[a]Anthocyanin: C-sam-malonylglu, cyanidin-sambubioside-malonylglucoside; C-sam-acetylglu, cyanidin-sambubioside-acetylglucoside; C-xyl-dihex, cyanidin-xylosyl-dihexoside; C-3-(*Z*)-cou-sam-5-glu, cyanidin-3-(*Z*)-*p*-coumaroyl-sambubioside-5-glucoside; C-3-(*E*)-cou-sam-5-glu, cyanidin-3-(*E*)-*p*-coumaroyl-sambubioside-5-glucoside; C-3-cou-sam, cyanidin-3-*p*-coumaroyl-sambubioside. [b]Different letters (a−j) denote statistically significant differences in individual anthocyanins among elderberry species or interspecific hybrid by Duncan multiple range test at $P < 0.05$.

dx.doi.org/10.1021/jf5011947 | J. Agric. Food Chem. 2014, 62, 5573−5580

var. *miquelli* (6% TAA) and *S. ebulus* only contained low amounts of cyanidin-3-sambubioside (less than 2% TAA). The second anthocyanin in peak 6 was identified as cyanidin-3-*O*-glucoside by its $[M]^+$ at m/z 449, which on MS^2 yielded a cyanidin fragment ion at m/z 287 formed by the cleavage of a 162 amu glucosyl unit. It was further confirmed by the addition of an external standard. *S. nigra* was characterized by highest levels of this anthocyanin (representing one-third of all anthocyanin analyzed in the fruit), followed by its hybrids: (JA × NI) × NI, JA × (JA × NI), and (JA × NI) × cv. Black Beauty. *S. ebulus* and *S. racemosa* var. *miquelli* contained only minor amounts of this anthocyanin. In accordance with our results, *S. nigra* samples analyzed by Watanabe et al.[38] contained more cyanidin-3-sambubioside than cyanidin-3-glucoside. On the other hand, Kaack and Austed[33] report higher levels of cyanidin-3-glucoside. In *S. nigra* berries analyzed in our study, cyanidin-3-sambubioside and cyanidin-3-glucoside combined represented approximately 95% TAA. These results are similar to those already reported in the literature by Seabra et al.[10] and Nakajima et al.[34]

Peak 7 showed a molecular ion at m/z 595, which fragmented to produce MS^2 ions at m/z 449 ($[M]^+ - 146$, loss of a rhamnosyl moiety) and m/z 287 ($[M]^+ - 308$, cleavage of rhamnosyl and glucosyl units), suggesting the presence of cyanidin-3-*O*-rutinoside. It was only present in specific hybrids; (JA × NI) × cv. Black Beauty was particularly rich in this anthocyanin (64.7 mg 100 g^{-1}) (Table 3). As one of the parents of the hybrid is *Sambucus nigra*, the results confirm the findings of Veberic et al.,[23] who reported 9.6 mg of cyanidin-3-rutinoside 100 g^{-1} in fruits of *S. nigra* 'Haschberg'. The second anthocyanin in peak 7 had an ion at m/z 829, which yielded a MS^2 fragment at m/z 667 ($[M]^+ - 162$, loss of a hexose unit) and MS^3 at m/z 449/287 ($[M]^+ - 132 - 162 - 86$, loss of xylosyl, glucosyl, and malonyl units). This compound is thus a cyanidin-pentosylhexoside-malonylhexoside, tentatively identified as cyanidin-sambubioside-malonyl-glucoside and present only in specific hybrids (JA × RAC, JA × CER, (JA × NI) × cv. Black Beauty, and MIQ). This is the first report of this compound in elderberry berries.

Peak 8 showed a molecular ion of m/z 551 and a neutral loss of 264 u, corresponding to two pentoses, so it was tentatively identified as a cyanidin dipentoside. It was detected in *S. cerulea* and *S. ebulus* fruit in levels below 0.5 mg 100 g^{-1}. This is the first report of cyanidin dipentoside ($[M]^+$ at m/z 551) in elderberry berries.

Peak 9 had $[M]^+$ at m/z 433 and on MS^2 yielded a fragment ion at m/z 271 (pelargonidin, $[M]^+ - 162$, loss of a hexosyl unit). On the basis of the mass spectra data, HPLC elution properties, and the addition of an external standard, peak 9 was identified as pelargonidin-3-*O*-glucoside. It was only detected in traces in berries of *S. nigra* and its hybrids (JA × NI) × NI, (JA × NI) × CER, JA × (JA × NI), and (JA × NI) × cv. Black Beauty (data not presented). Similarly, Lee and Finn[20] and Wu et al.[24] report low levels of pelargonidin-3-glucoside in *S. nigra* fruit.

The anthocyanin with a molecular ion of m/z 565 was identified as pelargonidin-3-*O*-sambubioside (peak 10). On MS^2 it produced a minor fragment at m/z 433 ($[M]^+ - 132$, loss of a xylosyl unit) and a major fragment at m/z 271 ($[M]^+ - 162$, loss of a glucosyl unit). It has been confirmed in the following species and hybrids: *S. nigra* and *S. cerulea*, (JA × NI) × NI, JA × (JA × NI), and (JA × NI) × cv. Black Beauty. Only low levels of this anthocyanin were quantified (data not presented), which is in accordance with Wu et al.[24] and their study on *S. nigra* fruit.

The compound in peak 11 showed a molecular ion at m/z 785 and MS^2 fragment at m/z 623 ($[M]^+ - 162$, loss of a hexose residue) and MS^3 fragment at m/z 449/287 ($[M]^+ - 42$ loss of acetyl; − 162 hexose and − 132 pentose moieties). This fragmentation pattern is similar to that observed for the compound in peak 6. Thus, peak 11 was identified as cyanidin 3-xylosylhexoside-acetyl-hexoside. Because sambubioside (i.e., 2-*O*-*β*-D-xylosyl-D-glucose) is the xylosylglucoside most frequently found as an anthocyanin substituent,[39] peak 11 could be tentatively identified as cyanidin-sambubioside-acetylglucoside. A similar fragmentation pattern of a cyanidin-based anthocyanin has previously been reported in *Sambucus* samples by Lee and Finn.[20] In our samples, it was merely present in two hybrids, JA × RAC (10.4 mg 100 g^{-1}) and JA × NI (3.5 mg 100 g^{-1}). Interestingly, hybrids of a similar origin (*S. javanica* as a mother plant) did not contain cyanidin-sambubioside-acetyl-glucoside.

Peak 12 presented a molecular ion $[M - H]^-$ at m/z 905, which yielded MS^2 fragment ion at m/z 743 ($[M]^+ - 162]^-$, loss of a hexoside moiety), and MS^3 fragment at m/z 449 ($[M]^+ - 132$, loss of a pentoside and − 162 a hexoside or caffeoyl moiety) and 287 (cyanidin, − 162 loss of a hexoside moiety). The fragmentation pattern is similar to that obtained for peak 1; the difference is one hexose or caffeoyl unit. The peak was tentatively identified as cyanidin-xylosyl-dihexoside or cyanidin-caffeoyl-sambubiosyl-glucoside. This anthocyanin was quantified in range of 2.6−15.9 mg 100 g^{-1} berries in the following hybrids: JA × RAC, (JA × NI) × CER, JA × (JA × NI), and JA × NI. As all hybrids share the same species, *S. javanica*, the latter potentially represents the genetic source for the accumulation of this specific anthocyanin.

Peaks 13 and 14 were characterized by the same mass spectral pattern. Both compounds had a molecular ion at m/z 889 that fragmented on MS^2 to produce ion at m/z 727 ($[M]^+ - 162$, loss of a glucosyl moiety) and on MS^3 produce the ions at m/z 449 ($[M]^+ - 132$ a pentosyl and − 146 a coumaroyl moiety) and 287 (cyanidin, − 162 a glucosyl moiety). According to the study of Lee and Finn[20] and Inami et al.,[40] this fragmentation pattern matches with cyanidin-3-(*Z*)-*p*-coumaroyl-sambubioside-5-glucoside and cyanidin-3-(*E*)-*p*-coumaroyl-sambubioside-5-glucoside. The results indicate that both anthocyanins are characteristic for *S. javanica* and *S. racemosa* fruit as they are only present in hybrids, where these species were used as parent plants. Statistically highest level of cyanidin-3-(*Z*)-*p*-coumaroyl-sambubioside-5-glucoside (11.9 mg 100 g^{-1}) and cyanidin-3-(*E*)-*p*-coumaroyl-sambubioside-5-glucoside (583 mg 100 g^{-1}) was determined in JA × RAC hybrid in which they combined to represent up to 71% total analyzed anthocyanins. On the other hand, *S. nigra*, *S. cerulea*, and *S. ebulus* fruit did not contain these two anthocyanins as reported also Jordheim et al.[41]

Peak 15 contained $[M]^+$ ion at m/z 727, which yielded MS^2 fragment at m/z 433 ($[M]^+ - 132$ and − 162, loss of xylosyl and glucosyl units) and MS^3 fragment at m/z 287 ($[M]^+ - 146$, loss of a coumaroyl unit). This corresponds to the fragmentation pattern of cyanidin-3-*p*-coumaroyl-sambubioside, which has previously been detected in elderberry fruit.[20,40] It was only detected in hybrids involving *S. javanica*, *S. cerulea*, or *S. racemosa* var. *miquelli* parent. The highest level of cyanidin-3-*p*-coumaroyl-sambubioside has been determined in (JA × NI) × CER (68.9 mg 100 g^{-1}) fruit. In accordance with our results,

Lee and Finn[20] reported that *S. nigra* fruit lacks cyanidin-3-*p*-coumaroyl-sambubioside.

Interestingly, berries of the CER × NI hybrid contained the last three mentioned anthocyanins (Table 4). The absence of the anthocyanins cyanidin-3-(*Z*)-*p*-coumaroyl-sambubioside-5-glucoside, cyanidin-3-(*E*)-*p*-coumaroyl-sambubioside-5-glucoside, and cyanidin-3-*p*-coumaroyl-sambubioside in *S. cerulea* and *S. nigra*, and their presence in their hybrid CER × NI, could be explained by homo- and heterozygosity in association with pollination system of elderberries, and genetic inheritance of these two anthocyanins (the interactions of two or more loci with dominant and recessive alleles and/or the involvement of inhibiting genes). Elderberries can be pollinated by wind and insects, and cross-pollination is probably more important than self-pollination.[3,42]

Elderberries are predominantly used as processed food or dietary supplements; therefore, it is useful to know their content of phenolic compounds, especially anthocyanins, which represent the highest share in elderberry fruit. The major anthocyanins detected in fruit of different species and interspecific hybrids were cyanidin-3-*O*-sambubioyl-5-*O*-glucoside, cyanidin-3,5-diglucoside, cyanidin-3-sambubioside, cyanidin-3-glucoside, and cyanidin-3-(*E*)-*p*-coumaroyl-sambubioside-5-glucoside. Conversely, in *S. javanica* and *S. racemosa*, hybrids cyanidin-3-(*Z*)-*p*-coumaroyl-sambubioside-5-glucoside and cyanidin-3-(*E*)-*p*-coumaroyl-sambubioside-5-glucoside prevailed. Total analyzed anthocyanins (TAA) varied greatly from hybrid to hybrid. Promising species or interspecific hybrids with TAA higher than 400 mg 100 g^{-1} were (JA × NI) × CER, (JA × NI) × cv. Black Beauty, *Sambucus nigra*, and, in particular, JA × RAC hybrid, which contained 834 mg 100 g^{-1} of anthocyanins. Berries of *S. nigra* var. *viridis* contained significantly lower levels of TAA, which is closely correlated with the pale color of their fruits; they are predominantly green with a slight hint of red color. Several minor anthocyanins have also been confirmed in different elderberries. Pelargonidin-3-glucoside, pelargonidin-3-sambubioside, cyanidin-3-galactoside, cyanidin-dipentoside ($[M]^+$ at m/z 551), and different cyanidin glycosides 1−3 ($[M]^+$ at m/z 581) were quantified in traces. Our results indicate that elderberry fruits are a superior source of anthocyanins to other fruit species, for example, apples, peaches, and strawberries.[43−45] However, a great variation in anthocyanin profile has been observed among elderberry species and hybrids. These differences may contain important implications and information, which may become evident in health effects studies. Some elderberry genotypes could be used to design new raw materials with high contents of anthocyanins, which can serve to produce elderberry products with health-promoting properties based on their positive health effects. Data from our research present new information for nutritional research in addition to breeding programs, which have turned their focus to fruit quality and strive to improve nutritional or health value to create new hybrids or cultivars with enhanced levels of bioactive components.

Supporting Information

ABSTRACT: *Uraria crinita* is an edible herb used as a natural food for childhood skeletal dysplasia. Ethyl acetate, *n*-butanol, and aqueous fractions of a 95% ethanol crude extract of *U. crinita* were obtained and the active ingredients isolated and purified using a bioguided method. In this manner, we isolated and identified a new active flavone glycoside, apigenin 6-*C*-*β*-D-apiofuranosyl(1→2)-*α*-D-xylopyranoside (**3**) and 10 known components with stimulatory activity on human osteoblast cells. The new compound **3** at 100 *μ*M significantly increased alkaline phosphatase activity (114.10 ± 4.41%), mineralization (150.10 ± 0.80%), as well as osteopontin (1.39 ± 0.01-fold), bone morphogenetic protein-2 (BMP-2, 1.30 ± 0.04-fold), and runt-related transcription factor 2 (Runx2, 1.43 ± 0.10-fold) mRNA expression through the activation of the BMP-2/Runx2 pathway. Two other components, dalbergioidin (**1**) and byzantionoside B (**9**), displayed similar effects. These results show that *U. crinita* and its active compounds may have the potential to stimulate bone formation and regeneration.

KEYWORDS: *Uraria crinita, human osteoblast cells, alkaline phosphatase, mineralization, apigenin 6-C-β-D-apiofuranosyl(1→2)-α-D-xylopyranoside, osteopontin, BMP-2/Runx2 pathway*

INTRODUCTION

Uraria crinita (L.) Desv. ex DC. (Fabaceae), an edible herb used in traditional medicine, is widely distributed throughout India, Thailand, Indonesia, southern China, and Taiwan. This herb has been reported to repress the formation of stress-induced ulcers[1] and to have antioxidant activity,[2] and its roots are used to treat chills, edema, and stomachache through effects that are possibly mediated by its anti-inflammatory activity.[3] In Taiwan, *U. crinita* is drunk as a tea that, similar to ginseng, is fragrant, sweet, and thirst-quenching, and it is therefore known as "Taiwanese ginseng." In traditional Chinese medicine, *U. crinita* roots are used as dietary supplements for treating childhood skeletal dysplasia as well as for sports injuries, stress fractures, sprains, and strains,[4] and its extracts are rich in *β*-sitosterol, flavonoids, butulin, stearic acid, and sucrose.[4,5]

Osteoblasts, the bone-forming cells that originate from mesenchymal stem cells, play a crucial role in creating and maintaining skeletal architecture. Bone formation involves a complex series of events that include the proliferation and differentiation of osteoblasts, and ultimately results in mineralization of the extracellular matrix (ECM).[6] Specific genes are sequentially expressed or repressed during each stage of osteoblast development; for example, histone 4 expression is a marker of proliferation, alkaline phosphatase (ALP) expression is a marker of differentiation,[7] and osteopontin (OPN) expression is a marker of mineralization.[8] Bone morphogenetic proteins (BMPs) are members of the transforming growth factor (TGF)-*β* family that activate SMAD proteins and other signaling pathways to stimulate the expression of a number of regulatory genes, including runt-related transcription factor 2 (Runx2). Both BMP growth factors and Runx2 transcription factors play essential roles in osteoblast differentiation and subsequent bone matrix mineralization.[9,10] Bone formation is necessary for the proper growth of bones in infants and children, prevention of bone mass loss in climacteric women, and healing and remodeling of bone fractures. Thus, there is a clinical need for nutritional and pharmacological agents that prevent bone loss and increase bone formation to support human health.

Primary osteoblast cell cultures are widely used as *in vitro* models to investigate the effects of new agents on osteoblast differentiation, matrix mineralization, and new bone formation. A number of factors influence the expression of the osteoblastic phenotype in cell culture.[11] For example, osteogenic supplements such as glucocorticoids, ascorbic acid, and *β*-glycerophosphate have been demonstrated to induce matrix mineralization in bone cell cultures and are extensively used to investigate agents that regulate bone formation *in vitro*.[6] Previous studies have revealed that many traditional Chinese herbal medicines affect bone formation, including *Puerariae radix*,[12] *Drynariae rhizome*,[13] and *Epimedium pubescens*.[14] However, there are no reports of the effects of *U. crinita* on osteoblasts. Therefore, this study was performed to determine whether *U. crinita* root extracts and their

active constituents have osteogenic effects on human osteoblast (HOb) cells.

MATERIALS AND METHODS

Plant Material. *Uraria crinita* roots were collected from the Mingjian Township Farmers' Association, Nantou, Taiwan and identified by Dr. Chao-Lin Kuo, School of Chinese Pharmaceutical Sciences and Chinese Medicine Resources, China Medical University, Taichung, Taiwan. A voucher specimen (M-343) was deposited at the Graduate Institute of Pharmacognosy, Taipei Medical University, Taipei, Taiwan.

Reagents and Chemicals. Dimethyl sulfoxide (DMSO), MTT, Triton X-100, *p*-nitrophenyl phosphate disodium, alizarin red-S, cetylpyridinium chloride monohydrate, ascorbic acid, and *β*-glycerophosphate disodium salt hydrate were purchased from Sigma-Aldrich (St. Louis, MO, USA). Phosphate-buffered saline (PBS) and trypsin were purchased from Gibco (Burlington, Canada). Osteoblast growth medium (OGM) and osteoblast differentiation medium (ODM) were purchased from Cell Applications (San Diego, CA, USA). A bicinchoninic acid (BCA) protein assay kit was purchased from Thermo Scientific (Rockford, IL, USA), 4-nitrophenyl phosphate disodium salt hexahydrate was obtained from Alfa Aesar (Ward Hill, MA, USA), High Pure RNA Isolation Kit and Universal Probe Library (UPL) probes were acquired from Roche (Mannheim, Germany), SuperScript II reverse transcriptase was obtained from Invitrogen (Burlington, Canada), and SafeView nucleic acid stain was purchased from NBS Biologicals (Huntingdon, UK). All chemicals and reagents were high-grade commercial products.

General Experimental Procedures. Optical rotations were measured on a Jasco P-1020 digital polarimeter (Tokyo, Japan). Ultraviolet spectra were recorded on a Hitachi U-2800 UV/vis spectrometer (Tokyo, Japan). 1D- and 2D-nuclear magnetic resonance (NMR) spectra were measured with a Bruker AM-500 spectrometer (Rheinstetten, Germany) using DMSO-d_6, methanol (MeOH)-d_4, and D_2O solutions. High-resolution eletrospray ionization mass spectroscopy (HRESI-MS) and ESI-MS analyses were performed using VG Platform Electrospray ESI/MS (Altrincham, Cheshire, UK).

Extraction and Isolation. Fresh roots (14.7 kg) of *U. crinita* were extracted three times with ethanol (EtOH, 95% v/v), and the filtrate was evaporated and dried under a vacuum. The dried extract (601.4 g) was suspended in H_2O and successively partitioned with ethyl acetate (EtOAc) and *n*-butanol (*n*-BuOH) to yield 32.0 and 133.9 g of extract, respectively. The EtOAc extract was subjected to Sephadex LH-20 column chromatography (Amersham Pharmacia Biotech, Uppsala, Sweden) and eluted with 95% EtOH to yield 9 fractions (UCE-1−9). Fraction UCE-3 was further separated by Sephadex LH-20 column chromatography and eluted with a MeOH/H_2O gradient (40−100%) to yield 17 fractions (UCE-3-1−17). Fraction UCE-3-7 was fractionated by MCI CHP-20 column chromatography (Supelco, Bellefonte, PA, USA) with an H_2O-MeOH gradient to yield 14 fractions (UCE-3-7-1−14). Compound **2** (98.1 mg) was obtained from the UCE-3-7-4 fraction after recrystallization from MeOH/H_2O. Fraction UCE-4 was further separated by Sephadex LH-20 column chromatography and eluted with a MeOH/H_2O gradient (50−100%) to yield 17 fractions (UCE-4-1−17). Fractions UCE-4-3 and UCE-4-10 were fractionated on an MCI CHP-20 column with a MeOH/H_2O gradient (30−100%) to yield 8 (UCE-4-3-1−8) and 11 (UCE-4-10-1−11) fractions, respectively. Compound **11** (12.0 mg) was obtained from the UCE-4-3-2 fraction after purification on a semipreparative C-18 reverse-phase HPLC column (Biotic Chemical Co., Taipei, Taiwan) with 10% MeOH as the eluent. Compound **4** (6.9 mg) was obtained from the UCE-4-10-2 fraction after purification on a semipreparative C-18 reversed-phase HPLC column with 25% acetonitrile as the eluent. Fraction UCE-5 was separated by MCI CHP-20 column chromatography with an H_2O−MeOH gradient to yield 24 fractions (UCE-5-1−24). Fractions UCE-5-15 and UCE-5-16 were subjected to Sephadex LH-20 column chromatography and eluted with 60% MeOH to yield 6 (UCE-5-15-1−6) and 10 (UCE-5-16-1−10) fractions, respectively. Compounds **3** (12.2 mg) and **1** (184.5 mg) were obtained from the UCE-5-15-1 and UCE-5-16-9 fractions, respectively, after purification on a semipreparative C-18 reversed-phase HPLC column with 55% MeOH as the eluent. The *n*-BuOH extract was subjected to Diaion HP-20 column chromatography (Mitsubishi Chemical Industries, Tokyo, Japan) and eluted with an H_2O−MeOH gradient to yield 6 fractions (UCB-1−6). Fractions UCB-3, UCB-4, and UCB-5 were further separated by Sephadex LH-20 column chromatography and eluted with 95% EtOH to yield 6 (UCB-3-1−6), 9 (UCB-4-1−9), and 6 (UCB-5-1−6) fractions, respectively. Fractions UCB-3-3 and UCB-5-2 were separated by MCI CHP-20 column chromatography with an H_2O−MeOH gradient to yield 6 (UCB-3-3-1−6) and 8 (UCB-5-2-1−8) fractions, respectively. Compounds **7** (38.3 mg) and **8** (15.3 mg) were obtained from the UCB-3-3-2 fraction. Compounds **5** (58.6 mg) and **6** (7.6 mg) were obtained from the UCB-3-3-3 and UCB-5-2-1 fractions, respectively, after purification on a semipreparative C-18 reversed-phase HPLC column with 20% MeOH as the eluent. Fractions UCB-4-3 and UCB-4-4 were separated on MCI CHP-20 columns and eluted with MeOH/H_2O gradients (60−100% and 20−100%, respectively) to yield 4 (UCB-4-3-1−4) and 9 (UCB-4-4-1−9) fractions, respectively. Compound **9** (38.5 mg) was obtained from the UCB-4-3-3 fraction after purification on a semipreparative C-18 reversed-phase HPLC column with 20% MeOH as the eluent. Compound **10** (13.5 mg) was obtained from the UCB-4-4-3 fraction after purification on a semipreparative C-18 reversed-phase HPLC column with 40% MeOH as the eluent.

Acid Hydrolysis of Compound 3. Compound **3** (1 mg) was dissolved in 6 N HCl and hydrolyzed at 80 °C for 6 h. The mixture was cooled, the acid was evaporated, and the remaining mixture was resuspended in double-distilled H_2O and filtered through a Millipore Millex-GX nylon membrane (EMD Millipore, Billerica, MA, USA).[15] Monosaccharides of **3** and polysaccharide hydrolysates were separated

HRESI-MS *m*/*z* 535.1459 $[M + H]^+$ (calcd for $C_{25}H_{27}O_{13}$, 535.1452).

Cell Culture. HOb primary cells were derived from a normal femoral bone of a 63-year-old Caucasian female and obtained from Cell Applications (San Diego, CA, USA). HOb cells attach and spread on tissue culture surfaces, proliferate in OGM, and express differentiation and mineralization markers when cultured in ODM containing ascorbic acid and β-glycerophosphate at 37 °C in a 5% CO_2 humidified atmosphere. The growth medium was changed every other day. To maintain exponential growth, cells were subcultured every 7 days. HOb cells were used for all assays.

Cell Viability Assay. HOb cell viability was determined using the MTT assay as described elsewhere.[16] In brief, HOb cells were seeded in 96-well plates at a density of 4000 cells/well. After 24 h, the culture medium was replaced with fresh medium containing the test extracts or compounds. After 72 h, the incubation medium was removed, and the MTT reagent was added for 4 h. The MTT reagent was then replaced with 100 μL of DMSO, and the wells were thoroughly mixed to dissolve the dark-blue crystals. The absorbance at 600 nm was recorded using an enzyme-linked immunosorbent assay reader.

Alkaline Phosphatase (ALP) Assay. ALP activity in HOb cells was measured by a colorimetric assay using *p*-nitrophenyl phosphate as the substrate.[17] HOb cells were seeded in 96-well plates at a density of 4000 cells/well, and after 24 h, the culture medium was replaced with fresh ODM containing the test extracts or compounds. After 72 h, the incubation medium was discarded, and cells were rinsed twice with cold PBS and then lysed by adding lysis buffer (PBS containing 0.1% Triton X-100). The protein concentration in the supernatant was determined by a BCA assay. Supernatants were incubated with the BCA reagent for 1 h at 37 °C. The reaction was stopped by the addition of 1 M NaOH, and the absorbance was measured at 560 nm. ALP activity in the supernatants was assayed by incubation for 1 h at 37 °C in 0.1 M $NaHCO_3$−Na_2CO_3 buffer (pH 10) containing 0.1% Triton X-100, 2 mM $MgSO_4$, and 6 mM *p*-nitrophenyl phosphate. The reaction was stopped by the addition of 1 M NaOH, and the absorbance was measured at 405 nm. ALP activity was normalized to the protein concentration in each supernatant.

Mineralized Matrix Formation Assay. HOb cell mineralization was measured by alizarin red-S staining of calcium.[18] HOb cells were seeded in 24-well plates at a density of 7 × 10^4 cells/well, and after 3 days, the culture medium was replaced with mineralizing medium (ODM supplemented with 50 μg/mL ascorbic acid and 10 mM β-glycerophosphate) containing the test extracts or compounds. Cells were incubated for 12 days and then fixed in 75% EtOH. Calcium deposits were stained for 15 min at room temperature with an alizarin red-S solution (40 mM, pH 4.2). The bound stain was eluted with a solution of 10% (w/v) cetylpyridinium chloride in 10 mM sodium phosphate (pH 7.0), and the absorbance was measured at 550 nm.

RNA Extraction and Q-RT-PCR. HOb cells were seeded in 6 cm dishes at a density of 7 × 10^5 cells/dish, and after 24 h, the culture medium was replaced with fresh ODM containing the test extracts. After 24 h, total RNA was extracted with High Pure RNA Isolation Kit and reverse-transcribed with SuperScript II reverse transcriptase according to the manufacturer's instructions. Q-RT-PCR was used to measure OPN, Runx2, and BMP-2 mRNA expression. Specific primers were designed using the Universal Probe Library Assay Design Center (www.roche-applied-science.com) and the suggested Universal Probe Library (UPL) probes. The detailed sequences of primers and probes are given in Table 2. All reactions were performed in triplicate using a Roche LightCycler 480 detection system using the $2^{-\Delta\Delta Ct}$ method. Runx2, BMP-2, and OPN mRNA expression results were

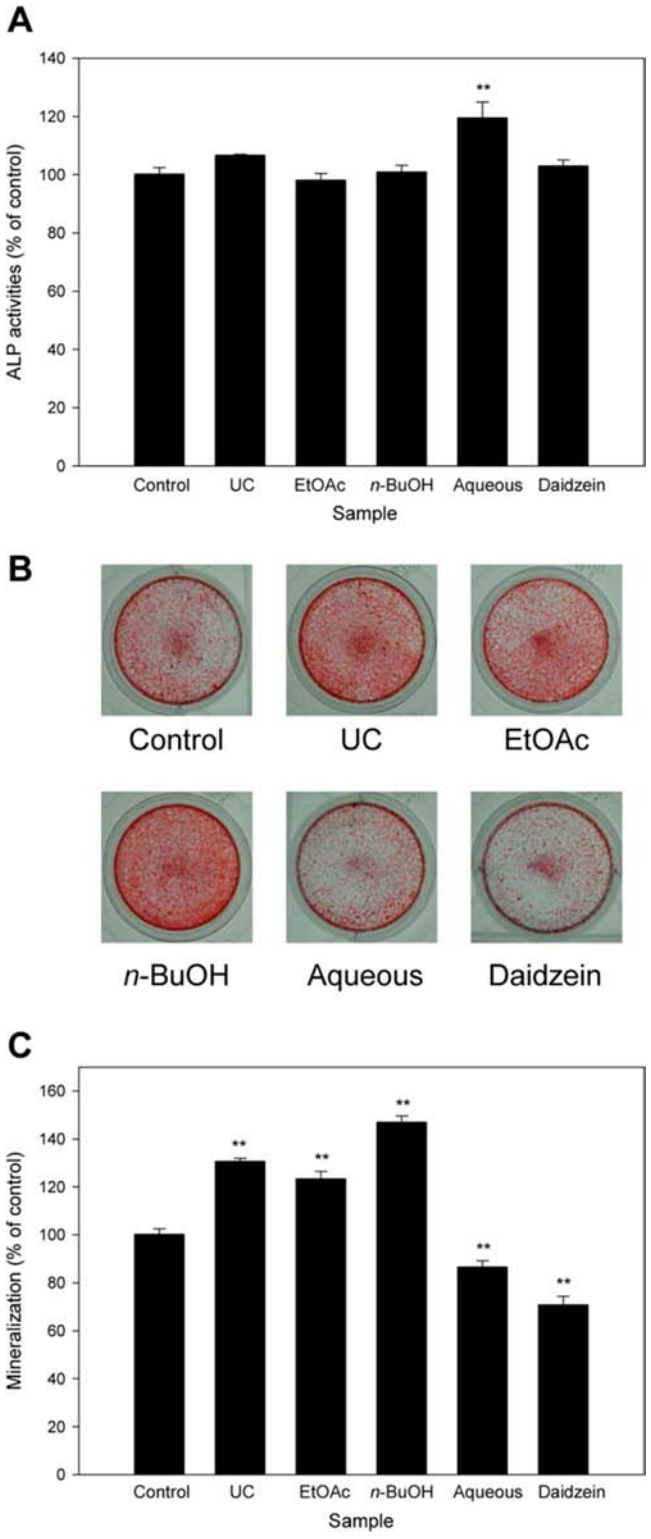

Figure 1. Effects of *U. crinita* extract (UC) and subfractions on ALP activity and mineralization in HOb cells. (A) HOb cells were seeded in 96-well plates and treated with 100 μg/mL of the indicated extracts for 72 h. ALP activity was measured using a colorimetric assay with *p*-nitrophenyl phosphate as the substrate. (B) HOb cells were plated in 24-well plates and treated with 100 μg/mL of the indicated extracts for 12 days. Mineralized nodule formation was assessed by alizarin red staining. (C) Quantitative analysis of the extent of mineralization. Daidzein (100 μM) was used as the positive control. Data are the presented as the mean ± SD (n = 3). * $p < 0.05$ and ** $p < 0.01$ compared to control cells.

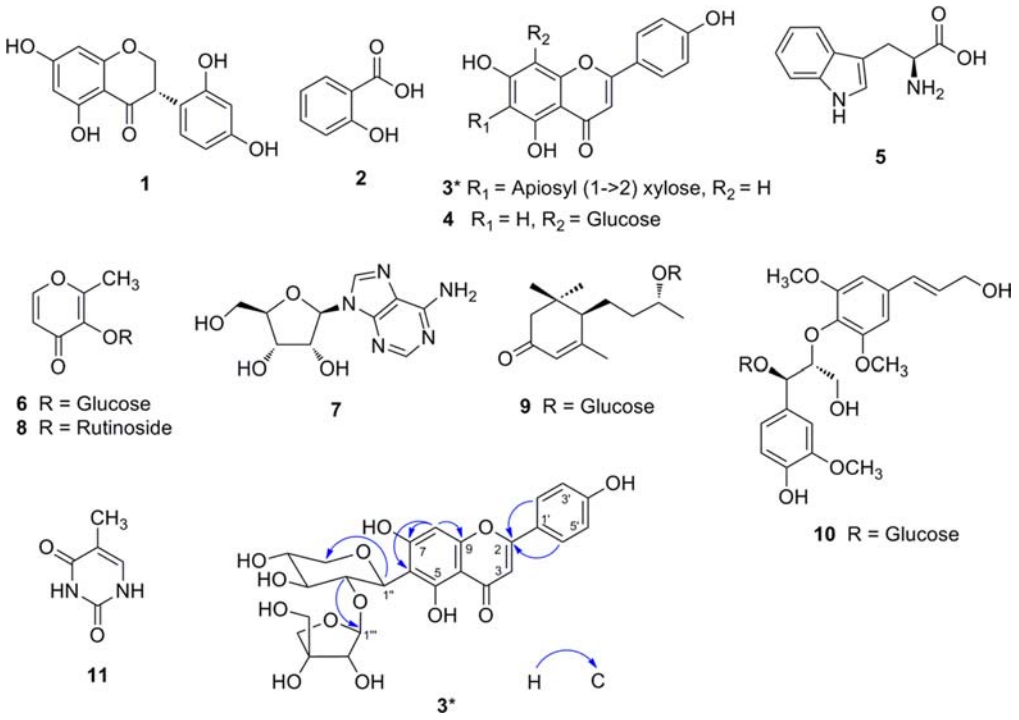

Figure 2. Schematic representation of the chemical structures of the isolated constituents from *U. crinita* and key HMBC correlations (H → C) for compound **3**.

normalized against GAPDH expression and expressed as relative expression compared with that of the controls.

Statistical Analysis. Data are expressed as the mean ± standard deviation (SD). Significant differences ($p < 0.05$ and $p < 0.01$) among the corresponding mean values were determined using one-way analysis of variance (ANOVA) followed by the Student−Newman−Keuls test. Probability values of $p < 0.05$ and $p < 0.01$ were considered statistically significant and extremely significant, respectively.

RESULTS AND DISCUSSION

Effect of *U. crinita* Extracts on Osteogenic Differentiation and Matrix Mineralization in HOb Cells. The fresh roots of *U. crinita* were extracted with 95% ethanol (EtOH) three times and the extract evaluated for osteogenic activity in HOb cells. This extract increased early bone differentiation marker alkaline phosphatase (ALP) activity and late mineralization activity by 106.51 ± 0.44 and 130.45 ± 1.51%, respectively (Figure 1A, B, and C). A bioguided method was then used to isolate and purify the active ingredients from the extract. Three fractions, EtOAc, *n*-BuOH, and aqueous fractions, were evaluated by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. No significant toxic effects were observed in HOb cells when 100 μg/mL concentrations of these extracts were used. The effects of these fractions on ALP activity and the calcium contents of the mineralized matrix of the HOb cells were then evaluated. Treatment with the aqueous fraction caused a 119.36 ± 5.64% increase in ALP activity (Figure 1A). Treatment with either the EtOAc or *n*-BuOH fraction significantly increased the calcium content of the mineralized matrix by 123.11 ± 3.28 and 146.73 ± 2.85%, respectively (Figure 1B and C).

During bone formation, osteoblast maturation causes bone matrix synthesis, and the bone matrix becomes progressively mineralized in the terminal stages of synthesis. The EtOAc and *n*-BuOH fractions significantly increased the calcium content of the mineralized matrix in HOb cells; therefore, we purified their active compounds in subsequent studies.

Bioguided Isolation and Identification of Active Compounds from *U. crinita*. For purification of active compounds, the active EtOAc and *n*-BuOH fractions were subjected to column chromatography and high-performance lipid chromatography (HPLC). One new compound, **3**, and 10 known compounds were obtained. The structures of the 10 known compounds were clarified by spectroscopic analysis and comparisons with reported physical data, permitting the identification of dalbergioidin (**1**),[19,20] salicylic acid (**2**),[21] vitexin (**4**),[22] tryptophan (**5**),[23] maltol-3-*O*-β-D-glucopyranoside (**6**),[24] adenosine (**7**),[25] spatholosineside A (**8**),[26] byzantionoside B (**9**),[27] (7*R*,8*R*)-threo-guaiacylglycerol-8-*O*-4′-sinapyl ether 7-*O*-β-D-glucopyranoside (**10**),[28] and thymine (**11**)[29] (Figure 2).

The new compound **3** was obtained as a yellow solid. Its molecular formula was determined, from its positive HRESI-MS *m/z* 535.1459 $[M + H]^+$ (calculated for $C_{25}H_{27}O_{13}^+$, 535.1452), to be $C_{25}H_{26}O_{13}$, a result consistent with the NMR data (Table 1). The NMR spectrum showed δ_H 6.75 (1H, s, H-3) together with signals of δ_C 102.8 (C-3), 163.5 (C-2), and 181.8 (C-4), a spectrum that suggested the presence of flavone moieties. The presence of signals at δ_H 6.91 (2H, d, J = 8.8 Hz, H-3′, H-5′) and 7.92 (2H, d, J = 8.8 Hz, H-2′, H-6′) in an A_2X_2 coupling system, together with signals of δ_C 116.0 (C-3′, C-5′) and 128.5 (C-2′, C-6′) observed in the NMR spectra suggested a mono-substituted aromatic moiety (ring B) in **3**. In the hetero-nuclear multiple bond correlation (HMBC) spectrum (Figure 2), one aromatic signal, δ_H 6.51 (1H, s, H-8), was assigned at H-8 due to long-range coupling with C-6, C-7, and C-9. These data suggested that **3** had a 4′,5,7,-trihydroxyflavone (apigenin) skeleton. The NMR spectrum at δ_H 2.52 to 5.15 and δ_C 64.5 to 109.1 also showed two sugar signals in the structure. After acid hydrolysis of **3**, the aqueous layer was separated by HPLC and

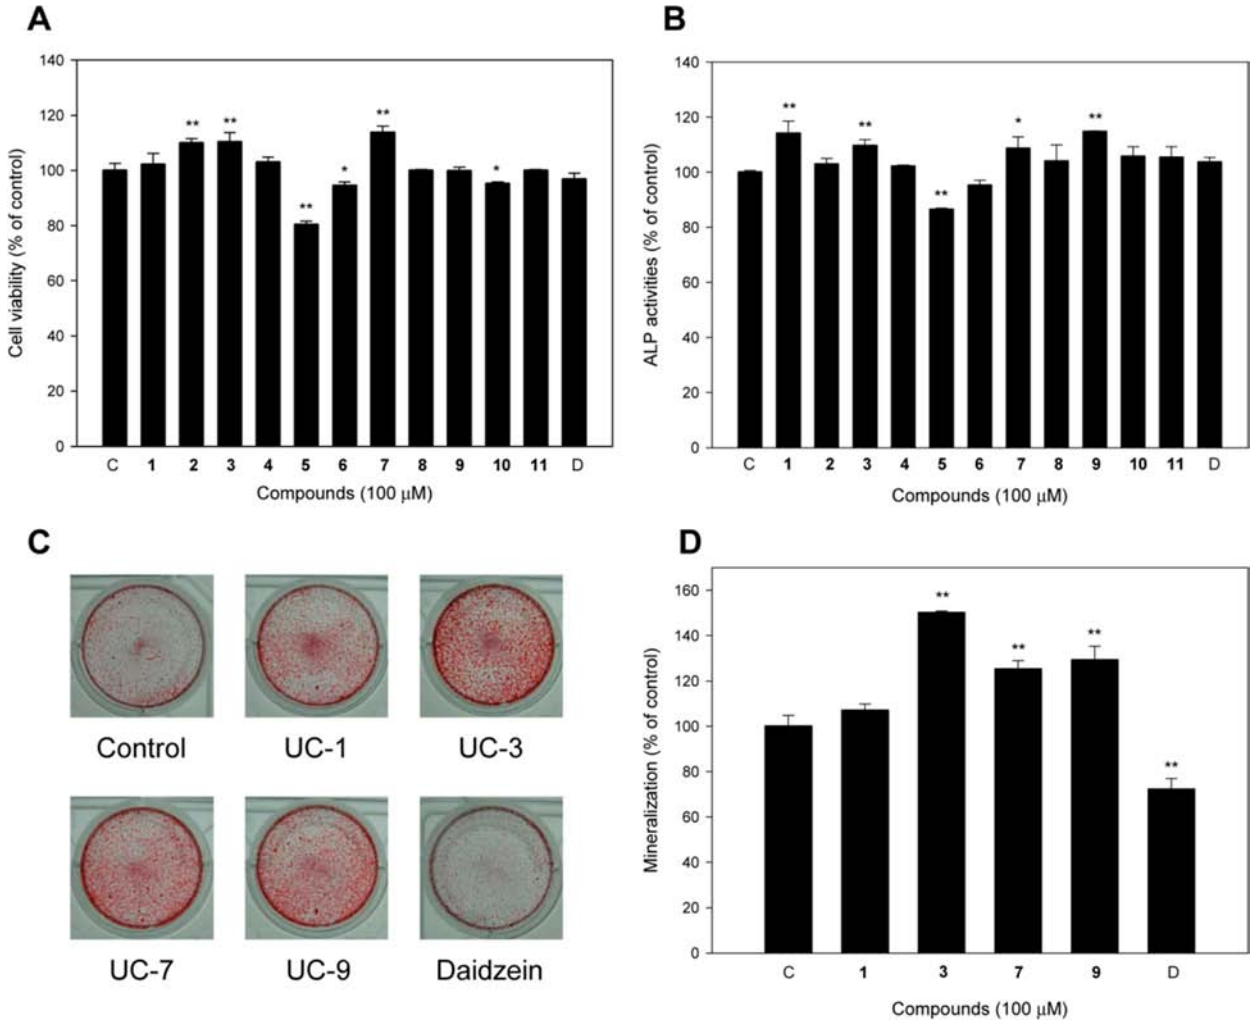

Figure 3. Effects of isolated compounds from *U. crinita* on cell viability, ALP activity, and mineralization in HOb cells. HOb cells were seeded in 96-well plates and treated with 100 μM of the indicated compounds for 72 h. (A) Cell viability was assessed using the MTT assay. (B) ALP activity was measured using a colorimetric assay with *p*-nitrophenyl phosphate disodium as the substrate. (C) HOb cells were plated in 24-well plates and treated with 100 μM of the indicated compounds for 12 days. Mineralized nodule formation was assessed by alizarin red-S staining. (D) Quantitative analysis of the extent of mineralization. Data are presented as the mean ± SD (n = 3). * $p < 0.05$ and ** $p < 0.01$ compared to control cells (C, control; D, daidzein).

compared to sugar standards to reveal one major sugar, apiose. The presence of *C*-D-xylopyranoside[30] and D-apiofuranoside[31] were determined from NMR, heteronuclear single quantum coherence (HSQC), ^{1}H−^{1}H correlation spectroscopy (COSY), HMBC spectra, and reported physical data.[32] Collectively, these data indicated that compound **3** was an apigenin linked with *C*-D-xylopyranoside and D-apiofuranoside moieties. The linkage of the sugar residues to the apigenin nucleus (C-1″ → C-6) was supported by the downfield NMR shifts of H-1″ (δ_H 4.55) of the *C*-D-xylopyranoside and the C-6 (δ_C 108.8) of the apigenin.[30,33,34] The position of the D-apiofuranoside and *C*-D-xylopyranoside linkage (C-1‴ → C-2″) was confirmed as C-1‴ at δ_C 109.1 and H-2″ at δ_H 4.27 (1H, brs) by HMBC correlations. The α-configuration of D-xylopyranoside and the β-configuration of D-apiofuranoside were deduced by the coupling constants of the anomeric protons H-1″ (δ_H 4.55, brs) and H-1‴ (δ_H 5.15, brs).[35] On the basis of these data, the structure of **3** was identified as apigenin 6-*C*-β-D-apiofuranosyl(1→2)-α-D-xylopyranoside.

Effects of the Isolated Compounds on Cell Viability, Osteogenic Differentiation, and Matrix Mineralization in HOb Cells. The effects of the isolated compounds on bone formation were assessed in HOb cells. Cell viability was measured using the MTT assay. Excluding compound **5**, none of the compounds at 100 μM reduced cell viability by more than 10% (Figure 3A). The effects of the nontoxic compounds on early osteoblast differentiation were investigated using an ALP activity assay, and their effects on late mineralization were assessed using alizarin red staining. The novel apigenin 6-*C*-β-D-apiofuranosyl(1→2)-α-D-xylopyranoside (**3**) and the known compounds dalbergioidin (**1**), adenosine (**7**), and byzantionoside B (**9**), significantly increased ALP activity in HOb cells by 109.68 ± 2.20, 114.10 ± 4.41, 108.70 ± 4.14, and 114.81 ± 0.18%, respectively (Figure 3B), when used at a concentration of 100 μM and also increased the calcium contents of the mineralized matrix by 150.10 ± 0.80, 107.09 ± 2.80, 125.21 ± 3.75, and 129.21 ± 6.13%, respectively (Figure 3C and D).

Effects of the Isolated Compounds on Osteogenesis-Related mRNA Expression in HOb Cells. We further investigated whether these four isolated compounds were able to promote osteogenesis-related mRNA expression by quantitative real-time PCR (Q-RT-PCR). At a concentration of 100 μM, dalbergioidin (**1**) upregulated the mRNA expression

dx.doi.org/10.1021/jf5012177 | J. Agric. Food Chem. 2014, 62, 5581−5588

of OPN, BMP-2, and Runx2 by 1.25 ± 0.05-, 1.21 ± 0.07-, and 1.71 ± 0.05-fold, respectively. Apigenin 6-*C*-*β*-D-apiofuranosyl-(1→2)-*α*-D-xylopyranoside (**3**) increased the expression of these substances by 1.39 ± 0.01-, 1.30 ± 0.04-, 1.43 ± 0.10-fold, respectively, adenosine (**7**) upregulated their expression by 1.14 ± 0.04-, 1.16 ± 0.09-, and 1.55 ± 0.05-fold, respectively, and byzantionoside B (**9**) increased their expression by 1.32 ± 0.07-, 1.21 ± 0.04-, and 1.28 ± 0.09-fold, respectively. The novel apigenin 6-*C*-*β*-D-apiofuranosyl(1→2)-*α*-D-xylopyranoside (**3**), dalbergioidin (**1**), adenosine (**7**), and byzantionoside B (**9**) increased OPN, BMP-2, and Runx2 mRNA expression in a concentration-dependent manner (Figure 4A, B, and C).

The BMP family plays an important role in the process of bone formation and remodeling.[36] In osteoblast cells, the action of BMP-2 is mediated by its binding to BMP-2 receptors and subsequent downstream regulation of the SMAD transcription factor SMAD1/5/8, which then forms a complex with SMAD4. Phosphorylated SMAD complexes translocate to the cell nucleus and bind to transcription factors including Runx2, Dlx5, and Osterix.[9,37] Extensive studies have demonstrated that BMPs stimulate osteoblast differentiation by upregulating Runx-2 expression and increasing the expression of ALP, type I collagen, OPN, and osteocalcin.[37] This is the first report demonstrating that apigenin 6-*C*-*β*-D-apiofuranosyl(1→2)-*α*-D-xylopyranoside (**3**), dalbergioidin (**1**), and byzantionoside B (**9**) significantly increase ALP activity in the early differentiation phase and OPN mRNA expression and bone nodule formation in the late mineralization phase in HOb cells. The osteogenic activity of the three compounds probably occurs through activation of the BMP-2/Smad/Runx2 signaling pathway, and these compounds had greater effects than daidzein (4′,7-dihydroxyisoflavone), the positive control, in HOb cells. Daidzein has been reported to induce the differentiation of rat or porcine osteoblast cells by upregulating BMP-2/Runx2 expression.[38,39] Adenosine (**7**) has been shown to increase osteoblast differentiation and bone formation in previous studies.[40,41] Natural isoflavonoids, such as daidzein, genistein (4′,5,7-trihydroxyisoflavone), and genistin (4′,5-dihydroxyisoflavone-7-*O*-glucoside), that enhance the expression of ALP, OCN, BMP-2, and osteoprotegerin have been reported to promote bone differentiation and mineralization both in vitro and in vivo.[39,42−44] Comparing dalbergioidin (**1**) (2′,4′,5,7-tetrahydroxyisoflavone) and the three isoflavones (genistein, genistin, and daidzein), we found that the OH groups at C-4′ and C-7 may be the important features of isoflavones needed for promoting bone formation. Additionally, compared with the flavonoid-6-*C*-glucosides of compound **3** and flavonoid 8-*C*-glucosides of compound **4**, we also observed that flavonoid-6-*C*-glycoside was an important unit for eliciting better osteogenic activity. The same pattern of flavonoid-6-*C*-glycoside was also found in the previous literature.[45] Our studies demonstrated that these four active compounds contained in *U. crinita* could stimulate osteogenic activity and enhance bone formation, possibly through the BMP-2/Smad/Runx2 pathway. Further studies are needed to understand the influence of different solvents and extraction methods on the osteogenic activity of *U. crinita*.

In conclusion, *U. crinita* extract contained the novel apigenin 6-*C*-*β*-D-apiofuranosyl(1→2)-*α*-D-xylopyranoside (**3**), which together with dalbergioidin (**1**), adenosine (**7**), and byzantionoside B (**9**) showed osteogenic activity by increasing ALP activity and calcium contents to regulate differentiation and mineralization in human osteoblast cells. Their mechanism of action may be through activation of the BMP-2 and Runx2 signal pathways. This is the first report that *U. crinita* and its active compounds exhibit osteogenic activity and suggests that in the future active constituents from this species may be applied for the prevention of bone loss and promotion of bone regeneration.

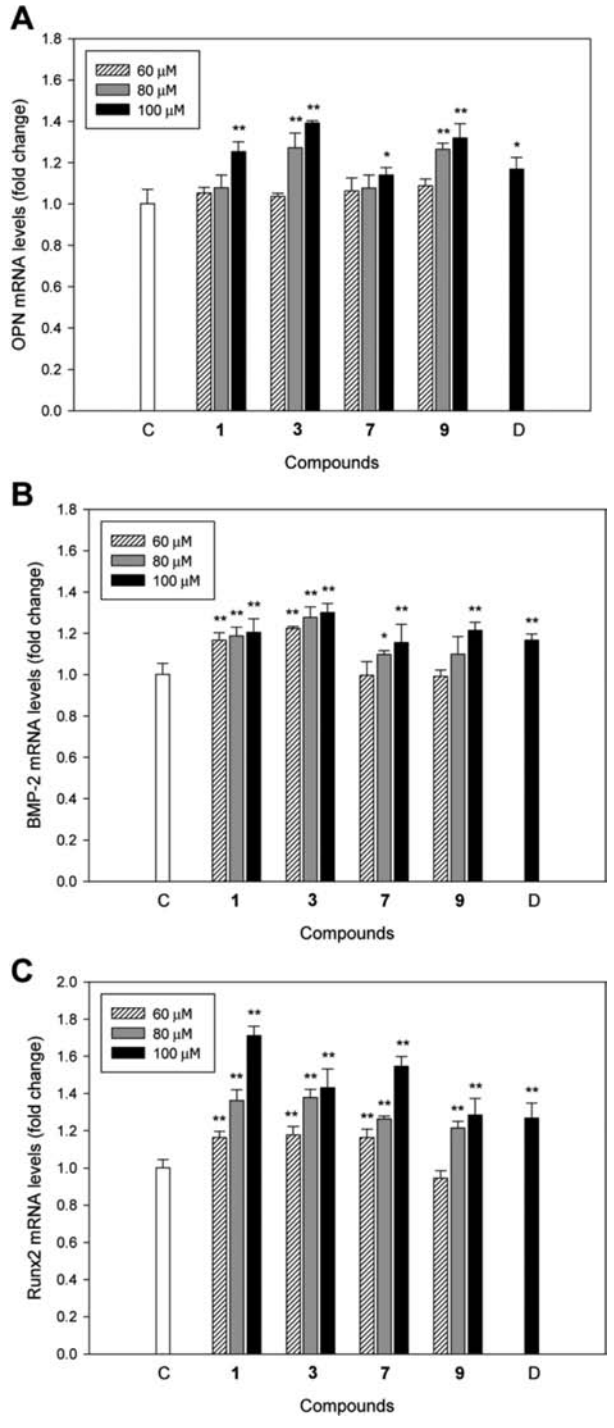

Figure 4. Effects of active compounds from *U. crinita* on osteogenesis-related mRNA expression in HOb cells. HOb cells were seeded in 6 cm dishes and treated with the indicated compounds for 24 h. Concentration-dependent effects of active compounds **1**, **3**, **7**, and **9** on (A) OPN, (B) BMP-2, and (C) Runx2 mRNA expression were determined by Q-RT-PCR analysis. Using the $2^{-\Delta\Delta Ct}$ method, Runx2, BMP-2, and OPN mRNA expression results were normalized against GAPDH expression. Data are presented as the mean ± SD (n = 3). * $p < 0.05$ and ** $p < 0.01$ compared to control cells (C, control; D, daidzein).

Cecal Succinate Elevated by Some Dietary Polyphenols May Inhibit Colon Cancer Cell Proliferation and Angiogenesis

ABSTRACT: This study demonstrated that 0.5% dietary rutin, ellagic acid, or curcumin markedly increased cecal succinate levels in rats fed a high-fat diet, whereas catechin, caffeic acid, and quercetin did not. Other organic acids were modestly or hardly affected by polyphenols. To clarify the effects of succinate levels increased by polyphenols, this study examined the effects of succinate on the growth and proliferation of colon cancer cells and angiogenesis. The growth and proliferation of HT29 human colon cancer cells and angiogenesis in an ex vivo model were significantly inhibited by succinate at a dose close to that in the cecum of rats fed polyphenols. Furthermore, succinate inhibited the migration of human umbilical vein endothelial cells. These findings suggest that the consumption of some polyphenols affects the health and diseases of the large intestine by elevating succinate.

KEYWORDS: *rats, polyphenols, succinate, colon cancer cells, angiogenesis*

INTRODUCTION

Polyphenols, which are abundant in plant foods, exhibit various beneficial activities such as antioxidative, antiatherogenic, antidiabetic, anticancer, antiviral, anti-inflammatory, and antiangiogenic activities.[1−3] We previously reported that the dietary addition of some polyphenols including curcumin, caffeic acid, catechin, rutin, and ellagic acid suppresses fecal levels of secondary bile acids, namely, deoxycholic acid and/or lithocholic acid (which are risk factors for colon diseases), in rats fed a high-fat diet.[4] A high-fat diet increases fecal secondary bile acids,[5,6] causing compensatory proliferation of colonic epithelium cells.[7,8] This suggests such polyphenols might have beneficial effects on colon health by reducing secondary bile acids in animals fed a high-fat diet.[4] High-fat diets not only increase fecal secondary bile acid levels but also lower cecal organic acid production.[6] Mounting evidence indicates the increased production of intestinal organic acids including butyrate and propionate is associated with a decreased risk of colon cancer and colitis.[9,10] Meanwhile, food constituents that are indigestible or digestible to only a limited extent, such as resistant starch[11] and inulin,[12] increase cecal organic acid levels in both rats and humans. However, there is limited information concerning the effects of dietary polyphenols on cecal organic acids. Therefore, this study examined the effects of dietary polyphenols on cecal levels of organic acids in rats fed a high-fat diet.

Succinate is an important metabolic molecule as an intermediate in the citric acid cycle. It is known as a "umami"-tasting substance and is found in shellfish, refined sake, and soy sauce. Recent studies suggest organic acids such as butyrate and propionate may contribute to intestinal immune and barrier function.[13−15] However, the role of succinate remains incompletely understood. In this study, we provide evidence that consumption of some polyphenols markedly elevated cecal succinate in rats fed a high-fat diet. Therefore, this study also examined the effect of succinate on the growth of colon carcinoma cells and angiogenesis.

MATERIALS AND METHODS

Materials. Rutin, curcumin, catechin, caffeic acid, quercetin, succinate disodium salt, and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) were purchased from Nacalai Tesque (Kyoto, Japan). Ellagic acid was obtained from Wako Pure Chemical Industry (Osaka, Japan). Human recombinant vascular endothelial growth factor (VEGF) was obtained from R&D Systems (Minneapolis, MN, USA). Other reagents were of special grade as commercially available.

Animals and Diets. Male Sprague−Dawley rats (Charles River Laboratories, Kanagawa, Japan) weighing 40−50 g (3 weeks old) were

used. The rats were individually housed in metal separate cages in a temperature-controlled (24 °C) room with a 12 h light−dark cycle (lights on from 8:00 a.m. to 8:00 p.m.). The rats were allowed a 1 week acclimation period before the experiments. The rats were maintained according to the *Guide for the Care and Use of Laboratory Animals* established by Hiroshima University. The protocol was approved by the Committee on the Ethics of Animal Experiments of the Hiroshima University (permit D08-16). The control group received a high-fat diet that contained 30% fat, without polyphenols. The basal diet comprised 30% beef tallow, 20% casein, 20.3% corn starch, 20% sucrose, 5% cellulose, 3.5% salt mixture (AIN-93G),[16] 1% vitamin mixture (AIN-93),[16] and 0.2% L-cystine (made up to 100% with corn starch). Rats allocated to the 0.5% polyphenol groups received the high-fat diet supplemented with 0.5% polyphenols including rutin, ellagic acid, curcumin, catechin, caffeic acid, or quercetin. All rats were fed the same amount of experimental diet (9, 10, 12, 14, and 15 g for days 1, 2−4, 5−7, 8−13, and 14−21, respectively) to suppress any variation in food intake due to ad libitum feeding. All diets were provided daily at 7:00 p.m. in food cups in the cages, and all rats had completely consumed the diets by the next morning. All rats had ad libitum access to deionized water. After 3 weeks of diet feeding, the rats were euthanized between 1:00 and 3:00 p.m. The cecal contents were removed, weighed, and stored at −80 °C for later analysis.

Cecal Contents Analysis. The levels of organic acids in the cecum were measured by high-performance liquid chromatography (HPLC) as described previously.[17] Cecal contents (300 mg) were homogenized by ultrasonication in 2 mL of 10 mM sodium hydroxide aqueous solution containing 0.5 g/L crotonic acid and subsequently centrifuged at 10000*g* for 15 min. Fat-soluble substances in the supernatant were removed by extraction with chloroform. The aqueous phase was filtered through a membrane filter, and the samples were subjected to HPLC. Organic acids were separated with an ion exclusion column and detected using an H-type cation exchanger column with a column temperature of 45 °C, mobile phase of 5 mM *p*-toluene sulfonic acid aqueous solution, positive polarity electroconductivity detector at 45 °C, and detection reagent of 20 mM bis-Tris aqueous solution containing 5 mM *p*-toluenesulfonic acid and 100 μM EDTA.

Cell Lines and Culture Conditions. HT29 human colon cancer cells were cultured routinely in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal bovine serum, penicillin (100 units/mL), and streptomycin (100 units/mL). Subcultures of HT29 were obtained by treating cell cultures with 2% trypsin/EDTA buffer. Human umbilical vein endothelial cells (HUVECs) were purchased from Kurabo Industries (Osaka, Japan) and grown in HuMedia EG 2 medium (Kurabo), which is modified MCDB 131 medium containing 2% fetal bovine serum, 10 ng/mL recombinant human epidermal growth factor, 1 μg/mL hydrocortisone, 50 μg/mL gentamicin, 50 ng/mL amphotericin B, 5 ng/mL recombinant human basic fibroblast growth factor, and 10 μg/mL heparin. Subcultures of HUVECs were obtained by treating the HUVEC culture with Hanks'-based enzyme-free cell dissociation buffer (Gibco, Grand Island, NY, USA). HUVECs at passages 3−7 were used in the experiment. All cells were maintained at 37 °C in a humidified incubator with 5% CO_2.

MTT Assay. For the growth assay of HT29 cells, cells were suspended in DMEM and plated onto 96-well culture plates (3.0×10^3 cells/100 μL). For the growth assay of HUVECs, cells were suspended in HuMedia EG2Medium and plated onto 96-well culture plates (1.5×10^3 cells/100 μL). Cells were incubated for 24 h at 37 °C in a humidified incubator with 5% CO_2. The media were replaced with fresh media containing sodium succinate (1−30 mM) or vehicle [phosphate-buffered saline (PBS)]. After the cells had been exposed for 24 or 72 h, MTT solution (final concentration, 5 mg/mL MTT in PBS) was added to each well, and the cells were incubated for 3 h. The media were aspirated, and the cells were lysed in dimethyl sulfoxide. Absorbance was measured at 550 nm in an ELNX96 microplate reader (TFB Inc., Tokyo, Japan). Reported values represent the averages for six wells.

Bromo-deoxyuridine (BrdU) Incorporation Assay. Experiments were conducted in 6-well plates (1×10^6 cells/well) with two replicates. After the cells with or without the media containing sodium succinate (30 mM) had been exposed for 24 h, HT29 cells were incubated with 100 μM BrdU for 2 h at 37 °C in a humidified incubator with 5% CO_2. To detect BrdU immunoreactivity, cells were washed with PBS and fixed with 4% paraformaldehyde at room temperature for 10 min. After washing twice with PBS, cell samples were incubated with PBS with 1% Triton X-100 at room temperature for 10 min. Cells were again washed twice with PBS and incubated with 2 N HCl. After removal of the HCl, cells were washed three times with 0.1 mM borate buffer (pH 8.5). For blocking, 4% skim milk with PBS was added, and the cells were slowly shaken at room temperature. After 1 h of incubation, the blocking buffer was discarded, and BrdU antibody (1:1000; 1 mL/plate) and DAPI (40 mg/mL, 1:1000) were added. The cells were incubated at room temperature for 1.5 h and then washed three times with PBS. Cy3-labeled anti-mouse IgG was added as a secondary antibody (1:1000; 1 mL/plate), and the cells were incubated for 30 min at room temperature. The cells were then washed three times with PBS. The cells were visualized by fluorescence microscopy, and BrdU-positive cells were counted on 10 image fields. The average number of BrdU-positive cells in each sample was subsequently calculated.

Ex Vivo Angiogenesis Assay. Male Wistar rats (6 weeks old, Charles River Laboratories) were maintained according to the guide established by Hiroshima University Animal Research Committee as mentioned above. The ex vivo angiogenesis assay was carried out in the rat aortic model[18,19] with slight modifications.[20] Briefly, a rat aortic segment coved with the collagen gel was overlaid with 2 mL of culture medium (RPMI 1640 medium) containing sodium succinate (10 or 30 mM) or vehicle (PBS) and incubated for 10 days in a fully humidified system of 5% CO_2 at 37 °C. The culture medium with sample was changed on the seventh day. After 10 days of incubation, microscopic fields were photographed with a digital camera (DSE330-A system,

dx.doi.org/10.1021/jf501142k | J. Agric. Food Chem. 2014, 62, 5589−5594

Olympus, Tokyo, Japan), and the length of the capillary was measured using Adobe Photoshop software CS3. Each reported value represents the average of three or four culture samples.

Endothelial Cell Tube Formation and Chemotaxis Assays. The HUVEC tube formation assay was performed using BD Matrigel (BD Biosciences, Franklin Lakes, NJ, USA) as described previously.[20] Reported values represent the averages of three samples. The HUVEC chemotaxis assay was performed in a modified Boyden chamber.[20,21] Migrated cells were counted in three fields of each membrane at 200× magnification, and the average number of cells in each field was calculated. The experiment was performed in triplicate.

Statistical Analysis. Statistical analysis was conducted by one-way analysis of variation (ANOVA) and Dunnet's multiple-range test (Excel Statistics 2006 for Windows, Social Survey Research Information Co. Ltd., Tokyo, Japan). Statistical significance was estimated at $p < 0.05$.

RESULTS

Effect of Polyphenols on Cecal Organic Acids in Rats Fed a High-Fat Diet. Dietary addition of polyphenols did not affect the food intake, final body weight, or liver weight of the rats (data not shown). The wet weight of cecal contents was higher in the curcumin and ellagic acid groups than the control group ($p < 0.05$, Table 1). The cecal concentration (μmol/g wet digesta) of succinate was markedly higher in the rutin (6.4-fold), ellagic acid (5.3-fold), and curcumin (4.6-fold) groups than in the control group ($p < 0.05$). Meanwhile, dietary catechin and caffeic acid tended to increase cecal concentrations of succinate ($p < 0.1$). Acetate and butyrate concentrations were significantly higher and isovalerate concentration was significantly lower in the quercetin group compared to the control group ($p < 0.05$). The concentrations of other organic acids including formate, propionate, isobutyrate, and valerate were unaffected by dietary polyphenols. Dietary rutin and ellagic acid significantly increased the concentrations of total organic acids compared to the control (1.9- and 1.6-fold, respectively, $p < 0.05$). The pH of digesta was significantly lower in the rutin group than in the control group ($p < 0.05$).

Effects of Succinate on HT29 Cell Growth and Proliferation. Succinate significantly inhibited the growth of the HT29 cells at both 10 and 30 mM (Figure 1, $p < 0.05$). Analysis of cell proliferation by BrdU incorporation into the cells indicated 30 mM succinate significantly reduced (−30%) the proportion of proliferative cells (control vs succinate: 32.6 ± 2.0 and 22.8 ± 1.8%, respectively, $n = 6$, $p < 0.05$).

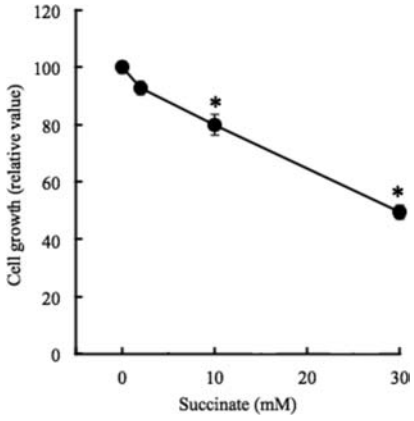

Figure 1. Effects of succinate on the growth of HT29 cells. Cultured cells (3.0×10^3 cells/well) were exposed to the medium for 24 h. Cell growth was determined by the MTT assay. Values are means ± SEM ($n = 6$). *, significantly different from the control by Dunnet's multiple-range test ($p < 0.05$).

Effects of Succinate on ex Vivo Angiogenesis and Endothelial Cell Functions. In the ex vivo angiogenesis model using a rat aortic ring, microvessels appeared from the ends of aortic rings and elongated in the absence of succinate (Figure 2A). Meanwhile, microvessel growth was significantly inhibited in the presence of 30 mM succinate (Figure 2C,D, $p < 0.01$).

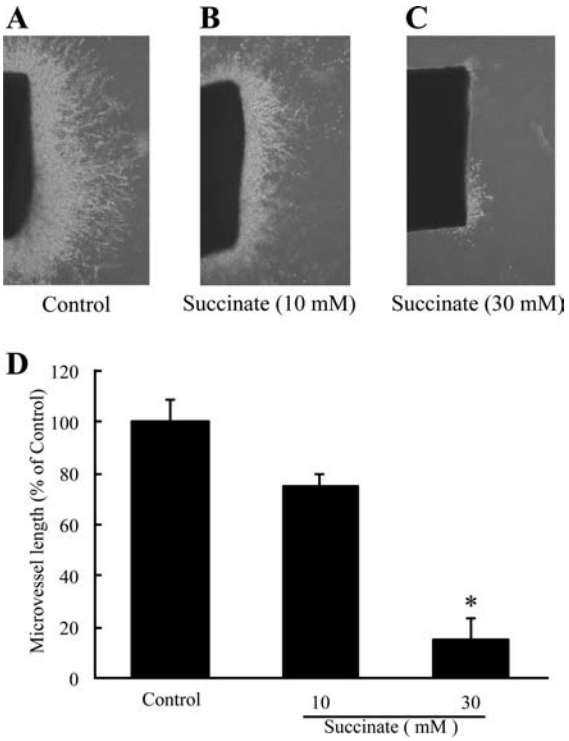

Figure 2. Effect of succinate on ex vivo angiogenesis with the use of a rat aortic ring: (A−C) representative result as to the inhibitory effects of succinate; (D) microvessel length measured on day 10 of culture. Values are means ± SEM ($n = 3, 4$). *, significantly different from the control by Dunnet's multiple-range test ($p < 0.01$).

The effects of succinate on HUVEC functions including tube formation on a reconstituted basement membrane, chemotaxis, and growth are shown in Figure 3. HUVECs inoculated onto a reconstituted basement membrane migrated, attached to each other, and finally formed tube structures in the tube formation assay model. In this assay, succinate did not significantly suppress HUVEC tube formation (Figure 3A). However, succinate at both 10 and 30 mM significantly inhibited HUVEC migration stimulated with VEGF in a gelatin-coated Boyden chamber (Figure 3B, $p < 0.01$). However, succinate did not significantly affect the growth of HUVECs (Figure 3C).

DISCUSSION

We previously reported that some dietary polyphenols suppress fecal levels of secondary bile acids, namely, deoxycholic acid and/or lithocholic acid, in rats fed a high-fat diet.[4] This study further provides novel evidence indicating dietary supplementation of rutin, ellagic acid, and curcumin to a high-fat diet markedly increase cecal succinate concentrations in rats. However, dietary catechin, caffeic acid, and quercetin hardly

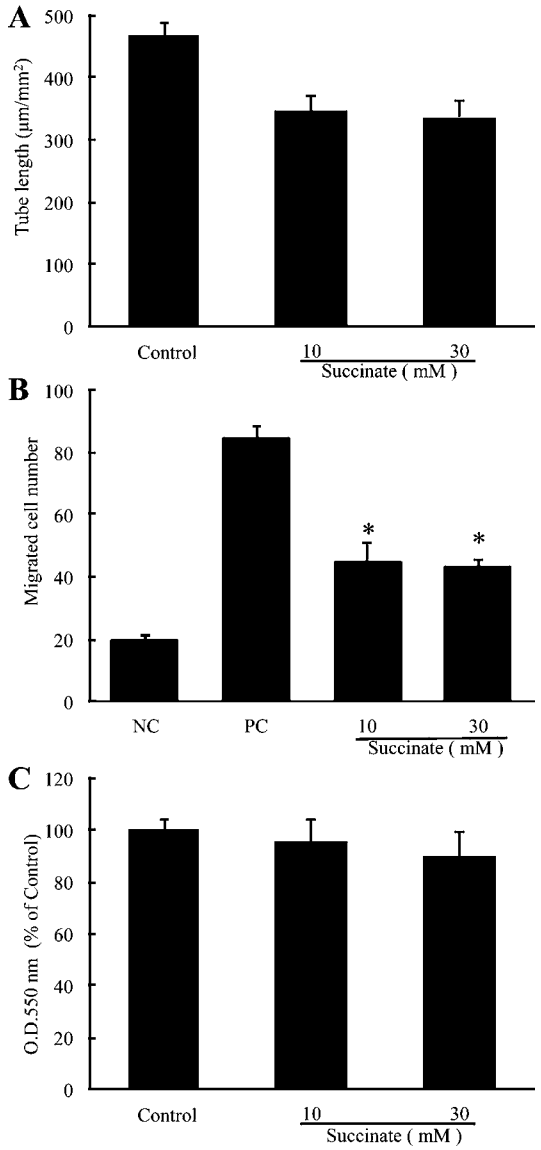

Figure 3. Effect of succinate on HUVEC functions. (A) Effect of succinate on HUVEC tube formation on reconstituted basement membrane. Capillary length was measured. Values are means ± SEM (n = 3). (B) Effect of succinate on HUVEC chemotaxis. HUVECs that migrated to the lower surfaces of the filters after 6 h of incubation were counted in three 200× fields of the filters. Means of a field of three filters ± SEM (n = 9) are shown. NC, negative control (medium without VEGF and sample); PC, positive control (VEGF containing medium without sample). (C) Effect of succinate on the growth of HUVEC. Cultured cells (1.5×10^3 cells/well) were exposed to the medium for 72 h. Cell growth was determined by the MTT assay. Values are means ± SEM (n = 6). *, significantly different from the positive control (PC) by Dunnet's multiple-range test ($p < 0.01$).

affected cecal succinate concentrations. Aprikian et al. report that adding a polyphenol-rich apple concentrate (~0.7 g polyphenol/kg diet) to a normal diet (with 5% corn oil) did not affect cecal succinate concentrations in rats.[22] Furthermore, in our preliminary study, dietary addition of 0.5% ellagic acid to a low fat-diet (5% beef tallow) failed to elevate cecal succinate levels in rats (Haraguchi et al., unpublished data), but the reason for the lack of an effect is unknown. Thus, the effect of polyphenols on cecal succinate levels might be dependent on dietary fat intake as well as the kinds and levels of polyphenols in the diet. Intriguingly, the dietary addition of rutin significantly increased cecal succinate levels, whereas quercetin did not. Quercetin and its glycosidic form, rutin, are common flavonoids in edible foods. However, the absorption processes of these polyphenols are quite different. Crespy et al. report quercetin can be partly absorbed in the stomach, whereas rutin cannot.[23] Dietary rutin likely escapes absorption in the stomach and small intestine to reach the large intestine, leading it to significantly affect cecal succinate production.

Because succinate is the major metabolite of *Bacteroides* in the large intestine,[24] we examined the effect of the polyphenols on the cecal profile of the microflora by 16S rDNA-based terminal restriction fragment length polymorphism analysis. The results indicate dietary 0.5% curcumin, ellagic acid, and rutin did not significantly affect the proportion of cecal microflora including *Bacteroides*, *Clostridium*, *Lactobacillales*, and *Bifidobacterium* (unpublished data). Thus, the increased production of cecal succinate by such polyphenols cannot be accounted for by the microfloral profile. In our previous study, besides 0.5% dietary curcumin, ellagic acid, and rutin, 0.5% dietary caffeic acid and catechin also markedly reduced fecal toxic secondary bile acids such as deoxycholic and lithocholic acid (which are risk factors for colon diseases) in rats fed a high-fat diet.[4] Therefore, the overall association between alterations in the cecal profile of organic acids and fecal secondary bile acids appears to be weak.

To gain further insight into the polyphenol-induced increase in cecal succinate levels, we examined the effects of succinate on colon cancer cells and angiogenesis. The results indicate 30 mM succinate, which corresponds to the cecal level in the rats fed various polyphenols, inhibits the growth and proliferation of HT29 colon cancer cells. An animal study by Inagaki et al. also demonstrates 100 mM succinate inhibits epithelial cell proliferation in the colon mucosa in rats.[25] Succinate accumulates in colon and stomach cancers,[26,27] although it remains unclear if succinate itself is related to colon cancer. Succinate is known to inhibit the function of HIF prolyl hydroxylases (PHDs); a line of data indicates PHDs have essential functions in cell growth and proliferation.[28] Therefore, it would be of interest to determine if the inhibitory effect of succinate on the growth and proliferation of colon cancer cells is mediated by the inactivation of PHDs.

Angiogenesis plays a key role in the development of malignant tumors and inflammatory bowel disease.[29] The inhibition of angiogenesis prevents tumor growth and metastases and, thus, inflammatory bowel disease. The results of the present ex vivo angiogenesis model indicate succinate has antiangiogenic effects at 30 mM, which is the dose corresponding to cecal levels in rats fed various polyphenols. Furthermore, the addition of succinate inhibited HUVEC migration but not HUVEC tube formation or growth. Thus, the antiangiogenic effect of succinate might be at least in part mediated by suppression in VEGF-induced HUVEC migration. Succinate at the micromolar order is reported to enhance retinal angiogenesis by mediating G-protein-coupled receptor 913.[30] However, in our study, the concentrations of succinate at 100−500 μM did not affect angiogenesis in an ex vivo model (unpublished data). This discrepancy might be due to differences in experimental models. Although succinate inhibits PHDs, some conflicting evidence indicates PHDs either suppress or activate angiogenesis.[28] Dietary rutin, ellagic acid, and curcumin are reported to suppress colon carcinogenesis in rodents.[31,32] This raises the question of whether the

suppression of colon cancer by polyphenols is related to the concentrations of intestinal succinate elevated by polyphenols.

Interestingly, this study indicated that dietary supplementation of quercetin increases cecal concentrations of butyrate and acetate in rats. Butyrate produced by intestinal microbial fermentation exerts potentially useful effects on prevention and inhibition of colonic carcinogenesis and other intestinal and extraintestinal disoders.[33] A recent study indicated moderate anti-inflammatory activity of acetate in LPS-stimulated RAW264.7 cells.[34] It was reported that fermentation of apple extracts containing quercetin compounds resulted in an increase of butyrate and acetate in vitro with human fecal flora.[35] To our knowledge, our study provides the first in vivo evidence for the elevations in these organic acids in the cecum of animals fed quercetin.

In summary, this study provides the first evidence that the consumption of some polyphenols remarkably increases cecal succinate levels in rats. Furthermore, succinate at levels close to those in the colonic ruminal environment suppressed the proliferation of colon cancer cells and angiogenesis. These findings provide novel insights into the roles of some polyphenols in the health and diseases of the large intestine.

Supporting Information

ABSTRACT: Crude extracts of 33 plant species were assessed for fungal plasma membrane (PM) H^+-ATPase inhibition. This led to identification of 18 extracts showing more than 95% inhibition at a concentration of 7.5 mg/mL and/or a concentration-dependent activity profile. These extracts were selected for semi-high-resolution fungal PM H^+-ATPase inhibition screening, and, on the basis of these results, *Haplocoelum foliolosum* (Hiern) Bullock and *Sauvagesia erecta* L. were selected for investigation by high-resolution fungal PM H^+-ATPase inhibition screening. Structural analysis performed by high-performance liquid chromatography-high-resolution mass spectrometry-solid-phase extraction-nuclear magnetic resonance spectroscopy (HPLC-HRMS-SPE-NMR) led to identification of chebulagic acid (**1**) and tellimagrandin II (**2**) from *H. foliolosum*. Preparative-scale isolation of the two metabolites allowed determination of IC_{50} values for PM H^+-ATPase, and growth inhibition of *Saccharomyces cerevisiae* and *Candida albicans*. Chebulagic acid and tellimagrandin II are both potent inhibitors of the PM H^+-ATPase with inhibitory effect on the growth of *S. cerevisiae*.

KEYWORDS: *fungal plasma membrane H^+-ATPase, high-resolution screening, HPLC-HRMS-SPE-NMR, chebulagic acid, tellimagrandin II, antifungal, Haplocoelum foliolosum*

INTRODUCTION

Fungi are capable of colonizing a large variety of food and animal feed, and it has been estimated that 5−10% of the world's food production is lost due to fungal spoilage.[1] Fungal infections lead to substantial damage manifested as general spoilage such as discoloration and off-flavors as well as nutritional losses. The spoilage is often caused by excretion of exoenzymes during growth, and once inside the food the enzymes may continue their deteriorating activities despite the removal of the fungal mycelium. However, the most important aspect of fungal spoilage is the production of mycotoxins, which are often toxic to vertebrates and may lead to immune suppression and different types of cancers.[2] Thus, in addition to the financial consequences, fungal spoilage poses a serious threat to the health of immuno-compromised as well as healthy individuals. Fungi are also known to cause systemic infections in immunocompromised patients and are considered as a major healthcare problem. There are an increased number of infections that cannot be treated with the medicines available today, in part caused by infections with fungi that have become resistant to existing drugs,[3,4] but also due to infections with newly emerging fungal pathogens, which are not susceptible to the existing drugs.[5]

A large number of fungal proteins have been proposed as potential targets for novel antifungal agents.[3,6] However, current available antifungal agents are primarily targeting the intracellular membrane and cell wall biosynthesis,[3] and thus need to enter the fungus to act. In our search for novel and more efficient antifungal compounds, we are focusing on the plasma membrane (PM) H^+-ATPase enzyme as target. The PM H^+-ATPase enzyme consists of 10 trans-membrane helices and plays a pivotal role in eukaryotic cell physiology in maintaining the trans-membrane electrochemical proton gradient necessary for nutrient uptake.[7,8] Characterization of the PM H^+-ATPase from various fungi has shown it to comprise a single 100 kDa subunit, containing both a membrane-spanning transport domain as well as a catalytic ATP hydrolyzing domain located in the cytoplasm. The *PMA1* gene encoding for the enzyme has been shown to be highly conserved among fungi, but having only 32% sequence identity to its counterparts in plants[9,10] (sequence alignment of plant H^+-ATPase AHA2 (accession number P19456) and *Saccharomyces cerevisiae* H^+-ATPase PMA1 (accession number P05030) made with ClustalW2). Gene-disruption experiments with *S. cerevisiae* have confirmed the essential nature of the gene product of *PMA1*.[11] Thus, the low sequence identity with plant PM H^+-ATPases as well as its accessibility from the cell exterior, that is, circumventing potential problems with multidrug resistance pumps,[12,13] make the fungal PM H^+-ATPase a good target for new antifungal drugs.

[a]Extracts showing inhibition higher than 95% for all concentrations or extracts showing a concentration-dependent activity profile are marked with bold and were selected for semi-high-resolution screening. [b]Different collections.

Plants are exposed to a wide array of phytopathogenic fungi in their natural habitat, and have been forced to develop antifungal metabolites to survive.[14,15] Hence, as was previously suggested by Monk and co-workers,[16] it is reasonable to assume that the PM H$^+$-ATPase enzyme is a target for antifungal plant metabolites. However, plant extracts are very complex mixtures, and the traditional bioassay-guided fractionation used for identification of individual bioactive components is very time-consuming and suffers from inherently low resolution during the fractionation process.[17] To circumvent this, we have developed a bioanalytical platform that combines high-resolution microplate bioassays[18,19] with a hyphenated system consisting of high-performance liquid chromatography, solid-phase extraction, and nuclear magnetic resonance, that is, HPLC-SPE-NMR.[20,21] HPLC-SPE-NMR has proven successful for fast and efficient chemical analysis of crude plant extracts;[22−24] including the combination with circular dichroism to establish the absolute configuration of the separated analytes.[25] However, HPLC-SPE-NMR alone does not give any information about the pharmacological activity of the analytes,

dx.doi.org/10.1021/jf501605z | J. Agric. Food Chem. 2014, 62, 5595−5602

and therefore the extension with high-resolution assays, that is, HR-BIOASSAY/HPLC-SPE-NMR,[26−31] is probably the most important improvement to the basic HPLC-SPE-NMR setup in recent years.

Here, we report crude extract screening of 46 plant extracts (from 33 different plant species) for fungal PM H^+-ATPase inhibitors, followed by high-resolution bioassay and HPLC-HRMS-SPE-NMR analysis for identification of individual active constituents.

EXPERIMENTAL SECTION

Chemicals. Amphotericin B, RPMI 1640 medium, dimethyl sulfoxide, analytical grade HPLC solvents, and methanol-d_4 (99.8 atom % of deuterium) were purchased from Sigma-Aldrich (St. Louis, MO). Water used for HPLC was purified by deionization and 0.22 μm membrane filtration (Millipore, Billerica, MA).

Purification of the Yeast Plasma Membrane H^+-ATPase by Recombinant Expression. Heat competent *S. cerevisiae* RS72 yeast cells were prepared and transformed according to Gietz and Woods[32] with a yeast multicopy vector,[33] containing the full-length cDNA of the *S. cerevisiae* plasma membrane H^+-ATPase isoform *PMA1* under control of the *PMA1* promoter.[34,35] Transformed yeast cells were precultured in 100 mL of sterile SGAH medium (7.04 g/L yeast nitrogen base, 19.8 g/L galactose, 64 mg/L adenine, and 64 mg/L histidine) for 3 days at 25 °C and 150 rpm. The preculture was transferred to 500 mL of sterile SGAH medium and further incubated for 3−4 days. 100 mL from the cell culture was transferred to 1 L of YPAD medium (10 g/L yeast extract, 20 g/L bacto-peptone, 20 g/L glucose, 20 mg/L adenine) and incubated at 25 °C for 18−20 h. Recombinant yeast was harvested by 2−3 min of centrifugation at 3000*g* and 4 °C, followed by two times washing in milli-Q water. Harvested cells were incubated in 10% glucose for 10 min on a shaking table, and centrifuged at 3000*g* and 4 °C. Cells were resuspended in homogenization buffer (50 g/L glucose, 28.3% glycerol, 0.1 M Tris-HCl pH 7.25, 10 mM EDTA pH 8.0, 50 mM KCl, 1 mM DTT, 200 μM PMSF, 2 μg/mL Pepstatin A), and disrupted with 165 g of glassbeads (500 μm) by runs in a BeadBeater (Biospec Products, Bartlesville, OK). The disrupted cells were centrifuged at 4 °C for 5 and 15 min at 1400*g* and 12 000*g*, respectively. The supernatant was collected and centrifuged at 251 000*g* for 1 h with 112 μM phenylmethylsulfonyl fluoride (PMSF) and 1.1 μg/mL Pepstatin A. The resulting pellet was resuspended in $GTEK_{20}$ buffer (20% glycerol, 10 mM Tris-HCl pH 7.25, 25 mM KCl, 0.5 mM EDTA pH 8.0, 1 mM DTT, 0.2 mM PMSF, 2 μg/mL Pepstatin A) and centrifuged for 45 min at 251 000*g* and 4 °C. Pellet was then resuspended in $STKED_{20}$ buffer (200 g/L sucrose, 40 g/L glucose, 50 mM Tris-HCl pH 7.25, 50 mM KCl, 1 mM EDTA pH 8.0, 1 mM DTT, 0.2 mM PMSF, 2 μg/mL Pepstatin A), homogenized, and diluted with $STKED_{20}$ buffer. The plasma membranes were recovered at the interface of a 43%/53% (w/w) step sucrose gradient containing sucrose in 50 mM Tris-HCl pH 7.25, 50 mM KCl, 1 mM EDTA, and 1 mM DTT. Centrifugation was done for 16 h at 154 000*g* and 4 °C. The plasma membrane fraction was collected and diluted with $GTEK_{20}$ buffer and centrifuged for 1 h at 274 000*g*. Pellet was collected and homogenized in $GTEK_{20}$ buffer and stored at −80 °C.

Determination of Protein Activity. The protein activity was determined by measuring the amount of liberated phosphate (Pi) from the ATP hydrolysis reaction. Reactions, with or without 2 μL sample, were performed in an assay buffer consisting of 20 mM MOPS-NaOH pH 6.5, 8 mM $MgSO_4$, 50 mM KNO_3, 25 mM NaN_3, 250 μM Na_2MoO_4, and initiated by the addition of Na-ATP to a final concentration of 2.5 mM, followed by incubation for 30 min at 30 °C. The amount of Pi was measured after addition of STOP-solution (mixture of A, 170.3 μM $C_6H_8O_6$ in 0.5 M HCl; and B, 28.3 mM $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ in H_2O) with an incubation of 10 min at room temperature and thereafter addition of arsenite solution (154 mM $NaAsO_2$, 68 mM $Na_3C_6H_5O_7\cdot 2H_2O$, 0.35 M CH_3COOH). OD was measured at 860 nm after an additional incubation for 30 min at room temperature.

Protocol for Growth Assay. Minimum inhibitory concentrations (MICs) were determined on *S. cerevisiae* (FuSc041 − De Danske Gærfabrikker, Grenå, Denmark) and *Candida albicans* (SC5314 − LGC Standards, Borås, Sweden) as the lowest concentration that inhibited fungal growth with 50%. Fungal freeze stocks were transferred to YPD-agar plates (10 g/L yeast extract, 20 g/L bacto-peptone, 20 g/L glucose, 20 g/L agar) and incubated at 30 °C overnight (O/N). Cells were suspended in sterile H_2O, and the start OD_{600} was adjusted to *C. albicans* OD_{600} at 0.025, *S. cerevisiae* OD_{600} at 0.05. Three microliters of sample or DMSO, 100 μL of cell suspension, and 97 μL of 2 × RPMI-medium (20.8 g/L RPMI-1640 medium, 0.33 M MOPS, 36 g/L glucose) were pipetted into a microtiter plate and incubated for 24 h at 30 °C, followed by OD measurement at 490 nm.

Plant Material and Extractions. Ground plant material (0.3 g of dried material) of 46 plant samples from an in-house collection was extracted with 3.6 mL of ethanol (96%) by sonication for 2 h. Extracts were filtered (Q-Max RR 13 mm 0.45 μm Nylon, Frisenette, Denmark) and concentrated in vacuo before defatting by partitioning between 2 mL of 90% aqueous methanol and 1.5 mL of petroleum ether (bp 40−65 °C). Defatted extracts were dissolved in DMSO to a concentration of 30 mg/mL. Samples selected for HPLC-HRMS-SPE-NMR/bioassay analysis were extracted with 35 mL of ethanol (ca. 1.2 g of ground plant material) by sonication for 2 h. Extracts were concentrated in vacuo and defatted by partitioning between 20 mL of 90% aqueous methanol and 15 mL of petroleum ether (bp 40−65 °C). Defatted extracts were dissolved in methanol to a concentration of 10 mg/mL for semi-high-resolution bioassay analysis.

Crude Extract Screening. The defatted extracts of 46 plant samples (Table 1) were tested for PM H^+-ATPase inhibition at concentrations of 30, 15, and 7.5 mg/mL. The assay was performed in duplicate according to the protocol described above.

Semi-High-Resolution PM H^+-ATPase Inhibition Assay. Chromatographic separation of crude extracts was performed with an Agilent 1200 series instrument (Santa Clara, CA) consisting of a quaternary pump, a degasser, a thermostated column compartment, a photodiode-array detector, a high-performance auto sampler, and a fraction collector, all controlled by Agilent ChemStation ver. B.03.02 software and equipped with a reversed phase Luna $C_{18}(2)$ (Phenomenex, 150 × 4.6 mm, 5 μm, 100 Å) maintained at 40 °C. The aqueous eluent (A) consisted of water/acetonitrile (95:5, v/v), and the organic eluent (B) consisted of water/acetonitrile (5:95, v/v), both acidified with 0.1% formic acid. The eluent flow rate was maintained at 0.5 mL/min with the following elution profile: 0 min, 0% B; 5 min, 0% B; 35 min, 100% B; 43 min, 100% B; 45 min, 0% B, and 10 min equilibration with five successive injections of 10 μL. The column eluent was directed to an automated fraction collector, and eluent from 10 to 40 min was collected in 183 μL aliquots in 80 wells of a 96-well V-shaped microplate (Brand, Wertheim, Germany) (excluding outer columns), concentrated in vacuo, and redissolved in 25 μL of DMSO. Two microliters was transferred to a 96-well microplate, and the PM H^+-ATPase assay was conducted as described above.

High-Resolution PM H^+-ATPase Inhibition Assay. Chromatographic separation of the two selected plant extracts (*Haplocoelum foliolosum* and *Sauvagesia erecta* L.) was performed on the Agilent 1200 series instrument described above with similar conditions (column, solvent composition, temperature, and flow rate). The elution profiles were: 0 min, 5% B; 50 min, 40% B; 52 min, 100% B; 57 min, 100% B; 58 min, 5% B; and 10 min equilibration for *H. foliolosum*; and 0 min, 5% B; 50 min, 30% B; 52 min, 100% B; 57 min, 100% B; 58 min, 5% B; and 10 min equilibration for *S. erecta*. Single chromatographic separations after injection of 7 μL (from 170 mg/mL solution) and 30 μL (from 50 mg/mL solution) were used for microfractionation of *H. foliolosum* and *S. erecta*, respectively. The eluate from 10 to 40 min was collected in 94 μL aliquots in 160 wells of 2 × 96-well V-shaped microplates (excluding the outer columns). The chromatographic solvent was evaporated to dryness in vacuo, and the contents of each well were redissolved in 40 μL of DMSO. From each well, 3 × 2 μL and 3 × 3 μL were used for the PM H^+-ATPase and growth assays, respectively.

HPLC-HRMS-SPE-NMR. The HPLC-HRMS-SPE-NMR system consisted of an Agilent 1100 chromatograph comprising quaternary pump, degasser, thermostated column compartment, auto sampler, and photodiode array detector (Santa Clara, CA), a Bruker micrOTOF-Q II mass spectrometer (Bruker Daltonik, Bremen, Germany) equipped with an electrospray ionization source and operated via a 1:99 flow splitter, a Knauer Smartline 100 pump for postcolumn dilution (Knauer, Berlin, Germany), a Spark Holland Prospekt 2 SPE unit (Spark Holland, Emmen, The Netherlands), a Gilson 215 liquid handler equipped with a 1 mm needle for automated filling of 1.7 mm NMR tubes, and a Bruker Avance III 600 MHz NMR spectrometer (^{1}H operating frequency 600.13 MHz) equipped with a Bruker SampleJet sample changer and a cryogenically cooled gradient inverse triple-resonance 1.7 mm TCI probe-head (Bruker Biospin, Rheinstetten, Germany). Mass spectra were acquired in both positive and negative ion modes, using drying temperature of 200 °C, capillary voltages of −4100 and +4000 V for positive and negative ion modes, respectively, nebulizer pressure of 2.0 bar, and drying gas flow of 7 L/min. The negative ion mode HPLC-HRMS analysis was performed in a different experiment using identical chromatographic condition. A solution of sodium formate clusters was injected in the beginning of each run to enable internal mass calibration. Cumulative SPE trapping of *H. foliolosum* (peaks *3*−*6*) was performed after eight consecutive separations using the chromatographic conditions (column, solvent composition, temperature, flow rate, and elution profile) described above. The HPLC eluate was diluted with Milli-Q water at a flow rate of 1.5 mL/min prior to trapping on 10 × 2 mm i.d. resin GP (general purpose, 5−15 μm, spherical shape, polydivinyl-benzene phase) SPE cartridges from Spark Holland (Emmen, The Netherlands), and analytes were trapped using absorption thresholds (254 nm). Overlapped peaks (peaks *1* and *2* of *H. foliolosum*) were manually collected from repeated chromatographic separations, evaporated to dryness in vacuo, and reconstituted in methanol to afford 9 mg/mL. This solution was subjected to HPLC-HRMS-SPE-NMR analysis using the following isocratic elution profile: 0 min, 13% B; 24 min, 13% B; 25 min, 100% B; 30 min, 100% B; 31 min, 13% B; and 4 min equilibration. A total of eight cumulative trappings was performed using absorption thresholds (254 nm). SPE cartridges were conditioned with 1000 μL of methanol at 6 mL/min and equilibrated with 500 μL of Milli-Q water at 1 mL/min prior to trapping. Loaded cartridges were dried with pressurized nitrogen gas for 45 min each. Separations were controlled by Bruker Hystar version 3.2 software, automated filling of NMR tubes was controlled by PrepGilsonST version 1.2 software, and automated NMR acquisition was controlled by Bruker IconNMR version 4.2 software. NMR data processing was performed using Bruker Topspin version 3.2 software.

NMR Experiments. All NMR spectra were recorded in methanol-d_4 at 300 K. ^{1}H chemical shifts were referenced to the residual solvent signal (δ 3.31). One-dimensional ^{1}H NMR spectra were acquired in automation (temperature equilibration to 300 K, optimization of lock parameters, gradient shimming, and setting of receiver gain) with 30° pulses, 3.66 s interpulse intervals, 64k data points, and multiplied with an exponential function corresponding to line-broadening of 0.3 Hz prior to Fourier transform. Phase-sensitive DQF-COSY spectra were recorded using a gradient-based pulse sequence with a 20 ppm spectral width and 2k × 256 data points (processed with forward linear prediction to 1k data points). Multiplicity-edited HSQC spectra were acquired with the following parameters: spectral width 20 ppm for ^{1}H and 165 ppm for ^{13}C, 2k × 256 data points (processed with forward linear prediction to 1k data points), and 2.0 s relaxation delay. HMBC spectra (without a low-pass filter) were optimized for $^nJ_{C,H}$ = 10 Hz and acquired using the following parameters: spectral width 20 ppm for ^{1}H and 222 ppm for ^{13}C, 2k × 128 data points (processed with forward linear prediction to 1k data points), and 1.5 s relaxation delay.

Targeted Isolation and Determination of IC_{50} Values of 1 and 2. An injection solution of 0.17 g/mL (*H. foliolosum*) was subjected to a preparative chromatography using the Agilent 1100 system equipped with two preparative solvent delivery units, a multiple wavelength detector, an autosampler, and an optional fraction collector. Separation was performed using a 250 mm × 21.2 mm i.d. Phenomenex Luna C18 (5 μm) column operated at room temperature. Repeated injection (3 × 800 μL) of the above solution, followed by a gradient elution (similar to the one used for HR screening), afforded 9.5 mg of fraction A (collected in a retention time range 22−24 min). Fraction A was reconstituted in 800 μL of 50% MeOH and subjected to further preparation purification using an isocratic elution (12% B) for 30 min. Single injection of 400 μL was performed, and peaks *1* and *2* were manually collected. After concentration under reduced pressure and lyophilization, 0.82 mg of **1** and 0.49 mg of **2** were obtained. The two compounds were reconstituted in DMSO to a final concentration of 5 mM, and subsequently IC_{50} values in PM H^+-ATPase and fungal growth assays with *S. cerevisiae* and *C. albicans* were assessed.

RESULTS AND DISCUSSION

Crude Extract Screening. From our in-house plant collection, 33 different plant species were selected for this study. For some of the species, different parts were available, yielding a total of 46 samples of ground plant material (see Table 1). The material was extracted with ethanol, and the dried extracts were defatted by partitioning between 90% aqueous methanol and petroleum ether. The defatted extracts were tested for their ability to inhibit the PM H^+-ATPase enzyme at concentrations of 30, 15, and 7.5 mg/mL, and extracts showing inhibition higher than 95% for all concentrations or extracts showing a concentration-dependent activity profile (indicated with bold in Table 1) were selected for semi-high-resolution screening. Thus, *Alchornea cordifolia*, *Baissea leonensis* (fruits as well as leaves + twigs), *Caloncoba gilgiana*, *Haplocoelum foliolosum*, *Mussaenda tristigmatica*, *Pierreodendron kerstingii* (leaves), *Salacia pyriformis*, and *Sauvagesia erecta* were selected on the basis of the former criteria, whereas *Hubertia ambavilla*, *Hubertia tomentosum*, *Hypericum scabrum*, *Lophira alata*, *Orthopichonia barteri*, *Pierreodendron kerstingii* (stem bark), *Pleiocarpa mutica*, *Pycnocycla spinosa*, and *Sphenocentrum jollyanum* were selected on the basis of the latter criteria.

Semi-High-Resolution PM H^+-ATPase and Growth Inhibition Profiles. The 18 samples selected for semi-high-resolution screening were separated using a HPLC method starting at 5% acetonitrile (plus 0.1% formic acid) for 5 min, and using a linear gradient from 5% to 95% acetonitrile (plus 0.1% formic acid) from 5 to 35 min. The eluate from 10 to 40 min was collected in 80 wells of a 96-well microplate (omitting the first and last columns), yielding fractions of 183 μL. The eluate was evaporated, and the dried material in each well was redissolved in DMSO. These solutions were assayed for their ability to inhibit the PM H^+-ATPase as well as their ability to inhibit growth of *C. albicans* and *S. cerevisiae*. The results were plotted under the HPLC traces at 254 nm, and all semi-high-resolution biochromatograms are given in Supporting Information, Figures S1−S18. The results show that the tested extracts can be placed in three different groups as illustrated in Figure 1. The first group consists of *Hubertia ambavilla*, *Hubertia tomentosum*, *Hypericum scabrum*, *Lophira alata*, *Orthopichonia barteri*, *Pierreodendron kerstingii* (stem bark), *Pleiocarpa mutica*, *Pycnocycla spinosa*, *Salacia pyriformis*, and *Sphenocentrum jollyanum*, which show very low PM H^+-ATPase inhibition and/or no distinct peaks with PM H^+-ATPase inhibition. The second group consists of *Alchornea cordifolia*, *Baissea leonensis* (fruits as well as leaves + twigs), *Caloncoba gilgiana*, *Mussaenda tristigmatica*, and *Pierreodendron kerstingii* (leaves), where the observed PM H^+-ATPase inhibition is correlated with a broad hump at approximately 10−30 min. This hump is attributed to tannin-rich fractions, and the PM

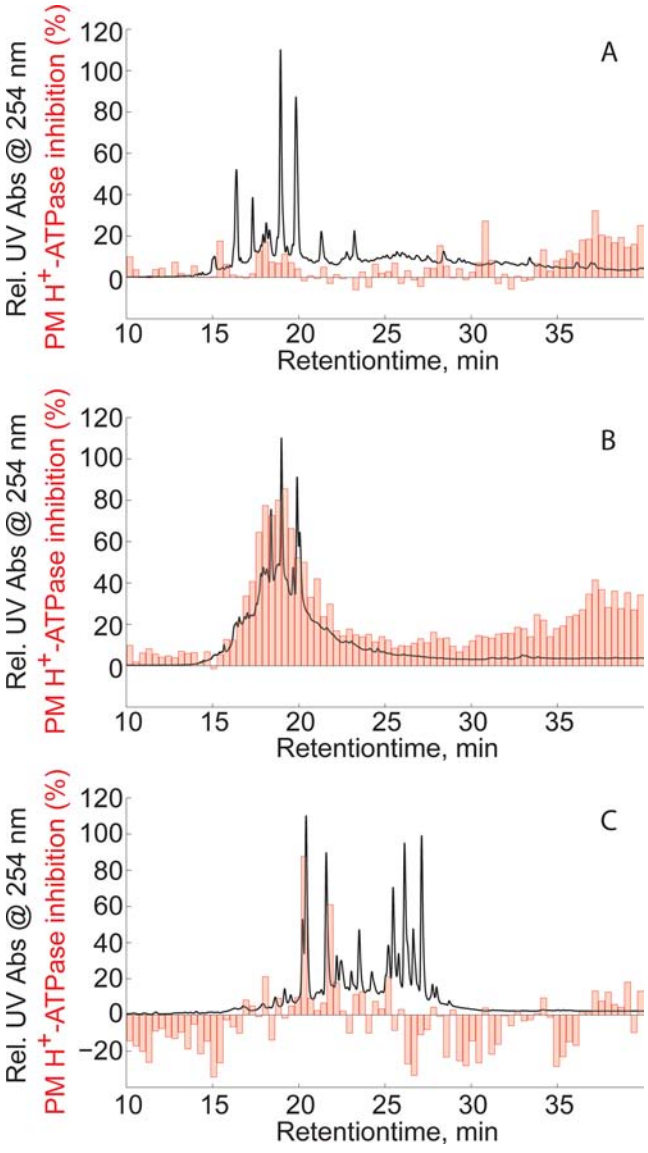

Figure 1. Three representative inhibition profiles obtained through semi-high-resolution antifungal screening: *Hypericum scabrum* (A, group 1), *Caloncoba gilgiana* (B, group 2), and *Haplocoelum foliolosum* (C, group 3).

H^+-ATPase inhibition is therefore likely to be caused by tannins, which are of little interest due to their inherent ability to precipitate proteins. The third group consists of two samples, *Haplocoelum foliolosum* and *Sauvagesia erecta*, showing direct correlation between individual peaks and inhibition of the PM H^+-ATPase. Therefore, the two plants from the last group were selected for a high-resolution PM H^+-ATPase assay to correlate the observed activities with individual metabolites.

High-Resolution PM H^+-ATPase Profiles. Extracts of *H. foliolosum* and *S. erecta* were reanalyzed using the high-resolution PM H^+-ATPase inhibition assay with optimized separation condition and a higher number of data points per retention time (5.33 points/min). Furthermore, higher chromatographic loading (1.2 and 1.5 mg for *H. foliolosum* and *S. erecta*, respectively) allowed triplicate assaying of the time-sliced fractions to assess statistical variations of the assay. The biochromatograms for the two plants were therefore plotted with standard deviation from the triplicate measurements (Figure 2 and Supporting Information Figure S19 for *H. foliolosum* and *S. erecta*, respectively). From *H. foliolosum* two

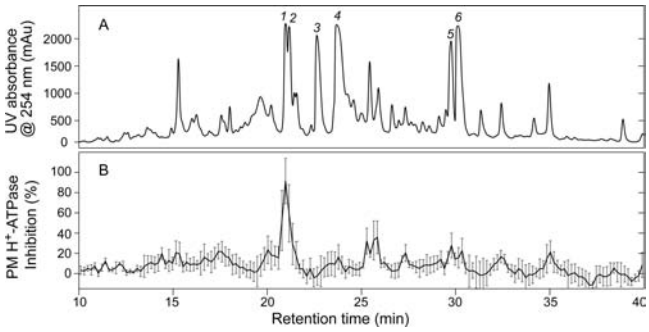

Figure 2. High-resolution antifungal screening of *Haplocoelum foliolosum* crude extract. (A) HPLC chromatogram at 254 nm. (B) High-resolution fungal plasma membrane H^+-ATPase inhibition profile (an average of triplicate measurements with standard deviations are plotted).

overlapping peaks at 23.6 min were correlated with >80% inhibition of the PM H^+-ATPase. *S. erecta*, however, did not show any peaks in the HPLC chromatogram correlating with a discrete peak in the inhibition profile of the optimized high-resolution assay (Supporting Information Figure S19). This is despite the noticeable inhibition in both the crude extract screening (Table 1) and the semi-high-resolution assay (Supporting Information Figure S18). This can be caused by loss of synergistic activities of multiple constituents that are separated in the high-resolution biochromatogram but assessed collectively in the semi-high-resolution biochromatogram as well as in the crude extract screening. Therefore, *S. erecta* was excluded from further investigation.

HPLC-HRMS-SPE-NMR. The two active peaks from *H. foliolosum* (peaks *1* and *2*) and four other major metabolites (peaks *3*–*6*) were subjected to HPLC-HRMS-SPE-NMR analysis. Detailed HRMS and NMR analysis resulted in identification of six compounds **1**–**6** (Figure 3) corresponding to peaks *1*–*6*, respectively. ^{1}H NMR, UV, and HRMS data of **1**–**6** obtained in the HPLC-HRMS-SPE-NMR mode are given in Table S1 in the Supporting Information.

HRMS data of compound **1** showed a base peak at *m*/*z* 785.0836, which was attributed to $C_{34}H_{25}O_{22}^+$. However, inverse-detected heteronuclear experiments revealed 41 carbon atoms. After a detailed analysis of 1D and 2D NMR experiments and comparison of the observed NMR data with literature data, the analyte was identified as chebulagic acid (**1**)[36] (molecular formula $C_{41}H_{30}O_{27}$). The observed base peak for **1** at *m*/*z* 785.0836 was assigned to a fragment ion [M + H − H_2O − galloyl]$^+$ ($C_{34}H_{25}O_{22}^+$, ΔM −0.5 ppm), similar to the fragment ion at *m*/*z* 769.0863 [M + H − H_2O − galloyl group]$^+$ ($C_{34}H_{25}O_{21}^+$, ΔM 2.5 ppm) observed as the base peak for compound **2**. Such fragmentation product has previously been reported for **1**.[37] The molecular ion peaks of compound **1** and **2** could not be detected in positive ion mode, even when studying extracted ions chromatograms from HPLC-HRMS. The molecular formulas are, however, supported by the presence of ammonium adducts in positive ion mode of *m*/*z* 972.1295 [M + NH_4]$^+$ ($C_{41}H_{34}NO_{27}^+$, ΔM 1.8 ppm) and *m*/*z* 956.1331 [M + NH_4]$^+$ ($C_{41}H_{34}NO_{26}^+$, ΔM 3.5 ppm) as well as molecular ion peaks in negative ion mode of *m*/*z* 953.0875 [M − H]$^-$ ($C_{41}H_{29}NO_{27}^-$, ΔM 2.8 ppm) and *m*/*z* 937.0924 [M −

tellimagrandin II (**2**)	10.6 ± 3.1	1.8 ± 0.9	>75
vanadate	2.3 ± 1.2		
amphotericin B		0.08 ± 0.05	0.08 ± 0.05
fluconazole		7.6 ± 4.9	0.9 ± 0.6

[a] n = 3, results reported in micromolar. [b] Determined as MIC for 50% inhibition.

$H]^-$ ($C_{41}H_{29}NO_{26}^-$, ΔM 2.9 ppm), compounds **1** and **2**, respectively.

The ^1H NMR spectrum of **2** shows five deshielded aromatic proton resonances, 7.05 (s, 2H, H-2′/H-6′), 6.95 (s, 2H, H-2″/H-6″), 6.92 (s, 2H, H-2‴/H-6‴), 6.62 (s, 1H, H-3⁗), and 6.49 (s, 1H, H-3⁗′). Three of these signals were integrated to two protons each, and thorough analysis of characteristic ^2J and ^3J HMBC correlations to the corresponding quaternary aromatic carbons and a carboxyl carbon revealed three galloyl groups. Seven relatively deshielded resonances with discrete COSY spin system were assigned to a glucose moiety with esterification of all hydroxyls. The esterification positions were established by ^3J HMBC correlations of the sugar proton resonances H-1 (δ 6.11, d, J = 8.2 Hz), H-2 (δ 5.55, dd, J = 9.1,8.4 Hz), and H-3 (δ 5.76, t, J = 9.6 Hz) with the galloyl carboxyl carbon resonances C-7′ (166.2 ppm), C-7″ (166.6 ppm), and C-7‴ (167.4 ppm), respectively. After identifying a hexahydroxydiphenoyl (HHDP) moiety bridging two oxygens of glucose at positions 4 and 6 through similar HMBC data analysis, the structure of peak 2 was confirmed as tellimagrandin II (**2**).[38]

In addition to the two active metabolites (**1** and **2**), four major metabolites (peaks 2–6) of *H. foliolosum* were investigated. HRMS analysis of peak 3 (HR-ESIMS(+) m/z 449.0698 $[M + H]^+$ [$C_{20}H_{17}O_{12}^+$, ΔM −3.7 ppm]) revealed the molecular formula of compound **3** to be $C_{20}H_{16}O_{12}$. After analysis of 1D and 2D NMR data and comparison of chemical shifts with literature values, compound **3** was identified as ellagic acid 4-*O*-α-L-rhamnopyranoside.[39] Peak 4 was identified as rutin (HR-ESIMS(+) m/z 611.1606 [$C_{27}H_{31}O_{16}^+$, ΔM −0.1 ppm]) by comparing HRMS and ^1H NMR data with an authentic reference compound. On the basis of HRMS analysis, peak 5 was assigned the molecular formula $C_{21}H_{20}O_{11}$ (HR-ESIMS(+) m/z 449.1075 [$C_{21}H_{22}O_{11}^+$, ΔM −0.8 ppm]). AMX and AX spin systems and a characteristic flavone H-3 resonance (6.63 ppm) observed in the downfield region of the ^1H NMR spectrum were in agreement with luteoline aglycone. A discrete spin system observed in COSY was attributed to a glucose moiety. After establishing the glycosidic linkage at C-4′ with ^3J HMBC correlations, compound **5** was identified as luteolin 4′-*O*-β-glucopyranoside.[40] The ^1H NMR spectrum of compound **6** (HR-ESIMS(+) m/z 463.0868 $[M + H]^+$ [$C_{21}H_{19}O_{12}^+$, ΔM 0.7 ppm]) displayed signals and multiplicity patterns similar to those of compound **3**, but with an additional methoxy resonance at 4.19 ppm. These observations and comparison of chemical shifts with literature revealed compound **6** as 3-*O*-methylellagic acid 4-*O*-α-L-rhamnopyranoside.[41]

After observation of their significant PM H^+-ATPase inhibitory effects in high-resolution screening, chebulagic acid (**1**) and tellimagrandin II (**2**) were isolated by preparative-scale HPLC, and the materials were used for assessing IC_{50} values in the PM H^+-ATPase inhibition assay and fungal growth inhibition assays (Table 2).

Chebulagic acid and tellimagrandin II had an inhibitory effect against PM H^+-ATPase with IC_{50} values of 15.8 and 10.6 μM, respectively. The two compounds also showed antifungal activity against *S. cerevisiae*, and were equally potent with MIC of 1.8 μM. This is better than Fluconazole that possess a MIC of 7.6 μM, but not as potent as Amphotericin B with a MIC of 0.08 μM for *S. cerevisiae*. Both compounds were also tested against *C. albicans*, but did not show any antifungal activity at concentrations lower than 75 μM, and this is despite conserved PM H^+-ATPase among the fungal species (83% sequence

dx.doi.org/10.1021/jf501605z | J. Agric. Food Chem. 2014, 62, 5595−5602

identity; sequence alignment of *C. albicans* PMA1 (accession number P28877) and *S. cerevisiae* H^+-ATPase PMA1 (accession number P05030) made with ClustalW2). Furthermore, the compounds have a higher IC_{50} value against the PM H^+-ATPase than MIC value against *S. cerevisiae*. Taken together, this could indicate that not only the inhibition of PM H^+-ATPase contributes to the antifungal effect of chebulagic acid and tellimagrandin II, but other factors may also play a role. Hydrolyzable tannins, including tellimagrandin II, have been shown to have membrane-damaging activity on liposomes prepared from egg-yolk phosphatidylcholin, but not affecting the viability of MKN-28 cells derived from human gastric epithelium.[42] It remains to be determined if chebulagic acid and tellimagrandin II, in addition to their PM H^+-ATPase inhibitory effect, have membrane-damaging activity on *S. cerevisiae*, which contributes to the observed antifungal activity.

In the literature, chebulagic acid has been identified as an active inhibitor of xanthione oxidase with an IC_{50} = 48.5 μM[43] and with both antibacterial and antifungal effect in doses of 100 μM.

In conclusion, chebulagic acid and tellimagrandin II are two potent inhibitors of the plasma membrane H^+-ATPase with inhibitory effect on the growth of *S. cerevisiae*. Further studies on isolated and/or semisynthetic analogues are planned to investigate the structure−activity relationship and specificity.

Protective Effect of Anthocyanidins against Sodium Dithionite-Induced Hypoxia Injury in C6 Glial Cells

Yu-Chun Lin, Pei-Feng Tsai, and James Swi-Bea Wu*

Graduate Institute of Food Science and Technology, National Taiwan University, P.O. Box 23-14, Taipei City 10672, Taiwan

ABSTRACT: The present study investigated the neuroprotective effect of anthocyanidins, including cyanidin, delphinidin, malvidin, pelargonidin, and peonidin, against hypoxia in C6 glial cells. The cells were first incubated with a medium containing anthocynidin in normoxia condition and then with a medium containing sodium dithionite ($Na_2S_2O_4$) in an anaerobic incubator for the hypoxia treatment. Methylthiazole tetrazolium test and evaluation of antioxidant enzyme activities and glutathione concentration were performed on the treated cells. At least 74% of the C6 cells preincubated with 25 mg/L of any of the five anthocyanidins in serum-free Dulbecco's modified Eagle's medium at 37 °C for 24 h survived the hypoxia treatment as compared with a survival rate between 47 and 59% for the control that was preincubated without an anthocyanidin. The cells preincubated with any of the five anthocyanidins showed higher catalase activity and glutathione concentration after the hypoxia treatment as compared with the corresponding samples without the preincubation with anthocyanidin. The cells preincubated with malvidin, pelargonidin, or peonidin also showed higher superoxide dismutase activities. The results of this study justify further research for the development of anthocyanidins into neuroprotective food ingredients against hypoxia injury.

KEYWORDS: *anthocyanin, anthocyanidin, antioxidant, hypoxia, glial cell*

INTRODUCTION

Mammalian cells rely on oxygen for survival. Hypoxia happens during various pathophysiologic conditions such as ischemia, respiratory disease, and tumorigenesis[1] and promotes the generation of reactive oxygen species (ROS), including superoxide anion ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), and hydroxyl radicals, in the cell. The increase in ROS levels may lead to the occurrence of oxidative stress.[2] Oxidative stress has long been associated with the development of brain cell damage and neurodegenerative disorders.[3−5]

ROS are byproducts of both normal and irregular metabolic processes that utilize molecular oxygen. Antioxidant enzymes, such as catalase (CAT) and superoxide dismutases (SODs), are involved in the elimination of ROS.[6] Without the protection of antioxidant enzymes, various types of intracellular oxidative damages, such as DNA alteration[7] and lipid and protein peroxidations,[8] may occur and cause deterioration in health. Brain tissue is particularly vulnerable to oxidative damage, possibly due to its high consumption of oxygen and the consequent generation of high quantities of ROS during oxidative phosphorylation.[9]

Due to their abundance and ability to sustain the homeostatic environment of the central nervous system (CNS), glial cells play a critical role in maintaining neuronal function under both physiological and pathological conditions. Glial cells constitute the most common cell type in the brain and play critical roles in normal brain function and during infection and injury.[10,11] Astrocytes make up the largest subpopulation of glial cells and are a key factor in alleviating ischemic damage to neurons.[12] Impairment in the functions of these astrocytes during brain ischemia and other insults may be fatal to neurons.[13]

Astrocyte functions that are known to support the survival of neurons include glutamate uptake, glutamate release, free radical scavenging, water transport, and production of cytokines and nitric oxide.[14] The C6 glial cell line was originally derived from rat brain tumor induced by *N*-nitrosomethylurea. C6 cells are characterized with important functional analogy to normal rat brain astrocytes and therefore widely used to imitate astrocytes,[15] for example, in studies on oxidative stress with responsive effects to redox-active compounds.[16]

Anthocyanins occur widely in plants. They are well-known free radical scavengers against oxidative damage in the cell and are reported as a potential chempreventive agent.[17] A growing number of scientific papers show that anthocyanins and anthocyanin-rich berries or derived extracts exhibit a wide range of protective effects with potential benefits for human and animal health.[18] Ghosh et al.[19] proposed that the systemic antioxidative effects of absorbed anthocyanins or their metabolites may reduce oxidative stress and the risk of certain chronic and degenerative diseases. Anthocyanins are glycosides of polyhydroxyl and polymethoxyl derivatives of flavylium salts. Aglycons of anthocyanins, anthocyanidins, are widely present in pigmented fruits and vegetables such as pomegranate, berry, grape, sweet potato, red cabbage, and eggplant.[20,21]

There are quite a few cell studies investigating the effect of anthocyanidins to protect health.[22−24] Tarozzi et al.[25] studied the neuroprotective effect of cyanidin in SH-SY5Y cells under oxidative stress and proposed that it may play an important role in brain health promotion. However, little research has been done on the neuroprotective effect of anthocyanidins against hypoxia. The present study was to evaluate the effect of anthocyanidins in preventing hypoxia injury in the nervous

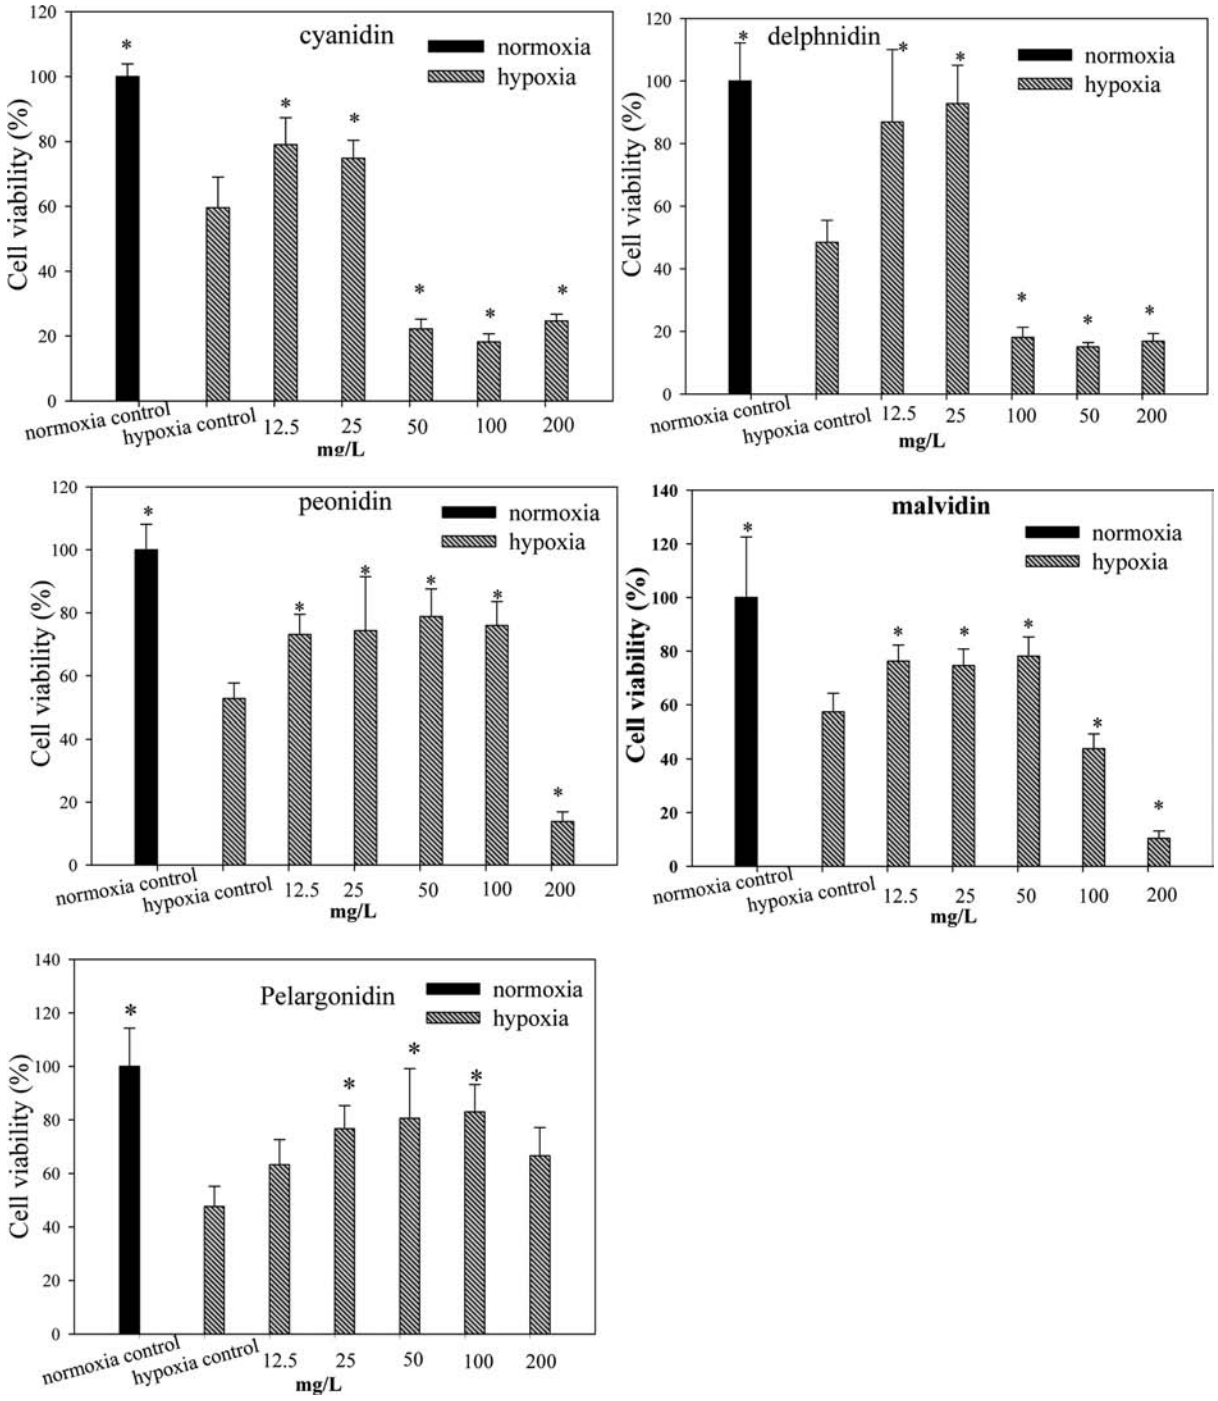

Figure 1. Neuroprotective effect of anthocyanidins on C6 cells against $Na_2S_2O_4$-induced hypoxia. The cells in the treatment groups were preincubated in DMEM containing an anthocyanidin in 12.5−200 mg/L at 37 °C for 24 h and then treated with 5 mM $Na_2S_2O_4$ for 30 min in anaerobic environment. Cell viability was evaluated by MTT test. Normoxia control: cells preincubated in DMEM containing no anthocyanidin and then treated with PBS in normoxia condition. Hypoxia control: cells preincubated in DMEM containing no anthocyanidin and then treated with PBS in hypoxia condition. Data are means ± SD from three independent experiments. Statistical analysis was performed using one-way ANOVA and Duncan's new multiple-range test. (∗) $p < 0.05$ versus the hypoxia control.

system. C6 glial cells were used to imitate brain astrocytes, whereas sodium dithionite ($Na_2S_2O_4$) was used to cause chemical hypoxia that mimics the hypoxic/ischemic condition.[26]

MATERIALS AND METHODS

Reagents. Anthocyanidins (cyanidin, delphinidin, malvidin, pelargonidin, and peonidin, all in chloride form) were obtained from Extrasynthese Corp. (Genay Cedex, France). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl, bovine serum albumin (BSA), and trypsin/ethylenediaminetetraacetic acid (EDTA) were purchased from Sigma (St. Louis, MO, USA). Catalase (CAT), glutathione (GSH), and superoxide dismutase (SOD) activity kits were purchased from Cayman Chemical Co. (Ann Arbor, MI, USA). All the chemical reagents were of analytic grade.

Cultivation of Cells. C6 glial cells were obtained from Bioresource Collection and Research Center (Hsinchu, Taiwan). The cells were

dx.doi.org/10.1021/jf501564h | J. Agric. Food Chem. 2014, 62, 5603−5608

inoculated into Dulbecco's modified Eagle's medium (DMEM) (Gibco, Grand Island, NY, USA) supplemented with 10% fetal bovine serum (Gibco), containing 100 units/mL penicillin and 100 units/mL streptomycin, and then held in humidified 5% CO_2/95% air environment at 37 °C. Exponentially growing cells were detached from the culture flasks with the addition of 0.05% trypsin/EDTA and collected by centrifuging the suspension. For the methylthiazole tetrazolium (MTT) test, the harvested cells were suspended in serum-free DMEM at a density of 2×10^4 cells/well and then placed on 96-well plates. For CAT, SOD, and GSH assays, 6-well plates instead of 96-well plates were used. All of the plates were held at 37 °C for 24 h before the following treatments.

Preincubation. Preincubation of C6 cells with each of the five common anthocyanidins was practiced prior to the hypoxia treatment for revealing the protective effect of these anthocyanidins on neuronal cells from hypoxia injury. Anthocyanidins were dissolved in phosphate buffer saline (PBS, pH 7.2) in various concentrations from 12.5 to 200 mg/L and added into wells on the plate. After another 24 h of incubation, each well was rinsed with PBS. Samples containing no anthocyanidins were taken as controls.

Hypoxia Treatment. A 200 μL aliquot of 5 mM $Na_2S_2O_4$ was added to each well for the generation of hypoxia stress. The plates were then incubated at 37 °C for 30 min in an anaerobic incubator with 1% O_2, 5% CO_2, and 94% N_2 atmosphere.

MTT Test. The protective effects of anthocyanidins against hypoxia were determined by MTT test.[27] Samples of cultured cells were taken from the plates periodically. A filtered solution of 0.5 mg MTT/mL serum-free DMEM was added to each well. The plates were then incubated at 37 °C for 2 h. The supernatant, which contained unreacted dye, was removed. DMSO was added to dissolve the MTT formazan crystals left in each well. The 570 nm absorbance of each sample in the well was measured 15 min later. The viability of cells was calculated using the following equation:

$$\text{cell viability (\%)} = (\text{absorbance of sample}) / (\text{absorbance of normoxia control}) \times 100\%$$

CAT Assay. CAT activity was measured using a Catalase Assay Kit (Cayman). The cell samples were collected from the 6-well plate by a rubber policeman, mixed with 1 mL of cold buffer (pH 7.0, 50 mM potassium phosphate/1 mM EDTA), sonicated on ice, and then centrifuged at 10000*g* and 4 °C for 15 min. A 20 μL aliquot of the supernatant was placed in a well on a 96-well plate and mixed with 100 μL of assay buffer, 30 μL of methanol, and 20 μL of hydrogen peroxide. The plate was covered and incubated at room temperature for 20 min with shaking. To each well was then added 30 μL of potassium hydroxide to terminate the reaction, followed by 30 μL of Purpald for color development. The plate was covered again and incubated for an additional 10 min at room temperature with shaking. To each well was added 10 μL of potassium periodate, and then the plate was incubated at room temperature for 5 min with shaking. The protein content of the cell sample was evaluated using a protein assay dye (Bio-Rad, Hercules, CA, USA) following the above-described procedure. The absorbance at 540 nm was measured for evaluating the CAT activity in the cell sample, expressed as U/mg protein.

SOD Assay. SOD activity was measured using a Superoxide Dismutase Assay Kit (Cayman). The cell samples were collected from the 6-well plate by a rubber policeman, mixed with 1 mL of cold 20 mM HEPES buffer (pH 7.2, containing 1 mM EGTA, 210 mM mannitol, and 70 mM sucrose), sonicated on ice, and then centrifuged at 1500*g* and 4 °C for 5 min. A 10 μL aliquot of the supernatant was mixed with 200 μL of radical detector in a well on a 96-well plate. A 20 μL aliquot of xanthine oxidase was added followed by another mixing. The plate was covered and then incubated at room temperature for 20 min with shaking. The protein content of the cell sample was evaluated using a protein assay dye (Bio-Rad). The absorbance at 450 nm was measured for evaluating the SOD activity in the cell sample, expressed as U/mg protein.

GSH Assay. GSH was measured using a Glutathione Assay Kit (Cayman) following the protocol. Briefly, the cell samples were collected from the 6-well plate by a rubber policeman, mixed with 1 mL of cold buffer (50 mM phosphate at pH 6–7, containing 1 mM EDTA), sonicated on ice, and then centrifuged at 10000*g* and 4 °C for 15 min. A 50 μL aliquot of the supernatant was mixed with 150 μL of freshly prepared assay cocktail. The plate was covered and then incubated in the dark at room temperature for 25 min with shaking. The absorbance at 410 nm was measured for evaluating the GSH activity in the cell sample, expressed as μM.

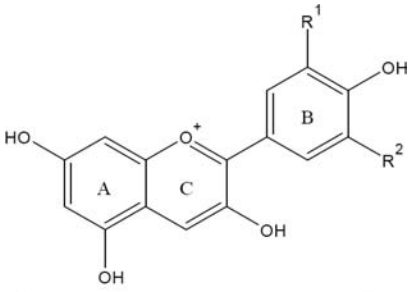
Statistical Analysis. The data were analyzed by one-way ANOVA and Duncan's new multiple-range test. Differences with a p value <0.05 were considered significant.

RESULTS AND DISCUSSION

Protective Effects of Anthocyanidins against Hypoxia-Induced Cell Damage. In the present study, C6 glial cells, either preincubated with an anthocyanidin or not, were suspended in 5 mM $Na_2S_2O_4$ solution and incubated in an anaerobic environment at 37 °C for 30 min as the hypoxia treatment. The viability of cells preincubated without anthocyanidin was reduced in the hypoxia treatment to 47–59% of the original value (Figure 1). Preincubation of the cells with an anthocyanidin at proper concentration may effectively improve the viability in the hypoxia treatment. The concentration of an anthocyanidin up to 50–200 mg/L may cause cell toxicity. This might be because the anthocyanidins used in the present study are all in chloride form. The osmotic pressure or pH of solution may cause cell toxicity. Among the five anthocyanidins tested, delphinidin at 25 mg/L concentration showed the highest protective effect on C6 cells against the hypoxia treatment, by retaining >90% of the cell viability as compared with a survival rate between 47 and 59% for the hypoxia control that was preincubated without an anthocyanidin. The lowest protective effect came from peonidin, which retained 74% of the cell viability. The protective effect may be attributed to the antioxidant activity of anthocyanidins. Delphinidin and cyanidin are among those anthocyanidins that have a completely conjugated structure to allow ROS delocalizing their electrons and forming very stable radical products.[28] The antioxidant activities of these two anthocyanidins are therefore higher than the other three in the present study. The third hydroxyl group in the B ring also enhances the radical scavenging activity.[29] Delphinidin, which has hydroxyl groups in three positions, 3′-, 4′-, and 5′-, was more antioxidative than cyanidin, which has hydroxyl groups in only two positions, 3′- and 4′- (Figure 2). Higher stability, reactivity, and chemical antioxidant activity of an anthocyanidin may lead to higher cell antioxidant capacity at the cytosol level.[25]

No apparent dose dependency for the protective effect of anthocyanidins on C6 glial cells was observed. Generally, at least 74% of the C6 glial cells preincubated with an anthocyanidin at 25 mg/L survived the hypoxia treatment (Figure 1). The concentration of 25 mg/L was therefore chosen for the subsequent experiments.

Antioxidant Enzymes and Protein in Cells Subjected to Hypoxia Treatment. Hypoxia causes an increase of oxidative stress that is detrimental to cells. Extra activities of antioxidant enzymes, including CAT and SOD, and GSH may be induced in the cell to scavenge free radicals as a defensive response. The increments in antioxidant enzyme activities and GSH concentration can be indicators for the effectiveness of the antioxidant defense system in cells.[30] Intracellular superoxide anions could be converted to H_2O_2 by SOD and then to H_2O and O_2 by CAT.[31] GSH is the most abundant free cellular



Anthocyanidin	R^1	R^2
Pelargonidin	H	H
Cyanidin	OH	H
Delphinidin	OH	OH
Peonidin	OCH_3	H
Malvidin	OCH_3	OCH_3

Figure 2. Structural formulas of five common anthocyanidins.

thiol in eukaryotes and a well-characterized ROS scavenger in the brain. The GSH content in cells is consumed to counteract the accumulation of ROS in hypoxia.[30]

In the present study, we treated C6 cells with five different anthocyanidins and assessed the activities of antioxidant enzymes CAT and SOD and the concentration of GSH in the cells for evaluating the effect of anthocyanidins on the antioxidant defense system.

CAT. CAT catalyzes the conversion of hydrogen peroxide into H_2O and O_2 in attenuating the oxidative stress. As shown in Figure 3, CAT activity in C6 glial cells preincubated with an anthocyanidin was increased in the hypoxia treatment ($p < 0.05$). The increments of CAT activity in cells in hypoxia were 49, 43, 33, 23, and 16%, in diminishing order, for delphinidin, peonidin, malvidin, pelargonidin, and cyanidin, respectively. C6 cells suffer from the increase of oxidative stress in hypoxia condition. Anthocyanidins may induce extra activities of CAT in the cell to scavenge more free radicals. The increase in CAT activity may be involved in the neuroprotective effect of anthocyanidins.

Propofol is a synthetic chemical that has been demonstrated to be neuroprotective in several in vivo and in vitro models of cerebral hypoxia reoxygenation injury.[32] Propofol contains a phenolic hydroxyl group, and thus its structure resembles that of α-tocopherol, a natural antioxidant. Moreover, propofol has been shown to induce and regulate intracellular signaling pathways, and the neuroprotective effects of propofol may also be mediated indirectly via the induction of cell-based antioxidant mechanisms. Its neuroprotective activity was attributed to the antioxidation activity from the phenolic chemical structure. Anthocyanidins are natural phenolic compounds and also have antioxidative activity. The anthocyanidins in the present study presumably protect the neuronal system in hypoxia on the basis of their phenolic structures as well.

Martin et al.[33] found that procyanidins may promote the activity of CAT in the cell. In the present study, we found similar promotion of cellular CAT activity in incubation with an anthocyanidin.

SOD. The presence of delphinidin in the culture medium resulted in a higher SOD activity in the aerobic preincubation as compared with the normoxia control and the presence of another anthocyanidin ($p < 0.01$) (Figure 4).

Cells preincubated with malvidin, pelargonidin, and peonidin were enabled to increase their SOD activity in the hypoxia treatment by 72, 11, and 49%, respectively, whereas those incubated with cyanidin and delphinidin showed decreased

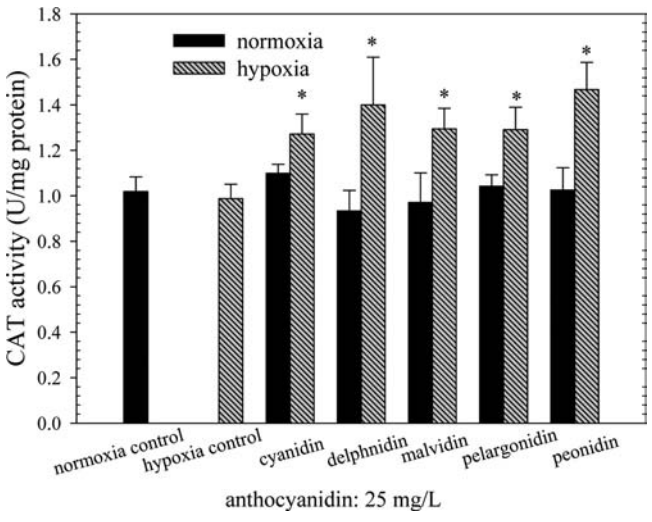


Figure 3. Effect of anthocyanidins on CAT activity in C6 cells in normoxia and hypoxia conditions. The C6 cells in the treatment groups were preincubated in DMEM containing an anthocyanidin at 37 °C for 24 h and then incubated for 30 min either in the hypoxia condition induced with 5 mM $Na_2S_2O_4$ under anaerobic environment or in the normoxia condition with PBS. CAT activity is expressed as U/mg protein. Normoxia control: cells preincubated in DMEM containing no anthocyanidin and then treated with PBS in normoxia condition. Hypoxia control: cells preincubated in DMEM containing no anthocyanidin and then treated with PBS in the hypoxia condition. (*) $p < 0.05$ versus the hypoxia control.

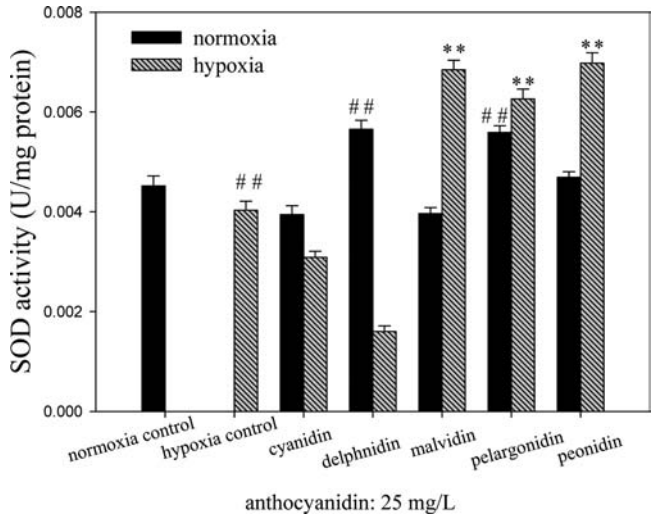

Figure 4. Effect of anthocyanidins on SOD activity in C6 cells in normoxia and hypoxia conditions. The cells in the treatment groups were preincubated in DMEM containing an anthocyanidin at 37 °C for 24 h and then incubated for 30 min either in the hypoxia condition induced with 5 mM $Na_2S_2O_4$ under anaerobic environment or in the normoxia condition with PBS. SOD activity is expressed as U/mg protein. Normoxia control: cells preincubated in DMEM containing no anthocyanidin and then treated with PBS in normoxia condition. Hypoxia control: cells preincubated in DMEM containing no anthocyanidin and then treated with PBS in the hypoxia condition. (##) $p < 0.01$ versus the normoxia control. (**) $p < 0.01$ versus the hypoxia control.

SOD activity. Wu et al.[34] reported that nerve growth factor (NGF) prevents hypoxic insults in cultured cerebral cortical neurons by increasing the activity of SOD. The increase in SOD activity may contribute to the neuroprotective effects of malvidin, pelargonidin, and peonidin in the present study. SOD activity readings in C6 cells preincubated with cyanidin and delphinidin were apparently decreased in the hypoxia treatment, by 21 and 72%, respectively (Figure 4), whereas the cell viability readings were maintained at 75 and 90%, respectively, which were better than the hypoxia control (Figure 1). Presumably, cyanidin and delphinidin do not provide protection on C6 cells against hypoxia by playing the role of promoters to SOD activity. The availability of the hydroxyl group on the B ring of an anthocyanidin, such as cyanidin and delphinidin, is fundamental to the antioxidant activity of these compounds because hydroxyl moieties can donate hydrogen to scavenge radicals.[35] Therefore, we postulate that playing antioxidants themselves may be an important mechanism for these two anthocyanidins to protect C6 cells against hypoxia.

GSH. The GSH concentrations in C6 cells were elevated in the aerobic preincubation with malvidin, pelargonidin, and peonidin ($p < 0.05$) (Figure 5). The increase in GSH continued

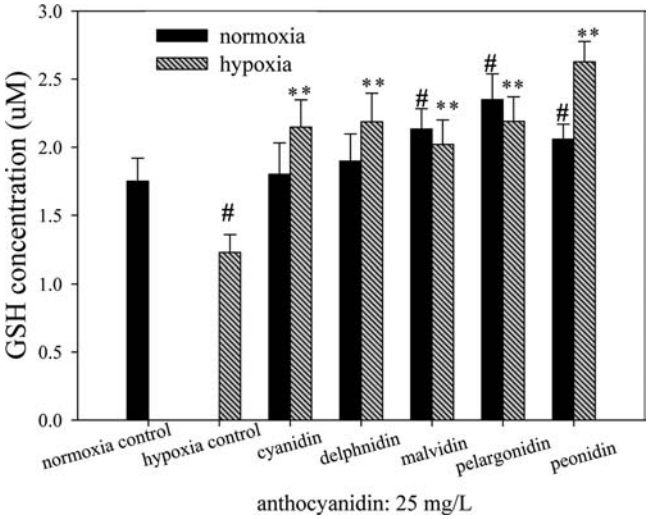

Figure 5. Effect of anthocyanidins on GSH concentration in C6 cells in normoxia and hypoxia conditions. The cells in the treatment groups were preincubated with an anthocyanidin at 37 °C for 24 h and then incubated for 30 min either in the hypoxia condition induced with 5 mM $Na_2S_2O_4$ under anaerobic environment or in the normoxia condition with PBS. GSH concentration is expressed as μM. Normoxia control: cells preincubated in DMEM containing no anthocyanidin and then treated with PBS in normoxia condition. Hypoxia control: cells preincubated in DMEM containing no anthocyanidin and then treated with PBS in the hypoxia condition. (#) $p < 0.05$ versus the normoxia control. (**) $p < 0.01$ versus the hypoxia control.

in the hypoxia treatment for cells preincubated with peonidin, by 27%. In response to the hypoxia-induced oxidative stress, a marked depletion in the concentration of GSH occurred in the brain.[36] In the present study, the preincubation with anthocyanidins enabled cells to increase their GSH concentrations in the subsequent hypoxia treatment. An explanation is that anthocyanidins initiate the promotion of GSH-related enzyme expressions in the preincubation.[37]

Several brain disorders are accompanied by a decrease in GSH and other indications of oxidative stress in cells.[38] The brain is particularly susceptible to oxidative insults, and its antioxidant defense is dependent on the GSH content.[39] The present study found that preincubations with malvidin, pelargonidin, and peonidin are able to increase GSH content in C6 cells, reconfirming the potential for these anthocyanidins to be used in the protection of the nervous system against hypoxia injury.

Limited information has been collected on the bioavailability, metabolism, and absorption of anthocyanins and anthocyanidins, although they generally appear in human plasma quickly after digestion.[40] Animal studies also confirm that these compounds rapidly cross the blood–brain barrier.[41,42] The present study provided supporting evidence in cell study for the development of anthocyanidins to be a health food ingredient for the prevention of neuronal injury in hypoxia condition.

Conclusion. In recent years, the inclusion of phytochemicals in the human diet has gained considerable attention. Anthocyanins occur widely in plant materials. Anthocyanidins are the aglycon part, which can be released from anthocyanins during digestion. The present study demonstrates the protective effect of five anthocyanidins, namely, cyanidin, delphinidin, malvidin, pelargonidin, and peonidin, on neuronal cells against hypoxia injury and supports the development of anthocyanidins as ingredients in health food. The results also indicate that the neuroprotective effect may be related to the increase in the activities of antioxidant enzymes CAT and SOD and the concentration of antioxidant protein GSH. Further studies to elucidate the mechanism for anthocyanidins to protect the nervous system shall be worthwhile.

Supporting Information

ABSTRACT: We compared the detergent fiber and dietary fiber methods to analyze the cellulose and hemicellulose contents of commelinid and non-commelinid magnoliophyta biomass. A good linear correlation was found between both methods. Compared to the more accurate dietary fiber method, the detergent fiber method overestimates the content of cellulose, whereas the detergent fiber method, as compared to the dietary fiber method, overestimates and underestimates the hemicellulose content in commelinid and non-commelinid magnoliophyta biomass, respectively. Because of the good linear correlations, conversion factors were determined to predict the cellulose, hemicellulose, and xylan contents to be expected from the dietary fiber method, on the basis of analyses made by the faster, cheaper, and more commonly practiced detergent fiber method. Nevertheless, the dietary fiber method offers the advantage of providing the detailed composition of the hemicelluloses (xylan, arabinan, hemicellulosic glucan, galactan, and mannan), and that is of interest for biorefining purposes.

KEYWORDS: *cellulose, hemicelluloses, xylan, correlation, biofuels*

INTRODUCTION

The main chemical components of a plant biomass are generally cellulose (linear structural polysaccharide homogeneously composed of D-glucose units), hemicelluloses (ramified structural polysaccharides heterogeneously composed of D-xylose, L-arabinose, D-mannose, D-galactose, and D-glucose units) and lignin (phenyl propanoid polymer composed of syringyl, guaiacyl, and *p*-hydroxyphenyl units).[1,2] A plant biomass also contains other components such as pectins (ramified heterogeneous structural polysaccharides mainly composed of D-galacturonic acid units), starch (linear or ramified homogeneous nonstructural polysaccharide composed of D-glucose units), soluble sugars (D-glucose, D-fructose, sucrose, and fructans), proteins, and mineral compounds.[1,2]

The Van Soest sequential fiber solubilization method is widely used to assess the cellulose, hemicellulose, and lignin contents of plant feedstocks and to predict the nutritive value of these materials. This gravimetric method classifies the cell wall components of a plant biomass into three types of insoluble residues: neutral detergent fiber (NDF), acid detergent fiber (ADF), and acid detergent lignin (ADL) residues. The neutral detergent extraction is operated by refluxing a biomass sample in a boiling aqueous neutral detergent at pH 7 for 1 h.[3] The neutral detergent fiber residue represents the incompletely digestible portion of forages that is composed of cellulose, hemicelluloses, and lignin.[4] Acid detergent extraction is conducted by refluxing a biomass sample in a boiling aqueous detergent containing 0.5 mol/L sulfuric acid for 1 h.[5] Cellulose and lignin are the cell wall components recovered in the insoluble acid detergent fiber residue. The acid detergent extraction has been developed as a pretreatment prior to the measurement of lignin as acid detergent lignin. After the acid detergent procedure, the remaining structural carbohydrates of the acid detergent fiber residue are solubilized by 12.2 mol/L sulfuric acid at room temperature for 3 h.[5] The residual insoluble acid detergent lignin fraction represents an indigestible portion of forages.[4] The gravimetric difference between ADF and ADL insoluble residues is used to estimate the content of cellulose. The gravimetric difference between the NDF and ADF insoluble residues is used to estimate the content of hemicelluloses. The acid detergent lignin insoluble residue is used to estimate the content of lignin.[4,6] The detergent fiber method shows some deficiencies in accuracy. It overestimates the contents of cellulose and hemicelluloses and underestimates the content of lignin.[6−8] This can be explained by the fact that (1) the neutral detergent fiber residue contains some proteins,[6,7] (2) the acid detergent fiber residue contains some pectins when the analyzed biomass (such as a non-commelinid magnoliophyta biomass) has a high content of pectins,[4,6,9] (3) the acid detergent fiber residue contains some hemicelluloses,[10] and (4) the acid detergent lignin residue does not contain the acid soluble lignin.[6]

The dietary fiber method is based on the Uppsala method.[7,11] It is used to assess dietary fiber in animal and human food and in crop feedstocks that are of interest as a source of fibers, biofuels (such as bioethanol and biobutanol), and biobased chemicals.[11] The dietary fiber method is used to determine more accurately the contents of cellulose and hemicelluloses, compared to the accuracy of the detergent fiber method. This method quantitates the structural polysaccharides based on their monosaccharidic

components (D-glucose, D-xylose, L-arabinose, D-mannose, and D-galactose).[12−14] In the dietary fiber method, samples are first extracted one or several times by solvents (e.g., water, ethanol, neutral detergent, ether, and/or hexane) to remove all components that interfere with the subsequent sulfuric acid hydrolysis and chromatographic quantitation of the cellulosic and hemicellulosic monosaccharides. The total glucan, xylan, arabinan, galactan, and mannan contents are then determined by a two-stage sulfuric acid hydrolysis method (SAH). The first stage solubilizes the structural carbohydrates with 12.2 mol/L sulfuric acid at 30 °C for 1 h, and the second stage hydrolyzes these solubilized structural carbohydrates with 0.419 mol/L sulfuric acid at 121 °C for 1 or 2 h.[12−14] The released monosaccharides are separated and quantitated by liquid chromatography or gas chromatography. The content of hemicellulosic glucan is determined by the same dietary fiber method except that the cellulose solubilization step (incubation with 12.2 mol/L sulfuric acid at 30 °C for 1 h) is omitted. The content of cellulose (cellulosic glucan; i.e., D-glucose of cellulose in its polymeric form) is calculated as the difference between the total glucan and hemicellulosic glucan contents.[14] The monosaccharidic components (D-xylose, L-arabinose, D-glucose, D-mannose, and D-galactose) of hemicelluloses are expressed as their polymeric forms (xylan, arabinan, hemicellulosic glucan, mannan, and galactan, respectively).[14] In the dietary fiber method, the hemicellulose content is considered as the sum of the xylan, arabinan, hemicellulosic glucan, galactan, and mannan contents. To correct the results for any underestimation of the monosaccharide concentrations due to acidic degradation, a standard mixture of monosaccharides is treated with sulfuric acid in parallel with the samples.[12−14]

The relationship between the contents of cellulose and hemicelluloses determined by the detergent fiber and dietary fiber methods has been investigated on a data set that includes miscanthus (*Miscanthus sinensis* Anderss.), reed canarygrass (*Phalaris arundinacea* L.), smooth bromegrass (*Bromus inermis* L.), and alfalfa leaf and stem (*Medicago sativa* L.).[7] They showed that the detergent fiber method overestimates the content of cellulose and hemicelluloses, as compared to the dietary fiber method, except for alfalfa (a non-commelinid magnoliophyta biomass compared to other biomasses that are commelinids) where the detergent fiber method underestimates the content of hemicelluloses. The detergent fiber and dietary fiber methods have also been compared on alfalfa stems and on corn stover.[4,16] In spite of the bias mentioned above, there was a very good correlation between both methods. Cellulose results of one method can be consistently and confidently converted to the expected results of the other method because of this correlation. The reliability of this conversion has not been established for the other parameters, such as hemicellulose content.

The Van Soest detergent fiber method is faster, cheaper, and more commonly practiced than the dietary fiber method.[4,7,16] The advantage of the chromatographic dietary fiber method, as compared to the gravimetric detergent fiber method, is that the dietary fiber method also provides the monosaccharidic composition of the hemicelluloses (xylan, arabinan, hemicellulosic glucan, galactan, and mannan) and cellulose (cellulosic glucan).[14,15]

Predicting the cellulose, hemicellulose, and xylan contents directly from the results of the detergent fiber method would offer an interesting alternative to the time- and resource-consuming dietary fiber method. The purpose of this study is to check the feasibility and reliability of such a prediction on commelinid and non-commelinid magnoliophyta biomass. The correlation between the results of the dietary fiber and detergent fiber methods was therefore investigated for the contents of cellulose, hemicelluloses, the non-individualized sum of cellulose and hemicelluloses, and the hemicellulosic components (xylan, arabinan, hemicellulosic glucan, galactan, and mannan) of a wide diversity of plant biomasses. The sum of the cellulose and hemicellulose contents (cellulose+hemicelluloses) has also been taken into account in our assessment to compare more globally the dietary fiber and detergent fiber methods.

MATERIALS AND METHODS

Biomass Material. Miscanthus giganteus (*Miscanthus* × *giganteus* J. M. Greef and Deuter ex Hodk. and Renvoize), switchgrass (*Panicum virgatum* L.), fiber sorghum [*Sorghum bicolor* (L.) Moench], spelt straw [*Triticum aestivum* L. ssp. *spelta* (L.) Thell.], "cocksfoot-alfalfa" mixture (*Dactylis glomerata* L.-*M. sativa* L.), tall fescue (*Festuca arundinacea* Schreb.), immature rye (*Secale cereale* L.), fiber corn (*Zea mays* L.), hemp (*Cannabis sativa* L.), and Jerusalem artichoke leaves and stalks (*Helianthus tuberosus* L.) came from randomized block designed crop trials performed in 2007, 2008, 2009, and/or 2010 at Libramont, Belgium [498 m above sea level (asl), average annual temperature of 8.6 °C, average annual precipitation of 1260 mm, 49°55′N 05°24′E], and at Gembloux, Belgium (161 m asl, average annual temperature of 9.8 °C, average annual precipitation of 856 mm, 50°33′N 04°43′E). Depending on the crop, trials were performed with different nitrogen fertilization levels, different cultivars, and/or different harvest periods. For each biomass sample, a plot between 9 and 24 m^2 of the whole above ground biomass was harvested 10 cm from the ground and chopped.

Reed [*Phragmites australis* (Cav.) Trin. ex Steud], spelt grains [*T. aestivum* L. ssp. *spelta* (L.) Thell.], onion leaves and bulbs (*Allium cepa* L.), yucca leaves (*Yucca gloriosa* L.), tulip tree wood (*Liriodendron tulipifera* L.), Japanese knotweed [*Fallopia japonica* (Houtt.) Ronse Decr.], cabbage leaves (*Brassica oleracea* L.), rapeseed straw (*Brassica napus* L.), pumpkin leaves and stalks (*Cucurbita maxima* Duchesne), bean leaves and stalks (*Phaseolus vulgaris* L.), alfalfa leaves and stalks (*M. sativa* L.), lupine leaves and stalks (*Lupinus albus* L.), oak wood (*Quercus* sp.), beech wood (*Fagus sylvatica* L.), willow wood (*Salix* sp.), aspen wood (*Populus* sp.), flax straw (*Linum usitatissimum* L.), nettle (*Urtica dioica* L.), bramble leaves and stalks (*Rubus fruticosus* L.), comfrey leaves and stalks (*Symphytum officinale* L.), Jerusalem artichoke tubers (*H. tuberosus* L.), sunflower leaves and stalks (*Helianthus annuus* L.), tagetes (*Tagetes patula* L.), green (unforced) and white (forced) leaves of chicory (*Cichorium intybus* L.), unforced and forced roots of chicory (*C. intybus* L.), and leaves, stalks, and roots of carrot (*Daucus carota* L.) were harvested manually in 2010 and/or 2011 at Gembloux, Belgium, 10 cm from the ground and chopped.

Immediately after the harvest, two representative subsamples of 750 g of the whole of each biomass were dried at 60 °C for 72 h in a forced air oven. After being dried, the two subsamples were first milled with a 4 mm screen BOA hammer mill (Waterleau, Herent, Belgium) followed by a second milling step with a 1 mm screen Cyclotec cyclone mill (FOSS Benelux N.V., Brussels, Belgium). The samples were stored in airtight bags at room temperature and protected from light in a dark box.

Chemical Analysis. All chemicals were of analytical grade or equivalent. Duplicate aliquots were measured for each component quantitation on each of the 439 biomass samples.

Structural Polysaccharides Analyzed by the Van Soest Method. The neutral detergent fiber residue (NDF, weight of the neutral detergent fiber residue) of the Van Soest method was determined as described previously,[3] except that a 16.67 μkat/g of DM sample of an analytical thermostable α-amylase (Megazyme, Wicklow, Ireland) was added before the Van Soest neutral detergent step for biomass containing starch. The acid detergent fiber (ADF, weight of the acid detergent fiber residue corrected for its content of mineral compounds) residue, and acid detergent lignin (ADL, weight of the acid detergent lignin residue corrected for its content of mineral compounds) of the Van Soest method were determined as described previously,[5] except

that, prior to the acid detergent extraction, an extraction with the Van Soest neutral detergent without adding sodium sulfite was conducted as described for the Van Soest neutral detergent extraction. Cellulose +hemicelluloses of the Van Soest method was calculated as NDF − ADL. The cellulose VS content was calculated as ADF − ADL, and the hemicellulose VS content was calculated as NDF − ADF.[3,5] The term "detergent fiber method" will be used to refer to data generated by the Van Soest fiber data (NDF, ADF, ADL, and their combinations).

Structural Polysaccharides Analyzed by the Sulfuric Acid Hydrolysis Method. The samples were fractionated by the Van Soest neutral detergent extractions, with extraction 1 being 0.1 mmol/L phosphate buffer at pH 7 for 15 min at 90 °C where a 16.67 μkat/g of DM sample of an analytical thermostable α-amylase (Megazyme) was added when the sample contained starch and extraction 2 being Van Soest neutral detergent at 100 °C for 1 h.[14] The xylan, arabinan, galactan, mannan, and total glucan contents of the insoluble residue left after these extractions were determined by a two-stage sulfuric acid hydrolysis method (SAH), with stage 1 being solubilization by 12.2 mol/L sulfuric acid at 30 °C for 1 h and stage 2 being hydrolysis by 0.419 mol/L sulfuric acid at 121 °C for 2 h.[14] The released monosaccharides were separated and quantitated by a liquid chromatography system with an analytical liquid chromatography column [300 mm × 7.8 mm (inside diameter), 7 μm, Carbo Sep CHO-682 Pb (Interchrom, Montluçon, France)] at 80 °C using deionized water at a rate of 0.4 mL/min as the mobile phase, with a charged aerosol detector, as described previously.[14] The hemicellulosic glucan content was determined by the same sulfuric acid hydrolysis method except that the cellulose solubilization step (incubation with 12.2 mol/L sulfuric acid at 30 °C for 1 h) was omitted. The cellulose SAH (cellulosic glucan, i.e., D-glucose of cellulose in its polymeric form) content is calculated as the difference between the total glucan and hemicellulosic glucan contents. The hemicellulose SAH content is calculated as the sum of the xylan, arabinan, galactan, mannan, and hemicellulosic glucan contents. The content of cellulose+hemicelluloses SAH is calculated as the sum of the cellulose and hemicellulose contents. The term "dietary fiber method" will be used to refer to data generated by the dietary fiber data (total glucan, xylan, arabinan, galactan, mannan, hemicellulosic glucan, and their combinations). The monosaccharidic components (D-xylose, L-arabinose, D-glucose, D-mannose, and D-galactose) of hemicelluloses are expressed under their polymeric form (xylan, arabinan, hemicellulosic glucan, mannan, and galactan).

Hemicellulosic Components of the Acid Detergent Fiber and Weende Residues. The acid detergent fiber residue was prepared as described previously,[5] except that, prior to the acid detergent extraction, an extraction with the Van Soest neutral detergent (without adding sodium sulfite) was performed as mentioned above. The Weende residue was extracted as described previously.[17] Briefly, biomass samples were refluxed, in chronological order, with 0.13 mol/L boiling sulfuric acid for 30 min and with 0.13 mol/L boiling potassium hydroxide for 30 min. The xylan, arabinan, mannan, galactan, and hemicellulosic glucan contents of the acid detergent fiber and the Weende residues were determined by the same sulfuric acid hydrolysis method as described above.

Statistical Analysis. The linear least-squares regression analyses of structural carbohydrate contents between the detergent fiber and dietary fiber methods and the other statistical assessments were performed using JMP 11 (SAS Institute, Tervuren, Belgium). The prediction performance made by a linear regression line is considered excellent ($R^2p \geq 0.95$, and $RPDp \geq 4.0$), successful ($R^2p \geq 0.90$, and $RPDp \geq 3.0$), moderately successful ($R^2p \geq 0.80$, and $RPDp \geq 2.3$), or moderately useful (for the purpose of semiquantitative screening) ($R^2p \geq 0.70$, and $RPDp \geq 1.8$).[18]

The mean comparison tests (with $\alpha = 0.05$) were based on the Student's t test. The data were paired for the comparison between the detergent fiber and dietary fiber methods. The differences (with $\alpha = 0.05$) between two coefficients of correlation of prediction (Rp) were assessed using a Fisher z-transform. The differences (with $\alpha = 0.05$) between two root-mean standard errors of prediction (RMSEp) were assessed using an F-test of variances. These statistical analyses were performed using JMP 11 (SAS Institute).

RESULTS AND DISCUSSION

Main Structural Carbohydrates. The summary statistics of the mean structural carbohydrate contents among the 333 commelinid and the 108 non-commelinid magnoliophyta

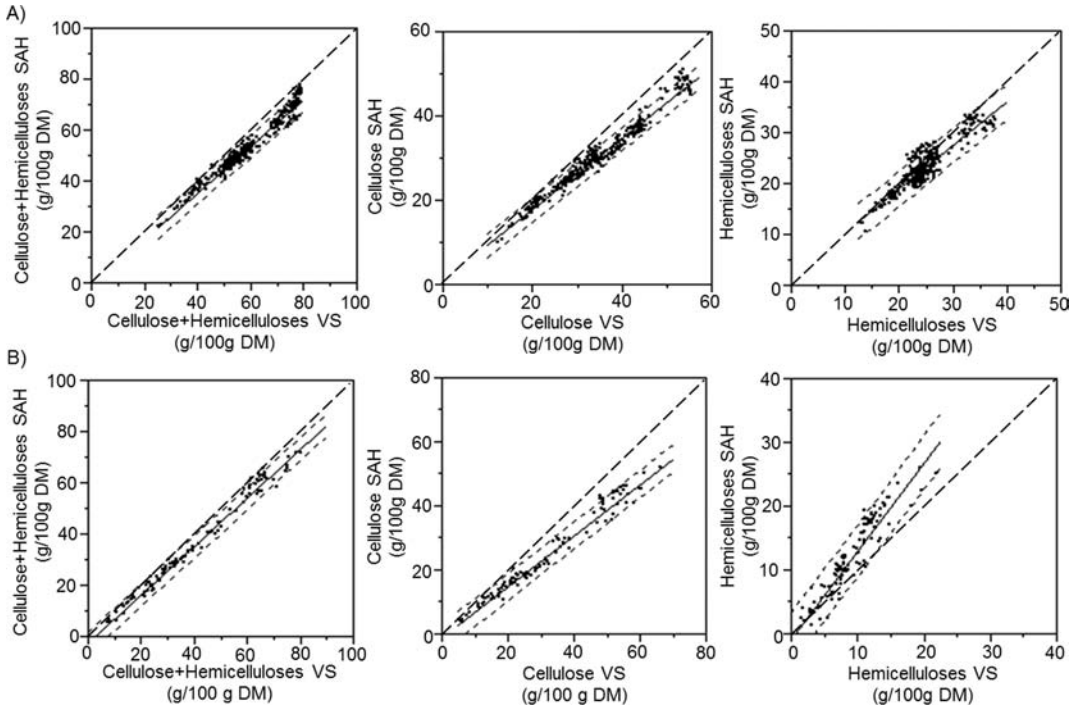

Figure 1. Relationship between the detergent fiber and dietary fiber methods for the contents of cellulose+hemicelluloses (left), cellulose (center), and hemicelluloses (right) in commelinid (n = 333) (A) and non-commelinid magnoliophyta (n = 108) (B) biomass. The black dashed line in each plot is the line of equality ($y = x$). The black plain line in each plot is the regression line. The black lines with smaller dashes in each plot are the 95% confidence lines of the regression.

[a]Uncertainties are expressed as ± the standard deviation. [b]The intercept of regression is not significantly different from zero ($p \geq 0.05$).

samples are listed in Table 1. These two types of biomass were separated because of the differences between their cell wall components. The statistical difference between these two types of biomass for each of the contents of the analyzed structural carbohydrate components is significant ($p < 0.001$, except cellulose VS that has a p value between 0.01 and 0.05) for each type of method. Commelinid magnoliophyta have higher cell wall contents of arabinoxylans, β-glucans, and lignin.[1,2] Non-commelinid magnoliophyta have higher cell wall contents of xyloglucans, mannans, and pectins.[1,2] The structural carbohydrates contained in these samples were determined by the detergent fiber and dietary fiber methods. Table 1 shows that cellulose and hemicelluloses are the main chemical components of the dry matter. The average content of cellulose+hemicelluloses represents more than the half of the dry matter of the analyzed commelinid biomass, while it is less than the half of the dry matter for the non-commelinid magnoliophyta biomass. The higher content of cellulose+hemicelluloses in commelinid magnoliophyta biomass can be explained by the higher content of hemicelluloses and lower content of pectins in their cell walls.[1,2]

Figure 1 illustrates the relationship among the contents of cellulose+hemicelluloses, cellulose, and hemicelluloses determined by the detergent fiber and dietary fiber methods. Table 2

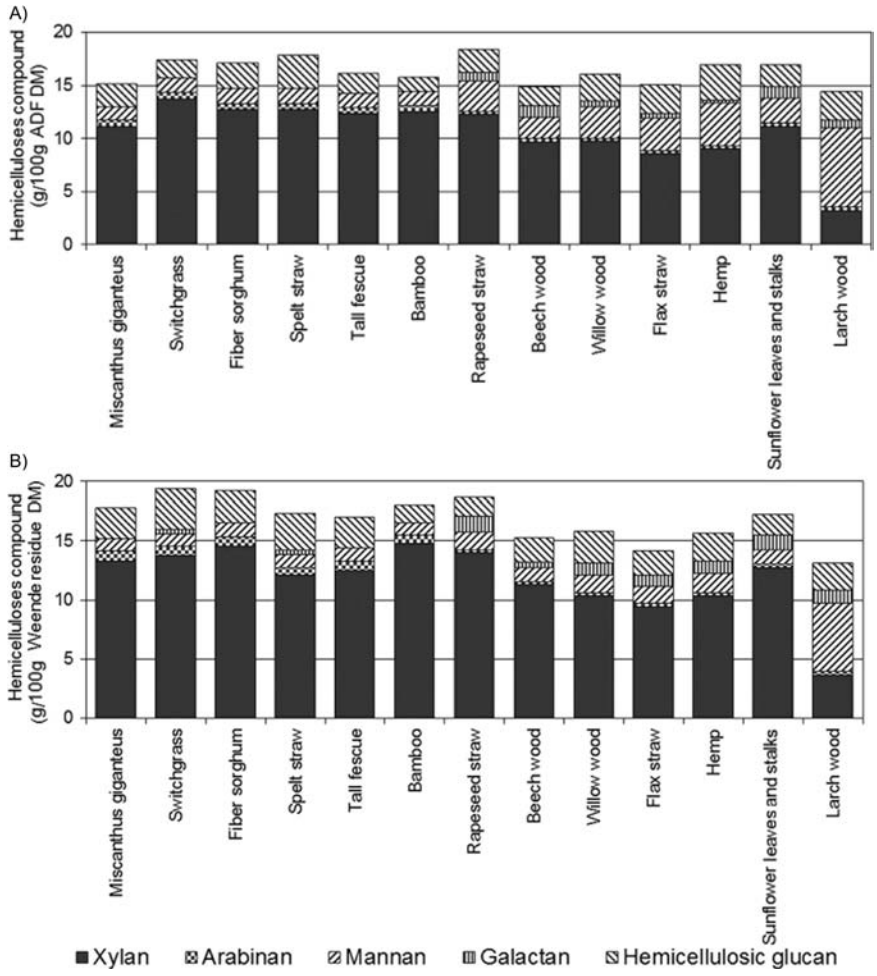

Figure 2. Hemicellulosic components detected in the acid detergent fiber residue (ADF) (A) and in the Weende residues (B).

presents the corresponding regression information. The contents of cellulose+hemicelluloses, cellulose, and hemicelluloses determined by the detergent fiber method are always higher than those determined by the dietary fiber method, except in the case of the content of hemicelluloses in non-commelinid magnoliophyta biomass (Tables 1 and 2 and Figure 1). The statistical difference between these two methods for the contents of cellulose+hemicelluloses, cellulose, and hemicelluloses is significant ($p < 0.001$) for each type of biomass. The overestimation of cellulose and hemicelluloses determined by the detergent fiber method can be explained by the fact that it is based on gravimetric differences between residues that are contaminated by undesired compounds, while the dietary fiber method measures specifically the monosaccharidic contents of cellulose and hemicelluloses.[6] The bias of the estimations of the contents of cellulose and hemicelluloses by the detergent fiber method depends mainly on the neutral detergent fiber residue, which also contains some proteins, and the acid detergent lignin residue, which does not contain the acid soluble lignin.[6] The acid soluble lignin fraction is higher in commelinid than in non-commelinid magnoliophyta biomass.[7] In commelinid magnoliophyta, lignin and hemicelluloses are bound through ferulate esters, which are indeed more sensitive to acid hydrolysis.[1,6] Non-commelinid magnoliophyta have cell walls with a content of pectins higher than that of cell walls of commelinids.[1] The presence of some pectins in their acid detergent fiber residue also explains an overestimation of cellulose and an underestimation of hemicelluloses by the detergent fiber method.[1,6,9] This information confirms that the relationship among the contents of cellulose+hemicelluloses, cellulose, and hemicelluloses determined by the detergent fiber and dietary fiber methods for commelinid and non-commelinid magnoliophyta biomass must be determined separately.

The slope of the regressions (Table 2) is an assessment of the bias between the detergent fiber and dietary fiber methods. The bias between these two methods affects, by order of increasing importance, the contents of cellulose+hemicelluloses, cellulose, and hemicelluloses. This could be explained by the fact that the acid detergent fiber residue of the detergent fiber method contains some residual hemicelluloses, as also suggested previously.[10] Indeed, an average of 16.3 g of hemicelluloses per 100 g was detected in the acid detergent fiber residue of the analyzed biomass (Figure 2A). An average of 16.8 g of hemicelluloses per 100 g was also detected in the Weende residue (Figure 2B). The Weende method aims to gravimetrically determine the cellulose content by means of an acid and alkaline extraction of all the other components, including hemicelluloses.

Hemicelluloses are made of four types of structural polysaccharides: arabinoxylan, xyloglucan (which also contains galactan), β-glucan, and mannan (which also contains galactan and hemicellulosic glucan).[19,20] In the acid detergent fiber and the Weende residues, the relative hemicellulosic components showed increased relative contents of hemicellulosic glucan and

mannan and decreased relative contents of xylan, arabinan, and galactan compared to the contents of the relative hemicellulosic components of native hemicelluloses of the analyzed samples, as described previously.[2] This suggests that interaction of cellulose is stronger with xyloglucan and mannan than with arabinoxylan. The high content of mannan in larch wood (Figure 2) is explained by its high content in the native hemicelluloses of the larch wood.[2] Larch wood is a part of pinophyta biomass, which is known to have a high content of mannan in their hemicelluloses.[1,2]

The higher relative bias for cellulose+hemicelluloses of commelinid biomass, as compared to non-commelinid magnoliophyta biomass, is mainly due to the acid soluble lignin fraction that is higher in commelinid biomass as explained above.[7] The higher relative bias for cellulose and hemicelluloses of non-commelinid magnoliophyta biomass, as compared to commelinid biomass, is mainly due to the presence of some pectins in the acid detergent fiber residue of non-commelinid magnoliophyta as explained above.[6,9]

Because of the large range of the contents of the various components and good prediction performances ($R^2p \geq 0.80$, and RPDp ≥ 2.3) (Table 2), the regression lines seem to be reliable enough to use the relatively simple detergent fiber method to predict quantitatively the values to be expected by the more expensive and time-consuming dietary fiber method.[4,7,16] This is especially the case for the prediction made by cellulose +hemicelluloses VS and cellulose VS.

The suitability of using directly the neutral detergent fiber content to predict the contents of cellulose+hemicelluloses SAH, cellulose SAH, and hemicelluloses SAH to be expected from the dietary fiber method was also tested (Table 2). The neutral detergent fiber residue-based predictions are generally less reliable for the commelinid magnoliophyta biomass, especially for the prediction of hemicelluloses SAH, which is not reliable. This last regression line for commelinid magnoliophyta biomass has prediction performances that are too low ($R^2p < 0.80$, and/or RPDp < 2.3) (Table 2). The generally lower prediction performances made by the neutral detergent fiber residue can be explained by the fact that it also contains cellulose and lignin. This lower prediction performance is only significant ($p < 0.05$) in terms of the coefficient of correlation of prediction (Rp) and the root-mean standard error of prediction (RMSEp) for the

Table 5. Best Linear Regression Lines and Their Prediction Performances for the Monosaccharidic Content of Hemicelluloses in Commelinid (n = 333) and Non-Commelinid Magnoliophyta (n = 108) Biomass between the Detergent Fiber and Dietary Fiber Methods[a]

independent variable	dependent variable	slope	intercept	R^2p	RMSEp	RPDp
Commelinid Magnoliophyta Biomass						
NDF	xylan	0.245 ± 0.005	1.21 ± 0.37	0.86	1.45	2.8
Non-Commelinid Magnoliophyta Biomass						
hemicelluloses VS	xylan	1.043 ± 0.038	−2.35 ± 0.38	0.88	1.48	3.0
NDF	xylan	0.185 ± 0.006	−1.57 ± 0.33	0.89	1.39	3.2

[a]Uncertainties are expressed as ± the standard deviation.

prediction of cellulose SAH of both types of biomass. In the case of the non-commelinid magnoliophyta biomass, the prediction performance of hemicelluloses SAH is more reliable on the basis of the neutral detergent fiber residue, as compared to that based on the hemicelluloses VS. This can be explained by the overestimation of hemicelluloses VS due to the presence of some pectins in the neutral detergent fiber residue.[6,9] This higher prediction performance is significant ($p < 0.05$) in terms of the coefficient of Rp and RMSEp.

The acid detergent fiber residue content can also be used to predict the cellulose SAH of the dietary fiber method because of the excellent prediction performances ($R^2p \geq 0.95$, and RPDp ≥ 4) (Table 2). This prediction is generally slightly less reliable than the cellulose VS-based prediction probably because of the presence of lignin in the acid detergent fiber residue. This difference of prediction is significant ($p < 0.05$) in terms of the coefficient of Rp for the non-commelinid magnoliophyta biomass and is not significant ($p \geq 0.05$) in terms of Rp for commelinid magnoliophyta biomass or in terms of RMSEp for both types of biomass. The acid detergent fiber residue always provides a slightly better prediction of the cellulose SAH compared to the same prediction given by the neutral detergent fiber residue, probably because of the higher cellulose content in the acid detergent fiber residue than in the neutral detergent fiber residue. This difference in prediction is significant ($p < 0.05$) in terms of the coefficient of Rp for the commelinid magnoliophyta biomass and not significant ($p \geq 0.05$) in terms of Rp for the non-commelinid magnoliophyta biomass or in terms of RMSEp for both types of biomass.

The relationship between the detergent fiber and dietary fiber methods is driven by the neutral detergent solubilized fraction (components such as nonstructural carbohydrates, pectins, proteins, organic acids, alcohols, pigments, lipids, and mineral compounds) for the contents of cellulose+hemicelluloses, cellulose, hemicelluloses, and xylan. Indeed, the neutral detergent fiber residue showed quite constant contents of these components for both commelinid and non-commelinid magnoliophyta biomass (Tables 3 and 4). When these contents are expressed without taking into account the solubilized fraction by the neutral detergent (i.e., as relative contents of the neutral detergent fiber residue, which is also called "extractives-free basis"), as compared to these contents expressed on the total dry matter, the relative standard deviation (RSD) and the range (maximum to minimum) of these contents decreased significantly (Tables 3 and 4). In addition, as compared to these contents expressed on the total dry matter, the neutral detergent fiber residue-based predictions of these contents expressed as relative contents of the neutral detergent fiber residue are no longer reliable for commelinid or non-commelinid magnoliophyta biomass (data not shown).

The relationship between the detergent fiber and dietary fiber methods is driven by the acid detergent solubilized fraction (components such as hemicelluloses, nonstructural carbohydrates, pectins, proteins, organic acids, alcohols, pigments, lipids, and mineral compounds) for the cellulose content. When it is expressed without taking into account the solubilized fraction by the acid detergent (i.e., as the relative content of the acid detergent fiber residue) (Tables 3 and 4), as compared to the cellulose content expressed on the total dry matter, the same observations are made as mentioned above for the neutral detergent fiber residue.

Monosaccharidic Components of Hemicelluloses. The mean composition of the hemicelluloses and the corresponding summary statistics are listed in Table 1 for the data set of the 333 commelinid and 108 non-commelinid magnoliophyta samples. The composition of the hemicelluloses can be determined by only the dietary fiber method. Xylan is the major hemicellulosic component of the analyzed samples, with contents more than 2 times higher in commelinid than in non-commelinid magnoliophyta biomass. The content of hemicelluloses is indeed known to be higher in commelinid cell walls, where hemicelluloses substitute for the pectins that are more present in non-commelinid magnoliophyta cell walls.[1,21−23] In addition, commelinid cell walls are known to have hemicelluloses with higher contents of arabinoxylan and β-glucan, whereas non-commelinid magnoliophyta cell walls have higher contents of xyloglucan and mannan.[1]

The average content of hemicellulosic components in commelinid biomass is, by order of decreasing importance, xylan, arabinan, hemicellulosic glucan, galactan, and mannan, while it is xylan, hemicellulosic glucan, galactan, mannan, and arabinan for non-commelinid magnoliophyta biomass (Table 1). This is consistent with the known hemicellulose compositions of these two types of biomass as mentioned above.[1,21−23]

Table 5 indicates that xylan is the only individual hemicellulosic component that is sufficiently correlated with the hemicelluloses VS and neutral detergent fiber residue to perform quantitative predictions ($R^2p \geq 0.80$, and RPDp ≥ 2.3), except for the hemicelluloses VS of commelinid magnoliophyta biomass. Further investigation showed that no useful linear regression lines with quantitative prediction performances ($R^2p < 0.80$, and/or RPDp < 2.3) can be detected between hemicelluloses VS or neutral detergent fiber residue and other individual SAH hemicellulosic components (data not shown). The fact that only xylan is highly correlated can be explained by its dominating contribution in the hemicellulosic component (73 mass percent in commelinids and 61 mass percent in non-commelinids magnoliophyta biomass) (Table 1) and its large range compared to those of the other hemicellulosic components.

Relevance of the Detergent Fiber and Dietary Fiber Methods in the Biomass Valorization Sector. Because of the reliable conversion factors determined in this study, the relatively simple detergent fiber method was used to predict the values to be expected by the more time- and resource-consuming dietary fiber method.[4,7,16] Nevertheless, the advantage of the chromatographic dietary fiber method is that it also provides the composition of the hemicelluloses (xylan, arabinan, hemicellulosic glucan, galactan, and mannan).[14,15] The detergent fiber method can then be very useful in the sector of biofuels (such as bioethanol and biobutanol) and biobased chemical production to rank plant feedstock samples with a good accuracy according to their contents of cellulose+hemicelluloses, cellulose, hemicelluloses, and xylan, while the dietary fiber method may be required for an optimal valorization of hemicellulosic components.

Supporting Information

ABSTRACT: The aim of this work was to develop and analytically validate a quantitative RT-PCR method, using novel primer sets designed on Pru du 1, Pru du 3, Pru du 4, and Pru du 6 allergen-coding sequences, and contrast the sensitivity and specificity of these probes. The temperature and/or pressure processing influence on the ability to detect these almond allergen targets was also analyzed. All primers allowed a specific and accurate amplification of these sequences. The specificity was assessed by amplifying DNA from almond, different *Prunus* species and other common plant food ingredients. The detection limit was 1 ppm in unprocessed almond kernels. The method's robustness and sensitivity were confirmed using spiked samples. Thermal treatment under pressure (autoclave) reduced yield and amplificability of almond DNA; however, high-hydrostatic pressure treatments did not produced such effects. Compared with ELISA assay outcomes, this RT-PCR showed higher sensitivity to detect almond traces in commercial foodstuffs.

INTRODUCTION

In developed contries, food allergy is considered an important health problem. Its prevalence is about 3% in adults and 6 to 8% of the pediatric population.[1] Its clinical manifestations can be gastrointestinal, cutaneous, systemic, or respiratory symptoms, and even life-threatening anaphylaxis can be induced with some foods.[2,3] Tree nuts are one of the eight groups of potentially allergenic foods known to be responsible for almost 90% of human allergies caused by food ingestion. Almond (*Prunus dulcis* Miller) is currently the main tree nut crop in world production regarding plantings and value of its raw and processed kernels. Almond nut consumption could produce numerous immune reactions, including life-threatening anaphylaxis.[4,5] So far, eight allergenic proteins have been described in almond: Pru du 1 (PR-10 protein), Pru du 2 (thaumatin-like protein), Pru du 2S albumin, Pru du 3 (lipid transfer protein), Pru du 4 (profilin), Pru du 5 (60S ribosomal protein), Pru du 6 (11S-legumin), and Pru du γ-conglutin (7S vicilin).[6] Of these eight allergens, Pru du 3, Pru du 4, Pru du 5, and Pru du 6 are recognized as such and included in the WHO–IUIS allergen list.

Foods are subjected to several processing methods in order to improve their quality and safety. Thermal processing can degrade food constituents, modify them, or facilitate interactions with other food matrix components; therefore, this processing can modify allergenic properties of food proteins.[7] Thermal sterilization is still the most widely used method of food preservation.[8] Its basic function is to inactivate food spoilage by microorganisms in sealed containers of food using heat treatments at temperatures above the boiling point of water in pressurized steam retorts (autoclaves).[9] However, emerging technologies, such as high hydrostatic pressure (HHP), act by inactivation of microorganisms without the need for substantial heating.[10] HHP-treated foodstuffs are normally exposed for periods of a few seconds up to several minutes to hydrostatic pressures above 150 MPa.[11] These treatments have the potential to modify food proteins, which could alter food allergenicity, i.e., increasing or decreasing IgE reactivity.[12,13] From current information is not possible to identify which variables could be employed in the analysis of the effect of processing on protein allergenicity.[1,14,15] To date, the effects of HHP on food allergenicity have been studied in beef,[16,17] apple,[14,18] celery,[14] peanut,[18] and nuts such as almond.[19] HHP did not affect most food allergens, and even an increase of soybean antigenicity has been reported.[20] However, there is scarce information on the effects of such food processing techniques on almond allergenicity.

The European regulation (EU) 1169/2011/EC[21] requires labeling of food products regarding the contents of almond and other allergenic components. Similar requirements are in use in the USA[22] and in other countries. Several methodologies can be applied to detect potential allergens in foods.[3] According to these authors the limit of detection (LOD) for food allergens

should be less than 100 mg/kg. Data from a Spanish retrospective study indicated that 119 out of 530 food allergic reactions in adults were due to the exposure to "hidden" allergens which were not described in the label.[23] Since food contamination with hidden allergens might happen at any processing stage, some analytical approaches are necessary in order to ensure food safety for allergic consumers.

Enzyme-linked immunosorbent assay (ELISA) is the most common protein detection method used to detect the presence of food allergens in complex matrices. Currently, several almond specific ELISA assays are on the market.[6] However, as the food proteins could be affected by high temperature or high pressure and, hence, the integrity of the allergenic proteins too, consequently, the reliability of techniques based on protein for processed foods could be disminished.[7,18] A DNA-based method could be an advantegeous alternative for allergen detection, in which specific DNA sequences amplified by the polymerase chain reaction (PCR) are the target molecules. In spite of these techniques representing an indirect approach to detection of the allergenic components, DNA-based methods have higher stability vs seasonal and geographical variations than proteins and DNA is less affected and more efficiently extracted at severe conditions from food matrices.[3] Quantitative real-time PCR using fluorescence probes has been the most widely applied PCR strategy to detect food allergens. The target sequences of DNA could be a species-specific region of the allergenic food genome or gene coding for an allergenic protein.[24] Real-time PCR has been used to detect almond in food samples using different target sequences and dying methods.[25−31]

It is important to study the effects that food processing might exert on the detection of almond-allergen specific markers because consumers are commonly exposed to processed ingredients in complex food matrices.[32] The effects of high-temperature and/or high-pressure processing on the detectability of DNA targets in complex food matrices have been analyzed in peanut[24] and hazelnut.[33,34]

The aim of the present study was to set up and to analytically validate a quantitative SYBR Green real-time PCR method using specific primer sets designed de novo on Pru du 1, Pru du 3, Pru du 4 and Pru du 6 allergen-coding sequences in order to improve the sensitivity of RT-PCR techniques for detection of traces of almonds in commercial foods. In addition, how the detectability of almond DNA targets in complex food products is affected by high-temperature and/or high-pressure treatments was also analyzed.

MATERIALS AND METHODS

Samples. Almond cultivars (*Prunus dulcis* Miller) used in this work were provided by the almond collection of Institut de Recerca i Tecnología Agroalimentàries (IRTA-Mas de Bover, Tarragona, Spain). The four cultivars used were "Nonpareil", "Marcona", "Francolí", and "Vairo". "Nonpareil" and "Marcona" are both traditional cultivars of Californian and Spanish origins, respectively. "Nonpareil" is the main cultivar worldwide and used as reference. "Marcona" is a highly reputed cultivar used mainly in the Spanish almond industry.[35] "Francolí" and "Vairo" are both new releases from the IRTA's almond breeding program.[36−38] DNA from other *Prunus* species (peach *P. persica,* cherry *P. avium,* sand-cherry *P. besseyi,* bird-cherry *P. padus,* flowering almond *P. triloba*), other Rosaceae species as *Malus floribunda* and other common food plant species used as food ingredients (hazelnut, walnut, peanut, rice, wheat, barley, and rye) were employed in specificity analysis. To prepare the standards or spiked samples, binary mixtures containing 1; 10; 100; 1,000; 10,000; 100,000; and 500,000 mg/kg (0.0001% to 50% w/w) of defatted raw almond flour "Marcona" in defatted peanut flour matrices were prepared to a final weight of 200 g. The analytical validation of the method was carried out with several commercial foods (biscuits, chocolates, etc.) obtained in local food markets. All samples were grounded and homogenized using a kitchen robot (Thermomix 31-1, Vorwerk Elektrowerke, GmbH & Co. KG, Wüppertal, Germany).

Heat and High Hydrostatic Pressure (HHP) Treatments. Almond nuts were immersed in distilled water (1:5 w/v) and autoclaved using a Compact 40 Benchtop autoclave (Priorclave, London, U.K.) at 121 °C (120 kPa) and at 138 °C (260 kPa) for 15 and 30 min. Raw and autoclaved almond nuts were ground and defatted with *n*-hexane (34 mL/g of flour) for 4 h and air-dried after filtration of the *n*-hexane. High-pressure experiment conditions were carried out according to Omi et al.[39] and Kato et al.[40] Almond defatted flours were dissolved in distilled water (1:4 w/v) 20 h before HHP treatment, and the suspensions were subjected to HHP, using pressures of 300, 400, 500, and 600 MPa for 15 min in multivessel high-pressure equipment (HHP, ACB, France) at 15 °C.

Genomic DNA Isolation. DNA was extracted using the CTAB/phenol/chloroform-based method as previously described by Iniesto et al.[33] DNA was cleaned using a silica membrane in a spin column from Power Plant DNA isolation kit (MoBio, CA USA) and finally eluted in 50 μL of H_2O Milli-Q.

The CTAB-based extraction was selected to obtain DNA from raw and processed almond (200 mg), as well as from spiked samples and complex food matrices (400 mg). DNA quantity and quality was determined with NanoDrop ND-1000 spectrophotometer (Thermo-Fisher, Waltham, MA, USA) by measuring the absorbance at 230, 260, and 280 nm. DNA quality was also evaluated on 0.8% agarose gels.

Conventional PCR, Cloning, Sequencing, and RT-PCR Primer Design. Sets of primers were designed with Oligo Primer Analysis Software on the target coding sequences of the six Pru du genes (data not shown). The four most sensitive and specific to evaluate the almond content were used: Pru du 1 (GenBank accession no. EU424247.1, Pru du 1f AGTGTATTGTGATTGGCTCCC; Pru du 1r AGTCTTTGGCTTGCATTTGG), Pru du 3 (GenBank accession no. FJ652103, Pru du 3f GGCGGTGATGTGCTGC; Pru du 3r TGTAAGGGATGCCATTGACGG), Pru du 4 (GenBank accession no. AY081850.1 Pru du 4f AGTACGTCGATGACCACTTGA; Pru du 4r CTTAACAGTAATGCCACCAGA), and Pru du 6 (GenBank accession no. GU059261.1 Pru du 6 f GACAACCACATTCAGTCC; Pru du 6r CTTGTTGTTGCGGGTTA). These primers were used in conventional PCRs.

The PCR reactions were carried out using DNA from the cultivars Marcona, Vairo, and Francolí of almond, and the resulting amplicons were cloned in TOPO TA Cloning Kit (Invitrogen, Inc., U.K.), according to the manufacturer's instructions. Plasmid DNA was extracted using High Pure Plasmid Isolation Kit (Roche, Germany) and sequenced in an ABI PRISM 3700 sequencer (Applied Biosystems, Foster City, CA, USA) from "Unidad de Genómica, Parque Científico de Madrid". DNA sequences were edited using Chromas Pro 1.22 software (Technelysium Pty, Ltd., Australia). These sequences were compared with those present in the GenBank (NCBI) nonredundant nucleotide (nr/nt) databases through BLAST. Alignments between sequences of the same amplicon obtained from the three cultivars were performed using the ClustalW algorithm.[41]

Specific almond primer for real-time PCR was designed from the conserved sequences of Pru du 1, 3, 4, and 6 by Primer Express 2.0 (Applied Biosystems, Foster City, CA, USA) (data in Table 1 of Supporting Information). Primers met the following requirements: length between 20 and 24 bases and to produce an amplicon between 75 and 150 bp. A conventional PCR was performed using these pairs of primers in order to amplify the genomic DNA sequences of Pru du genes. The PCR products were electrophoresed on 2% agarose gels. The specificity of all primers was assessed by testing the amplification of non-almond DNA extracts from a wide variety of plant samples.

