Do Sun- versus Shade-Grown Kiwifruits Perform Differently upon Storage? An Overview of Fruit Maturity and Nutraceutical Properties of Whole and Fresh-Cut Produce

Marco Landi, Francesca Tardelli, Damiano Remorini, Rossano Massai, and Lucia Guidi*

Department of Agriculture, Food and Environment, University of Pisa, 56124 Pisa, Italy

ABSTRACT: Fresh-cut produce represents a good method to save about 25% of the kiwifruit not useful to meet the fresh fruit-marketing standard due to improper size and shape. For that reason, fresh-cut kiwifruit has been extensively studied. However, the comprehension of the influence of some aspects of cultivation might further increase the shelf life as well as the nutritional values of that fruit. This study explored the hypothesis that kiwifruits grown fully exposed to sunlight or partially shaded differently perform upon storage as whole fruit and as minimally processed produce. Flesh firmness (FF), total solids soluble (SSC), ascorbate (AA_T), flavonoids (TFO), and phenols (TF) contents were evaluated in sliced and whole fruit upon 3 days of storage at 4 °C after 75 days of cold chamber storage at 0 °C. The activities of two enzymes related to the softening process, polygalacturonase (PG) and pectinmethylesterase (PME), were evaluated as well. FF and SSC were constitutively higher in sun-exposed fruit, and those characteristics remained higher during the storage as whole fruit. Greater constitutive content of AA_T, TFO, and TP was found in sun-exposed whole fruit, although after cutting the reduction in their content was significantly lower in shaded fruits. PME and PG activities were higher only in whole shaded fruits, whereas no relevant differences occurred after cutting. In summary, sun-exposed fruits were more suitable for the fresh-fruit market, whereas the shaded counterpart displayed a good predisposition for use as fresh-cut produce, maintaining similar fruit maturity properties but higher nutraceutical values when sliced than fruit grown under full sun.

KEYWORDS: *Actinidia deliciosa 'Hayward', antioxidant, ascorbic acid, flavonoids, phenols, shelf life*

INTRODUCTION

Kiwifruit [*Actinidia deliciosa* (A. Chev.) C.F. Liang and A.R. Ferguson cv. 'Hayward'] is a highly nutritious fruit rich in bioactive compounds and particularly in vitamin C.[1] In fact, ascorbic acid content in kiwifruit ranges between 25 and 155 mg 100 g^{-1} of fruit fresh weight (fw).[2] Additionally, kiwifruit is a good source of a wide variety of other phytochemicals, such as polyphenols and natural antioxidant substances,[3] including β-carotene, lutein, anthocyanins, and ellagic acid.[4]

A relevant problem for the kiwifruit market is that approximately 25% of kiwifruits may not meet the fresh fruit-marketing standard due to improper size and shape. Nevertheless, these kiwifruits could be saved through processing. This is why kiwifruit importance as fresh-cut products has been targeted by several studies regarding its preservation as sliced fruit.[5,6] However, little has been reported about the physiological, microbiological, and nutritional changes that may occur in fresh-cut kiwifruit slices.[7−9] It is well-known that physical damages and wounding cause several biochemical defensive reactions where cellular decompartmentation leads to intermixing of enzymes and substrates, as well as release of acids and hydrolyzing enzymes. All of these actions limited strongly the shelf life of this kind of produce during storage,[10] kiwifruits being particularly sensitive to softening phenomena.

The amount of the bioactive compounds, as well as the maturity, is strongly influenced by different factors[11] and, among those, storage conditions have surely a great impact.[7,12] Certainly, long-term cold storage is the best method to maintain kiwifruit quality[13] considering that kiwifruit has a relatively long storage life (4−6 months at 0−4 °C). Flesh firmness (FF) is the most important parameter and the best predictor of kiwifruit ripening progress. It defines postharvest quality, considering that a 2 kg threshold is the minimum kiwifruit FF to avoid physical damage during standard postharvest handling.[14] FF is very high at harvest time (6 kg) but rapidly declines when fruit is ready to eat, between 1.3 and 1.8 kg, according to established firmness criteria.[15]

During the storage period, changes in quality characteristics are accompanied by fruit softening, a process attributable to structural changes in the cell wall. For kiwifruit, softening largely occurs as a result of the enzyme-mediated hydrolysis of cell wall, due to ethylene production.[16,17] Several enzymes are involved in this complex process, including polygalacturonase (PG; EC 3.2.1.15) and pectinmethylesterase (PME; EC 3.1.1.11). The involvement of the enzyme PG in kiwifruit softening was already confirmed;[18] PG is, indeed, the main enzyme promoting pectin solubilization as it hydrolyzes α-1,4-glycosidic bonds that hold galacturonic acid residues in de-esterified galacturonan chains produced by PME. In fact, although there is not so much clarity about that, PME activity seems to be the first involved in the softening process[19] because it is responsible for the removal of methyl groups of galacturonic acid residues from pectin,[20] leading to depolymerization.[21] After that, the rapid increase in PG activity is related to progressive increase of fruit softening.[19] PG can be classified

into endo-PG and exo-PG, albeit in general endo-PG is the major PG involved in kiwifruit softening.[17]

In addition to storage, canopy position, and consequently the degree of sunlight exposure of kiwifruit, represents another determinant factor to be taken into account for its influence in determining the quantity of bioactive compounds and fruit maturity characteristics. Indeed, it has been reported that fruits exposed to direct sunlight have greater sugar content when compared to fruits grown partially shaded.[22] Higher contents of AA_T, TP, and TFO were also found in full-sun-grown kiwifruits as compared to fruits collected from shade.[23] Moreover, for other fruits, a direct exposure to sunlight is responsible for making them firmer than those grown in the shade.[24]

The aim of this work was the evaluation of fruit maturity and nutritional characteristics of 75 day cold-stored kiwifruit grown under full sun or partially shaded, either as whole fruit or as minimally processed produce upon storage, to establish which was more suitable or, in other terms, less depreciable and with a reduced loss of quality for each type of market segment (as whole fruit or minimally processed produce).

■ MATERIALS AND METHODS

Fruit Material. Trials were carried out in 2009 and 2010 seasons on fruits from a commercial kiwifruit orchard located in Rigoli, Pisa, Italy (43°78′71″ N, 10°24′52″ E), where vines were treated as a free palmette. *A. deliciosa* (cultivar 'Hayward') fruits were harvested in November 2009 and 2010. Climatic parameters were continuously monitored by means of a stationary weather station from fruit set to fruit harvest; minimum and maximal temperatures averaged 20 and 28 °C, respectively, and maximum temperature reached 31−34 °C during sunny hours. Daily global radiation and mean air temperature averaged, respectively, 12.3 MJ m^{-2} and 25.7 °C. Detailed information about precipitation distribution within the growing period and relative humidity conditions are available at http://www.meteopisa.net/archivio_storico/.

To evaluate the effect of solar irradiation, fruits were harvested both from external portions of the canopy, characterized by 100% of daily intercepted solar radiation, and from partially shaded portions (−80 to −90% of incident sunlight). Immature fruits were immediately stored at 0 °C in a cold chamber, and the evaluation of quality, fruit maturity, and physiological indices was performed after 75 days of cold storage.

Slice Preparation. Forty kiwifruits, randomly chosen among 180 harvested, were removed from cold storage and kept at 25 °C for 48 h before being washed in tap water and distilled water and then dried with sterile paper. After the removal of tops and peels, each whole fruit was sliced into seven segments (~30−35 mm diameter) with a sharp knife. Slices were first held in ice-cold (4 °C) chlorine dioxide sanitizer (for 2 min), dipped in ice-cold Milli-Q water with 0.5% citric acid preservative solution (for 2 min), washed in ice-cold Milli-Q water (for 2 min), dried with paper, and randomized into clear rectangular polyethylene tetraphthalate (PET) hinged containers (750 cc, Commital Cofresco, Italy). Sliced samples[7] were put into each box. All boxes were kept at 4 °C under light, simulating the commercial conditions of sale. Whole unpeeled fruits were put in the same type of box (one fruit for each box to equalize the sample material present in fresh-cut boxes). Samples were collected from both fresh-cut and whole fruits during the storage period immediately after cutting (0 h) and at 24, 48, and 72 h. The samples were immediately frozen in liquid nitrogen and kept stored at −80 °C before the analysis.

Flesh Firmness. Measurements were carried out on a flat surface by a stand drill mounted penetrometer (8 mm probe; model 53205, TR, Forlì, Italy). FF was estimated among the mean of six readings and expressed as kilograms.

Soluble Solids Concentration. Soluble solids content (SSC) was estimated among the mean of six replicates taken from kiwi juice. A digital refractometer (model 53011, TR, Forlì, Italy) was used. Measurements were carried out at the same sites as FF and were expressed as degrees Brix.

Ascorbic Acid Content. Total ascorbic acid content (AA_T) was determined spectrophotometrically following the method described by Kampfenkel et al.[25] slightly modified by Degl'Innocenti et al.[26] Total

dx.doi.org/10.1021/jf405008c | J. Agric. Food Chem. 2014, 62, 4377−4383

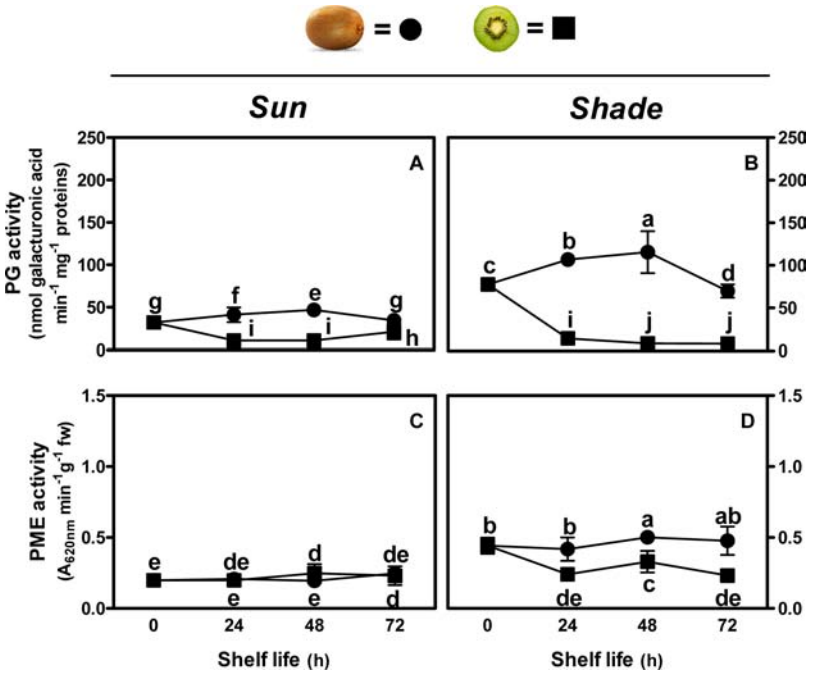

Figure 2. Polygalacturonase (PG; A, B) and pectinmethylesterase activities (PME; C, D) of full sunlight- and shade-grown Hayward kiwifruit stored for 0, 24, 48, and 72 h as fresh-cut and whole produce. Each value represents the mean of six replicates ± SD. Means were compared following two-way ANOVA test with treatment light exposure during growth and storage period as variability factors. Means flanked by the same letters are not significantly different after Fisher's least-significant difference test (LSD).

ascorbic acid was reported as milligrams of ascorbic acid per 100 g of fresh weight.

Total Polyphenols and Total Flavonoids. The extraction of TP and TFO was based on the method reported by Du et al.[27] slightly modified. Fruit tissue (ca. 3 g) was at first homogenized in 12 mL of ethanol/acetone (7:3; v/v) at 37 °C for 1 h. The extract was filtered using Whatman no. 41 paper and subsequently rinsed in 3 mL of the same extraction solution. Filtrates were collected and recovered at −20 °C and until the analysis of TP and TFO.

TP content was determined using the Folin−Ciocalteu assay, according to the method of Dewanto et al.[28] TP concentration was expressed as gallic acid equivalents (μg GAE 100 g^{-1} fw) using a calibration curve (50−600 μg mL^{-1}).

TFO concentration was determined at 506 nm. TFO content was expressed using rutin (mg RE 100 g^{-1} fw) as standard (6.25−1000 μg mL^{-1}).

Polygalacturonase and Pectinmethylesterase Activity. PG activity determination was carried out as described by Lazan et al.[29] with slight modifications. An aliquot of the extracted mixture was desalted with a Sephadex G-25 (1 cm × 10 cm) column prior to assay for polygalacturonase activity. PG activity was determined according to the original method described by Gross.[30] The assay of PG activity was based on the hydrolytic release of reducing groups from polygalacturonic acid. The absorbance was determined at 276 nm. PG activity was expressed as mole-reducing groups release per minute per milligrams of protein (nmol galacturonic acid min^{-1} mg^{-1} protein). Protein determination was performed according to the method of Lowry et al.[31]

PME extraction was carried out as described by Sanchez and Morais.[32] Frozen kiwifruit samples were homogenized in a solution of 1.5 M NaCl in an external ice bath for 6 min. The kiwifruit/NaCl solution ratio was 1:4 (w:w). The homogenate was centrifuged at 20000*g* for 30 min at 4 °C, and then the supernatant was filtered with a 6-fold cheesecloth, collected, and adjusted to pH 7.5 with a solution of 0.1 M NaOH. PME activity was spectrophotometrically determined according to the method of Zocca et al.[33] PME activity was monitored immediately after the extract addition and read at 620 nm at room temperature for 40 min. One blank was made for each sample, without bromothymol blue. Specific PME activity was defined as a decrease of A_{620} per minute per gram of fw.

