ABSTRACT: Wild Alaskan *Vaccinium* berries, *V. vitis-idaea* (lowbush cranberry) and *V. uliginosum* (bog blueberry), were investigated in parallel with their commercial berry counterparts, *V. macrocarpon* (cranberry) and *V. angustifolium* (lowbush blueberry). Lowbush cranberry accumulated about twice the total phenolics (624.4 mg/100 g FW) and proanthocyanidins (278.8 mg/100 g) content as commercial cranberries, but A-type proanthocyanidins were more prevalent in the latter. Bog blueberry anthocyanin and total phenolic contents of 220 and 504.5 mg/100 g, respectively, significantly exceeded those of the lowbush blueberry. Chlorogenic acid, however, was quite high in lowbush blueberry (83.1 mg/100 g), but undetected in bog blueberry, and the proanthocyanidins of lowbush blueberry had significantly higher levels of polymerization. Antioxidant capacity (DPPH, APTS, and FRAP) correlated with phenolic content for each berry. A polyphenol-rich fraction from lowbush cranberry exhibited dose-dependent inhibition of LPS-elicited induction of IL-1β in RAW 264.7 cells, indicative of strong anti-inflammatory activity. These results corroborate the historic use of wild Alaskan berries as medicinally important foods in Alaska Native communities.

KEYWORDS: *Vaccinium vitis-idaea, V. uliginosum, V. macrocarpon, V. angustifolium, phenolics, antioxidant, anti-inflammatory*

INTRODUCTION

Epidemiological studies have shown that increased consumption of fruits and vegetables correlates with improved cardiovascular health as well as reduced risk of cancer, stroke, degenerative diseases, loss of functionality associated with aging, and more.[1−3] Whereas fruits and vegetables are rich sources of vitamins and minerals, recent attention in biomedical research has focused heavily on phenolic components, flavonoids in particular, for their antioxidant, anti-inflammatory, and other health-relevant bioactivities.[4−6] Although not fully understood, these health-promoting effects have been mainly related to interactions between the phenolic compounds and several key enzymes, signaling cascades involving cytokines and regulatory transcription factors, and antioxidant systems.[7]

Many types of wild berries are indigenous to Alaska, and seasonal harvests are major community events, especially in rural Alaska Native villages. Wild Alaskan berries are delicious fresh, frozen, dried, or turned into any number of tasty creations: jams, muffins, fruit leathers, sauces, and agutuk (otherwise known as Alaskan/Eskimo ice cream, made from seal oil and berries).[8] People commonly harvest berries of the *Vaccinium* genus, blueberries, lowbush cranberries, and other wild berries, when the berries are ripe in July, August, and September and use them for both food and medicine. The summer season is short, and the day length of summer is dramatically longer than that found at lower latitudes, which can have a profound impact on the phytochemical composition and content of the fruits.[9]

The genus *Vaccinium* includes several popular commercial berry species, including lowbush, highbush, and rabbiteye blueberries, domesticated cranberries, and lingonberries. In general, *Vaccinium* berry fruits are widely renowned for their health benefits, reportedly due to their high concentrations of phenolic compounds and/or the presence of specific, particularly potent polyphenolic compounds that may interact (additively or synergistically) to ameliorate human health conditions.[10]

The influence of the growing environment on both phenolic concentrations and profiles has been previously described,[11,12] which could condition the health-relevant potency of berries from wild and cultivated regimes. However, the composition and merits of most wild *Vaccinium* selections have not been well documented. In this study, we comparatively examined two wild Alaskan berry species, lowbush cranberry (*Vaccinium vitis-idaea*, also known as lingonberry or cowberry in many other parts of the world) and bog blueberry (*Vaccinium uliginosum*, also known as alpine blueberry or bilberry), and their corresponding commercial counterparts, American cranberry (*Vaccinium macrocarpon*) and lowbush blueberry (*Vaccinium angustifolium*), because considerable baseline data have already been generated for the latter two commercially cultivated species. *V. vitis-idaea* and *V. uliginosum* are among the most significant wild berries in Nordic countries, Russia, and other circumpolar regions, and their phenolic profiles have been

investigated previously.[13,14] However, only scant analysis has been conducted to determine phytochemical profiles or anti-inflammatory bioactivity of these species in Alaska. Streamlined and sophisticated analytical protocols were applied to rigorously establish and cross-compare the phytochemical profiles and antioxidant capacities of these berries to provide information on their potential suitability for different applications. Also, the effect of berry extracts on the expression of four well-known genetic biomarkers of inflammation was investigated in vitro in a lipopolysaccharide-stimulated murine RAW 264.7 macrophage model.

MATERIALS AND METHODS

Reagents and Materials. Reference compounds procyanidin A2 (PAC-A2), procyanidin B2 (PAC-B2), catechin, and epicatechin were purchased from Chromadex (Irvine, CA, USA). 4-Dimethylamino-cinnamaldehyde (DMAC), Folin−Ciocalteu reagent, 2,2-diphenyl-1-picrylhydrazyl (DPPH), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH), phosphate buffer, 2,4,6-tri(2-pyridyl)-*s*-triazine (TPTZ), iron(III) chloride hexahydrate, and fluorescein sodium salt (FL) were purchased from Sigma-Aldrich Inc. (St. Louis, MO, USA). All organic solvents were of HPLC grade and obtained from VWR International (Suwanee, GA, USA).

Berry Sources. Wild Alaskan lowbush cranberry (*V. vitis-idaea* L.) and bog blueberry (*V. uliginosum* L.) were handpicked when fully ripe from the vicinity of Fairbanks, AK, USA. Lowbush cranberry was collected at latitude 64.8 N, longitude 147.7 W, in September 2012. Bog blueberry was collected at latitude 65.5 N, longitude 145.4 W, in July 2012. A total of 3 kg of fruit was collected from each species in the growing region over a 1 week period. Berries were immediately stored at −80 °C before freeze-drying. Freeze-dried berries were ground before sampling and analysis. A composite sample of commercially grown lowbush blueberries (*V. angustifolium* Aiton) was obtained from the Wild Blueberry Association of North America (Old Town, ME, USA). The blueberries were a composite of fruits from all major growing sites in Canada (Prince Edward Island, New Brunswick, Nova Scotia, Quebec) and the United States (Maine). The composite was made in the fall 2012, frozen by Cherryfield Foods, Inc., at −15 °C (Cherryfield, ME, USA), and subsequently stored at −80 °C. American cranberries (*V. macrocarpon* Ait) were obtained from The Cranberry Network, LLC (Wisconsin Rapids, WI, USA) in fall 2012 and stored at −80 °C. Commercial berries (5 kg each) were freeze-dried and then ground prior to sampling and extraction. Dry matter (DM) percentage was calculated on the basis of the difference between berry fresh weight (FW) and the weight after freeze-drying (FD). All extractions were performed on the freeze-dried material, and results were calculated on a fresh weight basis by considering the water content in each berry.

Extraction and Polyphenol Enrichment. Freeze-dried ground berry fruits (2.5 g × 3 replicates) were blended (Waring, Inc., Torrington, CT, USA) with 30 mL of acidified 70% aqueous methanol (0.5% acetic acid) for 2 min. The mixture was centrifuged (Sorvall RC-6 plus, Asheville, NC, USA) for 20 min at 4000 rpm, and the supernatant was transferred to 100 mL volumetric flasks. The extraction of the pellet was repeated two more times and the combined extracts were brought to a final volume of 100 mL. Samples of crude extracts (CE) were filtered, using a 0.20 μm PTFE syringe filter (Fisher Scientific, Pittsburgh, PA, USA), before analysis using HPLC, LC-MS, and MS/MS, and antioxidant capacity bioassays. An aliquot of the crude extract (2 mL) was dried down completely before testing for anti-inflammatory activity, as described below. The crude extract (50 mL) was evaporated to about 2 mL before loading onto two SPE cartridges (Supelclean LC-18, 12 mL) preconditioned with methanol and then acidified water (0.01% HCl). Each cartridge was washed with 50 mL of acidified water before elution with 100% methanol until all color eluted off. The methanol extract was evaporated and freeze-dried to get the polyphenol-rich fraction (PRE), which was subjected to HPLC, LC-MS analyses, and anti-inflammatory bioassays.

Determination of Total Phenolics, Anthocyanins, and Proanthocyanidins. The CE from each berry was diluted to appropriate concentrations for analysis. Total phenolics (TP) were determined with Folin−Ciocalteu reagent according to the method of Singleton.[15] Concentrations were expressed as milligrams per liter gallic acid equivalents based on a created gallic acid standard curve. Total monomeric anthocyanin (ANC) content was measured by using the pH differential spectrophotometric method,[16] using a Shimadzu UV-2450 (Tokyo, Japan) spectrophotometer. ANC concentration was calculated as milligrams per liter cyanidin 3-*O*-glucoside equivalents. Total proanthocyanidins (PAC) concentration was determined colorimetrically using the DMAC method in a 96-well plate as previously described.[17] A series of dilutions of standard procyanidin A2 dimer were prepared in 80% ethanol ranging from 1 to 100 μg/mL. Blank, standard, and diluted samples were analyzed in triplicates. The plate reader protocol was set to read the absorbance (640 nm) of each well in the plate every minute for 30 min (SpectraMax M3, Sunnyvale, CA, USA). Concentration of PAC in the solution was expressed as milligrams per liter procyanidin A2 equivalent.

Reversed Phase HPLC and LC-ESI-MS Analysis. HPLC analyses for anthocyanins were conducted using an Agilent 1200 HPLC (Agilent Technologies, Santa Clara, CA, USA), according to our previously published protocol.[18] Quantification of anthocyanins was performed using the peak areas recorded at 520 nm to construct the calibration curve for cyanidin-3-*O*-glucoside.

HPLC for chlorogenic acid was performed using a Phenomenex Synergi 4 μm Hydro-RP 80A column (250 mm × 4.6 mm × 5 μm; Torrance, CA, USA). The mobile phase consisted of 2% acetic acid in distilled H_2O (solvent A) and 0.5% acetic acid in 50% acetonitrile in water (solvent B). The flow rate was set at 1 mL/min with a step gradient of 10, 15, 25, 55, 100, and 10% of solvent B at 0, 13, 20, 50, 54, and 60 min, respectively. Quantification was performed from the peak areas recorded at 280 nm to the calibration curve obtained with reference standard.

LC-MS analysis was performed using a Shimadzu LC-MS-IT-TOF instrument equipped with a Prominence HPLC system. The LC separation was performed using a Shim-pack XR-ODS column (50 mm × 3.0 mm × 2.2 μm) at 40 °C with a binary solvent system composed of 0.1% formic acid in water (A) and methanol (B). Compounds were eluted into the ion source at a flow rate of 0.35 mL/min with a step gradient of B of 5−8% (0−5 min), 8−14% (10 min), 14% (15 min), 20% (25 min), 25% (85 min), 5% (35 min), and 5% (40 min). Ionization was performed using an ESI source in the negative ion mode. Compounds were characterized and identified by their MS, MS/MS spectra, and LC retention times and by comparison with available reference samples and our previous analyses.[18,19]

Normal Phase HPLC−Fluorescence Analysis of Proanthocyanidins. HPLC analyses were conducted using an Agilent 1200 HPLC with fluorescence detector (FLD) and photodiode array detector (DAD). Proanthocyanidin separation was performed according to the method of Wallace and Giusti,[20] using a Develosil Diol column, 250 mm × 4.6 mm × 5 μm (Phenomenex). PAC were identified by comparison with available standards, our previous analyses,[18] reported literature,[20] and LC-ESI-MS. Quantification of proanthocyanidin was calculated using peak areas and a calibration curve for PAC-A2, and amounts were expressed as PAC-A2 equivalents.

Free Radical Scavenging (DPPH Assay). The radical scavenging activity was measured using the stable DPPH and Trolox as reference substances.[21] Samples were diluted 10 times with 80% methanol before mixing with the reagent. An aliquot (100 μL) of each sample was pipetted into 3.9 mL of DPPH solution (0.08 M in 95% ethanol) to initiate the reaction. After a reaction time of 3 h at ambient temperature, the reaction had reached completion. The decrease in absorbance of DPPH free radicals was read at 515 nm against ethanol as a blank using a Shimadzu UV-2450 spectrophotometer. Trolox (0, 100, 200, 300, 400, and 500 μM) was used as a standard antioxidant

compound. Analysis was performed in triplicate for each sample and each concentration of standard. The antioxidant activity was reported in micromoles of Trolox equivalents per gram fresh weight (μmol TE/g FW).

Free Radical Scavenging (ABTS Assay). The ABTS assay was performed as described by Re[22] and is based on the reduction of $ABTS^{\bullet+}$ radicals by antioxidants in the berry extracts. ABTS radical cation ($ABTS^{\bullet+}$) was produced by reacting ABTS solution (7 mM) with 2.45 mM potassium persulfate (final concentration) and allowing the mixture to stand in the dark at room temperature for 12−16 h before use. For the assay, the $ABTS^{\bullet+}$ solution was diluted in deionized water or ethanol to an absorbance of 0.7 (±0.02) at 734 nm. After the addition of 100 μL of berry extract solutions to 3 mL of $ABTS^{\bullet+}$ solution, the absorbance reading was taken at 30 °C 10 min after initial mixing (A_E). All determinations were carried out in triplicate. The antioxidant activity was reported in micromoles of Trolox equivalents per gram fresh weight (μmol TE/g FW).

Ferric Reducing Antioxidant Power (FRAP) Assay. This method is based on the reduction, at low pH, of a colorless ferric complex (Fe^{3+}−tripyridyltriazine) to a blue-colored ferrous complex (Fe^{2+}−tripyridyltriazine) by the action of electron-donating antioxidants. The ferric reducing power of berry extracts was performed in a 96-well microplate using the FRAP assay[23] with minor modifications. The working FRAP reagent was prepared daily by mixing 10 volumes of 30 mM acetate buffer, pH 3.6, with 1 volume of 10 mM TPTZ in 40 mM hydrochloric acid and with 1 volume of 20 mM $FeCl_3$. A standard curve was prepared using various concentrations of $FeSO_4 \cdot 7H_2O$. All solutions were used on the day of preparation. FRAP solution (175 μL) freshly prepared and warmed at 37 °C was added to three replicates of each sample (25 μL), whereas the same volume of acetate buffer was added to the fourth one (blank). The reaction mixture was incubated for 30 min at 37 °C, and then the absorbance was measured at 593 nm. The absorbance of the blank was subtracted from the absorbance of the samples. In this assay, the reducing capacity of the extracts tested was calculated with reference to the reaction signal given by a Fe^{2+} solution. FRAP values were expressed as micromoles of Fe^{2+} per gram of fresh berry.

Macrophage Cell Culture. The mouse macrophage cell line RAW 264.7 (ATCC TIB-71, obtained from American Type Culture Collection, Livingstone, MT, USA) was maintained in Dulbecco's modified Eagle's medium (DMEM, Life Technologies, Grand Island, NY, USA), supplemented with 100 IU/mL penicillin/100 μg/mL streptomycin (Fisher) and 10% fetal bovine serum (Life Technologies) at a density not exceeding 5×10^5 cells/mL and maintained at 37 °C in a humidified incubator with 5% CO_2.

Anti-inflammatory in Vitro Assay. Cells were subcultured by TrypLE (Life Technologies) when dishes reached up to 90% confluence with a 1:5 ratio in fresh medium. Cells were seeded in 24-well plates (5×10^5 cells/well) 24 h prior to treatment. The cells were then treated in triplicates with berry extracts at predetermined doses for 1 h before elicitation with LPS at 1 μg/mL for an additional 4 h. For every experiment, one positive control (cells treated with dexamethasone (Dex) at 10 μM) and one negative control (cells treatment with vehicle) were included. Three replicates were made for both the treatments and the controls. At the end of the treatment period, cells were harvested in TRIzol reagent (Life Technologies) for subsequent cellular RNA extraction.

Cell Viability Assay and Dose Range Determination. RAW 264.7 cells were seeded in a 96-well plate for the viability assay. Cell viability was measured by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay[24] in triplicate and quantified spectrophotometrically at 550 nm using a SynergyH1 microplater reader (BioTek). The concentrations of test reagents that showed no changes in cell viability compared with that vehicle (ethanol) were selected for further studies.

Total RNA Extraction, Purification, and cDNA Synthesis. The total RNA was isolated from RAW macrophages using TRIzol reagent (Life Technologies) following the manufacturer's instructions. RNA was quantified spectrophotometrically using the SynergyH1/Take 3 (BioTek, Winooski, VT, USA). The cDNAs were synthesized using 2 μg of RNA for each sample using commercially available high-capacity cDNA Reverse Transcription kit (Life Technologies), following the manufacturer's protocol on an ABI GeneAMP 9700 (Life Technologies).

Quantitative PCR Analysis. The resulting cDNA was amplified by real-time quantitative PCR using SYBR green PCR Master Mix (Life Technologies). To avoid interference due to genomic DNA contamination, only intron-overlapping primers were selected using Primer Express version 2.0 software (Applied Biosystems, Foster City, CA, USA) as follows: β-actin, forward primer, 5′-AAC CGT GAA AAG ATG ACC CAG AT-3′, reverse primer, 5′-CAC AGC CTG GAT GGC TAC GT-3′; COX2, forward primer, 5′-TGG TGC CTG GTC TGA TGA TG-3′, reverse primer, 5′-GTG GTA ACC GCT CAG GTG TTG-3′; iNOS, forward primer, 5′-CCC TCC TGA TCT TGT GTT GGA-3′, reverse primer, 5′-TCA ACC CGA GCT CCT GGA A-3′; IL6, forward primer, 5′-TAG TCC TTC CTA CCC CAA TTT CC-3′, reverse primer, 5′-TTG GTC CTT AGC CAC TCC TTC-3′; and IL1β, forward primer, 5′-CAA CCA ACA AGT GAT ATT CTC CAT G-3′, reverse primer, 5′-GAT CCA CAC TCT CCA GCT GCA-3′. Quantitative PCR (qPCR) amplifications were performed on an ABI 7500 Fast real time PCR (Life Technologies) using 1 cycle at 50 °C for 2 min and 1 cycle of 95 °C for 10 min, followed by 40 cycles of 15 s at 95 °C and 1 min at 60 °C. The dissociation curve was completed with 1 cycle of 1 min at 95 °C, 30 s at 55 °C, and 30 s at 95 °C. mRNA expression was analyzed using the ΔΔCT method and normalized with respect to the expression of the β-actin housekeeping genes using 7500 Fast System SDS software v 1.3.0 (Life Technologies). A value of <1.0 indicates transcriptional down-regulation (inhibition of gene expression) compared with LPS, which shows maximum genetic induction (1.0). Therefore, lower values indicate greater anti-inflammatory activity. Values of >1.0 imply overexpression of the particular gene in excess of LPS stimulation. Amplification of specific transcripts was further confirmed by obtaining melting curve profiles. A 2-fold change in gene expression was

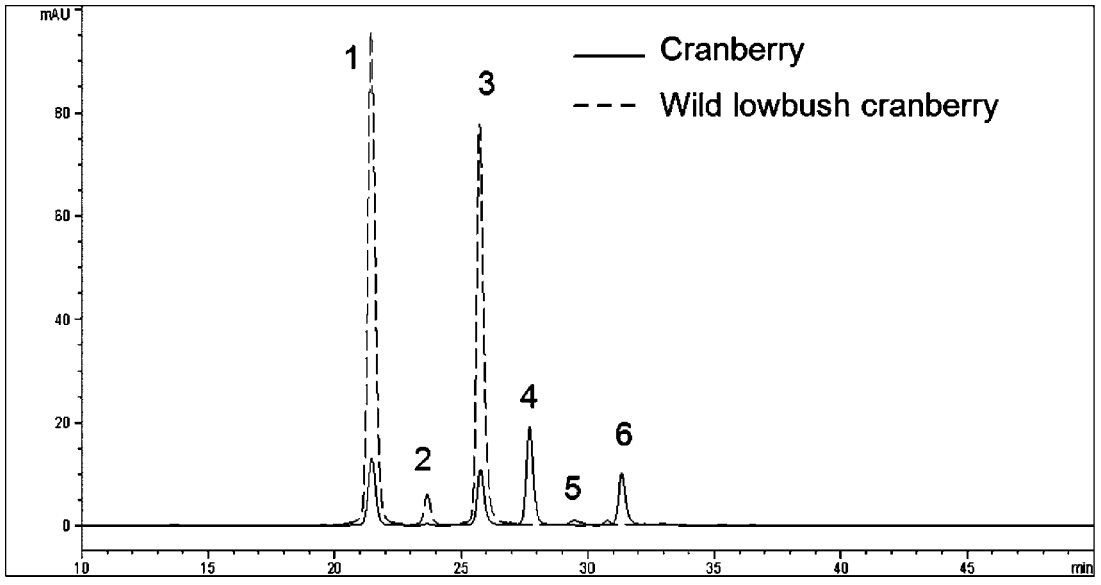

Figure 1. Reversed phase HPLC chromatograms for anthocyanins (A_{520}) in crude extracts of commercial cranberry (*V. macrocarpon*) and wild Alaskan lowbush cranberry (*V. vitis-idaea*).

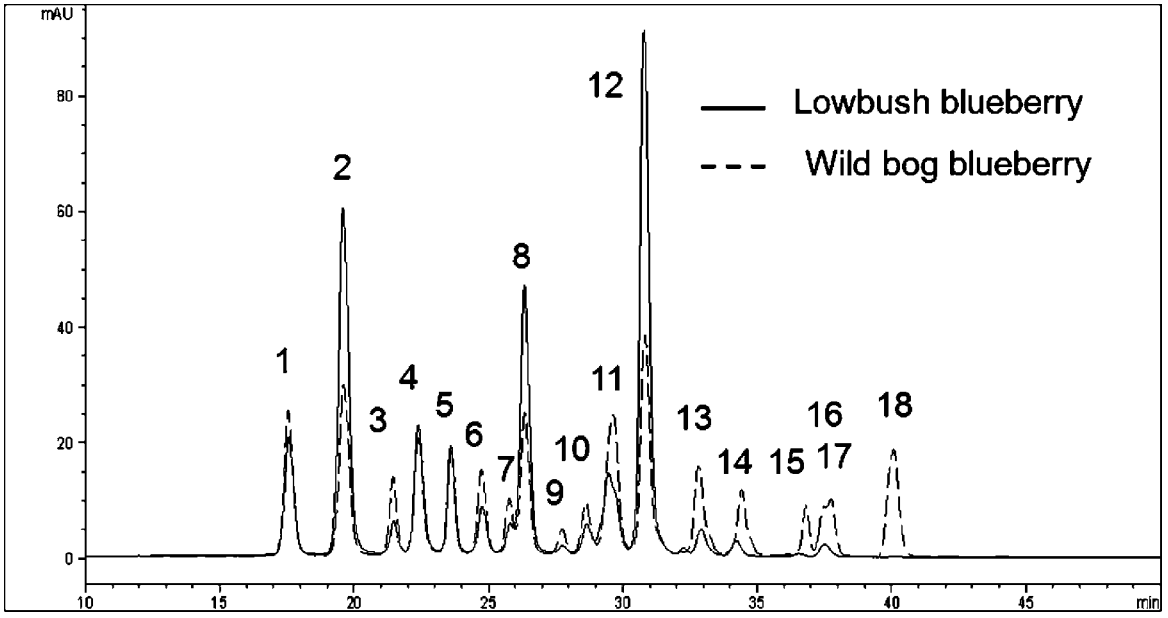

Figure 2. Reversed phase HPLC chromatograms for anthocyanins (A_{520}) in crude extracts of commercial lowbush blueberry (*V. angustifolium*) and wild Alaskan bog blueberry (*V. uliginosum*).

determined to be sufficient to eliminate background noise; therefore, 2-fold or higher values were used as a reliable estimation of relative expression ratio.[25]

Statistical Analysis. Statistical analyses were performed using Prism 4.0 (GraphPad Software, San Diego, CA, USA). Data were analyzed by one-way ANOVA with treatment as a factor. Post hoc analyses of differences between individual experimental groups were made using Dunnett's multiple-comparison tests.

RESULTS AND DISCUSSION

Total Monomeric Anthocyanins, Proanthocyanidins, Total Phenolics, and Chlorogenic Acid. Dry matter (DM) content of the berries used in this study ranged from 16% for commercial lowbush blueberry (*V. angustifolium*) to 24.6% for commercial American cranberry (*V. macrocarpon*). Wild Alaskan lowbush cranberry (*V. vitis-idaea*) and bog blueberry (*V. uliginosum*) contained 21.3 and 18.4% DM, respectively (Table 1).

Total anthocyanins (ANC) measured by pH differential assay indicated that the wild Alaskan lowbush cranberry contained levels of ANC (194.6 ± 6.4 mg/100 g FW) comparable to those of the commercial lowbush blueberry (189.8 ± 8.0 mg/100 g) but less than the wild Alaskan bog blueberry (220.0 ± 11.9 mg/100 g), whereas commercial cranberry contained significantly lower ANC concentration (76.6 ± 3.2 mg/100 g) (Table 1). ANC content of wild lowbush cranberry was >2.5-fold higher than that of commercial cranberry. In another study, *V. vitis-idaea* from Canada exhibited 1.4-fold greater ANC content than that of commercial cranberry, measured using the same assay.[26] Conversely, other researchers estimated that *V. vitis-idaea*

grown in Finland contained less ANC than European cranberry (257.0 and 299.3 mg/100 g, respectively, estimated by HPLC and based on dry weight).[27] In our comparison, bog blueberry from Alaska accumulated the highest ANC concentration, which is within the same range for this species grown in northern Europe (155−256 mg/100 g FW).[14,28]

Proanthocyanidins, measured spectrophotometrically by DMAC assay, exhibited highest levels in wild Alaskan lowbush cranberry (278.8 ± 19.6 mg/100 g FW), which was comparable to the PAC content of the same species in Finland (260 mg/100 g FW).[27] Commercial cranberry contained 132.7 ± 5.7 mg/100 g FW PAC, about half the PAC concentration of wild lowbush cranberry from Alaska. Wild Alaskan bog blueberry and commercial lowbush blueberry showed much lower levels of PAC (85.5 ± 5.9 and 71.2 ± 3.3 mg/100 g, respectively) with no significant difference at $P < 0.05$. Chlorogenic acid was highly accumulated in commercial lowbush blueberry (83.1 ± 1.0 mg/100g) but not detected in Alaskan bog blueberry. Wild Alaskan lowbush cranberry and commercial cranberry contained 18.3 ± 0.9 and 12.2 ± 0.2 mg/100 g chlorogenic acid, respectively. Total phenolics (TP) measured using Folin−Ciocalteu assay and expressed as gallic acid equivalents were much higher for Alaskan lowbush cranberry (624.4 ± 34.2 mg/100 g) than for the other three species and were comparable to same species grown in Canada.[26] Second to lowbush cranberry, the Alaskan bog blueberry exhibited TP of 504.5 ± 32.2 mg/100 g, whereas both the commercial berries, cranberry and lowbush blueberry, contained 350.5 ± 16.1 and 371.3 ± 2.2 mg/100 g, respectively, with no significant differences (Table 1).

Anthocyanin Profiles of Berries. The HPLC-DAD chromatograms of anthocyanins for all four berries are illustrated in Figures 1 and 2. Commercial cranberry is known to contain six anthocyanins, which are the galactosides, glucosides, and arabinosides of both cyanidin (peaks 1−3, 44%) and peonidin (peaks 4−6, 56%) (Table 2).[29] Wild Alaskan lowbush cranberry displayed only cyanidin glycosides as the dominant anthocyanin, with nondetectable levels of peonidins. This agrees with the results reported on the same species grown in Finland.[30] Environmental, geographical, or other factors in the northernmost latitudes of Finland were linked to higher relative content of cyanidin glycosides. Cyanidin glycosides were also present in slightly higher concentration in blueberries from the northern latitudes (Norway and Sweden), whereas delphinidin glycosides were better represented in the berries from southern latitudes (Italy, Poland, and Romania).[31] The HPLC chromatograms of Alaskan bog berry and commercial lowbush blueberry (Figure 2), and percentage of each anthocyanin (Table 2) indicated that the glucosides of delphinidin, petunidin, and malvidin (peaks 2, 8, and 12) were highly represented in wild bog blueberry (21.6, 14.8, and 29.2%, respectively) as compared to commercial lowbush blueberry (11.0, 4.3, and 13.1%, respectively). On the other hand, although lowbush blueberry contained a total of 17.4% acylated anthocyanins, none of these derivatives were detected in wild bog blueberry, which concurs with a previous report on *V. uliginosum* recently collected from different regions of Alaska.[9]

Proanthocyanin Profiles of Berries. Normal phase HPLC with fluorescence detection was able to separate proanthocyanin components in the berry extracts according to their degree of polymerization (Figures 3 and 4). Commercial cranberry had higher percentages of A-type dimers and trimers (23.2 and 12.1%, respectively) than B-type analogues (9.2 and 3.6%, respectively). Wild lowbush cranberry exhibited a higher percentage of B-type dimers (16.5%) and trimers (12.8%) than A-type analogues (7.8 and 2.6%, respectively). Comparison of wild bog blueberry to commercial lowbush blueberry revealed the former accumulated higher percentages of A-type dimers (13.7%) and trimers (11.7%) than the latter (2.0% and under the limit of detection, respectively). Among all of the berries, commercial lowbush blueberry contained the highest percentage of polymeric proanthocyanidins (25.1%) (Table 3).

[a]Compounds were quantified on the basis of peak area measurements. Cn, cyanidin; Pn, peonidin; Dp, delphinidin; Pt, petunidin; Mv, malvidin; gal, galactoside; glu, glucoside; ara, arabinoside. [b]Wild species collected from Alaska.

Phenolic Profile of Berries by LC-ESI-TOF-MS^n. On the basis of extracted ion chromatogram (EIC), catechin predominated in wild lowbush cranberry, whereas epicatechin predominated in commercial cranberry and Alaskan bog blueberry. PAC-A2 was prominent in commercial cranberry (Tables 3 and 4). PAC-B1 was prominent in wild lowbush cranberry and commercial lowbush blueberry, whereas PAC-B2 was present in commercial cranberry, lowbush bluberries, and bog blueberries but weak in wild lowbush cranberry (Table 4). Procyanidin A-type trimers were highly detected in all berries except commercial lowbush blueberry, which showed very weak signal. Chlorogenic acid was very prominent in commercial lowbush blueberry compared to the three other berries.

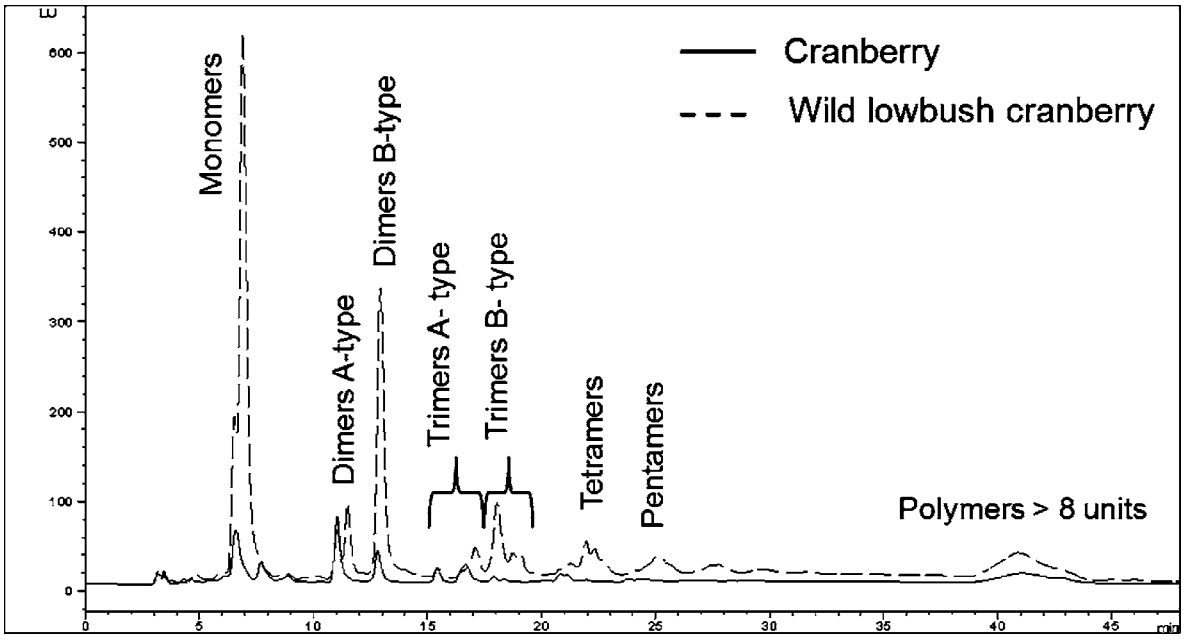

Figure 3. Normal phase HPLC-FLD chromatograms for proanthocyanidins (excitation, 230 nm; emission, 320 nm) in crude extracts of commercial cranberry (*V. macrocarpon*) and wild Alaskan lowbush cranberry (*V. vitis-idaea*).

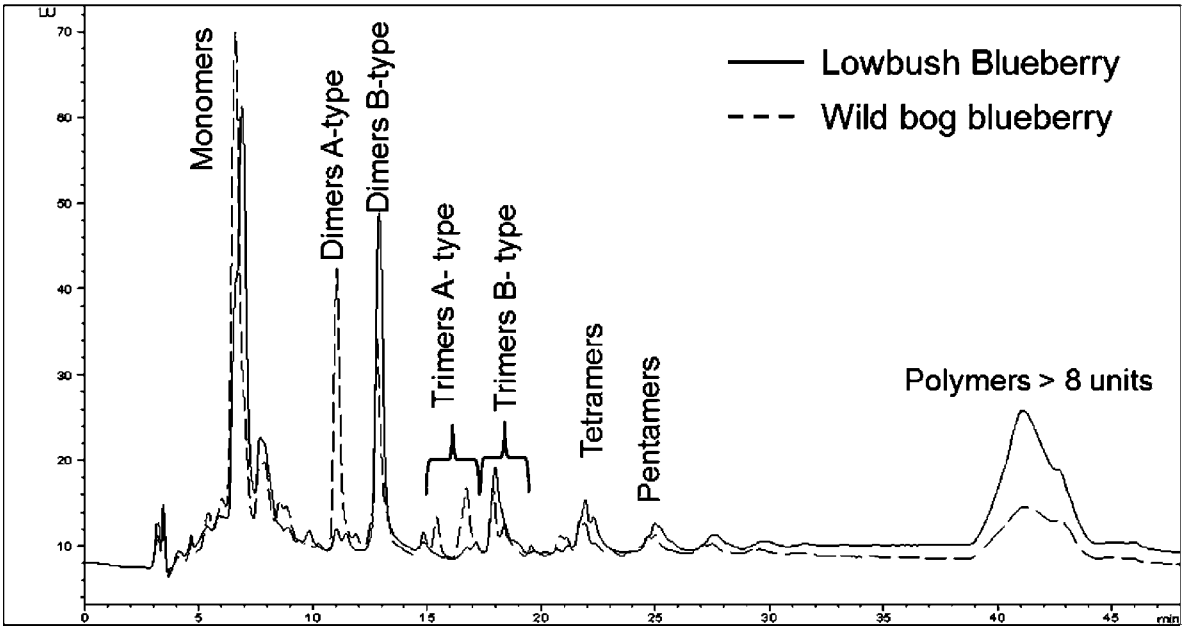

Figure 4. Normal phase HPLC-FLD chromatograms for proanthocyanidins (excitation, 230 nm; emission, 320 nm) in crude extracts of commercial lowbush blueberry (*V. angustifolium*) and wild Alaskan bog blueberry (*V. uliginosum*).

Commercial cranberry contained quercetin, myricetin, syringetin, and laricitrin glycosides, whereas wild lowbush cranberry was deficient in the last two flavonol glycosides. Commercial lowbush blueberry displayed quercetin, myricetin, and syringetin glycosides with no laricitrin, compared to wild bog blueberry, which contained the four flavonol glycosides. Additional results are shown in Table 4.

Antioxidant Capacity. The relative antioxidant capacity as measured by DPPH, ABTS, and FRAP assays mirrors the polyphenolic content of the investigated berries. Table 1 shows that wild lowbush cranberry had the highest radical scavenging activity in the three antioxidant capacity assays performed here (51.3 ± 2.2 and 69.3 ± 2.2 μM TE/g FW for DPPH and ABTS assays, respectively, and 122.2 ± 4.6 μM Fe^{+}/g for FRAP assay). DPPH, APTS, and FRAP assay results correlated well with the total phenolic content of the four investigated berries (R^2 = 0.98, 0.99, and 0.997, respectively). A previous study on the antioxidant capacity of Alaskan wild berries utilizing the H-ORAC$_{FL}$ assay indicated that lowbush cranberry collected from interior and south-central Alaska had about 2.5-fold the activity as wild bog blueberry from the same regions.[32]

A cleanup procedure was conducted on the crude extract, using a C18 RP-SPE cartridge (Supelco), to remove sugars, pectins, and lipophilic material and to concentrate polyphenolic compounds. Anthocyanins were more concentrated in the commercial lowbush blueberry polyphenol-rich (PPR) fraction

[a]Means with different letters within the same column are significantly different at $p < 0.05$. [b]ANC, anthocyanins, quantified by pH differential assay as cyanidin-3-*O*-glucoside. [c]PAC, proanthocyanidins, quantified by DMAC assay as procyanidin A2. [d]TP, total phenolics, quantified by Folin−Ciocalteu assay as gallic acid equivalent; [e]Wild species collected from Alaska.

(193.1 mg/g), whereas PAC were highest in wild lowbush cranberry PPR fraction (215.6 mg/g). The PPR contained an average of 30-fold the concentrations of TP in the crude extracts (see Table 5 for concentrations of ANC, PAC, and TP in crude and PPR extracts). The PPR was tested alongside the dried crude extract for anti-inflammatory activity.

Anti-inflammatory Assay. Many studies have suggested that exposure of mammalian cells to the main component of the outer membrane of the Gram-negative bacteria, lipopolysaccharide (LPS), can lead to release of pro-inflammatory cytokines and in turn activate inflammatory cascades including cytokines, lipid mediators, and adhesion molecules such as interleukin-1β (IL-1β), cyclooxygenase-2 (COX-2), inducible

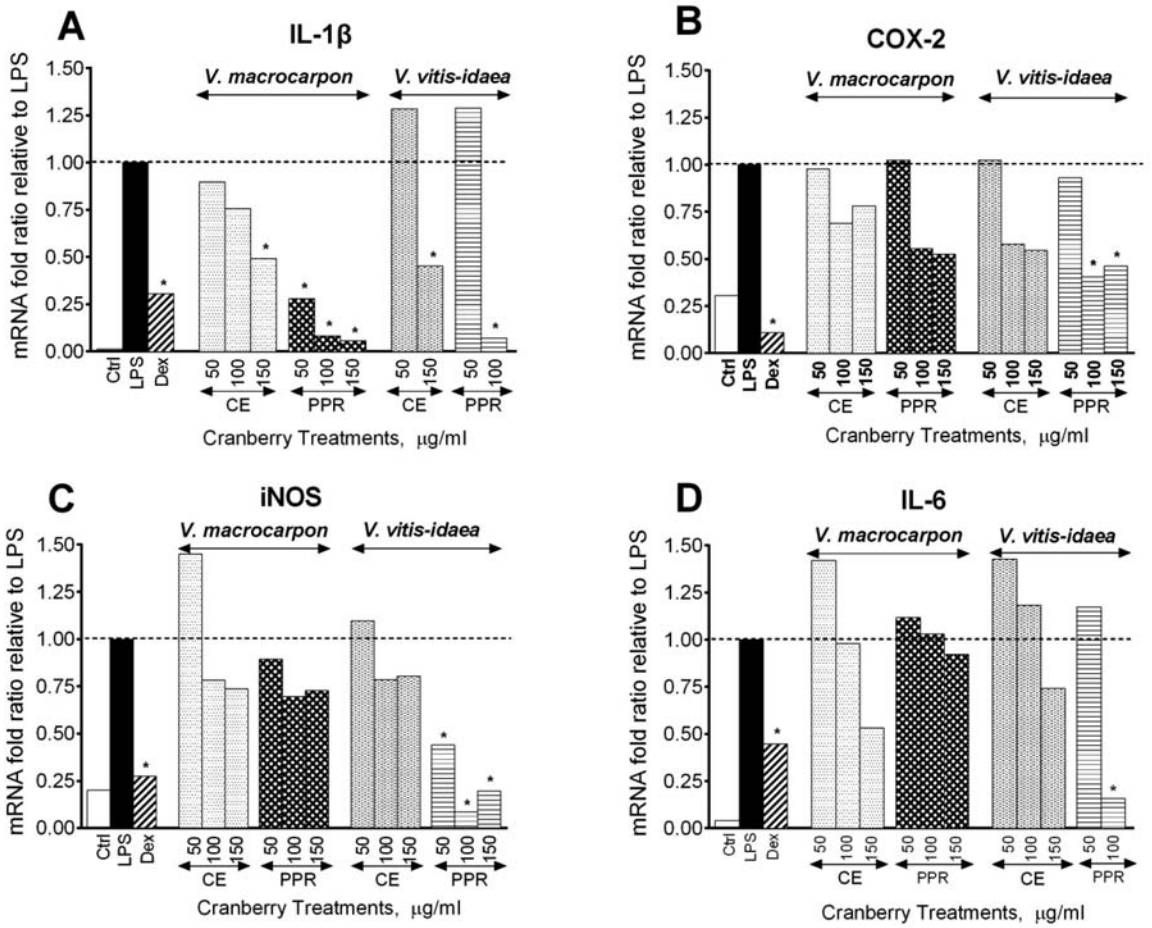

Figure 5. Anti-inflammatory bioactivity of wild Alaskan and commercial *Vaccinium* crude extracts (CE) and polyphenol-rich fractions (PPR); effects on the expression of the inflammatory biomarker genes in the LPS-stimulated RAW264.7 macrophages at 50, 100, and 150 μg/mL. Genes involved in the acute-phase response, inflammatory response, and humoral immune responses are represented: IL-1β assay (A), COX-2 assay (B), iNOS assay (C), and IL-6 assay (D). Changes in gene expression were measured by comparing mRNA quantity relative to LPS. A value of <1.0 indicates transcriptional down-regulation (inhibition of gene expression) compared with LPS, which shows maximum genetic induction (1.0). Therefore, lower values indicate greater anti-inflammatory activity. Ctrl, cells treatment with vehicle only; Dex, dexamethasone at 10 μM used as positive control.

nitric oxide synthase (iNOS), and interleukin-6 (IL-6). These four well-known genetic biomarkers involved in the acute-phase response, inflammatory response, and humoral immune responses were investigated in vitro in the LPS-stimulated murine RAW 264.7 macrophage model. The in vitro experiments were designed to quantify the relative amount of transcripts for target genes within the total RNA in individual cell batches undergoing dose-dependent treatments (50, 100, and 150 μg/mL) with four CE and four PPR fractions. For each assay, three control sets were monitored. The negative control (no LPS treatment) maintained a constant amount of transcripts for all constitutively expressed genes and served as a reference baseline; the induction control (treated with LPS) showed the maximum up-regulation of the marker genes; and the positive control (treated with LPS and Dex) served as a reference for the effectiveness of the assay.[31] Because noncytotoxic doses were predetermined by the MTT assay (data not shown), the observed changes in gene expression (genetic down-regulation) were not due to cell death.

On the basis of gene expression results, wild lowbush cranberry exhibited a potent anti-inflammatory activity in the macrophage cell culture based on a 2-fold or higher change in biomarker gene expression relative to the LPS-stimulated controls (Figures 5 and 6). In some instances, 10-fold reduction was observed in pro-inflammatory gene expression similar to or exceeding that of the positive control (Figures 5A and 6A). PPR fractions of cranberry and lowbush blueberry effectively inhibited LPS-elicited induction of pro-inflammatory inducible cytokine IL-1β and two enzyme coding genes cyclooxygenase-2 (Cox2) and nitric oxide synthase (Figure 5B,C).

Determination of pharmacologically relevant and attainable doses for polyphenol-rich cranberry extracts in vivo will be an important next step toward developing novel preventive or clinical applications based on cranberry supplementation. Cranberry polyphenols are a complex mixture composed of monomeric catechins, epicatechins, polymeric proanthocyanidins (with and without additional substitutions), and multiple anthocyanins (Tables 1 and 2). Whereas anthocyanins are known for their low bioavailability, monomeric proanthocyanidins from fruits have been known to reach systemic circulation at the level of 50−80 μg/mL of plasma,[33] which is comparable to the low and intermediate level doses used in this study. It is therefore likely that the in vitro anti-inflammatory effects of wild lowbush[33] cranberry will be observed in vivo in circulating macrophages and especially in resident intestinal macrophages that receive higher exposure to dietary poly-

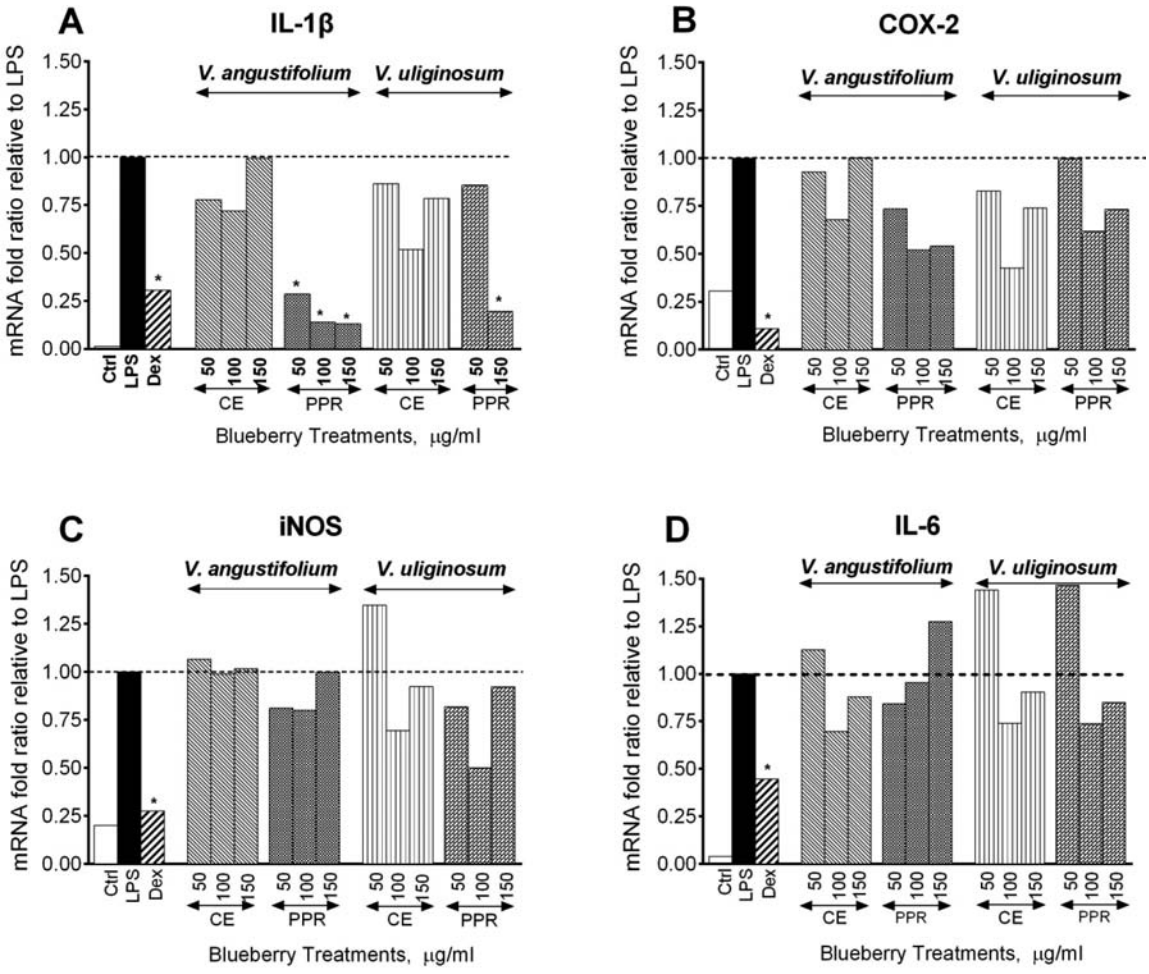

Figure 6. Anti-inflammatory bioactivity of wild Alaskan and commercial *Vaccinium* crude extracts (CE) and polyphenol-rich fractions (PPR); effects on the expression of the inflammatory biomarker genes in the LPS-stimulated RAW264.7 macrophages at 50, 100, and 150 μg/mL. Genes involved in the acute-phase response, inflammatory response, and humoral immune responses are represented: IL-1β assay (A), COX-2 assay (B), iNOS assay (C), and IL-6 assay (D). Changes in gene expression were measured by comparing mRNA quantity relative to LPS. A value of <1.0 indicates transcriptional down-regulation (inhibition of gene expression) compared with LPS, which shows maximum genetic induction (1.0). Ctrl, cells treatment with vehicle only; Dex, dexamethasone at 10 μM used as positive control.

phenols.[34] All PPR fractions were highly enriched with ANC, PAC, and TP, with the Alaskan lowbush cranberry showing the highest concentration of PAC (215.6 mg/g, Table 5). Lowbush blueberry PPR extract contained the highest ANC content among all berries and higher levels of PAC compared to bog blueberry. The anti-inflammatory capacity of the berries is likely to be conditioned by the combination of flavonoid phytochemicals contained in the extracts, as has been noted in previous research.[35]

In summary, wild Alaskan lowbush cranberry and commercial American cranberry are both rich in PAC, comprising about 45 and 38% of TP, respectively. The PAC content in wild lowbush cranberry was >2-fold higher than that in commercial cranberry. Compositional analyses indicated that commercial cranberry accumulates a richer concentration of procyanidin A-type dimers and trimers, whereas wild lowbush cranberry accumulates predominantly B-type dimers and trimers (>2 times that of A-type). Wild Alaskan lowbush cranberry is characterized by high levels of the flavan-ol catechin (32.4% of proanthocyanidin content) compared to commercial cranberry, in which epicatechins comprise most of the monomer content (21.8%). Cranberry A-type procyanidins are known to inhibit the attachment of uropathogenic *Escherichia coli* to uroepithelial and vaginal cells,[36] whereas wild lowbush cranberry has not been well evaluated for antiadhesion capacity. Alaskan bog blueberry demonstrated higher levels of all phenolic groups investigated and higher antioxidant capacity than commercial lowbush blueberry. Bog blueberry lacks acylated anthocyanins but contains higher levels of procyanidin A-type than lowbush blueberry. Investigations on acylated anthocyanins indicated that they may be less easily absorbed/less bioavailable than the nonacylated forms, a phenomenon which has been linked to their greater hydrophobicity.[37,38] Thus, compositional differences between berry sources may affect their biological activities. Alaskan wild berries are rich sources of antioxidants, based on their polyphenolic content and antioxidant capacity. Although wild berries in Alaska have limited accessibility, distribution, and availability and could not compete in commercial markets with cultivated berries, the enhanced accumulation of heath-beneficial wild berry constituents may represent a novel opportunity for development of Alaskan berries as a potential new niche market commodity, an American-grown specialty functional food to compete in the same market as several other exotic berry species currently in vogue.[39]

Changes in Chokeberry (*Aronia melanocarpa* L.) Polyphenols during Juice Processing and Storage

Kail Wilkes, Luke R. Howard,* Cindi Brownmiller, and Ronald L. Prior

Department of Food Science, University of Arkansas, 2650 North Young Avenue, Fayetteville, Arkansas 72704, United States

Supporting Information

ABSTRACT: Chokeberries are an excellent source of polyphenols, but their fate during juice processing and storage is unknown. The stability of anthocyanins, total proanthocyanidins, hydroxycinnamic acids, and flavonols at various stages of juice processing and over 6 months of storage at 25 °C was determined. Flavonols, total proanthocyanidins, and hydroxycinnamic acids were retained in the juice to a greater extent than anthocyanins, with losses mostly due to removal of seeds and skins following pressing. Anthocyanins were extensively degraded by thermal treatments during which time levels of protocatechuic acid and phloroglucinaldehyde increased, and additional losses occurred following pressing. Flavonols, total proanthocyanidins, and hydroxycinnamic acids were well retained in juices stored for 6 months at 25 °C, whereas anthocyanins declined linearly. Anthocyanin losses during storage were paralleled by increased polymeric color values, indicating that the small amounts of anthocyanins remaining were present in large part in polymeric forms.

KEYWORDS: *anthocyanins, chokeberries, flavonols, hydroxycinnamic acids, juice, processing, proanthocyanidins, storage*

INTRODUCTION

Chokeberries (*Aronia melanocarpa*) are gaining popularity as a result of their exceptional content of polyphenols. The berries are exceptionally rich in anthocyanins, which are responsible for the deep purple color. Chokeberry anthocyanins consist mainly of cyanidin glycosides (glucoside, xyloside, galactoside, and arabinoside), but the galactoside and arabinoside generally account for >75% of total anthocyanins.[1] Chokeberries are also rich in proanthocyanidins (PACs), which impart a very astringent taste. The proanthocyanidin profile of the berries is complex, ranging from monomers to decamers and to exceptionally high levels of polymers.[1] The berries also contain high levels of hydroxycinnamic acids (chlorogenic acid and neochlorogenic acid) and considerable levels of flavonols, mostly quercetin derivatives.[2−5] As a result of their exceptional polyphenol composition, chokeberries are thought to play an important role in protection against many chronic diseases. There is accumulating evidence that chokeberries or polyphenolic-rich extracts from chokeberries possess cardioprotective, hepatoprotective, antidiabetic, and anticarcinogenic effects.[6−10]

Due to their astringent taste, chokeberries are commonly processed and consumed in various shelf-stable forms including juices, nectars, wines, and liqueurs. Unfortunately, chokeberry processing has been shown to result in marked losses of anthocyanins.[11−13] Several studies have reported on the concentration of polyphenols in chokeberries, pomace, and juice, but results are expressed on a dry weight basis and do not provide any indications of actual concentrations in the three fractions as weights of the berries, juice, and pomace were not measured or taken into account.[3,13]

In addition to anthocyanin losses during juice processing, further extensive losses of anthocyanins during storage have been reported in other anthocyanin-rich berries.[14−16] Anthocyanin losses in these studies were paralleled by increased polymeric color values indicating anthocyanin−tannin polymers were formed during storage; these polymers are resistant to bleaching in the presence of potassium metabisulfite. Because chokeberries are particularly rich in polyphenols, we suspect that similar losses of anthocyanins and possibly other polyphenols occur during juice processing and storage. The objective of this study was to determine the fate of chokeberry anthocyanins, total PACs, hydroxycinnamic acids, and flavonols during various stages of juice processing and throughout 6 months of storage at ambient temperature.

MATERIALS AND METHODS

Frozen Berries. Frozen chokeberries (*A. melanocarpa* cv. Viking) were obtained from Mae's Health and Wellness (Omaha, NE, USA). The berries grown outside Davenport, NE, USA, were harvested at commercial ripeness and frozen within 4 hours after harvest. They were then transported overnight under refrigeration to the University of Arkansas, Food Science Department. Upon receipt, the berries were stored at −20 °C for <2 weeks prior to processing.

Chemicals and Reagents. A mixture of 3-*O*-*β*-glucoside standards of delphinidin, cyanidin, petunidin, peonidin, pelargonidin, and malvidin was obtained from Polyphenols Laboratories (Sandnes, Norway). HPLC grade methanol, acetone, formic acid, and acetic acid were obtained from Sigma-Aldrich (St. Louis, MO, USA). Chlorogenic acid, rutin, protocatechuic acid, phloroglucinaldehyde, (+)-catechin, 4-dimethylaminocinnamaldehyde, and quercetin were also obtained from Sigma-Aldrich.

Juice Processing. Chokeberries were processed into nonclarified juice as previously described.[14] The juice processing scheme with five sampling points indicated is shown in Figure 1. Frozen berries were

simultaneously heated and mixed with a Mixco Batch mixer (Avon, NY, USA) in a large steam kettle until the berry mash reached a temperature of 95 °C. After 3 min of incubation, the mash was allowed to cool to 40 °C prior to depectinization. Pectinex Smash XXL (Novozyme, Bagsvared, Denmark) was added at a concentration of 0.0827 mL/kg, and the mash was incubated for 1 h at 40 °C. Complete depectinization was verified by the negative alcohol precipitation test where no flocculation of pectin was observed following the addition of 2 volumes of 96% ethanol (v/v) to 1 volume of juice. The mash was then pressed in a 25 L Enrossi bladder press (Enoagricol Rossi, s.r.l., Calzolaro, Italy) operated at 20 psi to separate the juice from the presscake. The nonclarified juice was dispensed into 6 oz glass bottles and heated in a steam box (American Sterilizer Co., Erie, PA, USA) until the juice temperature monitored using a thermocouple reached 90 °C. The bottle caps were tightened, and the juices were allowed to cool overnight. Samples of each juice treatment were stored in the dark at 25 °C. Five samples were taken at each sampling point during the juicing process, and five bottles of juice were sampled after 1, 2, 3, 4, 5, and 6 months of storage at 25 °C.

Extraction of Polyphenols. For isolation of anthocyanins, hydroxycinnamic acids, and flavonols, five samples each of frozen and blanched berries, enzyme-treated mash, and presscake were homogenized with 20 mL of methanol/water/acetic acid (60:37:3, v/v/v) using a EuroTurrax T18 tissuemizer (Tekmar-Dohrman Corp., Mason, OH, USA) and then filtered through MiraCloth (Calbiochem, La Jolla, CA, USA). The residue was collected, the extraction repeated two more times, and the volume of the extracts adjusted to 100 mL with extraction solvent. The same protocol was used to isolate PACs except acetone/water/acetic acid (70:29.5:0.5, v/v/v) was used as extraction solvent. Juice samples were analyzed directly and required no extraction.

HPLC Analysis of Anthocyanins and Hydroxycinnamic Acids. Methanol/water/acetic acid extracts (8 mL) were dried using a SpeedVac concentrator (ThermoSavant, Holbrook, NY, USA) and resuspended in 1 mL of 3% formic acid in water. The reconstituted samples were passed through 0.45 μm PTFE syringe filters prior to HPLC analysis. Anthocyanin monoglycosides and hydroxycinnamic acids were separated by reverse phase HPLC on a Symmetry C_{18} column (Waters Corp., Milford, MA, USA) according to the method described by Cho et al.[17] Anthocyanins were monitored at 520 nm and hydroxycinnamic acids at 320 nm. Anthocyanin glycosides were quantified as cyanidin 3-glucoside equivalents and hydroxycinnamic acids as chlorogenic acid equivalents using external calibration curves of authentic standards. Protocatechuic acid and phloroglucinaldehyde were monitored at 280 nm and quantified using external calibration curves of authentic standards.

HPLC and HPLC-MS Analysis of Flavonols. Methanol/water/acetic acid extracts extracts (8 mL) were dried using a SpeedVac concentrator and resuspended in 1 mL of 50% methanol in water. The reconstituted samples were passed through 0.45 μm PTFE syringe filters prior to HPLC analysis. Individual flavonols were separated by reverse phase HPLC on an Aqua C_{18} column (Phenomenex, Torrance, CA, USA) according to the method described by Cho et al.[18] Flavonol peaks were monitored at 360 nm and quantified as rutin equivalents using external calibration curves of an authentic standard. Quercetin was quantified using an external calibration curve of an authentic standard. The identification of flavonols was performed by HPLC-MS using the HPLC conditions described above, except the HPLC system was interfaced to a Bruker Esquire LC-MS ion trap mass spectrometer (Billerica, MA, USA). Mass spectral analysis was conducted in negative ion electrospray mode using conditions previously described in Cho et al.[18]

Percent Polymeric Color Analysis. Percent polymeric color of methanol/water/acetic acid extracts from samples taken throughout juice processing and juices was determined using the spectrophotometric assay of Giusti and Wrolstad.[19] Absorbance values of two matching samples, one treated with water (control) and the other with potassium metabisulfite, were recorded at 420, 520, and 700 nm. Potassium metabisulfite was used to bleach the monomeric anthocyanins present in the juices, whereas polymeric anthocyanins resistant to bleaching remain colored. The ratio of the absorbance value of the potassium metabisulfite bleached sample to the control sample (nonbleached) × 100 reflects percent polymeric color.

Total Proanthocyanidin Analysis. Total PACs were measured by the 4-dimethylaminocinnamaldehyde (DMAC) assay of Prior et al.[20] The absorbance (640 nm) of samples in 96-well plates was measured every min for 30 min on a BioTek Synergy HT (Winooski, VT, USA) plate reader. Catechin was used as standard with results expressed as milligrams of catechin equivalents per 100 g berry fresh weight.

Calculations. To account for dilution and concentration effects, anthocyanin, flavonol, proanthocyanidin, hydroxycinnamic acid, and phenolic acid concentrations were converted to original berry weight to allow comparison of all samples on an equivalent basis. The following equation was used:

$$C_{berry} = C_{product} \times R$$

C_{berry} = concentration on original berry weight basis, R = mass of the product divided by mass of original berry, and $C_{product}$ = concentration in the product.

Statistical Analysis. The effects of processing and storage on anthocyanin, hydroxycinnamic acid, flavonol, total proanthocyanidin, and phenolic acid concentrations and percent polymeric color were determined by one-way analysis of variance (ANOVA) using JMP 8.0 (Cary, NC, USA). Differences between means (n = 5) were determined by Student's t test (α = 0.05).

RESULTS AND DISCUSSION

Polyphenol Composition of Chokeberries and Juice. Cyanidin 3-galactoside (cyd 3-gal), cyanidin 3-glucoside (cyd 3-glu), cyanidin 3-arabinoside (cyd 3-ara), and cyanidin 3-xyloside (cyd 3-xyl) were identified and quantified by HPLC (Supporting Information Figure S1), and the results are presented in Table 1. These anthocyanins were previously identified in chokeberry juice by HPLC-MS using identical HPLC conditions described above.[21] Cyd 3-gal and cyd 3-ara

were the major anthocyanins in the chokeberry samples and juices, confirming previous results.[1−4] Two hydroxycinnamic acids, neochlorogenic acid (NCA) and chlorogenic acid (CA), were present in the berries and juices (Supporting Information Figure S2 and Table 1). The high concentrations of NCA and CA in chokeberry samples and juices confirm previous findings.[3,4] Eight flavonols were identified by HPLC and HPLC-MS (Supporting Information Figure S3) and included the following derivatives of quercetin: two dihexosides (m/z 625/301), vicianoside (arabinosyl-glucoside) (m/z 595/301), robinobioside (rhamnosyl-galactoside) (m/z 609/301), rutinoside (rhamnosyl-glucoside) (m/z 609/301), galactoside (m/z 463/301), glucoside (m/z 463/301), and aglycone (m/z 301). All of these compounds have previously been identified in chokeberries.[4,5] The quantities of individual flavonols in samples taken throughout juice processing are presented in Table 2. The relative abundance of quercetin derivatives in frozen berries was similar to findings of Mikulic-Petkovsek,[5] who reported that galactoside was the predominant quercetin derivative followed by glucoside, rutinoside, vicianoside, robinobioside, and dihexosides. The amount of total flavonols in frozen chokeberries in our study, 33.9 mg/100 g FW, falls within the range of values (26−71 mg/100 g FW) previously reported for fresh chokeberries.[4,5]

Processing Changes in Chokeberry Polyphenols and Percent Polymeric Color. *Anthocyanins.* Anthocyanins were readily degraded during the two thermal treatments, blanching and pasteurization, as well as physical removal of the presscake (Table 1). Cyd pentosides (ara and xyl) were more susceptible to degradation during blanching (63 and 64% losses, respectively) than cyd hexosides (gal and glu, 52 and 45% losses, respectively). A similar trend was observed in response to pasteurization with cyd 3-ara and cyd 3-xyl, each incurring 69% losses, whereas cyd 3-gal and cyd 3-glu showed 58 and 50% losses, respectively, compared with levels found in nonpasteurized juice. Our results are consistent with previous studies reporting anthocyanin hexosides to be more stable than pentosides.[12,21,22] Following pasteurization, the juices contained only 8, 12, 4, 4, and 7% of the levels of cyd 3-gal, cyd 3-glu, cyd 3-ara, cyd 3-xyl, and total anthocyanins found in frozen chokeberries. A major loss of anthocyanins also occurred during the pressing operation when presscake containing seeds and skins was removed from the mash. The presscake contained 52, 51, 54, and 54% of the levels of cyd 3-gal, cyd 3-glu, cyd 3ara, and cyd 3-xyl found in the enzyme-treated mash, respectively, with most of the balance transferred to the juice. These results indicate that chokeberry presscake is an excellent source of anthocyanins and may be useful as a substrate for recovering natural pigments. The anthocyanin losses observed in response to thermal treatments were much higher than those previously reported for blueberry,[14] blackberry,[15] and black raspberry[19] juices processed under similar conditions. The extensive anthocyanin losses observed in this study could be due to several factors. It is clear that thermal treatments had a detrimental effect on anthocyanins. We observed significant increases in two HPLC peaks following blanching that were identified as protocatechuic acid (PCA) and phloroglucinaldehyde (PGA) (Figure 2), and the concentrations of these two compounds increased upon thermal treatments (Figure 3). Levels of PCA and PGA increased by 343 and 400% after blanching, by 30 and 24% from blanched berries to enzyme treated mash, and by 29 and 7% from nonpasteurized to pasteurized juice. The formation of PCA and PGA in response

to thermal treatments is consistent with the scheme of cyanidin 3-glycoside degradation proposed by Sadilova et al.[23] According to Sadilova et al.,[23] the first step of pH-dependent thermal degradation of cyanidin at pH 3.5, which is similar to the pH of chokeberries used in this study, involves opening of the pyrilium ring and chalcone glycoside formation. The next step involves deglycosylation to yield chalcone, which degrades quickly in the presence of heat to protocatechuic acid, 4-hydroxybenzoic acid, and phloroglucinaldehyde. We did not detect 4-hydroxybenzoic acid in our chromatograms, which is consistent with results reported for heated elderberry extracts that are also rich in cyd glycosides.[23] However, the increases in

cyd degradation products PCA and PGA during processing accounted for only about 3% of the losses in total anthocyanins that occurred during processing. The presence of ascorbic acid and pro-oxidant metals in the chokeberries may have played a role in anthocyanin degradation.[24] Enzymes such as polyphenol oxidase and peroxidase are also reported to cause degradation of anthocyanins,[25−27] but the frozen chokeberries used in this study were immediately blanched to inactivate enzymes. The extensive loss of anthocyanins during blanching was most likely due to the long time it took the 23 kg batch of frozen chokeberries to heat to the blanching temperature of 95 °C and then cool to 40 °C. In an additional experiment involving a 5.4 kg batch of chokeberries, in which it took 12 min for the frozen berries to heat to 95 °C and 3 min to cool to 40 °C, we observed a 25% loss of anthocyanins. Because chokeberry anthocyanins appear to be very heat labile, use of a blanching treatment prior to depectinization may be counterproductive, especially if the berries contain low polyphenol oxidase activity.

Percent Polymeric Color. Percent polymeric color values decreased in response to blanching and enzyme treatments, which may indicate cleavage of some anthocyanin−tannin linkages (Table 1). The major change in polymeric color occurred when juice was pasteurized, from 13.4% in non-pasteurized juice to 29.4% in pasteurized juice. According to Kunsagi-Mate et al.[28] the formation of anthocyanin−tannin polymers is slow at room temperature due to the high activation energy of the reaction, but is accelerated at elevated temperatures. Hence, the increased polymeric color values observed following pasteurization may reflect higher levels of anthocyanin−tannin polymers, which may account for some of the losses of monomeric anthocyanins.

Hydroxycinnamic Acids. The level of NCA did not change in response to blanching, whereas the level of CA increased by 14%, indicating CA was not completely extracted from frozen berries (Table 1). Significant losses of HCAs occurred during the pressing operation. The presscake contained 33 and 37% of the levels of NCA and CA found in enzyme-treated mash, respectively, whereas the NP juice contained 67 and 62% of NCA and CA, respectively. Levels of NCA and CA were minimally affected by pasteurization with CA and total HCAs showing no losses and NCA showing a 7% loss compared with the value for NP juice. Following pasteurization, the juices contained 60, 65, and 63% of the levels of NCA, CA, and total HCAs found in frozen chokeberries, respectively.

Total Proanthocyanidins. The levels of total PACs were stable upon blanching, but increased by 11% following the enzyme treatment (Table 1). Disruption of cell wall polysaccharides presumably allowed for enhanced extraction of the PACs following enzyme treatment. The major loss of total PACs occurred during the pressing operation. The presscake contained 60% of the levels of total PACs found in enzyme-treated mash, whereas the NP juice contained 46%. Surprisingly, PACs increased 17% in response to pasteurization. This may be due to disruption of cell wall polysaccharide−proanthocyanidin complexes, which allowed more PACs to react with the DMAC reagent. It is also possible that pasteurization resulted in depolymerization of large molecular weight PACs to monomers, which are reported to react more readily with the DMAC reagent than polymers.[20]

Flavonols. Levels of quercetin dihexosides, vicianoside, robinobioside, and rutinoside showed modest increases (11−20%) in response to either blanching or enzyme treatment, compared with values for frozen berries, whereas levels of the

[a]Mean values (n = 5) within a column with different letters are significantly different ($p \leq 0.05$). Values in parentheses represent percent retention compared with pasteurized juice.

two major quercetin conjugates, galactoside and glucoside, and total flavonols were stable (Table 2). Significant losses of flavonol glycosides occurred during the pressing operation, with 39−49% of the compounds being retained in the presscake, whereas 54−64% were expressed into the juice. The less polar quercetin hexosides (galactoside and glucoside) were retained to a greater extent in the presscake (48 and 49%) than the more polar quercetin diglycosides (39 and 41%). Additionally, the majority of the nonpolar quercetin aglycone was retained in the presscake, whereas only 27% was expressed into the juice. Pasteurization did not affect levels of the two quercetin hexosides, but other derivatives decreased by 16−21% in response to pasteurization. Although present at low level, the concentration of quercetin aglycone increased by 63% in response to pasteurization, indicating that some sugar conjugates were cleaved from the quercetin glycosides in response to thermal treatment. Overall, total flavonol levels decreased by 15% in response to pasteurization.

Storage Changes in Chokeberry Polyphenols and Percent Polymeric Color. *Anthocyanins.* Levels of cyd 3-gal, cyd 3-glu, cyd 3-ara, cyd 3-xyl, and total anthocyanins in juices declined in a linear fashion over 1−5 months of storage at 25 °C, but levels appeared to stabilize from 5 to 6 months (Table 3). After 6 months of storage, the juices lost 75, 75, 76, 64, and 75% of the levels of cyd 3-gal, cyd 3-glu, cyd 3-ara, cyd 3-xyl, and total anthocyanins, respectively, found in juices after 1 month of storage. These results are consistent with other studies reporting marked losses of anthocyanins during ambient-temperature storage of chokeberry juice,[21,29] nectars, and purees.[11] The type of sugar attached had little effect on anthocyanin stability during long-term storage, which contrasts with results observed in response to thermal treatments during processing, where hexosides showed greater retention than pentosides (Table 1). Consistent with our findings, Hellstrom et al.[29] reported no differences in stability of chokeberry anthocyanin glycosides stored at 4, 9, and 21 °C over 12 weeks of storage. The mechanisms responsible for anthocyanin degradation during storage have not been well elucidated, but may be associated with water nucleophilic attack at the 2-position of the anthocyanin nucleus, resulting in decolorization,[30] or the formation of anthocyanin−tannin polymers.[31] Levels of PCA and PGA were stable for up to 3 months of storage and then declined about 30% from 3 to 6 months of storage (data not shown), indicating that anthocyanins were not degraded into phenolic acids during ambient temperature storage.

Percent Polymeric Color. Percent polymeric color values of the juices increased (from 34.8 to 44.5%) from 1 to 6 months of storage, and these values were inversely correlated with anthocyanins (r = −0.81) (Table 3). These changes indicate that some losses of anthocyanins throughout storage may be due to the formation of anthocyanin−epicatechin polymers that are resistant to bleaching by potassium metabisulfite in the polymeric color assay. However, it is also possible that the anthocyanin−epicatechin polymers formed in the juices during processing were more resistant to degradation during storage. The anthocyanin−epicatechin polymers appeared to play an important role in color stability as the juices retained a dark purple color despite marked losses of monomeric anthocyanins.

Hydroxycinnamic Acids. In contrast to anthocyanins, levels of NCA, CA, and total HCAs were stable from 1 to 3 months of storage (Table 3), but levels declined by about 30% from 3 to 6 months of storage. Levels of chlorogenic acid in blueberry and chokeberry juices were also found to be relatively stable over long-term storage at ambient temperature.[29,32]

Total Proanthocyanidins. Levels of total PACs were stable (>90% retention) from 1 to 6 months of storage (Table 3). The stability of PACs over storage contrasts with the marked decline in anthocyanins and increase in percent polymeric color values observed from 1 to 6 months of storage. These results indicate that PACs did not react with anthocyanins to any great extent to form polymeric pigments throughout storage. This finding supports the hypothesis that polymeric pigments formed during processing are more resistant to degradation than monomeric anthocyanins and play an important role in color stability.

Flavonols. Quercetin glycosides and aglycone were stable from 1 to 4 months of storage at 25 °C, but levels decreased by 17−29% from 4 to 6 months (Table 4). Total flavonol levels decreased by 21% from 4 to 6 months of storage at 25 °C. Levels of quercetin followed the same trend as quercetin glycosides, indicating that losses of glycosides from 4 to 6 months of storage were not due to cleavage of sugar moieties. The losses of flavonols late during storage may be due to physical binding to insoluble solids, resulting in precipitation, or oxidation to quinones.

In summary, juice processing had a much greater effect on polyphenol losses in chokeberries than did storage of juices at 25 °C. Anthocyanins were more susceptible to losses during

processing than flavonols, total PACs, and hydroxycinnamic acids as a result of thermal degradation, evident by increased levels of protocatechuic acid and phloroglucinaldehyde, and polymerization, evident by increased polymeric color values. The juice pressing step resulted in losses of all polyphenols due to physical removal of skins, but anthocyanins and total PACs were retained in the presscake to a greater extent than hydroxycinnamic acids and flavonols. Flavonols, total PACs, and hydroxycinnamic acids were well retained over 6 months of storage at 25 °C compared with anthocyanins, which degraded in a linear manner up to 5 months. Losses of anthocyanins during storage were accompanied by increased polymeric color values, indicating that the small amounts of anthocyanins remaining after long-term storage were present largely in polymeric forms. The polymeric forms of anthocyanins appear to be more stable than monomeric anthocyanins and likely play an important role in color stability. Novel, cost-effective treatments are needed to stabilize anthocyanins during chokeberry juice processing and storage.

ABSTRACT: Polyphenolic phytochemicals (PPs) have been extensively studied as potential nutriceuticals for maintenance of health and treatment of cancer, inflammation, and neurodegeneration. However, the reported beneficial outcomes are inconsistent. The biological activities of PPs have been attributed to their pro-oxidative and antioxidative actions and effects on signaling mechanisms and epigenomic modifications. These diversified properties were described or postulated on the basis of a variety of experimental studies using cell culture and animal models, even though most have not been replicated and results are not validated. This review attempts to give an overview of biological properties of PPs, based on the coherent results from relevant studies, and evaluate critically the experimental conditions and possible artifacts. Complicated molecular mechanisms and multitargeting genomic interactions of PPs are discussed, with a view that reasonable mechanistic propositions are usually obtained from well-designed in vivo studies.

KEYWORDS: *phytochemical polyphenols, antioxidation, pro-oxidation, signaling, epigenetic*

INTRODUCTION

Polyphenolic phytochemicals (PPs) are bioactive secondary metabolites found in a variety of plants. These compounds have diversified chemical structures and properties and are formed by one or more six-carbon aromatic rings with at least two hydroxyl groups. According to the structure and position in the biosynthetic pathways,[1−3] they can be classified into three major classes: (1) hydroxycinnamic acids, (2) chalcone, and (3) flavonoids, which include flavonols, flavones, isoflavones, flavanones, procyanidins, and anthocyanins/cyanidin (Figure 1). Although hydroxycinnamic acid has only one hydroxyl group, it shares common functional properties with other polyphenols.

PPs are commonly found in different species of plants and are involved in many biological activities essential for survival. They contribute to the color in leaves, flowers, and fruits, attracting insects and facilitating reproduction and dissemination. They protect plants against pathogens, repel insect attacks, and minimize harmful effects of ultraviolet light. They act also as antioxidants to scavenge free radicals generated during photosynthesis.[4,5]

Most polyphenols are flavonoids. Their nuclear structures are composed of two aromatic rings, A and B, linked to an oxygenated heterocyclic ring C. They are further divided into subclasses according to the extent of hydrogenation and the position of the heterocyclic ring. Polyphenols are commonly found in fruits and vegetables. Various types of quercetin glucoside derivatives are commonly found in onion, broccoli, lemon, and grapefruit,[6−8] whereas rutin is rich in asparagus and buckwheat.[9,10] Isoflavones are found in soy milk, beans, and vegetable proteins;[6,11] anthocyanidins in red and bluish cherries;[6,12] proanthocyanidins in grape seed and red wine;[13,14] ellagic acid derivatives in grapes and strawberries;[15−17] catechins in green and black tea;[6,18] and kaempferol glycosides and derivatives in broccoli and radish[19,20] (Table 1). Other important polyphenol groups are phenylpropanoids (e.g., hydroxycinnamic acid), stilbenoids (e.g., resveratrol), and benzoic acids.

Structural Properties. The potent antioxidant property of polyphenols is mainly attributed to the chemical structures. Polyphenols contain an ortho-diol or trihydroxyl group in the B ring and a meta-5,7-dihydroxyl group in the A ring. The diol group forms a complex with metal ions, allowing the polyphenol to scavenge catalytic ions and prevent free radical generation.[21,22] The 2,3-double bond conjugates with keto groups in the C ring. Hydroxyl groups are present at the 3- and 5-positioned for efficient hydroxylation without steric hindrances.[23−25] The hydroxyl group maintains chemical stability by delocalizing electrons captured from free radicals and reacts with peroxyl radicals to form anthocyanin-like compounds,[26] seven-member B-ring anhydride dimers, and ring-fission compounds. In addition, some flavonoids are both lipophilic and hydrophilic, enabling them to dissolve at the interface between plasma membrane and aqueous layer.[25,27] Therefore, they can quench the propagation of free radicals formed during

Table 1. Phytochemicals and Their Natural Sources

phytochemicals	natural sources	refs
quercetin glucoside derivatives	onions, broccoli, lemon, and grapefruit	6−8
rutin	asparagus and buckwheat	9, 10
isoflavones	soy milk, beans, and vegetable proteins	6, 11
anthocyanidins	red and bluish cherries	6, 12
proanthocyanidins	grape seed and red wine	13, 14
ellagic acid derivatives	grapes and strawberries	15−17
catechins	green and black tea	6, 18
kaempferol glycosides and derivatives	broccoli and radish	19, 20

lipid peroxidation. They also regenerate oxidized α-tocopherol in the lipid membrane and oxidize ascorbic acid and glutathione in the aqueous layer.[28,29]

Different mathematical methods for structure−activity relationships have been used to predict the antioxidant and pro-oxidant properties of flavonoids. Antioxidative potency and inhibitory effect on matrix metalloproteinase (MMP) expression are related positively to the number of OH groups on the B ring (e.g., in myricetin, queretin, kaempferol, luteolin, apigenin, and chrysin), as determined by diphenyl-2-picrylhydrazine (DPPH) and xanthine/xanthine oxidase assays.[30,31] Fukumoto and colleagues[32] also used β-carotene bleaching and HPLC to study the antioxidative activity of polyphenolic compounds and found PPs with more hydroxyl groups and less

dx.doi.org/10.1021/jf500080z | J. Agric. Food Chem. 2014, 62, 4026−4038

glycosylation demonstrate higher antioxidative activities. Quantitative structure−activity relationship (QSAR) models are applied to correlate physical properties of polyphenols with pro-oxidant activity. The cytotoxicity is associated with single electron oxidation in polyphenols.[33,34] Hydrophobicity, in terms of partition coefficient (w/o), is also found correlated to apoptosis and cytotoxicity.[35,36] The three-dimensional (3D) topographic structure has been used to predict the effect of PPs on caspase-mediated apoptotic activity.[37] Comparative molecular field analysis (CoMFA) and comparative molecular similarity indices analysis (CoMSIA) have shown positive correlation of steric and hydrophobic fields of different phenols with caspase-mediated apoptosis. Substituents with larger hydrophobicity at position 2 and less hydrophobicity at position 4 favor the activity, whereas substituents with more electronegativity at position 4 and less electronegativity at position 3 also increase the activity. On the other hand, the position of hydroxyl groups, dipole moment magnitude, and the shape of molecules also correlate with the inhibition of lipid peroxidation and antioxidation observed in melatonin derivatives and flavonoids.[38,39] The 3D structure of flavonoid has also been related to the radical-scavenging activity.[40,41] The energy of the highest occupied molecular orbital and the energy of heat formation both contribute significantly to the radical-scavenging activity. These may explain why flavonoids with 3′,4′-dihydroxy groups at the B ring, a 3-OH group, or an increased number of −OH groups show higher radical-scavenging activity. The methyl or *o*-glucoside substituent does not affect the activity. In summary, the concentration, physicochemical property, and physical and topological structures are important factors influencing the antioxidant, pro-oxidant, and enzyme modulatory properties of polyphenols.

BENEFICIAL EFFECTS OF POLYPHENOLIC PHYTOCHEMICALS TO HUMAN HEALTH

Epidemiological Studies. Epidemiological studies, however, do not indicate conclusive results on beneficial effects of PP consumption on human health. There are difficulties in interpreting results of case-control studies, likely caused by differences in confounding factors, variations in quantifying dietary PP consumption, lack of objective biomarker measurements, differences in disease etiology, geographic location and population, and genetic polymorphism and heterogeneity.[42] Nevertheless, there are strong links between PP intake and reduced incidence of cardiovascular disease and cancer.[43] Also, over 200 case-control studies and cohort studies have shown associations between tea consumption and reduced risk for colon, lung, stomach, breast, prostate, ovarian, pancreatic, kidney, and bladder cancers.[42] However, the results reported in these studies are rather inconsistent.[44] More epidemiological studies and intervention trials are needed to confirm the direct beneficial effects of PPs.

Animal Studies. Well-designed intervention studies may provide a better understanding of beneficial effects of PPs.[45−47] For cancer prevention, most in vivo studies are carried out in animal disease models. In particular, many studies have shown that tea polyphenols are able to inhibit tumorigenesis during the initiation, promotion, and progression stage of cancers.[48] Cancer models of the alimentary canal have been investigated extensively with positive results.[44] The anti-carcinogenic effectiveness is possibly due to direct exposure of high concentration of PPs to the tissues along the alimentary tract. Tea polyphenols inhibit the spontaneous development of small intestinal tumors in a dose-dependent manner, which is associated with an increased E-cadherin signaling and reduced expression of nuclear β-catenin, MYC (transcription factor regulating gene), phospho-Akt (protein kinase B), phospho-ERK1 (extracellular-signal-regulated kinases 1), and phospho-ERK2.[49] Skin and lung cancers are also studied with favorable outcomes. In a mouse model of adenocarcinoma, a high dose of green tea extract (0.5% Polyphenon E) is given daily to mice for 52 weeks. This treatment has shown to inhibit cell proliferation, increase apoptosis, and decrease levels of phosphorylated transcription factors Jun, ERK1 and ERK2.[50] Co-treatment of tea polyphenols and lipid-lowering agent Atorvastatin can down-regulate the anti-apoptotic proteins, induce myeloid leukemia cell differentiation protein (MCl1) and B-cell lymphoma-extra-large protein (Bcl-XL), and so stimulate apoptosis in a synergistic inhibitory manner both in vivo and in vitro.[51]

Cell Culture Studies. Under certain circumstances, flavonoids are pro-oxidative, especially at high doses and in the presence of metal ions.[52,53] It has been reported that a lot of food contains polyphenols, especially flavonoids (quercetin, myricetin, kaepferol, and caffeic acid) that exert pro-oxidant effects.[54−57] Although the pro-oxidant property of polyphenols has been postulated to prevent colon cancers,[58,59] pro-oxidation can induce mitochondrial dysfunction, leading consequently to apoptosis of cancer cells and mobilization of endogenous catalytic copper, which induces oxidative damage of proteins, DNA, mitochondria, and lipids inside the cell.[60,61] Although these reactions occur mainly in in vitro condition, diseases that involve increased systemic ion overload, such as hemochromatosis,[107] may result in serious internal lesions if highly reducing polyphenols are administered to reduce the free ion loading.[62]

BIOLOGICAL PROPERTIES OF POLYPHENOLIC PHYTOCHEMICALS

Antioxidation. PPs can scavenge directly the reactive oxygen species (ROS) and chelate divalent metal ions to reduce the oxidative activity. PPs also exert indirect antioxidant effects through induction of endogenous protective antioxidative enzymes. This indirect activity acts primarily through activation of nuclear factor-erythroid-2-related factor 2 (Nrf2), which stimulates antioxidative enzymes such as glutathione peroxidase (GPx), glutathione *S*-transferase, catalase, NAD(P)H:quinone oxidoreductase-1 (NQO1), and/or phase II enzymes.[63] Notably, these indirect activities involve up-regulation of antioxidant enzymes or cytoprotective proteins[64] and provide more efficient antioxidant actions in vivo.[65,66] Although PPs are strong antioxidants in vitro, their direct free radical neutralization activity is reported in only a small number of in vivo studies, because of the limited bioavailability[67] and the presence of excessive oxidative stress.

Pro-oxidation. PPs can be oxidized to generate ROS in cell culture medium that results in cell death.[68] This pro-oxidant effect appears to be responsible for the induction of apoptosis in cancer cell studies. The pro-oxidant activity is most prominent under experimental conditions such as high pH and excessive availability of transition metal ions and oxygen molecules,[69] which cause chemical instability, depletion of cellular GSH, and mobilization of cellular copper ions.[65] The ROS generation may subsequently activate Nrf2 antioxidant-responsive element pathway to induce production of antioxidative and detoxifying enzymes.[70] Nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) has

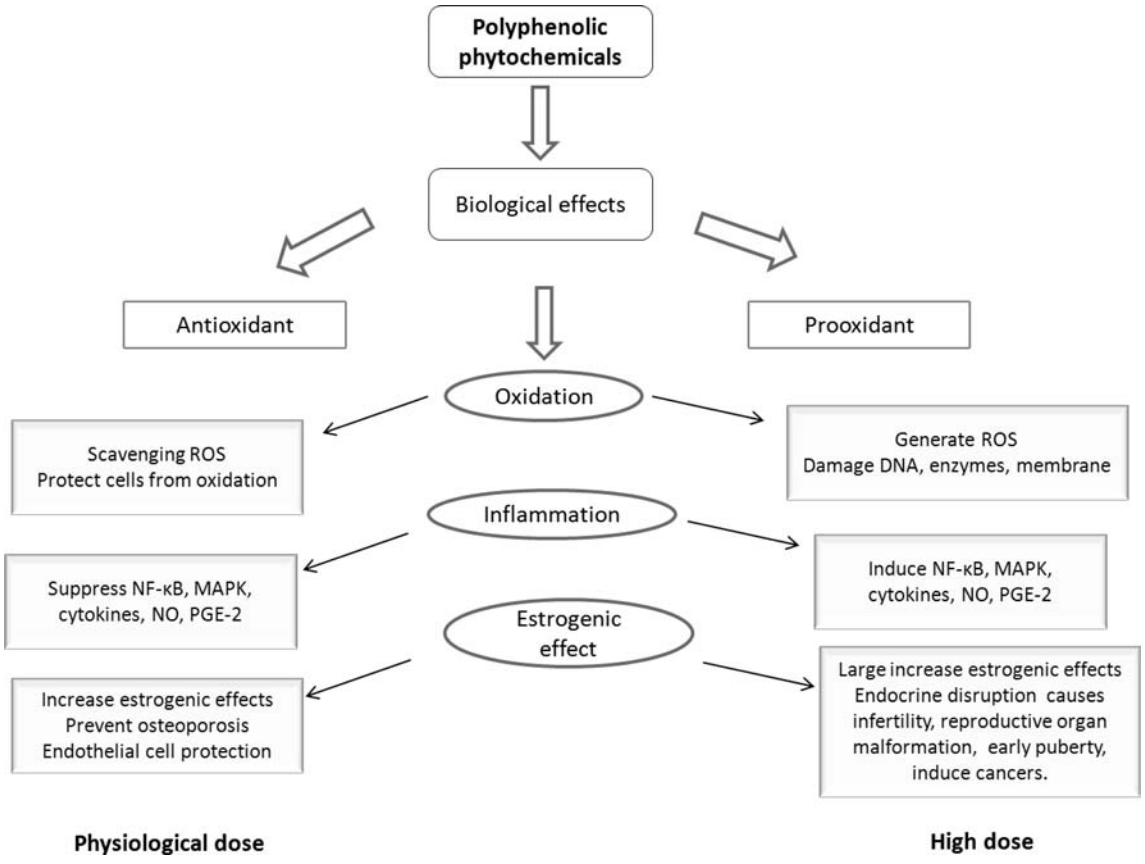

Figure 2. Schematic diagram shows PPs exhibit different biological effects under different dosages.

been described as a redox-regulated transcription factor because it is activated by oxidative stress and inhibited by various antioxidants. Interactions between these NRF2 and NF-κB occur likely because their upstream signaling molecules, such as mitogen-activated protein kinases (MAPK), phosphatidylinositide 3-kinases (PI3K), and protein kinase C (PKC), are closely regulated.[71]

Inflammation Inhibition. PPs may act as inflammation modulatory agents by down-regulating NF-κB and inducing inflammatory cytokine release through ROS generation.[72] Oxidized low-density lipoprotein (LDL) is a major constituent of atherogenic plaques on the vascular wall that induce macrophage foam cell formation and thrombotic activity.[73] PPs inhibit oxidation of LDL[74] and modulate the inflammatory process through inhibition of mitogen-activated protein (MAP) kinases, NF-κB, and tumor necrosis factor alpha (TNF-α) and induction of vascular cell adhesion molecules (VCAM) and c-Jun N-terminal kinase activity.[75]

Interaction with Signaling Molecules and Enzymes. EGCG has been studied extensively and shown to be an enzyme inhibitor in the phosphorylation of proteins and kinases such as JNK, JUN, MEK1, MEK2, ERK1, ERK2, and ETS domain-containing protein (ELK1). The inhibition is associated with activator protein 1 (AP1) transcriptional activity and cell transformation.[76,77] Cyclin-dependent kinase 2 (CDK2) and CDK4, which are associated with cell cycle at G0 and G1 phases, are inhibited by EGCG.[78] EGCG has also been reported to inhibit the chymotryptic activity of 20S proteasomes, leading to G0 and G1 cell cycle arrest and accumulation of p27 and NF-κB inhibitor (IκB).[79] EGCG also increases the expression of tissue inhibitor of metalloproteases 1 (TIMP1) and TIMP2[80] and activates dihydrofolate reductase, glucose-6-phosphate dehydrogenase, and glyceraldehyde-3-phosphate dehydrogenase.[63] Moreover, green tea extract, in which EGCG is the major polyphenol, also up-regulates γ-glutamyltransferase, glutamate cysteine ligase, hemoxygenase-1, and glutathione *S*-transferase P.[81,82] On the other hand, curcumin prevents hematogenous breast cancer metastases in immunodeficient mice through reduction of NF-κB activity and down-regulation of AP-1 to suppress MMPs expression.[83]

Many studies have demonstrated an inhibitory effect of EGCG on EGF receptor signaling pathways, which are frequently overexpressed in cancers and associated with poor prognosis.[84] Phosphorylation of hepatocyte growth factor receptor (HGFR) and AKT1, which are important in epithelial-mesenchymal transition in tumorigenesis and metastasis, has been shown to be completely blocked by EGCG.[85] EGCG also decreases the RNA and peptide level of vascular endothelial growth factor A (VEGFA), disrupts VEGFA-induced VEGFR2 dimerization, and suppresses the downstream PI3K activity.[86] In prostate cancer models, tea polyphenols suppress cell proliferation and increase apoptosis through inhibition of VEGF-A, MMPs, and insulin-like growth factor 1 (IGF1) signaling pathways.[87,88] Currently, more than 20 human trials with tea polyphenol preparations have been planned or conducted. However, only a few have been completed or have yielded clear and consistent conclusions.[89]

The eight hydroxyl groups of EGCG can serve as hydrogen bond donors. EGCG has been shown to bind to salivary proline-rich proteins, fibronectin, fibrinogen, histidine-rich glycoproteins, metastases associated 67 kDa laminin receptor, and the BH3 pocket of anti-apoptosis Bcl-2 proteins.[90] Using a

Sepharose 4B column, 2D electrophoresis, and MALDI-TOF mass spectroscopy, EGCG is reported to bind directly to vimentin, insulin-like growth factor 1 receptor (IGF1R), proto-oncogene tyrosine-protein kinase (FYN), glucose-regulated proteins (GRP78), and zeta-chain-associated protein kinase 70 (ZAP70), which are associated with cell cycle regulation, cell proliferation, and cell survival.[63] In addition, EGCG can physically bind to nucleic acids, suggesting that DNA and RNA are also targets of tea polyphenols.[91]

Epigenomic Modulation. PPs function as potent modulators for mammalian epigenetic regulation through DNA methylation, histone acetylation, and histone deacetylation.[92] EGCG inhibits both DNA methyltransferase (DNMT) and histone acetyltransferase (HAT), leading to DNA demethylation and histone H3 and H4 deacetylation in human telomerase-reverse transcriptase (hTERT) promoter, respectively. These events affect epigenomic regulation and chromatin restructuring that result in hTERT down-regulation and telomerase inhibition, leading ultimately to cell apoptosis.[93,94] Inhibition of DNMT also causes demethylation of hypermethylated promoters of tumor suppressor gene such as inhibitors of CDK4A (INK4A), retinoic acid receptor-β, the DNA repair genes MutL homologue 1 (MLH1), and methylguanine methyltransferase.[95] Such epigenetic inhibition of estrogen receptors is mainly due to hypomethylation of hTERT promotor, deacetylation of histone by DNMT, and HAT inhibition.[96] EGCG causes chromatin remodeling by histone acetylation and DNA methylation to reactivate ERα receptor of breast cancer cells; that is, antiestrogen treatment is possible.

EGCG can also suppress DNA methylation, DNMT, and histone deacetylase (HDAC) activity. It lowers DNMT expression and increases histone acetylation. These effects lead to suppression of cancer proliferation.[97−99] EGCG also modulates immunity, possibly through epigenetic regulation of T cells, to suppress autoimmune diseases.[100] Curcumin also produces necrosis and apoptosis of cancer cells through epigenetic regulation of HAT, HDAC, DNMT, and miRNA to modulate gene expression.[101−103] The epigenetic inhibition also targets the upstream phosphodiesterase, which hydrolyzes signaling molecules such as cAMP and cGMP, resulting in antiproliferation of melanoma cells.[104]

CONTROVERSY OF BIOLOGICAL EFFECTS OF POLYPHENOLS

Oxidative stress is the result of overproduction of oxygen-derived free radicals caused by ultraviolet light exposure, allergen, pollution, smoking, emotional stress, intensive exercise,[105,106] and excessive fat and carbohydrate consumption.[107−109] Even normal cellular metabolism can generate oxygen-derived reactive species that need antioxidants for neutralization.

Controversy on Antioxidation and Pro-oxidation Properties. PPs are known for their antioxidative effects, which are presumably beneficial to health. Many diseases are attributed to chronic exposure to oxygen-derived radical species, for example, cardiovascular diseases,[110] cancers,[111] and neurodegenerative disorders.[112] Antioxidant treatment, in particular PP, has been proposed to alleviate these diseases by free radical neutralization. These antioxidative properties have been demonstrated in many studies. For example, quercetin (a flavonoid) protects rat H41E cells against H_2O_2-induced cytotoxicity at low doses (10−25 μM).[113] γ-Resorcyclic acid and hydrobenzoic acid[114] remove excess ions at low pH by chelating ions and forming stable complexes. Green tea can inhibit lipoprotein oxidation induced by Cu^{2+} ion.[115] However, these antioxidative effects have been demonstrated only in cell culture experiments.[116]

Table 2. Key Publications of Biological Mechanisms of Polyphenols

mechanism	contents	refs
antioxidation	• reaction mechanisms of different polyphenols scavenging free radical and oxidized to different compounds	21, 26
	• indirect antioxidant increase anti-oxidative enzymatic and signaling activities	64
	• bioavailability of polyphenols	67
pro-oxidation	• polyphenols generate ROS present in culture medium	125, 126
	• pro-oxidation appears at high concentration PPs and ions	69, 70
	• pro-oxidative effect provokes enzymatic and signaling molecular activation	70, 71
inflammation	• pro-oxidative effect provokes enzymatic and signaling molecular activation	74
modulation signaling and enzymes	• PPs involve different signaling pathways and regulation enzymes	76, 79, 81, 82
epigenomic modulation	• pro-oxidative effect provokes enzymatic and signaling molecular activation	92, 94, 102

In contrast, many cell culture studies instead show polyphenols exhibit pro-oxidant properties, particularly when they are applied at high doses.[117,118] For example, quercetin at 50 μM promotes superoxide production in cell culture condition.[117] The survival rate, viability, thiol level, total antioxidative capacity, and antioxidative enzyme activities are all reduced under this high dose.[118] The cytotoxic effect is probably caused by DNA damage and apoptosis as a result of ROS production through autoxidation at high concentration.[119,120] However, the toxicity is not observed even at an oral dose as high as 2000 mg/kg in mice, probably because of low bioavailability and the high metabolic rate in the animals.[121]

Moreover, instead of chelating metal ions, a high level of strong antioxidant PPs (e.g., 50 μM−1 mM EGCG) can induce a pro-oxidative effect in the presence of metal ions.[119,122,123] EGCG induces DNA fragmentation in cells as a result of oxidative damage[119] by hydrogen or electron donation to catalytic metal ions, for example, Fe^{3+} and Cu^{2+}, that generates free radicals via the Fenton reaction.[107] In addition, PPs, including EGCG, can generate free radicals, superoxides, and hydrogen peroxide species in cell culture medium, for example, Dulbecco's modified Eagle medium (DMEM).[124−126] Oxidative stress may be arbitrarily induced in the surrounding medium instead of through the intracellular biological processes in some cell culture experiments.

Extrapolation of Results from Cell Culture Studies. Many beneficial effects of PPs and their association with antioxidant and pro-oxidant properties have been proposed on the basis of studies in cultured cell lines. It has been speculated from experimental conditions that cannot be recapitulated in in vivo conditions. For example, to demonstrate the pro-oxidative effect, high concentrations of PPs are added into the culture

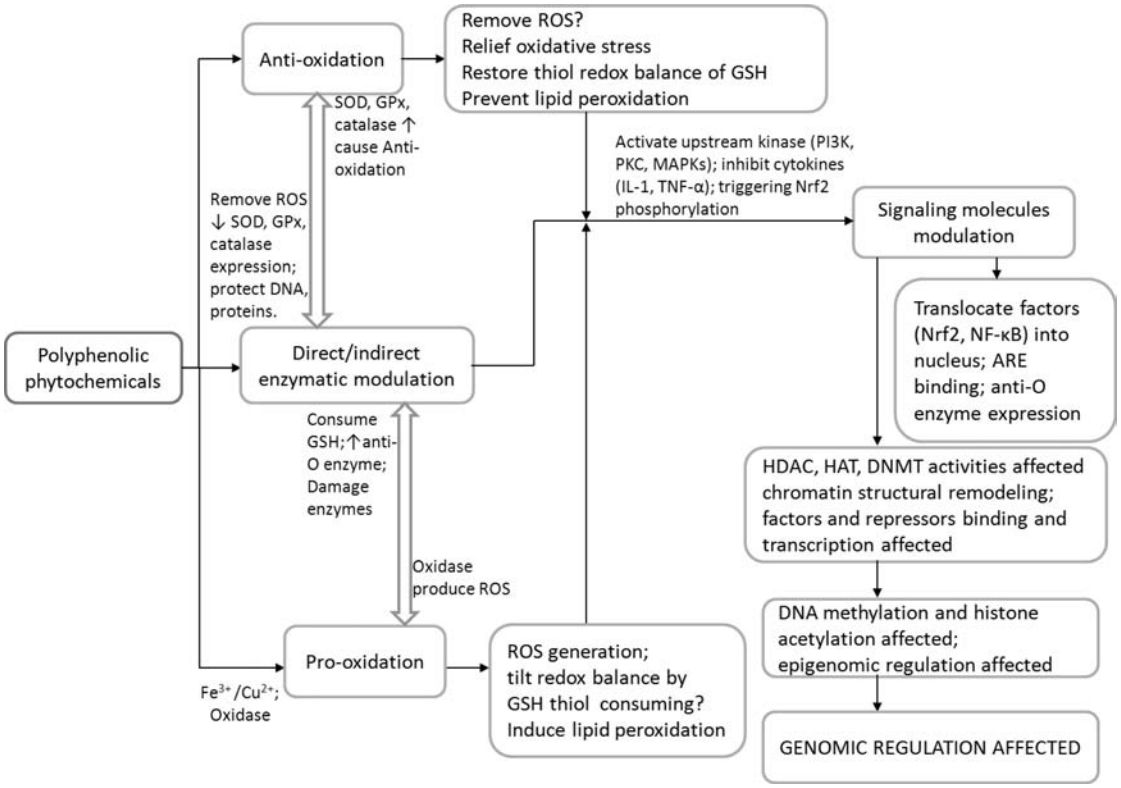

Figure 3. Schematic diagram shows the possible interactions between different mechanisms affecting the final genomic regulation. Polyphenolic phytochemicals can act as antioxidants or prooxidants under different conditions to tilt the redox status that affects signaling molecules response, modify the epigenetic regulation, and eventually affect genomic expression. On the other hand, they can directly bind to regulatory enzymes or indirectly influence their activities that induce the signaling cascades and eventually affect the genomic regulation.

medium.[127] An extraordinarily high concentration (250 μM) of flavonoid (quercetin and fisetin) has been used to show that flavonoid can induce DNA damage and apoptosis.[113] However, this high level of flavonoid cannot be reached in physiological conditions in vivo. Moreover, because most flavonoids are not completely water-soluble, to achieve such a high concentration the researchers have to dissolve the compounds in dimethyl sulfoxide (DMSO).[128] The solvent may enhance membrane permeability to increase the intracellular concentration of PPs. Practically, this method cannot be applied for human treatment. For the green tea extract, Polyphenon E, which has been used for clinical trial in humans suffering from colon cancer, the maximum dose, 1200 mg of EGCG, tested produces only a C_{max} of EGCG in plasma at about 7.3 μM for a transient period.[129] The bioavailability of PP is actually limited in in vivo condition. On the other hand, some researchers apply strong reducing antioxidants to high concentration of free ions, such as Fe^{3+} and Cu^{2+}, to investigate their pro-oxidative potential.[62,119] Again, this condition is not achievable under normal physiological conditions because almost all catalytic ions are bound onto proteins, cofactors, and enzymes. Only a low concentration of free ions (e.g., ~10^{-18} M intracellular Cu^{2+})[130] is available. Flavonoids at such low ion concentrations would act as chelators instead[131] (Figure 2).

Controversy in Reaction Kinetics and Pharmacokinetics of Polyphenols. The scavenging property of PPs has been questionable because the rate of free radical generation is very fast (rate constant ranged from 8.29×10^6 M^{-1} s^{-1} for phenol to 4.03×10^9 M^{-1} s^{-1} for catechol) when compared to scavenging rates of polyphenols (~4×10^3 M^{-1} s^{-1}).[132,133] Therefore, the free radicals are expected to have damaged surrounding molecules before they are captured by the polyphenol. In addition, from the pharmacokinetic point of view, it remains suspicious that whether the low in vivo concentration of PPs, for example, a plasma level of green tea (0.1−0.7 μmol/L for an intake of 90−150 mg catechins), cocoa (0.25−0.7 μmol/L for an intake of 70−165 mg cocoa procyanidins), or red wine (0.09 μmol/L flavonoids for an intake of 35 mg polyphenols),[134,135] is able to neutralize the surge in production of free radicals from the chain reaction. Furthermore, only a transient and modest increase in total antioxidant activity is reported in the plasma of humans[136] and rats,[137] even after administration of a substantial dose of green tea extract (GTE), probably caused by a limited bioavailability[138] and strong redox buffering in plasma.[139]

Controversy in Experimental Design. It is still unclear whether PPs have any direct antioxidant effects in vivo.[140] To confirm the antioxidative protection of EGCG, some studies precondition the retinal pigment epithelial cells with high concentrations of EGCG (~100 μM) before exposure to oxidative stress induced by H_2O_2 in the cell culture.[141] However, the results showed that the antioxidative enzyme and protein kinase levels (superoxide dismutase, catalase, and protein kinase C) are increased after addition of EGCG, indicating that EGCG, on the contrary, acts as a pro-oxidant during the preconditioning period, inducing expression of antioxidative enzymes to adapt and defend against later oxidative insult through receptor binding.[142,143] These pro-oxidative phenomena have been demonstrated in other studies, showing that endogenous antioxidative systems are induced in normal tissues to protect against later carcinogenic insults.[58] The preconditioning involves direct activation of NF-κB

without association with antioxidation. Furthermore, EGCG has been supplemented to a cancer cell culture to study its antioxidative effects. However, the anticancer effect is abolished after the addition of SOD and catalase, which is consistent with its pro-oxidative role.[144] These findings show that many in vitro experimental designs suffer from hypothesis-driven biases and may overlook some basic properties of experimental parameters.

Further investigations would be needed to confirm whether these effects can be extrapolated to in vivo situations or used for therapeutic application. The partial pressure of oxygen is much lower in the in vivo environment than in cell culture medium. The physiological composition of biological fluid is different from the medium. The bioavailability of polyphenols cannot be achieved to the same level as in the cell culture condition. The pH and redox buffering capacity is more effective in in vivo condition than in culture condition. Moreover, compartmental barriers appear in vivo. Digestion and metabolic transformations occur in vivo but not in vitro. In fact, our unpublished results showed that both antioxidative and pro-oxidative effects coexist in the rat eye after administration of green tea extract. The oxidative status depends on the type of tissues and the EGCG dosage. In short, the biological effects of PPs in vivo are the results of complex and interacting mechanisms, suggesting that animal models should be used to investigate the biological properties of PPs rather than using cell culture models.

Moreover, to understand the biological effects of a particular PP isolated from natural products in vivo, it is more appropriate to compare the effects of a genetically modified natural product without the PPs with the same natural product that contains a high concentration of those PPs. This type of experimental design includes the effect of matrix present in the natural products. With the recent advanced targeting genome editing technologies,[145] such as single guided RNA cleavage, these mutants are easily generated nowadays to facilitate in vivo analysis.

Biological Differences between Compounds Present in Natural Products and Purified Form. Epidemiological studies demonstrate that constant intake of polyphenols from a natural diet offers many health benefits.[146−149] These results imply that long-term administration of PPs at low dose from natural sources (e.g., 143 mg of flavonoids per 100 g of apple[150]) provides beneficial health effects. It is different from taking isolated polyphenols because no apparent health benefits or even harms are reported in long-term administration.[151,152] This discrepancy may be attributed to the presence of plant matrix and synergic effects of different PPs from natural products. It is supported by a study in the rat that the heart is protected from ischemia-reperfusion injury after taking mutated anthocyanin deficient maize added with concentrated anthocyanins compared to the pure mutant maize.[153] Although some animal models of diseases showed that purified polyphenols, such as quercetin, rutin, and EGCG, alleviate oxidative damages induced by ischemia-reperfusion and other interventions,[154,155] other studies reported carcinogenicity and toxicity in rodents on high-dose and long-term administration.[156,157] Therefore, the source, dosage, duration of administration, and animal model are important factors to determine whether the effects are beneficial or harmful.

Interactions with Signaling Molecules. Recently, the biological effects of polyphenols have been attributed to their interactions with signaling molecules. Examples include inhibition of phosphorylation of mitogen activated protein (MAP) kinase,[158] AP-1, and ELK-1/2 through direct competitive binding on the proline-rich site.[159] The importance of this interaction is further supported by congeners with similar chemical properties. EGCG and its related compound theaflavin-3,3′-digallate inhibit the MEK1 and Raf-1 pathways, respectively, suggesting that the effects are independent of redox status but with their specific structures. The interaction can involve direct binding or indirect signaling modulation.[84] Interestingly, the IC_{50} doses reported in these studies are about 0.1 μM, which is close to the physiological level of PPs.

Flavonoids have been shown to bind to many key binding sites including the ATPase binding site, which affects a number of signaling molecules such as calcium plasma membrane ATPase and protein kinases,[160] which are involved in the regulation of many cellular processes. This may explain why PPs affect a wide range of biological activities, which could be beneficial in one instance and harmful in others. For example, the estrogen-like activity of isoflavones through binding to β-estradiol receptors can relieve menopause symptoms but induce breast and prostate cancer.[161,162]

These biological activities likely involve multiple molecular mechanisms rather than single receptors or molecular targets. Apart from antioxidative and pro-oxidative mechanisms, PPs also inhibit inflammation, enzyme activities, and signal transduction pathways, resulting in the suppression of cell proliferation and enhancement of apoptosis, as well as inhibition of cell invasion, angiogenesis, and metastasis in cancer cells. PPs have been shown to bind directly to several receptors[163,164] and signaling molecules,[165] and also inhibit the functions of key receptors,[166] kinases,[167] proteinases, and other enzymes.[168,169] These results may explain why PPs have such a variety of biological effects[80,95,170−172] and account for the fact that addition of SOD or catalase in the cell culture experimental studies cannot abolish completely PPs' actions.[173] However, evidence of direct interactions with receptors and enzymes comes largely from cell culture studies that involve high concentrations of PPs (5−100 μM) and defined experimental conditions. These direct interactions may not reflect the actions in physiological condition as nonspecific binding may occur at high concentration, and the polyphenol per se may be modified in the culture environment. For example, EGCG is epimerized to GCG when SOD is added.[174] This epimerized product inhibits epidermal growth receptor (EGFR) phosphorylation that may complicate the outcome of the experiment.[175]

Epigenomic Modulation. In addition to enzymatic and signaling regulation, polyphenols also exert antioxidative action through genomic and epigenomic regulations. EGCG is involved in the epigenetic regulation of apoptosis in cancer cells, which involves upstream inhibition of HAT and DNMT epigenetic mechanisms[176] that eventually affect the gene expression of antioxidative enzymes. As PPs are known to act as effective antioxidants, they may regulate functions of cellular epigenome through their antioxidative effects on the redox status.[177] PPs also act as pro-oxidants in the presence of Fe^{3+} and oxygen or in concert with oxidases to induce oxidative stress, which in turn cause modulation of cellular epigenome through oxidant and thiol-redox signaling. PPs are also known to involve in biotransformation into metabolites catalyzed by the cellular phase I and phase II xenobiotic-metabolizing enzymes, which may regulate the cellular epigenome through signaling cascades.

Summary. The complex properties and possible actions of polyphenols are summarized in Table 2 and Figure 3. Again, most molecular and genomic studies are conducted in cell culture studies. Whether these mechanisms reflect the biological processes in animals remains to be determined in future experiments.

PROSPECTIVES

Although aglycones can be absorbed from the small intestine, most natural polyphenols are esterified with glycosides. They need to be hydrolyzed by intestinal enzymes or colonic microflora before absorption.[178] Flavonoids are conjugated by methylation, sulfation, and glucuronidation in the small intestine, liver, and colon.[179] The remaining flavonoids in the colon are metabolized extensively by microflora to form small phenolic derivatives such as protocatechuic acid.[180] The hydrolyzed aglycones and breakdown products are absorbed into the colon and excreted into the bile in enteroheptic circulation.[179] Therefore, the bioavailability of polyphenols is low, and the systemic concentration of biochemical metabolites is usually far higher than that of their parent compounds.

To investigate the candidates and mechanisms contributing to the actual therapeutic effect, animal models should be the main tool for investigations instead of cell culture models, in which many essential parameters contributing to biological mechanisms cannot be replicated. Because of extensive biotransformation, the metabolites should be investigated as well as their parent compounds to find the effective constituents and understand the actual structure−activity relationship occurring in vivo. With the advanced development of high-throughput and sensitive LC-MS, GC-MS, and bioinformatics, a metabolomic approach may help to identify potential PPs and their metabolites as candidate drugs for various pathological processes.[181] Some biomarkers and indices such as oxidative stress level,[182] nitrogen oxidase synthetase, and COX pathways[183] have been established and evaluated extensively in rodents. High-sensitivity proteomic techniques should be used to detect changes of these biomarkers in a single sample, which can more likely help hunt down true candidates that contribute proper target responses for in vivo protection.

Discovery of PPs with multitargeting properties brings forth treatments with more therapeutic potential than those using a one-target−one-drug approach.[184] These drugs regulate relevant pathways simultaneously to achieve desirable biological effects, which are more effective, and the dosage and side effects are minimal. Moreover, an in vivo high-throughput screening (HTS) approach may help to characterize pharmacokinetics properties of PPs.[185,186] This approach involves giving a mixture of compounds with different scaffold structures into an animal disease model. By means of computational deconvolution technique, the lead compound with major action can be identified.[187] With these innovative technologies, the lead PP candidates and their underlying mechanisms in therapeutic treatments can soon be unraveled.

ABSTRACT: Recent advances in biofuel and bio-oil processing technology require huge supplies of energy feedstocks for processing. Very recently, new carinata seeds have been developed as energy feedstocks for biofuel and bio-oil production. The processing results in a large amount of coproducts, which are carinata meal. To date, there is no systematic study on interactive association between biopolymers and biofunctions in carinata seed as energy feedstocks for biofuel and bioethanol processing and their processing coproducts (carinata meal). Molecular spectroscopy with synchrotron and globar sources is a rapid and noninvasive analytical technique and is able to investigate molecular structure conformation in relation to biopolymer functions and bioavailability. However, to date, these techniques are seldom used in biofuel and bioethanol processing in other research laboratories. This paper aims to provide research progress and updates with molecular spectroscopy on the energy feedstock (carinata seed) and coproducts (carinata meal) from biofuel and bioethanol processing and show how to use these molecular techniques to study the interactive association between biopolymers and biofunctions in the energy feedstocks and their coproducts (carinata meal) from biofuel and bio-oil processing before and after biodegradation.

KEYWORDS: *carinata, molecular structure, biopolymer functions, nutrient profiles, molecular spectroscopy application, nutrient utilization, coproducts, biofuel/bio-oil processing*

INTRODUCTION

Carinata Seeds as Energy Feedstocks for Biofuel and Bio-oil Processing. With the development of environmentally friendly biofuel industry and bio-oil industry, vegetable oil is extracted from oilseed crops and widely utilized for biofuel and food oil production, because these oilseeds are renewable, nontoxic, nutritive sources and the biofuel made from them has lower emissions (e.g., particulates, carbon monoxide, hydrocarbons) than the normal fuel from petroleum.[1]

Brassica carinata (or Ethiopia mustard), which originates in Ethiopia, is an oilseed crop with development potential for the dry western Canadian prairie because of its good tolerance of heat and drought climate, high-salt[2] or clay soil, and its more productive character, compared with canola, which prefers to grow in a cooler environment with good moisture.[2−4] Recently, Ban and Yu[3] summarized growth conditions of carinata in comparison with canola.

Carinata seeds have a lower oil content (26−40%) compared with canola *Brassica napus*, and *Brassica carinata* has less oleic acid (28%) than *B. napus* (62%).[4−6] In addition, the linoleic and linolenic acid contents of carinata seeds are higher than those of *B. napus*.[4−7] With the development of the high oleic acid and low linolenic acid *B. carinata* germplasm,[8] the oil extracted from those seeds could be utilized for the food-grade oil industry.[3]

Similar to canola seeds, carinata seed and carinata meal still contain some antinutrients, which may inhibit the bioactivities of digestive enzymes and so decrease the digestibility and absorption of some important nutrients.[5,6,9] These antinutrients include erucic acids, glucosinolates, and condensed tannins. The structures of these antinutrients could be found on the Web[3] (http://en.wikipedia.org/wiki).

The oil extracted from canola seeds has <2% erucic acid (monounsaturated 22:1 omega-9 fatty acid with formula $CH_3(CH_2)_7CH{=}CH(CH_2)_{11}COOH$),[10] and for the whole canola seeds, the glucosinolates are around 16 μmol/g and the condensed tannins are 1.5−3.0 g/100 g.[9] A previous study showed that conventional carinata has a higher concentration of glucosinolates.[4] In our preliminary recent study,[5] we reported the antinutrient levels in carinata yellow and brown lines on the basis of a few samples.

Carinata Meal as Coproducts from Biofuel and Bio-oil Processing. With the rapid development of biofuel and bio-oil processing industries and the widely utilized oil seeds (e.g., carinata) in Canada, a large amount of coproducts, products after bio-oil extraction and biofuel processing, is generated. The carinata meal is regarded to be a good source of protein (48%) for animal feed, compared with canola meal (40%) in a

preliminary study for CFIA.[11] However, the metabolizable protein contents of carinata are still in question in comparison with canola meal.

Many research projects have been done on the application of both canola seeds and canola meal in the ruminant feed industry[12−17] and the monogastric feed industry.[18,19] However, few papers from other research groups could be found in the literature on carinata seeds and their coproducts (carinata meal) for their physiochemical or nutrient structure profiles and biopolymer functions as well as structure associated with nutritive degradation and digestion, so the quality of the carinata seeds and carinata meal from biofuel and bio-oil production is still unknown.

Molecular Spectroscopic Studies on Carinata Seeds and Their Coproducts from Biofuel and Bio-oil Processing. The true nutritive values of feeds are associated with both chemical composition and internal molecular structure, because the nutrient bioavailability and fermentation features are influenced by internal structure.[20,21] However, the inherent structures of feed samples are usually destroyed during the conventional "wet chemical analysis" methods (e.g., AOAC[22,23]), and the wet chemical analysis fails to link chemical composition to inherent structure.[20,24]

In recent publications,[24−26] cutting edge Synchrotron radiation based Fourier Transform Infrared Microspectroscopy (SR-IMS) has been applied as a rapid and noninvasive advanced technique to reveal the structure of feedstuff on a molecular basis within intact tissue. With six components (electron gun, linear accelerator, booster ring, storage ring, beamlines, and experimental stations), the synchrotron could turn electrons into extreme bright light and then show inherent structure of biological tissues.[27] This synchrotron-based technique is capable of showing four kinds of tissue information (tissue structure, tissue chemistry, tissue environment, and tissue composition) within different layers at the same time.[25,27,28] Several studies have been done with the successful application of this synchrotron technique to reveal molecular structure and structure changes by different treatments of various feedstuff in our laboratories.[20,21,29,30] With the development and application of this technique, the relationship between molecular structure and biological functions could be explained from the revealed differences in spectra from SR-IMS according to the previous research.[31−33] However, to date, few studies have been found on molecular structure in relation to biofunctions and bioavailability of nutrients in carinata seeds and carinata meal except our preliminary study.

Aims of This Review. This paper aims to provide research progress and updates in molecular spectroscopy on the energy feedstock (carinata seed) and the coproducts (carinata meal) from biofuel and bioethanol processing and show how to use the molecular techniques to study the interactive association between biopolymers and biofunctions in carinata seeds and their coproducts (carinata meal) from biofuel and bio-oil processing before and after biodegradation using a system approach.

Our research program with several projects aims to (1) systematically study the structure, physicochemical, and nutrition features of the yellow and brown types of carinata seeds for biofuel and bio-oil production as well as the coproducts after the processing compared with canola seeds and canola meal in terms of (a) molecular structural spectral features by synchrotron SR-IMS and ATR-FT/IR techniques, (b) special chemical compounds and chemical profiles, (c) protein and carbohydrate fractions and their contributions to rumen bypassed protein and carbohydrate (d) energy values in beef and dairy production, (e) rumen degradation kinetics/rumen fermentation characteristics, and (f) intestinal availability of primary nutrients and true nutrient supply to dairy cattle; and (2) explore the relationship between new line structure and nutrient availability to assist further development of new lines of carinata seeds for the biofuel, bio-oil, and animal feed industries.[3]

CURRENT CARINATA BIOFUEL AND BIO-OIL PROCESSING AND THEIR COPRODUCT PRODUCTION

Biofuel Process and Coproduct Production. The biofuel process of carinata seed is similar to that of rapeseed. Reference 34 provides a schematic graph to clearly show detailed biofuel processing from rapeseeds.[34] As stated in GEA,[34] "Bio-fuel from rapeseed oil seed is one of the most promising biofuels. In contrast to bio-diesel, Bio-fuel from rapeseed oil is a chemically unmodified vegetable oil. Transesterification is not required and the basic molecular structure of the vegetable oil can be retained, to allow it to be used in the engines of trucks, airplanes or agricultural vehicles converted to use rapeseed oil",[34] so do carinata seeds.

Bio-oil Processing and Coproduct Production. The bio-oil process of carinata seed for human consumption is similar to that of rapeseed, too. Reference 35 also provides a very good schematic graph to show bio-oil processing from rapeseeds.[35] The detailed processing procedure has been reported in many papers with some modifications in the procedure. We do not repeat it here.

CURRENT BIOFUNCTION/NUTRITION STUDIES ON CARINATA AS ENERGY FEEDSTOCKS AND COPRODUCTS (CARINATA MEAL) FROM BIOFUEL AND BIO-OIL PROCESSING

Synchrotron-Based Molecular Spectroscopy for Molecular Structure Studies of Carinata Seed as Energy Feedstocks for Biofuel and Bio-oil Processing. Synchrotron radiation based infrared microspectroscopy (SR-IMS), as a rapid and noninvasive advanced technique, has several advantages and is capable of showing four kinds of tissue information: structure, chemistry, environment, and composition.[24,26,28] To date, no study has been found on molecular structure in relation to biofunctions and nutrient availability in carinata seeds and carinata meal in other laboratories. Currently we are trying to apply synchrotron-based technology (the SR-IMS technique) to compare newly developed yellow-type and brown-type carinata seeds.

Brief Procedure for Synchrotron Study. Carinata seeds are cut into thin cross sections and then transferred to spectral IR windows for the SR-IMS study. Then a microscope linked to a digital camera from the window in the synchrotron centers takes photomicrographs of the cross section of the sample tissues.[25,32] Our previous paper[25] provided a detailed description of the methodology and procedure. The synchrotron infrared spectra are obtained in the mid-IR region (ca. 4000−800 cm^{-1}) with an aperture setting of 10 × 10 μm and 128−256 co-added scans at a spectral resolution of 4 cm^{-1}.

Univariate Molecular Spectral Analysis. The parameters shown on the spectrum could be analyzed for the band intensities, integrated intensities, band frequencies, and band intensity ratios.[36] OMNIC software (Spectra Tech., Madison,

WI, USA) is used to analyze the spectral data. Several parameters of carbohydrate and protein functional groups are detected as the following: structural carbohydrate peak height and area (SCHO with theoretical baseline of ca. 1487−1190 cm^{-1}); cellulosic compound peak height and area (CELC with theoretical baseline of ca. 1306−1191 cm^{-1}); total carbohydrate peak height and area (CHO with theoretical baseline of ca. 1198−896 cm^{-1}); protein amide I and II height and area (theoretical baseline of ca. 1728−1478 cm^{-1}; peaks are amonbetween ca. 1728−1576 and 1576−1478 cm^{-1}); α-helix and β-sheet peak height and area (peaks within ca. 1662−1650 and ca. 1636−1620 cm^{-1}, theoretically). The detailed peak intensity height and area ratios would be calculated.

Multivariate Molecular Spectral Analysis. The multivariate data analysis creates spectral corrections and maps according to all of the spectral information. Statistica 8.0 software (StatSoft Inc., Tulsa, OK, USA) is used to analyze the differences of carbohydrate-related and protein-related molecular conformation between carinata seeds and canola seeds in our preliminary study. The multivariate analyses agglomerative hierarchical cluster analysis (AHCA) and principal component analyses (PCA).[37−39] In AHCA, distance matrix and then the two most similar IR spectra (minimal distance) within the distance matrix are calculated. Then new "hierarchical group" (or "cluster") is obtained by combining these spectra, and spectral distances between all remaining spectra and the new cluster are recalculated. The results of the spectral data set would be shown as dendrograms. In PCA, the original variables are transformed to the uncorrelated variables called "principal components" (PCs), of which the first few account for >95% of the variance, to reduce the amount of linear combinations (PCs) with the same information.[37−39]

Infrared Molecular Spectroscopy of ATR-FT/IR for Molecular Structure Studies on Biofuel and Bio-oil Coproducts (Carinata Meals). The carbohydrate, protein, and lipid molecular spectra of the carinata meal and canola meal can be studied by infrared molecular spectroscopy of ATR-FT/IR or DRIFT.[5,11,40−46] Brief procedure is as follows: Sample spectral data are collected using the FT/IR with ATR (JASCO Corp., Tokyo, Japan). All of the samples are ground through a 0.25 mm screen two times. Then the IR spectra are obtained under the mid-IR region (ca. 4000−800 cm^{-1}) with 64 or 128 co-added scans at a spectral resolution of 4 cm^{-1}. For univariate molecular spectral analysis, the parameters shown on the spectrum can be analyzed for the band intensities, integrated intensities, band frequencies, and band intensity ratios.[36] OMNIC 7.3 (Spectra Tech., Madison, WI, USA) is used to analyze the spectral data. Several parameters of carbohydrate and protein functional groups are detected as follows:[5,11,41−43] structural carbohydrate peak height and area (SCHO with theoretical baseline of ca. 1487−1190 cm^{-1}); cellulosic compound peak height and area (CELC with theoretical baseline of ca. 1306−1191 cm^{-1}); total carbohydrate peak height and area (CHO with theoretical baseline of ca. 1198−896 cm^{-1}); protein amide I and II height and area (theoretical baseline of ca. 1728−1478 cm^{-1}, peaks between ca. 1728−1576 and ca. 1576−1478 cm^{-1}); α-helix and β-sheet peak height and area (peaks within ca. 1662−1650 and ca. 1636−1620 cm^{-1}, theoretically). For multivariate molecular spectral analysis, the multivariate data analysis creates spectral corrections and maps according to all of the spectral information. Statistica 8.0 software (StatSoft Inc.) is used to analyze the differences of carbohydrate-related and protein-related molecular conformation using the multivariate analyses.[39] For the detailed application, please see the following sections.

Wet Chemical Profile Studies. To access the chemical profiles and nutrient value of energy feedstocks and coproducts, analysis of their constituent compositions is essential. The most common method of nutrient constituent evaluation is proximate analysis, which separates nutrients that are required by the animal. With the proximate analysis, water, crude protein, crude fat, fiber, nonfiber carbohydrate, minerals, etc., can be measured. In this way, the magnitude of differences in chemical profiles can be detected.[11] Brief analysis procedures are as follows: The samples are ground and screened to a final particle size of 1 or 0.5 mm for the following chemical analyses. All of the samples are analyzed in duplicate and repeated if the error exceeds 5%. Detailed compositions and methods were dry matter (DM, %, AOAC official method 930.15), ash (% DM, AOAC official method 942.05), EE (or crude fat, % DM, AOAC official method 954.02), and crude protein (% DM, AOAC official method 984.13) analyzed by the procedures of AOAC.[22,23] Different types of fiber and lignin [acid detergent fiber (ADF, % DM, % NDF), neutral detergent fiber (NDF, % DM), acid detergent lignin (ADL, % DM, % NDF)] are analyzed by the procedures in Van Soest et al.[47] Samples are incubated with bicarbonate−phosphate buffer and filtered through Whatman filter paper for analyzing total soluble crude protein (SCP, % CP, % DM). The nonprotein nitrogen (NPN, % SCP, % CP, % DM) content is obtained by precipitating true protein in the filtrate with trichloroacetic acid (TCA, 10%) and determined as the difference between total N and the N content of the residue after filtration. Acid detergent insoluble protein (ADICP, % CP, % DM) and neutral detergent insoluble protein (NDICP, % CP, % DM) are measured according to the procedures of Licitra et al.[48] Starch (% DM, % NFC, % CHO) is analyzed using the Megazyme Starch Assay Kit. The nonstructural carbohydrates (NSC) or nonfibrous carbohydrates (NFC) (% DM, % CHO), fatty acids (FA, % DM), and NDFn (N adjusted) are calculated according to the formula of NRC dairy.[49] NSC is measured by enzymatic methods (Smith, 1981). NFC = 100 − (% NDF + % CP + % fat + % ash); FA = EE − 1; NDFn = NDF − NDICP). The detailed chemical profiles of carinata seed and meals have been reported recently.[11,41]

Biodegradation and Bioavailability Prediction Using the Cornell Net Carbohydrate and Protein System (CNCPS) Based on Chemical Profiles in Energy Feedstocks and Coproducts. The CNCPS is a mathematical model developed on the basis of animals, feeds, management conditions, and different environmental conditions. The protein fractions are partitioned according to CNCPS 6.1.[50−52] The characterizations of the protein fraction can be divided as fraction PA (nonprotein N), fraction PB (true protein), and PC (unavailable protein). In fraction PB, there are fraction PB1 (rapidly degraded protein with degradation rate of 1.20−4.00/h), PB2 (intermediately degraded protein with degradation rate of 0.03−0.16/h), and PB3 (slowly degraded protein with degradation rate of 0.0006−0.0055/h) divided according to the differences on ruminal degradation rates. Fraction PB1 is degraded in the rumen, fraction PB2 is insoluble in buffer but soluble in neutral detergent, and fraction PB3 is soluble only in acid detergent. Fraction PB2 can be estimated with the differences between buffer-insoluble protein and fraction PB3. Fraction PC is considered to be undergradable protein (like ADICP) because it is highly resistant to microbes and

mammalian enzymes. The CHO fraction is partitioned based on CNCPS 6.1 into fraction CA1 (volatile fatty acids, VFA), fraction CA2 (lactic acid), fraction CA3 (other organic acids), fraction CA4 (sugars), fraction CB1 (starch), fraction CB2 (soluble fiber), fraction CB3 (available neutral detergent fiber, NDF), and fraction CC (unavailable NDF).

In the CNCPS 6.1 model, rumen degraded and bypassed protein as well as bypassed CHO will be estimated on the basis of the contribution from each fraction. The following parameters will be determined: RDPA, RDPB1, RDPB2, RDPB3, total RDP = RDPB1 + RDPB2 + RDPB3, where RDPA is ruminally degraded protien A fraction, RDPB1 is ruminally degraded PB1, RDPB2 (g/day) is ruminally degraded PB2, RDPB3 is ruminally degraded PB3, and total RDP is ruminally degraded peptides/protein REPB1, REPB2, REPB3, and REPC, where REPB1 is ruminally escaped protein B1, REPB2 is ruminally escaped protein B2, REPB3 is ruminally escaped protein B3, and REPC is ruminally escaped protein C. RDCA is ruminally degraded CA, RDCB1 is ruminally degraded CB1, and RDCB2 is ruminally degraded CB2. RECA is ruminally escaped carbohydrate A, RECB1 is ruminally escaped carbohydrate B1, RECB2 is ruminally escaped carbohydrate B2, and RECC is ruminally escaped carbohydrate C. The fraction studies in carinata seed and carinata meals by CNCPS system have been reported recently from our laboratories.[11,41]

Energy Evaluation. In the NRC-2001 model, energy requirements for maintenance and milk production are described on the premise of metabolic body size (NE_m), tissue (NE_g), and milk (NE_L) composition. The feed energy values are also expressed on the basis of feed NE_m, NE_g, and NE_L values. In feeds, the total digestible nutrient (TDN) and digestible energy (DE), metabolizable energy (ME), and net energy (NE) are used to estimate available energy according to the NRC dairy 2001. Gross energy is measured using a Parr adiabatic bomb calorimeter (model 1200, Parr Instrument Co., Moline, IL, USA). Using the NRC 2001 system, tdNDF, tdNFC, tdCP, tdFA (% DM), TDN_{1X}, ME_{3X}, NE_m, NE_g, and NE_{Lp} can be determined. Detailed energy studies in energy feedstock (carinata seeds) and coproducts (carinata meals) have been reported recently from our laboratories.[5,11,41−43]

In Situ Technique for Degradation Kinetic Study. In situ incubation is a widely used method of evaluating ruminant feed according to the rate and extent of degradation. This involves suspension of tested feed material in the rumen, allowing for contact between the tested feed and actual rumen environment.[53] The rate and extent of rumen degradation of particular test feed are evaluated by the analysis of in situ residue samples after incubation. This fractionates nutrients into three fractions depending on their rumen availability. These fractions are soluble, potentially degradable, and undegradable fractions, named A, B, and C or S, D, and U, respectively.[54,55]

Brief Procedure. The samples are ground through 3 mm screens or using a roller (coarsely ground); then ca. 7 g of DM is placed into each nylon bag with the pore size of approximately 40 μm and subsequently put into the rumen. The rumen incubation is performed according to the schedule of "gradual addition − all out" for 48, 24, 12, 8, 4, 2, and 0 h. After that, all of the bags should be pulled out and washed in cool water without detergent and then dried at 55 °C for 48 h (including the 0 h bags). Later, the dried samples will be pooled and stored at 4 °C.[54]

The rumen degradation parameters can be estimated according to the modified first-order kinetics model[56−58] and NRC model.[49] The soluble fraction (S), undegradable fraction (U), and potentially degradable fraction (D) and the degradation rate in % h^{-1} (K_d) and the lag time (T_0) can be calculated on the basis of the first-order kinetic models to fit the fermentation or disappearance curves (goodness of fit) using the nonlinear and logarithmic-linear mathematical models.[56,59,60]

Gamage[61] summarized the potential sources of variation associated with the in situ nylon bag technique as animal, bag, substrate, temporal, procedural aspects and mathematical component, bag pore size, sample to bag ratio, particle size, bag incubation sequence, relative location of nylon bags suspended in the rumen, feeding frequency, diet composition, type of animal used, washing after incubation, and selection of mathematical model. In our preliminary study, we reported detailed kinetics studies in carinata seed and meals and their rumen residues.[5,11,41−46]

Intestinal Digestion Estimation. Intestinal digestibility of rumen undegraded feed protein (% RUP) is estimated by a three-step in vitro procedure (using in situ 12 or 16 h rumen incubation residue).[62] A brief procedure is as follows: (1) If using 16 h rumen incubation, nylon bags need to be filled with feed samples and then incubated in the rumen for 16 h. (2) After 16 h of rumen incubation, the residue is weighed to contain about 15 mg of N and put into a 50 mL centrifugation tube. Then 10 mL of 0.1 N HCl solution containing 1 g/L of pepsin is added into the tube, and the weighed residue is incubated for 1 h at 38 °C. (3) After incubation, the pH is neutralized by adding 0.5 mL of 1 N NaOH and 13.5 mL of pancreatin solution (pH 7.8, 0.5 M KH_2PO_4 buffer containing 50 ppm of thymol and 3 g/L pancreatin). The tube is vortexed and incubated at 38 °C in a shaker water bath for 24 h. All of the samples should be vortexed every 8 h. (4) Then 3 mL of a 100% (w/v) trichloroacetic acid solution is added to the tube immediately to stop the enzymatic action precipitating undigested protein. The tube is vortexed and kept for 15 min. (5) The samples are centrifuged at 10000*g* for 15 min and analyzed for soluble N in the supernatant. Pepsin−pancreatin digestion of protein is calculated as trichloroacetic acid-soluble N divided by sample nitrogen content (bag residues).[62] This technique has been used to estimated intestinal digestion of protein in energy feedstock (carinata seed) and coproducts (carinata meals).[5,11,41−46]

Modeling Truly Absorbable Protein Supply to the Small Intestine. To model true protein digested and absorbed in the small intestine, three models are most widely used, TDN-based NRC-2001 model in North America and non-TDN-based model DVE/OEB model[57,58,63] and PDI system in Europe. These models have been developed on the basis of the many previously developed nutritional models and incorporate some new approaches.[54,64−66] There is an updated version of DVE/OEB protein evaluation system, which is DVE-2010. Based on truly absorbable protein supply or metabolizable protein value, the feed milk vaule (FMV) will be determined.[15,49] Detailed comparisons among the three models have been reported.[64,66−68]

In our recent study,[43] we used modeling approaches to determine metabolizable protein supply of carinata meal to dairy cattle in comparison with conventional canola meal and found that "the value of true protein digested in the intestine predicted by the DVE/OEB system was 153 g/kg DM in carinata meal, which was similar to that in canola meal. Carinata meal had a positive degraded protein balance (+248 g/kg DM)", which has been reported.[43]

CURRENT MOLECULAR STRUCTURE STUDIES ON CARINATA AS ENERGY FEEDSTOCKS AND THEIR COPRODUCTS FROM BIOFUEL AND BIO-OIL PROCESSING

Study Interactive Association between Biopolymers and Biofunctions in Carinata Meal -Coproducts from Biofuel and Bio-oil Processing before and after Rumen Biodegradation. *Application 1 of Molecular Spectroscopy To Study the Relationship between CHO Structure and CHO Availability in Carinata Meal (Coproducts).* Molecular analyses with FTIR technique with attenuated total reflectance (ATR) and chemometrics may enable detection of structural features on a molecular basis. In this study,[11] we used FTIR-ATR spectroscopy in our laboratory to "investigate spectral features of carbohydrate conformation in carinata meal and investigate differences in carbohydrate molecular functional group spectral intensities after in situ ruminal fermentation at 0, 12, 24, and 48 h compared to conventional canola meal as a reference". Our measured parameters included[11] SCHO (mainly associated with hemicellulosic and cellulosic compounds; region and baseline ca. 1483−1184 cm^{-1}), cellulosic compounds (CELC, region and baseline ca. 1304−1184 cm^{-1}), total carbohydrates (CHO, region and baseline ca. 1193−889 cm^{-1}) as well as the spectral ratios calculated on the basis of respective spectral intensity data of carbohydrates. In this study we also published a typical ATR-FTIR molecular spectrum of carinata meal in the mid-IR region ca. 4000−800 cm^{-1}; please check our previous paper for the spectral graph.[11] In this study, we reported that "the spectral profiles of carinata meal were different from that of canola meal in CHO 2nd peak area (center at ca. 1091 cm^{-1}, region: 1102−1083 cm^{-1}) and functional group peak intensity ratios such as SCHO 1st peak (ca. 1415 cm^{-1}) to 2nd peak (ca. 1374 cm^{-1}) height ratio, CHO 1st peak (ca. 1149 cm^{-1}) to 3rd peak (ca. 1032 cm^{-1}) height ratio, CELC to total CHO area ratio and STCHO to CELC area ratio. The results indicated that carinata meal may not in full accord with canola meal in carbohydrate utilization and availability in ruminants. Almost all the spectral parameters were decreased during 48 h ruminal degradation in both carinata meal and canola meal."[11]

Application 2 of Molecular Spectroscopy To Study the Relationship between Protein Structure and Protein Availability in Carinata Meal (Coproducts). To date, no study in other laboratories was found on nutritive values and molecular structural characteristics associated with protein biopolymers of carinata meal from biofuel and bio-oil processing.[41] In this project,[41] we investigated the possible relationship between protein intrinsic structural features and nutrient profiles of carinata meal in comparison with conventional canola meal. We found that "carinata meal had 20−31% greater IR absorbance in protein amide I height and area as well as α-helix and β-sheet heights than canola meal. But agglomerative hierarchical cluster analysis and principal component analysis indicated these two types of the meals could not be distinguished completely within protein spectrum region (ca. 1728−1478 cm^{-1})."[41] We also observed some close correlations between protein structural parameters and protein nutrient profiles and subfractions" as reported in our individual project publication.[41]

Application 3 of Molecular Spectroscopy To Study Rumen Residue of Canola Meal (Coproducts). No study was found on whether protein structure changes during rumen fermentation from other research teams. In these studies,[41,42] we characterized protein structure spectral changes in carinata meal during ruminal fermentation using the FTIR technique. We wanted to find out "1) whether protein amide profile and protein 2nd structure profile changed after ruminal fermentation at 0, 12, 24, and 48 h in carinata meal and canola meal; 2) whether there were some correlation between protein spectral parameters and chemical profile in in situ rumen residue samples".[41,42] In the publications, we reported that "Protein structure spectral features in both carinata meal and canola meal were altered as incubation time increased and linear and curvilinear relationships on amide II height and area, height and area ratio of amide I and II as well as height ratio of α-helix and β-sheet were observed within 48 h ruminal fermentation. The amide I height and area as well as α-helix height and β-sheet height were in the highest level of IR absorbance at 0 h and then gradually declined linearly by 30−38% after 48 h incubation. We found that not only quantities decreased but also inherent structure changed in protein chemical make-up during ruminal fermentation. Strong correlations were found between protein spectral parameters and some basic nutrients profile such as CP (positively) and NDF (negatively). And multivariate spectral analysis showed that rumen residues from carinata meal (were) not distinguished from those from canola meal, suggesting some relationship in structural make-up exhibited between them within protein region during 48 h rumen fermentation".[41,42]

Study Interactive Association between Biopolymers and Biofunctions in Carinata Seeds as Feedstock for Biofuel and Bio-oil Processing. *Application 4 of Molecular Spectroscopy To Study the Relationship between CHO Structure and CHO Availability in Energy Feedstock (Carinata Seeds).* In this study,[41] we investigated the correlations between carbohydrate structural features and nutritional profiles in yellow and brown types of carinata seeds, with comparison to common canola seed as a reference. The key findings in this study were reported as follows: "carinata lines showed significantly different IR intensities in structural carbohydrate (SCHO), cellulosic compounds (CELC) and total CHO profiles from Canola seeds. The changes of CELC and CHO peak intensities were highly related with some changes in CHO chemical profile, energy values and NDF degradation kinetics in carinata and canola seeds."[41]

Application 5 of Molecular Spectroscopy To Study the Relationship between Protein Structure and Protein Availability in Carinata Seeds (as Energy Feedstock). In this study,[44] we detected "the correlations between protein intrinsic structural features and most important nutritional profiles of DVE, OEB and FMV values in three lines of carinata in yellow and brown seed coats, with comparison to canola seed as a control reference".[44] We found "significant differences in protein amide II peak height, amide I peak area and β-sheet height among the different carinata lines. However, multivariate spectral analyses indicated a similarity in protein structural make-up in these four kinds of oilseed. Not very strong correlations showed in our study implied that the limited sample size and narrow range in biological and spectral variation might be (a) response (to) the weak relationships between chemical profile and mid-IR spectral data." Nutritive values of DVE, OEB, and FMV from carinata seed and canola seed and multivariates molecular spectral analysis among the carinata lines were graphically presented in this publication.[44]

Application 6 of Molecular Spectroscopy To Study the Lipid-Related Chemical Functional Spectral Profile in Carinata Seeds (as Energy Feedstock). To date, information

dx.doi.org/10.1021/jf405809m | J. Agric. Food Chem. 2014, 62, 4039−4047

is lacking on the lipid molecular structural characteristics in relation to contents of oil, fatty acids, and antinutritional compounds in *B. carinata*.[5] In this study,[5] we investigated (1) oil content and fatty acid profile; glucosinolate profile, total polyphenols, and condensed tannins; and lipid-related inherent molecular structures in terms of CH stretching bands, unsaturated lipid bands (ULB) and lipid ester C═O carbonyl (LECC) bands in seeds from yellow-seeded and brown-seeded carinata lines [for typical ATR-FTIR molecular spectrum of carinata seeds and canola seed as a reference control in the mid-IR region ca. 4000−800 cm^{-1}, please see our publication[5]]; and (2) the relationship between the molecular spectral data and the contents of oil, fatty acids, and antinutritional compounds in the oilseeds.[69−71]

In this study, we reported that "brown-seeded carinata had lower contents of oil, C17:0, C18:0, C20:1, C20:2n-6, C24:1n-9 and total saturated fatty acids, and higher contents of C22:0, C22:1n-9 and C24:0 than yellow-seeded carinata. However, the contents of glucosinolates, polyphenols and condensed tannins were not different between the yellow and brown seeds. There were marked differences between carinata and canola seeds in the contents of oil, fatty acids profile, glucosinolates profile and polyphenols. The yellow seeds had lower peak heights of asymmetric CH_2 and symmetric CH_2, however, no changes were found in other spectral parameters. The absorbed peak intensities of CH stretchings, ULB and LECC of both types of carinata seeds were markedly stronger than those of canola seeds. The multivariate, cluster and principal component analyses showed no significant differences in the lipids molecular structures between the yellow-seeded and brown-seed carinata seed; whereas, the molecular structures of canola seeds were fully distinguished from both types of carinata seeds in the regions of CH stretchings and ULB. The lipid-related spectral bands intensities were strongly correlated to oil content, fatty acids, glucosinolates and polyphenols. The regression equations gave relatively high predictive power for the estimation of oil (R^2 = 0.99); all measured fatty acids (R^2 > 0.80), except C14:0, C20:3n-3, C22:2n-9 and C22:2n-6; 3-butenyl, 2-OH-3-butenyl, 4-OH-3-CH_3-indolyl and total glucosinolates (R^2 > 0.686) and total polyphenols (R^2 = 0.935)."[5] (For a detailed typical ATR-FTIR lipid molecular spectrum of carinata seeds and canola seed, please check our publication.)[5]

Application 7 of Molecular Spectroscopy To Study Heat-Induced Molecular Structure Change in Lipid-Related Chemical Functional Spectral Profile in Carinata Seeds (as Energy Feedstock). In this study,[46] we explored the effect of different autoclave heating times (30, 60, and 90 min) on fatty acid supply and molecular stability in carinata seed. In this work,[42] heat-induced molecular structure changes in lipid-related chemical functional spectral profile in carinata seeds detected by FTIR-ATR were presented graphically.[42] We reported that "autoclaving treatments decreased total fatty acids content in a linear fashion in carinata seed as heating time increased; and reduced concentrations were observed in C18:3n3, C20:1, C22:1n9, monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA), omega 3 (ω-3) and 9 (ω-9) fatty acids. Correspondingly, the heated seeds showed dramatic reductions in all the peak intensities within lipid-related spectral regions. Results from agglomerative hierarchical cluster analysis (AHCA) and principal component analysis (PCA) indicated that the raw oilseed had different structural make-up from the autoclaved seeds in both CH_3 and CH_2 asymmetric and symmetric stretching region (ca. 2999−2800 cm^{-1}) and lipid ester C═O carbonyl region (ca. 1787−1706 cm^{-1}). However, the oilseeds heated for 30, 60, and 90 min were not grouped into separate classes or ellipses in all the lipid-related regions, indicating that there still exhibited similarities in lipid biopolymer conformations among autoclaved carinata seeds. Moreover, strong relationships observed in our study implied that lipid-related spectral parameters might have a potential to predict some fatty acids content in oilseed samples like *B. carinata*. However, more data from (a) large sample size and diverse range would be necessary and helpful to draw up a final conclusion."

All of the above results are based on limited samples in our laboratory, an experiment with a large sample size with detailed and systematical studies is on the way to confirming our findings in our preliminary study and exploring new findings in our large-scale study. For example, carinata meals with a higher crude protein content but contained less metabolizable protein supply for dairy cattle and had lower feed milk values when compared with conventional canola meals. These results should be checked and confirmed again. The correlation between inherent structures and nutrient biofunctions and bioavailability are inconclusive and should be studied with a large range of sample sizes. To improve nutrient availability predictions in energy feedstock and coproducts, the new concept of digestion in various functional groups could be tested in the new studies. In summary, this paper reviewed (1) the carinata seeds as energy feedstocks, biofuel and bio-oil processing procedures, and their processing coproducts; (2) potential synchrotron-based, globar-based molecular sepctroscopy and conventional evaluation methods on energy feestock (new carinata seeds) and coproducts (carinata meal) from biofuel and bio-oil processing; and (3) interactive association between biopolymers and biofunctions in carinata seeds and carinata meal, coproducts from biofuel and bio-oil processing before and after rumen biodegradation, and how molecular structural changes affect nutrient bioavailability and biofunctions.

$NE_{L3\times}$ (NE_{Lp}) net energy for lactation at 3 times maintenance (i.e., production level)
NE_m net energy for maintenance in growing animals
NFC nonfiber carbohydrate
NPN nonprotein nitrogen
NSC nonstructural carbohydrate
OEB degraded protein balance
OM organic matter
PA nonprotein nitrogen defined by CNCPS (K_d is assumed to be infinity)
PB1 rapidly degradable protein subfraction defined by CNCPS (K_d = 120−400% per h)
PB2 intermediately degradable protein subfraction defined by CNCPS (K_d = 3−16% per h)
PB3 slowly degradable protein subfraction defined by CNCPS (K_d = 0.06−0.55% per h
PC undegradable protein subfraction defined by CNCPS
PCA principal component analysis
PUFA polyunsaturated fatty acids
RDCA ruminally degraded carbohydrate A
RDCB1 ruminally degraded carbohydrate B1
RDCB2 ruminally degraded carbohydrate B2
RDPA ruminally degraded protein A
RDPB1 ruminally degraded protein/peptide B1
RDPB2 ruminally degraded protein/peptide B2
RDPB3 ruminally degraded protein/peptide B3
RDP ruminally degraded peptides
RECA ruminally escaped carbohydrate A
RECB1 ruminally escaped carbohydrate B1
RECB2 ruminally escaped carbohydrate B2
RECC ruminally escaped carbohydrate CC
REPB1 ruminally escaped protein B1
REPB2 ruminally escaped protein B2
REPB3 ruminally escaped protein B3
S potential soluble fraction in the in situ ruminal incubation
SCHO structural carbohydrates
SCP soluble crude protein
SR-IMS synchrotron-based Fourier transform infrared microspectroscopy
T_0 lag time
TCA trichloroacetic acid
tdCP truly digestible crude protein
tdFA truly digestible fatty acid
TDN total digestible nutrients
$TDN_{1\times}$ total digestible nutrients at maintenance
$TDN_{3\times}$ total digestible nutrients at 3 times maintenance (i.e., production level)
tdNDF truly digestible neutral detergent fiber
tdNFC truly digestible nonfiber carbohydrate
U potential undegradable fraction in the in situ ruminal incubation
ULB unsaturated lipid bands

Diacetyl: Occurrence, Analysis, and Toxicity

Takayuki Shibamoto*

Department of Environmental Toxicology, University of California, Davis, California 95616, United States

ABSTRACT: Diacetyl possesses a butter-like flavor and has been widely used as a flavoring agent. It forms from sugars and lipids via various bacteria and heat treatment in various foods and beverages, such as milk. The toxicity of diacetyl, especially when inhaled, has recently attracted the attention not only of consumers but also of regulatory agencies. Even though accurate quantitative analysis of diacetyl is extremely important in evaluating its possible adverse effects, precise quantitative analysis of diacetyl in foods and beverages, as well as in ambient air, is considerably difficult because it is highly reactive and soluble in water. Among the many analytical methods developed for measuring diacetyl, preparation of 2,3-dimethylquinoxaline followed by gas chromatography has been most commonly used in the analysis of various foods, beverages, and air samples. This mini-review summarizes the formation mechanisms, analytical methods, occurrence, and toxicity of diacetyl.

KEYWORDS: *diacetyl, α-dicarbonyl compounds, inhalation toxicity, lipids, sugars*

INTRODUCTION

Diacetyl is a degradation product of various food components, including fatty acids/triglycerides, carbohydrates/sugars, and proteins/amino acids. Formation of diacetyl from sugar degradation had already been reported by the middle of the past century.[1] Around that time, diacetyl was found in lipid peroxidation products.[2,3] More recent research has shown that diacetyl forms by the action of lactic bacteria.[4] Diacetyl is also known to form as a natural product of the action of microorganisms during fermentation in some food products, such as yogurt[5] and fermented soybeans.[6] Consequently, diacetyl has been found in many foods and beverages, particularly in dairy products.

Diacetyl is listed in the FDA's GRAS (generally regarded as safe) list and has been used widely in the preparation of butter and related food products, at levels of 6−9 μg/g, because it possesses a unique, butter-like flavor with an odor threshold of 50 ppb.[7,8] On the other hand, NIOSH proposed limits on diacetyl exposure for factory workers, who might be exposed to vapor-phase diacetyl in related production factories.[9−11] Toxicities associated with diacetyl, such as interacting with other factors to cause lung damage[12] and playing a role in oxidative stress, have also been reported.[13] Determination of toxicity is the first avenue to establishing the safety level of chemicals. Establishing regulatory values of diacetyl, however, is rather difficult because sufficient information, such as actual levels in foods and beverages, vapor-phase levels, formation mechanisms, and toxicities, is required before the safety level can be set. This information is not yet completely known.

A number of reviews involved in specific issues of diacetyl, such as analytical and biochemical considerations,[14] foodborne microorganisms,[15] respiratory sensitizer,[16] and brewery fermentation,[17] have been published. However, virtually no reviews providing sufficient information on the occurrence, toxicity, and analytical method of diacetyl are available.

Analysis of diacetyl is not easy because it is highly reactive, volatile, and water-soluble. The mainstream practice in diacetyl analysis is therefore to prepare a stable compound, such as 2,3-dimethylquinoxaline, and then analyze it using gas chromatography.[18] Various less commonly used methods, such as colorimetric,[19] fluorometric,[20] GC-MS,[5] GC-ECD,[21] and HPLC-UVD analyses,[22,23] have also been reported. The recent development of LC-MS analysis may provide an ideal analytical method for diacetyl in the near future.

CHEMISTRY AND FORMATION MECHANISMS OF DIACETYL

Physical Nature. Diacetyl (CAS Registry No. 431-03-8) is a simple α-dicarbonyl compound with a molecular weight of 86.0892. Another common name for diacetyl is 2,3-butanedione. It is a yellow liquid at room temperature and soluble in most organic solvents and water. Its melting point is between −2 and −4 °C, and its boiling point is 88 °C.

Chemical Formation. Many carbonyl compounds, including diacetyl, are known to be formed from lipids upon oxidation. Figure 1 summarizes the generally recognized proposed formation pathways of carbonyl compounds from lipids, which were reported in the early 1980s.[24,25] It has also been known since the 1960s that sugars degrade into many low-molecular-weight carbonyl compounds including diacetyl.[1,26] Formation of diacetyl in milk by heat treatment had already been demonstrated in the late 1960s.[27] Figure 2 shows the proposed formation pathways of diacetyl from sucrose. In these pathways, the first step is tautomerization of a free sugar group, followed by cleavage at keto−enol bonding in acidic or alkaline solution.[28] A recent study reported that higher levels of diacetyl were formed from sugars in acidic or basic solutions than in neutral solutions.[29]

In addition to the formation pathways of α-dicarbonyl compounds shown in Figures 1 and 2, there is a pathway by which a lipid or sugar produces various low-molecular-weight radicals, such as $^{\bullet}CH_3$, $^{\bullet}C{=}O$, and $^{\bullet}C{=}O(CH_3)$, and these radicals subsequently combine to yield diacetyl. This pathway

could be proposed when the reaction systems absorb high levels of energy from exposure to high temperatures, as in cooking or photoirradiation.[30] In fact, when cod liver oil was irradiated by UV, 27.23 nmol/mg glyoxal and 5.72 nmol/mg methylglyoxal were formed, suggesting that the radicals listed above combined to produce these diacetyl analogues.[31]

Maillard Reaction. The Maillard reaction is one of the most important reactions that form carbonyl compounds, including diacetyl, in foods. The Maillard reaction occurs between carbonyl compounds, such as sugars and lipids, and nitrogen-containing compounds, such as amino acids. It is generally recognized that nitrogen comes from an amino acid via Strecker degradation.[32] The sources of carbonyl compounds are sugars and lipids.[33] Formation of diacetyl from a Maillard model system consisting of L-rhamonse and ammonia was reported in the late 1970s.[34] Despite the fact that carbonyl compounds do not contain a nitrogen atom, amine compounds react with a sugar or a lipid to promote the formation of carbonyl compounds, including diacetyl,[35] suggesting that amine compounds act as catalysts for sugar or lipid degradation. Maltose, for example, degraded into diacetyl through an Amadori product intermediate when it was incubated with L-lysine.[36] In this study, diacetyl was recovered as a quinoxaline derivative ranging from 0.08 to 0.14 mmol/mol maltose.

Bacterial Formation. Formation of diacetyl by bacterial treatment may follow the pathway shown in Figures 1 and 2

[a]Number of chemicals reported. [b]NR, not reported in the reference.

because the processes are mild compared with thermal degradation. There have been many reports on the formation of diacetyl by various bacteria.[37] Lactic bacteria were used to enhance butter flavor by inducing diacetyl.[38] *Lactobacillus casei* was also used to increase the capacity to synthesize diacetyl from lactose in whey permeate.[39] A low level of citrate contained in cheeses was proposed to produce diacetyl by *Streptococcus diacetylactis*.[40] One interesting study reported that diacetyl could be used as a microbial spoilage marker for meat products using PTR-MS.[41] The amount of diacetyl produced in Jerusalem artichoke juice by the action of 10 *Lactobacillus* strains ranged from 0 to 179 μmol/L.[37]

ANALYSIS OF DIACETYL IN FOODS AND BEVERAGES

Analytical Methods. Table 1 shows typical reports on diacetyl in foods and beverages along with the analytical methods used. In this table, unit amounts were harmonized to micrograms per gram because the units used in the original papers were varied (e.g., ppm, mg/kg, and μg/g). However, some units, such as milligrams per liter and millimoles per milliliter, which could not be changed to mcirograms per gram are shown as they were in the original papers.

The colorimetric method involves formation of color from diacetyl and a color reagent prepared with creatine and β-naphthol, after which its UV absorption at 525 nm is measured.[37] One study demonstrated that the detection and quantification limits of HPLC were 0.002 and 0.006 mg/L, respectively.[23]

There are two types of diacetyl analysis. In the first, diacetyl is included as one component of the volatile chemicals found in foods and beverages. The second analysis is specific to α-dicarbonyl compounds, including diacetyl. As mentioned above, due to its high reactivity and water solubility, it is difficult to conduct a quantitative analysis of diacetyl. The use of appropriate derivatives to perform quantitative determination of this type of chemical is a commonly recognized method of analysis. One of the most widely used derivatives for diacetyl is 2,3-dimethylquinoxaline, which is a product of diacetyl and 2,3-phenylenediamine.[18] Figure 3 shows the reaction between α-dicarbonyl compounds and 2,3-phenylenediamine to form a corresponding quinoxaline derivative. This reaction occurs readily under mild conditions in a slightly basic solution at room temperature.[31] Quinoxalines themselves were reported as flavor chemicals in heat-treated foods in the early 1970s.[54] Diacetyl has been quantified in various foods and beverages using this quinoxaline derivative. For example, 2.72 μg/g diacetyl was reported in roasted coffee using this derivative.[49]

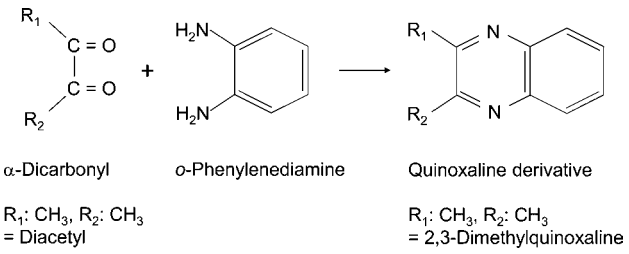

Figure 3. Reaction between α-dicarbonyl compounds and 2,3-phenylenediamine to form a corresponding quinoxaline derivative.

One study showed that 6-nitro-2,3-dimethylquinoxaline derived from diacetyl with 4-nitro-*o*-phenylenediamine yielded better separation in an HPLC column than 2,3-dimethylquinoxaline when diacetyl was analyzed in beer samples by HPLC-UVD.[52] In addition to the method reported in the above references, the OSHA has summarized the recommended sample preparation and analytical methods of diacetyl.[55,56]

Diacetyl Found in Foods. The presence of diacetyl in various fruits, such as apples[57] and pineapples,[58] has been known since the 1960s. When analyzed as one of the volatile components of food and beverage samples, diacetyl has been directly observed by gas chromatography and GC-MS without the use of derivatives. The quantity of diacetyl has therefore generally been reported as a GC peak area percentage rather than an absolute amount. When diacetyl is analyzed for assessment of flavor characteristics or toxicity evaluation, it is necessary to analyze the absolute amount present in samples. Quantitative analysis of trace levels of highly reactive and volatile chemicals such as diacetyl, however, is rather difficult.[18] There are many reports of the presence of diacetyl in foods and beverages, but only a few studies have reported the levels of diacetyl. The presence of diacetyl and 70 other volatile

dx.doi.org/10.1021/jf500615u | J. Agric. Food Chem. 2014, 62, 4048−4053

chemicals was reported in fresh milk, for example, but without quantitative analysis.[46] On the other hand, analysis of a volatile sample recovered from fermented soybean curds using a simultaneous steam distillation and extraction apparatus resulted in a quantitative measure of 0.001−0.17 μg/g diacetyl.[44] Diacetyl found in 12 brands of beer using a slightly modified quinoxaline derivative ranged from 0.034 to 0.11 μg/g.[52]

Diacetyl has been found to be one of the volatile chemicals that contributes the characteristic butter flavor to various foods and beverages. It was reported as one of the most intense volatile compounds, for example, in the aroma of pasteurized AA butter.[55] These reports indicate that diacetyl is also present in the headspace of food and beverage samples. Determination of diacetyl in the vapor phase has therefore become important in assessing the flavor quality of butter and related products as well as in evaluating its inhalation toxicity.

Among over 120 volatile compounds reported in yogurt, diacetyl was described as one of the major chemicals contributing to the characteristic yogurt flavor.[5] Starter distillates, which are used as ingredients in the formulation of various foods, such as cottage cheese, margarine, and sour cream, contained 1.2−22000 μg/g diacetyl in their headspace when analyzed using SPME and GC-MS.[53] Amounts (5−600 ppb) of diacetyl vaporized from beer at high temperature were monitored using an automatic flow system after diacetyl was derivatized into 2,3-dimethylquinoxaline.[59] Vapor-phase diacetyl in cigarette smoke analyzed using quinoxaline derivative resulted in measurements of 301−433 mg/cigarette in 14 brands of cigarette.[60] Recently, between 13.9 and 2835.7 ng/g of diacetyl were reported in the headspace of heated butter and cheese samples using a unique simultaneous purging and extraction apparatus.[29]

The headspace from spoiled fish samples was successively trapped using a SPME fiber made of carboxen/polydimethylsiloxane.[48] Analysis of the trapped sample by GC-MS resulted in the identification of 86 volatile compounds, including diacetyl. The absolute amounts of the volatiles, however, were not reported in this article due to the difficulty of performing quantitative analysis using SPME.[61] Later, diacetyl in the headspace of goat's milk jack cheese during the aging process was successfully determined using static headspace GC with an internal standard.[51]

TOXICITY OF DIACETYL

Diacetyl toxicity (mutagenicity) was first reported in 1979 as a positive finding in an Ames assay.[62] Later, mutagenicity of diacetyl was reported using a mammalian cell gene mutation assay in L5178Y mouse lymphoma cells.[63] Another early study demonstrated that various carbonyl compounds, including diacetyl, induced chromosome loss when they were combined with subacute concentrations of propionitrile.[64]

Since the recent publication of comprehensive studies of the respiratory toxicity of diacetyl using C57BBI/6 mice,[65] occupational health issues among workers in plants associated with diacetyl vapor, such as butter-flavoring production plants, have received much attention.[11] Diacetyl has been produced in large amounts (228,000 pounds in 2005) for use as a flavoring agent in food products. It has recently been linked to bronchiolitis obliterans occurring among factory workers.[10]

A recent review indicated that diacetyl is associated with chronic forms of diffuse parenchymal lung disease.[66] When human epithelial lung cells were exposed to diacetyl vapor, increases in some disease indicators, including inflammatory mediators, IL-6, and TNF-α, were observed.[67] Another recent study indicated that diacetyl aggregated amyloid-β, which is associated with Alzheimer's disease.[68] The same authors proposed, on the basis of the identification of a diacetyl/2-deoxyguanosine adduct, that diacetyl forms this adduct with the guanosine residue of DNA, which leads to cell death.[69]

Since the inhalation toxicity of diacetyl was first reported, many studies have focused on occupational lung disease among factory workers. A study using experimental mice demonstrated that diacetyl induced dose-dependent irritation in the respiratory tract and that sensory irritation in humans was estimated to occur at levels >20 μg/g.[70] After NIOSH investigated lung disease associated with the butter flavoring used in popcorn, the safety level of diacetyl in ambient air was targeted for restriction by some regulatory agencies. When the inhalation toxicity of a given chemical is assessed, it is extremely important to know the exact amount of that chemical inhaled by the target subjects, whether animal or human. A detailed discussion of diacetyl toxicities associated with occupational health, such as bronchiolitis obliterans,[71] is not within the scope of this mini-review.

CONCLUSIONS

Diacetyl is known as a flavor chemical possessing a butter-like flavor, and it is found in various foods and beverages. It has begun to receive attention as a possible cause of certain lung diseases in the past 5 years. The toxicity of α-dicarbonyl compounds glyoxal and methylglyoxal has been reported frequently, but reports on diacetyl toxicity were very infrequent until the 2000s. After NIOSH reported its inhalation toxicity, limits on diacetyl became a pressing need to protect factory workers. It is therefore important to know the formation mechanisms and occurrence of diacetyl to assess the safety of foods and beverages as well as indoor air containing diacetyl.

ABSTRACT: Kale has a high number of structurally different flavonol glycosides and hydroxycinnamic acid derivatives. In this study we investigated the interaction of moderate UV-B radiation and temperature on these compounds. Kale plants were grown at daily mean temperatures of 5 or 15 °C and were exposed to five subsequent daily doses (each 0.25 kJ m^{-2} d^{-1}) of moderate UV-B radiation at 1 d intervals. Of 20 phenolic compounds, 11 were influenced by an interaction of UV-B radiation and temperature, e.g., monoacylated quercetin glycosides. Concomitantly, enhanced mRNA expression of *flavonol 3′- hydroxylase* showed an interaction of UV-B and temperature, highest at 0.75 kJ m^{-2} and 15 °C. Kaempferol glycosides responded diversely and dependent on, e.g., the hydroxycinnamic acid residue. Compounds containing a catechol structure seem to be favored in the response to UV-B. Taken together, subsequent exposure to moderate UV-B radiation is a successful tool for enhancing the flavonoid profile of plants, and temperature should be considered.

KEYWORDS: *Brassica oleracea, UV-B, flavonoids, flavonol glycosides, hydroxycinnamic acids, flavonol 3′-hydroxylase*

INTRODUCTION

Ultraviolet-B (UV-B) radiation (280−315 nm) is a naturally occurring part of solar radiation. However, with depletion of the stratospheric ozone layer, enhanced levels of UV-B radiation are now reaching the earth's surface.[1] In response to these higher levels of UV-B radiation, plants induce the biosynthesis of phenolic compounds, such as flavonoids and hydroxycinnamic acids,[2] which act as shielding components and antioxidants in the defense against reactive oxygen species (ROS).[3,4] Phenolic compounds containing a catechol structure have also been reported to exhibit an especially high antioxidant activity.[5]

Kale (*Brassica oleracea* var. *sabellica*) has a large number of naturally occurring flavonol glycosides and hydroxycinnamic acid derivatives[6−10] and is cultivated mainly in Central and Northern Europe as well as in North America. As a leafy vegetable that has a large exposed surface area, it is an ideal model crop to study the effect of radiation on the biosynthesis of its phenolic compounds.[9] In kale, a total of 71 flavonol glycosides have been tentatively identified by HPLC-DAD−MS^n, including 27 non-acylated, 30 monoacylated, and 14 diacylated glycosides based on the flavonol aglycons quercetin, kaempferol, and isorhamnetin, respectively (Figure 1a).[9] Seven of these 71 compounds have been further identified with NMR in a previous study.[10] A general structure of a complex diacylated flavonol tetraglycoside is shown in Figure 2. The main flavonol glycosides in kale are non-acylated and monoacylated quercetin and kaempferol glycosides; the majority of other flavonol glycosides are acylated with hydroxycinnamic acids (Figure 1b).[9] Acylation of flavonol glycosides leads to a shift of the light-absorbing π-electron system band II in the flavonol structure to lower wavelengths.[11] For instance, in kale, acylated flavonol glycosides have absorption maxima between 328 and 340 nm,[9] which make this vegetable an interesting plant for investigating the influence of UV-B radiation on phenolic compounds. The main

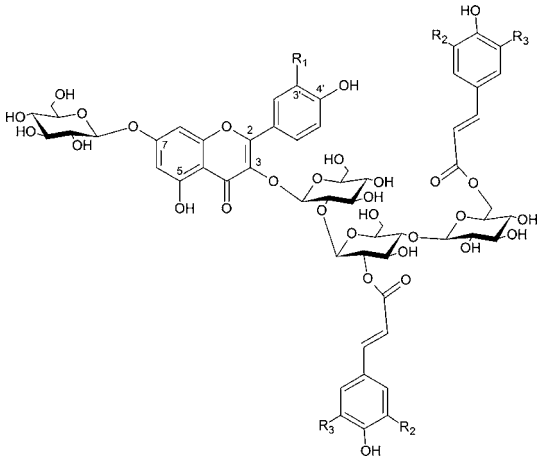

Figure 2. Kaempferol-3-*O*-disinapoyl-triglucoside-7-*O*-glucoside (R1 = H; R2 = MeOH; R3 = MeOH) in kale was identified by mass spectrometry (MS)[9] and nuclear magnetic resonance (NMR) spectroscopy.[10]

hydroxycinnamic acid derivatives in kale, namely, caffeoylquinic acid (chlorogenic acid), disinapoyl-gentiobiose, and sinapoyl-feruloyl-gentiobiose, provide antioxidant properties and have been further identified with NMR in a previous study.[5,10] The absorption maxima of hydroxycinnamic acids range from 318 to 328 nm, thereby suggesting that in kale plants they take an active response when exposed to UV-B radiation.

UV-B radiation is able to modify the flavonoid profile of different plant species. In the majority of studies ambient subsequent doses of UV-B radiation led to an enhanced quercetin to kaempferol ratio in comparison to UV-B exclusion for days up to weeks[12−14] and a study with high doses of additional UV-B radiation[15] in annual vegetables and ornamentals. Mainly quercetin glycosides can be enhanced by UV-B radiation in *Arabidopsis* (*Arabidopsis thaliana*).[16,17] However, only a small number of studies have assessed the effects of moderate UV-B exposure during cultivation,[18] and most of these applied additional UV-B for one week or more. Moderate UV-B radiation is defined as being less than 5 kJ m^{-2} d^{-1}.[19] In a recent study on kale examining the changes in flavonol glycoside profile to single doses of moderate UV-B radiation (less than 1 kJ m^{-2} d^{-1} UV-B_{BE} (biologically effective UV-B radation)), the quercetin and kaempferol glycosides as well as the hydroxycinnamic acid derivatives responded dose- and structure-dependently.[20] However, there is still a lack of knowledge on the interaction of UV-B radiation with other ecophysiological parameters such as temperature. Even though several investigations showed an effect of UV-B in combination with temperature on the flavonoid glycosides in pak choi (*Brassica campestris* L. ssp. *chinensis* var. *communis*)[21] and in willow (*Salix myrsinifolia*).[22] In contrast, an increase in caffeoylquinic acid in willow and arnica (*Arnica montana*) was reported only upon a temperature decrease independent of the UV-B dose applied.[22,23] Finally, although low temperature[24] and high UV-B levels[25] have been reported to modify the gene expression coding for key enzymes of flavonol biosynthesis, such as flavanone 3β-hydroxylase, flavonol synthase, and flavonol 3′-hydroxylase, a study examining the effects of interaction of UV-B radiation and temperature has not yet been performed.

The aims of this study were (I) to investigate whether, in contrast to a single dose of moderate UV-B, subsequent levels of targeted moderate UV-B radiation during cultivation of kale can enhance levels of flavonol glycosides and hydroxycinnamic acid derivatives, (II) to determine the effect of the flavonol glycoside structure in response to subsequent doses of moderate UV-B radiation, (III) for the first time to assess whether there are any interactive effects due to UV-B radiation and temperature on the biosynthesis of flavonol glycosides and hydroxycinnamic acid derivatives to find growing conditions that reveal a high concentration of health-promoting phenolics, and (IV) to perform corresponding gene expression studies to ascertain which key genes, namely, flavanone 3β-hydroxylase, flavonol synthase, and flavonol 3′-hydroxylase, involved in flavonol biosynthesis are up- or downregulated by moderate UV-B radiation treatment.

MATERIAL AND METHODS

Reagents and Standard Solutions. Methanol and the standards quercetin-3-*O*-glucoside, kaempferol-3-*O*-glucoside, and caffeoylquinic acid were purchased from Roth (Karlsruhe, Germany), acetic acid was purchased from Merck (Darmstadt, Germany), and acetonitrile was purchased from J. T. Baker (Griesheim, Germany). All reagents were of HPLC-grade quality.

Plant Material and Experimental Design. Kale (*B. oleracea* var. *sabellica*) plants of the cv. Winterbor (by Bruno Nebelung, Norken, Germany) were sown on Jan 3, 2010 (experiment I) and on Jan 10, 2010 (experiment II). All plants were grown up to the four- to five-leaf stage under greenhouse conditions (20 °C and ambient light). In the greenhouse, two experiments were conducted with equal UV-B radiation conditions at different daily mean temperatures (5 ± 1 °C (experiment I) and 15 ± 1 °C (experiment II)). For both experiments, the plants were cultivated in potting soil (Einheitserde type 1, Fitz Kausek GmbH & Co. KG, Mittenwalde, Germany) and set in a randomized block design spaced 0.02 m × 0.02 m away from each other. Water supply was given as needed by the plants, and fertilization was given as nutrient solution (pH 6.4, 41 mg L^{-1} P, 43 mg L^{-1} Mg, 154 mg L^{-1} NO_3, 205 mg L^{-1} Ca, 230 mg L^{-1} K, 280 mg L^{-1} SO_4, 0.82 mg L^{-1} Zn). The plants were exposed to one to five subsequent consecutive daily doses of 0.5 kJ m^{-2} d^{-1} UV-B radiation for 1 h with acclimatization intervals of 23 h. UV-B radiation was supplied by five UV-B fluorescent light sources (TL 40W 12 RS, Philips, Hamburg, Germany), and the distance of the UV-B lamps from the plants was 60 cm. UV-B radiation was determined using a UV-B sensor (type DK-UVB 1.3-051, deka Sensor + Technologie, Teltow, Germany) with a spectral range of 265−315 nm. Compared to that of Sangtarash et al.,[19] the UV-B dose administered is moderate, and the total dose given within 5 d was 2.5 kJ m^{-2} UV-B. The corresponding biologically effective UV-B radiation treatment level of 0.25 kJ m^{-2} d^{-1} UV-B_{BE} (total dose 1.25 kJ m^{-2} UV-B_{BE}) was calculated with the generalized plant weighting function according to Caldwell.[26] Environmental conditions were 5 °C and 93 μmol m^{-2} s^{-1} photosynthetic photon flux density (PPFD) for experiment I and 15 °C and 272 μmol m^{-2} s^{-1} PPFD for experiment II. Both experiments were carried out in the greenhouse in February 2010 at Grossbeeren, Germany (52.37° N, 13.33° E) under partly overcast skies. Three plants per replication and three biological replications per treatment were harvested from the block of plants every day after an acclimatization period of 24 h following the UV-B treatment.

Sample Preparation. For each replication, the leaves (excluding the middle rib) taken from three four- to five-leaf stage plants were frozen in liquid nitrogen, stored until lyophilization at −40 °C, lyophilized, and then ground to a powder. The samples were stored in darkness at room temperature until they were required for analysis. To analyze flavonol glycosides and hydroxycinnamic acid derivatives, the samples were extracted as described[20] with the following modifications. In analytical duplicates, 20 mg of freeze-dried and ground powder was extracted with 600 μL of 60% aqueous methanol for 1 h with high agitation at room temperature. Samples were centrifuged at 19000*g* for 10 min, and the supernatants were collected in a new tube.

[a]The concentration of the quercetin glycosides was quantitated as quercetin-3-*O*-glucoside equivalents. Values with the same letters are not significantly different (Tukey's HSD test ($n = 3$) is calculated at $p \leq 0.05$) for each quercetin glycoside. Key: *, significant at $p \leq 0.05$; **, significant at $p \leq 0.01$; ***, significant at $p \leq 0.005$; ns, not significant. Abbreviations: Q, quercetin; soph, sophorose; glc, glucose; diglc, diglucoside; triglc, triglucoside; fer, feruloyl; hfer, hydroxyferuloyl; sin, sinapoyl; disin, disinapoyl. [b]The compound was tentatively identified by HPLC-DAD−MS^n as shown by Schmidt et al.[9] [c]The compound was identified with NMR as shown by Fiol et al.[10]

The extraction procedure was repeated with 400 and 200 μL for 20 and 10 min, respectively. The supernatants were added together and were evaporated to dryness while being rotated. The residue was dissolved in 200 μL of distilled water. The extract was then filtered through Corning Costar Spin-X plastic centrifuge tube filters with a cellulose acetate mambrane (Sigma-Aldrich Chemical Co., St. Louis, MO) for HPLC analysis.

HPLC-DAD−ESI-MS^n. The HPLC-DAD−ESI-MS^n method for the tentative identification[9] and quantitation[20] of the flavonol glycosides and hydroxycinnamic acid derivatives in kale was done with an HPLC series 1100 by Agilent (Waldbronn, Germany) consisting of a degaser, binary pump, autosampler, column oven, and photodiode array detector. An ion trap (Agilent series 1100 MSD) with an ESI ion source in negative ionization mode was used as the mass spectrometer. The parameters for HPLC-DAD−ESI-MS^n have been previously described.[20] Mass fragments for the identification of the compounds have been previously given.[9] The main flavonol glycosides (10 compounds) and structurally related minor flavonol glycosides (7 compounds) and hydroxycinnamic acid derivatives (3 compounds) were selected for the investigation (Tables 1−5). The standards quercetin-3-*O*-glucoside (for quercetin glycosides), kaempferol-3-*O*-glucoside (for kaempferol glycosides), and caffeoylquinic acid (for hydroxycinnamic acid derivatives) were used to obtain an external calibration curve ranging from 0.1 to 10 mg 100 mL^{-1} for a semiquantitative approach. The variation coefficient for the reproducibility of the major flavonoid glycosides was 0.7−3.3% for the extraction and 0.5−3.4% for the HPLC analysis. The variation coefficient for the reproducibility of the hydroxycinnamic acid derivatives was 1.5−1.9% for the extraction and 1.0−1.7% for the HPLC analysis.

Gene Expression Analysis by Semiquantitative Real-Time PCR. The RNA extraction was carried out as previously described by Neugart et al.[27] Quantitative two-step RT-PCR was performed using a SYBRR Green 1 protocol in 96-well reaction plates on an Applied Biosystems 7500 real-time PCR system according to Neugart et al.[27] Data were exported to LinReg software[28] to determine the PCR amplification efficiency for each primer pair. Relative transcript levels were normalized on the basis of expression of an invariant control orthologous to At3g18780 (ACT2) AF044573 using the equation $2 - \Delta CT$.[29] Quantitative PCR was performed on three biological replicates measured in analytical duplicates for each gene, and nontemplate controls were included.

Statistical Analysis. All data were statistically analyzed by a two-factorial ANOVA. Fisher's F test was performed to assess the main effect of the factors UV-B radiation and temperature and their interactions followed by a comparison of the factor levels using Tukey's HSD test. For nonsignificant interactions, the means of the levels of the main factors were separated, while for significant interactions, all combinations of the factor levels were compared. Residuals were tested for Gaussian distribution using the Kolmogorov−Smirnov test. All tests were conducted at a significance level of 5%. Calculations were performed using Statistica for Windows (version 9.0, Statsoft Inc., Tulsa, OK).

RESULTS AND DISCUSSION

Juvenile kale plants are rich in structurally different flavonol glycosides and hydroxycinnamic acid derivatives. In total 71 flavonol glycosides have previously been tentatively identified in kale.[9] A total of 7 of these 71 compounds have been further identified with NMR in a previous study (Tables 1−5).[10] The

[a]The concentration of the kaempferol glycosides was quantitated as kaempferol-3-*O*-glucoside equivalents. Values (means ± standard deviation) with the same letters are not significantly different (Tukey's HSD test (n = 3) is calculated at $p \leq 0.05$) for each kaempferol glycoside. Key: *, significant at $p \leq 0.05$; **, significant at $p \leq 0.01$; ***, significant at $p \leq 0.005$; ns, not significant. Abbreviations: K, kaempferol; soph, sophorose; glc, glucose; caf, caffeoyl; fer, feruloyl; hfer, hydroxyferuloyl; sin, sinapoyl. [b]The compound was tentatively identified by HPLC-DAD−MS^n as shown by Schmidt et al.[9] [c]The compound was identified with NMR as shown by Fiol et al.[10]

main hydroxycinnamic acid derivatives in kale are caffeoylquinic acid, disinapoyl-gentiobiose, and sinapoyl-feruloyl-gentiobiose and have been further identified with NMR in a previous study.[10] Kale seems to be an ideal model crop plant to investigate the interaction of moderate UV-B and temperature due to the high number of structurally different flavonoid glycosides and hydroxycinnamic acid derivatives. In this study, 20 compounds were investigated, revealing a structure-specific response of the main flavonol glycosides (10 compounds) and structurally related minor flavonol glycosides (7 compounds) and hydroxycinnamic acid derivatives (3 compounds) to moderate UV-B radiation at daily mean temperatures of 5 and 15 °C. The flavonol glycosides were classified by the type of aglycon, the number of sugar moieties, the acylation pattern (non-acylated and acylated flavonol glycosides), and the type of hydroxycinnamic acid acylated. The results point to a structure-dependent response of flavonol glycosides to UV-B radiation and temperature. Of the 20 investigated compounds, 12 and 11 were influenced by UV-B radiation and temperature, respectively (Tables 1−4). An interaction of both these factors was obtained for monoacylated quercetin glycosides and 6 of 11 kaempferol glycosides (the monoacylated kaempferol diglycosides and the non-acylated and the caffeic and hydroxyferulic acid monoacylated kaempferol triglycosides). All investigated quercetin glycosides and the non-acylated as well as the monoacylated kaempferol glycosides that have a catechol structure in the hydroxycinnamic acid residue were affected by UV-B radiation. With regard to temperature, the monoacylated quercetin glycosides and 6 of 11 kaempferol glycosides (mainly the non-acylated and monoacylated kaempferol triglycosides) were influenced. For the expression of genes coding for key enzymes involved in flavonol biosynthesis, an effect of moderate UV-B radiation and an interaction of UV-B radiation and temperature was determined (Table 5).