The conventional PCR reactions were carried out in 20 μL, containing 10 ng of DNA, 0.25 μM of each primer and 1× Taq PCR Master Mix (Qiagen, Germany). SensoQuest LabCycler (Progen

Scientific Ltd., Germany) was used and the following PCR program: an initial denaturation step at 95 °C, 4 min, followed by 35 cycles of denaturation at 94 °C for 45 s; annealing at 62−64 °C for 1 min; elongation at 72 °C for 1 min; last step at 72 °C for 6 min.

Real-Time PCR Conditions. Real-time PCR reactions were carried out in a volume of 20 μL, using 7900HT Fast Real-Time PCR System (Applied Biosystems, Foster City, CA, USA). Each reaction consisted of 10 μL of SYBR Premix Ex Taq (Takara, Japan), 2 μmol of primer, and a variable amount of template DNA. All samples were analyzed in duplicate. On each plate, at least two non template controls (NTC) were used to check the PCR performance. The following PCR program was used: initial denaturation at 95 °C for 10 min followed by 40 cycles of denaturation at 95 °C for 15 s and primer annealing and elongation at 60−65 °C for 1 min. Dissociation studies were performed on PCR products at a constant temperature increase (60−95 °C), recording fluorescence each 10 s.

Standard curves for real-time PCR were generated using the cycle threshold (Ct) value obtained from 10-fold serial dilutions of almond genomic DNA. The efficiency of each reaction was calculated from the slope of the standard curve (Ct vs log DNA concentration) as indicated in the Applied Biosystems manual. Standard curves for real-time PCR were generated using the cycle threshold (Ct) value obtained from 10-fold serial dilutions of almond genomic DNA. The efficiency of each reaction was calculated from the slope of the standard curve (Ct vs log DNA concentration) as indicated in the Applied Biosystems manual.

ELISA Assay. Almond protein detection by imunochemistry was performed using a commercial almond ELISA kit (RidaScreen Fast, R-Biopharm, Germany) according to the manufacturer's instructions. The kit includes microtiter strips coated with specific policlonal antibody against water-soluble almond proteins.

RESULTS AND DISCUSSION

Gene Target Selection, Primer Design, and Sequence Analyses. To specifically detect genes coding for different almond allergens (Pru du 1, Pru du 3, Pru du 4, and Pru du 6), sequences from these genes deposited in the GenBank database of NCBI were chosen to design the primers. These primers were checked for their specificity utilizing BLAST and employed for the amplifications of partial allergen-coding sequences of three almond cultivars. This procedure makes it possible to assess the intraspecific polymorphism which could produce false negatives.[42] All the amplicons showed the expected size, and their sequences were homologous to those employed for designing the specific primers (data in Table 1 of the Supporting Information). The sequences obtained for each primer pair from three cultivars (Marcona, Vairo, and Francolí) were aligned, showing a high similarity degree among them (Pru du 1 = 99.95%; Pru du 3 = 100%; Pru du 4 = 99.98%; Pru du 6 = 99%). The aligments were used to design the specific real-time PCR primers from each one of the target sequences.

The coding sequences of Pru du 1 (PR-10 protein), Pru du 3 (LTP), and Pru du 4 (profilin) proteins were chosen as target sequences since, until now, there has not been a specific RT-PCR method to detect them. So far, different RT-PCR protocols to detect almond have been developed by other authors,[6,28] and Pru du 6 (11S) and a nsLTP related to Pru du 3 genes have been previously used as targets.[27,28]

Optimization of Real-Time PCR Assays with SYBR Green. The first step to develop a reliable real-time PCR protocol is to optimize the DNA extraction regarding yield and quality values. Such parameters are important for the optimal detection of the target sequences besides other real-time PCR requirements such as efficiency, Ct, and R^2 values. As some nut components could inhibit polymerase reaction (polyphenols and fat),[43] they have to be eliminated from the DNA sample. To test DNA quality the 260/230 and 260/280 ratios were employed since these components absorb at 230 nm and the proteins at 280 nm.

By combining the CTAB−phenol−chloroform extraction with sample cleaning employing a silica membrane from Power Plant DNA Isolation Kit, the yield, concentration and quality of the extracted DNA were notably improved.[33] This procedure was employed for all the DNA extractions producing a high yield of good quality DNA from raw and processed almond foods and giving 260/280 = 2.11 ± 0.04 and 260/230 = 1.98 ± 0.06 ratios for raw samples.

Instead of a multiplex strategy, single RT-PCR reactions for each sequence were performed.[27] This procedure allows the analysis of the effect of each sequence on the most relevant parameters of RT-PCR (specificity, amplification efficiency, and sensitivity) and to compare them. The SYBR Green I methodology has been chosen because, giving equal sensitivity and performance as the TaqMan one, its cost is lower.[44]

Specificity. Through DNA amplification from almond by PCR, a 100−103 bp amplicon for each primer pair tested was obtained (Table 1 of the Supporting Information). To assess their specificity, DNA from different species of *Prunus* and other common food plant species used as food ingredients (hazelnut, walnut, peanut, rice, wheat, barley, and rye) were used as templates in conventional PCR, and the results of the amplification were electrophoresed on agarose. Primers for Pru du 1 and Pru du 4 genes were 100% specific for almond, while primers for Pru du 3 and Pru du 6 also amplify from peach DNA a product of the target size. As an example, Figure 1a shows the amplification of Pru du 6 and Figure 1b corresponds to Pru du 1.

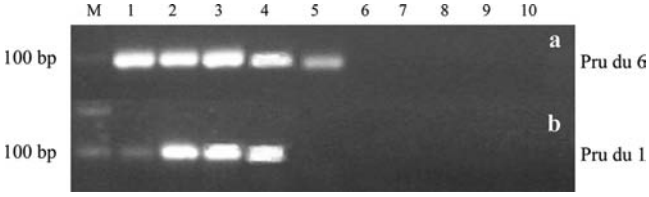

Figure 1. Real-time PCR primers specificity. Amplicons obtained with Pru du 6 (a) and Pru du 1 (b) primer pairs in different *Prunus*-related species. Lanes 1−4: *Prunus dulcis* cv Marcona, Vairo, Francoli, and Nonpareil. Lane 5: *P. persica*. Lane 6: *P. avium*. Lane 7: *P. besseyi*. Lane 8: *P. padus*. Lane 9: *P. triloba*. Lane 10: *Malus floribunda*. Electrophoresis in 2% (w/v) agarose gel. M: 100 pb ladder (Fermentas).

By the evaluation of the dissociation curves the primer specificity was confirmed (Figure 2). When DNA from almond cultivars was used as template, a single amplicon was observed and no amplification was detected from other plant samples. Similar results have been previously reported.[25,27,45]

Amplification Efficiency and R^2 Coefficient. To estimate the reaction amplification efficiency in a RT-PCR procedure, the slope of the standard curve is used. According to the supplier's instructions, a 100% efficient PCR reaction corresponds to a standard curve slope of −3.32. The R^2 describes the correlation between the Ct value and the logarithm of the amount of DNA in the standard curve. In order to produce the standard curves, three different DNA extractions of raw almond were carried out, the DNA was 10 times serially diluted, and 5 μL of each dilution was used in the reaction tube. The values obtained for all standard curves were optimal in agreement to ENGL

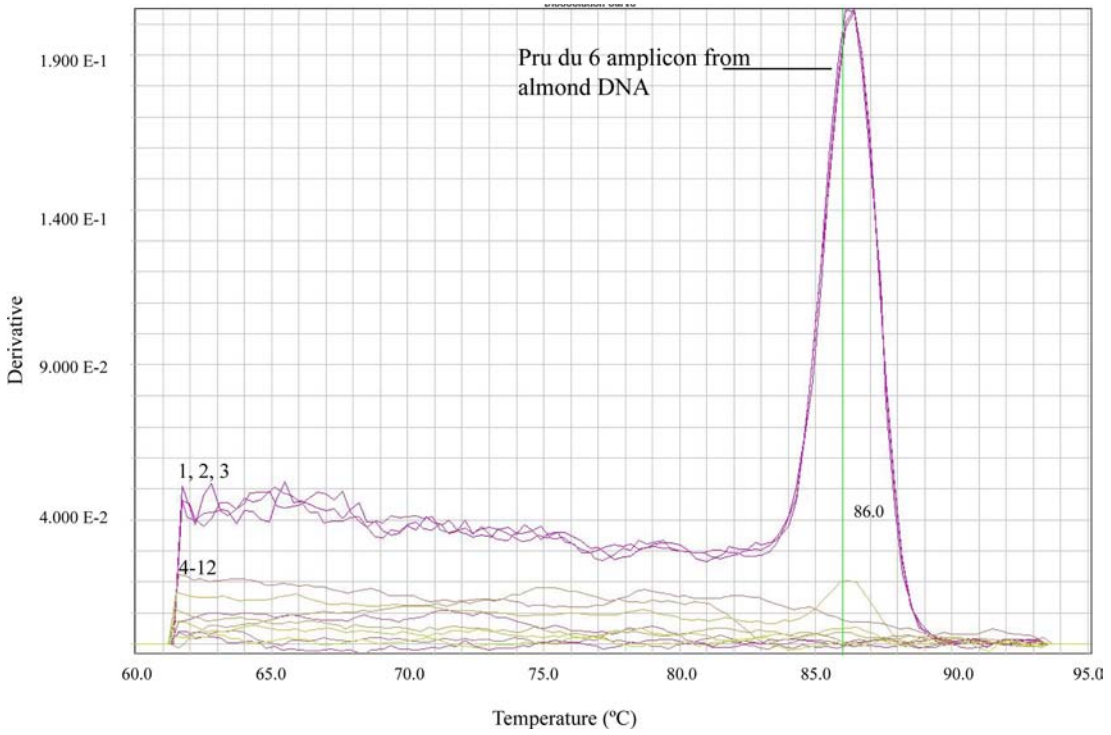

Figure 2. Melting curve obtained by real time-PCR. Amplification with SYBR Green dye target Pru du 6 gene of almond and applied to other food samples. 1, 2 and 3: almond cultivars. 4−12: other plants.

acceptance criteria (slope between −3.1 and −3.6 and correlation coefficient higher than 0.98).[46] The efficiency values were 102% for Pru du 1, 99.75% for Pru du 3, 99.75% for Pru du 4, and 97.5% for Pru du 6 (Figure 1 of the Supporting Information).

By overlapping the 3 standard curves obtained from separate samples in independent assays, the interassay reproducibility was studied. The Ct values were similar for all the varieties used, and the mean slope varied between −3.22 for Pru du 1 and −3.49 for Pru du 6; therefore, according to these results it can be concluded that this RT-PCR method is highly reproducible.

Sensitivity. At least three independent DNA extractions of almond have been used to assess the sensitivity of this RT-PCR protocol. Similarly to the efficiency experiments, the DNA was 10 times serially diluted, and 5 μL of each dilution was used in the reaction tube. The limit of detection (LOD) was 2.5 pg for Pru du 3 and 25 pg for Pru du 1, Pru du 4, and Pru du 6. This method allowed detection of a 1:10,000 dilution with the Pru du 3 primer pair. So far, the most sensitive RT-PCR method to detect almond had been described with the Pru du 5 probe, detecting up to 10 pg of almond DNA.[6,25]

In order to check the sensitivity of this procedure with food products, we carried out PCRs using defatted peanut flour mixed with known amounts of defatted almond flour (from 0.0001% to 1% w/w). The DNA of all spiking levels was extracted and analyzed by RT-PCR in duplicate. The LOD determined was 0.0001% w/w (1 mg/kg) of almond in peanut, that correspond to 1 ppm for the four allergen sequences. The literature on the specific detection of almond using real-time PCR reported a relative LOD of 50 mg/kg of almond in walnut,[25] 10 mg/kg of almond spiked in cookies,[26] and 5 mg/kg of almond in food products.[28] Taking this into account, the present procedure showed a higher sensitivity than those previously reported, this fact being its main advantage in comparison with others.

The sensitivity of this method could be related to the use of SYBR Green methodology for detection. Although SYBR Green is a non sequence-specific binding system, it showed a sensitivity and efficiency as high as other systems used to trace almond allergens, such as TaqMan probes[28] or high-resolution melting analysis.[25] The SYBR Green I methodology has been chosen because, according to other authors, it gives equal sensitivity and performance as the TaqMan one, but with lower cost.[44]

Effect of High-Pressure and Autoclave Treatments. To investigate the action of high-pressure and thermal treatments on the detection ability of this RT-PCR procedure, a calibration curve for each primer pair (Pru du 1, Pru du 3, Pru du 4, and Pru du 6) was performed using DNA extracted from the spiked samples made by mixing defatted peanut and known amounts of defatted almond flour (from 1% to 50% w/w). A linear regression was obtained in all cases, by plotting the Ct values against the logarithm of the almond quantity (Figure 2 of the Supporting Information). To quantify the amount of almond DNA in unprocessed and processed samples, these curves were used. From each treatment three DNA extracts were obtained and analyzed in duplicate. The mean values were normalized to the almond content measured in the unprocessed samples. Data are shown in Figure 3.

The autoclave treatment applied reduced significantly the ability to detect almond DNA. Similar results have been reported for hazelnut[33] and peanut,[24] all of which showed that thermal processing causes an important decrease in the DNA detectability when PCR methods are used. The samples treated only with high pressure did not show this reduction; on the contrary, the amount of almond detected in these samples was higher than in those untreated. These results could be related

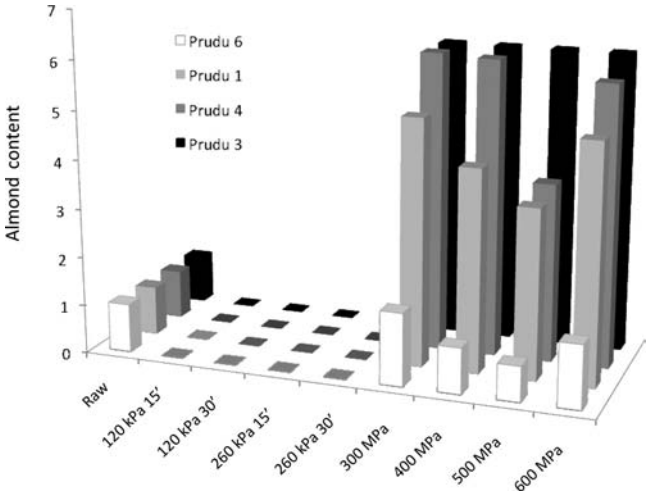

Figure 3. Estimation of almond content in different raw and treated samples. Raw; autoclaved 120 kPa, 15 min; autoclaved 120 kPa, 30 min; autoclaved 260 kPa, 15 min; autoclaved 260 kPa, 30 min; high-pressure 300 MPa; high-pressure 400 MPa; high-pressure 500 MPa; high-pressure 600 MPa.

to higher DNA extractability of HHP treated almond compared to the untreated samples. These findings are quite similar to the results obtained with protein in rice.[47] Therefore, while the autoclaving process strongly decreased the capability to detect almond DNA, high pressure at low temperature increased it. The effect of treatments on the detection of almond DNA may take place at two different levels: on the quality or on the amplificability of DNA.

In order to evaluate how processing can affect the amount and/or integrity of almond DNA, both were analyzed in the present work. DNA quantification of unprocessed and processed almond samples showed a progressive reduction in the extraction yield parallel to heat and time treatment increases (Table 1). The yield of DNA was disminished from

Table 1. DNA Extraction Yields Obtained from Raw and Processed Almond Samples[a]

almond samples	Yields ($nm \cdot mg^{-1}$)
raw	37.76 ± 6.64 a
autoclaved	
120 kPa, 15 min	23.66 ± 1.92
120 kPa, 30 min	3.23 ± 0.65
260 kPa, 15 min	1.53 ± 0.36
260 kPa, 30 min	0.56 ± 0.08
HHP	
300 MPa	52.19 ± 20.94 a,b
400 MPa	71.43 ± 14.53 b
500 MPa	59.53 ± 19.02 a,b
600 MPa	46.73 ± 15.81 a,b

[a]The mean values with the same letter are not significantly different when compared by Student's t test ($P < 0.05$).

37.76 ± 6.64 ng/mg in raw almond to 0.56 ± 0.08 ng/mg in autoclaved samples at 138 °C during 30 min. When DNA integrity was determined by agarose gel electrophoresis, the results were compatible with the DNA degradation in the heat processed samples (Figure 3 of the Supporting Information). High pressure (HHP) seems to increase the DNA extraction yield, but this treatment apparently breaks the DNA, since a smear at low molecular weight is observed when HHP treated samples are electrophoresed.

HHP treatment of foods can be used to create new products (new texture or taste) or to obtain analogue products with minimal effect on flavor, color, and nutritional value and without any thermal degradation. The effect of HHP on allergenicity is being currently investigated mainly through changes in protein structure.[48] Higher pressures can unfold the protein, and the usual pressure needed for the unfolding is about 500 MPa, but it can vary from protein to protein, ranging from 100 MPa to 1 GPa, or reaching even higher pressures in some cases.[48] The effects of HHP on food allergenicity have been studied in beef,[14,16−18] apple,[14,18] celery,[14] and nuts such as peanut.[18]

The DNA quality or integrity was also analyzed through amplificability studies in unprocessed and processed samples. For this objective the amount of DNA was standardized to 25 ng and the analysis was in duplicate. Unprocessed and high-pressure-treated almonds presented similar low Ct values, 24.96 ± 0.01 and 24.54 ± 0.03, respectively, but thermally treated almond (autoclaved) had higher Ct values, 33.74 ± 0.5 at 121 °C 30 min and 30.31 ± 0.08 at 138 °C 30 min. These data confirmed that degradation of DNA produced in the heat processed samples reduced the ability to amplify and detect almond by qRT-PCR. Although the high-pressure treatments at low temperature can break the DNA, they have no effect on their amplificability, because the expected size of the fragments is probably over the amplicon size (around 100 bp).

Scaravelli et al.[24] report a considerable peanut DNA extraction decrease as thermal treatment increases while DNA quality or integrity is not reduced. Our present data corroborated that the thermal treatment here applied decreased the DNA yield, aside from the almond DNA integrity or quality, is also affected, as previously described in hazelnut by Iniesto et al.[33] Such decrease was not detected in the almond samples treated only with high pressure at low temperature; on the contrary, the amount of almond detected in HHP treated samples was higher than in those untreated. This fact could be due to the smaller size of fragments, which makes their amplification easier. The effect of high-pressure treatments on the detection of allergenic tree nuts has been studied in hazelnut, where it did not affect the extraction yield, DNA quality, integrity, and amplicability.[33]

A similar conclusion has also been reported by other authors.[34] They concluded that food processing affects hazelnut detection using real-time PCR as well as ELISA. Moreover, they suggested that both methods lacked robustness in relation to food processing, without drawing any firm conclusion about the technique. This study hence illustrates that both food matrix and processing can lead to an erroneous quantification of the almond (DNA) content in food samples. This fact might pose a risk for the allergic consumer in cases where quantitative results are applied in risk assessment procedures.

Applicability on Commercial Foods. The applicability of this RT-PCR procedure for detecting almond allergens in food samples was evaluated by analyzing 10 commercial foodstuffs (chocolates, cookies, snacks, nougat, etc.). Two of these foods declared in the label the percentage of almond, six of them adverted that the product could have traces of tree nuts, and the other two did not declare any almond content. These commercial foodstuffs were also subjected to ELISA analysis, and the results are summarized in Table 2, in order to compare the outcomes of both techniques.

Table 2. Almond Detection in Commercial Food Products Analyzed through Real-Time PCR (Ct Value Average) and ELISA (+ = Detected; − = Nondetected)

commercial foods	almond declaration	Pru du 1	Pru du 3	Pru du 4	ELISA
cereal snack	contain	28.46 ± 0.33	26.69 ± 2.01	28.34 ± 0.20	+
chocolate with hazelnut	contain hazelnut	−	−	−	−
cereal snack I	might contain nuts	−	−	−	−
chocolate	might contain nuts	29.05 ± 0.33	−	−	−
chocolate with cereal	might contain nuts	25.62 ± 0.99	29.44 ± 2.12	28.08 ± 2.53	+
cookies with cereal and chocolate	might contain nuts	28.94 ± 0.62	−	−	+
cookies with fiber	not declared	−	−	−	−
nougat	might contain nuts	25.29 ± 0.19	26.72 ± 0.47	26.12 ± 0.12	+
chocolate snack with cookie	not declared	29.02 ± 0.79	−	−	−
Russian cake	contain	21.25 ± 0.21	22.36 ± 0.34	22.34 ± 0.48	+

The study was performed with the three primer pairs Pru du 1, Pru du 3, and Pru du 4, which were more sensitive to detect almond in the processed samples. The three primers detected the almond declared in the label, even at trace levels. This real-time PCR method based on three target sequences reduced the probability of false negatives or positives ensuring more reliable results.

The probe Pru du 1 was the most sensitive to detect almond traces in commercial food samples. There is correspondence between RT-PCR results and those obtained by ELISA for 8 of the 10 foods studied with Pru du 1, confirming the reliability of this method. In two samples (chocolate and chocolate snack with cookies), the signal obtained with the RidaScreen Fast ELISA assay was under its limit of detection (1.7 ppm), however, trace amounts of almond DNA were detected in these samples by the Pru du 1 primer. Röder et al.[28] described a similar relationship between the detectable signal and the amount of almond for both RT-PCR and ELISA.

According to Stephan and Vieths,[32] the detection of almond DNA by RT-PCR in a nondeclared sample whose results in the ELISA analysis were negative, such as chocolate snack with cookies, corroborates the higher sensitivity of such RT-PCR procedure. The method developed in this study seems to be more reliable than the ELISA assay tested.

In conclusion, a highly specific and sensitive RT-PCR procedure to detect almond DNA is described in this work. The primers designed de novo allow the amplification of DNA of the coding region of several almond allergens (Pru du 1, Pru du 3, Pru du 4, and Pru du 6). The present RT-PCR method seems to be the most sensitive of those previously reported for the detection of almond because of its very low LOD (1 ppm). In addition, when the outcome is compared with an ELISA assay, it offers a higher sensitivity to detect almond traces or even hidden almond allergens in food products where ELISA yields negative results. When processed samples or complex food products are analyzed, the effect of heat processing should be taken into account. In spite of the decrease in DNA quantitiy and quality elicited by the thermal treatment applied, the almond DNA detection has always been possible and accurate in the present study.

S *Supporting Information*

ABSTRACT: DNA methyltransferase 1 (DNMT1) catalyzes DNA methylation and is overexpressed in various human diseases, including cancer. A rational approach to preventing tumorigenesis involves the use of pharmacologic inhibitors of DNA methylation; these inhibitors should reactivate tumor suppressor genes (TSGs) in tumor cells and restore tumor suppressor pathways. Antroquinonol D (3-demethoxyl antroquinonol), a new DNMT1 inhibitor, was isolated from *Antrodia camphorata* and identified using nuclear magnetic resonance. Antroquinonol D inhibited the growth of MCF7, T47D, and MDA-MB-231 breast cancer cells without harming normal MCF10A and IMR-90 cells. The SRB assay showed that the 50% growth inhibition (GI50) in MCF7, T47D, and MDA-MB-231 breast cancer cells following treatment with antroquinonol D was 8.01, 3.57, and 25.08 μM, respectively. D-Antroquinonol also inhibited the migratory ability of MDA-MB-231 breast cancer cells in wound healing and Transwell assays. In addition, antroquinonol D inhibited DNMT1 activity, as assessed by the DNMT1 methyltransferase activity assay. As the cofactor SAM level increased, the inhibitory effects of D-antroquinonol on DNMT1 gradually decreased. An enzyme activity assay and molecular modeling revealed that antroquinonol D is bound to the catalytic domain of DNMT1 and competes for the same binding pocket in the DNMT1 enzyme as the cofactor SAM, but does not compete for the binding pocket in the DNMT3B enzyme. An Illumina Methylation 450 K array-based assay and real-time PCR assay revealed that antroquinonol D decreased the methylation status and reactivated the expression of multiple TSGs in MDA-MB-231 breast cancer cells. In conclusion, we showed that antroquinonol D induces DNA demethylation and the recovery of multiple tumor suppressor genes, while inhibiting breast cancer growth and migration potential.

KEYWORDS: *breast cancer, DNA methyltransferase, DNA methylation, Antrodia camphorata, tumor suppressor genes, cell migration*

INTRODUCTION

The wild natural fruiting body of *Antrodia camphorata* has long been used by aboriginal peoples to treat hepatitis, cirrhosis and liver cancer and has been used in Taiwan to cure diarrhea, abdominal pain, hypertension, itching of the skin and liver cancer.[1] Due to its extremely slow growth rate and high host specificity for the endangered tree *Cinnamomum kanehira* Hay (Lauraceae), the fruiting body cannot be mass-produced for commercialization. Therefore, the mycelium of *A. camphorata* has recently been developed by industrial companies as a health food and has been reported to have antitumor effects.[2,3] The process of tumorigenesis is initiated and promoted by molecular abnormalities, including oncogene activation and tumor suppressor gene (TSG) inactivation.[4] Down-regulation of tumor suppressor genes (TSGs) by 5′CpG island hypermethylation is an important event in tumor development.[5] CpG island hypermethylation inactivates TSGs and is a major epigenetic modification of the mammalian genome that is not accompanied by changes in the DNA sequence.[6] Aberrant promoter hypermethylation of TSG-associated CpG islands can lead to transcriptional silencing and result in tumorigenesis.[7]

DNA methylation disorders give rise to several significant human diseases, including various cancers, neurological disorders, psychosis and cardiovascular diseases, many of which are mediated by altered DNA methyltransferase 1 (DNMT1) expression and activity.[8−12] Previous reports have indicated that DNMT1 is overexpressed in lung, hepatocellular, colorectal, gastric and breast tumors, as well as acute and chronic myelogenous leukemias.[13−18] Abnormal expression of DNMT1 in vivo induces cellular alterations such as transformation, whereas inhibition of DNMT1 expression or activity results in the reversal of fos transformation.[19] The inhibition of DNA methyltransferase (DNMT), the enzyme that methylates the cytosine residues of CpG islands, may inhibit or reverse the process of epigenetic silencing.[10] Therefore, the use of pharmacologic inhibitors of DNA methylation represents an attractive, rational approach to the reversal of epigenetic TSG silencing. These inhibitors will hopefully reactivate TSGs in tumors and restore activity in critical cellular pathways.

Several DNMT inhibitors have exhibited potent antitumor activities in human xenograft models, indicating their potential usefulness as new cancer therapeutic agents. The first extensively studied DNMT inhibitors were 5-azacytidine (Vidaza) and 5-aza-2′-deoxycytidine (decitabine), which have been approved by the US Food and Drug Administration (FDA) for the treatment of myelodysplastic syndrome. However, these inhibitors induced hematopoietic toxicity and neutropenia in clinical trials.[20−22] Some non-nucleoside drugs and natural compounds, such as epigallocatechin-3-gallate (EGCG), RG108, mithramycin A and procaine, have also been reported to inhibit DNMT activity.[23,24] However, 5-aza-2′-deoxycytidine and EGCG were found to be genotoxic,[25] and mithramycin A has been observed to cause marked hemorrhagic toxicity in patients.[26] Procaine and EGCG failed to induce significant genomic DNA demethylation in some of the tested cell lines.[25] Therefore, other effective, minimally toxic DNMT inhibitors could potentially be developed to provide additional DNMT inhibitors for clinical use.

In the present study, we discovered that a ubiquinone derivative, antroquinonol D, may act as a DNMT1 inhibitor. Antroquinonol D, isolated from the mycelium of *Antrodia camphorata* (*A. camphorata*), can inhibit DNMT1 enzyme activity, induce the re-expression of multiple tumor suppressor genes, increase cancer cell death without harming normal cells, and inhibit the migratory ability of MDA-MB-231 breast cancer cells.

MATERIALS AND METHODS

Isolation of Antroquinonol D. The culture conditions of *A. camphorata* and the extraction method of antroquinonol D were performed as previously reported.[2] From 500 g dried powder of cultured *A. camphorata* mycelium, 9.6 mg of antroquinonol D was obtained. ^{1}H- and ^{13}C NMR of antroquinonol D were acquired using a Bruker DMX-500 SB spectrometer (Ettlingen, Germany). Mass spectra were obtained using a Thermo Finnigan LCQ-Duo spectrometer (Waltham, MA). The following data were recorded for 3-demethoxyl antroquinonol (Figure 1): slight yellowish oil; $[\alpha]^{23}_{D}$: +52.2 (*c* 0.5, MeOH); ^{1}H NMR data (CD_3OD, 500 MHz): δ_H 5.91 (1H, d, *J* = 5.6 Hz, H-3), 5.21 (1H, t, *J* = 7.3 Hz, H-8), 5.10 (1H, t, *J* = 6.9 Hz, H-12), 5.09 (1H, t, *J* = 7.2 Hz, H-16), 4.48 (1H, dd, *J* = 5.6, 3.7 Hz, H-4), 3.59 (3H, s, H_3-23), 2.67 (1H, m, H-6), 2.26−1.95 (10H, H_2-7, -10, -11, -14 and -15), 1.78 (1H, m, H-5), 1.65 (3H, s, H_3-18), 1.62 (3H, s, H_3-21), 1.60 (3H, s, H_3-20), 1.57 (3H, s, H_3-19), 1.16 (3H, d, *J* = 6.9 Hz, H_3-22); ^{13}C NMR data (CD_3OD, 125 MHz): δ_C 198.7 (C-1), 152.0 (C-2), 138.1 (C-9), 136.0 (C-13), 132.1 (C-17), 125.5 (C-16), 125.3 (C-12), 123.3 (C-8), 116.6 (C-3), 65.0 (C-2), 55.3 (C-23), 47.5 (C-5), 43.4 (C-6), 41.0 (C-10), 40.9 (C-14), 28.2 (C-7), 27.8 (C-15), 27.4 (C-11), 25.9 (C-18), 17.8 (C-19), 16.3 (C-21), 16.2 (C-20), 13.1 (C-22); ESI-MS: *m*/*z* = 383 $[M + Na]^+$; HR-ESI-MS: *m*/*z* = 383.2560 $[M + Na]^+$; calculated for $C_{23}H_{36}O_3 + Na^+$: 383.2562.

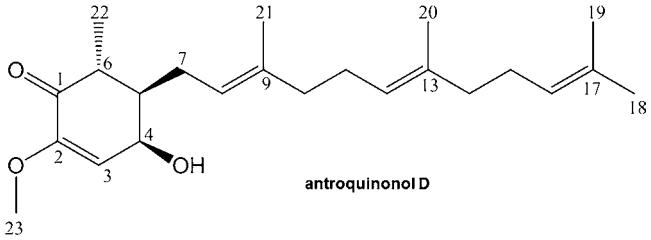

Figure 1. Structure of antroquinonol D. Antroquinonol D, a ubiquinone derivative, was isolated from the solid-state fermented mycelium of *Antrodia camphorata* (Polyporaceae, Aphyllophorales), a parasitic fungus that is indigenous to Taiwan. The structure of antroquinonol D is completely different from that of other non-nucleoside DNMT inhibitors, such as epigallocatechin-3-gallate (EGCG), RG108, mithramycin A and procaine.

Molecular Modeling and Docking. For the molecular docking experiments, the amino acid sequence of the DNMT1 catalytic domain was used as the query to perform a BLAST search against the RCSB Protein Data Bank. The crystal structure of DNMT1 in complex with sinefungin (PDB code 3SWR) was used to rebuild the model of the human DNMT1 catalytic domain. The DNMT3B catalytic domain was modeled using the crystal structure of DNMT3A (PDB code 2QRV) as a template. The structure was validated using Profile3D and PROCHECK. AutoDockTools 1.5.4 was used to prepare the pdbqt files for the ligands/protein and the control-parameter file for gridding and docking.[27] Autodock 4.2 was used to implement the docking process and calculate the binding energies.[28] The Autodock program software uses Monte Carlo-simulated annealing and a Lamarckian genetic algorithm to create a set of possible conformations. All of the ligand bonds were set to be rotatable. A grid box with a dimension of 50 × 80 × 50 points and default grid spacing of 0.375 Å was set around the active sites, covering the DNA-binding region and allowing ligands to move freely. Grid maps were generated using the Autogrid program. The best conformation was defined as the one with the lowest docked energy after the docking search had been completed. The interactions of the protein/ligand complex, including hydrogen bonds and bond lengths, were analyzed using Pymol.

DNMT1 and DNMT3B Methyltransferase Activity Assays. The drug screening was performed using a DNA Methyltransferase 1 Activity/Inhibitor Screening Assay Kit (Abnova). One hundred nanograms of the DNMT1 enzyme and the indicated concentrations of the potential DNMT inhibitors were added into a CpG-enriched DNA-coated 96-well plate and incubated for 2 h. The DNMT1 enzyme transfers a methyl group to cytosine from *S*-adenosyl methionine (SAM), thereby methylating the DNA substrate. The methylated DNA can be recognized using an anti-5-methylcytosine antibody. The ratio or amount of methylated DNA, which is proportional to the enzyme activity, can then be colorimetrically quantified using an ELISA-like reaction. Finally,

we detected the colorimetric reaction (OD450 nm) using an ELISA reader. The inhibitory effects of all of the drugs were calculated as follows: The relative DNMT1 activity (%) = (the OD450 of the sample-the OD450 of the blank)/(the OD450 of the DMSO control-the OD450 of the blank) × 100. To further confirm the specificity and underlying mechanism of the antroquinonol D-mediated DNMT inhibition, we measured the DNMT1 (Active Motif) and DNMT3B (BPS Bioscience, San Diego, CA) enzyme activity in the presence of 40, 80, or 160 μM of SAM following antroquinonol D, antroquinonol or EGCG (Sigma-Aldrich) treatment using an EpiQuik DNA Methyltransferase (DNMT) Activity/Inhibition Assay Kit (Epigentek, Farmingdale, NY). The key principles, methodology and protocols are similar to the DNA Methyltransferase 1 Activity/Inhibitor Screening Assay Kit. Antroquinonol D and antroquinonol were provided by Golden Biotechnology Corporation.

Cell Lines and Drug Treatments. The MCF7, T47D and MDA-MB-231 breast cancer cell lines were obtained from the Bioresource Collection and Research Center (BCRC, Hsinchu, Taiwan). MCF10A, a normal mammary gland cell line, was obtained from the American Tissue Cell Culture collection. IMR-90, a normal fibroblast-like cell line that was established from the lung tissue of a female fetus, was obtained from the BCRC. The MCF7, MDA-MB-231 and IMR-90 cell lines were cultured in DMEM (Invitrogen) supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin. The T47D cell line was cultured in RPMI 1640 (Invitrogen) that had been supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin. The cells were treated with DMSO, antroquinonol D, or the DNMT inhibitors 5-azacytidine (AZA) and decitabine (DAC) for the indicated durations. Antroquinonol D was dissolved in DMSO. AZA (Sigma-Aldrich) and DAC (Sigma-Aldrich) were dissolved in acetic acid/water (1:1).

Sulphorhodamine B (SRB) Assays. A sulphorhodamine B (SRB) assay was used to determine the cell growth rate. Based on the growth curves of the MCF7, T47D, MDA-MB-231, MCF10A and IMR-90 cell lines, the cells were seeded in 96-well plates at densities of 5000, 8000, 3000, 2000, and 6000 cells/well, respectively, and incubated with the indicated drugs for 3 days. Additionally, MCF7, T47D, MDA-MB-231, MCF10A and IMR-90 cells were seeded in 96-well plates at densities of 3000, 5000, 750, 500, and 4000 cells/well, respectively, and incubated with the indicated drugs for 6 days. The growth curves of the MCF7, T47D, MDA-MB-231, MCF10A and IMR-90 cell lines over 6 days are shown in Figure S1, Supporting Information. The cells were fixed with 10% trichloroacetic acid at the indicated times. Cell growth was assessed via OD determination at 515 nm using a microplate reader. The data for antroquinonol D were normalized to its solvent control (DMSO). The 5-azacytidine (AZA) and decitabine (DAC) data were also normalized to their solvent controls (50% acetic acid). The solvent controls were added in the same amounts as those used for the treatment drugs at the indicated concentrations. The growth inhibition rates were calculated using the following equation: Cell growth inhibition rate (%) = $100 - [(Ti - Tz)/(C - Tz)] \times 100$ ($Ti \geq Tz$). Cytotoxicity rate (%) = $[(Tz - Ti)/Tz] \times 100$ ($Tz \geq Ti$). Ti = the OD of the inhibitor sample. Tz = the OD of the basal cells. C = the OD of the control.

MTT Assays. The cells were seeded in 96-well microtiter plates (100 μL/well) at densities of 5000 cells/well and grown in culture medium. The next day, the culture medium was replaced with 100 μL of culture medium containing different concentrations of DMSO or a DNMT1 inhibitor, and cell viability was assayed using an MTT assay (3-(4,5-dimethylthiazol-2yl)-2,5-diphenyltetrazolium bromide) after 72 h of incubation. Cell viability was assessed using OD determinations at 570 nm using a microplate reader. MTT powder (Sigma-Aldrich) was dissolved in phosphate-buffered saline at 3.3 mg/mL and filtered.[29]

Wound Healing Assays for Migration Analyses. Treated and untreated cells were plated at densities of 2×10^5 cells in 10 cm culture dishes in quadruplicate and incubated at 37 °C. After the cells had been treated with 15 μM antroquinonol D for 6 days, wound healing assays were performed using Culture-Inserts (Ibidi). Cell-free gaps of 500 μm were created after removing the Culture-Inserts. After seeding the cells overnight, the Culture-Inserts were removed, and images of the wounded areas were acquired using an inverted microscope (Nikon) at the indicated time points. The percentage of closure of the wounded area was measured and analyzed using ImageJ software, and the migratory ability was calculated.

Transwell Assays for Migration Analyses. The Transwell consists of upper and lower chambers that are separated by a layer of membrane that has a pore size of 8 μm (Falcon). Approximately 2×10^4 treated and untreated MDA-MB-231 cells were seeded onto the upper chambers with 300 μL of serum-free medium containing drugs, and 800 μL of DMEM containing 10% FBS was added to the lower chambers as a chemoattractant. The seeded cells were incubated for 16 h. The cells that did not invade were removed using a scraper and washed twice with PBS, then fixed and stained using 1% crystal violet/ddH_2O for 60 min at room temperature. Five random views were photographed under a microscope (Nikon) and then counted and quantified using ImageJ.

Cell Migration Assays Using the xCELLigence Biosensor System. Migration assays were performed using the RTCA DP instrument (Roche Diagnostics GmbH, Germany), which was placed in a humidified incubator and maintained at 5% CO_2 and 37 °C, as previously described.[30] The cells were seeded into specifically designed 16-well plates (CIM-plate 16, Roche Diagnostics GmbH) that had 8 μm pores that were similar to conventional Transwells and contained microelectrodes on the undersides of the upper chamber's membranes. The cells (20 000 cells/well) were seeded into the upper chambers in serum-free medium, and media containing 10% FBS was added to the lower chambers. Each sample was treated under the same conditions in four independent wells. The CIM-plate 16 was monitored every 10 s for 40 min and once every hour thereafter. The greater the number of cells attached to the electrodes, the larger the increases in electrode impedance. The electrode impedance, which was displayed and recorded as the Cell Index (CI) value, reflected the biological statuses of the monitored cells, including the cell numbers, viabilities, morphologies and degrees of adhesion. The data analyses were performed using the RTCA software program v1.2, which was supplied with the instrument. The *t* test was to analyze the data differences.

DNA and RNA Extractions. Genomic DNA from the cell lines was prepared using the Blood and Tissue Genomic DNA Extraction Miniprep System (Viogene, Sunnyvale, CA). Total mRNA was extracted from the cells using the TRIzol reagent (Invitrogen). The DNA and RNA were quantified, and the

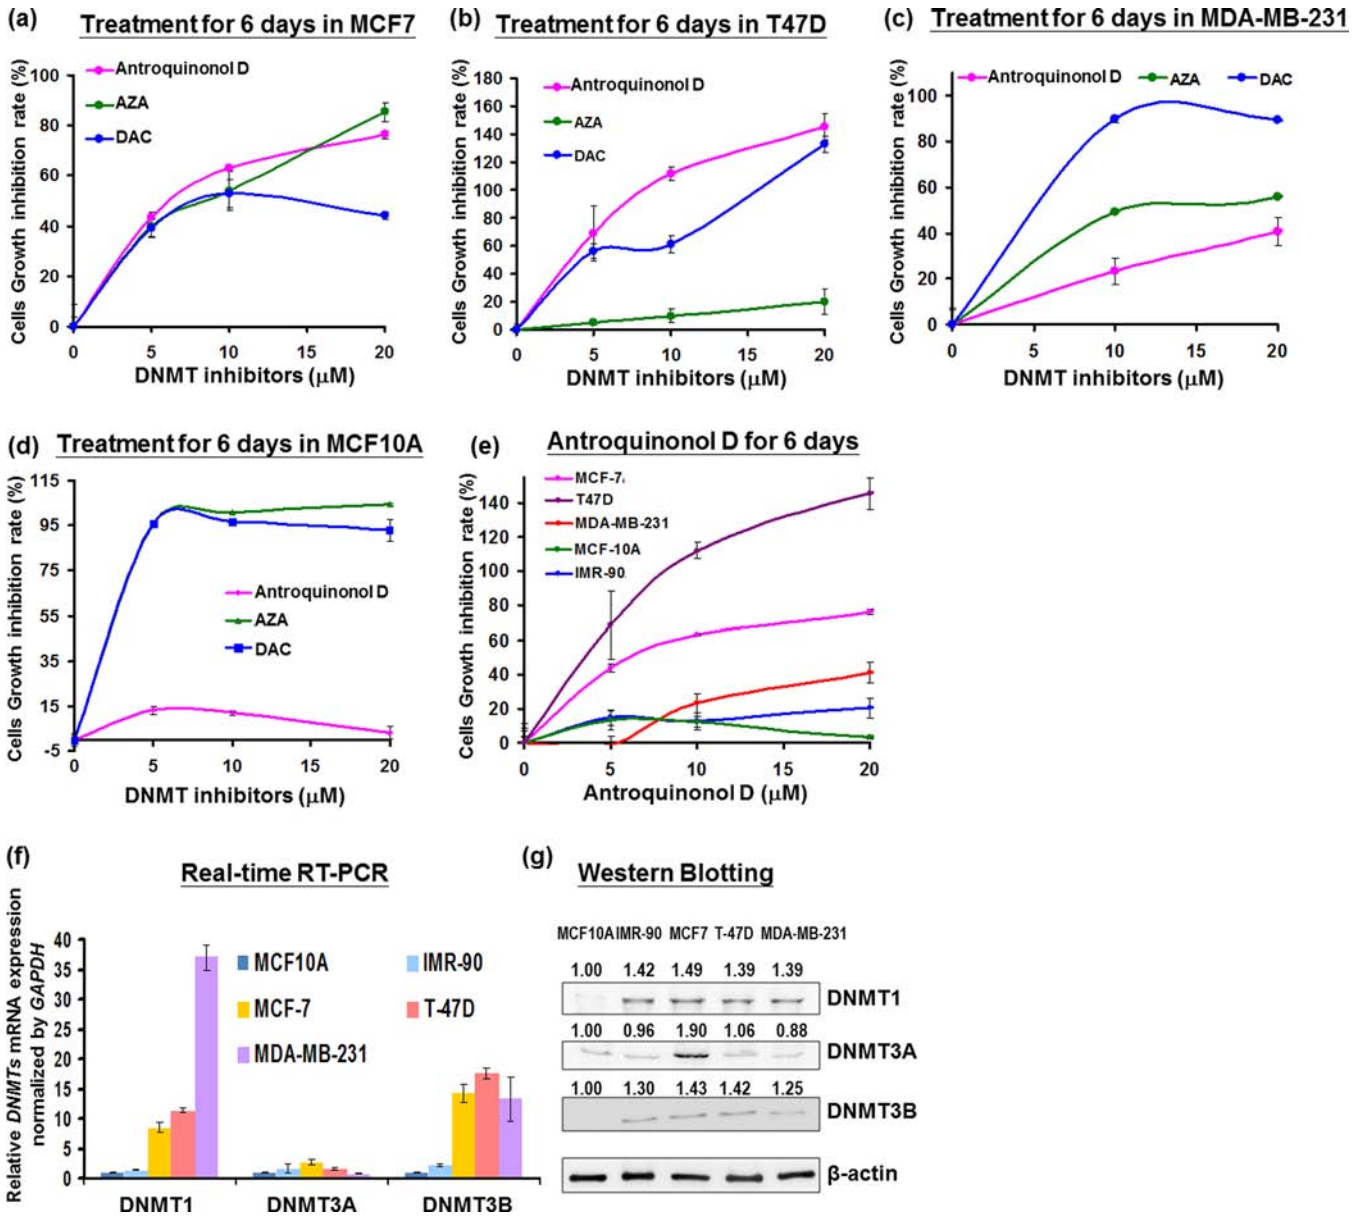

Figure 2. Growth of the breast cancer cell lines MCF7, T47D, MDA-MB-231 and the normal cell line MCF10A and IMR-90 following treatment with DNMT1 inhibitors. The growth of the MCF7 (a), T47D (b) and MDA-MB-231 (c) cancer cell lines, the MCF10A normal mammary gland cells, and the IMR-90 normal lung cell line (d and e), was determined using the SRB assay after the cells had been treated with antroquinonol D or the DNMT inhibitors azacitidine (AZA) and decitabine (DAC) at the indicated concentrations for 6 days. Cell growth inhibition rate (%) = 100 − [(Ti − Tz)/(C − Tz)] × 100 (Ti ≥ Tz). Ti = the OD of the inhibitor sample; Tz = the OD of the basal cells; C = the OD of the control. The cytotoxic effects of antroquinonol D in normal MCF10A and IMR-90 cells were lower than those of AZA and DAC after 6 days of treatment. (f) *DNMT1*, *DNMT3A* and *DNMT3B* mRNA expression levels were analyzed using real-time RT-PCR and were normalized to *GAPDH*. (g) DNMT1, DNMT3A and DNMT3B protein expression levels were analyzed using Western blotting. The data are presented as the means ± s.d. All experiments were performed with at least two biological duplicates and three technical replicates.

purities were verified by measuring the A_{260} and A_{260}/A_{280} ratios (which ranged from 1.8 to 2.0).

DNA Methylation Assays. The DNA methylation statuses of the MDA-MB-231 cells were determined following treatment with 15 μM antroquinonol D for 6 days. Five hundred nanograms of genomic DNA were bisulfite-converted using an EZ Methylation Gold kit (Zymo Research, Irvine, CA) according to the manufacturer's recommended protocol. The DNA methylation analyses were performed using Illumina Methylation 450 K array-based assays (Illumina, San Diego, CA). The array analyses were performed by Health GeneTech Corporation, Taiwan. Methylation scores for each CpG site were classified as "Beta" values that ranged from 0 (unmethylated) to 1 (fully methylated) by determining the ratios of the methylated signal intensities to the sums of the methylated and unmethylated signal outputs. Functional annotation clustering of differentially demethylated genes was performed using Functional DAVID Bioinformatics Resources 6.7.[31] Supporting Information Figure S9 was generated using XMind 3.2.1. The methylation patterns of the *FANCC* and *CACNA1A* genes were further confirmed and quantified using pyrosequencing. Because no primers were found that could be used for pyrosequencing that targeted the DNA regions of the *FANCC* and *CACNA1A* genes (which were detected using the

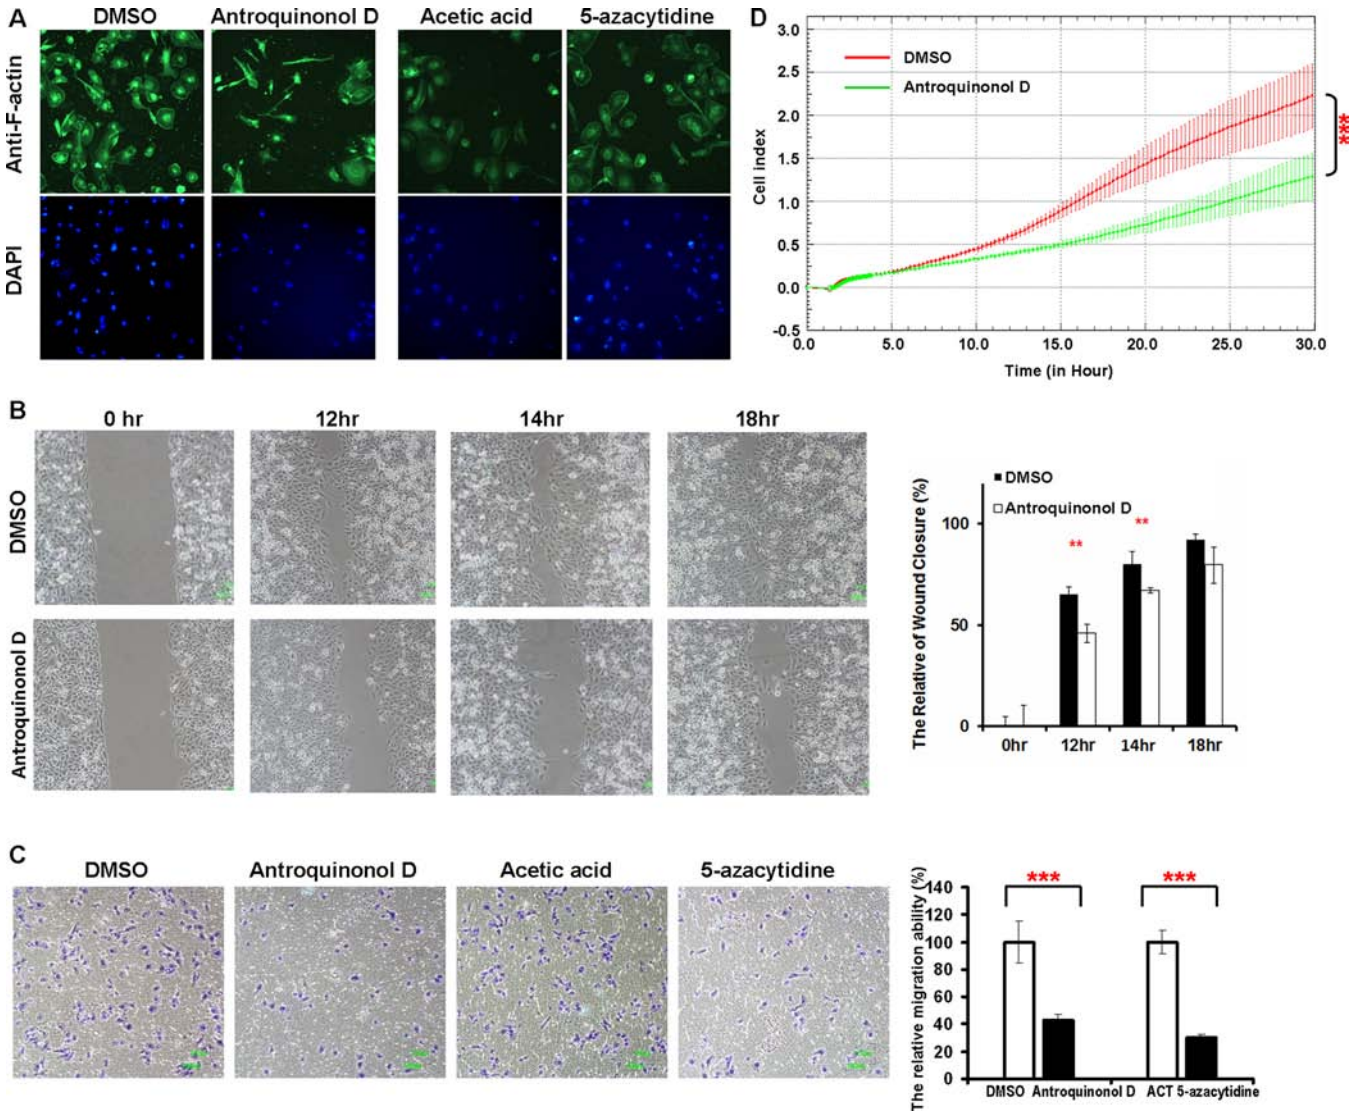

Figure 3. Antroquinonol D inhibits the migration of MDA-MB-231 breast cancer cells. (a) The distribution of F-actin (green) was detected by immunofluorescence staining and fluorescence microscopy using anti-F-actin antibody (original magnification 200X). DAPI was used to label cell nuclei (blue). (b) Wound healing was determined using a Culture-Insert assay to analyze the migratory abilities of the cells. The cells were photographed at 0, 12, 14, and 18 h. The images represent the untreated (upper panel) and treated (lower panel) cells (original magnification × 100). The data indicate that antroquinonol D decreased the migration of MDA-MB-231 cells compared to the DMSO control. The experiment was performed with at least two biological duplicates and three technical replicates. (c) A Transwell assay was used to further investigate the migratory abilities of the cells. The images represent treatment with DMSO, antroquinonol D, acetic acid (the solvent control for 5-azacytidine) or 5-azacytidine (original magnification ×100). The average number of migratory cells (those that passed through the membrane) was counted in five different fields. Antroquinonol D significantly decreased the migration of MDA-MB-231 cells. *** $p \leq 0.001$. The experiment was performed with three technical replicates. (d) Cell migration was also assessed using specifically designed 16-well plates (CIM-plate 16) that had 8 μm pores. The CIM-plate 16 was monitored every 10 s for 40 min and then once every hour. Data analyses were performed using the RTCA software v1.2 program that was supplied with the instrument. The Cell Index (CI) value reflects the biological status of the monitored cells, including the cell number, cell viability, morphology and degree of adhesion. The experiments were performed in technical quadruplicate. The data are presented as the means ± s.d. ** $p \leq 0.005$, *** $p \leq 0.001$. The t test was used to calculate group differences in all experiments.

Methylation 450 K array-based assay), we designed primers that were targeted to the promoter regions of the *FANCC* and *CACNA1A* genes for use in the pyrosequencing assay. The primers were designed using the MethPrimer[32] and Methyl Primer Express v1.0 (ABI) software programs. The PCR reactions were performed using biotinylated primers to convert the PCR products to single-stranded DNA templates. The pyrosequencing reactions and methylation quantification were performed using PyroMark Q24, which was provided by the Mission Biotech Corporation, Taiwan. The primers are described in Table S1, Supporting Information.

Real-time RT-PCR. The mRNA expression levels were measured by performing real-time RT-PCR using a LightCycler 480 (Roche Applied Science, Mannheim, Germany). Real-time PCR was performed using the LightCycler 480 Probe Master kit (Roche Applied Science) with the specific primers and the corresponding Universal Probe Library probe (Roche Applied Science) according to the manufacturer's instructions. Normalized gene expression values, which were calibrated to the control group, were obtained using the LightCycler Relative Quantification software program (ver. 2.0, Roche Applied

dx.doi.org/10.1021/jf4056924 | J. Agric. Food Chem. 2014, 62, 5625−5635

Science). *GAPDH* was used as a reference gene. The primers are described in Table S1, Supporting Information.

Cell Lyses and Immunoblotting Analyses. For Western blotting assays, the cells were lysed on ice in radioimmunoprecipitation buffer (0.05 M Tris-HCl [pH 7.4], 0.15 M NaCl, 0.25% deoxycholic acid, 1% Igepal CA-630, and 1 mM ethylenediaminetetraacetic acid). The lysates were then centrifuged at 13 000 r.p.m. at 4 °C for 10 min. The protein extracts were solubilized in sodium dodecyl sulfate (SDS) gel loading buffer (60 mmol/L Tris base, 2% SDS, 10% glycerol and 5% β-mercaptoethanol). Samples containing equal amounts of protein (40 μg) were separated on an 8% SDS-polyacrylamide gel using electrophoresis and electroblotted onto Immobilon-P membranes (Millipore, Bedford, MA) in transfer buffer. Immunoblotting was performed using antibodies that had been raised against DNMT1 (1:1000, GeneTex, TX), DNMT3A (1:1000, Cell Signaling, Danvers, MA), DNMT3B (1:250, Abcam, Cambridge, U.K.), FANCC (1:500, GeneTex, Hsin-Chu, Taiwan), and CACNA1A (1:250, Abcam, Cambridge, U.K.), total AKT (1:1000, Cell Signaling, Danvers, MA), phosphor-AKT Ser473 (1:500, Cell Signaling, Danvers, MA). β-Actin (1:5000, GeneTex, TX) was used as an internal control. For Immunofluorescence staining assays, cells were seeded in 4-well glass chamber slides (Nunc). After DNMT inhibitor treatment, cells were fixed in 4% formaldehyde and stained with anti-F-actin (1:200, Abcam, Cambridge, U.K.) cells. The image was detected by using the Olympus IX71 Inverted Microscope System.

RESULTS AND DISCUSSION

Identification of Antroquinonol D. Antroquinonol D was obtained as a slight yellowish oil. Its molecular formula, $C_{23}H_{36}O_3$, was deduced through analysis of the ^{13}C NMR and HRESIMS data. The ^1H NMR spectrum of antroquinonol D exhibited resonances compatible with those of antroquinonol except that a 3-methoxyl group at C-3 was substituted by an olefinic methine signal atδ_H 5.91 (d, J = 5.6 Hz, H-3) in antroquinonol D.[2] The difference was also reflected in the ^{13}C NMR of antroquinonol D, in which C-24 disappeared and a quaternary C-3 was replaced by a tertiary C-3 atδ_C 116.6. Thus, the gross structure of antroquinonol D was determined to be 3-demethoxyl antroquinonol. The relative configuration of cyclohexenone was consistent with that of antroquinonol. The configurations of Δ^8, Δ^{12} and Δ^{16} were *E* as corroborated by the chemical shifts of C-21, C-20 and C-19 at respectiveδ_C 16.3, 16.2, and 17.8. Accordingly, the structure of antroquinonol D is shown in Figure 1. We examined signals and noise in the 1H NMR spectrum of antroquinonol D, and the purity of antroquinonol D (LTH-0909−1) was determined to be greater than 95% (Supporting Information Figure S2).

Antroquinonol D Inhibits the Growth of Breast Cancer Cells, but not normal cells. Clinical toxicity is a major concern for the clinical application of anticancer agents. Therefore, we treated normal cell lines, MCF10A and IMR-90, and three breast cancer cell lines, MCF7, T47D and MDA-MB-231, with the DNMT inhibitor for 3 or 6 days. The drug treatment protocols are described in Supporting Information Figure S3. Antroquinonol D suppressed the growth of MCF7 and T47D cells as effectively as AZA and DAC treatment at 6 days (Figure 2a and Figure 2b). The SRB assay showed that the GI50 in MCF7, T47D and MDA-MB-231 breast cancer cells following antroquinonol D treatment is 8.01, 3.57, and 25.08 μM, respectively. Antroquinonol D could lead to cytotoxic effects in T47D and MCF7 cells (Figure S4a, Supporting Information). In addition, antroquinonol D treatment displayed lower cytotoxicity to normal mammary gland cells (MCF10A) and human fibroblast cells (IMR-90) than AZA and DAC treatment for 3 days (Figure S4b, Supporting Information) and 6 days (Figure 2d and Figure 2e), respectively. The antroquinonol D-mediated cell growth inhibition and cell death at 72 h, assessed by the MTT assay, was also stronger than that demonstrated by another DNMT inhibitor, EGCG, in MCF7 and NDA-MB-231 cells (Figure S4c, Supporting Information).

Antroquinonol D Inhibits the Migration of MDA-MB-231 Breast Cancer Cells. Metastasis is the primary cause of mortality for most cancer patients. The mobility of tumor cells is a key step in the metastatic process. The MDA-MB-231 cells exhibit invasive tumor features with rapid migration ability. The MDA-MB-231 cells are good cell models for analyzing whether antroquinonol D could also inhibit cell migration ability. We observed morphological changes in MDA-MB-231 cells, including cell shrinkage and fragmentation, after antroquinonol D treatment for 6 days (Supporting Information Figure S5 right panel) that were greater than those observed following DMSO treatment (Supporting Information Figure S5 left panel). Dynamic regulation of the filamentous actin (F-actin) cytoskeleton is critical to cell adhesion and migration.[33] Immunofluorescence imaging revealed that the network expansion of F-actin was not as extensive after antroquinonol D treatment as after DMSO control treatment (Figure 3a). Cell motility was further analyzed using wound healing and Transwell assays. The results of the wound healing assays indicated that the MDA-MB-231 cells migrated more slowly when treated with 15 μM antroquinonol D for 6 days compared to the DMSO control-treated cells (Figure 3b). The Transwell migration assays also revealed that antroquinonol D decreased the migration ability of MDA-MB-231 cells by 56.9% (Figure 3c). Antroquinonol D and a positive control DNMT inhibitor, AZA, displayed similar suppression effects on the migratory ability of MDA-MB-231 breast cancer cells. To further confirm that the DNMT inhibitor antroquinonol D influenced the migratory ability of breast cancer cells, a migration assay was performed using the xCELLigence biosensor system, and the numbers of cells that migrated were reflected by the cell index. As shown in Figure 3c, the cell indices in the DMSO-treated control cells and antroquinonol D-treated cells were 2.2 and 1.3, respectively, after 30 h. The migratory ability was reduced to approximately 41% in the antroquinonol D-treated cells compared to the DMSO-treated control cells (Figure 3d). These results indicate that this DNMT inhibitor can suppress the migratory ability of MDA-MB-231 breast cancer cells.

Antroquinonol D Can Inhibit DNMT1 Enzyme Activity. A previous study reported that antroquinonol induces anticancer activity in human pancreatic cancers through an inhibitory effect on PI3-kinase/Akt/mTOR pathways.[34] In our study, neither antroquinonol nor antroquinonol D can inhibit AKT phosphorylation in MDA-MB-231 cells (Supporting Information Figure S6), suggesting that the anticancer effect mediated by antroquinonol D is mediated through another pathway. Down-regulation of tumor suppressor genes (TSGs) by 5′CpG island hypermethylation is an important event in tumor growth and progression.[5] Blocking DNA methyltransferase (DNMT) could potentially inhibit or reverse the process of epigenetic silencing. To develop a new DNMT inhibitor and

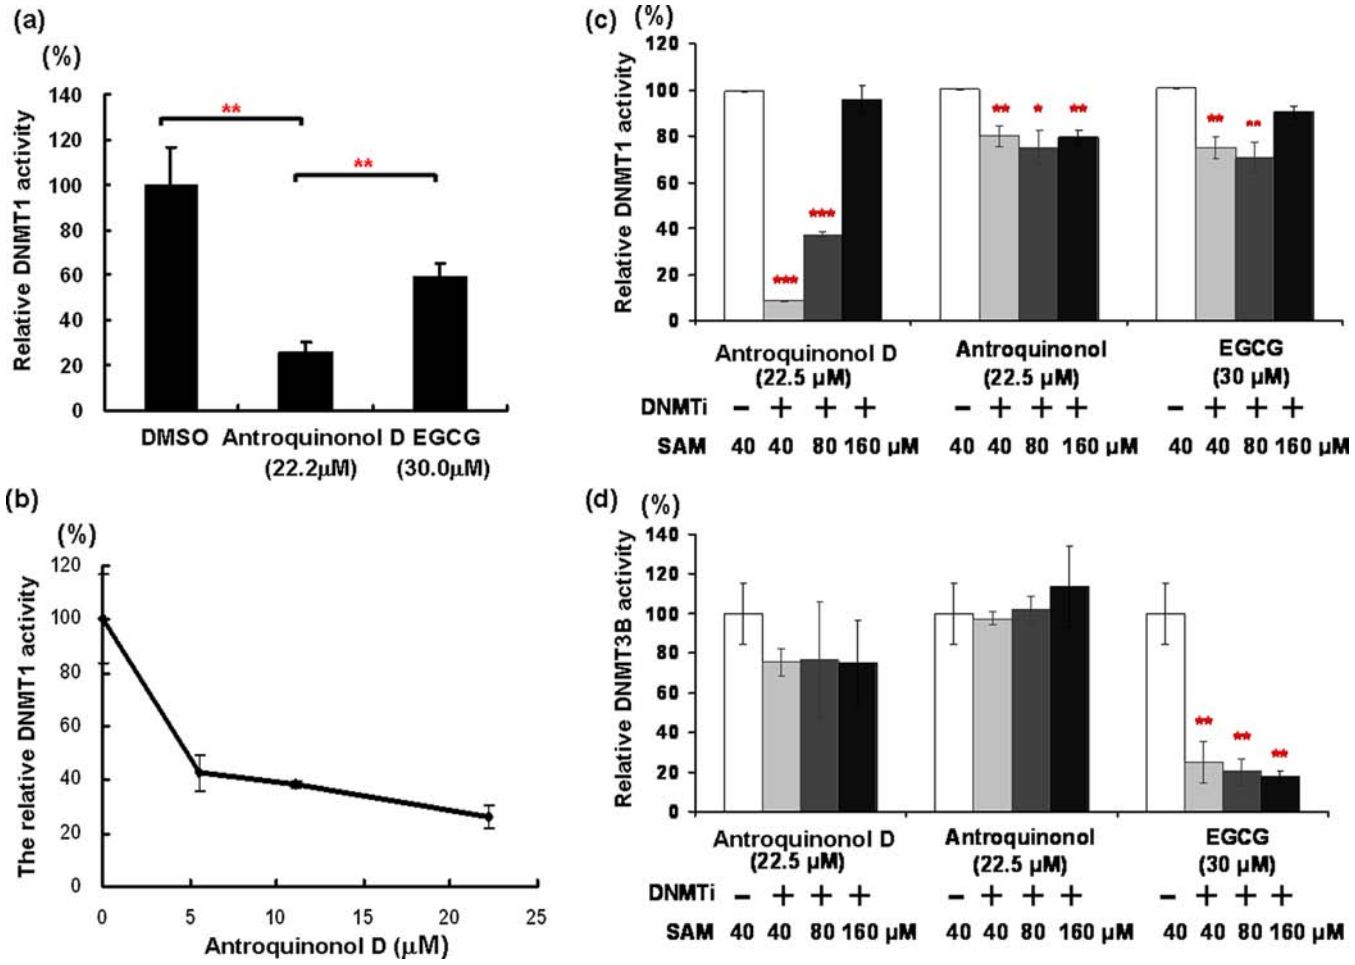

Figure 4. Antroquinonol D inhibits DNMT1 enzyme activity. (a) Antroquinonol D (22.5 μM) significantly suppressed DNMT1 activity. The experiments were performed with at least three biological and three technical replicates. (b) Antroquinonol D inhibited the methylation activity of DNMT1 followed by increasing of Antroquinonol D. The DNMT1 activity assays were analyzed based on the methylation levels catalyzed by DNMT1 in the presence of either an inhibitor or the control (DMSO). EGCG was used as a positive control DNMT inhibitor. The inhibitory effects of antroquinonol D, antroquinonol or EGCG on the DNMT1 (c) or (d) DNMT3B enzymes were analyzed in the presence of 40 to 80 and 160 μM of the cofactor SAM. * $p \leq 0.05$, ** $p \leq 0.005$, *** $p \leq 0.001$. The data are presented as the means ± s.d. All the experiments were performed with at least three technical replicates. The t test was used to calculate group differences in all experiments.

further determine whether the D-antroquinonol-mediated inhibition of cancer cell growth and migration resulted from the suppression of DNMT1 activity, we analyzed DNMT1 activity using the DNMT1 Activity/Inhibitor Screening Assay Kit. We collected natural compounds from the Graduate Institute of Pharmacognosy of Taipei Medical University, including phenolics, curcumin analogues, ubiquinone and sesquiterpene derivatives, and serially examined the DNMT1 activity. In addition to phenolics, curcumin analogues and sesquiterpene derivatives, we discovered that a ubiquinone derivative, antroquinonol D, may act as a DNMT1 inhibitor in vitro (Figures 1 and 4a, $P = 0.0036$). Its inhibitory effects were stronger than those of the positive control DNMT inhibitor, EGCG (Figure 4a, $P = 0.0027$). The IC50 of antroquinonol D on DNMT1 activity was much lower than 5 μM (Figure 4b). In addition, antroquinonol D inhibited DNMT1 activity in the presence of 40 μM SAM. After increasing the SAM concentration from 40 to 80 and 160 μM, the inhibitory effects of antroquinonol D on DNMT1 gradually decreased in a dose-dependent manner (Figure 4c). These results further indicate that antroquinonol D may be inserted into the putative cytosine pocket and compete with the cofactor SAM, resulting in decreased DNMT1 activity. One antroquinonol D analogue, antroquinonol, was isolated in 2007 and was reported to be toxic to cancer cells.[2] Antroquinonol does not inhibit DNMT1 enzyme activity as well as antroquinonol D does (Figure 4c). For DNMT3B enzyme activity assay, antroquinonol D only slightly reduced DNMT3B enzyme activity (Figure 4d). These results may also indicate that antroquinonol D competes for the same binding pocket in the DNMT1 enzyme as SAM, but does not compete for the binding pocked in the DNMT3B enzyme (Figure 4c and d). High levels of DNMT1 mRNA and protein expression were observed in three breast cancer cell lines (MCF7, T47D and MDA-MB-231) (Figure 2f and g) that were sensitive to antroquinonol D treatment compared to normal MCF10A cells (Figure 2d and e). However, real-time RT-PCR and Western blotting analyses found that DNMT1, DNMT3A and DNMT3B mRNA and protein levels were not significantly decreased after antroquinonol D treatment (Supporting Information Figure S7).

Molecular Modeling of the Interaction between antroquinonol D and DNMT1. To investigate the putative mechanisms involved in the antroquinonol D-mediated inhibition of DNMT1 activity, the crystal structure of

dx.doi.org/10.1021/jf4056924 | J. Agric. Food Chem. 2014, 62, 5625−5635

DNMT1 in complex with sinefungin (PDB code 3SWR) was used to build the model of the human DNMT1 catalytic domain (Figure 5a). Molecular docking of antroquinonol D

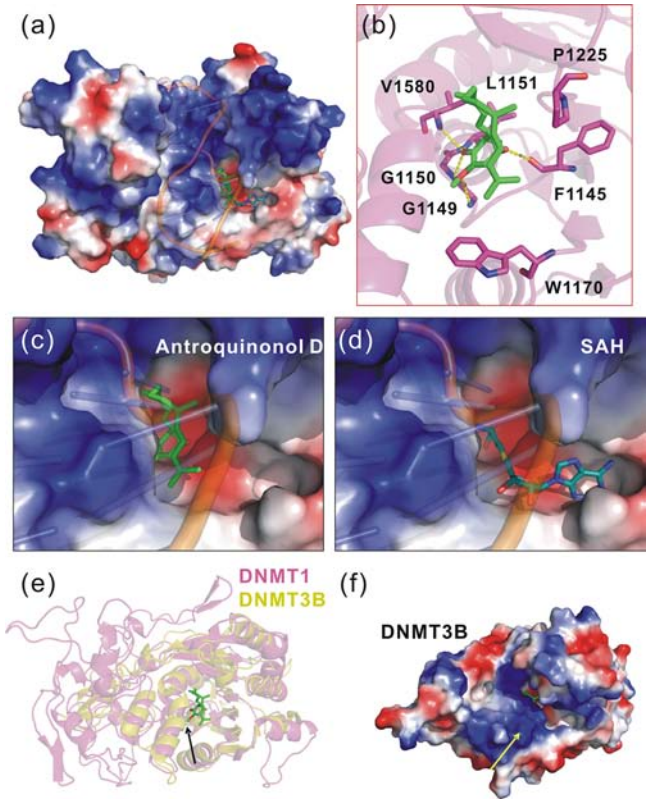

Figure 5. Molecular docking model of the DNMT1 catalytic domain binding to antroquinonol D or hemimethylated DNA. (a) Docking of antroquinonol D and hemimethylated DNA (brown line) in the catalytic pocket of DNMT1. (b) The binding mode of antroquinonol D upon docking to DNMT1. The hydrogen-bonding interactions of F1145, G1149, G1150, L1151 and V1580, and the van der Waals interactions with P1225 and W1170, are shown. Antroquinonol D (c) bound to the same pocket as SAH, which is the product of DNMT1 catalytic reactions (d). The ligands and site residues are shown in stick representation and colored by atom type, with the exception of the carbon atoms, which are indicated in green, cyan and purple for antroquinonol D, SAH, and the site residues, respectively. (e) Superimposition of DNMT1 (pink) and DNMT3B (yellow) structures revealed that antroquinonol D was not suitable to fit into the binding pocket of DNMT3B. (f) Bulky antroquinonol D had a crash (arrow) with the binding pocket of DNMT3B when overlapping antroquinonol D bound DNMT1 with DNMT3B.

onto the DNMT1 catalytic domain was performed. The hydrogen-bonding interactions of F1145, G1149, G1150, L1151 and V1580, and van der Waals interactions of P1225 and W1170 were observed on the residues of DNMT1 that were bound to antroquinonol D (Figure 5b). Antroquinonol D was found to bind to the same pocket as SAH, which is the SAM cofactor product of DNMT1 catalytic reactions (Figure 5c and d). DNMT3B catalytic domain was also modeled using the crystal structure of DNMT3A (PDB code 2QRV) as a template. Interestingly, when superimposing the structure of antroquinonol D bound DNMT1 with DNMT3B structure, antroquinonol D could fit into the binding pocket of DNMT3B (Figure 5e and f). The steric effect of DNMT3B on the bulky antroquinonol D entry may be the reason for the lower inhibition ability of antroquinonol D to DNMT3B compared to DNMT1 (Figure 5e and f). The enzyme activity assay and molecular modeling of the interaction between antroquinonol D and DNMTs support that antroquinonol D selectively inhibits the DNMT1 enzyme, but not DNMT3B. The structure–activity relationships between antroquinonol and antroquinonol D with the DNMT1 enzyme was also analyzed by molecular modeling. The data showed that antroquinonol, with an additional 3′-O–CH_3 group, may interfere with the binding of DNMT1 more than antroquinonol D does (Supporting Information Figure S8).

Antroquinonol D Induces Tumor Suppressor Gene Demethylation and Re-expression in Cancer Cells. Aberrant DNA hypermethylation of TSGs is an important mechanism underlying tumorigenesis.[21,35] Consequently, researchers are now searching for potential demethylating agents that can be used to reactivate TSGs in tumor cells, which may possibly lead to the suppression of cancer cell growth and invasion. To determine whether antroquinonol D can induce gene demethylation in cells, we analyzed changes in genomic methylation using the Illumina Methylation 450 K array-based assay. We discovered that treatment with 15 μM antroquinonol D for 6 days decreased the methylation status of 159 CpG sites and 113 specific genes in MDA-MB-231 breast cancer cells (Figure 6a and Supporting Information Table S2). Functional annotation clustering of differentially demethylated genes induced by following antroquinonol D treatment was performed using a Functional DAVID Bioinformatics Resources 6.7 analysis (Supporting Information Figure S9). The greatest decreases in methylation levels and increases in mRNA expression levels following antroquinonol D treatment were observed in five tumor suppressor genes: *FANCC*, *CACNA1A*, *CDH15*, *ASB9* and *COL4A2* (Figure 6a,b and Table 1). FANCC gene expression has been reported to be lower in stage III samples compared to stage I samples from ovarian cancer patients.[36] The CACNA1A gene encodes the α_{1A} pore-forming subunit of Ca^{2+} voltage-gated Cav2.1 channels. A recent report identified the *CACNA1A* gene as a novel tumor suppressor candidate that is methylated in lung cancer tumors.[37] Frequent promoter methylation of *CDH15* in hepatocellular carcinoma is associated with a poor prognosis.[38] Low expression of ASB9 in colorectal cancer is associated with a poor prognosis.[39] COL4A2 protein retards the growth of pancreatic cancer in a dose-dependent manner by inhibiting angiogenesis.[40] Pyrosequencing was used to further confirm the decreases in the methylation statuses of two of the tumor suppressor genes, *FANCC* and *CACNA1A*. The CpG island methylation levels in the *FANCC* and *CACNA1A* genes were decreased by approximately 9–51% and 20–51%, respectively, following antroquinonol D treatment (Figure 6c). We also used Western blotting to determine whether FANCC and CACNA1A protein expression was induced following antroquinonol D treatment. The data indicated that the FANCC and CACNA1A protein expression levels had also increased by 1.7- and 2.3-fold, respectively, following antroquinonol D treatment (Figure 6c). Note that DNA demethylation of the *ASB9* and *RPS6KA2* genes was detected using a Methylation 450 K array-based assay. However, RPS6KA2 mRNA expression cannot be detected using real-time RT-PCR. The ASB9 mRNA expression levels only increased 2-fold. A probable reason for these results may be that the DNA demethylation regions of RPS6KA2 and ASB9 were not close to the CpG islands (Table 1). Interestingly, the DNA demethylation regions of the

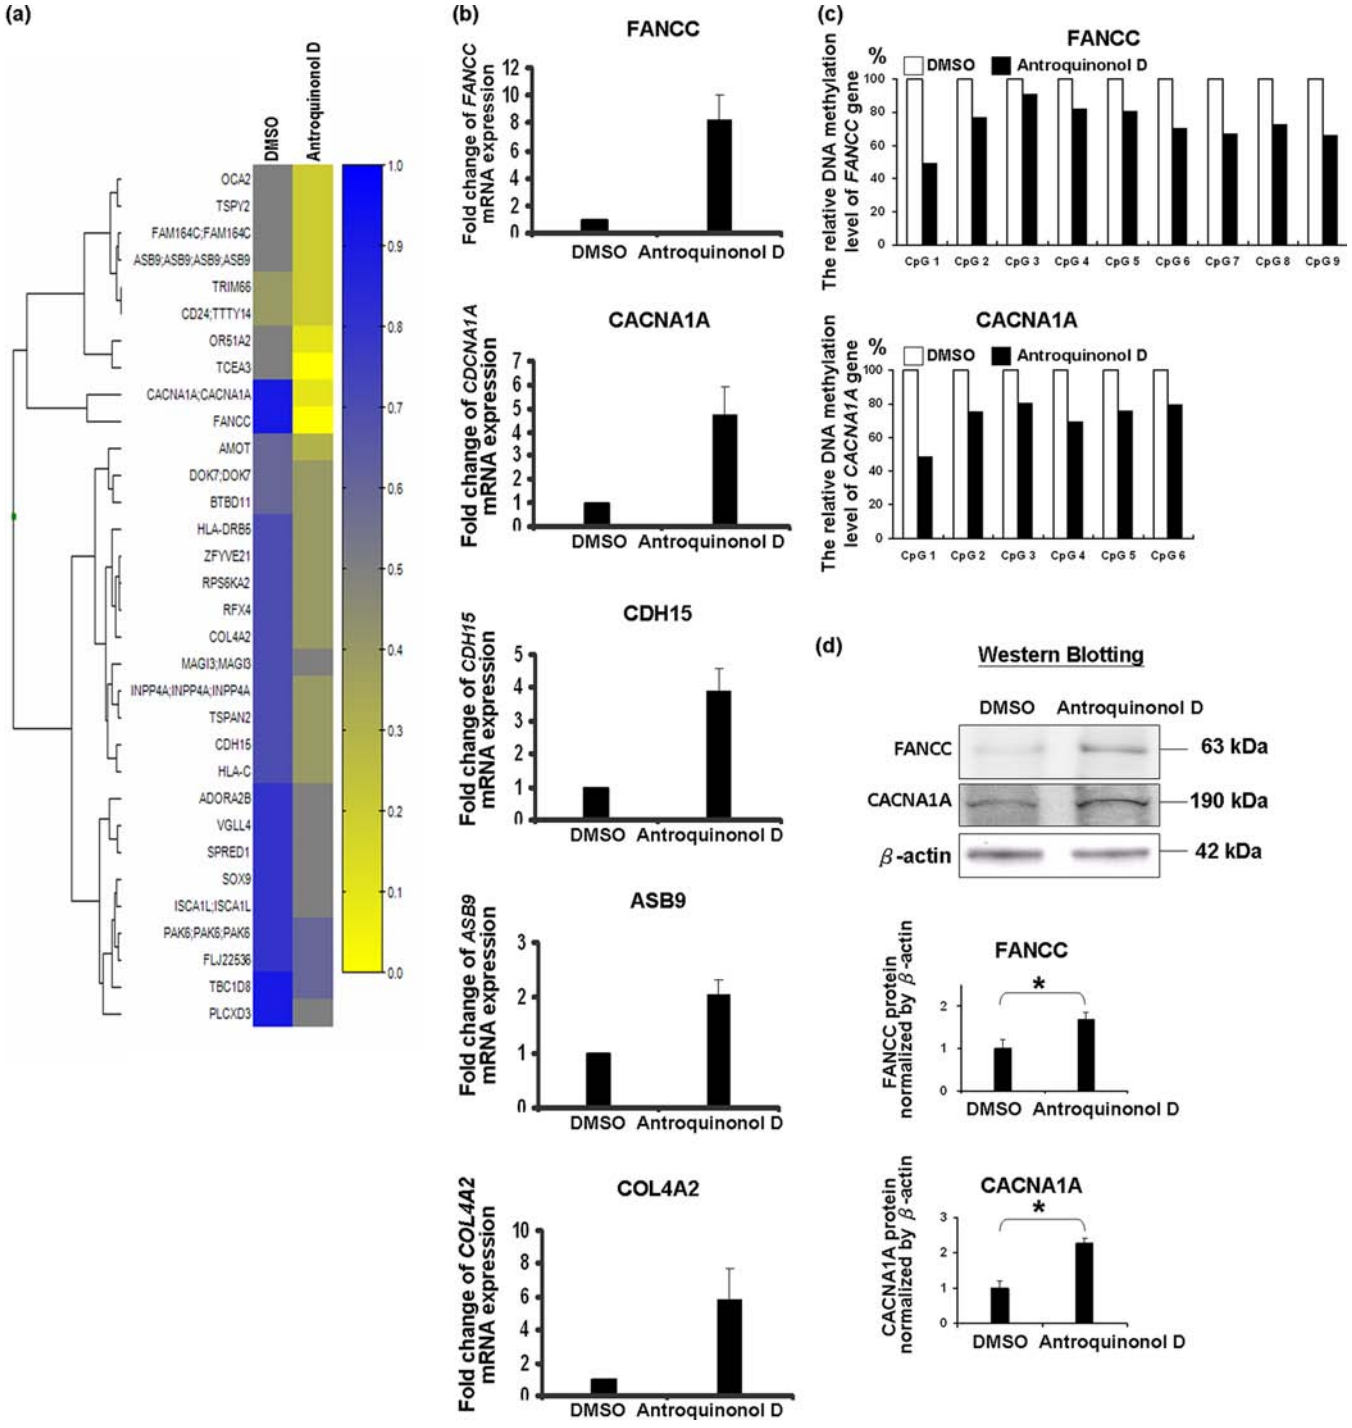

Figure 6. Antroquinonol D induces tumor suppressor gene demethylation and re-expression in cancer cells. (a) Methylation levels (ΔAvg_Beta >0.25) at the differentially methylated loci were identified using an Illumina Methylation 450 K array-based assay following treatment with DMSO or 15 μM antroquinonol D for 6 days in MDA-MB-231 cells and are represented on the heat map. The scale shows the relative methylation status (yellow indicates hypomethylation and blue indicates hypermethylation). (b) The mRNA levels of *FANCC*, *CACNA1A*, *CDH15*, *ASB9* and *COL4A2* were identified using real-time RT-PCR after the cells had been treated with 15 μM antroquinonol D for 6 days. The data are presented as the means ± s.d. Note that the DNA demethylation status of RPS6KA2 was detected using the Methylation 450 K array-based assay. However, RPS6KA2 mRNA expression cannot be detected using real-time RT-PCR. The experiments were performed with at least three technical replicates. (c) Pyrosequencing was used to confirm the DNA methylation status of the *FANCC* and *CACNA1A* genes following treatment with 15 μM antroquinonol D for 6 days in MDA-MB-231 cells. (d) The protein expression levels of FANCC and CACNA1A were analyzed via Western blotting following treatment with 15 μM antroquinonol D for 6 days. The data are presented as the means ± s.d. * $P \leq 0.001$. The experiments were performed with at least three technical replicates. The *t* test was used to calculate group differences in all experiments.

CACNA1A, *CDH15* and *COL4A2* genes were located within their gene bodies (Table 1). Whether those regions are important for gene expression requires further investigation. Fewer genes were demethylated following antroquinonol D treatment than were previously reported to be demethylated following DAC treatment.[41] We postulated that DAC

dx.doi.org/10.1021/jf4056924 | J. Agric. Food Chem. 2014, 62, 5625−5635

Table 1. Demethylation of Tumor Suppressor Genes

demethylation (Δ Avg_Beta)[a]	gene name	coverage of gene regions[b]	relation to CpG island[c]	function	reference
−0.881	FANCC	5′UTR	island shore	DNA repair	Low expression of FANCC is observed in late stage of ovarian cancer.[37]
−0.702	CACNA1A	gene body	island shore	calcium channels	High methylation of *CACNA1A* is determined in lung tumors.[38]
−0.323	CDH15	gene body	island shelf	cell−cell adhesion	Frequent promoter methylation of *CDH15* is associated with poor prognosis in liver cancer.[39]
−0.277	ASB9	TSS200	no	inhibition of cytokine signaling	Low expression of ASB9 in colorectal cancer is associated with poor prognosis.[40]
−0.274	RPS6KA2	gene body	no	inhibition of proliferation	RPS6KA2 reduces proliferation, causes G1 arrest, increases apoptosis.[43]
−0.253	COL4A2	gene body	within island	inhibition of angiogenesis	COL4A2 protein retards the growth of pancreatic cancer through inhibiting angiogenesis.[41,42]

[a]Demethylation (ΔAvg_Beta) indicates that the change level of DNA methylation in specific gene between DMSO control and antroquinonol D treatment. The data were calculated by antroquinonol D. Avg_Beta − DMSO.Avg_Beta. "Beta" scores are based on the ratio of methylated signal intensity to the sum of both methylated and unmethylated signal outputs. [b]The relative position between DNA demethylation region and the specific tumor suppressor gene. [c]The relative position between DNA demethylation region and the CpG island.

incorporates into replicating DNA, inducing the chelation and degradation of the DNMT1 protein, thereby preventing DNA methylation. Therefore, the mechanism underlying antroquinonol D-mediated DNMT1 inhibition differs from that of DAC and AZA, and therefore, antroquinonol D may be used as an alternative DNMT inhibitor. Antroquinonol D may induce far fewer cytotoxic effects than DAC because only certain genes are demethylated following antroquinonol D treatment. Therefore, antroquinonol D may still be worth optimizing to generate a more specific DNMT inhibitor.

In conclusion, we identified a new DNMT1 inhibitor, antroquinonol D, which induced DNA demethylation and reversed the silencing of multiple tumor suppressor genes, induced cancer cell death and inhibited cell migration. Further investigation of antroquinonol D using molecular biochemistry assays, animal studies, pharmacokinetics assays and clinical studies is required to determine whether antroquinonol D can be used clinically.

Coumestan Inhibits Radical-Induced Oxidation of DNA: Is Hydroxyl a Necessary Functional Group?

Gao-Lei Xi and Zai-Qun Liu*

Department of Organic Chemistry, College of Chemistry, Jilin University, Changchun 130021, China

Supporting Information

ABSTRACT: Coumestan is a natural tetracycle with a C═C bond shared by a coumarin moiety and a benzofuran moiety. In addition to the function of the hydroxyl group on the antioxidant activity of coumestan, it is worth exploring the influence of the oxygen-abundant scaffold on the antioxidant activity as well. In this work, seven coumestans containing electron-withdrawing and electron-donating groups were synthesized to evaluate the abilities to trap 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonate) cationic radical ($ABTS^{\bullet+}$), 2,2′-diphenyl-1-picrylhydrazyl radical (DPPH), and galvinoxyl radical, respectively, and to inhibit the oxidations of DNA mediated by $^{\bullet}OH$, Cu^{2+}/glutathione (GSH), and 2,2′-azobis(2-amidinopropane hydrochloride) (AAPH), respectively. It was found that all of the coumestans used herein can quench the aforementioned radicals and can inhibit $^{\bullet}OH$-, Cu^{2+}/GSH-, and AAPH-induced oxidations of DNA. In particular, substituent-free coumestan exhibits higher ability to quench DPPH and to inhibit AAPH-induced oxidation of DNA than Trolox. In addition, nonsubstituted coumestan shows a similar ability to inhibit $^{\bullet}OH$- and Cu^{2+}/GSH-induced oxidations of DNA relative to that of Trolox. The antioxidant effectiveness of the coumestan can be attributed to the lactone in the coumarin moiety and, therefore, a hydroxyl group may not be a necessary functional group for coumestan to be an antioxidant.

KEYWORDS: *coumestan, antioxidant, free radical, DNA oxidation*

INTRODUCTION

Coumestan is a naturally occurring skeleton with a coumarin moiety and a benzofuran moiety sharing a C═C bond (structure in Scheme 1). 2-Methoxy-3,8,9-trihydroxy coumestan, also called as wedelolactone, is the typically natural coumestan and exhibits various biological activities[1] such as antifibrotic,[2] antiadipogenesis,[3] and immunosuppressive effects.[4] However, the antioxidant effects of coumestans, especially substituent-free coumestans, are not usually reported.[5] In previously published studies, the pharmacological activities of coumestans are regarded as the contributions from hydroxyl groups.[6] In particular, the hydroxyl group attached to the benzofuran (ring D) mainly controls the redox state[7] and thus plays the major role in the biological activities for coumestans.[8] However, the influence of substituents at ring D on the antioxidant effectiveness remains unclear. In particular, it is worth clarifying the function of the coumestan scaffold itself (without any substituents attached) on the antioxidant effectiveness. These backgrounds encourage us to investigate the antioxidant effectiveness of coumestan with and without the substituent attached to ring D and to clarify whether the hydroxyl group is a necessary substituent for generating the antioxidant effectiveness.

The radical-induced oxidation of DNA is a suitable experimental system for estimating the antioxidant effectiveness of natural or synthetic compounds.[9] $^{\bullet}OH$, Cu^{2+}/glutathione (GSH), and 2,2′-azobis(2-amidinopropane hydrochloride) (AAPH) are usually used as radical initiators because they are able to mimic DNA undergoing oxidation caused by hydroxyl, glutathione, and peroxyl radicals. In addition, as the stable radicals at room temperature, 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonate) cationic radical ($ABTS^{\bullet+}$), 2,2′-diphenyl-1-picrylhydrazyl radical (DPPH), and galvinoxyl radical are applied to evaluate the ability of an antioxidant to donate its hydrogen atom to N- and O-centered radicals. Therefore,

presented herein is a study on the antioxidant effects of seven coumestans with electron-withdrawing groups (−Cl, −Br) and electron-donating groups (−OCH_3 and −OH). The abilities to quench $ABTS^{\bullet+}$, DPPH, and galvinoxyl radical, respectively, and to inhibit the oxidations of DNA caused by $^{\bullet}OH$, Cu^{2+}/GSH, and AAPH, respectively, are estimated to reveal the role of the coumestan scaffold in the generation of antioxidant effectiveness.

MATERIALS AND METHODS

Materials and Instrumentation. ABTS, DPPH, and galvinoxyl radicals were purchased from Fluka Chemie GmbH, Switzerland, and AAPH and naked DNA sodium salt were purchased from Acros Organics, Belgium. Other agents were of analytical grade and used directly. The structures of products were identified by ^1H and ^{13}C NMR (Bruker Avance III 400 MHz sprctrometer), and the spectra are included in the Supporting Information.

Synthesis and Identification of Coumestan Structure. Esterification of Methyl Salicylate. To a mixture of methyl salicylate (1.52 g, 10 mmol) and the corresponding phenylacetic acid (11 mmol) in 10 mL of pyridine at 0−10 °C was added dropwise $POCl_3$ (1.1 mL, 12 mmol) within 0.5 h under stirring. After the above mixture was stirred for 3 h at 0−10 °C, the concentrated HCl was added to adjust pH 5−6 at the same temperature. The mixture was extracted by ethyl acetate at room temperature, and the organic phase was washed by brine and dried over Na_2SO_4. After the solvent was evaporated under vacuum, the obtained crude product was purified by silica chromatography with ethyl acetate and petroleum ether being eluents to afford a white product with a yield >70%.

Ester Condensation for the Formation of Coumarins. The phenylacetic ester of methyl salicylate (5 mmol) was mixed with anhydrous pyridine (5 mL), followed by the addition of KOH powder (0.7 g, 12.5 mmol) at room temperature. After the mixture was stirred for 6 h in a nitrogen atmosphere, pyridine was evaporated under vacuum, and 15 mL of NaOH (2.0 M) was added. The water phase was washed with ethyl acetate and then acidized by concentrated HCl to adjust the pH to 4−5. The aqueous solution was cooled to afford the crude product, a white solid with a yield >55%.

Oxidative Annulation for the Formation of Coumestans. To 30 mL of dried 1,2-dichloroethane solution of the ester condensation products (2.5 mmol) were added anhydrous $FeCl_3$ (1.625 g, 10 mmol) and silica powder (1.625 g), and the mixture was refluxed for 10 h. The solvent was then evaporated under vacuum, and the residue was purified by silica chromatography with ethyl acetate and petroleum ether being eluents to afford white coumestans with yields >60%.

To obtain hydroxyl-substituted coumestan, the methoxyl group should be converted into a hydroxyl group by demethylation. In brief, methoxyl-substituted coumestan (1.0 mmol, dissolved in 10 mL of anhydrous CH_2Cl_2) was added dropwise to 10 mL of CH_2Cl_2 solution of BBr_3 (1.0 M) within 30 min at 0 °C and stirred overnight at room temperature. The reaction mixture was hydrolyzed at 0 °C. The obtained precipitate was purified by silica chromatography with ethyl acetate and petroleum ether (1:2, v/v) being eluent to afford a white product with a yield >90%.

*9-Bromo-6H-benzofuro[3,2-c]chromen-6-one (**5**):* R_f = 0.39 (ethyl acetate/petroleum ether = 1:9, v/v), 0.42 g of white product, yield 53%; mp 213−215 °C; ^1H NMR (400 MHz, $CDCl_3$) δ 8.03 (t, J = 8.0 Hz, 2H), 7.87 (d, J = 1.2 Hz, 1H), 7.61−7.68 (m, 2H), 7.53−7.55 (m, 1H), 7.45 (t, J = 7.6 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 160.3, 157.7, 155.6, 153.8, 132.3, 128.8, 124.8, 122.7, 122.6, 121.9, 120.1, 117.6, 115.4, 112.3, 105.6.

*9-Hydroxy-6H-benzofuro[3,2-c]chromen-6-one (**6**):* R_f = 0.29 (ethyl acetate/petroleum ether = 1:2, v/v), 0.24 g of white product, yield 96%; mp 291−293 °C; ^1H NMR (400 MHz, DMSO-d_6) δ 10.16 (s, 1H), 8.03 (s, 1H), 7.78 (s, 1H), 7.69 (s, 1H), 7.60 (m, 1H), 7.49 (s, 1H), 7.22 (s, 1H), 7.00 (s, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 158.1, 157.7, 157.1, 156.4, 152.5, 131.5, 124.9, 121.2, 121.1, 117.0, 114.4, 114.3, 112.1, 105.3, 98.6.

*8,9-Dihydroxy-6H-benzofuro[3,2-c]chromen-6-one (**7**):* R_f = 0.18 (ethyl acetate/petroleum ether = 1:2, v/v), 0.24 g of white product, yield 91%; mp > 300 °C; ^1H NMR (400 MHz, DMSO-d_6) δ 9.65 (s, 1H), 9.53 (s, 1H), 8.00 (d, J = 8.0 Hz, 1H), 7.64−7.68 (m, 1H), 7.57−7.59 (m, 1H), 7.48 (t, J = 7.6 Hz, 1H), 7.30 (s, 1H), 7.24 (s, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 158.2, 157.9, 152.8, 149.9, 147.0, 145.2, 131.7, 125.4, 121.6, 117.5, 114.3, 112.9, 106.0, 105.4, 99.4.

Scavenging $ABTS^{\bullet+}$, DPPH, and Galvinoxyl Radicals. A 2.0 mL of aqueous solution containing 4.0 mM ABTS and 1.41 mM $K_2S_2O_8$ was kept for 20 h to form $ABTS^{\bullet+}$ and then diluted by 100 mL of ethanol. The absorbance of $ABTS^{\bullet+}$ was around 1.00 at 734 nm ($\varepsilon_{ABTS^{\bullet+}} = 1.6 \times 10^4\ M^{-1}\ cm^{-1}$). DPPH and galvinoxyl radicals were dissolved in ethanol directly. The absorbances of DPPH and galvinoxyl radicals were around 1.00 at 517 nm ($\varepsilon_{DPPH} = 4.09 \times 10^3\ M^{-1}\ cm^{-1}$) and 428 nm ($\varepsilon_{galvinoxyl} = 1.4 \times 10^5\ M^{-1}\ cm^{-1}$), respectively. A certain concentration of DMSO solution of a coumestan (0.1 mL) was added to 1.9 mL of $ABTS^{\bullet+}$, DPPH, and galvinoxyl radical solutions, respectively. The decreases of the absorbance of these radicals were recorded at 25 °C at a certain time interval.

Cu^{2+}/GSH- and $^{\bullet}OH$-Induced Oxidations of DNA. Cu^{2+}/GSH-induced oxidation of DNA was carried out according to the following description. Briefly, DNA, $CuSO_4$, and GSH were dissolved in phosphate-buffered solution (PBS_1: 6.1 mM Na_2HPO_4, 3.9 mM NaH_2PO_4), and coumestans were dissolved in dimethyl sulfoxide (DMSO) as the stock solution. Then, a solution of 2.0 mg/mL DNA, 5.0 mM Cu^{2+}, 3.0 mM GSH, and 0.2 mM coumestan was poured into test tubes with each containing 2.0 mL. The test tubes were incubated at 37 °C for initiating the oxidation of DNA. Three test tubes were taken out at 90 min and cooled immediately. PBS_1 solution of EDTA (1.0 mL, 30.0 mM) was added to chelate Cu^{2+}, followed by adding 1.0 mL of thiobarbituric acid (TBA) solution (1.00 g of TBA and 0.40 g of NaOH dissolved in 100 mL of PBS_1) and 1.0 mL of 3.0% trichloroacetic acid aqueous solution. The test tubes were heated in boiling water for 30 min and cooled to room temperature, and 1.5 mL of *n*-butanol was added and shaken vigorously to extract thiobarbituric acid reactive substance (TBARS) for measuring the absorbance at 535 nm.

$^{\bullet}OH$ can be generated in the mixture of H_2O_2 and tetrachlorohydroquinone (TCHQ, dissolved in DMSO as the stock solution). DNA and H_2O_2 were dissolved in phosphate-buffered solution (PBS_2: 8.1 mM Na_2HPO_4, 1.9 mM NaH_2PO_4, 10.0 μM EDTA). A solution of 2.0 mg/mL DNA, 4.0 mM TCHQ (dissolved in DMSO as the stock solution), 2.0 mM H_2O_2, and 0.2 mM coumestan (dissolved in DMSO as the stock solution) was poured into test tubes with each containing

dx.doi.org/10.1021/jf500013v | J. Agric. Food Chem. 2014, 62, 5636−5642

2.0 mL. The test tubes were incubated at 37 °C for initiating the oxidation of DNA. Three test tubes were taken out at 30 min and cooled immediately. Then, 1.0 mL of TBA solution (1.00 g of TBA and 0.40 g of NaOH dissolved in 100 mL of PBS_2) and 1.0 mL of 3.0% trichloroacetic acid aqueous solution were added and heated in boiling water for 30 min. After the test tubes were cooled to room temperature, 1.5 mL of *n*-butanol was added and shaken vigorously to extract TBARS for measuring the absorbance at 535 nm. In the aforementioned two tests, the absorbances in the control experiment and in the presence of coumestans were assigned as A_0 and A_{detect}, respectively. The effects of coumestans on the oxidation of DNA were expressed by $A_{detect}/A_0 \times 100$.

AAPH-Induced Oxidation of DNA Test. A solution of 2.0 mg/mL DNA (dissolved in PBS_2), 40 mM AAPH (dissolved in PBS_2), and a certain concentration of a coumestan (dissolved in DMSO as the stock solution) was poured into test tubes with each containing 2.0 mL. The test tubes were incubated at 37 °C for initiating the oxidation of DNA. Three of them were taken out every 2 h and cooled immediately. Then, 1.0 mL of TBA solution (1.00 g of TBA and 0.40 g of NaOH dissolved in 100 mL of PBS_2) and 1.0 mL of 3.0% trichloroacetic acid aqueous solution were added and heated in boiling water for 15 min. After the test tubes were cooled to room temperature, 1.5 mL of *n*-butanol was added and shaken vigorously to extract TBARS for measuring the absorbance at 535 nm. The absorbance of TBARS was plotted versus the reaction period.

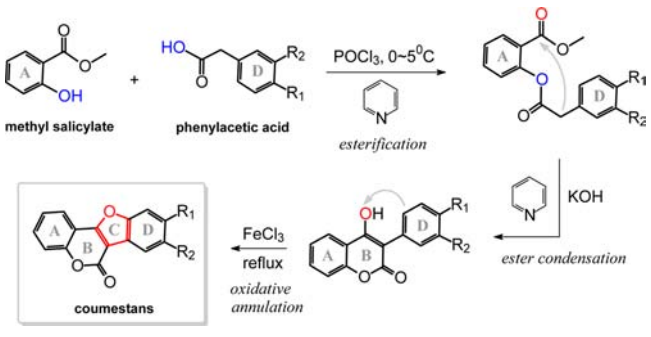
Statistical Analysis. All of the data were the average value from at least three independent measurements with the experimental error within 10%. The equations were analyzed by one-way ANOVA in Origin 6.0 professional software, and $p < 0.001$ indicated a significance difference.

RESULTS AND DISCUSSION

Synthesis of Coumestans and Scavenging Radicals. As a naturally occurring oxygen-abundant tetracycle, the structure of coumestan contains a coumarin and a benzofuran with a C═C shared by the lactone of coumarin and the furan ring. In the past decade, efforts contributing to the synthesis of coumestan have mainly focuseed on constructing the lactone ring.[10,11] The applications of some reactions such as Sonogashira and Suzuki coupling conditions simplify the ring closure of lactone in coumarin,[12,13] but the difficulty in the preparation of catalysts still limits the widespread use of the aforementioned method in the synthesis of coumestans. As shown in Scheme 2, we herein follow another paper, in which furan ring closure acts as the key step catalyzed by $FeCl_3$.[14]

$FeCl_3$ drives the dehydrogenation from the aromatic ring (D) and hydroxyl group (attaching to ring B) to form a furan ring in the refluxing 1,2-dichloroethane. An intramolecular ester condensation in phenylacetate of methyl salicylate leads to the formation of lactone in coumarin before the final step. Therefore, it can be found that substituents in coumestan should be allocated at phenylacetic acid and methyl salicylate in advance. In this work, chloro-, bromo-, and single- or double-methoxyl-substituted phenylacetic acids are used as the reagents, and the substituents locate at the benzofuran ring of coumestans. We herein used the results from our previous studies (shown in Scheme 3) to emphasize the importance of the coumestan structure for enhancing the antioxidant effectiveness. Therefore, xanthotoxol is selected as the model for a multiheterocycle containing a single hydroxyl group, whereas compounds MPCP and **4a** are chosen to be the model for a catechol moiety linking with coumarin via a single C−C bond. The antioxidant effect of the hydroxyl group in xanthotoxol, a furan-substituted coumarin, is not high enough.[15] In comparison with the high antioxidant effectives of coumestan, it can be concluded that a hydroxyl group directly attaching to the coumarin scaffold cannot exhibit high antioxidant effectiveness, but the coumarin scaffold can increase the antioxidant effectiveness of the hydroxyl group attaching to coumestan. Moreover, our previous research indicates that the hydroxyl group at coumarin in compound **4a** (see Scheme 3, the stoichiometric factor, *n*, is 6.15, for the physical meaning, see below) cannot improve the antioxidant effectivess of catechol moiety. Contrarily, a hydroxyl-free coumarin moiety enhances the antioxidant effectiveness of compound MPCP (see Scheme 3, the stoichiometric factor, *n*, is 6.60).[16] By comparing the stoichiometric factors (n) of compound **4a** and MPCP, it can be concluded that coumarin cannot remarkably influence the antioxidant effectiveness of the catechol moiety linking coumarin with a single C−C bond. Therefore, the result presented herein reveals that the benzofuran in combination with the coumarin scaffold is able to generate high antioxidant effectiveness even without an attached hydroxyl group.

Scheme 2. Synthetic Routines of Coumestans



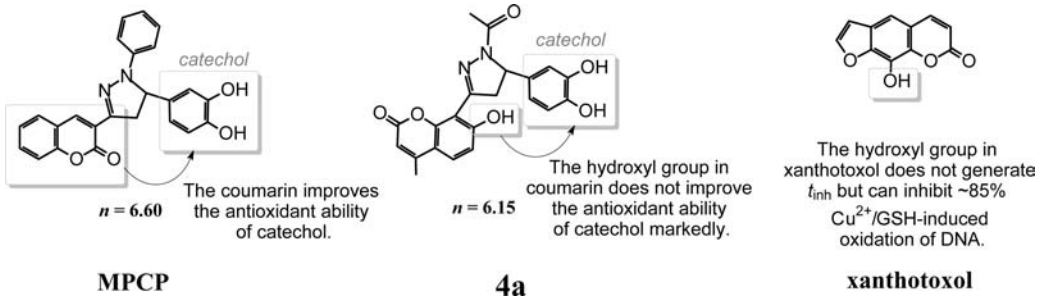
Scavenging radicals is regarded as the primary property of an antioxidant, and $ABTS^{\bullet+}$, DPPH, and galvinoxyl radicals are stable radicals at ambient temperature for evaluating the abilities of the antioxidant to reduce and to donate its hydrogen atom to N- and O-centered radicals, respectively.[17] Figure 1S in the Supporting Information outlines rapid decays of the concentrations of these radicals in the presence of coumestans. The coumestans are able to quench these radicals even in the absence of a hydroxyl group, indicating that the hydroxyl group is not a necessary functional group for coumestans to quench radicals. In addition to some thermodynamic methods for expressing the radical-scavenging ability of the antioxidant,[18] kinetic parameters such as the rate constant (k) can reveal the reaction rate between an antioxidant and a radical. We herein apply the rate constant to characterize the radical-scavenging abilities of coumestans. It has been proved that the reaction between an antioxidant and DPPH follows second-order kinetics as shown in eq 1.[19]

$$-\frac{\mathrm{d[DPPH]}}{\mathrm{d}t} = r = k[\mathrm{DPPH}][\mathrm{antioxidant}] \quad (1)$$

The above equation expresses the relationship among the concentrations of two reagents and the reaction rate (r) during the whole reaction period. Thus, eq 1 is also available when the reaction time is 0, and $[\mathrm{DPPH}]_{t=0}$ and $[\mathrm{antioxidant}]_{t=0}$ represent the concentrations of DPPH and the antioxidant at the beginning of the reaction. If the reaction rate at the beginning of the reaction (r_0) is measured according to the method in a previous paper[20] (data in Table 1S), the rate constant (k) can be calculated by using eq 2:

dx.doi.org/10.1021/jf500013v | J. Agric. Food Chem. 2014, 62, 5636−5642

Scheme 3. Contributions of Coumarin and Furan Moieties to the Antioxidant Effects



$$r_0 = k[\mathrm{DPPH}]_{t=0}[\mathrm{antioxidant}]_{t=0} \quad (2)$$

On the basis of the above method,[20] the rate constants (k) of coumestans in trapping $ABTS^{\bullet+}$, DPPH, and galvinoxyl radicals are obtained and listed in Table 1. It is worth noting that the reaction between an antioxidant and a radical behaves as first-order when the concentration of the antioxidant is in excess of the radical, but the concentration of the antioxidant should exceed that of the radical for ~100-fold to keep the concentration of the antioxidant almost constant during the reaction. As listed in the footnote of Table 1S, the antioxidant concentrations used herein are generally in excess of that of radicals by 5−10-fold, and thus, the reaction rate cannot be readily obtained following the first-order kinetics. As pointed out in eq 1, the reaction rate is simultaneously related to the concentrations of the antioxidant and the radical. Hence, a double-exponential function is selected to express the correlation of the reaction rate with the concentrations of two reagents to precisely estimate the reaction rate as shown in Table 1S, of which the important data are collected in Table 1. The data in the second column of Table 1 show that the k values of coumestans in trapping $ABTS^{\bullet+}$ are lower than that of Trolox. The reaction of an antioxidant with $ABTS^{\bullet+}$ shows the ability of the antioxidant to reduce the radical, and the coumestans possess low abilities to reduce the radical. This can be understood from a previous paper,[21] in which the oxidative potential of compound **7** (591.4 mV), a hydroxyl-substituted coumestan, is higher than that of general phenolic antioxidants. Therefore, the reductive ability of the coumestan is still dependent upon the phenolic hydroxyl group. On the other hand, the data in the third column of Table 1 show that the k values of coumestans in trapping DPPH are higher than that of Trolox (0.353 mM^{-1} s^{-1}). In particular, the k values of compounds **6** and **7** are as high as 7.20 and 14.81 mM^{-1} s^{-1}, respectively, and the k values of compounds **1**−**5** range from 0.6 to 1.0 mM^{-1} s^{-1}. The reaction between an antioxidant and DPPH shows the ability of the antioxidant to donate its hydrogen atom or electron to N-centered radicals, so the hydrogen atom of the hydroxyl group in coumestan still plays the major role in quenching N-centered radicals, and the coumestan scaffold (without the hydroxyl group attached) can also provide the electron for N-centered radicals. This is in agreement with a previous study on coumestan with electron-transferring efficiency higher than that of other phenols.[22] In this work,[22] coumestan was applied to modify an electrode for electro-oxidizing hydrazine with the anodic peak potential being 320 mV, whereas the oxidation cannot take place until 1100 mV on an unmodified electrode, demonstrating that coumestan plays the electron-transferring role in the oxidation at the electrode. This can be understood by eq 3 (see below), in which the cleavage of the C−O bond generates double single electrons for accepting electrons from other species. However, the electron-donating activity of coumestan also depends upon the electron receptor because, as can be seen from the data in the fourth column of Table 1, the coumestans used herein exhibit different properties in reacting with DPPH and galvinoxyl radicals. The hydroxyl-involved coumestans such as compounds **6** and **7** possess higher k values (2.40 and 6.99 mM^{-1} s^{-1}, respectively) than Trolox (1.70 mM^{-1} s^{-1}) in quenching the galvinoxyl radical, whereas the k values for compounds **1**−**5** (ranging from 0.1 to 0.5 mM^{-1} s^{-1}) are lower than that of Trolox. The galvinoxyl radical as an O-centered radical accepts the hydrogen atom from the hydroxyl group of coumestans readily but shows difficulty in accepting the electron from the coumestan scaffold. The hydroxyl group other than the coumestan scaffold plays the major role in quenching the O-centered radical. Thus, the coumestan scaffold can also be an electron donator for quenching radicals. This finding encourages us to test whether the radical-scavenging property of coumestans can also be applied to inhibit radical-mediated oxidation of biological species.

Table 1. Rate Constant (k) for Coumestans and Trolox in Scavenging $ABTS^{\bullet+}$, DPPH, and Galvinoxyl Radicals

	rate constant for coumestans and Trolox in scavenging radicals, k (mM^{-1} s^{-1})		
compd	$ABTS^{\bullet+}$	DPPH	galvinoxyl radical
1	0.14	0.73	0.17
2	0.19	0.65	0.34
3	0.14	1.02	0.14
4	0.23	0.79	0.34
5	0.25	0.79	0.44
6	3.06	7.20	2.40
7	8.95	14.81	6.99
Trolox	29.2	0.353	1.70

Inhibiting Cu^{2+}/GSH and $^{\bullet}OH$-Induced Oxidations of DNA. GSH can be oxidized by copper ions (Cu^{+} and Cu^{2+}) to form the glutathione radical ($GS^{\bullet}$) in vivo,[23] and $^{\bullet}OH$ is a well-known radical generated from the metabolism in the process of in vivo oxidative stress.[24] Both $GS^{\bullet}$ and $^{\bullet}OH$ are harmful radicals that can initiate oxidative damage of biological species, in which DNA is one of the susceptible biological species to the aforementioned radicals. The in vitro oxidations of DNA caused by $GS^{\bullet}$ and $^{\bullet}OH$ can be used as the experimental system for evaluating the antioxidant activity because the oxidative products from the oxidation of DNA can be readily detected after reaction with TBARS.[25] Thus, the activities of coumestans are characterized by inhibiting Cu^{2+}/GSH- and $^{\bullet}OH$-induced oxidations of DNA. The absorbances of TBARS

dx.doi.org/10.1021/jf500013v | J. Agric. Food Chem. 2014, 62, 5636−5642

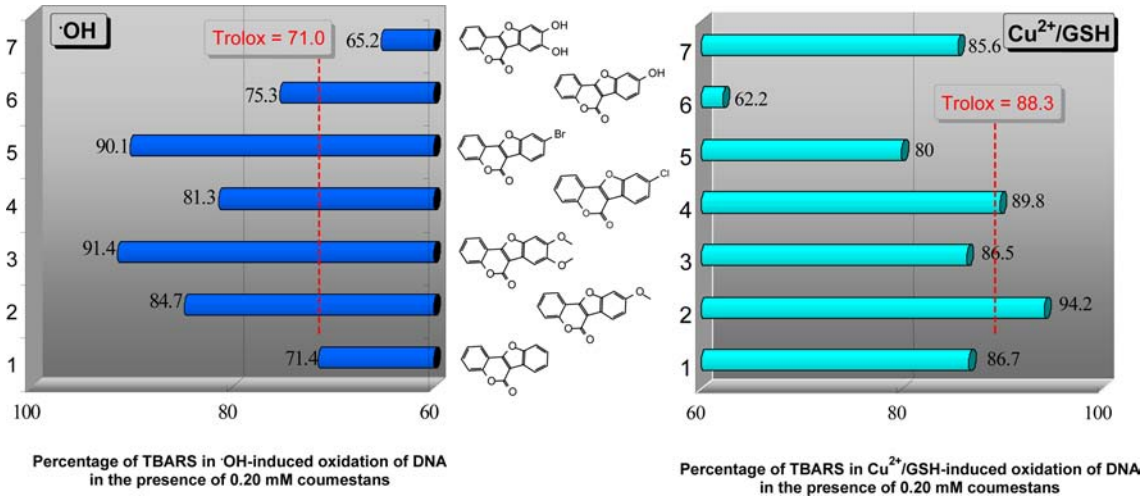


Figure 1. Percentage of TBARS in the presence of 0.20 mM coumestans when the oxidation of DNA (2.0 mg/mL) is caused by 5.0 mM Cu^{2+} and 3.0 mM GSH for 90 min (right panel) or 4.0 mM H_2O_2 and 2.0 mM tetrachlorohydroquinone (TCHQ) for 30 min (left panel).

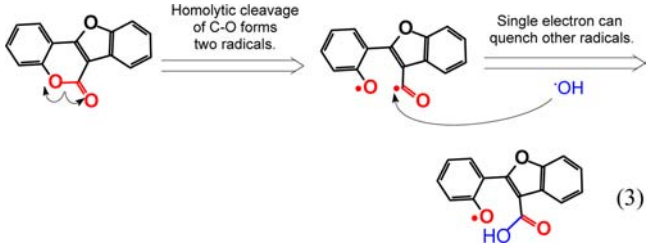
when DNA undergoes Cu^{2+}/GSH-induced oxidation for 90 min and •OH-induced oxidation for 30 min are assigned to be 100% as the control. The absorbances of TBARS in the presence of 0.20 mM various coumestans and Trolox are compared with the control and shown in Figure 1, in which a low percentage of TBARS means a high antioxidant effectiveness.

The data in Figure 1 show that all of the coumestans used herein can inhibit both Cu^{2+}/GSH- and •OH-induced oxidations of DNA, and thus coumestans either containing a hydroxyl group or not behave as antioxidants to protect DNA against the aforementioned oxidative damage. Especially, the TBARS percentage of Trolox in inhibiting •OH-induced oxidation of DNA (71.0%) is similar to that of compound **1** (71.4%), revealing that the coumestan scaffold is able to protect DNA against •OH-induced oxidation. Compound **7** generates a low TBARS percentage (65.2%), because it contains double hydroxyl groups at adjacent positions, a classic structure for antioxidant. The TBARS percentages in the presence of other coumestans (compounds **2**–**6**) are higher than that of compound **1**, indicating that substituents are not beneficial for enhancing the antioxidant abilities of coumestans in this case. In the experimental system of Cu^{2+}/GSH-induced oxidation of DNA, the TBARS percentage in the presence of compound **1** (86.7%) also approaches that of Trolox (88.3%), indicating that the unsubstituted coumestan can also protect DNA against Cu^{2+}/GSH-induced oxidation. Moreover, as reported in our previous work, xanthotoxol (structure in Scheme 3) decreases the TBARS percentage only to 85%,[15] similar to that of the coumestan (86.7%). Therefore, one hydroxyl group attaching to the coumarin moiety (as xanthotoxol) results in the same antioxidative efficiency as the coumestan scaffold (without any substituents attached). Moreover, a hydroxyl group attaching to coumestan as in compound **6** decreases the TBARS percentage to 62.2%, indicating that one hydroxyl group attached to the benzofuran moiety leads to a high activity for coumestan to inhibit Cu^{2+}/GSH-induced oxidation of DNA. The TBARS percentages of other coumestans (compounds **2**–**5** and **7**) are around that of coumestan (86.7 ± 10%), implying that these substituents do not influence the inhibiting effects of coumestans on Cu^{2+}/GSH-induced oxidation of DNA markedly. The antioxidant mechanism of hydroxyl-substituted coumestan is undoubtedly attributed to the hydroxyl group providing a hydrogen atom to quench radicals. •OH is so reactive that it can attack any part of the molecule, including the aromatic rings. However, in a previous study the lactone of the coumarin moiety is hypothesized to be the receptor for the nucleophilic addition.[26] This may be a mechanism for coumestan to scavenge radicals. As shown in eq 3, the homolytic cleavage of the ester bond in the lactone (the only bond not participating in the aromatic system of coumestan) generates two single electrons, which can recombine with other radicals. Therefore, it is necessary to measure how many radicals can be trapped by one molecule of coumestan.



(3)

Inhibiting AAPH-Induced Oxidation of DNA. The AAPH-induced oxidation of DNA is selected to be the experimental system[27] because the number of radicals trapped by an antioxidant in this case can be calculated according to chemical kinetic deduction,[28] and the oxidative products from DNA can be followed by measuring TBARS as well. We have measured the numbers of radicals trapped by some antioxidants in this experimental system,[29] and here we also adopt the same experimental system for quantitatively comparing the antioxidant effectiveness of coumestans. Therefore, as shown in Figure 2S, an increase of the absorbance means that much TBARS is generated the longer the reaction time in the blank experiment. However, the addition of coumestan hinders the formation of the TBARS for a period, and then the TBARS are produced as in the blank experiment. The inhibition period (t_{inh}) can be measured from the beginning of the reaction to the cross point of tangents for the inhibition and the increasing period in the absorbance line. The relationships between t_{inh} and the concentrations of coumestans are outlined in Figure 3S

dx.doi.org/10.1021/jf500013v | J. Agric. Food Chem. 2014, 62, 5636−5642

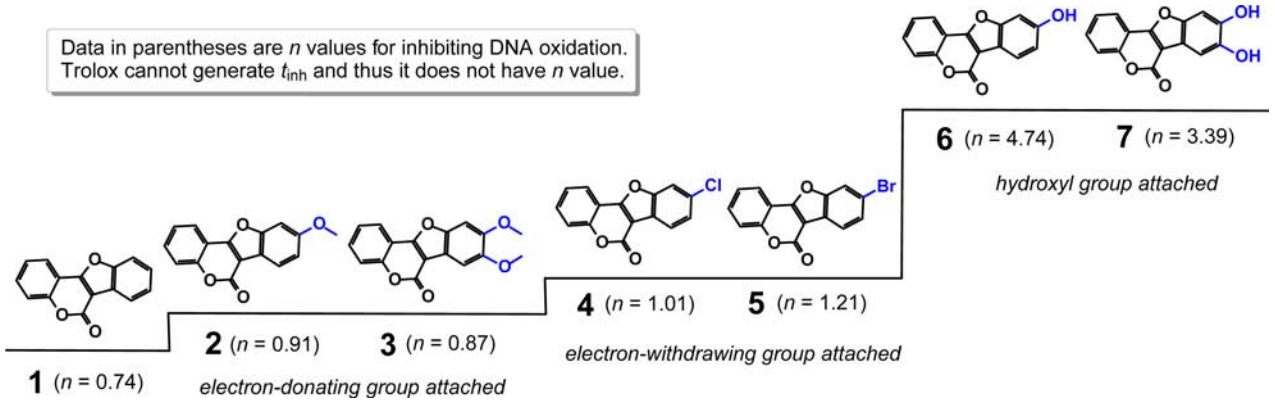


Figure 2. *n* values of coumestans in inhibiting 40 mM AAPH-induced oxidation of 2.0 mg/mL DNA at 37 °C.

and expressed by the equation of $t_{inh} \sim$ [coumestans] (listed in Table 2S). On the basis of the equation $t_{inh} \sim$ [coumestans], the number of radicals trapped by coumestans can be calculated following chemical kinetics.

In view of chemical kinetics, the t_{inh} correlates proportionally with the concentration of an antioxidant as shown as in eq 4:[30]

$$t_{inh} = (n/R_i)[\text{antioxidant}] \quad (4)$$

R_i refers to the initiation rate of the radical-induced reaction. Both AAPH and the sodium salt of DNA are water-soluble compounds, and radicals generated from AAPH can attack DNA at the same phase. R_i is thereby assumed to be equal to the radical generation rate (R_g, $R_g = (1.4 \pm 0.2) \times 10^{-6}$[AAPH] s^{-1}[30]). *n* stands for stoichiometric factor, which is the number of the radicals trapped by one molecule of the antioxidant. The coefficient in the equation of $t_{inh} \sim$ [coumestan] is equivalent to (n/R_i) in eq 4. Hence, when $R_i = R_g = 1.4 \times 10^{-6} \times 40$ mM s^{-1} = 3.36 μM min^{-1} in this experimental system, the *n* value is the product of the coefficient in the equation of $t_{inh} \sim$ [coumestan] and R_i. The obtained *n* values of coumestans (listed in Table 2S) are outlined at different steps in Figure 2, in which the structures of coumestans are involved for revealing the influence of coumestan structure on *n* values.

The data in Figure 2 show that compounds **1**−**3** can scavenge less than one radical and compounds **4** and **5** can trap about one radical. The coumestans even in the absence of hydroxyl groups or in the presence of electron-withdrawing groups such as −Cl and −Br are still able to inhibit AAPH-induced oxidation of DNA. Interestingly, compounds **6** and **7** can trap 4.74 and 3.39 radicals, respectively, revealing that the phenolic hydroxyl group remarkably improves the antioxidant abilities of coumestans. However, compound **6**, a single-hydroxyl-substituted coumestan, can trap more radicals (*n* = 4.74) than compound **7**, a double-hydroxyl-substituted coumestan (*n* = 3.39), revealing that compound **6** exhibits a higher antioxidant effect than compound **7**. This is in agreement with the observation on Cu^{2+}/GSH-induced oxidation of DNA, in which compound **6** is a stronger antioxidant than compound **7**. On the other hand, as shown in Scheme 3, MPCP and **4a** are coumarin-substituted dihydropyrazoles with 6.60 and 6.15 *n* values, respectively,[16] higher than that of coumestans used herein. Therefore, the coumarin moiety as a single substituent can improve the antioxidant effect of the catechol moiety within the same molecule. On the contrary, the coumarin moiety as a part of the tetracycle cannot markedly ameliorate the antioxidant effect of the catechol moiety. Figure 2 also shows that the *n* values of compounds **2** and **3** (0.91 and 0.87, respectively) are lower than those of compounds **4** and **5** (1.01 and 1.21, respectively), indicating that an electron-withdrawing group such as −Cl or −Br can improve the antioxidant effect more than the electron-donating group such as $-OCH_3$ and double $-OCH_3$. This fact can be understood from eq 3. The formation of a radical by the cleavage of lactone is the key step for coumestan to accommodate the single electron from other radicals. An electron-withdrawing group is beneficial for coumestan to dispense electrons around the benzofuran and phenolic rings. Furthermore, we have also detected the effects of Trolox and xanthotoxol on AAPH-induced oxidation of DNA.[15] It is found that Trolox and xanthotoxol just affect the increasing rate of TBARS and cannot generate t_{inh}, leading to the *n* values of Trolox, and xanthotoxol cannot be obtained. Thus, coumestan (compound **1** with a 0.74 *n* value) possesses a higher antioxidant effect than Trolox and xanthotoxol.

In conclusion, as a naturally occurring structure, coumestans exhibit wide antioxidant properties, which are attributed not only to the hydroxyl group but to the coumestan scaffold donating or accommodating a single electron. On the contrary, substituents are not beneficial for enhancing antioxidant effectiveness when coumestans are applied to inhibit Cu^{2+}/GSH- and $^{\bullet}OH$-induced oxidations of DNA. In addition, the coumestan scaffold is more active in inhibiting AAPH-induced oxidation than Trolox and xanthotoxol. Therefore, the hydroxyl group may not be a necessary factor in inhibiting radical-mediated oxidation of DNA, and the lactone shared with other heterocycles may be a novel structural feature in antioxidants.

ABSTRACT: Barley protein Z7 (BSZ7) is a well-known serine protease inhibitor that was regarded as a major effector of beer foam stability. Moreover, it has also been suggested to participate in haze formation and affect wort filterability. The present study purified BSZ7 from barley malt and characterized its secondary structure and modification, as well as its relationship with peroxidase, to elucidate the molecular base of BSZ7 that supports its multiple roles in malt and beer. It was found that after 30 min of heating, the secondary structure was not affected. BSZ7 has no inhibiting effect on nonspecific protease originated from malt, suggesting its negative role in wort filterability was accomplished by other means. Furthermore, the glycation of BSZ7 by the Maillard reaction may make some contribution to its survival during wort boiling. The interaction of BSZ7 with polysaccharides and polyphenols found by adding experiment may explain how it acts as a negative factor on wort filterability. Greater understanding of BSZ7 and other proteins of malts will lead to better improvements in brewing quality.

KEYWORDS: *BSZ7, secondary structure, glycation, melanoidins, wort filterability, peroxidase*

INTRODUCTION

Barley protein Z belongs to the serine protease inhibitor family (serpin). Due to the high lysine content, it acts as a storage protein in the endosperm. In addition, it is also responsible for defense against insect pathogens because of its protease-inhibiting activity.[1−3] Protein Z displays different isoforms, including protein Zx (BSZx), protein Z4 (BSZ4), and protein Z7 (BSZ7),[4] the latter two being major beer proteins with the capacity to survive during brewing.[5] The genes encoding BSZ4 and BSZ7 are present on chromosomes 4 and 7 of barley, respectively,[6] and BSZ4 comprises 80% of total protein Z in either barley or malt and thus is the predominant one.[7] Both of them are suggested to be positive effectors on foam stability.[8,9] BSZ7 was also found to be included in the silica eluent part during beer brewing, indicating it is a haze-forming protein in beer.[10] In our previous work, comparative proteomics was performed between Dan'er and Metcalfe malts showing different wort filterability, and multiple BSZ7 spots were found to be in more abundance in Dan'er malt, indicating its negative role in wort filterability.[11] Addition of BSZ7 to the mashing process significantly decreased the separation rate of wort, which further confirmed its effect on filterability.[11] Besides these, BSZ7 has been demonstrated to be an inhibitor of α-chymotrypsin.[12]

Although multiple roles of BSZ7 have been explored, the biochemical characterization of the protein was not fully studied. By Evans and Hejgaard,[7] the content of BSZ7 was observed to be 38−771 μg/g in barley seeds of 91 varieties and consisting of 397 amino acid residues with an apparent molecular mass of 39 kDa.[12,13] The primary structure of BSZ7 has been elucidated. BSZ7 shares 69, 72, and 71% identity with wheat chymotrypsin inhibitor WSZ1, barley BSZ4, and BSZx, respectively. Furthermore, BSZ7 shares 69−72 and 25−32% positional identity with plant and mammalian serpins. In the primary structure of BSZ7, four N-glycosylation sequences Asn-Xxx-Ser/Thr were found at positions 154, 171, 205, and 316, respectively.[13] The partial modification of lysine residues with sugars has been demonstrated by isoelectric focusing of protein Z.[14]

Dan'er and Metcalfe are typical malting malts in beer brewing. Dan'er is the most popular domestic barley in China. However, due to the deficiency in wort filterability of Dan'er malt, Metcalfe is imported from Canada every year and used for malting and brewing instead. In our previous study, proteomic

analysis and adding experiments confirmed the negative effect of BSZ7 on filterability.[11] Therefore, the two malts were selected for further purification and characterization of BSZ7 in the present study, to elucidate the structural and biochemical bases that support the multiple roles of BSZ7 during malting and brewing. More detailed analyses and better comprehension of BSZ7 may help improve brewing quality using the domestic barley Dan'er.

MATERIALS AND METHODS

Commercial Barley Malt. Samples of barley malts, the domestic Dan'er and the imprted Metcalfe, were collected from commercial maltsters in China and stored at 4 °C in our laboratory. Each maltster has its specialized malting conditions for these two barley cultivars. The Dan'er malt was produced with Dan'er barley that was harvested in 2011 in Jiangsu province of China. Barley of Metcalfe was harvested in 2011 in western Canada and imported to China for malting. Congress wort was obtained by the European Brewery Convention (EBC) Congress mash.

Total Protein Extraction from Malt and Wort of Dan'er and Metcalfe. Malt sample was ground into flour and then added into 5 times volume of 0.02 M PBS buffer (pH 5.5) supplemented with 0.1 M NaCl, to extract proteins at 4 °C overnight. The soluble proteins were obtained by centrifugation of crude extract at 4 °C (5000 *g*, 30 min) and precipitated with 100% saturation of ammonia sulfate. For wort sample, proteins were precipitated with 100% saturation of ammonia sulfate directly. All of the pellet was then resuspended in 0.02 M PBS buffer (pH 5.5) appending 0.1 M NaCl and then dialyzed against 2 L of the same buffer five times (4 h each time).

Purification of BSZ7 from Dan'er Malt. The soluble protein of Dan'er malt was fractionally precipitated with 20% and then 70% saturation of ammonia sulfate. The precipitant was collected and resuspended in 0.02 M PBS buffer (pH 5.5) containing 0.1 M NaCl and then dialyzed against 2 L of the same buffer five times (4 h each time). After that, the crude BSZ7 solution was incubated at 75 °C for 15 min to precipitate the hot unstable proteins, which were then removed by centrifugation at 10000 *g* for 15 min and filtered through a 0.22 μm membrane. The filtration was then loaded on a size exclusion column Hiload 26/60 Superdex 75 pg and then washed with 0.02 M PBS buffer (pH 5.5) containing 0.1 M NaCl at a flow rate of 2 mL/min. The eluted solutions were collected every 5 mL per tube. To discriminate the fraction containing BSZ7, 20 μL of sample in each tube was displayed on SDS-PAGE, and finally fractions containing the 39 kDa band corresponding to molecular weight of BSZ7 were pooled and concentrated by ultrafiltration for a second size exlusion column Hiload 26/60 Superdex 75 pg purification. After the two rounds of size exclusion purification, BSZ7 was collected and the protein concentration was analyzed using RC-DC quantity kit (GE Healthcare, Pittsburgh, PA, USA). To test the purity of collected BSZ7, 20 μL of sample was displayed on SDS-PAGE, and the corresponding band was then cut for MALDI-TOF/TOF identification. In detail, the 39 kDa band was manually excised from the SDS-PAGE gel and washed with the destaining buffer (25 mM ammonia sulfate, 50% (v/v) acetonitrile), followed by dehydration with 100% acetonitrile. The protein was in-gel digested by trypsin and then submitted to the Ultraflex MALDI-TOF/TOF mass spectrometer (Bruker-Daltonics Inc., Billerica, MA, USA) as described.[11]

Circular Dichroism (CD) Spectroscopy. BSZ7 was diluted with deionized water to a final concentration of 0.5 mg/mL and then submitted on the MOS-450 AF-CD (Biologic, France) for secondary structure determination. Far-ultraviolet (far-UV, 190−250 nm) and quartz cell with 0.2 mm path length were used. The secondary structure was analyzed with CONTIN software, and data were expressed as mean-residue ellipticity.

Hydrophobic Index Determination. A series of concentrations of BSZ7 (0.10, 0.15, 0.20, 0.25, 0.30, 0.35, and 0.40 mg/mL) was obtained by diluting the purified BSZ7 with 0.02 M PBS buffer (pH 7.0). Two hundred microliters of each sample was added to two separate wells of a 96-well plate, after which 2.5 μL of substrate solution (8 M 8-anilino-1-naphthalenesulfonate (ANS) dissolved in 0.02 M PBS buffer (pH 7.0)) was added to one well, whereas the other sample well without substrate buffer was used as blank control. The fluorescence intensity (FI) was determined using a SmartSpec microplate spectrophotometer (Bio-Rad, Hercules, CA, USA) with excitation and emission wavelengths at 390 and 470 nm, respectively. The protein hydrophobic index was calculated by plotting the FI on protein concentration. The hydrophobic index of total proteins in malt and wort of Dan'er and Metcalfe was detected with the same method.

Malt Nonspecific Protease Activity Assay. Protease was extracted with the following procedures. Three grams of finely ground malt was mixed with 30 mL of 0.1 M citric acid/Na_2PO_4 buffer (pH 5.2) and then incubated at 20 °C for 1 h in a water bath to extract the protease. The crude extracts were centrifuged at 8000*g* for 10 min and then filtered with Whatman no. 4 filter paper (Whatman PLC, Maidstone, UK). The supernatant was collected and stored for protease activity analysis at 680 nm by determining tyrosine produced. The reaction mixture for the hydrolysis reaction (2 mL) contained 1% (w/v) bovine hemoglobin in 0.1 M citric acid/Na_2PO_4 buffer (pH 5.2) and an appropriate amount of protease extract. Both the protease extract and bovine hemoglobin were preheated at 40 °C before being added into the assay mixture. Reactions were initiated by adding the protease extract and terminated by the addition of 0.4 M trichloroacetic acid (TCA) after incubation at 40 °C for 30 min. The mixture was then allowed to stand for 10 min to precipitate nonhydrolyzed proteins. For blank control, TCA was added together with the bovine hemoglobin before reaction initiation. All of the reactions were repeated in three parallels. After centrifugation, 1 mL of the supernatant was mixed with 5 mL of 0.4 M Na_2CO_3 and 1 mL of Folin's reagent and incubated at 40 °C for 20 min. Optical density was read at 680 nm, representing the tyrosine production. One unit of enzyme was defined as the amount of protease that produced 1 μg of tyrosine per minute at pH 5.2 and 40 °C.

Melanoidins Extraction and Detection. Malt melanoidins was extracted using an ethanol−water solution method.[15] Thirty grams of ground malt was added to 100 mL of 10% ethanol (v/v) and allowed to stand for 20 h to extract melanoidins. The crude extract was then centrifuged at 5000*g* for 10 min to remove insoluble material, after which the supernatant was added to ethanol to a final concentration of 65% and allowed to stand for 12 h to dissolve melanoidins. The ethanol was evaporated with a rotary evaporator RV10 (IKA, Staufen, Germany) before centrifugation. The corresponding supernatant was then mixed with isometric acetone to precipitate melanoidins and collected by centrifugation. As the acetone volatilized, melanoidins were resuspended with distilled water and dialyzed as soon as possible. The extracted melanoidins were separated by SDS-PAGE and detected with glycoprotein gel staining kit Protein Stains R (Sangon Biotech, Shanghai, China) following the manufacturer's instructions.

Adding Experiment of Purified BSZ7 to Mashing Process. A series of amounts of purified BSZ7 (0, 200, 400, and 600 μg/g malt) was added to the EBC Congress Mashing process with Dan'er malt. Macromolecular content and protease activity were measured as follows. The contents of arabinoxylan (AX), β-glucan, and polyphenaol were determined using the Douglas method,[16] Congo-Red method,[17] and Folin−Ciocalteu colorimetry,[18] respectively. High molecular weight protein (HWP) was precipitated with tannin[19] and then measured.

RESULTS AND DISCUSSION

Purification of BSZ7 from Dan'er Malt. BSZ7 is one of the thermally stable beer proteins that can survive during boiling. Therefore, the crude extracts were heated at 75 °C for 15 min prior to chromatographic separation, so that most of the hot unstable proteins were denatured and precipitated during the heating process. A few of the surviving proteins, including BSZ7, were then submitted to the Superdex G75 size exclusion column. All of the fractions collected were exhibited on SDS-PAGE gel (Figure 1a), and the one containing a single 39 kDa

band corresponding to BSZ7 was considered to be purified BSZ7, which was further confirmed by MALDI-TOF/TOF.

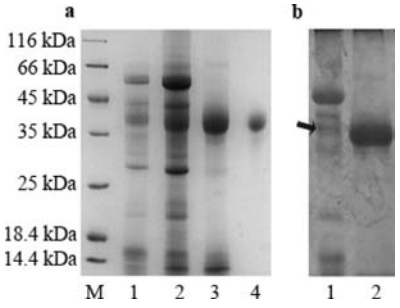

Figure 1. (a) SDS-PAGE of BSZ7 samples during the purification process: lane 1, crude extract; lane 2, salt fractionation; lane 3, heat treating; lane 4, size exclusion column. (b) SDS-PAGE of melanoidins and BSZ7 stained with the glycoprotein gel staining kit; the band corresponding to BSZ7 in melanoidins is indicated by the arrow.

Secondary Structure of BSZ7. CD was used to study the thermal and optical properties of BSZ7. There are two negative minima (280 and 222 nm) and a maximum (192−195 nm), representing a typical α-helix structure, in the far-UV spectra of purified BSZ7 (Figure 2). As shown in Table 1, a significant

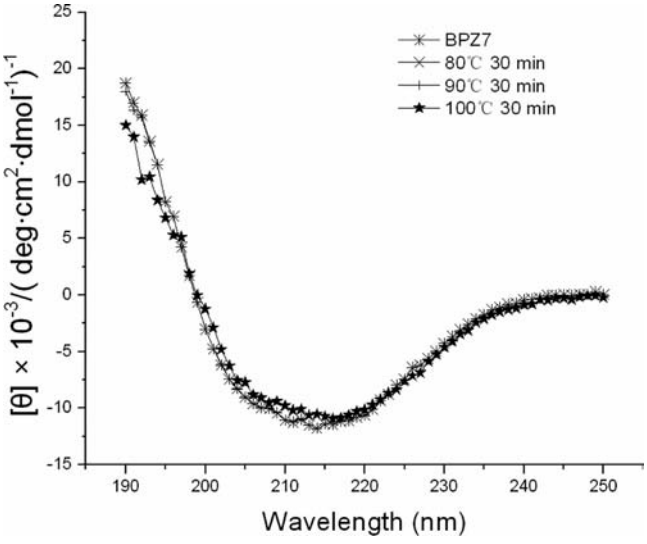

Figure 2. CD spectra of primary and heat-treated BSZ7.

Table 1. Secondary Structure Elements of Heat-Treated BSZ7

	secondary structure elements (%)			
heat treatment	α-helix	β-sheet	β-turn	random coil
untreated control	75.4	0.0	4.4	20.2
80 °C, 30 min	75.2	0.1	4.4	20.3
90 °C, 30 min	72.6	0.8	4.6	21.9
100 °C, 30 min	63.8	2.9	10.8	22.5

fraction of ordered secondary structural elements was found. There was a large amount of α-helix with a small proportion of random coil in the BSZ7 molecular, and no β-sheet or β-turn was found.

To observe the influence of wort boiling on BSZ7, SDS-PAGE and CD were performed following heat treatment of BSZ7 at different degrees for 30 min. There was no degraded band displayed in the SDS-PAGE gel (Supporting Information supplementary Figure 1), and there was only a decrease in band intensity of the heated BSZ7s spectra. No significant peak shifts were revealed (Figure 2). With increasing temperature the fraction of α-helix decreases, whereas the fraction of β-sheet and β-turn increases (Table 1). Despite these changes in secondary structure unit contents, the content of α-helix remains high, giving BSZ7 thermal stability.

Hydrophobicity of BSZ7. Compared with proteins in malt and wort, BSZ7 was the most hydrophobic one (Figure 3).

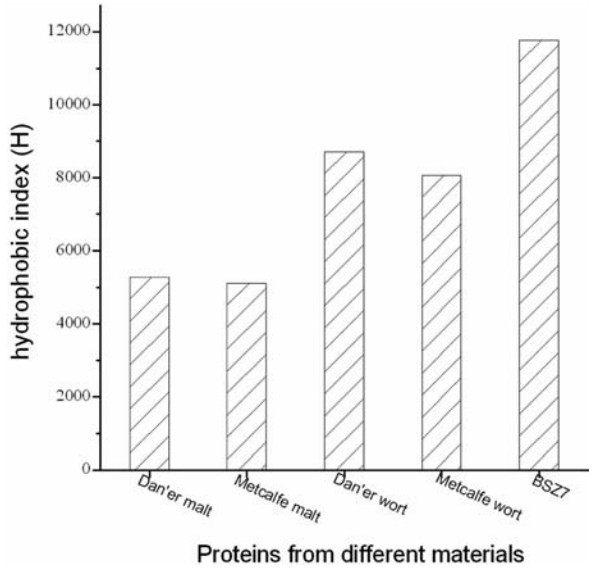

Figure 3. Surface hydrophobic index of BSZ7 and proteins from Dan'er malts and worts.

Previous studies have suggested that the hydrophobicity of a protein would increase its positive effect on beer foam.[20,21] Another well-known foam-promoting protein, LTP1, was found to decrease rapidly during boiling, thus reducing beer foam stability,[22] wheereas, after heating for 30 min, BSZ7 showed no degradation or secondary structure alteration (Supporting Information Supplementary Figures 1 and 2). This result suggested a greater contribution of BSZ7 than LTP1 in beer foam promotion. However, the high hydrophobicity of BSZ7 will also lead to its greater tendency to be left in the spent grain and precipitate to form beer haze, because it was suggested to be able to bind and precipitate with small fragments during wort boiling.[23]

No Inhibiting Effect of BSZ7 on Malt Nonspecific Protease. In the previous comparative proteomic research, it was found that the deficiency on filterability of Dan'er malt was partially caused by BSZ7.[11] The barley serpins were reported to be responsible for protecting the barley grain against insects and fungal infection by inhibiting the activity of pest proteases that digest the contents of grains.[24] However, none of these inhibitors has been shown to have inhibiting activity on the endogenous protease of barley or malt.[24] As a negative effecter on malt filterability, more BSZ7 in Dan'er malt was first thought to hinder the wort filtering through inhibiting protease activity and leaving more proteins in wort. Unexpectedly, the purified BSZ7 from malt showed no effect on nonspecific protease activity of malt (Suppporting Information supple-

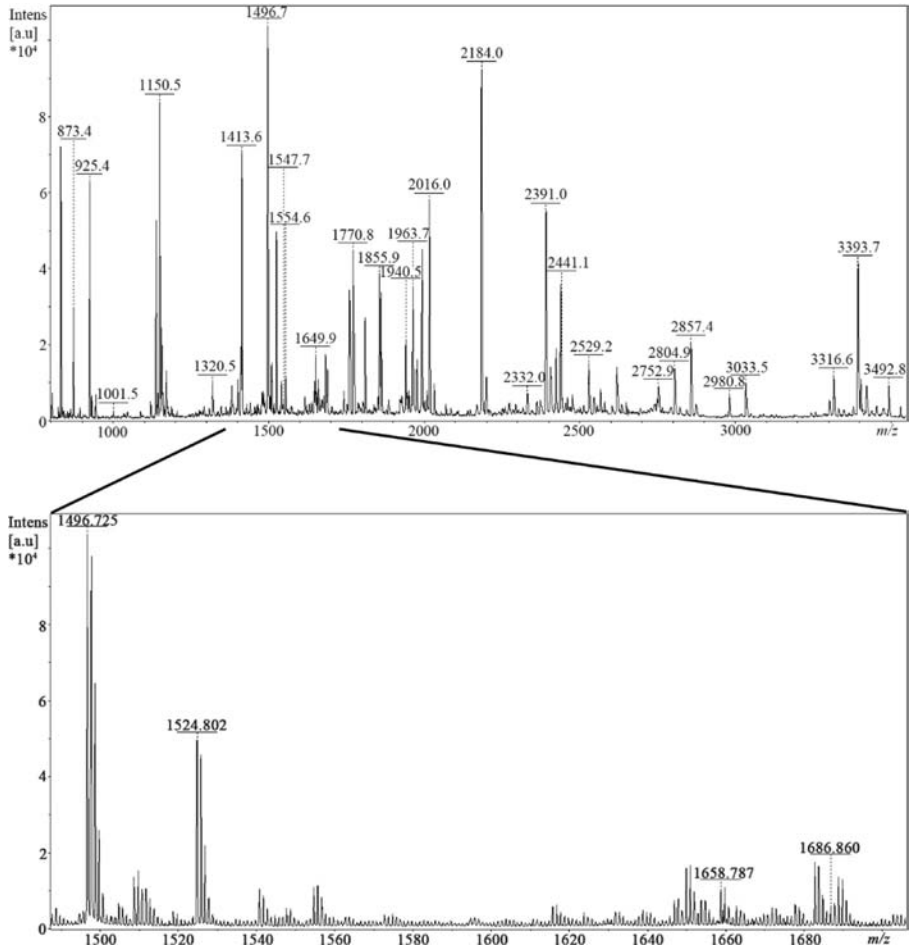

Figure 4. MALDI-TOF MS spectra of purified BSZ7. The marked signals correspond to the unmodified peptides and their glycated form with 162 Da increment of BSZ7.

mentary Figure 2), suggesting it plays its negative role in wort filterability through other actions.

BSZ7 Is a Component of Melanoidins. Melanoidins are complicated compound products of the Maillard reaction from sugars and proteins or amino acids during food processing and preservation.[25] BSZ7 was detected to display multiple spots in the 2DE maps (Supporting Information supplementary Figure 3).[26] Moreover, it has been suggested that protein Z was glycated during processing through the Maillard reaction in the previous study.[14,27] Therefore, BSZ7 was proposed to be one component of the melanoidin compounds. Stained with a glycoprotein gel staining kit, a band in the melanoidins lane showed a migration rate similar to that of the BSZ7 one (Figure 1b), indicating BSZ7 is a component of melanoidins, which was further identified by MALDI-TOF/TOF as described under Materials and Methods. In agreement with studies on the nonenzymatic glycated LTP1 and protein Z during malting and brewing processes,[27,28] several peaks in the MALDI-TOF MS spectra of BSZ7 were found to have 162 Da increments (Figure 4). Two peptides, m/z 1658.787 and 1686.860, were observed to have an increase of ~162 Da compared to the unmodified peptides m/z 1496.725 and 1524.802, both of which contained the glycation site lysine (K).[13] The glycation of protein Z has been proved to protect it from precipitation in the wort boiling process and improve foam stability.[29] In addition, the melanoidins participate in beer color formation and stabilize the oxidation−reduction processes,[25] which indicated another role of BSZ7 in malt and beer.

No peaks with increment of 162 Da were found in the MALDI-TOF MS spectra of the two BSZ7 spots in 2DE maps of Dan'er malt. As shown in Figure 5, panels a and b, the MS of one BSZ7 spot contained one cluster of peaks and the other showed two clusters, in which the major signals were m/z 1486.783 and 2421.329 and m/z 3052.489, respectively. Four peaks in the second cluster (m/z 3052.495, 3442.772, 3459.765, and 3456.799) were calculated to be glycopeptides analyzed by the oligosaccharide structure prediction tool GlycanMod (http://web.expasy.org/glycomod/). They were thought to be the glycation products of peptide NVTAGLIEEILPAGS-IDNTTR (154−174, m/z 2148.143), which contains two of the four N-glycosylation sequences Asn-Xxx-Ser/Thr (NXS or NXT) in BSZ7.[13] The N-oligosaccharide components were $HexHexNAc_1-NeuAc-PentPhos$ (m/z 550.13), $Hex_2HexNAc-Deoxyhexose_2NeuGc-Pent$ (m/z 1258.433), $Hex_2HexNAc_2-DeoxyhexosePent_3$ (m/z 1272.449), and $Hex_4HexNAc-Deoxyhexose_2Pent$ (m/z 1275.449), respectively. The latter three structures are paucimannose-type ($Man_nGlcNAc$-based structure), and the Pent is probably core xylosylation universally existing in plant glycoproteins.[30] BSZ7 purified from barley flour was shown to be non-glycosylated;[12] however, this does not mean that BSZ7 in malt was N-terminally blocked. As previously suggested, glycation can stabilize the protein conformation through hydrogen bonds

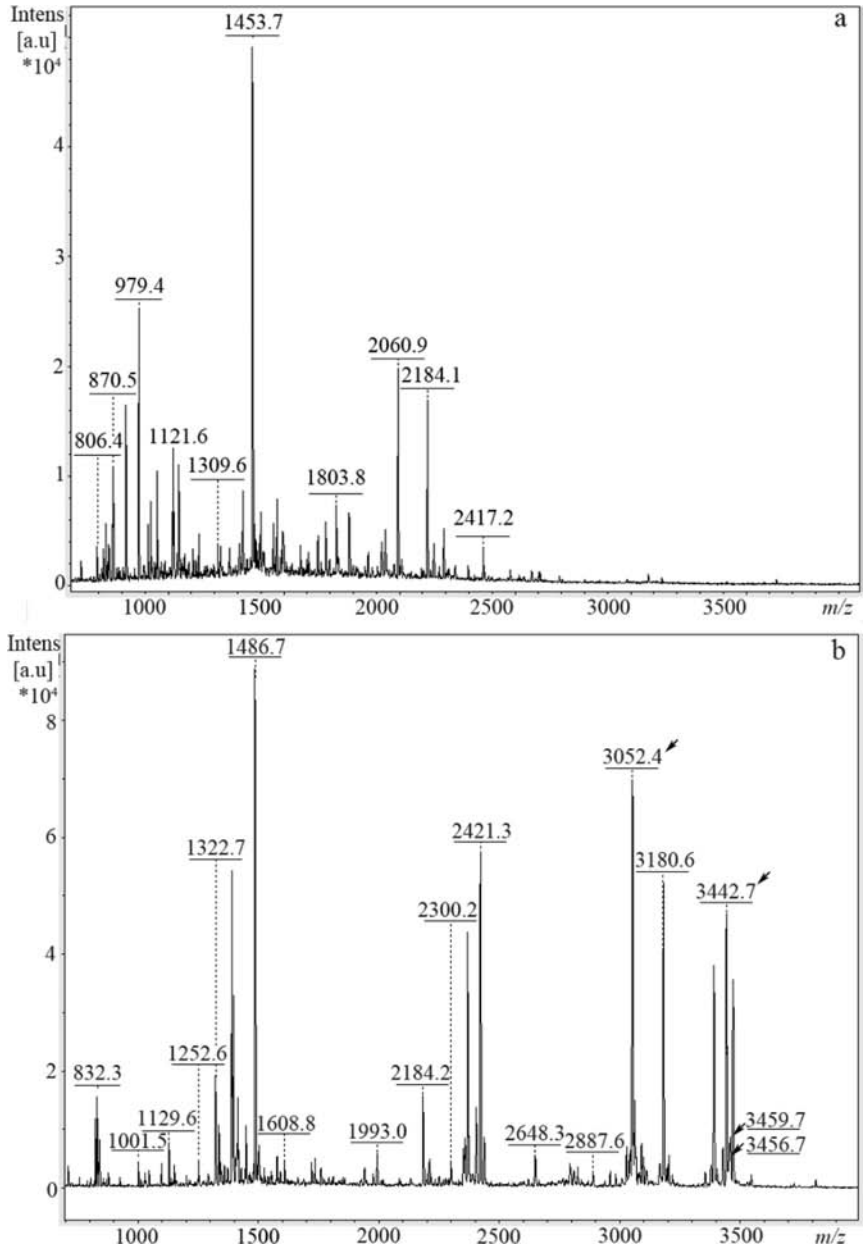

Figure 5. MALDI-TOF MS spectra of the two different spots corresponding to BSZ7 in the 2DE map of Dan'er barley malt. The putative glycopeptides are indicated by arrows.

or van der Waals contacts and thus endows the protein with resistance against wort boiling,[31] which further explains the superior thermal stability of BSZ7.

Effect of BSZ7 on Wort Filterability. According to BSZ7 content in various barley cultures, a series of amounts of purified BSZ7 was added as EBC Congress mashing with Dan'er malt to observe the effect of excess BSZ7 on wort filterability.

Our previous research has shown that extra BSZ7 will seriously decrease the wort separation rate and the turbidity, but have little effect on viscosity.[11] To explain this effect, macromolecular contents in the wort with distinct added BSZ7 were analyzed (Figure 6a–c). With increasing added BSZ7, the concentrations of polysaccharides including β-glucan and AX were decreased, and no difference in HWP among the wort was found. However, β-glucan and AX were degraded by their corresponding hydrolysis enzymes, which have not been reported to be affected by BSZ7. Therefore, we propose the hypothesis that the decreased contents of β-glucan and AX were due to their interaction with BSZ7 by the Maillard reaction, which well explained the unchanged viscosity of wort but decreased turbidity. Due to the high viscosity of polysaccharides, the strong hydrophobicity, and huge size of compounds, they cannot easily pass the filter membrane and therefore caused the decreased wort separation rate.

Besides these, the contents of polyphenols were also decreased significantly with increased extra BSZ7 (Figure 6d). It has been proved that the cross-link or oxidative polymerization between protein and polyphenols is an important negative factor in wort filterability.[32] However, there was no significant change of polyphenol concentrations in the wort using Metcalfe malt by adding a similar amount of BSZ7 (Supporting Information supplementary Figure 4), indicating there is an enzyme promoting the cross-link, and this enzyme

dx.doi.org/10.1021/jf405699z | J. Agric. Food Chem. 2014, 62, 5643–5650

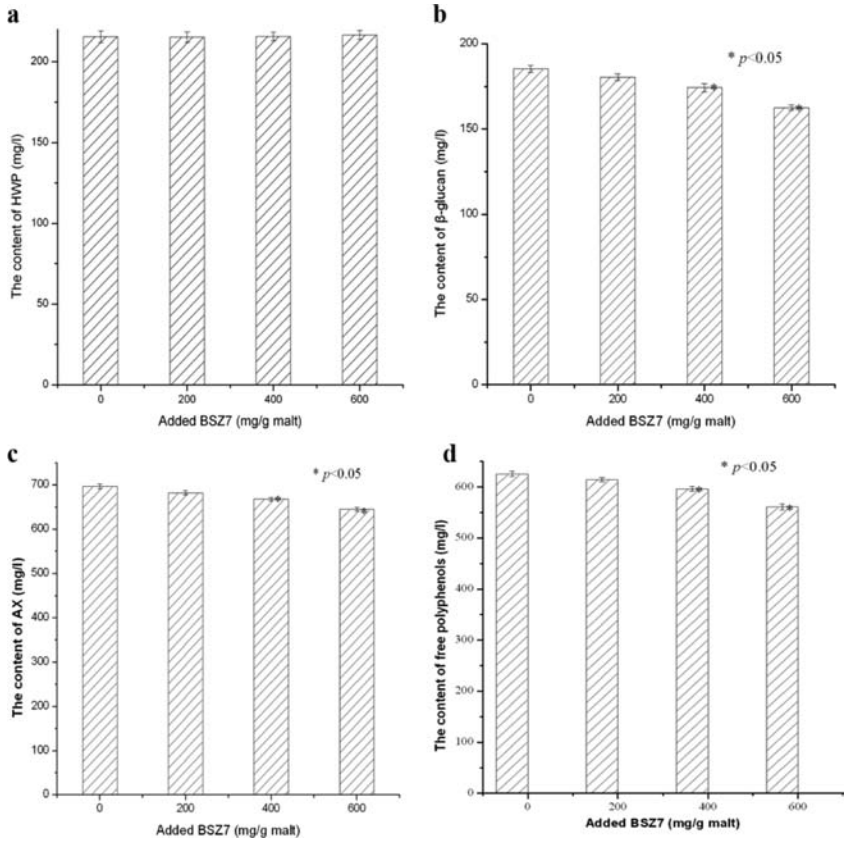

Figure 6. Effect of added BSZ7 during mashing on the contents of HWP (a), β-glucan (b), AX (c), and polyphenols (d) in wort.

was in a different redundancy or exhibited distinct activity between these two malts. Peroxidases (POD) from barley are heat-stable enzymes responsible for phenolic substrate oxidative polymerization, which caused the increased color and turbidity of wort.[33,34] They have been found to be in more abundance in Dan'er malt compared with Metcalfe malt.[11] Furthermore, the activity of POD was higher in Dan'er malt than in Metcalfe (Supporting Information supplementary Figure 5). Therefore, a series of amounts of horeadish peroxidase (0, 200, and 400 U/g malt, Sino-American Biotech., China) instead of malt POD was mixed with purified BSZ7 (600 μg/g malt) and then added simultaneously to test their synergetic effect on wort filterability. As peroxidase increased, the concentration of free polyphenols decreased significantly (Figure 7). At the same time, the wort separation rate was negatively hindered by them.

In conclusion, the present study has characterized BSZ7, a well-known serpin Z of barley playing multiple roles in barley, malt, and wort. The secondary structure and glycation facilitate its survival during wort boiling and improvement of foam stability in beer. Moreover, its existence in melanoidins indicated its potential role in the oxidation−reduction process. However, the high hydrophobicity of BSZ7 and its interaction with polysaccharides in the wort may hinder the compound's passing through the filter membrane, although it may decrease the viscosity to some degree. Finally, our data indicated that the cross-links induced by POD between polyphenols and BSZ7 may also create a negative effect on wort filterability. The glycation of BSZ7 and interaction between polysaccharides and BSZ7 still need more evidence. At the same time, the catalytic mechanism of POD is under study by another project.

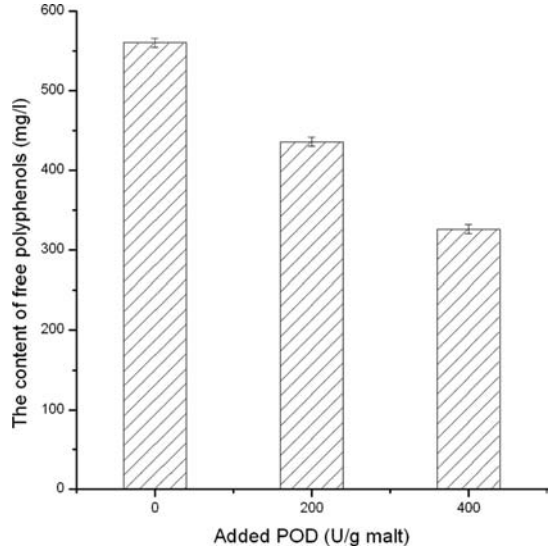

Figure 7. Effect of simultaneous addition of BSZ7 and POD on the content of polyphenols in wort.

Supporting Information

ABSTRACT: Pinking is the terminology used for the salmon-red blush color that may appear in white wines produced exclusively from white grape varieties. The isolation of pinking compounds and their analysis by RP-HPLC-DAD and ESI-MS^n showed that the origin of the pinking phenomenon in white wines from *Vitis vinifera* L. of Síria grape variety are the anthocyanins, mainly malvidin-3-*O*-glucoside. The analysis showed that the anthocyanins were located both in the pulp and in the skin. Wine pinking severity was negatively related with the increase of the average temperature of the first 10 days of October, the final period of grape maturation. The minimum amount of anthocyanins needed for the pink color visualization in wine was 0.3 mg/L. The appearance of pinking in white wines after bottling is due to the lowering of free sulfur dioxide, which leads to an increase of the relative amount of the anthocyanins red flavylium form and their polymerization, resulting in the formation of colored compounds resistant to pH changes and sulfur dioxide bleaching.

KEYWORDS: *Vitis vinifera, white grapes, Síria variety, white wines, pinking, anthocyanins*

INTRODUCTION

Pinking is a term that describes the appearance of a salmon-red blush in white bottled wines produced exclusively from white grape varieties. It is perceived as an undesirable phenomenon by both wine consumers and the industry.[1,2] Although with seasonal and regional variations, pinking has been observed worldwide, with predominance in white wines produced from *Vitis vinifera* L. grape varieties such as Chardonnay, Chenin blanc, Crouchen, Muscat Gordo blanco, Palomino, Riesling, Sauvignon blanc, Semillon, Sultana, and Thompson Seedless.[1,3]

Pinking is mainly observed when white wines are produced under reducing conditions.[1−4] The pinking phenomenon is usually observed after bottling and storage of white wines or after alcoholic fermentation, although sometimes it occurs as soon as the grape must is extracted.[5−7] Susceptibility of reductively produced wines to pinking may be effectively overcome by maintaining adequate levels of free sulfur dioxide, especially when ascorbic acid is used.[8,9] Pinking is thought to be due to oxidative changes in white wines when exposed to oxygen,[1,7] although the compounds responsible for the pinking phenomena are unknown.[10] In addition, inhibition of polyphenol oxidase activity has been linked to pinking potential in white wines,[11] and added hydrogen peroxide can induce it.[1] It has been proposed that white wine pinking can be a result of the rapid conversion of accumulated flavenes to the corresponding red flavylium salts formed from the hydrolysis of leucoanthocyanins.[12] However, this coloration may be caused by at least 10 different compounds and polymeric materials.[2] Also, it was reported that a 2-*S*-glutathionyl-caftaric acid derivative may be the pink chromophore.[4]

There are various preventive or curative enological treatments for the pinking problem, including adding polyvinylpolypyrrolidone (PVPP) or PVPP associated with bentonite or increasing the redox potential using ascorbic acid in the prebottling stage.[10] Nevertheless, the use of these treatments increases wine production costs and can change wine sensory properties.[13] Also, the use of high levels of ascorbic acid has been shown to increase the browning potential of white wines.[14] In white wine production, hyperoxidation of juice is not recommended, as it alters significantly the white wine flavor, decreasing the fruity aroma intensity and consequently the wine quality.[4,8]

The main purpose of this work was to get a deeper insight into the pinking phenomenon, its origin, and technological factors influencing its appearance in white wines. For this, Síria, a white grape variety, was used. Knowledge of the compounds responsible for this color alteration would increase the treatment efficiency of those wines by allowing the choice of the most correct treatment to optimize their removal.

MATERIAL AND METHODS

Chemicals. Oenin chloride, kuromanin chloride, and delphinidin 3-*O*-*β*-D-glucoside chloride were purchased from Sigma (USA).

Grape and Wine Samples. The white grapes and white wines from *V. vinifera* L., Síria variety, used in this study were from the vintages 2010−2012, harvested at the designation of origin Beira Interior, subregion Castelo Rodrigo, in Portugal, and provided by the Producers Union "Adega Cooperativa de Figueira de Castelo Rodrigo" (ACFCR). This region is characterized by an altitude ranging between 400 and 700 m. The soils are mostly granite or schist. In this subregion the principal white grape varieties are Síria and Malvasia Fina. The white wines from this region have medium acidity (4−5 g/L tartaric acid), pH 3.2−3.4, light color, medium sensitivity to oxidation, intense aroma, and balanced notes of unripe tropical and citrus fruits.

Winemaking was carried at the ACFCR, in Portugal. Grapes were manually harvested at optimum technological maturity (18−20 °Brix) and transported to the winery. They were immediately destemmed and crushed, and the grape juice was treated with sulfur dioxide (60 mg/L) to avoid must oxidation. Then, crushed grapes were pressed at a maximum pressure of 2 bar in a pneumatic press machine. Grape juice was clarified by decantation in a stainless steel tank during 24 h at 8 °C. The alcoholic fermentation was started using active dry yeasts, carried out at controlled temperature (14−15 °C), and finished when residual sugars were <2 g/L. After alcoholic fermentation, the wine was racked and the free sulfur dioxide was adjusted (~40 mg/L). All conventional analytical methods were performed according to OIV methods.[15]

Visible Absorption Spectra and Wine Chromatic Characteristics. The visible absorption spectra were acquired in a 4 cm path length glass cell from 380 to 780 nm. The spectra were converted into a 1 cm path length, and the chromatic characteristics of the wines according to CIELab were calculated by using the method MA-E-AS2-11-CARCHR of the OIV.[15] All analyses were performed in duplicate.

Isolation of the Pinking Compounds by PVPP Column Chromatography. To a white wine (1 L) presenting pinking, was added 0.8 g of PVPP (Polyclar V), and the suspension was filtered through a cheesecloth and washed with 100 mL of water followed by 100 mL of ethanol 95%. After this washing, the PVPP, presenting a pink color, was loaded on an empty SPE cartridge with frits and eluted sequentially with 3 mL of (1) acetonitrile, (2) acetone, (3) aqueous solution of 1% HCl, (4) ethanol, and (5) 0.1 M NH_3 in ethanol. Each eluent was separately collected, the solvent was removed by centrifugal evaporation, and the solution was reconstituted with 0.2 mL of a methanol/water (1:1 v/v) solution before analysis by HPLC. All analyses were performed in duplicate.

Isolation of Pinking Compounds by Reversed Phase Solid Phase Extraction. The pinking compounds present in the samples were purified and concentrated by reversed phase (C-18) solid phase extraction (Supelclean LC-18 SPE tube, 1 g of solid phase, and 6 mL volume). Briefly, 1 g of C-18 SPE column was conditioned by applying four times 5 mL of methanol and 4 times 5 mL of a 0.1 M HCl solution. Then, the samples were applied: (1) 35 mL of grape juice or must resulting from pressing Síria white grape varieties adjusted to pH 1 with 3 M HCl or (2) 100 mL of white wines from Síria grape variety or a blend from Síria and Malvasia Fina grape varieties adjusted to pH 1 with 3 M HCl. After application of the sample, the column was washed with four times with 5 mL of the 0.1 M HCl solution, and the compounds retained were eluted with four times 5 mL of methanol. The fractions were pooled, and the methanol was removed by rotary evaporation at 35 °C. The dried residue was dissolved in 2 mL of a methanol/water (1:1 v/v) solution and analyzed by HPLC. All analyses were performed in duplicate.

High-Performance Liquid Chromatography with Photodiode Array Detector. The chromatographic analysis of the phenolic compounds present in grape must and wine water/methanolic extract was performed by reversed phase (C-18) high-performance liquid chromatography using an Ultimate 300 solvent delivery system equipped with a PD-100 UV−vis diode array detector. Separation was performed by gradient elution on an ACE 5 C-18 column, 5 μm particle size (250 mm × 4.6 mm) (Advanced Chromatography Technologies, Scotland). Conditions of HPLC analysis were as follows: solvent A was a mixture of 95:5 water/formic acid (v/v), and solvent B was methanol. A linear gradient analysis for a total run time of 80 min was used as follows: starting from 5% solvent B during 2 min, increase to 80% solvent B over 68 min and then isocratic for 8 min, decrease to 5% solvent B over 2 min, and finally isocratic for 5 min. The sample volume injected was 100 μL, the flow rate was 1.0 mL/min, and the column temperature was maintained at 35 °C during the run. The eluent was continuously monitored from 250 to 600 nm with a photodiode array detector (PDA-100, Dionex). All analyses were performed in duplicate. Anthocyanin identifications were made by injection of pure standards in the case of cyanidin-3-*O*-glucoside, delphinidin-3-*O*-glucoside, and malvidin-3-*O*-glucoside and by comparison of their retention times and UV−vis spectra. Other anthocyanins were identified by comparison of the elution order and UV−vis spectra reported in the literature. Additionally, all anthocyanin-3-*O*-glucosides were confirmed by tandem mass spectrometry.

Determination of Total Monomeric Anthocyanins. Total monomeric anthocyanins were determined using the pH differential method AOAC Official Method 2005.02 with a minor modification.[16] Due to the low concentration of anthocyanins present in pinking white wines, for the anthocyanin determination by the pH differential method, the absorbance was measured at 520 and 700 nm using a 10 cm path length glass cell, and total monomeric anthocyanins were expressed as milligrams of malvidin-3-*O*-glucoside per liter (molar extinction coefficient of 28000 L/cm/mol and molecular weight of 493.4 g/mol). All analyses were performed in duplicate.

Electrospray Ionization Mass Spectrometry (ESI-MS). ESI-MS and tandem ESI-MS (ESI-MS^n) spectra of SPE-purified and concentrated must and wines were carried out on an LXQ linear ion trap mass spectrometer (Thermo Fisher Scientific Inc., Waltham, MA, USA). Typical operating conditions were as follows: electrospray voltage was 5 kV, capillary temperature was 275 °C, capillary voltage was 1 V, and tube lens voltage was 40 V. Samples were introduced at a flow rate of 8 μL/min into the ESI source. Nitrogen was used as nebulizing and drying gas. In the ESI-MS^n experiments, the collision energy used was set between 18 and 31 (arbitrary units). Data acquisitions were carried out on an Xcalibur data system. For all ESI-MS analyses, samples dissolved in water were diluted in methanol/formic acid (99:1, v/v), and the spectra were acquired in the positive mode, scanning the mass range from m/z 100 to 1500. All analyses were performed in duplicate.

Tissue Fractionation and Anthocyanin Content. For the analysis of anthocyanin distribution in Síria white grape variety, the skins were removed from the frozen grapes (hypodermal tissue samples) and the seeds were removed from the flesh (mesocarp tissue samples).[17] The hypodermal and mesocarp samples were homogenized in a mortar and pestle at 4 °C in the presence of 0.1% HC1 (v/v) in methanol containing 50 ppm of SO_2. The homogenate was centrifuged at 3400*g* for 6 min, and the supernatant was concentrated under vacuum. The residue was suspended in 2 mL of a water/methanol solution (1:1 v/v) and analyzed for anthocyanin by HPLC-DAD. All analyses were performed in duplicate.

Climate Data. The climate data corresponds to the period from 2005 to 2011 of the vineyards located at Figueira de Castelo Rodrigo (40° 52′ N, 6° 54′ W, 635 m). The climate is of the Mediterranean type (warm temperate climate with dry and warm summer) characterized by a sinusoidal pattern of precipitation with dry summers and wet winters. In the experimental area, long-term annual precipitation is about 590 mm, with roughly a third falling from April to September. Corresponding annual average minimum and maximum temperatures are 6.4 and 18.3 °C.[18]

Weather variables kindly supplied by the Portuguese state agricultural services (Direção Regional de Agricultura e Pescas do Centro) included daily records of maximum, minimum, and average temperatures and total precipitation, from which 10 day averages were computed. This set of data was recorded from a standard automatic weather station close to the experimental site. Additionally, thermal

amplitudes and growing degree days (with a 10 °C base temperature) were calculated.

The pinking severity over this period of time was indirectly calculated on the basis of the amount of PVPP used (grams) for white pinking treatment and the total volume of wine treated (liters).

To examine linear dependencies between climatic variables and pinking severity, Pearson correlation coefficients were computed. Statistical significance was considered at the 95% confidence level. As the synthesis of anthocyanins in berries occurs over the maturation period, the months used for the analysis included August (véraison), September, and October (harvest).

RESULTS AND DISCUSSION

Isolation of the Pinking Components and Characterization by HPLC-DAD. In Figueira de Castelo Rodrigo, designation of origin Beira Interior, subregion Castelo Rodrigo (Portugal), white wines are produced mainly from the Síria grape variety, although some white wines are produced by a blend of Síria and Malvasia Fina grape varieties. Producers at the ACFCR state that whatever wine they produce, monovarietal or blended, pinking has appeared in the past 12 years. In this period, the white wines have been produced under reducing conditions, although not with the same severity each year. Figure 1a presents the visible absorption spectra of a white wine (Síria 2010) and the same white wine where pinking was induced by standing in a glass during 24 h. After 24 h, the color of the wine changed from a clear pale yellow (L^* = 99.3; a^* = −0.471; b^* = 3.288) to a pale salmon (L^* = 98.4; a^* = 0.392; b^* = 4.004), with a clear increase in the absorbance in the visible region (ΔE^* = 1.39). After subtraction of the initial absorbance from the absorbance after 24 h, a peak in the visible region between 440 and 630 nm was clearly observed, with a maximum around 500−520 nm. This behavior is the pinking phenomenon described in the literature, where the appearance of the pink-salmon color is induced by oxidation of the white wines.[1]

In some years, pinking is observed before bottling, and the addition of PVPP is used to eliminate it. This strategy of using PVPP to remove the pinking from white wines was used in the present work as a first step for characterization of the pinking compounds present in white wines. After addition of PVPP to

the wines, the PVPP becomes pink and the white wine recovered a pale yellow color. The PVPP-retained pink compounds, after extensive washing, were eluted with an ethanol solution containing 0.1 M NH_3, and a pink band was observed to migrate from the PVPP. When the compounds were eluted from the column, the pink color disappeared and, after neutralization of the solution with acetic acid, the pink color reappeared. The analysis of the compounds eluted from the PVPP by HPLC-DAD yielded a maximum of 18 peaks (Table 1), all with absorbance in the visible region, with maxima in the 500−540 nm range, which correspond to the wavelength of the pinking compounds.[1] Anthocyanins show a broad absorption band in the blue end of the visible spectra with maxima in the 500−535 nm region. Absorption bands in the UV region from about 277 to 284 nm are also observed due to the aromatic ring structure, and occasionally another weak UV band is observed in the region from about 328 to 346 nm. The UV−visible absorption spectra of the main compounds show that 10 of the 18 identified peaks recovered from the white wine with pinking, representing 86% of the total area, have a clear anthocyanin-like absorption spectra. Peaks at retention times of 21.58, 24.27, and 30.68 min were coincident with the retention times and UV spectra of pure standards of delphinidin-3-*O*-glucoside, cyanidin-3-*O*-glucoside, and malvidin-3-*O*-glucoside. Also, the retention times of all components match accordingly those of young red wines analyzed under the same conditions (data not shown). Although the analysis of the UV−vis spectra and retention times (Table 1) allows the assignment of the anthocyanins,[19,20] to confirm their presence in the white wines under study, the anthocyanins were recovered by reversed phase solid phase extraction. Also, other wines made from Síria and a blend made from Síria and Malvasia Fina grape varieties, from a different harvest, were also analyzed, allowing the clear identification of the presence of anthocyanins.

When the white wine was adjusted to pH 1 without previous exposure to air, it turned pink (L^* = 97.3; a^* = 2.495; b^* = 3.946). The change in the visible spectrum was much more intense than that observed for the wine in which pinking was induced by exposure to air (Figure 1b). These observations are also in accordance with the presence of anthocyanins, as will be further discussed below. When the difference absorption spectrum was calculated, the anthocyanin-like spectrum was observed, showing also that the pink color of the white wines in which the pinking phenomena are observed could arise from anthocyanins. The amount of total monomeric anthocyanins was determined by the differential pH method, and the higher amount of anthocyanins was observed for the Síria 2010 white wine, containing 0.33 mg of anthocyanins/L, followed by the blend 2012 white wine, containing 0.27 mg of anthocyanins/L, and the Síria 2012 white wine containing 0.20 mg of anthocyanins/L. When the white wines blend 2012 and Síria 2012 were left in a glass for 24 h, no pink color could be detected by eye, suggesting that the total amount of monomeric anthocyanins required to have the pink color is close to 0.3 mg/L.

These results show that the main compounds present in pinking Síria white wines, absorbing in the visible range of the light spectra, should be anthocyanins, as further confirmed by tandem mass spectrometry.

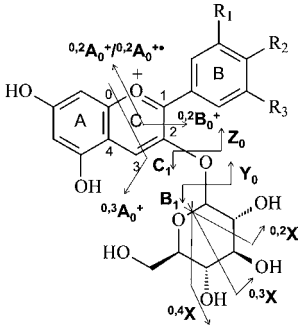
Tandem Mass Spectrometry Confirmation of the Chemical Nature of the Pinking Components. The

dx.doi.org/10.1021/jf500825h | J. Agric. Food Chem. 2014, 62, 5651−5659

identity of the different anthocyanins as the pinking-related compounds was confirmed by off-line mass spectral analysis, including MS^2 to MS^3 fragmentation. The ions at m/z 449, 463, 465, 479, and 493 were observed in the MS, attributed to the anthocyanidin-3-*O*-glucosides, which aglycones correspond to cyanidin, peonidin, delphinidin, petunidin, and malvidin, respectively (Table 2). It was also possible to observe an ion at m/z 433, attributed to pelargonidin-3-*O*-glucoside that could not be observed in the HPLC-DAD analysis as this anthocyanin is known to be present in grapes in insignificant amounts, preventing its detection by HPLC-DAD.[21]

To confirm the identities of selected ions, they were induced to fragment to obtain MS^2 and MS^3 spectra. Product ions formed in tandem mass spectrometry experiments of anthocyanidins bearing glycosyl residues are usually named according to the nomenclature proposed by Domon and Costello[22] and Ma et al.[23] (Scheme 1). Sugar fragment ions that retain the charge at the aglycone are designated X when originated by cross-ring cleavages, or Y and Z when originated by cleavage of the glycosidic linkage. Product ions that retain the charge at the sugar residue are designated A when originated by cross-ring cleavages or B and C when originated by cleavage of the glycosidic linkage. For free aglycones, the $^{i,j}\mathbf{A}^+$ and $^{i,j}\mathbf{B}^+$ labels are used to designate primary product ions containing intact A and B rings, respectively, in which the superscripts *i* and *j* indicate the C-ring bonds that have been broken (see Scheme 1). For conjugated aglycones, an additional subscript 0 to the right of the letter is used to avoid confusion with the A_i^+ and/or B_i^+ ($i \geq 1$) labels that have been used to designate carbohydrate fragments containing a terminal (nonreducing) sugar unit. The $^{i,j}\mathbf{A}^+$ and $^{i,j}\mathbf{B}^+$ ions can undergo further fragmentation by losing small neutral molecules, such as H_2O and CO, or combinations thereof. These product ions are denoted by the combined use of $^{i,j}\mathbf{A}^+$ (or $^{i,j}\mathbf{B}^+$) and the lost molecules. For simplicity, the ions formed by the direct loss of radicals or small neutral molecules such as a methyl group, water, carbon monoxide, and ketene from the M^+ ion are not indicated with special labels.

Scheme 1. Nomenclature of Fragment Ions from Anthocyanidin-3-*O*-glucosides according to Domon and Costello[29] and Ma et al.[30]



The ESI-MS^2 and MS^3 mass spectra of the anthocyanidin-3-*O*-glucosides corresponding to the ions at m/z 433, 449, 463, 465, 479, and 493 are shown in Figure 2, and the product ions observed are identified in Table 2. The fragmentation observed for the MS^2 spectra is consistent with the attributed structure (Figure 3) and in accordance with previous reports on anthocyanin fragmentation by tandem mass spectrometry.[24,25] For all ions a loss of a hexose residue (Hex_{res}; −162 Da) is observed, yielding the Y_0 ions corresponding to the respective aglycones (Table 2). Also observed in some MS^2 spectra are the Z_0 ions corresponding to the loss of a hexose (−180 Da). Observed in all spectra is one to all the possible cross-ring cleavage of the sugar residue, corresponding to the loss of 60, 90, and 120 Da, assigned as $^{0,4}X_0$, $^{0,3}X_0$, and $^{0,4}X_0$ ions. There are also small neutral losses including those corresponding to water (18 Da) and $CH_3^\bullet$ + $OH^\bullet$ (−32).

The MS^3 spectra were acquired and presented the typical fragmentation of anthocyanidins, corresponding to methyl loss,

R_1	R_2	R_3	Anthocyanidins	MM	λmáx
H	OH	H	Pelargonidin	271	505
OH	OH	H	Cyanidin	287	515
OCH_3	OH	H	Peonidin	301	515
OH	OH	OH	Delphinidin	303	523
OH	OH	OCH_3	Petunidin	317	526
OCH_3	OH	OCH_3	Malvidin	331	530

Figure 3. Structure, monoisotopic mass, and maximum visible absorption wavelength of anthocyanidins in *Vitis vinifera*.

dx.doi.org/10.1021/jf500825h | J. Agric. Food Chem. 2014, 62, 5651−5659

water loss, CO loss, and H_2CO loss, among others. The diagnostic $^{0,2}B^+$, $^{0,3}A^+$, and $^{0,2}B^+$ ions could be detected in some but not all spectra. This is in accordance with previous reports that show that under low energy induced fragmentation, the neutral losses are more important than the formation of these fragment ions.[26]

The ions at *m/z* 521, 535, and 639 corresponding to petunidin-3-*O*-acetylmonoglucoside, malvidin-3-*O*-acetylmonoglucoside, and malvidin-3-*O*-(6-*O*-*p*-coumaroyl)monoglucoside were also observed in the MS spectra, and although the MS^2 spectra did not have enough quality due to the low abundance of these ions, a loss of 204 could be observed for the ions at *m/z* 521 and 535, consistent with the presence of an acetylated hexose residue. The loss of neutral molecules with 146 + 162 observed in the MS^2 of the ions at *m/z* 639 corresponds to the loss of a coumaroyl and hexose residue (data not shown).

Anthocyanin Distribution on Síria White Grapes and Effect of Pressing Method and Storage on the Pinking White Wine Anthocyanin Profile. As no pink color was observed in Síria white grape variety (Figure 4), it could be inferred that the anthocyanins were not concentrated in any particular grape berry tissue. Nevertheless, it was possible to detect anthocyanins in the skin and pulp of the Síria white grapes. Grapes may be either not-colored or colored, ranging from the lightest pink to the darkest purple tones according to the amount of anthocyanin accumulated in the berry skin, this being the primary factor characterizing the grapes and wines.[27] Síria grapes are undoubtedly accordingly classified as white grapes (Figure 4);[28] nevertheless, this variety has the capacity to synthesize small amounts of anthocyanins not concentrated in the skin as is common in red and pink grape varieties.[17,29] The synthesis of flavonoids in plants arises from the action of multiple enzymes of the phenylpropanoid pathway. Most of the genes coding for these enzymes have been identified in the *Vitis* genus.[30] White grapes contain the genes responsible for the synthesis of all enzymes in the anthocyanin pathway; some of them share in the formation of other polyphenols present in white grapes.[31] The absence of red color in the white varieties (i.e., the absence of anthocyanins) results from multiallelic mutations of the *VvMYBA1* and *VvMYBA2* genes,[29,32−34] which control the last biosynthetic step of anthocyanin synthesis, a glycosylation reaction mediated by the UDP-glucose flavonoid 3-*O*-glucosyltransferase enzyme. Also, the occurrence of light-red and rosy-skinned bud sports resulting from the color recovery in berries of grape of the white cultivar 'Italia' caused by a novel allele at the *VvmybA1* locus has been described.[35] Therefore, another possibility is that the clone of the Síria grape variety cultivated in Figueira de Castelo Rodrigo region is a bud sport of the original Síria white grape variety or that the Síria grape variety never completely lost the ability to produce anthocyanins. Furthermore, the Síria grape variety from this region presents the highest genetic diversity.[28] This point deserves further study.

Figure 4. Síria grape variety at technological maturity.

The 2012 vintage was followed in all steps of winemaking from Síria white grapes, from the reception of the grapes, their pressing to give the must, to the final product, the wine. The analysis of the must, just at the reception of the Síria white grapes, allowed the detection of anthocyanins, corroborating the presence of anthocyanins in Síria pulp. During grape pressing, the anthocyanin profile and amount of must sampled at different pressures show that higher amounts of anthocyanins were extracted at pressure stage 2. The must presented clearly a pink color, and the color changed with the change of pH, more intense at pH 1.39 and completely disappearing at pH 4.01. At pH 4.01 no pink color could be detected, showing that the anthocyanins were the only compounds with pink color present in the must. Lower amounts of anthocyanins were extracted at pressure stage 4, and the amount of anthocyanins extracted increased slightly again at pressure stage 6 due to the presence of anthocyanins also in the grape skin. White wine produced from these grapes also contained anthocyanins, even after PVPP treatment. In fact, when the white wine was exposed to oxygen, the appearance of pinking was observed from the top to the bottom of the bottle, attributed to the depletion of free sulfur dioxide due to the exposure to oxygen.

Anthocyanins are not stable during bottling. To follow their fate during storage in the pinking white wines, the Síria 2010 wine that turned pink after bottling was analyzed also after 12 months of storage. The chromatographic profile changed considerably, a lump and small amounts of malvidin-3-*O*-glucoside being observed. The observed lump is a feature characteristic of old red wines due to the polymerization of anthocyanins.[36] The amount of monomeric anthocyanins of the Síria 2010 white wine decreased to 0.035 mg/L after storage, showing that there was a decrease in the monomeric anthocyanin content during storage. This can explain the results previously reported by Jones, who described the pinking phenomena as being caused by at least 10 different compounds and polymeric material, suggesting that polymerization had occurred in the analyzed samples.[2]

The severity of pinking each year during the past 12 years in Figueira de Castelo Rodrigo wine was not the same, possibly due to the influence of weather conditions. Therefore, the pinking severity of each year was indirectly assessed by measuring the amount of PVPP used in winemaking in relation to the amount of white wine produced between 2005 and 2011, ranging from 0.111 g/L (2011) to 0.299 g/L (2008). This interannual variability was negatively related with the average temperatures of the first 10 days of October ($r = -0.92$, $p < 0.003$), suggesting that higher temperatures occurring during that period decreased the coloration of wines. No significant linear relationships were found for other periods of October (middle and last 10 days) and September. Nevertheless, they need to be cautiously interpreted as the data series is limited to seven vintages. On the other hand, August temperatures and thermal amplitudes displayed inconsistent outputs. The measures of heat accumulation, such as degree-days, did not show closer relationships. Furthermore, precipitation of the above periods presented no statistically significant correlations with pinking severity (data not shown). These results may be ascribed to the influence of temperature on anthocyanin

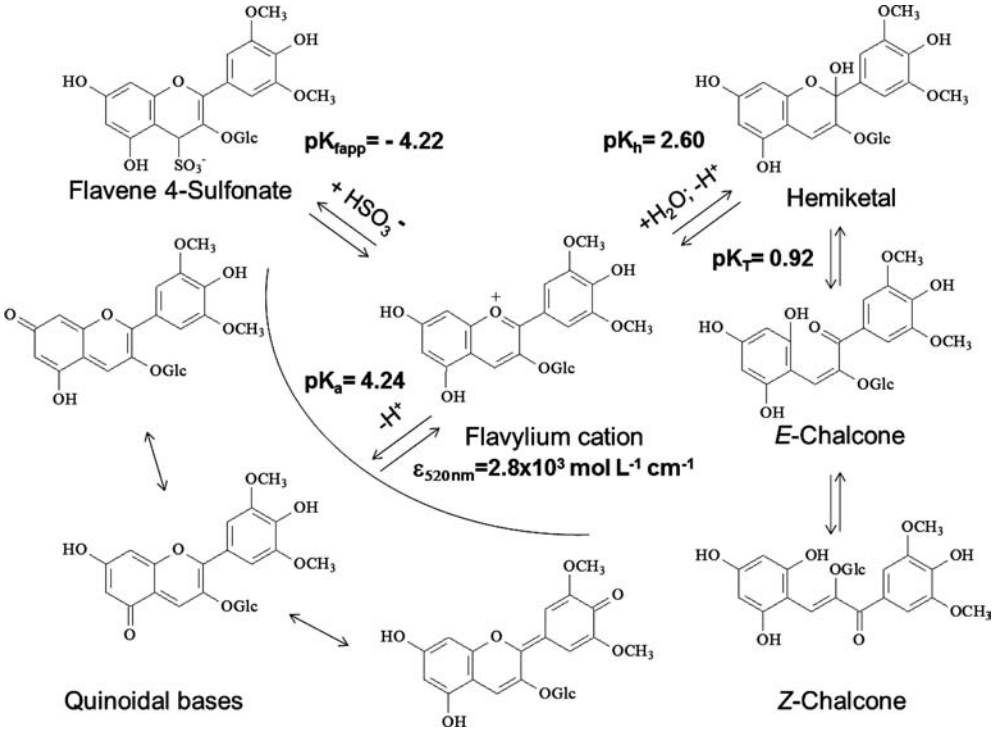

Figure 5. Effect of pH on anthocyanin equilibria in aqueous solution and in the presence of hydrogen bisulfite.

biosynthesis.[37,38] Therefore, it may be inferred that lower average temperatures in early October promote the synthesis of anthocyanins in Síria grape varieties and, consequently, white wine pinking.