Statistical Analysis. About 60 plants with different geographical orientations within the orchard (N; S; W; E) were randomly selected to collect fruits. Experiments were carried out twice with similar results, and a representative data set is reported herein. For each sample, the result is the mean of six replicates (n = 6) ± SD. Means of data were compared by two-way ANOVA considering light exposure (fully or partially shaded) and storage period (0, 24, 48, and 72 h) as treatments. Differences among treatment means were evaluated by Fisher's least-significant difference test (LSD) for P = 0.05. All statistical analyses were performed using the CoStat software package (CoHort Software, 1994; Berkeley, CA, USA).

RESULTS AND DISCUSSION

Fruit Maturity Properties and Softening-Related Enzymes. FF was constitutively similar in both sunny and shade whole kiwifruits in agreement with previous findings[18,34] (Figure 1A,B). Conversely, Tombesi et al.[34] pointed out a reduction of FF only when kiwifruits were grown almost completely shaded (<50 μmol quanta m^{-2} s^{-1}). In addition, the similar decline of FF we found in whole fruit at the end of the storage period, independent of light exposure, confirms previous results.[3,18] The process is mainly dependent on the activity of softening-related enzymes, that is, PG and PME. In addition, FF decremented strongly after cutting, in a similar way in kiwifruit collected under full sun or in shade conditions (−85 and −79%, respectively, at 72 h after cutting) when compared to the fruit before cutting. Thus, the effect of canopy position, and consequently the amount of light intercepted by fruit, does not affect the FF upon storage period.

FF is one of the most relevant parameters for consumer acceptability as well as SSC. In our experiments, SSC was constitutively greater in full sun-exposed kiwifruits than in the shaded counterpart (15.5 ± 0.62 vs 13.43 ± 0.54 °Brix, respectively; Figure 1C,D), confirming results previously

dx.doi.org/10.1021/jf405008c | J. Agric. Food Chem. 2014, 62, 4377−4383

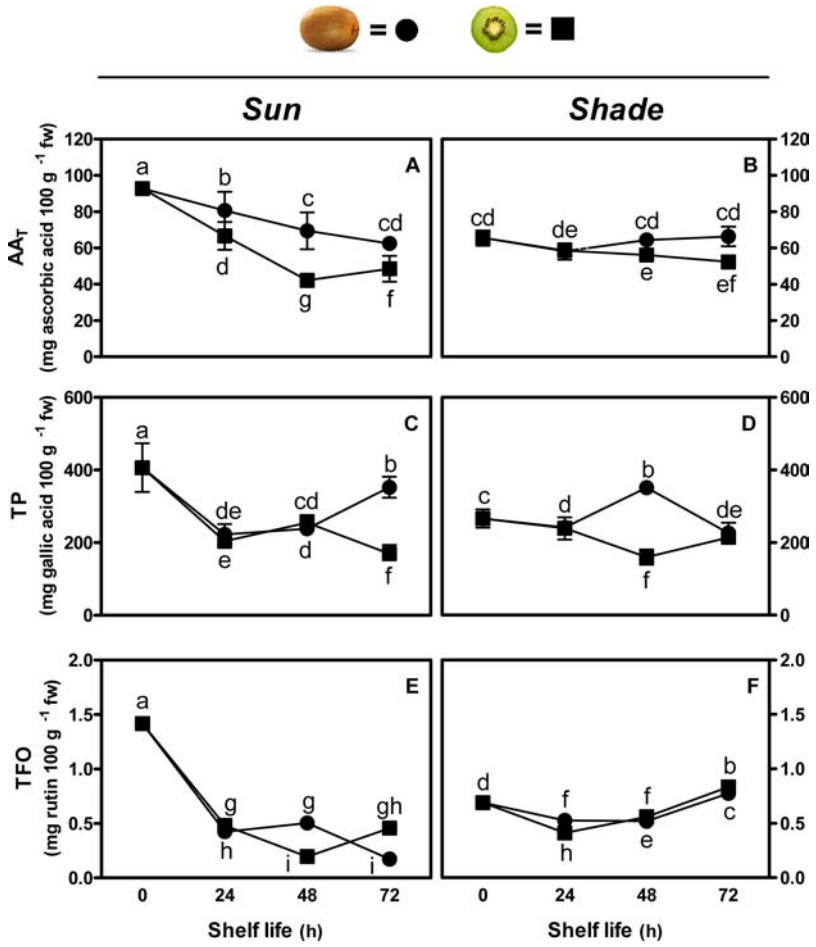

Figure 3. Total vitamin C content (AA_T; A, B), total phenols (TP; C, D), and total flavonoids (TFO; E, F) of full sunlight- and shade-grown Hayward kiwifruit stored for 0, 24, 48, and 72 h as fresh-cut and whole produce. Each value represents the mean of six replicates ± SD. Means were compared following two-way ANOVA test with treatment light exposure during growth and storage period as variability factors. Means flanked by the same letters are not significantly different after Fisher's least-significant difference test (LSD).

described.[34] In addition, SSC values were higher than 13 °Brix in both sun and shaded fruits, indicating a high acceptability level for consumers.[15] Thus, the hypothesis that the conversion of starch into soluble sugars typically characterizes ripening phenomena and leads to an increase in SSC[13,35] appeared realistic for these experiments, too. Indeed, light intensity has the potential to increase fruit photosynthesis, promoting indirectly starch synthesis and total carbohydrate content.[36] Whereas no relevant changes occurred in SSC upon storage period as whole fruit, when kiwifruits were minimally processed, the reduction in SSC values was reasonably comparable in fruit grown under full sunlight or in partially shaded condition, suggesting cutting exerts a similar effect independent of light received by fruit during the growing season (Figure 1).

Although softening is a visually evident effect, that process remained a partially unclear biochemical mechanism in which several enzyme-catalyzed mechanisms act together, inducing changes in cell wall.[37] Fruit softening is the result of a cumulative effect caused by different types of modifications that are responsible for texture changes and loss of firmness.[38] The activity of enzymes correlated with softening processes (PG and PME) was evaluated, and the results are reported in Figure 2. PG activity was statistically higher ($P < 0.05$) in fruit collected in shade canopy portions at the beginning of the experiments, and the enzymatic activity of PG upon storage time revealed a slight reduction in both types of sliced kiwifruit, independent of the degree of light exposure. On the other hand, the most remarkable result is the severe enhancement of PG activity in whole shaded fruits at 24 and 48 h, reaching at 72 h values similar to those found at the beginning of storage. The conservation as whole fruit, conversely, incremented only slightly PG activity in sun-exposed fruit (Figure 2A,B).

The PME pattern is reported in Figure 2C,D. The activity was higher in shade fruit (about +55%) before cutting. PME activity decreased upon storage period as fresh-cut produce, reaching values statistically similar to those of sun-exposed fruit stored in a similar way. Conversely, in shaded whole fruit values of PME activity remained high and even slightly increased compared with values found at time 0 upon all three storagec conditions.

Although little research has been focused on the effects of shade conditions on fruit physiology, it seems that shade determines a buildup of ethylene production, which is strictly linked to inner mesocarp firmness reduction.[38] Kiwifruit is, indeed, one of the climacteric fruits classified among the commodities with "high" ethylene production (10−100 μL C_2H_4 kg^{1-} h^{-1}) as reported by Kader.[39] In agreement with our findings, the latter author reported that processes during kiwifruit storage caused an acceleration of tissue softening when

dx.doi.org/10.1021/jf405008c | J. Agric. Food Chem. 2014, 62, 4377−4383

fruits were grown in shaded conditions. Conversely, high temperatures (i.e., during full sunlight exposure) are responsible for a general increment of heat shock protein transcription and translation,[24] metabolic processes that lead to a reduction in tissue respiration and to a decrease in ethylene production as well as in fruits' ability to respond to ethylene.[40] In accordance, we found fruit exposed to full sunlight appeared less sensitive to softening phenomena as compared to the counterpart grown under shade when stored as whole fruit. On the contrary, in fresh-cut produce no relevant differences were found in FF or in either PG or PME activity independent of the canopy position of fruit, suggesting that the activity of those enzymes is more relevant for whole fruit than for minimally processed produce.

Nutraceutical Compounds. On the one hand, the FF and the SSC, coupled with softening-related enzyme activities, draw a picture of fruit maturity of sun-exposed and shaded kiwifruits stored in different ways; on the other hand, investigation of ascorbate, phenols, and flavonoids sharpens the picture contributing to the understanding of the differences in terms of nutraceutical properties. The relevance of vitamin C content in kiwifruit is widely accepted, and it has been reported that the antioxidant capacity is mainly (but not only) attributable to that organic molecule.[18,23] In fruit grown in full sunlight we found the highest ascorbic acid content (Figure 3). Indeed, as well documented by previous studiets, fruits exposed to high light were commonly characterized by a higher vitamin C content,[7] ascorbate being directly synthesized from sugars produced at greater levels when photosynthesis highly performs.[41] However, in this work ascorbate is rapidly lost upon storage as whole fruit (−31% at 72 h) and also when fruit was stored as fresh-cut produce (−52% at 72 h). Conversely, the effect of storage was less severe in partially shaded fruit, where at the end of the storage as whole fruit AA_T was not significantly dissimilar to that found at time 0. A further confirmation of the less deleterious impact of storage period on AA_T in shaded fruit is that in minimally processed shaded kiwifruit at 72 h after cutting AA_T content (48.5 ± 7.1 mg 100 g^{-1} fw) was statistically not dissimilar from that found in full-sunlight sliced fruit (52.4 ± 2.3 mg 100 g^{-1} fw). The decrease of ascorbate is, however, commonly associated with fruit tissue degradation;[42] thus, if storage as whole fruit, and much more storage as fresh-cut produce,[43] enhances that metabolic process, the reduction of ascorbate is predictable. In addition, vitamin C content in fruit after cold storage is usually lower than the one recorded for fresh fruits,[7,13] although the degree of vitamin C degradation is strictly dependent on the length and temperature of storage.[44]

Ascorbate is usually recognized as one of the most powerful antioxidants, but the nutraceutical value of phenols and flavonoids is surely not negligible for their positive influence on human health.[45] Total phenols and flavonoids contents upon storage period are reported in Figure 3C−F. The constitutive content of those compounds (both TP and TFO) was remarkably higher in fruit grown in full sunlight when compared to the shaded counterpart (+31% for TO and +51% for TFO). These results represent clear evidence that the synthesis of phenols and flavonoids in kiwifruit is positively related to the extent of light intercepted on the canopy during the growth. However, both TP and TFO contents dramatically decreased in sun-grown fruit upon storage. Analyses of TP in shaded fruit revealed only a slight decline in the amount of those classes of metabolites in both whole and sliced fruit, whereas TFO was even increased at 72 h. In addition, despite a lower content of TP and TFO than found in shaded fruit at the beginning of storage, at 72 h inherent values of both TP and TFO were significantly greater than those found for sun fruit. A similar decline of TP was pointed out by Cocci et al.[46] after 2 days of shelf life. Other authors, conversely, found that whole and fresh-cut kiwifruits stored for 9 days had no statistically different values of phenols upon storage.[47] Thus, due to the high variability of kiwifruit material attributable to (I) orchard location, (II) agronomic practices applied in the orchard, (III) postharvest operations, and, obviously, (IV) genetic variability among plants, all of these factors might partially lead to different results.

After the necessary predication above, what we consider a useful result for scientific progress as well for direct industrial applications is the observation that shaded fruits, with an improper size and/or shape to be merchandized as whole fruit, are better suited for fresh-cut production than are fruits with similar defects grown in full sunlight. Conversely, full sun-exposed fruits, belonging to the same plants from which shaded fruits were collected, have greater amounts of ascorbate, phenols, and flavonoids, but unfortunately all of those nutraceutical compounds are rapidly lost upon storage. Thus, full sunlight grown fruits should be preferentially consumed as fresh produce to maximize their properties.

ABSTRACT: Spectrophotometry and fluorescence combined with docking and molecular dynamics simulations are used to study the effect of the carrier proteins β-lactoglobulin and human serum albumin on the degradative *trans*-to-*cis* conversion of resveratrol. The spectroscopic measurements quantify the concentration of resveratrol isoforms after 2 h of irradiation with light at 340 nm, showing that their ratio depends linearly on temperature between 20 and 50 °C and obeys an Arrhenius law with activation energies of photoisomerization of 7.8 and 11.2 kcal/mol for β-lactoglobulin and albumin, respectively, compared to 5.1 kcal/mol in solution. Thus, both proteins protect *trans*-resveratrol from degradation, with albumin being more effective than β-lactoglobulin. The computational techniques clarify details of the binding of *trans*-resveratrol to the proteins and show that the stabilizing effect correlates with an increase of the dihedral order parameter of the ligand. These findings suggest that transport proteins are viable carriers to stabilize and deliver resveratrol *in vivo* in the biologically effective *trans* form.

KEYWORDS: *resveratrol, β-lactoglobulin, human serum albumin, absorbance, fluorescence, docking, molecular dynamics*

INTRODUCTION

Resveratrol is a phenolic compound of the stilbene family that is naturally present in some plants, such as grapes, peanuts, and mulberries, to protect against fungal infections or environmental stresses.[1,2] Resveratrol is also found in food and beverages, particularly red wine.[3,4] From a structural point of view, resveratrol consists of two aromatic rings, one single- and another double-hydroxylated joined by a methylene bridge, and can occur in two isomers, *trans*- and *cis*-resveratrol (Figure 1).

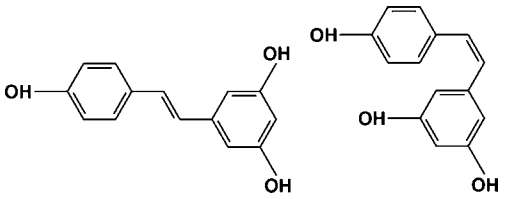

Figure 1. Chemical structures of (left) *trans*- and (right) *cis*-resveratrol.