All *quercetin glycosides* were affected by UV-B radiation (Table 1). Temperature was observed to influence only the concentration of the four monoacylated quercetin glycosides, and an interaction of UV-B radiation and temperature was found for these compounds. The concentration of the non-acylated quercetin-3-*O*-sophoroside-7-*O*-D-glucoside increased with increased radiation from 0.25 to 1.0 kJ m^{-2} UV-B_{BE}, while the temperature had no effect. The highest concentrations of the monoacylated quercetin-3-*O*-feruloyl-sophoroside-7-*O*-D-glucoside and quercetin-3-*O*-sinapoyl-sophoroside-7-*O*-D-glucoside/quercetin-3-*O*-sophoroside-7-*O*-sianpoyl-diglucoside were observed at 1.25 kJ m^{-2} UV-B_{BE} and at 15 °C. In contrast, the concentrations of quercetin-3-*O*-hydroxyferuloyl-sophoroside-7-*O*-D-glucoside increased at a high UV-B radiation level of 1.25 kJ m^{-2} UV-B_{BE} at 5 °C. However, at 15 °C and for all UV-B radiation levels the concentrations of this compound were even higher. The concentrations of the complex diacylated quercetin-3-*O*-disinapoyl-triglucoside-7-*O*-D-glucoside rose with increasing UV-B radiation from 0.25 to 0.75 kJ m^{-2} UV-B_{BE}, and this was independent of temperature. Our study underlines the importance of investigating the *acylation pattern* (non-acylated, mono- and diacyalted), since the profiles and concentrations of these compounds are affected by the

[a]The concentration of the kaempferol glycosides was quantitated as kaempferol-3-*O*-glucoside equivalents. Values (means ± standard deviation) with the same letters are not significantly different (Tukey's HSD test (n = 3) is calculated at $p \leq 0.05$) for each kaempferol glycoside. Key: *, significant at $p \leq 0.05$; **, significant at $p \leq 0.01$; ***, significant at $p \leq 0.005$; ns, not significant. Abbreviations: K, kaempferol; soph, sophorose; glc, glucose; diglc, diglucoside; triglc, triglucoside; hfer, hydroxyferuloyl; sin, sinapoyl; disin, disinapoyl. [b]The compound was tentatively identified by HPLC-DAD−MS^n as shown by Schmidt et al.[9] [c]The compound was identified with NMR as shown by Fiol et al.[10]

interaction of UV-B radiation and temperature. Monoacylated quercetin glycosides were affected by UV-B radiation dependent on the temperature. To account for this, we assume that a higher antioxidant activity in the plant is due to the hydroxycinnamic acid residue compared to the non-acylated quercetin glycoside. Interestingly, the non-acylated and the diacylated quercetin glycosides were affected by UV-B radiation only. The effect of the *aglycon* was confirmed as quercetin glycosides increased with higher UV-B radiation, which we assumed to be an adaptation of the plant and which has previously led to an assumption that the catechol structure of the B-ring enhances the antioxidant activity against ROS in kale.[5] In contrast, another study on kale showed that a single dose of moderate UV-B radiation (0.44 kJ m^{-2} d^{-1} UV-B_{BE}) mainly resulted in a decrease of quercetin glycosides.[20] An increase of quercetin glycosides has also been shown for several plant species with UV-B radiation levels of approximately 5 kJ m^{-2} d^{-1} UV-B_{BE} and higher for several weeks.[2] In silver birch (*Betula pendula*) leaves, quercetin glycosides increased at 3.74−4.48 kJ m^{-2} d^{-1} UV-B_{BE} for 30 days comparable to our results.[17] In canola (*Brassica napus*) leaves, the non-acylated quercetin-3-*O*-sophoroside-7-*O*-D-glucoside and the corresponding kaempferol triglycoside as well as the sinapic acid monoacylated quercetin glycoside were enhanced by 13 kJ m^{-2} d^{-1} UV-B_{BE} for 16 days, while the sinapic acid monoacylated kaempferol glycoside concentration was not affected.[29] Our study showed that even moderate UV-B radiation applied in subsequent daily doses can modify the flavonoid profile by increasing polyhydroxylated compounds, namely, quercetin glycosides. This finding is underlined by a study of Gotz et al.,[16] where quercetin glycosides increased at 0.54 kJ m^{-2} d^{-1} UV-B_{BE} for several days in *Arabidopsis*. A decrease in temperature (ambient temperature (14−28 °C) compared to 2 °C higher than ambient (16−30 °C)) and an increase of UV-B radiation (32% higher than ambient (0.04−0.11 kJ m^{-2} d^{-1} UV-B_{BE} on a summer day)) for several weeks led to higher concentrations of quercetin glycosides in willow;[22] however, interactions between UV-B radiation and temperature were not reported. In a study on arnica, quercetin-3-*O*-β-D-glucoside and kaempferol-3-*O*-β-D-glucoside were not affected by UV-B radiation, comparing ambient UV-B radiation (8.0 kJ m^{-2} d^{-1} UV-B_{BE}) to zero UV-B radiation for one month.[23] However, the overall quercetin to kaempferol ratio was enhanced at lower temperatures of 20 °C compared to 25 °C. As a mountain plant, arnica might be adapted to higher UV-B radiation levels. The enhancement of acylated quercetin glycosides in field-grown kale was caused by a decrease in temperature from 12 to 0 °C rather than a decrease of photosynthetic active radiation (PAR) from 20 to 4 mol m^{-2} d^{-1}.[30] However, non-acylated and monoacylated quercetin glycosides increased at moderate PAR compared to low PAR at 5 and 10 °C under defined conditions in climate chambers.[27] In the present experiment moderate UV-B radiation given in subsequent daily doses led to a higher increase of monoacylated quercetin glycosides. We therefore hypothesize that a higher ROS level results from UV-B radiation rather than PAR. In *Arabidopsis*, not only structurally different quercetin glycosides, including quercetin-3-*O*-glucoside-7-*O*-rhamnoside, quercetin-3-*O*-rhamnoside-7-*O*-rhamno-

side, and quercetin-3-*O*-rhamnoside-glucoside-7-*O*-rhamnoside, but also the corresponding kaempferol glycosides were observed to increase at 0.627 kJ m^{-2} d^{-1} UV-B_{BE} for 12 days.[31] In contrast, in kale, several kaempferol glycosides were enhanced (Tables 2 and 3), while others were not affected, thereby suggesting a different role of kaempferol glycosides in the plant's response to UV-B radiation at different temperatures.

Of 11 investigated *kaempferol glycosides*, 6 responded to different interactions of UV-B radiation and temperature (Tables 2 and 3). At 5 °C, the non-acylated kaempferol glycoside had the highest concentration combined with UV-B radiation levels of 0.5−1.25 kJ m^{-2} UV-B_{BE}, whereas at 15 °C a UV-B radiation level of 0.25 kJ m^{-2} UV-B_{BE} was adequate to produce the highest concentration. Moreover, the concentration levels of the monoacylated kaempferol diglycosides show a response to an interaction of UV-B radiation and temperature. Kaempferol-3-O-feruloyl-sophoroside was not affected by UV-B radiation or temperature. The corresponding hydroxyferulic acid monoacylated kaempferol diglycoside was also not affected at 5 °C under different UV-B radiation conditions, whereas, at 15 °C, its highest concentration was determined at 0.75 kJ m^{-2} UV-B_{BE}. In contrast, the sinapic acid monoacylated kaempferol diglycoside increased at 5 °C with increasing UV-B radiation levels of up to 1.25 kJ m^{-2} UV-B_{BE}, whereas, at 15 °C, the doses of UV-B radiation had no effect. For kaempferol triglycosides, the results showed that kaempferol-3-*O*-caffeoyl-sophoroside-7-*O*-D-glucoside strongly increased with UV-B radiation levels from 0.25 up to 1.25 kJ m^{-2} UV-B_{BE} at 5 °C, and at 15 °C, an increase was determined from 0.25 up to 1.0 kJ m^{-2} UV-B_{BE}, thereby showing a clear response to an interaction of UV-B radiation and temperature for this compound. The hydroxyferulic acid monoacylated kaempferol triglycoside was also influenced by interacting UV-B radiation and temperature. The lowest concentration for this compound was found at 0.25 kJ m^{-2} UV-B_{BE} and 15 °C. The ferulic acid and sinapic acid monoacylated kaempferol triglycosides were not affected by an interaction of UV-B radiation and temperature, but were strongly affected by temperature alone, which resulted in higher concentrations at 5 °C compared to 15 °C. Kaempferol tetraglycosides acylated with hydroxyferulic acid (kaempferol-3-*O*-hydroxyferuloyl-sophoroside-7-*O*-diglucoside) and sinapic acid (kaempferol-3-*O*-sinapoyl-sophoroside-7-*O*-diglucoside) were not affected by an interaction of UV-B radiation and temperature. The level of the hydroxyferulic acid monoacylated kaempferol tetraglycoside decreased when the compound was exposed to 0.75−1.0 kJ m^{-2} UV-B_{BE}, and this reaction was found to be independent of temperature. In contrast, the sinapic acid monoacylated kaempferol tetraglucoside was present at higher concentrations at 5 °C, and this was independent of the UV-B intensities. To summarize, the *hydroxycinnamic acid residue* influenced the response of flavonol glycosides to UV-B radiation and temperature; e.g., the caffeic acid and hydroxyferulic acid monoacylated kaempferol triglycosides (containing a catechol structure) were affected by UV-B radiation and showed an interaction of UV-B radiation and temperature. Of note is that the ferulic and sinapic acid monoacylated kaempferol triglycosides (no catechol structure) were affected by temperature alone. Similarly, as in kale, the ferulic acid and sinapic acid monoacylated kaempferol triglycosides were not affected by the UV-B treatment in leafy *Brassica* pak choi irradiated with high dosages of 20−24 kJ m^{-2} d^{-1} UV-B_{BE} for 7 days.[21] Furthermore, in pak choi at 9 °C, the concentration of the

[a]Relative transcript levels (means ± standard deviation) in juvenile kale plants were normalized on the basis of expression of actin. Values with the same letters are not significantly different (Tukey's HSD test (n = 3) is calculated at $p \leq 0.05$). Key: *, significant at $p \leq 0.05$; **, significant at $p \leq 0.01$; ***, significant at $p \leq 0.005$; ns, not significant.

caffeic acid monoacylated kaempferol triglycoside decreased, but it was not affected at 22 °C.[21] In contrast, in kale, the kaempferol-3-*O*-caffeoyl-sophoroside-7-*O*-glucoside increased after five subsequent daily doses of moderate UV-B radiation with an interaction of UV-B radiation and temperature. The influence of temperature on the effect of UV-B radiation was less evident in pak choi[21] than in our study despite a higher dose (20−24 kJ m^{-2} d^{-1} UV-B_{BE} for 7 days)[21] compared to the moderate dose of UV-B radiation (0.25−1.25 kJ m^{-2} UV-B_{BE} for 5 d) used here in kale that elicited a higher impact in terms of affecting the concentrations of flavonol glycosides. A characteristic structure prevalent in kale's flavonoid glycosides was the *number of glucose moieties*. However, in silver birch seedlings, the flavonol glycosides quercetin-3-galactoside, quercetin-3-rhamnoside, and kaempferol-3-rhamnoside were enhanced after UV-B radiation (7.3−8.5 kJ m^{-2} d^{-1} UV-B_{BE} for 10 d), whereas several other quercetin and kaempferol glycosides remained unaffected.[32] Although we found only glucose as the sugar moiety in kale,[10] there is a substitution effect of the 7-*O* position for diglycosides (no glucose moiety in the 7-*O* position) and tri- and tetraglycosides (one and two glucose moieties in the 7-*O* position, respectively). In summary, the monoacylated kaempferol diglycosides showed interactions of UV-B radiation and temperature independent of the acylated hydroxycinnamic acid residue. For monoacylated kaempferol triglucosides, interactions of UV-B radiation and temperature were observed only if the acylated hydroxycinnamic acid included a catechol structure. In contrast, the monoacylated kaempferol tetraglycosides were not influenced by the interaction of UV-B radiation and temperature. One possible reason for this is that the molecule size influences the activity and the synthesis in response to ROS-induced stress. The complex diacylated kaempferol-3-*O*-disinapoyl-triglucoside-7-*O*-D-glucoside was affected by neither UV-B radiation nor temperature. The effect of the *acylation pattern* has been discussed for the quercetin glycosides. However, the acylated hydroxycinnamic acid and the number of glucose moieties seem to have a higher impact.

The *hydroxycinnamic acid derivatives* were hardly affected by UV-B radiation or temperature in kale (Table 4). Hydroxycinnamic acids were previously shown to act as scavengers to ROS induced by UV-B radiation.[3] In pak choi irradiated with 20−24 kJ m^{-2} d^{-1} UV-B_{BE} for 7 d, the malate esters of coumaric, caffeic, ferulic, hydroxyferulic, and sinapic acid increased at 9 °C due to the applied UV-B radiation, but were not affected at 22 °C.[21] The opposite phenomenon was observed in kale where concentrations of disinapoyl-gentiobiose and sinapoyl-feruloyl-gentiobiose did not change in response to UV-B radiation and temperature interactions. However, the concentration of disinapoyl-gentiobiose generally increased at 15 °C compared to 5 °C, while for sinapoyl-feruloyl-gentiobiose no effect of UV-B radiation or temperature was found. The biosynthesis of hydroxycinnamic acids is probably reduced in favor of flavonoid biosynthesis at the moderate UV-B we used in this experiment compared to ambient and higher UV-B levels as demonstrated in pak choi. To add to this notion, in willow and in arnica only a decrease in temperature resulted in higher concentrations of caffeoylquinic acid and its derivatives, but an increased UV-B radiation had no effect.[22,23] In addition, neither Morales et al.[17] nor Anttila et al.[33] found any influence of UV-B radiation (3.74−4.48 kJ m^{-2} d^{-1} UV-B_{BE} for 30 d and 2.75−5.23 kJ m^{-2} d^{-1} UV-B_{BE} for several weeks, respectively) on caffeoylquinic acid in silver birch, underlining the findings in kale where caffeoylquinic acid was influenced by an interaction of UV-B radiation and temperature but neither UV-B radiation nor temperature had a significant effect on this compound.

Moreover, 5-caffeoylquinic acid increased at 7.3−8.5 kJ m^{-2} d^{-1} UV-B_{BE} for 10 d in silver birch, but 3-caffoeylquinic acid was not affected.[32] This finding supports the conclusion that the hydroxycinnamic acid response is structure-specific.

qRT-PCR expression analysis was performed for *key genes involved in the flavonol biosynthesis* pathway in *B. oleracea*. For this purpose, primer pairs were developed to specifically analyze the expression differences of genes presumably coding for flavanone 3*β*-hydoxylase (*F3H*; formation of dihydroflavonols from flavanones), flavonol synthase (*FLS*; formation of flavonols from dihydroflavonols), and flavonol 3′-hydroxylase (*F3′H*; hydroxylation of the B-ring of flavonoids) (Table 5). Kilian et al.[25] demonstrated that, due to UV-B stress, genes were up- or downregulated in a time-dependent manner with a maximum expression 6 h after the treatment. In the present study, the kale plants were harvested after an adaptation time of 24 h, suggesting that the mRNA expression was adjusted during the adaptation time. The expression of the genes of the key enzymes involved in flavonol biosynthesis increased with maximum expression at 0.5 kJ m^{-2} UV-B_{BE} (*F3H*, *FLS*) or 0.75 kJ m^{-2} UV-B_{BE} (*F3′H*). This observation suggests that the kale plants were still affected by ROS due to the applied moderate UV-B radiation as also reported for several species at higher UV-B radiation doses.[2] For all three investigated genes, their expression patterns were influenced by an interaction of UV-B radiation and temperature. UV-B radiation affected the expression of all three genes, while temperature affected the expression of *FLS* and *F3′H*, but not of *F3H*. The expression of the *F3H* gene was highest at 0.5 kJ m^{-2} UV-B_{BE} and was independent of temperature. This expression was observed to correspond to the higher concentrations of the non-acylated kaempferol triglycoside—a precursor of the monoacylated kaempferol triglycosides that occur in high concentrations. Consistent with a study of purple kale,[24] a cold-induced induction of *F3H* was reported and is supported by our data where at 5 °C (0.5 kJ m^{-2} UV-B_{BE}) the expression of *F3H* was higher than at 15 °C. Furthermore, the expression of the *FLS* gene was also highest at 0.5 kJ m^{-2} UV-B_{BE} at 5 °C, but hardly affected under different levels of UV-B radiation at 15 °C. This could be responsible for the increased concentrations of the hydroxyferulic acid monoacylated kaempferol triglycoside at 5 °C compared to 15 °C, since the catechol structure of the acylated hydroxyferulic acid seems to be important in the plant's response to UV-B radiation. In soybean (*Glycine max*), a single dose of UV-B radiation (not specified) led to a higher activity of the enzymes flavanone 3*β*-hydroxylase and flavonol synthase.[34] Both of these enzymes are important for the biosynthesis of kaempferol—a finding that adds further support to our study. In contrast, the expression of the *F3′H* gene was high at 0.75 kJ m^{-2} UV-B_{BE} at 15 °C, but not affected under different levels of UV-B radiation at 5 °C. The high mRNA expression of *F3′H* resulted in higher concentrations of monoacylated quercetin glycosides compared to those at 5 °C. We assume that this is due to an increased response to the UV-B-induced ROS in kale.[35]

In summary, the present study in kale underlines the structure-dependent response of flavonol glycosides. Additionally, the response of flavonol glycosides and hydroxycinnamic acid derivatives was clearly dependent on the interaction of UV-B radiation and temperature. All quercetin glycosides increased by higher UV-B radiation. Nevertheless, high concentrations of monoacylated quercetin glycosides were determined at 15 °C compared to 5 °C. In contrast to quercetin glycosides, kaempferol glycosides showed a more diverse response to UV-B radiation and temperature. A catechol structure in quercetin glycosides and in the acylated hydroxycinnamic acid residues seems to be important for the response to UV-B radiation. Moreover, the expression of genes coding for key enzymes involved in flavonol biosynthesis was increased by UV-B exposure. As the potential beneficial health effects of kale are directly related to the profile and concentration of flavonol glycosides and hydroxycinnamic acid derivatives,[11] moderate UV-B doses combined with pointed temperature treatment might be a suitable application for enhancing the phenolic profile in the plant.

ABSTRACT: Thirty-eight nicotinamide derivatives were designed and synthesized as potential succinate dehydrogenase inhibitors (SDHI) and precisely characterized by ^{1}H NMR, ESI-MS, and elemental analysis. The compounds were evaluated against two phytopathogenic fungi, *Rhizoctonia solani* and *Sclerotinia sclerotiorum*, by mycelia growth inhibition assay in vitro. Most of the compounds displayed moderate activity, in which, **3a-17** exhibited the most potent antifungal activity against *R. solani* and *S. sclerotiorum* with IC_{50} values of 15.8 and 20.3 μM, respectively, comparable to those of the commonly used fungicides boscalid and carbendazim. The structure−activity relationship (SAR) of nicotinamide derivatives demonstrated that the meta-position of aniline was a key position contributing to the antifungal activity. Inhibition activities against two fungal SDHs were tested and achieved the same tendency with the data acquired from in vitro antifungal assay. Significantly, **3a-17** was demonstrated to successfully suppress disease development in *S. sclerotiorum* infected cole in vivo. In the molecular docking simulation, sulfur and chlorine of **3a-17** were bound with PHE291 and PRO150 of the SDH homology model, respectively, which could explain the probable mechanism of action between the inhibitory and target protein.

KEYWORDS: *nicotinamide, antifungal activity, succinate dehydrogenase inhibitors*

INTRODUCTION

As one of the most important categories of agrochemicals,[1,2] carboxamide fungicides have been intensively employed throughout the world to fight against highly destructive plant pathogens, such as *Botrytis cinerea*, *Sclerotinia* spp., *Leveillula taurica*, and *Spherotheca macularis*.[3−5] From the first carboxamide fungicide carboxin for crop protection to those newly discovered, these molecules cover boscalid (BASF), bixafen (Bayer), fluopyram (Bayer), and isopyrazam (Syngenta) (Figure 1). The initial narrow biological spectrum was broadened with progress of the chemical structure modification. These pyridine carboxamide group of pesticides have a common target receptor, succinate dehydrogenase (SDH, EC 1.3.5.1).[6] They act as SDH inhibitors (SDHIs) and disrupt the mitochondrial tricarboxylic acid cycle and respiration chain.

On the basis of the molecular structure of boscalid, a new series of nicotinamide compounds containing an active skeleton, ortho-replaced pyridine amide, have been synthsized. As shown in Figure 2, the *p*-chloride phenyl ring of boscalid was removed, and the chloride atom on the ortho position of pyridine was replaced by sulfur methyl or sulfur benzyl. This modification kept the nicotinamide moiety, which is important to the fungicide activity, and ensured molecular weight and pharmacological properties such as solubility similar to those of boscalid.

In this study, structure-based drug design strategies and homology modeling in the development of novel SDH inhibitors are presented using Discovery Studio 3.1 (Accelrys Inc.).[7,8] To explore the advantage of different substituents at the ortho position of pyridine, we calculated the interaction energy (Table 1) by docking these ligands to the binding site of porcine SDH. On the basis of scores of binding energy, we revealed that sulfur methyl was more suitable than sulfur benzyl for introduction into the ortho position of pyridine. Thus, we focused on sulfur methyl substituted target compounds while synthesizing some sulfur benzyl substituted target compounds to verify our virtual screening.

MATERIALS AND METHODS

Chemicals and Instruments. *Instruments.* All chemicals and reagents used in the current study were of analytical grade (provided by Nanjing Chemical Regent Co., Ltd.). The reactions were monitored by thin layer chromatography (TLC) using precoated silica gel GF_{254} plates from Qingdao Haiyang Chemical, China. Melting points (uncorrected) were determined on an SPSIC WRS-1B digital melting-point apparatus (Shanghai, China). ESI mass spectra were obtained on a Mariner System 5304 mass spectrometer. ^{1}H NMR spectra were collected on a Bruker Avance III 400 NMR spectrometer with $CDCl_3$ as solvent at room temperature. The chemical shifts (δ) are reported in parts per million with reference to internal TMS, and coupling constants (J) are given in hertz. Elemental analyses were performed on a CHN-O-Rapid instrument and were within ±0.4% of the theoretical values.

[a]The higher the scores of -cdock_interaction_energy, the easier the bonding between chemical ligands and receptor.

*2-(Methylthio)nicotinic acid (**2a**).* 2-Mercaptonicotinic acid (1.55 g, 10 mmol) was dissolved in *N*,*N*-dimethylformamide (DMF, 40 mL), and K_2CO_3 (4.14 g, 30 mmol) was added. Iodomethane (685 μL, 11 mmol) was added dropwise, and the mixture was stirred for 1 h at room temperature. With stirring, the pH of the solution was adjusted to 2−3 with 5% HCl solution. The precipitated solid was filtered, washed with cold water, and allowed to air-dry overnight to afford 1.61 g of the acid **2a** (9.5 mmol, 95%) as a white solid: mp 171−172 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 2.59 (s, 3H, CH_3), 7.12 (dd, 1H, J = 7.7, 4.8 Hz, Py−H), 8.34 (dd, 1H, J = 7.8, 1.6 Hz, Py−H), 8.67 (dd, 1H, J = 4.6, 1.6 Hz, Py−H); MS (ESI), 170.02 ($C_7H_7NO_2S$, $[M + H]^+$). Anal. Calcd for $C_7H_7NO_2S$: C, 49.69; H, 4.17; N, 8.28. Found: C, 49.88; H, 4.11; N, 8.32.

*2-((2-Fluorobenzyl)thio)nicotinic Acid (**2b**) and 2-((4-Nitrobenzyl)-thio)nicotinic Acid (**2c**).* 2-Mercaptonicotinic acid (32 mmol, 5.0 g) was dissolved together with potassium hydroxide (20 mol, 1.2 g) in 30 mL of ethanol. Benzyl bromide (1-(bromomethyl)-2-fluorobenzene or 1-(bromomethyl)-4-nitrobenzene) was added dropwise, and the mixture was refluxed for 30 min. After cooling, the reaction mixture was concentrated to approximately 15 mL. The residue was treated with 20 mL of water and slightly acidified with 5% HCl solution. The precipitate was filtered, washed with water, and recrystallized from ethanol to give white crystals of **2b** or **2c** as a white or yellow solid, respectively.

Data for **2b**: yield, 72.5%; mp, 184−185 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 4.40 (s, 2H, S−CH_2−Ar), 7.12−7.16 (m, 2H, Py−H, Ar), 7.26−7.28 (m, 1H, Ph−H), 7.29−7.23 (m, 1H, Ph−H), 7.52 (dt, 1H, J = 7.7, 1.4 Hz, Ph−H), 8.23 (dd, 1H, J = 3.8, 1.8 Hz, Py−H), 8.52 (dd, 1H, J = 7.6, 3.8 Hz, Py−H); MS (ESI), 264.04 ($C_{13}H_{10}FNO_2S$, $[M + H]^+$). Anal. Calcd for $C_{13}H_{10}FNO_2S$: C, 59.31; H, 3.83; N, 5.32. Found: C, 59.48; H, 3.61; N, 5.42.

Data for **2c**: yield, 71.9%; mp, 163−164 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 4.42 (s, 2H, S−CH_2−Ar), 7.14−7.15 (m, H, Py−H), 7.56 (dd, 2H, J = 8.8 Hz, Ph−H), 8.14 (d, 2H, J = 8.0 Hz, Ph−H), 8.24 (dd, 1H, J = 4.2, 1.7 Hz, Py−H), 8.50 (dd, 1H, J = 7.8, 2.9 Hz, Py−H); MS (ESI), 291.04 ($C_{13}H_{10}N_2O_4S$, $[M + H]^+$). Anal. Calcd for $C_7H_7NO_2S$: C, 53.79; H, 3.47; N, 9.65. Found: C, 53.52; H, 3.50; N, 9.49.

*General Procedure for the Synthesis of Compounds **3**.* A mixture of compound **2** (1 mmol) and $SOCl_2$ (15 mL, acted as both reactant and solvent) was stirred and refluxed at 75 °C for 2 h. Remaining $SOCl_2$ was removed by distillation under reduced pressure. After $SOCl_2$ was completely removed, the solid residue was then directly dissolved in anhydrous CH_2Cl_2 (20−30 mL). Appropriate substituted aniline or alkylamine (1 mmol) was added slowly (finished in 1 min), and the mixture was stirred at room temperature for 2−3 h.

The reaction mixture was washed with HCl solution (5%, 50 mL) and NaOH solution (5%, 50 mL) several times. The CH_2Cl_2 solution was collected and dried by anhydrous Na_2SO_4. Further purification was carried out by silica gel column chromatography with petroleum ether/EtOAc (5:1) as eluent. After recrystallization from EtOAc, final compounds **3a-01**−**3a-27**, **3b-01**−**3b-06**, and **3c-01**−**3c-05** were obtained.

*2-(Methylthio)-N-phenylnicotinamide **3a-01**:* white powder; yield, 80.3%; mp, 151−152 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 2.47 (s, 3H, S−CH_3), 7.12 (t, 1H, J = 7.4 Hz, Ph−H), 7.26 (dd, 1H, J = 7.5, 4.9 Hz, Py−H), 7.36 (t, 2H, J = 7.7 Hz, Ph−H), 7.70−7.72 (m, 2H, Ph−H), 7.91 (dd, 1H, J = 7.6, 1.6 Hz, Py−H), 8.59 (dd, 1H, J = 4.8, 1.6 Hz, Py−H), 10.46 (s, 1H, CONH); MS (ESI), 245.07 ($C_{13}H_{12}N_2OS$, $[M + H]^+$). Anal. Calcd for $C_{13}H_{12}N_2OS$: C, 63.91; H, 4.95; N, 11.47. Found: C, 63.63; H, 4.54; N, 11.46.

*N-(2-Fluorophenyl)-2-(methylthio)nicotinamide **3a-02**.* white powder; yield, 57.0%; mp, 163−164 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 2.48 (s, 3H, S−CH_3), 7.14 (dd, 1H, J = 8.4, 1.6 Hz, Ph−H), 7.29 (dd, 1H, J = 7.6, 4.3 Hz, Py−H), 7.41−7.44 (m, 1H, Ph−H), 7.47 (d, 1H, J = 8.0 Hz, Ph−H), 7.70 (dd, 1H, J = 9.4, 1.8 Hz, Ph−H), 8.02 (dd, 1H, J = 7.5, 1.9 Hz, Py−H), 8.71 (dd, 1H, J = 6.2, 1.7 Hz, Py−H), 10.56 (s, 1H, CONH); MS (ESI), 263.06 ($C_{13}H_{11}FN_2OS$, $[M + H]^+$). Anal. Calcd for $C_{13}H_{11}FN_2OS$: C, 59.53; H, 4.23; N, 10.68. Found: C, 59.37; H, 4.45; N, 10.96.

*N-(2-Chlorophenyl)-2-(methylthio)nicotinamide **3a-03**:* white crystal; yield, 85.2%; mp, 196−197 °C; ^{1}H NMR (400 MHz, DMSO-

d_6) δ 2.48 (s, 3H, S−CH_3), 7.26−7.33 (m, 2H, Ph−H, Py−H), 7.41 (dt, 1H, J = 7.6, 1.4 Hz, Ph−H), 7.57 (dd, 1H, J = 8.0, 1.4 Hz, Ph−H), 7.63 (dd, 1H, J = 7.9, 1.3 Hz, Ph−H), 8.00 (dd, 1H, J = 7.1, 1.6 Hz, Py−H), 8.62 (dd, 1H, J = 4.8, 1.7 Hz, Py−H), 10.22 (s, 1H, CONH); MS (ESI), 278.03 ($C_{13}H_{11}ClN_2OS$, $[M + H]^+$). Biological Testing. *Plant Pathogenic Fungi.* The test fungi, *Rhizoctonia solani* and *Sclerotinia sclerotiorum*, were provided by the Laboratory of Plant Disease Control, Nanjing Agricultural University. After retrieval from the storage tube, the strains were incubated in PDA at 25 °C for a week to get new mycelia for the antifungal assay.

Antifungal Bioassay. The fungicidal activity of the synthetic compounds was tested in vitro against two plant pathogenic fungi using a mycelia growth inhibition method.[9] The synthesized compounds were dissolved in DMSO to prepare the 10 mg/mL stock solution before mixing with molten agar below 60 °C. The media containing compounds at a concentration of 25 mg/mL for the initial screening were then poured into sterilized Petri dishes. After appropriate days at 25 °C, the colony diameter of each strain was measured with the original mycelial disk diameter (5 mm) subtracted from this measurement. Percentage inhibition was calculated as $(1 - a/b) \times 100\%$, where a is the colony diameter in Petri dishes with compounds and b is the mean colony diameter in Petri dishes without tested

dx.doi.org/10.1021/jf405437k | J. Agric. Food Chem. 2014, 62, 4063−4071

compounds. DMSO served as negative control, whereas commercially available agricultural fungicides carbendazim and boscalid were used as positive controls. Each measurement consisted of at least three replicates. The concentration-dependent curve was the values of inhibition rates for the *Y* axis against the test sample concentrations (mg/mL) for the *X* axis. The IC_{50} value (Table 2) was defined as the concentration required for 50% inhibition of mycelial growth.

In Vivo Testing on Cole Leaves Infected by S. sclerotiorum. Strain *S. sclerotiorum* and susceptible cole leaves collected from Pailou Experimental Centre of Nanjing Agricultural University were used to measure the efficacy of compounds in vivo.[10] Healthy cole leaves were sprayed with compounds (0.5 mg/mL) and subsequently cultivated at 20 °C for 24 h before artificial inoculation with strain *S. sclerotiorum*. Results were observed as diameters of symptoms after cultivation at 20 °C for 36 h. Carbendazim (50% WP, Jiangsu Rotam Lanfeng Biochemical Co., Ltd., China) was coassayed as the positive control. The efficacy of disease control was calculated as $(1 - c/d) \times 100$, where c is the diameter of the treatment and d is the diameter of the negative control. The disease control picture is shown in Figure 3.

Figure 3. Effects of compound **3a-17** against *S. sclerotiorum* infected cole leaves.

Enzyme Assay in Vitro. *Isolation of R. solani and S. sclerotiorum.* Fungus mitochondrial was isolated according to a previously reported method.[11] Cultures were inoculated at 0.05 $OD_{600\ nm}$ and grown on a reciprocal shaker (180 rpm, 25 °C) for 5 days in Sabouraud maltose broth (SMB) medium. Cells were harvested by vacuum filtration and disrupted in liquid nitrogen using a mortar and pestle. The resultant powder was resuspended to 10% w/v in mitochondrial extraction buffer (10 mM KH_2PO_4, pH 7.2, 10 mM KCl, 10 mM $MgCl_2$, 0.5 M sucrose, 0.2 mM EDTA, 2 mM PMSF). The extract was clarified by centrifugation (5000*g*, 4 °C for 10 min, 2 times), and intact mitochondria were then pelleted at 10000*g* for 20 min at 4 °C and resuspended in the same buffer. Mitochondrial suspensions were brought to a concentration of 10 mg/mL and stored at −80 °C until use. SDH activity was found to remain stable for months.

Succinate:Ubiquinone/DCPIP Activity Inhibition. Mitochondrial suspensions were diluted 1/20 in extraction buffer and preactivated at 30 °C for 30 min in the presence of 10 mM succinate. Succinate:ubiquinone/DCPIP activity inhibition measurements were performed by adding 10 μL of preactivated mitochondria to 200 μL of assay buffer (50 mM phosphate-sodium, pH 7.2, 250 mM sucrose, 3 mM NaN_3, 10 mM succinate) supplemented with 140 μM dichlorophenolindophenol (DCIP) and 1 mM 2,3-dimethoxy-5-methyl-1,4-benzoquinone (Q_0). Inhibitor concentrations ranged between 4.4 and 150 μM, with uniform 2× dilution factor steps (six inhibitor concentrations + DMSO control). A total of 96 well plates were pre-equilibrated at reaction temperature (30 °C) for 10 min before the reactions were started by the addition of 10 μL of preactivated *R. solani* mitochondrial suspension. DCPIP reduction was conducted at 30 °C and monitored at 595 nm. Calculated absorbance slopes (OD/h) were used for half-inhibitory concentration (IC_{50}) calculations using GraphPad Prism 5.0 software.

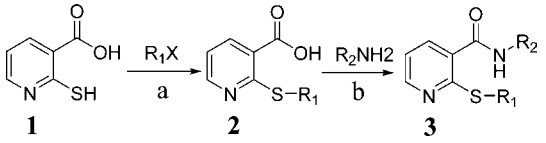
Molecular Docking. *Homology Modeling.* The NCBI protein database (http://www.ncbi.nlm.nih.gov/sites/entrez) was used to search the SDH amino acid sequence of *S. sclerotiorum*. The employed hypothetical protein sequences were XP_001591238, XP_001594577, XP_001597467, and XP_001593251, reported by Birren. The BLAST server (http://blast.ncbi.nlm.nih.gov) was used to search the templates for these four chains. We applied succinate dehydrogenase from porcine heart (PDB code 1ZOY) and avian (PDB code 1YQ3) as two templates, and the homologies of amino acid sequences were aligned. Homology modeling of SDH from *S. sclerotiorum* was carried out using DS MODELER, which is a module integrated in Discovery Studio (version 3.1). The obtained models were evaluated by Ramachandran plots using Discovery Studio software. All of the algorithms and parameters were set as default.

Molecular Docking. The automated docking was performed with DS-CDocker implemented in Discovery Studio (version 3.1).[12] The three-dimensional structures of picked compounds were constructed using Chem. 3D ultra 11.0 software [Chemical Structure Drawing Standard; Cambridge Soft Corp., USA (2009)]. Then they were energetically minimized by using MOPAC with 100 iterations and minimum RMS gradient of 0.10. The Gasteiger−Hückel charges of ligands were assigned. All bound water and ligands were eliminated from the protein, and the polar hydrogens and the Kollman-united charges were added to the proteins.

RESULTS AND DISCUSSION

Chemical Synthesis. Scheme 1 and Table 2 describe the synthesis and chemical structures of these nicotinamide

Scheme 1. General Synthesis of Compound 3a, 3b, and 3c[a]



1 2 3

[a]Reagents and conditions: if $R_1X = CH_3I$, (a) DMF, pH 8−9, rt, 16−24 h; 5% $HCl_{(aq)}$, pH 2−3; if R_1X = BnBr, (a) ethanol, K_2CO_3, rt, 1−2 h; 5% $HCl_{(aq)}$, pH 2−3; (b) $SOCl_2$, 75 °C, reflux, 3−4 h; CH_2Cl_2, rt, 3 h.

derivatives. Compound **1** is reacted with RX (iodomethane or benzyl bromide) to afford corresponding compound **2**. Compounds **2** were first transformed into nicotinyl chloride in the presence of $SOCl_2$ and then reacted with appropriate substituted aniline or alkylamine to afford the target compounds **3a**, **3b**, and **3c**. All of the synthetic compounds gave satisfactory analytical and spectroscopic data, which were in full accordance with their depicted structures.

Among them, **2b**, **2c** and 26 compounds of **3a**, **3b**, and **3c** series are first reported and others were reported with antifungal activities for the first time (Table 2).

Fungicidal Activities. The antifungal activities of the synthetic molecules, which are expressed as IC_{50} (median inhibitory concentration) values, were determined using a mycelia growth inhibitory rate method. All of the synthetic compounds exhibited antifungal effects to *R. solani* and *S. sclerotiorum*. The results are shown in Table 2.

Compared to **3a**, most compounds of the **3b** and **3c** series showed weak antifungal activity with IC_{50} values >150 μM. However, when other groups replacing sulfur methyl are introduced at the R_1 position, the IC_{50} values of series **3a** compounds decreased at least 4−5-fold, which were observed by comparing the data **3a-01** (IC_{50} = 42.7 μM) and **3b-01** (IC_{50} > 250 μM), **3c-01** (IC_{50} = 187.7 μM); **3a-12** (IC_{50} = 35.5 μM) and **3c-02** (IC_{50} = 171.3 μM); **3a-15** (IC_{50} = 28.4 μM) and **3c-05** (IC_{50} = 185.8 μM) for *R. solani* inhibition activity. The result verified the previous design idea that sulfur methyl had more advantages in antifungal activity than sulfur benzyl at the R_1 position. It seems a small steric hindrance at R_1 position is conducive to combining the nicotinamide ligands and the SDH

dx.doi.org/10.1021/jf405437k | J. Agric. Food Chem. 2014, 62, 4063−4071

active domain. Therefore, it is more reasonable that we mainly synthesized **3a** series compounds, which were more likely to be developed as potential fungicides.

Most **3a** derivatives exhibited antifungal effects with IC_{50} of <250 μM except **3a-26** and **3a-27**. With the alkane and cyclohexane substitution at the R_2 position, these two compounds show IC_{50} values of >500 μM to both *R. solani* and *S. sclerotiorum*, far larger than the expected activity, indicating that the presence of a nonaromatic group at the R_2 position may cause significant loss of fungicidal activity of **3a** derivatives.

In total, 7 compounds (**3a-01**, **3a-11**, **3a-12**, **3a-15**, **3a-16**, **3a-17**, and **3a-19**) and 11 compounds (**3a-01**, **3a-04**, **3a-05**, **3a-11**, **3a-12**, **3a-15**, **3a-16**, **3a-17**, **3a-18**, **3a-19**, and **3a-23**) displayed IC_{50} values of <100 μM against *R. solani* and *S. sclerotiorum*, respectively. Among them, **3a-17** exhibited the highest activity against *R. solani* with an IC_{50} value of 15.8 μM, which was half-fold that of the positive control carbendazim. Besides, **3a-12** exhibited the second highest activity against the two pathogens. Other compounds exhibited moderate to weak antifungal activities with IC_{50} values ranging from 100 to 250 μM. The best four compounds against two fungi were all substituted in the meta-position, demonstrating that the presence of substitution in the meta-position of the side phenyl ring was favorable for antifungal activity. This finding was similar to the previous Masatsugu ODA's study.[15]

The structure−activity relationships of these compounds can be summarized: (1) Sulfur methyl has more advantages for antifungal activity than sulfur benzyl at the R_1 position. (2) The presence of an aromatic ring at the R_2 position plays an important role in the antifungal activity. (3) Substitution in the meta-position of the side phenyl ring (R_2) may be essential for enhancing antifungal activity.

In Vivo Testing on Cole Leaves Infected by *S. sclerotiorum*. Among the compounds tested for antifungal activity in vitro, **3a-17** was found to be potent against *S. sclerotiorum*. Therefore, it was further evaluated in the greenhouse for the control of *S. sclerotiorum* infected cole. The efficacy of the treatment is shown in Figure 3. The untreated negative control (pathogen only) resulted in 100% disease incidence (0% healthy plant standard) 24 h after transplantation. Treatment with 0.5 mg/mL **3a-17** resulted in 43.9% healthy plant standard after 36 h of treatment (Table 3). In contrast, leaves treated with carbendazim at the same concentration resulted in 64.2% healthy plant standard. Thus, significant differences existed among the treated and untreated groups for disease control experiments in the greenhouse cole leaves.

Table 3. In Vivo Efficacy of 500 μg/mL Compounds on Cole Leaves Infected by *Sclerotinia sclerotiorum*[a]

	diameter of lesions (mm)	protection efficacy (%)
3a-17	8.3 ± 0.8	43.92
carbendazim	5.3 ± 0.4	64.19
negative control	14.8 ± 0.9	

[a]Statistical analysis of the data was performed by analysis of variance (one-way ANOVA). A probability value of $p \leq 0.05$ was considered to denote a statistically significance difference.

Fungal SDH Inhibition Activities. Seven compounds with IC_{50} values of <100 μM were selected and tested against SDH enzymes in vitro. As demonstrated in Table 4, **3a-17** showed the best activity and inhibitory abilities against SDH enzymes of the tested compounds with IC_{50} values from 20 to 50 μM and exhibited the same tendency as the data acquired by using the mycelia growth inhibition assay in vitro. It fully proved that the nicotinamides designed in this paper displayed as good inhibitory effects on SDH enzymes as other successfully developed carboxamide fungicides.

Table 4. IC_{50} Values of Fungal SDH Inhibition Activity (in Vitro)

	IC_{50} (μM)	
compd no.	*R. solani*	*S. sclerotiorum*
3a-01	24.0 ± 0.1	30.7 ± 0.2
3a-11	30.8 ± 0.2	36.3 ± 0.1
3a-12	21.1 ± 0.2	30.0 ± 0.2
3a-15	28.5 ± 0.3	36.8 ± 0.2
3a-16	40.8 ± 0.2	35.7 ± 0.3
3a-17	19.6 ± 0.2	23.9 ± 0.2
3a-19	40.1 ± 0.2	32.6 ± 0.2

Interactions with SDH. *Homology Modeling.* The trace, the templates, and the homology model and the secondary and tertiary structures of the protein are quite similar, all of which is shown in Figure 4A,B). A Ramachandran plot of this minimized model showed that 95.41% of the residues were located in the allowed regions (91.16% most favored) and only 4.59% (54 residues) were outside the allowed regions for the model. As these disallowed residues were far from the succinate dehydrogenase active site, they did not significantly contribute to the function of protein acceptor. Evaluated by the plot, the quality of the homology model is suitable as a molecular docking receptor.

Binding Mode Analysis. In an effort to elucidate the possible mechanism of inducing fungicidal activity by these nicotinamide compounds and explain the previous assumption, molecular docking of **3c-17** and another 10 selected compounds into the homology model according to the binding site of ubiquinone on reported SDH complex structure (1ZOY and 1YQ3, pdb) was performed, respectively. Boscalid was docked as contrast at the same time. The CDOCKER scores are provided in Table 5, in which, compounds got the same tendency with their antifungal and SDH inhibitory activities. Boscalid and **3c-17** showed the best two −cdock_interaction_energy scores of 34.27 and 27.93, respectively. Three-dimensional schematic diagrams clearly explained the possible optimal combination between the ligands and receptor protein. Boscalid is well bound to the receptor protein with its amino hydrogen toward the carboxyl oxygen of GLU171 of chain B, and its amide oxygen interacted with the indole hydrogen of TRP167. Besides, two rings of indole both had pi−pi interactions with 3.8 Å distance to reinforce molecular boscalid near TPR167 (Figure 5A), and the amide group of boscalid interacted well with residues around the binding site. As shown in Figure 5B, sulfur and chlorine of **3a-17** are well bound with the amino hydrogen of PHE291 and the pyrrolidine hydrogen of PRO150, respectively. Two-dimensional diagrams are also displayed as Figure 6, in which all of the amino acid residues interacted with the ligand, including weak interaction such as van der Waals interactions and polar interactions. Thus, a stable complex based on these interactions was formed. Associated with the virtual screening results (Table 1), this binding model indicated that the introduction of a sulfur methyl moiety allowed the ligand to more easily combine with SDH.

The docked compounds mainly interacted by H-bond with B, C, and D chains of receptor protein, which is consistent with previous studies on boscalid and other SDHIs (such as carboxin,

Three-dimensional schematic and Ramachandran plot of *S. sclerotiorum* SDH homology model and templates (1ZOY and 1YQ3): (A) tube trace of the two templates and the model (white color shows model, yellow color shows the template 1YQ3, and blue color shows the template 1ZOY); (B) secondary structures model (1) and templates 1YQ3 (2) and 1ZOY (3); (C) Ramachandran plot of the model (residues distribution plot).

Table 5. -cdock_interaction_energy of Compounds and *S. sclerotiorum* SDH (Homology Model)

compd no.	-cdock_interaction_energy ΔGb (kcal/mol)	compd no.	-cdock_interaction_energy ΔGb (kcal/mol)
3a-01	23.07	**3a-17***	27.93
3a-11*	23.17	**3a-18***	21.63
3a-12*	25.44	**3a-19***	24.59
3a-14*	20.71	**3b-02***	19.54
3a-15	24.09	**3c-02***	20.61
3a-16*	24.93	boscalid	34.27

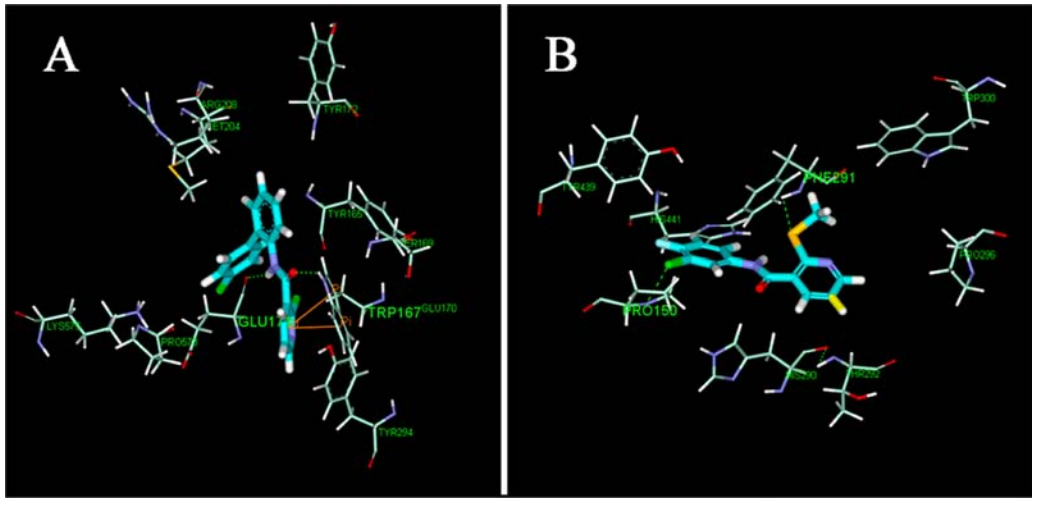


Figure 5. Interaction of boscalid, **3a-17**, and amino acid residues near the ligands (3D diagram).

fluopyram, bixafen, and isopyrazam).[13] Docking studies predicted the activity level and even possibly resistance site through identifying the key amino acid residues that were important for binding of different SDHIs. Resistant fungal genotype analysis verified that most of those key residues involved in forming the binding cavity were related to resistance formation.[14,15]

In conclusion, a series of nicotinamide derivatives as SDHIs were designed, prepared, and evaluated for their antifungal activity against *R. solani* and *S. sclerotiorum*. Some synthetic compounds displayed potent antifungal inhibitory activities with compound **3a-17** being the most effective. In vivo testing demonstrated that **3a-17** could effectively control the disease on *S. sclerotiorum* infected cole leaves. Meanwhile, the structure–activity relationships and molecular modeling study offered further insight into interactions between the receptor and ligand. The binding model of **3a-17** implied that the introduction of a

Supporting Information

ABSTRACT: Current research has demonstrated the presence of sub parts per billion levels of Sudan dye in paprika fruits during the vegetation process, which is difficult to understand on the basis of the conventional concept of cross-contamination or malicious addition. Detailed surveys on Sudan dyes I–IV in paprika fruits, soils, and agronomic materials used from seven fields of Xinjiang (China) were conducted to investigate the natural contamination. Results revealed that Sudan dyes II–IV were never detected and that Sudan I existed in almost all samples except for the mulching film and irrigation water. The higher total amount of Sudan I in soils, pesticides, and fertilizers compared to coated seeds indicated the combination of Sudan I-contaminated soils and application of Sudan I-containing agronomic materials constitutes a major source of 0.18–2.52 μg/kg levels of Sudan I in fruits during the growth period. The study offers a more reasonable explanation for the previously observed Sudan I in paprika fruits.

KEYWORDS: *paprika fruit, Sudan I, agricultural environment, agronomic materials, UPLC-MS/MS, GPC*

INTRODUCTION

Sudan dyes I–IV are attractive as coloring additives in foodstuffs due to their intense red-orange color (Figure 1).[1]

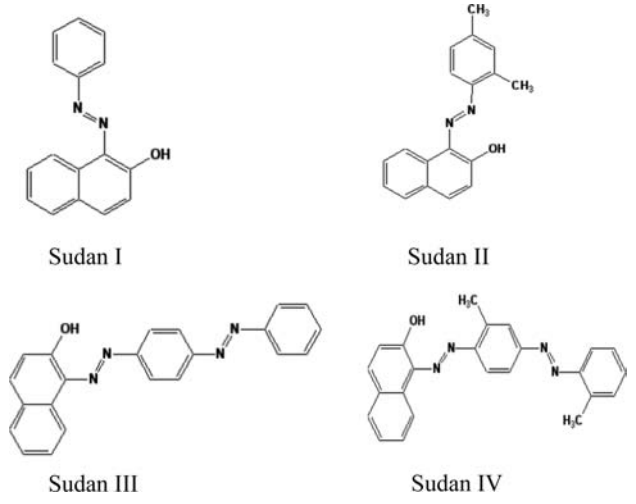

Figure 1. Chemical structures of Sudan dyes I–IV.

However, Sudan dyes have been classified as category 3 carcinogens by the International Agency for Research on Cancer,[2] and thus Sudan dyes are not allowed as food additives in most countries, including the European Union and China.[3−6] Consequently, monitoring and controlling the abuse of Sudan dyes in foodstuffs is of great importance for guaranteeing the safety of consumers.

Various analytical methods for the determination of Sudan dyes have been developed, including high-performance liquid chromatography (HPLC) with different detectors,[7−11] liquid chromatography–mass spectrometry (LC-MS),[12−14] enzyme immunoanalysis,[15−17] voltammetric techniques,[18] and chemiluminescence flow injection analysis.[19] Among them, LC-MS/MS displays outstanding advantages in both rapidly identifying Sudan dyes and accurately quantitating the amount at ultratrace levels. As the detection level was lowered through innovative techniques, more and more incidents involving Sudan dyes at sub parts per million levels were documented in recent years. For example, the 2011 RASFF (Rapid Alert System for Food and Feed) annual report showed that, of 18 entries with detections of Sudan dye (mainly Sudan dyes I and IV) in different foodstuffs, 13 samples measured showed only low-level ranges of 0.1–3.8 mg/kg.[20] Among a total of 21 samples of various spices and foodstuffs analyzed, 15 of them were found to contain Sudan dye I, III, or IV at low concentrations in the range of 0.0033–0.87 mg/kg.[21]

With the increasing presence of Sudan dyes at milligram per kilograms levels, it is inevitable for researchers to be focused on the contamination source in the context of reducing the levels where possible. Until now, their presence is ascribed to two possible explanations: either illegal addition or cross-contamination. Generally, levels of several 100–1000 mg/kg of Sudan dyes are needed to enhance the color of paprika and paprika

products.[22] For this reason, the European Union set 500 μg/kg as an action limit for Sudan dyes in foodstuffs to differentiate between adulterations and cross-contaminations.[23] The explanation of cross-contamination can be supported by several observations. Hoenicke reported that Sudan dyes I and IV at milligram per kilogram level were detected in red bags used for drying, transportation, and storage of the paprika pods and in lubricants used for greasing of the extraction plants and, thus, suggested that Sudan dyes detected may result from cross-contamination caused by some materials containing Sudan dyes.[24] Similar conclusions of cross-contamination have been reported by RASFF[20] and Schummer et al.[21]

The aim of the present study was to identify the source of the natural contamination of Sudan dyes in paprika fruits by investigating the potential presence of Sudan dyes I−IV and their contents in agricultural materials used. Our results showed that only Sudan I was present and, therefore, we have studied the distribution of Sudan I within the paprika as well as its contamination in some agronomic materials and the soils. This study provides a new insight into re-evaluating the origin of Sudan dyes in paprika fruits and paprika products.

MATERIALS AND METHODS

Reagents and Materials. Sudan dyes I−IV were obtained from Dr. Ehrenstorfer GmbH (Augsburg, Germany). Acetonitrile was purchased from Fisher Scientific (Waltham, MA, USA). All other chemicals and solvents such as HPLC grade isopropyl alcohol and formic acid were purchased from Kermel Chemical Co. Ltd. (Tianjin, China). Ultrapure water was produced by using a Master-S UVF ultrapure water system (Shanghai, China). Stock standard solutions of Sudan dyes I−IV (100 mg/kg) were prepared with acetonitrile in a volumetric flask and stored at 4 °C in the dark. Intermediate working mix solutions at 1 mg/kg were obtained by appropriate dilution of the stock solution with acetonitrile.

Apparatus. All analyses were performed on an Acquity TQD ultraperformance liquid chromatography (UPLC) system equipped with an autosampler system (Waters, Milford, MA, USA), coupled to tandem mass spectrometry operated in positive electrospray ionization (ESI+) mode and multiple reactions monitoring (MRM) mode. The data measured were processed with MassLynx V4.1 software.

Sample Collection and Preparation. Sample collection was undertaken in seven planting areas (30−50 km apart from each other) in the Xinjiang Uygur Autonomous Region (China). These fields were away from industry and roads and were amended with commercial pesticide (imidacloprid) and fertilizer (chili special-purpose fertilizer) after growth for 7, 30, and 60 days. For each field, paprika samples at three different stages of ripening including green, orange, and red fruits were collected from the same plant at the 80th, 86th, and 95th days after seeding, respectively. Each batch of samples in the same maturation degree comprised three replicates of subsamples from different paprika plants. All of the corresponding paprika stems and soils adhering to the root system (rhizosphere soils) were sampled 95 days after sowing. The sample type and amount are listed in Table 1. In addition, samples of the pesticide, fertilizer, mulching film, coated seed, and irrigation water were collected from farmers in the planting areas.

Paprika fruit and stem samples were dried at 80 °C in an oven and then ground using an FW135 universal grinder (Taisite Instrument Co., Ltd., Tianjin, China). Air-dried soils and chemical fertilizers were pulverized and sieved through an 80-mesh stainless steel sieve. All of the dry powdered samples were homogenized and stored in glass bottles at room temperature prior to extraction and analysis. Mulching films were cut finely into 0.4 cm^2 fragments using scissors and homogenized awaiting extraction. All samples were stored at room temperature prior to extraction and analysis.

Extraction Procedure. Extraction and analysis were conducted using a modification of the method of the European Commission.[25] A 5.0 g (fertilizer), 20.0 g (soil, coated seed, and mulching film), 1.0 g (stem and fruit), or 10 mL (irrigation water) aliquot of the sample was transferred into a 250 mL volumetric flask and diluted with 10 mL (60 mL for 20 g samples) of acetonitrile. Thereafter, samples were shaken for 2 min by an XW-80A model vortex apparatus (Jingke Co., Ltd., Shanghai, China) and then extracted in an ultrasonic bath (TH-300B model ultrasound cleaner, Tianhua Ultrasound Instrument Co., Ltd., Jining, China) for 10 min (30 min for 20 g samples). After

dx.doi.org/10.1021/jf5013067 | J. Agric. Food Chem. 2014, 62, 4072−4076

centrifugation (H-2050R model freezing centrifuge, Changsha Xiangyi centrifuge equipment Co., Ltd., Changsha, China) at 10000 rpm for 5 min at 5 °C, supernatants of samples were filtered through a 0.22 μm syringe filter into a 2 mL screw-cap vial. Then, 10 μL of this solution were injected into UPLC-MS/MS for analysis.

The pesticide samples were 0.5 mL and dissolved in 10 mL of cyclohexane/ethyl acetate (50:50, v/v), then purified through a PrepLinc gel permeation chromatography (GPC) system (J2 Scientific, Columbia, MD, USA) and eluted with cyclohexane/ethyl acetate (50:50, v/v) at a flow rate of 5 mL/min using a modification of the method of Song et al.[26] Finally, the eluates were evaporated and redissolved with acetonitrile, followed by filtering through a 0.22 μm syringe filter into a 2 mL screw-cap vial awaiting UPLC-MS/MS analysis.

UPLC-MS/MS Conditions. A 50 mm × 2.1 mm × 5 μm reversed phase C18 Waters Acquity BEH column, heated at 35 °C, was eluted using a mixture of acetonitrile (A) and 0.1% formic acid water solution (B) at a flow rate of 0.35 mL/min. The gradient elution was realized as follows: 0−0.5 min, 70% A; 0.5−3.0 min, 70−95% A; 3.0−4.0 min, 95% A; 4.0−5.0 min, 95−70% A.

The optimized experimental design parameters for ESI were as follows: capillary voltage, 1.0 kV; extractor cone voltage, 3.0 V; RF lens, 0.0 V; source temperature, 120 °C; desolvation temperature, 420 °C; desolvation gas flow, 700 L/h; cone gas flow, 50 L/h. The qualitative ion pairs of Sudan dyes I−IV as well as the cone voltage and the collision energy are shown in Table 2.

Data Analysis. Qualitative analysis was performed by comparing the retention times of qualitative ion pair peaks of the samples with those of standard chromatograms. Quantification was based on the external standard method. The matrix-matched standard curve of paprika fruit was done with blank samples spiked with 10 gradient concentrations of Sudan dyes I−IV immediately prior to UPLC-MS/MS analysis. The concentrations of Sudan dyes were then quantified by comparing the peak area of the particular compound in sample extracts with the corresponding external standard after replicate analysis.

Quality Assurance. Standard solutions of Sudan dyes I−IV were run at the beginning of the sample analysis to determine the relative response factors and evaluate peak resolution. A solvent blank was processed through the entire procedure and analyzed prior to and after each set of eight samples.

Each sample analysis was set up in duplicate. Results were considered invalid when the difference between duplicate analyses was >10% of the mean value of three values. Any sample showing no response or less than the limit of quantitation (LOQ) was concentrated to recheck or else reported as nondetected (ND).

RESULTS AND DISCUSSION

Analytical Performance of UPLC-MS/MS for Sudan Dyes. UPLC-MS/MS displays outstanding advantages in both rapidly identifying Sudan dyes and accurately quantitating the amount at ultratrace levels and, thus, was selected to determine the Sudan dye contamination in this study.

The major analytical performances of the method for Sudan dyes I−IV were investigated. As shown in Table 1, the limit of detection (LOD) and the limit of quantitation (LOQ) of 0.05−0.12 and 0.09−0.31 μg/kg were estimated on the basis of 3 and 10 times the signal-to-noise ratio (S/N), respectively. Recovery experiments were carried out by spiking three different concentrations (0.4, 4.0, 10.0 μg/kg) of standard solutions into a selected sample. The mean recovery was in the range of 70.4−91.5%. The precision of the analytical method was evaluated by repeatedly analyzing the spiked samples five times, yielding reproducible responses with the relative standard deviation of 7.3−12.4%. Sudan dyes I−IV exhibited good linearity ($R^2 \geq 0.9990$), indicating this method offered improved sensitivity.

Confirmation of Sudan I Contamination in Paprika Fruit. Figures 1 and 2 depict the UPLC-MS/MS chromatographic separation of Sudan dyes I, II, III, and IV in a standard solution (0.5 μg/kg) and a random paprika fruit sample. The retention times of standard solution are 1.44 min for Sudan I, 2.18 min for Sudan II, 2.91 min for Sudan III, and 4.90 min for Sudan IV, whereas for the paprika sample, only a Sudan I peak is observed at 1.47 min; Sudan dyes II, III, and IV were not detected, suggesting that Sudan dyes II, III, and IV did not exist in the paprika sample. Further analysis showed that the abundance ratio of Sudan I between the two ions of m/z 249.3 → 156.1 and 249.3 → 93.1 (qualitative ion pair) in paprika sample was 0.48 and 2.1% higher than that of the standard (0.47), which was within the acceptable deviations (±20%).[27] Therefore, it was concluded that only Sudan I contamination occurred in the paprika fruit.

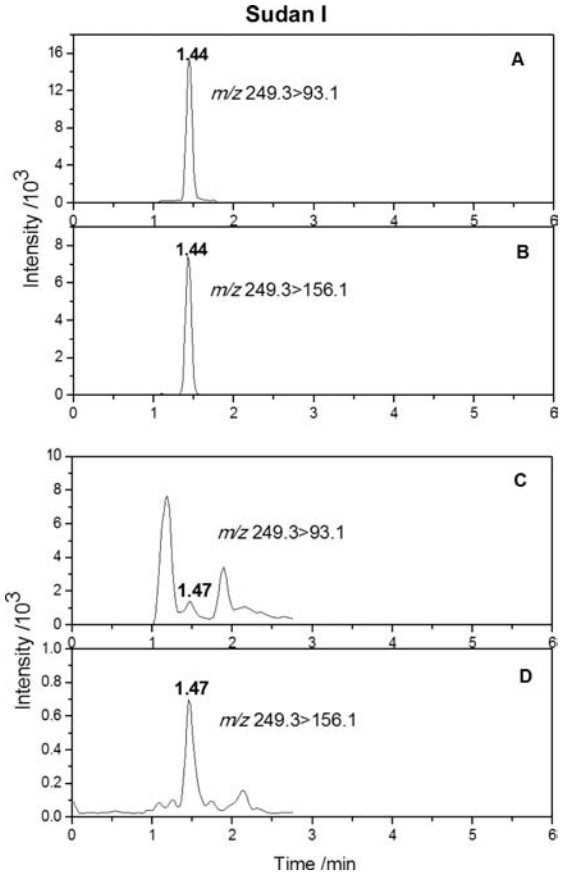

Figure 2. UPLC-MS/MS MRM trace obtained from standard solution (0.5 μg/kg) of Sudan I (A, B) and paprika sample of Sudan I (C, D).

Level of Sudan I Contamination in Paprika Fruit. Sudan I levels in paprika fruits and paprika stems from seven fields in Xinjiang (China) were investigated in triplicate (three aliquots of the same sample individually extracted and injected). As shown in Table 2, ultratrace levels of Sudan I contamination occurred in not only all paprika fruits but also the corresponding paprika stems. Considering all samples were directly collected by researchers from the field, neither addition nor cross-contamination occurred during the sample preparation and analysis processes, indicating that Sudan I contamination in paprika had really occurred over its growth period and was a universal phenomenon in the surveyed regions.

Table 3. Concentrations of Sudan I in Different Agronomic Materials (Soil, Pesticide, Fertilizer, Mulching Film, Coated Seed, and Irrigation Water) from Different Fields (Mean ± SE, n = 3)

field	soil (μg/kg)	pesticide (μg/kg)	fertilizer (μg/kg)	mulching film (μg/kg)	coated seed (μg/kg)	irrigation water (μg/kg)
1	0.0180 ± 0.0005	0.75 ± 0.04	0.03 ± 0.02	ND[a]	0.03 ± 0.02	ND
2	0.0090 ± 0.0004	0.50 ± 0.03	0.02 ± 0.01	ND	0.04 ± 0.01	ND
3	0.0120 ± 0.0005	0.62 ± 0.02	0.04 ± 0.02	ND	0.07 ± 0.03	ND
mean	0.013	0.62	0.03	ND	0.05 ± 0.02	ND

[a]Not detected. All samples were prepared independently.

The spatial variability of Sudan I was investigated by comparing the concentrations of Sudan I in five mature urn samples from different fields. As seen from Table 2, variability of the Sudan I levels of the same type changed with fields, with the maximum value of 1.08 μg/kg in field 5 and the minimum value of 0.26 μg/kg in field 2. Conversations with farmers revealed that such a large difference among fields ($p < 0.05$) was possibly attributable to the different operating conditions among different farmers.

To assess the evolution of Sudan I level over different stages of maturation, green paprika, orange paprika, and red paprika samples were collected from four fields (fields 1, 2, 3, and 6) for analysis. As shown in Table 2, no clear variation tendency of Sudan I level was observed with respect to paprika colors; four values at the same maturity stage were averaged, and the mean concentrations were 0.53 μg/kg for green paprika, 0.44 μg/kg for orange paprika, and 0.50 μg/kg for red paprika. These findings suggested that the Sudan I level remained almost unchanged with various maturation periods, and there may be no enrichment or degradation of Sudan I during the maturation process of paprika fruit.

Source of Sudan I Contamination in Paprika Fruits. To trace the source of Sudan dye contamination in paprika fruits, Sudan dye concentrations in reagents used in experiments, soils, and several agronomic materials, including pesticide, fertilizer, mulching film, coated seed, and irrigation water, were determined.

No Sudan dyes were detected in any of the reagents used. Sudan dyes II, III, and IV were never detected in any samples, and Sudan I was detected only in soils, pesticides, fertilizers, and coated seeds (Table 3). Generally, about 10.00 g of fertilizer, 0.03 g of pesticide, and 60.00 g of rhizosphere soil are applied in the process from sowing to maturity for a paprika fruit; however, only 0.008 g of coated seed is used. With this planting mode taken into account, the total amount of Sudan I in soils, pesticides, and fertilizers seems to correlate well with Sudan I concentration in paprika fruits (Table 4). Moreover, the mean Sudan I contents in soils, pesticides, and fertilizers were at least 2 orders of magnitude higher than that in coated seeds. These all together provide evidence for the major contribution of pesticide, fertilizer, and soil to Sudan I contamination in paprika fruit during its vegetation period.

Table 4. Total Amounts of Fruit, Soil, Pesticide, Fertilizer, Coated Seed per Fruit, and Total Amount of Sudan I in These Materials per Fruit

sample	total amount (μg) used per fruit	total amount (μg) of Sudan I in materials[a]
fruit	5.0×10^6	9.0×10^{-4}–5.4×10^{-3}
soil	6.0×10^7	6.0×10^{-4}–1.2×10^{-3}[b]
pesticide	9.0×10^4	$(4.5–6.9) \times 10^{-5}$
fertilizer	1.0×10^7	$(2.0–4.0) \times 10^{-4}$
coated seed	8.0×10^3	$(2.4–5.6) \times 10^{-7}$

[a]The amount range represented the different values for different species. [b]The data were calculated by using the rhizosphere soil.

During paprika cropping, Sudan I from the fertilizer may be absorbed by the root and transported to other parts of the plant including the stem and fruit. When pesticides are sprayed, Sudan I from the pesticide may be absorbed by the fruit or absorbed by the soil and then transported to the fruit. Soil contamination of planting areas may come from cumulative agriculture practices for many years due to application of Sudan I-containing pesticide and fertilizer, and when paprika was planted in the Sudan I-contaminated soil, Sudan I may migrate from the soil to different parts of the plant including the fruit.

As for the source of Sudan I in the pesticide and fertilizer, it can be traced to usage of Sudan dyes in chemical industry. Sudan dyes I–IV are widely used for different industrial and scientific applications such as oils, fats, plastics, printing inks, waxes, and spirit varnishing, among others,[28] which were often used as raw and auxiliary materials in manufacturing agronomic materials or in their packaging due to great access. Therefore, the most effective way of controlling Sudan I contamination in paprika is to eliminate the abuse of Sudan dyes in the manufacture of agronomic materials and packages.

To our knowledge, the present study is the first to report the occurrence of sub parts per billion levels of Sudan I contamination in paprika fruits in the process of growth. The Sudan I-contaminated soil combined with application of Sudan I-containing agronomic materials contributes to paprika fruit contamination. Due to the widespread use of Sudan I-containing agronomic materials during agricultural production, soils are contaminated with Sudan I to some extent, which results in the Sudan I contamination in paprika in conjunction with the effect of agronomic materials during the growth period. This discovery has significant implication for re-evaluating the origin of Sudan I in paprika fruits and paprika products.

Supporting Information

ABSTRACT: Anthranilic and phthalic diamides act on the ryanodine receptor (RyR), which constitutes the Ca^{2+}-activated Ca^{2+} channel and can be assayed as shown here in *Heliothis* thoracic muscle tissue with anthranilic diamide [^{3}H]chlorantraniliprole ([^{3}H]Chlo), phthalic diamide [^{3}H]flubendiamide ([^{3}H]Flu), and [^{3}H]ryanodine ([^{3}H]Ry). Using *Heliothis* with [^{3}H]Chlo or [^{3}H]Flu gives very similar anthranilic and phthalic diamide binding site structure−activity correlations, indicating a common binding site. The anthranilic and phthalic diamide stimulation of [^{3}H]Ry binding in *Heliothis* generally parallels their inhibition of [^{3}H]Chlo and [^{3}H]Flu binding. In *Musca* adults [^{3}H]Ry binding site stimulation is a good predictor of in vivo activity for anthranilic but not phthalic diamides, and no high-affinity [^{3}H]Flu specific binding site is observed. These relationships establish species differences in diamide target site specificity important in structure optimization and target site-based resistance mechanisms.

KEYWORDS: *ryanodine receptor, anthranilic diamides, phthalic diamides, structure−activity relationship, toxicity*

INTRODUCTION

Diamides are the newest major class of insecticides.[1−6] They combine outstanding potency on many major agricultural pests with low mammalian toxicity. The current diamides are of two chemotypes. Anthranilic diamides are exemplified by chlorantraniliprole (Chlo) and cyantraniliprole (Cyan)[3−6] and phthalic diamides by flubendiamide (Flu).[1,2] Their mode of action is different from that of all other insecticides so target site cross resistance is not a problem.[7] Both chemotypes are Ca^{2+} channel modulators and ryanodine (Ry) receptor (RyR) activators in essentially the same way; that is, no differences are apparent in their electrophysiological effects on insect muscle preparations.[1−6] Cross resistance between Chlo and Flu in control of *Plutella xylostella*[8−10] further suggests a common mode of action.

The molecular targets of Ry and the diamides in insects are partially characterized with appropriate radioligands, that is, [^{3}H]Ry,[11,12] [^{3}H]Chlo,[13] and [^{3}H]Flu[2,14] (Figure 1). Species differences are apparent in these binding sites. The [^{3}H]Flu, [^{3}H]Chlo, and [^{3}H]Ry sites have been studied in muscle tissues of *Musca*, *Apis*, *Heliothis*, and *Agrotis*[15] with major differences between species: [^{3}H]Ry binding and [^{3}H]Chlo binding have common characteristics in all of these insects based on Ca^{2+} and ATP effects and interactions with unlabeled Ry, Chlo, Cyan, and Flu, but no high affinity [^{3}H]Flu binding site was evident in *Musca* and *Apis* under our test conditions.[15] The goal of this investigation is to establish if the anthranilic and phthalic diamides have a common target site in some species but not others (e.g., *Heliothis* versus *Musca*) and if radioligand binding studies reflect the in vivo actions and toxic effects. These relationships are important in insecticide design, species specificity, and resistance management.

MATERIALS AND METHODS

Chemicals. [^{3}H]Ry (95 Ci/mmol) was purchased from PerkinElmer Life Sciences (Boston, MA, USA). [^{3}H]Chlo was synthesized in house.[13] Twenty-six anthranilic and phthalic diamides with generic structures shown in Figure 2 were used to compare the chemotype−activity relationships of binding assays with toxicity. Although the structures of individual compounds were not revealed for reasons of patenting status, their classification into two distinct chemotypes provided the opportunity to establish the relevance of the binding site assay results to toxicity in both the anthranilic and phthalic diamide series. [^{3}H]Flu and 11 analogues of Chlo were provided by Bayer CropScience (Monheim, Germany), and 12 analogues of Flu were supplied by Nihon Nohyaku (Tokyo, Japan). The compounds are numbered on the general basis of potency from the most to the least in the *Heliothis* thoracic muscle binding assay with [^{3}H]Chlo for the anthranilic diamide set and [^{3}H]Flu for the phthalic diamides as described later.

[^{3}H]Chlo, [^{3}H]Flu, and [^{3}H]Ry Binding Assays in Vitro. Membranes with associated RyR from *Heliothis* and *Musca* thoracic flight muscle were prepared as described and stored at −80 °C.[15] Each reaction mixture contained 1 nM [^{3}H]Chlo, [^{3}H]Flu, or [^{3}H]Ry, 200 μg of membrane protein,[13,15] and 30 nM test compound (in 2 μL of dimethyl sulfoxide) in binding buffer (0.8 mM $CaCl_2$, 2 mM ATP-Mg^{2+} salt, and 1.5 M KCl in 10 mM Hepes, pH 7.4) with a final volume of 412 μL. Incubations were for 120 min at 37 °C. Nonspecific binding was determined with 10 μM Chlo for [^{3}H]Chlo, 10 μM Flu for [^{3}H]Flu, and 10 μM Ry for [^{3}H]Ry binding. Bound radioligand

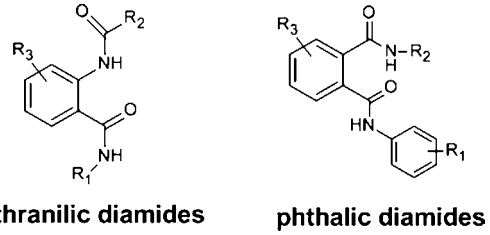

Figure 2. Diamides with various substituents (R_1, R_2, and R_3). The phthalic diamides are also referred to as 1,2-benzenedicarboxamides (BDCAs).

was harvested by filtration and quantitated according to earlier studies, and the percentage inhibition or stimulation versus control was determined.[13,15]

Heliothis and Spodoptera Bioassays. The efficacy of diamides against insecticide-susceptible strains of *Heliothis virescens* and *Spodoptera frugiperda* was tested using an artificial diet-based bioassay as described elsewhere.[16] Briefly, cylinders of artificial diet (height, 0.6 cm; diameter, 1.5 cm) were placed in 24-well tissue culture plates. Insecticide stock solutions were prepared by dissolving active ingredient in a 3:1 (v/v) mixture of dimethylformamide and emulsifier W. Subsequently, the stock solution was diluted with water. Twelve diet cylinders were each applied with 100 μL per concentration and represented one replicate. The experiment was repeated three times with two replicates per concentration. One second-instar larva was transferred to each treated cylinder. The plates were covered with tissue paper, sealed with a ventilated lid, and stored at room temperature in the dark. Percentage efficacy was assessed after 7 days. The toxicity ratings were generated by summing the assessed percentage efficacy (larvae dead or showing irreversible symptoms of poisoning) for each individual concentration tested; for example, in tests at 1000, 200, 40, 8, 1.6, 0.32, 0.064, and 0.0128 ppm and corresponding efficacy values of 100, 100, 100, 100, 100, 70, 20, and 0%, the toxicity index is 590.

***Musca* Poisoning Signs and [^{3}H]Chlo and [^{3}H]Ry Binding Assays in Vivo.** Twenty adult *Musca* anesthetized with carbon dioxide for 10 min were individually injected with a discriminating dose of each compound of 0.1 μg/fly (about 5 μg/g) into either the thorax or the abdomen (two sets of flies). Two hours after treatment, poisoning signs were observed for each fly to obtain a total rating for the set of 20 flies using the following system: 0 for normal, 1 for impaired movement, and 2 for dead. The final poisoning signs were equal to the number of impaired flies plus twice the number of dead flies multiplied by 2.5, that is, 100% impaired movement = 50 and 100% mortality = 100 poisoning rating. Thoraces were recovered 2 h after injection to determine ex vivo inhibition or stimulation of binding. Ten thoraces were homogenized by a Polytron (Brinkmann Instruments) in 1 mL of membrane preparation buffer (10 μM phenylmethanesulfonyl floride, 0.8% bovine serum albumin, and 303 mM sucrose in 20 mM Tris-maleate, pH 7.0) for 40 s.[15] Each homogenate was filtered through four layers of 64 μm mesh nylon screen after centrifuging at 700*g* for 30 min, and then 200 μL was used for radioligand binding assay as described above for binding in vitro.[15]

Statistical Analysis. Linear regression was performed to calculate the correlation among [^{3}H]Chlo, [^{3}H]Flu, and [^{3}H]Ry binding or versus toxicity for each compound with *Heliothis* or [^{3}H]Chlo and [^{3}H]Ry binding in vitro versus in vivo and binding in vitro/in vivo versus toxicity for each compound with *Musca*. GraphPad Prism 5.0 software was used to plot and analyze data.

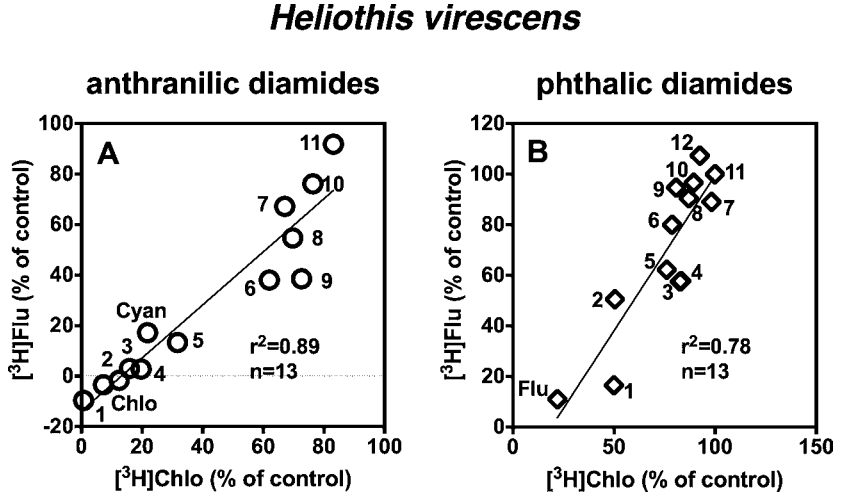

Figure 3. *Heliothis* toxicological profiles for anthranilic (A) and phthalic (B) diamide inhibition of [^{3}H]Chlo and [^{3}H]Flu binding assayed at 30 nM test compound.

RESULTS

Heliothis RyR. *Diamide Toxicological Profiles for [^{3}H]Chlo and [^{3}H]Flu Binding Sites.* The 11 anthranilic analogues plus Chlo and Cyan were tested at a discriminating concentration (30 nM) for inhibition of [^{3}H]Chlo and [^{3}H]Flu binding (Figure 3A), and the same experiment was made with the 12 phthalic analogues plus Flu at 30 nM (Figure 3B). The anthranilic and phthalic diamides have the same efficacy for inhibiting binding at the Chlo site as for the Flu site (Figure 4).

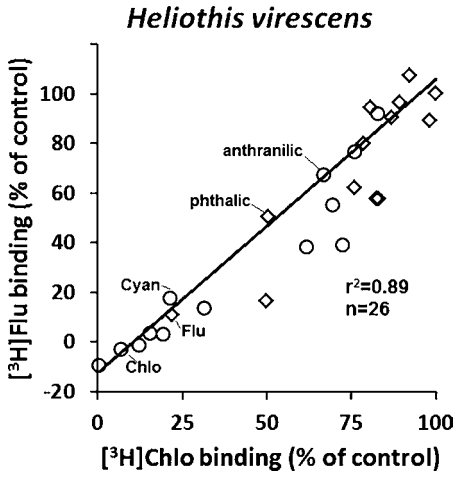

Figure 4. *Heliothis* toxicological profiles for anthranilic and phthalic diamide inhibition of [^{3}H]Chlo and [^{3}H]Flu binding assayed at 30 nM test compound. Individual compounds are identified in Figure 3.

Diamide Toxicological Profiles Relative to Insecticidal Activity. The binding site profiles were compared with the insecticidal activities for the anthranilic diamides with [^{3}H]Chlo (Figure 5A) and [^{3}H]Flu (Figure 5B). The potency of the anthranilic diamides to inhibit [^{3}H]Chlo and [^{3}H]Flu binding is consistent with their insecticidal activity. Because [^{3}H]Chlo and [^{3}H]Flu binding data are very similar, this also means that with *Heliothis* the use of either radioligand predicts toxicity in both diamide chemotypes.

Diamides Increase [^{3}H]Ry Binding. The two sets of diamides inhibitory to [^{3}H]Chlo and [^{3}H]Flu binding (Figure 5A, B) were assayed for effect on [^{3}H]Ry binding (Figure 5C) with a much lower correlation to toxicity (r^2 = 0.08). Inhibition at the diamide binding site assayed with [^{3}H]Chlo and [^{3}H]Flu is generally associated with increased binding at the [^{3}H]Ry site, that is, they are negatively correlated (Figure 6).

Musca RyR. *Diamide Toxicological Profiles for [^{3}H]Chlo and [^{3}H]Ry Binding Sites.* The experiments for in vitro inhibition of [^{3}H]Chlo and [^{3}H]Ry binding by 13 anthranilic diamides and 13 phthalic diamides described above with *Heliothis* RyR were also performed with *Musca* RyR under the same conditions. The toxicological profile was defined for the [^{3}H]Chlo binding site but not for the [^{3}H]Flu site because the latter radioligand does not undergo sufficient specific binding for meaningful determinations. Some anthranilic diamides inhibit [^{3}H]Chlo binding and can greatly stimulate [^{3}H]Ry binding (Figure 7A), whereas phthalic diamides can double [^{3}H]Chlo binding with less effect on [^{3}H]Ry binding (Figure 7B,A+B). The diamides were assayed both in vitro and in vivo, giving a good correlation between the findings for [^{3}H]Chlo binding with anthranilic diamides but a poor correlation with phthalic diamides (Supporting Information Figure 1) and the same trend for [^{3}H]Ry binding assays (Supporting Information Figure 2).

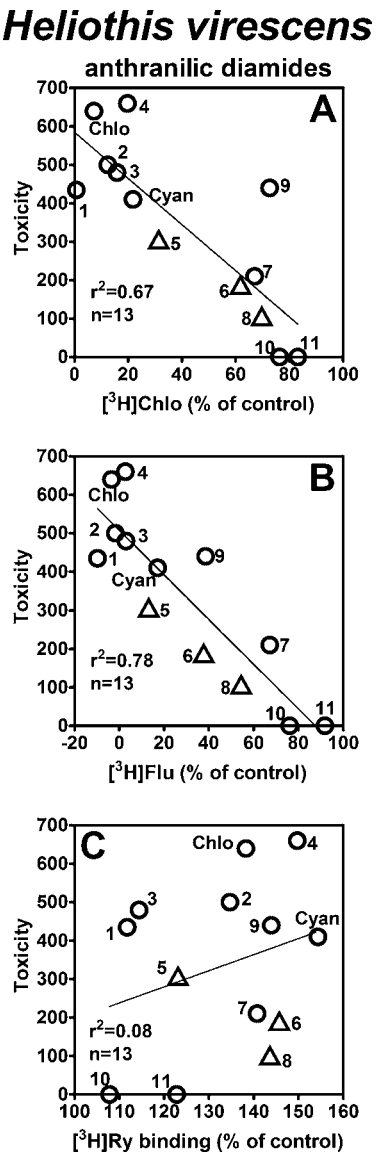

Figure 5. *Heliothis* and *Spodoptera* insecticidal activity of anthranilic diamides relative to potency for inhibition of *Heliothis* [^{3}H]Chlo (A) and [^{3}H]Flu (B) binding and stimulation of [^{3}H]Ry (C) binding assayed at 30 nM test compound. Toxicity data for *Heliothis* are used for eight compounds (○) and for *Spodoptera* with the other three compounds (**5**, **6**, and **8**) (△) where *Heliothis* data were not available. The *Heliothis* value averaged 90 ± 30% of the *Spodoptera* value for the eight compounds assayed with both species (see Supporting Information Table 1).

Diamide Toxicological Profiles for [^{3}H]Chlo and [^{3}H]Ry Binding Relative to Insecticidal Activity. [^{3}H]Chlo (Figure 8A,B) and [^{3}H]Ry (Figure 8C,D) binding site profiles were compared with the insecticidal activities for the anthranilic and phthalic diamide sets. The insecticidal activity of the anthranilic and phthalic diamides is poorly related to their inhibition of [^{3}H]Chlo binding but better correlated with their stimulation of [^{3}H]Ry binding. Generally similar results were observed with in vivo binding studies (Supporting Information Figures 1 and 2).

Species Differences in Binding Sites for [^{3}H]Chlo and [^{3}H]Ry. In the binding studies with *Heliothis* and *Musca*,

dx.doi.org/10.1021/jf501236h | J. Agric. Food Chem. 2014, 62, 4077−4082

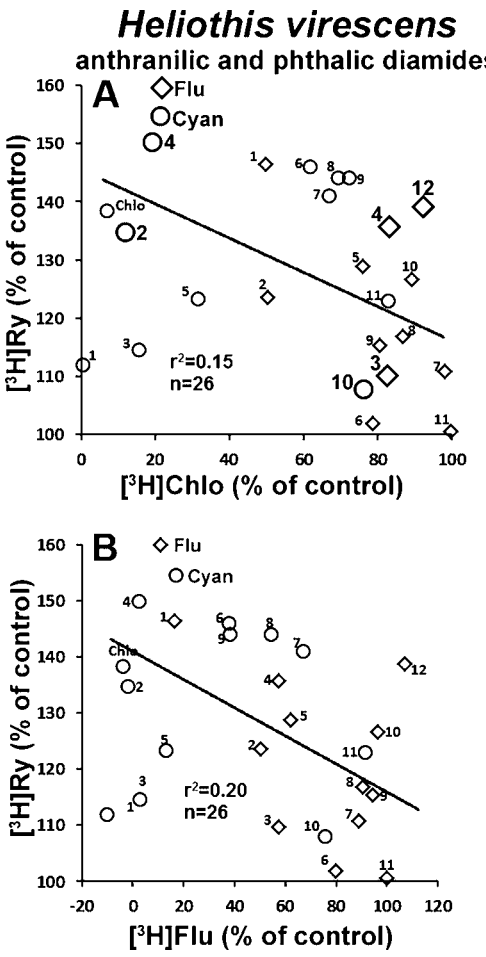

Figure 6. *Heliothis* toxicological profiles for anthranilic diamide and phthalic diamide inhibition of [^{3}H]Chlo (A) and [^{3}H]Flu (B) binding versus stimulation of [^{3}H]Ry binding assayed at 30 nM test compound.

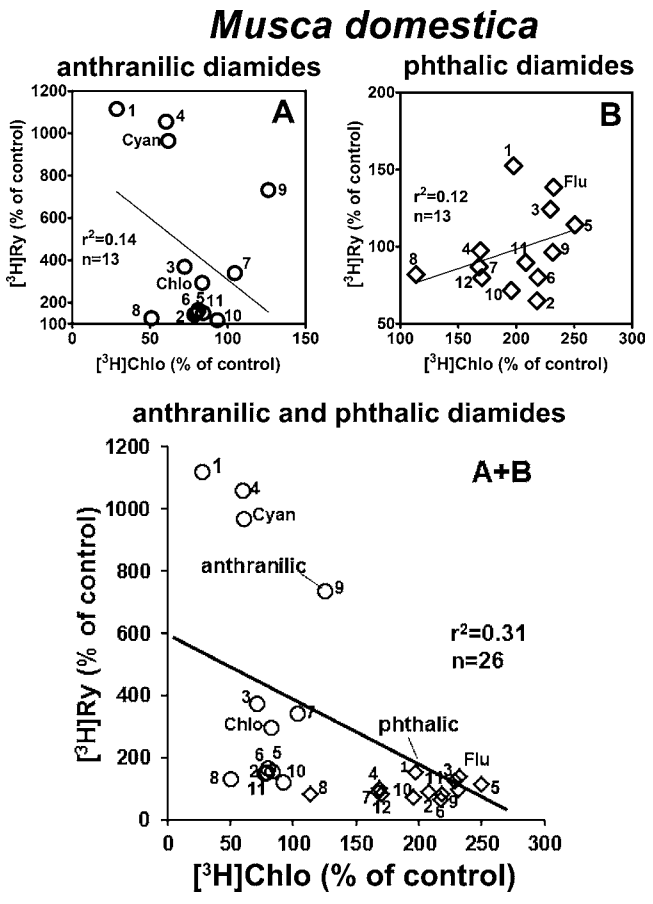

Figure 7. *Musca* toxicological profiles for anthranilic (A) and phthalic (B) diamides or both (A+B) relative to effects on [^{3}H]Chlo and [^{3}H]Ry binding assayed at 30 nM test compound.

anthranilic diamides generally inhibit [^{3}H]Chlo binding (Supporting Information Figure 3A) and stimulate [^{3}H]Ry binding (Supporting Information Figure 3B). In contrast, phthalic diamides generally inhibit [^{3}H]Chlo binding in *Heliothis* but stimulate binding in *Musca* (Supporting Information Figure 3A). The stimulation of [^{3}H]Ry binding by anthranilic diamides is much greater in *Musca* than in *Heliothis* (Supporting Information Figure 3B).

DISCUSSION

The RyR is recognized as a major target for insecticide action, and now more and more genomic analysis information is available on target and nontarget insect species.[17,18] The present study is an early step in evaluating species variations in insect RyR toxicology. There appears to be more than one type of diamide site in insects. In *Musca* the [^{3}H]Chlo, [^{3}H]Ry, and [^{3}H]Flu binding sites are conformationally different, but in *Heliothis* RyR, anthranilic and phthalic diamide insecticides displace each other when determined as either [^{3}H]Chlo or [^{3}H]Flu binding and therefore probably bind at the same or closely coupled sites.

Mammalian genomes express three different isoforms of the RyR, whereas insect genomes encode only a single RyR gene, and the low amino acid identity between mammal and insect RyRs probably contributes to the high selectivity of diamides.[19,20] To date, neither Chlo[21] nor Flu[22] has been found to exhibit cross resistance with other commercial insecticides. All field-evolved resistant lepidoptera populations that have been tested against the two diamides have shown cross-resistance between Chlo and Flu, which appears to be due to a single amino acid mutation in the RyR C-terminal transmembrane domain, which encodes the proposed binding site of diamides.[10] There is high homology between lepidoptera RyR genes; thus, the conserved transmembrane region might contribute to the same binding sites for Chlo and Flu.

A set of anthranilic diamides and another of phthalic diamides were evaluated with [^{3}H]Chlo and [^{3}H]Flu binding assays as predictors of toxicity using data from ingestion of the anthranilic diamides by lepidoptera larvae in the Bayer laboratory and injection of both diamide chemotypes into *Musca* in the Berkeley laboratory. In *Heliothis*, the [^{3}H]Chlo and [^{3}H]Flu binding assays were good predictors of toxicity for both the anthranilic and phthalic diamides. In *Musca*, the binding site−toxicity correlations were less favorable or absent, possibly due in part to diamide detoxification. Although the data are not shown, the in vivo RyR inhibition in *Musca* was nearly the same for injections into either the thorax or the abdomen, indicating that thoracic muscle RyR binding occurred mostly in vivo rather than during the binding assay.

The potency of diamides as inhibitors of [^{3}H]Chlo and [^{3}H]Flu binding is generally correlated with their effectiveness in stimulating [^{3}H]Ry binding; that is, binding at the Chlo/Flu site opens or increases the open time of the Ca^{2+} channel. A

dx.doi.org/10.1021/jf501236h | J. Agric. Food Chem. 2014, 62, 4077−4082

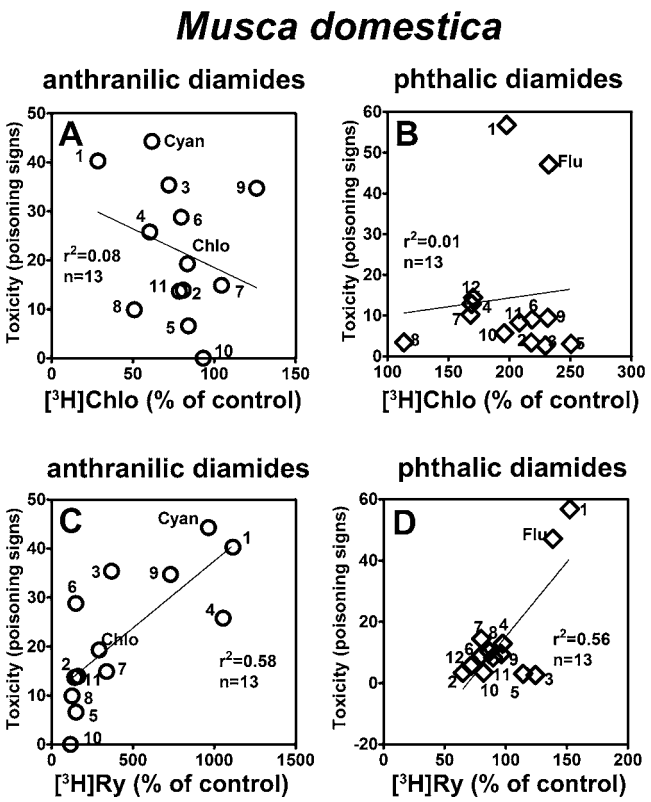

Figure 8. *Musca* insecticidal activity of anthranilic (A) and phthalic (B) diamides relative to potency for inhibition of [^{3}H]Chlo binding (A, B) and stimulation of [^{3}H]Ry (C, D) binding assayed at 30 nM test compound.

series of Chlo analogues was tested with *Musca* RyR both in vitro and in vivo for effects on [^{3}H]Ry binding with stimulation in most cases, a relationship also observed with a number of Flu analogues, further generalizing the diamide activity as a stimulator of the [^{3}H]Ry site. Thus, the observation of enhanced [^{3}H]Ry binding seems to be a reliable indicator of diamide action at the Ca^{2+}-modulated Ca^{2+} channel.

The stimulation of [^{3}H]Chlo binding to *Musca* membranes by phthalic diamides may be due to the fact that their affinity for the *Musca* RyR is much lower (our estimate of the apparent K_d of Flu is about 185 nM) than for the *Heliothis* RyR. Therefore, the phthalic diamide concentrations used in this study may not be sufficient to provide effective competition with the high-affinity radioligand [^{3}H]Chlo, as is the case with the *Heliothis* receptor having a higher affinity for phthalic diamides. An increase in the open probability of the *Musca* RyR induced by phthalic diamides could plausibly explain the stimulatory effect on [^{3}H]Chlo binding by increasing the number of radioligand binding sites. The underlying assumption is that diamides are conformation-sensitive ligands which preferentially bind to the open channel as shown for [^{3}H]Flu.[23]

Continuing progress in defining insect RyR regions critical to both anthranilic and phthalic diamide sensitivity is helping to define the basis for diamide selectivity among insect species and between insects and mammals.[24]

Supporting Information

ABSTRACT: Effects of sublethal levels of the photosystem-interfering herbicides atrazine (Atr) and methyl viologen (MV) on photosynthetic electron transport were investigated in *Arabidopsis thaliana* mutants with defects in cyclic electron transfer (CET) activity. Analysis based on chlorophyll fluorescence parameters showed that *pgr*5 mutant (a defect in the PGR5 pathway) was more sensitive to both Atr and MV than wild type (Wt) and *pnsB*3 mutant (a defect in the NDH pathway). Real-time PCR (polymerase chain reaction) analysis of transcripts indicated that Wt plants showed marked increases in transcripts in the PRG5 and NDH pathways under treatment with either Atr or MV. In contrast, Atr increased the gene transcripts in CET, but MV decreased them in *pnsB*3 mutant plants. Atr did not increase the transcripts, while MV down-regulated them in *pgr*5 mutant. Immunoblot analysis partially supported the changes in the transcripts; that is, the protein levels of PGRL1 and PGR5 were increased in *pnsB*3 mutant, while no protein level was increased in *pgr*5 mutant after the herbicide treatment. The present results suggest that cyclic electron transport is very sensitive to photosystem-interference induced by chemicals and that the PGR5 pathway is very critical for regulation. Thus, *pgr*5 mutants may be useful plants for monitoring photosystem-interfering herbicides.

KEYWORDS: *Arabidopsis thaliana, cyclic electron transport, pgr5, pnsB3, herbicide*

INTRODUCTION

Increasing amounts of herbicides are being used to control weed growth, and these now account for up to 50%−60% of total nonfertilizer chemicals in agriculture.[1] Although herbicides do effectively control weed growth, almost 99.9% of them enter the environment, where they affect nontarget organisms.[2,3] Among herbicides, the inhibition of photosynthesis is the most common and effective mechanism of action, since photosynthesis is ubiquitous in plants. Atrazine (Atr) and methyl viologen (MV) are commonly used herbicides. Atr displaces plastoquinone from its binding site (the Q_B site) in the D1 protein[4] and inhibits chloroplast electron flow from plastoquinone A to Q_B, and reduces ATP and NADPH production and CO_2 fixation.[5] MV accepts electrons from the Fe-SA/Fe-SB iron−sulfur cluster of photosystem I (PSI) and reduces NADPH generation and CO_2 fixation.[6] MV reduced by PSI, in turn, reduces molecular oxygen to a superoxide radical and then induces the peroxidation of lipids and other cellular components, leading to a rapid loss of membrane integrity, photooxidation, desiccation, and plant death.[7]

Although their primary targets have been well-characterized, the effects of sublethal doses of these chemicals diffused into the environment, as mentioned above, are not yet clear. The application of sublethal concentrations of these chemicals may disrupt linear photosynthetic electron transfer (LET) and decrease the production of the energy-rich compounds NADPH and ATP. Plants may cope with this stress by adjusting photosynthetic electron transfer in various ways, such as by intensifying electron transfer through a process known as cyclic electron transfer (CET) to produce more ATP to drive protein repair.[8−11] The additional ATP arising from CET may compensate for the insufficient production of ATP from LET, thus supporting CO_2 fixation, since LET alone cannot produce sufficient ATP to satisfy the required stoichiometry.[12] In fact, CET is an essential physiological process for efficient photosynthesis.[13] CET can balance the ATP/NADPH production ratio to protect photosystems[14−16] by inducing nonphotochemical quenching (qN) to dissipate excessive absorbed light energy.[17] CET generally occurs through two routes in higher plants: the PGR5 and chloroplast NAD(P)H dehydrogenase (NDH) pathways. In the PGR 5 pathway, electron transfer is mediated by the proton gradient regulation 5 (PGR 5) and pgr5-like 1 (PGRL1) proteins. In the NDH pathway, electrons are cycled around PSI by the thylakoid-embedded NDH complex.[11,14]

To verify the effects of sublethal levels of photosystem-interfering herbicides on CET, we measured photosynthetic electron transfer activity based on chlorophyll fluorescence parameters, gene expression, and protein accumulation of components in the LET and CET pathways using two *A. thaliana* mutants, which have defects in either the LET or CET

pathway: i.e., a *pgr*5 mutant, which is deficient in antimycin A-sensitive cyclic flow from ferredoxin to plastoquinone,[18] and a *pnsB*3 mutant, which is deficient in NDH-dependent cyclic flow from NADPH to plastoquinone.[19] Our experimental results revealed that cyclic electron transport is very sensitive to photosystem-interference induced by chemicals and the PGR5 pathway is very critical for regulation.

MATERIALS AND METHODS

***Arabidopsis thaliana* Culture.** Seeds of *A. thaliana* (ecotype Columbia; Wt and *pgr*5 and *pnsB*3 (formerly *ndf*4) were sterilized and germinated on Murashige-Skoog (MS) medium containing 0.8% w/v agar and 1% w/v sucrose for 2 weeks before transfer to a 6 cm pot containing compost with vermiculite (1:1). After 2 weeks in soil, the seedlings were transferred to 1/2 MS liquid medium to adapt to the culture conditions. The seedlings were exposed to 0.2 μM Atr or 0.8 μM MV for 6 days. These herbicide concentrations, which were selected based on a previous report by Sato et al.,[23] did not cause growth inhibition of *A. thaliana* phenotype after 6 days of growth. The plants were grown in an air-conditioned room at 23 °C under a 10 h light/14 h dark cycle at a light intensity of 40 μmol photons m^{-2} s^{-1}. Four to eight replicates were prepared for each treatment. Samples were collected after 3 and 6 days of herbicide treatment for photosynthetic chlorophyll fluorescence and gene expression analyses.

Chlorophyll Fluorescence Analysis. One seedling in the herbicide-treated or control group was collected and immersed in *N*,*N*-dimethylformamide to extract chlorophyll according to the method of Inskeep and Bloom.[24] The chlorophyll-extracted liquids were measured for absorbance values at 647 and 664.5 nm using a spectrophotometer, and chlorophyll a (chl a) and chlorophyll b (chl b) contents were calculated according to the formula reported in Inskeep and Bloom.[24] Chlorophyll fluorescence parameters were measured using a MINI-PAM (pulse-amplitude modulation) portable chlorophyll fluorometer (Walz, Germany). The maximum quantum yield [F_v/F_m], the quantum yield of photochemistry in PSII [$\Phi_{II} = (F_m' - F_s)/F_m'$], photochemical quenching [$qP = (F_m' - F_s)/(F_m' - F_o')$], and nonphotochemical quenching [$qN = 1 - (F_m' - F_o')/(F_m - F_o)$] were calculated based on the measured chlorophyll fluorescence. The leaves were exposed to both low light (270 μmol photons m^{-2} s^{-1}, LL) and high light (1410 μmol photons m^{-2} s^{-1}, HL) for the measurement of all chlorophyll fluorescence parameters. For detailed explanations of each chlorophyll fluorescence parameter, see van Kooten and Snel.[25]

Real-Time Quantitative PCR (polymerase chain reaction). Total RNA was extracted from control and herbicide-treated seedlings using the RNeasy PlantMini Kit (Qiagen, CA, USA). RNA concentrations were measured spectrophotometrically at 260 nm. The 260/280 nm ratios were determined and closed to 2.0, which showed the purity of the total RNA was high. The integrity of RNA was verified by visualizing the samples on ethidium bromide-stained agarose gels (Figure S1 of the Supporting Information); no significant degradation was observed. A 1-μg sample of the total RNA was used as a template for cDNA synthesis using SuperScript III reverse transcriptase (Invitrogen) with random primers. Real-time PCR was performed using iQ SYBR Green Supermix (Bio-Rad) in the CFX96 real-time PCR detection system (Bio-Rad). The cycle parameters consisted of one cycle of 3 min s at 95 °C and then 39 cycles of 10 s at 95 °C followed by 10 s at 55 °C and 30 s at 72 °C. The obtained data were analyzed using CFX manager software (Bio-Rad). Sixteen genes involved in the LET and CET pathways were selected for analysis; the primer pairs for each of these genes are listed in Table S1 of the Supporting Information. Expression of the housekeeping gene Actin 2 was used to normalize the expression profiles of the analyzed genes. Relative quantification of gene expression among the treatment groups was performed using the $2^{-\Delta\Delta Ct}$ method.[26]

Extraction of Crude Thylakoid Membrane Fraction, Protein Electrophoresis, and Western Blot Analysis. Rosette leaves from herbicide-treated plants and control plants were collected for extraction of the thylakoid membrane fraction on ice. As described by Takabayashi et al.,[19] rosette leaves were homogenized with protein extraction buffer (0.3 M sorbitol, 50 mM HEPES-KOH (pH 7.6), 1 mM $MgCl_2$, 1 mM $MnCl_2$, 2 mM EDTA, 30 mM KCl, 0.25 mM KH_2PO_4). The pellet obtained after centrifugation at 3000*g* for 5 min was then washed twice with 1× HEPES buffer without sorbitol. The isolated thylakoid fraction was finally treated in SDS−PAGE sample buffer (10 mM EDTA, 0.2 M DTT, 4% SDS, 0.2% Bromephenol blue, 20% glycerol, 100 mM Tris−HCl, pH 6.8) at 37 °C for 1 h. Protein corresponding to 0.5 g of chlorophyll was subjected to SDS−PAGE with a 12.5% polyacrylamide−SDS gel. The proteins in the gel were then blotted onto a polyvinylidene difluoride (PVDF) membrane (Millipore Corporation) using a transblot apparatus (Bio-Rad). A Western blot analysis was performed with rabbit antibodies against PNSB1, PNSB3, NDHH, PGRL1, PGR5, PsaB, Cytf, and RbcL. The blotted bands were detected using Western Lightning Chemiluminescence Reagent Plus (PerkinElmer Inc.) together with anti-rabbit IgG (Amersham). The amounts of protein in each sample were qualitatively compared using Coomassie Brilliant Blue (CBB) dye to stain the SDS-polyacrylamide gels, and normalized before the samples were subjected to Western blot analysis.

Data Analysis. The data are presented as the mean ± standard error of the mean (SEM). Statistical significance was tested via one-way ANOVA. Values were considered significantly different at a p value of less than 0.05.

RESULTS

Effects of Atr and MV on Chlorophyll Content and Photosynthetic Activities. Treatment with Atr and MV did not cause severe growth defects in Wt *Arabidopsis* seedlings, as noted in the Materials and Methods. However, the measurement of chlorophyll content, a biomarker that reflects the status of photosynthesis in plants, revealed that there were different effects in mutants (Table 1). Whereas untreated and Atr-treated Wt, *pnsB*3, and *pgr*5 seedlings, as well as MV-treated Wt and *pnsB*3 seedlings, showed no effects on Chl a and Chl b content, MV-treated *pgr*5 significantly decreased the Chl a and Chl b contents to 65% and 50% of the control levels, respectively.

The measurement of chlorophyll fluorescence parameters, i.e., the maximal quantum yield (F_v/F_m), the quantum yield of PSII (ΦII), photochemical quenching (qP), and nonphotochemical quenching (qN) under low light (LL) and high light (HL), revealed more differences in mutants, whereas the concentrations of the herbicides used did not significantly alter the fluorescence parameters in Wt plants (see Figure 1, 3 days treatment). First, we compared F_v/F_m in nontreated seedlings of Wt and mutants, and we found that F_v/F_m was almost the same in the Wt, *pgr*5, and *pnsB*3 plants. Treatment with herbicides for 3 days also did not cause severe changes in F_v/F_m, and the value was approximately 0.75 (Figure 1A). Treatment with Atr or MV for 6 days also did not cause a statistically significant decrease in F_v/F_m in both Wt and the *pnsB*3 mutant. In the *pgr*5 mutant, however, F_v/F_m significantly decreased, in comparison with the control (*pgr*5-Con), after 6 days of treatment with Atr or MV.

The quantum yield of PSII (Φ_{II}) showed similar but much greater changes than F_v/F_m, especially under HL (Figure 1B and C). The control without chemical treatment for 3 days showed no significant differences in Φ_{II} between Wt and the two mutants under both LL and HL conditions. In the *pgr*5 mutant, however, Φ_{II} was significantly lower than those in the Wt and *pnsB*3 mutant after culture for 6 days even under control conditions without chemical treatment, especially under HL, as reported previously.[18] Treatment with Atr for 3 days also did not induce significant changes in the Φ_{II} level under LL or HL conditions, whereas treatment for 6 days clearly

[a]Data are expressed as the mean ± SEM. [b]Different letters represent statistically significant differences at $p < 0.05$ based on one-way ANOVA.

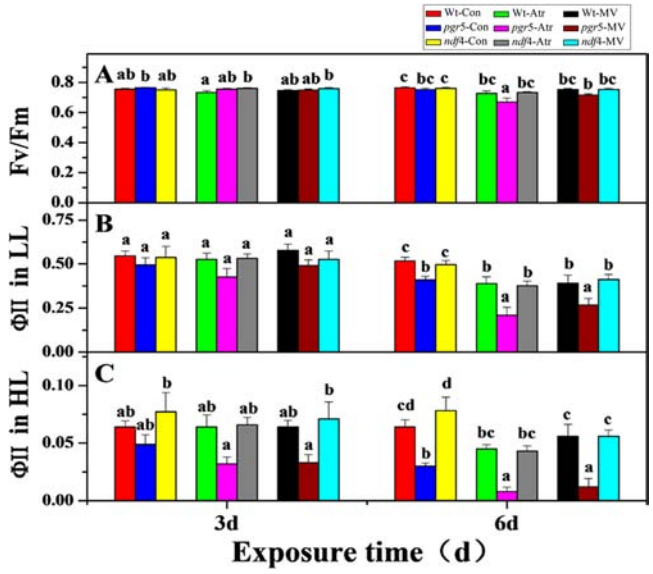

Figure 1. PSII fluorescence parameters: maximum quantum yield of PSII (F_v/F_m) and the quantum yield of photochemistry in PSII (ΦII) under LL and HL conditions. Different letters represent statistically significant differences at $p < 0.05$ based on one-way ANOVA.

decreased the Φ_{II} level in all seedlings in comparison with the levels in untreated seedlings (Figure 1B), and the reduction induced by Atr was more evident under HL conditions (Figure 1C). The changes in Φ_{II} under the treatment with MV were similar to those under treatment with Atr. Under all treatment conditions, the *pgr*5 showed the lowest Φ_{II} among the three genotypes, and this difference was more pronounced under HL conditions.

The *pgr*5 mutant showed a clear decrease in photochemical quenching (qP) in comparison with the Wt and *pnsB*3 plants after 3 days of culture even under control conditions (Figure 2A). Treatment with either Atr or MV, especially under HL conditions, produced an even greater decrease in qP in the *pgr*5 mutant, and this reduction was more enhanced after culture for 6 days (Figure 2B). While both the Wt and *pnsB*3 mutant also showed decreases in qP under treatment with Atr or MV after 6 days of culture, the reduction in the *pgr*5 mutant was extreme. Since a low qP reflects a reduced plastoquinone pool, these results support the importance of the PGR5 pathway for the maintenance of electron transfer.

The *pgr*5 mutant also showed lower nonphotochemical quenching (qN) than the Wt and the *pnsB*3 mutant even under control untreated conditions (Figure 2C and D), indicating the importance of the PGR5 pathway for qN formation. On the other hand, treatment with Atr and MV did not affect qN in Wt and *psnB*3 under either LL or HL conditions. While the *pgr*5 mutant showed a reduced qN under all conditions, the differences among the genotypes were much smaller than those for qP (Figure 2C).

Treatment with Atr and MV and Photosynthesis-Related Gene Transcription in Mutants. Given that Atr and MV affected chlorophyll fluorescence parameters in both Wt and mutants significantly until 6 days of exposure, we collected 6-day-treated samples to analyze gene transcripts. The expression of genes related to PSI (*psa*D1), PSII (*psb*A), Fd (*fd*1 and *fd*2), FNR (*fnr*1 and *fnr*2), CET (*pnsB*3, *lhca*5, *ndh*H, *pnsB*1, *ppl*2, *ndh*N, *pgr*5, *pgrl*1A, and *pgr*1B), and the Calvin cycle (*rbc*L) was analyzed in Wt, *pnsB*3, and *pgr*5 plants under

control conditions after 6 days of culture without herbicide treatment (Figure 3). While there were no significant

differences in the transcript levels of many of these genes among the three genotypes, the *rbc*L transcript level in the *pnsB*3 mutant was higher than those in the Wt and *pgr*5 mutant and the transcript level of *fd*1 in the *pgr*5 mutant was lower than that in the *pnsB*3 mutant. Naturally, there was no transcription of the *pnsB*3 gene in the *pnsB*3 mutant.

When gene expression in seedlings that were treated with Atr or MV was compared with that in a control culture without treatment, the three genotypes showed considerably different responses. In the Wt plants, Atr and MV up-regulated the transcriptions of several photosynthesis-related genes (Figure 4A and B). In fact, the levels of 12 and 6 gene transcripts involved in the CET and LET pathways were up-regulated in Atr- and MV-treated samples, respectively, compared to the control. Interestingly, both Atr- and MV-treatment significantly increased transcript levels of *fnr*1, *pgrl*1A, and *pgrl*1B. On the other hand, the *pgr*5 and *pnsB*3 mutants showed much smaller increases than the Wt (Figure 4D−F). Only several genes were significantly increased in both *pgr*5/*pnsB*3 mutants treated with Atr and MV, although the genes that were increased differed between the *pgr*5 and *pnsB*3 mutants; e.g., none of the transcripts examined in the NDH pathway were increased in *pgr*5, whereas some showed an increase in the *pnsB*3 mutant (Figure 4C and E). The levels of the *fd*2, *pgr1*lA, and *psb*A transcripts were increased approximately 2-fold in Atr-treated *pnsB*3 mutant, whereas more than a 2-fold increase was observed for *fnr*1 and *pgr1*lB in Atr-treated *pgr*5 mutant.

Treatment with MV considerably decreased the transcript levels of most of the genes examined in both the *pgr*5 and *pnsB*3 mutants in comparison with those in the Wt (Figure 4D and F). The electrophoresis of the extracted RNAs confirmed that the mRNA of all samples was high quality (Figure S1 of the Supporting Information), indicating that the decrease of photosynthesis-related gene transcripts examined in CEF mutants was caused by herbicides treatment, not by RNA degradation in the extracted process, and that MV showed stronger inhibitory effect on gene transcript than Atr. These stronger effects of MV on gene expression were in contrast to its modest effects on photosynthetic activities as measured by chlorophyll fluorescence analysis.

Treatment with Atr and MV and the Accumulation of Chloroplast Proteins in Mutants. To confirm the effects of herbicides on protein accumulation in mutants, immunoblot analysis was conducted. While the accumulation of NDH complex proteins in the *pnsB*3 mutant or of proteins (PGR1 and PGRL1) in the PGR5 pathway in the *pgr*5 mutant was considerably reduced due to their respective mutations, the levels of other proteins were almost constant among the Wt and mutants under control growth conditions without herbicide treatment (Figure 5). Whereas treatment with Atr or MV increased the expression of many photosynthetic genes in Wt plants, these herbicides had only marginal effects on the accumulation of the corresponding proteins; e.g., while treatment with either Atr or MV increased the accumulation of PNSB3, Atr reduced, and PG increased, the accumulation of NDHH. The accumulation of PNSB1 was not significantly affected by herbicide treatment. Similarly, the effects of herbicides in both the *pgr*5 and *pns*B3 mutants were not as dramatic as the changes in transcript levels; while treatment with Atr decreased the accumulation of NDHH in *pgr*5 mutant, the accumulation of other NDH subunit proteins was unaffected by treatment with Atr or MV. There was a dramatic change in the accumulation of RbcL; while treatment with Atr reduced the accumulation of RbcL in Wt, it increased the accumulation of RbcL in both the *pgr*5 and *pns*B3 mutants, and treatment with MV did not affect the accumulation of RbcL in the Wt or mutants.

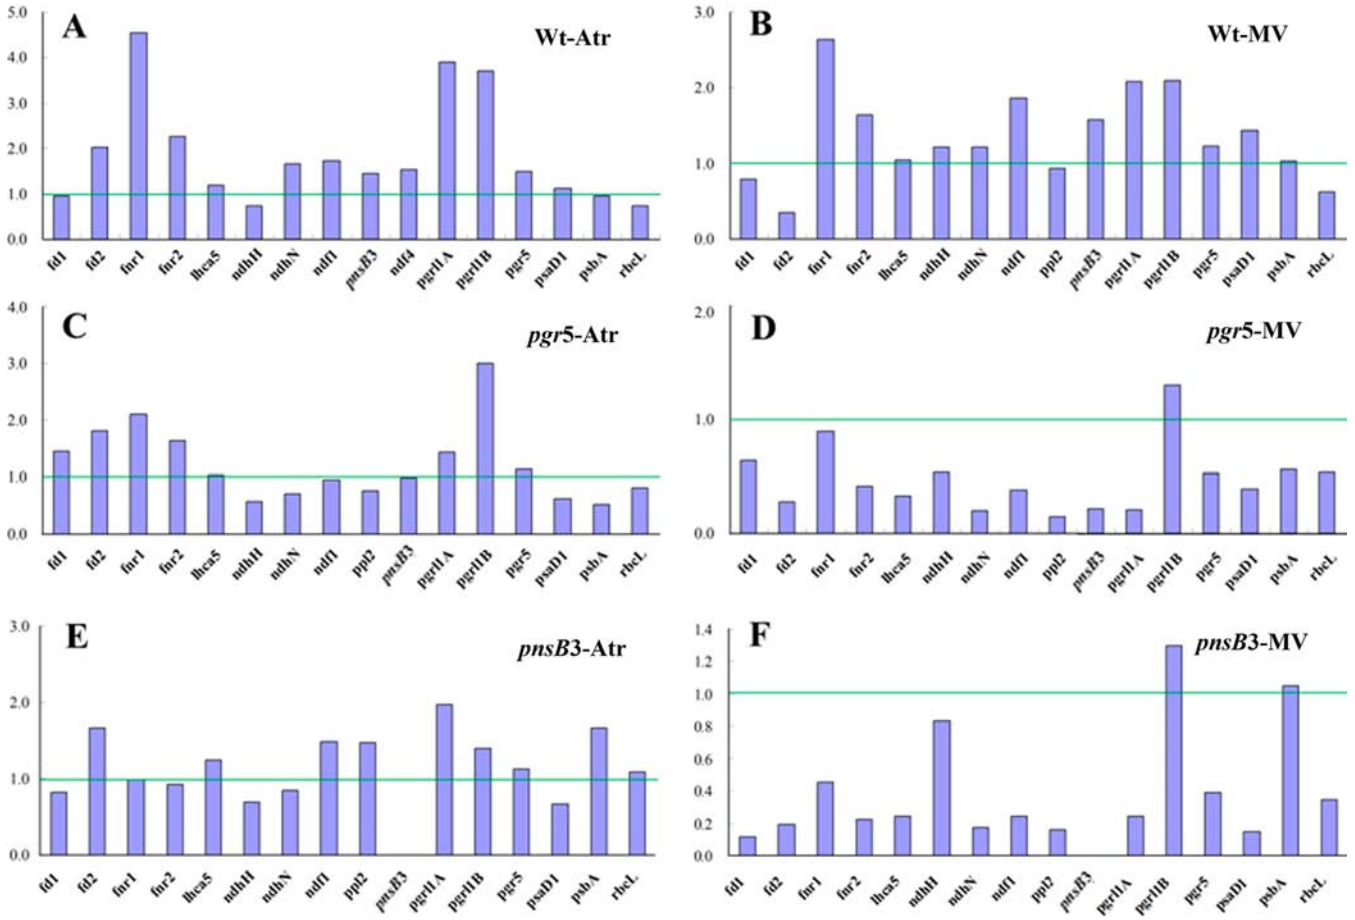

Figure 4. Relative transcript levels in Atr- and MV-treated plants compared to the corresponding controls. The columns indicate the relative transcript levels in treated plants compared to the corresponding controls. Transcript levels were measured using real-time PCR and normalized to the expression of the reference gene Actin 2. One indicates no change in transcript levels; <1 indicates a decrease in transcript levels; and >1 indicates an increase in transcript levels under drought stress compared to the control.

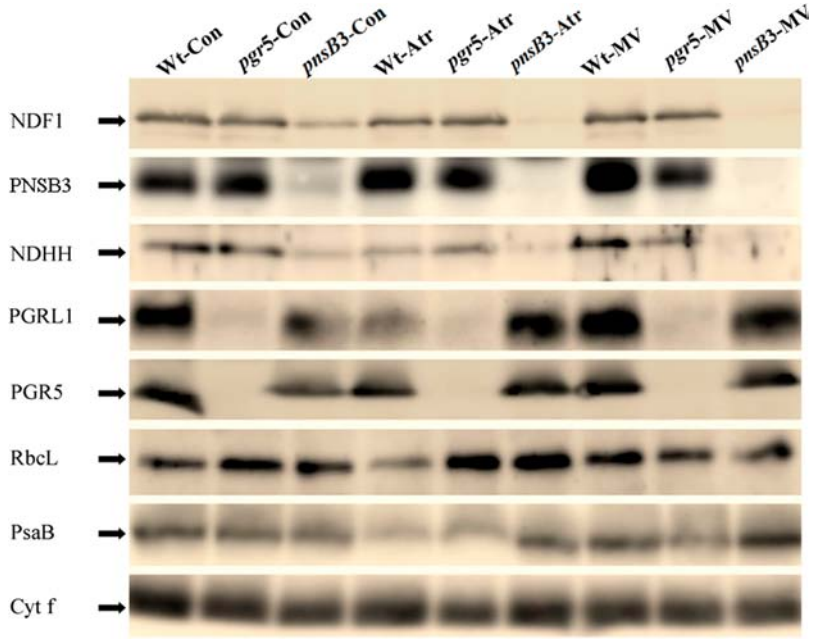

Figure 5. Effects of Atr and MV on translation of the following proteins: PNSB1, PNSB3, NDHH, PGRL1, PGR5, RbcL, PsaB, and Cyt f. Equal amounts of protein were extracted from the stroma and thylakoid membrane fractions, and the lanes were loaded with protein samples corresponding to 0.5 mg of Chl. All eight tested proteins were immunodetected using specific antibodies.

DISCUSSION

We examined the effects of sublethal concentrations of Atr and MV, both of which are well-known photosystem-interfering herbicides that are widely used in agriculture,[20] on photosynthetic activity, gene expression, and protein accumulation in plants, since residual Atr and MV from farms contaminate soil, groundwater, rivers, and ponds and are frequently detected in the environment. The concentration of Atr has been shown to reach 120 μg/L in agricultural basins, 14 μg/L in urban basins, and 22 μg/L in river basins,[21] while the levels of MV in soil are as high as 8.1−35.02 ppm.[22] We used concentrations of Atr (0.2 μM, 51.2 μg/L) and MV (0.8 μM, 103 μg/L) that were close to the concentrations observed in the environment. We also used two CET mutants (*pgr*5 and *pnsB*3), which have mutations in the PGR5 and NDH pathways, since we expected that both Atr and MV would affect photosynthetic electron transport and, consequently, CEF. In fact, these two mutants grew well as Wt plants under herbicide-free conditions,[13,19] and they should be suitable for monitoring the effects of sublethal concentrations of herbicides.

Chlorophyll fluorescence was more sensitive to the herbicide treatment than chlorophyll content and other growth parameters, implicating that even if phenotypic symptoms are not detected, electron transfer may be disturbed before photodamage emerges, as reflected by F_v/F_m. Results from the chlorophyll fluorescence demonstrated that *pgr*5 mutant was more sensitive to the herbicide treatment than *pns*B3 mutant, implicating that the PGR5 pathway plays a crucial role in the regulation of electron transfer, and *pgr*5 mutants should be suitable plants for monitoring herbicides, especially photosystem-interfering herbicides. An interesting question raised by our results is how Atr and MV, which have different primary targets in electron transfer, induce similar effects in photosynthetic electron transfer, as reflected by chlorophyll fluorescence parameters. For example, the reduction of Φ_{II} and qP in Wt by MV (see Figure 2A and B), and the increase in qN in *pgr*5 by Atr (see Figure 2C) cannot be explained simply by inhibition of the primary targets of these chemicals. Furthermore, treatment with Atr and MV similarly enhanced transcripts of photosynthetic genes in Wt plants. One of the possible reason might be that both Atr and MV may form reactive oxygen species (ROS), which in turn may decrease the efficiency of electron transport, i.e., ΦII (Figure 1B and C) and qP (Figure 2A and B). Another possibility is the limitation of electron transfer through the cytochrome b6/f complex induced by the inhibition of PSII or by electron leakage through MV in PSI. This limited impairment of electron flow in cytochrome b6/f would be enhanced in *pgr*5 mutants, which should limit the transfer of electrons from PSI.

Another interesting finding is a discrepancy in the effects of these herbicides on gene transcript and protein translation. Two possibilities may exist for explaining this discrepancy. One was that sublethal concentrations of Atr and MV have very limited effects on photoinhibition, as reflected by the small changes in F_v/F_m. Thus, even if transcription is disturbed by these chemicals, their effects on protein accumulation are rather marginal. Another possibility is that *Arabidopsis* is a eukaryotic species and that it is uncoupling between gene transcription and translation; the dynamics of protein accumulation is different from that of transcription. Therefore, the differences at the protein level are probably not detectable at the same time points as transcription. While Atr and MV had similar effects on parameters of chlorophyll fluorescence, they showed considerably different effects on the transcription of several photosynthetic genes. Whereas the transcripts of many photosynthetic genes in Wt were induced by both chemicals, most of their transcripts decreased in CET mutants, especially by treatment with MV. This difference in their effects may be helpful for understanding the molecular responses of plants induced by low concentration of these two herbicides.

In conclusion, CET plays a crucial role in the regulation of photosynthetic electron transfer, and *pgr*5 mutant is more sensitive to photosystem-interfering chemicals. The *pgr*5 mutant should be a suitable plant for monitoring pollution by these chemicals. Chlorophyll fluorescence and transcript analysis are sensitive for detecting disturbance, and they can be given priority to analyze herbicide toxicity as biological parameters in sublethal concentrations.

Improvement in Day Zero Recoveries in Field Soil Dissipation Studies Using Larger Diameter Soil Samples

Ashok K. Sharma,* Harry J. Strek,† and Aldos C. Barefoot

Stine Haskell Research Center, E. I. DuPont de Nemours and Co., Newark, Delaware 19711, United States

ABSTRACT: Obtaining acceptable recovery of the applied test substance at zero time in field soil dissipation studies has been a subject of considerable interest among scientists conducting regulatory field studies. In particular, achieving recoveries of ≥90% in soil samples collected immediately after applications in most studies has been elusive. This study investigated a modified soil sampling method, which could be used not only on day zero but for the entire study duration, to see if the recoveries in soil samples, especially in the early stages, can be improved. The modified sampling system has demonstrated that recoveries averaging 90% are possible and can be routinely obtained on day zero. Description of this modified sampling procedure and statistical analysis of the data collected for day zero samples are discussed.

KEYWORDS: *day zero recoveries, field dissipation studies, large diameter soil cores*

INTRODUCTION

Field dissipation studies for crop protection chemicals are an important and expensive portion of the environmental fate studies required for registration of new agrochemicals. Typically, a test substance is applied to a leveled bare soil plot of suitable size, and then soil samples are collected in 6 in. depth segments to a depth of 36 in.[1,2] or more. Soil sampling is typically initiated immediately after application (zero time samples) and continued until substantial dissipation of the applied chemical and its metabolites has been demonstrated. To meet the study objectives, it is essential to achieve a nearly quantitative recovery of the applied chemical in zero time samples, commonly referred to as day zero samples. As noted in the EPA's guideline[1] "time zero concentration lays the foundation for all subsequent sampling and is used to build confidence that the pesticide was applied uniformly and accurately".

Using the commonly employed soil sampling procedures, in which soil cores of approximately 2 in. diameter are collected in 6 in. depth segments, the uppermost 6 in. deep sample should have 100% of the applied chemical at time zero. However, such day zero samples frequently fail to show acceptable recovery. Zero time recoveries are often below 75−80% and display high levels of variability. This shortcoming has been a subject of several symposia at agrochemical scientific conferences[4] and the EPA's rejection rate analysis,[3] as well as several presentations at scientific conferences.[5,6]

Low recoveries at day zero have been considered a significant deficiency in the conduct of field dissipation studies, because they imply either gross errors in the chemicals' application process, poor sampling technique, or deficient analytical methods. Although all of these factors can cause poor recoveries in theory, application methods and analytical methods were set aside as major causes because the test substance applications are typically conducted by skilled field and laboratory personnel and always initiated under favorable weather conditions. Analytical methods employed are usually robust and typically deliver 80−110% recoveries in concurrent analysis with 10−15% standard deviation; otherwise, the methods would be unacceptable for regulatory authorities. On the basis of the analytical methods' capabilities averaging 90% recovery, day zero soil sample recoveries of equal magnitude should be achievable.

Before embarking on attempts to improve the recoveries, we analyzed the data available from a large number of our own field studies as well as information from recent symposia. Data compiled in appendices of ref 4 provided a good starting point to formulate a working hypothesis. The hypothesis was that better recoveries in soil cores could be achieved if the amount of treated soil, as a percentage of the total sample collected, could be increased substantially by not only increasing the sampled area but reducing the sample depth at the same time. Our statistical analysis of data in ref 4 indicated that day zero recoveries based on the secondary sample type (Figure 1), such

as Petri dishes and foam pads, were consistently good but soil samples collected to 6 in. depth were frequently quite deficient. A different perspective of the same data, illustrated in Figure 2,

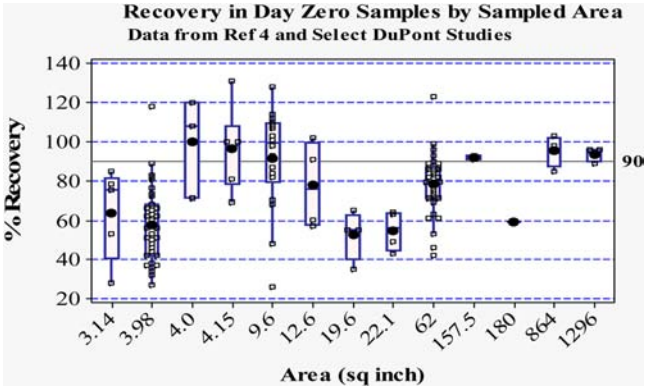

Figure 2. Recovery in day zero samples by sampled area [data from ref 4 and select DuPont studies].

focused on the surface area sampled without regard to the device used. It also suggested that samples with larger surface area had a higher probability of achieving good recovery. In our opinion, secondary devices frequently achieved good recoveries primarily because they have a larger surface area than soil cores. In our own experience also, secondary devices such as Petri dishes or papers, which had a larger surface area, and in which the applied test substance could be analyzed without the encumbrances associated with the soil homogenization and matrix extractions, were generally successful in obtaining good day zero recoveries. However, 2 in. diameter soil cores collected to 6 in. depth, a method used consistently at all sampling intervals, invariably showed day zero recoveries that seldom exceeded 75−80%.

Our objective, therefore, was to determine if the soil sampling method or sampling device could be modified so that the day zero recoveries in soil cores collected could be improved substantially. This was important not only because the degradation kinetics always employ the soil core data but also because it is the only device used over the entire study duration. If day zero recoveries in soil cores are unreliable, one cannot be certain at which later sampling intervals the recoveries begin to be reliable. The secondary devices can verify application rates; however, they can be used only at day zero but not for later sampling intervals. We postulated that if a chemical can be applied accurately as often supported by the recoveries in secondary monitoring devices, then for a vast majority of the agrochemicals, and for most of the formulations employed, recoveries equivalent to the average recovery delivered by the analytical method should be achievable in soil samples.

MATERIALS AND METHODS

We assumed that low recoveries in 6 in. deep soil cores having a 2 in. diameter were possibly due to two shortcomings of these soil samples. First, the portion of soil in a 6 in. deep sample carrying the applied test chemical on day zero was miniscule (approximately 1%) as compared with the total amount of soil sampled. Unless homogenization procedures capture this entire residue and mixe it uniformly in the entire sample, lower recoveries would be encountered. One possible solution was to collect the uppermost soil sample to depth of 2 in., instead of the traditional 6 in. depth. Second, a 2 in. surface area for sampling the uppermost soil sample appeared inadequate because the small surface area in a field study was vulnerable to spot-to-spot variability of the residue present on soil surface. Therefore, we decided to collect a larger surface area of at least 4 in. or possibly 6 in. diameter to a depth of only 2 in. for the uppermost sample.

Although soil cores of larger than 2 in. diameter have been attempted by many working in this area, sampling has generally been to a typical 6 in. depth. Perhaps for that reason, we are not aware of any published studies that have demonstrated consistently high recoveries in large-diameter soil samples. In particular, increasing the collection of treated soil as a percentage of total sample by collecting a shallower depth was considered an essential element of sampling the uppermost soil core. To our knowledge a systematic study that utilized a combination of larger surface area and shallow depth for sampling the uppermost soil sample has not been reported in peer-reviewed literature. Initially, we decided to evaluate a comparison of a shallower uppermost depth of only 2 in. instead of 6 in. and a larger surface area

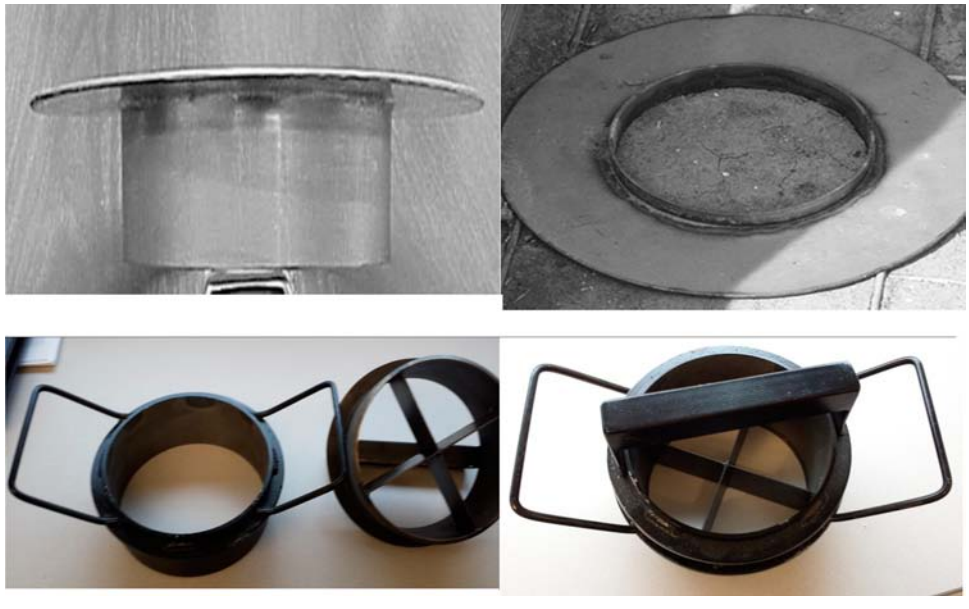

Figure 3. Large-diameter soil sampling devices.

of 4−6 in. diameter in parallel with traditional 2 in. on day zero to determine if such sampling leads to better day zero recoveries.

To test this hypothesis, we conducted multiple types of soil sampling within the same studies at four sites each in the United States and European Union. In conformance with regulatory guidelines, three replicate samples, each composed of five cores sampled from randomly selected areas, were collected at each location and for each sample type. Within each study, at least two types of soil samples were collected for the uppermost soil horizon. One of the sample types was a set of traditional 2 in. (5 cm) cores with standard 6 in. (15 cm) depth; a second set was of either medium core (4 in. diameter) or large core (6 in. diameter), both to a 2 in. depth. Collection of the 2 in. depth soil samples was performed using the device displayed in Figure 3. Such devices, which had ca. 4 in. internal diameter in the European studies and ca. 6 in. diameter in the U.S. studies, were collected by pressing the device into the soil until the upper lip was in line with the soil surface. Soil inside this sampler was collected using a spoonlike implement by scraping soil to a 2 in. depth. The depth sampled was easily noted when soil up to the bottom of this device had been removed. After uppermost depth had been collected, the device remained in place until all lower depth soil sampling had been completed. In each case, lower depths were sampled as usual, namely, 2 in. diameter samples for all deeper soil samples, although the depth of these lower segments was changed slightly from the regular 6 in. (illustrated in Figure 4).

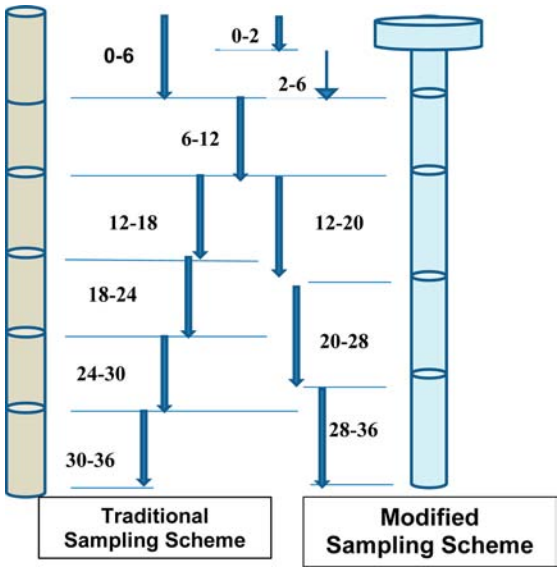

Figure 4. Traditional and modified soil sampling schemes (depth segments in inches).

All soil samples were five replicate cores combined to generate one sample. The combined sample, typically weighing 2−3 kg for 2 in. cores, 4−5 kg for 4 in. cores, and 7−8 kg for 6 in. cores, was homogenized using a mechanical soil mixer with added dry ice to prevent chemical changes during homogenization. After homogenization, a subsample weighing approximately 500 g was saved for analysis and stored in a freezer until the start of analysis. Typically, 10 g aliquots of homogenized soil were extracted and analyzed using analytical methods specific for the test substance applied. For the purpose of this paper, only the uppermost depth samples are reported because the test substance resides only in the uppermost samples on day zero. Remaining lower depth samples were also analyzed and submitted to various regulatory authorities. Because the depth segments using the two devices were different, a comparison of the data by these two methods was possible by converting the residues obtained in parts per billion into mass per unit area (g/ha or lb/acre) and were then calculated as percent of applied amounts. Equations for such calculations are shown below:

$$\text{residue}\left(\frac{\text{g}}{\text{ha}}\right) = \frac{\text{ppb in soil sample}\left(\frac{\text{ng}}{\text{g}}\right) \times \text{wt of 5 cores (g)} \times \text{area 1 ha (sq cm)}}{\text{surface area of 5 cores (sq cm)} \times \text{conversion factor}\left(\frac{\text{ng}}{\text{g}}\right)}$$

$$\text{recovery (\%)} = \frac{\left(\frac{\text{g}}{\text{ha}}\right)\text{found} \times 100}{\left(\frac{\text{g}}{\text{ha}}\right)\text{applied}}$$

One calculation for illustrative purposes is shown below:

ppb in soil = 209.10

soil weight of 5 cores (g) = 7146.9

inside diameter of 2 in. deep core = 15.3 cm (radius = 7.65cm)

surface area of 5 cores = 5 × pi × $(7.65\ \text{cm})^2$ = 919.269 sq cm

area of 1 ha in sq cm = 10^8 sq cm

Therefore

$$\text{g/ha in sample} = \frac{7146.9\ \text{g} \times 209.100\ \text{ppb} \times 10^8\ \text{sq cm/ha}}{(10^9\ \text{ng/g} \times 919.269\ \text{sq cm})} = 162.57\ \text{g/ha}$$

amount applied = 200 g/ha

recovery (%) = (162.57 × 100)/200 = 81.3%

Soils weights and areas used were for five cores because five replicate cores were collected and combined to obtain one sample for analysis as is customary in regulatory studies. When multiple samples of each type were collected in a study, the replicates were not averaged for statistical analysis and the residues were not corrected for fresh fortification recoveries. The analytical method employed in the initial investigation provided 92% recovery with 10% standard deviation. Recovery numbers obtained were rounded to one decimal place for use in statistics. All statistical analysis was conducted using Minitab software, version 16.1.

RESULTS AND DISCUSSION

Results from the initial trials (four in the United States and four in the European Union), where a small diameter (2.25 in. surface diameter) and an additional either 3.8 or 5.75 in. diameter sample had been collected for the uppermost depth, are displayed in Figure 5. These samples were collected concurrently from the same test sites and for the same chemical applied. Samples collected were analyzed by using the same method for comparison of recoveries on day zero (note 3.75 and 5.75 in. diameter samples are sometimes referred to as 4 or 6 in. samples for simplicity). Data summarized in Figure 5 (24 samples of each type) illustrated that larger diameter soil cores collected to a shallower depth were indeed more accurate in demonstrating the day zero residues. Whereas small-diameter samples found an average 80% recovery for all samples collected, the larger cores averaged >90%. Statistically the difference in recoveries was significant when small-core data were compared with medium (3.75 in.) or larger cores (5.75 in.). In the studies conducted in the United States, we even analyzed a separate set of 10 large-diameter samples as single replicates and compared them with their respective 5-sample composites (obtained by combining 5 large cores from one

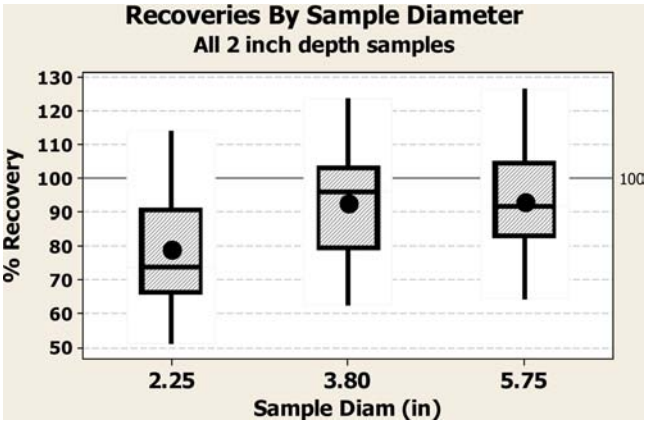

Figure 5. Day zero recoveries using small- and large-diameter devices.

subplot) to see if each individual sample also achieved the desired results of acceptable recovery. Even the single-replicate samples (Figure 6) showed an average recovery in the 90%

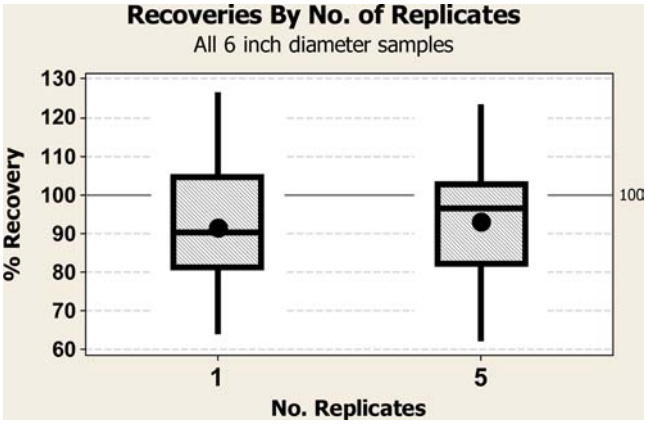

Figure 6. Large diameter sample recoveries by number of replicates.

range, even though sample-to-sample variability was somewhat higher as compared to the 5-sample composites. These results appeared to validate the hypothesis that acceptable recovery in day zero samples could be achieved if larger-diameter samples were collected to a shallow depth for the uppermost soil samples.

As a result of the encouraging data from trial experiments described above, we changed our sampling practice for subsequent field dissipation studies to collect the uppermost soil sample as a minimum 4 in. diameter and only to a 2 in. depth (modified sampling illustrated in Figure 4). For practical reasons, our European contract facilities have all adopted the medium (10 cm internal diameter) devices, whereas all U.S. cooperators have been using the larger (5.75 in. internal diameter) device, not only for day zero samples but for the entire study duration. The reason for extending this sampling practice beyond day zero was that we do not always know in advance when a test substance will have migrated into lower depths. Moreover, varying sampling practices within the same study could create bias among various intervals due to changing sampling methods. Once the uppermost sample is collected with a spoonlike implement, the large-diameter sampler is kept in place and all lower depth samples are collected from areas inside this device. Because these larger diameter devices have been adopted into practice, our day zero samples from most field studies have shown consistently improved recoveries (Figure 7). Results from more than 40 field studies (N = 161 is

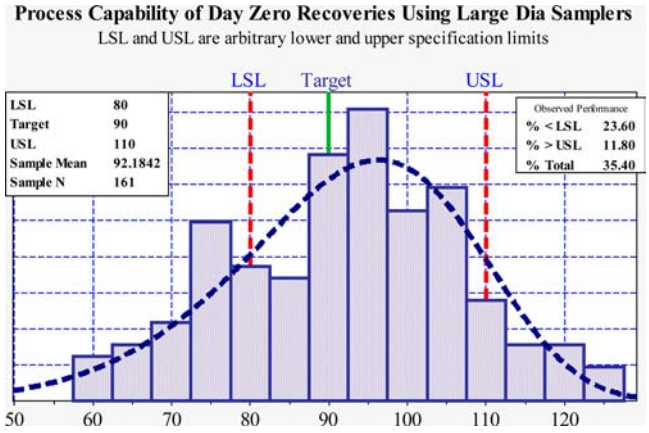

Figure 7. Day zero recoveries using larger diameter 2 in. deep cores.

the total number of day zero samples from all studies) conducted over 5 years and with four different test substances applied at different use rates are summarized in Figure 7. It should be noted that all four test substances were nonvolatile (chlorsulfuron, penthiopyrad, chlorantraniliprole, and cyantraniliprole) but had significantly different physicochemical properties. Even though water solubility, dissipation rates, or formulations used varied substantially among these compounds, we do not believe such properties have a significant impact on the capability of achieving good day zero recoveries.

For statistical analysis, 80 and 110% were arbitrarily chosen as the lower and upper specification limits (LSL and USL, respectively) because most of the analytical method recoveries were in the same range, and average analytical method recovery of about 90% for all four compounds was set as the target. In addition, choice of lower and upper specification limits for recoveries in the 80−110% range was based on the assumption that such results are considered acceptable by most regulatory authorities. Selection of a somewhat less strict specification of 70% for the LSL and 120% for the USL would also be acceptable, and Figure 7 shows essentially all results obtained are within the less strict range. We still encounter <80% recoveries in some individual samples, as is obvious from the illustration in Figure 7; however, such occurrences are less frequent with our modified sampling system. Undoubtedly, factors other than sampling methods (such as inadvertent errors in sample collection, homogenization, or analysis) continue to play a role. Nevertheless, results from nearly 45 field studies conducted within the past 5 years have shown that fewer than 23.6% samples displayed recoveries below 80%. Within this data set, we examined if the amount of test substance applied or the nature of chemical carried any statistical significance (Figure 8). Analysis of means (at 95% confidence) based on such groups did not display dependence of recoveries, either on the nature of the test substance or on the application rate for chemicals used. Instead, the variability simply reflected the variability observed in the analytical method for analysis of a large number of samples. A somewhat lower average recovery for one test compound (TM-1) was in line with slightly lower average recoveries in fresh fortifications for the analytical method employed for that compound and had nothing to do with the nature of this compound. In our view, this new sampling method may help improve day zero

dx.doi.org/10.1021/jf500607r | J. Agric. Food Chem. 2014, 62, 4090−4094

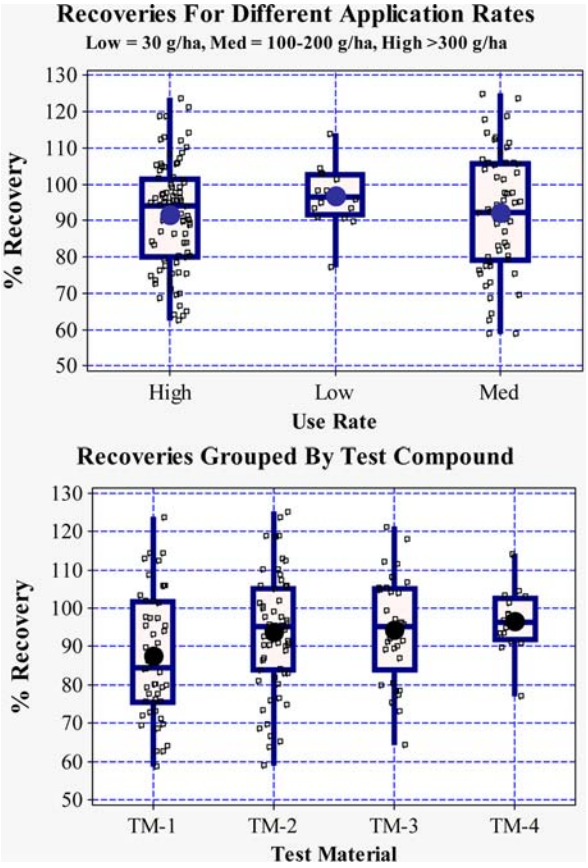

Figure 8. Recoveries based on test substance and application rates.

recoveries for all test compounds, regardless of the use rate, chemical structure, or formulation used.

Use of 6 in. diameter devices for sampling the uppermost 2 in. of soil as a standard practice is currently carried out using our most recent sampler[7] displayed in the bottom part of Figure 3. This sampler is a two-piece device, in which the inner piece with four quadrants is placed inside the outer casing, shown on the left side of the figure. The assembled device is pressed into soil with a hydraulic press. The lip at the top of the outer casing stops the device at a 2 in. depth. Technicians can grab the handle and rotate the inner piece of this sampler by approximately 30°, which cleanly separates the uppermost 2 in. of soil from the column below. The inner piece can be lifted and held above a bag into which soil is dislodged by gently hitting the device with a rubber hammer. The inside device quadrants assist in not only separating the uppermost 2 in. of soil but also help keep the soil in place while the inside portion is lifted. If a portion of the soil falls within the outer casing, it is recovered using a spoonlike implement.

An important point worth reiterating is that large-diameter samplers are effective in combination with a shallow (2 in.) depth only, and the 6 in. diameter is perhaps the upper limit beyond which any further increase in area sampled begins to create homogenization issues. Five replicate cores (6 in. diameter−2 in. depth] composited to obtain one sample generate soil samples that weigh 7−9 kg. The homogenization equipment in use at most facilities we work with can handle samples of 2−10 kg, but work best for 2−5 kg sample sizes. Larger diameter cores collected to 6 in. depths will lead to substantially large sample weights (around 20 kg), and homogenization issues will again negate the advantage offered by larger surface area. For this reason, we have not attempted using large-diameter cores for any lower depths or any >2 in. depth samples.

In conclusion, instead of collecting 2 in. diameter soil cores to a 6 in. depth for the uppermost soil sample (a standard practice), a larger diameter device and collection of a shallower depth for the uppermost soil core can be used to achieve a significant improvement in day zero recoveries.

ABSTRACT: The study focuses on the response of apple primary and secondary metabolism and some important quality parameters to three living mulch treatments, classical herbicide fallow, and black polypropylene strip application in two apple cultivars. Primary and secondary metabolites were analyzed after 10 years of ground cover experiments. Soluble solids, firmness, and color measurements indicate differences among orchard floor management treatments. Significantly, lower levels of individual sugars have been measured in fruit of different living mulch treatments compared with fruit harvested from trees subjected to the herbicide strip treatment. Total sugar content was higher in fruit of the herbicide strip treatment in both cultivars analyzed. Significantly higher levels of total organic acids were only detected in 'Pinova' fruit of the *Festuca ovina* L. treatment. Long-term response of both cultivars to living mulch treatments indicated that apples increase the accumulation of almost all analyzed individual phenolic compounds.

KEYWORDS: *Malus domestica Borkh., living mulch, black polypropylene strip, sugars, organic acids, phenolics*

INTRODUCTION

Proper choice of orchard floor management system protects the soil from weed occurrence, reduces soil erodability, improves the supply of water and nutrients to the plants, and supports sustainable fruit production for many decades.[1] Among several weed control options applicable in organic fruit production, the introduction of living mulch (green cover plants) deserves particular consideration because of its potential benefits to orchard biodiversity and improvement of soil quality.[2] Moreover, living mulch protects the soil surface similar to sod during the vegetation periods of fruit trees.[3] The widespread adoption of this system is hindered by the fact that the covering plant competes with the fruit tree, which can potentially result in reduced growth and yield of the fruit crop.[2] An effective cropping system can be maintained with a living mulch strip to control water runoff and soil erosion. These plants can also produce suitable allelochemicals to control weed seed germination and possibly suppress established weeds without affecting growth and yield of the primary crop. The living mulch should be noncompetitive or easily suppressed to render it noncompetitive without losing its allopathic characteristics. This might be accomplished by gene transfer from an organism known to have allopathic characteristics, such as subterranean clover, into a compatible living mulch plant.[2]

The implementation of living mulch in the rows of apple trees was shown to delay the beginning of cropping[4−6] and often contributed to the reduction of cumulative yield in the years of fruit production peak.[1,7] Experiments monitoring fruit trees of various stages consistently determined significantly lower competition of annual cover crop species compared to perennials.[8,9] The application of living mulch affects both external and internal fruit quality parameters. Hornig and Bünemann[10] analyzed fruit from a young apple orchard and reported that white clover (*Trifolium repens* L.) living mulch led to a reduction of mean fruit weight compared to a herbicide treatment. On the contrary, Lipecki and Wieniarska[8] could not confirm any significant differences in fruit quality when comparing several annual species used as a green cover. It has additionally been determined that the introduction of living mulch, particularly grass species, contributes to an increase of red surface skin area of apple fruits.[10,11] This effect could also be observed in full cropping period of the trees.[9]

Apples are a rich source of different classes of phenolic compounds. They have been reported as a source of naturally occurring antioxidants, which contribute to prevention of oxidative damage caused by free radicals which lead to development of many chronic human diseases.[12] The content and profile of phenolics in fruit is influenced by several factors, including climate,[13] the effect of light,[14] cultivars,[15,16] temperature, mineral nutrition, water management, grafting, application of elicitors, stimulating agents, plant activators,[17] and exposure to various kind of stress.[18] Mikulic-Petkovsek et al.[15] established that organically grown apples exhibited a higher content of phenolic compounds in apple compared to apples cultivated according to integrated practices. This may be due to the absence of synthetic fertilizers, pesticides, and growth regulators, which are banned in organic production. Therefore, organically grown plants are more exposed to environmental

stress and form specific stress metabolites which can beneficially contribute to internal fruit quality.[18]

The present trial was conducted to evaluate the long-term effects of different living mulches on selected quality parameters and content and diversity of primary and secondary metabolites in comparison to traditional herbicide strip weed prevention. It is important to identify the production systems which stimulate the synthesis of important plant metabolites and simultaneously present a minimal negative impact on the environment. The aim of this study was to determine the influence of different ground cover management systems (many years of orchard floor treatment) on fruit quality parameters, and profiles of primary and secondary metabolites after a ten-year period of tree adaptation. Up to the present date, research has been limited to short-term experiments and did not focus on the effect of living mulches on primary and secondary metabolites.

MATERIALS AND METHODS

Field Experimental. Apple trees (*Malus domestica* Borkh.) of the 'Ligol' and 'Pinova' cv. grafted on a semidwarf rootstock P2 were planted in spring 2004 at the planting distance of 3.5 m × 1.2 m (2380 trees per ha) on the haplic luvisol derived from silty light loam. The trees were planted at the Fruit Experimental Station in Samotwor (51°06′12″N, 16°49′52″E) managed by the University of Environmental and Life Sciences in Wroclaw (Poland). The average annual temperature of this area is 8.6 °C and the total rainfall 586 mm per year. Five treatments (orchard floor management systems) were established, and 1 m wide strips were randomly assigned to each treatment located in the center of tree rows. Immediately after apple planting, three living mulch plants were sown: (1) annual French marigold (*Tagetes patula* L.), dwarf cultivars "Carmen" or "Columbina" (15 kg per ha), renewed in the subsequent years of experiment, (2) perennial colonial bent grass (*Agrostis vulgaris* With.), cultivar "Frasek" (34 kg per ha), and (3) perennial blue fescue (*Festuca ovina* L.), cultivar "Edolana"(30 kg per ha). The latter was sown in spring 2005 to replace the annual dwarf nasturtium (*Tropaeolum majus nanum* L.), which was only maintained in the first year of orchard establishment. The other two treatments consisted of the application of black polypropylene fabric or maintenance of herbicide strip in the row. Black polypropylene fabric (AGRO 84F-170 TKANINA PP, 94 g·m^{-2}) was applied in spring of 2004 and maintained during the course of the experimental trial. Herbicide treatment was maintained in accordance with current recommendations for commercial orchards. Following the second year after planting, two or three applications of a glyphosate and 2-methyl-4-chlorophenoxyacetic acid (MCPA) mixture were sprayed 4.0 + 2.0 L per ha.

Grassy strips were maintained between tree rows and mown several times per vegetation season. Slender spindles were formed, and trees were fertilized with nitrogen (ammonium nitrate or urea) each year at an average rate of 50 kg per ha. Apple tree protection was carried out in accordance with current recommendations of the Orchard Protection Program.

The experiment was established in a randomized block design in four replications. Within each replication, 4.8 m × 1 m plots were delimited for each orchard floor management system with four trees per plot. Each year (2010−2013), yield per plot was measured for each replication separately. Late spring frost (−2 °C, May 3, 2011) caused flower damage of apple trees in the full blooming period in the entire Lower Silesia area, and thus the 2011 yield was relevant.

Plant Material. Apple fruit of 'Ligol' and 'Pinova' cv. were harvested between September 18−19 and 25−27, depending on the cultivar. The optimal harvest time was established based on the average harvest time for both cultivars in the Lower Silesia area. Apples were delivered to the laboratory of the University of Ljubljana in Slovenia, Chair for Fruit, Wine and Vegetable Growing, where they were immediately analyzed.

Chemicals. Sucrose, glucose, fructose, sorbitol, citric, malic, shikimic, and fumaric acids from Sigma-Aldrich Chemie GmbH (Steinheim, Germany) were used for quantification of sugars and organic acids. The standards used to determine the phenolic compounds in samples were: chlorogenic acid (5-caffeoylquinic acid) and quercetin-3-*O*-rutinoside from Sigma-Aldrich, (−)-epicatechin, (+)-catechin, procyanidin B2, procyanidin B1, phloridzin dihydrate, cyanidin-3-*O*-galactoside, quercetin-3-*O*-rhamnoside, quercetin-3-*O*-galactoside, quercetin-3-*O*-glucoside, quercetin-3-*O*-arabinofuranoside, and quercetin-3-*O*-xyloside from Fluka Chemie (Buchs, Switzerland). Methanol for extraction of phenolics was acquired from Sigma-Aldrich. The chemicals for the mobile phases were HPLC-MS grade sulfuric acid, acetonitrile, and formic acid from Fluka. Water for mobile phase was double distilled and purified with the Milli-Q system (Millipore, Bedford, MA).

Fruit Quality Parameters. Fruit quality parameters were estimated in the tenth year after planting (2013). The firmness was measured on two peeled sides in the equatorial plane of the fruit with a penetrometer (TR, Turini, Italy) equipped with an 11 mm tip. The depth of tip penetration was 8 mm. To determine soluble solids content (SSC), the pulp from each fruit was crushed and the intact juice was immediately analyzed with a digital refractometer (model WM-7, Atago, Tokyo, Japan). Peel color was measured with a portable colorimeter (CR-200 b Chroma; Minolta, Osaka, Japan) with C illuminant and expressed with L^* parameter and hue angle. The colorimeter was calibrated with a white standard calibration plate before use. In the CIE Lab system of color representation, the L^* value corresponds to a dark−bright scale and represents the relative lightness of colors with a range from 0 to 100 (0 = black, 100 = white). The hue angle ($h°$) is expressed in degrees from 0 to 360 (0°, red; 90°, yellow; 180°, green; 270°, blue). Peel color was measured on sun-exposed sides in the middle of each fruit to ensure equal measurement conditions.

Analysis of Individual Carbohydrates and Organic Acids. Apple fruit harvested in 2013 were analyzed for the content of carbohydrates (sorbitol, sucrose, glucose, and fructose) and organic acids (malic, citric, shikimic, and fumaric acids). The stalk, sepal, and core were removed from the fruit, and 5 g of fresh weight (FW) were immersed into 25 mL of double-distilled water and homogenized with a homogenizer (T25 basic Ultra-Turrax, IKA Labortechnik, Janke and Kunkel GmbH, Staufen, Germany). Fruit samples were left for half an hour at room temperature with frequent stirring. Samples were centrifuged for 4 min at 10 000 rpm; the supernatants were filtered through a 0.25 μm cellulose filter produced by Macherey-Nagel (Düren, Germany), poured into vials, and analyzed using high performance liquid chromatography (HPLC; Thermo Scientific, San Jose, CA, USA). For the analysis of organic acids, a Rezex ROA Organic acid column (300 mm × 7.8 mm) (Phenomenex, Torrance, CA, USA), heated to 65 °C, with 4 mM sulfuric (VI) acid as the mobile phase and a UV detector set to 210 nm, was used.

For the determination of sugars, a Rezex RCM-monosaccharide column (300 mm × 7.8 mm) (Phenomenex, Torrance, CA, USA) heated to 65 °C, with double-distilled water as the mobile phase and a RI detector, were utilized. The concentrations were recalculated using the calibration curve of standards of known concentrations.

Analysis of Individual Phenolics. The apples were peeled with a mechanical peeler, and the peel was separated from the pulp. The extraction of fruit samples (peel and pulp separately) was done as described by Slatnar et al.,[19] with some modification. Fresh apple samples were ground to a fine powder in a mortar chilled with liquid nitrogen. The samples of 10 g of pulp or 3 g of peel were extracted with 10 mL of methanol containing 3% (v/v) formic acid in a cooled ultrasonic bath for 1 h. After extraction, the fruit extracts were centrifuged for 7 min at 10000 rpm. The supernatant was filtered through a Chromafil AO-45/25 polyamide filter produced by Macherey-Nagel and transferred to a vial prior into injection in the HPLC system.

Phenolic compounds were analyzed on a Thermo Scientific Dionex UltiMate 3000 series UHPLC+ focused (Thermo Scientific, San Jose, CA, USA) with a diode array detector at 280 nm (flavanols, cinnamic acid derivatives), 350 nm (flavonols), and 530 nm (anthocyanins). Spectra of the compounds were recorded between 200 and 600 nm.

[a]Different letters (a–c; NS, not significant) in rows represent statistically significant differences among treatments at $p < 0.05$ (Duncan test) for each cultivar separately.

The column was a Gemini C_{18} (150 mm × 4.6 mm 3 μm; Phenomenex, Torrance, CA, USA) operated at 25 °C. The elution solvents were aqueous 0.1% formic acid in twice-distilled water (A) and 0.1% formic acid in acetonitrile (B). Samples were eluted according to the linear gradient from 5% to 20% B in the first 15 min, followed by a linear gradient from 20% to 30% B for 5 min, then an isocratic mixture for 5 min, followed by a linear gradient from 30% to 90% B for 5 min, and then an isocratic mixture for 15 min before returning to the initial conditions.[20] The injection amount was 20 μL and flow rate 0.6 mL min^{-1}.

All phenolic compounds were identified by an HPLC-Finnigan MS detector and an LCQ Deca XP MAX (Thermo Finnigan, San Jose, CA, USA) instrument with electrospray interface (ESI) operating in positive (for anthocyanins) and negative (other phenolic groups) ion mode. The analyses were carried out using full scan data-dependent MS^n scanning from m/z 110 to 1500. Column and chromatographic conditions were identical to those used for the HPLC-DAD analyses. The injection volume was 10 μL, and the flow rate maintained at 0.6 mL min^{-1}. The capillary temperature was 250 °C, and the sheath gas and auxiliary gas were 60 and 15 arbitrary units, respectively; the source voltage was 3 kV for negative ionization and 4 kV for positive ionization and normalized collision energy was between 20–35%. Spectral data were elaborated using the Excalibur software (Thermo Scientific). The identification of compounds was confirmed by fragmentation, comparison of retention times and compound spectra as well as by adding the standard solution to the sample.

Statistical Evaluation. Results were statistically analyzed with a Statgraphics Plus program for Windows 4.0, using one-way analysis of variance (ANOVA). The difference in content levels were estimated with Duncan's Multiple Range Test. *P*-values of less than 0.05 were considered statistically significant. The data of yield quantity was analyzed using one-way analysis of variance for a randomized block design. The multiple comparisons were performed at the 5% significance level using Duncan's Multiple Range Test.

Multivariate statistical analysis (hierarchical cluster analysis) was conducted in order to interpret the differences in analyzed compounds among orchard floor management systems. Ward's method based on squared Euclidian distance was used to interpret the differences in all analyzed compounds.

RESULTS AND DISCUSSION

Yield, External Fruit Quality Parameters, and Primary Metabolites. The mean yield (2010–2013) at harvest differed among soil management treatments and ranged from 12.31 to 17.22 kg per tree in 'Ligol' and from 6.51 to 12.19 kg per tree in 'Pinova' cultivar (Table 1). No significant differences among treatments have been determined for 'Ligol' cultivar. However, in 'Pinova' cultivar, significant differences have been observed among treatments. Higher yields have been monitored in herbicide treatment in comparison with *Agrostis vulgaris* With. and *Festuca ovina* L. living mulches (Table 1). Similarly, lower yield has been reported in research by some authors,[2,4,5] who investigated the effect of living mulches in young apple orchards. Moreover, Yao et al.[7] determined that *Festuca rubra* L. caused lower yields during several years of monitoring in a full cropping orchard.

Soluble solids concentration was significantly higher in the herbicide treatment in comparison with all other orchard floor management systems in 'Ligol' cultivar. However, no significant changes in soluble solids have been noted among treatments in 'Pinova' cultivar (Table 1).

Firmness provides information on fruit freshness and is often considered a crucial parameter in a consumer's decision making for an apple purchase. In the present experiment, the firmness level at harvest ranged from 6.89 to 7.20 kg cm^{-2} in 'Ligol' and from 7.57 to 8.33 kg cm^{-2} in 'Pinova' cultivar (Table 1). Again, types of soil management exhibited different responses to treatments in this fruit parameter. No significant differences among treatments have been determined for firmness in 'Ligol'. However, significantly higher values have been measured for the 'Pinova' cultivar of the *Agrostis vulgaris* With. and *Tagetes patula* L. treatments.

In the study by Fausett and Rom,[21] black plastic fabric treatment caused an increase of average fruit firmness and a decrease of average soluble solids in "Gala" apples. Similarly, fruit sampled from trees subjected to black polypropylene fabric treatment also contained lower soluble solids in 'Ligol' cultivar.

To evaluate the potential of different ground cover management systems on color development, the changes in the colorimetric parameter L^* and hue angle ($h°$) were monitored. The hue angle ($h°$) is one of the most appropriate indicators of color changes during apple fruit growth.[22] Different orchard floor management systems did not exhibit any influence on hue value or colorimetric parameter measured on the sun-exposed side of apple fruit of both analyzed cultivars (Table 1). Several authors similarly report that fruit from organic and conventional practices do not differ in peel color,[23] which could be linked to the results of our study. Namely, organic production is mostly characterized by the implementation of weed control practices other than herbicides and a herbicide strip is frequently used in integrated orchard management. Kühn and Lindhard Pedersen[9] conversely reported that grass (*Festuca rubra* L. with *Poa pratensis* L.)

decrease leaf N content level, shoot growth, and yield but increase the percentage of optimal colored fruit.

In addition to different aromatic compounds, sugars and organic acids play important roles defining the character and quality of flavor and organoleptic properties of apples. Sucrose, fructose, glucose, and sorbitol have been quantified in apple fruit harvested from trees subjected to different orchard floor management treatments (Tables 2 and 3). Hecke et al.[24] and Mikulic-Petkovsek et al.[25] obtained similar results for apple fruit sugar composion. Significantly lower levels of individual sugars (with the exception of glucose, where differences among treatments were not significant for both cultivars) have been measured more often in fruit of different living mulch treatments compared with fruit harvested from trees subjected to the herbicide strip treatment. Consequently, total sugar content was higher in fruit of the herbicide strip treatment in both cultivars analyzed (Tables 2 and 3).

Malic and citric acids were the prevalent components from the group of organic acids, and shikimic and fumaric acids were only quantified in minor amounts. Similar composition has previously been reported by Mikulic-Petkovsek et al.[25] The results on organic acid composition in apple fruit subjected to different orchard floor management treatments were less conclusive compared to the data on individual/total sugar content (Tables 2 and 3). Generally, the content of organic acids was similar in all treatments, however, in the case of citric acid in 'Ligol' and shikimic and fumaric acid in both cultivars, the content was significantly higher in fruit from different living mulch combinations (Tables 2 and 3). Subsequently, significantly higher levels of total organic acids were only detected in 'Pinova' fruit of the *Festuca ovina* L. strip treatment. Differences in sugar/organic acid composition among treatments could be explained by the competition for nutrients between fruit trees and green cover plants mostly affecting sugar synthesis. In a study by Nazrala,[26] titratable acidity increased and cell sap pH level decreased when vines were grown in combination with a cover crop compared to the control treatment where bare soil was left under the plants.

Phenolic Compounds in Pulp and Peel. Phenolic compounds are a class of secondary metabolites, i.e., compounds that are not essential for the survival of plants but are produced to enhance their ability to withstand various stress factors. Principally, due to their antioxidant properties, there is much interest in the potential health benefits of phenolic compounds in our diets.[27] These two reasons must be considered when new orchard management techniques with possible effects on fruit and leaf phenolic content are introduced. The analyzed phenolics in apple fruit were classified into five groups: hydroxycinnamic acids, dihydrochalcones, flavan-3-ols, flavonols, and anthocyanins.

The occurrence and content of different phenolic compounds has previously been reported in many apple cultivars[15,25] and confirmed also in our present study. However, the content of phenolic compounds in apple fruit is greatly

treatments was thus performed in both outer (peel) and inner (pulp) fruit tissue and discussed separately.

The content of individual phenolic groups and compounds in apple pulp differed between cultivars and among treatments analyzed (Tables 4 and 5). However, different orchard floor management systems did not exhibit any influence on the content of analyzed phenolic groups in 'Pinova' apples although changes in individual phenolic compounds have been determined (Table 4). On the other hand, specific green cover systems: living mulches positively affected the content of hydroxycinnamic acids, dihydrochalcones, and flavonols in "Ligor" cultivar (Table 5). Individual phenolic compounds as well as their sum were often significantly higher in fruit harvested from trees of the *Tagetes patula* L. (Table 5) treatment.

This indistinct differences in pulp phenolic composition among treatments was expected because the pulp is less exposed to outer environmental stress if compared with peel. Apples of the 'Ligol' cultivar could intensively react to nutrient and water competition between green cover plants and trees and up-regulate the synthesis of phenolic compounds (induced stress response). On the other hand, 'Pinova' cultivar trees did not exhibit the same physiological behavior. Organic mulching can also modify many soil properties and, according to Janick,[28] apple trees form a network of fibrous fine roots in the top 15 cm soil, responsible for increased absorption of water and nutrients. This uppermost soil layer is the area where mulch type affects the biotic and abiotic properties of the underlying soil. Brady and Weil[29] suggest that temperature buffering, moisture conservation, and increased biological diversity could result from the application of organic mulches. These have the ability to moderate soil temperature, act as a source of organic carbon for soil organisms, reduce evaporation, and improve infiltration, and therefore mulching is a superior form of weed control to herbicide applications.

The qualitative composition of apple peel polyphenols was almost analogous to that determined for pulp, with the exception of cyanidin glycosides, which were detected in skin of both red-colored cultivars. Fruit of the 'Pinova' cultivar contained similar levels of analyzed phenolic groups (with the

exception of flavanols) regardless of different orchard floor management systems used (Table 6). However, the content of some individual phenolic compounds from the groups of hydroxycinnamic acids and flavan-3-ols were significantly higher in the *Festuca ovina* L. or *Agrostis vulgaris* With. treatment. Interestingly, the application of herbicide or the use of black polypropylene fabric cover caused lower levels of specific individual phenolic compounds (Table 6). These results potentially indicate lesser environmental stress conditions of these trees compared with living mulches causing decreased synthesis of stress-induced phenolics. Similar studies on apple and stress-related phenolic compounds have been reported by different authors.[15,30,31]

Statistical comparison of orchard floor management systems in regard to the phenolic profile of 'Ligol' apples revealed significant differences in content levels of phenolic groups and individual compounds (Table 7). Similar to 'Pinova' cultivar, the synthesis of individual phenolic compounds increased/decreased as a response to different ground cover treatments. However, in 'Ligol' cultivar, significantly higher levels of phenolic groups have been analyzed in apples harvested from trees subjected to different living mulches. It is hard to determine the optimal green cover plant causing the highest phenolic content of most stress-induced phenolics (Table 7). The *Festuca ovina* L. and *Tagetes patula* L. effects on total and some individual anthocyanin content were significant, but all living mulches also affected the synthesis of individual phenolic from groups hydroxycinnamic acids, dihydrochalcones, flavan-3-ols, and flavonols (Table 7). Lee and Steenwerth[32] similarly reported that barley (*Hordeum vulgare* L.) green cover plant positively influenced the formation of grape anthocyanins.

Optimal orchard management systems includes maintenance of green cover plants under the tree canopy controlling water runoff and soil erosion. Moreover, some of these living mulches produce alleochemicals preventing weed germination or even suppress the established weeds without affecting the growth and yield of the main crop. The variation in primary and secondary metabolites observed in response to management

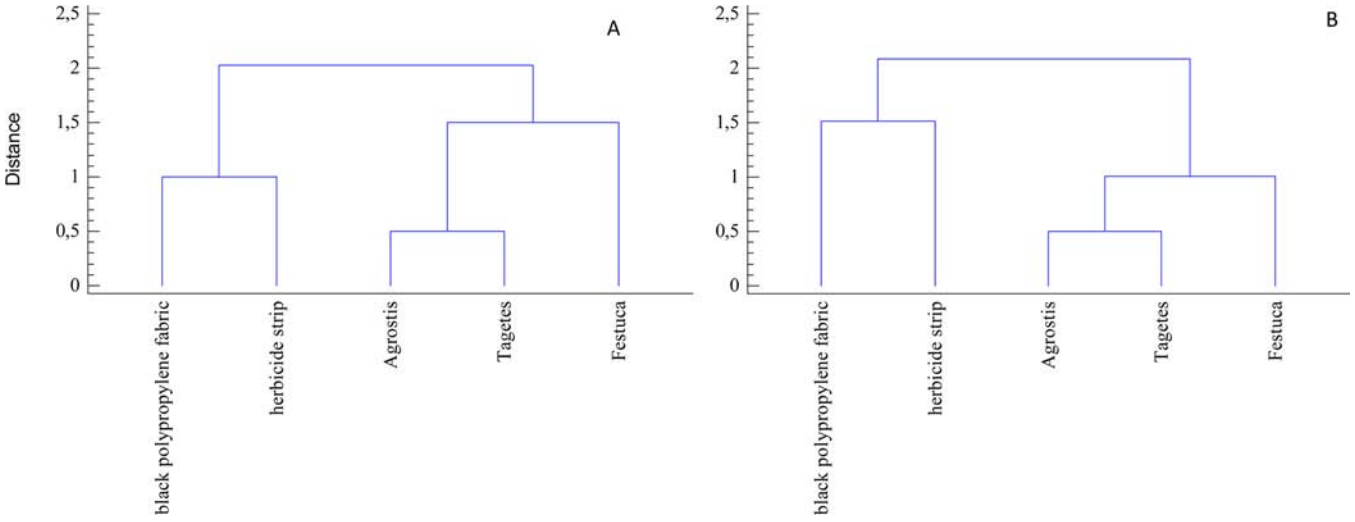

Figure 1. Dendrogram of 'Pinova' (A) and 'Ligol' (B) cultivars managed according to different orchard floor management systems, using Ward's method based on square Euclidian distance considering analyzed primary and secondary metabolites.

practices is not surprising considering the wide range of climatic, edaphic, cover crop, and other conditions affecting their synthesis. The effect of living mulches is immediately evident in fruit peel but less in apple pulp. This could be associated with the physiological role of skin in providing a physical and chemical barrier against environmental stress. Clustering the effects of different green cover plants on primary and secondary metabolites revealed similarities among *Agrostis vulgaris* With., *Tagetes patula* L., and *Festuca ovina* L. treatments in both cultivars analyzed (Figure 1). Average values were considered for the cluster analysis which revealed similarities among living mulch treatments. The reason for the formation of these groups can be found in similar patterns of primary and secondary metabolite composition of apple fruit subjected to living mulch treatments. The differences in phenolic compound levels among treatments were more distinct in 'Ligol' cultivar, but cluster analysis also revealed similarities among green cover treatments in 'Pinova' apples as they generally contained higher levels of individual phenolic compounds. On the other hand, total sugar levels of both cultivars were significantly lower in apples harvested from trees of all three living mulches (Tables 2 and 3).

Can the competing relationship between green cover plants and trees therefore be regarded as a positive measure? If we strive to produce apples with increased content level of phenolic compounds and enhanced defense of plants to stress (such as pathogen attack), the use of green cover plants should be promoted. Are apples harvested from trees subjected to increased stress also healthier? According to many studies describing health beneficial properties of apple phenolics,[27] the results confirm the positive effects of green cover plants under the tree canopy not just only on environmental levels (biodiversity, weed/erosion control) but at the same time providing healthy fruit for health-conscious consumers. The present research can represent a foundation for primary and secondary component profiling of apples managed according to different orchard floor management systems. Further studies are needed to fully encompass the impact of living mulches on apple fruit composition.

Combination of Running-Buffer-Mediated Extraction and Polyamidoamine-Dendrimer-Assisted Capillary Electrophoresis for Rapid and Sensitive Determination of Free Fatty Acids in Edible Oils

Jingqing Wu, Ying Ge, and Weidong Qin*

Key Laboratory of Theoretical and Computational Photochemistry, Ministry of Education, College of Chemistry, Beijing Normal University, Beijing 100875, China

Supporting Information

ABSTRACT: A method was developed for determining free fatty acids in edible plant oils by incorporation of running-buffer-mediated liquid−liquid extraction and polyamidoamine-dendrimer-assisted capillary electrophoresis−capacitively coupled contactless conductivity detection. The recoveries for the extraction were in the range of 90.1% and 110.3%. Addition of dendrimer to the running buffer improved the separation of fatty acids. Under the optimized buffer conditions, i.e., 3 mM pelargonic acid, 39 mM tris(hydroxymethyl)aminomethane, 30 mM polyoxyethylene 23 lauryl ether, 35% acetonitrile, 15% 2-propanol, 2.5% 1-octanol, and 300 μM polyamidoamine generation 2 at apparent pH 8.53, the 10 model fatty acids were separated in 18 min with detection limits ranging from 0.46 to 3.28 μM. The successful determination of fatty acids in real samples suggests that the method is simple, cost-effective, and easy to operate and is suitable for scanning free fatty acid in edible plant oils.

KEYWORDS: *capillary electrophoresis−capacitively coupled contactless conductivity detection, polyamidoamine dendrimer, free fatty acids, edible plant oil*

INTRODUCTION

Free fat acids (FFAs) in edible plant oils ordinarily originate from crude plant oils and hydrolysis of triacylglycerols (TAGs) during processing and storage. FFAs affect the flavor quality of the oil. Moreover, they are chemically unstable, and a high concentration of FFAs may lead to the rancidity of the oil and formation of peroxides that are toxic to humans. Therefore, FFA content is one of the most concerned indices of edible oils.

Total FFAs in edible plant oil can be determined by nonaqueous titrimetry recommended by the American Oil Chemists' Society (AOCS).[1] The method is simple but uses a large amount of organic solvents and cannot determine the contents of individual FFAs. The individual FFA concentration in edible oil can be obtained by chromatography methods.[2−4] In gas chromatography (GC), FFAs are derivatized to methyl or trimethylsilyl esters.[5,6] In high-performance liquid chromatography (HPLC), they can be directly detected[7] but are often derivatized for higher detection sensitivity.[8,9] Owing to its high separation efficiency, capillary electrophoresis (CE) has been considered as an alternative technique for fatty acid analysis.[10−13] Capacitively coupled contactless conductivity detection (C^4D) is based on conductivity differences between the sample zones and the background electrolyte (BGE); it is an ideal detection approach for analytes lacking chromophores. Moreover, C^4D overcomes the problem of short path length that is encountered by the on-column photometric detection. Despite the obvious advantages of CE−C^4D, only a few works applied this technique in FFA analysis.[14,15]

Another aspect should be considered for CE analysis of FFA is separation. Since fatty acids (FAs) possess carboxyl groups, they can be separated straightforwardly under normal polarity mode in neutral or basic running buffers, in which they migrate to the detector following the cathodic electroosmotic flow (EOF).[11] However, it was suggested that reversed EOF combined with a negative separation voltage is favorable, because in this case the solutes comigrate with EOF and better reproducibility of migration time could be achieved.[16,17] The commonly used strategy for reversing EOF is dynamic coating due to its versatility and simplicity;[18] for this application, cationic surfactants such as tetradecyltrimethylammonium bromide (TTAB)[19,20] and cetyltrimethylammonium bromide (CTAB) are often used. Usually cationic surfactants at millimolar levels are needed for EOF reversal in aqueous media, but the concentrations can be higher in nonaqueous solutions.[21] This is not favorable if C^4D is employed, because the baseline noise would markedly increase upon elevated buffer conductivity.

Polyamidoamine (PAMAM) dendrimers are highly branched, symmetrical macromolecules with high-density functional groups.[22] They possess three kinds of structural components: cores, interior repeating units, and terminal groups. PAMAMs terminated with primary amine groups are full-generation dendrimers (G*n*, where *n* is an integer), whereas those terminated with methyl ester groups are half-generation ones (G*n*.5). Due to protonation of the amino groups, the full-generation PAMAMs are positively charged at pH <10[23] and, therefore, can readily adsorb on the silica surface. This property

renders PAMAMs potentially ideal EOF reversers for C^4D analysis, because no anions were introduced into running buffers as the conventional surfactant salts do.

We herein investigate CE−C^4D analysis of FFAs of different chain lengths varying from C8 to C20, including saturated and unsaturated, *trans*- and *cis*-FFAs, using PAMAMs as additive to reverse EOF and to improve separation. We are also to demonstrate the highly effective liquid−liquid extraction of FFAs from the plant oils using the PAMAM-containing, alkaline running buffer as extraction solution. The advantages of the extraction are obvious: neither desorption as in solid-phase extraction[24] nor back-extraction or evaporation as in conventional liquid−liquid extraction[25] is required; indeed, the extract can be directly analyzed. The influences of PAMAM generation and concentration, buffer composition and pH, organic solvents, and C^4D parameters were investigated and optimized. Finally, the developed method was applied to analysis of FFAs in real edible oil samples.

MATERIALS AND METHODS

Chemicals and Solutions. All reagents were of analytical grade. Cetyltrimethylammonium bromide (CTAB), methanol (MeOH), acetonitrile (ACN), tris(hydroxymethyl)aminomethane (Tris), 1-octanol, 2-propanol, and *n*-hexane were purchased from Beijing Chemical Plant (Beijing, China). Polyoxyethylene 23 lauryl ether (Brij 35) and pelargonic (C9:0), palmitic (C16:0), linoleic (C18:2 *cis*-9, *cis*-12), oleic (C18:1 *cis*-9), and elaidic (C18:1 *trans*-9) acids were the products of Aladdin (Shanghai, China). Hexanoic (C6:0), octanoic (C8:0), capric (C10:0), lauric (C12:0), myristic (C14:0), and stearic (C18:0) acids were obtained from Labebuy Reagents (Hangzhou, Zhejiang, China). Individual fatty acid stock solutions, at 20.0 mM each, and working standard mixtures, typically at 0.02 mM each, were prepared in methanol and stored in a refrigerator until use.

Synthesis of PAMAM Dendrimers. PAMAMs of different generations were synthesized following the procedures described elsewhere.[22] Briefly, methyl acrylate was added dropwise to the methanolic solution of ethylenediamine, and the mixture was allowed for Michael addition at room temperature for 24 h. Afterward, the adduct was let for amidation with excessive ethylenediamine under room temperature for 64 h, yielding amine-terminated PAMAM. The first two steps produced PAMAM generation zero (G0). Synthesis of higher generation PAMAMs was accomplished by repeating progressively the Michael addition (for half-generations)/amidation (for entire generations) cycles. The product of each step was purified by washing with methanol, followed by drying under vacuum. The PAMAMs were tested by a Bruker Advance III-400 MHz NMR spectrometer (Rheinstetten, Germany). The ^1H NMR results of PAMAMs G0, G1, G2, G3, and G4 are given in section 1 of the Supporting Information.

Capillary Electrophoresis. A high-voltage supply HB-F303-1AC (Hengbo, Tianjin, China) was employed to offer potentials for electrophoretic separation. A VC2002 function generator (Shengli Cooperation, Shenzhen, Guangdong, China) delivered a sinusoidal wave at a frequency between 1 Hz and 2 MHz and amplitude between 0 and 20 $V_{p\text{-}p}$ (peak to peak) to the excitation electrode of a homemade C^4D instrument, which was described previously.[16] The data were collected by an IBM PC compatible computer via a CT22 data acquisition unit (Qianpu, Shanghai, China) and processed with a HW2000 chromatography station (Qianpu).