Implications of Anthocyanins in White Wine Pinking. Although it cannot be excluded that the pinking of different grape varieties of white grapes can have a different origin from that observed for the Síria grape variety, all of the technical descriptions of the pinking process fit with the known chemical properties and reactivity of anthocyanins. It is described that the inhibition of wine PPO increases the pinking potential of white wines,[10] and hyperoxidation of grape must reduces pinking potency of white wines. In grape juice, PPO mainly catalyzes the oxidation of caftaric acid to the unstable *o*-quinones that bleach anthocyanins by two different mechanisms, depending on the anthocyanin structure.[39,40] The nonenzymatic generation of *o*-quinones from caftaric acid and other polyphenols containing an *o*-diphenol structure such as (+)-catechin/(−)-epicatechin, gallocatechin, gallic acid and its esters, and caffeic acid, which are the most readily oxidized wine compounds,[41,42] can occur under hyperoxidation of grape must. Anthocyanin bleaching can occur in the case of anthocyanins containing an *o*-diphenolic structure on the B-ring such as cyanidin, delphinidin, and petunidin by coupled oxidation to very unstable quinones, regenerating the initial caftaric acid or other quinones present in solution.[43] Condensation reactions of anthocyanin in its hemiketal form to the *o*-quinone produce a colorless adduct, which is then equilibrated to the corresponding flavylium form.[39,43] Pinking can be observed just after crushing of the grapes, and its decrease can be observed with the addition of sulfur dioxide to the grape must. The monomeric anthocyanins in solution, and in the presence of free sulfur dioxide, are involved in a series of dynamic equilibria among five major molecular forms (Figure 5), including the bisulfite addition flavene compound, the quinoidal base, the flavylium cation, the hemiketal or carbinol pseudobase, and the chalcone (*E*- and *Z*-forms). The relative proportions of each form are dependent on the pH, free sulfur dioxide concentration, and temperature.[44−48] At wine pH (3.0), using the available equilibrium constants[45−47] and the apparent formation constant for the bisulfite addition flavene compound[48] for malvidin-3-*O*-glucoside, the main anthocyanin present in the pinking white wines, and neglecting the effect of ionic strength and ethanol concentration, it is possible to calculate the relative proportion of all compounds in equilibrium with the flavylium cation (Figure 5). Without the presence of free sulfur dioxide, the flavylium cation represents 26% of all forms in equilibrium, with the most abundant being the hemiketal, which represents 65%. The presence of free sulfur dioxide changes considerably these proportions in a concentration-dependent manner. In the presence of 50 ppm of free sulfur dioxide, a normal level used in bottling of white wines, the flavylium cation abundance decreases significantly to 6%, the hemiketal form also decreases significantly to nearly 15%, and the bisulfite addition flavene compound becomes the most abundant form in equilibrium, representing 76% of all forms. The decrease in the free sulfur dioxide content to 20 ppm increases the relative abundance of the flavylium cation to 11%, increases the amount of the hemiketal form to 28%, and decreases the relative abundance of the bisulfite addition flavene compound to 56%. The appearance of pinking after bottling and after standing in the air can be explained by the decrease of the free sulfur dioxide in wine that increases the amount of the anthocyanins in the flavylium cation form to a level that can be perceived.

During storage, the polymerization of anthocyanins was also observed. As the color of the polymeric anthocyanins is resistant to sulfur dioxide bleaching,[49] the polymerization of anthocyanins can also contribute to the appearance of pinking during bottling. In fact, it is known that polymeric

dx.doi.org/10.1021/jf500825h | J. Agric. Food Chem. 2014, 62, 5651−5659

anthocyanins, besides being quite resistant to bleaching by sulfur dioxide, have a color much more insensitive to pH changes than the monomeric forms.[49] Probably, this is why often pinking is described as being insensitive to sulfur dioxide bleaching and pH change.[1]

The results obtained by the test developed by Simpson[1] to evaluate the pinking sensitivity of white wines can also be rationalized according to the equilibrium of anthocyanins and their polymerization under oxidative conditions. In this test, the addition of hydrogen peroxide (75 mg/L) is used presumably to accelerate the oxidation of the white wine pink color precursors. Nevertheless, the hydrogen peroxide consumes the available bisulfite (HSO_3^-)[50] present in wine (up to an equivalent amount of 141 mg sulfur dioxide/L when no other compounds able to consume the hydrogen peroxide are present), and in a normal white wine the amount of free sulfur dioxide is much lower than this value. This results in the increase of the relative proportion of the flavylium cation and the consequent appearance of pink color that can also be due to the polymerization of the anthocyanins under the oxidative conditions used in the test. In fact, the amount of free sulfur dioxide does not influence the outcome of the method as long the amount of free sulfur dioxide is below 40 mg/L.[1]

ABSTRACT: A chitinase was purified from *Vitis vinifera* Manzoni Bianco grape juice and characterized. On the basis of proteomic analysis of tryptic peptides, a significant match identified the enzyme as a type IV grape chitinase previously found in juices of other *V. vinifera* varieties. The optimal pH and temperature for activity toward colloidal chitin were found to be 6 and 30 °C, respectively. The enzyme was found to hydrolyze chitin and oligomers of *N*-acetylglucosamine, generating *N*,*N*′-diacetylchitobiose and *N*-acetylglucosamine as products, but was inactive toward *N*,*N*′-diacetylchitobiose. The enzyme exhibited both endo- and exochitinase activities. Because yeast contains a small amount of chitin in the cell wall, the possibility of growth inhibition was tested. At a concentration and pH expected in ripe grapes, no inhibition of wine yeast growth by the chitinase was observed.

KEYWORDS: *grape chitinase, chitinase activity, yeast inhibition*

INTRODUCTION

Chitinases (EC 3.2.1.14) are glycosyl hydrolases that catalyze the degradation of chitin, a β-1,4-linked polymer of *N*-acetylglucosamine (GlcNAc) found in fungal cell walls among other natural sources.[1] Although higher plants lack chitin, they harbor chitinase genes and express them in response to pathogens or developmental cues in susceptible tissues.[2,3] In *Vitis vinifera*, type IV chitinase activity has been reported to increase dramatically in berries during ripening, presumably to provide protection from potential fungal attack.[4] Type IV chitinases have been detected in the juice of a number of varieties of *V. vinifera* species[4−7] and in wines made thereof.[7−11] Chitinase concentration in bottled white wines has also been found to correlate with the formation of heat-induced turbidity, a recognized quality defect.[12] Chitinase activity was reported to decrease significantly from initial levels detected in Pinot noir berries through the various stages of sparkling wine production to undetectable levels in the final wine.[13]

Chitinases have been classified into two major categories: endochitinases and exochitinases.[14] However, the current nomenclature for chitinolytic enzymes is confusing, due in part to the fact that the former classification scheme has not been abandoned.[15,16] The former scheme distinguished the exochitinases (EC 3.2.1.29), which catalyze progressive release of dimeric chitobiose residues from the nonreducing end, from the *N*-acetyl-β-D-glucosaminidases (EC 3.2.1.30), which release monomeric GlcNAc residues from chitin oligomers.[14] Currently, the International Union of Biochemistry and Molecular Biology (IUBMB) recognizes a single β-*N*-acetylhexosaminidase class of enzyme, EC 3.2.1.52, that includes the former EC 3.2.1.29 and EC 3.2.1.30 enzyme classes. Furthermore, some authors have described the enzymes that release small oligomers (including dimers) from the reducing end as endochitinases (EC 3.2.1.14), differentiating them from even the strictly endotype enzymes.[17] In the present paper, we use the nomenclature proposed by Harman et al., in which the difference between endo- and exochitinases is substrate specificity: endochitinases require at least tetrameric GlcNAc, whereas the minimum substrate for an exochitinase is the GlcNAc trimer. In addition, we refer to the enzyme that catalyzes the release of dimers as chitobiosidase.[18]

Although a number of studies have characterized family 19 chitinases, which include the type IV enzyme,[19,20] to our knowledge, the grape type IV chitinase has been subjected to limited biochemical analysis.[21,22] Here, we determined enzyme activity and substrate specificity and asked whether chitinase activity likely to be present in ripe grapes has the potential to inhibit yeast growth during wine fermentation.

MATERIALS AND METHODS

Purification of Grape Chitinase. Initially, 6 L of grape juice from *V. vinifera* Manzoni Bianco was treated overnight at 4 °C with 4 g/L of polyvinylpolypyrrolidone (PVPP) (Fluka), 2 g/L activated charcoal (Sigma), and 3 g/L of pectolytic enzymes (Pectazina DC, Dal Cin). The juice was decanted, filtered through a GF/A filter (Whatman), adjusted to pH 3.0 with HCl, and then filtered through a 0.2 μm cellulose acetate filter (Sartorius). Chitinase was purified from the filtered juice essentially as described.[5] The only modification was the substitution of the MacroPrep High S resin with an S-Sepharose resin (220 mL). Fractions containing a single band at 31 kDa (corresponding to the molecular weight of grape chitinase) were pooled, dialyzed against water (3500 Da cutoff dialysis membrane), and freeze-dried. The purity of the protein was checked by HPLC as described.[6]

Chitinase Identification by LC-MS/MS Analysis of Tryptic Peptides. The freeze-dried purified 31 kDa fraction was processed for in-solution trypsin (Promega Trypsin Gold) digestion in the presence of a protease enhancer (Promega ProteaseMAX Surfactant) according to the manufacturer's protocol. LC-MS/MS analysis was conducted on an LTQ-FT MS (Thermo Fisher Scientific, San Jose, CA, USA) instrument coupled to a nanoAcquity UPLC system (Waters Corp., Milford, MA, USA). A binary solvent system consisting of solvent A, water with 0.1% formic acid, and solvent B, acetonitrile with 0.1% formic acid, was used for the analyses. Tryptic peptides (2 μL) were loaded onto a peptide trapping column (Cap Trap, Michrom) and separated using a C18 column (Agilent Zorbax 300SB-C18, 250 × 0.3 mm, 5 μm). Peptides were trapped and washed with 3% solvent B for 3 min at a flow rate of 5 μL/min. Peptide separation was achieved using a linear gradient from 10 to 30% B at a flow rate of 4 μL/min over 102 min. The LTQ-FT mass spectrometer was operated using data-dependent MS/MS acquisition with an MS precursor ion scan, performed in the ICR cell, from m/z 350 to 2000 with the resolving power set to 100,000 at m/z 400, and MS/MS scans performed by the linear ion trap on the five most abundant doubly or triply charged precursor ions detected in the MS scan.

Thermo RAW data files were processed with Proteome Discoverer v1.4.0. Mascot software (v2.3) and were used to search against the *V. vinifera* database downloaded from UniprotKB on July 8, 2013 (http://www.uniprot.org/), which included common processing contaminants. The following parameters were used to search the database: the digestion enzyme was set to Trypsin/P, and two missed cleavage sites were allowed. The precursor ion mass tolerance was set to 10 ppm, whereas a fragment ion tolerance of 0.8 Da was used. Dynamic modifications that were considered included carbamidomethyl (+57.02 Da) for cysteine, oxidation (+15.99 Da) for methionine, and deamidination (+0.98 Da) of asparagine and glutamine. Scaffold_3.3.1 (Proteome Software, Portland, OR, USA) was used for search data compilation and data evaluation with an embedded X!Tandem database searching algorithm. Peptide identifications were accepted if they could be established at >90.0% probability. Peptide Probabilities from X! Tandem were assigned by the Peptide Prophet algorithm[23] with Scaffold delta-mass correction. Peptide Probabilities from Mascot were assigned by the Scaffold Local FDR algorithm. Protein identifications were accepted if they could be established at >90.0% probability and contained at least two identified peptides. Protein probabilities were assigned by the Protein Prophet algorithm.[24] Proteins that contained similar peptides and could not be differentiated on the basis of MS/MS analysis alone were grouped to satisfy the principles of parsimony. Identified MS/MS spectra were manually validated, and ion assignments were made according to the spectral output of the Scaffold program.

Purification of Chitin Oligomers. Two grams of crab shell chitin (Fluka 22780) were hydrolyzed by suspension in 32 mL of 12 M HCl initially for 10 min at room temperature followed by an additional 110 min at 40 °C. The solution was neutralized on ice by slow addition of 32 mL of 50% NaOH. Insoluble matter was removed by centrifugation, and the clear supernatant was adjusted to pH 7 and ultrafiltered on an apparatus equipped with a 500 Da cutoff membrane (Amicon) to remove excess salt and to concentrate the oligomers. When a volume of 3 mL was reached, 1.5 mL was loaded onto a Bio-Gel P2 (Bio-Rad Laboratories) column (100 × 1.5 cm) and eluted at a rate of 0.25 mL/min using distilled water. One milliliter fractions were collected, freeze-dried, and resuspended in 20 μL of water.

TLC Analysis. TLC analysis was performed using silica TLC plates and a butanol/acetic acid/water (2:1:1) solvent[25] to determine oligomer purity in the Biogel P2 fractions and subsequently to determine the mechanism of chitinase action. Two microliters of the Bio-Gel P2 fractions was analyzed, and fractions with the same profile were pooled and freeze-dried. *N*-Acetylglucosamine (GlcNAc) and $(GlcNAc)_{2-3}$ standards (Sigma-Aldrich, St. Louis, MO, USA) were used for reference. Higher oligomers, $(GlcNAc)_{4-6}$, that were not commercially available were identified on the basis of mobility relative to the monomer and $(GlcNAc)_{2-3}$ oligomers.

Amino sugars were detected by staining with a solution of aniline/diphenylamine (4 mL of aniline, 4 g of diphenylamine, 200 mL of acetone, 30 mL of 85% phosphoric acid), followed by incubation for 3 min at 180 °C.

Chitinase Activity. Colloidal chitin used as substrate was prepared essentially as described by Sheng et al. starting with crab shell chitin.[26] For the determination of pH and temperature optima, chitinase activity was measured using an assay that specifically detected GlcNAc by reaction with *p*-dimethylaminobenzaldehyde (DMAB).[27] One unit of activity was defined as the amount of enzyme that catalyzed the release of 1 nmol of GlcNAc per minute at 37 °C and pH 5.5. A different chitinase assay was used to quantify activity when the inhibition of yeast growth was assessed. Specifically, chitinase added to yeast cultures was assayed prior to the addition by determining a linear increase in soluble reducing sugar over 1 h[28] using a commercial kit (Thermo Scientific Pierce Micro BCA Protein Assay Kit 23235) and GlcNAc as standard. Although this Cu-based assay kit is designated for protein quantification, the same reaction measures reducing sugar as well.[29] For this assay, one unit of chitinase activity was defined as that which liberated 1 mg of GlcNAc equivalents per hour at 25 °C.

Activity versus pH Determination. Two buffers were prepared at 50 mM strength: a citric acid−phosphate McIlvaine buffer, covering the pH range from 2.5 to 8, and a glycine buffer, covering the pH range from 8.5 to 10.5. For each pH tested, 800 μL of colloidal chitin was washed three times with 2 volumes of the corresponding buffer and resuspended in a final volume of 1600 μL (0.5% w/v final chitin concentration). Half of the solution volume was kept as a control, whereas chitinase was added to the other 800 μL of substrate to a final concentration of 50 μg/mL. After 2 h at 37 °C, both the sample and the control were centrifuged (12000*g*, 5 min), and 250 μL of clear supernatant was used to quantify GlcNAc. The difference between the absorbance of the sample and that of the control was used to determine the enzyme activity.

Activity versus Temperature Determination. Chitinase activity was determined as a function of temperature in 50 mM sodium acetate buffer, pH 6. Colloidal chitin (800 μL) was washed three times with 2 volumes of buffer and resuspended in a final volume of 1600 μL (0.5% w/v final chitin concentration). After a 30 min equilibration of substrate at each chosen temperature, 50 μg/mL of enzyme was added to initiate reactions. After a 1 h incubation, samples were centrifuged (12000*g* for 5 min) and GlcNAc concentrations were determined in 250 μL of clear supernatant.

Determination of Substrate Specificity. Activity against *N,N′*-diacetylchitobiose and the oligomers $(GlcNAc)_{3-6}$ was assessed under the following conditions. Two microliters of individual substrates at 10 mg/mL in water was diluted into a final volume of 50 μL of 50 mM ammonium acetate, pH 5.5, to which 1 μL of enzyme (10 mg/mL) was added. Two control reactions were run per substrate: one with substrate but without enzyme and the other with substrate and heat-inactivated enzyme (100 °C for 5 min). After a 1 h incubation at 37 °C, samples were freeze-dried, during which the ammonium acetate was evaporated. The residues were then resuspended in 3 μL of water and loaded onto TLC plates.

Yeast Strains, Growth Media. Four strains of *Saccharomyces cerevisiae* were used; laboratory strain S288c (*MATα SUC2 gal2 mal mel flo1 flo8−1 hap1 ho bio1 bio6*); a brewing strain, 2007-Pilsen Lager (Wyeast Laboratories); and the wine strains EC1118 and RC212 (Lallemand). Strains were grown in yeast nitrogen base (YNB) without amino acids, pH 5.2 (Difco), containing 2% glucose (YNB + glu) or in YNB containing 2% glucose adjusted to pH 3.5 by the addition of 26.6 mM tartaric acid (YNB + glu + tartrate, pH 3.5).

Yeast Growth Assay. Growth inhibition was assessed as a reduction in cell yield (A_{600}) in treated versus control cells. Treated cells were grown in the presence of grape chitinase, whereas control cells were grown in the presence of the same amount of boiled grape chitinase. Cells were grown overnight in YNB + glu or YNB + glu + tartrate, pH 3.5, washed twice in sterile distilled water, and then diluted to an initial concentration of 10^3 cells/mL in 1 mL aliquots of YNB + glu or YNB + glu + tartrate, pH 3.5, respectively, containing 50 μg of chitinase or boiled chitinase (control). In 100 mM sodium

phosphate at pH 6.0, 5.2, and 3.5, 50 μg of grape chitinase was found to contain $0.0237 \pm 9.7 \times 10^{-4}$, $0.0288 \pm 1.3 \times 10^{-3}$, and $0.0249 \pm 1.8 \times 10^{-3}$ units of activity ($n = 2$), respectively. Initial cell concentrations were determined by use of a hemacytometer. Cells were incubated in triplicate for 48 or 72 h at 30 °C and 200 rpm in 1.5 mL screw-capped polypropylene tubes, after which A_{600} values were measured. Growth inhibition was expressed as the ratio $[A_{600}$ (treated cells)$/A_{600}$ (control cells)$] \times 100$. The significance of differences was assessed using Student's two-sided, two-tailed t test ($p < 0.05$).

RESULTS AND DISCUSSION

Chitinase Purification and Identification. After the two purification steps, 130 mg of chitinase (97% purity by HPLC, calculated as peak area on the chromatogram) was obtained from 6 L of Manzoni Bianco grape juice (Figure 1), comparable to yields obtained by Van Sluyter et al., 45 and 10 mg/L for Semillon and Sauvignon blanc juices, respectively.[5]

The purified 31 kDa protein was identified as a type IV chitinase on the basis of significant matches with three different tryptic peptides (Table 1) shared by two enzymes designated Q7XAU6_VITVI (UniProtKB) based on the deduced amino acid sequence of cDNA VvChi4D (EMBL AAQ10093.1) and the *V. vinifera* chitinase designated O24530 (UniProtKB), the sequence of which was deduced from cDNA VvChi4A.[4] Q7XAU6_VITVI was previously detected in juice from Semillon and Sauvignon blanc grape varieties.[5,30,31] It is possible that the two proteins are allelic variants encoded by the same gene (Figure 2a). Tandem mass spectra of ion fragments derived from the three identified peptides are listed in Figure 2b–d. Although protein and peptide identification probabilities were set to >90%, the peptides listed in this figure have peptide identification probabilities of 100%.

Determination of Substrate Specificity. Because tetramers and larger oligomers of GlcNAc were unavailable commercially, these substrates were purified from a partial chitin hydrolysate by size exclusion chromatography. Figure 3 shows the purified oligomers $(GlcNAc)_{3-5}$ separated by TLC. The fractions were freeze-dried and resuspended in water at 10

Letters A−F indicate substrates $GlcNAc_1$−$GlcNAc_6$, respectively. Numbers indicate treatment. Number 1 indicates incubation of substrate in the absence of enzyme. Numbers 2 and 3 indicate incubation with enzyme or heat-inactivated enzyme (100 °C for 5 min), respectively.

As expected, the monomer GlcNAc was not affected (Figure 4A1−A3), nor was *N,N′*-diacetylchitobiose degraded (Figure 4B1−B3), indicating an absence of 1,4-*β*-*N*-acetylglucosaminidase activity. On the other hand, chitotriose was split into the monomer GlcNAc and dimer *N,N′*-diacetylchitobiose (Figure 4C1−C3). Therefore, on the basis of the classification of Harman et al.,[18] this grape enzyme should be considered an exochitinase. However, as noted below, this designation is not consistent with the products generated from degradation of the tetramer $(GlcNAc)_4$. The degradation of $(GlcNAc)_4$ (Figure 4D1−D3) yielded both a dimer, as would be expected if chitobiosidase activity alone were present, and the monomer. On the basis of the absence of 1,4-*β*-*N*-acetylglucosaminidase activity (Figure 4B1−B3), we speculate that formation of the monomer was due to transient production of the trimer during cleavage, suggesting an endochitinase-based mechanism. Both monomer and dimer were also obtained from hydrolysis of the pentamer (Figure 4E1−E3) and hexamer (Figure 4F1−F3) as previously observed with other endochitinases.[25] The intermediate oligomers present in lanes E3 and F3 (Figure 4) are likely due to some chitinolitic activity present in the heat-denatured chitinase samples. This can be due to an incomplete denaturation of the catalytic domain or to its refolding upon cooling. Indeed, it was previously demonstrated that the grape chitinase is able to recover its activity after a 5 min treatment at

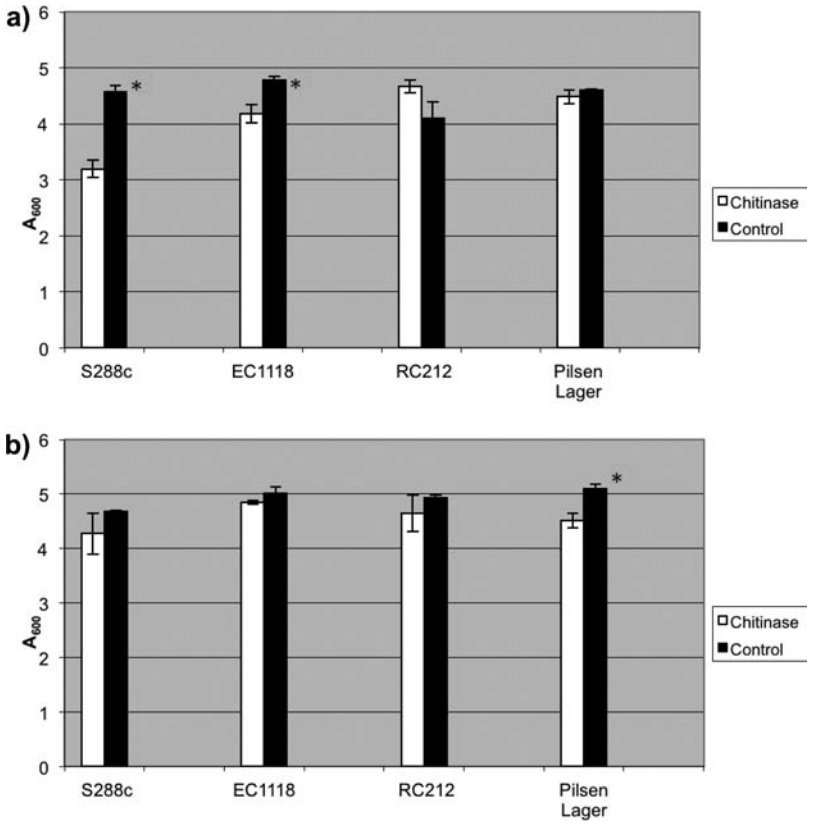

Figure 7. Inhibition of yeast growth: (A) inhibition after 48 h in YNB + glu assessed as a reduction in cell yield (A_{600}) in the presence of 50 μg of chitinase or boiled chitinase (control) starting with an initial inoculum of 10^3 cells/mL; (B) inhibition after 72 h in YNB + glu + tartrate, pH 3.5 assessed as a reduction in cell yield (A_{600}) in the presence of 50 μg of chitinase or boiled chitinase (control) starting with an initial inoculum of 10^3 cells/mL. Data are means of triplicate assays. An asterisk indicates a significant difference between treatment and control (Student's two-sided, two-tailed t test, $p < 0.05$).

100 °C followed by SDS-PAGE migration.[32] The presence of oligomers is consistent with endochitinase activity. These results are in agreement with a previous study that found the major grape chitinases to be class IV endochitinases on the basis of protein sequence.[4] However, a chitinase purified from *Bacillus brevis* characterized as an endosplitting enzyme produced mostly oligomers much larger than $(GlcNAc)_4$ from a substrate consisting of a hydrolysate of colloidal chitin.[26] In addition, it has been reported that to determine chitinase activity from a variety of sources (e.g., soybean seeds[33] or *Streptomyces*[34]), a specific chitobiase is needed to degrade the disaccharide to produce p-DMAB-reactive GlcNAc. In our case, it was possible to quantify enzymatic activity directly using p-DMAB without the addition of an exogenous chitobiase.

The pattern of degradation products observed here from various GlcNAc oligomers is very similar to that reported for an *Aspergillus fumigatus* chitinase, presumed to be a family 18 enzyme,[35] that exhibited exo- and endochitinase and transglycosylation activities.[36] On the other hand, a chitinase from *Pyrococcus kodakaraensis* classified as an endochitinase[25] produced $(GlcNAc)_2$ and GlcNAc from $(GlcNAc)_3$ and $(GlcNAc)_2$ along with small amounts of GlcNAc from $(GlcNAc)_{4-6}$.

In summary, both exochitinase activity and the previously described endochitinase activity are suggested for the enzyme purified from grape juice.

Determination of Temperature and pH Optima for Chitinase. Enzyme activity was assessed as a function of temperature and pH. The optimal temperature for chitinase activity was evaluated between 10 and 70 °C (Figure 5). Highest activity was observed between 30 and 40 °C, consistent with a 42 °C optimum found for grape chitinase isolated from *V. vinifera* Red Globe.[21] At temperatures above 50 °C, activity was found to decrease drastically, in agreement with a reported denaturation temperature of about 55 °C.[37] However, it must be noted that this latter result was obtained at pH 3 and that later it was reported that the melting temperature of the grape chitinase increased from 55 to 65 °C by raising pH from 3 to 4.[31] Therefore, the 30% residual activity found here after heating at 70 °C at pH 6 could be due to the effect of pH. More recently, Saito et al. described three chitinase isoforms in *V. vinifera* Semillon with temperature optima between 50 and 60 °C.[22]

The optimal pH for activity was found to be about 6, with relatively high activity observed in the range pH 5−6.5 (Figure 6). The same optimum was found by Gomes et al., although these researchers also detected a second peak of activity at about pH 3.[21] In our case, outside the pH 5−6.5 range, including the pH of grape juice, 3−3.5, activity was found to decrease sharply. On the other hand, chitinase isoforms purified from Semillon exhibited an optimal pH in the range of 4−4.5.[22]

Experiments performed at a pH and temperature close to those of winemaking conditions (25 °C and pH 3.2) demonstrated that the enzyme retained 12% of its maximal activity (data not shown), suggesting that residual activity could be present in grape must during fermentation.

Inhibition of Yeast Growth. Like other pathogenesis-related plant proteins, chitinases are synthesized in response to

biotic or abiotic stresses. However, in grapes, they are also generally expressed in a constitutive manner during ripening.[4] As a consequence, the concentration of chitinases can reach relatively high levels in grape juice.[38,39] The question of whether potential activity in grape juice could affect the major yeast species that mediates the wine fermentation is thus relevant because the cell wall of the wine yeast *S. cerevisiae* contains a small amount of chitin (1−2% dry wt), localized in bud scars.[40] Indeed, a class IV-like chitinase from *Streptomyces* was found to inhibit growth of *S. cerevisiae* at pH 5.8.[41] Because chitinase activity could potentially interfere with yeast growth under winemaking conditions, the effect of chitinase on cell yields of four different strains of *S. cerevisiae* was assessed using very low initial inoculum levels and an amount of chitinase expected in ripe grapes, 50 μg/mL. Although this concentration was found to reduce cell yield of the laboratory strain S288c by 30% and that of the wine strain EC1118 by 12% after 48 h in YNB + glu (Figure 7A), after 72 h, no reduction in cell yield was observed for any of the four strains tested (data not shown). In YNB + glu + tartrate, pH 3.5, a modest reduction in cell yield (12%) was observed only for the Pilsen Lager strain after 72 h (Figure 7B). No reduction was observed for either the laboratory or wine strains (data not shown). It is important to note that the chitinase activity tested here was about 10^4 less than that previously reported to inhibit growth of an unspecified strain of *S. cerevisiae*.[41]

These data suggest that yeast growth in a standard medium (YNB + glu) is slowed transiently if at all by the chitinase treatment and that cells recover if given sufficient time. After 72 h at pH 3.5, only growth of the brewing strain was reduced (modestly). Whether greater inhibition might be observed toward the wine strains during vinification in actual grape must (pH 3−4) when cells are exposed to greater osmotic stress at the higher initial sugar levels (∼20−25%) and higher ethanol levels is an open question.

In conclusion, we speculate that chitinase is unlikely to have an inhibitory effect on yeast growth during vinification, presuming the activity tested here is representative of that present in grape must and the fact that winemakers who use starter cultures typically inoculate with at least 10^6 cells/mL, which is about 10^3-fold higher than the level evaluated in the present study. Even if highly stressed cells might be more susceptible to chitinase-mediated growth inhibition, such cells in a wine fermentation have ceased growth for other reasons but continue to produce a significant amount of ethanol during stationary phase. Thus, growth inhibition per se would be unlikely to arrest fermentation, unless endogenous grape chitinase levels were high enough to inhibit initial growth of the starter culture or that of the naturally occurring yeasts present in uninoculated fermentations. On the other hand, we do not know if chitinase can interfere with fermentation in an indirect manner, unrelated to growth, by inhibiting other cellular processes.

Comparative Study of Phytosterol Derivatives in Monovarietal Olive Oils

Raquel B. Gómez-Coca,* Gabriel D. Fernandes, Chellah del Aguila-Sánchez, María del Carmen Pérez-Camino, and Wenceslao Moreda

Instituto de la Grasa-CSIC, Avenida Padre García Tejero 4, E-41012 Sevilla, Spain

ABSTRACT: Plant sterols and their derivatives are minor compounds that have been extensively studied in vegetable oils, mainly in olive oil, where they are closely related with its identity. The objective of this work is to determine the content of free and esterified steryl glucosides and their profiles in olive oil in relation to different geographical situation of olive orchards, cultivar, farming modality, and sampling time. The orchards under study were located in the outer ring of the submetropolitan area of Madrid (Spain), where olives from Cornicabra, Manzanilla Cacereña, Manzanilla Castellana, and Picual varieties were grown under traditional and organic modes, and harvested in four different samplings. Conclusions state that cultivar, farming mode, and light exposure do not have outstanding effects, whereas pedoclimate might affect the steryl glucoside presence in a substantial way. Further studies are being carried out presently in order to confirm such statement. Also glucoside derivative profiles are discussed, and reasons for differences with results in previous studies pointed out.

KEYWORDS: *olive oil, solid phase extraction (SPE), steryl glucoside (SG), esterified steryl glucoside (ESG), pedoclimate*

INTRODUCTION

Phytosterols, as well as their derivatives, are compounds of the unsaponifiable matter of vegetable oils, whose amount and profile are important parameters of oil identity. In the case of sterol derivatives, SG consist of a glucose moiety bound at the C3 position of the sterol residue via an acetyl bond. If additionally a fatty acid is esterified at the C6 position of the sugar, ESG are formed.

The presence of free and esterified steryl glucosides in edible matrices has been widely studied, although their synthesis pathway and influencing factors are not clear yet.[1] The health promoting effects of steryl glucosides have been unknown for a long time. Their use for the treatment of pathologies related to elevated cholesterol in blood was never compared to those of FS solutions[2] or functional foods,[3] and it was not until 2009 that studies in this field demonstrated the potential health benefits of glucosylated phytosterols in both free and esterified (acylated) forms.[4,5] Actually, SG could get reductions of around 37% in cholesterol absorption in the gut of human subjects, a value similar to the 30% obtained with SE.[4] As a consequence, research on possible steryl glucoside sources became more relevant and groups started publishing detailed data on the content and composition of glucosylated sterols in edible plant matrices to facilitate comparisons of the potential contribution of different foods as sources of steryl glucosides when included in the diet.[6] Those studies did not usually include olive oil, which justifies our studies on the presence of both SG and ESG in this matrix.

One would expect the SG and ESG composition to be closely related to the free sterol pool, and therefore the contribution of both SG and ESG to be bound to the oil identity. The procedure for isolating steryl glucosides from olive oil had been developed earlier. Initially the method was applied to a small number of oil samples of different categories and origins,[7] and then to a wider number also from different cultivars and treated with different refining processes,[8] reaching the conclusion that the only SG that might be present was BSSG, whose concentration in olive oil was never higher than 3 mg·kg^{-1}. Regarding ESG, mass spectrometry results confirmed that in the majority of the samples the only ESG present -at concentration sometimes above 8 mg·kg^{-1}- was EBSSG, possibly eluting just before small quantities of EAvSG.

In this case we have determined the composition and content of free and esterified steryl glucosides in a more systematic way, paying special attention to the contribution of each steryl glucoside to the total glucoside concentration. We have focused on monovarietal olive oils from different geographical situations, farming modalities, and sampling times. Our intention has been not only to start determining the factors affecting the steryl glucoside presence but also to contribute in a direct way to nutrient databases.

MATERIALS AND METHODS

Reagents. The internal standard ChSG, commercial mixtures of ESG and SG, and the analytical-grade chemical reagents used in the course of this research were the same as those utilized previously.[8]

Samples and Standard Solutions. Virgin olive oils were obtained from Cornicabra, Manzanilla Cacereña, Manzanilla Castellana, and Picual olive varieties. They were directly extracted in the laboratory of Doctor Pérez Jiménez group (IMIDRA) using an Abencor system identical to that described earlier.[8] Our blank sample (chemically refined olive-pomace oil) was obtained directly from the producers.

Stock solutions (100 μg·mL^{-1}) and samples were treated as described formerly,[7,8] in short: solutions of ESG standard were prepared by dissolving the standard mixture in chloroform. Stocks solutions of SG and of ChSG were made with a chloroform:methanol (2:1, by volume) blend. Samples consisted of 2 g of oil dissolved in 4 mL of chloroform, spiked with 100 μL of ChSG stock solution. The hydroxyl groups were

derivatized (1 h at 60 °C) with 200 μL of a mixture of Py:HMDS:TMCS (9:3:1, by volume) before carrying out the GC analysis.

Olive Orchards and Olive Oil Extraction. The orchards were situated in Madrid, the center part of Spain, near the Manzanares River (Mediterranean climate), where they could be kept under optimal cultivation conditions. Specifically they were located in eight municipalities in the southern outer ring of the submetropolitan area (Table 1).

Table 1. Identification and Coding System of Studied Samples

In these regions winters are cold due to the altitude (average of 667 m above sea level), January being the coldest month with temperatures between 3 and 10 °C, and 148 sunshine hours. These are dry climate areas; actually the common annual precipitations are between 400 and 500 mm per year in AC, AG, CR, CH, and VG, and below 400 mm per year in AZ, TI, and VS, which concentrate from October to May, October and December being the wettest months (56 mm).

Fruits from four different cultivars—Cornicabra, Manzanilla Cacereña, Manzanilla Castellana, and Picual cv.—were obtained from irrigated traditional orchards (drip irrigation). Additionally, olives from Manzanilla Castellana and Cornicabra cultivars were also obtained from organic orchards (Table 1).

The olive plantations were in a classical frame with around 300 trees per hectare. Fruits were handpicked according to the sampling time shown in Table 1.

To ensure maximum oil quality, olives were kept in darkness at 4 °C, and oil was extracted within 24 h after harvesting using an Abencor system and a small-quantity mill simulating commercial oil-extraction procedures (MC2 Ingeniería de Sistemas, Sevilla, Spain): the olives were crushed with an Abencor hammer mill equipped with a 4 mm sieve; 700 g of paste was processed using the system's malaxer and centrifuge during 1 min at 3500 rpm. Conditions: malaxation temperature, 27 °C; malaxation time, 20 min, plus 10 min after water addition; amount of distilled water added to the paste, 300 mL; amount of talc added, 20 g. The mixtures were left to decant during 24 h before proceeding to oil separation and filtration. To facilitate the work comprehension, the oil samples were coded according to Table 1.

Instrumentation. GC analyses of the sterol glucosides were carried out with an Agilent 6890N gas chromatograph (Agilent Technologies, Santa Clara, California) equipped with an Agilent 7683B automatic liquid sampler and FID. Acquisition of data was done with the Agilent ChemStation for GC System program. The conditions for the GC assays were as follows: TRB-5HT column (5% diphenyl−95% dimethylpoly-

[a]A minimum of two independent measures was made in each case. The standard deviation is also given; ND (nondetected). [b]The use of the same letters (a–e) indicates the absence of statistical difference between samples according to ANOVA and TUKEY test.

siloxane; 30 m × 0.32 mm i.d. × 0.10 μm film; Teknokroma, Sant Cugat del Vallés, Barcelona, Spain), 1.0 μL injection volume, hydrogen carrier gas at 3 mL·min^{-1}, and ECP cool on-column injection. The oven temperature program was as follows: 80 °C (1 min), 50 °C·min^{-1} to 320 °C (12 min), and 40 °C·min^{-1} to 360 °C (19 min). The detector temperature was 360 °C.

Steryl Glucoside Analysis. The SPE procedure developed previously[8] was utilized. The method consists of the conditioning of the cartridges (ExtraBond Si 1 g; Scharlab S.L., Barcelona, Spain) with 5 mL *tert*-butyl methyl ether, 5 mL hexane, 5 mL chloroform, and 10 mL of a newly prepared blend consisting of chloroform:methanol 4:1, by volume. Samples are then quantitatively transferred using 1 mL chloroform to wash the walls of the containers. The loaded cartridges are washed with 10 mL hexane, 10 mL of *tert*-butyl methyl ether, and 10 mL chloroform, applied one after the other. The steryl glucosides are eluted with 5 mL of the chloroform:methanol 4:1, by volume, solution. The procedure was carried out under negative pressure (1 mmHg) in a vacuum manifold. The eluted fractions are evaporated to dryness under nitrogen flux, derivatized and chromatographed using cool on-column injection.

The quantitative evaluation of the SG was carried out using ChSG as internal standard, whereas we quantified the ESG using three-point calibration curves (one specific curve for each ESG) built by spiking the in-house blank sample with the commercial standard mixture. This evaluation together with the purity, qualitative, and quantitative composition of the commercial standards is comprehensively described in our former work.[8]

All statistical analyses were run using the GraphPad Prism software, version 5.01 for Windows. The samples were compared by an ANOVA, with statistical significance of $p < 0.05$. After that they were differed by a TUKEY average comparison test.

RESULTS AND DISCUSSION

In the present study we have analyzed 44 oil samples, each of them at least in triplicate, in a relatively short time (six determinations/hour) and with fairly little solvent volumes, in comparison with former techniques, e.g., column chromatography.[9] This has proved the suitability of the system to be applied on a routine basis.

The quantitative results of the present study are shown in Tables 2–5. For the SG, the total amount is within the range 0.59 ± 0.01 to 2.62 ± 0.04 mg·kg^{-1}, the lowest and the highest amounts being those of Manzanilla Castellana samples from Valdelaguna, MCLL_T_VG_3 and MCLL_O_VG_4, respectively. If we compare them with those obtained previously,[8] it is clear that the SG concentration in virgin olive oils, devoid of defects, keeps constant within certain ranges. Consequently, we could assume that the SG concentration in virgin olive oils will be within the 0.6–2.7 mg·kg^{-1} range.

In the case of the SG profile, BSSG is always the main SG present, contributing at least with 70.52 ± 1.18% to the total. Actually, MCLL_T_VG_3 and MCLL_T_VS_3 only show BSSG. On the other hand, CSG and AvSG have great importance in almost all samples. MCAC_T_CR_4 has the highest CSG concentration (13.38 ± 0.03%) whereas MCLL_T_AC_4 exhibits the highest amounts of AvSG (14.96 ± 0.28%). SSG was present only in two Manzanilla Cacereña samples: MCAC_T_VS_3 (11.91 ± 1.45%) and MCAC_T_CR_4 (3.29 ± 0.82%). If we compare these results with the FS profile from olive oil, it is clear that there is no relationship between them beyond the fact that β-sitosterol derivatives are always present.

[a]A minimum of two independent measures was made in each case. The standard deviation is also given; ND (nondetected). [b]The use of the same letters (a−e) indicates the absence of statistical difference between samples according to ANOVA and TUKEY test.

ESG contents are within a range from 0.18 ± 0.01 to 3.07 ± 0.07 mg·kg^{-1}. Previous studies[8] show varieties with very high ESG concentrations (e.g., Uovo di Pichone, 11.29 ± 2.75 mg·kg^{-1}, and Blanqueta, 9.63 ± 0.71 mg·kg^{-1}), which are not discussed here. If we compare the samples that were common to both studies (Cornicabra and Picual), ESG concentrations are nearly the same. Compiling global results from both studies, it is possible to establish a concentration interval from 0.2 to 14.0 mg·kg^{-1} for ESG presence in olive oil. As far as the profiles are concern, ECSG was never detected, while ESSG was seen only in two samples, which where those where SSG could be determined. EAvSG was detected in 70% of the samples (3.23−74.82% range). Except in the case of MCLL_T_VS_3, where EBSSG was 25.18 ± 2.34% of total ESG, in all the others samples, EBSSG was the main ESG, showing concentrations above 69%. Although it has already been demonstrated that there is no correspondence between the SG profile and that of their esterified counterparts,[6,8] this lack of any equivalence is still striking. Once again, it becomes clear that there is no connection between both SG and ESG concentrations, and that the SG:ESG rate does not have to be lower than 1 (Tables 4 and 5). Actually it is above 1 in more than 77% of the instances. Furthermore, there is not a correlation between global steryl glucoside quantities and their corresponding profiles. The fact of having high SG and/or elevated ESG concentration(s) does not imply richer profile(s), and vice versa. Actually, all four SG have been found in sample MCAC_T_CR_4 (Figure 1), together with three other ESG, and the respective concentrations of both kinds of sterol glucoside derivatives are not significantly higher than with "poorer" sets.

The cultivars tested in the present study cannot be considered different as far as the (E)SG content is concerned. However, we may observe that the Cornicabra variety shows the highest SG:ESG relationship, being in some cases surprisingly elevated (samples COR_O_VG_4, COR_T_CH_4, and COR_O_-AZ_3, with values of 8.6, 6.1, and 4.7, respectively). On the other hand the values are the lowest (around 1) in Manzanilla Cacereña cv. Finally, Picual cv. presents a more even distribution of the SG:ESG correlation.

Although correlation and cluster analysis, and other statistical analysis (PCA and HCA) did not let us get a clear distribution pattern to correlate sample characteristics with their (E)SG composition and content, calculation of three times the standard deviation allowed us to group results provisionally. Table 6 shows the SG and ESG results grouped according to the origin of the olive fruits. The fact of having somehow acceptable relative SD values (between 1 and 30%) when observing the SG concentration as a function of the location of the olive tree, and not on dependence of the cultivar, drives us to think that it might actually be the pedoclimate (soil water, nutrients, and aeration) that has any real influence on such values and not the fruit variety, as one might think a priori. Wider studies on this aspect are presently being carried out. On the other hand, the ESG behavior remains quite random, supporting our previous statement that both kinds of phytosterols (SG and ESG) behave independently of each other. The same trend is observed when classifying the results according to the sampling time (Table 7), whereas results on the two different farming modes (traditional and organic) cannot be conclusive, mainly due to the lack of enough sample material.

Table 5. Total Esterified Steryl Glucoside Contents (mg·kg^{-1}) of Olive Oil from Different Cultivars, and Relative Composition Regarding Esterified Stigmasteryl Glucoside (ESSG), Esterified β-Sitosteryl Glucoside (EBSSG), and Esterified Δ5-Avenasteryl Glucoside (EAvSG) (Part 2)[a]

[a]A minimum of two independent measures was made in each case. The standard deviation is also given; ND (nondetected). [b]The use of the same letters (a−e) indicates the absence of statistical difference between samples according to ANOVA and TUKEY test.

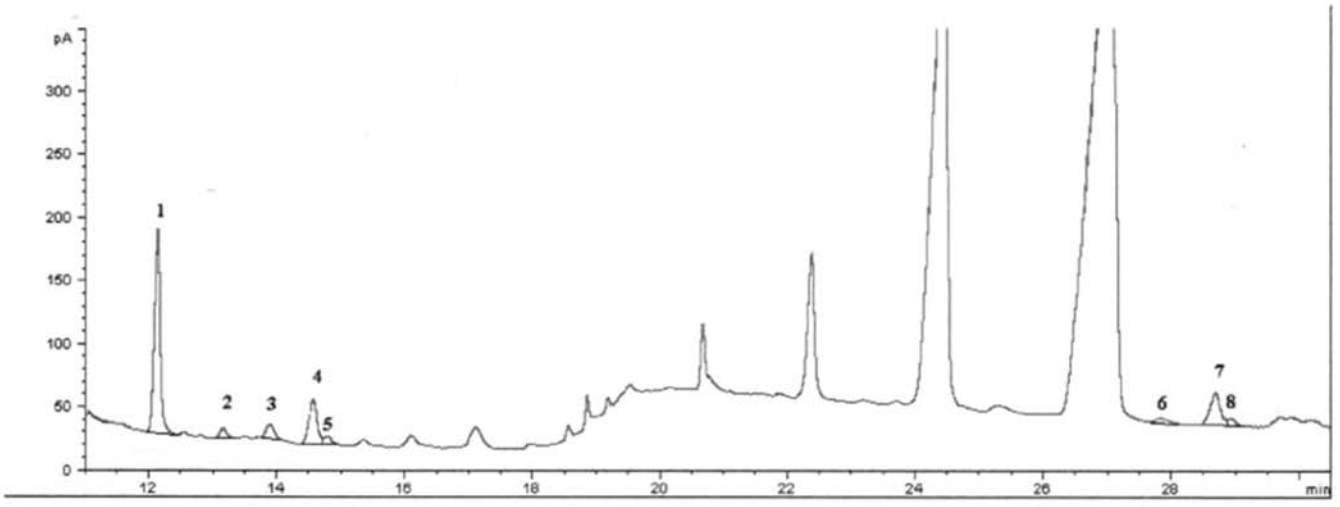

Figure 1. GC-FID chromatogram for steryl glucosides in virgin olive oil extracted from olive fruits of the Manzanilla Cacereña cultivar (sample MCAC_T_CR_4). This chromatogram has been obtained after analyzing the sample according to the proposed method and it shows the following: 1, the internal standard cholesterol glucoside; 2, campesteryl glucoside; 3, stigmasteryl glucoside; 4, β-sitosteryl glucoside; 5, (presumptive) Δ5-avenasteryl glucoside; 6, esterified stigmasteryl glucoside; 7, esterified β-sitosteryl glucoside; 8, (presumptive) esterified Δ5-avenasteryl glucoside.

To summarize we will conclude as follows: The performance of more than one hundred analyses in a relatively short time and with no waste of solvent has demonstrated the suitability of the procedure to be applied on a routine basis.

The presence of steryl glucosides in olive oil is not just limited to BSSG and EBSSG as thought previously, but also AvSG, EAvSG, and CSG have been found in an extensive number of samples. This might also be symptomatic either of different sample treatment or of differences during the oil extraction process. Actually it seems that industrial samples,[8] which have been obtained using a two or three phase decanter (higher water addition), have poorer (E)SG profiles than those samples

2	1.99 ± 0.34	1.44 ± 0.90
3	2.03 ± 0.58	1.40 ± 1.56
4	1.94 ± 0.35	1.38 ± 1.75

[a]Three times the standard deviation is also given.

obtained with the Abencor system, where water addition has been scarce. This reasoning seems to be supported by the fact of finding certain molecules (e.g., CSG) in Abencor samples, and not finding them in industrial oils. In any case a larger number of determinations under controlled circumstances must be carried out before drawing definite conclusions.

Olive cultivar, sampling time, and farming mode have no influence on the parameters under study. Pedoclimate (soil aeration, micronutrient presence, and water content) seems to have some influence on the glucoside presence. In this way further studies are being carried out to confirm such a relationship.

Thermodynamics of Dissolution of Calcium Hydroxycarboxylates in Water

Martina Vavrusova,[†] Ran Liang,[‡] and Leif H. Skibsted*[,†]

[†]Food Chemistry, Department of Food Science, University of Copenhagen, Rolighedsvej 30, DK-1958 Frederiksberg C, Denmark

[‡]Department of Chemistry, Renmin University of China, Beijing 100872, China

ABSTRACT: Aqueous solubility of calcium L-lactate, calcium D-gluconate, and calcium D-lactobionate increases with temperature (10−30 °C investigated), most significantly for the least soluble D-gluconate, while the calcium ion activity of the saturated solutions decreases with temperature, as measured electrochemically, most significantly for the most soluble D-lactobionate. This unusual behavior is discussed in relation to dairy processing and explained by endothermic binding of calcium to hydroxycarboxylate anions determined to have ΔH°_{ass} = (31 ± 3) kJ·mol^{-1} for L-lactate, (34 ± 2) kJ·mol^{-1} for D-gluconate, and (29 ± 3) kJ·mol^{-1} for D-lactobionate in 1:1 complexes with thermodynamic binding constants at 25 °C of K_{ass} = 49 (L-lactate), 88 (D-gluconate), and 140 (D-lactobionate). Quantum mechanical calculations within density functional theory (DFT) confirm the ordering of strength of binding. The complex formation is entropy driven with $\Delta S^{\circ}_{ass} > 0$, resulting in decreasing calcium ion activity in aqueous solutions for increasing temperature, even for the saturated solutions despite increasing solubility.

KEYWORDS: *calcium L-lactate, calcium D-gluconate, calcium D-lactobionate, calcium ion activity, endothermic calcium binding*

INTRODUCTION

Dairy products are an important source of dietary calcium, and calcium binding to the caseins and to proteins, peptides, and anions of the serum phase of milk prevents precipitation on calcium salts in the intestines during digestion ensuring high bioavailability of calcium.[1−4] Calcium is also important for structure development in fermented milk products and in cheeses as calcium binds electrostatically to caseins initiating protein network formation for conditions of decreasing pH and during enzymatic protein hydrolysis.[5−9]

An understanding of calcium binding to other milk components and to components added to dairy products or formed during milk processing accordingly is important both for improvement of dairy technology and for optimizing calcium bioavailability of dairy products.[10,11] Notably, it was recently shown that cooling of acidified skim milk for cheese production resulted in increased concentration of free calcium at the expense of complex bound calcium in the milk serum phase indicating that calcium binding is an endothermic process most likely involving carboxylate groups of peptides or of hydroxycarbolylates.[9]

Mixtures of hydroxycarboxylates of relevance for dairy products have further been shown to result in increased solubility of sparingly soluble calcium salts like calcium lactate otherwise known to precipitate in some cheeses during maturation.[11−14] Such synergistic effects on calcium hydroxycarboxylate solubility may for certain conditions of relevance for biomineralization even result in spontaneous formation of supersaturated solutions during isothermal dissolution.[15] Such phenomena, which at a first glance seem to violate thermodynamics, invite further investigations of the dissolution processes of calcium hydroxycarboxylates. It seems also of importance to make distinctions not only between bound and free calcium, but for the free calcium also between calcium ion concentration and calcium ion activity for the saturated and supersaturated calcium salt solutions.[6,16] Accordingly, we now report the results of investigations of calcium speciation in saturated solutions of calcium L-lactate, calcium D-gluconate, and calcium D-lactobionate combining electrochemical determination of calcium ion activity at varying temperature with quantum mechanical calculations of calcium binding to hydroxycarboxylate anions.

MATERIALS AND METHODS

Chemicals. Calcium L-lactate pentahydrate, calcium D-gluconate monohydrate, calcium D-lactobionate monohydrate, anhydrous calcium chloride, and ammonium purpurate 5,5-nitrilodibarbituric acid were all from Sigma-Aldrich (Steinheim, Germany). Ethylenediaminetetraacetic acid disodium salt dihydrate (EDTA), sodium chloride, and sodium hydroxide were all from Merck (Darmstadt, Germany). All aqueous solutions were made from purified water from Milli-Q Plus (Millipore Corporation, Bedford, MA).

Solubility Determination. Saturated aqueous solutions of calcium L-lactate pentahydrate and calcium D-gluconate monohydrate were prepared by combining 15.0 and 10.0 g with 100 mL of water, respectively, while 40.0 g of calcium D-lactobionate monohydrate was combined with 50 mL of water at 10 and 20 °C and with 35 mL at 30 °C. Equilibration time for each of the calcium salts to reach saturation was found to be less than 2 h under constant stirring at 10 °C, 20 °C, or 30 °C in a thermostated water bath. Samples were filtered (589/3, Whatman, Dassel, Germany) prior to each analysis. Total calcium concentration was determined by EDTA titration, and the calcium ion activity was determined by a calcium ion selective electrode for solutions of each of the three salts saturated at each of the three temperatures. pH was measured in the saturated solutions at the specified temperatures. All samples were prepared in duplicate.

EDTA Titration. Standardization of the EDTA solution for titration with the concentration of 0.0500 mol·L^{-1} was obtained against a 0.0200 mol·L^{-1} aqueous solution of $CaCl_2$. 1.000 mL of sample was transferred to a titration flask and diluted with 40 mL of water. 2.0 mL of 2.0 mol·L^{-1} solution of NaOH was added to each sample to maintain basic pH, and 0.30 mL of 0.50% murexid solution was used as an indicator. Samples were titrated until the initial pink color changed to dark purple, indicating the end point.

Electrochemical Measurement of Calcium Ion Activity. A calcium ion selective electrode ISE25Ca with a reference REF251 electrode from Radiometer (Copenhagen, Denmark) was calibrated using aqueous 1.00×10^{-4}, 1.00×10^{-3}, and 1.00×10^{-2} mol·L^{-1} $CaCl_2$ solutions prepared from a 1.000 mol·L^{-1} $CaCl_2$ stock solution at 10 °C, 20 °C, or 30 °C. Calcium ion activity, $a_{Ca}{}^{2+}$, in the standard solutions was calculated based on the relationship between activity and concentration according to

$$a_{Ca}{}^{2+} = c_{Ca}{}^{2+} \cdot \gamma^{2+} \quad (1)$$

where γ^{2+} is the activity coefficient calculated from the Davies equation:[17]

$$\log \gamma^{2+} = -A_{DH} z^2 \left(\frac{\sqrt{I}}{1 + \sqrt{I}} - 0.30I \right) \quad (2)$$

where A_{DH} is the Debye−Hückel constant with the numerical value of A_{DH} = 0.498, 0.506, or 0.515 at 10 °C, 20 °C, or 30 °C, respectively.[17] For aqueous solution, z (=2) is the charge of the calcium ion, and I is the ionic strength. The ionic strength was calculated as follows, taking all ions present in the solution into account including the calcium hydroxycarboxylate complexes:

$$I = \frac{1}{2} \sum cz^2 \quad (3)$$

The calcium ion activities of the standard solutions at 10 °C, 20 °C, or 30 °C may be found in Table 1. In the samples, the calcium ion activity, $a_{Ca}{}^{2+}$, was calculated from the linear relationship according to the Nernst equation between the electrode potential (in mV) measured for the calibration solutions and pCa (=−log $a_{Ca}{}^{2+}$) of the calibration solution, see Figure 1.

Table 1. Calcium Ion Activities in Standard Solutions at 10, 20, And 30 °C As Calculated According to Davies' Equation.[17]

	pCa = −log $a_{Ca}{}^{2+}$		
$c_{Ca}{}^{2+}$/mol·L^{-1}	10 °C	20 °C	30 °C
1.00×10^{-4}	4.034	4.034	4.035
1.00×10^{-3}	3.102	3.103	3.105
1.00×10^{-2}	2.276	2.281	2.286

DFT Calculation. Geometries of calcium hydroxycarboxylates in aqueous solutions were optimized using the Gaussian 09 package[18] on the basis of the B3LYP method combined with polarizable continuum model (PCM) at the 6-31G** level. Calcium binding enthalpies were calculated on the basis of stationary point energies of the calcium complexes and the hydroxycarboxylate anions at their optimized geometries, respectively, and relative association rate constants were calculated based on the approximation of

$$\Delta H_{binding} \approx \Delta G_{binding} = -RT \ln K_{rel} \quad (4)$$

RESULTS AND DISCUSSION

The aqueous solubility of the three calcium hydroxycarboxylates investigated for the temperature interval 10 to 30 °C in relation to calcium speciation and calcium salt precipitation in dairy products increased for increasing temperature and was in fair agreement with previous reports of calcium salt solubility.[11,12,19−21] The solubility of calcium L-lactate at 10, 20, and 30 °C, as determined by complexometric titration, is presented in Table 2, and the solubility of calcium D-gluconate and calcium D-lactobionate in Tables 3 and 4, respectively. The overall dissolution process for each of the three calcium hydroxycarboxylates is accordingly endothermic with $\Delta H^{\circ}_{dissol} > 0$, as for most food related calcium salts in water, except calcium sulfate, where a solid state phase transition around 40 °C makes the temperature dependence more complicated.[22] Calcium D-gluconate, the least soluble of the three hydroxycarboxylates investigated, showed a solubility ratio of 1.9 for the temperature interval of 20 °C investigated, the highest temperature sensitivity, while calcium D-lactobionate as the most soluble showed the lowest temperature sensitivity corresponding to a factor of 1.3. The solubility ratio for calcium D-gluconate and for calcium D-lactobionate was calculated by dividing the highest solubility by the lowest solubility to give an impression how much the solubilities of the investigated calcium hydroxycarboxylates will change with temperature.

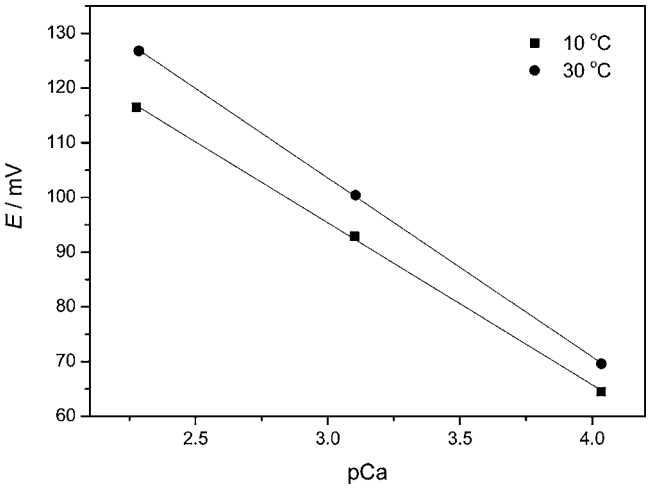

Figure 1. Calcium ion activity standardization of calcium selective electrode using the standard solutions of Table 1 based on the Davies equation. Slope of regression line at 10 °C is −29.6 mV^{-1} and at 30 °C −32.7 mV^{-1}.

The calcium ion activity of the saturated aqueous solutions of the three calcium hydroxycarboxylates showed opposite trends. The measured activities were based on activity standards correcting the calcium ion concentration according to the Debye−Hückel theory using the Davies equation for single ion activity.[17,23] Notably, activity standardization has to be performed at the actual temperature of measurement, and it is encouraging that the electrode response is in agreement with the Nernst equation and with an increasing slope for increasing temperature, see Figure 1. For each of the three calcium hydroxycarboxylates, the calcium activity in the saturated solution decreased with increasing temperature, which is remarkable, since the solubility increased. For the most soluble calcium D-lactobionate the effect was the largest, but still for calcium L-lactate and calcium D-gluconate, the effect is significant, compares Table 2, 3, and 4.

In order to understand this unusual effect of decreasing calcium ion activity for increasing calcium hydroxycarboxylate concentration, the calcium speciation needs to be considered. The dissolution of each of the three calcium hydroxycarboxylates occurs stepwise,[11,17,23]

[a]Calcium ion activity, $a_{Ca^{2+}}$, was determined electrochemically. Free calcium ion concentration, [Ca^{2+}], activity coefficient, $\gamma_{Ca^{2+}}$, free lactate concentration, [$Lact^{-}$], the calcium complex concentration [$CaLact^{+}$], and the resulting ionic strength, I, were calculated by an iterative procedure.

$$CaL_2(s) \rightleftharpoons CaL^+ + L^- \quad (5)$$

$$CaL^+ \rightleftharpoons Ca^{2+} + L^- \quad (6)$$

with the reaction of eq 5 resulting in a complete dissociation into CaL^+ and L^-, where L^- is L-lactate, D-gluconate, or D-lactobionate, and CaL^+ the 1:1 complex of each of these anions with Ca^{2+}. The reaction of eq 6 corresponds to the dissociation of the complex, for which the association constant is defined as

$$K_{ass} = \frac{a_{CaL^+}}{a_{L^-}a_{Ca^{2+}}} = \frac{\gamma_{CaL^+}[CaL^+]}{\gamma_{L^-}[L^-]a_{Ca^{2+}}} \approx \frac{[CaL^+]}{[L^-]a_{Ca^{2+}}} \quad (7)$$

The approximation included in eq 7 is based on the assumption that the activity coefficient only depends on the charge of the ion as is also an assumption for the Davies equation.[17,23]

An iterative calculation procedure was used for each of the three salts for each of the three temperatures. From an initially estimated ionic strength neglecting complex formation ($I = 3c_{Ca^{2+}}$, where $c_{Ca^{2+}}$ is the concentration of calcium hydroxycarboxylate), $\gamma_{Ca^{2+}}$ was calculated according to eq 2 leading to a concentration of free ligand of

$$[L^-] = c_{Ca^{2+}} + [Ca^{2+}] = c_{Ca^{2+}} + \frac{a_{Ca^{2+}}}{\gamma_{Ca^{2+}}} \quad (8)$$

and a concentration of complex of

$$[CaL^+] = c_{Ca^{2+}} - [Ca^{2+}] = c_{Ca^{2+}} - \frac{a_{Ca^{2+}}}{\gamma_{Ca^{2+}}} \quad (9)$$

based on correction of $a_{Ca^{2+}}$ to free calcium concentration, [Ca^{2+}], using eqs 1 and 2. A new estimate of the ionic strength was made according to

$$I = \frac{1}{2}(4[Ca^{2+}] + [L^-] + [CaL^+]) \quad (10)$$

and the calculation procedure repeated until the ionic strength, I, was not influenced further, and the final values for the ion concentrations of the three calcium hydroxycarboxylates were calculated at each of the three temperatures.

The speciation for calcium L-lactate, calcium D-gluconate, and calcium D-lactobionate, resulting from measurement of total calcium, $c_{Ca^{2+}}$, and calcium ion activity, $a_{Ca^{2+}}$, and the iterative calculation procedure, is found in Tables 2, 3, and 4, respectively. Included in these tables are values for K_{ass} for the calcium complexes of L-lactate (Table 2), D-gluconate (Table 3), and D-lactobionate (Table 4), each at three temperatures as calculated from eq 7.

D-Lactobionate forms the strongest complex with calcium, L-lactate the weakest, with D-gluconate being intermediate according to the thermodynamic association constant for all of the three temperatures. The binding is, however, for each hydroxycarboxylate significant especially for the high concentrations of the saturated solutions, as evident from the speciation seen for the three calcium hydroxycarboxylates in Tables 2, 3, and 4. The temperature dependence of the three thermodynamic association constants further allows determination of ΔH°_{ass} and ΔS°_{ass} for the complex formation reaction using the van't Hoff equation.

$$\ln K_{ass} = -\frac{\Delta H^\circ_{ass}}{RT} + \frac{\Delta S^\circ_{ass}}{R} \quad (11)$$

The linearity of the plot of Figure 2 confirms the validity of the iterative calculation procedure and leads to the thermodynamic values of Table 5 including K_{ass} at 25 °C using standard regression methods. Since the complex formation is endothermic corresponding to $\Delta H^\circ_{ass} > 0$, the complex formation must be entropy driven with $\Delta S^\circ_{ass} > 0$. The increasing entropy resulting from binding seems related to release of water bound both to the calcium ion and to the carboxylic group of the hydroxycarboxylate. The association constants were determined for the natural pH around 6 of the saturated solutions, see Tables 2, 3, and 4. The pK_a values of the hydroxycarboxylic acids are around 3.6, and acid/base equilibria will accordingly not affect the calcium binding in the pH region of relevance for normal foods.[23]

The thermodynamic association constants for the three hydroxycarboxylate complexes of calcium and the derived thermodynamic parameters were determined in saturated aqueous solutions of each of the calcium hydroxycarboxylates. However, they should be of more universal use for aqueous solutions, since they are based on calcium ion activity rather than on calcium ion concentration as previously used.[11] Values available for K_{ass} are for other solution conditions, but for calcium L-lactate, a value of $K_{ass} = 35$ has been reported, which is comparable to the value of 49 of Table 2.[24] For D-gluconate a value $K_{ass} = 77$ was previously obtained by extrapolation of K_{ass} valid at varying ionic strength to infinite dilution.[23] Also this value for K_{ass} based on calcium ion activity compares well with the value of $K_{ass} = 88$ of Table 2. A more recent value based on ^{13}C NMR spectra is somewhat lower, with $K_{ass} = 63$.[25]

Binding of calcium to sugar derived ligands is of general interest for sugar metabolism, and structural assignment of the functional groups in the partly metabolized sugars binding calcium has been attempted.[25,26] Calcium seems to bind to a carboxylic group but also with involvement of hydroxylic groups apparently with equilibration between five- and six-membered rings.[25] In order to understand the structural effects on calcium binding for the three hydroxycarboxylates, quantum mechanical calculations within DFT were used to obtain optimized structures of the three calcium complexes in aqueous solution followed by calculation of $\Delta H_{binding}$ for the reaction correcting for solvent interaction:

$$Ca^{2+} + L^- \rightarrow CaL^+ \quad (12)$$

[a]Calcium ion activity, a_{Ca}^{2+}, was determined electrochemically. Free calcium ion concentration, $[Ca^{2+}]$, activity coefficient, γ_{Ca}^{2+}, free gluconate concentration, $[Gl^-]$, the calcium complex concentration $[CaGl^+]$, and the resulting ionic strength, I, were calculated by an iterative procedure.

The values of $\Delta H_{binding}$ are included in Table 5. The ordering of affinity of calcium ion to hydroxycarboxylates is D-lactobionate > D-gluconate > L-lactate, in agreement with the experimentally determined values for K_{ass}. Moreover, the relative strength of binding of calcium to D-gluconate and L-lactate is 1.6, as obtained from the theoretical calculations, which is surprisingly close to the ratio of 1.8 indicated by the experimentally determined values for K_{ass} at 25 °C, see Table 5.

The optimized structures of the calcium complexes are presented in Figures 3, 4, and 5. For L-lactate, calcium ion binds solely to the oxygen atoms of the carboxylate with equal bond lengths. For D-gluconate, calcium ion binds also to the two carboxylate oxygens but also to the hydroxyl group of C-3 of D-gluconate for the optimized (lowest energy) structure. However, separated by only 8.3 kJ·mol^{-1} is another conformation where calcium is bound to only one of the two carboxylic oxygens, but also to the hydroxyl groups both at C-2 and C-3, see Figure 4a. Calcium binding to D-lactobionate follows a similar pattern with the lowest energy conformation characterized by binding to the two carboxylic oxygens and to a hydroxyl group (C-5). As for D-gluconate, another conformation of the calcium complex of D-lactobionate is only 10.4 kJ·mol^{-1} above the optimized structure, with binding to only the two carboxylic oxygens as for L-lactate and not involving any hydroxyl groups, compare Figures 4 and 5. In the view of the small energy separation between the two local minima of calcium complexes of D-gluconate, it is suggested that they coexist in solution.

The strongest binding of calcium is characterized by three calcium-to-oxygen bonds as for D-gluconate and D-lactobionate, while the weaker binding of calcium for L-lactate only involves two oxygens. For D-lactobionate, an easy shift between binding to two carboxylic oxygens and binding including an additional hydroxyl group may explain the higher affinity for calcium by D-lactobionate than by D-gluconate.

The speciation of calcium in the saturated calcium hydroxycarboxylate solutions presented in Tables 2, 3, and 4 provides the information required to calculate the solubility product:

$$K_{sp} = a_{Ca^{2+}}a_{L^-}{}^2 \approx a_{Ca^{2+}}[L^-]^2\gamma_{L^-}{}^2 \quad (13)$$

The values for K_{sp} for each of the three calcium hydroxycarboxylates at three temperatures are presented in Table 6 applying the Davies equation for calculation of γ_{L^-} at the ionic strength of the saturated solutions. For the more soluble calcium L-lactate and calcium D-lactobionate, the uncertainty is rather large for these calculations, and since solubility products normally only are considered as a thermodynamic parameter for sparingly soluble salts, the temperature dependence on K_{sp} is only analyzed for the least soluble calcium D-gluconate as seen in Figure 6. Based on the van't Hoff equation as presented in eq 11, values of ΔH°_{sol} = (16 ± 1) kJ·mol^{-1} and $\Delta S^\circ_{sol} = -(26 \pm 5)$ J·mol^{-1}·K^{-1} were calculated, see Figure 6. The solubility product obtained for 20 °C, log K_{sp} = −4.26, is in good agreement with the value obtained by others, log K_{sp} = −4.19, also corrected for complex formation and based on activity standard.[21]

The dissolution of calcium hydroxycarboxylates in water involves the two reactions of eqs 5 and 6. While the thermodynamic parameters obtained for complex formation solely are associated with the process of eq 6, ΔH°_{sol} and ΔS°_{sol} obtained for calcium D-gluconate are valid for the hypothetical

[a]Calcium ion activity, $a_{Ca^{2+}}$, was determined electrochemically. Free calcium ion concentration, [Ca^{2+}], activity coefficient, $\gamma_{Ca^{2+}}$, free lactobionate concentration, [$Lacto^-$], the calcium complex concentration [$CaLacto^+$], and the resulting ionic strength, I, were calculated by an iterative procedure.

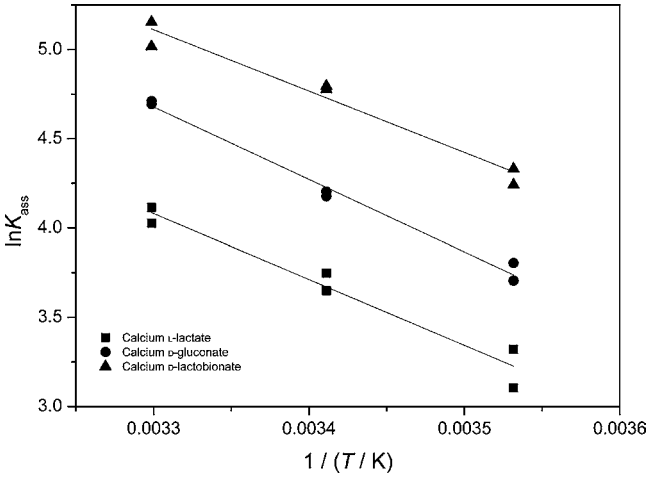

Figure 2. Effect of temperature on thermodynamic association constant of 1:1 complexes, K_{ass}, of calcium with (■) L-lactate, (●) D-gluconate, and (▲) D-lactobionate in water.

process of dissolving 1 mol of calcium D-gluconate in an already saturated solution of the specified temperature corresponding to the differential enthalpy and entropy of dissolution for a saturated solution as partial molar quantities. In order to assign the thermodynamic parameters directly to the dissolution process of eq 5, where a solid is dissolved in pure water to obtain integral enthalpy and entropy of dissolution, other types of experiments based on dissolution calorimetry are needed.

For a more practical use of the results in the food industry, the calcium ion activity in aqueous solutions was calculated for increasing concentration of each of the three calcium hydroxycarboxylates for 25 °C based on the association constants and correcting for the effect on the activity coefficient of calcium from the increasing ionic strength using iterative methods similar to those described for determination of the complex constants. The calculations were extended to concentrations above the saturation for each calcium hydroxycarboxylate as seen in Figure 7. The result is striking: up to saturation, the calcium ion activity continues to increasing steadily, but the continuing increase in activity is far less significant, when the concentration approaches the solubility limit especially for D-lactobionate and D-gluconate. For calcium

D-gluconate, the calcium ion activity is rather constant for up to 10 times supersaturation and the driving force for precipitation becomes small. This seem to be part of the explanation for the well-known phenomenon that calcium D-gluconate forms a supersaturated solution which may stay supersaturated for years before precipitation starts.[15] D-Gluconate also protects against calcium L-lactate precipitation in cheeses during maturation, and similar effects of supersaturation may be involved.[14]

Table 5. Thermodynamic Association Constants of 1:1 Calcium Hydroxycarboxylate Complexes in Water at 25 °C and Thermodynamic Parameters ($\Delta G°_{ass}$, $\Delta H°_{ass}$, $\Delta S°_{ass}$) for Complex Formation from Electrochemical Measurement, Binding Enthalpy, $\Delta H_{binding}$, and Relative Stability Constant, K_{rel}, of Complexes Based on DFT Calculations

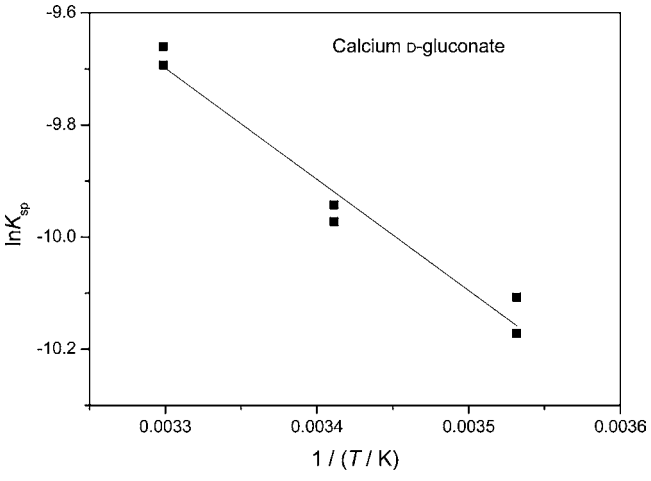

Figure 6. Effects of temperature on thermodynamic solubility product, K_{sp}, for calcium D-gluconate in water. Experimental data from Table 3.

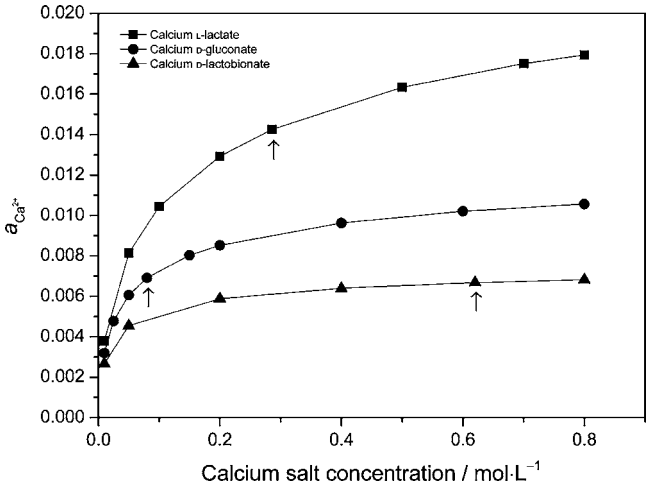

Figure 7. Calcium ion activity in calcium hydroxycarboxylate aqueous solutions of increasing concentration at 25 °C. Calcium concentration was corrected to calcium activity using the Davies equation based on an iterative calculation procedure correcting for complex formation. Solubilities (↑) of calcium L-lactate, calcium D-gluconate, and calcium D-lactobionate are 0.286 mol·L^{-1}, 0.080 mol·L^{-1}, and 0.620 mol·L^{-1}, respectively, in water at 25 °C.[11,19]

Calcium L-lactate, calcium D-gluconate, and calcium D-lactobionate also find use as calcium supplements because of their nonbitter taste in contrast to calcium chloride. Calcium bound in the hydroxycarboxylates is not bitter tasting, and in the mouth the increasing temperature will even mask any bitter taste after intake due to the entropy driven lowering of the calcium ion activity.

Physical and Molecular Changes during the Storage of Gluten-Free Rice and Oat Bread

Anna-Sophie Hager,* Geertrui M. Bosmans, and Jan A. Delcour

Laboratory of Food Chemistry and Biochemistry and Leuven Food Science and Nutrition Research Centre (LFoRCe), KU Leuven, Kasteelpark Arenberg 20, B-3001 Leuven, Belgium

ABSTRACT: Gluten-free bread crumb generally firms more rapidly than regular wheat bread crumb. We here combined differential scanning calorimetry (DSC), texture analysis, and time-domain proton nuclear magnetic resonance (TD ^{1}H NMR) to investigate the mechanisms underlying firming of gluten-free rice and oat bread. The molecular mobility of water and biopolymers in flour/water model systems and changes thereof after heating and subsequent cooling to room temperature were investigated as a basis for underpinning the interpretation of TD ^{1}H NMR profiles of fresh crumb. The proton distributions of wheat and rice flour/water model systems were comparable, while that of oat flour/water samples showed less resolved peaks and an additional population at higher T_2 relaxation times representing lipid protons. No significant crumb moisture loss during storage was observed for the gluten-free bread loaves. Crumb firming was mainly caused by amylopectin retrogradation and water redistribution within bread crumb. DSC, texture, and TD ^{1}H NMR data correlated well and showed that starch retrogradation and crumb firming are much more pronounced in rice flour bread than in oat flour bread.

KEYWORDS: *gluten-free, time-domain proton nuclear magnetic resonance, proton mobility, amylopectin retrogradation, crumb firming*

INTRODUCTION

Celiac disease is one of the most frequent genetically based food intolerances. It affects approximately 1% of the Western population.[1] The only available therapy is lifelong avoidance of storage proteins from wheat, rye, and barley, which, in the context of this disease, are termed gluten. While oat has been considered unsuitable for celiac patients, recent scientific evidence has allowed the conclusion that most gluten-intolerant people can consume oat without adverse health effects.[2] Today, a gluten-free diet is also followed by an increasing number of individuals who do not have celiac disease but appear to benefit from avoiding gluten. These include sufferers of non-celiac gluten sensitivity[3] and dermatitis herpetiformis.[4,5] In addition, the increasing number of individuals following a gluten-free diet as a life style choice creates an increasing demand for tasteful gluten-free bakery products with a texture comparable to that of their wheat counterparts. Because of the lack of a viscoelastic gluten network, production of leavened baked goods from non-wheat sources is challenging, and the resulting bread has low volume and a firm crumb.[6] Because of its wide availability, bland taste, and white color,[7] rice is the most commonly used gluten-free raw material.[8] However, rice flour contains levels of nutrients such as protein, fiber, and minerals lower than those of wheat flour.[9] Hence, rice-based gluten-free products are often nutritionally inferior to standard wheat products. Oat bread has not only better nutritional quality than rice bread but also improved volume, texture, and taste.[10]

Crumb firming of wheat bread is mainly related to changes in the starch fraction that result in a continuous, rigid, crystalline starch network.[11−15] On a molecular scale, amylose crystallizes during cooling after baking, while amylopectin does so over a longer time span in a process called retrogradation.[12,16−18] The amylose and amylopectin crystallites create network junction zones. These serve as nucleation sites for an intermolecular and maybe even intergranular mesoscale network[18] that includes unfreezable water. These changes can be monitored with differential scanning calorimetry (DSC) as an increase in melting enthalpy of retrograded amylopectin and a concomitant decrease in the amount of freezable water (FW).[15] The fast-forming amylose network and the thermoset gluten network are largely responsible for initial crumb firmness and resilience, while amylopectin retrogradation strengthens the network during bread storage.[18] In wheat bread crumb, part of the water included in the continuous starch network is withdrawn from the amorphous networks, which therefore lose plasticizing water. In addition, the thermodynamic incompatibility of starch and gluten causes water to diffuse from gluten to starch as shown for a model system.[19] The changes, which occur in the biopolymers during wheat bread baking as starch gelatinizes and gluten cross-links, and during storage as amylopectin retrogrades,[20] probably cause the water diffusion process to proceed until (new) equilibria are reached. Water not only is redistributed within bread crumb during storage but also migrates from crumb to crust, leading to a further local reduction in the moisture content of the biopolymer networks. As a result, the moisture content of the gluten network can drop below that needed for full plasticization during storage. The resulting increase in the stiffness of the gluten network then also contributes to crumb firming, mostly after storage for a couple of days.[15]

The molecular mobility of water and biopolymers in wheat model systems and wheat bread has already been studied with time-domain proton nuclear magnetic resonance (TD ^{1}H

NMR).[15,21−25] Six populations with different mobilities, depending on the local environment of the water and biopolymer protons, were categorized for fresh wheat bread crumb and interpreted by comparing the obtained NMR profiles to those of heated and cooled biopolymer model systems.[21] The least mobile and hence most rigid fraction contains nonexchanging CH protons of amylose crystals formed during cooling and of amorphous starch and gluten not in contact with water. Higher-mobility proton populations include CH protons of amorphous starch and gluten in little contact with water and exchanging protons of confined water, starch, and gluten. The largest population consists of mobile exchanging protons of water, starch, and gluten in the formed gel network. Finally, lipid protons represent a population with the highest T_2 relaxation time.[15,26−28] Molecular and physical changes that occur during the storage of starch-containing systems result in changes in proton distributions. Amylopectin retrogradation can be observed as an increase in the area of the population containing rigid CH protons and a decrease in areas of populations containing protons of amorphous starch due to a shift of protons to lower-mobility populations. In addition, the mobility of the exchanging protons is reduced, which can be attributed to strengthening of the starch network, loss of water from the gluten network, and migration of moisture from the crumb.[15] On the basis of this, TD ^{1}H NMR appears to be promising for also studying changes on a molecular scale during storage of gluten-free bread. So far and to the best of our knowledge, only one publication has reported on the use of ^{1}H NMR to investigate gluten-free bread. It stated that the mobility of the most mobile proton population, representing movable water, decreases during storage. However, no population assignment was conducted.[29]

Against this background, this study investigates the mechanisms underlying firming of the crumb of gluten-free rice and oat bread. Storage-related changes are studied on a macroscopic level (loaf volume and crumb texture) and on a molecular level (proton mobility, amylopectin retrogradation, and FW). Interpretation of complex NMR proton distributions in bread crumb is based on observations from simple oat and rice flour/water model systems.

MATERIALS AND METHODS

Materials and Analysis of Their Composition. Rice flour [11.8% moisture, 7.1% wet basis (wb) protein, 70.1% wb total starch, 0.9% wb lipids, and 0.46% wb ash] and commercial wheat flour (Crousti) (13.4% moisture, 11.4% wb protein, 65.5% wb total starch, 2.4% wb lipids, and 0.61% wb ash) were obtained from BENEO-Remy (Wijgmaal, Belgium) and Dossche Mills (Deinze, Belgium), respectively. Oat flour was purchased from E. Flahavan & Son (Kilmacthomas, Ireland) and sifted to obtain flour particle sizes of <400 μm. The sifted flour consisted of 10.7% moisture, 11.1% wb protein, 60.2% wb total starch, 6.6% wb lipids, and 1.39% wb ash. Dry yeast was obtained from Puratos (Groot-Bijgaarden, Belgium). Sugar and salt were purchased at a local supermarket. All reagents, solvents, and chemicals were purchased from Sigma-Aldrich (Bornem, Belgium) and were of analytical grade unless otherwise specified.

Flour and crumb moisture contents (MC) were determined according to AACC Approved Method 44-15.02.[30] The flour protein content was determined using an adaptation of the AOAC Official Method[31] with an automated Dumas protein analysis system (EAS VarioMax C/N, Elt, Gouda, The Netherlands). For the conversion of nitrogen content to protein content, the following factors were used: 5.7 for wheat, 5.8 for oat, and 6.0 for rice flour.[32] The starch content was calculated as 0.9 times the monosaccharide glucose content, determined by gas−liquid chromatography as described by Van Craeyveld et al.[33] The total lipid content was measured gravimetrically following extraction with water-saturated butanol (WSB). The ash content was determined according to AACC Approved Method 08-01.01.[34] All analyses were performed in triplicate.

Defatting of Oat Flour and Lipid Extraction. Oat flour was defatted with WSB. In practice, 1.0 g of oat flour was shaken in 10 mL of WSB for 60 min and the solvent was removed from the residue with a rotational vacuum concentrator (RVC, Q-Lab, Vilvoorde, Belgium) (60 °C, 1 mbar). This cycle was repeated twice before the resulting defatted flour was air-dried overnight, used to prepare flour/water model systems, and analyzed via TD ^{1}H NMR (see below).

The total lipid extract was obtained by WSB extraction of oat flour with an ASE200 (Dionex, Amsterdam, The Netherlands) as described previously by Gerits et al.[35] The obtained total lipid extract was then further purified to remove protein and other nonlipid material by discarding the upper phase obtained following addition of chloroform, methanol, and water [1:1:0.9 (v/v/v) ratio] to the total lipid extract and vigorous shaking as described by Bligh and Dyer.[36] Upon evaporation of the solvent with a RVC (40 °C, 1 mbar), the total lipid extract was transferred into NMR tubes and subjected to analysis (see below).

Flour/Water Model Systems. Flour/water model systems with an MC of 47% (representing a typical wheat dough MC) were prepared via the gentle stirring of flour and water to obtain homogeneous mixtures. After resting for 30−120 min, all model systems were analyzed with DSC and TD ^{1}H NMR before and after being heated and subsequently cooled to room temperature. Heating of the flour/water model systems was conducted in sealed NMR tubes placed in an oil bath (10 min at 110 °C).

Bread Making. Gluten-free formulations usually consist of complex mixtures of ingredients. To reduce the complexity and to allow comparison with wheat bread recipes, simple formulations based solely on flour, water, sugar, salt, and yeast described previously by Hager et al.[10] were used here. Batters were prepared by using 1.5% salt, 6.0% sugar, 3.0% yeast, and a water addition level of 95.0% for oat and rice (percentages based on flour weight). Optimal water addition levels were determined by preliminary baking tests. To control mold growth during storage, 0.1% calcium propionate and 1.6% potassium sorbate were added to oat and rice batter, respectively (percentages based on flour weight). Yeast was suspended in the water (30 °C) and rested for 10 min in a fermentation chamber (National Manufacturing, Lincoln, NE) at 30 °C and a relative humidity of 90%. The suspension was then added to the premixed dry ingredients. Mixing was conducted for 60 s at speed 1 with a KitchenAid KPM5 mixer (KitchenAid, St. Joseph, MI) equipped with a batter blade. The bowl content was scraped down and then further mixed for 90 s at speed 4. Greased baking tins [internal dimensions (width × length × height) of 8.0 cm × 14.5 cm × 5.5 cm] were filled with batter (350 g) and placed in the fermentation chamber for 30 min. Bread was then baked in a Condilux deck oven (Hein, Strasse, Luxemburg) for 45 min at 195 °C top and bottom heat. Prior to analyses, bread loaves were cooled for 2 h.

Bread Storage and Crumb Sampling. Cooled fresh bread loaves were wrapped in plastic foil and stored in sealed plastic bags for up to 120 h at 23 °C. Three bread loaves each were analyzed by crumb texture analysis and DSC 2, 48, and 120 h after removal from the oven. Additionally, center-crumb samples were withdrawn at these time points and transferred into NMR tubes, which were then sealed and analyzed (see below).

Loaf Volume and Crumb Texture Analysis. After the loaves had cooled for 2 h, loaf volume was determined using a VolScan Profiler (Stable Micro Systems, Surrey, U.K.). The firmness and springiness of crumbs were measured 2, 48, and 120 h after removal from the oven using an Instron 3342 instrument (Norwood, MA) equipped with a cylindrical probe (diameter of 25 mm). From the center of each of three fresh and stored bread loaves, three slices were cut (25 mm thickness), from which cylindrical samples were obtained with a cookie cutter (diameter of 35 mm). In a first test (test speed of 100 mm/min), one indentation was made. The force required to cause an indentation of 30% in the center of the samples is termed firmness. In

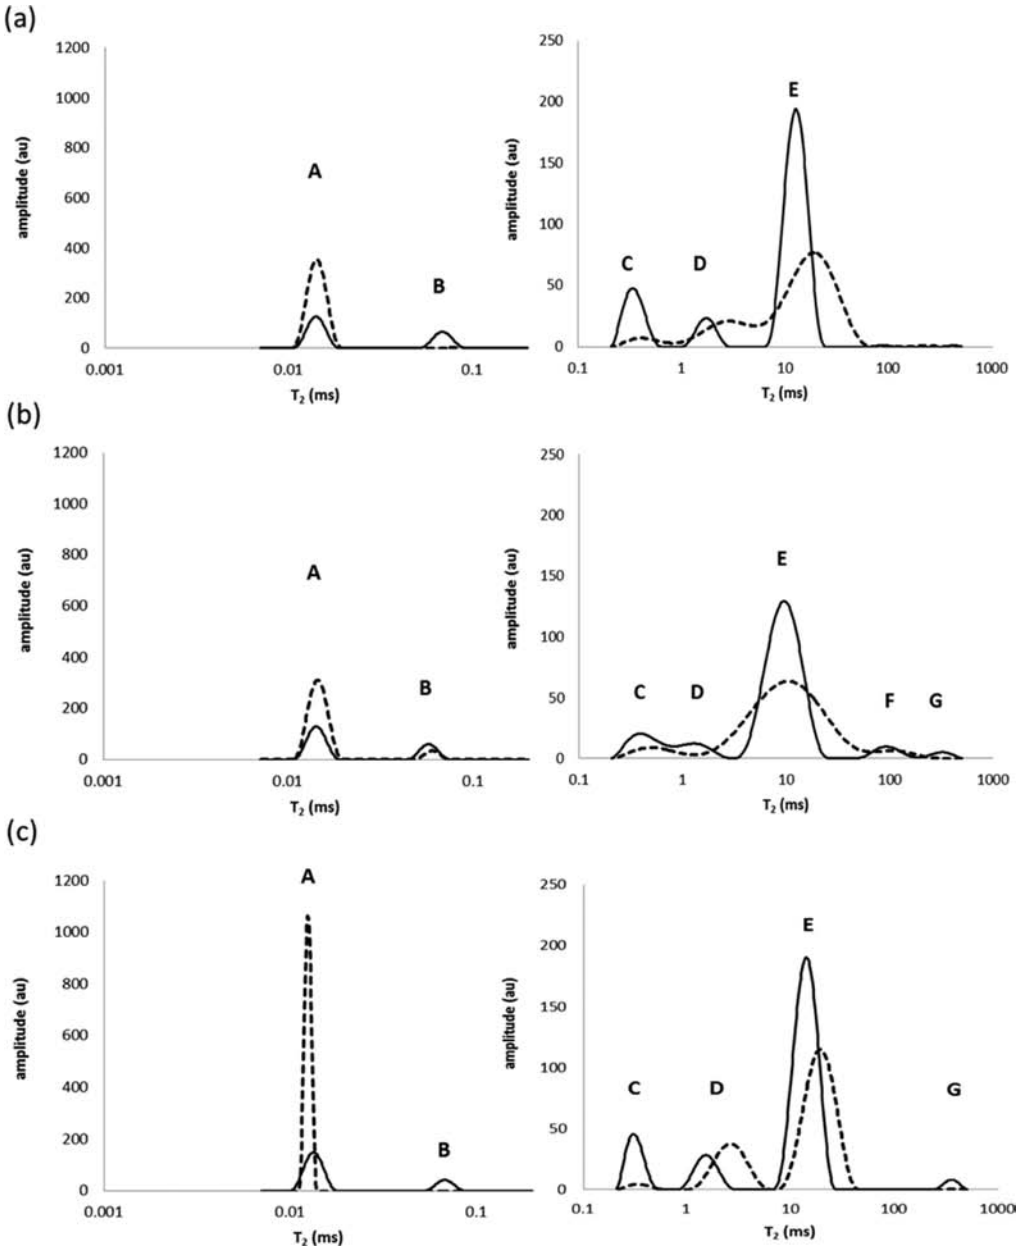

Figure 1. Proton distributions of unheated (---) and heated and cooled (—) flour/water model systems (water content of 47%) prepared from (a) wheat, (b) oat, and (c) rice flour obtained by the inverse Laplace transformation of the single-pulse free induction decay (left) and the decay obtained with the Carr−Purcell−Meiboom−Gill pulse sequence (right). Amplitudes are given in arbitrary units (au). The different proton populations are indicated with capital letters in order of their increasing mobility.

the second test (same test speed), two indentations of 30% in the center of the samples were made with a resting period of 60 s between them. The maximal force in the second indentation cycle divided by the maximal force in the first indentation cycle is the springiness, which is a measure of the reversibility of imposed bread crumb deformation.

Differential Scanning Calorimetry. DSC was conducted using a Q1000 DSC instrument (TA Instruments, New Castle, DE) previously calibrated with indium. To determine the temperatures and enthalpies corresponding to the melting of natively present amylopectin crystals or such crystals formed as a result of retrogradation, 2.5−4.0 mg of sample was accurately weighed in triplicate in aluminum pans (PerkinElmer, Waltham, MA). Deionized water was added in a sample dry matter:water ratio of 1:3 (w/w). Flour/water model systems were analyzed as such, while bread crumb was freeze-dried and ground prior to analysis. Pans were hermetically sealed and equilibrated at 0 °C together with an empty reference pan before being heated to 120 °C at a heating rate of 4 °C/min. Samples were measured after storage for 2, 48, and 120 h. The resulting endotherms were evaluated using TA Instruments Universal Analysis software. Enthalpies were expressed in joules per gram of sample dry base (db).

For the determination of the portion of FW, i.e., the water that transforms into ice during cooling to −40 °C, fresh bread crumb (10−15 mg) was accurately weighed in quadruplicate in aluminum pans. The samples were equilibrated at 15 °C and cooled to −40 °C at a rate of 4 °C/min. The portion of FW (eq 1) was calculated from the melting enthalpy of the sample ($\Delta H_{melting}$, in joules per gram of sample measured between −6 and 0 °C), the MC of the sample (grams of water per gram of sample), and the melting enthalpy of ice (ΔH_{ice} = 334 J/g of ice).

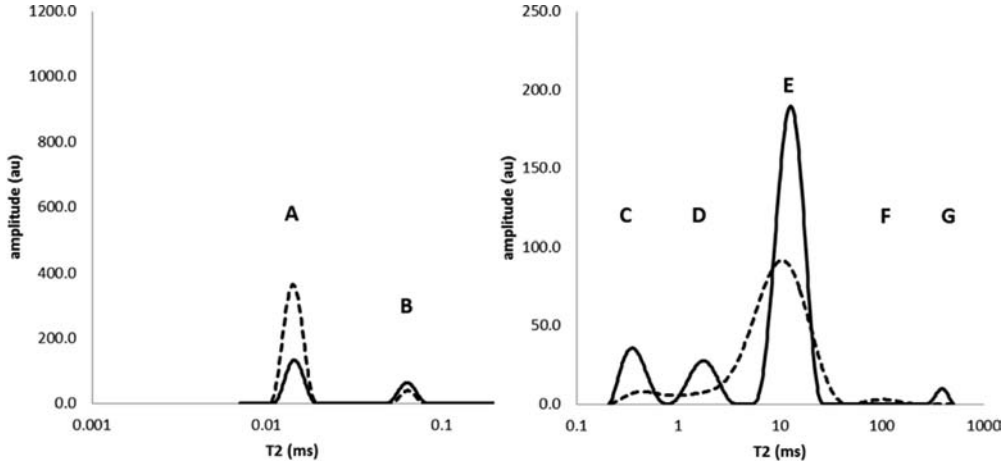

Figure 2. Proton distributions of unheated (---) and heated and cooled (—) flour/water model systems (water content of 47%) prepared from defatted oat flour (consecutive hexane and water-saturated butanol extraction) obtained by the inverse Laplace transformation of the single-pulse free induction decay (left) and the decay obtained with the Carr−Purcell−Meiboom−Gill pulse sequence (right). Amplitudes are given in arbitrary units (au). The different proton populations are indicated with capital letters in order of increasing mobility.

$$\%\mathrm{FW} = \frac{\Delta H_{\mathrm{melting}}}{\Delta H_{\mathrm{ice}} \times \mathrm{MC}} \times 100 \quad (1)$$

The FW content of fresh bread crumb was analyzed using samples withdrawn within 12 h of baking. Pans with fresh crumb withdrawn after baking and stored at 23 °C were also analyzed after storage for 48 and 120 h.

Time-Domain Proton Nuclear Magnetic Resonance. Measurements of proton distributions in model systems and bread were performed as described by Bosmans et al.[21] with a Minispec mq 20 TD NMR spectrometer (Bruker, Rheinstetten, Germany) at an operating resonance frequency of 20 MHz for ^{1}H (magnetic field strength of 0.47 T). An external water bath maintained the temperature of the probe head at 25 ± 1 °C. Relaxation curves were acquired using a single 90° pulse [free induction decay (FID)] and a Carr−Purcell−Meiboom−Gill (CPMG) pulse sequence with 90° and 180° pulse lengths of 2.86 and 5.42 μs, respectively. For the FID, an acquisition period of 0.5 ms was used and 500 data points were collected. For the CPMG sequence, the 90° and 180° pulses were separated by 0.1 ms and 2500 data points were acquired. For both measurements, a recycle delay of 3.0 s was used and 32 scans were accumulated to increase the signal-to-noise ratio. Three samples (approximately 0.3 g, accurately weighed) of a model system or bread crumb were placed in three different NMR tubes (10 mm external diameter). All samples were tightly compressed to a height of ∼8 mm to remove air bubbles. Each tube was analyzed in triplicate, and the exact sample weight in each tube was taken into account during the computations.

The CONTIN algorithm of Provencher[37] (software provided by Bruker) was applied to transform the transverse relaxation curves with an inverse Laplace transformation to a continuous distribution of transverse or spin−spin (T_2) relaxation times, which are related to proton mobility. The area under the curve of a population with a certain T_2 relaxation time is proportional to the number of protons in that population. The calculations were performed on 500 data points logarithmically spread between T_2 relaxation times of 0.007 and 0.5 ms and of 0.2 and 500 ms for the FID and CPMG measurements, respectively. Because the inhomogeneity of the static magnetic field affected the output for the most mobile FID population found around 0.5 ms,[38,39] this fraction was not taken into account in the following discussion.

Statistical Analysis. Statistical analysis was performed using R version 3.0.2 "Frisbee Sailing" (The R Foundation for Statistical Computing, Vienna, Austria) and the package "Agricolae". Analysis of variance was conducted, followed by the Shapiro Wilk normality test and Tukey's honest significant difference test.

RESULTS AND DISCUSSION

Flour/Water Model Systems. The molecular mobility of water and biopolymers in wheat, oat, and rice flour/water model systems and changes thereof after heating and subsequent cooling to room temperature were investigated first. The obtained proton distribution patterns of unheated and heated gluten-free flour/water models were comparable to those of wheat flour/water models,[21] and population assignment, therefore, was performed in a similar way. Figure 1 shows the FID and CPMG proton distributions of unheated and heated wheat, oat, and rice flour/water model systems. The unheated samples showed one predominant FID population (population A) (Figure 1, left panel). On the basis of previous studies, this population contains rigid CH protons of crystalline and amorphous starch[21,40] and proteins not in contact with water.[21,28]

With regard to the CPMG proton distributions, population E was most abundant in all samples (Figure 1, right panel). This population contains mobile OH protons of water in the extragranular space, which are in exchange with starch OH protons on the granule surface and with exchangeable protons of proteins.[21] Population C of the wheat flour/water model system contains CH protons of amorphous starch and gluten in contact with water.[21] Population D then contains OH protons of intragranular water and starch, but also some CH protons of gluten and exchanging protons of confined water and gluten.[21,41] It can reasonably be assumed that CH protons of rice or oat protein are also part of populations C and D.

For unheated rice and wheat samples, three distinct CPMG populations (C−E) were observed, even if these were not fully resolved for wheat. The difference from the oat samples is that in the latter population E was much broader and peaks C and D were not resolved. The total lipid extract from oat flour showed CPMG populations with T_2 relaxation times corresponding to populations C, E, and F of oat flour (results not shown). The lipid T_2 relaxation times apparently are too similar to those of the mobile and exchangeable protons of starch and protein to permit the clean separation of peaks. In the case of unheated oat flour, an additional proton population F was observed with a T_2 relaxation time of approximately 100 ms (Figure 1b, right panel). Prior removal of lipids from oat flour by WSB extraction

Proton distributions of oat (a) and rice (b) bread obtained by the inverse Laplace transformation of the single-pulse free induction decay (left) and the decay obtained with the Carr–Purcell–Meiboom–Gill pulse sequence (right) after storage for 2 h (—), 48 h (···), and 120 h (---). Amplitudes are given in arbitrary units (au). The different proton populations are indicated with capital letters in order of their increasing mobility.

reduced the area of population F (Figure 2, right panel). Thus, this peak probably represents protons of the lipid fraction. That such a peak was present in the oat flour/water model system is in line with the higher endogenous lipid content of oat than of either wheat or rice.

For heated flour/water model systems, DSC did not detect endothermic peaks (results not shown), confirming that heating model systems for 10 min at 110 °C fully gelatinized the starch in each flour model system.

Heat treatment and subsequent cooling of the flour/water model system resulted in similar changes in proton distributions. The area of population A decreased, while those of populations B and C increased (Figure 1). These changes were related to starch gelatinization, resulting in a decrease in the number of protons in a rigid environment due to melting of the starch crystals and swelling of the previously densely packed amorphous starch not in contact with water (present in population A), and an increase in the number of protons of amorphous starch in contact with water (present in populations B and C).[21] The area of population E, representing mobile protons in strong interaction with water, increased upon heating. The mobility of this population decreased during heat treatment. The reduced mobility was also observed for a starch/water model system and attributed to starch gelatinization and gelation.[21] After heating and subsequent cooling, this population consisted of mobile exchanging protons of water, starch, and proteins present in the formed gel network. The reduced mobility was possibly caused by more intense contact between the biopolymers and water.[21] The CPMG populations of heated wheat and rice flour/water model systems were well

Table 2. T_2 Relaxation Times and Areas of the Free Induction Decay (FID) of Population A (rigid protons of starch crystals and amorphous starch and protein not in contact with water) and Carr−Purcell−Meiboom−Gill (CPMG) Population E (mobile exchanging protons of water, starch, and protein in the formed gel network) of Oat and Rice Bread Loaves Stored for 2, 48, and 120 h at 23 °C[a]

		FID population A		CPMG population E	
	storage time (h)	area (au)	T_2 (ms)	area (au)	T_2 (ms)
oat bread	2	4234 ± 83 b	0.013 ± 0.001 a	9576 ± 105 a	15.7 ± 0.4 a
	48	4627 ± 316 ab	0.013 ± 0.001 a	9500 ± 15 a	15.3 ± 0.2 a
	120	5636 ± 904 a	0.013 ± 0.002 a	9540 ± 110 a	14.3 ± 0.5 b
rice bread	2	4504 ± 26 C	0.012 ± 0.001 A	9745 ± 39 A	14.7 ± 0.4 A
	48	8451 ± 1059 B	0.013 ± 0.000 A	11578 ± 789 A	13.8 ± 0.1 B
	120	10229 ± 579 A	0.012 ± 0.000 A	11932 ± 168 A	13.1 ± 0.4 B

[a]Values in the same column followed by the same letter are not significantly different ($p < 0.05$).

resolved, while this was not the case for the heated oat flour/water model system. The broadness of the oat peaks can possibly be attributed to the presence of endogenous lipids, as clearly resolved peaks were observed after heating and subsequent cooling of the oat flour model system prepared with defatted flour (Figure 2). Heated model systems prepared with oat or rice flour contained an additional small population G with a T_2 relaxation time of 300 ms. The population was not influenced by defatting and, hence, does not contain protons of the lipid fraction, but possibly results from expulsion of water from the flour proteins during heating. This small proton population with a very high mobility was also observed for heated and cooled egg[28,42] and gluten.[21]

Oat and Rice Bread. The loaf specific volume was significantly higher ($p < 0.05$) for oat (1.9 ± 0.1 mL/g) than for rice (1.2 ± 0.0 mL/g) bread. During storage of wheat bread, the level of moisture gradually increases in the crust and decreases in the crumb.[15] Such water redistribution has also been reported for bread made from mainly cassava, maize, or rice starch[43] as well as for commercial gluten-free bread based on wheat starch and milk powder.[29] The crust moisture content could not be determined for oat and rice bread of this study because it was not possible to remove the fine crust from the crumb. Moisture contents of the crumb center of oat and rice bread were 51.4 ± 0.1 and 50.4 ± 0.4%, respectively, and did not change significantly ($p < 0.05$) over the examined storage period. Hence, crumb to crust moisture migration did not contribute to a significant degree to firming of these bread loaves.

The amylopectin melting enthalpy of crumb from fresh rice bread (0.22 ± 0.07 J/g) was comparable to that of wheat bread (0.25 ± 0.02 J/g) in the study of Bosmans et al.[15] Little if any melting enthalpy was detected for fresh oat crumb. As expected, the melting enthalpy of retrograded amylopectin significantly increased during storage of both bread types (Table 1). This increase was substantially more pronounced for rice bread. Concomitantly, the amount of FW significantly decreased from 59.3 to 50.1% during the storage of rice bread for 120 h, while no significant ($p < 0.05$) reduction in FW was observed for oat bread (Table 1). These differences between oat and rice bread can possibly be attributed to the high lipid content of oat.

Crumb firming, therefore, is mainly caused by formation of a rigid, partially crystalline starch network and the concomitant diffusion of water from the surrounding amorphous phase to the retrograding starch where it is rendered unfreezable, in line with observations of Bosmans et al.[15] for wheat bread crumb stored without crust.

The initial firmness was much lower for oat (2.3 ± 0.2 N) than for rice (12.0 ± 1.4 N) bread crumb (Table 1). Native oat starch lipids seem to reduce the level of leaching of amylose from the granule during baking, thereby reducing initial crumb firmness by lowering the extent of amylose network formation during cooling.[44] As a result of storage for 120 h, crumb firmness has increased and crumb springiness has decreased much more for rice than for oat bread (Table 1). This went hand in hand with less pronounced amylopectin retrogradation in oat bread than in rice bread such as observed with DSC (Table 1).

Proton distributions of gluten-free bread (Figure 3) were comparable to those of wheat bread[15,21] as well as those of the heated flour/water model systems investigated here (Figure 1). Therefore, population assignment was done in a similar way. Two FID populations (A and B) and four CPMG populations (C−F) were observed. Population F, related to protons of the lipid fraction, was not observed for the rice flour/water model system but could be detected in rice bread. These lipid protons probably originated from shortening used to grease the baking tins. For the oat bread, both endogenous oat lipids and shortening contribute to population F.

During the 120 h storage, no considerable changes were observed in the proton distributions of oat bread while those of rice bread changed significantly (Figure 3). The area of population A, containing rigid CH protons of amylose crystals formed during cooling and of amorphous starch and protein not in contact with water, increased during storage of rice bread. A positive relationship was observed between the area of population A and the melting enthalpy of retrograded amylopectin. The latter evidently is related to starch crystallinity, whereas population A of bread crumb contains protons not only from starch but also from other biopolymers such as protein. Nevertheless, the relation between both shows that the increase in the area of population A is associated with amylopectin retrogradation. This shift in protons to lower mobility can be explained by amorphous amylopectin CH protons from more mobile populations becoming incorporated into the forming crystalline structures, hence losing mobility and becoming part of population A.[15] The area of population D decreased for both gluten-free bread types, indicating that nonexchanging CH protons of protein and exchanging protons of confined water, protein, and starch became less mobile and shifted to populations with shorter T_2 relaxation times. The area of population E, containing exchanging protons of the formed gel network, did not significantly change for oat and rice bread (Table 2). This is in line with the observation that the overall crumb moisture content did not noticeably change

during storage. The T_2 relaxation time of population E decreased significantly during storage of oat and rice bread, showing that protons in this population had lost mobility. Because the overall moisture content of the bread loaves remained constant throughout the investigated storage period, this reduction in mobility must be attributed to changes in constituents within the bread crumb. Because amylopectin retrogradation results in a water-containing network,[15,45] the reduced mobility of population E was most probably caused by strengthening of the starch network and by the loss of water from proteins as observed for a gradually dried gluten/water model system.[15] A relation between the increase in firmness and the decrease in the T_2 relaxation time of population E was found. Hence, the extent of amylopectin retrogradation can be deduced from the NMR profiles as an increase in the area of population A, and the extent of crumb firmness can be deduced as a reduction in T_2 relaxation time of population E.

In conclusion, it can be said that the combination of DSC, texture analysis, and TD ^{1}H NMR allowed us to monitor molecular and textural changes during storage of oat and rice bread. The increase in melting enthalpy of retrograded amylopectin during storage was in line with the increase in the area of population A. The increase in firmness correlated well with the reduction of the T_2 relaxation time of population E. No loss of moisture from the crumb was observed, and hence, firming of oat and rice bread could mainly be related to changes in the starch fraction and redistribution of water within the crumb. Because of the increased extent of formation of amylopectin crystals, the crumb firmness of rice bread increased more rapidly than that of oat bread. The latter did not firm considerably during the observed storage period, possibly because of the higher endogenous lipid content of oat flour. This study hence showed that the use of oat flour for gluten-free bread making is beneficial in terms of shelf life.

Migration of Components from Cork Stoppers to Food: Challenges in Determining Inorganic Elements in Food Simulants

T. Corona, M. Iglesias, and E. Anticó*

Department of Chemistry, University of Girona, 17071 Girona, Spain

Supporting Information

ABSTRACT: The inorganic elements potentially migrating from cork to a food simulant [a hydroalcoholic solution containing 12 and 20% (v/v) ethanol] have been determined by means of inductively coupled plasma (ICP) with atomic emission and mass spectrometric detection. The experimental instrumental conditions were evaluated in depth, taking into account spectroscopic and nonspectroscopic interference caused by the presence of ethanol and other components in the sample. We report concentrations ranging from 4 $\mu g\ kg^{-1}$ for Cd to 28000 $\mu g\ kg^{-1}$ for Al in the food simulant (concentrations given in kilograms of cork). The values found for Ba, Mn, Fe, Cu, and Zn have been compared with the guideline values stated in EU Regulation 10/2011. In all cases, cork met the general safety criteria applicable to food contact material. Finally, we have proposed water as an alternative to the hydroalcoholic solution to simplify quantification of the tested elements using ICP techniques.

KEYWORDS: *elemental composition, cork, food simulant, migration, matrix interferences, spectroscopic interferences*

INTRODUCTION

Cork is a natural product obtained from the bark of *Quercus suber*, a common species in the Mediterranean region. Because of its unique physical properties, such as elasticity and low permeability, cork has long been used in the production of cork stoppers, frequently used in the wine industry to seal wine bottles.[1] The cork stopper fabrication process involves various steps: the stripping of the cork plank from the tree stem, a first rest or maturation in the field or factory, followed by boiling and resting in open air, a further boiling step and resting in the store room with a high relative humidity, and finally elimination of the outer corkback and the cork material cut and shaped according to use (stoppers for still wine and disks for sparkling wine). Surface modification is also performed using paraffins and other additives.[2]

The chemical characterization of cork has been investigated mainly with respect to organic compounds.[3,4] However, little attention has been paid to determining its elemental composition. The sources of the inorganic elements present in cork bark and cork stoppers may differ. On the one hand, plants and trees can accumulate trace elements, especially heavy metals, and act as passive receptors; the uptake of nutrients and trace elements through the roots has been extensively studied.[5] On the other hand, contamination from atmospheric particles, pesticides, and the cork stopper fabrication process itself may also contribute to the distribution of metals in cork material. Some studies have addressed the mineral composition of cork material and its relationship with mineral nutrition, the climate, or tree characteristics.[6] In these cases, it is mainly nutrients that are analyzed. In addition, some authors have used tree barks as bioindicators of heavy metal pollution in the atmosphere because of their ability to accumulate metals. The role of bark as a cation exchanger has been highlighted.[7]

Another very important issue to consider is the interaction of cork with wine when cork stoppers are used to seal wine bottles. European Regulation No. 1935/2004 (repealing Directives 80/590/EEC and 89/109/EEC) requires that food contact materials are safe and do not transfer their components into food in quantities that could endanger human health, change food composition in an unacceptable way, or deteriorate the taste and odor of the food.[8] Annex I of the regulation mentioned above lists the groups of materials that may be covered by specific measures, including cork. Specific regulations for cork are listed in Resolution ResAP(2004)2, adopted by the Committee of Ministers, in its composition restricted to Representatives of the States members of the Partial Agreement in the Social and Public Health Field.[9] Among other recommendations, the document states that Directives 82/711/EEC, 85/572/EEC, 93/8/EEC, 97/48/EEC, and 2002/72/EEC and their future amendments should be applied, and that there should be verification of compliance with the quantitative restriction according to the conditions laid out in "Technical document No.2-test conditions and methods of analysis for cork stoppers and other cork materials and articles intended to come in contact with foodstuffs". In this respect, a migration test should be performed under conditions simulating long-term storage (10 days at 40 °C) using a food simulant consisting of a 12% ethanol solution. The potential migrants from agglomerated cork stoppers associated with synthetic products (additives, surface treatments, and lubricants) have been previously studied in line with this approach.[10]

In general, elemental concentration in food simulant solutions obtained from corks is expected to be very low, and for this reason, extremely sensitive analytical techniques are needed. A common technique for determining elements in aqueous matrices is by means of inductively coupled plasma

(ICP), which allows reliable results and high sample throughput. Depending on concentration level, different detection systems are available, such as ICP-AES (atomic emission spectroscopy) for elements present at concentrations higher than ~0.1 mg L^{-1} and ICP-MS (inductively coupled plasma with mass spectrometry detection) for those present at lower concentrations. The latter technique shows good analytical performance but suffers from interferences of different types, such as matrix and spectroscopic interferences.[11] In the particular case of a hydroalcoholic solution, the presence of a carbon source such as ethanol is of special concern. For example, some polyatomic interferences have been described for Cr ($^{12}C^{40}Ar$ and $^{13}C^{40}Ar$).[12] Additionally, the determination of elements with low ionization potential such as Zn, Se, and As is also challenging because of the increase in their degree of ionization in the plasma when an additional carbon source is simultaneously present.[13−15] To overcome these problems, several strategies were developed, including complex sample treatment procedures, the use of interference equations, collision cell devices, and high-resolution instruments.[15]

In this study, we have assessed the elemental composition of a food simulant originating from cork soaks with two objectives: (1) providing a reliable method for their determination, avoiding, if possible, the use of ethanol in calibration standards, and (2) ascertaining whether cork may be considered a safe material for use as a stopper for bottled wine according to the aforementioned EU directive.

MATERIALS AND METHODS

Reagents. The reagents used were analytical grade suprapur quality: nitric acid (Suprapur, Merck, Darmstadt, Germany) and hydrogen peroxide (Trace Select, Fluka, Gilligham, Dorset, U.K.). Water obtained from a Milli-Q purifier system (Millipore Corp., Bedford, MA) was used throughout the study. For matrix matching standards, ethanol absolute (UV-IR-HPLC) PAI was used, from Panreac.

Monoelemental ICP standard solutions (1000 or 5000 mg L^{-1} for Ba) for each element studied were purchased from Pure Chemistry, ROMIL, UKAS calibration.

Apparatus. An ETHOS PLUS Milestone microwave with an HPR-1000/10S high-pressure rotor (Sorisole, Bergamo, Italy) was employed for acid digestion of samples.

A sequential inductively coupled plasma atomic emission spectrometer (ICP-AES, Liberty RL, Varian) in radial configuration was used for major and minor element determination. For trace element determination, a quadrupole-based ICP-MS system (Agilent 7500c, Agilent Technologies, Tokyo, Japan) was used, equipped with an octapole collision reaction cell.

Sample Collection. Samples consisting of cork granules (samples C1 and C2) and cork slabs (C3) were obtained from local producers in Girona, Spain. In all cases, the cork material was obtained from the cork residues discarded in the final stages of the production process, i.e., shaping of the cork slab to obtain the cork stoppers or cork disks. Theses residues are ground in the manufacturing to obtain cork granules intended to be used in the fabrication of different synthetic cork and other cork types (samples C1 and C2). In the case of cork sample 3, we obtained from the producer cork slices that were ground in our laboratory using a conventional grinder (Moulinette D56, Moulinex España, Barcelona, Spain).

Sample Treatment. The migration tests were performed according to the European Directive using a hydroalcoholic (HA) solution [12% (v/v) ethanol] as a food simulant. Four grams of cork granules or previously ground cork slabs was immersed in 100 mL of a food simulant solution at 40 °C for a period of 10 days.[10] The solid parts were then separated by filtering the sample through glass wool. Prior to analysis, a precise weight of cork soak was taken, and the desired amount of the internal standard (IS) solution was added. A small volume of HNO_3 was also added to acidify the sample.

To determine the total content of elements in cork samples, the following procedure was followed.[16] Nine milliliters of concentrated HNO_3 and 1 mL of hydrogen peroxide were added to a 0.5 g cork sample placed in a Teflon reactor. Once the vessel was sealed, it was placed in the microwave oven and the following program was run: 5 min to reach 180 °C, 10 min at 180 °C, and finally a cooling period. After cooling to ambient temperature, the reactor was opened, and the resultant solution was quantitatively transferred to a vial, where the total weight was carefully measured.

To prepare the samples for analysis, the necessary amount of the IS solution was added to 5 g of the digested solution. The samples were measured using the prepared calibration set, as explained below.

To avoid the presence of ethanol in the samples and standards, we tried other migration treatments. In particular, we evaluated the possibility of performing the migration tests by using water instead of a hydroalcoholic solution at different temperatures.

Determination of Elements in the Food Simulant. *For Minor and Trace Element Determination (Ba, Mn, and Al).* Standard solutions were prepared in water or a hydroalcoholic solution. The calibration standards were prepared from individual standard solutions in 1% HNO_3, containing Y (1 mg L^{-1}) or Rh (3 mg L^{-1}) as an internal standard, as indicated. IS correction was conducted by taking into account the intensity of the line for the measured element and for the internal standard. Additionally, because of the different behavior traditionally observed for ionic and atomic lines, each ionic line was corrected using an ionic line from the internal standard and each atomic line was corrected using an atomic line[15] (see Table 1).

Table 1. Selected Atomic and Ionic Lines for ICP-AES Measurements

element	line type	wavelength (nm)	IS	line type	wavelength (nm)
Ba	II	455.403	Y	II	371.030
Zn	II	202.551	Y	II	371.030
Cu	I	324.754	Rh	I	343.489
Fe	II	259.940	Y	II	371.030
Mn	II	257.610	Y	II	371.030
Al	I	396.152	Rh	I	343.489

For Ultratrace Element Determination (Cr, Fe, Ni, Cu, Zn, Pb, Cd, As, and Se). From the commercial standard solutions, an intermediate solution in 1% (w/w) HNO_3 containing the measured elements over the appropriate range of concentrations was prepared and used to obtain the calibration set, either in water or in a hydroalcoholic solution.

The isotope ^{103}Rh was used for internal standard correction after checking that it was not present in the samples at the concentration range studied (results from a semiquantitative analysis). The concentration of IS in the standard solutions prepared for calibration and in the samples was around 3.7 ng g^{-1}.

The experimental conditions for determining this set of elements were optimized taking into account different criteria: abundance of the selected isotope, correction of isobaric and polyatomic interferences under the vented or pressurized collision cell, type and flow rate of the gas used in the pressurized collision cell, correction of matrix interferences by the IS used, and finally the presence of other matrix interferences that cannot be corrected with the IS.

Octopole and quadrupole potentials were varied according to cell conditions, being fixed at −12 and −11.1 V, respectively, when a pressurized cell was used and −6.4 and −4.5 V, respectively, under vented conditions.

Some other parameters, such as ion lens settings, were adjusted daily to obtain the maximal sensitivity and precision. The oxide level (CeO^+) and doubly charged ion level (Ce^{2+}) were kept under 1 and 3%, respectively.

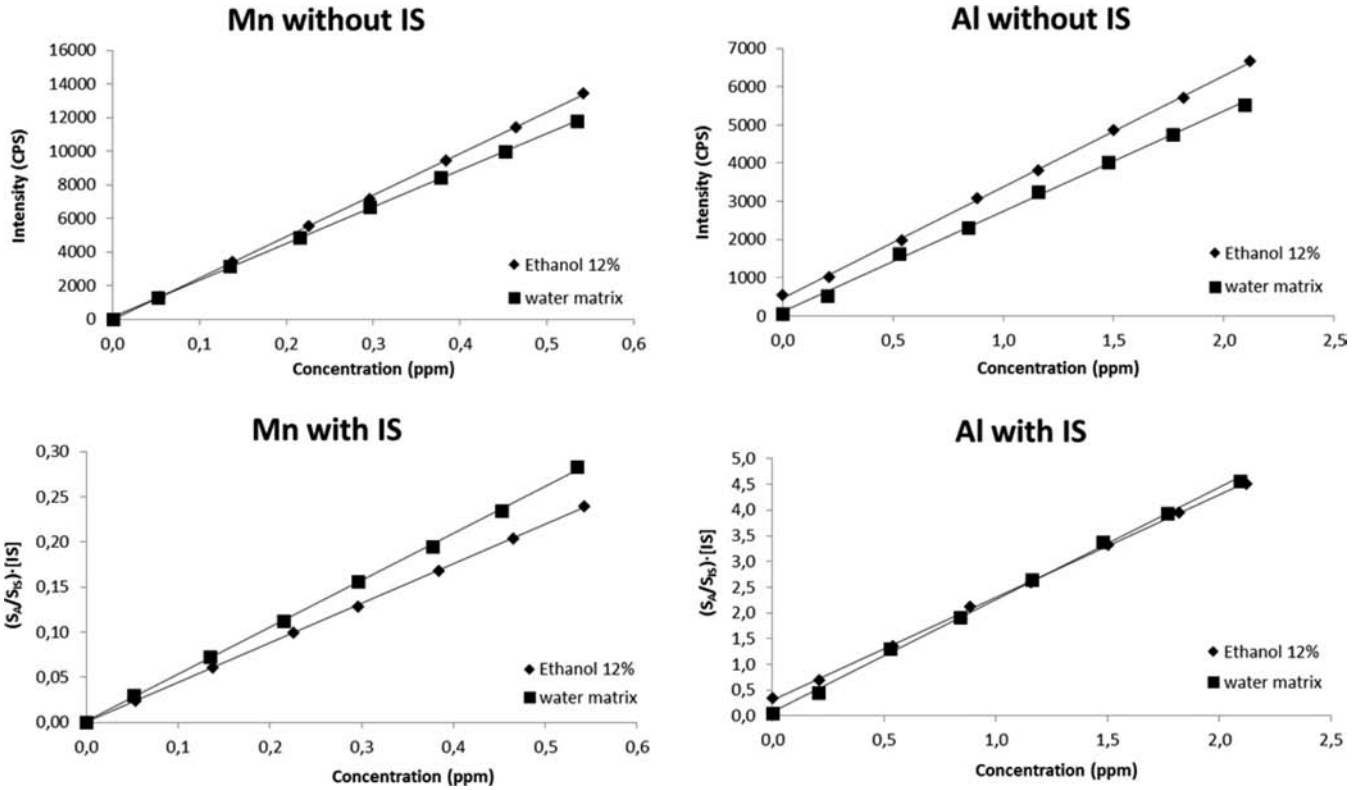

Figure 1. Calibration curves for Al and Mn with and without IS.

Statistical Analysis. The statistical package provided by Excel was used to perform analysis of variance to evaluate whether differences between treatments were significant ($p < 0.05$).

RESULTS AND DISCUSSION

Evaluation of Experimental Conditions for Determining Elements. The elements of interest were selected according to the results of preliminary semiquantitative studies conducted in our laboratory. To quantify these elements using ICP-AES and ICP-MS techniques, matrix interferences and spectral interferences are of great concern because of the presence of ethanol and other carbon sources in the matrix derived from the sample itself. In a previous work dealing with wine samples,[17] we evaluated the influence of the presence of ethanol and demonstrated that use of an adequate IS allows the calibration set to be prepared in water instead of a HA solution. For this reason, we devoted much effort here to studying whether choosing an adequate IS makes it possible to appropriately correct the different types of interferences. The elements determined by ICP-AES will be discussed separately from those measured by ICP-MS in the following sections.

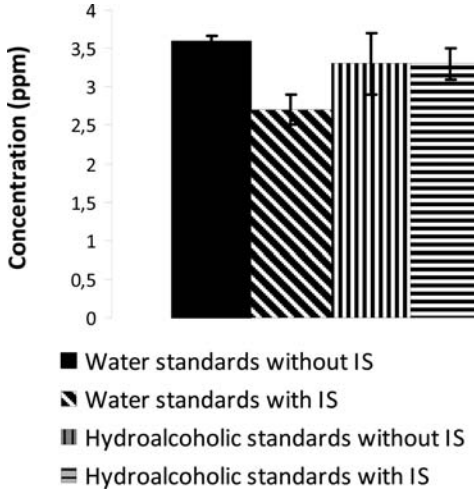

Figure 2. Results obtained for Mn determination in a cork soak under different calibration conditions.

ment. The main problem associated with determining the elements is sample composition due to the presence of the alcohol, which may cause differences in nebulization efficiency and aerosol transport compared to those of water samples. Figure 1 shows calibration curves for Al and Mn (see Table S1 of the Supporting Information for calibration parameters). As we can see, the addition of Rh and Y as internal standards allows for an appropriate correction of matrix interference due to the presence of ethanol for Al. Similar results were obtained for Ba. For Mn, calibration curves are statistically different [$p < 0.05$ (see Table S2 of the Supporting Information)] for both matrices even in the presence of the internal standard, which means that matrix effects other than nebulization efficiency and transport contribute to the response at the selected wavelength. To verify this fact, a sample was measured in triplicate and the manganese concentration was determined using the calibration plots shown in Figure 1, i.e., aqueous standards, aqueous standards with IS, standards in a hydroalcoholic solution, and standards in a hydroalcoholic solution with IS. The results obtained (Figure 2) demonstrate that the aqueous standards, even with IS, do not allow the correct determination of this element. On the other hand, when ethanol standards are used, the same result is obtained with and without IS, so the presence of ethanol is the main matrix effect in manganese determination.

Metals Determined by ICP-MS (Cr, Fe, Ni, Cu, Zn, Pb, Cd, As, and Se). For those elements present at lower concentrations, ICP-MS was used. In this case, spectroscopic and nonspectroscopic interferences are of particular concern and different situations can be envisaged: (1) when matrix interference due to the presence of ethanol in the samples is corrected by use of the appropriate IS, (2) when polyatomic interferences exist that are corrected by the use of a pressurized cell and the conditions in the cell need to be optimized, and (3) elements with a high ionization potential that also need special instrumental conditions.

We performed separate experiments depending on the characteristics of each element.

Cadmium, Lead, Iron, Nickel, and Copper. For lead and cadmium, no important polyatomic interferences have been described. Therefore, the most abundant isotope was selected for their measurement. Calibration curves were measured in water and hydroalcoholic solutions both with IS, and results showed that the use of the internal standard allows appropriate correction for the presence of ethanol in the solution. In both cases, without using the pressurized collision cell, calibration could be performed with standards prepared in water. Additionally, the values obtained for Cd and Pb, measured in a sample obtained from soaked cork, showed no significant differences when both calibration sets were used and with IS

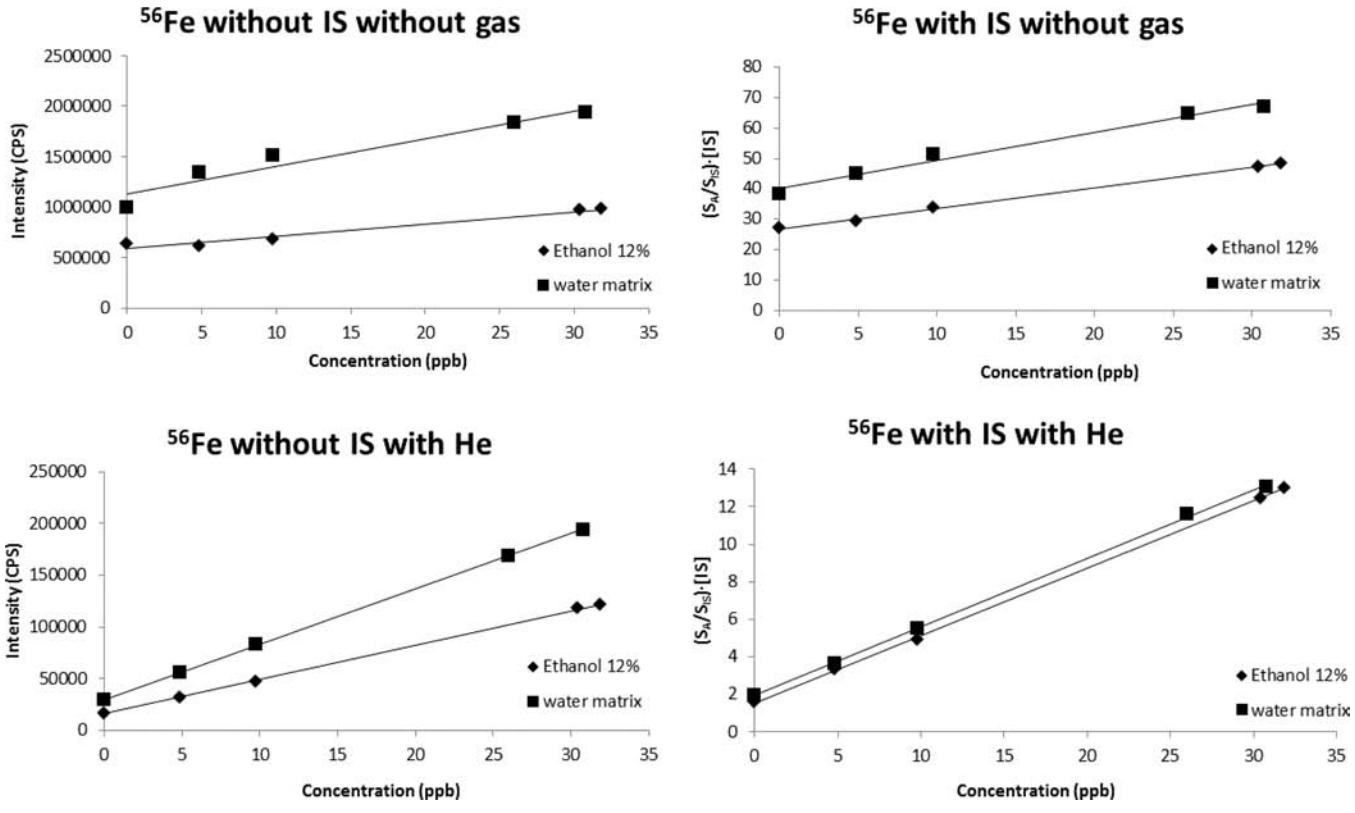

Figure 3. Calibration curves for ^{56}Fe under different conditions (pressurized cell with He at 2 mL min^{-1} and IS correction).

dx.doi.org/10.1021/jf500170w | J. Agric. Food Chem. 2014, 62, 5690−5698

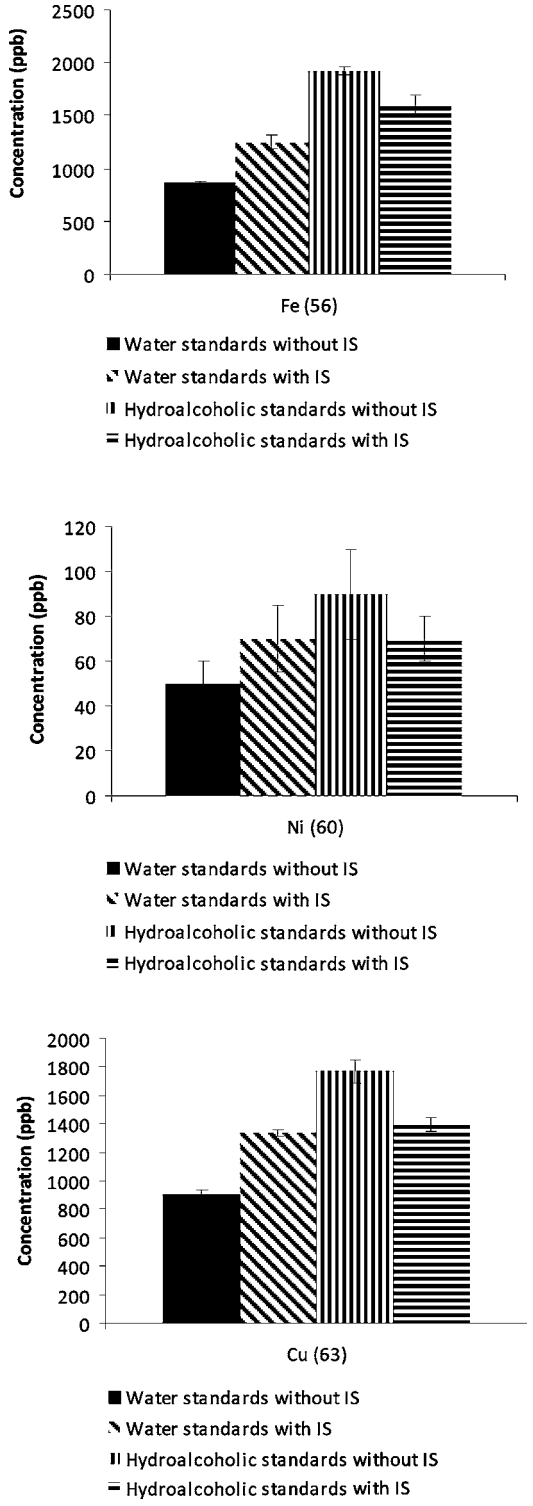

Figure 4. Results obtained for determination of ^{56}Fe, ^{60}Ni, and ^{63}Cu in a cork soak under different conditions.

correction. Some differences were encountered when the values obtained for calibration with ethanol were compared with the results obtained for calibration with ethanol and IS, probably due to matrix interferences other than ethanol.

For Ni, Fe, and Cu, common polyatomic interferences are known (see Table 2). Calibration data were compared for the most abundant isotopes under different conditions (internal standard and vented or pressurized cell). Similar behavior is observed in all six cases (two isotopes for each element): the use of the pressurized cell with He at 2 mL min^{-1}, as previously described,[18] allows for a good correction of polyatomic interferences, while matrix interferences deriving from the presence of ethanol can be mostly overcome by employing IS correction. The most abundant isotope providing better sensitivity was then chosen (Table 3). In Figure 3 and Table S3 of the Supporting Information, the case of ^{56}Fe is depicted by way of example.

The experimental conditions were verified by analyzing the three metal cations in a cork soak (Figure 4). When the results obtained from calibration with water standards were compared with those obtained with the hydroalcoholic solution, no significant differences were obtained for Ni and Cu if the IS is used for quantification. For Fe, the matrix interferences are not adequately corrected, and it is therefore compulsory to perform calibration using hydroalcoholic solutions. It should be taken into account that the cork soak solution has a complicated composition, so other matrix effects, different from those related to ethanol content, may be present.

Chromium. As explained in the Introduction, determination of chromium by means of ICP-MS is hampered by the presence of spectroscopic interferences due to the presence of carbon or chlorine in the sample matrix (see Table 2). Several strategies for overcoming these interferences have been proposed in the literature.[12] When the instrumentation available was taken into account, the use of pressurized cell conditions with He was chosen as the best alternative. As preliminary work, different He flow rates in the collision reaction cell were tested to obtain a high signal background ratio (SBR). A rate of 2 mL min^{-1} was finally chosen as a compromise between a low level of interferences and sufficient analyte signal. Calibration curves, with standards in water or a hydroalcoholic solution, were obtained under different conditions (vented and pressurized cell conditions and with and without IS) for the most abundant chromium isotopes, ^{52}Cr and ^{53}Cr. Additionally, the effect of the presence of chloride was also evaluated, because Cl has been determined to be an abundant element in cork.[19]

The addition of helium in chromium determination decreases spectroscopic interferences, which can be observed in Figure 5. However, the presence of a fairly important spectroscopic interference is still observed when ^{52}Cr is measured. In contrast, the use of He at a rate of 2 mL min^{-1} in the collision cell virtually eliminates the interference on ^{53}Cr. The use of IS does not result in much difference in this case.

Because chromium was present at a concentration level below the limit of detection in our particular samples, it could not be determined in the cork soak.

Arsenic, Zinc, and Selenium. These elements are also difficult to determine by means of ICP-MS because of their high ionization potential, which produces a low degree of ionization in the plasma. Additionally, they also suffer from spectroscopic interferences (see Table 2). It is already known that some of these elements show an important increase in sensitivity in ICP-MS when a quite large amount of C is present in the plasma source.[13] This effect has been explained as a charge transfer process from C ions to these elements and has been extensively studied for As and Se.[20] Some studies also include other elements with high ionization potentials, like Zn.[21]

The presence of important polyatomic interferences in As, Se, and Zn measurements makes it necessary to use pressurized cell conditions. Some studies found in the literature conclude

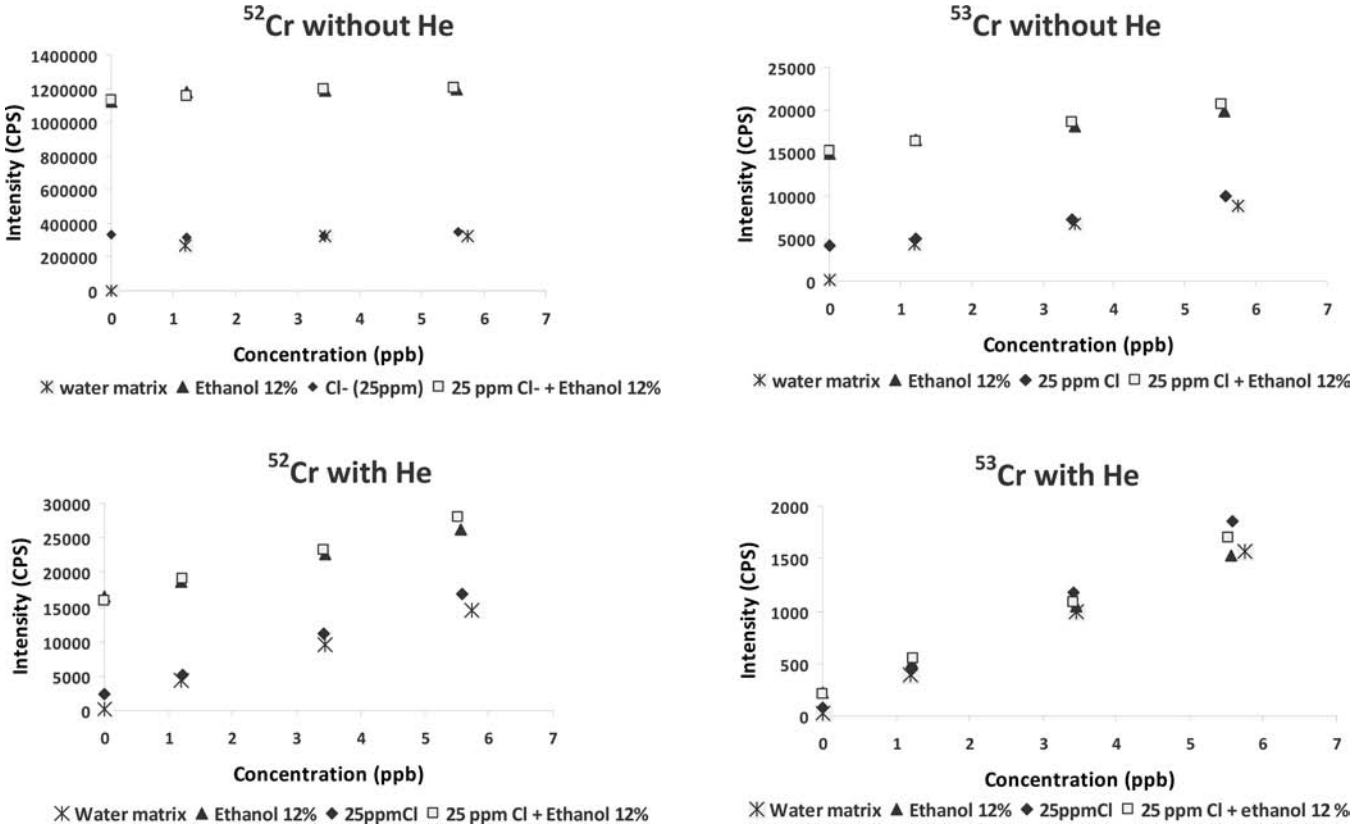

Figure 5. Intensity for ^{52}Cr and ^{53}Cr under different conditions in the collision cell. IS is used in all cases.

that the use of H_2 together with a small amount of He in the reaction cell (H_2 at 3 mL min^{-1} and He at 0.5 mL min^{-1}) gives good results for the determination of As and Se.[15] We therefore decided to use these conditions in our measurements. In the case of Zn, we compared the results obtained using He at 2 mL min^{-1} (same conditions used for Cr, Ni, Fe, and Cu) and H_2 at 3 mL min^{-1} and He at 0.5 mL min^{-1} (same conditions used for As and Se). Both gave similar results, so we decided to use the latter because of the greater sensitivity obtained in this case.

Upon comparison of the calibration curves obtained with and without ethanol and using IS, the internal standard does not correct properly for any of these elements, as expected. As already mentioned, the signal enhancement produced, due probably to a higher degree of ionization in the plasma, which in turn is related to the presence of C atoms from the matrix, is observed only for elements with high ionization potentials; this is not the case with Rh (our IS). The use of ethanol matrix standards to obtain the calibration curves is therefore once again compulsory. When a cork soak was measured (see Figure 6) and the results were compared, we again observed a difference between calibration in an aqueous matrix and calibration in a hydroalcoholic solution, both with IS. When standards in water are used, the concentration of these three elements is overestimated.

In Table 3, final collision cell conditions are summarized for the determination of arsenic, zinc, and selenium.

Method Validation. Because of the lack of certified cork soaked material, we validated the final conditions by performing recovery experiments. Three cork soaks were obtained, one for each sample type (C1−C3), and element concentrations were measured. The desired amount of stock solution was then added and a new measurement performed. Spiked levels and recoveries are listed in Table 4. Recovery values were obtained by using calibration curves with hydroalcoholic standards, with and without the IS correction. If we compare the data in the table for those elements measured with ICP-AES, the need to use the internal standard becomes clear because recoveries in the range of 130−176% were obtained without IS.

On the other hand, no statistical differences were obtained between the results for the other measured elements (recoveries obtained using calibration with IS compared with those without IS), except for As and Se. Taking into account the fact that the use of an IS is recommended in ICP-MS to account for variations in the plasma signal during one single run, we adopted this procedure to prepare the calibration set in the hydroalcoholic matrix.

Migration Tests. To calculate the percentage of an element that has migrated to the simulant, we previously determined the total concentration of each element in the three different cork samples (C1−C3). To do this, we used microwave-assisted acid digestion, establishing the condition described in the experimental part. Table 5 shows the concentrations found. We have also included some values obtained from the literature in the table. As shown in the table, few data are available for microelements. The results reported from PIXE analyses obtained from the bulk layer of a cork stopper[19] do not significantly differ from those obtained in our work in the case of Cu, while for Fe and Mn, PIXE concentrations are lower than ours. Additionally, when Pb is determined in a cork stopper used to seal a bottle of a French wine,[22] a relatively high concentration at the end in contact with the wine was found, compared with the concentration at the center of the cork. In this context, it has to be considered that lead content in wines is regulated,[23] and for that reason, its concentration in

dx.doi.org/10.1021/jf500170w | J. Agric. Food Chem. 2014, 62, 5690−5698

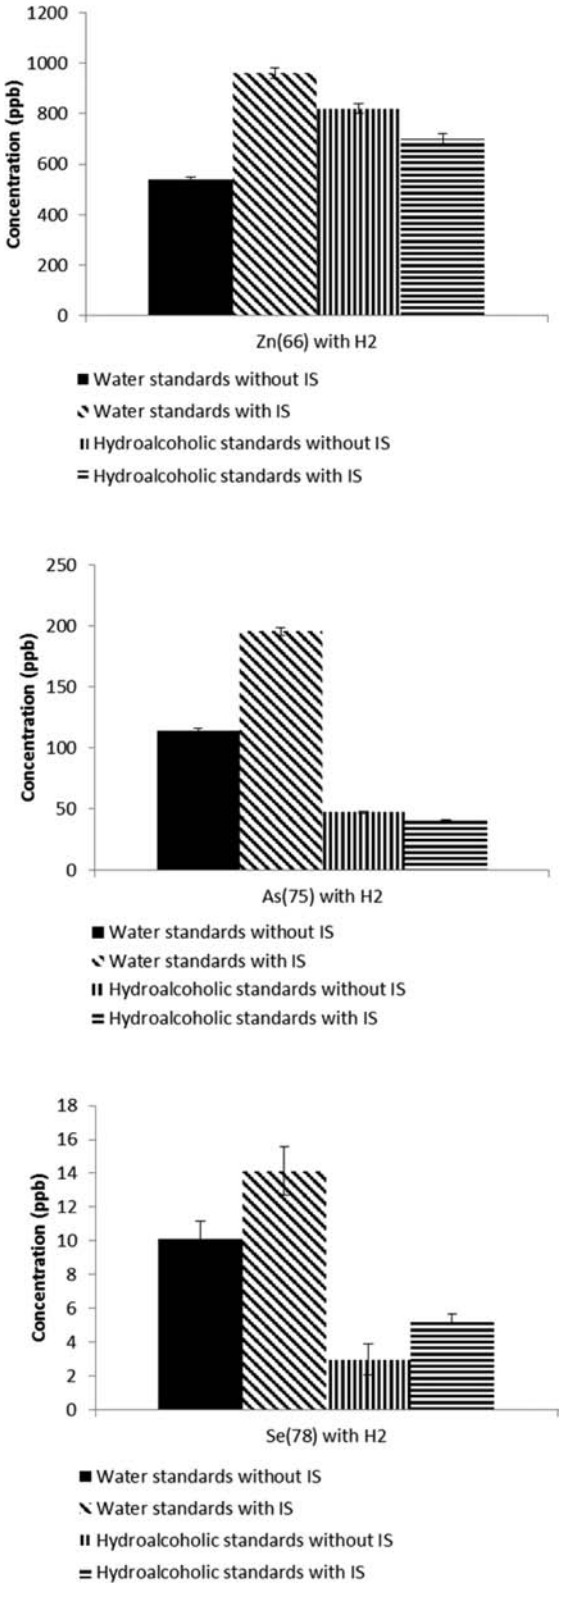

Figure 6. Results obtained for ^{66}Zn, ^{75}As, and ^{78}Se under different calibration conditions.

cork material and the migration to wine deserve special attention. With respect to the values we found for samples C1−C3, high variability was obtained between samples, presumably depending on the provenance of the cork. Catalonia is one of the most important regions producing cork stoppers, but the majority of producers obtain the cork material from forests in Andalusia, Extremadura, or Portugal. In this respect, it is hard to determine the precise origin of the material. It is also worth mentioning the differences between cork granules (corks 1 and 2) and cork slabs (cork 3), which may be attributed to the fabrication process applied to obtain cork granules, i.e., contamination due to the grinding process, when the cork material remains in close contact with the metallic parts of the machine for long periods of time.

Table 4. Recovery Results (R) Obtained for Spiked Samples

	added (μg/kg of food simulant)	R% without IS (SD)[a]	R% with IS (SD)[a]

Cd	6−6.5	96 (3)	106 (8)

[a]Three cork soaks (n = 3) were used, corresponding to each sample type (C1−C3), except for Ba and Mn (n = 2; C1 and C2) and Al (n = 1; C2).

The amount of each element transferred from the cork sample to the food simulant solution is presented in Table 6. The results are given as micrograms of the element measured in the solution divided by the total amount of cork used for the experiment. The percentage of the element migrated from the cork to the solution is also given. As we can see, the percentages vary from 0.6% for Ba to 67% for Se. Although this last migration percentage seems quite high, some studies in the literature reported Se migration values of up to 37% from yeast in hot water (50 °C) for 24 h.[24] It should be mentioned that selenoamino acids and inorganic Se (mainly selenite and selenate) are water-soluble.[25]

Prior to 2011, no reference values were established by the EU to determine whether these results might be considered safe. Recently, the EU has approved a new directive (EU directive 10/2011)[26] establishing maximal migration values for Ba, Cu, Fe, Mn, and Zn. Additionally, because cork stoppers are considered to be a material that comes into contact with wine, the new directive recommends the use of a food simulant consisting of 20% (v/v) ethanol in water. For this reason, we have measured the amount of the element that migrates not only in a 12% ethanol/water mixture but also in a hydroalcoholic solution with 20% ethanol. The values obtained for sample C2 are listed in Table 7. As we can see, the cork samples analyzed give migration results well below the maximum established, Ba and Mn being the most critical elements with respect to the maximal concentrations allowed. It is also worth mentioning that, in general, concentrations in a hydroalcoholic solution containing 20% ethanol are slightly higher than those in 12% ethanol, which may indicate that the solubility of metallic species increases at higher ethanol concentrations.

Migration Tests Using Water. Finally, we tested other conditions to perform the migration test using only water as a food simulant. In this way, we were able to avoid the presence

[a]Milligrams per kilogram of cork. [b]Micrograms per kilogram of cork.

of ethanol in the samples, resulting in fewer spectroscopic and nonspectroscopic interferences. Obviously, water is expected to have less extraction power than hydroalcoholic solutions. To address this difference, we increased the temperature (40–75 °C) while retaining the total contact time (10 days). Results are listed in Table 8, where those values that are similar to or slightly higher than those obtained for the food simulant [hydroalcoholic solution with 12% (v/v) ethanol] are underlined. As a general trend, we observe an increase in the amount of the element that migrated from the cork when the temperature is increased. With the exceptions of As and Se, the migration tests with water at 55 °C resulted in concentrations higher than those obtained with a HA solution. Taking into account the fact that most of the interferences in ICP-MS analysis of a food simulant are related to the presence of ethanol, we can propose the use of water at 55 °C as an alternative for making the analytical procedure easier.

ABSTRACT: Species-specific PCR–ELISA assays for the identification of Atlantic cod (*Gadus morhua*), Alaska pollock (*Gadus chalcogrammus*), and ling (*Molva molva*) in food products have been developed. The method, comprising a set of primers common to the first two species, a set of primers for *M. molva*, and a probe for each species, was designed using *ND4* and *cytochrome b* genes as molecular markers. The sensitivity and selectivity were then determined for each assay. These assays were afterward used to analyze DNA extracted from commercial fish products. The presence of the target species was successfully detected in all analyzed samples, demonstrating the applicability of this method to the analysis of food products.

KEYWORDS: *Gadus chalcogrammus, Gadus morhua, Molva molva, species identification, PCR–ELISA*

INTRODUCTION

The Gadidae family includes a large number of species, many of them of great economic value, such as *Gadus morhua*, which is marketed worldwide. However, due to several factors such as overfishing and climate change, some natural cod stocks are threatened, and the total world catch is currently <1 million tons, whereas in 1970 it was 3.5 million tons.[1]

Gadoid species can be identified in a relatively simple manner on the basis of their morphological characteristics in fresh and unprocessed fish; however, they are usually commercialized with some degree of processing, that being, frozen, gutted, filleted, smoked, canned, etc. Therefore, morphological characteristics that differentiate the species are, in many cases, absent. This situation favors some species eventually being replaced by other species, either accidentally or intentionally. This produces mislabeled fishery products, which affects directly or indirectly the consumer, the environment, and the industry. These consequences include human health risks[2−4] and overexploitation and depletion of some of the most consumed and valued species by consumers.[5−7] Other consequences are economic losses for the consumers[5] due to the addition of undeclared cheaper fish species or the sale of species that have a defined fishing quota and are captured over them, under the name of other species. For all this legislation is needed to control the correct labeling of fishery products.[8−13] European Union labeling regulations (EC No. 13/2000) specify that the commercial and scientific names should be included on the label of seafood products.

From this point of view, molecular DNA-based techniques are the most suitable option as an alternative to morphological analysis. Different genetic authentication techniques based on DNA have been proposed during the past decades for gadoid identification: polymerase chain reaction (PCR),[13,14] PCR–restriction fragment length polymorphism (RFLP),[16,17] real-time PCR,[15,18−21] forensically informative nucleotide sequencing (FINS),[22] single-stranded conformation polymorphism analysis (SSCP),[23] and single-nucleotide polymorphism (SNPs).[24]

One of the advantages of the PCR–ELISA methodology is that it can be applied to fresh, frozen, or processed products and that it requires only a conventional PCR system (thermocycler), because the results can be evaluated with the naked eye. This approach has been used in the detection of viruses,[25] bacteria,[26−28] and fish.[29,30]

The main objective of the present study was to develop a specific molecular technique to identify *G. morhua*, *Gadus chalcogrammus*, and *Molva molva* in seafood products.

MATERIALS AND METHODS

Fish Samples. Thirteen specimens of each of the Gadiformes target species were collected: *G. morhua*, *G. chalcogrammus*, and *M. molva*.

In addition, 20 representative specimens of other Gadiformes, Lophiiformes, Perciformes, and Cupleiformes orders were included in this study. Scientific and common names of these species are listed in Table 1.

During the validation step of the developed methodology, 19 commercial cod samples were used, purchased in different local markets (Table 2). All samples were analyzed in triplicate.

DNA Extraction. DNA was extracted from 0.3 g of thawed muscle and tissue of commercial samples, which were digested overnight in a thermoshaker at 56 °C with 860 μL of lysis buffer (1% SDS, 150 mM NaCl, 2 mM EDTA, and 10 mM Tris-HCl at pH8), 100 μL of 5 M guanidium thiocyanate (Sigma-Aldrich), and 40 μL of proteinase K (20 mg/mL) (Gibco Invitrogen, LifeTechnologies). After 3 h, extra proteinase K (40 μL) was added to the solution, and it was left overnight. After digestion, DNA was isolated employing the Wizard DNA Clean-Up System kit (Promega) following the manufacturer's instructions. DNA was quantified by using a NanoDrop 2000

Thunnus obesus	1	bigeye tuna

spectrophotometer (Thermo Scientific) at 260 nm and the ratio 260/280, respectively. The 260/280 ratio was between 1.8 and 2.0. DNA concentration was adjusted to 50 ng/μL. The purified DNA was stored at −20 °C.

Design of PCR−ELISA Systems. An extensive number of partial DNA sequences (nuclear and mitochondrial) and a wide number of fish species were analyzed (data not shown) during the study.

Two PCR systems were designed to amplify two mitochondrial fragments: a small fragment of the *cytochrome b* gene and a fragment of the *ND4* gene. Specific sets of primers were designed for each system to include the previously identified polymorphisms among the target species and other gadoid using Oligo Analyzer v. 1.0.3 (Freeware, Teemu Kuulasmaa, Finland). The 5′ biotin-labeled probes Gmor_ND4-P, Gchal_ND4-P, and Mmol_Cytb-P were designed to hybridize with the specific polymorphism to *G. morhua*, *G. chalcogrammus*, and *M. molva* PCR amplification products, respectively (Figure 1). HPLC purification grade primers and probes were synthesized by Sigma Genosys. Primer and probe sequences designed and used are listed in Table 3.

PCR Amplification and Digoxigenin-11-dUTP (DIG) Labeling Conditions. Primers and magnesium chloride concentrations were optimized to perform PCR DIG-labeling reactions in a final volume of 25 μL containing molecular grade water, 1.5 mM final concentration magnesium chloride (Bioline), DIG dNTPs (Roche) final concentrations of 200 μM of each of dATP, dCTP, dGTP, 190 μM dTTP, 10 μM DIG-11dUTP, primers T/G_ND4-F and T/G_ND4-R (final concentration 0.24 μM), primers Mmol_Cytb-F and Mmol_Cytb-R (final concentration 0.36 μM), BIOTAQ DNA polymerase (final concentration 0.5 U), and 50 ng of DNA template. Thermal cycling parameters were as follows: 95 °C for 5 min; followed by 25 cycles of 95 °C for 20 s, 63 °C for 30 s, 72 °C for 30 s; and a terminal extension step of 72 °C for 5 min. Negative controls (molecular grade water) were included in each set of reactions. These PCR reactions were carried out in an Applied Biosystems 2720 thermocycler.

The amplification products were tested in a 2% agarose gel (Pronadisa), containing RedSafe 1× (iNtRON Biotechnology) in 0.5× TBE buffer (Sigma). DNA fragments were visualized using the Gel Documentation System Gel Doc XR System and the software Quantity One v 4.5.2 (Bio-Rad).

The PCR products were purified using the Nucleospin Extract II kit (Macharey-Nagel) according to the manufacturer's instructions. The concentration and purity were estimated by means of UV spectrometry at 260 nm using a NanoDrop 2000 spectrophotometer (Thermo Scientific).

To verify the correct assignation of the specimens used in the method setup, a new PCR product was amplified and sequenced on an ABI Prism 310 Genetic Analyzer (Applied Biosystems). This analysis was carried out using the primers L14735 and H15549D.[31] The resulting cytochrome *b* nucleotide sequences were also analyzed by FINS[32] and, to confirm, were compared with those present in the NCBI database using Megablast.

Once the correct performance of each PCR for the two designed systems was verified individually, a duplex PCR for the two systems was set up. Primer concentrations and thermal protocol were the same as the ones previously used in simplex PCR.

Detection of DIG-Labeled PCR Products by ELISA. The PCR−ELISA DIG detection kit (Roche) was used for the detection of labeled PCR products according to the manufacturer's instructions. A volume of 10 μL of each DIG-labeled PCR product (5 ng/ μL) was denatured in 20 μL of denaturation solution at 25 °C for 10 min; this solution and 170 μL of hybridization buffer, containing the biotinylated probe at a concentration of 5.3 nM, were then transferred to the wells of a streptavidin-coated microtiter plate strip, and the plate was incubated at 59 °C for 3 h. The microtiter plate wells then were washed, and anti-DIG-POD (anti-digoxigenin−peroxidase-conjugate) working solution (200 μL) was added to each well; the microtiter plate was incubated afterward at 37 °C for 30 min. After another washing step, peroxidase substrate, 2,2′-azinobis(3-ethylbenzthiazoline sulfonate) (ABTS), was added, and the plate was incubated at 37 °C for 30 min to allow color development. The absorbance of the contents of each well was read in a SynergyMx spectrophotometer (BioTek Instruments), at a wavelength of 405 nm.

To obtain the method's detection limit, mixtures of three species' DNA template were diluted in molecular biology grade water, obtaining 50 ng−50 pg per microliter. These dilutions were used in the PCR−ELISA reaction, and the labeled products were detected using the three probes.

Positive reactions were determined by a calculation of cutoff values as follows: cutoff = 4 × absorbance at 405 nm of the mean of 10 replicates of negative detection control.

Validation of the Methodology with Commercial Samples. Once the methods were optimized, they were applied to 19 commercial samples purchased in markets and shops from different places in Spain.

RESULTS AND DISCUSSION

The aim of the present study was the development and evaluation of a PCR−ELISA technique for the authentication of

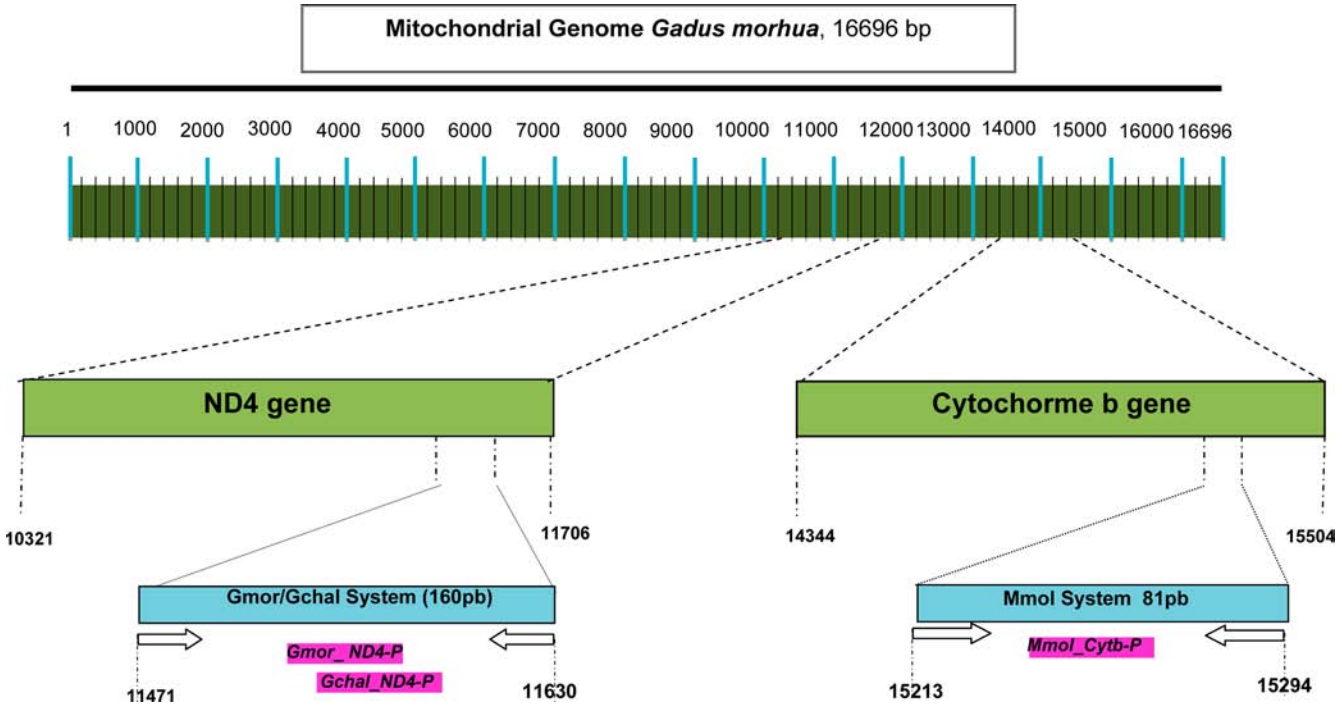

Figure 1. Location and position of primers and probes designed in this work.

G. morhua, *G. chalcogrammus*, and *M. molva* species in seafood products. Due to their low cost, when ling (*M. molva*) and Alaska pollock (*G. chalcogramma*) lose their morphological characteristics, they are highly susceptible to being used in fishery products for the replacement of more expensive fish species such as cod (*G. morhua*).[5]

PCR–ELISA System Design. For the correct design of the PCR–ELISA system, a large number of DNA sequences of nuclear and mitochondrial genes from a large number of fish

species were analyzed previously. Mitochondrial DNA has been extensively studied and used as a marker for phylogenetic classification species of fish as well as for their detection in commercial products. This is because in the cells, mitochondrial DNA is more abundant than the nuclear, have a higher mutation rate, and contains more sequence diversity.[33,34]

To achieve sufficient sensitivity to accurately identify the species of Atlantic cod, ling, and Alaska pollock in processed samples, one of the objectives of this work was to find a system (comprising primers and probe) as short as possible.

This system must be designed in a region of DNA that contains sufficient interspecific variability and low or null intraspecific variability for the primers and biotin-labeled probe to be specifically bound and avoiding false negatives and false positives.[35]

The hybridization of the biotin-labeled probe with specific PCR products allows the detection of the target species, therefore increasing the number of interspecific differences the increasing the specificity. It is shown that this specificity is also dependent on the length, hybridization temperature,and GC content of the capture probe. Sails et al.[26] in their work onidentifying *Campylobacter jejuni* and *Campylobacter coli* observed that short capture probes (18−20 nucleotides) with nucleotide differences in the central region and high annealing temperatures (up to 55 °C) can identify a single nucleotide difference in the sequence target.

The designed systems consisted of a 160 bp fragment (Gmor/Gchal_ND4 system) and an 81bp fragment (Mmol_-cytb system) (Figure 1).

The sequences of the selected primers and probes are listed in Table 3.

Specificity of PCR−ELISA Assay. Detection of PCR products by simple electrophoresis in agarose gel may not be sufficiently specific, giving rise to false positives if a verification of the sequence is not performed by hybridization to specific probes;this may occur due to the difficulty in determining the exact size of the amplicons and the possible occurrence of artifacts with the same size as that of PCR products.[36] However,

the results of this assay showed that specific PCR products were always obtained and that non-false positives were produced in any case (Figure 2). The designed PCR systems allowed a certain degree of specificity to be obtained; for instance, if primer pair Gmor/Gchal_ND4 is used, a 160 bp DIG-labeled PCR product will be produced only when mitochondrial DNA used as template is from *G. chalcogrammus* and *G. morhua*.

Similarly, primer pair Mmol_Cytb generates an 81 bp DIG-labeled PCR product only when template DNA is from *M. molva*.

Both primer pairs were tested for their specificity using 50 ng/μL DNA of all species listed in Table 2.

Thanks to the joint use of specific sets of primers and probes, a highly specific hybridization is achieved, allowing the high specificity necessary to verify the DNA sequence of the PCR products, to avoid false positives, and to correctly identify the target species.

Detection of DIG-Labeled PCR Products. For the determination of the specificity of detection of the three labeled probes, these were tested for specific identification of labeled PCR products from the three problem species by measuring their absorbance at 405 nm (Table 4), considering positive those samples having an absorbance at 405 nm that was >0.604. This cutoff value was calculated as follows: cutoff = 4 × absorbance at 405 nm of the mean of 12 replicates of negative detection control (0.151 ± 0.009). Furthermore, the results showed a positive green coloration detectable to the naked eye.

Table 4. Comparative Specificity of the Different Probes for the Detection of *M. molva*, *G. chalcogrammus*, and *G.morhua*

sample	*N*	absorbance readings at 405 nm ± standard deviation
Molva molva	13	0.818 ± 0.07
Gadus chalcogrammus	13	1.904 ± 0.50
Gadus morhua	13	2.39 ± 0.8
negative	12	0.151 ± 0.00

With the purpose of evaluating the sensitivity and detection limit of the PCR–ELISA developed, a series of dilutions from 16 ng to 60 pg of the extracted sample of positive control DNA were amplified and subsequently used in an assay for PCR–ELISA and a conventional agarose gel electrophoresis assay to compare the signals obtained in both assays (Table 5; Figure 3). These assays showed that PCR–ELISA was at least 100-fold more sensitive than the detection method based on gel. The minimum amount of DNA template detectable in the PCR–ELISA assay with the Gmor_ND4-P probe was 123 pg, and with Gchal_ND4-P and Mmol_Cytb-P probes it was 416 pg, whereas with the conventional agarose gel electrophoresis method, the minimum amount of DNA template easily visually detected was 16.7 ng. The data here presented indicate that the PCR–ELISA technique based on the detection of cytochrome *b* and ND4 gene products is highly sensitive.

Table 5. PCR–ELISA Readings at 405 nm of Different Amounts of Purified PCR Products

DNA template	absorbance readings at 405 nm		
	G. morhua probe	*G. chalcogrammus* probe	*M. molva* probe
16.7 ng	2.59	1.74	1.72

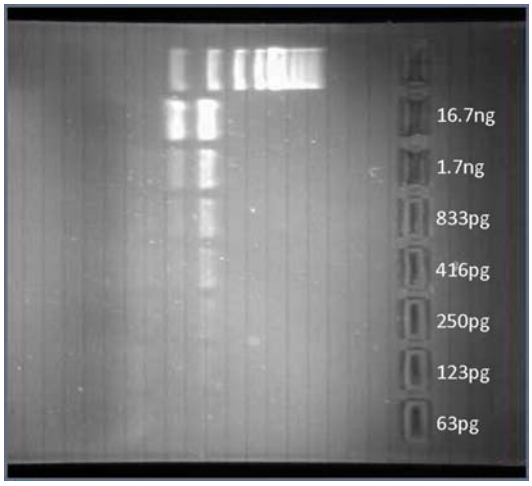

Figure 3. Agarose gel electrophoresis of amplification products obtained by a duplex PCR from mixtures of *G. morhua*, *G. chalcogrammus*, and *M. molva* DNA extracts, ranging from 16 ng to 60 pg of DNA of each DNA template.

Although there are other molecular detection techniques that require less time, such as TaqMan real-time PCR, PCR–ELISA can also be considered as a rapid technique, requiring less than a day's work to obtain the results.[27] The PCR–ELISA approach can be immediately adopted by most identification laboratories because the results can be visually read, eliminating the need for expensive equipment, and a large number of samples can be handled.

PCR Amplification and Sequencing. The success of the methodology used depends on the correct design of specific probes labeled with biotin that will be linked through an antigen–antibody reaction to a microplate with streptavidin and the incorporation, during the PCR process, of a triphosphate nucleotide labeled with DIG, allowing amplicon detection.

The annealing temperature was adjusted to allow the correct amplification of problem species while avoiding the amplification of other closely related species (Figure 2). Finally, this parameter was adjusted to 63 °C, because it allows the efficient amplification of *G. morhua*, *G. chalcogrammus* DNA with Gmor/Gchal_ND4 primers, and *M. molva* in Mmol_Cytb primers. Each primer set was independently tested and optimized first.

With the aim of reducing the number of steps of the identification methodology, PCR amplification of the two designed systems was grouped in a duplex PCR;[37] this also allows the identification of three species, even when mixed, in a single step.[38] The conditions were the same as used in simplex PCR. In these conditions, similar concentrations of PCR products were obtained in both duplex PCR.

The main advantage of multiplex PCR strategy is the reduction of the number of reactions required, decreasing labor time and total cost. It is particularly justified when a mix of

dx.doi.org/10.1021/jf500173j | J. Agric. Food Chem. 2014, 62, 5699–5706

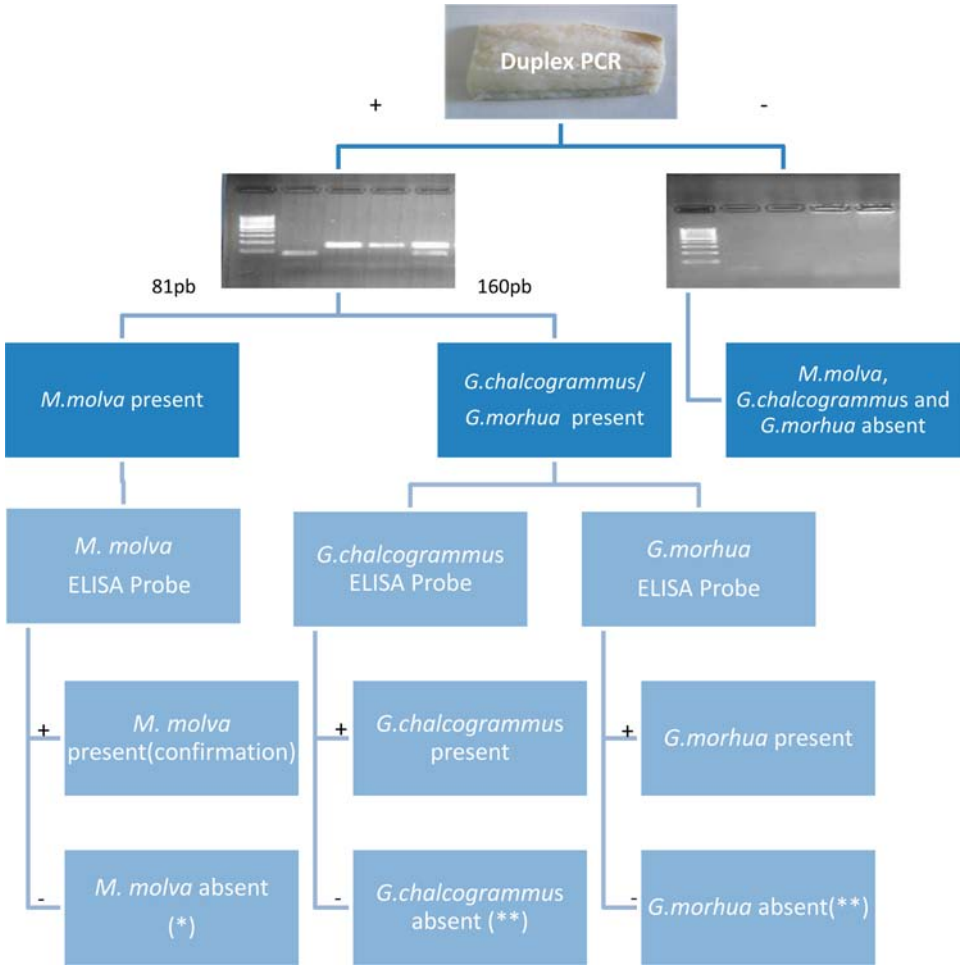

Figure 4. Flow diagram of the proposed method: *, unlikely to occur (if this occurs, it is recommended to check the ELISA test components including a positive control); **, 160 bp PCR product but double-negative hybridization of both *Gadus* probes is unlikely to occur (if this occurs it is recommended to check the ELISA test components including positive controls).

species is suspected in the sample or when the assurance of the presence/absence of the three target species is desired (Figure 4). The duplex PCR allows verification of the presence of *Gadus morhua/chalcogrammus* and/or *M. molva* DNA in a tissue or DNA mixture.

Alternatively, the individual use of each particular system is also possible, allowing determination of the presence of any of the three studied species.

The set of primers L14735 and H1549D was used as amplification control in PCR, to avoid the occurrence of false-negative amplifications due to problems associated with the samples, such as the presence of inhibitors and poor-quality or fragmented DNA associated with the transformation process.

To confirm the correct identification based on morphological characters, a 460 bp fragment from each of the specimens used in this study was amplified, sequenced, and analyzed by FINS. Moreover, to verify that these sequences were correctly assigned to particular species, they were compared with those present in the NCBI database using Megablast.

Validation of the Methodology with Commercial Samples. Once the method surpassed the validation step, it was applied to 19 commercial samples (Table 2) following the flowchart proposed (Figure 4), allowing us to evaluate and broadly determine the labeling situation of these products in the Spanish market. All samples analyzed were correctly identified. The positive and negative results were clearly visualized without the need of a spectrophotometer or ELISA plate reader (Figure 5). Four analyzed samples contained different species from those indicated on the label; one of them was identified as a mixture *G. morhua* and *M. molva*. This mislabeling would not have been possible to detect using DNA sequencing analysis (FINS) (Table 2).

In conclusion, the technique described in this paper represents a useful tool to unequivocally authenticate the species *G. morhua*, *M. molva*, and *G. chalcogrammus*.

In no cases were false negatives or false positives obtained. The purpose of this study was the development and evaluation of a PCR−ELISA technique for the detection of *G. morhua*, *M. molva*, and *G. chalcogrammus* in fish products, which has been successfully accomplished.

This methodology proves useful for enforcing labeling regulations in the authentication of fresh or elaborated fish products and could be used as a routine analysis in food control laboratories.

We indeed identified the species *M. molva* in these products, whereas, according to law, cod can only be manufactured with the species *G. morhua* and *G. macrocephalus*. *M. molva* is a less economically valued species and thus frequently used in transformed food products in which substitution is impossible to detect by simple visual inspection.

Effect of Almond Processing on Levels and Distribution of Aflatoxins in Finished Products and Byproducts

Rosanna Zivoli, Lucia Gambacorta, Giancarlo Perrone, and Michele Solfrizzo*

Institute of Sciences of Food Production (ISPA), National Research Council of Italy (CNR), Via Amendola 122/O, 70126 Bari, Italy

ABSTRACT: The fate of aflatoxins during processing of contaminated almonds into nougat, pastries, and almond syrup was evaluated by testing the effect of each processing step (blanching, peeling, roasting, caramelization, cooking, and water infusion) on the distribution and levels of aflatoxins. Blanching and peeling did not reduce total aflatoxins that were distributed between peeled almonds (90−93%) and skins (7−10%). Roasting of peeled almonds reduced up to 50% of aflatoxins. Up to 70% reduction of aflatoxins was observed during preparation and cooking of almond nougat in caramelized sugar. Aflatoxins were substantially stable during preparation and cooking of almond pastries. The whole process of almond syrup preparation produced a marked increase of total aflatoxins (up to 270%) that were distributed between syrup (18−25%) and spent almonds (75−82%). The increase of total aflatoxins was probably due to the activation of almond enzymes during the infusion step that released free aflatoxins from masked aflatoxins.

KEYWORDS: *aflatoxin, almond, processing, pastries, nougat, syrup*

INTRODUCTION

Almonds are the edible seeds of the almond tree (*Prunus dulcis*) originating from regions of Central Asia and currently cultivated around the world in dry and temperate climates. The world production in 2012 was mainly distributed among the United States (mainly California, 37.2%), Spain (11.1%), Australia (7.4%), Iran (5.2%), Morocco (5.1%), Italy (4.6%), and the Syrian Arabic Republic (4.5%). The remaining production (24.9%) is distributed in other countries, each of them producing <4% of the total.[1] Almonds are used in the food industry to produce pastries (amaretti, cantucci biscuits, dragée, etc.), almond syrup, nougat, and marzipan. Among food commodities, almonds are considered to have an intermediate risk of aflatoxin contamination.[2] From 2010 the European maximum levels of total aflatoxins in almonds intended for further processing (15 μg/kg) and ready-to-eat (10 μg/kg) have been aligned with those of Codex Alimentarius after a positive opinion of the European Food Safety Authority (EFSA).[3−6] Among mycotoxins, aflatoxins are in the hazardous category, with the highest number of notifications in the European Union (EU) Rapid Alert System for Food and Feed (RASFF). The number of aflatoxin notifications for the category of nuts, nut products, and seeds decreased from 568 in 2007 (75 for almonds) to 214 in 2013 (8 for almonds).[7] The reduction of the number of lots rejected in 2013 could be probably due to the new EU limits for aflatoxins in tree nuts.

Freshly harvested almonds are dehulled, and in-shell almonds are dried until the water content is <6%.[8] Dried in-shell almonds can be stored for several months before being used by the food industry.[9] Factors affecting aflatoxin contamination in almonds are shell characteristics (soft or hard), insects, drought stress, and harvest techniques that can spread fungal contamination.[10−14]

Although aflatoxins are highly stable compounds, studies have indicated a reduction during thermal processing.[15] The efficacy of sorting, blanching, and electronic color sorting for reducing aflatoxins in pistachios, peanuts, and almonds has also been reported.[10,13,16] For almonds, the effect of some processing (e.g., peeling, roasting, cooking, and infusion) on aflatoxins has not been tested or limited. The objective of this study was to investigate the fate of aflatoxins during the different processing steps of almonds into pastries, nougat, and syrup (blanching, peeling, roasting, cooking, and water infusion), traditional Italian almond-based food products.[17] The mass balance approach was used to quantitatively determine the distribution of aflatoxins in final and waste fractions of almond processing.

MATERIALS AND METHODS

Safety. Aflatoxins are powerful human carcinogens and should be handled with care. All experiments were carried out in a fume hood using gloves and protective masks. All used laboratory glassware was treated with an aqueous solution of sodium hypochloride (5%) for 2 h and an equal volume of aqueous acetone for 30 min before discarding to minimize health and environmental risks due to aflatoxin contamination.

Production of Aflatoxin-Contaminated Almonds. Due to the unavailability of naturally contaminated almonds, shelled almonds were inoculated with a strain of *Aspergillus flavus* (ITEM 7828) that produces aflatoxins B_1 and B_2, taken from the Agri-Food Toxigenic Fungi Culture Collection of the Institute of Sciences of Food Production (ISPA), Bari, Italy.[18] In particular, 4 kg of shelled almonds (cv. Genco) was purchased in a local market in Conversano (Bari province, Italy) and subjected to a mild sterilization by immersion for 2 min in a solution of 1% sodium hypochlorite with manual agitation. Subsequently, almonds were washed with sterile water and then further surface-disinfected with 70% ethanol for 1 min as described above. Almonds were then transferred, under sterile conditions, in four 5 L sterile flasks, and each flask containing 1 kg of almonds was treated

with 300 mL of a conidial suspension containing 3.3×10^5 conidia/mL of *A. flavus*. The conidial suspension was obtained from *A. flavus* inoculated on plates of potato dextrose agar (PDA) and grown for 4 days in the dark. Fungal conidia were collected from the surface of plates by using a sterile spatula and sterile water. The concentration of conidial suspension was determined with a cell-counting Thoma chamber (HBG Henneberg-Sander GmbH, Gießen, Germany). Appropriate dilutions with sterile water were made to obtain a final concentration of 3.3×10^5 conidia/mL. After inoculation, flasks were manually stirred to uniformly distribute the conidial suspension on almonds' surface and closed with a stopper of raw cotton and a sheet of aluminum foil to avoid excessive water evaporation. The four flasks were incubated for 4 days at 28 °C in the dark. After incubation, almonds were dried at 50 °C for 24 h. Then three aliquots of almonds (20 g each) were randomly collected from each batch, content of flask, and analyzed for their aflatoxin content. The four batches of contaminated almonds were vacuum sealed and stored in the dark until used for processing experiments. In particular, batches 1−3 were used to evaluate the effect of steam blanching and peeling on levels and distribution of aflatoxins and to produce almond pastries and almond syrup. Almond nougat was prepared by using almonds of batches 1 and 3. Almonds of batch 4 were used to test the effect of peeling and roasting on levels and distribution of aflatoxins.

Blanching and Peeling of Almonds. Steam blanching was carried out in a model HD 9140 steamer (Philips Electroincs, Eindhoven, The Netherlands) for 40 min, whereas water blanching was carried out in boiling water for 5 min. Almonds of batches 1−3 and aliquots of batch 4 were submitted to steam blanching. For comparison, aliquots of almonds of batch 4 were submitted to water blanching. After water blanching, the almonds were separated from boiling water and peeled manually to separate peeled almond from skins. Wastewater was cooled, weighed, and stored at −20 °C until analysis. Steam-blanched almonds were also manually peeled. Peeled almonds and skins were separately cooled, freeze-dried, and weighed. Triplicate aliquots of peeled almonds, skins, and wastewater were sampled from each batch and analyzed for their aflatoxin content.

Roasting of Peeled Almonds. The effect of roasting on aflatoxin levels was evaluated at 120 and 150 °C for 30, 60, and 120 min on aliquots of peeled almonds of batch 4. Before roasting, peeled almonds were coarsely chopped with a knife and placed in two thin aluminum trays. For aflatoxin determination 3 × 10 g of chopped almonds was randomly sampled from each tray at 0, 30, 60, and 120 min. After each sampling, chopped almonds were mixed in the tray and put back in the oven. Samples of chopped almonds sampled before, during, and after roasting were analyzed for their aflatoxin content.

Aliquots (2 × 317 g) of peeled almonds from batches 1 and 3 were roasted without chopping at 150 °C for 30 min and used to prepare almond nougat.

Roasting experiments were also performed with blank peeled almonds that were spiked with the four aflatoxins at two levels and roasted for 30, 60, and 120 min at 150 °C. Aliquots of 10 g of peeled almonds (9−10 peeled kernels) were placed in aluminum trays, and each kernel was individually spiked on both sides with a standard solution containing the four aflatoxins. The two spiking levels of aflatoxins were 10 and 50 μg/kg for AFB_1 and AFG_1 and 2.5 and 12.5 μg/kg for AFB_2 and AFG_2. Quadruplicate experiments were performed for a total of 24 treatments.

Production of Almond Nougat, Almond-Based Pastries, and Almond Syrup. *Almond Nougat.* The two aliquots of roasted almonds of batches 1 and 3 were coarsely chopped and thoroughly mixed. From each batch, 40 g was sampled, ground, and analyzed in triplicate for their aflatoxin content. For each batch two types of nougat were produced (sugar nougat and sugar−honey nougat). In particular, 134 g of sugar was melted in a pot heated on a hot-plate to prepare the caramel. While the melted caramel was still hot, chopped roasted almonds (134 g) were added and mixed continuously for 7−10 min until the caramel adhered to the walls of the almonds. The mixture of almond and caramel was then manually shaped into small heaps by using a spoon and cooled at room temperature to reach their typical consistency. Sugar−honey nougat was prepared by melting 94 g of sugar and then adding 40 g of honey to obtain a homogeneous mixture. Then chopped roasted almonds (134 g) were hot mixed and portioned as described above. The four aliquots of nougats were singularly weighed, ground, and analyzed in triplicate for their aflatoxin content.

Almond Pastries. Aliquots of peeled almonds of batches 1−3 were separately ground with a blender and used to prepare almond pastries and almond syrup. The initial content of aflatoxins was determined in 3 × 10 g aliquots of each batch. Pastries were prepared by mixing ground peeled almonds (300 g) of each batch with sugar (180 g) and egg white meringue (from two eggs), and then each mixture was divided in three aliquots that were shaped in small spherical pastries and cooked at 140 °C for 30 min, at 160 °C for 20 min, or at 180 °C for 15 min, respectively. The inner temperatures of pastries (82, 95, and 98 °C, respectively) were measured with a thermometer at the end of each cooking period. After cooking, pastries were cooled, freeze-dried, and ground. Samples of initial ground peeled almonds and cooked pastries were analyzed in triplicate for their aflatoxin content.

Almond Syrup. Aliquots of peeled almonds of batches 1−3 were separately ground as described above and used to prepare almond syrup by using two procedures of water infusion. For the first procedure ground peeled almonds (100 g) were infused in tap water (300 mL) for 5 h at room temperature. After infusion, the soaked ground almonds were filtered under vacuum on a 9 cm diameter no. 4 filter paper (Whatman, Maidstone, UK) on a Büchner funnel fitted on a tailed vacuum flask. Spent ground almonds were collected from the filter paper, freeze-dried, and weighed. The infusion was sugared with 400 g of sugar and boiled until the solutions assumed the typical consistency of a syrup. For the second procedure ground peeled almonds (100 g) were infused in sugared water (300 mL of water + 400 g of sugar) for 5 h at room temperature. Almond syrups were cooled and stored at −20 °C until analysis. Samples of initial ground peeled almonds, syrup, and spent almonds were analyzed in triplicate for their aflatoxin content.

Chemicals and Reagents. Methanol (MeOH), acetonitrile (MeCN), and acetone were purchased from Carlo Erba (Rodano, Italy); 95% ethanol (EtOH) was purchased from Mallinckrodt Baker (Milan, Italy). Ultrapure water was produced with a Milli-Q system (Millipore, Bedford, MA, USA). AflaTest WB wide-bore affinity columns were purchased from Vicam L.P. (Watertown, MA, USA). The mixed aflatoxins standard solution (purity = 99 ± 1%), prepared in acetonitrile and containing 2.00 μg/mL AFB_1, 2.02 μg/mL AFG_1, 0.50 μg/mL AFB_2, and 0.50 μg/mL AFG_2, was purchased from Romer Laboratories Diagnostic (Tulln, Austria). This solution was used to prepare calibration solutions for HPLC-FLD determinations and to carry out recovery experiments.

Determination of AFB_1, AFB_2, AFG_1, and AFG_2. The method of Arranz et al.,[19] originally developed for determination of AFB_1 in medical herbs, was slightly modified and used herein for aflatoxin determination in almonds and derived products. In particular, the HPLC injection volume was 100 μL instead of 500 μL, the HPLC column was a pentafluorophenyl-propyl-bonded silica instead of C18-bonded silica, the HPLC mobile phase was MeCN/H_2O (30:70 v/v) instead of H_2O/MeCN/MeOH (60:20:30 v/v/v), and sample extracts with high aflatoxin content were directly analyzed by HPLC without immunoaffinity cleanup. Briefly, 10 g of dry ground sample was poured in a 250 mL Pyrex screw-capped glass flask, and 100 mL of extraction mixture of acetone/water (85:15 v/v) was added. The extraction was performed by sonication for 30 min. After filtration on fluted no. 4 filter paper (Whatman), 5 mL of filtered extract was diluted with 75 mL of ultrapure water and filtered with a GF/A glass microfiber filter (Whatman). Forty milliliters of filtered diluted extract (equivalent to 0.25 g of matrix) was passed through the immunoaffinity column (IAC) AflaTest (Vicam, Milford, MA) at the flow rate of 1−2 drops/s. Then the column was washed twice with 10 mL of ultrapure water, and aflatoxins were eluted with 1.5 mL (3 × 0.5 mL) of methanol. The three eluates were collected, diluted with ultrapure water up to 5 mL in a volumetric flask, and analyzed by HPLC-FLD. Immunoaffinity sample cleanup was not necessary for the determination of aflatoxins in samples of almonds and derived products obtained from almonds

inoculated with *A. flavus* due to the high levels of aflatoxins. In particular, after extraction with acetone/water (85:15 v/v), an aliquot of the filtered sample extract (0.5 mL) was diluted with 30 mL of MeCN/H_2O (30:70 v/v), stirred, filtered through a 0.45 μm PTFE filter (Sartorius Stedim Italy SpA, Bagno a Ripoli, Firenze, Italy), and injected into the HPLC system. Liquid samples (0.5 mL of almond syrup or wastewater from blanching) were diluted with 7.5 mL of MeCN/H_2O (30:70 v/v), stirred, filtered through a 0.45 μm PTFE filter, and injected into the HPLC system.

