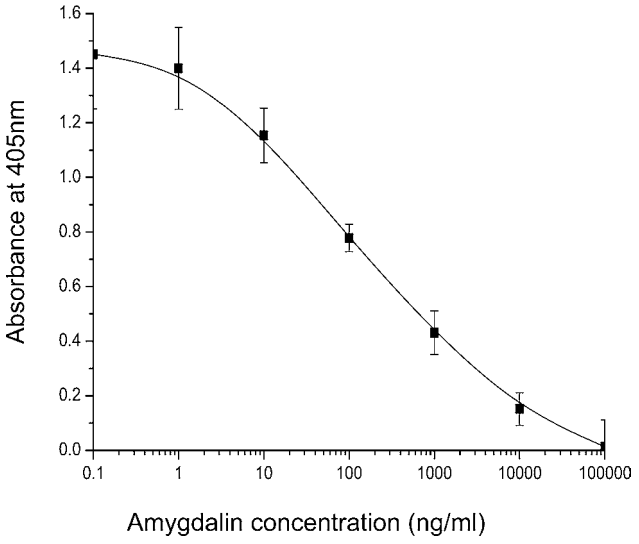

Figure 2. ELISA standard curve for amygdalin.

hydroxyl group used for coupling of hapten to protein. Even prunasin, a metabolite of amygdalin, did not inhibit antibody binding despite the close structural similarity to amygdalin. There was also a lack of reaction of the antibody with dhurrin (0.01%), where the additional hydroxyl group has a significant effect on antibody recognition. It can be assumed that the two sugar residues are key factors in antibody recognition. Other slight changes in other parts of amygdalin structure dramatically reduced antibody recognition for the other cyanogenic glycosides tested.

Quantification of Amygdalin in Commercially Available Food Products. Fruit kernels and processed products were analyzed by icELISA and HPLC after extraction of amygdalin. Figure 3 shows the correlation of the results with the two methods. The correlation is excellent ($r = 0.983$) across the whole range of amygdalin contents. The sample extraction procedure used for the ELISA is considerably simplified compared to that employed for HPLC. In addition, the batchwise nature of the ELISA further contributes to the high rate of sample throughput compared to HPLC.

Table 3 shows the values for amygdalin concentrations as determined by ELISA. Among the food samples analyzed in this study, fruit juices had the lowest amygdalin content (0.001−0.07 mg g^{-1}) followed by products (0.04−0.15 mg g^{-1}) and squashes (0.05−0.17 mg g^{-1}). However, high levels of amygdalin were detected in fruit seeds (0.04−4.52 mg g^{-1}) and kernels (2.14−9.75 mg g^{-1}). Lower levels of amygdalin observed in juices and processed products could be a result of the effect of processing on amygdalin. Processing methods have been reported to reduce the toxicity of cyanogenic glycosides (see the Introduction). Although low levels of cyanide would be generated from fruit juices, products, and squashes, the levels of cyanide that would be generated from fruit seeds (0.005−0.6 mg of equivalent HCN) and kernels

Table 2. Cross-Reactivity of the Anti-amygdalin Antiserum[a]

Compound	Chemical structure	IC_{50} (μg mL^{-1})	CR (%)
Amygdalin		0.05	100
Prunasin		3.75	1.3
Dhurrin		>500	<0.01
Mandelonitrile		50	0.1
Linamarin		>500	<0.01

[a]Each value is expressed as the mean ± standard deviation (n = 3 determinations).

(0.3−1.3 mg of equivalent HCN) are relatively high. The lethal dose of cyanide is 0.5−3.5 mg kg^{-1} body weight.[4] Cyanide toxicity could easily occur from the consumption of fruit seeds and kernels, unless appropriate processing techniques are used and monitored.

Application of the icELISA to Cyanogenic Plants. Extracts of apricot kernels (a natural cyanogenic plant) having a high amygdalin content showed linearity (R^2 = 0.998) of the icELISA assay (result not shown). This further illustrates the detection of amygdalin by the developed ELISA method.

The reliability of the icELISA method was assessed by repeated ELISA analysis of amygdalin standard and food extract, 10 times on the same day (intraday variations) and 10 times on different days (interday variations). The coefficients of variation of both interday and intraday analyses were <1.0. The mean recovery of amygdalin (10 μg) added in triplicate to each of the 30 food samples analyzed in this study was determined to be 99 ± 1.2% (results not shown). The developed icELISA is a sensitive, cost-effective, and simple method for the quantification of amygdalin in food, capable of high sample throughputs.

Further research will investigate the efficiencies of processing techniques used with cyanogenic plants.

Few studies on carotenoid content of bee pollen are published worldwide,[1,13,16,26,27] and, to the best of our knowledge, no studies related to carotenoid and also fatty acid composition of multifloral bee-collected pollen from Romanian (Transylvania) have been done, although pollen is often consumed as a food supplement. With respect to adopting the European Regulations regarding bee product labeling, the present work aims to offer new important information about the lipid classes present in pollen samples and also about total and individual carotenoid composition of multifloral pollen loads collected by bees in different regions from Transylvania (Romania). For the first time, a classification of pollen samples was achieved by subjecting the data obtained in chemical analysis to principal component analysis (PCA) with cross-validation (full model size and center data).

MATERIALS AND METHODS

Pollen Samples. Sixteen bee pollen samples (0.5 kg each) were collected between May and August 2010 from three different counties in the Transylvania region (Romania) (Supporting Information Table S1). The areas were characterized by rich spontaneous and also cultivated plants. Bee pollen was obtained with a bottom fitting pollen trap placed in the front of the hives, daily harvested, cleaned of impurities, and stored immediately at −18 °C until analysis.

Physicochemical analyses of pollen samples were made according to literature studies[1] and existing pollen regulations, and results were published previously.[24]

Palynological Origin. The bases of palynological analysis were the methods described by Almeida-Muradian et al.,[1] Morais et al.,[6] and Louvreaux et al.[28] adapted for pollen load.

A sample of 2 g, corresponding to approximately 200 pollen pellets, was considered to be representative for botanical origin determination. The pellets were grouped into subsamples according to their color, and each subsample was weighed to calculate the percentage from the main bee-collected pollen samples.[1,6] From each subsample, one microscopic slide was prepared without acetolysis, by dissolving and washing the pollen in diluted H_2SO_4 (5‰) and colored using a mixture of glycerin−gelatin−fuxine for permanent preparation.[28]

Slide examination was performed using a Nikon Eclipse 50i optic microscope at 1000× magnification (for identification) and 400× magnification for counting. Five hundred pollen grains were counted from every slide, and percentages of different botanical species were calculated. For the identification of pollen type, reference pollen collection slides from the Beekeeping Department, University of Agricultural Sciences and Veterinary Medicine from Cluj Napoca, were used, as well as different pollen guides.[29,30]

Chemicals and Reagents. All reagents (used for the lipid extraction and fatty acid methyl esters (FAMEs) preparation) were of chromatographic grade (Sigma-Aldrich, St. Louis, MO, USA). The FAMEs standard (37 component FAME Mix) were purchased from Supelco (Bellefonte, PA, USA).

Methanol, ethyl acetate, petroleum ether, diethyl ether, sodium chloride, triethylamine, and anhydrous sodium sulfate were purchased from Sigma Chemical Co. The purity of carotenoid standards (98% for β-cryptoxanthin, 96% for β-carotene, and 97.5% for lutein) was estimated by UV−vis spectra and by an individual HPLC analysis. Solvents used for carotenoid analysis (ethyl acetate, and acetonitrile) were purchased from Merck.

Analytical Methods. *Carotenoids Identification. (a) Carotenoids Extraction.* Total carotenoids were extracted from 5 g of fresh bee pollen with a mixture of methanol/ethyl acetate/petroleum ether (1:1:1, v/v/v) containing BHT as antioxidant, following the procedure described by Breithaupt and Schwack.[31] Extraction was carried out under agitation and diminished light and was repeated until the bee pollen became colorless. The combined extracts were washed in a separation funnel with sodium chloride and diethyl ether, and the upper collected phase was evaporated to drynes.

(b) Saponification. Every sample of obtained oleoresin was dissolved in 20 mL of diethyl ether and divided for further analysis. Ten milliliters of extract was saponified with 30% methanolic KOH, at room temperature, in the dark, for 24 h. For the removal of soaps and alkalis, the solution was washed three to four times with a sodium chloride saturated solution and distilled water. The organic layer containing carotenoids was dried over anhydrous sodium sulfate and evaporated to dryness.[32] Samples were kept under nitrogen at −20 °C until further utilization.

Total carotenoids content was estimated spectrophotometrically from saponified samples, at 450 nm, using a Shimadzu UV-2102 PC scanning spectrophotometer.