An uncoated fused-silica capillary (Yongnian Optical Fiber, Hebei, China) of 55 cm length (48 cm effective length) × 50 μm i.d. was used for separation. The fresh capillary was conditioned by pressure flushing, successively, with 0.5 mM NaOH (20 min), deionized water (20 min), and running buffer (10 min). Every day before use the capillary was rinsed with deionized water for 10 min, followed by running buffer for 10 min. All solutions were filtered through 0.45 μm filters (Jiu Ding High Tech., Beijing, China) before use. Samples were injected hydrostatically at a height difference of 35 cm for 20 s, corresponding to an injection volume of 19.5 nL, as estimated using CE Expert software (Beckman Coulter, Fullerton, CA). Separations were performed at 15 kV at ambient temperature. Between runs, the capillary was regenerated by flushing with running buffer for 5 min. If the running buffer changed, the capillary was rinsed with the new buffer for 20 min before experiment. The EOFs were determined using the method proposed by Williams et al.[26]

Orthogonal Design. The organic solvents acetonitrile, 2-propanol, and 1-octanol were commonly used agents in CE; in this experiment, they were added to running buffer to increase the solubility and separation of FAs. To obtain the best resolution in short analysis time, orthogonal design (OD) was employed to optimize the concentrations of the organic solvents. The boundaries of individual organic solvents were determined by preliminary experiments, based on which three-level three-factor OD was built, and a total of nine experimental conditions were tested, as shown in Table S1 of the Supporting Information. To rank the CE performance of each condition, chromatographic optimization functions (COFs) were adopted as criteria[27]

$$\mathrm{COF} = \sum_{i=1}^{n-1} A_i \ln\left(\frac{R_i}{R_{i\mathrm{D}}}\right) + B(t_\mathrm{D} - t_n) \quad (1)$$

where A_i and B are weighting parameters, which are both assigned to 1 in this experiment. R_i and $R_{i\mathrm{D}}$ (set to 1.5) are the determined and desired resolution values for the ith peak pair. The time terms t_D and t_n stand for a desired maximum analysis time (20 min in this experiment) and the time of the last peak, respectively. The higher COF value represents the better CE performance.

The R_i in eq 1 was defined as

$$R_i = \frac{2(t_2 - t_1)}{W_2 + W_1} \quad (2)$$

where t_1, t_2 and W_1, W_2 are the migration times and the peak widths of two successive peaks, peak 1 being the first one and peak 2 the next one adjacent to it.

Analysis of Edible Plant Oil Samples. *CE−C^4D Analysis.* Samples of soybean oil, sunflower seed oil, and maize oil were bought from a local supermarket. For simplicity and efficiency in sample preparation, the buffer-mediated liquid−liquid extraction was adopted. Briefly, a 0.25 mL oil sample was added to 0.5 mL of running buffer. The admixture was vortexed for 9 min (this is the optimal extraction time; see section 3 of the Supporting Information for details) and then centrifuged at 3500 rpm for 5 min. The aqueous phase was diluted 5−50 times with methanol and used directly for CE analysis.

Recoveries (R%) of FFAs from the plant oil samples were assessed on the basis of three spiking levels, using

$$R\% = \frac{S_2 - S_1}{S_0} \times 100 \quad (3)$$

where S_1 and S_2 are the peak areas of an FFA in unspiked and spiked samples, respectively; S_0 is the peak area of this FFA prepared in matched matrix at the spiking concentration.

GC−Mass Spectrometry (MS) Analysis. Extraction of FFAs from oil samples and the subsequent esterification of the FFAs were carried out following refs 24, 28, and 29, with slight modification. Briefly, 5.0 mL of vegetable oil sample was extracted three times with 10 mL of Na_2CO_3 solution (2 g/100 mL). The aqueous phase was titrated with 1 M HCl to pH 2 and extracted three times with 10 mL methylene chloride. The methylene chloride fractions were combined and evaporated to dryness. The residue was dissolved in 3 mL of methanol, added slowly with 0.15 mL of concentrated sulfuric acid, and refluxed at 80 °C for 2 h. To extract the fatty acid methyl esters, 5 mL of *n*-hexane was added, followed by 5 mL of aqueous NaCl solution (1%, w/w) to facilitate phase separation. The mixture was vortexed for 5 min, and then the supernatant was collected and diluted (typically 200 folds) with *n*-hexane before GC−MS analysis.

GC−MS analysis was performed on an Agilent 7890A gas chromatograph (Agilent Technologies, Santa Clara, CA) coupled to an Agilent HP 5975C quadrupole mass spectrometer (Agilent). The gas chromatograph was equipped with an Agilent HP-5 fused-silica capillary column (length, 30 m; i.d., 250 μm; film thickness, 0.25 μm). The flow rate of the helium carrier gas was 1 mL/min. The GC oven temperature program was as follows: initial oven temperature 30 °C, ramped to 230 °C at 20 °C/min, afterward to 270 °C at 5 °C/min, and then to 280 °C at 10 °C/min, and held for 7 min. The interface, injector, ion source, and quadrupole were kept at 280, 250, 230, and 150 °C, respectively. One microliter of the esterified FFAs prepared in *n*-hexane was injected in splitless mode using an autosampler (Agilent HP 7683B). The solvent delay time was set at 3 min. For each oil sample, the MS was first operated on the total ion current (TIC) mode, scanning from *m*/*z* 50 to 500, for identification purposes and then on selected ion monitoring (SIM) mode for quantification.

AOCS Nonaqueous Titrimetry. The total FFA contents in plant oil samples were determined according to the method recommended by the American Oil Chemists' Society (AOCS).[1] For calibration, a blank titration of the organic solvent was performed following the procedures in the literature.[30]

RESULTS AND DISCUSSION

Preliminary experiments suggested that higher-generation PAMAMs had stronger EOF-reversing ability (Figure S2 of the Supporting Information). However, PAMAM G2 could provide the best CE performance in terms of separation efficiency and analysis time. Therefore, it was chosen for the following method development.

Comparison of PAMAM and CTAB as EOF Reversers. Figure 1 indicates that, in the presence of 30 μM PAMAM G2, the EOFs reversed for the buffers of Tris and carboxylic acids (chain lengths from C6 to C12) prepared in 50% (v/v) methanol. With regard to CTAB as EOF reverser, however, the cathodic EOF mobility was only slightly reduced at 1 mM, reached nearly zero at 5 mM, reversed with further increase in CTAB concentration, and leveled off at 10 mM, with a maximum anodic EOF mobility of -0.5×10^{-4} cm^2 V^{-1} s^{-1}. This value was only about one-third of that generated by 30 μM PAMAM G2 in the same buffer, which is not favorable for quick analysis. Moreover, the baseline noise with a high concentration of CTAB increased dramatically and no peaks corresponding to FAs could be identified (Figure S3 of Supporting Information).

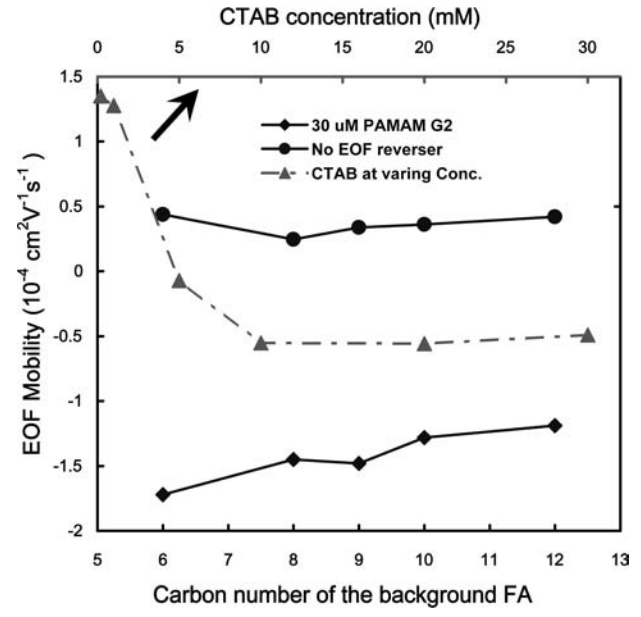

Figure 1. Comparison of EOF reversal ability of PAMAM G2 and CTAB. Testing buffers contained 10 mM Tris, 5 mM FAs (pelargonic acid for CTAB experiments), 50% (v/v), and EOF reversers as depicted in the figure legends.

The results suggested that PAMAM G2 was positively charged in the buffer containing high-concentration organic solvents, and was an effective EOF reverser, predominantly owing to its high densities of surface functional groups.[31] The slight cathodic increase in EOF as a function of chain length of the background fatty acids might be the consequence of the stronger wall adsorption of the longer hydrophobic chains.[21]

Effect of PAMAM on Separation. Figure 2A depicts that the analysis time decreased rapidly, from ca. 35 to ca. 21 min, when the PAMAM concentration increased from 30 to 100 μM. In the presence of 300 μM dendrimer, the FAs were

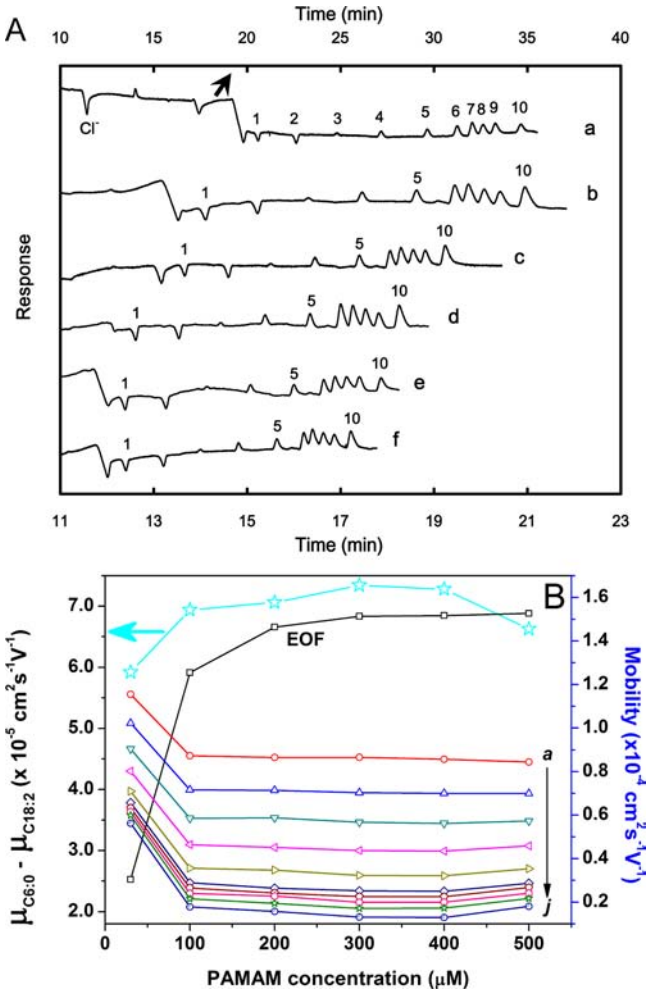

Figure 2. Influence of PAMAM concentration on electropherograms (A) and mobilities (B). Conditions in panel A: The buffers contained 39 mM Tris, 3 mM pelargonic acid (C9:0), 30 mM Brij 35, 20% 2-propanol, 30% acetonitrile, 2.5% 1-octanol. The PAMAM G2 concentrations were 30, 100, 200, 300, 400, and 500 μM for traces a, b, c, d, e, and f, respectively. All the contents of organic solvents in buffers were of volume percentages. Capillary: 55 cm × 50 μm. Separation voltage: 15 kV. C^4D: 20 $V_{p\text{-}p}$ × 100 kHz. Peak identities: 1, C6:0; 2, C8:0; 3, C10:0; 4, C12:0; 5, C14:0; 6, C18:2; 7, C16; 8, C18:1; 9, C18:1(t); 10, C18:0. Conditions in panel B: curves a−j corresponded to FAs 1−10 in panel A.

dx.doi.org/10.1021/jf4056105 | J. Agric. Food Chem. 2014, 62, 4104−4111

baseline separated within 18 min. Although the analysis time was further shortened with progressive addition, resolution between the FAs deteriorated.

Migration of the FAs in capillary is influenced by their interactions with capillary wall and with PAMAM. The former is adsorption, leading to low migration velocity and, usually, low separation efficiency; it is intensified by the increasing FA chain length.[21] The latter is based on electrostatic attraction. To understand in depth the effect of PAMAM, the EOF mobility and effective mobilities of the FAs were plotted versus dendrimer concentration (Figure 2B). The anodic EOF mobility increased rapidly with PAMAM concentration from 30 to 200 μM and leveled off at 300 μM. On the other hand, the FA mobilities significantly decreased with PAMAM concentration from 30 to 100 μM. In addition, variation of the mobility difference between the first and the last FAs, C6:0 and C18:2, as a function of dendrimer concentration shows a convex profile, with a maximum at 300 μM, under which condition high resolution could be realized. The results suggest that PAMAM dendrimer played an important role in separation time and resolution.

Selection of BGE Constituents. The C^4D response is theoretically determined by conductivities of analyte, BGE co-ion and counterion, and the transfer ratio as well.[32] BGE co-ion is empirically highly influential on peak intensity and shape and should be selected carefully. Increasing conductivity difference between analyte and BGE co-ion can improve detection sensitivity, but can also result in more fronting or tailing peaks, which are unfavorable for high resolution. Given the fact that the carbon numbers of the FFAs occurring naturally in plant oils are usually even, from 12 to 22,[33] and taking into consideration both the detection sensitivity and peak symmetry, we choose pelargonic acid (C9:0) as buffering acid in BGE.

Regarding background counterions, the following bases were investigated: tributylamine, methylamine, ethylamine, triethylamine, ammonia, and Tris. Although some fatty acids could be detected with tributylamine, they suffered from the drawbacks of long analysis time and low signal-to-noise ratio (trace a of Figure 3). The electropherograms with buffers containing methylamine, ethylamine, and triethylamine showed serious baseline noise such that the signal from fatty acid could be hardly identified (traces b–d). While all the fatty acids could be detected with the BGE buffered by ammonia, the palmitic acid, oleic acid, and elaidic acid were not baseline separated (trace e), and the resolution was not improved with further optimization. For Tris as the background cation (trace f), relatively low baseline noise was exhibited and all the fatty acids could be detected with high sensitivity in acceptable analysis time; moreover, the resolution among the peaks could be further optimized to realize baseline separation. Consequently, Tris was selected as background cation for subsequent method development.

Influence of Organic Solvents and Brij 35. Table 1 lists the COF values of each run as well as the sum of the COFs under investigating variables (K1–K3). According to the largest donating rule, the largest sum of COF corresponds to the optimum level of the factor. Therefore, the optimal organic solvent composition in the buffer should be 15% 2-propanol (A2), 35% acetonitrile (B2), and 2.5% 1-octanol (C3).

As an often-used organic additive, Brij 35 affected the separation performance. By investigating the dependence of resolution and analysis time on the Brij 35 concentration

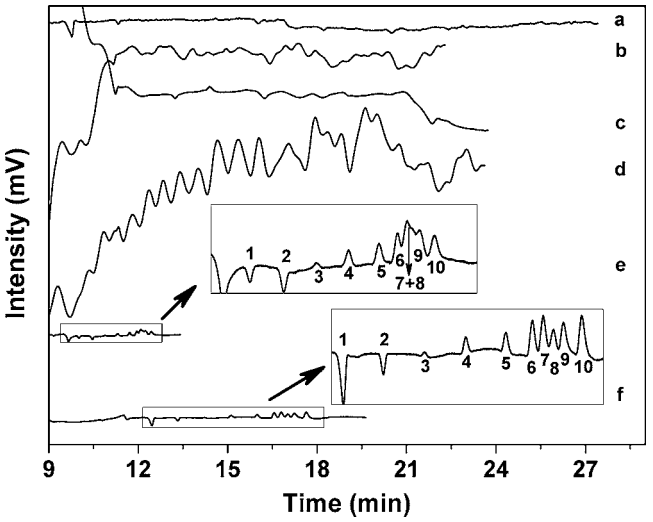

Figure 3. Influence of BGE cation buffers: 300 μM PAMAM G2, 30 mM Brij 35, 20% 2-propanol, 30% acetonitrile, 2.5% 1-octanol, 5 mM pelargonic acid (C9:0), and the following cations at 45 mM each: a, tributylamine; b, ethylamine; c, triethylamine d, methylamine; e, ammonia; f, Tris. All the other conditions were the same as Figure 2.

[a]Detailed information is listed in Table S1 of the Supporting Information.

(Figure S4 of the Supporting Information), we found that Brij 35 at 30 mM was optimal.

Influence of Buffer pH. The running buffers were prepared by mixing aqueous buffer solutions with organic solvents; therefore, the pH values of the aqueous phases and the apparent pH values (denoted by pH*) of the final mixtures were measured. The influence of buffer pH was investigated at a fixed buffer concentration of 42 mM, by altering the Tris/pelargonic acid ratio from 41/1 to 33/9, corresponding to pH* and pH values of 8.79–9.36 and 8.29–8.67, respectively. It was found that the migration times of the FAs decreased upon increasing buffer acidity; at pH* 8.53 (pH 9.18), all the FAs were well-separated with the highest detection sensitivity (Figure S5 of the Supporting Information).

Increasing buffer acidity was achieved by increasing the pelargonic acid/Tris ratio of the BGE. Theoretically, the

effective mobilities of FAs in low pH* buffer would decrease, resulting in prolonged analysis time. Therefore, the phenomenon was not caused by protonation/deprotonation of FAs. We think two important factors should be considered in interpreting the migration of FAs. One is protonation of the terminal amino group of PAMAM molecules. Adsorption of these positively charged molecules on the inner wall of the capillary would enhance the anodic EOF, leading to high apparent mobilities of the FAs. However, in the running buffer, migration of FAs would be retarded by the interaction with the protonated PAMAMs. The second is the elution effect of pelargonic acid. It was reported that significant wall adsorption occurred for FAs at all chain lengths during separation, even in buffer prepared in pure organic solvent.[21] Increasing the background pelargonic acid concentration for higher buffer acidity would also promote the elution of FAs from the capillary wall, giving rise to two consequences that oppositely affect the CE performance: (a) suppressing peak tailing and hence providing better resolution and (b) enhancing the mobilities of the FAs and often unfavorably degrading the separation. As a compromise between analysis time and resolution, the BGE containing 39 mM Tris and 3 mM pelargonic acid at pH* 8.53 was adopted.

Optimization of C^{4}D Parameters. It was found that the peak intensity increased proportionally with growing excitation voltage; therefore, the maximum output of the functional generator, 20 $V_{p\text{-}p}$, was employed. The influence of the oscillation frequency was studied between 50 and 200 kHz (Figure S6 of the Supporting Information), and highest peak heights were achieved at 100 kHz. The decreasing response at higher frequency was likely attributed to the high stray capacitance between the electrodes.[34]

Analytical Performance and Application. The method was evaluated using the optimized buffer comprising 39 mM Tris, 3 mM pelargonic acid (C9:0), 30 mM Brij 35, 35% ACN, 15% 2-propanol, 2.5% 1-octanol, and 300 μM PAMAM G2 at pH* 8.53. The limits of detection (LODs, signal-to-noise ratio of 3) for most FAs were at sub-micromolar level, in the range of 0.46−3.28 μM, equivalent to mass concentrations of 0.12−0.57 μg/mL (Table 2). The higher LOD for capric acid might result from the utilization of pelargonic acid as background co-ion. The two FAs differ by only one carbon in chain lengths, and the small mobility difference between analyte and background co-ion theoretically accounts for the low detection sensitivity.[34] However, employing PAMAM rather than the conventional cationic surfactants with higher conductivity as EOF reverser significantly decreased the baseline noise, resulting in the higher sensitivity of the C^{4}D method. The overall detectability for fatty acids averaged 34-fold more sensitive than the commonly adopted CE−indirect UV method.[35] It is superior to the previous CE−C^{4}D results (35−319 μM[14]) and better than the recently reported 0.9−1.5 μg/mL,[15] which is the best detection sensitivity so far published on CE−C^{4}D. Indeed, it is even comparable to liquid chromatography−C^{4}D.[36]

The linearity of the detector response for each fatty acid was investigated on seven concentration levels, and calibration curves were constructed by plotting the peak areas of each fatty acid against the concentrations. Table 2 indicates that, in the concentration range studied, the squared correlation coefficients (r^2 values) for all the calibration graphs were higher than 0.996, suggesting the good linearity of the method. The precisions of migration times and peak areas were studied on the standard mixture at 20 μM each, using C6:0 as internal standard. Five consecutive injections were performed for intraday repeatability evaluation (n = 5), and interday reproducibility was estimated on three consecutive days (n = 3 × 5 = 15). It was found that the intraday and interday variabilities of the migration time, expressed in relative standard

dx.doi.org/10.1021/jf4056105 | J. Agric. Food Chem. 2014, 62, 4104−4111

deviations (RSDs), were no more than 0.49% and 0.47%, respectively. The corresponding values for peak areas were no more than 9.91% and 8.99%, respectively. The good precision of the migration time should partly originate from the utilization of dendrimer as EOF reverser. The precisions of migration time and peak area were in accordance with the requirements set by the US FDA guidelines.[37] The data of peak areas were statistically checked for random errors with *F*-test and systematic errors with *t*-test. No significant differences within the data were found, with $F \leq 5.71$ ($F_{(4,4)} = 6.39$, at 95% confidence limit) and $t \leq 2.57$ ($t_8 = 2.90$, at 98% confidence limit).

The running-buffer-mediated extraction process was optimized in terms of extraction time. The extracted FFA content increased with extraction time and leveled off at 9 min (Figure S1 of the Supporting Information). With an extraction time of 9 min, the recoveries of FFAs from the plant oils at three concentration levels were between 90.1% and 110.3% (Table 3), suggesting the effectiveness of the PAMAM-containing running buffer as extraction solution. The surface primary amino groups of the PAMAM G2 molecule have protonation constants (pKs) of ca. 9.0;[23] therefore, in the running buffer at pH* 8.53, the dendrimers were partly positively charged. On the other hand, the FFAs were negatively charged because the pK_a values of their carboxyl groups are around 5.[11] The PAMAM−FFA interaction, driven by acid−base chemistry and ion pairing, resulted in assembly of FFAs on the PAMAM surface,[38] facilitating the FFAs partitioning into the running buffer.

To demonstrate its applicability, the developed method was applied in determination of FFAs in plant oil samples (Figure 4). Due to the influence of sample matrices, the migration times

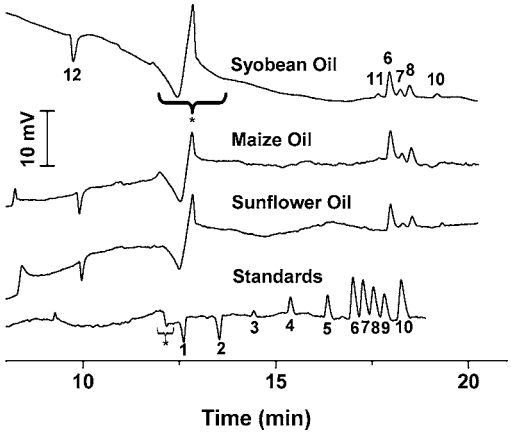

Figure 4. Electropherograms of the FFAs in real samples. Peak identities: 1−10 were the same as Figure 2; 11, unknown; 12, Cl^-; *, system peak. The concentration of PAMAM G2 was 300 μM. The extracts of soybean oil, maize oil, and sunflower seed oil were diluted 5-, 10-, and 50-fold, respectively, with methanol. The concentrations of FAs in standard solution were 0.02 mM each.

of the peaks in oils shifted, and the baseline noise increased for some samples (baseline noises for the traces in Figure 4 were 37, 23, 52, and 63 μV for standard solution, soybean, sunflower seed, and maize oils, respectively; the baseline noise of the detector was different during daytime and night—it was usually somewhat lower at night). However, the FFAs in real samples were separated with slightly better resolution yet much shorter analysis time than the previous report.[15] Moreover, treatments of oil samples were simple, efficient, and easy to operate, and the total analysis time is no more than 35 min. For comparison, the FFAs in the oil samples were also analyzed by AOCS nonaqueous titration and GC−MS (for chromatograms, refer to Figure S7 of the Supporting Information). Table 4 indicates

[a]Under the LOD. According to the sample preparation procedure, the FFAs in maize oil sample were 20-fold diluted before injection.

that the results from the three methods agreed well. C16:0, C18:0, C18:1, and C18:2 were all detected in soybean oil and sunflower seed oil by CE−C^4D and GC−MS. Although a discrepancy is found between the two methods on the concentration of C18:0 in maize oil, we think this is mainly due to the overall 20-fold dilution of the FFAs for this oil during sample preparation, making the final concentration of C18:0 below the LOD. None of the edible oils studied contained trans fatty acid C18:1(*t*). The FFA concentrations (as lauric acid) were in the range of 0.0138%−0.121%, in compliance with the China national standards on maize, soybean, and sunflower seed oils.[39−41] The FFA contents determined in this work were higher than those reported by Wei et al.,[24] but the total FFA contents in our sample oils were lower than the previous reports (for maize oil,[30,42] soybean oil,[30] and sunflower seed oil[42,43]). In fact, contents of different FFAs in edible oils vary widely,[24] and some FFAs may occur at trace levels. Therefore, though only four FFAs were detected in the oil samples by CE−C^4D and GC−MS, other FFAs might also exist, but at extremely low concentrations, i.e., lower than the LOD of GC−MS, which was ca. 0.05 μg/mL (for C16:0; the value could be lower for shorter-chain FFAs) in TIC mode for oil samples in this experiment.

To evaluate this new strategy in depth, a previously reported CE−UV method[44] for determining fatty acids was carried out. Figure S8 of the Supporting Information indicates that the peaks of the FFAs in the real samples overlapped due to the tailing shapes. Moreover, the detection sensitivities were low, with LODs of 1.2−9.0 μg/mL for FA standards.

Summing up, the running-buffer-mediated liquid−liquid extraction approach enables quick and quantitative extraction of FFAs from the plant oils. Addition of PAMAM dendrimers to running buffer effectively shortens the analysis time and improves the separation of the analytes, and the CE−C^4D analysis based on the PAMAM-containing buffer provides higher detection sensitivity relative to those using conventional cationic surfactants as EOF reversers. The methodology is a promising alternative for determining FFAs in edible oils; importantly, it is fast, cost-effective, and easier to operate than the traditional chromatographic techniques.

Supporting Information

ABSTRACT: A dopant-assisted atmospheric pressure photoionization (APPI) with liquid chromatography tandem mass spectrometry (LC-MS/MS) method was developed to determine patulin in apple juice and apple-based food. Different dopants, dopant flow rates, and LC separation conditions were evaluated. Using toluene as the dopant, the LC-APPI-MS/MS method achieved a linear calibration from 12.5 to 2000 μg/L (r^2 > 0.99). Matrix-dependent limits of quantitation (LOQs) were from 8 μg/L (solvent) to 12 μg/L (apple juice). [^{13}C]-Patulin-fortified apple juice samples were directly analyzed by the LC-APPI-MS/MS method. Other apple-based food was fortified with [^{13}C]-patulin, diluted using water (1% formic acid), centrifuged, and filtered, followed by LC-APPI-MS/MS analysis. In clear apple juice, unfiltered apple cider, applesauce, and apple-based baby food, average recoveries were 101 ± 6% (50 μg/kg), 103 ± 5% (250 μg/kg), and 102 ± 5% (1000 μg/kg) (av ± SD, n = 16). Using the suggested method, patulin was detected in 3 of 30 collected market samples with concentrations ranging from <LOQ to 18 μg/L. The use of [^{13}C]-patulin allowed quantitation using solvent calibration standards with satisfactory precision and accuracy.

KEYWORDS: *patulin, apple juice, APPI, dopant-assisted, stable isotope dilution, LC-MS/MS*

INTRODUCTION

The United States has the largest consumer market of apple juice in the world. To meet the demands of the market, 1.3 billion pounds of apples was processed to produce apple juice and cider in 2010.[1] Interestingly, the United States is also the world's largest importer of apple juice and spent more than $400 million on this product between 2006 and 2007.[2]

The current apple juice production procedures of heating, filtration, and pasteurization cannot eliminate patulin,[3] a toxic mycotoxin excreted by fungal species of the genera *Penicillium* and *Aspergillus*, especially *Penicillium expansum*, which grow on fruits.[4−6] The presence of patulin in fruit juices and processed apple foods highlights the importance of regulatory controls to minimize dietary exposure to patulin. Many countries, including the United States, have established a tolerance or action level of patulin at 50 μg/L (ppb) in apple juice.[7,8] The European Union (EU) maximum levels of patulin in baby foods and fruit juices are 10 and 50 μg/L, respectively.[9]

Gas chromatography−mass spectrometry (GC-MS),[10−12] LC-UV,[13−15] and thin layer chromatography (TLC)[16] methods have been developed to determine patulin in fruit juices and enforce established regulatory limits of patulin. These testing methods require multiple, time-consuming sample preparation steps, involving extraction, partitioning, concentration, and derivatization, to achieve the sensitivity and specificity necessary for regulatory control. A fluorescence immunoassay was developed for the determination of patulin, but it required noncommercially available antibodies.[17]

In recent years, LC-MS/MS has been increasingly used for patulin analysis because of its superior sensitivity and specificity.[18−21] Most LC-MS/MS methods use an electrospray ionization (ESI) source operating in positive or negative mode. As an alternative to ESI, an atmospheric pressure photoionization (APPI) source can be coupled with LC for the analysis of polar and nonpolar chemical compounds.[22,23] In the APPI ionization source, target analytes can be directly ionized by photons or charge exchange reactions with the ion molecules of a primary reagent (dopant) if direct photoionization cannot provide sufficient sensitivity.[24,25] Because of its characteristic gas-phase ionization mechanism, APPI is less prone to matrix ion suppression than ESI,[26] which means that for certain compounds, APPI produces better sensitivity and eliminates the need to use matrix-matched calibration standards for quantitation. So far, only a few studies have explored whether APPI can be applied for the analysis of mycotoxins in foods,[27−29] and information regarding APPI analysis of patulin has not been well-documented.[30] The objective of this study was to develop an APPI method with a simple sample preparation procedure that can detect patulin in apple juice and processed apple foods. Important APPI parameters, such as candidate dopants, dopant flow rate, and LC flow rate, were

evaluated and optimized to determine whether APPI is a viable tool for patulin analysis.

MATERIALS AND METHODS

Chemicals and Materials. LC grade acetonitrile, acetone, methanol, water, toluene (99.9%), MS grade formic acid, and ammonium formate were purchased from Fisher Scientific (Pittsburgh, PA, USA). Anisole (≥99%), bromobenzene (99.9%), and chlorobenzene (99.9%) were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Standards. Stock solutions of patulin (100 μg/mL, in acetonitrile) and a stable isotope-labeled internal standard (IS), [^{13}C]-patulin (25 μg/mL, in acetonitrile) were purchased from Romer Laboratories, Inc. (Union, MO, USA). Structures, CAS Registry Numbers, and molecular weights of patulin and [^{13}C]-patulin can be found in Table 1. Spiking solutions of patulin at 1000, 5000, and 20000 μg/L were prepared by diluting the stock solution using acetonitrile and stored at −20 °C in the dark. A working solution of [^{13}C]-patulin at 2000 μg/L was prepared in the same fashion. Fresh solvent-only and matrix-matched (apple juice, applesauce, apple-based baby food, and apple cider) calibration solutions at 12.5, 25, 50, 100, 250, 500, 1000, and 2000 μg/L were prepared on the day of experiments by a series of dilutions of prepared spiking solutions using water with 1% formic acid or blank sample matrix extracts in volumetric flasks. Prior to LC-MS analysis, each calibration standard (1.0 mL) was pipetted into LC autosampler vials and fortified with 25 μL of the [^{13}C]-patulin working solution (2000 μg/L). The final concentration of [^{13}C]-patulin was 50 μg/L.

Sample Preparation. Clear and unfiltered apple juice samples (1.0 ± 0.05 mL) were pipetted into LC sample vials and spiked with 25 μL of the [^{13}C]-patulin working solution, followed by manual shaking for 1 min. Clear juice samples were analyzed by LC-APPI-MS/MS without any additional sample preparation. Unfiltered apple juice or apple cider samples were transferred into Amicon Ultra-4 centrifugal filters with Ultracel-3 membrane (EMD Millipore, Billerica, MA, USA) and centrifuged for 15 min at 4500 rpm (4200*g*). The collected filtrates were analyzed by LC-APPI-MS/MS. Other processed apple samples (1.0 ± 0.05 g of applesauce or apple-based baby food) were weighed out in 15 mL disposable glass vials, fortified with 25 μL of the [^{13}C]-patulin working solution, and homogenized by manual shaking for 2 min with 1 mL of water (1% formic acid). Homogenized samples were transferred into the same centrifugal filters and centrifuged (CR 4i, ThermoElectro Corp., Milford, MA, USA) for 15 min at 4500 rpm (4200*g*). The resulting filtrates were pipetted into autosampler vials for LC-APPI-MS/MS analysis.

Recovery Studies. Recovery studies were conducted in clear apple juice, unfiltered apple cider, applesauce, and apple-based baby food matrices at 50, 250, and 1000 μg/kg (Table 2). Blank samples (1.0 g) were fortified using 50 μL of the spiking solutions at 1000, 5000, and 20000 μg/L and 25 μL of the [^{13}C]-patulin working solution and prepared as described above. At each fortification level, samples were prepared in quadruplicates. Patulin was quantitated using solvent calibration standards with the IS, [^{13}C]-patulin. No patulin was detected in the blank samples used for recovery studies. Blank samples were collected from the Washington, DC, USA, metropolitan area.

Table 2. Recoveries in Fortified Matrices

	recovery (%, ±SD, n = 4)				
fortification (μg/L)	apple cider (unfiltered)	apple juice (clear)	apple sauce	apple-based baby food	av (n = 16)
50	110 ± 2	98 ± 3	100 ± 4	96 ± 2	101 ± 6
250	107 ± 3	96 ± 5	104 ± 2	103 ± 2	103 ± 5
1000	103 ± 3	96 ± 5	105 ± 3	103 ± 4	102 ± 5

Matrix-Dependent Instrument Limit of Detection. The matrix-dependent limits of detection and quantitation (LOD and LOQ, respectively) for patulin were obtained by following procedures from the U.S. Environmental Protection Agency's (EPA) protocol.[31] The matrix-dependent LOD was determined by analyzing eight replicates of patulin solvent and matrix-matched calibration standards at 12.5, 25, and 50 μg/L, respectively. Matrix-matched calibration standards were made by spiking a patulin working solution (1000 μg/L) into blank matrix extracts of clear apple juice, unfiltered apple cider, applesauce, and apple-based baby food. Blank matrix extracts were prepared as described above. The mean and standard deviation (SD) of patulin were obtained from the eight replicates. The matrix-dependent LOD was calculated using the formula LOD = 2.998 × SD (critical $t_{0.01}$ = 2.998 for degree of freedom (df) of 7). The corresponding matrix-dependent LOQ was calculated as 3 × LOD. At the LOQ the second transition (m/z 153.0 to 81.0) for patulin was measurable.

LC-APPI-MS/MS Analysis. All sample analyses were performed on a Shimadzu Prominence/20 series (Columbia, MD, USA) LC coupled with an Applied Biosystems 5500 quadruple linear ion trap mass spectrometer with an APPI interface source. A Phenomenex Kinetex XB-C18 LC column (100 mm × 2.1 mm i.d., 2.6 μm) and a 10 × 2.1 mm guard cartridge were used for LC separation (Torrance, CA, USA). The LC mobile phases consisted of 10 mM ammonium formate/0.1% formic acid/water (A) and 10 mM ammonium formate/0.1% formic acid/methanol (B). Gradient elution at 0.1 mL/min flow rate started at 5% B, ramped to 40% B in 3 min and then to 100% B by 3.5 min, held for 3 min, and changed to 5% B at 7 min. Total run time was 10 min, including 3 min of column conditioning time. The injection volume was 5 μL, and the column temperature was 40 °C.

The mass spectrometer was operated in negative ionization mode with scheduled multiple reaction monitoring scanning (sMRM). Scan time was 0.5 s, and the sMRM detection window was 60 s. The APPI

source was equipped with a krypton lamp that can emit photons with 10.0 eV. The MRM transitions of patulin and [^{13}C]-patulin were generated by directly infusing calibration standards into the APPI source (Table 1). Ionization source-dependent parameters were set by flow injection experiments as follows: curtain gas (CUR), 30 psi; ion spray voltage, − 800 V for the negative mode; nitrogen collision gas (CAD), medium; source temperature (TEM), 450 °C; and ion source gases 1 and 2 (GS1 and GS2), at 80 and 30 psi. Resolution at Q1 and Q3 was set to unit. Dopants were introduced into the ion source using a Harvard model 11 syringe pump (Harvard Apparatus, Holliston, MA, USA) at predefined rates. Analyst 1.6.1 was used to operate the instruments, and MultiQuan 2.0 was used to process data files (Applied Biosystems, Foster City, CA, USA).

RESULTS AND DISCUSSION

Unlike electrospray ionization, atmospheric pressure photoionization happens in the gas phase. In the course of LC-APPI-MS analysis, analytes, coeluted matrix components and LC mobile phases are first evaporated and then introduced into an APPI ion source, followed by reactions with dopant photoions. Dopant is added to the photoionization region via postcolumn infusion, reacting with photons emitted by a krypton discharge lamp. The selection of dopant, dopant flow rate, and LC flow rate can affect the sensitivity of target analytes, so these important parameters were evaluated and optimized as described below.[22]

Dopant-Assisted APPI (DA-APPI). When direct APPI cannot provide sufficient sensitivity, a dopant is often introduced into the APPI source, improving the photoionization efficiency of target analytes via charge exchange reactions, a procedure often referred to as DA-APPI. It is important to compare available candidate dopants when DA-APPI methods are developed.[24] Under identical LC and APPI conditions, the dopants, acetone, anisole, bromobenzene, chlorobenzene, and toluene[24] were introduced into the APPI source at 60 μL/min and were compared using the slope coefficient of an eight-point apple juice matrix-matched calibration curve (12.5−2000 μg/L), background noise, and the signal-to-noise ratio (S/N). Without using dopant or using bromobenzene as dopant, patulin could not be detected below 100 μg/L. To screen patulin at the FDA action level, 50 μg/L, one would prefer to use a method with a LOQ below the action level (e.g., LOQ ≤ 2/5 at a specified level as suggested by Codex).[32] Therefore, bromobenzene was not selected.

In general, a larger slope coefficient indicates better signal intensity. On the basis of the slop coefficients associated with anisole, acetone, chlorobenzene, and toluene (Figure 1), anisole and toluene should be more efficient dopants than acetone or

chlorobenzene. Anisole has been reported to produce better photoionization efficiency than toluene,[24] but the better response (peak area/height) of target analytes could be accompanied by a higher background noise due to the fact that dopant photoions could not differentiate target analytes from ionizable matrix components or impurities in the source. Indicatively, the S/N of patulin (estimated using the S/N script in Analyst 1.6.1) at 12.5 μg/L for toluene (16), anisole (15), chlorobenzene (10), and acetone (5) suggested that comparable S/N ratios were achieved using toluene and anisole as dopant. The better signal intensity of patulin was offset by a higher background noise when using anisole as dopant. The background noise (intensity of baseline) associated with anisole was around 8000 cps, whereas it was 4500 cps with toluene (Figure 1, inset), so either anisole or toluene could be chosen as the final dopant for the study. As a more routinely used chemical reagent, toluene was chosen as the dopant for the following studies.

Effect of Dopant Flow Rate. The abundance of dopant photoions plays an important role in the ionization efficiency of

dx.doi.org/10.1021/jf5006726 | J. Agric. Food Chem. 2014, 62, 4112−4118

target analytes. Because of the consumption of dopant photoions by solvent, neutral species, and other matrix components, sufficient dopant photoions would lead to a complete reaction of analyte molecules in the APPI source, achieving good sensitivity. Under identical LC conditions, toluene was infused into the APPI source at 10, 30, 60, and 90 μL/min. The corresponding slope coefficients and peak areas/heights of patulin at 50 μg/L (average of four replicates) were monitored. Figure 2 clearly demonstrates that once the toluene flow rate reached 30 μL/min, the increase in the slope coefficient was just marginal at a higher dopant flow rate. When the dopant flow rate was changed from 10 to 30 μL/min, from 30 to 60 μL/min, and from 60 to 90 μL/min, the corresponding increases in the peak area/height were around 50, 10, and 2%, respectively, suggesting that a flow rate of 60 μL/min would be sufficient to have a majority of patulin molecules ionized in the ion source. Additionally, when toluene was infused into the APPI source at 30, 60, and 90 μL/min, the corresponding S/N of patulin was similar. On the basis of these findings, the final dopant flow rate was set at 60 μL/min.

Effect of LC Flow Rate. APPI is a mass-flow-dependent ionization source. A higher LC flow rate would introduce more LC mobile phase into the source, competing with analyte molecules for dopant photoions. The impact of the LC flow rate on the intensity of patulin was investigated using flow rates of 100, 200, 300, and 400 μL/min. The slope coefficient at 100 μL/min is 1.5, 2, and 3 times more than the slope coefficient at 200, 300, and 400 μL/min, respectively (Figure 3). The peak area/height of patulin at 50 μg/L (average of four replicates) decreased with increasing LC flow rates (Figure 3, inset). Similar observations were reported in previous studies.[29,33] When samples were eluted using 400 μL/min, the retention time of patulin was 1.8 min, whereas when samples were eluted using 100 μL/min, patulin was eluted from the column at 6.2 min. However, the faster LC separation caused a significant decrease in signal intensity. For example, the peak area/height of 50 μg/L patulin would shrink more than 70% when the LC flow rate was switched from 100 to 400 μL/min. Our observations demonstrate that the APPI source is more suited for lower LC flow rates; therefore, the LC flow rate was set at 100 μL/min.

Calibration Range and LOQs. Solvent and matrix-matched calibration curves were compared using calibration standards ranging from 12.5 to 2000 μg/L. Matrix-matched calibration curves were established in blank matrices of apple juice, apple cider, applesauce, and apple-based baby food. Although good linearity ($r^2 > 0.99$) is achieved in all matrices, the slopes of solvent and matrix-matched calibration curves vary to some extent (Figure 4). For example, when [^{13}C]-patulin is not used, the slope difference between the solvent and matrix for apple sauce is statistically different. Using [^{13}C]-patulin makes the slopes statistically identical between the solvent and matrix, suggesting that [^{13}C]-patulin enhances the quantitation. If a stable isotope uniformly labeled IS can be fortified into samples prior to sample preparation, quantitation with the IS would offset any variations caused by matrix effects, sample loss, or instrumental performance.[21,34,35]

Due to the 2 times dilution in the sample preparation procedures, an LOQ lower than 25 μg/L is desirable. This way we could quantitate samples containing patulin at 50 μg/L or higher concentrations. Following the EPA protocol, the LOQs in the solvent and in the four apple matrices were estimated in a statistical manner. The LOQs were from 8 μg/L (solvent) to 12 μg/L (apple juice). The LOQ for this method suggests it would be sensitive enough to monitor patulin.

Recovery Studies. Recovery studies were conducted in clear apple juice, unfiltered apple cider, applesauce, and apple-based baby food. Fortified samples were prepared using a few simple steps, fortification of [^{13}C]-patulin, dilution, centrifugation, and filtration. Individual recoveries at each fortification level ranged from 96% (50 μg/L, baby food) to 110% (50 μg/L, unfiltered apple cider) with a standard derivation (SD) of <6%. For the four tested matrices, the average recoveries were 101 ± 6% (50 μg/L), 103 ± 5% (250 μg/L), and 102 ± 5% (1000 μg/L) (av ± SD, n = 16).

Incurred Samples. Ten clear apple juice samples, 5 unfiltered apple cider samples, 10 applesauce samples, and 5 apple-based baby food samples were collected from local stores and analyzed using the LC-APPI-MS/MS method. In two of the apple juices samples, patulin was detected at 15 ± 1 and 18 ± 1 μg/L (n = 3), and in one of the applesauce samples, patulin was detected at <10 μg/L. The occurrence of patulin in fruit juices is unavoidable, but in the three incurred samples, detected concentrations were below the FDA action level. These samples were collected for method development and testing purposes but not for official surveys for risk assessment. The results of this study should not be interpreted as a representation of the local apple juice market.

Method Uncertainty. Uncertainty is a summarized statistic on the performance of an analytical method within a defined time period. Method uncertainty can be estimated using method detection limit, accuracy, and standard derivation of recovery of analyte in spiked samples because these factors reflect the performance of instrument and sample preparation.[36] Therefore, the performance of our method was evaluated using eight batches of apple juice samples analyzed within a 4 week time period. In each batch, 12 blank apple juice samples were fortified with patulin at 50, 250, or 1000 μg/L, with 4 replicates at each fortification concentration. The resulting recoveries of the 96 samples are plotted in Figure 5. The expanded uncertainties (k = 2) with 50, 250, and 1000 μg/L are 26, 11, and 9%, respectively (Supporting Information).

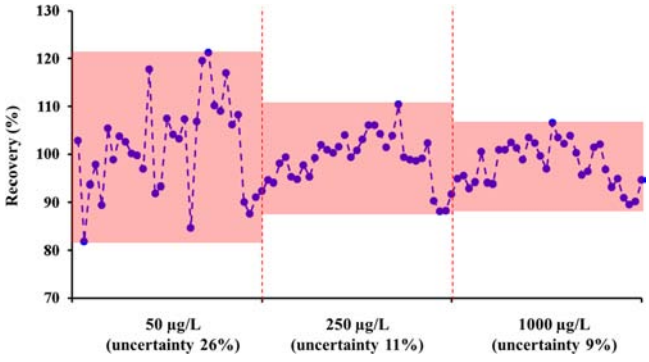

Figure 5. Method uncertainty (96 quality assurance recovery samples analyzed within 4 weeks).

Data quality in this study was ensured by the use of isotope dilution MS quantitation with satisfactory reproducibility in the four apple-based matrices tested. The sensitivity of the LC-APPI-MS/MS method is superior or comparable to those of existing methods but does not require time-consuming sample preparation or matrix-matched calibration standards. This

method would enhance the operation efficiency of routine surveillance activities and improve turnaround time.

ABSTRACT: This study aimed at elucidating the influence of food matrix on the release of antioxidant activity from five plant foods (apple, spinach, walnut, red bean, and whole wheat). To this purpose a protocol based on sequential enzymatic digestion was adopted. The total antioxidant capacity (TAC) of both solubilized and insoluble materials was measured at each step. Results showed that the overall TAC obtained by enzyme treatments was usually higher than that obtained by chemical extraction-based methods. In apple most of the TAC was released upon water washing and after pepsin treatment, whereas in spinach, beans, and whole wheat the TAC released by treatments with bacterial enzymes was prominent. Walnut had the highest TAC value, which was mainly released after pancreatin treatment. Therefore, the enzyme treatment is fundamental to estimate the overall potential TAC of foods having a high amount of polyphenols bound to dietary fiber or entrapped in the food matrix.

KEYWORDS: *in vitro digestion, foods, antioxidant capacity, phytochemicals, bioaccessibility*

INTRODUCTION

Epidemiological studies have associated the consumption of fruits, vegetables, whole grains, and legumes to a reduced risk of chronic diseases such cardiovascular diseases, diabetes, and some type of cancers, especially colorectal cancer.[1−4]

The amount and the type of dietary fiber and phytochemicals were recognized as major determinants responsible for the health benefits of these foods. Many phytochemicals are chemically reactive compounds that can counteract the action of reactive oxygen species, thus preventing the oxidation of biological substrates such as lipids, DNA, and proteins. During the past 20 years researchers' attention was focused on phytochemicals antioxidant properties and vast knowledge was built over time on specific food molecules, body metabolites, and cellular mechanisms acting in biological systems following their ingestion.[5,6]

It was well established that even for phytochemicals showing a high antioxidant capacity in vitro this property alone cannot explain the systemic health benefits. The extended biotransformation of many dietary phytochemicals once ingested and their low bioavailability led to tissue concentrations that are much below those showing antioxidant ability in vitro. Mounting evidence indicated that other biological properties including modulation of inflammation, detoxification, and immune response can play a major role in body defense at a systemic level.[7−10]

On the other hand, inside the gastrointestinal (GI) tract (stomach, small intestine, and lower gut) the antioxidant activity of dietary phytochemicals may have a central role: their concentration is mainly dependent on the amount in the ingested food, and their chemical form is usually the same present in the food. Phytochemicals can be found in food in either free or bound form. In the latter case they can be covalently linked to polysaccharides (as occurs to phenolic acids in cereal/nut/legume dietary fiber) or physically aggregated with chloroplast proteins (as occurs to carotenoids in tomatoes or spinach).[11−15] In nuts, fruits, and vegetables, phytochemicals are present mainly in free form that can be extracted in water or hydroalcoholic solutions. Contrarily, in whole cereals and legumes, bound antioxidants are the most dominant form that can be extracted only after chemical hydrolysis. Apples' main antioxidant molecules are soluble polyphenols such as chlorogenic acid, catechin, epicatechin, and phloridzin.[16] Spinach composition is similar to that of apple with many free phenolic compounds; however, they have a more consistent fiber structure that could limit the phytochemicals' extractability.[17] Walnut antioxidant capacity was principally attributed to ellagic and gallic acids that are present as polymers and bound to sugars, forming hydrolyzable tannins; their solubility depends on their degree of polymerization.[18] Polyphenol compounds are the major phytochemicals in red beans,[19,20] and many of them are bound to polysaccharides and proteins of cell wall with ester and ether links.[21,22] Whole wheat antioxidant capacity is due to phenolic acids, principally to ferulic acid and flavonoids: 90% of them are covalently bound to cell wall polysaccharides that are insoluble in organic solvents.[23,24]

After ingestion, the digestion processes modified foods' physical structure regulating the bioaccessibility (i.e., the possibility to be released in the lumen and eventually absorbed) as well as the antioxidant capacity (i.e., availability to react with oxidant species) of bound phytochemicals in the GI environment. We have previously demonstrated that an in vitro

sequential enzyme digestion of the water-insoluble fraction of cocoa resulted in the release of antioxidant capacity (due to material solubilized by digestion) and in a contemporary increase of the antioxidant capacity of the remaining insoluble material.[25] Moreover, it has been recently reported that the antioxidant capacity of the insoluble wheat bran can be restored by treatment with an antioxidant-rich soluble beverage.[26]

In vitro digestion protocols have been widely used to study the digestibility, bioaccessibility, and structural changes of food macronutrients, particularly proteins and starch.[27]

Recently, also the effects of digestive process on the food antioxidant activity and on some phytochemicals were studied. Saura-Calixto et al.[28] studied the bioaccessibility of polyphenols from different foods after enzymatic hydrolysis and after colonic fermentation: results indicated that about 48% of polyphenols are bioaccessible in the small intestine, whereas 42% become bioaccessible in the large intestine. More recently, Pastoriza et al.[29] developed the global antioxidant response (GAR) measuring the total antioxidant capacity (TAC) of the soluble and insoluble fraction throughout an in vitro digestion. They found that after digestion TAC was higher than that obtained with the usual chemical extraction and the QUENCHER method. Finally, Gong et al.[30] studied the TAC of cereals after in vitro digestion. Also, these authors confirmed that TAC measured after enzymatic digestion is much higher than that observed on undigested foods.

This study aimed at (i) elucidating the influence of food matrix and phytochemical disposition on the potential food antioxidant activity, (ii) providing a complete picture of the contribution of different plant foods to keep a redox balance inside the GI environment, and (iii) giving useful data to design foods providing a controlled release of phytochemicals. To this purpose five plant foods (apple, spinach, walnut, red bean, and whole wheat) having different physical structures, as well as different macronutrient and phytochemical compositions and forms, were selected; a sequential multistep enzyme treatment-based protocol was developed; and the release of antioxidant activity as well as the antioxidant capacity of insoluble food material was measured at each step.[11]

MATERIALS AND METHODS

Chemicals and Reagents. 6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 2,2-diphenyl-1-picrylhydrazyl (95%), sodium bicarbonate, and sodium hydroxide were purchased from Sigma-Aldrich (Milan, Italy). Cellulose (powder from spruce) was purchased from Fluka (Buchs, Switzerland).

All chemicals and solvents used were of HPLC grade; ethanol was purchased from Carlo Erba (Milan, Italy), whereas the other solvents were from Merck-Millipore (Darmstadt, Germany).

The enzymes pepsin (≥250 U/mg solid) from porcine gastric mucosa, pancreatin (4 × USP) from porcine pancreas, protease from *Streptomyces griseus*, called also Pronase E (≥3.5 U/mg solid), and Viscozyme L were purchased from Sigma-Aldrich (Milan, Italy).

Samples. The tested plant foods were apple (var. *annurca*) without skin, frozen spinach after microwave cooking, walnuts, canned red beans, and whole wheat breakfast cereals. As whole grain, Shredded Wheat (General Mills, Minneapolis, MN, USA) was used, whereas the other foods were purchased at a local market and immediately freeze-dried. The macronutrient composition of foods expressed as percentage of each nutrient class by total weight is shown in Table 1. After freeze-drying, all samples were ground by a mill (Grindomix-Retsch GM200 type), and the digestion protocols were run three times on each sample. The TAC of each sample was also measured in triplicate.

Table 1. Macronutrient Composition of the Studied Foods Expressed in Percentage by Dry Weight

	protein	fat	carbohydrate	dietary fiber	insoluble vs total DF (%)
apple	2	1	80	17	65
spinach	37	0	39	24	77
bean	23	2	56	19	77
whole wheat	12	2	73	13	84
walnut	15	73	5	7	87

Chemical Extractions. *Hydroalcoholic Extraction.* One gram of dry food was extracted with 10 mL of methanol/water (70:30 v/v) for 30 min in an ultrasonic bath. The solution was centrifuged at 2800*g* for 5 min at 4 °C, and the antioxidant activity of the supernatant was measured with the DPPH assay as described below.[28] The TAC of hydroalcoholic extract (HAE_TAC) was expressed as millimoles of Trolox equivalent (TE) per kilogram of dry matter.

Alkaline Hydrolysis. Alkaline hydrolysis was performed on the pellets obtained after hydroalcoholic extraction that were added with 20 mL of 4 M NaOH for 2 h under agitation.[12] At the end of the reaction, the pH was brought between 2 and 3 with 6 M HCl, and the sample was centrifuged at 2800*g* for 15 min at 4 °C. The supernatant was extracted three times with 50 mL of ethyl acetate, and the combined extracts were evaporated to dryness and subsequently dissolved in methanol/water (70:30 v/v). Ten milliliters of methanol/water (70:30 v/v) was added to the pellet, and the mixture was kept in agitation for 30 min; mixture centrifugation and supernatant collections followed. The antioxidant activity of individual extracts was measured by the DPPH assay as above-described and finally summed to obtain the total antioxidant activity of the chemical extraction (TPE_TAC).

In Vitro Digestion Procedure. Each food was digested using a protocol including water washing and a sequential multistep enzymatic treatment.[29] Samples were incubated with the enzymes in agitation to 120 oscillations/min at 37 °C using a shaking thermostatic bath. The digestion scheme is summarized in Figure 1: at the end of each digestion step the soluble and insoluble materials were separated by centrifugation (2800*g* for 3 min, 4 °C). The soluble part was used for the TAC measurement, whereas the insoluble part was further digested in the following step. The final insoluble material obtained

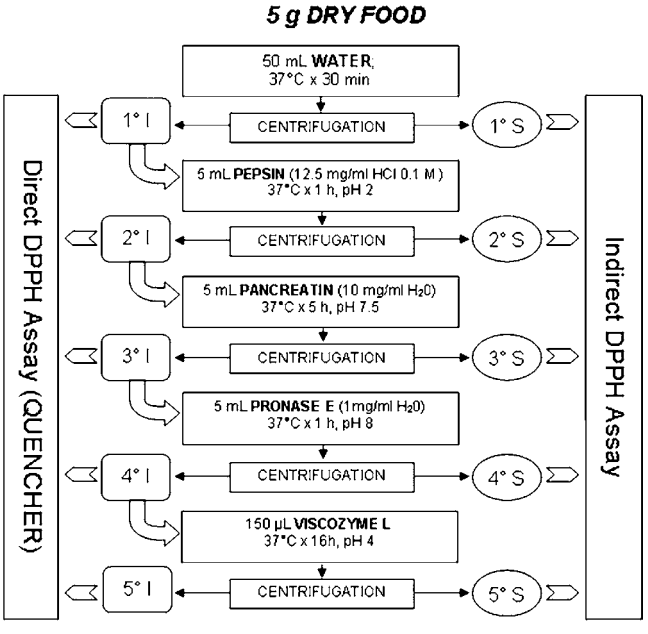

Figure 1. Protocol of the in vitro multistep enzymatic digestion.

after the four enzymatic digestions (sample 5°I) and the soluble fractions were used to calculate the overall TAC.

Five grams of milled dry sample of each food was subjected to in vitro digestion. The first step was done by suspending the material in 50 mL of water to extract all of the water-soluble component. After 30 min at 37 °C under stirring, the samples were centrifuged, and the pellets obtained by centrifugation (1°I) were resuspended in acidified water (6 M HCl up to pH 2); 5 mL of pepsin solution (12.5 mg/mL 0.1 M HCl) was added, and the mixture was incubated for 1 h (gastric phase). The subsequent centrifugation of the mixture allowed the recovery of the insoluble material (2°I); after increase of the pH to 7.5 with $NaHCO_3$, 5 mL of a 10 mg/mL pancreatin solution was added, and the mixture was kept for 5 h in agitation (duodenal phase). Finally, the remaining insoluble materials were treated first (3°I) with 5 mL of 1 mg/mL Pronase E solution (pH 8, 1 h) and then (4°I) with 150 μL of Viscozyme L (16 h, pH 4), obtaining the final pellet (5°I). Pronase E could simulate bacterial protease activity and is particularly suitable to hydrolyze insoluble material, whereas Viscozyme L, containing a mix of enzymes hydrolyzing complex polysaccharides, was used to obtain a final disruption of the plant food matrix chemical structures.

At each step the antioxidant activities of both soluble and insoluble parts were measured. In particular after separation, both supernatants and the pellets were weighed; then an aliquot of the supernatant was used to calculate the dry weight of the supernatant, whereas the remaining part was stored at −40 °C to measure soluble antioxidant activity. A small aliquot (<5%) of the pellet was weighed, frozen, and lyophilized to measure the antioxidant activity of the insoluble fraction using the QUENCHER method,[11] whereas the rest was used for the successive enzymatic incubations.

The dry matter of each supernatant was subtracted from the dry weight of each pellet from the previous digestive step; therefore, the soluble and insoluble TAC values were calculated on the basis of the effective amount of each supernatant and pellet.

Measurement of Antioxidant Activity. *DPPH Assay on Soluble Material.* The DPPH assay was applied to measure TAC of digestion soluble fractions (supernatants) and hydroalcoholic and alkaline hydrolysis extracts. The DPPH scavenging capacity was evaluated by diluting DPPH in pure methanol by adjusting the absorbance of the DPPH radical solution to 0.9 ± 0.02 at 517 nm.[31] Two hundred microliters of sample was added to 1 mL of DPPH solution, and after 10 min, the absorbance was measured. Percentage of inhibition was calculated against a control and compared to a Trolox standard curve, 5−125 μM. TAC was expressed as millimoles of TE per kilogram of dry matter. Each extraction and alkaline hydrolysis was performed in duplicate.

It is relevant to mention that in a first set of experiments we also employed ABTS instead of DPPH as probe to measure the released TAC. However, we observed that using ABTS both the switches of pH and the enzyme solutions interfered with the measure of TAC, whereas when using DPPH this problem was overcome.

Direct DPPH Assay (QUENCHER). TAC values of freeze-dried whole foods (W_TAC) and insoluble fractions obtained at each step of digestion procedure were evaluated using the QUENCHER procedure adopting DPPH as colorimetric probe.[11] This method was based on the direct contact of the dry sample with the DPPH solution obtained after dilution of stock solution with methanol/water (50:50 v/v) until an absorbance of 0.9 ± 0.02 at 517 nm was obtained. The sample was incubated with DPPH radical in agitation for 2 h; subsequently, the mixture was centrifuged at 2800*g* for 3 min at 4 °C, and the supernatant absorbance was measured at a wavelength of 517 nm.

Calculation and Statistical Analysis. The overall soluble TAC was called potentially bioaccessible TAC (PB_TAC) and was calculated as the sum of TAC of soluble fractions at each digestion step (PB_TAC = Σ (1° → 5°) S_TAC).

The overall potential TAC (OP_TAC) was calculated as the sum of the potentially bioaccessible TAC and that of the last insoluble fraction (OP_TAC= PB_TAC + 5°I_TAC)

The food TAC due to free phytochemicals was measured on material derived from water washing of food (Free_TAC = 1°S) upon digestion protocol or on hydroalcoholic extracts upon chemical protocol (HAE_TAC).

The food TAC due to bound phytochemicals was calculated as the sum of TAC of soluble fractions after pepsin, pancreatin, Pronase E, and Viscozyme L treatment upon digestion protocol (Bound_TAC = Σ(2° → 5°)S_TAC) or was that obtained on alkaline hydrolysis extract upon chemical protocol (AHE_TAC).

Overall TAC (TPE_TAC) measured by the chemical method was calculated as the sum of HAE_TAC and AHE_TAC.

Data were reported as the mean ± standard error of three analyses for each type of extraction and parameter. The significance of differences was determined by ANOVA, Duncans' post hoc test, and bivariate correlation using SPSS 13.0. Significance level was set at p = 0.05.

RESULTS

Figure 2 shows TAC values of the five foods measured directly on the whole foods by using the QUENCHER method

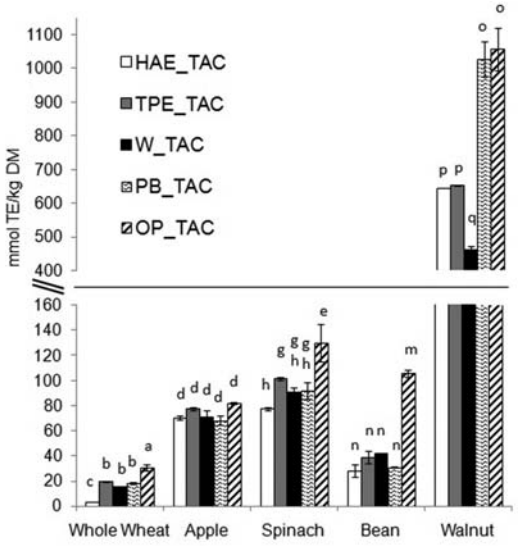

Figure 2. Comparison of TAC (mmol TE/kg dry matter ± SEM) obtained with hydroalcoholic extraction (HAE), alkaline hydrolysis after hydroalcoholic extraction (TPE), direct measure without extraction, QUENCHER (W), and enzymatic extraction. TAC of the latter is calculated both as only the sum of potentially bioaccessible antioxidant activity in the gastrointestinal tract (B) and as the sum of bioaccessible antioxidant activity with the last insoluble fraction (OP).

(W_TAC), on chemical extracts (only hydroalcoholic and total hydroalcoholic plus alkaline hydrolysis, HAE_TAC and TPE_TAC, respectively), on fractions solubilized upon in vitro GI digestion (potentially bioaccessible TAC; PB_TAC), and on all fractions solubilized plus the insoluble fraction collected after the last in vitro digestion step (overall potential TAC; OP_TAC). The values of TAC, expressed as millimoles of Trolox equivalent per kilogram of dry matter, ranged from 3.2 to 30.5, from 68.2 to 82.1, from 77.7 to 130.1, from 28.2 to 105.8, and from 462.0 to 1056.9 for whole wheat, apple, spinach, bean, and walnut, respectively.

Looking at the values obtained by chemical extraction methods (HAE_TAC and TPE_TAC), data confirmed that most of TPE_TAC in whole wheat was due to bound phytochemicals. With regard to the other foods, only in spinach did bound phytochemicals contribute to differentiate TPE_-TAC from HAE_TAC, there being no difference between these two measures in beans, apples, and walnuts. On the other hand,

[a]Different letters within the same column indicate statistically significant differences ($P < 0.05$).

direct measure of TAC on the whole food by QUENCHER procedure gave results substantially in line with those achieved with multiple chemical extraction procedures, W_TAC being well in line or slightly higher in all cases, but in walnuts it was significantly lower.

Interestingly, looking at the TAC values of fractions obtained upon in vitro GI digestion, data showed that the last insoluble material collected at the end of the in vitro GI digestion (sample 5°I) did not contribute significantly to the OP_TAC in the case of apple and walnut (i.e., most of the antioxidant compounds were released during the first three digestion steps). On the contrary, the last insoluble fractions of wheat, spinach, and bean significantly contributed to the OP_TAC.

The results of soluble and insoluble TAC obtained for each sample after each digestion step by the various enzymes are summarized in Table 2. The values (mmol TE/kg) of soluble TAC at each digestion step ranged from 2.5 to 27.7, from 3.0 to 38.1, from 0.8 to 11.3, from 1.6 to 6.8, and from 40.7 to 443.5 for apple, spinach, bean, whole wheat, and walnut, respectively. The insoluble fractions have TACs (mM/kg) ranging from 9.1 to 19.8, from 38.1 to 107.1, from 39.5 to 74.9, from 3.8 to 12.5, and from 16.7 to 431.0 for apple, spinach, bean, whole wheat, and walnut, respectively.

It is worth noting that also the percentages of soluble and insoluble antioxidant activity of each step were completely different among the various foods; they varied for the soluble fraction from 1% after bean digestion by Viscozyme L to 86% after walnut treatment by Pronase E.

In apple the treatment with water and the following one with pepsin extracted most of the antioxidants having a water-soluble nature, leaving at each step about 30% of the TAC in the insoluble material. The following steps resulted in small but significant TAC release (between 17 and 30%). Interestingly, despite the release of soluble TAC, the TAC of insoluble moiety was not reduced and it remained more or less constant (ranging between 10 and 20 TE/kg).

Unlike the apple, in spinach a large percentage (74−92%) of antioxidant compounds remained in the insoluble material after treatment with water. In particular, the first pellet has the highest value of antioxidant activity. As expected, soluble antioxidant activity as well as insoluble antioxidant activity decreased progressively during the digestion.

Also for the beans, the insoluble TAC was very high (71−99%) at each digestion step, and it even increased (from 40 to 75 mmol TE/kg) upon digestion; the highest value was found after Viscozyme L treatment, thus suggesting that in beans many antioxidant compounds are buried in the tight polysaccharide/protein network typical of legumes and are released during this kind of enzymatic digestion process.

Whole wheat had the lowest absolute TAC values among the tested foods. However, similarly to the beans, it showed the highest value of insoluble TAC after the last enzymatic treatment. Interestingly, a significant percentage of antioxidant activity was also released by the action of pancreatin.

Walnut antioxidant activity values were by far the highest among the investigated foods. In the first step, about 50% of the

antioxidant activity was solubilized and the other 50% remained bound to the matrix; this soluble fraction was about half of the soluble TAC, whereas another 30% was released after pancreatin action.

DISCUSSION

The systemic effects of dietary phytochemicals could occur through powerful anti-inflammatory mechanisms that might be also triggered by the low concentration of their metabolites found in the blood and other tissues.[5,32,33] However, the control of oxidative stress operated by dietary antioxidants inside the GI environment, also resulting in modulation of GI permeability, is emerging as a physiologically relevant function.[34] Within this framework, the ability of a food to quench free radicals inside the GI tract may be fundamental to predict its health benefits in situ.

The values of TAC used to construct food antioxidant activity databases were mainly obtained on hydroalcoholic extracts of the foods,[12,35] thus taking into account only the activity of soluble phytochemicals and not considering those present in the insoluble polymerized form, covalently bound to food structures or physically entrapped in the food matrix.[35] Already in 1998, Saura Calixto and co-workers first pointed out the concept of antioxidant dietary fiber, highlighting the importance of this food component.[36] More recently, the possible physiological role of antioxidant bound to cereal dietary fiber and in general to the insoluble food material was proposed.[37,38]

Use of Enzymes Is Fundamental To Properly Assess Food TAC. The first finding of the present study was that the TAC measured taking into account the bound compounds which are released during the in vitro enzymatic digestion procedure is usually much higher ($p < 0.05$) than that calculated by the standard extraction methodology or even by the direct measure (QUENCHER) on undigested foods. In all foods but apples the value of OP_TAC was significantly higher than the TPE_TAC. The difference was about 20% in spinach, 40% in whole wheat and walnut and 60% in bean. The difference due to the enzymatic digestion becomes enormous in whole wheat if the TAC of the hydroalcoholic extract (HAE) instead of the alkaline hydrolysis extract (TPE) was considered, confirming the previous finding by Delgado et al.[39] It should be taken into account that alkaline hydrolysis is very efficient in releasing phenolic compounds from wheat bran; however, it has no physiological meaning.[40]

This evidence fully confirmed the findings by Pastoriza and co-workers,[29] who simulated the digestion of 27 foods and calculated the so-called GAR by adding soluble and insoluble antioxidant activities at the end of the digestion process. These authors did not measure the TAC at each step (as reported in the present paper); however, they clearly demonstrated that the total TAC after enzymatic digestion is much greater than that obtained by the chemical extraction as well as by the direct QUENCHER procedure for all of the tested foods. It is worth noting that these authors performed oral gastric and small intestine simulated digestion, whereas in the present study also a step simulating the protease and polysaccharidase activity of intestinal bacteria has been performed.

TAC Release during the Multistep Enzymatic Digestion Is Different for the Five Foods. The relevance of the detailed information that was obtained considering the TAC released for each food at the various digestion steps can be appreciated from the data presentation reported in Figure 3. In this figure the TAC values were split into free TAC, that obtained with water extraction, and bound TAC, which is further subdivided in pepsin, pancreatin, and Pronase E plus Viscozyme L.

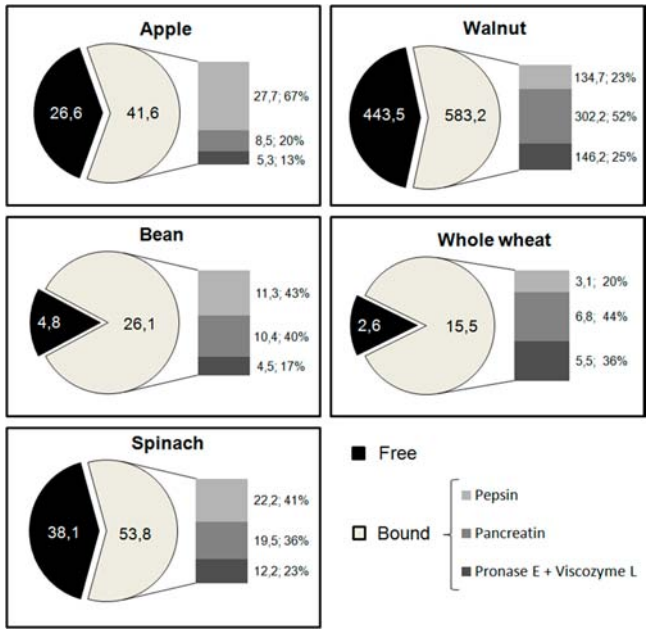

Figure 3. Release of TAC (expressed in mmol TE/kg DM) during the multistep enzymatic digestion illustrated in Figure 1. "Free" TAC is the value measured on the fraction after water extraction, whereas "bound" TAC is that after pepsin, pancreatin, pronase E, and Viscozyme L actions.

Among the tested foods whole wheat had by far the largest proportion of insoluble TAC when the chemical procedure was applied. This is related to the presence of phenolic acids covalently bound to the insoluble polysaccharides.[23] Digestion data were not different regarding the absolute TAC value; however, they demonstrated that the insoluble material is not significantly solubilized with the pepsin, whereas the action of pancreatin is able to release part of the TAC. This is in agreement with a previous hypothesis highlighting the role of cereal dietary fiber in transporting the antioxidants through the gut, allowing a slow release during digestion and intestinal microbiota fermentation.[41]

Looking at the TAC data from the chemical extractions, apple and walnut behaved opposite to whole grain: in these foods the large majority of TAC is extracted with hydroalcoholic solution, and a limited fraction can be released after alkaline hydrolysis. Interestingly, looking at the enzymatic procedure for apples, the OP_TAC and TPE_TAC values are similar and the antioxidant activity is mostly released after gastric digestion. On the other hand, when the enzymatic procedure was applied on walnut, the contribution to the TAC of the insoluble part is much larger than expected and a very significant part of TAC is released only after pancreatin and Pronase E actions. This is well in line with the claimed potential effects raised by the metabolites produced by the microbiota action on nut polyphenols.[42,43]

The pattern of TAC solubilized with the enzyme treatment from bean and spinach showed many similarities, although spinach has absolute values about 3 times higher than bean. In both foods, about 30% of the TAC measured by chemical extraction was obtained using alkaline hydrolysis. Also, the

patterns of the release during the various digestive steps were quite similar. On the other hand, looking at the PB_TAC, the amount of TAC present in the insoluble material is much higher in bean (showing a picture similar to that of whole grain) than in spinach (which is similar to apple). This is probably related to the high content of dietary fiber in beans that is presumably bound to many antioxidant compounds.[44] This is confirmed by the experimental finding that a very significant amount of TAC is released from beans after Viscozyme L addition.

Release of Antioxidant Activity Is Dependent on the Nature of the Food Matrix. The overall findings of this paper were consistent with the chemical and physical nature of the food investigated and with the amount of insoluble total dietary fiber in walnut (~87%) > whole wheat (~84%) > beans = spinach (about 77%) > apple (about 65%).[45,46] In this study the contribution of phytochemicals bound to the fiber was considered in the calculation of the OP_TAC, using a multienzyme complex (Viscozyme L) containing a wide range of carbohydrases (including arabanase, cellulase, β-glucanase, hemicellulase, and xylanase). Moreover also Pronase E, a preparation containing a mixture of bacterial protease particularly suitable for insoluble material, was adopted.

This difference in the experimental approach with respect to the works previously performed was of utmost importance. In fact, data clearly showed that in foods having a high amount of insoluble dietary fiber and/or phytochemicals bound to dietary fiber or entrapped in the food structures (as in whole wheat, spinach, and bean), the action of bacterial enzymes might dramatically increase the antioxidant potential of the food residues in the lower GI tract. We have previously highlighted the physiological importance of this phenomenon for cereal dietary fiber and whole grains.[41] Here this relevance was extended to all foods having a strong fiber structure, such as spinach,[47] as well as to other polyphenol-rich foods having a significant amount of insoluble component made up of polysaccharides and proteins bound with phenolic acids, flavonols, anthocyanins, and proanthocyanidins.[19−22] It is worth remembering that this in vitro approach does not take into account the bacterial biotransformation, being focused only on the relationship between disruption of food structure and release of TAC from chemical and enzyme points of view.

Have These Findings Any Possible Health Implications? Epidemiological studies indicated that dietary fiber content in plant foods may majorly contribute to the negative associations between their intake and colorectal cancer risk.[48−50] Looking at the results of this paper with a wider physiological prospective, they suggested that the TAC of the insoluble material produced at each step of the digestion, more than the simple amount of dietary fiber, might be considered for a more reliable evaluation of the potential benefits of some foods inside the GI tract. It has been recently reported that individuals with a low bacterial richness harbored a more pronounced inflammation-associated microbiota when compared with high bacterial richness individuals.[51] The insoluble material present in the colon after the whole digestion, through a chemical action in the gut environment, may play a major role in reducing local oxidative stress and in modifying microbiota composition, consequently ameliorating gut permeability and boosting anti-inflammatory mechanisms and immunity.

The data demonstrated that for those foods having a high amount of polyphenols bound to dietary fiber or entrapped in the food matrix, the action of bacterial enzyme is fundamental to predict the overall potential TAC. Moreover, they highlighted the amount of TAC bound to the insoluble material for five main representative plant foods. In this way a measure of the overall antioxidant potential of a food against oxidative stress was provided. These findings clarified the physiological relevance of the antioxidant activity of the insoluble components that can be also restored by the presence of soluble antioxidant as recently proposed by Gökmen and coworkers.[26]

This finding pointed out the need to reconsider the correlations performed between TAC dietary intake and health outcomes. In fact, for many foods the TAC reported in the available food antioxidant database were determined with conventional extraction methods, and for many foods they gave poor indications.[35,52] In the future, it would be advisable to use the TAC measured after enzymatic digestion procedure, including microbiota-like bacterial enzymes, to obtain a more reliable picture, particularly when the health effects of the foods within the gastrointestinal tract are considered.

Immune Regulation and Anti-inflammatory Effects of Isogarcinol Extracted from *Garcinia mangostana* L. against Collagen-Induced Arthritis

Yanxia Fu,[†,∥] Hailing Zhou,[†,∥] Mengqi Wang,[†] Juren Cen,[†,‡] and Qun Wei*[,†]

[†]Department of Biochemistry and Molecular Biology, Beijing Normal University, Gene Engineering and Biotechnology Beijing Key Laboratory, Beijing 100875, People's Republic of China

[‡]Key Laboratory of Protection and Development Utilization of Tropical Crop Germplasm Resources, Ministry of Education, College of Landscape and Horticulture, Hainan University, Haikou 570228, People's Republic of China

ABSTRACT: Isogarcinol is a natural compound that we extracted from *Garcinia mangostana* L., and we were the first to report that it is a new immunosuppressant. In the present study, we investigated the immune regulation and anti-inflammatory effects of isogarcinol on collagen-induced arthritis (CIA) and explored its potential mechanism in the treatment of rheumatoid arthritis. The oral administration of isogarcinol significantly reduced clinical scores, alleviated cartilage and bone erosion, and reduced the levels of serum inflammatory cytokines in CIA mice. Isogarcinol inhibited xylene-induced mouse ear edema in vivo. In vitro, isogarcinol decreased iNOS and COX-2 mRNA expression and NO content by inhibiting NF-κB expression. Furthermore, isogarcinol decreased the activity of NFAT and inhibited IL-2 expression. The mechanism of action of isogarcinol is associated with down-regulation of both autoimmune and inflammatory reactions.

KEYWORDS: *Garcinia mangostana Linn., isogarcinol, collagen-induced arthritis, inflammation, immunity*

INTRODUCTION

It is well-known that the consumption of fruits can reduce the incidence of cancer, arthritis, inflammation, heart disease, and brain dysfunction.[1] Mangosteen (*Garcinia mangostana* L.) is a slow-growing tropical evergreen tree with leathery, glabrous leaves. The edible portion of the mangosteen fruit is milky white, whereas the pericarp of mangosteen is dark-purple to red-purple. The pericarp, which accounts for approximately two-thirds of the entire fruit weight, is agricultural waste. People in Southeast Asia have used this waste pericarp in folk medicine for the treatment of abdominal pain, diarrhea, dysentery, infected wounds, suppuration, and chronic ulcers;[2] furthermore, the consumption of mangosteen products has increased as a dietary supplement in the United States because of their potent antioxidant properties.[3] Experimental studies have demonstrated that extracts of mangosteen have antitumor, antioxidant, and antibacterial activities,[4] and using mangosteen extracts for the prevention of chronic diseases is very popular.[2]

Rheumatoid arthritis (RA) is an autoimmune disease that is characterized by chronic inflammatory symptoms such as pain, swelling, and progressive destruction of joints and results in disability.[5] The prevalence of arthritis has increased over the past decade because of the world's aging population; approximately 1−2% of the world's population is thought to be affected by RA, and one in three patients is likely to become severely disabled within 20 years.[6] To date, the exact etiology of RA remains unknown, and a cure has not yet been developed.[7]

Because RA is characterized by overactive immune responses, most current treatment options involve the administration of immune suppressants alone or in conjunction with disease-modifying antirheumatic drugs (DMARDs) or destruction of autoreactive lymphocytes with antibodies.[8] Unfortunately, these drugs are not suitable for long-term treatment due to their side effects and toxicity.[9] DMARDs can retard joint destruction, but many patients cannot tolerate the side effects of these drugs.[5] Calcineurin (CN) inhibitors such as cyclosporin A (CsA) and tacrolimus (also called FK-506) have potent immunosuppressive and anti-inflammatory effects and have been shown to be beneficial in the treatment of inflammatory and autoimmune diseases such as RA.[10] However, the use of these drugs is associated with severe hepatotoxicity and nephrotoxicity.[11] Cytokine antagonists decrease inflammation and joint destruction, but they interfere with immune defense; in addition, they must be administered by injection, which increases the risk of infections.[12] The future treatment for RA should provide more effective relief with fewer side effects and lower cost. Due to the long-term use and side effects of antiarthritis drugs, dietary supplements are widely used to treat arthritis. According to the 2007 National Health Interview Survey (NHIS) in the United States, the use of natural products (17.7%) is an important part of alternative medicine. The frequency of adults who use alternative medicine to treat arthritis reached 8.7%, indicating that the treatment of arthritis with natural products is popular in the United States.[13]

Our group has focused on screening immunosuppressants from natural products with CN as the target enzyme and docking the binding domain between CN and CN inhibitors.[14,15] Isogarcinol (Figure1) is a natural compound that we screened from *Garcinia mangostana* L. with CN as the target enzyme. It was reported that isogarcinol is a new powerful, low-toxicity

immunosuppressant because it significantly inhibits the proliferation of spleen T-lymphocytes induced by concanavalin A (ConA) and the mixed lymphocyte reaction (MLR); the oral administration of isogarcinol in mice resulted in a dose-dependent decrease in delayed type hypersensitivity (DTH) and prolonged graft survival in allogeneic skin transplantation. More importantly, isogarcinol had lower toxicity on liver and kidney function than CsA in experimental animals.[16]

CN plays a crucial role in the autoimmune and inflammation responses and involves a variety of physiological and pathological processes.[17] The clinical interest in CN is mainly focused on T cells and other cells of the immune system and particularly involves CN and nuclear factor of activated T cells (NFAT) signaling, which is the principal target of widely prescribed immunosuppressive drugs, such as CsA and FK506.[13] It was reported that nuclear transcription factor kappa B (NF-κB) was also controlled by CN in immune cells.[18] Both isogarcinol and CsA are CN inhibitors, and because of the efficacy but high

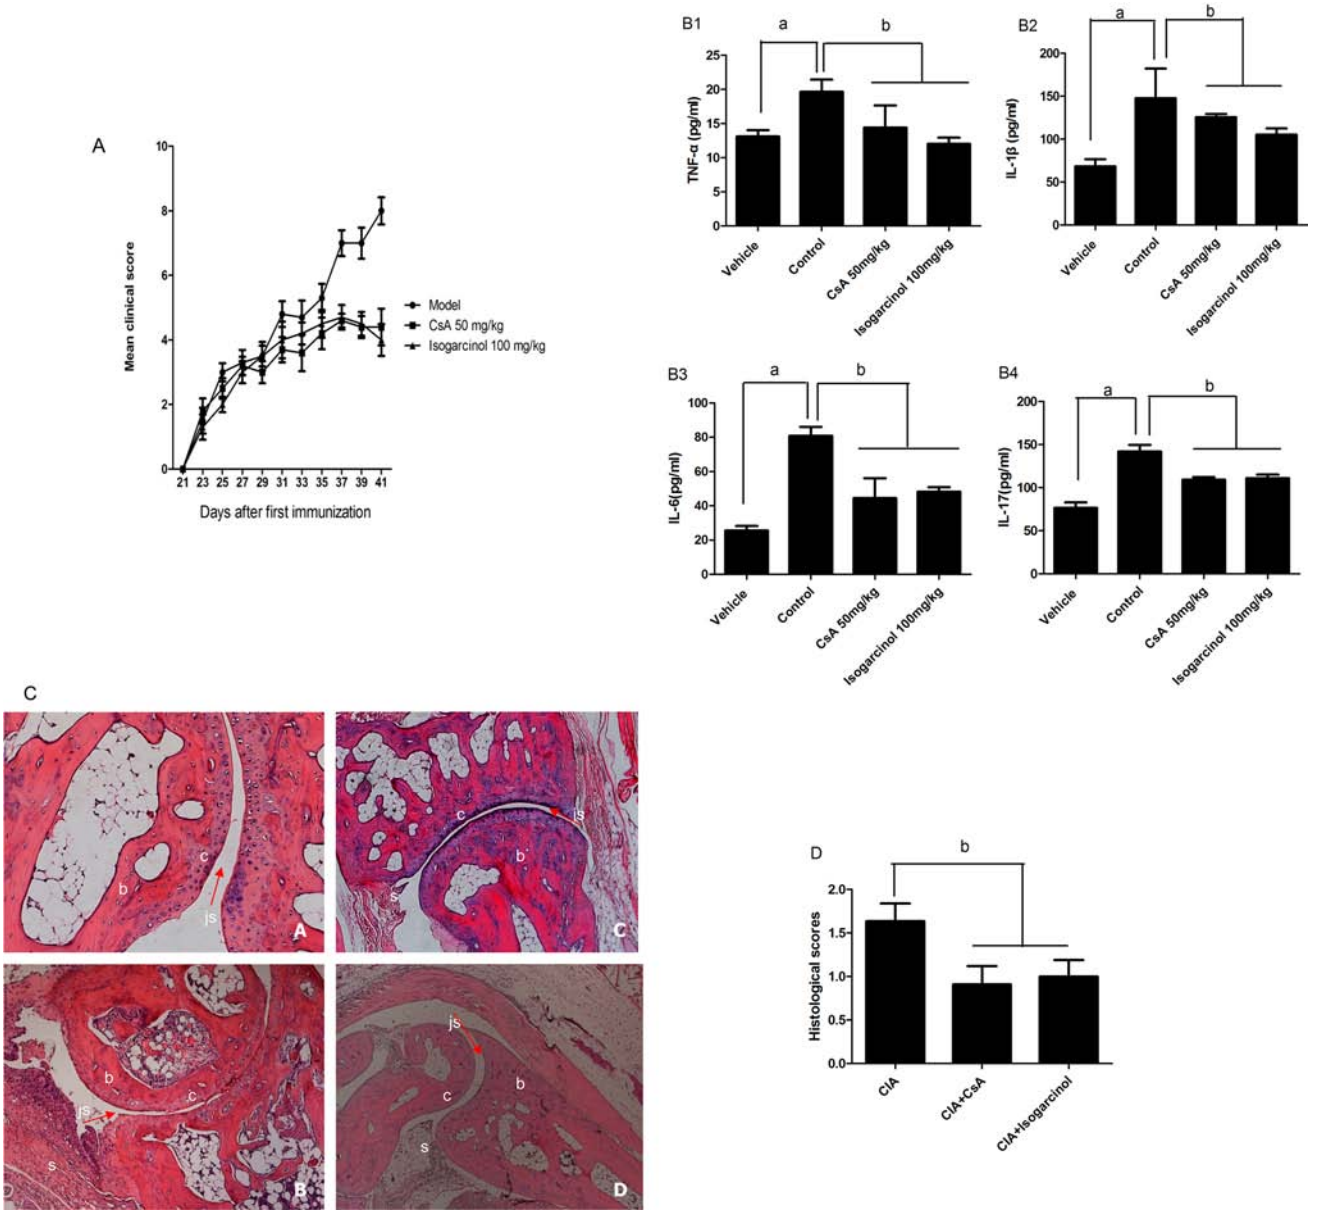

Figure 2. Isogarcinol attenuates collagen-induced arthritis: (A) mean of clinical scores; (B1) isogarcinol reduced the content of TNF-α in the serum of CIA; (B2) isogarcinol reduced the content of IL-1β in the serum; (B3) isogarcinol reduced the content of IL-6 in the serum; (B4) isogarcinol reduced the content of IL-17 in the serum; (C) representative histological changes of joint tissues stained with H&E (×100 original magnification). The upper case A represents vehicle mice; B, CIA mice; C and D, CIA mice treated with CsA or isogarcinol, respectively. The lower case b denotes the bone; c, the cartilage; s, the synovium; and js, the joint space. (D) Histological scores of isogarcinol are expressed as the mean ± SD (n = 7). Different letters above bars designate significant difference between groups, $P < 0.05$.

liver and kidney toxicity of CsA, we wanted to determine whether orally administered isogarcinol could be a novel and effective agent for the treatment of rheumatoid arthritis and to elucidate the potential underlying mechanisms.

MATERIALS AND METHODS

Materials. Bovine type II collagen and complete Freund's adjuvant that induced collagen-induced arthritis (CIA) were purchased from Chondrex (USA). RAW 264.7 murine macrophages were obtained from the American Type Culture Collection. Specific pathogen-free male DBA/1J mice were acquired from the National Resource Center for Mutant Mice Model Animal Research Center of Nanjing University. Specific pathogen-free male ICR mice (6−8 weeks) were purchased from the Vital River Laboratories (Beijing, China). All mice were set aside under standard conditions with a 12 h light/dark cycle after initial acclimatization for approximately 1 week with ad libitum access to standard mouse chow and water. All animal experimental procedures were approved by the Animal Ethics Committee of Beijing Normal University and were carried out in strict accordance with institutional guidelines. All efforts were made to minimize the number of animals used and their suffering.

Induction of CIA. CIA was induced as previously described.[19] Briefly, DBA/1J mice were intradermally injected at the base of the tail with 100 μg of bovine type II collagen emulsified with an equal volume of Freund's complete adjuvant. The day of the first immunization was defined as day 0. Three weeks after the primary immunization, the mice were boosted with 100 μg of CII in Freund's incomplete adjuvant via the same route. After the secondary immunization, the mice were randomly divided into four groups (seven per group): (1) normal nonimmunized group, (2) CIA group, (3) CIA plus CsA group (50 mg per kg), and (4) CIA plus isogarcinol group (100 mg per kg). Mice in the normal group received an oral gavage of 0.2 mL of peanut oil containing 1% DMSO daily from day 21 to 42; mice in the isogarcinol or CsA group received an oral gavage of the same volume containing 100 mg/kg isogarcinol or 50 mg/kg CsA daily from day 21 to 42. On day 42, after anesthetization with pentobarbital, blood samples were collected from all mice via cardiac punctures. The levels of IL-1β, TNF-α, IL-6, and IL-17 in serum were measured using ELISA kits according to the manufacturer's instructions.

Clinical Assessment and Histopathological Analysis of Arthritis. The clinical severity of arthritis in the paws was evaluated in a double-blind manner using a semiquantitative scoring system as described previously:[20] 0 = no evidence of erythema and swelling, 1 = swelling and erythema of the digit, 2 = mild erythema of the limb, 3 = gross erythema and swelling of the digit, and 4 = ankylosis of the limb or gross swelling deformity and the inability to use the limb. On the final day of the experiments, the hind paws were harvested, fixed, decalcified, and then embedded in paraffin. The tissues were longitudinally cut into 5 μm serial sections and stained with hematoxylin and eosin (H&E). Histopathological changes in the joints were examined under light microscopy and scored in a range from 0 to 3, where 0 = normal, 1 = mild synovitis or slight cartilage erosion, 2 = moderate synovitis and cartilage erosion, and 3 = erosion of the cartilage or bone destruction.

Xylene-Induced Mouse Ear Edema. The ear edema model was employed to evaluate anti-inflammatory activity. For this model, 30 min after drug administration, inflammation was induced by the topical application of xylene (30 μL) on the inner and outer surfaces of the right ear of each ICR mouse. The left ear was kept as the control. At 30 min after xylene application, the animals were killed by cervical dislocation. Disck sections of 8 mm in diameter were punched from each ear and then weighed. The inflammation was assessed on the basis of the difference in weight between the punches from the right and left ears.[21]

Real-Time Quantitative PCR for iNOS, COX-2, and IL-2. RNA was extracted using TRIZOL (BioTeke, China) as described by the manufacturer. Real-time quantitative PCR was performed to detect the mRNA expression of iNOS, COX-2, and IL-2 in RAW 264.7 cells. The primer sequences for the reference genes were as follows: for β-actin, AGAGGGAAATCGTGCGTGAC (forward) and CAATAGTGATGACCTGGCCGT (reverse); for IL-2, CCTGAGCAGGATGGAGAATTACA (forward) and TCCAGAACATGCCGCAGAG (reverse); for iNOS, GGCAGCCTGTGAGACCTTTG (forward) and GCATTGGAAGTGAAGCGTTTC (reverse); and for COX-2, TGAGTACCGCAAACGCTTCTC (forward) and TGGACGAGGTTTTTCCACCAG (reverse). Real-time quantitative PCR was performed on an Applied Biosystems 7500. The relative quantification of target mRNA was calculated using the comparative $2^{-\Delta\Delta CT}$ method after normalization with the internal control. Reactions were performed in triplicate. The results are shown as the mean ± SD.

Nitrite Determinations. Measurement of nitrite accumulation into the culture medium was used to determine NO production. RAW 264.7 cells were induced with LPS (10 μg/mL) or a combination of LPS (10 μg/mL) and isogarcinol or CsA in 6-well plates for 24 h, the culture medium was collected, and nitrite was measured using Griess reagent (Applygen, China) according to the manufacturer's instructions.

Western Blot Analysis for IκB-α. The secretion of IκB-α was induced by incubating Jurkat cells with 100 ng/mL phorbol 12-myristate 13-acetate (PMA) and 1 μM ionomycin (Ion). Cells were treated with PMA and Ion or a combination of CsA or different doses of isogarcinol and PMA and Ion. The cells were harvested by centrifugation after 24 h and washed twice with PBS. Then, the cells were lysed on ice for 20 min. The cell-free supernatant was collected for Western blot analysis. Protein quantitation was performed with a bicinchoninic acid (BCA) protein quantitation kit. The samples were separated using discontinuous SDS-PAGE and transferred to PVDF membranes, which were blotted with primary antibody and secondary antibodies, and specific bands were visualized using an electrochemiluminescene (ECL) kit.

Dual-Luciferase Reporter Gene Assay. NFAT transcription activity was investigated using two reporter gene assay systems. RAW 264.7 macrophage cells plated in 24-well plates were cotransfected with the p-firefly luciferase (FL)-NFAT plasmid and the p-renilla luciferase (RL)-SV40 endogenous control plasmid. Twenty-four hours after transfection, cells were incubated with PMA + Ion or a combination of different doses of isogarcinol and PMA + Ion for 24 h. NFAT activity was measured using a Dual-Luciferase Reporter Kit (Promega) according to the manufacturer's protocol.

Statistics. All data presented were obtained from three independent experiments and are presented as mean ± standard deviation (SD). One-way analysis of variation (ANOVA) followed by Bonferroni's Multiple Comparison Test was used to compare experimental groups with the control groups using GraphPad Prism 5.0 software. The mean values were compared using Student ' s t test. Values of $P \leq 0.05$ were considered to be significant.

RESULTS

Isogarcinol Inhibited Collagen-Induced Arthritis. The experimental results showed that isogarcinol treatment reduced

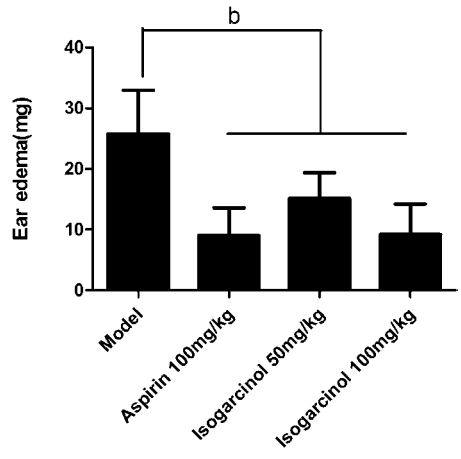

Figure 3. Isogarcinol inhibited xylene-induced mouse ear edema. All values are expressed as the mean ± SD (n = 7). Different letters above bars designate significant difference between groups, $P < 0.05$.

the mean arthritis scores (Figure 2A) and reduced the levels of IL-1β,TNF-α, IL-6, and IL-17 (Figure 2B) in the serum based on measurements with ELISA kits. The histopathological change in the joints was examined under light microscopy and scored from 0 to 3, based on the synovitis and cartilage or bone destruction scales. We can see from Figure 2C,D that there was obvious evidence of synovial hyperplasia, joint space narrowing, and bone and cartilage erosion in the joints of the CIA group mice, whereas in the isogarcinol-treated group these changes were scarcely observed.

Effects of Isogarcinol on Acute Inflammatory Animal Models in Vivo. Xylene-induced mouse ear edema was used to inspect the action of isogarcinol on inflammatory experiments in vivo. Figure 3 shows that isogarcinol reduced the ear edema induced by xylene. Oral administration of 100 mg/kg isogarcinol has a similar effect to that of aspirin on xylene-induced ear edema.

Effect of Isogarcinol on Anti-inflammation in Vitro. RAW 264.7 cells were cultured in 6-well plates at a density of 1×10^6/mL and treated with LPS (10 μg/mL) or a combination of LPS (10 μg/mL) and isogarcinol for 24 h. Then the supernatant was collect to test NO by Griess assay, and the cells were collected to test iNOS and COX-2 mRNA expression by real-time quantitative PCR. Panels A and C of Figure 4 show that isogarcinol significantly inhibited iNOS and COX-2 mRNA expression. Furthermore, isogarcinol suppressed NO production in the supernatant of RAW 264.7 cells (Figure4B). In this study, we tested the expression of IκB-α by Western blot in

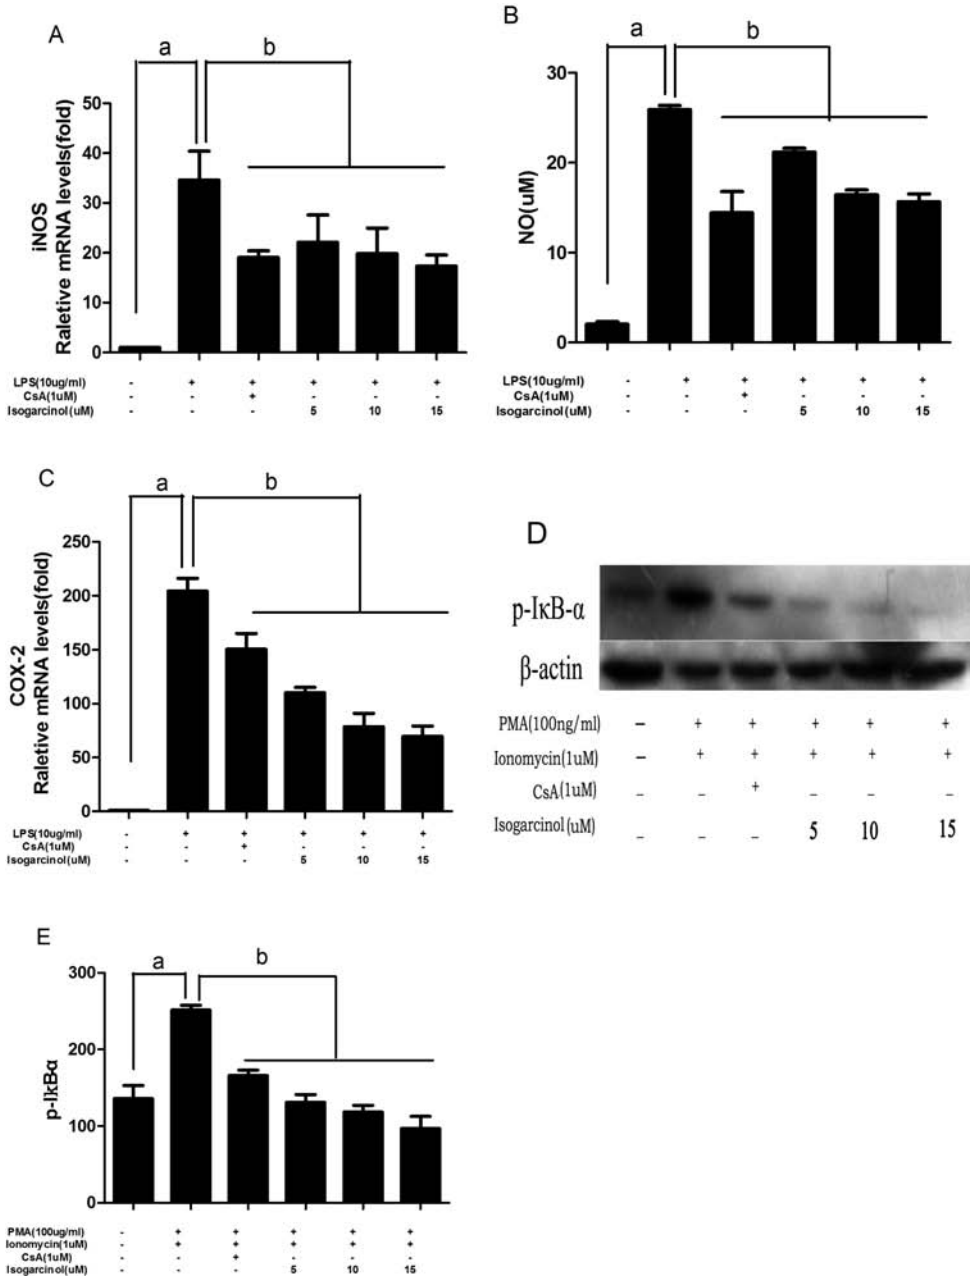

Figure 4. Anti-inflammatory mechanism of isogarcinol: (A) isogarcinol inhibited iNOS mRNA expression in RAW 264.7 cells; (B) isogarcinol inhibited the production of NO in RAW 264.7 cells; (C) isogarcinol inhibited COX-2 mRNA expression in RAW 264.7 cells; (D) effects of isogarcinol on the expression of p-iκb-α; (E) quantification of Western blot. All values are expressed as the mean ± SD of three independent experiments performed in triplicate (n = 3). Different letters above bars designate significant difference between groups, $P < 0.05$.

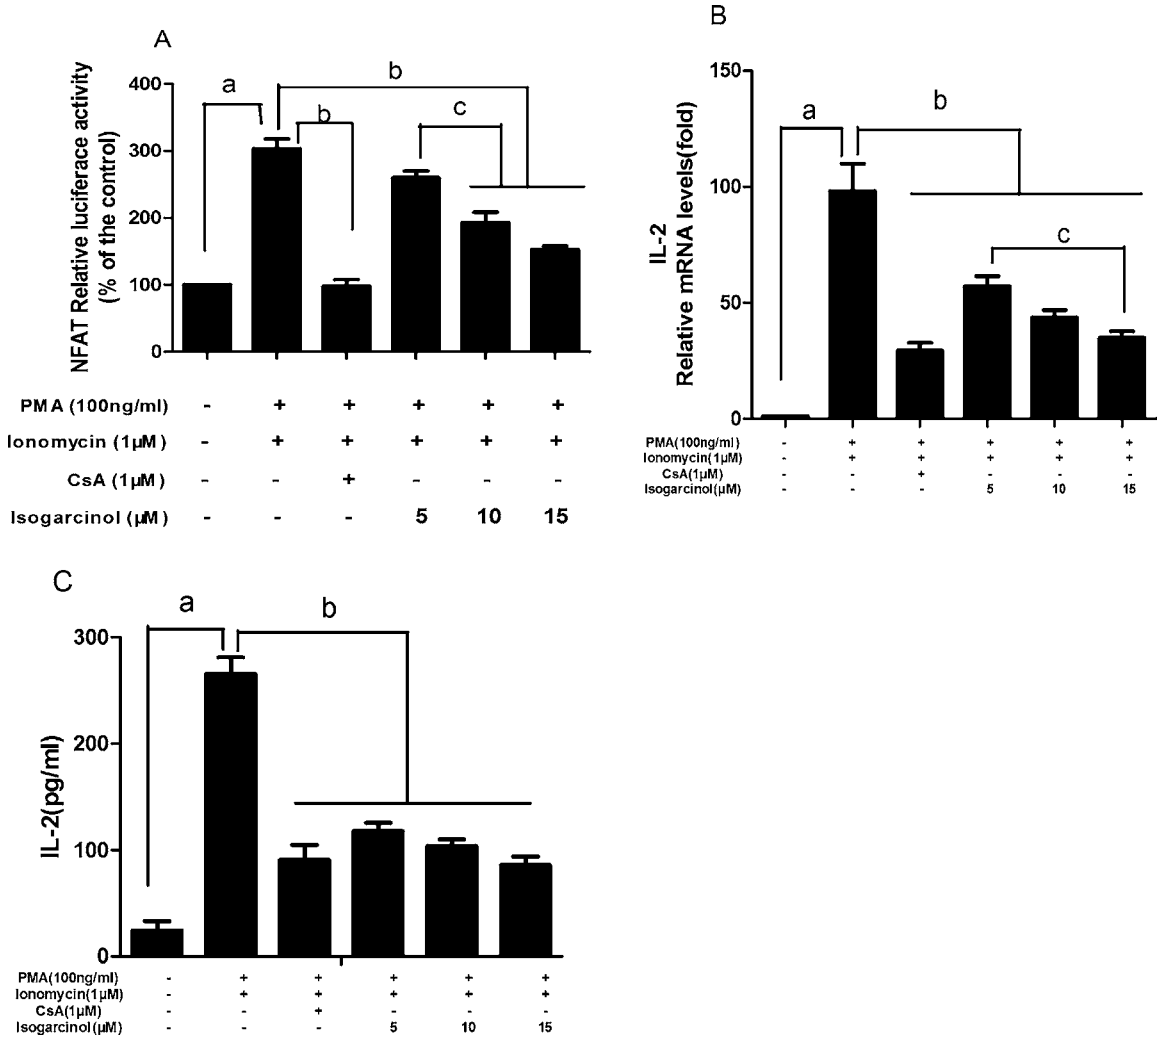

Figure 5. Immune regulation mechanism of isogarcinol: (A) isogarcinol suppressed NFAT activity; (B) inhibitory effect of isogarcinol on IL-2 activity; (C) inhibitory effect of isogarcinol on IL-2 expression. Results are mean values ± SD of three independent experiments performed in triplicate (n = 3). Different letters above bars designate significant difference between groups, $P < 0.05$.

Jurkat cells to determine whether isogarcinol affected NF-κB. As shown in Figure4D, the content of p-iκB increased with PMA and Ion stimulation and then decreased when treated with isogarcinol.

Effect of Isogarcinol on Immune Regulation in Vitro. CsA displays its immunosuppressive effect by inhibiting the NFAT/IL-2 signaling pathway. To determine whether isogarcinol influenced the NFAT/IL-2 signaling pathway, RAW 264.7 cells were treated with PMA + Ion or a combination of isogarcinol and PMA + Ion for 24 h. Then the supernatant was collect to test IL-2 by ELISA assay; the cells were collected to test NFAT and IL-2 mRNA expression using the dual-luciferase reporter gene assay and real-time quantitative PCR, respectively. The data in Figure5A suggest isogarcinol inhibition of NFAT and IL-2 mRNA expression (Figure 5B) and IL-2 content (Figure 5C).

■ DISCUSSION

In this study, we find that the immunosuppressant isogarcinol markedly inhibited joint swelling; significantly decreased clinical and pathological scores; reduced IL-1β, TNF-α, IL-17, and IL-6 levels in the serum; and prevented joint damage caused by collagen in DBA/1J mice. Pro-inflammatory cytokines such as IL-1β, TNF-α, and IL-6 are highly expressed in the rheumatoid joint and play key roles in the pathogenesis of RA.[22] IL-17 is a T cell-derived cytokine, which leads to angiogenesis, joint inflammation, cartilage destruction, and bone erosion; the inhibition of IL-17 limits inflammation and joint erosion in several animal models of arthritis.[23,24] Inhibition of the production of IL-17 may be one factor in the cartilage protection by isogarcinol.

Isogarcinol significantly decreased NO production and iNOS mRNA expression in the LPS-stimulated RAW 264.7 macrophages. NO is an essential messenger molecule produced during the inflammatory response by activated macrophages,[25] but overproduction of NO is associated with the initiation of apoptosis of chondrocytes.[26] The inhibition of excessive NO by the suppression of iNOS mRNA expression may be another factor in the cartilage protection of isogarcinol. It was reported that CN is necessary for iNOS expression,[27] and compounds that inhibit the iNOS enzymatic level have anti-inflammatory effects.[28] COX-2, which is an inducible isoform and catalyzes the rate-limiting step in the oxidation of arachidonic acid to prostaglandins, plays a major role in inflammatory reactions and is responsible for the characteristic inflammatory symptoms.[29] COX-2 and iNOS are important inducible enzymes that mediate inflammatory processes; isogarcinol significantly

dx.doi.org/10.1021/jf405790q | J. Agric. Food Chem. 2014, 62, 4127−4134

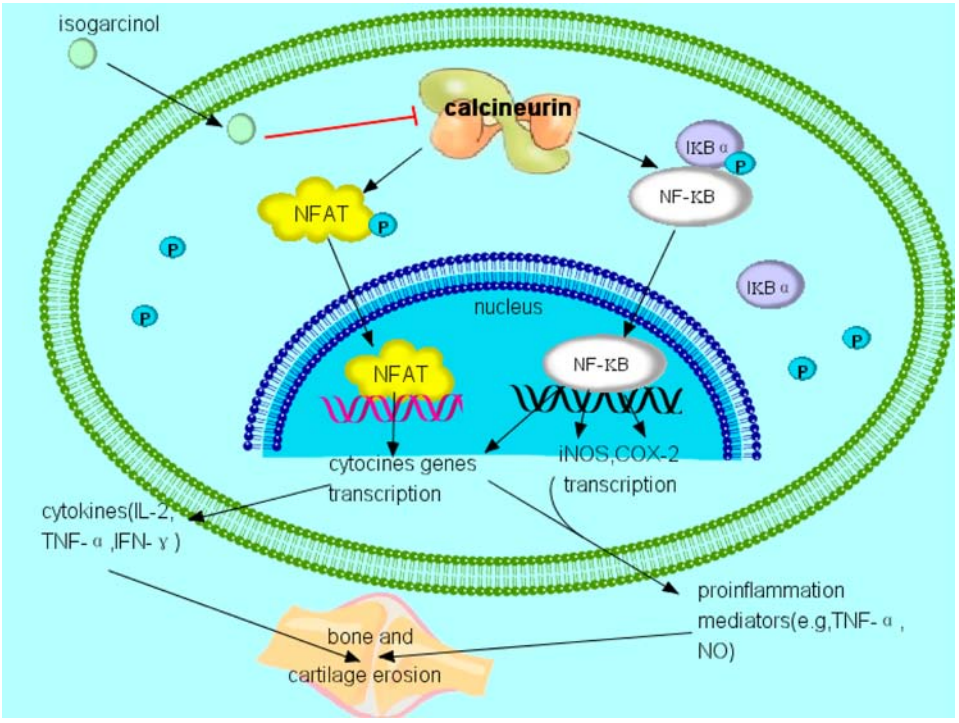

Figure 6. Mechanism of action of isogarcinol. The green, round cell membrane represents the membrane of the immune cell, and the semicircular blue membrane represents the nuclear membrane. CN activates the transcription factors, NFAT and NF-κB, which transcribe cytokines and inflammatory inducible enzyme (iNOS, COX2) genes, respectively, and then the expression of inflammatory factors, such as IL-1β, TNF-α, IL-6, and NO, which lead to articular bone and cartilage erosion. Isogarcinol is an inhibitor of CN; it inhibits CN activity and then inhibits NFAT and NF-κB transcription inflammatory factors and thus exerts its immune regulation and anti-inflammatory effects.

inhibited iNOS and COX-2 levels, decreased NO production, and reduced ear edema induced by xylene. Therefore, isogarcinol is an effective anti-inflammatory agent, and these findings may explain why isogarcinol inhibits chronic inflammatory arthritis.

NF-κB plays an important role in the inflammatory response, and it regulates the expression of numerous components in the immune system, including IL-2, pro-inflammatory cytokines (IL-6, IL-1β, and TNF-α), and inducible enzymes (iNOS and COX2).[30] In rest cells, NF-κB is constitutively localized in the cytosol with an inhibitory protein called inhibitor κB (IκB). The degradation and phosphorylation of IκB-α is necessary to release NF-κB from the cytoplasmic NF-κB/IκB-α complex and allow its subsequent translocation to the cell nucleus.[31] Nuclear factor-κB acts at the crossroads of many signaling pathways; the excessive activation of NF-κB can lead to inflammatory and autoimmune diseases or cancers.[32] NF-κB plays an important role in the pathogenesis of RA, its mainly pro-inflammatory regulators TNF-α, IL-1β, and IL-6, linked directly to cartilage degradation and bone erosion in RA.[33,34] It was reported that oral administration of NF-κB inhibitors could attenuate CIA.[35] In recent years, there has been extensive research on the connection between inflammation and cancer; inhibition of NF-κB could inhibit inflammation and reduce the incidence of cancer.[36,37] It was reported that garcinol possesses anti-inflammatory and anticancer activities.[38,39] In this study, we found that isogarcinol significantly inhibited inflammatory cytokines, COX-2 ,iNOS, and NF-κB expression, and it may be effective as an anticancer agent, but this requires further study.

The NF-κB pathway is a key regulator in the development of regulatory T cell (Tregs).[40] Tregs are crucial for restoring immune tolerance, and they are likely to play a regulatory role in RA.[41] Isogarcinol inhibited $CD4^+$ and $CD4^+$ $CD25^+$ in spleen cells stimulated by ConA (data not shown here). It was reported that NF-κB can be activated by CN and that the activity of CN was strongly correlated with the severity of arthritis in an RA animal model.[42] We find that isogarcinol inhibited CN activity but did not influence CN content in Jurkat cells (data not shown here). Glycyrol, another immunosuppressant screened by our group with CN as its target enzyme, has an action similar to that of isogarcinol on RA. It was reported that immunosuppressive and anti-inflammatory effects of curcumin were achieved by inhibiting NFAT and NF-κB signal pathways through blocking Ca^{2+} mobilization.[43]

NF-κB is only one of many CN substrates; NFAT is the main substrate of CN in immune cells. CN and NFAT regulate the expression of a large number of cytokines and cell-surface receptors that are essential for a productive immune response.[44,45] Despite the lack of structural similarity between FK506 and CsA, the mechanisms of action of these two drugs are very similar as they both inhibit CN and NFAT to exert their immune-suppressive effects. We found that isogarcinol inhibits NFAT activity and IL-2 expression. To summarize our experimental data and referenced studies mentioned above, we draw a possible mechanism of action of isogarcinol in RA (Figure 6). CN activates the transcription factors, NFAT and NF-κB, which transcribe cytokines and inflammatory inducible enzyme (such as iNOS and COX-2) genes, respectively, and then the expression of inflammatory factors, such as IL-1β, TNF-α, IL-6, and NO, which lead to articular bone and cartilage erosion. As an inhibitor of CN, isogarcinol inhibits CN activity and then inhibits NFAT and NF-κB transcription inflammatory factors and thus plays its immune regulation and anti-inflammatory roles.

RA is a Th1-mediated autoimmune disease that is characterized by chronic inflammatory symptoms, so we wanted to

ensure anti-inflammation or immunosuppression, which are the major mechanisms of action of isogarcinol in RA. To date, the actual mechanism is not clear because inflammation and immunity are inseparable at the cellular and molecular levels of many chronic inflammatory diseases; inflammation and immunity are two aspects of one issue, and they overlap but are inseparable. However, what is clear is that the use of anti-inflammatory drugs or immunosuppressive drugs alone is not effective. The development and application of drugs that combine anti-inflammatory activity and immune regulatory activity will be main research aims. In this study, we found both immunosuppression and anti-inflammatory effects of isogarcinol extracted from mangosteen fruit; therefore, we expect that this compound will become a potential drug candidate for RA.

Overall, isogarcinol is a low toxicity, peroral compound that we extracted from mangosteen fruit; the experimental data in this study showed that it is effective as an antiarthritis agent, and the therapeutic effect was associated with the down-regulation of both the inflammatory and autoimmune reactions.

Kinetics and Molecular Docking Studies of the Inhibitions of Angiotensin Converting Enzyme and Renin Activities by Hemp Seed (*Cannabis sativa* L.) Peptides

Abraham T. Girgih,[†] Rong He,[†,‡] and Rotimi E. Aluko*[,†]

[†]Department of Human Nutritional Sciences and The Richardson Centre for Functional Foods and Nutraceuticals, University of Manitoba, Winnipeg, Manitoba R3T2N2, Canada

ABSTRACT: Four novel peptide sequences (WVYY, WYT, SVYT, and IPAGV) identified from an enzymatic digest of hemp seed proteins were used for enzyme inhibition kinetics and molecular docking studies. Results showed that WVYY (IC_{50} = 0.027 mM) was a more potent ($p < 0.05$) ACE-inhibitory peptide than WYT (IC_{50} = 0.574 mM). However, WYT (IC_{50} = 0.054 mM) and SVYT (IC_{50} = 0.063 mM) had similar renin-inhibitory activity, which was significantly better than that of IPAGV (IC_{50} = 0.093 mM). Kinetics studies showed that WVYY had a lower inhibition constant (K_i) of 0.06 mM and hence greater affinity for ACE when compared to the 1.83 mM obtained for WYT. SVYT had lowest K_i value of 0.89 mM against renin, when compared to the values obtained for WYT and IPAGV. Molecular docking results showed that the higher inhibitory activities of WVYY and SVYT were due to the greater degree of noncovalent bond-based interactions with the enzyme protein, especially formation of higher numbers of hydrogen bonds with active site residues.

INTRODUCTION

Food-protein-derived peptides have been shown to exert a variety of bioactivities during in vitro and in vivo testing as antioxidant,[1−3] antihypertensive,[4−6] and immunomodulatory[7,8] agents. Other works have also produced food-protein-derived peptides with antibacterial,[9−11] anticancer,[12−14] antidiabetic,[15−17] and anti-inflammatory[18−20] properties. These bioactive peptides could be generated from animal and plant sources through enzymatic hydrolysis of the isolated proteins with single or a combination of proteases. In this respect, several studies have produced natural antihypertensive peptides that may be used to prevent or manage hypertension.[5,21−24] The use of natural peptide sequences as antihypertensive agents is attractive because in some patients pharmaceutical drugs have been reported to cause undesirable side effects and health complications, such as dry cough, edema, skin rashes, and diarrhea during prolonged administration.[25−27] Hypertension in human beings is regulated by the renin−angiotensin systems (RAS), which also ensures fluid homeostasis; a malfunctioning of this system could result in the development of chronic diseases such as hypertension, kidney failure, liver malfunction, diabetes, and cancer.[28] Three enzymes, namely, renin, angiotensin I converting enzyme (ACE), and chymase, are the key catalysts involved in the operation of RAS. The RAS operates as follows: renin, an aspartyl protease produced from the kidney, converts angiotensinogen (a product of the liver) into an inactive angiotensin I (AT-I).[29] Subsequently, ACE catalyzes the conversion of AT-I into a pro-hypertensive octapeptide and potent vasoconstrictor angiotensin II (AT-II). ACE also inactivates a vasodilator named bradykinin, which leads to increased vasopressive effects and contributes to blood pressure (BP) elevation.[29] Studies have shown that prolonged therapy with ACE-inhibitory antihypertensive drugs leads to AT-I accumulation and could activate an alternate pathway involving chymase, which is also capable of converting AT-I to AT-II independent of ACE; such a reaction can result in the failure of the antihypertensive drug therapy.[30] In contrast, there is growing evidence that direct inhibition of renin could offer a better control of elevated BP than ACE because accumulation of AT-I in substantial amounts that could be converted to AT-II in some organs via an ACE-independent pathway catalyzed by chymase is prevented. However, sole inhibition of renin may not prevent ACE-catalyzed bradykinin degradation; therefore, a dual strategy for inhibition of renin and ACE simultaneously is suggested to be the more effective therapy for BP control when compared to single ACE therapy approach.[31]

Currently, our main research focus is to purify and identify food-based antihypertensive or bioactive substances that would possess dual ability to inhibit renin and ACE activities. Recently, a number of antihypertensive peptides with multifunctional properties capable of inhibiting ACE and renin enzymes in vitro and in vivo conditions have been produced from various plant and animal food sources. Peptides with dual ability to inhibit ACE and renin have through enzymatic hydrolysis been identified from seaweeds,[32] yellow field pea

seeds,[33] flaxseed,[34] rapeseed,[21] and hemp seed.[35,36] Previous work also showed that a pea protein hydrolysate reduced renal renin mRNA production in a chronic kidney disease rat model after 8 weeks of oral diet intake.[37] Our previous work has shown that dietary inclusion of a multifunctional hemp seed protein hydrolysate was effective in the prevention and management of hypertension in spontaneously hypertensive rats.[38] We have also determined the amino acid sequence of peptides that may be responsible for the antihypertensive effect of hemp seed protein hydrolysate and confirmed BP-reducing effects of the peptides in spontaneously hypertensive rats (SHR).[36] Despite the potential bioactive properties as well as health benefits of hemp seed peptides, there is paucity of information in the area of structure−function of blood-pressure-lowering peptides as well as enzyme inhibition kinetics studies. Structure−function studies will provide new information on the relationships of amino acid composition and sequence with antihypertensive activity, which could enhance method development to produce potent peptides from food proteins. Information from structure−function studies could also enhance development of novel and potent peptidomimetics using known peptide sequences as templates. Kinetic studies will provide useful information to decide the optimal dose of the peptide needed to achieve maximal preventive effects. In addition, the mode of inhibition of ACE and renin activities when determined by kinetics and molecular docking studies will provide additional information for structure−function studies of antihypertensive peptides. Therefore, the objective of this study was to determine the kinetics of ACE and renin inhibitions as well as potential enzyme−ligand binding configurations by four hemp seed peptides that have been shown to reduce systolic BP in SHR.

MATERIALS AND METHODS

Materials. *N*-[3-(2-Furyl)acryloyl]phenylalanylglycylglycine (FAPGG) and ACE from rabbit lung (EC 3.4.15.1) were purchased from Sigma-Aldrich (St. Louis, MO). Human recombinant Renin Inhibitor Screening Assay Kit was purchased from Cayman Chemicals (Ann Arbor, MI). Hemp seed protein-derived peptide sequences (WYT, WVYY, SVYT, and IPAGV) with demonstrated antihypertensive effects in SHR[36] were synthesized (>95% purity) by GenWay Biotech (GenWay Biotech Inc., San Diego, CA).

Kinetics of ACE Inhibition. The ability of WYT and WVYY to inhibit in vitro activity of ACE was measured in triplicates as previously reported.[34] Briefly, 1 mL of 0.5 mM FAPGG (dissolved in 50 mM Tris−HCl buffer containing 0.3 M NaCl, pH 7.5) was mixed with 20 μL of ACE (final activity of 20 mU) and 200 μL of peptide in 50 mM Tris−HCl buffer. The rate of decrease in absorbance at 345 nm was recorded for 2 min at room temperature. Tris−HCl buffer was used instead of peptide solutions in the blank experiment. ACE activity was expressed as a rate of reaction (ΔA/min) and inhibitory activity was calculated using the equation below

$$\text{ACE inhibition (\%)} = [[(\Delta A/\text{min})_{\text{blank}} - (\Delta A/\text{min})_{\text{sample}}] / (\Delta A/\text{min})_{\text{blank}}] \times 100$$

where $(\Delta A/\text{min})_{\text{sample}}$ and $(\Delta A/\text{min})_{\text{blank}}$ are the ACE activity in the presence and absence of peptides, respectively. The concentration of each peptide that inhibited ACE activity by 50% (IC_{50}) was calculated using nonlinear regression from a plot of percentage ACE inhibition versus peptide concentration. The kinetics of ACE inhibition was studied with 0.0625, 0.125, 0.25, and 0.5 mM FAPGG. The mode of ACE inhibition was determined from the Lineweaver−Burk plots, while inhibition constant (K_i) was calculated as the *X*-axis intercept from a plot of the slope of the Lineweaver−Burk lines against peptide concentration.[39]

Kinetics of Renin Inhibition. In vitro inhibition of human recombinant renin activity was conducted according to the previously described method,[33] using the Renin Inhibitor Screening Assay Kit. Prior to the assay, renin buffer was diluted with 50 mM Tris-HCl, pH 8.0, containing 100 mM NaCl. The renin protein solution was diluted 20 times with assay buffer before use, and the assay buffer was prewarmed to 37 °C before the reaction was initiated in a fluorometric microplate reader (Spectra MAX Gemini, Molecular Devices, Sunnyvale, CA) maintained at 37 °C. Before the reaction, (1) 20 μL of substrate, 160 μL of assay buffer, and 10 μL of Milli-Q water were added to the background wells; (2) 20 μL of substrate, 150 μL of assay buffer, and 10 μL of Milli-Q water were added to the control wells; and (3) 20 μL of substrate, 150 μL of assay buffer, and 10 μL of peptide samples (WYT, SVYT, or IPAGV) were added to the inhibitor wells. The reaction was initiated by adding 10 μL of renin to the control and sample wells. The microplate was shaken for 10 s to mix followed by incubation at 37 °C for 15 min; fluorescence intensity (FI) was recorded using excitation and emission wavelengths of 340 and 490 nm, respectively. The percentage inhibition was calculated as follows:

$$\text{inhibition\%} = \{[(\text{FI of control well}) - (\text{FI of sample well})] / (\text{FI of control well})\} \times 100$$

The peptide concentration that inhibited 50% of renin activity was determined and defined as the IC_{50} value and was calculated by nonlinear regression as performed for ACE. The renin inhibition kinetics studies were conducted using 0.625, 1.25, 2.5, 5, and 10 μM of substrate in the absence and presence of peptides. Lineweaver−Burk plots were used to calculate inhibition constant as described above for ACE.

Molecular Docking Studies. Molecular docking was performed using Accelrys Discovery Studio software 2.5 (DS 2.5) as previously described.[40] The structures of WYT, WVYY, SVYT, and IPAGV were generated with DS 2.5, and the energy was minimized with the CHARMm program. For ACE docking, a crystal structure of human ACE bound with lisinopril (an ACE-inhibitory drug) (PDB ID 1O8A) was used as ACE molecule. A binding site was created by the digital removal of lisinopril with the radius of 15 Å, and coordinates x = 41.268, y = 34.559, z = 45.393. Automated molecular docking was performed using the partial flexibility CDOCKER tool of the DS 2.5 software in the presence of cofactors (zinc and chloride ions). For renin docking, a crystal structure of human renin bound with aliskiren (a renin-inhibitory drug) (PDB ID 2V0Z) was used. All the water molecules present in the protein except two water molecules (H_2O184 and H_2O250) and aliskiren were digitally removed and hydrogen atoms were added to the protein structure. A binding site was created using a radius of 10 Å around the ligand and with coordinates x = 7.568, y = 46.092, z = 68.842.[41] Evaluation of the molecular docking was performed according to the scores and binding-energy value in order to obtain the best poses for peptides. DS 2.5 software was also used to identify the hydrogen bonds as well as the hydrophobic, hydrophilic, electrostatic, and coordination interactions between residues located at the ACE and renin active sites.

Statistical Analysis. Enzyme inhibition assays were conducted in triplicates and analyzed by one-way analysis of variance. Data are reported as mean ± standard deviation. Statistical significance of differences was evaluated by Duncan's multiple range test ($p < 0.05$) using the Statistical Analysis Systems software version 9.2 (SAS, Cary, NC).

RESULTS AND DISCUSSION

ACE- and Renin-Inhibitory Activities of Hemp Seed Peptides. Figure 1A shows that the ACE-inhibitory IC_{50} values for WVYY and WYT were 0.027 and 0.574 mM, respectively ($p < 0.05$). These IC_{50} values are lower than the values previously reported for pea dipeptides IR (2.25 mM), KF (7.23 mM), and EF (2.98 mM).[33] The IC_{50} value for WYT is similar to 0.3−0.7 mM but higher than the 0.115−0.129 mM values reported for various mushroom peptides.[42] However, the IC_{50} value for WVYY shows

dx.doi.org/10.1021/jf5002606 | J. Agric. Food Chem. 2014, 62, 4135−4144

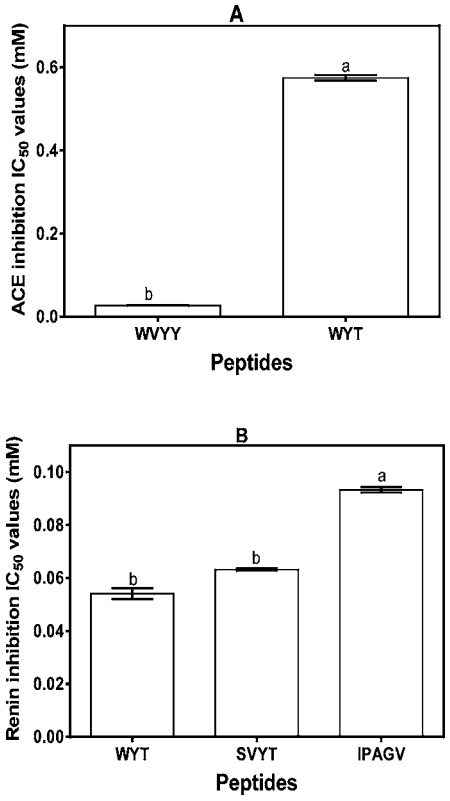

Figure 1. Inhibitory concentration of synthesized hemp seed peptides that reduced 50% (IC_{50}) in vitro activity of (A) ACE and (B) renin. Bars with different letters have mean values that are significantly different at $p < 0.05$. Values are means ± SD ($n = 3$).

that this peptide is a better ACE inhibitor than the mushroom peptides. The strong ACE-inhibitory activities exhibited by WVYY are consistent with earlier reported results, which showed that the presence of hydrophobic or aromatic amino acid residues such as phenylalanine, tyrosine, and proline at the C-terminal of peptides positively contributed toward the enhancement of ACE-inhibitory activities.[43,44] Hayes et al.[45] reported the identification of a range of novel propeptide angiotensin converting enzyme inhibitors in a casein fermentate produced by the action *Lactobacillus animalis* DPC6134. The casein fermentate peptides showed showed a correlation between the C-terminal tripeptide sequences and degree of ACE inhibition. In particular, binding of casein fermentate peptides to ACE active sites was shown to be influenced by the hydrophobicity of the three C-terminal amino acid residues, with aromatic or branched side chain amino acid residues being preferred. Thus, the presence of valine (V) in the tripeptide C-terminal sequence of WVYY may have contributed to the strong ACE-inhibitory properties of this peptide. The availability of two bulky tyrosine (Y) groups at the C-terminal may also have potentiated stronger inhibition of ACE activities when compared to WYT that has a hydrophilic amino acid threonine (T) at the C-terminal. Moreover, on the basis of other studies,[46−48] the presence of a branched-chain aliphatic amino acid such as valine at the N-terminal as well as the availability of an ionizable functional group (e.g, in tryptophan, W) may have also contributed to making WVYY a better ACE inhibitor than WYT.

Renin catalyzes the first and rate-limiting step that initiates production of vasoconstricting peptides responsible for BP elevation; therefore, down-regulation of renin's activity may enhance vasodilation. To the best of our knowledge, there is scanty information about the properties and occurrence of renin-inhibitory peptides from natural sources. Currently, there is only one known commercially available potent nonpeptidic renin inhibitor (aliskerin, IC_{50} = 0.6 nM), thus justifying the ongoing research for renin inhibitors from naturally occurring food sources. The IC_{50} values of the synthesized hemp seed peptides identified in this study with potent renin inhibitory properties are shown in Figure 1B. The tripeptide WYT exhibited the strongest inhibitory capacity with the lowest IC_{50} value of 0.054 mM when compared to the tetrapeptide (SVYT = 0.063 mM) and the pentapeptide (IPAGV = 0.093 mM). Renin-inhibitory IC_{50} values of the hemp seed peptides are very low when compared to the 9.20, 17.78, and 22.66 mM values for pea peptides IR, KF, and EF, respectively. Similarly, higher renin-inhibitory IC_{50} values were reported for rapeseed peptides RALP (0.968 mM), LY (1.868 mM), and TF (3.061 mM).[21] The potent renin-inhibitory data obtained in this study is in agreement with results from previous works that have suggested the presence of all or at least some of the following characteristics for good renin inhibition: one hydrophobic side chain at the N-terminal, bulky chains at the C-terminal, one

[a] K_m is the Michaelis constant, V_{max} is maximum reaction velocity, CE is the catalytic efficiency (V_{max}/K_m), and K_i is the enzyme−inhibitor dissociation constant.

dx.doi.org/10.1021/jf5002606 | J. Agric. Food Chem. 2014, 62, 4135−4144

hydrogen bond donor, and two hydrogen bond acceptors.[41,49,50] This is because the hemp seed peptides had most of these qualities as a result of the presence of P, L, Y, W, I, and V amino acid residues.

Kinetics of ACE Inhibition. A Lineweaver–Burk plot was used for the estimation of the modes of ACE inhibition by the hemp seed peptides, and results are shown in Figure 2 for

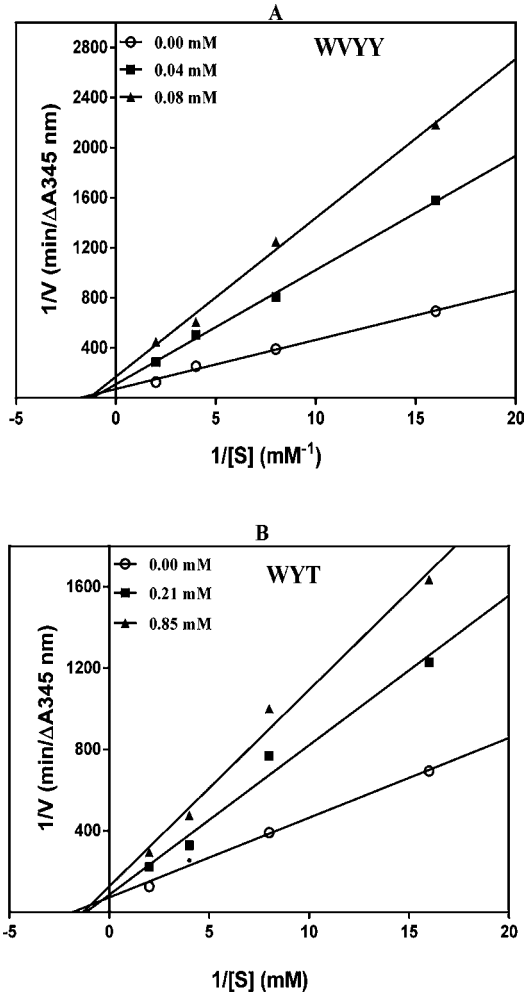

Figure 2. Lineweaver–Burk plots of angiotensin I-converting enzyme (ACE) inhibition by different concentrations of synthesized hemp seed peptides at varying substrate concentrations (0.0625–0.5 mM). V = the initial rate of reaction [ΔA_{345} (nm)/min].

WVYY (A) and WYT (B). From the linear regression fit of the kinetics data, the K_m value of ACE activity in the absence of the inhibiting peptide was estimated to be 0.543 mM (Table 1A). The K_m value was higher in the presence of peptides, which is an indication that more substrate was required for enzyme catalysis, and hence, the enzyme was less efficient. However, the K_m value reduced when peptide concentration was increased, which suggests that, at higher peptide levels, more peptides become bound to the enzyme active site to prevent formation of an enzyme–substrate complex. The V_{max} for uninhibited ACE reaction was 0.014 A min^{-1}, and this velocity decreased dose-dependently in the presence of peptides (WVYY and WYT), though WVYY appeared to be more effective (Table 1A). The lower V_{max} in the presence of WVYY is consistent with the higher potency (lower IC_{50} value) when compared to WYT as

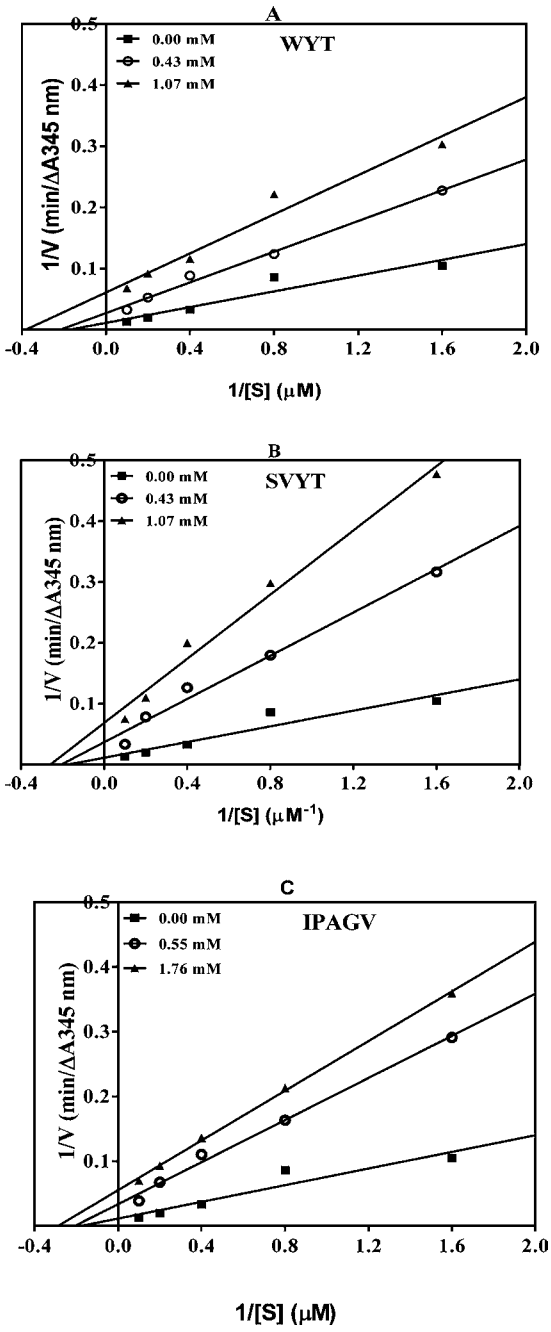

Figure 3. Lineweaver–Burk plots of the inhibition of human recombinant renin by different concentrations of synthesized hemp seed peptides at varying substrate concentrations (0.625–10 μM); V = initial rate of reaction (change in fluorescence intensity/min).

ACE inhibitors. Thus, the results indicate that the activation energy of the catalytic reaction was increased in the presence of WVYY and WYT because the rate of enzyme reaction was slowed down. The K_m and V_{max} values obtained in this study are slightly higher than those previously reported for hemp seed protein hydrolysate and its ultrafiltration membrane fractions.[35] The catalytic efficiency (CE) of the uninhibited ACE-catalyzed reaction was 0.026, which decreased in a dose-dependent manner in the presence of WVYY and WYT. The reduced CE is directly related to lower V_{max} and IC_{50} values, suggesting that the peptides had some binding affinity to the enzyme, which led to reduced catalytic ability. WVYY and WYT exhibited a

[a]The residue numbers belong to tACE (PDB ID 1O86). [b]H-bond position:donor or acceptor atoms. Repeated residues indicate formation of two separate H-bonds by the same amino acid. "E", "D", and "Z" represent the presence of other residues near the donor or acceptor atom.

mixed-type mode of enzyme inhibition, implying that the peptides bind to the ACE enzyme at positions that include both the active and nonactive sites in order to reduce catalytic activity. Binding to either the active or nonactive site would have, respectively, blocked substrate binding or produce enzyme conformations that reduced substrate affinity for the active site. The K_i of WVYY and WYT for ACE inhibition were calculated to be 0.039 mg/mL (0.06 mM) and 0.858 mg/mL (1.83 mM), respectively, which are lower than the 2.55−4.74 mg/mL (3.92−7.31 mM) values reported for the hemp seed protein hydrolysate and its membrane fractions,[35] indicating a stronger inhibitory capacity of the pure peptides in comparison to the peptide mixture. The lower K_i value for WVYY is consistent with the observed greater reductions in V_{max} and CE when compared to the reductions produced by WYT.

Renin-Inhibitory Kinetics. Parts A, B, and C of Figure 3 illustrate the double-reciprocal plots of the renin-catalyzed reaction in the absence or presence of WYT, SVYT, and IPAGV, respectively. These three peptide sequences were

found to display mostly uncompetitive mode of renin inhibition. For example, the K_m of WYT showed a greater reduction from 4.631 to 2.623 μM when compared to the decrease in K_m observed for SVYT and IPAGV (Table 1B). SVYT, however, exhibited the lowest ranges of V_{max} (25.73−16.57 FI/min) and CE (5.249−4.247) values, which is an indication of reduced enzyme velocity in the presence of the peptide. The uncompetitive mode results suggest that the peptide bind mostly to the renin−substrate complex to cause reductions in the reaction velocity as well as the catalytic efficiency. It is presumed that the binding of the peptide to the renin−substrate complex is responsible for the simultaneous decreases in V_{max} and K_m values (Table 1). This is because the reduced effectiveness of the renin−substrate complex (reduced V_{max}) will lead to increased affinity of renin for the substrate and hence reduction in the K_m value. Renin inhibition by the peptides, which was reflected in the reduced CE as peptide level was increased, indicated the lower ability of the enzyme to convert the substrate into products. The lower K_i of SVYT indicated that this peptide may be able to more strongly bind to the renin−substrate complex (resistant to substrate-dependent dislodgement) when compared to WYT and IPAGV. The K_m for renin substrate in the absence of the inhibitor was determined to be 5.621 μM, which is higher than those from other studies, such as 1.3,[51] 4.416,[34] and 4.01 μM,[52] but is, however, lower than the 6.4 μM value reported by Yuan et al.[53] The difference in K_m values could be attributed to the different sources from which renin enzyme was procured for these studies and/or the variations in experimental conditions/approaches that may have been used.

Molecular Docking Studies. Figure 4 shows the best poses for the WVYY and WYT when present within the ACE catalytic site and in the presence of Zn^{2+}. The best pose for each peptide was stabilized mainly by electrostatic interactions and hydrophobic interactions that exist between amino acid residues of ACE and those of each peptide within a distance of 3.5 Å (Table 2). The poses were also stabilized by hydrogen bond formation with ACE amino acid residues (Table 3). WVYY had a higher number of total interactions (26) with ACE residues, which could have contributed to the higher inhibitory activity (lower IC_{50} value) when compared to WYT, which showed 22 interactions. This was confirmed by the lowest binding electrostatic energy value of −114.06 kJ/mol for WVYY when compared to −92.91 kJ/mol for WYT. Similarly,

dx.doi.org/10.1021/jf5002606 | J. Agric. Food Chem. 2014, 62, 4135−4144

the van der Waals energy of −5.23 kJ/mol was lower for WVYY when compared to −0.67 kJ/mol for WYT. The binding energy data agree with the fact that WVYY had higher ACE-binding affinity (lower K_i value) when compared to WYT, as shown in Table 1. The higher activity of WVYY may also be due to a higher degree of interactions with S1 (Ala354, Glu384, Tyr523 residues) and S2′ (Gln281, Tyr520, Lys511, His513, His353) subsites of the active site of ACE (Table 2). WVYY interacted with these S1 and S2′ subsites residues in a similar manner to the observed interactions between lisinopril and ACE.[54] In contrast, the weaker WYT interacted with all the ACE S1 and S2′ subsites residues with the exception of Lys511 (Table 2). As shown in Table 3, the ability of peptides to form multiple H-bond interactions with ACE could have contributed to peptide-induced inhibition of enzyme activity by stabilizing the noncatalytic enzyme−peptide complex structure. Similar results showing multiple H-bond formation between ACE-inhibitory peptides VPP or IPP and ACE residues have also been reported.[55] Also important is that the inhibitory capacity seem to be directly correlated to the number of H-bonds formed; lisinopril has the highest ACE-inhibitory activity and formed nine H-bonds, followed by WVYY (seven bonds) and WYT (five bonds). It is not only the number of H-bonds that seems to contribute to ACE-inhibitory potency of the peptides but also the ACE residues involved. This is because the more potent WVYY formed two H-bonds with Gln281 as well one H-bond each with His353 and His513 (Table 3), all amino acid residues that are critical components of the ACE active site. The weaker-acting WYT does not form any H-bond with Gln281, His353, and His513. The docking results also showed that the interactions between ACE-inhibitory pepitdes and Zn^{2+} at the enzyme active site also play a significant role in modulating catalysis, as previously suggested.[56] Figure 4 shows that WVYY and WYT were well-positioned to interact with the active site Zn^{2+} atom. Since the distance between the peptide C-terminal residue carbonyl oxygen and Zn^{2+} has been shown to account for the varied degrees of inhibition by peptides, then the shorter the Zn^{2+} distance to the carbonyl oxygen of the peptide, the greater the degree of inhibition.[57] The average distance between the WVYY peptide bond carbonyl oxygen and Zn^{2+} was 2.28 Å in comparison to 2.38 Å for WYT, hence the higher ACE-inhibitory activity (lower IC_{50} value, Table 1) observed for WVYY. A previous work has also shown that arachin-derived peptides IKP and IEP with 2.73 and 3.036 Å Zn^{2+} coordination distances had 7 and 18 μM IC_{50} values, respectively, for ACE inhibition.[57]

Figure 5A−C shows the docking of peptides with the active site of renin. SVYT had the lowest electrostatic binding energy value of −113.08 kJ/mol when compared to −83.96 kJ/mol for IPAGV and −92.91 kJ/mol for WYT. The results are consistent with the kinetics data (Table 1), which showed that SVYT had the highest binding affinity (lowest K_i value) followed by WYT and then IPAGV. Potential binding energy was also lowest for SVYT (−106.16 kJ/mol) when compared to IPAGV (−70.37 kJ/mol) and WYT (−80.74 kJ/mol). In contrast, the van der Waals energy values were −13.51, −8.36, and −0.67 kJ/mol for IPAGV, SVYT, and WYT, respectively. The results suggest that SVYT had better affinity toward renin followed by WYT and IPAGV in that order. The total number of interactions between each peptide and renin active site residues is very similar; in contrast, aliskiren had a greater number of interactions (Table 4). A previous report had shown that binding to the unique S3 subpocket ($S3^{sp}$) (Gln13, Tyr14, Val30, Tyr155, Ala218, Ser219, Ala303) of renin is necessary for high-affinity inhibition of enzyme activity.[58] In this respect, SVYT showed interactions with five of these residues (Gln13, Tyr14, Val30, Ala218, and Ser219), while WYT (Val30 and Ala218) and IPAGV (Ala218 and Ser219) interacted with two residues each (Table 4). In contrast, the powerful drug aliskiren formed interactions with all the $S3^{sp}$ residues. The lower peptide binding capacity to $S3^{sp}$ residues may be responsible for lower renin-inhibitory activity when compared to aliskiren. The results are in agreement with a previous work that had suggested peptide modification to improve lipophilic character as a means of enhancing binding to $S3^{sp}$ residues and increase renin-inhibitory capacity.[58] However, the fact that the three peptides still showed high renin-inhibitory capacity (low IC_{50} values) may be due to their ability to form electrostatic and hydrophobic interactions with the aspartate residues Asp32 and Asp215 (Table 4); these two residues are critical participants during renin catalysis.[59] The inhibitory activity of the three peptides may also be correlated to their ability to form multiple H-bonds with renin residues, as shown in Table 5. While the high renin-inhibitory activity of SVYT may be due to the higher

[a]The residue numbers belong to renin (PDB ID 2V0Z). [b]H-bond position:donor or acceptor atoms. Repeated residues indicate formation of two separate H-bonds by the same amino acid. "D", "G", and "N" represent the presence of other residues near the donor or acceptor atom.

number (nine) of H-bond formation, only WYT formed H-bonds with the critical catalytic residues Asp32 and Asp215 (Table 5). Aliskiren also formed H-bonds with Asp32 and Asp215. In contrast, IPAGV formed the lowest number of H-bonds (four) and none of the bonds involved Asp32 and Asp215; the lower number and absence of interaction with active site residues may be responsible for this peptide having the lowest renin-inhibitory activity (higher IC_{50} value). It is important to note that though both WYT and aliskiren formed H-bonds with Asp32 and Asp215 residues, the bond length was shorter for the drug (2.16 and 2.11 Å) when compared to the peptide (2.47 and 2.33 Å), hence the higher drug renin-inhibitory activity. These results suggest that the renin or ACE-inhibitory properties of peptides depend not only on the number of interactions with active site residues but the quality of such interactions such as type of residue (catalytic versus noncatalytic) and length of the bond.

Supporting Information

ABSTRACT: Three new sesquiterpenes (**1**−**3**) and two new rutinosides (**4** and **5**) along with 17 known compounds (**6**−**22**) were isolated from the leaves of *Murraya koenigii* (L.) Spreng. The new compounds were elucidated as (3*R*,5*S*,6*R*)-3,5,6-trihydroxy-1,1,5-trimethylcyclohexyl-8-butyn-9-one (**1**), (8*E*,9*R*)-ethyl-7-(3*S*,5*R*,6*S*)-3,6-dihydroxy-1,1,5-trimethylcyclohexyl-9-hydroxybut-8-enoate (**2**), (3*R*)-3-*O*-*β*-D-glucoside-6′-D-apiose-*β*-ionone (**3**), 4-*O*-*β*-D-rutinosyl-3-methoxyphenyl-1-propanone (**4**), and 1-*O*-*β*-D-rutinosyl-2(*R*)-ethyl-1-pentanol (**5**) based on their spectroscopic data. Compounds **1**, **4**, **5**, **18**, and **21** (10 *μ*M) exhibited moderate hepatoprotective activities.

KEYWORDS: *Murraya koenigii, sesquiterpene, rutinoside, hepatoprotective activity*

INTRODUCTION

Murraya koenigii L. (Rutaceae) is well-known as curry leaf, which has been widely cultivated as a spice in tropical and subtropical countries. The leaf of *M. koenigii* has been used for hundreds of years in southeast Asia as a traditional medicine and functional food to prevent and treat various diseases.[1]

Different kinds of compounds, including carbazole alkaloids,[2] volatile oils,[3] and other compounds, had been isolated from the leaves of *M. koenigii*.[4] These compounds exhibited various bioactivities, such as hypoglycemic and hypolipemic,[5] antidiarrheal,[6] antioxidant and radical-scavenging,[7] and antimicrobial activities.[8]

A preliminary screening assay exhibited that the *n*-butanol-soluble fraction from the leaves of *M. koenigii* inhibited hepatoprotective activities, which prompted us to further investigate its constituents. As a result, 22 compounds (Figure 1), including three new sesquiterpenes (**1**−**3**) and two new rutinosides (**4** and **5**) along with 17 known compounds (**6**−**22**), were isolated from the active fraction of *M. koenigii*. Their structures (Figure 1) were elucidated by extensive analysis of their spectroscopic data. Meanwhile, we evaluated their hepatoprotective activities against D-galactosamine-induced WB-F344 cell damage and found that compounds **1**, **4**, **5**, **18**, and **21** (10 *μ*M) showed moderate hepatoprotective activities.

MATERIALS AND METHODS

General Experimental Procedures. The optical rotations were measured on a PerkinElmer 241 polarimeter at 20 °C.[9] Melting points were recorded on a XT5B microscopic melting point apparatus (Beijing Tech Electro-Optical Instrument Factory, China), which was uncorrected.[10] The circular dichroism (CD), infrared (IR), and ultraviolet (UV) spectra were measured with a JASCO J-815 CD spectrometer, a Nicolet 5700 FTIR microscope spectrometer, and a Hitachi UV-240 spectrophotometer, respectively.[11] Nuclear magnetic resonance (NMR) spectra were recorded on Varian Mercury-300 and Inova-500 spectrometers, with tetramethylsilane (TMS) as an internal standard. The high-resolution electrospray ionization mass spectrometry (HRESIMS) data were acquired on an Agilent 1100 series LC/MSD Trap SL mass spectrometer. Reversed-phase high-performance liquid chromatography (HPLC) was performed on a Shimadzu LC-6AD instrument using a SPD-20A detector and a YMC-Pack ODS-A column (250 × 20 mm, 5 *μ*m). Column chromatography was carried out on Sephadex LH-20 (Amersham Pharmacia, Sweden), silica gel H, 100−200 and 200−300 mesh (Qingdao Marine Chemical, Inc., Qingdao, China). Thin-layer chromatography (TLC) was performed on pre-coated silica gel GF254 plates, and the spots were visualized under UV light (254 or 356 nm) or spraying with 10% H_2SO_4 in 95% EtOH, followed by heating.[12]

Plant Material. The leaves of *M. koenigii*, family Rutaceae, were collected from Xishuangbanna, Yunnan, China, in August 2010[10] and authenticated by Prof. Lin Ma (Institute of Materia Medica, Beijing, China). A voucher specimen (ID-S-2436) has been deposited in the Herbarium of Institute of Materia Medica, Beijing, China.

Extraction and Isolation. The air-dried leaves of *M. koenigii* (22.50 kg) were extracted 3 times with 95% EtOH (3 × 20 L) heating under reflux to give 2.10 g of crude extract. The combined extracts were successively partitioned with $CHCl_3$, EtOAc, and *n*-butanol to yield three fractions: $CHCl_3$-soluble fraction (33.50 g), EtOAc-soluble fraction (24.90 g), and *n*-butanol-soluble fraction (221.20 g).

The *n*-butanol-soluble fraction was subjected to the macroporous adsorbent resin (Diaion-101) column, which were eluted with 20, 40, 60, and 95% ethanol to obtain four fractions: A (25.50 g), B (30.60 g),

C (12.80 g), and D (5.40 g). The A part was purified on a Sephadex LH-20 column with a gradient system of MeOH/H_2O to give two sub-fractions: A-a and A-b. The separation of A-b (6.40 g) by medium-pressure liquid chromatography (MPLC) (10−30% MeOH−H_2O) and preparative HPLC (detection at 205 nm, 7 mL/min),[9] successively, yielded compounds **4** (9.00 mg), **5** (7.00 mg), and **22** (7.00 mg). Similarly, the B part was chromatographed over Sephadex LH-20 eluted with MeOH to give two sub-fractions: B-a and B-b. The separation of B-a (3.65 g) by MPLC (15−40% MeOH−H_2O) and preparative HPLC (detection at 205 nm, 7 mL/min), successively, yielded compounds **3** (10.00 mg), **13** (4.00 mg), **14** (10.31 mg), and **16** (11.76 mg). The separation of B-b (12.50 g) by MPLC (20−50% MeOH−H_2O) and preparative HPLC (detection at 205 nm, 7 mL/min), successively, yielded compounds **1** (6.51 mg), **2** (7.40 mg), **6** (3.10 mg), **7** (3.30 mg), **8** (4.70 mg), **9** (9.53 mg), **10** (12.30 mg), **11** (3.44 mg), **12** (6.63 mg), **15** (16.23 mg), **17** (18.43 mg), **18** (10.60 mg), **19** (5.43 mg), **20** (6.10 mg), and **21** (12.31 mg).

(3R,5S,6R)-3,5,6-Trihydroxy-1,1,5-trimethylcyclohexyl-8-butyn-9-one (1). White amorphous power. $[\alpha]_D^{20}$ −2.48 (*c* 0.08, MeOH). Melting point (mp): 153.4−154.9 °C. HRESIMS: *m*/*z* 263.1264 (calcd for $C_{13}H_{20}O_4Na$, 263.1254). UV (MeOH) λ_{max}: 201, 264 nm. CD (MeOH): 314 ($\Delta\varepsilon$, +0.33), 263 ($\Delta\varepsilon$, −2.04) nm. *1-O-β-D-Rutinosyl-2(R)-ethyl-1-pentanol (**5**).* White amorphous power. $[\alpha]_D^{20}$ −1.55 (*c* 0.50, MeOH). mp: 143.3−145.6 °C. HRESIMS: *m*/*z* 447.2214 (calcd for $C_{19}H_{36}O_{10}Na$, 447.2201). UV (MeOH) λ_{max}: 203 nm. CD (MeOH): 242 ($\Delta\varepsilon$, −0.04) nm. IR ν_{max}: 3384.6, 2928.8, 1362.8 cm^{-1}. ^{1}H NMR (CD_3OD, 300 MHz) and ^{13}C NMR (CD_3OD, 125 MHz) data: see Table 3.

Hepatoprotective Assay. We evaluated the hepatoprotective activities of compounds **1**−**22** (Figure 1), which were tested against D-galactosamine-induced toxicity in WB-F344 cells using a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) colorimetric method.[8] The WB-F344 cell lines were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 3% fetal calf serum, 100 units/mL penicillin, and 100 units/mL streptomycin in 5% CO_2 and incubated at 37 °C, which were placed in a 96-well microplate and precultured for 24 h.[13]

After this, the cultured cells were measured for cytotoxic effects, which were exposed to 40 mM D-galactosamine after 24 h. At last, the medium was replaced with the surum-free medium (0.5 mg/mL MTT) for 3.5 h of incubation. After removal of the medium and the addition of DMSO (150 μL/well) into the microplate, the formazan crystals were redissolved.[13] The optical density (OD) was measured by a microplate reader at a wavelength of 492 nm, and the inhibition was calculated as inhibition (%) = $[(OD_{(sample)} - OD_{(control)})/(OD_{(normal)} - OD_{(control)})] \times 100$.[16]

Statistical Analysis. Compounds **1**−**22** were bioassayed with the bicyclol (hepatoprotective activity drug) as the positive control for their hepatoprotective activities against D-galactosamine-induced toxicity in WB-F344 cells.[14] The results of pharmacological activities are shown in Table 4, with the inhibition (%) of compounds **1**, **4**, **5**, **18**, and **21** based on the computing formula with values of 43.7, 54.3, 45.1, 27.0, and 49.5, respectively. Furthermore, all of the values were expressed as means ± standard deviation (SD) of three experiments. The significance of unpaired observations between normal or control and tested samples was determined by Student's *t* test.[16] Differences were considered significant at $p < 0.05$.[15] Therefore, compounds **1**, **4**, **5**, **18**, and **21** exhibited moderate hepatoprotective activities.

RESULTS AND DISCUSSION

Structure Elucidation of New Compounds. Compound **1** was obtained as a white amorphous power. Its molecular formula was deduced as $C_{13}H_{20}O_4$ from the analysis of its HRESIMS at *m*/*z* 263.1264 (calcd for $C_{13}H_{20}O_4Na$, 263.1254) corresponding to four degrees of unsaturation. The UV spectrum showed the adamantane-type sesquiterpene absorp-

18	60.2 ± 0.2[b]	27.0
21	72.5 ± 8.5[b]	49.5

[a]Results were expressed as means ± SD (n = 3; for normal and control, n = 6). Bicyclol was used as a positive control (10 μM). [b]p < 0.05.

tions at λ_{max} 201 and 264 nm.[17] Its IR spectrum indicated the presence of hydroxy (3454.9 cm^{-1}), carbonyl (1670.8 cm^{-1}), and methyl (1381.7 cm^{-1}) functionalities.

The ^{1}H NMR spectrum of compound **1** showed the presence of a multiplet at δ_H 4.08 (1H, m, H-3) and three methyl group singlets at δ_H 1.31 (3H, s), 0.96 (3H, s), and 0.79 (3H, s) (Table 1). These spectral characteristics coupled with the biosynthetic pathway (biogenetic isoprene rule) indicated the presence of the adamantane-type sesquiterpene[18] skeleton in compound **1**. The ^{13}C NMR spectrum (Table 1) showed 13 carbon signals. Besides one carbonyl (δ_C 191.6), four methyl carbons, and two sp-hybridized carbons, the remaining six sp^3-hybridized carbons were attributed to the cyclohexane. The planar structure of compound **1** was established on the basis of the correlations of H-2/C-1, C-3, C-4, and C-6; H-4/C-2, C-3, and C-6; and 10-CH_3/C-8 (Figure 2) in the heteronuclear multiple-bond correlation (HMBC) spectrum, and its relative configuration was determined by the correlations of H-3/5-OH and 3-OH/13-CH_3 (Figure 2) in the nuclear Overhauser effect spectrometry (NOESY) spectrum.

The absolute configuration of compound **1** was determined by the CD method. Because the $Mo_2(OAc)_4$-induced CD method has been successfully used to determine the absolute configuration of dozens of organic compounds with a 1,2-diol substructure,[19] we study the $Mo_2(OAc)_4$-induced CD spectrum of compound **1**, which contained a 5,6-diol unit. A positive Cotton effect was observed at 314 nm in the CD spectrum, and the absolute configurations of C-5 and C-6 were determined as 5*S* and 6*R*, respectively, by applying the spiral rule.[19] In addition, according to the correlations of the NOESY spectrum, the absolute configuration of C-3 was deduced as 3*R*. Thus, compound **1** was identified as (3*R*,5*S*,6*R*)-3,5,6-trihydroxy-1,1,5-trimethylcyclohexyl-8-butyn-9-one.

Compound **2** was isolated as a white amorphous power. The molecular formula was deduced as $C_{15}H_{26}O_5$ from HRESIMS at m/z 309.1648 (calcd for $C_{15}H_{26}O_5Na$, 309.1672), indicating three degrees of unsaturation. Its UV spectrum showed absorbance at λ_{max} 203 nm, and the IR spectrum indicated the presence of hydroxy (3392.5 cm^{-1}), carbonyl (1737.5 cm^{-1}), and methyl (1368.3 cm^{-1}) functionalities. The UV and IR spectrum data of compound **2** were similar to those of compound **1**. Therefore, compound **2** was concluded to be an adamantane-type sesquiterpene.[17]

The ^{1}H NMR spectrum of compound **2** showed the presence of a multiplet at δ_H 3.77 (1H, m, H-3) and three methyl group singlets at δ_H 0.97 (3H, s), 0.84 (3H, s), and 0.79 (3H, s)

dx.doi.org/10.1021/jf5005034 | J. Agric. Food Chem. 2014, 62, 4145−4151

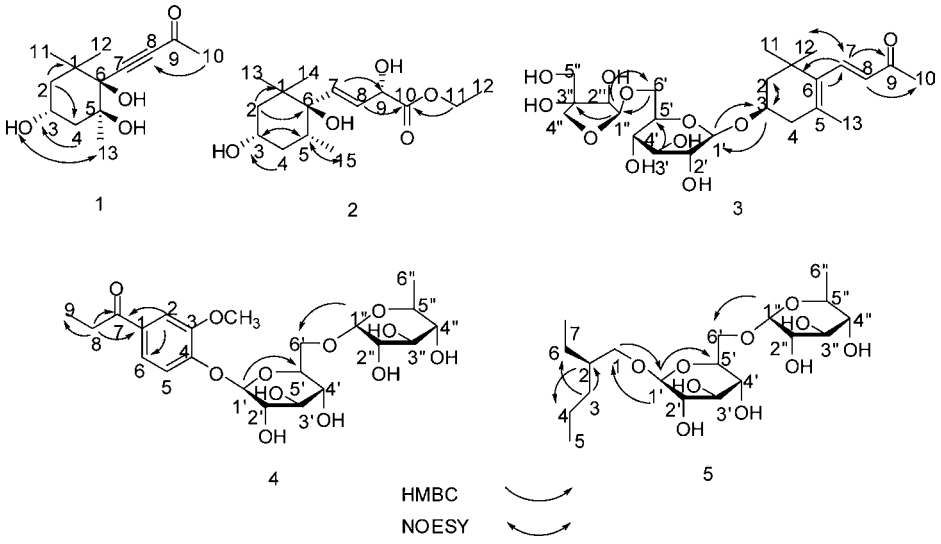

Figure 2. Key HMBC (H → C) and NOESY correlations of compounds **1**−**5**.

(Table 1). The above data suggested that compound **2** possessed the adamantane-type sesquiterpene skeleton.[20] A trans-double bond at δ_H 5.83 (1H, d, J = 16.5 Hz, H-7) and 5.81 (1H, d, J = 16.5 Hz, H-8) and a $-CH_2CH_3$ fragment at δ_H 4.16 (2H, dd, J = 14.1 and 6.6 Hz) and 1.22 (3H, t, J = 14.1 and 6.6 Hz) were observed in the ^{1}H NMR spectrum of compound **2**. The ^{13}C NMR spectrum (Table 1) showed 15 carbon signals consisting of one carbonyl (δ_C 173.8), two trans-double bond carbons, six saturated carbons of the cyclohexane, etc. Moreover, the structure of compound **2** was determined by the HMBC correlations of H-2/C-1, C-3, C-4, and C-6; H-4/C-2, C-3, C-5, and C-6; H-5/C-1 and 15-CH_3; H-7/C-6, C-8, and C-9; H-8/C-7, C-9, and C-10; and H-9/C-10 (Figure 2) and the NOESY correlations of H-3/H-5 and H-5/15-CH_3.

The absolute configurations of C-3, C-5, and C-6 were determined as 3*S*, 5*R*, and 6*S*, respectively, by biosynthetic considerations and the literature.[20] In addition, the absolute configuration of C-9 was determined as 9*R* on the basis of a negative Cotton effect at 222 nm in the CD spectrum.[20] Hence, compound **2** was identified as (8*E*,9*R*)-ethyl-7-(3*S*,5*R*,6*S*)-3,6-dihydroxy-1,1,5-trimethylcyclohexyl-9-hydroxybut-8-enoate.

Compound **3** was obtained as a white amorphous power. Its molecular formula was deduced as $C_{24}H_{38}O_{11}$ based on HRESIMS at m/z 525.2323 (calcd for $C_{24}H_{38}O_{11}Na$, 525.2306), indicating six degrees of unsaturation. The UV spectrum showed absorptions at λ_{max} 203, 221, and 291 nm. Its IR spectrum displayed absorptions of hydroxy (3318.6 cm^{-1}), carbonyl (1667.0 cm^{-1}), and methyl (1373.2 cm^{-1}) functionalities.

The ^{1}H NMR spectrum of compound **3** showed a multiplet at δ_H 4.11 (1H, m, H-3) and three methyl groups singlet at δ_H 1.17 (3H, s), 1.14 (3H, s), and 1.82 (3H, s), which revealed the typical characteristic of the adamantane-type sesquiterpene skeleton.[20] In the aromatic field, the signals at δ_H 7.37 (1H, d, J = 16.2 Hz, H-7) and 6.18 (1H, d, J = 16.2 Hz, H-8) suggested the existence of a trans-double bond. Moreover, two anomeric protons resonated at δ_H 4.46 (1H, d, J = 7.8 Hz, H-1′) and 5.02 (1H, d, J = 3.9 Hz, H-1″) indicated the presence of glucosyl and apiosyl moieties[21] in compound **3** according to the data of ^{1}H and ^{13}C NMR spectra (Table 2). The structure of compound **3** was established on the HMBC correlations of H-2/C-1, C-3, C-4, and C-6; H-3/C-1′; H-4/C-2, C-3, and C-6; H-7/C-1, C-5, C-8, and C-9; H-8/C-6, C-9, and C-10; 10-CH_3/C-9; H-1′/C-3; and H-1″/C-6′ (Figure 2) and the NOESY correlations of H-2/H-3 and H-3/H-4.

The absolute configuration of C-3 was determined by the CD method. First, compound **3** was hydrolyzed[22] to afford the aglycone **3a**. The positive Cotton effect at 276 nm and the negative Cotton effect at 322 nm were observed in the CD spectrum of compound **3a**. According to the spiral rule and the literature,[23] the absolute configuration of C-3 was determined as 3*R*. Therefore, compound **3** was identified as (3*R*)-3-*O*-*β*-D-glucoside-6′-D-apiose-*β*-ionone.

Compound **4** was obtained as a white amorphous power. Its molecular formula was established as $C_{22}H_{32}O_{12}$ on the basis of HRESIMS at m/z 511.1797 (calcd for $C_{22}H_{32}O_{12}Na$, 511.1786) corresponding to four degrees of unsaturation. The UV spectrum showed absorptions at λ_{max} 203, 222, 266, and 301 nm. Its IR spectrum displayed the presence of hydroxy (3399.3 cm^{-1}) and benzene ring (1671.8, 1592.9, and 1512.1 cm^{-1}) functionalities.

In the ^{1}H NMR spectrum of compound **4**, an ABX system was shown at δ_H 7.61 (1H, d, J = 1.8 Hz, H-2), 7.22 (1H, d, J = 8.4 Hz, H-5), and 7.70 (1H, dd, J = 8.4, 1.8 Hz, H-6) in the aromatic field. The anomeric signals at δ_H 5.03 (1H, d, J = 7.2 Hz, H-1′) and 4.69 (1H, d, J = 1.8 Hz, H-1″) suggested the existence of a rutinosyl moiety[24] in compound **4** according to the ^{1}H and ^{13}C NMR spectra (Table 3). Additionally, a quartet at δ_H 3.07 (2H, dd, J = 14.4 and 7.2 Hz, H-8) and a triplet at δ_H 1.20 (1H, t, J = 7.2 and 3.6 Hz, H-9) were displayed in the ^{1}H NMR spectrum, which suggested the presence of the $-CH_2CH_3$ fragment in compound **4**. The structure of compound **4** was determined by the HMBC correlations of H-2/C-4, C-6, and C-7; H-5/C-1, C-3, and C-4; H-6/C-4, C-5, and C-7; H-8/C-7 and C-9; H-1′/C-3′, C-4, and C-5′; and H-1″/C-2″ and C-6′ (Figure 2). Consequently, compound **4** was identified as 4-*O*-*β*-D-rutinosyl-3-methoxyphenyl-1-propanone.

Compound **5** was isolated as a white amorphous power. Its molecular formula was deduced as $C_{19}H_{36}O_{10}$ from HRESIMS data at m/z 447.2214 (calcd for $C_{19}H_{36}O_{10}Na$, 447.2201), implying two degrees of unsaturation. The UV spectrum showed absorption at λ_{max} 203 nm, and the IR spectrum indicated the presence of hydroxy (3384.6 cm^{-1}) and methyl (2928.8 and 1362.8 cm^{-1}) functionalities.

dx.doi.org/10.1021/jf5005034 | J. Agric. Food Chem. 2014, 62, 4145−4151

In comparison of the ^{1}H NMR data of compounds **5** and **4**, compound **5** also had two typical doublets at δ_H 4.25 (1H, d, J = 7.5 Hz, H-1′) and 5.02 (1H, d, J = 1.8 Hz, H-1″) in the ^{1}H NMR spectrum and a rutinosyl[24] was concluded in compound **5** by the ^{1}H and ^{13}C NMR spectra (Table 3). Moreover, some typical signals at δ_H 4.06 (2H, d, J = 2.1 Hz, H-1), 1.60 (1H, m, H-2), 0.87 (3H, s, 5-CH_3), and 0.89 (3H, s, 7-CH_3) were observed in the ^{1}H NMR spectrum, which concluded the 2-ethyl-2-pentanol fragment in compound **5** according to correlations of H-2/C-4; H-3/C-2 and C-6; and H-6/C-2 and C-3 in the HMBC spectrum. Finally, the planar configuration of compound **5** was determined by the HMBC correlations of H-1/C-1′; H-1′/C-1, C-3′, and C-5′; and H-1″/C-3″ and C-6′ (Figure 2).

Acid hydrolysis of compound **5** afforded the aglycone **5a**,[25] and the 2*R* chirality of **5a** was deduced from the optical value $[\alpha]_D^{20}$ −3.20 (*c* 0.10, MeOH) by comparing to ref 26. Therefore, compound **5** was identified as 1-*O*-*β*-D-rutinosyl-2(*R*)-ethyl-1-pentanol.

In addition, 17 known compounds were isolated and identified as (*R*)-(−)-dehydrovomifoliol (**6**),[27] blumenol C (**7**),[28] blumenol A (**8**),[29] icariside B1(**9**),[30] icariside B1 aglycone (**10**),[31] (3*S*,5*R*,6*R*,8*E*)-3,5,6-trihydroxy-1,1,5-trimethylcyclohexyl-8-buten-9-one (**11**),[32] (4*R*)-4-hydroxy-2,6,6-trimethyl-1-cyclohexene-1-methanol (**12**),[33] (8*E*)-3(*R*)-*O*-*β*-D-glucopyranosyloxy-1,5,5-trimethyl-7-cyclohexen-8-buten-7-one (**13**),[34] 3*β*-glucopyranosyloxy-*β*-ionone (**14**),[35] 3*β*-hydroxy-5*α*,6*α*-epoxy-7-megastigmen-9-one (**15**),[36] 3-*O*-*β*-D-glucopyranosyloxy-5*α*,6*α*-epoxy-7-megastigmen-9-one (**16**),[37] loliolide (**17**),[38] (−)-epiloliolide (**18**),[39] (3*R*,6*R*,7*E*)-3-hydroxy-*α*-ionone (**19**),[38] 5,6-dihydrovomifoliol (**20**),[40] (3*S*,9*R*)-9-hydroxy-7-butynyl-1,1,5-trimethyl-5-cyclohexen-3-ol (**21**),[41] and 8-phenylethyl-*O*-*β*-D-rutinoside (**22**)[24] by comparison of their physical and spectroscopic data to those reported in the references. Among them, compounds **6**−**21** belonged to sesquiterpenes and compound **22** belonged to rutinosides.

Acid Hydrolysis of Compounds 3−5. Compounds **3**−**5** (4 mg) were each treated in 5% HCl (0.5 mL) and heated at 90 °C for 2 h.[42] After cooling, each reaction mixture was extracted with EtOAc, and the aqueous layer was neutralized with 0.1 M NaOH. Therefore, glucose and apiose were obtained from compound **3**, which was detected by TLC with authentic sugars. Similarly, we obtained glucose and rhamnose from compounds **4** and **5**. The types of these sugars were identified by the TLC method.[43] Under the condition of 14:6:1 $CHCl_3$/MeOH/H_2O (Kieselgel 60 F_{254} plate), the R_f values of glucose, apiose, and rhamnose were 0.13, 0.31, and 0.24, respectively. Meanwhile, the R_f values (6:4:3 *n*-BuOH/pyridine/H_2O, Cellulose 60 F plate) of glucose, apiose, and rhamnose were 0.37, 0.55, and 0.47, respectively.

Hepatoprotective Activities. Compounds **1**−**22** were evaluated for their hepatoprotective activities against D-galactosamine-induced WB-F344 cell damage. Among of them, compounds **1**, **4**, **5**, **18**, and **21** (10 μM) exhibited moderate hepatoprotective activities (Table 4).

ABSTRACT: Cell migration plays an important role in angiogenesis and wound repair. Vascular endothelial growth factor (VEGF) is an endothelial cell-specific mitogen that is essential for endothelial cell survival, proliferation, and migration. Docosahexaenoic acid (DHA), an n-3 polyunsaturated fatty acid, shows both anti-inflammatory and antioxidant activities in vitro and in vivo. This study investigated the molecular mechanism by which DHA down-regulates VEGF-induced cell migration. HUVECs were used as the study model, and the MTT assay, Western blot, wound-healing assay, and phosphatase activity assay were used to explore the effects of DHA on cell migration. GPR120 is the putative receptor for DHA action. The results showed that DHA, PD98059 (an ERK1/2 inhibitor), and GW9508 (a GPR120 agonist) inhibited VEGF-induced cell migration. In contrast, pretreatment with okadaic acid (OA, a PP2A inhibitor) and *S*-nitroso-*N*-acetyl-DL-penicillamine (an NO donor) reversed the inhibition of cell migration by DHA. VEGF-induced cell migration was accompanied by phosphorylation of ERK1/2 and eNOS. Treatment of HUVECs with DHA increased PP2A enzyme activity and decreased VEGF-induced phosphorylation of ERK1/2 and eNOS. However, pretreatment with OA significantly decreased DHA-induced PP2A enzyme activity and reversed the DHA inhibition of VEGF-induced ERK1/2 and eNOS phosphorylation. These results suggest that stimulation of PP2A activity and inhibition of the VEGF-induced ERK1/2/eNOS signaling pathway may be involved in the DHA suppression of VEGF-induced cell migration. Thus, the effect of DHA on angiogenesis and wound repair is at least partly by virtue of its attenuation of cell migration.

KEYWORDS: *cell migration, docosahexaenoic acid (DHA), human umbilical vein endothelial cells (HUVECs), nitric oxide (NO), vascular endothelial growth factor (VEGF)*

INTRODUCTION

Docosahexaenoic acid (DHA, 22:6, n-3) is enriched in fatty fish and fish oil supplements and is well-known for its anti-inflammatory,[1] immunomodulatory,[2] and anticancer[3] properties. Cancer is among the leading causes of death in both economically developed countries and developing countries.[4] Epidemiological studies show that a diet rich in n-3 polyunsaturated fatty acids (PUFAs) is correlated with reduced risk of angiogenic diseases such as cancers.[5,6] DHA has been shown to inhibit vascular sprout formation in retinal microvascular endothelial cells.[7] However, the mechanism underlying the inhibition of cell migration by DHA, which is critical for angiogenesis and wound repair, is not fully understood.

G protein-coupled receptors (GPRs) are important signaling molecules involved in many cellular functions. Specific ligand binding to GPRs stimulates and induces a variety of cellular responses via several second messenger pathways, for example, regulation of cAMP generation, the phospholipase C pathway, ion channels, and mitogen-activated protein kinases.[8−10] In a previous study, Oh et al.[11] found that DHA exerted potent anti-inflammatory effects through GPR120.

Angiogenesis, the process of the formation of new blood vessels by sprouting of the preexisting microvascular network, is involved in numerous physiological processes including embryogenesis, tissue remodeling, wound healing,[12] and disease development such as diabetic retinopathy, rheumatoid arthritis, tumor growth, and growth of atherosclerotic plaques.[13] Angiogenesis is controlled by vascular endothelial growth factor (VEGF), a pro-angiogenic factor.[14] VEGF-induced signal transduction involves binding to tyrosine kinase receptors, which leads to endothelial cell proliferation, migration, and new vessel formation.[15] VEGF was reported to induce a wide variety of signaling pathways, including protein kinase C, phospholipase C-γ, extracellular signal-regulated kinase (ERK), p38 MAPK, phospholipase C, and phosphatidyl inositol 3-kinase (PI3K)/Akt.[16] Hence, it is critical to understand the VEGF-activated signaling pathways that play an important role in VEGF-mediated cell processes.

Nitric oxide (NO), which is synthesized from the amino acid L-arginine by the NOS family of enzymes, is a gaseous molecule

with a wide range of physiological and pathophysiological activities, including the regulation of angiogenesis.[17] The NOS family is composed of three members: neuronal NOS (nNOS), endothelial NOS (eNOS), and inducible NOS (iNOS). eNOS is constitutively expressed in endothelial cells, but various physical and chemical stimuli affect eNOS levels in vivo and in vitro.[18] Moreover, eNOS is activated upon exposure to fluid shear stress and numerous agonists via cellular events such as protein phosphorylation.

Protein phosphatase 2A (PP2A) is a heterotrimeric complex composed of three subunits including a structural subunit (PP2A-A), a regulatory subunit (PP2A-B), and a catalytic subunit (PP2A-C).[19] PP2A is a crucial intracellular serine/threonine phosphatase.[20] In addition, PP2A plays a significant role in the regulation of specific signal transduction cascades including ERK1/2,[21] JNK,[22] and p38 MAPK.[23] In recent years, PP2A was shown to have tumor suppressor activity in myeloid CML-BC patient-derived mononuclear marrow cells.[24] Thus, enhancement of PP2A tumor suppressor activity may represent a potential therapeutic strategy for malignancy.

The antitumor effect of DHA has been studied in MCF-7 human breast cancer cells by induction of heme oxygenase 1 and inhibition of TPA-induced matrix metalloproteinase 9 (MMP-9) expression.[3] Moreover, DHA was reported to have a potent anti-angiogenic effect.[25] The pro-angiogenic effect of VEGF and NO has also been demonstrated.[15] In this study, therefore, we investigated whether DHA has an opposing effect on cell migration that is associated with angiogenesis and wound repair and the possible mechanisms involved.

MATERIALS AND METHODS

Reagents. Medium 199 (M199), Dulbecco's modified Eagle's medium, 0.25% trypsin−EDTA, and penicillin−streptomycin−amphotericin solution were from GIBCO-BRL (Grand Island, NY, USA); endothelial cell growth supplement (ECGS) was from Upstate Biotechnology (Lake Placid, NY, USA); fetal bovine serum (FBS) was from HyClone (Logan, UT, USA); DHA was from Cayman Chemical (Ann Arbor, MI); 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, sodium bicarbonate, heparin, gelatin, *S*-nitroso-*N*-acetyl-DL-penicillamine (SNAP, NO donor), LY294002 (PI3K kinase inhibitor), GW9508 (GPR120 agonist), and antibody against β-actin were from Sigma-Aldrich (St. Louis, MO, USA); VEGF was from Peprotech (Rocky Hill, NJ, USA); okadaic acid (OA) was from Millipore (Darmstadt, Germany); PD98059 (ERK1/2 inhibitor) was from TOCRIS (Ellisville, MO, USA); and antibodies against ERK1/2, phospho-ERK1/2, eNOS, and phospho-eNOS were from Cell Signaling Technology (Danvers, MA, USA).

Cell Cultures. The human umbilical vein endothelial cell line (HUVEC; CC-2517) was obtained from Clonetics (San Diego, CA, USA) and was cultured on gelatin-coated cell culture dishes in M199 supplemented with 2.2 g/L sodium bicarbonate ($NaHCO_3$), 0.1 g/L heparin, 37.5 mg/L ECGS, 20% FBS, 100,000 units/L penicillin, 0.25 mg/mL amphotericin, and 100 mg/L streptomycin at 37 °C in a 5% CO_2 humidified incubator.

DHA Preparation. DHA samples were prepared as described previously.[1]

Cell Viability Assay. Cell viability was assessed by the MTT assay. The MTT assay measures the ability of viable cells to reduce a yellow 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide to a purple formazan by mitochondrial succinate dehydrogenase. HUVECs were grown to 80−90% confluence and then treated with various concentrations of DHA (0−200 μM) and GW9508 (1−10 μM) with or without VEGF (50 ng/mL) for 8 h in M199 containing 2% FBS. Finally, the medium was removed, and the cells were washed with phosphate-buffered saline (PBS). The cells were then incubated with MTT (0.5 mg/mL) in M199 medium at 37 °C for an additional 3 h. The medium was removed, and 2-propanol was added to dissolve the formazan. After centrifugation at 10000*g* for 5 min, the supernatant of each sample was transferred to 96-well plates, and absorbance was read at 595 nm in an ELISA reader. The absorbance in the control group was regarded as 100% cell viability.

Western Blotting Analysis. After each experiment, cells were washed twice with PBS and were harvested with 150 μL of lysis buffer (10 mM Tris-HCl, pH 8.0, 0.1% Triton X-100, 320 mM sucrose, 5 mM EDTA, 1 mM PMSF, 1 mg/L leupeptin, 1 mg/L aprotinin, and 2 mM DTT). Cell homogenates were centrifuged at 14000*g* for 20 min at 4 °C. The resulting supernatant was used as a cellular protein for Western blotting analysis. The total protein was analyzed by use of the Coomassie Plus protein assay reagent kit (Pierce Biotechnology Inc., Rockford, IL, USA). Equal amounts of cellular proteins were electrophoresed in a sodium dodecyl sulfate (SDS)−polyacrylamide gel, and proteins were then transferred to polyvinylidene fluoride membranes (Millipore Corp., Bedford, MA, USA). Nonspecific binding sites on the membranes were blocked with 5% nonfat milk in 15 mM Tris/150 mM NaCl buffer (pH 7.4) at room temperature for 2 h. Membranes were probed with anti-ERK1/2, antiphospho-ERK1/2, anti-eNOS, antiphospho-eNOS, and anti-β-actin. The membranes were then probed with the secondary antibody labeled with horseradish peroxidase. The bands were visualized by using an enhanced chemiluminescence kit (PerkinElmer Life Science, Boston, MA, USA) and were scanned by use of a luminescence image analyzer (LAS-4000, FUJIFILM, Japan). The bands were quantitated with ImageGauge software (FUJIFILM).

Cell Migration Assay. An in vitro wound-healing assay was used to measure directional endothelial cell migration. HUVECs were seeded onto gelatin-coated 6-well plates and allowed to form a confluent monolayer. Monolayers were wounded by using a sterile 200 μL pipet tip, washed with PBS to remove floating cells, and photographed (time 0). Cells were then cultured in M199 medium containing 2% FBS and 50 ng/mL VEGF. Meanwhile, the cells were treated with various concentrations of DHA (0−100 μM) with or without SNAP (20 μM) or OA (10 nM) for 8 h. In addition, the cells were treated with GW9508 (10 μM) for 8 h. Cells were then photographed (100× magnification) to monitor cell migration into the wounded area, and the width of the cell-free zone (distance between the edges of the injured monolayer) was calculated.

PP2A Activity Assay. PP2A activity was determined by use of a Ser/Thr phosphatase assay kit according to the instructions of the manufacturer (Upstate, Darmstadt, Germany). After treatment, cells were scraped with lysis buffer (10 mM tris/Triton X-100, 0.32 M sucrose, 5 mM EDTA) and protease inhibitors, sonicated for 10 s, and centrifuged at 2000*g* for 5 min. Thereafter, phosphopeptide (K-R-pT-I-R-R) was added to the cell lysate, followed by incubation at room temperature for 15 min, and then Malachite Green phosphate was added and the reaction was allowed to proceed at room temperature for another 15 min for color development. The relative absorbance was measured at 650 nm in a microplate reader (Bio-Rad).