Calibration Curves. A mixed aflatoxins stock solution was prepared by diluting 500 μL of commercial standard solution to 10 mL with acetonitrile in a volumetric flask. The four HPLC calibration solutions of combined aflatoxins (AFB_1 + AFB_2 + AFG_1 + AFG_2) were prepared by diluting appropriate volumes of stock solution with MeOH/H_2O (40:60 v/v). The toxin concentration ranges of the four calibration solutions were 0.40−3.64 ng/mL for AFB_1 and AFG_1 and 0.10−0.90 ng/mL for AFB_2 and AFG_2.

HPLC-FLD Equipment and Conditions. The HPLC-FLD analyses were performed with an Agilent 1100 series (Agilent Technologies, Inc., Wilmington, DE, USA), consisting of a binary pump (G1312A), an autosampler (G1313A) with a 100 μL loop, a fluorescence detector (G1321A) fixed at 365 nm λ_{ex} and 435 nm λ_{em}, a thermostatic oven set at 30 °C, and software for Microsoft Windows 2000 (HP ChemStation). The column used was a 150 mm × 4.6 mm i.d., 3 μm, Luna PFP (2) (pentafluorophenyl-propyl) (Phenomenex, Torrance, CA, USA) with a 3 mm i.d., 0.45 μm pore size guard filter (Rheodyne, Cotati, CA, USA). The chromatographic separations were performed in the isocratic condition using a mixture of MeCN/H_2O (30:70 v/v) at flow rate of 0.8 mL/min. A photochemical postcolumn derivatization UVE system (LCTech, Dorfen, Germany) was used to enhance the fluorescence of AFB_1 and AFG_1.

Statistical Analysis. Mean and standard deviation (SD) of data were calculated with a SigmaPlot for Windows version 12.0 statistical software package (Sistat Software, Inc., Chicago, IL, USA). SigmaPlot was also used to perform one-way analysis of variance (ANOVA) followed by Tukey's pairwise multiple-comparison test and a least significant difference (LSD) test at 95% confidence levels ($p = 0.05$) to identify significant differences among groups.

Recovery Experiments. The performances of the analytical method that involves the use of the IAC column were checked on blank samples of shelled almonds, peeled almonds, skins, and almond-based pastries spiked in triplicate at 10.0 μg/kg AFB_1 and 24.9 μg/kg total aflatoxins. Each matrix was spiked in triplicate with 50 μL of commercial standard solution to check recovery and within laboratory repeatability of results. Spiked samples were left overnight in the dark at room temperature to allow solvent evaporation.

The performances of the "dilute and shoot" method were checked on blank samples of sugar nougat, sugar−honey nougat, almond syrup, and caramelized sugar spiked in triplicate at higher aflatoxin levels (394.7 μg/kg AFB_1 and 31.7 μg/kg AFB_2). The spiking solution for these recovery experiments was obtained from extracts of almonds inoculated with a strain of *A. flavus* producing AFB_1 and AFB_2. In particular, 10 g of aflatoxin contaminated almonds was extracted by sonication with 100 mL of acetone/water (85:15 v/v) and filtered with a fluted filter paper. The concentrations of AFB_1 and AFB_2 (AFG_1 and AFG_2 were not detected) in the filtered extract were measured by HPLC-FLD by using calibration curves of authentic standards of AFB_1 and AFB_2.

RESULTS AND DISCUSSION

Method Performance. Preliminary recovery experiments were carried out with the CEN/AOAC method[20] that uses a mixture of MeOH/H_2O (80:20 v/v) as extraction solvent mixture, IAC column cleanup, and HPLC-FLD end determination with post-column derivatization. Acceptable mean recoveries, between 69 and 90%, were obtained for shelled almonds, peeled almonds, and almond-based pastries, whereas low mean recoveries were obtained for almond skins, those being 33% for AFB_1 and 42% for total aflatoxins. It was therefore decided to test the method of Arranz et al.,[19] originally developed for medical herbs, that uses acetone/water (85:15 v/v) as extraction solvent mixture. As shown in Table 1, good mean recoveries, between 89 and 107%, and good within-laboratory repeatability of results, between 1 and 12%, were obtained for all of the matrices used in these studies including almond skins. Similar results were also obtained when the sample extracts in acetone/water (85:15 v/v) were diluted with HPLC mobile phase and directly analyzed by HPLC-FLD (Table 1). No interfering peaks at retention times of aflatoxins were visible in the chromatograms of tested sample extracts, and acceptable values of LOD and LOQ, ranging between 0.2 and 1.2 μg/kg and between 0.4 and 2.5 μg/kg, respectively, were obtained. The values of LOD and LOQ were calculated as signal-to-noise ratios of 3 and 6, respectively. Acetone/water (85:15 v/v) was therefore used as extraction solvent mixture for aflatoxin determination in all samples tested in this study.

Table 1. Results of Recoveries (Mean of Three Replicates) and Within-Laboratory Repeatability of Results (RSD_r) of Aflatoxins for Spiked Matrices

matrix	toxin	spiking level (μg/kg)	recovery (%)	RSD_r (%)
shelled almonds[a]	AFB_1	10.0	95	7
	AFtot	24.9	90	7
peeled almonds[a]	AFB_1	10.0	89	12
	AFtot	24.9	92	7

[a]Sample extracts were purified with immunoaffinity columns before HPLC analysis. [b]Sample extracts were appropriately diluted with MeCN/water (30:70 v/v) before HPLC analysis.

Aflatoxin Determination in Inoculated Almonds. The unavailability of naturally contaminated almonds prompted us to produce contaminated almonds by inoculating almonds with a toxigenic strain of *A. flavus*. Chromatographic analysis of diluted extracts of shelled almonds inoculated with *A. flavus* (ITEM 7828) showed the presence of AFB_1 and AFB_2 and the absence of AFG_1 and AFG_2, a typical toxigenic profile of *A. flavus* species as reported for this strain on the Web site of the ITEM culture collection.[18] Aflatoxin B_1 was identified and measured in batches 1, 2, 3, and 4 of inoculated almonds at mean levels of 8379, 49782, 2012, and 1383 μg/kg, respectively. The mean levels of AFB_2 were 2447, 11904, 993, and 135 μg/kg in batches 1, 2, 3, and 4, respectively. The four batches were kept separated and processed separately to determine the influence of different processing procedures on almonds containing different levels of aflatoxins. When possible, the contaminated almonds were thoroughly ground/blended before processing to homogenize aflatoxins within the sample

and accurately measure the initial level of aflatoxins. It was not possible to grind/blend almonds when the effects of peeling, roasting, and nougat preparation were evaluated because these processes have to be performed with whole almonds (peeling) or at most with chopped almonds (roasted almonds and nougat).

Blanching and Peeling Procedures. The results of the effect of steam blanching on levels and distribution of aflatoxins between skins and peeled almonds are shown in Figure 1. In general, comparable levels of aflatoxins were measured in peeled almonds and skins (Figure 1A). However, from the mass balance of aflatoxins it was calculated that skins contained 10% AFB_1 and 7% AFB_2, whereas 90−93% of aflatoxins remained in peeled almonds. Similar results were obtained for water-blanched almonds with 7% AFB_1 and 6% AFB_2 measured in the skins, 92−93% measured in the peeled almonds, and only 0.9% in the water used for blanching. The very low transfer of aflatoxins from almonds into water during blanching could be explained by the low water solubility of aflatoxins and the high retention capacity of almonds for these mycotoxins. Considering that skin represents 6−7% of the total weight of shelled almond, these results suggest that aflatoxins do not accumulate in the skin and are homogeneously distributed between the kernel and the skin. The process of peeling, therefore, only partially reduces aflatoxins content in the almonds because 92−94% of the toxins remain in the peeled kernels. Although our results were obtained with almonds inoculated with *A. flavus* at laboratory scale, it is presumable that a similar aflatoxin distribution occurs in naturally contaminated almonds. To confirm this hypothesis, three samples of apricot kernels naturally contaminated with AFB_1 and AFB_2 and kindly provided by a local importer were submitted to steam blanching followed by peeling. The results of aflatoxin analyses showed that 94−96% of aflatoxins were found in peeled kernels, whereas 4.8−5.7% of aflatoxins were found in the skins (data not shown). No specific studies are available in the scientific literature on the distribution of aflatoxins among skins, peeled almonds, and water used for blanching.[10,13,14] Taken together, our results show that the passage of aflatoxins in boiling water is negligible and the separation of skins removed only 6−7% of total aflatoxins present in the shelled almonds as well as in naturally contaminated apricot kernels. In addition to the low water solubility of aflatoxins, the high capacity of almonds to retain the toxins may explain the negligible passage of aflatoxins from almonds to boiling water. The high levels of fat (54%) contained in almonds may explain the high capacity of almonds

to retain aflatoxins, which belong to the less polar mycotoxins. In fact, when aflatoxin-contaminated ginger tea, a fat-free matrix, was steeped in boiling water for 5−10 min, 30−40% of aflatoxins passed in water.[21] On the other hand, a mean aflatoxin reduction of 27% was observed during blanching and peeling of roasted peanuts.[22] Sorting and sizing processes are used to separate aflatoxin-contaminated almonds from uncontaminated ones. In particular, up to 97% of total aflatoxins were found in almonds damaged by insects or mold or mechanically injured, whereas 3% of total aflatoxins were found in high-quality almonds that accounted for 84% of the total kernel mass.[13]

Roasting. The results of different roasting conditions on aflatoxin levels in peeled almonds are shown in Table 2. For almonds roasted at 150 °C, mean AFB_1 and AFB_2 reductions ranged between 55 and 84% and between 20 and 69%, respectively, after 30, 60, or 120 min. A lower reduction of aflatoxins was observed at 120 °C. However, these reductions were not statistically significant ($p > 0.05$) when compared to initial levels (Table 2). This was probably due to the inhomogeneous distribution of aflatoxins in chopped almonds that produced high values of standard deviation for replicate analyses that made problematic the statistical comparison of the mean levels measured before and after roasting. No aflatoxin reduction was observed for almonds roasted at 120 °C for 30 min, whereas mean reductions of 54−58% for AFB_1 and 24−30% for AFB_2 were observed after 60−120 min, although these reductions were not statistically significant. Similar mean reductions were observed at 120 °C for 120 min (54% for AFB_1, 24% for AFB_2) and at 150 °C for 30 min (55% for AFB_1, 20% for AFB_2) (Table 2). Taken together, these data suggest that AFB_2 may be more resistant to roasting because a lower reduction, compared to AFB_1, was observed at both 120 and 150 °C. However, the percent reduction may also be a function

dx.doi.org/10.1021/jf5018548 | J. Agric. Food Chem. 2014, 62, 5707−5715

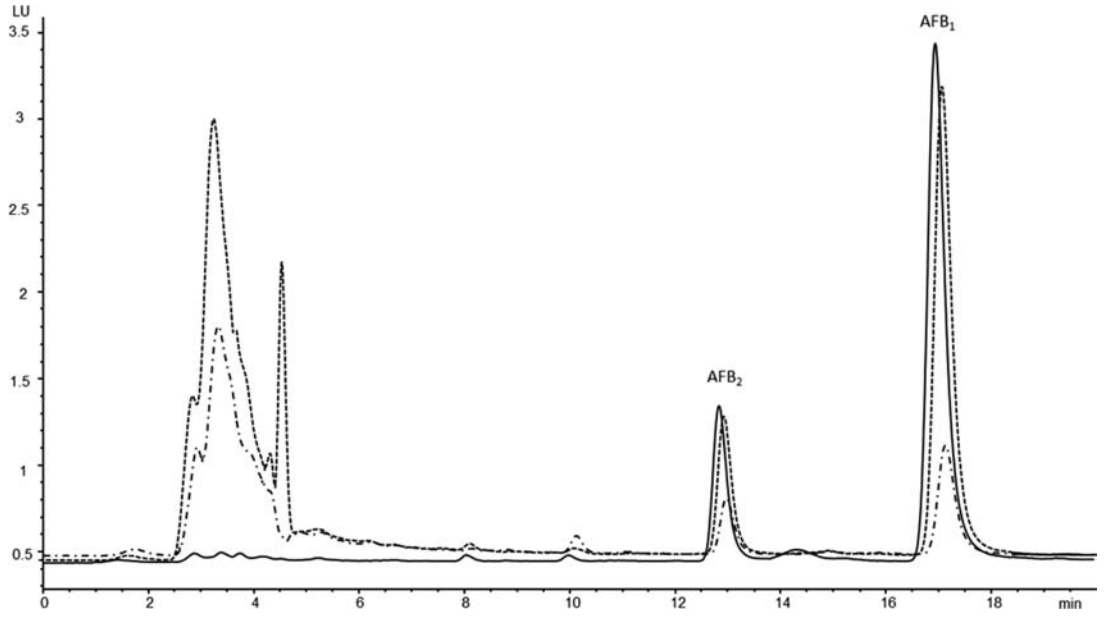

Figure 3. HPLC chromatograms of sugar spiked with AFB_1 (394.7 μg/kg) and AFB_2 (31.7 μg/kg) (- - -), sugar caramelized and then spiked with AFB_1 (394.7 μg/kg) and AFB_2 (31.7 μg/kg) (—), and sugar spiked with AFB_1 (394.7 μg/kg) and AFB_2 (31.7 μg/kg) and then caramelized (- · · -).

of aflatoxin concentration; that is, the higher the concentration, the higher the percent reduction, because the levels of AFB_2 tested in this study were always lower than those of AFB_1 (Tables 2 and 3). Although 150 °C for 120 min produced the highest reduction of aflatoxins, these conditions seem to be impracticable because roasted almonds appeared blackened/burned and most probably lost their organoleptic characteristics, making them inedible. The results of roasting experiments conducted at 150 °C with blank almonds spiked with the four aflatoxins at two levels are shown in Table 3. After 120 min, the AFB_1 reductions were 39 and 48% for the two spiking levels, whereas for AFB_2 the reductions were 25 and 31%, respectively. Lower reductions were observed after 30 min, those being 11 and 23% for AFB_1 and 6 and 14% for AFB_2 for the two spiking levels. As observed in the previous experiments, a higher reduction was observed for AFB_1 as compared to AFB_2, and roasting times >30 min (60−120 min) irreversibly altered the characteristics of almonds (color, smell etc.), making them unfit for consumption.

Although no data are available in the literature on the effect of roasting on aflatoxins in almonds, our results are comparable with those published for other nuts. Yazdanpanah et al.[23] reported that roasting pistachios at 90, 120, and 150 °C for 30, 60, and 120 min reduced the content of aflatoxins at levels ranging between 17 and 95%, and the maximum reduction was obtained at higher temperature and longer roasting time. Mean AFB_1 reductions of 78−80% were reported for spiked and naturally contaminated peanuts roasted at 150 °C for 120 min.[24] A similar reduction of AFB_1 (79%) was observed for peanuts inoculated with *A. flavus* and roasted at 150 °C for 30 min.[25] Roasting naturally contaminated and spiked peanuts at 150 °C for 30 min produced 48−61 and 30−44% AFB_1 reductions, respectively.[26]

No degradation products of aflatoxins have been isolated and chemically characterized from roasted nuts so far, and no attempts were performed in this study. Further studies are necessary to obtain these data that are necessary to establish the possible toxicity or harmlessness of degradation products and to define the roasting conditions that inactivate aflatoxins.[23−26]

Almond Nougat. The results of aflatoxin levels and aflatoxin mass balance in roasted almonds and nougat obtained from contaminated almonds of batches 1 and 3 and cooked with caramelized sugar or caramelized sugar−honey are reported in Figure 2. Clear reductions of AFB_1 and AFB_2 levels were observed in both types of nougat. The mass balance of toxins confirmed these reductions. For batch 1, the average reductions were 54 and 70% for AFB_1 and 83 and 93% for AFB_2 in sugar nougat and sugar−honey nougat, respectively. Similar reductions were observed for batch 3 (Figure 2B). The contact of almonds with hot caramel may have produced the reduction of aflatoxins. To verify this hypothesis, additional experiments were performed in the absence of almonds. In particular, aliquots of sugar were spiked with AFB_1 (394.7 μg/kg) and AFB_2 (31.7 μg/kg) and then caramelized in a pot and successively analyzed for aflatoxins. For comparison, aliquots of sugar were spiked with the same levels of AFB_1 and AFB_2 and successively analyzed for aflatoxins. The second control was constituted of aliquots of caramelized sugar that were spiked with AFB_1 and AFB_2 and successively analyzed for aflatoxins. As shown in Figure 3 the peaks of AFB_1 and AFB_2 in the chromatogram of spiked sugar submitted to caramelization are markedly lower than the corresponding peaks of spiked sugar and spiked caramelized sugar with an average reduction of 82% for both AFB_1 and AFB_2. This reduction is quantitatively equivalent to the reduction observed during nougat preparation; therefore, the caramelization of sugar may be responsible for aflatoxin reduction. However, mixing almonds with sugar during its caramelization should partially explain the big reduction of aflatoxin observed during nougat preparation because only the surface of almonds is affected by sugar caramelization. On the other hand, almonds contain high levels of sucrose (11−22%) followed by raffinose (0.7−2.1%), glucose (0.4−1.5%), and fructose (0.1−0.6%)[27] that should be caramelized during nougat preparation. Caramelization occurs when food surfaces are heated strongly.[28] Thermally induced

caramelization of sugars contained in almonds may therefore contribute to the aflatoxin reduction occurring during nougat preparation. Caramelization of almond sugars may also occur during roasting of almonds and may explain the reduction of aflatoxins observed during almond roasting (Tables 2 and 3). Further investigations are necessary to understand if this reduction is a result of degradation or conjugation of aflatoxins with reactive sugar degradation products such as hydroxymethylfurfural, hydroxyacetylfuran, and hydroxydimethylfuranone that have been reported as degradation products formed during sugar caramelization.[28]

Almond Pastries. The results of aflatoxin levels and aflatoxin mass balance in ground peeled almonds and pastries obtained from contaminated almonds of batches 1−3 and cooked at three different temperatures and times are reported in Figure 4. The grinding of peeled almonds allowed a good aflatoxin homogenization as demonstrated by the low SD values for triplicate analyses performed for each batch. In general, mean levels of AFB_1 and AFB_2 in cooked pastries were lower than those measured in ground peeled almonds. However, these reductions were mainly due to the dilution effect of ingredients (sugar and egg white meringue) used for pastry preparation. The whole results of aflatoxin levels and relevant mass balance did not result in a clear trend related to cooking conditions. In particular, the increase of cooking temperature from 140 to 180 °C did not result in a clear

dx.doi.org/10.1021/jf5018548 | J. Agric. Food Chem. 2014, 62, 5707−5715

reduction of aflatoxins also because the increase of temperatures paralleled the reduction in cooking time. Altogether these results suggest that aflatoxins remained substantially stable during the cooking conditions tested in this study, probably because the maximum inner temperature measured in pastries was 98 °C and sugar caramelization should be excluded. The stability of aflatoxins during cooking and baking has been reported by various studies on different matrices. A substantial stability of aflatoxins during cooking of ground peanuts has been reported.[29] Experiments with microwave (700 W for 6 min) and home cooking (177 °C for 45 min) of spice sauces did not produce a significant decrease of aflatoxin levels in the sauce.[30] Baking of biscuits (10 min at 250 °C) produced only a 17% reduction of AFB_1, whereas a greater reduction (89%) was attributed to the mixing of contaminated wheat flour with leavening agents.[31] A significant reduction of AFB_1 was observed during the kneading in preparing bread, whereas no further reduction of AFB_1 was observed during baking.[32] On the other hand, a 34% reduction of AFB_1 was observed during cooking (20 min at 160 °C) of polished rice.[33] We did not use leavening agents for the preparation of almond pastries because they are not required by the recipe.

Almond Syrup. Almond syrup can be prepared by infusing ground peeled almonds with water or with sugared water. After infusion, spent almonds are separated from the infuse, which is boiled until reaching typical syrup consistency. For the infusion conducted only with water, the sugar is added to the infusion after separation of spent almonds. In Figure 5 are shown the results of aflatoxin levels and aflatoxin mass balances in ground peeled almonds, almond syrup, and spent ground peeled almonds obtained from contaminated almonds of batches 1−3. Surprisingly, the levels of AFB_1 and AFB_2 in spent almonds were significantly higher than those measured in ground peeled almonds. These results were confirmed with the mass balance of aflatoxins. On average, for the three batches, the sum of AFB_1 measured in the syrup and spent almonds was more than twice the amount the AFB_1 measured in the initial ground peeled almonds. Similar results were obtained for AFB_2 (Figure 5B). With regard to the passage of aflatoxins from almonds to the syrup, on average, for the three batches, the percentage of total AFB_1 that passed into the syrup was 18%, whereas for AFB_2 it was 25%. These percentages increased to 39 and 46% for AFB_1 and AFB_2, respectively, when they were calculated with respect to aflatoxin levels measured in the initial ground peeled almonds. These results were obtained by infusing ground peeled almonds with water that was successively sugared after separation from spent almonds. The same results were obtained when ground peeled almonds were infused in sugared water. A similar mean percentage of AFB_1 (14%) was transferred into the liquid phase during mashing of naturally contaminated maize grits and malted barley.[34] This is the first study that has monitored aflatoxins during water infusion of contaminated tree nuts. A possible explanation of this robust increment of aflatoxins during water infusion may be the presence of masked aflatoxins in almonds that were released by enzymatic activity because almonds are rich sources of various glycosidases.[35,36] Several masked mycotoxins have been reported to occur in plant-based foods and feeds, but no masked aflatoxins have been identified to date.[37] Further investigations are necessary to confirm the increase of aflatoxin levels during water infusion of naturally contaminated almonds and to isolate and chemically characterize the masked aflatoxins. In conclusion, the main outcomes of this study are the efficacy of processing such as caramelization in reducing aflatoxin levels in almonds and the increase of aflatoxin content in spent almonds after infusion.

Advances in the Understanding of Dairy and Cheese Flavors: Symposium Introduction

ABSTRACT: A symposium titled "Advances in the Understanding of Dairy and Cheese Flavors" was held in September 2013 at the American Chemical Society's 246th National Meeting in Indianapolis, IN, USA. The symposium, which was sponsored by the Division of Agricultural and Food Chemistry, was to discuss the state of the art in the detection and quantitation of flavor in dairy products. The authors of two of the presentations have been selected to expand on their talks by submitting full papers about their research.

The Division of Agricultural and Food Chemistry held the symposium "Chemistry and Flavors of Dairy Products" at the National Meeting of the American Chemical Society (ACS) in Philadelphia in August 2004. ACS Symposium Series Book 971, edited by co-organizers Keith R. Cadwallader, MaryAnne Drake, and Robert J. McGorrin, was published three years later and contained 14 chapters by the presenters. More progress has been made in this field since then, necessitating a new symposium held in September 2013 in Indianapolis.

Milk and the foods made from it are high in calcium, potassium, and protein, but these nutrients confer no advantage to a consumer who does not purchase the product. One study concluded that taste is a prime consideration in the selection of dairy foods, along with health, convenience, and process-related quality,[1] and a study of consumers revealed the top reason for choosing dairy beverages is sensory appeal, ahead of brand, price, health aspects, and other factors.[2] Therefore, much research has been performed around the world on identifying and improving flavors in dairy products. Reviews on flavor compounds in milk,[3] Cheddar cheese,[4] whey protein,[5] and yogurt[6] have been published since 2010, along with reviews of the relationship between sensory and instrumental analysis of dairy products,[7] aroma perception of dairy products,[8] and lactic acid bacteria in cheese flavor development.[9]

The two papers here deal with specific aspects of flavor in dairy products. Bitter peptides are the subject of the paper by Xiaowei Liu, Deshou Jiang, and Devin Peterson, which deals with whey protein hydrolysate. The authors have identified specific bitter peptide sequences and the proteins from which they originated. This research may result in the removal of bitter flavor from a dairy product.

The second paper, by Ming-Kai Cao, Tonya C. Schoenfuss, and Scott A. Rankin, describes the development of flavor in blue cheese, focusing on methyl ketones. The authors varied homogenization pressure and lipase treatment to determine the methyl ketone concentration and extent of lipolysis. Some two-way interactions were observed, indicating that flavor development of blue cheese flavor is complex.

We thank the Division of Agricultural and Food Chemistry for sponsoring the symposium, and we are grateful to the speakers/authors for their contributions. We also thank James Seiber and his editorial staff at the *Journal of Agricultural and Food Chemistry* for their invitation to publish these papers. We hope that they will provide a resource for furthering the progress in the area of dairy flavor analysis.

Identification of Bitter Peptides in Whey Protein Hydrolysate

Xiaowei Liu, Deshou Jiang, and Devin G. Peterson*

Department of Food Science and Nutrition, 145 FScN Building, University of Minnesota, 1334 Eckles Avenue, St. Paul, Minnesota 55108, United States

ABSTRACT: Bitterness of whey protein hydrolysates (WPH) can negatively affect product quality and limit utilization in food and pharmaceutical applications. Four main bitter peptides were identified in a commercial WPH by means of sensory-guided fractionation techniques that included ultrafiltration and offline two-dimensional reverse phase chromatography. LC-TOF-MS/MS analysis revealed the amino acid sequences of the bitter peptides were YGLF, IPAVF, LLF, and YPFPGPIPN that originated from α-lactalbumin, β-lactoglobulin, serum albumin, and β-casein, respectively. Quantitative LC-MS/MS analysis reported the concentrations of YGLF, IPAVF, LLF, and YPFPGPIPN to be 0.66, 0.58, 1.33, and 2.64 g/kg powder, respectively. Taste recombination analysis of an aqueous model consisting of all four peptides was reported to explain 88% of the bitterness intensity of the 10% WPH solution.

KEYWORDS: *whey protein hydrolysates, bitter, peptides sequence, antihypertensive*

INTRODUCTION

Whey protein is hydrolyzed to generate a product with unique functionality. Protein ingredients with smaller (versus larger) molecular weight peptides have been reported to be more rapidly digested and absorbed[1] to improve the heat stability and solubility in aqueous systems,[2] to be less allergenic than the nonhydrolyzed peptides,[3,4] and also to generate peptides possessing various biological and functional properties.[5−7] Common applications of whey protein hydrolysates (WPH) in the food and healthcare industry include the production of nutritional bars, sports drinks, and hypoallergenic infant formulas, among others.

Hydrolysis of protein can also introduce bitter-tasting attributes that limit the utilization of these ingredients because of their unfavorable influence on product acceptability.[8−11] The degree of hydrolysis on bitterness intensity has been previously investigated in WPH[9] as well as various other flavor defects.[12] In other dairy-based products, the breakdown of protein is well-known to generate bitterness such as cheese,[13−20] casein hydrolysates,[21,22] and other protein-rich ingredients such as soy protein hydrolysates.[23] Peptides have also been isolated to investigate, albeit with limited success, the structure−activity relationships related to bitterness perception.[16,23,24] To our knowledge, no studies have identified the peptides that impart bitterness in commercial WPH. The identification of the bitter peptides provides a more targeted basis to develop bitterness reduction strategies in related products.

The overall goal of this work was to identify the primary bitter peptides in a commercial WPH powder using sensory-directed taste fractionation techniques.

MATERIALS AND METHODS

Chemicals and Materials. A whey protein hydrolysate sample obtained from PGP International was stored at −20 °C. Trifluoroacetic acid, formic acid, and HPLC grade solvents were obtained from Sigma-Aldrich Co. Synthetic peptides YGLF, IPAVF, LLF, and YPFPGPIPN were obtained from EZBiolab Inc.

Ultrafiltration. WPH dissolved at 0.75% (w/v) in water was separated into a low molecular weight fraction (fraction 1) and a high molecular weight fraction (fraction 2) by means of an Amicon 8200 ultrafiltration cell (Millipore, Bedford, MA, USA) using a 3000 Da cutoff membrane (Millipore) at a nitrogen pressure of 30 psi; see Figure 1. Yields were 64 and 36% for fractions 1 and 2 after freeze-drying, respectively.

Preparative High-Performance Liquid Chromatography (Prep-HPLC). The prep-HPLC system consisted of a binary pumping system (Shimadzu, LC-8A), a manual injector (SIL-10vp), a water bath column heater, a variable-wavelength UV−vis detector (Shimadzu, SPD-10A), and a reverse phase C18 column (250 mm × 21.2 mm, pursuit 5, Varian, Palo Alto, CA, USA).

First-Dimensional HPLC Fractionation. Fraction 1 (<3000 Da) was dissolved in water (10%, w/v) and membrane filtered (cellulose acetate membrane syringe filter, 0.45 μm). Aliquots (10 mL) were separated by a preparative C18 column (250 mm × 21.2 mm, pursuit 5, Varian) maintained at 40 °C. Monitoring the effluent at 275 nm, the chromatography was performed using a binary solvent system of water (A) and methanol (B), both containing 0.1% trifluoroacetic acid. The mobile phase consisted of a linear gradient of B in A starting at 10% B in A (0−2 min), increasing to 100% B in A (2−30 min), and then held at 100% for 5 min (30−35 min). The flow rate was 15 mL/min. The effluent was collected into 26 fractions with a fraction collector (Figure 2). The corresponding fractions (termed 1-1−1-26) obtained from several runs were pooled and liberated from solvent (freeze-dried two times). The resulting residues obtained were then dissolved in water (10 mL) and evaluated for bitterness intensity by sensory analysis.

Second-Dimensional HPLC Fractionation. HPLC fractions 1-17, 1-18, and 1-19 were individually dissolved in 10 mL of water, and after membrane filtration (cellulose acetate membrane syringe filter, 0.45um), aliquots (5 mL) were further fractionated by preparative RP HPLC using a C18 column (250 mm × 21.2 mm, pursuit 5, Varian). The mobile phase consisted of a binary solvent system of 10 mM

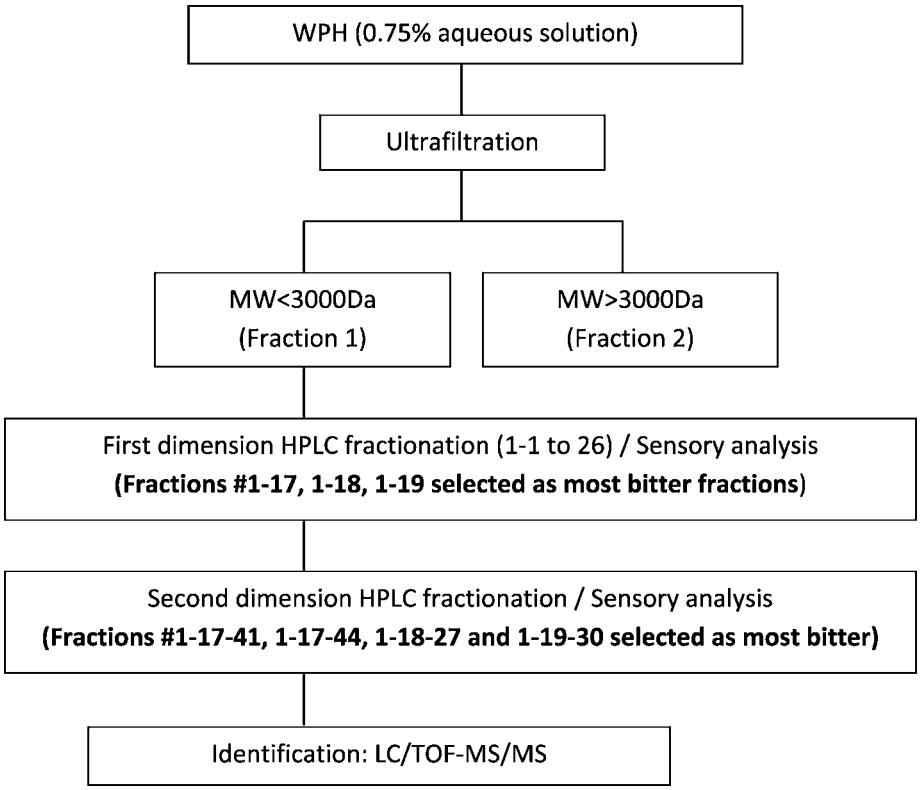

Figure 1. Separation scheme for identification of bitter peptides from WPH.

ammonium acetate, pH 5 (A), and acetonitrile (B). Chromatography was performed using a linear gradient at a flow rate of 15 mL/min monitored at 220 nm. The mobile phase conditions were as follows: for fraction 1-17, initially 15% B in A (0−25 min), increasing to 30% B in A (25−55 min), then held at 30% for 5 min (55−60 min); for fraction 1-18, initially 16% B in A (0−25 min), increasing to 35% B in A (25−60 min), then increasing to 100% B in A (60−61 min), held at 100% for 5 min (61−66 min); for fraction 1-19, initially at 17% B in A (0−25 min), increasing to 40% B in A (25−70 min), then increasing to 100% B in A (70−71 min), held at 100% for 5 min (71−76 min). Total numbers of subfractions collected were for fraction 1-17, 56 (1-17-1 to 1-17-56); for fraction 1-18, 58 (1-18-1 to 1-18-58); and for fraction 1-19, 58 (1-19-1 to 1-19-58). All subfractions were liberated from solvent (freeze-dried two times) and dissolved in water (5 mL) for subsequent sensory analysis.

LC-MS/MS-ESI. Analysis was performed with a Waters Ultra-Performance LC system (Waters ACQUITY UPLC) coupled with a Waters triple-quadrupole mass spectrometer (Waters Quattro Premier XE) equipped with an electrospray ionization (ESI) probe. The UPLC system included the ACQUITY UPLC sample organizer, column manager and heater/cooler, binary solvent manager, sample manager, and a reverse phase C18 column (XTerra RP18 column, 3.5 μm, 100 mm × 2.1 mm). Mass spectrometric ionization conditions were as follows: desolvation temperature, 250 °C; source temperature, 110 °C; capillary voltage, 3 kV. MRM methods setup, ion transitions, cone voltages, and collision energies were optimized via autotune.

LC-MS/Qtof-ESI. Analysis was conducted with an Acquity UPLC system coupled with a Waters Qtof G2 mass spectrometer equipped with an electrospray ionization (ESI) probe, run in positive mode. The UPLC system consisted of a degasser, a binary pumping system, an autosampler, a column heater, and a reverse phase C18 column (XBridge RP18 column, 2.5 μm, 50 mm × 2.1 mm). Mass spectrometric ionization conditions were as follows: desolvation temperature, 400 °C; source temperature, 120 °C; capillary voltage, 3 kV. For scan mode, the range of m/z was 100−2300; for daughter ion analysis, a collision energy ramp was used, ramping from 40 to 120 eV.

Purification of Synthetic Peptides. Purchased synthetic peptides were purified prior to use for sensory analysis. The individual peptides dissolved in water were purified by a preparative C18 column (250 mm × 21.2 mm, pursuit 5, Varian) using a water/methanol gradient at a flow rate of 15 mL/min. Purified peptides were freeze-dried twice prior to use.

Quantification of Bitter Peptides in WPH. Analysis was conducted using an Acquity UPLC system coupled with a Quattro Premier XE mass spectrometer (Waters Co., Milford, MA, USA). An Acquity UPLC 2.1 × 100 mm HSS C18 1.8 μm column with a VanGuard 2.1 × 5 mm HSS C18 1.8 μm precolumn was used for separation. The mass spectrometer was operated in positive ion mode, and the spectra were collected by multiple reaction monitoring (MRM). MRM methods were set up via autotune. For an internal standard, leucine enkephalin ion transition 556 → 136 was monitored. For peptides YGLF, YPFPGPIPN, IPAV,F and LLF, ion transitions 499 → 86, 1001 → 337, 546 → 169, and 392 → 199 were monitored, respectively. Individual synthetic peptides were dissolved in water, and five-point calibration curves were constructed using the peak areas obtained from corresponding ion transitions. Quantitative analysis was performed in triplicate.

Sensory Analysis. A trained sensory panel, ages 22 to 45 years, consisting of two males and five females evaluated the bitterness intensity of the peptide fractions, a commercial WPH sample, and recombination models. All evaluations were conducted with nose clips by a sip and spit method. Samples were evaluated on a 15-point intensity scale, anchored on the left with "none" and on the right with "extreme". Three reference levels were provided to panelists (0.03, 0.08, and 0.15% of caffeine w/w in water), corresponding to bitterness intensity ratings of 2, 5 and 10, respectively.[1] Judge's performance was evaluated by ANOVA. The reconstituted models and fraction samples were evaluated in duplicate. Panelists were instructed to wait 5 min between samples; water and unsalted crackers were used as palate cleansers. Sensory data were analyzed using ANOVA with mean separation to determine differences in bitterness between the commercial WPH sample and the recombinant model (Excel 2010, Microsoft).

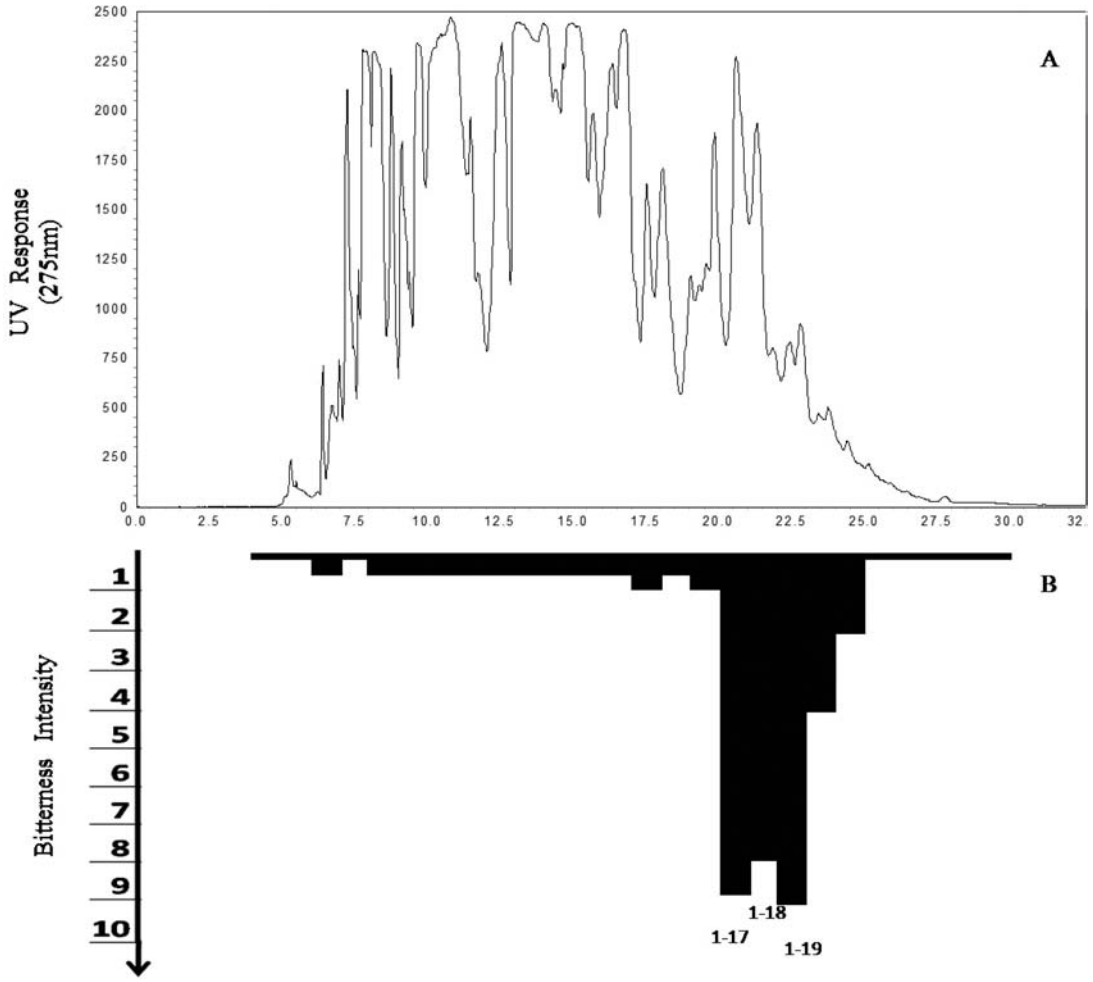

Figure 2. First-dimension HPLC-UV chromatogram (A) and taste intensity chromatogram (B) of low molecular weight fraction. Numbers listed indicate most bitter fractions perceived and selected for further investigation; bitterness scale levels of 2, 5, and 10 were equivalent to 0.05, 0.08, and 0.15% caffeine aqueous solution.

Recombination Sensory Analysis. A bitter taste 10% WPH model was prepared by dissolving four purified peptides, YGLF (0.66 mg), YPFPGPIPN (2.64 mg), IPAVF (0.58 mg), and LLF (1.33 mg), in 100 mL of water. A commercial WPH sample was also prepared for comparison by dissolving 10 g of WPH in 100 mL of water. The bitterness intensity of each individual peptide was also evaluated at the corresponding concentrations of a 10% WPH solution.

RESULTS AND DISCUSSION

The compounds responsible for the bitterness of a 10% w/v WPH solution (see Table 1) were characterized. On the basis of prior literature indicating that the bitter taste of WPH was correlated to lower molecular weight peptides,[12] ultrafiltration was selected as the initial preparative step. Using a 3 kDa cutoff membrane, the dissolved WPH sample was separated into a low molecular weight fraction and a high molecular weight fraction (Figure 1). These two fractions after freezing-drying were redissolved in water at the same concentrations as the original 10% (w/v) WPH solution. The 10% (w/v) WPH sample was also prepared for comparison. Sensory analysis of these three samples revealed that the bitter-taste peptides in WPH sample were located in the low molecular weight fraction, whereas the high molecular weight fraction was tasteless.

The low molecular weight fraction (1) was subsequently further separated by preparative RP-C18 column (mobile phase with TFA at pH 2) to give 26 fractions (Figure 2A), which were freed from solvents (freeze-dried twice), dissolved in 10 mL of bottled water for sensory analysis. Fractions 1-17, 1-18, and 1-19 were rated with the highest bitterness intensity, all of which were rated close to a score of 10, or similar to a 0.15% caffeine solution (Figure 2B).

Because the retention times of ionizable peptides on a RP column are sensitive to the mobile phase pH, second-dimensional HPLC was performed using the same RP column, but with different mobile phase pH. Separation of fractions 1-

17, 1-18, and 1-19 by means of preparative RP C18 (mobile phase with ammonium acetate at pH 5) yielded 56 (1-17-1 to 1-17-56), 58 (1-18-1 to 1-18-58), and 58 (1-19-1 to 1-19-58) subfractions, respectively (Figures 3, 4, and 5). All of the subfractions were freed from solvents (freeze-dried twice) and dissolved in 4 mL of water for sensory analysis. Among these samples, four pronounced bitter subfractions were identified (1-17-41, 1-17-44, 1-18-27, and 1-19-30), the intensities of which were rated as 8, 10, 5, and 8, respectively, and were primarily responsible for the bitterness of the corresponding parent fractions. Each of these four subfractions was subsequently analyzed by LC-MS. One major peptide (based on m/z intensity) was reported in each respective fraction, and the sequence was identified by LC-TOF-MS/MS analysis with variable collision energy. The MS spectrum for one elucidated peptide (IPAVF) is shown in Figure 6; Y and B ions and possible internal ions are labeled. For subfraction 1-19-30, two peptide sequences were possible, ILF or LLF. The retention

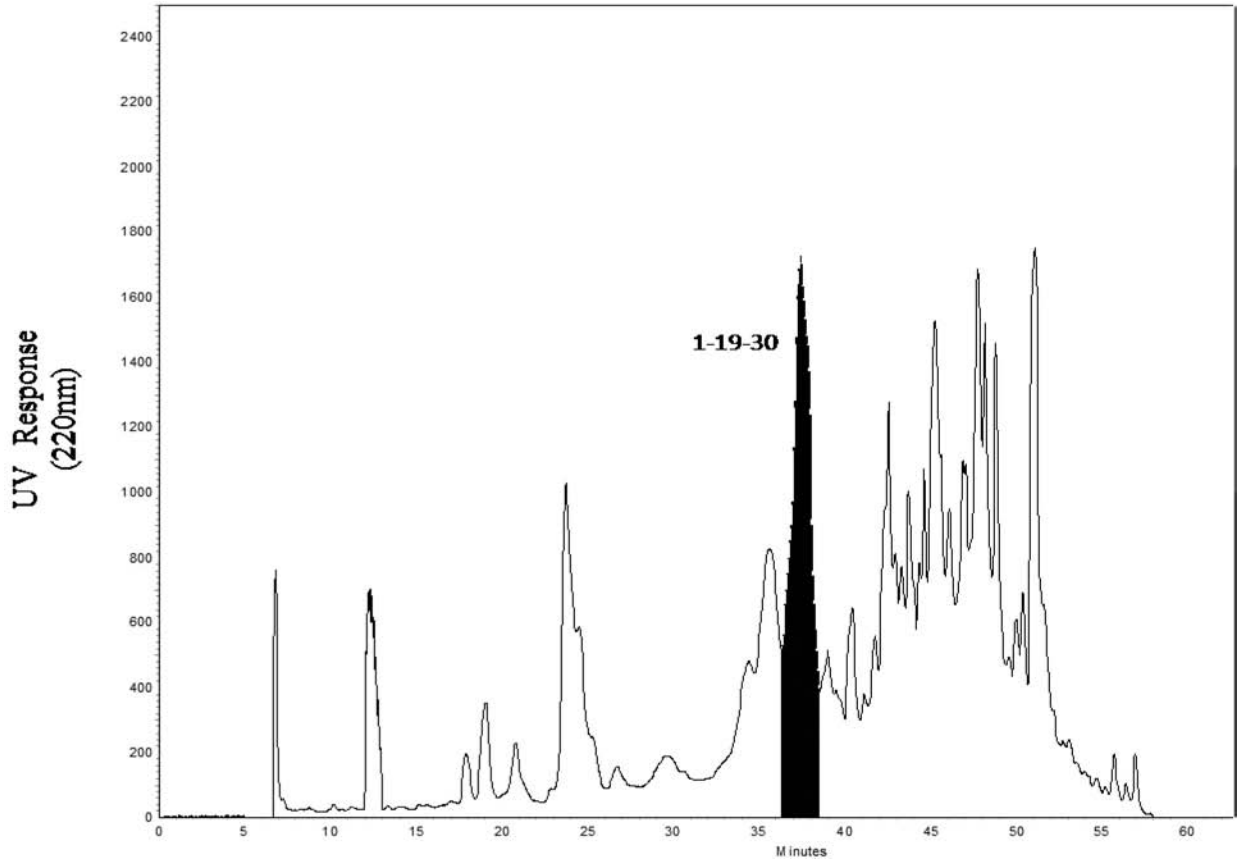

Figure 5. Second-dimension HPLC-UV chromatogram of fraction 1-19. Highlighted fraction is primary bitter fraction.

times of authentic peptides ILF and LLF were compared to the corresponding peptide in the sample, and the sequence LLF was correctly identified.

The concentrations of the bitter peptides YGLF, YPFPGPIPN, IPAVF, and LLF were subsequently determined to be 0.66, 2.64, 0.58, and 1.33 g/kg powder (Table 2). To determine the contribution of these peptides to the overall bitterness of the 10% WPH solution, the bitterness intensity of each peptide, as well as the resultant mixture, was evaluated by sensory analysis. Each peptide was reported to be bitter (Table 1) and, when added as a mixture, was reported to have a bitterness intensity rating of 7.5 compared to 8.5 for the reference (10% WPH solution); sample means were significantly different (p value = 0.02; LSD critical difference = 0.8). The four peptides explained on average 88% of the bitterness intensity reported in the reference WPH sample. Further evaluation of the bitterness potency of each peptide as measured by dividing the perceived bitterness intensity by the concentration of each peptide in the aqueous sample is shown in Table 2 (termed the taste intensity value (TIV)). The two peptides at the lowest concentrations were reported to be the most potent (YGLF and IPAVF) with the highest bitterness response per unit concentration.

On the basis of previously reported bitter peptides, researchers have attempted to elucidate structure−activity relationships. Ney[25] introduced the Q rule, pointing out a relationship existing between the degree of hydrophobicity and if a peptide was bitter (or not). The degree of hydrophobicity (the Q value) was calculated using the equation $(\sum\Delta f)/n$, where $\sum\Delta f$ is the sum of the hydrophobicity values of all the amino acid side chains of a peptide and n is the number of amino acid residues. Peptides (up to 6000 Da) with a Q value > 1400 cal/res were predicted to have a bitter taste. The Q values for the bitter peptides identified in the current study were also calculated on the basis of the free energy (Δf) values of amino acid side chains[26,27] and determined to be 1985, 2107, 2132, and 2497 cal/res for YGLF, YPFPGPIPN, IPAVF, and LLF, respectively. Although bitterness perception of a peptide cannot be solely predicted by the Q value,[16] our data supported the Q rule. The Q rule merely predicts peptides that may be bitter. The limitations of the Q calculation are that it does not account for the amino acid sequence (or geometry) on bitter taste, much less take into account if the compound is perceived (is above the sensory threshold). More recently, others[24] have correlated the bitterness of di- and tripeptides with a bulky hydrophobic amino acid at the C-terminus and a bulky amino acid at the N-terminus, whereas for larger peptides the bulky N-terminal amino acid was specific to basic amino acids. Our finding was in line with C-terminal postulation, but not in line with the N-terminal. Phenylalanine has been considered to be a functional residue of the bitter taste of peptides based on primary structures of three bitter peptides isolated from casein hydrolysates.[28] It has also been suggested that the bitterness of a peptide might be enhanced when its amino or carboxyl groups are blocked by forming peptide bonds.[10,28] This hypothesis was supported by our results. The four bitter peptides identified from the WPH sample all consist of a phenylalanine residue bonded with other amino acids via an amino group or both amino and carboxyl groups.

Whey proteins are typically considered a mixture of β-lactoglobulin, α-lactalbumin, and serum albumin. Sequence alignment of the four peptides identified in this study (see Figure 7) revealed the origin of YGLF in fraction 1-17-41 was

from α-lactalbumin, IPAVF in fraction 1-18-27 was from β-lactoglobulin, and LLF in fraction 1-19-30 was from serum albumin, whereas YPFPGPIPN in fraction 1-17-44 originated from β-casein, which has also been identified as a bitter metabolite in cheese.[16] This indicated the bitterness of our WPH sample partly came from contamination of casein when whey was isolated from cheese.

Interestingly, the four bitter peptides identified in WPH in the current study have been previously reported to have positive health bioactivities. Peptides YGLF,[29,30] YPFPGPIPN,[30−32] and LLF[30,33] have been previously demonstrated to be antihypertensive peptides and lowered blood pressure in a spontaneously hypertensive rat (SHR) model. transformed to IPA during digestion in the human intestinal tract, whereas IPA possessed antihypertensive activity in SHR.[34] This observation is another example of the correlation between bitter taste and potential bioactivity and suggests potential complications of removing bitterness for acceptability while maintaining potential positive health benefits.

ABSTRACT: A specific range of methyl ketones contribute to the distinctive flavor of traditional blue cheeses. These ketones are metabolites of lipid metabolism by *Penicillium* mold added to cheese for this purpose. Two processes, namely, the homogenization of milk fat and the addition of exogenous lipase enzymes, are traditionally applied measures to control the formation of methyl ketones in blue cheese. There exists little scientific validation of the actual effects of these treatments on methyl ketone development. The present study evaluated the effects of milk fat homogenization and lipase treatments on methyl ketone and free fatty acid development using sensory methods and the comparison of selected volatile quantities using gas chromatography. Initial work was conducted using a blue cheese system model; subsequent work was conducted with manufactured blue cheese. In general, there were modest effects of homogenization and lipase treatments on free fatty acid (FFA) and methyl ketone concentrations in blue cheese. Blue cheese treatments involving *Penicillium roqueforti* lipase with homogenized milk yielded higher FFA and methyl ketone levels, for example, a ∼20-fold increase for hexanoic acid and a 3-fold increase in 2-pentanone.

KEYWORDS: *blue cheese, homogenization, lipase, ketone, GC-MS*

INTRODUCTION

Blue cheese is noted for its distinctive moldy flavor and blue-green veined appearance, both of which result from metabolic activities of the mold *Penicillium roqueforti*. Characteristic blue cheese flavor is caused by the presence of a collection of methyl ketones, especially 2-pentanone, 2-heptanone, and 2-nonanone, each derived from fatty acid metabolism[1] via β-oxidative pathways.[2] Current industry practices consider several practices for managing methyl ketone accumulation including the use of raw milk (as a source of native lipoprotein lipase), milk fat homogenization, and exogenous lipase addition. However, there is little scientific underpinning for the practices of homogenization and lipase addition.

Typical homogenization practices in the United States for dairy products involve the mechanical pumping of milk at high pressures through small openings, resulting in a partial disruption of the milk fat globule membrane, a reduction in the average particle size, and an increase in milk fat droplet surface area. As applied to blue cheese manufacture, these physical changes to the milk fat globule are thought to enable increased enzymatic and metabolic activities through improved access to the milk fat triglyceride substrate. Subsequently, lipase addition to homogenized milk, as an industry practice for blue cheese manufacture, is based on the hypothesis that increasing free fatty acid (FFA) concentration is a contributing factor for the conversion of milk fat into corresponding methyl ketone derivatives.

There are few data available to factually conclude that milk fat homogenization in conjunction with lipase addition is a functional control mechanism for the generation of methyl ketones and thus a means of controlling blue cheese flavor. Therefore, the present study examined the effects of milk fat homogenization and the addition of exogenous lipase on the generation of methyl ketones and blue cheese flavor. Lipase and homogenization variables were evaluated in a model system using instrumental measures of FFA and methyl ketone volatiles, followed by a subsequent study with pilot-scale manufactured blue cheeses evaluated for FFA and methyl ketone volatiles and by an evaluation of specific sensory attributes associated with blue cheese flavor and these treatment variables. The hypotheses of this work are that homogenization and lipase treatments of milk are means of controlling methyl ketone production in a blue cheese system through the modification of the milk fat globule and the liberation of FFA substrate, respectively.

MATERIALS AND METHODS

Materials and Reagents. Raw milk for the model system was obtained from Babcock Dairy Plant (Madison, WI, USA) and for the cheese manufacture from Land O'Lakes (Arden Hills, MN, USA). Fresh cheese for use as cheese matrix base was obtained from Roth Kase USA, Ltd. (Monroe, WI, USA). The following were obtained from Sigma-Aldrich (St. Louis, MO, USA): *p*-nitrophenyl butyrate, acetonitrile, porcine pancreatic lipase, butyric, pentanoic, hexanoic, octanoic, and *n*-decanoic acid, 4-methyl-2-pentanone, 2-pentanone, 2-

heptanone, 2-nonanone, 2-undecanone, 2-pentanol, 2-heptanol, 2-nonanol, and Triton X-100. Sodium phosphate monobasic, sodium phosphate, and sulfuric acid were from Fisher Scientific, Fair Lawn, NJ, USA. Sodium chloride was from Acros, Fair Lawn, NJ, USA. Lipase (EC 3.1.1.34) enzyme assay was obtained from Sigma-Aldrich. The following materials were obtained, as indicated: calf pregastric esterase

dx.doi.org/10.1021/jf4048786 | J. Agric. Food Chem. 2014, 62, 5726−5733

(Dairy Connection, Madison, WI, USA), *P. roqueforti* lipase (Biocatalysts, Wales, UK), porcine pancreatic lipase (Sigma, St. Louis, MO, USA), *P. roqueforti* spores for the model system (Danisco, Copenhagen, Denmark), *P. roqueforti* for the cheese manufacture (PR3, Chr. Hansen Inc., Milwaukee, WI, USA), and liquid chymosin (CHY-MAX 73863, Chr. Hansen Inc.). Direct vat set (DVS) mixed culture of *Lactobacillus helveticus* was obtained from Danisco (Madison, WI, USA) and FD-DVS Flora Danica (*Lactococcus lactis* subsp. *cremoris*, *Leuconostoc*, *Lactococcus lactis* subsp. *lactis*, *Lactococcus lactis* subsp. *lactis* biovar *diacetylactis*) from Chr. Hansen Inc. Antimycotic solution of natamycin (DelvoCid XT 1) was from DSM Food Specialties, Parsippany, NJ, USA.

Gas Chromatography (GC-MS). The gas chromatograph was an Agilent 6890N (Agilent Technologies, Inc., Palo Alto, CA, USA) with the following capillary column: 5% diphenyl−95% dimethyl polysiloxane fused silica capillary column (Rtx-5MS, 30 m, 0.25 mm i.d., 0.5 μm film thickness) (Restek Corp., Bellefonte, PA, USA). The carrier gas was helium, 99.999%. The mass selective detector used was an Agilent 5973 MS under the following conditions: mode, electron ionization, 70 eV; m/z scan range, 33−300 amu collected at 4.44 scans/s; ion source temperature, 230 °C. Chemstation software (rev, D.02.00 SP1, Agilent Technologies, Inc.) was used for signal analysis; compound identification was considered positive by matching unknown mass spectra to those in a published database (National Institute of Standards and Technology (NIST) version 1.7, Gaithersburg, MD, USA) and by common retention times of authentic standards.

Lipase Standardization. A solution of *p*-nitrophenyl butyrate in acetonitrile was used as the standardizing substrate. The three selected lipase enzyme treatments (calf pregastric esterase, *P. roqueforti* lipase, and porcine pancreatic lipase) were each separately dissolved in 100 mM sodium phosphate buffer with 150 mM sodium chloride and 0.5 mL/100 mL Triton X-100, and the pH was adjusted to 7.2 at 37 °C. Solution absorption was observed by a continuously temperature-controlled spectrophotometer (SpectraMax Plus384, Molecular Devices Corp, Sunnyvale, CA, USA) under the following conditions: 37 °C; light wavelength, 400 nm; 1 cm cuvette. One unit of activity produces 1.0 nmol (10^{-9} mol) of *p*-nitrophenol per minute at pH 7.2 and 37 °C.[3,4] Lipase activity was calculated according to EC 3.1.1.34 enzyme assay (Sigma-Aldrich) as follows:

$$\text{units/mL enzyme} = \frac{\left(\frac{\Delta A400}{\text{min}}\text{test} - \frac{\Delta A400}{\text{min}}\text{blank}\right)(1.01)(\text{df})}{(0.0148)(0.1)}$$

ΔA400/min is the maximum linear rate of absorption change per minute for both the test and blank; 1.01 is the volume (in milliliters) of the assay; df is the dilution factor; 0.0148 is the micromolar extinction coefficient of 4-nitrophenol at 400 nm; and 0.1 is the volume (in milliliters) of enzyme solution used.

Blue Cheese Model System Experimental Details. *Homogenization and Milk Fat Globule Size Measurement.* Homogenization was applied to pasteurized whole milk (3.5 g/100 g fat content) by a two-stage, high-pressure homogenizer (Gaulin K6-8TBS). As is typical in industry practices, the second stage of the homogenizer was fixed at 3.5 MPA, and the first stage was set at either 3.5 or 10.5 MPa. Unhomogenized milk was the third treatment; thus, there were three homogenization treatments: unhomogenized, 7 MPa total (3.5 MPa first stage, 3.5 MPa second stage), and 14 MPa total (10.5 MPa first stage, 3.5 MPa second stage). Milk samples were collected after pressure treatments, then pasteurized at 72 °C for 20 s, and stored at 4 °C. The fat globule size distributions in milk of different pressure treatments were measured by laser light scattering (Mastersizer 2000, Malvern, UK) with an absorption coefficient of 0.0001. Milk samples were preheated to 40 °C, and then 100 μL of each sample was diluted with 100 mL of distilled water to reach 12−13% laser obscuration (optimal conditions for particle size measurement). All analyses were performed in triplicate. Density was considered as 0.998 g/cm^3 (aqueous samples with dilute dispersed milk fat). Parameters reported by the system software included volume diameter ($D(4,3)$) and average surface area ($D(3,2)$). Refractive indices used were 1.456 for the milk fat globule and 1.33 for the aqueous dispersion medium with a ratio of 1.095.

FFA Profiles of Blue Cheese Model System Milks. Milk samples (100.0 g) were transferred into 150 mL flasks and heated to 40 °C. Each flask was treated with 2000 activity units of enzyme/100 g milk and then held for 3 h with continuous stirring.[5−7] FFA profiles were determined on the basis of previous methods as follows.[8,9] Samples of 10.00 g of lipolyzed milk with 1 mM pentanoic acid (internal standard) were placed into 20 mL septum-sealed headspace vials (Supelco, Bellefonte, PA, USA), and then the pH was adjusted to 1.5−1.6 with sulfuric acid (0.01 N). SPME analysis was conducted wherein the SPME fiber (85 μm carboxen/polydimethylsiloxane, Supelco) was exposed to the headspace for 30 min at 70 °C without agitation. Analysis of FFAs was carried out by GC-MS as described above with a flow rate of 1.5 mL/min and the following temperature program: from 40 to 250 °C, at 5 °C/min, initial holding 2 min, and equilibration time 0.50 min. MS parameters were as described above.

Blue Cheese Model System and Ketone Profiles. All glassware and tubing were heat sterilized in an autoclave (121 °C for 20 min). Sodium chloride (3.0 g) and 0.0010 g of *P. roqueforti* spores were added to yield a total of 100.00 g of lipolyzed milk sample while 50 mL/min of air was injected into the flask by a peristaltic pump. The milks were agitated by means of a magnetic stir bar. The reaction was conducted in an incubator at 20 °C for 24 h.

The method for volatile profiles was adapted from various references[10−12] and included the following parameters. A 1.00 g sample was placed into an 8 mL glass GC vial with 1.00 g of 4-methyl-2-pentanone water solution (50 μg/g final concentration) added as an internal standard. The SPME fiber (85 μm carboxen/polydimethylsiloxane, Supelco) was exposed to headspace for 30 min at 45 °C. Analysis of methyl ketones was carried out by GC-MS as described, with the following temperature program: injection temperature, 250 °C; 70 °C for 2 min; increased to 140 °C at 6 °C/min; 140 °C for 2 min; increased to 220 °C at 6 °C/min; and held at 220 °C for 5 min. MS parameters were as described above. The entire experiment was replicated three times.

Blue Cheese Experimental Details. *Cheese Manufacture (Figure 1).* Raw milk (544 kg) was centrifuged using a cream separator (Westfalia, Naperville, IL, USA); raw cream was standardized to 14 g/100 g fat using HTST pasteurized skim milk (73 °C for 15 s)[13] (APV, Goldsboro, NC, USA). Standardized cream was split into two parts, unhomogenized and two-stage homogenization (Gaulin, Delvan, WI, USA), at 13.8 MPa (10.3 MPa first stage, 3.44 MPa second stage). Each treatment was subsequently pasteurized and then blended with 1/3 pasteurized skim milk (final mik fat of 9.5 g/100 g) in an open cheese vat with mechanical stirring (Tetra Pak Cheese and Power System Inc., Fond du Lac, WI, USA). Direct vat set (DVS) mixed cultures of *Lactobacillus helveticus* (1.29 g/100 kg) and FD-DVS Flora Danica (*Lactococcus lactis* subsp. *cremoris*, *Leuconostoc*, *Lactococcus lactis* subsp. *lactis*, *Lactococcus lactis* subsp. *lactis* biovar *diacetylactis*) (2.02 g/100 g) were added to the standardized milks at 31 °C (DVS culture was incubated in pasteurized milk at 22.2 °C for 16 h before use). The following steps included the addition of *P. roqueforti* mold spores (1 g/100 kg milk) and calcium chloride (20 g/100 L milk) and mechanical stirring for 1 h. After renneting with liquid chymosin (10 mL/100 L), the curd was cut using 9.5 mm wire knives and agitated for 30 min at 31 °C, and the whey was drained at 20% of original volume, 50% after 30 min, and curd level after an additional hour of agitation. At a final pH of 6.05, 7.3 kg of cheese curds and 7.3 kg of whey were distributed into five tubs[14] followed by the addition of 392 g of salt blended with 0.61 g of each standardized lipase solutions. The whey−curd mixture was continuously stirred for 10 min and transferred into open-ended, perforated cheese hoops (diameter = 19.7 cm, height = 20.32 cm) on a stainless steel drain table and allowed to set and drain for 1 h before being inverted. Hoops were inverted every hour for the next 4 h and once again at 12 h post hooping. Wheels (still in hoops) drained overnight at room temperature on a drain table. Each cheese wheel was surface salted after removal from hoops on day 1 and subsequently on days 2 and 4 postmanufacture at 2, 1, and 0.5 g/100 g of initial cheese wheel weight,

respectively. During salting, cheese wheels were stored at 14 °C and 90% relative humidity. Cheese wheels were dipped into a 10 g/100 mL natamycin solution (DelvoCid) for mold control and pierced with 120 holes on each side using a single-wheel pneumatic punch with 40 needles. Cheeses were wrapped loosely in plastic bags and incubated at 14 °C and 90−95% relative humidity over 2 weeks for mold sporulation and then aged at 5 °C for 4 months.[15] Aged blue cheeses were vacuum-packed and stored at −20 °C for analysis.

Blue Cheese Volatile Analysis. Frozen blue cheese samples were thawed at 4 °C overnight. A composite sample of 10 g of cheese was placed in a 40 mL headspace vial with 10 mL of monosodium phosphate (25g/100 mL) containing 200 μg/g of 4-methyl-2-pentanone as internal standard and a magnetic stir bar.[10,16,17] Each vial was capped with a Teflon-lined septum. A manual SPME fiber holder unit with a carboxen polydimethylsiloxane fiber (Supelco) was exposed to the headspace at 65 °C for 30 min with continuous stirring at 600 rpm.[10,16] All analyses were performed in triplicate.

Gas Chromatography−Mass Spectrometry. Analysis of volatile compounds was carried out by GC-MS, as described above, with a 1.2 mL/min flow rate and the following temperature program: from 40 to 250 °C, at 5 °C/min, initial holding, 1.00 min; and equilibration time, 0.50 min.

Quantification of Compounds in Blue Cheese with Internal Standards by GC-MS-SPME. A multiple-point internal standard method was used to quantify selected volatile compounds in blue cheese samples.[18,19] Response factors of each analyte were tested using fresh cheese as cheese matrix base. Volatile profiles of fresh cheese were analyzed by GC-MS-SPME and showed no significant levels of FFAs or methyl ketones. Each analysis contained internal standard (4-methyl-2-pentanone) at 200 μg/g in 10 mL of monosodium phosphate (25 g/100 mL), 10.00 g fresh cheese, and each analyte of interest covering five-point concentration ranges as follows: butyric acid (5−8000 μg/g), hexanoic acid (20−2000 μg/g), octanoic acid (30−2000 μg/g), *n*-decanoic acid (100−700 μg/g), 2-pentanone (1−200 μg/g), 2-heptanone (2−400 μg/g), and 2-nonanone (1−400 μg/g). All analyses were performed in triplicate.

Descriptive Sensory Analysis (DSA) of Blue Cheese Samples. Fourteen panelists were trained through DSA for blue cheese. Flavor attributes included waxy, soapy, methyl ketone, chemical/medicinal, fruity, musty/cave, mushroom, salt, sweet, acid, and bitter (Table 1).[20−22] A linear scale from 0 (absent) to 15 (extreme) was used to measure flavor intensity. Blue cheese samples were stored at −20 °C to inhibit continued activity of *P. roqueforti* and, before analysis, defrosted overnight at 4 °C. Descriptive analysis of 0.5 cm size crumbles at 10 °C was done during eight separate days to prevent panel fatigue with three samples tested per day. Panelists were given 10 min to test each sample and 5 min between each sample. Panelists evaluated all cheeses within isolated, individual tasting booths with approximately 860 lx of white lighting.

Table 1. Terms and Definitions Used To Describe the Flavor of Blue Cheese Using Descriptive Analysis Method[a]

term	definition	standard (reference used neat or as noted in water)
rancid	aroma associated with milk fat lipolysis	butyric acid (500 mg/kg)
waxy	sweet aromatic associated with wax paper	capric acid
soapy	detergent-like taste and smell	lauric acid
methyl ketone	aroma associated with blue-vein cheeses	2-heptanone (40 mg/kg)
medicinal	aroma associated with unclean notes	*p*-cresol (100 mg/kg)
fruity	taste and aromatic blend of different fruits	ethyl hexanoate (10 mg/kg)
musty	aroma of a damp room, associated with closed air spaces	2,4,6-trimethoxy-benzaldehyde
mushroom	taste and aromatics associated with raw mushrooms	3-octan-3-ol (50 mg/kg)
basic tastes	salty, sweet, acid, bitter	salt, sugar, citric acid, caffeine (500 mg/kg)

[a]Adapted from Drake.[30]

Statistical Analyses. Statistical analysis was done using statistical software (JMP Pro 10, SAS Institute Inc., Cary, NC, USA). The main effects of exogenous lipase, homogenization pressure, and their interaction on each volatile compound's response in blue cheese samples were analyzed by least-squares model with an α of <0.05. The effects of lipase, pressure, and panelist on each flavor attribute were similarly evaluated with ANOVA at the same error rate.

RESULTS AND DISCUSSION

Homogenization Effects on Milk Fat Globule Size and Surface Area (Model System). The reported changes in milk fat globule size profiles are intended to demonstrate the relative degree of homogenization treatment variables achieved. Most noticeably, average diameters decreased and surface areas increased as homogenization pressures increased (Table 2), typical of commercial-scale homogenization processes.

Table 2. Mean (Standard Deviation) of Diameters and Surface Areas of Milk Fat Globules after Homogenization at Different Pressures[a]

first/second stage (MPa)	unhomogenized	3.5/3.5	10.5/3.5
diameter (μm)	3.62 (0.03)a	1.34 (0.04)b	0.37 (0.01)c
surface area (m^2/g)	1.78 (0.03)a	11.57 (1.20)b	25.10 (0.81)c

[a]Means within a row with different letters are significantly different at the α <0.05 level.

FFA Profiles of Homogenized, Lipase-Treated Milk (Model System). Overall triglyceride hydrolysis activities of calf pregastric, porcine pancreatic, and *P. roqueforti* were determined to be 2.12, 250, and 83.77 U/mg, respectively. Ten *n*-FFAs were positively identified in most treatments including butanoic (C4), hexanoic (C6), heptanoic (C7), octanoic (C8), nonanoic (C9), decanoic (C10), undecanoic (C11), dodecanoic (C12), tetradecanoic (C14), and hexadecanoic (C16) acids; C4, C6, C8, and C10 FFAs were selected for quantification on the basis of their potential to contribute to methyl ketones of significance to blue cheese aroma. The variation in FFA profiles and concentrations is expected to subsequently result in a difference in methyl ketone generation based on the conversion of FFA into methyl ketones. Overall, the main effects of homogenization treatment, lipase addition, and the two-way homogenization × lipase interactions significantly affected concentrations of the FFAs quantified (*n*-C4 to C10, even numbered). The mean concentrations and standard deviations of these FFAs in lipolyzed milk with different pressure treatments are shown in Table 3. The variation of the mean calculations was high for many treatments and probably results from a number of factors including slight differences in lipase activities and unexplained errors in the analytical steps. In general, significant increases in each [FFA] were observed by comparing the nonhomogenized milks to the 7 MPa homogenization treatment. However, that response was not further increased at the 14 MPa level and, in fact, the levels of some FFAs were decreased compared to the 7 MPa treatment.

Table 3. Average (Micrograms per Gram, Standard Deviations in Parentheses) FFA Concentrations as a Function of Homogenization and Lipase Treatments in Blue Cheese Model System[a]

lipase	pressure (total MPa)	butanoic	hexanoic	octanoic	decanoic

Although statistically significant overall main and interaction effects were observed, the vast majority of treatment level combinations yielded only minor actual concentration changes with most treatment FFA concentrations falling in the 500−1300 μg/g range. The lowest levels of FFA were for the *P. roqueforti* × 0 MPa homogenization treatment at C4. Interestingly, the highest levels of lipolysis were for the *P. roqueforti* × 14 MPa treatments for C10, demonstrating that for this enzyme, homogenization strongly influences the hypothesized effect in aiding in the liberation of FFA. For octanoic acid (precursor for a key blue cheese flavor compound, 2-heptanone), neither calf nor porcine lipase demonstrated strong effects on changing the [FFA] as a function of homogenization. Alternatively, *P. roqueforti* lipase treated milk showed ≈10-fold increases in essentially all FFA concentrations when homogenization was applied at the 7 MPa level.

Calf pregastric esterase[23] and porcine pancreatic lipase[24] have shown preference for FFAs on sn-1 and sn-3 positions where most short-chain FFAs are located. *P. roqueforti* lipase has a preference similar to that of calf pregastric esterase and has been shown to display lower activity toward triglycerides of larger molecular weight.[24]

Ketone Generation in Blue Cheese Model System. There were eight ketones positively identified including 2-pentanone, 2-hexanone, 2-heptanone, 2-octanone, 8-nonen-2-one, 2-nonanone, 2-decanone, and 2-undecanone; 2-pentanone, 2-heptanone, and 2-nonanone were selected for quantitation on the basis of their known high impact on actual blue cheese flavor. The compound 8-nonen-2-one was found in every sample; this latter compound is thought to contribute to baked and mushroom-like aromas.[25] The formation of 8-nonen-2-one is associated with β-oxidation, but primarily results from the oxidation of specific unsaturated fatty acids, namely, linoleic or linolenic acid. Observations of ketone generation suggest loose patterns of correlation with the general patterns of FFA profiles, suggesting that the mechanism of ketone generation is only moderately influenced by FFA substrate availability rather than intact triglyceride. For example, hexanoic acid levels were not significantly different for the calf lipase, but increased for the *P. roqueforti* and porcine enzymes over the course of increasing homogenization. Subsequently, the hexanoic acid-derived methyl ketone, 2-pentanone, displayed a similar pattern of evolution across these enzyme/homogenization treatments. These results by no means denote stoichiometry or mass balance for such reactions, but do demonstrate that there is some correlation between the hypothesized substrate (FFA) and the generation of the corresponding methyl ketone. There is some evidence that *P. roqueforti* metabolism is thwarted by high FFA levels[26−28] and, as a result, the actual preferred conditions for metabolism may be more favorable under lower levels of lipolysis.[29]

The effects of homogenization and lipase treatment (and interactions) were significant but not for every methyl ketone. For instance, changes in homogenization pressure had little effect on 2-pentanone generation with the calf lipase treatment, but were positively correlated with increasing homogenization pressures (and increasing [FFA]) for *P. roqueforti* lipase treated samples (Table 4). In general, concentrations of methyl ketones were higher in samples made with homogenized milk compared to the unhomogenized samples. The 14 MPA homogenization treatment resulted in a numerical if not statistically significant reduction in methyl ketone concentration across most treatments, reflecting a similar trend in [FFA] values as noted above.

Identification of Volatile Compounds in Blue Cheese. Although entire volatile profiles were complex, efforts were

Table 5. Average and Total (Micrograms per Gram, Standard Deviations in Parentheses) FFA Concentrations as a Function of Homogenization and Lipase Treatments in Blue Cheese[a]

[a]Means within a column with different letters are significantly different at the α <0.05 level.

focused on specific volatile compounds wherein the following compounds were positively identified, including six *n*-FFA's (butanoic, hexanoic, octanoic, decanoic, dodecanoic, and tetradecanoic), acetic acid, five methyl ketones (acetone, 2-pentanone, 2-heptanone, 2-nonanone, and 2-undecanone), 8-nonen-2-one, and three secondary alcohols (2-pentanol, 2-heptanol, and 2-nonanol). These latter secondary alcohols are regarded as reduction products of the corresponding methyl ketones.

FFA Levels in Blue Cheese. In general, homogenization promoted lipolysis for each enzyme treatment across each fatty acid, but homogenization had little effect on the calf lipase treatment (Table 5). Interestingly, there was little effect on the concentrations of octanoic from either lipase or homogenization with the exception of the homogenized *P. roqueforti* lipase treated samples that had about a 2-fold increase over the other treatments. The treatment without added lipase (none) displayed a strong, positive effect of homogenization wherein [FFA] values increased by >10-fold (except octanoic). This lipolytic activity would most likely result from the innate lipolytic capabilities during *P. roqueforti* metabolism during ripening. Added *P. roqueforti* lipase also strongly responded to homogenization treatment of the milk, displaying >10-fold increases in [FFA]. Although not as dramatic, porcine lipase displayed modest activity in the cheese system toward FFA liberation, primarily for butyric acid. Compared to the model system work, there are some noted correlations, primarily relating to the *P. roqueforti* lipase treatment, wherein little lipolytic activity is displayed by this enzyme when homogenization is not employed.

Resulting Methyl Ketones in Blue Cheese. Although the premise is that an ability to increase the pool of FFA substrate (as affected by lipase and homogenization treatments) influences the resulting mass conversion into methyl ketone metabolites, no such cause and effect was readily noted (Table 6). Overall, the eventual ratio of FFA substrate and methyl ketone derivative was extremely low; for example, overall hexanoic acid concentrations ranged from 54 to 2100 μg/g, and the corresponding methyl ketone derivative, 2-pentanone, ranged from "not detected" to 49 μg/g. The *P. roqueforti* lipase treatment again showed the only response in harmony with the hypothesis wherein the presence of the enzyme and the application of homogenization generated significantly higher levels of methyl ketone as compared to the "none" treatment and the unhomogenized samples.

Descriptive Sensory Analysis. Means and standard deviations of sensory data are shown in Table 7. The sensory terms were primarily selected on the basis of the potential influence of the experimental variables on these terms. Only the terms *soapy* and *methyl ketone* displayed any form of significant treatment effects. Most notably, and consistent with the instrumental assays above, is the ability of the *P. roqueforti* lipase enzyme with homogenization treatment to increase the intensity of *soapy* and *methyl ketone*, wherein these terms were taught to the panel as resulting from the FFA lauric acid and 2-heptanone (Table 1), respectively. No changes in other sensory attributes were detected including *rancid* and *waxy*, despite changes in the concentrations of the compounds that contribute to these attributes. In general, the blue cheese samples presented an extremely high overall flavor intensity for sensory panelists. As such, fatigue and other panelist errors may have played a role in the outcomes we observed. However, to change the sensory response toward these somewhat related, lipid-derived compounds, the change in actual compound concentration must be quite large, especially in such a highly flavored cheese. For instance, a nearly 10-fold increase in concentration of butyric acid was found in milks classified as "distinctly rancid" compared to freshly pasteurized milks.

General Considerations. Blue cheese volatile chemistry results from a complex system of reactions involving milk quality, lipase activity, mold metabolism, aging parameters, oxygen availability/redox potential, and so forth. There is a dogma associated with the manufacture of blue cheese that suggests both homogenization and exogenous lipase addition influence characteristic blue cheese aroma through the mechanisms noted in the aforementioned hypothesis. Research designed to examine this hypothesis may range from the very basic to the very applied in scope; this work focused on the applied approach in design, but illustrates the need for a more basic understanding of the chemistry at hand. First, there is

some merit to the use of a model system as utilized in this work as a means of improved experimental control and expense. Such a system may be applied in future work to better understand the time course of methyl ketone generation and the relative roles of FFA versus triglyceride substrate for methyl ketone generation. Additionally, it is similarly critical to understand the conditions wherein methyl ketones are further reduced to their corresponding secondary alcohols (and resulting change of aroma), an element of this system not addressed by this work. Additionally, there is a further need to investigate the role of indogenous or native *P. roqueforti* lipase activity resulting from the metabolic activities of this mold during ripening or aging as well as the potential for native bovine lipoprotein lipase from raw milk to influence methyl ketone development.

However, albeit applied in nature, this work demonstrates the effectiveness of exogenous *P. roqueforti* lipase as an agent in ultimately increasing methyl ketones in cheese as well as the dependence of *P. roqueforti* lipase on homogenization of milk fat; other lipases were very much less effective toward this end, emphasizing the need for careful selection of lipase treatments.

ABSTRACT: Food allergies are induced by proteins belonging to a limited number of families. Unfortunately, relationships between protein structure and capacity to induce the immune response have not been completely clarified yet, which precludes possible improvements in the diagnosis, prevention, and therapy of allergies. Plant chitinases constitute a good example of food allergenic proteins for which structural analysis of allergenicity has only been carried out partially. In plants, there are at least five structural classes of chitinases plus a number of chitinase-related polypeptides. Their allergenicity has been mostly investigated for chitinases of class I, due to both their higher prevalence among plant chitinases and by the high structural similarity between their substrate-binding domain and hevein, a well-known allergen present in the latex of rubber trees. Even if allergenic molecules have been identified for at least three other classes of plant chitinases, the involvement of the different structural motifs in the allergenicity of molecules has been disregarded so far. In this review, we provide a structurally based catalog of plant chitinases investigated for allergenicity, which could be a useful base for further studies aimed at better clarifying the structure−allergenicity relationships for this protein family.

KEYWORDS: *plant food, food allergy, chitinase, allergen*

INTRODUCTION

Food allergies are recognized as a major health concern, affecting about 4% of the total world population, and reaching peaks of 8% in infants.[1] In recent years, their occurrence in Westernized countries has shown a steady increasing trend, and currently no viable treatments are available for people with food allergies.[2] Food allergies are determined by a limited number of proteins, which, recognized as allergens by specific IgE, cause the release of histamine from mastocytes and basophils with resulting symptoms of variable severity, from mild pruritis to life-threatening anaphylaxis.

Among the more than 13,000 protein families listed in the Pfam database (http://pfam.sanger.ac.uk/),[3] food allergens fall within a relatively small group of about 30 families,[4−6] which are also described in Allfam (http://www.meduniwien.ac.at/allergens/allfam/), a database specific for allergen families.[4] Biological activity of these proteins is even more restricted being limited to few biochemical functions: hydrolysis of proteins, polysaccharides, and lipids; binding of metal ions and lipids; and storage of nutrients and cytoskeleton association.[4] These findings led to the assumption that allergens must meet specific, but not yet completely elucidated, structural features which are at the basis of their allergenic potency. Their disclosure could greatly accelerate research advances in the prevention, diagnosis, and therapy of allergies. Additionally, in the case of food allergens, uncovering the structural basis of allergenicity would provide insights for understanding the effects of food processing and contribute to a safer management of food proteins.[7] There are examples of food allergens which retain allergenic potency even after cooking or transformation processes as has been shown for Cor a 1 in roasted hazelnuts[8] and nonspecific lipid transfer proteins (nsLTP) in some plant derived foods (sterilized peach juice and polenta)[9] and fermented products (wine and beer).[10,11] While strong structural constraints (such as disulfide bridges) can be evoked to explain the maintaining of some conformational epitopes and allergenicity for cooked food proteins, the allergenic potency that unfolded proteins still maintain can be attributed to their linear epitopes, as in the case of "fermented" nsLTPs and caseins (Mills et al.[7] and references therein). In any case, at the moment there are no definitive, reliable ways to predict structural signatures for allergens in general and food allergens in particular.[4]

Food allergens can be distinguished as those that are directly involved in the sensitization process in the gastrointestinal tract, which generally show high stability toward heating and proteolysis, and those that cross-react with IgE related to pollen or other nonfood allergens, which are mostly easily degradable.[12] Cross-reactivity syndromes, i.e., the onset of food allergies in subjects already sensitized to nonfood allergens, are usually determined by similar structural features among allergens.[13]

Among food allergens, those of plant origin constitute an essential part, and numerous reviews are available reporting their classification and discussions about biological function, cross-reactivity syndromes, influence of protein structure on allergenic potency, and effects of cooking and other food processing as well.[1,6,7,13,14] Here, we report a comprehensive analysis on the involvement of plant chitinases in food-allergies.

Chitinases are enzymes that catalyze the hydrolysis of chitin, a linear homopolymer of β-1,4-*N*-acetyl-D-glucosamine units. They are ubiquitous in nature, having been detected in animals, plants, fungi, bacteria, and viruses. In plants, chitinases play a major role as pathogenesis related (PR) proteins, active in defense mechanisms against fungi and pathogens.[15,16] While a clear structural classification of plant chitinases has long been reported,[17−19] a precise classification of plant chitinases as allergens is still missing. The aim of this review is to update the knowledge on the relationships between the structures and properties of plant chitinases and their allergenicity. It will furnish the basis to establish in the future more detailed analyses of the structural determinants of allergenic chitinases.

CLASSIFICATION OF PLANT CHITINASES

Chitinases are classified into families 18 or 19 of glycoside hydrolases (GH), depending on the adoption of the so-called *retaining* or *inverting* hydrolysis mechanism, which results in the retention or inversion of the anomeric configuration of the hydrolysis product, respectively.[20] While chitinases of family 18 have heterogeneous origin, chitinases of family 19 mostly belong to plant and bacterial species.

From a structural point of view, plant chitinases of either families 18 or 19 can be further classified according to the presence of specific modules. Indeed, in addition to essential presequence (PM) and catalytic (CM) modules, the presence of additional chitin-binding (CtBM) and linker (LM) modules distinguishes particular classes. CMs can also exhibit different lengths, similarities, and architectures, according to the presence of structural loops on the protein surfaces. A schematic representation of the identified structural classes is reported in Figure 1. Only classes I and IV have the CtBM and

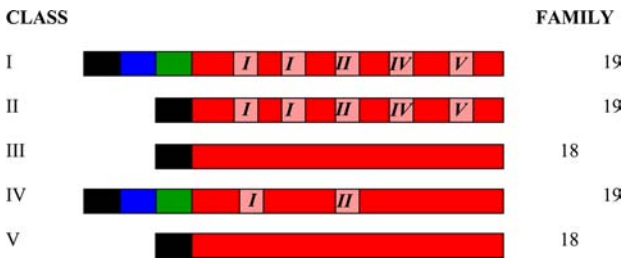

Figure 1. Schematic representation of different classes of chitinases of the 18 and 19 GH families. Color code: black = PM, blue = CtBM, green = LM, red = CM, and pink = surface loops. In order to adhere to previous literature, classes and surface loops have been both indicated with Roman figures, but italic font has been introduced for loops. Lengths of structural modules and positions of surface loops are only indicative. Adapted with permission from ref 24. Copyright 2009 Springer.

LM modules. CM modules can be distinguished on the basis of sequence similarities with reference enzymes (see Levorson and Chlan[21] and references therein). Class I and II chitinases, which share highly homologous CM modules, are at least 50% identical to tobacco Chia1 chitinases.[18] Chitinases of class III show no sequence similarities with class I or II chitinases and have higher than 50% sequence identities with a tobacco class III/lysozyme enzyme.[22] Class IV chitinases have CM modules which are at least 50% identical to the *Phaseolus vulgaris* PR-4 chitinase. CM modules in class IV chitinases are about 50 amino acids shorter than in class I and II chitinases. In chitinases of the classes I, II, and IV, up to five surface loops can be identified in the CM modules.[23,24] Chitinases of class V have CM modules which share consensus motifs with those of class III but are clearly distinguishable on the basis of an additional α/β domain (see the Class V section).

CLASSES OF PLANT CHITINASES AND ALLERGIES

The possibility that plant chitinases may act as food allergens[13] constitutes an important problem for human nutrition, also due to specific features of these proteins, which can be either overexpressed as PR-proteins[25−28] or can be unexpectedly present as transgenic chitinases, used for enhancing resistance to fungi and pathogens[29−31] (see the Class I section for a discussion about the induced expression of allergenic chitinases).

It has long been accepted that the allergenicity of plant chitinases derives from the presence of the CtBM, according to its high identity (65−70%) with hevein, a major allergen identified in the latex of rubber trees (*Hevea brasiliensis*).[32] Therefore, class I chitinases were the main object of the first studies on allergenic chitinases. It must be clarified that hevein, even if essentially constituted by a CtBM, is not a chitinase (its characteristics are further described in the Other Chitinase-Related Allergens section). Because of the presence of common or highly similar structural epitopes, hevein and class I chitinases have been indicated as largely responsible for the cross-reactive syndrome known as latex-fruit syndrome.[33,34] However, even at lower levels than hevein other latex allergens can be involved in latex-fruit cross-reactivity (see Radauer et al.[35] and references therein). Avocado, banana, chestnut, and kiwi fruits are considered as those with the highest degree of association to latex allergy.

Only more recently have chitinases from other classes been identified as allergens, resulting in a larger array of fruits and vegetables containing possible chitinase-type allergens. A summary of plant chitinases and structurally related proteins (hevein and other CtBM-like polypeptides), which have been indicated as allergens on the basis of their IgE-binding capacity, is reported in Table 1. With the exception of specific allergens detected in rubber tree latex, Japanese cedar pollen, and obeche dust, all the allergens can be regarded as food (or food-related) allergens. A literature-based list of allergenic chitinases is available in the Allergome database (http://www.allergome.org/). It must be emphasized that different approaches have been adopted to study the allergenicity of these chitinases (and of all allergens in general) and that not all are equivalent. For some of them, a rigorous analysis has been carried out, using both purified and recombinant proteins to study the alleged allergenicity. In a number of cases, the polypeptide has only been identified on the basis of partial sequence or mass-spectrometry analysis of molecules detected by either immunodetection assays using specific antibodies or immunoblot experiments carried out with sera of allergic patients. However, their isolation and complete characterization have not yet been accomplished. Up to now, chitinases acting as possible allergens have been identified in classes I−IV of plant chitinases. Details of studies carried out to investigate the allergenic activity of chitinases in each of the different structural classes, together with a short description of the main structural features, are given below.

Class I. This class contains most of the chitinases identified as allergens in plants. The first plant fruit chitinase with the capacity to bind IgE from allergic subjects was described in avocado (*Persea americana*) and is known by the name Pers a

[a]Chitinases identified as putative allergens are listed according to their classification into different classes. Chitinase-related polypeptides are listed separately. When available, protein names, accession numbers, IUIS allergen names, structure accession numbers in Protein Data Bank are reported. [b]IUIS is the acronym for International Union of Immunological Societies (http://www.allergen.org/). [c]Eight amino acids are available as the N-terminal sequence. This region shows homology with a class I chitinase (BAD02824) from *Taxodium distichum* (bald cypress). A 26 kDa allergen is recognized by a rabbit antichitinase antibody. Assignment to class I chitinase needs to be confirmed. [d]Data in the literature and databases are confusing. The Allergome site http://www.allergome.org/ reports the existence of a class I chitinase allergen, but contradictory cross-references are reported. The cited Uniprot sequence (P81241) leads to a class II sequence, and the literature citation[81] refers to a class IV chitinase. [e]Experimentally identified as an allergen but not yet added to the IUIS database. [f]Fourteen amino acids are available as the N-terminal sequence. This region shows 100% identity with Q6UZ78, a class I chitinase from kidney bean. [g]Allergen is present in the Allergome database and not in IUIS. [h]The gene is induced by the fungus *Fusarium graminearum*.[28]

1.[36] In this case, a 32 kDa protein from avocado fruit, identified by immune-reaction in the sera of 15 out of 20 avocado allergic patients, was purified and partially sequenced. The corresponding cDNA was also obtained. Analysis of polypeptides and cDNA sequences identified an open reading frame coding for a 326 amino acid protein with a leader peptide of 25 amino acids, a CtBM of 43 amino acids, and additional consensus motifs characteristic of a class I chitinase. The avocado mature chitinase, obtained as a recombinant molecule in *Pichia pastoris* cells, showed the expected endochitinase activity and was effective in inhibiting the binding of allergic patients' IgE to the 32 kDa protein in avocado extracts. Almost simultaneously, other plant chitinases were identified as allergens by procedures including purification of chitinases (with the aid of antihevein or specific antichitinase antibodies for their identification), N-terminal sequencing, immunoblot assays of plant protein extracts with sera of patients allergic to rubber latex, and immunoblot inhibition assays using purified chitinases (or hevein) as inhibitors. Two polypeptides of 32 and 33 kDa were identified as allergenic chitinases in banana (*Musa acuminata*). N-Terminal sequencing of the purified banana polypeptides revealed high identity (around 80%) with hevein.[37] A 32 kDa allergenic polypeptide was also identified as a class I chitinase in chestnut. The reported N-terminal sequence (27 amino acids) was 81% similar to hevein.[38] In this case also, the activity of the purified chitinase was assayed. Interestingly, in turnip (*Brassica rapa*), among polypeptides whose expression was enhanced in roots after chemical treatments for the activation of plant defense mechanisms, a class I allergenic chitinase was identified. The same polypeptide was not identifiable with antisera when proteins were extracted from untreated plants.[27] A strongly induced allergenic chitinase of class I was also identified in green bean subjected to ethylene treatment.[26]

Subsequently, a real class I chitinase from *Hevea brasiliensis* was described showing 58% identity between its CtBM and hevein and different IgE binding capacities.[39] Recently, a

putative class I allergenic chitinase has been identified in tomato fruits infected with *Pepino mosaic virus* by 2D comparative immunoblot assay with sera of tomato allergic subjects and mass spectrometry analysis.[40] Skin prick tests conducted with tomato allergic subjects did not, however, show any significant difference between infected and noninfected tomato fruits, indicating that the overall fruit allergenicity was, at least in this case, not appreciably changed by virus infection. More detailed studies have to be performed to clearly establish the allergenic risks due to inducible proteins like chitinases.

Other class I chitinases from plants which have been shown to react with IgE of allergic patients have been reported in kiwi, papaya, obeche, and wheat (Table 1).

Generally, relationships between chitinase three-dimensional structures and allergenicity have not so far received sufficient attention, perhaps due to the assumption that their allergenicity is mainly due to the CtBM. Evidence is emerging, however, indicating that other regions of chitinase molecules can act as allergen epitopes as well (see the Class II section) making a deeper structure−allergenicity analysis of their CM modules important. Knowledge about the structure of class I chitinases comes from a unique work carried out for the CM of the *Brassica juncea* chitinase (EBI accession number Q9SQF7). Even if there are no indications about its allergenicity, its structural analysis can be relevant for possible comparisons with known allergenic chitinases of other classes. The *B. juncea* chitinase is defined as a highly α-helical protein, with a single and irregular β-sheet.[23] The protein has a bilobate shape with a wide cleft in which the active site (Glu-212 and Glu-234) interacts with chitin. The overall structure is stabilized by three disulfide bridges and shows five flexible surface loops (*I*−*V* in Figure 1), some of which were located at the border of the active site cleft.

Class II. Chitinases of class II are highly similar to class I enzymes except for the absence of the CtBM module. They have not usually been considered as allergens, according to the assumption that allergenicity of chitinases mainly resides in the hevein-like CtBM. At least this is what emerged from a study on class II chitinases isolated from chestnuts and avocado fruits and assayed against the sera of allergic patients, for whom no IgE binding capacity was identified.[38] Data, however, are now emerging which indicate that the CM modules of class II chitinases can be the source of allergenicity. Recently, one class II chitinase has been identified as a possible allergen in wheat flour.[41] By immunoblotting analysis of wheat flour proteins with sera of 22 patients with a suspect history of wheat allergy and high levels of specific IgE, and successive mass-spectrometry analysis of reactive proteins, two chitinases were identified: a 26 kDa protein, which shows high similarity with a class I chitinase from *Hordeum vulgaris* (EBI accession number P11955), and an additional chitinase corresponding to a wheat class II chitinase (EBI accession number Q4Z8L8). The purified class II chitinase was reactive to at least 20 out of the 22 available patients' sera. No further details are available about the allergenicity of this molecule. Another wheat class II chitinase (EBI accession number Q8W429) is present in the Allergome database with the code 1274, for which additional information is not available.

Additionally, the Allergome database reports as allergen (code 1273) a class I chitinase from tomato fruits. It corresponds to two almost identical sequences (EBI accession numbers Q05539 and Q7Y0S1) which, however, do not contain the CtBM. The mature polypeptide has an acidic isoelectric point of 5.6, which further enables its classification among class II chitinases.[42] For these reasons, the allergen, named Sola 1 chitinase, has been listed in this review among class II chitinases (Table 1).

The structure of class II chitinases has been described for enzymes purified from barley,[43] papaya,[44] and rye,[45] for which there is currently no information about allergenicity. Also in these cases, as for class I enzymes, the structure is rich in α-helices and shows a substrate-binding groove located between two lobes, with three disulfide bridges contributing to protein folding.

Class III. Class III chitinases are structurally different from class I and class II enzymes and initially not considered as allergens. Recently, however, four plant chitinases belonging to this class have been identified as possible allergens.

The first plant fruit class III chitinase showing IgE binding capacity and IgE-cross reactivity with latex allergens has been identified in Indian jujube (*Zizyphus mauritiana*).[46] It is a protein of 330 amino acids, including a leader peptide of 25 residues. Both the purified and the recombinant proteins were immunoreactive with sera from latex and Indian jujube allergic patients (seven out of eight patients). This chitinase showed 45.2% identity with hevamine, a class III chitinase present in rubber tree latex, where it had been previously described as an unimportant allergen since only a reduced percentage of examined sera (about 3%) contained reactive IgE.[47]

Mass-spectrometry analysis of IgE-reactive proteins allowed the identification of a class III chitinase also among the allergens extracted from fresh raspberries (*Rubus ideaeus*).[48] As in the case of Indian jujube chitinase and different from hevamine, for raspberry fruits the protein was found to react with most (>80%) of the sera of patients allergic to raspberries. The involvement of plant chitinases of class III in allergic reactions has been recently confirmed by a study conducted on coffee (*Coffea arabica*) allergens.[49] By screening a phage display library of coffee cDNA with sera of two patients allergic to green coffee beans, a cDNA sequence corresponding to a class III chitinase was identified among those coding for IgE-reactive polypeptides. The recombinant polypeptide (rCofa 1) was subsequently produced and showed immunoreactivity with the sera of the two patients allergic to green coffee and 3 out of 17 sera from workers in coffee industries, all with allergenic symptoms to coffee dust. Immunoreactivity of rCof a 1 with IgE of sera from latex allergic patients was also found.

Currently, there are no studies about three-dimensional structures of class III chitinases among plant food proteins. Only for the nonfood plant chitinase hevamine has the structure been established.[50] It consists of an $(\alpha/\beta)_8$ barrel fold, different from that described for class I and II chitinases, leading to the assumption of a different structural base for allergenicity.

Class IV. As for class IV chitinases, IgE-binding capacity has been reported in maize kernels, grapes (*Vitis vinifera* and *V. lambrusca*), and wines by immunoblot analysis of plant protein extracts with sera of allergic patients, and subsequent mass spectrometry identification.[11,51,52] None of these allergens has been currently isolated, preventing further studies of their biological and structural characteristics. Only one chitinase of this class, identified as an allergen in Japanese cedar (*Cryptomeria japonica*) pollen, has been isolated and characterized for its enzymatic activity and allergenicity.[53] IgE binding was confirmed in all of the sera of the 31 tested allergic patients, with levels comparable with those observed for the Cry j 1 C.

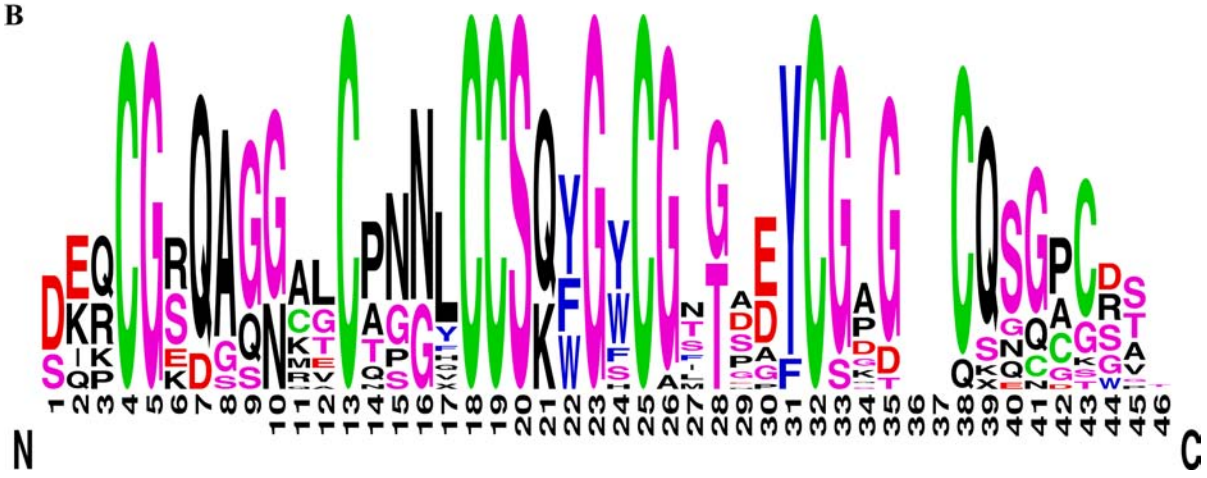

Figure 2. (A) Multialignment of hevein with CtBMs of class I and class IV chitinases and hevein-like regions of WGAs. With the exception of hevein, all the sequences are in the same order as that in Table 1. Class I (Cl_I) enzymes are reported before class IV (Cl_IV) enzymes. The last eight sequences refer to the chitinase-related polypeptides in Table 1. When possible, the sequence names report the name of the allergen; otherwise, the first letters of the plant's scientific name are indicated. All of the names of sequences contain the EBI accession number. Amino acids of the hevein linear epitopes have been underlined. Trp-21 and Trp-23, together with the other amino acids of the carbohydrate-binding site, are in bold. (B) Graphical representation of the hevein-CtBMs multiple sequence alignment obtained by the WebLogo program[66] with the following color code: green (C), purple (G, S, T), blue (Y, F, W), and red (D, E).

japonica major allergen. Interestingly, preincubation of the purified molecule with rubber tree latex completely inhibited IgE reaction in pooled sera of *C. japonica* allergic patients.

There are only two structures established for this class of chitinases. The first is that of the Norway spruce (*Picea abies*) chitinase.[24] The structure of the CM region shows a high content of α-helices and a small irregular β-sheet, assembled in a bilobate arrangement containing three disulfide bridges and forming a wide cleft exposed on the protein surface. The structure of the CtBM was obtained by homology modeling. It resembles those of class I enzymes and of hevein as well (see also the Other Chitinase-Related Allergens section). More recently, the 3D structure of the putative allergenic chitinase A from maize has also been determined.[54] In this case, a recombinant truncated form lacking the CtBM was investigated, which shows the same structural components of chitinases of the GH19 family and still retains activity levels comparable with those of the full-length enzyme.

Which module of class IV chitinases (CtBM or CM) is responsible for allergenicity has not been investigated yet. Even if the presence of a CtBM region, highly homologous to those of class I chitinases and hevein, can be considered as an obvious explanation of their allergenicity, the relatively close structural relationships between their CM modules with that of class II enzymes (among which allergens have been detected) open the possibility that other domains of these proteins could induce allergy. Obviously, this could be the case also for class I chitinases.

Class V. Allergens within this class have not yet been identified. Class V chitinases have been described only in *Arabidopsis thaliana*, *Nicotiana tabacum*, and *Cycas revoluta*, with structures established in the first two cases.[55,56] Putative chitinases have also been identified in *Medicago truncatula*, rice, and oil palm.[57,58] Class V chitinases share a similar $(\alpha/\beta)_8$ barrel fold with class III chitinases with which they also share the consensus DXDXE motif containing the catalytic glutamic acid. Other elements, however, clearly distinguish the two classes of chitinases. In particular, class V chitinases have an extra α/β region of about 65−70 amino acids and do not possess six cysteine residues involved in the formation of

dx.doi.org/10.1021/jf5007962 | J. Agric. Food Chem. 2014, 62, 5734−5742

disulfide bridges in class III chitinases. In addition, while the sequence identity of molecules within each class is relatively high (around 40% within class III and in the 40−60% range for class V), identity between members of classes III and V is less than 20%. If further confirmed, the absence of allergens within members of class V could provide valuable information to study structural determinants of allergenicity for class III chitinases.

Other Chitinase-Related Allergens. Hevein is the paradigm of chitinase-related allergens. It is a protein of 43 amino acids detected in the latex produced by specialized cells of the rubber tree (*Hevea brasiliensis*), with a possible role as a defense-related protein due to its capacity to bind chitin and inhibit the growth of chitin-containing fungi.[59] Additionally, thanks to its capacity to bind to glycosylated receptors, a role as a coagulation factor of rubber particles has also been assigned.[60] Hevein is known as a major allergen present in natural rubber latex which is the cause of allergies among people using latex-derived products, reaching percentages in the range of 3−17% for health-care workers.[32,61] The hevein gene encodes a polypeptide of 204 amino acids, constituted by a signal sequence of 17 amino acids, the hevein domain, and a 144 amino acid-long carboxy-terminal region showing high homology to wound-inducible potato polypeptides.[25] Hevein is rich in cysteine and glycine amino acids and shows high sequence similarities to the CtBM of class I chitinases (higher than 65%), the C-domain of wheat germ agglutinin (WGA) (around 60%), and the CtBM of class IV chitinases (in the 40−60% range). Similar domains have also been detected in other plant proteins (lectins, wound-induced proteins) and fungi (chitinases, toxins, and cell-wall enzymes).

The three-dimensional structure of hevein shows an ovoid shape containing an antiparallel β-sheet and a short four-amino-acid α-helix, assisted by four disulfide bonds.[62,63] More recent studies, carried out using chemically modified hevein molecules, highlighted the essential role of the surface exposed Trp-21 and Trp-23 amino acids for IgE recognition.[64] These amino acids are part of the carbohydrate binding site of the molecule and belong to a conformational epitope derived from the structural association of two previously identified linear epitopes.[65] Most of the aromatic and acid amino acids forming the hevein carbohydrate-binding site are present in other hevein-like molecules identified as allergens, such as WGA and class I and IV chitinases. All of these molecules share the consensus motif C(12)XXXXCCSXφXφCGXΩXAcYC(31) (where X = any amino acid; φ = an aromatic amino acid; Ω = Thr, Ser, or Gly; Ac = Glu or Asp).[64] Figure 2 reports the alignment of the hevein sequence with the corresponding region of class I and class IV chitinases, and with WGAs.

A recent study based on the cross-reactivity of recombinant hevein and specific plant class I chitinases from banana and avocado fruits, carried out by ELISA assays with sera of latex-allergic patients (for which the involvement in latex-associated plant food syndrome was not known), showed that only subfractions of patients' sera having hevein-specific IgE cross-reacted with banana and avocado chitinases. Also, cases of latex-allergic patients with IgE specific for the chitinases from the two fruits but without specificities for hevein could be observed. Structural analysis of hevein, CtBM-like domains of WGAs, and model structures of class I chitinases clearly indicated that surface variability of allergens is much higher than expected from the alignments of their amino acids sequences,[35] making the prediction of cross-reactivity even more challenging.

Conclusions and Perspectives. From the above-reported data, it appears that the general statement that plant chitinases can be allergenic molecules deserves more detailed clarifications. We can assume that plant food chitinases constitute a heterologous group of allergenic molecules, in which at least three different subgroups can be identified: the hevein-like (or CtBM-like) molecules (including both class I and class IV chitinases), the class II chitinases, and the class III chitinases. While a considerable amount of work has been carried out for the identification of class I chitinases as food allergens, chitinases of classes II, III and, IV have been little investigated so far for their potential allergenicity. It is notable that they have been identified as possible allergens in cultivated plants worldwide, widely used in human nutrition, in some cases even as raw food (e.g., salads and fresh fruits).

From a structural point of view, the identification of allergenic molecules belonging to class II chitinases, which do not contain the CtBM module, opens the possibility that the allergenicity of chitinases may not be exclusively due to the CtBM module. This aspect should be properly investigated among class I and class IV chitinases.

Plant chitinases are, therefore, a clear example of molecules for which further studies are required in the near future to better define their allergenic determinants and evaluate their relevance. Recombinant technologies, including techniques based on combinatorial approaches,[49] combined with advanced structural and physicochemical analysis[6] can provide useful tools to allergology investigations to firmly establish the structural determinants of allergenicity in chitinases.

ABSTRACT: White tea (WT) presents high levels of catechins, which are known to reduce oxidative stress. WT is the least processed tea, unfermented and prepared only from very young tea leaves. The subject of this paper is the use of the spin trap method and electron paramagnetic resonance (EPR) spectroscopy as the analytical tool to measure, for the first time, the radical scavenging activity of WT and its major catechin components, epicatechin (EC), epicatechin-3-gallate (ECG), epigallocatechin (EGC), and epigallocatechin-3-gallate (EGCG), against the methoxy radical, using ferulic acid as antioxidant pattern. The antioxidant activity has been measured by the decrease of the intensity of the spectral bands of the adduct DMPO−OCH_3 in the EPR with the amount of antioxidant in the reactive mixture. Tea leaves and buds were extracted with waterless methanol. It has been proved that tea compounds with more antiradical activity against methoxy radical are those with the gallate group, EGCG and ECG.

KEYWORDS: *white tea, EPR, spin trap, antioxidant activity, radical scavenging*

INTRODUCTION

Tea (*Camellia sinensis* (L.)) is one of the world's most consumed beverages, and its medicinal properties have been widely explored. It can be classified in three types: unfermented (green and white teas), partially fermented (oolong tea), and completely fermented (black tea).[1] White tea (WT) is exclusively prepared from young tea leaves or buds, harvested before being fully opened. It is the least processed tea, because leaves are only air-dried and it does not suffer any fermentation process.[2−4] The strong antioxidant capacity of WT is linked to its high content in catechins. The main catechins of tea are epigallocatechin (EGC), catechin (C), epigallocatechin gallate (EGCG), epicatechin (EC), and epicatechin gallate (ECG).[2,5] Scavenging capacity of WT can be measured by different antioxidant tests such as ORAC, TEAC, FRAP, or DPPH, among others.[6] Nowadays, WT is used as a promising antioxidant additive medium, even better than green tea.[7] It is also suggested that the mechanism of protective actions of WT against oxidative stress in vitro is related to its antioxidant potential and the maintenance of the normal redox status of the cell when it is attacked by radicals or hydrogen peroxide (H_2O_2).[8]

In this context, radical scavenging measurements by traditional methods have their limitations. An essential antioxidant test, extensively used in the literature, deals with the scavenging activity of antioxidants against the hydroxyl radical ($HO^•$) or the superoxide ($O_2^{•−}$), which are the main harmful reactive oxygen species (ROS). The activity of the antioxidant is measured in a competitive reaction with 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), an excellent $HO^•$ and $O_2^{•−}$ nitrone spin trap. Spin trapping is a technique in which a transient radical, very unstable under normal conditions, reacts with a spin trap to form a much more stable radical adduct, detected by electron paramagnetic resonance (EPR) spectroscopy. Nitrones have been the molecules chosen as spin trap species due to their specificity and ability to quantify transient ROS. It is well-known that the spin trapping technique can provide direct evidence of the presence of transient radicals in any reaction system and, therefore, it is very useful for discriminating trapped radical species. In fact, various short-lived radical intermediates have been identified by this technique.[9,10] Thus, EPR spectroscopy has been an indispensable tool for the detection of many harmful ROS ($O_2^{•−}$, $HO^•$, $HO_2^•$, $RO_2^•$, $RO^•$) via spin trapping.[10−13] Thereby, the antioxidant activity of a single polyphenol or a natural extract (mixture of polyphenols) is measured by the decrease of the intensity of the radical adduct spectra in the presence of the antioxidant relative to the decrease in the presence of an antioxidant pattern.[14−22]

Some studies about the radical scavenging activity of green and black teas against 2,2-diphenyl-1-picrylhydrazyl (DPPH) by using the EPR technique have been reported.[10,23−27] However, there are no publications about the use of EPR in the analysis of the antioxidant capacity of WT with a transient oxygen radical, much more unstable than DPPH.

Following our research work related to the antioxidant and antimicrobial properties of WT,[28−30] the aim of this paper is to measure the radical scavenging activity of WT and its major constituents, those being epicatechin (EC), epicatechin-3-gallate (ECG), epigallocatechin (EGC), and epigallocatechin-3-gallate (EGCG), against methoxy radical, generated in the Fenton reaction in methanol (MeOH) as solvent, using ferulic acid as antioxidant pattern. The alkoxy radicals are also considered

among ROS species in biological processes as critical mediators in several serious human diseases. The classical Fenton reaction in aqueous media is used in most cases to generate the harmful hydroxyl radical $HO^{\bullet}$. However, when the reduction of H_2O_2 with $FeSO_4$ is conducted in MeOH as solvent, the transient radical generated is the methoxy radical $CH_3O^{\bullet}$, as explained below.

MATERIALS AND METHODS

Materials. Commercially available WT was obtained from a local market. Ferulic acid, ECG, EGC, EGCG, and EC were bought from Sigma-Aldrich. Iron(II) sulfate ($FeSO_4$), DMPO, H_2O_2, and MeOH were of analytical grade and supplied by Panreac (Barcelona, Spain).

Extraction and Quantification of WT. The extraction was executed in two different ways: (a) Dried WT (10 g) was mixed with MeOH (100 mL) and extracted for 24 h at 4 ± 1 °C, stirred (103 rpm) and light protected. (b) Dried WT (10 g) was mixed with hot water (100 mL) and extracted for 4 min at 90 ± 1 °C, stirred (103 rpm) and light protected.

In both cases, the resulting infusions were filtered with qualitative filter papers (Watmann no. 1) in a vacuum system. To determine the soluble concentration of WT, the solvent was removed at low pressure (Buchi RE111, Flawil, Switzerland) and subsequently treated in a freeze-dryer (Unicryo MC2L ±60 °C, UniEquip, Martinsried/München, Germany). Finally, WT lyophilized pulps were weighed, and the concentration recovered from extract (g/L) was determined. The lyophilized extracts were kept in a desiccator, protected from light, until analysis.

An adequate dilution of each extract was prepared to be analyzed by HPLC method to determine the concentration of different flavonoids.

The results of the main catechins for the water extraction were (mg/100 g dry tea leaves) EC, 51.3 ± 3.7; EGC, 157 ± 9.5; EGCG, 1631 ± 97; and ECG, 280 ± 23.2.

In methanol, an average of 7.5 ± 0.2 g of soluble extract was collected from 100 g of dry WT. The major phenolic compounds found in methanolic WT extracts by HPLC analysis are listed in Table 1.

Table 1. Concentration of Polyphenols Found in MeOH WT Extracts by HPLC Analysis

compd	retention time (min)	concn (mg/100 g dry tea leaves)
EGC	1.913	260.9
EC	2.91	94.9
EGCG	4.715	2113.8
ECG	7.757	382.2

Determination of Methoxy Radical Scavenging Activity by EPR. The solutions of the different components were prepared in deoxygenated MeOH. A spin-trapping reaction mixture consisted of 100 μL of DMPO (35 mM); 50 μL of H_2O_2 (10 mM); 50 μL of pure polyphenols EC, ECG, EGC, and EGCG at different concentrations or WT extract (0−8.13 g/L) or 50 μL of ferulic acid used as reference (0−20 g/L) or 50 μL of pure MeOH used as a control; and, finally, 50 μL of $FeSO_4$ (2 mM), added in this order. The final solutions (250 μL) were passed to a narrow (inside diameter = 2 mm) quartz tube and introduced into the cavity of the EPR spectrometer. The spectrum was recorded 10 min after the addition of the $FeSO_4$ solution, when the radical adduct signal is greatest.

X-band EPR spectra were recorded with a Bruker EMX-Plus 10/12 spectrometer under the following conditions: microwave frequency, 9.8762 GHz; microwave power, 30.27 mW; center field, 3522.7 G; sweep width, 100 G; receiver gain, 5.02×10^4; modulation frequency, 100 kHz; modulation amplitude, 1.86 G; time constant, 40.96 ms; conversion time, 203.0 ms.

Each measurement was carried out three times. The first derivative of the absorption signal was twice integrated, resulting directly proportional to the concentration of the remaining radical adducts values, when the competitive reactions of the methoxy radical with DMPO and the antioxidant were completed. Then, these values were compared with those obtained with ferulic acid.

RESULTS AND DISCUSSION

Antioxidant Capacity Assay. In the present study, the free radical scavenging activity of WT extracts was evaluated against methoxy ($CH_3O^{\bullet}$) radical by a competitive method in the presence of DMPO as spin trap, using EPR spectroscopy. $CH_3O^{\bullet}$ radical was generated according to the Fenton procedure in MeOH instead of H_2O as solvent. Methoxy radical, with a relatively short half-life, was identified by EPR because of its ability to form a stable nitroxide adduct with DMPO, DMPO−OCH_3 (hyperfine splitting constants, a_N = 13.9 G and a_H = 8.3 G).[31]

Because iron has a variable valence, its oxidation by H_2O_2 may occur via one or two electron transfer reactions. Therefore, two different mechanisms of the Fenton reaction have been extensively discussed in the literature:[32−39] a radical mechanism with Fe(II) salt as one-electron donor and the generation of hydroxyl ($HO^{\bullet}$) radical (reaction 1)[40] and a nonradical mechanism, which involves a direct interaction between Fe(II) and H_2O_2. This interaction finally produces an iron oxide species of Fe(IV) (reaction 2).[41] In each case, the predominance of one mechanism over the other may depend on different variables, mainly the nature of the metal ligand, the solvent, and the pH of the medium.

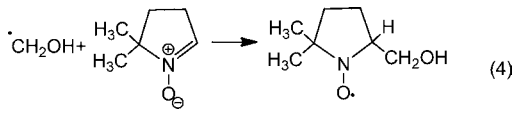
$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^- + HO^{\bullet} \quad (1)$$

$$Fe^{2+} + H_2O_2 \rightarrow [Fe^{2+}\cdot H_2O_2] \rightarrow [Fe^{IV}O]^{2+} + H_2O \quad (2)$$

As stated above, our experiments have been carried out in MeOH due to the low solubility of ferulic acid in water. Assuming a radical mechanism in the Fenton reaction in MeOH, the generated hydroxyl radical would abstract a hydrogen atom mainly from the α position of MeOH to yield a hydroxymethyl radical (reaction 3),[42]

$$HO^{\bullet} + CH_3OH \rightarrow H_2O + {}^{\bullet}CH_2OH \quad (3)$$

which, in turn, would react with DMPO to yield the radical adduct DMPO−CH_2OH[43] (reaction 4) (hyperfine splitting



(4)

constants a_N = 14.7 G and a_H = 20.7 G).[44]However, in the reduction process of H_2O_2 with Fe(II) in MeOH as solvent in the presence of DMPO as spin trap, the unique bands of significant intensity shown in the EPR spectrum corresponded to those of the methoxy adduct, DMPO−OCH_3, and no relevant bands to the DMPO adducts with hydroxyl and α-hydroxymethyl radicals were detected. Therefore, we assume a nonradical process as the dominant mechanism in the Fenton reaction in these conditions (reaction 2), and we suggest that the oxidant action of Fe(IV) oxide in MeOH leads to the generation of methoxy radical in two consecutive one-electron paths (reactions eq 5 and eq 6) yielding

$$\left[Fe^{IV}O\cdot CH_3OH\right]^{2+} \downarrow \left[Fe^{III}(OH)^{2+}, {}^{\bullet}OCH3\right] \longrightarrow \left[Fe^{III}(OH)\right]^{2+} + {}^{\bullet}OCH3 \quad (5)$$

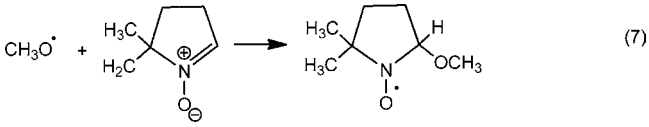
(6)

in the presence of the spin trap the radical adduct DMPO−OCH_3 (reaction 7). At this point, it should be emphasized that



(7)

the involvement of an ionic mechanism in the formation of the radical adduct DMPO−$OCHH_3$ by nucleophilic addition of MeOH is discarded because the intensity of the EPR spectrum decreases with the addition of methoxy radical scavengers.Pure polyphenols or WT extracts added to methanolic solutions of H_2O_2 and small amounts of $FeSO_4$ in the presence of an excess of DMPO may compete with the spin trap in the scavenging of methoxy radicals. This effect reduces the amount of radical adducts and, accordingly, the intensity of the EPR signal decreases. The double-integration value of the signal of the spectrum for each experiment in the presence of an amount of antiradical relative to the value in the presence of the same amount of ferulic acid gives a measure of the antiradical activity of the test sample.

Figure 1 (left) shows the EPR spectra of the DMPO adduct of methoxy radical at different concentrations of ferulic acid. The

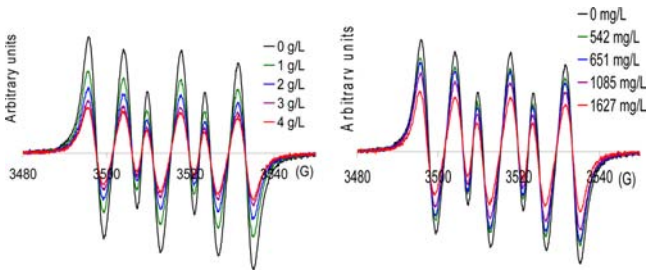


Figure 1. Electron paramagnetic resonance (EPR) spectra of the radical adduct DMPO−OCH_3 generated from a solution of H_2O_2 (2 mM) and $FeSO_4$ (0.04 mM) with DMPO (14 mM) as spin trap in MeOH as solvent: (left) decrease of the EPR signal with the increase of the concentration of ferulic acid as the reference sample; (right) decrease of the EPR signal with the increase of the concentration of the white tea extracts. EPR measurement conditions were as described under Materials and Methods.

spectra were recorded 10 min after the addition of $FeSO_4$ to the reaction mixture, when the radical adduct signal was the greatest. The signal intensity of the spectrum decreased with the increase of the amount of ferulic acid. Table 2 shows the values of the double integration at five different concentrations of ferulic acid. The best fitting with these data was an exponential function (Figure 2) that, if concentration values of ferulic acid are in grams per liter, corresponds to eq I:

$$y = 26.75\ e^{-0.21x};\ R^2 = 0.972 \quad (I)$$

The evolution of the signal intensity of the DMPO adduct in the presence of different amounts of WT extract is shown in Figure 1 (right). The radical scavenging activity values of WT extract against methoxy radical are presented in Table 3 as the

equivalents of ferulic acid in grams per liter per gram of WT. The scavenging activity of the WT extract is evaluated from four different concentrations of the extract. The last column in Table 3 shows that the activity of the extract is slightly higher than the activity of ferulic acid in grams per liter.

The radical scavenging activity of pure polyphenols toward methoxy radical was examined. Solutions of H_2O_2 (2 mM) and $Fe(SO_4)$ (0.4 mM) in the presence of DMPO (14 mM) and various amounts of polyphenol were introduced into the EPR cavity, and the double integration of the spectrum, obtained 10 min after the addition of the Fe(II) salt to the reaction mixture, was collected to calculate results. The overall chemical process can be defined as a system of two competing reactions between DMPO and the pure antioxidant over the methoxy radical. The action of the spin trap is to capture the methoxy radical to yield the radical adduct and, besides, the scavenging action of the antioxidant on the methoxy radical reduces the amount of radical adduct. In each experiment, the amount of spin trap was constant and the amount of antioxidant was varied. Then, the amount of

dx.doi.org/10.1021/jf501707p | J. Agric. Food Chem. 2014, 62, 5743−5748

radical adduct decreases exponentially as the amount of polyphenol increases, and the antioxidant efficiency is measured by the exponential coefficient α of eq II

$$y = y_0\, e^{-\alpha x} \quad \text{(II)}$$

where y is the value of the double integration of the spectrum of DMPO−OCH_3 at a given polyphenol concentration and y_0 represents the value of the double integration in the absence of polyphenol. The variable x represents the polyphenol concentration. Graphics for polyphenols EC, ECG, EGC, and EGCG are shown in Figures 3−6. In each case, experimental values are

fitted to exponential functions inserted in the figures with good correlation coefficients (R), α being a measure of the antioxidant activity of polyphenols against the methoxy radical.

The graphics corresponding to ECG and EGCG (Figures 4 and 6) show some anomalies. For the exponential regression approach of the results, only low concentration values of polyphenol are well fitted to exponential functions. Both polyphenols show strong antioxidant properties at very low concentrations. High values of concentration give rise to values of integration well above the values that correspond to the exponential functions. This anomalous behavior may indicate the complex processes taking place to remove methoxy radicals within the reaction mixture. This is because the degradation byproducts of polyphenols may in turn act as radical scavengers.

The best-fitting function is an exponential curve with the equation given inside the graphic and in the text.

The antioxidant efficiency coefficients of polyphenols relative to that of ferulic acid are displayed in Table 4. All polyphenols

Table 4. Values of the Antioxidant Activity Coefficients (α) of Pure Polyphenols EC, ECG, EGC, and EGCG toward the Methoxy Radical and Its Value Relative to Ferulic Acid (FA)

polyphenol	α (mmol/L)	α (FA relative)
FA	0.04	1
EC	0.34	8.5
ECG	2.43	60.75
EGC	1.51	37.75
EGCG	3.83	95.75

exhibit antioxidant efficiency well above that of the ferulic acid. The presence of the pyrogallol group and/or gallate group in the molecular structures of ECG, EGC, and EGCG greatly increases the methoxy radical scavenging relative to EC. EGCG is the most active polyphenol with both groups, gallate and pyrogallol.

These results with the spin trap method indicate that EGCG has the greatest radical scavenging activity, and it is consistent with those obtained by other more traditional methods, such as trolox equivalent antioxidant capacity (TEAC) with ABTS radical or oxygen radical antioxidant capacity (ORAC) with AAPH radical.[45,46] The values obtained with the spin trap method show a much greater difference in antioxidant activity

[a]Milligrams. [b]Ferulic acid equivalents in mg/L. [c]Ferulic acid equivalents in g/g of sample.

among the polyphenols than the other methods, although the order of activity is the same. An advantage of the spin method is that it works with ROS, the true mediators of human diseases, whereas TEAC and ORAC methods work with "atypical" and more stable radicals.

Table 5 shows the scavenging activity of WT methanolic extract with the different methods. The fact that the correlation is good in all of them is remarkable. The sensitivity of the EPR method is in the middle of the others (expressed in FA equiv/g sample (1.3 ± 0.3)) and near the value obtained for the ORAC (1.75 ± 0.6 FA equiv/g sample), the most sensitive radical scavenging method among traditional methods.

Moreover, the results obtained in this paper confirm that the presence of gallate in catechins leads to a higher radical scavenging activity. This also corroborates the results of ORAC or TEAC, which work similarly to the spin trap method. Furthermore, there is no correlation between the composition in catechins found in tea extract and the antioxidant activity values obtained by the spin trap method. That is, a greater proportion of ferulic acid equivalents in grams per liter than the value shown in Table 3 would be expected per gram per liter of tea extract. This anomaly may be because the competition established between catechins finally leads to non addition of the respective activities. It seems that the main catechin in the composition of WT, EGCG, is most responsible for the radical scavenging effect, measured by the spin trap method.

In conclusion, we have studied the antioxidant activity of WT extracts and the activity of the most abundant catechins of the WT versus methoxy radical, using ferulic acid as standard. An HPLC analysis of the extracts in MeOH shows the presence of EC, ECG, EGC, and EGCG in significant amounts. The source of methoxy radicals has been the reduction of H_2O_2 by $FeSO_4$ (Fenton reaction) in a ratio of 5:1, in MeOH as solvent. The experiments were conducted by EPR using the spin trap technique in the presence of DMPO, a good methoxy radical scavenger, and in the presence of various amounts of antioxidant. In these conditions, the oxidant mixture generates methoxy radical as the only radical species in significant amounts, being identified by EPR as the stable radical adduct DMPO−OCH_3. Therefore, we suggest that the dominant mechanism in the Fenton reaction in these specific conditions is a nonradical mechanism with a two-electron transfer process from Fe(II) to the formation of ferryl ion $[Fe^{IV}O]^{2+}$. This oxidizing species reacts with MeOH to give methoxy radical and regenerates Fe(II).

The antioxidant activity of the WT extracts and polyphenols has been measured by the decrease of the intensity of the spectral bands of the adduct DMPO−OCH_3 in the EPR with the increase of the amount of antioxidant. The activity of WT extracts is slightly higher than that of ferulic acid as shown in Table 4. In addition, the antioxidant efficiency of all catechins is much greater than that of the ferulic acid; being the activity of EGCG and ECG, which contain the gallate group, the highest and that of EC the lowest.

Nutritional and Nutraceutical Quality of Strawberries in Relation to Harvest Time and Crop Conditions

Ikram Akhatou and Ángeles Fernández-Recamales*

Department of Chemistry and Materials Science, Faculty of Experimental Sciences, and International Campus of Excellence CeiA3, University of Huelva, 21007 Huelva, Spain

ABSTRACT: Three strawberry varieties cultivated in soilless systems were studied for their content of primary and secondary metabolites in relation to harvest time and crop conditions. The three varieties were chosen based on their sensitivity level to environmental stress: Palomar (very sensitive), Festival (sensitive), and Camarosa (resistant). Throughout the campaign, three samplings were performed: December (extra-early production), January, and March (early production). Differences among cultivars and harvest times were observed based on the contents of sugars, organic acids, phenolic compounds, and antioxidant capacity. The higher levels for total anthocyanins and flavan-3-ols were found in Camarosa and Festival strawberries, both in the January harvest. The Palomar variety showed higher total sugar/total organic acids ratio in the March harvest. The influence of cultivation practices and environmental conditions was assessed by nested ANOVA and PLS-DA. Differences in the sugar and phenolic content were observed depending upon variety and coverage type. TEAC was most influenced by the substrate type.

KEYWORDS: *strawberry, quality, metabolites, cultivars, soilless system, crop conditions*

INTRODUCTION

Strawberries (*Fragaria* x *ananassa* Duch.) are one of the most popular berry fruits. They are widely used for industrial food processing but mainly consumed as fresh fruit. Its consumption has been increasing over the years due to the fact that epidemiological studies have revealed the relationship between diets which are rich in fruits and vegetables, and a lower incidence of some major human chronic diseases. Besides its proven health benefits,[1−3] strawberries have an attractive red color and flavor, and these attributes influence the choice of consumers and strawberries marketability.

The sugar content is very important from a nutritional point of view and, in combination with organic acids, contributes to strawberry taste and flavor. So, good taste is the result of a balance between sweetness provided by sugars and the sourness of organic acid. It depends not only on the total sugar and organic acid contents but also on the type and quantity of individual compounds. Different sugars differ from sweetness level percepted by human tongue. For this reason, the relative proportion of each sugar is important for sweetness perception and consumer acceptability.The strawberry color is related to the presence of pigments, among which, anthocyanins play an essential role. Moreover, anthocyanins and other phenolic compounds have attracted a great deal of attention due to their properties as antioxidants, which can protect the human body against cellular oxidation reactions through scavenging of free radicals. These antioxidants have been shown to reduce the risk of cardio- and cerebrovascular diseases, cancer and other age-related diseases[4,5] and also contribute to the high nutritional quality of the fruit. However, it should also be considered that antioxidants protective effect can be dose-dependent and some of them may be harmful at high doses.[6]

Recent studies postulated that the antioxidant potential of anthocyanins and other phenolic compounds, as a basic mechanism of biological activity, is compromised by their low level of bioavailability especially when compared to the concentrations of endogenous antioxidants. Consequently, further research in this area is required in order to target other mechanisms of action that could be involved in the health-promoting effects beyond antioxidant activity.[2,3]

Strawberry is widely cultivated in several areas under different cultivation conditions and every year new varieties come into trade and cultivation. In Spain, strawberry is one of the most important crops, especially in the south of Huelva (southwest of Spain) due to soil and climatic conditions and water quality. Strawberry production in this region is accounting for 35% of strawberry production in the EU and 90% of national production. The economic importance of this crop and its great competitivity in the strawberry market drive strawberry producers to develop new growing methods such as soilless culture,[7] and to use early varieties. These varieties come into market in winter with enhanced fruit quality, higher resistance to stresses (biotic and abiotic) as well as higher productivity.

The chemical composition of berry fruits is affected by a number of preharvest and postharvest factors. Among the preharvest factors, the variety is considered the main source of variation in composition. Their effects on the nutritional and sensorial quality are well-known[8−10] and several breeding and biotechnological programs are focused on them.[3] In addition, nutritional and nutraceutical quality is also influenced by crop conditions (environmental and cultivation techniques), sampling time and the degree of ripeness, among other factors.[11−17] Ripeness and maturity are the key factors that influence the taste of the fruit. In wild strawberry, climatic conditions, such as

light, temperature, and rainfall are the main factors to be considered since fruit maturation is depending on these conditions. However, strawberry is currently cultured under controlled conditions, where light intensity is reduced by plastic covers; temperature is higher under plastic than in the outside mainly in coldest months and moisture is controlled by regular irrigation. Other factors such as soil composition and texture can affect phytochemical content and composition of fruits. The comparison between strawberries cultivated in soil and soilless systems revealed significantly differences in the mineral composition, content of sugars and related parameters.[18] Wang and Millner[13] studied the effect of matted row, black plastic mulch, and compost socks cultural systems on the phenolic and anthocyanin content of strawberry. They observed a higher phytochemical content in the compost sock system compared to the other two production systems.

Basic knowledge related to these aspects will allow the optimization of culture systems (environmental and agronomic conditions) and also may help to prevent some physiological disorders, such as the known as dry calyx.[19] This physiological disorder differs from salinity damage and its origin is unknown. For these reasons, the aim of the present work was to assess the influence of environmental, seasonal and genetic factors on nutritional and nutraceutical quality of strawberry fruits. Also, it will allow to correlate them with changes in concentration of primary (sugars and organic acids) and secondary (phenolic compounds) metabolites and their bioactivity (antioxidant activity).

MATERIAL AND METHODS

Experimental Design and Sampling. The study was conducted in experimental plantations managed by the University of Huelva, in southwestern Spain (latitude 37°14′N, longitude 6°53′W, and altitude 23 m) where strawberry plants (*Fragaria* x *ananassa* Duch.) were grown in soilless systems. The assay consisted of two macrotunnels whose dimensions were 60 × 6 m. One of them was covered with plastic Tricoat 800 gauges on the arched structure of galvanized iron, and the other one was uncovered. Each macrotunnel contained three breeding lines of plants grown under different conductivities. Each line of breeding plants was composed of three strawberry cultivars. Finally, each cultivar was grown in three different commercial substrates.

The experimental design (Table 1) was a strip-split-split-plot, where the main plot corresponds to crop covered (T) and culture exposed (D, without plastic cover). The subplot corresponds to the electrical conductivity of irrigation (EC = 1, 2, and 3 dS/m), the subsub-plot corresponds to the variety (Palomar, Festival and Camarosa) and the basic plot represents the substrate type (coconut fiber, perlite and rockwool). The three varieties were chosen basing on their sensitivity to environmental conditions: Palomar (very sensitive), Festival (sensitive), and Camarosa (resistant). Throughout the campaign, three samplings were performed: December (extra-early production), January (early production), and March (early production).

The strawberries were harvested at commercial ripeness, specifically when 75% of the surface showed a red color, which corresponds to stage 5 in terms of commercial criterion. For each treatment, several fruits were collected in our experimental plantations to generate a representative pooled fruit sample. Immediately after harvesting, fruits were sorted. Those showing damage, defects, or small size were removed. Then, sample lots were frozen in situ in a deep freezer and shipped to our laboratory in polystyrene punnents. Fruits were washed, sepals were dissected, and finally, fruits were gently homogenized by means of a kitchen mixer. The pastes obtained were subsequently stored for 2 months at −21 °C for further analysis.

Reagents, Materials, and Apparatus. Methanol, ethanol, and acetonitrile were of HPLC grade. Trolox (6-hydroxy-2, 5, 7, tetramethylchroman-2-carboxylic acid) and ABTS (2, 2′-azino-bis (3-

ethylbenzothiazoline-6 sulfonic acid)) were purchased from Sigma-Aldrich (Steinheim, Germany), and potassium persulfate was purchased from Panreac (Barcelona, Spain).

Standards (purity ≥99%) of fructose, glucose, malic acid, citric acid, oxalic acid, tartaric acid, and ascorbic acid were purchased from Merck (Darmstadt, Germany); sucrose was purchased from Panreac (Barcelona, Spain).

Polyphenol standards were supplied as follows: cyanidin-3-glucoside, pelargonidin-3-glucoside, peonidin-3-glucoside, malvidin-3-glucoside, petunidin chloride, procyanidin B1, luteolin, apigenin, quercetin-3-*O*-glucoside, kaempferol, and isorhamnetin were purchased from Extrasynthese (Genay, France); tyrosol, (+)-catechin, procyanidin B2, vanillic acid, *m*-coumaric acid, caffeic acid, and cinnamic acid were purchased from Fluka (Buchas, Switzerland); and epicatechin gallate, gallic acid, ellagic acid, *p*-coumaric acid, and quercetin were purchased from Sigma-Aldrich (Steinheim, Germany).

HPLC was used for separation, identification, and quantification of primary and secondary metabolites in strawberry. Chromatographic analyses were performed by means of an Agilent 1100 series HPLC system (Palo Alto, CA) equipped with a photodiode-array detector (PDA), which was set to scan from 200 to 770 nm, and RI detector.

Spectrophotometric determinations were carried out using a Helios Gamma UV−vis spectrophotometer (Thermo Fisher Scientific, USA) with 1 cm path length cuvettes.

Antioxidant Capacity Assay. To assess strawberries antioxidant power, 0.5 g of homogenized fruit were extracted with 10 mL of methanol−water (80% v/v) and the pH value was adjusted to 5.0 ± 0.2 with NaOH (0.5M) and then centrifuged (at 10.000 rpm for 10 min at 4 °C). The supernatant was filtered through 0.45 μm filter and diluted with ethanol in 1:15 ratio.

The free-radical scavenging activity was determined by ABTS radical cation decolorization assay according to the method of Pellegrini et al.[20] The assay was carried out using a Helios Gamma UV−vis Spectrophotometer. The ABTS was dissolved in water to a 7 mM concentration. The ABTS radical cation ($ABTS^{\bullet+}$) was produced by reacting ABTS stock solution with 2.45 mM potassium persulfate (final concentration), and the solutions were allowed to react at room temperature in the dark for 16 h. The ($ABTS^{\bullet+}$) solution was diluted with ethanol to obtain an absorbance of 0.70(±0.01) at 734 nm. An aliquot of 100 μL of the diluted extract was added to 2900 μL of diluted $ABTS^{\bullet+}$ solution and the absorbance was read exactly 6 min after initial mixing. The linear range of the calibration standard Trolox was 0.00−100 μM. Results from the assay were expressed in terms of micromoles of Trolox per gram of strawberry fresh weight (TEAC).

Extraction and Determination of Sugars and Organic Acids. Different extraction procedures were applied to strawberry samples for the determination of individual sugars (fructose, glucose and sucrose) and organic acids (citric, malic, oxalic, tartaric and ascorbic). Homogenized fruits (5.0 g) were dissolved with 25 mL of methanol, sonicated for 30 min and then centrifuged 10 min at 10 000 rpm 4 °C. Supernatants were concentrated by means of a rotary evaporator at 40 °C and the residues were redissolved in 3 mL of 50% methanol. The concentrated extracts were filtered through 0.45 μm filters (Hydrophilic PVDF, Millipore Millex-HV, Bedford, MA) prior to their injection in HPLC system for sugars analysis.

Separation of sugars was carried out using an Ultrabase NH_2 column (5 μm, 250 mm × 4.6 mm i.d.) with temperature maintained at 35 °C. Elution was performed at isocratic conditions with acetonitrile:water (70:30 v/v) as mobile phase, and at a constant flow rate of 0.5 mL/min. Refractive index (RI) detector was used for monitoring eluated sugars.

For extraction of organic acids, 1 g of strawberries was homogenized in 10 mL of phosphoric acid pH 2.20 (mobile phase) and then centrifuged at 10 000 rpm during 10 min. The supernatant was filtered through a 0.45 μm filter. The extract was diluted with phosphoric acid (pH 2.20) in 1:4 ratio (v/v).

Organic acids were analyzed by HPLC using an Ultrabase C18 column (2.5 μm, 100 mm × 4.6 mm i.d.) as stationary phase operating at a temperature of 50 °C. Organic acids were monitored at 210 nm and ascorbic acid at 254 nm. The mobile phase was phosphoric acid pH 2.20 prepared with Milli-Q water and the separation was carried out by isocratic elution, at a constant flow rate of 0.4 mL/min. The injection volume was set at 20 μL and the duration of analysis was 10 min.

Sugars in strawberry extracts were identified by comparison of their retention times to those of standards. The organic acids were identified by their retention times and UV spectra. For quantification, calibration curves were constructed using standards at 0.5−8 mg/L (ascorbic acid), at 1−60 mg/L (oxalic acid), at 20−100 mg/L (tartaric and malic acids), at 60−200 mg/L (citric acid), and at 1−50 g/L (sugars). Concentrations were expressed as g per kg fresh weight.

HPLC Analysis of Phenolic Compounds and Anthocyanins. Samples were prepared as described above for extraction of sugars. Extracts were injected (20 μL) into a reverse phase Ultrabase C18 column (2.5 μm, 100 mm × 4.6 mm i.d.) following the methodology previously described by our previous studies,[12] but adapted to the new column. The modified method was further validated and their performance characteristics were confirmed. As for anthocyanins, the HPLC analyses was carried out according to the methodology described by Kallithraka et al.[21]

For analysis of colorless flavonoids and phenolic acids, elution solvents were water:methanol:acetic acid (93:5:2) as eluent A, and methanol:acetic acid (98:2) as eluent B. Applied elution conditions were as follows: 0−29 min, 40% B isocratic; 29−34.8 min, linear gradient 40−60% B; 34.8−37.7 min, linear gradient 60−75% B; 37.7−40.6 min, linear gradient 75−100% B; 40.6−46.4 min 0% B. The flow was 0.8 mL/min, and the column temperature was set at 20 °C.

As for anthocyanins, the mobile phase consisted of 10% aqueous formic acid (A) and HPLC grade methanol (B). The gradient profile was as follows: 0−0.70 min, 5% B; 0.70−16.60 min, linear gradient 5-50% B; 16.60−18.60 min, linear gradient 50−95% B; 18.60−20.60 min 95% B isocratic. Flow rate was 0.8 mL/min and temperature of the column was set at 30 °C.

Identification of phenolic acids and flavonoids was achieved by comparison of their retention times and UV spectra at specific wavelenght with those of appropriate standards. For quantification, the external standard method was applied considering the following wavelengths: 260 nm for ellagic acid and derivatives, 280 nm for benzoic acids and flavan-3-ols, 320 nm for cinnamic acids, and 360 nm for flavonols. Each standard was dissolved in methanol at a concentration of 1 mg mL^{-1}, and five diluted solutions from these stock solutions were used to prepare calibration curves of each standard (for duplicate). Anthocyanins were monitored at 520 nm. Calibration curves were constructed using standards at 1−50 mg/L (cyanidin-3-glucoside) and at 10−200 mg/L (pelargonidin-3-glucoside). The obtained linear equation was used to calculate the concentration of anthocyanins in strawberries.

Statistical Analysis. ANOVA followed by the Newman-Keuls post hoc test was applied in order to make multiple comparisons of mean values to evaluate if there were significant differences between the studied strawberries cultivars at different times of harvesting. A significant difference was statistically considered at the level of $p < 0.05$. Nested ANOVA was carried out for assessing the influence of different cultural and environmental factors. Data processing was performed using Statistica software package for statistical analysis (Statsoft, USA).

Pattern recognition (PR) techniques, including principal component analysis (PCA) and partial least-squares discriminant analysis (PLS-DA), were also carried out using Statistica software (StatSoft, USA) and SIMCA-P v11.5 software (UMETRICS, Umeå, Sweden), respectively. PCA is one of the most powerful and common techniques used for reducing dimensionality of large sets of data without losses of information. New variables are obtained as a linear combination of the original ones. They are calculated in such a way to keep most of the original data set information, and mantain the least possible number of new variables or principal components (PCs). PLS-DA is a supervised pattern recognition method based on searching an optimal set of latent variables (or components) in order to discriminate between the previously defined categories. PLS-DA method consists of a classical PLS regression where the dependent

variable Y is categorical and represents samples class membership. It can be conveniently used when the number of objects is fewer than the number of variables. The principle of PLS is to find the components in the matrix $\boldsymbol{X}$ (matrix of predictors) which describe, as much as possible, the relevant variations in the input variables and, at the same time, have maximal correlation with the target value in $\mathbf{Y}$ (matrix of responses). This gives less weight to the variations which are irrelevant or noisy.[22] That is, PLS searches for a set of components that performs simultaneous decomposition of X and Y with the constraint that these components explain, as much as possible, the covariance between X and Y. The optimal number of components is, in general, achieved by cross-validation techniques. The overall quality of PLS-DA models was described by $R_X{}^2$ and Q^2 values. $R_X{}^2$ is defined as the proportion of variance in data explained by models and indicates goodness of fit. Q^2 measures the predictive ability of the model.

The PCA and PLS-DA output consisted of scores plots and loading plots. They allow to visualize the contrast between different samples and to explain class separation, respectively. Prior to both, PCA and PLS-DA, data were mean-centered and scaled to "Unit Variance".

RESULTS AND DISCUSSION

Chemical Composition and Antioxidant Capacity. In this study, the chemical composition of three strawberry varieties cultivated in a soilless system was assessed. Table 2 shows the mean, minimum, and maximum values of data obtained from analysis of the different chemical parameters.

Table 3. Weather Parameters Recorded Outside the Macrotunnel During the Harvest Time

harvest time	min temp (°C)	max temp (°C)	rainfall (mm)	relative humidity (%)	global radiation (MJ/m^2)
December	8.2	16.1	156.9	86.4	197.78
January	6.6	15.9	55.2	88.9	246.45
March	7.5	18.8	124	82.4	504.37

Sugars, organic acids, and phenolic compounds were determined in strawberries and expressed on a fresh basis. Table 2 also shows antioxidant activity values.

The soluble sugars identified and quantified in strawberry fruits were fructose, glucose, and sucrose. Fructose was the major sugar (50% of total sugars) in all cultivars, glucose being the second one (45%). The relationship between the content of both sugars was about unity, regardless of the cultivar. In general, the analyzed fruits contained lower sucrose concentration compared to fructose and glucose, and its participation in total sugar content ranged from <LD (below the detection limit) to 20% of total sugar content. As regards the organic acids, citric acid was the major organic acid found in analyzed strawberries followed by malic acid (Table 2). Other organic acids such as oxalic, tartaric, and ascorbic acids were found in

dx.doi.org/10.1021/jf500769x | J. Agric. Food Chem. 2014, 62, 5749−5760

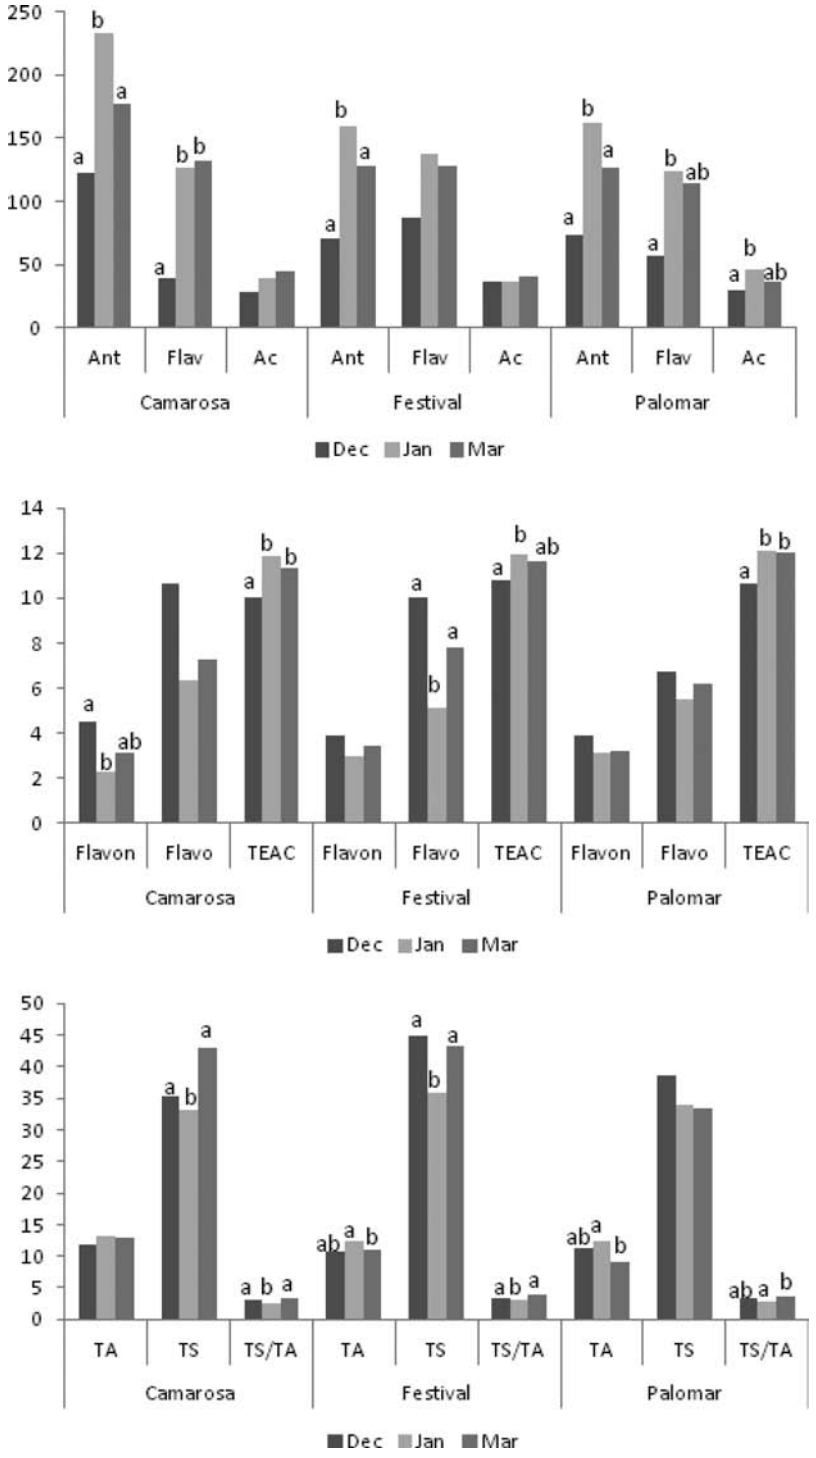

Figure 1. Content of phenolic compounds (sum of anthocyanins (Ant), flavan-3-ols (Flav), acids and derivatives (Ac), flavones (Flavon) and flavonols (Flavo)), sugars (TS), organic acids (TA), total sugars/total organic acids ratio (TS/TA), and antioxidant activity (TEAC) in three strawberry cultivars harvested in December (Dec; n = 14), January (Jan; n = 73), and March (Mar; n = 50). Columns belonging to the same set of data with different letters are significantly different (p < 0.05) by Kruskal–Wallis test.

lower concentrations. These results are in good agreement with those found in the literature.[13,15−17] The Festival variety presented the highest mean contents in the three sugar types (41.05 mg/g, as sum of sugars). The lowest level of total sugar was found in cv. Camarosa (38.92 mg/g), which had the highest contents of all acids (13.08 mg/g). In view of these results, Festival was the sweetest genotype and also had the highest total sugars/total acids ratio; therefore, this cultivar was seemingly more palatable and balanced. However, this should be confirmed by consumer panels.

Twenty five different phenolic compounds were identified and quantified. They were classified into five different groups: (a) phenolic acids and derivatives (gallic, vanillic, tyrosol, caffeic, *m*-coumaric, *p*-coumaric, caffeic derivative, ellagic and ellagic derivative acid); (b) flavonols (quercetin, kaempferol, hiperoside, isorhamnetin and quercetrin); (c) flavones (luteolin

electrical conductivity (B(A))	$MS_B^2 = \frac{rdc\sum_{i=1}^{a}\sum_{j=1}^{b}(\overline{x_{ij}} - \overline{x_i})^2}{a(b-1)}$	MS_B^2/MS_C^2	$(MS_B^2 - MS_C^2)/rdc$
variety (C(B(A)))	$MS_C^2 = \frac{rd\sum_{i=1}^{a}\sum_{j=1}^{b}\sum_{k=1}^{c}(\overline{x_{ijk}} - \overline{x_{ij}})^2}{ab(c-1)}$	MS_C^2/MS_D^2	$(MS_C^2 - MS_D^2)/rd$
substrate (D(C(B(A))))	$MS_D^2 = \frac{r\sum_{i=1}^{a}\sum_{j=1}^{b}\sum_{k=1}^{c}\sum_{l=1}^{d}(\overline{x_{ijkl}} - \overline{x_{ijk}})^2}{abc(d-1)}$	MS_D^2/MS_R^2	$(MS_D^2 - MS_R^2)/r$
residual	$MS_R^2 = \frac{\sum_{i=1}^{a}\sum_{j=1}^{b}\sum_{k=1}^{c}\sum_{l=1}^{d}\sum_{n=1}^{r}(\overline{x_{ijkln}} - \overline{x_{ijkl}})^2}{abcd(r-1)}$		MS_R^2

and apigenin); (d) flavan-3-ols (catechin, epicatechin gallate and procyanidins B1 and B2); (e) anthocyanins (pelargonidin-3-glucoside, cyanidin-3-glucoside and pelargonidin-3-rutinoside).

Total phenolic content (considering the sum of all the individual phenolics) ranged from 307.43 μg/g of fresh fruit (cv. Palomar) to 373.82 μg/g of fresh fruit (cv. Camarosa). Anthocyanins were the predominant group, accounting for 48.0% of the total phenolic content. This is in agreement with results found in the literature.[3,23] As also previously reported,[10,24] the three major anthocyanins were pelargonidin-3-glucoside (mean value of 110.14 μg/g), pelargonidin-3-rutinoside (mean value of 41.95 μg/g) and cyanidine-3-glucoside (mean value of 3.66 μg/g). The levels of pelargonidin-3-glucoside and cyanidine-3-glucoside were in agreement with those reported by Crespo et al.[15] Other minor anthocyanins pelargonidin derivatives were observed but they could not be quantified. Camarosa cultivar was the richest in anthocyanins, which agreed well with our previous study findings[12] and with results reported by other authors.[25]

Flavan-3-ols was the second most important group in quantitative terms and accounted for 37.0% of the total phenolic content. In absolute terms, the highest levels were found in cv. Festival (143.01 μg/g of fresh fruit, as mean value) and the lowest in cv. Palomar (120.74 μg/g of fresh fruit, as mean value). Procyanidin B1 was the predominant flavanol in the three surveyed strawberry cultivars, with a mean value of 51.2 μg/g, following by catechin (37.6 μg/g) and procyanidin B2 (32.9 μg/g). Catechin has been reported to be the major flavan-3-ol in Spanish strawberries.[26] These authors found a global flavanols content of 4.9 mg/100 g, and the catechin content (1.57 mg/100 g) was lower than our results. However, Padula et al.[10] and Aaby et al.[27] reported higher contents of catechin in cv. Camarosa (5.86 mg/100g) and in Totem (6.2 mg/100 g) and Puget Reliance (9.0 mg/100 g) cultivars, respectively. With regard to the proanthocyanidins content, de Pascual et al.[26] reported the presence of four proanthocyanidins dimers (B1, B2, B3, and B4) in strawberry, being B3 the most abundant. Aaby et al.[23] quantified three procyanidin dimers, a trimer, and a pentamer in 27 strawberry cultivars using HPLC-DAD-MS^2. The total proanthocyanidin concentration ranged between 8.6 and 36.8 mg/100 g of fw. The results obtained by Buendía et al.[28] were higher (54−168 mg/100 g of fw), as expected, due to the fact that they used the phloroglucinolysis

dx.doi.org/10.1021/jf500769x | J. Agric. Food Chem. 2014, 62, 5749−5760

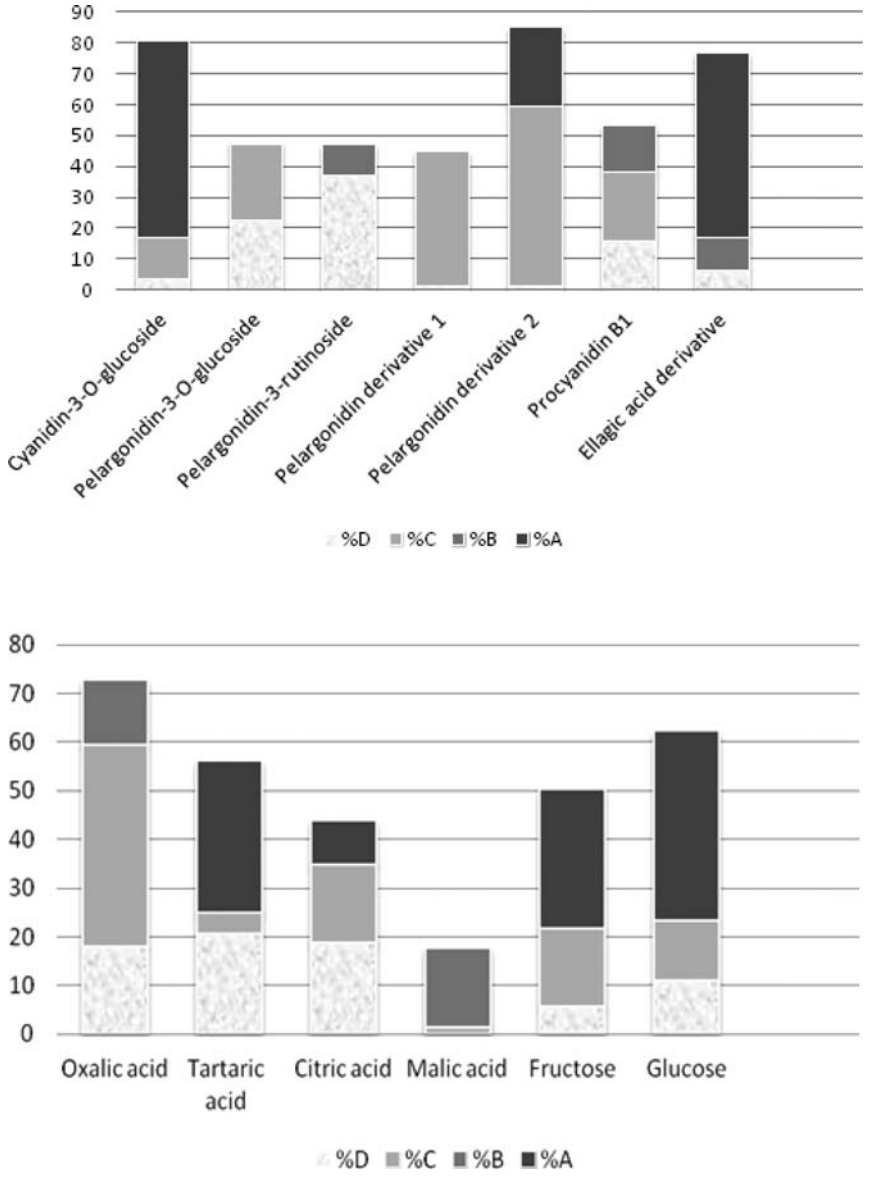

Figure 3. Variance component (%) corresponding to the different sources of variability coverage (A), electrical conductivity (B), variety (C), and substrate (D).

method. This approach generally leads to higher results compared with other methods. So, proanthocyanidins were the main strawberry phenolics found by these authors. In general, our results were lower than those previously found in the literature[27,28] and this could be explained by the analytical method used in addition to the differences between cultivars. Among the berries, the occurrence of galloyl esters was typical of strawberries.[29] Epicatechin gallate was found in the three surveyed strawberry cultivars (mean value 2.47 μg/g). Our results were lower than those reported by de Pascual et al.[26]

In general, the differences between results found in the literature and those shown here may be due to the variation in genotype, production area, soil and climatic conditions, and/or agricultural practices. Some of the differences may also stem from the variation in sample preparation and analysis procedures. Sample preservation and sample preparation parameters are critical for accurate estimation of phytochemicals present in foods. The freezing and thawing conditions can affect the content of strawberry phenolics. The extraction efficiency of phenolic compounds is influenced by the type of solvent, extraction procedure and conditions. Therefore, these factors must be taken into account when comparing data with literature.

The total content of phenolic acids of the three strawberry cultivars was similar among them, as can be seen in Table 2. This group of compounds comprised 12.0% of the total content of phenolics. Ellagic and ellagic derivative acids are the major phenolic acids in the samples studied and represent approximately 50% of the total phenolic acids). This was in consonance with other authors findings.[30] The highest level of *p*-coumaric acid was found in cv. Palomar (2.20 μg/g of fresh fruit, as mean value) and the lowest, in cv. Festival (1.55 μg/g of fresh fruit, as mean value). Other hydroxycinnamic acids such as *m*-coumaric acid, caffeic acid and caffeic acid derivative were also quantified. The last one was the most abundant (mean value 2.5 μg/g). Regarding hydroxybenzoic acids, vanillic (mean value 3.23 μg/g) and gallic (mean value 4.64 μg/g) acids were found in all samples analyzed. Previous

[a]Figures in bold indicate significant F-tests at the level of significance showed in the table.

studies on strawberries have generally reported variable composition and contents of phenolic acids. Hydroxycinnamic acids occurred mainly as esters. Thus, *p*-coumaroyl-glucoside acid has been described as the major hydroxycinnamic acid in strawberries,[10,28,29,31,32] while *p*-coumaric acid has been described as the most abundant aglycon.[29,33] Padula et al.[10] reported relatively high contents of caffeic acid (from 0.7 to 11.40 mg/100 g fresh weight) and ferulic acid (from 0.76 to 13.99 mg/100 g fresh weight) in 20 strawberry cultivars grown in Italy. On the other hand, Mättila et al.[33] found caffeic, *p*-coumaric, *p*-hydroxybenzoic, cinnamic, and gallic acids in three strawberry cultivars grown in Finland (expressed as aglycones) but ferulic and vanillic acids were only detected in some of the strawberry cultivars. However, Määttä et al.[29] reported only the presence of p-coumarylester in cv. Jonsok.

The minor groups were flavonols and flavones, which accounted for 2.5 and 0.9%, of the total phenolic compounds, respectively. Regarding the family of flavonols, the mean content was 8.3 μg/g. The highest levels were found in cv. Festival (9.3 μg/g of fresh fruit, as mean value) and the lowest in cv. Palomar (7.6 μg/g of fresh fruit, as mean value). Hiperoside (quercetin-3-O-galactoside) was the most important flavonol in terms of quantity (3.15 μg/g) in the three cultivars. Other major flavonols were quercetin and isorhamnetin with mean values of 2.28 and 1.25 μg/g, respectively. Kaempferol and quercitrin were found in lower levels, whereas myricetin was not found at detectable levels in analyzed samples. Furthermore, two flavones, luteolin and apigenin, were detected in the three strawberry varieties. The mean content was 0.93 μg/g for luteolin and 2.16 μg/g for apigenin. As with the phenolic acids and other flavonoids, there are differences between results found in the literature. Glucosides and glucuronides of quercetin and kaempferol have been identified as the main flavonols in strawberry.[29,34] Our results for flavonol contents, averaging 8.4 μg/g, were low compared to those reported in the literature.[27−29]

The total antioxidant capacity was measured according to the ABTS method. Trolox (vitamin E analogue) was used as standard, and results, expressed as micromoles of Trolox equivalents per gram (TEAC), are displayed in Table 2. It can be observed that TEAC values were quite similar in the three surveyed strawberry cultivars, with a mean value of 11.66 μmoles TE/g. These results were of the same magnitude as those previously reported.[8,15] Jossuttis et al.[14] reported higher values of antioxidant capacity for two strawberry cultivars (Everest and Elsanta) grown in Germany. The cultivars were grown in three different conditions. Two of them were cultivated in a tunnel covered with two films which vary in their UV transparency, and another one was cultivated under open-field conditions.

Comparison of Harvest Time. The three varieties of strawberry were planted in September and harvested in

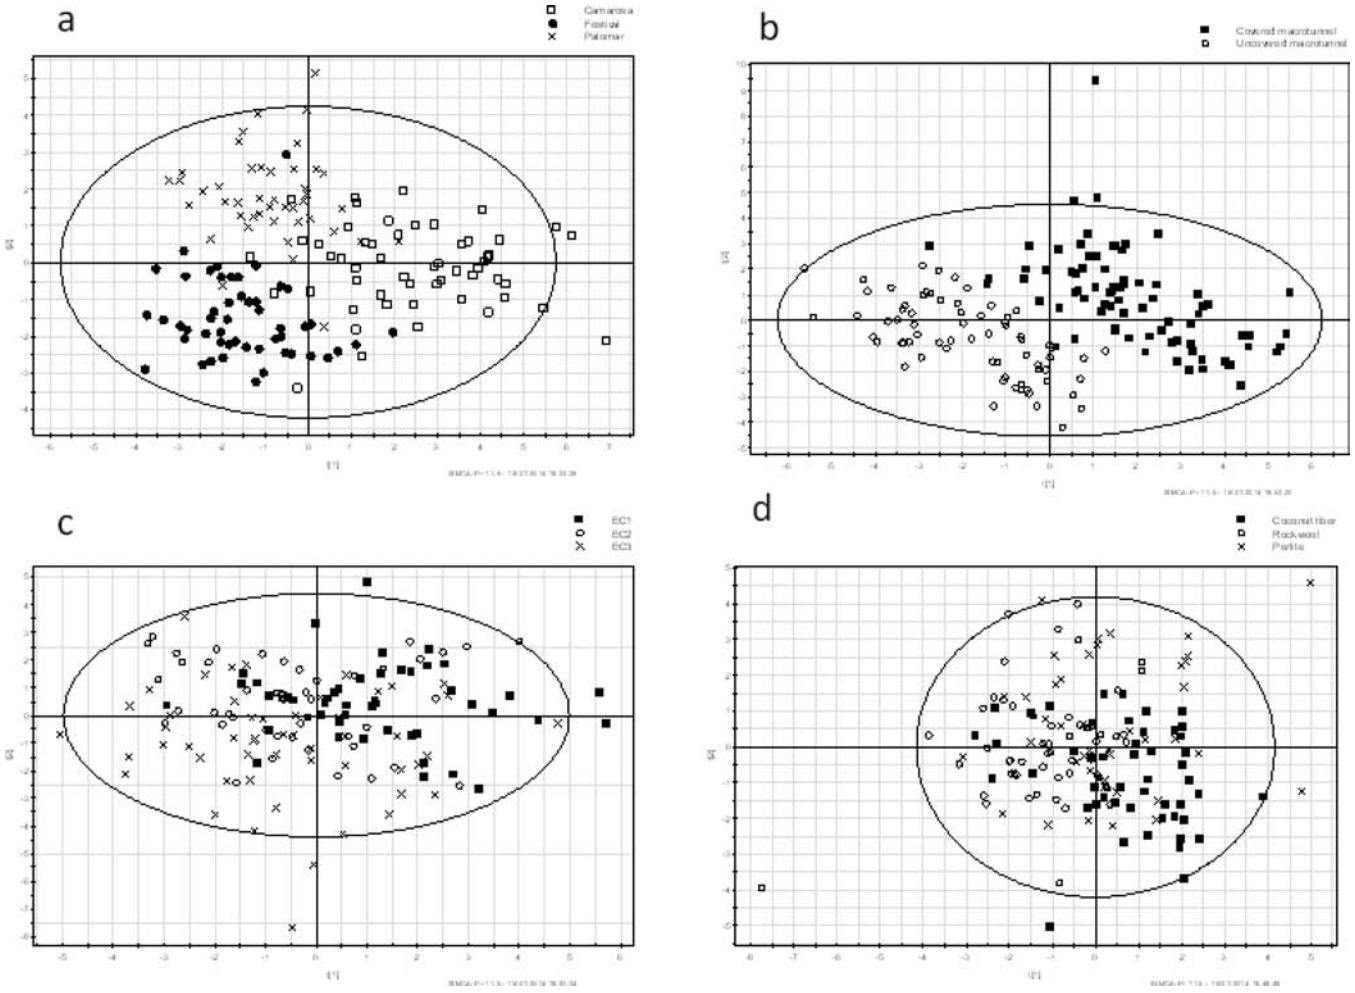

Figure 4. PLS-DA scores plots based on chemical composition of strawberry samples (n = 162) according to cultivars (a), covered or uncovered macrotunnel (b), electrical conductivity (c), and substrate (d).

December (extra-early production), January (early production), and March (early production) in order to assess differences in their profiles as a function of both variety and harvest time. Table 3 shows the monthly weather parameters (outside the macrotunnel) during the experimentation period. These values are considered normal according to the climatological data recorded in the area (period 1971−2000).

The contents of average total sugars, total organic acids and five groups of polyphenols and TEAC as a function of strawberry variety and harvest time are displayed in Figure 1. The comparison between three harvest times shows a similar trend in the three varieties. The amount of anthocyanins and flavan-3-ols (considering the sum of all individual phenolics) was higher in January (when rainfall, maximum and minimum temperatures were lower and relative humidity higher), whereas the total sugars content was more abundant in March (when maximum temperature and global radiation were higher). It has been previously observed that the content of many phenolic compounds and the antioxidant capacity increase in berry fruits as temperature increases.[32] On the other hand, low light intensity[35] and high temperatures[36] in day and night lead to decreased synthesis of sugar and ascorbic acid. Our results are apparently contradictory with these findings. However, Pereira et al.[37] observed it difficult to separate the effects of temperature from the photochemical effects. Moreover, the cultivation of strawberries under plastic tunnels decreases the dependency of quality on the climatic conditions.

The higher levels for total anthocyanins and flavan-3-ols were verified in cv. Camarosa and Festival strawberries, respectively, both in January harvest; while the fruits of Palomar variety showed higher total sugar/total organic acids ratio in March harvest.

In order to find out significant differences of analyzed compounds between the three considered harvested times, the multiple comparison test of Kruskal−Wallis was applied. Results are also shown in Figure 1. The harvests of December and January present statistical differences for anthocyanins and antioxidant activity in the three varieties. Additionally, Camarosa and Palomar cultivars also present differences for flavan-3-ols, and Festival cultivar for flavonols. Taste related parameters differentiate fruits harvested in January from March ones. The TS/TA ratio increased for the three varieties surveyed in March. Due to the importance of this parameter for strawberry flavor, seasonal changes in this ratio may influence consumer acceptance.

In order to confirm these results a principal component analysis (PCA) was carried out. PCA allows to visualize data trends and to provide a first evaluation for the discriminant power of the variables. PCA is applied to the data set to obtain linear combinations of variables, which are called principal components (PCs). It retains information about the variability

dx.doi.org/10.1021/jf500769x | J. Agric. Food Chem. 2014, 62, 5749−5760

of the data set, so that the first PC expresses the largest variability, and each successive PC represents as much of the residual variability as possible. In this case, five PCs, which account for 60% of the total variance, were extracted according to Kaiser Criterion (eigenvalues higher than 1.0). Figure 2 shows samples distribution in the plane defined by two first components. As can be observed, samples harvested in January and December appear separated along of PC1, while fruits harvested in March are located in the negative part of PC2. The variables that contribute most to the first component are pelargonidin-3-glucoside and the sum of anthocianyns and flavan-3-ols, all with negative loadings. In the case of PC2, the most contributing variables are glucose, sum of sugars and total sugar/total organic acids ratio, also with negative loadings. Regarding the meteorological variables, PC1 is positively correlated to minimum temperature and rainfall. PC2 is positively correlated to relative humidity and negatively to maximum temperature and global radiation.

Influence of Agronomical Practices. To meet the second overall objective of the study, that is, to examine changes in fruit quality depending on the cultivation practices and environmental conditions, a nested ANOVA was carried out. For this test, the expressions gathered in Table 4 were applied.

Nested ANOVA is used when the variation of the factor is subordinated to another variation factor. So, the survey had the following objectives: to explore whether chemical composition of strawberries varied in a purely random way across the two macrotunnels or whether it showed a variation due to different factors studied (electrical conductivity (B), variety (C), and substrate (D)). In the last case, the variance components associated with the levels of nested design is evaluated (Figure 3). The effect significance of factors is tested by Fisher F test.

Table 5 shows the F-test results (as p-value) from nested ANOVA for each variable. As can be observed, no statistically significant differences were found in the content of catechin, epicatechin gallate, and luteolin between two macrotunnels, electrical conductivity, variety or substrate. The type of coverage has a significant influence on the content of cyanidin-3-*O*-glucoside, pelargonidin-3-*O*-glucoside, pelargonidin-3-rutinoside, pelargonidin derivative 2, tyrosol, vanillic acid, *m*-coumaric acid, ellagic acid derivative, caffeic acid and caffeic acid derivative, apigenin, all flavonols, sugars and organic acids except for malic acid. So, the content of anthocyanins was higher in the cover macrotunnel, while the levels of flavan-3-ols, flavonols, ellagic acid and derivative, cinnamic acids and sugars were higher in the uncovered macrotunnel. These results were in agreement with those reported by Josuttis et al.[14] These authors found a higher content of flavonols and a lower total content of anthocyanins and pelargonidin related anthocyanins in open-field strawberry fruits compared to tunnel-grown fruits. The F-test also indicates significant differences between variety, mainly for the anthocyanins, sugars and organic acids. The electrical conductivity and type of substrate also influence the content of some studied compounds, mainly phenolic compounds. Keutgen and Pawelzik[38] observed that the NaCl stress significantly increased the concentration of most of organic acids in cv. Elsanta (sensitive), while remained fairly constant in cv. Korona (less sensitive). They also observed that in both cultivars the individual sugars decreased progressively due to NaCl. On the other hand, these authors found that moderate salt stress significantly increased the antioxidant capacity, total phenolic compounds and anthocyanins in cv Korona.[39]

Figure 3 shows, for a selection of variables, the estimated contribution of the various levels of the nested design to the total variance. For most variables, the variance of the residual errors was the largest variance component. For phenolic compounds the variance components associated with the coverage and variety contributed substantially to the total variance in addition to residual error. These findings are consistent with those found by other authors. They identify the genotype as the main source of variation for phenolic compounds[8,10,15] but they are also affected by crop conditions.[11,13,14] For sugars, the variance component due to coverage contributed noticeably to the total variance. Finally, the organic acids had different patterns of variation. The variance component associated with the substrate generally account for 1/5 of the total variance for citric, tartaric and oxalic acids. For oxalic and tartaric acids, the higher source of variability was due to variety and coverage, respectively.

The influence of agronomical practices was also investigated by multivariate chemometric method. Data were subjected to supervised chemometrics using partial least-squares discriminant analysis (PLS-DA). PLS-DA is a supervised method that explains the maximum variation in the data set (X) using a dummy matrix (Y), which can be used to sharpen the separation between groups or observations. Four models were constructed to assess the influence of strawberry cultivars and the growing conditions (macrotunnel type, electrical conductivity and substrate). In the first case, a two-component model was obtained with good quality of fit and validity (R^2 = 0.202) and prediction (Q^2 = 0.529). Figure 4a shows the scores plot obtained for the three strawberry cultivars, grouped accordingly to the first two components. As it can be observed, the separation between cultivars was satisfactory and they were clearly discriminated. PLS models also provided the possibility of obtaining a quantitative measure of the discriminating power of each variable by means of variable importance for the projection (VIP). This is a weighted sum of squares of the PLS loadings which takes into account the amount of explained Y-variance of each PLS component. X-variables, characterized by VIP values which are larger than 1, had major importance for modeling the responses, whereas variables with VIP values smaller than 0.5 had little or no influence on the model. The VIP scores indicated that anthocyanins were the most important parameters for cv. Camarosa, whereas glucose, fructose, total sugars and TS/TA ratio were more relevant for cv Festival and phenolics acids and flavonols for cv. Palomar.

A second model was obtained with data from strawberries grown in two macrotunnels, covered and uncovered. This three-component model explained 35.5% of the variance (R^2 = 0.355), and the t1 and t2 components allowed discrimination between two sets of samples (Figure 4b): strawberries grown in covered macrotunnel (positioned on the right side of the plot) and strawberries grown in uncovered macrotunnel (positioned on the left side of the plot). The variables which contribute the most to the discrimination between samples were anthocyanins, ellagic acid derivative, glucose and fructose contents and total sugars. All these variables had VIP values higher than 1.0. The loading plot showed how the first component (t1) was related to glucose, fructose, total sugars and ellagic acid derivative on the negative side where the uncovered grown samples were situated (data not shown), and with pelargonidin and their derivatives on the positive side where covered grown samples were situated, confirming the results discussed above.

The effect of the other two factors, electrical conductivity and substrate, was also evaluated. In this case, the PLS-DA scores plots showed a poor separation between samples (Figure 4c,d), resulting in low predictability of the models as indicated by a Q^2 of 0.0878 and 0.0188, for electrical conductivity and substrate, respectively.

In summary, we have shown that the content of several metabolites related to strawberry quality, including sugars, organic acids, phenolic compoundas and TEAC, depend on cultivar and growing conditions. Festival was the sweetest genotype and also had the highest total sugars/total acids ratio, whereas Camarosa was richest in anthocyanins. Considering the harvest time and after applying pattern recognition techniques such as PCA, it was concluded that strawberry harvested in January and March (early production) had higher quality. Fruits harvested in January were richer in phenolic compounds whereas fruits harvested in March were richer in taste-related compounds. The influence of agronomical conditions was investigated by nested ANOVA and PLS-DA. The type of coverage and the variety were the main source of variation for most of the variables studied mainly phenols and sugars. A good discrimination between three cultivars and macrotunnel type was also achieved by PLS-DA, confirming the results from Nested ANOVA. The VIP scores indicated that anthocyanins were the most important parameters for cv Camarosa, whereas glucose, fructose, total sugars and TS/TA ratio were more relevant for cv Festival and phenolics acids and flavonols for cv Palomar. Strawberries grown in covered macrotunnel were richer in pelargonidin and their derivatives. Uncovered grown samples were richer in glucose, fructose, total sugars, and ellagic acid derivative. Other growing conditions, such as electrical conductivity and substrate did not provide a clear discrimination between samples.

Supporting Information

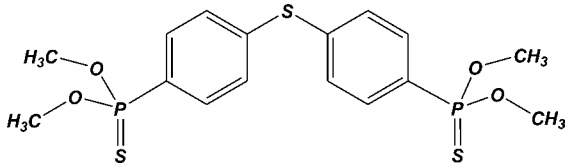
ABSTRACT: A series of temephos (Tem) derivatives were synthesized and characterized by ^{31}P, ^{13}C, and ^{1}H NMR and FT-IR spectral techniques. Also, the crystal structure of compound **9** was investigated. The hydrogen bonding energies (E^2) were calculated by NBO analysis of the crystal cluster. The activities and the mixed-type mechanism of Tem derivatives were evaluated using the modified Ellman's and Lineweaver−Burk's methods on cholinesterase (ChE) enzymes. The inhibitory activities of Tem derivatives with a P═S moiety were higher than those with a P═O moiety. Docking analysis disclosed that the hydrogen bonds occurred between the OR (R = CH_3 and C_2H_5) oxygen and N−H nitrogen atoms of the selected compounds and the receptor site (GLN and GLU) of ChEs. PCA−QSAR indicated that the correlation coefficients of the electronic variables were dominant compared to the structural descriptors. MLR−QSAR models clarified that the net charges of nitrogen and phosphorus atoms contribute important electronic function in the inhibition of ChEs. The validity of the QSAR model was confirmed by a LOO cross-validation method with q^2 = 0.965 between the training and testing sets.

KEYWORDS: *bisphosphoramidothioate, crystal structure, cholinesterase inhibitor, QSAR, molecular docking*

INTRODUCTION

In recent years, organophosphorus compounds have been of great interest. A wide range of applications in the areas of medicinal, agricultural, and industrial chemistry have been found owing to their significant biological and physical properties.[1] Among many known phosphorus compounds, bisphosphoramidothioates (BPAT) with the general structure of $R_1R_2P(S)NH-X-NHP(S)R_1R_2$ comprise an important class of compounds that exhibit insecticide properties to inhibit cholinesterase (ChE) enzymes.[2] Little attention has been given to the interaction mechanism of the ChE enzymes and BPATs.[3,4] Temephos (Scheme 1) with the general formula is

Scheme 1. Synthesis Pathway and Chemical Structure of Compounds 1−24



a useful insecticide to control the larvae of mosquitoes, midges, and moths;[5,6] however, it has side effects on humans as an anti-acetylcholinesterase (AChE) as well as carcinogenic potential.[7] Therefore, designing and producing the selective compounds of Tem category having high insecticide potential with fewer anti-AChE and carcinogenic effects are required. To extend and to evaluate this problem, two new methods have so far been introduced to overcome the inhibition mechanism.[8] Integrated molecular docking and QSAR approaches were employed to explore the binding interactions between the Tem analogues and the AChE and butyrylcholinesterase (BChE).[9] Molecular docking was performed to define a model for the comprehension of the binding interactions between ligands and receptor. QSAR models elucidated the effective parameters of molecular structure computed by the density function theory (DFT) in the inhibition process.[10]

In this study, 24 novel Tem analogues with the general formula of $(RO)_2P(X)YP(X)(OR)_2$, (X = O and S; Y = NH−$(CH_2)_2$−NH, NH−$CH(CH_3)$−CH_2−NH, N(CH_3)−$(CH_2)_2$−N(CH_3), NH−$(CH_2)_3$−NH, NH−CH_2−$C(CH_3)$−CH_2−NH, NH−$(CH_2)_4$−NH, N−$(CH_2)_4$−N, N−$(CH_2)_5$−N, and NH−(C_6H_{10})−NH; R = OCH_3 and OC_2H_5) (**1−24**) were synthesized and characterized by ^{31}P, ^{13}C, and ^{1}H NMR and IR spectroscopy. The solid state structure of $(CH_3O)_2P(S)$-$NH(C_6H_{10})NHP(S)(OCH_3)_2$ (**9**) was determined by X-ray crystallography and used as reference for quantum mechanical (QM) calculations at the B3LYP level. The electronic aspects of two different hydrogen bonds (P═S···H−N) in the crystal structure of compound **9** were studied by NBO and Atoms in Molecules (AIM) analyses. The activities of Tem derivatives on AChE and BChE were determined using a modified Ellman's method.[11] Also, the inhibition mechanisms of the prepared compounds were evaluated by Lineweaver−Burk plot.[12] Docking analysis was used to find the most efficient parameters to introduce a better mechanism of interaction between the

selected molecules and the receptor site of human AChE and BChE. The appropriate molecular structural parameters were computed by DFT method and adopted to construct QSAR equations.

MATERIALS AND METHODS

Instruments. The enzyme AChE (human erythrocyte; Sigma catalog no. C0663) and BChE (bovine erythrocyte, Sigma catalog no. B4186), acetylthiocholine iodide (ATCh, 99%, Fluka), 5,5′-dithiobis-(2-nitrobenzoic acid)) (DTNB, 98%, Merck), Na_2HPO_4, NaH_2PO_4 (99%), ethylenediamine, propylenediamine, 1,2-propylenediamine, 2,2-dimethylpropylenediamine, butylenediamine, and 1,2-cyclohexylanediamine (99%, Merck), *N*,*N*′-dimethylethylenediamine (95%, Alfa Aesar), piperazine (99%, Acros), homopiperazine (98%, Acros), triethylamine (99.5%, Merck), $CDCl_3$ (99%, Sigma-Aldrich), $(CH_3O)_2P(S)Cl$, $(CH_3CH_2O)_2P(S)Cl$, and $(CH_3CH_2O)_2P(O)Cl$ (97%, Sigma-Aldrich) were used as supplied. ^1H, ^{13}C, and ^{31}P spectra were recorded on a Bruker Avance DRX 500 spectrometer. ^1H and ^{13}C chemical shifts were determined relative to internal TMS and ^{31}P chemical shifts relative to 85% H_3PO_4 as external standard. Infrared (IR) spectra were recorded on a Shimadzu spectrometer (model IR-60) using KBr pellets. Melting points were obtained with an electrothermal instrument. A UV spectrophotometer was used using a Perkin-Elmer Lambda 25. The insecticide and anti-AChE activities of Tem derivatives were predicted by the Prediction of Activity Spectrum for Substances (PASS) software (version 1.193).[13] The three-dimensional X-ray structures of human AChE (PDB code 1B41) and BChE (PDB code 1POI) were chosen as the template for the modeling studies of selected compounds. The PDB files about the crystal structure of the ChE enzymes domain bound to P22303 (1B41.pdb) and P06276 (1POI.pdb) were obtained from the RCSB protein data bank (http://www.pdb.org). Molecular docking to both ChEs was carried out by using the AutoDock 4.2.3 package software.[14] The correlation analysis was performed by the Statistical Package for Social Scientists (SPSS), version 16.0 for Windows.[15] X-ray data of compound **9** were collected at 120 K on a Bruker SMART 1000 CCD area detector with graphite monochromated Mo Kα radiation (λ = 0.71073 Å) and refined by full-matrix least-squares methods against F^2 with SHELXL97.[16] CCDC 863609 contains the supplementary crystallographic data for compound **9**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax (+44) 1223-336-033 or e-mail deposit@ccdc.cam.ac.uk).

Statistical Analysis. To identify the effect of descriptors on the activity of AChE and BChE, QSAR studies were undertaken using the model described by Hansch and Fujita.[17] The stepwise multiple linear regression (MLR) procedure was used for model selection, which is a common method used in QSAR studies for selection descriptors. MLR fits a linear model of the form (eq 1)

$$Y = b_0 + b_1X_1 + b_2X_2 + ... + b_nX_k + e \quad (1)$$

where Y is a dependent variable, X_1, X_2, ..., X_k are independent variables (descriptors), e is a random error, and b_0, b_1, b_2, ..., b_k are regression coefficients.[18] The MLR method performed by the software package SPSS 16.0 was used for selection of the descriptors. The electronic and structural descriptors (X) were obtained by both the quantum chemical calculations and theoretical studies.[19] The electronic descriptors include the highest occupied and the lowest unoccupied molecular orbital (E_{HOMO} and E_{LUMO}), electrophilicity (ω), polarizability (PL), and net atomic charges (Q). Dipole moment (μ) and molecular volume (Mv) are the structural descriptors. E_{HOMO}, E_{LUMO}, ω (expressed in terms of chemical potential and hardness), PL (the charge difference between the atoms in functional groups), Q, μ, and

dx.doi.org/10.1021/jf5011726 | J. Agric. Food Chem. 2014, 62, 5761−5771

Mv (the size and geometrical shape of the molecule, dependent on three-dimensional coordinate of atoms in a molecule) values were obtained from the DFT results by using the Gaussian 03 program package.[20] In this study, only the variables containing the information required for modeling were used. Principal component analysis (PCA) was utilized to find the relationship between the dependent and independent variables and reducing the set of independent variables (MINITAB software, version 14).[21] The linear combinations form a new set of variables, namely principal components (PCs), which are mutually orthogonal. The first PC contains the largest variance, the second new variable contains the second largest variance, and so on.[22] The validity of the QSAR model was evaluated by LOO cross-validation method, and an external data set was tested to evaluate the model. The high square value of the cross-validation coefficient (q^2) in the training set shows only a good internal validation; however, it does not automatically refer to its high validity for an external test set, because q^2 usually overestimates the validity of the model. Therefore, the QSAR model should be determined with a test set to confirm its validity. The performance of external validation was characterized by determination coefficient (R^2), standard error (S_{reg}), and q^2.[23]

Synthesis. The synthesis pathway of compounds **1**−**24** is represented in Scheme 2. For example, compound **1** was prepared by the reaction of a solution of diethylenamine (1 mmol), and triethylamine (2 mmol) in THF was added to a solution of $(OCH_3)_2P(S)Cl$ (2 mmol) in THF. After 4 h of stirring at 0 °C, the solvent was removed under vacuum, and the resulting white powder was washed with distilled solvent.

Crystal Structure Determination. A crystal suitable for X-ray crystallography was obtained from a mixture of THF at room temperature for compound **9** (Figure S1 in the Supporting Information). The solid state structure as starting point was fully optimized by using DFT calculations in the gas phase. Whereas X-ray crystallography cannot determine accurately the position of hydrogen atoms, optimization of hydrogen atom positions was performed to investigate the hydrogen bond characters in solid state structures. The H atoms of N−H groups were objectively localized in the difference Fourier synthesis and refined in isotropic approximation. To achieve this goal, the solid state structure of the crystal was modeled as a cluster, in which the target molecule is surrounded by two neighboring molecules (Figure 1). Other atoms were kept frozen during the optimization. Such computational justifications have also been used to describe well the geometry and electronic aspects of X-ray structure.[24,25] Taking into consideration the large number of atoms in the model cluster, all optimizations were performed at the B3LYP/6-311+G** level. NBO[26] analysis was performed to compare the electronic features of gas phase structures of compound **9** with those of the model clusters at the B3LYP/6-311+G** level. Natural population analysis (NPA) was performed at the same level by using the Reed and Weinhold scheme.[27] As part of this study deals with investigation of the hydrogen bonds between S···H atoms, AIM analysis at the B3LYP/6-311+G** level has much importance. Two hydrogen bonds with different lengths were observed in compound **9**. The hydrogen-bonding energies were calculated on the basis of energy difference between the hydrogen-bonded trimer and its fragments, as represented in the equation $E_{HB} = E_{trimer} - (E_{dimer} + E_{monomer})$, where dimer is composed of two monomers (central and neighboring molecules on the right, in Figure 1). Then the hydrogen-bonding energies were corrected for basis set superposition error (BSSE) using the counterpoise method.[24,28] All quantum chemical calculations were carried out by using the Gaussian 03 program package.[29]

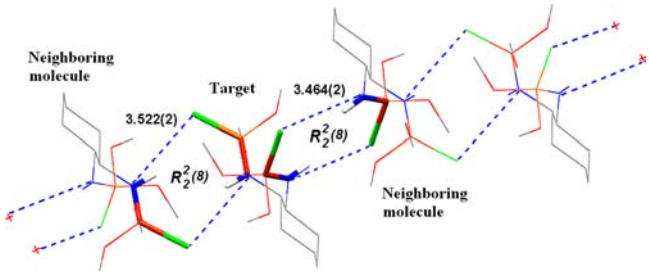

Figure 1. Illustration of $R_2^2(8)$ graph sets in $(CH_3O)_2P(S)NH(C_6H_{10})NHP(O)(OCH_3)_2$; a model to describe the hydrogen-bonded cluster for DFT calculations, in which the molecule is the target molecule in the center. A similar model was considered for another molecule, in which the molecule in the center is the target molecule.