HPLC Analysis. HPLC-DAD of all samples was performed on a system with a Waters 990 PDA detector, Kontron pumps and controller, and a reversed phase C 18 column Zorbax ODS (250 × 4.6 mm), 5 μm. The mobile phase consisted of mixtures of acetonitrile/water (9:1, v/v) with 0.25% triethylamine (solvent A) and ethyl acetate with 0.25% triethylamine (solvent B). The gradient started from 20% B to 50% B at 3 min. The percent of B increased to 75% at 12 min and continued isocratically up to 25 min. The flow rate was 1 mL/min. The chromatograms were monitored at 450 nm.

The carotenoids identification was made by comparing the retention times of sample compounds with available standards and according to UV−vis spectra recorded by PDA detector.

Calibration curves for lutein, β-cryptoxanthin, and β-carotene were used for quantitative analysis. The results were expressed as micrograms per gram of pollen (fresh and dry weight).

Fatty Acid Analysis. (a) Lipids Extraction. The total lipids (TLs) of the honeybee-collected pollen samples were extracted using a chloroform/methanol mixture.[33,34] The sample (5 g pollen) was homogenized in methanol (20 mL) for 1 min with a high-power homogenizer (MICCRA D-9, Germany), then chloroform (40 mL) was added, and homogenization was continued for 2 min. The mixture was filtered, and the solid residue was resuspended in chloroform/methanol mixture (2:1, v/v, 60 mL) and homogenized again for 3 min. The mixture was again filtered, and the residue was washed with 60 mL chloroform/methanol (2:1, v/v). The filtrates and washings were combined and cleaned with an 0.88% potassium chloride water solution and a methanol/water solution (1:1, v/v). The purified lipid layer (bottom) was filtered and dried over anhydrous sodium sulfate, and the solvent was removed in a rotary evaporator. The recovered total lipid fractions were transferred to vials with 4 mL of chloroform, forming the stock solution, and stored at −18 °C for further analysis.

(b) GC Analysis of FAMEs. The fatty acid methyl esters (FAMEs) were prepared from TLs using the acid-catalyzed transesterification procedure described by Christie.[35] The FAMEs were determined by gas chromatography−mass spectrometry (GC-MS).[34] A PerkinElmer Clarus 600 T GC-MS (PerkinElmer, Inc., Shelton, CT, USA) equipped with a Supelcowax 10 (60 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco Inc., Bellefonte, PA, USA) capillary column was used. The injector temperature was set at 210 °C. The temperature program for the column was as follows: initial temperature, 140 °C; increase by 7 °C/min to 220 °C; and hold for 23 min. The flow rate of the carrier gas (helium) was 0.8 mL/min, and the split value was a ratio of 1:24. The injected volume was 0.5 μL. The positive ion electron impact (EI) mass spectra was recorded at an ionization energy of 70 eV and a trap current of 100 μA with a source temperature of 150 °C. The mass scans were performed within the range of m/z 22−395 at a rate of 0.14 scan/s with an intermediate time of 0.02 s between the scans. Identification of FAMEs was achieved by comparing their retention times with those of known standards (37 component FAME Mix, Supelco no. 47885-U) and the resulting mass spectra to those in our database (NIST MS Search 2.0). The amount of fatty acids was expressed as percent of total fatty acids.

Statistical Analysis. Three different replicates of each honeybee-collected pollen were assayed. The analytical results reported for the fatty acid compositions are the average of triplicate measurements of three independent total lipid fractions ($n = 3 \times 3$). Results reported for carotenoid determination represent the mean of three independent analyses. Statistical differences among samples were estimated using ANOVA (one-way analysis of variance; Tukey's multiple-comparison test; GraphPad Prism version 4.0, Graph Pad Software Inc., San Diego, CA, USA). A probability value of $p < 0.05$ was considered to be statistically significant.

Table 1. Plant Species Giving the Predominant, Secondary, and Minor Pollen in the Analyzed Samples

	predominant pollen (>45%)		secondary pollen (16−45%)		important minor pollen (3−15%)		minor pollen (<3%)

[a]Different letters in each column denote statistical difference at $p < 0.05$. The values represent the mean of three replicates, separately analyzed. nd, not detected; tr, traces.

The classification of pollen samples was achieved by subjecting the data obtained for palynological analysis, fatty acids, total lipids content, lutein, β-cryptoxanthin, β-carotene, and total carotenoids to PCA with cross-validation (full model size and center data). All of the statistical analyses were performed using Unscrambler X software version 10.1 (CAMO Software AS, Oslo, Norway).

RESULTS AND DISCUSSION

Palynological Identification. Table 1 presents the identified plant families and species giving the predominant, secondary, and minor pollen in the analyzed samples.

According to palynological analysis, all pollen samples were found to be heterofloral, having different pollen types and percentages as constituents. Six plant families were found in the 16 pollen samples as predominant pollen constituents (>45% from the total content): Rosaceae (*Crataegus monogyna*, *Filipendula ulmaria*, *Malus domestica*, *Prunus* sp.,*Rosa canina*); Fabaceae (*Trifolium repens*, *Anthilis* sp., *Robinia pseudoacacia*); Asteraceae (*Calendula officinalis*, *Taraxacum officinale*); Brassicaceae (*Brassica* sp.); Ericaceae (*Calluna vulgaris*); and Salicaceae (*Salix* sp.); another 10 botanical species were found to be secondary pollens for bee pollen samples (Table 1).

The Rosaceae family was dominant (>45%) in sevem pollen samples and was present as secondary pollen (16−45%) in another three samples, whereas the Fabaceae family was the

dx.doi.org/10.1021/jf5020318 | J. Agric. Food Chem. 2014, 62, 6306−6316

predominant pollen for three samples and the secondary pollen for another three samples. The Asteraceae family with *Taraxacum officinale*, *Calendula officinalis* and *Carduus* sp. was present in three different samples.

Pollen botanical origin from the pollen pellets may vary according to the region of collection, vegetation available for bees at the collecting moment, and climatic conditions.[36]

Carotenoid Determination. The total carotenoid content in saponified honeybee-collected pollen samples was determined using UV−vis spectrophotometry.

Quantitative analysis showed a wide range of concentrations for total carotenoid content: 49.90−425.32 μg/g in freshly collected bee pollen and 63.94−527.27 μg/g when reported to each sample's dry weight (Table 2). The highest carotenoid concentration was found in sample P8, having *Taraxacum officinale* as predominant pollen, and the lowest in sample P6, *Prunus spinosa* predominant pollen. In *Filipendula ulmaria* bee pollen (samples P2, P3, and P9) total carotenoid content was quantified as 295.40, 59.30, and 207.31 μg/g fresh weight, respectively. The results obtained for samples P2 and P9 are significantly different and also significantly different from P3 (lower catorenoid content), this fact being attributed to the secondary pollen found in this sample. In P2 and P9 *Hypericum* sp. is the secondary pollen (high content of total carotenoids quantified) and *Calluna* sp. the secondary pollen in P3, where low amounts of carotenoids were found.

Taraxacum officinale is reported to be the richest natural vegetable source of β-carotene,[37] above carrots, broccoli, and spinach.[38] *Filipendula ulmaria* is also a rich source of β-carotene (36.32 μg/g plant).[39] These data are additional proof of the results obtained in our study. No statistical differences on total carotenoid content were found between samples P1, P3, P11, and P13, reported as either fresh or dry weight.

HPLC-PDA analysis of carotenoids from bee pollen allows the separation, identification, and quantification of individual carotenoids present in the samples. Obtained results are presented in Table 2.

Lutein and β-cryptoxanthin were identified in all analyzed samples.

Lutein was the major carotenoid found in pollen samples. The concentration varied between 44.52 and 392.52 μg/g fresh weight (57.04 and 476.30 μg/g dry weight). The highest concentration was found in sample P8 (392.52 μg/g), followed by sample P10 (317.11 μg/g). The lowest lutein concentration was found in sample P6 (44.52 μg/g). Lutein concentration showed no significant statistical difference for samples P1, P3, P6, P11, P13, and P15.

The concentration of β-cryptoxanthin ranged between 1.02 and 24.96 μg/g fresh weight; the highest concentration (found in sample P12) is significantly different from that of sample P10, in which the concentration was 21.04 μg/g. The lowest concentration of β-cryptoxanthin was found in samples P1 and P13 with no statistical differences between the mentioned samples (1.04 and 1.02 μg/g fresh weight).

With regard to β-carotene content, in some of the samples only traces were detected, whereas the highest contents were found in samples P2 and P10 (13.20 and 12.56 μg/g fresh weight and 18.18 and 17.18 μg/g dry weight). No statistical differences between these two pollen samples was observed.