Statistical Analysis. Data were analyzed by using analysis of variance (SAS Institute, Cary, NC, USA). The significance of the difference between mean values was determined by one-way analysis of variance followed by Tukey's test. p values <0.05 were taken to be statistically significant.

RESULTS

Effect of DHA and GW9508 on Cell Viability in the Presence or Absence of VEGF. As measured by the MTT assay, the cell viabilities of HUVECs treated with VEGF alone; 50, 100, or 200 μM DHA; or VEGF and 50, 100, or 200 μM DHA were 110.5 ± 6.6, 92.9 ± 1.2, 92.4 ± 2.7, 12.1 ± 2.5, 103.6 ± 7.4, 98.5 ± 7.8, and 11.8 ± 0.8%, respectively, compared with the unstimulated controls (100%). Thus, there were no adverse effects on the growth of cells up to a concentration of 100 μM DHA in the presence or absence of 50 ng/mL VEGF, which was used to induce cell migration. The

highest concentration of DHA used in the present study was 100 μM.

The cell viabilities of HUVECs treated with VEGF alone, 1 or 10 μM GW9508, or VEGF and 1 or 10 μM GW9508 were 116.3 ± 5.8, 97.6 ± 3.5, 99.1 ± 2.5, 107.6 ± 4.5, and 107.0 ± 7.3%, respectively, compared with the unstimulated controls (100%). Thus, there were no adverse effects on the growth of cells up to a concentration of 10 μM GW9508 in the presence or absence of 50 ng/mL VEGF.

DHA Inhibits VEGF-Induced Cell Migration of HUVECs. Endothelial cell migration is necessary to angiogenesis and wound repair. In addition to activation by chemotactic, hepatotactic, and mechanotactic stimuli, angiogenesis involves degradation of the extracellular matrix by matrix metalloproteinases (MMPs) to enable progression of the migrating cells.[26] Moreover, at least 10 MMPs are up-regulated during wound healing by epidermal, dermal, fibroblast, and blood cells in mammals.[27] To determine the effect of DHA on endothelial cell migration in vitro, confluent monolayers of HUVECs were scratched and cultured with M199 medium containing 2% FBS plus 50 ng/mL VEGF alone or in addition to 100 μM DHA. As shown in Figure 1, VEGF significantly induced cell migration, whereas coculture with DHA inhibited the VEGF-induced cell migration ($p < 0.05$).

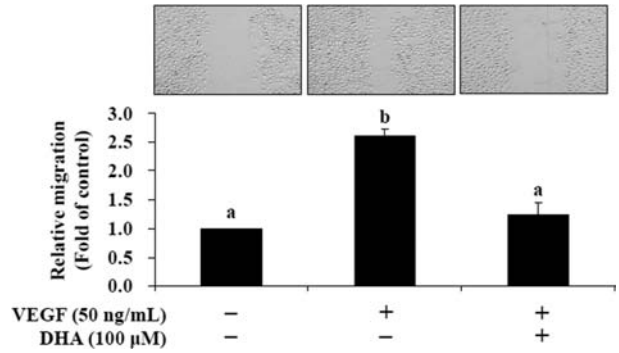

Figure 1. DHA inhibits VEGF-induced migration of HUVECs. Cells were scratched and then stimulated with 50 ng/mL VEGF in the presence or absence of 100 μM DHA for 8 h. Migration was observed by using a phase-contrast microscope, at 100× magnification. Values are the mean ± SD, $n = 3$. Values not sharing the same letter are significantly different ($p < 0.05$).

Phosphorylation of ERK1/2 and eNOS Is Involved in VEGF-Induced Cell Migration. VEGF has been shown to induce a wide variety of signaling pathways that transduce the physiological or pathophysiological activities of VEGF. ERK1/2 is one such pathway. It has been shown that there is a relationship between ERK1/2 phosphorylation and eNOS activation in rat sinusoidal endothelial cells.[28] Thus, we determined the effect of VEGF on both ERK1/2 and eNOS phosphorylation. As shown in Figure 2A, VEGF stimulated the phosphorylation of ERK1/2 and eNOS, and this activation was abolished by the ERK1/2 inhibitor PD98059. However, VEGF showed no effect on Akt phosphorylation (data not shown). VEGF stimulated cell migration, and this effect was dependent on ERK1/2 (Figure 2B). These results suggested that VEGF stimulation of cell migration is mediated by the ERK1/2/eNOS pathway.

Inhibition of VEGF-Induced Cell Migration by DHA Is Associated with the Induction of PP2A Enzyme Activity and the Inhibition of ERK1/2 and eNOS Phosphorylation. Tumor metastasis, the spreading of the primary tumor to distant organs, is recognized to be one of the major causes of failure in the treatment of cancer.[29] Thus, intervention in a key step in the metastatic process, such as angiogenesis, is an effective mechanism for cancer therapy. VEGF plays a critical role in tumor angiogenesis and has been shown to phosphorylate eNOS on Ser1177 in glomerular endothelial cells.[30] NO produced by activation of eNOS regulates angiogenesis. Dephosphorylation of phosphorylated eNOS is mediated by protein phosphatase 2A (PP2A).[31] In the present study, the role of DHA in VEGF-induced cell migration was studied by using a wound-healing assay. As shown in Figure 3A, DHA inhibited VEGF-induced cell migration, and this inhibition was abolished by treatment with the PP2A inhibitor, OA. These results suggested that DHA inhibition of VEGF-induced cell migration is likely associated with activation of PP2A enzyme activity.

Recently, it was shown that PP2A has tumor suppressor activity in myeloid CML-BC patient-derived mononuclear marrow cells.[24] We used the Ser/Thr phosphatase assay to measure PP2A enzyme activity. As shown in Figure 3B, DHA significantly stimulated PP2A enzyme activity compared with that in the control group, and this activation was attenuated by treatment with OA. We next examined whether OA reversed the DHA inhibition of VEGF-induced ERK1/2 and eNOS phosphorylation. As shown in Figure 3C, VEGF induced phosphorylation of ERK1/2 and eNOS, and pretreatment with DHA attenuated this induction. Nevertheless, pretreatment with OA reversed the inhibition of eNOS phosphorylation by DHA. OA also reversed the attenuation of VEGF-induced ERK1/2 phosphorylation by DHA, although this effect was not significant.

Effect of GPR120 Agonist on VEGF-Induced Phosphorylation of ERK1/2 and eNOS as well as Cell Migration. GPR120 is a physiological receptor for long-chain fatty acids, in particular n-3 fatty acids, such as α-linolenic acid, eicosapentaenoic acid (EPA), and DHA.[11,32] To determine the role of GPR120 in DHA's inhibition of cell migration, we used the GPR120 agonist GW9508. As shown in Figure 4A, GW9508 had an effect similar to that of DHA on the VEGF-induced phosphorylation of ERK1/2 and eNOS. Moreover, the inhibitory effect of DHA on VEGF-induced cell migration was replicated by GW9508 (Figure 4B). These results suggested that the effects of DHA were highly associated with binding to GPR120.

SNAP Reverses DHA Inhibition of VEGF-Induced Cell Migration. VEGF activates eNOS and stimulates the release of NO from HUVECs.[33] Endothelium-derived NO is critical regulator of endothelial cell migration, survival, and angiogenesis.[34] To determine the effect of the NO donor SNAP on endothelial cell migration in vitro, confluent monolayers of HUVECs were scratched and cultured in M199 medium containing 2% FBS plus vehicle, 50 ng/mL VEGF, 100 μM DHA and 50 ng/mL VEGF, or 100 μM DHA, 20 μM SNAP, and 50 ng/mL VEGF, respectively. As shown in Figure 5, SNAP reversed DHA inhibition of VEGF-induced cell migration.

■ DISCUSSION

Cancer has attracted considerable attention in the past decades because it is among the leading causes of death globally.[4] Protection against cancer by DHA is attributed to the anti-

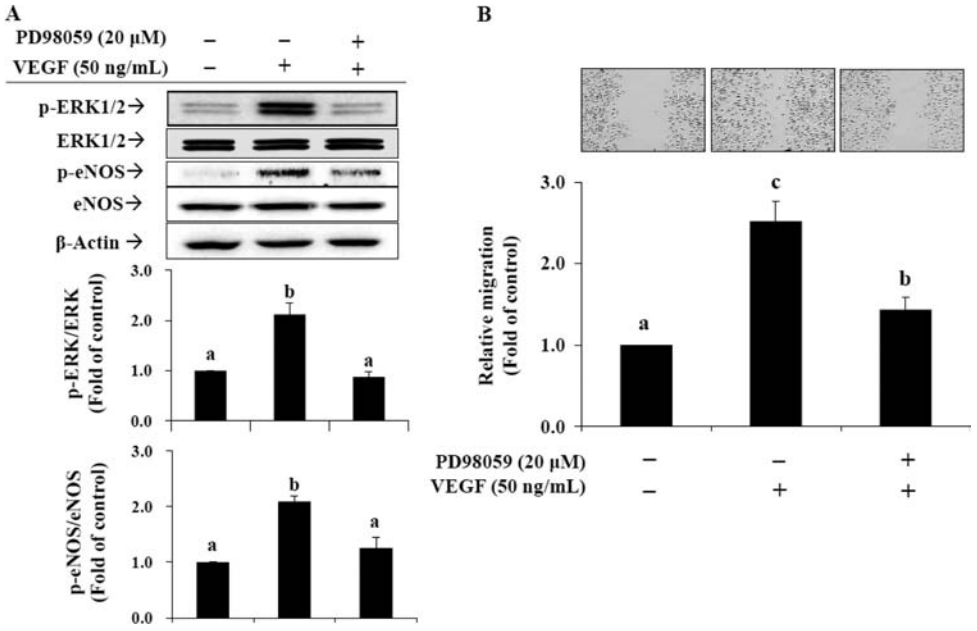

Figure 2. Phosphorylation of ERK1/2 and eNOS is involved in VEGF-induced migration of HUVECs. (A) Cells were starved in M199 containing 2% FBS for 7 h and then pretreated with 20 μM of the ERK1/2 inhibitor PD98059 for 1 h followed by incubation with 50 ng/mL VEGF for another 15 min. (B) Cells were scratched and were cotreated with 20 μM PD98059 and 50 ng/mL VEGF or treated with 50 ng/mL VEGF for 8 h. Values are the mean ± SD, n = 3. Values not sharing the same letter are significantly different (p < 0.05).

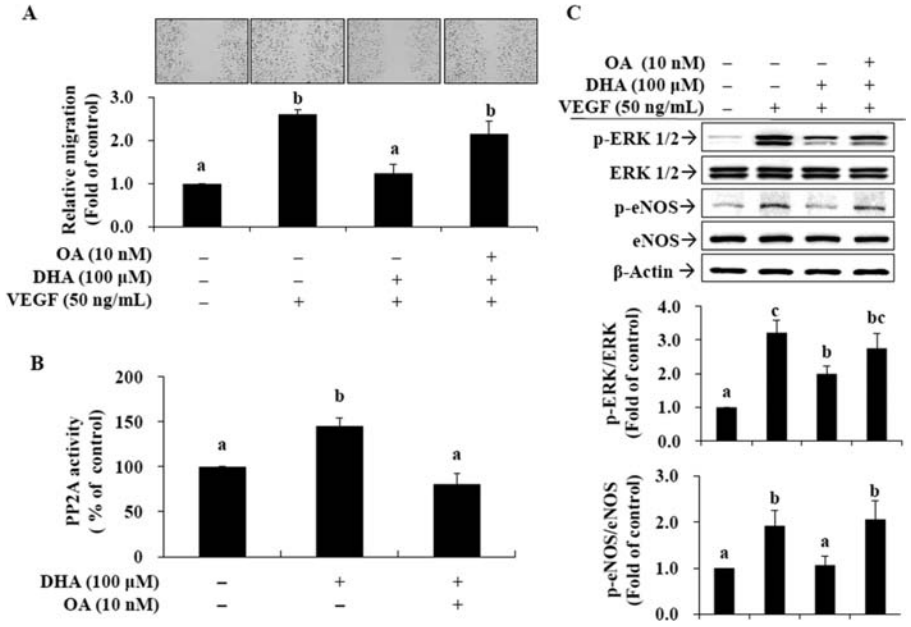

Figure 3. Protein phosphatase 2A (PP2A) is involved in DHA inhibition of VEGF-induced phosphorylation of ERK1/2 and eNOS and cell migration. (A) HUVECs were scratched and pretreated with or without 10 nM of the PP2A inhibitor okadaic acid (OA) for 1 h and were then treated with 100 μM DHA along with 50 ng/mL VEGF or with 50 ng/mL VEGF for another 8 h. (B) HUVECs were pretreated with or without 10 nM OA for 1 h and were then treated with 100 μM DHA for another 4 h. (C) HUVECs were pretreated with 10 nM OA for 1 h and were then treated with 100 μM DHA for 8 h before being challenged with 50 ng/mL VEGF for another 15 min. Values are the mean ± SD, n = 3. Values not sharing the same letter are significantly different (p < 0.05).

angiogenic activity of DHA.[35] However, the mechanisms by which DHA inhibits angiogenesis are still not fully clarified. In this study, we explored the inhibition of HUVEC cell migration by DHA and the possible mechanisms involved. We demonstrated that DHA inhibits VEGF-induced HUVEC cell migration and that this suppression is likely associated with binding to GPR120, activation of PP2A enzyme activity, and inhibition of the ERK1/2/eNOS signaling pathway.

Several mechanisms have been proposed to demonstrate the inhibitory role of DHA in angiogenesis, including induction of apoptosis and reduction of cell proliferation.[36−38] Rose and Connolly[36] proposed that the inhibition of breast cancer cell proliferation by DHA was related to the reduced production of series 2 eicosanoids. Although DHA may prevent the occurrence of angiogenic diseases, it has potential side effects on subjects receiving revascularization therapy because of its

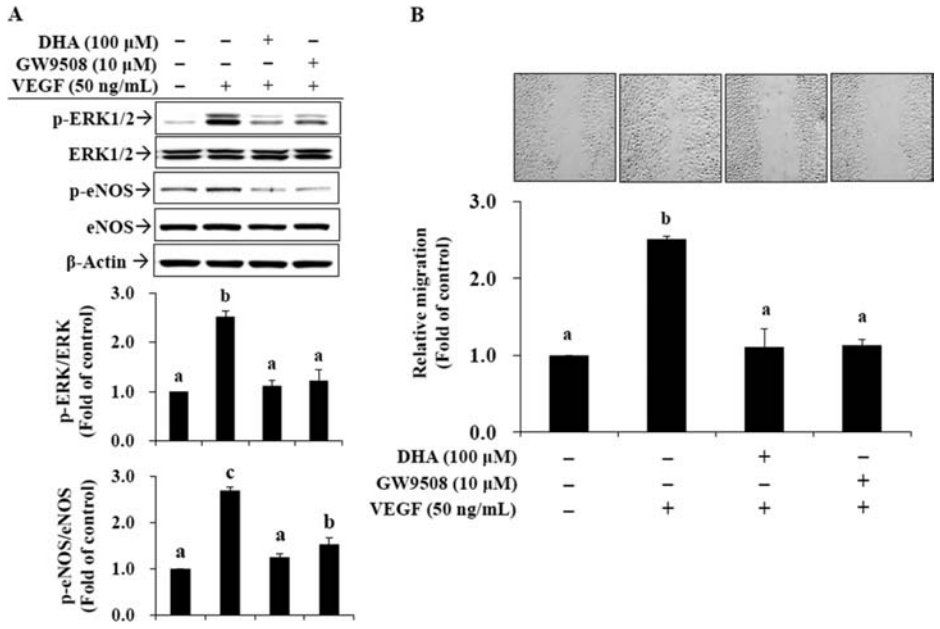

Figure 4. Effect of GPR120 agonist on phosphorylation of ERK1/2 and eNOS and cell migration induced by VEGF in HUVECs. (A) Cells were pretreated with 100 μM DHA or 10 μM GW9508 for 8 h followed by incubation with 50 ng/mL VEGF for another 15 min. (B) Cells were scratched and were cotreated with 100 μM DHA or 10 μM GW9508 along with 50 ng/mL VEGF for 8 h. Values are the mean ± SD, n = 3. Values not sharing the same letter are significantly different ($p < 0.05$).

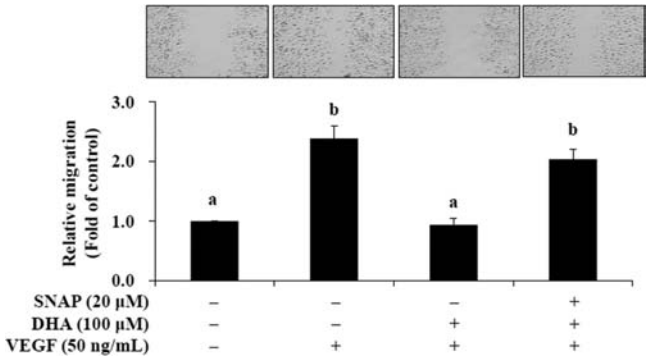

Figure 5. SNAP reverses DHA inhibition of VEGF-induced migration in HUVECs. Cells were scratched and were treated with 50 ng/mL VEGF alone, cotreated with 100 μM DHA and 50 ng/mL VEGF, or cotreated with 20 μM SNAP, 100 μM DHA, and 50 ng/mL VEGF for 8 h. Values are the mean ± SD, n = 3. Values not sharing the same letter are significantly different ($p < 0.05$).

inhibition of cell migration.[39] In recent years, EPA and DHA have been shown to inhibit angiogenesis, possibly by regulating the production or activation of various pro-angiogenic factors such as eNOS, VEGF, cyclooxygenase 2 (COX-2)-derived prostanoids, and MMP-9.[7,40,41] Moreover, EPA and DHA dose-dependently inhibit ERK1/2 phosphorylation, and this is likely associated with reduced PGE_2 and VEGF production by EPA and DHA in HT-29 human colorectal cells.[40]

VEGF has been shown to induce eNOS phosphorylation and cell migration in HUVECs, and this activation is abolished by DHA.[42] Moreover, DHA has been demonstrated to inhibit TPA-induced MMP-9 expression and cell migration and invasion in MCF-7 breast cancer cells.[3] Consistent with the results of these previous studies, our data showed that DHA exerted an inhibitory effect on VEGF-induced cell migration in HUVECs (Figure 1). Cell migration is essential for angiogenesis. Thus, the results of the present study suggest that DHA is a potential anti-angiogenic agent.

ERK1/2 is known to play an important role in cell proliferation, and protein phosphatases are generally identified as inhibitors of cell proliferation via dephosphorylation of ERK1/2.[21] Activation of the Akt/eNOS[43] or ERK1/2/eNOS[30] pathways is reported to be involved in VEGF-induced NO release. In the present study, VEGF activated phosphorylation of ERK1/2 but not of Akt (data not shown). Pretreatment with the ERK1/2 inhibitor PD98059 abolished VEGF-induced phosphorylation of ERK1/2 and eNOS in HUVECs (Figure 2A). These results suggest that eNOS is the downstream target of ERK1/2. Moreover, DHA was shown to inhibit VEGF-induced cell migration via suppression of the ERK1/2/eNOS signaling pathway (Figure 3A,C). Similar to DHA treatment, the ERK1/2 inhibitor PD98059 abolished cell migration (Figure 2B). Furthermore, as shown in Figure 5, SNAP reversed the DHA inhibition of VEGF-induced cell migration. These results strongly suggest that the DHA inhibition of VEGF-induced cell migration is through the ERK1/2/eNOS-mediated signaling pathway.

Reversible protein phosphorylation plays an important role in many cellular processes.[20] In general, cells use protein phosphorylation to alter enzyme properties such as activity and cell distribution of key regulatory proteins involved in specific pathways. Through the use of specific PP2A inhibitors and gene silencing technique, PP2A has been shown to play a key role in the regulation of cell cycle, cell morphology, and development. In addition, PP2A was demonstrated to be a tumor suppressor and can be a target for cancer therapy.[44] For example, it is reported that conjugated linoleic acid inhibits the proliferation of MCF-7 human breast cancer cells and that the working mechanisms include activation of PP2A and inhibition of ERK1/2 activation.[21] Pretreatment with the PP2A inhibitor OA reverses the effect of conjugated linoleic acid on both increased PP2A expression level and dephosphorylation of ERK1/2. This

result strongly suggests that dephosphorylation of ERK1/2 is mediated by PP2A.

Phosphorylated eNOS is also a substrate of PP2A.[31] It is reported that endostatin inhibits endothelial cell migration and angiogenesis by down-regulating the phosphorylation of eNOS at Ser1177 via PP2A, which results in a decrease in NO synthesis.[45,46] In the present study, we demonstrated that DHA activated PP2A enzyme activity, which was inhibited by OA pretreatment (Figure 3B). Pretreatment with OA reversed the inhibitory effect of DHA on VEGF-induced cell migration and phosphorylation of ERK1/2 and eNOS (Figure 3A,C). These results indicate that PP2A participates in the DHA inhibition of VEGF-induced ERK1/2/eNOS phosphorylation and cell migration. Activation of PP2A by DHA is by an as yet unidentified signaling pathway.

DHA exerts anti-inflammatory effects, but the mechanisms of these effects are not fully understood. It has been shown that GPR120 functions as an n-3 PUFA receptor.[11] In an in vitro study using RAW 264.7 cells and primary intraperitoneal macrophages, stimulation of GPR120 with n-3 PUFAs or the chemical agonist GW9508 causes a wide range of anti-inflammatory effects. All of these effects are abolished by GPR120 knockdown. Therefore, we hypothesize that DHA inhibits VEGF-induced cell migration through binding with GPR120. We used the GPR120 agonist GW9508 to simulate the activation of GPR120 by DHA in the suppression of VEGF-induced cell migration. The results showed that GW9508 significantly inhibited VEGF-induced cell migration, and the inhibitory effect was similar to that of DHA (Figure 4B). In addition, GW9508 significantly suppressed VEGF-induced phosphorylation of ERK1/2 and eNOS (Figure 4A), which is critical to cell migration.

Our findings in the present study are presented schematically in Figure 6. In conclusion, DHA significantly inhibits VEGF-induced phosphorylation of ERK1/2 and eNOS and cell migration via binding to GPR120 and induction of PP2A enzyme activity in HUVECs. Treatment with the NO donor SNAP reverses the DHA inhibition of VEGF-induced cell migration. Taken together, these results support an opposing role of DHA in cell migration, which is implicated in its anticancer and anti-wound-repair properties.

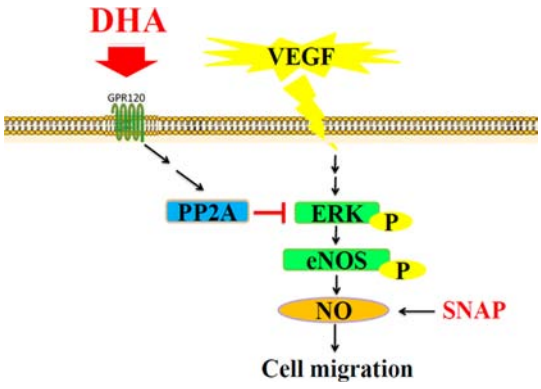

Figure 6. Model showing the pathways that mediate DHA inhibition of VEGF-induced cell migration in HUVECs. DHA inhibits VEGF-induced cell migration via binding to GPR120, activation of PP2A, and inhibition of ERK1/2 and eNOS phosphorylation.

Supporting Information

ABSTRACT: The antioxidant activity and delayed aging effects of hot water extracts from leaves of *Chamaecyparis obtusa* var. *formosana* were investigated. Free radical, superoxide radical scavenging, and total phenolic content assays were employed to evaluate the *in vitro* activities of the extracts. In addition, *in vivo* assays using the nematode *Caenorhabditis elegans* were also performed in this study. The results showed that among all soluble fractions obtained from the extracts, the ethyl acetate-soluble fraction has the best *in vitro* and *in vivo* antioxidant activities. Moreover, it decreased significantly the deposition of lipofuscin (aging pigment) and extended the lifespan of *C. elegans*. Bioactivity-guided fractionation yielded six potent antioxidant constituents from the ethyl acetate-soluble fraction, namely, catechin, quercetin, quercetin-3-*O*-α-rhamnoyranoside, myricetin-3-*O*-α-rhamnoyranoside, vanillic acid, and 4-hydroxybenzoic acid. Quercetin-3-*O*-α-rhamnoyranoside pretreatment showed the highest survival of *C. elegans* upon juglone exposure. Taken together, the results revealed that hot water extracts from *C. obtusa* var. *formosana* leaves have the potential to be used as a source for antioxidant or delayed aging health food.

KEYWORDS: *antioxidant activity, Chamaecyparis obtusa var. formosana, delayed aging effect, Caenorhabditis elegans*

INTRODUCTION

Chamaecyparis obtusa var. *formosana* is a conifer species indigenous to Taiwan and is commonly called "Taiwan Hinoki". It can be found in mountains at elevations from 1800 to 2600 m. Several studies have revealed that *C. obtusa* var. *formosana* exerts various biological activities, including cytotoxic, allopathic, antioxidant, and antitermite activities.[1−5] However, to the best of our knowledge there is no prior report on the antioxidant activities of hot water extracts from *C. obtusa* var. *formosana* leaves. Thus, this study was the first to investigate the antioxidant compounds of *C. obtusa* var. *formosana* leaves.

Oxidative stress has been linked to the development of various diseases, including inflammation, diabetes, cancers, aging, and Alzheimer's disease.[6−9] Oxidative stress reflects an imbalance between the production of free radicals and reactive metabolites, also known as oxidants or reactive oxygen species (ROS) in organisms. Intracellular ROS are considered harmful because they react with proteins, lipids, DNA, and other important biomolecules, thus leading to progressive loss of cellular integrity and functionality.[10] In particular, an increase in intracellular oxidative stress has been linked to play a vital role in aging and age-related diseases.[11,12]

The soil nematode *Caenorhabditis elegans* has become a prominent model for studying stress resistance, aging, and age-related diseases[13] due to its relatively short lifespan and developmental cycle and the existence of mutants and genetic and environmental manipulations that influence its lifespan.[13,14]

This study evaluated the antioxidant activities of hot water extracts and their constituents from leaves of *C. obtusa* var. *formosana* both *in vitro* and *in vivo*. The nematode *C. elegans* was used as an *in vivo* model to examine their protective potential including oxidative stress resistance and longevity. Our findings showed that a hot water extract of *C. obtusa* var. *formosana* leaves provides resistance against oxidative stress and delayed aging effects in an intact organism.

MATERIALS AND METHODS

Plant Materials. The fresh, mature leaves of *Chamaecyparis obtusa* var. *formosana* were sampled from Mt. Chilan in Ilan County, Taiwan. The species was identified by Yen-Ray Hsui at the Taiwan Forestry Research Institute, and a voucher specimen (ChObvFoL31) was deposited in the laboratory of wood chemistry, School of Forestry and Resource Conservation, National Taiwan University. The materials were air-dried at ambient temperature (25 °C).

Chemicals. 1,1-Diphenyl-2-picrylhydrazyl (DPPH), Folin−Ciocalteu reagent, quercetin, nitroblue tetrazolium chloride (NBT), xanthine oxidase, and (+)-catechin were purchased from Sigma Chemical Co. (MO, USA). HPLC grade methanol, Na_2CO_3, and KH_2PO_4 were purchased from Merck (Darmstadt, Germany). Ethyl acetate and *n*-butanol were purchased from ECHO Chemical Co. (Miaoli, Taiwan). Ethanol was purchased from Shimakyu Co. (Osaka, Japan). Gallic acid, Na_2EDTA, KOH, and NMR solvent were purchased from Acros (Geel, Belgium).

Extraction and Identification of Compounds. Fresh leaves were added to boiling double-distilled water and allowed to infuse for 6 h. The extract was decanted, filtered under vacuum, concentrated in a rotary evaporator, and then lyophilized. The resulting crude extract (579 g) was fractionated successively with ethyl acetate, *n*-butanol, and

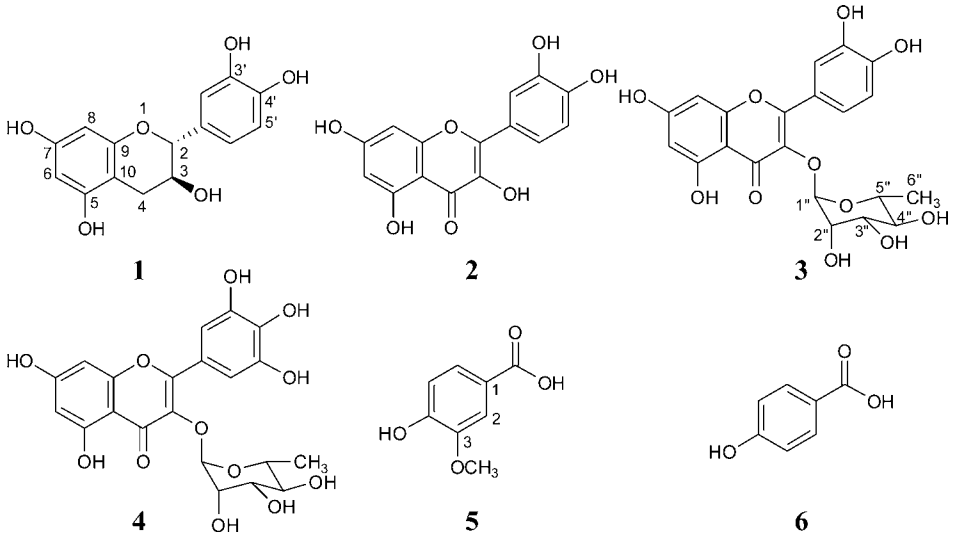

Figure 1. Structures of six phytochemicals in the ethyl acetate-soluble fraction of a hot water extract from *C. obtusa* var. *formosana* leaves: catechin (**1**); quercetin (**2**); quercetin-3-*O*-α-rhamnopyranoside (**3**); myricetin-3-*O*-α-rhamnopyranoside (**4**); vanillic acid (**5**); 4-hydroxybenzoic acid (**6**).

water to yield soluble fractions of ethyl acetate (46.7 g), *n*-butanol (138.5 g), and water (377.3 g). The phytochemicals from the ethyl acetate-soluble fraction were separated and purified by semipreparative HPLC on a Agilent model 1100 pump equipped with a UV detector (Agilent 1100) and a 250 mm × 10.0 mm i.d., 5 μm Luna RP-18 column (Phenomenex, CA, USA). The mobile phase used was solvent A (100% methanol) and solvent B (ultrapure water). Elution conditions were 0−40 min of 25−60% A to B (linear gradient); 40−60 min of 60−100% A to B (linear gradient). ESI-MS data were collected using a Finnigan MAT-95S mass spectrometer, and NMR spectra were recorded by a Bruker Avance 500 MHz FT-NMR spectrometer. The structures of chemical compounds **1**−**6** (as shown in Figure 1) were identified by ESI-MS and NMR, and all spectral data were consistent with those reported in the literature.[15−19]

1,1-Diphenyl-2-picrylhydrazyl Assay. The DPPH radical scavenging activity of the test extracts or compounds from *C. obtusa* var. *formosana* leaves was examined according to the method previously reported.[20] Briefly, 10 μL of test samples in dimethyl sulfoxide (DMSO) were mixed with 90 μL of 50 mM Tris-HCl buffer (pH 7.4) and 200 μL of 0.1 mM DPPH−ethanol solution. After 30 min of incubation at ambient temperature, the reduction of the DPPH radical was measured by reading the absorbance at 517 nm using an ELISA reader (SpectraMax 190, Molecular Devices, CA, USA). (+)-Catechin was used as a positive control. Three replicates were made for each test sample. The inhibition percentage was calculated according to the following equation:

$$\%\ \text{inhibition} = [(\text{absorbance of control} - \text{absorbance of sample})/\text{absorbance of control}] \times 100$$

Superoxide Radical Scavenging Assay (NBT Assay). Measurement of superoxide radical scavenging activity was carried out according to the method of Chang et al.[20] Briefly, 20 μL of 15 mM Na_2EDTA in buffer (50 mM KH_2PO_4/KOH, pH 7.4), 50 μL of 0.6 mM nitroblue tetrazolium chloride in buffer, 30 μL of 3 mM hypoxanthine in 50 mM KOH, 5 μL of the test extracts or compounds in methanol, and 145 μL of buffer were mixed in 96-well microplates. The reaction was started by adding 50 μL of xanthine oxidase in buffer (1 unit in 10 mL of buffer) to the mixture. The reaction mixture was incubated at ambient temperature, and the absorbance at 570 nm was determined every 1 min up to 8 min using the ELISA reader. (+)-Catechin and quercetin, well-known antioxidants, were used as positive controls. Three replicates were made for each test sample. The percent inhibition ratio was calculated according to the following equation:

$$\%\ \text{inhibition} = [1 - (\text{rate of sample reaction}/\text{rate of control reaction})] \times 100$$

Total Phenolic Content Measurement. The amount of total phenolics was measured by the Folin−Ciocalteu method according to Chang et al.,[20] using gallic acid as a standard, and a calibration curve was obtained with solutions of 0.08, 0.04, 0.02, 0.01, and 0.005 mg/mL of this compound. A 0.4 mL aliquot of diluted extract (all fractions were diluted with methanol to adjust the absorbance within the calibration limits), 0.4 mL of 1 mol/L Folin−Ciocalteu reagent, and 0.8 mL of Na_2CO_3 (20%, w/v) were mixed. After 8 min, the mixture was centrifuged at 15300*g* for 10 min. Then the absorbance of the supernatant solution was measured at 730 nm by using ELISA and against a blank prepared similarly but containing distilled water instead of extract. The concentration of phenolics thus obtained was multiplied by the dilution factor, and the results were expressed as the equivalent to milligrams of gallic acid per gram of extract (mg GAE/g).

***C. elegans* Handling.** The strain used in this study was Bristol N2 (wild-type), which was obtained from the *Caenorhabditis* Genetics Center (CGC; University of Minnesota). *C. elegans* was maintained and assayed at 20 °C on nematode growth medium (NGM) agar plates carrying a lawn of *Escherichia coli* (*E. coli.*) OP50. Synchronization of nematode cultures was performed by hypochlorite treatment of gravid hermaphrodites.[21]

***C. elegans* Oxidative Stress Resistance Assays.** Synchronized wild-type L1 larvae were incubated in liquid S-basal medium containing *E. coli* OP50 bacteria at 10^9 cells/mL with extract or 0.1% DMSO (Wako, Saitama, Japan) as the solvent control for 72 h. Subsequently, adult nematodes were immediately subjected to the oxidative stress assay. For this assay, juglone (5-hydroxy-1,4-naphthoquinone) (Sigma, MO, USA), an ROS-generating compound, was employed to induce oxidative stress in *C. elegans*. Extract-treated and control adult nematodes were transferred to S-basal medium containing 250 μM juglone for 2.5 h[22,23] and then scored for viability. The survival of *C. elegans* was determined by touch-provoked movement.[24] Nematodes were scored as dead when they failed to respond to repeated touching with a platinum wire pick. The test was performed independently at least three times.

***C. elegans* Intracellular Reactive Oxygen Species Measurement.** Wild-type nematodes were raised from L1 larvae as described in the oxidative stress resistance assays. Subsequently, intracellular ROS in *C. elegans* were measured using 2′,7′-dichlorodihydrofluorescein diacetate (H_2DCFDA) (Sigma, MO, USA). Approximately 100 nematodes were sonicated after extract treatment, and the lysates were

then collected for ROS measurement.[23,25,26] Worm samples were incubated with H_2DCFDA (at a final concentration of 50 μM in phosphate-buffered saline) in an FLx800 microplate fluorescent reader (Bio-Tek Instruments, VT, USA) for quantification of fluorescence with excitation at 485 nm and emission at 530 nm. Samples were read after 3 h.

C. elegans Lifespan Assays. *C. elegans* lifespan analyses were performed in the same manner for all treatments at 20 °C. Synchronized L1 larvae were transferred to NGM plates in the absence or presence of 2 or 20 μg/mL ethyl acetate-soluble fraction, and *C. elegans* was allowed to develop to adulthood. Surviving and dead animals were counted daily (starting on the first day of adulthood) until all nematodes died. Animals that did not move when gently prodded (with a platinum wire) were scored as dead. Nematodes suffering from internal hatch (a defect in egg laying) and those that crawled off the NGM plate were not included in the lifespan counts. During the reproductive period, adult nematodes were transferred to fresh NGM plates every day during the progeny production period and then every other day thereafter. To avoid antibacterial effects of extract, lifespan assays were conducted with UV-killed *E. coli* OP50 according to Gruber et al.[27] The lifespan assays were performed at least three times.

C. elegans Intracellular Lipofuscin Assays. Wild-type animals were raised from L1 larvae as in the lifespan assays. On the fourth and eighth days of adulthood, the intestinal autofluorescence of lipofuscin was analyzed according to Liao et al.[28] Randomly selected worms from each set of experiments were mounted onto microscope slides coated with 3% agarose, anesthetized with 2% sodium azide, and capped with coverslips. The autofluorescence of lipofuscin was captured with a Leica epifluorescence microscope (Leica, Wetzlar, Germany) using the DAPI filter set (with excitation at 340−380 nm and emission at 435−485 nm) and a cooled charge-coupled device camera. The lipofuscin level for each worm was quantified by determining the average pixel intensity in each animal's intestine using Image-Pro Plus software (Media Cybernetics, MD, USA).

Statistical Analyses. For the lifespan assays, survival of *C. elegans* was plotted using Kaplan−Meier survival curves and analyzed by the log-rank test using GraphPad Prism (GraphPad Software, Inc., CA, USA). Other data were expressed as mean ± SE (n = 3). The significance of difference was calculated by Scheffe's test, and values of $p < 0.05$ were considered significant.

RESULTS AND DISCUSSION

***In Vitro* Antioxidant Activities of a Hot Water Extract from *C. obtusa* var. *formosana* Leaves.** Strong activity in scavenging DPPH and superoxide radical of hot water extracts is shown in Table 1. The DPPH free radical inhibitory (IC_{50}) ability of the hot water extract is 8.5 ± 0.2 μg/mL, and the IC_{50} values of three fractions increased as follows: ethyl acetate (6.3 ± 0.2 μg/mL), *n*-butanol (7.2 ± 0.1 μg/mL), and water (30.2 ± 3.1 μg/mL). In addition, the scavenging ability of superoxide, the most common radical in our organisms, was also tested. Their IC_{50} values decreased in the order ethyl acetate-soluble fraction (1.6 ± 0.0 μg/mL), crude extract (2.6 ± 0.2 μg/mL), *n*-butanol-soluble fraction (3.1 ± 0.1 μg/mL), and water-soluble fraction (8.4 ± 0.1 μg/mL). These results demonstrated that the hot water extract has potential as an antioxidant source. Among all soluble fractions, the ethyl acetate-soluble fraction has the best inhibitory effect on free radical scavenging ability.

Table 1. DPPH Radical and Superoxide Radical Scavenging Activity and Total Phenolic Contents of a Hot Water Extract from *C. obtusa* var. *formosana* Leaves and Its Soluble Fractions[a]

	DPPH	NBT	TPC
specimen	IC_{50} (μg/mL)	IC_{50} (μg/mL)	(mg GAE/g)
HWE	8.5 ± 0.2 b	2.6 ± 0.2 b	282.4 ± 7.3 c
EAF	6.3 ± 0.2 c	1.6 ± 0.0 c	649.8 ± 9.6 a
BF	7.2 ± 0.1 c	3.1 ± 0.1 b	368.2 ± 12.1 b
WF	30.2 ± 3.1 a	8.4 ± 0.1 a	147.7 ± 5.2 d

[a]HWE: hot water extract; EAF: ethyl acetate-soluble fraction; BF: *n*-butanol-soluble fraction; WF: water-soluble fraction. DPPH: DPPH free radical scavenging effect; NBT: superoxide radical scavenging assay; TPC: total phenolic content. Different letters (a−d) are significantly different at $p < 0.05$ according to Scheffe's test (mean ± SE, n = 3). The IC_{50} value of catechin is 2.9 μg/mL (DPPH) and 2.7 μg/mL (NBT), respectively.

Total Phenolic Contents of a Hot Water Extract from *C. obtusa* var. *formosana* Leaves and Its Soluble Fractions. Phenolic compounds are well-known radical scavengers in the plant kingdom, and they have been proved to have various biological effects.[29−32] Table 1 shows the total phenolic content of the crude extract and its derived fractions calculated as gallic acid equivalent (GAE) in milligrams per gram of sample. Accordingly, the total phenolic content of the ethyl acetate-soluble fraction (649.8 ± 9.6 mg GAE/g) was significantly higher than that of the *n*-butanol-soluble fraction (368.2 ± 12.1 mg GAE/g), crude extracts (282.4 ± 7.3 mg GAE/g), and water fraction (147.7 ± 5.2 mg GAE/g). These results indicated that the total phenolic content of the hot water extract from *C. obtusa* var. *formosana* leaves could be effectively enriched in the ethyl acetate-soluble fraction.

Enhanced Oxidative Stress Resistance of Wild-Type *C. elegans* by a Hot Water Extract from *C. obtusa* var. *formosana* Leaves. According to the above-mentioned results, the hot water extract of *C. obtusa* var. *formosana* leaves, especially the ethyl acetate-soluble fraction, has an excellent *in vitro* antioxidant activity. To further investigate the antioxidant activity of the hot water extract and different fractions in living organisms, the *C. elegans* model was employed. Wild-type L1 larvae were pretreated with the hot water extracts (2 and 20 μg/mL) and 0.1% DMSO as the solvent control for 72 h before immediate exposure to juglone (250 μM), a redox cycler that generates intracellular oxidative stress, and then incubated for 2.5 h.[22,23]

During pretreatment with the extracts, no adverse effects on the worms including survival, growth rate, and morphological changes were observed (data not shown). Pretreatment with 2 and 20 μg/mL extracts enhanced the worms' resistance to juglone-induced oxidative stress (survival of 2 μg/mL- and 20 μg/mL-treated worms was 69.3 ± 6.0% and 88.1 ± 3.2%, respectively). Since as low as 2 μg/mL extract was able to significantly defend against the juglone-induced oxidative stress, 2 μg/mL extract was chosen as the working concentration for further experiments.

Different soluble fractions derived from hot water extracts were further examined. As shown in Figure 2, both the hot water crude extract and ethyl acetate-soluble fraction increased significantly the survival of *C. elegans* compared with the control (0.1% DMSO). In addition, the ethyl acetate-soluble fraction exhibited higher survival against juglone-induced oxidative stress (Figure 2). The increase in the worms' survival may be attributed to the chemical components in extracts with abilities for scavenging free radicals to reduce the juglone-induced oxidative stress in *C. elegans*, which was in good agreement with the *in vitro* antioxidant data (Table 1).

Influence of Hot Water Extracts from *C. obtusa* var. *formosana* Leaves on Intracellular ROS Levels in *C.*

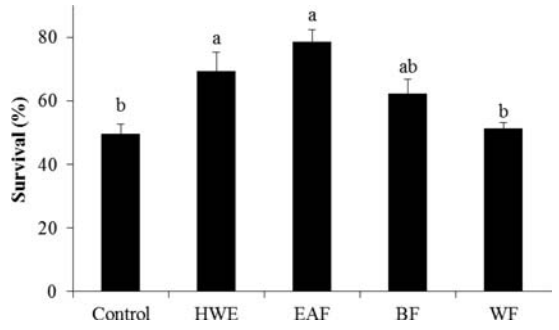

Figure 2. Survival of *C. elegans* (wild-type) treated with 2 μg/mL hot water extract of *C. obtusa* var. *formosana* leaves and its soluble fractions under oxidative stress induced by juglone. HWE: hot water extract; EAF: ethyl acetate-soluble fraction; BF: *n*-butanol-soluble fraction; WF: water-soluble fraction. Different letters (a, b) are significantly different at $\alpha = 0.05$ according to Scheffe's test (mean ± SE, $n = 3$).

***elegans*.** After pretreatment with extracts, the intracellular ROS levels in *C. elegans* were then examined. Nonfluorescent DCF-DA is a freely cell-permeable dye, which is readily converted to the fluorescent 2′,7′-dichlorofluorescein (DCF) due to an interaction with intracellular H_2O_2. As shown in Figure 3, the fluorescence intensities of the control and hot

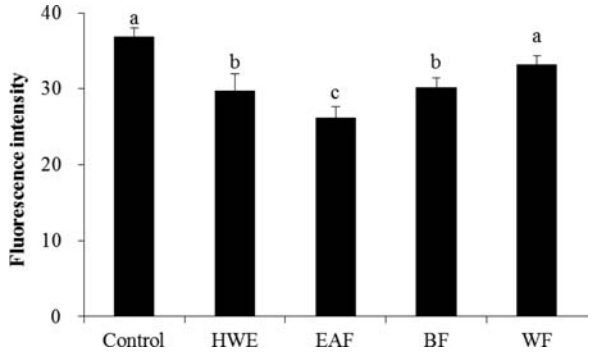

Figure 3. Effects of 2 μg/mL hot water extract from *C. obtusa* var. *formosana* leaves and its soluble fractions on ROS accumulation. Results are expressed as relative fluorescence units (RFU), fluorescence relative to total proteins in worm lysates. HWE: hot water extract; EAF: ethyl acetate-soluble fraction; BF: *n*-butanol-soluble fraction; WF: water-soluble fraction. Different letters (a–c) are significantly different at $\alpha = 0.05$ according to Scheffe's test (mean ± SE, $n = 3$).

water crude extract were 36.9 ± 1.1 and 29.7 ± 2.3 units, respectively, revealing that the hot water crude extract significantly decreased the intracellular ROS in wild-type L1 larvae pretreated at 2 μg/mL. Among three subfractions of crude extract, the ethyl acetate-soluble fraction showed a significant decrease in the fluorescence intensity (26.2 ± 1.5 units) compared with the control and hot water crude extract. These results demonstrated that the crude extract and its ethyl acetate-soluble fraction may act against oxidative stress due to its ROS-scavenging ability.

Effects of Ethyl Acetate-Soluble Fraction of a Hot Water Extract from *C. obtusa* var. *formosana* Leaves on Lifespan Extension of *C. elegans*. The ethyl acetate-soluble fraction of a hot water extract from *C. obtusa* var. *formosana* leaves not only had the highest phenolic contents but also exhibited the best antioxidant activity in both *in vitro* and *in vivo* antioxidant tests (Table 1, Figure 2). Accordingly, the ethyl acetate-soluble fraction was selected to evaluate the ability of lifespan extension using the *C. elegans* model. Adult wild-type worms grown under our standard laboratory conditions at 20 °C (feeding with UV-killed bacteria) have a mean lifespan of 20.0 ± 0.5 days with a maximum lifespan of 35.0 ± 0.9 days (the age at death of the oldest animals) (Figure 4). Ethyl

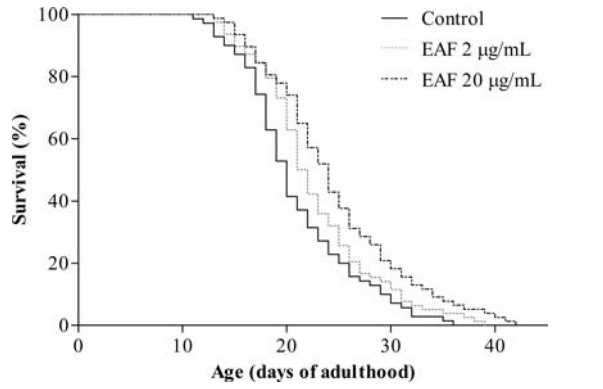

Figure 4. Effects of the ethyl acetate-soluble fraction of a hot water extract from *C. obtusa* var. *formosana* leaves on *C. elegans* (wild-type) lifespan. Survival curve's *p* value (compared with the control by log-rank test) of EAF 2 and 20 μg/mL are 0.0035 and 0.0008, respectively. EAF: ethyl acetate-soluble fraction.

acetate soluble fraction-treated worms had a statistically significant increased lifespan compared with untreated ones (log-rank test $p = 0.0035$ and 0.0008 for 2 and 20 μg/mL, respectively, untreated vs treated) (Figure 4, Table 2). This result suggests that the ethyl acetate-soluble fraction of a hot water extract from *C. obtusa* var. *formosana* has a beneficial effect against aging for organisms.

Effects of Ethyl Acetate-Soluble Fraction of a Hot Water Extract from *C. obtusa* var. *formosana* Leaves on Lipofuscin Levels in *C. elegans*. Lipofuscin (aging pigments) levels in the intestines of the *C. elegans* were examined, as lipofuscin is an endogenous intestinal autofluorescent material that accumulates in aged *C. elegans*. The lipofuscin levels in the intestines of control and ethyl acetate soluble fraction-treated worms on the fourth and eighth days of adulthood were measured. On the fourth day of adulthood, the intestinal lipofuscin levels of ethyl acetate soluble fraction-treated worms were similar to those of the control (Figure 5). On the eighth day of adulthood, there was a significant decrease in intestinal lipofuscin level between the control (12.4 ± 0.6 unit) and ethyl acetate soluble fraction-treated worms (2 and 20 μg/mL: 9.7 ± 0.2 units and 9.1 ± 0.6 units). The results suggest that the ethyl acetate-soluble fraction of the hot water extract from *C. obtusa*

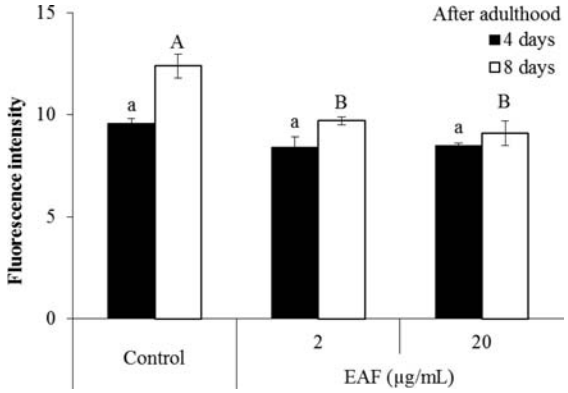

Figure 5. Effects of the ethyl acetate-soluble fraction of a hot water extract from *C. obtusa* var. *formosana* leaves on the lipofuscin accumulation of *C. elegans* (wild-type). Results are expressed as relative fluorescence units (RFU), fluorescence relative to total proteins in worm lysates. Different letters (a, A, B) are significantly different at $\alpha = 0.05$ according to Scheffe's test (mean ± SE, $n = 3$). EAF: ethyl acetate-soluble fraction.

var. *formosana* leaves could delay aging in *C. elegans* by inhibiting lipofuscin accumulation.

Constituents of Ethyl Acetate-Soluble Fraction of a Hot Water Extract from *C. obtusa* var. *formosana* Leaves and Their Antioxidant Activities. Constituents from the ethyl acetate-soluble fraction that might contribute to the observed oxidative stress resistance were then determined. By following the bioactivity-guided fractionation procedure, phytochemicals in the ethyl acetate-soluble fraction of a hot water extract from *C. obtusa* var. *formosana* leaves were isolated using semipreparative high-performance liquid chromatography (HPLC). NMR spectra and mass spectroscopy were employed to identify six constituents (Figure 1): catechin (**1**), quercetin (**2**), quercetin-3-*O*-α-rhamnopyranoside (**3**), myricetin-3-*O*-α-rhamnopyranoside (**4**), vanillic acid (**5**), and 4-hydroxybenzoic acid (**6**). The highest content of phytochemicals in *C. obtusa* var. *formosana* leaves was **3** (17.70 ± 0.6 mg/g of crude extracts), followed by **4** (6.79 ± 0.2 mg/g of crude extracts) > **1** (5.89 ± 0.1 mg/g of crude extracts) > **2** (4.17 ± 0.1 mg/g of crude extracts) > **5** (2.34 ± 0.3 mg/g of crude extracts) > **6** (1.21 ± 0.0 mg/g of crude extracts).

In vitro and *in vivo* antioxidant activities of each chemical were investigated. In the DPPH free radical scavenging assay, **2** had the lowest IC_{50} value (6.6 ± 0.4 μM), followed by **4** < **3** < **1**, with IC_{50} values of 7.2 ± 0.2, 8.5 ± 0.1, and 10.6 ± 0.2 μM, respectively. Compounds **5** and **6** did not have significant inhibitory effects on scavenging DPPH free radicals, and their IC_{50} values were higher than 50 μM (Table 3). Furthermore, in the *C. elegans* oxidative stress resistance assay, the antioxidant activities of phytochemicals can be ranked as **3** > **2** > **4** > **1** > **5** = **6** (Table 3). All compounds exhibited higher survival than that of the control (48.3 ± 0.5%). Previous studies had reported that **1** and **2** were excellent antioxidant agents in *C. elegans*.[33,34] It is interesting to note that **5** and **6** did not show significant *in vitro* antioxidant activity, whereas they showed a beneficial antioxidant effect in the *C. elegans* model.

Among the six compounds derived from *C. obtusa* var. *formosana* leaves, quercetin-3-*O*-α-rhamnopyranoside (**3**) has the highest content and was the most effective antioxidant in the *C. elegans* model. This finding suggests that quercetin-3-*O*-α-rhamnopyranoside (**3**) from the ethyl acetate-soluble fraction of *C. obtusa* var. *formosana* leaves might play a key role in the observed oxidative stress resistance. Additionally, quercetin (**2**) is a well-known antioxidant in both the *in vitro* assay and the *C. elegans* model.[35,36] It is noted that compound **3** is quercetin with a rhamnopyranoside group at the 3-position. This study found that the antioxidant activity in the *C. elegans* model was enhanced when quercetin contains a sugar. The antioxidant effect may be attributed to the moiety promoted by the rhamnopyranoside that can facilitate flavonoid absorption as described in the animal model.[37]

Table 3. Contents and Antioxidant Activities of Six Phytochemicals from the Ethyl Acetate-Soluble Fraction of Hot Water Extracts from *C. obtusa* var. *formosana* Leaves[a]

phytochemical	contents (mg/g of crude)	IC_{50} (μM) DPPH radical	*C. elegans*[b] survival (%)
catechin (**1**)	5.89 ± 0.1	10.6 ± 0.2 a	61.7 ± 1.0 d
quercetin (**2**)	4.17 ± 0.1	6.6 ± 0.4 d	77.3 ± 0.8 b
quercetin-3-*O*-α-rhamnopyranoside (**3**)	17.70 ± 0.6	8.5 ± 0.1 b	90.5 ± 0.5 a
myricetin-3-*O*-α-rhamnopyranoside (**4**)	6.79 ± 0.2	7.2 ± 0.2 c	70.1 ± 0.7 c
vanillic acid (**5**)	2.34 ± 0.3	>50	53.4 ± 0.7 e
4-hydroxybenzoic acid (**6**)	1.21 ± 0.0	>50	54.3 ± 0.6 e
control (0.1% DMSO)			48.3 ± 0.5 f

[a]Different letters (a–f) are significantly different at $\alpha = 0.05$ according to Scheffe's test (mean ± SE, $n = 3$). [b]Concentration of sample is 10 μM and observed after 2.5 h of 250 μM juglone exposure.

In conclusion, results obtained from this study revealed that hot water extracts from *C. obtusa* var. *formosana* leaves had excellent *in vitro* antioxidant activities via free radical and superoxide radical scavenging and total phenolic content assays. Furthermore, the hot water extracts promoted the resistance of oxidative stress in *C. elegans*. Among all soluble fractions obtained from hot water extracts, the ethyl acetate-soluble fraction exhibited the best antioxidant activities in both *in vitro* and *C. elegans* models. Moreover, it delayed the aging phenomenon (reduction of lipofuscin deposition and lifespan extension). Moreover, six potent antioxidant constituents, namely, catechin, quercetin, quercetin-3-*O*-α-rhamnopyranoside, myricetin-3-*O*-α-rhamnopyranoside, vanillic acid, and 4-hydroxybenzoic acid, were identified from the ethyl acetate-soluble fraction by bioactivity-guided fractionation. Among them, quercetin-3-*O*-α-rhamnopyranoside exhibited the best *in vivo* antioxidant activity and was of the highest content in hot water extracts, suggesting that it might play the key role in the observed antioxidant activity of extracts. The results in the present study indicated that hot water extracts from *C. obtusa* var. *formosana* leaves have the potential to be used as a source for an antioxidant or delayed aging health food and warrants further investigations.

Savinase, the Most Suitable Enzyme for Releasing Peptides from Lentil (*Lens culinaris* var. Castellana) Protein Concentrates with Multifunctional Properties

Patricia Garcia-Mora, Elena Peñas, Juana Frias, and Cristina Martínez-Villaluenga*

Department of Food Characterization, Quality and Safety, Institute of Food Science, Technology and Nutrition, Juan de la Cierva 3, 28006 Madrid, Spain

ABSTRACT: The aim of this study was to produce multifunctional hydrolysates from lentil protein concentrates. Four different proteases (Alcalase, Savinase, Protamex, and Corolase 7089) and different hydrolysis times were evaluated for their degree and pattern of proteolysis and their angiotensin I-converting enzyme (ACE) inhibitory and antioxidant activities. Alcalase and Savinase showed the highest proteolytic effectiveness ($P \leq 0.05$), which resulted in higher yield of peptides. The hydrolysate produced by Savinase after 2 h of hydrolysis (S2) displayed the highest ACE-inhibitory (IC_{50} = 0.18 mg/mL) and antioxidant activity (1.22 μmol of Trolox equiv/mg of protein). Subsequent reverse-phase HPLC−tandem mass spectrometric analysis of 3 kDa permeates of S2 showed 32 peptides, mainly derived from convicilin, vicilin, and legumin containing bioactive amino acid sequences, which makes them potential contributors to ACE-inhibitory and antioxidant activities detected. The ACE-inhibitory and antioxidant activities of S2 were significantly improved after in vitro gastrointestinal digestion ($P \leq 0.05$). Multifunctional hydrolysates could encourage value-added utilization of lentil proteins for the formulation of functional foods and nutraceuticals.

KEYWORDS: *lentil protein hydrolysates, alkaline proteases, antioxidant peptides, ACE-inhibitory peptides*

INTRODUCTION

Hypertension is a public health problem associated with cardiovascular complications affecting 25% adult population worldwide.[1] Moreover, the increasing number of individuals with metabolic syndrome is contributing to the rising prevalence of hypertension. In view of its high prevalence, pharmacotherapy and diet and lifestyle modifications are applied for treatment of hypertension. Inhibition of angiotensin I-converting enzyme (ACE; EC 3.4.15.1) has been used as a target therapy for treatment of hypertension.[2] This enzyme plays a crucial role in the renin−angiotensin and kinin−kallikrein systems regulating blood pressure.[3] Inhibition of ACE reduces the concentration of angiotensin II, a vasoconstrictor octapeptide, while it increases levels of the vasodilator peptide bradykinin, which results in the lowering of blood pressure.[2]

A recent study has shown increased participation of reactive oxygen species and reduced antioxidant enzymatic defense in the pathogenesis of hypertension.[4] Oxidative stress affects several cellular signaling cascades and cellular functions,[5] reducing the bioavailability of nitric oxide, a vasodilatory molecule involved in smooth muscle relaxation in the cardiovascular system.[6] In addition, oxidation of membrane lipids brings about lipid peroxidation products, which damage proteins in the cardiovascular system.[7] Therefore, amelioration of oxidative stress in addition to inhibition of ACE provides a multitarget therapy that may improve the clinical efficacy of pharmacological treatments for management of hypertension and other cardiovascular disorders.

Because of the adverse side effects of synthetic drugs, functional foods containing natural compounds are alternative strategies to drug therapy.[8] Food-derived bioactive peptides with more than one bioactivity have multifunctional properties that can potentially be useful in targeting the multiple pathophysiological conditions underlying hypertension.[9] Much research has been focused on the generation of peptides derived from animal and plant food proteins for the management of hypertension.[10] To date, milk is the main source of ACE-inhibitory peptides, in addition to egg, meat, and fish.[11] However, plant sources have gained less attention in this respect.

Lentil is a traditional pulse crop providing economic benefits in addition to the benefits derived from crop rotation, nitrogen fixation, and sustainable agriculture.[12] Lentils are a staple food in many countries, providing an inexpensive source of protein in the diet (20−30%); however, they are largely underexploited for new emerging applications in the functional foods and nutraceutical areas. Previous studies have shown the potential of lentil proteins as source of ACE-inhibitory peptides.[13,14] In contrast, no studies have been conducted to produce multifunctional hydrolysates from lentil proteins exhibiting both ACE-inhibitory and antioxidant activities so far, which would open up new possibilities for value-added applications of lentil.

Bioactive peptides may be produced by enzymatic hydrolysis of food proteins with enzymes of microbial, plant, or gastrointestinal origin. Several enzymes have been used to produce lentil hydrolysates with bioactive properties such as Alcalase + Flavourzyme, bromelain, papain, and gastrointestinal enzymes.[13,14] These studies have shown that ACE-inhibitory activity of lentil hydrolysates strongly depends on protease specificity. Moreover, the release of bioactive peptides and,

consequently, the biological activity of protein hydrolysates can be affected by operational conditions such as hydrolysis time.[15] The objective of this work was to produce multifunctional lentil hydrolysates with ACE-inhibitory and antioxidant peptides. The effect of protease type and hydrolysis time on the proteolytic pattern and ACE-inhibitory and antioxidant activities of lentil hydrolysates was also studied. This information is critical for the development of value-added products, particularly as ingredients for the functional food and nutraceutical markets.

MATERIALS AND METHODS

Materials. Lentil seeds (*Lens culinaris* var. Castellana) were provided by Semillas Iglesias S.A. (Salamanca, Spain) and stored in polyethylene bins at 4 °C. Commercial food-grade enzymes Alcalase 2.4L FG, Savinase, and Protamex were kindly provided by Novozymes (Bagsvaerd, Denmark). Alcalase and Savinase are alkaline serine proteases from *Bacillus licheniformis* and *Bacillus* sp., respectively. Protamex is a *Bacillus* protease complex consisting of subtilisin and neutral protease (EC 3.4.24.28). Corolase 7089 is a fungal neutral protease provided by AB Enzymes GmbH (Darmstadt, Germany). Tripeptide Abz-Gly-Phe(NO_2)-Pro was purchased from Cymit-Quimica (Barcelona, Spain). All other chemicals were purchased from Sigma–Aldrich Quimica (Madrid, Spain) unless otherwise specified.

Preparation of Lentil Protein Concentrates. Whole lentil seeds were ground in a coffee mill (Moulinex, Allençon, France) and passed through a 60-mesh sieve and 0.5 mm pore size. The lentil powders were stored at −20 °C before use. Total protein concentration in lentil flour was determined as total nitrogen multiplied by 6.25. Total nitrogen of lentil flours was analyzed in duplicate on a Leco Trumac apparatus (Leco Corp., St. Joseph, MI).

Lentil protein concentrates were prepared by alkaline extraction. Briefly, lentil flour was suspended in water (solid-to-solvent ratio 1:10 w/v) and the pH value was adjusted to 8. The suspension was stirred in an orbital shaker (Infors, Switzerland) at 20 °C for 1 h and then vacuum-filtered through a filter funnel (100–160 μm nominal pore size) to remove solids. Finally, filtrates were freeze-dried and stored under vacuum and dark conditions in plastic bags at −20 °C until further analysis. The soluble protein concentration in the filtrates was determined by the DC protein assay (Bio-Rad Laboratories, Hercules, CA) following the manufacturer's protocol. Bovine serum albumin (BSA) was used as standard at a concentration range from 0 to 1 mg/mL.

Enzymatic Proteolysis. Freeze-dried lentil protein concentrates were suspended in deionized water (2% w/v) and equilibrated at 40 °C, and the pH value was adjusted to 8 with 0.1 M NaOH. Enzymatic proteolysis was carried out at an enzyme to substrate ratio (E/S) of 0.1 AU/mg of soluble protein at 40 °C and pH 8. Aliquots were withdrawn at 0, 1, 2, 3, 4, 5, and 6 h from reaction mixtures and heated at 80 °C for 15 min for enzyme inactivation. Finally, hydrolysates were centrifuged at 23430*g* at 10 °C for 10 min, freeze-dried, and stored at −20 °C until use. Protein concentration was determined by the DC protein assay (Bio-Rad). Samples were coded for protease type (A = Alcalase, S = Savinase, P = Protamex, and C = Corolase 7089) followed by hydrolysis time (1, 2, 3, 4, 5, and 6). For example, S2 hydrolysates are those produced from lentil concentrate hydrolyzed by Savinase for 2 h. Hydrolysis were performed at least in triplicate for each enzyme.

Degree of Hydrolysis. The degree of hydrolysis (DH) was calculated by determination of free amino groups by reaction with 2,4,6-trinitrobenzenesulfonic acid according to Adler-Nissen.[16] Total number of amino groups in lentil protein concentrate was determined after acid hydrolysis in 6 N HCl at 110 °C for 24 h in vials sealed under nitrogen. Analyses were performed in duplicate. Degree of hydrolysis (percentage) was calculated from the following equation:

$$DH = 100 \times [(AN_2 - AN_1)/N_{pb}]$$

where AN_1 is amino nitrogen content in the protein substrate before hydrolysis, AN_2 is amino nitrogen content in the free protein after hydrolysis, and N_{pb} is the total amino groups in the protein substrate (all expressed as milligrams of tyrosine equivalents/gram of protein) as determined with 6 N HCl at 110 °C for 24 h.

Sodium Dodecyl Sulfate–Polyacrylamide Gel Electrophoresis. SDS–PAGE analysis of the protein hydrolysates was performed on NuPAGE Novex 4–12% Bis-Tris gels in the XCell-sure lock mini-cell system (Invitrogen, Madrid, Spain). Electrophoresis was carried out at 200 V. NuPAGE MES-SDS and NuPAGE LDS were used as running and sample buffers (Invitrogen), respectively. Runs were carried out under nonreducing conditions in which 2-mercaptoethanol was omitted in the denaturing buffer. Electrophoretic bands were stained with SimplyBlue SafeStain (Invitrogen), followed by destaining in deionized water. The molecular weights of poly- and oligopeptides were determined by comparison with the molecular weight marker solution Mark 12 (Invitrogen).

ACE-Inhibitory Activity. ACE-inhibitory activity of samples was measured in duplicate following the fluorescence-based protocol of Sentandreu and Toldrá.[17] The generated fluorescence was read every minute for 30 min at emission and excitation wavelengths of 355 and 405 nm, respectively, in a microplate fluorometer, Synergy HT (Biotek, Winooski, VT). IC_{50} values, expressed in protein concentration (milligrams per milliliter), were calculated for the most active hydrolysates. IC_{50} was determined by dose–response curves in which the range of protein concentration (0–0.5 mg/mL) was distributed in a logarithmic scale and by use of the nonlinear regression sigmoidal curve-fit function in GraphPad Prism 4.00 (Graphpad Software Inc., San Diego, CA). Protein concentration of 3 kDa permeates was measured by DC protein assay (Bio-Rad).

Oxygen Radical Absorbance Capacity. ORAC of samples was measured in duplicate by fluorescence as described previously.[18] Results were expressed as micromoles of Trolox equivalents (TE) per milligram of protein.

Proteomic Analyses. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) analysis was performed for the most active hydrolysates. Peptide mass fingerprint was performed on a Voyager-DE Pro mass spectrometer (Applied Biosystems, Foster City, CA) equipped with a pulsed 337 nm nitrogen laser (1 ns pulse width and 3 Hz frequency), which was operated in the reflector mode for positive ions. Parameters of the instrument were as follows: acceleration voltage of 20 kV, an extraction voltage of ions generated by laser desorption was introduced into a time-of-flight analyzer (1.3 m flight path) with an acceleration voltage of 20 kV, 76% grid voltage, 0.001% ion guide wire voltage, and delayed extraction time of 400 ns. The samples were mixed with the matrix at a ratio of 1:5 (v/v), and 1 μL of this solution was spotted onto a flat stainless-steel sample plate and dried in air. Mass spectra were obtained over the m/z range 500–4000. External mass calibration was applied by use of the monoisotopic $[M + H]^+$ values of des-Arg^1-bradykinin, angiotensin I, insulin, Glu^1-fibrinopeptide B, and adrenocorticotropic hormone fragments 1–17, 18–39, and 7–38.

For peptide identification, 10 μg of the most active hydrolysate was desalted by reverse-phase (PorosR2) chromatography with 80% acetonitrile (ACN)/0.1% trifluoroacetic acid (TFA). Later, the peptides were dried and resuspended in 10 μL of 0.1% TFA. An aliquot of 5 μL of resuspended sample was injected into the linear trap quadrupole (LTQ) Orbitrap Velos (Thermo Scientific). Peptides were loaded onto a C18-A1 ASY-column 2 cm precolumn (Thermo Scientific) and then eluted onto a Biosphere C18 column (C18, inner diameter 75 μm, 15 cm long, 3 μm particle size) (NanoSeparations) at a flow rate of 250 nL/min on a nanoEasy high-performance liquid chromatography (HPLC) instrument (Proxeon) coupled to a nanoelectropray ion source (Proxeon).

The mobile phases used consisted of 0.1% formic acid/2% ACN (solvent A) and 0.1% formic acid in 100% ACN (solvent B). The solvent gradient was from 100% A to 35% B in 140 min. Mass spectra were acquired in the positive-ion mode. Full-scan MS spectra (m/z 400–1800) were acquired with a target value of 1 000 000 at a resolution of 30 000 at m/z 400, and the 15 most intense ions were

selected for collision-induced dissociation fragmentation in the LTQ with a target value of 10 000 and normalized collision energy of 38%. Precursor ion charge-state screening and monoisotopic precursor selection were enabled. Singly charged ions and unassigned charge states were rejected. Dynamic exclusion was enabled with a repeat count of 1 and exclusion duration of 30 s.

Proteome Discoverer 1.4.288 (Thermo) with MASCOT 2.3 was used to search in NCBI database, taxonomy Viridiplantae (1 530 236 sequences) and a homemade database with the *Lens culinaris* entries in UniProt (336 sequences, 75 114 residues). Database search parameters used were the following: peptide tolerance, 10 ppm; fragment ion tolerance, 0.8 Da; no enzyme and variable modification, methionine oxidation. In all peptide identification, the probability scores were greater than the score fixed by Mascot as significant with a *p*-value minor than 0.05. The automatic decoy database search function of Protein Discover was enabled to allow estimation of false discovery rate (FDR). Sequence identification with reported biological activity was compared with bioactive peptide sequences submitted to the BIOPEP database (http://www.uwm.edu.pl/biochemia/index.php/pl/biopep).

In Vitro Gastrointestinal Digestion. Lentil hydrolysates produced by selected protease type and hydrolysis time were further subjected to simulated gastrointestinal digestion by sequential hydrolysis with pepsin and pancreatin.[19] Digestions were stopped by heating samples in boiling water for 10 min. Samples were stored at −20 °C and then freeze-dried. Protein content was determined for each sample by the DC protein assay (Bio-Rad).

Statistical Analysis. Data were subjected to one-way analysis of variance (ANOVA) by Statgraphics Centurion XVI software, version 16.1.17 (Statistical Graphics Corporation, Rockville, MD). Differences between samples were compared by Duncan's multiple-range test at $P \leq 0.05$ probability levels.

RESULTS AND DISCUSSION

Protein content of lentil flour (27.4% ± 0.1% on dry basis) was within the range of reported values for lentil flours.[20] Alkaline extraction at pH 8 led to 80% extraction of total protein. Thus, protein content of lentil var. Castellana protein concentrate was 75.54% ± 0.2% on dry basis, which was comparable to previous data for red and green lentil protein concentrates (78.2% ± 0.2% and 79.1% ± 0.3%).[21] The obtained lentil protein concentrate was hydrolyzed by different enzymes (Alcalase, Savinase, Protamex, and Corolase 7089) to determine the most effective one for hydrolyzing lentil proteins and releasing ACE-inhibitory and antioxidant peptides.

Proteolytic Pattern of Hydrolysis. To evaluate hydrolysis efficiency, the degree of hydrolysis (DH) value is a widely used criterion, as it is highly related to the hydrolytic process yield. Figure 1 shows the effect of protease type and hydrolysis time in the DH of lentil proteins. DH values increased gradually, reaching a plateau at 5 h for Alcalase, Savinase, and Protamex (23%, 15%, and 11%) and at 4 h for Corolase 7089 (10%). The significant differences ($P \leq 0.05$) found among DH values of lentil hydrolysates may be attributed to different enzyme specificity.[22] Subtilisins have a broad specificity, which explains the higher proteolytic efficiency of Alcalase and Savinase compared to Protamex and Corolase 7089. Our results agree with previous studies showing the ability of Alcalase to produce protein hydrolysates with higher DH than other enzymes.[23] Maximum DH observed in the present study for Alcalase hydrolysates (23%) is comparable to values reported in earlier studies for other legume proteins.[24,25] In contrast, the degree of hydrolysis of cowpea and bean proteins by Alcalase was found to be significantly different from that of lentil proteins (35.7% and 14%, respectively) .[26,27] These differences in the susceptibility of lentil proteins to hydrolysis might be attributed

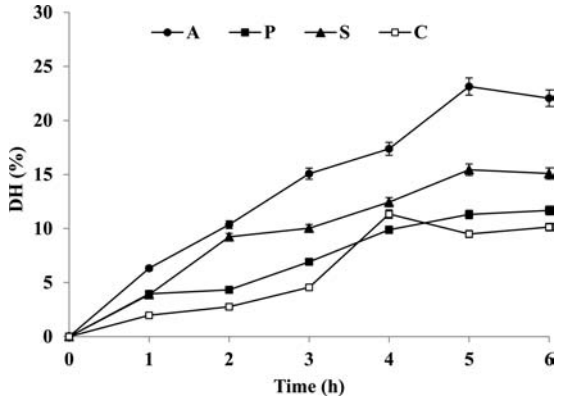

Figure 1. Degree of hydrolysis (DH) of lentil proteins for different proteases and hydrolysis times. The experiments were performed in duplicate. Bars indicate standard deviation. A, Alcalase; S, Savinase; P, Protamex; C, Corolase 7089.

to their particular structure.[28] Enzymatic treatments with sequential addition of Alcalase (1 h) and Flavourzyme (1.5 h) have also been used to increase proteolytic efficiency in the production of lentil hydrolysates.[29] In this case, high DH values were obtained (58% and 64% for red and green lentil proteins, respectively); however, extensive proteolysis is not recommended because peptides generated may produce bitterness and worsen important technological properties required for particular food industry applications.

Figure 2 shows the electrophoretic profiles of lentil hydrolysates produced by (A) Alcalase, (B) Savinase, (C) Protamex, and (D) Corolase 7089. Nonhydrolyzed protein concentrate (Figure 2, lanes 2) showed nine intense bands with apparent molecular masses (MM) from 14.4 to 95 kDa. The major bands found in lentil concentrate had estimated MM of 50 and 65 kDa, which probably correspond to subunits of vicilin (48 kDa) and convicilin (63 kDa), respectively.[30] Other bands with lower MM of 40, 20, and <15 kDa were considered to belong to 11S acidic subunit, 11S basic subunit, and a mixture of γ-vicilin and albumin polypeptides, respectively.[31] The electrophoretic profile of protein concentrates from lentil var. Castellana was similar to that reported for green and red lentil concentrates.[13] Major polypeptides found in lentil protein concentrate were readily hydrolyzed by Alcalase to small peptides <10 kDa after 1 h (Figure 2A, lane 3). Longer hydrolysis times from 4 to 6 h induced further breakdown of peptide bonds and formation of much smaller fractions at MM < 6 kDa (Figure 2A, lanes 6−8). Our results agree with previous studies in which Alcalase digestion was efficient in producing small peptides with MM below 10 kDa from chickpea[24] and bean[26,31] proteins. In addition, sequential use of Alcalase and Flavorzyme to produce peptides from lentil proteins has been proven more effective than the use of gastrointestinal enzymes, papain, and bromelain.[13] Similarly to Alcalase, protein digestion by Savinase was also efficient. A sharp reduction of most polypeptides (30, 40, 50, 55, and 65 kDa) present in lentil protein concentrate was observed after 1 h of hydrolysis, appearing as new bands under 14 kDa (Figure 2B, lane 3). As hydrolysis progressed, polypeptides with estimated MM of 50, 55, and 65 kDa were completely degraded (Figure 2B, lanes 4−8). In addition, the reduction of intensity of bands with MM <14 kDa suggested further degradation of the peptides into much smaller fragments. In contrast, Protamex and Corolase 7089 digestions were not as

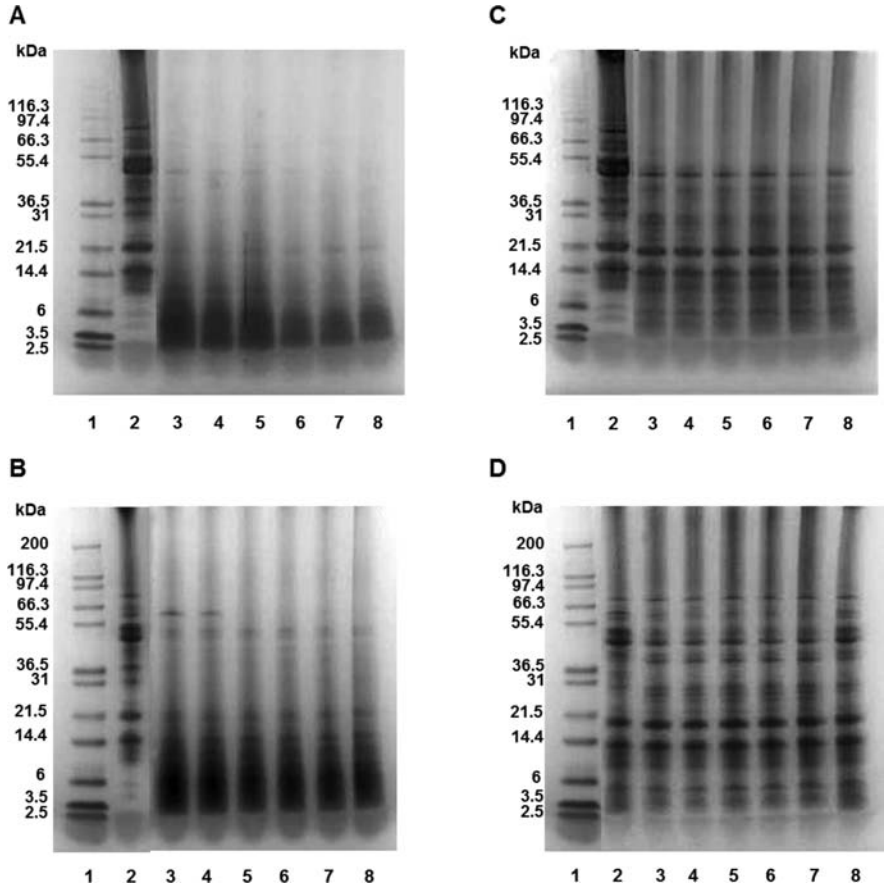

Figure 2. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) profiles of lentil hydrolysates obtained for different proteases and hydrolysis times. (A) Alcalase; (B) Savinase; (C) Protamex; (D) Corolase 7089 hydrolysates. Lane 1, molecular weight marker Mark 12; lanes 2−8, respectively 0, 1, 2, 3, 4, 5, and 6 h of hydrolysis.

efficient as Alcalase and Savinase digestions, consistent with DH values (Figure 2C,D). Protamex digestion completely degraded high- and medium-molecular weight polypeptides (estimated MM 30, 37, 60, 67, and 90 kDa) within 1 h (Figure 2C, lane 3). As a consequence, the appearance of some bands between 30 and 20 kDa and <10 kDa was observed. Further treatment with Protamex resulted in slight changes in the digest profile, such as the disappearance of some bands with apparent MM between 30 and 20 kDa, and increased intensity of the fraction <10 kDa (Figure 2C, lanes 4−8). Finally, Corolase 7089 treatment decreased the intensity of bands with MM 50, 55, 67 kDa, while the appearance of lower MM bands at 25 and 28 kDa and under 6 kDa were observed after 1 h (Figure 2D, lane 3). Longer digestion time had little impact on the SDS−PAGE profiles, in which only the increased intensity in the fraction under 6 kDa was observed (Figure 2D, lanes 4−8). Resistance of lentil and other legume proteins to proteases such as Protamex and Corolase 7089 has not been reported previously.

ACE Inhibitory Activity of Lentil Protein Hydrolysates. ACE-inhibitory peptides are generally short amino acid sequences, since the active site of ACE cannot accommodate large peptide molecules.[32] Therefore, samples were ultrafiltered through a 3 kDa cutoff membrane and the permeate was used for ACE-inhibitory analysis. Nonhydrolyzed lentil protein concentrate showed weak ACE-inhibitory activity (20% inhibition). ACE-inhibitory activity of hydrolysates was significantly affected by the protease used and the hydrolysis time (Table 1). Alcalase and Savinase hydrolysates exhibited higher ACE inhibition (64−71% and 56−63%, respectively) than Protamex (31−46%) and Corolase 7089 (28−50%)

Table 1. Effect of Hydrolysis Time and Protease Type on ACE-Inhibitory Activity of Lentil Hydrolysates[a]

digests, regardless of hydrolysis time. ACE-inhibitory efficacy is directly associated with chain length and peptide sequence. Short peptide chains containing between 3 and 12 amino acid residues and Tyr, Phe and Pro or hydrophobic amino acids are reported to be the most favorable sequences for ACE inhibition.[10] Alcalase and Savinase produced hydrolysates with a higher yield of shorter peptide sequences (Figure 2A,B) that, in conjunction with their specificity for aromatic or hydrophobic residues at position P1[22], is consistent with their higher ACE-inhibitory efficacy. ACE-inhibitory activity of hydrolysates gradually increased ($P \leq 0.05$), reaching maximum values after 1−3 h depending on the enzyme, while this activity decreased with extended hydrolysis time ($P \leq 0.05$) likely due to active amino acid sequences were cleaved by protease. IC_{50} values were calculated for A3 and S2 hydrolysates, selected for their highest ACE-inhibitory activities. The selected hydrolysis time (3 h for Alcalase and 2 h for Savinase) was chosen because no significant improvements were found with further digestion times ($P \geq 0.05$). The A3 and S2 hydrolysates exhibited significantly different ($P \leq 0.05$) IC_{50} values of 0.25 ± 0.02 and 0.18 ± 0.02 mg of protein/mL, respectively. It is worth noting the considerably higher ACE-inhibitory activity of S2 hydrolysates compared to A3 hydrolysates ($P \leq 0.05$). These results suggest that Savinase should generate peptides with more favorable amino acid sequences than Alcalase. As far as we know, this is the first evidence showing the effectiveness of Savinase in releasing ACE-inhibitory peptides from legume proteins. IC_{50} values of ACE-inhibitory peptides in A3 and S2 hydrolysates are higher when compared to activities of peptides released from lentil proteins by gastrointestinal enzymes (0.43−0.89 mg/mL).[14,33,34] Moreover, the ACE-inhibitory activity of S2 hydrolysates found in this work is within the range of reported IC_{50} values for red and green lentil concentrates hydrolyzed by Alcalase/Flavourzyme, bromelain, and papain (0.19−0.08 mg/mL), although it is noteworthy that much longer hydrolysis time (8 h) were used in the case of both plant proteases.[13] The ACE-inhibitory activity of A3 and S2 hydrolysates is quite promising in comparison to activities reported for Alcalase hydrolysates from different legumes such as cowpea, chickpea, mung bean, and soybean, exhibiting IC_{50} values ranging from 2.5 to 0.13 mg/mL.[23,25,27,35]

Antioxidant Activity of Lentil Protein Hydrolysates. The effect of hydrolysis time and protease type on the potential antioxidant activity of lentil hydrolysates was determined by the ORAC-FL method, which reflects peroxyl radical scavenging activity.[36] Antioxidant mechanism assayed with ORAC method is based on a hydrogen atom transfer mechanism. A radical initiator is used to generate peroxyl radical $ROO^{\bullet}$ that abstracts a hydrogen atom from antioxidant molecules present in the sample. Results in Table 2 indicate that ORAC values of nonhydrolyzed lentil proteins were significantly lower compared to those of lentil hydrolysates ($P \leq 0.05$). Hydrolysis time and protease used greatly affected the radical scavenging activity of lentil protein hydrolysates. Hydrolysates produced with Alcalase, Savinase, and Corolase 7089 displayed a gradual increase in peroxyl scavenging activity, reaching the highest values after 4, 2, and 3 h, respectively ($P \leq 0.05$). In contrast, Protamex hydrolysates showed the highest activity ($P \leq 0.05$) at the shortest time (1 h), after which a gradual decrease was observed ($P \leq 0.05$). The differences in antioxidant activity observed at different hydrolysis times could be attributable to the different peptides and amino acid sequences released during hydrolysis. This leads to a difference in their ability to act as donors of hydrogen atoms that may inhibit oxidative chain reactions or prevent their initiation. Higher antioxidant activity potential of A4 and S2 hydrolysates may be explained by the higher efficiency of Alcalase and Savinase in producing smaller peptides (Figure 2A,B). The molecular weight of peptides is believed to play a key role in scavenging oxygen radicals. Recent studies pointed out that the radical scavenging activity of cowpea and bean protein hydrolysates increased with decreasing molecular weight.[27,37] In fact, identified antioxidant peptides derived from food proteins are composed of 2−16 amino acid residues.[38] The higher efficiency of subtilases in releasing peroxyl scavenging peptides observed in the present study is consistent with their preferential specificity to cleave hydrophobic amino acids, which have been shown to act as proton donors.[39] Comparison of the ORAC values showed that S2 hydrolysate exhibited the highest peroxyl scavenging activity (0.8 μmol of TE/mg of protein), followed by A4 hydrolysate (0.7 μmol of TE/mg of protein). These results indicate that Savinase released antioxidant peptides with more favorable amino acid sequences than Alcalase. The ORAC values of permeates <3 kDa from S2 and A4 hydrolysates were also analyzed. Radical scavenging activity was 2-fold higher in these fractions compared to whole hydrolysates. A4 permeates exhibited 0.91 ± 0.05 μmol of TE/mg of protein and S2 permeates exhibited 1.22 ± 0.06 μmol of TE/mg of protein, suggesting that short peptides may be responsible for the potential antioxidant activity of protein hydrolysates, in agreement with previous studies.[27,37] To our knowledge, this is the first study on the production of hydrolysates with antioxidant activity from lentil proteins. The antioxidant activity of A4 and S2 hydrolysates, measured by the ORAC-FL method, was more than 2 times higher compared to that of Alcalase hydrolysates from different soybean cultivars.[40] In addition, lentil hydrolysates produced by subtilases in the present study exhibited ORAC values within the range of reported values for common vegetables (green pepper, spinach, purple onion, broccoli, beet, and cauliflower) considered as leading sources of antioxidant activity against peroxyl radicals (0.023−0.3 μmol of TE/mg dry weight).[36]

Table 2. Effect of Hydrolysis Time and Protease Type on Antioxidant Activity of Lentil Hydrolysates[a]

time (h)	ORAC (μmol of Trolox/mg of protein)

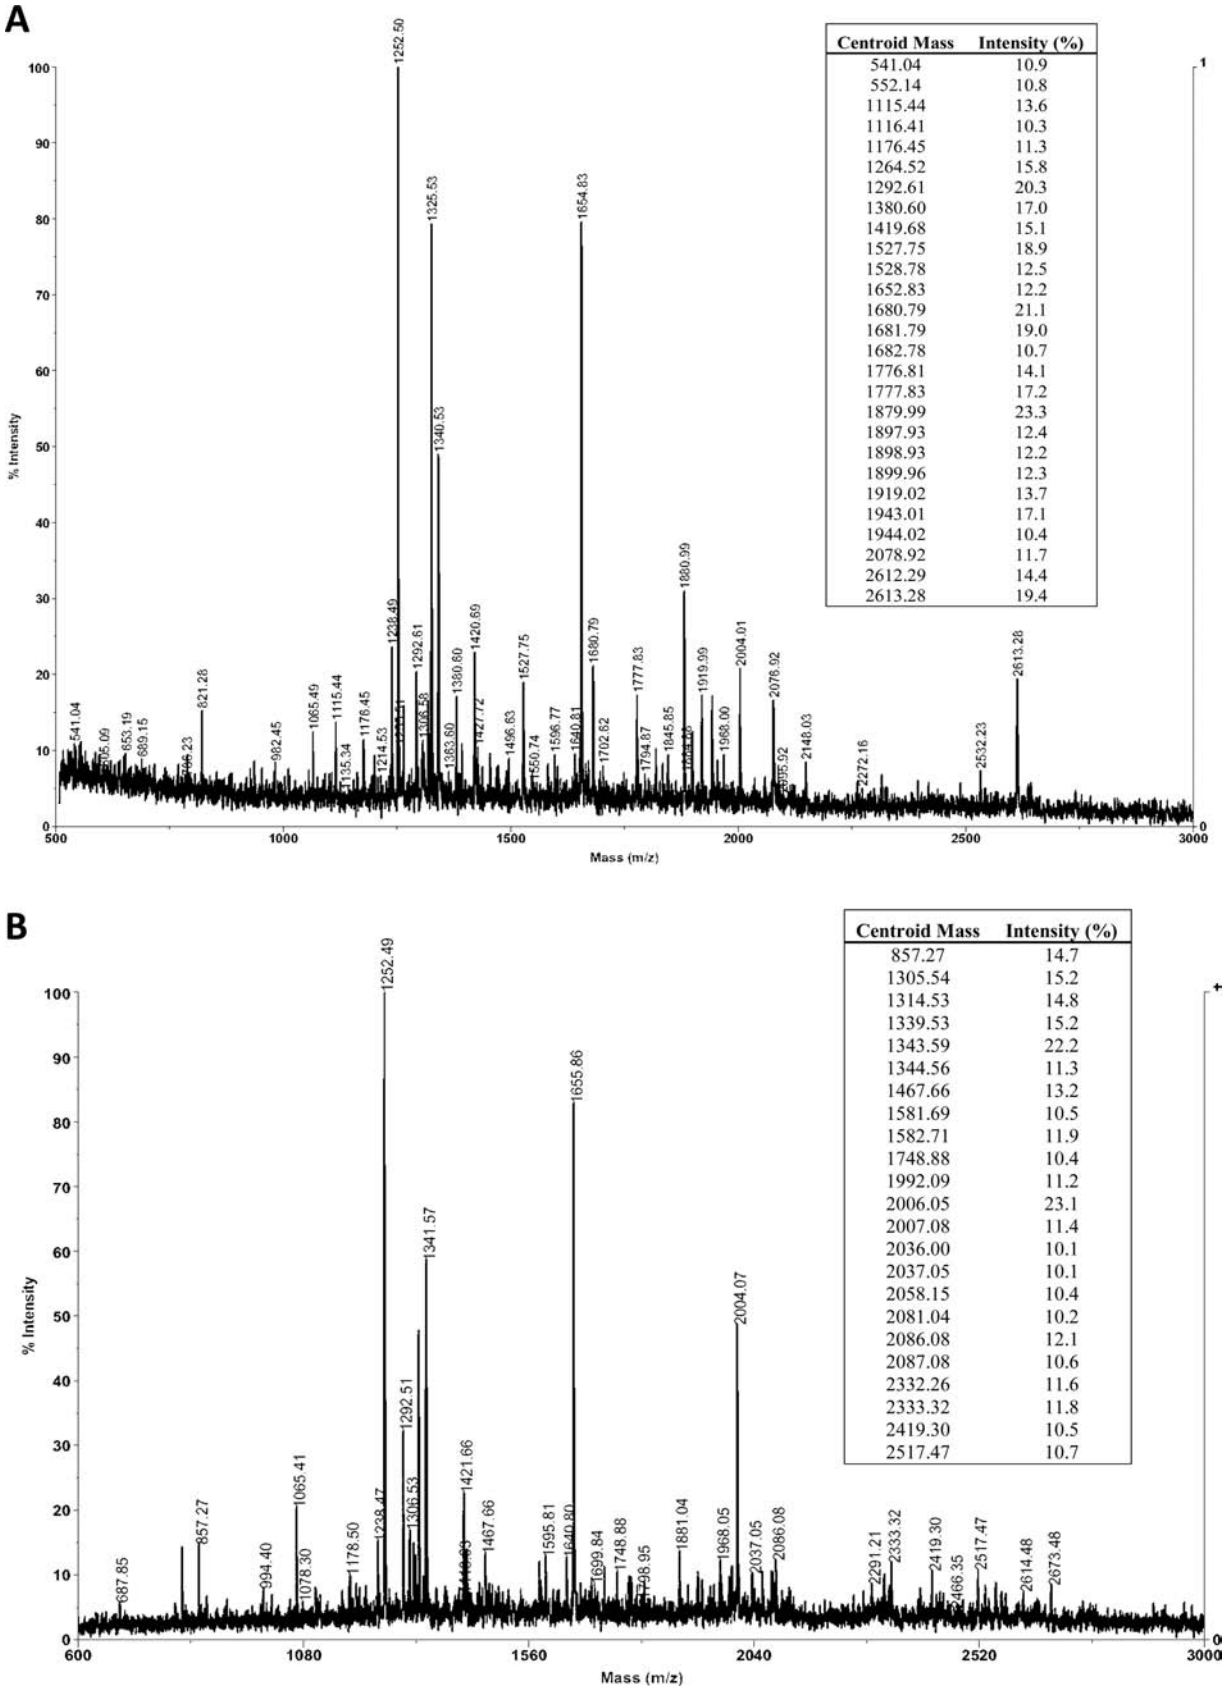

Figure 3. Peptide mass fingerprint of 3 kDa permeates of lentil hydrolysates: (A) A4 hydrolysate; (B) S2 hydrolysate. Mass spectra were obtained by MALDI-TOF in the reflector mode for positive ions. The respective table insets show differential peptide masses observed for each hydrolysate.

Peptide Mass Fingerprint of Selected Lentil Hydrolysates. A4 and S2 hydrolysates were selected for MALDI-TOF analysis on the basis of their highest biological activities. Figure 3 shows mass spectra of the 3 kDa permeates of A4 and

dx.doi.org/10.1021/jf500849u | J. Agric. Food Chem. 2014, 62, 4166−4174

S2 hydrolysates. Comparison of the spectra showed similarities between A4 and S2 hydrolysates such as the presence of high-intensity signals (m/z 1251.1−1255.5, 1325.5−1327.5, 1340.5−1342.5, 1652.8−1657.8, and 2004.0−2007.1) referred to either matrix-related clusters or peptides that could represent concomitants including nonspecific digestion products.[41,42] It is worth noting that A4 and S2 hydrolysates showed differential peptide masses with reduced intensity (see the inset mass peptide list in Figure 3). The different peptide profiles observed for A4 and S2 hydrolysates indicates that Alcalase and Savinase have different enzyme specificities, which is consistent with the above-mentioned results.

Identification of Bioactive Multifunctional Peptides. S2 hydrolysate was selected for peptide identification on the basis of its higher ACE-inhibitory and antioxidant activities, and the 3 kDa permeate was analyzed by reverse-phase (RP) HPLC−tandem mass spectrometry (MS/MS). Table 3 shows the list of peptides identified that contain, within their amino acid sequences, reported ACE-inhibitory (boldface) and antioxidant activity (underlined) sequences according to BIOPEP database. Identified peptides were fragments derived from lentil storage proteins (convicilin, vicilin, legumin, and albumin), allergen Len c 1, and lectin having at the C-terminus residues such as alanine (A), valine (V), leucine (L), tyrosine (Y), phenylalanine (F), and tryptophan (W). The presence of some of these amino acids in the ultimate position fulfils the rule proposed by Cheung et al.[43] about residues being preferred for ACE inhibitors and substrates. Moreover, peptides identified were characterized by the presence of several hydrophobic amino acids such as Ala (A), Pro (P), Val (V), Ile (I), Leu (L), Phe (F), Trp (W), Tyr (Y), and Met (M), which may act as proton donors .[39] Specifically, Tyr (Y) and Trp (W) have been reported as mainly responsible for the antioxidant activity of peptides in the ORAC-FL model.[44,45] In some peptides His (H) was also found, which has been commonly associated with antioxidant activity due to its hydrogen-donating and radical-trapping imidazole ring.[39] Taken all together, identification of the amino acid sequence of peptides in Savinase lentil hydrolysates has demonstrated their multifunctional properties that could make an important contribution in dietary interventions for prevention/therapy of hypertension. This is the first study showing an exhaustive characterization of the peptide fraction of lentil protein hydrolysates. So far, only three ACE-inhibitory peptides (KLRT, TLHGMV, and VNRLM) released by sequential pepsin−pancreatin hydrolysis from lentil proteins have been identified,[33] and none of them were identified in the present work.

Stability of ACE-Inhibitory and Antioxidant Peptides in Selected Lentil Hydrolysate to Gastrointestinal Digestion. There are numerous in vivo studies in animal models of hypertension and human clinical studies in hypertensive patients showing that oral administration of bioactive peptides from food proteins with ACE-inhibitory activity or foods containing these peptides results in the reduction of hypertension.[46] This body of evidence demonstrates that ACE-inhibitory peptides can resist gastrointestinal digestion to be absorbed in the intestine and ultimately reach the target molecule. Nevertheless, gastrointestinal enzymes may cause structural degradation of bioactive peptides and loss of their bioactivity. Therefore, it is important to determine their stability to gastrointestinal digestion. For this purpose, the most potent peptide fraction (3 kDa permeate of S2 hydrolysate) was further sequentially digested with pepsin and pancreatin to simulate gastrointestinal digestion. Some studies have reported a relationship between peptide structure and bioavailability; thus, small hydrophobic peptides tend to be resistant to gastrointestinal digestion and, therefore, are generally absorbed.[48] Accordingly, based on the cleavage mechanism of

Savinase, lentil hydrolysates produced in the present study were hydrophobic and with molecular masses below 3 kDa, which supports the potential bioavailability of such hydrolysates. Figure 4 shows ACE-inhibitory and antioxidant activities of 3

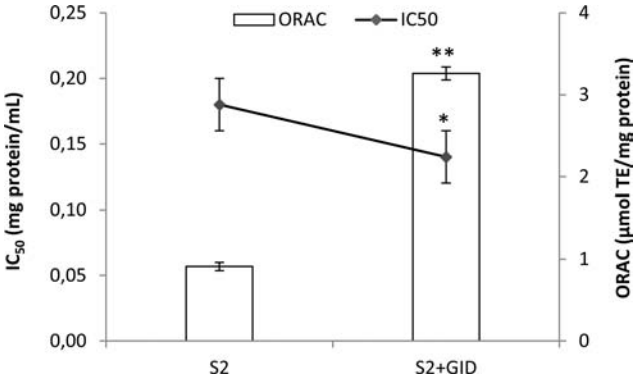

Figure 4. Stability to gastrointestinal digestion of ACE-inhibitory and antioxidant activity of 3 kDa permeates of A3 and S2 hydrolysates. Lines represent ACE-inhibitory activity, and bars show antioxidant activity before and after in vitro gastrointestinal digestion. *Statistical difference at $P < 0.05$; **Statistical difference at $P < 0.001$ (Duncan's test).

kDa permeate of S2 hydrolysate before and after in vitro gastrointestinal digestion. When peptides were subjected to in vitro gastrointestinal digestion, IC_{50} was slightly lower (0.14 mg of protein/mL) compared to that before digestion (0.18 mg of protein/mL), which indicates a higher ACE-inhibitory potency ($P \leq 0.05$). In addition, antioxidant activity of peptides in the 3 kDa fraction increased 3 times after gastrointestinal digestion ($P \leq 0.05$). These results suggest that peptides in S2 hydrolysates were either resistant or liberated new fragments with ACE-inhibitory and antioxidant activity after simulated gastrointestinal digestion. As consequence, peptides in S2 hydrolysate could preserve or improve its multifunctionality in the gastrointestinal tract.

In conclusion, this study reveals that subtilisins are the most suitable enzymes for lentil proteolysis and production of hydrolysates with ACE-inhibitory and antioxidant activities. The highest ACE-inhibitory and antioxidant activities were found in lentil hydrolysates treated with Savinase for 2 h at 40 °C. Therefore, Savinase is the best choice for cost-effective production of lentil multifunctional hydrolysates. Several peptides with amino acid sequences rich in hydrophobic amino acids were identified in these hydrolysates, which make them potential contributors to the dual bioactivity detected. Multifunctional hydrolysates could encourage value-added utilization of lentil proteins as functional ingredients of nutraceuticals for prevention of hypertension and cardiovascular diseases.

Effects of Different Industrial Heating Processes of Milk on Site-Specific Protein Modifications and Their Relationship to in Vitro and in Vivo Digestibility

Yasuaki Wada[†,‡] and Bo Lönnerdal*[,†]

[†]Department of Nutrition, University of California, Davis, One Shields Avenue, Davis, California 95616, United States

ABSTRACT: Heating processes are applied to milk and dairy products to ensure their microbiological safety and shelf lives. However, how differences in "industrial" thermal treatments affect protein digestibility is still equivocal. In this study, raw milk was subjected to pasteurization, three kinds of ultra-high-temperature (UHT) treatment, and in-can sterilization and was investigated by in vitro and in vivo digestion and proteomic methods. In-can sterilized milk, followed by UHT milk samples, showed a rapid decrease in protein bands during the course of digestion. However, protein digestibility determined by a Kjeldahl procedure showed insignificant differences. Proteomic analysis revealed that lactulosyllysine, which reflects a decrease in protein digestibility, in α-lactalbumin, β-lactoglobulin, and caseins was higher in in-can sterilized milk, followed by UHT milk samples. Thus, industrial heating may improve the digestibility of milk proteins by denaturation, but the improvement is likely to be offset by heat-derived modifications involved in decreased protein digestibility.

KEYWORDS: *heating processes, milk proteins, protein digestibility, Maillard reaction, mass spectrometry*

INTRODUCTION

Milk is heat-treated in the dairy industry to ensure microbiological safety and to prolong shelf life. Pasteurization is the most common way to heat milk, typically at 72 °C for 15 s, which allows storage at 4 °C for a few weeks. Milk is also sterilized by ultra-high-temperature (UHT; 135−150 °C for 2−6 s) treatment, and the combination with aseptic packaging makes it distributable at ambient temperature for months. Similar to milk, ready-to-use (liquid) infant/enteral formulas are sterilized for the purpose of distribution at ambient temperature, and UHT treatment and in-can sterilization (>110 °C for 20−30 min) are commonly used. These types of heat treatment can affect their sensory, physicochemical, and nutritional qualities. The nutritional value of milk protein, which is generally recognized as excellent, is influenced by heating processes.[1]

Unfolding of tertiary and secondary structures (denaturation) is the principal change caused by heat treatment, and this generally increases protein digestibility, as is commonly known for legume proteins.[2] However, nonenzymatic posttranslational modifications also occur in milk proteins, which influence their nutritional properties negatively. The so-called Maillard reaction modifies the side chain of the protein; ε-amino groups of lysine (Lys) residues represent the primary target for an attack by reducing sugars such as lactose to form the Amadori product lactulosyllysine (Figure 1a), which can subsequently undergo a series of advanced reactions leading to a variety of modified structures such as N^{ε}-carboxymethyllysine (CML; Figure 1b).[3] Blocking of the ε-amino groups of Lys residues hinders tryptic digestion as well as the action of other digestive enzymes and, as a consequence, reduces protein digestibility.[4−6] The blocked Lys is no longer bioavailable, leading to a reduction in the biological value of milk protein.[7] Furthermore,

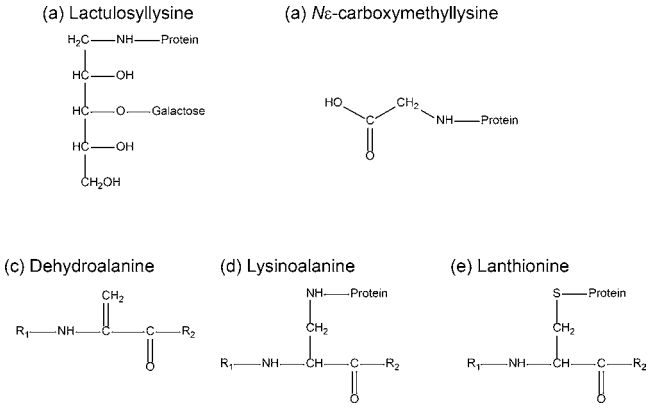

Figure 1. Chemical structures of heat-derived protein modifications. Lactulosyllysine (a) and N^{ε}-carboxymethyllysine (CML; b) are early/advanced Maillard reaction products, respectively. Dehydroalanine (c) is the precursor of cross-linked products lysinoalanine (d) and lanthionine (e).

β-elimination reactions occur to phosphoserine and cystine/cysteine (Cys) residues to form dehydroalanine (Figure 1c), which subsequently reacts with Lys and Cys residues to give cross-linked products such as lysinoalanine and lanthionine (Figure 1d,e)[8,9] They also reduce protein digestibility by inhibiting enzymatic proteolysis.[10] In addition, heating causes disulfide bond interchanges between proteins,[11] and some of the non-native complexes are resistant to digestion.[12] It is therefore important to identify and quantify these chemical

modifications from the standpoint of nutritional quality control of milk and dairy products. The recent advent of highly sensitive mass spectrometry (MS) technology has enabled direct determination of modifications in milk proteins, and the combination with enzymatic digestion prior to MS analysis has further allowed site-specific identification and semiquantification.[13−15]

The aim of this study was to use proteomic techniques to compare protein modifications of milk proteins exposed to different industrial heat processes. The same reference raw milk was subjected to pasteurization, three kinds of UHT (plate heat exchange, steam infusion, and steam injection) treatment, and in-can sterilization. Protein digestibility of milk samples was characterized in both in vitro and in vivo experiments. Milk samples were also applied to in-gel tryptic digestion followed by liquid chromatography (LC)-MS/MS analysis for simultaneous identification and semiquantification of modifications such as formation of lactulosyllysine, CML, and dehydroalanine. Lactulosyllysine and CML are early/advanced Maillard reaction products, respectively, and serve as markers of the thermal history. Dehydroalanine was selected instead of lysinoalanine and lanthionine because it is compatible with the analysis of lactulosyllysine and CML, whereas lysinoalanine and lanthionine are not. Formation of dehydroalanine has also been reported to reflect the thermal history, similar to lysinoalanine and lanthionine.[16]

MATERIALS AND METHODS

Milk Samples. Raw milk was heat-processed at the pilot plant of Morinaga Milk Industry Co., Ltd. (Zama, Japan), and the heating conditions were set by reference to those of the manufacturer's commercial products (Table 1). The heated milk samples were homogenized at 30 MPa, followed by lyophilization. The reference raw milk was lyophilized without homogenization. The lyophilized milk powders were stored at 4 °C until use. Indices of thermal history such as whey protein nitrogen index (WPNI) and lactulose contents were determined in all of the lyophilized milk samples by the Analytic Center of Morinaga Milk Industry,[17,18] and the results are shown in Table 2. On the basis of the results that in-can sterilized milk showed the highest lactulose and the lowest WPNI values, compositions such as protein, fat, carbohydrate, water, and ash were compared for lyophilized raw milk and in-can sterilized milk with standard methods in Morinaga Milk Industry, confirming that no notable change occurred after heat treatment (Table 3).

Table 1. Heat Treatment of Milk Samples

treatment	holding temp/time	F_0	reference product[a]
pasteurization	73 °C for 15 s	0	milk
plate UHT	140 °C for 2 s	2.6	milk
steam infusion	135 °C for 2 s	0.8	milk
steam injection	151 °C for 4 s	65	liquid enteral formula
in-can sterilization	121 °C for 20 min	20	liquid enteral formula

[a]Heating conditions were set by reference to those of the manufacturer's commercial products.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE) of Milk Samples. Milk powder samples were reconstituted with Milli-Q water (Millipore, Billerica, MA, USA) and subjected to centrifugation at 8500*g* for 30 min twice, and the upper fat layer was removed. The tiny pellet, formed after centrifugation, was thoroughly mixed with the skimmed milk fraction. Protein concentrations of skimmed milk were determined by using the Bradford method,[19] and they were adjusted to be the same among samples by dilution with deionized water. SDS-PAGE was performed under reducing/nonreducing conditions to separate the proteins (Bio-Rad, Hercules, CA, USA). Protein concentrations were determined by using the Bradford method, and 50 μg of protein was loaded for each sample onto 15% acrylamide resolving gel (pH 8.8) and 6% acrylamide stacking gel (pH 6.8). Electrophoresis was run at 150 V for 90 min, and gels were stained with Coomassie Brilliant Blue R-250 (Sigma-Aldrich, St. Louis, MO, USA).

Table 3. Nutrient Composition of Lyophilized Raw and In-Can Sterilized Milk

component (g/100 g)	raw	in-can sterilized
protein	25.5	25.5
fat	28.7	28.3
carbohydrate	38.2	38.2
ash	5.5	5.6
water	2.1	2.4

Proteomic Analysis. Proteomic analysis was conducted at the Proteomic Core Facility at the University of California, Davis, to site-specifically semiquantify lactulosyllysine, CML, phosphorylation on serine (Ser), threonine (Thr), and tyrosine (Tyr), and dehydroalanine formed from phosphoserine and Cys residues.

In-Gel Digestion. In-gel reduction, alkylation, and tryptic digestion were done as published previously.[20,21] Briefly, milk samples were reconstituted with deionized water and applied to electrophoresis to excise the fraction containing the entire protein band. The gel piece was dehydrated using acetonitrile (ACN), reduced with dithiothreitol, and alkylated using 55 mM iodoacetamide. Following further dehydration, sequencing grade modified trypsin (Promega, Madison, WI, USA; in 50 mM ammonium bicarbonate) was added in a 1:30 ratio (trypsin/protein), and the gel was incubated overnight at 37 °C. While the supernatant was collected into a new tube, 60% ACN (in 0.1% trifluoroacetic acid) was added to the remaining gel piece, which was then sonicated and centrifuged for collecting another supernatant. The supernatants were then dried by vacuum centrifugation.

Protein Identification. Digested peptides were analyzed by a Thermo Scientific Q Exactive Orbitrap mass spectrometer in conjunction with a Paradigm MG4 HPLC (Michrom Bio Resources, Auburn, CA, USA). The digested peptides were loaded onto a Michrom C18 trap and desalted before they were separated using a Michrom 200 μm × 150 mm Magic C18 AQ reverse phase column. A flow rate of 2 μL/min was used. Peptides were eluted using a 90 min gradient composed of buffers A (0.1% formic acid) and B (100% ACN), with 2−35% B over 70 min, 35−80% B for 5 min, 80% B for 2 min, then a decrease from 80 to 2% B in 1 min, and held at 2% B for 12 min. A spray voltage of 2.2 kV was used with a transfer capillary temperature of 200 °C. A MS survey scan was obtained for the m/z range of 300−1600. MS/MS spectra were acquired using a top 15 method, where the top 15 ions in the MS spectra were subjected to high-energy collisional dissociation. An isolation mass window of 2.0 m/z was used for the precursor ion selection, and a normalized collision energy of 27% was used for fragmentation. A 5 s duration was used for the dynamic exclusion.

Database Searching. Tandem mass spectra were extracted and charge states deconvoluted and deisotoped. All MS/MS samples were analyzed using X! Tandem (The GPM, thegpm.org; version TORNADO (2010.01.01.4)). X! Tandem was set up to search the

Table 2. Indices of Thermal History for Lyophilized Milk Samples

component	raw	pasteurized	plate UHT	steam infused	steam injected	in-can sterilized
WPNI (mg/g)	7.51	6.91	1.75	4.29	2.22	1.33
lactulose (mg/100 g)	20.2	19.6	204	42.0	241	1490

digestion enzyme trypsin. X! Tandem was searched with a fragment ion mass tolerance of 20 ppm and a parent ion tolerance of 20 ppm. Iodoacetamide derivative of Cys was specified in X! Tandem as a fixed modification. One of the targeted modifications [lactulosyllysine on Lys (+324.105647), CML on Lys (+58.005479), phosphorylation on Ser, Thr, and Tyr (+79.966331), dehydration of Ser (−18.010565), or dehydroalanine on Cys (−33.987721)], as well as acetylation of the N-terminus, ammonia loss of the N-terminus, *pyro*-glutamination of the N-terminus, and oxidation of methionine and tryptophan, were specified in X! Tandem as variable modifications.

Criteria for Protein Identification. Scaffold (version Scaffold_4.1.1, Proteome Software Inc., Portland, OR, USA) was used to validate MS/MS-based peptide and protein identifications, taking into consideration the Peptide Prophet algorithm, Protein Prophet algorithm, and false-discovery rates.[22−24] Proteins that contained similar peptides and could not be differentiated on the basis of MS/MS analysis alone were grouped to satisfy the principles of parsimony.

Peptide Semiquantification. Scaffold data were imported into Skyline (version 1.4.0.4421, MacCoss Lab, Department of Genome Science, University of Washington) to determine retention time and peak areas of peptides with targeted modifications. On the basis of the retention time, three different monoisotopic peak areas (M, M + 1, M + 2) were integrated for each specified peptide with Xcalibur (version 2.2 SP1.48, Thermo Scientific, Waltham, MA, USA), and they were summed to obtain higher confidence. For normalization between samples, the summed peak area was divided by the exclusive spectrum counts of all modified and nonmodified peptides derived from the parental protein, in Scaffold.

In Vitro Digestion. Milk powder samples were reconstituted and defatted as above and subjected to in vitro digestion.[25] Simulated gastric digestion was started with adjusting the pH to 2.0 (adult model) or 4.0 (infant model) with 1 M HCl. Porcine pepsin (Sigma-Aldrich; 2% in 1 mM HCl) was added to the sample in a 1:12.5 ratio (pepsin/protein). Samples were placed in an incubating shaker (New Brunswick Scientific, Edison, NJ, USA) at 140 rpm at 37 °C for 5, 10, 15, or 30 min. After this incubation, the pH of the samples was adjusted to 7.0 with 0.1 mol/L $NaHCO_3$.

Simulated intestinal digestion was performed following the gastric digestion (at pH 2.0 or 4.0). After the pH was adjusted to 7.0, pancreatin (Sigma-Aldrich; 0.4% in 0.1 mol/L $NaHCO_3$) was added to the samples in a 1:62.5 ratio (pancreatin/protein). Samples were placed in an incubator shaker at 140 rpm at 37 °C for 5, 10, 30, or 60 min. After the incubation, the enzymes were inactivated in a water bath at 85 °C for 3 min.

The digested samples were applied to reducing SDS-PAGE as described above, and each lane was loaded with the equivalent of 50 μg of protein before digestion. Protein digestibility of the samples subjected to gastric/intestinal digestion was determined using a Kjeldahl procedure as described previously.[26,27] Briefly, total nitrogen (N), and nonprotein N [NPN; soluble fraction after trichloroacetic acid (TCA; 12% final concentration) precipitation] were measured in milk samples before/after the digestion. Protein digestibility was defined as the ratio of $(NPN_{\text{after digestion}} - NPN_{\text{before digestion}})/(\text{total } N_{\text{before digestion}} - NPN_{\text{before digestion}})$. Protein digestibility was analyzed six times for each pH condition/time period tested.

In Vivo Digestion. A suckling rat pup model was used to investigate in vivo digestion of milk samples.[25,28−30] The study was approved by the International Animal Care and Use Committee of the University of California, Davis (protocol 17128), which is accredited by the American Association for the Accreditation of Laboratory Animal Care. Sprague−Dawley rats with litters of 12 pups (6 males + 6 females) were obtained commercially (Charles River, Wilmington, MA, USA), maintained in polycarbonate cages with wood shavings in a temperature-, humidity-, and light-controlled facility (22 °C, humidity 60%, and 12 h light/dark cycle), and allowed to consume deionized water and standard rat chow diet (Ralston Purina, St. Louis, MO, USA) ad libitum. Pups were randomly assigned as 3 males + 3 females/milk sample/time point. After acclimation to facility conditions, on day 14 postpartum, pups were separated from their dams for 6 h and then intubated with one of six types of milk (reconstituted, defatted, and adjusted to 30 g/L of protein), in a 1:36 v/w ratio [milk (mL)/body weight (g)]. Pups were euthanized with CO_2 asphyxiation at 0.5, 1, or 2 h after intubation. Stomach contents were collected and weighed. The small intestine was cut into upper and lower parts, and each part was perfused twice with 0.2 mL of phosphate-buffered saline (PBS) containing protease inhibitor cocktail (P2714, Sigma-Aldrich). Collected perfusates were stored at −80 °C until analysis.

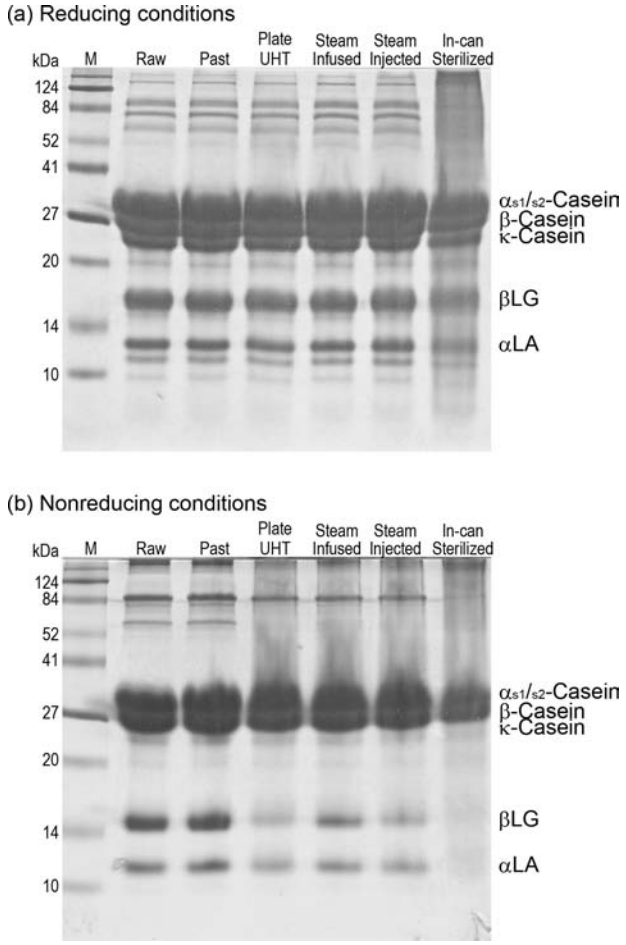

Figure 2. Electrophoresis of milk proteins. Milk samples were applied to SDS-PAGE analysis under (a) reducing and (b) nonreducing conditions. Fifty micrograms of protein was loaded onto a 15% gel, and the gel was stained with Coomassie Brilliant Blue R-250.

The perfusates underwent Western blotting. On the basis of the results obtained in the in vitro study, β-lactoglobulin (β-LG) was used as a marker protein of in vivo digestibility. The perfusates (5 μg of protein) were applied to reducing SDS-PAGE, and proteins were transferred to a Hybond ECL nitrocellulose membrane (GE Healthcare, Pewaukee, WI, USA). The membrane was blocked with 2% bovine serum albumin [in PBS containing 0.05% Tween-20 (PBST)] for 45 min at room temperature. After the membrane was washed three times with PBST, it was probed with rabbit anti-bovine β-LG antibody (Bethyl Laboratories Inc., Montogomery, TX, USA) in a 1:20000 dilution (antibody/blocking buffer) at room temperature for 45 min. After three washings with PBST, the membrane was probed with donkey anti-rabbit IgG antibody conjugated with horseradish peroxidase (GE Healthcare) in a 1:20000 dilution (antibody/blocking buffer) at room temperature for 45 min. After three washings with PBST, β-LG was detected by Pierce ECL Western Blotting Substrate (Thermo Scientific).

Statistical Analysis. Data on protein digestibility (Kjeldahl procedure) and stomach contents resulting from in vivo digestion were analyzed by one-way ANOVA and post-tested by the Tukey test

using Prism 4 (version 4.03 GraphPad Software Inc., San Diego, CA, USA), and significance was demonstrated at $p < 0.05$.

RESULTS

Electrophoresis of Milk Proteins. Milk samples were applied to SDS-PAGE, and the band patterns were compared (Figure 2). A notable difference was observed for in-can sterilized milk; proteins smeared in a wide range of molecular weights, and the bands of intact milk proteins decreased under reducing/nonreducing conditions. This trend, although to a lesser extent, was also observed for the three UHT-treated milk samples under nonreducing condition, where disulfide bonds are kept intact. These results suggest that pasteurization essentially does not induce any protein associations; the three kinds of UHT treatments caused new disulfide bond formation between proteins, facilitating protein aggregation, and in-can sterilization modified the proteins to a greater extent by forming new disulfide bonds and possibly other noncovalent interactions.

Proteomic Analysis. Milk samples were applied to LC-MS/MS analysis following in-gel tryptic digestion for identifying and semiquantifying modifications involved in protein digestibility, such as lactulosyllysine, CML, and dehydroalanine on Ser and Cys residues, in major milk proteins. Relative amounts of quantified peptides with the above modifications are shown in Tables 4−6. It should be noted that some of the peptides containing the specified modifications were identified but could not be quantified probably because of low abundance. In-can sterilized milk had the highest signal intensity for lactulosyllysine at all of the modified sites in α-LA, β-LG, and CNs, followed by plate UHT and steam-injected milk. A similar trend was observed for CML; the highest signals were observed at Lys77

in β-LG and all of the modified sites in CNs for in-can sterilized milk, which was followed by plate UHT and steam-injected milk. Some of the lactulosyllysine/CML sites could not be solely assigned, such as lactulosyllysine of Lys83/91 in β-LG, lactulosyllysine of Lys76/80 in α_{S2}-CN, CML of Lys47/69/70 in β-LG, and CML of Lys34/36 in α_{S1}-CN. However, by taking into consideration the fact that CML should be converted from lactulosyllysine and that trypsin can never recognize lactulosyllysine as a cleavage site,[3,5] it can be assumed that lactulosyllysine of Lys76/80 in α_{S2}-CN would be Lys76, CML of Lys47/69/70 in β-LG would be Lys47, and CML of Lys34/36 in α_{S1}-CN would be Lys 36. If this is true, all of the quantified CML sites would overlap the quantified lactulosyllysine sites except Lys152 in α_{s2}-CN and Lys105 in β_{s2}-CN. It should be noted that lactulosyllysine was also identified (but not quantifiable) at these sites (data not shown). In contrast with lactulosyllysine/CML, dehydroalanine could be quantified only at three sites in all of the major proteins. These signals were weak, and no clear trend was observed among the milk samples, indicating that dehydroalanine formation in the milk samples is very limited.

In addition to the above-mentioned modifications, phosphorylation on Ser, Thr, and Tyr was also semiquantified as it may provide further information in the context of heat treatment and proteins; milk proteins have generally been considered to be dephosphorylated after heat treatment of milk,[31] whereas proteins can be phosphorylated in the presence of phosphate after dry heating.[32,33] In this study, phosphorylation could be quantified at three Ser residues in α_{S1}-CN, α_{S2}-CN, and β-CN (Table 7). In general, they appear to be dephosphorylated after heating, but to a very limited extent, although phosphorylation of Ser46 increased in in-can sterilized milk.

In Vitro Digestion of Milk Samples. SDS-PAGE analysis of milk samples after in vitro digestion is shown in Figure 3. A rapid decrease in α-LA, β-LG, and CN bands was observed during the course of digestion in in-can sterilized milk, indicating that in-can sterilization facilitated enzymatic digestion of these proteins. The bands for α-LA and β-LG, but not CN, decreased over time in the three UHT-treated milk samples, but this did not occur as rapidly as in in-can sterilized milk. The digestibility appeared to be plate UHT > steam injected > steam-infused milk, according to the remaining band

Table 7. Phosphorylation of Ser in Milk Proteins[a]

protein	residue	amino acid	charge	raw[b]	pasteurized	plate UHT	steam infused	steam injected	in-can sterilized

[a]Milk samples were treated with trypsin, followed by LC-MS/MS analysis for identifying and semiquantifying trypic peptides containing phosphorylation on Ser in milk proteins. [b]Peak areas of the specific peptides are expressed as mean values (n = 2); normalized to raw milk.

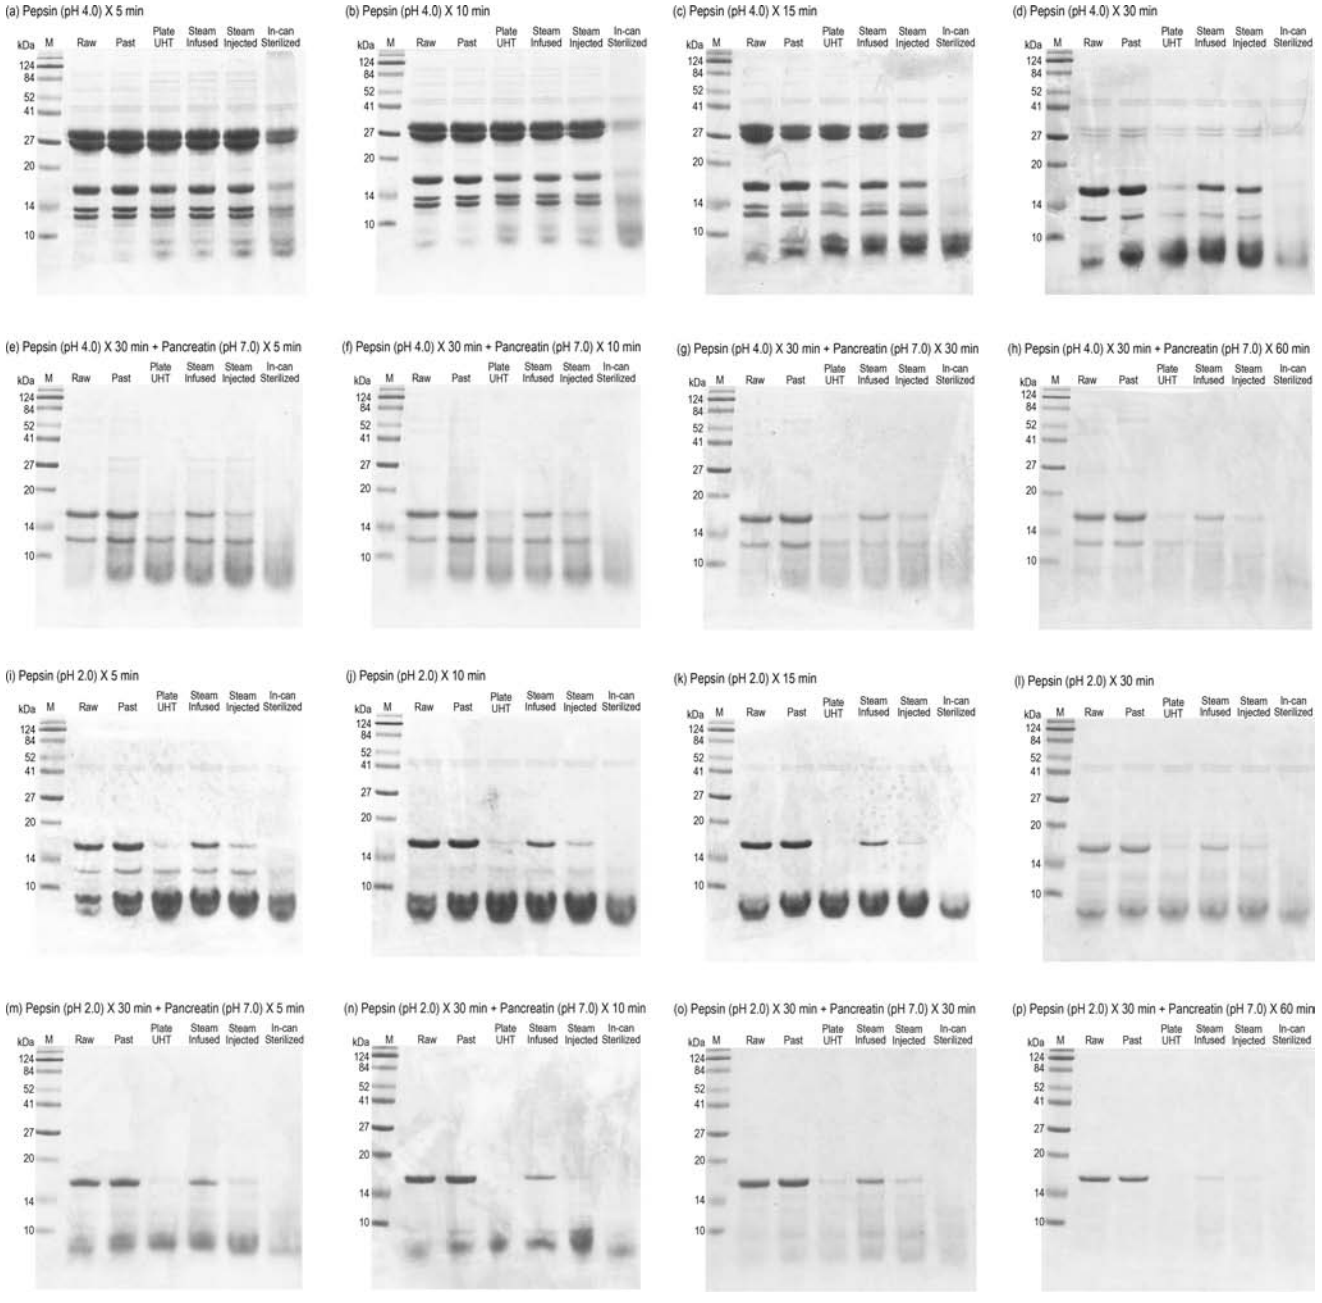

Figure 3. Electrophoresis of milk proteins after in vitro digestion. Milk samples were subjected to in vitro digestion using pepsin and pancreatin for different time periods. Both infant (a-h) and adult (i-p) digestion conditions were simulated by adopting different pH values during the peptic digestion. Fifty micrograms of protein (before digestion) was loaded onto a 15% gel, and the gel was stained with Coomassie Brilliant Blue R-250.

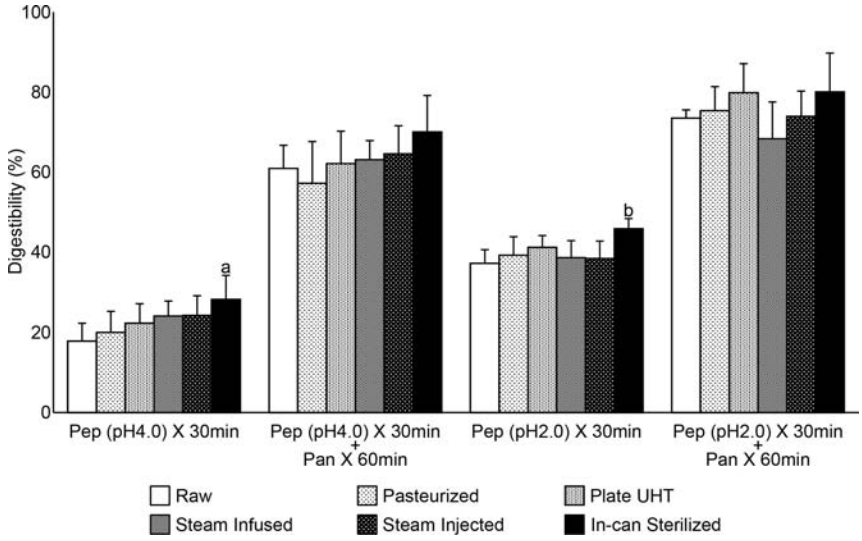

Figure 4. Protein digestibility of milk proteins after in vitro digestion. Protein digestibility was defined as the increase in NPN after in vitro digestion, which was determined by the combination of TCA precipitation and a Kjeldahl procedure. Each digestion and the subsequent procedures were conducted six times, and data are expressed as means ± SD. "a", $p < 0.05$ (in-can sterilized vs raw milk); "b", $p < 0.05$ (in-can sterilized vs raw or steam-injected milk).

intensities for α-LA and β-LG. In contrast to in-can sterilized milk and the three UHT-treated milk samples, pasteurized milk showed the same band patterns as raw milk throughout the digestion experiments, suggesting that pasteurization does not affect the digestibility of the milk proteins to any significant extent.

At the final time points of each peptic/pancreatic digestion, the digestibility of total milk protein was determined using a Kjeldahl procedure (Figure 4). In-can sterilized milk showed the highest digestibility of all the digestion conditions. However, the differences in total protein digestibility among the samples seem equivocal compared with the observations for the above SDS-PAGE.

In Vivo Digestion of Milk Samples. White coagulates, which are likely acid-precipitated CNs, were observed in the stomachs of rat pups after intubation with the milk samples (Figure 5a). Pups fed in-can sterilized milk had the smallest contents at 0.5 and 1 h, which was statistically lower at 1 h compared with the plate UHT milk-fed group ($p < 0.05$). At 2 h, there were no notable differences in stomach contents among the milk samples. This indicates that extensive heat treatment such as in-can sterilization can affect coagulation of CN negatively as previously reported for pasteurized milk.[34] Furthermore, a notable decrease in the pH of the stomach content was observed in the in-can sterilized milk-fed group at 2 h (Figure 5b), which may also corroborate damaged casein coagulation potential, manifested as impaired buffering activity.

Perfusates from the upper small intestine showed complex protein band patterns by SDS-PAGE (data not shown). Because β-LG exhibited a prominent difference in in vitro digestion among the milk samples, this protein was chosen to assess in vivo digestibility and was analyzed by Western blotting (Figure 6). At 0.5 h, strong β-LG bands were observed for raw milk and pasteurized milk in its intact form as well as partially fragmented forms, whereas intact bands were barely detected in the three UHT-treated milk samples and in-can sterilized milk. At 1 h, β-LG was still visible in raw milk, but the bands were barely detectable or invisible for the remaining five milk samples. At 2 h, no β-LG band was detectable for any of the milk samples. Western blotting of β-LG was also conducted for the lower intestine perfusates, but the bands were very faint and no clear differences were observed among the milk samples (data not shown).

DISCUSSION

MS techniques have extensively been utilized to characterize chemical modifications of milk proteins. However, the link between chemical characterization of the proteins and their nutritional consequences has rarely been discussed. In this study, heated milk samples were manufactured from the same reference raw milk and they were investigated in terms of both protein digestibility and proteomic characterization.

Sites of protein modifications have been a major interest in proteomic studies of milk proteins, and lactulosyllysine sites are often identified. In this study, α-LA had only one lactulosylation site at Lys98, which is the main lactulosylation site in this protein. This modification has been identified in UHT milk and powdered infant formulas.[35−37] As for β-LG, all five lactulosylation sites have previously been identified in pasteurized milk, UHT milk, and/or powdered infant formulas.[5,35,37] Among them, Lys47 is the best studied site because of its high reactivity.[38,39] Semiquantification has also been conducted using various kinds of dairy products.[15] All of the lactulosyllysine sites in CNs, except Lys199 in α_{S2}-CN, agree with previous studies.[5,37] Thus, the general agreement of the lactulosyllysine sites substantiates the validity of this study, and the new lactulosyllysine site (Lys199 in α_{S2}-CN) could be found probably due to methodological differences. With regard to semiquantification of protein modifications, our results look controversial at first glance in that both lactulosyllysine and CML were quantifiable in all heat-treated milk samples as well as raw milk (despite the absence of heat treatment). However, this observation is reasonable because some studies could quantify furosine, an indirectly measured product from Amadori compounds, and CML in raw milk samples.[40,41] The highest signals for lactulosyllysine and CML were observed at almost all of the sites in in-can sterilized milk, reflecting the severe thermal history resulting from slow rates of temperature rise/fall and the longest holding time at high temperature. To a lesser extent, the signals for the three UHT-treated milk

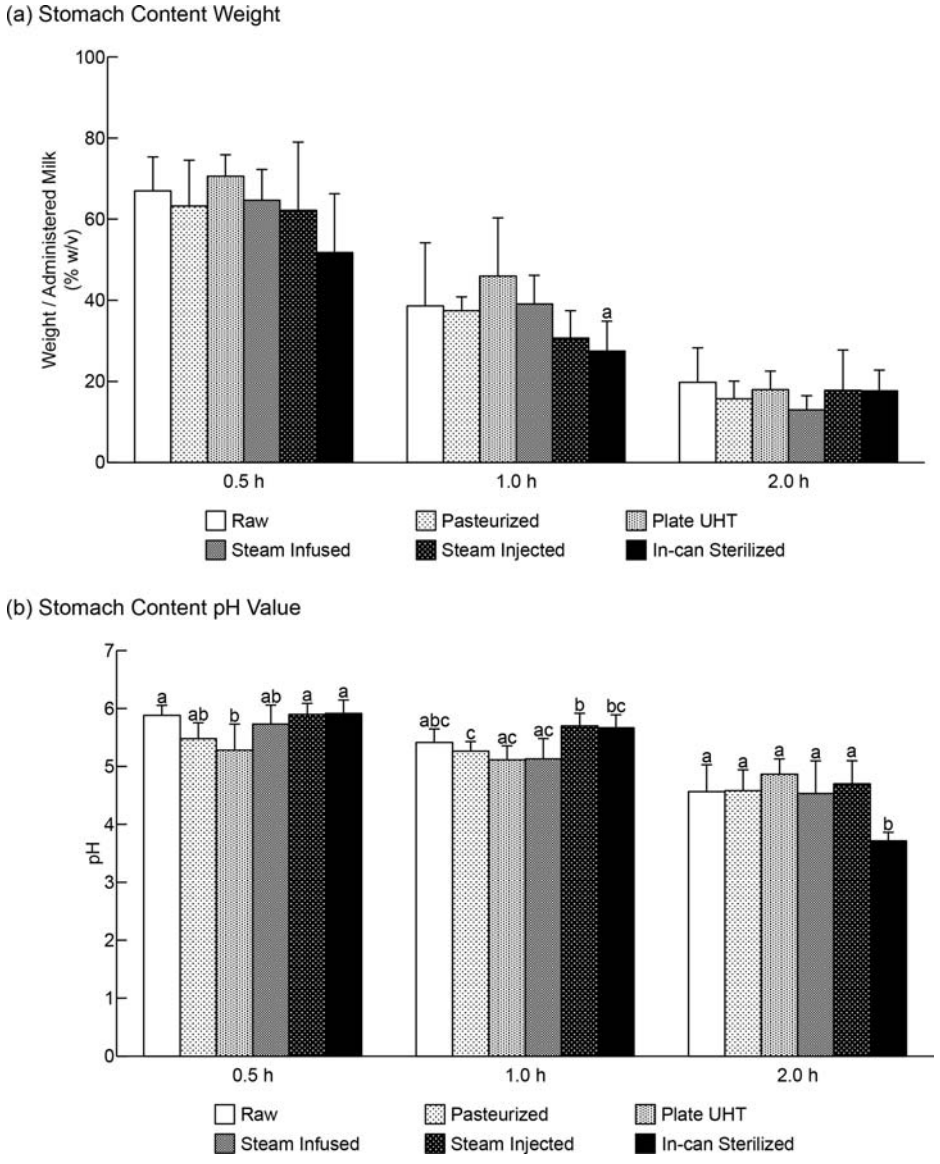

Figure 5. Stomach contents of suckling rat pups. Rat pups fed different milk samples were euthanized at 0.5, 1, and 2 h after intubation, and the stomach contents were obtained. Weight (a) and pH values (b) were measured, and data are expressed as means ± SD (n = 3 males + 3 females). "a", $p < 0.05$ (in-can sterilized vs plate UHT milk).

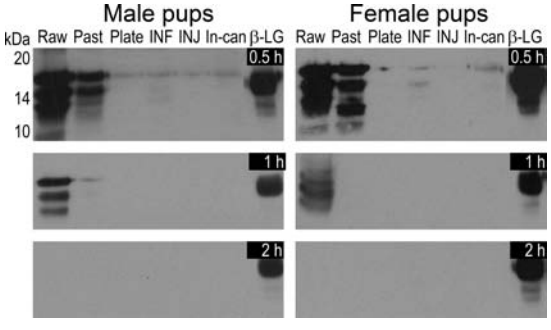

Figure 6. Western blotting of β-LG in upper intestine perfusates from suckling rat pups. Rat pups fed different milk samples were euthanized at 0.5, 1, and 2 h after intubation, and the upper intestines were perfused with PBS containing protease inhibitor. Five micrograms of protein was loaded, and β-LG was detected by Western blotting as an index of in vivo protein digestibility.

samples were also higher, probably because of the high holding temperature. However, steam-infused milk tended to show the lowest signals among the UHT-treated milk samples. The lowest heat damage of steam-infused milk among the three UHT-treated milk samples could arise not just from the lowest holding temperature but also from the dilution effect derived from the steam infusion.[42] No CML was identified in α-LA, and there were no distinct differences in CML amounts among the milk samples at the sites of β-LG compared with those of CNs. This possibly implies that CNs, the dominant proteins in cow's milk, might be competitive with whey proteins for progress of the Maillard reaction.

Both of the electrophoretic analyses in the in vitro and in vivo digestion assays demonstrated that in-can sterilization, followed by the three UHT treatments, facilitated enzymatic digestion of the major milk proteins, especially of β-LG. Facilitated digestion of intact milk proteins has also been observed in a study similar to ours; raw milk, pasteurized milk,

and sterilized milk were applied to in vitro digestion, and proteins in sterilized milk but not pasteurized milk exhibited better digestion.[43] With regard to β-LG, it has been shown in several studies that heat treatment promotes its digestion.[12,34,44,45] These positive effects of heat treatment on protein digestion can be attributed to protein denaturation, accelerating exposure of peptide bonds to digestive enzymes. Denaturation of milk proteins was apparent as WPNI values decreased for in-can sterilized milk followed by the three UHT-treated milk samples, and a faster gastric emptying rate/impaired gastric buffering activity of in-can sterilized milk was observed for in vivo digestion.

In contrast to the facilitated protein digestion discussed above, protein digestibility of milk samples, determined by a combination of in vitro digestion and a Kjeldahl procedure, showed insignificant differences among the milk samples. Similar results have been reported previously,[46,47] with some of the studies reporting positive effects accompanied by adverse consequences; some amino acids were not digestible, and small fragments resistant to digestion were formed.[43,44] Plausible explanations for these negative outcomes would be the fact that heating facilitates the formation of lactulosyllysine, the aggregation of proteins via cross-linked products such as lysinoalanine and lanthionine, and some newly formed disulfide bonds; these chemical structures inhibit the action of trypsin as well as other digestive enzymes, leading to a decrease in protein digestibility. In this study, in-can sterilized milk manifested the greatest formation of lactulosyllysine at many Lys residues in major milk proteins, such as α-LA, β-LG, and CNs, to an extent followed by plate UHT and steam-injected milk. With regard to protein aggregation, whereas proteomic analysis indicated that formation of lysinoalanine in all of the milk samples seems quantitatively limited, the results of SDS-PAGE suggest that the three kinds of UHT treatment caused new disulfide bond formation and that in-can sterilization modified the proteins to a greater extent by forming new disulfide bonds and possibly other noncovalent interactions. Thus, it can be speculated that a denaturation-mediated improvement in protein digestibility might be "offset" by the concomitant lactulosyllysine formation and protein aggregation involved in reducing protein digestibility. It should be added that the surface hydrophobicity of milk proteins, determined by a SDS-binding method,[48] showed only insignificant differences among milk samples (data not shown). Heating decreases surface hydrophobicity of caseins (the majority of total milk protein), whereas progress of the Maillard reaction increases surface hydrophobicity of total milk proteins. This observation may therefore reflect another "offset" chemistry in milk proteins. However, the possibility should be taken into consideration that total milk protein digestibility was practically the same because the heat treatment facilitates protein digestion but the resulting peptides might still be too large to be TCA-soluble.

Whereas no adverse effects on protein digestibility of heated raw milk were observed in this study even after in-can sterilization (despite the greatest formation of Amadori product on Lys residue causing inhibition of digestive enzymes such as trypsin), it seems that a decrease in protein digestibility has mostly been reported for milk-based infant/enteral formulas.[27,49−51] In general, the thermal history of milk-based formulas is more extensive than that for cow's milk because milk proteins are heat-treated as both "ingredients" and as "products (i.e., formulas)", which would promote the formation of Amadori products and cross-links (whereas our data of dehydroalanine suggested formation of cross-links may be limited after heating raw milk). In the context of ingredient manufacturing, industrial CN isolation involves isoelectric precipitation followed by neutralization at alkaline pH, and the alkaline treatment would facilitate the formation of cross-links such as lysinoalanine and lanthionine.[9] Furthermore, some of the above modifications proceed during long storage of ingredients/products at ambient temperature, possibly augmenting the modifications.[52]

In conclusion, industrial heating may improve the digestibility of proteins in raw milk by denaturation, but the improvement is likely to be offset by heat-derived modifications involved in the decrease in protein digestibility. However, this phenomenon may not hold true for dairy products such as infant/enteral formulas. Continuing studies are in progress to verify how protein modifications and consequential protein digestibility would differ between cow's milk samples and infant formulas.

ABSTRACT: The structural changes occurring during the thermal conversion of insoluble native waxy maize starch granules to cold-water-soluble pyrodextrin under acidic conditions have been investigated by multiple techniques, including synchrotron small-angle X-ray scattering (SAXS), wide-angle X-ray scattering, differential scanning calorimetry, and gel permeation chromatography. In a mixture of water/glycerol (20/80, w/w), the SAXS characteristic peak at ca. 0.6 nm^{-1} decreased in intensity as pyrodextrin solubility increased. The peak disappeared as pyrodextrin solubility reached 100%. Starch crystal size, its associated melting enthalpy, and pyrodextrin molecular size decreased as solubility increased. Although starch structure changed during thermal conversion, the pyrodextrins appeared identical to the native starch when observed in glycerol under a normal and polarized light microscope. It is proposed that the starch backbone is hydrolyzed by acid in the amorphous region and the crystalline region with starch molecules being hydrolyzed into small molecular fractions but persisting in a radial arrangement.

KEYWORDS: *pyrodextrin, dextrin, thermal treatment, small-angle X-ray scattering, starch structure*

1. INTRODUCTION

Thermal treatment of dry starch usually causes depolymerization at temperatures below 300 °C.[1] A degraded starch product prepared in the dry state by heating, or through a combination of heat and acid, is commonly called a "pyrodextrin".[2] The closely related term "dextrin" broadly refers to all degraded starch products regardless of the method used in the process. Dextrins may be produced by hydrolysis of starch with enzymes or acids in water, as well as by dextrinization or pyroconversion, or heating starch in its dry form.[2] Depending on the temperature, time, and level of acid used, pyrodextrins are generally classified into three categories: white dextrin, yellow or canary dextrin, and British gum;[2,3] however, these broad classifications are arbitrary, and classifying a given pyrodextrin product is not always easy. The properties of the products cover a wide range depending on pretreatment, level of acid used, and process conditions (e.g., temperature and time).[2] Yellow dextrin and more degraded British gum are soluble in cold water and become a viscous liquid with gummy and adhesive properties.[2] Traditionally, pyrodextrins have wide application in industry as adhesives, coatings, binders, and encapsulating agents.[1,2,4] The various applications and biological activities of pyrodextrins have been reviewed.[1] Pyrodextrin is suggested to be resistant to α-amylolysis and is considered as soluble dietary fiber,[4−10] which has many applications in the food industry. Preparation of indigestible dextrins by pyroconversion has been described.[11,12]

Changes in molecular structure during the dextrinization process have been suggested to involve hydrolysis, transglycosidation, and repolymerization of the glucans.[2,13] Starch molecules are significantly degraded by heat and acid, as reflected in a continual decrease in starch molecular weight, a progressive increase in solubility in water, decreased viscosity in water, and increased reducing value.[2,4,14] Transglycosidation results from the hydrolysis of the α-1,4 glucosidic linkages followed by a recombination of the fragments with nearby free hydroxyl groups to produce branched structures.[2] Transglycosidation and the branched structure of pyrodextrin have been proposed from the evidence of methylation[15,16] and reduced degree of β-amylolysis.[17] In addition, repolymerization has additionally been proposed due to the slight increase in viscosity and the decrease in reducing sugar content observed on dextrinization.[2]

Compared with extensive studies in molecular structure, few attempts have been made to understand the precise long-range structural changes during dextrinization. Pyrodextrins look identical to native granular starch when viewed in glycerol under both normal and polarized light microscopes,[2,4,18] and pyrodextrins have a wide-angle X-ray scattering (WAXS) pattern similar to native starch but with broader and weaker peaks.[5] However, the molecular arrangement in the pyrodextrin granules has not been thoroughly investigated; furthermore, it is not well understood why pyrodextrin is partially crystalline and retains its granular shape yet is readily soluble in water.

Small-angle X-ray scattering (SAXS), which probes larger length scales than WAXS, has been used to characterize the structure of native and modified starches.[19−29] Blazek and Gilbert[30] reviewed the application of SAXS to investigate starch structure. Native starch molecules are suggested to be arranged in a lamellar structure with a repeat spacing of ca. 9 nm, which corresponded to a SAXS peak at 0.6−0.7 nm^{-1}.[31] This SAXS peak disappears due to the loss of lamellar order in the case of starch gelatinization[22,32] and acid hydrolysis.[20,27] In this study, SAXS and WAXS were used to investigate the granular structure of pyrodextrin. We propose a model of starch

structural changes during thermal decomposition based on scattering, microscopy, gel permeation chromatography (GPC), and differential scanning calorimetry (DSC). These findings enable a greater understanding of the granular structure of pyrodextrin and the implications to its functionality.

2. EXPERIMENTAL SECTION

Materials. Waxy maize (WM) starch (Amoica TF) was obtained from National Starch LLC (Bridgewater, NJ, USA). Other chemicals used in the study were analytical grade.

Methods. *Preparation of Pyrodextrins.* Waxy maize starch (100 g dry weight) was suspended in water (150 mL), and the pH of the slurry was adjusted to 3.0 by 0.5 M HCl and stirred for 30 min. Starch was filtered to a cake with moisture content at approximately 50%. The starch cake was broken and dried in an oven at 40 °C for 24 h to a moisture content of 10−15%. The pH of the air-dried starch was approximately 4.0 at 10% solids in water. The dried starch was ground, passed through a screen (100 mesh), and heated in a forced-air oven at 170 °C. Samples were collected at 0.5, 1, 2, 3, and 4 h during heating and were kept at ambient temperature overnight. The resulting moisture content of the pyrodextrin samples was about 7%. In a separate experiment, the pH was adjusted to 2.5, and pyrodextrin was prepared as described above.

Light Microscopy. Starch granules were observed in glycerol or a mixture of glycerol and water using an optical microscope with a digital camera (model BX51, Olympus Co., Japan) under normal visible and polarized light.

Solubility. Starch (0.100 g) was dissolved in distilled water (0.9 mL) and centrifuged at 6708*g* for 3 min. Starch concentration in the supernatant (solubility) was determined by a hand-held refractometer (Fisher Scientific, Pittsburgh, PA, USA).

Gel Permeation Chromatography. GPC analysis was performed as previously described.[33] Starch hydrolysates (4 to 16 mg) were dissolved in DMSO (4 mL) by stirring at room temperature for 12 h. The solutions were filtering through a 2 μm filter (Millex-AP, Millipore, Billerica, MA, USA) and injected by an autosampler into a PL-GPC 220 system (Polymer Laboratories Inc., Amherst, MA, USA) with three Phenogel columns (00H-0642-K0; 00H-0644-K0; 00H-0646-K0; Phenomenex Inc., Torrance, CA, USA), one guard column (03B-0290-K0, Phenomenex Inc.), and a differential refractive index detector. The eluting solvent was DMSO containing 0.5 mM $NaNO_3$, and the flow rate was 0.8 mL/min. The column oven temperature was controlled at 80 °C. Standard dextrans (American Polymer Standards Co., Mentor, OH, USA) with different MWs were used for MW calibration. GPC results were analyzed using Cirrus GPC software version 3.0 (Agilent Technologies, Santa Clara, CA, USA).

Differential Scanning Calorimetry. Thermal properties of native starch and pyrodextrin products were determined by a Pyris-1 DSC (PerkinElmer, Norwalk, CT, USA). Samples were mixed with solvents of distilled water, water/glycerol mixture (20/80, w/w), or glycerol at a ratio of 1:3 (starch:solvent, w/w) and were lightly stirred with a spatula. Pyrodextrin pastes were sealed in a centrifuge vial and allowed to stand for 12 h at 25 °C for hydration. Pyrodextrin pastes (40−55 mg) were accurately weighed with a microbalance and placed into large DSC stainless steel pans. The DSC pans were sealed and held at 10 °C for 1 min and heated to 160 °C at 10 °C/min. Onset (T_o), peak (T_p), and conclusion (T_c) temperatures as well as enthalpy (ΔH) were determined. An empty pan was used as a reference. Native waxy maize starch was included as a control. Samples were analyzed in duplicate.

SAXS and WAXS. Pyrodextrin paste in water, water/glycerol mixture of 20/80 and 40/60 (w/w), or glycerol at a ratio of 1:1 (w/w) was prepared by manually mixing with a spatula followed by equilibrating at room temperature for 15 min.

Native starch and pyrodextrin pastes were examined by SAXS and WAXS at the X27C beamline at the National Synchrotron Light Source, Brookhaven National Laboratory. The details of the experimental setup at the X27C beamline have been reported elsewhere.[34−37] The wavelength of the X-ray was 1.371 Å. Two-dimensional WAXS and SAXS images were collected with an X-ray CCD detector (MarUSA) with resolution times of 30 and 60 s, respectively. The sample-to-detector distance was 155.6 mm for WAXS and 2018.5 mm for SAXS, respectively. The scattering angle in WAXS was calibrated using a polypropylene standard and an Al_2O_3 standard from the National Institute of Standards and Technology (Gaithersburg, MD, USA). The scattering angle in SAXS was calibrated by a AgBe standard. Pyrodextrin samples were sealed in a sample holder and placed on the hot stage (Instec Inc., Boulder, CO, USA).[33] The WAXS and SAXS spectra were background-subtracted by using an empty sample holder covered with two layers of Kapton film. Data are displayed in terms of arbitrary intensity versus q for SAXS where q is the magnitude of the scattering vector and is equal to $(4\pi \sin \theta)/\lambda$, where λ (nm) is the wavelength of the X-ray source and 2θ is the scattering angle. WAXS data are plotted as arbitrary intensity versus scattering angle.

Starch crystallinity was calculated as described elsewhere.[38] The approximate average size (D) in nm of crystallites in the samples was calculated from the Scherrer formula:

$$D = \frac{0.89 \times \lambda}{\beta \times \cos \theta}$$

where β is the angular width in radians at the half-maximum intensity corrected for instrumental line broadening and θ is half of the angular position of the peak in radians. In the present case, such broadening has a negligible influence compared to the width of the peaks observed.

Statistical Analysis. Each experiment was performed in duplicate. One-way analysis of variance was performed with the Minitab software (version 16.1.0, Minitab Inc., State College, PA, USA). Least significant differences for comparison of means were computed at $p < 0.05$.

3. RESULTS AND DISCUSSION

3.1. Solubility and Molecular Weight Distribution. The solubility of pyrodextrin was affected by process parameters including pH, temperature, and heating time. At a pH of 2.5 and 170 °C, starch became 100% soluble after heating for 0.5 h. At pH 3 and 170 °C, pyrodextrins with a solubility from 21% to 100% were produced by heating from 0.5 to 4 h (Table 1).

Table 1. Solubility of Pyrodextrin in Water Prepared at Different pH, Heating Temperature, and Heating Time

pH	temperature (°C)	time (h)	solubility (%)
2.5	170	0.5	100.0 a
3.0	160	4.0	42.0 b
3.0	170	0.5	21.2 c
		1.0	22.1 c
		2.0	97.1 a
		3.0	100.0 a
		4.0	100.0 a

Starch solubility increased rapidly during the first 2 h of the conversion. As the conversion continued, relatively little change occurred in the solubility. In contrast, at pH 3 and 160 °C, starch was only 42.0% soluble after being heated for 4 h (Table 1).

Molecular breakdown was indicated by a shift in molecular size distribution profile (Figure 1). The molecular weight of the waxy maize starch decreased rapidly at the beginning (0.5 to 1 h) of the conversion and slowed after 2 h. At the latter stage of dextrinization, starch molecular size remained in the range of 4.3×10^4 to 3.6×10^5 (Figure 1). These results suggest that starch molecules were hydrolyzed by acid and heat during dextrinization. Molecular scission was promoted by low pH, high temperature, and long reaction time, which is in agreement

dx.doi.org/10.1021/jf5000858 | J. Agric. Food Chem. 2014, 62, 4186−4194

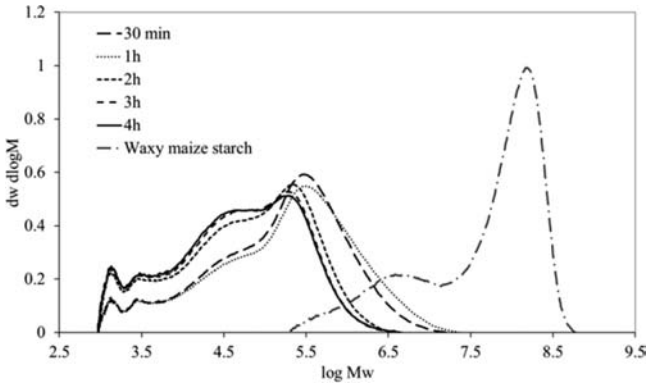

Figure 1. Molecular weight (M_w) distribution of native waxy maize starch and pyrodextrins prepared from heating at pH 3 and 170 °C for 0.5 to 4 h. The M_w is relative to dextran standards.

with previous studies.[2,5,14] To investigate the structural changes of starch from insoluble granules to water-soluble pyrodextrin, samples prepared by heating at pH 3 and 170 °C from 0.5 to 4 h were selected because their solubility ranged from 21% to 100%.

3.2. Birefringence of Pyrodextrin. After dextrinization, starch granules remained and products had a characteristic yellow color. When examined under a microscope, pyrodextrins in glycerol appeared identical to native starch and, under polarized light, showed strong birefringence (Figure 2), indicating a radial orientation of molecules. However, when the pyrodextrin was suspended in water, the starch granules ruptured quickly. Starch granules disappeared as starch molecules dissolved. Similar results have been reported in other studies.[2,39] It has been suggested that the crystallites of starch granules are oriented together in a parallel arrangement and undergo significant changes upon dextrinization.[17] To fully understand these changes in granular structure, SAXS and WAXS were employed to characterize the crystalline and amorphous regions and lamellar structure of pyrodextrins.

3.3. Small-Angle X-ray Scattering. The SAXS lamellar peak of native starch evolves only upon sufficient hydration,[28,40] but the solubility of pyrodextrins in water increases after dextrinization (Table 1), and starch granules of pyrodextrins with high solubility disintegrate in water and lose their structural information. To effectively probe the structural changes of starch granules during dextrinization by SAXS and WAXS, different ratios of glycerol to water were used to deliberately modulate the degree of plasticization. Glycerol is a less effective plasticizer than water, and pyrodextrins retain their granular shape in glycerol (Figure 2). Thus, using this approach, it becomes possible to elucidate the structure of pyrodextrins with different water solubility.

Native waxy maize starch and pyrodextrins showed no SAXS characteristic peak in glycerol at room temperature (Figure 3); however, a well-defined SAXS peak at 0.62 nm^{-1} was observed for the native starch in a mixture of water and glycerol (20/80 or 40/60, w/w) (Figures 3 and 4), which was attributed to the periodic lamellar arrangement of semicrystalline starch with a repeat distance of ca. 9 nm.[31] Compared with the native starch, pyrodextrins showed significantly different SAXS patterns in water/glycerol (20/80, w/w) (Figure 4). A characteristic SAXS peak was observed for starch heated for 0.5 and 1 h, but the scattering intensity at ca. 0.6 nm^{-1} was both lower and less resolved than for native starch, suggesting a partial reduction in lamellar periodicity. There also appears to be a slight shift in peak position to higher q (from 0.62 to 0.65 nm^{-1}), indicating a possible decrease in the repeat distance of the alternating crystalline and amorphous lamellae. Such a decrease in lamellar spacing may result from the hydrolysis of amorphous lamellae and a partial disruption in the crystalline lamellae, resulting in a closer periodic arrangement. However, since the peak width is also broader, this rearrangement is not uniform. The 9 nm scattering peak becomes less prominent after 2 h of dextrinization (Figure 4); this indicates that the lamellar structure of granular starch is significantly disrupted during the dextrinization process with a corresponding reduction in long-range order.

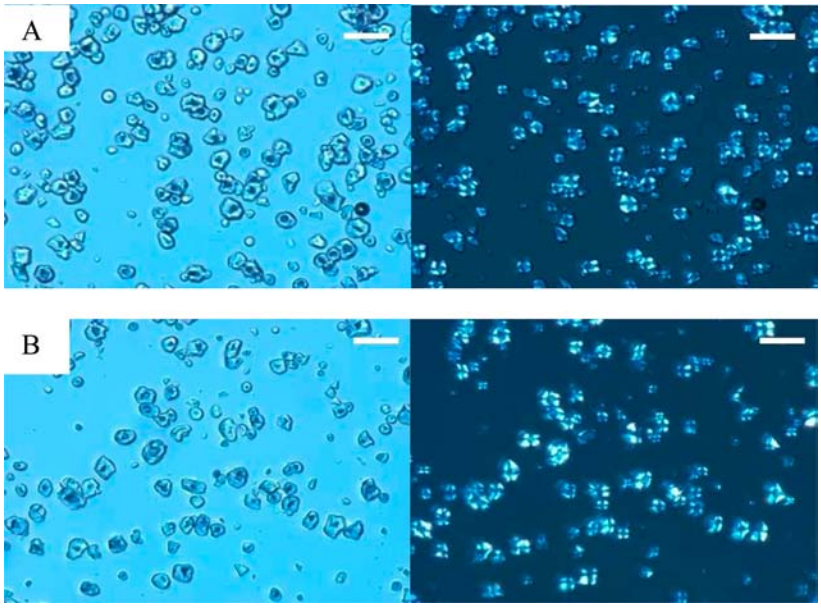

Figure 2. Microscopy images of (A) native waxy maize starch and (B) soluble pyrodextrin (100% solubility) in glycerol. Pyrodextrin was prepared at pH 3 and heated at 170 °C for 4 h. Scale bar in each graph represents 30 μm. Left images: unpolarized; right images: polarized.

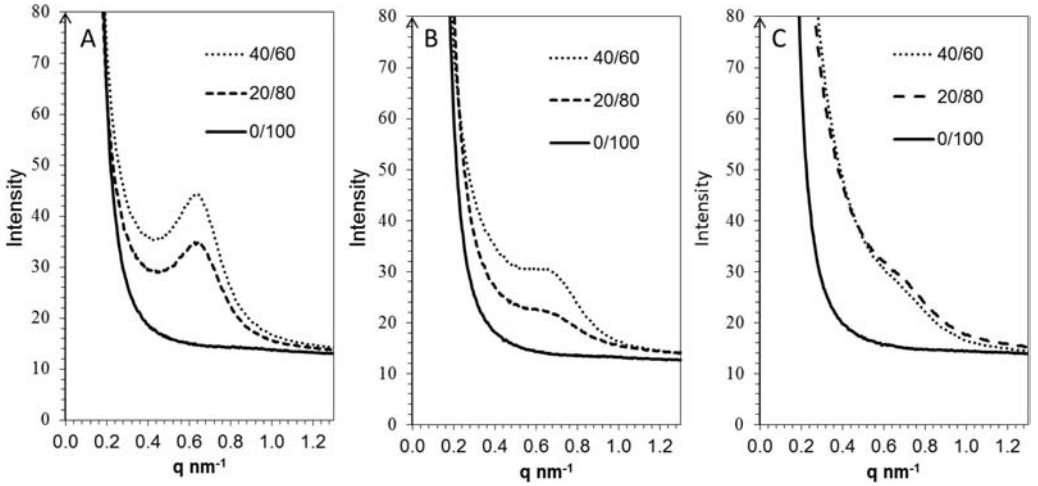

Figure 3. SAXS patterns of (A) native starch, (B) pyrodextrin after 0.5 h, and (C) pyrodextrin after 4 h in a solvent of water/glycerol with ratios of 40/60, 20/80, and 0/100.

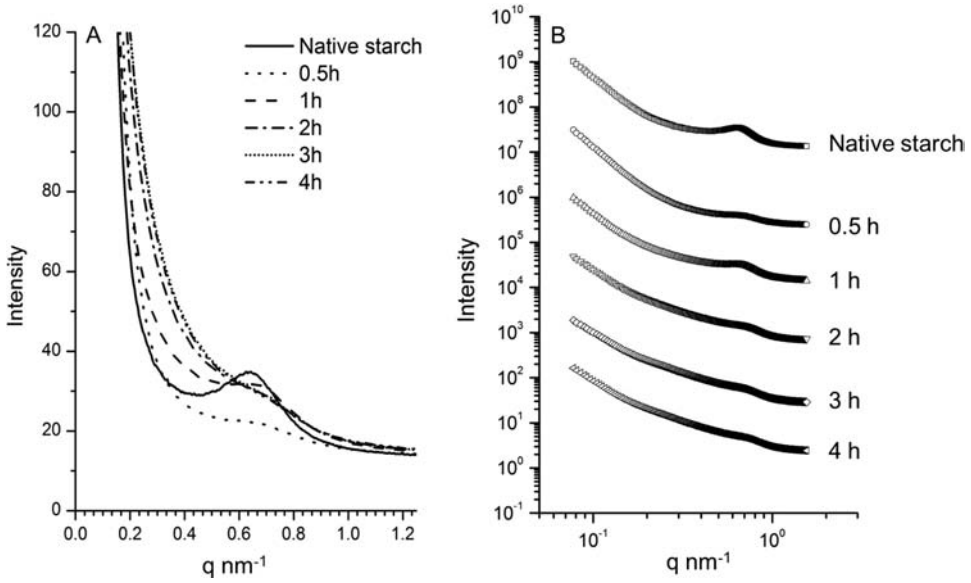

Figure 4. (A) Linear and (B) double-log scale SAXS plot of native starch and pyrodextrins in a solvent of water/glycerol (20/80, w/w). Data shown in log−log plot have been shifted vertically for clarity.

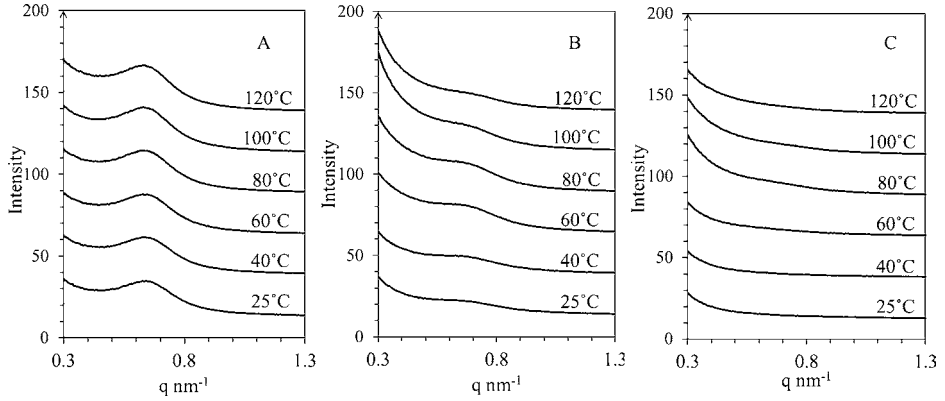

Figure 5. Small-angle X-ray scattering (SAXS) curves of native waxy maize starch (A), dextrin (pH 3, 170 °C, 0.5 h) (B), and dextrin (pH 3, 170 °C, 4 h) (C) in a mixture of water/glycerol (20/80, w/w). Data have been vertically offset for clarity.

The ratio of water to glycerol from 20/80 (w/w) to 40/60 (w/w) reveals interesting differences (Figure 3). For native starch, the size and position of the peak at ca. 0.62 nm^{-1} were little changed, but the peak for the 0.5 h pyrodextrin sample

dx.doi.org/10.1021/jf5000858 | J. Agric. Food Chem. 2014, 62, 4186−4194

became slightly more prominent. However, there appears to be an absence of a peak for the 4 h pyrodextrin sample, indicating a substantial loss of periodic lamellar order.

In addition to changing the ratio of water to glycerol (i.e., the degree of plasticization), both the native starch and pyrodextrin were heated in a mixture of water and glycerol (20/80, w/w), and their changes were examined by SAXS (Figure 5). The peak at ca. 0.62 nm^{-1} was little changed when the native waxy maize starch was heated from 25 to 100 °C.[33] For the 0.5 h pyrodextrin sample, the intensity of the peak at ca. 0.62 nm^{-1} became more pronounced from 25 to 60 °C but decreased after 60 °C, and the peak almost disappeared at 100 °C. These changes indicate that heating initially provides mobility and promotes the alignment of the periodic lamellar structure but destabilizes that structure at high temperatures.

Water plays dual roles when added to the pyrodextrins, functioning as either a plasticizer or solvent depending on the level of water used and the structure of the pyrodextrin. Glycerol alone is not able to solvate starch granules, and no SAXS peak is observed due to insufficient plasticization; thus they lack long-range order.[40,41] When water is added, hydration enables sufficient chain mobility to occur such that a proportion of the amylopectin branches are able to align (Figure 3). Conversely, in the absence of water, the branches maintain greater disorder and lamellar scattering is reduced. This is often considered within the formalism of nematic and smectic behavior; in the smectic state, helices are aligned into lamellae, with this breaking down into a laterally nonaligned, smectic, state in the absence of water. A water to glycerol ratio of 20/80 (w/w) is sufficient to allow the evolution of the 9 nm lamellar peak for starch granules at room temperature.[40] In this study, for the 0.5 h pyrodextrin, the SAXS peak at ca. 0.62 nm^{-1} increased as the ratio of water to glycerol increased from 0/100 to 40/60 (w/w) (Figure 3); however, for the 4 h pyrodextrin, no SAXS peak was observed by increasing the level of water (Figure 3) or heating (Figure 5), indicating permanent loss of any significant long-range order of the alternating lamellar structure. The 4 h pyrodextrin retained its granular shape and was birefringent in glycerol (Figure 2), but in the mixture of water and glycerol (40/60, w/w), it lost both its birefringence and granular shape (data not shown), indicating that its granular structure was so weak that it was disrupted by the mixture of water and glycerol. Water, acting as a solvent, was able to completely dissolve the 4 h pyrodextrin sample (Table 1).

It is proposed here that the loss of the periodic lamellar structure is due to the hydrolysis of the amorphous regions of starch and partial disruption of crystalline lamellae by heat. Acid primarily hydrolyzed the amorphous regions of the starch granule.[2] After a significant number of glycosidic bonds are cleaved and crystalline lamellae are disrupted, it is likely that it is no longer possible to form a periodic lamellar structure.

Comparing the SAXS results in this study (heating starch in dry form with acid) with the findings on the acid hydrolysis of starches in water is revealing.[20,27] When hydrolyzed by acid in water, the lamellar peak intensity increased during the early stages of acid hydrolysis followed by a decrease in the latter stages of hydrolysis. In studying the acid hydrolysis of pea starch in water, Wang et al.[27] also reported that the position of the lamellar peak was essentially constant within the first 6−12 days of hydrolysis but shifted to higher q after 35 days of hydrolysis. Relative crystallinity increased after the amorphous regions were selectively hydrolyzed in water and removed during filtration. In contrast, hydrolyzed products remained inside starch granules in this study, and the crystallinity decreased during dextrinization (Figure 6) as discussed in the next section.

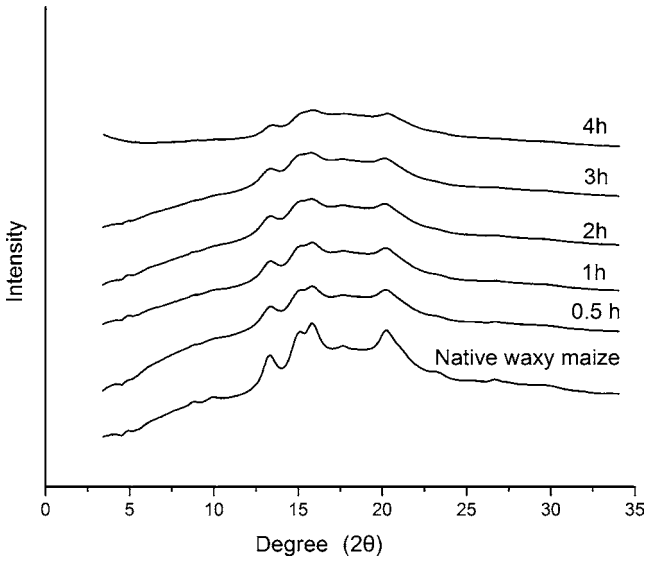

Figure 6. WAXS patterns of pyrodextrins (50%, w/w) in water/glycerol (20/80, w/w) mixture. Native waxy maize is shown as a reference. Pyrodextrins were prepared by heating waxy maize starch (pH 3.0) at 170 °C for 0.5, 1, 2, 3, and 4 h.

The SAXS data from the dextrinization were fitted using the unified method,[42] which has previously been shown to elucidate useful structural information on starch samples.[43] The results are shown in Table 2. Here two levels of fitting were used, a terminal power law for the low-q region, combined with a high-q power law/Guinier region and interference peak as described by Doutch and Gilbert.[43] The final data set at 4 h was fitted with a single power law and background.

The unified approach here is challenged by limited spatial dimension probed because of the limited q range used. However, the fitted parameters appear to indicate progressive loss of an ordered, periodic structure within the granules. This is shown most spectacularly at 4 h, with a loss of interference peak. The intensity of the lamellar peak shows a general decreasing trend through the time course of the experiment, followed by sudden loss between the measurements taken at 3−4 h. There is some variation in the Guinier region fitted, which may imply changes in the overall lamellar structure.[43] The changes in terminal power law also point to disruption in larger scale structures within the granules.

3.4. Wide-Angle X-ray Scattering. Native starch and pyrodextrins showed an A-type crystalline WAXS pattern[33] in the water/glycerol (20/80, w/w) mixture (Figure 6). It should be noted that the Bragg angle values for the peaks in this study were slightly different compared with an A-type crystalline pattern as measured by a conventional X-ray diffraction instrument[5] because the synchrotron X-ray wavelength used in this study was different.[33] Pyrodextrins showed broadened peaks with reduced intensity at 13, 16, and 21 degrees 2θ compared with the native starch (Figure 6). Similar results have been reported previously.[5] Crystallinity and crystal size were estimated[44] and are shown in Table 3. Crystallinity of the native waxy maize starch was approximately 43%, which is close to

	2.0	24.4	1.07	7.0
	3.0	20.3	1.08	7.0
	4.0	17.4	1.07	7.0

previous literature values.[44] Heating at 170 °C for 0.5 and 4.0 h reduced crystallinity to 31.4% and 14.0%, respectively. In addition, crystal size was reduced from 9.6 nm of native starch to 7.8 and 7.0 nm of pyrodextrins. These results indicate a loss of structural organization in a direction lateral to the semicrystalline lamellae due to the dextrinization process; however, for the 4 h pyrodextrin, WAXS still showed an A-type crystalline pattern in a mixture of water and glycerol (20/80, w/w), indicating the existence of a crystalline structure. Therefore, the crystalline region of starch was not completely destroyed, but crystallites became smaller during the dextrinization process. Weak crystallites after dextrinization also were noted when the starch and pyrodextrin samples were heated in the mixture of water and glycerol (20/80, w/w) (Figure 7). Crystallinity of native waxy maize starch changed little when it was heated from 26 to 80 °C. In contrast, the crystallinity of the 0.5 h pyrodextrin was significantly reduced at 80 °C, and 4 h pyrodextrin became essentially amorphous at 80 °C.

3.5. Thermal Properties. A reduction in the crystallinity of pyrodextrins from native starch (Table 3 and Figure 7) is also reflected in the DSC data (Figure 8 and Table 4). Once again, to effectively probe the structure and properties of pyrodextrins, different ratios of water to glycerol were used to deliberately modulate the degree of plasticization. In water, 0.5 h pyrodextrin showed a lower onset temperature and reduced enthalpy of melting endotherm compared with native starch. Pyrodextrins with higher solubility (2.0 h and 4.0 h samples) did not have an endothermic peak, indicating the loss of starch crystallinity in water at room temperature. In 80% glycerol, the gelatinization endotherm for the native starch was shifted to higher temperatures relative to water. Similar results were reported by other studies.[40,45−48] The enthalpy values of pyrodextrins (Table 4) decreased with increasing dextrinization time and are correlated with their degree of crystallinity (Table 3). Higher gelatinization enthalpy suggests higher crystallinity.[44,49]

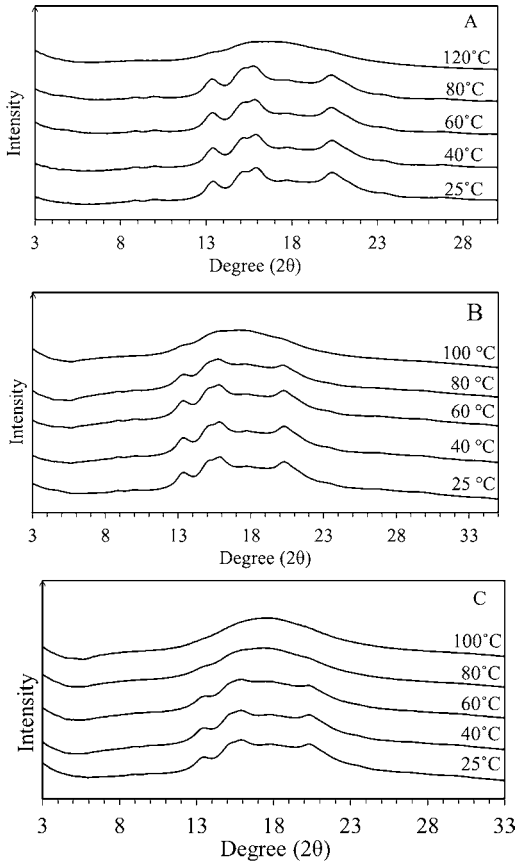

Figure 7. WAXS patterns of (A) waxy maize starch, (B) dextrin (solubility 21%), and (C) dextrin (solubility 100%) in a mixture of water/glycerol (20/80). Data have been offset vertically for clarity.

Comparing thermal properties of pyrodextrins in water and 80% glycerol reveals interesting results. For the 0.5 h pyrodextrin in 80% glycerol, the gelatinization peak was much broader and the enthalpy was much greater than that in water, suggesting that a portion of crystallites was sufficiently weak that they dissolved in water at room temperature but not in 80% glycerol. Glycerol has a large molecular weight and is not as effective as water as a plasticizer.[21] A broad melting peak also was observed for pyrodextrins of 2.0 and 4.0 h in the glycerol/water mixture (Figure 8), which supports this reasoning. The DSC results in 80% glycerol suggest that the crystalline region existed for all the pyrodextrin samples. Dextrinization affected the crystalline region and reduced the crystallinity and crystal size. The less perfect crystallites with short double helices exhibit sufficiently weakened interchain

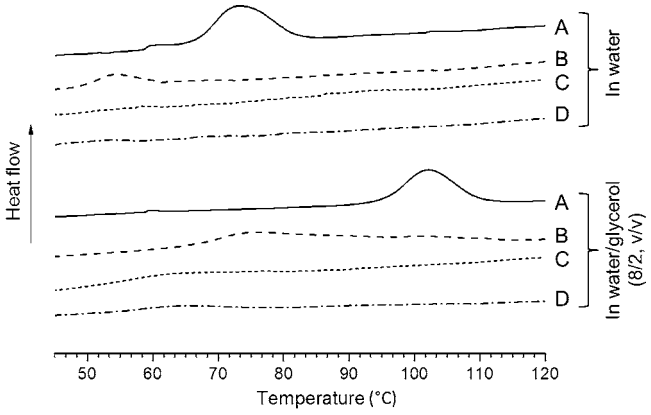

Figure 8. DSC profiles of (A) native starch and (B–D) pyrodextrins prepared at pH 3 and 170 °C for (B) 0.5 h, (C) 2 h, and (D) 4 h.

interactions that they disassociated in water at room temperature.

Native starch and pyrodextrins were also analyzed in 100% glycerol (Figure 9). The melting endotherm of each sample shifted to higher temperatures as expected. In addition, an exothermic peak was observed for all analyzed samples. The exothermic peak has been suggested to result from a starch–glycerol "interaction", including the plasticization of amorphous lamellar regions that enable the crystalline lamellae to form a periodic lamellar structure and thus enhance crystallization.[40] On the basis of the model proposed by Perry and Donald,[40] the DSC results therefore suggest that the starch–glycerol interaction exists for pyrodextrin samples of different solubility. The process of rearranging crystalline lamellae to form a periodic lamellar structure upon plasticization, as well as crystallization, exists for all the pyrodextrins in glycerol during heating. It is also worthy of note that when the native starch was heated by two heating–cooling cycles of 10–110–10–150 °C, the exothermic peak was observed in the first heating cycle but disappeared in the second heating cycle (Figure 9). In addition, little difference was observed for the endothermic peak between the two heating steps (Figure 9). The results suggest that the starch–glycerol interaction is irreversible and occurs prior to the melting of crystallites.

On the basis of WAXS and DSC results, in addition to the effect of hydrolysis of the amorphous region, it is proposed that changes in crystalline regions also affected the SAXS peak. For the 0.5 h pyrodextrin, although the crystalline region was affected by the dextrinization process, it still showed sufficient contrast, with respect to the hydrated amorphous region, to exhibit a SAXS peak. However, in highly soluble pyrodextrins, the overall crystalline region was significantly altered by the process, and the contrast between crystalline and amorphous areas was significantly reduced. The radial arrangement of the starch molecules was not altered during the dextrinization process however.

In conclusion, structural changes from native starch to pyrodextrin have been proposed in the literature[50] and are shown in Figure 10A. In this traditional model, starch was converted by acid hydrolysis in combination with heat into smaller fragments. Starch molecules repolymerized into a branched structure; however, native starch granules are partially crystalline, which is not reflected in the model.

A new model describing long-range structural changes of starch during dextrinization is proposed based on a complementary arsenal of characterization methods, namely, microscopy, GPC, SAXS, WAXS, and DSC (Figure 10B). As starch is heated at 170 °C for 0.5 h, the starch backbone is hydrolyzed by acid in the amorphous region and the crystallite size decreases. Starch molecules are hydrolyzed into small molecule fractions but remain in a radial arrangement. The semicrystalline lamellar structure still persists in the early stage of dextrinization. Upon proper plasticization, double helices tend to arrange in a periodic order; however, the periodicity is not as perfect as in native starch due to the hydrolyzed starch backbone and disrupted crystalline region.

	ΔH (J/g)	To (°C)	Tp (°C)	Tc (°C)
1 step	14.3	125.1	134.2	142.5
2 steps	14.0	123.4	133.0	142.8

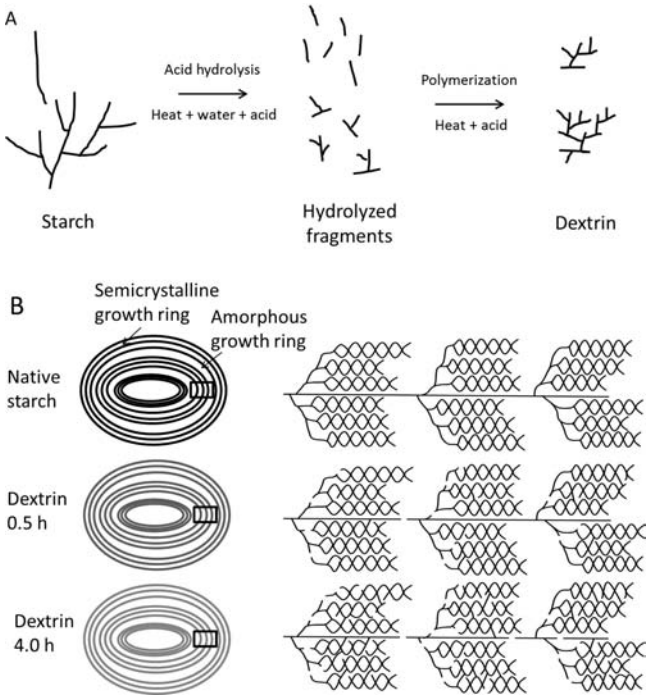

Figure 10. Structure changes from native starch to pyrodextrin. Part A is adapted from Rutenberg.[50] The new model (B) incorporates the concept of cluster model and reflects that native starch is partially crystalline.