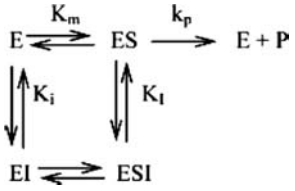
Cholinesterase Assay. Human cholinesterase activity measurements were performed essentially according to the method of Ellman.[11] The reaction was carried out at 37 °C in millimolar phosphate buffer (Na_2HPO_4/NaH_2PO_4, pH 7.4) containing the AChE enzyme (10 μL volume, diluted 100 times in phosphate buffer, pH 7.4), DTNB (10^{-4} M concentration), and ATCh (1.35×10^{-4} M concentration). Each compound was dissolved in dimethyl sulfoxide (DMSO, 99%, Merck), which was then added to the buffer for in vitro cholinesterase assays. The highest concentration of DMSO used in the assays was 5%. In the independent experiments without the inhibitor, 5% DMSO had no effect on the inhibition activity of the enzyme. The absorbance change at 37 °C was monitored with the spectrophotometer at 412 nm for 3 min, and three replicates were run in each experiment (Supporting Information Figure S2). In the absence of inhibitor, the absorbance change was directly proportional to the enzyme level. The reaction mixtures for determination of IC_{50} values (the median inhibitory concentration) consisted of DTNB solution, 100 μL; inhibitor, x μL; acetylthiocholine iodide (ATCh) solution, 40 μL; phosphate buffer, $(850 - x)$ μL; and AChE (human erythrocyte; Sigma catalog no. C0663) solution, 10 μL (26.7 u). The activity of BChE (bovine erythrocyte, Sigma catalog no. B4186) was determined the same as the AChE activity by measuring the concentration of thiocholine, which reacted with DTNB after hydrolysis of BTCh. The lyophilized BChE was diluted with 100 mM phosphate buffer (pH 7.4) for use in the activity assay. The plot of V_I/V_0 (V_I and V_0 are the activity of the enzyme in the presence and absence of inhibitors, respectively) against log[I] (where [I] is the inhibitor's concentration) gave the IC_{50} values of 12 compounds **1**−**4**, **6**−**9**, **15**, **17** **18**, **20**, and **24** (as anti-AChE) and 11 compounds **1**, **2**, **4**, **6**−**11**, **13**, **15**, and **24** (as anti-BChE) (Table 1; Figure 2).

Inhibition Mechanism Study. One of the ways in which the inhibition of enzyme-catalyzed reactions can be discussed is in terms of the following general scheme (eq 2): It is assumed that the enzyme-



containing complexes are in equilibrium with each other, that is, the breakdown of ES to generate product does not significantly disturb the equilibrium. In the present work, all data obtained for a particular system were analyzed using the mixed model of enzyme inhibition as described in the equation

$$\frac{1}{V_0} = \frac{K_m\left(1 + \frac{[I_0]}{K_i}\right)}{V_{max}}\frac{1}{[S_0]} + \frac{\left(1 + \frac{[I_0]}{K_I}\right)}{V_{max}} \quad (2)$$

where V_0 is the initial reaction rate, V_{max} is the maximum reaction rate, K_m is the Michaelis constant for the substrate to the enzyme, and K_i and K_I are the inhibition constants for binding of the inhibitor to the enzyme or to the enzyme−substrate complex, respectively. In this model, a mixed inhibitor displays finite but unequal affinity for both the free enzyme (E) and the ES complex; hence, the dissociation constants from each of these enzyme forms inhibitors must be considered in their kinetic analysis.[12,30] K_i and K_I were determined using the secondary plots as described by the following equation:

[a]Predictive activities were calculated using the QSAR model. [b]Residual for molecule is the difference between the experimental and predicted property.

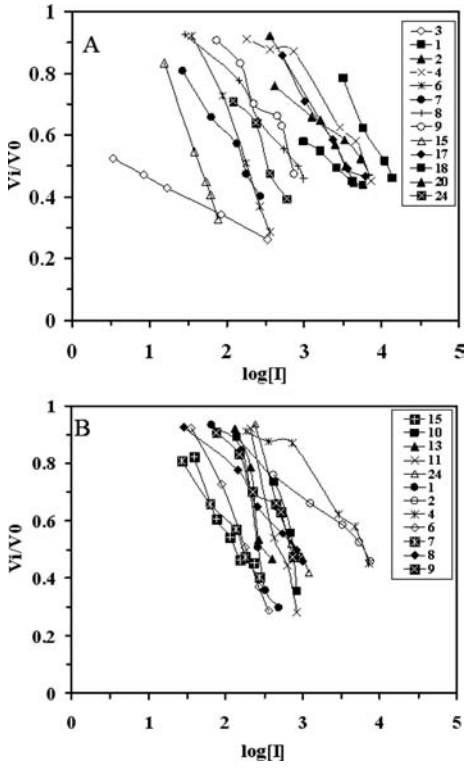

Figure 2. Plot of V_I/V_0 against log[I] for inhibitors. V_I and V_0 are the AChE (A) and BChE (B) enzyme's activities (OD min^{-1}), and [I] is the inhibitor concentration (μM).

$$\frac{1}{V'_{max}} = \frac{\left(1 + \frac{[I_0]}{K_I}\right)}{V_{max}} \quad (3)$$

slope for inhibited reaction

$$= \text{slope for uninhibited reaction} \times \left(1 + \frac{[I_0]}{K_i}\right)$$

Hence, a secondary plot of $1/V'_{max}$ against $[I_0]$ will be linear, and the intercept on $[I_0]$ axis gives $-K_I$; a graph of the slope of primary plot against $[I_0]$ will also be linear, and the intercept on $[I_0]$ axis gives $-K_i$. The Lineweaver−Burk plots related to the reversible inhibitory effects of compounds showed a typical pattern of mixed inhibition (Figure 3). The K_m and V_{max} values were calculated in the absence and presence of inhibitor from which the secondary plots were obtained, and the equilibrium dissociation constants, K_i and K_I, were calculated (Table 2). A mixed inhibitor displays affinity for both the free enzyme (K_i) and the enzyme−substrate complex (K_I). Thus, mixed-type inhibitors interfere with the substrate binding (increase K_m) and hamper the catalysis in the ES complex (decrease V_{max}). When $K_I > K_i$, the inhibitor preferentially binds to the free enzyme, and the plots cross to the left of the $1/V_0$ axis, but above the $1/[S_0]$ axis (Figure 3). In this situation, it is also termed competitive noncompetitive inhibition.

RESULTS AND DISCUSSION

Spectral Study. The ^{31}P NMR chemical shift at room temperature in $CDCl_3$ appears in the ranges of 68.31−78.82 ppm for P═S derivatives and 5.42−8.64 ppm for P═O derivatives. The ^{31}P NMR spectra of compounds **2**, **9**, **11**, and **18** appeared as two separate signals. The ^1H NMR spectrum of compound **3** revealed that two doublets at 2.76 ($^3J_{PNH}$ = 10.0 Hz) and 3.63 ($^3J_{POH}$ = 15.0 Hz) ppm are related to the methyl

proton in the NCH_3 and OCH_3 groups, respectively. The ^1H NMR spectra of compounds **9**, **16**, and **24** exhibited two signals for the methylene protons of the six-membered piperazinyl rings. Two protons of the NH group of all compounds exhibited as a multiple peak in the ranges of 3.48–5.37 ppm for P═S derivatives and 3.06–3.88 ppm for P═O derivatives. The ^{13}C NMR spectra of compounds **9**, **16**, and **24** indicated three separate peaks for the six carbon atoms that are due to different orientations of the aliphatic six-membered rings. The analysis of the IR spectra indicated that the fundamental ν(P═S) stretching modes for compounds **1**–**16** appeared in the range of 770.4–955.1 cm^{-1}. The P═O stretching frequencies for compounds **17**–**24** were exhibited over the range of 1223.8–1252.1 cm^{-1}. Moreover, the N–H stretching frequencies for all compounds were observed in the range of 3189.1–3580.0 cm^{-1}.

H-Bond Analysis. The crystal data and the details of the X-ray analysis of compound **9** are given in the Supporting Information (Table S1). The phosphorus centers are in typical tetrahedral environments. P═S bond lengths of 1.9288(9) and 1.9316(9) Å were observed for P(1)—S(1) and for P(2)—S(2), respectively, in $(CH_3O)_2P(S)NH(C_6H_{10})NHP(S)(OCH_3)_2$ (**9**). It seems that the difference in the bond lengths is correlated to the various orientations of cyclohexyldiamine rings and OCH_3 groups. These orientations lead to the creation of different hydrogen-bonding patterns between the P═S and N—H functional groups. The one-dimensional polymeric chains form in the crystal lattice with cyclic $R_2^2(8)$ motifs in which the monomers are connected to each other via two P═S···H—N hydrogen bond distances of 3.464(2) and 3.522(2) Å (Figure 1; Table 3). The $R_Y^X(Z)$ graph-set notation is descriptive of a Z-membered ring produced by the X hydrogen bonds between the Y donor–acceptor units.[31,32] Weak interactions, particularly P(2)–S(2)···H(3)–C(3) (2.970 Å) and P(2)–S(2)···H(2)–C(2) (2.902 Å), create different hydrogen-bonding lengths of the motifs. The large atomic radius and the low electronegativity of sulfur atoms decreased the strength of the hydrogen bonding between P═S and NH. The electronic parameters of the hydrogen-bonded clusters of compound **9** were calculated by AIM and NBO methods. The results of AIM and NBO analyses for the mentioned clusters are presented in Table 3 and Figure 1. As shown, the bond lengths in this cluster are equal to those obtained from the X-ray structures, except for the C–H and N–H bonds, because the optimizations have been performed only for the hydrogen atoms' positions. Also, the donor–acceptor distances for the hydrogen bonds in the model cluster are equal to the experimental values. The results of AIM analysis show that the electron density (ρ) value at the bond critical point (bcp) of S(1)···H(1) (0.104 $eÅ^{-3}$) bond path is larger in magnitude than the that calculated for the S(2)···H(2) (0.093 $eÅ^{-3}$) in the model cluster. The smaller ρ value at the bcp of the N–H bond confirms the presence of the stronger hydrogen bonds in P(1)–S(1)···(1)H–N(1) with the linear N–H···S contact angle in comparison with the values obtained for P(2)–S(2)···(2)H–N(2). The ρ value at the bcp of N–H bonds is 2.24 $eÅ^{-3}$ for the fully optimized structure in the gas phase, which decreases to 2.211 and 2.217 $eÅ^{-3}$, respectively, in N(1)–H(1) and N(2)–H(2). The mean N–H distance increases from the isolated molecules from 1.012 to 1.017 Å in their hydrogen bonded model cluster. The electronic delocalization of $Lp(S)_i \rightarrow \sigma^*(N–H)_j$ occurs when the hydrogen bonds are formed between the subunits i and j within a cluster. Such an electronic effect leads to weakening of the N–H bond. It has been previously explained that the stabilizing energy E^2 increases by a decrease in the donor–acceptor distance of hydrogen bond.[32] The stabilizing energies E^2 of $Lp(S)_i \rightarrow \sigma^*(N–H)_j$ electron density transfer in P═S···H–N hydrogen bonds in the model cluster have been calculated as 19.94 and 16.34 kJ mol^{-1}, respectively. This is in agreement with the values of distance for these hydrogen bonds in two P(1)—S(1)···(1)H—N(1)

(C, D) 2D model of the hydrogen atoms of the N—H group of compounds **2** (C) and **11** (D) forming an H-bond with the C═O group containing GLU197 (d = 2.760 Å) and (d = 2.822 Å) of BChE enzyme.

(3.464(2) Å) and P(2)−S(2)···(2)H—N(2) (3.522(2) Å) models. The hydrogen-bonding energy in the P(1)—S(1)···(1)H—N(1) model (−33.3 kJ mol^{-1}) is smaller than the value calculated for P(2)—S(2)···(2)H—N(2) (−42.4 kJ mol^{-1}), although the stabilizing energies E^2 of P═S···H—N hydrogen bonds are larger in the former (Table 3).

It is noteworthy that the term E^2 refers to the stabilization energy of electronic delocalization between the donor−acceptor orbital and differs from the hydrogen-bonding energy. The molecule−molecule interaction energy is the sum of the total attractive and repulsive forces between two hydrogen-bonded fragments. The results of AIM analysis revealed some critical points with very small ρ values for the C—$H_{(methyl)}$···S(2)—P(2) and C—$H_{(cyclohexane)}$···S(2)—P(2) contacts. It can be said that the steric repulsion between the diaminocyclohexane, OCH_3 group, and P═S bond in the model crystal leads to a decrease in P(2)—S(2)···(2)H—N(2) hydrogen-bonding energy rather than the P(1)—S(1)···(1)H—N(1) model.

Prediction of Biological Potential. PASS software predicts 900 types of biological activities on the basis of the structural formula.[33] The default list of predictable biological activities (P_a) includes the main and side pharmacological effects, molecular mechanisms, and specific toxicities. The PASS prediction results for a compound are presented as a list of activity names and probability activity (Pa) values. The Pa values are interpreted as if Pa > 0.7, 0.5 < Pa < 0.7, and Pa < 0.5; then the chance of finding this activity in the experiments is high, low, and lower, respectively.[34,35] Insecticide potential, anti-AChE activity, and carcinogenic effect of 24 newly designed molecules were obtained by using PASS software (Table 1). Table 1 shows that anti-AChE and carcinogenic properties of compounds decrease owing to the change of $(CH_3O)_2P$═S to $(C_2H_5O)_2P$═S in compounds **1**−**16**. Furthermore, the replacement of P═S in **10**−**16** to P═O in **17**−**24** increased the anti-AChE property and decreased the carcinogenic activity. The insecticidal properties of all compounds are predicted in the range of 0.496−0.635. The comparison of experimental data and the prediction of anti-AChE activities are shown in Figure S2A in the Supporting Information. As shown in Figure S2B in the Supporting Information, a linear relationship gives the plot of probable insecticide potential against anti-AChE activity. To test the anti-ChE activity of the synthesized compounds, we evaluated the inhibitory potential of titled compounds against AChE and BChE enzymes.

dx.doi.org/10.1021/jf5011726 | J. Agric. Food Chem. 2014, 62, 5761−5771

Bioassay. The inhibition constant (IC_{50}) values of AChE against compounds **1**−**4**, **6**−**9**, **15**, **17**, **18**, and **20** were in the range of 5.01−11402.50 μM (Table 1). Compound **3** displayed the most potent inhibitory activity (IC_{50} = 5.01 μM). The inhibitory potential of compound **15** with OC_2H_5 was more greater than that of **7** with an OCH_3 substituent (Table 1). A review of the literature demonstrates that the inhibitory potential of monophosphoramides (P═O moiety) is higher than that of the monophosphoramidothiates (P═S moiety),[36] whereas comparison of bisphosphoramidothioate **2** (IC_{50} = 674.53 μM) and bisphosphoramide **18** (IC_{50} = 11402.50 μM) reveals the inhibitory activity of P═S to be greater than that of P═O in contrast with the AChE. In the present work, the synthesized compounds **1**, **2**, **4**, **6**−**11**, **13**, and **15** showed inhibition of BChE with IC_{50} values between 149.62 and 7481.69 μM. In general, the inhibitory activities of Tem derivatives with the P═S moiety were better than those of derivatives with the P═O moiety. The mixed-type and reversible mechanisms of these compounds were evaluated by Lineweaver−Burk plots (Table 2). To gain a better understanding of the inhibitory potential of the synthesized compounds and to study the reversible mechanism in more detail, it was necessary to examine the interaction of the Tem derivatives with the ChE structures by using the molecular docking method.

Molecular Docking Study. The interactions between Tem derivatives and AChE receptor were achieved by molecular docking, which can facilitate the selection of appropriate molecular parameters in the subsequent QSAR studies. The binding models of titled compounds against AChE and BChE are depicted in Figure 2. They are located in the active site gorge of both AChE and BChE so as to maximize the favorable contacts. The hydrogen bonds and van der Waals forces are the main features of the interactions of compounds **2** (Figure 4A) and **18** (Figure 4B) with the polar charged site of AChE, as well as the interactions of **2** (Figure 4C) and **11** (Figure 4D) with the esterastic site of BChE. H-bond formation in the polar charged site was found to occur between the P—OCH_3 and P—OC_2H_5 oxygen of compounds **2** (P═S) and **18** (P═O) with the hydrogen of H—N of GLN181 (d = 3.131 Å) and GLN291 (d = 2.100 Å), respectively. Panels C and D of Figure 4 show the 2D representation of the interaction mode of compounds **2** and **11** at the active site of BChE. It can be clearly seen from Figure 4C,D that the hydrogen atoms of the N—H group of compounds **2** and **11** form an H-bond with the C═O group containing GLU197 (d = 2.760 Å) and (d = 2.822 Å) moieties. The docking data including inhibition constant (K_i), electrostatic energy (E_{elect}) and the rest of the H-bonds distances are given for the ChEs in Table S3 in the Supporting Information. Panels A and A′ of Figure 3 indicate that the increase of the H-bond distances of RO···H—N enhances their inhibitory potential, whereas these correlations are reversed in the interaction between BChE and ligands (Figure 5B,B′). To continue work, the QSAR technique was used to find the effective electronic and structural parameters.

QSAR Analysis. QSAR studies were done to recognize the effect of descriptors on the activity of AChE and BChE enzymes. The stepwise MLR procedure, which is a common method used in QSAR studies, was used for model selection. The electronic and structural descriptors were obtained by quantum chemical calculations (Supporting Information Table S3). The number of independent variables is equal to the training set compounds, as shown in Tables 1 and S3

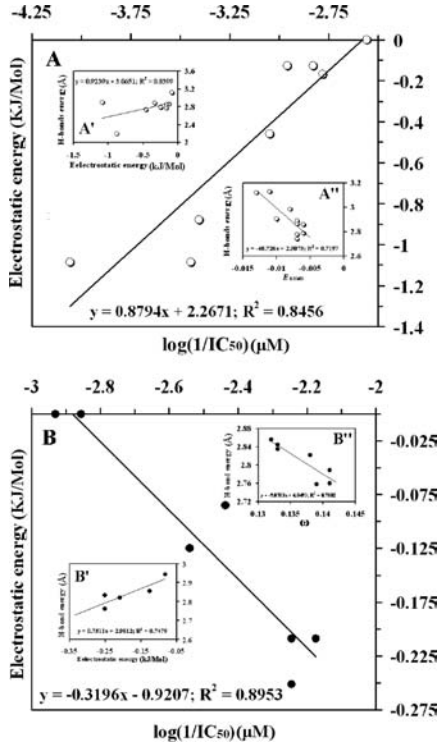

Figure 5. Linear plot of the electrostatic energy of docking analysis against $\log(1/IC_{50})$ for AChE (A) and for BChE (B); linear plot of the H-bond energy against the electrostatic energy of docking analysis for AChE (A′) and for BChE (B′); linear plot of the H-bond energy of docking analysis against ELUMO for AChE (A″) and against ω for BChE (B″).

(Supporting Information). Therefore, the PCA method was used to reduce the independent variables. The variable selection in PCA was performed by using the Fisher's weights approach,[37] and the results are summarized as eqs 4a and 4b:

$$PC_1 = +0.411Q_{P(1)} + 0.411Q_{P(2)} - 0.400Q_{X(S,O)} - 0.080Q_N + 0.410PL_{p=X} - 0.407E_{HOMO} - 0.052E_{LUMO} + 0.316\omega + 0.142\mu + 0.035Mv \quad (4a)$$

$$PC_2 = +0.064Q_{P(1)} + 0.053Q_{P(2)} - 0.042Q_{X(S,O)} + 0.547Q_N + 0.121PL_{p=X} - 0.028E_{HOMO} + 0.500E_{LUMO} - 0.334\omega + 0.343\mu + 0.035Mv \quad (4b)$$

The results showed the total variances of the first and second factor PC were 51.4 and 19.0%, respectively. Figure S3 in the Supporting Information shows the score and the loading plots of $PC_1 \times PC_2$. The score plot shows that separation of the compounds with P═O (right side) and P═S (left side) groups has been provided by PC_1, which contains the majority of the variance. From the above equations, it is deduced that the electronic parameters (Q_P, Q_X, Q_N, $PL_{P=X}$, E_{LUMO}, E_{HOMO}, and ω) are the largest compared to the structural parameters (μ and Mv). Consequently, these nine descriptors with higher correlation coefficients were selected to carry out the stepwise multiple linear regression (MLR) analysis, which led to an

dx.doi.org/10.1021/jf5011726 | J. Agric. Food Chem. 2014, 62, 5761−5771

optimal QSAR equation based on the anti-AChE potency (eq 5):

$$\log(1/IC_{50}) = +0.017\mu + 64.805Q_P + 1.690Q_{X(S,O)} - 8.967Q_N - 31.967PL_{P=X} - 25.193E_{HOMO} - 217.942E_{LUMO} - 243.834\omega + 0.016Mv - 33.690 \quad (5)$$

$$n = 13;\ R^2 = 0.721;\ S_{reg} = 0.966;\ F_{statistic} = 0.862$$

n is the number of compounds, R^2 is the determination coefficient of regression, S_{reg} is the standard deviation of regression, and $F_{statistic}$ is Fisher's statistic.[38] The variables with a high value of variance inflation factor (VIF > 10) are candidates for exclusion from the model.[39] The low determination coefficient value (R^2 = 0.721) and high residual value (S_{reg} = 0.966) with high VIF value (see Table 4) are associated with the multicollinearity problem. The improvement in eq 2 was carried out by omitting compounds **7**, **8**, and **24** from the training set compounds and replacing E_{LUMO} with ω and E_{HOMO}, as well as Q_P with $PL_{P=X}$ and Q_X. The linear regression was performed using the remaining five parameters that yielded the following model with increasing of R^2 = 0.922 and decreasing of S_{reg} = 0.438 (eq 6):

Table 4. VIF[a] Values for the QSAR Equations

	AChE		BChE	
independent variable	eq 2	eq 2	eq 3	eq 5
Q_P	5154.635	4.060	2416.392	2.122
$Q_{X(S,O)}$	82.623		70.221	
Q_N	46.154	12.411	31.865	3.105
$PL_{P=X}$	6368.558		3547.065	
E_{HOMO}	1677.977		313.179	
E_{LUMO}	1529.029	3.422	468.766	
ω	3249.905		688.616	2.629
μ	7.195	4.140	26.590	1.281
Mv	6.540	6.665	10.261	2.635

[a]VIF = $1/(1 - R_i^2)$, where R_i is the multiple correlation coefficient of the ith independent variable on all of the other independent variables.

$$\log(1/IC_{50}) = +0.175\mu + 0.845Q_P + 29.699Q_N - 129.903E_{LUMO} - 0.019Mv + 27.921 \quad (6)$$

$$n = 10;\ R^2 = 0.922;\ S_{reg} = 0.438;\ F_{statistic} = 9.473$$

The correlating parameters have VIF < 10; thus, there is no colinearity problem (Table 4). In this equation, the inhibitory potency of AChE is influenced mainly by the electronic parameters. E_{LUMO} with the coefficient value of −129.903 has the highest contribution to $\log(1/IC_{50})$ rather than the structural parameters. The negative sings of E_{LUMO} in $\log(1/IC_{50})$ disclose that the compound with lower E_{LUMO} is indicative of higher toxicity against the AChE enzyme. The net charge of the N−H nitrogen (Q_N) with the coefficient value of +29.699 reveals the highest effect of function on the inhibitory potential rather than the net charge of P═O phosphorus (+0.845). The correlation matrix was used to determine the interrelationship between the independent variables. A high interrelationship was observed between E_{LUMO} and Q_N (r = +0.456) (Table 5). Therefore, compound **3** with Q_N = −0.893 and compound **18** with Q_N = −1.031 showed the highest and the lowest inhibitory potentials, respectively. Consequently, the net charge of the nitrogen atom is able to control the influence of molecular orbital energy in the inhibition of human AChE. Also, the interaction of BChE as a secondary target was investigated against the tested compounds (**1**−**24**), and the same procedures were carried out. The QSAR modification model based on anti-BChE potency produced the following equation:

$$\log(1/IC_{50}) = -0.148\mu + 7.065Q_P + 1.720Q_{X(S,O)} + 0.430Q_N + 0.469PL_{P=X} + 100.702E_{HOMO} - 100.525E_{LUMO} - 104.965\omega - 0.002Mv + 22.751 \quad (7)$$

$$n = 12;\ R^2 = 0.566;\ S_{reg} = 0.862;\ F_{statistic} = 0.290$$

Table 4 shows that the regression equation is not favorable with VIF > 10. The improvement in eq 7 was performed by excluding compounds **1** and **24** from the selected compounds and replacing ω with E_{LUMO} and E_{HOMO}, as well as Q_P with $PL_{P=X}$ and Q_X. Consequently, a new multiple regression resulted without collinearity (eq 8):

$$\log(1/IC_{50}) = -0.116\mu + 3.768Q_P - 0.32Q_N - 106.212\omega + 0.004Mv + 3.397 \quad (8)$$

$$n = 10;\ R^2 = 0.848;\ S_{reg} = 0.352;\ F_{statistic} = 4.479$$

The model described by eq 8, similar to eq 6, depicts the share of molecular orbital energy in the inhibition of BChE. The most effective variable in the interaction of BChE and Tem derivatives was ω, with the coefficient value of −106.212. The interrelationships between the variables and the correlation matrix results are presented in Table 5. The high interrelationship between ω and Q_P (r = +0.680) shows that Q_P controls the affect of molecular orbital energy in the inhibition of human BChE. Compounds **5** (Q_P = +2.027) and **2** (Q_P = +1.997) are in order of the highest and the lowest inhibitory potentials.

Table 5. Correlation Matrix for the Anti-AChE and Anti-BChE Parameters and the Selected Variables in Equations 6 and 8

	AChE						BChE					
selected variable	μ	Q_P	Q_N	E_{LUMO}	Mv	selected variable	μ	Q_P	Q_N	ω	Mv

Mv	+0.105	+0.417	+0.404	−0.033	1.000	Mv	+0.246	+0.077	+0.734	−0.049	1.000	

dx.doi.org/10.1021/jf5011726 | J. Agric. Food Chem. 2014, 62, 5761−5771

DFT-QSAR models of AChE and BChE revealed that changing in the net charge of nitrogen and phosphorus atoms contributes an important function in the inhibition mechanism of AChE and BChE, respectively. The above results are relatively good, but the validity of QSAR models and docking output must be examined by NBO and LOO cross-validation methods.

Validation of MLR-QSAR Model. The LOO cross-validation method was used for the training sets to select the optimum values of parameters. This procedure consists of three stages: (i) removing one sample from the training set, (ii) constructing the equation on the basis of only the remaining training data, and (iii) testing of the model on the removed and innovative samples.[40] A total of 10 samples was used as a training set, and the remaining compounds (**7**, **8**, and **24**) for AChE-QSAR (eq 6) were adopted as a test set for validating the models. A new equation is proposed to determine the outliers using LOO cross-validation coefficient q^2_{n-i}, which is equal to the q^2 of compound i computed by the new cross-validation procedure after leaving this datum from n compounds. The compound with an unduly high q^2_{n-i} value can be considered as an outlier, and the compound with a low value can be taken as an influential point. Compound **4** has too large a q^2_{n-i} value in the training set, so this compound can be confirmed to be an outlier from the AChE-QSAR model. After omission of compound **4**, two optimal models are obtained (eq 9):

$$\log(1/\mathrm{IC}_{50}) = +0.254\mu + 0.063Q_{\mathrm{P}} + 30.879Q_{\mathrm{N}} - 191.801E_{\mathrm{LUMO}} - 0.018\mathrm{Mv} + 29.838 \quad (9)$$

$$n = 9;\ R^2_{\mathrm{adj}} = 0.907;\ S_{\mathrm{reg}} = 0.335;\ r = 0.10$$

$$F_{\mathrm{statistic}} = 16.59;\ q^2 = 0.965;\ P < 0.0214$$

q^2 is the square of the LOO cross-validation coefficient. A good QSAR model has characters of large F, small r, and S_{reg}, low P value, and R^2 and q^2 values close to 1.[41] Therefore, the above-established eq 9 shows appropriate statistical quality. To check the validity of eq 9, we selected our previously omitted compound (**4**) as the test set; the dependent and independent variables with their residuals of test set compounds are shown in Table 1. Table 1 and particularly residuals data show that the inhibition results are the same in the empirical and prediction techniques. Figure 6 indicates that the predicted values of $\log(1/\mathrm{IC}_{50})$ are in good agreement with the experimental ones. The integrity was validated by the determination coefficient of $R^2 = 0.851$ with the residuals between the training and testing sets.

Natural Bond Orbital Analysis. The stabilization energy (E^2) data clarify that electron transfers lead to change in the net charge of phosphorus and nitrogen atoms and, accordingly, alter the inhibitory properties of compounds against enzymes. The NBO analysis reveals an electronic delocalization between the lone pair of X atom in the P = X(O, S) group, $\mathrm{Lp}(\mathrm{X_P})$, and the vacant σ^* ($\mathrm{P{-}O_2}$) orbital. Stabilization energies of 9.211 kJ/mol for compound **2** with the P═S moiety and 103.706 kJ/mol for compound **18** with the P═O moiety were obtained for the $\mathrm{Lp}(\mathrm{X_P}) \rightarrow \sigma^*$ ($\mathrm{P{-}O_2}$) interaction (Table 6). This interaction increases the electron density of OR (R = $\mathrm{CH_3}$ and $\mathrm{C_2H_5}$) oxygen atom and raises the hydrogen bond energy of $(\mathrm{R{-}O})_{\mathrm{ligand}}\cdots(\mathrm{H{-}N})_{\mathrm{enzyme}}$ type (Figure 4). Compared to **18**, compound **2** has a higher inhibitory potential in contrast to AChE. The H-bond energy of $\mathrm{CH_3{-}O\cdots H{-}N}$ (GLN181) for compound **2** is lower than the energy of $\mathrm{C_2H_5{-}O\cdots H{-}N}$ (GLN291) for compound **18**. Hence, there is not a direct correlation between the E^2 of $\mathrm{Lp}(\mathrm{X_P}) \rightarrow \sigma^*$ ($\mathrm{P{-}O_2}$) interaction and the hydrogen bond energy against the AChE activity. In other words, compound **2** with E^2 = 18.601 kJ/mol and compound **18** with E^2 = 16.218 kJ/mol for the $\mathrm{Lp}(\mathrm{X_P}) \rightarrow \sigma^*$ ($\mathrm{P{-}N_1}$) interaction (Table 6) prove that the negative charge of the nitrogen atom (Q_{N}) versus the hydrogen bond energy of $(\mathrm{R{-}O})_{\mathrm{ligand}}\cdots(\mathrm{H{-}N})_{\mathrm{protein}}$ affects the $\log(1/\mathrm{IC}_{50})$ factor. For instance, compound **3** with the highest E^2 and Q_{N} behaves as a strong inhibitor in the process of the inhibition of AChE. In addition, the high E^2 = 16.678 kJ/mol of $\mathrm{Lp}(\mathrm{N_1}) \rightarrow \sigma^*(\mathrm{P{-}O_2})$ interaction for compound **18** compared to compound **2** (E_2 = 12.582 kJ/mol) leads to the increase of the electron density of the oxygen atom on the alcohol substituent and consequently to the rise of the energy of the hydrogen bonding and to the decline of the inhibition potential. By investigating the interaction mechanism of ligand and BChE enzyme, it can be said that the $\mathrm{Lp}(\mathrm{O_2}) \rightarrow \sigma^*(\mathrm{P{-}N_1})$ interaction of selected compounds (**2** and **11**) increases the electron density of the N–H nitrogen and raises the hydrogen bond energy of $(\mathrm{N{-}H})_{\mathrm{ligand}}\cdots(\mathrm{O{=}C})_{\mathrm{enzyme}}$ type (Figure 4). The H-bond energy of $\mathrm{N{-}H\cdots O{=}C}$ (GLU197) for compound **2** is higher than that of **11**, whereas compound **2** has a lower inhibitory potential compared to compound **11** in contrast to BChE. Thiss means

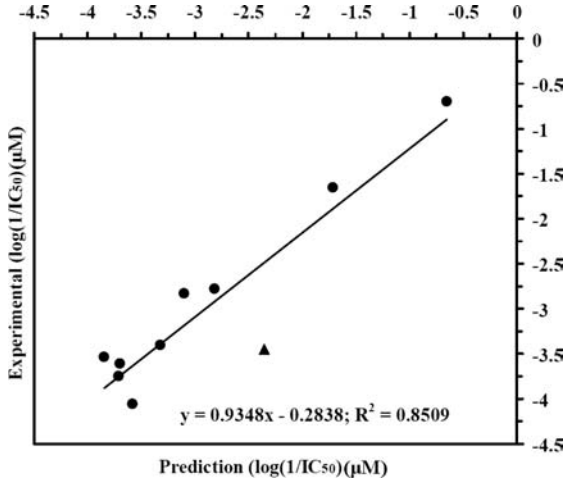

Figure 6. Plot of predicted activities versus experimental ones for the QSAR model, in which 10 compounds are the training set (●) and corresponding one compound is the test set (▲).

Table 6. Stabilization Energies (E^2) of the NBO Analysis of Some of the Compounds

	E^2 (kJ/mol)			
electronic delocalization	**2**	**3**	**11**	**18**
$\mathrm{Lp}(X_1) \rightarrow \sigma^*$ (P − $\mathrm{N_1}$)	18.601	58.478		16.218
$\mathrm{Lp}(X_1) \rightarrow \sigma^*$ ($\mathrm{P{-}O_2}$)	79.211			103.706
$\mathrm{Lp}(\mathrm{N_1}) \rightarrow \sigma^*$ ($\mathrm{P{-}O_2}$)	12.582		14.254	16.678
$\mathrm{Lp}(\mathrm{O_2}) \rightarrow \sigma^*$ ($\mathrm{P{-}N_1}$)	39.124		38.999	
$\mathrm{Lp}(\mathrm{O_2}) \rightarrow \pi^*$ (P = X_1)	17.430		21.694	

dx.doi.org/10.1021/jf5011726 | J. Agric. Food Chem. 2014, 62, 5761−5771

that the net charge of the phosphorus atom's (Q_P) effect inverts the H-bond energy of $(N—H)_{ligand}\cdots(O=C)_{enzyme}$. Figures 5A″ and 5B″ demonstrate that the H-bond energy of the docking analysis of AChE and BChE is negative, proportional to the Q_N and Q_P parameters.

Concluding Remarks. Twenty-four bisphosphoramidothioates with the general formula of $(RO)_2P(S)XP(S)(OR)_2$ (**1**–**24**) were synthesized and characterized by spectroscopy methods. The cyclic motif of $(CH_3O)_2P(S)NH(C_6H_{10})NHP(S)(OCH_3)_2$ (**9**) was determined by X-ray crystallography. The results of NBO analysis showed that the H-bond energies in the P(1)–S(1)···(1)H–N(1) and P(2)–S(2)···(2)H–N(2) models were −33.3 and −42.4 kJ mol^{-1}, respectively. Docking analysis disclosed that reversible noncovalent interactions, especially hydrogen bonds, occurred between the OR (R = CH_3 and C_2H_5) oxygen and N—H nitrogen atoms of selected compounds, and the H—N atoms of GLN with O=C of GLU. The MLR-QSAR models (to R^2 = 0.922 and 3.422 < VIF < 12.411 for AChE and to R^2 = 0.845 and 1.281 < VIF < 3.105 for BChE) and correlation matrix clarified that the net charge of N–H nitrogen and R_2NP = X phosphorus atoms contributes an important electronic function in the inhibition of ChEs. The interrelationship shows that the net charge of nitrogen and phosphorus atoms controls the modification of the molecular orbital energy of Tem analogues. The predicted values of $\log(1/IC_{50})$ are in good agreement with the experimental ones; the validity of the QSAR model was confirmed by LOO cross-validation method with q^2 = 0.965 between the training and testing sets. Increasing E^2 for the $Lp(X_P) \rightarrow \sigma^*$ (P–N) and $Lp(N) \rightarrow \sigma^*$ (P–O) interactions and the electron density of the N–H nitrogen with the OR oxygen of Tem analogues verify the integrity of the QSAR equation and docking results in the inhibition process of ChE enzymes.

Supporting Information

ABSTRACT: In a recent paper, we reported the synthesis and photosynthesis-inhibitory activity of a series of analogues of rubrolides. From quantitative structure−activity relationship (QSAR) studies, we found that the most efficient compounds are those having higher ability to accept electrons. On the basis of those findings, we directed our effort to synthesize new analogues bearing a strong electron-withdrawing group (nitro) in the benzylidene ring and evaluate their effects on photosynthesis. However, the employed synthetic approach led to novel cyclopent-4-ene-1,3-diones as major products. Here, we report the synthesis and mechanism of action of such cyclopent-4-ene-1,3-diones as a new class of photosynthesis inhibitors. These compounds block the electron transport at the Q_B level by interacting at the D1 protein at the reducing side of Photosystem II and act as Hill reaction inhibitors, with higher activity than the corresponding rubrolides. To the best of our knowledge, this is the first report on the photosynthesis inhibitory activity of cyclopentenediones.

KEYWORDS: *analogues of rubrolides, cyclopentenediones, chlorophyll a fluorescence, polarography, PSII inhibitors, Hill reaction inhibitors*

INTRODUCTION

Weed infestations constitute a major cause of crop losses worldwide, making agricultural yields highly dependent upon the management of such invasive plants.[1,2] Since the discovery of the herbicidal property of 2,4-dichlorophenoxyacetic acid (2,4-D) in the mid-1940s,[3] chemical control has been the most effective method for weed management. However, the continuous and repetitive use of herbicides has exerted selective pressure, leading to the replacement of sensitive by herbicide-resistant biotypes.[4−7] This problem has been worsened by the wide adoption of herbicide-resistant crops, which has contributed to an indiscriminate use of broad activity spectrum herbicides.[8−10] As a whole, this scenario has made the development of new herbicides a great concern and an important area of activity in industry and academy.

The use of phytotoxic natural products as models for the development of novel active molecules have been regarded as a promising strategy in the search for new herbicides.[11−14] Examples of the potential of such an approach are the commercial herbicides cinmethylin and mesotrione, derivatives from phytotoxic plant metabolites, and bialafos, synthesized from a phytotoxin isolated from species of the genera *Streptomyces*.[13,15] In line with such tendency, our research group have been using several natural compounds as models for the development of new bioactive molecules.[16−22]

In a recent paper, we reported the synthesis and photosynthesis-inhibitory activity of a series of analogues of rubrolides (Figure 1), a family of natural butenolides isolated from marine ascidians.[23] In that work, we found that derivatives bearing a nitro electron-withdrawing group at the *para* position in the benzylidene ring (Figures 1, compounds 2a and 2b) showed the higher activities, with IC_{50} 1 order of magnitude higher than that of commercial herbicides Diuron. In the same study, quantitative structure−activity relationship (QSAR) analyses indicated that the most efficient compounds are those having higher ability to accept electrons.

On the basis of these findings, we envisaged that rubrolide analogues bearing electron-withdrawing groups, such as nitro, for example, on the *meta* position of the benzylidene ring (Figure 1, compounds 3a and 3b), would be active as photosynthesis inhibitors. Because a nitro group acts as an electron-withdrawing group, its presence reduces the redox potential of the compound, making the molecule more able to accept an electron and interfere with the photosynthetic electron transport.[23] We then tried to prepare compounds **3a** and **3b**; however, this attempt led to unexpected and novel compounds, identified as 4-bromo-5-(2-methoxyphenyl)-2-(3-nitrophenyl)cyclopent-4-ene-1,3-dione (**4a**) and 4-bromo-5-(4-fluoro-2-methoxyphenyl)-2-(3-nitrophenyl) cyclopent-4-ene-1,3-dione (**4b**) (Figure 1), as major products. These compounds were assayed for their inhibitory activity on the photosynthetic electron transport chain and showed high

activities. Their synthesis and photosynthesis-inhibitory activities are presented herein.

MATERIALS AND METHODS

General Experimental Procedures. All reagents and solvents were prepared following the procedure already reported in the literature[24] or were purchased from commercially available suppliers and used without any further purification. Compounds **5a** and **5b** were prepared employing a synthetic procedure previously reported.[23] Melting points are uncorrected and were obtained from a MQAPF-301 melting point apparatus (Microquimica, Brazil). Analytical thin-layer chromatography analysis was conducted on aluminum-packed pre-coated silica gel plates. Column chromatography was performed over silica gel 230−400 mesh. All compounds were fully characterized by infrared (IR), Electron ionization−mass spectrometry (EI−MS), ^{1}H and ^{13}C nuclear magnetic resonance (NMR), correlation spectroscopy (COSY), heteronuclear correlation (HETCOR), and nuclear Overhauser effect difference (NOEDIFF) NMR spectroscopy. IR spectra were recorded on a PerkinElmer Paragon 1000 fourier Transform infrared (FTIR) spectrophotometer using potassium bromide (1%, w/w) disks or as a thin liquid film on NaCl plates. Mass spectra were recorded on a Shimadzu GCMS-QP5050A instrument by direct insertion, using EI mode (70 eV). High-resolution mass spectra were recorded on a Bruker MicroToF [resolution = 10 000 full width at half maximum (fwhm)] under electrospray ionization (ESI) and are given to four decimal places. The ^{1}H and ^{13}C NMR spectra were recorded on a Varian Mercury 300 spectrometer at 300 and 75 MHz, respectively, using $CDCl_3$ as the solvent and tetramethylsilane (TMS) as the internal reference, unless otherwise stated. The energy gap between highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of the compounds was calculated with MOPAC[25] software using the AM1 method.[26,27]

Synthesis of Compounds 3a and 4a. In a two-necked round bottomed flask (25 mL) under a nitrogen atmosphere were added 3-bromo-4-(2-methoxyphenyl)furan-2(5*H*)-one (**5a**) (100 mg, 0.37 mmol), 3-nitrobenzaldehyde (67 mg, 0.44 mmol), dichloromethane (3 mL), *tert*-butyldimethylsilyl trifluoromethanesulfonate (TBDMSOTf) (101 μL, 0.44 mmol), and *N*,*N*-diisopropylethylamine (DIPEA) (130 μL, 0.74 mmol). The resulting mixture was stirred at room temperature for 1 h. After this period, 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) (110 μL, 0.74 mmol) was added, and the resultant mixture was refluxed for 1 h before the addition of dichloromethane (70 mL). The organic phase was washed with 3 mol L^{-1} HCl (2 × 25 mL) and brine (2 × 25 mL). The combined organic layers were dried over magnesium sulfate, filtered, and concentrated under reduced pressure in a rotary evaporator. The residue obtained was purified by column chromatography on silica gel eluted with hexane/ethyl acetate (3:1, v/v), affording compound **4a** with a 42% yield. Compound **3a** was isolated in a 30% yield, but although observed as a unique peak in gas chromatography−mass spectrometry (GC−MS) analysis, it was unstable in $CDCl_3$.

(*Z*)-3-Bromo-4-(2-methoxyphenyl)-5-(3-nitrobenzylidene)-furan-2(5*H*)-one (3a). The compound was a yellow amorphous residue. FTIR (KBr) ν_{max}, cm^{-1}: 3068, 2923, 2847, 1771, 1606, 1531, 1491, 1281, 988, 750. ^{1}H NMR, δ_H (300 MHz, $CDCl_3$): 3.86 (s, 3H), 5.98 (s, 1H), 7.08−7.16 (m, 2H), 7.27 (dd, 1H, *J* = 8.0 and 1.5 Hz), 7.52−7.60 (m, 2H), 8.14−8.17 (m, 1H), 8.22 (brd, 1H, *J* = 8.1 Hz), 8.39−8.40 (m, 1H). ^{13}C NMR δ_C (75 MHz, $CDCl_3$): 55.6, 110.3, 111.7, 113.7, 117.1, 120.8, 123.4, 125.0, 129.9, 130.2, 132.3, 134.3, 135.7, 148.4, 149.4, 152.2, 156.5, 164.5. EM, *m*/*z* (%): 403 (98) $[M + 2]^{+\bullet}$, 401 (100) ($C_{18}H_{12}BrNO_5$) $[M^{+\bullet}]$, 322 (46), 294 (50), 281 (20), 279 (21), 277 (20), 219 (25), 205 (20), 189 (21), 176 (26), 163 (58), 131 (65), 119 (36), 115 (36), 103 (48), 102 (26), 95 (36), 91 (21), 89 (64), 88 (64), 77 (70), 63 (36), 51 (25), 39 (48).

4-Bromo-5-(2-methoxyphenyl)-2-(3-nitrophenyl)cyclopent-4-ene-1,3-dione (4a). The compound was a yellow amorphous residue. FTIR (NaCl, film) ν_{max}, cm^{-1}: 3080, 2955, 2923, 2852, 1750, 1709, 1604, 1529, 1486, 1463, 1347, 1265, 1144, 1021, 735, 732, 691. ^{1}H NMR, δ_H (300 MHz, $CDCl_3$): 3.89 (s, 3H), 4.38 (s, 1H), 7.05−7.14 (m, 2H), 7.37 (dd, 1H, *J* = 7.8 and 1.8 Hz), 7.50−7.58 (m, 1H), 7.60 (brd, 1H, *J* = 7.8 Hz), 7.67 (brd, 1H, *J* = 7.8 Hz), 8.16−8.17 (m, 1H), 8.22 (dt, 1H, *J* = 8.1 and 1.5 Hz). ^{13}C NMR, δ_C (75 MHz, $CDCl_3$): 55.8, 56.1, 111.6, 117.1, 120.7, 123.3, 123.4, 130.0, 132.8, 133.7, 135.3, 145.1, 148.5, 156.8, 156.9, 191.8, 194.1. EM, *m*/*z* (%): 403 (38) $[M + 2]^{+\bullet}$, 401 (38) ($C_{18}H_{12}BrNO_5$) $[M^{+\bullet}]$, 322 (28), 294 (28), 219 (22), 150 (41), 149 (20), 135 (21), 131 (84), 124 (31), 119 (36), 115 (34), 109 (23), 103 (39), 102 (19), 97 (23), 95 (27), 94 (24), 91 (21), 89 (61), 88 (79), 86 (58), 84 (87), 77 (100), 76 (26), 75 (31), 71 (20), 63 (49), 61 (28), 57 (34), 51 (81), 50 (24). High-resolution mass spectrometry (HRMS) (ESI) calculated for $[C_{18}H_{12}BrNNaO_5]^{+}$, 423.9791; found, 423.9787.

Synthesis of Compound 6. Compound **5b** (100 mg, 0.37 mmol), 3-nitrobenzaldehyde (67 mg, 0.44 mmol), dichloromethane (3 mL), TBDMSOTf (101 μL, 0.44 mmol), and DIPEA (130 μL, 0.74 mmol) were added to a two-necked round-bottom flask (25 mL), under a nitrogen atmosphere. The resulting mixture was stirred at room temperature for 1 h. The resulting organic phase was washed with 3 mol L^{-1} HCl (2 × 25 mL) and brine (2 × 25 mL). The combined organic layers were dried over magnesium sulfate, filtered, and concentrated under reduced pressure. The resulting residue was purified by column chromatography on silica gel eluted with hexane/dichlorometane (1:1, v/v). Compound **6** was obtained with 80% yield.

3-Bromo-5-((*tert*-butyldimethylsilyloxy)(3-nitrophenyl)-methyl)-4-(4-fluoro-2-methoxyphenyl)furan-2(5*H*)-one (6). The compound was a white solid. Melting point (mp): 161.2−162.8 °C. FTIR (KBr) ν_{max}, cm^{-1}: 2957, 2929, 2856, 2855, 1763, 1609, 1528, 1500, 1469, 1353, 1286, 1127, 1020, 837, 781. ^{1}H NMR, δ_H (300 MHz, $CDCl_3$): −0.38 (s, 3H), −0.28 (s, 3H), 0.78 (s, 9H), 3.92 (s, 3H), 4.84 (d, 1H, *J* = 2.4 Hz), 5.83 (d, 1H, *J* = 2.4 Hz), 6.72 (dd, 1H, *J* = 2.4 and 10.5 Hz), 6.80−6.86 (m, 1H), 7.50−7.54 (m, 1H), 7.66−7.74 (m, 2H), 8.03−8.05 (m, 1H), 8.13−8.16 (m, 1H). ^{13}C NMR, δ_C (75 MHz, $CDCl_3$): −5.7, −4.6, 17.8, 25.4, 55.9, 73.0, 86.1, 100.0 (d, *J* = 26.0 Hz), 108.0 (d, *J* = 21.7 Hz), 110.3, 114.7 (d, *J* = 3.3 Hz), 121.5, 123.3, 129.3, 132.3 (d, *J* = 10.4 Hz), 133.4, 141.9, 147.8, 156.1, 158.3 (d, *J* = 10.3 Hz), 165.2 (d, *J* = 251.9 Hz), 168.2. Scheme 1. Synthesis of Compounds 3a and 4a

Synthesis of Compounds 3b and 4b. Compound **6** (100 mg, 0.18 mmol), dichloromethane (3 mL), and DBU (49 μL, 0.36 mmol) were added to a two-necked round-bottom flask (25 mL), under a nitrogen atmosphere. The resultant mixture was refluxed for 1 h. Dichloromethane (70 mL) was added, and the organic phase was washed with 3 mol L^{-1} HCl (2 × 25 mL) and brine (2 × 25 mL). The organic layer was dried over magnesium sulfate, filtered, and concentrated under reduced pressure. The residue obtained was purified by column chromatography on silica gel eluted with hexane/ethyl acetate (3:1, v/v) to afford compounds **3b** and **4b** in 35 and 49% yields, respectively.

(*Z*)-3-Bromo-4-(4-fluoro-2-methoxyphenyl)-5-(3-nitrobenzylidene)furan-2(5*H*)-one (3b). The compound was a yellow solid. mp: 156.1−158.6 °C. FTIR (KBr) ν_{max}, cm^{-1}: 3033, 2997, 2967, 2935, 1769, 1617, 1597, 1527, 1499, 1347, 1281, 987, 839. ^{1}H NMR, δ_H (300 MHz, $CDCl_3$): 3.86 (s, 3H), 5.96 (s, 1H), 6.80−6.89 (m, 2H), 7.23−7.28 (m, 1H), 7.58 (t, 1H, *J* = 8.1 Hz), 8.15−8.19 (m, 1H), 8.22 (d, 1H, *J* = 8.1 Hz), 8.39−8.40 (m, 1H). ^{13}C NMR, δ_C (75 MHz, $CDCl_3$): 56.0, 100.3 (d, *J* = 25.9 Hz), 107.8 (d, *J* = 22.0 Hz), 110.3, 112.6, 113.1 (d, *J* = 3.3 Hz), 123.6, 125.1, 129.9, 131.4 (d, *J* = 10.6 Hz), 134.2, 135.8, 148.4, 149.3, 151.2, 158.1 (d, *J* = 10.4 Hz), 164.3, 165.2 (d, *J* = 249.9 Hz). Study of the Conversion of Rubrolide Analogues to Cyclopentenediones. To verify the hypothesis that cyclopent-4-ene-1,3-dione was formed through rearrangement of the corresponding rubrolide analogues, we have tried to obtain compound **4b** by treating compound **3b** with DBU (2.0 equiv) in dichloromethane under reflux for 1 h. The resulting mixture was worked-up as described for the synthesis from compound **6**. Compound **4b** was obtained with 50% yield, and 50% of compound **3b** was recovered.

Chloroplast Isolation and Total Chlorophyll (Chl) Determination. Intact chloroplasts were obtained from market spinach leaves (*Spinacea oleraceae* L.) as published[28,29] by homogenization and differential centrifugation, and they were resuspended in a small volume of the following medium: 400 mM sucrose, 5 mM $MgCl_2$, 10 mM KCl, and 30 mM tricine−KOH (pH 8.0). The Chl concentration was determined as reported.[29,30]

Chl and Fluorescence Determinations. Chl *a* fluorescence transients of Photosystem II (PSII) were measured in thylakoids with a Handy plant efficient analyzer (PEA, Hansatech, King's Lynn, Norfolk, U.K.) as previously described.[31,32] The maximum fluorescence yield from the sample was generated by illumination for 2 s with continuous light (650 nm peak wavelength, intensity equivalent of 2830 μmol of photons m^{-2} s^{-1}, and gain of 0.7) provided by an array of three light-emitting diodes. The reaction medium set was that employed in basal non-cyclic electron transport measurements without methyl viologen (MV). To monitor Chl and fluorescence transients, aliquots of dark-adapted thylakoids for 5 min containing 60 μg of Chl were transferred to a filter paper by gravity with a dot-blot apparatus (Bio-Rad, Hercules, CA) to ensure a homogeneous and reproducible distribution of thylakoids. The filter paper was dipped immediately in 3 mL of the medium with different concentrations of the tested compounds, and the control contained medium plus the amount of dimethyl sulfoxide (DMSO) employed for dissolving each compound at the different used concentrations. Chloroplasts infiltrated with 50 μM 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU) were used as a positive control.

Measurement of Adenosine Triphosphate (ATP) Synthesis. To measure ATP synthesis, intact chloroplasts (20 μg/mL of Chl) were broken by osmotic rupture in non-buffered solution with 100 mM sorbitol, 10 mM KCl, 5 mM $MgCl_2$, 0.5 mM KCN, 50 μM MV (MV was used as an electron acceptor), 1 mM Na^+−tricine (pH 8.0), and 1 mM ADP (pH 6.7). The pH was adjusted to 8.0 with 50 mM KOH, and the mixture was illuminated for 1 min. The synthesized ATP was calculated as micromoles of ATP per milligram of Chl per hour.[29,33]

Measurement of the Rate of Non-cyclic Electron Transport. Electron flow (basal, phosphorylating, and uncoupled) from water to MV was monitored with a Yellow Springs Instrument (YSI) oxygraph using a Clark-type electrode.[29,34] Light-induced non-cyclic electron transport determinations were performed in the presence of 50 μM MV. Chloroplasts were efficiently lysed to yield free thylakoids prior to each experiment by incubating them in the following basal electron transport medium: 100 mM sorbitol, 10 mM KCl, 5 mM $MgCl_2$, 0.5 mM KCN, and 30 mM *N*-tris[hydroxymethyl]methylglicine (tricine) buffer (pH 8.0 with the addition of KOH). A total of 20 μg of Chl/mL of medium was illuminated for 1 min. Phosphorylating non-cyclic electron transport was measured as the basal non-cyclic electron transport medium in the addition of 1 mM ADP and 3 mM KH_2PO_4. Uncoupled electron transport was tested in the basal transport medium by adding 6 mM NH_4Cl as the uncoupler agent.

Uncoupled PSII and Photosystem I (PSI) Electron Flow Measurements. These experiments were performed in an uncoupled non-cyclic electron transport assay. The activities were monitored with a YSI oxygen monitor, model 5300A, using a Clark-type electrode. Uncoupled PSII from water to 2,5-dichloro-1,4-benzoquinone (DCBQ)[35] was monitored using the basal electron transport medium, and 1 μM 2,5-dibromo-6-isopropyl-3-methyl-1,4-benzoquinone (DBMIB), 100 μM DCBQ, and 6 mM NH_4Cl were added. MV was omitted. DCBQ accepts electrons at the D1 protein. Partial reaction of PSII electron transport from water to sodium silicomolybdate (SiMo) was determined as in PSII with the same basal electron transport medium without MV, and 50 μM SiMo and 10 μM DCMU were added.[35] These electron flow activities were monitored with a YSI oxygen monitor, model 5300, using a Clark-type electrode.

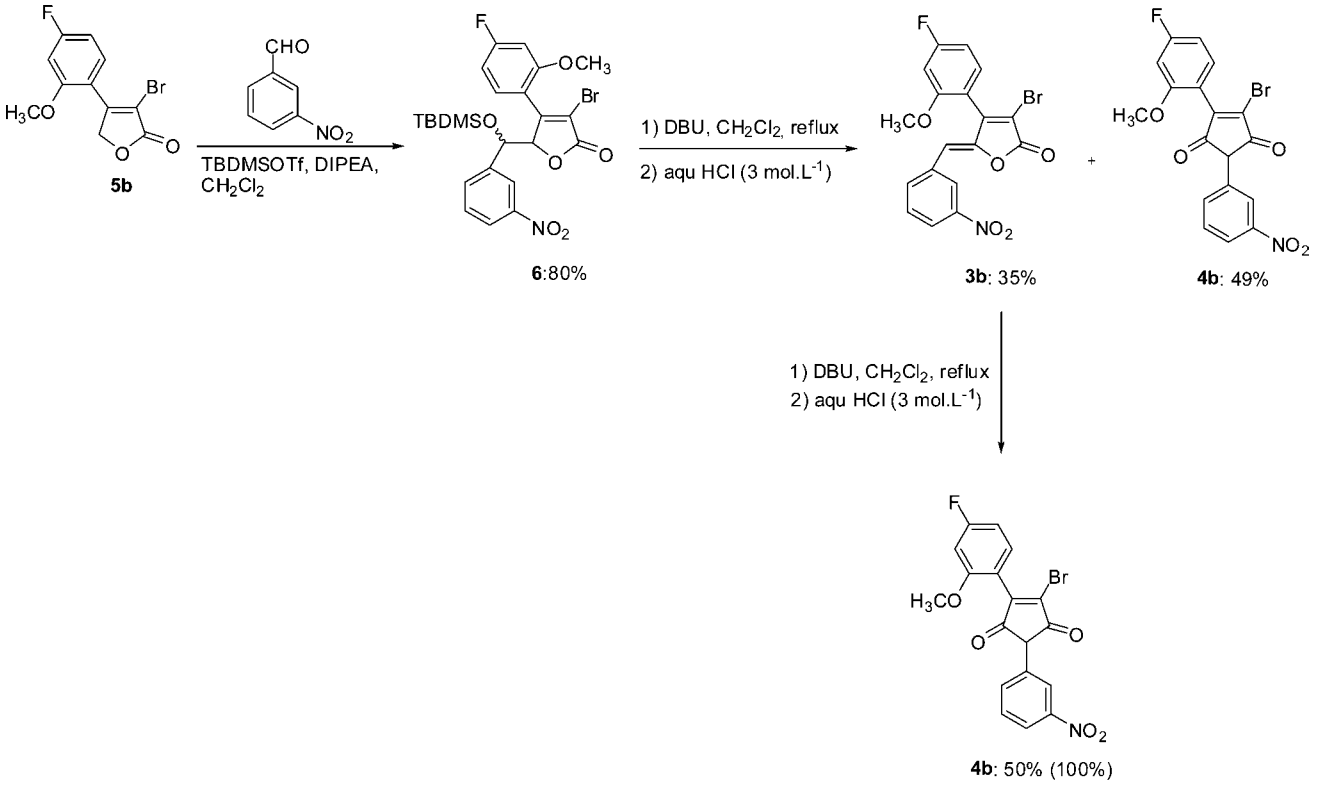
Scheme 2. Synthesis of Compounds 3b and 4b



RESULTS AND DISCUSSION

Synthesis. In attempting to synthesize rubrolide analogues bearing a nitro group at the *meta* position (**3a** and **3b**), we employed the same approach used for the preparation of rubrolide analogues **2a** and **2b**.[23] Briefly, lactone **5a** (Scheme 1) was treated with *tert*-butyldimethylsilyl trifluoromethanesulfonate and *N*,*N*-diisopropylethylamine to yield the corresponding *tert*-butyldimethylsilyl intermediate, which was reacted *in situ* with 3-nitrobenzaldehyde. The silylated adducts were treated with DBU to afford the desired rubrolide analogue **3a** (30% yield). However, cyclopent-4-ene-1,3-dione **4a** was isolated as a major product (42% yield). This result was surprising and unexpected because this methodology has been previously applied for the preparation of other rubrolide analogues, and no rearranged products were reported.[23,36,37]

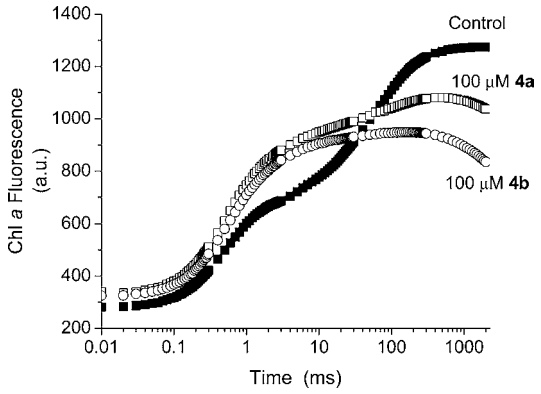


Figure 2. Fluorescence rise kinetics of freshly lysed broken chloroplasts infiltrated with (□) compound **4a** and (○) compound **4b** and compared to the (■) control chloroplasts. Chl *a* fluorescence induction curves were measured at room temperature. Details are in the Materials and Methods. Data are averages of three replicates.

Base-catalyzed rearrangement of alkylidenebutenolides to the isomeric cyclopentenediones has already been documented in the literature,[38−40] and this approach has been used for the synthesis of a range of natural cyclopent-4-ene-1,3-diones and derivatives.[40,41] Commonly, this procedure is carried out by treating butenolide with sodium methoxy in methanol. The suggested mechanism involves the electrophilic attack to carbon of the carbonyl group of benzylidene, which results in the opening of the ring, followed by a new cyclization to the cyclopentenedione ring.[40]

To verify if cyclopentenedione **4b** was in fact formed by means of a rearrangement of rubrolide **3b**, instead of being produced directly from the sililated intermediate, the former was reacted with DBU, in the same reaction conditions, affording compound **4b** with 50% yield (Scheme 2). Despite the strong Lewis basic property of DBU, it is not a good nucleophile and unlikely to be responsible for the opening of the butenolide ring.[42] A good example is the synthetic procedure reported by Tan and co-workers[41] for the synthesis of the natural cyclopentenedione known as methyl linderone. In this approach, the reaction of a precursor butenolide with sodium methoxy led to the desired cyclopent-4-ene-1,3-dione. However, treatment of the same precursor with DBU resulted in a basic catalyzed elimination reaction but not to the conversion of butenolide to cyclopentenedione. When the product of this elimination was reacted with NaOMe, cyclopentenedione was obtained with 71% yield.[41]

Thus, in view of the poor nucleophilic property of DBU, we supposed that the rearrangement of the rubrolide analogues to cyclopent-4-ene-1,3-diones could be caused by the presence of traces of water in DBU. In fact, Cota et al.[42] demonstrated that the DBU−water system acts as a basic catalyst for aldol

condensation reactions. By means of NMR studies, the authors showed that the reaction with water changes the DBU structure to a second resonance structure, which contains hydroxide ions responsible for the nucleophilic attack in the aldol condensation (see Scheme S1 of the Supporting Information).[42]

The presence of water in DBU used was confirmed by IR spectroscopy. Thus, we suppose that the water−DBU system is responsible for the rearrangement of rubrolide to cyclopentenedione. Also, this rearrangement can be facilitated by the presence of the electron-withdrawing NO_2 group in the benzylidene ring, which makes the lactone carbonyl more

Table 2. Derived Parameters, Their Description, and Their Formula Using Data Extracted from the Chl *a* Fluorescence (OJIP) Transient Presented in This Work

fluorescence parameters derived from the extracted data	
$M_0 = 4(F_{300\,\mu s} - F_0)/(F_M - F_0)$	approximated initial slope (in ms^{-1}) of the fluorescence transient $V = f(t)$
$Sm = (area)/(F_M - F_0)$	normalized total complementary area above the OJIP transient (reflecting multiple turnover Q_A reduction events)
yields or flux ratios	
$\varphi_{Po} = TR_0/ABS = [1 - F_0/F_M]$	maximum quantum yield of primary photochemistry at $t = 0$
$\varphi_{Eo} = ET_0/ABS = [1 - F_J/F_M)]$	quantum yield for electron transport at $t = 0$
$\psi_{Eo} = ET_0/TR_0 = (1 - V_J)$	probability (at $t = 0$) that a trapped exciton moves an electron into the electron transport chain beyond Q_A^-
$\varphi_{Do} = 1 - \varphi_{Po} = (F_0/F_M)$	quantum yield (at $t = 0$) of energy dissipation
$\delta R_0 = RE_0/ET_0 = (1 - V_I)/(1 - V_J)$	efficiency with which an electron can move from the reduced intersystem electron acceptors to the PSI end of electron acceptors of PSI
$\varphi R_0 = RE_0/ABS = \varphi_{Po}*\psi_{Eo}*\delta R_0 = 1 - (F_I/F_M)$	quantum yield for the reduction of end of acceptors of PSI per photon absorbed
$RE_0/TR_0 = \psi_{Eo}\delta R_0$	efficiency with which a trapped exciton moves an electron into the electron transport chain from Q_A^- to the PSI end of electron acceptors
specific energy fluxes or activities [per reaction Q_A^- reducing the PSII reaction center (RC)]	
$ABS/RC = M_0(1/V_J)(1/\varphi_{Po})$	absorption per RC
$TR_0/RC = M_0/V_J$	trapped energy flux per RC (at $t = 0$)
$ET_0/RC = M_0(1/V_J)(\psi_{Eo})$	electron transport flux per RC (at $t = 0$)
phenomenological energy fluxes [per excited cross-section (CS)]	
ABS/CS_0	absorption flux per CS
TR_0/CS_0	trapped energy flux per CS (at $t = 0$)
ET_0/CS_0	electron transport flux per CS (at $t = 0$)
de-excitation rate constants	
K_p	photochemical de-excitation rate constant
K_n	non-photochemical de-excitation rate constant
sum K	sum of photochemical and non-photochemical rate constants
performance index at $t = 0$	
	performance index on absorption basis

$$PI_{ABS} = \frac{RC}{ABS}\frac{\varphi_{Po}}{1-\varphi_{Po}}\frac{\psi_{Eo}}{1-\psi_{Eo}}$$

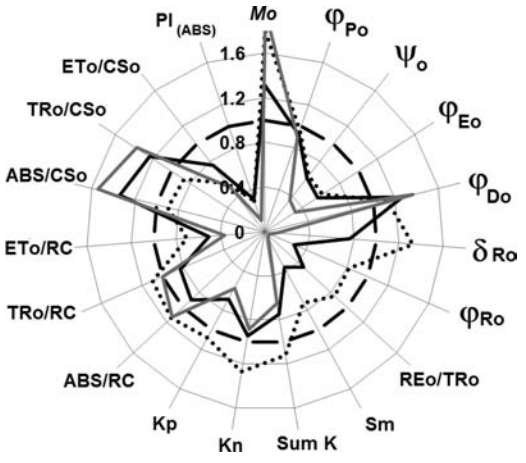

Figure 5. Radar graph showing the effects of compound **4a** (dotted line) and compound **4b** (black line) at 50 μM in comparison to 50 μM DCMU (gray line) on the derived parameters calculated from the OJIP transients of Chl *a* presented by dark-adapted freshly lysed chloroplasts. The control is represented by a dashed black line at the center of the radar and is equal to the unity.

electrophilic and susceptible to a nucleophilic attack. This supposition led us to speculate why cyclopentenedione was not isolated in our previous work[23] as a co-product of the reaction that afforded compounds **2a** and **2b**. Then, we decided to treat compound **2b** with the same DBU used in the present work, under the same reaction conditions. As the reaction was monitored by thin-layer chromatography (TLC), we observed a degradation of the starting material and no signs of the corresponding cyclopent-4-ene-1,3-dione. We suppose then that the reason for this degradation could be attributed to the higher electron-withdrawing effect of the nitro group in the *para* position, which, by means of the resonance effect, makes the lactone carbonyl even more susceptible to nucleophilic attack, resulting in different products. The formation of acyclic products from some other butenolides from the treatment with a strong base has already been reported.[40]

Chl and Fluorescence Transient Measurements in the Presence of Compounds 3b, 4a, and 4b. Chl *a* fluorescence measurements on photosynthetic organisms under different conditions, including stress, can be analyzed to provide detailed information about the structure, conformation, and function of the photosynthetic apparatus, especially of PSII and electron transport activity.[32] On this premise, different concentrations of compounds **3b**, **4a**, and **4b** were assayed on Chl *a* fluorescence of freshly lysed spinach chloroplasts. Compound **3a** was not tested because of degradation, as assessed by ^{1}H NMR experiments. Figure 2 shows the effects of compounds **4a** and **4b** at 100 μM on the induction curve of fluorescence of Chl *a*. Compound **3b** did not show any modification in the transients (data not shown).

OJIP transients were analyzed according to the JIP test, and the measured parameters are presented in Table 1: fluorescence intensity level (F_0) when plastoquinone electron acceptor pool, Q_A, is fully oxidized and fluorescence of the Chl *a* level when Q_A is transiently fully reduced (F_M). F_1 is the fluorescence Chl *a*

dx.doi.org/10.1021/jf5014605 | J. Agric. Food Chem. 2014, 62, 5772−5780

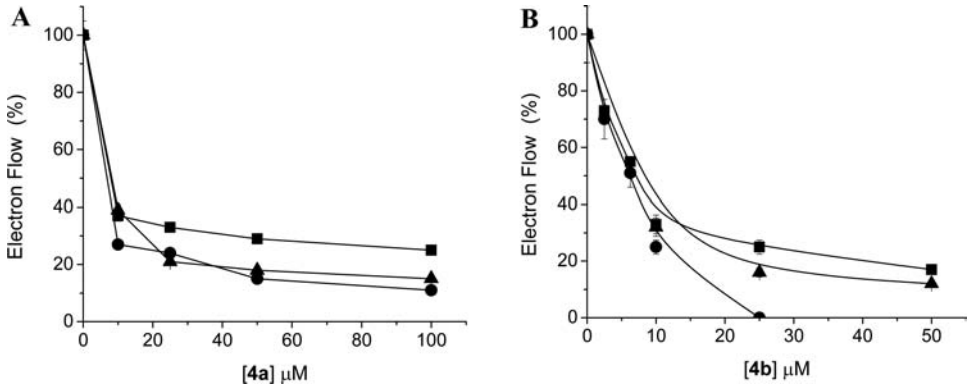

Figure 6. Effect of compound **4a** on electron transport flow: (■) basal, (●) phosphorylating, and (▲) uncoupled conditions. Control values in = 100% = 450, 880, and 1200 μequiv of e^- mg^{-1} of Chl h^{-1}, respectively. Each curve is the average of three replicates. Other conditions are indicated in the Materials and Methods.

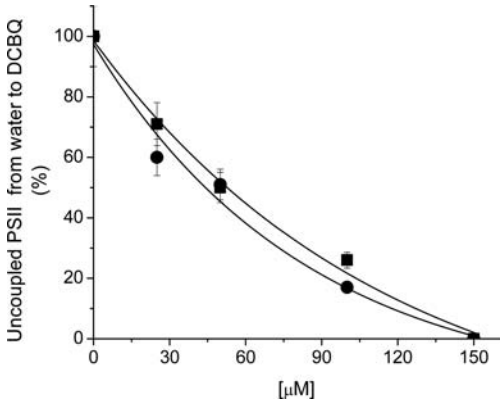

Figure 7. Effects of (■) compound **4a** and (●) compound **4b** on uncoupled electron transport flow of PSII measured from water to DCBQ. Control values = 100% = 300 μequiv of e^- mg^{-1} of Chl h^{-1}, respectively. Each curve is the average of three replicates.

intensity level at 0.05 ms; F_2 is the fluorescence Chl *a* intensity level at 0.1 ms; F_3 is the fluorescence Chl *a* intensity level at 0.3 ms; F_4 or F_J is the fluorescence Chl *a* intensity level at 2 ms; and F_5 is the fluorescence Chl *a* intensity level at 30 ms. The area is the area over the curve between F_0 and F_M and relates the pool size of PSII electron transport acceptors.[43,45]

The OJIP data were normalized using the equation $V_t = (F_t - F_0)/(F_M - F_0)$ and are presented as the kinetics of relative variable fluorescence between F_0 and F_M (Figures 3A and 4A). The difference between the normalized treated transients minus the control transients showed an increase in the 2−4 ms range, a J band (Figures 3B and 4B). The fluorescence rise to the J band provides information about single-turnover events of the primary reactions of the photochemistry, mainly Q_A reduction. This reflects light-driven accumulation of Q_A^- with Q_B, indicating that the electron transport beyond Q_A is blocked at the Q_B level, just like the commercial herbicide DCMU. These finds suggest that both compounds (**4a** and **4b**) interact at the D1 protein site and the unused energy is dissipated as heat.[32]

Using the program Biolyzer HP3 (from a laboratory at the University of Geneva; available at http://www.unige.ch/sciences/biologie/bioen), data from Table 1 were used to calculate other parameters related to the electron transport activity, such as the yield ratios φ_{Po}, ψ_{Eo}, φR_0, and RE_0/TR_0.[32] These derived parameters are depicted in Table 2, and the effects of compounds **4a** and **4b** and DCMU at 50 μM on these parameters are shown as a radar plot in Figure 5 (the effects at other concentrations are not shown for graph clarity). The normalized area (Sm), the electron transport per reaction center and per cross-section, and the performance index on an absorption basis were decreased by the compounds, while M_0 and φ_{Do} were increased by both compounds **4a** and **4b**. However, ABS/CS_0 and TR_0/CS_0 were increased only by compound **4b** and DCMU. These results suggest that compounds **4a** and **4b** inhibit the photosynthetic electron transport in the same site as herbicide DCMU, with compound **4b** being more potent than compound **4a**.

Effect of Cyclopent-4-ene-1,3-diones 4a and 4b on the Electron Transport Rate from Water to MV. To corroborate the site and mechanisms of action of cyclopentenediones on electron transport flow, different concentrations of compounds **4a** and **4b** were assayed by polarography on the electron transport under basal, phosphorylating, and uncoupled conditions. Because compound **3b** did not modify the Chl *a* fluorescence measurements, it was not subjected to this test. Panels A and B of Figure 6 show that all three conditions of the electron transport flow were inhibited by both compounds. The IC_{50} values (i.e., the concentration required to inhibit 50% of the activity) for the uncoupled electron flow were 9.5 and 8.4 μM for compounds **4a** and **4b**, respectively. These results indicate that both compounds act as Hill reaction inhibitors. DCMU inhibits both oxygen evolution and ATP synthesis at 5 μM;[44] therefore, compounds **4a** and **4b** have similar potency as an inhibitor to the PSII reducing side, just like DCMU.

To localize the target of compounds **4a** and **4b** on the thylakoid electron transport chain, effects on partial reactions of PSII and PSI electron transport were determined using appropriate artificial electron donors, electron acceptors, and electron transport inhibitors.[31,45] Figure 7 shows that compounds **4a** and **4b** inhibited PSII measured from water to DCBQ, with I_{50} values of 50 and 44 μM, respectively. Contrarily, these compounds showed no effects on PSI (data not shown). Furthermore, the activity of H_2O to SiMo was not affected by these compounds, indicating that the interaction and inhibition site of both compounds **4a** and **4b** are located in the PSII electron transport chain. These data corroborate the results obtained from measurements of the Chl *a* fluorescence transient.

The higher activity of compound **4b** when compared to compound **4a** may be related to the presence of the fluorine

dx.doi.org/10.1021/jf5014605 | J. Agric. Food Chem. 2014, 62, 5772−5780

substituent at the benzene ring of the first. Because of its high electronegativity, fluorine acts as an electron-withdrawing group and contributes to reduce the redox potential of compound **4b** relative to compound **4a**, thus enhancing the ability of compound **4b** to act as electron acceptors and inhibit the photosynthetic electron transport.

In a previous work, a QSAR study showed that the photosynthetic inhibition ability of rubrolide analogues was mainly correlated to the HOMO and LUMO energies.[23] However, using those data in attempting to explain the higher activity of cyclopentenediones is hindered by the difference in the structural skeleton between these two classes of compounds. On the other hand, a series of studies has concluded that biological activities (including herbicide properties) of various classes of organic compounds are related to the high-energy gap between HOMO and LUMO. For many of these studies, the higher the HOMO−LUMO energy gap of the compounds, the higher their biological activity.[46−50] Thus, we decided to calculate the HOMO−LUMO energy gap for compounds **3a**, **3b**, **4a**, and **4b**. Results obtained showed that cyclopentenediones **4a** and **4b**, which have higher biological activities, also have higher energy gaps (7.940 and 7.950 eV, respectively) than the corresponding rubrolides **3a** and **3b** (7.577 and 7.580 eV, respectively). This finding may suggest that the ability to accept electrons and interfere in the photosynthetic electron transport of these compounds may be related to higher energy gaps between HOMO and LUMO. Also, the energy gap between HOMO and LUMO for compound **4b** was found to be higher than that for compound **4a**, thus helping to explain the higher activity of the first in comparison to the former.

In this work, we have shown that rubrolide analogues bearing a nitro group at the benzylidene ring (*meta* position) can be converted into cyclopent-4-ene-1,3-diones using excess DBU with traces of water in the reaction medium. When assayed on Chl *a* fluorescence of freshly lysed spinach chloroplasts, these cyclopent-4-ene-1,3-diones were more active than the precursor rubrolides, displaying the same degree of potency as the commercial herbicide DCMU. Also, the presence of a fluorine atom at one of the benzene rings enhances the interference of cyclopent-4-ene-1,3-diones in the Chl *a* transients. By means of the polarography assay, we have further demonstrated that cyclopent-4-ene-1,3-diones act as Hill reaction inhibitors by binding the D1 protein at the reducing side of the PSII. These findings clearly show that cyclopent-4-ene-1,3-diones bearing electron-withdrawing groups at the aromatic rings can be regarded as promising candidates for the development of novel photosynthesis-inhibiting herbicides.

Supporting Information

ABSTRACT: The peptide elicitor PIP-1 (YGIHTH-NH_2) induced various defense responses in tobacco cells. Types of defense responses induced by PIP-1 were different based on its concentration range: oxidative burst (an early response) was induced at low micromolar levels, but phytoalexin production (a late response) required about 10−50-fold higher concentrations than those required for oxidative burst. We assumed that rapid decreases in the PIP-1 concentration due to enzymatic hydrolysis in the culture media could cause this difference. To examine the potential impact of such degradation particularly on induction of phytoalexin biosynthesis, we designed a degradation-resistant analogue, MePIP-1, in which the amide bond between the fifth and sixth residues was N-methylated. MePIP-1 was considerably more stable than PIP-1 and induced significant phytoalexin production upon treatment at low micromolar levels. Further investigation of the mechanism of action of MePIP-1 showed a requirement of continuous elicitor stimulation for 3−6 h for the phytoalexin production, which is likely to be regulated by long-lasting MAP kinase activation.

KEYWORDS: *peptide elicitor, plant immunity, phytoalexin, MAP kinases*

INTRODUCTION

Plants face challenges from a variety of pathogens such as bacteria, fungi, and viruses. To maintain their growth and subsequent reproduction against pathogens, plants have evolved unique immune systems.[1,2] When plants sense pathogenic infections, they produce various defense responses, including oxidative burst, reinforcement of the cell wall, phytoalexin synthesis, and hypersensitive response (HR), to protect themselves.[3−5] Plants recognize various molecules derived from the pathogens, which are referred to as either elicitors or pathogen-associated molecular patterns, to initiate a series of defense responses.[6]

Elicitors with various chemical properties have been reported. Peptides are among the most well-studied elicitors, which include the following: flg22, a 22 amino acid peptide from bacterial flagellin; elf18, an 18 amino acid peptide from bacterial elongation factor Tu; and Pep13, a 13 amino acid peptide from transglutaminase of *Phytophthora sojae*.[7−9] In addition, several endogenous peptide elicitors released from host plants upon wounding and/or infection were identified. For example, a 23 amino acid peptide AtPep1 was isolated from *Arabidopsis* and its orthologue ZmPep1 from maize.[10,11] These elicitors are mainly perceived by distinct receptor-like kinases (RLKs). RLKs activate the downstream signaling networks controlled by mitogen-activated protein (MAP) kinase and/or calcium-dependent protein kinase cascades, which further regulate the production and the activity of transcription factors, enzymes, hormones, and phytoalexins.[12]

Recently, we discovered a peptide elicitor (YGIHTH-NH_2, PIP-1) by screening of a synthetic combinatorial random hexapeptide library.[13] PIP-1 induces typical defense responses, such as oxidative burst, phytoalexin biosynthesis, and defense-related gene expressions, in tobacco cells via a jasmonic acid signaling pathway. Intriguingly, the types of defense responses induced by PIP-1 were different based on its concentration range: oxidative burst, which is observed immediately after treatment of PIP-1, was induced at low micromolar concentrations, but for the induction of capsidiol biosynthesis (Figure 1), which is induced 6−24 h after treatment, 10−50-fold higher concentrations than those required for oxidative burst were necessary. Since PIP-1 is a linear short peptide, it readily undergoes enzymatic degradation in and/or on the surface of the plant cells. Although the exact fate of applied PIP-1 after treatment in the culture media of tobacco cells has not been examined yet, the decreases in PIP-1 concentrations due to degradation may affect the duration of the stimulation of immune systems, leading to failure to induce late-stage defense responses such as phytoalexin biosynthesis.

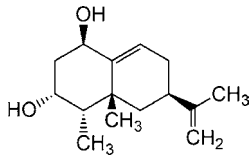

Figure 1. Structure of capsidiol.

In the present study, we hypothesized that inhibition of enzymatic degradation of PIP-1 can change the profile of

induced defense responses in tobacco, in which oxidative burst and phytoalexin production would be induced at the similar concentration range. Therefore, a degradation-resistant PIP-1 analogue was designed based on the degradation profile of PIP-1. Using this analogue, we examined the effect of elicitor stabilization on induction of defense responses including oxidative burst, phytoalexin biosynthesis, and HR-like cell death. To our knowledge, this is the first report demonstrating that enzymatic degradation of elicitors in the culture media considerably affects the induction of defense responses, particularly those in the late stage, such as phytoalexin biosynthesis in tobacco cells.

MATERIALS AND METHODS

Plant Cell Culture. Suspension-cultured tobacco cells (*Nicotiana tabacum* cv. Xanthi) were grown in a 100 mL Erlenmeyer flask with 25 mL of liquid Linsmaier and Skoog (LS) medium at pH 5.75 containing 1-napthalenacetic acid (10 μM), 5-benzyladenine (1 μM), and 3% sucrose. The cell suspensions were maintained at 25 °C under continuous illumination on a rotary shaker (100 rpm) with subculture every 2 weeks and used at 9 and 10 days after subculture for experiments.

Chemicals. *N*-(9-Fluorenylmethoxycarbonyl) (Fmoc)-protected amino acids, Fmoc-NH-SAL resin, and Cl-Trt(2-Cl) resin were purchased from Watanabe Chemical Industries (Hiroshima, Japan). (Carboxymethylaminocarbonyl)-4,4′-bis(dimethylamino)-diphenylamine sodium salt (DA-64) was obtained from Wako Pure Chemical Industries (Osaka, Japan). The peptides YGIHTH-NH_2, YGIHTH-OH and D-(YGIHTH)-NH_2 were previously synthesized in our laboratory.[13] K252a was obtained from LC laboratories (Woburn, MA).

Synthesis of Peptide Analogues. PIP-1 analogues (YGIHT-OH, YGIH-OH, and YGIHTmeA-NH_2) were manually synthesized by using the Fmoc-based solid-phase peptide synthesis technique. The C-terminal amino acids of YGIHT-OH and YGIH-OH were attached to Cl-Trt(2-Cl) resin, and that of YGIHTmeA-NH_2 was attached to Fmoc-NH-SAL resin. Fmoc was deprotected with 20% piperidine in *N*,*N*-dimethylformamide (DMF) three times for 3, 3, and 20 min. Each Fmoc-protected amino acid (3 equiv) was coupled in the presence of *O*-(benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (3 equiv), 1-hydroxybenzotriazole (3 equiv), and *N*,*N*-diisopropylethylamine (6 equiv) in DMF. The reaction was monitored by Kaiser test.[14] After completion of the coupling reaction, the resin was sequentially washed with DMF, diethyl ether, and methanol and dried in vacuo. Cleavage of peptides from the resin and removal of side-chain protecting groups were carried out using the solution A (trifluoroacetic acid (TFA)/triisopropylsilane (TIPS)/dimethoxybenzene (92.5:2.5:5, v/v/v)) for YGIHTmeA-NH_2 and solution B ((TFA/TIPS/distilled water (95:2.5:2.5, v/v/v)) for YGIHT-OH and YGIH-OH, which were reacted with each resin for 2 h at room temperature. After the resin was removed by filtration, cold diethyl ether was added to the filtrate to precipitate the peptides, followed by washing with cold diethyl ether twice and drying in vacuo. The desired peptides were purified by high-performance liquid chromatography (HPLC) using a 250 mm × 10 mm i.d., 5 μm, protein and peptide C18 semipreparative column (Grace, Columbia, MD), and lyophilized. Peptides were identified by electrospray ionization liquid chromatography/mass spectrometry (ESI-LC/MS) on a Shimadzu LCMS-2010 (Kyoto, Japan).

Evaluation of Degradation of PIP-1 and Its Analogues. Tobacco cells were collected using Miracloth (Calbiochem, San Diego, CA), and 0.2 g of cells was resuspended in a microtube containing 1 mL of LS medium. The cells were incubated for 1 h at 25 °C by a tube rotator, and the solution of PIP-1 or its analogues in distilled water (final concentration of 10 μM) was added to the cells. After incubation at 25 °C for a given time period (0−24 h), the media were collected and filtered through syringe filters (0.45 μm pore size). The filtrates were frozen in liquid nitrogen and stored at −80 °C to prevent further peptide degradation. Each sample was subjected to HPLC analysis using a 150 mm × 2.1 mm i.d., 3 μm, Discovery BIO wide pore C18 column (Supelco, St. Louis, MO) for quantitation. The following condition was used for HPLC analysis: flow rate, 0.2 mL/min; column temperature, 40 °C; mobile phase, 0.1% TFA in H_2O (solvent A) and 0.1% TFA in acetonitrile (solvent B); gradient, 10−30% solvent B for 20 min; UV detection, 215 nm. The amount of peptides in the medium was determined based on a calibration curve constructed using the synthesized standard peptides. Degradation products were identified by comparison of their m/z values and retention times on ESI-LC/MS analysis using an LCMS-2020 (Shimadzu) with those of the synthesized standard peptides.

Measurement of H_2O_2 Generation. H_2O_2 generation was measured as described previously.[15] Briefly, tobacco cells (0.2 g) resuspended in 1 mL of assay buffer (175 mM mannitol, 0.5 mM $CaCl_2$, 0.5 mM K_2SO_4, 2.0 mM MES, pH 5.75) were incubated for 1 h at 25 °C using a tube rotator. After incubation, the cells were treated with PIP-1 analogues (10 μL) and incubated for a given time period (0−12 h) including 2 min to allow cell sedimentation. The supernatants (60 μL) of cell suspension were mixed with the H_2O_2 indicator solution (140 μL; 100 mM DA-64, 1 U/mL horse radish peroxidase, 100 mM PIPES, pH 7.0) in a 96-well microplate, and incubated for 10 min at 37 °C. The absorbance at 727 nm was read with a Benchmark microplate reader (Bio-Rad, Hercules, CA). The amount of H_2O_2 was determined based on a calibration curve.

Quantitation of Capsidiol. Capsidiol was quantitated as described previously.[13] Tobacco cells (0.6 g) resuspended in 3 mL of LS medium were incubated for 1 h. The cells were treated with PIP-1 analogues and incubated for 24 h at 25 °C on a rotary shaker under continuous illumination. After incubation, the culture medium was extracted twice with 4 mL of ethyl acetate and dried in vacuo. The residue was dissolved in 1 mL of ethyl acetate and subjected to QP-2010 gas chromatography/MS (GC/MS) analysis (Shimadzu), equipped with a 30 m × 0.25 mm, 0.25 μm phase thickness, DB-5MS capillary column (J&W Scientific, Folsom, CA). For GC separation, helium was used as a carrier gas (100 kPa), and splitless injections were carried out at 220 °C. The column temperature was initially set at 100 °C for 2 min, then increased up to 270 °C at a rate of 4 °C/min for 42.5 min, and held at 270 °C for 2 min. The interface and ion source were set at 270 and 200 °C, respectively. Spectra were acquired in electron ionization mode with a scan range of m/z 45−500. Capsidiol was identified by comparison of spectra and retention times with authentic standards obtained from *Capsicum annuum* fruits.[16] The amount of capsidiol was quantitated from peak areas of the total ion chromatogram, based on a calibration curve constructed with authentic standards.

Cell Death Assay. Cell death assay was performed as described previously with slight modifications.[17] Tobacco cells (0.2 g) resuspended in 1 mL of LS medium were incubated for 1 h. The cells were treated with PIP-1 analogues and incubated for 24 h at 25 °C using a tube rotator. After incubation, the solution of Evans blue (Wako Pure Chemical Industries) was added into the cell suspension to a final concentration of 0.01%. The cells were reincubated for 15 min and then washed 3 times with distilled water to remove the unabsorbed dye. Washed cells were transferred into 50% methanol containing 1% SDS to extract the dye in the dead cells. After incubation for 1 h at 60 °C, the cells were centrifuged for 15 min at 1900*g*. Absorbance at 595 nm of the supernatant was read on a microplate reader (Bio-Rad).

Analysis of Gene Expressions. Tobacco cells (0.6 g) resuspended in 3 mL of LS medium were incubated for 1 h at 25 °C. The cells were treated with PIP-1 analogues for a given time period (0−6 h). After removal of the medium by filtration, cells were ground in liquid nitrogen using a mortar and pestle. Total RNA was extracted with Trizol reagent (Life Technologies, Carlsbad, CA) according to the manufacturer's instructions. The RNA (40 μg) was treated with 10 U of RQ1 RNase-free DNase (Promega, Madison, WI) for 30 min at 37 °C and then extracted by phenol and chloroform. Resultant RNA (1 μg) was reverse transcribed to cDNA in a final volume of 20 μL by using a PrimeScript RT reagent kit (Takara Bio, Otsu, Japan) according to the manufacturer's instructions. For

semiquantitative reverse transcription polymerase chain reaction (RT-PCR), 1 μL of the cDNA template was used for PCR in a solution (final volume of 20 μL) containing 0.5 U of TaKaRa Ex Taq (Takara Bio), 200 μM each of dNTP mixture, and 0.3 μM each of forward and reverse primers: *SIPK*, 5′-GATGTCTGATGCGGGGGCGG-3′ and 5′-GTGGCTCAACGTCGCCGGAA-3′; *WIPK*, 5′-CGGTGGAGGTCAATTCCCTG-3′ and 5′-CATTTACCAAAAGGTTGCTC-3′;[18] *Actin*, 5′-CCATTGGCTCAGAGAGGTTC-3′ and 5′-GTTGGAAGGTGCTGAGAG-3′.[19] PCR was performed on a T100 thermal cycler (Bio-Rad) at 95 °C for 3 min (first cycle), 95 °C for 30 s (denaturation), 54−56 °C for 30 s (annealing), 72 °C for 60 s (extension; 26−28 cycles), and 72 °C for 5 min (last cycle). PCR products were separated on a 2% or 3% agarose gel and stained by EtBr (0.5 μg/L) for visualization. For quantitative RT-PCR, 2 μL of the cDNA template was amplified on a Thermal Cycler Dice (Takara Bio) in the presence of amplification buffer (25 μL of final volume) containing SYBR Premix Ex *Taq*II (Takara Bio) and 0.4 μM each of following forward and reverse primers: *HMGR2*, 5′-GAGGGGAGAGGAAAGTCTGTAG-3′ and 5′-TCTCTATGTTCTGAGCTGGGTC-3′; *EAS*, 5′-GTAAGGACTCATGCTGACGA-3′ and 5′-TCCACCACCTTGATACTTCG-3′. The relative quantities were determined using *Actin* as a reference gene.

In-Gel Kinase Assay. Protein extraction and an in-gel kinase assay were performed as described previously with modifications.[20] Tobacco cells (0.6 g) resuspended in 3 mL of LS medium were incubated for 1 h at 25 °C. Cells were treated with PIP-1 analogues for a given time period (0−9 h). After removal of medium, tobacco cells were ground in liquid nitrogen using a mortar and pestle. Powdered tobacco cells were homogenized with 1.5 mL of extraction buffer (50 mM HEPES, pH 7.4, 5 mM EDTA, 5 mM EGTA, 5 mM DTT, 10 mM NaF, 10 mM Na_3VO_4, 50 mM β-glycerophosphate, 1 mM 4-(2-aminoethyl)-benzenesulfonyl fluoride, 2 μg/mL antipain, 2 μg/mL aprotinin, and 2 μg/mL leupeptin) and centrifuged at 16 000*g* for 30 min at 4 °C. Supernatants were quickly frozen in liquid nitrogen and stored at −80 °C. Extracts containing 10 μg of proteins were electrophoresed on 12% SDS-polyacrylamide gels embedded with 0.25 mg/mL myelin basic protein (MBP) (Sigma, St. Louis, MO) as a kinase substrate. After electrophoresis, the gel was washed with washing buffer (20% 2-propanol, 50 mM Tris, pH 8.0) three times for 20 min each at room temperature to remove SDS and incubated with buffer A (50 mM Tris, pH 8.0, 5 mM DTT) for 1 h. The proteins in the gel were denatured in denaturation buffer (50 mM Tris−HCl, pH 8.0, 6 M guanidine·HCl, 20 mM DTT, 2 mM EDTA) twice for 30 min each. The kinases were allowed to renature on incubation with buffer A containing 0.04% Tween 20 overnight at 4 °C with five changes of buffer. After equilibration with assay buffer (50 mM HEPES, pH 8.0, 2.0 mM DTT, 0.1 mM EGTA, and 20 mM $MgCl_2$) for 30 min at room temperature, the gel was incubated in 20 mL of assay buffer containing 30 μM ATP and 1.85 MBq of [γ-^{32}P]-ATP (111 TBq/mmol) (PerkinElmer, Waltham, MA) for 1 h at room temperature. The reaction was stopped by transferring the gel into the solution containing 10% trichloroacetic acid (w/v) and 1% sodium phosphate (w/v). The gel was washed five times with the same solution for 2 h each to remove unincorporated [γ-^{32}P]-ATP and dried on filter paper using a vacuum gel-dryer. The dried gel was exposed to BAS-MS2040 imaging plates (Fujifilm, Tokyo, Japan) and analyzed using BAS-2500 (Fujifilm). Prestained size markers (Nacalai Tesque, Kyoto, Japan) were used to estimate the size of the kinases.

RESULTS AND DISCUSSION

Phytoalexin Production Induced by PIP-1. Capsidiol is a major sesquiterpene phytoalexin accumulated in the extracellular medium of tobacco cells after elicitor treatment (Figure 1), which is synthesized through the mevalonate pathway in plants.[21,22] Treatment with PIP-1 at a 100 μM concentration induced a significant amount of capsidiol (4.24 ± 0.51 μg/g FW) in tobacco cells, whereas no capsidiol was detected after treatment with distilled water alone as reported previously.[13] On the other hand, only a marginal level of capsidiol production (0.04 ± 0.07 μg/g FW) was observed upon treatment with 10 μM of PIP-1, which is a 4.5-fold higher concentration than that required for a half-maximum response of oxidative burst. Oxidative burst is an early stage defense response initiated within 5 min, whereas phytoalexin production is a late-stage response observed 6−24 h after elicitor treatment.[23] Since linear peptides such as PIP-1 could be easily degraded in the presence of living cells, we assumed that a rapid decrease in PIP-1 concentrations due to the degradation was attributed to the requirement of high concentrations to induce phytoalexin biosynthesis. This also implies that early short stimulation by PIP-1 may not be enough for induction of phytoalexin biosynthesis. To explore this hypothesis, we first examined the effect of the duration of PIP-1 stimulation on capsidiol production by using various sample treatment procedures. When PIP-1 was removed from the culture media by washing the cells with fresh medium 1 h after treatment at 100 μM, no capsidiol production was detected. To further confirm that long-term stimulation by PIP-1 is required for capsidiol production, a small amount of PIP-1 was repeatedly added (1 μM, 10 times) to the medium over 3 h, which amounted to only 10 μM at most. This repeated treatment induced a significant level of capsidiol (2.17 ± 0.61 μg/g FW), indicating that continuous stimulation of the immune system by PIP-1 is required for capsidiol production in tobacco cells. These results motivated us to synthesize a degradation-resistance PIP-1 analogue, which should allow the induction of phytoalexin biosynthesis at low micromolar concentrations.

Design of Degradation-Resistant PIP-1. Prior to finding a way of preventing the degradation of PIP-1, we investigated its degradation process in the presence of tobacco cells by LC/MS analysis. While PIP-1 (m/z observed for $[M+2H]^{2+}$: 363.8) was detected in the extracellular medium at a retention time of 13.8 min immediately after its treatment at 10 μM, a new peak with m/z of 364.3 at a retention time of 14.9 min appeared as early as after 15 min (Figure 2). The observed molecular mass

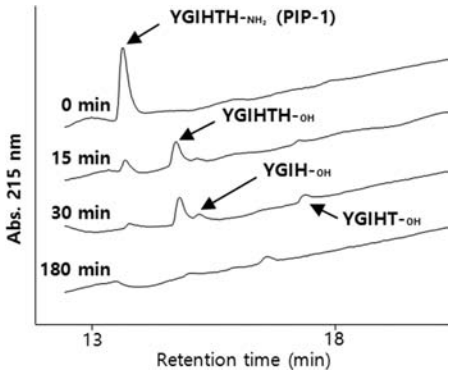

Figure 2. Degradation of PIP-1 (10 μM) in the culture medium of tobacco cells analyzed by LC/MS. Only LC/UV chromatograms were shown. Each peak was identified using synthesized standards.

was consistent with that of C-terminally deamidated PIP-1 (YGIHTH-OH, m/z calculated for $[M+2H]^{2+}$: 364.2).[13] After 30 min, two other peaks were detected at the retention times of 15.2 min (m/z 245.3) and 17.4 min (m/z 295.7), which were respectively identified to be YGIH-OH (m/z calculated for $[M+2H]^{2+}$: 245.1) and YGIHT-OH (m/z calculated for $[M+2H]^{2+}$: 295.7), based on the comparison with synthesized standards.

dx.doi.org/10.1021/jf501679p | J. Agric. Food Chem. 2014, 62, 5781−5788

Thereafter, PIP-1 and these degradation products underwent further degradation, and neither of them could be detected 3 h after the treatment. Thus, PIP-1 was found to be hydrolyzed rapidly from its C-terminal residue. This degradation could be catalyzed by proteases present in the extracellular space because PIP-1 cannot enter the cells due to its hydrophilic nature. In plants, several proteases have been identified from the extracellular space,[24] some of which are induced by pathogen infection.[25] Although further investigation is needed, proteases responsible for degradation of PIP-1 might be associated with defense responses in tobacco cells.

The bioassay data showed that, while YGIHTH-OH was significantly elicitor-active, YGIHT-OH and YGIH-OH were practically inactive, so it is noted that the activity was lost in the media within 3 h at the longest. This result supports the findings that the repeated additions of PIP-1 could induce the capsidiol production even at low concentrations.

On the basis of this degradation profile, we designed a degradation-resistant analogue of PIP-1 (Figure 3). Since

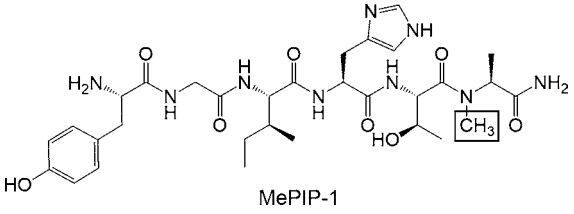

Figure 3. Structure of degradation-resistant PIP-1 analogue (MePIP-1).

methylation of amide nitrogen is known to improve stability against enzymatic degradation,[26,27] we introduced an N-methylated Ala residue into PIP-1 to substitute the C-terminal His residue, taking the observed hydrolysis of PIP-1 from the C-terminal end into consideration. As the previous study showed that the substitution of the C-terminal His residue with Ala had little effect on elicitor activity,[13] the PIP-1 analogue having N-methylated Ala at the C-terminus (MePIP-1) exhibited rather higher activity (about 3.5-fold) than PIP-1, in terms of oxidative burst induction. This is possibly due to a conformation change of the peptide as a consequence of N-methylation at the C-terminal residue, which may favorably interact with the receptor.[27,28] Since PIP-1 is likely to be recognized by the membranous receptors of plant cells,[13] the effect of a possible increase in intracellular uptake due to N-methylation can be ruled out.

We then monitored the degradation of MePIP-1 and compared it with that of PIP-1. When the tobacco cells were treated at 10 μM, MePIP-1 was present at 78% of the initial concentration after 3 h and was still detectable at 30% even after 24 h (Figure 4). This was in good contrast with the case of PIP-1, which was rapidly decreased to 3% of the initial concentration in 1 h upon the treatment with at 10 μM and completely disappeared after 3 h. The survival time of PIP-1 was extended to some extent when its initial concentration was raised to 100 μM, but it was decreased to an almost undetectable level as early as 6 h after the treatment. In this case, however, a significant level of elicitor-active YGIHTH-OH was present even after 6 h, which likely contributed to the induction of capsidiol production at least in part. Since no degradation products of MePIP-1 were detected 24 h after treatment, apparent reduction of MePIP-1 was likely due to its

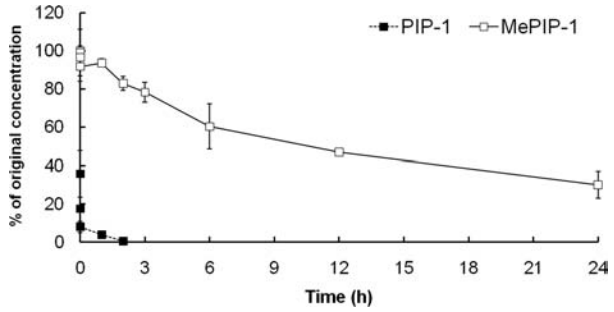

Figure 4. Comparison of degradation profiles of PIP-1 (10 μM) and MePIP-1 (10 μM) in the culture medium of tobacco cells. Vertical bars indicate ± SD of three independent replicates.

adsorption to tobacco cell surfaces rather than degradation. To confirm this, we evaluated the effect of adsorption using an elicitor-inactive but degradation-resistant PIP-1 analogue (D-PIP-1), which is composed of all D-forms of amino acid residues.[13] As expected, D-PIP-1 showed a decrease similar to MePIP-1 through 24 h incubation with tobacco cells. These results clearly indicate that MePIP-1 is highly resistant to enzymatic degradation in the presence of tobacco cells.

Defense Responses Induced by MePIP-1. We investigated the effect of degradation-resistance of MePIP-1 on defense responses induced in tobacco cells. In terms of the oxidative burst, both PIP-1 and MePIP-1 induced similar H_2O_2 production profiles over 12 h (Figure 5A). On the other hand, a significant difference was observed for capsidiol production between PIP-1 and MePIP-1. Treatment with 10 μM MePIP-1 induced significant capsidiol production (4.7 μg/g FW), whereas marginal levels of capsidiol were induced by 10 μM PIP-1 (Figure 5B). To confirm that this difference was due to its degradation-resistance, MePIP-1 was removed from the medium by washing the cells after treatment. As expected, no capsidiol production was observed when MePIP-1 was removed 1 or 3 h after treatment (Figure 5C). However, washing the cells 6 or 9 h after the treatment had no effect on the induction of capsidiol production, although the amount was relatively low. These results indicate that the degradation-resistance of MePIP-1 critically contributes to its higher potency in inducing capsidiol production by enabling the continuous stimulation of the immune system. Induction of HR-like cell death, which is also a late-stage defense response, was then examined (Figure 5D). As expected, a significant difference was observed between MePIP-1 and PIP-1: only MePIP-1 induced cell death when they were treated at 10 μM. This suggests that continuous stimulation by PIP-1 is also required for the HR induction, like in the case of capsidiol production.

Effects of MePIP-1 on MAP Kinase Activity. We then investigated the factors involved in triggering capsidiol biosynthesis in tobacco cells through continuous stimulation by MePIP-1. MAP kinase cascades play pivotal roles in signaling events associated with the recognition of pathogen and/or elicitors, which crucially affect downstream signaling events for induction of defense responses.[12] It is known that activation of salicylic acid induced protein kinase (SIPK) and/or wound-induced protein kinase (WIPK), representative MAP kinases in tobacco, is involved in defense responses induced by elicitors.[29,30] To investigate the possible involvement of MAP kinase activation in capsidiol production induced by MePIP-1, we first examined the effect of a kinase inhibitor on capsidiol production. When K252a, a general protein kinase inhibitor,

was added to the tobacco cells before addition of MePIP-1, production of capsidiol was inhibited in a dose-dependent manner (Figure 6). This suggested that activation of MAP

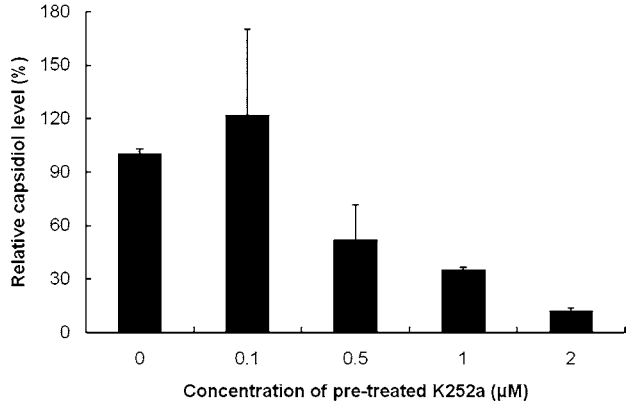

Figure 6. Inhibitory effect of K252a on capsidiol production induced by MePIP-1. Amounts of capsidiol were quantitated 24 h after treatment with MePIP-1. Capsidiol production without treatment with K252a was set at 100%. Vertical bars indicate ± SD of three independent replicates.

kinases, such as SIPK or WIPK, may be associated with capsidiol production. Thus, the effect of MePIP-1 on activation of SIPK and WIPK was investigated to examine its potential relevance to continuous elicitor stimulation prerequisite for capsidiol production. We first examined the expression of *SIPK* and *WIPK* transcripts. Consequently, no significant difference was observed between PIP-1 and MePIP-1 for induction of *SIPK* and *WIPK* transcripts (Figure 7A). Since it is known that the activity of these MAP kinases is regulated post-translation-

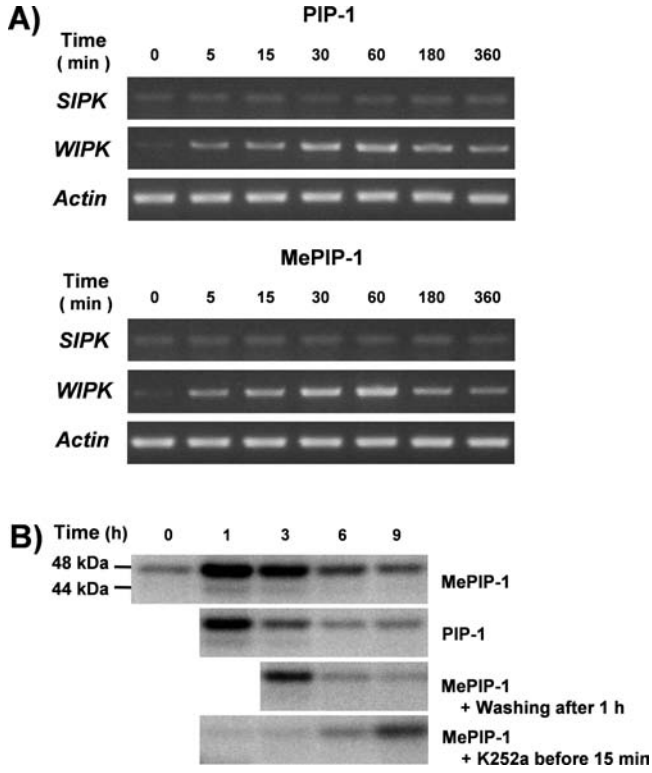

Figure 7. Effect of MePIP-1 on activation of MAP kinases. (A) Accumulation of transcripts of MAP kinases in response to PIP-1 and MePIP-1 at 10 μM. *Actin* was used as a control. (B) Activation of MAP kinases after treatment with PIP-1 or MePIP-1 at 10 μM. Activity was monitored by the in-gel kinase assay using MBP as a substrate.

ally by phosphorylation, not by an increase in transcript or protein levels,[29,30] we then examined whether these MAP kinases are differently activated by PIP-1 and MePIP-1 by an in-gel kinase assay. Upon treatment of either PIP-1 or MePIP-1, a significant activation of a 48 kD kinase, which corresponds to SIPK, was observed. However, a considerable difference between PIP-1 and MePIP-1 was observed for their activation of SIPK in the late phase (Figure 7B). SIPK was activated 1 h after the treatment with PIP-1 but rapidly decreased to a base level after 6 h. In contrast, MePIP-1 induced a long-lasting activation of SIPK even up to 9 h after the treatment. When MePIP-1 was removed from the medium 1 h after the treatment by washing of the cells, SIPK activity was decreased 6 h after the treatment, which was similar to that of PIP-1 treatment. These results clearly indicate that a prolonged SIPK activation is induced by a continuous stimulation by MePIP-1. In addition, when K252a (1 μM) was pretreated, activity of SIPK was significantly suppressed. In this case, activation was observed 9 h after treatment, but it could have been caused by inactivation of the inhibitor, probably by its degradation.[31] These results strongly suggest that a prolonged SIPK activation is necessary for the activation of downstream signaling events that could be associated with capsidiol production.

It is known that the strength of a defense response can be influenced by the magnitude and duration of MAPK activation. For instance, cryptogein, a proteinaceous elicitor derived from *Phytophthora cryptogea*, caused a prolonged activation of both SIPK and WIPK, which is necessary for induction of late-stage defense responses, such as HR-like cell death and long-lasting production of reactive oxygen species, in tobacco cells.[32] When cryptogein was removed from the medium 0.5 h after treatment, no induction of HR-like cell death was observed, which coincided with rapid inactivation of both SIPK and WIPK. On the other hand, fungal cell wall elicitor, which induced only transient SIPK activation, failed to induce the late-stage responses such as HR-like cell death.[29] Although the reason why the fungal cell wall elicitor could not induce prolonged SIPK activation is unknown at present, it is possible that the enzymatic degradation of the elicitor by plant cells may be responsible for transient SIPK activation, which leads to failure to induce the late-stage responses, like in the case of PIP-1. Thus, the duration of SIPK activation may determine the induction of late-stage defense responses, which could be regulated transcriptionally and/or post-translationally.

Capsidiol Biosynthesis-Related Gene Expression Induced by MePIP-1. To examine the possible involvement of transcriptional regulation of capsidiol biosynthesis through prolonged SIPK activation, expression of capsidiol biosynthesis-related genes was investigated. Capsidiol is synthesized via the mevalonate pathway in plants.[21,22] In this pathway, 3-hydroxy-3-methylglutaryl CoA reductase (HMGR) is considered to be a key enzyme,[33] which catalyzes the rate-limiting step in the biosynthesis of all isoprenoid compounds, including capsidiol. The transcription level of this gene is known to be regulated by elicitor recognition.[34,35] Farnesyl pyrophosphate (FPP) is synthesized from mevalonate in several steps and is located at a final branch point for sesquiterpene and sterol synthesis. FPP is converted to capsidiol in several steps including the reaction catalyzed by 5-epi-aristolochene synthase (EAS), which is demonstrated to be induced in response to elicitor treatment.[21] To evaluate whether the degradation-resistance of MePIP-1 affects the transcription level of these capsidiol biosynthesis-related genes, we examined the expression of *HMGR2* and *EAS* genes after treatment either with PIP-1 or MePIP-1 using quantitative RT-PCR. Since continuous activation by MePIP-1 for 3−6 h was shown to be required for capsidiol biosynthesis in our result, we analyzed the gene expression 4 h after the treatment with PIP-1 or MePIP-1. Consequently, expression of these genes was induced by both PIP-1 and MePIP-1, and no statistically significant difference was observed between them (Figure 8). To further examine the effect of the degradation-

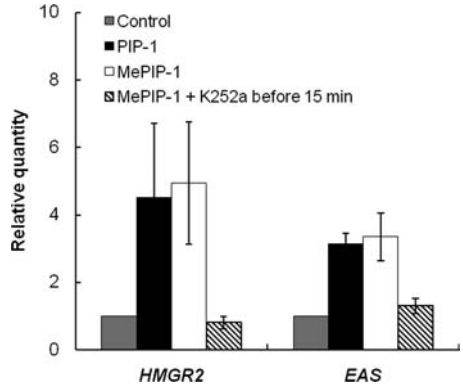

Figure 8. Relative transcription levels of capsidiol biosynthesis-related genes in response to PIP-1 and MePIP-1 at 10 μM. Values are the mean of three independent replicates. Vertical bars indicate ± SD.

resistance of MePIP-1 on the expression of *HMGR2* and *EAS* transcripts, time-course analysis for up to 18 h was conducted for both PIP-1 and MePIP-1. Again, no significant difference in these expression profiles was observed between them. These results indicate that the early short stimulation by PIP-1 is sufficient for expression of *HMGR2* and *EAS* genes but not enough for capsidiol biosynthesis. On the other hand, no induction of these genes was observed when K252a (1 μM) was pretreated (Figure 8), suggesting that the activation of SIPK in the early phase (<3 h) is necessary for induction of expression of these genes.

Isoprenoids play essential roles in plants as primary and secondary metabolites, which are synthesized in response to environmental and developmental cues or pathogen infection.[36] Biosynthesis of each isoprenoid is regulated at transcript and protein levels to control precursor availability via activation of biosynthesis-related enzymes or suppression of other branch-points.[37] In the present study, we found that the expression of *HMGR2* and *EAS* genes was induced by early short stimulation by PIP-1 but capsidiol production was initiated only after continuous stimulation by PIP-1. These facts suggest that capsidiol biosynthesis induced by PIP-1 is regulated translationally or post-translationally through long-lasting SIPK activation.

The early short-term activation of SIPK by PIP-1, which leads to increases in expression levels of capsidiol biosynthesis-related genes without production of capsidiol, could be comparable to the actions of chemicals referred to as "plant activators" that have so-called defense priming effects. These chemicals are known to stimulate the plant into a primed state, where the signal systems are ready for inducing the defense responses but still remain inactive.[38,39] Once activated into this primed state, the plant is able to display much faster and robust defense responses against subsequent biotic or abiotic stresses, compared to the nonprimed plant.[40−42] Conrath et al.[40] hypothesized that the primed plant accumulates the crucial

transcription factors to induce the relevant defense-related genes enabling their rapid expression in response to the subsequent stimulus. In *Arabidopsis*, priming is associated with the accumulation of the inactive forms of MPK3 and MPK6, orthologues of WIPK and SIPK, respectively.[39] Upon exposure to subsequent stress, these kinases are strongly activated to induce the enhanced defense responses. Thus, the state of the tobacco cells after the short-term stimulation by PIP-1 could be analogous to the primed state, where SIPK is transiently activated and mRNAs of WIPK and capsidiol biosynthesis-related enzymes are accumulated, and is ready for inducing the strong defense responses by the following continuous recognition of PIP-1. From an economic point of view, full activation of immune systems for the continuous production of phytoalexin or large-scale cell death is considered to require a substantial fitness cost and to be disadvantageous to the normal growth of the plant. Therefore, priming is believed to be more effective for the protection of plants from various stresses without major trade-off effects on growth and reproduction. The results of this study suggest that the plant may have a "suspending" system regarding the induction of defense reactions. The complete set of defense reactions are not induced until the plant judges the attack of a pathogen to be quite serious after continuously monitoring the elicitors for several hours, which should be beneficial for maintaining the balance of energy used for defense and growth.

In summary, we observed that PIP-1 was rapidly degraded in the media of suspension-cultured tobacco cells, probably by proteases from the cells. To prevent the degradation of PIP-1, we synthesized a degradation-resistant analogue, MePIP-1, in which the C-terminal His residues was substituted with Ala and the amide bond between fifth and sixth residues of PIP-1 was N-methylated. MePIP-1 induced H_2O_2 generation with a time-course similar to that by PIP-1, whereas significant differences were seen between PIP-1 and MePIP-1 in the late-stage defense responses such as phytoalexin production and HR-like cell death. Using the degradation-resistant PIP-1 analogue, we found that continuous stimulation of the immune system by PIP-1 is necessary for the induction of late-stage defense responses, and whether the late-stage responses are induced or not may depend on the duration of SIPK activation caused by the continuous elicitor stimulation.

ABSTRACT: The physical and sensory properties of oil coatings on the tongue formed by five oil/water emulsions varying in oil content were investigated. A total of 20 subjects processed orally each emulsion for 30 s in triplicate. *In vivo* fluorescence measurements at the front and back of the anterior tongue were made to quantify the oil fraction deposited at different time points. Calibration lines relating fluorescence intensity to oil fraction were determined using pig tongues at 37.5 °C to mimic oral conditions. The oil fraction on the tongue increased linearly with an increasing oil content of the emulsions. The oil fraction deposited at the back of the anterior tongue was 1.5−2.0× larger than at the front. The intensity of sensory attributes describing after-feel perception was related to the oil fraction by Weber−Fechner's law. This study uses *in vivo* fluorescence to study food behavior in the mouth and unravel new insights in after-feel perception of emulsions.

KEYWORDS: *oral coating, tongue, oral processing, fraction of oil, fluorescence, curcumin, emulsion, sensory perception, mouth-feel sensation, after-feel perception*

INTRODUCTION

Residues of foods and beverages that coat the oral mucosa after consumption are termed oral coatings. Only limited information is available on the chemical and physical properties of oral coatings. A method to quantify the lipid content of oral coatings has been proposed by rinsing the oral cavity after food ingestion and subsequently determining the turbidity of the spat out liquid.[1,2] de Jongh and Janssen used attenuated total reflection infrared (ATR IR) spectroscopy to analyze the chemical composition of oral coatings taken with swabs from distinct parts of the oral cavity.[3] This method allowed us to determine the relative content of fat, protein, and carbohydrate of oral coatings.[3] Pivk et al. developed an *in vivo* method to characterize the thickness of oral oil coatings on the tongue using fluorescence measurements.[4] Fluorescence was quantified with a fluorescence spectrometer coupled with a remote read fiber optic probe fitted with a tip for measurements on surfaces, such as the tongue.[4] Pivk et al. showed that thicker lipid coatings were formed at the back of the anterior tongue compared to the lateral tongue area.[5] The *in vivo* fluorescence method provides a direct measure of the thickness of oral coatings and allows us to study the spatial variation of coatings on the tongue and to link instrumental measurements to sensory perception.[5] Pivk et al. used thickness of the coating as the physical parameter to describe oil coatings.[4,5] Thickness suggests that a continuous, homogeneous film of oil is deposited on the tongue. That may be the case for orally processed oils, as studied by Pivk et al.[4,5] However, most beverages contain oil in water (o/w) emulsions and are stable under in-mouth conditions. When o/w emulsions form an oral deposit, it is likely that the coating consists of individual oil droplets adhering to the tongue surface rather than a continuous, homogeneous oil film. Therefore, the mass of oil deposited on the tongue is a more descriptive parameter to characterize oral coatings formed by o/w emulsions rather than thickness.

The calibration of fluorescence intensity versus coating deposition is a crucial step for the *in vivo* fluorescence method. Pivk et al. calibrated the fluorescence intensity with the thickness of the oil coating by spreading different volumes of medium-chain triglycerides (MCT) oil containing curcumin, a hydrophobic, food-grade fluorescent dye, in a Petri dish at room temperature to obtain oil coatings varying in thickness.[4,5] It is known that fluorescence intensity depends upon the temperature. Therefore, the calibration temperature should reflect the temperature of the coating in the oral cavity. The surface properties used for the calibration can also influence the fluorescence intensity. Thus, the surface should be as similar to the human tongue as possible. The surface of a Petri dish is different from the surface of a human tongue, which is rougher and covered with papillae. Pig tongues are considered to be good models for human tongues.[6,7] Pigs are omnivores, and the anterior part of their tongues is covered by fungiform papillae scattered between filiform papillae similar to human tongues.[8] Filiform papillae of the human and pig tongues have similar shapes.[8]

Oral coatings are one of the known factors that can influence after-feel, mouth-feel perception, and taste. de Wijk et al. demonstrated that fat containing oral coatings lubricate the movement of the food bolus, leading to decreased roughness and increased creaminess perception.[9,10] Lynch et al. showed that oral coatings formed by different oils reduce the subsequent perception of taste intensity of gels.[11] It was

suggested that oral fat coatings influence taste by modification of the partitioning of specific compounds between food, saliva, and taste receptors or forming a hydrophobic layer creating a physical barrier for hydrophilic tastants, limiting access to taste receptors.[11] Although it is well-known that oral coatings can linger in the mouth after swallowing, little is known about the influence of oral coatings on after-feel sensory perception (mouth-feel perception occurring after swallowing). We hypothesize that psychophysical relationships can describe the link between oil coatings lingering on the tongue after expectoration and after-feel perception.

This study is based on the method previously described by Pivk et al.[4,5] The aims of this study were to (i) develop an appropriate calibration method for *in vivo* fluorescence measurements, which represents closer the *in vivo* conditions occurring in the mouth, (ii) apply the method with the new calibration using o/w emulsions varying in oil content, and (iii) establish psychophysical relationships between oil coatings formed on the tongue and after-feel perception.

MATERIALS AND METHODS

Materials. Sunflower oil (Euroshopper, purchased from a local retailer), reverse osmosis water, sodium caseinate (Excellion sodium caseinate S, DMV International, Netherlands), and curcumin (7% curcumin solution in propylene glycol and polysorbate, L-WS, Sensient, Netherlands) were used. Pig tongues were provided by VION Food Group (Netherlands). All ingredients used were food-grade.

Emulsion Preparation. Five o/w emulsions were prepared with an oil content of 1, 5, 10, 15, and 20% (w/w). A total of 3.2% (w/w) sodium caseinate was added to the water phase of all emulsions independent of the oil content. The emulsions were pre-homogenized using an ultra turrax (IKA RW 20 Digital) and homogenized (Niro-Soavi S.p.A. NS1001L2K) with pressures between 300 and 400 bar. The droplet size distribution was determined by light scattering (Mastersizer 2000, Malvern Instruments, Goffin Meyvis). The average diameter of emulsion droplets ($d_{3,2}$) is presented in Table 1. Curcumin solution was added immediately before consumption to each o/w emulsion (Table 1) until saturation, which was verified through fluorescence intensity measurements (data not shown). All samples were prepared in a food-grade environment and stored at 4 °C for a maximum of 2 days.

Table 1. Composition of All o/w Emulsions Used in This Study and Average Diameter of Emulsion Oil Droplets ($d_{3,2}$)[a]

$[oil]_{emulsion}$ (%, w/w)	[curcumin] (‰, v/w)	oil droplet size $d_{3,2}$ ± standard error (μm)
1	0.027	1.16 ± 0.07
5	0.040	1.32 ± 0.12
10	0.070	1.37 ± 0.15
15	0.088	1.34 ± 0.16
20	0.105	1.17 ± 0.07

[a]All o/w emulsions contained 3.2% (w/w) Na caseinate.

Pig Tongue Preparation. Pig tongues were prepared and preserved as previously described.[6] The pig tongues were collected immediately after slaughter and stored in a physiological salt solution for transportation. The tongues had a length of about 18 cm. Only the middle part of about 6−8 cm was used because the back part of the tongue has larger papillae compared to the human tongue and the front part was damaged during processing in the slaughterhouse. The pig tongues were cut into three parts. The middle part was snap-frozen in liquid nitrogen and stored at −80 °C. The pig tongues were thawed shortly before use in tap water. The pig tongues were cut into pieces of 2 × 2 cm, resulting in a tongue surface area of 4 cm^2.

Confocal Laser Scanning Microscopy (CLSM): Microstructure of o/w Emulsions on Pig Tongues. The microstructure of the o/w emulsions on pig tongues was analyzed by CLSM (TCS SP5 confocal laser scanning microscope, Leica Microsystems, Heidelberg, Germany). The objective lens used was a dry HCPL apo 20×/0.70CS (zoom 2). A layer of human saliva was added to the pig tongues. Images were collected under three experimental conditions: (i) plain pig tongue with a layer of human saliva without o/w emulsion, (ii) pig tongue with a layer of human saliva and 10% (w/w) o/w emulsion, and (iii) pig tongue with a layer of human saliva and 10% (w/w) o/w emulsion after being rubbed with another piece of pig tongue to simulate the rubbing of the human tongue against the palate during drinking. The emulsions were stained with an aqueous solution of 0.5% (w/w) Nile Blue.

Fluorescence Measurements and Calibration. Calibrations were made to correlate fluorescence intensity of curcumin in the o/w emulsion to the oil content deposited on the tongue. For this purpose, a single-point fluorescence measurement (Fluorolog Instruments SA, Inc., Jobin Yvon Spex) was used with an excitation wavelength of 440 nm, an emission wavelength of 495 nm, a slit width of 0.95 mm, and a measurement time of 0.1 s. A fluorescence remote read fiber optic probe was used to measure on tongue surfaces. A plastic ring (diameter of 16.9 mm and height of 5 mm) was attached to the end of the probe to ensure that the distance between the probe and the surface remained constant. The probe was put gently on the tongue to avoid deformation of the tongue surface. For all measurements, the background (autofluorescence intensity of the surface without a sample) was measured first. The background measured immediately before the sample measurement was always subtracted afterward from the sample measurement.

The calibration correlates fluorescence intensity of curcumin of the o/w emulsions to the oil fraction per surface area of tongue. For this purpose, we used pig tongues at room temperature (21 ± 0.5 °C) and body temperature (37.5 ± 0.5 °C) as surfaces. For each measurement, a fresh piece of tongue was used. Five o/w emulsions at room temperature were spread on the pig tongue surface to achieve the target oil fraction (Table 2).

Table 2. Fraction of Oil (mg/cm^2) Used for the Calibrations at Room Temperature (21 °C) and Body Temperature (37.5 °C)[a]

oil fraction (mg/cm^2)	$V_{emulsion}$ (μL)	$[oil]_{emulsion}$ (%, w/w)
0.01	4	1
0.02	8	
0.15	12	5
0.20	16	
0.50	20	10
0.60	24	
1.05	28	15
1.20	32	
1.80	36	20

[a]Each fraction of oil was obtained by spreading the specified volume of o/w emulsion ($V_{emulsion}$) with the specified concentration ($[oil]_{emulsion}$) on pig tongues with a constant surface area of 4 cm^2.

The oil fraction was defined as

$$\text{oil fraction } (mg/cm^2) = \frac{m_{oil}}{A_{surface\ tongue}}$$

$$\text{with } m_{oil} = V_{emulsion}[oil]_{emulsion}$$

where m_{oil} is the mass of oil on the tongue, $V_{emulsion}$ is the volume of the emulsion spread on the tongue, $[oil]_{emulsion}$ is the concentration of oil in the emulsion, and $A_{surface\ tongue}$ is the surface area of the pig tongue where the sample is dispersed. The calibrations were made for

Table 3. List of Sensory Attributes with Attribute Definitions and Evaluation Protocol

sensory attribute	definition	evaluation protocol
roughness	roughness sensed on teeth, palate, and tongue	after spitting out the sample: analysis between tongue and palate by sliding, degree of roughness of the surface
fatty film	sensation of feeling a layer of oil covering the mouth	after spitting out the sample: slide the tongue on the palate and lips and the lips on one another
flavor intensity	overall flavor intensity of aroma and taste	after spitting out the sample: the flavor intensity perceived

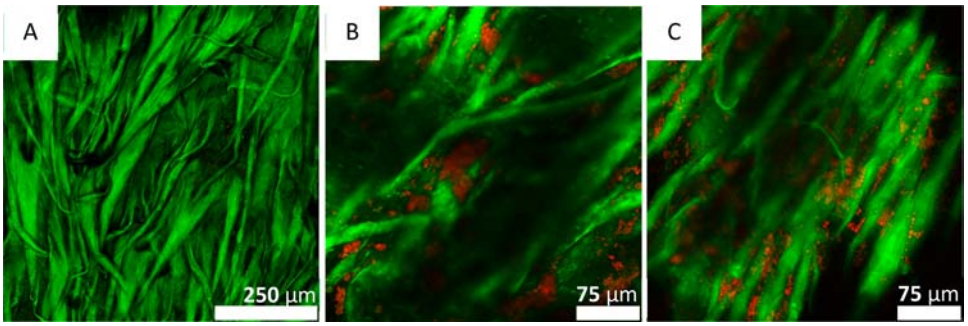

Figure 1. CLSM images: (A) pig tongue with a layer of human saliva, (B) pig tongue with a layer of human saliva and o/w emulsion (10%, w/w), and (C) pig tongue with a layer of human saliva and o/w emulsion (10%, w/w) after being rubbed with another piece of pig tongue. The same pig tongue was used to collect the three images. Papillae are represented in green, and oil droplets are represented in red.

targeted oil fractions between 0.01 and 1.8 mg/cm^2 (9 points) at room temperature (21 ± 0.5 °C) and body temperature (37.5 ± 0.5 °C). All measurements were performed in triplicate.

***In Vivo* Fluorescence Measurements.** A total of 20 untrained subjects (6 men and 14 women, with a mean age of 24 ± 1.7 years) tested the five o/w emulsions in triplicate. A randomized complete block design (randomization of five products per session) was used. Each sample was served in plastic cups in doses of 20 mL. The samples were coded with randomized three-digit numbers and served at room temperature. The test was performed in a controlled temperature and ventilated room. All subjects signed a written consent form and were given financial compensation. The materials and methods used did not require medical ethical approval under Dutch regulations.

Determination of the Oil Fraction on the Tongue. Each subject was instructed to ingest 20 mL of the o/w emulsion and process the sample in the mouth for 30 s while moving the sample around freely before spitting it out. This procedure was followed to create a maximum oil deposition on the tongue rather than to mimic natural drinking behavior. After expectoration, fluorescence measurements were made on the front and back of the anterior tongue at 0, 15, 30, 45, 60, 90, 120, and 180 s after expectoration. While waiting for the next measurements, subjects were free to swallow saliva and instructed to not speak or drink water. After 180 s, the subjects were given a recuperation time of approximately 5 min to cleanse their mouth with crackers, a tongue scraper, and warm (40 °C) and room temperature water to remove the residue of the oral coating. Before each sample was presented to the subject, a background fluorescence measurement (autofluorescence of the tongue) was made and subtracted from the subsequent sample measurement.

Sensory Perception of Oral Coatings. During the fluorescence measurement, the subjects were asked to rate the intensity of three sensory attributes: "roughness", "fatty film", and "flavor intensity". These attributes were chosen because they are descriptors that have been generated previously by quantitative descriptive analysis (QDA) panels to describe after-feel sensations of o/w emulsions.[12,13] In our study, the three attributes were evaluated by the untrained subjects after the stimuli were expectorated. The definition of descriptors and the evaluation protocol are shown in Table 3. The evaluation was performed using a continuous 100 mm visual analogue scale (VAS) line scale anchored with little and very at 5% from each end. The intensity of the attributes was rated 0, 30, 60, 90, 120, and 180 s after expectoration immediately after the fluorescence measurements.

Data Analysis. Descriptive statistics was used to obtain the mean and standard error (SE). A preliminary test for equal variances and normality was performed. Because these assumptions were not met for all of the fluorescence measurements, the data were normalized with a $\ln(x + 1)$ transformation. The effect of the position of the probe (within subject factor: front back), sample (within subject factor: 1, 5, 10, 15, and 20%, w/w), time (within subject factor: 0, 15, 30, 45, 60, 90, 120, and 180 s), and interactions on the oil fraction of the coating was tested by repeated-measures analysis of variance (ANOVA). For the sensory data, a repeated-measures ANOVA was used to investigate the effect of samples (within subject factor: 1, 5, 10, 15, and 20%, w/w) and time (within subject factor: 0, 30, 60, 90, 120, and 180 s) and the interactions on "roughness", "fatty film", and "flavor intensity"-scores. These analyses were performed in SPSS Statistics, version 19. A significance level of $p < 0.05$ was chosen.

RESULTS

Stability of o/w Emulsions under Mimicking In-Mouth Conditions. The stability of the 10% (w/w) o/w emulsion on a pig tongue was analyzed using CLSM (Figure 1). First, a layer of human saliva was added to the pig tongue in the absence of the 10% (w/w) o/w emulsion (Figure 1A). Second, the 10% (w/w) o/w emulsion was added to the pig tongue previously covered with human saliva (Figure 1B). Third, to mimic the oral processing behavior during drinking (i.e., rubbing of the tongue against the palate), the piece of pig tongue covered with a layer of human saliva and the 10% (w/w) o/w emulsion was rubbed against a second pig tongue (Figure 1C). The papillae are represented in green, and the oil droplets are represented in red. The microstructure of the 10% (w/w) o/w emulsion did not change considerably under the mimicked in-mouth conditions by mechanical stress through rubbing. A qualitative comparison between panels B and C of Figure 1 reveals no noticeable change in the microstructure of the emulsion. Panels B and C of Figure 1 both show individual oil droplets adhering to the tongue papillae. No coalescence of oil droplets after application of mechanical stress is observed.

Calibration Lines for *in Vivo* Fluorescence Measurements. Calibration lines were made using pig tongues as

dx.doi.org/10.1021/jf5010868 | J. Agric. Food Chem. 2014, 62, 5789−5795

surfaces at room temperature (21 ± 0.5 °C) and body temperature (37.5 ± 0.5 °C) to mimic in-mouth conditions (Figure 2). Five o/w emulsions were used to achieve the target

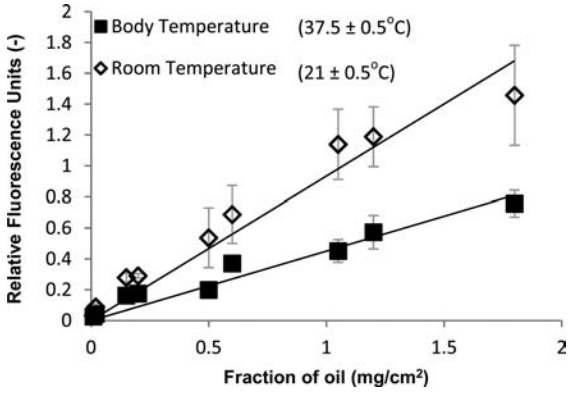

Figure 2. Calibration lines, relating the RFU to the fraction of oil on the tongue surface ($[oil]_{fraction}$). Error bars represent the standard deviation.

oil fractions for the calibration lines (Table 2). The five o/w emulsions were the same as the ones used for the *in vivo* fluorescence measurements. The data obtained from both calibrations were fitted with a linear regression to correlate the relative fluorescence units (RFU) with the oil fraction per surface area of tongue ($[oil]_{fraction}$). At room temperature (21 ± 0.5 °C), RFU = 0.94$[oil]_{fraction}$ (R^2 = 0.96) was obtained, and at body temperature (37.5 ± 0.5 °C), RFU = 0.45$[oil]_{fraction}$ (R^2 = 0.94). Both linear regressions passed through the origin. The increase of the temperature by 16.5 °C decreased the fluorescence intensity by 45%. In the following, the calibration line with the pig tongue at body temperature was used to calculate the oil fraction deposited on the tongue because the calibration resembles the in-mouth conditions closer.

Influence of the Oil Content of o/w Emulsions on Spatial Variation of Oral Coatings. Panels A and B of Figure 3 show the decay of the oil fraction deposited on the tongue after expectoration over time. The effects of probe position, sample, time, and their interactions on the oil fraction were statistically analyzed. Mauchly's test indicated that the assumption of sphericity had been violated for the main effect of the oil content of emulsions and the interactions. Therefore, the degrees of freedom were corrected using Greenhouse–Geisser estimates for sphericity. All effects are significant at $p < 0.001$. There was a significant main effect of probe position [$F(1, 59) = 166.5$], sample [$F(3.7, 215.9) = 52.5$], time [$F(7, 413) = 620.4$], and probe position × sample × time [$F(15.3, 903.6) = 2.07$; $p = 0.009$]. The oil fraction deposited on the front of the anterior tongue was significantly lower than on the back of the anterior tongue. The oil deposition on the front decreased on average by 42% after 15 s and by 67% after 45 s after expectoration. After 90 s, no significant difference of the oil fraction at the front of the anterior tongue was found between emulsions (Figure 3A). At the back of the anterior tongue, the oil fraction decreased in average by 34% after 15 s and by 60% after 45 s after expectoration (Figure 3B). After 120 s, there was no significant difference between emulsions. We conclude that the oil clearance was faster at the front of the anterior tongue compared to the back of the anterior tongue. The oil fraction on the front and back of the anterior tongue

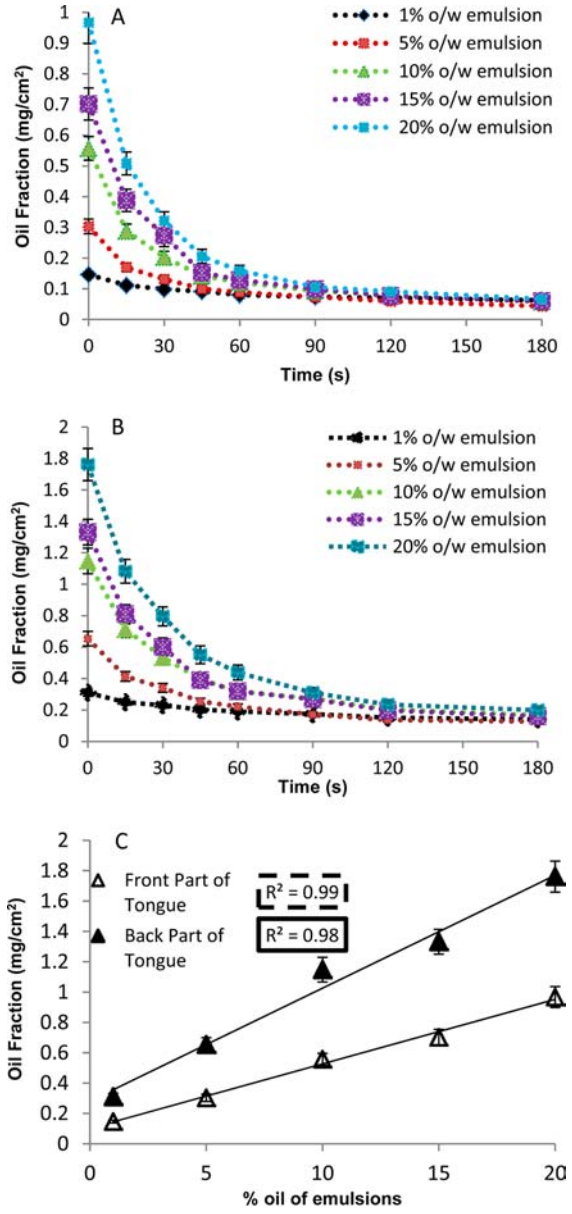

Figure 3. Oil fraction deposited on (A) front and (B) back of the anterior tongue over time for five o/w emulsions differing in oil concentration. Each point represents the average of n = 20 subjects and 3 replicates. Lines are drawn to guide the eye. Error bars represent the standard error. (C) Oil fraction deposited at the front and back of the anterior tongue immediately after expectoration (0 s) as a function of the emulsion oil concentration.

differed by a factor of 1.8 at 0 s, 2.2 at 30 s, and 2.4 at 180 s after expectoration.

The oil fraction deposited on the front and back of the anterior tongue surface immediately after expectoration of the stimulus (0 s) increased linearly with the oil content of the o/w emulsion (Figure 3C).

After-Feel Perception of Oral Coatings. Panels A and B of Figure 4 show the averaged intensities of the attributes "fatty film" and "flavor intensity" of the five o/w emulsions over time. The effect of sample, time, and sample × time on the attributes "fatty film", "flavor intensity", and "roughness" (data not shown) was tested. All effects were tested for sphericity with Mauchly's test. The effects that violated the sphericity assumption were corrected by Greenhouse–Geisser estimates.

dx.doi.org/10.1021/jf5010868 | J. Agric. Food Chem. 2014, 62, 5789–5795

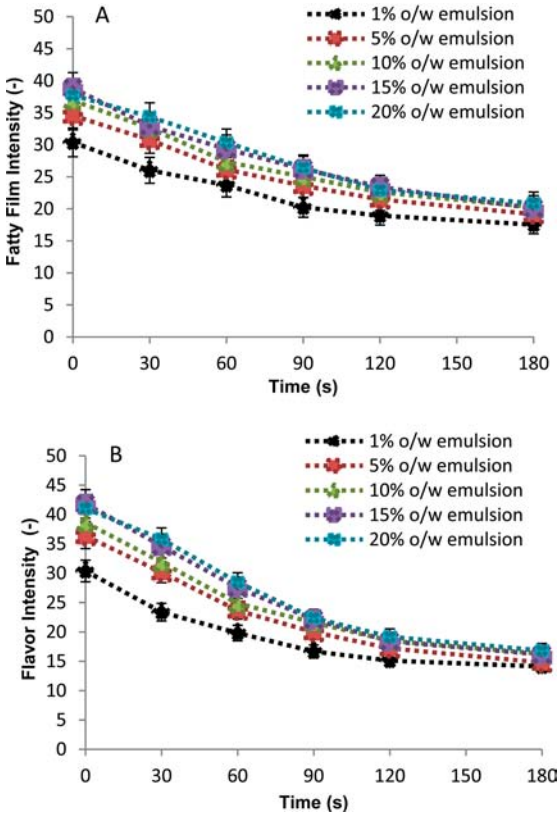

Figure 4. Intensity of the attributes (A) fatty film and (B) flavor intensity of five o/w emulsions over time. Each point represents the average of n = 20 subjects and 3 replicates. Lines are drawn to guide the eye. Error bars represent the standard error.

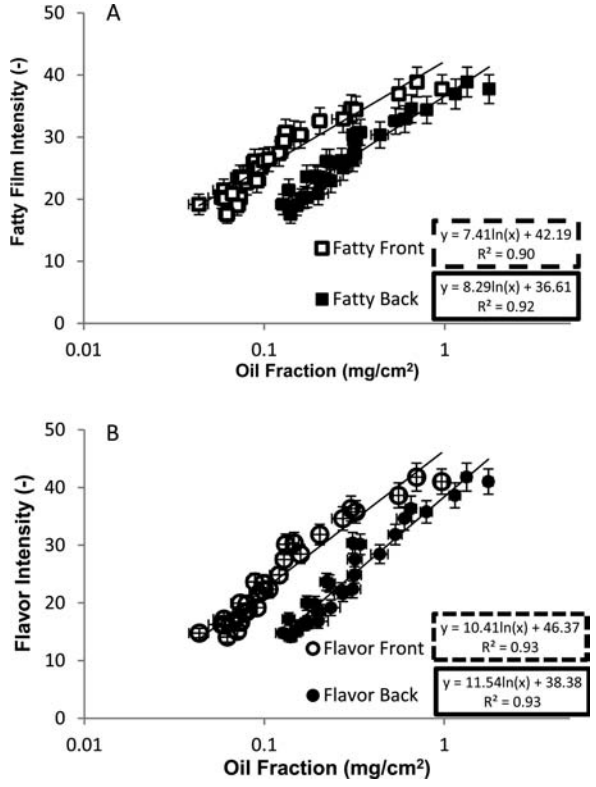

Figure 5. (A) Fatty film intensity and (B) flavor intensity as a function of oil deposition of different emulsions at the front and back of the anterior tongue at 0, 30, 60, and 90 s. Each point represents the average of n = 20 subjects and 3 replicates. Lines represent the linear regression of all points. Error bars represent the standard error.

For the attribute "roughness", all effects were not significant (sample, p = 0.11; time, p = 0.063; and sample × time, p = 0.175). For the attribute "flavor intensity", the effects of sample [F(3.2, 189.1) = 25.3], time [F(1.8, 108.6) = 94.0], and the interaction sample × time [F(9.5, 562.3) = 6.2] were significant at p < 0.001. The attribute "fatty film" was significantly influenced by the same effects: sample [F(4, 236) = 15.2; p < 0.001], time [F(1.6, 91.6) = 117.5; p < 0.001], and the interaction sample × time [F(9.3, 548.3) = 2.3]. At time 0 s, both attributes were perceived as more intense with an increasing oil content of o/w emulsions (panels A and B of Figure 4). For both attributes, the 1% (w/w) o/w emulsion was perceived as significantly different from all other samples up to 120 s (p < 0.001). At time point 180 s, all samples were perceived equally intense. The attributes "fatty film" and "flavor intensity" were linearly correlated for all samples (R^2 > 0.98; regression data not shown).

Psychophysical Relationships between Oil Coatings Formed on the Tongue and After-Feel Perception. Panels A and B of Figure 5 show the relationships between the after-feel perception of attributes "fatty film" and "flavor intensity" with the oil fraction deposited on the tongue. Each data point represents a different sample at a different time point after expectoration of the stimulus. The perceived intensity of a stimulus can be related to the physical intensity of the stimulus by a logarithmic relationship known as Weber–Fechner's law: $P = k \log I$, where P is the perceived intensity of the stimulus, I is the physical intensity of the stimulus, and k is a constant.[14] The psychophysical relationships between the attributes "flavor intensity" and "fatty film" and the oil fraction deposited on the tongue after expectoration of the stimulus were fitted using Weber–Fechner's law to determine the psychophysical functions for after-feel perception of the o/w emulsions (panels A and B of Figure 5). Weber–Fechner's law described the relationships between after-feel perception of the two attributes and the oil fraction ($R^2 \geq 0.90$).

DISCUSSION

Stability of o/w Emulsions under Mimicking In-Mouth Conditions. The stability of the 10% (w/w) o/w emulsion was qualitatively determined under mimicking in-mouth conditions using CSLM. The oil droplets remained stable and did not reveal coalescence after application of mechanical stress through rubbing the pig tongue covered with the emulsion against another pig tongue. Dresselhuis et al. reported that the occurrence of coalescence in the mouth depends upon the characteristics of the emulsion (droplet size, interfacial layer, type of emulsifier, and type of fat), the shear applied, and the characteristics of the oral mucosa. The coalescence in the mouth was shown to be more probable when the emulsions were less stable, i.e., stabilized by a low concentration of emulsifier.[15] The concentration of emulsifier used in the preparation of all of our emulsions [3.2% (w/w) Na caseinate] was in excess to cover the o/w interface. Therefore, as expected, the oral coating formed by the emulsion consists of individual oil droplets embedded in a mixture of water and saliva adhering to the tongue papillae and does not consist of a homogeneous layer of coalesced oil. Hence, thickness should not be used as the physical parameter to describe and quantify oral coatings formed by (stable) emulsions. The oil fraction is a more

dx.doi.org/10.1021/jf5010868 | J. Agric. Food Chem. 2014, 62, 5789–5795

suitable physical parameter to describe the mass of oil that adheres to the surface of the tongue.

Calibration Lines for *in Vivo* Fluorescence Measurements. The first aim of this study was to develop a new calibration method for *in vivo* fluorescence measurements that represents closer the *in vivo* conditions occurring in the mouth. Pig tongues were used as the contact surface for the calibration because they are known to be a good model for human tongues.[6,7] The calibration of the fluorescence method was made with o/w emulsions. To test the effect of the temperature on fluorescence, calibrations were performed with pig tongues at body temperature and room temperature. We observed a large effect of the temperature on the fluorescence intensity of curcumin in the emulsions on the tongue surface. This clearly demonstrates the importance of performing the calibration at temperatures close to those occurring during the *in vivo* measurements in the oral cavity. The experimental conditions of the calibration should resemble the in-mouth conditions during the *in vivo* measurements as much as possible.

Influence of the Oil Content of o/w Emulsions on Spatial Variation of Oral Coatings. The second aim of this study was to apply the *in vivo* fluorescence method with the new calibration using o/w emulsions varying in oil content. The *in vivo* fluorescence measurements showed more oil deposition on the back of the anterior tongue than on the front of the anterior tongue (panels A and B of Figure 3). This spatial variation of the oil fraction increased over time. An explanation for this finding may lay in the morphology of the tongue. Fungiform papillae, which are the smallest papillae, are present on the front of the anterior tongue. The papillae circumvallate are located on the back of the anterior tongue and secret cleaning liquid.[16] The most important papillae for the formation of the oral coating might be the filiform papillae, which are more predominant at the back of the tongue. These papillae contribute considerably to the roughness of the tongue surface. The differences between the papillae result in a smoother surface at the front of the anterior tongue compared to the back.[17] The difference in the surface morphology might partly explain the observed differences in spatial variation of oral oil deposits because oil droplets are likely to be entrapped between the papilla. The movement of the tongue might also influence the spatial variation of the oil deposit. The participants were allowed to swallow freely during the experiments. When swallowing, the front of the tongue moves against the teeth and palate.[18,19] This movement results in friction, which might degrade the oil coating more on the front of the anterior tongue compared to the back. This effect might also explain the increase in spatial variation over time. The oil fraction deposited on the tongue surface immediately after expectoration (0 s) increased linearly with an increasing oil content of the o/w emulsion (Figure 3C). Dresselhuis et al. studied the effect of stable and unstable emulsions on the oil retention in the mouth. It was concluded that increasing the oil content of the emulsions resulted in larger amounts of oil deposition on the tongue.[15] In contrast, results by Pivk et al. showed that deposition of MCT oils in the mouth followed a logarithmic increase with increasing volumes of oil.[5] A reason for the difference between these results may lay in the level of saturation of the oil coverage of the surface of the tongue. Complete coverage of the tongue surface by oil (saturation) is more likely to be reached by oils than by emulsions that contain considerably less oil, and the oil droplets can be stable against coalescence.

After-Feel Perception of Oral Coatings. The decrease of the oil fraction on the tongue with time lead to a decrease of "fatty film" and "flavor intensity" with time (panels A and B of Figure 4). The oral coating might lead to a prolonged release of odor compounds into the nasal cavity and to a higher lubrication in the mouth. Hence, more coating might result in a higher concentration of odors and, thus, increase flavor perception.[1] The increase of after-feel intensity at $t = 0$ s with an increasing emulsion oil content was not a linear probably because the flavor release also does not linearly depend upon the oil content.[15] It should be noted that no flavor substances were added to the emulsion to examine flavor release over time. The flavor of the o/w emulsions comes from the inherent flavor of the sunflower oil. The attribute "flavor intensity" was used as an indirect measurement of the presence of an oral coating. The attribute "roughness" showed no significant differences for any of the effects tested. This might have been due to a low consensus for the attribute "roughness" between the untrained subjects. The definition of "roughness" might have been unfamiliar or unclear to the untrained subjects, leading to misinterpretations or confusion. This effect would probably have been suppressed when a trained panel would have been used.

Psychophysical Relationships between Oil Coatings Formed on the Tongue and After-Feel Perception. The third aim of the study was to establish psychophysical relationships between oil coatings formed on the tongue and after-feel perception. For both attributes "fatty film" and "flavor intensity", a semi-logarithmic relation with the oil fraction of the coating was found (panels A and B of Figure 5). The relationship between after-feel perception of the attributes "fatty film" and "flavor intensity" and oil fraction deposited on the tongue can hence be described by Weber–Fechner's law. The k values of Weber–Fechner's law are an indication for the sensitivity of the sensory system toward a specific physical stimulus. In our study, we cannot determine a meaningful k value from our data because we used a direct intensity scaling method to quantify after-feel perception. To determine the k value of Weber–Fechner's law, usually indirect methods, such as two alternative forced choices (2AFCs) and/or the method of constant stimuli, and/or magnitude estimation methods are used.[20−24] The indirect methods are known to work well to quantify k values for taste and smell perception. Our study demonstrates that after-feel perception of o/w emulsion is dynamic and intensity of attributes strongly depends upon time after expectoration. Using indirect sensory methods to determine after-feel perception while accounting for perceptual changes of after-feel in time will be challenging to perform. Because we cannot determine a meaningful k value from our data, we cannot compare it to k values reported in the literature for other sensory systems, such as taste and smell.

In conclusion, we developed a new calibration method for *in vivo* fluorescence measurements and applied the methodology to investigate the psychophysical relationships between the oil fraction deposited on the tongue after expectoration of o/w emulsions and after-feel perception. We recommend a new calibration method using pig tongue surfaces at body temperature for the calibration procedure to resemble in-mouth conditions. We conclude that the after-feel perception of oral coatings follows Weber–Fechner's law. This study demonstrates the potential of *in vivo* fluorescence measurements for studying food behavior in the mouth. We suggest to continue the studies focusing on the effect of beverage

composition on the formation and clearance of oral coatings for improved design of low-fat products.

Characterization of the Key Odorants in Light Aroma Type Chinese Liquor by Gas Chromatography−Olfactometry, Quantitative Measurements, Aroma Recombination, and Omission Studies

Wenjun Gao, Wenlai Fan,* and Yan Xu

Key Laboratory of Industrial Biotechnology, Ministry of Education, Synergetic Innovation Center of Food Safety and Nutrition, Laboratory of Brewing Microbiology and Applied Enzymology, School of Biotechnology, Jiangnan University, Wuxi, Jiangsu 214122, China

ABSTRACT: The light aroma type liquor is widely welcomed by consumers due to its pleasant fruity and floral aroma, particularly in northern China. To answer the puzzling question of which key aroma compounds are responsible for the typical aroma, three typical liquors were studied in this paper. A total of 66 aroma compounds were identified in three liquors by means of gas chromatography−olfactometry (GC-O) coupled with mass spectrometry (MS), and 27 odorants were further screened out as the important odorants according to quantitative study and odor activity values (OAVs). For OAV calculation, odor thresholds of the odorants were determined in a hydroalcoholic solution at 46% ethanol by volume. The typical light type aroma dominated by fruity and floral notes was successfully simulated by dissolving these important odorants in the 46% vol hydroalcoholic solution in their natural concentrations. Omission experiments further confirmed β-damascenone and ethyl acetate as the key odorants and revealed the significance of the entire group of esters, particularly ethyl lactate, geosmin, acetic acid, and 2-methylpropanoic acid, for the overall aroma of the light aroma type Chinese liquor.

KEYWORDS: *Chinese light aroma type liquor, gas chromatography−olfactometry, gas chromatography−mass spectrometry, odor activity value, aroma recombination and omission, β-damascenone*

INTRODUCTION

Chinese liquor, also called *baijiu* or *shaojiu*, is a worldwide consumed distilled alcoholic beverage of great reputation, especially in China. It commonly has an ethanol content of 40−55% by volume.[1] Due to the great varieties of production processes, Chinese liquors from different manufacturers have significant differences in aroma profile. On the basis of the aroma characteristics, they are generally classified into the following categories: light aroma type, strong aroma type, soy sauce aroma type, sweet and honey aroma type, and miscellaneous aroma type liquors.[2] Among them, light aroma type liquor is widely welcomed by consumers due to its pleasant fruity and floral aroma, particularly in northern China.

As known to all, the quality of a beverage is influenced by many factors, such as raw materials and the fermentation process. In general, the main raw materials used for light aroma type liquor production are sorghum, barley, and pea: the former is used for making liquor, and the latter two are used for making *qu*.[3] In addition, rice husks are used as a fermentation accessory. *Qu*, which is made of pulverized barley and pea, is usually used as a fermentation starter to initiate the fermentation process. The various microorganisms and complex enzyme system in *qu* can generate abundant aroma compounds during the fermentation process.[4] The major producing steps of light aroma type liquor are as follows: mixing raw materials with *qu*, solid-state saccharification and fermentation in a pottery jar (350−400 L) under anaerobic conditions, and distillation.[2] Subsequently, the freshly distilled liquors are aged in sealed ceramic jars to develop balanced aroma and taste. Finally, the aged liquors are adjusted to a target ethanol concentration and blended for a constant quality of the final product.[5]

The aroma of Chinese liquor is an important factor in product quality, and it is mostly influenced by the complex aroma active compounds. Some studies have been made previously, and various techniques have been applied to investigate these aroma compounds. Fan and co-workers[5−7] have identified 126 odorants in *Wuliangye* and *Jiannanchun* liquor by gas chromatography−olfactometry (GC-O) and gas chromatography−mass spectrometry (GC-MS) techniques in 2006; afterward, they studied 27 pyrazines in Chinese liquors using GC-MS and headspace solid phase microextraction (HS-SPME) coupled with gas chromatograpy−flame thermionic detector (GC-FTD) in 2007, and later in 2011, they quantitated 76 volatile compounds in *Langjiu* through stir bar sorptive extraction (SBSE) coupled with GC-MS. Moreover, Zhu et al.[8] have shown the great complexity of the composition in *Maotai* liquor with 528 volatiles identified by means of comprehensive two-dimensional GC−time-of-flight MS. However, most of these studies were focused on the identification and quantitation of aroma compounds, and none comprehensively explored the contribution of key odorants from numerous constituents to the overall aroma.

Recently, techniques including not only GC-O and quantitation analysis but also odor activity value (OAV) analysis, descriptive profile test, aroma recombination, and

omission experiments are being extensively and successfully used to investigate the key aroma compounds of alcoholic beverages, such as whiskey,[9,10] beer,[11] brandy,[12] and Chinese rice wine,[13] as well as other foods.[14−17]

Therefore, to answer the puzzling question of which key aroma compounds are responsible for the typical aroma of light aroma type Chinese liquor, our study investigated three representative liquors in the following ways: identify and quantitate their potent aroma compounds in common, rate these compounds on the basis of OAVs and find the important odorants, and, finally, confirm the aroma contribution of selected important odorants by means of aroma recombination and omission experiments performed in the *Fenjiu* liquor. These data can be used for the optimization of the aroma and flavor of Chinese liquors during their production.

MATERIALS AND METHODS

Liquors. Three premium Chinese light aroma type liquors from different origins were under investigation: *Fenjiu* liquor (FJ, 45% ethanol by volume, from Shanxi province in north-central China), *Baofeng* liquor (BFJ, 46% ethanol by volume, from Henan province in central China), and *Qingke* liquor (QKJ, 52% ethanol by volume, from Qinghai province in northwestern China). All liquors (500 mL for each) were supplied by corresponding cooperant distilleries and stored at 4 °C until analysis.

Chemicals. Authentic standards were obtained from commercial sources: 1-Propanol, 1-butanol, 1-pentanol, 1-hexanol, 1-heptanol, 1-octanol, 2-methylpropanol, 3-methylbutanol, 1-octen-3-ol, 2-butanol, 2-heptanol, ethyl acetate, ethyl propanoate, ethyl 2-methylpropanoate, 2-methylpropyl acetate, ethyl butanoate, ethyl 3-methylbutanoate, 3-methylbutyl acetate, ethyl pentanoate, ethyl hexanoate, hexyl acetate, ethyl lactate, ethyl heptanoate, ethyl octanoate, ethyl nonanoate, ethyl decanoate, diethylbutanedioate, 3-methylbutyl hexanoate, ethyl undecanoate, ethyl dodecanoate, ethyl 2-hydroxyhexanoate, propanoic acid, 3-methylbutanoic acid, pentanoic acid, hexanoic acid, decanoic acid, 3-methylbutanal, hexanal, nonanal, decanal, 2-nonanone, (*E*,*Z*)-2,6-nonadienal, benzaldehyde, phenylacetaldehyde, ethyl benzoate, ethyl 2-phenylacetate, 2-phenylethyl acetate, ethyl 3-phenylpropanoate, benzenemethanol, 2-phenylethanol, phenol, 4-methylphenol, 4-methylguaiacol, 4-ethylguaiacol, furfural, 2-acetyl-5-methylfuran, *β*-damascenone, *γ*-hexalactone, *γ*-nonalactone, 1,1-diethoxyethane, 1,1,3-triethoxypropane, and geosmin were purchased from Sigma-Aldrich (Shanghai, China). Acetic acid, 2-methylpropanoic acid, butanoic acid, and naphthalene were obtained from Alfa Aesar (Tianjin, China). Octyl propanoate (internal standard, IS), 2,2-dimethylpropanoic acid (IS), pentyl acetate (IS), and L-menthol (IS) (Sigma-Aldrich, Shanghai, China) were used as internal standards. A C_5−C_{30} *n*-alkane mixture (Sigma-Aldrich, Shanghai, China) was employed for determination of linear retention indices (RIs). All of the substances used above were of GC quality, with at least 97% purity.

Sodium chloride (NaCl), anhydrous sodium sulfate (Na_2SO_4), sodium bicarbonate ($NaHCO_3$), sulfuric acid (H_2SO_4), and absolute ethanol were from China National Pharmaceutical Group Corp. (Shanghai, China). Diethyl ether and pentane from ANPEL Scientific Instrument Co., Ltd. (Shanghai, China) were freshly distilled before use.

Aroma Extraction and Fractionation. Following ref 5, liquors (50 mL) were diluted to 10% ethanol by volume with boiled ultrapure water, saturated with NaCl, and then extracted with diethyl ether (3 × 20 mL). The combined extracts were further separated into acidic/water-soluble, neutral, and basic fractions, using a mixture of pentane/diethyl ether (1:1 by volume) as extraction solvent. Afterward, each fraction was dried with anhydrous Na_2SO_4 overnight and concentrated under a gentle stream of nitrogen to a final volume of 200 μL. These concentrated fractions were stored at −20 °C prior to the GC-O analysis.

Identification by GC-O and GC-MS Analysis. GC-O and GC-MS analysis were performed on an Agilent 6890N GC coupled to an Agilent 5975 mass selective detector (MSD) and an olfactometer.

GC-MS Analysis. The concentrated fraction (1 μL) was injected in splitless mode. Samples were analyzed on both a DB-Wax column (30 m × 0.32 mm i.d. × 0.25 μm, J&W Scientific) and a DB-5 column (30 m × 0.32 mm i.d. × 1 μm, J&W Scientific). Helium at a constant flow rate of 2 mL/min was used as carrier gas. The injector was held at 250 °C. The oven temperature was held at 50 °C for 2 min, then programmed to 230 °C at a rate of 6 °C/min, and finally kept at 230 °C for 20 min. The column flow was split at the end of the capillary; one was directed to a heated olfactometer (Olfactory Detector Port ODP 2, Gerstel Inc., Mülheim, Ruhr, Germany), whereas the other one was directed to the MSD. The temperature of the olfactory port was 280 °C. Mass spectra in the electron ionization mode (MS-EI) were recorded at 70 eV ionization energy, and the ion source temperature was set at 230 °C. Full-scan acquisition was used in the 30−350 amu range of masses.

GC-O Analysis. Six trained panelists (three males and three females, 26 years old on average) from the Laboratory of Brewing Microbiology and Applied Enzymology at Jiangnan University were recruited to perform GC-O analysis. The panelists were trained for 3 months in GC-O using at least 30 odor-active reference compounds in a concentration 10 times above their odor thresholds in air. During a GC run described above, a panelist placed his/her nose close to the sniffing port, responded to the aroma intensity of the stimulus, and recorded the aroma descriptor and intensity value as well as retention time. The sniffing time of each run was not more than 30 min. The aroma descriptors were determined by an evaluation of the odor quality of reference odorants previously. A six-point scale ranging from 0 to 5 was used for intensity judgment: 0 = none, 1 = very weak, 2 = weak, 3 = moderate, 4 = strong, and 5 = very strong. The Osme value for aroma intensity was an average result of the six panelists.[18]

Identification of Aroma Compounds. Peak identifications of the odorants were performed by comparison of mass spectra with those of the NIST 05 a.L database (Agilent Technologies Inc., Santa Clara, CA, USA). Positive identification was achieved by comparison of their odors, retention indices (RIs), and mass spectra with those of pure standards. RIs of the odorants were calculated from the retention times of *n*-alkanes (C_5−C_{30}), according to a modified Kovats method.[19]

Quantitation by HS-SPME-GC-MS. An automatic headspace sampling system (MultiPurposeSample MPS 2 with a SPME adapter, from Gerstel Inc., Mülheim, Ruhr, Germany) with a 50/30 μm divinylbenzene/carboxen/poly(dimethylsiloxane) (DVB/CAR/PDMS) fiber (2 cm, Supelco Inc., Bellefonte, PA, USA) was used for extraction of volatile aroma compounds. The liquors were diluted with boiled ultrapure water to a final concentration of 10% ethanol by volume. A total of 8 mL of this diluted sample was transferred into a screw-capped vial, saturated with NaCl, and spiked with 10 μL of a mixed internal standard (octyl propanoate and L-menthol, with a final concentration of 66.7 or 125.2 μg/L, respectively). Tightly capped with a Teflon-faced silicone septum, the sample was equilibrated at 50 °C for 5 min and extracted for 45 min at the same temperature under stirring at the rotation speed of 250*g*. After extraction, the fiber was inserted into the injection port of GC for a 5 min desorption. The injector and oven temperatures were identical to those used for GC-MS analysis described previously, and a DB-Wax column was used. All samples were performed in triplicate

Selective ion monitoring (SIM) mass spectrometry was used to quantitate the aroma compounds. The ions monitored of octyl propanoate and L-menthol in the SIM run were *m*/*z* 75 and 138, respectively. The standard curve for individual volatile aroma compound was built up by plotting the response ratio of target compounds and corresponding ISs against the concentration ratio as reported (Table 2).[20]

Liquid−Liquid Microextraction (LLME) for Quantitation of Fatty Acids. Due to the poor adsorption of the DVB/CAR/PDMS fiber to strong polar fatty acids, LLME was used as a separate extraction of these acids. According to the method described by Wang and co-workers,[21] each liquor sample was diluted with boiled ultrapure water

Table 1. Aroma Compounds Identified by GC-O in Three Light Aroma Type Chinese Liquors

[a]The odorants were identified by comparing their RIs, mass spectra, and aroma attributes with those of standards. [b]The odorants were detected in fraction A, acidic/water-soluble fraction; N, neutral fraction; or B, basic fraction. [c]FJ, *Fenjiu* liquor; BFJ, *Baofeng* liquor; QKJ, *Qingke* liquor.

to a final concentration of 10% ethanol by volume. Eighteen milliliters of diluted liquor sample with 6 μL of IS solution (3.40 mg/L final concentration of 2,2-dimethylpropanoic acid (IS)) was saturated with NaCl and then mixed for 3 min with 1 mL of redistilled diethyl ether. After extraction, 1 μL of extract was injected into the injection port of the GC (250 °C) for analysis. The SIM method was used to quantitate the fatty acids (Table 2). The ion monitored of 2,2-dimethylpropanoic acid was m/z 57. The standard curves for fatty acids were built up as mentioned above.

GC-FID for Quantitation of Some Compounds with High Concentrations. GC-FID was employed for quantitation of ethyl acetate and ethyl lactate, because these two compounds have a high concentration of >1 g/L (Table 2). It was carried out using an Agilent 6890 GC equipped with a FID, modified from the method of ref 22. The column carrier gas was nitrogen at a constant flow rate of 1 mL/min. The separations were performed using a DB-Wax column (30 m length, 0.25 mm i.d., 0.25 μm film thickness; J&W Scientific) with an oven temperature program of 60 °C (3 min), ramped at 5 °C/min to 150 °C (15 min), and then ramped at 10 °C/min to 230 °C (5 min). One microliter of diluted liquor sample (40% ethanol by volume) with 176 mg/L final concentration of pentyl acetate was injected into the GC. The split ratio was 37:1. Injector and detector temperatures were 250 °C. The identification of compounds and the correction factors calculated in 40% ethanol by volume were performed according to ref 22.

Determination of Odor Thresholds. On the basis of the method previously described,[23] the orthonasal thresholds of the odorants were determined by a forced-choice test at seven concentration steps. A certain amount of the odorant in ethanol was pipetted into a Teflon vessel containing 50 mL of hydroalcoholic solution at 46% ethanol by volume, stirred for 2 min, and stepwise diluted (1:3 by volume, with the hydroalcoholic solution). Triangular series including one glass of the dilution and two glasses of hydroalcoholic solution were prepared. All of the series were labeled with random four-digit numbers and presented in decreasing concentrations. A sensory panel consisting of 32 panelists was asked to sniff each triangular series and select the differing one. The minimum concentration that the assessors correctly selected and the maximum concentration incorrectly selected were recorded. The odor threshold of each odorant was calculated by using the formulas described in ref 23. Sensory tests were performed at 21 ± 1 °C in a sensory room, and all of the panelists were national liquor tasters and had prior sensory training in Chinese liquor evaluation.

Aroma Recombination of FJ. A hydroalcoholic solution at 46% ethanol by volume was used as the matrix for recombination. All 27 odorants with OAVs ≥ 1 simultaneously in three liquors were dissolved in the matrix in their natural concentrations (Table 2) and then equilibrated for 10 min at ambient temperature; thus, a complete recombinate was obtained. This recombinate of 20 mL was finally presented in a glass covered with aluminum foil. Besides, a glass of FJ liquor was also prepared for the following sensory evaluation.

Descriptive profile tests were performed by 10 assessors (5 males and 5 females, 32 years old on average), 6 of whom were from the GC-O analysis and the other 4 were laboratory staff members familiar with the sensory attributes of Chinese liquors. All of the assessors were previously trained in orthonasal odor perception and participated regularly in sensory evaluation. Eight attributes were chosen as the most relevant odor to describe the overall aroma: fruity, floral, acid, earthy, alcoholic, grassy, mushroom, and coconut. The assessors were asked to evaluate the odor intensity of these attributes on a six-point scale from 0 to 5 (same as that described for GC-O analysis). The results obtained from 10 assessors were averaged and finally plotted in a spider web diagram. All of the tests were conducted in a sensory panel room at 20 ± 1 °C.

Omission Experiments. Triangle tests were performed to determine the significance of certain compounds according to the method previously reported.[24] For this purpose, 15 aroma omission models were prepared in the same way as complete recombinate but omitting one or a group of selected components, shown in Table 4. Three samples, including one omission model and two complete recombinates, were presented simultaneously to the assessors. All of the samples (20 mL) were randomly coded, and the assessors were the same people from the descriptive profile tests. The assessors were asked to sniff the samples and determine the differing one. The significance of difference between omission model and complete recombinates was determined according to the method described.[24]

RESULTS AND DISCUSSION

Identification of Odor-Active Constituents. By extraction with diethyl ether, an organic phase was obtained, which exactly elicited the typical light type aroma when sniffed by the panelists on a fragrance blotter. Thus, the isolation method used in this study turned out to be appropriate and reliable. For the purpose of facilitating GC-O analysis and compound identification, the extract obtained was further separated into acidic/water-soluble, neutral, and basic fractions to reduce complexity as previously described by Fan and Qian.[5] To identify the constituents responsible for the odors, odor-active areas were first located by GC-O and their RIs on both DB-Wax and DB-5 columns were determined. Besides, mass spectra in EI mode were recorded in the meantime, which were then compared with those available in NIST05a.L (Agilent Technologies, Inc.). To confirm these compounds further, their RIs, mass spectra, and aroma attributes were finally compared to the data obtained from the respective reference compounds.

Following this procedure, a total of 66 aroma compounds were identified in three light aroma type liquors in this study (Table 1). Among them, the highest Osme value of 4.67 was determined for β-damascenone and 2-phenylethanol. 2-Phenylethanol exhibited rosy and honey odors and β-damascenone presented honey and floral aromas. Both of these two compounds were previously reported as important odorants in whiskey, rum, and brandy.[9,12,25] One further compound with an Osme value above 4.00 simultaneously in three liquors was identified as ethyl octanoate, which showed an intense fruity odor. In addition, odorants with somewhat lower Osme values

[a]FJ, *Fenjiu* liquor. [b]BFJ, *Baofeng* liquor. [c]QKJ, *Qingke* liquor. [d]av, average concentration of triplicates. [e]RSD, relative standard deviation of the average concentration. [f]These compounds were quantitated by GC-FID method. Correction factors of ethyl acetate and ethyl lactate were 1.47 and 1.54, respectively. [g]The concentration was mg/L. [h]These compounds were quantitated by LLME coupled with GC-MS method. [i]nd, not detected.

were identified as ethyl acetate (pineapple), 2-methylpropanol (malty), 3-methylbutanol (malty), ethyl phenylacetate (rosy and honey), and 2-phenylethyl acetate (floral). With their high Osme values, which were above 4.00 in at least one of the three liquors, these compounds were likely to contribute a lot to the overall light type aroma. However, other odorants, such as 3-methylbutanal (green and malty), 2-butanol (fruity), hexyl acetate (fruity), propanoic acid (vinegar), γ-hexalactone (sweet and coconut), naphthalene (mothball-like), and benzenemethanol (floral), appeared with lower Osme values below 2.00 in all three liquors. Most of these compounds have been earlier identified as aroma compounds in FJ, as well as in other aroma types of Chinese liquor.[5,8,26] Among them, β-damascenone was detected for the first time in BFJ and QKJ.

Quantitation of Odor-Active Compounds and OAV Analysis. Although GC-O analysis is an effective means for

dx.doi.org/10.1021/jf501214c | J. Agric. Food Chem. 2014, 62, 5796−5804

odorant identification, it could not indicate a final importance of the odorant to the overall aroma. One main reason is the fact that compounds in GC-O analysis were significantly separated and concentrated before sniffing, but in authentic liquors only the odorant present at a concentration above its odor threshold contributes to the overall aroma. Besides, as Grosch[27] reported, the influence of ethanol concentration on the volatility of an odorant should not be ignored. Taking these cases into consideration, the odor activity value (OAV) concept,[28] which correlated quantitative data to odor thresholds in a matrix, was applied to get closer to the liquors themselves.

For this reason, a total of 47 odorants with Osme values of ≥2.00 simultaneously in three liquors were quantitated (Table 2). Among these odorants, ethyl acetate and ethyl lactate, which had been reported as the most abundant odorants in light aroma type liquor,[29] appeared with the highest concentrations as expected. Both of them were >1.00 g/L. Besides, odorants 1,1-diethoxyethane, 2-methylpropanol, 3-methylbutanol, and acetic acid had higher concentrations of 0.1−0.9 g/L. However, two notable odorants, namely, β-damascenone (12−29 μg/L) and geosmin (1.0−1.2 μg/L), were present only in trace amounts, far lower than any other compounds.

To get as close as possible to the authentic liquor, the thresholds of single compounds were determined in a hydroalcoholic solution at 46% ethanol by volume, the typical ethanol content in Chinese liquor. Except that of geosmin, all of these thresholds were determined for the first time. As shown in Table 3, odorants such as ethyl acetate had a fairly high threshold of 32.6 mg/L in 46% vol hydroalcoholic solution. However, thresholds of some compounds present at trace amounts in Chinese liquors were extremely low, such as β-damascenone and geosmin. In this study, β-damascenone was determined with a threshold value of 0.12 μg/L, 10 times higher than that in water.[23] The threshold value of geosmin in 46% vol hydroalcoholic solution was determined at 0.11 μg/L according to the previous study, also 10 times higher than that in water.[1] These data revealed that the higher ethanol concentration in Chinese liquor might lead to a higher threshold than that in water.

Subsequently, OAVs of the odorants in light aroma type liquors were calculated and are summarized in Table 3. The results indicated that altogether 27 odorants were calculated with OAVs > 1 simultaneously in three liquors. These odorants should be the important contributors to the characteristic aroma of light aroma type Chinese liquor. Among these odorants, ethyl octanoate had the highest OAV value, which exhibited an intense fruity aroma. Two odorants, β-damascenone (floral and honey) and 1,1-diethoxyethane (fruity), could also be significant according to their higher OAVs (>100). Other odorants with high OAVs (>10) were 3-methylbutyl acetate, ethyl acetate, ethyl hexanoate, ethyl butanoate, ethyl 2-methylpropanoate, and geosmin. They could also contribute to the overall aroma but to a lesser degree.

Aroma Recombination and Omission Experiments. To confirm that the odorants showing high OAVs were actually the important odorants of light aroma type liquor, aroma recombination and omission experiments based on FJ (the most representative light aroma type liquor in China) were undertaken. For this purpose, an aroma recombinate, consisting of 27 odorants with OAVs ≥ 1 simultaneously in the three liquors in their natural concentrations (Table 2), was prepared.

[a]Thresholds in 46% volume hydroalcoholic solution detected in this study, μg/L. [b]FJ, *Fenjiu* liquor; BFJ, *Baofeng* liquor; QKJ, *Qingke* liquor. [c]Odor thresholds were taken from ref 1.

Descriptive profile tests were then conducted by a sensory panel consisting of 10 trained assessors, and odor attributes of the recombinate and original liquor were compared. As shown in Figure 1, the aroma profile of the recombinate was in good similarity to that of the original liquor. Consequently, this result indicated the success in simulating the typical aroma of the

investigated liquor by combining 27 odorants in their natural concentrations, using a 46% vol hydroalcoholic solution as the matrix.

To achieve a deeper investigation of the aroma contribution of certain compounds, 15 aroma omission models were prepared by omitting either a single odorant or a group of odorants from the complete recombinate (Table 4). Each of the omission models was presented to the assessors in comparison with the complete recombinate, using a triangle test. The results are shown in Table 4.

[a]Number of correct judgments from 10 assessors evaluating the aroma difference by means of a triangle test. [b]Significance: ***, very highly significant ($\alpha \leq 0.001$); **, highly significant ($\alpha \leq 0.01$); *, significant ($\alpha \leq 0.05$).

In the tests, all assessors were able to detect the omission model lacking the entire group of esters (model 1), thus leading to a very highly significant difference between the omission model and complete recombinate. This result revealed the fairly important role of these fruity note odorants to the overall aroma. Among them, ethyl octanoate was calculated for extremely high OAVs (Table 3), but as omission model 1A revealed, the absence of this compound was correctly detected by only 4 of 10 assessors in triangle tests. Therefore, no significant difference was determined for its omission compared with the complete recombinate. Thus, this compound was excluded as the most important aroma contributor. Ethyl acetate and ethyl lactate were traditionally regarded as the most potent aroma compounds because of their particularly high concentrations,[29,30] but in our study their OAVs were not so much high. Therefore, several omission models were set up for a deeper investigation. When ethyl acetate and ethyl lactate were omitted together (model 1D), a high significance was evaluated. However, no significant difference was observed when all esters except these two compounds (model 1E) were omitted. This indicated the important role of these two fruity note odorants. Furthermore, when solely lacking ethyl acetate (model 1B), the assessors could detect a highly significant difference, whereas the omission of single ethyl lactate (model 1C) was determined as only significantly different by the assessors. This revealed a slightly more important role of ethyl acetate compared with ethyl lactate. In conclusion, these data indicated that ethyl acetate and ethyl lactate together rather than ethyl octanoate were responsible for the typical fruity note of light aroma type liquor, probably due to their high concentrations, and this finding fitted well with the conclusion previously drawn.[30] As reported previously, esters were formed mainly through esterification of alcohols and fatty acids during the fermentation, distillation, and aging processes.[31,32]

However, another fruity-smelling odorant, 1,1-diethoxyethane, should be mentioned, just as the case of ethyl octanoate. Despite its relatively high OAV calculated in Table 3, omission of this compound was detected with no significant difference by the assessors (model 2). This might be due to the very intense fruity note of the esters, which made up for the absence of the single 1,1-diethoxyethane.

An omission model without β-damascenone was evaluated with a very highly significant difference compared to the complete recombinate (model 3), thereby pinpointing the crucial role of this floral- or honey-like-smelling compound for the typical aroma of light aroma type liquor. This result was in accordance with the high OAVs determined for β-damascenone (Table 3). However, no difference of the model lacking in aromatic compounds, which exhibited a floral odor as well, was detected by the assessors (model 4). Consequently, the floral note present in the profile of overall aroma could be greatly linked to β-damascenone rather than the aromatic compounds. β-Damascenone has already been detected in many alcoholic beverages, such as whiskey, wine, and beer.[9,33,34] Researchers have suggested that 3-hydroxy-7,8-dihydro-β-ionol was the key precursor for the formation of β-damascenone through an acid-catalyzed pathway.[35] On the basis of these findings, Poisson and Schieberle[10] assumed that cereals could contain similar precursors leading to the generation of β-damascenone during fermentation and/or distillation.

As shown in Table 4, the omission of acetic acid and 2-methylpropanoic acid (model 5) was rated with a highly significant difference. This elucidated the important role of these two acidic- or vinegar-smelling odorants to the overall aroma. In addition, the omission of the earthy-smelling odorant geosmin (model 8) also resulted in a highly significant difference from the complete recombinate. This compound was previously detected in Chinese liquors by Du and co-workers.[1] However, the model lacking in alcohols (model 6) was not determined as significantly different when compared with the complete recombinate; thus, the alcoholic note from the aroma profile could not be correlated to certain odorants in

dx.doi.org/10.1021/jf501214c | J. Agric. Food Chem. 2014, 62, 5796−5804

this study. Aldehydes mostly showed a grassy or green note; omission of this group of compounds was also determined with no significant difference by the assessors (model 7). The same results also occurred with γ-nonalactone (coconut smelling) and 1-octen-3-ol (mushroom smelling), as shown in models 9 and 10.

To sum up, with all of the findings above taken into account, conclusions can be drawn: (i) Aroma-active compounds in three representative Chinese light aroma type liquors have been successfully identified through GC-O analysis, and 27 odorants were further screened out as the important odorants according to quantitative study and OAV data. (ii) By means of aroma recombination and omission experiments, the typical light type aroma dominated by fruity and floral notes was successfully simulated using these 27 important odorants, and, additionally, ethyl acetate and β-damascenone were demonstrated as the key aroma contributors among them.

A careful literature inspection showed that this study is the first to investigate the key odorants of Chinese light aroma type liquor and to mimic its overall aroma through recombination and omission studies. Although limitations still exist, such as the simplified aroma model matrix that ignores the influence of nonvolatile compositions, our investigation could contribute to a better understanding of Chinese liquor.

Development of an Ultraperformance Liquid Chromatography–Tandem Mass Spectrometry Method for the Analysis of Perfluorinated Compounds in Fish and Fatty Food

Stephen W. C. Chung* and Chi Ho Lam

Food Research Laboratory, Food and Environmental Hygiene Department, 4/F Public Health Laboratory Centre, 382 Nam Cheong Street, Hong Kong SAR, China

Supporting Information

ABSTRACT: This paper reports the development of a method for the quantitative analysis of perfluorinated compounds (PFCs), including C_6–C_{14} perfluorinated carboxylic acids (PFCAs) and C_4–C_{12} perfluorinated sulfonates (PFSAs), in fish and fatty foods by ultraperformance liquid chromatography–electrospray ionization–tandem mass spectrometry (UPLC-ESI-MS/MS) in which the UPLC was equipped a PFC Analysis Kit to eliminate background contamination. Rapid baseline separation was achieved for 17 PFCs within 12 min, and PFCs were well-resolved from potential interferences from taurodeoxycholic acid and branched isomers of PFCs. The method was validated according to Commission Regulation 2002/657/EC of the European Commission with matrices including salmon, beef, egg, and butter. Average spiked recoveries, measured at concentration levels of 0.02 (method limit of quantification (MLOQ)), 0.2, and 2 μg/kg, were in the range of 68–117% with relative standard deviations below 20%. Matrix effects were evaluated and found to be correctable by internal standardization, especially for short- and long-chained PFCs. Trueness was verified against two certified reference materials. The method has also been successfully applied to the analysis of more than 200 food samples of a risk assessment study.

KEYWORDS: *perfluorinated compounds, PFCAs, PFSAs, fish, fatty food, UPLC-MS/MS*

INTRODUCTION

As perfluorooctanesulfonate (PFOS) and perfluoroctanoic acid (PFOA) are persistent and can bioaccumulate in animals, it is not surprising that various studies reported the general public is exposed to these two chemicals.[1,2] Food and water were found to be the main sources of exposure. Studies conducted by various authorities around the world, including Canada,[3] China,[4] the United States,[5] the United Kingdom,[6] Germany,[7] The Netherlands,[8] Spain,[9] Sweden,[10] and the European Union,[11] found that PFOS and PFOA can present in certain foods up to 20 μg/kg. Some of these reports stated that fish (marine and fresh water) contain higher levels of these two PFCs. Studies also found some fatty foods including beef, offal (e.g., liver and kidney), butter, etc., can have PFOS/PFOA.

Owing to the lack of native and labeled reference standards, early studies of PFCs in fish were concentrated in PFOS, PFOA, and PFCAs.[12−16] More standards are available recently, including perfluoropentanesulfonate, perfluorononanesulfonate, and perfluorododecanesulfonate. Ion-pair extraction[13,15,17] and solid–liquid extraction[12,14,18,19] were commonly used. Both approaches coextract other matrix constituents, including lipids, and affect the mass spectrometric analysis (signal suppression).[20] Alkaline digestion can reduce the interference from fatty matrix, but is time-consuming.[7,18] Besides, the former extraction method may have the problem of loss of analytes in the solvent exchange process,[13,17] whereas the latter would show low recoveries for long- and short-chain PFCs.[19] In 2010, Ballesteros-Gomez et al.[21] introduced the THF–water extraction method for the analysis of 14 PFCs in food and applied it to the dietary intake study of PFOS and PFOA in The Netherlands.[22] Although eight labeled standards were used, the correction of hydrophilic short-chained and hydrophobic long-chained PFCs for a range of complex and heterogeneous matrices was still found to inefficient. Besides, phase separation occurred for fatty fish samples.

According to the European Food Safety Authority (EFSA) report,[23] most occurrence data of PFOS were reported without information on the isomer types analyzed: linear, branched, or both types. Owing to differences in bioaccumulation potentials,[24] linear and branched isomers should be analyzed separately for better estimation of their dietary exposure. The developed ultraperformance liquid chromatography–mass spectrometry (UPLC-MS) method resolved linear PFOS from 10 different branched isomers and well-known interference taurodeoxycholic acid (TDCA). Besides, this method can quantify nine PFCAs and eight PFSAs within 12 min. Validation was performed with fish, meat, egg, and butter according to the requirement of the Commission Decision 2002/657/EC of the European Commission (EC), and the results fulfilled the recommendations in Commission Recommendation 2010/161/EU on monitoring of perfluoroalkylated substances in food. Furthermore, method accuracy and extraction efficiency were verified by two fish certified reference materials obtained from the National Institute of Standards and Technology.

MATERIALS AND METHODS

Chemicals and Standards. LC-MS grade acetonitrile (MeCN) and methanol (MeOH) were purchased from Anaqua Chemicals Supply (Houston, TX, USA) and Fisher Scientific (Waltham, MA, USA), respectively. Water was purified through a Milli-Q synthesis system integral with LC-Pak polisher from Millipore (Billerica, MA, USA). Absolv. grade *n*-hexane was purchased from Tedia Co. (Fairfiled, OH, USA). Analytical reagent grade ammonia solution was purchased from VWR international (Poole, UK). HPLC grade tetrahydrofuran (THF), ammonium acetate, acetic acid, ammonium formate, and formic acid were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Native perfluorinated compounds (PFCs), including perfluoro-*n*-hexanoic/heptanoic/octanoic/nonanoic/decanoic/undecanoic/dodecanoic/tridecanoic/tetradecanoic acid (PFHx/Hp/O/N/D/Ud/Do/TrD/TeDA) and sodium perfluoro-1-butane/pentane/hexane/heptane/octane/nonane/decane/dodecanesulfonate (PFB/Pe/Hx/Hp/O/N/D/DoS), were purchased from Wellington Laboratories (Ontario, Canada). Isotopically labeled standards perfluoro-*n*-[1,2,3,4,6-$^{13}C_5$]hexanoic acid ($^{13}C_5$PFHxA), perfluoro-*n*-[1,2,3,4-$^{13}C_4$]-heptanoic acid ($^{13}C_4$PFHpA), perfluoro-*n*-[$^{13}C_8$]octanoic acid ($^{13}C_8$PFOA), perfluoro-*n*-[$^{13}C_9$]nonanoic acid ($^{13}C_9$PFNA), perfluoro-*n*-[1,2,3,4,5,6-$^{13}C_6$]decanoic acid ($^{13}C_6$PFDA), perfluoro-*n*-[1,2,3,4,5,6,7-$^{13}C_7$]undecanoic acid ($^{13}C_7$PFUdA), perfluoro-*n*-[1,2-$^{13}C_2$]dodecanoic acid ($^{13}C_2$PFDoA), perfluoro-*n*-[1,2-$^{13}C_2$]-tetradecanoic acid ($^{13}C_2$PFTeDA), sodium perfluoro-1-[1,2,3-$^{13}C_3$]-hexanesulfonate (Na$^{13}C_3$PFHxS), and sodium perfluoro-1-[$^{13}C_8$]-octanesulfonate ($^{13}C_8$PFOS) were purchased from Wellington Laboratories (Ontario, Canada), and ammonium perfluoro-[$^{18}O_2$]-butanesulfonate ($^{18}O_2$PFBS) was obtained from RTI International (Research Triangle Park, NC, USA).

TDCA sodium salt was purchased from Steraloids Inc. (Newport, RI, USA), and perfluoro-1/-2/-3/-4/-5/-6-methylheptanesulfonate (P1/2/3/4/5/6MHpS), perfluoro-2/-3/-4/-5/-6-methylheptanoic acid (P2/3/4/5/6MHpA), perfluoro-4,4/-5,5/-3,5/-4,5-methylhexanesulfonate (P44/55/35/45DMHxS), and perfluoro-4,4/-5,5/-3,5/-4,5-methylhexanoic acid (P44/55/35/45DMHxA) in methanol were purchased from Wellington Laboratories.