Most of the papers published on carotenoid determination from bee pollen (either total carotenoids or individual) report their results as micrograms per gram of fresh or dehydrated sample. To have a better comparison with literature data, our

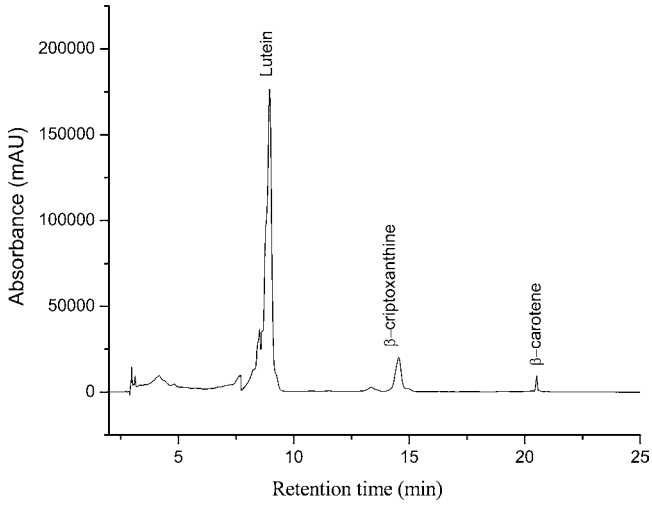

Figure 1. Chromatogram of identified carotenoids from saponified extract of bee pollen P2.

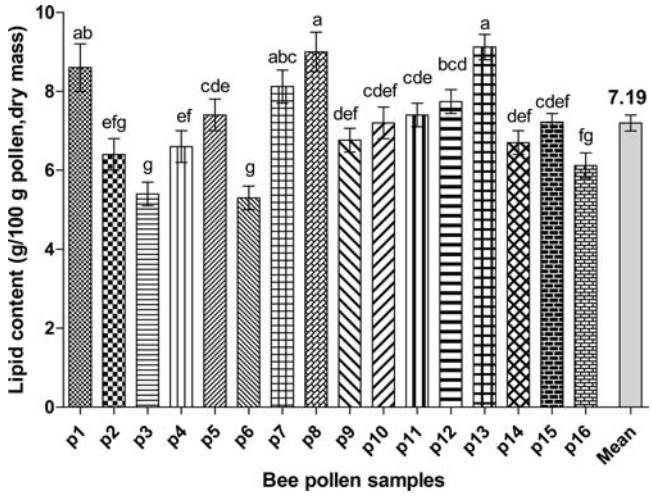

Figure 2. Total lipid content of honeybee-collected pollen samples from Romania (Transylvania). Results are given as the mean ± SD (n = 3). Values with different letters (a−g) are significantly different ($p < 0.05$), using ANOVA Tukey's multiple-comparison test. P1−P16, samples of multifloral pollen.

results regarding carotenoids are also reported on fresh and dry weight bases.

Almeida-Muradian et al.,[1] analyzing 10 Brazilian bee pollen samples, found a wide range of total carotenoid content: from "traces" (in 2 of the samples) to 451.50 μg/g fresh weight (489.20 μg/g dry weight). Although pollen samples were designated by the producers as monofloral pellets, botanical origin analysis showed the presence of 17 plant taxa in the 10 samples. The authors concluded that botanical origin is directly connected with carotenoid content; the highest value was obtained in pellets with high contents of *Senecio* and *Vernonia* pollen grains. The lack of β-carotene in all samples was attributed to the drying process of the samples.

Pereira de Melo and Almeida-Muradian,[27] analyzing fresh and dehydrated pollen samples from Brazil, found total carotenoid contents in fresh bee pollen ranging from 27.08 to 344.6 μg/g. β-Carotene content, quantified by HPLC by the same authors, varied from 3.77 to 99.27 μg/g fresh bee pollen samples. With regard to total carotenoid content, the results obtained from Romanian samples are in agreement with amounts determined

dx.doi.org/10.1021/jf5020318 | J. Agric. Food Chem. 2014, 62, 6306−6316

from Brazilian fresh samples, but β-carotene content was significantly lower in Romanian samples (from traces to 13.2 μg/g fresh bee pollen). This can be attributed to different flora and climatic conditions between the samples.

Muniategui et al.[26] found 50−150 μg/g of carotene and 140−400 μg/g xanthophylls in four samples of fresh pollen. The same authors reported that total carotene content varied widely between samples. The small number of pollen samples analyzed in this case is not very conclusive, due to the fact that multifloral bee pollen is very different in composition because of the botanical origin of floral pollen. Also in this study, the high variability of total and individual carotenoids found could be attributed to climatic differences and the floral contribution to the pollen.

The HPLC-PDA chromatogram for one pollen sample (P2) is presented in Figure 1.

Besides carotenoids, other classes of biologically active compounds make important contributions to the nutritional and therapeutic properties of bee pollen. From previous research,[3,25] it is obvious that bee pollen can compete with other important sources of polyphenols,[32,39−43] having also high amounts of polyphenols and different classes of flavonoids.

Lipid Contents. The TLs contents in 16 honeybee-collected pollen samples are presented in Figure 2. Generally, the yields varied significantly ($p < 0.05$) within the analyzed pollen samples, with the highest levels of fats in P13 (9.12 g/100 g bee-collected pollen) and the lowest in P6 (5.30 g/100 g bee-collected pollen). Correlation with botanical origin is again confirmed, the highest amount of lipids being found in the sample having *Brassica* sp. as predominant pollen. Bee pollen samples having high amounts of total lipids (P7, P1, and P8) have in their botanical compositions different amounts of *Brassica* sp. pollen. It is known that *Brassica* sp. are rich sources of oleic, linoleic, and linolenic acids.[44] Pollens with high lipid concentrations are considered attractive to bees.[45] Previous studies have shown that the cytoplasm of pollen can contain twice as much lipids as found on the outermost layer of the pollen wall (pollenkitt).[2,18,22] The values obtained in this work were similar to those observed in the samples of honeybee-collected pollen originating from Poland (ranged from 6.74 to 10.99% dry matter), but higher, on average, than those determined for Korean (5.5% dw) and Chinese (6.2% dw) samples.[21] Differences in the lipid content of bee pollen may be attributed to the geographical and climate conditions, apicultural practices, and, last but not least, the genetic composition of plant species.[21]

Fatty Acid Composition. The fatty acid compositions, total n-3, n-6, n-9 polyunsaturated fatty acids (PUFAs) and the n-6/n-3 ratios of TLs from the Romanian honeybee-collected pollen are presented in Table 3. There were no qualitative differences in the fatty acid profiles of the TLs in all samples, except for the caproic acid (6:0) and caprylic acid (8:0), which are absent in the TLs of P1 and P15, respectively. Fourteen fatty acids were identified in the pollen extracts (Figure 3), from which the most abundant was α-linolenic (18:3n-3) acid, ranging between 20.28% (P1) and 49.37% (P11). The next most abundant fatty acids were linoleic acid (18:2n-6) (from 7.62%, P11, to 33.21% P1), followed by palmitic (16:0) (from 18.39%, P8, to 30.93%, P11) and oleic acids (18:1n-9) (from 3.86%, P5, to 15.34%, P6). Small and very small amounts (<3%) of stearic (18:0), myristic (14:0), lauric (12:0), arachidic (20:0), 11-eicosenoic (20:1n-9), behenic (22:0), elaidic [18:1(9 *t*)n-9), caproic (6:0), caprylic (8:0), and capric (10:0) acids were also determined. The ratios of n-6 to n-3 PUFAs ranged from 0.15 (P11) to 1.64 (P1) (Table 3). The average value of these ratios (0.76) is close to the values

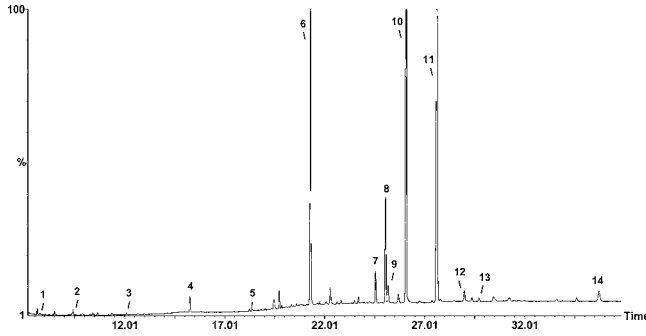

Figure 3. GC-MS chromatogram of FAMEs in the TLs of the honeybee-collected multifloral pollen (P16) from Romania (Transylvania) analyzed with a Supelcowax 10 capillary column. Peak identification: (1) caproic (6:0); (2) caprylic (8:0); (3) capric (10:0); (4) lauric (12:0); (5) myristic (14:0); (6) palmitic (16:0); (7) stearic (18:0); (8) oleic (18:1n-9); (9) elaidic [18:1(9*t*)n-9]; (10) linoleic (18:2n-6); (11) α- linolenic (18:3 n-3); (12) arachidic (20:0); (13) 11-eicosenoic (20:1(n-9); (14) behenic (22:0) acids.

recommended by Simopoulos[46] (n-6/n-3 = 1−5/1) as beneficial for good health.