The *trans* isomer is the natural form and converts to the *cis* isomer as a consequence of exposure to sunlight or UV radiation.[5] To the biologically active *trans* isomer are ascribed health benefits that make resveratrol particularly interesting for applications in the pharmaceutical and nutraceutical fields.[6] The beneficial health properties include antioxidant and antiatherosclerotic effects,[7] inhibition of blood platelet aggregation,[8] cardioprotective activity,[9] and chemopreventive action against cancer proliferation.[10,11]

In spite of its biological positive effects, resveratrol shows limitations such as low solubility in aqueous media, and consequently in biological fluids,[1,11] weak absorption after oral administration, and rapid metabolization *in vivo*, resulting in poor bioavailability. In addition, the conversion of the *trans* form into the less active *cis* isomer reduces resveratrol action. These limitations are overcome via loading the polyphenol into water-soluble carriers, which also offer protection from degradative processes. Among soluble carriers, proteins are optimal for the loading and cellular delivery of drugs. Resveratrol has been shown to have an affinity for various proteins, such as breast cancer resistance protein and human cyclin-dependent kinase,[12] insulin,[13] buttermilk proteins,[14,15] plasmatic lipoproteins,[16] and other transport proteins such as hemoglobin,[17] β-lactoglobulin,[18−20] and albumins.[17,21−26]

β-Lactoglobulin (βLG) and human serum albumin (HSA) are the most abundant proteins in bovine milk and in human blood plasma, respectively, and they are considered model carriers for a number of ligands. βLG (162 residues, 18.3 kDa) is a member of the lipocalin protein family, involved in the binding and transport of hydrophobic and amphiphilic molecules such as fatty acids and retinoids.[27] It is characterized by nine β-strands and a three-turn α-helix. Eight out of the nine β-strands are antiparallel and form a β-barrel sandwich with a central cavity, usually referred to as the protein calyx, which constitutes the main binding site.[28] Other external sites have been characterized or proposed for several ligands.[27] HSA (585 residues, 66 kDa) has an α-helical structure and can bind, store, and transport a wide variety of exogenous and endogenous molecules that include drugs, metals, and, with strong affinity, fatty acids.[29] Within the protein, two drug sites for binding aromatic and heterocyclic compounds[30] and 11 sites for medium- and long-chain fatty acids have been identified.[31]

In this paper we study the stability of *trans*-resveratrol bound to βLG and HSA as compared to when it is free in solution, either in aqueous buffer or in ethanol. UV light at 340 nm has

been used as the external perturbation to probe the photostability of *trans*-resveratrol. At this wavelength neither the two proteins nor *cis*-resveratrol absorb, and only *trans*-resveratrol is excited. Samples are investigated prior and after 2 h of continuous illumination at different temperatures, between 20 and 50 °C. The study is carried out experimentally by spectrophotometry and intrinsic resveratrol fluorescence, which allow quantifying the fraction of the two resveratrol isoforms present after irradiation and to assess the stabilizing effect of the proteins. Jointly, docking calculations and molecular dynamics (MD) simulations have been performed to gain insights into the binding modes and the dynamical behavior of resveratrol in interaction with both βLG and HSA, providing details on the mechanism of stabilization of the molecule.

MATERIALS AND METHODS

Materials and Sample Preparation. *trans*-Resveratrol (3,4′,5-trihydroxy-*trans*-stilbene), βLG (A and B variant, purity ≥90%), and HSA (fatty acid-free and globulin-free, purity approximately 99%) were from Sigma-Aldrich (St. Louis, MO, USA). The reagent-grade salts for the 10 mM phosphate buffer solution (PBS) at pH 7.4 were from Merck (Darmstadt, Germany), and ethanol was from Carlo Erba (Milan, Italy). All materials were used as purchased with no further purification. Bidistilled water was used throughout.

Solutions of *trans*-resveratrol either in PBS or in ethanol were prepared daily at a concentration of 5 μM, which is below the resveratrol solubility in water (0.023 mg/mL). A gentle stirring was used to dissolve it in PBS. Resveratrol concentration in both PBS and ethanol was determined by spectrophotometry, by using a molar extinction coefficient ε_{304} = 30 135 M^{-1} cm^{-1} and ε_{308} = 30 000 M^{-1} cm^{-1}, respectively.[5,32]

Protein−resveratrol complexes were prepared by mixing an amount of protein stock solution (at a concentration of 50 μM) and *trans*-resveratrol solution in PBS at the molar ratio of 10:1. HSA and βLG concentration were determined spectrophotometrically by using ε_{280} = 35 219 M^{-1} cm^{-1} and ε_{278} = 17 600 M^{-1} cm^{-1}, respectively.[33,34] To protect resveratrol from degradation due to radiation effects, sample handling and storage were carried out under light-protected conditions.

Absorbance and Fluorescence Measurements. Absorbance data were acquired with a JASCO 7850 spectrophotometer equipped with a TPU-436 Peltier thermostated cell holder (accuracy ±0.5 °C) and an EHC-441 temperature programmer, using 1 cm optical path quartz cuvettes. Temperature was measured directly by a YSI thermistor dipped into the cuvette.

Intrinsic *trans*-resveratrol fluorescence data were collected on an LS 50B spectrofluorometer (PerkinElmer, Beaconsfield, UK) equipped with a Peltier temperature programmer PTP-1 (accuracy ±0.5 °C) using 1 cm path length cuvettes. The excitation wavelength was 340 nm, whereas the slit widths of excitation and emission were 6 and 4 nm, respectively. Buffer background was subtracted from the raw emission spectra.

Absorbance and fluorescence measurements were carried out at temperatures of 20, 25, 37, 45, and 50 °C on either freshly prepared nonilluminated resveratrol-containing samples (t = 0 h) or samples illuminated for 2 h with light at 340 nm. Irradiation was performed within the spectrofluorometer after loading the sample into the cuvette. A 2 h time interval of irradiation was suitable for obtaining maximum conversion of the *trans*- to the *cis*-resveratrol isomer. The reproducibility of the results has been assessed by performing three independent experiments.

Docking Calculations. The binding of *trans*-resveratrol to both βLG and HSA was first predicted by molecular docking and subsequently simulated in the presence of explicit solvent. The structure of resveratrol was built by using the UCSF Chimera software.[35] The starting structures of the two proteins were modeled on the basis of their crystallographic configurations, as previously described.[36,37]

The apo form of βLG (3NPO entry[28] in the Protein Data Bank (PDB) repository) was used. Docking results were further tested with the βLG structure in complex with retinol and retinoic acid (1GX8 and 1GX9 entries,[27] respectively). For HSA, the crystallographic structures in association with palmitic acid (1E7H entry[31] of the PDB) and with both myristic acid and warfarin (1H9Z entry[38]) were considered. In particular, the latter was used to compare directly our docking results with those previously reported by Lu and co-workers.[17] Although extracted from complexes, only the coordinates of protein atoms were used in all cases.

Docking calculations to estimate the binding affinity of resveratrol and to obtain the starting structure for the protein−ligand complexes were performed by using AutoDock Vina,[39] allowing full flexibility for the ligand. Computations were repeated to ensure the reproducibility of the docking location, and the affinity energy values are calculated over multiple runs.

Molecular Dynamics Simulations. After docking, protein−resveratrol complexes were solvated in a rhombic dodecahedron with a minimum distance of 1 nm from any box edge, resulting in 6571 water molecules for βLG and 30415 for HSA. The systems were neutralized by adding 8 and 15 Na^+ counterions for βLG and HSA, respectively. Energy minimization was performed to relax the system and avoid bad atomic contacts.

Simulations were carried out by using the GROMACS 4.5 software package[40] with the AMBER ff99SB force field.[41] The GAFF force field[42] was used for resveratrol, and the TIP3P model[43] for water. Long-range electrostatic interactions were calculated through the particle-mesh Ewald (PME) method.[44]

Periodic boundary conditions were applied to avoid edge effects, and sampling was performed in the isothermal−isobaric ensemble. A Bussi−Donadio−Parrinello thermostat[45] and Berendsen barostat[46] were used, with reference values of 300 K and 10^5 Pa, respectively. Production runs were carried out for 50 ns, saving the simulation trajectories with a sampling time of 1 ps. The software package VMD[47] was used for trajectory visualization.

RESULTS AND DISCUSSION

Photostability of *trans*-Resveratrol in Solution and in the Carrier Proteins βLG and HSA. The absorbance and fluorescence spectra at 37 °C of resveratrol in PBS before illumination (black lines) and after 2 h of continuous irradiation at 340 nm (red lines) are reported in Figure 2A and B, respectively. The absorbance spectrum of nonirradiated resveratrol shows a broad maximum between 300 and 320 nm, as expected for *trans*-resveratrol in aqueous solution at

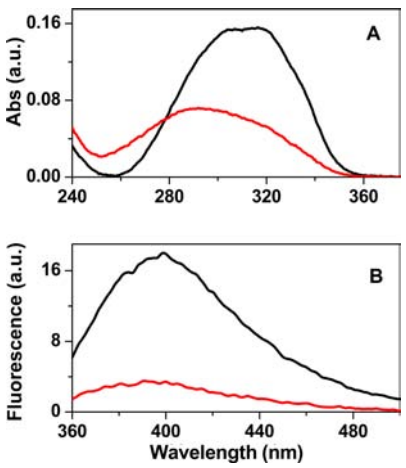

Figure 2. (A) Absorbance and (B) fluorescence spectra at 37 °C of *trans*-resveratrol in PBS before (black line) and after (red line) exposure for 2 h to radiation at 340 nm.

neutral pH.[5,32,48] By comparing the absorbance curves of the irradiated and nonirradiated sample in Figure 2A it is evident that UV light induces in the absorbance a marked attenuation of about 55%, a shift to lower wavelength of λ_{max}, and an enhancement at 260 nm. These spectral features are typical of *cis*-resveratrol.[32,48] They indicate that resveratrol is not stable and tends to isomerize from *trans* to *cis* form when perturbed with radiation at 340 nm. The emission spectrum of the illuminated sample in Figure 2B is characterized by a pronounced quenching of the fluorescence quantum yield compared to the nonilluminated one. Similarly, this is due to the formation of the *cis* isoform upon irradiation at 340 nm, at which only *trans*-resveratrol is excited. The attenuation of fluorescence intensity cannot be attributed to resveratrol aggregation, because of the low concentration used, 5 μM. In fact, aggregation is reported to occur for resveratrol concentrations higher than 12.5 μM at pH 5.5 and 37 μM at pH 10.5.[49] Thus, the results in Figure 2 clearly indicate that *trans*-resveratrol in PBS solution, exposed for 2 h to radiation at 340 nm, partially converts to *cis*-resveratrol, resulting in a coexistence of *trans*- and *cis*-resveratrol populations in the samples.

Absorbance and fluorescence measurements have been carried out on resveratrol−PBS samples at temperatures both lower and higher than 37 °C (i.e., 20, 25, 45, and 50 °C) (curves not shown). The spectra of irradiated samples are markedly and progressively affected by the temperature increase, in a manner consistent with the progressive conversion of *trans*- to *cis*-resveratrol. In contrast, no significant spectral variations are recorded in nonilluminated samples at each temperature, indicating that the sole temperature does not affect the stability of *trans*-resveratrol, whereas it affects the ratio of the two isoforms that coexist in solution upon UV irradiation.

The stability of *trans*-resveratrol against UV irradiation has been also investigated in ethanol solution. Absorbance and fluorescence curves (not shown) indicate, also in this solvent, a temperature-dependent degradation of *trans*-resveratrol due to light irradiation.

Resveratrol binds to βLG with a binding constant[18,20] between 10^4 and 10^6 M^{-1} and to HSA with a binding constant[25] of about 10^5 M^{-1}. The number of resveratrol molecules bound per protein is 1 for HSA[25] and 1[18] or 1.1[20] for βLG. The excess of protein in solution (protein to resveratrol molar ratio is 10:1) gives a saturation in the fluorescence signal, ensuring that all *trans*-resveratrol is bound to the proteins. The absorbance and fluorescence spectra for resveratrol in βLG and the fluorescence spectra for resveratrol in HSA recorded at 37 °C before (black lines) and after 2 h (red lines) of continuous irradiation at 340 nm are shown in Figure 3A, B, and C, respectively. For the HSA−resveratrol complex the absorbance measurements are not given because of the high superposition of the spectrum of the protein with those of both *trans*- and *cis*-resveratrol.

The absorbance spectra in Figure 3A are obtained by subtracting the βLG spectrum from the spectrum of the βLG−resveratrol complex. By comparing the curves in Figure 3 (relative to resveratrol−protein complexes) with those reported in Figure 2 (relative to resveratrol−PBS samples), it emerges that the formation of *cis*-resveratrol consequent to UV illumination also occurs when the ligand is bound to the protein, although it is clearly reduced.

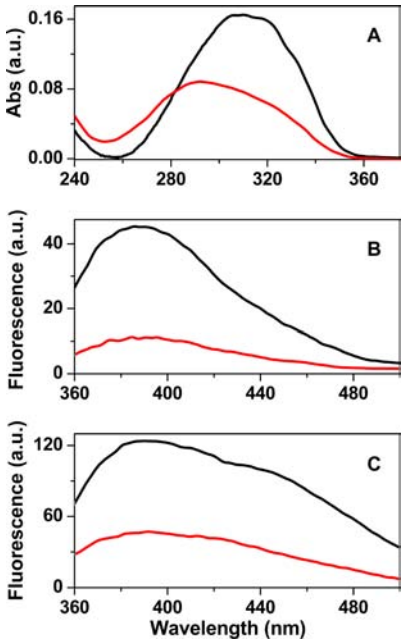

Figure 3. (A) Absorbance and (B) fluorescence spectra at 37 °C of *trans*-resveratrol bound to βLG before (black line) and after (red line) exposure for 2 h to radiation at 340 nm. (C) Fluorescence spectra of *trans*-resveratrol bound to HSA as in (B).