Intermediate mixed standard solutions (10 mg/L) were prepared with methanol. Working standard solutions for calibration were freshly prepared with MeCN/water (5:5 v/v). All solutions were stored at −20 °C.

Sample Preparation. A portion of 10 g of homogenized sample was weighed and placed into a 50 mL polypropylene centrifuge (PP) tube (Sarstedt, Nümbrecht, Germany). Isotopically labeled internal standards each of 1 ng were spiked. The sample was then defatted by vortexing with 20 mL of *n*-hexane for 10 min with a multipulse vortexer (Glas-Col, LLC, Terre Haute, IN, USA). The mixture was centrifuged by a centrifuge (Kendro, Newtown, CT, USA), and the *n*-hexane layer was discarded. The defatted sample was then freeze-dried for 24 h to remove the sample moisture by a freeze-dryer (SP Industries, Warminster, PA, USA). Twenty milliliters of THF/water (75:25) solution was added for extraction. The mixture was vortexed for 10 min and was recentrifuged for 10 min at 8500 rpm (or 6770*g*) (Falcon 6/300, MSE, UK). Any residual oil layer was discarded. Ten milliliters of extract was pipetted into a 15 mL PP centrifuge tube (Sarstedt). The volume of extract was reduced to 6 mL under a slow stream of nitrogen at 50 °C and then made up to 15 mL with water before cleanup.

The 15 mL sample solution was loaded onto a preconditioned weak anion exchange cartridge, Strata X-AW (6 mL, 200 mg) obtained from Phenomenex, at a rate of 1 drop/s. After loading, the cartridge was washed with 4 mL of 25 mM acetate buffer at pH 4 and 6 mL of a 50:50 (v/v) THF/MeCN mixture at a rate of 2 drop/s. Then, the SPE WAX cartridge was coupled to the ENVI-carb cartridge (6 mL, 250 mg), which obtained from Sigma-Aldrich, via a suitable polyethylene (PE) adaptor cap. The target analytes were eluted out with 6 mL of 0.1% ammonia in MeOH. The eluate passed through the graphitized carbon cartridge, too. Cartridges were dried under vacuum to ensure maximal recovery of the eluate. The eluate was evaporated to dryness (50 °C, N_2) and reconstituted with 0.5 mL of MeCN/water 1:1 (v/v). Finally, the extract was filtered by syringe (Terumo, Leuven, Belgium) with a 0.2 μm regenerated cellulose syringe filter (Sartorius AG, Goettingen, Germany) into a PP LC vial with a PP screw cap (Waters) for UPLC-MS/MS analysis.

For fat/oil samples, no defatting and freeze-drying were done. The rest of the sample preparation was the same as described above.

Ultraperformance Liquid Chromatography−Mass Spectrometry. The chromatographic separation was carried out using a Waters Acquity UPLC system, which consisted of a sample manager, a column manager, and a binary solvent manager (Milford, MA, USA) equipped with a UPLC column with perfluoro-C8 stationary phase, Epic FO LB, 1.8 μm, 5 cm × 2.1 mm (ES Industries Chromega, West Berlin, NJ, USA). Column temperature was set at 35 °C. Gradient elution was made with MeCN and aqueous buffer with 1.3 mM ammonium formate and 0.7 mM formic acid at a constant flow rate of 0.45 mL/min. Initial mobile phase composition of 13% MeCN was held for 3 min. MeCN composition was linearly increased to 55% at 7.5 min and subsequently to 95% at 10 min. Washing with 95% MeCN was held from 2 min. MeCN composition was then reduced back to 13% and followed by a 3 min reconditioning of the column. The total run time was 15 min. Five microliters of extract was injected in this study. Besides, the UPLC system was installed with an Acquity PFCs analysis kit. Epic FO LB was used as an isolation column.

The UPLC system was coupled to a Qtrap 5500 triple-quadrupole mass spectrometer (AB Sciex, Framingham, MA, USA) equipped with a TurboV ion source for analysis. The data system was installed with Analyst software (version 1.5.2). The tandem mass spectrometer was operated in negative electrospray ionization mode (−ve ESI-MS/MS). Scheduled multiple reaction monitoring algorithm mode was used to maximize the instrument performance. Ion spray voltage was set at −4 kV. Nitrogen was used as collision gas and set at medium. Curtain gases, GS1 and GS2, were set at 20, 50, and 50, respectively. Source temperature was set at 600 °C. Both quadrupole 1 (Q1) and quadrupole 3 (Q3) resolution were set as unit. The entrance potential was set as −10 V. The optimized settings for collision energy (CE) and the declustering (DP), entrance (EP), and collision cell exit potentials (CXP) were tested for each target analyte and their ISs by flow injection analysis resulting from the most abundant precursor ion and are summarized in the Supporting Information (Table S1), as well as the indicative retention times on the column. All PFCAs were monitored as their deprotonated ions ($[M - H]^-$), whereas all PFSA anions were directly monitored ($[M]^-$). Softwares Acquity UPLC Console (Waters) and Analyst (AB Sciex) were used to operate the UPLC and MS/MS, respectively. Software MultiQuant (AB Sciex) was used for data processing.

Internal standardization was used for PFC quantification. Matching of native and labeled standards is summarized in Table S1 in the Supporting Information. Fifteen-point calibration curves with concentrations from 0.05 to 50 μg/L (which covered 3 orders of magnitude) using weighted linear regression were established for quantification. Two MRM transitions were monitored to fulfill the identification points and ion ratio requirement. The maximum permitted tolerances on the MRM ratio as well as relative retention time (RRT) deviation tolerances (2.5%) followed 2002/657/EC guidelines. The minimum signal-to-noise ratio for both quantification and confirmation MRM of a quantified signal was 3.

RESULTS AND DISCUSSION

Method Development. Despite more and more PFC standards becoming commercially available, PFCs being mainly present in fish and meat, linear and branched PFCs should be quantified separately, and improvement in high-throughput analytical procedure is requested. The key issue of this paper was to develop a new method with good resolution power of PFCs for rapid quantification in fatty foods. As PFPeS (C_5), PFNS (C_9), and PFDoS (C_{12}) are commercially available, the scope of analysis increased to nine PFCAs (C_6−C_{14}) and eight

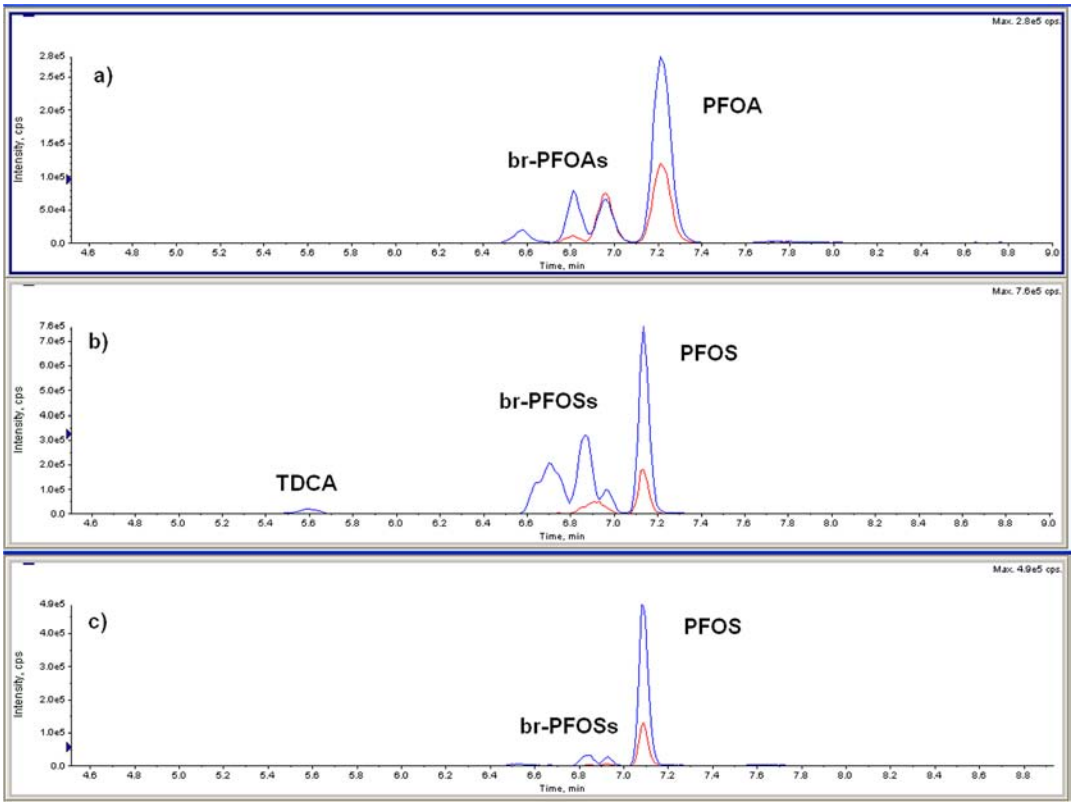

Figure 1. Chromatograms of the two MRM transitions of (a) PFOA and their branched isomers of a mixed standard solution, (b) PFOS, their branched isomers, and TDCA of a mixed standard solution, and (c) PFOS and their branched isomers of a fish sample. The blue trace refers to 413/369 and 499/80 for PFOA and PFOS, respectively, whereas the red trace refers to 413/169 and 499/99, respectively.

PFSAs (C_4−C_{12}). SPE WAX conditions were slightly modified for this wider scope of PFCs. We attempted to include perfluorohexadecanoic acid and perfluorooctadecanoic acid as well but did not succeed because their recoveries were comparatively low and none of the internal standards was found to be suitable for correction of recovery.

The run time was much shortened after the LC analysis migrated to a UPLC system. Seventeen PFCs were eluted within 12 min. It is worth mentioning that a small change in pH value of the buffering system affected PFC retentions. To ensure reproducibility, the mobile phase buffers were prepared by mixing of acid and salt solution instead of adjusting to the desired pH. Formic acid to ammonium formate ratios of 1:4, 1:2, and 1:1 in mobile phase were tested. PFBS was found to have no retention under buffer ratio 1:4, whereas PFTeDA had a strong retention, which led to undesirable peak boarding under buffer ratio 1:1. Although a systematic multivariate analysis of chromatographic conditions was not performed, the buffer system with an acid-to-salt ratio of 1:2 produced a suitable retention for both short- and long-chain PFCs.

Background PFCs Contamination. The UPLC-MS/MS offered excellent sensitivity to the PFCs, and analytes at the nanograms per liter level could be easily detected. As such, stringent control on background contamination from reagents, labware, and instrument was essential for reliable quantification of any trace amount of PFCs detected in samples. LC-MS grade MeOH (LabScan or Fisher) was used in the entire method as significant residual PFOA was noted in HPLC grade MeOH. Using PP centrifuge tubes, non-PTFE SPE vacuum manifold accessories, PP LC vials, and septumless polyethylene caps were necessary to reduce background. An Acquity PFC Analysis Kit was installed into the Waters UPLC system; those parts such as stainless steel tubings/screws/ferrules/filters of the LC system that contained PTFE parts were replaced by PEEK. An Epic FO LB was connected in-line between the solvent mixer and the injection of the LC system so that the PFCs leached out from the system were retained in it. The same type of column was used for both isolation and analytical separation such that the separation of the leached out PFCs could be ensured. High back pressure was generated by the isolator column of the PFC Analysis Kit and analytical separation column (i.e., two UPLC columns in series). The problem was resolved by replacing MeOH with MeCN as organic mobile phase and setting the analytical column temperature at 35 °C.

Trace amounts of PFHxA, PFHpA, and PFOA in method blank were controlled at ∼0.02 μg/L, which was less than the lowest calibration level at 0.05 μg/L in vial (i.e., 1/4 method limit of quantification (MLOQ)), whereas other PFC background contamination was much lower.

Method Performance. *Specificity.* The method specificity, which referred to the discrimination between analytes and closely related substances, was mainly focused on eliminating interference from branched PFCs isomers and TDCA as the method applied to fish and meat.

Branched (br-) PFOSs and PFOAs (dimethylhexane/methylheptane isomers) can also be monitored by the same principle transition from 499 to 80 and from 413 to 369 as PFOS and PFOA, respectively, but with different responses ranging from 7 to 340%. A similar observation was also noted for their secondary transitions from 499 to 99 and from 413 to 169. A systematic trend cannot be identified, and the MRM ratio varied among isomers. Thus, coelution of any branched

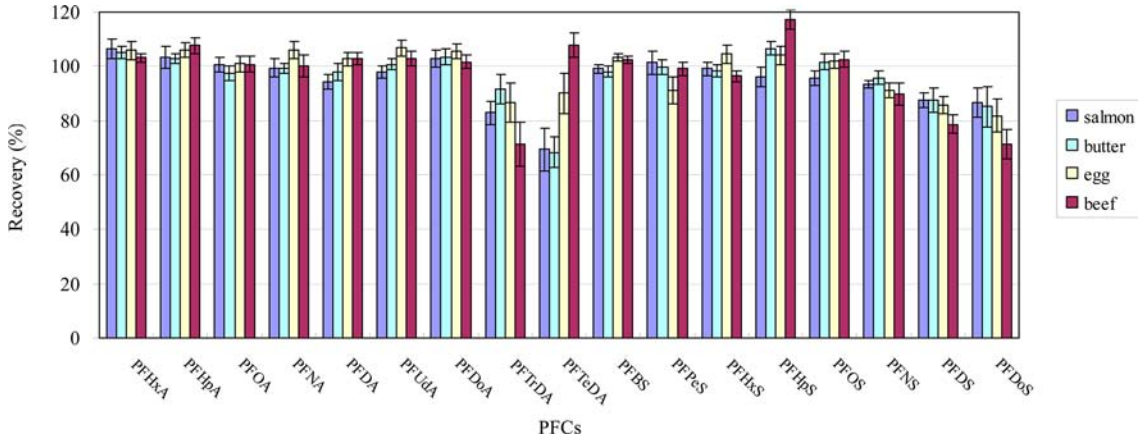

Figure 2. Average recovery and precision of sample spike of four matrices.

isomers could affect quantification as well as confirmation of PFOA/PFOS. Standard solutions of 10 br-PFOSs and 9 br-PFOAs at concentrations of 2 ng/mL were tested by the UPLC-MS/MS system and were baseline separated from their straight-chain isomer. Chromatograms of mixed standards of PFOAs and PFOSs are depicted in Figure 1, panels a and b, respectively, to show the separations achieved. From the real sample results, br-PFOS isomers were detected in almost all of the fish and seafood samples. Hence, good chromatographic separation was necessary for analyzing PFOS. An example is depicted in Figure 1c. In some cases, br-PFOS isomers could contribute to >30% of the signal, and overestimation occurred if br-PFOS isomer signals were not resolved. Further separation of branched isomers individually was not attempted.

TDCA in matrices of animal origin has been reported to interfere with the 499/80 MRM transition of PFOS, especially for fish. A standard solution of TDCA in 20 ng/mL was analyzed to evaluate the resolution of the UPLC program. It was found to elute much earlier than PFOS (Figure 1b). No interference from TDCA was expected as its retention time fell outside the MRM monitoring window in our finalized method.

Interference was noted for the MRM transition from 402 to 80 for $^{13}C_3$ PFHxS in fish samples. Thus, a matrix interference free of MRM transition of from 402 to 99 was used for correction.

Calibration. Linearity was checked through calibration curves, which were constructed by 15 concentration levels from 0.05 to 50 μg/L, equivalent to a working range from 0.005 to 5 μg/kg in sample, with coefficients of determination (R^2) values >0.995. Individual residual deviations were <15% for calibration levels greater than the MLOQ. Mandel's fitting test was performed to check the linearity. Calibration curves showed good linearity, with some exceptions. To achieve the linearity fulfilling Mandel's fitting, calibration ranges for PFPeS and PFHxA, PFNA and PFUdA, and PFTrDA and PFTeDA were narrowed to 0.05−40, 0.05−35, and 0.05−20 μg/L, respectively. Despite some working ranges being narrowed, we considered the calibrations were fit-for-purpose as high-level contaminations of these PFCs in real samples are rare.

Recovery, Precision, and Trueness. The accuracy and precision of the method were studied by means of spiked recovery experiments at three levels, MLOQ, 10× MLOQ, and 100× MLOQ (0.02/0.2/2 μg/kg), on four different days in four representative fatty matrices, namely, salmon, beef, egg, and butter. The overall performance of validation is summarized in Figure 2, with details given in Table S2 in the Supporting Information. The average recoveries in general fulfilled the recommended 70−120% in Commission Recommendation 2010/161/EU. Slightly lower recoveries (>65%) were observed for PFTeDA. Poor recoveries (>50%) and precision (>20%) of PFTrDA and PFTeDA in beef were improved when the recently available $^{13}C_2$PFTeA was used as internal standard for correction.

Method accuracy and trueness were also evaluated by four replicate analyses of certified reference materials (CRMs), fish tissues SRM 1946 and SRM 1947. Only reference values of PFOS were available in the two CRMs, and information values of PFNA, PFDA, PFUnDA, and PFTrDA were available in SRM 1947. Results obtained were compared to these values and are given in Table 1. Good method performance was observed for PFOS determination. The recoveries were about 103% with CV < 4%. Larger deviations were noted for the other PFCs with recoveries ranging from 84 to 119% and CV ranging from 2.0 to 6.2%.

Table 1. Recovery and Precision of CRM Analysis[a]

	reference value (μg/kg)	information value (μg/kg)	recovery (%)/ RSD (%)
SRM 1946 Lake Superior fish tissue			
PFOS	2.19 ± 0.08		103/3.9
SRM 1947 Lake Michigan fish tissue			
PFOS	5.90 ± 0.39		104/3.7
PFNA		0.20	110/4.6
PFDA		0.26	84/4.7
PFUnA		0.28	99/6.2
PFTrDA		0.20	119/2.0

[a]Number of replicates = 4.

CCα, CCβ, and Method Limit of Quantification. For the evaluation of decision limit (CCα) and detection capability (CCβ), matrix-matched calibration curves with four equidistant levels at concentrations close to MLOQ (which were 0.5×, 1×, 1.5×, and 2× MLOQ) were prepared in duplicate in the four fatty matrices. The calculation of CCα and CCβ was based on ISO 11843-2:2000 and referenced to Verdon et al.[25] The CCαs and CCβs calculated are summarized in Table S3 in the Supporting Information. Both CCα and CCβ obtained for each PFC were <0.01 μg/kg.

The lowest concentration of PFCs that was validated for all samples with satisfactory recovery and precision, 0.02 μg/kg,

[a]Internal standardization values. [b]No internal standardization values. [c]PFTrDA and PFTeDA in beef were corrected by $^{13}C_2$PFTeDA.

was taken as the MLOQ, which was much lower than the 1 μg/kg recommended by Commission Recommendation 2010/161/EU. Figure 3 shows the UPLC-MS/MS chromatogram for 17 target analytes at the MLOQ level. It could be observed that a level below 0.01 μg/kg can be easily estimated.

Matrix Effect. It is well-known that the ionization of target analyte in LC-MS/MS analysis can be affected when competition between the analyte and coeluting component(s) for the available charge occurs. In most cases, signal suppression of the analyte is observed. The same set of CCα and CCβ study data was used for evaluation of the matrix effect. The matrix effect is obtained from the ratio of the slope of matrix-matched standards to that of solvent standards, and the matrix effects with and without internal standardization are summarized in Table 2.

Matrix effects were found to range from 0.52 to 2.05 when internal standard correction was not applied. Besides, PFCAs were noted to be subjected to greater matrix effect than PFSAs. Furthermore, the matrix effect could be different even on closely eluted PFCs, which indicated the matrix effect could be also analyte dependent. For example, the matrix effect was found to be ~1.9 for PFOA in salmon but only ~1.2 for PFOS, despite PFOA and PFOS being closely eluted.

When internal standard correction was applied, differences between slopes were found to be in general <10%. A larger difference was observed for PFTeDA when $^{13}C_2$PFDoA (quite different in retention time) was applied as internal standard for correction. In fact, slope ratios were closer to 1 for PFTeDA without the correction by $^{13}C_2$PFDoA. This further supports there were differences in matrix effects at different retention times.

dx.doi.org/10.1021/jf502326h | J. Agric. Food Chem. 2014, 62, 5805−5811

Strong ion suppression was noted in beef, especially for PFDoA and other late-eluting PFCs. The matrix effect for PFTeDA was found to be 1.56 when $^{13}C_2$PFDoA (eluted 1 min earlier) was used as internal standard for correction. Better correction was obtained when isotopically labeled $^{13}C_2$PFTeDA was made available recently. The supplementary validation with additional labeled $^{13}C_2$PFTeDA as internal standard was performed only in beef, but it was expected that the matrix effect should also be reduced for other matrices.

We performed quantitation with internal standardization instead of using matrix-matched calibration. This can avoid the trouble of finding a representative blank sample, especially for fish and seafood as they were commonly contaminated with PFOS.

Application of the Method to Real Samples. The method was applied for the analysis of 200 risk assessment study samples containing various types of food samples including fish and seafood, meat and meat products, eggs, fats, and oils. To ensure the quality of the results, method blank and duplicate samples spiked at 10× MLOQ were carried out with each batch of samples to avoid any false positives due to contamination and to assess the recovery, respectively. Average recoveries of the PFCs ranged from 65 to 120%.

Traces of PFCs, most of them were of <2 μg/kg, were detected in the samples. Only one freshwater fish sample was found to contain PFOS at >2 μg/kg. Besides, PFOS was the most frequently detected PFC in foods; it was detected in almost every fish or shellfish samples. For PFCAs, the most frequently detected were PFUdA and PFTrDA, then PFDoA, PFDA, PFNA, PFTeDA, and PFOA. Basically, such a sequence is similar to other reported findings in seafood.

In summary, the performance of the described methods for the determination of PFCs through different fatty matrices, especially with respect to the detection limit and its capability, was demonstrated. Moreover, the low detection limit (0.02 μg/kg) enabled us to quantify the content of PFCs at low parts per trillion level in various food products, which accounted for the major contributors of the dietary exposure of PFCs. This method gives quantitative results for C_6−C_{14} perfluorinated carboxylic acids (PFCAs) and C_4−C_{12} perfluorinated sulfonates (PFSAs), including PFPeS, PFNS, and PFDoS for comprehensive dietary exposure assessment. The analysis time has been shortened by using UPLC. Even so, 17 PFCs were eluted within 12 min with good separation of PFCs, especially on resolving branched PFOS and TDCA from PFOS. Comparability of the method was supported by satisfactory results for the analysis of CRMs.

Development of an Improved Reverse-Phase High-Performance Liquid Chromatography Method for the Simultaneous Analyses of *trans*-/*cis*-Resveratrol, Quercetin, and Emodin in Commercial Resveratrol Supplements

Jaclyn M. Omar,[†] Haifeng Yang,[†] Suzhen Li,[‡] Ronald R. Marquardt,[‡] and Peter J. H. Jones*[,†]

[†]Richardson Centre for Functional Foods and Nutraceuticals, University of Manitoba, 196 Innovation Drive, Winnipeg, Manitoba R3T 2N2, Canada

[‡]All Natural Nutritional Products, Incorporated, 196 Innovation Drive, University of Manitoba Smartpark, Winnipeg, Manitoba R3T 6C5, Canada

ABSTRACT: The objectives of the study were to develop a reverse-phase high-performance liquid chromatography method for the simultaneous analyses of *trans*-/*cis*-resveratrol, emodin, and quercetin and to determine the concentrations of these polyphenols in 28 resveratrol supplements. Samples were separated within 15 min in a C18 reversed-phase column using mobile phases containing 0.1% formic acid and methanol/0.1% formic acid. The calibration graphs for all four compounds were linear from 0.1 to 410 μg/mL ($r^2 = 0.99$). The concentration of resveratrol as stated on the labels was often different from the analytical results, with 21 and 11% of the total supplements having low or high values, respectively. Many of the supplements also contained variable but generally low levels of emodin, a compound known to cause diarrhea. The proposed method is a rapid, sensitive, accurate, and cost-effective procedure that can be used for the simultaneous quantification of four polyphenols in resveratrol supplements.

KEYWORDS: *reversed-phase HPLC method, trans-/cis-resveratrol, quercetin, emodin, extracts, Polygonum cuspidatum, supplements*

INTRODUCTION

Phenolic acids and flavonoids are bioactive compounds that are present in a wide variety of plants. They have been shown to possess beneficial biological properties through their strong antioxidative activity. Resveratrol is a polyphenolic phytoalexin (3,5,4′-trihydroxystilbene) that is found in the skin of red grapes and most notably in red wine. It has been acknowledged for its potent cardioprotective and other beneficial properties.[1−3] Resveratrol naturally occurs in two isoforms, *trans* and *cis* forms, of which *trans*-resveratrol is the isoform mainly present in red grapes, red wine, and other products and is largely responsible for its many health benefits.[4] Japanese knotweed (*Fallopia japonica* syn. *Polygonum cuspidatum*) is also found to have concentrated amounts of resveratrol and has become a common source of resveratrol for most dietary supplements.[5] Emodin and quercetin are additional phenolic compounds that are commonly found in varying amounts alongside resveratrol in dietary supplements depending upon the source of resveratrol. Quercetin is a flavanol that is found in the skins of grapes and, thus, is present in resveratrol supplements obtained from red grapes, including red wine extracts.[6,7] Emodin, in contrast, is generally absent in resveratrol supplements obtained from grapes but is naturally present in supplements obtained from *P. cuspidatum* in varying amounts.[8] Supplements made from lower purity *trans*-resveratrol may contain unacceptably high amounts of emodin and, as such, can act as a laxative, causing stomach cramping, gas production, bloating, and diarrhea.[8,9] However, moderate amounts of emodin has traditionally been used in Chinese and Japanese herbal medicine as a natural laxative and has more recently been shown to have antitumor properties.[8]

Currently, validated methods have been published for the detection of *trans*-resveratrol and, in some cases, *cis*-resveratrol, quercetin, and/or emodin. Most established analytical methods are based on gas chromatography−mass spectrometry (GC−MS),[10] reversed-phase liquid chromatography,[11−13] and high-performance liquid chromatography (HPLC) with tandem ultraviolet (UV) absorption and fluorimetric detection.[14] However, a single method that incorporates the simultaneous detection of all four polyphenolic compounds is lacking. Similarly, methods for the simultaneous detection of multiple polyphenols have been validated using capillary electrophoresis and have been found to be comparable qualitatively and quantitatively; however, sample preparation is laborious, and reproducibility and precision may be compromised because of the short capillary lifespan.[15−18] A previous evaluation of common analytical methods for the measurement of *cis*- and *trans*-resveratrol in commercial wines determined that reverse-phase (RP) HPLC with diode array detection was the most robust method for the simultaneous quantitation of multiple polyphenols of interest, which included *cis*- and *trans*-resveratrol, and may serve as an optimal method for routine quality control application, as compared to other methods (GC−MS and normal-phase HPLC).[19] Thus, the primary

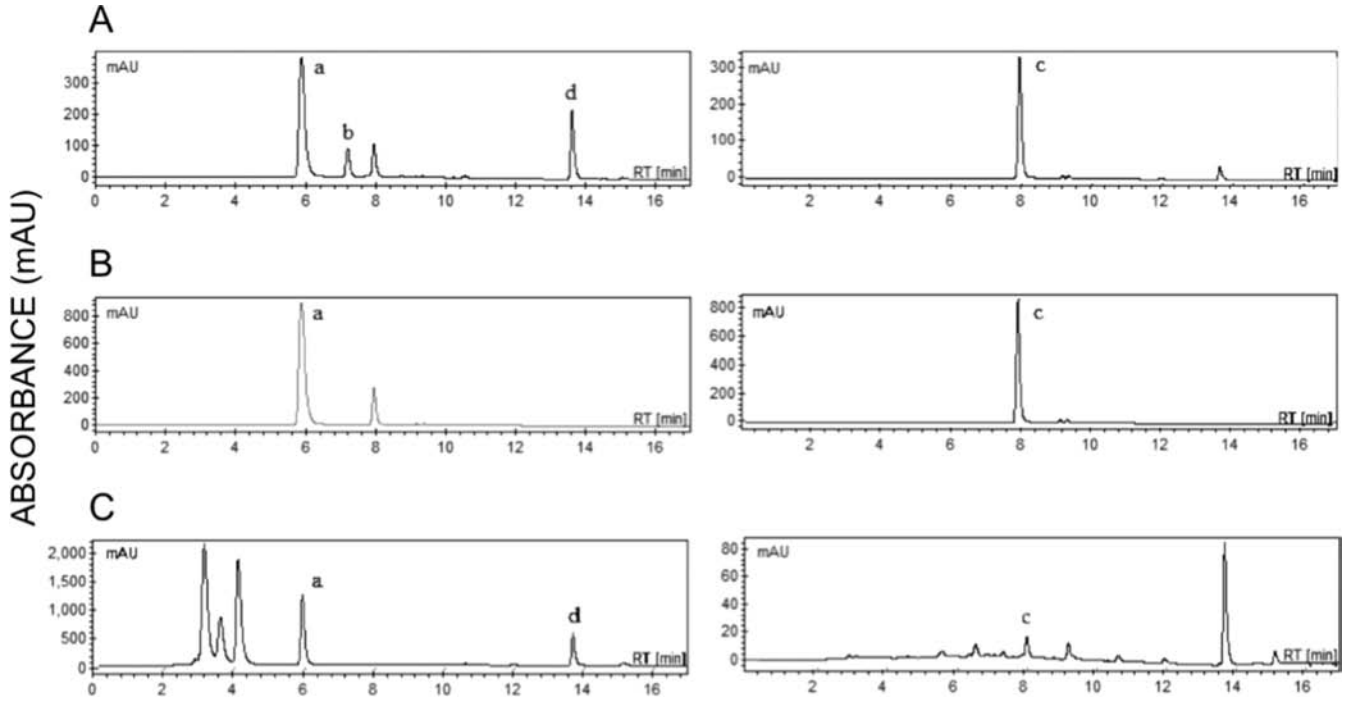

Figure 1. Representative HPLC chromatograms of resveratrol reference standards and resveratrol-containing products. Peaks detected at 290 nm are depicted on the left panel, and peaks detected at 369 nm are depicted on the right panel. (A) Reference standards: peak a, *trans*-resveratrol (20 μg/mL); peak b, *cis*-resveratrol (20 μg/mL); peak c, quercetin (10 μg/mL); and peak d, emodin (10 μg/mL); (B) commercial sample P2 (reference Table 3), consisting of resveratrol extract and quercetin; and (C) commercial sample P4 (reference Table 3), consisting of *P. cuspidatum* extract, green tea extract, and caffeine.

objective of this study was to develop and validate a rapid, simple, and cost-effective RP-HPLC analytical method for the simultaneous detection of *trans*-/*cis*-resveratrol, quercetin, and emodin in dietary supplements. The ability to determine the concentration of these polyphenols in resveratrol and other supplements using a sensitive and efficient method will aid in the quality assessment of commercially available dietary supplements because extract sources can originate from a variety of sources, each having a unique polyphenolic composition, as is the case in red wine extract and *P. cuspidatum* as sources of resveratrol. This will help to ensure that the consumer will obtain a product of known composition. A secondary objective was to measure *trans*-resveratrol in 28 commercially available resveratrol supplements using the validated method and compare these values to the labeled *trans*-resveratrol content as well as measure levels of detectable emodin and quercetin in each product.

MATERIALS AND METHODS

Samples. A total of 28 commercial resveratrol supplements were acquired via purchase from commercial Canadian and U.S. sources or generously donated as gifts. Samples were in the form of either tablets (n = 3), soft gel capsules (n = 3), or gelatin or vegetable capsules (n = 22).

Chemicals and Standards. *trans*-Resveratrol and *cis*-resveratrol standards were purchased from Cayman Chemical Company (Ann Arbor, MI). Emodin and quercetin standards were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA). HPLC-grade methanol and formic acid were purchased from Fisher Scientific Canada. Ultrapure water (18.2 MΩ cm) was obtained using a Millipore Milli-Q 10 water system for the preparation of the buffer solution (Billerica, MA).

Standard Preparation. Stock solutions of each standard (*trans*-/*cis*-resveratrol, quercetin, and emodin) were prepared by dissolving each analyte (1 mg/mL) in pure methanol. The stock solution was aliquoted (1.5 mL) into LC vials and stored at −80 °C. The working solution was prepared by diluting the stock solution to obtain appropriate concentrations for calibration curves.

Sample Preparation. A total of 10 capsules/tablets/soft gels from each sample were weighed individually along with their respective empty capsules to determine the net weight of each sample. The content of the 10 capsules/tablets/soft gels were pooled and homogenized. A total of 100 milligrams of each sample was extracted with 20 mL of methanol for 10 min in a 25 mL aluminum-foil-covered volumetric flask using a bath sonicator, thermostatically set at 22 °C with a frequency of 33 kHz, and then brought to a final volume of 25 mL with methanol. The solution was then incubated for 10 min at room temperature, after which 100 μL of supernatant was diluted 20-fold. The diluted solution was filtered through a 0.2 μm syringe filter (Phenomenex, Torrance, CA), and an aliquot of 20 μL was injected onto a HPLC column for analysis in triplicate.

HPLC. Quantitative analysis was performed using a Varian 920LC HPLC coupled with an UV detector (Varian, Palo Alto, CA). The chromatographic separation was carried out on a Luna C18 (2) column (250 × 4.6 mm, 5 μm, Phenomenex, Torrance, CA) protected by a guard column (Security Guard Cartridge C18, 4 × 2.0 mm inner diameter, Phenomenex, Torrance, CA) and maintained at 35 °C. A linear elution gradient consisting of mobile phase A (0.1% formic acid) and B (methanol containing 0.1% formic acid) was programmed as follows: initially 50% A and 50% B, linearly changed to 100% B over 10 min, and then held for 5 min at 100% B. The system was then re-equilibrated for 7 min with the initial solvent (50% solvent A and 50% solvent B). The autosampler was operated at room temperature. The detection wavelength was set at 290 nm for *trans*-/*cis*-resveratrol and emodin and 369 nm for quercetin. System control and data acquisition were performed using Galaxie (Varian, Inc., Mississauga, Ontario, Canada).

Statistical Analysis. Statistical analysis was conducted using Statistical Analysis Software (SAS, version 9.4, Cary, NC), and values are expressed as the mean ± standard deviation (SD).

RESULTS AND DISCUSSION

Optimization of the Chromatographic Condition. A RP-HPLC method was developed for the simultaneous analyses of four polyphenols: *trans*-resveratrol, *cis*-resveratrol, quercetin, and emodin. Several chromatographic conditions using different columns and elution systems were tested to determine optimum resolution, peak shape, efficiency, ease of operation, and cost-effectiveness of preparing the mobile phases. Conditions were established using a Luna C18 column (2) (250 × 4.6 mm, 5 μm) and a water/methanol mixture containing 0.1% (v/v) formic acid elution system for the detection of the different compounds. The UV detector was set at 290 nm for the monitoring of *trans*-/*cis*-resveratrol and emodin and 369 nm for the monitoring of quercetin. Previous methods have achieved individual maximum UV absorbance of emodin, *cis*-resveratrol, and *trans*-resveratrol at 254, 286, and 304 nm,[14,20,21] respectively; however, to achieve optimal UV absorbance for all three analytes, 290 nm was selected and demonstrated a high degree of sensitivity and precision. Interestingly, an emodin peak was detected at 369 nm but to a considerably lesser degree than at 290 nm. Maximum UV absorbance for quercetin has been reported at a variety of wavelengths, ranging from 280 to 370 nm, depending upon the sample and detector;[20−23] therefore, maximum UV absorbance was set at 369 nm for quercetin based on our objectives and equipment. Accordingly, quercetin was detected in Figure 1B at both 290 and 369 nm but at significantly greater absorbance at 369 nm. The use of methanol instead of acetonitrile significantly reduced solvent cost, reduced separation time (15 min/run), and demonstrated well-separated and defined peak shapes, consistent with previous reports.[14] Formic acid (0.1%) was selected as the mobile phase additive to provide improved pH control, simplified preparation, good methanol solubility, and high volatility, imparting a simpler and more efficient preparation, and was found to achieve good peak intensity and resolution when added to the aqueous solution. The peaks for each of the four reference compounds were well-resolved with retention times of 5.88, 7.20, 7.95, and 13.61 min, respectively (Figure 1).

HPLC Chromatograms. Chromatograms of standards and representative samples containing *trans*-/*cis*-resveratrol, quercetin, and emodin are shown in Figure 1. Figure 1A depicts reference standards of each analyte with their respective peak. Panels B and C of Figure 1 represent commercial resveratrol samples P2 and P4 (reference Table 3), respectively, as characteristic examples of resveratrol supplements containing *trans*-resveratrol and either quercetin or emodin, respectively. Of the polyphenols simultaneously analyzed, it was found that samples containing *trans*-resveratrol, quercetin, and emodin yielded distinct and large peaks, while the peak size for *cis*-resveratrol was low (Figure 1A) or undetected (panels B and C of Figure 1). *trans*-Resveratrol and quercetin but not emodin was detected in extracts prepared from grapes and grape extracts, whereas *trans*-resveratrol and emodin were detected in extracts from *P. cuspidatum*.

Method Validation: Linearity, Limits of Detection (LODs), and Limits of Quantification (LOQs). The linearity for each reference standard was investigated over the range of

ND = not detected.

concentrations: 0.1−400 μg/mL for *trans*-resveratrol, 0.095−380 μg/mL for quercetin and emodin, and 0.05−100 μg/mL for *cis*-resveratrol; all ranges were covered by 13 points (Table 1). *trans*-Resveratrol, quercetin, and emodin were prepared as a mixture, while *cis*-resveratrol was prepared separately because of the presence of *trans*-resveratrol as an impurity. The regression equation was plotted as the peak area versus the corresponding concentration of the analyte. The high linear correlation

dx.doi.org/10.1021/jf5001277 | J. Agric. Food Chem. 2014, 62, 5812−5817

coefficients (r^2 > 0.99) indicated good linearity between the peak area of the compound and its concentration. The LODs (signal/noise ratio > 3) for all analytes were below 0.03 μg/mL. The LOQs (signal/noise ratio > 10) for *trans*-resveratrol, *cis*-resveratrol, and quercetin were below 0.1 μg/mL and the LOQ for emodin was 0.95 μg/mL.

Precision and Reproducibility. The intra- and interday precision of the assay at four concentration levels for each compound are shown in Table 2. The method was found to be precise with the intraday relative standard deviation (RSD) values being between 0.21 and 0.62% for *trans*-resveratrol, between 0.30 and 1.50% for *cis*-resveratrol, between 0.19 and 2.21% for emodin, and between 0.18 and 0.74% for quercetin. Similarly, interday RSD values were within 0.08−1.83% for *trans*-resveratrol, 0.33−1.12% for *cis*-resveratrol, 0.28−2.57% for emodin, and 0.11−1.25% for quercetin. Intra- and interday RSDs below 2.6% for all compounds and concentrations indicate a high level of precision and reproducibility.

Stability. *trans*-Resveratrol, quercetin, and emodin were stable when stored at room temperature (24 °C) in amber glass vials over 12 h with no conversion of *trans*-resveratrol into its *cis* isomer (Figure 2). The RSDs of the peak area over this period were 0.58, 0.65, and 0.52% for *trans*-resveratrol, emodin, and quercetin, respectively. The stability of a cocktail of all standard compounds when stored over 21 days at 3 °C was also stable (data not shown). These results demonstrate that *trans*-resveratrol, quercetin, and emodin can be analyzed via HPLC without autosampler temperature control. *cis*-Resveratrol was found to be somewhat unstable at room temperature to isomerize to *trans*-resveratrol and requires preventative measures to maintain sample integrity, such as refrigeration, protection from light, and rapid processing times (data not shown).

Accuracy. The accuracy of the method was established by determining the recovery of *trans*-resveratrol, *cis*-resveratrol, emodin, and quercetin spiked to the sample in three known concentrations of the four mixed standards, corresponding to low, mid, and high (2, 10, and 20 μg/mL for *cis*-resveratrol and 10, 50, and 100 μg/mL for *trans*-resveratrol, quercetin, and emodin) LODs. The mean recovery of spiked samples for each concentration (low to high; n = 3) ranged from 96.7 to 103.0% for *trans*-resveratrol, from 97.3 to 99.8% for *cis*-resveratrol, from 97.5 to 101.8% for emodin, and from 98.0 to 104.7% for quercetin (data not shown). The proposed method had higher recovery rates for *trans*-resveratrol, quercetin, and emodin compared to previous HPLC methods using diode array detection[24] and HPLC−UV.[14]

HPLC Analysis of the Resveratrol Supplement. Resveratrol, emodin, and quercetin (Table 3) were simultaneously analyzed via the optimized HPLC−UV method in 28 resveratrol supplements using the conditions described above. Quantitative analyses were performed by means of the external standard methods. Product accuracy, as defined in the footnotes of Table 3, was determined by comparing the concentration of resveratrol as given on the product label with the HPLC-analyzed values. Six samples contained 11−76% less resveratrol than that stated on the label (21% of the total), while three samples had 18−162% higher contents of *trans*-resveratrol than that reported. The amounts of resveratrol in the remaining 18 samples were in fairly good agreement with those given on the product labels. Collectively, these data suggest only about 68% of the stated concentration of resveratrol in the supplements was reasonably accurate. In addition, there was a wide range in the concentrations of resveratrol per 100 mg of product among different commercial products, with some having relatively high concentrations (around 87.3−98.2 mg/100 mg; two products), some intermediate concentrations (20.3−51.4 mg/100 mg; nine products), and most relatively low concentrations (1.3−18.6 mg/100 mg) of resveratrol. Quercetin was only detected in three of the resveratrol supplements, of which quercetin was an added ingredient according to the product label, explaining the high concentrations in these few samples. Low concentrations of emodin were detected in many of the supplements derived from *P. cuspidatum* extracts, with values ranging from 0.12% to a maximum of 2.26%. The two supplements prepared from *P. cuspidatum* that had a high range of resveratrol (A5 and G2) did not contain detectable levels of emodin. The amount of emodin that will cause intestinal distress has not been reported in the literature, as far as the authors are aware, and therefore, the amount of emodin that can be consumed without an adverse effect is not known. However, it has been suggested that low-purity resveratrol (supplements from *P. cuspidatum* extracts with 50% or less resveratrol, having proportionately higher levels of emodin) should be avoided and only resveratrol supplements that are of high purity (i.e., >98% resveratrol) should be consumed.[24]

A simple, sensitive, accurate, and cost-effective RP-HPLC−UV method was developed and validated for the rapid and simultaneous analyses of *trans*-/*cis*-resveratrol, emodin, and quercetin in dietary resveratrol supplements. The proposed extraction and chromatographic method for the determination of resveratrol demonstrated good efficiency and stability with no shift in the *cis*/*trans* isomer ratio. The proposed method is superior to previously published isocratic RP-HPLC methods for the detection of *trans*-resveratrol in the recovery of product, repeatability, and speed of analysis, as previously published GC and HPLC methods can be time-consuming, costly and may cause instability of the *trans* isomer of resveratrol due to the extraction techniques, solvents used, and derivatization for enhanced volatility,[25,26] respectively. Overall, the proposed method demonstrates increased cost efficiency compared to other methods because of the substitution of acetonitrile for methanol and formic acid for phosphate buffers, which are commonly used solvents in most HPLC methods but are expensive and are becoming increasingly in short supply.[27−30] Most importantly, this novel method was optimized to simultaneously detect multiple polyphenols (*trans*-/*cis*-resveratrol, quercetin, and emodin) and may potentially serve as a basis for the simultaneous detection of other analytes.

Data from the current study demonstrate that the amount of resveratrol detected among different products tends to be highly variable and may not be as stated on product labels and that dietary resveratrol supplements derived from *P. cuspidatum* extract contain concentrations of emodin that are likely too low to induce a diarrheal effect. These results represent a need for this analysis for quality control systems by manufacturers and regulators to ensure efficacy and safety prior to production to prevent deleterious side effects or negligible and insignificant health benefits for the consumer public. The benefits of the applied RP-HPLC method demonstrate that this method is appropriate and feasible for the simultaneous quantification of multiple polyphenols of biological interest for routine application of quality control measures of commercial natural health products.

Supporting Information

ABSTRACT: Dispersive liquid-phase microextraction with solidification of floating organic drop (SFO−DLPME) is one of the most interesting sample preparation techniques developed in recent years. In this paper, a new, rapid, and efficient SFO−DLPME coupled with high-performance liquid chromatography (HPLC) was established for the extraction and sensitive detection of banned Sudan dyes, namely, Sudan I, Sudan II, Sudan III, and Sudan IV, in foodstuff and water samples. Various factors, such as the type and volume of extractants and dispersants, pH and volume of sample solution, extraction time and temperature, ion strength, and humic acid concentration, were investigated and optimized to achieve optimal extraction of Sudan dyes in one single step. After optimization of extraction conditions using 1-dodecanol as an extractant and ethanol as a dispersant, the developed procedure was applied for extraction of the target Sudan dyes from 2 g of food samples and 10 mL of the spiked water samples. Under the optimized conditions, all Sudan dyes could be easily extracted by the proposed SFO−DLPME method. Limits of detection of the four Sudan dyes obtained were 0.10−0.20 ng g^{-1} and 0.03 $\mu g\ L^{-1}$ when 2 g of foodstuff samples and 10 mL of water samples were adopted, respectively. The inter- and intraday reproducibilities were below 4.8% for analysis of Sudan dyes in foodstuffs. The method was satisfactorily used for the detection of Sudan dyes, and the recoveries of the target for the spiked foodstuff and water samples ranged from 92.6 to 106.6% and from 91.1 to 108.6%, respectively. These results indicated that the proposed method is simple, rapid, sensitive, and suitable for the pre-concentration and detection of the target dyes in foodstuff samples.

INTRODUCTION

Sudan dyes (Sudan I−IV; Scheme 1) are a class of artificially synthesized fat-soluble azo dyes.[1] The azo dyes have been widely used as organic colorants in all aspects of the chemical industry to improving the appearance of the products.[2] However, these lipophilic azo dyes are considered to be genotoxic carcinogens, imposing a threat to public health once entering the food chain.[3] For instance, Sudan dyes have been widely contacted by painters, hairdressers, etc., resulting in a high occurrence of bladder cancer.[4] In particular, Sudan I, a widely used additive in the food industry, has been reported to induce tumors in the liver of some animals, such as mice, and to show a carcinogenic potential for humans.[5] Because of this, the International Agency for Research Cancer (IARC) has listed the Sudan dyes as a category 3 carcinogenic to humans.[5] Many countries (including the European Union) have banned the use of Sudan dyes as an additive in the food industry.[6] However, Sudan dyes are still illegally used in some areas of Europe and Asia, where the contaminations of foodstuffs by Sudan dyes, in particular Sudan I, are reported.[7,8] Therefore, to monitor the illegal use of Sudan dyes in foodstuff samples, development of a

simple, rapid, and sensitive method for the detection of the target Sudan dyes in the contaminated food stuffs is desirable.

In the past few decades, various methods, including high-performance liquid chromatography (HPLC)−ultraviolet (UV),[1,7−11] HPLC−mass spectrometry (MS),[12] micellar electrokinetic chromatography,[13] and enzyme-linked immunoassay,[14] have been constructed for the analysis of Sudan dyes. Considering the complicated sample matrix as well as very low concentrations of Sudan dye residues in real samples, it is highly crucial to simultaneously isolate and enrich Sudan dyes using sample preparation methods before instrumental analysis. Various pretreatment procedures,[15−19] in particular, solid-phase extraction (SPE),[16−19] have been widely used for the separation and pre-concentration of Sudan dyes in foodstuffs.

Recently, a different mode of liquid-phase microextraction format using solidification of floating organic droplet (SFO−LPME), which incorporated sampling, extraction, and concentration into a single step, has attracted much attention.[20−24] In this technique, a drop of organic solvent is used for extraction. Thus, in comparison to liquid−liquid extraction (LLE), SFO−LPME is a miniaturized LLE technique.[23] When the extraction equilibrium is reached, the organic extract droplet is collected facilely via solidifying it in an ice bath because of the lower density than water and suitable melting point of the used organic extraction solvent. Thus, it has been used to the pre-concentration of organic and inorganic targets in various matrices.[24−30] However, the extraction time was somewhat long because of the long time required for equilibrium.

On the other hand, a dispersive liquid-phase microextraction (DLPME)-based pretreatment process has also gained much attention since the first one developed by Assadi and co-workers in 2006.[31] In DLPME, target extraction is realized by injection of a suitable mixture of extractant and dispersant into an aqueous sample, resulting in the formation of an emulsion solution. Because of the high dispersion of the extractant in the aqueous phase, the target extraction is completed within a few seconds because of the markedly enhanced contact area between phases. Thus, in comparison to classic liquid-phase microextraction (LPME), DLPME is a time-saving extraction technology and promises the advantages of simplicity and good extraction efficiency with a high pre-concentration factor.[32,33] Unfortunately, the commonly used extraction solvents, including $CHCl_3$, CCl_4, chlorobenzene, and CS_2, are difficult to be separated from the aqueous solution because the density of these solvents are higher than that of water. In addition, all of them are toxic and not environmentally friendly. Furthermore, the extract requires evaporation and reconstitution in an appropriate solvent for HPLC analysis. This leads to the increased analysis time and the risk of analyte losses.[23]

On the basis of the advantages of both DLPME and SFO−LPME, a new technique coupling dispersive liquid-phase microextraction and solidification of floating organic droplet (SFO−DLPME) has been proposed for extraction and pre-concentration of various organic targets, such as polycyclic aromatic hydrocarbons (PAHs),[34] phthalate esters,[35] chlorinated anilines,[36] and antidepressant drugs,[37] from aqueous matrices. It combines the best advantages of DLPME and SFO−LPME, eliminating or reducing their disadvantages. However, to the best of our knowledge, no investigation on the use of SFO−DLPME for extraction and enrichment of Sudan dyes from foodstuffs and water samples has been reported.

In present study, on the basis of solidification of the floating organic droplet, a new, rapid, and efficient dispersive liquid-phase microextraction method (SFO−DLPME) coupled with HPLC−UV is proposed for the extraction and sensitive detection of banned Sudan dyes (I, II, III, and IV) in foodstuffs and environmental water samples. Hence, the purposes of this work were (1) to confirm the suitability of the SFO−DLPME for the extraction of Sudan dyes, (2) to optimize the predominant factors affecting the enrichment efficiency of SFO−DLPME for Sudan dyes, and (3) to illustrate the feasibility of the developed method by analyzing the target Sudan dyes in foodstuffs and environmental water samples. The results demonstrate that this approach promises fastness, low consumption of organic solvent, and simplicity and is an interesting alternative for the concentration of organic targets in complex matrices.

EXPERIMENTAL PROCEDURES

Reagents and Chemicals. Sudan I and Sudan II were supplied by Shanghai Chemical Reagents Co. (Shanghai, China). Sudan III and Sudan IV were provided by Kasei Kogyo (Japan). An appropriate amount of four Sudan dyes was dissolved in methanol to obtain the standard stock solution, and the resulting solution was stored at 4 °C in the dark. The methanol was of HPLC grade and provided by Scharlau Chemie S.A. (Scharlau Chemie S.A., Spain). Humic acid (HA) was purchased from Sigma-Aldrich (Shanghai, China). Ultrapure water was supplied by a Milli-Q water purification system in our laboratory. 1-undecanol, 1-dodecanol, acetone, ethanol, HCl, acetonitrile, NaCl, and all other chemicals used were of analytical reagent grade, unless otherwise stated, and were provided by Chongqing Chemical Reagents Co. (Chongqing, China).

Instrumental Analysis. The HPLC system (JASCO Corporation, Japan) consisted of PU-2080i binary pumps, CO-2060 column thermostat, and UV-2075 detector. A Hypersil ODS chromatographic column (150 × 4.6 mm, 5 μm) was supplied by Waters Corporation (Milford, MA) and used for separation of four Sudan dyes. Methanol was used as the mobile phase. The flow rate of methanol was set to 1.0 mL min^{-1}. The column temperature was thermostated at 30 °C. The chromatographic peaks of Sudan I−IV were recorded at 506 nm. The injection volume was 20 μL.

SFO−DLPME Procedures. In all experiments, to optimize operational parameters of the SFO−DLPME procedure, 20 μg L^{-1} Sudan I, Sudan II, and Sudan III and 40 μg L^{-1} Sudan IV in a sample volume of 10 mL were used. The recovery of the target Sudan dyes was used as the criterion for optimizing the parameter for the proposed method. It was acquired on the basis of the ratio of the obtained content of Sudan dyes to the expected content of Sudan dyes, expressed as a percentage. The finally adopted SFO−DLPME procedure was as follows: after 1 g of NaCl (final concentration of 10% as w/v) and 10 mL of the fortified sample are introduced into a 15 mL centrifuge tube, 100 μL of 1-dodecanol and 400 μL of ethanol are rapidly injected by a microsyringe, leading to the formation of a homogeneous turbid solution. Then, the tube is immediately immersed in a water bath at 70 °C for 20 min, followed by centrifugation at 4500 rpm for 5 min, and finally placed in an ice bath for 5 min. The solid organic phase was transferred to a conical vial with the help of a spoon, and then it melts rapidly at room temperature. The melted organic solvent was mixed with 50 μL of methanol, and then 20 μL of the mixture was used for HPLC−UV analysis.

Sample Preparation. The foodstuffs, including tomato sauce, chili sauce, and chili oil samples used in this study, were obtained from the local market. For analysis of food samples, about 2 g of the selected food samples was put into a 10 mL glass centrifuge tube and mixed with 5 mL of ethanol. Then, the resulting mixture was shaken for 20 min at 30 °C and then centrifuged at 4000 rpm for 10 min. The transparent solution was transferred to a sample vial, dried under a nitrogen atmosphere, and then diluted to 10 mL with 10% NaCl (w/

dx.doi.org/10.1021/jf5006403 | J. Agric. Food Chem. 2014, 62, 5818−5826

v) solution (pH 7.0). Finally, the obtained sample solution was extracted with the optimized extraction protocols.

In this work, several aqueous samples, such as river water samples, tap water samples, and wastewater samples were pretreated by the proposed SFO–DLPME method for the analysis of four Sudan dyes. The river water samples were obtained from the Beibei section (Beibei, Chongqing) of the Jialingjiang River. The tap water samples and the sewage water samples were collected from our laboratory and a constructed wetland system for domestic sewage treatment situated in Southwest University (Beibei, Chongqing), respectively. Prior to analysis, all aqueous samples were passed through 0.45 μm micropore membranes and kept in glass bottles at 4 °C in a refrigerator. The extraction of target Sudan dyes from unspiked and spiked water samples was carried out according to the recommended SFO–DLPME procedures.

RESULTS AND DISCUSSION

Optimization of the SFO–DLPME Procedures. *Effect of the Kind and Volume of Extraction Solvent.* During the extraction process, selecting a suitable extraction solvent is a very important work using the SFO–DLPME method because the extraction efficiency was mainly determined by the extraction solvent in SFO–DLPME.[35] To improve extraction efficiency, three organic solvents, namely, 1-undecanol (melting point of 13–15 °C), 1-dodecanol (melting point of 22–24 °C), and *n*-hexadecane (melting point of 18 °C), were considered as

the extraction solvents in this work. Because of its high hydrophobicity, n-hexadecane is not miscible with a common dispersive solvent. Here, only 1-undecanol and 1-dodecanol were evaluated for extraction of Sudan dyes in this work. On the basis of the obtained result (see Figure S1 of the Supporting Information), the best extraction efficiency was obtained when 1-dodecanol was used as the extractant. Hence, 1-dodecanol was selected as the extraction solvent in the present work, and its volume was optimized in the range of 50−250 μL. From Figure 1, the recoveries of Sudan dyes rised rapidly when the volume of 1-dodecanol ranged from 50 to 100 μL and then remained stable ranging from 93.8 to 116.9%. Also, the effect of 1-dodecanol (as an extractant) volume on the pre-concentration factor (PF) was supplied in Table S1 of the Supporting Information. Here, PFs were obtained according to the following formula:

$$\mathrm{PFs} = C_p/C_i \quad (1)$$

where C_p and C_i are the concentrations of Sudan dyes in the floating phase after extraction and in the sample solution before extraction, respectively. As seen, the PFs decreased with an increase in the volume of 1-dodecanol. However, the quantitative recoveries of Sudan dyes were obtained with 100 μL of 1-dodecanol (Figure 1). Therefore, 100 μL of 1-

dodecanol was chosen as an appropriate extractant to obtain the quantitative results.

Effect of the Kind and Volume of Dispersion Solvent. Several organic solvents, namely, ethanol, acetonitrile, acetone, isopropanol, and methanol, were evaluated as the dispersion solvent for extraction of Sudan dyes. The experimental results indicated that acetone, ethanol, acetonitrile, and methanol gave better dispersion ability than that of isopropanol (see Figure S2 of the Supporting Information). In SFO–DLPME, the major consideration for choosing a dispersion solvent is mainly based on its miscibility with the extractant and aqueous phase. Generally, the good disperser solvent has good miscibility with the extraction solvent and sample solution.[30] In the selected dispersion solvents, ethanol, methanol, acetone, and acetonitrile are strong polar solvents, whereas isopropanol is a moderate polar solvent. The polarity of the five organic solvents follows the order of ethanol ≈ methanol > acetone > acetonitrile > isopropanol. Therefore, ethanol, methanol, acetone, and acetonitrile could be miscible with the water well, leading to the better dispersion ability than isopropanol. Because of low toxicity and low cost, finally, ethanol was selected as the dispersion solvent for further investigation. Also, the effect of the volume of ethanol ranging from 0 to 1000 μL was evaluated. From Figure 2, the recoveries of Sudan dyes increased when the volume of ethanol increased to 400 μL and then remained stable, ranging from 93.0 to 105.2%. A total of 400 μL of ethanol was selected to obtain high extraction efficiency in our work.

Effect of the Ion Strength and Sample pH. NaCl was used to study the effect of the ionic strength. The tested concentration of NaCl were in the range of 0–20% (w/v). As shown in Figure 3, the addition of NaCl into sample solution could efficiently improve the extraction efficiency of Sudan dyes when the concentration of NaCl was in the range of 0–10%. However, there is no obvious change of extraction efficiency of Sudan dyes if the concentration of sodium chloride exceeds 10%. This could be explained by the salting-out effect. The solubility of the hydrophobic organics in water samples was decreased when the salt was added. This could cause an increase in extraction efficiency.[38,39] On the basis of these results, 10% (w/v) NaCl solution was selected in the subsequent experiments.

The effect of solution pH, ranging from 4.0 to 11.0, on the extraction of Sudan dyes by SFO–DLPME was studied. From Figure 4, the extraction recoveries of four Sudan dyes remained a minor increase when solution pH ranged from 4.0 to 7.0 and then remained stable in the pH range from 7.0 to 9.0, above which it decreased. This is probably due to their instability in strong acid and alkali medium.[40] Hence, below pH 7.0 and above pH 9.0, the recoveries of Sudan dyes decreased. Considering that the best extraction of Sudan dyes was obtained at pH 7.0, the optimal pH 7.0 was adopted as solution pH in this work.

Effect of the Extraction Time and Solution Temperature. In SFO–DLPME, analytes are distributed between the sample solution phase and organic phase. Thus, the mass transfer of analyte between the aqueous phase and the organic solvent was greatly affected by the extraction time. To guarantee the equilibrium between phases as well as the maximal extraction of Sudan dyes, the extract time ranging from 0 to 25 min was investigated. According to Figure 5, the influence of the reaction time on recoveries of Sudan dyes was significant. This implies that the transfer of Sudan dyes from sample solution to extraction solvent is slow, which is probably due to the high fat-soluble property of Sudan dyes. A similar result was reported by Regueiro et al.,[26] working on extraction of fat-soluble contaminants by ultrasound-assisted emulsification–microextraction. It was found that extraction time presented a key role in the extraction of polycyclic musk fragrances, musk moskene, di-2-ethylhexyl phthalate (DEHP), and di-*n*-octyl phthalate (DOP). The recoveries of Sudan dyes increased with extraction time up to 20 min, above which no obvious change in extraction recovery was found. Finally, 20 min was selected for the subsequent experiments.

For liquid-phase microextraction, the efficient extraction can be achieved by increasing the temperature because an increasing temperature facilitates mass transfer of the targets from the aqueous phase to the organic phase, leading to shortening the analysis time.[41,42] Thus, the temperature effect was investigated from 50 to 75 °C by dispersing 1-dodecanol into the water samples containing Sudan dyes. According to Figure 6, the extraction recoveries of Sudan dyes were increased as the solution temperature increased from 50 to 70 °C. However, the higher temperature (>70 °C) resulted in a mild decrease in recovery. Thus, 70 °C was selected as the optimal temperature.

Effect of the Sample Volume. Increasing the volume of sample solution could increase the amount of targets migrated

[a]Limit of quantification (LOQ). [b]In units of ng mL^{-1}.

into the extraction phase from aqueous phase, which improves the sensitivity of the proposed method. However, this also might lead to the decreased extraction recovery in a fixed extraction time.[28] The influence of the sample volume on the extraction of four Sudan targets was investigated by changing the sample volume from 5 to 13 mL. The results in Figure 7 indicated that the quantitative results (recovery of >95%) were obtained when the aqueous-phase volume varied from 5 to 11 mL. Finally, the volume of 10 mL was selected and used as the optimal sample volume in our work.

Application of the SFO−DLPME−HPLC Method to Real Foodstuff Samples. For the determination of Sudan dyes in foodstuffs, various solvents, including methanol,[10,16] acetonitrile,[1,6,17,43] and ethanol,[14,44,45] have been used alone for extraction of Sudan dyes in various foodstuffs. Considering that the recovery of Sudan IV could be improved using ethanol as an extraction solvent[44] and the ratio of the sample weight to the volume of the extractant has no obvious effect on extraction recovery,[46] in our work, about 2 g of the selected food samples was extracted with 5 mL of ethanol. To evaluate the potential application of the SFO−DLPME−HPLC method for the detection of Sudan dyes in real samples, the analytical characteristics were evaluated using the spiked food samples. The results are indicated in Table 1. As seen, the linear ranges, in terms of the peak area and sample concentration for four Sudan dyes, were in the range of 1−1250 ng g^{-1}. The correlation coefficients (r^2) were in the range of 0.9921−0.9990, demonstrating the good linearity of the proposed method. The limit of detection (LOD; S/N = 3) was in the range of 0.10−0.20 ng g^{-1}. Validation of the SFO−DLPME−HPLC method was evaluated by determining the recoveries of the spiked foodstuffs with Sudan I−IV at 0.05, 0.10, and 0.50 μg g^{-1}. The precision of the SFO−DLPME−HPLC method was evaluated by carrying out analysis of the spiked foodstuffs in 6 replicates in the same day and 9 successive days. The relative standard deviations (RSDs; precision) of inter- and intraday were ≤4.8% (Table 1), suggesting that the reproducibility was satisfactory. No target dyes were detected in the tomato sauce, chili oil, and chili sauce samples. Figure 8 shows the typical chromatograms of Sudan dyes from chili sauce and chili oil samples. The recoveries varied from 92.6 to 106.6% for the target Sudan dyes in tomato sauce, chili sauce, and chili oil (Table 2), showing that the proposed method was reliable for analysis of trace levels of Sudan dyes in complicated foodstuffs.

The proposed method was compared to other methods.[1,9,10,12,15,17,18,43,47−53] As seen from Table 3, the LODs of the proposed method in this work were lower than most methods reported. Meanwhile, a relatively short extraction time (20 min), good recoveries (92.6−106.6%), and low RSD were obtained with the reported pretreatment technique. This shows that the SFO−DLPME is an ideal microextraction technique in the pre-concentration of four Sudan dyes in real foodstuffs.

Application of the SFO−DLPME−HPLC Method to Environmental Water Samples. To assess the potential application of the SFO−DLPME−HPLC method for the detection of Sudan dyes in aqueous samples, first, the effect of the commonly co-existing ions (NO_3^-, CO_3^{2-}, PO_4^{3-}, Ca^{2+}, Mg^{2+}, K^+, NH_4^+, etc.) in natural waters was studied under the above-selected extraction conditions. The results demonstrated that quantitative recoveries of the target dyes were obtained in the presence of co-existing substances (see Table S2 of the Supporting Information), showing the good selectivity of the proposed SFO−DLPME method to Sudan dyes. Also, the effect of natural organic matter (NOM) on the extraction of Sudan dyes was evaluated because NOM is widely present in natural waters. To do this, sample solutions containing different concentrations of humic acid were treated by this SFO−

dx.doi.org/10.1021/jf5006403 | J. Agric. Food Chem. 2014, 62, 5818−5826

DLPME method. From Figure S3 of the Supporting Information, the quantitative recovery of Sudan dyes could be reached at less than the 5 mg L^{-1} level of humic acid. The humic acid contents in the natural waters are less than 4 mg L^{-1} for river water samples;[54] thus, it did not interfere with Sudan dye determination, indicating the good selectivity of the proposed SFO−DLPME method.

Second, under the selected extraction conditions indicated above, the analytical performance was tested. The analytical data, such as linear range, correlation coefficients, detection limits, and precision, are shown in Table S3 of the Supporting Information. As seen, good linear relationships could be obtained for four Sudan dyes between the peak area and the sample concentration from 0.2 to 500 $\mu g\ L^{-1}$. The LOD was 0.03 $\mu g\ L^{-1}$. The recoveries of Sudan dyes varied in the range of 91.1−108.6% when 10 mL of aqueous sample at three spiked concentration levels (5, 10, and 20 $\mu g\ L^{-1}$ Sudan dyes) were tested (see Table S4 of the Supporting Information), indicating the utility of the proposed method for the detection of Sudan dyes in environmental water samples.

In conclusion, for the first time, we demonstrated that the proposed SFO−DLPME−HPLC method can be used as a useful protocol for pre-concentration and detection of trace Sudan dyes. Our results indicate that SFO−DLPME is an efficient sample preparation technique for the extraction of banned Sudan dyes (I, II, III, and IV) in a complex matrix. The proposed method promises simplicity, less organic solvent consumption, and high sensitivity. Also, it allows for the determination of Sudan dyes in complex matrices with good accuracy and reproducibility.

Supporting Information

ABSTRACT: In this paper, we first discovered that Co_3O_4 nanoparticles (NPs) possess intrinsic oxidase-like activity and can catalytically oxidize peroxidase substrates, such as 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) and 3,3′,5,5′-tetramethylbenzidine (TMB), to form colored products, in the absence of exogenously added H_2O_2. The presence of sulfite inhibited the TMB−O_2−Co_3O_4 NPs reaction system and caused a change in color of the reaction system. On the basis of this phenomenon, a colormetric approach to detect sulfite was established with a good linear relationship ranging from 0.2×10^{-6} to 1.6×10^{-5} M and a detection limit of 5.3×10^{-8} M. The method was used to detect sulfite in foods. Good recoveries ranging from 93.8% to 100.5% were obtained. Furthermore, the mechanism was studied and results showed that the oxidase-like activity of the Co_3O_4 NPs was not from $^{\bullet}OH$ or $O_2^{\bullet-}$ radical generated. It may probably originate from their ability to transfer an electron between the peroxidase substrate and oxygen absorbed on the surface of the Co_3O_4 NPs.

KEYWORDS: *Co_3O_4 nanoparticles, oxidase mimic, colorimetry, sulfite, mechanism of oxidase-like activity*

INTRODUCTION

Sulfite is one of the oldest and most ubiquitous food additives, which has been widely used as blanching and preservative agents in a large variety of foodstuffs (dried fruit, vermicelli, preserves, etc.) to improve the appearance of food and prevent bacterial growth.[1,2] However, the ingestion of foods containing large amounts of sulfite can cause asthmatic attacks and allergic reactions in sensitive individuals.[3,4] Owing to the potential toxicity, the sulfite in foods is strictly limited in many countries.[5] Hence, sulfite determination in food products is essential for the purposes of public health, food assurance, and quality control. In recent years, numerous methods have been developed for determining sulfite in foods, including titrimetry, flow injection analysis, anodic stripping voltammetry, ion chromatography, chemiluminescence, gas chromatography, fluorometry, high-performance liquid chromatography, and colorimetry.[6−8]

Colorimetric biosensing has become more attractive because of its low cost, simplicity, and practicality. However, the key challenge for colorimetric sensors is transforming the detection events into color changes. Since color changes can be read by the naked eye, a colorimetric sensor does not require expensive or sophisticated instrumentation and can be applied to field analysis.[9−11] To this end, enzyme-like nanomaterials-based sensors have emerged as an important colorimetric tool. Since the first report of Fe_3O_4 magnetic nanoparticles (MNPs) possessing intrinsic peroxidase-like activity,[12] nanoparticles-based enzyme mimics have received great attention due to their merits relative to native enzymes (e.g., low cost, high stability, and tunability in catalytic activity). More and more nanoparticles have been found as enzymatic mimics, such as metal oxide nanomaterials,[13] sulfide nanomaterials,[14−17] selenide nanomaterials,[18,19] metal nanomaterials,[13,20] carbon nanomaterials,[13,20] nanocomposites,[21−28] and other nanomaterials.[29−31] These enzyme-like nanomaterials could be employed in colorimetry to detect nucleotides,[32] H_2O_2,[33−35] glucose,[33−35] melamine,[36] and so on. To the best of our knowledge, however, the colorimetric detection of sulfite in food using the enzyme-like property of nanoparticles has not been explored up to now, which might be attributed to the complication of food samples' matrices and the difficulties in constructing an effective nanoparticles-based enzyme mimic sensing platform to detect micro amounts of food additive.

Herein, we have developed a TMB−O_2−Co_3O_4 NPs colorimetric system for detection of sulfite in foods, based on the property of oxidase-like activity of Co_3O_4 NPs. In this method, the existence of sulfite can cause a change in color of the reaction system, and the color change can be visually observed directly. We also investigated the mechanism of oxidase-like activity of Co_3O_4 NPs by XPS, contrast experiments, and cyclic voltammetry.

EXPERIMENTAL PROCEDURES

Materials. $Co(CH_3COO)_2{\cdot}4H_2O$ were obtained from Tianjin Guangfu Chemical Reagent Factory (Tianjin, China). 3,3′,5,5′-Tetramethylbenzidine (TMB) and 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) were purchased from Sigma-Aldrich. Ammonium hydroxide (25−28 wt %) was purchased from Baiyin Liangyou Chemical Reagent Factory (Baiyin, China). Sodium acetate, glacial acetic acid, anhydrous sodium sulfite, sodium

dihydrogen phosphate, and other regents were obtained from Tianjin Guangfu Chemical Reagent Factory (Tianjin, China). A sulfite solution was prepared daily by dissolving anhydrous sodium sulfite in water and was standardized by iodimetric titration when needed. All other chemicals were of analytical reagent grade and used without further purification. Deionized water was used throughout the experiment.

Apparatus and Characterization. A TU-1901 double-beam UV−vis spectrophotometer (Beijing Purkine General Instrument Co. Ltd., China) was used to record absorption spectra and measure absorbance. A FEI Tecnai G^2 F30 microscope (TEM) was used for measuring the morphologies and size of Co_3O_4 NPs. The X-ray diffraction (XRD) pattern of Co_3O_4 NPs was determined on a Rigaku D/Max-2400 X-ray diffractometer with Cu Kα radiation (λ = 0.154056). The chemical state of the coating surface was analyzed using X-ray photoelectron spectroscopy (XPS, PerkinElmer PHI-5702 multifunctional photoelectron spectrometer). Element determination was measured by a 4300 DV inductively coupled plasma−atomic emission spectrometer (ICP-AES). Zeta potential measurements of Co_3O_4 NPs were performed with a Malvern Nano-ZS apparatus. ESR spectra were acquired using a JES-FA200 electron spin resonance spectrometer. Electrochemical experiments were performed on a CHI 832 electrochemical workstation (Shanghai Chenhua Instrument Co., China) and a conventional three-electrode system. The conventional three-electrode system contained a Pt wire counter electrode, a saturated calomel electrode as reference electrode, and an as-prepared

dx.doi.org/10.1021/jf500950p | J. Agric. Food Chem. 2014, 62, 5827−5834

working electrode. The specific surface area was measured using a multipoint Brunauer–Emmett–Teller technique (ASAP 2020, Micromeritics, USA).

Preparation of Co_3O_4 Nanoparticles. Co_3O_4 NPs were prepared using a hydrothermal method as described in the literature.[37] Briefly, 0.5 g of $Co(CH_3COO)_2{\cdot}4H_2O$ was dissolved in 25 mL of ethanol, and then 2.5 mL of ammonia solution was added under vigorous stirring. After stirring for 10 min, the obtained suspension was transferred into a 50 mL autoclave. Then the autoclave was sealed and kept at 150 °C for 3 h followed by cooling to room temperature naturally. Finally, the product was separated via centrifugation and alternately washed thoroughly several times with deionized water and ethanol until the pH of supernatant was about 7.0, then dried at 60 °C for 4 h.

Kinetic Assay of Oxidase-like Co_3O_4 NPs. Kinetic experiments were carried out at 40 °C using 120 μL of 1.0 mg mL^{-1} Co_3O_4 NPs in 2.8 mL of acetic acid–acetate buffer solution (0.2 M, pH 4.0) with 80 μL of TMB/ABTS as substrate, unless otherwise stated. Kinetic measurements were carried out in time course mode by monitoring the absorbance change at 652/417 nm for 4 min using a TU-1901 UV–vis spectrophotometer. The Michaelis–Menten constant was calculated using a Lineweaver–Burk plot:[12]

$$1/v = K_m/V_{max}(1/[S] + 1/K_m)$$

where v is the initial velocity, V_{max} represents the maximal reaction velocity, and [S] is the substrate concentration. K_m is the Michaelis–Menten constant, which is an indicator of enzyme affinity for its substrate.

Preparation of Samples. Dried lily bulbs, vermicelli, and haw roll were purchased randomly from a local market in Lanzhou, China. Samples were minced by a mixer. An accurately weighed minced sample was transferred to a beaker, and 40 mL of EDTA (1.0×10^{-4} M) was added.[5] After shaking and ultrasonication for 15 min, the mixture was filtered with a 0.45 μm syringe membrane filter. The filtrate was diluted to 100 mL with EDTA (1.0×10^{-4} M). All samples were stored in a refrigerator at 4 °C before analysis.

Detection of Sulfite. The amount of sulfite in samples was determined according to the following steps: (a) 80.0 μL of sample solution, 150.0 μL of 5 mM TMB, and 120.0 μL of Co_3O_4 NPs solution (1.0 mg mL^{-1}) were added into 2.65 mL of a 0.2 M acetic acid–acetate buffer solution (pH 4.0) and then thoroughly mixed to make it uniform; (b) the as-mixed solution was maintained in a 40 °C water bath for 10 min to hold the reaction and then kept in an ice–water bath for 10 min to terminate the reaction. The solution was then used to perform the adsorption spectroscopy measurement at 652 nm wavelength. For the control experiments, 80.0 μL of deionized water was used instead of sample solution.

RESULTS AND DISCUSSION

Oxidase-like Activity of Co_3O_4 NPs. The oxidase-like activity of Co_3O_4 NPs was evaluated in the catalysis of typical substrates TMB and ABTS in the absence of H_2O_2. As can be seen from Figure 1a, Co_3O_4 NPs catalyzed the oxidation of TMB and ABTS to produce the typical colored products.

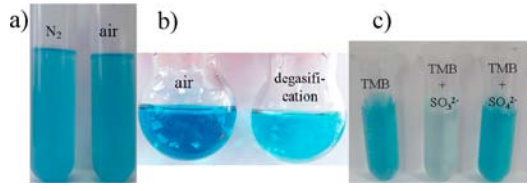

Figure 3. Photographs of TMB solutions in the absence and presence of an O_2 oxidation reaction catalyzed by Co_3O_4 NPs (a). Photographs of a TMB solution oxidation reaction catalyzed by Co_3O_4 NPs without degassing and Co_3O_4 NPs degassed by three freeze–pump–thaw cycles (b). Photographs of the oxidation color reaction of TMB, TMB-SO_3^{2-}, and TMB-SO_4^{2-} catalyzed by Co_3O_4 NPs, respectively (c).

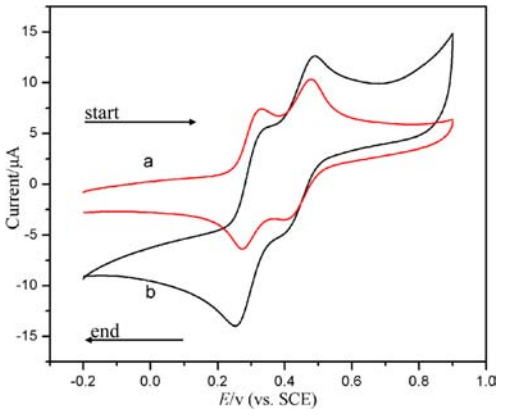

Figure 4. Cyclic voltammograms of bare GCE (a) and the Co_3O_4 NPs-modified GCE (b) in a 0.2 M acetic acid–acetate buffer (pH 4.0) + 0.25 mM TMB solution.

Similar to other peroxidase/oxidase mimic reactions, the maximum absorbance peaks of the oxidation products of TMB and ABTS were located at 652 and 417 nm, respectively.[12,33] Nevertheless, there was no absorbance at 652 or 417 nm in the absence of Co_3O_4 NPs in the system (Figure 1b and c). The results suggested that Co_3O_4 NPs exhibit intrinsic oxidase-like activity. The presence of mixed valence states of Co^{2+} and Co^{3+} ions in Co_3O_4 NPs is considered the key in their catalysis. As an oxidase mimic, the states of Co in the Co_3O_4 NPs did not change before or after the reaction.

In order to further confirm the property of oxidase mimic of the Co_3O_4 NPs, XPS was performed to find the oxidation state of Co in the Co_3O_4 NPs before and after the reaction. Figure 2e shows the deconvoluted XPS spectra of Co $2p_{3/2}$ of Co_3O_4 NPs after the reaction. The relative ratio of Co^{2+} and Co^{3+} was almost unchanged in Co_3O_4 NPs before and after the reaction. The high-resolution XPS spectra O 1s of unused and used Co_3O_4 NPs are presented in Figure 2c and f, respectively. The relative ratio of O–Co^{2+} and O–Co^{3+} peaks in O 1s XPS spectra was similar to Co $2p_{3/2}$ XPS results (Table S1). It is suggested that the states of Co in the Co_3O_4 NPs did not change before or after the reaction. These results confirmed that Co_3O_4 NPs exhibited intrinsic oxidase-like activity.

It is important to confirm the possibility that the observed activity was not caused by cobalt ions leaching from Co_3O_4 NPs in acidic solution. To test this, Co_3O_4 NPs were incubated in the reaction buffer (pH 4.0) for 2 h and then removed from the solution by centrifugation. As shown in Figure S5, comparing the activity of the leaching solution with that of Co_3O_4 NPs under the same conditions, the leaching solution had no activity, showing that the observed oxidase-like activity was due to intact Co_3O_4 NPs. Figure S6 shows the amount of cobalt ions leaked from Co_3O_4 NPs in the buffer solutions (pH 3.0–7.0) for 2 h, which was implemented by ICP-OES. The ICP results exhibited that there were few cobalt ions in the leaching solution. They probably came from residual Co_3O_4 NPs after centrifugation.

Possible Mechanism of Oxidase-like Activity of Co_3O_4 NPs. As an oxidase mimic, Co_3O_4 NPs catalyze an oxidation–reduction reaction involving oxygen (O_2) as the electron acceptor. However, in the reaction system of TMB–O_2–Co_3O_4 NPs, oxygen is present in the aqueous solution and also exists on the surface of Co_3O_4 NPs due to the high specific surface

area of nanomaterials. In order to determine whether the oxygen in the solution played a role in the TMB−O_2−Co_3O_4 NPs system, two sets of experiments were conducted: the first one was carried out in the presence of oxygen; the other was performed under high-purity nitrogen and the solution was degassed before the reaction, as in the photograph shown in Figure 3a. It was found that they exhibited the same color. The absorbance of the first one was 0.747; the other was 0.770 at 652 nm. The absorbance of the latter was higher than the former; one possible reason was that nitrogen played a role in mixing and speeded up the reaction. This indicated that the oxygen in the solution had no effect on the reaction, which was different from the behavior of some nanoparticles-based oxidase mimics reported.[8,38] For further study, the Co_3O_4 NPs without degassing and Co_3O_4 NPs degassed by three freeze−pump−thaw cycles that catalyze the oxidation of TMB were implemented in the degassed solutions. They produced different colors, as in the photograph shown in Figure 3b, and the degassed Co_3O_4 NPs also catalyzed the oxidation of TMB to produce the typical color reaction. It is suggested that the oxygen on the surface of Co_3O_4 NPs was due not only to physical adsorption. Chemisorbed oxygen probably existed on the surface of Co_3O_4 NPs because of the low oxygen Co−O bond strength of Co_3O_4 and the larger surface energy of nanomaterials caused by a large surface to volume ratio.[39] In addition, the O 1s peak at 533.0 eV in the XPS spectrum shown in Figure 2c indicated that there was chemisorbed oxygen on the surface of Co_3O_4 NPs.[40] It is indicated that both the physically absorbed and chemisorbed oxygen on the surface of Co_3O_4 NPs played a key role in the TMB−O_2−Co_3O_4 NPs system. In order to further confirm the above conclusion, oxidation experiments of TMB, TMB-SO_3^{2-}, and TMB-SO_4^{2-} catalyzed by Co_3O_4 NPs were carried out. The results are shown in Figure 3c. TMB-SO_3^{2-} system presented a lower absorbance than the other two systems. Since the volume of SO_3^{2-} is smaller than TMB, and Co_3O_4 NPs have a positive charge at pH 4.0 (Supporting Information), SO_3^{2-} is more easily adsorbed on the surface of Co_3O_4 NPs. Then SO_3^{2-} consumed oxygen absorbed on the surface of the Co_3O_4 NPs and interfered with the TMB−O_2−Co_3O_4 NPs system. This supported the above result that the oxygen absorbed on the surface of the Co_3O_4 NPs oxidized TMB in this system.

The oxidation of TMB is an electron transfer process.[41] The electrocatalytic behavior of a Co_3O_4 NP modified glassy carbon electrode (GCE) toward the electrochemical oxidation of TMB was studied using cyclic voltammetry (CV), in order to

investigate the mechanism of oxidase-like catalytic activity of Co_3O_4 NPs. The CVs of TMB at a bare GCE and the Co_3O_4 NPs-modified GCE are shown in Figure 4. Two pairs of redox peaks of TMB were found under the bare GCE, and increased current was obviously observed under the Co_3O_4 NPs-modified GCE. It is suggested that Co_3O_4 NPs exhibited an electrocatalytic activity to oxidate TMB, which indicated that the Co_3O_4 NPs had the ability to accelerate the electron transfer.[42]

In order to further demonstrate that the oxidase-like activity of the Co_3O_4 NPs was not from $O_2^{\bullet-}$ and $^{\bullet}OH$, an EPR spin trapping experiment was carried out under the optimized experimental conditions. The results revealed that no DMPO-$O_2^{\bullet-}$ or DMPO-$^{\bullet}OH$ spin adducts were detected (Figure S7).

Table 1. Results for the Determination of the Sulfite in Three Kinds of Foods

sample	initial amount (mg g^{-1})	added (μg mL^{-1})	recovery (%)	average recovery (%)	RSD (n = 3) (%)
dried lily bulbs	1.7	0.5	96.3−99.4	98.9	0.6
		1.0	94.4−99.5	96.5	2.8
		1.5	98.4−100.6	100.3	2.6

		1.0	99.1−101.6	100.5	3.3
		1.5	97.8−99.9	98.9	1.1

dx.doi.org/10.1021/jf500950p | J. Agric. Food Chem. 2014, 62, 5827−5834

It is suggested that TMB was not oxidized by $O_2^{\bullet-}$ and $^{\bullet}OH$ radicals in the TMB−O_2−Co_3O_4 NPs system, which was different from the behavior of $CoFe_2O_4$ NPs.[8] Therefore, the nature of oxidase-like activity of the Co_3O_4 NPs does not originate from the $O_2^{\bullet-}$ and $^{\bullet}OH$ radicals generated.

Taken together, although the detailed mechanism remains unclear, these observations demonstrated that Co_3O_4 NPs accelerated the electron transfer from the peroxidase substrate to oxygen absorbed on the surface of the Co_3O_4 NPs. The possible mechanism of oxidase-like activity of Co_3O_4 NPs is presented in Scheme 1; that is, TMB was absorbed on the surface of the Co_3O_4 NPs and donated electrons to the Co_3O_4 NPs, resulting in an increase in electron density and mobility in the Co_3O_4 NPs, thus accelerating the electron transfer to oxygen absorbed on the surface of the Co_3O_4 NPs. After the completion of the electron transfer, the Co_3O_4 NPs reverted to their original state.

Steady-State Kinetic Assay of Co_3O_4 NPs. Since Co_3O_4 NPs exhibited oxidase-like activity, the kinetic parameters of only TMB/ABTS were determined by changing the concentration of TMB/ABTS. A typical Michaelis−Menten curve (Figure 5a,b) was obtained with TMB/ABTS by monitoring the absorbance change at 652/417 nm for 4 min (Figure S8a,b). The Michaelis−Menten constant (K_m) and maximum initial velocity (V_{max}) were obtained using a Lineweaver−Burk plot. The values of K_m and V_{max} for the Co_3O_4 NPs with TMB were 0.051 mM and 3.30×10^{-8} M s^{-1}. The values of K_m and V_{max} for the Co_3O_4 NPs with ABTS were 0.037 mM and 3.20×10^{-8} M s^{-1}. The K_m value of Co_3O_4 NPs with ABTS was smaller than that with TMB. It is suggested that Co_3O_4 NPs have higher affinity toward ABTS than TMB, because ABTS has a higher affinity toward a positively charged nanoparticle surface and TMB has a stronger affinity toward a negatively charged nanoparticle surface.[43]

Optimization of Experimental Conditions. The reaction conditions were optimized to establish the optimum analytical conditions. The pH value not only decides the charge of the surface of Co_3O_4 NPs (Supporting Information), which affects the interaction between Co_3O_4 NPs and sulfite, but also affects the catalytic activity of Co_3O_4 NPs. The catalytic activity of Co_3O_4 NPs is also dependent on the incubation temperature. In addition, the concentrations of TMB and Co_3O_4 NPs determine the color level of the reaction system. Therefore, they were investigated in this study as influencing factors. Figure 6a indicates that ΔA, where $\Delta A = A_{(blank,652nm)} - A_{(sulfite,652nm)}$, increased and then decreased with increasing pH and had a maximum at 4.0. The reaction temperature-dependent response curve is shown in Figure 6b. It showed that ΔA of the reaction system had a peak value at 40 °C. Therefore, 4.0 and 40 °C were taken as the optimal pH and temperature. The concentrations of TMB and Co_3O_4 NPs response curves are shown in Figure 6c and d; the optimal concentrations of TMB and Co_3O_4 NPs were 0.25 mM and 40 μg mL^{-1}, respectively.

Analytical Performance for Sulfite Determination. As an oxidase mimic, Co_3O_4 NPs can catalyze TMB to form colored product in the absence of H_2O_2. The sulfite inhibits the TMB−O_2−Co_3O_4 NPs system and causes a change in color of the reaction system, which suggested that sulfite can be indirectly detected. Since sulfite is easily adsorbed on the surface of Co_3O_4 NPs and consumes absorbed oxygen more easily than dissolved oxygen, the sulfite that is consumed by dissolved oxygen is neglected in the reaction. The calibration graphs for the determination of sulfite were constructed under the optimum conditions described above. The calibration data of ΔA versus sulfite concentration are shown in Figure 7. The results indicated that the concentration of detectible sulfite could be 0.2×10^{-6} M with a linear range from 0.2×10^{-6} to 1.6×10^{-5} M. The limit of detection (LOD) for sulfite was 5.3×10^{-8} M. (LOD = KS_0/S, where K is a numerical factor chosen according to the confidence level desired, S_0 is the standard deviation (SD) of the blank measurements ($n = 10$, $K = 3$), and S is the slope of the calibration curve.[44])

Effect of Foreign Substances. The effect of foreign substances was tested by analyzing the mixed solution and standard solution of sulfite (12 μM). The molar ratio of other ion and sulfite was 20 in the mixed solution. The relative ΔA values ($(\Delta A_{total} - \Delta A_{sulfite})/\Delta A_{sulfite}$) are presented in Figure 8. As can be seen, Fe and Cu were the main interferences for sulfite determination, since trace amounts of heavy metal ions in the water are believed to act as the catalyst in the oxidation of sulfite by oxygen.[45] EDTA was selected as a chelate reagent for the present study to eliminate the interferences derived from Fe, Cu, and other coexisting transient metals in the samples.

Detection of Sulfite in Real Samples. As an illustration of analytical application, the proposed method was used to determine sulfite in real samples under the optimal experimental conditions. The results are listed in Table 1. The recoveries of the three samples ranged from 93.8% to 100.5%. Hence, the proposed method can be considered a useful tool for the quantification of sulfites in real samples.

In summary, Co_3O_4 NPs were first found to possess oxidase-like activity and could catalyze the oxidation of TMB and ABTS to produce the typical color reaction in the absence of exogenously added H_2O_2. It was found that the oxygen absorbed on the surface of the Co_3O_4 NPs oxidizes the peroxidase substrate, rather than the oxygen dissolved in the solution. The oxidase-like activity of Co_3O_4 NPs was not from the generated $O_2^{\bullet-}$ or $^{\bullet}OH$ radical, probably originating from their ability to transfer an electron between the peroxidase substrate and oxygen absorbed on the surface of the Co_3O_4 NPs. Moreover, as the existence of sulfite inhibited TMB−O_2−Co_3O_4 NPs system and caused a change in color of the reaction system, a new colorimetric method for detecting sulfite was developed. The colorimetric method showed a good response toward sulfite detection with a linear range from 0.2×10^{-6} to 1.6×10^{-5} M and good recoveries ranging from 93.8% to 100.5% in three real samples using Co_3O_4 NPs as an oxidase mimic. The detection platform showed great potential applications in reducing substrates. In addition, Co_3O_4 NPs can be expected to provide potential applications for chemical sensing, biochemical analysis, electrochemical biosensing, and even clinical chemistry.

Supporting Information

ABSTRACT: Global and targeted mass spectrometry-based proteomic approaches were developed to discover, evaluate, and apply gluten peptide markers to detect low parts per million (ppm) wheat contamination of oats. Prolamins were extracted from wheat, barley, rye, and oat flours and then reduced, alkylated, and digested with chymotrypsin. The resulting peptides were subjected to LC-MS/MS analysis and database matching. No peptide markers common to wheat, barley, and rye were identified that could be used for global gluten detection. However, many grain-specific peptide markers were identified, and a set of these markers was selected for gluten detection and grain differentiation. Wheat flour was spiked into gluten-free oat flour at concentrations of 1−100,000 ppm and analyzed to determine the lowest concentration at which the wheat "contaminant" could be confidently detected in the mixture. The same 2D ion trap instrument that was used for the global proteomics approach was used for the targeted proteomics approach, providing a seamless transition from target discovery to application. A powerful, targeted MS/MS method enabled detection of two wheat peptide markers at the 10 ppm wheat flour-in-oat flour concentration. Because gluten comprises approximately 10% of wheat flour protein, the reported wheat gluten-specific peptides can enable detection of approximately 1 ppm of wheat gluten in oats.

KEYWORDS: *wheat, gliadin, proteomics, LC-MS/MS, celiac disease, gluten-free*

INTRODUCTION

Gluten is a complex network of proteins present in the endosperm of cereals that is responsible for giving dough its viscoelasticity.[1] Gluten is composed of two fractions: (1) monomeric, alcohol-soluble prolamins; and (2) polymeric, alcohol-insoluble glutelins.[2] Gluten proteins from wheat, barley, and rye can trigger an autoimmune disorder known as celiac disease (CD), and some wheat gluten and other wheat proteins can cause an IgE-mediated allergic response.[3,4] There are some celiac/allergy common immunoreactive proteins, and the only successful treatment for patients with a wheat allergy or CD is a wheat- or gluten-free (GF) diet devoid of these grains.[5] Although some oat cultivars have proven to be celiacogenic, pure oats can be an important source of nutrition in the GF diet because it is generally believed that the prolamins from oats (avenins) do not trigger an autoimmune response in most patients with CD, even though they are homologous to the prolamins from wheat (gliadins), barley (hordeins), and rye (secalins).[4,6,7] However, oats are frequently contaminated with one or more of the three celiacogenic grains during farming, transport, storage, and processing.[7,8]

Analytical techniques for the detection of gluten in food are important to ensure accurate food labeling and thereby protect consumers with CD from exposure to gluten. The U.S. FDA recently established that food labels bearing a "gluten-free" claim must contain <20 ppm of gluten from wheat, barley, rye, or their crossbred varieties.[9] Enzyme-linked immunosorbent assay (ELISA) is the only validated method available for the detection and quantitation of gluten; however, the different commercially available kits can respond differently to the gluten from wheat, barley, and rye. Recently, the accuracy of ELISA-based quantitation of gluten proteins has come into question due to the lack of a standardized reference material.[10] Concerns have also been raised with respect to the cross-specificity of the ELISA antibodies and the efficiency of the gluten protein extraction procedure, which can lead to over- or under-estimation of the total gluten content.[11] For example, most ELISA antibodies bind epitopes present in prolamins; however, the "cocktail" solution used to extract the gluten proteins can also extract glutelins. ELISA kits recommend multiplying the measured prolamin content by two to determine total gluten content; however, if the antibody cross-reacts with glutelins, then the total gluten content will be overestimated.[11]

Mass spectrometry (MS) offers a complementary method with unique capabilities that can provide molecularly specific information, including peptide identification, relative abundance determination, and protein inference. MS can be used to supplement or confirm ambiguous ELISA results, such as the differentiation of grains or the identification of specific protein sequences present in certain cultivars. MS-based proteomic strategies have been employed for the analysis of gluten for several years.[12] For example, MS has been used to identify the immunogenic gluten peptides responsible for causing CD and to determine how different gluten proteins affect flour quality.[13−16] The analysis of intact proteins by MS has been used to develop low-resolution fingerprints for gluten detection and grain source identification for the enforcement of gluten-

free labeling regulations.[17,18] Bottom-up proteomics, which is based on enzymatic digestion of proteins and identification of the resulting peptides, was developed for mammalian proteomics, but has been less successful when applied to plants, for several reasons.[19] Incomplete genomes and poorly annotated protein databases for the three celiacogenic grains have made the identification of gluten proteins and peptides very challenging.[20] Nonetheless, bottom-up proteomic studies have been performed on wheat gluten, exclusively, and have yielded some candidate peptide markers that could be used to detect gluten from wheat in food.[21,22] The quantitation of gluten by mass spectrometry has been hindered by many challenges including, but not limited to, the lack of a standardized reference material, the large number of highly homologous proteins, cultivar heterogeneity, and variable growth conditions.

In this work, two proteomic strategies are used to develop a qualitative MS screening method to detect a gluten contamination of GF flour at concentrations below the maximum amount of gluten allowed in products labeled "gluten-free," which has been set at 20 ppm. In the first approach, a global proteomics analysis, which aims to characterize all of the proteins in a given sample, is used to identify grain-specific gluten peptide markers for wheat, barley, and rye that can be used for either total gluten detection or differentiation of the grains. In the second approach, a targeted proteomics assay is developed to detect low concentrations of wheat flour in GF oat flour. The complexity of the background matrix can greatly affect the sensitivity of mass spectrometric methods toward a particular analyte. Because wheat contamination of oats is common, oats are used here to provide a relevant matrix for the validation of the wheat candidate peptide markers.[7,8] The transition from a global proteomics method to a targeted method requires a thoughtful selection of the marker peptides according to a set of established guidelines[23] and rigorous verification of the gluten fragments that will serve as optimum markers of gluten in commercial foods. The selected wheat-specific peptide markers were targeted with a scheduled pseudo-selected reaction monitoring (pSRM) method.[24] This method involves acquiring full MS/MS spectra for each peptide of interest rather than following only a few selected parent-to-product ion transitions, as is done in traditional multiple reaction monitoring (MRM) methods.[25] pSRM is performed with the same instrument used for global proteomics analysis, a 2D linear ion trap, providing a seamless research pipeline from marker discovery to validation to application.[23]

MATERIALS AND METHODS

Gluten Sources. Gluten from wheat (Sigma), three single-grain flours, and seven commercial flours were obtained for this study: Duster wheat (hard red winter), King Arthur wheat (hard red), NIST standard reference material 1567a wheat (blend of hard red spring and hard red winter), Bob's Red Mill (BRM) wheat (hard red spring), Post90 barley, BRM barley, Wheeler rye, BRM dark rye, BRM oat, and BRM GF oat. The BRM GF oat flour was confirmed to be gluten-free via ELISA analysis with both R-Biopharm AG (R5 antibody) and Morinaga kits (data not shown). The three single-grain flours were prepared by grinding the whole grains with a Sorvall Omni-Mixer 17105 (DuPont) using a chamber assembly with cutting blades.

Wheat Flour-in-Oat Flour Sample Preparation. The 100,000 ppm wheat flour-in-oat flour mixture was prepared by mixing 0.5 g of BRM wheat flour and 4.5 g of BRM GF oat flour using a Spex SamplePrep Geno/Grinder 2010 at 1500 strokes/min for 5 min. Subsequent 10-fold dilutions of 0.5 g of wheat flour-in-oat flour mixtures with 4.5 g of BRM GF oat flour were made to produce 10000, 1000, 100, 10, and 1 ppm wheat flour-in-oat flour mixtures.

Gluten Extraction. The gluten extraction protocol used was an adaptation of the classic Osborne procedure.[26,27] For the neat wheat, barley, rye, and oat flours, 10 mg of each sample was washed twice with 1 mL of 0.5 M NaCl (1 h at 25 °C with vortexing) to remove albumins and globulins. After two washings with 1 mL of distilled water (1 h at 25 °C with vortexing), the prolamins were extracted twice with 1 mL of 70% ethanol (EtOH) or 50% EtOH for oats (1 h at 25 °C with vortexing), as recommended by Tatham et al.[26] The prolamin fraction was extracted from the Sigma wheat gluten sample with 70% EtOH without the NaCl and water washes. For the wheat flour-in-oat flour mixtures, 0.5 g of each sample was washed twice with 5 mL of 0.5 M NaCl and twice with 5 mL of distilled water and then extracted twice with 5 mL of 70% EtOH (each for 1 h at 25 °C on a Stuart SRT6 roller mixer at 33 rpm). A Qubit Protein Assay Kit (Invitrogen) was used to determine the amount of protein extracted from each sample by performing a spectroscopic measurement based on fluorescence according to the manufacturer's instructions. Experimental details for SDS-PAGE analysis of the prolamin extracts can be found in the Supporting Information.

Sample Digestion and Preparation. A 30 μg aliquot of each prolamin extract, as determined by Qubit analysis, was dried in a centrifugal evaporator (SpeedVac) without heating, resuspended with 20 μL of 50 mM ammonium bicarbonate and 5 μL 1% *Rapi*Gest SF (Waters) in 50 mM ammonium bicarbonate, and heated at 95 °C for 10 min. After the mixture had cooled to ambient temperature, 1.25 μL of 105 mM DTT was added to reduce the proteins with 5 mM DTT (final concentration) at 60 °C for 30 min. After the mixture had again cooled to ambient temperature, 1.25 μL of 330 mM iodoacetamide was added to alkylate the proteins with 15 mM iodoacetamide (final concentration) at 25 °C for 30 min. The proteins were then digested with either trypsin (1:100 enzyme-to-substrate ratio at 37 °C) or chymotrypsin (1:100 enzyme-to-substrate ratio at 25 °C) for approximately 18 h. To assess digestion efficiency, 60 pmol of intact bovine serum albumin (BSA, Sigma) was added to the samples prior to digestion. The resulting peptides were desalted using C18 spin columns (Pierce) according to the manufacturer's instructions. The samples were dried in a SpeedVac and reconstituted in an aqueous solution containing 0.1% formic acid (FA) and 3% acetonitrile (ACN) to obtain concentrations of 100 ng/μL prolamins and 200 fmol/μL BSA (based on the quantity of intact protein starting material) and subjected to mass spectrometric analysis. Angiotensin-II (A-II) was added to each sample at a concentration of 250 fmol/μL to serve as an injection internal standard to monitor run-to-run variations in instrument performance.

LC-MS/MS Analysis. A Thermo LTQ XL mass spectrometer equipped with a Waters nanoAcquity HPLC and Michrom CaptiveSpray source was used for global and targeted mass spectrometric analyses. For each sample, 1 μL was injected onto a Symmetry C18 (5 μm particle size, 180 μm i.d. × 20 mm length at 25 °C) trap column using an isocratic gradient at 0.5% B for 3 min at 5 μL/min (solvent A, 0.1% FA in water; solvent B, 0.1% FA in ACN). Peptide separation was accomplished with a BEH130 C18 column (1.7 μm particle size, 100 μm i.d. × 100 mm length at 35 °C) using a gradient of 3−40% B over 60 min at 500 nL/min. The LTQ was operated in either a Top9 data-dependent acquisition mode or a scheduled pSRM acquisition mode. For the Top9 method, a full MS scan was acquired first, and then the nine most abundant peaks were selected for MS/MS analysis. For the pSRM method, the global, non-data-dependent mass list and 5 min retention time (RT) windows were used for targeted MS/MS analysis of four wheat peptides, three BSA peptides, and the injection standard A-II. LTQ operation parameters include 35% collision energy, 2 Da precursor ion isolation width, 30 ms fragmentation time, 1.7 kV spray voltage, and 31 V capillary voltage. The automatic gain control (AGC) target values were 30000 and 10000 for full scans and MS^n or SIM scans, respectively. Maximum ion injection times were 10 and 100 ms for full scans and MS^n or SIM scans, respectively.

LC-MS/MS Data Analysis. The global proteomics data were searched with MASCOT (Matrix Science) to identify peptides and infer protein assignments from a database that consisted of the reviewed and unreviewed entries for the BEP clade (Bambusoideae, Ehrhartoideae, Pooideae) and PACMAD clade (Panicoideae, Arundinoideae, Chloridoideae, Micrairoideae, Aristidoideae, and Danthonioideae) of the Poaceae family listed in the Uniprot database (downloaded on November 1, 2012, filtered by taxonomy, ~380,000 entries). MASCOT search parameters included 2 maximum missed cleavages, +2 and +3 peptide charge states, ±1.8 Da peptide tolerance, ±0.8 Da MS/MS tolerance, carbamidomethyl (C) as a fixed modification, and oxidation (M) as a variable modification. Scaffold (Proteome Software) was used to organize and evaluate the confidence of peptide identifications and protein assignments. Scaffold filters applied to the search results included 99.0% protein threshold, two minimum peptides, and 95% peptide threshold. Scaffold results were exported to Excel as spectrum reports to enable spectral counting for individual peptides using pivot tables. All of the spectra assigned as "false" were removed (to avoid double counting of spectra), and the total number of spectra assigned to each peptide sequence was calculated. Skyline (University of Washington) was used to determine relative peptide abundances on the basis of the sum of the peak areas of the five most abundant fragment ions in the MS/MS spectra from each target peptide. Skyline allowed confirmation of the targeted peptides by visual inspection of peak shape to ensure coelution of the individual transition traces, as well as measurements of the RT and selected fragment ion abundance ratios. Xcalibur Qual Browser (Thermo) was used to interrogate the raw data by extracting ion chromatograms (XICs) and evaluating the full MS/MS spectra. Xcalibur was used to calculate the S/N ratio of the XIC peak areas for individual fragment ions via the ICIS peak detection model with default parameters.

RESULTS AND DISCUSSION

Digestion Optimization Using a Gluten Standard. Development of a global proteomics method usually begins with digestion optimization for the analyte of interest. Trypsin is traditionally used in bottom-up proteomics because it is reliable and specific, cleaving C-terminally to lysine and arginine residues. However, because prolamin proteins are low in lysine and arginine content, trypsin produces only a small number of very large peptides that are not of optimal size for ESI-MS/MS analysis. Chymotrypsin, which cleaves C-terminally to tyrosine, phenylalanine, tryptophan, and leucine (but not before proline), is less specific but is an acceptable alternative enzyme to trypsin.[28,29] A reduction and alkylation step is also traditionally included before digestion to cleave cysteine-cysteine disulfide bonds and derivatize the resulting free cysteines and thereby unfold the protein for improved digestion. The number of gluten peptides that could be identified in a 70% EtOH extract of the Sigma wheat gluten sample was evaluated using the four following digestion conditions: with or without reduction/alkylation and with either trypsin or chymotrypsin. The chymotryptic digestion with reduction and alkylation yielded the largest number of unique gluten peptide identifications; approximately 2 times more peptides were identified compared to the trypsin digestion with reduction and alkylation (125 vs 62 peptides, see Table 1).

A larger number of identified peptides demonstrates superior digestion efficiency and provides improved confidence in the protein assignments from database matching. In addition, a large pool of potential gluten peptide markers is preferred because not all peptides will be suitable markers after rigorous selection criteria are applied. For example, peptide markers should have 7−30 residues and average hydrophobicity and not contain potential modification sites, such as methionine residues, which can be oxidized.[23] A peptide marker should be reproducibly observed with high peak intensity, proper chromatographic peak shape, and a high-quality MS/MS spectrum with many abundant fragment ions with high S/N.[23]

Table 1. Number of Gluten Peptides Identified with the Indicated Digestion Conditions

digestion conditions			
trypsin	reduction/alkylation + trypsin	chymotrypsin	reduction/alkylation + chymotrypsin
33	62	96	125

The use of mulitple enzymes, separately or sequentially, has been reported.[13,20] However, multienzyme digestions require additional time and reagents, and because the chymotrypsin-alone digestion produced many candidate peptide markers, this strategy was used for the remainder of the experiments presented. The reduction/alkylation/chymotrypsin digestion protocol was further improved using the Sigma wheat gluten sample in a digestion time course study (2, 4, 8 and 18 h of digestion time) with various enzyme-to-substrate ratios (1:20, 1:50, 1:100, and 1:200). An enzyme-to-substrate ratio of 1:100 and a digestion time of 18 h were found to be optimal conditions for reproducible generation of gluten peptides (data not shown).

Characterization of Gluten Using a Global Proteomics Approach. A variety of flour samples were studied (Supporting Information Supplemental Table SI) to ensure that the technique developed will be applicable to a wide range of food products through the consistent production and detection of the selected markers. Gluten protein sequences may differ in these flours due to grain cultivar and plant growth conditions, as well as variable flour processing techniques such as bromation, bleaching, or refinement.[22] The wheat flours selected for the study are from hard red wheat and represent what is commonly used in the United States to make bread and hard-baked goods. The prolamin extracts were analyzed with SDS-PAGE to provide a coarse comparison of wheat gliadins, barley hordeins, rye secalins, and oat avenins; however, this technique offers a limited qualitative visualization. For instance, it would be difficult to determine a low-level gluten contamination via SDS-PAGE analysis. Supplemental Figure S1 in the Supporting Information is the SDS-PAGE image showing the most abundant prolamins extracted from wheat, barley, rye, and oat flours. Analysis of the second ethanol extract indicated an efficient first extraction because only 12.7 ± 1.4% more protein was extracted the second time.

Each prolamin extract was reduced, alkylated, and digested with chymotrypsin using the optimized digestion protocol and analyzed by LC-MS/MS. The reproducibility of the method was evaluated by extracting and digesting the BRM wheat, barley, rye, and GF oat flours three times. The LTQ mass spectrometer was operated in a Top9 data-dependent mode, and the data were analyzed in the same manner as described above (MASCOT search, Scaffold summary, Excel pivot table, and data compilation). The total numbers of unique peptides assigned to the top protein hits from each neat flour sample are summarized in Supplemental Table SII in the Supporting Information. For each type of flour tested, the protein matches derived from the MS/MS data cluster together by grain type (wheat, barley, rye, or oats). For example, peptides identified from each of the wheat flours matched the same top 10 wheat

[a]Peptide reported in the literature differs by a missed cleavage.

entries in the protein database and did not match confidently to proteins from any of the other grain types. Generally, the most abundant proteins from each grain source correlate to the specific prolamin type for that grain (wheat gliadins, rye secalins, barley hordeins, and oat avenins) except for one γ-gliadin, B6DQC4_LOPEL, which was observed in all of the wheat and rye flours.

To discover gluten peptide markers, the peptide identifications from each flour were grouped by grain source (wheat, barley, rye, or oats). The peptide lists were evaluated for peptides common to the grains (total gluten markers) and peptides unique to each grain (gluten grain source differentiation markers). Figure 1 displays the peptide identifications as a Venn diagram of the total number of unique peptides from gluten proteins that were identified in all of the flour samples from wheat, barley, and rye. No gluten peptide markers common to all three grains were identified; however, this does not imply that peptides common to all three grains do not exist. All MS-based proteomic strategies are limited by database quality because the identification of peptides and the assignment of proteins are restricted to the proteins present in the database. Unfortunately, the protein databases available for wheat, barley, rye, and oats are incomplete and not well curated. Because a unified gluten detection method is not possible using this strategy, a set of markers composed of representatives from each grain would be required to ensure the method is capable of gluten detection regardless of the grain source.

Many grain-specific peptides were identified for each grain, which could be used to differentiate wheat, barley, and rye. Wheat and rye were the most similar, with 13 peptides in common; wheat and barley had 3 peptides in common, and barley and rye did not have any peptides in common. Some of the peptides that were found in common between wheat and rye had similar sequence motifs and differ only by a single amino acid polymorphism (SAAP) or a missed cleavage site (e.g., five peptides contain the subsequence TLPTMCNVY and another five peptides contain QCNPVSL). Similarly, two of the three peptides common to wheat and barley have a SAAP (K → Q). None of the grain-specific peptide markers identified from wheat, barley, or rye were identified in oats.

Global Proteomics Analysis of Wheat Flour Spiked into Gluten-free Oat Flour. To refine the group of wheat-specific peptides identified above into a set of useful peptide markers, a global proteomics analysis was performed on samples consisting of wheat flour spiked into GF oat flour at concentrations of 1−100,000 ppm. The different concentration levels were used to evaluate the peptide markers and determine those that would enable detection of the lowest concentration of the "contaminant" grain in the mixture.

The prolamin fraction was extracted from each flour mixture and digested using the optimized protocol. Using the global proteomics approach, 16 of the 425 wheat-specific peptides observed in the neat wheat flours were identified consistently in the wheat flour-in-oat flour samples with a linear signal intensity response from 1,000 to 100,000 ppm. Peptide sequences, protein accession numbers, and gliadin classes for the identified peptides are listed in Table 2. Almost half of the wheat-specific peptide makers that we identified have been reported in the literature.[13,16,22,28,30] The candidate peptide markers satisfy the selection criteria discussed previously and are of average length and hydrophobicity, do not contain methionine residues, and reproducibly provide high-quality LC-MS/MS data. Representative peptides from each prolamin class (α/β-, γ-, and ω-gliadins) are also preferred as well as peptides that contain ELISA epitopes. Because ELISA is the only validated method for gluten analysis, using peptide markers that contain ELISA epitopes will enable a direct comparison of a MS-based method with ELISA. Known gluten ELISA antibody epitopes include QLPYPQP for the A1 antibody from Romer Laboratories, QPQLPY for the G12 antibody from Romer Laboratories, and QQPFP for the R5 antibody from R-Biopharm AG.[31,32] Peptide W4 contains the G12 epitope (underlined), and peptide W14 contains the G12 epitope (underlined) and the A1 epitope (highlighted in bold).

Data from digests of the prolamin extracts from neat flours were searched to ensure that each of the 16 candidate peptide markers were reproducibly observed in the three replicate analyses of BRM wheat flour as well as in each different source of wheat flour. Most of the peptides were reproducibly detected in each replicate analysis except peptide W13, which was observed in only one BRM wheat flour replicate, and peptides W6, W7, and W15, which were observed in two of the three BRM wheat flour replicates. The majority of peptides (14 of 16) were observed in all of the wheat flour types except peptides W10 and W15, which were not observed in the Duster wheat flour. None of the candidate markers for wheat was observed in the barley, rye, or oat flours except peptide W16, which was observed in every rye flour. Although 15 of the 16 candidate makers matched specifically to wheat protein entries in the flours studied, no definite conclusion can be made on the absolute specificity of the wheat peptide makers because the databases for the other gluten-containing grains are incomplete. Because of the homology between these cereal grains, one should exercise caution when attempting to derive the grain source of gluten on the basis of the detection of a single peptide.

Targeted Proteomics Analysis of Wheat Flour Spiked into Gluten-free Oat Flour. Using the global proteomics approach, wheat flour could be confidently detected in the GF oat flour at concentrations of 1000 ppm or greater, which is significantly higher than the GF labeling threshold of 20 ppm. With a Top9 data-dependent acquisition mode, the wheat gluten peptides were not of sufficient abundance, with respect to the oats background, to trigger MS/MS analysis. Therefore, a targeted MS/MS method was developed so that the wheat-specific peptide markers could be observed at lower concentrations. Targeted methods can increase the selectivity and sensitivity of peptide detection by directing the mass spectrometer to analyze a small number of peptide ions with specified *m/z* and RT values. A scheduled pSRM method was used, in which the mass spectrometer collects full MS/MS spectra for selected precursor ions during designated RT windows.[24] The MS/MS scan events were time scheduled with small RT windows to minimize overlap between targets. Acquisition of MS/MS spectra for a small number of peptides at any given time increases the number of times the parent ion is sampled across the eluting LC peak (and therefore the number of data points per peptide), resulting in an improved measurement of peak area and relative abundance determination.

The pSRM approach is in contrast to a Top9 data-dependent method, which collects full MS scans and then MS/MS spectra for untargeted but highly abundant peptides, or an MRM method, which does not collect full MS/MS spectra and relies on specific parent-to-product ion transitions. A pSRM method maintains the selectivity advantage of MRM by monitoring product ion peaks in MS/MS spectra, which results in a peak that is more easily distinguished against the background. This is especially important for low-resolution instruments, such as the LTQ, where interferences from chemical noise result in low S/

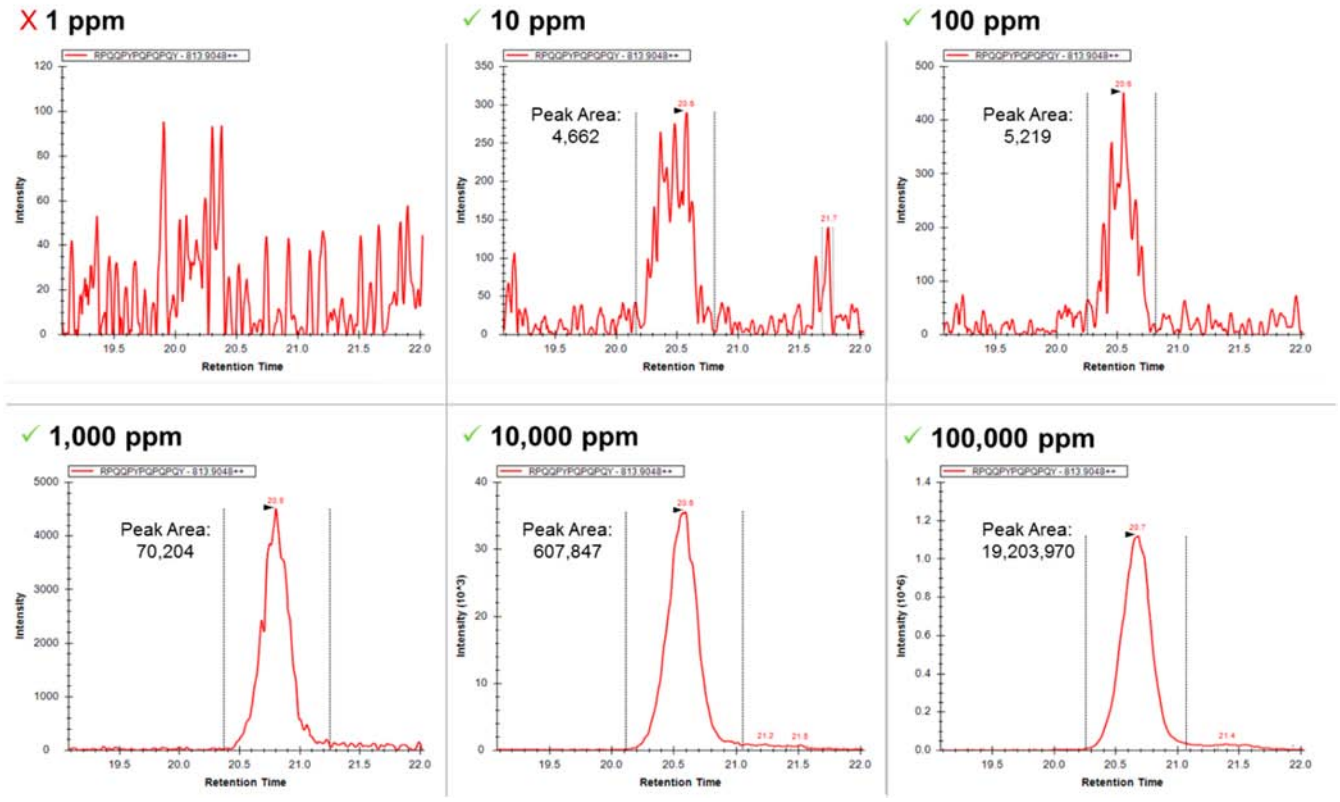

Figure 2. Chromatographic peaks representing the sum of the peak areas of the five most abundant fragment ions for peptide W1 as measured by pSRM analysis of the six wheat flour-in-oat flour samples.

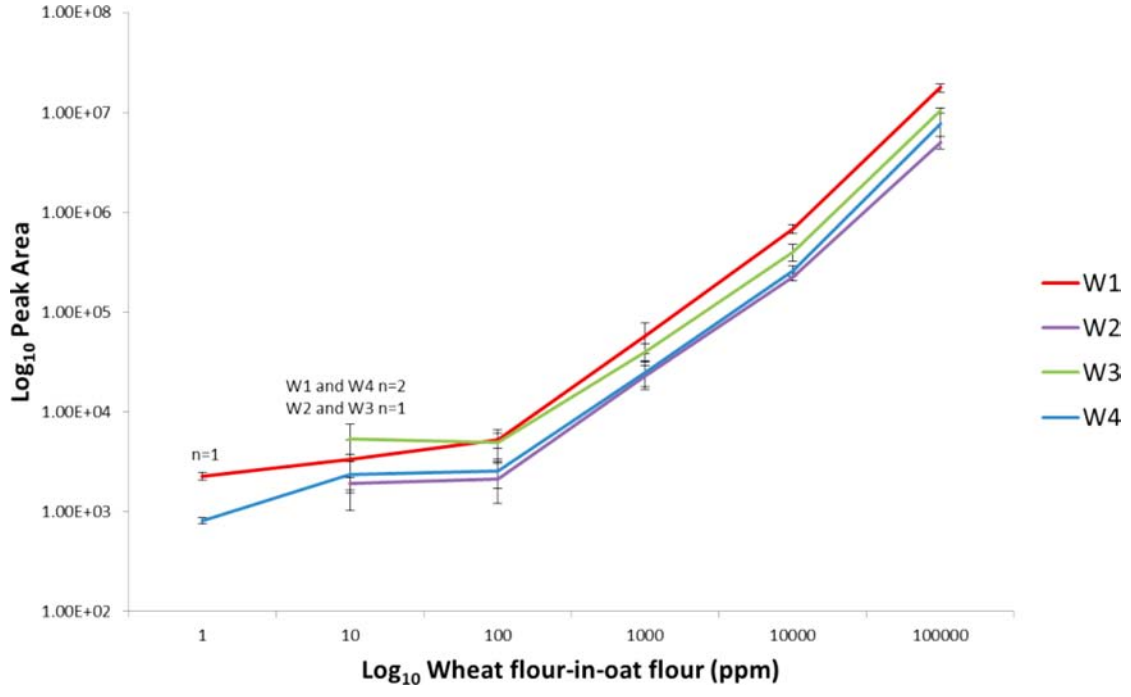

Figure 3. Log–log plot of the pSRM peak areas for the four targeted wheat-specific peptide markers versus the concentration of wheat flour in each wheat flour-in-oat flour sample. Data points correspond to the average of three replicate analyses. Lines connecting data points indicate a trend in decreasing peak area and do not represent a line of best fit.

N that can make distinction of precursor ion peaks (MS1) difficult. Because full MS/MS spectra are acquired with a pSRM method, false positives or negatives can be quickly verified by matching a large number of product ions in the acquired MS/MS spectrum with product ions in a reference spectrum. Data processing methods can be changed postacquisition to include as many product ions as is necessary to make a confident assignment, which is not possible with MRM.

dx.doi.org/10.1021/jf500997j | J. Agric. Food Chem. 2014, 62, 5835–5844

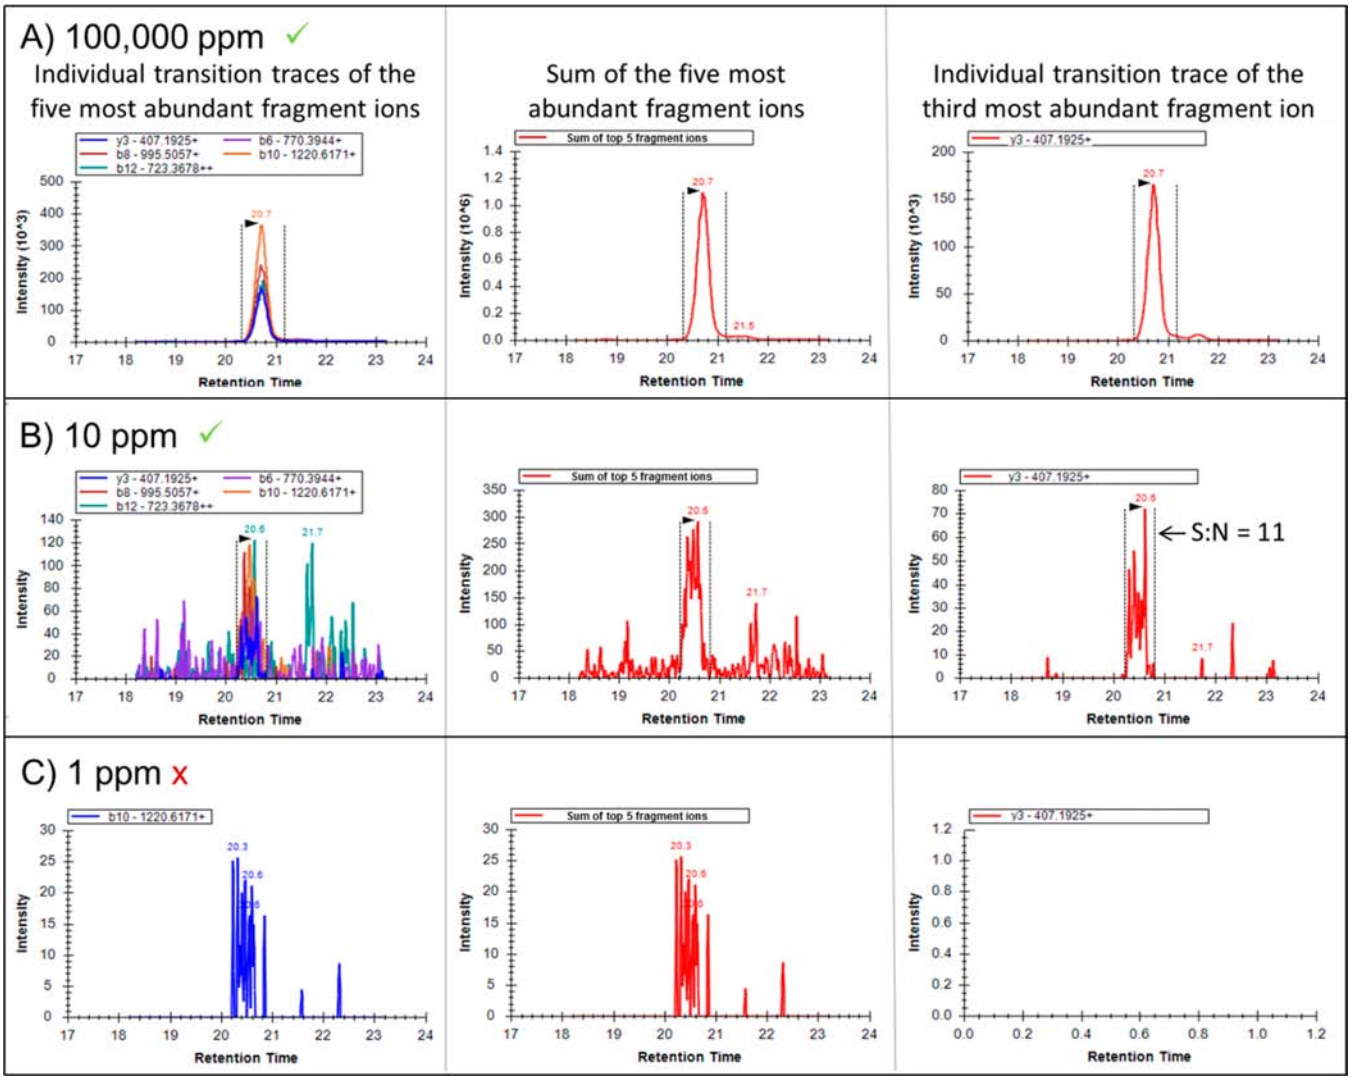

Figure 4. Chromatographic peaks for peptide W1 acquired by targeted analysis of the 100,000 ppm (A), 10 ppm (B), and 1 ppm (C) wheat flour-in-oat flour samples. Application of strict criteria ensured confident detection of peptide W1 at the 100,000 and 10 ppm concentrations, but not at the 1 ppm concentration. The leftmost column shows the individual transition traces for the five most abundant fragment ions. The middle column shows the sum XIC of the five most abundant fragment ions. The right column shows the individual transition trace for the third most abundant fragment ion.

With the global proteomics approach, 3 of the 16 wheat-specific candidate peptide markers, W1−W3, were observed at the 1000 ppm concentration ($R^2 \geq 0.991$). These peptides as well as an ELISA epitope-containing peptide (W4 contains the G12 ELISA epitope QPQLPY) were chosen for targeted analysis using pSRM. Three BSA peptides and A-II were also monitored to ensure proper digestion efficiency and instrument performance. Table 3 contains information on the pSRM targets including peptide sequence, protein source, m/z, and RT. The wheat flour-in-oat flour samples were mixed and digested three separate times at each concentration to ensure the reproducibility of the method.

Skyline was used to extract ion chromatograms and calculate the total peak area for each target peptide as the sum of the peak areas of the five most abundant fragment ions.[24,33] Figure 2 shows Skyline plots of pSRM data for peptide W1 at each concentration of the wheat flour-in-oat flour samples. The total peak area for each target peptide, determined using Skyline's default algorithm, was plotted versus wheat flour concentration to establish a dynamic range of the method. A log−log plot of the observed trend is shown in Figure 3. A linear response is observed from all four peptides for concentrations from 100 to 100,000 ppm. The peptides that were detected in samples below the 100 ppm concentration did not appear consistently in all replicates and did not continue the linear response, a phenomenon that has been observed by others.[24,34] Peptides W1 and W4 were detected at the 10 ppm concentration in two of the three sample replicates and observed at the 1 ppm concentration in one of the sample replicates. Peptides W2 and W3 were detected at the 10 ppm concentration in only one of the sample replicates.

To objectively and confidently confirm peptide detection at the lowest concentrations, the following six criteria were applied to pSRM data: (1) the transition traces from the five most abundant fragment ions from each peptide must coelute; (2) the retention time must agree with the authenticated retention time of the peptide ±15 s; (3) the individual XIC peak areas for the three most abundant fragment ions must have a S/N ≥ 3; (4) the m/z values for the more abundant b- and y-ions must be accurate and correctly represent the peptide

dx.doi.org/10.1021/jf500997j | J. Agric. Food Chem. 2014, 62, 5835−5844

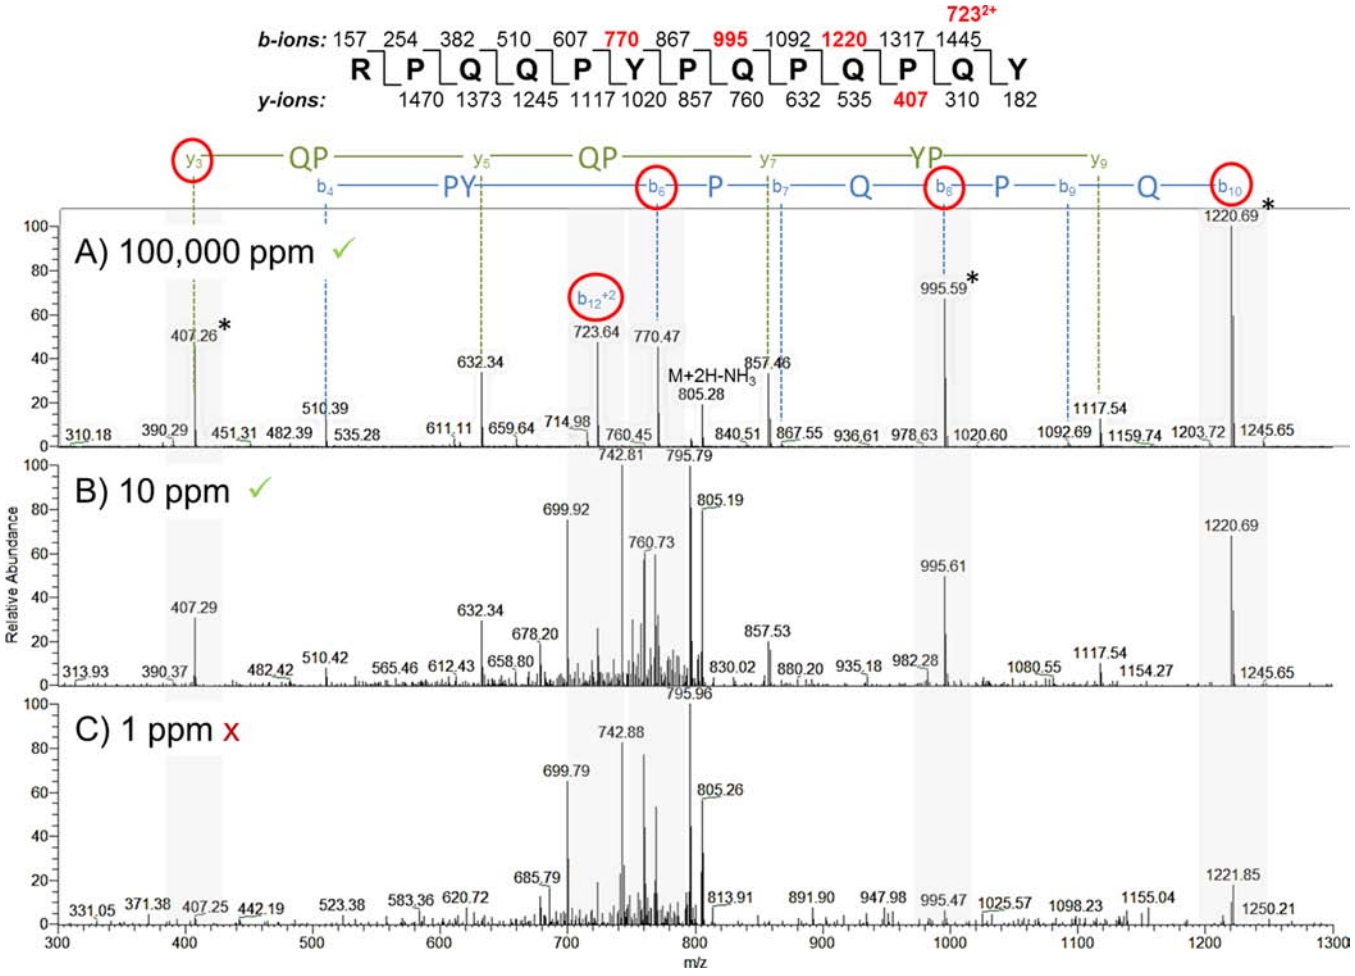

Figure 5. MS/MS spectra for peptide W1 at the 100,000 ppm (A), 10 ppm (B), and 1 ppm (C) concentrations obtained by averaging the MS/MS spectra across the XIC peaks in Figure 4. The b- and y-ion series were used to confirm the peptide sequence. The five most abundant fragment ions that were monitored in the pSRM data analysis are circled in red. The top three fragment ions (∗) were used to calculate the fragment ion abundance ratios.

sequence; (5) the abundance ratio of product ions must be within a prescribed range; (6) the peptide must be reproducibly observed in the replicate analyses. The criteria used are based on recommended guidelines established for the field of targeted peptide measurements.[35,36]

Figure 4 is representative XIC data for peptide W1, which was positively observed at the 100,000 ppm (A) and 10 ppm (B) wheat flour-in-oat flour concentrations, but not detected at 1 ppm (C). The left column shows the coelution of the individual transition traces for the five most abundant fragment ions for peptide W1. The middle column shows the sum of the five most abundant fragment ions for peptide W1, which was used to create the concentration−response relationship curve (Figure 3). The retention times of the peptides were consistent within 5.8 ± 1.4 s across the 6 orders of magnitude in concentration for the individual sample replicates, indicating the background matrix had minimal effect on chromatographic separation. The retention times of the peptides were consistent within 10.1 ± 1.7 s between the three sample replicates, which demonstrates the reproducibility of the method and instrument performance. The right column shows the individual transition trace for the third most abundant fragment ion for peptide W1, which must have a S/N ≥ 3 to ensure positive peptide observation. Peptide W2 fragments poorly and does not have many prominent peaks in its MS/MS spectrum; therefore, the second most abundant fragment ion was required to have a S/N ≥ 3.

Figure 5 is the model MS/MS spectrum for peptide W1 at 100,000 ppm (A), an acceptable spectrum at 10 ppm (B), and an unacceptable spectrum at 1 ppm (C) obtained by averaging the MS/MS spectra across each XIC peak in Figure 4 using the boundaries determined by Skyline. Even though only five fragment ions were used to calculate the peptide abundance, several additional fragment ions (b_4, y_5, y_7, and y_9) were detected with adequate S/N in samples with low concentrations of wheat flour-in-oat flour (Figure 5B). This ability of the pSRM method to capture full MS/MS spectra is important for reliable detection of low-concentration analytes in complex mixtures because it can provide increased confidence in peptide identifications. An acceptable fragment ion abundance ratio is determined by the ratio of the most abundant fragment ion with respect to the second and third most abundant fragment ions ±20−50% relative units depending on the relative intensity of the fragment ion with respect to the base peak.[37] Because the product ions could be assigned very reliably at high concentrations, the ion ratios from the 1000−100,000 ppm samples were used to establish the criteria for lower concentration samples. Overall, the fragment ion abundance

dx.doi.org/10.1021/jf500997j | J. Agric. Food Chem. 2014, 62, 5835−5844

ratios between the first and second most abundant fragment ions were within ±20%, except peptide W4 with a tolerance of ±40.9% at 1 ppm and a tolerance of ±21.1% at 10 ppm. The fragment ion abundance ratios between the first and third most abundant fragment ions were also within the accepted range. Although because full MS/MS spectra were acquired, the criterion for the fragment ion abundance ratios did not need to strictly apply for reliable peptide detection, if other criteria are sufficiently satisfied.[38]

The combination of these criteria allows a confident identification of wheat in oats at the 10 ppm concentration using peptides W1 and W4, which is below the 20 ppm "gluten-free" labeling threshold. Peptides W2 and W3 were not consistently observed at the 10 ppm concentration, which provides an example of why the largest initial pool of candidate markers is desired, as was previously discussed. It is very difficult to predict a priori which peptide markers will perform better in a complex sample due to factors such as suppression of ions of interest by coeluting peptides.

A unique aspect of this work is the use of the same mass spectrometer for the global and targeted proteomics methods, which has advantages over moving from a data-dependent method on an ion trap or QToF to a traditional MRM method on a triple-quadrupole instrument for targeted analysis. The optimal gluten peptide markers may change with different gluten sources because of the large number and variety of grain cultivars and processing techniques.[22] Gluten peptide marker discovery or confirmation by global proteomics may be necessary for different gluten-containing sample types prior to targeted analysis. Using the same instrument for both the discovery and validation phases streamlines the research and minimizes the time lost in transferring a method from one instrument platform to another. With the use of two different LC-MS systems, the peptide markers may differ with respect to chromatography, ionization, and fragmentation. In addition, the need for two mass spectrometers increases the cost per sample significantly.

Overall, we have demonstrated how a MS-based proteomics approach can be used for the qualitative detection of low concentrations of wheat in oats. After a global proteomics approach was used to identify a set of wheat-specific peptide markers (with respect to barley, rye, and oats), a targeted proteomics approach was used to enable detection of a 10 ppm wheat flour contamination of GF oat flour. The wheat flour used in this study consists of approximately 11.42% protein (micro-Kjeldahl analysis using a conversion factor of 5.7). Assuming 80% of wheat protein is gluten, the wheat flour contains approximately 9.1% gluten;[30] therefore, the concentration of gluten is approximately 1 ppm, which is well below the desired GF labeling threshold of 20 ppm. This combined global and targeted MS proteomics strategy is complementary to ELISA in that it can provide confirmatory, low-level, qualitative gluten detection with molecular specificity and enable grain differentiation. Because the detection of gluten has the potential to be complicated by variability in protein sequence due to differences in cultivar, growth conditions, and protein homology, a preliminary global proteomics analysis is important for each new application to confirm the validity of the gluten peptide markers or identify better peptide markers if necessary.

The strategy reported here could be improved by using an instrument with greater mass resolution and accuracy. Higher resolution will lead to fewer contaminants in the targeted m/z and RT window, and the increase in S/N could result in the observation of wheat gluten peptides at lower "contamination" concentrations.[39] Isotopically labeled peptide standards will be employed for an isotope dilution study to elucidate the extent of matrix suppression and background interference on the detection of the wheat-specific peptide markers. In addition, the method will be further developed toward the ultimate goal of a targeted quantitative method. Both MS and ELISA will be used to analyze gluten-incurred and suspected gluten-contaminated commercial foods to provide method performance comparison and determination of optimum gluten-in-food measurement strategies.

ABSTRACT: Biologically active low-molecular-mass thiols, mainly including glutathione (GSH), cysteine (Cys), homocysteine (Hcy), and cysteinylglycine (Cys-Gly), are important physiological components in biological fluids, and their analytical methods have gained continuous attention over recent years. We developed and validated a novel HPLC method for the quantification of GSH, Cys, Hcy, and Cys-Gly in human plasma, urine, and saliva using 4-chloro-3,5-dinitrobenzotrifluoride as the derivatization reagent. Analyses were linear from 0.15 to 500 μM with the coefficient regression range of 0.9987−0.9994. Detection limits ranged from 0.04 to 0.08 μM (S/N = 3). The developed method was applied to quantification of four thiols in human biological fluids collected from five donors with the concentration range of 2.50−124.25 μM, 0−72.81 μM, and 0−4.25 μM for plasma, urine, and saliva, respectively. The present method seemed to be an attractive choice for the determination of thiols in plasma, urine, and saliva.

KEYWORDS: *cysteine, glutathione, homocysteine, high performance liquid chromatography, precolumn derivatization, 4-chloro-3,5-dinitrobenzotrifluoride*

1. INTRODUCTION

Biologically active low-molecular-mass thiols, mainly including glutathione (GSH), cysteine (Cys), homocysteine (Hcy), and cysteinylglycine (Cys-Gly), are important physiological components in biological fluids and important biomarkers for a wide range of human diseases.[1,2] GSH is the most abundant nonprotein thiol, and its altered levels occur in plasma of patients with leukemia, diabetes, or AIDS.[3] Cys is involved in a variety of important cellular functions, and its levels in urine have been recognized as an important indicator for kidney stones and cystinuria.[4,5] The elevated level of Hcy in plasma is considered as a risk factor for cardiovascular disease.[1,6] Increased concentration of Cys-Gly in plasma or urine has been observed to be linked to rheumatoid arthritis.[1] Therefore, quantification of these thiols in biological fluids is important for monitoring some special pathological conditions of human.

There have been many analytical methods for these thiols, which mainly involved fluorescent assays,[7] electrochemical assays,[8] capillary electrophoresis,[9,10] gas chromatography,[11,12] high performance liquid chromatography (HPLC),[13−37] gas chromatography with mass spectrometry,[38,39] and liquid chromatography with mass spectrometry.[40,41] Recently, the derivatization followed by HPLC determination of the resulting derivatives attracted more attention because it is relatively simple and can simultaneously determine several thiols with good sensitivity.[33,42] The derivatization reagent is very important for the method sensitivity and recovery because it can provide chromophore or fluorophores and stabilize the thiol molecules. There have been a number of commonly used derivatization reagents, such as 2-chloro-1-methylquinolinium tetrafluoroborate (CMQT),[16−18] 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB),[19] *o*-phthalaldheyde (OPA),[24,25] monobromobimane (mBrB),[26,27] ammonium-7-fluoro-2,1,3-benzoxadiazole-4-sulfonate (SBD-F),[28] and 4-(aminosulfonyl)-7-fluoro-2,1,3-benzoxadiazole (ABD-F).[29,30] Although these reagents have been well adapted in many fields, new labeling reagents are still needed to improve the detection properties.

Ion-pairing chromatography is a mature and valuable analytical and separation strategy in biological fluids. Its used has been reported in a very wide range of applications concerning organic and inorganic ions, neutrals, and zwitterionic compounds.[13−18] Therefore, the ion-pairing chromatography would be a better approach in separation and analysis of GSH, Cys, Hcy, and Cys-Gly in biological fluids.

In our previous studies, 4-chloro-3,5-dinitrobenzotrifluoride (CNBF) has been demonstrated to be a feasible and superior derivatization reagent for amino compounds.[43−45] CNBF has one activated halide leaving group which can be easily displaced by the thiol group (−SH), leading to formation of the stable thioether with well-defined absorbance at 230 nm. The aim of the present work is to develop and validate a novel HPLC method for the quantification of GSH, Cys, Hcy, and Cys-Gly in human plasma, urine, and saliva. Then the levels of thiols in three biological fluids collected from five healthy donors were determined with this novel method.

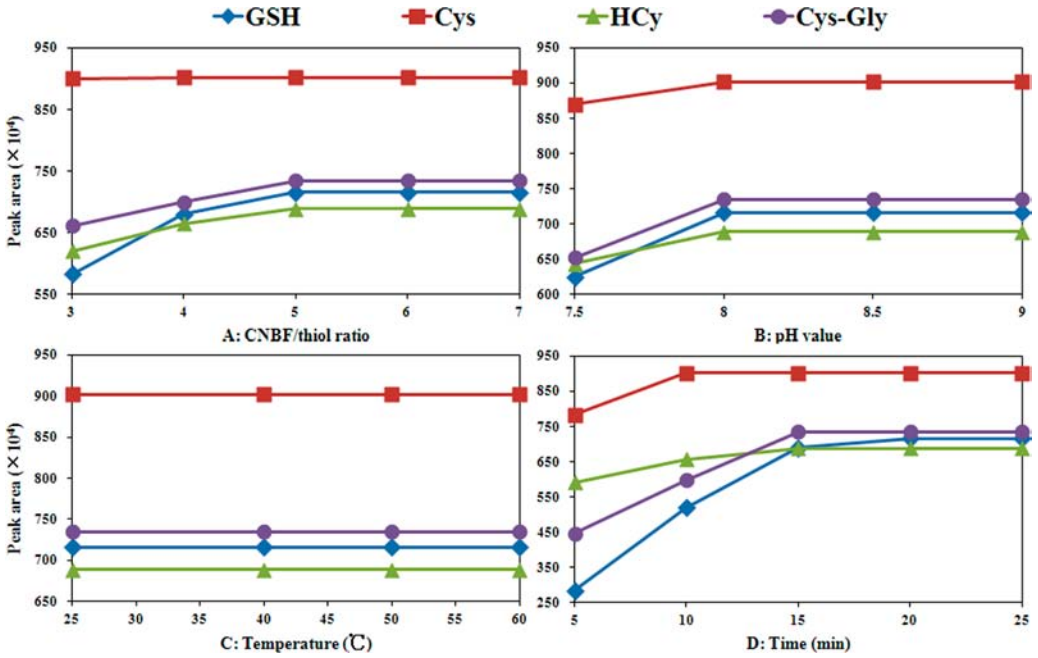

Figure 2. Effects of CNBF/thiol molar ratio (A), pH (B), reaction temperature (C), and reaction time (D) on the resulting peak areas of the thiol derivatives. (A) Constant conditions: thiol standard 100 μM, pH 8.0, 25 °C, 20 min. (B) Constant conditions: thiol standard 100 μM, CNBF 500 μM, 25 °C, 20 min. (C) Constant conditions: thiol standard 100 μM, CNBF 500 μM, pH 8.0, 20 min. (D) Constant conditions: thiol standard 100 μM, CNBF 500 μM, pH 8.0, 25 °C.

dithiobis(2-nitrobenzoic acid), and trifluoroacetic acid (TFA) were analytical grade reagent and purchased from Sinopharm Chemical Reagent Beijing Co., Ltd. (Beijing, China). CNBF was provided by Alfa Aesar (Ward Hill, MA, USA). Tris(2-carboxyethyl)phosphine (TCEP) was purchased from Fluka (Germany). Acetonitrile and methanol (HPLC grade) was purchased from J.T. Baker (Phillipsburg, NJ, USA). The ultrapure water was obtained by a Milli-Q water purification system (Millipore, Billerica, MA, USA). The standard solutions of 5.0 mM GSH, Cys, Hcy, and Cys-Gly were prepared in ultrapure water. The CNBF standard solution of 40.0 mM was prepared in methanol. The stock solutions were stored in the dark at 4 °C when not in use. H_3BO_3–$Na_2B_4O_7$ buffer was prepared by mixing 0.2 mol/L H_3BO_3 solution with 0.05 mol/L Na_2B_4O7 solution to the required pH value.

2.2. Instruments. A HPLC system, consisting of two LC-20ATvp pumps and an SPD-20Avp ultraviolet detector (Shimadzu, Japan), was applied for the separation and analysis. A reversed-phase Kromasil ODS C_{18} column (250 mm × 4.6 mm, 5 μm) and Chromatograph Solution Light Chemstation for LC system were employed to obtain and process chromatographic data.

2.3. Sample Preparation. In the present study, venous blood samples (about 2.0 mL), urine samples (about 5.0 mL), and saliva samples (about 1.0 mL) were collected from five healthy donors (male:female = 3:2, 23–30 years of age, Beijing, China) on April 27th, 2012. Blood samples were placed in precooled ethylenediaminetetraacetic acid (EDTA) Vacutainer tubes and immediately centrifuged at 2500*g* for 10 min at 4 °C. The supernatant liquid (plasma) was collected and stored at −80 °C for the analysis. The urine samples were collected and stored in a 5 mL tube at −80 °C until analysis. Five minutes after the gargling with distilled water, donors kept tongue in touch with palate and made the saliva naturally flow down into a 5 mL tube. Then the saliva samples were stored at −80 °C for analysis.

The pretreatment method was referenced to the report by Cevasco et al.[33] with some modifications. After thawing, 100 μL of sample (plasma, urine, or saliva) was mixed with 10 μL of a solution of TCEP (50 mM in borate buffer, pH 7.4) in a vial and incubated at 25 °C for 10 min. Then 90 μL of a solution containing 1% TCA and 1 mM EDTA was added and the total solution was centrifuged for 10 min at 10000*g*. The obtained supernatant was collected for the subsequent derivatization.

dx.doi.org/10.1021/jf5014007 | J. Agric. Food Chem. 2014, 62, 5845–5852

2.4. Derivatization Method. After the pretreatment step, 100 μL of the supernatant, 20 μL of 10 mM CNBF solution, 20 μL of methanol, and 50 μL of borate buffer (0.2 M, pH 8.0) were mixed and incubated at 25 °C for 20 min. Then the derivatization was terminated with 10 μL of 2 M HCl. The resulting solution was filtered through a 0.22 μm filter membrane (Millipore Corporation, Belfast, MA, USA) and injected into the chromatographic system.

2.5. Chromatographic Method. Before the analysis, the C_{18} column equipped with a C_{18} guard column (4 mm × 3 mm i.d.) was pre-equilibrated with the mobile phase for 20 min. HPLC separation of the thiol derivatives was carried out on a reversed-phase Kromasil ODS C_{18} column. The mobile phase was composed of acetonitrile (eluent A) and water with 0.1% (v/v) TFA (eluent B).

Optimum separation for plasma samples was achieved in gradient condition as follows (expressed as the proportion of eluent B): 0−9.0 min, a linear gradient starting from 70% to 20%; 9.0−10.0 min, 20%; 10.0−15.0 min, linear gradient from 20% to 70%. Optimum separation for urine and saliva samples (proportion of eluent B): 0−5.0 min, a linear gradient starting from 70% to 20%; 5.0−8.0 min, 20%; 8.0−11.0 min, linear gradient from 20% to 70%. The analysis was executed with injection volume of 20 μL, flow rate of 1.0 mL/min and UV detection wavelength at 230 nm. Each sample was injected in triplicate, and the analysis was carried out at 25 °C.

2.6. Comparison with a Reference Method. To validate this method, the thiols in the plasma samples from the five donors were also determined by a reference method[19] and the data from the two methods were compared by the Independent Sample t-Test using SPSS (version, 17.0). The plasma sample was derivatized with 10 mM DTNB at room temperature in pH 7.2 for 5 min, filtered, and injected into HPLC. The mobile phase was composed of methanol (A) and 100 mM KH_2PO_4 (B) with the ratio of 12:88 (A/B, v/v). The analysis was executed with injection volume of 20 μL, flow rate of 1.2 mL/min, and UV detection wavelength at 230 nm.

3. RESULTS AND DISCUSSION

3.1. Optimization of Derivatization Conditions. The general reaction of CNBF with thiols is shown in Figure 1. CNBF can react with thiols in low concentration to form stable thioether derivatives under alkaline conditions. The main factors affecting the derivatization yields were concentration ratio of CNBF to thiol, pH value, reaction temperature, and reaction time. To determine the optimum derivatization conditions, the effects of the four factors on the peak areas (yields) were investigated, and the results are shown in Figure 2.

The optimum concentration ratio of CNBF to thiol was of primary importance. Its effects on the peak areas are shown in Figure 2A. The thiol (100 μM) was reacted with various concentrations of CNBF (300, 400, 500, 600, and 700 μM, CNBF/thiol = 3−7:1). At concentration ratio ≥5:1, the peak areas of four thiols reached the most and kept constant. The levels of GSH, Cys, Hcy, and Cys-Gly in human fluids were reported to be in the range of 2.07−17.80, 72.0−312.70, 1.30−9.20, and 0.49−11.30 μM.[14,22,33] In the real analysis, 2.0 mM was the adequate concentration for CNBF to keep the concentration ratio ≥5:1. The optimum reaction pH value was determined by derivatizing thiols in H_3BO_3−$Na_2B_4O_7$ buffer with the pH values ranging from 7.5 to 9.0. Figure 2B shows that the peak areas of thiol-CNBF are the most at pH range of 8.0−9.0. Because high pH could lead to the hydrolysis of CNBF, pH 8.0 was selected for all experiments. A temperature range of 25−60 °C was used to study the optimum temperature. Figure 2C shows when other conditions are kept constant, temperature has no significant influence on the peak areas of four thiols. Therefore, 25 °C (room temperature) was selected for the derivatization temperature. The reaction time was also an essential factor, and its effects on derivatization were studied (Figure 2D). It can be seen that when the time ≥ 20 min, the peak areas of four thiol derivatives reached the most. Therefore, the derivatization time was 20 min.

CNBF has relatively poor water solubility, thus organic solvent should be added to the reaction medium to avoid the precipitation of the reagent and derivative. The tests showed the content of methanol in the total solutions should be more than 15%, especially for the derivatization of Cys.

3.2. Optimization of Separation Conditions. Test showed that, without ion-pairing reagents in the mobile phase, the thiol derivatives were too polar to be well retained on the reversed-phase column, which resulted in difficulty in the separation. In the present study, TFA was used as the ion-pairing agent to achieve fast and optimum separation of four thiol derivatives, CNBF, and matrix interferences. The effects of TFA concentration (range of 0.01−0.20%) on separation of the derivatives were also studied. It was found that high concentration may cause damage to the C18 column. Test also indicated 0.1% (v/v) TFA was the optimum adding concentration. To obtain better separation within shorter analysis time, the separation conditions for plasma, urine, and saliva were investigated respectively as previously mentioned in section 2.5. In the present work, a wavelength of 230 nm was selected in the HPLC-UV analysis to obtain good absorption and minimize the interferences.

Typical chromatograms of reaction of thiols with CNBF and plasma sample with spiking thiols are shown in Figure 3, in which the retention times of GSH, Hcy, Cys-Gly, and Cys were 4.05, 5.45, 7.50, and 11.80 min respectively and the separation can be completed within 15 min. Typical chromatograms of reaction of thiols with CNBF, urine sample with spiking thiols, and saliva sample with spiking thiols are shown in Figure 4, in which the retention times of GSH, Hcy, Cys-Gly, and Cys were 3.85, 4.95, 6.50, and 9.00 min respectively and the separation can be completed within 11 min.

3.3. Stability of the Derivative. The stability of thiol-CNBF in methanol−water (20:80, v/v) at 4 °C was investigated over 5 days without light irradiation. Results showed there was no significant change in the peak areas of GSH-CNBF, Cys-CNBF, Hcy-CNBF, and Cys-Gly-CNBF. When sample was illuminated by ordinary light of 100 W bulb for 24 h, there was also no significant change in the peak areas of the four thiol derivatives. Seven days later, the average degradation rates at room temperature were 4.20%, 5.05%, 5.40%, and 4.85% for GSH-CNBF, Cys-CNBF, Hcy-CNBF, and Cys-Gly-CNBF respectively. It appeared that the thiol derivatives were very stable.

3.4. Validation of the Method and Application to Sample Analysis. Text mixtures of different concentrations of thiols were prepared and analyzed by using the optimized derivatization procedure and separation conditions. Sensitivity of the method was determined by the limit of detection (LOD) at a signal-to-noise ratio of 3 and the limit of quantification (LOQ) at a signal-to-noise ratio of 10.[29,30] The usual numerical value used is the relative standard deviation (RSD) for reproducibility. The reproducibility of this analytical method was evaluated both intraday and interday with thiol concentration of 50 μM. The linear calibration range, regression equation, R^2, LOD, LOQ, and RSD of four thiols with this new method were calculated, and the results are listed in Table 1. Results showed that the correlation coefficients for

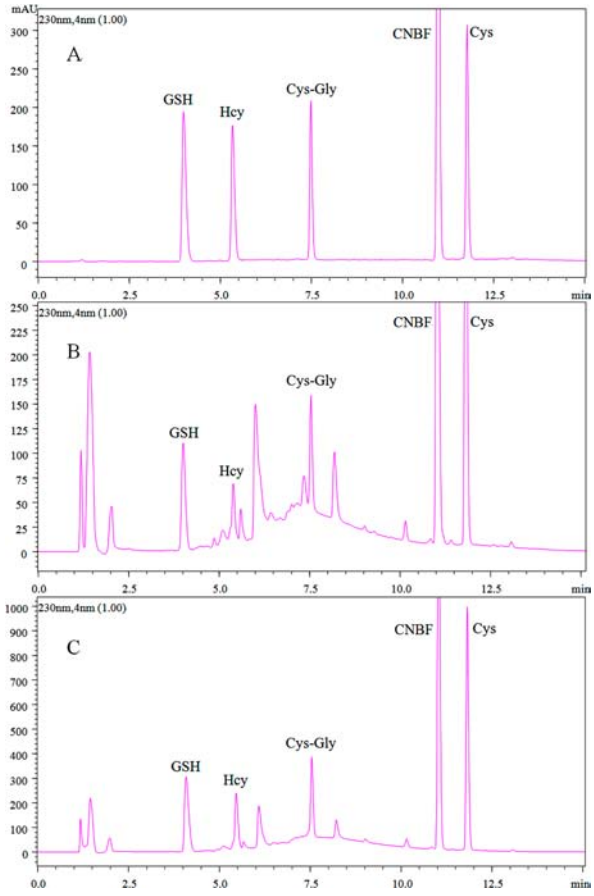

Figure 3. Chromatograms obtained from the reaction of CNBF with thiols (A, 40 μM of GSH, Cys, Hcy, and Cys-Gly; B, plasma samples; C, plasma samples with spiking 40 μM of GSH, Cys, Hcy, and Cys-Gly). Chromatographic conditions: column, reversed-phase Kromasil ODS C_{18} column (250 mm × 4.6 mm i.d., particle size 5 μm); UV detection, λ = 230 nm; mobile phase, acetonitrile (A) and water with 0.1% (v/v) TFA (B). Gradient conditions: B, 0−9.0 min, a linear gradient starting from 70% to 20%; B, 9.0−10.0 min, 20%; B, 10.0−15.0 min, linear gradient from 20% to 70%; flow rate, 1.0 mL/min; 25 °C.

these thiols were from 0.9987 to 0.9994. The RSDs for the thiol-CNBF are from 2.26% to 2.92% for within-day determination (n = 6) and from 2.65% to 3.55% for between-day determination (n = 6). The detection limits for four thiols ranged from 0.04 μM to 0.08 μM.

In the present work, the applicability of the proposed method was evaluated in plasma, urine, and saliva. Four thiol peaks were identified by spiking thiol standards to the fluid sample. Before adding the reducing reagent TCEP, the fluid sample was spiked with thiol standard 5 and 50 μM, respectively. Then the fluid samples with and without spiking were extracted and analyzed. Because the fluid contained thiols, the recovery should be calculated by the formula

$$\text{recovery} = (C - C_d)/C_s \times 100\%$$

where C represents the total found concentration of thiol after spiking, C_d represents the initially measured concentration before spiking, and C_s represents the spiked concentration. The recoveries of thiols from plasma, urine, and saliva were investigated. Table 2 shows the recoveries of thiols are in the range of 82.5% to 91.6% for plasma, 86.8% to 95.0% for urine, and 80.5% to 88.5% for saliva, depending on the sample

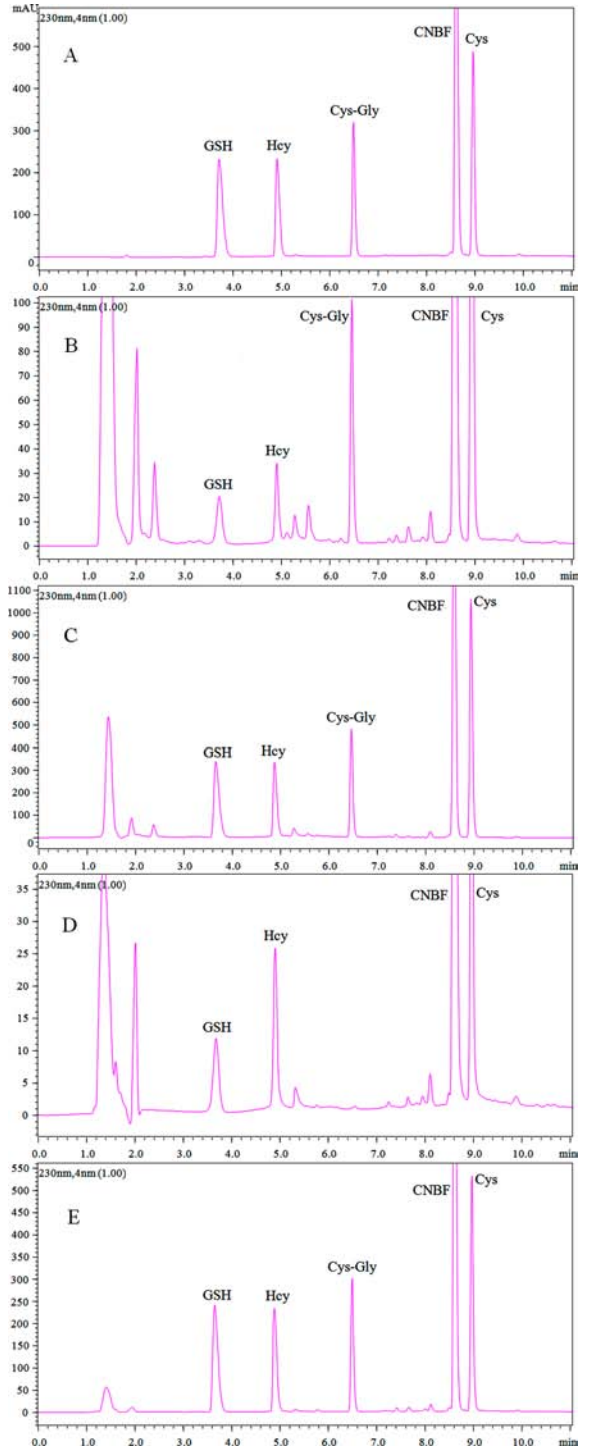

Figure 4. Chromatograms obtained from the reaction of CNBF with thiols (A, 50 μM of GSH, Cys, Hcy, and Cys-Gly; B, urine samples; C, urine samples with spiking 50 μM of GSH, Cys, Hcy, and Cys-Gly; D, saliva samples; E, saliva samples with spiking 50 μM of GSH, Cys, Hcy, and Cys-Gly). Chromatographic conditions: column, reversed-phase Kromasil ODS C_{18} column (250 mm × 4.6 mm i.d., particle size 5 μm); UV detection, λ = 230 nm; mobile phase, acetonitrile (A) and water with 0.1% (v/v) TFA (B). Gradient conditions: B, 0−5.0 min, a linear gradient starting from 70% to 20%; B, 5.0−8.0 min, 20%; B, 8.0−11.0 min, linear gradient from 20% to 70%; flow rate, 1.0 mL/min; 25 °C.

investigated. RSDs are from 1.75% to 3.62% for plasma, 1.85% to 3.84% for urine, and 2.00% to 4.08% for saliva.

3.5. Comparison of CNBF with Other Derivatizing Reagents. The comparison of CNBF with these reported derivatizing reagents is given in Table 3. In comparison to the ultraviolet derivatizing reagents, CNBF was superior to CMQT and BCPB in the method sensitivity but inferior to them in the derivatization velocity. Although the methods with AuNPs (Au nanoparticles) and TCDI (1,1′-thiocarbonyldiimidazole) as the derivatizing reagent were more sensitive than the present method, the derivatization times with them were much longer (2 h). In comparison to several fluorescent reagents, the present method was more sensitive than the method with NDA or 5-BMF as the derivatizing reagent but showed no superiority to that with OPA, mBrB, SBD-F, SBD-BF, ABD-F, MIPBO, and TMPAB-o-M. However, derivatization with SBD-F, SBD-BF, ABD-F, MIPBO, and TMPAB-o-M required more time or higher temperature than that with CNBF. mBrB has the one drawback that the reagent itself, the hydrolysis products, and the impurities are fluorescent, which may interfere with analysis.[46] Apart from thiols, OPA can also very easily react with primary amino compounds in biological samples, resulting in an increase of interferences in the form of amino−OPA adducts.[42] CNBF can easily react with thiols (25 °C, pH 8.0), but its reaction with amines needed higher temperature (60 °C) and higher pH (9.0),[43−45] indicating that CNBF has good selectivity for the analysis of thiols. In conclusion, this CNBF-derivatization based method showed superiority in relative sensitivity and selectivity. Besides, HPLC with a UV detector, known for its stability, universality, and low demand in terms of maintenance, belongs to the standard instrumentation of an analytical laboratory for clinical samples.[2,23] Therefore, the proposed method is an attractive choice for the determination of thiols in human biological fluids.

3.6. Analysis of Fluid Samples and the Validation by the Reference Method. The developed method was applied to quantification of GSH, Cys, Hcy, and Cys-Gly in plasma, urine, and saliva collected from five donors. The detected concentrations of GSH, Cys, Hcy, and Cys-Gly are given in Table 4. In the plasma samples, the concentrations were in the range of 8.75 to 26.50 μM, 86.45 to 124.25 μM, 2.50 to 10.57 μM, and 11.20−27.00 μM for GSH, Cys, Hcy, and Cys-Gly

Table 3. Comparison of the Derivatization Conditions and Detection Limit of the Derivatizing Reagents Reported for Determination of Thiols in Different Matrix[a]

anal. meth	thiol analytes	derivatizing reagent	derivatization conditions	matrix	detection limit	ref
CE-LIF	GSH, Cys, Hcy, Cys-Gly	5-BMF	RT, 10 min	human plasma, urine	0.061−0.156 μM	9

	04	1.25 ± 0.20		3.55 ± 0.70		0.98 ± 0.08		ND[c]	
	05	0.90 ± 0.11		1.24 ± 0.20		1.33 ± 0.12		0.55 ± 0.08	

[a]Each fluid sample was determined in triplicates. [b]The data was obtained with a reference method described in section 2.6. [c]Not detected.

respectively, with highest average concentration for Cys and lowest for Hcy. For urine samples, the concentration ranges were 1.43−12.11 μM, 56.75−72.81 μM, 0−2.45 μM, and 3.24−12.09 μM for GSH, Cys, Hcy, and Cys-Gly, respectively. As in saliva, the range values were 0.90−3.20 μM, 1.24−3.25 μM, 0.75−1.33 μM, and 0−0.55 μM for GSH, Cys, Hcy, and Cys-Gly, respectively. It can be concluded that the concentrations of total thiols in saliva were far lower than those in plasma or urine.

The data obtained with the reference method[19] is also given in Table 4. The data with two methods was compared, and significant differences were considered at the $P < 0.05$ level. The results showed that there were no significant differences

between the data ($P > 0.05$). Therefore, the data with the proposed method can be validated by the reference method.

Based on the reaction of CNBF with thiols, we developed a novel method for the determination of four physiologically important thiols, GSH, Cys, Hcy, and Cys-Gly, in plasma, urine, and saliva. The application of CNBF as a derivatization reagent seemed to be an attractive choice for the determination of thiols with TFA in mobile phase, which showed good separation of derivatized thiols from the interferences. The reaction of CNBF with thiols was rapid, required moderate reaction conditions, and led to stable products. In comparison to other derivatizing reagents for thiols, application of CNBF showed superiority in relative sensitivity, selectivity, and efficient derivatization procedure. The developed method was applied to quantification of four thiols in human biological fluids collected from five donors with the concentration range of 0−124.25 μM. This study provides a feasible HPLC method for the routine analysis of thiols required for clinical evaluation.

Supporting Information

ABSTRACT: Donkey milk has been recently revalued intensely due to its nutritional properties. Moreover, donkey milk has been proposed as an effective alternative food for some infants with cow milk allergy. Two fast analytical methods were proposed to detect the fraudulent practice of blending cow milk to donkey milk. Detection of cow α_{s1}-casein bands along the profiles of experimental donkey−cow milk mixtures analyzed by isoelectric focusing was adequate to estimate cow milk used as adulterant of donkey milk starting from 5% (v/v). An ELISA-based method using the antipeptide antibodies raised against the 1−28 sequence stretch of cow β-casein was also developed for an accurate definition of composition of donkey−cow milk mixtures. The presence of cow milk at levels as low as 0.5% (v/v) was detected in donkey−cow milk mixtures prepared at laboratory scale and assayed by ELISA.

KEYWORDS: *donkey milk, adulteration, antipeptide antibodies, cow milk allergy, PAGIF, immunoblotting, ELISA*

INTRODUCTION

After a 5000 year partnership between human and donkey in agricultural work, mechanization led to a sharp decline of the donkey population in the world. Indeed, donkey has remained important only for rural economies in semiarid and mountainous regions of the world.[1] Over the past few decades the asinine species has been included in projects on equid diversity preservation and donkey milk has been intensively studied as a food source in the human diet. Current worldwide donkey distribution and milk production have been recently reported.[2] In Europe, some hundreds of dairy donkey farms (30−50 donkeys in average per farm) are experiencing an innovative multifunctional system where a wide variety of activities are carried out, from agritourism and agritainment to health and beauty activities, besides milk production. They are mainly located in marginal areas of Italy, France, Portugal, Spain, Greece, Belgium, and Cyprus. A special value has been ascribed to donkey milk since ancient times. Recently, preliminary experimental evidence based on in vitro tests has indicated that donkey milk possesses unique properties. Thus, bioactive compounds were found in donkey milk, displaying a variety of potentially health promoting activities.[3−8] In addition, donkey milk has been reported to be a potential food for the immune recovery of aged consumers[9] and may exert beneficial effects in the prevention of atherosclerosis.[10] Furthermore, donkey milk has been proposed as an alternative dietary ingredient in children with cow milk allergy.[11,12] Basics of donkey management and milking procedures have been established.[13] Like other expensive unconventional milks (buffalo, camel, horse, etc.), also donkey milk (10−15 €/L) is a potential target for adulteration through the fraudulent addition of the cheaper and more readily available cow milk (about 0.5 €/L). Ascertainment of milk genuineness is an important topic in the dairy sector, mainly for commercial reasons.[14] However, it becomes crucial for safety reasons when donkey milk is proposed in the diet therapy of cow milk allergic subjects. Indeed, intake of donkey milk adulterated by cow milk, even in trace, can be hazardous to the health of very sensitive patients. Two analytical methods for the detection of cow milk in donkey milk had been recently proposed. One of these had been developed according to stereospecific analysis of triacylglycerol fraction from milks of different animal species.[15] The other method had been based on monitoring of the two most abundant whey proteins (α-lactalbumin and β-lactoglobulin) from cow milk using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry.[16] However, both these methods require expensive equipment and highly skilled operators, and the procedures for quantitative analysis are laborious and time-consuming. In addition, speciation analysis of donkey−cow milk mixtures based on the composition of the triacylglycerol fraction[15] can be impaired by adding defatted cow milk to donkey milk. On the other hand, the method based on the detection of cow α-lactalbumin and β-lactoglobulin[16] is fully reliable only if raw cow milk is used as adulterant, as whey proteins are susceptible to even mild heat treatments applied to milk, as previously reported.[17,18]

Immunoassay technology has been advantageously applied to dairy research since the early 1980s, leading to the development of a number of fast, sensitive, reliable, and user-friendly analytical methods.[19] Despite the overall complexity of the protein fraction in milk and dairy products, due to genetic variability, discrete phosphorylation, glycation, and limited hydrolysis by native milk proteinases, a single protein component could be selectively and sensitively recognized provided that the appropriate antibody preparation was used as

immunoreagent. Above all, definition of the composition of milk mixtures by immunochemical tools is a real challenge. As a rule, polyclonal antibodies raised against a specific milk protein also cross-react with the homologous counterparts included in milk from all of the other species. Consequently, cumbersome purification procedures, such as immunoabsorption and immunoaffinity chromatography, are required to avoid antibody cross-reactions. Alternatively, novel immunoreagents suited to milk speciation can be obtained by predetermining the antibody binding specificity, as allowed by the antipeptide antibody technology. Indeed, high levels of antibody species specificity can be attained using as immunogens peptides reproducing short sequence stretches within protein chains with species-specific features.

This work was directed to develop original, fast, and reliable analytical methods for the quantitative detection of cow milk in donkey milk. Two analytical approaches were planned. The first was based on the fact that cow α_{s1}-casein displays a p*I* different from that of donkey α_{s1}-casein, as described in a previous report.[20] The second aimed to develop an immunochemical assay using the antipeptide antibody preparation raised against the 1−28 peptide from cow β-casein, chosen as the immunoreagent according to its species-specific performances.[21]

MATERIALS AND METHODS

Protein Sequences and Determination of Homology Degrees. All of the milk protein amino acid sequences considered in the present work were drawn from the UniProtKB/Swiss-Prot database,[22] and their respective primary accession numbers were as specified in Table 1. In addition, the sequence marked as P11839 in UniProtKB/Swiss-Prot database was considered as sheep β-casein. Homology was calculated using the SIM alignment tool for protein sequences presently available in the ExPASy Web site,[23] according to the method used for comparative analysis of the protein sequences from milk of the animal species of dairy interest.[12]

Milk Sampling and Preparation of Milk Mixtures and Whole Casein. Raw cow milk was supplied by a local cattle farm (Savoia, Roccabascerana, Italy) and managed according to current sanitary regulations. Raw donkey milk from a private dairy donkey farm (Ciucolandia, Capestrano, Italy) was mechanically drawn according to the procedure previously described.[13] Standard mixtures of donkey milk containing 0.5, 1, 2, 5, 10, 20, 40, and 60% (v/v) of cow milk were prepared at laboratory scale. These milk mixtures as well as donkey milk and cow milk were subsequently centrifuged at 4500 rpm for 10 min at 4 °C using a Labofuge 400R equipped with a swinging bucket rotor 4 × 180 mL (Heraus, Germany), and the upper fat layer was manually removed. The skimmed milk mixtures and pure milk samples were diluted 1:5 in 50 mM NH_4HCO_3, pH 8.5, for competitive ELISA experiments whereas they were diluted with 9 M urea to a final concentration of 3.6 M urea for isoelectric focusing on polyacrylamide gel (PAGIF) analysis. Whole casein was recovered from defatted cow and donkey milk samples by adjusting pH to 4.6 with 1 M HCl under pHmeter control and centrifuging as described above for defatting. The humid pellet, after two washes with 10 mM of CH_3COONH_4 at pH 4.6, was dissolved at a final concentration of 70 mg/mL in 9 M urea containing 1% (v/v) β-mercaptoethanol and analyzed by immunoblotting.

Immunoreagents. The two antipeptide antibody preparations used to recognize cow β-casein and cow α_{s1}-casein were produced as described in previous works.[21,24,25] Apart from the peptide used as immunogen, reproducing a selected sequence stretch of either bovine β-casein or α_{s1}-casein, each antiserum was able to detect properly the parent protein. The antiserum developed against the 1−28 phosphopeptide of cow β-casein was kindly granted by Prof. F. Addeo (Department of Food Science, University of Naples, Portici, Italy).

Electrophoresis and Immunoblotting. PAGIF was performed essentially as previously described.[24] Aliquots of Pharmalyte (GE Healthcare, Uppsala, Sweden) 2.5−5.0, 4.5−5.4, and 4.0−6.5 were added to the polyacrylamide solution in the ratio 1.6:1.4:1 (v/v/v) to obtain a final pH gradient from 2.5 to 6.5 in the gel. The polyacrylamide solution was allowed to polymerize in the form of an ultrathin-layer gel (thickness, 0.25 mm). Gel prefocusing and protein separation were carried out on the PhastSystem apparatus (Pharmacia, Uppsala, Sweden). Coomassie Brilliant Blue G-250 staining was performed according to the procedure described by Blakesley and Boezi.[26] For immunoblotting analysis, the PAGIF profiles were transferred by capillary diffusion to a nitrocellulose paper previously rinsed in phosphate-buffered saline solution (PBS: 1.5 mM KH_2PO_4, 8.1 mM Na_2HPO_4, 136 mM NaCl, 2.7 mM KCl, pH 7.4). The paper was then held into blocking buffer (10% v/v heat-inactivated horse serum in PBS) for at least 1 h at room temperature. Immunodetection was carried out by incubating the paper with the appropriate rabbit antiserum at a 1:1000 dilution in blocking buffer for 1 h at room temperature and, after three washes with blocking buffer, with horseradish peroxidase-labeled goat anti-rabbit polyclonal antibodies (Bio-Rad, Hercules, CA) at a 1:2000 dilution in blocking buffer for 1 h at room temperature. For protein band detection, the nitrocellulose paper was placed in 10 mM Tris-HCl, pH 7.5, containing 0.5 mg/mL of 3,3-diaminobenzidine (Fluka, Buchs, Switzerland) and 0.06% (w/v) $NiCl_2$ hexahydrate (Fluka). To start the reaction between horseradish peroxidase-labeled goat anti-rabbit IgG antibodies and 3,3-diaminobenzidine, 100 μL of 30% (v/v) hydrogen peroxide was added to 20 mL of solution. Incubation of the nitrocellulose membrane was performed at room temperature with agitation and examined periodically until the protein bands became suitably dark (1 to 5 min). The reaction was stopped by rinsing the nitrocellulose membrane with distilled water.

Analysis of Donkey−Cow Milk Mixtures by Competitive ELISA. A 2 μg/mL solution of RP-HPLC purified bovine β-casein in 50 mM NH_4HCO_3, pH 8.5, was used to coat microtiter plates (cod. 3911, Falcon, Oxnard, CA). After overnight incubation at 4 °C and the saturation step, the wells were washed with PBS and then filled up with blocking buffer (10% v/v heat-inactivated horse serum in PBS) to

saturate the remaining sites for protein binding. Microplates were placed at 37 °C for at least 1 h in a humid atmosphere. They were emptied and kept at −20 °C, ready for immediate use. Each milk sample was serially diluted ($1{:}4^n$, n = 1 to 4 except for defatted cow milk sample, where n = 1 to 8) in 50 mM NH_4HCO_3 pH 8.5, and each dilution was analyzed in duplicate. 50 μL aliquots of the serial dilutions were introduced in each well, and then 50 μL of a 1:2000 (v/v) dilution of the antiserum in the blocking buffer was added. Maximal binding of the antibodies to the plate was determined by adding to the wells 50 μL of 50 mM NH_4HCO_3 pH 8.5 instead of milk sample dilution. After 1 h at 37 °C in a humid atmosphere, the wells were emptied and washed five times with PBS. A 100 μL aliquot of a 1:2000 (v/v) dilution of horseradish peroxidase-labeled goat anti-rabbit IgG polyclonal antibodies (Bio-Rad, Hercules, CA) was then added to each well. Following incubation for 1 h at 37 °C in a humid atmosphere and five washings with PBS, 100 μL amounts of a solution of tetramethylbenzidine (Sigma, Saint Louis, MO) 0.1 mg/mL in 50 mM citrate−phosphate buffer, dimethyl sulfoxide 10% (v/v), pH 5.0, containing 0.01% (v/v) hydrogen peroxide were added to each microtiter well. After 10−15 min at room temperature the reaction was stopped by adding 100 μL of 1 M H_2SO_4. The ELISA signals were recorded at 450 nm with a Benchmark microplate reader (Bio-Rad, Hercules, CA). The net ELISA absorbance value of each dilution was used for calculations. It was the difference between each mean value of ELISA absorbance and the mean ELISA signal given by pure cow milk. Data were elaborated according to the log/logit curve fit method of Microplate Manager III Data Analysis software (Bio-Rad, Hercules, CA). Pure cow milk was used as internal standard, and its cow β-casein content was assumed as 100. Accordingly, the cow β-casein amounts detected in donkey−cow milk mixtures were obtained as percentages of the amount of cow β-casein included in pure cow milk.

RESULTS AND DISCUSSION

Donkey Milk Proteins in Comparison to Cow Milk Proteins. Similarity between the protein components included in milk from two different animal species reflects generally the phylogenetic relationship between the two mammals.[12] Both donkey and cow are members of the same class and superorder, that is Mammalia and Laurasiatheria, but are classified in a different order, Perissodactyla and Artiodactyla, respectively. Apart from the total protein content estimated in the two milks (3.2% w/w in cow milk versus 2.2% w/w in donkey milk), the ratio of casein to whey protein is clearly different, being 80:20 in cow milk whereas it is 58:42 in donkey milk. Based on current information about the primary structure of the main milk proteins, the percentage homology between the primary structures of the main proteins from cow and donkey milk is reported in Table 1. According to these data, homology between cow and donkey milk proteins was limited compared to that found between the proteins from cow and water buffalo milk (on average, about 96%) or from cow and sheep milk (on average, about 91%), especially as regards caseins.

PAGIF Detection of Cow Milk in Donkey Milk. Significant differences had been found by comparing the PAGIF electrophoretic profiles of caseins from cow and donkey milk.[20] Most importantly, cow α_{s1}-casein and its donkey counterpart were clearly separated by PAGIF due to their different pI values. Indeed, by immunostaining the PAGIF profiles with polyclonal antipeptide antibodies directed against the 186−199 sequence stretch of bovine α_{s1}-casein, the C-terminal region of the protein, the parent α_{s1}-casein was recognized as a group of bands migrating in the low pH zone of the electrophoretic profile of cow milk, as previously reported.[26] Donkey α_{s1}-casein was identified as a group of bands migrating in the pH zone diametrically opposite to that occupied by cow α_{s1}-casein.[20] Intriguingly, cross-reactivity of the antipeptide antibody preparation toward donkey α_{s1}-casein indicated that the substitution of four amino acids and the insertion of one amino acid, as found in the C-terminal region of donkey α_{s1}-casein (Table 2), did not prevent antibody recognition of the donkey counterpart of the C-terminal region of cow α_{s1}-casein. The different location of cow and donkey α_{s1}-casein in the PAGIF profiles was exploited to detect adulteration of donkey milk by cow milk. As shown in Figure 1, eight mixtures of donkey milk containing different amounts

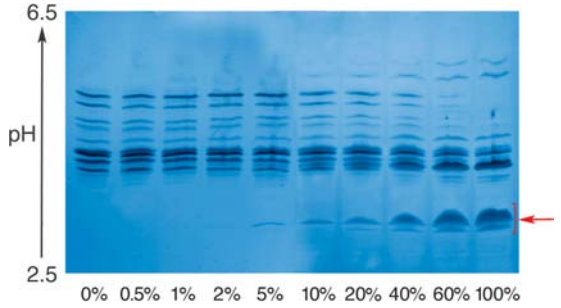

Figure 1. PAGIF analysis of donkey milk containing different percentages of cow milk (v/v) as reported. The gel area of cow α_{s1}-casein migration is indicated by the red arrow.

of cow milk were analyzed by PAGIF in addition to the two genuine milks. A group of protein bands focusing in the low pH gel zone was gradually detected in the profiles of the milk mixtures at increasing cow milk content from 5% v/v. These bands were selectively immunostained by the antipeptide antibodies directed against the 186−199 sequence stretch of bovine α_{s1}-casein (results shown in Figure S1, Supporting Information). Based on the results hitherto exposed, a direct PAGIF analysis of milk samples and Coomassie Brilliant Blue G-250 staining of the profiles proved to be effective in detecting more than 5% v/v of cow milk included in donkey milk using cow α_{s1}-casein as indicator of cow milk adulteration. Due to its rapidity, high-throughput, and cheapness, such a method can be usefully employed by competent authorities as a screening test of a large number of donkey milk samples. However, the method might not be sufficiently sensitive to detect trace amounts of cow milk, as required to guarantee safety of donkey milk designed for consumption by cow milk allergic patients. Immunostaining of the PAGIF profiles using antipeptide antibodies anti 186−199 bovine α_{s1}-casein could improve sensitivity of cow α_{s1}-casein detection with respect to Coomassie Brilliant Blue G-250 staining (results shown in

Figure S1, Supporting Information). Nevertheless, implementation of immunoblotting after PAGIF analysis, according to the method previously proposed for detecting cow casein in water buffalo milk,[24] would heavily affect quickness and simplicity of the analytical determinations. On the other hand, this antibody preparation was not suitable as an immunoreagent for developing an ELISA test to determine directly cow milk added to donkey milk because of its reactivity toward both cow and donkey α_{s1}-casein, simultaneously occurring in mixtures of cow and donkey milk.

ELISA Immunodetection of Cow Milk in Donkey Milk. In order to evaluate cow milk content in donkey milk samples by direct immunoassays, antibodies recognizing selectively any protein from cow milk were required. A broad library of antipeptide antibody preparations have been collected in our lab over about 20 years' work directed to the analysis of dairy products by immunochemical tools. In order to select immunoreagents suited for the specific detection of cow milk proteins in mixture with donkey milk proteins, the antipeptide antibody preparations directed against cow-specific sequence stretches of milk protein components were taken into consideration. According to previous results,[19,21] the antipeptide antibodies obtained by using the plasmin-released 1−28 phosphopeptide of cow β-casein as immunogen were able to recognize the parent β-casein from cow as well as water buffalo milk, but not from sheep and goat milk. Based on the 1−28 sequence stretch of β-casein from these four different animal species, the antibody binding specificity resulted to be strictly related to the amino acid residues located in positions 3, 9, and 12 of β-casein.[21] Similarly to sheep β-casein, donkey β-casein displayed three amino acid substitutions with respect to cow β-casein in the same positions 3, 9, and 12. Furthermore, the donkey N-terminal β-casein sequence included the insertion of six amino acid residues and two additional amino acid substitution. All of these differences are reported in Table 3, where the 1−28 sequence of cow β-casein was aligned with the homologous region of sheep and donkey β-casein to the best of juxtaposition.

Taken together, these findings suggested that the antipeptide antibodies raised against the 1−28 phosphopeptide of cow β-casein could be employed as a cow-specific reagent for the analysis of donkey−cow milk mixtures. To check this possibility, whole casein from cow milk was analyzed in comparison with whole casein from donkey milk by PAGIF and immunoblotting analysis using this antipeptide antibody preparation as immunoreagent. As shown in Figure 2, the two Coomassie Brilliant Blue G-250 stained profiles (panel A) reacted differently to the antibodies (panel B). A complex pattern of protein bands was recognized along the profile of whole casein from cow milk, as previously found.[21] By contrast, a very weak antibody cross-reaction was detected in the profile of whole casein from donkey milk. Occurrence of β-casein in donkey milk was verified by immunostaining the PAGIF

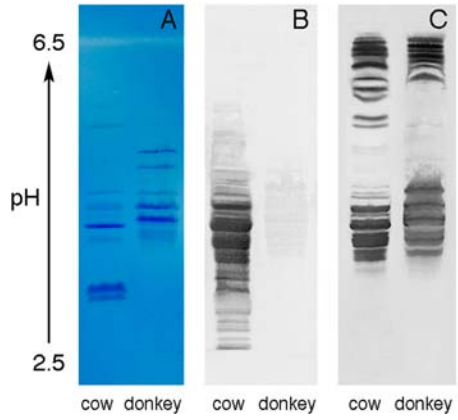

Figure 2. PAGIF analysis of whole casein from cow and donkey milks, as indicated. Panel A: aspecifical staining with Coomassie Brilliant Blue G-250. profiles with another antipeptide antibody preparation, produced using the peptide reproducing the 195−209 sequence of cow β-casein as immunogen (panel C). Specific immunostaining of donkey β-casein using the antibodies raised against the 195−209 sequence of cow β-casein had been already obtained by proteomic tools.[20] Nevertheless, antibody cross-reactivity toward donkey β-casein was unusual. By comparing the amino acid sequences of the C-terminal region of β-casein from cow and donkey milk, a significant sequence homology could be found only in the last four amino acids of the two primary structures (Table 4). Therefore, antibody ability in detecting donkey β-casein in addition to cow β-casein seemed to indicate that the antipeptide antibodies were mainly directed against the last four amino acid residues of the peptide reproducing the 195−209 sequence of cow β-casein. It has been generally agreed that a peptide including at least six amino acid residues of a protein sequence has to be used as immunogen to obtain antipeptide antibodies able to detect the parent protein,[28] but even a peptide reproducing a sequence stretch of five amino acid residues had proved to be effective.[24] Furthermore, it is worth noting that the presence of a proline residue affects peptide conformation and that the protein sequences containing proline residues are generally more exposed on the surface of the native protein than the other sequences, as previously described.[27] Accordingly, the proline residue included in the last four amino acid residues of the peptide used as immunogen might have forced the immune response toward the terminal peptide sequence and/or might support the exposition of the sequence in the native protein for antibody attainment. Finally, additional homology between different regions along donkey β-casein and the 195−209

sequence of cow β-casein might be involved in antibody recognition of donkey β-casein, most likely the 63−77 sequence stretch of donkey β-casein displaying a 40% homology with the 195−209 sequence of cow β-casein. Once cow specifity of the antipeptide antibodies raised against the 1−28 phosphopeptide of cow β-casein was ascertained by immunoblotting, as recommended in the literature,[28] an ELISA-based assay of cow milk in donkey milk could be developed. A typical ELISA curve obtained in response to pure cow milk is shown in Figure S2, Supporting Information. A linear relationship was found between the experimental values of the cow β-casein concentration determined by ELISA and the actual volume percentages of cow milk included in the standard donkey−cow milk mixtures prepared at laboratory scale. By plotting the cow β-casein amount detected in donkey−cow milk mixtures, reported as the percentage of that detected in pure cow milk, versus the volume percentage of cow milk included in donkey−cow milk mixtures, a straight line with a slope very near to 1 was typically obtained (Figure 3). As shown in the inset of Figure 3, additions as low as 0.5% (v/v) of cow milk to donkey milk could be successfully detected. These results showed that cow β-casein, as detected by the antipeptide antibodies directed against its 1−28 phosphopeptide, could be regarded as a suitable marker of foreign cow milk in donkey milk. In addition to current advantages of ELISA-based determinations in terms of performance and convenience, this method was especially valuable as it did not require any pretreatment of the milk sample, except for a simple centrifugation to separate the aqueous phase including proteins from the lipid fraction. Furthermore, cow milk, largely available on commercial market, can be currently used as internal standard. Finally, this method, using thermostable cow β-casein to trace cow milk, was able to provide reliable evaluation of the cow milk amounts added to donkey milk up to 0.5% (v/v), regardless of either heat treatments or other technological expedients, such as defatting, applied to cow milk used as adulterant, overcoming some limits of available methods with similar sensitivity levels.[15,16]

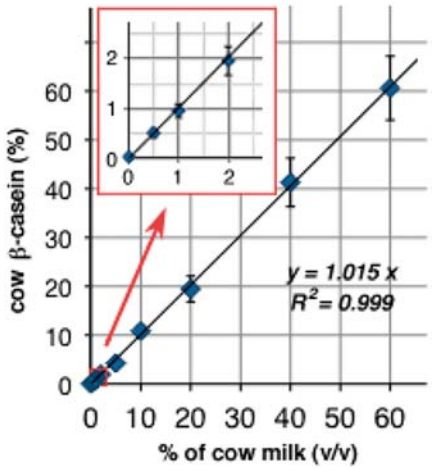

Figure 3. Analysis of donkey−cow milk mixtures by ELISA using the antipeptide antibodies raised against the 1−28 phosphopeptide of cow β-casein. The volume percentage of cow milk included in standard milk mixtures was placed in the *x*-axis. The cow β-casein amount detected in donkey−cow milk mixtures, reported as the percentage of that found in pure cow milk, was placed in the *y*-axis. The square of the diagram limited by red edges was magnified in the inset to emphasize the assay sensitivity. The estimated standard error of mean for concentration of each sample, calculated by using Microplate Manager III Data Analysis software (Bio-Rad), was graphically represented as *Y* error bar.