Several studies suggest that lowering the dietary n-6/n-3 fatty acid ratio may reduce the risk of coronary heart disease and cancer.[47,48]

It is generally known that the dominant fatty acids present in pollens are palmitic, oleic, linoleic, and α-linolenic acids.[21] Significant differences were reported by different authors for compositions of myristic and arachidic acids.[21,44] It is interesting to note that the study of Bastos et al.,[49] carried out on 14 pollen samples from Brazil, demonstrated that one of the predominating fatty acids appeared to be arachidic acid (ranging from 8.90 to 42.7%). In contrast, the content of this long-chain saturated fatty acid estimated in our study and those of other researchers did not exceed even 1.50%.[21]

Manning[22] mentioned that pollen lipids, dominated by long-chain unsaturated (linoleic and linolenic) and saturated (myristic and lauric) fatty acids, have bactericidal and antifungal properties, playing an important role in inhibiting the growth of the spore-forming bacteria *Paenibacillus* (American foulbrood), *Melissococcus pluton* (European larvae larvae foulbrood) and other microorganisms that inhabit the brood combs of beehives. For larvae and young adult bees the fatty acids and other lipid classes are important sources of energy. The honeybees use the lipids for the synthesis of fat reserve and glycogen and for the production of royal jelly.[2]

The statistical analysis of fatty acid classes showed significant differences ($p < 0.05$) between pollen samples (Figure 4). The highest values of saturated fatty acids (SFAs) ($p < 0.05$) were registered in the TLs of P12 and P14 (~39%) (Figure 4A), whereas P6 (16.15%), P1 (15.59%), and P15 (14.90%) were the richest sources of monounsaturated fatty acids (MUFAs) (Figure 4B). On the other hand, small variations ($p < 0.05$) were found in PUFAs contents (Figure 4C), with the highest proportions in P16 (61.43%) and the lowest in P7 (48.65%). Different ratios of saturated and unsaturated fatty acids as quality index for pollen loads were determined. As shown in Figure 4D, the levels of the PUFAs/SFAs ratios were significantly higher ($p < 0.05$) in TLs of P16 (due to the high values of 18:3 (32.33%) and 18:2 (29.10%) fatty acids) than in the TLs of the other 15 pollen samples. The UFAs (unsaturated fatty acids)/SFAs ratio, considered as a quality index of bee pollen, determined in the present study was similar to the values reported by Serra Bonvehi

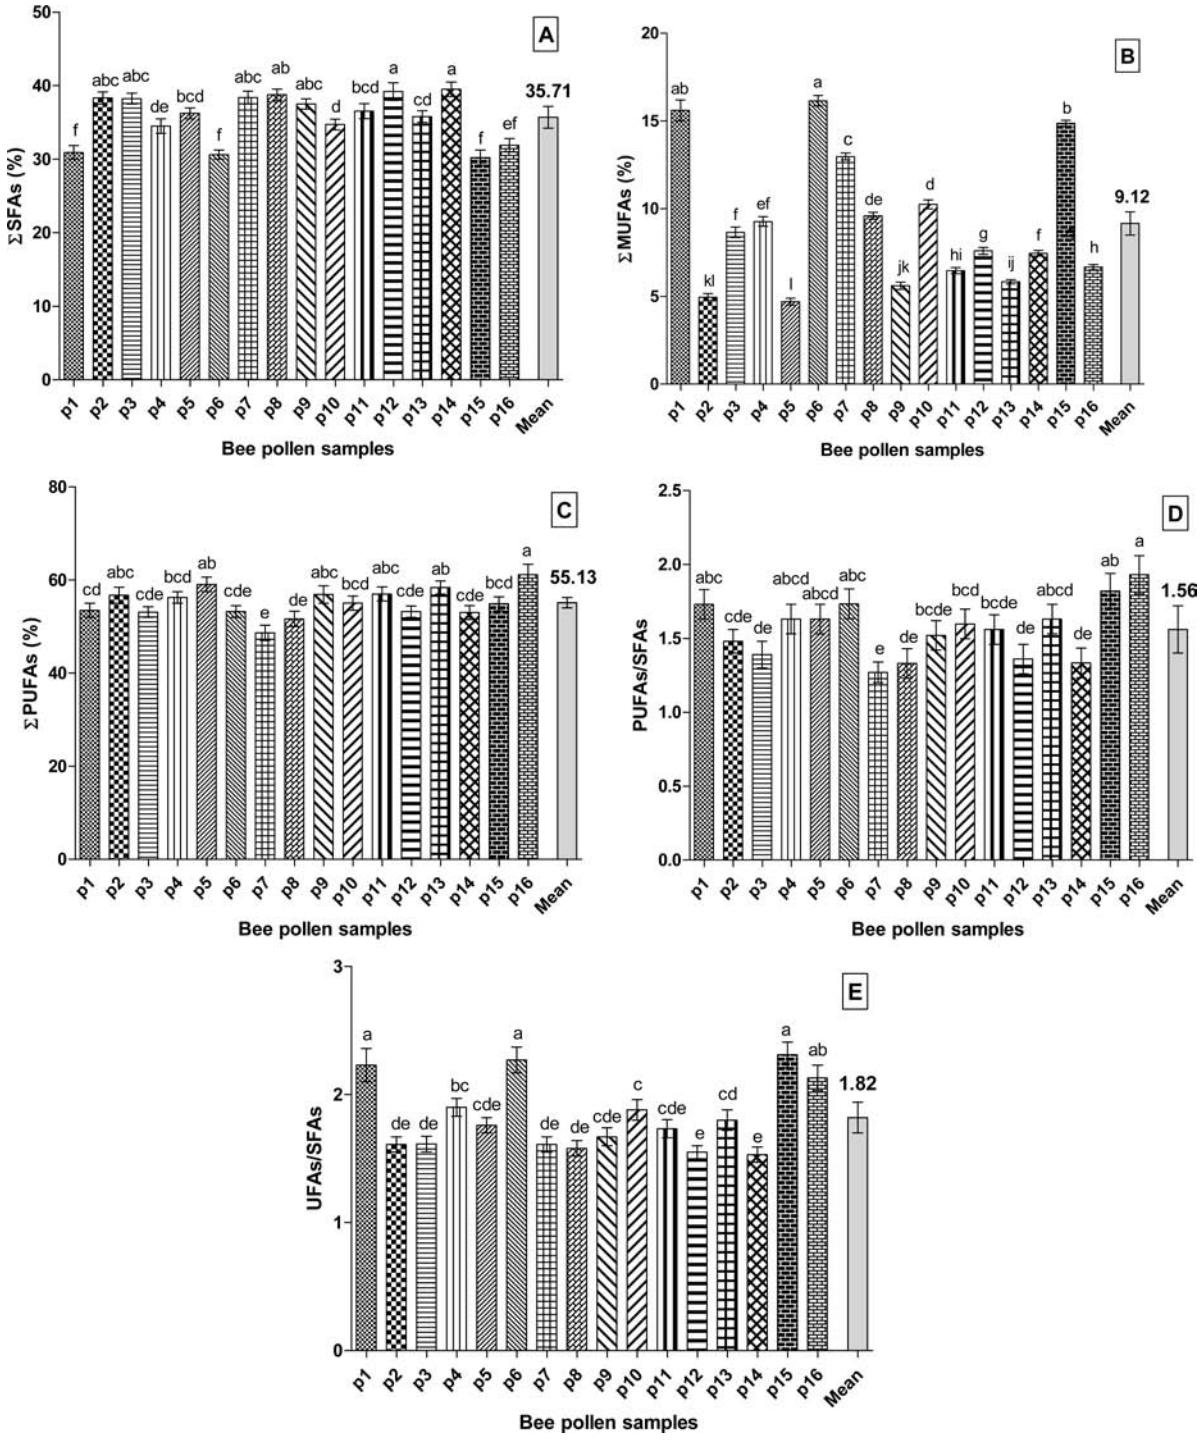

Figure 4. Comparative representation of fatty acid classes from total lipids of honeybee-collected pollen samples from Romania: (A) SFAs, saturated fatty acids; (B) MUFAs, monounsaturated fatty acids; (C) PUFAs, polyunsaturated fatty acids; ratio of polyunsaturated fatty acids to saturated fatty acids (D) and unsaturated fatty acids to saturated fatty acids (E) from multifloral bee collected pollen. Values are the mean ± SD of three samples, analyzed individually in triplicate ($n = 3 \times 3$). Values with different letters (a–l) are significantly different ($p < 0.05$), using ANOVA Tukey's multipl-comparison tes". P1–P16, samples of multifloral pollen

and Escora Jorda[50] and Szczęsna[21] and accounted for about 1.82 on average (Figure 4E).