The absorbance and fluorescence data have been analyzed to estimate the concentration of *trans*-, C_{trans}, and *cis*-resveratrol, C_{cis}, present in solution after 2 h of exposure to light at 340 nm. The concentrations of the two resveratrol isoforms are determined from the absorbance measurements by the following formulas, which are valid when starting from a 100% *trans*-resveratrol solution of known initial concentration, $C_0 = A_0/\varepsilon_{trans}$:[5]

$$C_{trans} = \frac{1}{R-1}\left(\frac{RA}{l\varepsilon_{trans}} - C_0\right) \quad (1)$$

$$C_{cis} = \frac{1}{1-R}\left(\frac{A}{l\varepsilon_{cis}} - RC_0\right) \quad (2)$$

where $R = \varepsilon_{trans,304\ nm}/\varepsilon_{cis,304\ nm} = 30\,135/9749 \approx 3.09$ in 10 mM phosphate buffer solution[5] and $R = \varepsilon_{trans,308\ nm}/\varepsilon_{cis,308\ nm} = 30\,000/12\,500 = 2.4$ in ethanol,[32] ε_{trans} and ε_{cis} are the molar extinction coefficients of *trans*- and *cis*-resveratrol, respectively, A is the measured absorbance at 304 nm in buffer and at 308 nm in ethanol, and l is the optical path length. The fractions of the two isoforms are simply given by $f_{trans} = C_{trans}/C_0$ and $f_{cis} = C_{cis}/C_0$. From the fluorescence data, the fraction of *trans* isomers is $f_{trans} = F_t/F_0$ and the corresponding concentration is $C_{trans} = f_{trans}C_0$, where F_t is the fluorescence maximum after irradiation (t = 2 h) and F_0 the fluorescence maximum before irradiation (t = 0 h). The fraction and the concentration of *cis* isomers are given by $f_{cis} = 1 - f_{trans}$ and $C_{cis} = C_0 - C_{trans}$, respectively.

Table 1 reports the data deduced by using the equations given above. The values indicate that comparable fractions are obtained from the two techniques at each temperature. The values of f_{trans} decrease (f_{cis} increase) with a temperature increase. For resveratrol in PBS, 2 h of UV illumination promotes the formation of a marked *cis* population already at 20 °C, about 73%, which increases to 86% at 50 °C. In addition,

the fractions of *cis* isomer, f_{cis}, are slightly higher in ethanol, ranging from 79%−81% to 88−90% in the whole temperature range. This finding should be taken into account in the context of the possible use of ethanol in dissolving resveratrol for pharmaceutical applications.

A number of studies have dealt with the isomerization of resveratrol in solution. It has been reported that, except in buffers at high pH, *trans*-resveratrol is stable in the dark from hours to several days,[32] whereas different treatments, including exposure to sunlight,[5] direct illumination with tubular lamps that emit at all visible wavelengths,[18] and UV irradiation,[25,32,48,50] induce the formation of *cis* isomers starting from a pure *trans*-resveratrol solution. Specifically, for a UV-illuminated resveratrol solution, the formation of the *cis* isoform is influenced by physicochemical parameters such as resveratrol concentration, pH of the dispersion media, and wavelength and duration of the excitation.[25,32,48,50] In addition, it has been demonstrated that no other products are present except *trans*- and *cis*-resveratrol when UV light interacts with a resveratrol solution.[48] Within this framework, it is of interest to compare our results for resveratrol free in solution with those obtained in the above-mentioned studies. At 20 °C, upon illumination at 260 nm (i.e., a wavelength suitable to excite *cis*-resveratrol) of a 5.7 μM solution, 50.9% of *trans*-resveratrol is converted into *cis*-resveratrol after 150 min, and 59.6% is converted after 330 min.[50] By using HPLC/UV, Camont et al. report that 8 h of sunlight exposure reduces to 30% the concentration of *trans*-resveratrol starting from a pure 100 μM solution.[5] Trela and Waterhouse report that a 418 μM solution of *trans*-resveratrol in ethanol was converted to 90.6% *cis*-resveratrol after 100 min of illumination at 366 nm and to 63% after 10 h at 254 nm.[32]

The data in Table 1 relative to the two proteins clearly indicate that they decrease resveratrol isomerization induced by radiation at 340 nm. Indeed, compared to that obtained in PBS or ethanol, at any temperature the fraction of *trans*-resveratrol is increased (*cis*-resveratrol is reduced) in the presence of βLG and even more in the presence of HSA. This occurs more efficiently at low than at high temperature. For comparison, by using spectrophotometry, Liang et al. reported that complexing resveratrol with βLG provides a slight increase in photostability relative to resveratrol−buffer solution.[18] In fact, samples exposed to white light are almost stable in *trans*-configuration for up to 21 h, when absorbance at 305 nm is decreased to about 80% of the initial value in the absence of βLG and to about 90% in its presence. For the HSA−resveratrol complex, after repeated fluorescence measurements at λ_{ex} = 315 nm, the fraction of resveratrol in *trans* form is 50.5% compared to 34% for resveratrol in PBS.[25]

Arrhenius plots of the temperature dependences of C_{trans}/C_{cis} deduced from fluorescence data for resveratrol in PBS (squares), ethanol (circles), βLG (triangles), and HSA (diamonds) are given in Figure 4. In all cases, the temperature dependence is linear, conforming well to an Arrhenius law with

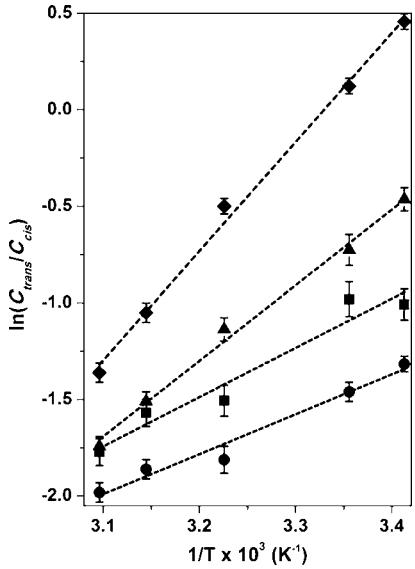

Figure 4. Temperature dependence of C_{trans}/C_{cis} ratio deduced from fluorescence data for resveratrol in PBS (squares), ethanol (circles), βLG (triangles), and HSA (diamonds). The lines are least-squares linear fits of the data according to Arrhenius law.

an activation energy of photoisomerization of 5.1 ± 0.7 and 4.1 ± 0.4 kcal/mol for resveratrol in PBS and ethanol, respectively. These values translate to 7.8 ± 0.3 and 11.2 ± 0.4 kcal/mol for resveratrol in βLG and HSA, respectively.

The activation energy of photoisomerization for *trans*-resveratrol in PBS at pH 4 was previously reported to be 3.7 ± 0.3 kcal/mol upon excitation at 260 nm for different time periods and at temperatures between 20 and 50 °C.[50] On the whole, the spectroscopic data indicate that the two proteins, although not being able to prevent the formation of the *cis* isomer, are able to protect *trans*-resveratrol from degradation, and in this respect HSA is more effective than βLG.

Docking and MD Simulations of Protein−Resveratrol Complexes. Docking of *trans*-resveratrol to βLG was carried out by using the unliganded protein form and resulted in two poses of the ligand on the protein surface, as shown in Figure 5A. Pose 1 corresponds to several slightly different binding modes with resveratrol placed at the entrance of the protein calyx and an estimated energy of −6.2 ± 0.3 kcal/mol. Pose 2 occurs in an external region on the opposite site with respect to the protein calyx, with one −OH group of resveratrol forming a hydrogen bond with the exposed carboxyl oxygen of Trp19, and a binding energy of −5.8 ± 0.2 kcal/mol.

In a single case, a binding mode of pose 1 was found with resveratrol more deeply inserted into the protein calyx. However, stable association within this site can be excluded on the basis of experimental data[19] indicating that binding of resveratrol takes place in another site because it occurs even at

dx.doi.org/10.1021/jf405584a | J. Agric. Food Chem. 2014, 62, 4384−4391

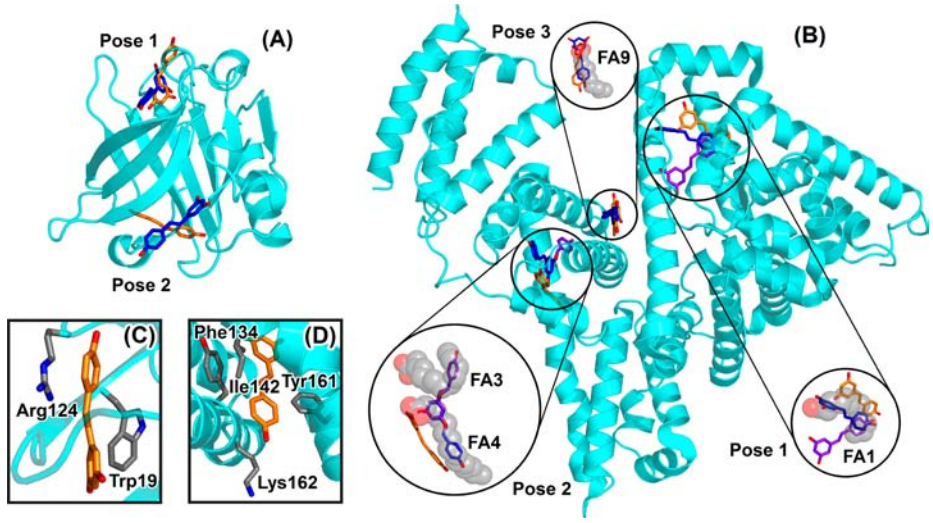

Figure 5. *trans*-Resveratrol bound to (A) βLG and (B) HSA, with the ligand in the docking poses (blue and purple) and after MD simulations (orange). For HSA, superposition with crystallographic binding sites for fatty acids (FA1, FA3, FA4, and FA9) is evidenced. Details of protein residues interacting with the ligand in (C) βLG and (D) HSA are also shown.

low pH, when the inner region of the hydrophobic cavity is inaccessible,[27] and at high temperature when the calyx is disrupted.[51] Therefore, this particular binding mode of pose 1 can be considered an artifact, possibly due to the docking scoring function not taking into account the specificity of the binding site of βLG, which is an extreme case of a large and yet completely dehydrated cavity.[52]

Additional docking calculations were carried out by using the crystallographic βLG structure containing within the protein calyx either retinol or retinoic acid, both possessing a β-ionone ring whose steric hindrance resembles that of either of the two resveratrol rings. The structure of βLG alone was extracted from the complexes with both retinol and retinoic acid and used to accommodate *trans*-resveratrol. Nevertheless, estimates for binding modes and affinity of resveratrol to these protein structures were found to be similar to the unliganded protein form.

Classical MD simulations were performed with the ligand initially placed according to the binding modes obtained by the docking procedure, to determine the main features of βLG–resveratrol interaction when all the degrees of freedom of the protein are free to move and in the presence of solvent. Figure 6 shows the simulated number of water molecules within a distance of 0.3 nm with respect to resveratrol. When the ligand is initially placed in pose 1, at the opening of the protein calyx, it is in contact on average with 40 water molecules compared with about 75 contacts when it is fully solvated in water. Thus, the curve indicates that resveratrol remains within the upper region of the funnel, without penetrating the main βLG binding site. A similar behavior was observed in five other simulation runs, with the molecule variously interacting with several protein residues, such as forming transient hydrogen bonds with either O-Met107, O-Ser116, or O^{γ}-Ser116. Migration of resveratrol deep into the binding site was never observed in simulation.

Simulations starting with the ligand in pose 2 (Figure 5A) show that resveratrol initially explores the surroundings of the docking placement while remaining in contact with the protein main chain in correspondence with the Trp19 residue. In this position, resveratrol is in contact on average with 60 water molecules (see Figure 6). Quick reduction of the number of

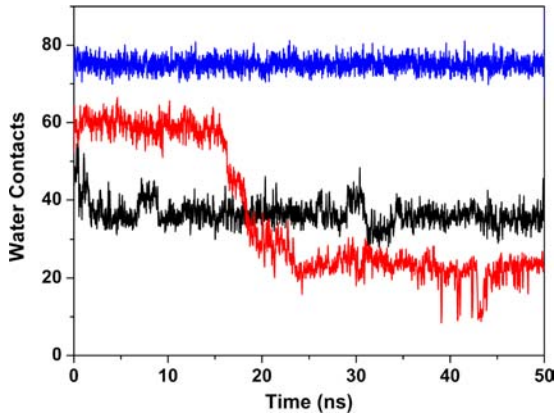

Figure 6. Number of water molecules in contact with *trans*-resveratrol (blue line) free in the solvent, (black line) at the entrance of the βLG calyx (pose 1), and (red line) close to Trp19 (pose 2), as a function of the simulation time. Data are averaged over 50 ps for clarity of presentation.

contacts, which is visible in the curve at 16–18 ns, indicates that resveratrol partially penetrates the protein surface. As shown in Figure 5C, the ligand accommodates in between the side chain of Arg124, which is exposed to the solvent, and the side chain of Trp19, which is more distant from the protein surface. In this position resveratrol is more specifically attached to the protein and protected from the solvent compared with any location at the calyx entrance. Both hydrophobic and hydrophilic contacts contribute to secure the ligand to the protein, the former playing a major role as previously suggested on the basis of experimental data.[19,20]

The docking procedure was repeated by using protein structures obtained in simulation after 20 ns. A binding energy of -7.1 ± 0.5 kcal/mol was found for resveratrol in the binding site between Trp19 and Arg124. In contrast, no appreciable variation was observed for the binding affinity of resveratrol at the entrance of the protein calyx, compared with the starting protein structure. Therefore, the overall simulation results suggest that the region close to the Trp19 residue is the most

dx.doi.org/10.1021/jf405584a | J. Agric. Food Chem. 2014, 62, 4384–4391

likely binding site for resveratrol to βLG, in agreement with fluorescence quenching[19] and other techniques.[20]