As the dextrinization process continues, the starch backbone in the amorphous region is further hydrolyzed along with the crystalline region. Crystallinity decreases, crystallite size is reduced, and starch molecules are hydrolyzed to a smaller molecular weight. While a crystalline arrangement may still exist upon plasticization, due to the significant hydrolysis of the crystalline and amorphous region, a periodic structure of crystalline and amorphous lamellae can no longer be formed. Starch molecules still exist in a radial arrangement, however, and result in birefringence being maintained.

Supporting Information

ABSTRACT: Novel refreshments with pleasant flavors were developed by fermentation of wort with basidiomycetes. Among 31 screened fungi, shiitake (*Lentinula edodes*) produced the most pleasant flavor. It was perceived as fruity, slightly sour, and plum-like. Flavor compounds were isolated by liquid−liquid extraction (LLE) and by headspace solid phase microextraction (HS-SPME). The key odor-active compounds were analyzed by a gas chromatography system equipped with a tandem mass spectrometry detector and an olfactory detection port (GC-MS/MS-O) and aroma extract dilution analysis (AEDA). For HS-SPME, a revised method of increasing the GC inlet split ratio was used. Most of the key odor-active compounds (e.g., 2-acetylpyrrole, β-damascenone, (*E*)-2-nonenal, and 2-phenylethanol) were detected with both extraction techniques. However, distinct differences between these two methods were observed.

INTRODUCTION

Basidiomycetes are able to synthesize pharmacologically relevant secondary metabolites, natural flavor compounds, and highly sought after enzymes.[1] Because of their unique biochemical potential, basidiomycetes are ideal tools for the food industry. In addition to their nutritional value, therapeutic applications of basidiomycetes, based on their antibiotic, antioxidative, and anticarcinogenic properties, have been discussed.

Because of their high nutritional value and good microbial stability, fermented beverages are becoming increasingly popular all over the world.[2] They are produced by various manufacturing techniques, raw materials, and microorganisms.[3] The most common microorganisms used in traditional fermented beverages such as beer, wine, kwass, kombucha, and Chinese liquor are yeasts, lactic acid bacteria, acetobacter species, and lower fungi.

Only a few studies on beverage production using basidiomycetes have been published. Hill produced a soluble tea product with champagne-like properties in combination with Manchurian mushroom.[4] Lin et al. developed a novel beverage by *Saccharomyces* using shiitake stipe extract as a nitrogen source.[5] Hou and co-workers prepared a novel beverage by mixing polysaccharides extracted from BaChu mushroom with hawthorn juice and apple juice.[6] Okamura et al. reported on beer-like fermented drinks using *Pleurotus ostreatus*, *Tricholoma matsutake*, or *Agaricus subrufescens* instead of *Saccharomyces cerevisiae* as all of these fungi possess an alcohol dehydrogenase activity.[7,8] However, the unique capabilities of basidiomycetes in producing a wide range of natural flavors in beverages have been ignored for submerged cultivations so far. Because of consumers' demand for natural food, basidiomycetes producing natural flavor compounds are ideal candidates for developing novel fermentation systems. With the recent worldwide declining consumption of beer,[9] breweries are eagerly searching for innovative nonalcoholic alternatives to compensate for this negative trend. In a previous study, complex and pleasant flavor mixtures were formed by fermentation of byproducts of the food industry with basidiomycetes.[10] This approach was adopted and transferred to the development of novel beverages by utilizing basidiomycetes for the fermentation of wort.

Traditional liquid−liquid extraction (LLE) and headspace solid phase microextraction (HS-SPME) are commonly used in flavor analysis. HS-SPME is a rapid and solvent-free method with low detection limits, which has been used for the analysis of a wide variety of compounds. Key odor-active compounds may be determined by aroma extract dilution analysis (AEDA).[11] In contrast to LLE, no dilutable organic flavor extract is obtained by using HS-SPME. Therefore, successively diluted original samples were analyzed by SPME in previous studies.[12−16] A different approach, namely, increasing gas chromatograph (GC) inlet split ratios, has only been reported by Kim et al.[17]

In this study, novel refreshments with pleasant flavors were developed by fermentation of wort with basidiomycetes. The cultures were extracted using two different extractions techniques (LLE and HS-SPME). The key odor-active compounds were determined and compared using a GC equipped with a tandem mass spectrometry detector and an olfactory detection port (GC-MS/MS-O) and AEDA. For

aroma dilution analysis (ADA) by HS-SPME, increasing GC inlet split ratios were used.

MATERIALS AND METHODS

Chemicals and Materials. Thirty-one different basidiomycetes were obtained from the Centraalbureau voor Schimmelcultures (CBS, Utrecht, The Netherlands), the German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig, Germany), and the Department of Molecular Wood Biotechnology and Technical Mycology (WBTM, Göttingen, Germany).

Authentic flavor standards were purchased from Alfa Aesar (Karlsruhe, Germany), Fisher Scientific (Schwerte, Germany), Sigma-Aldrich (Steinheim, Germany), TCI Deutschland (Eschborn, Germany), Th. Geyer (Hamburg, Germany), and VWR (Darmstadt, Germany). The chemicals were of analytical grade. For GC helium 5.0 and nitrogen 5.0 were used.

Wort Preparation. Wort (Kölsch type, 13 °Plato) was provided by the University of Applied Sciences (Giessen, Germany). Pilsner (80%, w/w), Munich (13%, w/w), and wheat (7%, w/w) malts were used for the production of the wort with a KB50 pilot-scale brewing device (Alfred Gruber GmbH, Eugendorf, Austria). After cooking, the wort was filtered (0.2 μm), filled into aluminum bottles, and pasteurized at 80 °C for 30 min. The wort was stored at −20 °C prior to usage.

Precultures and Fermentation of Wort. Culture flasks containing standard nutrition solution (100 mL/250 mL, medium volume/flask volume) were inoculated with fungal mycelium as published previously.[18] This preculture was incubated on a rotary shaker (24 °C, 150 rpm, 25 mm shaking diameter) in the dark until sufficient growth was obtained. Mycelia of 10 mL preculture broth were precipitated by means of centrifugation (4000 rpm, 2150*g*, 10 min, 20 °C) and washed three times with sterile water. The fungal pellets were resuspended in 10 mL of heat sterilized wort. This suspension was added into an Erlenmeyer flask (250 mL) containing 100 mL of wort. The fermentation was carried out at 24 °C for up to 48 h under aerobic conditions in a rotary shaker (150 rpm). During the fermentation, samples were taken every 2−4 h and were subsequently analyzed by sensory evaluation.

Sensory Evaluation of Cultures. The mycelium was removed by centrifugation (4000 rpm, 2150*g*, 5 min, 4 °C), and the supernatant was transferred to odorless snap-cap vials (20 mL). After storage for 15 min at 4 °C, the odor of the supernatant was assessed by at least three experienced sensory assessors. The odor intensity was rated on a scale of 1−5 (1, low intensity; 5, intense, strong odor). Samples with a distinctive and potent odor were additionally evaluated by tasting. Promising fermentations were repeated at least three times. In the final analysis the flavor was described by 10 panelists.

Headspace Solid Phase Microextraction. For HS-SPME, PDMS fibers (polydimethylsiloxane, film thickness = 100 μm, fiber length = 1 cm) (Supelco, Steinheim, Germany), PDMS/DVB fibers (polydimethylsiloxane/divinylbenzene, 65 μm, 1 cm), CAR/PDMS fibers (carboxen/polydimethylsiloxane, 75 μm, 1 cm), and DVB/CAR/PDMS fibers (divinylbenzene/carboxen/polydimethylsiloxane, 50/30 μm, 1 cm) in combination with an MPS 2XL multipurpose sampler (GERSTEL, Mülheim an der Ruhr, Germany) were used. Ten milliliters of the culture broth was transferred into a headspace vial (20 mL). The samples were agitated for 20 min (250 rpm) at 50, 55, or 60 °C, followed by headspace extraction, at the same temperature as

during the incubation, for 40, 45, or 50 min. Afterward, the analytes were directly desorbed in the split/splitless inlet at 250 °C using a SPME liner with 0.75 mm i.d. (Supelco) of the GC-MS/MS-O system for 1 min. After desorption, the fiber was heated at the respective recommended conditioning temperature in the SPME fiber conditioning station for 20 min.

Liquid−Liquid Extraction. The mycelium was removed from the fermentation broth by centrifugation (4000 rpm, 2150*g*, 5 min, 4 °C), and the culture supernatant was extracted three times with equal amounts of pentane/diethyl ether (1:1.12, v/v). The organic phases were combined, dried over anhydrous Na_2SO_4, and concentrated by means of a Vigreux column (water bath temperature = 45 °C) to a final volume of approximately 1 mL. Afterward, 100 μL of thymol (300 mg/L in pentane/diethyl ether) was added as internal standard (IS). The sample was used for AEDA in combination with GC-MS/MS-O analysis.

Aroma (Extract) Dilution Analysis. For LLE the flavor dilution (FD) factors were determined by AEDA. The organic extracts of the cultures were diluted with pentane/diethyl ether (1:1.12, v/v) in a series of 1:1 dilutions, and each dilution was sniffed twice until no odorants were perceived at the ODP 3 olfactory detection port (GERSTEL) of the GC-MS/MS-O system.

For HS-SPME, aroma dilution analysis was performed by increasing GC inlet split ratios.[17] Prior to sample analysis, the method was validated using six authentic flavor standards. Ten milliliters of the standard solution [43.9 mg of 2-acetylpyrrole (**37**/**2**), 24.6 mg of β-damascenone (**32**/**2**), 46.1 mg of methyl 2-methylbutanoate, 39.1 mg of 2-phenylacetaldehyde, 44.5 mg of 2-phenylethanol, and 46.5 mg of 3-phenylpropanol dissolved in 50 mL of ethanol and subsequently diluted 1:1000 with distilled water] was transferred into a HS vial (20 mL) and sealed with a Teflon screw cap. The standard solution was incubated at 60 °C for 20 min and extracted at the same temperature by means of HS-SPME with a CAR/PDMS fiber for 45 min. The volatiles were diluted stepwise by controlling the split ratio as follows: splitless (splitless time = 2 min), 2:1, 4:1, 8:1, 16:1, 32:1, 64:1, 128:1, and 256:1. The same procedure was applied for the samples.

Gas Chromatography. Gas chromatography was carried out using an Agilent 7890A gas chromatograph (Agilent Technologies, Waldbronn, Germany) equipped with an Agilent 7000B triple-quadrupole mass spectrometry (MS/MS) detector (Agilent Technologies). The column used was a polar 30 m × 0.25 mm i.d., 0.25 μm Agilent J&W VF-WAXms unless stated otherwise. Helium was used at a constant flow rate of 1.56 mL/min as the carrier gas. At the end of the capillary column, the carrier gas was split 1:1 into the Agilent 7000B detector and into the ODP 3. The oven temperature was programmed from 40 to 240 °C at 5 °C/min, with initial and final hold times of 3 and 12 min, respectively. Other conditions were as follows: inlet temperature, 250 °C; septum purge flow rate, 3 mL/min; scan mode, total ion current (TIC) in Q1; scan range, *m*/*z* 33−330; electron ionization energy, 70 eV; source temperature, 230 °C; quadrupole temperature, 150 °C; MS/MS transfer line temperature, 250 °C; He quench gas, 2.25 mL/min; N_2 collision gas, 1.5 mL/min; ODP 3 transfer line temperature, 250 °C; ODP 3 mixing chamber temperature, 150 °C; ODP 3 makeup gas, N_2.

GC-MS analyses were performed using an Agilent 7890A gas chromatograph (Agilent Technologies) equipped with a model 5975C mass spectrometry detector (Agilent Technologies), under the following conditions: carrier gas, helium; constant flow rate, 1.2 mL/min; inlet temperature, 250 °C; split ratio, 10:1; septum purge flow rate, 3 mL/min; 30 m × 0.25 mm i.d., 0.25 μm Agilent J&W DB-5MS column; temperature program, 40 °C (3 min), 5 °C/min to 300 °C (12 min); scan mode, TIC; scan range, *m*/*z* 33−330; electron ionization energy, 70 eV; source temperature, 230 °C; quadrupole temperature, 150 °C; transfer line temperature, 250 °C.

Compound Identification. For the identification of the flavor compounds, the odor impressions, the retention indices (RI), and the mass spectra of each compound were compared to authentic standards on two columns of different polarities (VF-WAXms and DB-5MS columns), published data, and the NIST 2011 MS library.

RESULTS AND DISCUSSION

Sensory Evaluation. Thirty-one different basidiomycetes were screened for the fermentation of wort. With most of the fungi significant changes of the aroma were observed. During the fermentation process the odor varied in quality and intensity. The most characteristic and intense odor impressions of the fermentations are listed in Table 1.

The odor of the cultures may be classified into three groups: pleasant, unpleasant, and odorless. The main pleasant odors included fruity (e.g., *Lentinula edodes*, *Polyporus umbellatus*, and *Trametes versicolor*), toasted (e.g., *Agrocybe aegerita* and *Pleurotus cornucopiae*), and honey-like (e.g., *Trametes versicolor* and *Panellus serotinus*) notes. Unpleasant odors, such as chlorine, medicinal, metallic, moldy, and smoky, were produced by a few basidiomycetes (e.g., *Agaricus arvensis*, *Flammula alnicola*, *Ganoderma applanatum*, *Laetiporus sulphureus*, and *Pholiota nameko*). Some basidiomycetes (e.g., *Meripilus giganteus*, *Pleurotus eous*, and *Pleurotus flabellatus*) diminished the typical odor of wort, some of them to completely odorless (e.g., *Clitocybe geotropa* and *Hericium erinaceus*). The cultures produced this variety of different odor impressions within the short fermentation time of up to 48 h. This phenomenon is remarkably different from previous investigations. Gallois et al. studied the capability of 29 different ligninolytic basidiomycetes to produce odors in 6 different media.[19] Flavors were perceived after an incubation period of 7−10 days. Kawabe and Morita reported that *Polyporus tuberaster* K 2606 produced a fruity and floral odor on day 13 in peptone−glucose−yeast medium.[20] The fast formation of flavor compounds in this study might be related to the available nutrients and flavor precursors in the wort. Wort represents a complex mixture of fermentable carbohydrates, peptides, proteins, lipids, metal and nonmetal ions, and polyphenols.[21] Therefore, it provides all essential nutrients and a proper environment for the growth of basidiomycetes. Furthermore, various potential flavor precursors such as phenolic acids, fatty acids, and amino acids were found in wort.[22−24] Hence, transformation time and transformation products strongly depend on the composition of medium used.

The generation of flavor compounds was often accompanied by a change of the color of the fermentation broth. Compared to the substrate wort, the color of most culture supernatants turned darker and reddish-brown (Table 1). The simultaneous production of aroma compounds and pigments by macrofungi was already reported by Badcock.[25] However, in the current study, the synthesis of odor and pigments was not correlated in all cases. *P. umbellatus* generated a strong and interesting fruity odor reminiscent of cherry and kiwi, but the color of the culture supernatant became lighter and more transparent.

After sensory evaluation by 10 panelists, wort fermented by shiitake was classified as the most interesting one. Shiitake produced a fresh, fruity, plum-like, sweet, and slightly sour flavor. During the fermentation the broth turned reddish-brown in color.

Shiitake represents an ideal candidate to develop a novel fermentation system. Due to its flavor, nutritional value, and presumed medicinal properties, shiitake has attracted high interest in recent years.[26] To the best of our knowledge, no studies on the volatile compounds of submerged-grown shiitake cultures in wort have been published so far. Shiitake is the second most popular edible mushroom in the global market and was the first medicinal macrofungus to enter the realm of

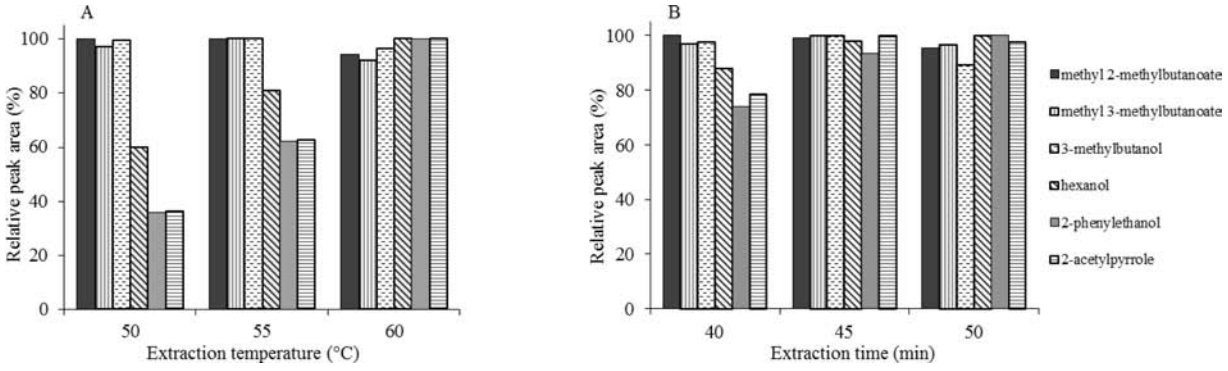

Figure 1. Influence of the extraction temperature (A) (CAR/PDMS fiber, 45 min extraction time) and extraction time (B) (CAR/PDMS fiber, 60 °C extraction temperature) on the extraction efficiency of selected odor compounds, expressed in percent of the maximum area.

modern biotechnology.[27] Therefore, high consumer acceptance and high market potential for the novel fermented beverage are expected.

Optimization of HS-SPME Parameters. SPME was invented by Pawliszyn in 1989.[28] This solvent-free extraction technique simplifies the sample preparation procedure considerably and has been widely used for food analysis. For the optimization of the HS-SPME method, six previously identified flavor compounds from the fermented wort were chosen. All of them matched the following criteria: baseline separation; distributed over the chromatographic run; and different chemical families.[15] In our study, common SPME parameters, including extraction temperature, extraction time, and fiber type, were found to greatly affect the number and intensity of perceived aroma compounds.

Extraction Temperature. The influence of different extraction temperatures (50, 55, and 60 °C) on the extraction efficiency was evaluated with a CAR/PDMS fiber. The peak areas of methyl 2-methylbutanoate, methyl 3-methylbutanoate, and 3-methylbutanol changed only slightly with elevated temperatures. The extraction efficiencies for 2-phenylethanol, 2-acetylpyrrole (**37/2**), and hexanol were enhanced significantly at increased temperatures (Figure 1A). With increased extraction temperature, the extraction efficiency for compounds with higher boiling points improved. This was in good agreement with a previous study.[29] Maximum relative peak areas were observed at 60 °C. Higher temperatures were not considered to avoid the formation of artifacts (e.g., Maillard reaction products) in the complex matrix wort. Therefore, 60 °C was selected as the optimum extraction temperature for further studies.

Extraction Time. For most compounds the extraction efficiency increased with extraction time, until equilibrium was reached after 45 min (Figure 1B). A prolonged extraction time led to a slight decrease of the areas of methyl 2-methylbutanoate, methyl 3-methylbutanoate, and 3-methylbutanol. Therefore, further experiments were carried out with an extraction time of 45 min.

Fiber Type. The extraction efficiencies of different SPME fiber types (CAR/PDMS, DVB/CAR/PDMS, PDMS/DVB, and PDMS) were evaluated by analyzing fermented wort samples by means of HS-SPME-GC-MS/MS-O. The coating material of the SPME fibers strongly influenced the extraction efficiency of odor-active compounds.

The number of odor-active compounds perceived at the ODP after extraction with the CAR/PDMS, DVB/CAR/PDMS, PDMS/DVB, and PDMS fibers were 30, 23, 19, and 8, respectively. The CAR/PDMS fiber was the most sensitive one, although two odors (octanal and an unidentified compound) could not be perceived. With the DVB/CAR/PDMS fiber a slightly reduced number of flavor compounds were detected during the first 15 min of the GC run (RI ≤ 1329). Seven of 32 flavor compounds [2-phenylacetaldehyde, 2-acetylthiazole, 2-phenylethanol acetate, β-damascenone (**32/2**), 2-phenylethanol, γ-nonalactone, and *o*-aminoacetophenone] were identified with all four fibers tested. DVB/CAR/PDMS fibers are widely used for flavor analysis, as the combination of three different materials can catch a wider range of polarities and volatilities.[30] However, for the analysis of fermented wort, a CAR/PDMS fiber was most efficient. This also indicates that the selection of the SPME fiber used for analysis depends strongly on the characteristics of the flavor compounds of the respective matrix. Due to its overall better performance, the CAR/PDMS fiber was chosen for further analysis of odor-active compounds.

Aroma (Extract) Dilution Analysis by LLE and HS-SPME. To evaluate the aroma profile of the fermented beverage, changes of the main odor-active compounds during the fermentation of wort were analyzed by two different extraction methods (LLE and HS-SPME) followed by an aroma (extract) dilution analysis. Different from LLE, no liquid dilutable aroma extract is obtained by SPME. For dilution analysis the original sample may be diluted. However, this might influence phase equilibrium due to a modified matrix composition. Therefore, ADA was performed after microextraction by applying different split inlet ratios. In preparation, the linear relationship between the peak area of the respective analyte and the split ratio of GC-MS/MS-O system was investigated by using a standard solution comprising six different flavor compounds. The regression plots showed a linear relationship with R^2 >0.989. Slopes of the respective equations ranged from −1.0 to −1.3. Kim et al. reported insufficient linearity for low and high split ratios due to an unstable carrier gas flow.[17] In our study, linear responses for all tested substances were obtained for a wide range of split ratios from splitless up to 256. Thus, increasing GC inlet split ratios was a fast and reliable tool for determining key odor-active compounds. Although the maximum split ratio of the GC was limited by the pneumatic controller, changing GC inlet split ratios combined with successive dilution of the original sample makes this method suitable even for very concentrated samples. The odor-active compounds identified by means of GC-MS/MS-O after LLE and HS-SPME of unfermented wort and wort fermented by shiitake are summarized in Table 2. A selection of

detected only in LLE. [g]MS spectrum was ambiguous; the compound was tentatively identified on the basis of RI, odor, and literature data,[33] [h]nd, no distinct MS spectrum on DB-5MS column. [i]−, odor was not perceived.

identified structures of aroma compounds with FD factors >1 are shown in Figure 2.

Main Odor-Active Compounds Identified after LLE. In total, 18 odor impressions were perceived in the liquid−liquid extracts of wort fermented with shiitake at the ODP during GC-MS/MS-O analysis (Table 2). The corresponding odor-active compounds were identified by comparison of the Kovats indices and mass spectra with those of the database and literature data and were confirmed by authentic standards on both polar and nonpolar GC columns. On the basis of the determined FD factors, 2-phenylethanol was the most important flavor compound in the fermented wort (FD 256). The compound with its typical rose odor was biosynthesized by shiitake during fermentation, possibly by biotransformation of L-phenylalanine. It has been shown that this metabolic pathway exists in basidiomycetes such as *Ischnoderma benzoinum*.[31] Other key odor compounds were 2-phenylacetic acid (FD 64), 2-methoxyphenol (FD 32), maltol (**37**/**1**) coeluting with 2-acetylpyrrole (**37**/**2**) (FD 32), a yet unknown compound with a burnt odor (FD 32), and (*E*)-2-nonenal (FD 16). The unknown compound was present in such low concentrations that a distinct mass spectrum could not be obtained. Further investigations are needed for a reliable identification.

All major odor-active compounds identified in the organic extract of the fermented wort after LLE (FD ≥ 16) were also present in the unfermented wort, but in different concentrations. The aroma compounds of wort with the highest FD factors were 2-methylbutanoic acid coeluting with 3-methylbutanoic acid (FD 256), maltol (**37**/**1**) coeluting with 2-acetylpyrrole (**37**/**2**) (FD 256), and γ-nonalactone (FD 256). γ-Nonalactone, maltol (**37**/**1**), and 2-acetylpyrrole (**37**/**2**) exhibited odor impressions typical for wort, such as malty, caramel, and toasted. After fermentation these predominant odors became less important (1 ≤ FD ≤ 32). 2-Methylbutanoic acid and γ-nonalactone could be perceived only in the undiluted fermented wort extract (FD 1).

Besides 2-phenylethanol, shiitake produced 3-phenylpropanol (39) (Figure 3), which was detected in the fermented beverage by mass spectrometry but not perceived at the ODP. Shiitake also produced 3-methylbutanol and 2-methylpropanoic acid. On the other hand, the peak areas of 3-methylbutanoic acid, hexanoic acid, cinnamic acid (50) (Figure 3), and palmitic acid (51) (Figure 3) decreased significantly during the fermentation. None of these compounds had a high impact on the overall flavor of fermented wort. Certain compounds (e.g., 3-methylbutanoic acid and cinnamic acid) were even below their limit of detection after fermentation. This implies that a wide variety of extracellular fungal enzymes, including laccases, lipoxygenases, and hydroperoxide lyases, might have catalyzed the degradation of these carboxylic acids, which can serve as an immediate carbon source for fungal growth.[18] However, these carboxylic acids might also have been precursors of some of the odor compounds, as shiitake produced aroma compounds such as 3-methylbutanol, 2-methylpropanoic acid, and 3-phenylpropanol. Krings et al. observed that 3-phenylpropanol was produced from cinnamic acid and L-phenylalanine.[31] The observed increase of the concentration of 3-methylbutanol might be associated with the simultaneous decrease of 3-methylbutanoic acid concentration.

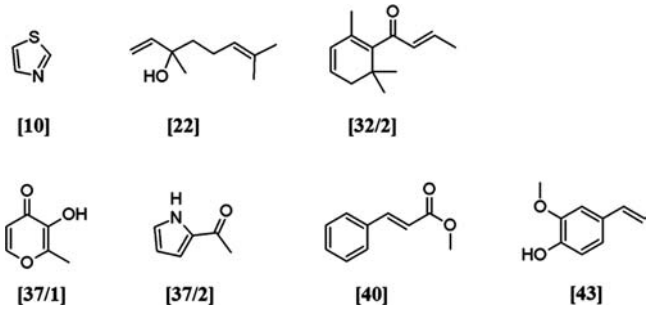

Figure 2. Selection of identified aroma compounds.

Although most of the odor impressions were caused by a single compound, two impressions (28 and 37) (Figure 3) originated from a mixture of compounds in both extracts. 2-Methylbutanoic acid and 3-methylbutanoic acid coeluted and represented a potent odor of wort (FD 256). They imparted a cheesy and sourish odor impression (28). During fermentation the FD factor was reduced to 1. Impression 37 (sweetish, burnt) was identified as a mixture of maltol (**37**/**1**) and 2-acetylpyrrole (**37**/**2**), which both impart a typical sweetish and burnt odor (Table 2).

The dominant odor impression of wort fermented with shiitake was fresh and fruity and thereby strikingly different from that of nonfermented wort. However, a single representative fruity flavor compound was not perceived by GC-MS/MS-O experiments after LLE. One possibility was that the fruity aroma did not result from the biosynthesis of new compounds, but from quantitative changes of several compounds. All of the most potent odor-active compounds of the culture were found in the wort extract as well, only the intensity of the aroma compounds changed remarkably. The intensity of typical aroma compounds of wort such as γ-nonalactone, maltol (**37**/**1**), 2-acetylpyrrole (**37**/**2**), and 2-acetylthiazole was very low in the fermented beverage.[32−34] The other possibility was that the compounds responsible for the fruity aroma were lost during either the extraction process or the GC-MS/MS-O analysis.[35] Hence, another extraction method was chosen for analyzing the fermentation system.

Main Odor-Active Compounds Identified by HS-SPME. By means of HS-SPME, 30 odor impressions were perceived for the unfermented wort and 29 from the fermented wort (Table 2). Methional (FD 256), methyl hexadecanoate (FD 256), 2-acetylthiazole (FD 128), β-damascenone (**32**/**2**) (FD 64), and 2,5-dimethylpyrazine (FD 64) were determined as the most potent odor-active compounds in wort. After fermentation by shiitake, the most important odorants (FD 64) were methional, methyl 2-methylbutanoate, methyl hexadecanoate, 2-phenylethanol acetate coeluting with β-damascenone (**32**/**2**), and 2-phenylethanol. Among them, methyl 2-methylbutanoate was detected only in the fermented beverage. The FD factor of 2-phenylethanol increased from 4 to 64 during the fermentation. It is noteworthy that especially the FD factors of the well-known typical wort flavors methional (FD 256), methyl hexadecanoate (FD 256), and 2-acetylthiazole (FD 128) decreased significantly during the fermentation (FD 64, 64,

dx.doi.org/10.1021/jf5005463 | J. Agric. Food Chem. 2014, 62, 4195−4203

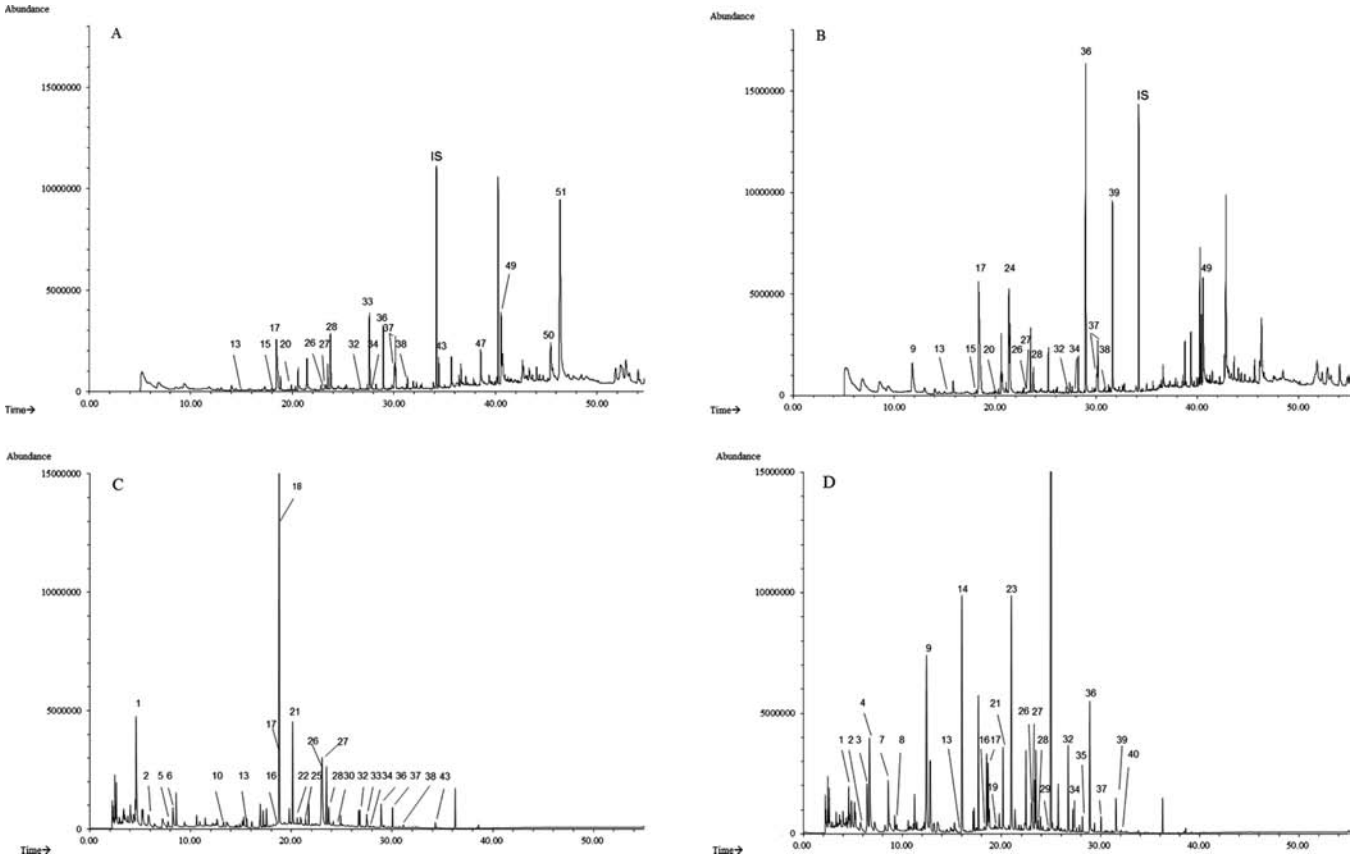

Figure 3. GC-MS/MS-O total ion current chromatograms of organic extracts of unfermented wort (A), of wort fermented by shiitake (B), after HS-SPME of unfermented wort (C), and of wort fermented by shiitake (D).

and 8, respectively). In addition, (*Z*)-3-nonen-1-ol (green), a yet unknown compound (burnt), (*E*)-methyl cinnamate (**40**) (fruity), and *o*-aminoacetophenone (grape) were also identified as potent odors in fermented wort (FD 16).

Despite not being perceivable at the ODP, shiitake produced methyl 3-methylbutanoate (4) (Figure 3), hexanol (14) (Figure 3), and 1-octanol (23) (Figure 3) de novo, whereas the peak area of furfural (18) (Figure 3) decreased significantly during the fermentation.

Analysis of the key odor-active compounds revealed the formation of methyl 2-methylbutanoate and (*E*)-methyl cinnamate (**40**) by shiitake. Both compounds have a typical fruity flavor and could not be detected in unfermented wort. In contrast to LLE, it was thus possible to identify the flavor compounds imparting the fruity aroma by means of HS-SPME. This is the first time that the formation of these compounds by shiitake is reported. As 2-methylbutanoic acid and cinnamic acid were detected in the LLE of wort, shiitake might transform these organic acids into their corresponding esters. Branched carboxylic acid and phenolic acids are known as flavor precursors in microbial cultures.[36]

Comparison of Potent Odor-Active Compounds Identified by LLE and HS-SPME. The extraction method may strongly influence the results of olfactometric analyses.[37] Depending on the extraction technique, an aroma compound might be detected or not during olfactometric analysis.[14] In our study, most of the determined key odor-active compounds of the fermented beverage were similar after LLE and HS-SPME. However, the FD factors of the individual compounds differed and some distinct differences were observed. LLE allowed the recovery of some key aroma compounds, such as 2-phenylacetic acid, a polar compound with a high boiling point (266 °C), which was hardly extracted by HS-SPME. This implied that HS-SPME was less sensitive for trapping low volatile and polar acids. This is in good agreement with a study of Yang and Peppard, who reported the adsorption of fatty acids on SPME fibers with low affinity.[38] On the other hand, HS-SPME was more appropriate for other main aroma compounds of the fermented beverage (e.g., methyl 2-methylbutanoate, methional, methyl hexadecanoate, and *o*-aminoacetophenone), which were not perceived in olfactometric analysis after LLE. The ester methyl 2-methylbutanoate is highly volatile as indicated by a RI of 1018. *o*-Aminoacetophenone and methional have low odor thresholds.[39,40] In the case of methional, panelists could recognize the potato-like smell above an olfactory threshold of 0.2 ppb in water.[40] These results suggest that HS-SPME has a better capacity for extracting highly volatile and trace compounds, which are easily lost during the extraction or concentration process of LLE, as already observed by Mebazaa et al.[41] The high sensitivity of SPME enabled trapping and identification of flavor compounds with low odor thresholds present in low concentrations with potentially high impact on the overall aroma of the sample.

In conclusion, all of the selected basidiomycetes grew well in wort, and many interesting odors were produced. Among them, shiitake was rated as the most promising species for producing a novel fermented beverage, exhibiting an interesting plum-like aroma. Odor-active compounds of the fermented beverage were identified using a combination of two different extraction methods. Odor-active compounds produced by shiitake, such as

dx.doi.org/10.1021/jf5005463 | *J. Agric. Food Chem.* 2014, 62, 4195−4203

2-phenylethanol, methyl 2-methylbutanoate, 2-phenylethanol acetate, and (*E*)-methyl cinnamate (**40**), were responsible for the overall flavor.

ABSTRACT: Winter barley (*Hordeum vulgare* L.), a potential feedstock for fuel ethanol production, may be contaminated with the trichothecene mycotoxin deoxynivalenol (DON). DON is a threat to feed and food safety in the United States and may become concentrated during the production of distillers dried grains with solubles (DDGS). DDGS is a coproduct of fuel ethanol production and is increasingly being used as feed for domestic animals. Therefore, new strategies to reduce the threat of DON in DDGS need to be developed and implemented for grain destined for fuel ethanol production. It is known that large concentrations of DON accumulate in the hulls of wheat and barley. Consequently, improved methods are needed to carefully remove the hull from the grain and preserve the starchy endosperm. Whole kernels from five Virginia winter barley genotypes were used to evaluate the abilities of two different milling strategies (roller milling and precision milling (FitzMill)) for their ability to remove the hull-enriched tissue from the kernel while maintaining starch levels and reducing DON levels in the endosperm-enriched tissue. After whole kernels were milled, DON and starch levels were quantified in the hull-enriched fractions and endosperm-enriched fractions. Initial milling experiments demonstrated that the precision mill system (6 min run time) is able to reduce more DON than the roller mill but with higher starch losses. The average percent DON removed from the kernel with the roller mill was 36.7% ± 5.5 and the average percent DON removed from the dehulled kernel with the precision mill was 85.1% ± 9.0. Endosperm-enriched fractions collected from the roller mill and precision mill contained starch levels ranging from 49.0% ± 12.1 to 59.1% ± 0.5 and 58.5% ± 1.6 to 65.3% ± 3.9, respectively. On average, the precision mill removed a mass of 23.1% ± 6.8 and resulted in starch losses of 9.6% ± 6.3, but produced an endosperm-enriched fraction with relatively very little average DON (5.5 ± 2.7 $\mu g\ g^{-1}$). In contrast, on average, the roller mill removed a mass of 12.2% ± 1.6 and resulted in starch losses of 2.1% ± 0.5, but produced an endosperm-enriched fraction with high average DON (20.7 ± 13.5 $\mu g\ g^{-1}$). In a time course precision milling experiment, we tested barley genotypes Nomini, Atlantic, and VA96-44-304 and attempted to reduce the starch loss seen in the first experiment while maintaining low DON concentrations. Decreasing the run time of the precision mill from 5 to 2 min, reduced starch loss at the expense of higher DON concentrations. Aspirated fractions revealed that the precision milled hull-enriched fraction contained endosperm-enriched components that were highly contaminated with DON. This work has important implications for the reduction of mycotoxins such as DON in barley fuel ethanol coproducts and barley enriched animal feeds and human foods.

KEYWORDS: *barley, hull, dehulling, milling, mycotoxin reduction, deoxynivalenol, starch retention, fermentation, distillers dried grains with solubles (DDGS)*

INTRODUCTION

Fusarium head blight (FHB), caused by the fungal plant pathogen *Fusarium graminearum* Schwabe (teleomorph *Gibberella zeae*), can be a devastating disease of grains such as wheat and barley.[1] During infection, the fungus produces a mycotoxin called deoxynivalenol (DON).[2] DON is a protein synthesis inhibitor[4] and ingestion of DON may lead to vomiting, feed refusal, and a compromised immune system.[5] Grain contaminated with DON may be rendered unusable for feed and food products.[3]

Distillers dried grains with solubles (DDGS), a coproduct of fuel ethanol production, is increasingly being used as feed for domestic animals. When grain, such as winter barley,[6] containing DON is used as feedstock to produce fuel ethanol, DON becomes concentrated in the DDGS.[7,8] The fuel ethanol industry relies on the sale of DDGS as feed for domestic animals for generating profits[9] and DDGS contaminated with mycotoxins such as DON are unmarketable.

Current methods to reduce or alleviate mycotoxin contamination in grain include blending clean grain with

contaminated grain (prohibited in Europe and not approved by the U.S Federal Drug Administration (FDA)), washing grain with water, and using adsorbents to bind mycotoxins.[10,11] Strategies to prevent DON production during storage include electron beam irradiation[12] and fungistats to prevent fungal growth.[13] These strategies may be effective, but are likely to require high equipment and labor costs. New cost-effective and commercially viable methods need to be developed and implemented to reduce DON contamination in barley destined for food and feed products.

Planting resistant barley cultivars can be one of the most effective ways to reduce FHB and DON accumulation; however, resistance conferring complete immunity to FHB has not been identified to date. In Virginia, new hulled and hulless barley cultivars that are resistant to FHB and DON accumulation are being developed.[14,15] With hulled barley, the hull is tightly fixed to the pericarp epidermis, while with hulless barley the hull loosely covers the caryopses.[16] Previous work has demonstrated that mycotoxins such as DON accumulate in the hull and outer regions of the kernel.[17−20] Thus, an alternative to hulled barley would be to plant hulless genotypes whose hull can be easily removed and that have higher starch content.[6] However, higher yields and higher revenues with hulled barley (bushels per acre) do not make hulless barley an attractive alternative for growers.[6] Past attempts at milling or pearling hulled grain to reduce mycotoxin levels were proven effective and showed reductions that ranged from 30% to 66%.[19−25] Inevitably, grain mass losses (i.e., starch, protein) occur and have ranged from 10% to 32%.[22,25−27] Recent advances in hull removal have led to a more effective and simpler dehulling strategy that may be more cost-effective and may minimize losses in grain mass.[28] The Fitzpatrick Comminuting Machine (precision mill) was shown to dehull kernels and produce fractions with much higher starch content than that of the original hulled kernel (71% vs 60% starch, respectively). Moreover, the process minimized starch loss to less than 1.5%.[28]

In this study, we evaluated the abilities of a FitzMill precision mill and a roller mill to remove the hulls and reduce DON in Virginia hulled barley samples without causing major starch losses. We hypothesized that the precision mill (compared to the roller mill) would more effectively remove hull-enriched tissue from hulled barley, thereby resulting in larger reductions of DON, higher starch concentrations, and smaller starch loss. Our work has important implications for the reduction of mycotoxins in barley fuel ethanol coproducts and barley enriched animal feeds and human foods.

MATERIALS AND METHODS

Barley Genotypes and Infection. Five Virginia winter hulled barley genotypes (Callao, Nomini, Atlantic, VA06B-32, VA96-44-304) were planted in 2009 in a randomized complete block with two replications in mist-irrigated nurseries at Mt. Holly, VA.[14] Research plots had dimensions of 1.5 m × 13.4 m and *Fusarium graminearum* colonized corn (*Zea mays*) kernels were applied to the plots at the boot stage to encourage infection and DON contamination in the harvested grain.[7,15] Grain was harvested in summer 2010 using a small plot research combine.

Roller Milling and Precision Milling. Ten hulled barley samples (five genotypes) from Virginia winter barley genotypes Callao, Nomini, Atlantic, VA06B-32, and VA96-44-304 were used to evaluate the abilities of two different milling strategies (roller milling and precision milling (FitzMill)) for their ability to remove the hull-enriched tissue from the kernel while maintaining starch levels and reducing DON levels in the endosperm-enriched tissue. The samples were first cleaned using a dockage tester (Carter Day International, Minneapolis, MN). For each barley genotype, two 500 g samples were roller milled, and two 500 g samples were precision milled. The roller mill flow consisted of one pass through 16 corrugations per 25.4 mm (mm) rolls with a 0.127 mm gap. After roller milling, the material was sifted with a SWECO sifter (SWECO, Florence, KY) containing a 24SSBC sieve. The milled kernel fraction (endosperm-enriched fraction) passed through the sieve while the hull-enriched fraction remained on top of the sieve screen. The precision milling was carried out similarly to that described by Hicks et al.[28] using a Fitzpatrick Comminuting Machine (Model D, W.J. Fitzpatrick Company, Chicago IL) also referred to as a FitzMill. Each 500 g sample was milled for 6 min using a 2AA sieve (1.9 mm) with the sharp blades rotating forward at 1750 rpm. Tests were run batch-wise in duplicate. Samples were loaded in the FitzMill chamber and during milling, the hull-enriched fractions were collected beneath the mill and the dehulled kernel fractions (endosperm-enriched fraction) were retained in the milling chamber. A comparison of hull removal efficiency was determined by measuring the mass fraction (% dry weight basis, (% d.w.b)) of the barley hull and dehulled kernel remaining after processing through the roller mill or precision mill.

Time Course Precision Milling. Three hulled barley genotypes (Nomini, Atlantic, and VA96-44-304) were chosen to determine the optimum run time for the FitzMill necessary to efficiently remove tissue enriched in hull from the kernel while minimizing starch loss. The grains used for these experiments were harvested in 2011 from barley genotypes that were planted in 2010 in a randomized complete block in mist-irrigated nurseries at Mt. Holly, VA and treated with *Fusarium graminearum* as described above. For each barley genotype, whole kernel subsamples of 500 g were dehulled using the FitzMill as described above except that samples were milled for only 2, 3, 4, or 5 min rather than the 6 min in the original experiment. A logarithmic trend line was applied to % mass fraction data derived from grain processed in the time course precision milling experiment.[28] Additionally, some of the individual hull and kernel fractions from these experiments were aspirated using a Grainman model 63-115-60VS Grain Cleaner Laboratory Aspirator (Grain Machinery Mfg. Corp., Miami, Florida, U.S.A.). The speed setting was 7, the feeder was set at 5, and the air control was set at 0.2. Two fractions were collected: the heavy fraction that was composed primarily of starch-enriched fractions (endosperm) and the light fraction composed primarily of fibrous hull.

Extraction of Deoxynivalenol. Samples containing approximately 10 g of whole kernels, hulls, and dehulled kernel fraction were ground in a coffee grinder (Hamilton Beach, model 80365, Southern Pines, NC) positioned at the expresso and 12 cup setting (Figure S1 in the Supporting Information [SI]). Mycotoxin extractions were performed following standard protocols on 1 g subsamples of the ground whole kernel, ground hull, and ground kernel (Figure S1).[29−31] Each subsample was combined with 10 mL extraction solvent (86% (v/v) acetonitrile in DI water) in a capped polypropylene tube. The solvent−sample mixture was placed on a shaker at 200 rpm for 1 h at room temperature and then passed through a cleanup column composed of a 1 g mixture of Bakerbond C18 (VWR, Radnor, PA) and aluminum oxide (active, neutral) (Sigma-Aldrich, St. Louis, MO) at a 1:3 ratio.

All samples were extracted for DON so the final concentration in isooctane was diluted ×20. If the sample was quantified to have a DON concentration of 0.5 $\mu g\ g^{-1}$ or less on the GC−MS, then the sample extract was quantified at a smaller dilution of ×2.5. This was done to ensure that DON levels fell within the standard curve.

For 1:20 dilutions, a 1 mL aliquot of eluent was transferred to a glass test tube and evaporated to dryness using a nitrogen evaporator set at 55 °C. Dried samples were then silylated with a 100 μL mixture of *N*-trimethylsilylimidazole (TMSI) and trimethylchlorosilane (TMCS) at a 100:1 ratio. Samples were then resuspended in 2 mL of isooctane containing 0.5 $\mu g\ g^{-1}$ mirex, followed by 2 mL of water to quench the reaction. Samples were vortexed for 10 s, and 100 μL of the isooctane−mirex supernatant was removed and transferred to

chromatography vials for gas chromatography−mass spectrometry (GC−MS) analysis. For 1:2.5 dilutions, the same method was followed, except that a 2 mL aliquot was dried down and resuspended in 0.5 mL of isooctane−mirex mixture.

GC−MS Analysis for Deoxynivalenol Quantification. GC−MS analysis was conducted using an Agilent 6890/5975 system operating in selected ion monitoring (SIM) mode. A 1 μL volume of each sample or known standard was injected by an autosampler in splitless mode onto an Agilent HP-5MS column, 0.25 mm inner-diameter by 0.25 μm film thickness by 30 m length. The inlet temperature was set to 250 °C with a constant column flow rate of 1.2 mL/min. The initial column temperature was held at 150 °C for 1 min, increased to 280 °C at a rate of 30 °C/min, and held constant for 3.5 min. A postrun method ramped the oven temperature to 325 °C and was held for 2.5 min. Mirex (Sigma-Aldrich, St. Louis, MO) was used as an internal control at 0.5 μg g^{-1}. SIM mode detected DON target ions at a mass:charge ratio of 512, with reference ions at 422 and 497.[32] SIM mode detected mirex target ions at mass:charge ratio of 272 with reference ions at 276 and 237. DON was quantified using a standard curve of ratios of DON area to mirex area versus DON standard concentration and fit to a linear regression model. DON standards (Romer Laboratories, Austria) were prepared in a DON-free wheat matrix[29] at concentrations of 0.05, 0.1, 0.25, 0.5, 1.0, 2.5, 5.0, 10, and 15 μg g^{-1}. The limit of quantitation (LOQ) for this method was determined to be 0.1 μg g^{-1}. Sample results were initially quantified using a standard curve with the first five standards (0.05 to 1 μg g^{-1}). If raw DON values were quantified as greater than 1 μg g^{-1}, calculations were performed using a standard curve containing all points. For quality assurance, samples of barley and wheat containing known levels of DON were concurrently prepared and interspersed among test samples for each GC−MS run. Quality assurance samples were considered acceptable if the quantified DON concentration did not deviate more than 20% of the expected concentration. DON recovery for barley using the DON extraction method described above has been reported to range between 100% and 105%.[30] The percentage of DON removed by milling an individual kernel was determined by adjusting the DON values of each fraction by multiplying by the appropriate mass fraction (% d.w.b) (Figure 1 or Figure 2) and then calculating the proportion of DON in the hull-enriched tissue that was removed relative to the total DON (the DON concentration in the kernel's hull-enriched tissue plus the DON concentration in the kernel's endosperm-enriched tissue). A logarithmic trend line was determined to be the best fit and was applied to the % DON removed from dehulling whole kernels processed in the time course precision milling experiment.

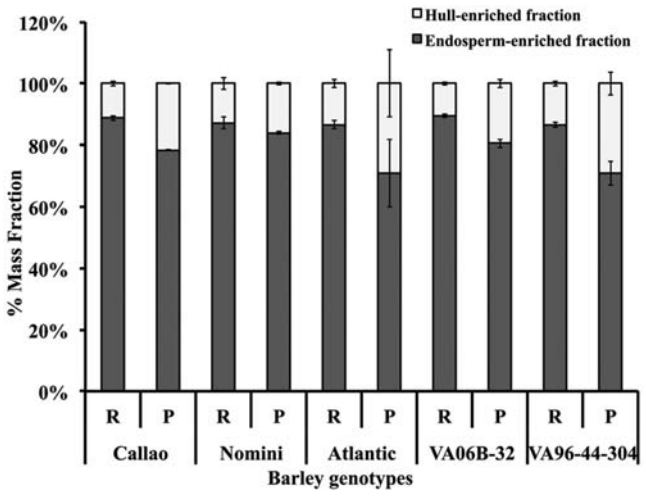

Figure 1. Percent mass fractions (% d.w.b.) of endosperm-enriched fractions and hull-enriched fractions from whole kernels processed in the roller mill (R) and precision mill (P). Five barley genotypes were used and run in duplicate and values given are mean ± standard deviation.

Statistical Analyses. A two-way analysis of variance (ANOVA) was performed to test for significant differences among genotypes, mill type, and time points during precision milling using PROC GLIMMIX in SAS (version 9.2; SAS Institute, Cary, NC). A Tukey−Kramer's honestly significant difference (HSD) posthoc test was performed for variables that differed at $P \leq 0.05$. A correlation analysis was performed between DON levels in the whole kernels and % hull mass fraction using JMP (version 9.0.0; SAS Institute Inc., Cary, NC). For the time course precision mill experiment, an analysis was performed to determine if % DON reduction and % hull mass fraction were correlated and if % starch loss and % hull mass fraction were correlated using JMP (version 9.0.0; SAS Institute Inc., Cary, NC).

Starch Analysis. Starch content was determined through chemical analysis of the hull-enriched and endosperm-enriched fractions remaining after precision milling and roller milling. A logarithmic trend line was applied to starch content data derived from grain processed in the time course precision milling experiment.[28] Fractions with high starch content were considered to be endosperm-enriched fractions, and fractions with low starch were considered hull-enriched fractions. Starch content of hull and kernel samples was determined by analyzing approximately 100 mg of sample using a starch determination kit (Megazyme International Ireland Ltd., Bray Business Park, Bray, Co. Wicklow, Ireland.[33] Enzyme digestions were conducted following the Megazyme protocol,and the hydrolyzed starch solutions were diluted to 50 mL with water. This method was modified by use of an YSI 2700 Analyzer (YSI Incorporated, Yellow Springs, Ohio) fitted with an YSI 2710 turntable for automated glucose determination. The percentage of starch lost by milling an individual kernel was determined by adjusting the starch compositional values of each fraction by multiplying by the appropriate mass fraction (% d.w.b.) (Figure 1 or Figure 2) and then calculating the proportion of starch in the hull-enriched tissue that was removed relative to the total starch composition (the starch in the kernel's hull-enriched tissue plus the starch in the kernel's endosperm-enriched tissue).

RESULTS

Mass Fractions from the Roller Mill and Precision Mill. After milling whole kernels in the roller mill and precision mill, components were separated into endosperm-enriched fractions and hulled-enriched fractions. Under the conditions tested, the precision mill system resulted in larger hull-enriched mass fractions and smaller endosperm-enriched mass fractions than the roller mill system. An ANOVA confirmed an effect of milling strategy on hull-enriched and endosperm-enriched mass fractions ($P \leq 0.05$) (Table S1). The roller mill resulted in endosperm-enriched percent mass fractions that ranged from 86.6% ± 1.3 to 89.6% ± 0.5 and hull-enriched percent mass fractions that ranged from 10.5% ± 0.5 to 13.4% ± 1.3 (Figure 1). The precision mill resulted in endosperm-enriched percent mass fractions that ranged from 70.8% ± 10.9 to 84.1% ± 0.4 and hull-enriched percent mass fractions that ranged from 16.0% ± 0.4 to 29.2% ± 10.9 (Figure 1). On average, the roller mill yielded endosperm-enriched and hull-enriched fractions of 87.8% ± 1.5 and 12.2% ± 1.6, while the precision mill yielded an average percent mass fraction of endosperm-enriched and hull-enriched fractions of 76.9% ± 6.8 and 23.1% ± 6.8, respectively (Figure 1). Average mass recovery was 97.3% and 99.8% for the roller mill and precision mill, respectively (not shown).

Deoxynivalenol Levels in Barley Fractions. DON levels in whole kernels ranged from 14.3 ± 4.6 μg g^{-1} (Nomini) to 38.8 ± 14.6 μg g^{-1} (Atlantic) (Table 1). Whole kernels that were processed in the roller mill resulted in endosperm-enriched fractions containing DON concentrations that ranged

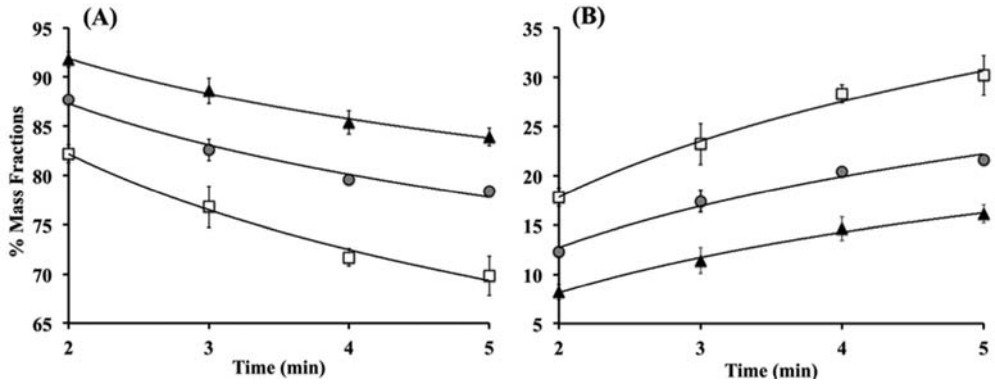

Figure 2. Time course precision mill percent mass fractions (% d.w.b.) of (A) hull-enriched fractions from whole kernels of barley genotypes Nomini (**triangle**, $y = -8.85 \ln(x) + 98.02$, $R^2 = 0.99$), Atlantic (**circle**, $y = -10.37 \ln(x) + 94.49$, $R^2 = 0.98$), and VA96-44-304 (**square**, $y = -14.00 \ln(x) + 91.88$, $R^2 = 0.99$) and (B) endosperm-enriched fractions from whole kernels of barley genotypes Nomini (**triangle**, $y = 8.85 \ln(x) + 1.98$, $R^2 = 0.99$), Atlantic (**circle**, $y = 10.37 \ln(x) + 5.51$, $R^2 = 0.98$), and VA96-44-304 (**square**, $y = 14.00 \ln(x) + 8.12$, $R^2 = 0.99$). Each time point for a given genotype was run in duplicate, and values given are mean ± standard deviation.

[a]Aspirated samples were single runs.

Starch Composition of Endosperm-Enriched and Hull-Enriched Fractions. Whole kernels processed in the roller mill resulted in starch levels in the endosperm-enriched fractions that ranged from 49.0% ± 12.1 to 59.1% ± 0.5 and starch levels in the hull-enriched fractions that ranged from and 7.2% ± 0.8 to 11.1% ± 0.1 (Table 2). Conversely, the precision mill resulted in starch composition in the endosperm-enriched fractions that ranged from 58.5% ± 1.6 to 65.3% ± 3.9 and starch levels in the hull-enriched fractions that ranged from 13.5% ± 3.2 to 30.0% ± 9.5 (Table 2). For the 5 barley genotypes analyzed, the grand mean starch concentration of the endosperm-enriched fractions and hull-enriched fractions from the roller mill was 56.4% ± 5.8 and 8.4% ± 1.7, while the average for the precision mill fractions was 61.2% ± 3.0 and 20.0% ± 7.4, respectively (Table 2). Starch lost from the milled kernel using the roller mill and precision mill ranged from 1.8% ± 0.5 to 2.5% ± 0.8 and 4.2% ± 1.0 to 16.7% ± 10.5, respectively (Table 2). Average starch loss from the roller mill was 2.1% ± 0.5 and average starch loss from the precision mill was 9.6% ± 6.3 (Table 2). An ANOVA demonstrated a significant ($P \leq 0.05$) effect of milling strategy on starch levels in the endosperm-enriched fractions and an effect of genotype, milling strategy, and genotype * mill interactions on starch levels in the hull-enriched fractions (Table S1).

Time Course Precision Milling-Percent Mass Fraction. Three of the barley genotypes that were analyzed in the first analysis (Nomini, Atlantic, and VA96-44-304) were subject to time course precision milling to locate a milling time that resulted in lower starch loss. Longer precision milling times resulted in larger amounts of hull-enriched fractions and smaller amounts of endosperm-enriched fractions (Figure 2). Time course precision milling generated hull-enriched mass fractions ranging from 8.2% ± 0.8 (2 min, Nomini) to 30.2% ± 2.0 (5 min, VA96-44-304) and endosperm-enriched mass fractions ranging from 69.8% ± 2.0 (5 min, VA96-44-304) to 91.8% ± 0.8 (2 min, Nomini) (Figure 2). Significant differences ($P \leq 0.05$) for genotype, time, and genotype * time interactions were observed for endosperm-enriched and hull-enriched % mass fractions in the time course precision mill experiment (Table S2). Aspirated samples revealed that hull-enriched fractions were contaminated with small amounts of components enriched in endosperm (which were separated by aspiration) and endosperm-enriched fractions that were contaminated with small amounts of components enriched in hulls (which were also separated by aspiration) (Table 3). Endosperm-enriched fractions that were contaminating the hull-enriched fraction ranged from 18.5% (Nomini, 5 min) to 30.1% (VA96-44-304, 5 min) and hull-enriched fractions that were contaminating the endosperm-enriched fraction ranged from 3.3% (VA96-44-304, 3 min) to 10% (Nomini, 3 min) (Table 3).

Time Course Precision Milling-DON and Starch Levels. From 2 to 5 min, barley genotypes Nomini, Atlantic, and VA96-44-304 had increases in the proportion of DON that was removed from the dehulled kernel, with percentages ranging from 45.0% ± 7.1 to 68.8% ± 8.5, 68.9% ± 7.2 to 90.5% ± 1.1, and 66.1% ± 4.3 to 92.7% ± 1.7, respectively (Figure 3). Thus, DON levels increased in the hull-enriched fractions and decreased in the endosperm-enriched fractions as precision milling time increased. For example, the endosperm-enriched fraction of Nomini, Atlantic, and VA96-44-304 had DON concentrations that decreased from 12.2 ± 2.9 to 8.1 ± 3.8, from 9.9 ± 4.0 to 3.1 ± 0.1, and from 19.8 $\mu g\ g^{-1}$ ± 1.9 (2 min)

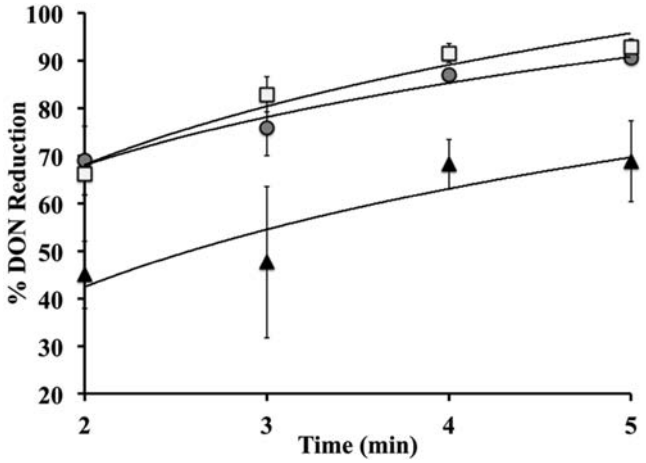

Figure 3. Percentage of DON removed by dehulling barley genotypes Nomini (**triangle**, $y = 29.73 \ln(x) + 21.82$, $R^2 = 0.84$), Atlantic (**circle**, $y = 24.82 \ln(x) + 50.79$, $R^2 = 0.97$), and VA96-44-304 (**square**, $y = 30.13 \ln(x) + 47.22$, $R^2 = 0.94$) in the precision mill from 2 to 5 min. Each time point for a given genotype was run in duplicate, and values given are mean ± standard deviation. The percentage of DON removed by milling an individual kernel was determined by multiplying the DON values ($\mu g\ g^{-1}$) of each fraction by the appropriate mass fraction value (Figure 2A, B) and then calculating the proportion of DON in the hull-enriched tissue that was removed relative to the total DON.

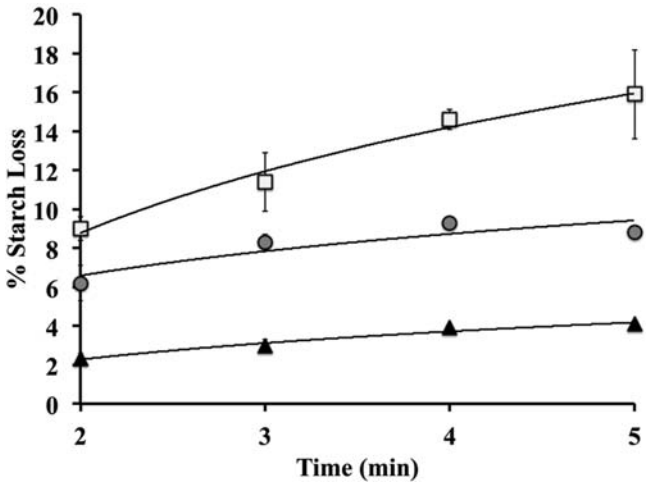

Figure 4. Percent starch lost (% d.w.b.) from dehulling kernels of barley genotypes Nomini (**triangle**, $y = 2.08 \ln(x) + 0.83$, $R^2 = 0.97$), Atlantic (**circle**, $y = 3.10 \ln(x) + 4.44$, $R^2 = 0.81$), and VA96-44-304 (**square**, $y = 7.82 \ln(x) + 3.36$, $R^2 = 0.98$) in the time course precision milling experiment. Each time point for a given genotype was run in duplicate, and values given are mean ± standard deviation. The percentage of starch lost by milling an individual kernel was determined by multiplying the starch compositional values (%) of each fraction by the appropriate mass fraction (Figure 2A, B) and then calculating the proportion of starch in the hull-enriched tissue that was removed relative to the total starch percentage.

to 5.1 $\mu g\ g^{-1}$ ± 0.4 (5 min), respectively (data not shown). Correspondingly, the hull-enriched fraction had DON concentrations that went from 110.6 ± 6.8 to 88.9 ± 2.1, from 150.8 ± 10.5 to 108.2 ± 10.5, and from 178.7 $\mu g\ g^{-1}$ ± 6.4 (2 min) to 152.0 $\mu g\ g^{-1}$ ± 10.2 (5 min), respectively (data not shown). There were significant differences ($P \leq 0.05$) in DON concentration between time points in the endosperm-enriched fractions and significant differences ($P \leq 0.05$) between genotypes and between time points in the hull-enriched fractions (Table S2).

When precision milling time increased (2 to 5 min), so did the proportion of starch lost when the hull-enriched tissue was removed likely due to simultaneous removal of small amounts of endosperm (Figure 4). As more and more hull was removed, eventually the precision mill blades struck the dehulled kernel and removed more endosperm.[28] Significant differences ($P \leq 0.05$) were observed for % starch loss between time points and genotypes (Table S2 in the SI). Starch loss ranged from 2.3% ± 0.3 to 4.1% ± 0.1 for Nomini, 6.2% ± 0.9 to 8.8% ± 0.1 for Atlantic, and 9.0% ± 0.6 to 15.9% ± 2.3 for VA96-44-304 (Figure 4). Barley genotype VA96-44-304 had the largest loss of starch during dehulling in the precision mill. Although starch loss increased from 2 to 5 min, precision milling led to increases in the starch concentration for the endosperm-enriched fractions. The starch composition (increasing in milling time) for the endosperm-enriched fractions of Nomini, Atlantic, and VA96-44-304 increased from 55.6% ± 0.3 to 60.0% ± 1.5, 57.6% ± 3.1 to 61.5% ± 1.0, and 55.9% ± 0.5 (2 min) to 61.2% ± 0.0 (5 min), respectively (data not shown). The starch composition (increasing in milling time) for the hulled-enriched fractions ranged from 14.8% ± 0.1 to 13.4% ± 0.3, 26.9% ± 2.4 to 21.4% ± 0.4, and 25.6% ± 0.1 (2 min) to 26.7% ± 2.2 (5 min), respectively (data not shown). There were significant differences ($P \leq 0.05$) in % starch between time points in the endosperm-enriched fractions and significant differences between genotypes and genotype ∗ time interactions in the hull-enriched fractions (Table S2).

The percent starch lost by dehulling and the percent DON removed in the precision mill was significantly correlated with the % hull mass fraction ($r = 0.95$, $P < 0.0001$ and $r = 0.87$, $P < 0.0001$, respectively) (Figure 5). When a linear model was fit to the trend lines, the slope (rate) of starch loss and DON removal were 0.63 and 2.26, respectively (Figure 5). However, the logarithmic model was a better fit for the DON removal (R^2 of 0.81, Figure 5).

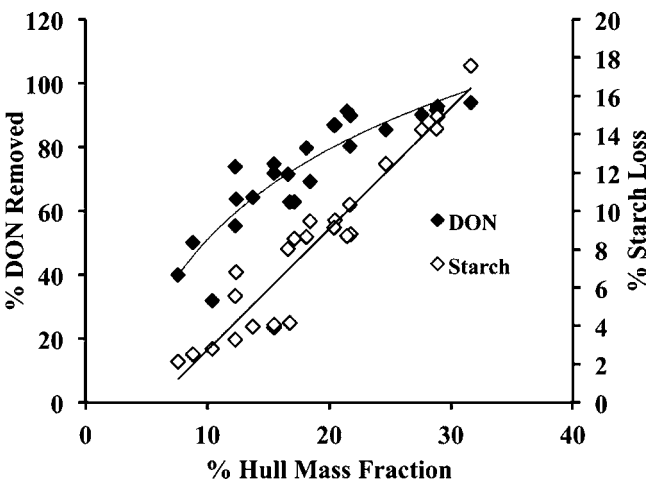

Figure 5. Percent DON removed ($y = 40.84 \ln(x) - 43.05$, $R^2 = 0.81$) and % starch loss ($y = 0.63x - 3.59$, $R^2 = 0.91$) as a function of the % hull mass fraction during time course precision milling. The amount of DON removed and the amount of starch lost increased as the mass of the hull fraction increased.

Time Course Precision Milling-Aspirated Samples. The aspirated hull-enriched fractions possessed components enriched in endosperm that contained DON levels ranging from 98.6 $\mu g\ g^{-1}$ (Nomini, 5 min) to 131.4 $\mu g\ g^{-1}$ (VA96-44-304, 4 min) and components enriched in hulls that contained DON ranging from 4.8 $\mu g\ g^{-1}$ (Nomini, 5 min) to 9.2 $\mu g\ g^{-1}$ (VA96-44-304, 5 min) (Table 3). The aspirated endosperm-enriched fractions possessed components enriched in hulls that contained DON levels that ranged from 2.6 $\mu g\ g^{-1}$ (Atlantic, 3 min) to 7.7 $\mu g\ g^{-1}$ (VA96-44-304, 2 min) and components enriched in endosperm that contained DON ranging from 1.8 $\mu g\ g^{-1}$ (Atlantic, 3 min) to 6.5 $\mu g\ g^{-1}$ (VA96-44-304, 2 min) (Table 3).

The hull-enriched fractions contained endosperm-enriched components that could be removed by aspiration, and these isolated subfractions had starch levels that ranged from 52.0% (Nomini, 5 min) to 65.6% (Atlantic, 5 min) and the hull-enriched components remaining after aspiration had starch composition that ranged from 4.7% (Nomini, 5 min) to 11.2% (Atlantic, 5 min) (Table 3). The endosperm-enriched fractions contained hull-enriched components that were isolated by aspiration and these isolated subfractions had starch levels that ranged from 0.8% (Nomini, 3 min) to 3.2% (Atlantic, 2 min). The endosperm-enriched components remaining after aspiration had starch levels that ranged from 55.6% (VA96-44-304, 2 min) to 66.1% (Atlantic, 3 min) (Table 3).

DISCUSSION

Previous interest in using barley as a potential feedstock for fuel ethanol production[6] led to the development of methods to create more efficient, high-starch ethanol feedstocks from hulled barley using a precision dehulling process.[28] Occasionally, barley kernels may contain high levels of the mycotoxin DON, and while such kernels can be used to make fuel ethanol, the DON concentrates in the ethanol coproduct DDGS, making it unmarketable. DDGS sales are critical for an ethanol plant's economic viability. In this report, we compared the abilities of two milling strategies (roller mill and FitzMill precision mill) to remove DON-contaminated hull-enriched tissue from winter barley, while preserving starch levels in the kernel. This work was based on the report that the FitzMill offers a simple process for dehulling hulled barley to produce a dehulled kernel with higher starch content[28] and other reports that have shown DON accumulating in the hull and peripheral regions of the kernel.[17−20]

Roller Mill vs Precision Mill. In our study, the roller mill removed a smaller mass of hull-enriched tissue from the kernel (Figure 1) and yielded endosperm-enriched fractions with larger concentrations of DON than the precision mill (Table 2). This result can be explained by the mechanics of the roller mill and precision mill systems. The roller mill is a common milling technique[27,34] that involves running kernels between multiple corrugated rolls and does not result in localized hull tissue removal, resulting in ground grain (Figure S1a, in the SI) that requires multiple flows and/or sieving steps[27] to separate hull from endosperm. In contrast, the precision mill system uses sharp blades that shear the barley, swiping the kernels parallel to the central axis and lifting the hull from the kernel resulting in an intact, dehulled kernel (Figure S1d and e [SI], kernel and hull processed in the precision mill, respectively).[28]

The precision mill had a 2-fold effect of reducing DON (Table 1) and increasing the starch concentration in the endosperm-enriched fractions relative to the results with the roller mill (Table 2), which is important for fuel ethanol production. Hicks et al.[28] reported that Thoroughbred, a hulled barley cultivar, processed in the precision mill resulted in hull mass fractions of ∼14% that were composed of less than 6% starch, which corresponded to less than 1.5% starch loss from the original kernel. However, in our study with five other barley genotypes, the precision mill removed much more mass than seen with Thoroughbred. On average, the precision mill removed a mass of 23.1% (hull-enriched fraction) while the roller mill resulted in only a 12.2% mass removal (Figure 1). Therefore, while the precision mill resulted in much lower DON levels in the endosperm-enriched fractions by removing more hull-enriched tissue (Table 1), the precision mill resulted in higher starch losses (Table 2). Hull-enriched fractions collected from the roller mill and precision mill, contained starch levels that ranged from 7.2% to 11.1% and 13.5% to 30.0% (Table 2), respectively. To calculate the amount of starch lost when the hull is removed, the starch contents in the hull-enriched fraction and endosperm-enriched fraction were adjusted on the basis of their respective percent mass fraction, and then the proportion of starch in the hull (i.e., the adjusted starch value in the hull-enriched fraction) relative to total starch was calculated. An evaluation of starch levels adjusted on the basis of the mass fraction showed that grain processed in the roller mill yielded an average of 49.5 g of starch per 100 g of kernel versus 47.1 g of starch per 100 g of kernel for grain processed in the precision mill. The average starch lost to the hull was 2.1% from grain processed in the roller mill and an average of 9.6% starch loss from grain processed in the precision mill (Table 2). This level of starch loss was larger than the previously reported starch loss of 1.5%.[28] Thus, comparison of the two milling strategies certainly demonstrated that the precision mill system is able to remove more DON (Table 1) than the roller mill (Table 1), but at the expense of starch loss (Table 2) for these genotypes. Consequently, to make up for starch loss, additional grain may have to be processed; however, using grain containing little DON would improve the quality of the DDGS and obviously be favored over starch losses observed when using the precision mill system.

Time Course Precision Milling. Since more endosperm-enriched tissue and starch were removed from the kernel during precision milling (Figure 1 and Table 2) than expected, a time course experiment was conducted by running the precision mill at increments of one min (2, 3, 4, or 5 min) using whole kernels from three of the five barley genotypes tested in the first experiment (Nomini, Atlantic, and VA96-44-304). Time course precision milling conducted at shorter run times provided fractions with improved percent mass values for which mass loss was reduced from the endosperm-enriched fraction into the hull-enriched fraction (Figure 2). A 2 min run time produced hull-enriched mass fractions that were closest to those reported in Hicks et al.[28] In the first precision mill experiment (Figure 1), the hull-enriched percent mass fraction for Nomini (16.0%), Atlantic (29.2%), and VA96-44-304 (29.2%) were reduced to 8.2%, 12.3%, and 17.8% at 2 min, respectively (Figure 2). Other examples of using milling to reduce DON include work using a semi-industrial semolina mill, which demonstrated a 45% loss of DON when 10% of the grain tissue was removed[22] and 66% DON reduction after 15 s of pearling using an abrasive type dehulling procedure when 15% of the grain mass was removed.[25] In our study, hull-enriched mass fractions of 10% and 15% corresponded to a

51% and 68% reduction of DON, respectively (Figure 5). Although we were able to reduce the mass lost during milling by reducing the run time, DON levels correspondingly increased, and the starch concentration decreased. DON levels in the endosperm-enriched fractions were as much as 4-fold higher (5.1 μg g^{-1} (5 min) vs 19.8 μg g^{-1} (2 min) for VA96-44-304) (data not shown) and starch concentrations were as much as 8.7% lower at 2 min (55.9%) versus 5 min (61.2% for VA96-44-304) (data not shown). Starch lost during milling was reduced with lower run times; however, even at 2 min the percent starch lost was still higher than 1.5%, with values of 2.3%, 6.2%, and 9.0% for barley genotypes Nomini, Atlantic, and VA96-44-304, respectively (Figure 4).

The results of this work were unexpected as we were not able to produce endosperm-enriched fractions from the precision mill with reduced losses in grain mass and reduced starch loss as those reported previously.[28] Hicks' group conducted their analysis using the Virginia winter barley genotype Thoroughbred, which was harvested in 2005, and may explain some of the differences between studies. Phenotypic differences between genotypes,[14,15] seasonal differences in FHB disease levels,[15] and grain quality and composition[6] may also impact kernel characteristics such as starch content and hull removal potential. Years with low FHB may yield unadulterated kernels with unaltered starch concentrations. In contrast, years with high FHB may yield kernels with reduced starch and brittle hulls that may fall off easily in the mill, leading to unintended removal of endosperm tissue.[3] These reasons, as well as differences in disease levels that may occur between plots of the same genotype in a given year, may help explain any high standard deviations seen with some of the data, such as the observations for the Atlantic genotype in the first milling experiment. A correlation analysis of data in this study revealed that concentrations of DON in the whole kernels were significantly correlated with the hull percent mass fractions (roller mill: $r = 0.81$, $P < 0.0001$; precision mill: $r = 0.86$, $P < 0.0001$). We also wanted to test the hypothesis that during precision milling some components of the endosperm-enriched tissue were included in the hull-enriched fraction and that some hull-enriched components were included in the endosperm-enriched fraction. Therefore, we aspirated these samples in an attempt to improve fraction purity. Following aspiration of time course, precision-milled samples, hull-enriched fractions were found to contain endosperm-enriched components at percent mass fractions that ranged from 18.5% (Nomini, 5 min) to 30.1% (VA96-44-304, 5 min) and endosperm-enriched fractions were found to contain hull-enriched components at percent mass fractions that ranged from 3.3% (VA96-44-304, 3 min) to 10.0% (Nomini, 3 min) (Table 3). This confirmed that cross contamination of milling fractions occurs when the precision mill is abrading the surface of the kernel to remove the hull, it is also removing some endosperm.

The hypothesis that milling will reduce DON levels was demonstrated with the removal of the hull-enriched tissue in the first experiment (Table 1, Figure 3), and we were able to further reduce the concentration of DON by aspirating the endosperm-enriched fractions to remove contaminating hull-enriched tissue. At the 2 min mark, DON was reduced in aspirated samples from 12.2 μg g^{-1} to 2.8 μg g^{-1} (Nomini), 9.9 μg g^{-1} to 3.5 μg g^{-1} (Atlantic), and 19.8 μg g^{-1} to 6.5 μg g^{-1} (VA96-44-304) (Table 3). Aspiration of the hull-enriched fractions from the time course, precision mill experiment revealed that the endosperm-enriched components in the hull-enriched fraction are highly contaminated with DON, while the purified hulls contained DON at relatively low levels (Table 3). This was in contrast to our initial understanding that DON accumulates in the barley hull, which was based on our first set of dehulling experiments and previous work[17,18] but is consistent with the results from Rios et al.[35] This group reported that the finest particles of semolina from durum wheat have a 3−5-fold increase in DON concentration and may indicate the need to control the distribution of these fine particles during milling.[35] Thus, while aspiration of endosperm-enriched tissue yielded a more pure endosperm-enriched fraction with reduced DON, it is unlikely that the aspiration process will be used in a dry grind ethanol plant to salvage starch lost to the hull-enriched fractions, which we found to be highly contaminated with DON. A more likely scenario is dehulling for roughly 6 min in the precision mill, using the more than 75% mass of endosperm for ethanol production (Figure 1), and burning the remaining DON contaminated hull-enriched fraction to generate energy for the plant. This process would improve the resultant DDGS by generating a coproduct with little DON and would improve the economics of fuel ethanol production. Also relevant to DDGS production is protein content in the milled grain. Prior work, reported that after 10 min using the precision mill system, the amount of protein in the processed kernel stayed relatively constant at about 8%.[28] Similarly, the protein content in our time course experiment stayed relatively even from two to 5 min with endosperm-enriched fractions containing protein on average of about 9.5% (data not shown). Future research efforts should focus on elucidating the distribution of DON in barley and methods to isolate and remove the highly contaminated endosperm-enriched tissue, while maximizing starch retention in barley and other cereal grains.

Commercial mills may be able to leverage the milling strategies described here for mitigating DON. When DON levels are of concern or exceed acceptable limits, millers could follow the milling guidelines presented in this study and modify their mill settings or separate products from different mill streams to minimize DON content in their finished products. Such strategies, however, may be linked in part to knowledge of the genotype/variety of barley that will be processed. If mills are primarily interested in using barley as a feedstock that is high in starch (e.g., for fuel ethanol production), then the comparative information presented here should be of value for maximizing the amount of desired product (flour or dehulled grain) versus byproducts (hulls), regardless of DON.

ABSTRACT: The effect of *Rhodotorula mucilaginosa* cultured in media containing chitosan on its antogonistic activity against postharvest diseases of strawberries and the possible mechanisms involved are discussed. Two-dimensional gel electrophoresis were applied in the analysis of the proteins of *R. mucilaginosa* in response to chitosan. Compared with the application of *R. mucilaginosa* alone, the biocontrol efficacy of the yeast combined with 0.5% chitosan was enhanced greatly, with significant increase in chitinase activity of antagonistic yeast, polyphenoloxidase, peroxidase, phenylalanine ammonia lyase, chitinase and β-1,3-glucanase activity, and with an inhibition of lipid peroxidation of strawberries. The population of *R. mucilaginosa* harvested from NYDB amended with chitosan at 0.5% increased rapidly in strawberry wounds compared with those harvested from NYDB without chitosan. In the cellular proteome, several differentially expressed proteins were identified, most of which were related to basic metabolism.

KEYWORDS: *chitosan, Rhodotorula mucilaginosa, antagonistic activity, strawberries, differentially expressed proteins*

INTRODUCTION

Rhizopus stolonifer and *Botrytis cinerea* are two of the most destructive fungi of strawberries which can cause *Rhizopus* decay and gray mold separately.[1] Due to these diseases, tremendous economic losses are caused. Traditionally, *R. stolonifer* and *B. cinerea* are controlled mainly by treatment with synthetic fungicides. However, with deeper research, gradually developed fungicide resistance in pathogens were detected and potential harmful effects on human health and the environment were perceived, which leads to an urgent demand for alternative control approaches with good efficacy, low residues, and ensured safety.[2]

Biological control with antagonistic yeasts has emerged as a potential method to reduce synthetic fungicide usage.[2,3] Phylloplane yeast *Rhodotorula mucilaginosa* combined with fungicides has been reported to effectively control *Botrytis cinerea* on geranium seedlings.[4] Our research team found that *Rhodotorula mucilaginosa* showed biocontrol efficacy against blue mold and gray mold of apples caused by *Penicillium expansum* and *B. cinerea*, respectively.[5] However, making biological control a practical way requires the enhancement of the consistency and efficacy of antagonistic yeasts (including *R. mucilaginosa*) in controlling postharvest diseases.[2,6]

Many attempts have been proposed to improve the performance of postharvest biocontrol yeasts. Besides combining antagonists with some exogenous substances (organic and inorganic additives),[2,6−9] combination with some physiological manipulation may also be an effective way.[2] For example, Teixido et al. (1998) found that the cultivation of the yeast in a low water activity modified liquid media can improve the biocontrol efficacy of *Candida sake*.[10] According to Li and Tian (2006), induced accumulation of internal trehalose could improve both the viability and biocontrol activity of *Cryptococcus laurentii* under stresses of low temperature and controlled atmosphere.[11] Recently, it has reported that the combination with chitin in the culture media may increase the bicontrol activity of *C. laurentii* significantly.[12]

Chitosan, a high molecular weight β-(1,4)-glucosamine polymer, produced from the chitin components by deacetylation, which is the second most abundant polysaccharide found in nature, is an important structural component of the cell wall of some plant-pathogenic fungi.[13] It has been demonstrated to be nontoxic and safe to animals and hold great potential for food applications with its unique physiological and biological properties.[14−16] Chitosan has been shown to form an ideal coating on fruit and also have antifungal activity against a wide range of fungal pathogens.[17] Li and Yu (2001) found that chitosan could reduce the incidence of brown rot caused by *Monilinia fructicola* significantly and delay the development of disease compared with the control.[18] Moreover, Yu et al. (2007) reported that combination of chitosan and antagonistic yeast *C. laurentii* resulted in a synergistic inhibition of the blue mold rot.[19] However, to our knowledge, there is no report referring to enhancing the biocontrol efficacy of antagonistic yeast against postharvest disease by addition of chitosan to the growth media and the mode of action involved.

The objective of this study was to determine the impact of adding chitosan in the culture media on the efficacy of the *R. mucilaginosa* against *Rhizopus* decay, gray mold decay, and natural decay of strawberries and discuss the possible physiological and molecular mechanisms involved.

MATERIALS AND METHODS

Fruits Material. Strawberries (*Fragaria ananassa* Duch.) cultivars "fengxiang" were harvested early in the morning and rapidly transferred to the laboratory. Berries were sorted on the basis of size, ripeness, and blemishes such as injuries or infections.

Chitosan. Chitosan with 90% deacetylation was bought from Sangon Company (shanghai, China) .

Antagonist and Growth Conditions. The yeast antagonist *Rhodotorula mucilaginosa* was isolated from the surfaces of peach blossom which was picked in unsprayed orchards. The yeast was first identified by a VITEK 32 Automicrobic system (BioMérieux Company, Marcy l'Etoile, France). To identify the yeast, sequence analysis of the 5.8S internal transcribed spacer (ITS) rDNA (rDNA) region was used.[20] In animal tests, including physiology experiments, acute toxicity studies, and the Ames test, *R. mucilaginosa* was demonstrated to be safe (our unpublished data). *R. mucilaginosa* isolates were maintained at 4 °C on nutrient yeast dextrose agar (NYDA) medium (8 g og nutrient broth, 5 g of yeast extract, 10 g of glucose, and 20 g of agar in 1 L of distilled water). Liquid cultures of the yeast were grown in 250 mL Erlenmeyer flasks containing 50 mL of nutrient yeast dextrose broth (NYDB) which had been inoculated with a loop of the culture. Flasks were incubated on a QYC-200 rotary shaker (FuMa, China) at 28 °C for 20 h. After incubation, cells were harvested by centrifugation at 7000*g* for 10 min by using a TGL-16 M centrifuge (XiangYi, China) and washed twice with sterile distilled water in order to remove the residual medium. Then the yeast cell pellets were resuspended in sterile distilled water, counted using a JSQA hemocytometer (HongTai, China), and adjusted to an initial concentration of 5×10^8 cells mL^{-1}. Then 1 mL of the above-mentioned yeast suspensions were added to nutrient yeast dextrose broth (NYDB) or NYDB amended with chitosan at different concentrations (0.01%, 0.1%, 0.25%, 0.5%, 1%) (NYDB + chitosan) on a rotary shaker at 200 rpm at 28 °C for 24 h. After incubation, centrifuged the yeast cells at 7000*g* for 10 min and washed twice with sterile distilled water. Cell pellets were resuspended and counted as described above and adjusted to a concentration of 1×10^8 cells mL^{-1}. Besides, the growth media was filtered through a Millipore membrane (0.45 μm) and the supernatant was used for biocontrol and chitinase activity assay.

Fungal Pathogen and Growth Conditions. The pathogen *Rhizopus stolonifer* (Ehrenb.: Fr) Vuill. and *Botrytis cinerea* (Pers.: Fr.) were isolated from infected strawberries. The organisms were identified according to their cultural and micro- and macroscopic morphological characteristics. These cultures were maintained on potato dextrose agar (PDA) media (containing the extract from 200 g of boiled potato, 20 g of glucose, and 20 g of agar in 1 L of distilled water) at 4 °C. Before use, the mold should be activated on PDA at 25 °C. Spore suspensions were prepared by removing the spores from the sporulating edges of a 7 day old culture with a bacteriological loop and suspending them in sterile distilled water. After counting with a hemocytometer, the spore concentration was adjusted to a required concentration.

Effects of Chitosan on Biocontrol of *R. mucilaginosa* to *Rhizopus* Decay and Gray Mold Decay of Strawberries. The surface of strawberries was wounded using a sterile cork borer (approximately 3 mm diameter and 3 mm deep) and treated with 30 μL of following solution: (1) the cell suspensions of *R. mucilaginosa* (1×10^8 cells mL^{-1}) which were harvested either from the media of NYDB or NYDB + chitosan at different concentrations (0.01%, 0.1%, 0.25%, 0.5%, 1%); (2) sterile distilled water as the control. Two hours later, 30 μL of *R. stolonifer* suspensions (1×10^4 spores mL^{-1}) or *B. cinerea* suspensions (1×10^5 cells mL^{-1}) were added into each wound of strawberries. After air-drying, the samples were put in trays sealed with plastic film. Then the samples in the trays were incubated at 20 °C and a high relative humidity (about 95%). The number of the infected fruits and their lesion diameters were observed after 3 d inoculation. There were three replicates per treatment and 18 fruits in each replicate. All treatments were arranged in a randomized complete block design, and the experiment was conducted twice.

Efficacy of Cell-Free Culture Filtrate of *R. mucilaginosa* Incubated in Different Media in Controlling *Rhizopus* Decay and Gray Mold Decay of Strawberries. Fresh fruits were treated as described above to evaluate the efficacy of *R. mucilaginosa* harvested from different media in the control of the *Rhizopus* decay and gray mold decay of strawberries. Then 30 μL of following solution were added in each wound of fruits: (1) a solution of cell-free filtered supernatant through a Millipore membrane (0.45 μm) from the media of NYDB or NYDB + chitosan at different concentrations (0.01%, 0.1%, 0.25%, 0.5%, 1%), (2) sterile distilled water as the control. Two hours later, 30 μL of *R. stolonifer* suspensions (1×10^4 spores mL^{-1}) or *B. cinerea* suspensions (1×10^5 cells mL^{-1}) were added into each wound. After air-drying, the samples were put in trays sealed with plastic film. Then the samples in the trays were incubated at 20 °C and a high relative humidity (about 95%). The number of the infected fruits and their lesion diameters were examined after 3 d inoculation. There were three replicates per treatment and 18 fruits in each replicate. All treatments were arranged in a randomized complete block design, and the experiment was conducted twice.

Effects of Chitosan on Biocontrol Efficacy of *R. mucilaginosa* to Natural Decay Development of Strawberries. To inoculate yeast on fruits, dipping them in the cell suspensions of (1) *R. mucilaginosa* (1×10^8 cells mL^{-1}) harvested from the media of NYDB, (2) *R. mucilaginosa* (1×10^8 cells mL^{-1}) harvested from the media of NYDB + chitosan at different concentrations (0.01%, 0.1%, 0.25%, 0.5%, 1%), and (3) sterile distilled water as the control respectively for 30 s, then air-dried. The treated fruits were sealed separately in polyethylene-lined plastic boxes to retain high humidity. Fruits were stored at 4 °C for 20 d, after that, transferred them to the condition at 20 °C for 7 d, which can determine the disease development under normal shelf life conditions. After observation, infection severity was recorded. There were three replicate trials of 20 fruits with a complete randomization in each test, and experiments were repeated twice.

Effects of Chitosan on Population Growth of *R. mucilaginosa* in Strawberry Wounds. Fruits were wounded as described above to evaluate the biocontrol efficacy against *Rhizopus* decay and gray mold decay of strawberries. Then 30 μL of 1×10^8 cells mL^{-1} *R. mucilaginosa* solution harvested either from NYDB or NYDB + 0.5% chitosan were added in each wound. At different times (0, 12, 24, 48, and 72 h) at 20 °C after the treatment, the samples were harvested. The tissue was removed with a sterile cork borer (9 mm diameter and 10 mm deep) and ground with a 150 mL Erlenmeyer flasks, grinding the sample pieces by a glass rod in 10 mL of sterile 0.85% sodium chloride solution. After that, serial 10-fold suitable dilutions were made and 0.1 mL of suitable dilution was spread in NYDA plates. The plates were incubated at 28 °C for 2 d, and the colonies were counted afterward. Population densities of *R. mucilaginosa* were expressed as log 10 CFU (colony-forming units) per wound. There were two replicates per treatment and 5 fruits per replicate, and the experiments were repeated twice.

Assay for Chitinase Activity of the Cell-Free Culture Filtrate of *R. mucilaginosa* Incubated in Different Growth Media. To determine the chitinase activity, a reaction mixture was prepared by adding 0.5 mL of 5 mg mL^{-1} colloidal chitosan containing 1.2 μmol sodiumazide and 56 μmol sodium acetate to 0.5 mL of enzyme supernatant.[21] The enzyme−substrate mixture was incubated at 37 °C for 2 h with constant shaking. After that, centrifuging at 7680*g* for 10 min was used to stop the reaction. Following the centrifuging, 0.5 mL of enzyme supernatant was incubated at 37 °C for 2 h with 0.1 mL of 3% (w/v) desalted snail gut enzyme (Sigma) and 0.1 mL of 1 mol L^{-1} potassium phosphate buffer (pH 7.1) to hydrolyze the chitosan oligomers.[22] The resulting *N*-acetyl-D-glucosamine(GlcNAc) was determined following the method described by Reissig et al. (1955) using internal standards of GlcNAc.[23] For the sample, substrate blanks and standard, each contained in a volume of 0.5 mL in a test tube, 0.1 mL of potassium tetraborate was added. The tubes were heated in a vigorously boiling water bath for exactly 3 min, and then the tubes were cooled in tap water. *p*-Dimethylaminobenzaldehyde (DMAB) reagent of 3 mL was added afterward, then they were mixed and placed in a bath at 37 °C. After precisely 20 min, the tubes were cooled

in tap water and read without delay at 585 nm. The specific activity was expressed as microgram of GlcNAc per milliliter. There were three replicates in each experiment. The experiment was conducted twice.

Effects of *R. mucilaginosa* Incubated in Different Growth Media on Strawberry Enzyme Activities and Lipid Peroxidation. Fruits were wounded as described above to evaluate the yeast biocontrol activity against *Rhizopus* decay and gray mold decay of strawberries. Then 30 μL of a cell suspension of *R. mucilaginosa* at 1×10^8 cells mL^{-1} harvested either from the media of NYDB or NYDB + 0.5% chitosan after the incubation for 24 h were added in each wound. Treatment with sterile distilled water was served as the control. After air-drying, the strawberries were put in trays sealed with plastic film. Then the samples in the trays were incubated at 20 °C and a high relative humidity (about 95%). At 0, 24, 48, and 72 h after treatment, samples were harvested. After removing the wound tissue with a sterile borer (6 mm diameter and 5 mm deep), the fresh tissue around the wound was picked up by another sterile borer (9 mm diameter and 10 mm deep). Two grams of the fresh tissue from six fruits was grounded with 10 mL of cold (4 °C) 50 mM different buffers containing 1.33 mmol per liter EDTA and 1% polyvinyl pyrolidone (PVPP) in a mortar and pestle to assay different enzymes: sodium acetate buffer (pH 5.0) for chitosanase and β-1,3-glucanase, sodium phosphate buffer (pH 6.4) for polyphenoloxidase (PPO), peroxidase (POD), and malondialdehyde (MDA) and borate buffer (pH 8.8) for phenylalanine ammonia lyase (PAL). The homogenates were centrifuged (4 °C) for 15 min at 12000*g*, and the supernatants were kept for the assay. There were three replicates per treatment. The experiment was conducted twice. The testing methods of enzyme activities were described as below.

The PPO activity was measured following the method described by Waite (1976) with some modifications.[24] First 0.1 mL of crude enzyme extract (supernatant extract) was added to 2.9 mL of catechol (50 mM sodium phosphate, pH 6.4, and 0.1 M catechol, incubated at 30 °C for 5 min) as a substrate. Then the change in absorbance at 398 nm was recorded once every 30 s for 3 min. The amount of the enzyme extract producing an increase of A_{398} by 0.01 in 1 min was defined as one unit of the PPO activity. The PPO enzyme activity was expressed as U per gram fresh weight (FW).

The POD activity was measured as the method described by Lurie et al. (1997) with some modifications, using guaiacol as a substrate.[25] The reaction mixture should be inoculated for 5 min at 30 °C, which containing 0.2 mL of crude enzyme extract, 2.2 mL of 0.3% guaiacol (prepared by 50 mM sodium phosphate buffer, pH 6.4, incubated at 30 °C for 5 min). Then 0.6 mL of 0.3% H_2O_2 (prepared by 50 mM sodium phosphate, pH 6.4, and incubated at 30 °C for 5 min) was added to initiate the reaction. The POD activity was determined by measuring at A_{470} once every 30 s for 3 min. A cuvette containing all components except added 0.6 mL of distilled water was used as a control. The POD activity was expressed as U per gram FW. One unit was defined as ΔA_{470} of 0.01 per min.

The PAL activity was assayed as the method described by Assis et al. (2001) with some modifications.[26] Simply, after preincubation of 3 mL of borate buffer (50 mM, pH 8.8) containing 10 mM L^{-1} phenylalanine for 10 min at 37 °C, 1 mL of crude enzyme extract was added. After mixing, the initial absorbance of the reaction mixture was immediately recorded at 290 nm. Then the reaction mixture was incubated at 37 °C. After 60 min, A_{290} was measured and recorded again. Calculating the difference value between the pre- and postabsorbance. The blank was a cuvette containing all components except 1 mL of distilled water was added. One unit of the PAL was defined as the formation of 1 μg of cinnamic acid equivalents per hour, and the specific activity was expressed as the U per gram FW.

The lipid peroxidation was determined in terms of MDA content by thiobarbituric acid (TBA) reaction as described by Du and Bramlage.[27] Briefly, 2 mL of 0.6% TBA in 20% trichloroacetic acid was added into 2 mL of crude enzyme sample. The solution was heated at 100 °C for 10 min, then quickly cooled in an ice-bath and centrifuged (4 °C) for 15 min at 10000*g*, and afterward the supernatants were harvested and assayed. The absorbance of supernatants was recorded at 532, 600, and 450 nm. MDA content was calculated according to the formula C_{MDA} (μmol L^{-1}) = $6.45 \times (A_{532} - A_{600}) - 0.56 \times A_{450}$ and expressed as μmol MDA g^{-1} FW.

Assay of chitinase activity of strawberries was determined as described above to evaluate the chitinase activity of different growth media, and the specific activity was expressed as the U per gram FW, one unit was defined as microgram of GlcNAc per hour.

β-1,3-Glucanase was assayed by measuring the amount of reducing sugar released from the substrate by the method reported by Ippolito et al., with some modifications.[28] A crude enzyme sample of 250 μL was routinely added to 250 μL of 0.2% laminarin (w/v) in 50 mM, pH 5.0, potassium acetate buffer, and incubated at 37 °C for 1 h. For the control, the same mixture was similarly diluted at zero incubation time. Then 1.5 mL of 3,5-dinitrosalicylate was added and boiled for 5 min on a water bath to stop the reaction, and the amount of reducing sugars was measured spectrophotometrically at 500 nm using a UV-1601 spectrophotometer (Shimadzu, Japan). The formation of 1 mg glucose equivalents per hour was defined as one unit of the β-1,3-glucanase activity, and the specific activity was expressed as the U per gram FW.

Protein Sample Preparation. Liquid cultures of the yeast were grown in NYDB or NYDB + 0.5% chitosan, respectively, as described above (Antagonist and Growth Conditions). The yeast cells were harvested from NYDB or NYDB + 0.5% chitosan by centrifuging at 10000*g* for 10 min (4 °C) and washed three times with cold double-distilled water to remove residual medium. The protein sample preparation for 2-DE, and image analysis were performed as described by Zhao et al.[29] Protein samples were kept at −70 °C until use. The protein concentration was determined according to Bradford's method using bovine serum albumin as standard.[30]

2-DE and Image Analysis. Two-dimensional electrophoresis (2-DE) and image analysis were performed as described by Wang et al.[31]

Protein In-Gel Digestion. Protein in-gel digestion was performed as described by Zhang et al.[32]

Protein Identification by MALDI-TOF/TOF and Database Query. Protein identification by MALDI-TOF/TOF and database query were performed as described by Wang et al.[31]

Statistical Analysis. The data were analyzed by the analysis of variance (ANOVA) using the statistical program SPSS/PC version II.x (SPSS Inc. Chicago, Illinois, USA). The Duncan's multiple range test was used for means separation. In addition, when the group of the data was two, the independent samples *t* test was applied for means separation. The statistical significance was assessed at the level $P = 0.05$.

RESULTS

Effect of Chitosan on Biocontrol of *R. mucilaginosa* to *Rhizopus* Decay and Gray Mold Decay of Strawberries. Compared with the control after 3 d storage at 20 °C, treatments of *R. mucilaginosa* at 1×10^8 cells mL^{-1} effectively controlled *Rhizopus* decay of strawberries (Figure 1, $P < 0.05$), and the application of chitosan at the concentration 0.5% during cultivation significantly improved the biocontrol efficacy of *R. mucilaginosa* compared with the cultivation without chitosan ($P < 0.05$).

Compared with the control after 3 d storage at 20 °C, *R. mucilaginosa* at 1×10^8 cells mL^{-1} cultivation in the NYDB had no impact on the disease incidence of gray mold decay (Figure 1, $P < 0.05$). However, treatments with application of *R. mucilaginosa* cultivation in the NYDB media amended with chitosan at all tested concentrations except 1% could reduce the disease incidence of gray mold decay of strawberries. The antagonistic activity of *R. mucilaginosa* was shown to be greatly enhanced through cultivation in the NYDB media amended with chitosan at the optimal concentration (0.5%) compared with that cultivated in NYDB without chitosan ($P < 0.05$).

Efficacy of Cell-Free Culture Filtrate of *R. mucilaginosa* Incubated in Different Media in Controlling *Rhizopus*

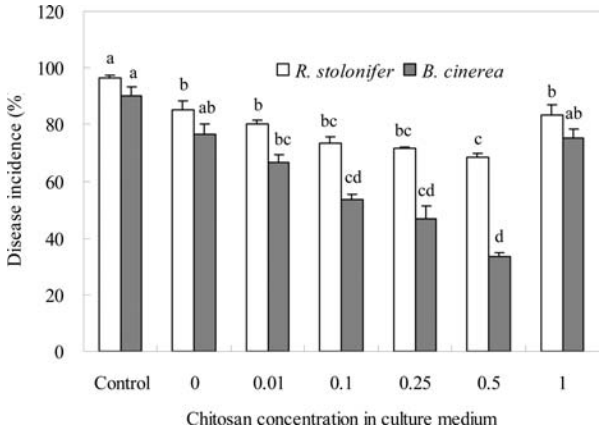

Figure 1. Effect of chitosan on biocontrol of *R. mucilaginosa* to *Rhizopus* decay and gray mold of strawberries. Fruit treatments are as follows: Control = sterile distilled water, 0 = *R. mucilaginosa* which were harvested from the media of NYDB (0.01%, 0.1%, 0.25%, 0.5%, 1%) = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at different concentrations (0.01%, 0.1%, 0.25%, 0.5%, 1%). Each value is the mean of two experiments. Bars represent standard deviations. Different letter indicates significant differences (P = 0.05) according to the Duncan's multiple range test.

Decay and Gray Mold Decay of Strawberries. The cell-free culture filtrates of *R. mucilaginosa* incubated in NYDB had no significant control efficacy on the *Rhizopus* decay and gray mold decay of strawberries after 3 d storage at 20 °C. However, compared with the control, the cell-free culture filtrates of NYDB media amended with 0.25% 0.5%, and 1% chitosan in which *R. mucilaginosa* was incubated for 24 h exhibited a significant control activity against *Rhizopus* decay in strawberry wounds after 3 d incubation at 20 °C (Figure 2). Similarly, the cell-free culture filtrates of NYDB media added with 0.5% chitosan significantly controlled the gray mold decay in strawberry wounds (Figure 2).

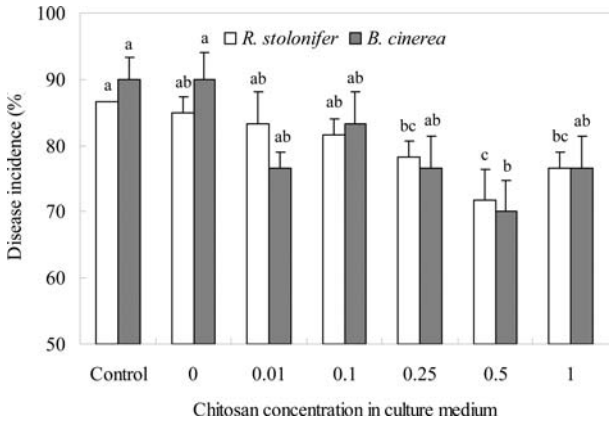

Figure 2. Effect of cell-free culture filtrate of *R. mucilaginosa* incubated in different media in controlling *Rhizopus* decay and gray mold decay of strawberries. Fruit treatments are as follows: Control = sterile distilled water, 0 = a solution of cell-free filtered supernatant from the media of NYDB (0.01%, 0.1%, 0.25%, 0.5%, 1%) = a solution of cell-free filtered supernatant from the media of NYDB + chitosan at different concentrations (0.01%, 0.1%, 0.25%, 0.5%, 1%). Each value is the mean of two experiments. Bars represent standard deviations. Different letter indicates significant differences (P = 0.05) according to the Duncan's multiple range test.

Effects of Chitosan on Biocontrol Efficacy of *R. mucilaginosa* to Natural Decay Development of Strawberries. Compared with the control after 20 d at 4 °C followed by 7 d at 20 °C, *R. mucilaginosa* at 1×10^8 cells mL^{-1} cultivated in the NYDB media had no impact on the natural decay incidence of strawberries (Figure 3). However, treatments with application of *R. mucilaginosa* cultivation in the NYDB media added with chitosan at all tested concentrations except 1% had a significantly biocontrol efficacy on the natural decay incidence of strawberries ($P < 0.05$). *R. mucilaginosa* cultivation in the NYDB media amended with 0.5% chitosan was the most effective in preventing natural decay development, which decreased the decay incidence of the fruit to 33.3% compared to 71.7% for the control and 58.9% for the *R. mucilaginosa* cultivation in the NYDB.

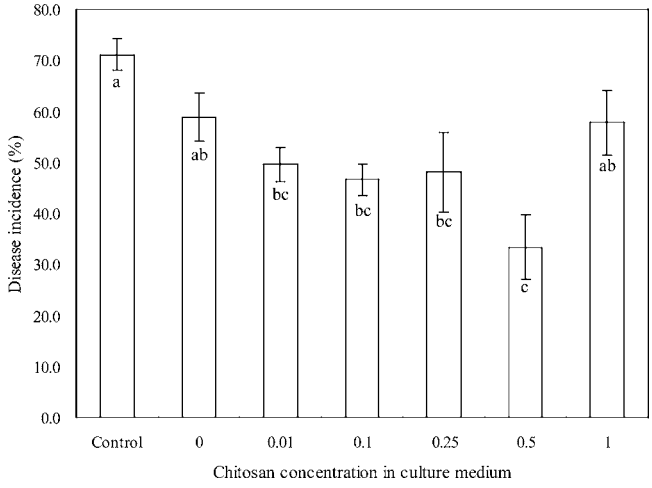

Figure 3. Effect of chitosan on biocontrol of *R. mucilaginosa* to natural decay of strawberries. Fruit treatments are as follows: Control = sterile distilled water, 0 = *R. mucilaginosa* which were harvested from the media of NYDB (0.01%, 0.1%, 0.25%, 0.5%, 1%) = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at different concentrations (0.01%, 0.1%, 0.25%, 0.5%, 1%). Each value is the mean of two experiments. Bars represent standard deviations. Different letter indicates significant differences (P = 0.05) according to the Duncan's multiple range test.

Effects of Chitosan on Population Growth of *R. mucilaginosa* in Strawberry Wounds. The antagonistic yeast *R. mucilaginosa*, whether cultivated in the NYDB or NYDB media amended with 0.5% chitosan, proliferated rapidly in strawberry wounds, especially during the first 24 h, and stabilized relatively thereafter (Figure 4). However, the population of *R. mucilaginosa* cultivated in NYDB amended with chitosan at 0.5% in strawberry wounds was higher than that of *R. mucilaginosa* cultivated in NYDB over the whole storage time except at 72 h ($P < 0.05$). Particularly, after 24 h of incubation in the wounds, the amount of *R. mucilaginosa* grown in chitosan-supplemented NYDB media was more than 3-fold higher than that of *R. mucilaginosa* grown in NYDB without chitosan.

Assay for Chitinase Activity of the Cell-Free Culture Filtrate of *R. mucilaginosa* Incubated in Different Growth Media. After 24 h incubation, the chitinase activity of the cell-free culture filtrates of *R. mucilaginosa* incubated in NYDB added with chitosan at 0.01, 0.5, and 1% had a higher level than that of *R. mucilaginosa* grown in NYDB. Especially

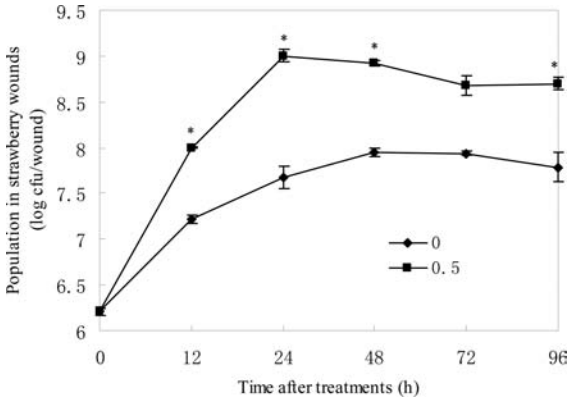

Figure 4. Effects of chitosan on population growth of *R. mucilaginosa* in strawberry wounds. 0 = *R. mucilaginosa* which were harvested from the media of NYDB 0.5% = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at the concentration of 0.5%. Bars represent standard errors. An asterisk (*) indicates significant differences ($P = 0.05$) according to the independent samples t test.

the chitinase activity of the cell-free culture filtrates incubated in NYDB with 0.5% chitosan had a higher level than that of the cell-free culture filtrates grown in NYDB amended with chitosan at other concentrations (Figure 5, $P < 0.05$). However,

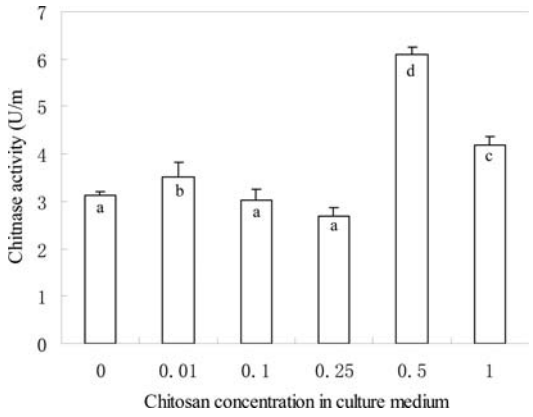

Figure 5. Chitinase activity of the cell-free culture filtrate of *R. mucilaginosa* incubated in media containing chitosan. Each value is the mean of two experiments. Bars represent standard deviations. Data in columns with different letters are statistically different according to Duncan's multiple range test at $P = 0.05$.

there was no significant difference of the chitinase activity between the cell-free culture filtrates of *R. mucilaginosa* grown in NYDB and the media added with 0.1 or 0.25% chitosan.

Effects of *R. mucilaginosa* Harvested from Different Media on PPO Activity of Strawberries. A peak of PPO activity of strawberries was exhibited in the treatment with *R. mucilaginosa* cultivated in the NYDB media amended with chitosan (0.5%) at 24 h after inoculation. However, after the decrease of the PPO activity at 24 h, it showed a following significant increase again after 48 h (Figure 6). On the other hand, no evident induction of PPO activity was observed in treatment with water or *R. mucilaginosa* cultivated in the NYDB throughout the whole storage period except at 72 h. It was obvious that the PPO activity of strawberries treated with *R. mucilaginosa* cultivated in the chitosan-supplemented media (0.5%) was higher than that of the control and that of strawberries treated with *R. mucilaginosa* cultivated in the

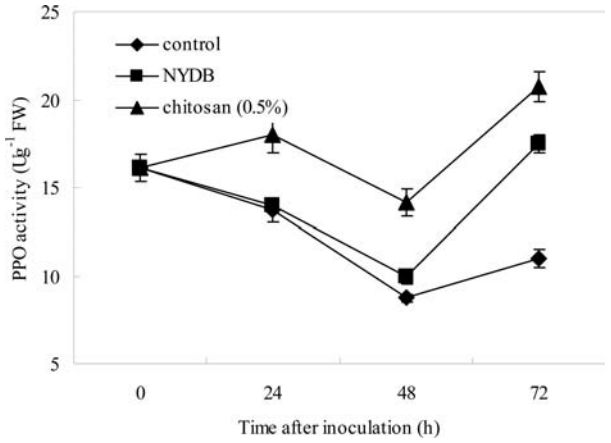

Figure 6. Effects of *R. mucilaginosa* harvested from different media on PPO activity of strawberries. Control = sterile distilled water, NYDB = *R. mucilaginosa* which were harvested from the media of NYDB, chitosan (0.5%) = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at the concentration of 0.5%. Each value is the mean of two experiments. Bars represent standard deviations.

NYDB without chitosan throughout the whole storage period (24, 48, and 72 h after inoculation).

Effects of *R. mucilaginosa* Harvested from Different Media on POD Activity of Strawberries. POD activity of strawberries treated with *R. mucilaginosa* cultivated in the chitosan-supplemented media (0.5%) and in the media of NYDB showed an uptrend within 48 h after inoculation, and, in the former, POD activity reached the highest peak at 72 h, while in the latter, almost no increase was observed after 48 h (Figure 7). The POD activity of the strawberries treated with *R.*

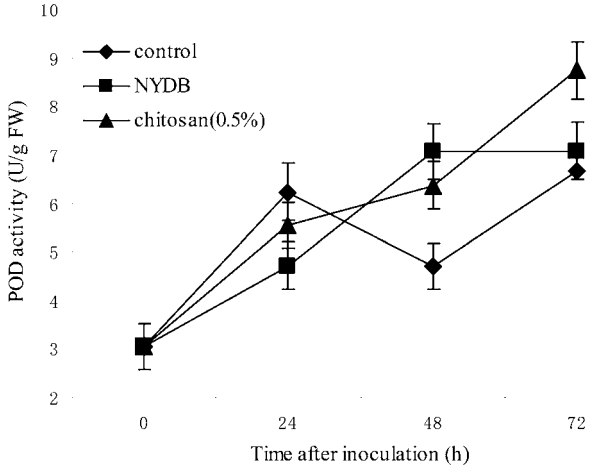

Figure 7. Effects of *R. mucilaginosa* harvested from different media on POD activity of strawberries. Control = sterile distilled water, NYDB = *R. mucilaginosa* which were harvested from the media of NYDB chitosan (0.5%) = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at the concentration of 0.5%. Each value is the mean of two experiments. Bars represent standard deviations.

mucilaginosa cultivated in the NYDB amended with chitosan (0.5%) was significantly higher than that of the control strawberries at 48 and 72 h.

Effects of *R. mucilaginosa* Harvested from Different Media on PAL Activity of Strawberries. Treatment with *R. mucilaginosa* cultivated in NYDB containing chitosan at 0.5% induced a peak of PAL activity of strawberries within 48 h after

inoculation and then decreased (Figure 8). Nevertheless, in the treatment with water or *R. mucilaginosa* cultivated in NYDB, no

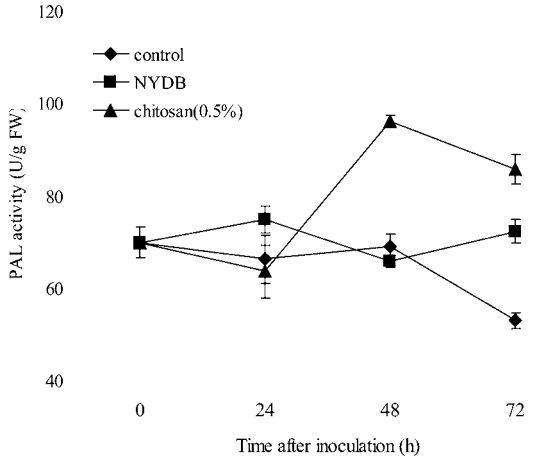

Figure 8. Effects of *R. mucilaginosa* harvested from different media on PAL activity of strawberries. Control = sterile distilled water, NYDB = *R. mucilaginosa* which were harvested from the media of NYDB, chitosan (0.5%) = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at the concentration of 0.5%. Each value is the mean of two experiments. Bars represent standard deviations.

evident peak of PAL activity was induced during the whole storage period. The PAL activity of strawberries treated with *R. mucilaginosa* incubated in chitosan-supplemented (0.5%) NYDB was significantly higher than that of strawberries treated with *R. mucilaginosa* incubated in NYDB and the control ($P < 0.05$) at 48 and 72 h after storage.

Effects of *R. mucilaginosa* Harvested from Different Media on MDA Content of Strawberries. The MDA contents of strawberries treated with *R. mucilaginosa* and water were demonstrated to have gradual linear ascending tendency during the storage period (Figure 9). The MDA content of strawberries treated with *R. mucilaginosa* cultivated in the NYDB amended with chitosan (0.5%) was obviously lower than that of the control ($P < 0.05$) at the whole storage period. What's more, it was obviously lower than that of strawberries

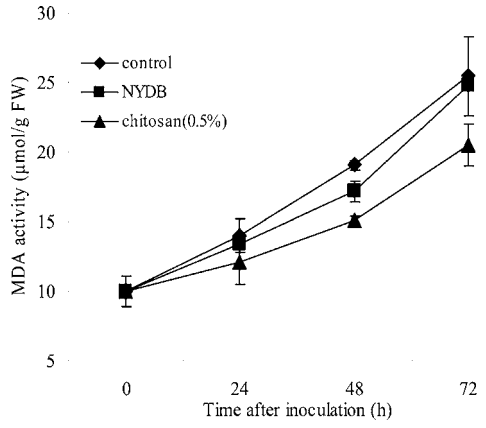

Figure 9. Effects of *R. mucilaginosa* harvested from different media on MDA content of strawberries. Control = sterile distilled water, NYDB = *R. mucilaginosa* which were harvested from the media of NYDB, chitosan (0.5%) = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at the concentration of 0.5%. Each value is the mean of two experiments. Bars represent standard deviations.

treated with *R. mucilaginosa* cultivated in the NYDB at 48 h after inoculation.

Effects of *R. mucilaginosa* Harvested from Different Media on Chitinase Activity of Strawberries. Throughout the whole storage period, the chitinase activity of strawberries treated with *R. mucilaginosa* cultivated both in the chitosan-supplemented media and in NYDB showed the similar tendency for change, moreover, the chitinase activity in the former treatment was slightly higher than that of the latter (Figure 10). However, in the control strawberries, the chitinase

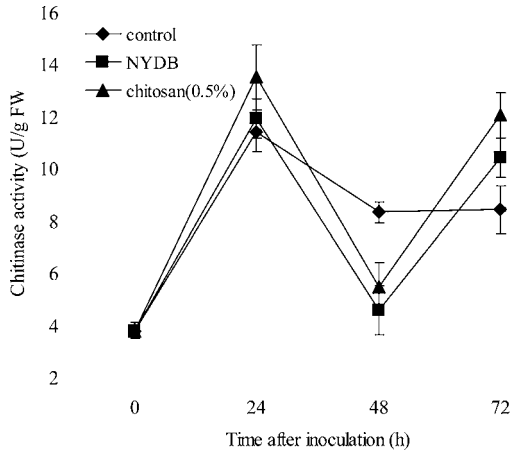

Figure 10. Effects of *R. mucilaginosa* harvested from different media on chitinase activity of strawberries. Control = sterile distilled water, NYDB = *R. mucilaginosa* which were harvested from the media of NYDB, chitosan (0.5%) = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at the concentration of 0.5%. Each value is the mean of two experiments. Bars represent standard deviations.

activity increased and reached the peak at 24 h, then decreased at 48 h, and then changed to be steady after 48 h. The chitinase activity of the control strawberries was significantly lower than those of the *R. mucilaginosa* cultivated in the chitosan-supplemented media treated strawberries at 24 and 72 h.

Effects of *R. mucilaginosa* Harvested from Different Media on β-1,3-Glucanase Activity of Strawberries. In the control strawberries, β-1,3-glucanase activity showed the down trend generally and only increased slightly at 48 h. A peak of β-1,3-glucanase activity at 48 h after inoculation and followed by an indistinctive decrease was observed in the treatment with *R. mucilaginosa* cultivated in the media of NYDB induced. However, compared with *R. mucilaginosa* cultivated in NYDB without chitosan and the control, the treatment with *R. mucilaginosa* cultivated in the NYDB media amended with chitosan (0.5%) can improve the β-1,3-glucanase activity of strawberries during the whole storage period, especially after 72 h incubation (Figure 11, $P < 0.05$).

Identification of Differentially Expressed Proteins. For protein identification by means of peptide mass fingerprints (PMF), MASCOT was applied to search protein database of Viridiplantae. In this study, ignoring very faint spots and spots with undefined shapes and areas, more than 480 protein spots were detected in each gel with Image Master 2D Elite software (Figure 12). A total of 52 proteins were differentially expressed when the yeast antagonist *R. mucilaginosa* were harvested from the NYDB amended with chitosan. Among the 52 proteins, there are 26 up-regulated proteins and 26 down-regulated

dx.doi.org/10.1021/jf500065n | J. Agric. Food Chem. 2014, 62, 4214−4224

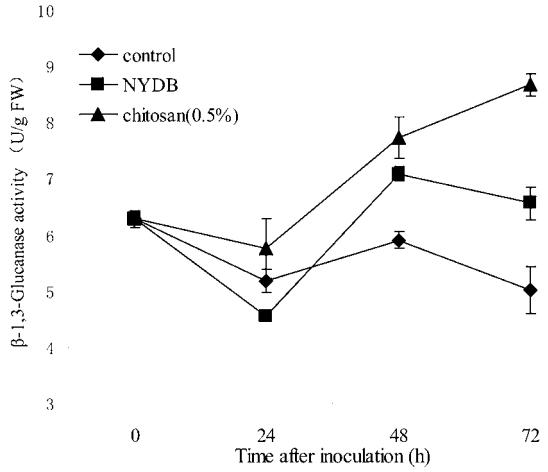

Figure 11. Effects of *R. mucilaginosa* harvested from different media on *β*-1,3-glucanase activity of strawberries. Control = sterile distilled water, NYDB = *R. mucilaginosa* which were harvested from the media of NYDB, chitosan (0.5%) = *R. mucilaginosa* which were harvested from the media of NYDB + chitosan at the concentration of 0.5%. Each value is the mean of two experiments. Bars represent standard deviations.

proteins. Due to the under-representation of yeast proteins in the protein database, only 16 protein spots were unambiguously identified by protein database analysis (Table 1). Of all the differentially expressed proteins identified, most of them were about the basic cell metabolism, including: N-6 DNA methylase (K-6), threonine synthase (K-14), glutaminase (K-4), phosphopantetheine-binding (K-15), amidohydrolase 3 (K-11), and actin (K-13), which can maintain cells normal morphology, protein kinase Cdc7 (K-10), which is involved in regulating complex cellular functions, while two-component system sensor protein (K-5) is concerned about osmotic stress on cells. In addition, we also identified sulfatase (K-3), bifunctional proline dehydrogenase/pyrroline-5-carboxylate dehydrogenase (K-16), putative peptidoglycan-binding protein, lysm containing domain (K-7), and several hypothetical proteins (K-1, -2, -8, -9, -12).

DISCUSSION

The results from this study showed that when *R. mucilaginosa* was cultivated in the media of NYDB amended with 0.5% chitosan, its antogonistic efficacy against the *Rhizopus* decay, gray mold decay, and natural decay of strawberries was greatly improved. Considering that the widely available natural component, chitosan, is cheap and safe to humans and the environment, it might be an effective, safe, and economical approach to enhance the biocontrol efficacy of *R. mucilaginosa* to postharvest decay of fruits. In our results, treatments with application of *R. mucilaginosa* cultivation in the NYDB media amended with chitosan at concentrations of 1% could not reduce the disease incidence of gray mold decay of strawberries compared with the control. This should be further studied to test the reason.

For harvested fruits, the diseases caused by fungi usually begin as a result of latent infections established in the field or wound infections.[2,33] The wounds, which inevitably occur during harvest, transport, and handling, not only damage the quality of harvested fruit[34] but also provide pathways for pathogen invasion, especially for the wound invading necrotrophic fungi such as *R. stolonifer*.[2,35] It has reported

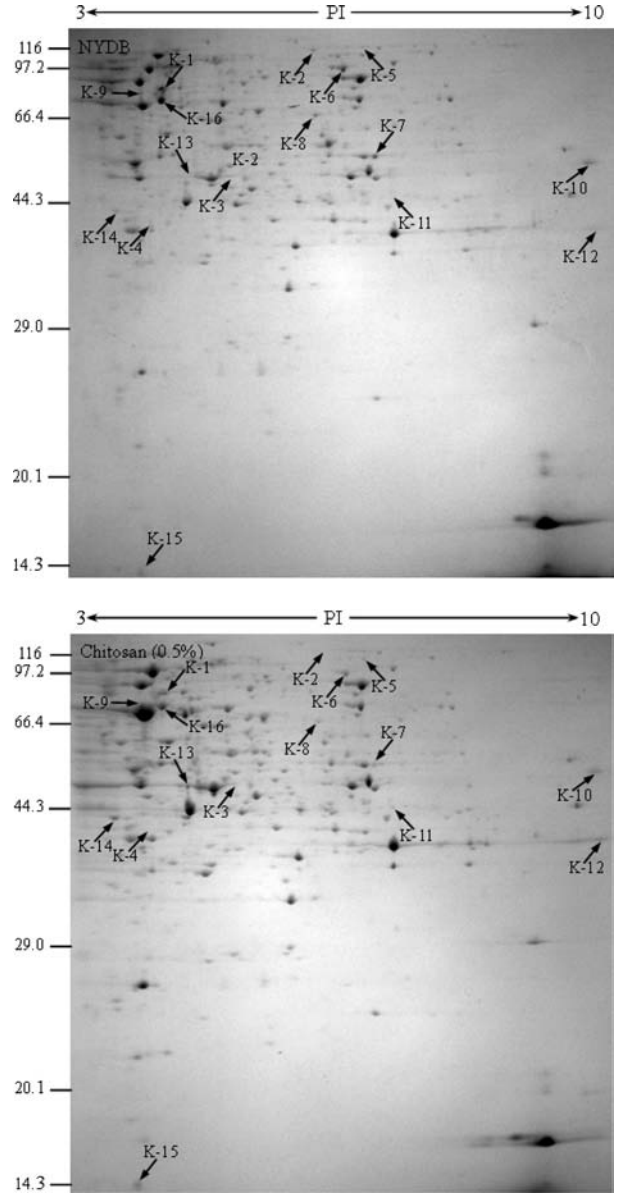

Figure 12. Two-dimensional pattern of intracellular proteins of *R. mucilaginosa* after cultivation in NYDB or NYDB amended with 0.5% chitosan powder.

that yeasts are capable of rapidly colonizing and growing in the wounds, which can provide an advantage over pathogen growth. Due to this property, antogonistic yeasts were chosen for biocontrol.[36] This study showed that *R. mucilaginosa* harvested from the chitosan-supplemented (0.5%) media proliferated more rapidly in strawberry wounds compared with those grown in NYDB without chitosan. Competition for nutrients and space is proposed to be the principal modes of action of *R. mucilaginosa* in antagonism with pathogens and the better biocontrol activity of the antagonists can be obtained with a higher the concentration of *R. mucilaginosa*,[5] we assume that the enhanced growth of the antagonistic yeast might be a major reason for adding chitosan in culture media, leading to the increased biocontrol efficacy of *R. mucilaginosa* against the *Rhizopus* decay, gray mold decay, and natural decay of strawberries.

In our test, chitinase activity was detected in different cell-free culture filtrate of *R. mucilaginosa* cultivated in different

media, so *R. mucilaginosa* can produce chitinase in all kinds of growth media, this was similar to some other strains of postharvest biocontrol yeasts such as *C. laurentii* and *Candida oleophila*, which were reported to be able to produce chitinase.[12,37,38] Besides, compared with the chitinase activity of the cell-free culture filtrates grown in NYDB media and NYDB plus chitosan at other concentrations, the activity of the cell-free culture filtrates of *R. mucilaginosa* grown in NYDB amended with 0.5% chitosan showed a higher level. On the test of efficacy of cell-free culture filtrate of *R. mucilaginosa* incubated in different media in controlling of *Rhizopus* decay and gray mold decay of strawberries, the filtrates incubated in NYDB had no significant control efficacy on the *Rhizopus* decay and gray mold decay of strawberries after 3 d storage at 20 °C. However, the cell-free culture filtrates of NYDB media added with 0.5% chitosan could effictively control the *Rhizopus* decay and gray mold decay in strawberry wounds compared to the control. The chitinase activity may have diverse biological roles including the antifungal activity, which is usually induced in the presence of the chitin.[39] Carstens et al. (2003) demonstrated that the chitinase produced by *Sacharomyces cerevisiae* could inhibit spore germination and hyphal growth of *B. cinerea* in vitro.[40] Yu et al. (2008) reported the antagonistic activity of *C. laurentii* combined with chitinase treatment showed a increased inhibition against blue mold decay caused by *Penicillium expansum* of pear fruit associated with the higher chitinase activities.[12] So we propose that the enhanced chitinase activity of antagonistic yeast is one of the determining factors to improve antagonistic activity of *R. mucilaginosa* against postharvest decay of strawberries.

In nature, plants survive the attack of many microorganisms by employing several layers of defense responses.[41] Besides constitutively expressed barriers, plants can recognize the presence of pathogens and respond by activating defense reactions.[42] The success of this defense response depends on some key factors, including the speed by which the plant recognizes the attacking pathogen and the intensity by which the appropriate defense mechanism is activated. According to the research, the effectiveness of this basal resistance can be improved by elicitors including specific biotic and abiotic stimuli experienced by the plant before contact with the pathogen.[43] Recent studies have revealed that the induction of disease resistance by elicitors is a sensitization process that primes the plant for more rapid deployment of the defenses.[44−46]

PPO catalyzes the oxidation of phenolics to quinones, which are more toxic to pathogens than the former.[47] Increased PPO activity is correlated with disease resistance in plants.[48,49] POD is bifunctional enzymes that can oxidize various substrates in the presence of H_2O_2, but it also produce reactive oxygen species (ROSs). POD catalyzes the last step of lignin biosynthesis. High POD activities are associated with the onset of induced resistance which involves several important plant defense mechanisms such as lignification and suberization.[25,28,33] So enhancement of lignification and suberization related to maintenance of integrity and vital functions of the cell and increased the levels of antimicrobial phenolic compounds in plant cells attacked by phytopathogens resulted in improvement of disease resistance. PAL is the first committed enzyme of the phenylpropanoid pathway which is directly involved in the synthesis of phenolics, phytoalexins, and lignins that are associated with the localized resistance processes.[50] It also has been reported that PAL is transcriptionally induced in response to development and ripening.[51] In addition, previous study reported that higher disease resistance and lower decay index accompanied by significantly increased PAL activity in MeJA-treated vegetable soybean pods, sweet cherry, and peach fruit.[52−54] Our results showed that PPO, POD, and PAL activity were enhanced in strawberry fruit while treated with *R. mucilaginosa* incubated in the NYDB media

amended with 0.5% chitosan compared with the case that without chitosan. On the basis of these, we assume that enhancement the activity of *R. mucilaginosa* to induce more defense enzymes such as PPO, POD, and PAL so as to enhance the resistance of strawberries may be another mechanism that chitosan enhances the antagonistic activity of *R. mucilaginosa* against postharvest decay of strawberries. *R. mucilaginosa* incubated in the NYDB media amended with 0.5% chitosan acted as biotic stimuli, which primed the strawberries for more rapid deployment of the defenses to pathogens.

MDA, a decomposition product of polyunsaturated fatty acids hydroperoxides, has been utilized very often as a suitable biomarker for lipid peroxidation, which is an effect of oxidative damage.[55] Increased lipid peroxidation has been regarded as a major characteristic of harvested fruits undergoing senescence and membrane injury.[56] In this study, MDA contents of strawberries treated with *R. mucilaginosa* cultivated in the culture media of the chitosan-supplement (0.5%) showed a lower level than that of both the control during the whole storage period and the treatment with *R. mucilaginosa* cultivated in NYDB at some storage time. This suggests that enhancing the activity of antagonistic yeast to inhibit the ripening and senescence of fruits may be one of the action modes by adding chitosan to improve antogonistic activity of *R. mucilaginosa* against postharvest decay of strawberries.

Our study displayed that *R. mucilaginosa* cultivated in the NYDB media amended with 0.5% chitosan induced more chitinase and a higher level of β-1,3-glucanase activity of strawberries compared with both the control and the *R. mucilaginosa* cultivated in NYDB. Previous study indicates that in plants, pathogenesis-related (PR) proteins are induced by a pathogen invasion, such as chitinases and β-1,3-glucanases, which are related to their capacity to degrade fungal cell wall in desease resistance process.[57] This induction can be enhanced by some elicitors with the improvement of resistance to pathogens in plants.[58,59] Therefore, we infer that improving the activity of antagonistic yeast to induce the production of pathogenesis-related (PR) proteins of strawberries may be another reason that a more remarkable upward trend was seen in the efficacy of *R. mucilaginosa* cultivated in the NYDB media amended with 0.5% chitosan in controlling postharvest decay of strawberries than the case in NYDB.

Furthermore, the identification of differentially expressed proteins showed that, compared with *R. mucilaginosa* harvested from the NYDB, there are a total of 52 proteins that were differentially expressed when the yeast antagonists were harvested from the NYDB amended with chitosan. Among the 52 proteins, there are 26 up-regulated proteins and 26 down-regulated proteins, and most of them are related to basic metabolism. This indicated that the basic metabolism of *R. mucilaginosa* was improved by chitosan induced incubation, so as to improve it's biocontrol efficacy to postharvest diseases of strawberries. Response patterns of *R. mucilaginosa* to chitosan induced incubation are complex, as the differentially abundant proteins are involved in multiple metabolic pathways.

In short, our results showed that chitosan induced incubation can improve the antagonistic activity of *R. mucilaginosa*, which may offer great practical potential in reducing the postharvest diseases of strawberry fruit. The mode of actions may include its ability to enhance competitiveness of yeast antagonist for nutrients and space with pathogens, to enhance chitinase activity of antagonistic yeast, to induce more defense enzymes such as PPO, POD, and PAL, to induce the production of pothogenesis-related (PR) proteins such as chitinase, β-1,3-glucanase of fruits, and to reduce lipid peroxidation, so as to enhance the resistance and delay the senescence of fruits. The proteomic analysis and comparison of *R. mucilaginosa* in response to chitosan suggested that 0.5% chitosan improved the basic metabolism of *R. mucilaginosa*, and this may be one of the molecular mechanisms by which enhancement the efficacy of *R. mucilaginosa* by adding chitosan in the culture media. All these should be further studied.

ABSTRACT: Nanopesticides or nano plant protection products represent an emerging technological development that, in relation to pesticide use, could offer a range of benefits including increased efficacy, durability, and a reduction in the amounts of active ingredients that need to be used. A number of formulation types have been suggested including emulsions (e.g., nanoemulsions), nanocapsules (e.g., with polymers), and products containing pristine engineered nanoparticles, such as metals, metal oxides, and nanoclays. The increasing interest in the use of nanopesticides raises questions as to how to assess the environmental risk of these materials for regulatory purposes. Here, the current approaches for environmental risk assessment of pesticides are reviewed and the question of whether these approaches are fit for purpose for use on nanopesticides is addressed. Potential adaptations to existing environmental risk assessment tests and procedures for use with nanopesticides are discussed, addressing aspects such as analysis and characterization, environmental fate and exposure assessment, uptake by biota, ecotoxicity, and risk assessment of nanopesticides in aquatic and terrestrial ecosystems. Throughout, the main focus is on assessing whether the presence of the nanoformulation introduces potential differences relative to the conventional active ingredients. The proposed changes in the test methodology, research priorities, and recommendations would facilitate the development of regulatory approaches and a regulatory framework for nanopesticides.

KEYWORDS: *nanopesticides, environmental risk, ecotoxicity, environmental fate*

INTRODUCTION

Engineered nanoparticles (ENPs) are being, or have the potential to be, used in many industrial sectors including defense, energy generation and storage, agriculture, and environmental remediation.[1] One sector where the use of ENPs is receiving increasing interest is the pesticide sector with the development of a range of plant protection products that are termed "nanopesticides".[2−5] Nanopesticides "involve either very small particles of a pesticide active ingredient (ai) or other small engineered structures with useful pesticidal properties".[6] For the purpose of this paper, we regard a nanopesticide as a plant protection product in which nanotechnology (e.g., use of materials that have a physical form with at least one size dimension in the range of 1−100 nm) is employed to enhance the efficacy or reduce the environmental footprint of a pesticide ai. It is noteworthy, however, that so-called "nano" formulations of patented pesticides often contain size fractions beyond the 100 nm conventional "nanorange".[7]

Nanopesticides represent an emerging technological development that, in relation to pesticide use, could offer a range of

benefits including increased efficacy, durability, and a reduction in the amounts of active ingredients that need to be used.[2] A range of formulation types have been suggested including emulsions (e.g., nanoemulsions), nanocapsules (e.g., with polymers), and inorganic ENPs, such as metals, metal oxides, and nanoclays.[3−5] These products, which are at different stages in the product development cycle, can be used to improve the efficacy of existing pesticide active ingredients or to enhance their environmental safety profiles, or both (Table 1). In some cases, the ENP itself (or a solubilized form of the ENP) may "drive" the biological effect (e.g., nanosilver when used as a pesticide where the active component is the ionic silver that is released from the ENP), whereas in other cases nanotechnology is used to protect an ai or enhance its delivery to the site of action. In the future, nanotechnology may also provide benefits for precision farming through "smart field systems"; for example, wireless sensors could be linked via satellite to a laptop computer to detect and locate crop infestation with pathogens and to trigger application of pesticide as needed.[5] These systems have the potential to overcome the need to apply a pesticide to the entire crop, thereby protecting the environment through the use of reduced quantities and targeted application of the pesticide ai.

The increasing interest in the use of nanopesticides raises questions over how the environmental risk of these materials should be assessed for regulatory purposes. There is an increasing body of evidence (including from other applications of ENPs) that the factors and processes affecting the environmental behavior and effects of ENPs may differ from "conventional" substances that do not contain ENPs and, consequently, that methods used in current risk assessment approaches may need refining or replacing to deal with these differences. For example, the REACH framework for assessment of chemicals is considering amendments to its Annexes to account for some of the unique factors associated with ENPs. With respect to pesticides, the Scientific Advisory Panel of the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) of the United States[8] discussed the adequacy of current procedures of hazard and exposure evaluation and concluded that (i) the potential risks of pesticides containing ENPs to humans and the environment may be different from those of conventional pesticides; (ii) the existing environmental fate and effects models are generally inadequate for predicting the behavior of nanopesticides; and (iii) additional metrics and parameters are needed for improved understanding of the environmental fate and effects processes associated with nanopesticides. European Union (EU) Regulation 1107/2009 for marketing authorization of plant protection products in Europe also requires the novel characteristics of a nanopesticide to be considered in the assessment process as it calls for due consideration of the interactions between the ai, safener (chemical substances used in combination with pesticides to make them "safer" and more targeted), synergists, and coformulants during the evaluation of a plant protection product.

In this paper, the current approaches for environmental risk assessment (ERA) of conventional pesticides are reviewed and their fitness for assessment of nanopesticides is analyzed (Table 2). In light of the insights generated, potential adaptations to existing ERA tests, as well as suitable alternative procedures for use with nanopesticides, are discussed. For the purpose of this review we consider three broad categories of nanopesticides: (i) where the nanoformulation is simply used to increase the apparent solubility/dispersion of the pesticide or to protect it from degradation in the formulation, but upon spraying is no longer associated with the ai; (ii) where the ENP is utilized to alter either the toxicokinetics or toxicodynamics of the pesticide, and as such is associated with the ai at least until it reaches the site of action; and (iii) where either the ENP itself or the nanopesticide complex is itself the active ingredient. It is the last category that presents the most complex scenario from a regulatory perspective. In all cases there exists also the potential for mixtures of "free" and nanoparticle-associated ai to coexist in the environment, the ratio of which may not be constant but change over time or as a function of the formulation and environmental conditions, thereby confounding measurements of efficacy and toxicity. Therefore, a key criterion for risk assessment purposes is the "durability" of the nano−ai complex following application of the nanopesticide.

CURRENT APPROACHES TO ENVIRONMENTAL RISK ASSESSMENT

Environmental risk assessments of pesticides are required in many regions of the world before a product can be placed on the market.[8,9] To limit the time, costs, and logistics needed for these risk assessments, a tiered approach focusing on key drivers of impact (e.g., Figure 1) is typically used. A tier is defined as a complete effect and exposure assessment resulting in an appropriate assessment end point. Each tier will involve the estimation of a predicted environmental concentration (PEC), which is the estimated concentration of an active substance in key environmental compartments including surface water, groundwater, and soil. The PECs are then compared to an effect end point such as a predicted no effect concentration (PNEC), the median effective concentration (EC_{50}), or no observed effect

Table 2. Different Environmental Fate Parameters Used for Conventional Pesticides and Their Relevance for Nanopesticides

characteristic	parameter/test currently used	is the characteristic relevant for NPs?	comments
distribution between soil, water, and air	K_{oc}/K_d	not appropriate	colloidal characteristics (aggregation, settlement, interaction with surfaces, matrix effects) drive the distribution, so other parameters may be needed; behavior will be concentration dependent, so studies should reflect likely environmental exposures; environmental parameters will affect particle behavior, so studies should cover environmentally relevant concentration ranges
	K_H	not appropriate	
	VP	not appropriate	
stability in soil, water, and sediment	DT_{50} soil	yes	half-lives of ENPs in different environmental matrices are relevant; the challenge is how to measure the ENPs; characteristics of the test matrices could be important in determining persistence, so a range of matrices should be tested
	DT_{50} water	yes	
	DT_{50} sediment	yes	
bioaccumulation	K_{ow} BCF	not appropriate	other parameters may emerge as understanding develops; rate constants for uptake and depuration may be a more suitable descriptor of potential accumulation; uptake is likely to be concentration dependent, so studies should reflect likely environmental exposures
		not appropriate	
environmental concentrations	PEC_{soil}	yes	mass concentration may not be the best metric for ENP risk, so it may be necessary to express exposure concentrations in other units such as particle number concentration or surface area concentration; exposure models may need refining to account for the processes important in transport of particles
	PEW_{sw}	yes	
	PEC_{sed}	yes	
	PEC_{gw}	yes	
	PEC_{air}	yes	
ecotoxicity	EC50, EC10	yes	maintenance of constant exposure conditions may be particularly challenging for nanopesticides; analytical characterization to support the tests may need to be considered; other units for effects concentration (e.g., particle size concentration) may be needed

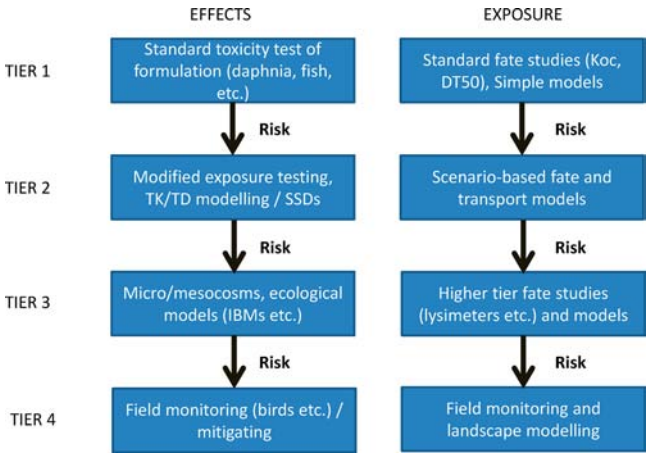

Figure 1. Tiered approach to environmental risk assessment of a pesticide.

concentration (NOEC) to derive a risk characterization ratio, which is compared with a regulatory trigger value. Uncertainty factors are incorporated into the process to account for the many uncertainties associated with extrapolating from regulatory fate and effect studies to impacts in the real environment.[10]

Under current regulations, PECs in soil, surface water, and groundwater need to be calculated for ERA purposes (e.g., FOCUS).[11] These concentrations are dependent on the use patterns of the product and the persistence and phase partitioning (e.g., sorption) of the ai in/between environmental compartments (e.g., soil, sediment, pore water). The movement of pesticide through the soil profile and ultimately to drainage systems or groundwater is described by models based on the convection−dispersion processes, whereas macropore transport is considered in some circumstances, for example, in the pesticide leaching model MACRO.[12] Pesticide runoff to surface streams is governed by off-site transport of pesticides in the solution phase, although erosion of the surface soil may also contribute to surface water contamination. Additional exposure pathways include off-target drifts during application, movement through subsurface drainage channels, and volatilization to, and deposition from, the atmosphere. Once in a water body, processes such as sorption, transformations, and flow dynamics influence the fate and risk of pesticides. These processes are characterized using the key parameters summarized in the following paragraphs.

Phase partitioning of the ai is often quantified with the sorption coefficients K_d or K_{oc}, (Table 2) and to characterize the nonlinear sorption behavior, the Freundlich isotherm is often measured. These measurements are usually carried out using the batch equilibration approach, where the soil and water phases are mixed to reach phase equilibrium.[13] Half-life ($t_{1/2}$) or half-dissipation time (DT_{50}) is used to indicate a pesticide's persistence in soil and can be measured in a laboratory incubation experiment or a field dissipation study.[14] The decrease of pesticide concentration in soil measured over time is used to fit kinetics models to derive $t_{1/2}$ or DT_{50}. Similarly, persistence is measured in water and sediment systems, and vapor pressure and Henry's law constant are required to estimate the potential for volatilization from soil or water.

The bioconcentration factor (BCF) is required to assess potential risks to high trophic levels and to classify compounds in terms of their persistence, bioaccumulation potential, or toxicity (PBT). Hydrophobicity (i.e., high K_{ow}) may trigger bioaccumulation tests that are conducted in accordance with relevant guidelines.[15] A BCF value for an ai can be derived in one of two ways. If bioaccumulation into nontarget organisms, such as fish, is viewed as a phase partitioning process, BCF can be calculated as the ratio of the uptake rate constant (K_{in}) to the depuration rate constant K_{out} measured in an exposure test that does not need to reach equilibrium. Alternatively, BCF can be calculated as the ratio of body residue to the concentration in water at the steady state.

The first tier of the assessment process typically uses simple exposure models with defined scenarios. For aquatic organisms, tests include studies with pelagic microalgae (green algae, blue-green algae, diatoms), aquatic plants (a monocotyledon and a dicotyledon), invertebrates (the crustaceans *Daphnia magna*, *Americamysis bahia*, the insect *Chironomus riparius*, oligochaeta *Lumbriculus variegatus*), and fish. For the terrestrial compartment, tests with earthworms (*Eisenia* sp., *Enchytraeus* sp.) and springtails (*Folsomia candida*) and studies into the effects on microbial community functions are most commonly conducted.

In the second tier, more complex exposure modeling may be used and more complex laboratory effect studies are likely to be employed such as modified exposure studies and/or toxicokinetic−toxicodynamic experiments and modeling or the development of species sensitivity distributions using additional nonstandard test species, preferably from taxa not included in the initial set of studies.

The third tier is used to assess processes such as biomagnification, recovery, and indirect effects using semirealistic exposure regimes and biological communities through the use of semifield experiments (i.e., microcosms, mesocosms) and ecological models. The last tier can include field monitoring of concentrations and effects of pesticide, although it is often difficult to get a clear view of the effects of a single pesticide given the presence of multiple stressors in agro-ecosystems. A diagrammatic representation of the tiered risk assessment approach currently used for pesticides is presented in Figure 1.

WHY MIGHT NANOPESTICIDES NEED A DIFFERENT APPROACH?

Over the past few years, understanding of the factors affecting the risks posed by ENPs to the environment has developed significantly. It is now recognized that many of the approaches and assumptions used to assess the risks of conventional chemicals may not be appropriate for ENPs and that some modifications may be required to risk assessment guidelines.[16,17] The OECD has a large work program that is considering how test guidelines may need to be adapted to assess the hazard of ENPs. In the following section we draw on some of this work, as well as the wider literature and the authors' expertise, to highlight how nanopesticides may differ from conventional pesticides in terms of their fate and effects and the implications of these differences for the ERA process.

For a conventional pesticide, it is usually assumed that ecotoxicity is related to ai mass concentration, and risk is therefore characterized using exposure and effects data expressed in terms of mass per volume or mass per mass of ai. However, for nanopesticides, other parameters such as particle number concentration and particle size distribution (PSD), as well as the ratio of "free" and nanoparticle-bound ai, may be important in determining the pesticide bioavailability and toxicity.[18−20] Analytical methodologies used to characterize the levels of available pesticides over time in regulatory fate and effect studies may therefore need to be supplemented with additional

methodologies that provide an understanding of the particle number concentration and particle size distribution over time. Approaches could include scattering methods (e.g., DLS), particle tracking methods (e.g., NTA), centrifugal methods (e.g., DCS), or fractionation methods (e.g., FFF), the latter method allowing for determination of ai size when coupled with appropriate chemical selective detectors. However, as these methods are not routine in pesticide analysis laboratories, this represents a significant change in approach. It is also important to note that nanopesticides will often undergo changes in their degree of dispersion or agglomeration over time, depending on the concentration of the nanopesticide and environmental factors such as pH, ionic strength, dissolved molecules of the test media, and as such are not equilibrium systems. Thus, characterization of a nanopesticide at different stages in its environmental life cycle and throughout fate and effect studies may be very important.

In standardized ecotoxicity studies, it is recommended that the test concentration should be kept within ±20% of the nominal test concentrations.[21] This is an important issue when considering products containing ENPs and so is also an issue for nanopesticides. For products containing ENPs, there is the question whether it is the mass concentration or the particle number concentration (and mean size) that should be maintained. It is clear that agglomerate/aggregate size and type will change throughout exposures. Furthermore, particle number varies markedly for ENPs of different sizes at a constant mass: for example, a particle mass of 100 ng corresponds to only 2.4×10^4 particles (spheres of unit density) of 2 μm in diameter, but to 2.4×10^{10} particles of 20 nm, or to 2.4×10^{13} particles of 2 nm.[22] Although the maintenance of a particle concentration to within ±20% of a starting concentration for a test is likely to be extremely challenging, it could be highly informative in understanding the risks of a nanopesticide to the natural environment.

The behavior of ENPs is similar to that of colloids, and therefore phase partitioning between environmental matrices cannot be assumed. For example, sorption and uptake into organisms are unlikely to be partitioning processes but rather involve active and receptor-mediated processes for uptake and aggregation and deposition processes for association with suspended matter, soil, or sediment. These processes will be dynamic,[23] whereas the phase partitioning driven process that occurs for conventional pesticides can to a large extent be modeled by equilibrium processes. Consequently, the use of soil sorption coefficients such as K_d or K_{oc} may not be relevant for modeling the movement of a nanopesticide within the environment (Table 2). Other factors such as the aggregation rate, sedimentation rate, and interaction of an ENP with surface receptors may need to be considered. The release rate of the ai from the ENP complex will also need to be characterized, as well as the ratio of free versus ENP-bound ai. Furthermore, transport of nanopesticides in air could be very different; for a conventional pesticide volatilization will be the process whereby the pesticide molecules transfer from soil and plant surfaces to the air, whereas for a nanopesticide the release of particles is likely to be important.

For aquatic and soil-dwelling organisms, dermal and respiratory surfaces represent a significant (often dominant) route of pesticide exposure. Partitioning principles govern the rate of entry across biological membranes such that the extent of absorption is driven by the chemical properties of the molecule (e.g., hydrophobicity) and the physiological structure (e.g., surface area, extent of sclerotization) of the biological surface. Upon entering the body, fugacity-driven distribution of the pesticide across different organs and tissues occurs, with fate in tissues determined by the organism's potential to biotransform molecules as a step toward elimination and by the potential to interact with the relevant cellular receptors. The primary (e.g., cytochrome P450), secondary (e.g., glutathione-s-transferase), and tertiary (e.g., ABC transporter) systems governing this metabolism and excretion are among the best studied biological pathways, whereas key uptake receptors are known as a function of the known mode(s) of action.

The diffusion and equilibrium partitioning that often dominate the cellular uptake of pesticides may not always be relevant for nanopesticides where the ai is bound to the ENP or is itself the ENP. As intact particles, there are a number of general mechanisms, such as passive and facilitated diffusion for direct transfer across biological membranes without enclosure[26] and active transport and endocytosis through membrane carrier proteins and channels,[27] that can result in the internalization of ENPs.[23,25]However, it is the mechanisms of endocytosis pathways that have received most attention through the use of pharmacological inhibitors[28] and gene activity disruption[29] to tease out the mechanisms and fluorescent labeled ENPs and antibody colocalization[30] studies to understand uptake kinetics and subcellular localization. Such studies have revealed that the size of ENPs taken up depends on the type of endocytosis and the corresponding vesicle sizes associated with their transport. Macropinosomes are generally 1−5 μm in diameter; calveolin-coated vesicles in the 50−80 nm range[31] and clathrin-mediated endocytosis structures are typically 120 nm in size. Most ENP have been found to localize in lysosomes following uptake,[32,33] which are sites of destruction for foreign or no longer useful materials, and there is thus the potential for release of locally high concentrations of pesticide from the lysosomes via the so-called "Trojan-horse" mechanism. The uptake pathway of a nanopesticide into organisms could therefore be very different from that of a conventional pesticide.

For conventional pesticides, the octanol/water partition coefficient (K_{ow}) is an important characteristic that indicates the affinity for lipid-rich tissues of nontarget organisms. Determining the K_{ow} values of ENPs is generally difficult because ENPs do not partition into either phase (Table 2). Rather, ENPs accumulate at the octanol/water interface because of their high surface energy.[34,35] Whereas the phase partitioning of organic molecules is driven partly by thermodynamics associated with water molecules versus the energy associated with partitioning to a surface, colloidal interactions are dependent on the net energy of attraction/repulsion with a surface.[36]

For pesticides it is usually assumed that dissipation, uptake, and distribution behavior is independent of the concentration. For nanopesticides it can be expected that phase partitioning, the relationship of mass concentration to particle concentration, uptake into biota, and distribution within organisms are all highly concentration dependent. It is likely that phase partitioning across membranes depends on the agglomeration status, size, and surface charge of ENPs; these parameters in turn depend on the concentration. For example, Handy et al.[37] in their idealized scenario of uptake of chemicals and ENPs by gills of freshwater fish, highlighted the key differences between lipophilic organic chemicals and ENPs. Prior to transfer across the gill epithelium, the substances must diffuse into the so-called unstirred layer (USL) made of water/mucous secretions. They observed that while small lipophilic organic molecules can easily diffuse into the USL and then through or between the

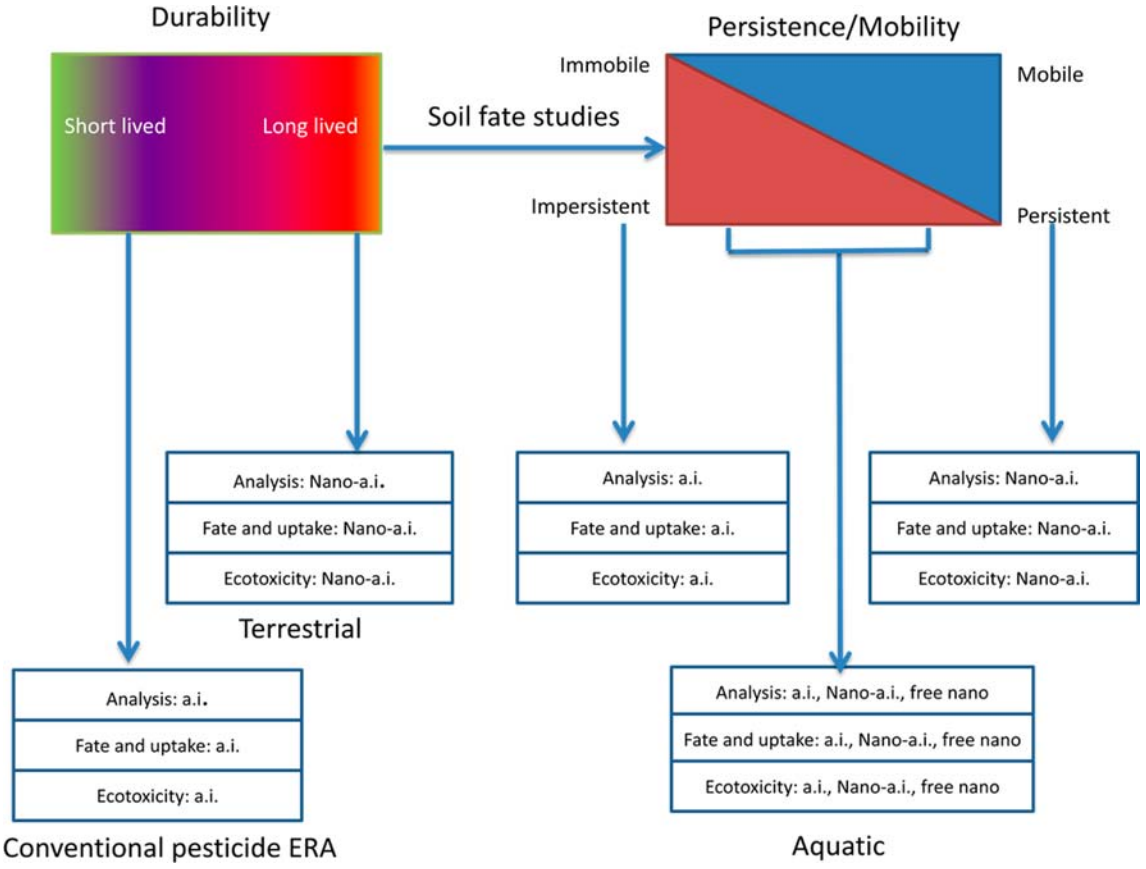

Figure 2. Conceptual strategy for assessing the environmental risks of a nanopesticide.

cells, ENPs are expected to diffuse at a slower rate that is influenced by humic substances and mucoproteins. In addition, ENPs may get entangled with mucoproteins, leading to prevention/retardation of their uptake. The size of ENPs precludes their uptake via ion or other transporters on the cell membranes. Furthermore, the Ca^{2+}- and Mg^{2+}-rich environment in the tight junctions between cells may trigger the aggregation of ENPs, thereby reducing their diffusion. Such processes at biological surfaces have the potential to alter the absorption and distribution of nanopesticides in comparison to traditional forms, with resultant effects on tissue distributions and biomagnification potential.

Quantifying internal exposure to ENPs may be required to understand the relationship between ENP properties and toxicity. For example, the rate of release of the ai will likely differ in different matrices. A consequence may be different exposure dynamics at target sites versus in the environment (e.g., fast release of ai in cellular compartments and slow release of ai in soil pore water due to different pH regimens and cellular enzymatic action). Quantitative property−toxicity relationships would help in the decision of how toxicity testing for ENPs should be standardized, but are not yet sufficiently developed or validated.

HOW COULD THE POTENTIAL RISK POSED BY A NANOPESTICIDE TO THE ENVIRONMENT BE ASSESSED?

It is clear from the above discussion that nanopesticides are likely to behave differently from conventional pesticides and that some of the traditional metrics used in ERA may be inappropriate for nanopesticides. Therefore, to adequately assess the environmental risk of a nanopesticide, alternative test methods and metrics may be required. Although in the future it may be possible to develop highly complex test methods and modeling approaches that accurately estimate the exposure and effects of a nanopesticide in a particular situation, we do not believe that the current knowledge allows us to do this at this time. It is also important to recognize that current approaches for conventional pesticide risk assessment employ many assumptions to address uncertainties and are by no means perfect themselves. To move forward in a pragmatic and implementable manner, we therefore propose a rational framework that accounts for the key differences between nanopesticides and conventional pesticides and where additional information may be required for their regulation. This aspect is further expanded in the sections below and illustrated schematically in Figure 2.

The proposed approach uses information on the durability of a nanopesticide product and the fate of the product in soil to make decisions on what component or mixture of components (e.g., conventional ai, nano−ai complex, or the free ENP acting as ai) should be tested and analyzed in aquatic fate studies and in aquatic and terrestrial ecotoxicity studies (Figure 2). The scientific rationale for this approach is that nanoformulation of a pesticide could be utilized to alter the toxicokinetics (i.e., the (rate of) uptake, biotransformation, distribution, and elimination) or the toxicodynamics (i.e., the mechanism or mode of toxic action of the ai), and by knowing which of these (or both) may be affected, rational decisions regarding modifications to existing tests or introduction of new tests could be made.

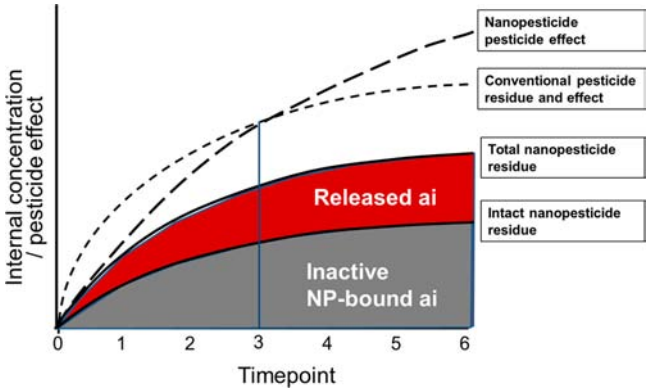

Figure 3. Schematic illustration of potential time-dependent (*x*-axis) effects on pesticide internal concentration and toxicity (*y*-axis) of nanoformulation pesticide preparations as compared to conventional forms. On the basis of the assumption that the ai is only active when released from the nanoformulation (which occurs over time), internal concentrations of released ai derived from the nanoformulation will increase over time as the pesticide is released from the nanocarrier. As a result, when exposure times are short in a test bioassay (e.g., up to timepoint 3), then the relatively small amount of ai that has been released may result in an observed toxicity that is lower than for the conventional ai formulation. In contrast, for longer term exposures (timepoints 4−6), the greater time allowed for ai release may result in higher internalized concentrations that can be associated with potential receptors to cause toxic effects that can be greater than for the conventional formulation.

Figure 3 provides an illustration of one scenario whereby the rate of release of ai from nanoformulation affects the duration of assessment required, assuming that the ai is only active in the free form. Other scenarios are also possible, such as the ai being active in the bound form also or even more active in the bound form, which would result in further alterations to the toxicokinetics diagram, but again an understanding of these effects would facilitate decision-making regarding appropriate testing durations and approaches. There is also potential for so-called Trojan-horse effects, whereby the uptake is of the nano−ai complex and the release of the ai occurs inside the plant cells; depending on the local environment, the release rate may be more dramatic, leading to extreme concentrations of ai that not occur via uptake of the free ai or to accumulation of NPs containing nonreleased ai. Such scenarios are not shown in Figure 3. Additionally, there is the potential that the ai may be more active in the bound state (nano−ai complex), in which case the nanoformulation would lead to higher local concentrations even at shorter time points.

If the nano component of a nanopesticide simply protects the ai from degradation in the formulation, then the fate and behavior of the ai will remain the same as in a conventional pesticide formulation and the nanocomponent will likely degrade during the application. Emulsions are a case in point. If the nanoformulation itself is the ai, or if the pesticide is more active when bound to the nanoparticle (e.g., as a result of increased local concentration, avidity effects, or optimal presentation of active site), then information about the conventional formulation will make only a minor contribution to understanding the nanoformulation. Thus, an understanding of where and how the nanoformulation is likely to affect the action of the ai will guide additional studies into characterization (e.g., particle number, ratio of free and nanoparticle-bound ai as a function of time/suspension conditions), fate and behavior, and efficacy, which may be required to gain regulatory approval. In the following sections we describe the different components of the scheme and the test approaches that could be employed. We start by considering the important elements of ENP characterization and quantification that are prerequisite to sound fate and effect assessment of nanopesticides.

CONSIDERATIONS FOR THE CHARACTERIZATION AND QUANTIFICATION OF NANOPESTICIDES

Similar considerations regarding the applicability of risk assessment approaches utilized for conventional chemicals to nanopesticides arise in terms of characterization, due to the challenges in analysis and characterization of nanobased materials in complex matrices.[38] Analysis of even conventional pesticides can be challenging at times.[39,40] Coupling this with the fact that techniques suitable for the detection, quantification, and characterization of nanopesticides (and indeed ENPs in general) in water, soil, and biota have not yet been validated or even developed in many cases leads to the conclusion that we are currently unable to adequately characterize these materials to support their risk assessment. Challenges are encountered due to the wide variety of nanopesticides and their presence as particle-bound forms making additional analysis (such as PSD, particle mass or number concentration, or surface charge) necessary. Expected environmental concentrations of nanopesticides will be low, and thus method sensitivity also becomes a challenge in the performance of fate and effect studies at environmentally relevant concentrations.

Techniques potentially suitable for the analysis of ENPs in environmental or food matrices have been extensively discussed in many reviews (e.g., Tiede et al.[41] and Hassellöv et al.[42]). To our knowledge no studies to date have examined the applicability of these methods of analysis to nanopesticides. Despite this, adequate analysis and characterization of nanopesticides are crucial for meaningful durability, fate, and ecotoxicity studies. This is indeed challenging, for not only the ai (conventional or ENP based) needs to be considered but the nano component (e.g., porous silica, metal oxide) also has to be characterized. Therefore, new methodologies will be required for nanopesticides, because extraction methods may alter the form of the nanopesticide, precluding any meaningful information on particle size distribution. Given the relatively high hydrophobicity of most pesticides,[43] strong nonpolar solvents under enhanced temperature and pressure conditions are often used to extract the residues.[39] However, such extraction procedures may affect the stability of the nano−ai complex.

On the basis of the assumption that various physical forms of the ai will display differences in mobility and toxicity, we propose a characterization scheme that employs the fractionation of the nanopesticides into three components: particulate (homo- and heteroaggregates incorporating ai), nanobound ai, and free ai. Size fractionation procedures (e.g., filtration, centrifugation) leading to operationally defined size classes are common in environmental analyses where size is relevant.[38,44] In particular, size fractionation, coupled to conventional pesticide analysis, could be used to determine the portion of the ai that remains associated with the nanocarrier and the agglomeration state of a nanocarrier, which will also influence ai fate and behavior. Although we propose that in principle this approach would in many cases provide an adequate level of characterization for risk assessment, current centrifugation and filtration methodologies require validation, and it is likely that further method development would be required to allow quantitative application.

dx.doi.org/10.1021/jf500232f | J. Agric. Food Chem. 2014, 62, 4227−4240

In some cases further characterization of the sample, or its size fractions, might be required. Physicochemical properties such as ENP size or shape could be characterized using the techniques outlined below and discussed in the literature. However, many conventional nanocharacterization methods (e.g., DLS, TEM) will lack the specificity needed to distinguish the nanopesticide from background particles as well as the sensitivity (limit of detection in terms of particle numbers) required for realistic environmental exposure concentrations.

Binary size separations (e.g., ultrafiltration, centrifugation), combined with appropriate physicochemical analysis of the fractions, can give information on the state of the ai as well as characteristics of the nanocarrier. Currently, two high-resolution size fractionation methods appear promising for application to nanopesticides. These are hydrodynamic chromatography (HDC),[45] which is somewhat analogous to the more commonly used size exclusion chromatography, and field flow fractionation (FFF). These approaches might find utility in cases when artifacts from filtration or centrifugation might be problematic or when a higher level of nanocharacterization (e.g., PSD of ai or nanocarrier) is desired. For some nonmetal based nanocomponents (e.g., polymers), detection, size characterization, and mass and/or particle number concentration analysis in environmental matrices could be particularly challenging.

For a nanopesticide consisting solely of a metal or metal oxide based ENP (i.e., where the ENP itself/dissolution of the ENP is the pesticide), conventional pesticide analysis is not required; however, chemical analysis for the element of interest (e.g., Ag, Si) using ICPMS will likely be possible. Element-specific size analysis is possible with specialized ICPMS techniques including FFF-ICPMS, HDC-ICPMS, and single particle ICPMS (spICP-MS) or even a combination of HDC-spICP-MS.[46−49] However, the use of complementary techniques such as TEM, NTA, and DLS is recommended to validate the measurements.

Recommended Approach for Characterization. Here we suggest a tiered analytical approach analogous to the tiered approach used in fate and ecotoxicology assessments. The degree to which one applies the methodology depends on the durability, mobility, and persistence of the respective nanopesticide. The tiered approach is detailed in Figure 4. At the simplest level (tier 1) the analytical approach is identical to what is currently performed for a pesticide ERA, namely, exhaustive extraction followed by analysis to quantify ai present in the samples. This is the most likely level needed for analysis of emulsions and short-lived, nonpersistent nanopesticides. However, if differences between nanoformulation and non-nanoformulation are seen in terms of durability, transport, and uptake, then additional "nano-analysis" of ai and carrier is required. This approach would likely be applied to polymer and "hard" ENPs (porous silica, metals, metal oxides). Although the approach involves methods that fractionate the nanocarrier, given the likely much higher toxicity of the ai over the nanocarrier, the chemical analysis of the fractions, or the online analysis in the case of HDC and FFF, is focused on quantification of the ai in each associated size fraction and on determination of whether the ai is free or nanobound. The exception is where the ai is the nanopesticide, for example, nano-Ag, in which case the additional physical characterization obtained by these methods (e.g., PSD of Ag) may prove valuable in the risk assessment.

EXPOSURE ASSESSMENT

Durability of the Product. The durability of the product will determine the extent to which the environment will be exposed to the nanopesticide. For some product types, for example, nanoemulsions or nanodispersions, that are used to enhance the apparent solubility, it is likely that following application the "nano" properties of the pesticide will be lost. In these cases we would recommend that the product be treated as a conventional pesticide in the risk assessment process. Information should be available from the product development studies that assist in assessing the likely durability of the nanopesticide following application. If the product is long-lived, we recommend that the terrestrial component of the risk assessment is carried out with the nano−ai complex. If available, persistence studies undertaken during product development would allow quantification of the release rates of the ai from the ai−nano complex as well as the ai and ENP degradation rates. Such measurements can be performed using the separation techniques described above.

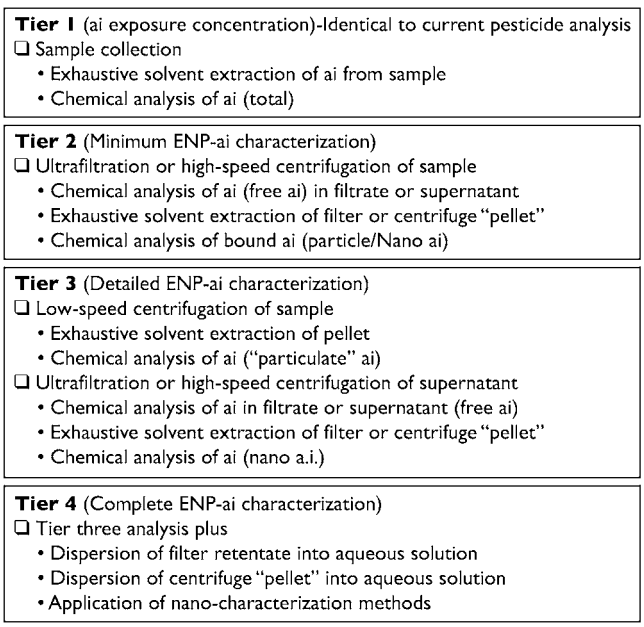

Figure 4. Tiered approach for analysis and characterization of nanopesticides.

Persistence. Using soil fate studies (e.g., column experiments, see Exposure Assessment below) nanopesticides can be characterized as persistent versus nonpersistent and mobile versus immobile. The outcome triggers how to continue the aquatic component of the risk assessment. If the nanopesticide (i.e., its nanoform) is nonpersistent, then the aquatic risk assessment may be conducted using only the ai. By contrast, if the nanopesticide is persistent, then the aquatic risk assessment has to be conducted using the nano−ai complex as well. If the persistence of the nano−ai complex is unclear or between those two clear-cut cases and threshold or trigger values need to be derived, then the aquatic risk assessment also needs to be carried out twice, that is, with the nano−ai complex and with the ai alone to cover possible worst case scenarios.

Persistence ($t_{1/2}$ or DT_{50}) of an ai may be influenced by its release from the carrier material. The release rate of the ai from the carrier and the degradation rate of the ai need to be quantified as both are key parameters in the transport models. We recommend incubation experiments with the ai as well as with the formulated product (i.e., the ENP−ai complex), where

the total concentration of the ai is measured. The difference between the experiment with the ai alone and with the ENP−ai complex would allow parametrization of the fate model by allowing estimates of release rate and degradation rate to be derived. However, it should be noted that this approach requires assumptions about the bioavailability of the ai when in the nano−ai complex. Two limit cases are possible: the ai in the nano−ai complex is equally accessible (bioavailable) for degradation as the ai without the nanocomplex, or the ai in the nano−ai complex is not degradable at all. An independent estimation of both the release rate and the degradation in the nano−ai complex is not possible from incubation experiments alone. However, an approach such as limited enzymolysis/proteolysis applied to the nano−ai complex and compared to the conventional ai would provide insights regarding the impact of the nanoformulation on the degradation/metabolism of the ai. This approach has been successfully applied to assess the impact of ENP on protein confirmation and degradation but has yet to be confirmed for environmental degradation. This approach could be a promising direction for initial testing.[50,51]

Mobility. The batch adsorption approach is not suitable for ENPs that are determined to undergo nonequilibrium processes. We suggest the use of column breakthrough experiments to derive nanopesticide mobility parameters as transport model inputs to estimate leaching or runoff/erosion movement. The experiments should not use excessive porewater velocity, as this may diminish the environmental relevance as velocity influences ENP fate.[52] These experiments should be undertaken with both the ai and the nanoformulation. In both cases, the concentration of ai in the leachate is measured and the fraction associated with the ENP−ai complex could be quantified using separation techniques, possibly in combination with advanced separation equipment such as FFF or HDC (as discussed in the characterization section above) to ensure robust quantification without interference from naturally occurring particles in the leachate. The fraction associated with soil colloids can be estimated from the difference in supernatant concentrations in the treatments (ai alone vs ENP−complex). Modeling techniques should be employed to derive the retardation (as opposed to sorption) parameters, which are based on the difference between the treatments using the release and degradation rates from durability studies, as described above.

Soils and Sediment−Water Test Systems for Sorption and Degradation Studies. The characteristics of soils for regulatory degradation and sorption studies are described in OECD guidelines.[13] Commonly used test soils are, in principle, suitable for studies with nanopesticides. However, additional criteria may be needed to ensure that soils with contrasting influences on ENP behavior are included in the studies. Important factors include pH, pore size distribution, ionic strength, dissolved organic carbon concentration, and clay content.[24] Characterization of persistence and sorption in sediment−water systems would follow the same principles as for soil, testing both the ai and the ENP−ai complex.

Fate and Exposure Modeling. The fate model would generally quantify free ai as well as the fraction of ai bound within the ENP−ai complex in different media. Existing fate models for pesticides could not be used without substantial revision and adaption to accommodate nanopesticide specific processes that are different from conventional pesticides. These differences include release of ai from nanopesticide complex, phase partitioning, agglomeration and changes in the ENP size distribution, possible interdependencies of particle size distribution, phase partitioning and degradation, as well as concentration dependence of all the above parameters.[36] The development of appropriate fate models for nanopesticides represents a significant challenge that will require substantial quantitative data from laboratory and field studies on nanopesticide behavior under various environmental conditions for model testing.

Uptake into Biota. Similarly to other ENPs, bioaccumulation cannot be viewed as a straight phase partitioning process, and K_{ow} is unlikely to be a good indicator for bioaccumulation potential of nanopesticides.[35] Therefore, BCF may not be estimated as the ratio of K_{in} and K_{out} in a short exposure tests and has been found to be not a relevant parameter to describe the bioaccumulation of ENPs.[53] It is generally considered that current standard protocols for bioaccumulation (e.g., fugacity-driven biomagnification) do not apply to ENPs (see below for more information; this has been reviewed previously[16,17]). As uptake processes for nanopesticides differ from those of conventional pesticides, the choice of test organisms may also have to be reconsidered. For example, filter feeders in aquatic environments (e.g., daphnids, bivalves) may be potentially vulnerable to elevated exposure due to their ability to process a large volume of media. For terrestrial systems, traditional test species such as earthworms that have a known potential for metal and organic chemical biomagnification are likely to be most relevant as they may accumulate larger amounts of nanopesticides. In the absence of a good predictor, such as K_{ow} for conventional pesticides, one has to rely on the testing of individual products. A test that reaches steady state may still yield the necessary information for assessing bioaccumulation potential, where bioaccumulation is calculated as the ratio of body residue over aqueous phase concentration at steady state. The experimental uptake test methods that explore uptake and depuration over time may be appropriate, but they need to (a) be designed using relevant dosing levels, (b) monitor steady state ENP concentrations in the media, (c) be representative of species likely to be exposed, and (d) be interpreted differently so as to reflect the uptake/depuration rates rather than the conventional BCFs. Whereas the need for global descriptors and predictive modeling frameworks for bioaccumulation assessment of ENPs is clear, considerable challenges remain in developing new or adapting existing protocols and approaches.[53] Time series based bioaccumulation studies to determine toxicokinetic parameters for nanopesticides are needed so the accumulation patterns of conventional pesticides and nanopesticides can be compared. These studies need to consider the form of the accumulated material (free versus nanobound ai) because this may have implications for the progression of toxicity over time (Figure 3).

EFFECTS ASSESSMENT

Are Current Standard Regulatory Approaches Applicable to Nanopesticides? As described above, there are standard regulatory approaches and tests that will need to be followed when the risks of conventional pesticides are assessed. A key question, therefore, is "are these standard ecotoxicity testing approaches appropriate for use on nanopesticides and are any modifications needed to these approaches?". The regulatory protection goals for a nanopesticide will be no different from those of a traditional pesticide, so the typical testing paradigm where acute and chronic effects data are generated for a range of trophic levels in different environmental compartments will be equally applicable to a nanopesticide. Questions

do, however, arise over which species should be tested and over whether specific test protocols need adaptation to cope with nanopesticides. The suitability of current standard test protocols for the assessment of hazard of products containing ENPs has been subject to much research and discussion. A technical workshop on the suitability of standard test methods for nanotoxicology[17] concluded recently that the standardized methods available for aquatic, sediment, and soil samples and mammalian and avian species provide a useful basis from which to develop appropriate effects studies for use with ENPs but that some modifications may be required. Some of these are discussed below.

Which Species Should Be Tested? Although the broad approach to testing may be relevant for effect assessment based on the range of currently utilized test organisms, the fate and form of a nanopesticide in an environment such as a surface water body could mean that certain organism types will have a higher degree of exposure than others. The requirement to include particle feeding organisms (e.g., filter or suspension feeders) in the test battery, as well as "conveyor-belt" feeders and benthic organisms, has already been proposed for general hazard assessment of ENPs, and these proposals should also apply to nanopesticides.

What Technical Modifications to Standard Test Protocols Could Be Needed? A wide range of technical modifications to standard test protocols have been proposed for ENPs,[16,17] which are likely to be equally required for nanopesticides. For example, appropriate references and controls (e.g., metal salts for metallic ENPs, larger scale (non-nanoscale) "bulk" materials, solvent controls) may be needed for comparative assessments; new dosing methods may be required to ensure homogeneous distributions of the material in the test systems; there may be a need for increased stirring/mixing of the water, or water changes, to maintain exposure concentrations in aquatic tests throughout a study; the duration of studies may need to be refined to reflect differences in the uptake kinetics of nanopesticides compared to conventional pesticides; and new characterization methods to track the dynamic behavior and fate of an ENP during an ecotoxicity study are likely to be needed and characterization may need to be done more frequently during a study than for a traditional pesticide. Some of the analytical approaches described under Recommended Approach for Characterization may be appropriate here. Two additional challenges associated with the application of standard test protocols for nanoformulations are (1) identification of the most appropriate dose metric and (2) accounting for nanoformulation agglomeration or aggregation, which also affects the available "nano" dose. As discussed earlier, mass is the metric utilized for ai and, indeed, for ENP to date, although there is considerable debate in the literature as to whether particle number, particle surface area, or reactive particle surface area would be more appropriate dose metrics for ENP[54] for dose–hazard and dose–exposure correlations. Aside from this, there is the unresolved question of how to compare the dose of conventional ai (free) versus nanoparticle-encapsulated/nanoparticle bound ai, which, as indicated in earlier sections, may be active in the bound form only or upon "release" only. Similar considerations apply to certain nanopharmaceuticals, and perhaps the approaches taken by medical regulators might be instructive in this respect. Considerations could include mass ai/ENP or mass ai/mass ENP while still reflecting the issue of durability of the nano–ai complex, as per Figure 2. Finally, the agglomeration potential of the nano–ai complex under actual exposure conditions would need to be factored into the assessment to correlate dose with response.

Role of Higher Tier Laboratory Ecotoxicity Testing Approaches. One of the main challenges in the risk assessment of nanopesticides will be how to combine the results from the standard effects studies and the exposure predictions. The use of higher tier laboratory ecotoxicity studies using, for example, natural waters rather than standard media or sediment–water test systems may overcome these issues. These approaches have been proposed for use in pesticide environmental risk assessment for some time now.[55] If designed correctly, the advantage of the approaches is that the test integrates the fate and effects processes that are likely to occur in the natural environment. Such approaches could be useful for assessing risk of nanopesticides until more mechanistic approaches are developed.

How Could Nanopesticides Interact with Other Environmental Contaminants? Whereas pesticides are assessed on a product by product basis, just like any other contaminant, in the real environment, they will co-occur with other substances, so mixture interactions are possible. Although risk assessment of environmental mixtures is not usually required for product risk assessment, it is possible that a nanopesticide will interact synergistically with other contaminants through the Trojan-horse effect.[56] This effect occurs when an ENP interacts with another substance and carries the substance into an organism or an organism tissue type. The effect can result in increased internal exposure to contaminants, which might not usually be accumulated. As our knowledge of these interactions increases, it may be necessary to incorporate these types of interactions into regulatory risk assessment schemes.

THE WAY FORWARD

Nanopesticides represent an attractive technological advancement from the standpoint of increased efficacy and protection of the environment and human health. The discussion in the preceding sections demonstrates that the factors and processes affecting the environmental behavior and effects of nanopesticides may differ from "conventional" pesticides, and therefore new or refined risk assessment approaches are needed. Unlike conventional pesticides, the uptake, bioavailability, and toxicity of nanopesticides are dependent on the particle number concentration and particle size distribution, as well as ratio of "free" and ENP-bound ai. Therefore, adaptation of existing methodologies and additional methodologies for analysis, characterization, environmental fate, and effect assessment are needed. However, considerable challenges exist, including maintenance of constant (±20%) particle concentration during the ecotoxicological tests, adequate characterization of the ENPs, identification and measurement of appropriate phase partitioning parameters (as conventional parameters may not apply), standardization of fate and toxicity testing protocols, and development of models (e.g., using quantitative structure–activity and property–toxicity relationships). Because current knowledge does not allow the accurate estimation of the exposure and effects of a nanopesticide in a particular situation, a pragmatic approach such as the one proposed here (Figure 2), coupled with a theoretical understanding of how nanoformulation might affect the toxicokinetics and/or toxicodynamics of the pesticide (Figure 3), is needed to move forward.

To implement this approach, a crucial decision-making step relates to the durability of a nanoformulated pesticide product and the fate of the product in soil. This allows identification of

whether the new product could be treated as a conventional pesticide or differently as a nanopesticide that demonstrates more activity as the ENP−ai complex. This step also guides the additional requirements in terms of ENP characterization and residue analysis as well as the fate and effect assessment. As discussed above, in several circumstances existing approaches can be used with some modifications and adaptations. Overall, the existing tiered risk assessment approach, such as that used in the EU, remains a useful framework for the risk assessment of nanopesticides, although with adaptions as presented above to account for potential alterations in the fate and behavior resulting from the nanoformulation. As the science of ENPs advances and new tools and techniques become available, the quality of data underpinning risk assessment will improve and further inform the regulatory requirements. In this regard, the collaborative efforts of the OECD Working Party on Manufactured Nanomaterials, the U.S. EPA, the APVMA, and other agencies may provide future guidance.