According to PCA, the botanical origin of pollen samples was correlated with the amount of total lipids and fatty acid profile.

High levels of total carotenoids were found in some of the samples, demonstrating the direct link of botanical species rich in carotenoids (*Taraxacum*, *Calendula*, and *Filipendula* sp.) and bee pollen, these pollen types being important providers of provitamin A.

The major carotenoids found in the samples were lutein, β-cryptoxanthin, and β-carotene. Lutein was present in all samples as the major carotenoid. In contrast, β-carotene was identified and quantified only in some of the analyzed samples, and there detected just in traces or very small amounts.

dx.doi.org/10.1021/jf5020318 | J. Agric. Food Chem. 2014, 62, 6306–6316

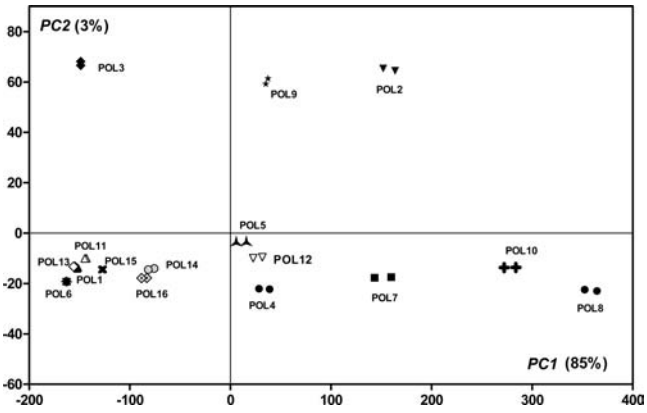

Figure 5. Principal component analysis biplot for the analyzed pollen samples. Two dimensions together explained 88% of the data variance.

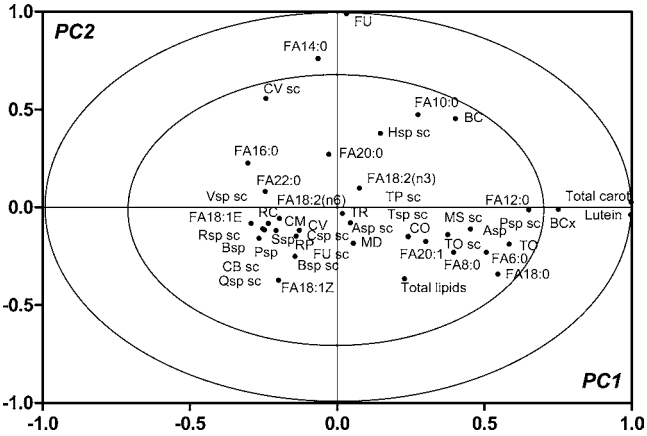

Figure 6. Correlation loading biplot for the analyzed pollen samples.

Lipid and carotenoid amounts in bee-collected pollen presented great variability between samples, which can be explained by the various botanical origins of those samples. In general, the investigated samples were characterized by high levels of α-linolenic (32.96% on average), palmitic (25.80, on average), and linoleic (22.17% on average) acids. Well-known is the beneficial effect of n-3 fatty acids in the prevention and management of cardiovascular disease, hyperinsulinemia, and possibly type 2 diabetes.[46] Bee-collected pollen with high levels of α-linolenic (n-3) acid together with a near 1:1 ratio of n-6 to n-3 PUFAs represents also a very balanced source of essential PUFAs for human health.

The PCA is a chemometric method that can be used to establish interrelationships between different sample variables, leading to the detection of similarities or differences between the patterns of the analyzed samples. On the basis of the PCA of the palynological analysis data, the pollen samples studied were not clearly discriminated, the first two principal components explaining only 31% of the variance of data. Instead, introducing also the fatty acid profile, total lipids content, lutein, β-cryptoxanthin, β-carotene, and total carotenoids contents as variables in PCA, a good discrimination of the pollen samples was achieved (the first two principal components explaining 89% of the variance of data). As shown in Figure 5, all analyzed pollen samples can be clearly differentiated on the basis of the above-mentioned parameters. Samples 2, 3, and 7−10 had a very distinctive pattern, whereas samples 1, 6, 11, 13, and 15 showed pattern similarities, as well as samples 5 and 12, respectively, and samples 14 and 16. The importance of individual variables can be assessed by computing the correlation loadings plot (Figure 6). The compounds from the inner ellipse indicate 50% of the explained variance, whereas those found in the outer ellipse indicate 100% of explained variance. Variables with loading values near zero have similar concentrations in all samples. Thus, it can be noted that total carotenoid content, lutein content, β-cryptoxanthin content, myristic acid (14:0) concentration, and *Filipendula ulmaria* predominant pollen significantly contribute to sample discrimination. According to the correlation loading plot, pollen samples 2, 3, and 9 are characterized by a high content in *Filipendula ulmaria* pollen and also in myristic acid compared to the other samples, whereas samples 7, 8, and 10 are richer in lutein, β-cryptoxanthin, and total carotenoids. With regard to carotenoid compounds, it has to be mentioned that a correlation loading plot showed that there is a strong positive correlation between total carotenoids and lutein.

Furthermore, recent studies have demonstrated a genotype effect on retention[9] and bioefficacy,[10] underscoring the importance to conduct studies in the varieties ready for release.

Therefore, the purpose of this study was to evaluate the retention of provitamin A carotenoids in biofortified maize hybrids from the National Performance Trials (NPTs) in Zambia taking into consideration the local conditions of processing, cooking and storage.

MATERIALS AND METHODS

Biofortified Provitamin A Maize. Four medium maturing three-way hybrids with levels ranging from 6 to 8 μg/g DW of provitamin A were evaluated for their provitamin A retention after storage, milling, and cooking: two, GV662A (HP1002) and GV665A (HP1005), were hybrids released in Zambia in 2012, and two, HP1001 and HP1003, were advanced genotypes.

Harvesting and Storage of Maize. The four biofortified maize genotypes were planted in November 2010 at the Golden Valley Agriculture Research Trust (GART) in Chisamba, Zambia. In April 2011, the maize was harvested at the "green" stage (60% moisture content), which were immediately boiled and roasted; two months later, the "dry maize" (12% moisture content) was harvested. On the day of harvest, ears of all four genotypes were labeled and transported to ZARI in Lusaka where half of them were shelled (kernels) and the other half kept unshelled (ears) for six months in a traditional storage bin at ambient temperature. The temperature and humidity inside the storage bin were recorded on a weekly basis during the duration of the study.

Maize samples were collected at several intervals from the storage bin, and raw, processed, and cooked samples were kept in a liquid nitrogen tank until the samples were shipped for analysis. The baseline value (i.e., control) of provitamin A for all four genotypes was obtained from maize samples that were tested within 24 h of harvest. Subsequently, maize samples, stored as kernels and ears, were analyzed every two weeks (HP1002 and HP1005) and three and six months after storage (HP1001 and HP1003).

Retention of Provitamin A. All processing and cooking of maize samples were performed at the National Institute of Scientific and Industrial Research (NISIR) in Lusaka. Samples were stored in liquid nitrogen until shipped to the laboratory at the University of Wisconsin—Madison for analysis.

Processing of Green Maize. Green maize is commonly eaten either roasted or boiled. Before roasting or boiling, three rows of kernels of the raw green ear were removed and mixed to form the pool of maize kernels for the baseline values of the "raw roasted" or "raw boiled". The maize kernels were mixed and divided into four quarters from which two opposite quarters were combined, discarding the other two quarters. This procedure was repeated, and 10 to 15 kernels were selected and packed in 5 mL vials with screw caps and stored in the freezer at −30 °C.

After removing the kernels to obtain the "raw samples", three ears from each genotype were placed on a brazier without the husk and roasted for 15−20 min until all sides had turned brown. After roasting, three rows of kernels were removed from each ear and mixed to obtain a sample of roasted maize.