Association of *trans*-resveratrol in the protein region in between Trp19 and Arg124 residues provides a straightforward explanation of the binding mechanism and of the stabilizing effect due to βLG on the *trans*-to-*cis* transition. In fact, in this binding site the ligand molecule is restrained in its dynamics and mostly protected from the solvent. Nevertheless, the protein does not provide a complete protection from the solvent, and it does not totally inhibit the possibility of rotation around the double bond in the methylene bridge of resveratrol. Furthermore, a fraction of resveratrol molecules may bind in nonspecific or low-affinity locations on the protein surface, including the entrance of the protein calyx, thus being unrestrained in the dynamics and markedly more in contact with the solvent compared to the binding location in correspondence with Trp19 and prone to convert to the *cis* form. This hypothesis would also explain why for βLG the number of resveratrol molecules bound per protein could vary from 1 to 1.1.[18,20]

For the HSA−resveratrol complex, the docking results indicate that resveratrol can bind HSA in three different poses (see Figure 5B), corresponding to sites that can be occupied by fatty acids or other small ligands. These sites are hereafter indicated with their conventional nomenclature.[31] Pose 1 was found in correspondence with the binding site FA1 of HSA and shows the highest affinity, with an interaction energy of −8.9 ± 0.2 kcal/mol. In this site resveratrol can associate in either of two binding modes. One of the two rings of resveratrol occupies the position corresponding to a fatty acid tail, whereas the other ring is placed either instead of the lipid headgroup or pointing toward the center of the protein (see Figure 5B). Similarly, pose 2 shows an interaction energy of −8.5 ± 0.2 kcal/mol and overlaps totally or in part with the binding site FA4, with two different binding modes. In fact, one of the two resveratrol rings can alternatively be in the place of the tail of a fatty acid in the binding site FA3. Such a combination is not unusual for HSA, because the two binding sites FA3 and FA4 can accommodate ligands bulkier than fatty acids by rearranging into the single cavity DS2, or drug site 2.[30] Finally, pose 3 has a binding affinity of −7.5 ± 0.3 kcal/mol and coincides with the binding site FA9, which is a cleft in the upper region of the central protein crevice and can be occupied by capric acid, but not by other fatty acids with a longer chain.[31]

It is interesting to note that our docking results do not detect any binding mode in the cavity between subdomain IB/IIA of the protein, which was previously predicted[17] as the only binding site for resveratrol by using the AutoDock 3.5 program.[53] In contrast, the drug site DS2 was already reported as the only binding site for resveratrol in bovine serum albumin[26] by using AutoDock 4.2. Such differences in the results can probably be attributed to the improvement of the scoring function of AutoDock, as well as to the higher accuracy of the new-generation function later adopted by AutoDock Vina,[39] which was used in our calculations.

MD simulations were performed on the HSA−resveratrol complex, with the ligand placed in the different poses selected through the docking. The results show that, except when placed in pose 3 (FA9) at the central protein crevice, resveratrol partially diffuses away from the starting position due to dynamical rearrangements of the protein matrix. In particular, when initially placed in pose 1, it relocates about 0.5 nm from the starting position and ends up being surrounded by Tyr161, Ile142, Phe134, and Lys162, as shown in Figure 5D. The first two residues are close to resveratrol from the beginning of the simulation; thus they move away from their starting position. Similarly, when placed in pose 2, resveratrol moves about 0.4 nm from the starting position.

To assess the strain exerted by the protein matrix, the distribution of values of the dihedral angle involved in the *trans*-to-*cis* conversion was calculated and compared to the equilibrium value found for resveratrol free in water, θ_{eq} = 180 ± 22°. The results reported in Figure 7 show that the highest strain is found in correspondence with the binding site FA9, as indicated by both the higher difference found for the average value and the lower variance in the distribution around this value. In contrast, less strain is found in correspondence with the other two positions, indicating that resveratrol is more easily accommodated within the protein in these sites.

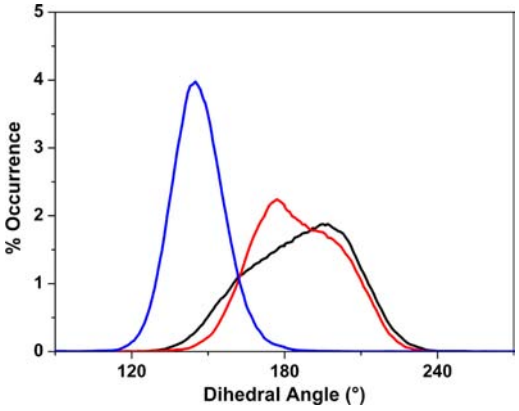

Figure 7. Distribution of dihedral angle for *trans*-resveratrol calculated in the time interval 25−50 ns in the binding sites of HSA: (black line) site FA1, (red line) site FA4, (blue line) site FA9.

Table 2 reports the dihedral order parameter S^2 and water contacts of *trans*-resveratrol in the different binding sites of HSA. Data for resveratrol free in water and associated with βLG are also reported for comparison. The parameter S^2 ranges from 0, for a dihedral angle free to sample any conformation, to 1 for a perfectly rigid system.[54] Thus, it gives a quantitative indication of the degree of inhibition for a rotation around the central methylene bridge of resveratrol.

Table 2. Dihedral Order Parameter and Solvent Contacts, Calculated in Simulation in the Time Interval 25−50 ns, for *trans*-Resveratrol Free in Water or Starting from Different Poses in Either βLG or HSA

environment	pose	binding site	order parameter	solvent contacts
water			0.86 ± 0.01	75 ± 3
βLG	2	Trp19/Arg124	0.89 ± 0.01	25 ± 6
HSA	1	FA1	0.91 ± 0.01	23 ± 7
HSA	2	FA4	0.94 ± 0.01	27 ± 6
HSA	3	FA9	0.95 ± 0.01	28 ± 8

The values found in the simulation show that the dihedral order parameter correlates with the stability of resveratrol against the *trans*-to-*cis* conversion found in our absorbance and fluorescence measurements: it is lower in the aqueous solvent, intermediate in βLG, and higher in HSA. In contrast, no clear correlation appears by comparing the contacts between *trans*-resveratrol and water in βLG and HSA. Although resveratrol

dx.doi.org/10.1021/jf405584a | J. Agric. Food Chem. 2014, 62, 4384−4391

complexed with HSA is more deeply buried and in contact with more amino acid compared to βLG, the difference of solvent contacts for the two proteins is not striking because the binding sites of HSA are hydrophobic cavities accessible to the solvent.[55]

Finally, docking of *trans*-resveratrol was performed again on HSA by using the simulation structures closer to the average configuration in the interval 25−50 ns. Only the protein structures were considered, and the search space for the docking was restricted to the region occupied by each ligand. The resulting affinity energies obtained placing the ligand in the three binding sites are, respectively, 8.9 ± 0.4, 8.1 ± 0.5, and 7.1 ± 0.3 kcal/mol. These values are consistent with the ones obtained for the three poses in the initial docking procedure. However, the energetic differences among the three binding sites in this case are more evident and in better agreement with previous experiments.[25] In fact, the stoichiometry of binding between resveratrol and HSA is not modified by the presence of 3 mol of stearic acid per mole of protein, whereas the amount of associated resveratrol is reduced when 5 mol of stearic acid is present. This suggests that the binding site FA1, which is not one of the three high-affinity binding sites for long-chain fatty acids,[56] is the one preferred by resveratrol. In contrast, the binding site FA4 has a high affinity for long-chain fatty acids;[31,56] thus it is reasonable to consider it at most a secondary binding site for resveratrol. Furthermore, the binding site FA9 cannot accommodate a long-chain fatty acid;[31] thus it cannot be a primary binding site for resveratrol, as in this case the stoichiometry of the HSA−resveratrol complex would have no or little change with varying amounts of stearic acid.

The overall results provide a possible explanation for the different degree of protection against the *trans*-to-*cis* transition of resveratrol in βLG and HSA. Limitations in the contact with the solvent, and especially restrictions in the freedom of fluctuation due to the hindrance of the protein matrix, likely stabilize the *trans*-resveratrol molecule. In this respect, the simulation data show that HSA protects resveratrol more efficiently than βLG. In particular, van der Waals interactions with a relatively high number of hydrophobic amino acid residues contribute to fasten resveratrol in HSA. Furthermore, the binding energy of *trans*-resveratrol to HSA is considerably lower than for βLG, thus providing a more stable complex. Other factors may also play an additional role, such as the fact that the binding site of HSA is more internal, so that the ligand may not easily escape back into the solvent.

In conclusion, the findings of the present work indicate that transport proteins can be conveniently used to store and deliver resveratrol in the *trans* form and suggest that other protein carriers may be further investigated with the aim of dispensing *in vivo* resveratrol or other similar ligands.

Mapping the Variation of the Carrot Metabolome Using ^{1}H NMR Spectroscopy and Consensus PCA

Morten Rahr Clausen,* Merete Edelenbos, and Hanne Christine Bertram

Department of Food Science, Aarhus University, Kirstinebjergvej 10, DK-5792 Aarslev, Denmark

Supporting Information

ABSTRACT: Genetic variation is the most influential factor for carrot (*Daucus carota* L.) composition. However, difference in metabolite content between carrot varieties has not been described by NMR, although primary metabolites are important for human health and sensory properties. The aim of the present study was to investigate the effect of genotype on carrot metabolite composition using a ^{1}H NMR-based metabolomics approach. After extraction using aqueous and organic solvents, 25 hydrophilic metabolites, β-carotene, sterols, triacylglycerols, and phospholipids were detected. Multiblock PCA showed that three principal components could be identified for classification of the five carrot varieties using different spectroscopic regions and the results of the two solvent extraction methods as blocks. The varieties were characterized by differences in carbohydrate, amino acid, nucleotide, fatty acid, sterol, and β-carotene contents. ^{1}H NMR spectroscopy coupled with multiblock data analysis was an efficient and useful tool to map the carrot metabolome and identify genetic differences between varieties.

KEYWORDS: *^{1}H NMR, carrots, consensus PCA, metabolite extraction*

INTRODUCTION

The appearance of carrots, their chemical composition, and quality are known to be affected by genotype and growth and storage conditions.[1,2] Recently, it was shown that genotype is the single most important factor that controls both the chemical composition (carotenes, sugars, phenolics, terpenes, falcarindiol) and sensory properties (sweetness and bitterness) of carrots.[3] Older papers, however, indicated that growing year and location also are important factors determining quality differences.[4,5]

The major aroma compounds of carrots are terpenes and sesquiterpenes.[6−8] These compounds significantly affect aroma and flavor attributes and interact with the taste attributes sweetness and bitterness.[7,9] Furthermore, phenolics and falcarinol and their derivatives have been extensively analyzed due to their implications for human health and sensory properties.[1,9−12] In fresh carrots, the sensory attribute bitterness was found to be related to the content of falcarindiol and a dicaffeic acid derivative of quinic acid.[13] Furthermore, data indicated that a high content of the carbohydrates sucrose, glucose, and fructose could mask bitterness.[6,13] Bitterness has also been attributed to the isocoumarin 6-methoxymellein, which increases after mechanical stress during handling and packaging of carrots.[1]

Although the content of secondary metabolites and carbohydrates has been extensively investigated in carrots, little is known about the variation of primary metabolites and lipids between genetically different carrots. To elucidate the effect of genotype on carrot metabolite composition, the aim of the present study was to investigate different carrot varieties by using a ^{1}H NMR-based metabolomic approach. Metabolomics is widely used as a tool to understand plant metabolism and food quality.[14,15] To understand the effects of postharvest storage and plant diseases, metabolomics has been used to investigate different root crops and their response to cold storage and microbial infections.[16−18] Furthermore, metabolomic phenotyping may lead to important information about authenticity of varieties grown under different conditions and has been used to discriminate different varieties of grass and legumes,[19] potatoes,[20] and Jerusalem artichoke tubers.[16]

MATERIALS AND METHODS

Plant Material and Sample Preparation. Five carrot varieties were selected for analyses: 'Bolero' (orange), 'Nipomo' (orange), 'Purple Haze' (purple with an orange core), 'Mello Yello' (yellow), and 'White Satin' (white). All varieties were F1-hybrids from Bejo Zaden (Warmenhuizen, The Netherlands) except for 'Bolero', which was bred by Vilmorin (La Ménitré, France). 'Bolero' was grown at the Department of Food Science, Aarhus University, Årslev, Denmark (10°27′ E, 55°18′ N) in a sandy loam soil (typical Agrudalf), whereas 'Nipomo', 'Purple Haze', 'Mello Yello', and 'White Satin' were grown at Tange Frilandsgartneri A/S, Bjerringbro, Denmark (9°34′ E, 56°20′ N) in a coarse sandy loam soil. All carrots were sown in April 2009 and hand-harvested in October 2009, when fully mature. Harvested roots were stored for 3 months at 1 °C and >95% relative humidity to keep shelf life and prevent loss of moisture. Five medium-sized roots of each variety were sampled and used for analyses. The roots had upper diameters between 31 and 41 mm and weights between 75 and 150 g. Roots were washed in tap water, and half of each root (the middle part) was sliced in approximately 0.5 cm disks, immediately frozen in liquid nitrogen and freeze-dried (48 h), vacuum-packaged in hermetically sealed aluminum foil pouches, and stored at −24 °C until analyses. Each carrot was treated as one replicate. At the time of analyses, freeze-dried material was ground using a pestle and a nitrogen-cooled mortar. Two subsamples of 50 mg of each carrot sample were weighed into 2 mL Eppendorf tubes, one tube for aqueous and one tube for organic extraction of the lyophilized carrot

powder. One milliliter of unbuffered deionized water (Elga, Marlow, UK) was used for aqueous extraction. Although buffering of the solvent could have minimized variations in chemical shifts, we corrected for such variations using Icoshift. One milliliter of chloroform 99.8% D, 0.05% tetramethylsilan (TMS) (Cambridge Isotopes Laboratories Inc., Andover, MA, USA) was used for organic extraction. Samples were sonicated for 15 min at room temperature and stored at −80 °C (organic extract) or sonicated for 15 min at room temperature and then extracted overnight at 4 °C and stored at −80 °C (aqueous extract). Samples were centrifuged (10000*g*, 10 min, 4 °C) before NMR analyses. The organic supernatants were filtered through a nylon filter, and 600 μL of sample was transferred to NMR tubes. The aqueous supernatant was transferred directly to NMR tubes (500 μL) and mixed with 100 μL of D_2O containing 0.05% 3-(trimethylsilyl)propionic acid-[2,2,3,3-d_4] (TMSP) (Aldrich Chemistry, Steinheim, Germany).