FUTURE NEEDS AND RECOMMENDATIONS

- Recent reviews on nanopesticides and ENPs used in crop protection and agricultural production[3−5] have discussed research priorities[57] and needs regarding nanospecific regulations.[58,59] Building on these, and including considerations of exactly where and how the nanoformulation might affect the environmental fate, behavior, and effects of a pesticide ai, we make the following recommendations relating to the development of a regulatory framework for nanopesticides. These are by no means exhaustive but merely indicative of different elements of an ERA (e.g., characterization, environmental fate and exposure, effect) required for an appropriate regulatory response for nanopesticides.
- A clear definition of what is/what is not a nanopesticide is needed for regulatory purposes. Definitions developed recently for nanomaterials in general may help, but these typically consider the size dimensions ranging between 1 and 100 nm and are only partially applicable to nanopesticides. Emerging pesticide nanoformulations are not only increasingly complex and biologically active but may also exhibit a potential change in the physicochemical properties and/or biological effects at a size range that is larger than the nanoscale (>100 nm). The need for inclusion of additional parameters[60] and larger size limits, for example, up to 1000 nm, has also been proposed for some nanomaterials.[61,62]
- Tools and techniques to characterize properties (such as primary particle shape, size range, surface properties) of complex formulations of nanopesticides are lacking. Without adequate analytical tools, regulatory requirements for robust data for risk assessment cannot be generated. Current ecotoxicological assessments have limited relevance due to a poor ability to characterize ENPs in complex environmental compartments at present, although this area is developing quickly. Despite greater attention to inorganic ENPs (compared to organic), detection and quantification of nanometal and metal oxides in complex matrices (e.g., formulations, environmental media) at environmentally realistic concentrations remain challenging. Nanopesticides are more complex products by design (Table 1) and therefore pose greater challenges to analysts. However, experience gained in the field of nanomedicine may be helpful for characterizing nanopesticides and should be integrated into the nanopesticide regulatory framework.
- Little advancement in exposure and effect modeling has so far occurred on ENPs and especially nanopesticides. Current models fail to take into consideration material sizes, shapes, functionalization, and surface properties and alterations in both ENPs and environmental matrices during exposure assessment.[63] Exposure models that differentiate the free and nanocomplex and the ENP size distribution and other toxicologically/fate relevant properties over time need to be developed as a matter of priority. Until we better understand the relationship between ENP properties and toxicity, we can only resort to toxicity testing case by case under conditions similar to those in the environment. As this may quickly become infeasible, sound ERA requires first the establishment of property−toxicity relationships based on comprehensive empirical data.
- Given the added uncertainty in risk assessment (such as that associated with detection and quantification, characterization, and exposure assessment) compared to "conventional" pesticides, the definition as well as the regulatory framework should consciously be made more adaptive and responsive to advancements in science and knowledge on nanopesticides. A pragmatic approach is to focus on understanding the persistence of the nano−ai complex and whether the nano−ai complex alters the activity of the ai relative to the conventional formulation as described here for reformulated pesticides. However, where the ENP itself is the ai, additional challenges remain.

Evidence-based decision-making is an expectation of contemporary regulators and demands that decisions are supported by science, and precaution is used where evidence is incomplete. To this end, regulators are warranted in erring on the side of caution until such time as the properties and behavior of nanopesticides are better understood. This may curtail the realization of full potential economic and environmental benefits of this rapidly expanding technology. It is also important that the product developer is aware that the nanoformulation of an already approved pesticide will require a separate ERA.

ACKNOWLEDGMENTS

This paper was developed during a workshop (York, May 17−18, 2013) as a part of an IUPAC project on "Guiding principles to facilitate a harmonized ecological risk assessment framework for nanopesticides in the environment". Financial support to the project by IUPAC and the Australian Pesticides and Veterinary Medicines Authority (APVMA) is gratefully acknowledged. We thank the University of York for hosting the workshop.

ABBREVIATIONS USED

ai	active ingredient
APVMA	Australian Pesticides and Veterinary Medicines Authority

BCF	bioconcentration factor
DCS	differential centrifugal sedimentation
DLS	dynamic light scattering
DT_{50}	dissipation half-life
EC	European Commission
EC50	half-maximal effective concentration
EFSA	European Food Safety Authority
ENP	engineered nanoparticle
ERA	Environmental Risk Assessment
EU	European Union
FDA	U.S. Food and Drug Administration
FIFRA-SAP	Federal Insecticide, Fungicide, and Rodenticide Act−Scientific Advisory Panel (USA)
FFF	field flow fractionation
FOCUS	forum for the co-ordination of pesticide fate models and their use
HDC	hydrodynamic chromatography
IBMs	individual-based models
ICPMS	inductive coupled plasma mass spectrometry
IUPAC	International Union of Pure and Applied Chemistry
K_d	soil/water partitioning coefficient; sorption coefficient
K_{oc}	soil organic carbon:water partitioning coefficient
K_{ow}	octanol/water partition coefficient
NOEC	no observed effect concentration
NTA	nanoparticle tracking analysis
MACRO	model designed to incorporate preferential flow
OECD	Organisation for Economic Co-operation and Development
PBT	persistent, bioaccumulative and toxic
PEC	predicted environmental concentration
PSD	particle size distribution
SEM	scanning electron microscopy
spICPMS	single-particle inductive coupled plasma mass spectrometry
SSD	species sensitivity distribution
$t_{1/2}$	decay half-life
TK/TD	toxicokinetics/toxicodynamics
TEM	transmission electron microscopy
USL	unstirred layer

Rapid HPLC-MS Method for the Simultaneous Determination of Tea Catechins and Folates

Monica Araya-Farias,[†,‡,§] Alain Gaudreau,[†,‡] Elodie Rozoy,[†,‡] and Laurent Bazinet*[,†,‡]

[†]Institute of Nutrition and Functional Foods (INAF) and [‡]Department of Food Sciences and Nutrition, Laval University, Quebec, QC, Canada G1V 0A6

ABSTRACT: An effective and rapid HPLC-MS method for the simultaneous separation of the eight most abundant tea catechins, gallic acid, and caffeine was developed. These compounds were rapidly separated within 9 min by a linear gradient elution using a Zorbax SB-C_{18} packed with sub 2 μm particles. This methodology did not require preparative and semipreparative HPLC steps. In fact, diluted tea samples can be easily analyzed using HPLC-MS as described in this study. The use of mass spectrometry detection for quantification of catechins ensured a higher specificity of the method. The percent relative standard deviation was generally lower than 4 and 7% for most of the compounds tested in tea drinks and tea extracts, respectively. Furthermore, the method provided excellent resolution for folate determination alone or in combination with catechins. To date, no HPLC method able to discriminate catechins and folates in a quick analysis has been reported in the literature.

KEYWORDS: *green tea, catechins, folates, HPLC, mass spectrometry*

INTRODUCTION

Green tea, a nonfermented tea, has become one of the most widely consumed beverages in the world. The increasing consumption of green tea can be explained by the health effects of some of its constituents. Indeed, green tea is rich in flavonoids (300−400 mg/g) and an excellent source of catechins, up to 20−30% of the green tea dry weight.[1,2] The eight most abundant catechins in tea are (−)-gallocatechin, (−)-epigallocatechin, (+)-catechin, (−)-epicatechin, (−)-epigallocatechin gallate, (−)-gallocatechin gallate, (−)-epicatechin gallate, and (−)-catechin gallate. The principal tea catechins are known for their strong antioxidant activity and their health benefits, including antiviral, antiallergic, anti-inflammatory, and anticariogenic properties.[3,4] In addition to tea catechins, green tea contains other polyphenols such as gallic acid, the main tea polyphenolic acid, and certain amounts of alkaloids such as caffeine. Although caffeine is well-known for its stimulatory effect, it has been reported that caffeine also exerts beneficial effects on human health including cardiovascular, gastrointestinal, and respiratory effects.[5] Caffeine affects also the taste of tea.[6] The composition of green tea catechins, phenolic acids, and caffeine varies according to variety, climate, horticultural conditions, and mainly in technologies applied during extraction, concentration, and storage.

Folates play a critical role in the reduction of neural tube defects in newborns and the risk of cardiovascular diseases.[7] Folic acid (FA) is not a significant natural form of folate. However, FA is synthetically produced and used as a dietary supplement because it is the most stable form of this vitamin. L-5-Methyltetrahydrofolic acid (L-5-MTHF) is a natural form of folate, and it is more bioactive than folic acid. However, it has limited stability especially when exposed to oxygen, light, or high temperatures.[8] Recently, research was focused on finding ways to stabilize this molecule in food matrices to reduce or replace the use of synthetic FA in fortified foods.[9,10] Rozoy et al.[10] showed that degradation of L-5-MTHF could be controlled by the addition of ascorbic acid. Some studies have proven that the antioxidant capacity of (−)-epigallocatechin gallate exceeds the effect of ascorbic acid at least 100 times.[11] Thus, the use of molecules with strong antioxidant activity such as catechins could be an interesting alternative to protect L-5-MTHF against oxidation.

To date, high-performance liquid chromatography (HPLC) remains the most used technique for the determination of catechins. Traditional HPLC coupled with ultraviolet (UV), photodiode array (DAD), electrochemical detection, and mass spectrometry (MS) are among the most employed methods in the identification of catechins.[12−20] In general, the analysis time is relatively long, 40−105 min, and between 5 and 10 compounds of interest can be simultaneously separated. From a quantitative point of view, fast HPLC approaches have not been extensively investigated, and only a few works have reported a simultaneous separation of all tea catechins in a relatively short time (within 25 min).[21−24] Most recently, ultrahigh-pressure liquid chromatography (UHPLC) has shown a considerable potential in terms of speed and separation efficiency.[25,26] However, UHPLC is still relatively new and requires specialized equipment able to withstand pressures of 1000 bar. Up to now, only a few applications of UHPLC have been reported for the analysis of catechins in tea samples.[27−30]

To enhance chromatographic performances in terms of efficiency and rapidity, several strategies can be implemented. An interesting approach would be to evaluate the use of columns packed with sub 2 μm particles. As described 30 years ago by Knox, Martin, and other authors, the use of short columns packed with small particles induces an increase in efficiency, optimal velocity, and mass transfer.[31−34]

The aim of this study was to develop an efficient and rapid HPLC method for the simultaneous separation of catechins, gallic acid, and caffeine in tea samples. To evaluate the resolution in other complex matrices, the method was applied to the determination of folates. Chromatographic analyses of L-5-MTHF in combination with green tea enriched extracts were also performed to evaluate the analytic performance of the method proposed in a complex solution. To perform faster analysis, a conventional HPLC system was equipped with a Zorbax Stable Bond (SB) C_{18} analytical column (4.6 × 50 mm) packed with 1.8 μm particles. HPLC was coupled with MS to attain sufficient sensitivity and selectivity for the identification of catechins, folates, and other constituents of tea samples. To the best of our knowledge, there is no method published yet on the simultaneous separation of catechins and folates.

MATERIALS AND METHODS

Chemical and Standards Preparation. Standards were purchased from Sigma Chemical Co. (St. Louis, MO, USA): gallic acid (GA, 98%), (−)-gallocatechin (GC, 98%), (−)-epigallocatechin (EGC, 98%), (+)-catechin (C, 98%), (−)-epicatechin (EC, 98%), (−)-epigallocatechin-3-gallate (EGCG, 95%), (−)-gallocatechin gallate (GCG, 98%), (−)-epicatechin gallate (ECG, 98%), (−)-catechin gallate (CG, 98%), and caffeine (CAF, 99%). HPLC grade water was obtained using a Siemens Purelab Ultra Water-Purification System (Siemens, USA). HPLC grade acetonitrile and formic acid were purchased from VWR International (Mississauga, ON, Canada) and Sigma-Aldrich (St. Louis, MO, USA) respectively.

The stock solutions were prepared by dissolving 5−10 mg of each standard compound in 10 mL of HPLC grade water/formic acid (99.9:0.1 v/v). Each stock solution was then used for the preparation of a mix of standards. Serial dilutions were then prepared with formic acid solution to produce calibration curves at different concentrations ranging between 3 and 50 μg/mL. All standard solutions were filtered through 0.2 μm PVDF syringe filters. A 10 μL aliquot of solutions was injected onto HPLC.

HPLC-MS Analysis. The HPLC UV-MS analyses were performed on an Agilent 1100 series (Santa Clara, CA, USA) HPLC system equipped with an Agilent diode array UV−vis detector (Agilent G1315 DAD), a vacuum degasser, a binary pump delivery (Agilent G1312A), a refrigerated autosampler (Agilent G1329A), and an HP mass spectrometer detector (MSD, model G1948B). Integration and data processing were performed by Chemstation software (LC/MSD Chemstation B.01.03 SR1). An Agilent Zorbax SB-C_{18} (4.6 mm id × 50 mm, 1.8 μm) column with a precolumn filter was used. HPLC UV-MS analyses were carried out using mobile phases consisting of 0.2% formic acid in water (A) and 0.1% formic acid in acetonitrile (B) (HPLC grade, EMD Chemicals Inc., Gibbstown, NJ, USA). The linear gradient elution system was as follows: 0−8 min, 0−5% (v/v) of B; 8−10 min, 5−25% (v/v) of B; 10−17 min, 25−100% (v/v) of B; and 17−23 min, 100−5% (v/v) of B, at a flow rate of 1 mL/min. The quantification of catechins by UV-DAD was performed at 230 nm. The column temperature was maintained at 25 °C, and the injection volume was 10 μL.

The same column of HPLC-DAD was used for analyses by MS. Mass spectra of catechins were recorded in the positive ionization mode using an electrospray (API-ES) ionizing source with nitrogen as drying gas. Spray chamber parameters were as follows: capillary potential, 3000 V; gas temperature, 350 °C; drying gas flow, 13 L/min; nebulizer pressure, 60 psi. Quantitative analysis by MS was carried out in the scanning mode, scan range being m/z 150−1000, setting the fragmentor value at 70 V with a molecular ion $[M+H]^+$ for each catechin chosen as the most abundant and representative signal.

Identification of compounds by HPLC-MS analysis was carried out by comparing retention times and mass spectra of the unknown peaks to those of the standards.

Preparation of Green Tea Samples. *Enriched Green Tea Drink.* An EGCG-enriched tea drink was prepared in our laboratory according to the procedure developed by Bazinet et al.[35] The green tea used in this experiment was a commercially available and Japanese green tea obtained from local retailer. Before being used, the green tea was stored in vacuum bags at room temperature in a dark and dry space. The EGCG-enriched tea drink was produced at a volume of 100 L, in conditions and with unit operations similar to the ones met in the food industry for the production of low-acid beverages. Dry leaves (3.5 kg) were brewed twice in 100 L of water. The first brewing step was carried out at 30 ± 2 °C for 10 min using a stainless steel double-jacket heated reservoir. The infusion was filtered to separate the leaves and to collect the filtrate. The filtered tea leaves were brewed again in 100 L of water at 80 ± 2 °C for1 h. The green tea leaves were squeezed and discarded. The second filtrate was adjusted to a pH value of 3.5 by lemon juice addition. The ECGC-enriched green tea was then pasteurized and aseptically bottled and stored at 4 °C.

Enriched Green Tea Extract. An enriched freeze-dried tea extract was prepared in our laboratory using the second filtrate, which was prepared according to the procedure previously cited. This extract was not adjusted to pH 3.5. The extracts were frozen at −30 °C for 48 h and lyophilized at 25 °C for 72 h (Virtis, Gardiner, NY, USA). For the analyses, 400 mg of extract was diluted to 25 mL with HPLC grade water. All prepared tea samples were filtered through 0.2 μm PVDF syringe filters. A 10 μL aliquot of this tea sample was injected onto HPLC. All tea samples were prepared and analyzed in triplicate for a total of nine analyses per sample.

Preparation of Folates. Solutions of folic acid and L-5-MTHF were prepared separately in CHES−HEPES buffer at a concentration of 227 μM. On the other hand, solutions of 1 mM L-5-MTHF with an enriched green extract (at 400 mg/L) were prepared in Britton−Robinson buffer[10] and analyzed by HPLC-MS.

Data Analysis. Calibration curves were done using standard solutions, and linearity was evaluated over six calibration points with three measurements for each calibration point. Detection limits (LOD) and quantitation limits (LOQ) were determined according to the ICH Harmonized Tripartite Guideline (Validation of Analytical Procedures: Text and Methodology Q_2 (R_1)).[36]

Repeatability of the method was calculated in terms of percent relative standard deviation (% RSD) by performing HPLC analysis on aliquots of each sample in triplicate on three consecutive days. Relative standard deviation (RSD) was defined as sample standard deviation divided by sample mean, multiplied by 100%.

RESULTS AND DISCUSSION

Description of Developing Steps To Improve the Methodology. A reversed-phase HPLC method coupled with mass spectrometry was developed. Two mobile phases, one containing HPLC grade water and the other containing acetonitrile, were tested. The formic acid was added to both mobile phases. The presence of acid in the mobile phases is essential to attain a complete separation of catechins.[17] Moreover, it was reported that catechins are most stable in acidic conditions.[37] Two different concentrations of formic acid (0.1 and 0.2%) were tested in the present study. Although a good separation was achieved with 0.1% formic acid in both mobile phases, improved peak shapes were obtained with the inclusion of 2% formic acid in the water mobile phase. Another reason for the use of the formic acid was its compatibility with mass spectrometry. The elution gradient program was described earlier.

Different absorption wavelengths have been reported in the literature for the determination of tea catechins, varying from 210 to 280 nm.[12−20] In our study, all catechins, gallic acid, and caffeine exhibited maximun absorbance at 210 and 230 nm. The absorbances at 210 nm were slightly larger than those at 230 nm, but the baseline shifts of chromatograms were also increased. Folates were found to have maximum absorbances at 280−290 nm, as was already mentioned in the literature.[38,39]

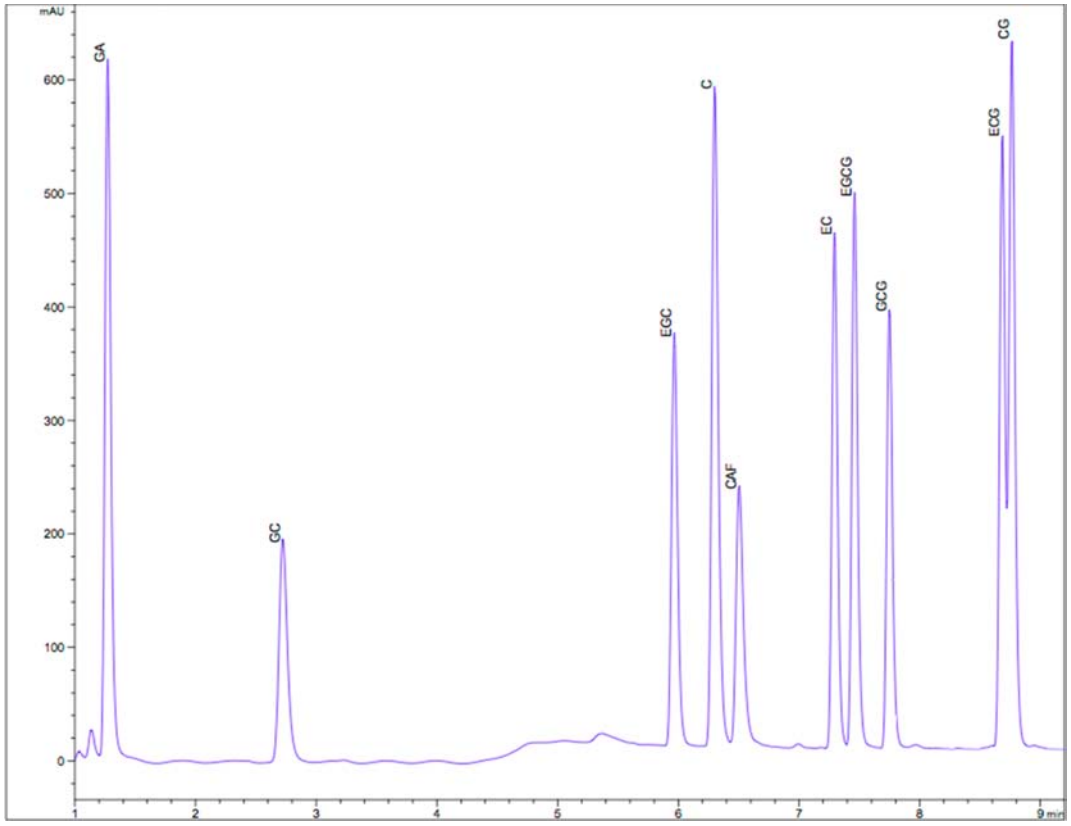

Figure 1. Chromatogram of mixed standards of GA, catechins, and CAF recorded by UV-DAD at 230 nm. GA, gallic acid; GC, gallocatechin; EGC, epigallocatechin; C, catechin; CAF, caffeine; EC, epicatechin; EGCG, epigallocatechin gallate; GCG, gallocatechin gallate; ECG, epicatechin gallate; CG, catechin gallate.

However, a strong absorption was also observed at the shortest wavelength (230 nm). The detector wavelength was then set at 230 nm as the best compromise to reach maximun absorbance for all compounds of interest.

To increase separation efficiency and speed of analysis, the HPLC system was equipped with a Zorbax SB-C_{18} column (4.6 mm id × 50 mm) packed with 1.8 μm silica-based particles. The use of small particles is one of the best solutions to improve chromatographic performances.[31−34] Moreover, good efficiency can be maintained with a short column and a high flow rate. On the other hand, the special and ultrapure silica support of the Zorbax SB-C_{18} column is designed to reduce or eliminate undesirable interactions between analytes and the silica surface, thereby providing best separation of all compounds. It is especially suited in applications that use high-sensitivity detectors such as mass spectrometers. That was another reason for the use of this specific column.

The performance of the Zorbax SB-C_{18} 1.8 μm column was compared to that of a YMC-Pack ODS-AM C_{18} 5 μm column, which has already been used for the determination of catechins. Both columns were tested under the same conditions. The Zorbax column gave good separation for all of the analytes within 9 min (Figure 1). However, the YMC-Pack ODS-AM column did not achieve a satisfactory resolution of EC, EGCG, ECG, and CG in the water/acetonitrile/formic acid system, and the separation time was generally long (47 min) (data not shown). In this context, the analysis time and solvent consumption were decreased by 5.2 times using the Zorbax SB-C_{18} column. The performance of the YMC-Pack ODS-AM column was better when the trifluoroacetic acid was added to the mobile phases as reported in our previous work.[19]

The critical step in the quantification of catechins, phenolic acids, and caffeine in tea by HPLC methods is the sample extraction. The extraction method must enable complete extraction of the compounds of interest without chemical modification or degradation. At present, a single extraction step with acetonitrile and methanol has been widely used to quantify polyphenols in tea.[14,16,24,40] However, our method allows the quantification of catechins in tea without any extraction with solvents. In fact, after the preparation of tea samples in boiling water, the samples needed only to be diluted and filtered prior to the HPLC analysis. Hu et al.[24] also analyzed catechins in tea after hot water brewing, but their method needed a semipreparative/preparative HPLC step prior to the identification of catechins by analytical HPLC.

Mass spectra of tea catechins was recorded in the 40−120 V fragmentor range to determine the highest sensitivity for each molecule. A fragmentor value of 70 V was chosen as the best compromise among all ions detected and applied to the tea samples. The method was tested in negative and positive ionization modes, but a better sensitivity and a significant improvement in signal-to-noise response were achieved when the mass spectrometer was operated in positive ionization mode. Pelillo et al.[22] also reported a better signal response when HPLC-MS analysis of green tea extracts was obtained with positive ion detection.

HPLC-MS Analysis and Peak Identification. The typical chromatogram of mixed standards of GA, catechins, and CAF is shown in Figure 1. For this separation, the generated back

GA, gallic acid; GC, gallocatechin; EGC, epigallocatechin; C, catechin; CAF, caffeine; EC, epicatechin; EGCG, epigallocatechin gallate; GCG, gallocatechin gallate; ECG, epicatechin gallate; CG, catechin gallate.

pressure was around 220 MPa, which is very compatible with conventional HPLC system (HPLC standard pressure, up to 400 bar, 40 MPa).

The principal advantage of the here-developed HPLC-MS method is the high baseline resolution of 10 compounds in a very short time with an excellent separation quality for GA and CAF. The elution order was GA, GC, ECG, C, CAF, EC, EGCG, CGC, ECG, and CG. These 10 compounds were successfully separated within 9 min by linear gradient elution of formic acid solution and acetonitrile (Figure 1). Most HPLC methods for the separation of tea catechins are carried out on C_{18} 5 μm columns (4.6 mm id × 250 mm or 4.6 mm id × 150 mm), and 5−10 compounds can be simultaneously separated in 40−105 min.[12−20] Using a Zorbax SB-C_{18} sub 2 μm column, the HPLC analyses could be performed 4.4−12 times faster than those reported for a C_{18} 5 μm column, and because the pressure was only 220 MPa and solvent consumption 9 mL by analysis, this method is an excellent option for the determination of catechins.

Catechin detection was linear over the ranges tested (3−50 μg/mL) with coefficients of determination (R^2) between 0.9998 and 1.0000. LODs and LOQs for most standards were in the range of 0.5−1.0 and 1.0−4.0 μg, respectively. CG had the highest LOD at 1.342 μg, and C had the lowest LOD at 0.450 μg. The results are summarized in Table 1.

The retention time and MS spectral data of standards are shown in Table 1. The results are in agreement with the values reported in the literature.[22−24,40] In Figure 2 chromatograms of standards recorded by both UV and MSD detectors are compared. As shown in Figure 2, EGC and CG exhibited different retention times, and two peaks can be easily differentiated in UV spectra. However, EGC and CG had identical $[M+H]^+$ ions at 443.08, and only one peak (with a shoulder) can be observed in MS spectra. A typical mass spectrum of EGCG is shown in Figure 3. The mass spectra

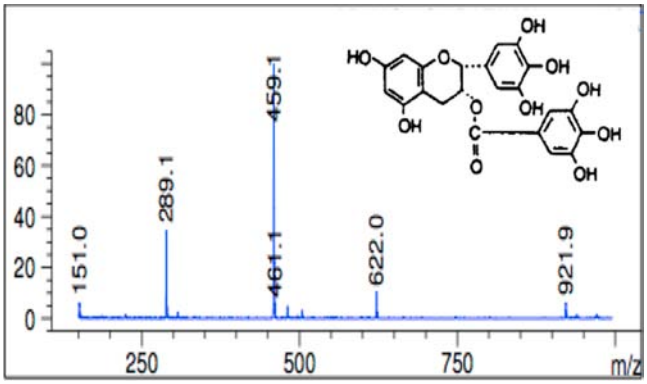

Figure 3. Mass spectrum of EGCG recorded by API-ES+ with the fragmentor set at 70 V.

showed a characteristic product ion of EGCG (m/z 459.1 is the $[M+H]^+$ion). Similar mass spectra were reported in the literature.[22] The mass spectrum contains several extra signals at m/z 151.1, 289.1, 622, 0 and 921.1. The m/z signal at 289.1 would be a typical fragment ion detected in the mass spectrum of catechins.[40]

To summarize the information given above, separation and identification of green tea compounds by HPLC are typically slow, requiring complex and time-consuming gradients.[12−20,41−,43] To date, only a few methods have allowed the simultaneous determination of the main catechins, gallic acid, and caffeine in <25 min. In the first study, four major catechins (ECGC, EGC, ECG, and EC), GA, and CAF were successfully separated within 20 min.[14] However, this study needed multiple extractions with aqueous methanol solutions. In the second study, 14 tea compounds including 8 catechins, GA, and CAF were separated within 15 min by a linear gradient elution of formic acid and methanol.[24] However, the method was focused principally on the preparation and purification of methylated catechins; thus, several steps of isolation and semipreparative HPLC were required. Furthermore, the time for cleaning and column conditioning was not mentioned. Although those methods are rapid, the preparation of samples may become a difficult task due to the numerous steps.

To our knowledge, only one chromatographic method based on the utilization of a Zorbax SB-C_{18} sub 2 μm column was developed for the analysis of phenolic compounds including tea catechins.[30] The analysis time was 12 min, and 6 standards (GC, EGCG, EC, GC, EC, CG) were separated with satisfactory resolution. However, there was no resolution for standards EGC and C. In the matrix of green tea infusion, the resolution was more critical, and only the peaks of GCG and ECG had good response and were sufficiently separated.

Separation and Identification of Catechins in Tea Samples. Identification of peaks of tea samples was carried out by comparing retention times and mass spectra of the standards and data in the literature (Tables 2 and 3). These results are in good agreement with catechin standards. The typical HPLC-UV profiles of enriched tea drink and green tea extracts are shown in Figures 4 and 5, respectively. In both tea samples we also observed a peak eluting at 8.4 min (not identified on the chromatogram) that could correspond to a second peak of GC.

The catechin contents in enriched green tea drink are shown in Table 2. The results obtained indicate that EGCG was in highest concentration (660.9 mg/L) in green tea drinks, whereas GA (3.0 mg/L) was the lowest. CG was not quantified due to its low level. As expected, calculated amounts of EGCG (the most interesting catechin compound) were higher than those of similar tea infusions or beverages[15] because we produced an EGCG-enriched green tea drink. Chen et al.[44] reported that one canned or bottled tea drink (250 mL) contained less green tea catechins (3−60 mg) than one cup of conventional brewed green tea drink (400−500 mg). The content of catechins in tea samples can vary depending on the conditions and technology used for the extraction and storage.[22] In terms of quantification, % RSD values obtained were quite low, ranging from 0.8 to 3.5%. The relatively low % RSD for GA, most catechins, and CAF indicated that this

method is repeatable and reproducible. Moreover, % RSD of HPLC retention time ranged from 0.0 to 1.3%.

The catechin contents of green tea extracts were 2−6 times higher than those of green tea drink (Table 3) (if compared on a dry basis). However, the % RSDs were slightly higher than those obtained in green tea drink samples. Generally, compounds with lower response (except ECG) had higher % RSD.

Recently, UHPLC-UV has shown considerable potential for the determination of tea compounds. One of the main advantages of UHPLC is related to the possibility of attaining either ultrafast or high resolving power separations.[27] In that study, they obtained an ultrafast and high-resolution UHPLC separation of a mixture of eight standards within 3−23 min depending on column length. However, when real tea samples are used, the identification of catechins is critical and the proposed method does not present enough resolving power to easily discriminate catechins contained in tea extracts. In this context, our method provides an excellent selectivity and resolution for catechins determination and quantification in real tea samples as shown in Figure 4 for enriched drink tea and in Figure 5 for green tea extract.

Application to Folate Determination. As demonstrated above, the method provides excellent separation and resolution

dx.doi.org/10.1021/jf4053258 | J. Agric. Food Chem. 2014, 62, 4241−4250

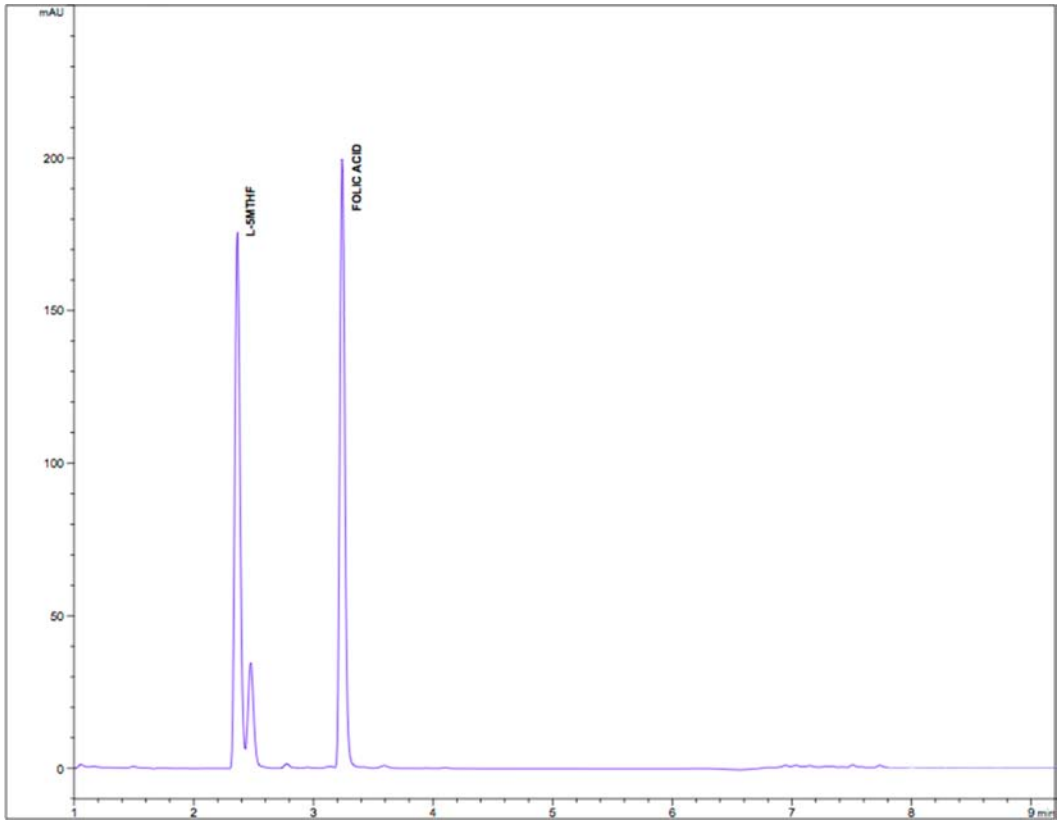

Figure 6. Chromatograms of folic acid and L-5MTHF recorded by UV-DAD detector at 230 nm.

dx.doi.org/10.1021/jf4053258 | *J. Agric. Food Chem.* 2014, 62, 4241−4250

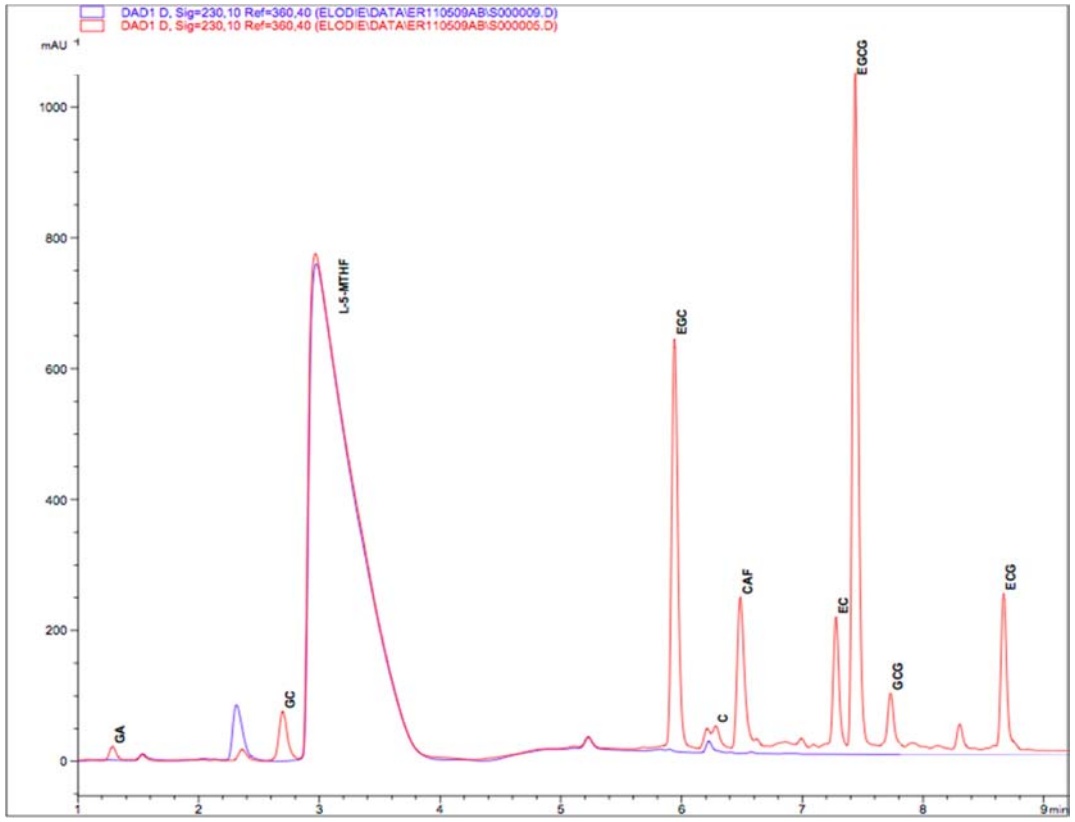

Figure 7. Chromatograms of L-5MTHF alone (blue line) or in combination with a green tea extract (red line) recorded by UV-DAD detector at 230 nm. GA, gallic acid; GC, gallocatechin; EGC, epigallocatechin; C, catechin; CAF, caffeine; EC, epicatechin; EGCG, epigallocatechin gallate; GCG, gallocatechin gallate; ECG, epicatechin gallate; CG, catechin gallate.

when applied in tea samples. To evaluate the resolution in other complex matrices, the method was thus applied to the determination of folates either alone or in combination with catechins. A typical chromatogram of folic acid and its natural form L-5MTHF is shown in Figure 6. The retention times were 2.36 and 3.44 min for L-5-MTHF (nonoxidized form) and folic acid, respectively. The small peak eluting at 2.48 min would correspond to an oxidation peak of L-5MTHF.[9] To illustrate the complexity of the matrix, L-5MTHF was mixed with green tea extract in Britton–Robinson buffer. The corresponding profiles are presented in Figure 7. The difference in the retention time for L-5MTHF after being mixed with catechins would be due to different buffers used during the analysis (CHES–HEPES vs Britton–Robinson). It appears from these figures that our method presents enough resolving power to discriminate folates from catechins in a very short time. Thus, it clearly demonstrated the potential of our HPLC-MS to provide qualitative and quantitative determinations when dealing with complex matrices.

Some important conclusions can be drawn from this study. First, we have developed a fast and simple method to determine catechins and catechin derivatives in tea samples. The chromatographic performances in terms of efficiency and rapidity were improved using a sub 2 μm column. In fact, 10 compounds from green tea were rapidly separated within 9 min with an excellent resolution. It represented roughly a 4.4–12-fold reduction in total analysis time (9 versus 40–105 min) from existing analytical methods for the analysis of catechins. Considering the lower solvent consumption (9 mL by analysis), our method was not only faster but also more ecological. The efficiency of the method was confirmed by analyzing complex matrices such as tea extracts. This represents one of the main advantages of this method because existing analytical methods do not present enough resolving power when dealing with real tea samples. Calibration data and % RSD demonstrate that this method is repeatable and reproducible. Finally, the proposed method was applied to the determination of folates maintaining excellent selectivity and sensitivity. Furthermore, the method provided excellent resolution even when the folates were mixed with the catechins. To our knowledge, no HPLC-MS method able to realize the simultaneous separation of antioxidants and a nutrient susceptible to oxidation has been yet published in the literature.

Re-evaluation of the 2,2-Diphenyl-1-picrylhydrazyl Free Radical (DPPH) Assay for Antioxidant Activity

J. Xie and K. M. Schaich*

Department of Food Science, Rutgers University, 65 Dudley Road, New Brunswick, New Jersey 08901, United States

ABSTRACT: Kinetics and stoichiometry of reactions between the 2,2-diphenyl-1-picrylhydrazyl (DPPH) stable radical and 25 antioxidant compounds with different structure, molecular weight, number of −OH groups, and redox potential were investigated by recording the loss of DPPH$^{\bullet}$ absorbance at 515 nm continuously for 10 min. A series of antioxidant concentrations was tested to determine linear response ranges and reaction saturation points. The primary feature distinguishing antioxidant activity—rate of initial reaction (<30 s)—was controlled by whether the dominant antioxidant mechanism was electron (very fast) or hydrogen atom (slow) transfer and by impairment of steric accessibility to the DPPH radical site by bulky ring adducts and multiple phenolic rings. Results raise serious questions regarding application of the DPPH assay for ranking antioxidants and natural extracts and suggest possible redirection of this assay to distinguish active reaction mechanisms by comparing reactions rates and patterns in different solvents and in 50% water/methanol mixtures at different pH values.

KEYWORDS: *antiradical activity, phenolic compounds, hydrogen atom transfer (HAT), single electron transfer (SET), DPPH, radical quenching kinetics, radical quenching capacity*

INTRODUCTION

The stable radical 2,2-diphenyl-1-picrylhydrazyl (DPPH$^{\bullet}$) (Figure 1) was first proposed for quantitating antioxidant (mostly phenol) content more than 50 years ago.[1,2] (Throughout this paper, DPPH denotes the stable radical DPPH$^{\bullet}$.) Reaction with DPPH was soon adapted for measuring radical quenching kinetics,[3,4] and since then, numerous variations in methods and time for following the reaction as well as for calculating relative antioxidant action by reaction stoichiometry have evolved.[5−10] The DPPH assay is simple and can be run in the most rudimentary laboratories; hence, it has seen extensive applications. Nevertheless, lack of standardization in sample preparation, reaction conditions, analytical protocols, and expression of antioxidant action make it difficult to compare results between laboratories.[11,12] To address this problem, assay protocols are currently being standardized by international bodies,[13] yet questions about which procedures should be standardized remain.

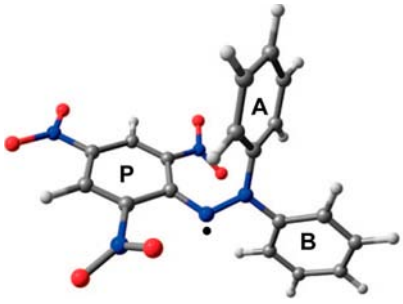

Figure 1. Three-dimensional structure of DPPH. Adapted from ref 14. Copyright 2008. American Chemical Society. Constituent atoms: oxygen (red), nitrogen (blue), carbon (gray), and hydrogen (white). The view is approximately perpendicular to the plane defined by the hydrazyl group N atoms and C-1 of the picryl ring (P). The radical site (N$^{\bullet}$) is protected by nitro groups oriented above and below it, by an *ortho* H atom on each of the phenyl rings (A and B), and by twisting of the rings to create a cage around N$^{\bullet}$.[14,15]

Largely ignored studies of DPPH reaction chemistry have shown that absolute and relative concentrations of DPPH and test antioxidants,[8] solvent polarity and hydrogen bonding strength,[2,16−19] pH,[11] temperature,[3] and oxygen all affect the rate and pathways of DPPH reaction with antioxidants. DPPH can be quenched by both electron[3] and hydrogen atom transfer[4] in at least four different sequences.[14] Solvent and pH, in particular, strongly influence the dominant mechanism and can screen for compounds acting by one specific mechanism or both. For example, hydrogen bonding solvents repress hydrogen atom transfer and favor electron transfer,[17−19] so compounds that are strongly active in hydrogen atom transfer appear to be slower reacting in the methanol and ethanol commonly used for the assay. Similarly, activity of compounds that quench primarily by electron transfer is strongly pH-dependent, being slowest in acid and increasing with pH as ionization of the phenolic group is facilitated.[20] Apparent reactivity of compounds with the capability of mixed quenching mechanisms thus can change markedly with reaction conditions.

Time and method of recording the reaction, as well as the reporting mode, determine which aspects of the reaction are observed and interpreted. Reporting mode is particularly problematic because many methods currently used for rating radical quenching activity yield numbers that allow comparison but provide little or no chemical information about the test antioxidants. Reporting methods such as IC_{50}[21] or EC_{50}

(antioxidant concentration required to reduce 50% of the DPPH present),[5,10] antioxidant efficiency (AE = $1/EC_{50}\cdot T_{EC50}$)[22,23] (where T_{EC50} is the time needed to reach the steady state at EC_{50} concentration), and % DPPH reduction[24,25] provide values from which stoichiometry can be derived (moles of DPPH reduced per mole antioxidant) but ignore reaction kinetics. Expression of antioxidant activity as μmol equivalents of standards such as vitamin C[26] or Trolox[23] ignores chemistry altogether and just ranks compounds, assuming all act by the same mechanisms.

There is a major flaw in stoichiometric approaches if results are to be used to predict antioxidant activity in living tissues or in foods. DPPH is a stable radical that persists for hours in solution, while the radicals most active in real materials—hydroxyl radicals ($HO^{\bullet}$), superoxide anion ($O_2^{-\bullet}$), nitric oxide ($NO^{\bullet}$), and lipid peroxyl ($LOO^{\bullet}$) and alkoxyl ($LO^{\bullet}$) radicals—have lifetimes on the order of milliseconds to seconds (Table 1). With such short radical lifetimes, the number of reactive groups per antioxidant is less important than how fast each group can quench the radicals present.

Table 1. Lifetimes of Radicals Commonly Active in Living Tissues and in Foods[a]

radical (10^{-3} M, 37 °C)	lifetime
$HO^{\bullet}$	10^{-9} s
$L^{\bullet}$ (lipid alkyl)	10^{-8} s
$RO^{\bullet}$	10^{-6} s
$AnOO^{\bullet}$ (arachidonic acid)	10^{-5} s
$ROO^{\bullet}$	10 s

As will be emphasized in this article, many compounds have a very fast initial reaction with DPPH that is missed in the conventional practice of monitoring absorbance only after reaching steady-state (many minutes to hours). Papariello et al.[2] proposed that this initial reaction is the only relevant period for reactivity comparison since the reaction is second order, dependent on concentrations of DPPH as well as a phenolic compound, and the reaction product, $DPPH_2$, inhibits the phenol reaction. Some DPPH studies have measured reaction kinetics but not connected the data to antioxidant structure or other characteristics. In a key paper that has provided the basis for many current assays, Brand-Williams et al.[5] generated reaction response curves by recording DPPH absorbance at 0 and 1 min, then every 15 min until a steady-state was reached, testing a range of antioxidant concentrations. These authors actually recorded differences in reaction rates, yet ignored the important kinetic information and reported only values that express stoichiometry. Allowing the reaction to run to "completion" (i.e., plateau), as commonly recommended to track slow reacting compounds,[28] regardless of the time required, virtually guarantees that the assay will reflect stoichiometry rather than kinetics and will report radical quenching proportional to the number of phenoxyl groups, i.e., two electrons or two DPPH radicals reduced per OH.

Other studies have recorded full reaction curves, calculated some kinetic value, and shown distinctively different patterns in reaction kinetics for different phenolic compounds yet also failed to apply and utilize the kinetic information. Sanchez-Moreno[29] observed that initial fast reactions were complete in <30 s and that the main part of moderate rate reactions were complete in <2 min for many phenolic compounds, yet ignored this information and instead determined kinetics as the time required to reduce DPPH by 50% (TEC_{50}). Villano et al.[9] combined EC_{50} values and kinetics into an antioxidant efficiency term for reactions of polyphenols with DPPH. However, their results were compromised by ignoring the initial rapid reaction occurring within seconds (obvious in reaction curves) and, instead, calculating rates from the slow reaction extending over 60 to 180 min. Both studies emphasized stoichiometric analyses in comparing antioxidants.

In contrast, Ingold and colleagues[14,17,18,30−35] have compiled an impressive body of work specifically utilizing DPPH kinetics in initial fast reactions to distinguish radical quenching mechanisms of various antioxidants, i.e., hydrogen atom transfer, electron transfer, combinations of the two, and sequences of action, and to determine solvent effects on reaction mechanisms and kinetics.

As part of a larger project studying mechanisms and standardizing procedures in antioxidant activity assays, this research reinvestigated the chemistry and reaction conditions of the DPPH assay to elucidate active reaction mechanisms, identify factors that control reactions and distinguish antioxidants, optimize methodology, provide a basis for standardization, and determine appropriate applications. Our investigations showed that most antioxidant reactions were much faster than the time scale monitored by Brand-Williams et al.[5] and that in addition, there were distinct differences between phenolic compounds in the kinetics of the reactions. Thus, a major focus of this study was to determine reaction kinetics, evaluate relationships between kinetics and chemical properties and structure, and compare kinetics to conventional stoichiometry calculations for accurately measuring antiradical activity.

MATERIALS AND METHODS

Reagents. Antioxidants tested in this study were of the highest purity available, typically >99%. High purity 2,2-diphenyl-1-picrylhydrazyl (DPPH) and gallic acid were purchased from Eastman Organic Chemical (Rochester, NY). *n*-Propyl gallate, ferulic acid, benzoic acid, quercetin dihydrate, catechin gallate, uric acid, catechol, and *p*-coumaric acid were purchased from Sigma (St. Louis, MO). Pyrogallol, caffeic acid, 3-methyl catechol, Trolox, α-D-glucose, and epicatechin were purchased from Aldrich (Milwaukee, WI). L-Ascorbic acid and hydrochloric acid were purchased from Fisher (Fair Lawn, NJ). α-Tocopherol was from Cargill (Eddyville, IA). Hydroquinone was from Allied Chemical (New York, NY). Resorcinol and glutathione were purchased from Nutritional Biochemicals (Cleveland, OH). Chlorogenic acid was from Indofine (Hillsborough, NJ). DL-Lysine was from California Corp. for Biochemical Research (Los Angeles, CA). Phenol was from Mallinckrodt (St. Louis, MO). Vanillic acid, protocatechuic acid, sodium hydroxide, and HPLC-grade solvents (methanol, ethanol, acetone) were purchased from Sigma-Aldrich (St. Louis, MO). Water purified to 18 MΩ resistivity in a Milli-Q water purification system (Model 13681, Millipore, Bedford, MA) was used whenever water was required.

Reagent Preparation. DPPH reagent standard solution: 0.0036 g of DPPH was dissolved in 100 mL of methanol to generate a 0.0913 mM DPPH stock solution; working solutions were prepared fresh daily by diluting the stock solution with solvent sufficiently to reduce the absorbance at 515 nm to 1.00 (±0.02). This provided a starting DPPH concentration of 9.17×10^{-5} M, assuming an extinction coefficient of 10,900 $M^{-1}cm^{-1}$.[36] Methanol was used because DPPH stability in this solvent was greater than that in ethanol[37,38] or acetone,[39] which have also been reported in the literature as DPPH assay solvents.

[a]Stoichiometry determined at AOX concentrations of 10 and 100 μM. [b]Ratio of DPPH consumption measured at end of total reaction (final, f; $\Delta DPPH_f$) vs initial rapid reaction (initial, i, $\Delta DPPH_i$) for 100 μM antioxidant. [c]Number of reactive −OH groups. [d]Redox potential at pH 7. [e]R_i determined for AOX=100 μM is presented as nmol DPPH/sec, then this value is normalized to antioxidant amount (/nmol AOX) and to number of reactive -OH groups present (/−OH). [f](-), no −OH group; NLR, no linear response range; nd, response too low to determine stoichiometry accurately.

dx.doi.org/10.1021/jf500180u | J. Agric. Food Chem. 2014, 62, 4251−4260

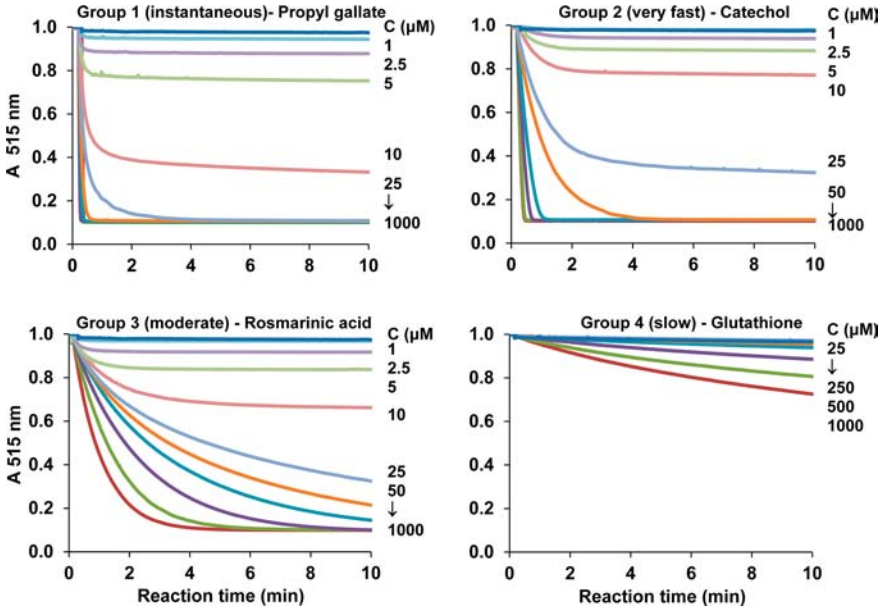

Figure 2. DPPH• reaction response curves for tested antioxidants fall into five classes: reactive Groups 1−4 are shown, Group 5 (no reaction) is not shown.

Antioxidant Preparation. Stock solutions (100 mM) of test antioxidants were prepared in methanol, then serially diluted to progressively lower concentrations for testing (typically 50, 25, 10, 5, 2.5, 1, 0.1, 0.05, 0.025, and 0.01 mM or until no reaction with DPPH was detectable). Antioxidant concentrations after the addition to DPPH (1000, 500, 250, 100, 50, 25, 10 μM, etc.) covered a range from well above [DPPH] to eliminate possible diffusion effects to well below the DPPH concentration to allow full reaction. From this point forward, all antioxidant concentrations noted are final reaction concentrations.

DPPH Quenching by Antioxidants. A Varian Cary 50 Bio Spectrometer system (Agilent, Santa Clara, CA) with Cary WinUV software was used to obtain all the data in this research. Three milliliters of diluted DPPH were pipetted into a quartz cuvette, and the absorbance at 515 nm was recorded to determine starting concentration. Thirty microliters of antioxidant solution were added and mixed rapidly by aspiration in the pipet, and recording of absorbance was initiated immediately. Adding microvolumes of antioxidant to a large volume of DPPH minimized dilution effects on the initial absorbance drop during reaction and facilitated accurate determination of reaction rates. Absorbance was recorded every 0.1 s for 10 min to generate reaction curves.

Solvent Effects. Catechol, hydroquinone, and resorcinol were selected as representative compounds from Groups 1−3 to test effects of solvent on reactivity with DPPH because they are isomers with great difference in reactivity but the same number of phenolic −OH groups and the same fundamental structure except for −OH position; they also have comparable solubility in the test solvents. Comparing phenolic compounds with different ring adducts would have made it difficult to distinguish solvation effects from shifts in radical quenching processes in the different test solvents. Glutathione was selected from Group 4 because it is a strong H donor, whereas reaction mechanisms of resorcinol and vanillic acid are unknown. To test the effect of solvent, 0.0913 mM DPPH stock solutions were prepared in ethanol, acetone, and 50% methanol as well as the standard methanol, and reactions were run with test antioxidants using the protocol described in the preceding paragraph. Initial reaction rates and final reaction stoichiometry were calculated as described under Data Analysis below.

pH Effects. Catechol, hydroquinone, resorcinol, and glutathione (representative samples from each group) were reacted with DPPH dissolved in 50% aqueous methanol as described above, with the addition of some samples for which the water phase was adjusted to pH 5 with HCl or to pH 9 with NaOH. Increases in reactivity with pH were used to identify electron transfer; H atom transfer is independent of pH.

Data Analysis. Initial reaction rates (R_i) were calculated from the initial absorbance drop (ΔA_i) in the linear reaction regions, determined by completion of reaction or regression equations with $R^2 > 0.9$. This region varied with antioxidant and concentration and so had to be determined separately for each compound; reaction times used for the calculations typically varied from 10 to 30 s. For compounds with incomplete reaction, the A at 30 s was used for R_i calculations. ΔA_i was converted to $\Delta[\text{DPPH}]_i$, and the initial rate (R_i) was reported directly as nmols DPPH quenched/s. Initial rates were also normalized to the amount of antioxidant (nmol DPPH/s/nmol AOX) and to the number of −OH groups (nmol DPPH/s/nmol AOX/number of −OH) to gain more insight into factors that may be controlling the DPPH reaction and antioxidant reactivity. Normalization to antioxidant concentration tracks how concentration affects the reaction and is important for elucidating the basic chemistry of the DPPH reaction, validating its use for rating antioxidants, and for determining protocols to be standardized. Rates were normalized to −OH groups because antioxidant reactivity in *in vitro* antioxidant capacity assays has so frequently been associated with this structural feature in test compounds. We wanted to investigate whether the relationships held also in rapid reactions that are most important for quenching short-lived radicals. R_i values were then plotted as a function of antioxidant concentration, and second order rate constants (k_2) revealing the concentration dependence of each antioxidant were determined from slopes of these curves.

Stoichiometry of the reaction (mols DPPH consumed/mol test antioxidant) was calculated from the absorbance drop after 10 min of reaction (ΔA_f) for 10 and 100 μM solutions. At the low antioxidant concentration (10 μM), interference with diffusion to DPPH was expected to be minimal; at 100 μM, the antioxidant concentration nearly equaled that of DPPH; hence, innate reactivity rather than diffusion should have controlled the reaction. Pearson correlation coefficients between various antioxidant properties and their reactions responses were calculated using the statistical functions in Excel software.

All glassware used was subjected to washes in denatured alcohol saturated with potassium hydroxide and in 1 N hydrochloric acid, with Milli-Q water rinses to remove potentially reactive contaminants. All analyses were performed at least in triplicate.

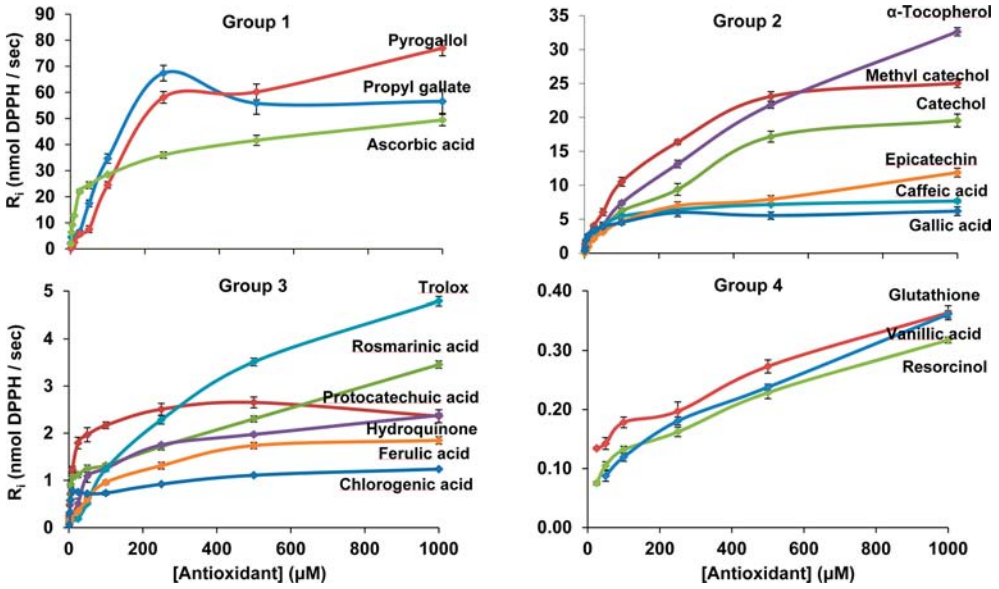

Figure 3. Effect of antioxidant concentrations on rates of initial reaction with DPPH.

■ RESULTS AND DISCUSSION

Preliminary studies in this laboratory recording DPPH loss continuously revealed a marked difference in the shapes of reaction curves for different antioxidants. Some antioxidants showed an immediate very fast reaction that was complete within seconds, while others showed a combination of fast and slower stages, and some showed only slow sustained reactions. To further investigate the reasons for these differences, determine best protocols for standardization of the DPPH antioxidant assays, and identify what useful chemical information can be derived from full reaction curves, reactions of 28 phenolic and nonphenolic compounds were studied in detail. Visual patterns of reaction curves were used for initial categorization, then initial reaction rates, antioxidant concentration dependence and linear reaction ranges, reaction stoichiometry, and degree of early reaction completion were calculated and compared with standard EC_{50} values, number of phenolic −OH (or other H donating) groups, and antioxidant redox potentials to learn more about factors controlling antioxidant reactions with DPPH.

Table 2 compiles these chemical properties and calculated reaction characteristics of tested antioxidants.

Kinetic Reaction Patterns and Initial Reaction Rates. Response curves of antioxidant reactions with DPPH revealed at least five distinctly different groups of reactivity (Figure 2) based on their reaction curve patterns and initial rates (R_i) at 100 μM (where antioxidant and DPPH concentrations are nearly equal, 0.1 mM AOX/0.0917 mM DPPH). (1) Extremely fast: instantaneous initial absorbance drop, R_i >20.0 nmol DPPH/s, the reaction is complete in less than 10 s, and $\Delta A_f/\Delta A_i = 1$; e.g., *n*-propyl gallate, pyrogallol, and ascorbic acid. (2) Fast: rapid initial absorbance drop, then the reaction continues more slowly, R_i = 4.0−10.0 nmol DPPH/s, and $\Delta A_f/\Delta A_i$ = 1−1.76; e.g., 3-methylcatechol, quercetin, catechol, α-tocopherol, caffeic acid, epicatechin, and gallic acid. (3) Medium: absorbance drop slow and continual over the reaction period, R_i = 0.5−4.0 nmol DPPH/s, and $\Delta A_f/\Delta A_i$ = 1.6−8.6; e.g., protocatechuic acid, rosmarinic acid, hydroquinone, Trolox, ferulic acid, and chlorogenic acid. (4) Slow: absorbance drop very slow and almost linear over time, R_i = 0.0−0.5 nmol DPPH/s, and $\Delta A_f/\Delta A_i$ = 3.3−3.7; e.g., glutathione, resorcinol, and vanillic acid. (5) Nonreactive: little or no drop of absorbance over the entire reaction time; e.g., phenol, benzoic acid, and *p*-coumaric acid.

As noted previously, antioxidants can quench DPPH by both electron and hydrogen atom transfer. Electron transfer is very fast (femtoseconds) and not diffusion-controlled, whereas hydrogen atom is slower and clearly diffusion-controlled.[40] Thus, compounds that reduce DPPH completely in less than 30 s (Group 1) act mostly, if not exclusively, by electron transfer in methanol. Compounds that reduce DPPH more slowly and require extended time for full reaction (Groups 2−4, $\Delta DPPH_f/\Delta DPPH_i$ > 1) act increasingly by hydrogen atom transfer, have reaction impeded by steric hindrance, or both.

Effects of Antioxidant Concentration on Reactivity with DPPH. Results of this study revealed significant variation among concentration−response patterns (Figure 3), k_2 and linear response range (Table 2), and saturation concentration (Figure 3) from the different reactivity groups.

For Group 1 (compounds with instantaneous reaction), k_2 values were the highest, and increase of initial reaction rates (R_i) was close to linear with antioxidant concentrations up to about 250 μM (final reaction concentration), then the reaction slowed. The one exception to this pattern was ascorbic acid, which was very reactive at the lowest concentrations, and small increases in concentration made dramatic differences in reaction rates, reflected in k_2 orders of magnitude larger than those of other antioxidants. This high reactivity is probably due to a combination of better accessibility to DPPH and low redox potential. At the same time, ascorbic acid reaction with DPPH also saturated rapidly with concentration (see linear range, Table 2) due to its propensity for secondary reactions at higher concentrations, and this was not reflected in k_2.

The k_2 values dropped as reactivity slowed progressively in Groups 1 through 4 (Table 2), indicating that increasing antioxidant concentrations had less effect on response. Indeed, for many compounds in Groups 2 and 3, reaction rates increased linearly with antioxidant only at the very low concentrations (100 and 10−50 μM, respectively), above which the response curves flattened, exhibiting more

dx.doi.org/10.1021/jf500180u | J. Agric. Food Chem. 2014, 62, 4251−4260

pronounced saturation with each group. There was no range of linear response in Group 4. That none of the antioxidants exhibited a perfectly linear response range and all exhibited some saturation demonstrate that factors other than antioxidant concentration also have important influences on reactivity. This poses a severe problem for quantitation of activity, especially in mixed extracts, since quantitative assays require that (1) the response is continually linear with reactant concentration or the assay must be conducted in a concentration range with linear response and that (2) analytes have comparable concentration dependence, as reflected in the second order rate constant (k_2), or a range of concentrations must be tested for each material.

The variability of k_2 within all groups warrants additional comment. As more antioxidant is added to the system, crowding of antioxidant molecules around the DPPH increases. This has two possible consequences, depending on antioxidant structure: (1) forcing reactive phenolic −OH groups into closer proximity to the DPPH radical site, thus facilitating reaction and (2) creating random molecular packing that impedes access to the DPPH radical. For compounds with lower k_2 values (e.g., hydroquinone, Trolox, and ferulic acid in Group 3), reaction curves were consistent with increased packing interference at higher antioxidant concentrations, while the curves of protocatechuic acid, rosmarinic acid, and chlorogenic acid showed greater reaction rate increase with added antioxidant (higher k_2), consistent with forced DPPH access by the increased packing.

Stoichiometry of Antioxidant Reactions. At 10 μM antioxidant concentrations (DPPH/AOX ∼10, conditions where multiple DPPH molecules should be sufficiently close to each antioxidant molecule that diffusion limitations on reaction are minimal), *n*-propyl gallate, tocopherol, and catechol were the only compounds to donate the expected two electrons per phenolic−OH group (Table 2). Ascorbic acid reacted one electron per OH group and other monophenols donated slightly less than one electron, while stoichiometry with compounds having more complex structure (epicatechin, rosmarinic acid, and quercetin) dropped still further. At antioxidant concentrations (100 μM) comparable to those of DPPH, stoichiometry dropped dramatically to fractions of an electron per OH group for every compound except tocopherol. Plots of stoichiometry over the entire antioxidant concentration range confirmed that stoichiometry was not constant but decreased with antioxidant concentration (Figure 4). The greatest stoichiometry change with concentration occurred at the lowest concentrations of the most reactive phenolic compounds. Differences in stoichiometry were obscured at high antioxidant concentrations, showing once again that reaction conditions markedly affected the picture given for both relative and absolute reactivity. Such nonconstant stoichiometry creates distinct problems for use of the DPPH assay in quantitating and comparing the antioxidant action of extracts with unknown composition and concentration.

As with initial rate, stoichiometry showed negligible correlation to the number of phenolic −OH groups per antioxidant molecule or to redox potential (Table 3). There was also little correlation between stoichiometry and initial reaction rate (0.52 and 0.14 for 10 and 100 μM antioxidant, respectively), so evaluations of antioxidant activity based on stoichiometric measures alone will miss differences between antioxidants at high concentrations and misrepresent the actual reactivity of many antioxidants at low concentrations.

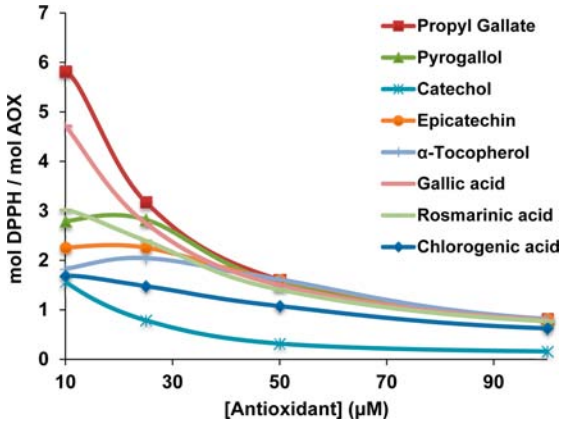

Figure 4. Inverse relationship between stoichiometry and antioxidant concentration for representative antioxidants from each reactivity group.

EC_{50}. As expected, antioxidant concentrations necessary to reduce DPPH by 50% appeared in reverse order to reactivity (Table 2, EC_{50} column). Less than 20 μM final concentrations were required by very fast reacting compounds (Group 1), and this value increased progressively in Groups 2 and 3. Compounds in Group 4 were unable to reduce DPPH by 50%. There was considerable variability within reactivity groups, which probably accounts for the lack of correlations between EC_{50} and M_w or redox potentials, and only a weak negative relationship to the number of phenolic −OH groups (−0.52), initial reaction rate (−0.36), and stoichiometry (−0.40) (Table 3). Thus, as with stoichiometry, the use of EC_{50} alone will give a distorted and inaccurate measure of actual antioxidant reaction with DPPH when comparing antioxidants from different structural classes.

Molecular Properties Controlling Antioxidant Reactivity with DPPH. Although previous studies have associated antioxidant activity within structural classes of phenolic compounds with redox potential[41] and number of phenolic −OH groups,[9] low Pearson correlation coefficients indicated that these factors could not explain the differences in reactivity between structural classes in this study (Table 3). Thus, alternate explanations must be sought.

Steric accessibility must be recognized as a key problem in reaction with DPPH since the radical site is protected inside a reaction cage formed by the two phenyl rings orthogonal to each other, and the picryl ring angled about 30° with its two nitro groups oriented above and below the radical site[14,15] (Figure 1). Most phenolic compounds in Groups 2−4 have more complex ring adducts or multiple rings that can impede the access of phenolic −OH groups to the hindered radical site of DPPH and reduce observed reactivity. Comparing $\Delta DPPH_f/\Delta DPPH_i$ provides support for steric accessibility to the DPPH radical site as a major controller of reactivity (last column, Table 2). Small monophenols with only −OH ring adducts showed a $\Delta DPPHf_f/\Delta DPPH_i$ ratio of ∼1, indicating that the reaction was complete within seconds. This ratio increased with the number and complexity of ring adducts, reflecting a slowing of reaction as molecules had to rotate to orient reactive groups toward the DPPH radical site and as bulky ring adducts or multiple rings interfered with free diffusion to DPPH. The pronounced saturation of DPPH reaction rates with increasing antioxidant concentration shown in slower reacting Groups 2−4 (Figure 3) as well as inhibition of reactions in mixtures of

Table 4. Comparison of Solvent Effects on DPPH Quenching Rate (R_i) and Total DPPH Consumption after 10 min of Reaction by Selected Antioxidants (100 μM Final Concentration)

	Solvent			
antioxidants	methanol	50% aq. methanol	ethanol	acetone
	Initial Rate, R_i (nmol DPPH/s)			
pyrogallol	21.02 ± 1.24	30.56 ± 1.32	1.56 ± 0.05	0.30 ± 0.01
catechol	6.18 ± 0.44	11.92 ± 0.54	0.47 ± 0.02	0.18 ± 0.01
hydroquinone	1.26 ± 0.03	6.84 ± 0.46	0.48 ± 0.03	0.12 ± 0.02
resorcinol	0.13 ± 0.01	0.35 ± 0.02	no reaction	no reaction
glutathione	0.18 ± 0.01	1.30 ± 0.09	0.10 ± 0.01	no reaction
	Total DPPH Consumption (μmol)			
pyrogallol	0.25 ± 0.02	0.24 ± 0.02	0.21 ± 0.01	0.015 ± 0.000
catechol	0.24 ± 0.01	0.24 ± 0.02	0.20 ± 0.01	0.003 ± 0.000
hydroquinone	0.17 ± 0.01	0.23 ± 0.02	0.13 ± 0.01	0.044 ± 0.001
resorcinol	0.01 ± 0.00	0.07 ± 0.00	no reaction	no reaction
glutathione	0.02 ± 0.00	0.14 ± 0.01	0.005 ± 0.000	no reaction

phenolic compounds (manuscript in preparation) are similarly consistent with steric interference imposed by molecules blocking access to the radical site, rather than accumulation of $DPPH_2$ that reportedly inhibits the reaction.[4] These results suggest that steric hindrance may be the most important factor limiting the reaction of phenolic compounds with DPPH and thus raise questions about the validity of the DPPH assay for rating the activity of antioxidants with different structures. Computer analysis of molecular docking of antioxidants with DPPH should clarify the role of steric accessibility in this assay.

Inductive effects of ring substituents on reactivity with DPPH must also be considered. Slower reacting phenolic compounds tended to have more electron-withdrawing ring substituents (COOH, C═C, and COOR) or multiple rings which deactivate phenolic −OH groups to ionization or H atom transfer. However, there was little direct correlation between reaction rates and estimated Hammett sigma constants, measures of how strongly ring substituents at meta and para positions donate or withdraw electrons from reactive groups (data not shown). Thus, other factors have a stronger influence than inductive effects on DPPH reaction rates.

Finally, DPPH is a mixed mode reagent, so the balance between electron and hydrogen atom transfer for individual compounds and in different reaction environments must contribute to the control of reaction rates with DPPH. As shown above, compounds capable of electron transfer react more rapidly with DPPH, while hydrogen atom donors react more slowly. Some insights into the relationship between the dominant mechanism and reaction rate are provided by the solvent effects on reactions discussed below.

Effects of Solvent on Antioxidant Reactivity with DPPH. To determine the optimum solvent for standardization and to explore whether these solvent effects could be further used to advantage to investigate reaction processes, we reacted DPPH with glutathione (a strong H donor) and phenols (pyrogallol, catechol, hydroquinone, and resorcinol) having closely related structure from each of the reactivity groups in methanol, ethanol, acetone, and 50% aqueous methanol, solvents most often in assays of antioxidant activity. For the phenolic compounds, reactions were fastest in methanol and slowed dramatically in ethanol or acetone (Table 4).

A number of papers have documented that hydrogen bonding solvents generally decrease hydrogen atom transfers because they complex with both DPPH[4,14] and phenolic compounds,[16,19,31] thus blocking reaction. Consistent with these observations, the relative rates for solvents in this study are in the reverse order of hydrogen bond accepting ability of the three solvents, i.e., hydrogen bond parameters β_2^H are 0.41, 0.44, and 0.50 for methanol, ethanol, and acetone, respectively.[42] Litwinienko and Ingold have shown that HAT cannot occur from hydrogen bonded complexes between solvent and hydrogen atom donor, XH···S, so the most simplistic explanation for the solvent effects is differences in the strength of hydrogen bonding of the solvent to phenolic −OH groups and/or to DPPH that interferes with the release of H atoms.[17,18,43]

Slowing of reactions in ethanol may also be attributed to increased viscosity slowing the diffusion of antioxidants to the DPPH radicals or to increased steric interference with phenol access to the DPPH radical site. Acetone is particularly effective in inhibiting hydrogen transfer from vicinal diphenols because it hydrogen bonds very strongly to both phenolic −OH groups, completely blocking both electron and hydrogen transfer.[16] In addition, DPPH reacts with phenolic compounds via rapid sequential proton loss electron transfer (SPLET) in ionizing solvents and by slower hydrogen atom transfer (HAT) in nonionizing solvents or in the presence of acid.[18] Both methanol and ethanol partially ionize, allowing both electron and hydrogen transfer, but acetone is nonionizing. Thus, DPPH radical quenching is minimal in acetone because both electron and hydrogen atom transfers are strongly inhibited.

Diluting methanol to 50% with water greatly increased the reaction rate by about 50% for pyrogallol, which is a strong electron transfer compound, but considerably more for

antioxidants that acted preferentially by hydrogen atom transfer. Glutathione, a strong hydrogen donor, increased more than seven times in rate. Water is a known proton transfer medium; it supports ionization of solutes, has lower hydrogen bonding strength (β_2^H = 0.38[42]) than the organic solvents tested, and stabilizes the polar transition states necessary for hydrogen atom abstraction.[41] All of these actions markedly facilitate hydrogen atom transfer.

Solvent effects extended variably to reaction stoichiometry. Fifty percent methanol did not alter the reactivity of pyrogallol and catechol (strong electron transfer antioxidants) relative to methanol but increased the total reaction of hydroquinone by 50% and of resorcinol and glutathione by 7 times.

In terms of DPPH assay standardization, these results indicate that of the solvents studied here, methanol is the solvent of choice. That it selects for antioxidants acting predominantly or exclusively by SET does present the disadvantage that strong electron transfer agents appear to be the most active antioxidants[17] while known physiological antioxidants such as glutathione and uric acid that act almost exclusively by HAT are tremendously underrated. Nevertheless, running DPPH assays in 50% aqueous methanol in parallel with neat methanol offers opportunities to distinguish compounds that act by HAT, elucidate dominant reaction mechanisms of individual antioxidants and of mixed composition extracts, and provide important insights into behaviors that may be expected in multiphase systems such as cells and foods where lipid phases would favor electron transfers and aqueous phases would favor hydrogen atom transfers.

Effects of pH on Kinetics and Reaction. Antioxidants from the solvent tests were further evaluated in 50% aqueous methanol in which the water portion was varied in pH (5, 7, and 9) by the addition of high purity HCl or NaOH. Initial rates for known electron transfer agents pyrogallol and catechol increased notably with pH, while hydrogen atom donors glutathione and resorcinol showed negligible change (Figure 5).

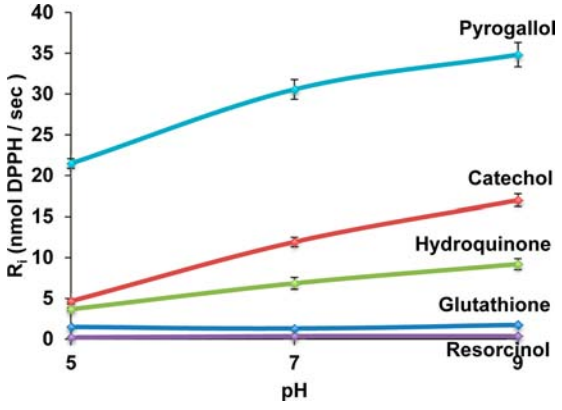

Figure 5. Effect of pH on initial rates of antioxidant reactions with DPPH. [AOX] = 100 μM (final); solvent = 50% aqueous methanol. pH effects on final stoichiometry in the same reactions were negligible.

Hydroquinone, which acts by both electron and hydrogen transfers, exhibited intermediate rate increases. Thus, pH effects on rates of antioxidant reaction with DPPH in 50% methanol can be advantageously combined with solvent effects to distinguish between electron and hydrogen atom transfers as dominant reaction mechanisms. Differences were only seen with reaction rates; essentially, no change occurred with reaction stoichiometry as pH was varied (data not shown).

Recommendations for the Use of DPPH Reactions in the Evaluation of the Radical Quenching Activity of Antioxidants. The DPPH reaction has been used extensively to compare and rank the antioxidant effectiveness of a wide range of natural extracts in now thousands of studies. Nonetheless, results reported here raise serious questions about its validity for quantitating and comparing the activity of antioxidants with different sizes and structures, and especially for ranking their relative reactivity due to the following significant limitations of the DPPH reaction: (1) Absorbance measurements only after long reaction periods are inadequate for quantitating antioxidant reaction with DPPH because they miss important initial reactions that provide critical distinction between the reactivity of antioxidants with different structures and do not determine reaction rates. Final stoichiometry determined from total absorbance drops reflects the numbers of hydrogen atom donating groups almost exclusively and thus overestimates the activity of polyphenols and underestimates activity of monophenols. These conventional analyses also ignore antioxidant concentration effects and reaction saturation.

(2) Full and accurate evaluation of antioxidant reactivity rather than capacity requires recording DPPH loss continuously over the full reaction time, with calculation of reaction kinetics from early response (immediate to 30 s). However, accurate measurements of the initial very rapid reaction rates requires fast kinetic techniques such as continuous or stopped flow mixing because the initial electron transfer from antioxidant to DPPH is too fast to quantitate using manual mixing and conventional spectrophotometers.

(3) Accurate information cannot be gained from single antioxidant concentrations, particularly in extracts not normalized to the concentration of phenolic compounds. Rather, reactions must be run over a range of antioxidant concentrations from dilute (diffusion controlled) to approximately equal to DPPH. Concentrations greater than DPPH as conventionally used to determine second order rate constants are not valid due to reaction saturation and interference with steric accessibility to DPPH. Determining reaction response as a function of antioxidant concentration clearly identifies valid linear response ranges and saturation levels, and differentiates reactivity patterns.

(4) Allowing reactions to run to completion over many minutes to hours is warranted for the quantitation of phenols, as described in early applications of DPPH,[2] and reflects potential antioxidant capacity but is irrelevant for determining the important initial rates of antioxidant reaction with DPPH. Analyses of immediate (0−2 min) rather than long reactions should be stressed when determining antioxidant reactivity.

(5) Steric accessibility to the DPPH radical site appears to control the reaction more than specific identifiable chemical properties of the antioxidants. Initial reaction rates are most rapid with the simplest phenolic compounds and decrease with the addition of bulky ring adducts and multiple rings. These differences are largely obscured and may even be reversed when reactions are monitored only after the long periods allowed for reaching equilibrium. Furthermore, compounds known to have strong antioxidant activity, e.g., glutathione and BHT,[11] show only slow reactivity with DPPH at least in part due to strongly steric limitations.

Because structure rather than chemistry appears to dominate the reaction rate, it is our scientific judgment that reaction with DPPH should not be used to compare or infer the potential antioxidant activity of antioxidant mixtures, prepared or in

extracts, where different structural classes are present and may not even be known. Ascorbic acid contents, in particular, will enhance reactivity disproportionately, so its concentrations in extracts must be determined to accurately interpret results.

A potential alternative application of the DPPH reaction may be distinction of electron transfer versus hydrogen atom transfer as dominant reaction mechanisms of individual antioxidant compounds. Even here, though, qualitative information about reaction mechanisms of mixtures and extracts can be derived from reaction response patterns and kinetic solvent effects, but rates of general radical reactivity for mixtures cannot be quantified accurately due to limitations in steric accessibility to the DPPH radical site.

ABSTRACT: A facile magnetic solid phase extraction (MSPE) of aflatoxins (AFs) from liquid samples was developed using polydopamine-coated magnetic nanoparticles (PD-MNPs) as the adsorbent. PD-MNPs were prepared from amine-terminated MNPs and dopamine via an in situ oxidative self-polymerization approach. Under the selected MSPE conditions, extraction yields ranging from 59.3% for AF G_2 to 89.0% for AF B_1 were obtained with good repeatability. Coupled with HPLC-MS/MS quantification, the MSPE procedure serves not only for sample cleanup but also for AFs enrichment that is highly desired for trace analysis. The proposed MSPE-HPLC-MS/MS method had a linear calibration curve in the concentration range from 0.00600 to 3.00 ng/mL aflatoxin and limits of detection of 0.0012 ng/mL for AF B_1, AF B_2, and AF G_1, and 0.0031 ng/mL for AF G_2.

KEYWORDS: *aflatoxin quantification, HPLC-MS/MS, sample pretreatment, magnetic solid phase extraction, polydopamine coated magnetic nanoparticles, wine analysis*

INTRODUCTION

Mycotoxins are toxic secondary metabolites produced by organisms of the fungi kingdom, commonly known as molds.[1,2] Aflatoxins (AFs) are mycotoxins derived by *Aspergillus flavus* (*A. flavus*) and *Aspergillus parasiticus* (*A. parasiticus*) and are listed as Group I carcinogens by the International Agency for Research on Cancer (IARC), a body of the World Health Organization (WHO). There are four major natural aflatoxins (i.e., AF B_1, AF B_2, AF G_1, and AF G_2). AF B_1 and AF B_2 are produced by *A. flavus*, whereas AF G_1 and AF G_2 are produced by both *A. flavus* and *A. parasiticus*. AF B_1 is the molecule with the highest toxic significance. The hierarchy of toxicity, carcinogenicity, and mutagenicity of different aflatoxins is in the order AF B_1 > AF G_1 > AF B_2 > AF G_2.[3,4] The occurrence of aflatoxins is influenced by certain environmental factors. Hence, the extent of contamination will vary with geographic location, agricultural and agronomic practices, and the susceptibility of commodities to fungal invasion during preharvest, storage, and/or processing periods. On a worldwide scale, aflatoxins are found in stored food commodities and oil seeds such as corn, peanuts, and so forth.[5,6]

To achieve quantitative analysis of aflatoxins, analytical methods based on various instrumental techniques have been developed.[7,8] High-performance liquid chromatography−mass spectrometric (HPLC−MS) methods have drawn the most interest due to their excelling selectivity. However, HPLC−MS analysis is prone to matrix effects, which are dependent on analytes, sample matrices, LC−MS conditions, and sample preparation.[9,10] To some degree, use of internal standards, especially stable isotope dilution, alleviates the problems associated with matrix effects.[11,12] A major disadvantage of HPLC-MS stable isotope dilution analysis is the need for expensive isotope-labeled analogues of the analytes. In addition, when analyte concentrations in a sample solution are below the limit of quantitation (LOQ) of the method, enrichment of the analytes must be carried out prior to analysis. Many procedures for sample cleanup and/or analyte enrichment have been reported. Immunoaffinity columns have been used for long to extract aflatoxins from various sample matrices.[13,14] The advantages of these affinity extraction procedures are that they are selective and sensitive. However, the immunoaffinity columns are normally costly. To reduce the cost of analysis, chemical mini-columns, particularly florisil-packed columns were proposed and proven effective for sample cleanup in aflatoxin analysis.[15−17] Major drawbacks of these column-based procedures include a time-consuming elution of the retained analytes and use of significant quantities of toxic organic solvents. Solid-phase extraction (SPE) of aflatoxins with C_{18} cartridges has been successfully developed.[18−20]

Magnetic solid-phase extraction (MSPE) is a new version of SPE. It is based on the use of superparamagnetic nanoparticles as adsorbent.[21−23] In MSPE, the adsorbent needs not to be packed into a cartridge as in traditional SPE. Instead, a suspension of the nanometer-sized adsorbent is added and mixed well with the sample solution to extract analytes. After extraction, the adsorbent can be easily separated from the solution and collected through magnetic decantation by means of an external magnet. There is no need for tedious centrifugation or filtration in MSPE. Therefore, MSPE is

quick, easy to perform, and importantly, well-suited to handle liter volumes of samples, which means a large enrichment factor can be conveniently obtained. Use of MSPE in quantitative analysis of estrogens[24] and isoflavones[25] in milk samples has been reported.

The aim of the present research was to develop a rapid, cost-effective, and efficient MSPE procedure for HPLC−MS/MS quantification of aflatoxins in liquid foodstuff samples. This procedure serves not only for sample cleanup, eliminating any potential matrix effects on the subsequent HPLC−MS/MS analysis, but also for AF enrichment, allowing the quantification at very low levels. To achieve high extraction efficiency, superparamagnetic Fe_3O_4 nanoparticles with different surface modifications were synthesized, characterized by using TEM and FTIR and evaluated as the MSPE adsorbent. MSPE parameters affecting the extraction efficiency, including extraction time, eluting solvent, and so forth were investigated. Finally, rapid analysis of low levels of aflatoxins in red wine samples by using the proposed MSPE−HPLC−MS/MS method was demonstrated.

MATERIALS AND METHODS

Reagents and Chemicals. Aflatoxin standards, dopamine (structures are shown in Figure 1), 1,6-hexamethylenediamine, anhydrous sodium acetate, iron(III) chloride hexahydrate ($FeCl_3·6H_2O$), ethylene glycol, HPLC grade acetonitrile, methanol, and formic acid were purchased from Sigma-Aldrich Chemicals (St. Louis, MO). Other chemicals and solvents were of analytical grade. Milli-Q water (Millipore, Bedford, MA) was used throughout the work.

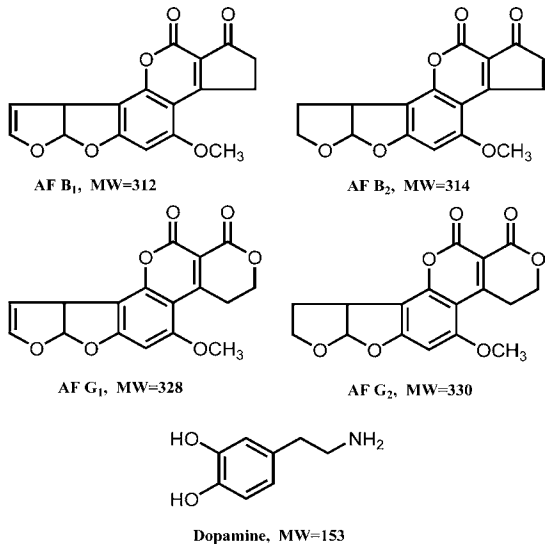

Figure 1. Chemical structures of the compounds involved in this work: AF B_1, AF B_2, AF G_1, AF G_2, and dopamine.

Preparation of Polydopamine-MNPs. Amine-terminated Fe_3O_4 magnetic nanoparticles (AMNPs) were prepared by a one-pot hydrothermal procedure previously reported (illustrated in Figure 2).[26] Briefly, 4.33 g of 1,6-hexanediamine, 1.33 g of anhydrous sodium acetate, and 0.66 g of $FeCl_3·6H_2O$ were dissolved in 25 mL of ethylene glycol by vigorously stirring at 50 °C to obtain a clear solution. It was then transferred to a Teflon-lined autoclave for 6 h at 198 °C to obtain AMNPs. The AMNPs were rinsed with water and ethanol twice. After each rinse step, the AMNPs were separated from the supernatant by using an external magnet. AMNPs were dried at 50 °C under N_2 overnight. To prepare polydopamine coated MNPs (PD-MNPs), an in situ oxidative self-polymerization procedure was used.[27−29] A suspension of AMNPs was prepared by dispersing 220 mg of AMNPs in 10 mL of 10 mM Tris-HCl buffer solution (pH 8.5) through sonication for 15 min. Dopamine HCl (2.5 mg/mL) was added to the AMNPs suspension with vigorous stirring, and the pH of the mixture was adjusted to 8.5 by addition of 10 mM sodium hydroxide. The solution was placed on a shaker for 12 h after which PD-MNPs were collected by magnetic decantation, washed three times with water, and finally redispersed in 5.0 mL water by sonication for 15 min.

Characterization of PD-MNPs. Transmission electron microscopic (TEM) images were acquired on a JEOL, JEM-1011 with a resolution of 0.2 nm lattice. FT-IR spectra were obtained by a Nexus 670 E.S.P. Fourier transform-infrared spectrometer.

Aflatoxin Standard Solutions. Aflatoxin standard mixture containing 1000 ng/mL AF B_1, AF G_1 and 300 ng/mL AF B_2, AF G_2 (Sigma-Aldrich, St. Louis, MO) was allotted at 100 uL per centrifuge tube and stored at −20 °C until use. The work standard solutions were prepared daily by appropriate dilution with methanol/water (50:50, v/v).

Magnetic Solid Phase Extraction of Aflatoxins. To an Erlenmeyer flask containing 50 mL of sample, 100 μL of the PD-MNPs suspension prepared above was added. The mixture was shaken for 10 min on an oscillator. The flask was placed on a magnet for 30 s to let PD-MNPs settle down. The supernatant was discarded. After washing twice with 500 μL of water, aflatoxins were eluted from the PD-MNPs with 250 μL of warm acetonitrile/methanol (1:1) at about 60 °C for 3 min. After magnetic separation, 100 μL of supernatant was transferred to a centrifuge vial and mixed with 100 μL of water. After being filtered through a 0.22 μm filtration membrane, portions (5 μL) were injected into the HPLC−ESI−MS/MS

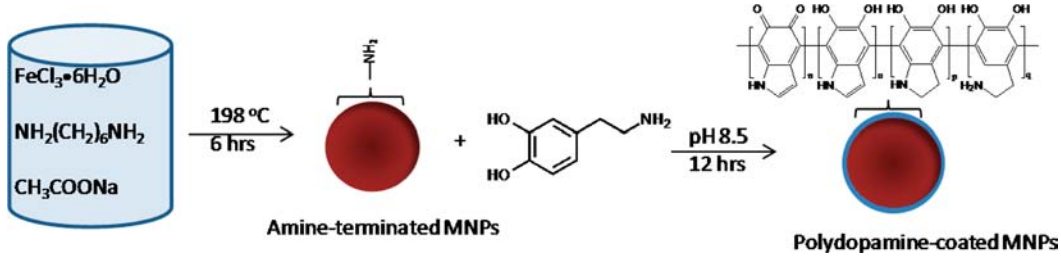

Figure 2. Illustration of PD-MNPs preparation involving two steps: (1) one-pot synthesis of amine-terminated magnetic nanoparticles (AMNPs) from $FeCl_3$ and hexanediamine and (2) coating AMNPs with polydopamine via in situ oxidative self-polymerization of dopamine.

system for analysis without further purification. The MSPE procedure is illustrated in Figure 3.

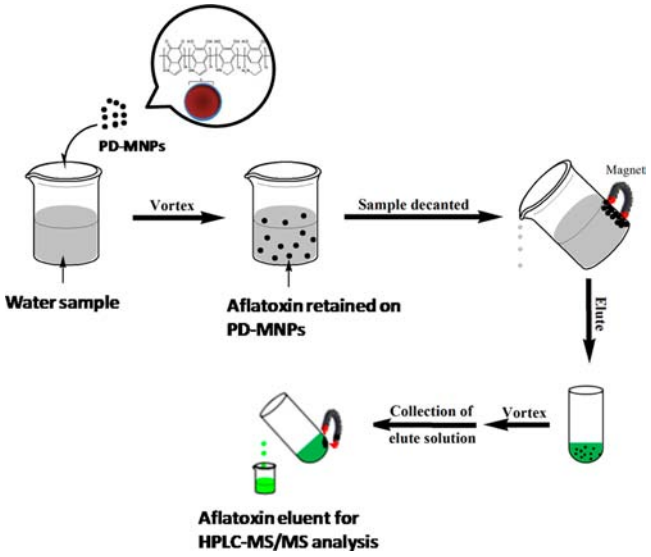

Figure 3. Illustration of the proposed MSPE procedure for facile extraction of aflatoxins followed by HPLC–MS/MS quantification.

HPLC–MS/MS Analysis of Aflatoxins. The system consisted of two pumps (LC-10ADvp, Shimadzu, Toyoto, Japan), an online degasser (DGU-12A, Shimadzu), and a triple quadrupole mass spectrometer equipped with a heated ESI source (TSQ Quantum, Thermo Scientific, San Jose, CA). Both the LC and mass spectrometer were controlled by Xcalibur software (Thermo Finnigan). A C_{18} reversed-phase column (Ascentis, 3 μm particle size, 10 cm × 2.1 mm, Sigma-Aldrich, St. Louis, MO) was used for separation. MeOH/water mixture (60/40, v/v) containing 5 mM ammonium acetate was used as the mobile phase at a flow rate of 0.150 mL/min. Sample injection volume was 5 μL. Data were acquired in full scan and SRM mode. The MS detector was operated in the positive ion mode with the following settings: spray voltage of 3 kV, vaporization temperature of 270 °C, capillary temperature of 300 °C, sheath gas pressure of 35 (arb), auxiliary gas pressure of 10 (arb), tube lens voltage of 150 V, and capillary voltage of 35 V. SRM parameters for MS detection of aflatoxins are summarized in Table 1.

Table 1. SRM Data Acquisition Parameters for Aflatoxins

aflatoxin	molecular weight	precursor ion (m/z)	product ion (m/z)	collision energy
AF B_1	312	313	285	28
AF B_2	314	315	259	28
AF G_1	328	329	243	28
AF G_2	330	331	245	28

RESULTS AND DISCUSSION

Synthesis and Characterization of PD-MNPs. MSPE is gaining attention because it is quick, easy to perform, inexpensive, and suitable for working with large volume samples.[21−23] The success of a MSPE procedure depends largely on the surface chemistry of the superparamagnetic nanometer-sized adsorbent particles. Polydopamine-coated nanoparticles have been widely used in biological and pharmaceutical technology arenas.[27−30] In this study, it was found that a highly stable polydopamine coating could be formed on the surface of amine-terminated Fe_3O_4 superparamagnetic nanoparticles via oxidative self-polymerization of dopamine. Because the polydopamine coating thus formed is composed of dihydroxyindole, indoledione, and dopamine units (as illustrated by Figure 2),[31,32] PD-MNPs are expected to have a high affinity for aflatoxins through a combination of charge transfer, π-stacking, and hydrogen-bonding interactions, and therefore, they are expected to serve as a highly effective MSPE adsorbent for extracting these compounds from solutions.

One-pot synthesis of amine-terminated MNPs (AMNPs) was achieved by following a procedure previously reported[26] using $FeCl_3{\cdot}6H_2O$ as the precursor of magnetic particles and hexamethylenediamine as an amino group source. From the TEM results, AMNPs prepared were ∼30 nm in diameter in average and had a circular shape. The FT-IR spectrum (Figure 4A) shows strong absorptions at 575 cm^{-1} arising from the vibration of the Fe−O bond and at 3133.5 and 3420.9 cm^{-1} from N−H $_{bond}$ in the amine group. PD-MNPs were easily prepared by incubating AMNPs with dopamine in a Tris buffer at pH 8.5 for 3 h. TEM analysis showed that PD-MNPs obtained had an average diameter of ∼40 nm. In the FT-IR spectrum of PD-MNPs (Figure 4B), a strong absorption band at 1400 cm^{-1} and a moderate band at 1600 cm^{-1} are observed, clearly indicating the presence of polymerized aromatic structures. In addition, an absorption band at 3100−3450 cm^{-1} is much stronger than that in AMNPs spectrum, which is due to the overlapping of hydroxyls and amines in polydopamine. These results suggest that PD coating of AMNPs was successful. It was also noted that the suspendability of PD-MNPs was much improved from that of the precursor AMNPs or bare Fe_3O_4 nanoparticles. A diluted suspension of PD-MNPs was stable for several days in terms of its appearance. UV−vis monitoring of the suspension for 1 week did not detect any leaching of polydopamine or its components from the nanoparticles.

MSPE of Aflatoxins with PD-MNPs. In the MSPE study, alflatoxin standard solutions prepared in water were used. PD-MNPs were added to 50 mL of a standard solution in each extraction test. Aflatoxins extracted from the solution were subsequently retrieved from the PD-MNPs and quantified by HPLC–MS/MS. Several HPLC–MS methods have been reported for aflatoxin quantification.[11,12,18,20,33] In the present study, several mobile phases, including MeOH/H_2O (60:40) containing 5 mM ammonium acetate, MeOH/H_2O (60:40) containing 0.1% formic acid, ACN/H_2O (60:40) containing 5 mM ammonium acetate, and MeOH/ACN/H_2O (60:20:20), were tested for the separation on a C_{18} column. It was found that isocratic elution with MeOH/H_2O (60:40) containing 5 mM ammonium acetate resulted in the best analytical results in terms of separation efficiency and detection sensitivity. The aflatoxins tested were separated within 4.5 min. Intriguingly, introducing ammonium acetate to the mobile phase significantly improved the detection sensitivity. However, no similar effects were observed with formic acid (0.1% v/v), a commonly used additive to enhance ionization efficiency in HPLC–MS analysis.

Effects of PD-MNPs amount on extraction efficiency were investigated. In a set of extraction tests, 10, 25, 50, 75, 100, 150, 200, and 500 μL of PD-MNPs suspension were added to different 50.0 mL portions of a standard solution containing 0.100 ng/mL AF B_1, respectively. On the basis of the peak areas

dx.doi.org/10.1021/jf501659m | J. Agric. Food Chem. 2014, 62, 4261−4267

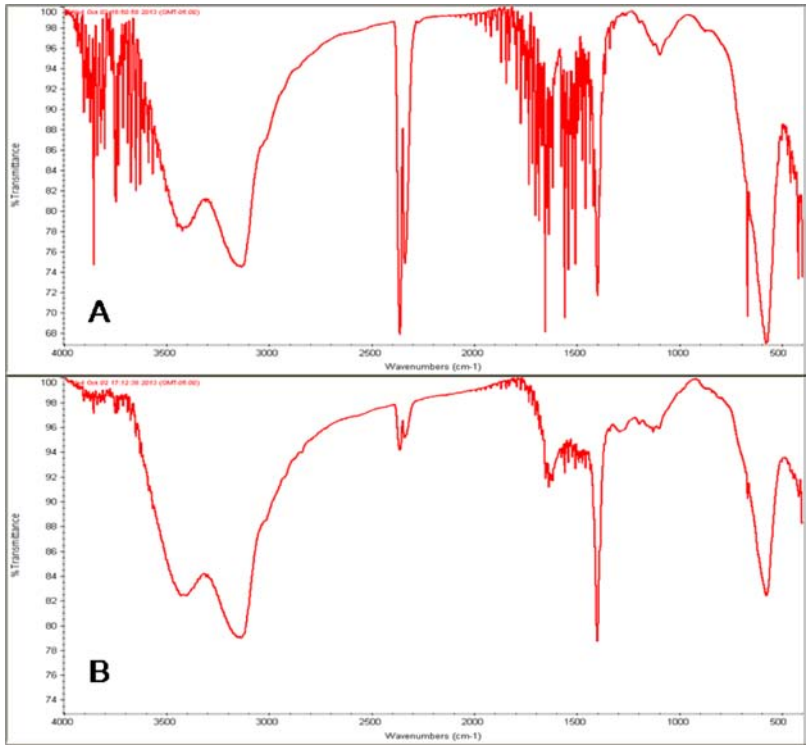

Figure 4. FT-IR spectra of AMNPs (A) and PD-AMNPs (B).

obtained from the HPLC–MS/MS analysis of the eluent from each test, the extraction efficiency of AF B1 was assessed. It was found that extraction efficiency increased [from 33.1 ± 7.2% to 89.2 ± 2.6% (n = 3)] with the increase in PD-MNPs amount and remained nearly constant when >75 μL of PD-MNPs suspension was used. For further studies, 100 μL of PD-MNPs suspension was added to 50 mL of sample to extract aflatoxins. Extraction times of 5, 10, and 20 min were tested. The extraction efficiency of AF B1 obtained were 86.7 ± 2.2%, 89.7 ± 1.7%, and 89.5 ± 0.3% (n = 3), respectively. Desorption of aflatoxins retained on PD-MNPs is also critical to the success of the MSPE development. Elution conditions, including eluting solvent, elution time (1, 2, 3, 5, and 10 min), and elution temperature (30, 45, 60, 80 °C) were investigated to achieve a high retrieval efficiency. Several eluting solvents were tested. Results of retrieval efficiency for AF B_1 are summarized in Figure 5. Elution with water produced an eluent solution containing nondetectable aflatoxins. Methanol/acetonitrile (1:1) was found most effective to retrieve aflatoxins from PD-MNPs. On the basis of these studies, methanol/acetonitrile (1:1) as the eluting solvent and an elution time of 3 min at 60 °C were selected for desorption of aflatoxin from PD-MNPs. An equal amount of water was added to the elution solution prior to HPLC–MS/MS analysis in order to minimize the solvent effects on the separation. Interestingly, when using AMNPs or bare Fe_3O_4 MNPs for MSPE of aflatoxin, the extraction efficiency was found to be significantly lower. This may be due to either a low affinity of aflatoxins to these adsorbents or poor desorption of aflatoxins from them under the selected elution conditions. PD-MNPs exhibit a very high affinity for aflatoxins because of combined interactions arising from charge transfer, π-stacking, and hydrogen bonding, most of which do not exist in the case of AMNPs or bare Fe_3O_4 MNPs.

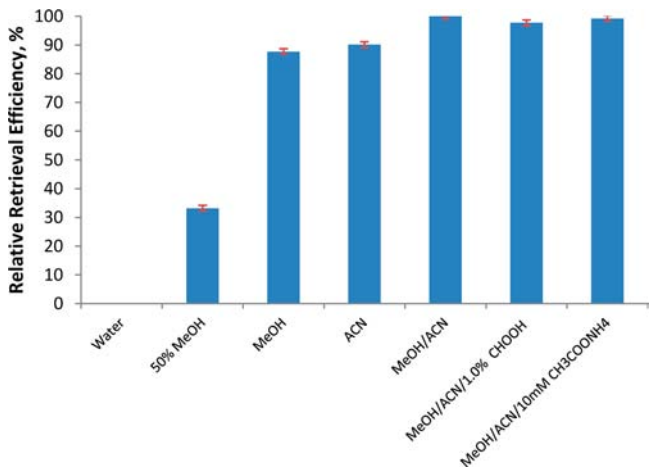

Figure 5. Comparing the effectiveness of retrieving AF B_1 retained on PD-MNPs with different eluting solvents.

Under the selected MSPE conditions, two standard solutions of aflatoxins at concentrations ranging from 0.0100–0.300 ng/mL were extracted to determine the extraction recovery for all the four aflatoxins tested. Aflatoxins extracted were quantified by using a calibration curve prepared from standard water solutions of aflatoxins. The recovery for the four aflatoxins ranged from 58.6 to 91.0% (Table 2). The difference in recovery is likely because of the fact that AF B_1 and AF B_2 are more hydrophobic than AF G_1 and AF G_2. These recovery values are significantly higher than many of those obtained from SPE procedures. It should be pointed out that the proposed MSPE offers an enrichment factor of 100, which is attractive for analysis of samples containing aflatoxins at very low levels.

Red wine: sample spiked with 0.0600 ng/mL of AF B_1 and G_1 and 0.0200 ng/mL of AF B_2 and G_2.

Quantification of Trace Aflatoxins in Red Wine Samples. Monitoring aflatoxin levels in foodstuff is highly important. In this work, quick, selective, and sensitive quantification of trace aflatoxins in red wines by coupling the proposed MSPE with HPLC−MS/MS analysis is demonstrated. To obtain the analytical figures of merit for the MSPE−HPLC−MS/MS method, simultaneous quantification of authentic AF B_1, AF B_2, AF G_1, and AF G_2 solutions was performed. The behaviors of chromatographic retention and product ion spectra of these four aflatoxins are shown in Figure 6. Under the selected HPLC−MS analytical conditions, the four aflatoxins were well-separated from each other. For each

ND: not detected.

aflatoxin tested, a characteristic product ion was obtained. Ion transitions (i.e., m/z 313 → 285 for AF B_1, m/z 315 → 259 for AF B_2, m/z 329 → 243 for AF G_1, and m/z 331 → 245 for AF G_2) were monitored using the SRM detection mode. Five-point calibration curves were prepared with authentic aflatoxin solutions at concentrations ranging from 0.00600 to 3.00 ng/mL in water. These solutions were submitted to the proposed MSPE procedure and injected into the HPLC−MS system for quantification. Peak areas were used for the calculation. Regression analysis of the results yielded linear calibration equations for all four aflatoxins tested with r^2 values >0.995. Interday (5 days) precisions of the slope and intercept of the calibration curves were found to be in the range between 3.5% and 5.6% (RSD, n = 5). From the calibration curves, the limits of detection were estimated to be in the range from 0.0012 ng/mL for AF B_1, AF B_2, and AF G_1 to 0.0031 ng/mL for AF G_2 (signal/noise = 3). These results indicate that the present method is very sensitive for the analysis of aflatoxins. It should be pointed out that these LODs are so low because the MSPE extraction provides a 100-fold enrichment factor (i.e., the sample is preconcentrated by a factor of 100 through the extraction), which is a significant gain of using the proposed MSPE procedure.

The proposed MSPE−HPLC−MS/MS method was applied to quantification of aflatoxins in liquid foodstuff samples, taking red wine as a model system. Two red wine samples were purchased from a local store and analyzed to determine the four aflatoxins. To verify the analytical results these samples were spiked with authentic aflatoxins and analyzed again. A typical chromatogram obtained from these analyses is shown in Figure 6. Peaks corresponding to AFs were well-identified. No unknown peaks appeared in the chromatogram, indicating that the method was specific for the determination of aflatoxins. The analytical results are summarized in Table 3. As can be seen, both the accuracy and the repeatability of the present MSPE−HPLC−MS method are good, because all recovery values are >90% and RSDs are <8%. These results suggest that the proposed method is useful for rapid quantification of aflatoxins in red wines. As shown in Table 3, aflatoxins were not detected in the wine samples tested. These results are in agreement with those reported previously.[12] Unlike some other mycotoxins such as ochratoxin A, aflatoxins in wine do not present a problem. Red wine samples are analyzed in this work as a model to demonstrate the usefulness of the proposed MSPE procedure. It is expected that the proposed method can be applied to analysis of other liquid foodstuff samples such as beer, vegetable fluids, among others. It is worth noting that because AF contents in these samples are normally below the LODs of HPLC−MS methods, enrichment of the analytes is needed prior to the analysis. The present MSPE procedure offers an enrichment factor of 100 for aflatoxins, which is attractive in analysis of these liquid foodstuff samples.

In conclusion, polydopamine-coated Fe_3O_4 core−shell superparamagnetic nanoparticles (PD-MNPs) can be easily prepared from amine-terminated Fe_3O_4 MNPs and dopamine via an in situ oxidative self-polymerization approach. The resultant PD-MNPs are of high stability and suspensibility. More importantly, they exhibit a high affinity to aflatoxins, thus enabling a facile and effective magnetic solid phase extraction (MSPE) of these toxins from large volume liquid samples. Using PD-MNPs as the adsorbent, MSPE of aflatoxins from liquid foodstuff samples proves effective for subsequent HPLC−MS/MS analysis and offers a considerable enrichment factor that is highly desired for quantification of trace aflatoxins. To the best of our knowledge, this is the first report on MSPE of this important group of toxins from foodstuff samples. As demonstrated in this work, the proposed MSPE−HPLC−MS/MS method is fast, very sensitive, and applicable to fast quantification of aflatoxins in water, red wine, and likely other liquid foodstuff samples.

Analysis of Phytostanyl Fatty Acid Esters in Enriched Foods via UHPLC-APCI-MS

Birgit Scholz,[†] Andreas Barnsteiner,[†] Katharina Feist,[†] Wolfgang Schmid,[‡] and Karl-Heinz Engel*[,†]

[†]Lehrstuhl für Allgemeine Lebensmitteltechnologie, Technische Universität München, Maximus-von-Imhof-Forum 2, D-85350 Freising, Germany

ABSTRACT: A method for the analysis of phytostanyl fatty acid esters, the functional ingredients of cholesterol-lowering enriched foods, was developed. The procedure is based on (i) separation of the intact esters via reversed-phase ultrahigh-performance liquid chromatography; (ii) detection by atmospheric pressure chemical ionization−mass spectrometry; and (iii) quantitation using selected ion monitoring (SIM) mode. Employing a C8 column, phytostanyl fatty acid esters sharing the same stanol nucleus could be separated according to the esterified fatty acids while esters with different stanol moieties could be distinguished via SIM based on the formation of an intense fragment ion $[M - \text{fatty acid} + H]^+$. The suitability of the approach was demonstrated using different types of enriched foods reflecting the diversity in potential matrices (skimmed milk drinking yogurt, margarine, and soft-cheese-style spread). The developed methodology extends the analytical basis for authenticity and quality assessments of functional foods enriched with phytostanyl fatty acid esters.

KEYWORDS: *phytostanyl fatty acid ester, enriched foods, RP-UHPLC-APCI-MS*

INTRODUCTION

An increased plasma cholesterol level is an acknowledged risk factor for the development of cardiovascular diseases.[1−4] By the 1950s phytosterols have been used to achieve cholesterol-lowering effects in humans.[2] There has been increasing scientific evidence for a negative correlation between dietary intake of phytosterols/-stanols and plasma and low-density lipoprotein cholesterol levels.[3,4] Therefore, phytosterols are incorporated into a broad spectrum of various food categories. For technological reasons, the plant sterols/stanols are commonly esterified with fatty acids (FA). In the course of their safety assessment, in the European Union the profiles of both the sterols/stanols and the fatty acids have been specified by the Scientific Committee on Food (SCF); sterols/stanols are to be obtained from vegetable oils or tall oil, and the fatty acids used for esterification have to be derived from vegetable oils.[5−7] In this context, the development of suitable analytical methods allowing the elucidation of the qualitative and quantitative compositions of the esters has received increasing scientific interest. They are the essential basis for authenticity assessments as required according to the aforementioned regulations. An additional aspect reinforcing the importance of knowledge on the detailed compositions of the intact esters is a potential difference between individual phytosteryl/-stanyl fatty acid esters concerning their cholesterol-lowering efficacies. *In vitro* and *in vivo* observations of intestinal hydrolysis rates, the decisive step for the release of the phytosterols/-stanols to exert their mechanism of action showed dependencies on both the phytosterol/-stanol structures and the fatty acid moieties of distinct esters.[8−10]

However, qualitative and quantitative chromatographic analysis of phytosteryl/-stanyl fatty acid esters in their intact form is not trivial. The ester preparations used for food fortification vary regarding sterol/stanol as well as fatty acid moieties; the resulting multitude of high molecular weight compounds with a high degree of structural similarities constitutes a challenge for chromatographic separations. Recent publications showed a medium polar and temperature-stable trifluoropropylmethyl polysiloxane column to be the best choice for the gas chromatography (GC)-based separation of plant stanyl and steryl fatty acid esters, with only the esters of saturated and monounsaturated fatty acid esters of the same chain length eluting at the same time.[11,12] A detailed compositional analysis of individual plant steryl/stanyl fatty acid esters contained in functional foods could thus be performed for the first time. Yet, due to the high boiling points of these constituents and due to the presence of reactive double bonds in the fatty acid moieties, thermal degradations during high-temperature GC are a critical disadvantage of this chromatographic technique. This drawback could be successfully compensated for by the use of respective correction factors.[11]

Nevertheless, liquid chromatography (LC)-based approaches seem to be more appropriate for the analysis of intact phytosterol/-stanol fatty acid esters. Billheimer et al.[13] were the first to report a reversed-phase (RP) liquid chromatography-based separation of molecular species of steryl fatty acid esters utilizing a C18 column, but resolution was not satisfactory and, owing to the UV-detector employed, the sensitivity of the method was low. Meanwhile, further efforts have been made regarding liquid chromatographic analysis; however, all of them suffer from either insufficient resolutions of the single esters, long analysis times, lack of sensitivity, or

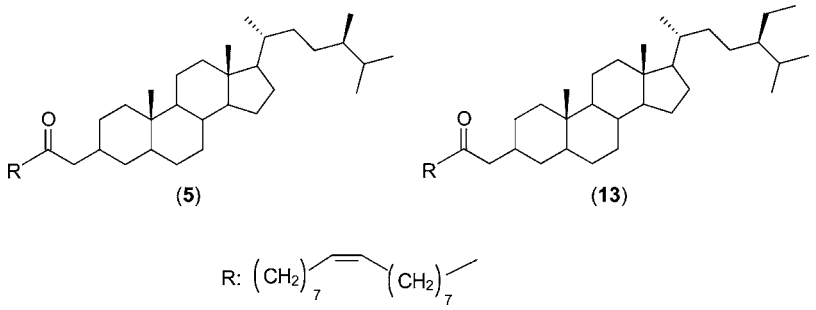

Figure 1. Structures of representative phytostanyl fatty acid esters: campestanyl-18:1, **5**; sitostanyl-18:1, **13**. The numbers correspond to those shown in Table 1 and Figure 2.

combinations of these chromatographic issues.[14−16] In addition to the application of electrospray ionization (ESI) as reported by Caboni et al.,[17] the work by Mezine et al.[18] described a promising approach using positive atmospheric pressure chemical ionization (APCI)−mass spectrometry (MS) detection, and differentiating steryl/stanyl esters that were incompletely separated or coeluting via ion extraction. Nevertheless, in addition to an unsatisfactory resolution, detailed qualitative and quantitative data on the individual esters analyzed in fortified foods were lacking.

Therefore, the objective of the present study was to develop a thermally nondestructive, rapid, and sensitive chromatographic method based on ultrahigh-performance liquid chromatography (UHPLC)-separation in combination with MS-detection for the quantitation of intact phytostanyl fatty acid esters. The suitability of the approach should be demonstrated using different types of enriched foods reflecting the diversity in potential matrices (skimmed milk drinking yogurt, margarine, and soft-cheese-style spread). Representative structures of the analyzed campestanyl and sitostanyl fatty acid esters are shown in Figure 1.

MATERIALS AND METHODS

Sample Material. Skimmed milk drinking yogurt "Emmi Benecol strawberry" enriched with phytostanyl esters (Emmi, Luzern, Switzerland) was purchased in a local supermarket (Munich, Germany). In the list of ingredients, the following information was included: 3.0 g of phytostanols, 2.1 g of fat (without stanol), and 3.0 g of protein/(100 g).

Margarine "Benecol—Margaryna roślinna o zwartości trzech czwartych tłuszczu" enriched with phytostanyl esters (Bunge Polska Sp. Z.o.o. Karczew, Poland) was purchased in a supermarket in Poland. In the list of ingredients, the following information was included: 8.0 g of phytostanols and 60 g of fat/(100 g).

Soft-cheese-style spread "Benecol—Soft Cheese style spread light" enriched with phytostanyl esters (McNeill Nutritionals Ltd., Wokingham, U.K.) was purchased in a supermarket in the U.K. In the list of ingredients, the following information was included: 4.0 g of phytostanols, 13.9 g of fat, and 8.1 g of protein/(100 g).

Chemicals. Cholesteryl linolenate (≥85%), diethyl ether (Et_2O; extra pure), ethyl acetate (EtOAc; CHROMASOLV, for HPLC), and hydrochloric acid (25%) were obtained from Sigma-Aldrich (Steinheim, Germany). Methanol (MeOH) (ROTISOLV, Ultra LC-MS) was purchased from Carl Roth (Karlsruhe, Germany). *n*-Hexane (AnalR NORMAPUR) and sodium sulfate (anhydrous) were purchased from VWR International (Darmstadt, Germany). Methyl *tert*-butyl ether (MTBE) was supplied by Evonik Industries AG (Essen, Germany) and was distilled prior to use. A mixture of phytostanyl fatty acid esters ("plant stanol ester", STAEST-115; 96.8% phytostanyl esters with an ester profile of 55.9% sitostanyl-18:1, 18.4% sitostanyl-18:2, 8.1% sitostanyl-18:3, 5.7% campestanyl-18:1, 4.1% sitostanyl-16:0, 1.9% campestanyl-18:2, 1.5% sitostanyl-18:0, 1.3% sitostanyl-20:1, 0.8% campestanyl-18:3, 0.5% sitostanyl-20:0, 0.4% sitostanyl-22:1, 0.4% campestanyl-16:0, 0.3% sitostanyl-22:0, 0.2% sitostanyl-16:1, 0.2% campestanyl-18:0, 0.1% campestanyl-20:1, 0.1% campestanyl-20:0, 0.04% campestanyl-22:1, 0.03% campestanyl-22:0, and 0.03% campestanyl-16:1) was provided by Raisio Group (Raisio, Finland). Reference compounds for stanyl fatty acid esters were synthesized according to previously described procedures.[12,19]

Lipid Extraction. The extraction of lipids from skimmed milk drinking yoghurts as well as from the soft-cheese-style spread was performed according to a previously described method.[11,20] First, the drinking yoghurt was homogenized by vigorous shaking and the soft-cheese-style spread by using an electric blender. A 300 μL aliquot of the internal standard (IS) cholesteryl linolenate [2.5 mg/mL in *n*-hexane/MTBE (3:2, v/v)] was put into a reaction vessel, and the solvent was removed by a gentle stream of nitrogen. A 100 mg amount of drinking yoghurt or 75 mg of soft-cheese spread, a magnetic stir bar, 400 μL of bidistilled water, and 1 mL of hydrochloric acid (25%) were added, and the sealed vessel was sonicated until the internal standard was dispersed; the completeness of the dispersion was examined visually. The digestion was performed at 130 °C for 45 min. After cooling to room temperature, 1 mL of bidistilled water was added, and the solution was filtered using a 0.45 μm membrane filter. The vial and the filter were washed three times with 5 mL of bidistilled water until the pH of the filtrate was neutral. The lipids were extracted three times with 5 mL of *n*-hexane/MTBE (3:2, v/v), and the combined extracts were dried with sodium sulfate. An aliquot of the drinking yoghurt extract was dried under nitrogen, re-dissolved in the same volume of EtOAc, and directly used for UHPLC-MS analysis. The soft-cheese-style spread extract was further subjected to solid-phase extraction (SPE).

For lipid extraction from the margarine sample, a previously published method was used.[11] A 30 mg amount of the sample was weighed into a vessel; 300 μL of the internal standard cholesteryl linolenate [2.5 mg/mL in *n*-hexane/MTBE (3:2, v/v)], 5 mL of *n*-hexane/MTBE (3:2, v/v), and sodium sulfate were added and sonicated for 1 min. The solution was filtered through a 0.45 μm membrane filter. The vessel and the filter were washed twice with 5 mL of *n*-hexane/MTBE (3:2, v/v), and the combined extracts were used for solid-phase extraction.

Solid-Phase Extraction. A 500 μL aliquot of the lipid extracts of the margarine and the soft-cheese-style spread was dried via a gentle stream of nitrogen and re-dissolved in the same volume of *n*-hexane. Aliquots of 120 μL of the lipid extract were loaded onto a Strata NH_2, 55 μm, 70 Å, 400 mg/(3 mL) SPE cartridge (Phenomenex, Aschaffenburg, Germany) previously conditioned with 2 × 3 mL of *n*-hexane, and the stanyl/steryl fatty acid esters were eluted with 2 × 3 mL of *n*-hexane/Et_2O (99:1, v/v). After evaporation of the solvent by a gentle stream of nitrogen, the residue was dissolved in 150 μL of EtOAc, filtered through a 0.45 μm membrane filter, and subjected to UHPLC-MS analysis.

Analysis by UHPLC-APCI-MS. Samples were analyzed by injecting 0.8 μL into a 1290 Infinity Series UHPLC system (Agilent Technologies, Waldbronn, Germany) coupled to a Surveyor MSQ Plus single quadrupole mass-selective detector, using an APCI source

dx.doi.org/10.1021/jf500957a | J. Agric. Food Chem. 2014, 62, 4268−4275

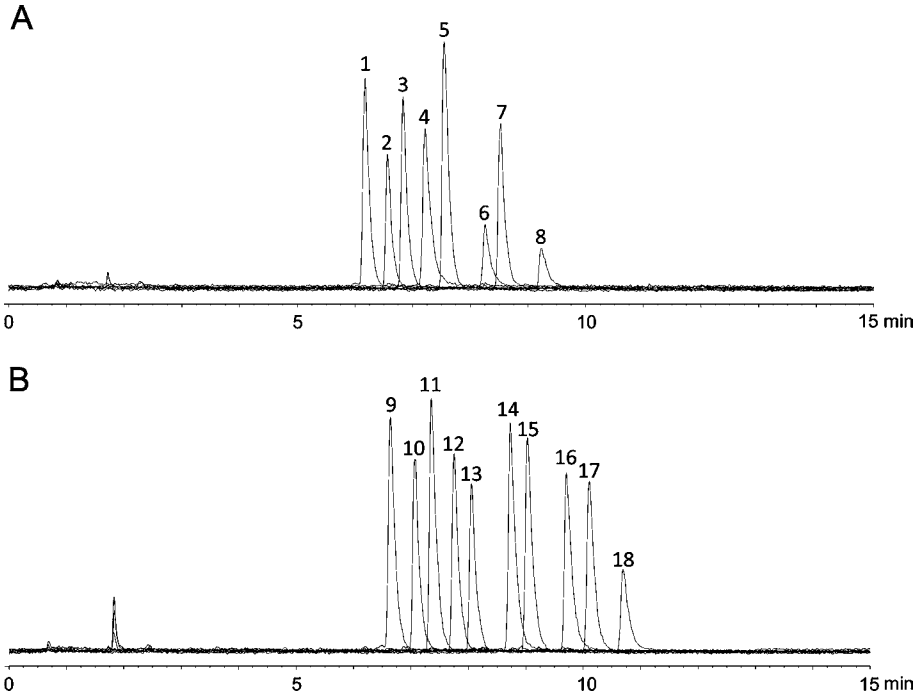

Figure 2. RP-UPLC-APCI-MS-based separation of synthesized phytostanyl fatty acid esters on a C8 column. Overlay of (A) SIM chromatograms of campestanyl fatty acid esters at m/z 385.3; (B) SIM chromatograms of sitostanyl fatty acid esters at m/z 399.3. The peak numbering corresponds to that in Table 1.

(Dionex Softron GmbH, Germering, Germany). UHPLC separation was carried out on a 150 mm × 2.10 mm i.d., 1.7 μm, 100 Å, Kinetex C8 column (Phenomenex, Aschaffenburg, Germany) at 50 °C and a flow rate of 0.58 mL/min. The mobile phase was composed of MeOH and water with the following gradient: from 90% to 95% MeOH within 1.20 min and holding until 3 min; from 95% to 100% MeOH between 3 and 12 min, and back to the initial 90% from 12 to 15 min. The MS parameters were set as follows: ionization mode, APCI (positive); probe temperature, 400 °C; N_2 nebulizer pressure, 45 psi; cone voltage, 80 V; coronal discharge, 8 μA. Instrument control and data acquisition were performed by Xcalibur software 2.0.7, Thermo MSQ 2.0 (Thermo Scientific, Austin, TX, USA), Chromeleon software 6.80 (Dionex Corp., Sunnyvale, CA, USA) in combination with Agilent Instrument Control Framework (Agilent Technologies, Waldbronn, Germany). Mass spectra of synthesized reference compounds were recorded in full scan mode at a mass range of m/z 100−750. For quantitative analyses the MS detector was adjusted to monitor positive ions in the selected ion monitoring (SIM) mode with a mass window of 0.2 at m/z 369.3, 385.3, and 399.3, respectively.

Identification and Quantitation by UHPLC-APCI-MS. The identities of the phytostanyl fatty acid esters extracted from enriched foods were confirmed via comparison of relative retention times to those of synthesized standard compounds in the respective SIM mode. Stanyl fatty acid esters were quantitated by generating five-point calibration functions with 0.1, 0.26, 0.43, 0.6, and 0.76 mg of total esters (STAEST-115)/mL, except for campestanyl-20:0, campestanyl-20:1, and campestanyl-18:0 which were quantitated via three-point calibration functions with 0.43, 0.6, and 0.76 mg of total esters (STAEST-115)/mL. Each calibration point was analyzed in triplicate. Linear regression was confirmed in ratio of areas (area of stanyl ester/area of IS) and amounts (amount of stanyl ester/amount of IS).

Validation of the UHPLC-APCI-MS-Based Approach. Recovery rates were determined by spiking nonenriched products with known amounts of the plant stanyl ester mixture STAEST-115. To 100 mg of skimmed milk yogurt (0.1% fat), 30 mg of margarine (45% fat), and 75 mg of cream cheese (13% fat) were added 5, 4.5, and 4.9 mg of the phytostanyl ester mixture, respectively. Subsequently, the spiked samples were subjected to the extraction procedures as described previously. The limits of detection (LOD) and the limits of quantitation (LOQ) were determined according to the method of Vogelgesang and Hädrich.[21] As quality control measures, the performance of the instrument was regularly confirmed by assessing the responses obtained for the calibration solutions and by analyzing and quantitating the same skimmed milk drinking yogurt extract each time a new batch of samples was subjected to LC-MS analysis.

■ RESULTS AND DISCUSSION

Optimization of RP-UHPLC-Separation. Using positive-ion APCI-MS, an intense formation of the fragment ion $[M - FA + H]^+$ has been described for phytosteryl and phytostanyl fatty acid esters.[18,22] Therefore, in order to establish suitable UHPLC conditions for the separation of synthesized reference compounds, the MS detector was operated in the positive-ion APCI SIM mode, at m/z 385.3 for campestanyl fatty acid esters and at m/z 399.3 for sitostanyl fatty acid esters; this resulted in a highly specific and sensitive detection of the analytes. The UHPLC separation was optimized for the stanyl esters of fatty acids occurring in the vegetable oils authorized as sources.[5−7] In addition, GC-FID data previously published for evaluating the composition of intact phytostanyl fatty acid esters in enriched foods were taken into account.[11] Former efforts to establish RP-LC-based analyses of individual plant steryl/stanyl fatty acid esters used C18 columns.[13−17,23] A more recent study employed a hexyl phenyl column; however, this column also did not yield sufficient separations.[18] In the present study a C8 (1.7 μm) column was shown to enable a separation of all stanyl fatty acid esters consisting of the same stanol nucleus within a rather short analysis time (12 min). The achieved resolution factors were all higher than 1. Preliminary studies confirmed that the particle size of the employed column significantly contributed to the achieved separation (data not shown). Those esters exhibiting different stanol nuclei were further distinguished via the selection of masses corresponding to the fragment ions $[M - FA + H]^+$ in the SIM mode. Overlays of

[a]Retention times relative to cholesteryl linolenate (Kinetex C8, 1.7 μ). [b]Relative retention times and mass spectra were determined using synthesized reference compounds. [c]Limits of detection (LOD) and limits of quantitation (LOQ) were determined using the plant stanyl fatty acid mixture STAEST-115 according to ref 21 and are expressed as μg of plant stanyl fatty acid ester/(mL of injection volume). [d]LODs and LOQs were not determined (n.d.) for campestanyl-16:1 and sitostanyl-16:1, as these compounds could not be detected in any of the samples analyzed.

the chromatograms obtained for the synthesized sitostanyl and campestanyl fatty acid esters are shown in Figure 2. The order of elution was impacted by both the chain length and the degree of saturation of the esterified fatty acids: the lower the carbon number and the higher the number of double bonds, the shorter was the retention time. Additionally, campestanyl fatty acid esters eluted earlier than the corresponding sitostanyl fatty acid esters. The observed retention behavior is similar to elution profiles described for phytosteryl/-stanyl as well as cholesteryl fatty acid esters on reversed phases.[13,14,17,18,24,25] In contrast to the approach chosen by Mezine et al.,[18] a step $MeOH/H_2O$ gradient was used instead of a linear gradient of acetonitrile in water, as on the one hand gradient elution improved the chromatographic separation and on the other

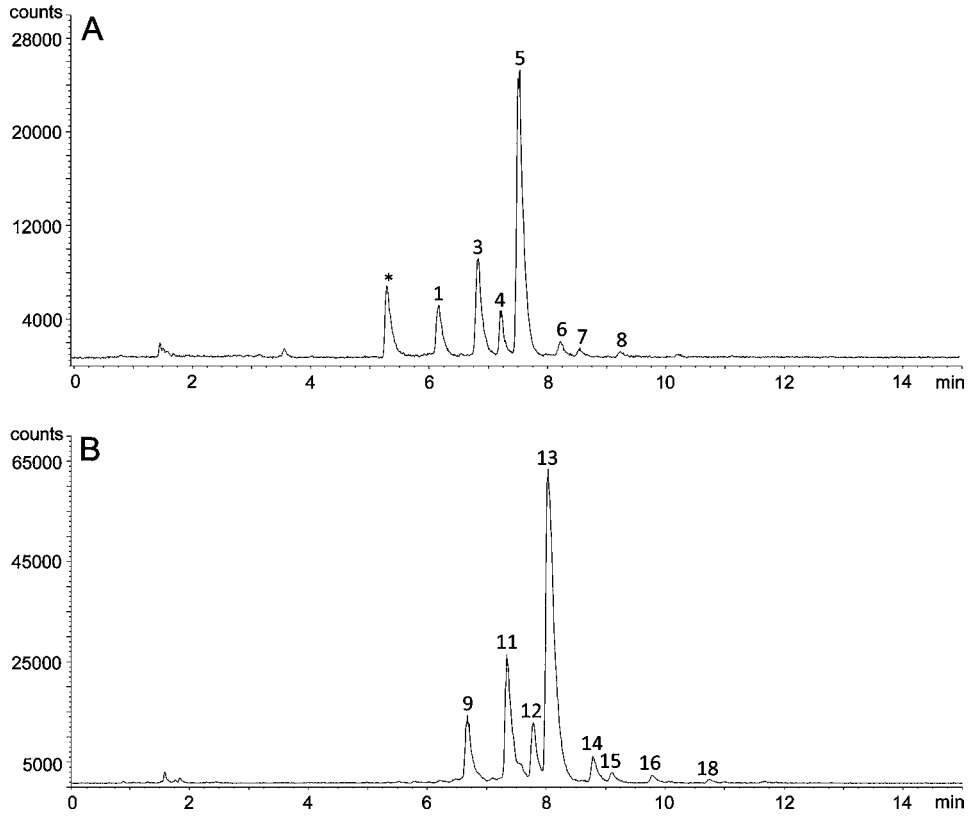

Figure 4. LC-APCI-MS analysis of phytostanyl fatty acid esters extracted from enriched skimmed milk drinking yogurt. (A) SIM chromatogram of campestanyl fatty acid esters at m/z 385.3. (B) SIM chromatogram of sitostanyl fatty acid esters at m/z 399.3. The peak numbering is in accordance with those of Figure 1 and Table 1. The asterisk in panel A is derived from the internal standard cholesteryl linolenate. For conditions, see Materials and Methods.

hand the use of methanol also provided a much better resolution and peak shape. In addition, an enhanced ionization efficiency has been ascribed to methanol as solvent in LC-APCI-MS applications due to a reduced proton affinity when compared to acetonitrile.[26]

LC-MS-APCI Data. Full scan APCI mass spectra of the synthesized reference compounds were recorded under the established LC conditions; as examples, the positive full scan mass spectra of sitostanyl stearate and sitostanyl linolenate are shown in Figure 3. The fragment ion $[M - FA + H]^+$ used for detection of the standard compounds was shown to constitute the base peak of all stanyl fatty acid ester spectra; a cone voltage of 80 V turned out to be optimum for the formation of this ion. Protonated molecular ions $[M + H]^+$ were only observed in spectra of stanols esterified to unsaturated fatty acids; however, intensities were low for stanyl esters of monounsaturated fatty acids, whereas poly-unsaturation favored the formation of molecular ions. Likewise, the extent of the formation of a characteristic fragment ion $[FA + H]^+$ correlated with the number of double bonds in the fatty acid moiety. When using ESI-MS, the addition of salts to the mobile phase was required to achieve sufficient ionizability of plant steryl fatty acid esters; however, this resulted in longer retention times and broader peak shapes.[17] This drawback could be avoided with the developed APCI-based approach.

LC-MS-APCI Quantitation. As the fragment $[M - FA + H]^+$ occurred in high abundance in the mass spectra of all esters, quantitation of campestanyl fatty acid esters (m/z 385.3) and sitostanyl fatty acid esters (m/z 399.3) in SIM mode was based on this ion. Chromatographic data and selected ions for individual phytostanyl fatty acid esters are shown in Table 1. The employed internal standard cholesteryl linolenate showed a fragmentation pattern similar to the plant stanyl fatty acid esters, thus enabling detection in SIM mode at m/z 369.3, the mass corresponding to the fragment ion $[M - FA + H]^+$. The chromatographic usefulness of cholesteryl linolenate as internal standard was confirmed via injection and subsequent selected ion monitoring at m/z 385.3 and m/z 399.3. The compound exhibited a fragment ion at m/z 385, indicating a cleavage of the acyl moiety. Owing to the shorter retention time of the internal standard, this fragment ion did not impair campestanyl ester quantitation, and therefore its concentration dependency was not further pursued.

The determined limits of detection and limits of quantitation of the individual plant stanyl fatty acid esters as occurring in the mixture STAEST-115 are also given in Table 1. For campestanyl fatty acid esters, they were in the same order of magnitude as those achieved for the previously described GC-based approach.[11] In contrast, for sitostanyl esters (except for palmitate), the LODs and LOQs obtained via the UHPLC analysis were considerably lower; this reflects the increased thermal degradation of these later eluting compounds in the course of high-temperature GC. The impact of the matrices and the different work-up procedures has been taken into account by the determination of individual recovery rates for each of the analyzed products.

In order to compensate for varying detector responses of distinct stanyl fatty acid esters, external five-point-calibration functions were generated, calibrating the response ratio of each individual stanyl fatty acid ester and the internal standard. Only

for campestanyl-18:0, -20:0, and -20:1 three-point-calibration functions were used, because of the lack of responses for these components in the calibration mixtures at the lowest concentrations. The coefficients of determination (R^2) were in the range of 0.9914−0.9997, confirming a linear relationship of each plant stanyl fatty acid ester within the respective concentration range in comparison to the internal standard. Area ratios and amount ratios of the investigated plant stanyl esters were consistently within the range of the calibration.

Plant Stanyl Fatty Acid Esters in Skimmed Milk Drinking Yogurts. Skimmed milk drinking yogurts were selected to test the suitability of the developed UHPLC-APCI-MS methodology because they are examples for protein-based, low-fat enriched dairy products. For this food category a method allowing the fast extraction of intact fatty acid stanyl esters has been described, based on acid digestion of the protein matrix.[11] No degradation or hydrolysis of the esters has been observed during this work-up step.[11,20] Due to the fat content of only 2.1% in this type of product, no interferences with lipid matrix constituents during chromatographic analysis were expected. Preliminary LC-MS experiments revealed a pronounced signal suppression caused by coeluting triglycerides only if the ratio of triglycerides and plant stanyl fatty acid esters in the injection solutions was higher than 1. EtOAc was chosen as injection solvent as the stanyl ester extracts could not be completely dissolved in more polar media. The SIM

chromatograms for campestanyl and sitostanyl fatty acid esters extracted from skimmed milk drinking yogurts are shown in Figure 4. The detailed compositions of phytostanyl fatty acid esters and the total contents of phytostanyl esters determined in skimmed milk drinking yogurts are given in Table 2. Oleic acid esters dominated the chromatogram followed by esters of linoleic, linolenic, and palmitic acid, whereas the fatty acids consisting of 20 and 22 carbon atoms were only esterified to a minor extent; this pattern indicated rapeseed oil as the fatty acid source for esterification.[27] The calculated amounts of total phytostanols were in good agreement with the labeling ("plant stanol 3.0%"). In addition, both the individual ester contents and percentage distributions determined via the presented approach are corresponding to data obtained via GC/FID on intact plant stanyl fatty acid esters in yogurt drinks of the same type and brand.[11] Phytostanyl esters of palmitoleic acid could not be identified, and sitostanyl-22:1 was also not detectable in the present work; however, a direct comparison of the two approaches, in that respect, is not possible due to coelution of esters of saturated and monounsaturated fatty acids in the GC-based method. Two bottles from different batches were analyzed in triplicate on 3 days by one operator, revealing excellent repeatability of the method. A quantitation of comparable ester contents after analysis of the samples by a second operator demonstrated the reproducibility of the method. Recovery rates of the analytical approach were calculated to be 97.70 ± 0.5%; they further confirm the stability of the analytes during acid digestion of the protein matrix.

Plant Stanyl Fatty Acid Esters in Enriched Margarines. Margarines enriched with plant stanyl fatty acid esters were selected as an example for fat-based food matrices. In this case, prior removal of interfering lipid matrix constituents was required. Recently, aminopropyl-based solid-phase extraction was shown to be a suitable tool for the selective separation of plant stanyl fatty acid esters from other lipids.[19,28] Hence, a rapid and efficient SPE-based preseparation was established, using aminopropyl-modified silica cartridges and a mixture of *n*-hexane/diethyl ether (99:1, v/v) for the elution of phytostanyl fatty acid esters. The recovery of the stanyl ester mixture STAEST-115 spiked to a nonenriched margarine was very good (97.19 ± 1.44%). Table 3 shows the quantitative data obtained after investigation of a commercial margarine on three different days and additionally by a second operator; the results were excellent regarding both repeatability and reproducibility. The calculated contents of total phytostanols were in very good agreement with the amounts declared on the label. Being similar to the pattern of the esters detected in skimmed milk drinking yogurts, the distribution of the plant stanyl fatty acid esters determined in margarine suggested rapeseed fatty acids having been used for esterification. In addition to the compounds determined in skimmed milk drinking yogurts, sitostanyl-22:1 could also be detected and quantitated, accounting for approximately 0.3% of total esters in the margarine sample.

Plant Stanyl Fatty Acid Esters in Soft-Cheese-Style Spread. The soft-cheese-style spread was selected because it consists of both considerable amounts of protein and fat. Consequently, a combination of the acid digestion applied to the skimmed milk drinking yogurts and the solid-phase extraction employed for removal of triglycerides in the margarine sample was used for this type of product. This allowed such a complex food matrix also to be analyzed quickly and without further methodological modifications. The approach showed good recovery rates of 96.39 ± 0.26% determined via the addition of the plant stanyl ester mixture STAEST-115 to a nonenriched cream cheese. The distributions of the plant stanyl fatty acid esters analyzed in two packages of soft-cheese-style spread resembled those determined in drinking yogurts and margarine, once more indicating rapeseed oil as the fatty acid source and at the same time confirming the reliability of the established analytical approach. Table 4 presents the quantitative data for two packages of cheese spread obtained by triplicate analyses on 3 days and by an

additional second operator, their low deviations proving excellent repeatability and good reproducibility. The calculated amounts of total phytostanol contents matched the declared amounts.

In conclusion, an RP-UHPLC-APCI-MS-based analytical approach enabling a simple, robust, and fast detection of plant stanyl fatty acid esters extracted from different types of enriched foods was established. Plant stanyl fatty acid esters consisting of the same stanol moiety could be resolved on a C8 column and analyzed in SIM mode for highly sensitive detection that differentiates esters depending on the esterified stanol moiety. Thus, an excellent separation was accomplished without having to manage the issue of thermal degradation of unsaturated long-chain fatty acid esters, the major drawback of GC-based approaches. Fast and facile sample preparation was used and extensively validated for three different types of enriched foods available on the European market, providing a range of extraction methods being suitable for either protein-based matrices, lipid-based matrices, or a combination of both. The aquired detailed qualitative and quantitative data on plant stanyl fatty acid esters will extend the analytical portfolio for the assessment of functional foods in terms of authenticity and in terms of the contribution of intact esters to the cholesterol lowering effects.

Sensitive Quantitation of Polyamines in Plant Foods by Ultrasound-Assisted Benzoylation and Dispersive Liquid−Liquid Microextraction with the Aid of Experimental Designs

Edgar Pinto, Armindo Melo, and Isabel M. P. L. V. O. Ferreira*

REQUIMTE/Departamento de Ciências Químicas, Laboratório de Bromatologia e Hidrologia, Faculdade de Farmácia, Universidade do Porto. Rua de Jorge Viterbo Ferreira 228, 4050-313 Porto, Portugal

Supporting Information

ABSTRACT: A new method involving ultrasound-assisted benzoylation and dispersive liquid−liquid microextraction was optimized with the aid of chemometrics for the extraction, cleanup, and determination of polyamines in plant foods. Putrescine, cadaverine, spermidine, and spermine were derivatized with 3,5-dinitrobenzoyl chloride and extracted by dispersive liquid−liquid microextraction using acetonitrile and carbon tetrachloride as dispersive and extraction solvents, respectively. Two-level full factorial design and central composite design were applied to select the most appropriate derivatization and extraction conditions. The developed method was linear in the 0.5−10.0 mg/L range, with a $R^2 \geq 0.9989$. Intra- and interday precisions ranged from 0.8 to 6.9% and from 3.0 to 10.3%, respectively, and the limit of detection ranged between 0.018 and 0.042 μg/g of fresh weight. This method was applied to the analyses of six different types of plant foods, presenting recoveries between 81.7 and 114.2%. The method is inexpensive, versatile, simple, and sensitive.

KEYWORDS: *plant foods, putrescine, cadaverine, spermidine, spermine, response surface methodology, HPLC−DAD*

INTRODUCTION

The polyamines putrescine, cadaverine, spermidine, and spermine are low-molecular-weight organic amines with aliphatic structure, which have been implicated in several biological processes, such as plant growth and development.[1] These compounds are naturally found in many plant foods and are involved in the regulation of a diverse range of vital cellular processes in eukaryotic cells. In plants, the most common polyamines are putrescine, spermidine, and spermine and are usually localized in the cytoplasm and organelles (e.g., vacuoles, mitochondria, and chloroplasts) of plant cells.[2,3]

The dietary intake of polyamines influences human health. Their biological role in humans includes participation in cell growth and proliferation, pain sensitization, stabilization of DNA, gene transcription, apoptosis, regulation of the immune response, maintenance of intestinal function, and protein synthesis.[4,5] It has been suggested that increasing polyamine intake has several health benefits, such as decreasing age-associated pathologies and increasing longevity.[6] However, a polyamine-deficient diet has also been proposed as an efficient nutritional strategy for several human conditions.[7]

Plant foods have very low levels of polyamines, ranging from a few milligrams to less than a 100 mg/kg. Thus, methods to perform polyamine quantitation in plant foods frequently report results as non-detectable or below the limit of detection (LOD)/limit of quantitation (LOQ) because of the high sensitivity required.[8−10] Plant foods are a very complex and variable matrix;[2,3] thus, efficient cleanup and pre-concentration techniques are needed to obtain sensitive and accurate quantitation of polyamines. Because plant foods are solid matrixes, an extraction/deproteinization is also required. The deproteinization process is usually performed with diluted strong acids, such as perchloric, hydrochloric, and trichloroacetic acids.[11−13]

Chemical derivatization has become widely accepted in polyamine analysis, enabling great sensitivity and selectivity to be achieved. Nowadays, there are several derivatization reagents that can be used for ultraviolet (UV) and/or fluorescence detection, including *o*-phthaldialdehyde, dansyl chloride, 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate, dabsyl chloride, 3,5-dinitrobenzoyl chloride, 1,2-naphthoquinone-4-sulfonate, benzoyl chloride, 4-chloro-3,5-dinitrobenzotrifluoride, diethyl ethoxymethylenemalonate, and others.[14,15] Among them, 3,5-dinitrobenzoyl chloride shows several advantages, such as its low price, commercial availability, and fast reaction times, at room temperature.[16]

Many sample preparation techniques have been developed for cleanup purposes. Liquid−liquid extraction (LLE) and solid-phase extraction (SPE) are some of the most widely used techniques; however, they require large quantities of organic solvents and are time-consuming.[12,13] Solid-phase microextraction (SPME) and single-drop microextraction (SDME) have been increasingly used in the last few years because of their eco-friendly nature.[17,18] However, these procedures also had some drawbacks, such as high price, short durability of the extraction fibers, and sample carryover.[19] Dispersive liquid−liquid microextraction (DLLME) is a novel sample preparation technique based on a ternary component mixture consisting of an aqueous sample, a dispersive solvent, and an extraction

solvent. It presents several advantages, such as simplicity, high recovery, quickness, and low cost.[20]

Several methods have been developed for the analysis of polyamines, including micellar electrokinetic chromatography,[21] gas chromatography (GC),[17] thin-layer chromatography,[22] ion chromatography,[23] and liquid chromatography (LC).[24] Overall, LC is the most widely used technique in the determination of polyamines in different kinds of food because of its high selectivity, sensitivity, and applicability.

Growing interest arises in coupling derivatization and DLLME, followed by chromatographic separation (i.e., LC or GC) for the analysis of different kinds of compounds.[25,26] The potentiality of these methods to simplify experimental procedures, decrease sample loss, increase method sensitivity, and remove interferences is seen as a great improvement in the analytical chemistry field.[27] The development of a derivatization and DLLME method requires selection of several variables (concentration of derivatization reagent, reaction time, reaction temperature, dispersive solvent volume, extraction solvent volume, and ionic strength) to establish optimum conditions. The optimization of a multivariable system through a one-variable-at-a-time procedure can be time-consuming and neglect potential interactions between variables. The two-level full factorial design is a useful tool for preliminary screening of experimental factors that needed to be optimized, whereas response surface methodology (RSM) aids to understand interactions among the parameters that should be optimized to determine the optimum operational conditions for the system or to determine a specific region that satisfies the operating specifications.[28] Consequently, these chemometric methods, when applied to derivatization and miniaturized extraction procedures, improve the quality of analytical data. However, until now, few studies apply these procedures.

A new method is presented for the detection and quantitation of putrescine, cadaverine, spermidine, and spermine using ultrasound-assisted benzoylation followed by DLLME and high-performance liquid chromatography−diode array detection (HPLC−DAD). The benzoylation procedure and extraction conditions were optimized with the aid of two-level full factorial designs and central composite design (CCD). The developed method was applied to several plant food samples.

MATERIALS AND METHODS

Chemicals and Standard Solutions. Putrescine dihydrochloride, cadaverine dihydrochloride, spermidine trihydrochloride, 1,7-diaminoheptane [internal standard (IS)], spermine tetrahydrochloride, hydrochloric acid, acetonitrile, methanol, acetone, and 3,5-dinitrobenzoyl chloride were purchased from Sigma-Aldrich (St. Louis, MO). Boric acid, sodium hydroxide, potassium chloride, and sodium chloride were from VWR (Radnor, PA). Perchloric acid ($HClO_4$), carbon tetrachloride, chlorobenzene, chloroform, dichloromethane, tetrachloroethylene, and trichloroethylene were obtained from Merck (Darmstadt, Germany).

Standard stock solutions were prepared by dissolving each compound in 0.1 M HCl at a final concentration of 1000 mg/L. Working standard solutions were prepared daily from the stock solutions by adequate dilution with 0.1 M HCl. Sodium borate buffer was prepared from dilution of H_3BO_3 and KCl in water (0.5 M each), followed by titration with NaOH (0.5 M) to pH 10. 3,5-Dinitrobenzoyl chloride (56 mM) was prepared by dissolving a proper amount of the solid compound in acetonitrile.

Instrumentation and Chromatographic Conditions. Chromatographic analysis was performed with an analytical HPLC unit (Jasco, Tokyo, Japan) equipped with Jasco PU-2080 HPLC pumps, Jasco MD-2010 Plus multiwavelength detector, and a column oven model 7981 (Jones Chromatography, Hengoed, U.K.). The column used was a 250 × 4.6 mm inner diameter, 5 μm, Ultracarb 30-ODS RP-18 (Phenomenex, Milford, MA). The Borwin PDA controller software (JMBS Developments, Le Fontanil, France) was used for system control and data acquisition. The column temperature was set at 35 °C, and the chromatographic separation was carried out by gradient elution with two solvent mixtures at a 1 mL/min flow rate. Solvent A consisted of 10 mM aqueous sodium formate/formic acid buffer at pH 3, and solvent B consisted of acetonitrile. The linear gradient program was as follow: 0−5 min, 40% B; 5−11 min, 58% B; 11−15 min, 58% B; 15−20 min, 65% B; 20−23 min, 65% B; 23−28 min, 95% B; 28−30 min, 95% B; and 30−40 min, column rinse and re-equilibration. The total run time, including polyamine separation, column rinse, and re-equilibration, was of 40 min. Diode array detection was carried out at the wavelength of 250 nm.

Sample Preparation. Plant food samples (lettuce, carrot, onion, cabbage, tomato, and apple) were purchased at local supermarkets. Samples were washed with ultrapure water, frozen at −80 °C, and freeze-dried. The lyophilized samples were homogenized by grinding in a blender and sieved through a nylon sieve of 150 μm mesh size. Free polyamines were determined according to Zhou and Yu,[11] with minor modifications. Lyophilized samples (100 mg) were homogenized in 2.5 mL of 5% (v/v) cold $HClO_4$ and incubated at 4 °C for 1 h. After centrifugation at 17000*g* for 30 min, the supernatant was collected and used as a sample extract to determine the content of polyamines.

Derivatization, Cleanup, and Pre-concentration. A 2 mL volume of standard solution or sample extract was placed in a 10 mL tube, and 0.5 M borate buffer (pH 10.0) and 2 M NaOH were added to adjust pH to 10. After that, 680 μL of 3,5-dinitrobenzoyl chloride in acetonitrile (56 mM) was added to the previous solution, which was subjected to vortexing. Afterward, the mixture was ultrasonicated for 15 min at room temperature. Benzoylated polyamines were extracted by the DLLME method by adding 500 mg of NaCl and 205 μL of carbon tetrachloride (extraction solvent) into the sample solution to form a cloudy solution. After vortexing for 1 min, the mixture was centrifuged for 5 min at 5000 rpm, and the organic phase was aspirated into a microsyringe and collected into a 2 mL glass vial. The organic phase was evaporated in a gentle stream of N_2 and reconstituted in 100 μL of acetonitrile. Finally, 20 μL was injected into the HPLC system for analysis.

Experimental Design. Several trials were conducted to optimize the benzoylation and DLLME conditions for the quantitative analyses of polyamines in plant foods using RSM. A two-level (2^k) factorial design was created to screen the main variables affecting the derivatization and extraction procedures. This technique is a powerful tool for screening the key variables in a multivariable system. Two different full factorial designs were created for trials at low (−1) and high (+1) concentration levels with five central points. The experiments were performed to evaluate the significance of seven variables (3,5-dinitrobenzoyl chloride concentration, 3,5-dinitrobenzoyl chloride volume, derivatization time, derivatization temperature, dispersive solvent volume, extraction solvent volume, and amount of NaCl) under study. In the first full factorial design, the evaluated variables were 3,5-dinitrobenzoyl chloride concentration (35−65 mM), 3,5-dinitrobenzoyl chloride volume (400−800 μL), derivatization time (15−40 min), and derivatization temperature (20−50 °C). The screening of the main variables affecting the derivatization procedure was performed without performing the extraction procedure to exclude potential effects arising from it. In the second full factorial design, the variables dispersive solvent volume (400−800 μL), extraction solvent volume (50−250 μL), and amount of NaCl (500−800 mg) were evaluated. The DLLME procedure was carried out after fixing the most suitable derivatization conditions. Afterward, the significant variables were optimized using a CCD.

Experiments with three independent variables, 3,5-dinitrobenzoyl chloride concentration (X_1), dispersive solvent volume (X_2), and extraction solvent volume (X_3), were conducted by applying a CCD consisting of a complete 20-factorial design with six center points and

two axial points on the axis of each design variable at a distance of α = 1.682 from the design center. The response was the sum of all polyamine peak areas. Experiments were carried out as follows: 3,5-dinitrobenzoyl chloride concentration (35−65 mM), dispersive solvent volume (400−800 μL), and extraction solvent volume (100−250 μL). The complete experimental design (see the Supporting Information) was performed using the Design Expert Trial Version 7 (Stat-Ease, Inc., Minneapolis, MN) software.

Method Validation. Mixed standard solutions (ranging from 0.5 to 10 mg/L) containing putrescine, cadaverine, spermidine, and spermine were subjected to the derivatization, cleanup, and preconcentration procedures described above. Calibration curves were constructed by the least-squares linear regression model, using the ratio between the peak area of each polyamine and the peak area of IS. The deviation from linearity was evaluated by applying the lack-of-fit test to the calibration curves of each polyamine. The intraday precision was calculated from the results of five replicate analyses in a single day of standards prepared at three concentration levels (0.5, 2.5, and 10 mg/L), whereas the interday precision was calculated from results obtained in five consecutive days. The LOD and LOQ were calculated on the basis of the calibration curve parameters according to Miller and Miller.[29]

Accuracy, on the basis of the recovery percentage {R, % = [(concentration of the spiked sample − concentration of the unspiked sample)/added concentration] × 100}, was estimated from triplicate experiments performed with lettuce, carrot, onion, cabbage, tomato, and apple samples (ca. 100 mg) spiked with 0.1 mL volume of a mixed standard solution (2.5 mg/L of each polyamine) to obtain a content of 2.5 μg/g in each plant food. Results of polyamine contents in plant foods were expressed as micrograms per gram of fresh weight.

The stability of the extracts was tested by analyzing the extract of 5 mg/L standard solution at 0, 1, 2, 6, and 24 h after the derivatization and extraction procedure. During this time period, extracts were stored at 4 °C.

RESULTS AND DISCUSSION

Experimental Parameter Selection. Working standard solutions containing putrescine, cadaverine, spermidine, and spermine (see chemical structures in Figure 1) at a fixed concentration (5 mg/L) were used to study the buffer capacity of the derivatization procedure and the performance of different dispersive and extraction solvents on the DLLME procedure. To evaluate the buffer capacity, standard solutions were diluted in 5% (v/v) $HClO_4$ solution to replicate the extraction conditions used in real plant food sample extraction. The obtained extracts presented a pH value around 1. Because the benzoylation reaction requires pH around 10, borate buffer (0.5 M) with 2 M NaOH provided a pH of 10 and was used in further experiments.

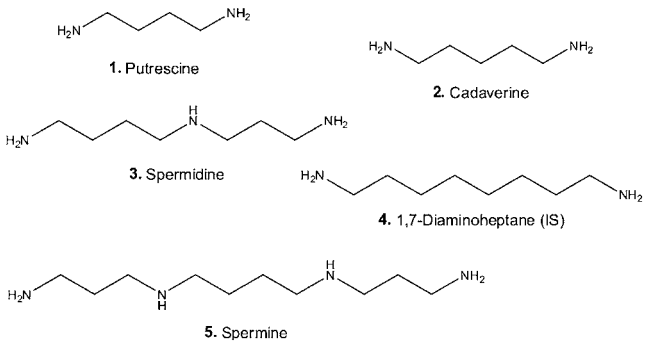

Figure 1. Chemical structure of (1) putrescine, (2) cadaverine, (3) spermidine, (4) IS, and (5) spermine.

Choosing the most suitable dispersive and extraction solvents is a crucial step to obtain the maximum extraction efficiency. The dispersive solvent should be miscible with both aqueous and organic phases, while the extraction solvent must have higher density than water, low water solubility, and high extraction efficiency for the target compounds.[20] Three dispersive solvents (methanol, acetonitrile, and acetone) and six extraction solvents (carbon tetrachloride, chloroform, chlorobenzene, dichloromethane, trichloroethylene, and tetrachloroethylene) were evaluated. The 5 mg/L standard solution was diluted in 5% (v/v) $HClO_4$ solution, derivatized, and subjected to the DLLME procedure. Triplicate measurements were performed for each tested solvent. The use of acetonitrile as a dispersive solvent led to higher peak areas for all of the tested polyamines (Figure 2A), indicating that higher sensitivity could be obtained with this solvent. Carbon tetrachloride presented higher extraction efficiency for all of the target compounds (Figure 2B); thus, it was selected as an extraction solvent.

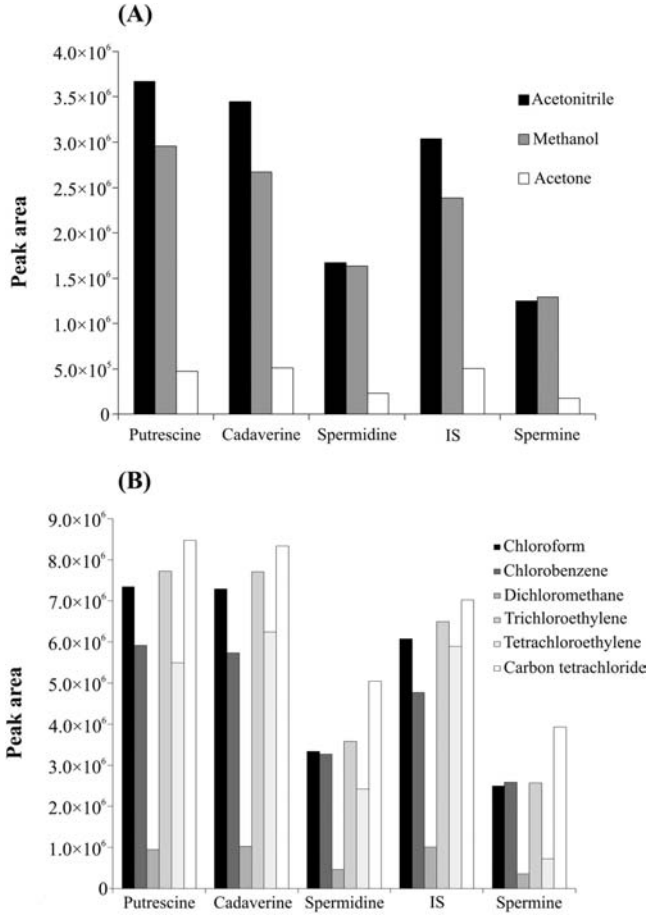

Figure 2. Selection of (A) dispersive and (B) extraction solvents.

Two-Level Full Factorial Design. The main effects of the seven studied variables in the screening experiments are presented in Figure 3 in the form of a Pareto chart. The same standard solution used to perform the selection of the dispersive and extraction solvents was used in the two-step experimental design (two-level full factorial design for screening and CCD for optimization). The magnitude of the effects is highlighted in an ordered bar chart, where the bar length of the vertical axis is proportional to the significance of the variables.

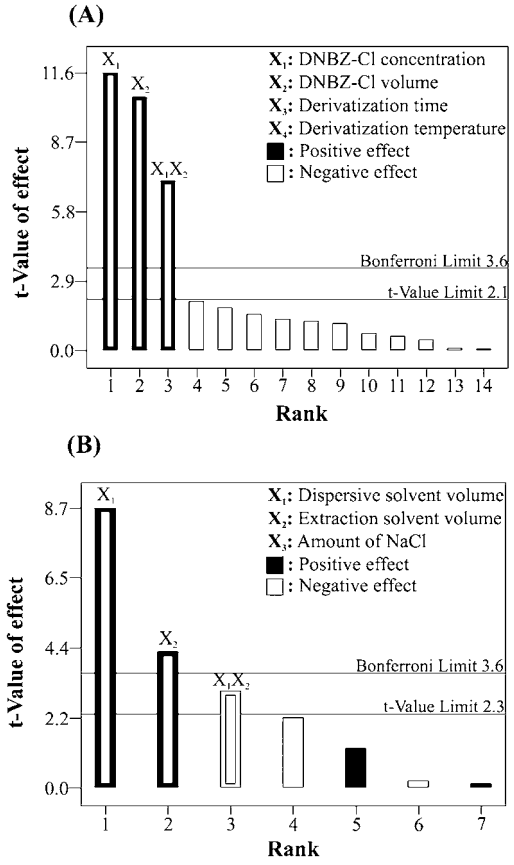

Figure 3. Main effect Pareto chart for the two-level full factorial design of the screening experiments of (A) derivatization and (B) extraction.

With regard to the derivatization procedure, the significance of the variables 3,5-dinitrobenzoyl chloride concentration, 3,5-dinitrobenzoyl chloride volume, derivatization time, and derivatization temperature was evaluated. The variables 3,5-dinitrobenzoyl chloride concentration and 3,5-dinitrobenzoyl chloride volume as well as the interaction between them were statistically significant ($p < 0.05$), with a positive effect on the response. Thus, these variables were selected for further assessment in the CCD. For the extraction procedure, the significance of the variables dispersive solvent volume, extraction solvent volume, and amount of NaCl was assessed. The variables dispersive solvent volume and extraction solvent volume as well as the interaction between them were statistically significant ($p < 0.05$) and, thus, were considered for optimization. Because the variables "3,5-dinitrobenzoyl chloride volume" and "dispersive solvent volume" tested in the first and second full factorial designs, respectively, rely on the use of acetonitrile, the two variables were designated throughout the optimization procedure as just "dispersive solvent volume". The variables derivatization time, derivatization temperature, and amount of NaCl showed no significant effect on the peak area of polyamines and, thus, were fixed for further experiments at 15 min, room temperature, and 500 mg, respectively. Faster reaction times, without the need for heating and with a lower amount of reagents involved, were achieved without compromising method sensitivity.

CCD. For CCD, 20 experiments were carried out with randomly selected different combinations of the 3,5-dinitrobenzoyl chloride concentration (X_1), dispersive solvent volume (X_2), and extraction solvent volume (X_3) parameters using statistically designed experiments. The sum of all polyamine peak areas as a function of X_1, X_2, and X_3 was used as a response for the CCD design. Models were validated by two diagnostic residuals, the R^2 and Q^2 values. Typical values indicating good models are $R^2 > 0.75$ and $Q^2 > 0.60$.[30,31] In our study, the values of R^2 predicted and R^2 adjusted were 0.92 and 0.97, respectively, and the Q^2 value was 0.92, indicating the goodness of the model. Adequate precision, measured as a signal-to-noise ratio, was 26.54 (greater than 4 as desirable), which also indicates the adequacy of the present model. As shown in Table 1, the F value was 66.1, which indicates that the regression model is statistically significant ($p < 0.01$) at the 99% confidence level. Values of probability > F for X_1, X_2, X_3, X_1X_2, X_2X_3, X_1^2, X_2^2, and X_3^2 were lower than 0.05, which indicates that they are significant model terms. Despite its non-significance, the interaction X_1X_3 was considered in the model. Thus, a hierarchical model was applied. The lack-of-fit was 1.29, non-significant as desired, and the quadratic model was valid.[32]

Three-dimensional surface and contour plots were drawn to investigate the interactive effect of two factors on the sum of polyamine peak areas (Figure 4). Figure 4A shows the combined effect of the 3,5-dinitrobenzoyl chloride concentration and dispersive solvent volume. Figure 4B shows the

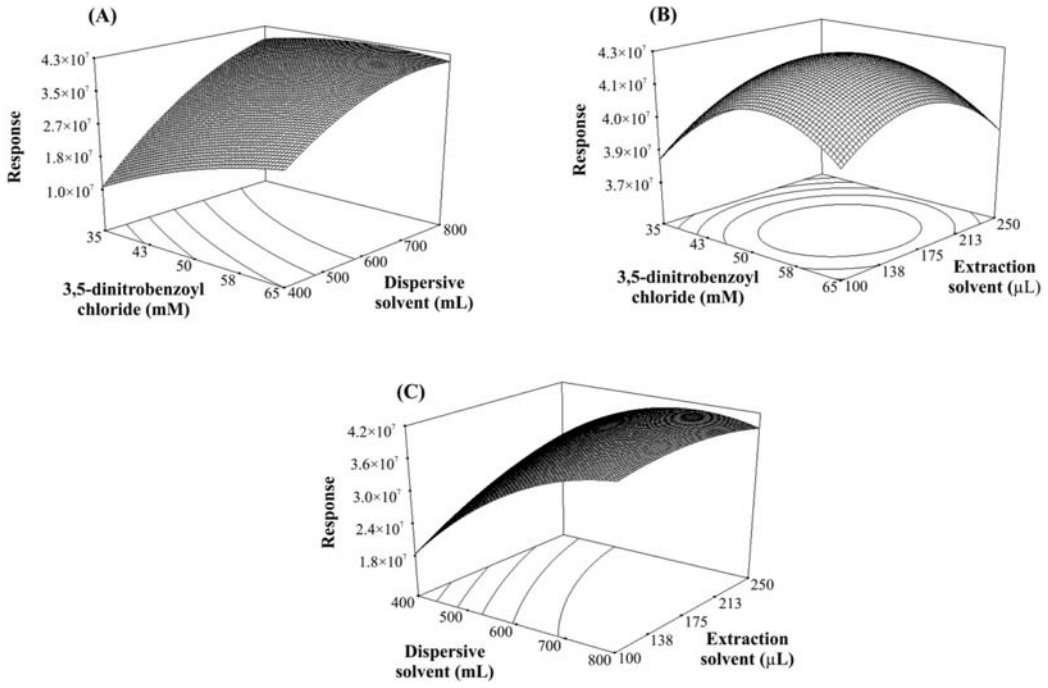

Figure 4. Response surface plots for the CCD: (A) concentration of 3,5-dinitrobenzoyl chloride and dispersive solvent volume, (B) concentration of 3,5-dinitrobenzoyl chloride and extraction solvent volume, and (C) dispersive solvent volume and extraction solvent volume.

combined effect of the 3,5-dinitrobenzoyl chloride concentration and extraction solvent volume, while Figure 4C shows the combined effect of the dispersive solvent and extraction solvent volumes.

An evaluation of the optimum combination of the three studied parameters was performed to maximize the response while reducing the extraction time. Desirability indices were achieved to maximize the response, and the following optimum conditions were selected: 56 mM 3,5-dinitrobenzoyl chloride, 680 μL of dispersive solvent, and 205 μL of carbon tetrachloride. Confirmatory experiments were conducted with the parameters selected by the experimental model. The obtained response of 3.82×10^6 was within the 95% prediction response interval (from 3.5×10^6 to 4.1×10^7), which indicates the adequacy of the obtained model given by the RSM. The optimization procedure enabled an enrichment of all polyamines in the aqueous extracts, resulting in a higher sensitivity, as shown in the chromatograms of Figure 5.

The use of the optimized 3,5-dinitrobenzoyl chloride concentration (56 mM) ensured a fast and efficient reaction. However, it also yielded some unwanted byproducts, which undesirably affected the analysis. To overcome this problem, the use of ultrasonication during the derivatization reaction was tested, and it proved to be effective in lowering the amount of byproducts, as also observed by Jia et al.[26] Thus, this procedure was adopted for further polyamine analyses.

Method Validation. Linearity, precision, intercept, and slope errors, LOQ, and LOD of the optimized analytical method were evaluated. Results are shown in Tables 2−4. Method validation was performed with standard solutions. The non-significant lack-of-fit obtained (calculated F values were lower than the tabulated value) for putrescine, cadaverine, spermidine, and spermine calibration curves proved their linearity in the 0.5−10.0 mg/L range. Moreover, correlation coefficients (R^2) of 0.9989 or higher were obtained (Table 2). Intra- and interday precisions for peak areas, expressed as

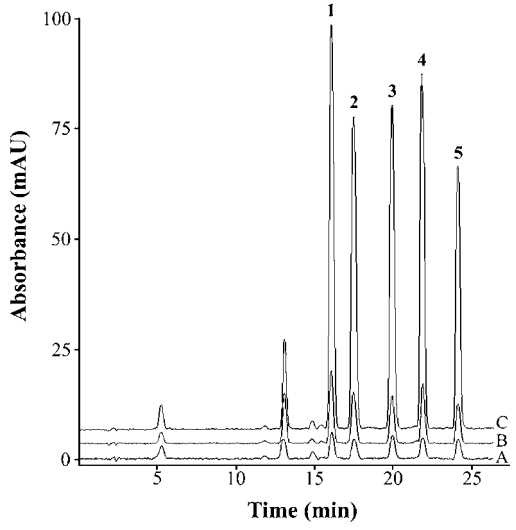

Figure 5. Chromatograms of method optimization for the standard concentration at 5 mg/L. (A) Before the optimization procedure. (B) After the derivatization optimization. (C) After the derivatization and DLLME optimization. Peaks: (1) putrescine, (2) cadaverine, (3) spermidine, (4) IS, and (5) spermine.

percent relative standard deviation (% RSD), ranged from 0.8 to 6.9% and from 3.0 to 10.3%, respectively (Table 3).

LOQ and LOD were expressed as micrograms per gram of plant food fresh weight considering a moisture content of 95, 87, 86, 91, 83, and 94% for lettuce, carrot, onion, cabbage, apple, and tomato, respectively. For all of the analyzed plant foods, the LOQs of putrescine, cadaverine, spermidine, and spermine ranged between 0.054 and 0.062, between 0.095 and 0.109, between 0.100 and 0.115, and between 0.123 and 0.141 μg/g, respectively. Similarly, the LODs of putrescine, cadaverine, spermidine, and spermine ranged between 0.016 and 0.018, between 0.029 and 0.033, between 0.030 and 0.034,

[a]Data are presented as the mean (n = 3).

and between 0.037 and 0.042 μg/g, respectively. The LOD achievable with our method was significantly lower when compared to other methodologies[9,12,23,24,33−41] because of the efficiency of cleanup and pre-concentration procedures. It was 28−111-fold lower than the micellar electrokinetic capillary chromatography (MECK)−UV method employing derivatization with benzoyl chloride applied to plant foods.[8,33] In fact, our method was 6-fold more sensitive for the quantitation of putrescine and spermine than one of the most sensitive methods described, which relies on the use of SPE and tandem mass spectrometry for the quantitation of polyamines in fish[34] and lower than the LOD reported in plant analysis.[9,35] The stability of the derivatized and extracted polyamines was very good over the 24 h, with a mean RSD of only 2.2%. This is a clear advantage over *o*-phthaldialdehyde and dabsyl derivatization procedures.

Plant Food Sample Analysis. To assess the applicability of the proposed method, putrescine, cadaverine, spermidine, and spermine were determined in six plant food samples (lettuce, carrot, onion, cabbage, tomato, and apple) (Figure 6). All four polyamines, including cadaverine, which is not usually detected in plant foods, were quantified in the analyzed plant food samples (Table 4). Generally, putrescine was the most abundant polyamine, with values ranging between 3.52 and 34.5 μg/g. Spermine was the second most abundant polyamine, with mean contents of 1.31, 5.85, 6.29, 5.52, 1.87, and 1.23 μg/g in lettuce, carrot, onion, cabbage, apple, and tomato, respectively. The mean content of spermidine in the analyzed plant food samples ranged between 0.24 and 1.17 μg/g, whereas mean contents for cadaverine were 0.16, 0.23, 1.86, 0.20, 0.42, and 0.18 μg/g in lettuce, carrot, onion, cabbage, apple, and tomato, respectively. The recovery percentage of polyamines, evaluated in lettuce, carrot, onion, cabbage, tomato, and apple, was between 81.7 and 114.2% (Table 4). For each concentration, a Student's t test was performed for each type of plant food, and the comparison between the expected and experimental concentrations presented no statistical difference ($p > 0.05$), which confirmed the accuracy of the method in these different types of matrixes. The RSD from three independent extractions with or without polyamine fortification ranged from 1.14 to 9.97%, indicating that reproducible results were obtained.

Moreover, this method is also inexpensive and easy to perform, and the derivatized polyamines dissolved in acetonitrile could be stored for 24 h at 4 °C without significant decomposition. The present method was successfully applied to analyze polyamines in six different types of plant foods with a wide range of polyamine contents (from 0.16 to 34.5 μg/g).

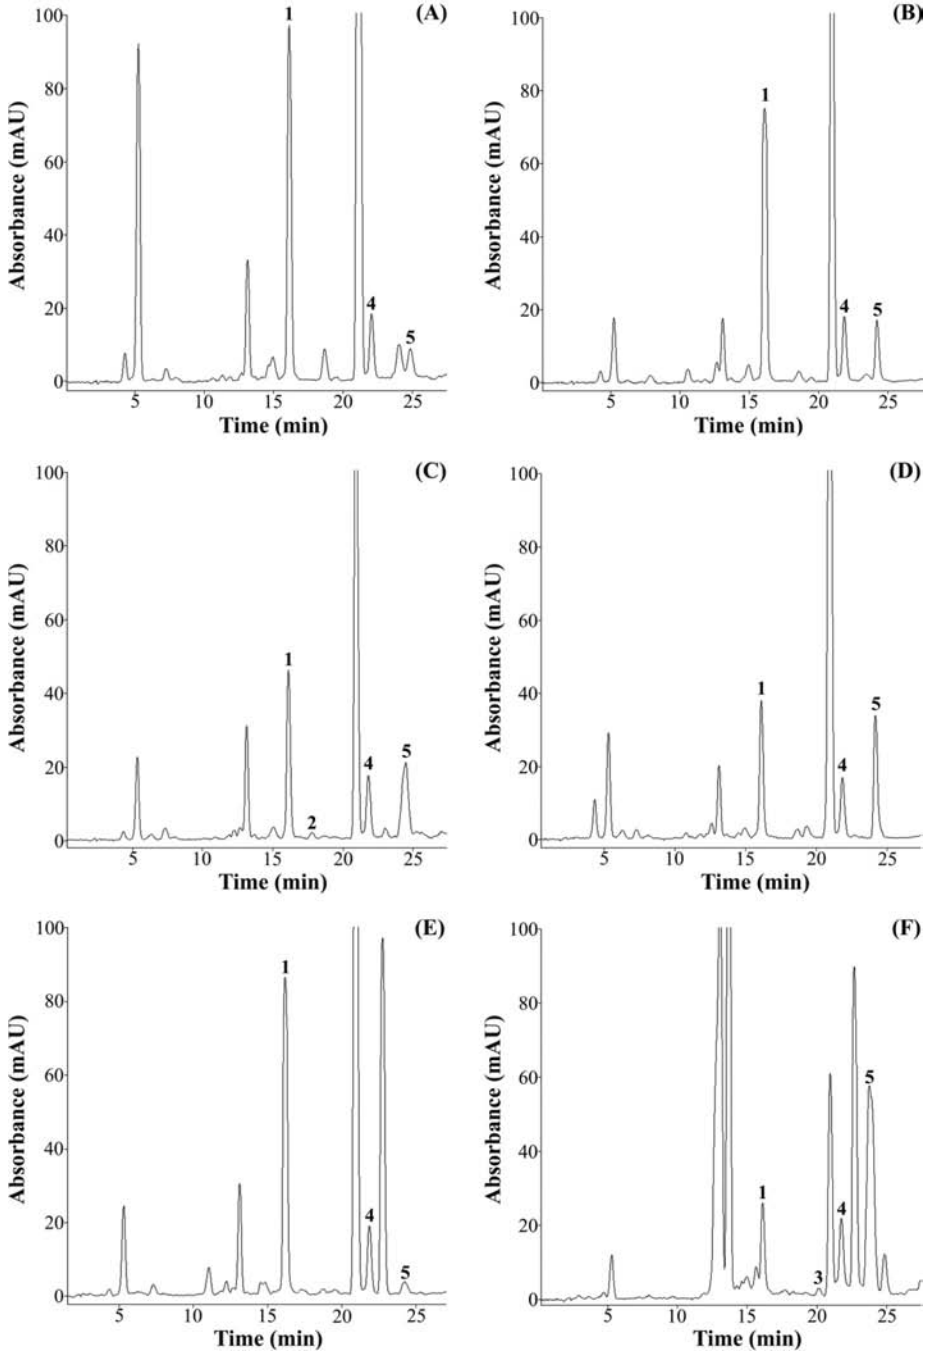

Figure 6. Representative chromatograms of plant food samples: (A) lettuce, (B) carrot, (C) onion, (D) cabbage, (E) tomato, and (F) apple. Peaks: (1) putrescine, (2) cadaverine, (3) spermidine, (4) IS, and (5) spermine.

The good recoveries of polyamines obtained in the analyses of plant food samples (81.7−114.2%) shown that the developed method has wide applicability and uses equipment easily available in quality control laboratories. Great precision was obtained, as observed from the low RSDs obtained in the six different plant foods.

ABSTRACT: Intestinal microbiota modulation is becoming an interesting approach to manage inflammatory bowel disease and can be achieved by the administration of prebiotics. Previous studies showed the intestinal anti-inflammatory effects of the prebiotic lactulose. The aim of the present study was to test the preventative effects of oligosaccharides derived from lactulose with prebiotic properties (OsLu) in the trinitrobenzenesulfonic acid model of rat colitis and compare them with those of lactulose. Both treatments modified bacterial profile in intestinal contents, increasing the bifidobacteria and lactobacilli counts and up-regulating the production of short-chain fatty acids, although OsLu generated a larger amount. OsLu also inhibited to a greater extent different pro-inflammatory markers such as interleukins (IL) 1, 6, 12, and 23 and chemokines (MCP-1 and CINC-1). However, both prebiotics equally restored colonic epithelial integrity, evaluated both with a histological score (OsLu, 9.8 ± 2.2; and lactulose, 12.1 ± 2.1, vs colitic control, 27.3 ± 3.3) and by measuring several key proteins of the mucosal barrier (MUC-2, MUC-3, and TTF-3). OsLu effect was also associated with an inhibition of iNOS expression and a reduction of Th17 cell activity in the inflamed tissue that facilitated the intestinal mucosa barrier recovery. In conclusion, OsLu showed a better anti-inflammatory profile than lactulose in this model of experimental colitis.

INTRODUCTION

Inflammatory bowel disease (IBD) usually refers to two related conditions, ulcerative colitis (UC) and Crohn's disease, characterized by chronic and spontaneously relapsing inflammation. Among the clinical symptoms of IBD are abdominal pain, diarrhea, rectal bleeding, malaise, and weight loss. Although the exact etiology of IBD remains unknown, both inflammatory conditions have similar pathophysiology background, and several studies indicate that a combination of factors such as genetic susceptibility, intestinal microbiota, dietary factors, intestinal barrier dysfunction, and an abnormal immune response to intestinal bacteria leads to chronic intestinal inflammation.[1] In fact, IBD may be considered as a maladaptation of host commensal mutualism that promotes intestinal microbiota imbalance, termed dysbiosis. It is typically characterized by a decline in bacterial diversity, with a relative predominance of potential pathogenic bacteria and an insufficient amount of protective species, which leads to chronic intestinal inflammation.[2] As a consequence, an interesting approach to IBD management could be a change of the microbiota, in a preventative and/or therapeutic manner, to protect the intestine against inflammation, stimulate tissue repair, and restore the homeostasis in genetically susceptible hosts. This could explain, at least partially, the remission that sometimes is achieved in intestinal inflammation after treatment with antibiotics such as metronidazole or ciprofloxacin.[3] Unfortunately, the prolonged use of antibiotics in the management of these intestinal conditions is limited due to the risk of severe adverse effects. For this reason, it is very important to find other effective strategies focused on microbiota balance restoration, with a better safety profile. This could be the case of prebiotics, which are defined as selectively fermented ingredients that allow specific changes, in both the composition and/or activity in the gastrointestinal microbiota, that confers benefits upon host well being and health.[4]

The efficacy of the prebiotics on intestinal inflammation has been most extensively studied in experimental colitis models, which, in addition, have provided insight into possible

mechanisms involved in their intestine anti-inflammatory properties.[5] One of these consists in the modification of the intestinal microbial composition by stimulating the growth of commensal protective bacteria and therefore enhancing resistance to disease-inducing bacteria colonization and contributing to colitis improvement. Besides, the promotion of protective bacteria growth can result in up-regulation of epithelial defense mechanisms that protect against intestinal inflammation. Prebiotics are fermented by anaerobic colonic microbiota, and there is an increase of short-chain fatty acids (SCFA), mainly acetate, butyrate, and propionate, that may also improve colitis condition; thus, butyrate is the major energy source for colonocytes and has an essential role in the maturation of colonic epithelium, regeneration of mucosa, and induction of cell differentiation.[6] Moreover, the impact of prebiotics on the host immune system can also contribute to their beneficial effects. In this regard, it has been described that prebiotics have the ability to modulate the production of pro- and anti-inflammatory cytokines and, thus, lessen the intestinal inflammation.

Many different substances are claimed to be prebiotics, but mainly carbohydrates have proven to display prebiotic properties in humans.[4,7] Lactulose is a synthetic disaccharide composed of fructose and galactose primarily used as a laxative and for the treatment of portal-systemic encephalopathy.[8−10] Following oral administration, intact lactulose reaches the colon, where it is split by bacteria in the distal small intestine and colon, lowering fecal pH, promoting beneficial microbiota growth such as bifidobacteria and lactobacilli, and inhibiting pathogenic bacteria expansion like *Salmonella*.[11]

In fact, preclinical studies have demonstrated a protective effect of lactulose in rodent models of colitis.[11−13] To date, there is only one pilot study reported in humans, in which oral lactulose was administered as adjuvant therapy to standard medication. The study concluded that prebiotic consumption did not ameliorate clinical activity, endoscopic score, or immunohistochemical parameters, although it improved the quality of life of UC patients receiving the prebiotic.[14] Furthermore, and although generally considered safe and innocuous, lactulose may be associated with several adverse events, including abdominal discomfort, abdominal distension, increased intestinal gas production, and flatulence, due to the fact that it is mainly consumed by the bacteria in the proximal colon.[15] All of these facts could justify the search for alternatives to lactulose with modified prebiotic properties, thus achieving a higher efficacy in intestinal inflammation with fewer side effects.

Oligosaccharides derived from lactulose (OsLu) are new bioactive carbohydrates synthesized with the aim of obtaining more slowly fermenting prebiotics able to reach the distal colon unhydrolyzed.[16−18] Different in vitro fermentation assays using pure cultures as well as fecal inoculums have demonstrated that when these oligosaccharides were used as sole carbon source, there was a stimulation of bifidobacteria and lactobacilli growth. Thus, when long incubation periods were used in fermentative assays, OsLu showed higher prebiotic index values than the native disaccharide.[19,20] These investigations proved that OsLu improved lactulose prebiotic properties and, therefore, it is reasonable to suppose that OsLu could present a higher efficacy in intestinal inflammation. More recently, the modulatory effects of OsLu on microbial composition in the cecum and colon of growing rats have been evaluated, with particular emphasis on their bifidogenic effect, showing that OsLu produced a significant and selective increase of *Bifidobacterium animalis* in these intestine locations.[21] All of these findings support a prebiotic role of galactosyl-fructoses in functional foods.

The aim of the present study was to test the preventative effects of OsLu in the trinitrobenzenesulfonic acid (TNBS) model of rat colitis, a well-established model of intestinal inflammation with some resemblance to human IBD,[22] and compare its efficacy with that of its parent compound, lactulose. Special attention was paid to their effects on the expression of some of the inflammatory mediators, such as pro-inflammatory cytokines (interleukins (IL)-1β, IL-6, IL-12, IL-17, and IL-23), chemokines (cytokine-induced neutrophil chemoattractant (CINC)-1 and monocyte chemotactic protein (MCP)-1), and an inducible enzyme (inducible nitric oxide synthase (iNOS)), as well as different markers of epithelial integrity in the mucosa, such as the mucins MUC-2 and MUC-3 and the protein trefoil factor (TFF)-3. The prebiotic capacity was assessed by measuring the production of SCFA and the effects on the microbiota composition. In summary, OsLu therapeutic efficacy was greater than that of lactulose, maybe due to its better immunomodulatory properties together with a superior capacity of SCFA production.

MATERIALS AND METHODS

This study was carried out in accordance with the *Guide for the Care and Use of Laboratory Animals* as promulgated by the National Institutes of Health. The experimental protocol was approved by the Commission of Ethics in Animal Experimentation (Protocol CEEA 2010-286) of the University of Granada (Spain).