Determination of Aristolochic Acids by High-Performance Liquid Chromatography with Fluorescence Detection

Yinan Wang and Wan Chan*

Department of Chemistry, The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

ABSTRACT: Nephrotoxic and carcinogenic aristolochic acids (AAs) are naturally occurring nitrophenanthrene carboxylic acids in the herbal genus *Aristolochia*. The misuse of AA-containing herbs in preparing slimming drugs has caused hundred of cases of kidney disease in Belgium women in a slimming regime in the early 1990s. Accumulating evidence also suggested that prolong dietary intake of AA-contaminated food is one of the major causes to the Balkan endemic nephropathy that was first observed in the late 1950s. Therefore, analytical methods of high sensitivity are extremely important for safeguarding human exposure to AA-containing herbal medicines, herbal remedies, and food composites. In this paper, we describe the development of a new high-performance liquid chromatography coupled fluorescence detector (HPLC−FLD) method for the sensitive determination of AAs. The method makes use of a novel cysteine-induced denitration reaction that "turns on" the fluorescence of AAs for fluorometric detections. Our results showed that the combination of cysteine-induced denitration and HPLC−FLD analysis allows for sensitive quantification of AA-I and AA-II at detection limits of 27.1 and 25.4 ng/g, respectively. The method was validated and has been successfully applied in quantifying AAs in Chinese herbal medicines.

KEYWORDS: *aristolochic acids, high-performance liquid chromatography, fluorescence, cysteine, hydrogenolysis*

INTRODUCTION

Nephrotoxic aristolochic acids (AAs) are a mixture of nitrophenanthrene carboxylic acids derived from the herbal genus *Aristolochia* and are classified as members of the most potent carcinogens in the Carcinogenic Potency Database.[1,2] Major components of AAs include aristolochic acid I (AA-I) and aristolochic acid II (AA-II) that differ by a methoxy group, as shown in Figure 1. AA-containing herbs had been widely used as Chinese herbal medicines to treat tumors, rheumatism, snake bites, small pox, and pneumonia, until AAs were observed to be strong human carcinogens and nephrotoxins.[1−4] Currently, the use of AA-containing herbs is prohibited in regions including China, Hong Kong, Taiwan, Japan, U.S.A., U.K., and many European countries.[1,5]

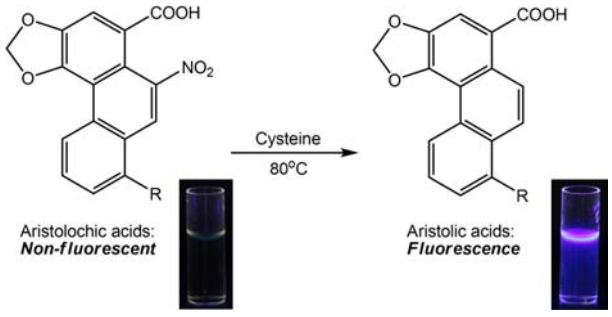

Figure 1. Cysteine-induced denitration of AA (AA-I, R = OCH_3; AA-II, R = H) forms of fluorescent aristolic acids for HPLC−FLD analysis.

Despite AA-containing herbs being banned from the markets worldwide, they are still available for sale on the Internet and misuse of AA-containing herbs exists.[6] For example, inadvertent substitution of *Stephania tetrandra* with AA-containing *Aristolochia fanghi* in the preparation of slimming drugs has caused about 100 cases of renal diseases in Belgium in the early 1990s.[1,4] The term Chinese herb nephropathy (CHN) has been used since then to describe this unique type of rapid progress renal fibrosis that is associated with prolonged exposure to AA-containing herbs or herbal products.[1,5] Cases of CHN were also reported in Australia, China, Hong Kong, Japan, Taiwan, U.K., and many other areas.[1]

Emerging evidence also suggested that chronic food poisoning through dietary intake of AA-contaminated flour, maize, and cucumber is responsible for the etiology of Balkan endomic nephropathy (BEN),[5−7] a peculiar renal disease that has been observed on thousands of farmers living alongside the Danube River for over the past 50 years. Because of the strong nephrotoxicity and potent human carcinogenicity of AAs and the reason that there is significant evidence showing that AAs are food/environmental contaminants,[7−10] analytical methods capable of detecting low concentrations of AAs in a complex matrix of herbal remedies, botanical products, and flour are highly necessary.

Current methods for AA determination include enzyme-linked immunosorbent assay (ELISA),[11] high-performance liquid chromatography with ultraviolet detection (HPLC−UV),[8−10] high-performance liquid chromatography with mass spectrometry (HPLC−MS),[11,12] capillary electrophoresis with ultraviolet detection (CE−UV),[13,14] capillary electrophoresis with electrochemical detection (CE−ECD),[15−19] and cyclic voltammetry.[20] As one of the most sensitive and selective analytical tools, the application of a fluorescence detector (FLD) on AA determination is only made possible recently by

converting the non-fluorescing AAs into their corresponding aristolactams that fluoresce.[2,10] However, these methods suffer from the drawbacks that individual samples have to be analyzed twice before the AA content can be determined. The reason underlying this is that the products from the derivatization reaction, i.e., the aristolactams, exist naturally in high abundance in the AA-containing herbs. The concentrations of endogenous aristolactams in the underivatized sample extracts must be determined and deducted from the total aristolactam levels in the derivatized sample extracts before the AA concentrations in the herbal samples can be elucidated. Consequently, although the developed high-performance liquid chromatography with fluorescence detection (HPLC−FLD) methods are sensitive, the necessities of duplicated analysis for a single sample rendered these methods inefficient for AA determination.

Herein, we report a novel HPLC−FLD method for the sensitive and efficient determination of AAs. The method makes use of cysteine-induced hydrogenolysis of AAs, in which the fluorescent-inhibiting nitro group is replaced by hydrogen and allows for sensitive and selective fluorometric determination of the otherwise non-fluorescing AAs by HPLC−FLD.[21] To the best of our knowledge, the application of the thiol-induced hydrogenolysis converting non-fluorescing nitroaromatics into fluorphores for their quantitative analysis by HPLC−FLD has not been reported before. Our proposed method offering superior sensitivity was validated and has been successfully applied in quantifying AAs in Chinese herbal medicines.

EXPERIMENTAL SECTION

Chemicals. All chemicals and reagents of the highest purity available were used without further purification, unless noted otherwise. AA (96% purity), a 1:1 mixture of AA-I and AA-II, was purchased from Acros (Morris Plains, NJ). Alanine, cysteamine, L-cysteine, cysteinylglycine, glutathione (GSH), and 2-mercaptoethanol were obtained from Sigma (St. Louis, MO). *Fructus Aristolochiae*, *Herba Aristolochiae*, *Aristolochiae mollissima*, *Radix Aristolochiae*, and *Aristolochiae cinnabarina* were purchased from the National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). *Herba Asari* and *Akebia Stem* were obtained from local Chinese drug stores in Hong Kong. HPLC-grade acetonitrile and methanol were purchased from Tedia (Fairfield, OH). Water was produced by a Milli-Q Ultrapure water purification system (18.2 MΩ, Millipore, Billerica, MA).

Sample Preparation. Herbal medicines and herbal preparations were powdered and sieved (size smaller than 100 μm) prior to analysis. Approximately 50 mg of the powdered samples were accurately weighted and extracted with 5.0 mL of methanol by sonication. After 30 min of sonication at 50 °C, 100 μL of the sample extracts were mixed with 900 μL of the denitrating reagent comprising 50 mM cysteine in potassium phosphate buffer (50 mM, pH 8.0). The reaction was conducted by heating the reaction mixture at 80 °C for 2 h. The cysteine-treated samples after being cooled to room temperature were centrifuged at 13 800 rpm for 5 min before the supernatant was transferred to a HPLC vial for HPLC analysis.

HPLC Analysis. HPLC analysis was conducted on an Agilent 1100 HPLC system coupled with a diode array detector (DAD) and a FLD connected in series (Palo Alto, CA). The DAD was set to monitor the UV absorption of the eluate at 254 nm, whereas the excitation and emission wavelengths for the FLD were set at 254 and 390 nm, respectively. A total of 10 μL of the cysteine-treated sample extract was injected into a Zorbax Eclipse XDB-C8 column (150 × 4.6 mm, 5 μm, Agilent). The HPLC mobile phases consisted of 20 mM, pH 7.0 ammonium acetate (A) and acetonitrile (B). A gradient elution program at a flow rate of 0.70 mL/min was applied to analyze the cysteine-treated samples. The solvent gradient was started from 10% B, programmed to 60% in 10 min, which was then ramped rapidly to 100% B in 0.1 min, and maintained 100% B for 5 min before reconditioning to 10% B for 8 min.

Calibration. A stock solution mixture of AA-I and AA-II each at 240 μg/mL was prepared in methanol and stored at −20 °C before use. Working standard solution mixtures of AA-I and AA-II of concentrations of 0.096, 0.24, 1.20, 2.40, and 4.80 μg/mL were prepared by diluting the stock solution with methanol. The calibration standard solutions were prepared by mixing 100 μL of the working standard solutions with 900 μL of the denitrating reagent, reacting, and HPLC analyzing as described above. Calibration curves were established by plotting the peak areas of the denitrated AAs against the AA concentrations in the calibration standard solutions.

Method Validation. The optimized method was also validated for analytical sensitivity, precision, and accuracy. The limit of detection (LOD) and limit of quantification (LOQ) were established as the amount of analyte in the blank sample extract that generated a signal 3 and 10 times the signal-to-noise ratio, respectively.[22,23] The method precision was evaluated by analyzing herbal extracts spiked with AAs at three different concentrations (0.096, 1.92, and 4.80 μg/mL), on the same day (n = 7) and over separate days in a month (n = 7). The method accuracy was determined by spiking AAs at the three stated concentrations to the blank herbal sample, processed, and analyzed as described above.

Method Comparison. The method accuracy was further gauged by direct liquid chromatography−mass spectrometry (LC−MS) analysis of AAs in the underivatized sample extracts on a Waters Acquity ultra-performance liquid chromatograph (UPLC) coupled with a Xevo G2 Q-TOF mass spectrometer with a standard electrospray ionization (ESI) interface (Milford, MA). AAs were resolved with a Waters BEH C18 column (50 × 2.1 mm, 1.8 μm) eluted with the following gradient of methanol in 20 mM ammonium acetate at a flow rate of 0.35 mL/min and 40 °C: 0−7 min, 1−40%; 7.1−9 min, 40−100%; 9−12 min, 100%; and 12.1−15 min, 1%. The LC eluate was analyzed by positive ESI−MS with the following parameters: capillary voltages, 3 kV; cone voltages, 25 V; desolvation temperature, 400 °C; and source temperature 120 °C. The peak areas of the pseudo-molecular ion ($[M + NH_4]^+$) of AAs (m/z 359 for AA-I and 329 for AA-II) were adopted quantifying AAs in the sample extracts. The results obtained from LC−MS analyses were compared to that obtained by HPLC−FLD analyses to evaluate the accuracy of the proposed method.

RESULTS AND DISCUSSION

Fluorometric Properties of AAs. Aromatic compounds generally fluoresce because of the presence of delocalized π electrons. However, the fluorescence of nitroaromatic hydrocarbons is not observed.[24] It is believed that the existence of a low-lying n → π* electronic transition in nitroaromatics that favors molecular relaxation by intersystem crossing the competing relaxation by fluorescence is therefore inhibited.[24]

AAs, although being rigid polycyclic aromatics, do not fluoresce.[2] The presence of an electron-withdrawing $-NO_2$ substituent inhibits their molecular fluorescence and, thus, hinders their fluorometric detections. Once the fluorescent inhibiting nitro group of AAs has been removed, the fluorescence of denitro AA products could be "turned on" to allow for sensitive and selective detection of AAs. To test this, we produced aristolic acids by reacting the mixed standard of AA-I and AA-II with cysteine and analyzed the reaction mixture by HPLC−FLD.

Characterization of the Cysteine-Induced Hydrogenolysis Product of AAs. Figure 2 depicts the chromatograms obtained from analyzing the underivatized (A and B) and cysteine-treated (C and D) AA-I and AA-II mixture. The HPLC analysis revealed the cysteine treatment of AAs indeed produced two fluorescing products at chromatographic

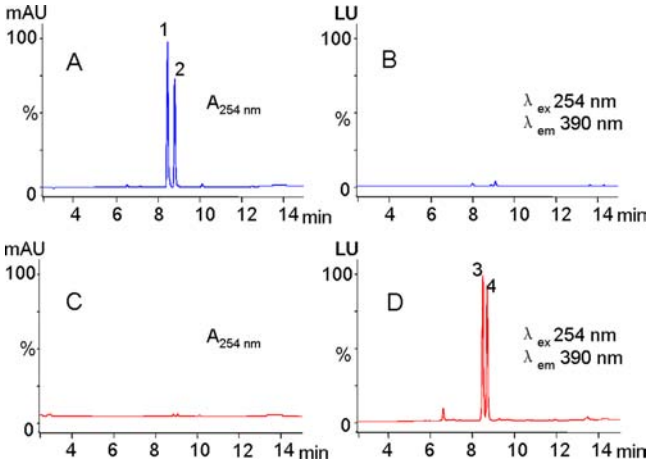

Figure 2. Typical chromatograms from HPLC analysis of underivatized (A, DAD trace; B, FLD trace) and cysteine-treated (C, DAD trace; D, FLD trace) AAs. Peaks 1, 2, 3, and 4 correspond to AA-II, AA-I, aristolic acid II, and aristolic acid I, respectively.

retention times of 8.71 and 8.91 min (Figure 2D), with their corresponding emission maxima at 385 and 390 nm, respectively (Figure 3A). UV absorbance measurements of

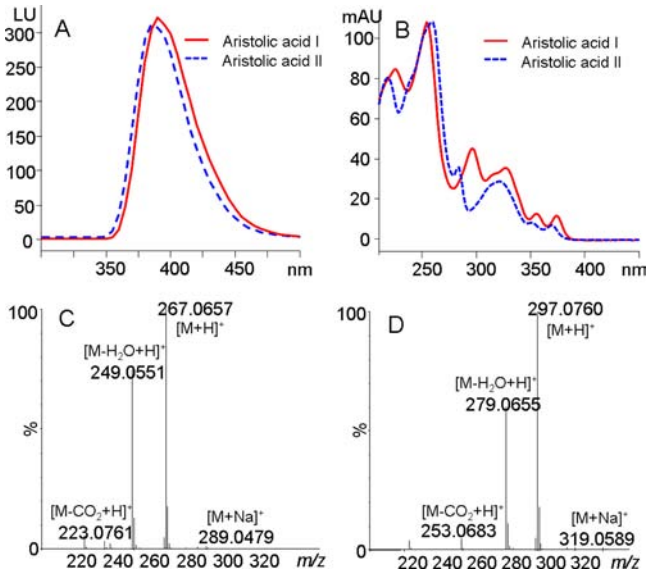

Figure 3. (A) Fluorescence emission and (B) UV absorption spectra of aristolic acids. (C and D) High-accuracy MS spectra of aristolic acid II and arstiolic acid I, respectively.

the chromatographic peak at 8.71 min revealed absorption maxima at 218, 258, 284, 320, 350, and 370 nm (Figure 3B). A similar UV absorption spectrum was also observed for the chromatographic peak at 8.91 min, with absorption maxima at 226, 254, 296, 326, 356, and 374 nm (Figure 3B).

High-accuracy MS analyses of the HPLC eluate collected at retention times of 8.71 and 8.91 min showed $[M + H]^+$ ions at m/z 267.0657 (Figure 3C) and m/z 297.0760 (Figure 3D), respectively. The close correlation between the measured (267.0657 and 297.0760) and theoretical (267.0657 and 297.0763) m/z values indicated that the fluorescing products were aristolic acid II ($C_{16}H_{11}O_4$) and aristolic acid I ($C_{17}H_{13}O_5$), respectively.

Selection of a Suitable Hydrogenolysis Reagent. As the basis for our method, Priestap and Barbieri recently reported that cysteine and GSH can induce hydrogenolysis of AAs at physiological relevant conditions, producing aristolic acids as the metabolites (Figure 1).[21] Aristolic acids, AAs with the fluorescent inhibiting nitro group replaced by hydrogen, exhibit fluorescence properties that allow for sensitive determination of AAs by spectrofluorometry (Figure 1).

With the hypothesis that other thiol-containing compounds may also be candidate denitrating reagents, cysteamine, cysteinylglycine, GSH, and 2-mercaptoethanol were investigated for their capabilites on producing the aristoloic acids from AAs. Our results showed that all of the tested thiol-containing reagents are capable of inducing AA hydrogenolysis, with cysteine being the most efficient reagent in removing the nitro group of AAs (Figure 4). Cysteine was therefore chosen as the hydrogenolysis reagent in this study.

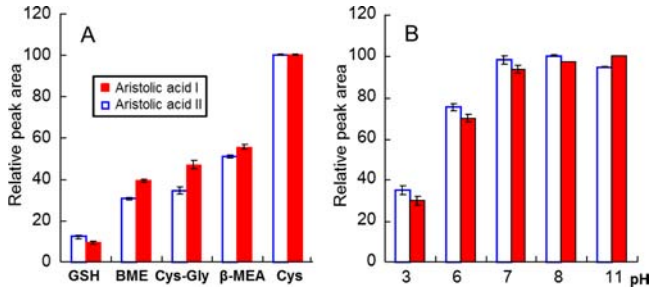

Figure 4. (A) Relative capability of some common thiol-containing compounds in inducing AA denitration and (B) effect of pH on the extent of cysteine-induced AA denitration. GSH, glutathione; BME, 2-mercaptoethanol; Cys-Gly, cysteinylglycine; *β*-MEA, cysteamine; and Cys, cysteine.

As an indirect approach to investigate the mechanism underlying the AA denitration reaction, we have also reacted AAs with alanine, an amino acid similar to cysteine but without the thiol functional group. Our results showed that no aristolic acids were produced in the alanine-catalyzed reaction, indicating that the thiol functional group is essential for the denitration process. Thus, we believed that the thiol functional group is participating in the electron transfer processes, which lead to the hydrogenolysis of AAs, producing the fluorophoric aristolic acids.

Optimization of the AA Hydrogenolysis Conditions. After the denitrating reagent was selected, the next step was to optimize the reaction conditions for AA denitration. Specifically, the formation of the aristoloic acids at different cysteine concentrations, pH values, temperatures, and reaction times were investigated. When the cysteine concentrations (from 10 to 150 mM) and pH (from 3.0 to 11.0) were changed in different reactions and the peak areas of aristolic acids in HPLC−FLD analyses were monitored, it was found that cysteine at 50 mM (Figure 5) and in pH 8.0 (Figure 4) is the most efficient for AA denitration. It is worth noting that the denitrating reaction is favored at alkaline conditions. This observation supports our proposed hydrogenolysis mechanism that the conjugated base of cysteine RS^- (pK_a = 8.36) initiated the AA denitration reaction and that the mechanism underlying the cysteine-induced denitration reaction appears to be

$$Ar{-}NO_2 + RS^- \rightarrow Ar{-}NO_2^{\bullet -} + RS^{\bullet}$$

dx.doi.org/10.1021/jf501609j | J. Agric. Food Chem. 2014, 62, 5859−5864

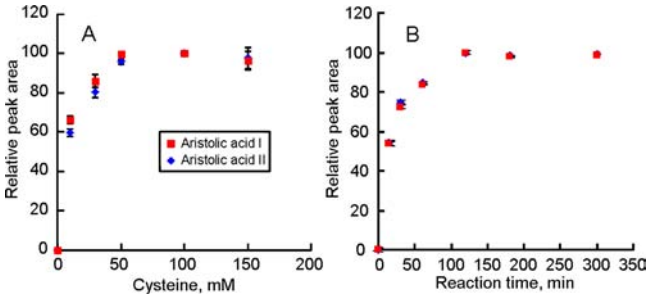

Figure 5. Influence of the (A) cysteine concentration and (B) reaction time on the denitration reaction of AAs. The data represent the mean ± standard deviation (SD) for three independent experiments with AAs at 4.80 μg/mL.

$$Ar{-}NO_2^{\bullet -} \rightarrow Ar^{\bullet} + NO_2^{-}$$

$$Ar^{\bullet} + H_2O \rightarrow - Ar{-}H + {}^{\bullet}OH$$

The influences of the reaction time and temperature on the extent of hydrogenolysis were studied over 1−5 h and from 25 to 80 °C, respectively. Our results showed that a 2 h reaction (Figure 5) at 80 °C (Figure 6) gave the best detector response.

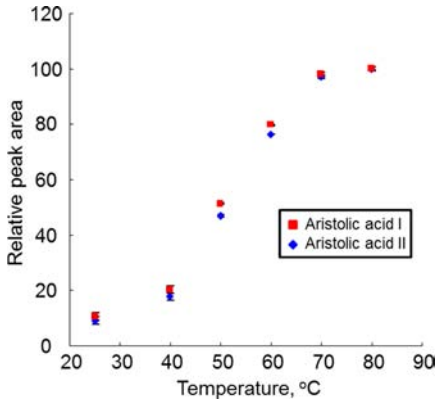

Figure 6. Influence of the reaction temperature on the cysteine-induced denitration reaction of AAs. The data represent the mean ± SD for three independent experiments with AAs at 4.80 μg/mL.

The optimized parameters above were selected and used in all studies. Under the developed hydrogenolysis conditions, the reaction yield of aristolic acid I and aristolic acid II from denitration of AA-I and AA-II were determined to be 95.2 and 96.4%, respectively.

Calibration and Method Validation. Calibration curves were constructed using standard solution mixture of AAs in triplicate reactions, with the concentrations of AA-I and AA-II ranging from 0.096 to 4.80 μg/mL. Depicted in Figure 7A is a typical chromatogram obtained from HPLC−FLD analysis of the reaction mixture containing AA-I and AA-II at 0.192 μg/mL. The peak areas of aristolic acids increased linearly over this concentration range, with r^2 values better than 0.9992. Table 1 summarizes the calibration slopes, intercepts, and coefficients of determination for the AAs determined in a calibration experiment.

The LODs defined as the concentrations of AA-I and AA-II that generated a signal 3 times the signal-to-noise ratio were 0.271 and 0.254 ng/mL,[22,25] respectively, corresponding to a method detection limit of 27.1 ng of AA-I and 25.4 ng of AA-II per gram of herbal medicines (Table 1). The LODs obtained

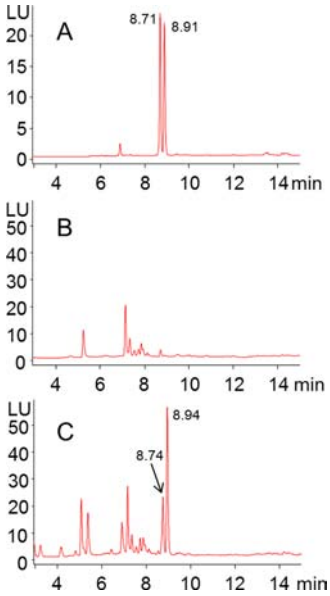

Figure 7. Typical chromatograms obtained from HPLC−FLD analyses of cysteine-treated AA-I (0.192 μg/mL) and AA-II (0.192 μg/mL), (A) standard mixture and (B) underivatized, and (C) cysteine-treated extracts of *Herba Aristolochiae* (*Tianxianteng*). The retention times of aristoic acid II and aristolic acid I were 8.7 and 8.9 min, respectively.

Table 1. Linear Regression Parameters of the Calibration Curves, Precision, Accuracy, and LOD of the Developed HPLC−FLD Method

	AA-I	AA-II
linear range (μg/mL)	0.096−4.80	0.096−4.80
slope	467.69	507.81

LOD (ng/mL)	0.271	0.254
LOD (ng/g)[a]	27.1	25.4

[a]The LOD is the sample extract based on 50 mg of sample.

by the HPLC−FLD method are not differentiated from the existing LC−MS/MS (0.14−250 ng/mL)[15,16] and HPLC−FLD methods (0.39−26.0 ng/mL).[2,10]

The intra- and interday reproducibility of the developed method were determined by evaluating three individual reactions containing a mixture of AA-I and AA-II. The relative standard deviations for the intra- and interday reproducibility were less than 1.48 and 2.95%, respectively, at the tested concentrations (0.096, 1.92, and 4.80 μg/mL). The method accuracy as determined by spiking AAs at the three stated concentrations to blank herbal samples, cysteine treating, and HPLC analyzing was less than 8.5% deviated from the true values. The results of the reproducibility and accuracy of the HPLC−FLD method are summarized in Table 1. The robustness and high analytical precision of the data demonstrated a good performance of the HPLC−FLD method for AA determination.

HPLC−FLD Quantification of AAs in Herbal Medicine. The developed method combining cysteine-induced denitration

Akebia Stem (*Mutong*)[c]	<LOD	<LOD	<LOD	<LOD

[a]The data represent the mean ± SD for three independent determinations. [b]Sample extracts were 10-fold diluted before the HPLC−FLD analysis. [c]Five samples of different origins from local drug stores in Hong Kong.

and HPLC−FLD analysis was applied for the determination of AAs in representative Chinese herbal medical samples. A total of 15 representative herbal samples were analyzed by the proposed HPLC method. Among the tested samples, five showed positive identification of AA-I and AA-II and *Aristolochiae mollissima* was found to contain the highest AA concentration (Table 2). Figure 7 shows the representative chromatograms obtained from HPLC analysis of underivatized (Figure 7B) and cysteine-treated (Figure 7C) sample extracts of *Herba Aristolochiae*. In agreement with previous studies, the concentration of AA-I is significantly higher than that of AA-II in all of the tested herbal medicine, which show a positive identification of AAs.

It is worth noting that the products from the cysteine-induced hydrogenolysis of AAs, the aristolic acids, were detected in only cysteine-treated sample extracts but none of the untreated samples. This observation implies that aristolic acids do not exist naturally in the tested herbal medicine and were only generated from hydrogenolysis of AAs. The absence of aristolic acids in herbal samples allows for AA quantification in a single HPLC analysis. In contrast to previous methods quantifying AAs by reducing AAs to aristolactams that require duplicated analyses of both the derivatized and underivatized sample extracts,[2,10] the current method has the advantage of being a more efficient and higher sample throughput for AA determination.

Method Comparison. The results from the HPLC−FLD analyses were also compared to that obtained from LC−MS analyses. Table 2 shows the result from LC−MS analysis of the sample extracts. No statistical difference was observed in the AA concentrations measured using the two methods. The mean deviation of the AA concentrations by the two methods was 4.89% for AA-I and 0.15% for AA-II, with no data pair difference exceeding 12%. With the strong correlation between the two methods, we believe that the newly developed HPLC−FLD method can accurately determine AA concentrations.

In conclusion, we have developed a new HPLC−FLD method for the sensitive and efficient detection of carcinogenic and nephrotoxic AAs. The method makes use of a novel cysteine-induced denitrating reaction converting the non-fluorescing AAs into aristolic acids that strongly fluoresce. This new derivatization methodology allows for fluorescence detection and quantification of AAs with high sensitivity. The method was validated for its accuracy, precision, and applied in quantifying AAs in herbal medical samples. It is believed that the developed HPLC−FLD method will find wide applications in detecting AAs in herbal preparations and food composites that are suspected to be AA-contaminated.

ABSTRACT: In this work, the influence of the electric field frequency and solids content on the degradation kinetics of ascorbic acid during ohmic heating of acerola pulp and acerola serum was investigated. The degradation percentage of ascorbic acid in the pulp after 120 min of heating varied between 12 and 17%. For the serum, the degradation percentage was in the range of 13 and 18%. The results were fitted to the first-order model, and the kinetic rate constants ranged from 1.1 to 1.6 × 10^{-3} min^{-1} and from 1.1 to 1.5 × 10^{-3} min^{-1} for pulp and serum, respectively. *D* values ranged between 1480 and 2145 min for the pulp and between 1524 and 1951 min for the serum. A distinct behavior between the kinetic parameters of the pulp and serum in electric field frequencies ranging from 10 to 1000 Hz indicates that the presence of distinct amounts and types of solids might affect the rate of the electron transfer in electrochemical reactions. These variables may also affect the polarization process stimulated by the oscillating electric field. The non-achievement of the equilibrium of the polarization process may have an influence on oxidation reactions, affecting the predisposition to hydrogen donation from the ascorbic acid molecule.

KEYWORDS: *ohmic heating, ascorbic acid, electric field frequency, polarization, solids content*

INTRODUCTION

Increasing consumer interest for nutritive fresh-like food products is driving the development of emerging processing technologies to ensure food safety and high nutritional and sensory properties. Ohmic heating (OH) is one alternative heat treatment where an alternating current (AC) is passed through food materials, thereby leading to heat generation.[1,2] This technology is particularly suitable for viscous products and liquid−particulate food mixtures because the heat is generated inside the food product.[1] It allows for processing at the rate of high-temperature, short-time (HTST) processes, but without the limitation of conventional HTST methods relative to heat transfer to particulates.[2]

For some years, it was presumed that the effects of the OH during food pasteurization and sterilization were solely thermal and that the applied electric field had no effect on biological cells and bioactive compounds.[3] However, some studies have shown that non-thermal effects exist within the range of moderate electric field (MEF) strengths associated with OH.[4−9] From this standpoint, the interaction of electric fields with food at the molecular, cellular, and tissue levels is important and needs to be evaluated. The effects of MEF treatments on bioactive components of foods have not been always considered, and the precise mechanism of MEF-induced changes is still not deeply understood.

In OH devices, the signal is an alternating bipolar current. When an electric field is applied to a sample, the molecules of the sample attempt to align themselves with the oscillating electric field in a process known as polarization. The electronic polarization is the displacement of electrons of atoms with respect to the nucleus, and the atomic polarization is the displacement of the atomic nuclei within the molecules.[10] When a low-frequency alternating voltage is used, orientational movements of molecules that arise from the polarization process are slow and molecules have enough time to move and rotate in the field. However, when a high-frequency alternating voltage is applied, movements of molecules that arise from the polarization process become faster and may not be accomplished. The polarization depends upon the relaxation time of the molecular dipoles, which is, in turn, influenced by the molecular weight, mobility of the molecules, and temperature.[11]

This work aimed to study the impact of MEF processing conditions during OH on the stability of bioactive compounds in food systems. Regardless of specific motivations or process objectives, it is of fundamental scientific interest to understand the kinetics of inactivation under various processing conditions, so that future processes may be designed with a full understanding of these effects. In a previous study, the effects of the electric field frequency on ascorbic acid degradation and color changes in acerola pulp were evaluated.[12] The objective of this study was to compare the degradation kinetics of the

acerola pulp and the acerola serum to investigate the influence of the presence of solids when using different frequencies. Thus, our specific objectives were (1) to conduct experimental studies with acerola serum at different electric field frequencies (from 10 to 10^5 Hz) and (2) compare these results to those previously reported by Mercali et al.[12] to obtain a better understanding of the influence of solids content on the precise mechanism of MEF-induced changes.

MATERIALS AND METHODS

Chemicals. Standard L-ascorbic acid with a purity of 99.7% and *meta*-phosphoric acid with a purity of 33.5−36.5% were obtained from Fisher Scientific Co. (Fair Lawn, NJ) and Sigma-Aldrich (St. Louis, MO), respectively. Potassium phosphate monobasic was purchased from Sigma-Aldrich (St. Louis, MO). Deionized water was used throughout.

Acerola Pulp. Acerola pulp, supplied by EcoFruits Company (South Jordan, UT), was received frozen and was stored immediately at −18 °C. The product had an initial vitamin C content of 1657 ± 45 mg/100 g.

Samples were thawed before each experiment by immersion in cold water. For acerola pulp, the experiments were conducted immediately after thawing. For the serum, thawed samples were then centrifuged (3000*g* at 5 °C for 10 min) and the supernatant fraction was used immediately for conducting the experiments. The ratio between the serum and pulp was approximately 0.7 (w/w). The total solids contents of the pulp and serum were 12.8 and 9.9 g/100 g, respectively. The pulp was characterized as a high-acid product with a pH of 3.3 ± 0.3. The initial temperature of the samples before starting the heating experiments was approximately 10−13 °C.

OH Process. The OH apparatus used to conduct the experiments was comprised of a function generator (Tektronix, Inc., model AFG3252, Richardson, TX), a power amplifier (Industrial Test Equipment, model 500A, Port Washington, NY), an Agilent 34970A data acquisition unit and HP BenchLink Data Logger software (Agilent Technologies, Inc., Palo Alto, CA), a computer, and an ohmic cell. A more complete description of the OH setup can be found elsewhere.[12] The temperature was measured by two type-T thermocouples: one located close to the electrode and the other located away from the electrodes. The difference between the two measurements was lower than 2 °C. The ohmic cell (9.9 cm of height) consisted of a 500 mL glass vessel with a water jacket. It had a lid to prevent evaporation from the product. The electrodes were made of titanium and curved to conform to reactor dimensions. The maximum interelectrode gap was 7.5 cm, and the minimum gap was 5.7 cm. The electrode height was 5.0 cm. The product was stirred using a magnet inside the cell and a magnetic stirrer plate (Fisher Scientific, Model Isotemp, Fair Lawn, NJ). The velocity of the agitation is an important factor to be considered because it has influence on the amount of oxygen incorporated in the product. In this manner, the velocity of the agitation of both products was matched to eliminate this variable during the experiments (500 rpm for the pulp and 350 rpm for the serum). Five different electric field frequencies (FQs) were studied: 10, 10^2, 10^3, 10^4, and 10^5 Hz.

The kinetic experiments were conducted at 85 °C for up to 2 h. A critical consideration in such experiments (to ensure that an effect may be attributed to an electric field effect) is the need to maintain the same temperature history for both ohmic and conventional treatments. OH has its unique electrical heating mechanisms and temperature histories that are fundamentally different from the ones of the conventional process. To be able to match the time−temperature histories between electric field treatments and thermal controls, OH experiments were conducted using a controlled temperature cooling water in the jacket (in actual practice, it used 30 V and 75 °C water in the jacket simultaneously). In contrast, because conventional heat treatment lacked an internal energy source, the jacket was maintained at the test temperature (85 °C). This procedure allowed for the evaluation of the non-thermal effects of electricity because the temperature histories for conventional and ohmic treatments were the same. Sample plots of the thermal histories for OH and conventional heating (Figure 1) for acerola serum show that we were able to closely

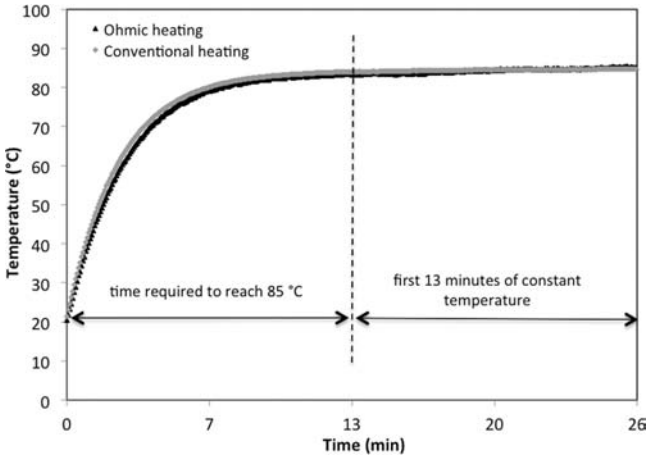

Figure 1. Time−temperature histories (the first 25 min of heating) of the ohmic and conventional treatments for acerola serum, showing closely matched thermal histories.

match temperature histories. Figure 1 represents the temperature measured close to the electrode. Time−temperature histories reported for acerola pulp showed a similar plot behavior.[12]

A model was developed to estimate the average electric field strength by solving Laplace's equation within the vessel domain. Figure 2 shows average electric field distribution within an ohmic cell when

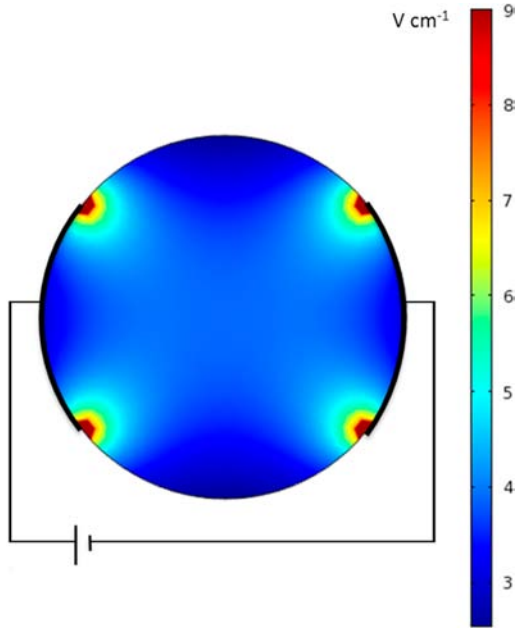

Figure 2. Average electric field distribution within the ohmic cell (cross-section) when 30 V is applied.

30 V is applied. The electric field within most of the cell is reasonably uniform, except for the electrode edges. The model did not account for the presence of the magnet and agitation. The agitation itself may not make a lot of difference unless the shape of the liquid surface is greatly changed by the agitation. The magnet will alter the local field, but the average field will likely be quite unaffected. In this manner, the assumed field strength was considered realistic.

The time zero was set when the sample reached the desired holding temperature. Samples were withdrawn at various heating times (0, 20,

40, 60, 80, 100, and 120 min). Determination of ascorbic acid levels was carried out immediately after the heating experiments.

Conventional Heating Process. The conventional heating process was conducted in the ohmic cell without an electric field. The samples were heated by passing hot water through the jacket using a thermostatic water bath (Brookfield Engineering Laboratories, model EX-100, Middleboro, MA). The kinetic experiments were conducted at the same temperature (85 °C), and samples were collected at the same heating times ranging from 0 to 120 min.

Determination of the Ascorbic Acid Content. The ascorbic acid content was quantified using high-performance liquid chromatography (HPLC, Hewlett-Packard, HP Agilent 1100 system, Norwalk, CT), reverse C_{18} Luna (5 μm, 250 × 4.6 mm, Phenomenex, Torrance, CA), and a diode-array detector (254 nm). The detailed methodology can be found elsewhere.[12]

Extraction of ascorbic acid was carried out adding *meta*-phosphoric acid solution to the samples. The mixture was homogenized for 30 s and centrifuged (1500*g* for 5 min). The supernatants were filtered through a 0.45 μm polytetrafluoroethylene (PTFE) membrane, diluted, and injected into the HPLC system. Samples were protected from light and kept on ice during all procedures.

Determination of the Kinetic Parameters. Traditionally, degradation of vitamin C in foods during thermal processing and storage has been described in terms of first-order kinetics and the Arrhenius equation.[13−16] Because the data seemed to follow a simple linear decrease, the zero-order kinetics was also considered. Then, a comparison between both models was carried out, and the model that better fit the experimental values was chosen to describe changes in ascorbic acid concentrations in acerola pulp during heating.

The zero- and first-order models are given by

$$C = C_0 - kt \quad (1)$$

$$C = C_0 \exp(kt) \quad (2)$$

where t is the time (min), k is the rate constant (min^{-1}), C_0 and C are the ascorbic acid contents at time zero and time t, respectively.

The decimal reduction time (D value), the time needed for a 10-fold reduction of the initial concentration at a given temperature, is related to k values according to eq 2.

$$D = \frac{\ln(10)}{k} \quad (3)$$

Statistical Analyses. Two independent experiments (replicates) were conducted for each frequency studied during OH and also for conventional heating. The results were fitted to the zero- and first-order models by linear and nonlinear estimation, respectively. The rate constants (k values) of all experiments were compared using the Tukey test (5% of the confidence level). Statistical analyses were performed using Statistica 7.0 (StatSoft, Tulsa, OK) and Microsoft Excel 2011 (MapInfo, Troy, NY).

The goodness of fit of the proposed models was evaluated by means of the χ^2 parameter, the determination coefficient (R^2), and the standard error of means (SEM). The average errors between the experimental values and the values predicted by the models (E) were also estimated.

RESULTS AND DISCUSSION

Degradation of ascorbic acid over time for acerola serum during conventional heating and OH (using different frequencies) is shown in Figure 3. Error bars have not been added because it would be impossible to distinguish between the different treatments. Standard deviations were lower than 3% for all experimental points. Figure 4 shows the results reported for acerola pulp.[12] The degradation percentage of ascorbic acid in acerola pulp after 120 min of heating varied between 12 and 17%. For the serum, the degradation percentage was in the range of 13 and 18%. These values were lower than expected on the basis of kinetic data reported in the literature.[16−20] It is likely that the oxygen dissolved in the medium is the limiting reactant because the vitamin C content in acerola is very high, approximately 40 times higher than that of orange juice (1657 mg/100 g compared to 40 mg/100 g). Therfore, there is not enough oxygen in the medium to react with this extremely high vitamin C content. Another possibility is the degradation of some other antioxidants (anthocyanins) that are competing for the available oxygen. According to de Rosso and Mercadante,[21] the high ascorbic acid content is the main cause of the low stability of anthocyanin extracts from acerola. A recently published study performed in our laboratory evaluated the degradation kinetics of monomeric anthocyanins in acerola pulp during thermal treatment by OH and conventional heating.[22] The anthocyanin degradation percentages after 90 min of OH at 75 and 90 °C were approximately 46 and 84%, respectively. This may be an indication that anthocyanin is degrading faster than ascorbic acid in acerola pulp. Another point that needs to be mentioned is that acerola has a very acidic pH (approximately 3.3), and at low pH, ascorbic acid is more stable.[23] When analyzing ascorbic acid degradation, it is important to consider that its stability is influenced by the intrinsic properties of the product and the process characteristics.[13,15,18,20,24−27] Vitamin C degradation can occur through aerobic and/or anaerobic pathways, depending upon a number

of factors, such as pH, acidity, metal ions, light, humidity, water activity, temperature, presence of amino acids, carbohydrates, lipids, and enzymes, among others.[23]

From Figures 3 and 4, it can be observed that pulp and serum showed a distinct behavior when analyzing the degradation curves in the same range of frequencies. For a better comparison between treatments, the results of the ascorbic acid concentration against time were fitted to the zero- and first-order equations. The quality of the adjustment was evaluated through the statistical parameters presented in Tables 1 and 2. Both first- and zero-order equations proved to be suitable for modeling acid ascorbic degradation because the determination coefficients were above 0.98 for all treatments. When compared to the zero-order model, the first-order model yielded a better fit of the experimental data, with a smaller deviation between the values estimated by the model and experimental data and lower SEM and χ^2 values. The accuracy of the first-order model is confirmed by the small deviation between the values estimated by the model and the experimental data. Thus, the first-order model was chosen for predicting the ascorbic acid retention of acerola pulp and acerola serum during OH and conventional heating.

Table 3 presents the kinetic parameters of the first-order model obtained for each frequency evaluated during OH and also for the conventional process for both products. According to Mercali et al.,[12] the pulp showed kinetic rate constants ranging from 1.1 to 1.6×10^{-3} min^{-1} and D values ranging between 1480 and 2145 min. For the serum, the rate constants were between 1.1 and 1.5×10^{-3} min^{-1} and D values ranged from 1524 to 1951 min. Some points observed when comparing Figures 3 and 4 are confirmed by the statistical analysis. For acerola pulp, there was no difference ($p > 0.05$) between ascorbic acid degradation rates for experiments carried out with electric field frequencies ranging from 100 to 10^5 Hz. Also, the rate constants of these experiments did not differ from that found for the conventional heating treatment. The rate constant of the OH process at 10 Hz was higher than the rate constants of all other treatments. However, for the serum, a different behavior was observed. The rate constant of the OH process at 10 Hz was statistically similar to the rate constants of the treatments at 100 and 1000 Hz. These three conditions showed rate constants statistically different from the experiments conducted at 10^4 and 10^5 Hz. Also, the conventional process showed similar rate constants to the ones obtained for treatments using 10^4 and 10^5 Hz.

Higher degradation rates at lower frequencies may be explained by the occurrence of electrochemical reactions (electrolysis of water and electrode corrosion). Electrolysis of water releases hydrogen and oxygen in the medium, which may cause additional oxidation of ascorbic acid.[28] Electrode corrosion releases metal ions that also catalyze the oxidation process.[28] Corrosion of electrodes and apparent (partial) electrolysis of the heating medium with most types of electrodes at low-frequency ACs were noticed in experiments carried out by Samaranayake and Sastry.[29] These authors verified that apparent electrolysis was seen at all pH values, even though titanium electrodes showed a relatively high corrosion resistance.

These electrochemical reactions occur within a narrow area between electrodes and the product, which acts as a capacitor. When an AC voltage starts flowing through the system, charges start to build up in this area close to the surface of the electrode. If a low-frequency alternating voltage is applied, there is enough time to reach the Faradaic threshold potential and the layer becomes saturated with charges. After the saturation point, any current that flows through it results in electrochemical reactions.[30] On the other hand, when a high-frequency alternating voltage is used, the potential raise and reverse before it reaches the Faradaic threshold potential point as a consequence the electrochemical reactions do not take place.

The distinct behavior shown between acerola pulp and acerola serum at frequencies ranging from 10 to 1000 Hz indicates that the presence of different amounts of solids may have an influence on this process. Moreover, the serum and pulp have a distinct composition of solids: in the serum, most of the solids are soluble solids, such as sugar, vitamins, and acids, while in the pulp, there are also insoluble solids, such as fibers, starch, pectin, and long-chain carbohydrates. The amount of solids and even the predominant type of solid (insoluble or soluble solids) may have affected the drag for ionic mobility and, consequently, the rate of electron transfer. The particle type, size, concentration, shape, and orientation in the electric field may affect the mass transport processes by diffusion and/or convection that occur in the narrow layer between the electrodes and the product, which, in turns, influences the rate of the electron transfer reactions.

In high frequencies (10^4 and 10^5 Hz), ascorbic acid degradation was similar to the degradation found in the conventional heating. This behavior was observed for both acerola pulp and serum. This means that the electrochemical reactions were probably minimized and the main mechanism of degradation was the oxidation. Some authors recommend the use of high-frequency ACs to effectively suppress electrochemical phenomena at electrode−solution interfaces.[2,28,31]

Another point that needs to be considered is the effect of the polarization stimulated by the oscillating electric field. The polarization process is critically dependent upon the relaxation time of the molecular dipoles. Relaxation time refers to the time taken by the dipoles to revert to random orientation when the field is removed and is influenced by their molecular weight, mobility, and temperature.[11,32] Because liquids and solids have different relaxation times, the polarization of the whole sample depends upon the relative contribution of the phases present in the sample. The acerola pulp had higher solids content and more insoluble solids (fibers, starch, pectin, and long-chain carbohydrates) than the serum, which makes them have different dielectric properties, and, consequently, different behaviors when subjected to electric fields.

The ascorbic acid is a small polar water-soluble molecule.[33] Even though its molecular weight is higher than water, some considerations can be performed comparing its behavior to the water molecule. When an electric field is applied at low frequencies to a polar liquid (such as water), the time interval taken for the field to reverse its polarity would presumably be longer than the relaxation times of the molecules. This means that there is enough time available for the molecules to respond and reorient in accordance to the direction of field changes. As the field frequency increases, the time interval between reverse movements in field polarity gradually becomes of a similar order to the relaxation times of the molecules. At this point, they still respond to the changing fields but with increasing lag time and energy absorption. At very high frequencies, the dipole motion can no longer keep up with the changing field. These molecules will cease to respond and remain in their random, steady-state orientations.[11,32]

However, in many materials, such as in acerola pulp, the water molecules are often chemically bound to other molecules in the material. The ascorbic acid is also chemically bound to water and other substances because of the presence of hydroxyl groups in its structure. According to Ryynänen,[34] hydrogen bonds restrict the free movement of the molecules, and therefore, bound molecules possess longer relaxation times. In the same way, the extensive intermolecular bonding interactions prevalent in solid materials restrict dipolar orientations.[11] In this manner, particle type, size, concentration, and polarity may affect bonding interactions and, consequently, influence the achievement of the equilibrium of the polarization process. These phenomena may have influenced the oxidation reactions during heating of acerola pulp and serum, affecting the predisposition to hydrogen donation from the ascorbic acid molecule.

This study highlights the importance of evaluating dielectric properties of food products to determine their behavior when subjected to an electric field. The increase in the use of electrical heating methods in recent years requires the knowledge of electrical properties and their effects on food processing. Further work is necessary to better understand the effects of the electric field frequency during OH.

Supporting Information

ABSTRACT: Forty-eight male Wistar rats were fed diets containing low (0.051% of diet) or high (0.153% of diet) levels of an ellagitannin-rich (ET) strawberry extract with dietary fructooligosaccharides (FOS) or cellulose (CEL) for 4 weeks. The in vivo study demonstrated that some positive changes in the cecal metabolism resulting from the ingestion of a diet enriched only with FOS were completely or slightly suppressed by the dietary ET. In particular, the pH value (7.21 vs 7.36), short-chain fatty acid production (41.2 vs 30.0 μmol/100g BW), and β-glucuronidase activity (20.2 vs 15.7 μmol/h/g) in the cecum of rats fed with FOS were affected upon the addition of the ET extract. Dietary FOS caused higher metabolism of the tested ET strawberry extract in the gastrointestinal tract of rats. Moreover, the systemic effect of the supplements when consumed together showed undesired serum HDL-cholesterol decrease (0.78 vs 1.02 mmol/L in the treatment with FOS only).

KEYWORDS: *strawberry extract, fructooligosaccharides, gastrointestinal tract, nasutin A, Wistar rats*

INTRODUCTION

"Fructan" is a general term used for naturally occurring plant oligo- and polysaccharides. As a type of fructan, FOS are plant-derived carbohydrates with well-established benefits for the modulation of gastrointestinal functions.[1] Currently, a number of studies have shown beneficial effects of the consumption of colorful fruits and vegetables that are rich in FOS and biologically active phytochemicals.[2,3] Dietary fiber including polyphenol-rich fiber complexes is resistant to endogenous enzymes of the upper part of the gut in humans as well as monogastric animals. Therefore, the compounds are transported in large quantities to the large intestine, where they undergo fermentation process.[1,4] In recent years, scientists have studied the impact of dietary fiber on the metabolism and absorption of phytochemicals.[5,6] However, there is little information regarding how phytochemicals may modulate the beneficial effects of FOS in the gastrointestinal tract.

An interesting source of phytochemicals, especially ellagic acid (EA) and anthocyanins, is the strawberry.[7] EA in this fruit occurs mainly in the form of macromolecular ET, whereas the free form of EA represents only a small proportion of the total content of its derivatives.[8] Numerous studies have demonstrated positive effects of ETs and EA on human health, primarily due to the antioxidant, anticarcinogenic, antineurodegenerative, and anti-inflammatory effects.[9,10] However, an increased content of polyphenols in the diet may inhibit the growth and reduce the abundance of gastrointestinal microflora.[11] ET polymers in the gastrointestinal tract can be absorbed after breaking the ester bonds, which leads to the formation of EA. EA absorption is very low, and the unabsorbed compounds released into the jejunum and colon are extensively metabolized to urolithins by specific microbiota.[12,13] The EA metabolism pathway is composed of many transitional forms. Some of the first forms are nasutin A and isonasutin derivatives, which are formed after removing the specific hydroxyls in the 3- and 3′-positions or in the 4- and 3′-positions of EA. Another form is urolithin, which is produced after opening the lactone rings in EA.[14,15] Urolithins easily pass into intestine−liver circulation, where they are glucuronidated and sulfated. Derivatives of urolithins that are transported in the blood may have a favorable effect on the levels and proportions of cholesterol fractions, the blood level of lipids, and vascular inflammation. In addition, some of the derivatives have proven biological activity, including as analogues of hormones.[9,14,16,17] Urolithins can remain in the body up to 4 days after the consumption of ET-containing foods, perhaps due to enterohepatic recirculation and slow microbial metabolism in the colon.[18]

The metabolism of ETs depends on the activity of individual colonic microflora.[18] Therefore, it can be assumed that high activity of the gastrointestinal microbiota will increase metabolism and absorption of the ETs derived from the diet. Well-known dietary ingredients that modulate microbiota are classified as nondigestible saccharides as part of dietary fiber, such as CEL and FOS. CEL has significantly lower susceptibility to fermentation processes in the hindgut than FOS, which has been shown to increase the production of short-chain fatty acids (SCFA) and to have a prebiotic effect.[5] In our earlier studies performed with a polyphenol concentrate, the addition of dietary FOS significantly enhanced the metabolic activity of quercetin.[6]

The environment of the large intestine is of paramount importance to host health. Our previous experiments showed beneficial action of dietary FOS[5] or strawberry polyphenols[17] in the rat's cecum. Therefore, in the reported experiment it was hypothesized that a dietary combination of both supplements, FOS and polyphenols, would increase the desired beneficial effect in the lower gut environment. Moreover, intensified metabolism of strawberry polyphenolic compounds when combined with dietary FOS was expected.

MATERIALS AND METHODS

Chemicals. Acetone (99.5%), pure p.a., was purchased from Basic POCH S.A. (Gliwice, Poland). Ethanol (96.2%), rectified, was purchased from "NORD CLAS" Sp. z o.o. (Łódz, Poland). Phloroglucinol for HPLC (≥99%), methanol for HPLC (99.9%), gradient grade, and sucrose, glucose, and fructose were purchased from Sigma-Aldrich (St. Louis, MO, USA). Acetic acid for HPLC (99−100%) and phosphoric acid (85−87%), ACS reagent grade, were purchased from J.T. Baker (Phillipsburg, NJ, USA). Ascorbic acid and hydrochloric acid (35−38%), pure p.a., were purchased from ChemPur (Piekary Śląskie, Poland). Acetonitrile (>99.9%), CHROMASOLV gradient grade for HPLC, was purchased from Sigma-Aldrich (Darmstadt, Germany).

FOS Preparation. A commercial FOS preparation (Raftilose P95) was kindly provided by Orafti (Oreye, Belgium). According to the producer's declaration, it contains 93.2−95.8% oligofructose, as 2−8 degree of polymerization (DP) of fructose polymers and no more than 7.0% of free fructose. The content of oligo-, di-, and monosaccharides in the preparation was characterized using an HPLC system (Knauer, Berlin, Germany) equipped with a EuroChrom 2000 data control system, RI K-2301 Knauer detector (Germany), and a Shodex NH2P (250 × 4 mm) column (Japan), using an acetonitrile−water mixture (67−33% v/v) as a mobile phase at a flow rate of 0.8 mL/min at 20 °C. FOS preparation (0.5 g) was weighed in a 50 mL volumetric flask and dissolved in water (concentration 10 mg/mL) and was injected to the chromatograph for separation and registration of signals by RI detector. The composition of the individual di- to heptamers was determined on the basis of registered areas of the signals. The results were as follows: fructose, 5.1%; DP 2, 2.7%; DP 3, 25.6%; DP 4, 31.2%; DP 5, 18.7%; DP 6, 12.3%; and DP 7, 4.4% (94.4% of oligofructose). Limit of detection for fructose as a standard was 0.06 mg/mL.

Strawberry Polyphenolic Extract. The strawberry press cake (750 kg) was taken from the concentrated juice production line of the Alpex Company (Łęczeszyce, Poland) and dried in an industrial vacuum dryer (Polfarmex Company, Kutno, Poland) at 70 ± 2 °C. After drying, the pomace (400 kg) was separated into a seed fraction (diameter 0.5−1 mm) and a seedless fraction (diameter 1−3 mm) using a vibration sieving machine with sieves of the sizes 0.5 mm, 1 mm, and 3 mm (each was designed by the company Polfarmex S.A. Kutno, Poland) equipped with a vibration device necessary to move the material on the sieve and to renew the surface of sieving. The material with particle sizes between 1 and 3 mm, constituting part of pomace devoid of seeds (achenes), was used for successive production of a strawberry polyphenolic extract applied in the present study. The water−acetone ET strawberry concentrate was prepared at laboratory scale using the seedless fraction and a 60% solution v/v of acetone (5 L per 1 kg of pomace). Extraction was conducted in two stages for a minimum of 12 h. After partial removal of the solvent by distillation, approximately 5% of the resulting solution was subjected to adsorption using 500 g of adsorbent Amberlite XAD 16 in a column with a diameter Φ of 40 mm and a height of 1000 mm. After washing away the saccharide dirt with water, the desorption of polyphenols was performed using 10%, 40%, and 60% solutions of ethanol successively in amounts of 0.5, 1, and 2 L per 1 kg of adsorbent, respectively. Solutions containing desorbed polyphenols from the Amberlite XAD were gathered and divided into fractions, of which only the eluates rich in ET were concentrated to approximately 15% of the dry weight and subjected to freeze-drying in a TG 5 Lyophilizer (VEB Hochvakuum Dresden, Germany). The yield of the dry weight of the preparation that was rich in polyphenols was 2.6% of the weight of the dried industrial, seedless strawberry pomace.

Chemical Analyses of the Polyphenolic Extract. The chemical composition of the preparations was determined by AOAC methods (2005)[19] using the following procedure: dry matter and ash content, 940.26; protein content, 920.152; crude fat, 930.09; total dietary fiber, 985.29. Sucrose, fructose, glucose, and other saccharides were measured after desalination of the strawberry extract solution in water (5 mg/mL) on an anion exchange column (two parts of Amberlite IRA 400 anion exchanger purchased from Sigma-Aldrich (Germany), one part of Amberlite IR 120 cation exchanger also purchased from Sigma-Aldrich (Germany)). The analysis was performed using an HPLC system (Knauer, Berlin, Germany) with an RI detector and a BIO-RAD Aminex HPX-87C column, 300 × 7.8 mm (Phenomenex, Torrance, CA, USA), with a flow rate of 0.5 mL/min at 85 °C. Sucrose (limit detection at 0.08 mg/mL), glucose (limit detection at 0.08 mg/mL), and fructose (limit detection at 0.04 mg/mL) were used as standards.

Determination of Polyphenols. The concentrations of EA and total ETs, such as agrimoniin, including agrimoniin alone and other polyphenols (anthocyanins and flavonols), were determined in 50% methanol solutions prepared by resolving 5−25 mg of the freeze-dried polyphenolic extract in 5 mL of methanol diluted in water to 10 mL according to Sójka et al. (2013).[20] The solution was then subjected to HPLC analysis. A Smartline (Knauer, Berlin, Germany) chromatograph equipped with degasser Smartline Manager 5000 unit, two pumps Smartline Pump 1000, mixing chamber, autosampler Smartline Autosampler 3950, column oven Jetstream 2 Plus, and detector Smartline PDA 2800 was used for the chromatographic analysis. The separation was conducted on a Phenomenex Gemini 5u C18 110A column (250 × 4.60 mm; 5 μm) (Phenomenex Torrance, CA, USA). The column was maintained at 35 °C. Eluent A contained 0.05% phosphoric acid in water, and eluent B contained 0.05% phosphoric acid in acetonitrile. The flow rate was 1.25 mL/min. The gradient program was as follows: 0−5 min, 4% eluent B; 5−12.5 min, 4−15% eluent B; 12.5−42.5 min, 15−40% eluent B; 42.5−51.8 min, 40−50% eluent B; 51.8−53.4 min, 50−55% eluent B; and 53.4−55 min, 4% eluent B. The volume of the injected sample was 20 μL. The detection conditions were as follows: 280 nm [*p*-coumaric acid, kaempferol-3-*O*-β-D-(6″-*E*-*p*-coumaroyl)-glucopyranoside, (+)-catechin agrimoniin], 360 nm (EA, quercetin, and kaempferol glycosides, quercetin, kaempferol), and 520 nm (anthocyanins). The data were registered by ClarityChrom (Knauer, Berlin, Germany) chromatography software. The following standards were used: EA, *p*-coumaric acid, and (+)-catechin (Sigma-Aldrich, St. Louis, USA) and quercetin-3-*O*-glucopyranoside, kaempferol-3-*O*-glucoside, quercetin, pelargonidin-3-*O*-glucoside, and kaempferol (Extrasynthese, Genay, France). The agrimoniin standard was obtained from strawberry press cake and was purified by preparative chromatography. The agrimoniin with limit detection at 0.55 mg/L was used as the basic standard for the ET content determination.

Analysis of Proanthocyanidins and Free Catechins. A proanthocyanidin degradation method in an acidic environment with an overdose of phloroglucinol was employed. The method was described by Kennedy and Jones (2001).[21] Approximately 20 mg of sample was weighed in a 2 mL Eppendorf tube, and 800 μL of a methanol solution containing phloroglucinol (75 g/L) and ascorbic acid (15 g/L) was added to the sample. Phloroglucinolysis was started by adding 400 μL of 0.2 mol/L hydrochloric acid to methanol. The incubation was conducted for 30 min at 50 °C. Next, the samples were instantly cooled in an ice bath, and the reaction was stopped by adding 600 μL of a 40 mmol/L sodium acetate solution. The samples were centrifuged for 5 min at 3600*g* and then diluted with a 40 mmol/L sodium acetate solution. The products of the acidic degradation of proanthocyanidins were separated with the Knauer Smartline chromatograph (Berlin, Germany) equipped with a UV−vis P2800 detector (Knauer, Berlin, Germany) and a fluorescent detector (FD) RF-10AXL (Schimadzu, Tokyo, Japan). The separation was conducted

on Gemini 5u C18 110A (250 mm × 4.6 mm; 5 μm) column (Phenomenex Torrance, CA, USA) using gradient elution with 2.5% water solution (v/v) of acetic acid (phase A) and 80% (v/v) acetonitrile in water (phase B). The following gradient was used: 0−10 min, 4−7% B; 10−27 min, 7−30% B; 27−29 min, 30−70% B; 29−34 min, 70% B; 34−35 min, 70−4% B; and 35−40 min, 4% B. The flow rate was 1 mL/min, the temperature was 25 °C, and the injection volume was 20 μL. The identification of components was conducted by comparing the retention times and the UV−vis spectra of standards of (−)-epicatechin, (+)-catechin, (−)-epicatechin-phloroglucinol, and (+)-catechin-phloroglucinol. Quantitative analyses of the released flavonols, i.e., (+)-catechin and (−)-epicatechin, were conducted based on chromatograms recorded with the FD detector set at an excitation wavelength of 278 nm and an emission wavelength of 360 nm. Quantities were calculated by standard curves of (−)-epicatechin (0.625−50 mg/L; detection limit at 0.03 mg/L) for terminal units, and (−)-epicatechin-phloroglucinol adduct for extender units (0.6−50 mg/L; detection limit at 0.3 mg/L). Phloroglucinol adducts were determined based on chromatograms registered with the PDA detector set at a 280 nm wavelength.

Extraction of Nasutin A (4,9-Dehydroxy-ellagic Acid) and Polyphenols. Polyphenol compounds, including nasutin A, were extracted with a 70% solution of acetone. A sample containing 0.5 g of the ground frozen digesta was placed in a 7 mL test tube; next, 5 mL of a solvent was added, mixed using a vortex (IKA Yellowline Test Tube Shaker TTS2, Wilmington, NC, USA) and sonicated (Inter Sonic IS-4, Inter Sonic s.c., Olsztyn, Poland) for 10 min. Following the sonication, the solution was left in the dark for 15 min for extraction. The solution was centrifuged for 5 min (4800*g*) and poured into a 20 mL tube with a cup. The above procedure was repeated three more times; the combined extracts were poured into a 20 mL tube with a cup. The obtained extracts were stored at 20 °C for a maximum of 3 days before further analysis. Next, the combined extracts were poured into a vacuum distillatory flask, and the solvent was removed. Next, the dry residue was dissolved in 2 mL of 70% methanol. The solution was centrifuged for 5 min (4800*g*) and was submitted to HPLC analysis. A Smartline (Knauer, Berlin, Germany) chromatograph equipped with the same elements as described above was applied for the chromatographic analysis. The separation was conducted on a Phenomenex Gemini 5u C18 110A (250 × 4.60 mm; 5 μm) column (Phenomenex, Torrance, CA, USA). The conditions of separation were the same as for the determination of polyphenols described above.

The urolithin A (3,8-dihydroxy-6*H*-dibenzo-[*β*-D]-pyran-6-one) was used as a standard for the determination of nasutin A. To date, commercial nasutin is not available. Urolithin A was prepared as described by Cerdá et al. (2004).[18] The raw material for the isolation of urolithin A was two liters of urine from three healthy volunteers (25−45 years old) who consumed 400 g of strawberry per day. The urine was acidified to pH 4.8 by acetic acid. Then, 1.2 mg of glucuronidase bovine liver (Sigma-Aldrich, St. Louis, MO, USA) was added, maintained at 37 °C for 60 min and passed through Amberlite XAd-7 (Sigma-Aldrich, St. Louis, MO, USA) resin for the absorption and purification of polyphenols. In the next step, the resin was washed, and the adsorbed polyphenols were desorbed by methanol. The methanol fractions rich in urolithin A were concentrated and subjected to purification on a Strata SPE 1 g column (Strata - x 33u Polymeric Reversed phase 1 g/20 mL, Giga Tubes Phenomenex, Torrance, CA, USA) and were separated on a preparative HPLC (Knauer, Berlin, Germany) chromatograph, composed of two pumps (Knauer K-501) forming gradient, Phenomenex Luna 10u C18 100A column (250 × 21, 20 mm; 10 μm) (Torrance, CA, USA), UV−vis detector, Foxy R1 Teledyne ISCO (Lincoln, USA) fraction collector, and Eurochrom chromatographic software. Two eluents were used for separation: eluent A, 0.1% water solution of formic acid; eluent B, 80% methanol. The flow rate was 15 mL/min. The following gradient was used: 0−15 min 30% eluent B; 15−50 min 30−75% eluent B; 50−60 min 75% eluent B; 60−63 min 75−30% eluent B; 63−66 min 30% eluent B; and 55−60 min 20% eluent B. The volume of injected sample was 500 μL. Selected fractions containing urolithin A were subjected to freeze-drying. The UV spectrum of the obtained substances had maxima at 246, 278, 305, and 356 nm, which was the same pattern as the main metabolite of ET detected in urine.[14,22]

Identification of Nasutin A. The UV spectra of polyphenols have often been used for their identification by HPLC DAD analysis. UV spectra are generally used for the identification of flavonoids and urolithins. In the present study, the spectra of ET metabolites were studied using HPLC UV-DAD to establish the structure of the microbial degradation of agrimoniin. The maximum UV wavelengths for the detected substance (with retention time 26 min) have been determined to be 250, 285, 373, and 389 nm. Next the solution of the substance, separated by HPLC, was directly injected into an ESI-MS/MS detector (LCQ DECA, Thermo-Finnigan). The analyses were conducted in the positive ion mode.[18] The source parameters were as follows: ion spray voltage 3.00 kV; capillary temperature 325 °C; sheath gas and auxiliary gas 30 and 10 units/min, respectively. To generate MS/MS data, the precursor ions were fragmented by helium gas collision in the ion trap by optimizing the collision energy in order to obtain an intensity of the precursor ion close to 10% of the relative scale of the spectrum. The MS $[M - H^+]$ 269 for the substance was determined. Data obtained for UV spectrum and value of $[M - H^+]$ indicate that nasutin A was the main metabolite in the experiment.[14]

In Vivo Experiment, Preparation of the Diets, and the Animal Protocol. The animal protocol used in this study was approved by the Local Institutional Animal Care and Use Committee, and the study was performed in accordance with EU Directive 2010/63/EU for animal experiments. The assessment was conducted on 48 male adult Wistar rats aged 130 d and weighing 440.3 g (pooled SEM 0.839). The rats were randomly divided into six groups of eight animals each. All animals were housed individually for 4 weeks in metabolic cages with free access to water and the experimental diets (Table 1). The selection of the animals and their maintenance over the 28 d experiment followed common regulations. The environment was controlled with a 12 h light−dark cycle, a temperature of 21 ± 1 °C, relative humidity of 50 ± 5%, and 20 air changes per h. Diets contained similar levels of protein (from casein supplemented with methionine), fat (soybean oil), and minerals and vitamins (from AIN-93 M mixtures)[23] and a similar content of fiber. However, the fiber was from different sources, i.e., insoluble *α*-cellulose (SIGMA, Poznań, Poland) or a prebiotic FOS that was fermentable in the lower gut (Orafti, Oreye, Belgium). In the standard-fiber diets, the content of CEL was 6%. In the prebiotic-supplemented diets, half of the dietary CEL was replaced with FOS. The strawberry polyphenolic preparation was added to each type of diet in an amount of 0.051% or 0.153% of the air-dried feed, which constituted 0.04% and 0.12% of total strawberry polyphenols in the diet, respectively (in regard to ETs, the main polyphenolic component of the extract, 0.03% and 0.09% of ETs, respectively). The individual BW and feed intake of the rats were recorded. At the termination of the experiment, the rats were anesthetized with sodium pentobarbital according to the recommendations for the euthanasia of experimental animals. After a laparotomy, blood samples were taken from the caudal vena cava, and then serum was prepared by solidification and low-speed centrifugation (350*g*, 10 min, 4 °C). The small intestine, cecum, and colon were removed and weighed. As soon as possible after euthanasia (ca. 10 min), the small intestinal, cecal, and colonic pH values were measured (pH meter model 301, Hanna Instruments, Vila do Conde, Portugal). The dry matter of the cecal digesta was determined at 105 °C for 4 h. In the fresh cecal digesta, ammonia (NH_3) was determined by microdiffusion analysis in Conway's dishes, and the SCFA were analyzed using GC as described previously.[24] For SCFA, the samples (0.2 g) were mixed with 0.2 mL of formic acid, diluted with deionized water, and centrifuged at 7211*g* for 10 min. The supernatant was loaded onto a capillary column (SGE BP21, 30 m × 0.53 mm) using an on-column injector. The initial oven temperature was 85 °C and was raised to 180 °C at a rate of 8 °C/min and held for 3 min. The temperatures of the flame ionization detector and the injection port were 180 and 85 °C, respectively. The sample volume for GC analysis was 1 μL. The cecal putrefactive SCFA (PSCFA) concentration was calculated as the sum of the isobutyrate, isovalerate, and valerate concentrations in the cecal

[a]α-Cellulose preparation was obtained from Sigma-Aldrich (No. C8002). [b]AIN-93 M (Reeves 1997),[23] g per kg mix: 357 g of anhydrous calcium carbonate (40.04% Ca), 196 g of monobasic potassium phosphate (22.76% P, 28.73% K), 70.78 g of potassium citrate and tripotassium monohydrate (36.16% K), 74 g of sodium chloride (39.34% Na, 60.66% Cl), 46.6 g of potassium sulfate (44.87% K, 18.39% S), 24 g of magnesium oxide (60.32% Mg), 6.06 g of ferric citrate (16.5% Fe), 1.65 g of zinc carbonate (52.14% Zn), 1.45 g of sodium meta-silicate·$9H_2O$ (9.88% Si), 0.63 g of manganous carbonate (47.79% Mn), 0.3 g of cupric carbonate (57.47% Cu), 221.026 g of powdered sucrose, and 0.275 g of chromium potassium sulfate·$12H_2O$ (10.42% Cr). The following components were added in mg per kg mix quantities: 81.5 mg of boric acid (17.5% B), 63.5 mg of sodium fluoride (45.24% F), 31.8 mg of nickel carbonate (45% Ni), 17.4 mg of lithium chloride (16.38% Li), 10.25 mg of anhydrous sodium selenate (41.79% Se), 10 mg of potassium iodate (59.3% I), 7.95 mg of ammonium paramolybdate·$4H_2O$ (54.34% Mo), and 6.6 mg of ammonium vanadate (43.55% V). [c]AIN-93 M (Reeves 1997),[23] g per kg mix: 3.0 g of nicotinic acid, 1.6 g of Ca pantothenate, 0.7 g of pyridoxine−HCl, 0.6 g of thiamin-HCl, 974.655 g of powdered sucrose, 0.6 g of riboflavin, 0.2 g of folic acid, 0.02 g of biotin, 2.5 g of vitamin B_{12} (cyanocobalamin, 0.1% in mannitol). The following components were added in IU per g quantities: 15.0 IU of vitamin E (*all-rac*-α-tocopheryl acetate, 500), 0.8 IU of vitamin A (*all-trans*-retinyl palmitate, 500000), 0.25 IU of vitamin D_3 (cholecalciferol, 400000), and 0.075 IU of vitamin K-1 (phylloquinone).

digesta. The activity of selected bacterial enzymes (α- and β-glucosidase, α- and β-galactosidase, and β-glucuronidase) released into the cecal environment was measured by the rate of *p*- or *o*-nitrophenol release from their nitrophenyl glucosides, according to a method that has been described elsewhere.[24]

The serum concentration of glucose, triacylglycerol (TG), total cholesterol (TC), and its HDL fraction (HDL-C), as well as the activity of alanine aminotransferase (ALT) and aspartate aminotransferase (AST), were estimated with diagnostic sets from Alpha Diagnostics Limited (Warsaw, Poland).

Statistical Analyses. The data are expressed as the means and pooled standard error of the mean (SEM). The STATISTICA software, version 10.0 (StatSoft Corp., Krakow, Poland), was used to determine whether variables differed among the treatment groups. Two-way ANOVA was applied to assess the effects of the dietary addition of the strawberry extract (E), the type of diet (standard diet with 6% CEL and diet with 3% FOS added instead of 3% CEL; F), and the interaction between the investigated factors (E × F). When the ANOVA indicated significant treatment effects, the means were evaluated using Duncan's multiple range test. One-way ANOVA and Duncan's test were applied to analyze the concentration of nasutin A in the intestinal contents. The data were checked for normality before statistical analysis was performed. Differences with $P < 0.05$ were considered to be significant.

RESULTS

The preparation obtained from strawberry used in this study contained 78.7 g of polyphenols per 100 g of preparation (Table 2). The main phenolic compounds in the preparation were ETs (59.3%) and proanthocyanidins (16.9%). Other compounds, including flavonoids (quercetin and kaempferol, their glycosides, and anthocyanins), free EA, and *p*-coumaric acid and its derivatives were detected in relatively lower concentrations (1.0%, 1.3% and 0.2%, respectively). Chemical analysis showed that the tested preparation was also a source of cell wall saccharides (11.6%). In the examined extract, there was no dietary fiber.

The initial body weights of the rats did not differ among treatments (data not shown). The applied dietary treatments had no effect on the final body weight of the rats or the feed intake during the study (the latter not shown, Table 3). The pH value of the digesta in selected gut segments was significantly affected by the type of dietary fiber and the addition of the strawberry extract. The addition of FOS resulted in significantly higher stomach pH and significantly lower pH values in the small intestine and cecum. The dietary extract, irrespective of the dietary dosage, contributed to significantly higher pH value in the digesta of the stomach, small intestine, and cecum. In comparison with the rats receiving CEL in their diets, the addition of FOS significantly increased the relative weight of the cecal tissue. The relative mass of the cecal digesta was significantly increased by FOS addition, and the dietary extract (both dosages) had the opposite effect (Table 4). The concentration of DM in the cecal digesta was reduced ($P < 0.05$) in rats receiving diets with FOS; in the case of dietary strawberry extract, a statistical tendency toward an increased

cecal DM percentage was observed ($P = 0.061$ vs treatment without extract). The applied dietary treatments had no significant effect on the concentration of ammonia in the cecal digesta. The feeding regimen with the strawberry extract diet caused a significant suppression in the activity of bacterial β-glucosidase released into the cecal environment, while the

dx.doi.org/10.1021/jf405612a | J. Agric. Food Chem. 2014, 62, 5871–5880

dietary FOS increased the activity of β-galactosidase. An interaction was observed between extract addition by dietary fiber type ($P < 0.05$) and cecal β-glucuronidase activity. Consumption of the FOS-diet without strawberry extract resulted in the lowest β-glucuronidase activity; the dietary application of the extract also significantly decreased β-glucuronidase activity compared to the C_{CEL} group, but to a lesser extent compared to FOS alone. Surprisingly, there was a significant difference in the activity of this bacterial enzyme in the cecal digesta between the C_{FOS} and EH_{FOS} groups ($C_{FOS} < EH_{FOS}$, $P < 0.05$).

The metabolism of ETs to nasutin A throughout the gastrointestinal tract is shown in Figure 1. The lowest

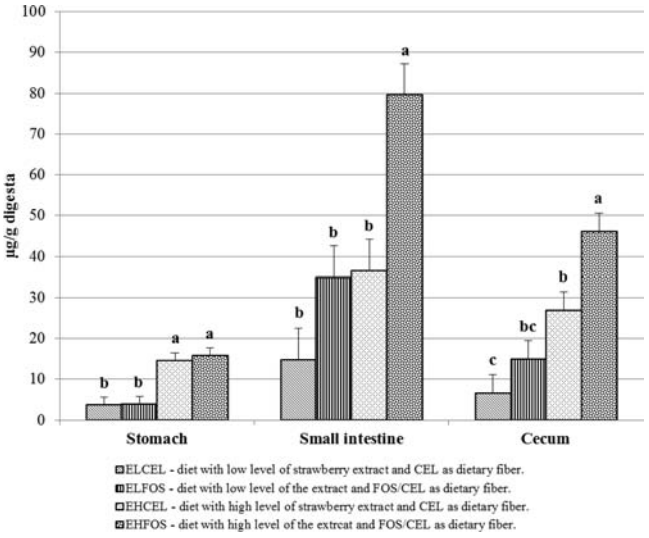

Figure 1. Concentration of nasutin A in the digesta of selected parts of the gastrointestinal tract. Mean values within a column with unlike letters a−c were shown to be significantly different ($P < 0.05$).

concentration of nasutin A was observed in the stomach (Figure 2, Supporting Information). Irrespective of the dietary fiber type, the groups with higher extract dosages had significantly increased concentrations of nasutin A in the stomach and cecal contents. As for the small intestine, the EH_{FOS} group was characterized by a significantly higher concentration of nasutin A (Figure 3, Supporting Information) compared to all other groups. A similar situation was observed in the cecum (Figure 4, Supporting Information) (EH_{FOS} > all other groups, $P < 0.05$). Additionally the EL_{CEL} rats had the lowest concentration of this metabolite, and it differed significantly in this respect from group EH_{CEL}.

Regardless of the diet type, the dietary application of both strawberry extract dosages significantly decreased the cecal concentration and pool of total SCFA, mainly due to the lower concentration of acetic acid (Table 5). The dietary supplementation with the higher dosage of strawberry extract significantly ($P < 0.05$) decreased the cecal concentration of putrefactive SCFA compared to the treatment without extract and with a lower extract dietary application. The dietary FOS significantly increased the cecal propionic and butyric acid concentrations and significantly decreased the concentration of total putrefactive SCFA. The cecal SCFA pool was also increased by dietary FOS application ($P < 0.05$). The analysis of the SCFA C2:C3:C4 profile indicates a lower ratio of acetic acid and an increased ratio of propionic and butyric acids after consumption of diets with added FOS (in all cases $P < 0.05$ vs treatment with 6% CEL).

Differences in the biochemical indicators in the blood serum from rats receiving the experimental dietary treatments are shown in Table 6. The results of a two-way ANOVA indicated that both main dietary treatments (both dosages of strawberry extract and FOS addition) significantly decreased the concentration of glucose in the serum. The lower serum TC concentration ($P = 0.068$) was observed in rats fed diets with added FOS. An interaction was observed between the extract addition by dietary fiber type ($P < 0.05$) and the serum HDL-C concentration and HDL-C profile. The C_{FOS} group was characterized by the highest HDL-C concentration ($P < 0.05$ vs other groups), that is, such a decrease was not observed when FOS was applied with the extract. The C_{FOS} group had the highest values of the HDL-C profile (percentage of the TC), and this group differed significantly not only from the C_{CEL} group but also from the EH_{CEL} and EH_{FOS} groups.

DISCUSSION

The results of the present study indicate that the ET strawberry extract obtained from strawberry press cake (including 2.4% proanthocyanidins; 1.5% free EA and its derivatives in the form of ETs; 0.11% flavonols and 0.09% anthocyanins) consisted of 785 g/kg of phenolic compounds, most of which were ETs (589 g/kg) and proanthocyanidins (169 g/kg). The range of the total content of phenolic compounds in fresh strawberry reported in other studies is very wide, ranging from 0.29 g/kg[25] to 1.44 g/kg.[26] Moreover, the contents of the key polyphenols present in this fruit (i.e., free and bound EA) are between 0.013 and 0.85 g/kg,[27,10] and for proanthocyanidins ranges have been reported from below 0.01 to greater than 0.16 g/kg.[28,29] The concentrations of these bioactive substances are strongly influenced by extrinsic factors, such as variations in plant type and growth, climate, season, temperature, and the degree of ripeness.[30] In this study, with the aid of the body surface area normalization method[31] and literature data for polyphenol content in the fruit, the higher dietary treatment was determined to correlate to a daily consumption of 0.38−1.8 kg fresh strawberries by an adult weighing 70 kg. Therefore, the diet used in this study could represent a realistic amount of fresh strawberries consumed by humans.

The addition of the extract to the diet did not reduce the diet intake or the body weight of the experimental rats, but it affected the activity of the intestinal microflora and its most important products. The administration of FOS leads to the enhancement of fermentative processes and SCFA production, which may decrease the pH of the digestive tract.[4−6] A number of authors have indicated that the acidification of the digesta promotes positive microbiota proliferation and decreases the growth of pathogenic bacteria species.[32] The present study showed that the addition of an ET strawberry extract and FOS together slightly diminished the beneficial effect of the latter on the acidification effect in the cecal digesta. The ET strawberry extract was a rich source of the ET, and it has been reported that this compound releases EA upon hydrolysis in vivo.[33] The higher pH value in the parts of the gastrointestinal tract can be explained by the poor solubility of EA in water and its ionization at physiological pH to form a complex with alkaline calcium and magnesium ions in the intestine.[34] Moreover, the poor solubility of EA most likely reduced the amount of bound water in the cecal digesta. This situation can also explain why dietary treatment with the ET strawberry extract significantly

decreased the amount of cecal digesta and tended to increase the cecal dry matter concentration. It was also noted that the FOS and ET strawberry extract showed an opposite effect on the measured parameters.

dx.doi.org/10.1021/jf405612a | J. Agric. Food Chem. 2014, 62, 5871−5880

The activity of microbiota in the cecum depends on the supplied nutrients. Kosmala et al. (2014)[35] have shown that the inclusion of 5% FOS significantly decreased α-galactosidase, β-glucosidase, and β-glucuronidase activity, while the activity of α-glucosidase and β-galactosidase did not change statistically when compared to the CEL-enriched diet. In our experiment, the addition of 3% FOS to the diet significantly reduced the activity of β-glucuronidase and increased that of β-galactosidase in the cecal digesta compared to the CEL groups. The addition of ET strawberry extract improved the effect of ingested diet by significantly decreasing the activity of β-glucosidase in the cecal digesta. However, the addition of FOS and a high level of the ET strawberry extract (group EH) together reduced the beneficial effect of FOS by increasing the β-glucuronidase activity in the cecal digesta. These enzymes may exert toxic, carcinogenic, or mutagenic effects in the gastrointestinal tract.[36] It can be assumed that the addition of ETs to diet could selectively modulate the composition of the microbiota and thus increase potentially harmful species of bacteria which were responsible for the enhanced activity of β-glucuronidase in the cecum. FOS is known as a prebiotic, which selectively stimulates the growth of bifidobacteria, thus causing significant changes in the composition of the gut microflora by increasing the number of potentially health-promoting bacteria and reducing the number of potentially harmful species, including *Escherichia coli* and *Clostridium*.[37] Larrosa et al. (2010)[38] found that ETs and ET metabolites from pomegranate decreased enterobacteria and increased lactobacilli and bifidobacteria. The ET strawberry extract in addition to ETs is a source of proanthocyanidins, which may reduce the activity of digestive enzymes when present at elevated levels.[39] The ET strawberry extract used in this study was also a source of flavonoids; previously, a flavonoid extract applied as a dietary supplement was shown to decrease the activity of bacterial β-glucosidase and β- and α-galactosidases in the cecal digesta of rats.[11] Roberton et al. (1982)[40] suggested that the most important factor in the modulation of β-glucuronidase activity in the rat large bowel is bile flow. Indeed, dietary fiber is the main factor that intensifies peristalsis and thus the bile flow through the large intestine.[41]

In this study, the identification and determination of the ET metabolites in the gastrointestinal tract of the rats revealed the presence of nasutin A and EA. However, urolithins, which are considered to be typical reaction products of ET metabolism in the gastrointestinal tract of humans and experimental animals, were not detected.[12,13] One of the possible ways in which the intensification or modulation of the ET biodegradation processes may be occurring is through an increase in the population of the lactobacilli bacteria that are capable of producing tannase and changes in the pH of the environment.[42] Tannase causes hydrolysis of ester bonds, including the bonds between hexahydroxydiphenic acid (HHDP) and glucose; free HHDP can then undergo spontaneous lactonization to EA. Lactonization of the acid with the hydroxyl group of the benzene ring can be accompanied by decarboxylation of the second acid moiety and the subsequent loss of hydroxyl residues to form urolithins.[14,15] A small amount of experimental data[14] and the results of computer simulations of chemical reactions[12] indicated the formation of nasutin A and isonasutin as byproducts of lactonization with the removal of two hydroxyl residues from EA. Nevertheless, there is no clear explanation for the spontaneity or the conditions of the formation process of nasutin A. The data presented in Figure 1 show a significant increase in the concentration of nasutin A in the gastrointestinal tract after the consumption of the diet with FOS and variable doses of the ET strawberry extract. In this study, trace amounts of nasutin A were observed in the stomach; it can be speculated that hydroxyls can be removed from EA under the physiological conditions of the stomach. The acidic environment of the stomach leads to the production of EA.[7,14] The highest concentration of nasutin A was observed in the small intestines. Larrosa et al. (2006)[43] showed that ETs are mostly hydrolyzed to EA under the physiological conditions of the small intestine. In the cecum, a lower concentration of nasutin A was observed compared to the small intestine. When ETs or EA reach the distal part of the small intestine and the colon, they are largely metabolized by the gut microflora to urolithins;[42] we speculated that the main differences in the concentration of nasutin A were associated with specific microflora that are not the same in all parts of the gastrointestinal tract. Determining the causes of such a phenomenon requires further experiments.

Numerous studies have shown that the administration of FOS leads to an enhancement of SCFA production, mainly acetate, propionate, and butyrate.[3,6] After absorption, SCFAs play important roles in an organism. Propionate has a positive influence on lipid metabolism in liver, whereas butyrate is an energy substrate for colonocytes.[37] In this study, the addition of FOS into the diet improved the cecal production of propionate and butyrate acids. Thus, a higher concentration of butyric may explain the significantly higher mass of cecal tissue in the groups consuming FOS. Zduńczyk et al. (2006)[11] demonstrated that the presence of polyphenols in inulin-containing diets did not change the total SCFA production in the cecum of rats. In addition, Juśkiewicz et al. (2010)[6] reported that the polyphenol concentrate from apple pomace and FOS did not show any serious negative effects on the basic parameters of the cecum and SCFA production. However, the addition of the ET strawberry extract into the diet slightly reduced the beneficial effect of FOS on enhancing the production of SCFA, especially acetic acid in the cecum. The high content of ETs and their metabolites suppressed the activity of the microbiota and thereby decreased the production of SCFA. The results of other studies indicate that an increased content of polyphenols in the diet may inhibit the growth and reduce the abundance of gastrointestinal microflora.[11,38] In this study, the group with a high content of ET strawberry extract exhibited significantly reduced production of PSCFA, which may suggest less intensive anaerobic bacterial fermentation of polypeptides and amino acids.[24]

Based on the results obtained in this study, we assume that the above changes in the cecal concentrations of SCFA were consistent with blood markers of the lipid profile in the rats. Propionate is reported to be involved in the cholesterol-lowering effect of fiber by impairing acetate utilization, especially when cholesterol synthesis is activated to compensate for enhanced fecal losses of steroids.[44] In this study, rats that consumed the diet with FOS had a significantly higher value of HDL-C, a significantly lower concentration of glucose in the blood, and a statistical tendency ($P = 0.068$) toward a lower serum TC concentration compared to rats that consumed the diet with CEL. These results confirm earlier observations made by Giacco et al. (2004),[45] who reported that positive systemic effects of fructans could reduce plasma glucose as well as the total and LDL cholesterol concentrations. The combination of a high level of the ET strawberry extract with FOS in the diet caused a higher reduction of glucose in the blood, and the

HDL-C level in the serum was lower than in the group without the ET strawberry extract in the diet. Other authors have found that ET metabolites, urolithins, are responsible for serum and liver lipid reductions.[43,16] Moreover, some studies have shown that polyphenolic compounds may reduce the activity of endogenous enzymes in the small intestine and thereby may influence the regulation of blood glucose levels.[22,46]

In summary, the present experiment demonstrated that some of the positive changes in the cecal metabolism of rats that resulted from the ingestion of a diet enriched only with FOS were suppressed or slightly suppressed by the addition of an ET strawberry extract. The pH value, SCFA production, and β-glucuronidase activity in the cecum of rats fed with FOS were affected upon the addition of the ET strawberry extract. The addition of FOS to the diet resulted in higher metabolism of the tested ET strawberry extract in the gastrointestinal tract of rats. Moreover, the systemic effect of the supplements when consumed together showed undesired decrease in HDL-C.

Modeling the Effect of Phase II Conjugations on Topoisomerase I Poisoning: Pilot Study with Luteolin and Quercetin

Luca Dellafiora,[†] Pedro Mena,[‡,§] Daniele Del Rio,*[,‡,§] and Pietro Cozzini*[,†]

[†]Molecular Modeling Laboratory, Department of Food Science, [‡]The Laboratory of Phytochemicals in Physiology, Human Nutrition Unit, Department of Food Science, and [§]LS9 Bioactives and Health, Interlaboratory Group, Department of Food Science, University of Parma, 43125 Parma, Italy

ABSTRACT: Topoisomerases are targeted by several drugs in cancer chemotherapy acting as key enzymes in cell viability. Some flavonoids and their glycosides may exert health protective effects through the poisoning of topoisomerases. However, previous studies did not consider the substantial modifications taking place after ingestion neglecting that only metabolites can interact with the internal compartments of the human body. Since the high number of possible metabolites hinders their systematic analysis, an in silico approach can be a valuable tool to prioritize compounds by identifying candidates for further characterization. Specifically focusing on luteolin and quercetin, among the most ubiquitous flavonoids in the human diet, this work reports a computational procedure to model the effect of hepatic phase II conjugative metabolism on poisoning of human Topoisomerase I. As a general effect, glucuronidation and sulphation might enhance and quench poisoning activity, respectively. Among all, quercetin-3-*O*-glucuronide represents a promising candidate to be analyzed more thoroughly.

KEYWORDS: *Topoisomerase I, poisoning, molecular modeling, flavones, metabolites, activity*

INTRODUCTION

Topoisomerases (Topos) are ubiquitous enzymes that control DNA supercoiling and intertwining. They allow DNA relaxing by introducing single- (Topo I) or double-strand breakage (Topo II) through respectively one or two transesterification reactions. When Topos activity is altered, abnormal DNA structures and delay of replication and transcription inevitably occur.[1] Both "canonical inhibition" and poisoning can disrupt Topos activity. The former requires the prevention/alteration of protein−DNA interaction, the latter turns the enzymes into a DNA damaging agent since poisoning compounds hinder DNA religation by stabilizing the so-called "cleavable complex".[2−4] Since Topos are involved in key steps of cell viability, topoisomerase inhibitors and poisons are widely used as antibacterial and anticancer agents.[5]

Flavonoids are low molecular weight secondary metabolites widely distributed in the plant kingdom. They are ubiquitous constituents of fruit- and vegetable-rich diets where they have potential protective effects against the onset of chronic conditions such as cancer and cardiovascular disease.[6] Among flavonoid subgroups, the most potent Topo I poisons are flavones and flavonols.[2] Quercetin, principally as glycoside conjugates, is an abundant flavonol in the human diet, occurring in products such as apples, red grapes, citrus, onions, garlic, and tea,[7] and its consumption has been linked to lower rates of certain cancers.[8] The flavone luteolin also occurs almost exclusively as glycoside conjugates and is found in carrots, peppers, celery, olive oil, peppermint, thyme, rosemary, and oregano.[7] Its consumption has been associated with a range of biological activities.[9]

Both quercetin and luteolin have been reported to poison DNA Topo I and II,[2,10,11] which supports their possible chemopreventive activity. However, results are conflicting and some works in the literature do not support flavonoids-mediated Topos poisoning.[12,13] A further factor to be taken into account is that, after consumption,[6] flavonoids are subjected to extensive phase II metabolism, and thus it would be their glucuronide and sulfate metabolites that might act as potential chemopreventive agents, rather than their parent compounds. The role of these circulating metabolites in poisoning Topo I has not been determined, yet. Therefore, considering that luteolin and quercetin are widely consumed through a normal balanced diet, it is relevant to investigate whether their phase II metabolites are able to act as Topo I poisons.

Nevertheless, the systematic characterization of metabolized forms of polyphenols based on in vitro assays may be a hard challenge due to the high number of hits and, sometimes, to the lack of commercially available standards at affordable costs. It becomes thus necessary a prioritizing system to drive experimental trials in a focused manner. The computational approach efficiently meet this need and because the Topos poisoning activity unequivocally involves protein/DNA complex-ligand recognitions, the use of 3D molecular modeling becomes paramount.[14] Hence, the present work presents a pilot study on luteolin and quercetin, with the aim of verifying the feasibility of modeling the effects of their phase II conjugation on Topo I poisoning by using already verified and effective technique.[15] In addition to plant-based glycosides (used for training procedure), several phase-II human metabolites, still untested to the best of our knowledge, were analyzed (luteolin-3′-*O*-glucuronide, luteolin-3′-*O*-sulfate, luteolin-4′-*O*-glucuronide, luteolin-7-*O*-glucuronide, luteolin-7-sulfate, quercetin-3-

O-glucuronide, quercetin-3′-*O*-glucuronide, quercetin-3-sulfate, quercetin-4′-*O*-glucuronide, quercetin-7-*O*-glucuronide, and quercetin-7-sulfate)[16,17] and ranked according to physicochemical prioritization criteria.

MATERIAL AND METHODS

The procedure involved docking simulations followed by rescoring procedures using a proper scoring function. Our intention was to develop a procedure easy to perform, without excesses of software and hardware requirements and avoiding complex mathematical and statistical analysis.

All experimental data were retrieved from literature[2] and query set contained metabolites observed under in-vivo-like conditions whose might be the predominant occurring form in circulatory system.[16,17]

Molecular Modeling. The model used for docking simulation was derived from the high resolution structure of human Topo I retrieved from Protein Data Bank (http://www.rcsb.org; PDB code 1K4T).[18] Protein structure and small molecules were processed using the molecular modeling software Sybyl, version 8.1 (www.tripos.com). All atoms were checked for atom- and bond-type assignments. Amino- and carboxyl-terminal groups were set as protonated and deprotonated, respectively. Hydrogen atoms were computationally added to the protein and energy-minimized using the Powell algorithm whit a coverage gradient of ≤0.5 kcal (mol Å)$^{-1}$ and a maximum of 1500 cycles.

Docking Simulations. The docking simulations of all compounds were performed with the program GOLD version 5.1 (CCDC; Cambridge, U.K.; http://www.ccd.cam.ac.uk) on a double-quad cores machine equipped with 1.86 GHz processor. All crystallographic waters and ligands were removed and 30 poses for each compound were generated. No constraints were set up and the explorable space was defined in a radius of 10 Å from the centroid of the binding pocket. For each GOLD docking search, a maximum number of 100 000 operations were performed on a population of 100 individuals with a selection pressure of 1.1. Operator weights for crossover, mutation, and migration were set to 95, 95, and 10, respectively. The number of islands was set to 5 and the niche to 2. The hydrogen bond distance was set to 2.5 Å and the vdW linear cutoff to 4.0. Ligand flexibility options "flip pyramidal *N*", "flip amide bonds", and "flip ring corners" were allowed.

Rescoring Procedure and Hydropathic Analysis. The software HINT (Hydropatic INTeraction)[19] was used as postprocessing tool to rescore all poses generated by GOLD. The HINT scoring function calculates the favor of protein−ligand recognition trough a sum of hydrophobic atom constants which derived from experimental LogPo/w values (the partition coefficient of a molecule in 1-octanol/water). Thus, HINT appears as a "natural"[20] and intuitive force-field by providing empirical and quantitative evaluation of protein−ligand interaction as a sum of all single atom−atom contributions using the following equation:

$$\text{HINT score} = \sum_i \sum_j b_{ij} = \sum_i \sum_j (a_i S_i a_j S_j T_{ij} R_{ij} + r_{ij})$$

where *bij* is the interaction score between atoms *i* and *j*, *a* is the hydrophobic atomic constant, *S* represents the solvent accessible surface area, *Tij* is a logic function assuming +1 or −1 values, depending on the nature of the interatomic interaction, *Rij* and *rij* are functions of the distance between atoms *i* and *j*.

dx.doi.org/10.1021/jf501548g | J. Agric. Food Chem. 2014, 62, 5881−5886

Positive and high HINT score correlates with favorable binding free energy, allowing the evaluation of the thermodynamic benefit of predicted complexes.[21−24] Because different conformations of the same molecule may coexist contributing to the whole energy of binding, a Boltzman average calculation was applied. In this way the contributions of different conformations to the predicted interaction were taken into account.[25] Thus, from here, we referred to HINT score (HS) as Boltzman averaged score.

Replicas of Docking Simulation and Rescoring Procedure. Because GOLD uses a Lamarkian genetic algorithm, results may slightly change from run to run. This implies that computing twice the same molecule is impossible to record exactly the same score, because two identical poses (i.e., the exact *xyz* coordinates for each atom) are virtually impossible to obtain. This may be a nontrivial issue potentially disruptive in place of rescoring procedures. GOLD results are intrinsically ranked by its internal scoring functions. Because of this, it is not possible to separate GOLD's pose generation from its ranking, and we were forced to apply HINT only to rescore pregenerated poses. Thus, in order to avoid not-causative fluctuations due to random component of docking algorithm, each analysis was repeated 5-fold and the mean value was considered.

RESULTS

Training Procedure and Training-Set Results. When the validation of computational models may be not mandatory, as in this instance due to the lack of sufficient and inherent experimental data, training procedures are compulsory.[26] In the current study, the procedure exploited experimental data retrieved from the literature.[2] Specifically, a training-set has been formed by luteolin, luteolin-8-*C*-glucoside, luteolin-4′-*O*-glucoside, luteolin-7-O-glucoside, quercetin, quercetin-3-*O*-rhamnoside, and quercetin-3-*O*-rutinoside (Figure 1). Data and results concerning the training procedure are reported in Table 1. Taking into account the high variability and, in some cases, the proximity of experimental data, the absolute and quantitative rank of compounds was not easy to resolve. However, it was possible to perform a semiquantitative and relative comparison; instead of a global potency rank, we defined a binary categorization describing conjugation-dependent effects of enhancing and quenching on luteolin and quercetin, respectively. For instance, luteolin and luteolin-7-*O*-glucoside shared proximal values and the high variability of luteolin-7-*O*-glucoside made their relative potency indefinable, as ranges that totally overlap cannot be resolved. Conversely, luteolin-4′-*O*-glucoside (less active) and luteolin-8-*C*-glucoside (more active) were unequivocally separated from luteolin. Likewise quercetin-3-*O*-rhamnoside and quercetin-3-*O*-rutinoside clearly diverged down from quercetin.

Table 1. Results of the Training-Set[a]

compound	experimental activity	activity category	mean HS	predicted effect
luteolin	**55 ± 8.2**	/	**683 ± 28.0**	/
luteolin-8-*C*-glucoside	69 ± 5.6	↑	804 ± 107.0	↑
luteolin-4′-*O*-glucoside	19 ± 4.3	↓	562 ± 76.0	↓
luteolin-7-*O*-glucoside	51 ± 14.0	↑↓	747 ± 136.0	↑↓
quercetin	**57 ± 15.6**	/	**718 ± 42.0**	/
quercetin-3-*O*-rhamnoside	15 ± 12.0	↓	240 ± 140.0	↓
quercetin-3-*O*-rutinoside	5 ± 1.8	↓	383 ± 194.0	↓

[a]Enhancing and quenching effects with respect to the reference aglyconic compounds (in bold) are represented by up- or down-arrow, respectively "↑↓" indicates indefinable relative potency. Hint scores are expressed as mean value of 5 replicates. All experimental data were retrieved from the literature and express relative potency of compounds respect to the reference standard camptothecin.[2]

The training-set underwent docking simulations and rescoring procedure in order to assess the applicability of the procedure to this specific case study. Overall, good correlation between computed and experimental data was obtained (Figure 2). Specifically, computed results were in agreement with experimental data and the procedure was trained according to the fact that the augmentation and reduction of HSs correlated to conjugation-dependent enhancing and quenching of poisoning activity, respectively. However, it was not possible to compare the relative activity of luteolin and luteolin-7-*O*-glucoside due to the same reasons reported above (Table 1).

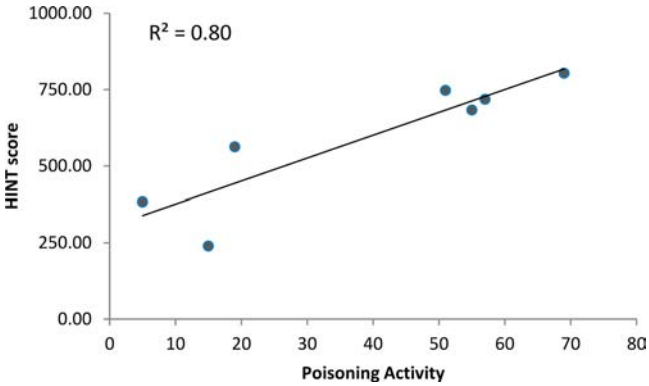

Figure 2. Correlation between computed results and experimental data. All experimental data were retrieved from the literature and express relative potency of compounds with respect to the reference standard camptothecin.[2]

Globally the procedure proved to be able to evaluate the relative effect of conjugations on poisoning activity of luteolin and quercetin.

Query-Set Results. The query-set underwent the same procedure of the training-set. Results were reported in Table 2.

Table 2. Results of the Query-Set[a]

compound	mean HS	predicted effect
luteolin	**683 ± 28**	/
luteolin-3′-*O*-glucuronide	756 ± 103	↑↓
luteolin-3′-sulfate	738 ± 24	↑
luteolin-4′-*O*-glucuronide	899 ± 163	↑
luteolin-7-*O*-glucuronide	891 ± 199	↑
luteolin-7-sulfate	354 ± 139	↓
quercetin	**718 ± 42**	/
quercetin-3-*O*-glucuronide	1766 ± 112	↑
quercetin-3′-*O*-glucuronide	782 ± 177	↑
quercetin-3′-sulfate	636 + 10	↓
quercetin-4′-*O*-glucuronide	756 ± 105	↑
quercetin-7-*O*-glucuronide	719 ± 41	–
quercetin-7-sulfate	618 ± 190	↓

[a]Enhancing and quenching effects with respect to aglyconic reference compounds (in bold) are represented by up- or down-arrow, respectively. "↑↓" indicates indefinable relative potency. "–" indicates comparable effect. HINT scores are expressed as mean value of 5 replicates.

dx.doi.org/10.1021/jf501548g | J. Agric. Food Chem. 2014, 62, 5881−5886

Overall, glucuronidation seemed to exert enhancing effects on both luteolin and quercetin, whereas sulphation, with the exception of luteolin-3′-sulfate, had the opposite effect. In addition, it is of interest to notice the out of range score of quercetin-3-*O*-glucuronide, indicating that this compound might be much more active than the others. Conversely, quercetin-7-*O*-glucuronide appeared virtually identical to quercetin and it could exert similar activity. Finally, once again, it was not possible to resolve the relative effect of luteolin-3′-*O*-glucuronide versus luteolin.

DISCUSSION

Topos I, as well as other topoisomerases, are key enzymes in cell viability which act on genome stability and accessibility during replication and transcription. Therefore, they are commonly targeted by antibacterial and anticancer chemicals. There are at least two mechanisms to disrupt Topo I activity: canonical inhibition by preventing protein−DNA recognition and poisoning by stabilizing DNA−protein complexes and hindering the DNA religation step. Enzyme poisoning rather than inhibition drives drug action. Several compounds act as Topo poisons, with many of them highly specific for Topo I, others for Topo II, and some promiscuous for both isoforms.[27] Currently camptothecin derivatives are the only anticancer drugs targeting Topo I approved by the FDA (Food and Drug Administration, http://www.fda.gov), although several promising compounds are under development.[5] Within this frame, flavonoids such as quercetin and luteolin might play critical roles. It is well-known that this class of compounds commonly occurs in edible parts of fruits and vegetables and exerts a broad spectrum of health-protective properties by interacting with several protein targets. Because advances in system biology suggest that multitarget compounds may prove higher efficacy rather than host-specific drugs,[28] these ubiquitous compounds might be of great relevance in cancer prevention, and TopoI poisoning may contribute to their health benefits. To better understand the underlying mechanisms of luteolin and quercetin putatively beneficial action, their metabolites, truly circulating in the bloodstream after their dietary intake, should be evaluated. Considering the wide array of possible metabolic phase II conjugation and the lack of commercially available standards, an in silico approach might be a useful prioritizing tool, acting by highlighting candidates for further characterization.

In silico techniques may be widely accessible and successfully applied also outside the boundaries of medicinal chemistry. The use of straightforward procedures (in terms of hardware and software requirements) may facilitate both the transition process and procedural automatizm in the field of the biological activity evaluation of phytocompounds. Several works in the literature show that computer driven analysis can contribute to decipher the mechanisms of action of a wide array of highly functional phytocomponents (e.g., refs 29−31). In addition, virtual screening has already proven to be a promising tool to make feasible the bioactivity evaluation of huge spectra of molecules of dietary origin,[32] including their metabolites,[33] or to discover novel enzymatic inhibitors.[34] However, to the best of our knowledge, relevant human metabolites of quercetin and luteolin have not been analyzed yet for their Topo I poisoning activity. For these reasons, we presented a virtual screening procedure performed on machines equipped with common hardware architecture similar to that of current portable devices (including laptops and smartphones). Concerning software, we chose GOLD, which is one of the most popular commercial docking software, and HINT, a natural and intuitive force-field to evaluate the favor of protein−ligand recognition. In addition, the use of such "linear" tools, avoiding complex mathematical and statistical models, contributes to reduce the risk of traps, such as overfitting phenomena and others erroneous or misleading results. The coupling of GOLD to perform docking simulations and HINT as rescoring function, has already proved to be a well working procedure to evaluate protein−ligand interaction,[33,35,36] thus no further validation was needed. Rather, as a proof of concept, we presented (i) the feasibility of a model able to evaluate the semiquantitative effect of conjugations on luteolin and quercetin by using the few inherent data available in literature and (ii) the application of such model to prioritize quercetin and luteolin metabolites for further experimental characterization. We focused on luteolin and quercetin due to their massive occurrence in plant-derived food and we took into account conjugated metabolites because glucuronidated and sulfated derivatives are the main circulating forms *in vivo*. Once assessed the capability to model the effect of conjugation on poisoning activity of luteolin and quercetin, glucuronidated and sulfated metabolites underwent the same procedure. In principle such approach can be applied to any other type of small molecule (and protein), but the procedural performance must be assessed case by case trough cross-check with experimental data.

Flavonoids able to effectively poison Topo I require hydroxyl group substitution at the C-3, C-7, C-3′, and C-4′ positions, a keto group at C-4, and a $\Delta^{2,3}$ double bond (3,3′,4′,7-tetrahydroxy-substituted flavones).[12] Quercetin and luteolin, as well as other flavonoids like apigenin, myricetin, fisetin, and morin, match these criteria and have been shown to poison Topo I.[2,11] However, the presence of sugar moieties has been pointed out to quench the poisoning effect of flavones and flavonols,[2] except for compounds glycosylated at the 8 position, as in the case of luteolin-8-*C*-glucoside (Table 1). In addition, the glucuronide form of SN-38, a potent topoisomerase I inhibitor derived from the pro-drug irinotecan (a derivative of camptothecin), has only 1% of the antitumor activity of its aglyconic active form.[37] Based on this observation, a limited poisoning effect of phase II metabolites containing a glucuronide conjugates should be expected. Nevertheless, most of the glucuronidated derivatives of the tested flavonoids showed enhanced Topo I poisoning effect with respect to their parent compounds (Table 2). On the contrary, sulfate derivatives, with the only exception of luteolin-3′-sulfate, showed a quenched effect when compared to aglycones.

In contrast to the marked role of the type of conjugation, its position in the flavonoid structure did not play a key role in the poisoning effect of these phenolic metabolites, with the exception of quercetin-3-*O*-glucuronide. The docking results revealed that the HINT score for quercetin-3-*O*-glucuronide was notably higher while the magnitude of the predicted effect was quite similar for most of the metabolites (Table 2). This might indicate that glucuronidation of flavonols at the C-3 position enhances their bioactivity as Topo I poisons. In this specific case, the substitution of the hydroxyl group by the glucuronide moiety occurs at the nonbenzene ring, the C ring. Thus, considering the essential role that the phenolic hydroxyl group plays in the activity of the chemotherapeutic SN-38,[37] this structural feature may at least partially explain the enhanced effect of quercetin-3-*O*-glucuronide. Overall, these results

indicate that quercetin-3-*O*-glucuronide is a promising candidate to be tested in further in vitro studies.

Sulfate and glucuronide conjugates are the major circulating metabolites of both quercetin and luteolin,[17,38−40] representing the physiological forms that may exert biological activities attributed to the consumption of their glycosidic precursors abundant in plant food. In the case of quercetin, quercetin-3′-*O*-sulfate and quercetin-3-*O*-glucuronide have been reported to be the predominant metabolites in plasma after the consumption of quercetin glycoside containing foods or supplements.[17,38−40] Therefore, in view of their putative quite opposite poisoning effect on Topo I, the study of their bioactivity on carcinogenic cell models could shed light on the real potential of dietary quercetin as Topo I poison. On the other hand, deconjugation processes consequent to cellular phenolic phase II conjugates uptake should also be taken into account, since this may condition their bioactivity, as already reported.[41]

In conclusion, the feasibility of an in silico model to evaluate conjugation-dependent effects of luteolin and quercetin on TopoI poisoning has been demonstrated by using literature experimental data. However, the applicability of the current model does not go beyond the prediction of potential effects and expanding the applicability of this model to other metabolic modifications and to other phenolic structures would be desirable. Further experimental results obtained on this specific biological feature will ultimately assess the validity of the applied model system. In addition, it is to be pointed out that in vivo effects cannot be inferred solely by using neither in silico models, nor cell-based or cell-free in vitro assays. However, such methods may suggest reasonable mechanisms of action that will then need to be deeply investigated.

This applied in silico model falls within the framework of "prospective" studies. The abuse of "retrospective" docking analysis, intended as aimed only at reproducing already published results, has been reported by several groups (e.g., ref 42). In this sense, our "pilot study" approach explored the feasibility of a good model that is neither definitive, nor a standalone analysis. Rather, it should be placed side by side to experimental works in order to help in prioritizing compounds by predicting putative activity.

Finally, the fact that different conjugations were linked, in this study, to opposite effects should be considered extremely relevant from a nutritional viewpoint, also beyond the results obtained within the specific applied model. The variability of hepatic phase II conjugation among subjects, as well as the interaction of dietary phytochemicals in this context, should be considered more complex than previously thought, and the putative beneficial nutritional effects of flavonoids, postulated by several epidemiological observations, should be evaluated taking carefully considering these observations.

Supporting Information

ABSTRACT: *Toona sinensis* leaf (TSL) has been shown to lower plasma triacylglycerol levels and diminish the size of visceral fat cells in vivo. The molecular mechanism of TSL ethanol extract (TSL-E) on lipid metabolism in 3T3-L1 adipocytes was investigated in this study. Oil Red O staining as well as immunoblotting, real-time PCR, and dual-Luciferase reporter system were performed to investigate the effect of TSL-E on lipid accumulation and the regulation of lipid metabolism, respectively. In addition, active compounds in the TSL-E were analyzed by HPLC. TSL-E significantly decreased lipid accumulation, stimulated free fatty acid (FFA) release, and up-regulated peroxisome proliferator-activated receptor-α (PPARα) and genes involved in peroxisomal (acyl-CoA oxidase) and mitochondrial (uncouple protein 3) fatty acid oxidation. TSL-E also up-regulated cytoplasmic triacylglycerol hydrolysis gene (adipose triglyceride lipase) and genes related to fatty acid oxidation (AMP-activated protein kinase, acetyl-CoA carboxylase, carnitine palmitoyltransferase I, PPARγ, and adiponectin). The major constituents directly inducing PPARα transactivity in TSL-E are gallic acid, rutin, palmitic acid, linoleic acid, and α-linolenic acid. These results indicate that the inhibitory effect of TSL-E on lipid accumulation was through PPARα activation and further up-regulation of PPARα-mediated genes plus up-regulation of cytoplasmic genes involved in lipid catabolism.

INTRODUCTION

Dysregulation of lipid metabolism leading to lipid accumulation inside the body is a major risk factor for chronic diseases including diabetes, cardiovascular diseases, and hypertension.[1−4] To reduce the risk of these diseases, it is important to ameliorate the dysregulation of lipid metabolism to diminish deposition of extra fat.

Peroxisome proliferator-activated receptors (PPARs), PPARα, PPARδ, and PPARγ, a family of ligand-activated transcription factors, are involved in the regulation of glucose and lipid metabolism, inflammation, and cell differentiation.[5−8] Among these three nuclear receptors, PPARα predominantly expressed in metabolically active tissues including liver, heart, skeletal muscle, kidney, and brown adipose tissue[7,9] plays a central role in peroxisomal and mitochondrial fatty acid oxidation. The activation of PPARα up-regulates the transcription of target genes for fatty acid oxidation such as uncouple protein-1 (UCP1), carnitine palmitoyltransferase I (CPT-1), and acyl-CoA oxidase (ACO).[10,11] Most interestingly, recent studies indicate that the activation of PPARα enhances fatty acid oxidation in white adipose tissue and decreases the levels of circulating lipid profiles in obese diabetic patients.[12,13] Therefore, stimulating PPARα activity using PPARα agonist or herbal product-derived PPARα activator could modulate lipid catabolism in adipocytes.

TSL is extensively used as a vegetable in Asia and currently considered as a functional food. TSL improves health outcomes including antioxidant properties with effective protection for atherogenesis,[14] strong 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activities with inhibitory effects on lipid peroxidation,[15] against H_2O_2-induced oxidative stress, and DNA damage in epithelial Madin−Darby canine kidney (MDCK) cells,[16] anti-LDL glycative activity,[17] and improvement of learning and memory through the reduction of lipid peroxidation and β-amyloid plaques in the brains of senescence-accelerated mice.[18] In addition to a wide spectrum of health beneficial activities, TSL also significantly lowers plasma triacylglycerol levels and diminishes the size of visceral fat cells in high fat diet induced obese mice.[19] The precise mechanism underlying the lipid lowering effects of TSL through PPARα activation remains unclear. In the present study, differentiated 3T3-L1 adipocytes were used to investigate the molecular mechanism of the TSL ethanol extract (TSL-E) on PPARα mediated lipid metabolism. We hypothesized that TSL-E with lipid metabolism-modulating effects up-regulates genes associated with peroxisomal and mitochondrial fatty acid oxidation and cytoplasmic triglyceride hydrolysis. To test our hypothesis and elucidate the underlying mechanism of TSL-E on the regulation of lipid metabolism in 3T3-L1 adipocytes, we examined its effects on lipid accumulation, PPARα target gene expression, and PPARα transcriptional activation. Furthermore, high-performance liquid chromatography (HPLC) analysis was used to identify major constituents responsible for PPARα activation in TSL-E.

MATERIALS AND METHODS

Preparation of TSL-E. The lyophilized extracts of TSL (1 g) purchased from the Taiwan Toona Biotech Corp. (Kaohsiung, Taiwan) were dissolved in 10 mL of ethanol (95%) and shaken at room temperature for 12 h. Crude extracts were collected from the supernatant and then concentrated by using a vacuum freeze-dryer. The TSL-E powder was collected and stored in the dark at room temperature for the following assays.

Cell Culture and Treatment. 3T3-L1 adipocytes (BCRC 60159) obtained from the Bioresource Collection and Research Center (Food Industry Research and Development Institute, Hsinchu, Taiwan) were grown in high-glucose DMEM (Gibco BRL, Rockville, MD, USA) supplemented with 10% bovine calf serum, 100 penicillin units/mL, and 100 μg/mL streptomycin (Hyclone, Logan, UT, USA) at 37 °C and 5% CO_2. When the cell density reached 100% confluence (day 0), adipocytes were grown in DMEM supplemented with 10% fetal bovine serum (FBS) (Biological Industries, Beit-Haemek, Israel), 10 μg/mL insulin (Humulin R, Lilly, Indianapolis, IN, USA), 1 μM dexamethasone (Sigma, St. Louis, MO, USA), and 0.5 mM isobutyl methyl xanthine (Sigma). After 4 days of differentiation (day 4), the medium was changed to DMEM with 10% FBS and 10 μg/mL insulin to induce lipid accumulation for a further 4 days (day 8). Unless noted otherwise, mature 3T3-L1 adipocytes with significant lipid accumulation were treated with dimethyl sulfoxide (DMSO) used as a control (Con) or other treatments dissolved in DMSO for an additional period of 4 days (days 8−12).

Oil Red O Staining. After an incubation period of 4 days (days 8−12), 3T3-L1 adipocytes were fixed with 10% formalin at room temperature for 10 min and then fixed with fresh 10% formalin for an additional 1 h. After fixation, cells were washed with 60% isopropanol and stained with Oil Red O (Sigma) at room temperature for 20 min. After staining, cells were washed four times with distilled water. Images were taken using a Nikon Eclipse TS100 inverted fluorescence microscope (Nikon Corp., Japan). After the image analysis, cells were lysed and dissolved in isopropanol (100%) and then harvested for lipid quantification.

Free Fatty acid (FFA) Quantification. Mature 3T3-L1 adipocytes with significant lipid accumulation (day 8) were treated with TSL-E (50 and 100 μg/mL) for 24 h (days 8 and 9). After 24 h of incubation, medium was collected. FFA concentrations were measured according to the manufacturer's instructions (BioVision, Milpitas, CA, USA).

Immunoblotting. After an incubation period of 4 days (days 8−12), 3T3-L1 adipocytes were sonicated for 10 s in ice-cold lysis buffer (20 mM Tris-HCl, 1 mM EDTA, 150 mM sodium chloride, 1 mM sodium orthovanadate, 1 mM sodium fluoride, 10 mM EDTA, 1% NP-40, 10 μg/mL aprotinin, 10 μg/mL leupeptin, and 2 mM PMSF), and the supernatant was obtained by centrifugation. Total protein in the supernatant was measured according to the BCA method (Bio-Rad, Hercules, CA, USA). An equal amount of protein (20−50 μg) for each preparation was added to an equal volume of 6× Laemmli sample buffer and separated using sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE). Protein was transferred on the PVDF membrane. The membrane was blocked with 5% nonfat dry milk in 0.1% Tween-Tris-buffered saline and then incubated in 5% dry milk Tween-Tris-buffered saline with PPARα, PPARγ (Santa Cruz Biotechnology, Dallas, TX, USA), adiponectin (Cell Signaling, Danvers, MA, USA), and β-actin (Novus Biologicals, Littleton, CO, USA) antibodies. β-Actin was used as loading control. Membranes were then washed and incubated with horseradish peroxidase-conjugated second antibody in Tween-Tris-buffered saline with 5% nonfat dry milk. Protein bands were visualized using a chemiluminescence kit (Millipore, Billerica, MA, USA), and densitometry analysis was performed using the LAS-4000 mini biomolecular imager (GE HealthCare Life Sciences, Pittsburgh, PA, USA).

RNA Extraction and Real-Time PCR. After an incubation period of 4 days (days 8−12), total RNA was isolated from all groups using a Trizol/chloroform procedure (Gibco BRL, Rockville, MD, USA). Total RNA concentration was quantified by the NanoDrop meter, and 1 μg of total RNA was reverse transcribed into cDNAs by using the kit (Invitrogen, Grand Island, NY, USA) according to the manufacturer's instructions. mRNA levels of PPARα, ACO, UCP3, CPT1, PPARγ, adiponectin, AMP-activated protein kinase (AMPK), acetyl-CoA carboxylase (ACC), and adipose triglyceride lipase (ATGL) in 3T3-L1 adipocytes were quantified using StepOnePlus real-time systems (Applied Biosystems, Foster City, CA, USA). Primer sequences are shown in the Supporting Information (Table 1). Real-time PCR was performed using a Fast Start SYBR Green master mix kit (Applied Biosystems). The PCR reaction included the following components: each primer at a concentration of 10 μM, diluted cDNA template, and Fast Start SYBR Green master mix and running 40 cycles. Each cDNA sample was run in triplicate, and GAPDH primers as an internal control were included in each run to correct sample-to-sample variation and to normalize mRNA levels. The relative mRNA level was calculated according to the comparative $\Delta\Delta$Ct method.

HPLC Analysis. Phytochemical compounds in TSL-E were analyzed by using an HPLC system consisting of a UV detector (Jasco UV157S, Jasco, Easton, MD, USA), an autosampler (Gilson 234, Gilson, Middleton, WI, USA), and a pump (Hitachi L-7100, Hitachi, Tokyo, Japan). Data were analyzed by chromatography EC2000 data system (Analab Corp., Taipei, Taiwan). The chromatography was performed on an Ascentis C18 column (250 mm × 4.6 mm i.d.). The mobile phase was a gradient prepared from (A) 100% methanol with 0.05% TFA and (B) 20% methanol with 0.05% TFA. A gradient was used as 0−9 min, 0−15% B; 9−12 min, 15% B; 12−17 min, 15−20% B; 17−35 min, 20−25% B; 35−55 min, 25−53% B; 55−65 min, 53% B. The flow rate was 1 mL/min at room temperature, and detection was performed at 280 nm.

To determine fatty acids in TSL-E, fatty acid was derivatized as described by Wood and Lee.[20] Fatty acid standards and TSL-E were converted to fatty acid *p*-bromophenacyl ester by reacting with α-bromoacetophenone and triethylamine. Bromophenacyl esters of fatty acids were used as standards for comparison of retention times to the derivatized TSL-E. Analytes were dissolved in a mixture of acetonitrile/acetone (1:1; v/v). The chromatographic elution was ACN + THF (99:1; v/v) at a flow rate of 1 mL/min. The injection volume was 20 μL, detection was at 258 nm, and all experiments were under room temperature. Calibration curves of fatty acids (palmitic acid, linoleic acid, α-linolenic acid; Sigma-Aldrich, St. Louis, MO, USA) and phytochemicals (gallic acid, catechin, methyl gallate, rutin, and quercetin; Sigma-Aldrich) were obtained by triplicate measurements on a single standard at increasing concentration.

Plasmids and Transfection Assay. The plasmids for PPARα-ligand binding domain (LBD) luciferase report assay, pBIND-PPARα-LBD and pG5luc-TK, were obtained from the Division of Biotechnology and Pharmaceutical Research, National Health Research Institutes, Taiwan.[21] HepG2 (human hepatocellular carcinoma cell line) cells were seeded (5×10^4 cells/well) in 12-well cell culture plates in DMEM supplemented with 10% FBS. After 24 h, transfections were performed using transfection reagent Lipofectamine 2000 (Life Technologies Corp., Carlsbad, CA, USA) according to the manufacturer's instruction. Cells were treated with bezafibrate, TSL-E, palmitic acid, linoleic acid, α-linolenic acid, gallic acid, methyl gallate, catechin, rutin, and quercetin for 24 h. Following treatment, cells were lysed, and firefly and renilla luciferase activities were measured using the Dual-Luciferase Reporter Assay System (Promega, Fitchburg, WI, USA). Bezafibrate was used as a positive control for PPARα activation. The results were expressed as fold difference compared to the Con group.

Statistical Analysis. Results are expressed as means ± standard error (SEM). When only the Con and TSL-E groups were involved, statistical analysis of the difference between the two groups was determined by using Student's *t* test (SigmaPlot 12.0). For multiple comparisons, one-way ANOVA was used to determine the statistical significance of the differences among the groups. ANOVA was followed by post hoc assessment by Student−Newman−Keuls method correction for multiple comparisons (SigmaPlot 12.0). A *P* value of <0.05 was considered to be statistically significant.

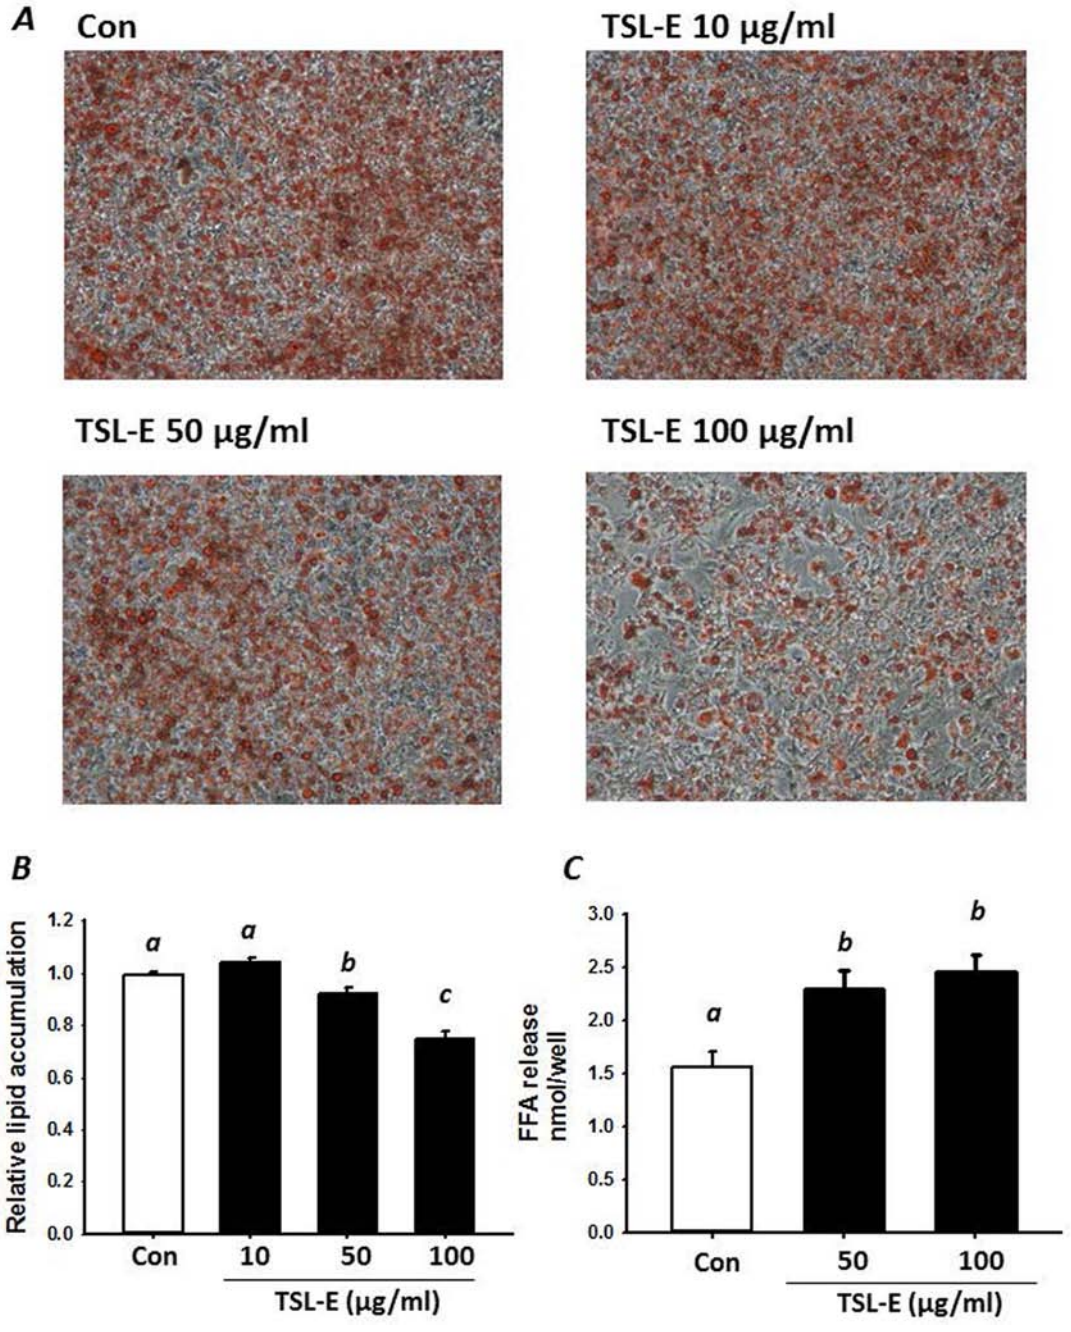

Figure 1. Lipid accumulation in mature 3T3-L1 adipocytes treated with TSL-E. Intracellular lipids were stained with Oil Red O (10× magnification) (A) and quantified (B) after treatment of TSL-E (10, 50, 100 μg/mL) or DMSO (Con) for 4 days (days 8−12). FFA were released in mature 3T3-L1 adipocytes treated with TSL-E (50, 100 μg/mL) or DMSO (Con) for 24 h (days 8−9) (C). Data represent the mean ± SE (n = 3, each in triplicate). Statistical analysis was performed using ANOVA followed by post hoc analysis using the Student−Newman−Keuls method. Significance ($P < 0.05$) among groups is denoted by different letters.

RESULTS

TSL-E Inhibits Lipid Accumulation and Stimulates FFA Release in 3T3-L1 Adipocytes. After 4 days of differentiation from preadipocytes into adipocytes (days 0−4) and 4 days of lipid accumulation (days 4−8), confluent cells were treated with TSL-E (0, 10, 50, and 100 μg/mL) for another 4 days (days 8−12). Oil Red O staining was performed to examine the content of lipid in mature 3T3-L1 adipocytes. As Figure 1B shows, there was no difference between a low concentration of TSL-E (10 μg/mL) and the Con group in lipid accumulation. Significantly lower lipid accumulation was observed at high concentrations of TSL-E extract (50 and 100 μg/mL) compared to the Con in mature 3T3-L1 adipocytes (Figure 1B). Release of FFA was significantly higher after 24 h of treatment of TSL-E (50 and 100 μg/mL) compared to the Con (Figure 1C).

TSL-E Up-regulates Protein and mRNA Expressions of Lipid Metabolism-Associated Genes in 3T3-L1 Adipocytes. To further understand the mechanisms underlying the inhibition of lipid accumulation by TSL-E, protein and mRNA from mature 3T3-L1 adipocytes were examined by Western blot and real-time PCR, respectively. A significant increase in

the protein expressions of PPARα and adiponectin was observed in mature 3T3-L1 adipocytes with TSL-E (100 μg/mL) compared to the Con group (Figure 2). Up-regulation of

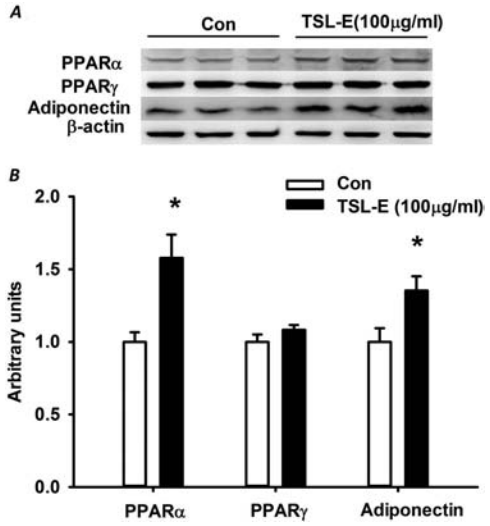

Figure 2. Protein expression in mature 3T3-L1 adipocytes treated with TSL-E for 4 days (days 8−12) and representative blots of three independent experiments (A). PPARα, PPARγ, and adiponectin relative levels were quantified by scanning densitometry of the bands (B). Results are expressed as means ± SE (n = 3/group). (*) $P < 0.05$.

PPARα gene expression was in parallel with protein expression after TSL-E treatment (Figure 3A). Other genes involved in peroxisomal (ACO) and mitochondrial (UCP3) fatty acid oxidation were significantly increased in mRNA levels after TSL-E treatment compared to the Con group in mature 3T3-L1 adipocytes. Moreover, the genes responsible for triacylglycerol hydrolysis (ATGL) and fatty acid oxidation related genes (CPT1, AMPK, and ACC) were significantly increased in mRNA levels after TSL-E treatment (Figure 3A,B). In addition to lipid catabolism, PPARγ and adiponectin involved in adipocyte differentiation and metabolism were also up-regulated by TSL-E (Figure 3C).

PPARα Antagonist GW6471 Attenuates the TSL-E-Induced Lipid Metabolism-Associated Gene Expression but Does Not Affect Lipid Accumulation in 3T3-L1 Adipocytes. To investigate whether the effect of TSL-E on inhibition of lipid accumulation is directly through the PPARα pathway, GW6471, a PPARα antagonist, was incubated with or without TSL-E in 3T3-L1 adipocytes (Figure 4). By using Oil Red O staining, a significant increase in lipid accumulation was observed in 3T3-L1 adipocytes incubated with GW6471 compared to the Con group. However, a marked decrease in lipid accumulation was observed in TSL-E and TSL-E + GW6471 compared to the Con, suggesting that TSL-E is not a specific agonist of PPARα.

With regard to lipid metabolism associated genes, as Figure 5 shows, no difference was observed between GW6471 and the Con group. GW6471 significantly attenuated TSL-E induced up-regulation of mRNA expression including PPARα (Figure 5A), CPT1, PPARγ, and adiponectin (Figure 5B). Furthermore, TSL-E mediated up-regulation of ACO, and UCP3 (downstream genes of PPARα) mRNA expression was completely inhibited by GW6471 (Figure 5A). Interestingly, TSL-E-mediated up-regulation of ATGL was not affected by GW6471 (Figure 5A).

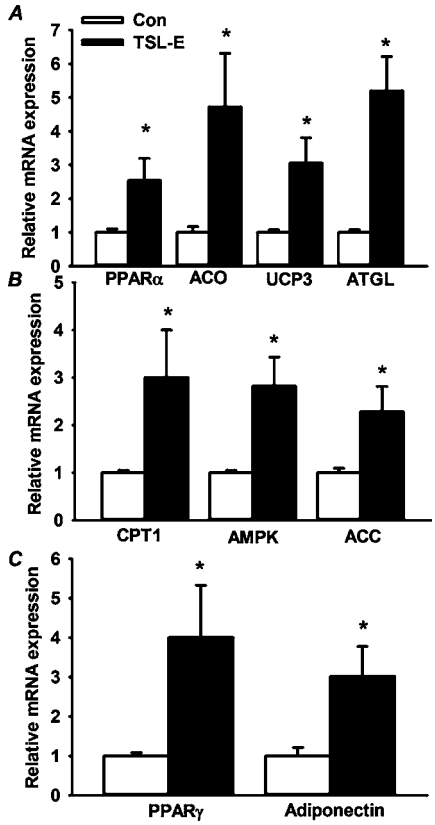

Figure 3. mRNA levels of lipid metabolism-associated genes in mature 3T3-L1 adipocytes treated with TSL-E for 4 days (days 8−12). mRNA levels of PPARα, ACO, UCP3, and ATGL (A), CPT1, AMPK, and ACC (B), and PPARγ and adiponectin (C) from the Con and TSL-E groups were determined by real-time PCR. mRNA levels are expressed as the mean ratio to control after normalization with GAPDH mRNA levels. Fold differences were calculated using the $\Delta\Delta$Ct method. Results are expressed as means ± SE (n = 3/group). (*) $P < 0.05$.

Phytochemicals and Fatty Acids in TSL-E Analyzed by HPLC. To identify active compounds in the TSL-E extract, major peaks (retention time) of TSL-E were observed at the same position as fatty acids and phytochemical standards (Figure 6). As compared to retention time and calibration at increasing concentrations of fatty acid standards, fatty acid compositions in TSL-E presented as a ratio of TSL-E were palmitic acid (2.1%), linoleic acid (2.1%), and α-linolenic acid (4.9%) identified in the present study (Figure 6A,B). In addition to various fatty acids, the identities of five phenolic compounds including gallic acid (4.1%), rutin (3.7%), catechin (0.6%), methyl gallate (0.5%), and quercetin (0.2%) were major phytochemicals in the TSL-E extract determined by comparison with standards (Figure 6C,D).

PPARα Luciferase Activity in TSL-E Extract, Polyphenols, and Fatty Acids. To investigate whether the induction of lipid metabolism associated genes in 3T3-L1 adipocytes by TSL-E resulted from a direct activation of PPARα, the PPARα ligand binding activity was examined by in vitro luciferase reporter assays. The results showed that TSL-E extract (50, 100, and 150 μg/mL) enhanced PPARα luciferase activity in a concentration-dependent manner (Figure 7A). To further examine whether fatty acids and phytochemicals in TSL-E act as bioactive ligands, PPARα luciferase activity in HepG2 cells transfected with PPARα reporter gene was also performed on palmitic acid, linoleic acid, α-linolenic acid, gallic

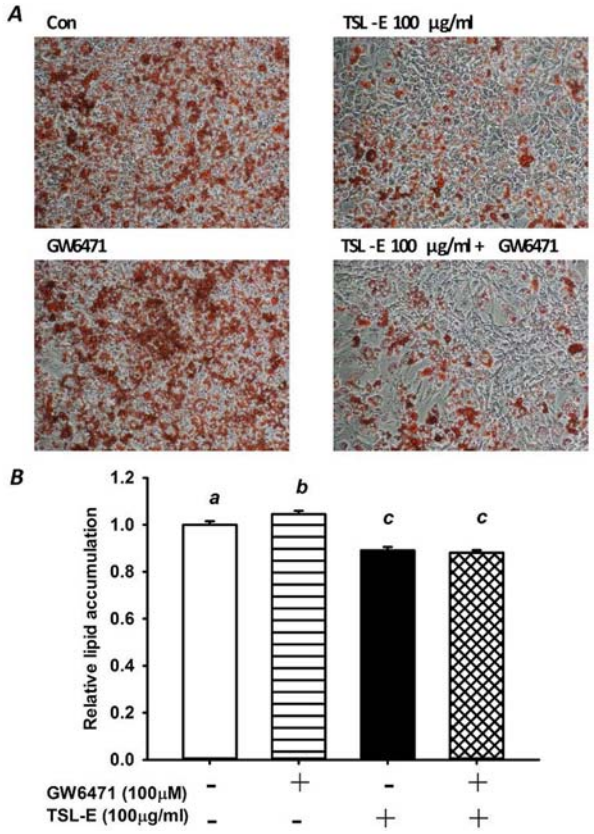

Figure 4. Lipid accumulation in mature 3T3-L1 adipocytes treated with or without PPARα antagonist GW6471 and TSL-E. Intracellular lipids were stained with Oil Red O (10× magnification) (A) and quantified (B) after treatment of DMSO-treated (Con), GW6471, TSL-E, and GW6471+TSL-E for 4 days (days 8−12). Data represent the mean ± SE (n = 3, each in triplicate). Statistical analysis was performed using ANOVA followed by post hoc analysis using the Student−Newman−Keuls method. Significance (P < 0.05) among groups is denoted by different letters.

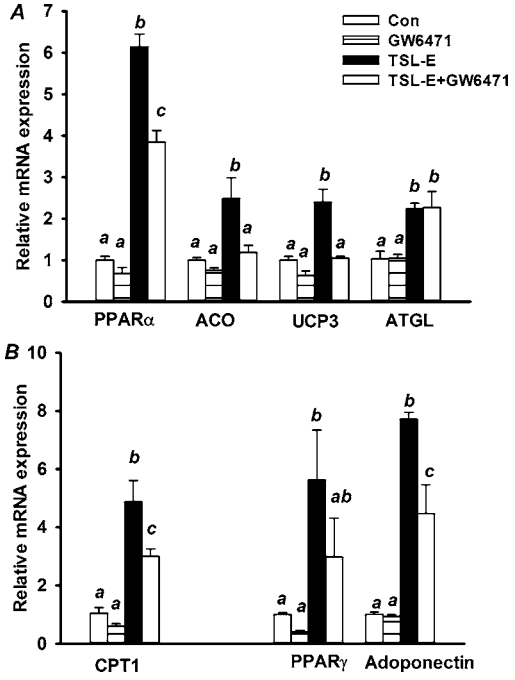

Figure 5. Lipid metabolism-associated genes in 3T3-L1 adipocytes treated with or without PPARα antagonist GW6471 and TSL-E for 4 days (days 8−12). mRNA levels of PPARα, ACO, UCP3, and ATGL (A) and CPT1, PPARγ, and adiponectin (B) from the Con, GW6471, TSL-E, and GW6471+TSL-E groups were determined by real-time PCR. mRNA levels are expressed as mean ratio to control after normalization with GAPDH mRNA levels. Fold differences were calculated using the ΔΔCt method. Results are expressed as means ± SE (n = 3, each in triplicate). Statistical analysis was performed using ANOVA followed by post hoc analysis using the Student−Newman−Keuls method. Significance (P < 0.05) among groups is denoted by different letters.

acid, methyl gallate, catechin, rutin, and quercetin in the present study. The concentration of each fatty acid as well as phytochemical used in PPARα luciferase activity was a ratio of TSL-E extract (150 μg/mL) based on HPLC analysis. Bezafibrate (an agonist for PPARα) was used as a positive control for PPARα activation. Transactivities of PPARα induced by palmitic acid, linoleic acid, α-linolenic acid, and bezafibrate (100 μM) were 1.7-, 1.9-, 2.5-, and 5.0-fold, respectively (Figure 7B). PPARα luciferase activity was significantly increased upon stimulation by palmitic acid, linoleic acid, and α-linolenic acid compared to the Con group. Among major phytochemicals in TSL-E, only gallic acid (1.4-fold) and rutin (1.14-fold) significantly enhanced PPARα luciferase activity compared to the Con group (Figure 7C).

DISCUSSION

The important finding of this study is that TSL-E is beneficial in suppressing lipid accumulation through activation of the PPARα pathway and up-regulation of genes involved in fatty acid oxidation in 3T3-L1 adipocytes. Fibrate drugs, the synthetic PPARα agonists commonly used to treat dyslipidemia,[22] have revealed potential adverse effects including elevated creatinine[23,24] and homocysteine levels,[25] which are biomarkers for renal disease and cardiovascular disease, respectively. Although the long-term effects of fibrates on these diseases require further examination, finding new PPAR modulators from natural products such as TSL-E with lower adverse effects is encouraged.

Results from a previous study indicate that PPARα is involved in the regulation of lipid metabolism through a ligand-dependent transcriptional activation of genes related to fatty acid oxidation.[26] PPARα agonists such as GW647 are known to up-regulate lipid regulatory genes including ACO (the rate-limiting enzyme for peroxisomal fatty acid oxidation) and CPT (the rate-limiting enzyme of mitochondrial fatty acid oxidation) in L6 myocytes.[27] A novel function of UCP2 is involved in mitochondrial fatty acid oxidation,[28] and hepatic UCP2 mRNA expression was up-regulated by using PPARα agonist, WY14643, in rodents.[12,29] In addition to liver and muscle, highly active metabolic tissues, recent studies demonstrated that PPARα was also expressed in white adipose tissue of humans and rodents.[12,26,30] Stimulating fatty acid oxidation through activation of PPARα in 3T3-L1 and human adipocytes[13,31] suggests that white adipose tissue is a potential pharmacological target for PPARα agonists to regulate lipid metabolism and whole body energy balance. TSL-E stimulated fatty acid oxidation through up-regulation of PPARα expression in protein and mRNA levels, leading to decreased lipid accumulation. ACO and UCP, PPARα downstream target genes, were up-regulated by TSL-E in mature 3T3-L1 adipocytes. The effect of TSL-E in augmented gene expression

in adipocytes, particularly those involved in fatty acid β-oxidation such as ACO and CPT1, is similar to that of GW7647, a specific PPARα agonist.[13] The effect of TSL-E on lowering triacylglycerol content and increasing release of FFA via up-regulated ATGL mRNA expression (the key enzyme for the breakdown of triacylglycerol) was observed in the present study and an earlier report on 3T3-L1 cells.[32] Taken together, TSL-E promotes lipolysis through initiation of triacylglycerol hydrolysis into nonesterified fatty acid, followed by breakdown of fatty acids into acetyl-CoA by β-oxidation in adipocytes.

It is noteworthy that TSL-E not only up-regulates PPARα but also promotes PPARγ mRNA expression in this study. Unlike a small amount of PPARα expressed in fat cells, PPARγ is expressed predominantly in adipose tissue, with lower levels in liver and muscle. Activation of PPARγ is recognized to promote adipocyte differentiation.[33] Adipocyte differentiation induced by PPARγ activation increases the number of fat cells with a smaller average size, which are insulin-sensitive adipocytes.[33] As a result, an increase in adiponectin mRNA expression, a downstream target gene of PPARγ, was observed in 3T3-L1 cells treated with TSL-E, whereas a PPARγ agonist,

thiazolidinedione, promotes small adipocyte differentiation, thereby preventing adipocyte hypertrophy.[34] It is generally accepted that there is an increased secretion of adiponectin from small adipocytes via the PPARγ pathway. Interestingly, synthetic PPARα agonists such as fenofibrate and bezafibrate have been reported to up-regulate adiponectin mRNA expression through PPARα activation in 3T3-L1 adipocytes.[26] Because adiponectin acts as an antidiabetic and antiatherosclerotic molecule,[35] such beneficial effects could be achieved by TSL-E-induced stimulation of adiponectin gene expression in adipocytes. In fact, antidiabetic property and normalized plasma adiponectin levels by TSL were observed in high fat diet induced obese mice.[19] Collectively, results from the present study suggest that PPARα as well as PPARγ is involved in the regulation of adipocyte differentiation by inducing PPARs pathways through TSL-E. Thus, the efficacy of TSL-E on adiponectin up-regulation mediated by PPARα/γ activation is a potential antidiabetic property.

Up-regulated gene expression of the AMPK/ACC pathway was also observed in 3T3-L1 cells treated with TSL-E in this study. The phosphorylation of AMPK on serine and threonine residues, a functional form of AMPK, was not determined in the present study. However, a previous study indicated that troglitazone, a PPARγ agonist, stimulated AMPK activation in the epididymal fat of rats.[36] In addition, direct AMPK activation by adiponectin was reported in 3T3-L1 adipocytes.[37] It is speculated that AMPK activation by TSL-E in 3T3-L1 adipocytes is through enhanced adiponectin expression and/or PPARs activation. Consequently, TSL-E plays an important role in the inhibition of anabolic pathways such as fatty acid, glycogen, and cholesterol synthesis and stimulation of catabolic pathways such as fatty acid oxidation and glycolysis in 3T3-L1 adipocytes.

To further elucidate whether TSL-E-mediated lipid catabolism is through the PPARα pathway or not, 3T3-L1 cells were treated with GW6471 (a PPARα antagonist), TSL-E, and the combination of GW6471 and TSL-E. Inhibition of lipid accumulation by TSL-E was not prevented by GW6471. In agreement with this result, GW6471 attenuated TSL-E-mediated lipid metabolism associated gene expression including PPARα, ACO, UCP, and CPT1. Interestingly, augmentation of ATGL mRNA expression mediated by TSL-E was not affected by GW6471, suggesting that TSL-E-mediated ATGL expression is not in a PPARα-dependent manner. As a result, the inhibitory effect of TSL-E on decreased lipid accumulation not only depends on activation of the PPARα pathway but also constantly promotes hydrolysis of triglycerides.

Because PPARα activation by TSL-E contributed to decreased lipid accumulation in adipocytes, active compounds responsible for PPARα activation were identified by HPLC analysis in TSL-E and indicated that palmitic acid, linoleic acid, α-linolenic acid, gallic acid, methyl gallate, catechin, rutin, and quercetin were the active fatty acids and phytochemicals in TSL-E extracts responsible for PPARα activation. It has been recognized that polyunsaturated fatty acids of 18−20 carbon groups consisting mainly of linoleic acid, α-linolenic acid, γ-linolenic acid, and arachidonic acid strongly induce PPARα transactivity.[38] Here we demonstrated that palmitic acid, linoleic acid, and α-linolenic acid in the TSL-E extract were the major active fatty acids to induce PPARα transactivity. Among the main five phytochemicals, only gallic acid and rutin act as PPARα agonists in vitro. It has been reported that rutin suppresses oleic acid induced lipid accumulation by up-regulating PPARα protein expression in hepatocarcinoma cells.[39] Similarly, gallic acid also effectively prevents lipid accumulation in the liver[40,41] and adipose tissue[40] from rodents fed a high-fat diet. Our results demonstrated that TSL-E-suppressed lipid accumulation was attributed to, at least in part, direct stimulation of PPARα activation by major constituents including long-chain fatty acids, gallic acid, and rutin. Taken together, an increase in adipose β-oxidation induced by TSL-E was the result of directly improved fatty acid oxidation enzymes at the PPARα-dependent transcriptional level.

In conclusion, activation of PPARα by TSL-E leading to the inhibition of lipid accumulation in mature 3T3-L1 adipocytes is due to attenuation of lipid accumulation by TSL-E on the regulation of systemic energy expenditure by the induction of molecules involved in fatty acid oxidation in adipocytes. Ultimately, results of this study are beneficial in the development of TSL-E as an antilipid accumulation agent for the prevention of obesity and obesity-related diseases.

ABSTRACT: This study investigated the protective properties of garlic essential oil (GEO) and its major organosulfur component (diallyl disulfide, DADS) against the development of nonalcoholic fatty liver disease (NAFLD). C57BL/6J mice were fed a normal or high-fat diet (HFD) with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) for 12 weeks. GEO and DADS dose-dependently exerted antiobesity and antihyperlipidemic effects by reducing HFD-induced body weight gain, adipose tissue weight, and serum biochemical parameters. Administration of 50 and 100 mg/kg GEO and 20 mg/kg DADS significantly decreased the release of pro-inflammatory cytokines in liver, accompanied by elevated antioxidant capacity via inhibition of cytochrome P450 2E1 expression during NAFLD development. The anti-NAFLD effects of GEO and DADS were mediated through down-regulation of sterol regulatory element binding protein-1c, acetyl-CoA carboxylase, fatty acid synthase, and 3-hydroxy-3-methylglutaryl-coenzyme A reductase, as well as stimulation of peroxisome proliferator-activated receptor α and carnitine palmitoyltransferase-1. These results demonstrate that GEO and DADS dose-dependently protected obese mice with long-term HFD-induced NAFLD from lipid accumulation, inflammation, and oxidative damage by ameliorating lipid metabolic disorders and oxidative stress. The dose of 20 mg/kg DADS was equally as effective in preventing NAFLD as 50 mg/kg GEO containing the same amount of DADS, which demonstrates that DADS may be the main bioactive component in GEO.

KEYWORDS: *garlic essential oil, diallyl disulfide, nonalcoholic fatty liver disease, lipid metabolism, oxidative stress*

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is regarded as the hepatic manifestation of the metabolic syndrome and represents the major cause of liver-related morbidity and mortality with an increased prevalence of hyperlipidemia, obesity, insulin resistance, and diabetes mellitus.[1] Along with rising numbers of patients with metabolic syndrome, the increase in the prevalence of NAFLD directly correlates with the obesity epidemic. NAFLD is defined as fat accumulation in the liver exceeding 5% by weight in the absence of excessive alcohol consumption (<20 g per day).[2] It comprises a spectrum of liver diseases ranging from steatosis to nonalcoholic steatohepatitis (NASH), which can progress to fibrosis, cirrhosis, and hepatocellular carcinoma.[3]

The initiation and progression of NAFLD is primarily attributed to imbalanced lipid metabolism and insulin resistance that induce the accumulation of triglycerides (TG) in hepatocytes, leading to the development of NASH in combination with oxidative stress, inflammation, and hepatic injury.[4] However, no specific or conventional treatment for NAFLD is available; thus, current research focuses on the molecular mechanisms underlying the development of NAFLD.[5] Numerous studies have characterized the effects of sterol regulatory element-binding proteins (SREBPs) or peroxisome proliferator-activated receptor alpha (PPARα)-dependent pathways on lipogenesis and lipolysis in hepatic lipid metabolism.[6] SREBPs regulate the expression of lipogenic enzymes such as acetyl-CoA carboxylase (ACC), fatty acid synthase (FAS), and 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR).[7] On the other hand, PPARα has been reported to be involved in fatty acid oxidation and to regulate the expression of carnitine palmitoyltransferase-1 (CPT-1), which catalyzes the rate-limiting step in fatty acid β-oxidation.[8] In addition, mounting evidence suggests that hepatic cytochrome P450 2E1 (CYP2E1) is a critical regulator of oxidative stress, inflammatory cytokines, and gut-derived endotoxins in the pathogenesis of NASH.[9] Therefore, it could act as a marker of oxidative stress associated with hepatic injury.

Garlic (*Allium sativum* L.) is a widely consumed traditional food and has various medicinal properties. Recent research has focused on the benefits of a variety of organosulfur compounds (OSCs) in garlic, which include water-soluble sulfur-containing compounds (*S*-allylcysteine (SAC), *S*-allylmercaptocysteine (SAMC), *S*-methylcysteine, and γ-glutamylcysteine derivatives) and oil-soluble sulfur-containing compounds (diallyl sulfide (DAS),

diallyl disulfide (DADS), diallyl trisulfide (DATS), allyl methyl trisulfide, vinyldithiins, and ajoene).[10,11] The biological benefits of garlic include antioxidant,[12] antimicrobial,[13] antihyperlipidemic,[14] antiobesity,[15] hepatoprotective,[16] and anticancer effects.[17] Garlic essential oil (GEO) is a commercial garlic product obtained from crushed garlic by steam distillation or organic solvent extraction. GEO has been reported to contain more than 30 OSCs, and DAS, DADS, and DATS have been identified as the three major components.[11] Previous studies have indicated that GEO exhibits beneficial effects on acute ethanol-induced fatty liver and high-fat diet (HFD)-induced liver injury based on elevating the antioxidant and detoxification system.[18−20] However, the protective effects and underlying mechanisms of GEO on NAFLD have not been explored.

The present study evaluated the protective potential of GEO and its major organosulfur component (DADS) against lipid accumulation during the development of NAFLD in a mouse model of long-term HFD-induced obesity. We aimed to investigate the dose-dependent effects of GEO and DADS in a well-established animal model of NAFLD and to explore the possible role in preventing the development of NAFLD. We further identify the underlying molecular mechanisms involved in the hepatic lipid metabolism via SREBP-1c or PPARα-dependent pathways and oxidative liver injury through CYP2E1 expression. This study provides possibilities for new applications of GEO and DADS as functional food ingredients.

MATERIALS AND METHODS

Preparation and Chemical Analysis of GEO. Garlic (*A. sativum* L.) was obtained from the Yunlin County Farmers' Association (Yunlin, Taiwan). Extraction of GEO was performed according to the procedure of Sheen et al.[21] Briefly, garlic was stirred with 2 volumes of distilled water and extracted by steam distillation for 4 h. Volatile extracts were then dehydrated to obtain GEO and stored at −20 °C until use. The yield of the GEO from fresh garlic was 0.30 ± 0.05% (w/w), calculated according to the mean fresh weight of garlic used in each extraction procedure. The three major components in GEO, DAS, DADS, and DATS, were determined using a gas chromatograph (GC, Thermo Scientific Focus GC) equipped with an AI 3000 II autosampler, a flame ionization detector, and a Stabilwax (Crossbond Carbowax-PEG, Restek) capillary column (60 m × 0.32 mm, 1.0 μm thick film). The GC settings were as follows: initial column temperature, 50 °C, increased at 5 °C/min to 200 °C and held for 10 min; injector temperature, 200 °C; and detector temperature, 200 °C. Samples (1 μL, diluted 1:100 in acetone) were injected, with a split ratio of 80:1 and nitrogen as carrier gas (30 mL/min flow rate). Calibration curves were constructed with reference standards and used to determine the concentrations of DAS, DADS, and DATS in GEO. DAS (purity = 97%) and DADS (purity 80%) were purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). DATS (purity > 95%) was purchased from ChromaDex Inc. (Santa Ana, CA, USA). As shown in the GEO chromatogram (Figure 1), the three major components of GEO, DADS (40.7%), DATS (21.6%), and DAS (6.7%) accounted for 69.0% of the total oil. This result is similar to previous studies demonstrating that DADS is the major organosulfur compound in GEO.[18,22] Therefore, DADS was selected for comparison with GEO in the present study.

Animal Experiments. The protocol for the animal experiments was approved by the Institutional Animal Care and Use Committee (IACUC) of the National Taiwan University (IACUC approval no. NTU-101-EL-124). The protocol complied with guidelines described in the Animal Protection Law, amended on June 29, 2011, Hua-Zong-(1)-Yi-Tzi-10000136211, Council of Agriculture, Taiwan. Six-week-old male C57BL/6J mice were purchased from the Animal Center of the College of Medicine, National Taiwan University (Taipei, Taiwan). All mice were housed under controlled temperature (23 ± 2 °C), relative humidity (50−70%), and a 12 h light/12 h dark cycle in the animal house facility. The animals were allowed to acclimatize for 2 weeks prior to the experiments. Mice were randomly assigned to groups of 10 animals each. Animals in the control group were fed a normal diet (13.5% kcal from fat, Laboratory Rodent Diet 5001, Lab Diet/PMI Nutrition International, Purina Mills LLC, Gray Summit, MO, USA); those in the negative control group and treatment groups were fed an HFD (60% kcal from fat, D12492, Research Diets, Inc., New Brunswick, NJ, USA) for 12 weeks to develop NAFLD. Mice of the treatment groups were administered either GEO (25, 50, or 100 mg/kg) or DADS (10 or 20 mg/kg) by daily oral gavage. GEO or DADS was mixed with 0.1 mL of olive oil before administration to the mice. Animals of the control and HFD groups received the same amount of olive oil. All mice had free access to food and water at all times. Body weight and food intake for each mouse were recorded weekly throughout the study. At the end of the experiment, animals were fasted overnight and sacrificed by CO_2 asphyxiation.

Serum Biochemical Analysis. Blood was obtained by cardiac puncture and centrifuged at 1000*g* for 10 min at 4 °C to obtain serum samples. The levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), total cholesterol (TC), and TG were measured in serum using an automatic chemistry analyzer (SPOTCHEM EZ SP-4430, ARKRAY, Inc., Kyoto, Japan). Serum levels of free fatty acids (FFA; BioVision, San Francisco, CA, USA) and insulin (Mercodia AB, Uppsala, Sweden) were determined using commercial kits according to the manufacturers' instructions.

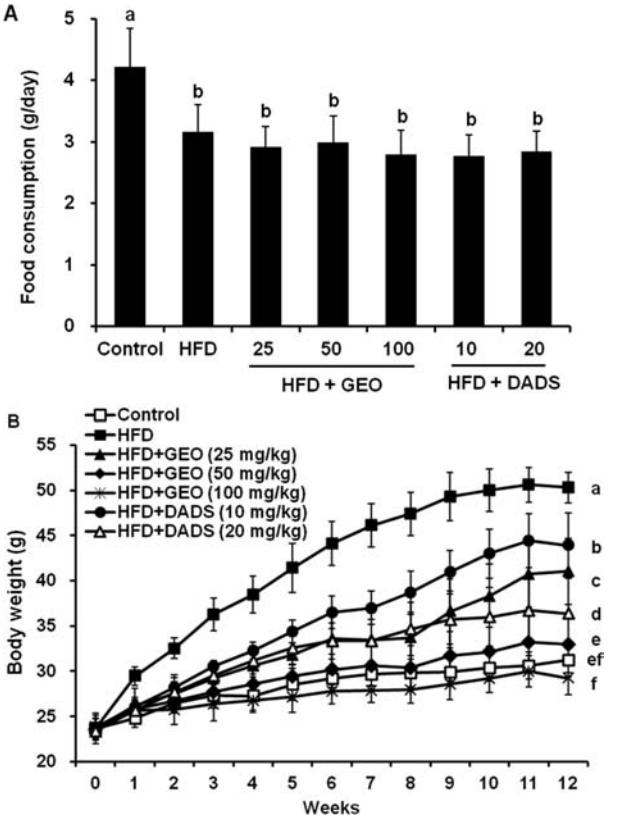

Figure 2. Effects of GEO and DADS on food consumption and body weight in C57BL/6J mice fed an HFD: (A) food intake and (B) body weight in mice fed a normal diet or HFD with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) administration by daily oral gavage for 12 weeks. Data are presented as the mean ± SD (n = 10 mice per group). Statistical analysis was performed using one-way ANOVA and Duncan's multiple-comparison test. Different letters indicate significant differences among groups at the level of $p < 0.05$ (letters are shown in panel B for the 12th week). HFD, high-fat diet; GEO, garlic essential oil; DADS, diallyl disulfide.

Histopathological Examination. Liver and fat pads (subcutaneous, epididymal, and perirenal fat) were collected, weighed, and photographed. A portion of the liver (the biggest lobe) was fixed overnight in 10% neutral-buffered formalin and then embedded in paraffin. Paraffin-embedded sections of liver tissue (5 μm) were stained with hematoxylin and eosin (H&E) to evaluate the morphological changes and assigned scores as an indicator of the degree of fatty liver by a pathologist. The extent of the lesions was graded from 1 to 5 according to severity: 1 = minimal (<1%); 2 = slight (1−25%); 3 = moderate (26−50%); 4 = moderate/severe (51−75%); 5 = severe/high (76−100%). Another portion of the liver was frozen-fixed in OCT mounting media (Sakura, Torrance, CA, USA), whereas the remaining part of the liver was immediately frozen at −80 °C for further investigations. Frozen sections of liver tissue (10 μm) were stained with Oil Red O (Muto Pure Chemicals Co., Ltd., Tokyo, Japan) to detect lipid droplets.

Liver Enzyme and Inflammatory Cytokines. Liver tissues (300 mg) were homogenized with 3 mL of cold homogenization buffer (8 mM KH_2PO_4, 12 mM K_2HPO_4, and 1.5% KCl, pH 7.4) and then centrifuged at 10000*g* for 30 min at 4 °C. The homogenate was stored at −80 °C for the following experiments. The total protein concentration of each sample was estimated with a Bio-Rad protein assay (Hercules, CA, USA) by using bovine serum albumin (BSA) as a standard and measuring the absorbance at 595 nm. The levels of hepatic TG, TC, and glutathione (GSH) and activities of glutathione peroxidase (GPx), glutathione reductase (GRd), glutathione *S*-transferase (GST), catalase (CAT), and superoxide dismutase (SOD) were assayed using commercial kits from Cayman Chemical Co. (Ann Arbor, MI, USA). Lipid peroxidation was evaluated by using a thiobarbituric acid-reactive substances (TBARS) assay kit obtained from Cayman Chemical Co. The levels of tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-6 (IL-6) in liver were quantified by immunoassay kits from eBioscience Inc. (San Diego, CA, USA) according to the manufacturer's protocols.

Western Blot Analysis. Proteins from liver tissues (100 mg) were extracted with 1 mL of cold lysis buffer (7 M urea, 2 M thiourea, 2% CHAPS, 0.002% bromophenol blue, 60 mM DTT, and a protease and phosphatase inhibitor cocktail). All mixtures were then disrupted in an ice−water bath with an ultrasonic cell crusher for 5 min and then centrifuged at 17500*g* for 30 min at 4 °C. Total proteins of the supernatants (whole tissue extracts) were measured using the Bio-Rad protein assay. The protein samples were mixed with 5× sample buffer (62.5 mM Tris-HCl, 10% glycerol, 2% SDS, and 0.01% bromophenol blue) and boiled at 95 °C for 10 min.

Equal amounts of each protein sample were separated by SDS−polyacrylamide gel electrophoresis (SDS-PAGE) and electrotransferred to polyvinylidene difluoride (PVDF) membranes (Millipore Corp., Bedford, MA, USA). Membranes were blocked with a blocking solution containing 5% BSA or skim milk powder in TBST buffer (20 mM Tris-base, 150 mM NaCl, 0.05% Tween 20) for 2 h and rinsed three times with TBST buffer for 5 min each. Incubation with the primary antibody was performed overnight at 4 °C. After washing, the membranes were incubated with the horseradish peroxidase

Table 1. Effects of GEO and DADS Supplementation on Adipose Tissue Weight in Mice Fed an HFD[a]

[a]C57BL/6J mice were fed a normal diet or HFD with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) administration by daily oral gavage for 12 weeks. Data are presented as the mean ± SD (n = 10 mice per group). Statistical analysis was performed using one-way ANOVA and Duncan's multiple-comparison test. Different letters indicate significant differences among groups at the level of $p < 0.05$. HFD, high-fat diet; GEO, garlic essential oil; DADS, diallyl disulfide; FFA, free fatty acid.

(HRP)-conjugated secondary antibody (GeneTex, San Antonio, TX, USA) at room temperature for 1 h and then washed again. Antibodies against SREBP-1c, FAS, ACC, HMGCR, PPARα, and CYP2E1 were purchased from GeneTex. The antibody against CPT-1 was obtained from Cell Signaling Technology Inc. (Beverly, MA, USA). The protein bands were finally visualized with enhanced chemiluminescence (ECL, PerkinElmer Life Sciences, Boston, MA, USA) and captured with a UVP BioSpectrum AC image system (UVP, Upland, CA, USA). Protein expression was quantified by densitometry using ImageJ software version 1.47 (NIH, Bethesda, MD, USA). The relative density of each individual protein band was normalized to that of the β-actin band and the results from three repeated and independent experiments.

Statistical Analysis. All data are expressed as the mean ± SD. Statistical comparisons among experimental groups were analyzed by one-way ANOVA and Duncan's multiple-comparison test using the SPSS software program (SPSS Inc., Chicago, IL, USA). p values <0.05 were considered statistically significant.

RESULTS

Body Weight, Food Consumption, and Adipose Tissue Weight. C57BL/6J mice were fed a normal diet or HFD (60% kcal from fat) for 12 weeks with treatment of GEO or DADS. Food intake and body weight were measured every week. As shown in Figure 2A, there was no significant difference among the diet groups with regard to food consumption; however, higher food intake during the study was noted in the control group. The average daily calorie intake of the HFD and treatment groups was 15.3 kcal, whereas that of mice fed the normal diet was 12.7 kcal. After 12 weeks, the average body weight of mice fed an HFD noticeably increased to 50.29 g from an initial weight of 23.67 g, whereas that of mice in the control group increased only to 31.23 g (Figure 2B). Daily oral administration of GEO or DADS significantly reduced the rate of body weight gain in mice, and the final average body weights of the groups treated with 25, 50, or 100 mg/kg GEO and 10 or 20 mg/kg DADS were 41.05, 32.95, 29.25, 43.92, and 36.38 g, respectively. The average body weight of mice treated with 100 mg/kg GEO was lower than that of mice in the control group, but the difference was not significant. Moreover, HFD-induced increase in the amount of subcutaneous, epididymal, and perirenal fat pads was significantly suppressed by GEO and DADS treatment in a dose-dependent manner (Table 1). Noticeably, treatment of 50 mg/kg GEO or 20 mg/kg DADS exerted a similar inhibitory effect on adipose tissue weight in mice fed an HFD for 12 weeks.

Serum Biochemical Analysis. As shown in Table 2, HFD significantly increased the serum levels of glucose, insulin, FFA, TG, and TC compared to the control group. Administration of GEO and DADS markedly suppressed the increase in the levels

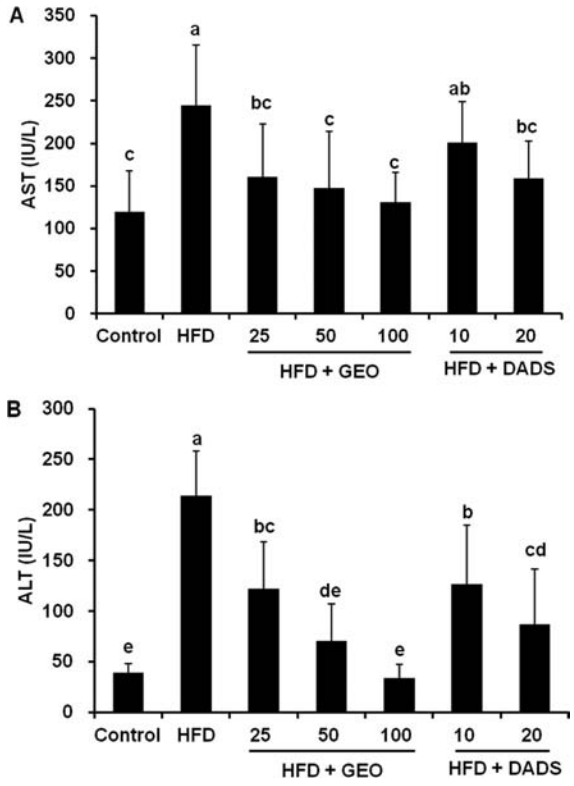

Figure 3. Effects of GEO and DADS supplement on serum AST and ALT levels in HFD-fed mice: serum levels of (A) AST and (B) ALT in C57BL/6J mice fed a normal diet or HFD with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) administration by daily oral gavage for 12 weeks. Data are presented as the mean ± SD (n = 10 mice per group). Statistical analysis was performed using one-way ANOVA and Duncan's multiple-comparison test. Different letters indicate significant differences among groups at the level of $p < 0.05$. HFD, high-fat diet; GEO, garlic essential oil; DADS, diallyl disulfide; AST, aspartate aminotransferase; ALT, alanine aminotransferase.

of serum biochemical markers in a dose-dependent manner. Treatment of 50 mg/kg GEO and 20 mg/kg DADS similarly reduced the elevated levels of glucose, insulin, FFA, and TG in HFD-fed mice. In addition, after 12 weeks of HFD, the serum levels of AST and ALT significantly increased by 2.0- and 5.5-fold, respectively (Figure 3). Supplementation of 25, 50, and 100 mg/kg of GEO resulted in the reduction of the serum AST levels by 34.1, 39.1, and 46.4%, respectively. Similarly, the serum ALT levels in mice treated with 25, 50, and 100 mg/kg GEO were decreased by 43.0, 67.1, and 84.2%, respectively.

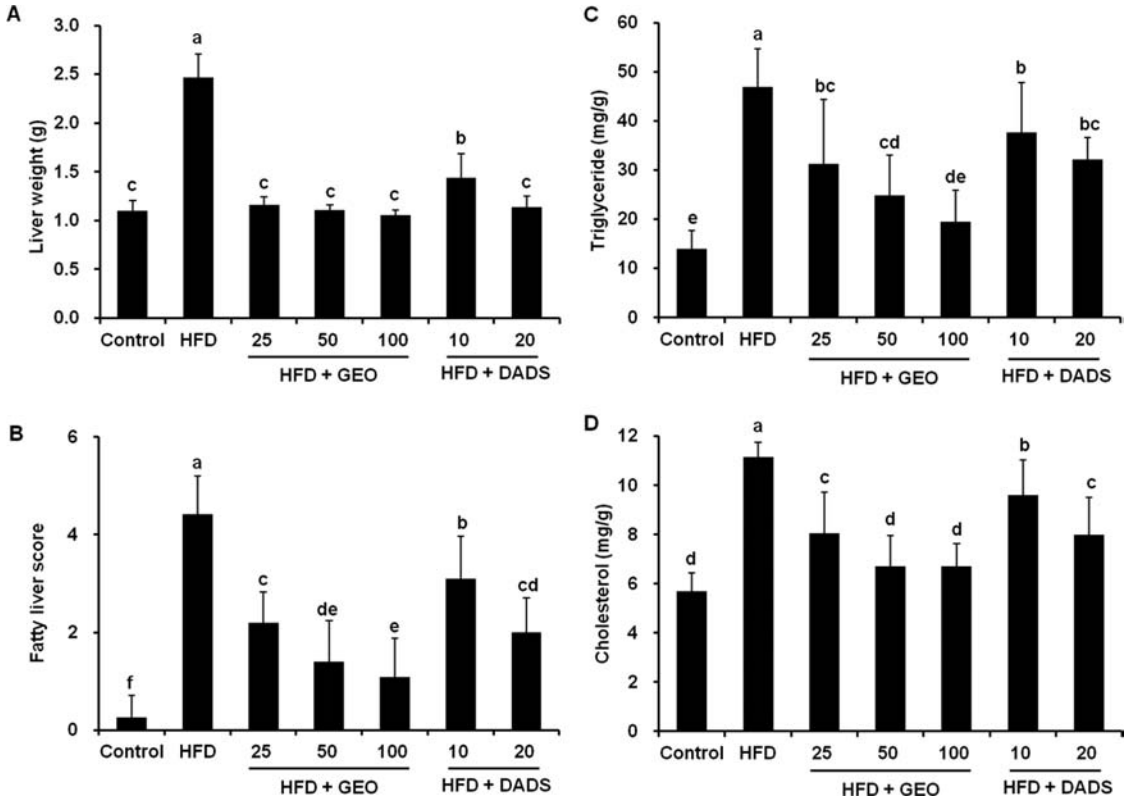

Figure 4. Effects of GEO and DADS on hepatic lipid content in HFD-fed mice: (A) liver weight, (B) fatty liver score, (C) hepatic triglyceride, and (D) total cholesterol in C57BL/6J mice fed a normal diet or HFD with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) administration by daily oral gavage for 12 weeks. Data are presented as the mean ± SD (n = 10 mice per group). Statistical analysis was performed using one-way ANOVA and Duncan's multiple-comparison test. Different letters indicate significant differences among groups at the level of $p < 0.05$. HFD, high-fat diet; GEO, garlic essential oil; DADS, diallyl disulfide.

The reduction of the serum AST and ALT levels by DADS treatment was similar to that observed for GEO treatment.

Hepatic Steatosis and Histopathological Analysis. Figure 4A shows that the average liver weight of HFD-fed mice was 2.2-fold higher than that of mice in the control group. Supplementation of GEO or DADS significantly suppressed the HFD-induced increase in liver weight. Hepatic lipid accumulation was further evaluated by H&E and Oil Red O staining. As shown in Figure 5, HFD-induced accumulation of lipid vacuoles and lipid droplets in mice liver was dramatically reduced by GEO and DADS treatments. Fatty liver scores were assessed in H&E-stained sections by morphometric analysis, which evidenced that the fatty infiltration with macrovesicles of hepatocytes was graded moderate/severe in the HFD-induced group (4.42), moderate in the 10 mg/kg DADS group (3.10), slight in the 20 mg/kg DADS group (2.00) and 25 mg/kg GEO group (2.20), and minimal in the 50 mg/kg GEO group (1.40) and 100 mg/kg GEO group (1.08) (Figure 4B). Similarly, the levels of hepatic TC and TG were significantly increased in HFD-fed mice and decreased dose-dependently by GEO or DADS treatment (Figure 4C,D).

Hepatic Oxidative Stress and Inflammation. Malondialdehyde (MDA) is a reactive aldehyde formed during lipid peroxidation. As shown in Table 3, the MDA levels in mice fed a normal diet and HFD were 3.15 and 4.60 nmol/mg protein, respectively. The MDA levels in mice fed HFD containing 25, 50, or 100 mg/kg GEO and 10 or 20 mg/kg DADS were 4.00, 3.36, 3.35, 4.37, and 3.63 nmol/mg protein, respectively, indicating that lipid peroxidation was attenuated by GEO treatment. The hepatic GSH level in HFD-treated mice was decreased by 29.0% compared to that of the control group, whereas treatment with 25, 50, or 100 mg/kg GEO and 10 or 20 mg/kg DADS resulted in increases in the hepatic GSH level by 17.7, 39.2, 47.7, 6.2, and 39.4%, respectively. In addition, 12 weeks of HFD feeding was accompanied by 16.7−49.5% inhibition of hepatic GPx, GRd, CAT, SOD, and GST activities compared to mice in the control group. The effect of HFD on the activities of these antioxidant enzymes was dose-dependently reversed by administration of GEO and DADS. Moreover, HFD induced a significant increase in the levels of TNF-α, IL-1β, and IL-6 in mouse livers, whereas the levels of these pro-inflammatory cytokines were also dose-dependently attenuated by GEO and DADS treatment. Furthermore, DADS at a dosage of 20 mg/kg, which is comparable to 50 mg/kg GEO, significantly reversed HFD-induced oxidative stress and inflammation after 12 weeks of treatment.

Hepatic Lipid Metabolism and Oxidative Stress. We further examined the effects of GEO or DADS administration on several representative hepatic proteins expression related to lipid metabolism and oxidative stress modulation by Western blotting. The expression of proteins involved in fatty acid synthesis in the liver are shown in Figure 6A−C; expression levels of SREPB-1c and its targets FAS and ACC in HFD-fed mice were 1.9-, 1.9-, and 2.4-fold higher than that in the control group, respectively. When compared to those of the mice in the HFD-fed group, the levels of SREPB-1c, FAS, and ACC were significantly down-regulated by GEO and DADS treatments in a dose-related manner. Figure 6D also shows that HFD-induced

dx.doi.org/10.1021/jf500803c | J. Agric. Food Chem. 2014, 62, 5897−5906

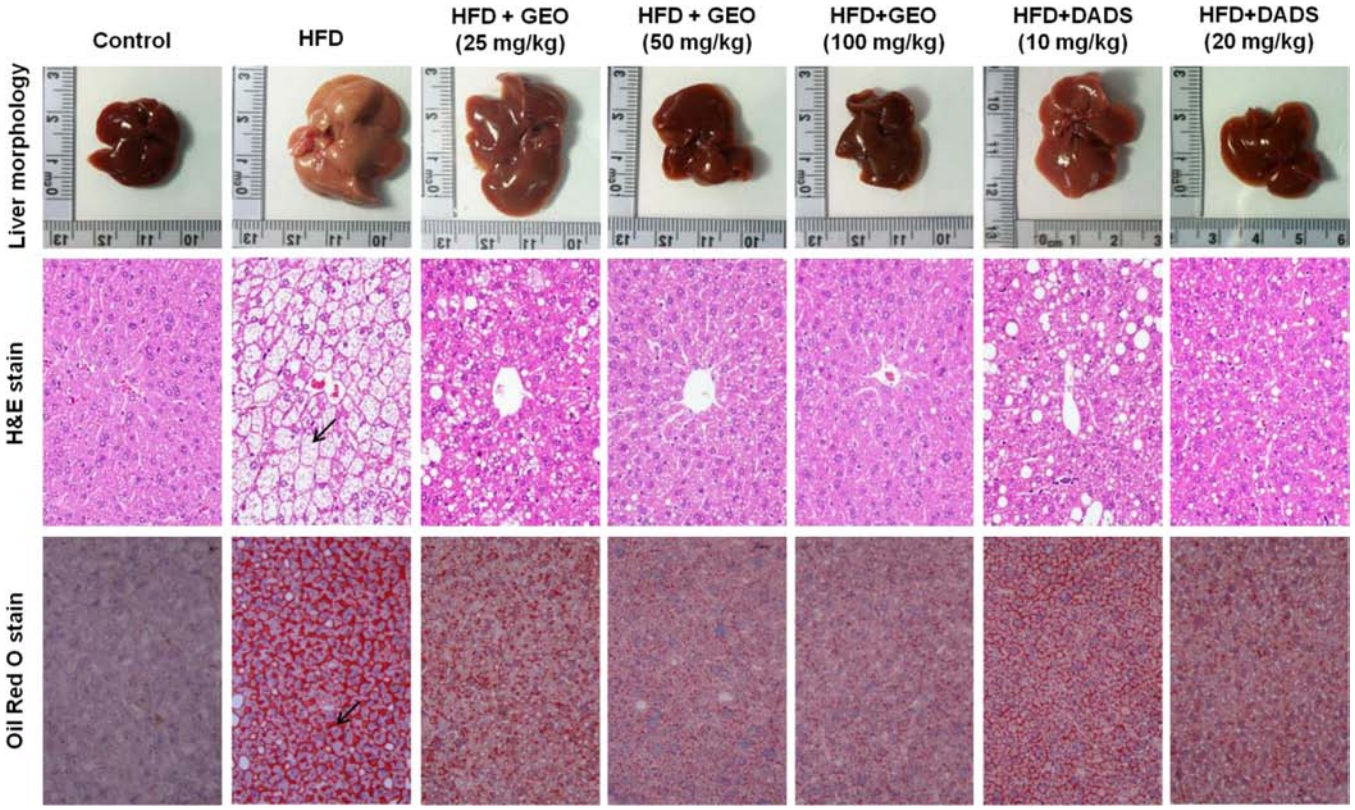

Figure 5. Effects of GEO and DADS supplement on liver histopathological alterations in HFD-fed mice. C57BL/6J mice were fed a normal diet or HFD with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) administration by daily oral gavage for 12 weeks. Liver morphology was assessed, and liver sections were stained with hematoxylin and eosin (H&E) and Oil Red O to visualize lipid droplets (in red). Representative images (magnification: 400×) of each group (n = 10 mice per group) are shown. Black arrows indicate regions of lipid vacuoles in H&E-stained sections and lipid droplets in Oil Red O-stained sections. HFD, high-fat diet; GEO, garlic essential oil; DADS, diallyl disulfide.

expression of the protein that regulates cholesterol synthesis, HMG-CoA reductase, was decreased by 10.7, 48.1, 52.4, 3.81, and 34.47% in the groups treated with 50, 100, or 200 mg/kg GEO and 10 or 20 mg/kg DADS, respectively. In contrast, the protein levels of lipid metabolism markers, PPARα and CPT-1, were significantly decreased by 44.0 and 49.3% in HFD-fed mice, respectively, compared to those in the control group (Figure 7A,B). Administration of 25, 50, or 100 mg/kg GEO and 20 mg/kg DADS to HFD-fed mice significantly up-regulated the hepatic PPARα and CPT-1 expression levels by 1.5−3.1-fold compared to those of HFD-fed mice. Moreover, CYP2E1 expression levels were significantly increased by 1.6-fold in livers of HFD-fed mice after 12 weeks. Administration of 50 or 100 mg/kg GEO and 20 mg/kg DADS markedly decreased the CYP2E1 expression levels by 20.4−42.7% compared to those in HFD-fed mice (Figure 7C). Similar results were observed that the HFD-induced increase in hepatic lipogenic protein expression and decrease of lipolytic protein expression were reversed by 12 weeks of treatment with DADS and GEO.

DISCUSSION

NAFLD is emerging as one of the most common causes of chronic liver disease, and obesity is intimately related to chronic metabolic disorders. Rodent animal models of NAFLD induced by HFD, which show the characteristics of metabolic disorders such as hyperlipidemia, obesity, and insulin resistance, have been widely used due to its similar pathogenesis in humans.[23] In the present study, we fed C57BL/6J mice an HFD (60% kcal from fat) for 12 weeks and found that glucose, TC, TG, AST, and ALT serum levels, hepatic TG and TC levels, and liver weight significantly increased; in addition, moderate levels of oxidative stress and inflammation were induced. However, earlier studies had failed to induce the development of NAFLD in combination with oxidative stress and inflammation.[24,25] These results suggest that long-term consumption of an HFD by mice causes typical NAFLD, with clinical characteristics similar to those observed in NAFLD patients. This model could help elucidate the alterations seen in target organs and the molecular mechanisms underlying the development of NAFLD.

The results of this study showed that administration of GEO and its major active component DADS imparted dose-dependent hepatoprotective effects in obese mice with long-term HFD-induced NAFLD. Administration of 50 or 100 mg/kg GEO and 20 mg/kg DADS lowered HFD-induced body weight and adipose tissue weight, accompanied by antihyperlipidemic effects by reducing serum TG and TC levels. Concurrently, supplementation of 50 or 100 mg/kg GEO and 20 mg/kg DADS resulted in a considerable reduction in FFA that were released by adipose tissue and improved insulin abnormalities by decreasing serum glucose and insulin levels. Imbalanced lipid metabolism and insulin resistance are regarded as key factors in the pathogenesis of NAFLD.[4] Serum AST and ALT, which are important clinical indicators of liver function, returned to levels similar to those observed in normal diet-fed mice through administration of GEO (50 or 100 mg/kg) and DADS (20 mg/kg). Histopathological analysis of liver sections revealed that GEO

[a]C57BL/6J mice were fed a normal diet or HFD with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) administration by daily oral gavage for 12 weeks. Data are presented as the mean ± SD (n = 10 mice per group). Statistical analysis was performed using one-way ANOVA and Duncan's multiple-comparison test. Different letters indicate significant differences among groups at the level of $p < 0.05$. HFD, high-fat diet; GEO, garlic essential oil; DADS, diallyl disulfide; MDA, malondialdehyde; GSH, glutathione; SOD, superoxide dismutase; CAT, catalase; GPx, glutathione peroxidase; GRd, glutathione reductase; GST, glutathione *S*-transferase; TNF-α, tumor necrosis factor-α; IL-1β, interleukin-1β; IL-6, interleukin-6.

and DADS improved HFD-induced hepatic lipid deposition in mice. These data strongly suggest that GEO effectively prevents long-term HFD-induced obesity and NAFLD, which is positively correlated with the reduction in the serum levels of TG, TC, FFA, and insulin.

Oxidative stress and the inflammatory response have emerged as an important mechanism involved in the development and progression of NAFLD.[4] Excessive intake of dietary fats makes the liver vulnerable to toxins and oxidative stress, leading to hepatocyte inflammation by induction of oxidative stress, pro-inflammatory cytokines, and hepatocyte mitochondrial dysfunction. Sustained inflammatory infiltrate upon chronic hepatocellular damage further induces the development of NASH.[26] In this study, GEO and DADS supplementation dose-dependently decreased the levels of pro-inflammatory cytokines (TNF-α, IL-1β, and IL-6) in liver, accompanied by diminished oxidative stress through decreasing MDA levels, elevating GSH levels and antioxidant enzyme activities (CAT, SOD, GPx, GRd, and GST) in HFD-fed mice. Similar effects of garlic on HFD-induced metabolic disorders have been previously reported in the literature. The dietary intake of the ethanol extract of garlic stem at doses of 100, 250, and 500 mg/kg reversed the HFD-induced increase in body weight and adipose tissue weight gain and decreased the levels of antioxidant enzymes, as well as improved abnormal serum and liver lipid profiles in mice.[27] Garlic extract at concentrations of 250 and 500 mg/kg significantly decreased the plasma levels of insulin and TC, as well as oxidative stress markers in obese insulin-resistant rats.[28] Nevertheless, with regard to similar food or calorie intake, the improvements in long-term HFD-induced NAFLD and oxidative injury through administration of GEO and DADS might be attributed to changes in metabolic regulation.

Disorders of lipid metabolism play a central role in the initiation and progression of several metabolic disorders such as obesity, metabolic syndrome, and NAFLD. Experiments and clinical cases indicate that a reduction in FFA absorption in subjects results in elevated FFA concentrations in the peripheral system and entry into the liver, which stimulates the SREBP-1c or PPARα-dependent pathways.[6] This leads to an increase in hepatic SREBP-1c expression and the activation of downstream lipogenesis pathways,[29] including increased expression of lipogenesis markers involved in fatty acid synthesis (ACC and FAS), cholesterol synthesis (HMGCR and SREBP-2), and TG synthesis (glycerophosphate acyl transferase), as well as decreased expression of lipolysis markers (PPARα and CPT-1).[30] When the concentration of fatty acids exceeds the metabolic capacity for fatty acid β-oxidation, fatty acids are deposited in the liver in the form of TG, which results in NAFLD.[31] In the present study, administration of 50 or 100 mg/kg GEO and 20 mg/kg DADS reversed the enhanced synthesis of hepatic fatty acids and cholesterol and the reduced fatty acid degradation in HFD-fed mice as evidenced by decreased expression of SREBP-1c, FAS, ACC, and HMGCR, along with increased expression of PPARα and CPT-1. The results indicated that GEO and DADS dose-dependently prevented hepatic lipid accumulation by reducing serum FFA levels and regulating lipid metabolism in long-term HFD-fed mice.