After removing three rows of kernels to obtain the "raw samples", three ears for each variety containing a thin layer of husk were put in an aluminum pot with 1200 mL of tap water. The pots were covered with lids and the ears were boiled for 35 min at 95 °C. After boiling, three rows of kernels were removed from each ear and mixed to obtain a sample of boiled maize.

Processing of Dry Maize. Most of the maize consumed in Zambia is in the form of "dry maize", which is usually milled and cooked into mainly three products for consumption: porridge, *nshima* (thick porridge), and *samp*. Dry maize can be stored for long periods of time. In order to study the retention of provitamin A during milling and cooking, 25 maize ears of each genotype were shelled, producing about 2.6−3.1 kg of kernels. Approximately 250 g of kernel was sampled per genotype to form the baseline pool.

Milling Methods. From the remaining maize kernels, about 2/3 was milled into *samp* and 1/3 was milled into maize meal using a local hammer mill. Approximately 250 g from each of the milled products was collected and formed the *raw samp* and *raw whole maize meal* samples. The effect of milling on retention was evaluated at baseline and three and six months.

Raw Maize *Samp*. First, 1700 g of whole dry kernels with 12% moisture (as-is-basis) was conditioned by steeping in cold water for 3−5 min to loosen the bran for decortication by a PRL dehuller (380 V, 50 Hz, 250−500 g/h, Canada) using abrasive carborundum disks, revolving at high speed in a barrel, and then bran was removed by aspiration. The dehulled kernels were collected as maize *samp* and bran as byproduct.

Whole Maize Meal (Mealie Meal). Whole maize kernels (400−900 g, 12% moisture) was put on a hopper through the hammer mills (Model-Commercial, 50T/24 Hr 380 V, 50 Hz, China) fitted with sieve no. 2 (8 mm opening) to produce fine whole maize meal for use in cooking porridge and/or *nshima*.

Cooking Methods. Three local women prepared the traditional Zambian maize dishes: porridge, *nshima*, and *samp* at NISIR in Lusaka. Their cooking methods were very similar; the recipes were standardized and each woman prepared only one dish in duplicate. Cooked products were prepared at baseline (time zero) and after the maize had been stored for three and six months. The cooking methods were standardized as follows:

Porridge. First, 100 g of maize meal was added to 700 mL of water at 50 °C in an aluminum pot. Then the mixture was continuously stirred with a wooden spoon until it started boiling and formed a gel at 95 °C. The pot was then covered with a lid, and the boiling continued for about 15 min. Total cooking time was 20 min.

Nshima. First, 150 g of maize meal was weighed and about 85 to 90 g was added to 600 mL of water at 50 °C in an aluminum pot. Then the mixture was continuously stirred with a wooden spoon until it started boiling and formed a gel at 95 °C and boiling was continued for 10 to 15 min. The remaining maize meal (60−65 g) was added to the pot with continuous stirring until a thick gel (*nshima*) was formed. The pot, covered with a lid, was allowed to simmer for about 5 min (total cooking time was 25 min).

Cooked Samp. First, 250 g of *samp* was weighed, washed with tap water, and transferred to an aluminum pot with 2000 mL of tap water (enough to cover the *samp*). Then the *samp* was boiled at 97 °C with occasional stirring and replenishing with tap water as needed. The total cooking time was 180 min.

Determination of Moisture. The moisture content of stored and processed samples was determined at baseline and three and six months by using a standard method (AOAC, 1984).

Extraction and Analysis of Carotenoids. The carotenoid extraction method from maize flour and maize porridge was based on a previously published procedure[11] with minor modifications. Whole maize samples were ground using a Knifetec 1095 sample mill (FOSS, Eden Prairie, MN, US). For all samples, 500 μL of 80% potassium hydroxide (w/v) was used for saponification. Saponification was performed to reduce the amount of lipid in the extract, which interferes with clean chromatography of carotenoids. Porridge samples were physically broken up after weighing but prior to the addition of ethanol and saponified for 45 min at room temperature. β-Apo-8′-carotenal (Sigma-Aldrich, St. Louis, MO, US) was used as an internal standard. Samples were reconstituted in 500 μL of 50:50 methanol:dichloroethane (v/v) and 50 μL injected into the HPLC system for quantification. The HPLC system was composed of a 1525 binary pump, a 717 autosampler, and a 2996 PDA detector (Waters, Milford, MA, US). Two mobile phases were used in a 40 min gradient system run through a C30 carotenoid column (3 μm, 4.6 mm × 250 mm) (YMC America, Allentown, PA). Solvent A, methanol:water (92:8, v/v) with 10 mmol/L ammonium acetate, and solvent B, 100% methyl-tertiary-butyl ether, were used. The gradient was run at 1 mL/min starting with 70% solvent A and transitioning to 40% within 30 min. The flow returned to 70% solvent A over 2 min, and then the column was equilibrated for 8 min prior to the next injection. Chromatograms were generated at 450 nm for quantification. β-

Carotene (Sigma-Aldrich, St. Louis, MO), α-carotene (isolated from freeze-dried carrots), β-cryptoxanthin (CaroteNature, GmbH, Lupsingen, Switzerland), lutein (GNC, Inc., Pittsburgh, PA), and zeaxanthin (GNC, Inc., Pittsburgh, PA) were identified using HPLC-purified standards. The β-carotene equivalents (BCE) were computed as follows: all-*trans*-β-carotene + 1/2 α-carotene + 1/2 β-cryptoxanthin + 1/2 13-*cis*-β-carotene + 1/2 9-*cis*-β-carotene.

Statistical Analysis. All data were analyzed using STATA version 13.0 (StataCorp, 2013). Descriptive statistics including mean and SD from duplicate analyses were calculated for the retention of carotenoids from processed maize. Means were compared using Student *t* tests and one-way ANOVA. Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

Carotenoid Profile of Biofortified Maize. *Green versus Dry Maize.* The total carotenoid content, on DW basis, ranged from 19.0 to 36.4 μg/g in the green maize and from 24.4 to 30.8 μg/g in the dry maize among all four genotypes (Table 1); the values in fresh weight are provided in Table 1A of the Supporting Information. As expected, the green maize had a higher (3−33%) total carotenoid content than the dry maize, except for genotype HP1003, which presented a 26% increase in the total carotenoid content in the dry maize. This was mainly due to the average decrease in the zeaxanthin and lutein levels from 14.8 to 9.2 μg/g DW and 5.0 to 3.87 μg/g DW, respectively. On the other hand, β-cryptoxanthin increased from 1.7 to 6.3 μg/g DW between the green and dry maturity stages among all four genotypes. Therefore, the BCE was higher in the dry maize compared to the green maize for most genotypes. The green maize is available during a short season and is consumed roasted or boiled, while the dry maize is consumed throughout the year on a daily basis. Unless specified, the results presented in the following sections refer to the dry maize.

Dry Maize. Several carotenoids are present in maize (Table 1). The non-provitamin A carotenoids, lutein and zeaxanthin, are the major carotenoids in all four biofortified genotypes. Among the different genotypes, zeaxanthin and lutein accounted for 35% (28−46%) and 15% (11−20%) of total carotenoids, respectively. Although these carotenoids do not have vitamin A activity, they have an important role in maintaining good eye health and are associated with a reduced risk for age-related macular degeneration (AMD), the leading cause of blindness among elderly people.[12−15]

β-Cryptoxanthin and all-*trans*-β-carotene, were the main provitamin A carotenoids in the dry maize, accounting for 24% (19−28%) and 16% (10−23%) of total carotenoids, respectively. Collectively, the two provitamin A carotenoids accounted for 40% (33−49%) of total carotenoids. The amounts of α-carotene were negligible, accounting for only 1.5% (0.1−2.9%) of total carotenoids, while the *cis*-isomers of β-carotene, 9-*cis* and 13-*cis*, accounted for 4.3% and 4.9%, respectively. Overall, the β-carotene equivalents among all four genotypes ranged from 7.5 to 10.3 μg/g DW (7.0−9.5 μg/g FW). Genotype HP1005 (released in Zambia as variety GV665A) had the highest BCE (10.3 μg/g DW). Genotype HP1002 (released in Zambia as variety GV662A) presented BCE of 8.0 μg/g DW, not significantly different from either genotype HP1001 (8.9 μg/g DW) or HP1003 (7.5 μg/g DW). However, the genotypes showed different levels of all-*trans*-β-carotene and its *cis*-isomers as reported in the literature.[26]

It is important to note that high levels of β-cryptoxanthin in the biofortified maize were twice as high as all-*trans*-β-carotene