Reagents and Synthesis of Oligosaccharides Derived from Lactulose (OsLu). All chemicals were obtained from Sigma Chemical (Madrid, Spain), unless otherwise stated. Glutathione reductase was provided by Boehringer Mannheim (Barcelona, Spain). A commercial preparation Duphalac (Abbott Healthcare, Barcelona, Spain), which contains 670 g/L lactulose, was used as control and to synthesize OsLu. Enzymatic reactions have been performed at 50 °C and pH 6.5 using a β-galactosidase from *Aspergillus oryzae* (16 Ud/mL) in an orbital shaker at 300 rpm for 24 h. Afterward, samples were immediately immersed in boiling water for 10 min to inactivate the enzyme. Then, the mixture of oligosaccharides was treated with yeasts to eliminate monosaccharides following the method of Sanz et al.,[23] with some modifications. Briefly, the oligosaccharide reaction mixture 20% (w/v) was treated with fresh *Saccharomyces cerevisiae* 1.5% (w/v) (Levital, Panibérica de Levadura, Valladolid, Spain) at 30 °C for 48 h in an orbital shaker (300 rpm) and submitted to vacuum filtration to remove the yeasts. Sample was concentrated at 38−40 °C in a rotary evaporator (Büchi Labortechnik AG, Flawil, Switzerland). Mono- and disaccharides as well as OsLu were analyzed by GC-FID.[24] Degree of polymerization (DP) of the oligosaccharides found in the purified fraction from the synthesis mixture was also determined by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS). Before yeast treatment, the transglycosylation mixtures contained 76% sugars, which corresponded to 40% monosaccharides, 6% lactulose, and 30% OsLu. After yeast treatment, the composition of mixtures was 28% of monosaccharides, 12% lactulose, and 36% OsLu (17% disaccharides, 13% trisaccharides, 5% tetrasaccharides, and 1% pentasaccharides. MALDI-TOF-MS analysis allowed detection of oligosaccharides with a higher DP of 6, 7, or 8, which could not be quantified by gas chromatography. Also, another analysis of OsLu showed the presence 5% salts and 1% nitrogen with a dry matter of 82%.

Experimental Design. Female Wistar rats (180−200 g) obtained from Janvier (St Berthevin Cedex, France) were housed individually in Makrolon cages, maintained in an air-conditioned atmosphere with a 12 h light−dark cycle, and provided with free access to tap water and food. The rats were randomly assigned to four groups (n = 10); two of

them (noncolitic and control groups) received tap water, and the others (treated groups) were given lactulose or OsLu in the drinking water, daily prepared, at the concentration of 2.5% (w/v) for 3 weeks. The average rat intake was approximately of 0.25 g/day (the mean water intake was 10.2 ± 0.9 mL/rat and day, without showing differences among groups). This dose was equivalent to that used in a previous study with lactulose in the same experimental model of rat colitis.[12]

Two weeks after the start of the experiment, the rats were fasted overnight and rendered colitic as previously described.[12] Briefly, they were anaesthetized with isofluorane and given 10 mg of TNBS dissolved in 0.25 mL of 50% ethanol (v/v) by means of a Teflon cannula inserted 8 cm through the anus. During and after TNBS administration, the rats were kept in a head-down position until they recovered from the anesthetic and were then returned to their cages. Rats from the noncolitic group were administered intracolonically 0.25 mL of phosphate-buffered saline instead of TNBS. All rats were killed with an overdose of halothane 1 week after colitis induction.

In another set of experiments, the efficacy of both lactulose and OsLu was evaluated in the same experimental model for a longer period of time, 3 weeks. In this assay, a second dose of 10 mg of TNBS dissolved in 50% ethanol was administered 2 weeks after the initial TNBS colonic instillation, in an attempt to mimic the relapses common in human IBD. Ten animals from each colitic group (control and prebiotic treated) and five from the noncolitic group were sacrificed after 1, 2, and 3 weeks of colitis induction, so the efficacy of OsLu after 1 week was performed twice.

Assessment of Colonic Damage. The body weight and water and food intakes were recorded daily throughout the experiment. Once the rats were sacrificed, the colon was removed aseptically and placed on an ice-cold plate and longitudinally opened, and luminal contents were collected for the microbiological studies (see below). Afterward, the colonic segment was cleaned of fat and mesentery and blotted on filter paper; each specimen was weighed and its length measured under a constant load (2 g). The colon was scored for macroscopically visible damage on a 0−10 scale by two observers unaware of the treatment, according to the criteria previously reported,[12] which take into account the extent as well as the severity of colonic damage. Representative whole gut specimens (0.5 cm^2) were taken from a region of the inflamed colon corresponding to the adjacent segment to the gross macroscopic damage and were fixed in 4% buffered formaldehyde for the histological studies. Equivalent colonic segments were also obtained from the noncolitic group. The colon was subsequently minced, aliquoted, and kept frozen at −80 °C until biochemical determinations and RNA extraction were performed.

For the histological studies, cross sections were selected and embedded in paraffin. Full-thickness sections of 5 μm were obtained at different levels and stained with hematoxylin and eosin. The histological damage was evaluated by a pathologist observer, who was blinded to the experimental groups, according to the criteria previously described by Arribas et al.[25]

Myeloperoxidase activity (MPO) was measured according to the technique previously described,[26] and the results were expressed as MPO units per gram of wet tissue; one unit of MPO activity was defined as that degrading 1 μmol of hydrogen peroxide per minute at 25 °C. Total glutathione content (GSH) was quantified with the recycling assay,[27] and the results were expressed as nanomoles per gram of wet tissue.

The analysis of gene expression in the colonic samples was performed by real-time quantitative PCR (RT-qPCR). For this purpose total RNA from colonic samples was isolated using Trizol following the manufacturer's protocol. All RNA samples were quantified with the Thermo Scientific NanoDrop 2000 spectrophotometer, and 2 μg of RNA was reverse transcribed using oligo(dT) primers (Promega, Southampton, UK). RT-qPCR amplification and detection were performed on optical grade 48-well plates in an Eco Real-Time PCR System (Illumina, San Diego, CA, USA) with 20 ng of cDNA, the KAPA SYBR FAST qPCR Master Mix (Kapa Biosystems, Inc., Wilmington, MA, USA), and specific primers at their annealing temperature (T_a) (Table 1). To normalize mRNA expression, the expression of the housekeeping gene, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), was measured. The mRNA relative quantitation was calculated using the ΔΔCt method.

Microbial Analysis of the Colonic Contents. For DNA extraction, samples from colonic contents were diluted 1:12 (w/v) in the lysis buffer ASL provided by the QIAamp DNA stool mini kit (Qiagen, Hilden, Germany), according to the manufacturer's instructions. The suspensions were transferred to a Lysing Matrix E tube that contained a mixture of ceramic and silica particles designed to efficiently lyse microorganisms (Qiagen). Tubes were shaken in a Precellys apparatus (VWR, Villeurbanne, France) at 5.5 rpm for 30 s twice. DNA was then extracted by using a QIAamp DNA stool minikit from Qiagen, as recommended by the manufacturer (protocol for isolation of DNA for pathogen detection), except that a supplemental mixture of enzymes (mutanolysin at 90 U and lysozyme at 9 mg/mL) was added to the lysis buffer. RT-qPCR was used to characterize the bacterial DNA present in the colonic content samples as reported previously.[28] For this purpose, a series of genus-specific primer pairs

was used (Table 2). PCR amplification and detection were performed on optical grade 48-well plates in an Eco Real-Time PCR System (Illumina). In this case, each reaction mixture (10 μL) was composed of 5 μL of KAPA SYBR FAST qPCR Master Mix (Kapa Biosystems, Inc.), 0.25 μL of each specific primer at a concentration of 10 μM, and 2 μL of DNA template. Standard curves were created using serial 10-fold dilutions of bacterial DNA extracted from pure cultures with a bacterial population ranging from 2 to 9 log colony-forming units (CFUs), as determined by plate counts. One strain belonging to each of the bacterial genera or groups targeted in this study was used to construct the standard curve. More specifically, the strains from which the DNA was extracted were the following: *Bifidobacterium longum* CECT 4551, *Clostridium coccoides* DSMZ 935, *Bacteroides fragilis* DSMZ 2151, and *Lactobacillus salivarius* CECT 2197. All of them were obtained from the Spanish Collection of Type Cultures (CECT) or the German Collection of Microorganisms and Cell Cultures (DSMZ).

Short-Chain Fatty Acid (SCFA) Determinations. To quantify the SCFA concentrations in the colonic luminal contents, the samples were homogenized with 150 mM $NaHCO_3$ (pH 7.8) (1:5 w/v) in an argon atmosphere. Samples were incubated for 24 h at 37 °C and stored at −80 °C until the extraction. To extract the SCFAs, 50 μL of the internal standard 2-methylvaleric acid (100 mM), 10 μL of sulfuric acid, and 0.3 mL of chloroform were added to 1 mL of the homogenate and, then, centrifuged at 10000*g* for 5 min at 4 °C. The organic layer was dehydrated with sodium anhydrous sulfate and centrifuged at 10000*g* for 5 min at 4 °C. One microliter of the supernatant was injected into a gas chromatograph (PerkinElmer Autosystem GC-FID, Waltham, MA, USA) equipped with a capillary column (CPWAX 52CB, 60 m × 0.25 mm, 0.25 μm, Varian, Middelburg, The Netherlands) and connected to a Star Chromatography WorkStation program (version 6, Varian) to quantify the samples. Operating conditions were as follows: injector, 275 °C; detector, 300 °C; initial column temperature, 90 °C for 0.1 min then increasing at 15 °C/min to 245 °C and held for 4 min at 245 °C. The flow of carrier gas (nitrogen) was 1 mL/min. The gas chromatography system had a split ratio 1:33. Acetate, propionate, and butyrate concentrations between 0.30 and 60 mM were used to make the standard curve. A linear relationship was found between the peak area ratio SCFA/IS using the same protocol as that for samples.

Statistics. All results are expressed as the mean ± SEM. Differences between means were tested for statistical significance using a one-way analysis of variance (ANOVA) with the Tukey post hoc test. Differences between proportions were analyzed with the chi-squared test. All statistical analyses were carried out with GraphPad Prism version 5.0 (La Jolla, CA, USA), with statistical significance set at $P < 0.05$.

RESULTS

Preventative Effects of Lactulose and OsLu on TNBS Rat Colitis. The administration of either lactulose or OsLu for 2 weeks did not induce any symptoms of diarrhea or significantly affect weight evolution. However, once the colitis was induced, both groups of treated rats showed an overall lower impact of TNBS-induced colonic damage compared to the TNBS control group. The anti-inflammatory effect was evidenced macroscopically by a significantly lower colonic damage score than that of control rats ($P < 0.05$), with a significant reduction in the extent of colonic necrosis and/or inflammation induced by the administration of TNBS/ethanol (Table 3). The weight/length ratio was increased significantly in colitic rats as a consequence of the inflammatory process when compared with noncolitic rats, and no significant differences were observed among the two treated groups and the corresponding colitic control (Table 3).

The histological evaluation of the colonic segments confirmed the intestinal anti-inflammatory effect of both lactulose and OsLu (Figure 1). The colonic samples from the untreated colitic control group showed extensive ulceration of the mucosa that typically affected >75% of the surface. Also, severe inflammation that involved all of the intestinal layers was observed, and it was associated with diffuse leukocyte infiltration, mainly composed of neutrophils in the mucosa layer and, to a lesser extent, lymphocytes in the submucosa. In addition, the inflammatory process was associated with severe goblet cell depletion (Figure 1B). In this group of rats, the grade of lesion was considered as severe, with a score value (mean ± SEM) of 27.3 ± 3.3 (Figure 1E). On the contrary, the histological assessment of the colonic specimens from rats treated with either lactulose (Figure 1C) or OsLu (Figure 1D) showed an evident recovery of the colonic tissue, displaying a significantly reduced score in comparison with untreated colitic rats. Thus, most of the samples revealed a restoration of the

group (n = 10)	damage score (0−10)	weight/length (mg/cm)	MPO (mU/g tissue)	GSH (nmol/g tissue)
noncolitic	0	63.9 ± 1.9	14.5 ± 1.4	1878 ± 29
TNBS control	7.9 ± 0.2	175.8 ± 9.8	616.5 ± 67.6	603 ± 91
lactulose	7.1 ± 0.2*	211.9 ± 26.7	355.5 ± 78.1*	871 ± 96*
OsLu	6.3 ± 0.3*#	156.8 ± 8.9#	335.7 ± 55.6*	878 ± 99*

[a]Data are expressed as means ± SEM. *, $P < 0.05$ vs TNBS control group. #, $P < 0.05$ vs Lactulose-treated group. All colitic groups statistically differ from the noncolitic group ($P < 0.05$).

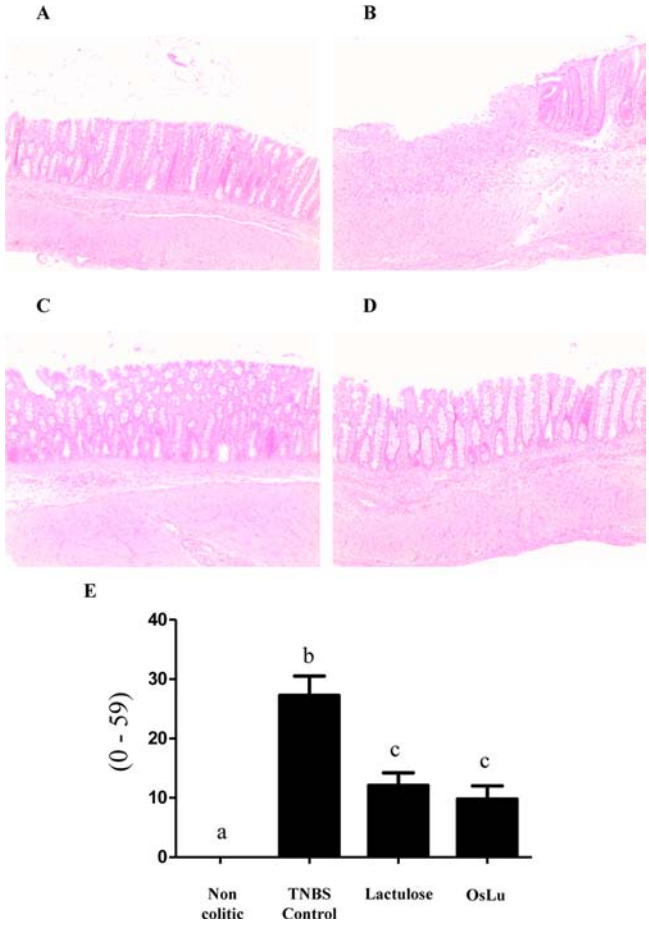

Figure 1. Histological sections of colonic tissue stained with hematoxylin and eosin showing the effects of lactulose and oligosaccharides derived from lactulose (OsLu) in TNBS rat colitis 1 week after damage induction: (A) noncolitic; (B) TNBS-control; (C) lactulose; (D) oligosaccharides derived from lactulose (OsLu); (E) microscopic score assigned according to the criteria previously described.[31] Data (n = 10 per group) are expressed as means ± SEM; groups with different letters statistically differ ($P < 0.05$).

epithelial cell layer, a maximum of only 25% of the epithelium being affected in contrast to the extensive ulceration observed in TNBS control group. In addition, goblet cells appeared replenished with their mucin content, and it a reduction in the inflammatory infiltrate was also observed, which was slight to moderate with a patchy distribution.

The intestinal anti-inflammatory effect was confirmed biochemically, because both treated groups showed significantly reduced colonic MPO activity (Table 3), which agrees with the reduction of neutrophil infiltration observed in the histological study and thus demonstrates the intestinal anti-inflammatory effect of the treatment.[29] In addition, the administration of lactulose or OsLu partially restored colonic glutathione content, a tripeptide with antioxidant properties, which was depleted in colitic rats as a consequence of the colonic oxidative stress induced by the inflammatory process, similar to that previously reported in this model of experimental colitis[12] (Table 3).

The colonic inflammatory status in control colitic rats was also characterized by an increased expression of the different pro-inflammatory markers evaluated, including the cytokines IL-1β, IL-6, IL-12, IL-17, and IL-23, the chemokines CINC-1 and MCP-1, and the inducible enzyme iNOS, in comparison with the noncolitic group. The evaluation of the cytokines revealed that the pretreatment of colitic rats with OsLu was able to significantly reduce the expression of all of them, whereas lactulose administration decreased the expression of only IL-6 in the colonic tissue, without showing statistical differences with the other cytokines assayed in comparison with untreated colitic rats (Figure 2). These results suggest that the amelioration of the altered immune response that characterizes the colonic inflammatory process is involved in the beneficial effect observed in both treated groups, but OsLu showed a higher efficacy than lactulose. Similarly, only the treatment of colitic rats with OsLu resulted in a significant reduction of the expression of colonic iNOS (Figure 2) and the chemokines CINC-1 and MCP-1 (Figure 3), which could support the lower infiltration of either neutrophils and macrophages in the inflamed tissue, that was evidenced both biochemically and histologically. Of note, both lactulose and OsLu managed to completely restore the expression of proteins involved in colonic epithelial integrity (MUC-2, MUC-3, and TFF-3), which were significantly reduced in colitic rats when compared to healthy ones (Figure 3) and could promote the recovery of the epithelial layer observed in the histological studies.

Effects of Lactulose and OsLu on TNBS-Reactivated Rat Colitis. In this assay the impact of a longer prebiotic treatment was evaluated. Also, and to simulate the "flare-ups" that occur in human IBD, a second intracolonic dose of 10 mg of TNBS in ethanol was administered 2 weeks after the first administration, which resulted in a reactivation of the colonic inflammatory process. The results confirmed the intestine anti-inflammatory effects exerted by lactulose or OsLu in this experimental model of colitis at the different time points evaluated. Thus, macroscopically, both compounds were able to significantly reduce the colonic score and weight/length ratio 1 and 2 weeks after the first colonic insult, as well as 1 week after the second TNBS administration (Table 4). These beneficial effects were confirmed biochemically by a reduction in the colonic MPO activity, thus reflecting a lower leukocyte infiltration, which was significant for all treated groups at the different time points evaluated, except for lactulose 1 week after reactivation of the inflammatory process (Figure 4). When the colonic oxidative status was assessed by glutathione content determination, both lactulose and OsLu were able to significantly reduce the depletion of this peptide 1 week after the first administration of TNBS, whereas only the lactulose derivative OsLu was able to significantly restore its colonic content after the reactivation of colonic damage (Figure 4).

The evaluation of the different biochemical markers by qPCR confirmed the results described above, for both lactulose and OsLu, when the inflammatory process was evaluated 1 week after the first administration of TNBS. The evaluation after 2 weeks revealed that the expression of the pro-inflammatory cytokines and chemokines was reduced in the control colitic group in comparison with the data observed in the same group at the first week, although most of them were still significantly higher than in healthy rats. However, the evaluation of the proteins related with the epithelial integrity (MUC-2, MUC-3, and TFF-3) revealed that only MUC-2 showed a significant reduced expression in comparison with noncolitic rats (Figures 5 and 6). Because the amelioration of the colonic inflammatory process took place at this time due to its normal resolution, the beneficial effects exerted by the treatments were less evident than in the first week of treatment. In fact, these were noticeable for both compounds when IL-6 or IL-17 was

dx.doi.org/10.1021/jf500678p | J. Agric. Food Chem. 2014, 62, 4285−4297

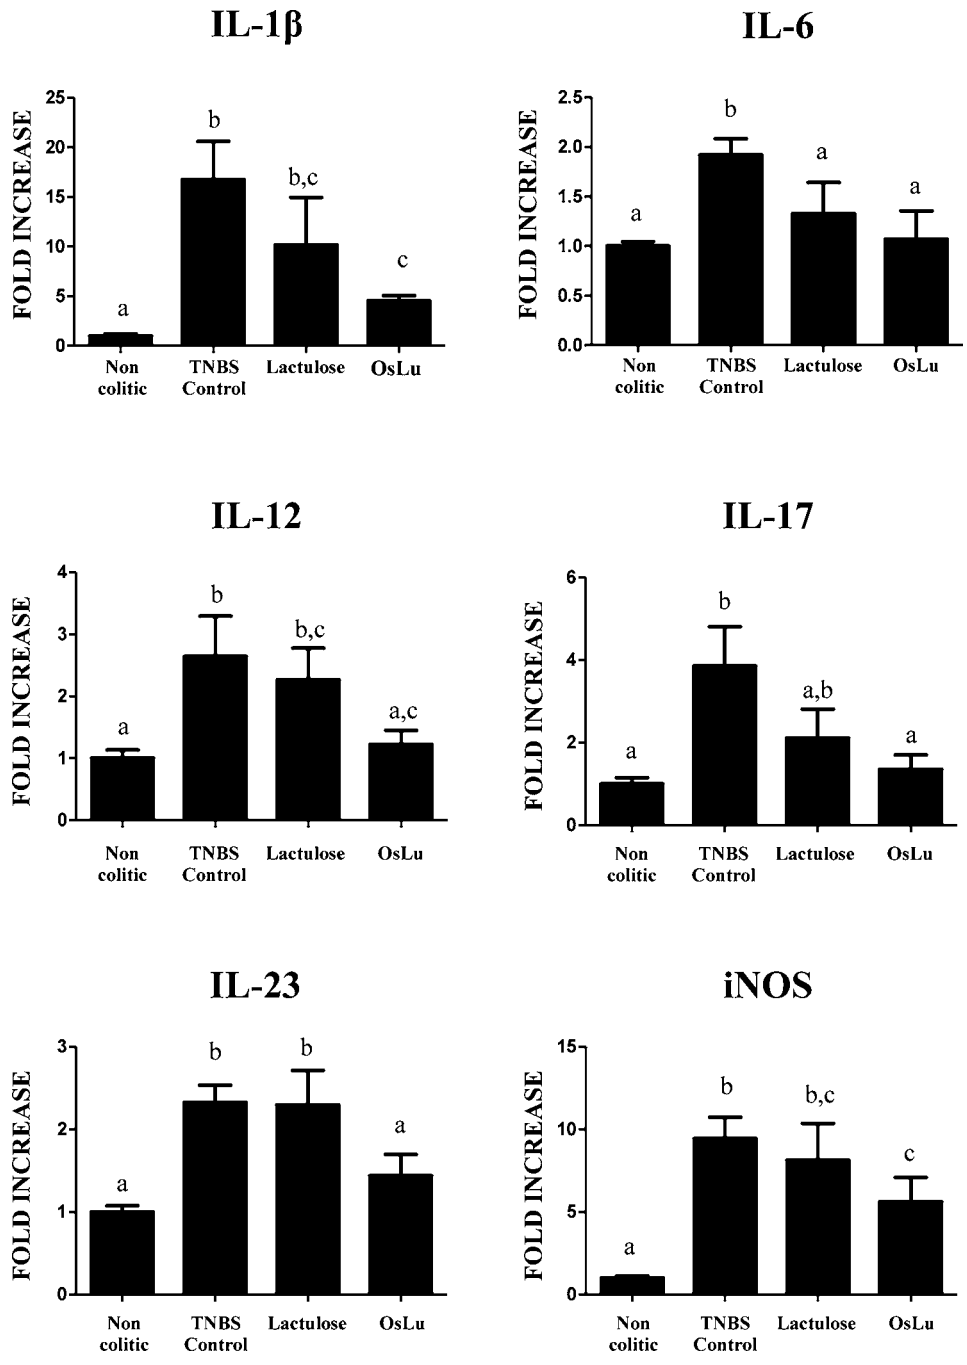

Figure 2. Effects of lactulose and oligosaccharides derived from lactulose (OsLu) on the colonic expression of the cytokines IL-1β, IL-6, IL-12, IL-17, and IL-23 and inducible nitric oxide synthase (iNOS) analyzed by RT-PCR in TNBS rat colitis 1 week after damage induction. Data (n = 10 per group) are expressed as means ± SEM; groups with different letters statistically differ (P < 0.05).

considered and only for OsLu when IL-12 or the chemokines MCP-1 and CINC-1 or the mucin MUC-2 was evaluated (Figures 5 and 6).

The reactivation of the inflammatory process typically resulted in a new increment of the expression of most of the pro-inflammatory cytokines, including IL-1β, IL-6, IL-12, and IL-23, as well as for iNOS, together with a reduction of the expression of the mucins and TFF-3. At this time, OsLu also showed a higher beneficial effect than lactulose, because the derivative reduced the expression of all the cytokines for which expression was up-regulated 1 week after the second administration of TNBS, whereas lactulose reduced only IL-6 (Figure 5). At this time, only MUC-2 expression was restored after the treatment with both lactulose and OsLu, without showing a significant effect in comparison with colitic control group, when MUC-3 or TFF-3 was considered (Figure 6).

Effects of Lactulose and OsLu on TNBS on Microbiota Composition and SCFA Production in Colitic Rats. The evaluation of the microbial content in the colonic lumen 1 week after the first administration of TNBS evidenced a significant decrease in the counts of both lactobacilli and bifidobacteria and, on the contrary, an increase in clostridia and bacteroides in TNBS colitic rats in comparison with the healthy ones (Figure 7). Treatment with lactulose or with OsLu resulted in a

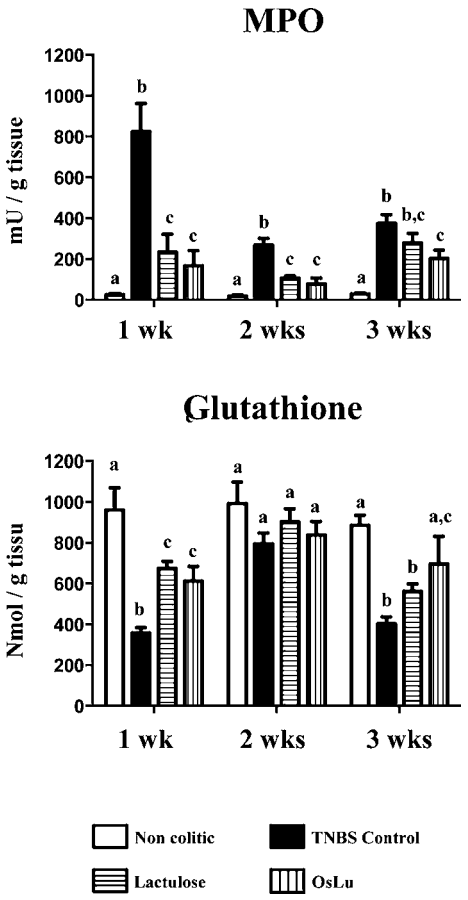

Figure 4. Effects of lactulose and oligosaccharides derived from lactulose (OsLu) on colonic myeloperoxidase (MPO) activity and glutathione content in reactivated TNBS-rat colitis. Data (n = 10 per group) are expressed as means ± SEM; groups with different letters statistically differ ($P < 0.05$).

content was evaluated after 2 weeks, a restoration in both lactobacilli and bifidobacteria counts was observed in the rats from the colitic control group, without showing statistical differences with the healthy group; however, increased counts of clostridia and bacteroides were obtained in colitic rats in comparison with noncolitic ones. No significant modification was obtained in any of the bacterial groups studied with either lactulose or OsLu when compared with the corresponding colitic control group (Figure 7).

The reactivation of the inflammatory process after the second dose of TNBS resulted in a new reduction of lactobacilli and bifidobacteria after 1 week, whereas the numbers of clostridia and bacteroides were increased. OsLu was again able to significantly increase the counts of lactobacilli and bifidobacteria in comparison with the control colitic rats, whereas lactulose was devoid of any significant effect. Also, no significant modifications were observed among colitic groups when clostridia or bacteroides were considered (Figure 7).

As a consequence, the colonic inflammatory process was associated, at weeks 1 and 3, with a significant reduction in the production of the different SCFA (acetate, propionate, and butyrate) evaluated (Figure 8), as it has been previously reported in the same model of experimental colitis.[25] The beneficial effects exerted by the treatments of lactulose and OsLu in colitic rats were associated with an increased production of all the SCFA 1 week after the first administration of TNBS. Moreover, OsLu was able to restore these levels without showing statistical differences with noncolitic rats (Figure 8). However, 1 week after colitis reactivation, only OsLu was able to raise the production of the SCFA in comparison with nontreated colitic rats (Figure 8).

DISCUSSION

A decrease in bacterial diversity has been reported to occur in IBD patients, characterized by reduced levels of protective species with relative predominance of pathobionts, thus promoting a deregulation of the immune response. As a consequence, an interesting approach to the treatment of intestinal inflammation would be the restoration of microbiota balance.[2]

In the present study we described the beneficial effects exerted by oligosaccharides derived from lactulose (OsLu) in the TNBS model of rat colitis, comparing them with those achieved by its precursor, lactulose. OsLu has been characterized by a slower fermentation by the colonic microbiota than lactulose, so the oligosacharides are able to reach the distal colon without great alterations.[19,20] Theoretically, these properties could be of great interest for the treatment of human IBD, because distal areas of the large intestine are typically affected in UC and very frequently in Crohn's disease. Furthermore, the delayed fermentation could account for a better patient tolerability than lactulose, because the effects derived from its fermentation in the proximal colon would be avoided. Actually, both lactulose and OsLu were able to reduce the colonic damage observed 1 week after colonic induction with TNBS. Previous studies carried out with different oligosaccharides also displayed an improvement in the macroscopic scores, indicating changes in the colitic rats receiving the pretreatment with oligosaccharides. Thus, for example, colitic rats pretreated with goat milk oligosaccharides[30] or FOS[31] showed significant amelioration of the intestinal inflammatory process in comparison with nontreated groups. It is interesting to note that this beneficial effect was also evidenced when the two prebiotics were administered for a longer period of time to colitic rats with a reactivation of the intestinal inflammation with a second instillation of TNBS, both prebiotics showing a similar efficacy. Unfortunately, a curative protocol with this type of product is not convenient because previous observations have shown a deleterious effect of lactulose or OsLu when the administration starts once the colitis is established. Other authors have reported similar observations with different treatments in experimental colitis in rodents.[32]

As expected, the treatments were able to modify intestinal bacteria composition that was altered due to the colitic process, mainly derived from their ability to increase the counts of either lactobacilli or bifidobacteria. In addition, the beneficial effect on microbiota composition exerted by both treatments was associated with an improvement of the defensive mechanisms of the intestinal epithelial barrier, the architecture of which appeared to be restored in the histological studies. The administration of lactulose or OsLu normalized the expression of the mucins MUC-2 and MUC-3, primary constituents of the mucus layer in the colon,[33] as well as of TFF-3, a bioactive peptide involved in epithelial protection and repair.[34] This could be one of the mechanisms for preserving the mucus-secreting layer that covers the epithelium and acts as a physical barrier protecting its integrity. This effect may be key for the intestinal anti-inflammatory capacity exerted by these pre-

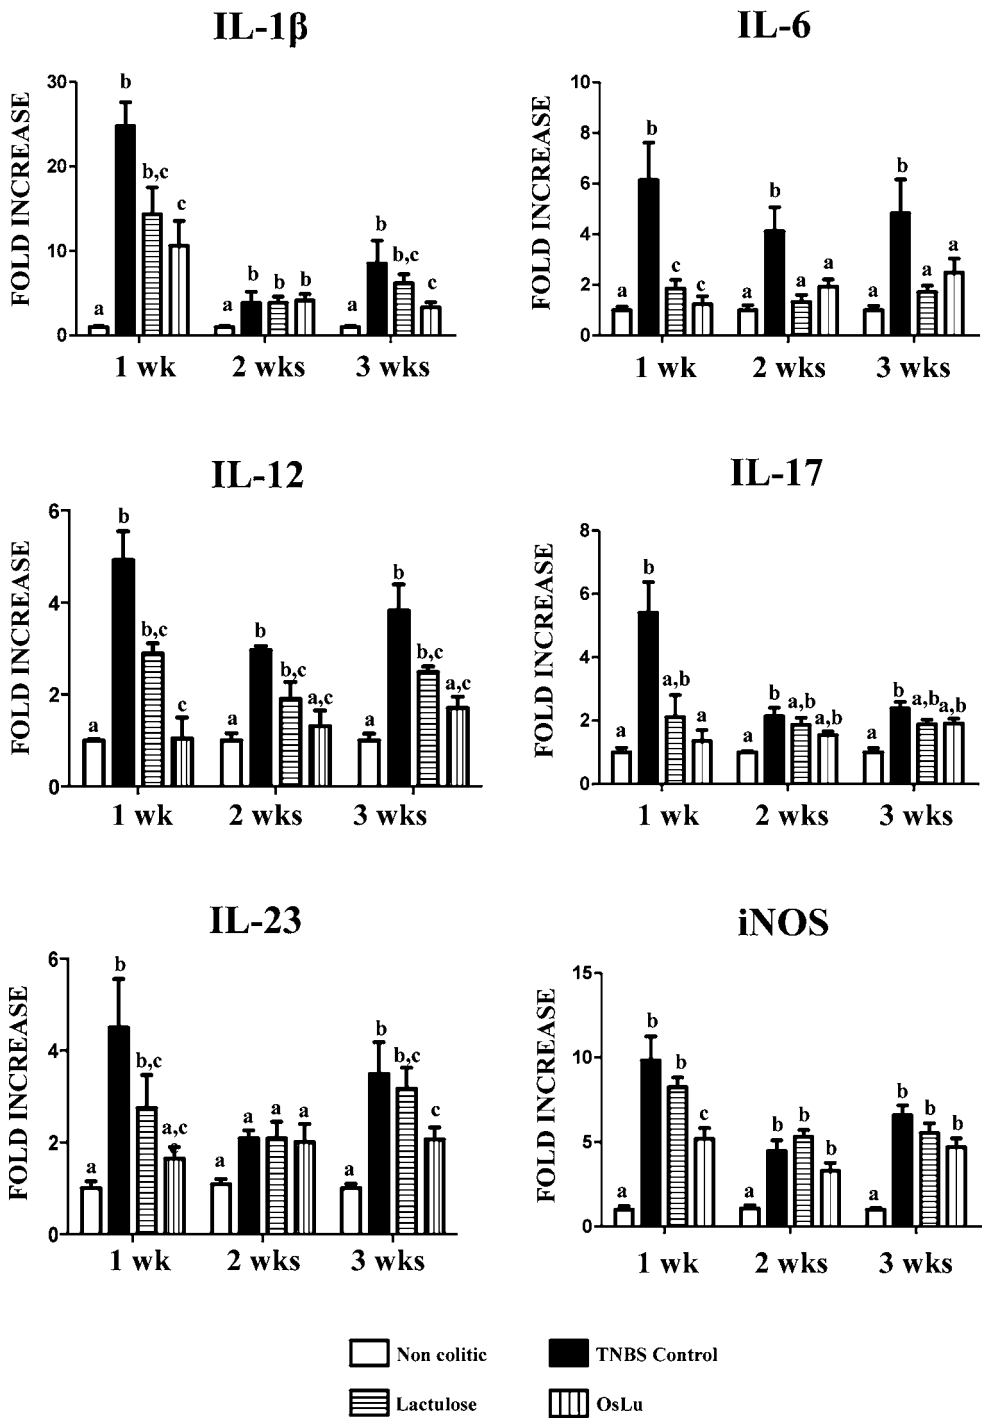

Figure 5. Effects of lactulose and oligosaccharides derived from lactulose (OsLu) on the colonic expression of the cytokines IL-1β, IL-6, IL-12, IL-17, and IL-23 and inducible nitric oxide synthase (iNOS) analyzed by RT-PCR in reactivated TNBS rat colitis. Data (n = 10 per group) are expressed as means ± SEM; groups with different letters statistically differ (P < 0.05).

biotics. Epithelial barrier function impairment is considered to be one of the initial steps in intestinal inflammation that facilitates the access of antigens from the intestinal lumen and, hence, generates an exacerbated immune response.[35,36] Moreover, human IBD has been associated with a defective colonic mucus layer and a reduced number of goblet cells.[37]

Furthermore, both lactulose and OsLu were able to increase the reduced production of SCFA observed in colitis rats, which may help with the regeneration of the inflamed mucosa, given the key role attributed to these acids in the intestine homeostasis and immune response.[38] This may be responsible for modifications in the biochemical markers of the immune response observed in the colonic tissue. It is interesting to note the differences observed between OsLu and lactulose on the Th17 pathway that could account for the higher anti-inflammatory efficacy of OsLu. The IL-17 pathway is crucial in the pathogenesis of IBD.[39] Thus, IL-17 contributes to neutrophil migration, expansion, and function and enhances dendritic cell maturation, T cell priming, and the production of inflammatory mediators from different cell types. Furthermore,

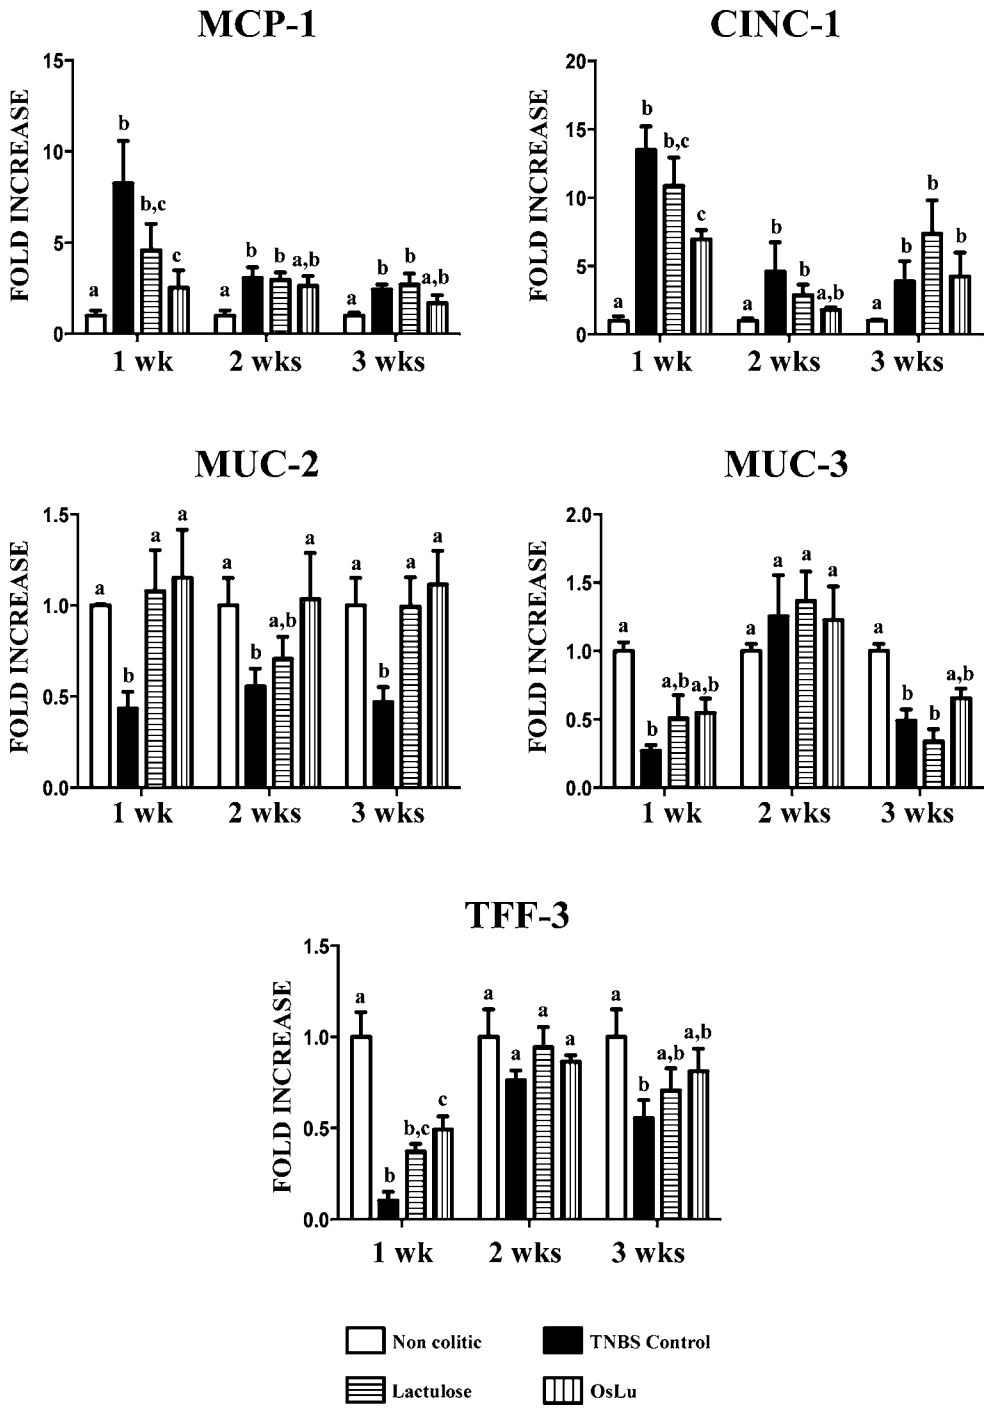

Figure 6. Effects of lactulose and oligosaccharides derived from lactulose (OsLu) on the colonic expression of the chemokines cytokine-induced neutrophil chemoattractant (CINC)-1 and monocyte chemotactic protein (MCP)-1, the mucins MUC-2 and MUC-3, and the trefoil factor (TFF)-3 analyzed by RT-PCR in reactivated TNBS rat colitis. Data (n = 10 per group) are expressed as means ± SEM; groups with different letters statistically differ ($P < 0.05$).

IL-17 can synergize with other cytokines to promote the release of additional pro-inflammatory cytokines, thus being essential for maintaining the inflammatory response in the intestine. As confirmed in the present study, experimental colitis has also been reported to be associated with an increased IL-17 production;[40] in fact, in TNBS colitis, the infiltration of CD4 lymphocytes and neutrophils, mostly driven by a Th1/Th17 cytokine response, is one of the predominant features in the initiation and perpetuation of the inflammatory process.[41] Furthermore, the inhibition in the expression of chemotactic mediators CINC-1 and MCP-1 in the inflamed tissue probably contributes to lowering the leukocyte infiltration and activation that could also account for the higher efficacy shown by OsLu because it is well described that, in the first steps of gut inflammation, margination and extravasation of circulating leukocytes probably result in the perpetuation of the inflammatory process.[42] Other mechanisms may also explain the differences displayed by both prebiotics, and one of these could be related to the ability of OsLu, but not lactulose, to significantly inhibit colonic iNOS expression in the inflamed

dx.doi.org/10.1021/jf500678p | J. Agric. Food Chem. 2014, 62, 4285−4297

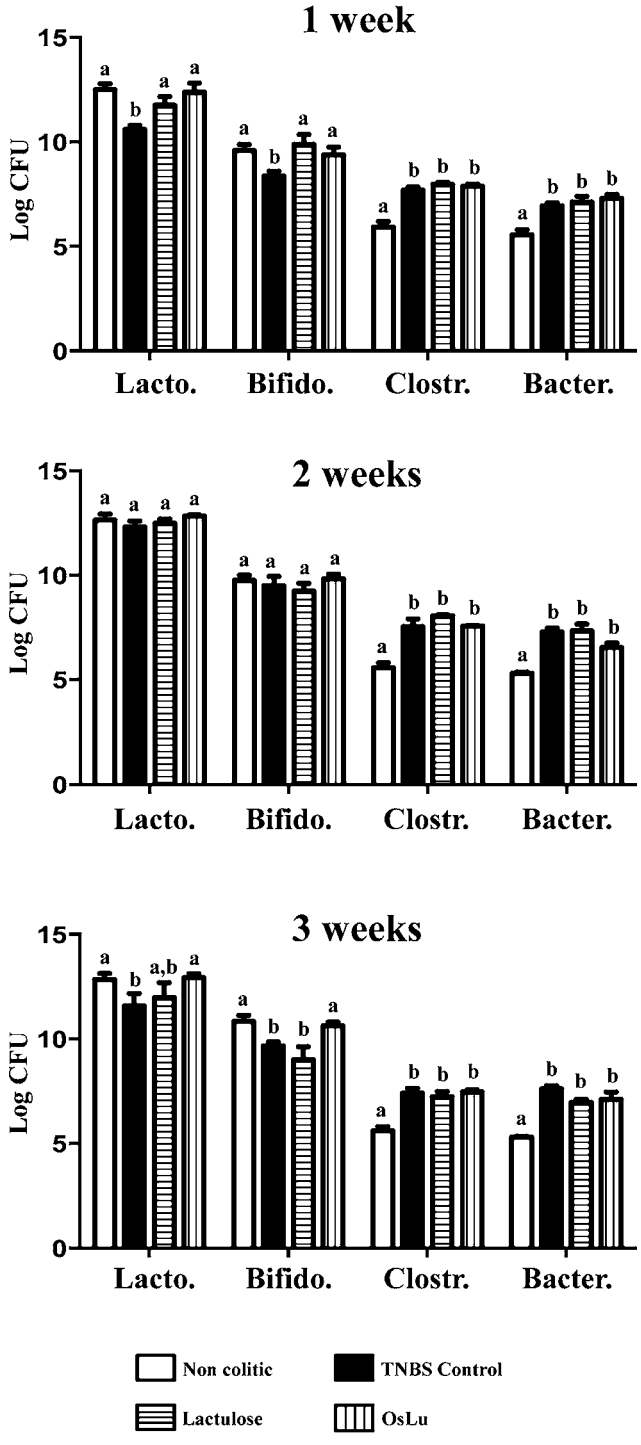

Figure 7. Effects of lactulose and oligosaccharides derived from lactulose (OsLu) on the bacterial profile in the colonic luminal contents in reactivated TNBS rat colitis. The counts of lactobacilli, bifidobacteria, clostridia, and bacteroides (expressed as log of colony forming units (CFU)) were analyzed by RT-PCR. Data (n = 10 per group) are expressed as means ± SEM; groups with different letters statistically differ (P < 0.05).

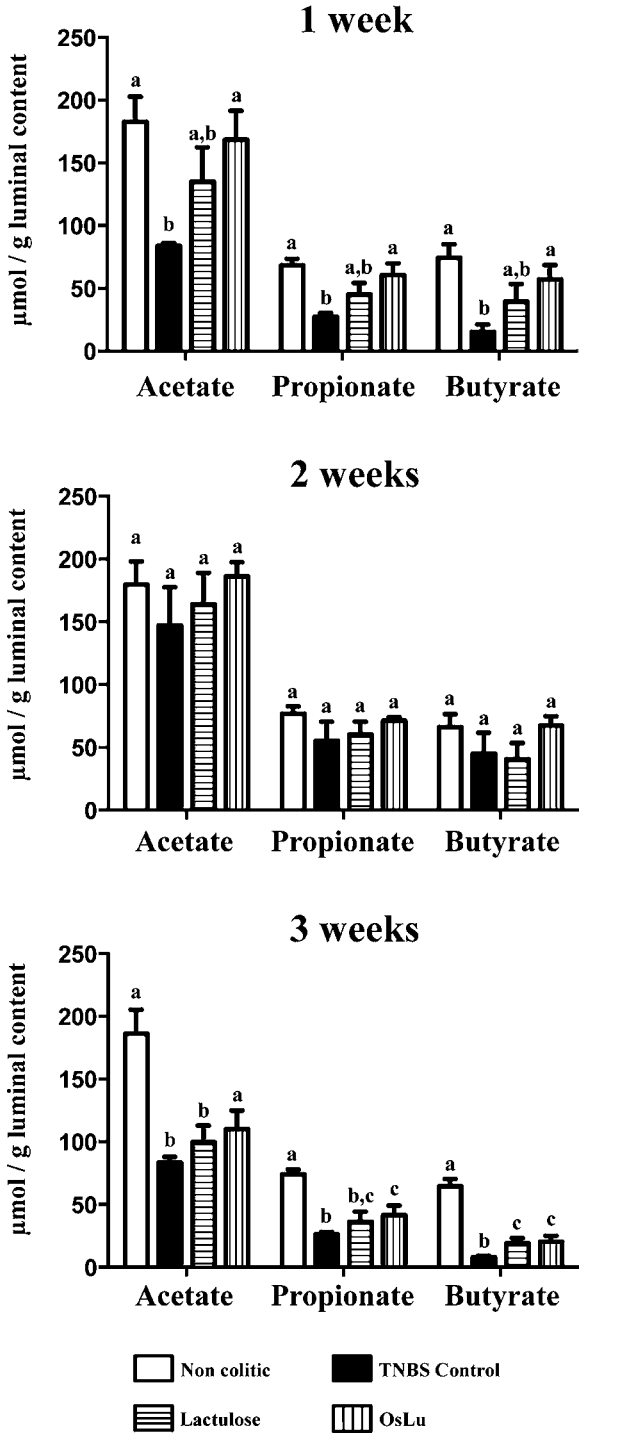

Figure 8. Effects of lactulose and oligosaccharides derived from lactulose (OsLu) on short-chain fatty acid (acetate, propionate, and butyrate) production in the colonic luminal contents in reactivated TNBS rat colitis. Data (n = 10 per group) are expressed as means ± SEM; groups with different letters statistically differ (P < 0.05).

intestine, thus avoiding the deleterious effect that NO overproduction may exert on the colonic tissue in these intestinal conditions.[43]

In conclusion, OsLu shows better anti-inflammatory properties than lactulose, probably derived from the improvement of the luminal microbiota balance and a greater SCFA production, which was associated with an inhibition of iNOS expression and a reduction of Th17 cell activity in the inflamed tissue that, in turn, promote intestinal membrane integrity and a faster recovery of the inflamed tissue. After this preclinical study of OsLu, these oligosaccharides could be considered for a clinical study to test its efficacy in maintenance of IBD remission and preventing relapses.

Supporting Information

ABSTRACT: The mitochondrion is a central organelle in cellular energy homeostasis; thus, reduced mitochondrial activity has been associated with aging and metabolic disorders. This paper provides biological evidence that coumestrol, which is a natural isoflavone, activates mitochondrial biogenesis. In cultured myocytes, coumestrol activated the silent information regulator two ortholog 1 (Sirt1) through the elevation of the intracellular NAD^+/NADH ratio. Coumestrol also increased the mitochondrial contents and induced the expression of key proteins in the mitochondrial electron transfer chain in cultured myocytes. A Sirt1 inhibitor and Sirt1-targeting siRNAs abolished the effect of coumestrol on mitochondrial biogenesis. Similar to an increase in mitochondrial content, coumestrol improved myocyte function with increased ATP concentration. Taken together, the data suggest that coumestrol is a novel inducer of mitochondrial biogenesis through the activation of Sirt1.

KEYWORDS: *coumestrol, mitochondrial biogenesis, Sirt1, myocyte*

INTRODUCTION

The mitochondrion produces most of the cellular ATP via aerobic respiration and regulates various cellular processes, including signaling pathways, growth, differentiation, cell cycle, and apoptosis.[1] Because the maintenance of mitochondrial functions is critical for maintaining energy homeostasis, mitochondrial biogenesis, which maintains cellular mitochondrial content, has been considered a critical biomarker to assess cellular longevity and functionality. Mitochondrial biogenesis is regulated by multiple factors, one of which is a nuclear-encoded transcription factor, nuclear respiratory factor 1 (NRF1), that induces the expression of transcription factor A mitochondria (tfam) and other mitochondria-related genes in nucleus DNA.[2] Tfam is a key mitochondrial transcription factor, which is responsible for the regulation of mitochondrial DNA (mtDNA)-encoded genes and the replication of mtDNA. Therefore, mitochondrial biogenesis is regarded as a complex process that is coordinated by nuclear (by NRF1) and mitochondrial (by tfam) genes.[1]

Although the molecular mechanism of mitochondrial biogenesis is not fully understood, it has been reported that peroxisome proliferator-activated receptor gamma coactivator 1 α (PGC1α) has been reported as a positive regulator that directly interacts with NRF1 to form a transcription complex.[3] PGC1α forms a transcription complex with NRF1 to increase the transcriptional activity of NRF1. In addition, PGC1α also regulates glucose and lipid homeostasis through interaction with various transcription factors, such as peroxisome proliferator-activated receptor γ, retinoid X receptor, and cAMP response element-binding protein.[4−6]

Silent information regulator two ortholog 1 (Sirt1), which is an NAD^+-dependent histone deacetylase, is a mammalian homologue of the silent mating-type information regulation 2 (Sir2) gene in *Saccharomyces cerevisiae*, which has been studied as a "longevity gene"; thus, Sir2 overexpression results in a lifespan extension in small-animal models, such as budding yeasts, nematodes, and fruit flies.[7−9] Calorie restriction has been known to exhibit a positive effect on lifespan extension,[10] whereas the deletion of Sir2 diminished the effect on lifespan extension.[11] These results imply that Sir2 activity mediates the effect of calorie restriction on longevity. Therefore, Sir2 is regarded as a central molecule in the network of energy metabolism and lifespan. In mammals, Sirt1 has been reported to regulate energy metabolism and response to calorie restriction.[12] For these reasons, small molecules that target Sirt1 are being developed to overcome metabolic disorders, including obesity, insulin resistance, and type 2 diabetes.

In addition to the roles in longevity, Sirt1 has been proposed to be one of the most important positive regulators for regulating cellular mitochondrial number.[13] Upon activation, Sirt1 facilitates the deacetylation and activation of PGC1α.[13] As above-mentioned, activated PGC1α can trigger mitochondrial biogenesis through interaction with NRF1. Thus, it is also feasible that mitochondrial biogenesis can be achieved by the activation of Sirt1.

Coumestrol, which is a daidzein-derived coumestan, is a natural organic compound that is found in some plants, including alfalfa, legumes, Brussels sprouts, spinach, clover, and soybeans.[14] Various biological activities of coumestrol have been reported, including antioxidant activity,[15] the inhibition of osteoclast differentiation,[16] the inhibition of adipocyte differentiation, and reduced lipid accumulation.[17] As a phytoestrogen, coumestrol also exerts an estrogenic effect, with strong binding affinities for estrogen receptors α and β,[14,18] and the positive effects of coumestrol on bone metabolism and uterine

growth are well-studied in ovariectomized animals.[19,20] Finally, coumestrol attenuated tumorigenesis.[21,22] However, the molecular target and mechanism of action of coumestrol have not been clearly understood.

Recently, it has been proposed that flavonoids and their derivatives induce mitochondrial biogenesis through the activation or expression of Sirt1 in proximal renal tubular cells.[23] Therefore, here we investigated whether coumestrol has positive effects on mitochondrial biogenesis and compared the activity of coumestrol with resveratrol, which is a compound that is known as a Sirt1 activator. Sirt1 activity was determined, and coumestrol-induced mitochondrial biogenesis was assessed by mitochondrial content and by the expression of mitochondria-related genes in differentiated myocytes. The effect of Sirt1 activation on the coumestrol-mediated induction of mitochondrial biogenesis was confirmed by utilizing a Sirt1 inhibitor and Sirt1-specific siRNAs. The effect of coumestrol-mediated mitochondrial biogenesis was confirmed by the measurement of cellular ATP concentrations.

MATERIALS AND METHODS

Reagents. Coumestrol and nicotinamide were purchased from Sigma (St. Louis, MO, USA). The antibodies for NADH dehydrogenase 1α subcomplex 9 (NDUFA9), succinate dehydrogenate complex subunit A (SDHA), ubiquinol cytochrome *c* reductase core protein 2 (UQCRC2), cytochrome oxidase subunit 1 (COX1), ATP synthase mitochondria F1 complex α subunit 1 (ATP5a), PGC1, and NRF1, as well as scrambled and Sirt1 siRNAs, were purchased from Santa Cruz Biotechnology (Dallas, TX, USA). The β-actin antibody was purchased from Cell Signaling Technology (Danvers, MA, USA), and horseradish peroxidase (HRP)-conjugated anti-mouse, anti-rabbit, and anti-goat secondary antibodies were purchased from Bio-Rad (Hercules, CA, USA).

Cell Culture. C2C12 mouse myocytes were purchased from the American Type Culture Collection (Manassas, VA, USA). Cells were grown in Dulbecco's modified Eagle medium (DMEM, Lonza), which was supplemented with 10% fetal bovine serum (FBS, HyClone, Logan, UT, USA). All media were supplemented with 100 units/mL penicillin and 100 mg/mL streptomycin (Sigma), and C2C12 cells were grown at 37 °C in a humidified atmosphere, which contained 5% CO_2. For differentiation, confluent C2C12 cells were maintained with DMEM, which was supplemented with 2% horse serum (HyClone) for 7 days. During differentiation, the medium was changed daily.

Sirt1 Activity Assay. Sirt1 activity was examined using a SIRT1 Fluorimetric Drug Discovery Kit (Enzo Life Sciences, Farmingdale, NY, USA) with minor modifications, as described previously.[24] Briefly, total protein (25 μg) was dissolved in the assay buffer and incubated in the presence of NAD^+ (100 μM) at 37 °C for 30 min. The acetylated substrate (Fluor-de-Lys-Sirt1 substrate) was then added, and the mixture was incubated at 37 °C for 45 min. After incubation, deacetylated substrates were detected on a TECAN M200 PRO fluorometric plate reader (Tecan, Männedorf, Switzerland).

Measurement of Cellular NAD^+/NADH Ratio. The NAD^+/NADH ratio was determined using an NAD/NADH assay kit (Biovision, Miltipas, CA, USA), following the manufacturer's protocol. Briefly, cells were lysed with extraction buffer (400 μL) by the freeze–thaw method. Extracts were vortexed for 10 s and centrifuged at 18000 rcf for 5 min. The supernatants were then equally divided into two microcentrifuge tubes. Half of the samples were incubated at 60 °C for 30 min to disrupt NAD^+ and remain NADH only. Unheated samples (NADt; NAD^+ plus NADH) and heated (NADH only) samples were incubated with a NAD cycling enzyme, which converts NAD^+ to NADH at room temperature for 5 min. Then, the mixtures were mixed with the NADH developing agent and incubated at room temperature for 1 h. NADH levels were determined by measuring the absorbance at 450 nm using a TECAN M200 PRO fluorometric plate reader. NAD^+ levels were calculated by subtracting NADH from NADt.

Measurement of Mitochondrial Density. Mitochondrial content was measured using the MitoTracker Green FM (Invitrogen, Carlsbad, CA, USA) reagent. Briefly, cells were rinsed with PBS and incubated with MitoTracker Green FM (50 nmol) for 30 min. Fluorescence was measured using a TECAN M200 PRO fluorometric plate reader to determine the density of mitochondria.

Western Blotting. An equal amount (60 μg) of protein per sample was separated on NuPAGE Novex Tris–acetate gels (Invitrogen) and transferred to membranes using an iBlot dry transfer device (Invitrogen). Membranes were blocked with 5% skim milk (Sigma) in Tris-buffered saline (Bio-Rad), which was supplemented with 0.1% Tween-20 (Sigma) (TBST) at room temperature for 30 min. After blocking, the membranes were incubated with primary antibodies, which were dissolved in TBST/5% bovine serum albumin (BSA, Sigma) with gentle shaking at 4 °C overnight. After three washings with TBST, the blots were hybridized with HRP-conjugated secondary antibodies in TBST/5% BSA at room temperature for 2 h and washed three times with TBST. After washing, the membranes were incubated with enhanced chemiluminescence reagents (Santa Cruz Biotechnology) and analyzed with an LAS-3000 imaging system (Fujifilm, Tokyo, Japan). Relative expression levels of proteins were measured using Multigauge software (Fujifilm).

siRNA Transfection. For the knockdown of Sirt1, differentiated C2C12 myocytes were transfected with scrambled or mouse Sirt1 siRNA using the Lipofectamine 2000 reagent (Invitrogen). After transfection, cells were incubated in Opti-MEM (Invitrogen) medium for 4 h. After transfection, the medium was replaced with fresh DMEM, which contained 10% FBS.

Measurement of ATP. ATP content was determined using an ATP determination kit (Invitrogen). Briefly, extracts were mixed with a reaction solution, which contained firefly luciferase and D-luciferin. ATP content was measured using a Wallac 1420 Victor^2 multilabel counter microplate reader (PerkinElmer, Waltham, MA, USA) and normalized with the protein concentration of each sample.

Glucose Uptake Assay. Glucose uptake was assessed by using a glucose uptake cell-based assay kit (Cayman Chemical Co., Ann Arbor, MI, USA), following the manufacturer's protocol with minor modifications. Briefly, cells in a 96-well black, clear-bottom plate were washed with PBS three times and the medium was changed into glucose-free DMEM (Lonza) containing 150 μg/mL 2-NBDG (fluorescent-labeled deoxyglucose analogue). Cells were incubated for a further 1 h, and the plate was centrifuged at 400 rcf for 5 min. After centrifugation, supernatant was discarded and cell-based assay buffer (200 μL) was added to each well. The plate was centrifuged at 400 rcf for 5 min, the supernatant was discarded, and cell-based assay buffer (100 μL) was added one more time. The amount of 2-NBDG taken up by the cells was immediately measured at the wavelength of 485/535 nm (excitation/emission) using a TECAN M200 PRO fluorometric plate reader.

Statistical Analyses. The results are representative of the data from three or more independent experiments. All data points represent the average of triplicate samples. Error bars represent the standard deviation (SD). The *p* values, which were calculated from a one-way ANOVA followed by Dunnett's procedure, that were <0.01 were interpreted as statistically significant.

RESULTS

Coumestrol Activates Sirt1. Coumestrol significantly and dose-dependently increased Sirt1 activity in differentiated C2C12 myocytes (Figure 1A). The effect of coumestrol (CMS; 1 and 10 μM) on Sirt1 activity was comparable with that of resveratrol (Res; 50 μM), which indicated that coumestrol is a potent inducer of Sirt1 activity. Sirt1 activity is directly regulated by the intracellular NAD^+/NADH ratio; thus, we measured the intracellular NAD^+/NADH ratio in cells that were stimulated with coumestrol. Corresponding with Sirt1 activity, coumestrol caused a dose-dependent induction of the intracellular NAD^+/NADH ratio, which demonstrated that

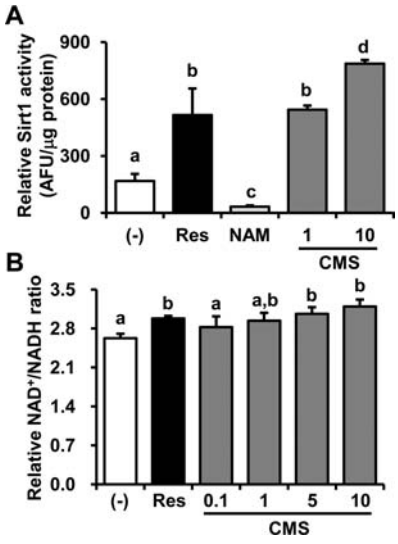

Figure 1. Coumestrol activates Sirt1. (A) Sirt1 activity assay. Differentiated C2C12 cells were treated with DMSO, resveratrol (Res; 50 μM), nicotinamide (NAM; 1 mM), or coumestrol (CMS; 1 or 10 μM, respectively) for 24 h, and Sirt1 activity assay was assessed as described under Materials and Methods. Relative Sirt1 activity is shown as a bar graph. AFU, arbitrary fluorescence unit. (B) Intracellular NAD^+/NADH ratio. C2C12 myocytes were treated with Res (25 μM) or CMS (0.1, 1, 5, and 10 μM, respectively) for 12 h. Cells were rinsed with PBS, and intracellular NAD^+/NADH ratio was measured. Values that do not share the same letter are significantly different ($p < 0.01$).

coumestrol activates Sirt1, at least in part, through the elevation of the intracellular NAD^+/NADH ratio (Figure 1B).

Coumestrol Induces Mitochondrial Biogenesis. We demonstrated that coumestrol activates Sirt1 (Figure 1), which induces mitochondrial biogenesis.[13] To determine whether coumestrol promotes mitochondrial biogenesis similar to other Sirt1 activators,[25,26] we quantified the mitochondrial density in differentiated C2C12 myocytes that were treated with coumestrol. Coumestrol increased the mitochondrial content in a dose-dependent manner (Figure 2A). Moreover, the protein expression of mitochondrial electron transfer chain (ETC) components, such as NDUFA9, SDHA, UQCRC2, COX1, and ATP5a, and transcriptional regulators that are responsible for mitochondrial biogenesis, such as PGC1 and NRF1, were augmented with coumestrol stimulation (Figure 2B,C). Corresponding with protein expression, the mRNA expression of mitochondria-related genes was also up-regulated by coumestrol (Supporting Information Figure S1), which suggested that coumestrol can induce mitochondrial biogenesis through the transcriptional regulation of the expression of mitochondrial biogenesis-related genes.

Chemical Inhibitor of Sirt1 Prevents Coumestrol-Mediated Mitochondrial Biogenesis. To establish whether Sirt1 plays an important role in mediating coumestrol-induced mitochondrial biogenesis, we examined the effects of the Sirt1 inhibitor nicotinamide. To inhibit Sirt1 activation, cells were stimulated with a high dose of nicotinamide (1 mM) before coumestrol stimulation. The results demonstrated that the mitochondriogenic effect of coumestrol was prevented by nicotinamide pretreatment, which was assessed with mitochondrial density (Figure 3A). Additionally, the expression of mitochondrial ETC-related genes was not increased upon coumestrol treatment in the presence of nicotinamide (Figure

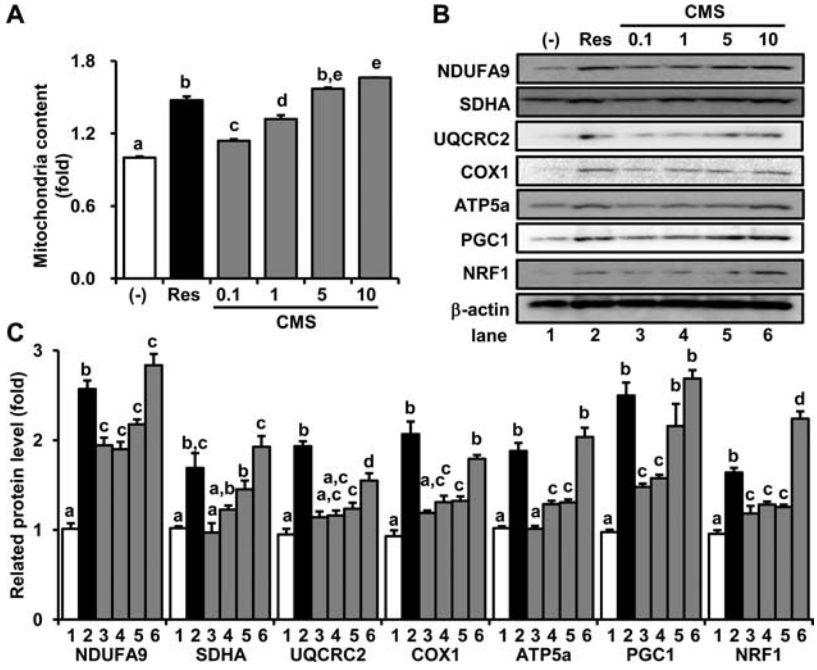

Figure 2. Coumestrol induces mitochondrial biogenesis. C2C12 myotubes were treated with resveratrol (Res; 25 μM) or coumestrol (CMS; 0.1, 1, 5, and 10 μM, respectively) for 24 h. (A) Mitochondrial density was measured using the Mitotracker Green FM reagent. Relative mitochondrial density is shown as a bar graph. (B) After rinsing with PBS, cells were harvested, and proteins were extracted and blotted with antibodies against specific proteins (NDUFA9, SDHA, UQCRC2, COX1, ATP5a, PGC1, and NRF1). β-Actin was used as a loading control. (C) Protein expression level of each protein shown in (B). Each number under the bar graph indicates the lane number in (B). Values that do not share the same letter are significantly different ($p < 0.01$).

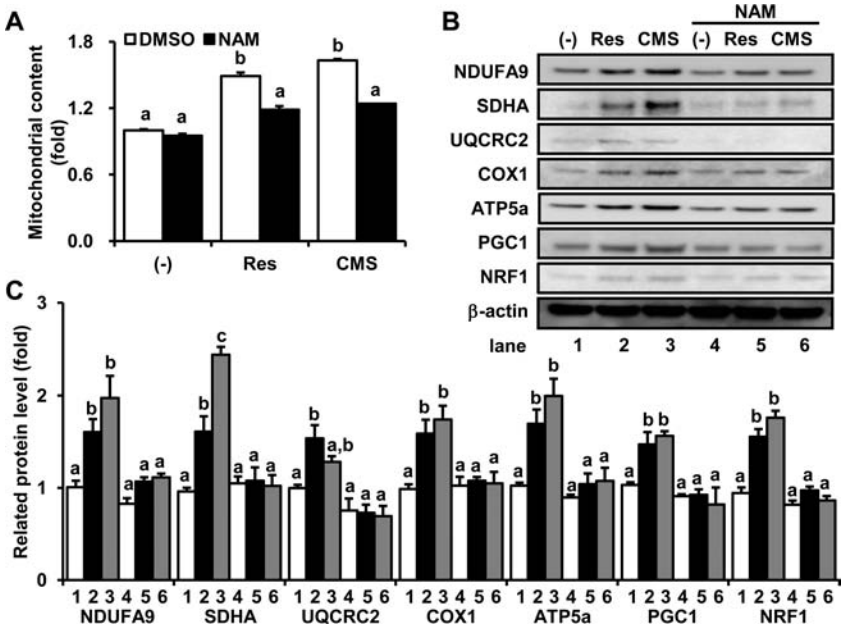

Figure 3. Nicotinamide prevents Sirt1-mediated mitochondrial biogenesis. C2C12 cells were pretreated with DMSO (control) or nicotinamide (NAM; 1 mM) for 2 h. Then, cells were treated with resveratrol (Res; 25 μM) or coumestrol (CMS; 10 μM) for an additional 24 h. (A) After incubation, mitochondrial density was determined. (B) After washing with PBS, cells were harvested, and proteins were blotted with specific antibodies. β-Actin was used as a loading control. (C) Densitometry of Western blots shown in (B). Values that do not share the same letter are significantly different ($p < 0.01$).

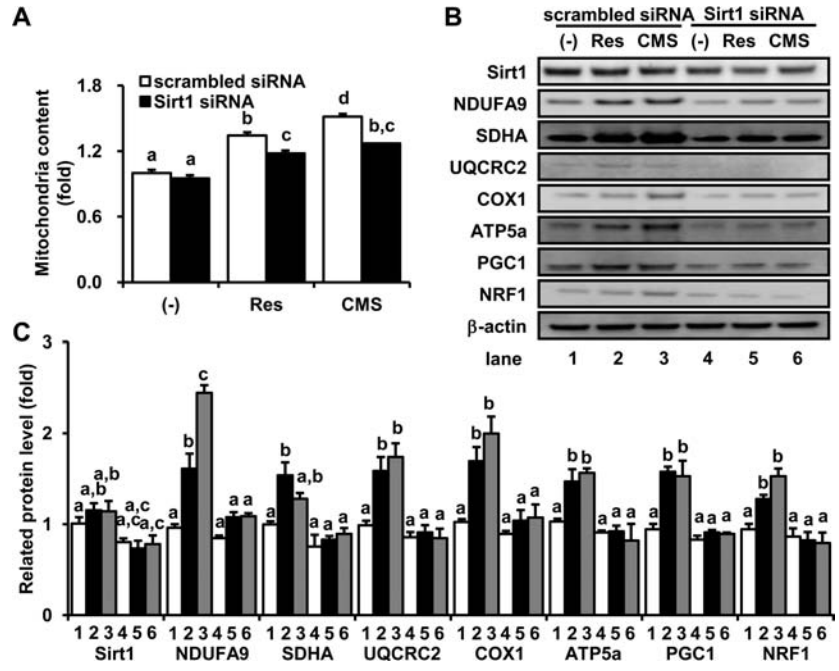

Figure 4. Sirt1 siRNA blunts the effect of coumestrol on mitochondrial biogenesis. C2C12 cells were transfected with scrambled or Sirt1 siRNA. After transfection, cells were treated with resveratrol (Res; 25 μM) or coumestrol (CMS; 10 μM) for 24 h. (A) Mitochondrial density was determined. (B) Proteins were blotted with antibodies that targeted mitochondrial proteins and their regulators. β-Actin was used as a loading control. The expression of each protein was normalized and shown as bar graphs (C). Values that do not share the same letter are significantly different ($p < 0.01$).

3B). These data suggest that Sirt1 mediates the mitochondriogenic effect of coumestrol in myocytes.

Knockdown of Sirt1 Lessens the Effect of Coumestrol on Mitochondrial Biogenesis. The nicotinamide treatment indicated that the inhibition of Sirt1 activity abolishes the effect of coumestrol on mitochondrial biogenesis (Figure 3). To confirm the Sirt1-dependent effect of coumestrol, the expression of Sirt1 was knocked down with Sirt1-specific siRNAs (Supporting Information Figure S2). Similar to the nicotinamide pretreatment, knockdown of the Sirt1 expression also abolished the effect of coumestrol on mitochondrial biogenesis (Figure 4A) and mitochondrial ETC protein

dx.doi.org/10.1021/jf404882w | J. Agric. Food Chem. 2014, 62, 4298−4305

expression (Figure 4B). Similar results were obtained with resveratrol. Taken together, these results demonstrate that both resveratrol and coumestrol induce mitochondrial biogenesis in a Sirt1-dependent manner.

Coumestrol Increases ATP Content in a Sirt1-Dependent Manner and Augments Glucose Uptake. To confirm whether coumestrol contributes to ATP production through the induction of mitochondrial content, we measured cellular ATP concentrations in cells that were stimulated with coumestrol. In agreement with increased mitochondrial content (Figure 2), coumestrol induced cellular ATP concentrations in C2C12 myocytes (Figure 5A); however, the blockade of Sirt1 activity with nicotinamide prevented coumestrol-mediated ATP production (Figure 5B). Collectively, these data indicate that coumestrol induces mitochondrial biogenesis and, consequently, increases cellular ATP level through the activation of Sirt1.

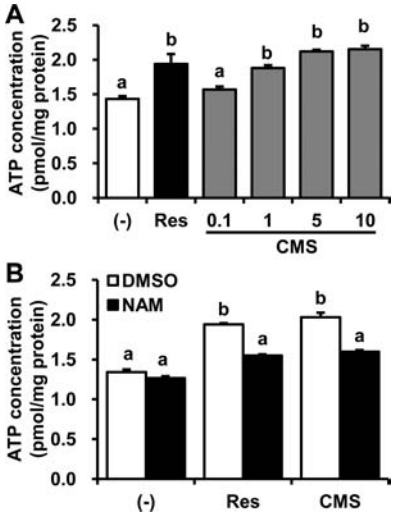

Figure 5. Coumestrol increases ATP content in cultured myocytes in a Sirt1-dependent manner. (A) Differentiated C2C12 cells were treated with resveratrol (Res; 50 μM) or coumestrol (CMS; 0.1, 1, 5, and 10 μM, respectively) for 24 h. After incubation, the ATP level was determined by using an ATP determination kit. (B) After differentiation, C2C12 myocytes were pretreated with DMSO (for control) or nicotinamide (NAM; 1 mM) for 2 h. Then, cells were treated with Res (50 μM) or CMS (10 μM) for 24 h. Cellular ATP content was measured as described under Materials and Methods. Values that do not share the same letter are significantly different ($p < 0.01$).

Glucose is the primary energy source for ATP production. Increased ATP content in coumestrol-treated myocytes (Figure 5) indicates that coumestrol might be associated with glucose uptake. To elucidate whether coumestrol enhances glucose uptake in skeletal muscle, we assessed the glucose uptake assay. As shown in Figure 6, coumestrol slightly but significantly increased glucose uptake, compared to control. These data suggest that coumestrol is able to enhance energy metabolism.

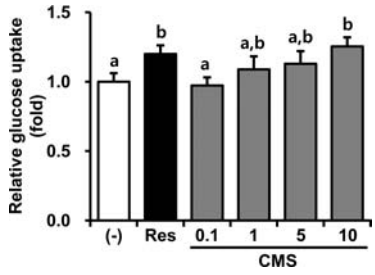

Figure 6. Coumestrol augments glucose uptake in differentiated myocytes. Differentiated C2C12 myocytes were treated with DMSO (for control), resveratrol (Res; 50 μM), or coumestrol (CMS; 0.1, 1, 5, and 10 μM, respectively) for 24 h. Cellular glucose uptake was measured as described under Materials and Methods and shown as a bar graph. Values that do not share the same letter are significantly different ($p < 0.01$).

DISCUSSION

As "power plants" of cells and regulators of diverse cellular activities, mitochondria play an important role in cellular energy balance and survival. Not surprisingly, mitochondrial dysfunction is associated with several cellular dysfunctions and diseases, including metabolic disorders. For example, mitochondrial dysfunction has been reported to be closely associated with β-cell failure.[27] Additionally, impaired mitochondrial bioenergetic capacity is observed in the skeletal muscle of type 2 diabetes patients.[28] In fat and muscle tissues from obese rodents, mitochondrial density, mitochondrial function, and ATP content are down-regulated.[29] Accordingly, it is likely that mitochondrial dysfunction can be observed in various organs or in tissues of metabolic syndromes. Therefore, maintaining mitochondrial function by inducing mitochondrial biogenesis is required to sustain a healthy life.

Here, we demonstrated that coumestrol is able to induce Sirt1 activity and mitochondrial biogenesis. By promoting mitochondrial content, coumestrol increased cellular ATP levels and glucose uptake, implying that coumestrol could improve energy metabolism. Interestingly, the expression and activity of Sirt1 gradually decline with aging, and mitochondrial content and function are also age-dependently decreased.[30−32] Considering the mitochondriogenic effect of Sirt1, it is feasible that decreased Sirt1 activity could be a causal factor of blunted mitochondrial biogenesis, which thereby diminishes mitochondrial density and causes aging-related dysfunctions in aged cells. As for other Sirt1 activators,[25,26,33] we demonstrated that coumestrol also increases mitochondrial content through the activation of Sirt1 in muscle cells. Therefore, it is feasible that coumestrol has the potential to attenuate aging-related mitochondrial dysfunction.

The benefit of Sirt1 activation is not limited to mitochondrial rejuvenation. For example, Sirt1 modulates glucose homeostasis by regulating PGC1α and forkhead box O1 activity in the liver.[34] The loss of function of Sirt1 in the pancreas is associated with decreased insulin secretion,[35] and Sirt1 is activated during glucose-stimulated insulin secretion.[36] These data imply that Sirt1 may be involved in the regulation of glucose homeostasis. Furthermore, Sirt1 is also able to control lipid metabolism. In fact, Sirt1 deacetylates and deactivates sterol regulatory element binding protein 1c (SREBP1c), which is a master transcriptional regulator of lipogenesis-related genes.[37] Conversely, Sirt1 enhances lipid catabolism through the activation of AMP-activated protein kinase (AMPK), which is a master regulator of energy metabolism.[38] Additionally, Sirt1 is implicated in the expression and secretion of adiponectin,[39,40] which is an adipocytokine that regulates glucose and lipid metabolism to promote insulin sensitivity. Therefore, it is feasible that Sirt1 activation can improve, or at least modify, glucose and lipid metabolism, which are closely related with metabolic disorders. Remarkably, we observed that coumestrol decreased the mRNA expression of lipogenic genes (e.g.,

SREBP1c and fatty acid synthase) in adipocytes and hepatocytes, whereas coumestrol increased fatty acid oxidation-related genes in myocytes (e.g., acyl-CoA oxidase and carnitine-palmitoyl transferase 1) (Supporting Information Figure S3), indicating that coumestrol could also modulate lipid metabolism to ameliorate metabolic disorders.

Although Sirt1 is beneficial to the regulation of energy metabolism, the effect of Sirt1 in cancer development is controversial. The ectopic expression of Sirt1 attenuated colon cancer progression in mice,[41] and an allelic loss or a mutation of Sirt1 is present in various tumor cells.[42] In contrast, Sirt1 expression level is up-regulated in some tumor cells, and Sirt1 enhances matrix metalloproteinase 2 expression and activity to promote cancer cell migration.[43,44] Furthermore, a specific Sirt1 activator has been reported to promote tumor cell migration and invasion in mice.[45] As an oncogene, Sirt1 activation could lead to tumorigenesis. However, coumestrol displayed anticancer activities by suppressing some tumor development with the modulation of estrogen receptor β and casein kinase II activities.[21,22] Thus, the collective effects of coumestrol appear beneficial without affecting cancer risk. The molecular mechanism of the coumestrol-mediated inhibition of tumor progression requires further study.

As the regulators of energy metabolism and mitochondrial biogenesis, it has been proposed that Sirt1 and AMPK activate each other. AMPK has been reported to increase NAD^+ to activate Sirt1.[46] In contrast, Sirt1 mediates the deacetylation of liver kinase B1,[47] which is an upstream regulator of AMPK. On the basis of these results, it is likely that Sirt1 and AMPK might assemble a positive feedback loop to enhance energy catabolism. According to the previous data, it might be possible that coumestrol could activate AMPK, which is a regulator of Sirt1. Although it remains unclear which one, Sirt1 or AMPK, is the upstream regulator of the other, we observed that coumestrol increased the phosphorylation level of the AMPKα catalytic subunit (Supporting Information Figure S4). Similar to Sirt1, AMPK is also reported to regulate mitochondrial biogenesis and catabolism.[38] On the basis of these data, it is likely that AMPK activation may boost the favorable effect of coumestrol on mitochondrial biogenesis and energy metabolism. Further studies, including in vivo experiments, will reveal the effect of coumestrol on energy metabolism and on the correlation between AMPK and Sirt1.

In conclusion, we demonstrated that coumestrol is an effective inducer of mitochondrial biogenesis. Coumestrol caused a small elevation in the intracellular NAD^+/NADH ratio, but a major induction of Sirt1 activation, which suggests that other factors in addition to NAD^+/NADH ratios are involved in this effect. The coumestrol-mediated mitochondrial biogenesis was abolished by the inhibition of Sirt1 activity. Increased mitochondrial content induced by coumestrol caused an elevation of cellular ATP levels and an increase of glucose uptake. Collectively, our data suggest that coumestrol is an effective Sirt1 activator and enhancer of mitochondrial number and function.

Supporting Information

ABSTRACT: In the present study, we aimed to investigate the antiobesity effect of CAPE in vivo, and the mechanism by which CAPE regulates body weight in vitro. To confirm the antiobesity effect of CAPE in vivo, mice were fed with a high fat diet (HFD) with different concentrations of CAPE for 5 weeks. CAPE significantly reduced body weight gain and epididymal fat mass in obese mice fed a HFD. In accordance with in vivo results, Oil red O staining results showed that CAPE significantly suppressed MDI-induced adipogenesis of 3T3-L1 preadipocytes. FACS analysis results showed that CAPE delayed MDI-stimulated cell cycle progression, thereby contributing to inhibit mitotic clonal expansion (MCE), which is a prerequisite step for adipogenesis. Also, CAPE regulated the expression of cyclin D1 and the phosphorylation of ERK and Akt, which are upstream of cyclin D1. These results suggest that CAPE exerts an antiobesity effect in vivo, presumably through inhibiting adipogenesis at an early stage of adipogenesis.

KEYWORDS: *caffeic acid phenethyl ester, diet-induced obesity, 3T3-L1 preadipocytes, adipogenesis, mitotic clonal expansion*

INTRODUCTION

Obesity is a major health problem worldwide that is associated with the increased risk of type 2 diabetes and other chronic diseases.[1,2] Obesity is characterized by an increase in adipose tissue mass, which is associated with an increased fat cell number (hyperplasia) and cell size (hypertrophy).[3] It is the murine 3T3-L1 cell line that can mimic in vivo fat cell hyperplasia and hypertrophy. The 3T3-L1 cell line is a well-established in vitro model for adipogenesis, a differentiation program of preadipocytes to adipocytes.[4−6] Adipogenesis of 3T3-L1 preadipocytes involves growth arrest, mitotic clonal expansion (MCE), and terminal differentiation.[6−8] In particular, MCE is a prerequisite step for transcriptional activation and terminal differentiation of adipocytes.[9] Thus, suppression of MCE could be an effective strategy for the prevention of adipogenesis during the development of obesity.

MCE is associated with elevated mRNA levels of adipogenic transcription factors, such as CCAAT/enhancer-binding protein (C/EBP) α, C/EBPβ, and peroxisome proliferator-activated receptor (PPAR) γ.[9] One of the major events that occur during MCE is increased levels of cell cycle regulators, including cyclins and cyclin-dependent kinases (CDKs).[10] During the G1 phase of cell cycling, activated cyclin D and E bind with their catalytic partners to form active kinase complexes. While cyclin D binds to CDK4 or CDK6 and cyclin E binds to CDK2, cyclin A and B interact with CDK2 and CDK1, leading to the initiation of cell cycle progression through S phase. These kinase complexes inactivate retinoblastoma (Rb) proteins and/or induce hyperphosphorylation of Rb,[11] resulting in transcriptional activation of the S phase-associated genes,[12] which allows the preadipocytes synchronously to pass through the G1/S checkpoint.[9] MCE is also associated with a decrease of p27, a CDK inhibitor,[13] which inhibits the phosphorylation of Rb through kinase complexes, such as CDK4/cyclin D1.[14] ERK and PI3K/Akt-mediated signaling pathways are also involved in the initiation of cell cycle progression, contributing to adipogenesis.[15,16] Therefore, blockade or a delay of the cell cycle progression by inactivating cell cycle regulators, upregulation of CDK inhibitors, and/or inhibiting MAPK and PI3K/Akt-mediated signaling pathways during MCE would effectively contribute to suppressing adipogenesis.

Caffeic acid phenethyl ester (CAPE) is a polyphenol abundantly found in propolis, a resinous mixture that honey bees collect from tree buds, sap flows, and other botanical sources. Approximately 12−17 mg/g of CAPE is obtained from propolis ethyl acetate extract.[17,18] So far, there has been no study about the antiobesity effect of CAPE in vivo. Although studies conducted by Juman et al.[19,20] demonstrated that CAPE reduced the production and secretion of adipokines as well as transcription factors associated with adipogenesis in 3T3-L1 preadipocytes, the molecular mechanism by which CAPE regulates adipogenesis is not studied. Hence, we investigated the antiobesity effect of CAPE in the diet-induced obesity (DIO) animal model and the mechanism by which CAPE regulates body weight using 3T3-L1 preadipocytes.

MATERIALS AND METHODS

Chemicals. CAPE (of which purity is 99.4%) was obtained from Chromadex Inc. (Santa Ana, CA, USA). Antibodies against p-Akt, Akt, and C/EBPα were purchased from Cell Signaling Biotechnology (Beverly, MA, USA), and antibodies against p-ERK, ERK, cyclin D1, cyclin A1, and PPARγ were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Antibody against β-actin was purchased from Sigma (St. Louis, MO, USA). Dexamethasone, 3-isobutyl-1-methylxanthine (IBMX), and insulin were purchased from Sigma.

Animals and Diets. Male C57BL/6N mice (5-wk old) were purchased from Koatech (Pyeongtaek, Korea). After 1 week of acclimation, mice were housed in climate-controlled quarters (23 ± 3 °C at 50 ± 10% humidity) with a 12-h light/12-h dark cycle. All experimental procedures were approved by Hallym University (Gangwon-do, Korea). Mice were divided into five dietary groups (n = 10−11 per each group): a normal diet (10% fat from calorie), a high fat diet (HFD; 60% fat from calorie), and a HFD supplemented with 0.02, 0.1, or 0.5% CAPE (w/w). The standard diet and HFD were purchased from Research Diets, Inc. (New Brunswick; NJ, USA) and were given in the form of pellets for 5 weeks. Body weight was recorded every week, and food intake was monitored every two days. Food was removed 12 h before the animals were sacrificed. The mice were anesthetized, and adipose tissue, the liver, and kidney were removed, weighed, and stored at −70 °C until analysis.

Cell Culture and Adipocytes Differentiation. 3T3-L1 mouse preadipocyte cell line was kindly provided by Dr. J. B. Kim (Seoul National University, Seoul, Korea). 3T3-L1 preadipocytes were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% bovine calf serum (BCS) at 5% CO_2 and 37 °C until confluence. Confluent cells were incubated in DMEM supplemented with 10% fetal bovine serum (FBS) and MDI cocktail [1 μM dexamethasone, 0.5 mM IBMX, and 5 μg/mL insulin]. After 2 days, the medium was replaced with DMEM containing 10% FBS and insulin (5 μg/mL). Medium was then replaced every two days with DMEM containing 10% FBS.

Oil Red O Staining. 3T3-L1 preadipocytes were seeded in 24-well plates at a density of 2.5×10^4 cells/well and incubated until confluence. The cells were then incubated with 10% FBS DMEM supplemented with MDI cocktail with or without CAPE (10, 20, and 40 μM). The medium was then changed to 10% FBS DMEM supplemented with 5 μg/mL of insulin, and replaced every two days. After the induction of cell differentiation, the medium was removed, and the mature 3T3-L1 adipocytes were fixed in 10% formalin. After fixing with 10% formalin, the cells were washed with 1,2-propanediol (Sigma, St. Louis, MO, USA) and stained with Oil red O solution. Stained cells were then washed with phosphate buffered saline (PBS), and the lipid droplets stained with Oil red O were eluted with isopropyl alcohol and quantified by measuring the absorbance at 515 nm by spectrophotometer.

Multimodal Coherent Anti-Stokes Raman Scattering (CARS) Microscope. CARS and two-photon excitation fluorescence (TPEF) imaging analysis were performed as described previously.[21] For CARS/TPEF imaging of lipid droplets in adipocytes, the wavenumber difference between the pump laser and Stokes laser was tuned to 2840 cm^{-1}, which matches the Raman shift of the symmetric CH_2 stretch vibration in lipid molecules. The forward detected CARS signal was collected by an air condenser (numerical aperture = 0.55), transmitted through a 600/65-nm bandpass filter and detected by a photomultiplier tube (PMT, H7422-40, Hamamatsu, Japan). For TPEF imaging of intracellular fluorescent CAPE, the back-reflected signal was collected by the objective, spectrally separated from the excitation source, transmitted through a 520/40-nm bandpass filter and detected by a PMT (H7422-40, Hamamatsu, Japan) mounted at the back port of the microscope. Acquisition time for each image was 1.12 s. Images were analyzed using Fluo-View software (Olympus, PA, USA).

Western Blot Assay. Western blot analysis was performed as previously described.[22] In brief, 3T3-L1 preadipocytes were seeded in a 6 cm dish at a density of 1.5×10^5 cells per dish and cultured for two days with DMEM supplemented with 10% BCS. Confluent cells were subjected to adipogenesis with MDI in the presence or absence of CAPE (10, 20, and 40 μM). Cells were lysed, loaded onto 10% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE), and transferred to nitrocellulose membranes (GE healthcare, Piscataway, NJ, USA). The membrane was blocked with 5% skim milk and incubated with the indicated primary antibodies. The membrane was then incubated with HRP-conjugated secondary antibodies. Protein bands were visualized by a chemiluminescence detection kit (Amersham Pharmacia Biotech; Piscataway, NJ, USA), and the density of the protein bands was quantified using the NIH Image J analysis program.

Trypan Blue Assay. 3T3-L1 preadipocytes were seeded in 24-well plates at a density of 2.5×10^4 cells per well and incubated in DMEM supplemented with 10% FBS with or without CAPE (10, 20, and 40 μM). Cells were trypsinized and stained with 0.4% trypan blue for 5 min. The stained cells were loaded onto a hematocytometer, and the viable cells were counted.

Flow Cytometry Using a Fluorescence-Activated Cell Sorter (FACS) Analysis. 3T3-L1 preadipocytes were seeded in a 6 cm dish at a density of 1.5×10^5 cells per dish. Confluent cells were differentiated with MDI cocktail in the presence or absence of CAPE (40 μM). After centrifugation (1,000 rpm for 3 min), cells were suspended in 70% ethanol (v/v) and fixed overnight at 4 °C. The fixed cells were then centrifuged (1,500 rpm for 3 min), resuspended in PBS containing propidium iodide (PI) solution (Sigma, St. Louis, MO, USA) and RNase (Amresco, Solon, OH, USA), and incubated at 37 °C in the dark (10 min). Cell fluorescence was measured using a FACS calibur flow cytometer (Becton-Kickinson; San Jose, CA, USA). Ten thousands cells in each sample were analyzed.

Real-Time Quantitative PCR. Messenger RNA (mRNA) was extracted from mouse epididymal fat tissue using RNA-Bee (TEL-TEST; Pearland, TX, USA) and reverse transcribed into cDNA using Promega product (Fitchburg, WI, USA). Real-time quantitative PCR was performed as described previously[23] using the SYBR Green RT-PCR kit from Fermentas (Glen Burnie, MD, USA). Each reaction yielded amplicons of 101 bp. Results are expressed relative to β-actin.

Statistical Analysis. In vitro data were expressed as the means ± SD, and Student's t test was used for comparisons. A probability value of $p < 0.05$ or $p < 0.01$ was used as the criterion for statistical significance. For in vivo study, data were expressed as the means ± SEM. One-way ANOVA with Newman−Keuls test was used to evaluate mean differences between groups. Data were analyzed using Graph Pad Prism (version 4.03; Graph Pad Software, Inc., San Diego, CA, USA). Means with superscripts of different letters were significantly different at $p < 0.05$.

RESULTS AND DISCUSSION

CAPE Suppresses HFD-Induced Body Weight Gain in C57BL/6N Mice. To investigate the antiobesity activity of CAPE in vivo, mice (5 wk old) were fed with a HFD supplemented with different concentrations of CAPE (0, 0.02, 0.1, or 0.5%) for 5 weeks. In regard to the antiobesity effect of CAPE in DIO animal model, Bezerra et al. reported that CAPE

improves glucose sensitivity and reduces hepatic steatosis without altering body weight.[24] However, in their study, they fed HFD to mice without CAPE for 8 weeks and started CAPE administration after the mice already became obese. Unlike the previous study, we started HFD and CAPE administration at the same time. The result shows that HFD-fed mice showed greater level of adiposity (Figure 1A). However, HFD-fed mice

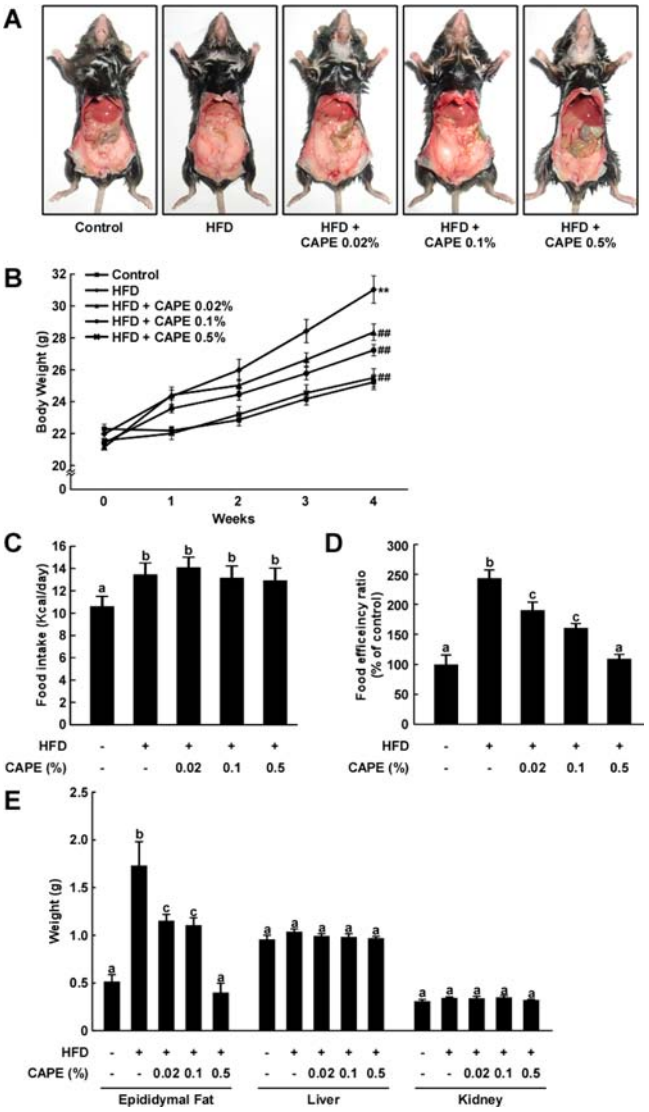

Figure 1. Effects of CAPE on HFD-induced obesity in C57BL/6N mice (n = 11). (A and B) CAPE treatment for 5 weeks alleviated HFD-induced weight gain in C57BL/6N mice. (C) Food intake was slightly reduced by CAPE (0.1 and 0.5%). (D) Food efficiency ratio was attenuated by CAPE treatment. (E) Epididymal fat tissue mass was significantly reduced by CAPE treatment, but liver and kidney tissue masses were unaffected by CAPE treatment. Values are expressed as the means ± SEM. The means marked with superscript letters are significantly different ($p < 0.05$).

supplemented with CAPE showed decreased level of adiposity in a dose-dependent manner (Figure 1A). Indeed, HFD-fed mice displayed significantly increased body weight ($p < 0.01$) (Figure 1B). CAPE decreased HFD-induced body weight gain completely to control levels at 0.5% ($p < 0.01$) (Figure 1B). Although food intake was affected slightly by HFD or CAPE as the same tendency as weight gain (Figure 1C), HFD or CAPE-induced body weight gain change was much more significant than food intake change. To normalize weight gain change to food intake, we estimated food efficiency ratio (FER) which was calculated by dividing the weight increase by the food intake. Compared to control mice, HFD-fed mice had 3.3 times greater FER, which was significantly decreased by the supplementation of CAPE at 0.02, 0.1, and 0.5% ($p < 0.05$) (Figure 1D). To investigate which organ was most affected by HFD, we weighed several organs including epididymal fat and liver. HFD increased epididymal fat mass by 3.5 times and CAPE significantly decreased epididymal fat mass ($p < 0.05$) without affecting the weights of other major organs, such as kidney and liver (Figure 1E). Indeed, dietary supplementation of CAPE at 0.5% decreased adipose tissue mass to control levels ($p < 0.05$) (Figure 1E). In particular, high concentration of CAPE (0.5%) nearly normalized it to the extent observed in the mice fed a control diet. We next examined the effect of CAPE on the expression of genes associated with adiposity. CAPE inhibited mRNA expression of adipogenic and lipogenic genes such as PPARγ, C/EBPα, and fatty acid synthase (FAS) (Figure S1, Supporting Information), and induced mRNA expression of lipolytic and thermogenic genes such as adipose triacylglycerol lipase (ATGL), peroxisome proliferator-activated receptor gamma coactivator 1α (PGC-1α), and long chain acyl CoA synthetase (ACSL) (Figure S2, Supporting Information). These data collectively suggest that the supplementation of CAPE attenuates HFD-induced body weight gain, which is attributable to fat mass reduction possibly by inhibiting adipogenesis and increasing energy expenditure.

CAPE Inhibits MDI-Induced Adipogenesis in 3T3-L1 Preadipocytes. To elucidate the underlying molecular mechanism of the antiobesity effect of CAPE, we used 3T3-L1 preadipocytes. Since Juman et al. reported that CAPE inhibits the differentiation of 3T3-L1 preadipocytes,[19,20] we confirmed the antiadipogenic activity of CAPE. Consistent with a previous report by Juman et al., CAPE dose-dependently inhibited the adipogenesis of 3T3-L1 preadipocytes (Figure 2A,B). We attempted to compare the antiadipogenic activity of CAPE with genistein, which is widely known as a suppressor of adipogenesis[25−27] during the differentiation of 3T3-L1 preadipocytes. Interestingly, a lower level of CAPE (40 μM) more effectively reduced cellular lipid contents than genistein (80 μM) (Figure 2B).

CARS/TPEF microscopy has recently been developed as a novel noninvasive and label-free imaging technique to visualize lipid-rich biological structures and naturally fluorescent intracellular molecules.[21] In an attempt to visualize lipid accumulation in differentiated adipocytes, CARS/TPEF microscopic analysis was performed. We observed that CAPE treatment dramatically reduces the number and size of lipid droplets of fully differentiated 3T3-L1 cells with a complete inhibition of adipogenesis at 40 μM (Figure 2C). Since CAPE is a naturally fluorescent molecule, CARS/TPEF microscopy also allowed us to visualize intracellular accumulation of CAPE, which is mostly found in the cytoplasm of differentiated 3T3-L1 preadipocytes (Figure 2C).

To confirm the antiadipogenic effect of CAPE at the molecular level, we checked the protein level of two well-known adipocyte marker genes, PPARγ and C/EBPα. Figure 2D showed that CAPE attenuated the protein level of PPARγ and C/EBPα (Figure 2D). We next performed the trypan blue assay to check whether these antiadipogenic activities of CAPE come from its cytotoxicity. The trypan blue assay showed that CAPE,

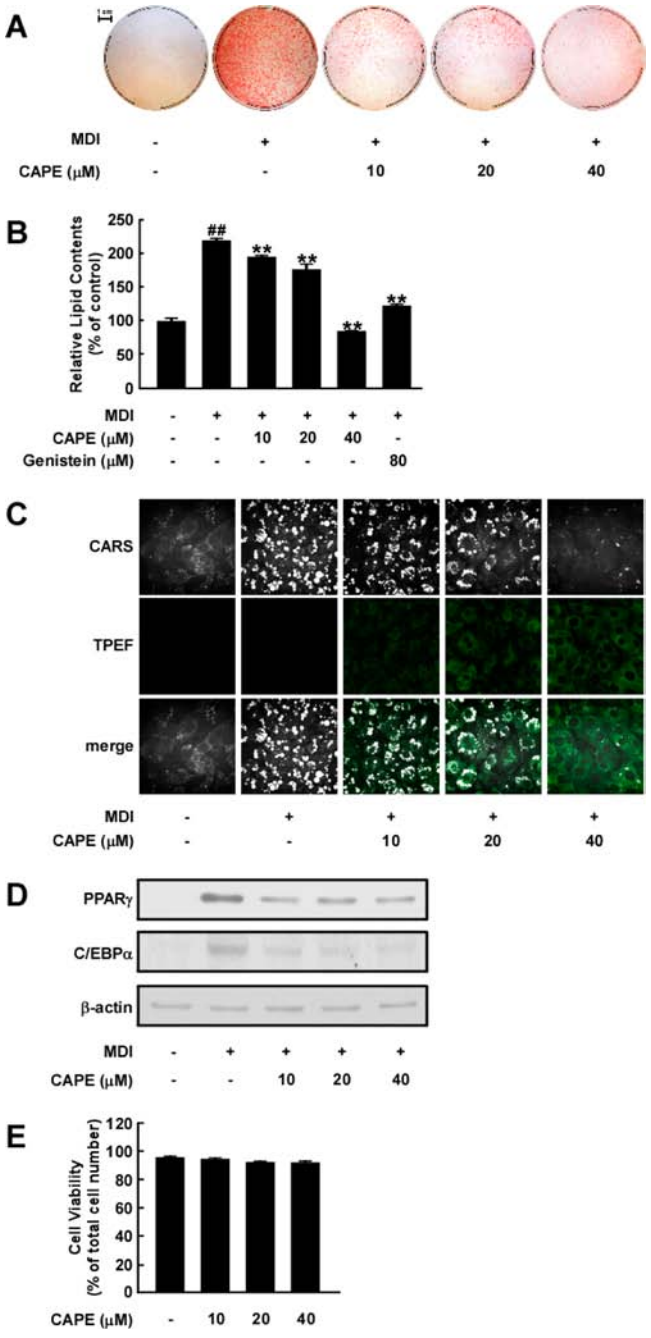

Figure 2. Effects of CAPE on MDI-induced adipogenesis in 3T3-L1 preadipocytes. (A,B) CAPE effectively inhibited MDI-induced adipogenesis of 3T3-L1 preadipocytes. Antiadipogenic effect of CAPE was better than that of genistein. Data are expressed as the means ± SEM from three separate experiments. (C) CAPE inhibited intracellular lipid accumulation of adipocytes, as evidenced by multimodal CARS/TPEF microscopy. (D) CAPE suppressed the protein expressions of MDI-induced PPARγ and C/EBPα. Data are representative of three independent experiments that showed the same tendency. (E) CAPE did not show cytotoxicity in 3T3-L1 preadipocytes up to 40 μM. Data are expressed as the means ± SEM from three separate experiments. ## indicate a significant difference between the control group and the group treated with MDI alone ($p < 0.01$), and ** indicate a significant difference between groups treated with MDI alone and treated with MDI plus CAPE ($p < 0.01$).

up to 40 μM, did not show any toxicity in 3T3-L1 preadipocytes (Figure 2E). Collectively, these findings indicate that CAPE suppresses MDI-induced adipogenesis of 3T3-L1 preadipocytes dose-dependently.

CAPE Exerts Its Antiadipogenic Activity at the Early Stage of Differentiation. A previous study conducted by Juman et al.[19] demonstrated that 50 μM CAPE significantly decreases total lipid contents of differentiated 3T3-L1 preadipocytes by ~17% compared to that of MDI-treated control cells.[19] However, our result showed that 40 μM CAPE completely inhibited adipogenesis of 3T3-L1 preadipocytes. We hypothesized that this discrepancy might be due to different CAPE-treated period, because they treated CAPE during days 3−7,[19] whereas we treated CAPE for the whole adipogenesis process. To clarify this discrepancy and to gain insight into the molecular mechanism underlying CAPE-inhibited adipogenesis, we examined the effect of CAPE (40 μM) on the adipogenesis of 3T3-L1 preadipocytes at different stages of cell differentiation (Figure 3A). Oil red O staining results showed that

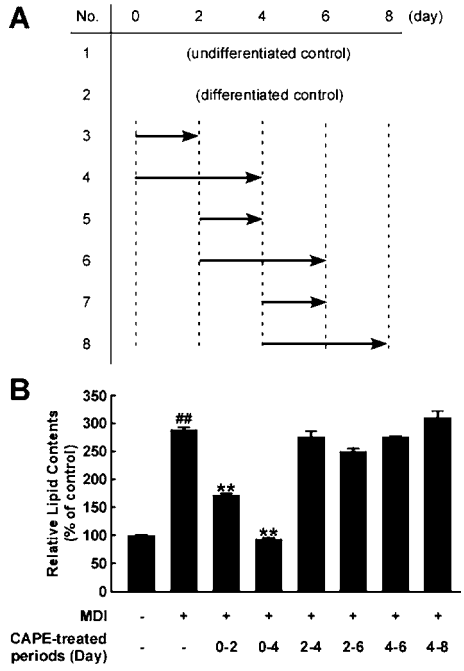

Figure 3. Effects of CAPE on 3T3-L1 preadipocytes during different stages of MDI-induced adipogenesis. (A) A time schedule for CAPE treatment during cellular differentiation. (B) CAPE reduced lipid accumulation when treated during days 0−2. Data are expressed as the mean ± SEM from three separate experiments. ## indicate a significant difference between the control group and the group treated with MDI alone ($p < 0.01$), and ** indicate a significant difference between groups treated with MDI alone and treated with MDI plus CAPE ($p < 0.01$).

CAPE treatment between days 0−2 and 0−4 significantly suppressed MDI-induced adipogenesis ($p < 0.01$) (Figure 3B). In particular, the treatment of CAPE at 40 μM during day 0−4 almost blocked lipid accumulation similar to the extent observed in undifferentiated control cells. Notably, CAPE exerted little effect on the adipogenesis of 3T3-L1 preadipocytes when it was treated at days 2−4, 2−6, 4−6, and 4−8. Since adipogenesis of 3T3-L1 preadipocytes consist of MCE in the early phase of differentiation and terminal differentiation,[6−8] these results indicate that CAPE inhibits adipogenesis by suppressing cellular differentiation during MCE, an early stage of adipogenesis. Also, CAPE treatment during days 2−4

dx.doi.org/10.1021/jf405088f | J. Agric. Food Chem. 2014, 62, 4306−4312

in our study showed antiadipogenic activity similar to the previous result by Juman et al. Since they treated CAPE after MDI treatment, their result corresponds to the CAPE treatment during days 2−4 in our study.

CAPE Delays Cell Cycle Progression during the Early Stage of Cellular Differentiation. We further attempted to elucidate the effect of CAPE on MCE during adipogenesis. The inhibitory effect of CAPE on cell cycle progression was examined (Figure 4). FACS analysis data showed that MDI-induced cell cycle progression was likely delayed by 40 μM of CAPE treatment (Figure 4A). The cell population in each stage of the cell cycle was quantified (Figure 4B). Untreated 3T3-L1 preadipocytes showed no remarkable changes in cell cycle progression during 36 h of culture, mostly staying in the G1/S checkpoint (basal state). However, cells passed the G1/S checkpoint at 16 h of MDI treatment and passed the S to G2/M phase at 20 h of MDI treatment. The cells exited the M phase and reentered into G1 phase from 24 to 36 h of MDI treatment. Meanwhile, cells treated with CAPE at 40 μM stayed at the G1/S checkpoint until 20 h of MDI treatment, but they entered S phase at 24 h. Moreover, we observed that cells treated with CAPE did not exit the G2/M phase and were arrested at the G2/M phase at 36 h (Figure 4B). These collectively indicate that CAPE delays cell cycle progression during MCE, thereby inhibiting adipogenesis of 3T3-L1 preadipocytes stimulated by MDI.

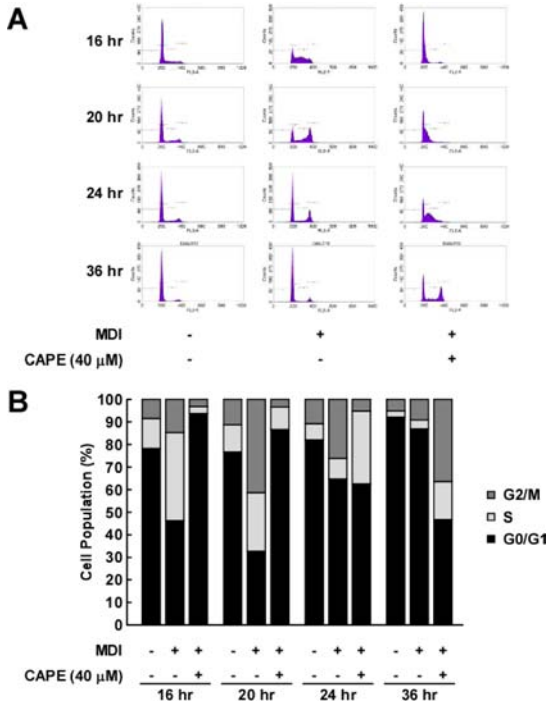

Figure 4. Effects of CAPE on MDI-induced cell cycle progression in 3T3-L1 preadipocytes. (A) CAPE inhibited the MDI-induced cell cycle progression of 3T3-L1 preadipocytes. Data are representative of three independent experiments that showed the same tendency. (B) The population of cells in each stage of the cell cycle was quantified.

CAPE Suppresses the Expression of Cyclin D1 during MCE. Since G1/S progression was significantly attenuated by CAPE treatment, we measured the protein expression level of cyclin D1, which has been reported to be implicated in G1/S transition. We found that the protein level of cyclin D1 was up-regulated in MDI-treated 3T3-L1 cells and that CAPE (40 μM) suppressed MDI-mediated upregulation of cyclin D1 (Figure 5A). We checked the mRNA expression level of cyclin D1 to investigate whether CAPE regulates cyclin D1 expression at the transcriptional level. We found that the mRNA level of cyclin D1 was also suppressed by 40 μM CAPE treatment (Figure 5B), indicating that CAPE inhibits cyclin D1 expression at the transcriptional level.

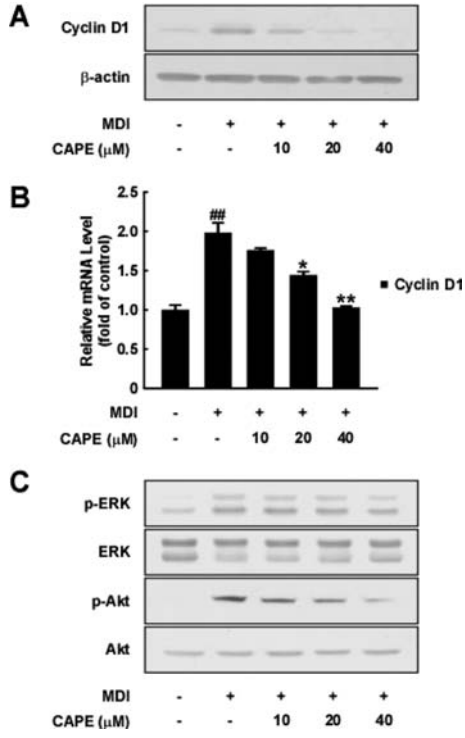

Figure 5. Effects of CAPE on cyclin D1 expression and its upstream signaling pathway in 3T3-L1 preadipocytes. (A) CAPE suppressed MDI-induced cyclin D1 protein expression. Data are representative of three independent experiments that showed the same tendency. (B) CAPE suppressed MDI-induced cyclin D1 mRNA expression. Data are expressed as the mean ± SEM from three separate experiments. ## indicate a significant difference between the control group and the group treated with MDI alone ($p < 0.01$), * indicates a significant difference between groups treated with MDI alone and treated with MDI plus CAPE ($p < 0.05$), and **, indicate a significant difference between groups treated with MDI alone and those treated with MDI plus CAPE ($p < 0.01$). (C) CAPE suppressed MDI-induced ERK and Akt phosphorylation. Data are representative of three independent experiments that showed the same tendency.

The result that CAPE decreased both the mRNA and protein levels of cyclin D1 prompted us to investigate the upstream signaling pathway of cyclin D1 expression. We estimated the effect of CAPE on MDI-induced ERK and Akt phosphorylation, which have been reported as upstream of cyclin D1. We found that MDI-induced phosphorylation of ERK and Akt was decreased by CAPE (40 μM) (Figure 5C). Collectively, CAPE suppressed mitotic clonal expansion of 3T3-L1 by down-regulating cyclin D1 by blocking MDI-mediated phosphorylation of ERK and Akt during MCE.

ABSTRACT: The antioxidant activity (AA) of fruits and vegetables has been thoroughly investigated but less is known about the AA of dietary supplements (DS). We therefore assessed the AA of three to five DS each from pomegranate, milk thistle, green tea, grapes, goji, and acai using four widely used standard methods. The secondary objective was to determine the effects of in vitro digestion on their AA. The AA of the DS prior to digestion ranked as follows: pomegranate > resveratrol > green tea > grape seed > milk thistle and very low in goji and acai with significant group variability in AA. The AA after in vitro simulated digestion of the mouth, stomach, and small intestine compared to undigested supplement was decreased for green tea and grape seed but increased for pomegranate, resveratrol, milk thistle, goji, and acai to various extents. Although polyphenols provide the major antioxidant potency of the tested supplements, our observations indicate that digestion may alter antioxidant properties depending in part on the variations in polyphenol content.

KEYWORDS: *pomegranate, antioxidant activity, in vitro digestion, dietary supplements, green tea, milk thistle, acai, goji, resveratrol, grape seed*

INTRODUCTION

Over half of U.S. adults consume at least one dietary supplement (DS) per day as estimated by data from the National Health and Nutrition Examination Survey (NHANES) 1999−2002.[1] According to Yang et al.,[2] DS provide 25% of dietary total antioxidant capacity in U.S. adults. Polyphenolic phytochemicals are the most frequently occurring phytochemicals in DS with in vitro antioxidant properties.[3] On the basis of an evaluation of the NHANES 2001−2002 data, flavonoid and proanthocyanidin intake contributes 56% of total antioxidants in the diet.[2] Although polyphenols are principally ingested in the diet, commercially available polyphenolic supplements are numerous and commonly used and may contribute to the antioxidant intake. Typical DS that contain antioxidant polyphenols are derived from pomegranate fruit (*Punica granatum* L.), green tea (*Camellia sinensis*), and grapes (*Vitis vinifera*). Other DS such as milk thistle (*Silybum marianum*) extract, acai (*Euterpe oleracea*), and goji berries (*Lycium barbarum* L.) are commonly consumed for their antioxidant activity (AA) but contain very different phytochemical structures (e.g., stilbenes for resveratrol), all of which have some AA.

The main phytochemicals held responsible for AA vary considerably in these DS. Pomegranate fruit contains ellagitannins, gallotannins, ellagic acid, and smaller amounts of flavonoids and anthocyanins.[4−6] Green tea extracts contain polyphenols including (−)-epicatechin, (−)-epigallocatechin, and their gallate derivatives (−)-epicatechin-3-gallate and (−)-epigallocatechin-3-gallate, which are distinguished by their potent antioxidant and anti-inflammatory properties, offering cardiovascular and neural protection, and for their effects on fat oxidation.[7] Proanthocyanidins in grape seed extract are the main polyphenolic ingredients responsible for its antioxidant, anti-inflammatory, and antimicrobial effects.[7,8] Resveratrol (3,5,4′-trihydroxystilbene) is a stilbene polyphenol that exerts anti-inflammatory, antioxidant, and estrogenic effects and anticancer properties.[9] Although advertised as a grape extract, it is commonly extracted from the root of Japanese knotwood and occurs as a phytoalexin on the skin of grapes grown in humid conditions, where they are susceptible to fungal infection. The fruit of the milk thistle plant, with its active ingredient and flavonoid complex, silymarin, has been used to promote liver health. Silybin, a flavonolignan, represents about 50−70% of the silymarin extract, among other flavonolignans and flavonoids. Silybin and the rest of the silymarin constituents have demonstrated liver-protective properties under experimental conditions due to their antioxidant and anti-inflammatory properties.[10] In recent years, two berry species rich in polyphenolic phytochemicals, acai berry (Amazonian palm berry) and goji berry, have been widely promoted as having antioxidant properties attributed to their primary active ingredients, β-carotene, β-cryptoxanthin, zeaxanthin, and polysaccharides in goji berry fruit[11] and anthocyanins and other polyphenols in acai berry.[12−15]

It was the objective of the present study to assess the variability of composition and AA of three to five commercially available DS from pomegranate, green tea, grape seed, milk thistle, resveratrol, acai, and goji berry using four antioxidant assays. The oxygen radical absorbing capacity (ORAC) hydrophilic and lipophilic, which measures a hydrogen atom transfer reaction, was used in addition to assays measuring electron transfer/reducing capacities such as the Trolox equivalent antioxidant capacity (TEAC), ferric reducing antioxidant power (FRAP), and free radical scavenging properties by the diphenyl-1-picrylhydrazyl (DPPH) radical.

In a second phase, we determined the effect of digestion on the AA of these popular DS because we were interested in whether antioxidant activity would survive the digestive processes. Although in vivo feeding or supplementation studies in animals or humans provide the ultimate tests, in vitro digestion models simulating digestive pH and enzymatic exposure provide a practical alternative for investigating the impact of digestion on DS antioxidant properties.[16] The DS were treated under in vitro simulated gastrointestinal conditions, and the AA was analyzed using the TEAC assay. The TEAC assay was chosen from among the four antioxidant assays used in the first phase of our studies because TEAC exhibited the highest correlation with the sum of all antioxidant assays. It was also the most reproducible among the methods used.

MATERIALS AND METHODS

Chemicals and Reagents. All solvents were purchased from Fisher Scientific Co. (Tustin, CA, USA). 2,2′-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), manganese dioxide, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), ferrous chloride, fluorescein sodium salt, and (2,4,6-tris(2-pyridyl)-s-triazine, 1,1-dipenyl-2-picrylhydrazyl (DPPH) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Randomly methylated β-cyclodextrin was purchased from CTD Holdings (Alachua, FL, USA).

Dietary Supplements. A total of 25 antioxidant DS from 7 different categories, acai berry (n = 3, A1−A3), goji berry (n = 3, G1−G3), grape seed (n = 3, GS1−GS3), green tea (n = 4, GT1−GT4), milk thistle (n = 4, MT1−MT4), pomegranate (n = 5 samples, PM1−PM5), and resveratrol (n = 3, Res1−Res3), were obtained on the basis of accessibility to the average consumer (purchased from retail stores, chain pharmacies, Internet, or mail order). The DS were delivered in the form of encapsulated powder (n = 17 samples), soft gel (n = 4), tablet (n = 2), or liquid (n = 2). The antioxidant activity of all DS was determined prior to the expiration date as stated on their packages. The main information found on the packaging label of all tested DS is listed in Table 1. The pomegranate extract DS tested were PomX (POM Wonderful LLC, Los Angeles, CA, USA), Healthy Pomegranate (Nature's Bounty, Bohemia, NY, USA), Full-Spectrum Pomegranate (Life Extension, Ft. Lauderdale FL, USA), Pomegranate 40:40 Complex (All Solar, Henderson, NV, USA), and Pomella (+PLUS) (Phytosensia, Indianapolis, IN, USA; and Pomella, Noblesville, IN, USA). The green tea extract DS tested were Green Tea Extract (Radiance, Encinitas, CA, USA), Green Tea Complex (Safeway Inc., Pleasanton, CA, USA), Standardized Extract Green Tea (Nature's Bounty), and Green Tea Standardized (Nature's Way, Lehi, UT, USA). The milk thistle extract DS used were Milk Thistle XTRA (Sundown Naturals, Boca Raton, FL, USA), Standardized Extract Milk Thistle (Nature's Bounty), Super Maximum Milk Thistle Extract (Vitamin Shoppe, North Bergen, NJ, USA), and Milk Thistle (Safeway, Pleasanton, CA, USA). The grape seed extract DS used were Grapeseed Extract (Radiance, Ronkonkoma, NY, USA), Masquelier's Tru-OPCs (Nature's Way), and ActiVin Grape Seed Extract (Paradise, Huntington Beach, CA, USA). The acai extract DS were Acai (Nature's Bounty), Acai Extract (Vitamin Shoppe), and Acai with Green Tea (Radiance). Resveratrol extracts obtained were Resveratrol forte (Enzymatic Therapy, Green Bay, WI, USA), Reservie and Trans-Resveratrol (Vitamin Shoppe), and Resveratrol, Synergistic Formula (Nature's Way). Goji berry juice/extracts used were Goji Gold (Dynamic Health, Brooklyn, NY, USA), Goji 100 (Genesis Today, Austin, TX, USA), and Goji Berry (Ultra Laboratories, Carson, CA, USA).

Table 1. Labeling Information of All Dietary Supplements[a]

ID	main ingredients
	pomegranate
PM1	pomegranate extract
PM2	pomegranate extract (40% ellagic acid)
PM3	pomegranate extract [30% punicalagins (120 mg)]; plus pomegranate blend [22% (30 mg) punicic acid]
PM4	vitamin C; plus pomegranate extract (40% punicalagins/40% ellagic acid)
PM5	pomegranate extract [30% punicalagins (240 mg)]
	green tea extract
GT1	green tea extract (15% polyphenols, 95 mg in two capsules)
GT2	green tea extract (25% polyphenols, 8.5% EGCG, 5% caffeine), 790 mg; plus green tea powder (leaf, 210 mg)
GT3	green tea extract (15% polyphenols 95 mg in two capsules)
GT4	green tea extract (9% polyphenols) plus green tea (leaf)
	resveratrol
Res1	resveratrol, 100% *trans*-resveratrol, 175 mg; plus Japanese sophora flower bud extract, 74% rutin (quercetin rutinoside), 75 mg
Res2	250 mg of *trans*-resveratrol; plus quercetin (quercetin dihydrate, 100 mg)
Res3	red wine extract (30% polyphenols, 60 mg); plus red wine powder; plus Japanese knotweed (50% resveratrol 75 mg)
	grape seed extract (95% polyphenols 95 mg)
	grape seed extract
GS1	grapeseed extract (50% polyphenols 100 mg); plus citrus bioflavonoids 300 mg
GS2	grape seed extract (95% antioxidants; 65% oligomeric procyanidins (OPCs), 30% other active polyphenols
GS3	grape seed extract 100:1
	milk thistle
MT1	milk thistle extract (80% silymarin 192 mg)
MT2	milk thistle extract (80% silymarin 140 mg)
MT3	milk thistle extract (80% silymarin 240 mg)
MT4	milk thistle extract (80% silymarin 140 mg)
	acai
Acai1	acai extract
Acai2	acai berry 5:1 extract
Acai +GT	acai (20:1 extract equivalent to 1000 mg); plus green tea (4:1 extract equivalent to 500 mg)
	goji
Goji1	100% goji juice
Goji2	goji liquid concentrate
Goji3	goji berry extract (20% polysaccharides)

[a]DS, dietary supplements; PM, pomegranate; GT, green tea; EGCG, (−)-epigallocatechin gallate; GS, grape seed; Res, resveratrol; MT, milk thistle.

Digestive Enzymes. All digestive enzymes were purchased from Sigma-Aldrich. All enzyme solutions were freshly prepared for each experiment to avoid potential decreases over time in enzyme activities. α-Amylase from *Aspergillus oryzae* (∼30 units/mg) was dissolved in the phosphate buffer saline (PBS) solution (160 units/mL) that was preadjusted to pH 6.5. Porcine pepsin from gastric mucosa (≥250 units/mg solid) was dissolved at 40 mg/mL in 0.1 M HCl. Pancreatin from porcine pancreas was mixed with a porcine bile extract mixture at a constant ratio of 1:6 and dissolved in 0.1 M $NaHCO_3$. Pancreatin contains several enzymes, including amylase, trypsin, lipase, ribonuclease, and protease. Bile extract contains glycine and taurine conjugates of hyodeoxycholic acid and other bile salts.

In Vitro Digestion. The in vitro digestion was performed according to the methods described by Chohan et al.[17] and Werner and Böhm.[18] Each digestion step was optimized separately. The AA of the in vitro digestion treatment (enzyme and pH adjustment alone) was minimal (0.12 mmol TE/100 g).

Salivary Step. Two hundred and fifty milligrams of aqueous sample extracts were crushed lightly and dissolved for 2 min in 4 mL of α-amylase in PBS solution (160 units/mL; adjusted to pH 6.5) by using a preheated pestle and mortar at 37 °C.

Gastric Step. Immediately after the salivary step, the mixture was acidified to pH 3.0 (with 0.1 M HCl) and incubated with pepsin solution in 0.1 M HCl for 60 min at 37 °C at ∼190 strokes/min.

Duodenal Step. Following the gastric simulation step, the mixture was raised to pH 6.5−7 with 1 M $NaHCO_3$ and incubated with pancreatin and bile extract in 0.1 M $NaHCO_3$ for 120 min at 37 °C in a shaking water bath at 190 strokes/min. The in vitro digested mixture was centrifuged at 2060*g* for 5 min at 4 °C, filtered through filter paper (Whatman grade 1) and a 0.2 μm pore size nylon filter, and adjusted to pH 5.5−6.0 with 0.1 M HCl. Digested samples were stored at −20 °C until analysis for no longer than 1 week.

Preparation of Nondigested (Control) Sample Extracts. Nondigested controls were prepared by extracting 250 mg per sample in water to a concentration matching the concentration of the in vitro digested sample mixtures.

Antioxidant Assays. Except for the lipophilic ORAC assay, the 25 nondigested DS were extracted in a 10-fold volume of methanol to weight (250 mg DS/2.5 mL). Samples were vortexed (10 min), sonicated (10 min), and centrifuged (10 min at 2000*g*). Supernatants were diluted with aqueous buffers depending on the assay. Sonication had no significant effect on the AA. For the digested and nondigested (control) DS, extraction was performed with water as mentioned above.

Trolox Equivalent Antioxidative Capacity (TEAC). The TEAC was determined by measuring the ability to scavenge ABTS radical cations produced by oxidation of ABTS with manganese dioxide. The assay was performed as previously reported.[19] Briefly, ABTS radical cations were prepared by adding solid manganese dioxide (80 mg) to a 5 mM aqueous stock solution of $ABTS^+$ (20 mL using a 75 mM sodium/potassium (Na/K) buffer of pH 7). Trolox, a water-soluble analogue of vitamin E, was used as an antioxidant standard. A standard calibration curve was constructed for Trolox at 0−0.3 mM concentrations. DS extracts (250 mg/2.5 mL of MeOH) were diluted in Na/K buffer. Diluted samples were mixed with 200 μL of $ABTS^+$ radical cation solution in 96-well plates, and absorbance was read (at 750 nm) after 30 min in a VersaMax microplate reader (Molecular Devices, Sunnyvale, CA, USA). TEAC values were calculated from the Trolox standard curve and expressed as Trolox equivalents (mmol TE/100 g). All samples were extracted in duplicate, and the TEAC assay was performed in triplicate for each extract.

Total Oxygen Radical Absorbance Capacity (ORAC). The ORAC assay was conducted as previously described.[20] For the hydrophilic ORAC a mixture of 200 μL of fluorescein sodium salt (0.1 μM) was used as the target of free radical attack, and 75 μL of 2,2′-azobis(amidinopropane) dihydrochloride (AAPH) (63.4 mM) was used as a peroxyl radical generator at 37 °C combined with 20 μL of each sample extract. DS extracts (250 mg/2.5 mL of MeOH) were diluted in Na/K buffer. Trolox standards ranged from 5 to 100 μM. For the lipophilic ORAC DS were extracted twice using hexane. The hexane extracts were combined and evaporated. The dried hexane extract was dissolved in 250 μL of acetone and diluted with 750 μL of 7% randomly methylated β-cyclodextrin (RMCD) solution (50% acetone/50% water, v/v). Extracts were further diluted in 7% RMCD. Trolox standard was also diluted in 7% RMCD. AAPH concentration was adjusted to provide a decay curve with no more than 5% of antioxidant activity remaining at the end of the reaction. The decrease in fluorescence was determined at excitation of 535 nm and emission of 595 nm every 2 min for 60 min in a SpectraMax GeminiEM plate reader (Molecular Devices). The ORAC value was evaluated as the area under curve (AUC) and calculated by taking into account the Trolox reading using the following equation: $(AUC_{sample} - AUC_{buffer})/(AUC_{Trolox} - AUC_{buffer}) \times$ dilution factor of sample × initial Trolox concentration (mM). For each sample, four serial dilutions in phosphate buffer (pH 7.4) were measured. The optimum concentration was used for further analyses in four to six replicates.

Free Radical Scavenging Capacity. The free radical scavenging capacity was analyzed by the DPPH assay.[19] DPPH is a stable organic nitrogen radical with purple color. Upon reduction by an antioxidant, the solution color fades and the reaction can be monitored by a spectrophotometer at 517 nm. The decrease in absorbance is proportional to the antioxidant capacity and can be measured in comparison to Trolox as standard. All samples and standard were diluted in methanol. Twenty microliter aliquots from the test compounds were mixed with 200 μL of DPPH (0.6 mM) in methanol, and the change in optical density (517 nm) was monitored after 30 min using a VersaMax plate reader (Molecular Devices).

Ferric Reducing Antioxidant Power Assay. The FRAP assay was performed using an established standardized method described by Benzie and Strain.[21] Reaction mixtures were prepared by combining 10 mM 2,4,6-tri(2-pyridyl-*s*-triazine) (TPTZ), 20 mM ferric chloride, and 30 mM (pH 3.6) sodium acetate buffer in a 1:1:10 ratio. Trolox was used as standard in a range from 0 to 0.1 mM. Samples extracted in a 10-fold volume of methanol (w/v) were diluted in acetate buffer. A 200 μL reaction solution was warmed to 37 °C for 10 min prior to the addition of 20 μL of diluted sample extracts. Sample absorbance was read at 593 nm in a VersaMax plate reader (Molecular Devices). Results were compared to the Trolox standard curve and expressed as TE.

Chemical Analysis. Chemical markers were analyzed by high-performance liquid chromatography (HPLC) using a Waters Alliance 2690/2695 HPLC system (Waters, Milford, MA, USA) with a 996 PDA detector. GT chemical markers were extracted with a 75% MeOH/25% H_2O mixture and separated using a Phenomenex Synergi 4 μ Hydro-RP column (150 × 4.6 mm, 80A) (Phenomenex, Torrance, CA, USA) with a gradient mobile phase of 0.25% H_3PO_4 in water (solvent A) and 0.1% H_3PO_4 in acetonitrile/MeOH (1:1, v/v) + 1.0% THF (solvent B). Solvent composition starting at T = 0 min with 95% solvent A and 5% solvent B changed to 20% solvent A and 80% B at T = 50 min and back to the initial mixture at T = 51−60 min. All standards were purchased from Sigma-Aldrich Co. or ChromaDex (Irvine, CA, USA). The pomegranate DS were homogenized in dimethyl sulfoxide, sonicated, and vortexed for 20 min each, diluted with methanol/water (1:1, v/v), centrifuged for 5 min at 8000*g*, and separated on a Zorbax SB C_{18}, column (5 μm 4.6 × 250 mm) (Agilent, Santa Clara, CA, USA) using a gradient of 0.1% H_3PO_4 in water (solvent A) and acetonitrile (solvent B). Solvent mixture changed from T = 0 min at 95% solvent A and 5% solvent B to 60% solvent A and 40% solvent B at 30 min. Resveratrol was quantified in a methanol extract using an Agilent Poroshell120 SB-C18 column (2.7 μm 100 × 4.6 mm) with a gradient mobile phase of 0.4% H_3PO_4 in water (solvent A) and acetonitrile (solvent B). The solvent mixture was changed from T = 0 min at 80% solvent A and 20% solvent B to 40% solvent A and 60% solvent B at 8 min and returning to initial solvent mixture at 9−13 min.

Determination of Total Phenolics. The colorimetric method by Singleton et al.[22] was used to determine the total phenol content. Gallic acid was used to prepare a standard curve, and final values are expressed in gallic acid equivalents (GAE). Diluted DS extracts were incubated with Folin−Ciocalteu phenol reagent (Sigma-Aldrich Co.). The color was developed by adding sodium carbonate (20%) and absorbance measured at 755 nm.

Statistical Analysis. Values in the results are means (95% CI), unless otherwise specified. With regard to nondigested antioxidant activity of all 25 samples, data were analyzed separately for each antioxidant assay method using one-way ANOVA in IBM SPSS Statistics (version 21.0; IBM Corp., Armonk, NY, USA), with type of DS as a between-group factor. Multiple-comparisons testing was adjusted using Tukey's honestly significant difference test when there was a significant group effect. Pearson's correlation coefficient was used to investigate the pairwise associations between variables, unless

[a]DS, dietary supplements; TEAC, Trolox equivalent antioxidant capacity; DPPH, diphenyl-1-picrylhydrazyl; FRAP, ferric reducing antioxidant power; ORAC, oxygen radical absorbing capacity; TE, Trolox equivalents; PM, pomegranate; GT, green tea; Res, resveratrol; GS, grape seed; MT, milk thistle. Mean values within a column with unlike letters were significantly different ($P < 0.05$; Tukey's multiple-comparison test). [b]One-way ANOVA of the absolute values in antioxidant activity for DS category effect; $P < 0.01$. [c]Except for acai and goji, which do not mix well with MeOH and were extracted in water. [d]PM2 is excluded from meanH (higher mean) and is included in meanL (lower mean).

Spearman's rho was used where specified. Differences were considered significant at $P < 0.05$.

RESULTS

Antioxidant Activity of 25 Nondigested DS by Different Assays. A total of 25 of the most popular DS categories sold in the United States were tested for their antioxidant activity by TEAC, DPPH, ORAC, and FRAP assays; methanol was used as the extraction solvent except for the lipophilic ORAC, in which hexane was used (Table 2). One-way ANOVA of the absolute values in antioxidant activity demonstrated a significant DS type effect for TEAC ($P = 0.004$), FRAP ($P = 0.000$), DPPH ($P = 0.000$), OPAC-hydro ($P = 0.001$), sum of methods ($P = 0.001$), but not for ORAC-lipo (NS). The AA varied depending on the solubility in water or organic solvents.

TEAC. Pairwise testing showed significantly higher TEAC values for pomegranate versus milk thistle ($P < 0.05$), acai ($P < 0.025$), and goji ($P < 0.01$); no other differences between types of DS reached statistical significance.

FRAP. FRAP values were higher for pomegranate versus green tea ($P < 0.025$), grape seed ($P = 0.01$), milk thistle ($P < 0.001$), resveratrol ($P = 0.01$), acai ($P < 0.01$), and goji ($P <$

resveratrol	18.2 ± 0.05	32.1 ± 0.3	10.9 ± 0.05	

[a]DS, dietary supplements; EGC, (−)-epigallocatechin; EC, (−)-epicatechin; EGCG, (−)-epigallocatechin gallate; ECG, (−)-epicatechin gallate.

0.001); no other differences between other DS types reached statistical significance.

DPPH. Pairwise testing demonstrated higher DPPH values for pomegranate versus green tea ($P < 0.05$), grape seed ($P < 0.05$), milk thistle ($P = 0.001$), resveratrol ($P < 0.01$), and goji ($P = 0.001$); no other differences between other DS types reached statistical significance (acai not included in the model due to lack of sample power).

ORAC-hydro. Contrary to the TEAC, FRAP, and DPPH, ORAC-hydro values were significantly higher only for resveratrol compared to grape seed ($P < 0.05$), acai ($P < 0.01$), goji ($P = 0.001$), and green tea ($P = 0.052$).

ORAC-lipo. The lipophilic ORAC evaluates the AA of the lipophilic antioxidants. The contribution of the AA measured by the lipophilic ORAC is minor in the supplements with high polyphenolic content. However, for goji juice (Goji1), the lipophilic ORAC contributed considerable AA to the total activity, whereas the goji extracts (Goji2 and Goji3) lost most of the lipophilic AA (Table 2).

Sum of Methods. For the sum of all methods that measure the AA, results were highly correlated to TEAC values; we found that the antioxidant capacity is highest in pomegranate and decreasing in the following order: pomegranate ≫ resveratrol > green tea > grape seed > milk thistle ≫ goji > acai, with significance reached for pomegranate versus milk thistle, acai, and goji ($P < 0.01$).

In addition, TEAC was highly correlated with FRAP, DPPH, and ORAC-hydro ($r = 0.79–0.92$, $P < 0.001$), and FRAP and DPPH were highly correlated with each other ($r = 0.99$, $P < 0.001$) and moderately correlated with ORAC-hydro ($r =$

dx.doi.org/10.1021/jf500106r | J. Agric. Food Chem. 2014, 62, 4313−4321

0.47−0.55, $P < 0.025$). The correlation matrix is depicted in Table 3.

Variation of AA in Each Category. Extensive differences in AA were observed among the DS in each category. For example, PM2 exhibited significantly lower AA compare to the other four pomgranate DS; GT4, Res2, and GS3 exhibited significantly higher AA compared to other DS in each category. This was closely correlated to the chemical composition of marker compounds.

Chemical Analyses and Associations with Antioxidant Activity. DS from pomegranate, green tea, and resveratrol/quercetin were analyzed using HPLC with PDA detection, and the concentration of known chemical markers was quantified before and after digestion (Tables 4 and 5). Total phenolic content was determined for the DS with high polyphenol content before and after digestion using the GAE assay (Table 6).

Table 5. Change in Content of Chemical Marker Compounds in Green Tea, Pomegranate, and Resveratrol DS during in Vitro Digestion[a]

dietary supplement	marker chemical	% of control
PM5	punicalagins A and B	88.5
	ellagic acid	208.7
GT4	theobromine	70.2
	EGC	51.0
	(±)-catechin	81.5
	caffeine	87.2
	EC	78.4
	EGCG	63.0
	ECG	73.3

Res2	resveratrol	239.8

[a]PM, pomegranate; GT, green tea; EGC, (−)-epigallocatechin; EC, (−)-epicatechin; EGCG, (−)-epigallocatechin gallate; ECG, (−)-epicatechin gallate; Res, resveratrol.

In pomegranate supplements, punicalagins A and B and ellagic acid were quantified. Pomegranate supplements with the highest content of punicalagins A and B (PM4 and PM5) showed high antioxidant activity, whereas pomegranate supplements with high ellagic acid showed the lowest antioxidant activity (PM2); a highly significant correlation coefficient was reported between pomegranate antioxidant activity by TEAC, FRAP, DPPH, or sum of methods and punicalagin A and B content (Spearman's rho = 0.90, $P < 0.05$). Although PM1 had low content of punicalagins A and B and ellagic acid, its antioxidant activity was relatively high. It appears that other polyphenols or ellagitannins of larger molecular weights may have contributed considerably to the AA of PM1, as indicated by the high content of total phenolics, expressed as GAE, in PM1. In fact, the AA was increased by 50% for PM1 after digestion compared to nondigested controls (PM1-digested, 667.1 ± 23.1 mmol TE/100 g; PM1-control, 420.6 ± 76.2 mmol TE/100 g).

Among the GT supplements, the ECG, EC, and EGCG contents were highly correlated ($r = >0.99$; $P < 0.01$) with the AA measured by TEAC, FRAP, DPPH, and ORAC-hydro, with the correlation coefficient between sum of catechins and sum of methods reaching $r = 1.0$ ($P < 0.001$). GT4 reported the highest catechin concentration and highest AA. However, after digestion, the catechin content of known chemical markers (ECG, EC, CG, EGC, EGCG, and GCG) was decreased by 90%, whereas the AA decreased by only 22%.

The resveratrol DS contained mixtures of resveratrol and quercetin, with quercetin highly correlating with TEAC ($r = 1.0$, $P < 0.025$) and sum of methods ($r = 1.0$, $P = 0.001$) and with resveratrol showing similar associations but without reaching significance due to the small sample size ($r > 0.93$, $P = 0.22$, $n = 3$). Within samples tested, Res2 showed the highest resveratrol/quercetin content and highest AA. Total phenolic content highly correlated with TEAC for both digested and nondigested (control) DS samples ($r = 0.9956$, $P < 0.01$).

Antioxidant Activity of Digested DS Samples. On the basis of the highest AA in the nondigested samples, one DS from each category was selected for in vitro digestion. The AA measured in the digested samples is summarized in Table 6. The order of antioxidant potency of the in vitro digested DS was as follows: PM5 > GT4 > GS3 ≫ Res2, MT3 > goji3, acai2 extracts. PM5 reported the highest TEAC values, 427 times higher than that of acai, the DS that exhibited the lowest TEAC values: 1109.4 ± 8.2 mmol TE/100 g compared to 2.6 ± 0.1 mmol TE/100 g, respectively. TEAC of in vitro digested GT4 and GS3 was 73 and 46.5% that of PM5 and 16.6 and 10.5 times greater than that of Res2, respectively.

Digested versus Nondigested (Control) DS Samples. The digestion was performed with water extracts of all DS and was compared to nondigested DS samples extracted in water (Table 6). Other than for GT4 and GS3, which showed 21.5 and 8.1% lower TEAC values after in vitro digestion compared to the nondigested samples extracted in H_2O, the other DS samples demonstrated either similar or higher TEAC values after in vitro digestion (Table 6). For resveratrol and milk thistle the AA was significantly lower in the digested sample compared to the nondigested sample extracted in methanol (Table 3) because their solubility is higher in methanol compared with water. For goji and acai the AA was very low in the digested and nondigested samples extracted in water or methanol.

DISCUSSION

To our knowledge, this is the first study to comprehensively evaluate and compare the antioxidant potency of commercially available polyphenol-rich antioxidant DS, including extracts from pomegranate, green tea, grape seed, resveratrol, milk thistle, and acai, and goji berry, utilizing different antioxidant assays before and after in vitro digestion. In the present study, pomegranate DS expressed the most potent antioxidant capacity, followed by resveratrol, green tea, grape seed, and milk thistle extracts, whereas acai and goji berry demonstrated negligible antioxidant properties across all four antioxidant assays and in the in vitro digestion model. The AA of resveratrol extract and milk thistle was influenced by the solvent used for extraction, with 10−20-fold greater values comparing the methanol to water extract. Hence, it appears that both resveratrol and milk thistle DS may efficiently express their AA when ingested in ethanol (alcoholic) solutions. There is earlier evidence showing that the solubility of *trans*-resveratrol in ethanol plus water mixtures increases with increasing mole fraction of ethanol,[23] which together with the present data might partly explain red wine's antioxidant properties. Previous studies on milk thistle evaluated its AA mainly in aqueous extracts[24,25] and have demonstrated even lower values for TEAC, with one study[25] reporting 133.4 μg TE/g of milk

[a]DS, dietary supplements; TEAC, Trolox equivalent antioxidant capacity; TE, Trolox equivalents; PM, pomegranate; GT, green tea; GS, grape seed; Res, resveratrol; MT, milk thistle.

thistle powder compared to 5 mmol TE/100 g = 12.5 mg TE/g of our aqueous milk thistle extract sample (Table 6). A similar ranking of the AA of beverages from previous research from our laboratory also showed the highest AA for pomegranate > red wine > grape juice.[19] Tea did not show considerable AA because bottled tea beverages were used.[19]

Significant variation in AA between DS from the same category corresponding to variation in the chemical composition was observed, although the DS, according to the label information, are supposed to provide the same health benefits. The AA of pomegranate DS was closely associated with the chemical composition. Except for PM2, all other pomegranate DS showed the highest AA. The AA of PM2 was very low compared to the other pomegranate supplements because it mainly contains ellagic acid and no punicalagins A and B. As previously described,[26] the official marker compound for pomegranate supplements is ellagic acid, whereas authentic pomegranate has only small amounts of ellagic acid. Whether ellagic acid from other sources is added to these supplements or the increase in ellagic acid occurred as the result of manufacturing was not determined. However, high amounts of ellagic acid only resulted in lower AA compared to supplements including punicalagins. Differential response of two pomegranate DS (PM1 and PM5) to in vitro digestion with α-amylase, pepsin, pancreatin, and bile salts was observed. Although PM5 showed no change of AA, the AA was increased by 50% for PM1 compared to nondigested controls. It appears that because PM1 contains relatively low concentrations of punicalagins A and B and ellagic acid, its AA is based on larger ellagitannins, which, during the in vitro digestion process, are further dissolved or converted to smaller compounds with higher antioxidant activity. Similar results have been found in another study where the AA of pomegranate juice increased significantly after in vitro digestion.[27] In vivo, the hydrolysis of pomegranate ellagitannins to ellagic acid and further metabolism by the gut microbiota to yield urolithins have been documented.[28−30] These metabolites in turn exhibit AA.[31]

In the current study, the antioxidant supplements with the lowest AA, and of minor significance, were acai and goji berries. Results from other published in vitro and in vivo studies testing the antioxidant effects of acai juice/pulp or goji berry fruit demonstrated strong variability in AA due to differences in sourcing and processing of the material. Freeze-dried acai pulp/skin powder demonstrated 1.03 mmol TE/g by the ORAC assay.[32] Enhanced AA in human plasma has been shown for acai pulp and acai juice after a single ingestion in one study utilizing the ORAC assay.[33] In vitro analyses of goji fruit extracts have captured its antioxidant properties, including inhibition of $DPPH^{-}$ radical-scavenging activity.[14,15,34] A study by Luo et al.[35] reported a stronger in vitro AA by TEAC and ORAC assays of goji fruit water, methanol extracts, and crude polysaccharide extracts compared to purified polysaccharide fractions. In the study by Luo, goji demonstrated levels of TEAC values of maximal 0.5 mmol TE/100 g, which are lower than the AA demonstrated by our goji samples.[35] Most likely the differences in antioxidant activity in the present study and earlier investigations of acai and goji berries are caused by losses of AA during processing of the berry pulp during manufacturing of the supplements. The main antioxidant compounds in acai and goji berries are anthocyanins, carotenoids, and polysaccharides, respectively. Anthocyanins are prone to degradation during processing and storage (pH, temperature, light, oxygen, enzymes, presence of ascorbic acid, sugars, sulfur dioxide or sulfite salts, metal ions, and copigments)[36] and were not likely to contribute to antioxidant activities, which were very small in any case. In the lipophilic ORAC test, the goji berries demonstrated high variability, with the goji juice (Goji1) exhibiting somewhat higher lipophilic AA compared to the goji extracts (Goji2 and Goji3), suggesting that the goji juice contained some carotenoids.

In the present study, in vitro simulation of gastrointestinal digestion did not adversely affect the antioxidant capacity of any of the DS extracts, other than for green tea, which lost 21.5% of AA during digestion. Similarly, earlier work on the impact of in vitro digestion on commercially available tea juices (longjing green tea, jasmine, and oolong) demonstrated a significant decrease of AA as well as total polyphenol content.[37] In the presented study the tea polyphenol content decreased by only 10%. Possibly the exposure to alkaline pH transformed EGCG and EGC to hetero- and homodimers such as theasinensin, which most likely retained the antioxidant activity.[39] A small decrease in AA was also observed for grape seed extracts (8.1%). However, a study by Janisch demonstrated an increase in release of flavans and procyanidins from grape seed extract with good scavenging potential against reactive oxygen species under conditions of in vitro digestion.[38] In addition to potential changes through the digestive process, possible interactions of food ingested concurrent with the DS have been reported[40] and more detailed future evaluations are warranted.

In agreement with our previous study on polyphenol-rich antioxidant beverages, the order of antioxidant capacity correlated well between the different methods with the exception of the ORAC method. The ORAC assay principle is based on a temperature-dependent free radical generator reaction and protection from oxidation over a 60 min period. Although the ORAC method is the most commonly used assay by food manufacturers,[19] our laboratory has reported poor reproducibility of this method due to temperature variation in commonly used plate readers (unpublished data). As we concluded in our earlier paper, it is important to run multiple antioxidant methods rather than just the ORAC method to get a better estimate of antioxidant capacity and to substantiate in vitro results with clinical studies. The TEAC assay correlated best to the sum of the assays and was the most reproducible. Using the DPPH assay all dilutions are performed using methanol instead of buffer, which lowers the reproducibility.

In conclusion, our results demonstrate that except for green tea and grape seed extracts no significant loss of antioxidant activity was observed during in vitro digestion.

Oxidative Degradation of Quercetin with Hydrogen Peroxide Using Continuous-Flow Kinetic Electrospray–Ion Trap–Time-of-Flight Mass Spectrometry

Jeremy S. Barnes and Kevin A. Schug*

Department of Chemistry and Biochemistry, The University of Texas at Arlington, Arlington, Texas 76019-0065, United States

ABSTRACT: The time-dependent hydrogen peroxide-induced oxidative degradation of aqueous quercetin at pH 7.4 was measured using an in-house-built online continuous-flow device made of concentric capillary tubes, modified to fit a photodiode array (PDA) detector and the inlet of an electrospray ionization–ion trap–time-of-flight mass spectrometer (ESI-IT-TOF-MS). As the reaction time was increased, the deprotonated quercetin ion signal, $[Q - H]^-$, decreased, and the formation of degradation product ions was observed. Structures for degradation product ions were proposed using higher order tandem mass spectrometry (up to MS^3) and high mass accuracy. The determined degradation pathways included oxidation, hydroxylation, cyclic peroxylation, ring cleavage, and small molecule loss. The most intense degradation product observed was 2,4,6-trihydroxybenzoate, which was proposed to be the end point of the peroxylation pathway and the favored degradation pathway under these conditions. This pathway is believed to be the result of nucleophilic attack by hydrogen peroxide at the C2 position of quercetin. This was followed by a cross ring cyclic peroxylation event at C2–C4, which resulted in an intermediate depside that was defined by C-ring-opening due to loss of C3-OH and cleavage of the peroxy bond. Further cleavage of the depside resulted in the 2,4,6-trihydroxybenzoate. A sodiated pseudo adduct of the dimerized trihydroxybenzoate was believed to be induced under electrospray conditions. A computational study was performed to justify the position within the C-ring for both the attack by nucleophilic oxidants and the cyclic peroxylated intermediate structure.

KEYWORDS: *quercetin, oxidative degradation, hydrogen peroxide, reactive oxygen species, continuous-flow kinetics, higher order fragmentation, mass accuracy, electrospray ionization, ion trap–time-of-flight mass spectrometry*

INTRODUCTION

Quercetin is one of the most abundant dietary flavonols and can be found in significant quantities as a glycoside in teas, red wine, and onions.[1] In addition to its promising potential to reduce the risk of cancer, quercetin has been shown to be a natural histamine reducer and an effective anti-inflammatory agent.[2−4] Some theories suggest that the quercetin aglycone may be involved in several signal transduction pathways and has been shown to interact with key receptors involved with the development of cancers, inflammation, and carcinogenesis.[5] Quercetin has been shown to be highly effective at scavenging reactive oxygen species (ROS) in vitro.[6] Because of this antioxidant characteristic, it is no surprise that quercetin has drawn significant interest in the supplement market and food industry. A recent study of improving nutrients in vegetables has even shown organic tomatoes to have a 79% increase in quercetin compared to tomatoes grown conventionally.[7] The protective nature of the compound may be a primary reason behind some of the related therapeutic benefits of organic vegetables.

The antioxidant characteristics of quercetin can be correlated to the many pharmacophores of its chemical structure (Figure 1). The catechol-like structures that can be formed between the hydroxyl group at C5 and the C4 keto group and between the hydroxyl group at C3 and the C4 keto group, as well as the *o*-dihydroxy structure located on the B-ring, allows for free radical neutralization via hydrogen atom donation. Quercetin becomes a free radical during the process, but due to electron delocalization, a characteristic of phenoxy radicals, the species is too low in energy to react.[8,9] These attributes provide multiple facets for quercetin to contribute to the body's antioxidant shield, providing balance against the oxidative attack of ROS.

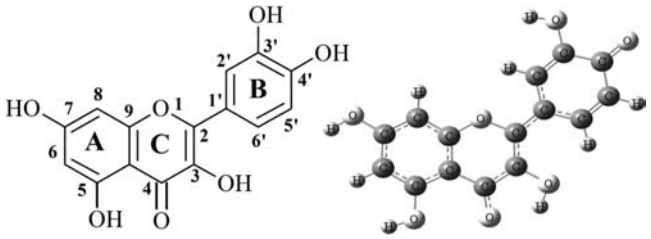

Figure 1. Generic resonance structure of quercetin and the deprotonated quercetin anion $[Q - H]^-$ in its lowest energy configuration (LEC) using Gaussian 03 and optimized with DFT/B3LYP and a 6-31G basis set.

One of the most common ROS in the body is hydrogen peroxide (H_2O_2). In addition to hydrogen peroxide being a nonradical ROS, decomposition of hydrogen peroxide in aqueous solution leads to the formation of hydroxyl and hydroperoxyl radicals.[10] Although it may have some protective function in the urinary system, H_2O_2 has been commonly

considered a cytotoxin.[11] Despite the fact it is commonly used around households to clean wounds, H_2O_2 may lead to further tissue injury.[12] This sterilizing agent is often used in aseptic packaging techniques and is commonly employed in wine production to oxidize sulfites, reducing allergic reactions. Hydrogen peroxide may also be used to decontaminate apples infected with *Escherichia coli*.[13]

Many studies have focused on quercetin's ability to shield against H_2O_2-induced DNA damage, even in trace amounts above 10 μM, by presumably scavenging the generated free radicals.[14−17] Lipid peroxidation may also be slowed by quercetin through scavenging of hydroxyl radicals spawned by UV photolysis of hydrogen peroxide.[18] In contrast, quercetin was suggested to combat lipid peroxidation by generation of hydrogen peroxide by donating protons from its hydroxyl groups to superoxide radicals.[19] This flavonol also plays a role in inhibiting platelet functions, such as platelet aggregation and platelet adhesion. These functions are believed to be driven by a signal pathway that includes a burst of hydrogen peroxide, which may explain the link between red wine consumption and reduced risk of cardiovascular disease.[20] To fully understand how quercetin may provide health benefits, the study of quercetin's interaction with hydrogen peroxide and the nature of the resultant oxidative degradation products should be considered a topic of substantial significance.

The polyphenolic structure of quercetin has strong absorption of UV-A (λ_{max} = 365 nm) and UV-C light (λ_{max} = 256 nm). Small changes to the skeletal structure could disrupt electron delocalization, so that by monitoring the UV spectrum, kinetic information on degradation reaction can be obtained. Some quercetin degradation pathways studied in this fashion have included UV-induced, electrochemical, free radical, enzymatic, metal-catalyzed, and autoxidation degradation.[21−24] Unfortunately, the multitude of species generated (up to 22 in studies by Zhou et al.[21]), combined with secondary oxidation events, can make the data convoluted and difficult to interpret. Without proper hyphenation, the results are limited to determining bulk antioxidant character and degradation rates and do not offer clues for elucidating degradative mechanisms or specific structural details of related reaction products.

Quercetin is also easily ionized, which makes electrospray ionization mass spectrometry and tandem mass spectrometry (ESI-MS^n) ideally suited to supplement UV data, allowing qualitative identification and structural characterization by fragmentation. A few studies have used this technique to characterize quercetin degradation pathways. Buchner et al. proposed thermal degradation of quercetin led to cross-ring cleavage and solvent adducts formed by nucleophilic attack at C2.[8] Along with solvent adducts, Hvattum et al. demonstrated degradation of quercetin by loss of CO at the C3 position when reacted with a free radical generator, 2,2-diphenyl-1-picrylhydrazyl (DPPH).[25] Zhou et al. completed an extensive comparative study of quercetin degradation by electrochemistry, air oxidation, enzymes, and the free radical generator azobis(isobutyronitrile) (AIBN).[21,26] They proposed that quercetin hydroxylated at the C2 position could lead to three separate pathways, one that follows the C-ring opening at the O1−C2 bond, one with C-ring opening at the C2−C3 bond, and one with C-ring opening at the C3−C4 bond.

Ion trap−time-of-flight (IT-TOF) mass detection provides the potential for definitive identification of polyphenolic compounds using higher order fragmentation and elemental formula determination with high mass accuracy.[27,28] Previously, the authors combined ESI-IT-TOF-MS with an in-house built capillary mixer with an adjustable reactor volume (motivated by Wilson and Konnermann[29]) to collect time-resolved mass spectral measurements of thermal degradation of quercetin in weakly acidic aqueous media and at physiological conditions.[30] In that study, it was proposed that thermally accelerated degradation followed a pathway that included a hydroxylation event at C2, which was proposed to lead to ring cleavage starting by C-ring opening at the O1−C2 bond. This led to a chalcan-trione intermediate structure. It was suggested that further nucleophilic attack of the chalcan-trione at the C2, C3, and C4 carbons resulted in A-type and B-type ions, of which the most preferred led to the A-type ions, 2,4,6-trihydroxy-2-oxo-2-phenylacetate and 2,4,6-trihydroxy-2-hydroxyl-2-phenylacetate ions.

Ab initio and semiempirical computational studies of quercetin's reactivity can provide insight into degradation pathways and solidify the understanding of how it neutralizes free radicals. Through the evaluation of bond dissociation energy (BDE) and reaction energies, it has been proposed that quercetin reacts with free radical ROS through hydrogen atom transfer (HAT) and that the activity is focused in the B- and C-rings.[31−35] In addition, interpretation of spin densities and charge distributions has consistently shown the C2 position in

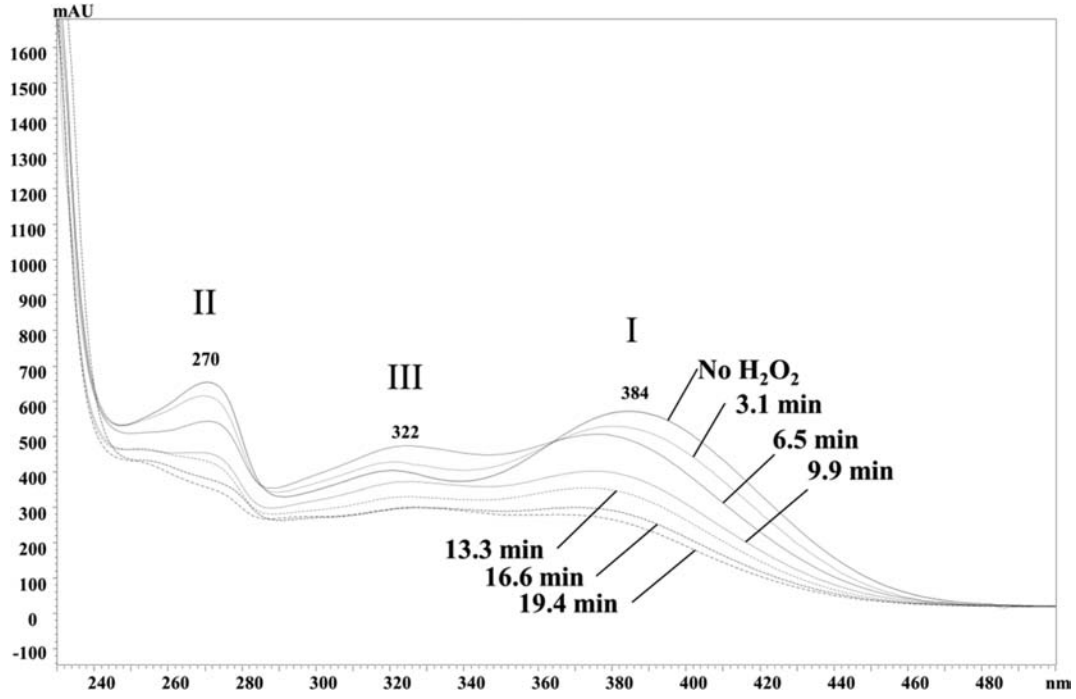

Figure 3. Changes to the UV−vis spectral profile with increasing reaction time after mixing 65 μM quercetin (pH 7.4) and 0.1% H_2O_2 at a ratio of 10:1.5 μL/min.

the C-ring to be the favored site for nucleophilic attack by single and double oxygen species.[23,32,35,36]

To witness the kinetic characteristics of the reactivity between aqueous quercetin and hydrogen peroxide, an in-house-built online capillary mixing device with an adjustable reactor volume was connected to a photodiode array detector. The eluent then was led into the electrospray inlet of an ion trap−time-of-flight (IT-TOF) MS system. The reaction time (3.1−19.4 min) could be controlled by making adjustments to the device. Incorporation of continuous-flow kinetic measurements with UV−vis, MS^n, and high mass accuracy allowed for a novel in-depth study of the interaction between quercetin and free radical species associated with hydrogen peroxide degradation. This embodiment and application of a combined online and mass spectrometry-based degradation study has not been previously conducted.

METHODS AND EQUIPMENT

Reagents and Solution. Aqueous solutions of quercetin (65 μM) were adjusted to pH 7.4 with sodium hydroxide (0.1 N) as described previously.[30] Fresh solutions were prepared at each measured time point. Hydrogen peroxide (0.1% v/v) was prepared by diluting hydrogen peroxide (3%; Walgreens, Deerfield, IL, USA) with LC-MS grade water (Burdick and Jackson, Muskegon, MI, USA).

Kinetic Device. Kinetic measurements were performed using a continuous-flow device, which was built in-house (Figure 2) and consisted of two concentric capillary tubes. Two 2.5 mL glass syringes (7.284 mm internal diameter (i.d.); Hamilton, Reno, NV, USA) were connected to a micromixing tee (IDEX, Lake Forest, IL, USA) via 1 ft lengths of polyetheretherketone (PEEK) tubing ($^1/_{16}$ in. outer diameter (o.d.); 0.005 in. i.d.). A 5 ft length of fluorinated ethylene propylene (FEP) tubing (400 μm i.d.; 1000 μm o.d.) was connected to the outlet end of the mixing tee. The downstream end of the FEP tubing was inserted over a 5 ft length of PEEK tubing (100 μm i.d.; 360 μm o.d.). A stainless steel union (0.052 in. thru-hole) was slid over the FEP tubing 2 in. from the downstream end of the outer capillary and tightened with a fitting and a ferrule to seal any leaks. The downstream outlet end of the PEEK tubing (outer capillary) was connected to a PDA, which in turn was connected to the inlet of the ESI. The syringes were driven by two syringe pumps (NE-1010, New Era Pump Systems, Farmingdale, NY, USA).

By moving the inner capillary, the volume of the reaction region was controlled, which allowed the ability to regulate the amount of reaction time after mixing. The aqueous solution of quercetin was pumped through one syringe at a flow rate of 10.0 μL/min. Hydrogen peroxide was introduced using the other syringe and was pumped at flow rates of 0.5, 1.0, and 1.5 μL/min. The most significant degradation was observed when hydrogen peroxide was pumped at 1.5 μL/min. This condition resulted in solutions that contained a quercetin concentration of 57 μM and a hydrogen peroxide concentration of 4 mM. Kinetic measurements were made by pulling the inner PEEK tubing out at 1 ft intervals. In the configuration in which the device had no extension (minimum dwell time), the total system volume was estimated to be 36 μL, based on 5 ft of inner tubing, 2 in. of outer tubing (seal union overlap), semimicro flow cell with a 10 μL capacity, and ∼1 ft of PEEK tubing (0.005″ i.d.) connecting the PDA to the ESI inlet, which made up the flow path downstream of the micromixer. At the combined flow rate of 11.5 μL/min, this allowed for measurements ranging from 3.1 to 19.4 min of reaction time.

Instrumentation. UV−vis spectra were collected using a Prominence SPD-M20A diode array detector (Shimadzu Scientific Instruments, Inc., Kyoto, Japan) set to acquire between 200 and 800 nm. Negative ion MS spectra were obtained using an ion trap−time-of-flight mass spectrometer (IT-TOF-MS, Shimadzu Scientific Instruments, Inc.) equipped with a conventional electrospray ionization (ESI) source. Analytical parameters for ionization, fragmentation, and detection were as follows: interface voltage, −3.5 kV; nebulizing gas (N_2), 1.5 L/min; drying gas (N_2), 10 L/min; curved desolvation line, 250 °C; detector voltage, 1.92 kV; ion accumulation time, 10 ms; precursor ion isolation width, 0.1 amu; collision gas (Ar), 50%; and frequency constant (q), 0.251. The estimated resolution of the instrument is 10000 at m/z 1000. A scanning rate of 100 ms was used. The estimated duty cycle at MS^3 with these settings was <0.5 s. The collision energy during collision-induced dissociation (CID) was adjusted at each tandem MS stage to determine the optimum parameters at which a maximum amount of signal information would be obtained. The IT-TOF was calibrated to <5 ppm error in mass accuracy using a solution of sodium trifluoroacetate.

Data collection and analysis were carried out using LCMS Solutions version 3.4 software. The Accurate Mass Calculator and Formula Predictor software tools were used to support determination of theoretical m/z values and elemental formulas of observed fragments. The software was configured to recommend formulaic possibilities based on the following requirements: 1−15 carbons, 0−10 oxygens, 0−15 hydrogens, 0−1 sodium, and within 25 ppm error. Isotopic ratios were also evaluated.

Computational Modeling. Three-dimensional Cartesian coordinates for structures of quercetin and related oxidated ions were submitted to Gaussian 03 for optimization using DFT/B3LYP and a 6-31G basis set.[37] The lowest energy conformation (LEC) was obtained by allowing the software to optimize the atoms in three dimensions.

RESULTS

Time-Resolved Measurements of Aqueous Quercetin Mixed with Hydrogen Peroxide. Changes in the UV and mass spectra due to increasing reaction time were evaluated by maintaining the same flow of the syringe pumps and increasing the length of the reaction chamber.

Changes in UV−Vis Spectra. The UV−vis spectral profile of quercetin in water was characterized by three distinct bands (I, II, and III) that had maxima at 384, 322, and 270 nm, respectively (Figure 3). Absorbance of band I has been associated with the cinnamoyl system of the B-ring, and the absorbance of band II has been associated with the benzoyl system of the A-ring. Band III has been connected with quinonic structures.[38,39] As H_2O_2 began to be mixed with quercetin, a decrease in the absorbance of bands I and II was observed. As the reaction time was extended, the absorbance of band I further decreased and a hypochromic shift of the maximum of band I from 384 to 360 nm was noted. A further decrease in intensity was also noted in band II as the reaction time was extended. In contrast, after the initial addition of H_2O_2, the absorbance in band III increased at the 3.1 and 6.5 min marks and then decreased at 9.9 and 16.6 min. Between 16.6 and 19.4 min, no change in band III was noted. A slight increase around 294 nm was seen at the 19.4 min mark. Two isosbestic points were noted at 285 and 364 nm.

Mass Spectral Analysis without H_2O_2. The signal for the deprotonated quercetin ion $[Q - H]^-$ (m/z 301.0343) has a significant intensity in the negative mode and can be easily observed at relatively low concentrations. This signal was the base peak observed in the spectra at room temperature. Although some quercetin-related ions were observed in the positive mode, they were not observed at significant intensity levels for informative analysis during any of the test conditions and, therefore, are not discussed in this assessment.

Evaluation of the $[Q - H]^-$ signal intensity over long periods showed that aqueous solutions of quercetin at a concentration of 65 μM and at pH 7.4 were relatively stable for >6 h at room temperature. In addition, trace signals for $[Q - 2H]^{2-}$ and $[2Q - H]^-$ (m/z 150.0135 and 603.0754) were observed at a level below 1% relative intensity. Other quercetin-related signals that could be observed at room temperature were classified into four categories: (1) simple oxidation events, (2) hydroxylated structures, (3) sodiated adducts, and (4) ions with small molecule loss (Table 1). The signals for $[Q - H_2 - H]^-$ and $[Q - 2H]^{\bullet-}$ at m/z 299.0189 and 300.0263, observed at 4 and 8% relative intensity, represent the initial oxidation events quercetin undergoes in aqueous solution. Two hydroxylated structures, $[Q + O - H]^-$ and $[Q + O - 2H]^{2-}$ at m/z

dx.doi.org/10.1021/jf500619x | J. Agric. Food Chem. 2014, 62, 4322−4331

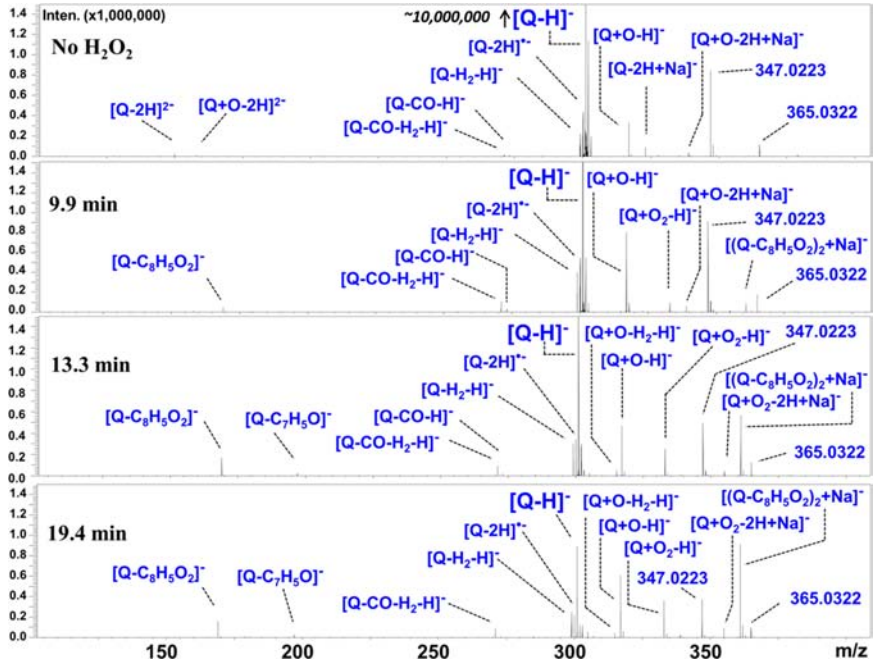

Figure 4. Comparative time-resolved spectra in the negative ionization mode after mixing 65 μM quercetin (pH 7.4) and 0.1% H_2O_2 at a ratio of 10:1.5 μL/min.

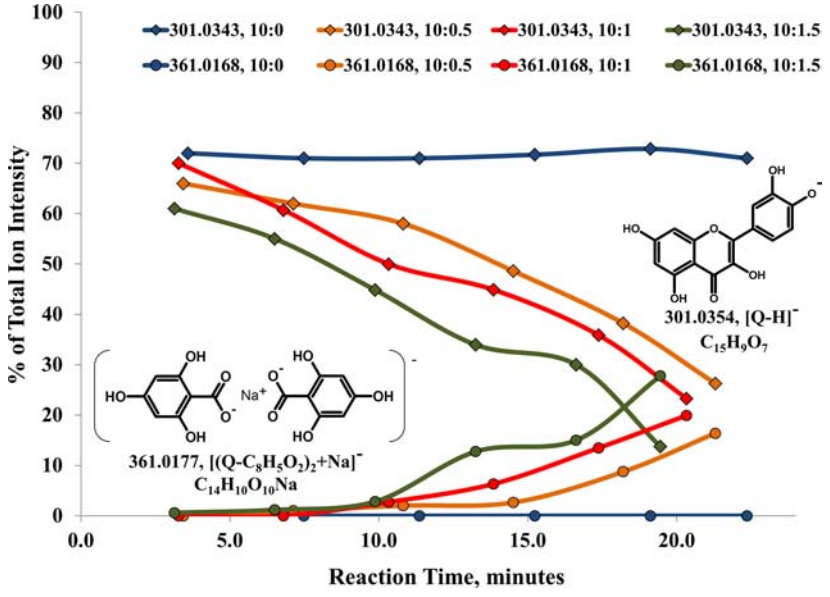

Figure 5. Plot of the H_2O_2-dependent oxidative degradation of $[Q - H]^-$ (m/z 301.0354) ion intensity (normalized against total ion intensity) over time. Formation of $[(Q - C_8H_5O_2)_2Na]^-$ (m/z 361.0177) was observed after addition of H_2O_2 and increased with increasing reaction time. The flow rate of quercetin (65 μM) was held constant at 10 μL/min while the flow rate of the 0.1% H_2O_2 solution was increased from 0.0 μL to 0.5, 1.0, and 1.5 μL/min.

317.0290 and 158.0108, were observed at 4 and ≪1% relative intensity. Two sodiated structures, $[Q - 2H + Na]^-$ (<1% relative intensity) and $[Q + O - 2H + Na]^-$ (<1%), at m/z 323.0154 and 339.0117, respectively, were observed and were believed to be formed due to influence from electrospray ionization.[40,41] An unidentified ion at m/z 347.0223 was observed at 13% relative intensity. Finally, trace amounts of signals at <1% relative intensity at m/z 273.0394 and 271.0239 were observed and were identified as $[Q - CO - H]^-$ and $[Q - CO - H_2 - H]^-$ on the basis of high mass accuracy.

Reaction with 3% Hydrogen Peroxide. Upon addition of 3% hydrogen peroxide with 65 μM quercetin (10:1; a postmixed H_2O_2 concentration of 0.3%) at the minimum dwell time allowed by the device (3.3 min), the $[Q - H]^-$ signal disappeared immediately and two signals at m/z 169.0140 and 361.0168 were observed. On the basis of mass accuracy they were determined to be ions with an elemental formula of $C_7H_5O_5$ and $C_{14}H_{10}O_{10}Na$, respectively. The latter structure was proposed to be a sodiated dimer of the former (see Discussion) and would therefore make the two ions $[Q - C_8H_5O_2]^-$ and $[(Q - C_8H_5O_2)_2 + Na]^-$, respectively. These

dx.doi.org/10.1021/jf500619x | J. Agric. Food Chem. 2014, 62, 4322−4331

two signals were seen in similar intensities and were the largest signals seen in the spectra. Numerous other quercetin-related signals could also be observed after the addition of hydrogen peroxide that were not previously observed in unmixed quercetin solutions. The concentration of hydrogen peroxide being mixed was lowered systematically until the signals for $[Q - C_8H_5O_2]^-$ and $[(Q - C_8H_5O_2)_2 + Na]^-$ were no longer observed above 1% relative intensity and the intensity of the $[Q - H]^-$ was unaffected. The postmixed concentration of hydrogen peroxide was 0.009% (~3 mM) when this was achieved. The ion signals forming from the simple oxidation events, $[Q - H_2 - H]^-$ and $[Q - 2H]^{\bullet -}$, appeared to also be unaffected at this concentration.

The presence of the hydrogen peroxide did appear to hinder the formation of some of the ions observed in the unreacted aqueous solutions, as the $[Q - 2H]^{2-}$, $[2Q - H]^-$, and $[Q - 2H + Na]^-$ ions could no longer be discernible from the baseline after mixing quercetin with even low levels of H_2O_2. The hydroxylated ion signals $[Q + O - H]^-$ and $[Q + O - 2H + Na]^-$ increased significantly (10 and 2% relative intensity), and two peroxylated ion signals, $[Q + O_2 - H]^-$ and $[Q + O_2 - 2H - Na]^-$, m/z 333.0242 and 355.0058, respectively, could be observed at trace levels below 1% relative intensity, which were previously unidentifiable before mixing. Additionally, the small molecule loss signals $[Q - CO - H]^-$ and $[Q - CO - H_2 - H]^-$ increased to 4% relative intensity.

Changes in MS Spectra Based on Increasing Reaction Time. To reduce the inherent variability of ion intensities observed over the course of many days and multiple preparations of reagents, quercetin and product ion intensities were normalized as a percent of total ion intensity. As can be seen in Figures 4 and 5, as the reaction time was increased, the intensity of the $[Q - H]^-$ signal was observed to decrease, reaching 13% of the total ion intensity at 19.4 min. In contrast, the intensity of the ions $[Q - C_8H_5O_2]^-$ and $[(Q - C_8H_5O_2)_2 + Na]^-$ grew as the reaction time was extended and reached a maximum of 7 and 28% of the total ion intensity, respectively. By 19.4 min, the signal for $[(Q - C_8H_5O_2)_2 + Na]^-$ had become the base peak observed in the spectra. At the 13.3 min mark, trace signals below 0.5% total ion intensity of $[Q - C_7H_5O]^-$ and $[Q - C_7H_7O_2]^-$, m/z 197.0086 and 178.9979, respectively, could be observed. These signals increased slightly to maxima of 0.9 and 0.6% total ion intensity by 19.4 min. At this time point, an ion at m/z 153.0186, $[Q - C_8H_5O_3]^-$, began to be observed in trace amounts below 0.5% total ion intensity.

To further investigate the origin of the signal at m/z 361.0168, believed to be $[(Q - C_8H_5O_2)_2 + Na]^-$, and to confirm it was a sodiated dimer of 2,4,6-trihydroxybenzoate (theoretical m/z 169.0142), quercetin solutions were prepared with KOH instead of NaOH and reacted with H_2O_2. The ion signal at m/z 169.0140 was observed; however, a signal near m/z 361.0177, $[(Q - C_8H_5O_2)_2 + Na]^-$, was not observed (data not shown). A small ion with ~1% relative intensity at m/z 376.9917, which would correspond to the ion $[(Q - C_8H_5O_2)_2 + K]^-$, was observed. Fragmentation of this signal returned a product ion at m/z 169.0133.

The ion $[Q + O - H]^-$ increased slightly from 3.1 to 6.5 min and reached its maximum of 11% total ion intensity at the 6.5 min mark and then steadily decreased at each time point, reaching 5% total ion intensity at 19.4 min (Figure 6). The ion $[Q + O_2 - H]^-$ also increased through 6.5 min and continued to increase at the 9.9 min mark, reaching a maximum of 6% total ion intensity, and then was observed to decrease steadily

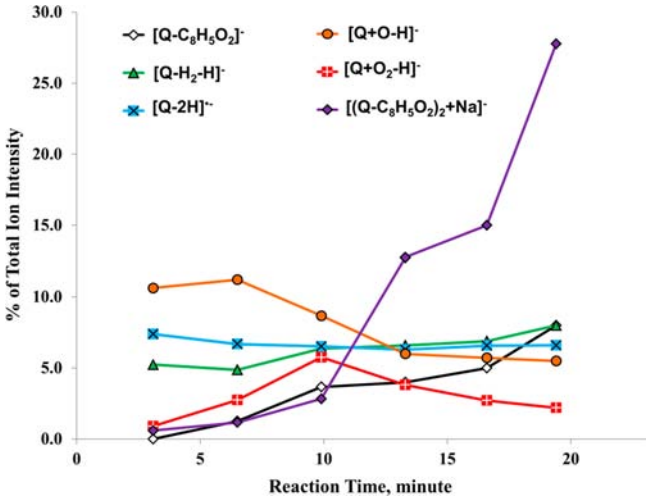

Figure 6. Plot of the H_2O_2-dependent oxidative degradation products of quercetin ion intensities (normalized against total ion intensity) over time. The flow rate of quercetin (65 μM) was held constant at 10 μL/min while the flow rate of the 0.1% H_2O_2 solution was 1.5 μL/min.

at each time point thereafter, reaching 3% at 19.4 min. At the 13.3 min mark, signals for $[Q + O - H_2 - H]^-$ and $[Q + O_2 - 2H + Na]^-$ could be distinguished above baseline at 0.5 and 1.5% total ion intensity, respectively (Figure 4). These signals remained consistent at these levels through 19.4 min. A signal at m/z 305.0293, $[Q + O_2 - CO - H]^-$, also appeared at the 13.3 min mark at 0.7% total ion intensity and remained consistent through 19.4 min.

Many ions were either unaffected or had only a slight change. The intensity for the ions representing the simple oxidation events of quercetin, $[Q - H_2 - H]^-$ and $[Q - 2H]^{\bullet -}$, increased only slightly and reached maxima of 6 and 7% total ion intensity for both ions. Ion signals at m/z 273.0394 ($[Q - CO - H]^-$) and 271.0239 ($[Q - CO - H_2 - H]^-$) also remained at a consistent level compared to the dwell time as the reaction time increased. The unidentified ion at m/z 347.0223 was consistently near 10% total ion intensity regardless of condition. Fragmentation of this ion resulted in product ions at m/z 206.9941, 299.0204, 300.0257, and 301.0314, suggesting that the parent ion was quercetin-related. On the basis of the isotopic distribution it was established that this ion was singly charged; however, no elemental formula could be determined that would agree within 20 ppm of the observed mass. Additionally, a singly charged ion at m/z 365.0322 was observed near 1.5% total ion intensity in all conditions, but its identification was also inconclusive.

DISCUSSION

Acid–Base Equilibrium and Simple Oxidation Ions. Because sample preparations were not sparged or prepared under evacuation of air, it should be assumed that aqueous quercetin would be in the presence of dissolved O_2 and ~250 nM hydroxyl ions from autoionization of water (depending on the pH). In addition to electrospray ionization effects, the presence of trace ROS may contribute to the formation of the simple oxidated quercetin ion $[Q - H_2 - H]^-$ and the radical ion $[Q - 2H]^{\bullet -}$ in fresh solutions at room temperature. The radical ion $[Q - 2H]^{\bullet -}$, which was observed to be pH-dependent in the previous evaluation of quercetin oxidation, was observed at ~2:1 higher intensities than the $[Q - H_2 -$

[a]C-ring intact. [b]C-ring opened. [c]C-ring intact and noncyclic peroxylated. [d]C-ring intact and cyclic peroxylated.

$H]^-$ ion and demonstrates the ability of the quercetin structure to stabilize a radical at ambient temperatures. As hydrogen peroxide is introduced, the levels of ROS would significantly increase, due to the decomposition of hydrogen peroxide into hydroxyl radicals, hydroxyl ions, peroxide radicals, and hydroperoxyl radicals. The notion that ROS promote simple oxidation of quercetin is further supported by the observed increase in the intensity of $[Q - H_2 - H]^-$ and $[Q - 2H]^{\bullet -}$ after the addition of H_2O_2. These simple oxidated ions do not appear to be further affected as the reaction time increases; only a slight increase in the $[Q - H_2 - H]^-$ near 20 min of mixing was observed (Figures 4 and 6).