NMR Spectroscopy. NMR spectra of extracts were obtained on a Bruker Avance III 600 equipped with a TXI probe (Bruker Biospin, Rheinstetten, Germany) operating at a ^{1}H frequency of 600.13 MHz and 298 K. One-dimensional (1D) proton NMR spectra of the aqueous extracts were acquired with a single 90° pulse, a relaxation delay of 5 s, and 64 scans sweeping 12.7 ppm/7288 Hz (offset 4.7 ppm) with 32K data points. The water signal was partially suppressed through irradiation with a weak presaturation pulse. NMR acquisition of the chloroform extracts was performed with a single 90° pulse, a relaxation delay of 1 s, and 64 scans sweeping 20.6 ppm/12335 Hz (offset 6.2 ppm) with 64K data points. All spectra were referenced to TMSP (aqueous extracts) or TMS (organic extracts).

Carrot metabolites were identified from pure standards, two-dimensional (2-D) NMR experiments (^{1}H−^{1}H homonuclear shift correlation (COSY) and ^{1}H−^{13}C heteronuclear single-quantum correlation spectroscopy (HSQC)), and comparison with published data.[21−25] The COSY spectra were acquired with a spectral width of 6130 Hz in both dimensions, 8K data points, and 512 increments with 32 transients per increment. The HSQC spectra were acquired with a spectral width of 8000 Hz in the F2 dimension and 25000 Hz in the F1 dimension, a data matrix with a size of 1K × 256 data points, and 64 transients per increment. All spectra were manually phased and baseline corrected.

Data Analysis. The NMR spectra of the aqueous extracts were aligned using the Icoshift procedure in Matlab version 8.1 (The Mathworks Inc., Natick, MA).[26] Alignment of NMR spectra of organic extracts was not necessary. The regions from 9.0 to 0.5 ppm were used for multivariate data analysis. Signals from residual water and nondeuterated solvents, which corresponded to the 5.0−4.7 ppm region in the aqueous extracts and the 7.24−7.14 and 1.7−1.5 ppm regions in the organic extracts, were left out. Compounds extracted from the filter at 8.02 and 4.63 ppm were also removed in the organic extracts. Prior to multivariate data analysis, NMR spectra were normalized according to the total spectrum intensity and Pareto scaled.

The multiblock method consensus PCA was performed in Matlab using the multiblock toolbox version 0.2 with full cross-validation.[27,28] With this method, the overall trend in the data was described at the super level, where the super scores (t_s) described how each sample was influenced over all blocks. The influence of each data block on this trend was described by the super block weights (w) and the weights were used to evaluate the importance of the different data blocks relative to each other. To examine the trend within blocks, block scores (t) were used to describe how each sample was influenced within each block. The influence of each variable on this trend was described by the block loadings (p).

For calculation of metabolite correlations, metabolites were integrated using an in-house developed Matlab script. Pearson correlation coefficients were calculated in Matlab using the corrcoeff function, and significant correlations are reported at $P \leq 0.01$.

RESULTS AND DISCUSSION

Figure 1 summarizes the metabolites identified in the carrot extracts; 25 hydrophilic metabolites were extracted and identified from lyophilized tissue of the carrots, and the hydrophobic metabolites identified comprised β-carotene, sterols, and peaks originating from fatty acid chains, the glycerol moiety of triacylglycrols, and the choline moiety of

dx.doi.org/10.1021/jf5014555 | J. Agric. Food Chem. 2014, 62, 4392−4398

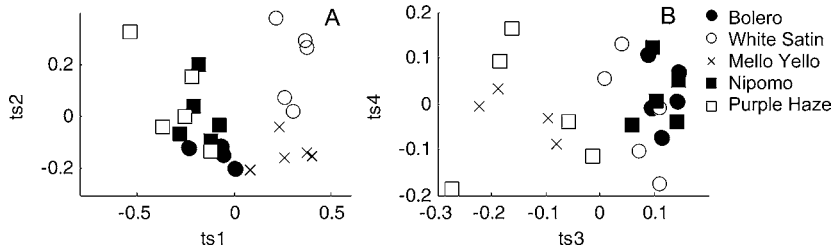

Figure 2. Consensus PCA super scores (t_s): (A) ts1 versus ts2; (B) ts3 versus ts4 of ^{1}H NMR spectra of carrot extracts divided into four blocks.

phospholipids. The detected sterol was similar to pure β-sitosterol; however, it could not be unambiguously assigned due to overlapping signals. The types of compounds in the four data blocks were as follows: block 1 covered the range 9−5.5 ppm in the aqueous extract and contained primarily aromatic amino acids, nucleotides/nucleosides, fumaric acid, and formic acid; block 2 covered the range 5.5−3.2 ppm in the aqueous extract and comprised primarily carbohydrates; block 3 covered the range 3.2−0.5 ppm in the aqueous extract and contained primarily organic acids and aliphatic amino acids; and block 4 covered the range 7.0−0.5 ppm in the organic extract and comprised sterols, fatty acids, carotene, phospholipids, and triglycerides.

In practice, extraction procedures are highly selective and will therefore not provide a complete picture of the metabolites present in a given sample.[29] In the present study the identified metabolites mainly comprised primary metabolites, whereas secondary metabolites were hardly detected; β-carotene, the primary carotenoid in orange carrots, could be detected in all orange varieties. Lutein, which is responsible for the yellow color in 'Mello Yello', and polyphenolics, which are responsible for the purple color in 'Purple Haze' were, however, not detected. Also, chlorogenic acid, which is common in carrots and reported in high concentrations in 'Purple Haze', was not identified.[13] This is in agreement with a previous study in which chlorogenic acid was detected only in trace amounts in roots using NMR,[30] whereas others found chlorogenic acid and feruloylquinic acid in leaf shoots.[31] On the other hand, we detected quinic acid, which is a precursor of chlorogenic acid, in all samples.

Multiblock methods are powerful tools to combine information from different data blocks obtained from the same objects, for example, metabolites that have similar metabolic origin or are obtained by different extraction methods.[27] In the multiblock analysis, data from the same objects are combined at a super level, and information is provided about the interrelationsships between blocks. Hence, the multiblock method may potentially reveal relationsships between metabolites extracted in different solvents or analyzed with different techniques.[27] Furthermore, multiblock analysis can be informative when minor trends in the data need to be revealed, either because they are not modeled[32] or simply because they are overlooked when loadings are inspected visually in a normal principal component analysis (PCA). The latter aspect may be corrected for by assigning data blocks the same weight in the analysis.

For this study, five carrot varieties with differences in appearance (mainly color) and chemical composition as revealed in previous studies were chosen.[6] Hydrophilic and hydrophobic metabolites were extracted using water and chloroform, and extracts were analyzed by ^{1}H NMR spectroscopy and data treated by multiblock statistical analysis. In principle, any number of blocks could be chosen to make the approach more data driven. However, that was not the purpose of the present study. The separation into blocks was mainly based on the need to integrate data from the two solvents in the same model. Furthermore, the division of the aqueous extract data into blocks was convenient because of the variation in peak intensities.

Consensus PCA was used to analyze the NMR data from the four assigned blocks. The carrot varieties could be discriminated by three principal components (PC1, PC2, and PC3) in the multiblock analysis (Figure 2), whereas no discrimination could be seen along PC4. A three-component model resulted in an acceptable cross-validated prediction error of 0.47, which did not improve significantly after inclusion of more principal components.

Along PC1, the varieties 'Mello Yello' and 'White Satin' were discriminated from the orange-colored 'Bolero', 'Nipomo', and 'Purple Haze'. A less clear discrimination was seen along PC2 between the varieties 'Bolero' and 'Mello Yello' and the rest of the varieties (Figure 2A). Along PC3, 'Nipomo' and 'Bolero' discriminated from 'Purple Haze' (Figure 2B). Overall, it was possible to separate the five genotypes by the multiblock method despite the fact that high between-root variations were observed for 'Purple Haze', 'Mello Yello', and 'White Satin' (Figure 2). The variety 'Purple Haze' is a two-colored F1-hybrid, which makes sampling of tissues of this variety challenging, for example, if the weight proportion of purple compared to orange tissues differs between roots. The other varieties were monochrome F1-hybrids with relatively even distributions of inner xylem (core) and outer phloem tissues (cortex).

The super weights (w) in Figure 3 allow us directly to extract which data blocks were most important for the discrimination

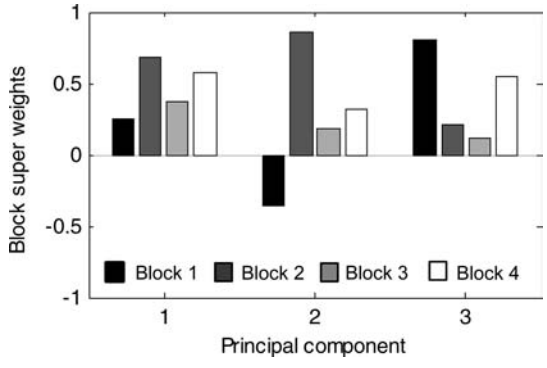

Figure 3. Consensus PCA block super weights showing the contribution of each block to the discrimination of the carrot varieties shown in Figure 2: block 1, 9−5.5 ppm in the aqueous extract; block 2, 5.5−3.2 ppm in the aqueous extract; block 3, 3.2−0.5 ppm in the aqueous extract; block 4, 7.0−0.5 ppm in the organic extract.

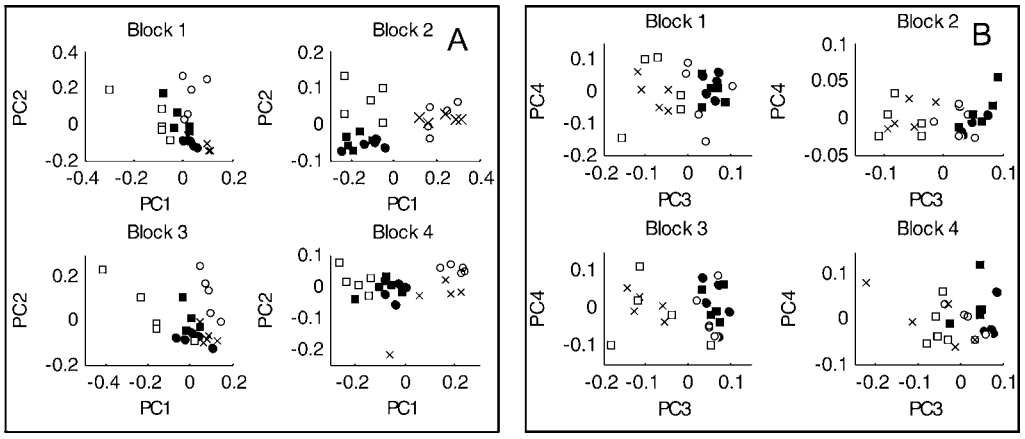

Figure 4. Block scores derived from the consensus PCA models: (A) PC1 versus PC2; (B) PC3 versus PC4; block 1, 9−5.5 ppm in the aqueous extract; block 2, 5.5−3.2 ppm in the aqueous extract; block 3, 3.2−0.5 ppm in the aqueous extract; block 4, 7.0−0.5 ppm in the organic extract. Legend is as in Figure 2.

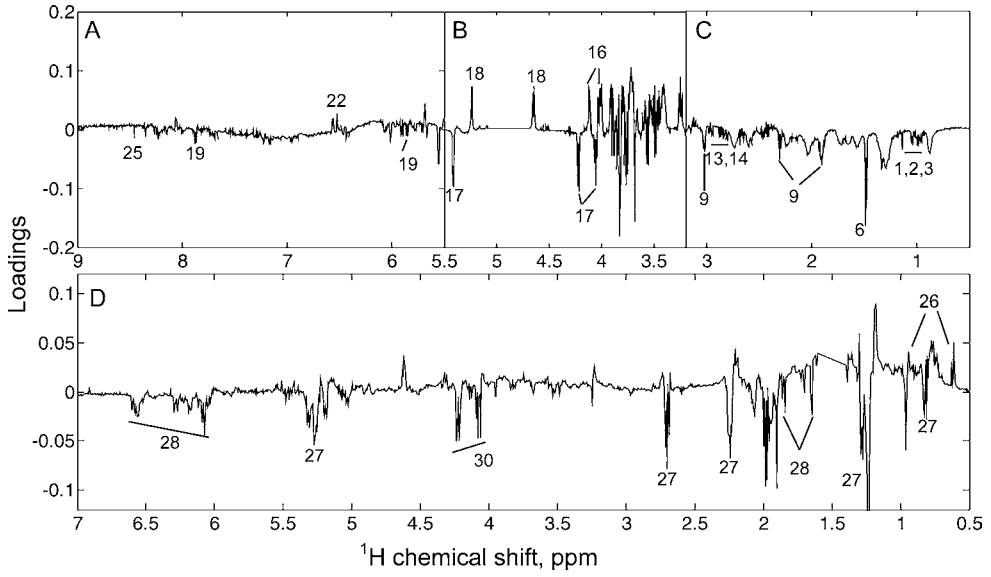

Figure 5. Block loadings for PC1 calculated on the basis of the consensus PCA for blocks 1−4. Peaks: 1, isoleucine; 2, leucine; 3, valine; 6, alanine; 9, γ-aminobutyric acid; 13, aspartic acid; 14, asparagine; 16, fructose; 17, sucrose; 18, glucose; 19, uracil; 22, fumaric acid; 25, formic acid; 26, sterols; 27, fatty acid chain; 28, β-carotene; 30, glycerol moiety triglycerides.

between varieties. Along PC1, all four blocks contributed to the discrimination of varieties; however, block 2 (carbohydrates) and block 4 (sterols, fatty acids, carotene, phospholipids, and triglycerides) had the highest super weights (Figure 3) and hence were most significant. Blocks 2 and 4 resulted in discrimination remarkably similar to that of the super level, which can be seen by comparing Figures 2A and 4A for those two blocks. The results showed that the orange varieties 'Bolero', 'Nipomo', and 'Purple Haze' discriminated from the yellow and white varieties 'Mello Yello' and 'White Satin' using information on the carbohydrate and lipid profiles. The results also indicated a connection between contents of carbohydrates and lipids in carrot roots. The block loadings in Figure 5 showed that discrimination between varieties could be attributed to differences in sucrose, fructose, glucose, and β-carotene contents. The yellow and white carrot varieties 'Mello Yello' and 'White Satin' contained no or only traces of β-carotene[6] and, furthermore, these varieties were characterized by higher contents of fructose and glucose than orange 'Bolero', 'Nipomo', and 'Purple Haze' roots, which had higher contents of sucrose and lipids, except for signals from sterols. The super weights for blocks 1 and 3 (organic acids, aromatic and aliphatic compounds) were smaller than for blocks 2 and 4 mainly due to between-root variation in 'Purple Haze' and the discrimination of this variety from the other varieties (Figures 3 and 4A). This result shows that the NMR approach using consensus PCA could reveal both major and minor metabolic phenotypes and easily assign them to the most significant data blocks.