CYP2E1 has been indicated as a marker of oxidative stress and inflammation associated with liver injury. In clinical and animal studies, up-regulation of CYP2E1 expression was found to be associated with decreased antioxidant enzyme activity in obesity-induced NAFLD or NASH.[32,33] The current study showed that treatment with 50 or 100 mg/kg GEO and

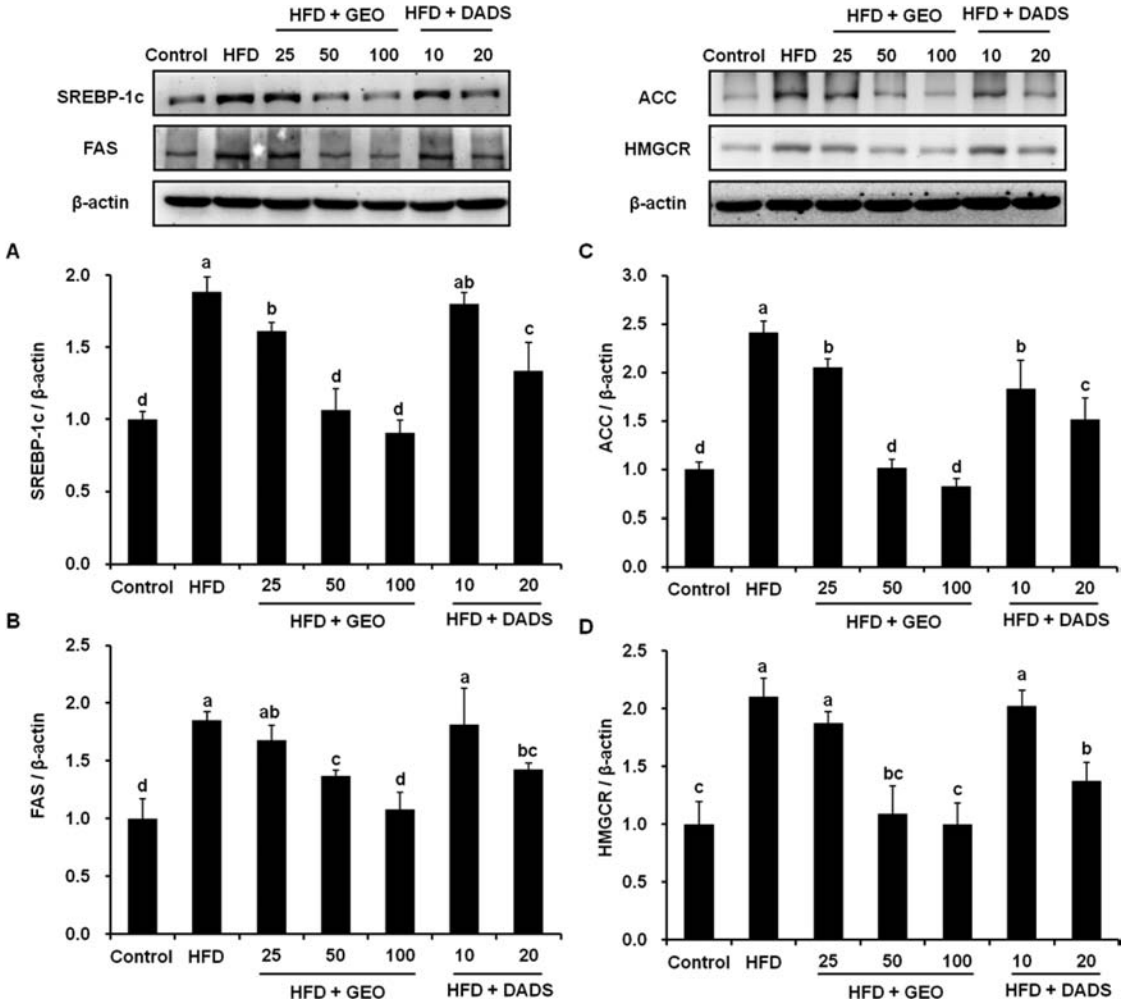

Figure 6. Effects of GEO and DADS supplementation on lipid synthesis-related hepatic protein expressions in HFD-fed mice. C57BL/6J mice were fed a normal diet or HFD with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) administration by daily oral gavage for 12 weeks. Protein expression of hepatic (A) SREBP-1c, (B) FAS, (C) ACC, and (D) HMGCR was analyzed by Western blot, and representative images are shown. Data are presented as the mean ± SD and analyzed with one-way ANOVA and Duncan's multiple-comparison test. Different letters indicate significant differences among groups at the level of $p < 0.05$.

20 mg/kg DADS significantly reversed the up-regulation in CYP2E1 protein expression induced by NAFLD. GEO and DADS restored the hepatic GSH level, enhanced the activities of the antioxidant enzymes, and prevented hepatocyte inflammation by reducing pro-inflammatory cytokine levels. Thus, the results indicated that treatment with GEO and DADS could protect against hepatic oxidative damage resulting from long-term HFD consumption. Moreover, the protection from liver damage may also be helpful for the regulation of fatty acid metabolism. GEO and DADS effectively regulated serum FFA concentrations and hepatic lipid metabolism; the regulation can help prevent SREBP-1c-mediated hepatic lipogenesis and the activation of PPARα-mediated hepatic lipolysis. This finding may explain the protective effects against HFD-induced oxidative injury and NAFLD that have been attributed to GEO and DADS. In addition, earlier studies have suggested that the sulfur compounds in garlic reduce HFD-induced hepatic steatosis and oxidative injury, possibly through modulation of SREBP-1c and CYP2E1.[34,35] The ability of garlic oil to prevent acute ethanol-induced fatty liver should be associated with its antioxidative activities.[20] Taken together, the results provided evidence that GEO and DADS not only prevented the occurrence of early-stage NAFLD but also protected the mice from developing NASH by regulating oxidative stress and suppressing inflammatory responses through CYP2E1 expression. Nonetheless, direct evidence for the mechanisms underlying the effects of GEO and DADS with respect to NASH still needs to be experimentally validated and further investigated.

In our study, the steam distillation of garlic produced GEO that was completely devoid of water-soluble compounds. The three major components of GEO are DADS (40.7%), DATS (21.6%), and DAS (6.7%), which account for 69.0% of the total oil. The various components in garlic work synergistically to provide various health benefits; however, because of garlic's chemical complexity, the efficacy of the preparation varies with the processing methods.[11] Previous studies on the sulfur-containing bioactive constituents of GEO, those being DAS, DADS, and DATS, have reported regulation of detoxification and the antioxidant system by these constituents.[18,36,37] However, the results of the present study suggest that administration of 50 or 100 mg/kg GEO and 20 mg/kg DADS significantly reduces the degree of HFD-induced NAFLD in mice by decreasing lipid accumulation and inflammation as well as by increasing hepatic antioxidant capacity. A single dose of 20 mg/kg DADS was more effective in controlling long-term HFD-induced adverse effects in

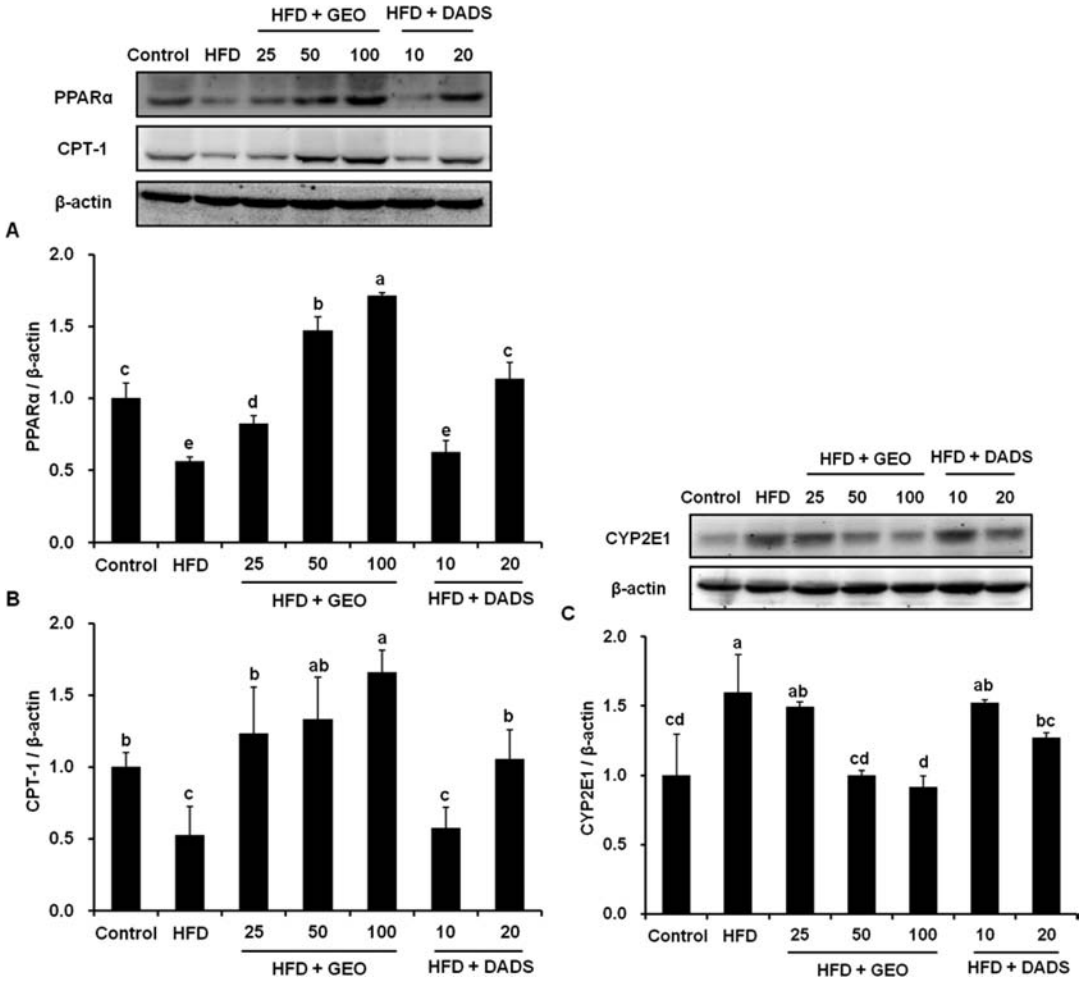

Figure 7. Effects of GEO and DADS supplementation on lipid oxidation-related hepatic protein expression and CYP2E1 expression in HFD-fed mice. C57BL/6J mice were fed a normal diet or HFD with/without GEO (25, 50, and 100 mg/kg) or DADS (10 and 20 mg/kg) administration by daily oral gavage for 12 weeks. Protein expression of hepatic (A) PPARα, (B) CPT-1, and (C) CYP2E1 was analyzed by Western blot, and representative images are shown. Data are presented as the mean ± SD and analyzed with one-way ANOVA and Duncan's multiple-comparison test. Different letters indicate significant differences among groups at the level of $p < 0.05$.

NAFLD mice than lower doses of DADS. This dose of DADS was equally effective in preventing obesity and NAFLD as 50 mg/kg GEO containing the same amount of DADS, which demonstrates that DADS may be the major active sulfur compound contributing to the protection by GEO.

This study is the first to demonstrate the potent protective effects of GEO and its major active component DADS administered to obese mice with long-term HFD-induced NAFLD. Moreover, the protective effects on regulation of hepatic lipid metabolism, antioxidant defense system, and inflammatory response are mainly mediated through SREBP-1c- and PPARα-dependent pathways and CYP2E1-dependent oxidative stress during NAFLD development. Furthermore, GEO and DADS could be considered as potent dietary supplements for preventing NAFLD-related metabolic diseases.

ABSTRACT: A method based on silica gel chromatography and GC-MS/GC-FID analyses was developed for the quantitation of alkaloidal compounds in imported fire ants, *Solenopsis richteri*, *S. invicta*, and their hybrid found in the southern United States. The *cis* and *trans* alkaloids from fire ant body extracts were successfully separated by silica gel chromatography, identified by GC-MS, and quantitated by GC-FID. Piperideine compounds were eluted together with the *cis* and *trans* piperidines, but were well-resolved on a nonpolar GC column. Eight pairs of piperidine isomers and 12 piperideines were quantitated. The ratios of *trans* alkaloids to corresponding *cis* isomers ranged from 87 to 378:1 in *S. invicta* and were significantly higher than in *S. richteri* and hybrid ants. The results were discussed in relation to the evolution of fire ant venom alkaloids and their role as host location cues for parasitic *Pseudacteon* phorid flies.

KEYWORDS: *quantitation, venom, piperidine, Solenopsis richteri, Solenopsis invicta, hybrid*

INTRODUCTION

In the southern United States, the four main species of *Solenopsis* fire ants are *S. geminata*, *S. xyloni*, *S. richteri*, and *S. invicta*. The first two species are native to the southeastern coastal plain of Florida to Texas and south through Central America to northern South America.[1] However, the last two species were introduced into the United States from South America through the port of Mobile, AL, in the early 20th century. All four species produce venoms containing various 2-methyl-6-alkyl (or alkenyl) piperidines,[2−5] and, significantly, the venom of each species possesses a characteristic alkaloidal "fingerprint".[6−8] These alkaloids are species-specific as the venom of each species has groups of similar compounds either dominating or almost completely lacking. Chemical profiles of venom alkaloids have been widely used as a taxonomic tool to define fire ant populations.[8]

Hybrid fire ants, *S. richteri* × *S. invicta*, which were discovered many years after the introduction of their parent species, were indistinguishable from the parent species solely on the basis of the morphological characters. Vander Meer et al.[9] first presented chemical evidence of the natural occurrence of hybridization between the two imported fire ant species as hybrids exhibited intermediate gas chromatographic profiles of both piperidine alkaloids and cuticular hydrocarbons.[10−12]

In addition to *cis* and *trans* 2-methyl-6-alkyl (or alkenyl) piperidines, a series of $\Delta^{1,2}$- and $\Delta^{1,6}$-2-methyl-6-alkyl (or alkenyl) piperideines have been recently identified from imported fire ant workers and alate queens.[13−18] Furthermore, $\Delta^{1,6}$-piperideines in the imported fire ants, *S. richteri*, *S. invicta*, and hybrids, showed significant interspecific variations very similar to those of the *trans* 2,6-dialkylpiperidines.[14]

Previous studies have mainly focused on identification of alkaloidal components from *Solenopsis* fire ants by using a GC-MS technique. To the best of our knowledge, however, no proper analytical method has been developed that permits a detailed quantitative analysis of fire ant venom alkaloids. In the present study, GC-FID was used for quantitation of venom alkaloids because of low detection limits, wide linearity range, and general utility for various analytes. GC-MS was used for discrimination of alkaloidal components instead of quantitative analysis because the MS detector response that requires calibration for each individual compound is less uniform and less convenient for quantitation purposes compared to the FID. A primary goal of this work was to establish a routine analysis procedure to determine alkaloidal components of *Solenopsis* fire ants. A comparative study of the venom alkaloids in *S. richteri*, *S. invicta*, and hybrid fire ants was undertaken to further assess the distribution of these 2,6-disubstituted piperidines and piperideines. The results may contribute to an understanding of the evolution of fire ant venom alkaloids and mechanisms of host specificity and preference in *Pseudacteon* phorid flies, which are important biological control agents of imported fire ants.

MATERIALS AND METHODS

Reagents and Standard. HPLC grade *n*-hexane used for extraction and purification of the venom alkaloids was purchased from CNW Technologies GmbH (Düsseldorf, Germany). Anhydrous sodium sulfate, acetone, and triethylamine purchased from Beijing Chemical Reagent (Beijing, China) were of analytical reagent grade. Acetone and triethylamine were redistilled before use. Silica gel (300−400 mesh) for column chromatography was obtained from the Qingdao Marine Chemical Factory (Qingdao, China). 4-(2,6-

Dimethyl-1-piperidinyl)-1-phenyl-1-butanone purchased from Sigma-Aldrich (St. Louis, MO, USA) was used as external standard for GC-FID analysis.

Collection and Identification of Fire Ant Colonies. Colonies of the black imported fire ant, *S. richteri* Forel, the red imported fire ant, *S. invicta* Buren, and their hybrid, *S. richteri* × *S. invicta*, were used in this test. We collected colonies of *S. richteri* in northern Mississippi and western Tennessee and colonies of *S. invicta* in Alabama (Auburn University campus) in mid-November 2011. At the same time, hybrid fire ant colonies were collected from northern Alabama and northeastern Mississippi, where hybrids are known to occur almost exclusively. Each colony containing workers, alates, broods, and queens was transferred in 1 gallon Rubbermaid plastic jars coated with Fluon to prevent escape. All colonies were reared in the laboratory and fed with 10% sugar water and crickets.

The identity of fire ant colonies was confirmed to be *S. richteri*, *S. invicta*, or hybrid fire ants by GC analysis using both alkaloid and hydrocarbon characters as previously reported.[17,19] Briefly, about 50 workers selected randomly from each colony were soaked in 1 mL of hexane for 2 h. A small aliquot (1 μL) of the hexane extract was injected into an Agilent 7890A GC equipped with a 30 m × 0.25 mm i.d., 0.25 μm, HP-5ms capillary column (Agilent Technologies) in splitless mode. Nitrogen was used as carrier gas at a flow rate of 2 mL/min. The injection port and detector temperatures were set at 270 and 280 °C, respectively. The GC oven was programmed at a rate of 15 °C/min from 90 to 270 °C, with a 2 min initial time and a 16 min final holding time.

Sample Preparation for Quantitative Analyses. A total of 32 colonies were analyzed in this study, including 8 colonies of *S. richteri*, 8 colonies of *S. invicta*, and 16 colonies of hybrids. Alkaloids were extracted and isolated from fire ant samples as previously reported.[15−17] For each colony, ant workers (1 g) were killed by freezing and extracted with hexane (enough hexane to cover ant bodies, ∼3.5 mL) for 24 h. The extract was dried over anhydrous

[a]Carbon numbers have been widely used to represent the trivial names of alkaloids found in *Solenopsis* fire ants, e.g., in *cis*-C11:1, with 11 referring to the chain length and 1 referring to the number of double bonds.[6] [b]Trace amount.

sodium sulfate, concentrated to 0.5 mL under a mild stream of N_2, and then loaded onto a 17 mm (o.d.) chromatography column (20 g of silica gel). The column was eluted with hexane containing 2% triethylamine and stepwise increasing amounts of acetone (hexane/acetone ratio ranging from 50:1 to 10:1) to obtain the alkaloids. The chemistry of each collection (ca. 2 mL) was analyzed by gas chromatography (GC) on an Agilent 7890A GC equipped with a flame ionization detector (FID) under the same GC conditions described above. The collections were pooled on the basis of changes observed in the GC chromatograms of each collection to obtain two major alkaloid fractions: *cis* and *trans* alkaloid fractions. The two alkaloid fractions of each colony were concentrated to a certain volume for GC-MS and GC-FID analyses. As imported *Solenopsis* fire ant workers contain large amounts of *trans* alkaloids compared to corresponding *cis* alkaloids, the final volume of the *trans* alkaloid fraction was 20 times more than that of the *cis* alkaloid fraction prior to GC injection to achieve proper concentrations of *trans* alkaloids for quantitation, that is, 2 mL for the *cis* alkaloid fraction and 40 mL for the *trans* alkaloid fraction.

A stock solution of standard compound, 4-(2,6-dimethyl-1-piperidinyl)-1-phenyl-1-butanone (2000 ng/μL), was prepared and then diluted to a series of concentrations ranging from 0.39 to 400 ng/μL. All dilutions were transferred to the GC autosampler, and 1 μL of each dilution was used for GC-FID analysis.

GC-MS and GC-FID Analysis. GC-MS analyses of alkaloid fractions were performed on an Agilent 7890A GC coupled to a 5975C mass selective detector, with an HP-5ms capillary column as described above. Helium was used as carrier gas at a flow rate of 1 mL/min. Injections (1 μL) were made in the splitless mode at an injector temperature of 230 °C. The GC oven temperature was programmed from 90 °C (isothermal for 1 min) to 160 °C at 10 °C/min, then to 250 °C at 3 °C/min, and held for 2 min. Total run time was 40 min. The transfer line temperature was set at 250 °C. Mass spectra were obtained using electron impact (EI, 70 eV). The chemical identities of alkaloids were determined by analysis of their mass spectra, as well as

by comparison of diagnostic ion fragments with published results on *Solenopsis* fire ants.[15−18]

Quantitative chromatographic analyses were carried out with the Agilent 7890A GC equipped with an FID. Nitrogen at a flow rate of 1 mL/min was used as the carrier gas. The GC conditions including the dimensions of capillary column, oven temperature program, and injection operation were the same as those for GC-MS. The detector temperature was set at 260 °C.

Statistical Analysis. A standard curve was calculated by linear regression analysis. The concentrations of the identified venom alkaloids were calculated against the standard curve. The absolute abundances of the alkaloids were analyzed using the PROC GLM procedure of one-way analysis of variance (ANOVA) followed by the Tukey−Kramer HSD comparison test ($P < 0.05$) to establish significant differences among the three fire ant species (we consider hybrid as a species in this study).[20] A PROC TTEST procedure ($P < 0.05$) was used to establish significant difference between, if applicable, any two of the three fire ant species.

RESULTS AND DISCUSSION

Fire ant venom alkaloids were readily extracted out of ant worker bodies by hexane. As previously reported,[15−17] the venom alkaloids of fire ant extract were separated into two alkaloid fractions (*cis* and *trans* alkaloid fractions) by silica gel chromatography, with the *cis* stereoisomers always being eluted before the corresponding *trans* stereoisomers. The two alkaloid fractions were then subjected to GC-MS analysis, and the chemical identities of alkaloidal components were determined by comparing mass spectrum and retention time with published data.[15−17] This routine procedure can be applied to the analysis of alkaloids from any *Solenopsis* or related alkaloid-containing ant species.

Typical GC-FID traces of the *cis* and *trans* alkaloid fractions of fire ant samples are shown in Figure 1. Both GC patterns of the two alkaloid fractions are species-specific. Almost all of the peaks show interspecific variations. Furthermore, both *cis* and *trans* alkaloids from hybrids show characteristics intermediate to those of the two parental species. A total of eight pairs of *cis* and *trans* alkaloids, those being **1**−**1′**, **2**−**2′**, **5**−**5′**, **7**−**7′**, **11**−**11′**, **13**−**13′**, **17**−**17′**, and **19**−**19′**, were identified by GC-MS on the basis of mass spectra with characteristic base peak m/z 98, molecular ion $[M^+]$, and $[M - 15]^+$,[2,3,5,6] meaning that there were eight pairs of diastereoisomers isolated from the three fire ant species (Table 1). Peaks 2, 5, 7, 11, 13 and their corresponding *trans* stereoisomers were found in all ant samples. However, peaks 1 and 1′ were not found in *S. invicta* samples, whereas peaks 17, 19, and their corresponding *trans* stereoisomers were not found in *S. richteri* samples. Peaks 17′ and 19′ were detected in trace amounts in the *trans* alkaloid fraction of hybrids, but their counterparts in the *cis* alkaloid fraction of hybrids were not detectable.

In both alkaloid fractions, two series of piperideines were found. $\Delta^{1,6}$-Piperideines, **3**, **6**, **8**, **12**, **14**, **18**, and **20**, were identified by characteristic mass ions m/z 96, 111, $[M^+]$, and $[M - 15]^+$, whereas $\Delta^{1,2}$-piperideines, **4**, **9**, **10**, **15**, and **16**, were identified by characteristic mass ions m/z 96, 97, 110, $[M^+]$, and $[M - 15]^+$.[6,13,15−17] As reduction of these piperideines to piperidine was proposed to be the final step of biosynthesis of piperidine alkaloids in *Solenopsis* fire ants, the absolute configuration of piperideines was established as (2*R*) or (6*R*).[15,21,22] GC trace of the *cis* alkaloid fraction had distinctive $\Delta^{1,6}$-piperideine peaks, mainly 12, 14, and 18 (for instance, in *S. invicta*), but fairly visible $\Delta^{1,2}$-piperideine peaks. GC traces of the *trans* alkaloid fraction also had $\Delta^{1,6}$-piperideine and $\Delta^{1,2}$-piperideine peaks in trace amounts. The intermolecular hydrogen bonding between nitrogen (−N═) of piperideine and hydrogen (H−*N*<) of piperidine might cause the inseparability of piperideines and piperidines and the slow elution of piperideines in the *trans* alkaloid fraction. The fact that we did not detect any alkaloidal components in the chromatographic collections between the *cis* and *trans* alkaloid fractions also supports this interpretation. The GC profile of piperideines in the *cis* alkaloid fraction of hybrids showed intermediate characteristics similar to those of the *cis* and *trans* alkaloids.

The external standard method was used to obtain the regression equation. We used log-transformed data to construct a calibration curve, $\log(A) = 0.9894 \log(C) + 1.2551$, where A is the peak area and C is the concentration of the standard compound (ng/μL). The selected piperidine standard showed good linearity ($r^2 = 0.9996$, $P < 0.001$) in relatively wide concentration ranges. Then the obtained calibration curve was used to determine alkaloidal components in all ant samples (Table 1).

Among the *cis* alkaloids, *cis*-C13:1 (peak 5) in *S. richteri* had the highest amount, 231.52 ± 33.97 μg/g, of ant workers. All three ant species had large amounts of shared *trans* alkaloids. *trans*-C13:1 (peak 5′) was quantitatively the most dominant component with 5618.02 ± 628.26 μg/g in *S. richteri*, whereas *trans*-C15:1 (peak 11′) was quantitatively the major component with 4257.75 ± 315.05 μg/g in *S. invicta*. These two components were both predominating in hybrids. The amounts of piperideines were all relatively low in the three ant species. In most cases, the amounts of these piperideines were under 10 μg/g of worker ants. The results of the statistical analysis showed that significant differences were detected for all peaks with only one exception, $\Delta^{1,2}$-C15:1 (peak 15), suggesting that there exists interspecific variation for all *cis* and *trans* alkaloids and piperideines. For any given alkaloidal component, the amount in hybrids was always intermediate to that of *S. richteri* and *S. invicta*. Although in some cases there was statistical nondifference between hybrids and the parental species, the amount of hybrids was always numerically either higher or lower than that of any parental species. Clearly, wide variation in alkaloid chemistry in hybrids resulted in the statistical indifference. This is why, in the current study, the number of hybrid colonies investigated was 2 times higher than that of the parental species. Peaks 11−14, however, were exceptions showing that these were higher in the hybrid than in both parental species. This inconsistency complicated the alkaloid chemistry of hybridization.

It has been previously hypothesized that the venom of ancestral *Solenopsis* species was simple (i.e., contained only a few components) and the evolution of venom alkaloids would have begun with a condition in which the venom contained abundant C11 and minute traces of C13, with the *cis* isomers dominating and the *trans* isomers at a much lower level.[23] The evolution of the alkaloidal compounds in *Solenopsis* could involve two steps: a switch from a probable normal production ratio of *cis*- and *trans*-C11 (**2** and **2′**), to a thermodynamically highly unfavorable decrease in *cis* and an increase in *trans* isomers and further evolution of abundant *trans*-C13 (**7′**) and *trans*-C13:1 (**5′**) and then the addition of *trans*-C15 (**13′**), *trans*-C15:1 (**11′**), *trans*-C17 (**19′**), and *trans*-C17:1 (**17′**), accompanied by a reduction in the production of *trans*-C11 (**2′**).[16,23,24] We first calculated the mean ratio of *trans* to *cis* alkaloids for *S. richteri*, *S. invicta*, and their hybrid (Table 2).

[a]Only *trans* alkaloids were detected.

The ratios of *trans* to *cis* alkaloids in *S. invicta* were significantly greater than in *S. richteri*, and the ratios in hybrids were numerically but not significantly greater than in *S. richteri*, indicating that this character in hybrids was intermediate to both parental species. The ratios for combined alkaloids with the same length of unsaturated and saturated side chains in *S. invicta* ranged from 87.37 to 305.88, suggesting that *trans* alkaloids were extremely predominant in this ant species. Brand et al.[23] gave rough estimates of the ratio of *trans*-C11 (**2′**), to *cis*-C11 (**2**), collected from 10 individuals of *S. richteri* and of *S. invicta*, which were all 10:1. In this study, we present data calculated from 1 g of pooled ant samples. The ratios of *trans*-C11 (**2′**), to *cis*-C11 (**2**), for *S. richteri* and *S. invicta*, were 28.31 ± 6.80, and 87.37 ± 24.23, respectively, which were much greater than the reported data.[23] The venoms of several species native to the United States, *Solenopsis aurea*, *S. xyloni*, and *S. geminata*, consisted mainly of *cis*-C11 (**2**) and *trans*-C11 (**2′**). The ratio of *trans*-C11 (**2′**), to *cis*-C11 (**2**), in pooled samples of the first two species was about 1:4, whereas it was 1:1.2−1.5 in the latter species.[7,8,23,25] On this basis, *S. aurea*, *S. xyloni*, and *S. geminata* would appear to be the more primitive species, whereas *S. richteri* and *S. invicta* are relatively newer species. The venom of *Solenopsis eduardi* (a close relative of *S. geminata*) collected from Colombia consisted of > 98% *trans*-C11 (**2′**) and about 1% of the corresponding *cis* isomer (**2**),[8] which represented a major shift from *cis*-C11 (**2**) to *trans*-C11 (**2′**). Furthermore, the ratios of *trans* alkaloids to *cis* alkaloids for *S. invicta* were significantly higher than for *S. richteri*, suggesting that *S. invicta* is a much newer species than *S. richteri*.

Second, we calculated the total alkaloids with the same side-chain length at the 6-position of the piperidine and/or piperideine ring (Table 3). The *cis* alkaloids and piperideines were minor components, whereas the *trans* alkaloids were major components. Furthermore, the *cis* alkaloids and piperideines in *S. richteri* were relatively higher than in *S. invicta*. The *trans* alkaloids C11 (**2′**) and C13 (**5′** and **7′**) were predominant in *S. richteri*, whereas the *trans* alkaloids C13 (**5′** and **7′**) and C15 (**11′** and **13′**) were predominant in *S. invicta*. Hybrids showed intermediate characteristics between the two parental species. However, there were two exceptions, *cis*-C15 (including *cis*-C15 (**13**) and *cis*-C15:1 (**11**)) and piperideines C15 (including **12**, **14**, **15**, and **16**). Hybrids had significantly greater amounts of *cis*-C15 (**11** + **13**) and piperideines C15 (**12** + **14** + **15** + **16**) than *S. richteri* and *S. invicta*, which possibly resulted from wide variations in alkaloid chemistry among hybrid colonies. Data from Table 3 clearly demonstrated the dominance of *trans*-C13 (**5′** + **7′**) along with the addition of *trans*-C15 (**11′** + **13′**) and *trans*-C17 (**17′** + **19′**), accompanied by a reduction in the production of *trans*-C11 (**2′**).

[a]Total alkaloids mean sum of the *cis*, *trans* piperidines and piperideines with the same side chain length at the 6-position of the piperidine and piperideine rings.

Third, we calculated the total amounts of the *cis* and *trans* alkaloids and all alkaloids detected from all three ant species (Figure 2). *S. invicta* had a significantly lower amount of *cis*

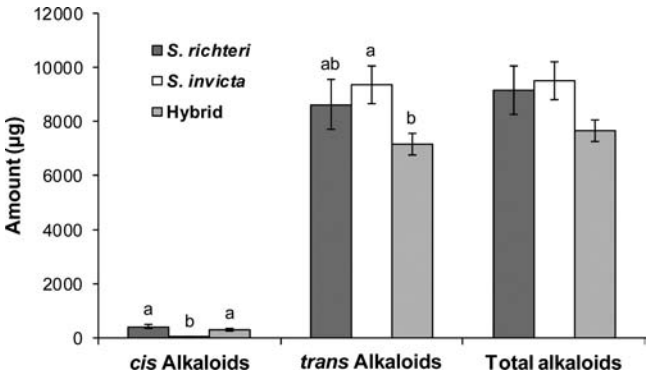

Figure 2. Amounts of alkaloids isolated from 1 g of ant workers. Total alkaloids are the sum of *cis* alkaloids, *trans* alkaloids, and piperideines. Means for same alkaloid type having no letter in common are significantly different ($P < 0.05$, Tukey–Kramer HSD test).

alkaloids than *S. richteri* and hybrids. In contrast, *S. invicta* had a significantly greater amount of *trans* alkaloids than hybrids and a relatively, but not significantly, greater amount than *S. richteri*. Hybrids produced a slightly lower amount of total alkaloids compared to the two parental species. The total amounts of alkaloids produced by 1 g of ant workers of the three species ranged from 8 to 10 mg, meaning that ant workers can produce up to 1% alkaloids of their body weight. The order of total amounts of alkaloids was *S. invicta* > *S. richteri* > hybrids even though the differences were not statistically significant (Figure 2). If the production of venom alkaloids represents competition ability of an ant species, a relatively lower production of total alkaloids in hybrids would decrease their fitness. It has been suggested that hybrid fire ants have reduced relative fitness compared to their parent species due to intrinsic selection.[26] Aggression toward heterospecifics has been used as a measure of fitness among sympatric congeneric species.[27] It was found that *S. invicta* had the lowest aggression threshold, whereas *S. richteri* was the least aggressive.[19] Moderate aggression threshold of hybrids might be related to intermediate chemistry in venom alkaloids shown in this study.

Piperideine alkaloid was first found in *S. xyloni* as $\Delta^{1,2}$-C11 (**4**).[6] Recently, several studies have reported the identification of a series of $\Delta^{1,2}$- and $\Delta^{1,6}$-piperideine alkaloids from the workers and alate queens of the imported fire ants.[13−18] The $\Delta^{1,2}$- and $\Delta^{1,6}$-piperideines have been proposed to function as precursors for biosynthesis of *cis* and *trans* alkaloids in fire ant venom.[15,22] Reduction of $\Delta^{1,6}$-piperideine or $\Delta^{2,3}$-piperideine gave a ratio of the *cis*-C11 to the *trans*-C11 of 4:1.[28,29] The composition of *cis*- and *trans*-C11 (**2** and **2′**), in *S. aurea* matched that of the equilibrium mixture formed during their chemical synthesis in the laboratory. This matchup supports the above hypothesis on the biosynthetic function of piperideines. As the imported *Solenopsis* fire ants have the biosynthetic capacity to synthesize mainly *trans* alkaloids, it is likely that enantioselective enzymes are present in these species which can reduce $\Delta^{1,2}$-piperideines exclusively into (2*R*,6*R*) dialkylpiperidines and $\Delta^{1,6}$-piperideines mainly into (2*R*,6*R*) and partially into (2*R*,6*S*) dialkylpiperidines. In most cases, the amount of $\Delta^{1,2}$-piperideine was similar to that of corresponding $\Delta^{1,6}$-piperideine (same side-chain length at the 6-position) (data shown in Table 1), suggesting that the two reduction routes are equally important in the biosynthesis of alkaloids in the imported fire ants.[15] In contrast, the detection of only $\Delta^{1,2}$-C11 (**4**) in *S. xyloni* together with a higher ratio of *cis*-C11 (**2**) to *trans*-C11 (**2′**) found in this species supported the hypothesis that the $\Delta^{1,2}$-C11 pathway could be more important than the $\Delta^{1,6}$-C11 pathway in more primitive *Solenopsis* species. Therefore, all *Solenopsis* fire ants may utilize similar biosynthetic pathways to produce both *cis* and *trans* alkaloids and even maintain favorable stereochemical composition diverging rather markedly from the thermodynamic equilibrium mixture.[15,16,22] Both $\Delta^{1,6}$-C17:1 (**18**) and $\Delta^{1,6}$-C17 (**20**) were found only in *S. invicta*, suggesting that this species possibly has evolved specific enzymes that could synthesize piperidines with longer and unsaturated side chains associated with greater toxicity and biological advantage.[8]

Pseudacteon phorid flies (Diptera: Phoridae) are parasitoids of ants, and many species are specific to *geminata* and/or *saevissima* species groups of the genus *Solenopsis*.[30] Nineteen of these parasitic flies are specifically associated with the *saevissima* group[31] and generally show an attack preference for imported fire ants over native fire ants.[32−40] Several phorid fly species, *Pseudacteon tricuspis*, *P. curvatus*, *P. litoralis*, *P. obtusus*, and *P. cultellatus*, have been introduced to the southern United States for biological control of the invasive imported fire ant complex in the past two decades.[41] Established populations of *P. tricuspis* have proved to be highly host specific to imported *Solenopsis* fire ants.[42] Previous studies have demonstrated that *P. tricuspis* utilizes fire ant venom alkaloids for host location.[43,44] In addition to five *cis* alkaloids (*cis*-C11 (**2**), *cis*-C13:1 (**5**), *cis*-C13 (**7**), *cis*-C15:1 (**11**), and *cis*-C15 (**13**)) and two *trans* alkaloids (*trans*-C11 (**2′**) and *trans*-C13:1 (**5′**)), two piperideine alkaloids, $\Delta^{1,6}$-C15:1 (**12**) and $\Delta^{1,6}$-C15 (**14**) from *S. invicta* were shown to elicit significant electrophysiological response in *P. tricuspis* by GC-EAD analysis. As shown in Figure 1 and Table 1, the quantities of these two $\Delta^{1,6}$-piperideines were relatively greater than those of the remaining piperideines. $\Delta^{1,6}$-C15:1 (**12**) and $\Delta^{1,6}$-C15 (**14**) from *S. richteri* and hybrids could also trigger a similar GC-EAD response in *P. tricuspis* (unpublished data). Dominance of the *cis* alkaloids suggests possible attraction of *P. tricuspis* to North America-native fire ants such as *S. xyloni* and *S. geminata*. *P. tricuspis* is frequently attracted to disturbed ant colonies, and venom release is part of the alarm response and probably a component of the complex alarm odor.[45] A recent study has proved that *P. tricuspis* was attracted to 2-ethyl-3,6 (or 5)-dimethylpyrazine, a commercially available mixture of fire ant alarm pheromone component (2-ethyl-3,6-dimethylpyrazine) and its isomer.[46] The alarm pheromone and venom alkaloids proved to act in concert to attract phorid flies to fire ant workers.[43] It is conceivable that the highly volatile pyrazine alarm pheromone serves as a general host location cue from long range, whereas the larger and less volatile venom alkaloids may play a major role in host preference and discrimination at close range.[43,46] As pyrazine alarm pheromone is a general odor in *Solenopsis* fire ants (R. K. Vander Meer, personal communication), it seems unlikely that phorid flies use ant alarm pheromone for host preference and discrimination.

Different *Pseudacteon* species display different levels of host specificity. Most fly species showed very low attack rate when tested in laboratory conditions against the native fire ant *S. geminata*. However, *P. curvatus* and *P. borgmeieri* freely attacked both *S. invicta* and *S. geminata*. Both fly species developed in *S.*

geminata but with apparent low success.[47] A recent study has demonstrated that *P. curvatus* preferred the alkaloid mixture (*cis* + *trans* alkaloids), whereas *P. tricuspis* showed relatively greater attraction to the *cis* alkaloids.[43] The alkaloid patterns, including the presence and quantity of individual alkaloid components, the ratios of the *trans* to *cis* alkaloids, and the presence of piperideines, are species-specific for *Solenopsis* fire ants. Attraction of *P. curvatus* and *P. borgmeieri* to *S. geminata* may be mediated by presence of the *cis* alkaloids, which generally predominate in native fire ants. A previous study showed that *P. tricuspis* is able to distinguish among *S. richteri*, *S. invicta*, and hybrid fire ants with greater preference for *S. invicta* and hybrids.[48] It is likely that the ratios of the *cis* and *trans* alkaloids, the presence of piperideines, and the quantitative difference in alkaloids detected in this study might be responsible for the reported host preference in phorid flies.

ABSTRACT: Food fortification is a strategy to overcome vitamin A deficiency in developing countries. Our aim was to investigate the involvement of the bovine milk protein β-lactoglobulin (β-Lg), a potential retinoid carrier, in vitamin A absorption. *In vivo* experiments were conducted by force-feeding mice with retinol or β-carotene associated with either β-Lg or oil-in-water emulsion, with subsequent determination of both vitamin A intestinal mucosa and plasma contents. Caco-2 cells were then used to investigate the mechanisms of vitamin A uptake when delivered by either β-Lg or mixed micelles. We showed that β-Lg was as efficient as emulsion to promote β-carotene, but not retinol, absorption in mice. Similar results were obtained *in vitro*. Interestingly, an inhibitor of the Scavenger Receptor Class B Type I significantly decreased the uptake of micellar β-carotene but not that of β-carotene bound to β-Lg. Overall, we showed that β-Lg would be a good vector for β-carotene food fortification.

KEYWORDS: *vitamin A, retinol, carotenoid, micelles, emulsion*

INTRODUCTION

Vitamin A insufficiency is still a public health issue in numerous countries. It affects more than 190 million children throughout the world, mostly in African and South East Asian developing countries.[1] Rising knowledge about the mechanisms of vitamin A absorption is therefore necessary to set up better approaches for ameliorating its bioavailability.[2]

Vitamin A refers to a group of polyunsaturated hydrocarbons playing important roles in different aspects of human development and health including gene transcription, vision, and dermatology.[3] It is found in the human diet either as preformed vitamin A in foods from animal origin, or as provitamin A carotenoids in foods from plant origin. The main molecules belonging to the preformed vitamin A are retinyl esters, and primarily retinyl palmitate, which is hydrolyzed to retinol during the digestion process.[4] The main provitamin A carotenoid is β-carotene, which is primarily converted to retinol in the intestine and somewhat in hepatic cells.[5]

β-lactoglobulin (β-Lg), the major whey protein of bovine milk, binds retinoids and carotenoids *in vitro* with apparent dissociation constants in the range of 10^{-8} M.[6] This protein belongs to the lipocalin family and shares similar structure with retinol binding protein (RBP).[7] Hattori et al. have shown that this protein protects retinoids from degradation and oxidation.[8] Due to its ability to bind various lipophilic molecules, β-Lg has been proposed as an oral drug carrier,[9] and its properties to transport retinol and some other lipophilic molecules through the intestinal cells have also been reported.[10−12] However, results concerning the intestinal transport of retinol bound to β-Lg by Caco-2 cells were not consistent with those found *ex vivo*. Indeed, Riihimaki and colleagues showed that retinol was transported in a more efficient manner across Caco-2 cells when it was free than when it was bound to β-Lg,[11] while other authors showed that the uptake of retinol by the intestinal tissues of suckling rat was higher when bound to β-Lg than when it was free.[13] Finally no data are available on the effect of β-Lg on β-carotene uptake by the enterocyte. Thus, the effect of β-Lg on vitamin A uptake by intestinal cells is barely known, and in spite of its interesting properties and its presumed carrier role, it is difficult to conclude its effect on vitamin A uptake as compared to vitamin A uptake in its physiological vehicle, i.e. mixed micelles.

The purpose of this study was thus to compare the uptake of vitamin A, either as retinol or as β-carotene, when it is associated with β-Lg or when it is incorporated into a lipid vector (micelles or emulsions). Retinol was chosen instead of retinyl palmitate in our experiments as in Caco-2 cells, the ester hydrolysis occurring during digestion cannot be mimicked.

MATERIAL AND METHODS

Chemicals. All-*trans*-retinol (≥99% pure), β-carotene (≥93% pure), 2-oleoyl-1-palmitoyl-*sn*-glycero-3-phosphocholine (phosphatidylcholine), 1-palmitoyl-*sn*-glycero-3-phosphocholine (lysophosphatidylcholine), monoolein, cholesterol, oleic acid, and sodium taurocholate, were purchased from Sigma-Aldrich (Saint-Quentin-Fallavier, France). Internal standards used were retinyl acetate (Sigma-Aldrich), echinenone (generously provided by DSM LTD formerly F. Hoffmann-La Roche, Basel, Switzerland) and tocopherol acetate (all-*rac*-α-TAC oil feed grade, purity: 95% generously provided by Adisseo, Anthony, France). Dulbecco's Modified Eagle Medium (DMEM) containing 4.5 g/L glucose, trypsin-EDTA (500 and 200 mg/L, respectively), nonessential amino

acids and penicillin/streptomycin were purchased from Life Technology (Saint Aubin, France). FBS was from PAA (Velizy-Villacoublay, France). Blocks lipid transport 1 (BLT1), which is a specific inhibitor of Scavenger receptor class B type I (SR-BI) that does not interfere with receptor-mediated endocytosis or other forms of intracellular vesicular traffic,[14] was purchased from Chembridge (San Diego, CA, U.S.A). Ezetimibe-glucuronide (the active metabolite of ezetimibe, which is the specific inhibitor of Niemann-Pick C1 Like 1, NPC1L1[15]) was a generous gift from E. Levy (CHU Ste Justine, Montréal, Canada).

Preparation of Retinol and β-Carotene Enriched Vectors for Mouse and Cell Experiments. *Preparation of Retinol and β-Carotene Protein Complexes.* Cow β-Lg variant A (≥95%) was extracted as judged from high performance liquid chromatography as described before.[6] Human retinol binding protein (RBP, ≥85% pure) and bovine serum albumin (BSA, ≥95% pure) were from Sigma-Aldrich. Each protein was diluted in DMEM, and then mixed with either retinol in ethanol or β-carotene in tetrahydrofuran (THF) in appropriate concentrations. The final ethanol or THF concentrations in the medium were less than 0.1%. β-Lg was prepared at concentrations varying from 0.1 to 10 mg/mL, depending on the experiment. BSA and RBP were used at a concentration of 0.1 mg/mL. In all experiments, retinol and β-carotene concentrations were fixed between 3.8 and 5 μmol/L.

Preparation of Retinol and β-Carotene-Rich Emulsions. For the delivery of retinol or β-carotene to mice, oil-in-water vitamin A-rich emulsions were prepared as follows. An appropriate volume of retinol and β-carotene stock solution was transferred into Eppendorf tubes to obtain a final amount of 250 μg in each tube. Stock solution solvent was carefully evaporated under nitrogen. Dried residue was solubilized in 100 μL of peanut oil, and 200 μL of PBS solution was added. The mixture was vigorously sonicated in water (Branson 3510 sonication bath, Branson, MO, U.S.A.) for 15 min and used for force-feeding within 10 min.[16] The particle size of the emulsions was measured using a Malvern Mastersizer (Malvern Instruments, Orsay, France) and was around 30 μm in diameter.

Preparation of Retinol and β-Carotene-Rich Micelles. For the delivery of retinol and β-carotene to human intestinal Caco-2 clone TC7 cell monolayers, mixed micelles were prepared as published previously[17] to obtain the following final concentrations: 0.04 mmol/L phosphatidylcholine, 0.16 mmol/L lysophosphatidylcholine, 0.3 mmol/L monoolein, 0.1 mmol/L free cholesterol, 0.5 mmol/L oleic acid, 3.8−5 μmol/L retinol or β-carotene,[18] and 5 mmol/L taurocholate. Measurements of the size distribution of the micelles were carried out to control the stability of the micelle size (∼13 nm of diameter) with a Malvern Zetasizer Nano ZS.

Mouse Experiments. *Animals.* Six-week-old wild-type male C57BL/6 Rj mice were purchased from Janvier (Le-Genest-St-Isle, France). The mice were housed in a temperature-, humidity-, and light-controlled room. They were given a standard chow diet and water ad libitum. During acclimation period, mice were housed four per cage. Mice were fasted overnight before each experiment. Eight male mice weighing 21−24 g were used for retinol gavage and eight male mice weighing 24−28 g were used for β-carotene gavage. The protocol was approved by the ethics committee of Marseilles (Agreement #4-5032010).

Postprandial Blood Sample Collection. For absorption studies, mice were force-fed with either a retinol- or a β-carotene-rich emulsion (n = 4) or with retinol or β-carotene bound to β-Lg (n = 4). At t = 1.5 and 3 h, blood samples were taken by retro-orbital puncture under sevoflurane anesthesia. A last sample was taken at 4.5 h by intracardiac puncture before animal euthanasia. For zero baseline samples, four mice were killed upon fasting, and blood samples were collected. Blood samples were collected in tubes with heparin and immediately centrifuged to separate plasma, which was placed on ice and then stored at −80 °C.

Postprandial Intestinal Sample Collection. At 4.5 h after gavage, the mice were killed by cervical dislocation, and their intestines were collected, carefully washed with PBS, and cut into seven fragments corresponding to small intestine (5 fragments of 6 cm), cecum (1 fragment), and colon (1 fragment of 6 cm). All samples were immediately frozen in liquid nitrogen and stored at −80 °C until analysis. Samples suspended in 2 mL RIPA buffer were then homogenized with stainless-steel balls using MM301 ball mills (Retsch, Eragny sur Oise, France). Aliquots of samples were used to assess protein concentrations using a bicinchoninic acid kit (Pierce, Montluçon, France).

Cell Experiments. *Cell Culture.* The human intestinal Caco-2 clone TC-7 cells[19] were cultured in the presence of DMEM supplemented with 20% heat-inactivated FBS, 1% nonessential amino acids, and 1% antibiotics (complete medium) as previously described.[17] For each experiment, the cells were seeded and grown during 21 days on 1 μM filters to obtain confluent differentiated cell monolayers. Twelve hours before each experiment, the medium used in the apical and basolateral chambers was changed to a serum-free complete medium.

Vitamin A-Enriched Vectors Uptake by Caco-2 Cells. The vectors used for vitamin A uptake assessment by Caco-2 cells were either micelles or DMEM supplemented with β-Lg, RBP or BSA or a mixture of micelles and β-Lg at different concentrations.

The apical side received the retinol or β-carotene enriched vector whereas the basolateral side received serum-free complete medium. Cells were incubated for 30 to 240 min at 37 °C, depending on the experiment. At the end of each experiment, media were harvested. Cells were washed in 0.5 mL PBS to eliminate adsorbed vitamin A, then scraped and collected in 0.5 mL PBS. Absorbed vitamin A was estimated as vitamin A found in scraped cells plus vitamin A found at the basolateral side.[20] (No vitamin A was recovered in the basolateral chambers after β-carotene incubation). Aliquots of cell samples were used to assess protein concentrations using a bicinchoninic acid kit.

Effect of SR-BI and NPC1-L1 Chemical Inhibitors on Retinol and β-Carotene Uptake. Differentiated cell monolayers were pretreated with either DMSO (control), BLT1 at 10 μM,[17] or ezetimibe glucuronide at 100 μM[15] in serum-free complete medium for 1 h. The cells then received retinol-enriched micelles or retinol bound to β-Lg in serum-free complete media supplemented with either DMSO, 10 μM of BLT1, or 100 μM of ezetimibe glucuronide. Similar experiments were carried out with β-carotene, and vitamin A uptake was measured as described above.

Verification of Vector Protein Integrity during the Caco-2 Experiments. Due to the presence of enzymes on the Caco-2 cell brush border membrane, degradation state of β-Lg, RBP,

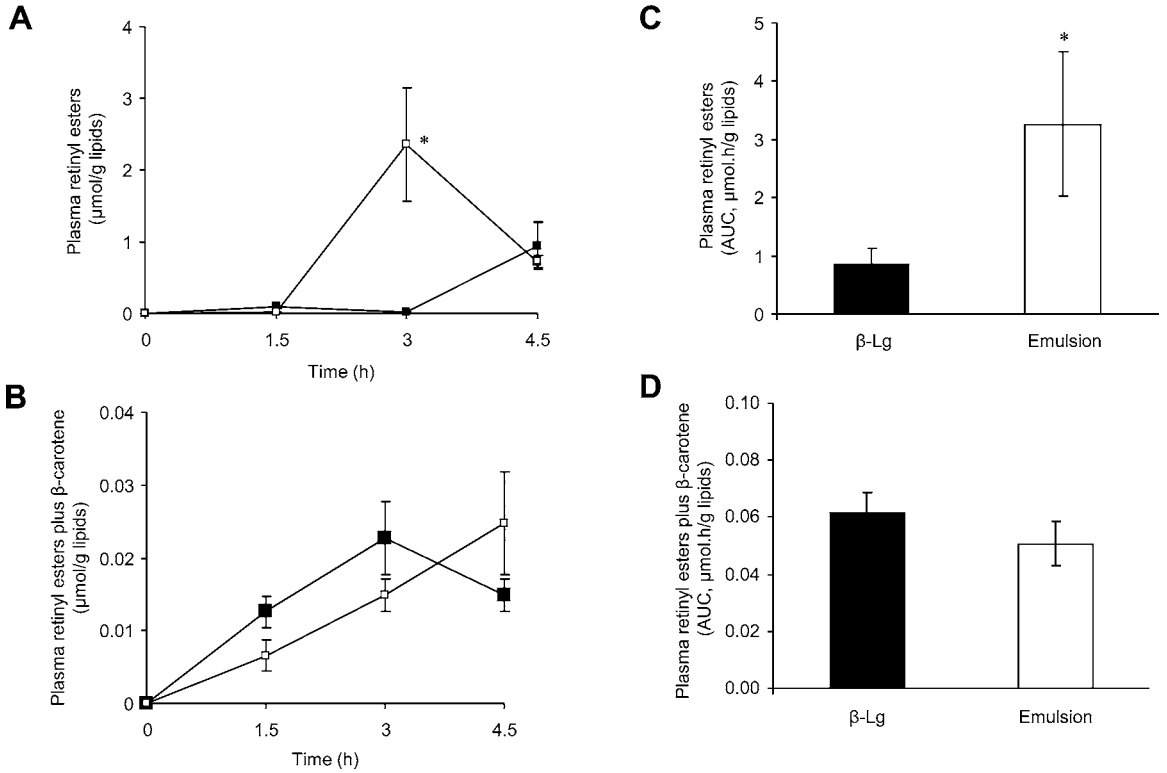

Figure 1. Postprandial changes in plasma total retinyl esters and β-carotene in wild type C57BL/6 Rj mice force fed with (A) retinol-enriched emulsion (□; $n = 4$) or retinol bound to β-Lg (■; $n = 4$) and (B) with β-carotene-enriched emulsion (□; $n = 4$) or β-carotene bound to β-Lg (■ ; $n = 4$). (C) Postprandial plasma retinyl ester responses (area under curves at 0−4.5 h) in mice force fed with retinol-enriched emulsion (□; $n = 4$) or retinol bound to β-Lg (■; $n = 4$). (D) Postprandial plasma retinyl ester plus β-carotene responses (area under curves at 0−4.5 h) after gavage with β-carotene-enriched emulsion (□; $n = 4$) or β-carotene bound to β-Lg (■; $n = 4$). Values are means ± SEM. Plasma samples were taken each 1.5 h after mice force-feeding and retinyl ester and β-carotene concentrations were analyzed. Asterisks indicate significant differences between β-Lg and emulsion ($p < 0.05$; Mann−Whitney U test).

and BSA after the incubation period was evaluated by SDS PAGE using 12% acrylamide gels under reducing conditions according to Laemelli:[21] samples from the apical side were compared to native protein at the same concentration.

Extraction and HPLC Analysis of Retinol, Retinyl Esters and β-Carotene. Retinol, retinyl esters, and β-carotene were extracted from 500 μL aqueous samples by using the following method. Distilled water was added to sample volumes <500 μL to reach a final volume of 500 μL. Retinyl acetate (internal standard for retinol experiments), echinenone (internal standard for *in vitro* β-carotene experiments), and tocopherol acetate (internal standard for *in vivo* β-carotene experiments) were added to the samples in 500 μL ethanol. The mixture was extracted once with 2 volumes of hexane for retinol and retinyl esters and twice with 2 volumes of hexane for β-carotene. All samples from intestinal explants were extracted twice. The hexane phases obtained after centrifugation (500 g, 10 min, 4 °C) were pooled if necessary and evaporated to dryness under nitrogen. The dried extracts were dissolved in either 200 μL acetonitrile/dichloromethane/methanol (70:20:10, vol:vol:vol) for retinol samples[20] or 200 μL acetonitrile/dichloromethane (65:35, vol:vol) for β-carotene.[22] A volume of 10−200 μL was used for HPLC analysis. Retinol experiment analyses were realized by using a 250 mm × 4.6 nm reversed-phase C18 5-μm Zorbax column (Interchim, Montluçon, France) maintained at a constant temperature (35 °C) and a guard column. β-Carotene analyses were performed on a 250 mm × 4.6 nm i.d. YMC C30 column maintained at 35 °C. Retinol was analyzed with a 70% acetonitrile, 20% dichloromethane and 10% methanol mobile phase (flow rate =1.8 mL/min), whereas β-carotene was analyzed with a gradient of methanol, methyl-*tert*-butyl ether, and water (flow rate =1 mL/min) according to Gleize et al.[22] The HPLC system comprised a Dionex separation module (P680 HPLC pump and ASI-100 Automated Sample Injector; Dionex, Aix-en-Provence, France), a Dionex UVD340U photodiode array detector (retinol, retinyl ester and β-carotene detection at 325 and 450 nm, respectively), and a fluorimetric detector (Jasco, Nantes, France). For the fluorimetric analysis, retinol and retinyl esters were detected at 450 nm after light excitation at 325 nm. Retinol, retinyl palmitate and β-carotene were identified by retention time compared with pure (>95%) standards. Quantification was performed by using Chromeleon software (version 6.50, SP4 Build 1000; Dionex Corporation) comparing peak area with standard reference curves. Retinyl linoleate, oleate, and stearate were identified by retention time and spectral analysis and quantified on the basis of their molecular extinction coefficiency ratio compared with retinyl palmitate.[20]

Statistical Analyses. Results are expressed as means ± SEM. Differences between the uptake efficiency in the different triplicates were analyzed by using the Kruskal−Wallis test. The Mann−Whitney U test was used as a post hoc test when the Kruskal−Wallis test showed significant differences ($p < 0.05$) between groups. $p < 0.05$ was considered significant. All

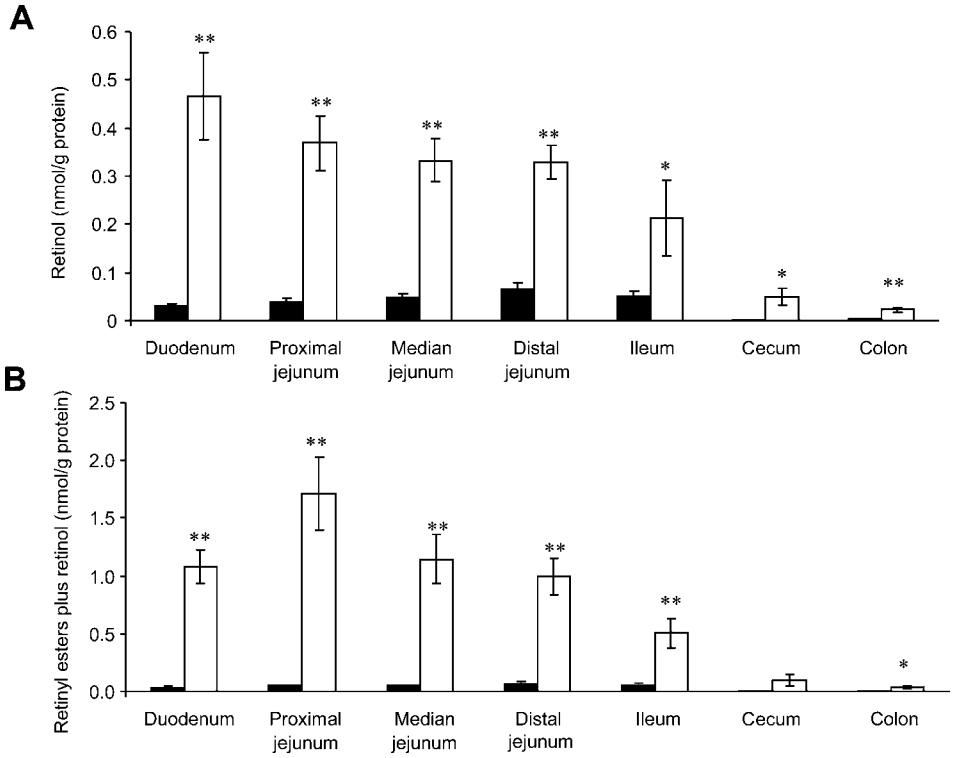

Figure 2. Retinol and retinyl ester contents of mouse intestinal fragments after force-feeding with retinol associated with either emulsion (□; $n = 4$) or β-Lg (■; $n = 4$); 250 μg of retinol were added to either 300 μL of oil-in-water emulsion or β-Lg at 50 mg/mL; 4.5 h after force feeding, mouse intestines were harvested and cut in seven fragments. Values are means ± SEMs. (A) Retinol recovered in the different segments of the intestine. (B) Retinol plus retinyl esters recovered in the different segments of the intestine. statistical analyses were performed using the Statview software version 5.0 (SAS Institute, Cary, NC, U.S.A.).

RESULTS

Retinol and β-Carotene Absorption in Mice after Gavage. *Posprandial Plasma Vitamin A Concentration.* To understand the putative role of β-Lg in vitamin A intestinal absorption, we first compared retinol and β-carotene absorption in mice when delivered via either an emulsion or bound to β-Lg. During fasting, vitamin A circulates as nonesterified retinol (associated with RBP). Indeed, no retinyl esters were detected in fasting mouse plasma. The retinol absorbed by the enterocytes is massively esterified into retinyl esters (i.e., retinyl palmitate, retinyl oleate, retinyl stearate, and retinyl linoleate) by acylcoA-acyltransferase, ARAT, or lecithin retinol acyltransferase, LRAT.[2] These esters were thus measured in the postprandial samples. Postprandial plasma retinyl ester responses after gavage by either retinol-enriched emulsion or retinol bound to β-Lg were significantly different: lower ester concentrations were recovered in plasma when retinol was delivered by β-Lg (0.02 ± 0.00 μmol after 3 h) as compared to emulsion (2.36 ± 0.79 μmol after 3 h) (Figure 1A). The postprandial plasma retinyl ester responses expressed as area under the curve in the two conditions described above were also more than 3 times higher with emulsion than with β-Lg (3.27 ± 1.23 μM vs 0.87 ± 0.26 μM, respectively, $p < 0.05$, Figure 1B).

Conversely, postprandial plasma retinyl ester plus β-carotene responses expressed as area under the curve at 0–4.5 h after gavage with either β-carotene-enriched emulsion or with β-carotene associated with β-Lg were similar (0.06 ± 0.01 μM vs 0.05 ± 0.01 μM, respectively, Figure 1D).

Vitamin A Uptake by Mouse Intestine. Retinol was quantified in all segments of mouse intestine. Retinol was mainly recovered in the duodenum and proximal jejunum (Figure 2). Figure 2A shows that at 4.5 h post gavage, retinol was recovered at higher concentrations in the intestinal mucosa when delivered by the emulsion as compared to that when delivered bound to β-Lg (0.46 ± 0.09 nmol vs 0.03 ± 0.00; $p < 0.001$ in the duodenum, respectively). The formed esters were also measured in the different fragments of the intestine. Figure 2B shows the sum of retinyl esters plus retinol in the different fragments. In all fragments, more vitamin A was recovered when mice received the retinol-enriched emulsion than when they received retinol associated with β-Lg (for example in the duodenum: 1.07 ± 0.14 nmol vs 0.04 ± 0.01 nmol; $p < 0.001$, respectively).

Similar experiments were carried out with β-carotene-enriched emulsion and β-carotene bound to β-Lg. Figure 3A shows that β-carotene was mainly recovered in the distal jejunum, ileum, and cecum. Figure 3A also shows that β-carotene content was generally higher in all fragments with the emulsion condition compared to the β-Lg condition, but the differences were significant in the proximal jejunum and in the cecum only. Two pathways have been described for the metabolism of β-carotene in the enterocyte.[2] The major pathway is the central cleavage catalyzed by β-carotene 15,15′-monooxygenase 1 (βCMO1), which yields retinal and then retinol. The produced retinol is then esterified into retinyl esters. In Figure 3B, after considering β-carotene conversion into retinol and retinyl esters, these differences were abolished,

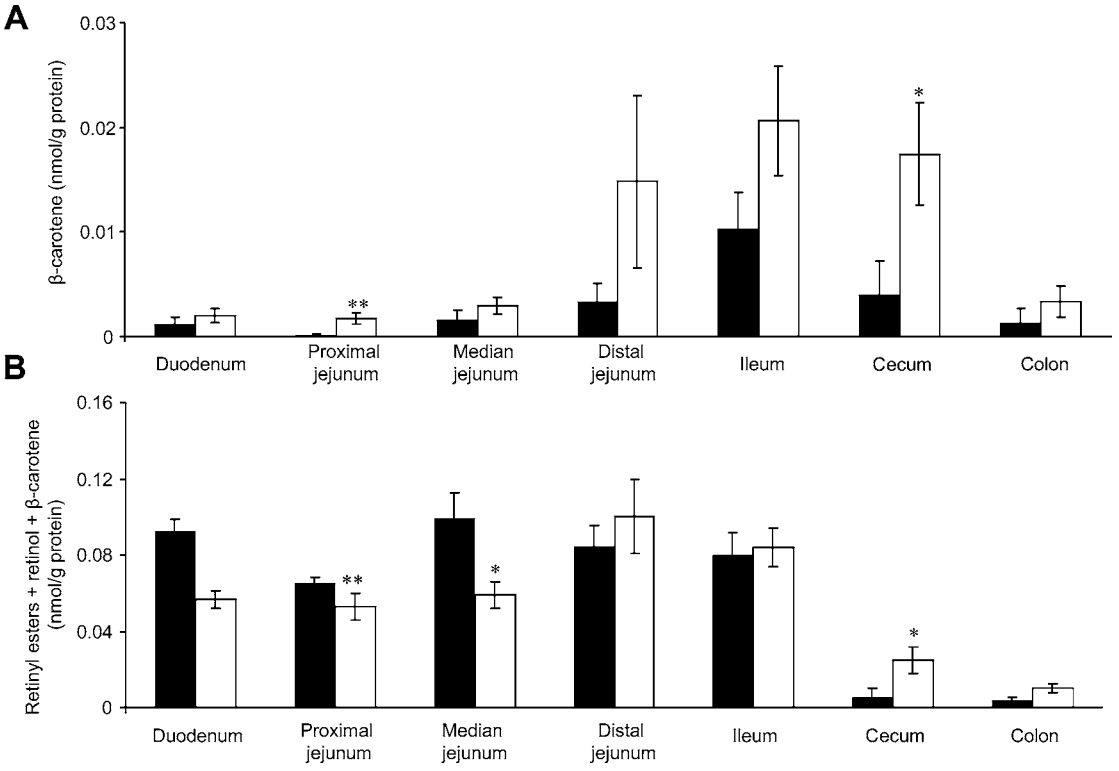

Figure 3. β-Carotene, retinol, and retinyl ester content of mouse intestinal fragments after force-feeding with β-carotene associated with either emulsion (□; $n = 4$) or β-Lg (■; $n = 4$); 250 μg of β-carotene was added to either 300 μL of oil-in-water emulsion or β-Lg at 50 mg/mL; 4.5 h after force-feeding, mouse intestines were harvested and cut in seven fragments. (A) β-Carotene recovered in the different segments of the intestine. (B) β-Carotene, retinol, and retinyl esters recovered in the different segments of the intestine. Values are means ± SEM. Asterisks indicate significant differences between emulsion and β-Lg (* $p < 0.05$, ** $p < 0.005$; Mann–Whitney U test).

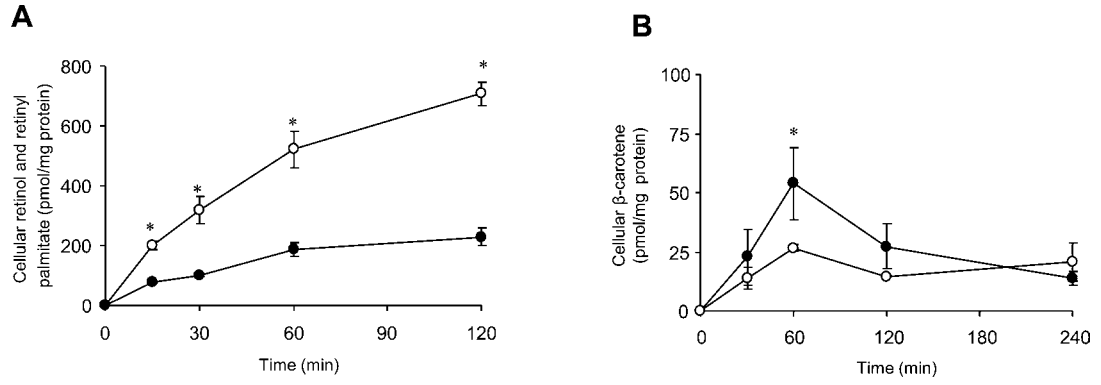

Figure 4. Uptake of retinol and β-carotene by Caco-2 TC-7 cells. The two vitamin A species were delivered either via mixed micelles (○; $n = 3$) or via β-Lg (●; $n = 3$). (A) Retinol uptake. The apical side received either retinol-enriched micelles at 3.8 μM, or retinol bound to β-Lg at 3.8 μM, and the basolateral side received FBS-free medium. Vitamin A absorbed = vitamin A recovered in the scraped cells + vitamin A recovered in the basolateral medium. (B) β-carotene uptake. The apical side received either β-carotene-enriched micelles at 5 μM, or β-carotene bound to β-Lg at 5 μM, and the basolateral side received FBS-free medium. Absorbed β-carotene was estimated as β-carotene found in scraped cells. Values are means ± SEM of three assays. Asterisks indicate significant differences between emulsion and β-Lg (* $p < 0.05$; Mann–Whitney U test).

and significantly higher vitamin A contents were recovered in the proximal and the median jejunum.

Retinol and β-Carotene Uptake by Caco-2 Cells. To focus on the mechanism involved in the uptake of retinol and β-carotene associated with the two different vectors, we then used Caco-2 cells. Figure 4 shows the kinetics of vitamin A uptake by Caco-2 cells when it was delivered via either micelles or β-Lg. After 2 h of incubation, retinol was more efficiently absorbed by Caco-2 cells when it was associated with micelles than when it was bound to β-Lg (Figure 4A). About 700 ± 40 pmol of retinol plus retinyl palmitate was recovered in cells incubated with retinol-rich micelles vs 228 ± 30 pmol in cells incubated with retinol associated with 2 mg/mL of β-Lg. Conversely, there was no significant difference between the amounts of micellar β-carotene and β-carotene bound to β-Lg after 4 h of incubation (Figure 4B).

Effect of β-Lg concentration on retinol and β-carotene uptake by Caco-2 cells. We investigated the effect of β-Lg concentration (varying from 0.1 to 10 mg/mL) on retinol and β-carotene uptake by differentiated Caco-2 cell

dx.doi.org/10.1021/jf501683s | J. Agric. Food Chem. 2014, 62, 5916–5924

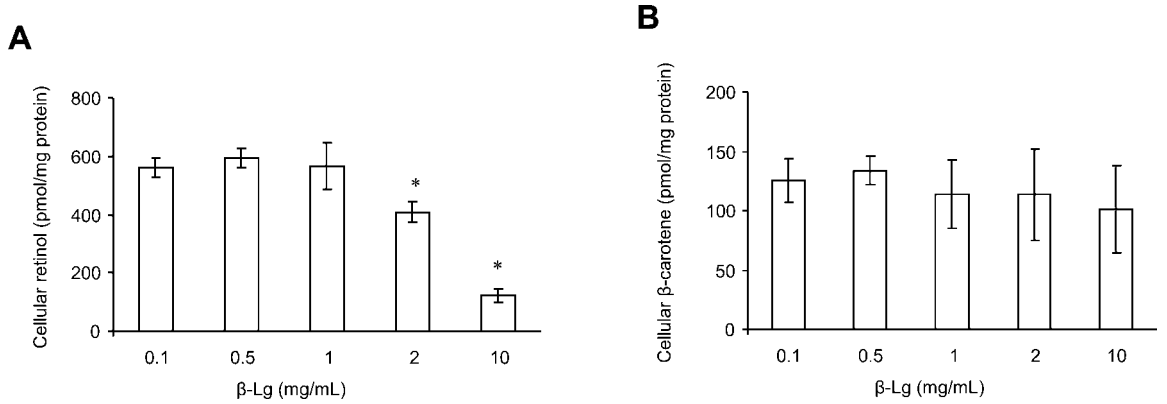

Figure 5. Effect of β-Lg concentration on retinol and β-carotene uptake by differentiated Caco-2 cell monolayers. (A) Retinol uptake by differentiated Caco-2 TC-7 monolayers during 120 min when delivered at 5 μM by different concentrations of β-Lg. The apical side received retinol bound to β-Lg, and the basolateral side received FBS-free medium. Vitamin A absorbed = vitamin A recovered in the scraped cells + vitamin A recovered in the basolateral medium. (B) β-Carotene uptake by differentiated Caco-2 TC-7 monolayers at 37 °C during 120 min when delivered at 5 μM by different concentrations of β-Lg. The apical side received 1 mL of β-carotene bound to β-Lg, and the basolateral side received 2 mL FBS-free medium. Absorbed β-carotene was estimated as β-carotene found in scraped cells. Values are means ± SEM of three assays. Asterisks indicate significant differences between different β-Lg concentrations (* $p < 0.05$; Mann–Whitney U test).

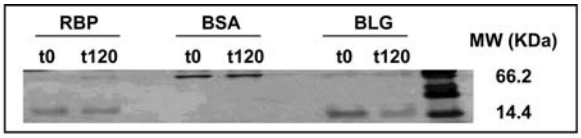

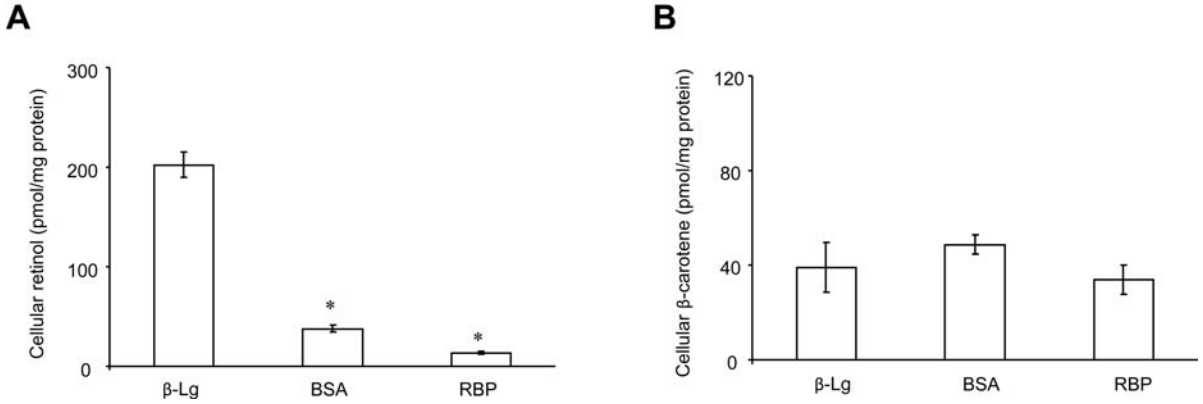

Figure 6. Uptake of retinol and β-carotene associated with lipocalins or BSA by differentiated Caco-2 cell monolayers. (A) The uptake of retinol associated with 0.1 mg/mL of either β-Lg, BSA, or RBP, was evaluated after 2 h of incubation. The apical side received each of the three proteins containing 5 μM of retinol. Vitamin A absorbed = vitamin A recovered in the scraped cells + vitamin A recovered in the basolateral medium. (B) The uptake of β-carotene associated with 0.1 mg/mL of either β-Lg, BSA, or RBP, was evaluated after 2 h of incubation. The apical side received each of the three proteins containing 5 μM of β-carotene and cellular β-carotene was quantified. Data are means ± SEM of 3 assays. Asterisks indicate significant differences between β-Lg, BSA, and RBP ($p < 0.05$; Kruskal–Wallis and Mann–Whitney U test). (Inset) SDS PAGE analysis of RBP, BSA, and β-Lg from the apical side of Caco-2 cells before ($t = 0$) and after incubation ($t = 120$ min).

monolayers during 2 h-incubations (Figure 5 A and B). Interestingly, high β-Lg concentrations significantly inhibited retinol but not β-carotene uptake.

Comparison of Two Lipocalins and BSA to Promote Retinol and β-Carotene Uptake by Differentiated Caco-2 Cell Monolayers. To understand whether the effect of β-Lg was specific to this protein, we compared its ability to deliver vitamin A to Caco-2 cells with 2 other proteins: RBP and BSA. We then compared vitamin A uptake after it was delivered by 0.1 mg/mL of β-Lg, by 0.1 mg/mL of BSA, or by 0.1 mg/mL of RBP. Figure 6A shows that retinol was more efficiently absorbed when bound to β-Lg (202.8 ± 7.4 pmol/mg protein) than when bound to BSA or RBP (37.9 ± 1.9; 13.3 ± 0.8 pmol/mg protein, respectively; $p < 0.05$). SDS PAGE analysis shows that, after 120 min of cells incubation, less β-Lg than BSA and RBP was recovered in the apical medium (Figure 6 inset).

Results obtained with β-carotene were completely different. The same amount of β-carotene was recovered into cells with the three proteins (Figure 6B).

Effect of SR-BI and NPC1L1 Chemical Inhibitors on the Uptake of Retinol and β-Carotene Delivered with Either β-Lg or Micelles to Differentiated Caco-2 Cell Monolayers. To evaluate whether the uptake pathways of vitamin A vectorized by either micelles or β-Lg were similar, we investigated the involvement of two membrane transporters

involved in micronutrient transport: SR-BI and NPC1L1, by using their respective inhibitors: BLT1 and ezetimibe glucuronide. The addition of BLT1 and ezetimibe glucuronide had no significant effect on retinol uptake when it was incorporated into either micelles or β-Lg (data not shown). Compared to the control condition (100%), the addition of BLT1 significantly decreased β-carotene uptake when incorporated into micelles (49.1 ± 3.9%) but not when fixed to β-Lg. Moreover, ezetimibe glucuronide significantly inhibited β-carotene uptake delivered by both micelles (31.9 ± 5.3%) and β-Lg (74.5 ± 2.1%).

DISCUSSION

In vivo studies were conducted at first to assess the effect of β-Lg on retinol and β-carotene absorption in mice. We compared (i) vitamin A postprandial plasma responses and (ii) vitamin A recovered in intestinal segments of mice force-fed with either retinol or β-carotene, which were delivered either in oil-in-water emulsions or associated with β-Lg. Plasma retinyl ester concentrations were higher when retinol was delivered by the emulsion as compared to β-Lg delivery. This difference may be explained by the fact that the presence of fatty acids likely increased retinyl ester synthesis and incorporation into chylomicrons,[23] which probably maintains the driving force for retinol uptake. To assess whether a similar mechanism occurred with carotenoids, we carried out the same experiment with β-carotene. Surprisingly, we found that plasma β-carotene and retinyl ester responses were similar when β-carotene was delivered by either emulsion or β-Lg. This is in agreement with a previous study that showed no effect of dietary fat (3 or 36 g) on the bioavailability of β-carotene from supplement.[24] The difference observed between retinol and β-carotene absorption may be explicated by the different stabilities of the two molecules into each vector. Retinol may be more degraded when bound to β-Lg than when included into an emulsion, which would induce a reduced absorption. On the contrary, the absence of difference between the two vectors with β-carotene suggests that β-carotene stability is similar in both vectors. This is consistent with previous results showing that retinyl palmitate, which is more stable toward oxidation than retinol,[25] was similarly absorbed by rats when incorporated into an oil carrier and when complexed to β-Lg.[26] Finally, it is interesting to note that, although less β-carotene was recovered in mouse intestinal mucosa with β-Lg compared to emulsion, β-Lg promoted β-carotene conversion in the enterocyte, leading to similar total vitamin A contents.

In order to clarify the mechanism involved in the intestinal absorption of retinol and β-carotene delivered by the two vectors, we studied their uptake in Caco-2 cell monolayers. First, retinol absorption efficiency was significantly higher than β-carotene absorption efficiency (30% for retinol vs 5% for β-carotene when delivered by micelles), similarly to what has been observed *in vivo* and according to our published data.[27] We observed that retinol uptake was more efficient when incorporated into micelles than when bound to β-Lg, which was also in accordance with our *in vivo* results. Moreover, this is in agreement with previous results in Caco-2 cells showing a low rate of retinol uptake when bound to β-Lg as compared to retinol delivered in ethanol.[11] Finally, results about β-carotene uptake were in agreement with our *in vivo* experiments as no significant difference was observed between uptake via β-Lg and via micelles.

Since it was demonstrated that both retinol and β-carotene have high affinity for β-Lg,[6] and that β-Lg may cross the intestinal cells,[10] we expected to observe a similar transport efficiency of retinol and β-carotene bound to β-Lg. This would support the hypothesis of the existence of a β-Lg ligand receptor at the brush border membrane.[13] However, retinol bound to β-Lg was more efficiently absorbed than β-carotene bound to β-Lg. Previous studies have similarly shown that retinol and palmitic acid transport efficiency across Caco-2 cells was different when bound to β-Lg[11] in spite of the high binding affinity of palmitic acid for the protein.[28] A possibility is that retinol and β-carotene dissociate from β-Lg before associating with cell membrane and/or with putative receptors. Indeed, it has been suggested that retinol dissociates from its binding protein before associating with liver cells[29] or with intestinal cells.[30] The putative dissociation of the complex β-carotene−protein is probably different than the complex retinol−protein as β-carotene and retinol were reported to have different binding sites on β-Lg.[6]

We then studied the effect of β-Lg concentration on retinol and β-carotene uptake. Retinol uptake by Caco-2 cells was significantly impaired by increasing amounts of β-Lg, according to previous data.[13] Conversely, β-carotene transport was not affected by high amounts of β-Lg. This finding can be attributed to their different uptake pathways.[31]

To further examine whether the effect of β-Lg was specific to this lipocalin, we compared its effect on vitamin A uptake with that of BSA and RBP, two other proteins that can bind vitamin A.[32,33] Results showed a lower absorption efficiency of retinol when it was bound to either BSA or RBP. This is in agreement with previous data showing that 26% of retinol associated with β-Lg was retained by Caco-2 cells vs 10% when bound to BSA after 24 h.[10] This may be explained by either a higher transport of β-Lg through cell monolayers or a higher hydrolysis of β-Lg by cell membrane enzymes compared to that of BSA,[10] as confirmed by the observed decrease of apical medium β-Lg content. Conversely, β-carotene was transported with the same efficiency with the three proteins used, which suggests unspecific uptake mechanisms.

Finally, we performed an uptake experiment in the presence of BLT1 and ezetimibe glucuronide, two specific chemical inhibitors of intestinal transporters that might be involved in uptake of vitamin A bound to β-Lg, i.e., SR-BI and NPC1L1, respectively. The uptake of retinol associated with either β-Lg or micelles was not inhibited by BLT1 and ezetimibe gluocuronide, according to the fact that neither BLT1[27] nor ezetimibe glucuronide[34] inhibited micellar retinol absorption in previous studies. Conversely, BLT1 significantly decreased the uptake of micellar β-carotene according to published data,[27] but not that of β-carotene bound to β-Lg. Ezetimibe glucuronide inhibited the uptake of micellar β-carotene, in agreement with previous results showing that β-carotene transport was decreased by 50% at 10 mg/mL of ezetimibe.[35] Interestingly, ezetimibe-glucuronide also inhibited the uptake of β-carotene bound to β-Lg. This finding suggests that SR-BI may be specifically implicated in the uptake of micronutrient included into a lipid vector, conversely to NPC1L1 that would not discriminate between the different vehicles. This may be due to the fact that NPC1L1 possibly acts like a cytosolic and not a membrane transporter,[36] and thus binds molecules after they dissociate from their vehicles in the cytosolic compartment.

In summary, our results show that β-Lg is at least as efficient as emulsion/micelles to promote the intestinal absorption of β-

carotene, but not that of retinol. β-Lg is thus a promising option for fortification with β-carotene. This should be taken into account in the formulation of vitamin A-fortified foods.

ABSTRACT: To evaluate the activity of botanicals used in Chinese Traditional Medicine as hypoglycemic agents for diabetes type II prevention and/or treatment, extracts prepared from 26 medicinal herbs were screened for their inhibitory activity on sodium-dependent glucose transporter 1 (SGLT1) by using two-electrode voltage-clamp recording of glucose uptake in *Xenopus laevis* oocytes microinjected with cRNA for SGLT1. Showing by far the strongest SGLT1 inhibitory effect, the phytochemicals extracted from *Gymnema sylvestre* (Retz.) Schult were located by means of activity-guided fractionation and identified as 3-*O*-*β*-D-glucuronopyranosyl-21-*O*-2-tigloyl-22-*O*-2-tigloyl gymnemagenin (**1**) and 3-*O*-*β*-D-glucuronopyranosyl-21-*O*-2-methylbutyryl-22-*O*-2-tigloyl gymnemagenin (**2**) by means of LC-MS/MS, UPLC-TOF/MS, and 1D/2D-NMR experiments. Both saponins exhibited low IC_{50} values of 5.97 (**1**) and 0.17 μM (**2**), the latter of which was in the same range as found for the high-affinity inhibitor phlorizin (0.21 μM). As SGLT1 is found in high levels in brush-border membranes of intestinal epithelial cells, these findings demonstrate for the first time the potential of these saponins for inhibiting electrogenic glucose uptake in the gastrointestinal tract.

KEYWORDS: *diabetes, SGLT1, inhibitor, Gymnema sylvestre, gymnemic acid V, gymnemic acid XV*

INTRODUCTION

Hyperglycemia is considered a major pathogenic factor in the development of acute and chronic diabetic complications such as diabetic ketoacidosis, retinopathy, nephropathy, and stroke.[1] Any practical and effective ways of maintaining long-time perfect glycemic control are lacking, thus leaving diabetics susceptible to developing acute and chronic complications such as cardiovascular diseases, blindness, amputation, and kidney failure.[2,3] Today, oral medication with euglycemic agents, such as sulfonylureas and thiazolidine derivatives,[4−6] combined with lifestyle intervention are applied to slow the progression of diabetic complications.[7−9] However, agents for glycemic control, targeting either insulin secretion or insulin action, can have significant adverse effects,[9] and thus additional treatment options are required. Lowering postprandial blood sugar excursions therefore becomes a focus in diabetes research and prevention programs.

Glucose is transported through biological membranes by the facilitative (GLUT) and sodium-dependent (SGLT) glucose transporters, which belong to the SLC2A and SLC5A gene families, respectively.[10] Facilitative glucose transport is mediated by 13 members of the GLUT protein family comprising GLUT1−12 and HMIT, which belong to a superfamily of transmembrane segment transporters identified in various tissue cells including liver, kidney, heart, brain, intestine, etc.[11] GLUT1, GLUT2, and GLUT4 have been reported to play a key role in glucose sensing in insulin secretion and for glucose uptake into insulin-sensitive organs.[12−14] The sodium/glucose cotransporters SGLT1 and SGLT2 are located primarily in epithelial cells of the intestine and kidney and transport glucose by the energy generated from the electrochemical gradient.[15] Exhibiting a high affinity to glucose and galactose, SGLT1 is predominantly located at the brush border membrane of the small intestine and carries these monosaccharides from the intestinal lumen into enterocytes.[15]

Both types of glucose transporters are currently targets in diabetes therapy. Among the GLUT protein family, for example, one strategy is to increase *m*RNA and protein expression of GLUT4 in the insulin-sensitive tissues or to increase the translocation of GLUT4.[16,17] For the sodium-dependent glucose transporters, the major strategy is to decrease glucose absorption by inhibiting or attenuating the transporter activity. SGLT1 in the kidney is responsible for only 2% of glucose reabsorption,[15] with the majority of glucose reabsorbed via SGLT2. Inhibitors of SGLT2 have been developed and are in clinical use and effectively increase glucose excretion via urine.[18] In contrast to kidney, the intestine only expresses SGLT1 that mediates glucose uptake through the apical membrane of intestinal epithelial cells. It could by its location be considered a promising target for diabetes prevention and/or therapy via specific inhibitors provided via the oral route.

To date, there are only a few studies published on natural SGLT1 inhibitors; for example, the dihydrochalcone phlorizin from apples was identified as a competitive inhibitor of glucose transporters including SGLT1 and was reported to normalize plasma glucose levels independent of insulin in diabetic animals.[19,20] To prevent its partial hydrolysis in the gastrointestinal (GI) tract, phlorizin was poly-*γ*-glutamylated and found to significantly decrease glucose-induced hyperglycemia.[21] Studies using two-electrode voltage clamp experiments

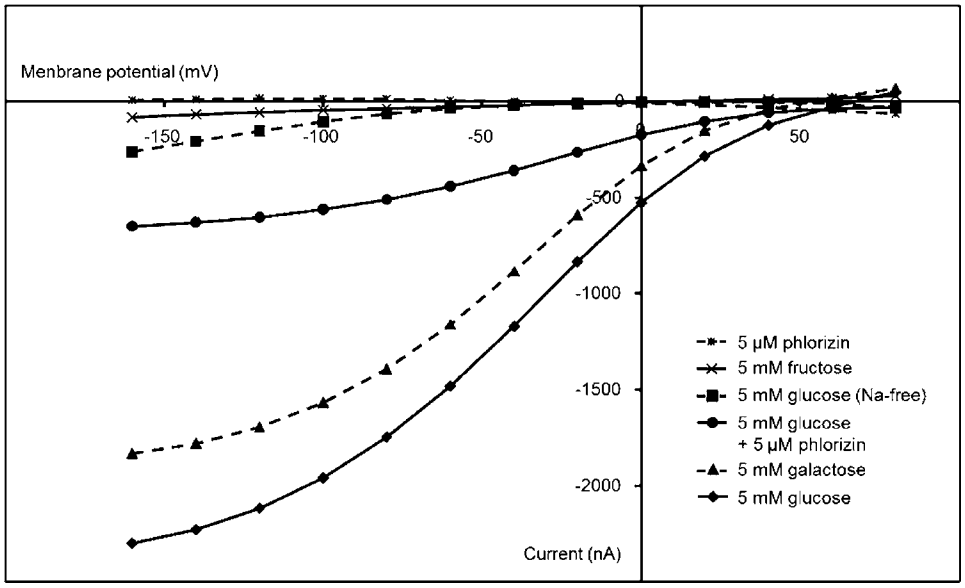

Figure 1. Comparative analysis of transporter currents induced by glucose, fructose, and galactose (5 mM each), and phlorizin (5 μM) and in a glucose/phlorezin mixture in *Xenopus* oocytes expressing hSGLT1. Data are mean values of 3−10 oocytes.

on *Xenopus* oocytes that express the human sodium-coupled glucose transporter hSGLT1 revealed that the inward current evoked by transport of α-methyl-D-glucopyranoside by SGLT1 is potently inhibited by the simultaneous application of flavonoid glycosides as well as by some aglycones.[22] Moreover, the green tea polyphenols epicatechin gallate and epigallocatechin gallate were found to have a modest SGLT1 inhibitory activity.[23]

Some medicinal herbs have been used in Asia for many centuries as hypoglycemic agents, for example, Huang Lian (*Rhizoma coptidis*), Mai Dong (*Radix ophiopogonis*), Fo-ti, Xuan Shen (*Radix scrophulariae*), Tian Men Dong (*Asparagi radix*), *Gymnema sylvestre* R. Schult, and Luo Han Guo (*Momordica grosvenori*).[24] However, their bioactive phytochemicals as well as their mechanisms of action remain elusive. The objective of the present study was to evaluate the SGLT1 inhibiting activity of a series of botanicals used in traditional Chinese medicine as hypoglycemic agents. Functional analysis was performed by two-electrode voltage-clamp recordings of glucose-associated transport currents in *Xenopus laevis* oocytes microinjected with the cRNA for hSGLT1 to identify the phytochemicals with SGLT1 inhibitory activity.

MATERIALS AND METHODS

Chemicals. The following compounds were obtained commercially: α-methyl-D-glucopyranoside (α-MDG), glucose, galactose, fructose, and phorizin as well as all chemicals used for preparation of the bath solution were obtained from Sigma-Aldrich (Taufkirchen, Germany). The bath solution (pH 7.5) contained 88 mM NaCl, 1 mM KCl, 0.8 mM $MgSO_4$, 0.4 mM $CaCl_2$, 0.3 mM $Ca(NO_3)_2$, 2.4 mM $NaHCO_3$, and 10 mM HEPES. Deuterated solvents were obtained from Euriso-Top (Gif-Sur-Yvette, France). All solvents were of HPLC grade (Merck, Darmstadt, Germany). Water for HPLC separation was purified by means of a Milli-Q Water Advantage A 10 water system (Millipore, Molsheim, France).

Medicinal Herbs. *Polygonatum sibiricum* Redouté (H1), *Polygonatum odoratum* (Mill.) Druce (H2), *Lycium chinense* Mill. (H3), *Arctium lappa* L. (H4), *Epimedium sagittatum* Maxim (H5), *Paeonia lactiflora* Pall. (H6), *Lycium barbarum* L. (H7), *Atractylodes macrocephala* Koidz. (H8), *Ligustrum lucidum* W. T. Aiton (H9), *Atractylodes macrocephala* Koidz. (H10), *Ophiopogon japonicus* (L.f.) Ker Gawl. (H11), *Rehmannia glutinosa* Steud. (H12), *Siraitia grosvenori* (H13), *Polygonatum odoratum* (Mill.) Druce (H14), *Angelica sinensis* (Oliv.) Diels (H15), *Eriobotrya japonica* (Thunb.) Lindl. (H16), *Cornus officinalis* Siebold & Zucc. (H17), *Panax ginseng* C. A. Mey. (H18), *Epimedium sagittatum* Maxim. (H19), *Coptis chinensis* Franch. (H20), *Cornus officinalis* Siebold & Zucc. (H21), *Paeonia lactiflora* Pall. (H22), *Panax ginseng* C. A. Mey. (H23), *Scrophularia ningpoensis* Hemsl. (H25), and *Paeonia lactiflora* Pall. (H26) were purchased from the Chinese Medicine Co. Tong Ren Tang (Beijing, China), *Gymnema sylvestre* (Retz.) R. Br. ex Schult (H24) was purchased from Magic Herbs (Ellerau, Germany).

Preparation of Oocytes. Maintenance of *Xenopus laevis* and the procedures of oocyte harvest were approved by the local authority for animal care in research (Regierung von Oberbayern, approval 211-2531.3-9/99). The surgical procedure and oocyte incubation were performed following the protocol reported earlier.[22] Oocytes were injected with 23 ng of hSGLT1-cRNA and incubated for 3−4 days at 17 °C. A solution of α-methyl-D-glucopyranoside (1 mM) was diluted with bath solution used as transport substrate for hSGLT1. In addition, oocytes that were not pretreated by cRNA injection and were lacking hSGLT1 were used as control.

Electrophysiology. Two-electrode voltage clamp experiments were performed as described previously in the literature[22] with oocytes placed in an open chamber and superfused (3 mL/min) with bath solution or with solutions containing the substrate. Oocytes were voltage-clamped, and transport current was measured at −60 mV using a TEC-05 amplifier and CellWorks software (npi electronic, Tamm, Germany). Current−voltage relationships were measured in a potential range from −160 to +80 mV, and the current generated by the transport at a given membrane potential was calculated as the difference of the currents measured in the presence and absence of substrate. The kinetic parameters of transport K_m and I_{max} (nA) were calculated from least-squares fits of at least three data points based on the Michaelis−Menten equation. The inhibition rate (IR) was calculated using the formula IR = [current(I) − current(0)]/(current(s) −current(0)), where current(0) is the transport current applied with bath solution and current(s) and current(I) are transport currents applied with α-MDG in the absence and presence of inhibitor, respectively. Dixon-type kinetic studies were performed at a membrane potential of −60 mV. To avoid errors due to the replenishment of the oocytes with α-MDG, the application time of the substrates was limited to 15 s at an increased (7 mL/min) perfusion speed. Activity of hSGLT1 in oocytes was measured for the monosaccharides glucose, fructose, and galactose (5 mM each) in bath solutions in the absence

or presence of phlorizin (5 μM) or as described above (Figure 1). In addition, 5 mM glucose in a sodium-free bath solution as well as a binary mixture of 5 mM glucose and 5 μM phlorizin in bath solution was analyzed.

Botanical extracts and subfractions as well as purified individual compounds were solubilized in DMSO at concentrations of 50−200 mM and were diluted with the α-MDG solution. The final concentration of DMSO in the test solutions was not higher than 1% (v/v).

Screening of Medicinal Herbs for SGLT1 Inhibitors. An aliquot of each ground botanical (10 g dry weight) was extracted with *n*-pentane (3 × 50 mL), followed by methanol/water (7:3, v/v; 3 × 50 mL) and methanol (3 × 50 mL). After removal of the solvents in a vacuum, aliquots (12 mg) of the pentane extractables (fraction I) and the methanol extractables (fraction II), respectively, were dissolved in small amounts of DMSO and made up with α-MDG solution to 50 mL to perform the hSGLT1 experiments (Figure 2). The final concentration of DMSO was not higher than 1% (v/v).

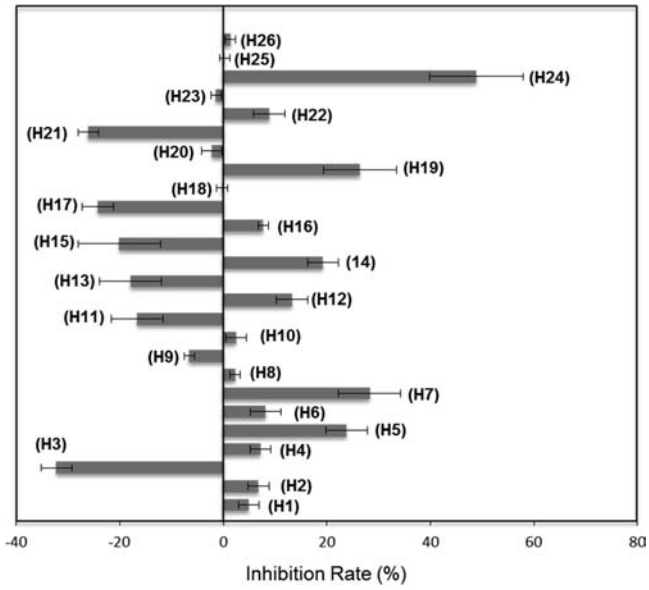

Figure 2. SGLT1 inhibitory activity of the methanol soluble fractions II of *Polygonatum sibiricum* Redouté (H1), *Polygonatum odoratum* (Mill.) Druce (H2), *Lycium chinense* Mill. (H3), *Arctium lappa* L. (H4), *Epimedium sagittatum* Maxim (H5), *Paeonia lactiflora* Pall. (H6), *Lycium barbarum* L. (H7), *Atractylodes macrocephala* Koidz. (H8), *Ligustrum lucidum* W. T. Aiton (H9), *Atractylodes macrocephala* Koidz. (H10), *Ophiopogon japonicus* (L.f.) Ker Gawl. (H11), *Rehmannia glutinosa* Steud. (H12), *Siraitia grosvenori* (H13), *Polygonatum odoratum* (Mill.) Druce (H14), *Angelica sinensis* (Oliv.) Diels (H15), *Eriobotrya japonica* (Thunb.) Lindl. (H16), *Cornus officinalis* Siebold & Zucc. (H17), *Panax ginseng* C. A. Mey. (H18), *Epimedium sagittatum* Maxim. (H19), *Coptis chinensis* Franch. (H20), *Cornus officinalis* Siebold & Zucc. (H21), *Paeonia lactiflora* Pall. (H22), *Panax ginseng* C. A. Mey. (H23), *Gymnema sylvestre* (Retz.) Schult (H24), *Scrophularia ningpoensis* Hemsl. (H25), and *Paeonia lactiflora* Pall. (H26).

Isolation and Identification of SGLT1 inhibitors from *Gymnemna sylvestre* (H24). Dried leaves of *Gymnemna sylvestre* (300 g) were ground, extracted with pentane (2 × 2L), and, finally, extracted with methanol/water (7:3, v/v; 2 × 2L), followed by methanol (2 × 2L). The latter two polar extracts were combined, solvents were separated by means of a Genevac Rocket evaporation system (Genevac Limited, Ipswich, UK), and the remaining residue was lyophilized to provide polar fraction II (104 g, 34.7% yield). Fraction II was dissolved in water (in sum 1 L), and 20 mL was applied each time onto a PP cartridge (i.d. = 40 mm, l = 150 mm) filled with RP18 material (LiChroprep RP18, 25−40 μm mesh material (Merck) and separated by MPLC by flushing the column with water (400 mL, fraction II-1), followed by methanol (400 mL, fraction II-2). After lyophilization, fractions II-1 and II-2 were both used for the SGLT1 bioassay. Fraction II-2 (51.7 g, 17.2%) showing SGLT1 inhibition was further separated by normal phase column chromatography using silica gel (400 × 30 mm, 5% water) as stationary phase and the following chloroform/methanol/water mixtures (v/v/v) as the mobile phase: fraction II-2/A (7:3:0.5), fraction II-2/B (6.9:3.1:0.57), fraction II-2/C (6.7:3.3:0.64), fraction II-2/D (6.6:3.4:0.71), fraction II-2/E (6.4:3.6:0.78), fraction II-2/F (6.3:3.7:0.86), fraction II-2/A (6.1:3.9:0.93), and fraction II-2/H (6:4:1) (Figure 3). An aliquot (1 g)

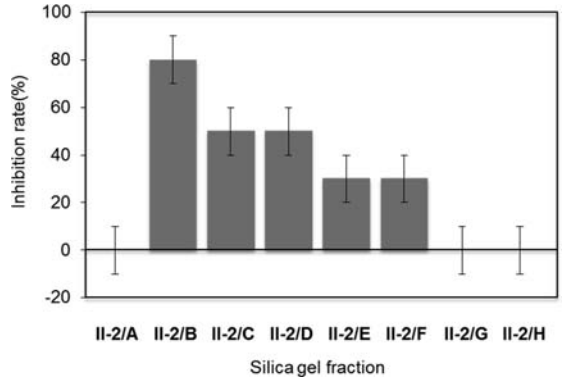

Figure 3. Inhibition of the hSGLT1 transport currents induced by α-methylglucose (1 mM) in the presence of fractions II-2/A−II-2/H isolated from *Gymnema sylvestre*. Data are mean values of 3−10 oocytes.

of fraction II-2/B was dissolved in acetonitrile/0.1% formic acid (30:70, v/v) and fractionated by means of preparative RP-HPLC. Twenty-eight fractions were collected individually in several runs, and the corresponding fractions were combined (Figure 4). HPLC fractions 22 and 24, showing the highest SGLT1 inhibitory activity, were separated from solvent using a Genevac Rocket evaporation system (Genevac Limited) and freeze-dried to yield gymnemic acids V (**1**) and XV (**2**), the structures of which were identified by means of LC-MS/MS, UPLC-TOF-MS, and 1D/2D-NMR experiments.

*Gymnemic acid V, **1**, Figure 5:* LC-MS (ESI$^-$), *m/z* 845 (100, [M − H]$^-$), 881 (12, [M + Cl]$^-$); MS/MS (DP = −64 V), *m/z* (%) 637 (89), 175 (74), 157 (100); LC-TOF-MS, *m/z* 845.4672 ([M − H]$^-$, measured), *m/z* 845.4687 ([M − H]$^-$, calcd for $C_{46}H_{69}O_{14}$); ^{1}H NMR (500 MHz, pyridine-d_5; COSY, *J*-RESOLVED, ROESY), δ 0.84−1.00 [m, 1H, H−C(1a)], 0.89 [s, 3H, H−C(25)], 0.92 [s, 3H, H−C(26)], 0.95 [s, 3H, H−C(24)], 1.02 [s, 3H, H−C(29)], 1.18−1.40 [m, 3H, H−C(6a,7a,19a)], 1.26 [s, 3H, H−C(30)], 1.30 [s, 3H, H−C(27)], 1.40−1.50 [m, 1H, H−C(1b)], 1.46 [d, 3H, *J* = 7.0 Hz, H−C(4‴)], 1.51−1.57 [m, 1H, H−C(15a)], 1.60 [d, 3H, *J* = 7.0 Hz, H−C(4″)], 1.62−1.73 [m, 4H, H−C(5,6b,7b,9)], 1.74−1.86 [m, 8H, H−C(11,5″,5‴)], 1.92−2.07 [m, 2H, H−C(2a,15b)], 2.14−2.27 [m, 1H, H−C(19b)], 2.27−2.35 [m, 1H, H−C(2b)], 3.11 [dd, 1H, *J* = 4.0 Hz, 14.0 Hz, H−C(18)], 3.74 [d, 1H, *J* = 10.8 Hz, H−C(23a)], 4.02 [d, 1H, *J* = 12 Hz, H−C(28a)], 4.10−4.19 [m, 1H, H−C(2′)], 4.19−4.28 [m, 1H, H−C(3′)], 4.23 [d, 1H, *J* = 12 Hz, H−C(28b)], 4.30−4.40 [m, 2H, H−C(3,23b)], 4.52−4.62 [m, 2H, H−C(4′,5′)], 4.99−5.08 [m, 1H, H−C(16)], 5.25 [d, 1H, *J* = 7.9 Hz, H−C(1′)], 5.33−5.39 [m, 1H, H−C(12)], 5.82 [d, 1H, *J* = 12.0 Hz, H−C(21)], 6.34 [d, 1H, *J* = 12.0 Hz, H−C(22)], 6.95−7.03 [m, 2H, H−C(3″,3‴)]; ^{13}C NMR (125 MHz, pyridine-d_5; HSQC, HMBC), δ 12.2 [C(5″)], 12.2 [C(5‴)], 13.6 [C(24)], 14.1 [C(4‴)], 14.2 [C(4″)], 16.2 [C(25)], 16.9 [C(26)], 18.1 [C(6)], 19.8 [C(30)], 23.9 [C(11)], 26.0 [C(2)], 27.4 [C(27)], 29.2 [C(29)], 32.5 [C(7)], 36.6* [C(10)], 36.8* [C(15)], 36.8 [C(20)], 38.8 [C(1)], 40.2 [C(8)], 42.6 [C(4)], 42.6 [C(18)], 43.5 [C(14)], 45.8 [C(19)], 47.1 [C(9)], 47.4 [C(5)], 48.0 [C(17)], 59.8 [C(28)], 64.4 [C(23)], 67.0 [C(16)], 73.5

Medium-Pressure Liquid Chromatography (MPLC). MPLC separation of the polar *Gymnemna sylvestre* extract was performed on a Sepacore chromatography system (Buchi, Flawil, Switzerland) consisting of two C-605 pumps with a C-615 pump manager, a manual Rheodyne injection port (20 mL loop), and a C-660 fraction collector. Data acquisition was performed by means of Sepacore Control 1.0 software (Buchi). Chromatographic separation was performed using PP cartridges (i.d. = 40 mm, l = 150 mm) and LiChroprep RP18, 25−40 μm, mesh material (Merck). Operated at a flow rate of 40 mL/min, the following gradient was used for chromatography: Starting with pure water (for 10 min) (water washing fraction), the methanol content was increased to 100% within 2 min and kept at 100% for 12 min (methanol/water fraction). Both fractions were individually collected; the solvent was removed using a Genevac Rocket evaporation system (Genevac Limited) and freeze-dried twice.

High-Performance Liquid Chromatography (HPLC). For analytical as well as for preparative analyses of fraction B, the HPLC apparatus (Jasco, Groß-Umstadt, Germany) was equipped with two PU-2087 Plus pumps, an AS-2055 Plus autosampler, a Sedex LT-ELSD detector model 85 (Sedere, Alfortville, France; split ratio was set to 1 mL/min for the ELSD; gain = 7), and a Rh 7725i type Rheodyne injection valve (Rheodyne, Bensheim, Germany). Data acquisition was performed by means of Chrompass 1.8.6.1 software (Jasco). Chromatographic separation was performed on a 250 × 21 mm i.d., 5 μm, NUCLEODUR C18 Pyramid column (Macherey-Nagel, Düren, Germany) operated with a flow rate of 20 mL/min. Using 0.1% formic acid in water (v/v) as solvent A and 0.1% formic acid in acetonitrile (v/v) as solvent B, chromatography was performed with the following gradient: 0 min, 30% B; 5 min, 30% B; 15 min, 40% B; 40 min, 40% B;

41 min, 45% B; 60 min, 45% B; 61 min, 65% B; 70 min, 65% B; 71 min, 100% B; 76 min, 100% B; 77 min, 30% B; 82 min, 30% B.

Liquid Mass Spectrometry (LC-MS). An API 4000 QTRAP mass spectrometer (AB Sciex, Darmstadt, Germany) with direct flow infusion was used to acquire electrospray ionization (ESI) mass spectra and product ion spectra. The MS system was operated in the full-scan mode detecting negative ions at an ion spray voltage at −4500 V. The MS/MS parameters were tuned for each compound to record fragmentation of the $[M - H]^-$ molecular ions into specific product ions. Data acquisition and instrumental control were performed with Analyst 1.4.2 software (AB Sciex).

UPLC/Time-of-Flight Mass Spectrometry (UPLC/TOF-MS). High-resolution mass spectra of the target substances were measured on a SYNAPT G2 HDMS (Waters UK Ltd., Manchester, UK) in the negative ESI and resolution modus with the following parameters: capillary voltage, 2.8 kV; sampling cone, 30; source temperature, 150 °C; desolvation temperature, 450 °C; cone gas, 5.0 L/h; and desolvation gas, 850 L/h. All saponins were dissolved in 1 mL water/methanol (90:10, v/v), and aliquots (1−5 μL) were injected into the UPLC/TOF-MS system. The samples were introduced into the instrument via an Acquity UPLC core system (Waters, Milford, MA, USA) consisting of a binary solvent manager, a sample manager, and a column oven. For chromatography, a 2 × 150 mm i.d., 1.7 μm, BEH C18 column (Waters) was operated with a flow rate of 0.4 mL/min at a temperature of 40 °C. The solvent system consisted of acetonitrile (A) and aqueous formic acid (0.1% in water, pH 2.5; B). The following gradient was used: 0 min, 50% B; 2 min, 100% B. The instrument was calibrated over a m/z range of 100−1200 using a solution of sodium formate (0.5 mM) in a 2-propanol/water mixture (90:10, v/v). All data were lock mass corrected using leucine enkephaline as the reference (m/z 556.2771, $[M + H]^+$). Data acquisition and interpretation were performed by using MassLynx software (version 4.1; Waters) and the tool "elemental composition".

Nuclear Magnetic Resonance Spectroscopy (NMR). 1D and 2D NMR spectra were acquired on a Bruker 500 MHz Avance III spectrometer (Bruker, Rheinstetten, Germany). 2D NMR experiments COSY, TOCSY, *J*-RESOLVE, HMQC/HSQC, DEPT, ROESY, and HMBC were carried out using the pulse sequences taken from the Bruker software library. Pyridine-d_5 was used as solvent, and chemical shifts are reported in parts per million relative to the pyridine-d_5 solvent signals (^{1}H NMR δ 7.19, 7.55, and 8.71; ^{13}C NMR δ 123.5, 135.5, and 149.5). Data processing was performed by using Topspin NMR software (version 3.1 and 2.1; Bruker) and Mestre-C (Mestrelab Research, A Coruña, Spain).

Statistical Analysis. Processing of raw data was done using Excel 2010 (Microsoft Corp.). Quantitative data are expressed as mean ± standard deviation unless otherwise noted. IC_{50} values were determined using Prism 6 software (GraphPad, La Jolla, CA, USA). A nonlinear regression was calculated using the log dose−response variable slope model.

RESULTS AND DISCUSSION

For identification of potent SGLT1 inhibitors from hypoglycemic botanicals used in traditional Chinese medication, a two-electrode voltage-clamp screening was used that records electronic glucose transport in *Xenopus laevis* oocytes microinjected with the cRNA for hSGLT1.

Functionality Testing. After the membrane voltage had been set to −60 mV, transport currents generated by SGLT1 were determined for glucose, fructose, and galactose (5 mM each) as well as the SGLT1 inhibitor phlorizin (Figure 1). As expected, neither application of fructose nor application of glucose in sodium-free solution caused any current, whereas a current was recorded when glucose or galactose was applied in the presence of sodium ions. These data confirmed the sodium dependency as well as the sugar specificity of SGLT1 as a selective glucose and galactose transporter. In the presence of only 5 μM phlorizin, glucose-mediated currents were significantly reduced, thus confirming the inhibitory activity of this polyphenol.[25]

Screening of Botanicals for SGLT1 Inhibition. A total of 26 Chinese medical herbs (H1−H26) were extracted with *n*-pentane, followed by methanol/water and, after removal of the solvents in a vacuum, the pentane extractables (fraction I) as well as the methanol extractables (fraction II) were used in the SGLT1-based screening. Whereas none of the pentane extracts showed any effect in the assay (data not shown), distinct SGLT1 inhibitory activities were found for some of the methanol-soluble fractions II (Figure 2). A total of nine botanical extracts increased SGLT1 activity and glucose transport, among which wolfberry (*Lycium chinense* Mill.; H3) and *Cornus officinalis* Siebold & Zucc. (H21) showed the highest activity by increasing the current by >30%. In comparison, 14 extracts induced a significant decrease in cellular sugar transport; the highest activity was found for *Gymnema sylvestre* (Retz.) Schult (H24), showing a 48% SGLT1 inhibition, followed by Digupi (*Lycium barbarum* L.; H7), Yin yang huo (*Epimedium sagittatum* Maxim; H5), and *Epimedium sagittatum* Maxim (H19) with somewhat lower SGLT1 inhibitory activities between 25 and 30%. As the leaves of *Gymnema sylvestre* R. Schult were found to show the highest SGLT1 inhibitory activity (Figure 2) and to exhibit hypoglycemic activities in diabetic subjects,[26−32] this botanical was selected for isolation of phytochemicals.

Activity-Guided Identification of SGLT1 Inhibitors in *Gymnemna sylvestre*. To identify the SGLT1 inhibitors, fraction II prepared from *Gymnema sylvestre* was separated by means of MPLC using water (fraction II-1) followed by methanol (fraction II-2) as the solvent. After lyophilization, fractions II-1 and II-2 were both used for the SGLT1 bioassay. Fraction II-1 did not exhibit any significant activity, but fraction II-2 showed SGLT1 inhibition similar to the activity found for the total fraction II (data not shown), thus suggesting the active target molecules to be present in fraction II-2. The latter fraction was, therefore, further separated by means of silica gel chromatography to afford eight fractions, namely II-2/A−II-2/H, which were again tested for their SGLT1 inhibitory activity (Figure 3).

Subfraction II-2/B showed the highest SGLT1 inhibition rate of 80% and was, therefore, further fractionated by means of preparative RP-HPLC using an evaporative light scattering detector. A total of 28 HPLC fractions were collected, separated from solvent in a vacuum and, finally, used for analysis of their SGLT1 inhibitory activity in their natural concentration ratios (Figure 4). By far the highest SGLT1 inhibition rates of 45 and 48%, respectively, were found for HPLC fractions 22 and 24, followed by fractions 2, 4, 6, 8−11, 13, 15, 18, 20, 21, and 23, all of which exhibited inhibition rates >5%. With the aim of determining the molecular structure of the molecules imparting the most intense SGLT1 inhibitory activity, LC-MS/MS, UPLC-TOF-MS, and 1D/2D-NMR experiments focused on the phytochemicals isolated from HPLC fractions 22 and 24 in semipreparative scale.

LC-MS(ESI$^-$) analysis of compound **1** isolated from HPLC fraction 22 revealed an intense pseudomolecular ion ($[M - H]^-$) with m/z 845, thus suggesting a molecular mass of 846 Da. This was confirmed by LC-TOF-MS indicating an empirical formula of $C_{46}H_{70}O_{14}$. Additional LC-MS/MS experiments led to the identification of the daughter ion m/z 669 $[M - 176 - H]^-$ and indicated the cleavage of one galacturonic acid moiety as expected for gymnema saponins.[33]

For further structure elucidation and NMR signal assignment, 1D/2D-NMR experiments including COSY, DEPT, TOCSY, *J*-RESOLVED, ROESY, HSQC, and HMBC were performed. The ^{13}C NMR spectrum showed a total of 46 signals for compound **1** resonating between 12.3 and 173.0 ppm, among which 30 signals were well in alignment with the aglycone structure of gymnemagenin.[33−35] After identification of the aglycone of **1**, the following spectroscopic experiments were focused on the structure determination of the intact saponin. As expected for tiglic acid ester moieties, the HMBC experiment revealed two long-range couplings between proton H−C(21) and H−C(22) resonating at 5.80 and 6.34 ppm and the carbon atoms C(1″) and C(1‴) observed at 167.8 and 167.5 ppm, which showed heteronuclear connectivity with the methyl protons H−C(5″) and H−C(5‴) at 1.76−1.86 ppm. In addition, 1D/2D-NMR spectroscopic experiments led to the identification of an anomeric proton resonating at 5.25 ppm. This proton signal showed a large coupling constant of 7.9 Hz, thus indicating a *β*-configuration of the galacturonic acid moiety. The full assignment of the carbohydrate moieties as well as their linkage alignment was achieved by means of COSY, TOCSY, and HMBC experiments; for example, the HMBC spectrum showed long-range correlations between H−C(1′) and C(3). With all of these findings taken into account, the phytochemical in fraction 22 was identified as 3-*O*-*β*-D-glucuronopyranosyl-21-*O*-2-tigloyl-22-*O*-2-tigloyl gymnemagenin, known as gymnemic acid V (**1**, Figure 5). Although the structure of **1** is known in the literature,[34−36] the SGLT1 inhibitory activity of this saponin has not yet been reported.

Separation of fraction 24 by means of semipreparative HPLC revealed the SGLT1 inhibiting key phytochemical **2** in a purity of >98%, which showed a pseudomolecular ion ($[M - H]^-$) with *m*/*z* 847 in the LC-MS spectrum recorded by means of electrospray ionization. This was confirmed by LC-TOF-MS experiments indicating an empirical formula of $C_{46}H_{72}O_{14}$. Comparison of the ^1H, ^{13}C, homonuclear (COSY, TOCSY), and heteronuclear (HMSC, HMBC) as well as ROESY data of **2** with those of **1** confirmed a methylbuturyl residue instead of a tiglinoyl moiety attached to aglycone carbon C(22). Comparison of all spectroscopic data with those reported in the literature[33−36] led to the unequivocal identification of compound **2** as 3-*O*-*β*-D-glucuronopyranosyl-21-*O*-2-methylbutyryl-22-*O*-2-tigloyl gymnemagenin, known as gymnemic acid XV (Figure 5). The SGLT1 inhibitory activity of **2** has not been previously reported.

SGLT1 Inhibitory Activity of Gymnemic Acids V and XV. Prior to cell experiments, the purity of the test compounds was confirmed by HPLC-MS as well as ^1H NMR spectroscopy to be >98%. Recording of dose/response functions, followed by the determination of IC_{50} data through Graphpad (Graphpad Prism 6), revealed $LogIC_{50}$ values of −5.224 for gymnemic acid V (**1**) and −4.781 for gymnemic acid XV (**2**), thus corresponding to IC_{50} values of 5.97 *μ*M for gymnemic acid V and 0.17 *μ*M for gymnemic acid XV, the structures of which are differing by just by the tigloyl and methylbutyryl moieties at position 21 of **1** and **2**, respectively. Interestingly, the IC_{50} value of gymnemic acid XV (**2**) matched the low value of 0.21 *μ*M measured for the high-affinity SGLT1 inhibitor phlorizin in our oocyte assay (Table 1). The latter value was in the same range as found for phlorizin in other studies by means of a radioactive (0.11 *μ*M)[37] as well as a nonradioactive assay (0.17 *μ*M)[38] using COS-7 cells transiently expressing human hSGLT1, but was lower when compared to an IC_{50} value of 42 *μ*M found for phlorizin when using a stably transfected Chinese hamster vvary (CHO) cell assay.[39]

Table 1. IC_{50} Values for SGLT1 Inhibitory Activity of Phytochemicals

compound	IC_{50} value[a] (*μ*M)
gymnemic acid V (**1**)[b]	5.97 ± 0.52
gymnemic acid XV (**2**)[b]	0.17 ± 0.05
phlorizin	0.21 ± 0.03

[a]IC_{50} values were calculated from dose−response recordings. [b]Structures of compounds are given in Figure 5.

Although gymnemic acids have been reported to decrease blood glucose level in rats after an oral glucose load,[40] the mechanism of action was not yet clear. Using the hSGLT1 bioassay, this is the first report on gymnemic acids as high-affinity SGLT1 inhibitors, among which gymnemic acids V and XV were found as the key molecules with the strongest SGLT1 inhibitory activity in *Gymnema sylvestre*. As SGLT1 is found in high levels in brush-border membranes of intestinal epithelial cells, our findings demonstrate for the first time the potential of these saponins for the inhibition of electrogenic glucose uptake in the GI tract.

ABSTRACT: Carnosine (CAR) is an endogenous peptide and present in lens, but there is little evidence for its effectiveness in calpain-induced proteolysis inhibition and its differential effects toward different wavelengths of ultraviolet (UV) irradiation. This study aimed to develop three in vitro cataract models to compare the mechanisms underlying the protective activities of CAR. Crude crystallins extracted from porcine lenses were used for antiproteolysis assays, and purified γ-crystallins were used for anti-UV assays. The turbidity in those in vitro models mimics cataract formation and was assayed by measuring optical density (OD) at 405 nm. The effectiveness of CAR on calpain-induced proteolysis was studied at 37 and 58 °C. Patterns of proteins were then analyzed by SDS-PAGE. The turbidity was reduced significantly ($p < 0.05$) at 60 min measurements with the increased concentration of CAR (10−300 mM). SDS-PAGE showed that the decreased intensities at both ∼28 and ∼30 kDa protein bands in heat-enhanced assays were ameliorated by CAR at ≥10 mM concentrations. In UV-B studies, CAR (200, 300 mM) reduced the turbidity of γ-crystallin significantly ($p < 0.05$) at 6 h observations. The turbidity of samples containing γ-crystallins was ameliorated while incubated with CAR (100, 300 mM) significantly ($p < 0.05$) following 4 h of exposure to UV-C. SDS-PAGE showed that the presence of CAR reduced UV-B-induced aggregation of γ-crystallins at ∼44 kDa and resulted in less loss of γ-crystallin following UV-C exposure. The result of modeling also suggests that CAR acts as an inhibitor of calpain. In conclusion, CAR protects lens proteins more readily by inhibiting proteolysis and UV-C-induced degradation than aggregation induced by UV-B irradiation.

KEYWORDS: *carnosine, calpain proteolysis, UV insults, lens turbidity, molecular modeling*

INTRODUCTION

Carnosine (β-alanyl-L-histidine; CAR), discovered by Russian scientists in 1990, is a dipeptide present in meat,[1] lens,[2] and other tissues. The endogenous CAR acts as a natural antioxidant to scavenge free radicals[3] and lipid peroxides.[4] Its L-histidine, more specifically its imidazole moiety, appears to be the prime bioactive component and may react nonenzymically with protein carbonyl groups, a process termed "carnosinylation" to show its antiaging actions.[5] In eye lenses, crystallins are the proteins essential for their transparency. Among lens crystallin proteins, α-crystallin is able to prevent aggregation of the other destabilized proteins (especially of γ- and β-crystallins). The reported abilities of CAR in disaggregating crystallins, inhibiting fibril formations,[6,7] and protecting α-crystallins against glycation[8] provide an explanation for the anticataract activity exerted by CAR eye drops.

The aggregations or degradations of crystallins in cataractous eye lenses may result from intracellular or environmental insults. Recent studies have suggested that a major cause of the insolubilization of crystallins may be the unregulated proteolysis by calpains.[9] Calpain is one of the widely distributed calcium-dependent cysteine proteases. Among the subtypes of calpains, calpain II is the major type in human and rodent lenses[10,11] and is present in the superior cortical region.[12] Calpastatin is an endogenous inhibitor of calpain II in certain tissues. Inappropriate regulation of the calpain−calpastatin proteolytic system is associated with several important human pathological disorders including cataract formation.[13]

In addition, increased exposure to ultraviolet light results in increased photo-oxidative stress and will increase the risk of cataractogenesis.[14] The human lens can absorb visible light, UV-A and UV-B, but ocular protection from UV-B (290−320 nm) is recommended.[15] Moreover, accidental overexposure to UV-C (200−290 nm) during germicidal therapy can cause corneal burns and severe sunburn to the face and eyes. The consequences of overexposure to UV-C include increased production of free radicals, increased sensitivity of proteolysis, and decreased chaperone activity of α-crystallin[16,17] and further cause lens protein conformation destruction by cross-linking lens protein and further decreasing lens transparency.

Cataract is the leading cause of blindness, accounting for approximately 50% of blindness worldwide. Previously, we demonstrated that compounds that protect γ-crystallins from UV-C damage[18,19] or interact with calcium[20−22] may potentially be used as anticataract agents. In certain countries, CAR is available as a dietary supplement or eye drops in the health promotion market. Clinical eye drops containing its prodrug, *N*-acetylcarnosine, were also demonstrated to be absorbed intraocularly to prevent and reverse cataract.[23,24] However, claims that CAR possesses ophthalmological benefits are, as yet, insufficiently supported for the medical community to recommend CAR as a topical treatment for cataracts. For

example, the modulation role of CAR on the lens calpain−calpastatin system is still unclear. To date, only one study has investigated CAR's effect on aggregation of β-L-crystallins induced by UV,[25] but there are no details for CAR's effects on γ-crystallin exposure to UV-B or -C. This study aimed to clarify the effects of exogenous CAR on lens crystallin turbidity formation, especially resulting from calcium imbalance and UV-B/C photo-oxidation of lens crystallins using in vitro bioassay systems. Absorption spectroscopy and molecular modeling and docking were applied to propose the biochemical mechanisms of CAR underlying its multitarget activities in protecting lens proteins.

MATERIALS AND METHODS

General. Porcine lenses purchased from a slaughterhouse were decapsulated and homogenized in lens buffer containing 50 mM Tris-HCl, 0.1 M NaCl, 5 mM EDTA, 0.01% β-mercaptoethanol, and 0.02% sodium azide, at pH 8.0, as described previously.[18] After centrifugation at 16060*g* for 30 min (Hermle Z300 K, Hermle Labortechnik, Wehingen, Germany), the supernatant was collected, and the protein concentration was determined according to the Bradford method (Bio-Rad Laboratories, Irvine, CA, USA). γ-Crystallins were purified from crude porcine lens proteins by gel filtration as previous described.[19,26] CAR was purchased from Sigma (St. Louis, MO, USA). Samples for the turbidity assay were incubated at 37 °C using microtiter plates (Microtest 96; Falcon; Fisher Scientific, Franklin Lakes, NJ, USA) except those for heat-enhanced assays. Turbidity was measured as the optical density (OD) at 405 nm, using an enzyme-linked immunosorbent assay (ELISA) reader (TecanSunrise, Tecan Group, Männedorf, Switzerland).

m-Calpain-induced Proteolysis of Crystallins. To determine the in vitro exogenous calpain-induced lens protein turbidity, exogenous lens calpain (EC 3.4.22.17) was activated by adding 1.5 mM calcium[22] or further enhanced by heating according to the Shih et al. study.[27] Incubations of 200 μL were prepared by adding 5 mg of lens-soluble proteins/mL and 7.5 units of calpain II (from porcine kidney; Calbiochem, Torrey Pines, CA, USA) with various concentrations of CAR (0.1, 1, 10, 30, 100, 300 mM). Proteolysis was initiated by adding 1.5 mM Ca^{2+}, processed for 10 min at 37 °C (TKS OS1500, KANSAN Instruments Co. Ltd., Taipei, Taiwan) in nonheat assays or heating at 58 °C (Pantech Firefox 6100) in heat-enhanced assays. The proteolysis was terminated by the addition of EDTA to a final concentration of 3 mM. After the measurements, the mixture from each well was collected and centrifuged at 15000*g* and 4 °C for 15 min and subjected to a SDS-PAGE (12%) analysis followed by Coomassie brilliant blue R-250 staining. The intensity of each band was digitized by ImageJ, a Java-based image processing program developed at the National Institutes of Health, USA.

Photodamage of γ-Crystallins by UV-B or UV-C in Vitro. Chemical modifications of lens proteins by UV irradiation may also contribute to opacities and have been shown to cause the turbidity of γ-crystallin.[28] To develop a feasible anticataract activity assay against UV-B-[18,29] or UV-C-induced turbidity within 6 h, 20 or 0.4 mg/mL γ-crystallin exposure to UV-B (VilberLoumat biolink cross-linker; 312 nm; 4 J/h) or UV-C (UVP CL-1000; 254 nm; 14 J/h) for up to 6 or 4 h was used. In general, 200 μL of lens buffer mixtures containing γ-crystallins, with or without various concentrations of CAR for anti-UV-B or -UV-C assay, were exposed for 6 or 4 h, respectively. Anticataract activity of CAR at 1−300 mM was then determined. Protein patterns were then analyzed by SDS-PAGE and ImageJ. Ultraviolet−visible spectroscopy (UV−vis) was applied for CAR's UV-filtering property.

Molecular Modeling and Docking. The 3D-structural model of the *Sus scrofa* calpain II catalytic subunit (protein sequence entry NP_001093658) was generated with the program Discovery Studio (Accelrys Software Inc.) based on the structure of rat calpain II (PDB code 3BOW) as template. The model of CAR was docked into the active site of the resulting *S. scrofa* calpain II model based on the binding mode of calpastatin in rat calpain II (3BOW).[30] On the basis of the structures of rat calpain II bound to calpastatin, the model of CAR was manually docked into the active site of *S. scrofa* calpain II model with the program Coot to generate an initial binding pose of carnosine in *S. scrofa* calpain II. This model of the calpain II−CAR complex was optimized by energy minimization with the program Discovery Studio, and the resulting model with the lowest value of potential energy was selected. The stereochemical quality of the model was further checked with the programs 3D-profile and PROCHECK. The structure figures were generated with the program PyMOL (Schrödinger, New York, NY, USA).

Statistical Analysis. Average turbidity formation (in absolute OD 405 nm) changes from the baseline or percentage changes versus the controls were calculated. The changes of turbidity after various treatments are expressed as the mean ± standard error of the mean ($n \geq 3$). The data were analyzed using an unpaired *t* test between two groups or by Kruskal−Wallis one-way analysis of variance (ANOVA) on ranks with a post hoc Dunn's test, using SigmaStat 2.03 (Systat Software, San Jose, CA, USA). Differences were considered significant when the *p* value was <0.05. The intensity of each band for SDS-PAGE determined by ImageJ was further normalized against its normal controls or negative controls, which are the ones exposed to the insults without CAR treatments.

RESULTS

CAR Ameliorates m-Calpain-Induced Proteolysis of Crystallins. To test the effects of CAR on proteolysis, we compared the calcium/calpain II-induced turbidity of porcine lens crystallins to the normal controls. Figure 1 shows two

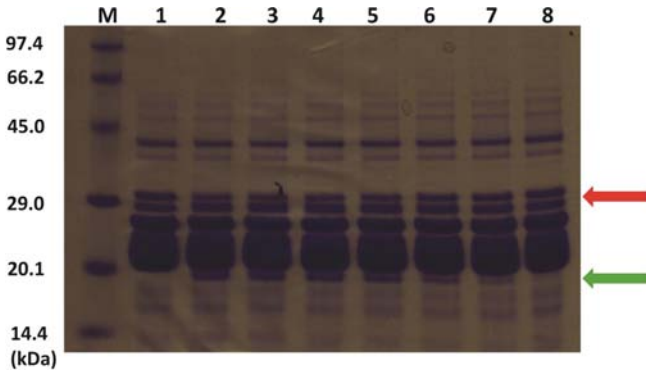

Figure 1. Effects of carnosine on exogenous m-calpain-induced cataract model. SDS-PAGE analysis of porcine eye lens crystallins subjected to exogenous calpain II induced proteolysis with or without carnosine. Lanes: M, markers; 1, normal crystallins; 2, crystallins with added calpain II; 3−8, crystallins with added calpain II solution containing 0.1, 1, 10, 30, 100, and 300 mM carnosine, respectively. Arrows indicate the noticeable crystallin band changes.

major differences: (1) The decreased β-crystallin band at ∼30 kDa was diminished in the presence of 30−300 mM CAR. The decreased β-crystallin band at ∼30 kDa was preserved in the presence of 30−300 mM CAR, but not at ∼28 kDa. (2) The appearance of degraded bands at ∼19 kDa increased by 42%, and the presence of CAR (0.1−100 mM) ameliorated the increased intensity of degraded protein bands by 1−27% when compared to the control or even prevented such proteolysis when incubated with 300 mM CAR.

To further confirm the effects of CAR, the heat-enhanced exogenous calpain II-induced proteolysis of crystallins was performed. The turbidity was measured at 0, 20, 40, and 60 min (Figure 2A). At 60 min, CAR at 0.1 and 1 mM did not inhibit turbidity formation, but CAR at higher concentrations (10, 100, 300 mM) decreased turbidity intensity values (0.14 ± 0.02,

dx.doi.org/10.1021/jf5017708 | J. Agric. Food Chem. 2014, 62, 5932−5938

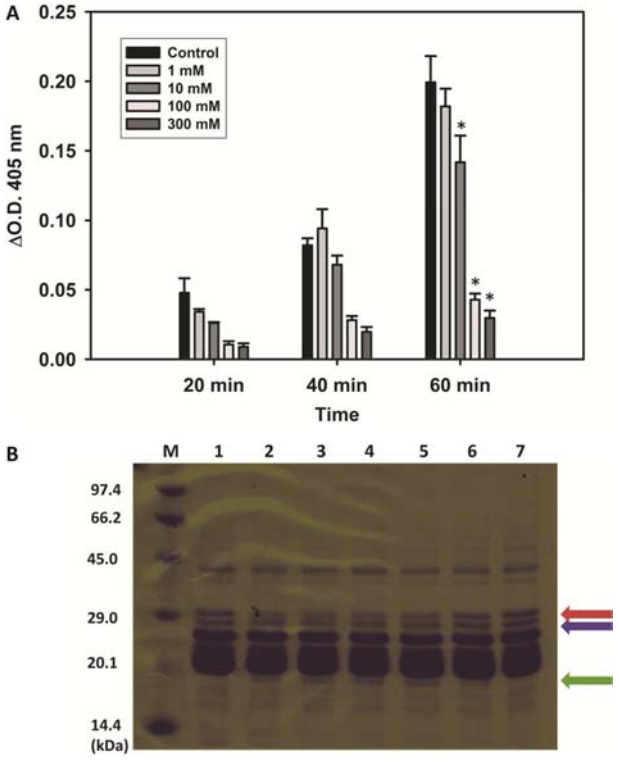

Figure 2. Effects of carnosine on heat-enhanced exogenous m-calpain-induced cataract model. (A) Turbidity changes of porcine eye lens crystallins subjected to heat-enhanced exogenous calpain II-induced proteolysis with various concentrations of carnosine. The control is the normal crystallins without carnosine incubations. The asterisk (∗) indicates statistically significant differences ($p < 0.05$). (B) SDS-PAGE analysis of porcine eye lens crystallins subjected to heat-enhanced exogenous calpain II-induced proteolysis. Lanes: M, markers; 1, normal crystallins; 2, crystallins with added calpain II after heating; 3−7, crystallins with added calpain II solution containing 0.1, 1, 10, 100, and 300 mM carnosine, respectively. Arrows indicate the noticeable changes of protein bands.

0.04 ± 0.01, 0.03 ± 0.01) in a dose-dependent manner compared with control (0.20 ± 0.02; $p < 0.05$). Digitalized image results of SDS-PAGE (Figure 2B) indicate that heat-enhanced exogenous calpain II induces proteolysis, which presented 11% decreases in proteins at ∼28 kDa compared to the ones without heating. CAR at concentrations ≥10 mM ameliorated the increased intensity of degraded protein bands at ∼28 kDa. The degraded proteins at ∼19 kDa increased by 22%, and the presence of CAR at a concentration of 100 mM ameliorated the increased intensity of degraded protein bands by 7% when compared to the negative control. According to the docking experiment of the 3D-structural model of the *S. scrofa* calpain II, CAR may bind to the calpain catalytic active site (Figure 3A) and possesses inhibitory activity similar to the activity of calpastatin. Multiple sequence alignments of calpain II showed high sequence identity among porcine, human, and rat (Figure 3B). The residues around the active site are conserved among these species.

Protective Effects of CAR from UV-B- and UV-C-Induced Photodamage of γ-Crystallins. Turbidity was determined at 405 nm for UV-B-induced photodamage of γ-crystallins after 0, 2, 4, and 6 h. CAR at 100 mM did not protect crystallins from UV insults; however, as shown in Figure 4A, after 6 h of UV-B exposure, the absolute turbidity of γ-crystallins without CAR (the controls) increased to 0.66 ± 0.02 and was significantly decreased to 0.30 ± 0.01 and 0.08 ± 0.01, respectively, in the presence of 200 or 300 mM CAR ($p < 0.05$). Results of SDS-PAGE revealed that there were no changes in the supernatants of γ-crystallin incubation samples (Figure 4B). With regard to the precipitate fractions of irradiated γ-crystallins, there are new protein bands at ∼44 kDa. A similar result was seen with 100 mM CAR. According to the digitalized image results of SDS-PAGE, precipitated fragments of irradiated γ-crystallins at ∼19 kDa decreased 22% when incubated with 200 or 300 mM CAR.

To evaluate CAR in protecting lens crystallins from UV-C damage, turbidity was determined after γ-crystallin solutions were exposed to UV-C for 0, 1, 2, 3, and 4 h. At 4 h, absolute turbidity of irradiated γ-crystallin incubated with 100 and 300 mM CAR increased to 0.36 ± 0.02 and 0.19 ± 0.01, whereas the ones without CAR increased to 0.51 ± 0.06 ($p < 0.05$) (Figure 5A). Compared to the intensity of normal controls, results of SDS-PAGE reveal that γ-crystallins degraded under UV-C irradiation, the intensity decreased 52%, and γ-crystallins were preserved 68% while 100−300 mM CAR was present (Figure 5B). The spectrum of CAR is shown in Figure 6.

DISCUSSION

In this study, we provided first evidence that CAR protects lens proteins by inhibiting calpain II activation regardless of incubations at 37 or 58 °C. Because the active sites of rat calpain II are conserved in porcine or human (Figure 3B), the calpain II inhibition activity of CAR may be common among these species. CAR's anti-UV activities are more precisely pronounced when UV-C is the source of insults rather than UV-B. Cataract is one of the main causes of blindness and low vision. Effective medications for preventing particular etiology of cataract formations remain important before cataract surgery is considered.

Activation of calpain II is related to cataract formation due to the cleavage of the N-terminal region of crystallins and resulting insolublization of these proteins.[31] The in vitro bioassay model of calcium-induced calpain II used in the current study mimicked this mechanism of senile cataract formation. The purpose of employing heating is to establish a fast turbidity formation assay system. The changes of porcine β-crystallins at ∼28 or ∼30 kDa and truncated α-crystallins at ∼19 kDa were similar to those proteolysis results previously reported by Shih et al.[27] When compared to the assays at 37 °C, less truncated α-crystallins at ∼19 kDa (22 vs 42%) were seen in heating condition. This may be because the truncated α-crystallins at ∼19 kDa were further broken down into smaller polypeptides due to thermal effects. Overall results reveal that CAR (10−300 mM) hampered proteolysis or degradation of β- and α-crystallins activated by calpain. Such results may[32] or may not[33] be related to complex formation by CAR with Ca^{2+}. Our modeling result shows that CAR may provide inhibitory effects on calpain and therefore subsequently inhibit calpain II-induced turbidity formation, which is similar to its antioxidation at levels of 5−15 mM in rabbit lenses.[34] CAR has shown good stability against intense heat treatments, even at temperatures as high as 120 °C for 20 min.[35] Therefore, the activity of this dipeptide in heat assays is assumed to be reserved. However, it cannot be ruled out that the presence of α-crystallins in the used crude lens proteins may also provide additional protective effects by their well-known chaperone activity, especially in assays of heat-enhanced calpain proteolysis.[28]

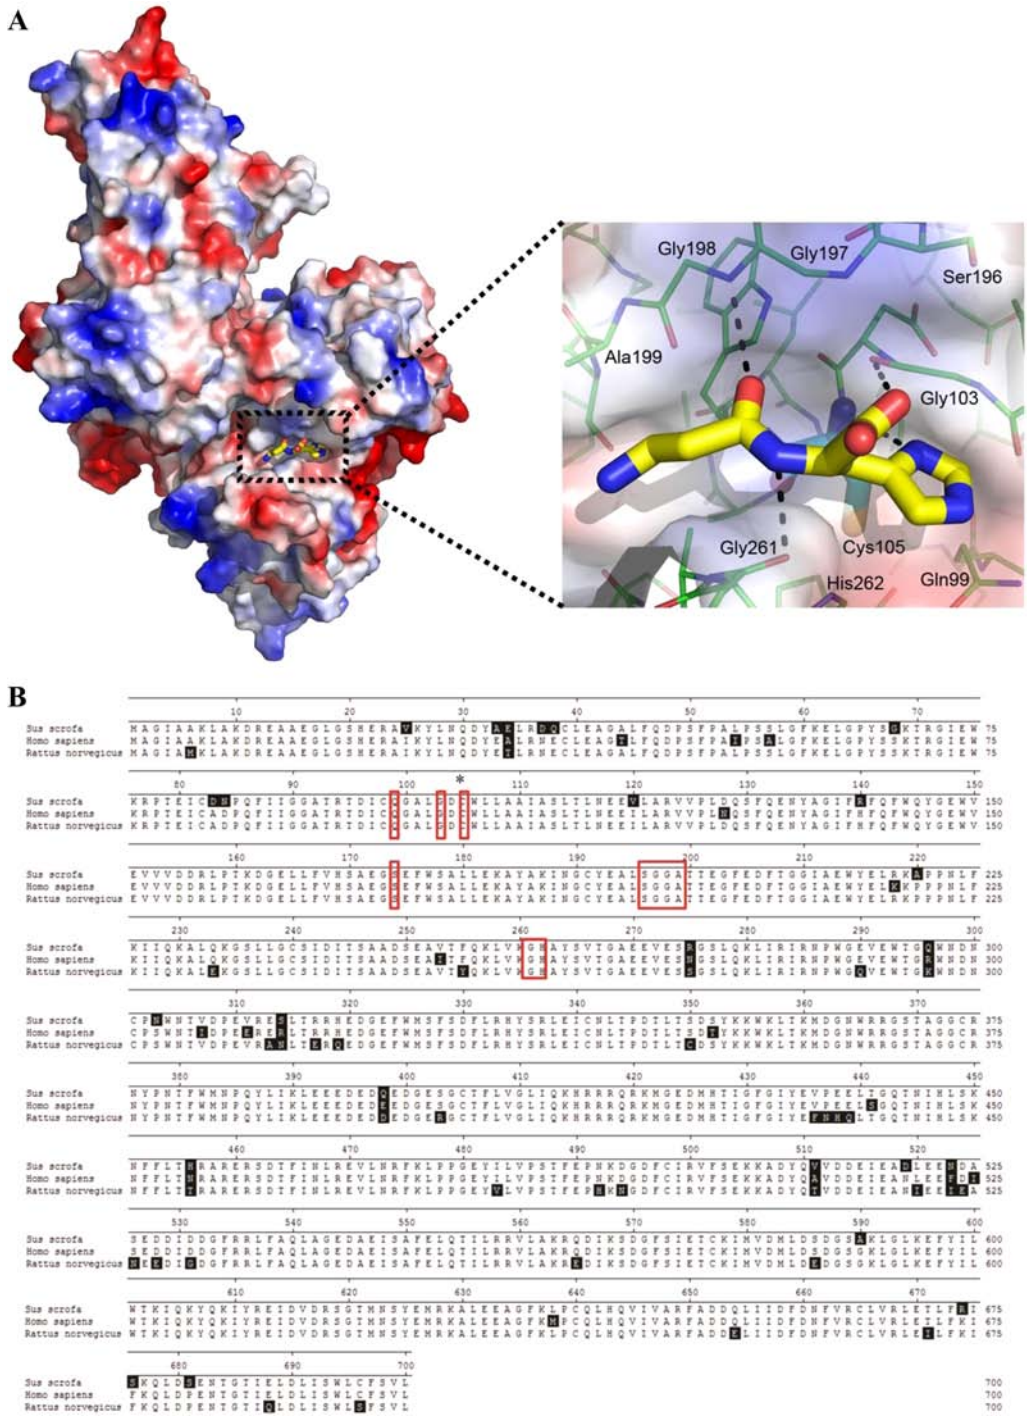

Figure 3. (A) 3D-structural model of *Sus scrofa* calpain II bound to carnosine. (Left) Surface representation of the *S. scrofa* calpain II catalytic subunit with yellow stick model depicting the bound carnosine molecule. The negative and positive charges of the surface are colored red to blue, respectively. (Right) Close-up view of the carnosine molecule bound in the active site of *S. scrofa* calpain II. The catalytic cysteine residue is drawn with a cyan stick model, and the possible hydrogen-bond interactions are indicated with dashed lines. (B) Multiple alignments of amino acid sequences of calpain II. Alignment was performed by using DNAstar MegAlign (Clustal W method). Human calpain II (*Homo sapiens*, NP_001739), porcine calpain II (*Sus scrofa*, NP_001093658), and rat calpain II (*Rattus norvegicus*, EDL94875) were used in this experiment. Nonidentical residues in all sequences are shaded in black, and the active site (Cys 105) is marked in asterisks (*). The conserved residues around the active site are shown in red boxes.

UV irradiation is a common risk factor of cataractogenesis in addition to calpain-induced proteolysis. α-Crystallin also provides additional protection against UV insults because it naturally presents with γ-crystallins in eye lenses. Even though the current results revealed that CAR required 100 or 200 mM or higher concentrations to protect γ-crystallins from UV-C or UV-B insults, doses of CAR needed for delaying lens opacity formation induced by daily light ultraviolet may be lower than the concentrations used in the current assays. Exposure of lens proteins to UV-C irradiation results in ROS production[36] and

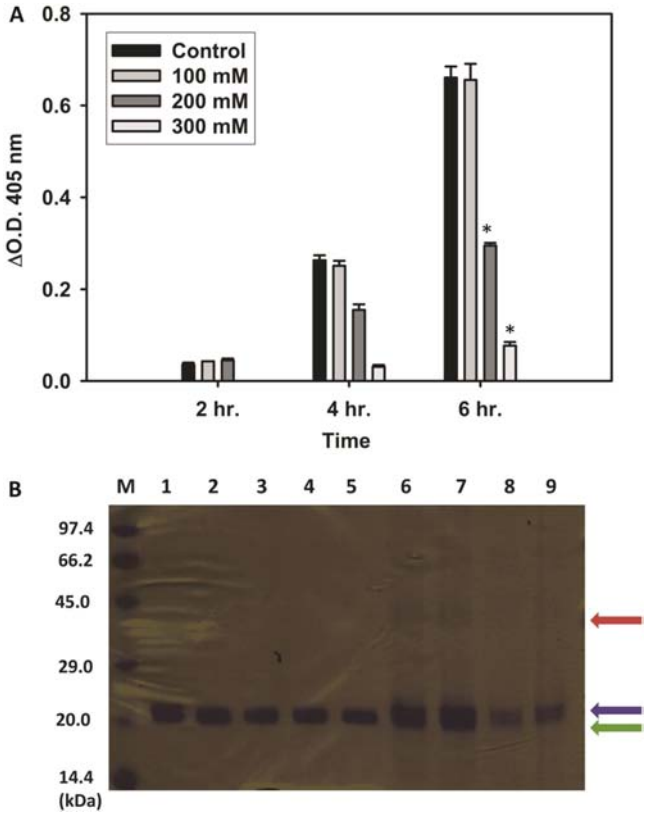

Figure 4. Anti-UV-B activity of carnosine. (A) Turbidity changes of crystallin solution with or without various concentrations of carnosine under UV-B irradiation for 2, 4, and 6 h. At 2 h, there is no turbidity change for the group with 300 mM CAR. The asterisk (∗) indicates statistically significant differences ($p < 0.05$). (B) Comparisons of supernatant and precipitate fractions by SDS-PAGE analysis: porcine γ-crystallins following UV-B irradiations. Lanes: M, markers; 1, normal γ-crystallin; 2−5, supernatant fractions of irradiated γ-crystallins incubated with carnosine (0, 100, 200, 300 mM); 6−9, precipitate fractions of irradiated γ-crystallin incubated with carnosine (0, 100, 200, 300 mM). Arrows indicate the noticeable crystallin bands changes.

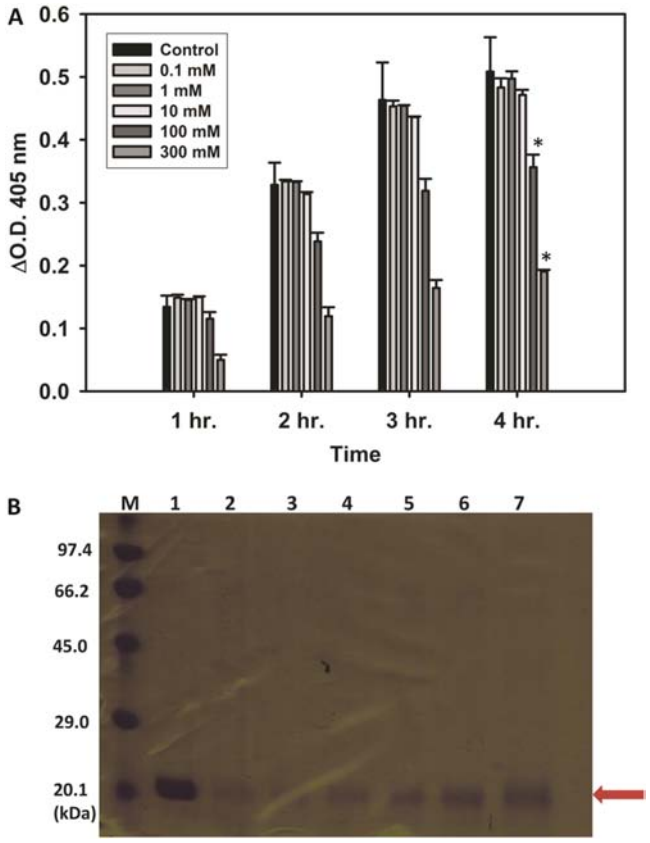

Figure 5. Anti-UV-C activity of carnosine. (A) Turbidity changes of crystallin solution with or without various concentrations of carnosine under UV-C irradiation. The asterisk (∗) indicates statistically significant differences ($p < 0.05$). (B) SDS-PAGE analysis of porcine γ-crystallin before and after UV-C irradiation. Lanes: M, markers; 1, normal γ-crystallin; 2−7, irradiated γ-crystallin incubated with carnosine (0, 0.1, 1, 10, 100, 300 mM). Arrows indicate the noticeable crystallin band changes.

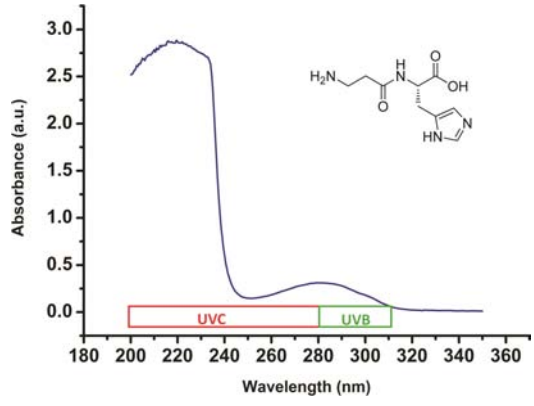

Figure 6. UV spectrum of carnosine in water (5 mg/mL). CAR absorbed in the UV-C domain, with a maximum absorption at 220 nm.

proteolytic degradation, whereas UV-B does not increase proteolytic susceptibility to the same extent but promotes the formation of cross-linked proteins[16,17] and increased content of carbonyl and disulfide bonding to form insoluble lens protein.[37]

Even though ultraviolet light is filtered by the dwindling ozone layer, increased exposure to UV-B is now considered to be a factor for increased cataract incidence. The observed UV-B-induced aggregation of γ-crystallins at ∼44 kDa (formation of dimers), similar to those of Andley et al.,[29] may be related to intermolecular disulfide bond formations induced by UV irradiation.[38] In addition, the protein bands at 15−18 kDa may have resulted from the degradation of γ-crystallins. The intensities of those new protein bands in precipitate fractions of irradiated γ-crystallins decreased when CAR increased to 100 mM. However, CAR at concentrations ranging from 1 to 100 mM provides little protective effect on γ-crystallins against UV-B. However, CAR provides better protection on porcine lens crystallins against UV-B irradiation and calpain proteolysis than pirenoxine[18] (an active ingredient of clinically used medication).

Moreover, our results suggest that CAR may possess better protective effects against UV-C than against UV-B insults because CAR at 100 mM significantly protects γ-crystallins from UV-C photodamage (accumulated intensity 56 J/4 h per 0.08 mg of γ-crystallins), but did not give adequate protection against UV-B, which was applied at lower intensity (accumulated intensity 24 J/6 h per 4 mg of γ-crystallins). The different anti-UV-B versus anti-UV-C activities exerted by CAR were also supported by its excellent UV filtering in the UV-C range between 200 and 240 nm, but not in the UV-B range (Figure

dx.doi.org/10.1021/jf5017708 | J. Agric. Food Chem. 2014, 62, 5932−5938

6). Therefore, the negative results of CAR reported by a Russian study[25] in inhibiting lens βL-crystallin aggregation are probably because UV-B was the choice of irradiation used in their assays. Moreover, the previously reported activity of CAR against free radicals, singlet oxygen, and superoxide[4] may provide support for its better anti-UV-C activity shown in the current study. However, CAR possesses slightly less protection in anti-UV-C activity when compared to pirenoxine.[18]

The physiological amount of CAR (16−30 μM) in lens[2] of healthy subjects may be enough to provide protection from ordinary UV light exposures, but predictably inadequate for intensive insults. Concentrations of 50−100 mM CAR show protective effects on in vitro crystalline fibrillation and decreased turbidity of lens organ cultures induced by quinidine.[6] A level of 50 mM CAR protects the chaperone activity of α-crystallin.[8] However, higher concentrations of CAR were also suggested to react with steroids after 1 week of incubation and to have a deleterious effect on the chaperone activity of α-crystallin.[39] The similar concentrations of CAR or higher used in this study are to counteract the applied thermally enhanced proteolysis and unusual irradiation insults; therefore, it may not suitable to directly apply our results for human trials. Therefore, further efforts to determine appropriate in vivo effective formulations and concentrations of eye drops containing prodrugs of CAR[24] to confirm the benefits of CAR instillation or supplementation in maintaining multifunctions of CAR in antiproteolysis or anti-irradiation from ordinary exposure to UV-B or UV-C are warranted.

In conclusion, the current study established convenient antiaggregation systems for assaying potential agents to prevent turbidity formation of lens proteins. The multifunctional effects of CAR in protecting lens proteins are more likely acting as an inhibitor on proteolysis and UV-C-induced degradation, rather than on aggregation induced by UV-B irradiation.

ABSTRACT: An environmentally friendly steam explosion process of bamboo, followed by alkali and alkaline ethanol delignification, was developed to fractionate lignins. Results showed that after steam explosion the lignins isolated showed relatively low carbohydrate contents (0.55−1.76%) and molecular weights (780−1050 g/mol). For each steam-exploded sample, alkali-extracted lignins presented higher phenolic OH values (1.41−1.82 mmol/g), *p*-coumaric acid to ferulic acid ratios (*p*CA/FA ratios 4.5−14.1), and syringyl to guaiacyl ratios (S/G ratios 5.0−8.5) than those from alkaline ethanol-extracted lignins (phenolic OH 0.85−1.35 mmol/g, *p*CA/FA ratios 1.6−5.2, and S/G ratios 3.5−4.8). The lignins obtained consisted mainly of β−O−4′ linkages combined with small amounts of β−β′, β−5′, and α−O−4/β−O−4 linkages. Antioxidant activities of the lignins obtained were tested by the 2,2-diphenyl-1-picrylhydrazyl, 2,2′-azobis(3-ethylbenzothiazoline-6-sulfonic acid), and ferric reducing activity power methods. It was found that alkali-extracted lignins obtained during the initial extraction process had higher antioxidant activities than alkaline ethanol-extracted lignins obtained during the second extraction process.

INTRODUCTION

Increasing concerns about global climate change and diminishing fossil resources have increased attention in the development of alternative forms of biofuels and materials from renewable resources. Lignocellulosic biomass, as the most abundant renewable resource, can serve as a source of carbon-neutral or carbon-negative feedback for the production of biofuels, chemicals, and polymers, generally referred to as the biorefinery. Nowadays, the most promising biorefinery is to integrate biofuel production into the process in which the major components (cellulose, hemicelluloses, and lignin) of the biomass can be converted into high value-added products.[1] Therefore, effective pretreatment technology is necessary to separate the three major components and enhance enzyme digestibility of cellulose.[2]

Generally, pretreatments include physical, chemical, and biological methods, such as steam explosion, dilute acid, organosolv, and aqueous lime or alkali pretreatments. Among these methods, steam explosion pretreatment offers several advantages as compared with other pretreatments, including opening up biomass structure effectively,[3] assisting in fractionation of biomass components,[4] and decreasing environmental impact and capital investment, as well as increasing energy efficiency. However, the pretreatment also has some limitations, such as only partial destruction of hemicelluloses and incomplete disruption of the lignin−carbohydrate matrix; therefore, lignin is removed only to a limited extent and redistributes on the cellulose surfaces.[5] To circumvent these drawbacks, a subsequent alkaline delignification process, namely, successive alkali and alkaline ethanol extractions, was developed to fractionate steam-exploded biomass. Alkaline treatment is effective to disrupt plant cell walls and cleave the hydrogen bonds and covalent bonds in the cell wall matrix.[6] In addition, alkaline ethanol treatment is also an effective method where ethanol swells the biomass structure and acts as a solvent for the lignin, therefore reducing surface tension of the refining liquor at high temperature and promoting penetration of alkali into the materials and diffusion of the breakdown products of lignin from the materials to the liquor.[7] This ensures that lignin can be extracted without extensive modification of its structure. The presence of sodium hydroxide prevents or reduces pentosan hydrolysis and improves the delignifying ability of ethanol.[7,8] Therefore, in the whole biorefinery process combining steam explosion with a two-step alkaline delignification (alkali and alkaline ethanol treatments), hemicelluloses and lignin can be effectively fractionated for the production of high value-added chemicals while cellulose can be used to produce biofuels. In this work, we focused on fractionating lignin from steam-exploded bamboo (*Phyllostachys pubescens*) by alkali and alkaline ethanol treatments.

Lignin is a heterogeneous polymer synthesized mainly from three *p*-hydroxycinnamyl alcohols differing in their degree of methoxylation: *p*-coumaryl, coniferyl, and sinapyl alcohols, each of which leads to a corresponding type of lignin unit named *p*-hydroxyphenyl (H), guaiacyl (G), and syringyl (S), respectively. The knowledge of lignin structure can not only provide valuable information to understand pretreatment mechanisms, and thus improve current approaches or develop new pretreatment methods, but also help to evaluate the potential utilization of lignin.[9] The present study focused on the application of steam explosion combined with alkali and

alkaline ethanol delignification in fractionating lignin from *Phyllostachys pubescens*, with the objective of determining the structure of the obtained lignin by sugar analysis, molecular weights, Fourier transform infrared (FT-IR), two-dimensional heteronuclear single-quantum coherence (2D HSQC), and ^{31}P NMR spectroscopies. Additionally, antioxidant activity of the lignins, which is closely related to lignin structure, was evaluated by 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2,2′-azobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), and ferric reducing activity power (FRAP) methods.

MATERIALS AND METHODS

Materials. *Phyllostachys pubescens* was obtained from Jiangxi Province, China. The chemical composition (% w/w) was determined to be 39.8% glucan, 22.8% xylan, 25.1% acid-insoluble lignin, 1.4% arabinan, 0.3% galactan, 2.1% acid-soluble lignin, and 2.3% ash, according to National Renewable Energy Laboratory (NREL) standard analytical procedure.[10] The bamboo material was air-dried and cut into an average size of 100 mm × 15 mm × 15 mm. 2,2-Diphenyl-1-picrylhydrazyl (DPPH), deuterated chloroform, cyclohexanol, chromium(III) acetylacetonate, and 2-chloro-1,3,2-dioxaphospholane were purchased from Sigma−Aldrich (Shanghai, China). 2,4,6-Tripyridyl-*s*-triazine (TPTZ) was purchased from Xiya Reagents (Chengdu, Sichuan, China). 2,2′-Azobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) was obtained from Lanyi (Beijing, China), and Trolox was obtained from Aladdin (Shanghai, China). Methanol, potassium persulfate ($K_2S_2O_8$), and $FeCl_3{\cdot}6H_2O$ were purchased from Xilong Chemical Co., Ltd. (Shantou, Guangdong, China). Sodium hydroxide (NaOH), dimethyl sulfoxide (DMSO), anhydrous pyridine, hydrochloric acid, acetic acid, and sodium acetate were purchased from Beijing Chemical Works (Beijing, China), in which acetic acid and sodium acetate were used to make acetate buffer. Sodium hydrogen phosphate heptahydrate ($Na_2HPO_4{\cdot}7H_2O$) and $NaH_2PO_4{\cdot}H_2O$ were obtained from Guangdong Guanghua Chemical Factory Co., Ltd. (Guangzhou, Guangdong, China) and were used to make phosphate buffer.

Steam Explosion Pretreatment and Fractionation Process. Before steam explosion pretreatment, bamboo chips were separated into three batches (300 g for each batch). To evaluate the effect of water impregnation on subsequent steam explosion pretreatment, two batches were immersed in distilled water at 25 °C for 24 h and another batch was kept dry at room temperature (without water impregnation). The steam explosion pretreatment was carried out in a 7.5 L stainless steel vessel designed especially for the processing of biomass. The reactor was heated with saturated steam to reach the required pressure. At the end of the steaming, the pressure was instantaneously released to stop the reaction, and the exploded feedstock was collected. Specifically, the sample without water impregnation (sample 1) was treated at 2.0 MPa for 5 min, while the two water-immersed samples were treated at 1.8 MPa (sample 2) or 2.0 MPa (sample 3) for 5 min. Then the three steam-exploded samples were treated with 0.5% NaOH with a solid-to-liquor ratio of 1:20 (w/v) at 80 °C for 3 h to obtain lignin fractions L_{A1}, L_{A2}, and L_{A3}, respectively. Next the corresponding residuals were further treated with 60% ethanol containing 1.5% NaOH with a solid-to-liquor ratio of 1:20 (w/v) at 80 °C for 3 h to obtain other three lignin fractions, L_{AE1}, L_{AE2}, and L_{AE3}, respectively. The lignin fractions obtained with alkali and alkaline ethanol were categorized as lignin-A (L_{A1}, L_{A2}, and L_{A3}) and lignin-AE (L_{AE1}, L_{AE2}, and L_{AE3}), respectively. The purification procedure of all lignin fractions was performed according to a previous literature procedure.[11]

Characterization of Isolated Lignins. The associated carbohydrate composition of all lignin fractions was determined by high-performance anion-exchange chromatography (HPAEC). Lignin fractions (5 mg) were hydrolyzed with 1.475 mL of 6% sulfuric acid at 105 °C for 2.5 h. After hydrolysis, these fractions were diluted 50-fold and analyzed by HPAEC system (ISC 3000, Dionex, Beijing, China) with an amperometric detector and AS50 autosampler. The column used was a 250 mm × 4 mm, CarbopacTM PA-20, with a 30 mm × 3 mm i.d. guard column of the same material (Dionex, Beijing, China). The sugars were separated in 18 mmol/L of NaOH (carbonate-free and purged with nitrogen) with postcolumn addition of 0.3 M NaOH at a rate of 0.5 mL/min. Run time was 45 min, followed by 10 min elution with 0.2 M NaOH to wash the column and then a 15 min elution with 18 mmol/L of NaOH to re-equilibrate the column.

The average molecular weights and molecular weight distribution of lignin fractions were examined by gel-permeation chromatography (GPC, Agilent 1200) on a PL-gel 10 μm Mixed-B 7.5 mm i.d. column. The detector was a differential refractive index detector. A 4 mg sample was dissolved in 2 mL of tetrahydrofuran, and 20 μL aliquots of lignin solution were injected. The column was operated at ambient temperature and eluted with tetrahydrofuran at a flow rate of 1.0 mL/min.

FT-IR spectra of all lignin fractions were recorded on a spectrophotometer (Bruker Tensor 27 FT-IR) in the range 4000−400 cm^{-1} with a resolution of 4 cm^{-1}. A KBr disc containing 1% finely ground sample was used for measurement.

HSQC spectra of the lignin fractions were acquired on a Bruker AVIII 400 MHz spectrometer at 25 °C. About 90 mg of lignin was dissolved in 0.5 mL of DMSO-d_6. The spectral widths were 5000 and 20 000 Hz for the ^{1}H and ^{13}C dimensions, respectively. The number of collected complex points was 1024 for the ^{1}H dimension with a recycle delay of 1.5 s. The number of transients was 64 and 256 time increments recorded in the ^{13}C dimension. $^1J_{CH}$ was set to 146 Hz. Before Fourier transformation, the data matrices were zero-filled to 1024 points in the ^{13}C dimension. The central solvent (DMSO) peak was used as an internal chemical shift reference point (δC/δH 39.5/2.49). ^{31}P NMR spectra were acquired according to a previous method[12] with minor modifications. Twenty milligrams of dry lignin was dissolved in 500 μL of anhydrous pyridine and deuterated chloroform (1.6:1.0 v/v) under stirring, followed by addition of 100 μL of cyclohexanol (10.85 mg/mL) as an internal standard (IS) and 100 μL of chromium(III) acetylacetonate solution (5 mg/mL in anhydrous pyridine and deuterated chloroform, 1.6:1.0 v/v) as relaxation reagent. Finally, the mixture was reacted with 100 μL of phosphitylating reagent (2-chloro-1,3,2-dioxaphospholane) for 15 min and then used for subsequent NMR analysis.

Antioxidant Activity Analysis. The antiradical activity of different lignin fractions was estimated according to the procedure reported by Delgado-Andrade et al.[13] with some modifications. DPPH solution was prepared by dissolving 7.4 mg of DPPH with 100 mL of methanol to obtain an absorbance of 1.8 at 520 nm. A 200 μL aliquot of lignin fraction was allowed to react with 1 mL of 74 mg/L DPPH in methanol. The mixture was shaken for 1 h, and then absorption was measured at 520 nm. The temperature in the measurement chamber was set at 30 °C. The standard curve was linear between 10 and 400 μmol of Trolox. Results are expressed as micromole equivalents of Trolox per gram of sample.

The ABTS assay was performed according to the procedure reported by Delgado-Andrade et al.[13] with some modifications. Briefly, $ABTS^{+\bullet}$ was produced by reacting 7 mmol of ABTS stock solution with 2.45 mmol of potassium persulfate and keeping the mixture in the dark at room temperature for 12 h before use. The $ABTS^{+\bullet}$ solution was diluted with 5 mmol of phosphate-buffered saline (pH 7.4) to an absorbance of 0.70 at 730 nm. After addition of 10 μL aliquots of lignin fractions and Trolox standard to 4 mL of diluted $ABTS^{+\bullet}$ solution, an absorbance reading was taken at 20 min on an ultraviolet/visible spectrophotometer (Tec comp, UV 2300). Calibration was performed, as described previously, with Trolox solution. Results were expressed as micromole equivalents of Trolox per gram of lignins.

The FRAP assay was performed according to a previous study[14] with some modifications. Fresh FRAP reagent was prepared before use, which contained 25 mL of acetate buffer (300 mmol/L, pH 3.6), 2.5 mL of TPTZ (2,4,6-tripyridyl-*s*-triazine) solution (10 mmol/L in 40 mmol/L HCl), and 2.5 mL of $FeCl_3{\cdot}6H_2O$ solution (20 mmol/L) and then warmed at 37 °C before use. Lignin fractions and Trolox (150 mL) were allowed to react with 2850 mL of FRAP solution at 37

°C for 30 min in the dark. Readings of the colored product were then taken at 593 nm. Trolox solution was used to perform the calibration curves. Results were also expressed as micromole equivalents of Trolox per gram of sample.

RESULTS AND DISCUSSION

Yields, Residual Carbohydrates, and Molecular Weight Distribution of Isolated Lignins. The yields of the lignin fractions (weight percent, oven-dried samples) and their residual carbohydrates are given in Table 1. In the present study, the yields of lignin fractions extracted with alkali and alkaline ethanol were 39.4−62.8% and 7.3−24.1% of the total acid-insoluble lignin, respectively. The total yields of lignins obtained from the two-step extraction procedure accounted for 70.1%, 63.5%, and 73.4% of total acid-insoluble lignin from steam-exploded samples 1, 2, and 3, respectively. Obviously, for water-immersed samples, the increase in steam pretreatment pressure from 1.8 MPa (sample 2) to 2.0 MPa (sample 3) resulted in a significant increment of total lignin yield in alkaline delignification. Besides, lignins extracted from sample 1 (without water impregnation) presented relatively lower yields as compared with those extracted from sample 3 (water impregnation), suggesting that water impregnation was an effective pretreatment method prior to steam explosion to increase the removal of lignin.

Obviously, the lignin fractions obtained by this process contained low levels of residual carbohydrates (0.55−1.76%), demonstrating that the two-stage process significantly cleaved ether bonds between lignin and carbohydrates in the plant cell walls of bamboo, in addition to partial saponification of hydroxycinnamic esters.[11] It is clear that xylose and glucose were the major sugars in the associated carbohydrates of lignins,

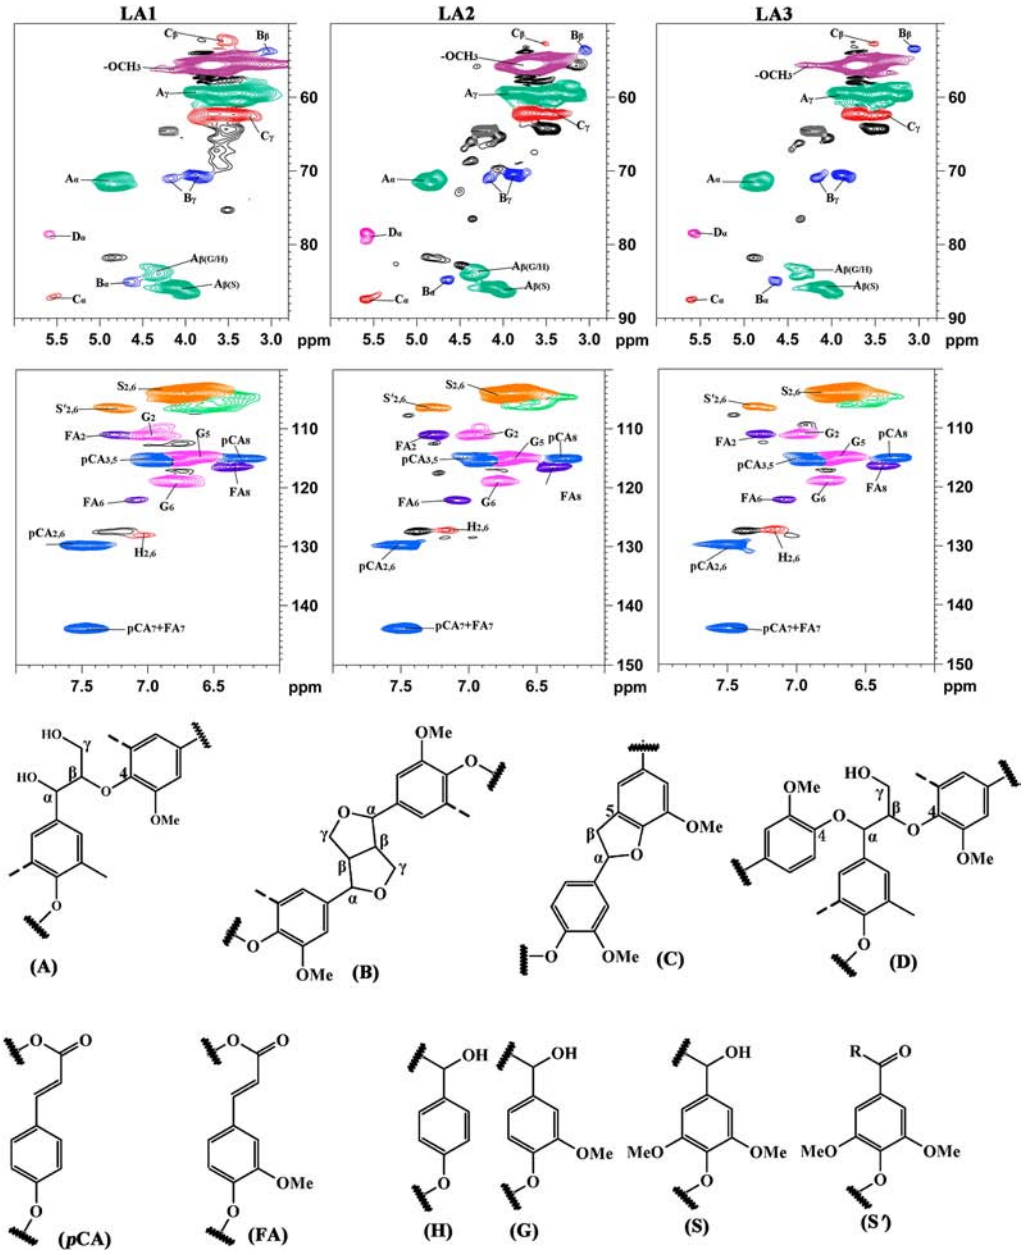

Figure 2. HSQC spectra of lignin-A fractions and their main substructures: **A**, β-aryl ether units (β−O−4′); **A′**, β−O−4′ alkyl aryl ethers with acylated γ-OH with *p*-coumaric acid; **B**, resinol substructures (β−β'); **C**, phenylcoumaran substructures (β−5′); and **D**, α,β-diaryl ethers (α−O−4/β−O−4). *p*CA, *p*-coumaric acid; FA, ferulic acid; H, *p*-hydroxyphenyl units; G, guaiacyl units; S, syringyl units; S′, oxidized syringyl units bearing a carbonyl at Cα.

whereas arabinose, galactose, and glucuronic acid were detected as minor quantities, as shown in Table 1. Therefore, low carbohydrate contents in the obtained lignins were beneficial for subsequent structure analysis of the lignins.

The weight-average (M_w) and number-average (M_n) molecular weights and the polydispersities (M_w/M_n) of all lignin fractions are also given in Table 1. The M_w and M_n values of the six lignin fractions were 780−1050 and 510−610 g/mol, which were lower than those of milled wood lignin (MWL, M_w = 6080 and M_n = 3230 g/mol), as reported by a previous study.[15] The results show that steam explosion, under the conditions given, significantly reduced M_w and M_n of the lignins, which were released during the steam explosion combined with alkali fractionation process. It should be noted that as the concentration of NaOH increased from 0.5% to 1.5%, M_w increased slightly from 780−1040 to 870−1050 g/mol. Apparently, in contrast to the M_w of L_{A1} and L_{AE1}, fractions L_{A3} and L_{AE3} present relatively higher M_w, implying that lignins obtained from dry sample had relatively lower M_w than those extracted from the water-immersed sample. This could be attributed to additional moisture adsorbing the heat applied during the steam explosion pretreatment, resulting in a decrease in the severity of treatment undergone by the chips at equivalent pretreatment condition,[16] thus presenting a low degradation degree of lignin in the water-immersed sample. Furthermore, for the water-immersed samples, an increase in steaming pressure from 1.8 to 2.0 MPa led to a slight increase in M_w from 780 to 870 g/mol for the alkali-extracted lignins and from 1040 to 1050 g/mol for the alkaline ethanol-extracted lignins. Additionally, all the lignin fractions showed narrow

molecular distributions (1.47−1.84), indicating homogeneous lignin fragment sizes.[17]

Fourier Transform Infrared Analysis. Figure 1 shows the FT-IR spectra of all lignin fractions; peaks were assigned according to the literature.[18,19] The band at 1691 cm^{-1} is related to carbonyl stretching in conjugated ketone and carboxylic acid groups, as indicated by the presence of *p*-coumaric acid (*p*CA). It can be observed that the weak intensity band at 1665 cm^{-1}, relating to carbonyl stretching of conjugated *p*-substituted aryl ketones, was present in lignin-A but almost disappeared in lignin-AE. This result implies that lignin-A had a relatively higher content of conjugated *p*-substituted aryl ketones as compared with lignin-AE. The bands at 1599, 1508, and 1423 cm^{-1} are assigned to aromatic skeletal vibrations and the band at 1462 cm^{-1} represents C−H deformation combined with aromatic ring vibration, indicating the primary structure of the obtained lignins. The bands at 1160 cm^{-1} (antisymmetric C−O stretching of ester groups) and 1125 cm^{-1} (aromatic C−H in-plane deformation) are typical for HGS lignin. It is worth mentioning that the band at 1160 cm^{-1} is less pronounced in lignin-A and almost disappeared in lignin-AE, suggesting that tiny ester bands in the initial fractionating lignins (lignin-A) were retained. However, this band disappeared in the subsequently isolated lignin-AE, indicating that the ester bonds of lignins were fundamentally cleaved during the alkaline ethanol extraction.

Two-Dimensional Heteronuclear Single-Quantum Correlation NMR. To further investigate the structural changes of lignins, 2D HSQC NMR was used. The HSQC spectra of lignin-A and lignin-AE are shown in Figures 2 and 3, respectively, and the main substructures are also depicted in Figure 2. The main assignments of lignin cross-signals in the HSQC spectra are listed in Table 2. From these well-resolved NMR spectra, $^{13}C-^{1}H$ correlations from all major units, representing the various linkages presenting in lignin units, were assigned according to previous literature.[20,21] In the side-

Table 2. Assignments of $^{13}C-^{1}H$ Cross-Signals in HSQC Spectra of Degraded Acid-Insoluble Lignin Fractions from Steam-Exploded Bamboo

label	$\delta C/\delta H$ (ppm)	assignment
C_β	52.4/3.51	$C_\beta-H_\beta$ in **C**[a]

FA_6	122.1/7.10	C_6-H_6 in FA
FA_7	143.9/7.48	C_7-H_7 in FA
FA_8	116.4/6.37	C_8-H_8 in FA

[a]Substructures are as follows: **A**, *β*-aryl ether units (*β*−O−4′); **B**, resinol substructures (*β*−*β*′); **C**, phenylcoumaran substructures (*β*−5′); **D**, *α*,*β*-diaryl ethers (*α*−O−4/*β*−O−4). *p*CA, *p*-coumaric acid; FA, ferulic acid; H, *p*-hydroxyphenyl unit; G, guaiacyl unit; S, syringyl unit; S′, oxidized syringyl unit bearing a carbonyl at C*α*.

dx.doi.org/10.1021/jf5023093 | J. Agric. Food Chem. 2014, 62, 5939−5947

chain region of the spectra, cross-signals from methoxyl groups (δC/δH 55.7/3.70) and side chains in β−O−4′ substructures **A** were most prominent. A signal located at δC/δH 71.8/4.85 is attributed to C_α−H_α in β−O−4′ substructure. Likewise, C_β−H_β correlations were identified at δC/δH 84.1/4.33 for β−O−4′ structure linked to G/H lignin units and at δC/δH 85.9/4.11 for β−O−4′ structure linked to S lignin units. The C_γ−H_γ correlations in β−O−4′ substructure were observed at δC/δH 59.6/3.66. Strong signals for resinol (β−β', **B**) substructures were observed, with the signals for their C_α−H_α and C_β−H_β correlations being observed at δC/δH 85.0/4.64 and 53.6/3.04, respectively, and those of C_γ−H_γ correlations showing the double signals at δC/δH 71.0/3.88 and 4.17. Interestingly, the signal for tetrahydrofuran (**B**′, formed by β−β' coupling of monolignols acylated at the γ-carbon)[22] substructures was observed in the spectra of MWL,[15] with characteristic C_α−H_α correlations at δC/δH 83.2/4.94, and the presence of substructures **B**′ is related to the high extent of γ-carbon acylation of S lignins.[23] However, this substructure was not detected in the lignins obtained, suggesting no or low extent of γ-carbon acylation of S lignins in the alkali and alkaline ethanol-extracted lignins obtained from steam-exploded bamboo. Signals for phenylcoumaran (β−5′, **C**) substructures were also observed in the spectra in noticeable amounts, with their C_α−H_α, C_β−H_β, and C_γ−H_γ correlations at δC/δH 87.2/5.57, 52.4/3.51, and 62.4/3.71, respectively. Finally, small signals corresponding to α,β-diaryl ethers (α−O−4/β−O−4, **D**) substructures could also be observed, with their C_α−H_α correlations being at δC/δH 78.4/4.58. Interestingly, although the substructures of spirodienones and γ-acylated cinnamyl alcohol end groups were found in MWL of *Phyllostachys pubescens*,[15] the two substructures were not observed in the alkali and alkaline ethanol-extracted lignins obtained from steam-exploded bamboo in this study. This difference was probably due to the different pretreatment and extraction methods. The lack of spirodienone units was potentially attributable to the steam explosion pretreatment because spirodienones are not stable under acidic conditions.[23] In addition, the γ-acylated cinnamyl alcohol end groups were cleaved as a result of subsequent alkaline treatment.

The main cross-signals in the aromatic regions of the HSQC spectra corresponded to different lignins and *p*-hydroxycinnamate units. Signals from H, G, and S units were observed. The S units show a prominent signal for $C_{2,6}$−$H_{2,6}$ correlations at δC/δH 104.0/6.70, whereas the signal for C_α-oxidized S units (S′) was observed at δC/δH 106.3/7.30. The G units show different correlations for C_2−H_2, C_5−H_5, and C_6−H_6 at δC/δH 111.1/6.98, 114.7/6.71, and 118.9/6.80, respectively. $C_{2,6}$−$H_{2,6}$ aromatic correlation signal from H units was observed at δC/δH 127.4/7.21. In addition, some condensed lignin structures likely occurred at $S_{2,6}$, but the detailed structures of the condensed lignin formed in S units remain unknown. One possible reason is that the condensed position in S units is located at C_α of the side chain and then can react with another lignin unit. In addition, signals corresponding to *p*CA were also observed in the HSQC spectra: $C_{2,6}$−$H_{2,6}$, $C_{3,5}$−$H_{3,5}$, C_7−H_7, and C_8−H_8 correlations at δC/δH 129.8/7.50, 115.4/6.84, 143.9/7.48, and 115.1/6.29, respectively. The correlations of ferulic acid (FA) were found at δC/δH 111.0/7.27 (C_2−H_2), 122.1/7.10 (C_6−H_6), 143.9/7.48 (C_7−H_7), and 116.4/6.37 (C_8−H_8).

According to semiquantitative methods, the relative amounts of interunit linkages present in lignins as well as *p*CA/FA and S/G molar ratios were calculated, and the results are shown in Table 3. These data indicate a similar composition in both alkali- and alkaline ethanol-extracted lignins. As seen in Table 3, the main lignin substructure was β−O−4′ aryl ether, which accounted for up to 73.9−79.0% of all interunit linkages, while low amounts of β−β', β−5′, and α−O−4/β−O−4 were also present. Furthermore, it was observed that alkali-extracted lignins had higher *p*CA/FA ratios than alkaline ethanol-extracted lignins. The ratios of S/G were estimated to be 5.0−8.5 for lignin-A and 3.5−4.8 for lignin-AE. This observation indicated that S-rich lignin was more easily released than G-rich lignin in the initial alkali process. Furthermore, the low S/G ratios of the alkaline ethanol-extracted lignins were probably due to the high content of condensed structure in these lignins because guaiacyl units were found to be reactive toward condensation.[24] All lignin fractions in this work had higher S/G ratios (3.5−8.5) than MWL (2.2). It has been reported that MWL mainly originates from middle lamella,[25] in which the lignin had fewer methoxyl groups per C9 than that in the secondary wall.[26] In other words, MWL with low yield (10%, acid insoluble lignin) had a low S/G ratio, while in this study the lignins with high yields (63.45−73.35% acid-insoluble lignin) had high S/G ratios, implying that the lignins from steam-exploded samples probably originated from whole plant cell walls.

Table 3. Characteristics of Degraded Acid-Insoluble Lignin Fractions from Quantitative 2D HSQC Spectroscopy

	lignin fraction

[a]Relative quantitative method based on 2D HSQC spectra (without IS). Substructures are as follows: **A**, β-aryl ether units (β−O−4′); **B**, resinol substructures (β−β'); **C**, phenylcoumaran substructures (β−5′); **D**, α,β-diaryl ethers (α−O−4/β−O−4). [b]*p*CA, *p*-coumaric acid; FA, ferulic acid. *p*CA/FA ratio was obtained as $0.5I(pCA_{2,6})/I(FA_2)$. [c]G, guaiacyl unit; S, syringyl unit. S/G ratio was obtained as $0.5I(S_{2,6})/I(G_2)$.

^{31}P NMR and Antioxidant Activity Analyses. ^{31}P NMR spectroscopy is a facile and direct analytical tool for quantitating the major hydroxyl groups in lignin, and the concentrations of different hydroxyl groups were calculated on the basis of the internal standard (cyclohexanol) and the integrated peak areas. The results from ^{31}P NMR can particularly provide an insight into the absolute amounts of aliphatic OH (α-OH and primary OH), phenolic OH (S-OH, $G_{5,5}$-OH, G-OH, and *p*-coumarate OH), and carboxylic OH (COOH) in the six lignin fractions. Figure 4 provides typical ^{31}P NMR spectra of bamboo lignin, and Table 4 provides the contents of different hydroxyl groups. The data show that the hydroxyl content of lignin isolated from *Phyllostachys pubescens* decreased following the order aliphatic OH (1.93−2.88 mmol/g) > phenolic OH (0.85−1.82 mmol/g) > COOH (0.08−0.32 mmol/g). In the present work, for L_{A1} and L_{AE1}, no significant variations in the contents of aliphatic OH, phenolic OH, and COOH were observed. In comparison, L_{A2} and L_{A3} contained

COOH	0.32	0.22	0.42	0.32	0.08	0.15

relatively higher amounts of aliphatic OH, phenolic OH, and COOH than their corresponding samples L_{AE2} and L_{AE3}, respectively. The higher amounts of phenolic OH in the alkali-extracted lignins indicated the occurrence of cleavage of β−O−4′ linkages (HSQC NMR results). The decrease in β−O−4′ linkage further provided evidence for the cleavage of β-aryl ether structure in lignins. Moxley et al.[27] also revealed that cleavage of aryl ether lignin bonds resulted in lignin fragments with low M_w. From the above results, higher pressure in steam explosion pretreatment resulted in a higher content of phenolic OH, which also corresponded to the lower β−O−4′ content and M_w. As seen in Table 4, the increase in pressure (from 1.8 to 2.0 MPa) was accompanied by an increase of aliphatic OH and a decrease of phenolic OH. As compared with L_{A2}, the content of COOH in L_{A3} increased from 0.22 to 0.42 mmol/g, and the same correlation was also observed for L_{AE2} (0.08 mmol/g) and L_{AE3} (0.15 mmol/g). The increased COOH content suggested that the oxidation of aliphatic OH occurred during the high-pressure steam explosion pretreatment.

The antioxidant activities of the lignin fractions by the three selected methodologies are summarized in Table 5. Data are expressed as micromole equivalents of Trolox per gram of

dx.doi.org/10.1021/jf5023093 | J. Agric. Food Chem. 2014, 62, 5939−5947

Table 5. Antioxidant Activities of Lignin Fractions As Determined by DPPH, ABTS, and FRAP Assays[a]

lignins, a commonly used unit for antioxidant assays. It must be pointed out that DPPH and ABTS assays estimated the antiradical activity, developed in methanolic and aqueous media, respectively, whereas FRAP analyzed the ferric reducing ability of lignins. DPPH and ABTS assays presented a very different quantitative response for all the lignin fractions, although with the same trend in both. The low response by the DPPH method in methanolic medium was probably due to the fact that some components making an important contribution to the antioxidant activity of the aqueous dilutions were not soluble in methanol.[13] As seen from Table 5, the alkali-soluble lignins obtained during the initial extraction process had higher antioxidant activities than those of the alkaline ethanol-soluble lignins obtained during the second alkaline extraction process. The stronger antioxidant capacity of alkali-extracted lignin was probably due to the higher content of phenolic OH, which could act as a hydrogen donor antioxidant,[28,29] as revealed by ^{31}P NMR spectra. However, the effect of aliphatic OH on the radical scavenging activity of lignin is not very clear. Pan et al.[28] reported that aliphatic OH content had a negative effect on antioxidant activity of organosolv ethanol lignin, while Dizhbite et al.[30] reported that the aliphatic OH had a positive influence on the radical scavenging activity of lignin model compounds, which needs further investigation.

In summary, bamboo chips with or without water impregnation were pretreated by steam explosion, followed with alkali and alkaline ethanol delignification to fractionate lignins. The lignins obtained showed low levels of associated hemicelluloses (0.55−1.76%) and low molecular weights (780−1050 g/mol). However, the alkali-soluble lignins had higher *p*CA/FA and S/G ratios than the alkaline ethanol-soluble lignins. HSQC spectral analysis revealed that the main lignin substructure was β−O−4′ aryl ether (73.9−79.0%), while low amounts of β−β′, β−5′, and α−O−4/β−O−4 were also present. Additionally, the alkali-soluble lignins obtained during the initial extraction process had higher antioxidant activities than those of the alkaline ethanol-soluble lignins obtained during the second extraction process by alkaline ethanol. The results suggest that the combination of steam explosion and alkaline treatments is an effective method to separate lignin from bamboo. Comprehensive structure elucidation and its antioxidant activity will provide useful information for the application of lignins in industry. More importantly, the delignified bamboo will be more easily hydrolyzed and then fermented into bioethanol, and this biorefinery process allows all major components of biomass to be converted into high value-added products.