Hydroxylated and Peroxylated Ions. The hydroxylated adduct of quercetin, $[Q + O - H]^-$, was also observed at room temperature without the addition of hydrogen peroxide. In the previous kinetic study of thermal degradation of quercetin, the authors suggested that the formation of this ion was due to, first, hydroxylation at the C2 position to form a 2-hydroxy-3,4-flavonedione and then formation of a 2,3,4-chalcan-trione anion. This was presumably by C-ring opening of the 2-hydroxy-3,4-flavonedione at the O1−C2 bond and formation of a double-bonded oxygen at C2 (Figure 7).[11] Krishnamachari et al. suggested that this chalcan-trione structure would further stabilize into a benzofuran.[42] As H_2O_2 was mixed, the

dx.doi.org/10.1021/jf500619x | J. Agric. Food Chem. 2014, 62, 4322−4331

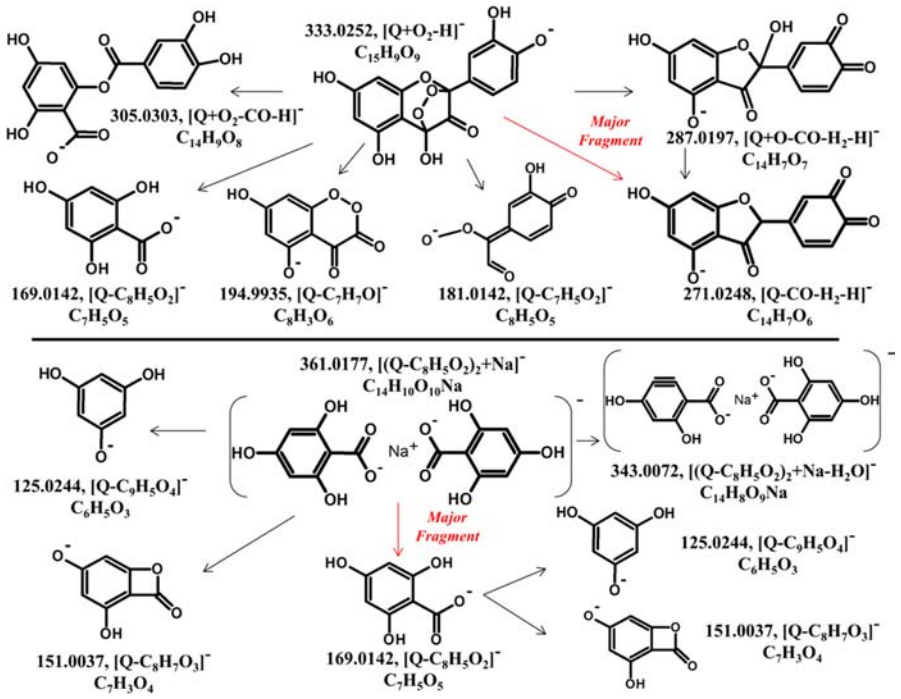

Figure 8. Proposed structures and theoretical m/z of product ions from higher order fragmentation (MS/MS and MS^3) of $[Q + O_2 - H]^-$, m/z 333.0252, and $[(Q - C_8H_5O_2)_2Na]^-$, m/z 361.0177.

concentration of hydroxyl ions and hydroxyl radicals increased, which led to increased hydroxylation of quercetin and a nearly 2-fold increase in the intensity of this ion, as compared to unreacted solutions of quercetin.

The peroxylated ion $[Q + O_2 - H]^-$ was observed only after the addition of H_2O_2. It can be assumed that the ion formation may be attributed to the reaction between quercetin and nucleophilic attack by hydrogen peroxide. Evaluation of the mulliken charges for the deprotonated quercetin $[Q - H]^-$ shows C2 as having the highest partial positive charge and represents the carbon in the C-ring that has the most carbocation characteristics and reactivity (Table 2). Additionally, many computational studies in the literature have demonstrated the charge distribution of the HOMO and LUMO located at this position.[32−36] Therefore, both hydroxylation and peroxylation would most likely occur at C2. The relationship between the increase in signal intensity for $[Q + O_2 - H]^-$ within 10 min and the decrease in the $[Q + O - H]^-$ after 6 min suggests competition between the individual ROS species for reactivity at this site on quercetin.

Decrease in the intensity of both of these ions may also suggest that these ions are only intermediates in the degradation pathway of quercetin when mixed with ROS generated by hydrogen peroxide. Decrease in intensity may be due to further oxidation of the hydroxylated and peroxylated quercetin ions, such as $[Q + O - H_2 - H]^-$ and $[Q + O_2 - 2H + Na]^-$. However, $[Q + O - H_2 - H]^-$ and $[Q + O_2 - 2H + Na]^-$ could be formed by hydroxylation or by peroxylation of simple oxidated quercetin $[Q - H_2 - H]^-$.

The structure for $[Q + O_2 - H]^-$ could exist in more than just one structure in solution. A few studies propose a cyclic peroxylated quercetin intermediate in which the peroxide reacts at the C2 position and forms a bridge across the C-ring by bonding with C4.[21,43] The fragmentation product ion of m/z 333.0242 $[Q + O_2 - H]^-$ further confirms this as a possible structure (Figure 8). The major fragment product ion of $[Q + O_2 - H]^-$ was m/z 271.0236 and represents an ion with the elemental formula $C_{14}H_7O_6$ (−4.4 ppm error). The neutral loss from fragmentation would be a loss of CH_2O and O_2. The loss of three oxygens and only one carbon suggests that the neutral loss involves the added peroxide as well as a carbonyl from either the C3 or C4 position.

Evaluation of the computationally simulated structure, in which peroxylation was only at C2 (and not bridged), suggested that bridging may also occur at C3, because C3 has a significantly higher estimated positive partial charge than C4 (Table 2). The C2 to C3 bridged peroxylated quercetin structure could also possibly lead to all of the fragmentation structures proposed in Figure 8. The calculated total energies of the noncyclic peroxylated quercetin, the 2,4-cyclic-peroxylated quercetin, and the 2,3-cyclic peroxylated quercetin were similar (within ±0.02 kJ/mol); however, the C2−C4 cyclic structure was slightly more energetically favorable than the other two (Table 2). Indeed, there may be a distribution of both the C2−C3 and C2−C4 bonded structures in solution. In a computational study of enzymatic oxygenolysis of quercetin, Fiorucci et al. concluded that the formation of cyclic peroxide would favor 1,3-cycloaddition, instead of 1,2-cycloaddition.[44]

Cleavage of the weak peroxide bond of the C2−C4 bond, followed by decarboxylation at the C3 site, would give rise to a depside structure with a m/z of 305.0303, which was observed in the late kinetic time points (Figures 4 and 7).[22,23] The computational analysis of the C2−C4 peroxylated quercetin confirms the potential reactivity and possibly decarboxylation at the C3 position on the basis of its higher partial positive charge compared to the C2 and C4 positions (Table 2). The observed ions at m/z 273.0394 and 271.0239 also suggest decarboxylation from the C-ring. The fact that the major fragment product ion seen when m/z 333.0242 was fragmented was m/z 271.0236 supports the notion that the appearance of m/z 271.0239 and 273.0394 in the initial MS scan is related to the peroxylated quercetin pathway. These ions were also observed

dx.doi.org/10.1021/jf500619x | J. Agric. Food Chem. 2014, 62, 4322−4331

in the thermal degradation study of quercetin and a study of copper-catalyzed quercetin degradation.[45]

Cross-Ring Cleavage Pathways. The structures for *m/z* 169.0140 and 361.0168 appear to be the preferred degradation products as they were observed to consistently increase as the reaction time was extended. Fragmentation of *m/z* 169.0140 resulted in *m/z* 125.0249 and 151.0044, which confirmed the precursor ion to be the A-type cross-ring cleavage product $[Q - C_8H_5O_2]^-$ (2,4,6-trihydroxybenzoate) observed in the thermal degradation study.[30] The major product ion that resulted from fragmentation of *m/z* 361.0168 was *m/z* 169.0148, and smaller intensity fragment ions included *m/z* 125.0242, 151.0045, and 343.0029. Higher order fragmentation of the product ion *m/z* 169.0148 (MS^3) provided further product ion signals at *m/z* 151.0032 and 125.0239. Refer to Figure 8 for the proposed fragment ion structures and theoretical masses. Considering the observed fragmentation data and that *m/z* 361.0168 does not form when NaOH is replaced by KOH, the ion at *m/z* 361.0168 must be due to a 2,4,6-trihydroxybenzoate dimer bridged by a sodium ion. Previously, Schug and McNair demonstrated a similar phenomenon in which they observed pseudomolecular ion formation of sodium-bridged dimers of aromatic carboxylic acids in the negative ionization mode by ESI.[40,41]

The depside generated by degradation of the 2,4-cyclic peroxylated quercetin may be the intermediate that leads to formation of the 2,4,6-trihydroxybenzoate. Additional nucleophilic attack by ROS at the C2 position of this depside could cause cleavage of the O1−C2 bond. This would make 2,4,6-trihydroxybenzoate be the charged leaving group. This preferred degradation product is different from the 2,4,6-trihydroxy-2-oxo-2-phenylacetate and 2,4,6-trihydroxy-2-hydroxy-2-phenylacetate degradation products (*m/z* 197.0092 and 199.0248) observed for the thermal degradation pathway.[30] The late kinetic time point of the hydrogen peroxide mixing study did show trace amounts of an ion at *m/z* 197.0086, along with two other A-type and B-type cross-ring cleavage product ions, *m/z* 153.0186 and 178.9979. Formation of these ions could be due to continued hydroxylation of the chalcan-trione, $[Q + O - H]^-$.

Interpretation of UV−Vis Spectral Profile. Details presented by the mass spectral data help to further explain the changes observed in the UV spectral profile. As expected, when the quercetin structure interacts with hydrogen peroxide at the C2 position and the hydroxylated and peroxylated structures are being formed, the cinnamoyl and benzoyl structures are interrupted, causing a decrease in the absorbance of bands I and II. Shift of the maxima in band I from 380 nm (Figure 3) may also be in part due to simple oxidation events and disruption of C-ring aromaticity. In addition to an effect from quinones, band III has been suggested to be influenced by the chalcone structure.[46,47] The increase in band III at the initial time points correlated with an increase in the $[Q + O - H]^-$ at the first two kinetic measurements, as well as the decrease in absorbance along with a decrease in intensity after 9.9 min. Further oxidation of the hydroxylated and peroxylated structures ($[Q + O - H_2 - H]^-$ and $[Q + O_2 - 2H + Na]^-$) may contribute to the hyperchromic shift of the maxima of band III. An HPLC-UV study by Zvezdanovic et al. identified 2,4,6-trihydroxybenzoate as a prominent quercetin degradant, which had a UV profile that consisted of a single band with a maximum at 294 nm.[47] At the last time point, the influence of the 2,4,6-trihydroxybenzoate may have begun to be seen in band III with the slight increase in absorbance at 294 nm. The trihydroxybenzoate structure would maintain the benzoyl system from the A-ring side and an absorbance near band II.[26,48]

Supporting Information

ABSTRACT: The phenolic acids and proanthocyanidins (PACs) of pecans possess bioactive properties, which might be useful in retarding the onset of and ameliorating the status of certain chronic disease states. There is a general lack of information in the literature regarding such compounds, especially the PACs. Crude phenolic extracts pooled from eight commercially significant cultivars were selected based on their relatively high antioxidant capacities. The pooled extracts were separated via Sephadex LH-20 column chromatography into five ethanolic low-molecular-weight (LMW) fractions and one acetonic high-molecular-weight (HMW) fraction. The preparations were then characterized using RP-HPLC-ESI-MS/MS and diol-phase HPLC-ESI-MS/MS in order to determine the key constituents present in the LMW and HMW fractions, respectively. As previously observed in pecan nutmeat, ellagic acid and (+)-catechin were found to be the major phenolics in the LMW fractions. The last eluting LMW fraction did not contain phenolic acids; rather it possessed PAC monomers and dimers. The HMW fraction comprised a majority of its PACs as dimers; yet, monomers, trimers, tetramers, pentamers, and hexamers were also separated and characterized.

KEYWORDS: *pecans, proanthocyanidins (PACs), Sephadex LH-20, RP-HPLC, diol-phase-HPLC, ESI-MS/MS*

INTRODUCTION

Pecans [*Carya illinoinensis* (Wangenh.) K. Koch] and other tree nuts are receiving increased attention due to their purported health benefits[1−4] and a qualified health claim approved more than 10 years ago by the U.S. Food and Drug Administration. Most reports associate these benefits with healthful lipid profiles (*i.e.*, MUFAs, PUFAs, α-tocopherol, and γ-tocopherol), but more recently attention has turned toward the favorable phenolic profiles that tree nuts possess. Endogenous pecan phenolics can be segregated into two main classes, namely, phenolic acids (e.g., ellagic and gallic acids as well as their derivatives) and condensed tannins/proanthocyanidins (PACs) with varying degrees of polymerization (DP).[5] Characterization of these important classes, especially the PACs, is lacking in the literature.[6]

PACs, or condensed tannins, are a type of phenolic polymer. There are two main types, that is, procyanidins and prodelphinidins. Procyanidins, the most prevalent PAC found in foods, are composed of (−)-epicatechin monomers, whereas the prodelphinidins comprise (−)-epigallocatechin monomers.[7] PACs are usually not classified based on the individual compound type; rather, they are centered on the DP that exist.[8] The DP can range anywhere from 2 (i.e., dimers) to 10^+ (i.e., polymers). The antioxidant properties and antimutagenic activity of PACs can vary based upon structure and DP.[7]

Pecan PACs and their flavan-3-ol monomers have shown potential for important health-related benefits *in vivo*.[6] In a randomized controlled trial employing a crossover design with a one-week washout period between treatments, Hudthagosol et al.[6] had 16 healthy men and women (23−44 years, BMI 22.7 ± 3.4) consume a test meal composed of either whole pecans, blended pecans, or an isocaloric meal of equivalent macronutrient composition. Blood was sampled at baseline and at intervals up to 24 h postingestion. Plasma antioxidant capacities and the levels of γ-tocopherol and epigallocatechin gallate (EGCG) from the panelists' blood were determined; each increased significantly ($p < 0.05$) postprandially. While the flavan-3-ol monomers can be absorbed in the small intestine, there is evidence that all PACs with a DP of 3 and higher may not be able to be properly absorbed.[9] If this is indeed the case, larger PACs can still participate in contributing a health benefit to humans, as these compounds can be broken down into smaller secondary metabolites by colonic microflora[10] and then be absorbed.

In this study, we employed Sephadex LH-20 column chromatography to fractionate pecan phenolic acids, their derivatives, and PACs. Once separated, these fractions were characterized by the total phenolics content (TPC) assay, UV spectral analysis, and RP-HPLC-ESI-MS/MS characterization of the low-molecular-weight (LMW) fractions and diol-phase

HPLC-ESI-MS/MS of the high-molecular-weight (HMW) fraction.

MATERIALS AND METHODS

Chemicals and Glassware. Washed sea sand, sodium carbonate, glass wool, ethanol (95%), and ACS-grade methanol, hexanes, and acetone as well as HPLC-grade water, methanol, hexanes, 2-propanol, and acetonitrile were acquired from Fisher Scientific Co., LLC (Suwanee, GA, USA). Glacial acetic acid and hydrochloric acid were purchased from VWR International, LLC (Suwanee, GA, USA). Sephadex LH-20, Folin−Ciocalteu's phenol reagent, (+)-catechin hydrate, gallic acid, ellagic acid, and protocatechuic acid were purchased from the Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Procyanidin B2 was acquired from Indofine Chemical Company, Inc. (Hillsborough, NJ, USA), and the cocoa PAC standards with both A- and B-type linkages of DP = 2−10 were obtained from Planta Analytica (Danbury, CT, USA). No differences in the composition of these PAC standards were expected compared to those endogenous to pecans.

Collection of Samples. Eighteen pecan cultivars were acquired from commercial and research pecan orchards in Georgia (11), New Mexico (2), and Texas (5) over a three-month period in the fall of 2011. All orchards had received commercial cultural management care according to the Cooperative Extension recommendations in each state. The nuts were raw and remained in-shell through transport, packaging, and storage. After arrival to the Department of Food Science & Technology, Athens, GA, the pecan samples were placed in labeled pouches (Sealed Air Corporation, Elmwood Park, NJ, USA), vacuum packed (Henkelman 600, Henkelman BV, The Netherlands) to retard oxidative degradation, and stored at −80 °C until analyzed. On the day of analysis, pecan samples were removed from the freezer, shelled, and allowed to warm to room temperature to ensure a proper mass reading. Roughly 12 g of nutmeat was placed in a −20 °C freezer and allowed to partially refreeze to facilitate grinding. Each nut sample was then combined with ∼60 g of washed sea sand and ground in a commercial coffee mill (Grind Central Coffee Grinder, Cuisinart, East Windsor, NJ, USA) to a very fine powder using an intermittent pulsing technique. In this manner, oils were not expressed from the nutmeat during the particle size reduction step.

Lipid Extraction. A Soxhlet apparatus was employed to facilitate the extraction of lipids from all pecan samples. Briefly, a known quantity of the ground matter (pecan and sand) was placed into a cellulose extraction thimble (single thickness, 43 mm *i.d.* × 123 mm *e.l.*, Whatman International Ltd., Maidstone, England) and the mass recorded. Glass wool was placed in the top of the thimble to ensure that the contents remained in place during extraction. Extraction was performed using ∼350 mL of hexanes for 20 h. Upon completion, the thimbles were removed, placed on aluminum foil, and allowed to dry overnight in a fumehood. The hexanes were removed from the lipid extract using a Büchi Rotavapor R-210 and a V-700 vacuum pump connected to a V-850 vacuum controller (Büchi Corporation, New Castle, DE, USA) at 45 °C. The lipid portion was weighed for gravimetric analysis.

Phenolic Compound Extraction. The defatted pecan nutmeat was removed from the dried thimble and placed in a beaker. As employed by Wu et al.,[11] a $(CH_3)_2CO/H_2O/CH_3COOH$ solvent mixture (70:29.5:0.5 v/v/v, 100 mL) was used to extract phenolic compounds. Extraction was carried out according to Craft et al.[12] Briefly, the contents in 250 mL Erlenmeyer flasks were heated at 50 °C for 30 min in an orbital-shaking water bath (New Brunswick Scientific, New Brunswick, NJ, USA). The extraction was performed 3×, and the supernates were pooled. Acetone was evaporated from the pooled supernate using the Rotavapor. The aqueous portion was poured into 100 × 50 mm [diameter × height] crystallizing dishes (VWR), covered with filter paper, and placed in a −80 °C freezer until frozen. The samples were then lyophilized in a FreeZone 2.5 L benchtop freeze-dryer (Labconco Corporation, Kansas City, MO, USA) to ensure all traces of moisture were removed. The dried extract was transferred to amber-colored vials, flushed with N_2, capped, and stored at 4 °C until analyzed. A total lipid and phenolic extraction was completed in triplicate for each of the 18 pecan cultivars.

Sample Selection and Extract Separation. On the basis of preliminary data (results not shown here), the eight cultivars with the best performance based on the H-ORAC$_{FL}$ assay were selected for use in this study. A 240 mg portion of each crude pecan extract was taken and pooled. The resultant extract (1.92 g) was mixed in a small volume of ∼75% (v/v) ethanol and sonicated to ensure its complete dissolution. The sample was then applied via a Pasteur pipet to the top of a chromatographic column packed with Sephadex LH-20 (bead size: 25−100 μm; Chromaflex column, 30 × 400 mm [i.d. × length], Kontes, Vineland, NJ, USA), and flow was conducted by gravity. The LMW phenolic compounds (molecular weight <600 Da) were eluted with ∼1.5 L of 95% (v/v) ethanol. Fractions (7 mL volume) were collected by a Beckman Coulter SC100 collector (Fullerton, CA, USA). The eluent was then switched to 50% (v/v) aqueous acetone, and an HMW phenolic fraction (molecular weight ≥600 Da) was eluted from the column with ∼600 mL of the second mobile phase. Total recovery of the extract from the column was 99%.

Fraction Determination. LMW phenolic fractions were analyzed using an Agilent 8453 UV−vis diode array detection (DAD) spectrophotometer (Agilent Technologies, Inc., Wilmington, DE, USA) scanning across a wavelength range of 200 to 400 nm. Spectral differences were used as a guide to group the collected fractions into five pooled lots. After combining, the ethanol was evaporated using the Rotavapor. To ensure complete removal of solvent and moisture, the pooled fractions were lyophilized with the Labconco freeze drier and then stored in amber-glass bottles at 4 °C until analyzed. Apropos the HMW fraction, acetone was also removed *in vacuo* and the aqueous residue lyophilized and stored as described above.

Total Phenolics Content Assay. The TPCs of the ethanolic fractions were determined based on a method adapted from Swain and Hillis[13] employing Folin−Ciocalteu's phenol reagent. Each fraction was diluted to 0.20 mg/mL in anhydrous CH_3OH. The assay was performed using 1 mL of methanolic extract, 7.5 mL of deionized water, 0.5 mL of Folin−Ciocalteu's phenol reagent, and 1 mL of saturated sodium carbonate. The solution was vortexed for 30 s, and the tubes sat for 1 h to allow for optimal color development. The absorbance of the resulting chromophore from this colorimetric reaction was measured at λ = 750 nm using the Agilent spectrophotometer. A standard curve was prepared using known concentrations of working solutions of (+)-catechin (1.6 to 8.0 μg/mL). TPC values are reported as g catechin equiv (CE)/g ethanolic extract.

HPLC Characterization. *Reversed-Phase HPLC Characterization (RP-HPLC-ESI-MS/MS).* The RP-HPLC method of Srivastava et al.[14] was followed to characterize the fractions of the pooled pecan cultivars. An Agilent 1200 series HPLC system consisting of a quaternary pump with degasser, autosampler, thermostated column compartment, UV−vis DAD with standard flow cell, and 3D ChemStation software (Agilent Technologies, Santa Clara, CA, USA) was employed for the chromatography. A reversed-phase Luna $C_{18}(2)$ column (4.6 × 250 mm, 5 μm particle size; Phenomenex, Torrance, CA, USA) was utilized. A gradient elution consisting of mobile phase A ($H_2O/CH_3CN/CH_3COOH$, 93:5:2, v/v/v) and mobile phase B ($H_2O/CH_3CN/CH_3COOH$, 58:40:2, v/v/v) from 0 to 100% B over a 50 min period at a flow rate of 1 mL/min was employed. A volume of 100 μL was injected for each of the crude fractions (4.0 mg/mL methanol). Detection wavelengths were λ = 255 nm (ellagic acid and ellagic acid derivatives), 280 nm (phenolic acids, (+)-catechin, (−)-epicatechin), 320 nm (phenolic acids, notably of the *trans*-cinnamic acid family), and 360 nm (flavonols). Tentative identification of separated components was made by matching UV−vis spectra and retention time (t_R) mapping with standard compounds prior to ESI-MS/MS analyses. Comparisons of chromatographed compounds were also made with those of selected published works.

RP-HPLC-ESI-MS/MS analyses of the crude extracts were performed on an Agilent 1100 HPLC system, with the same chromatography conditions as described above, coupled with a Bruker Esquire 3000^{plus} ion trap mass spectrometer (Bruker Daltonics Inc.,

Billerica, MA, USA), which was equipped with an ESI source. Instrument control and data acquisition were performed with Esquire Control 5.0 software. Raw data were analyzed using Data Analysis 4.1 (Bruker Daltonics Inc.). The dissolved crude extracts were infused into the source chamber from the HPLC via a T-junction delivering roughly one-third of the flow to the mass spectrometer. Mass spectra were acquired in the negative-ion mode with smart settings for a target mass at an m/z of 800. The voltage applied to the capillary was 4.0 kV with an end plate offset of −500 V. Nitrogen was used as the nebulizing gas at a pressure of 10 psi, a dry gas flow rate of 6 L/min, and a dry gas temperature of 280 °C. All collision-induced dissociation mass spectra were obtained at a fragmentation voltage of 1 V after isolation of the desired precursor ion. A full scan was performed over the mass range of 100 to 1000 Da at a rate of 13 000 m/z per second under standard−normal scan mode. The ion current control target was 50 000 with a maximum accumulation time of 50 ms. Each mass spectrum generated was based on an average of ten scans. The phenolic compounds were preliminarily fragmented using the auto-MS^2 mode with the following precursor ion selection parameters: two precursor ions, threshold abs of 10 000, threshold rel of 5.0%, ion excluded after two spectra, and exclusion release after 0.5 min.

Diol-Phase HPLC Characterization (Diol-Phase HPLC-ESI-MS/MS). PACs were separated based on their DP according to Kelm et al.[15] The same Agilent 1200 Series HPLC utilized for the reversed-phase analyses was employed, but with a PrincetonSPHER DIOL column (250 mm × 4.6 mm, 5 μm particle size, 60 Å; Princeton Chromatography, Inc., Cranbury, NJ, USA) equipped with a guard cartridge/holder system, a thermostated column compartment set at 30 °C, and a fluorescence detector. A gradient elution consisting of mobile phase (A) CH_3CN/CH_3COOH (98:2, v/v) and (B) $CH_3OH/H_2O/CH_3COOH$ (95:3:2, v/v/v) was utilized. The linear gradient was completed at 1.0 mL/min as follows: 0−35 min, 0−40% B; held for 5 min; 40−45 min, 40−0% B; and then an additional 5 min hold in order to equilibrate the system. A volume of 20 μL was injected for each sample; extracts were first dissolved in anhydrous CH_3OH (20 mg/mL) and then further diluted 1:9 (v/v) with mobile phase A to a final concentration of 2 mg/mL. Samples were passed through a 0.45 μm PTFE syringe filter prior to injection. Fluorescence detection was employed with excitation/emission at λ = 276/316 nm, respectively. The photomultiplier tube gain was held constant at 10 for the duration of the run time. Commercial purified standards were analyzed to determine the t_R's and area values for two monomers [(+)-catechin and (−)-epicatechin], three dimers (B2, 2a, 2b), and a set of polymers of varying DP ranging from 3 to 10. B2 is procyanidin B2, which is a B-type dimer and its structure is (−)-epicatechin-(4β→8)-(−)-epicatechin. The additional dimers, namely, 2a and 2b, are nonspecific A- and B-type dimers, respectively. Tentative identification based on the DP was made by t_R mapping of these authentic standards prior to ESI-MS/MS analysis. Quantification of samples was based on standard t_R's and area values. Further characterization of the PAC sample was accomplished by diol-phase HPLC-ESI-MS/MS. The same instrumentation and MS conditions were used as for the reversed-phase analyses described above. A full scan was performed over the mass range of 200 to 3000 Da at a rate of m/z 13 000 per second. Each mass spectrum generated was based on an average of five scans. PAC identity was determined based on t_R mapping, m/z comparison with those reported in the literature, and MS/MS fragmentations.

Statistical Analysis. All colorimetric and fluorescence assay measurements were repeated a minimum of three times. The results were expressed as mean ± standard deviation.

RESULTS AND DISCUSSION

On the basis of gravimetric analyses, the lipid content of the pecans ranged from 68 to 78 g oil/100 g nutmeat and the acetonic fraction yields ranged from 6.0 to 9.2 g fraction/100 g nutmeat. The eight best-performing defatted pecan nutmeat acetonic extracts, in terms of the H-$ORAC_{FL}$ assay, were selected to generate a composite product. The extracts selected exhibited antioxidant activities ranging from 18.0 to 25.5 mmol Trolox equivalents/100 g nutmeat. It was assumed that the antioxidant activity (comprehensive results not shown) was chiefly attributable to the phenolic constituents; hence, a pooled extract of the "top performers" likely would contain a complete phenolic profile that one could find in U.S. pecans.

Fraction Determination. Fractions eluting from the Sephadex LH-20 column with 95% (v/v) ethanol were analyzed spectrophotometrically. Pooling, based on observed similarities and differences in the spectra of the samples, yielded five fractions (Figure 1). Fraction I possesses a large band at ∼240 nm and a smaller one at ∼350 nm. As fraction I transitioned to fraction II, there appeared to be a shift to the left of the peak maximum. Fraction II can be characterized by a maximum absorbance at 208 nm and then a gradual decrease in absorbance with increasing wavelength. There is a slight increase in the absorbance at ∼260 nm. The transition from fraction II to fraction III was characterized by an increase in bands at 255 and 278 nm. Final development of fraction III was represented by a large peak at ∼210 nm and a secondary one with a maximum at 278 nm. The transition from fraction III to IV was identified by a drastic increase in absorbance at ∼250 nm. Fraction IV contained a peak maximum at ∼255 nm with minor peak maxima at 208 and 354 nm. Fraction V was highlighted by a reduction in all peaks to ∼0 with only a slight band at 210 nm. After freeze-drying, the mass of each fraction was recorded: fraction I comprised 77.4% of the total mass fractionated. The acetonic tannin fraction, referred to as VI, represented 16.5% of the mass. Fractions II, III, IV, and V each constituted less than 5% of the total mass with mass percentages of 3.6, 0.6, 1.0, and 0.7%, respectively.

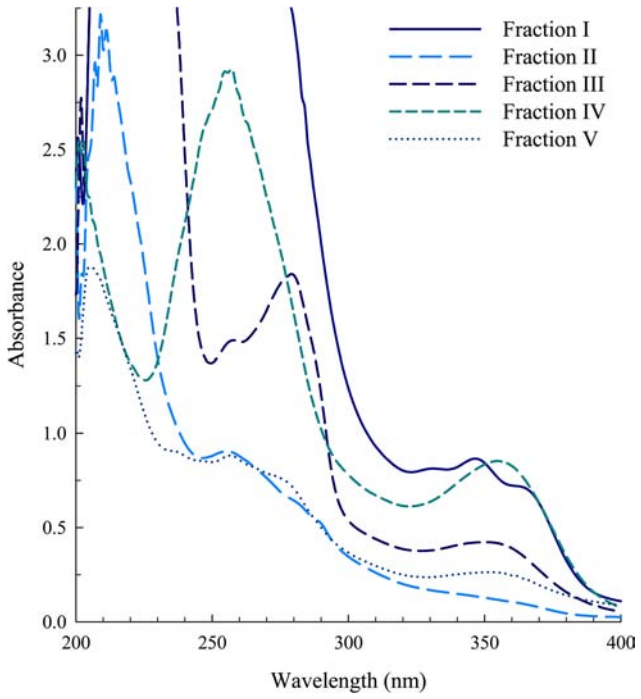

Figure 1. Spectral characteristics of five ethanolic fractions (I−V) isolated from a defatted pecan crude acetonic extract using Sephadex LH-20 column chromatography.

TPC Assay. The TPC was determined for each of the pooled fractions (Table 1). The TPC value is an indication of the quantity of phenolic compounds in a test sample, and it can potentially provide information as to the antioxidant capacity of

Table 1. Total Phenolics Content (TPC) of Five Ethanolic Fractions from a Pecan Crude Acetonic Extract Isolated by Sephadex LH-20 Column Chromatography

fraction[a]	TPC[b,c] (mg (+)-catechin equivalents/g fraction)
I	48 ± 1
II	67 ± 3
III	198 ± 4
IV	169 ± 2
V	180 ± 4

[a]Fractions I–V were eluted from the Sehpadex LH-20 column with 95% (v/v) ethanol. [b]Results are reported as mean ± standard deviation based on triplicate measurements. [c]Because of the high ellagic acid content in fractions II–IV, the TPC was also expressed as ellagic acid equivalents based on an ellagic acid standard curve. These values were 47 ± 2, 77 ± 4, 300 ± 7, 251 ± 3, and 269 ± 7 mg ellagic acid equivalents/g fraction for fractions I, II, III, IV, and V, respectively.

an extract. Fractions I and II exhibited markedly lower TPC values than fractions III–V. Fraction III gave the highest TPC value of 197 ± 4 mg CE/g fraction. Similarly, fractions IV and V exhibited marked values. This indicates that most of the phenolic compounds within the ethanolic fractions are present in fractions III–V. Because the majority of the phenolic compounds present in fractions II through IV were ellagic acid or its derivatives, the TPC was also determined in ellagic acid equivalents (EAE) (see footnote *c* of Table 1). These values ranged from 47 ± 2 mg EAE/g fraction for fraction I to 300 ± 7 mg EAE/g fraction for fraction III. Fractions IV and V had similar contents of 251 ± 3 and 269 ± 7 mg EAE/g fraction, respectively.

RP-HPLC Characterization of Pecan Phenolics. RP-HPLC was employed to profile the phenolics in the pooled ethanolic fractions. Four main groups of phenolic acids were identified across the five fractions, namely, gallic acid, protocatechuic acid, (+)-catechin, and ellagic acid. These compounds were quantified in each sample and reported as mg phenolic/g fraction (Table 2). Although fraction IV possessed only a small quantity of these four phenolic acids relative to the other fractions, it should be noted that several procyanidin dimers were identified in this fraction. Furthermore, fraction V displayed no peaks in the wavelength range of 250 to 350 nm by UV detection and did not appear to contain any phenolic acids identifiable by RP-HPLC. It was suspected that the ethanol may have eluted some of the LMW tannin compounds within the defatted pecan crude acetonic extract. This was confirmed through the use of diol-phase HPLC and by observing the spectral pattern of fraction V (Figure 1): both monomers and dimers were identifiable.

Table 2. Phenolic Acid Contents in Five Ethanolic Fractions from a Pecan Crude Acetonic Extract Isolated by Sephadex LH-20 Column Chromatography

fraction	gallic acid	protocatechuic acid	catechin[a]	ellagic acid[b]
I	nd[c]	tr[d]	nd	nd
II	tr	nd	16.5	31.7
III	nd	nd	35.5	41.3
IV	nd	nd	nd	4.97
V[e]	nd	nd	nd	nd

[a]Catechin values include free (+)-catechin, catechin hexoside, and (epi)catechin gallate. The data are expressed as mg catechin equivalents (CE)/g fraction. [b]Ellagic acid contents include free ellagic acid and all other ellagic acid derivatives. All data are reported as mg ellagic acid equivalents/g fraction. [c]nd = not detected; limit of detection (LOD) = 4.0, 0.74, 9.2, and 5.3 ng/mL for (+)-catechin (C), protocatechuic (PR) acid, gallic (G) acid, and ellagic acid (E), respectively. [d]A peak was detected, but not quantifiable. Limit of quantification (LOQ) = 12.7, 2.5, 30.6, 17.6 ng/mL for C, PR, G, and E, respectively. [e]Diol-phase HPLC-ESI-MS/MS confirmed the presence of low-molecular-weight tannin constituents in this fraction.

Fraction I contained a high amount of "filler" (i.e., nonphenolic constituents such as simple sugars) isolated from the defatted pecan crude acetonic extract. Even though it possessed the greatest mass content of the fractions, it displayed the lowest TPC. In fact, there were practically no identifiable phenolic acids present in the chromatogram of fraction I: the only two phenolic acids identified were protocatechuic acid and caffeic acid (see Table 3). Fraction II also displayed a comparatively lower TPC than that of fractions III through V. Six main phenolic acids, or their derivatives, were identified in fraction II: caffeic, gallic, protocatechuic, (+)-catechin, *p*-hydroxybenzoic, and ellagic acids (see Figure 2 and Table 3). While gallic acid was identified based on its t_R and UV spectrum, it was present below the limit of quantification. The (+)-catechin and ellagic acid (and their derivatives) contents of fraction II were determined to be 16.5 and 31.7 mg/g fraction, respectively. Both the (+)-catechin and ellagic acid derivatives were calculated as equivalents of the parent compound (NB, calculation was based on the standard curve of ellagic acid for all ellagic acid derivatives). This ellagic acid majority can be observed in the spectra of fraction II (Figure 1). There is a large peak below what could be expected for any of these phenolic acids, and then there is a slight rise around 255 nm signifying the presence of ellagic acid or a derivative. On the basis of the spectral pattern for fraction III, it was assumed that a high proportion of this fraction consisted of ellagic acid due to its peak maximum near 255 nm (Figure 1). Via RP-HPLC this was confirmed. Fraction III is composed of mainly ellagic acid and its derivatives but also includes some catechin derivatives. Table 2 shows that including the (epi)catechin gallate content, fraction III possessed 35.5 mg catechin/g extract and 41.3 mg ellagic acid/g extract. Fraction IV contained mainly procyanidin dimers along with a few ellagic acid derivatives. Originally, it was believed that this fraction contained a large quantity of catechin derivatives, based on the UV spectral pattern observed for the eluted peaks compared to that of a (+)-catechin and (−)-epicatechin commercial standard. After HPLC-ESI-MS/MS analyses, however, it was determined that these peaks were actually that of the PAC dimers (see Table 3).

No free caffeic acid was detected in any of the fractions. But a caffeic acid hexoside was identified in fractions I (F1-1), II (F2-2), III (F3-2), and IV (F4-1). The t_R's for this compound ranged from 2.69 to 4.00 min depending on the fraction analyzed. This variation in t_R may be due to slight differences in the caffeic acid hexoside structure, such as type or number of glycosidic moieties present. All four compounds exhibited a molecular ion $[M - H]^-$ at m/z 341 with a MS^2 fragment at m/z 179 corresponding to caffeic acid. Aiding in the identification of these compounds was the neutral loss of 162 amu, which is often associated by the presence of hexosides.[16] Fractions I and II both had a protocatechuic acid derivative present (F1-2 and F2-10); this identification was determined based on similarities between the UV spectrum of these peaks and that of a protocatechuic acid standard, as well as the MS^2 ion of m/z 153

[a]Retention time (t_R) from RP-HPLC analysis. [b]Tentative identifications were achieved using t_R mapping and fragmentation-pattern comparison to those of commercial standards as well as compounds previously reported in pecans by Boulekbache-Makhlouf et al.[16] and de la Rosa et al.[17] Abbreviations are as follows: HHDP glucose = bis(hexahydroxydiphenoyl)glucose; PD2A = proanthocyanidins A-type dimer; PD2B = proanthocyanidins B-type dimer.

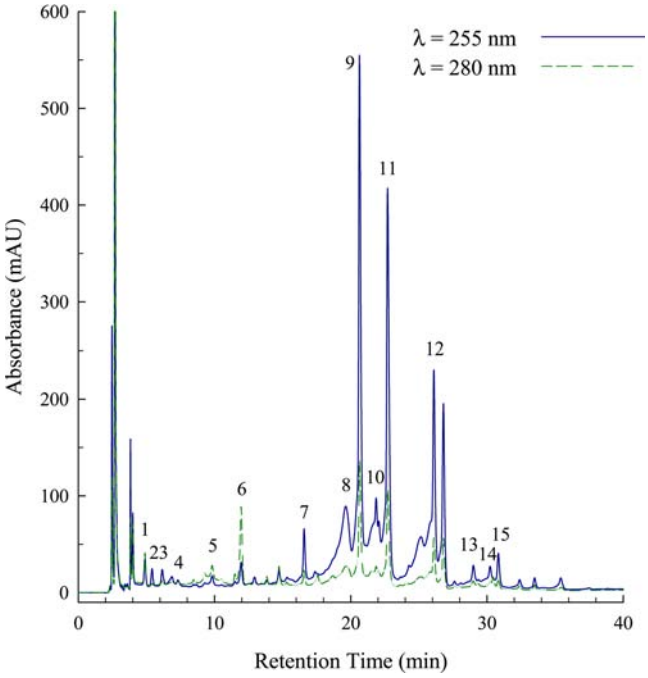

Figure 2. Reversed-phase HPLC chromatogram at λ = 255 and 280 nm of fraction II isolated from a defatted pecan crude acetonic extract on a Sephadex LH-20 column using 95% (v/v) ethanol. The phenolic acids identified were as follows: (1) gallic acid; (2) *p*-hydroxybenzoic acid; (3) a gallic acid hexoside; (4) a protocatechuic acid hexoside; (5) (+)-catechin; (6) an ellagic acid hexoside; (7) an ellagic acid pentose; (8) a methyl ellagic acid hexoside; (9) ellagic acid; (10) a dimethyl ellagic acid hexoside; (11) a methyl ellagic acid pentose; (12) a methyl ellagic pentose; (13) a dimethyl ellagic acid pentose; (14) a methyl ellagic acid galloyl pentose; and (15) dimethyl ellagic acid.

representing protocatechuic acid itself. Peak F2-10 is tentatively identified as a protocatechuic acid hexoside due to the neutral loss of 162 amu. While this loss is not observed in peak F1-2, the loss of 180 amu may be indicative of a hexoside and water group [loss of 162 + 18 amu]. The only fraction to include *p*-hydroxybenzoic acid was fraction II (F2-7), which was identified based on a comparison of its $[M - H]^-$ and UV spectral pattern to a commercial standard. Gallic acid was also identified only in fraction II and was present in two different forms: free gallic acid (F2-6) and as two gallic acid hexosides (F2-3 and F2-8). The free gallic acid eluted with a t_R of 4.90 min and had a $[M - H]^-$ of m/z 169, consistent with those observed for commercial standards. The other two peaks (F2-3 and F2-8) were identified to be gallic acid hexosides. Both hexosides were identified based on their fragment ions at m/z of 169, indicating the presence of gallic acid, as well as a neutral loss of 162 amu commonly associated with hexosides. There may be slight differences in the structure of these hexosides due to the presence of a second MS^2 fragment of m/z 125 for F2-6.

Ellagic acid and its derivatives accounted for almost one-third of the peaks present in four fractions. Fractions II, III, and IV all possessed several forms of this phenolic acid. Free ellagic acid (F2-25 and F3-15) was identified by its molecular ion $[M - H]^-$ at m/z of 301 and by matching t_R's and UV spectra with those of a commercial standard. Both ellagic acid hexoside and methyl ellagic acid hexoside were found in the analyzed samples (F2-17, F2-24, and F3-18). These could be identified at m/z 463 for $[M - H]^-$, the presence of a MS^2 fragment at m/z of 301 (or 315 in the case of a methyl ellagic acid hexoside), and a neutral loss of 162 amu indicating the cleavage of a hexose. Similar methyl ellagic acid derivatives have been previously reported in pecans by de la Rosa et al.[17] and in *Eucalyptus globulus* fruit by Boulekbache-Makhlouf et al.[16] Two ellagic acid pentoses were tentatively identified (i.e., F2-22 and F3-12) by their MS^2 fragment of m/z 301 and neutral loss of 132 amu, commonly associated with the loss of a pentoside.[16] A third group of compounds from the ellagic acid family, namely, methyl ellagic acid pentoses, were identified in fraction II, F2-27 and F2-28. These compounds displayed the same fractionation pattern as the ellagic acid pentoses with the addition of 15 amu to the m/z commonly associated with a methyl group. This "m/z increase" was also observed with the methyl ellagic acid hexosides (F2-24 and F3-18) compared against the ellagic acid hexosides reported above. These ellagic acid derivatives have been previously identified based on fragmentation patterns in other ellagic acid-rich products such as the fruit of *Eucalyptus globulus*, blackberries, and camu-camu.[16,18,19] Several other derivatives of these compounds and additional side groups were identified in the fractions isolated: dimethylellagic acid pentose (F2-30); dimethylellagic acid hexose (F2-26); methylellagic acid galloyl pentose (F2-31, F3-23, F3-24, and F3-25); digalloylellagic acid (F3-13); ellagic acid galloyl pentose (F3-20, F3-22, F4-11, and F4-12); ellagic acid HHDP glucose (F4-3); and dimethylellagic acid (F2-32). All of these compounds were identified based on key fragmentation patterns highlighted previously and comparison to literature sources.[16,19] Similar ellagic acid derivatives, namely, methyl ellagic acid, ellagic acid pentose, and ellagic acid rhamnose derivatives, were reported by de la Rosa et al.[17] in pecans from Mexico. Somewhat surprisingly, valoneic acid dilactone was identified in fraction III (F3-17) based on its key fragmentation ions of m/z 469 and 425. This compound has been previously identified in pecans and is a suspected

ellagitannin degradation product.[17] The authors were not expecting to observe this in a sample of LMW phenolic acids or a nonhydrolyzed sample. However, it should be noted that two other polymeric compounds, procyanidin A- and B-type dimers, also eluted in fraction III, signifying that it may be possible for some higher MW polymeric compounds to elute in the ethanolic fractions of a Sephadex LH-20 column.

The next prominent class of compounds found in these fractions was (+)-catechin and its derivatives. Free (+)-catechin was identified in fractions II and III with a $[M - H]^-$ at m/z 289 and a t_R of 9.61 and 9.82 min, respectively. Several catechin hexosides (F2-9, F2-11, F2-13, and F2-14) were also present in fraction II with t_R's ranging from 6.87 to 9.31 min. All of these peaks possessed a molecular ion $[M - H]^-$ at m/z 451 and were identified based on a daughter ion at m/z 289 and a neutral loss of 162 amu. In addition, several other forms of catechins were identified in the analyzed fractions. For instance, fraction I contained either epigallocatechin gallate or gallocatechin gallate at peak F1-5 with a t_R of 30.12 min and a molecular ion $[M - H]^-$ at m/z 457. Fraction III also contained (epi)gallocatechin (F3-5), (epi)catechin gallate (F3-9, F3-14, and F3-16), and ethyl gallate (F3-11).

Fraction IV contained no (+)-catechin or (−)-epicatechin monomers, but there were several peaks corresponding to procyanidin dimers (F4-2, F4-4, F4-5, F4-6, F4-7, F4-8, F4-9, and F4-10). Both procyanidin A- and B-type dimers were represented in this fraction. The A-type PAC peaks were identified by a molecular ion $[M - H]^-$ at m/z 575 and fragment ions at m/z 425, 407, and 289. No previous literature studies have identified A-type linkages present in pecan samples. However, they have been previously reported in peanut skins[20] and almonds.[21] In the peanut skin samples, Sarnoski et al.[20] also observed similar fragmentation patterns for a PAC dimer with A-type linkages. The authors found no other compounds with a similar MW and expected fragmentation patterns that would be a logical alternative to the PAC dimer. While the PD2A fragmentation patterns match well with those reported in peanut skins,[20] a more in-depth study of these compounds is warranted for a proper identification. Exact mass data and further information regarding the specific fragmentation patterns of the compound would be useful. A PAC dimer with B-type linkages, procyanidin 2B, was identified by a molecular ion $[M - H]^-$ at m/z 577 and neutral losses of 152 and 170 amu.

Currently, there is no other study in the literature that attempts to examine individual fractions of pecans separated by Sephadex LH-20 column chromatography with two mobile phases or identifies the presence of as many phenolic acid derivatives. Malik et al.[22] used Sephadex LH-20 chromatography to separate compounds within pecan extracts, but only employed a single mobile phase of 80% (v/v) methanol. The main phenolic acids identified in the present study match those previously reported in pecans[5,17,23] and also characterize others. Malik et al.[22] identified gallic acid, (+)-catechin, caffeic acid, ellagic acid, and some derivatives in their samples, but also had three additional phenolic acids that were not identified in our samples; they were catechol, *m*-coumaric acid, and chlorogenic acid. These discrepancies could be due to differences in the HPLC conditions employed as well as variations in pecan cultivar selection and growing location. Similar phenolic acids have previously been reported in other tree nut types. For example, John and Shahidi[24] identified gallic acid, protocatechuic acid, (+)-catechin, ellagic acid, and their derivatives in Brazil nut samples. Milbury et al.[25] investigated the phenolic acids in almonds and identified (+)-catechin, protocatechuic acid, and *p*-hydroxybenzoic acid, as well as other phenolic acids not identified in the pecan samples. Qualitative and quantitative comparison between our findings with those in the literature is difficult due to the chosen data reporting style. We believe that for this study it is best to present the data on a mg phenolic/g fraction basis. The current literature reports the data as mg/g pecan. Even though a gravimetric analysis was conducted and all recoveries were calculated, we believe that some phenolic material may have been lost during the spectrophotometric analysis. It is believed that accuracy would be lost if contents were extrapolated to the pecan nutmeat level.

Diol-Phase HPLC Characterization of Pecan Phenolics. The tannin fraction, isolated on Sephadex LH-20 using 50% (v/v) aqueous acetone as the mobile phase, was analyzed via diol-phase HPLC in order to tentatively identify the DP represented in the sample. Further investigation into the composition of this fraction was then accomplished by ESI-MS/MS analyses. The pooled cultivar possessed DP from monomers through hexamers (Figure 3). On the basis of a set of PAC standards,

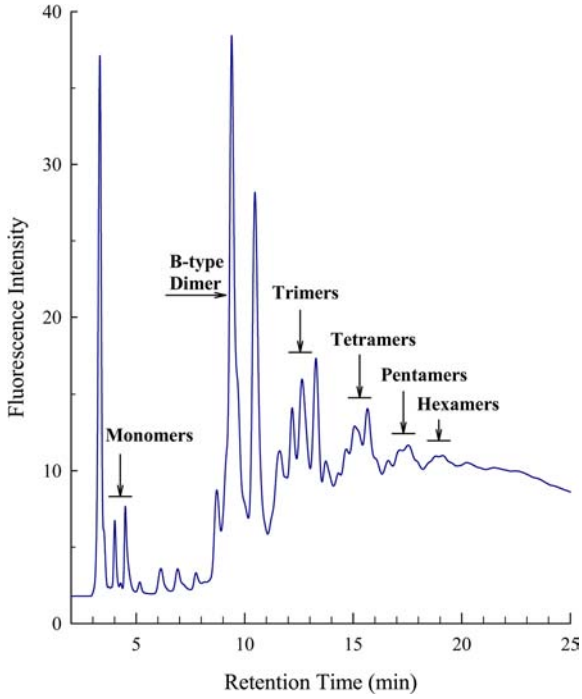

Figure 3. Diol-phase HPLC chromatograms for the tannin fraction isolated from eight pooled pecan cultivars. Fluorescence detection was employed with excitation/emission at λ = 276/316 nm, respectively.

monomers eluted from the diol-phase HPLC column roughly between 3 and 5 min; dimers, 7−11 min; trimers, 12−14 min; tetramers, 14−16 min; pentamers, 17−18 min; hexamers, 18−19 min; heptamers, 20−21 min; octamers, 21−22 min; nonamers, 22−23 min; and decamers, 23−24 min. The sample had 17.7% of its PACs represented by tetramers or larger polymers (Table 4). The greatest proportion of the tannin fraction was attributed to dimers, representing 56.6% of the tannin fraction. The next largest DP was the trimers, accounting for 25.3% of the total. The content of (+)-catechin + (−)-epicatechin monomers in the sample was only 0.289 mg/g tannin fraction. This low value was expected because the majority of the monomers should be present in the ethanolic

fraction(s). These findings demonstrate that the tannin fractions, in particular those with higher DP, may play a role in determining the observed *in vitro* antioxidant activity of a sample.

A deeper examination of the PAC composition was completed using diol-phase HPLC-ESI-MS/MS analyses. After completing a full scan over the mass range of 200 to 3000 Da, a search of common PAC mass ions from the literature[20,26] was undertaken: nine compounds were identified in the acetonic fraction (i.e., fraction VI; see Table 5). All of the

compounds present in the sample exhibited a B-type linkage, which was to be expected based on literature reports of pecan PACs.[8] Interestingly, the tannin fraction possessed both procyanidin and prodelphinidin compounds. Two PACs, one procyanidin and one prodelphinidin, were detected for each DP with the exception of the dimer, which had a single identification, and the hexamers, which were both prodelphinidins. The single dimer is composed of two (epi)catechin units based on a t_R of 6.5 min and a molecular ion $[M-H]^-$ at m/z 577. The two trimers identified in the pecan sample had molecular ions $[M-H]^-$ at m/z 865 and 881 and eluted at a t_R of 9.7 and 11.0 min, respectively. On the basis of the $[M-H]^-$, these compounds were identified as possessing 3 (epi)catechin units and 2 (epi)catechin + 1 (epi)gallocatechin unit. The two detected trimers differed in their molecular ions by 16 amu, and this trend continued for the three larger DP of m/z at 1153−1169, 1441−1457, and 1745−1761.

Gu et al.[8] stated that PACs are present in numerous different food types including pecans. These authors reported that the monomers, dimers, trimers, 4−6mers, 7−10mers, and >10mers constituted 3.4, 8.5, 5.3, 20.5, 17.0, and 45.2%, respectively, in pecans. It should be noted that in the present study we did not find any PACs larger than hexamers. With the removal of the 7−10mers and >10 mers from the Gu et al.[8] data set, the monomers, dimers, trimers, and 4−6mers now account for 9.2, 22.5, 13.9, 54.3%, respectively. In comparison to the prevalence of tetramers through hexamers in the former study, the present one found dimers to be most abundant. Earlier methods of PAC analysis (i.e., TLC analysis, RP-HPLC, and early normal-phase HPLC methods) were discredited for failing to separate compounds with DP > 4.[27] In preparing for this research, standards were run with DP of 8, 9, and even 10 with excellent resolution and detection on the diol-phase column and the fluorescence detector. For this reason, we believe that any PACs with DP > 7 would have been visible with this methodology and no suppression of ions occurred. In a study by Kelm et al.,[15] in which the diol-phase HPLC methodology was first introduced, there was also excellent resolution up to a DP = 14. On the basis of Kelm et al.[15] and the employment of the diol-phase column, we believe that PACs with higher DP would be properly resolved if they had been present in the defatted pecan acetonic extract. This was further confirmed by the MS data. No ions corresponding to PACs with a DP higher than 6 were identified in the sample. While the authors believe that all of the PACs containing (+)-catechin and (−)-epicatechin monomers were identified and quantified, there may be some PACs that are not properly captured with the fluorescence detector. Lazarus et al.[28] points out that fluorescence detection cannot be used for the identification of PACs with gallocatechin and gallic ester components. Further HPLC investigation of these compounds using diol-phase diode-array detection is necessary. Additional information regarding specific composition, monomer position, and length of the PACs could be acquired using the thiolysis preparation technique coupled with HPLC characterization. In thiolysis, individual PAC units are separated into end units and interior units through an acid-catalyzed cleavage of the interflavan bonds.[29] After cleavage, the interior unit intermediates are reacted with toluene α-thiol, forming thiol-flavonol adducts, and the end units remain as flavanol monomers.[29,30] These thiol adducts can then be separated and identified with HPLC analysis to give a better picture of the average DP of the PACs, as well as the position and type of the monomeric units.[30] We are not aware of any literature studies that have investigated pecan PACs using a thiolysis step.

It has also been noted that when PACs are separated on Sephadex LH-20 via isocratic elution, the first compounds to elute will be those PACs with smaller MWs and the heavier ones will elute last.[31] A possible reason for a reduction in the quantity of HMW PACs in our study could be that a sufficient quantity of the aqueous acetone was not employed to elute all PACs from the column. However, based on the mass balance performed in this work, it is not possible that this could account for the extreme differences observed. A total of 1.92 g of crude extract was loaded onto the Sephadex LH-20 column, and a mass of 1.90 g comprising the various fractions was recovered after lyophilization. This signifies that 99% of the crude extract applied to the column was recovered via the chromatography and that very small quantities of higher DP, if they existed, might remain on the Sephadex LH-20 column. Unfortunately the Gu et al.[8] study is the only literature source that quantifies and characterizes PAC components of pecan nutmeat. Further

and more extensive characterization of these compounds is necessary to determine more information about the contents of pecans, in particular the HMW PACs. By utilizing exact mass HPLC/MS technologies, one might be able to further elucidate the structure of these compounds in pecans from various growing locations and cultivar types. HPLC/MS^n analysis has previously been used to gain excellent information regarding the PAC profile of peanut skins.[20]

Researchers aim to quantify and characterize phenolic compounds in natural products due to their beneficial health benefits. The PAC compounds have been shown to remain intact in the low pH environment of the stomach and arrive to the small intestine intact.[32] In this form, the PACs are unable to be absorbed in large quantities.[10] However, colon microflora is able to breakdown PAC polymers to smaller metabolites that can be absorbed and utilized.[10] The full benefit of these metabolites is not fully understood, thereby making predictions of the biological activity of higher degree polymers difficult. Hudthagosol et al.[6] demonstrated adroitly that concentrations of the main PAC monomers, (+)-catechin and (−)-epicatechin, increased in the plasma of individuals after pecan consumption; these results are encouraging. Further research on the bioaccessibility (i.e., the extent of release of nutrients/phytochemicals from the food matrix during digestion) and the bioavailability (i.e., the extent of absorption and utilization of released nutrients/phytochemicals for normal physiological functions) of phenolic constituents and PACs of pecans need to be investigated to gain better insight into the role of these compounds in disease prevention.

ABSTRACT: The butyrate production by engineered *Escherichia coli* is afflicted by both low titer and low selectivity (defined as the butyrate/acetate (B/A) ratio). To address this issue, a strategy for metabolic engineering of *E. coli* was implemented including (1) elimination of all major NADH-dependent reactions in the fermentation metabolism, (2) reconstruction of a heterologous pathway leading to butyryl-CoA, (3) recruitment of endogenous *atoDA* for conversion of butyryl-CoA to butyrate with acetate as a CoA acceptor, and (4) removal of the acetate-synthesis pathway. Grown on glucose (20 g/L) plus acetate (8 g/L), the engineered strain consumed almost all glucose and acetate and produced 10 g/L butyrate as a predominant product within 48 h. It leads to high butyrate selectivity with the B/A ratio reaching 143. The result shows that our proposed approach may open a new avenue in biotechnology for production of butyrate in *E. coli*.

KEYWORDS: *butyric acid, Escherichia coli, metabolic engineering*

INTRODUCTION

Butyric acid is a short-chain fatty acid and has a broad range of applications in industry. Its derivatives such as butyrate esters are applied for fragrant- and flavor-enhancing agents in beverages, food, and cosmetics.[1,2] A polymer prepared from butyric acid and cellulose acetate can be utilized for the manufacture of plastics and textile fibers.[3,4] Serving as therapeutic prodrugs, the derived forms of butyrate are shown to exhibit an anticancer effect.[5] In addition, the commercial value of butyric acid is greatly acknowledged for its role as a precursor of biofuels, such as *n*-butanol. The approach by catalytic conversion of butyric acid to *n*-butanol is reportedly feasible by either biotransformation with microbes or the hydrogenation reaction using chemical catalysts.[2,6] *n*-Butanol is superior to ethanol for replacing gasoline in many ways.[7] Therefore, production of *n*-butanol from renewable resources (i.e., biobutanol) has recently gained a spotlight in both the academic and industry communities. It is conceived that the commercial availability of biobutanol enables a large reduction of the greenhouse effect caused by enormous consumption of fossil fuels.

Butyric acid currently on the market is mainly produced by a chemical synthesis method with the resource coming from crude oils.[8] However, the overwhelming concern of global warming and the rising desire for natural products have driven industrial attention toward fermentative production of butyric acid. *Clostridium* species, Gram-positive and strictly anaerobic bacteria, have long been investigated for the production of butyric acid because of their higher productivity and production titers. Many fermentation strategies have been proposed to achieve high butyrate production.[9] Nevertheless, the clostridial fermentation pattern is too complicated to operate. It needs careful investigation of key factors that affect butyrate production to optimize the fermentation process.[2] A typical fermentation feature of *Clostridium* involves the acidogenesis phase followed by the solventogenesis phase.[10] In the first phase, butyrate, acetate, and hydrogen are major products. Upon entry to the stationary phase, reassimilation of produced acids at the second stage leads to production of acetone, *n*-butanol, and ethanol, known as the ABE fermentation.[11] In addition, less availability of genetic tools and physiological information also hinders the advance of the butyrate production process based on *Clostridium*.

Escherichia coli is known as a biotechnology workhorse because it can be easily cultured and genetically manipulated. Moreover, its physiological information and fermentation technique are generally available. Intensive studies have been directed toward development of *E. coli* for the production of biofuels and high-value chemicals.[12,13] To improve the production efficiency, metabolic engineering of *E. coli* for the desired trait appears to be the most commonly adopted approach. This technique enables the evolution of living cells in a short time frame.[14,15] In general, strain improvement by metabolic engineering requires a strategy that includes deletion of undesired pathways, removal of bottleneck nodes, and/or extension of metabolic pathways leading to heterologous products.[16] Based on these strategies, recent studies have illustrated functional reconstruction of the *Clostridium* pathway in *E. coli*.[17,18] This advancement is conducive to the study on

production of butyrate by *E. coli* with the report of the production titer in the range 1.3−4.3 g/L.[19,20] The production titer is later improved to reach 7.2 g/L by a technique combining synthetic scaffolds and fed-batch cultivation.[21]

In this study, a biosynthetic pathway leading to butyrate was reconstructed in *E. coli*. Utilizing glucose and acetate as the substrates, the engineered *E. coli* strain was able to produce >10 g/L butyrate as a predominant product. This indicates the promise of this approach for the production of butyrate in the surrogate *E. coli* strain.

MATERIALS AND METHODS

Gene Deletion and Insertion. The main strains, plasmids, and primers applied in this study are listed in Table 1. DNA manipulation was routinely conducted using strain DH5α(pir) as the intermediate strain. Derived from *E. coli* strain BL21, strain BL-A1[22] was utilized for the experiment. The *frdA* gene of strain BL-A1 was deleted essentially following the previous report.[23−25] In brief, the DNA fragment containing *frdA* inserted with the FRT-*kan*-FRT cassette was amplified by polymerase chain reaction (PCR) from strain CGSC10964 with primers FrdA1 and FrdA2. By electroporation, the PCR DNAs were introduced into the strain carrying *λ* Red-borne plasmid pKD46.[26] Under the nonpermissive condition for the plasmid, integrants with the inserted DNAs via homologous recombination were selected for resistance to kanamycin but susceptibility to ampicillin. Later removal of the integrated marker from the integrant was carried out using helper plasmid pCP20 as described previously.[26] In a similar way, the DNA bearing *ldhA* inserted with the FRT-*kan*-FRT cassette was amplified from strain CGSC9216 with primers LdhA1 and LdhA2 and utilized for elimination of *ldhA*. Furthermore, *pta* was removed by using the PCR DNA that carries *pta* integrated with FRT-*kan*-FRT from plasmid pMC-ptaKm with primers Pta1 and Pta2.

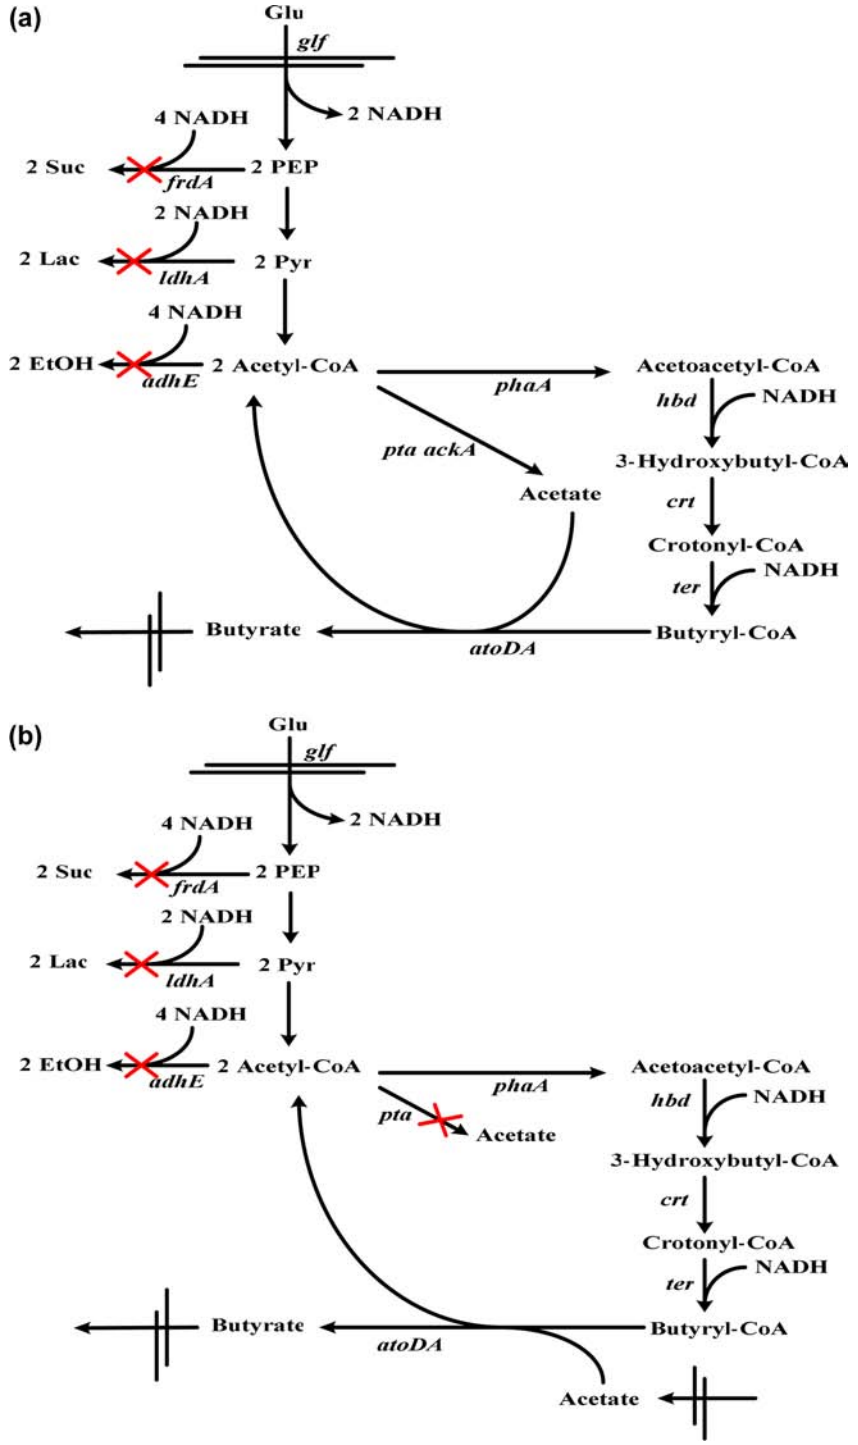

Figure 1. Metabolic pathway leading to butyrate from glucose in *E. coli*. (a) Endogenous acetate system. (b) Exogenous acetate system. The genes involved in the metabolic pathway: *ackA*, acetate kinase; *adhE*, aldehyde-alcohol dehydrogenase; *atoDA*, acetoacetyl-CoA transferase; *ldhA*, lactate dehydrogenase; *frdA*, subunit of *fumarate reductase; pta*, phosphate acetyltransferase; *phA*, *β*-ketothiolase; *hbd,* 3-hydroxybutyryl-CoA dehydrogenase; *crt*, crotonase; *ter,* trans-enoyl-CoA reductase. The deleted genes are marked by "X". Abbreviations: Glu, glucose; PEP, phosphoenolpyruvate; Pry, pyruvate; EtOH, ethanol; Lac, lactate; Suc, succinate.

Insertion of the heterologous genes into *E. coli* was conducted according to the previous report.[22] In brief, plasmid pPhi-Ter that carries the *ter* gene of *Terponema denticola* DSM14222 was transformed into the strain with helper plasmid pAH123,[27] which expresses *ϕ*80 integrase (Int). Under the nonpermissive condition for the plasmid, integrants with insertion of *ter* at *ϕ*80 *attB* were selected for resistance to kanamycin but susceptibility to ampicillin. The integrated marker of the integrant was then removed using helper plasmid pTH19-CreCs as described previously.[23] Subsequently, integration of the *crt* gene from *Clostridium acetobutylicum* DSM792 at *λ attB* was carried out in the same way. Plasmid pLam-Crt was simply transformed into the strain carrying helper plasmid pINT-ts that express phage *λ* Int.[27] Moreover, an extra *ϕ*80 *attB* site was created at *adhE* of the resulting strain. This was carried out by first amplification of the DNA comprising the *ϕ*80*attB*-LE*-*gen*-RE* cassette flanked by two homologous extensions of *adhE* from plasmid

dx.doi.org/10.1021/jf500355p | J. Agric. Food Chem. 2014, 62, 4342−4348

pBlue-P80Gn based on overlapping PCR with primers AdE1/AdE2 and AdE3/AdE4.[23] Followed by electroporation, the PCR DNA was introduced into the strain with plasmid pKD46. Integrants exhibiting the gentamicin-resistant and ampicillin-sensitive phenotype were then scored. One resulting strain was integrated with the gene cluster comprising *phaA* of *Cupriavidus necator* and *hbd* of *C. acetobutylicum* DSM792 at the created ϕ80 *attB* site by using plasmid pPhi-PhaAHbd, thus resulting in the knockout of *adhE*. Finally, removal of the inserted markers was aided with helper plasmid pTH19-CreCs.

Enhanced Expression of Endogenous Genes. Plasmid pPL-Gn was constructed by incorporation of the λP_L promoter ($P\lambda P_L$) into plasmid pBlue-LamGn. This was carried out by the first PCR with primers LPL1 and LPL2, followed by the second PCR with primers LPL1 and LPL3 using the first PCR DNA as the template. The resulting PCR DNA was digested with *Eco*RI and then self-ligated. This resulted in plasmid pPL-Gn carrying the LE*-*gen*-RE* cassette fused with $P\lambda P_L$ (LE*-*kan*-RE*-$P\lambda P_L$). Meanwhile, the DNA containing the upstream region and 5′-end structural sequence of *atoD* was amplified from *E. coli* strain BL21 by PCR with primers RC13034/RC13035. After digestion with *Eco*RV-*Sac*I, the PCR DNA and plasmid pBluescript were spliced together to obtain plasmid pBlue-atoD. The *Nde*I-*Bam*HI sites were then introduced into plasmid pBlue-atoD by PCR with primers RC13036/RC13037. Meanwhile, the DNA cassette bearing LE*-*gen*-RE*-$P\lambda P_L$ was recovered from plasmid pPL-Gn by *Nde*I-*Bam*HI and incorporated into plasmid pBlue-atoD to give plasmid pSPL-atoD. This plasmid carried the passenger DNA that contained the upstream region and the fusion of LE*-*gen*-RE*-$P\lambda P_L$ to the 5′-end structural sequence of *atoD*. By PCR with primers RC13034/RC13035, the passenger DNA was electroporated into the strain with plasmid pKD46. The resulting integrant harbored *atoDABE* driven by $P\lambda P_L$.

Bacterial Culturing. The bacterial growth was measured turbidimetrically at 550 nm (OD_{550}). *E. coli* strains were grown on Luria–Bertani (LB) medium at 37 °C overnight. The overnight culture was then inoculated into 125 mL Erlenmeyer flasks containing 50 mL of modified Terrific broth medium (12 g/L tryptone, 24 g/L yeast extract, 2.13 g/L KH_2PO_4, and 12.54 g/L K_2HPO_4) supplemented with 12 g/L glucose. The initial cell density was kept at an OD_{550} of 0.1. The oxygen-limited culture condition was performed according to our previous report.[23] Bacterial cultures were seeded into Erlenmeyer flasks (125 mL) containing 50 mL of medium and incubated at 37 °C and 100 rpm.

Analytical Methods. Glucose and organic acids (including butyric acid) were analyzed by high-performance liquid chromatography (HPLC) according to the method reported previously.[23] To determine the AtoDA activity, bacterial strains were harvested with 67 mM Tris-HCl (pH 8) by centrifugation after culturing for 24 h. Cells were disrupted using sonication and then fractioned by centrifugation. The supernatant was recovered as cell-free extract (CFX). The enzymatic reaction was then carried out by adding 10 μL of CFX into the reaction solution (90 μL), which consisted of 20 mM butyryl-coA, 0.4 mM sodium acetate, and 67 mM Tris-HCl (pH 8). The reaction proceeded for 20 min and was terminated by heating the solution at 100 °C for 10 min. The butyrate concentration in the reaction was determined by HPLC. The specific enzyme activity was defined as butyrate produced in μmol per min (U) per mg CFX.

RESULTS

Reconstruction of the Butyrate-Synthesis Pathway. The biosynthetic pathway leading to butyrate was developed by starting with *E. coli* strain BL-A1 in several steps (Figure 1). Strain BL-A1 was previously constructed by removal of *poxB*, and its native glucose uptake system was replaced by *glf* (encoding glucose facilitator) from *Zymomonas mobilis*.[22] First, *adhE*, *ldhA*, and *frdA* of strain BL-A1 were eliminated to conserve availability of NADH and to reduce production of waste byproducts. Second, heterologous genes including *phaA*, *hbd*, *crt*, and *ter* each under the control of $P\lambda P_L$ were integrated into the strain to obtain strain BuT-8L. Note that *adhE* of the strain was inactivated after insertion of the *phaA-hbd* gene cluster (see Materials and Methods). The approach resulted in the constructed pathway directing glucose flux to butyryl-CoA (Figure 1). Lastly, the expression level of endogenous *atoDA* in strain BuT-8L was enhanced by fusion of the gene cluster *atoDAEB* with $P\lambda P_L$, resulting in strain BuT-8LA. This final step was recruited to complete the butyrate-synthetic pathway by catalytic conversion of butyryl-CoA to butyrate at the expense of acetate. The functionality of AtoDA was further verified by assaying the enzyme activity. As a result, strain BuT-8LA exhibited 8-fold higher activity than control strain BuT-8L (0.56 vs 0.07 U/mg).

Production of Butyrate in Engineered *E. coli*. Production of butyrate was investigated for the engineered *E. coli* strains. Therefore, shake-flask cultures of strains BuT-8L and BuT-8LA were carried out in the presence of glucose. After 24 h of fermentation, strain BuT-8LA produced 3.4 g/L butyrate as a major product, whereas the butyrate production in control strain BuT-8L was around 1 g/L (Figure 2). The result

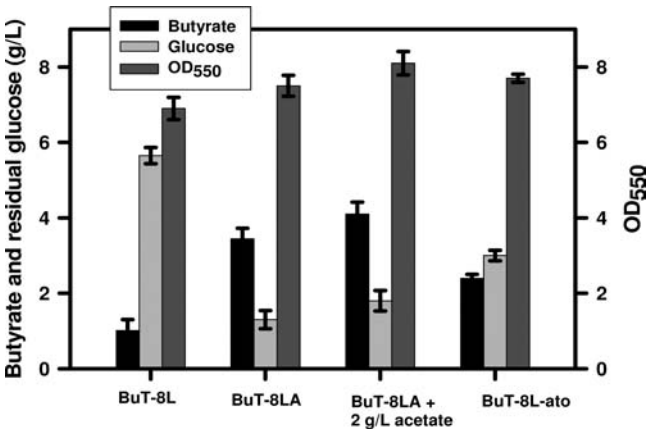

Figure 2. Production of butyrate in the engineered *E. coli* strains. The oxygen-limited fermentation was carried out with shake-flask cultures in the presence of 12 g/L glucose for 24 h. The experiments were conducted in triplicate.

indicates that the constructed pathway in *E. coli* is functional for the synthesis of butyrate. Nevertheless, AtoDA-catalyzed conversion of butyryl-CoA to butyrate requires acetate (Figure 1A). It was informative to investigate the effect of acetate on the butyrate production in strain BuT-8LA (*pta ackA* positive). First, 2 g/L acetate was supplemented in the medium, and the butyrate titer in this strain was increased to 4.1 g/L. Note that *pta and ackA* are mainly responsible for production of acetate in strain BuT-8LA. Moreover, *pta* was removed from strain BuT-8LA to obtain strain BuT-8L-ato. As a result, the *pta*-lacking strain produced less butyrate (2.5 g/L). Taken together, these results suggest that acetate plays a determining role in the synthesis of butyrate.

Effect of Acetate on Butyrate Production. Interestingly, intracellular acetate may be regenerated by coupling the Pta-AckA with AtoDA reactions (Figure 1A). However, this regeneration system in strain BuT-8LA does not seem to function sufficiently to provide acetate which meets the requirement for the butyrate production as illustrated in Figure 2 (i.e, strain BuT-8LA with acetate supplementation). This implies that the butyrate production in the strain is likely limited by the availability of acetate. Therefore, the approach by

supplementation of acetate was expected to improve the production of butyrate (Figure 1B). Strain BuT-8L-ato, deficient in *pta*, was utilized for the experiments. As shown in Figure 3, the strain consumed almost all glucose after 24 h of

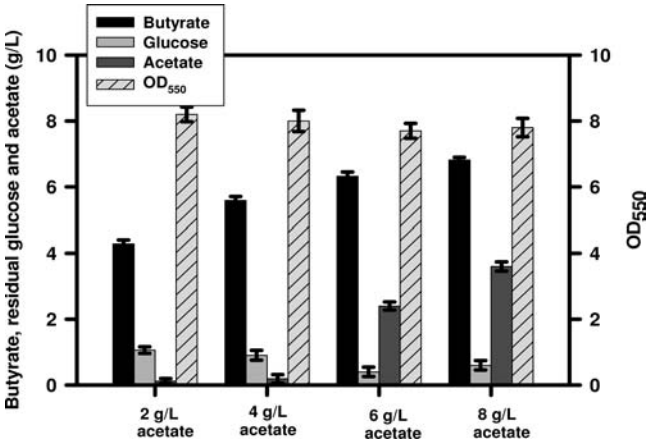

Figure 3. Effect of acetate on the butyrate production in the engineered *E. coli* strain. Strain BuT-8L-ato was grown on 12 g/L glucose supplemented with various concentrations of sodium acetate, and the oxygen-limited fermentation was carried out for 24 h. The experiments were conducted in triplicate.

fermentation, while its butyrate production increased with the increasing amount of supplemented acetate. The butyrate production reached the maximum (6.8 g/L) in the case where 8 g/L sodium acetate was augmented. The result indicates the positive contribution of acetate to the butyrate production.

Butyrate Production by Glucose Feeding. Indeed, it was found that around half of the supplemented acetate (8 g/L) still remained at the end of the fermentation, as illustrated in Figure 3. We reasoned that the strategy by supplementation of extra glucose might be useful to increase the butyrate production at the expense of remaining acetate. Therefore, strain BuT-8L-ato was initially cultured on the medium containing 12 g/L glucose plus 8 g/L sodium acetate. After 24 h, various amounts of glucose were added to the culture medium and the bacterial fermentation was continued. In general, the butyrate production in the strain increased along the time course (Figure 4). The butyrate production finally reached >10 g/L after 48 h of fermentation, when 8 and 10 g/L glucose were additionally supplemented. For the case of 10 g/L supplementation, glucose was not completely consumed by the strain. Nevertheless, there was only a trace amount of acetate (<0.07 g/L) left in the medium for both cases.

DISCUSSION

Clostridium species are native butyrate producers and carry out a butyrate-synthesis pathway typically consisting of *thl*, *hbd*, *crt*, *bcd*, *ptb*, and *buk* genes.[10] The enzymes encoded by the first four genes reduce acetyl-CoA to butyryl-CoA, while the latter two gene products convert butyryl-CoA to butyrate. In this study, the biosynthetic pathway of butyrate was reconstructed in *E. coli* by substitution of *thl* and *bcd* with *phaA* and *ter* from *C. necator* and *T. denticola* DSM14222, respectively. This heterologous pathway was previously proven functional to provide butyryl-CoA for the synthesis of *n*-butanol in *E. coli* by genomic engineering strategy.[23] Moreover, endogenous *atoDA* was employed to complete the synthetic pathway by conversion

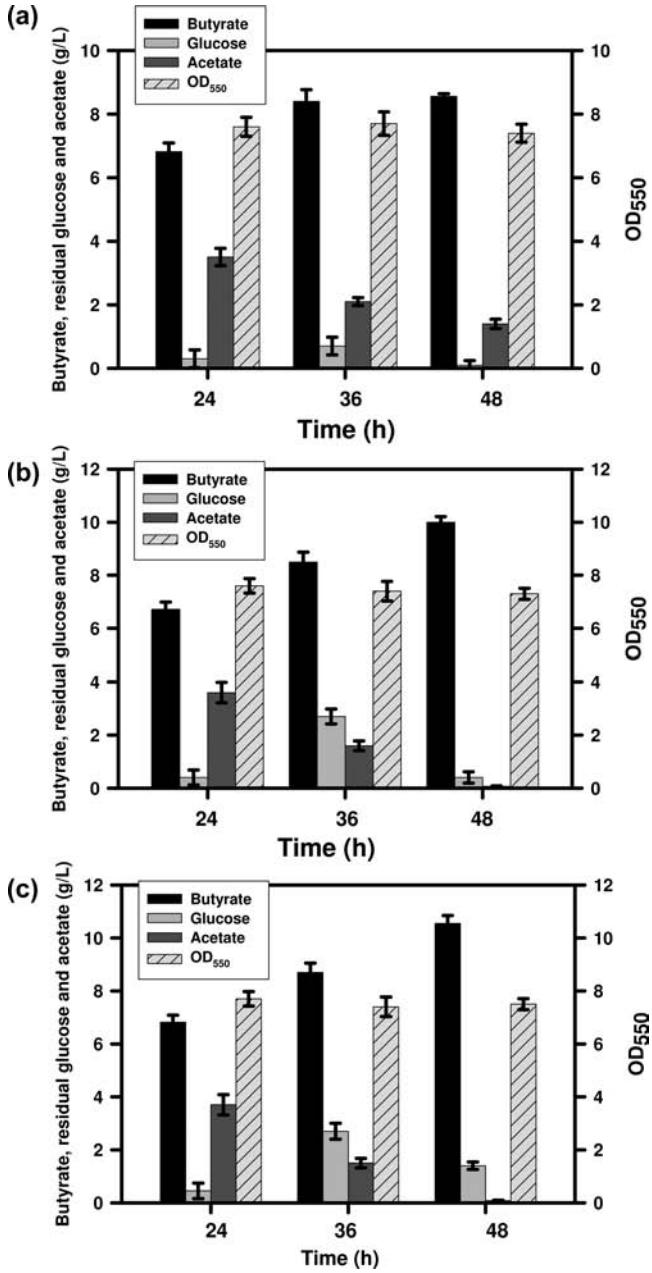

Figure 4. Time course production of butyrate in *E. coli* by glucose feeding. Under the oxygen-limited condition, strain BuT-8L-ato was cultured in the presence of 12 g/L glucose and 8 g/L sodium acetate. After 24 h, extra glucose was added into the culture broth. The experiments were conducted in triplicate. (a) Extra feeding of 6 g/L glucose; (b) extra feeding of 8 g/L glucose; (c) extra feeding of 10 g/L glucose.

of butyryl-CoA to butyrate. As known, AtoA and AtoD constitute the β and α subunits of acetoacetyl-CoA transferase, whose physiological function is responsible for activation of short-chain (C3−C6) fatty acids for their respective thioesters.[28] The *E. coli* strain cannot grow on butyrate unless it has a genotype of *fadR atoC*.[29] The *fadR* null mutation induces the *fad*-encoded β-oxidation enzymes, while the *atoC* constitutive mutation results in the expression of the *atoDAEB* operon, respectively. Therefore, *E. coli* with functional *atoDA* only is unable to assimilate butyrate, which is favorable for the butyrate production. Finally, the endogenous NADH-dependent path-

dx.doi.org/10.1021/jf500355p | J. Agric. Food Chem. 2014, 62, 4342−4348

way nodes were all removed from the central metabolism. This approach turns the heterologous pathway that reduces acetyl-CoA to butyryl-CoA into an electron sink, consequently driving carbon flux to butyrate (Figure 1). Such a strategy by balancing the redox state of cells has been proven useful for fermentative production of desired products.[30−32]

As illustrated in Figure 2, strain BuT-8LA, carrying the constructed synthetic pathway of butyrate, was able to produce butyrate. With the basal AtoDA activity (i.e., 0.07 U/mg), strain BuT-8L produced much less butyrate. AtoDA converts acetate and butyryl-CoA to butyrate and acetyl-CoA. In strain BuT-8LA, the two reactions mediated by Pta-AckA and PhaA can compete for the acetyl-CoA pool. Apparently, the reaction rate of the Pta-AckA step is not on a par with that of the PhaA step, consequently restricting the butyrate production. This view is supported by an increase in the butyrate titer for strain BuT-8LA that received extra acetate. By further removal of *pta*, the resulting strain BuT-8L-ato (*pta poxB* negative) produced 30% less butyrate than strain BuT-8LA (Figure 2). In addition, strain BuT-8L-ato deficient in *pta-ackA* and *poxB* may still synthesize acetate,[33] but perhaps limiting. Therefore, more supplemented acetate results in improvement of butyrate production for strain BuT-8L-ato (Figure 3). It should be noted that the ATP level is probably not a limiting factor in the engineered *E. coli*. As revealed from the synthetic pathway (Figure 1), the butyrate production requires NADH, and the ATP produced at the substrate-level phosphorylation is thus conserved. Acting like *atoDA*, the *ptb-buk* in the *Clostridium* pathway mediates the last synthetic step by generation of ATP per butyrate production. However, the *ptb-buk* expressed in *E. coli* exhibits a nonspecific function and generates crotonate as a byproduct.[34] Note that AtoDA may react with acetoacetyl-CoA to produce acetoacetate. Our analyses showed no detectable levels of acetoacetate and its decarboxylated product, acetone, in the culture broth.

There are a few studies centering on butyrate production in *E. coli*. One earlier approach employed the reverse β-oxidation pathway of fatty acids. Without involvement of any foreign genes, the engineered *E. coli* was shown to produce 1.3 g/L butyrate from 30 g/L glucose after 48 h of fermentation.[19] The result leads to a production yield of butyrate (g/L) on glucose (g/L), defined as $Y_{B/G}$, of 4.3%. Another study introduced the butyrate-synthesis pathway into *E. coli* using the clostridial pathway for reduction of acetoacetyl-CoA to butyryl-CoA and endogenous *tesB* (encoding thioesterase II) for consecutive conversion of butyryl-CoA to butyrate.[20] The result is encouraging, with the butyrate/acetate (B/A) weight ratio reaching 41. To improve the butyrate production based on this constructed pathway, a recent study implemented the synthetic scaffold to couple the three heterologous genes (*hbd*, *crt*, and *ter*) in a spatially organized pathway. Consequently with the fed-batch supplementation of glucose, butyrate production in the strain reached 7.2 g/L from 19 g/L glucose (i.e., $Y_{B/G}$ = 37.9%) at 84 h.[21] However, this approach is afflicted by the associated production of acetate (4 g/L) with the B/A ratio reaching 1.8. The butyrate selectivity (represented by the B/A ratio) is a key factor employed for evaluation of the clostridial fermentation performance since the lower ratio greatly increases the purification cost of butyrate.[9] Even with inactivation of the acetate synthesis, the potential butyrate producer *C. tyrobutyricum* still displayed a B/A ratio ranging between 5 and 7.[35] Most recently, a study reported the reconstruction of the whole butyrate synthetic pathway from *C. difficile* in *E. coli*. The butyrate titer was low (around 0.27 g/L) but with less acetate production.[36] Overall, the results of these previous studies are less impressive due to the low production titer and/or the low B/A ratio. In the present study, a synthetic pathway was designed to produce butyrate at the expense of acetate. This proposed approach resulted in a high butyrate titer as well as a trace amount of acetate and other known organic compounds. Consequently, 10 g/L butyrate could be obtained from 20 g/L glucose plus 8 g/L acetate within 48 h, and the B/A ratio reached 143 (Figure 4B). The butyrate production gives a $Y_{B/G}$ of 50%. In theory, one butyrate can be produced from 0.5 glucose plus one acetate according to the stoichiometry of the synthetic pathway (Figure 1). Therefore, this butyrate production on glucose and acetate accounts for 85.5% of the theoretical yield.

In conclusion, our proposed strategy for the production of butyrate in *E. coli* shows promise in terms of high production titer, productivity, and selectivity (i.e., the B/A ratio). Nevertheless, more efforts are required to improve the current approach. For instance, butyrate and acetate in the un-ionized form exhibit a similar inhibitory effect on *E. coli* metabolism.[37] Therefore, an *E. coli* strain with a high tolerance to the toxicity is expected to be useful for higher butyrate production. This work is currently being undertaken in our lab.

ABSTRACT: Two laboratories independently examined how the amount of starting material influences DNA extraction efficiency and, ultimately, the detection of low-level presence of genetically engineered (GE) traits in commercialized grains. GE traits from one maize, two canola, and two soybean samples were used as prototypical models in the study design as well as two commonly used DNA extraction methods, a small scale (0.1 and 0.2 g samples) and a large scale (1.0 and 2.0 g samples). The DNA samples were fortified (spiked) at 0.1 and 0.01% (w/w) levels. The amount of DNA recovery varied between the two laboratories, although a sufficient amount of DNA was obtained to perform replicate PCR analysis by both laboratories. Reliable detection of all five events was achieved by both laboratories at 0.1% level using either small-scale or large-scale DNA extractions. Reliable detection of the GE events was achieved at 0.01% level for soybean and canola but not for maize. Variability was observed among the two laboratories in terms of the Ct values generated. There was no difference between small-scale and large-scale DNA extraction methods for qualitative PCR detections of all five GE events.

KEYWORDS: *genetically engineered events, PCR, A2704, HCN92, OXY235, DP305423, MIR604, canola, soybean, maize*

INTRODUCTION

As grains move through the production and distribution chain, comingling of similar types and qualities routinely occurs, making the low-level presence (formerly known as adventitious presence) of mixed varieties a reality in bulk grain handling systems. With the advances of modern agricultural biotechnology, complex challenges have been introduced into global markets when trading grains. These challenges have become self-evident between exporting countries that produce a surplus of genetically engineered (GE) agricultural products and importing countries that apply different authorization standards to the same commodities. Grain quality and product compliance measures, based on sound scientific principles and reasonable outcomes, are necessary for the purpose of facilitating marketing of GE grain products. Low-level presence of unapproved or discontinued GE materials in non-GE commercial grains, oilseeds, and foodstuffs has been a contentious regulatory issue that often affects international grain trade.[1,2] A low-level presence of differing varieties potentially occurs when (1) naturally occurring drift of GE pollen, carried by wind and insects, contaminates neighboring fields; (2) planting equipment is shared between different types of farming operations; (3) equipment such as augers, conveyors, and elevators handle both GE and non-GE crops; (4) GE crops comingle with non-GE crops in grain bins and drying equipment; (5) harvesting machinery, such as combines, are utilized to harvest both GE and non-GE crops; and (6) during the field trial stage of development, GE seeds located in test plots infiltrate nearby plots being grown to generate foundation seed.

Two examples of a low-level presence of unapproved GE events that significantly affected commercial grain trade include FP967 flax in Canada[2] and LLRice601 in the United States.[3] Many countries have developed legislation regarding tolerance and traceability requirements for GE traits. However, there is a wide variation in tolerance and traceability requirements among countries, thus affecting grain trade.[1] Some of the challenges for detection of trace levels of GE traits include sampling and sample preparation, the amount of starting material when DNA extraction is performed, the amount of DNA recovered during the extraction, and the integrity of the DNA used for PCR.

According to European Commission Regulation No. 619/2011,[4] reliable detection of GE traits can be achieved at a 0.1% level. For the detection of FP967 transgenic flax event, detection limits of 0.0035%[2] and 0.001%[5] have been reported. However, there are some controversial opinions regarding laboratories' capacity to accurately and reliably detect the low-level presence of GE materials below the 0.1% level.[6] One study in particular suggests that relatively large amounts of starting material for DNA extraction (e.g., 2.0 g) provide better reproducibility and precision in the final analytical result.[7] Many of the commercially available DNA extraction kits cannot be used for extraction of DNA from relatively large amounts of ground samples such as 2.0 g (the kits are usually limited to ≤0.2 g ground material). The traditional sodium dodecyl sulfate (SDS)- and cetylmethylammonium bromide (CTAB)-based methods can be used for extraction of DNA from relatively large amounts of samples such as 1.0−5.0 g. However, both SDS- and CTAB-based DNA extraction methods are time-consuming and tedious. In addition, toxic chemicals such as phenol and chloroform are used for the large-scale DNA extraction methods. To date, the impact of the amount of starting

material for DNA extraction on the reliability of detection of low concentrations of GE traits by PCR has not been systematically studied. Therefore, this study was designed to compare the effect of using small-scale (0.1 and 0.2 g of starting materials) and large-scale (1.0 and 2.0 g of starting materials) DNA extractions on the detection of the low-level presence of GE traits (0.01 and 0.1% fortified or spiked samples) using data collected from two independent laboratories. It was also aimed to determine if there was variability among different crops and GE events in terms of detection of the low-level presence of GE traits by performing statistical analysis to evaluate the results.

MATERIALS AND METHODS

Seed Sources and Sample Preparation. Seeds of Armor BX GE canola variety (event OXY235) and Innovator (event HCN92) were received from the Oilseeds Monitoring unit of the Canadian Grain Commission (CGC). Certified seeds of non-GE canola variety, Eagle, were purchased from the American Oil Chemists' Society (AOCS, Urbana, IL, USA). The OXY235 and HCN92 GE canola events were not detected in the non-GE variety. For the DP305423 soybean event, certified ground reference materials ERM-BF426C (1%) and ERM-BF426D (10%) were used for making the 0.01 and 0.1% spike samples with a non-GE soybean variety. For the A2704-12 soybean event, certified seeds of the GE soybean variety PS2295 LL (Bayer Crop Science) were used for fortification. Seeds of the non-GE soybean variety Colby, obtained from Thompsons Ltd. (Chatham, ON, Canada), were used for fortification for both soybean events. The GE events DP305423 and A2704-12 were not detected in the Colby soybean variety (data not shown). Certified heterozygous maize reference samples 0407A (non-GE variety, Syngenta) and 0607A2 (MIR604eVent, Syngenta) were purchased from AOCS and used for fortification at 0.01 and 0.1% levels.

The canola and soybean samples (with the exception of DP305423 ground certified reference material) were ground with a Retsch model ZM100 Centrifugal Grinding Mill (Fischer Scientific, Ottawa, ON, Canada) using a 1.0 mm sieve. For 0.01% GE gravimetrically fortified samples, 0.01 g of GE powder sample was mixed with 99.99 g of non-GE powder sample, whereas for 0.1% fortified GE sample, 0.1 g of GE powder sample was mixed with 99.90 g of non-GE powder sample. The fortified powder samples were placed in 500 mL autoclaved Nalgene centrifuge tubes (Thermo Fisher Scientific, Ottawa, ON, Canada) and thoroughly mixed manually to maintain homogeneity. Subsamples of the ground materials from the same source were used by USDA/GIPSA and CGC laboratories for DNA extraction and PCR.

DNA Extraction and Quantification. For extraction of DNA from 0.1 and 0.2 g samples, a Fast ID Genomic DNA Extraction Kit (Genetic ID, Fairfield, IA, USA) was used following the manufacturer's recommendations. For soybean and maize, the procedure was slightly modified at CGC as the supernatant was not sufficient for the follow-up steps. A single 0.25 in. ceramic grinding ball (Qbiogen, Carlsbad, CA, USA) was added to each 2.0 mL centrifuge tube containing the sample, plus 1400 μL of lysis buffer, and the centrifuge tubes were pulverized in a mixer mill (Qiagen TissueLyser II, Toronto, ON, Canada) at 30 Hz for 60 s before incubation.

For extraction of DNA from 1 and 2 g samples, the CTAB DNA extraction method was followed.[8] Ten milliliters of extraction buffer was used for both 1 and 2 g samples. Before PCR assay, the DNA extracted with the CTAB-based method was purified with the DNA Clean & Concentrator 25 kit (Zymo Research, Cedarlane Laboratories, Ltd., Burlington, ON, Canada; and Zymo Research Corp., Irvine, CA, USA, for CGC and USDA/GIPSA laboratories, respectively).

DNA was quantified by fluorometry with a PicoGreen Assay Kit (Molecular Probes, Eugene, OR, USA) as recommended by the manufacturer. Assays were performed in 96-well fluorescence microtiter plates (Thermo Scientific, Waltham, MA, USA), and fluorescence was measured on a SpectraMax GeminiXS (MDS Analytical Technologies, formerly known as Molecular Devices, Toronto, ON, Canada). DNA samples used for a given PCR were quantified at the same time for all methods. The Abs260/280 and Abs260/230 ratios for the genomic DNA were determined with a SpectraMax Plus 384 (MDS Analytical Technologies, Sunnyvale, CA, USA) at the CGC. At the USDA/GIPSA, DNA was quantified using a fluorometric assay with a Luminometer 20/20 instrument (Turner Biosystems Inc., Sunnyvale, CA, USA) in conjunction with the Quant-iT PicoGreen (PG) assay kit (Molecular Probes). Stock DNA samples were diluted between 1:250 and 1:500 with 0.5× TE (Tris-EDTA) buffer to a target concentration of 20−200 pg/μL. The PG reagent was prepared according to the manufacturer's protocol; the diluted stock DNA test and reference samples were mixed 1:1 with PG reagent to a final volume of 200 μL to produce 1:500 to 1:1000 final dilutions and compared with fluorometric measurements from a standard curve. A calibration curve was generated from λ phage DNA, supplied by the manufacturer (Molecular Probes) at a stock concentration of 100 ng/μL and diluted to 250, 125, 62.5, 31.3, and 0.0 pg/μL with 0.5× TE buffer. Extracted DNA test samples were diluted to a working stock concentration of 20 ng/μL.

Polymerase Chain Reaction. For qualitative real-time PCR, the 25 μL volume contained 1× TaqMan Universal Master Mix, primers, probes, and 100 ng of genomic DNA. The DNA sequences and concentration of primers and probes used are provided in Table 1. Fortified reference DNA samples (0.01 and 0.1%), non-GE DNA, and no template controls were included for each PCR experiment. Both laboratories performed PCR in triplicate using an ABI 7500 real-time PCR system. The thermal profile for all events, except the OXY235 canola event consisted of initial holds for 2 min at 50 °C and for 6 min at 95 °C, followed by 45 cycles of 15 s at 95 °C and a 1 min annealing/extension step at 60 °C. For the OXY235 canola event, the thermal profile consisted of initial holds for 2 min at 50 °C and for 10 min at 95 °C, followed by 50 cycles of 15 s at 95 °C and 1 min annealing/extension step at 60 °C.

Statistical Analysis of Data. The data set of Ct values from real-time PCR was analyzed using SAS software (version 9.2 SAS Institute Inc., Cary, NC, USA). For purposes of ignoring distinction between grain types (i.e., maize, soybean, and canola) used in the study, the potential sources of variance in observed Ct values in the combined data set were composed of (1) laboratory differences (CGC vs USDA), (2) extraction method (CTAB vs Fast ID), (3) fortification level (0.1 vs 0.01% GM), (4) starting amount of sample (0.1 and 0.2 g with Fast ID vs 1 and 2 g with CTAB-Zymo), and (5) replication (×3) of Ct measurements within each level of sample amount. As distribution-fitting based on the small number of observations (n= 6) relevant to comparisons of interest would not be robust, the Wilcoxon nonparametric test was used as it does not make assumptions about the distribution of observed Ct values.[9] The Wilcoxon option was used with PROC NPAR1WAY[10] for making relative comparison of Ct values between groups. In addition to P values for Wilcoxon one-sided and two-sided two-group comparisons, analysis outputs included chi-square probabilities for the Kruskall−Wallis test, which were used to assess statistical difference between groups, as group comparisons did not assume matched pairs for observed Ct values.

RESULTS AND DISCUSSION

DNA Yield and Quality. DNA was extracted from finely ground canola, soybean, and maize samples to determine whether adequate amounts of intact DNA could be recovered and used to detect a low-level presence of GE traits by PCR. Highly variable DNA yields were obtained and verified by both the CGC and USDA/GIPSA laboratories for the Fast ID and CTAB-based DNA extraction methods (Table 2). CGC generally recovered greater amounts of DNA that ranged from 1.6 ± 0.3 to 182.9 ± 2.2 μg, whereas USDA/GIPSA generally recovered lesser amounts of DNA that ranged from 1.1 ± 0.2 to 84.0 ± 5.8 μg. Additionally, the data revealed that in most cases the Fast ID kit provided greater quantities of recovered DNA when using larger amounts of finely ground starting material

	2.0	CTAB	56.5 ± 0.4	48.1 ± 3.4	58.3 ± 3.3	50.2 ± 3.8

[a]The ± values are average of two DNA extractions. Fast ID, Fast ID DNA extraction method; CTAB, CTAB-based DNA extraction method (before Zymo purification of the DNA).

(Fast ID comparison of 0.1 vs 0.2 g). Similar observations were seen with the CTAB extraction method (comparison of 1.0 vs 2.0 g). Atypical quantities of recovered DNA were generated by CGC on the two soybean samples and the single maize sample using Fast ID kits. For CGC, consistently higher canola, soybean, and maize DNA yields were obtained for the Fast ID method

Table 3. Abs260/280 and Abs260/230 Ratios (CGC Laboratory) for Samples Fortified with GE Traits Obtained from Two DNA Extraction Methods

trait	DNA extraction method	fortification level (%)	average absorbance ratios for 260/280	260/230
OXY235 canola	Fast ID	0.01	1.77	0.55
	CTAB	0.01	1.87	2.03
	Fast ID	0.1	1.75	0.60
	CTAB	0.1	1.93	2.39
HCN92 canola	Fast ID	0.01	1.73	0.27
	CTAB	0.01	1.77	1.64
	Fast ID	0.1	1.47	0.48
	CTAB	0.1	1.92	1.83
A2704 soybean	Fast ID	0.01	1.90	1.20

	Fast ID	0.1	1.93	0.40
	CTAB	0.1	1.83	1.50

compared with USDA/GIPSA with the exception of 0.2 g maize sample fortified at 0.1%. The likely explanation for this observation could be that the CGC extraction method included a ceramic grinding ball in the centrifuge tube containing buffer and pulverization with the Mixer Mill for soybean and maize, which created a finer particle size thereby leading to a higher extraction efficiency (see Materials and Methods). With the Fast ID DNA extraction method, the DNA yield ranged from 1.1 ± 0.2 to 10.2 ± 1.6 μg. Six hundred nanograms of DNA was sufficient to carry out the experiments in triplicate for both the transgene and the endogenous control.

As predicted, much higher yields of DNA were obtained with the large scale CTAB-based extraction method (1.0/2.0 g sample) compared with the small-scale Fast ID extraction method (0.1/0.2 g sample (Table 2)). Interestingly, there were large differences in DNA yields between CGC and USDA/GIPSA laboratories using the CTAB extraction method. The CTAB protocol used by the two laboratories had some differences that might explain these observations. The USDA/GIPSA protocol excluded the reducing agent, β-mercaptoethanol, with their CTAB method during steps that required chloroform/isoamyl alcohol extractions. For the CGC, β-mercaptoethanol (0.01 M), phenol/chloroform/isoamyl alcohol 25:24:1 (1×) and chloroform/isoamyl alcohol 24:1 (2×) were used in the extraction steps. Modification of the DNA extraction protocol may have partially contributed to the variation in total canola DNA yield, even though the soybean and maize DNA yields were not affected as much. Because DNA yield extracted from the same amount of starting material provided significant variability, the use of equivalent amounts of DNA in the PCR was critical.

Table 4. Summary of Average Threshold Cycle (Ct) Values Obtained[a]

trait	DNA extraction amount (g)	DNA extraction method	average Ct values, target gene 0.01% CGC	0.01% GIPSA	0.1% CGC	0.1% GIPSA
OXY235 canola	0.1	Fast ID	37.85 ± 0.64	38.92 ± 0.76	33.23 ± 0.90	33.37 ± 0.48

[a]The ± standard deviation values are for 6 PCR results (2 DNA extractions × 3 PCRs). Fast ID, Fast ID DNA extraction; CTAB, CTAB DNA extraction. [b]The values in parentheses indicate the percentage detected of six samples (e.g., 83% indicates that five of the six PCR samples produced detectable PCR signal and one sample did not produce detectable signal; the Ct values are the averages of detectable signals).

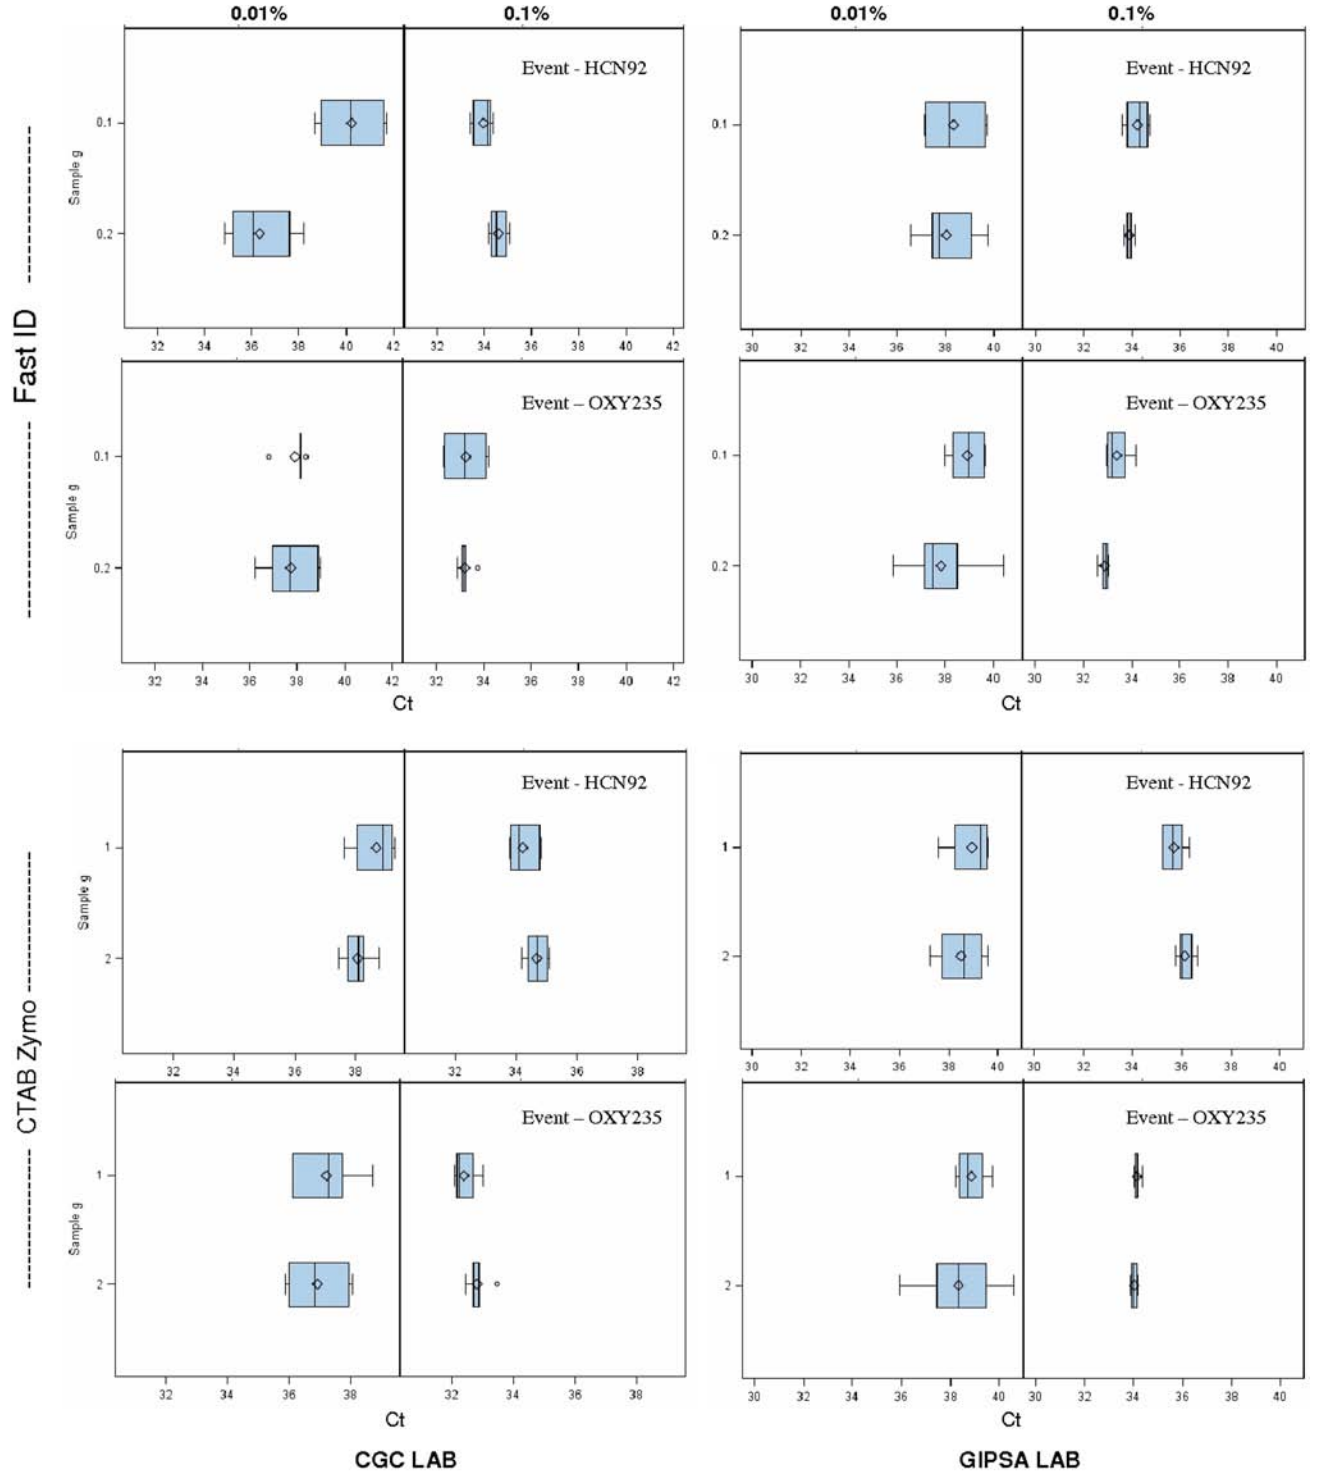

Figure 1. Distribution of Ct values from detection of two GM events in canola (HCN92 and OXY235) fortified at two levels (0.1 and 0.01% w/w), based on two DNA extraction methods (Fast ID and CTAB) conducted at two laboratories (CGC and USDA/GIPSA).

Both laboratories used a constant mass of 100 ng of DNA quantified with a PicoGreen assay for the PCR.

The Abs260/280 and Abs260/230 ratios of different DNA extractions were determined at the CGC. Most of the CTAB and Fast ID extracted DNA had relatively high Abs260/280 ratios indicative of suitable DNA quality for PCR (Table 3). The DNA extracted with the Fast ID method had low Abs260/230 values indicating the possible presence of contaminants that absorb at 230 nm. Low Abs260/230 ratios have been observed in DNA extractions using the Fast ID method on samples of canola, flax, and soybean even though this did not appear to affect PCR amplification.[11] Purification of 20 μg of CTAB DNA using a DNA Clean & Concentrator 25 kit (Zymo Research, Cedarlane Laboratories Ltd., Bulington, ON, Canada) from four canola, four soybean, and two maize samples was performed to determine the percentage of recovery at the CGC. Average DNA recoveries of 47, 74, and 80% were obtained for soybean, canola, and maize, respectively. The purification step

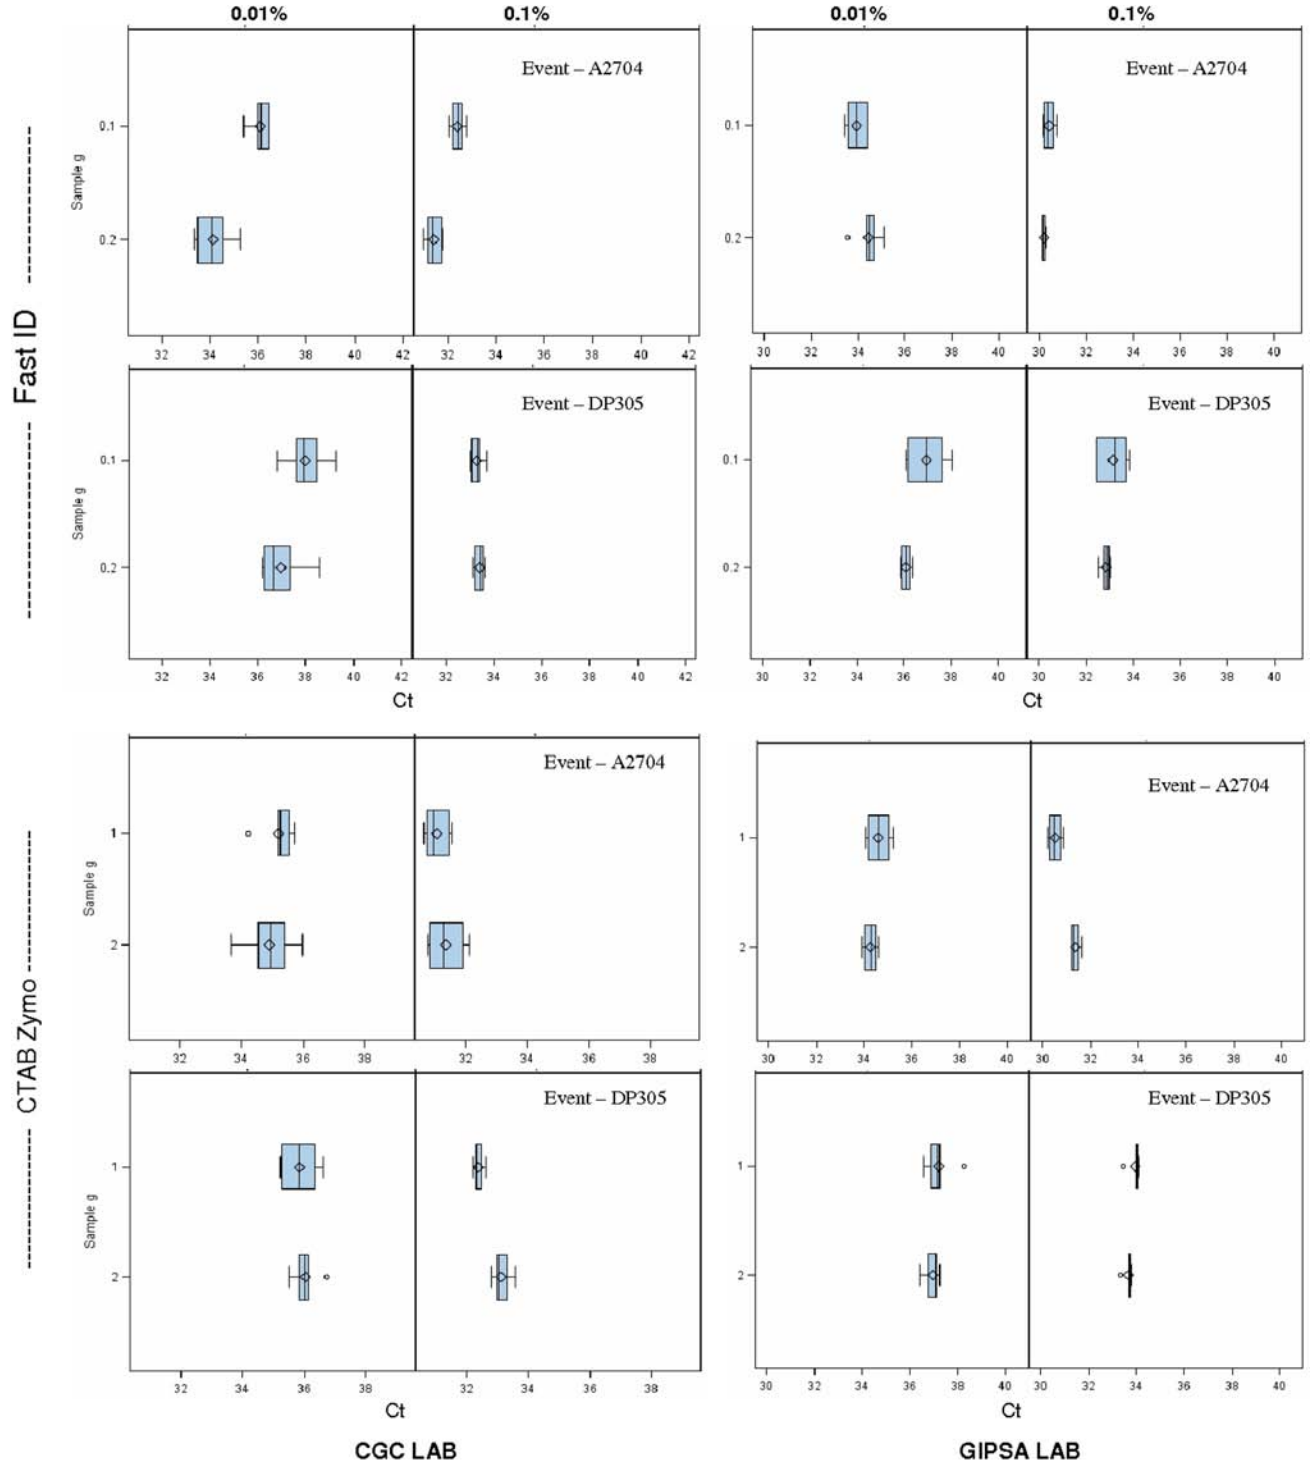

Figure 2. Distribution of Ct values from detection of two GM events in soybean (A2704 and DP305) fortified at two levels (0.1 and 0.01% w/w), based on two DNA extraction methods (Fast ID and CTAB) conducted at two laboratories (CGC and USDA/GIPSA).

used for CTAB-extracted DNA may have also contributed to the variation in DNA yield.

Small-Scale versus Large-Scale DNA Extractions for the Detection of LLP of GE Events. Comparable PCR results (in terms of Ct values) were obtained from DNA extracts using small-scale (Fast ID) and large-scale (CTAB) extraction methods. Higher Ct values were obtained for 0.01% fortified samples compared with 0.1% fortified samples as expected (Table 4). However, there was more variability among the Ct values generated by PCR for the 0.01% fortified samples (Figures 1−3). In general, detection of a low-level presence of GE events, such as 0.01% (1 in 10000), is relatively more challenging as the error rate due to DNA dilution, pipeting, etc., is amplified.[12]

For the 0.01% fortified samples and Fast ID extraction method, 0.2 g extraction samples had relatively lower Ct values (indicating a greater chance of detection) than 0.1 g extraction samples for HCN92 canola, DP305423 soybean, and A2704 soybean GE events (CGC; Table 4; Figures 1 and 2).

dx.doi.org/10.1021/jf500610w | J. Agric. Food Chem. 2014, 62, 4349−4358

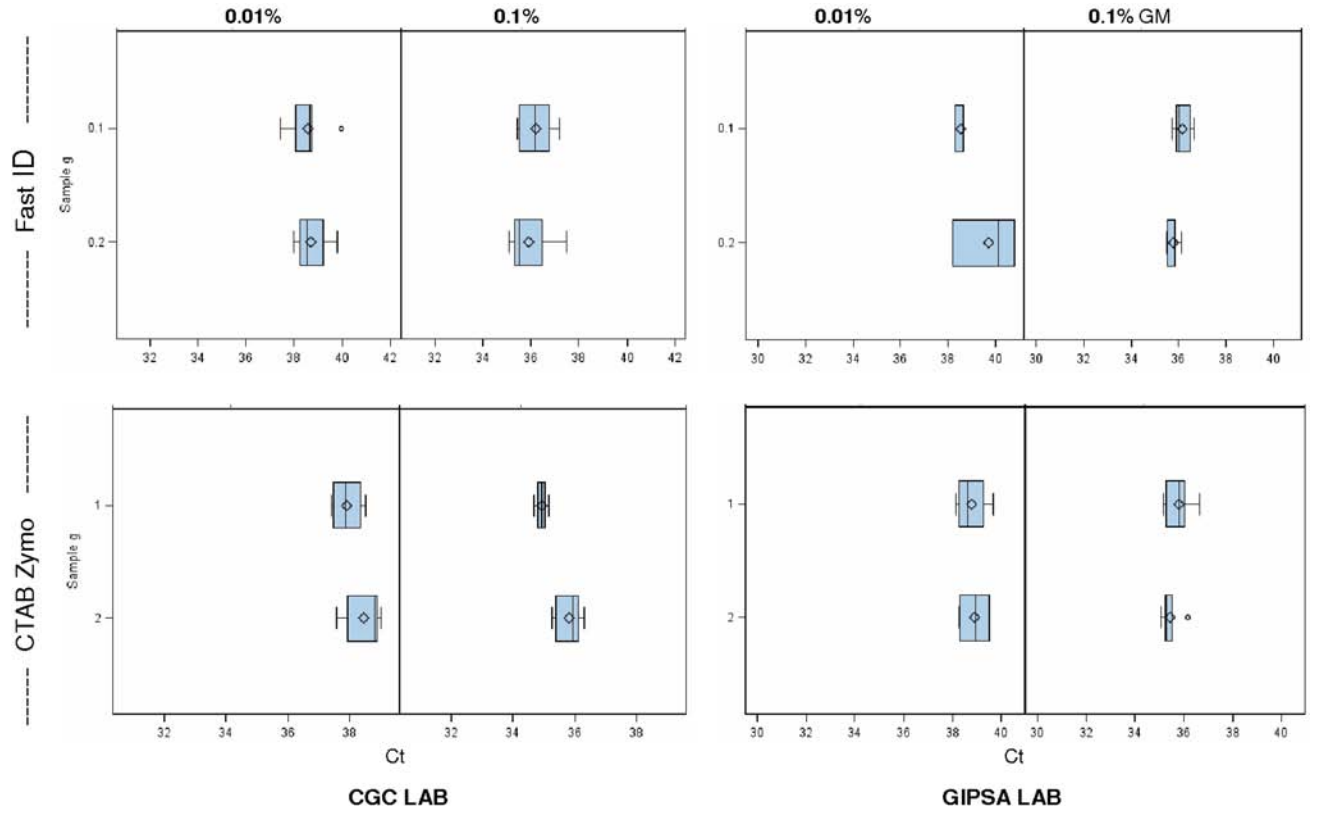

Figure 3. Distribution of Ct values from detection of GM event (MIR604) in maize fortified at two levels (0.1 and 0.01% w/w), based on two DNA extraction methods (Fast ID and CTAB) conducted at two laboratories (CGC and USDA/GIPSA).

On the basis of these data, improvement in the detection of the low-level presence of GE events may not necessarily be achieved as a result of using large-scale DNA extraction methods such as CTAB. The use of small-scale DNA extraction methods saves time and money. For the small-scale extraction method, sufficient amounts of DNA were achieved for replicate PCR and repeatable Ct values were obtained, especially for 0.1% fortified samples. Holden et al. suggested that samples prepared at the 0.1% fortification level can generate false-negative results when certain detergent-based DNA isolation methods are used.[13] The bulk of the false-negative results were attributed to the presence of inhibitors that inactivate Taq DNA polymerase in the PCR.

For the MIR604 maize event, repeatable and consistent detection by PCR was not achieved at the 0.01% fortification level regardless of the extraction method or the amount of starting material used under the conditions of this study design. In addition, significant variability was observed, including false-negative results, between the two DNA extraction methods as well as within replicates for the Ct values obtained (Table 4). The MIR604 heterozygous reference maize purchased from AOCS was reported to have a purity of 99.98%; thus, this may have also affected the fortification and in turn the detection of the MIR604 maize event at 0.01% level. Haploid genome weight for *Brassica napus* (canola), maize, and soybean has been reported to be 1.13 pg,[15] 2.3 pg,[16] and 1.12 pg,[17] respectively. On the basis of the described genome weights, 100 ng of DNA spiked at the 0.01% level will have approximately nine copies of OXY235 canola and DP305423 soybean and four copies of maize. Thus, the chance of detection of GE canola and soybean samples at low levels is higher than that of GE maize samples. This may potentially explain why we could not reliably detect 0.01% MIR604 maize samples.

In a collaborative trial validation study, 100% detection of 0.02% LLRice62 and MS8 canola (45 samples for each event were correctly identified) was reported.[14] For homogeneously prepared samples, GE trait testing laboratories can detect low concentration levels of GE events. Genetically engineered grains/seeds are not homogeneously distributed in a grain lot.[6,18] Thus, sampling is more of a challenge compared to detection of the GE traits using PCR.

Results of Statistical Analysis. With respect to statistical difference in Ct values between extraction sample amounts within Fast ID (0.1 vs 0.2 g) and CTAB (1 vs 2 g), OXY235 canola samples showed no difference for both methods, at both fortification levels and across both the CGC and USDA/GIPSA laboratories; the only exception was the 0.1% Fast ID method for the USDA/GIPSA laboratory (Table 5). For HCN92 canola, CGC results showed statistical differences for Fast ID extractions at both 0.1 and 0.01% fortifications, but no differences were seen in USDA/GIPSA results. With MIR604 maize, CGC results showed differences for CTAB extractions at the 0.1% fortification. Similar results were seen for A2704 soybean and DP305423 soybean, where one laboratory may see statistical difference but results from the other laboratory showed no difference. Although the majority of comparisons across the 0.1 and 0.01% fortification levels in both laboratories showed no statistical difference within Fast ID (0.1 and 0.2 g) and CTAB (1 and 2 g) DNA extraction methods for observed Ct values, variability for reproducibility of respective Ct values may be significant for some traits with respect to combinations of fortification level, DNA extraction method, and amount of extraction sample.

Table 5. Probability of Statistical Difference in Observed Ct Values within Fast ID (0.1 vs 0.2 g Samples) and CTAB (1 vs 2 g Samples) DNA Extraction Methods at 0.1 and 0.01% Fortification Levels Conducted at Two Laboratories (Kruskall–Wallis Test)

[a]Difference within DNA extraction methods for each %GM fortification level is deemed statistically significant where Pr > chi-square is ≤0.05 for 95% confidence.

In terms of comparing DNA extraction methods (Fast ID vs CTAB) for statistical difference in Ct values across fortification levels, differences in results between laboratories were found (Table 6). Only DP305423 soybean showed statistical difference between Fast ID and CTAB for both 0.1 and 0.01% fortification levels across both CGC and USDA/GIPSA laboratories. For MIR604 maize only CGC results showed statistical differences between extraction methods at 0.1% fortification, whereas for HCN92 canola only USDA/GIPSA results showed statistical differences at the 0.1% fortification level. Both laboratories found statistical differences between extraction methods for A2704 soybean fortified at the 0.1% level. Comparisons for OXY235 canola showed statistical differences for both fortification levels in CGC results, whereas USDA/GIPSA results showed differences only for the 0.1% fortification level. For these comparisons, however, Ct results

were aggregated across sample extraction amounts, and variance in Ct values due to different amounts of starting material used within each extraction method likely contributed to the observed variance between laboratories.

Summary. In this study, the influence of starting material on the detection of low-level presence of GE traits was investigated using five GE events (two events each for canola and soybean and one event for maize). Higher DNA yields were obtained with the larger scale DNA extraction method (1.0 and 2.0 g samples) compared to the smaller scale DNA extraction method (0.1 and 0.2 g samples). There was variability in the DNA yield obtained between the CGC and USDA/GIPSA laboratories involved in this study, especially for the large-scale DNA extraction method. CTAB-extracted DNA that was further purified on a DNA Clean & Concentrator Kit had greater purity (based on Abs260/280 and Abs260/230 ratios) compared with the Fast ID extracted DNA. When the large-scale CTAB DNA extraction method (1.0 and 2.0 g samples) was compared with a small-scale Fast ID DNA extraction method (0.1 and 0.2 g samples), the data did not reveal differences in terms of detection by PCR for four of the five GE events studied at 0.1 and 0.01% fortification levels. Overall, reliable detection of the GE events was achieved at the 0.1% level. Reliable detection at the 0.01% fortification level was achieved for the four canola and soybean GE traits, but not as reliably for the MIR604 maize GE trait. The 0.01% 100 ng maize DNA has a low MIR604 copy number, which may have resulted in unreliable detection. There was more variability in Ct values generated by the duplicate DNA extractions for the 0.01% fortified samples using 0.1 g of starting material. Thus, detection of samples at this fortification level using only 0.1 g of starting material could potentially produce false-negative results in maize but not in soybean or canola. In general, a kit-based DNA extraction method (using 0.1 and 0.2 g of sample) can be used instead of the large-scale CTAB DNA extraction method for the detection of low levels of GE events in ground grain samples, which could save time and cost.

Supporting Information

ABSTRACT: Dietary fiber and flavonoids, important components in berries, are suggested to improve metabolic health. This study investigates whether soluble and insoluble fractions isolated from bilberry, black currant, and raspberry affect the formation of short-chain fatty acids (SCFAs), uptake and excretion of flavonoids, and levels of cholesterol differently. Cecal SCFA pools were higher in rats fed the soluble than the insoluble fractions (525 vs 166 μmol, $P < 0.001$), whereas higher concentrations of butyric acid were found in the distal colon and serum of rats fed the insoluble fractions (5 vs 3 μmol/g and 58 vs 29 μmol/L, respectively, $P < 0.001$). The soluble bilberry fraction gave lower amounts of liver cholesterol (56 mg) than the other berry fractions (87 ± 5 mg), formed the highest amount of SCFAs (746 vs 266 ± 21 μmol), and contributed the highest intake of anthocyanins. Cyanidin-3-glucoside monoglucuronide was detected in the urine of all groups, whereas anthocyanins were found only in groups fed soluble black currant and raspberry.

KEYWORDS: *berries, fiber, SCFAs, anthocyanins, cholesterol*

INTRODUCTION

Berries are known to be an important part of a healthy diet and a good source of many vitamins and minerals. Many other imperative compounds can be found in berries, such as dietary fiber and flavonoids.[1] Dietary fibers have been connected to many positive health effects: they help in weight loss and appetite regulation and can reduce the risk of developing diseases such as type 2 diabetes and heart disease.[2−4] The flavonoids are not essential to humans, but the health benefits of berries are often related to these components, and through their antioxidative capacity they may have a protective role against various diseases associated with oxidative stress.[1,5] More than 4000 flavonoids have been described, and anthocyanins are a common group of flavonoids. Anthocyanins are found in high amounts in bilberries and black currants, whereas raspberries contain relatively low amounts, and they are responsible for the color of fruit and berry.[6,7] Bilberries also contain high amounts of proanthocyanidins and raspberries, ellagitannins, whereas black currants contain only small amounts of these components.[8] The bioavailability of various flavonoids is an important question in this respect.

Dietary fibers are not digested in the small intestine, but reach the large intestine, where microbial fermentation takes place.[2] Some fibers are also resistant to microbial degradation. The fermentation gives rise to short-chain fatty acids (SCFAs), mainly acetic, propionic, and butyric acids. The amount of SCFAs formed is dependent upon a number of factors, for example, the kind of dietary fiber that reaches the colon, the transit time, and the microbiota composition.[9,10] Some SCFAs have been shown to have positive health effects, and butyric acid has been mostly emphasized, but propionic may also have some interesting effects.[11] Butyric acid is an energy source for the colonic epithelial cells,[12] and impaired butyric acid metabolism has been associated with colonic diseases but also connected to decreased risk of metabolic diseases.[13,14] The physicochemical properties of the dietary fiber, such as solubility, are important for the health-promoting effects and the formation of SCFAs.[15] Very few studies have been focused on dietary fiber in berries.

Some phenolic compounds, such as the flavonoids, may be absorbed in the small intestine after cleavage by intestinal esterases. The flavonoids can also be more or less tightly bound to the dietary fiber complex, which affects the bioavailability of these components.[16,17] Depending on how they are associated with the dietary fiber, the substances may be released throughout the gut, and the specific physiological activity can vary on the basis of the site of release. Like the dietary fiber per se, another fraction of the flavonoids may be resistant to colonic degradation, thereby reaching feces intact and having no biological effect.

Interest in new food components with prebiotic properties is growing. Many byproducts are formed during, for example, juice production. To get an idea of where the flavonoids in berries are located, and also which fibers are most active, we

thought it would be useful to separate the raw material into soluble and insoluble fractions.

The aim of this study was to investigate whether soluble and insoluble fractions isolated from three Swedish berries, bilberry, black currant, and raspberry would affect physiological parameters associated with colonic and metabolic health. Fermentability of the dietary fiber, the formation of SCFAs in the hindgut (cecum and distal colon), and the amount of anthocyanins in blood, urine, and cecal contents were analyzed. Liver cholesterol and triglycerides and the level of SCFAs and inflammatory cytokines in portal blood of rats were also analyzed.

MATERIALS AND METHODS

Chemicals. The following chemicals were used: hexane and Triton X-100 (Sigma-Aldrich, St. Louis, MO, USA); isopropanol and 2,6-di-*tert*-butyl-4-methylphenol (BHT) (Merck, Darmstadt, Germany); Infinity Cholesterol reagent (Thermo Scientific, Middletown, VA, USA); Chemistry Calibrator (Pointe Scientific Inc., Canton, MI, USA); Hypnorm (Division of Janssen-Cilag Ltd., Janssen Phamaceutica, Beerse, Belgium); Dormicum (F. Hoffman-La Roche AG, Basel, Switzerland); Milliplex MAP rat cytokine kit (Merck Millipore, Billerica, MA, USA); serum tube (SST Advance, Plus Blood Collection Tubes, BD, Plymouth, UK); and plasma tubes containing EDTA (K2E 3.6 mg, Plus Blood Collection Tubes, BD).

Separation of Soluble and Insoluble Berry Fraction. Bilberry (*Vaccinium myrtillus*), black currant (*Ribes nigrum*), and raspberry (*Rubus ideaus*) were freeze-dried (Procordia, Eslöv, Sweden), and soluble and insoluble parts of the berries were separated before inclusion in rat diets. The following procedure resulted in three soluble and three insoluble berry fractions, and diets were formulated from the six test materials obtained. The freeze-dried berries were ground by hand in a mortar. To liberate as much soluble fiber as possible from the berries, different amounts of water, difffernt pH values, and

[a]Mean values with their SEM (n = 7). Values within a row with unlike letters (a–c) are significantly different ($P < 0.05$). [b]Values in groups fed insoluble fractions were significantly higher than in those fed soluble fractions. [c]Values in groups fed bilberries were significantly higher than in those fed raspberries.

different temperatures were tested. Another aim was to preserve the dietary fiber as intact as possible and extract all berry components. The maximal amount of fiber was referred to as the amount obtained under physiological conditions according to the dietary fiber methodology.[18,19] During the isolation and optimization process, the samples with different formulations were heated in a water bath at different pH values (1.5, 2 and 3), amounts of water (4–10 mL/g), and temperatures (70–85 °C). The test tubes were centrifuged, and the supernatant was filtered and precipitated with 95% alcohol and filtered with Celite (Fibertec System E 1023 Filtration Module) to estimate the amount of the soluble fiber fraction. The optimal parameters were found to be at pH 2 and 80 °C for all three berries, and the optimum amount of water was 5–7 L/kg freeze-dried berries. During the extraction of the dietary fiber from the berries, they were mixed with water and heated in a metal pot to 80 °C under constant stirring. The berry solution was centrifuged, and the supernatant (soluble fraction) was filtered through a sieve into plastic containers and frozen at −20 °C before subsequent evaporation in a rotary vacuum evaporator (Heidolph VV-60, Germany) and freeze-drying (Labconco Lyph-lock-18, Kansas City, MO, USA). The insoluble fraction (the pellet after centrifugation and the leftovers from the filter) was freeze-dried as well. The content of dietary fiber and anthocyanins was analyzed in the different berry fractions obtained.

Preparation of Diets. All diets contained the same amount of protein (120 g/kg casein dry weight basis, dwb) and fat (50 g/kg corn oil, dwb), and the amounts of added minerals (48 g/kg dwb) and vitamins (8 g/kg dwb) were also the same for all diets (Table 1). The energy contents of the diets were very similar (Table 1). Furthermore, the content of dietary fiber in the diets was 6 g/100 g (dwb) for the soluble and insoluble fractions of raspberries and black currants (corresponding to 771 g of the soluble berry fractions and 97–108 g of the insoluble berry fractions calculated on dwb). The dietary fiber content is shown in Table 2. For practical reasons the amount of dietary fiber in the diet containing the soluble fraction of bilberries had to be limited to 4.5 g/100 g (dwb), as it was not possible to incorporate more berries along with the chosen levels of nutrients (protein, fat, minerals, and vitamins). This also corresponded to 771 g (dwb) of the soluble bilberry fraction and 77 g (dwb) of the insoluble bilberry fraction. Because the primary goal was to compare the effects of insoluble and soluble fractions, the amount of fiber was the same in the insoluble bilberry fraction as in the soluble bilberry fraction. The amount of available carbohydrates was also more or less the same in the various diets, although from different origins. In the insoluble berry fractions the available carbohydrates were from added sucrose and wheat starch, known to be completely digested, containing no resistant starch and not giving rise to any SCFAs,[20] whereas the available carbohydrates (glucose, sucrose, and fructose) were from berries in the soluble fractions. The amount of antioxidants varied between different diets, but it would be impossible to take this into consideration, too. Despite this, the intakes of anthocyanins were quite similar for the insoluble and soluble bilberry and black currant fractions, whereas the intake was higher with the soluble raspberry fraction than with the insoluble one (see results, anthocyanins).

One diet was prepared from each soluble and insoluble dietary fiber berry fraction, resulting in six diets. The diets containing the soluble berry fractions had a slightly sour taste, especially with the soluble bilberry fraction, which the rats did not like. To retain the composition of nutrients, a sweetener was added to the diets, which resulted in good feed consumption (Table 3). The sweetener added was a mixture of Aspartame (2.0 mg/g feed, dwb) (SinoSweet Co. Ltd., Yixing, Jiangsu, China) and Acesulfam-K (0.7 mg/g feed, dwb) (Zhangjiagang Hope Chemicals Co. Ltd., Zhangjiagang, Jiangsu, China).

The content of dietary fiber (dwb) in the soluble fraction was 5.8 g/100 g in bilberry, 7.8 g/100 g in black currant, and 7.3 g/100 g in raspberry, whereas the dietary fiber content was considerably higher in the insoluble fractions: 58 g/100 g (dwb) in bilberry, 56 g/100 g in black currant, and 58 g/100 g in raspberry. The soluble fractions consisted of dietary fiber polysaccharides containing glucose (25–32%) and galactose (12–13%) (Table 2). Soluble fractions from black currant and raspberry also contained high proportions of uronic acids (28–33%) and raspberry arabinose (19%), whereas bilberry contained high amounts of xylose (32%). The insoluble fractions consisted of polysaccharides containing glucose (30–51%) and uronic acids (11–13%). Bilberry and raspberry also contained xylose (23–28%), whereas black currant contained high amounts of mannose (32%).

Experimental Design. Forty-two male Wistar rats (Taconic, Lille Skensved, Denmark), with a starting weight of 127.6 (SE 1.2) g, were randomly divided into six groups of seven animals. Each group was given one of the six diets (Table 1), and the feed intake was restricted to 12 g (dwb) per day, which is an adequate amount of feed for rats of this size,[21] but with unlimited access to water. The rats were housed individually in metabolic cages[22] in a room maintained at 22 °C, with a 12 h light–dark cycle. The animals were healthy and active throughout the experiment. The Ethics Committee for Animals Studies at Lund University approved the animal experiment (Application M 30-09).

The rats were allowed to adapt to the diets for 7 days followed by a 5 day experimental period, when feces and feed residues were collected quantitatively daily, whereas urine was collected during approximately 1–2 h every day, after the rats had been fed. The feces were stored at −20 °C, then freeze-dried and milled, before the composition of dietary fiber was analyzed. The urine samples were stored at −20 °C and analyzed for anthocyanins once the sampling was completed. To calculate the exact amount of feed ingested, the feed residues from each rat were weighed. After the experimental period, the animals were anesthetized by subcutaneous injection of a mixture (1:1:2) of Hypnorm, Dormicum, and water at a dose of 0.15 mL/100 g body weight. Blood was taken from the hepatic portal vein and placed in serum and plasma tubes containing EDTA (approximately 3 and 2 mL, respectively), which were centrifuged and stored at −40 °C until the analysis of SCFAs[23] (serum), cytokines (serum), and anthocyanins (plasma). The cecum was removed and the content transferred to a test tube and mixed, and the pH was measured with an InLab Semi-Microelectrode (Mettler Toledo, OH, USA). The cecal tissue was rinsed with water, dried, and weighed, and cecal contents were determined. The cecal content was stored at −40 °C for analysis of SCFAs and anthocyanins. The liver was removed, weighed, and stored at −20 °C, before being freeze-dried and mortared, and then analyzed

for cholesterol and triglycerides. Stool samples were collected from the distal colon and stored at −40 °C until the analysis of SCFAs.

Analytical Methods. *Dietary Fiber.* The amount of dietary fiber in the soluble and insoluble berry fractions was determined gravimetrically with the AOAC method developed at the department.[19] The composition of the isolated dietary fiber residues in raw materials was quantified by using GLC, for the neutral sugars, and a spectrophotometric method was used to analyze uronic acids.[18] The content of dietary fiber polysaccharides in feces was analyzed as for the raw materials but without the gravimetric step. Lignin was calculated as the difference between the dietary fiber content of raw materials obtained by the enzymatic gravimetric AOAC method, which include lignin in the measurements, and the sum of dietary fiber monomers analyzed by GLC. Previous studies have shown a good accordance with these two methodologies; that is, the difference should give a good measurement of lignin.[24]

SCFAs in Portal Blood. SCFAs (acetic, propionic, isobutyric, butyric, isovaleric, and valeric acid) were analyzed in serum according to the method of Zhao et al.[23] with some modifications.[25] Water (3335 mL) and 0.5 mM 2-ethylbutyric acid (internal standard) in 2 M hydrochloric acid (27 μL) were added to the serum samples (240 μL) to protonate the SCFAs. A hollow fiber, for supported liquid membrane extraction, was immersed in the serum solution for the extraction of SCFAs. After the extraction, the SCFAs were flushed from the hollow fiber and injected onto a fused-silica capillary column (DB-FFAP 125-3237; J&W Scientific, Agilent Technologies Inc., Folsom, CA, USA). GC ChemStation software (Agilent Technologies Inc., Wilmington, DE, USA) was used to analyze the data.[23]

SCFAs in Intestinal Content. The SCFAs (acetic, propionic, isobutyric, butyric, isovaleric, valeric, and caproic acids) and heptanoic acid were analyzed in the intestinal content (cecum and distal colon) using a GLC method.[26] Hydrochloric acid (0.25 M) and 2-ethylbutyric acid (internal standard) were added to the intestinal samples and homogenized with an Ultra Turrax T25 basic (IKA-Werke, Staufen, Germany) for 1 min. The homogenized samples were centrifuged (MSE Super Minor, Hugo Tillquist AB, Solna, Sweden), and the supernatant was analyzed using GLC as described above.

Multiplex Cytokine Assay. A Milliplex microbeads array system was used to analyze serum levels of six cytokines, interleukin (IL)-4, IL-12, IL-18, MCP-1, IFN-γ, and TNF-α, according to the manufacturer's instructions using Milliplex MAP rat cytokine kit assay technology, as previously described.[27]

Anthocyanins. The anthocyanins in the raw material (soluble and insoluble berry fractions) were extracted from 1 g of sample with 15 mL of methanol/water/acetic acid (85:15:0.5, v/v/v). The sample solution was sonicated for 15 min at room temperature and centrifuged (200*g*) for 15 min and the supernatant removed. This procedure was repeated using 10 mL of methanol/water/acetic acid, and the supernatants were combined and transferred into a clean flask. Methanol/water/acetic acid was used to fill to a final volume of 25 mL. One milliliter was then filtered using a 0.2 μm GH Polypro (GHP, hydrophilic polypropylene) (Pall Corp., Washington, NY, USA) membrane syringe filter (Acrodisc, Sigma-Aldrich, St. Louis, MO, USA).

Urine and plasma samples were thawed and syringe filtered with a 0.2 μm GHP membrane before analysis of anthocyanins. For the soluble berry fractions only urine samples from rats fed black currants and raspberries were analyzed for anthocyanins, because the urine from bilberries was blue, and it cannot be ruled out that the urine had been contaminated with bilberries. Cecal samples were thawed and then extracted with methanol/water (1:1, v/v) for 1 h at room temperature followed by centrifugation (15 min, 200*g*), and the supernatant was filtered using the same GPH membrane.[28]

Anthocyanins analysis was performed on an Agilent 1260 Infinity system equipped with a quaternary pump, a diode array (DAD), an autosampler, and a thermostat column compartment, coupled with an Agilent 6100 series quadrupole LC-MS operated with electrospray ionization (API-ESI-MS). A 250 × 4.6 mm i.d. Agilent Technology SB-C18 column (Santa Clara, CA, USA) was used for separation. Elution was carried out using two mobile phases, A (5% v/v formic acid in water) and B (methanol). The gradient system used has been reported by Wu et al.[28] The elution of anthocyanins was monitored at 520 nm (Agilent 6100 Infinity system equipped with a DAD detector) and then introduced into the ion-trap electrospray mass spectrometer equipped with API-ES (Agilent Technology 6120 quadrupole LC-MS). The mass spectrometer was operated in the positive ion mode, full scan, in the range m/z 100−1000 under the following conditions: capillary voltage, 3000 V; drying gas flow, 12 L/min; nebulizer pressure, 40 psig; and drying gas temperature, 300 °C. Cyanidin-3-glucoside was used to create a calibration curve for the quantification of anthocyanins.[29,30]

Liver Cholesterol. Livers were lyophilized and mortared. A 3:2 mixture of hexane and isopropanol with 0.005% (v/w) BHT (1 mL/0.1 g liver) was used to extract the liver cholesterol on an orbital shaker followed by centrifugations. The supernatant was transferred to a clean tube. The extraction was repeated four times, and the supernatants were combined and then dried under N_2 flow at room temperature. The extracted lipids were redissolved in 1 mL of isopropanol containing 1% (v/v) Triton X-100. Total liver cholesterol was determined spectrophotometrically using Infinity Cholesterol reagent and Chemistry Calibrator.

Calculations and Statistical Analysis. The design of the experiment was randomized. The berries used in the study were bilberry, black currant, and raspberry and, as the soluble and insoluble fractions of the berries were isolated, the study involved six groups of seven rats. Two-way ANOVA with Tukey's test was used to determine the effects of different berries (berry), solubility (sol), and their interactions (berry × sol) (Tables 2−8). When significant interactions (berry × sol) were found ($P < 0.05$), individual means were analyzed by one-way ANOVA using Tukey's multiple-range test ($P < 0.05$). When no interactions could be found, only P values for berries (berry) and solubility (sol) were evaluated, with Tukey's test. In Table 2 interactions were found for all components, except fucose, and therefore only results from Tukey's multiple-range test are shown in the table. All evaluations were performed with Minitab software (release 16). The results were normally distributed with the exception of some SCFAs and a few monosaccharides in fecal excretion, which became normally distributed after Box−Cox transformation of the data set. Values are presented as means and SEM in Tables 3−8, and differences with P values <0.05 are considered significant, whereas P values ≤0.1 were defined as tendency.

The level of each fatty acid (μmol/g) was multiplied by the cecal amount to obtain the cecal pool (μmol). The body weight gain was calculated in grams per gram of food consumed. The fecal excretion (Table 2) of the dietary fiber components was calculated as follows:

$$\frac{\text{g dietary fiber components in feces}_{\text{test diet}}}{\text{g dietary fiber component ingested}_{\text{test diet}}} \times 100$$

The fermentability (Table 3) of the dietary fiber was calculated as follows:

$$\left(1 - \frac{\text{g dietary fiber in feces}_{\text{test diet}}}{\text{g dietary fiber ingested}_{\text{test diet}}}\right) \times 100$$

The fecal bulking capacity (Table 3) was calculated as follows:

$$\frac{\text{fecal dry wt (g)}_{\text{test diet}}}{\text{g dietary fiber ingested}_{\text{test diet}}}$$

RESULTS

Feed Intake and Body Weight. The feed intake was lower in the groups fed the soluble fraction (mean = 9.9 ± 0.2 vs mean = 11.7 ± 0.1 g/day, dwb, $P < 0.001$) (Table 3). There was no difference between different berries. Groups fed soluble fractions also gained slightly less weight (mean = 0.21 ± 0.02 g/g feed vs mean = 0.30 ± 0.02 g/g feed for the insoluble fraction, $P = 0.002$).

[a]Mean values with their SEM ($n = 7$, with the exception of $n = 6$ for soluble bilberry). Mean values within a row with unlike letters (a–d) are significantly different ($P < 0.05$). [b]Values in groups fed raspberries were significantly higher than in those fed bilberries or black currants. [c]Values in groups fed soluble fractions were significantly higher than in those fed insoluble fractions. [d]Values in groups fed bilberries were significantly higher than in those fed raspberries or black currants.

Cecal Content, Tissue and pH, Dietary Fiber Fermentability, and Fecal Bulking Capacity. Soluble and insoluble fractions and also the type of berry affected cecal content and tissue weights ($P < 0.001$) (Table 4), and groups fed soluble fractions generally weighed more. Rats fed soluble bilberries weighed most (11.5 and 1.5 g for the cecal content and tissue, respectively), which was higher ($P < 0.001$) than the weights in groups fed the soluble fractions of black currants and raspberries (mean = 4.5 ± 0.3 and 0.9 ± 0.0 g for the cecal content and tissue, respectively). The insoluble fractions gave considerably lower weights than the soluble fractions (mean = 1.9 ± 0.1 and 0.5 ± 0.0 g for the cecal content and tissue, respectively). Rats fed the insoluble fractions had a lower cecal pH (mean = 6.8 ± 0.1) than rats fed the soluble fractions (7.4 ± 0.1, $P < 0.001$). Dietary fibers in both the soluble and insoluble fractions were highly fermented in the hindgut of rats, but the fermentability was higher for the soluble fractions (85 ± 1 vs 81 ± 2% for the insoluble fraction, $P = 0.041$) (Table 3). The insoluble fiber fraction of black currants was more fermented (89%) than the insoluble fraction of bilberries (74%, $P < 0.001$). The fecal bulking capacity was similar for all groups, but the groups fed the two raspberry fractions had a lower fecal bulking capacity compared with the corresponding bilberry fractions (1.0 ± 0.0 vs 1.3 ± 0.1, $P = 0.042$).

SCFAs in the Hindgut. *Cecum.* The total amount of cecal SCFAs was higher in groups fed the soluble berry fractions than those fed the insoluble fractions, 525 ± 52 vs 166 ± 6 μmol for the insoluble fractions, $P < 0.001$ (Table 4). Of the soluble

[a]Mean values with their SEM (n = 7). Mean values within a row with unlike letters (a,b) are significantly different (P < 0.05).

fractions, bilberries exhibited the highest cecal amount of SCFAs (746 ± 104 μmol), which was more than twice as large as for the group fed the soluble fraction of black currants (346 ± 41 μmol, P < 0.001). SCFAs formed from the insoluble berry fractions were considerably lower and rather similar between berries. Due to the higher amounts of SCFAs formed with the soluble berry fractions, the yield of the specific SCFAs was also generally higher with these fractions than with the insoluble fractions (acetic acid, propionic acid, and minor acids P < 0.001). There was a tendency toward a higher amount of butyric acid formed in rats fed soluble bilberry and raspberry fractions than in corresponding insoluble fraction, whereas the proportion of butyric acid was higher with the insoluble fraction (14 ± 0%) than with the soluble fractions (5 ± 0%, P < 0.001). Similarly, the ratio between acetic acid and propionic plus butyric acid was also lower with the insoluble fraction. The proportion of propionic acid between groups was quite similar.

Distal Colon. Higher concentrations of butyric acid and minor acids were seen with insoluble berry fractions than with soluble berry fractions in the distal colon of rats (P < 0.001 and P < 0.004, respectively), whereas the concentration of propionic acid was higher with the soluble fractions (P < 0.012) (Table 5). Of the various berries, the soluble raspberry fraction gave a higher propionic acid concentration in the rats than the soluble bilberry fraction (P < 0.05), and it was also higher than the insoluble fraction of raspberry. The proportion of propionic acid was higher with the soluble raspberry fraction than with the other berry fractions (P < 0.05).

SCFAs in Portal Blood. The concentration of acetic acid in serum was 605–915 μmol/L, that of propionic acid, 39–55 μmol/L, and that of butyric acid, 25–72 μmol/L. Smaller amounts of the minor acids were detected (15–27 μmol/L).

The soluble fraction of bilberry gave a higher concentration of acetic acid (915 μmol/L) in the rats than the insoluble fraction (655 μmol/L, P = 0.019) (Table 6). In contrast, the insoluble fractions gave higher concentrations of butyric acid (48, 54, and 72 μmol/L, respectively, for bilberry, raspberry, and black currant) than the soluble fraction (29, 33 and 25 μmol/L, respectively, P < 0.001). It is noteworthy that the soluble fraction of black currant gave the lowest concentration of butyric acid (25 ± 2 μmol/L) in the rats, whereas the insoluble fraction of black currant gave the highest concentration (72 ± 13 μmol/L, P < 0.001). No difference was seen for propionic acid.

Inflammatory Markers. No difference was seen in inflammatory cytokines (IL-12, IL-18, and MCP-1) for any of the groups (see the Supporting Information).

Liver Cholesterol and Triglyceride. The total amount of liver cholesterol was lower and triglycerides tended to be lower in rats fed the soluble berry fractions rather than the insoluble fractions (mean = 75 ± 4 mg vs 88 ± 2 mg, P = 0.002, for cholesterol and mean = 133 ± 8 vs 150 ± 7 mg, P = 0.081, for triglycerides) (Table 7). Of the different soluble berry fractions, the bilberry group had the lowest amount of cholesterol compared with the other groups (56 vs 89 ± 3 mg). Groups fed soluble bilberry and insoluble black currant also had lower amounts of triglycerides compared with the group fed insoluble bilberry (108 and 129 vs 175 mg).

Anthocyanins and Glucuronide Metabolites. The total content of anthocyanins was higher in the insoluble berry

[a]Mean values with their SEM (n = 7). Values in parentheses show the content of anthocyanins in the soluble and insoluble berry fractions (μg/g, dwb). [b]–, values are below the detection limit (<1.2 ng/mL).

dx.doi.org/10.1021/jf5007566 | J. Agric. Food Chem. 2014, 62, 4359−4368

fractions than in the soluble ones (1559 and 233 μg/g for the insoluble and soluble bilberry fractions, respectively; 355 and 46 μg/g for the insoluble and soluble black currant fractions, respectively; and 45 and 21 μg/g for the insoluble and soluble raspberry fractions, respectively) (Table 8). With regard to the intake of anthocyanins, it was more similar from the soluble and insoluble bilberry fractions (8774 ± 407 and 7765 ± 100 μg/5 days, respectively) and also for the soluble and insoluble black currant fractions (2253 ± 36 and 2613 ± 12 μg/5 days, respectively), whereas the intake from the soluble raspberry fraction was 4 times higher than from the insoluble fraction (1034 ± 20 vs 282 ± 6 μg/5 days, respectively). Both fractions of bilberries had the greatest number of anthocyanins (14 in both fractions), followed by black currants (4 in both fractions). Only two different anthocyanins were found in raspberries, where cyanidin-3-*O*-sophoroside was found only in raspberry, whereas delphinidin-3-*O*-rutinoside was also detected in black currants.

Anthocyanins were detected in the urine of rats fed the soluble fractions from black currant and raspberry (0.25−0.75 μg/mL for black currant and 0.15−0.32 μg/mL for raspberry) (Table 8). Rats fed soluble fractions from bilberry were contaminated with the diet; therefore, no reliable analyses on anthocyanins could be performed. No anthocyanins were detected in the urine of the rats fed the insoluble fractions. However, in the LC-MS analysis cyanidin-3-glucoside monoglucuronide (m/z 648) was detected as ($M + Na^+$) in all urine samples. No anthocyanins or glucuronide metabolites were detected in cecum or blood plasma for any of the groups.

DISCUSSION

The aim of the present study was to investigate whether soluble and insoluble fractions isolated from three Swedish berries would affect the formation and absorption of SCFAs and the uptake and utilization of flavonoids by using a rat model. Furthermore, levels of cholesterol, triglycerides, and inflammatory cytokines were analyzed. This may be important for physiological parameters associated with colonic and metabolic health and therefore of interest in the production of foods with health benefits. Interestingly, the largest differences in the physiological parameters analyzed were seen between soluble and insoluble berry fractions. The differences between different berries were also greater in the soluble fractions than in the insoluble berry fractions, which exhibited quite similar results. It is noteworthy that the soluble fractions gave lower liver cholesterol and triglycerides in the rats than the insoluble fractions, especially with the soluble bilberry fraction. This fraction also had a higher formation of SCFAs, especially of acetic acid, than the other soluble berry fractions. Furthermore, the anthocyanin intake was higher with the soluble bilberry fraction than with the other soluble fractions, which could be another reason for the lower triglycerides and cholesterol levels in the liver. Similar findings have been seen by Kim et al., who gave a soluble chokeberry extract to apo E−/− mice.[31] Thus, the plasma cholesterol and triglyceride levels decreased, which could be related to decreased antioxidant enzyme activities in the liver (glutathione peroxidase) and in plasma (paraoxonase and catalase), that is, enzymes usually linked with protection from oxidative damage. However, the gene expression connected to cholesterol metabolism, lipogenesis, and fatty acid oxidation was unaffected in that study. The cholesterol and triglyceride levels were significantly higher with the insoluble bilberry fraction than with the soluble fraction, despite a similar intake of anthocyanins, which may be due to the lower bioavailability of anthocyanins with the insoluble bilberry fraction, which unfortunately not could be evaluated. To avoid this problem in future studies, an idea would be to collect urine from the urinary bladder at the end of the experiment instead.

The amount of anthocyanins ingested was highest with bilberries, irrespective of solubility, followed by black currants and then raspberries. Although the contribution of anthocyanins from the insoluble berry fractions, at least for black currant and bilberry, was as high as from the soluble berry fractions, these could only be found in urine of rats fed soluble berry fractions from black currant and raspberry. On the other hand, cyanidin-3-glucoside monoglucuronide, detected only with LC-MS, could be seen in urine of all groups irrespective of solubility. However, this peak was not quantified. Similar results have also been found by others.[32] The presence of anthocyanins in urine of rats indicates that these components were absorbed before reaching the colon and explains why no anthocyanins could be found in the cecum of rats. The absence of anthocyanins in blood of rats may be because they are rapidly metabolized. However, the anthocyanins may have been fermented by the microbiota, leading to a different molecular structure and therefore not detectable in this study. Most anthocyanins have been reported to be absorbed to a low extent in the upper part of the gastrointestinal tract and therefore possibly degraded to phenolic acids by the colon microbiota.[33,34] This could also be a reason why none of the anthocyanins of the insoluble berry fractions could be detected in cecum, portal blood, or urine of rats. Another reason could be that anthocyanins were tightly bound to the dietary fiber and not free for extraction in the analyses or for uptake in the colon. Additionally, limited analyses of the glucuronidated form of anthocyanins and metabolites that have been methylated might also explain the low amounts detected. However, it cannot be excluded that the amounts consumed were too low, and because the levels are further diluted in the body, the compounds may have been below the detection limit of the analytical methodology used. On the other hand, the levels of anthocyanins consumed were similar to or up to 10 times higher compared with the study of Kim et al., in which apo E−/− mice got a chokeberry extract.[31] The anthocyanins were not analyzed in blood there either, only the activity of some antioxidant enzymes. The anthocyanin content in black currants and raspberries was 10 times lower than in a previous study using the same rat model.[27] A possible explanation for this is that the berries came from two different suppliers. Furthermore, the berries were treated differently in the two studies. In the previous study the whole berry was studied, whereas soluble and insoluble fractions were studied in the present study.

The somewhat lower feed intake in rats fed diets containing the soluble berry fractions than in those fed insoluble fractions may be due to the more sour taste of these diets. However, it could also be due to the soluble fractions per se absorbing more water and therefore giving greater satiety and a lower feed intake. Soluble fractions formed more SCFAs, which may affect hormones associated with appetite (e.g., adiponectin) and inflammatory factors (TNF-α and IL-6) as suggested by Galisteo et al.[14] This may explain the lower feed intake. The gut microbial metabolism is increasingly suggested to be a causative agent of obesity.[35] Furthermore, soluble and viscous dietary fibers have been shown to increase satiety in humans, and the higher the viscosity, the greater the effects, delaying the

dx.doi.org/10.1021/jf5007566 | J. Agric. Food Chem. 2014, 62, 4359−4368

gastric emptying and/or intestinal absorption of nutrients.[14,36] This may be another reason for the lower levels of cholesterol and triglycerides in the liver. A lower intake of feed containing soluble fibers than insoluble ones has been seen in rats in a previous investigation on wheat.[37]

The greater formation of SCFAs, especially acetic acid, with the soluble fractions may explain the lower liver cholesterol and triglycerides in the rats fed these fractions, as mentioned above. The lowest amounts were seen with the soluble fraction of bilberry, and this fraction exhibited the highest cecal formation and serum concentration of SCFAs. This fraction also gave the highest cecal formation of propionic acid, although not significant, which is interesting because several studies have suggested that this acid has a beneficial effect on lipid metabolism.[38] However, the proportion of propionic acid did not increase and the ratio between acetic and propionic acid did not decrease either in the cecum or in serum, factors that are considered to be important in this respect. In recent years, butyric acid has been suggested to have a positive effect on lipid metabolism,[39] but the lower amounts of lipids in the liver could not be related to this acid either. Instead, both black currants and raspberries had lower ratios of both acetic to propionic acid and acetic to propionic plus butyric acid. It may be questioned whether it is just the total amount of SCFAs formed that is important, and not the specific acids. The soluble fiber fraction in bilberries was more fermented than those in the other berries, but these types of fibers were also more prone to form SCFAs, especially acetic acid. Interestingly, the composition of the dietary fiber was different in the soluble bilberry fraction compared with the fiber in the other soluble berry fractions. Thus, bilberries contained higher amounts of polymers consisting of xylose and glucose and lesser amounts of those consisting of uronic acids, and it might be questioned if this could be why bilberries produce more acetic acid. Another important factor may be that the rats used in this study were conventional rats; that is, they were healthy, and perhaps it is more difficult to see connections between different biological parameters in such rats. The amounts of cholesterol and triglycerides in the liver of the rats were in the same range as those found in another investigation with other types of fiber (guar gum, pectin, and a mixture of the two) using a similar rat model.[40] In that study, the dietary fibers were shown to decrease the amount of liver cholesterol to the same extent and independently of the fiber type in rats, compared with a fiber-free diet. The use of conventional rats may also explain why there were no differences in inflammatory risk markers between groups.

The cecal content and cecal tissue weights were higher with the soluble berry fractions than with the insoluble ones. This is possibly due to the dietary fiber in the soluble berry fraction retaining more water than the insoluble fraction, enlarging the cecum and increasing tissue weight.[41] The cecal tissue weight has previously been shown to be more correlated to the cecal volume than the concentration of SCFAs.[27,41] However, cecal pH was lower in groups fed diets containing the insoluble fractions. This might seem strange, but the pH has been shown to be highly correlated to the cecal concentration of SCFAs.[42] Due to the considerably lower weight of cecal content in rats fed insoluble berry fractions, the cecal concentrations were considerably higher with these fractions than with the soluble ones (SCFA concentration not shown in any table). This also shows that the concentration of SCFAs is not that interesting to elucidate, at least not in this case.

The insoluble berry fractions had fewer effects, but the insoluble fraction of black currant gave the lowest amounts of triglycerides in the liver. Interestingly, this fraction also gave the highest serum concentration and distal proportion of butyric acid, where the latter may help to improve colonic health, because most colonic diseases occur in the distal part of the colon. The insoluble fraction of black currants was composed of polysaccharides containing large amounts of mannose (32%) that was more or less completely fermented. Guar gum, another type of dietary fiber, which to a great extent is composed of mannose (galactomannan), has been shown to give high amounts of both propionic and butyric acids.[25] The insoluble bilberry fraction gave higher amounts of liver triglycerides than the other insoluble berry fractions, which may be related to the higher ratio of acetic to propionic and butyric acid in the serum of rats fed this fraction. The compositions of the dietary fiber in the insoluble bilberry and raspberry fractions were quite similar, so that could not be the reason. The intake of anthocyanins was also considerably higher with bilberries. However, it may be due to other types of antioxidants present in raspberries, for example, ellagitannins, that are able to change the composition of the microbiota and also the formation of specific SCFAs.

The present study showed that the soluble berry fractions had greater impact on parameters related to dietary fiber, such as fermentation of the dietary fiber, formation and concentration of SCFAs in the blood and cecum, and lipids in the liver, than the insoluble berry fractions, indicating an influence of the colon microbiota. The type of berry was also more important for the effects of soluble berry fractions than for the insoluble ones, which had more similar effects. Only anthocyanins in the soluble berry fraction could be seen in the urine of rats.

ABSTRACT: Wood shavings are widely employed in vinegar making to reduce aging time. Accordingly, this study aims to evaluate the effects of using shavings from different wood species (acacia, cherry, chestnut, and oak) and of toasting on the release of phenolic compounds into vinegar during the aging process. The study involved aging vinegars using previously toasted shavings and untoasted ones, at 0.5% and 1% (w/v), and collecting samples at 15 and 30 days. The phenolic compounds were analyzed by LC-DAD during the aging process. As a result, wood markers naringenin and kaempferol (cherry), robinetin and fustin (acacia), and isovanillin (oak) were identified for the first time in vinegars. The results also showed that toasting wood shavings decreases the concentration of most flavonoid wood markers (e.g., (+)-taxifolin, naringenin, and fustin) in vinegar, but that it is essential for the highest releases of aldehyde compounds (syringaldehyde, protocatechualdehyde, and vanillin). Remarkably, 15 days was sufficient to obtain the highest increases of most polyphenol compounds in the vinegar. Statistical analysis (linear discriminant analysis) proved that the phenolic compounds identified in vinegars are useful for discriminating vinegars regarding the wood species of the shavings used to accelerate aging.

KEYWORDS: *acacia, cherry, chestnut, oak, vinegar, polyphenol, toasting*

INTRODUCTION

Wood chips are used extensively in enology to accelerate aging.[1−4] However, there are scarce data available for vinegar making, and the majority is fairly recent.[5,6] Most studies have focused on oak chips, since this is the most commonly used species.[5,7,8] Even though other wood species, such as acacia, chestnut, cherry, mulberry, and ash, have all been crucial in producing traditional high-quality balsamic vinegars,[9] the use of chips from these woods to diversify products remains virtually unexplored in the literature concerning vinegar making.[10]

The release of polyphenol compounds from wood chips, staves, and shavings into wine and vinegar is a matter of interest in scientific literature.[5,6,11−15] The main points of interest as regards the release of polyphenol from wood chips into beverages are wood species, wood treatment in chip making, and the beverage matrix. Several recent studies have evaluated the release of polyphenol compounds from different heartwoods, such as cherry, chestnut, acacia, ash, etc., for their further use in cooperage.[16−21] Certain phenolic compounds have been established as wood markers, such as naringenin, isosakuranetin, eriodictyol, aromadendrin, and (+)-taxifolin in cherry wood;[19,21,22] (+)-dihydrorobinetin, fustin, robinetin, robtin, butin, and leucorobinetinidin in acacia wood;[10,20,21] gallic and ellagic acid and hydrolyzable tannins of both the ellagitannins and gallotannins in chestnut wood;[21,23] and oleuropein, ligstroside, olivil, verbascoside, isoverbascoside, oleoside, tyrosol, syringaresinol, and cyclolovil in ash wood.[21]

The thermic treatment of wood is a determining factor in the release of polyphenols. Indeed, aldehydes, such as protocatechualdehyde and coniferaldehyde, have not been reported in vinegars aged in untoasted oak barrels,[22] while they have been identified in vinegars aged in toasted oak barrels.[24] These studies have recorded that vanillin took 7 months longer to be released in untoasted oak barrels than in toasted ones.[22,24] Further to this, it has also been shown that toasting led to the formation of benzoic acids (protocatechuic acid, *p*-hydroxybenzoic acid, vanillic acid, and syringic acid) in cherry and chestnut heartwood, and cinnamic acids (caffeic acid and ferulic acid) in acacia and chestnut heartwood, due to lignin degradation,[19−21] while it resulted in the degradation of flavonoid markers.[19−21] To be specific, (+)-dihydrorobinetin concentration decreased 20-fold in vinegar that was aged with toasted acacia shavings.[10] What is more, the concentration of (+)-taxifolin in cherry heartwood was reduced by 97% when it was toasted.[19] Previous studies have further reported that condensed and hydrolyzable tannin concentrations diminished remarkably (70−95%) or even disappeared in toasted cherry, acacia, and chestnut heartwood when compared to seasoned heartwood, due to their heat-sensitive nature.[19−21]

WINEGAR European Project (COOP-CT-2005-017269) identified certain phenolic compounds as markers in high-quality vinegar aged in different untoasted wood barrels, such as acacia (dihydrorobinetin), cherry ((+)-taxifolin), and chestnut (high concentration of gallic acid and gallic ethyl ester). This paper aims to evaluate the effect of toasting on the release of the wood markers previously established by WINEGAR and polyphenols, in general, from acacia, cherry, chestnut, and oak shavings into vinegar. Besides this, we intend to assess the use

of shavings as an option to shorten aging time, in order to produce differentiated high-quality products more economically.

MATERIALS AND METHODS

Woods and Vinegar. A young, monovarietal, *Cabernet Sauvignon* red wine, a 2007 vintage, produced under controlled experimental conditions by the "Rancho La Merced" research center (Jerez de la Frontera, Spain), was used to produce the vinegar samples under conditions described in a previous study.[25] The resulting vinegar had 8.97 g/100 mL of acetic acid and an alcoholic degree of 1.33° (%, v/v).

Acacia (*Robina pseudoacacia*), cherry (*Prunus avium*), chestnut (*Castanea sativa*), and oak (*Quercus sps.*) wood shavings (5−10 mm) were provided by Boteria Torner S.L. (Barcelona, Spain). Vinegar samples were aged for 15 and 30 days using previously toasted (at 180 °C for 3 h in the oven) and untoasted shavings at 0.5% and 1% (w/v). A total of 32 samples were analyzed in duplicate. Samples were filtered through a Millex-LCR 13 mm filter before injection.

LC-DAD Identification and Quantification of Phenolic Compounds. LC analyses of phenolic compounds were performed using an Agilent series 1100 system equipped with a quaternary pump (series 1100 G1311A), automatic injector (series 1100 G1313A), and degasser (series 1100 G1379A). Detection was carried out using a UV/vis diode detector (series 1100 G1315B) coupled to a Chemstation HP A.10.02 (HP/Agilent). The column was an Agilent Zorbax SB-C18, 4.6 × 250 mm and particle size 3.5 μm. The chromatographic conditions had previously been used for vinegar analysis.[5] The method uses a binary gradient, A (glacial acetic acid/water pH 2.65) and B (20% A + 80% acetonitrile), programmed for the following gradient: 0 min 0% B; 5 min 2% B; 10 min 4% B; 15 min 10% B; 30 min 20% B; 35 min 30% B; 40 min 100% B; 45 min 0% B. The sample volume injected was 50 μL. The flow rate was 1.5 mL/min, and the temperature was set at 40 °C. Quantification was performed by external calibration with respective standards, using detection at 365 nm (robinetin, quercetin-3-glucoside, and kaempferol), 320 nm (hydroxycinnamic acids and syringaldehyde), and 280 nm (the remaining compounds). Once successful spectral matching had taken place, the results were confirmed by spiking with respective standards to achieve a complete identification by means of the peak purity test. The peaks that did not fulfill these requirements were not quantified.

The standards of the identified phenolic compounds were purchased from Fluka [caffeic acid, gallic acid, *p*-coumaric acid, gallic ethyl ester, quercetin-3-glucoside, isovanillin, and tyrosol], Sigma [(+)-taxifolin, ellagic acid, syringic acid, protocatechualdehyde, kaempferol, protocatechuic acid, and syringaldehyde], Merck [vanillin], Extrasynthese [fustin and robinetin], and Chromadex [3-*o*-methylgallic acid, caftaric acid, and naringenin]. Dihydrorobinetin was isolated from vinegar.[10]

Statistical Analyses. Statistical analyses were performed using Statistica software.[26] One-way analysis of variance (ANOVA) was used to test significant differences between (i) samples aged with toasted and untoasted shavings, (ii) vinegars aged for different periods, and (iii) vinegars aged with different shaving proportions. Linear discriminant analysis (LDA) enabled functions to be constructed to classify samples according to the type of wood or wood toasting with which they were in contact. The forward stepwise method achieved the best results.

RESULTS AND DISCUSSION

A total of 21 phenolic compounds were detected in vinegars aged with cherry, acacia, chestnut, and oak wood shavings (Tables 1 and 2). Figure 1 shows the chromatograms of the vinegars aged with each wood. The concentrations of phenolic acids (gallic acid and ellagic acid) and their esters (gallic ethyl ester), phenolic aldehydes (protocatechualdehyde, vanillin, isovanillin, and syringaldehyde), and flavonoids ((+)-taxifolin, naringenin, kaempferol, quercetin-3-glucoside, robinetin, and fustin) changed depending on toasting, shaving percentage, and aging time. None of the other compounds changed under the different conditions.

Polyphenol Compounds Identified for the First Time in Vinegars. Naringenin and kaempferol were both identified for the first time in vinegars aged with cherry wood, confirming previous studies that have described them as a marker in cherry heartwood.[19,21,27] Recently, prunin and eriodictyol were established as markers of wine aged with cherry wood because they were determined after 2 months aging with cherry chips.[28] The values reported were low: concentrations ranged between 0.24 and 0.65 mg/L (eriodictyol) and between 0.31 and 0.97 mg/L (prunin). The shorter length of our experiment may account for the absence of the above-mentioned compounds in our samples. It would be worthwhile verifying whether these compounds could be a marker of the time in contact with this wood, in addition to their value as cherry species markers.

This is the first time that robinetin and fustin compounds have been determined in vinegars aged with acacia wood. They have been previously identified in acacia heartwood[20,29] and in red wine aged in acacia wood barrels,[30] but not in vinegars.

Isovanillin was detected only in vinegars aged with oak shavings. Thus, isovanillin can be proposed as a marker of vinegars in contact with oak wood. As far as we know, this is the first time isovanillin has been identified in vinegars in contact with oak wood. Hydroxycinnamic aldehydes such as coniferaldehyde and sinapaldehyde have been detected in previous studies in wood extracts using methanol/water (1:1), diethyl ether, and ethyl acetate as solvent.[19−21] They have not been not detected either in wine aged with these woods[28] or in vinegars that likely involved a matrix effect. Furthermore, in these studies, wood extracts were subsequently treated to concentrate minor compounds.[19−21] Conversely, our samples were only filtered before injection, to prevent any artifact formation during sample treatment. The absence of the sample treatment and concentration step in our experiment explains the absence of these compounds in our samples.

In summary, further to (+)-taxifolin and (+)-dihydrorobinetin, which have previously been identified in vinegars aged in cherry and acacia wood,[10,22] naringenin and kaempferol are also good markers of vinegars aged with cherry wood, and robinetin and fustin are wood markers of acacia.

Effect of Wood Toasting on Phenolic Composition. In general, toasting was crucial for decreasing the concentrations of flavonoids ((+)-taxifolin, naringenin, and fustin) and a certain phenolic acid (gallic acid). Furthermore, wood toasting is essential for the release of certain compounds, such as aldehydes, into the vinegar, which is crucial for quality and sensory purposes.[31] Indeed, vinegars that have no contact with wood maintain their polyphenolic composition with no changes.[32]

In our results, (+)-taxifolin concentration was 4−5 times higher in vinegars aged with untoasted shavings compared to vinegars aged with toasted shavings (Table 1). (+)-Taxifolin has been previously described as a marker of vinegar aged in untoasted cherry wood barrels,[22] but no studies have yet been performed to elucidate on the effect of toasting on its release into the vinegar. Sanz et al.[19] found that the (+)-taxifolin content in seasoned cherry wood was more than 35 times higher than in toasted wood. In this study, toasting showed similar effects on naringenin, where its concentration was 3 times higher in samples aged with untoasted cherry wood shavings (Table 1). Some authors have also shown toasting to

be crucial in the release of naringenin from cherry wood, its content being 9 times higher in seasoned heartwood compared to toasted heartwood.[19] A matrix effect should explain the differences in these concentration values obtained. Differences are greater if a solvent such as methanol/water (1:1), diethyl ether, or ethyl acetate[19] is used rather than wine[28] or vinegar (Table 1). In fact, red wine aged with toasted cherry chips has shown double the concentration of (+)-taxifolin[28] compared to our vinegar aged with toasted cherry chips in a similar proportion (Table 1), as a consequence of the higher solubility of this compound in an ethanol matrix. However, in similar conditions (toasting and chips content) naringenin showed similar concentrations in wine[28] and vinegar (Table 1).

The release of fustin into the vinegar was also affected by toasting; it presented a concentration 6−7 times higher in vinegars aged with untoasted acacia wood shavings (Table 2). Previous studies have reported that fustin is highly sensitive to thermic treatment; acacia heartwood toasted at medium plus conditions (185 °C for 45 min) did not show fustin content, while there was a high concentration in the seasoned one.[20] Similar thermic sensitivity has been previously described for (+)-dihydrorobinetin, which presented a concentration 20 times higher in vinegars aged with untoasted acacia shavings compared to the toasted ones.[10] In contrast, toasting had the reverse effect on robinetin content, which presented concentrations between 12 and 29% higher in vinegars aged with toasted acacia shavings (Table 2). Previous studies state that robinetin does not change significantly with toasting in acacia heartwood[20] and wine aged with acacia wood barrels,[30] appearing to be quite stable when heated.

A high concentration of gallic acid has been described as a marker of vinegars in contact with chestnut wood.[23] The present study shows that gallic acid was significantly influenced by toasting, showing concentrations more than 3 times higher in vinegars aged with untoasted shavings (Table 1). Sanz et al. agrees that gallic acid is extremely sensitive to heat treatment.[21]

On the other hand, phenolic aldehyde concentrations were higher in vinegars aged with toasted shavings, in accordance with previous data reported comparing toasted and untoasted heartwoods.[16,21] In particular, syringaldehyde was restricted to vinegars aged with toasted shavings (Tables 1 and 2). Wood species determined the release of aldehydes and their concentration in the vinegar. Specifically, protocatechualdehyde was identified in cherry and acacia; vanillin and syringaldehyde in acacia, chestnut, and oak; and isovanillin only in oak wood (Tables 1 and 2).

In addition to the aldehyde compounds, toasting significantly increased the release of ellagic acid in vinegars aged with chestnut and oak wood shavings, showing significantly higher ellagic acid concentration in those aged with chestnut wood. Previous studies also agree that toasting favors the release of this compound.[33] Kaempferol concentration was also significantly increased with toasting in vinegars aged with cherry shavings (Table 1). In contrast, Sanz et al. showed that kaempferol content was higher in seasoned cherry heartwood than in toasted heartwood.[19]

Effect of Shaving Amount and Aging Time on Phenolic Composition. It would seem likely that the higher the shaving percentage (w/v) used, the higher the content of phenolic compounds released into the vinegar. This tendency was observed for (+)-taxifolin and naringenin, whose concentrations remarkably doubled, at 1% compared to 0.5% of shavings, regardless of wood treatment (Table 1). This trend has also been described for wine aged with 3 and 6 g/L of cherry chips.[28] However, other phenolic compounds such as protocatechualdehyde, kaempferol, fustin, robinetin, and isovanillin significantly increased their concentration at 1% of shavings but not in the same proportion as the shaving amount (Tables 1 and 2). On the other hand, the concentration of other phenolic compounds, vanillin for instance, did not significantly change in accordance with shaving amount (Tables 1 and 2).

Aging time has no remarkable influence on most of the phenolic compounds released from wood (Tables 1 and 2), which is in line with previous data reported, in vinegars aged with chips.[5] Fifteen days was sufficient to obtain the highest polyphenol concentrations in the vinegar, except for gallic acid, (+)-taxifolin, syringaldehyde, robinetin, and fustin (Tables 1 and 2). Gallic acid concentration significantly increased at 30 days, when aging was performed only with untoasted chestnut (1% shaving) and cherry and acacia (0.5 and 1% shaving) wood, the highest increase being with chestnut (40%), due to the high gallic acid content present in chestnut wood species.[22] The concentration of (+)-taxifolin also increased (>50%) after 30 days of aging with untoasted cherry shavings (Table 1). Additionally, we observed that the longer the time, the higher the concentration of syringaldehyde in vinegars aged only with toasted acacia shavings (1%) (Table 2).

Remarkably, (+)-taxifolin, protocatechualdehyde and vanillin showed a higher concentration in vinegars aged with shavings (Tables 1 and 2) than in vinegars aged in barrels that were made specifically using the same untoasted wood.[22] For instance, (+)-taxifolin content was more than 7 times higher in vinegars aged with untoasted cherry shavings at 1% (v/v) for one month (Table 1) compared to vinegars aged in an untoasted cherry wood barrel for six months.[22] Additionally, vinegars aged with untoasted acacia shavings at 0.5% (v/v) for 15 days (Table 2) presented a protocatechualdehyde concentration 3 times higher than in vinegars aged in untoasted acacia wood barrels for 180 days.[22] Moreover, vanillin concentration was 4 times higher in vinegars aged with untoasted oak shavings at 0.5% (v/v) for 15 days (Table 2) compared with vinegars aged in an untoasted oak wood barrel for a year.[22] On comparing robinetin concentration in vinegars aged with toasted acacia shavings at 1% (v/v) for 15 days (Table 2) to its concentration in wines aged in toasted acacia wood barrels for 6 months,[30] its concentration was observed to be 3 times higher in the former.

These data therefore support that shaving is a useful practice to accelerate the aging process and release the highest quantity of certain polyphenol compounds, including wood markers.

Statistical Analysis. Phenolic compounds are a powerful tool for discriminating vinegars produced in different origins[34] and with different acetification processes[35] and woods.[22,24] They are chemical markers for authentication purposes.[36] Since this paper found phenolic compounds in vinegars for the first time, we analyzed their capability to be used for these purposes. In order to achieve this goal, a linear discriminant analysis (LDA) was performed on the whole set of samples, grouping the vinegars according to the species of wood shavings used for aging. By means of the forward stepwise method, 16 variables were included in the model (robinetin, kaempferol, (+)-taxifolin, naringenin, vanillin, isovanillin, syringaldehyde, gallic ethyl ester, gallic acid, ellagic acid, caffeic acid, caftaric acid, protocatechuic acid, 3-*O*-methylgallic acid, quercetin-3-glucoside, and tyrosol) and 3 factors obtained. Table 3 displays the

Table 3. Correlation of Variables with the Canonical Roots Using the Forward Stepwise LDA Analysis According to the Species of Wood Used for Vinegar Aging

(+)-taxifolin	0.043 024	0.012 397	0.011 742
gallic acid	−0.001 211	−0.039 380	−0.057 710
isovanillin	−0.021 178	0.070 516	−0.058 782

correlation of variables with the canonical roots obtained. Figure 2 shows the scatterplot obtained plotting root 1 versus root 2. The classification functions achieved 100% correct sample classifications according to wood species. Furthermore, a statistical analysis to discriminate samples according to thermal treatment of shaving was performed. Forward stepwise LDA allowed 100% of samples to be correctly classified; the variables in the model were dihydrorobinetin, kaempferol, naringenin, isovanillin, syringaldehyde, protocatechualdehyde, gallic ethyl ester, ellagic acid, caffeic acid, syringic acid, caftaric acid, protocatechuic acid, 3-*O*-methylgallic acid, and quercetin-3-glucoside. (+)-Taxifolin has been previously used as a wood marker to classify vinegars according to the kind of wood in which they were aged.[22] This paper shows for the first time that robinetin, kaempferol, and naringenin are wood markers that are useful for authentication purposes in vinegar making.

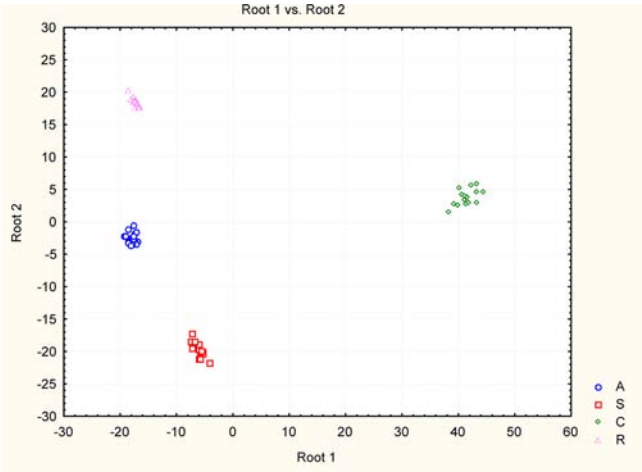

Figure 2. Plot of the first two roots issued from linear discriminant analysis (LDA): A, acacia; R, oak; S, chestnut; C, cherry.

This paper provides advanced knowledge of polyphenol composition in vinegars by describing naringenin, kaempferol, robinetin, fustin, and isovanillin in vinegars for the first time. The statistical treatment proves that certain newly detected phenolic compounds are also a useful tool for discriminating vinegars elaborated with shavings from different wood species.

Additionally, results show that toasting acacia, cherry, chestnut, and oak wood shavings mostly decreases flavonoid wood markers, such as (+)-taxifolin, naringenin, and fustin, while it is essential for the highest releases of aldehyde compounds into the vinegar. This paper provides data to develop a strategy to produce vinegars with an appropriate phenolic composition in a short time. If phenolic aldehydes are desired for their impact on the sensory properties of the product, toasting shavings is mandatory. Conversely, if the aim is to obtain a product that is rich in flavonoids, no toasting is recommended.