The discrimination between orange-colored varieties and the yellow and white varieties comprised the majority of the variation in the data. This variation resulted in characteristic metabolite compositions that could be modeled. 'Mello Yello' and 'White Satin' discriminated along PC2 (Figure 2A), and after inspection of their block scores and loadings, it was clear that this was due to higher contents of fumaric acid, malic acid, β-carotene, and several lipid components in 'Mello Yello' and higher contents of two unknown peaks, phospholipids and glutamine, in 'White Satin' (Figures 4A and 6). On the other hand, no discrimination in block 2 could be observed (Figure 4A). Likewise 'Bolero' could be discriminated from 'Nipomo'

dx.doi.org/10.1021/jf5014555 | J. Agric. Food Chem. 2014, 62, 4392−4398

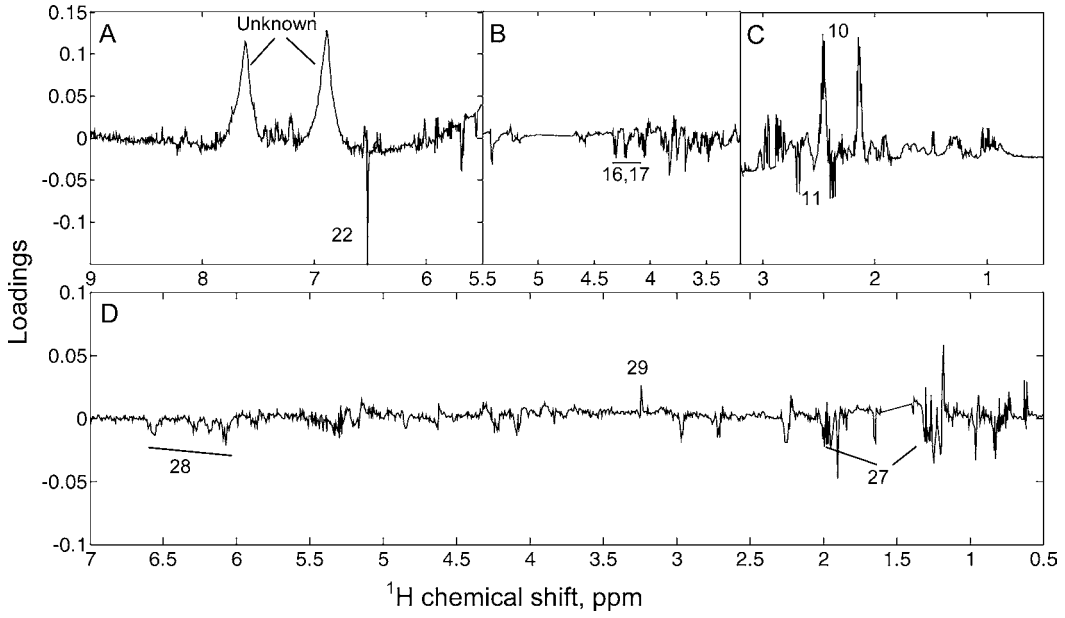

Figure 6. Block loadings for PC2 calculated on the basis of the consensus PCA for blocks 1−4. Peaks: 10, glutamine; 11, malic acid; 16, fructose; 17, sucrose; 22, fumaric acid; 27, fatty acid chain; 28, β-carotene; 29, phospholipids.

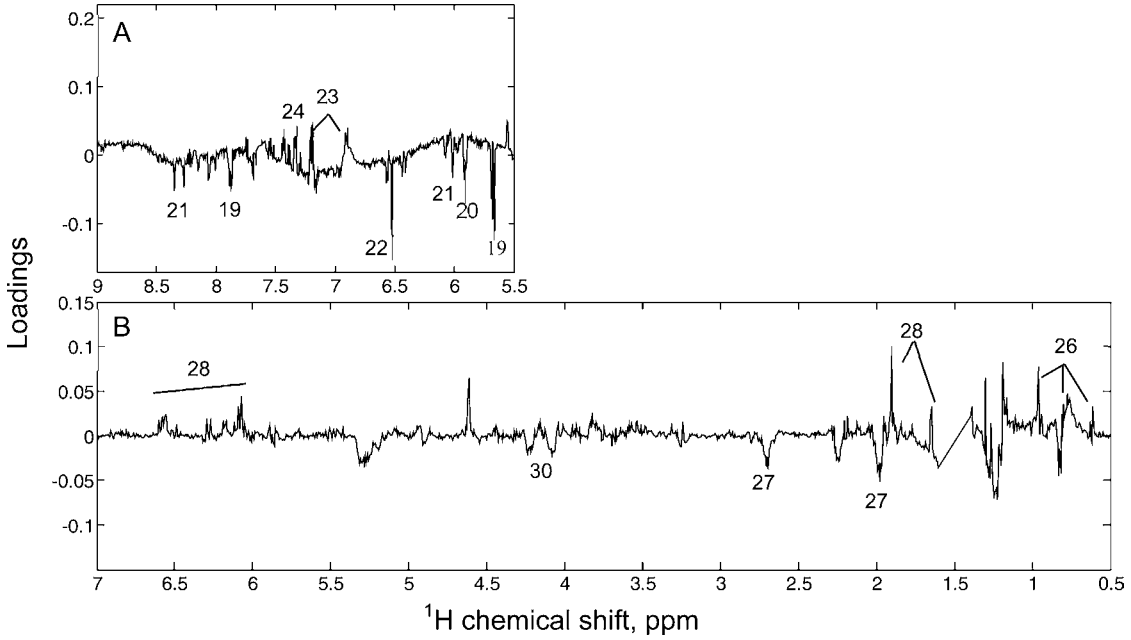

Figure 7. Block loadings for PC3 calculated on the basis of the consensus PCA. Only loadings from (A) block 1 and (B) block 4 are shown. Peaks: 19, uracil; 20, uridine; 21, β-adenosine; 22, fumaric acid; 23, tyrosine; 24, phenylalanine; 27, fatty acid chain; 28, β-carotene; 30, glycerol moiety triglycerides.

and 'Purple Haze' (blocks 1 and 3), and block 2 discriminated 'Purple Haze' from 'Bolero' and 'Nipomo'. Along PC3, Figure 2B shows a clear discrimination of 'Purple Haze' from 'Nipomo' and 'Bolero'. This separation was found in all block scores (Figure 4B). The super weights in Figure 3 clearly showed that block 1 (aromatic compounds) and block 4 (lipids) contributed most to this separation, and hence these two blocks were used for interpretation of PC3 (Figure 7). The loadings showed that 'Nipomo' and 'Bolero' were characterized by higher contents of β-carotene, sterols, fumaric acid, uridine, and β-adenosine, whereas 'Purple Haze' had higher contents of phenylalanine, tyrosine. and fatty acids, which was confirmed after integration of the corresponding peaks (data not shown).

The classifications of the carrot varieties from the carbohydrate (block 2) and lipid data (block 4) were remarkably alike (Figure 4A). This indicates that correlations between carbohydrates and lipids could exist for genetically different carrots. Hogstad et al.[2] reported a high correlation between sucrose and β-carotene in carrots grown in different years and soil types having variable supply of fertilizer. Pearson correlation analysis revealed a correlation coefficient of 0.91 between sucrose and β-carotene (Figure 8). The sucrose content was positively, and fructose and glucose contents were

dx.doi.org/10.1021/jf5014555 | J. Agric. Food Chem. 2014, 62, 4392−4398

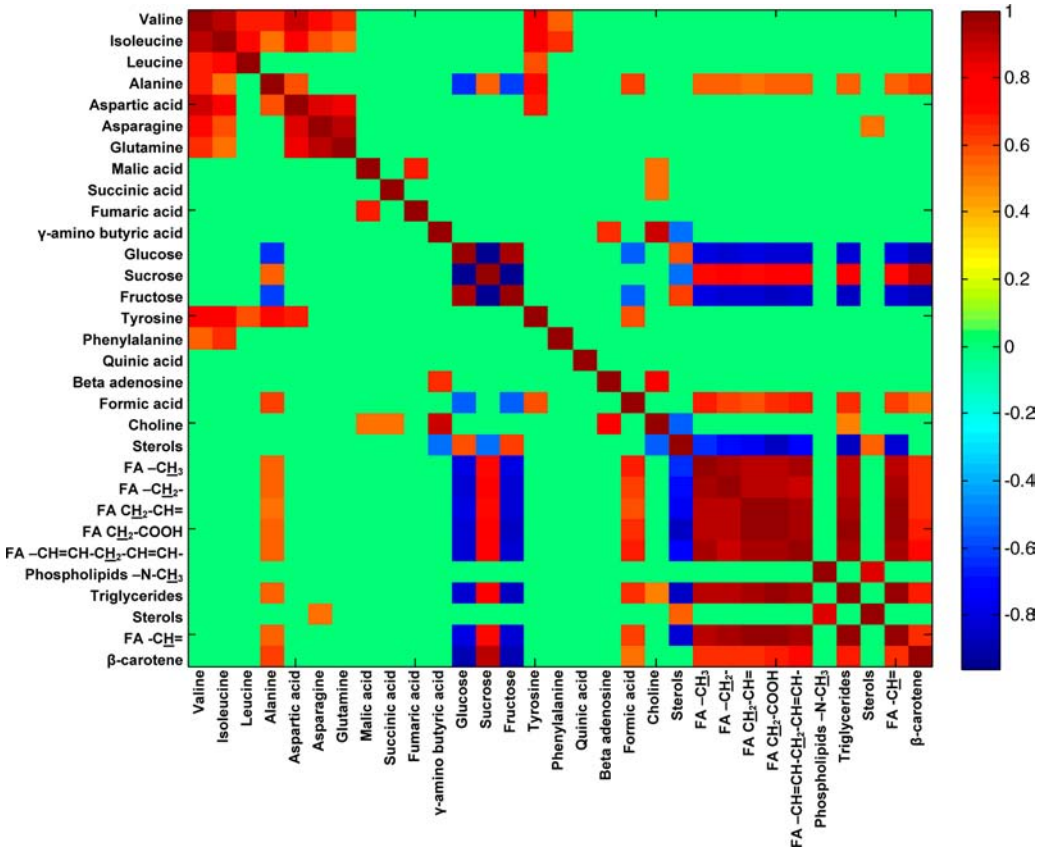

Figure 8. Pearson correlation coefficients between metabolites in carrots. Only correlations at $p \leq 0.01$ are shown. FA, fatty acid.

negatively, correlated with other metabolites in the lipid fraction (block 4), except for phospholipids and sterols, for which correlations were low and nonsignificant (Figure 8). Furthermore, the contents of most amino acids were correlated, and especially leucine/isoleucine and asparagine/glutamine were highly correlated. Many important aroma and flavor compounds are synthesized from compounds of the lipid metabolism or from degradation of lipids and amino acids.[33] Differences in these constituents may therefore be directly and/or indirectly responsible for variation in the sensory properties of carrots.

In conclusion, the present study revealed that ^{1}H NMR spectroscopy coupled with multiblock data analysis was an efficient and useful tool to map the carrot metabolome and identify compositional changes between varieties that could be determined by genetic differences, soil type, and growing strategy. The major differences were due to differences in the carbohydrate and β-carotene contents, where orange-colored varieties were characterized by relatively high contents of sucrose and β-carotene and relatively low contents of fructose and glucose. Minor differences, such as variations in the content of glutamine, fumaric acid, and malic acid, between the yellow ('Mello Yello') variety and the white ('White Satin') variety were also revealed. Consequently, because many precursors for aroma compounds were identified, the method could be used in addition to or to complement instrumental and sensory analysis of plant food products. Likewise, the methodology may find uses in studies of authenticity of plant food products and impact of terroir and growing system (e.g conventional and organic growing) as well as postharvest handling and storage on plant food quality to increase plant food quality and diversity on the market.