(HP1002 and HP1003) or at equal levels with HP1001 and HP1005. During the germplasm screening for genetic variation, the sources of high provitamin A were found among maize from temperate regions, which were then bred into varieties suitable for tropical conditions. Moreover, these tropical varieties contain more β-cryptoxanthin and less β-carotene, and the emphasis was to enhance the β-carotene, which provides two vitamin A molecules per carotenoid molecule.[2] However, animal studies have shown that β-cryptoxanthin is absorbed and stored in many tissues[16] and it maintains the vitamin A status of gerbils as efficiently or better than β-carotene.[17]

Most of the yellow maize grown and consumed throughout the world has less than 2.0 μg/g DW of provitamin A carotenoids in kernels.[2] The first wave of biofortified maize grown in Zambia contained 7.5 to 10.3 μg/g DW BCE and higher levels of β-cryptoxanthin, which is as efficient as β-carotene as a source of vitamin A. Most importantly was that the increase in β-cryptoxanthin and β-carotene did not compromise the levels of lutein and zeaxanthin, which have similar concentrations to those reported for yellow maize accounting for 30−50% of total carotenoids.[18]

Effect of Storage. At a household level, in Zambia, maize is harvested during the months of April−May, it is usually stored "as harvested" on the ears or shelled into kernels, and stored in bags under shelter for up to eight months at 16−27 °C and relative humidity 40 to 65%.[27] These postharvest storage methods are practiced in specific regions of the country. For example, in Nyimba district in the Eastern Province, the majority of households (84%) stored maize on ears, covered with leaves and in a barn, while in Mkushi district in the Central Province, the majority of households (92%) store shelled maize in bags (F. F. De Moura, personal communication). Therefore, both postharvest storage practices were evaluated during storage (kernels and ears) on carotenoid retention over a period of 6 months. Weekly records of humidity and temperature inside the storage bin were taken and are provided in Table 2A of the Supporting Information. In general, the retention of the provitamin A carotenoids for all four genotypes did not differ significantly according to the postharvest storage method in which the maize was stored, either as ears or kernels (data not shown). Therefore, only kernel retention data over a 6-month period are presented herein.

Figure 1 shows the retention of BCE in biofortified maize measured in 15-day intervals up to six months for stored ears of genotypes HP1002 and HP1005. All four genotypes followed a similar decay pattern for BCE with a 40% decrease occurring within the first 15 days of storage. A further 10% reduction within the next 15 days (total 30 days of storage) was observed, followed by a stabilization at 50% retention until 120 days of storage, thereafter declining to 40% retention between 120 and 180 days. The retention of BCE for genotypes HP1001 and HP1003 measured at baseline, 90 and 180 days of storage, followed a similar pattern achieving, respectively, 51.5% and 62.9% retention at 90 days and 40% and 63.1% retention at 180 days of storage.

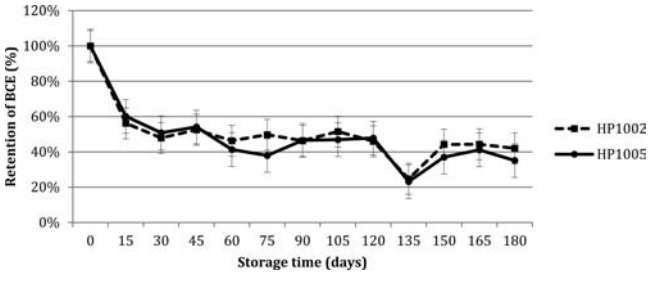

Figure 1. Effect of storage on BCE retention of maize when stored as kernels for six months under ambient conditions in Zambia for genotypes HP1002 and HP1005 at 15-day intervals. Day 135 did not follow the projected decay line.

Weber[19] reported an average total carotenoid retention of 58% among four inbred lines after 6 months of storage. Other provitamin A biofortified crops (e.g., sorghum, rice) also showed a comparable pattern of 40% degradation of provitamin A within the first few days of storage. Further postharvest research is needed to optimize storage conditions in order to minimize provitamin A degradation during storage, particularly immediately after harvest.

A similar better performance of some genotypes was observed by Burt et al.,[8] which reported an overall 25−60% decay of provitamin A among six genotypes after drying and four months of dark storage at 25 °C; total carotenoid loss ranged from 15 to 45% and 0 to 50% due to drying and storage, respectively. In this particular study, the researchers were able to categorize the genotypes into three groups, i.e., those with high losses due to drying and low loss due to storage, those with low losses due to drying, but high loss due to storage, and the intermediate genotypes with moderate losses due to both drying and storage. Another study showed a wide range of provitamin A degradation (7−45%) among six maize genotypes within the first four months of storage (unpublished data from Natalia Palacios).

Effect of Milling. *Milling into Mealie Meal.* Maize kernels are usually milled into whole maize meal (named mealie meal), which is a fine flour used for making *nshima* and porridge. Most of the carotenoids were retained during this process except for β-cryptoxanthin, which showed a consistent 60% retention across all genotypes (Table 3). These findings were contrary to those reported by Pillay et al.,[9] where a higher retention of β-cryptoxanthin (95.3−113.5%) was observed in milled maize. Different maize genotypes and milling processes could be a source of variation with reported studies. Moreover, Pillay et al.[20] reported that β-cryptoxanthin is the most abundant provitamin A carotenoid present in some biofortified varieties, and their range was higher than those reported by Li et al.[7]

Although lower β-cryptoxanthin retention was constant among genotypes in this study, Li et al.[7] reported small significant losses (7−10%) of provitamin A carotenoids after soaking and milling to produce wet-milled flour. It was not surprising to observe degradation because the maize was soaked for 24 h prior to milling. Traditionally, Zambians mill the maize kernels directly, limiting exposure to oxygen and light. Although not significantly different, the β-carotene levels were higher in the mealie meal than in the intact raw maize kernels, which is a reason for figures above 100% BCE retention in some genotypes (HP1003 and HP1005). The higher carotenoid levels in the final milled products than those found in the raw samples could be due to extraction efficiency from processed samples compared with those of raw fresh foods as elaborated by Rodriguez-Amaya and Kimura Rodriguez.[21] Overall, the BCE retention ranged from 80 to 110% among all four genotypes with HP1005 being the highest.

Milling into Samp. Maize kernels can also be milled into *samp* after conditioning or tempering (soaking in water) for 5

[a]Data are means ± SD, n = 2 independent analyses. [b]Different lowercase letters indicate a statistically significant difference among final products within each genotype/variety. Different uppercase letters indicate a statistically significant difference among the genotypes/varieties for the same final product. [c]Moisture content (as percentage of wet weight) of raw maize kernels (12%), raw whole maize meal (12%), raw samp (13%), cooked samp (70%), *nshima* (75%), and porridge (86%).

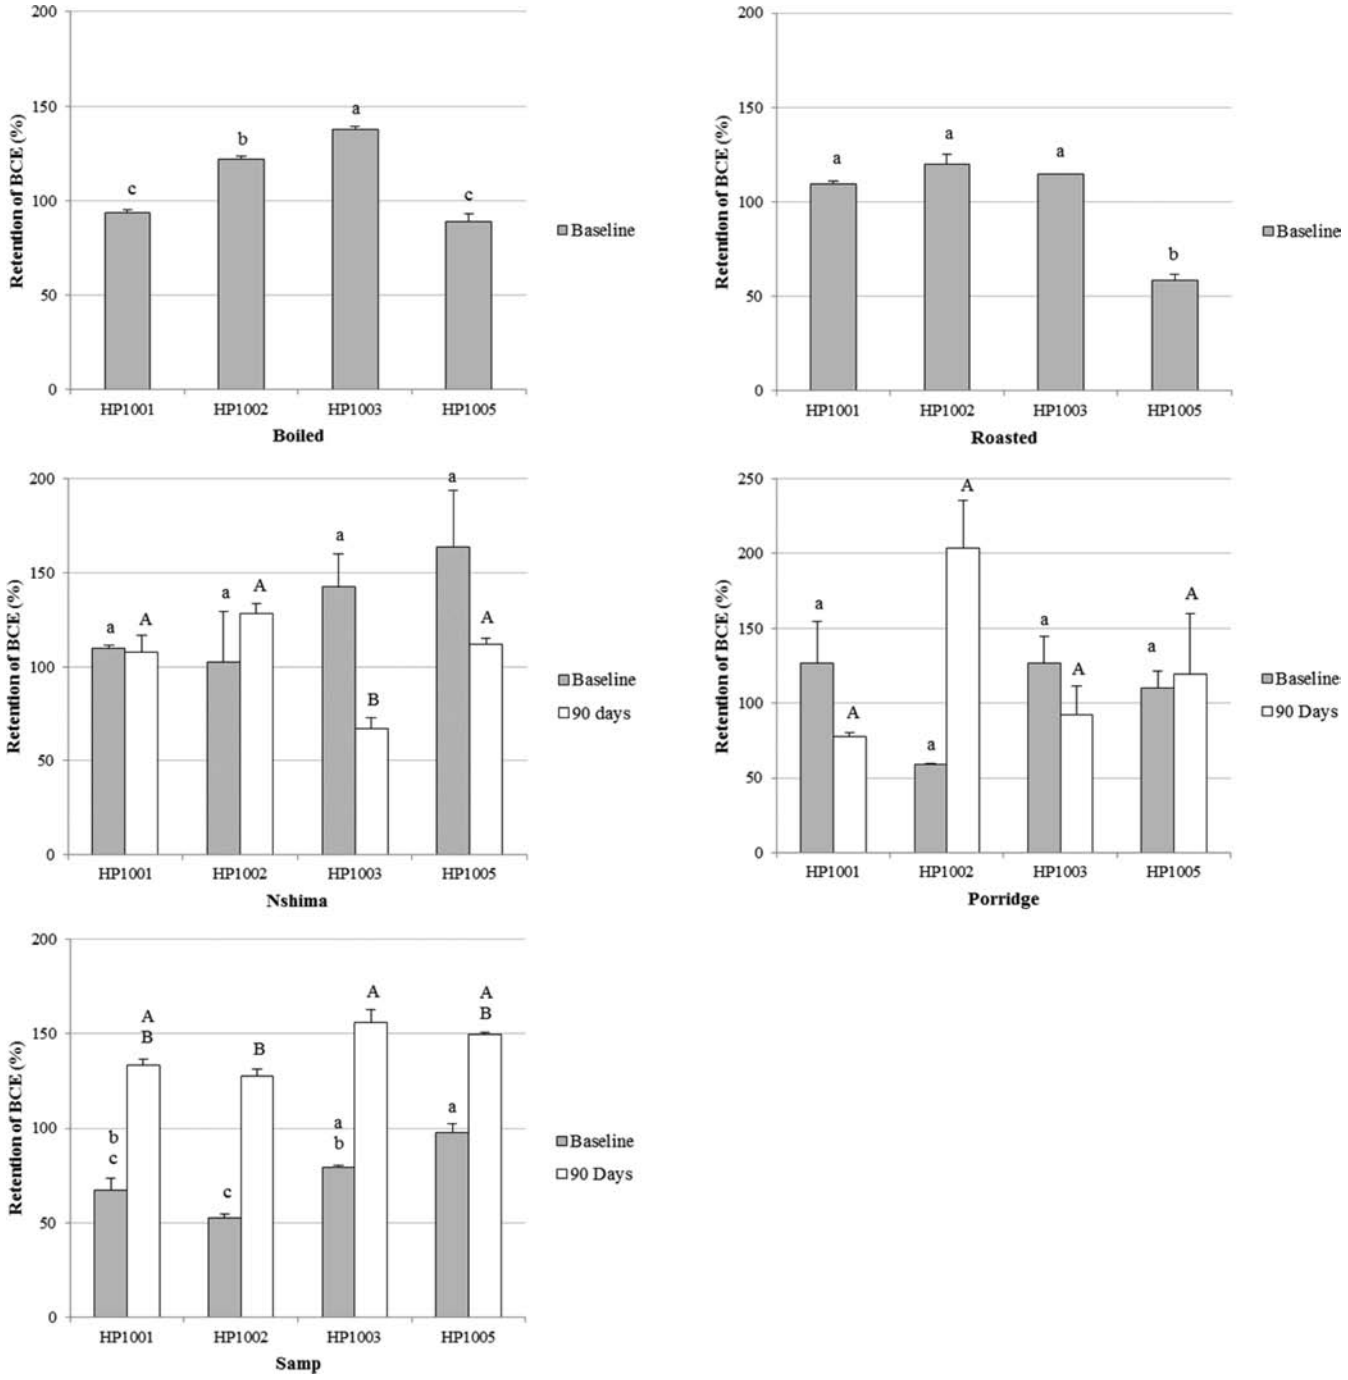

Figure 2. Retention of BCE of traditional Zambian cooked products from four genotypes of biofortified provitamin A maize (HP1001, HP 1002, HP1003, and HP1005) at baseline and after the maize was stored for 90 days at room temperature before cooking. For each cooking method, the different letters among genotypes indicates significant difference ($P < 0.05$) at baseline (lower case letters) and after 90 days (upper case letters). The error bars indicate standard deviations.

min for ease of bran removal to obtain the dehulled kernels. No significant carotenoid losses were observed after milling into *samp*, resulting in retention of BCE, in most cases, higher than 100%. Both β-carotene and β-cryptoxanthin were maintained in *samp*; therefore, yielding a final product with a higher retention range (95.7−154.7%) compared to maize milled into mealie meal (91.6−130.7%), although these values showed no significant difference at ($P < 0.05$) (Table 3). On the other hand, Pillay et al.,[9] reported that maize milled into mealie meal resulted in higher retention of zeaxanthin, β-carotene, and β-cryptoxanthin compared with milling into *samp*.

Effect of Cooking. *Green Maize.* After roasting the green maize for 20 min, the retention of BCE was above 100%, except for genotype HP1005, yielding a 59% BCE retention. This lower retention can be attributed to the reduction of almost 50% in all-*trans*-β-carotene content of raw green maize (Table 2). The *cis*-isomers of β-carotene increased after roasting, the 13-*cis* increased by 65% among genotypes HP1001, HP1002, and HP1003, and the 9-*cis* increased by 60% in genotype HP1001.

Similar retention was obtained after boiling the green maize for 35 min at 95 °C. Genotypes HP1002 and HP1003 obtained

dx.doi.org/10.1021/jf501233f | J. Agric. Food Chem. 2014, 62, 6317−6325

100% of the BCE retention and 90% of the BCE retention for genotypes HP1001 and HP1005 (Table 2). HP1005 lost almost 50% of the all-*trans*-β-carotene after boiling. No consistent trend was observed for the *cis*-isomers after boiling. Muzhingi et al.[22] also reported similar results on retention levels above 100% for all individual carotenoids, except for β-cryptoxanthin (92%), for yellow maize boiled for 1 h at 100 °C.

Dry Maize. The retention of individual carotenoids and BCE of all three cooked products, *nshima*, porridge, and cooked *samp*, are shown in Table 3. *Nshima*, by far the most popular maize dish consumed in Zambia, showed high BCE retention levels (103−164%) despite the lower retention (21−29%) of β-cryptoxanthin. Lutein and zeaxanthin were also significantly higher in *nshima* than raw maize. Porridge, which is consumed mostly by children at breakfast, likewise had high BCE retention (110−127%) except for genotype HP1002 (59%). The lower BCE retention observed in genotype HP1002 can be attributed to the drastic drop in the levels of β-cryptoxanthin from 6.9 to 0.8 μg/g DW. Similar results of high retention (>100%) of individual carotenoids were reported by Muzhingi et al.[22] for cooked products of yellow maize for "*sadza*", which is Zimbabwe's version of *nshima*, as well as porridge.[23−25] In particular in porridge, but not in *sadza*, the β-cryptoxanthin was significantly lower than in the raw kernels while the all-*trans*-β-carotene was constant in both products. Additionally, the muffins, which were baked for 25 min at 232 °C, showed significantly lower retention for all individual carotenoids, including 25% and 51% retention for all-*trans*-β-carotene and β-cryptoxanthin, respectively. Lastly, the cooked *samp* in the current study showed higher BCE retention when the maize was milled into *samp* (96−155%), although the combination of high temperature with prolonged cooking (3 h) resulted in a lower BCE retention range (53−98%) among the four genotypes.

Retention of β-Carotene Equivalents (BCE) among All Cooked Products. In this study, the BCE retention of cooked products from just harvested maize was compared with those of cooked products from maize stored for 90 and 180 days. The BCE retention did not differ significantly between the cooked products made from maize stored either at 90 or 180 days. Therefore, Figure 2 shows the BCE retention of different cooked products of maize that have just been harvested, including green and dry maize, and cooked products made from dry maize that had been stored for 90 days. On average, the genotypes, HP1001 and HP1003, showed high BCE retention among the different maize cooked products, except for a lower BCE retention in cooked *samp* as discussed in the previous section. Furthermore, genotype HP1002, besides lower BCE retention for *samp*, had 60% retention in cooked porridge. Interestingly, genotype HP1005 was the only type that showed a 60% BCE retention for roasted product, while the other three genotypes had BCE retention higher than 100%; however, it had the highest BCE retention, almost 100% when cooked as *samp*. The BCE retention of the cooked product was not affected by the maize being stored for 90 days, although the carotenoid levels decreased substantially (see the previous section on the Effects of Storage).