Supporting Information

ABSTRACT: Six commercial U.K. cultivars of winter wheat selected to represent different abilities to partition nitrogen into grain protein were grown in replicated field trials at five different sites over three seasons. The proportion of LMW glutenin subunits decreased and the proportion of gliadins increased during grain development and in response to N application. Differences were observed between the proportions of LMW glutenin subunits and gliadins in low- and high-protein grain, these two fractions being decreased and increased, respectively. There was little effect of grain protein content on the proportions of either the HMW glutenin subunits or large glutenin polymers, which are enriched in these subunits, with the latter increasing during development in all cultivars. The proportion of total protein present in polymers in the mature grain decreased with increasing N level. Correlations were also observed between the abundances of gliadin protein transcripts and the corresponding proteins.

KEYWORDS: *wheat, grain quality, grain protein, flour functionality*

INTRODUCTION

The relationship between fertilizer inputs and harvest outputs is of vital importance for all crops, particularly in the context of increasing pressure to reduce nitrogen usage. The availability of nitrogen in the environment has an effect on the protein content and composition of wheat, which in turn affects the processing properties. The application of nitrogen fertilizer is required to achieve the 13% dry weight protein specification for breadmaking wheat in the U.K. Such applications are costly and may have a negative environmental footprint. There is therefore a need to develop new varieties that are more efficient in their uptake and utilization of nitrogen. Several studies have identified differences in the nitrogen use efficiency of modern and older cultivars, including high-quality breadmaking cultivars such as Xi19, Hereward, and Malacca.[1] Furthermore, whereas an inverse correlation is generally observed between the yield and grain protein content of bread wheat,[2] some cultivars consistently accumulate higher protein contents than would be expected based on their yields. These have been defined as exhibiting grain protein deviation[3] and may provide a basis for the future development of wheat cultivars that require less nitrogen fertilization to achieve acceptable protein contents for breadmaking. However, protein content is only one factor affecting processing quality, with protein quality (composition) also being important. It is, therefore, important to understand the relationship between N nutrition, grain protein content, grain protein composition, and processing properties.

The relationships between genetically determined differences in gluten protein composition and grain processing properties are well established.[4,5] However, wheat grain quality is also known to be highly sensitive to environmental conditions, although the basis for these effects is poorly understood.[6] Unravelling the interactions between genotype, environment, and nutrition is essential to facilitate the development of new wheat varieties having high stability to environmental fluctuations and, in particular, to maintain quality across a range of nitrogen inputs.

This paper describes multisite trials of six wheat cultivars with different levels of nitrogen over three years, to investigate the content and composition of gluten storage proteins during development and at maturity (using SDS-PAGE and size exclusion HPLC). Furthermore, transcriptome profiling of the developing caryopses at 21 days post-anthesis allowed the gliadin protein accumulated to be related to the expression levels of the corresponding genes.

MATERIALS AND METHODS

Growth and Harvesting of Wheat. Five U.K. breadmaking wheat cultivars (Cordiale, Hereward, Malacca, Marksman, and Xi19) and one feed wheat cultivar (Istabraq) were grown in randomized block with three-blocks (replicated) field trials in 2009, 2010, and 2011 at five U.K. sites: Rothamsted Research (Harpenden, Hertfordshire), RAGT (Ickleton, Cambridgeshire), KWS (Thriplow, Cambridgeshire), Syngenta (Duxford, Cambridgeshire), and Limagrain (Woolpit, Bury St Edmunds, Suffolk). Nitrogen was applied at three levels (100, 200, and 350 kg/ha in total, split in up to three applications) before anthesis. Mature grain was sampled in all years. In 2009 and 2010 at Rothamsted, main stem ears were tagged at anthesis and whole

[a]The sites were Rothamsted Research (Harpenden, Hertfordshire), RAGT (Ickleton, Cambridgeshire), KWS (Thriplow, Cambridgeshire), Syngenta (Duxford, Cambridgeshire), and Limagrain (Woolpit, Bury St Edmunds, Suffolk). [b]Days post-anthesis. [c]Nitrogen SDS-PAGE data: three biological replicates, two technical replicates; SE-HPLC data: one biological replicate, one technical replicate. [d]M = maturity. [e]21 DPA samples for 200 kg N/ha only. [f]Gene expression data: three biological replicates, one technical replicate.

caryopses were harvested from the middle part of the ear at 21, 28, 35, and 42 days post-anthesis (DPA). In 2010 and 2011, caryopses were harvested at 21 DPA from the RAGT site.

Total Nitrogen Determination. Total nitrogen was determined in mature grain using the Dumas combustion method,[7] using a CNS (carbon, nitrogen, sulfur) combustion analyzer (Leco Corp., St. Paul, MN, USA).

SDS-PAGE. For sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), samples (35 mg) of wholemeal flour milled in a hand-operated grinder were extracted with 1 mL of 0.0625 M Tris-HCl, pH 6.8, 2% (w/v) sodium dodecyl sulfate (SDS), 1.5% (w/v) dithiothreitol, 10% (v/v) glycerol, and 0.002% (w/v) bromophenol blue. Gels (NuPAGE 12% Bis-Tris, Life Technologies, Paisley, UK) were stained with Coomassie brilliant blue and then scanned and analyzed using Total Lab TL120 version 2006F (Nonlinear Dynamics, Newcastle upon Tyne, UK) with an optical density curve calibrated using a Kodak T14 control scale (Tiffen, LLC, Rochester, NY, USA). Values for band optical density and band percent as a proportion of the total lane optical density were analyzed. Analysis was carried out for three biological replicates and two technical replicates of each gel that were run together on the same day and stained and destained together.

SE-HPLC. Size exclusion high-performance liquid chromatography (SE-HPLC) was used to determine the protein polymer size distribution of white flour samples milled using a Chopin CD 1 laboratory mill (Chopin Technologies, Villeneuve-la-Garenne Cedex, France). The analysis was performed according to the Profilblé method developed jointly by ARVALIS and l'Institut National de Recherche Agronomique.[8] Flour (160 mg) was mixed with 20 mL of 1% SDS (w/v) in 0.1 M phosphate buffer (pH 6.9), sonicated (Misonix Microson XL2000, Qsonica, LLC, Newtown, CT, USA) to solubilize the polymeric gluten proteins, and then centrifuged for 10 min at 4500*g*. An aliquot of the supernatant was sealed in a HPLC vial ready for analysis. SE-HPLC was conducted using a Jasco (Jasco Ltd, Great Dunmow, Essex, UK) system operating with a TSK gel G 4000SW column (30 cm × 7.5 mm) and a TSK gel SK guard column (7.5 cm × 7.5 mm). The flow rate was 0.7 mL/min, and detection was performed at 214 nm. Samples from the three biological replicates were pooled prior to analysis. The chromatograms were integrated using a combination of automated algorithms and manual rules developed as part of the Profilblé method. Peak ratios were calculated as reported by Millar (2003).[9]

RNA Extraction. Twenty-one DPA caryopses for RNA extraction were frozen at −80 °C until required. RNA was extracted using a method based on Chang et al. (1993).[10,11] About 1.5 g of whole caryopses was ground in a cooled mill, and RNA was extracted in CTAB buffer (2% CTAB, 2% PVP K30, 100 mM Tris-HCl, pH 8.0, 25 mM EDTA, 2.0 M NaCl, 0.5 g/L spermidine, 2% (w/v) 2-mercaptoethanol) with chloroform/isoamyl alcohol (24:1) to remove proteins. The RNA was precipitated by incubation with 10 M LiCl on ice overnight and then dissolved in SSTE buffer (1.0 M NaCl, 0.5% (w/v) SDS, 10 mM Tris HCl pH 8.0, 1 mM EDTA) to remove polysaccharides and extracted once with chloroform/isoamyl alcohol. After ethanol precipitation, total RNA was dissolved in DEPC-treated water and stored at −80 °C.

Gene Expression Profiling. Transcriptome profiling was performed using the Affymetrix GeneChip Wheat Genome Array and the standard one-cycle cDNA synthesis protocol and hybridization (as described in the GeneChip Expression Analysis Technical Manual) at the University of Bristol. Transcriptome data were analyzed using the GeneSpring version 11 (Agilent Technologies Inc., Santa Clara, CA, USA) package. The standard workflow was followed for two-factor experiments (nitrogen level, variety). Gene expression analysis was carried out for each of three biological replicates of whole caryopses harvested at 21 DPA from one site (Rothamsted Research) only, in 2009 and 2010.

Statistical Methods. Protein composition and gene expression data were determined for all six cultivars for each of different combinations of sites, years, time points, and N levels, as described in Table 1.

SDS-PAGE data were analyzed by residual maximum likelihood (REML) using GenStat (14th edition, VSN International Ltd, Hemel Hempstead, UK) to fit a linear mixed model consisting of random (design) and fixed (treatment) effects. The main effects and interactions between cultivar, N level, and time point factors formed the fixed part of the model. The effects of sites and years and further nested effects relating to blocking at the field (blocks and plots) and laboratory (gels and lanes within gels) stages were taken as design features, so that results for the combinations of cultivar, N level, and time point were effectively without issues of unequal representation across different sites and years. Data were subjected to $\log_e$ transformation to ensure a Normal distribution and homogeneity of variance. Comparisons of predicted means of statistical ($p < 0.05$, F-test) relevance from the model were made using estimated standard error of the difference values on the corresponding degrees of freedom, thus providing least significant difference (LSD) values at the 5% ($p = 0.05$) level of significance.

SE-HPLC data were transformed by using a $\log_e$-centering transformation[12] due to their compositional nature. To give an overall description and to afford a separation of the profiles of the samples in the absence of biological replication due to pooling, a multivariate method, principal coordinates analysis (PCO),[13] was applied.

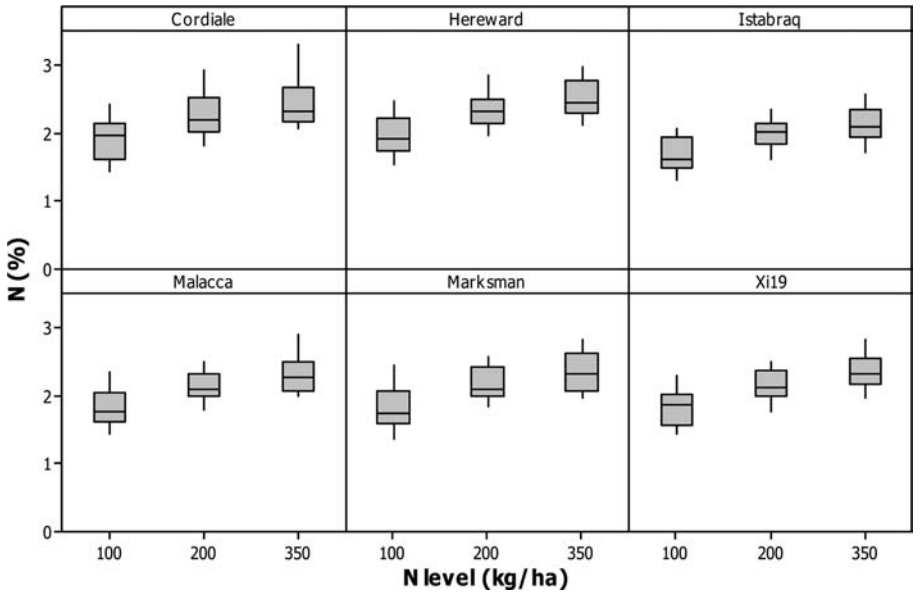

Figure 1. Box plots of the wholegrain N content (%) at maturity for each of six wheat cultivars grown at three different levels of N fertilization (100, 250, or 350 kg N/ha. Data displayed represent the distribution of means of samples collected over combinations of three years and five sites with three biological replicates (N = 594 in total, n = 11 per box plot).

Following regression analysis of the original variables on the two coordinate vectors (PCo1 and PCo2) retained, the variables were ranked, via the regression F-statistics, in order of the importance of their contribution to the principal coordinate vectors and therefore to any discrimination seen in the two dimensions. The means for the SE-HPLC data across combinations of years and sites were calculated to allow visualization of general trends over development, with standard error based on variation across years and sites.

Gene expression values were subjected to $\log_e$ transformation to ensure a Normal distribution and homogeneity of variance. The data were analyzed by REML using a model with the main effects and interaction between cultivar and N level as the treatment structure and with the field blocking (blocks and plots) nested within the two years (2009 and 2010) as the design structure.

Pearson correlations between gene expression data for the Rothamsted Research site at 21 DPA in the two years (2009 and 2010) and for all varieties and N levels, with the protein variables from either SDS-PAGE (with replication) or SE-HPLC (without replication), were calculated and tested for significance (F-tests).

RESULTS

Determination of Protein Content and Composition. The percentage N content of the wholegrain samples increased with increasing N fertilization for all varieties, from a mean of 1.83% (approximately 10.43% protein, conversion factor = 5.7) at 100 kg N/ha to 2.34% (approximately 13.34% protein) at 350 kg N/ha (Figure 1). Istabraq had the lowest protein content and Hereward the highest at all N-fertilization levels.

The content and composition of gluten proteins in the samples were determined using both SDS-PAGE and SE-HPLC.

SDS-PAGE Analysis. Quantitative gel scanning of SDS-PAGE separations of fractions extracted under reducing conditions was used to determine the proportions of bands corresponding to the major groups of gluten protein subunits: the HMW subunits of glutenin (HMW GS), LMW subunits of glutenin (LMW GS), and gliadins. Combining data from the SDS-PAGE analyses of samples from three years and five sites (with three biological and two technical replicates of each) showed broadly similar patterns for these protein groups for the six cultivars, but with some statistically significant (p < 0.05, LSD) differences (Figure 2).

The HMW GS (Figure 2A) accounted for between about 8% and 18% of the total gluten protein fraction, depending on the cultivar, stage of development, and N level (p = 0.001, F-test). Generally, the proportions of HMW GS were not strongly influenced by the N level. However, Marksman contained the highest proportion of HMW GS at all N levels and also showed a small overall increase in response to N. The LMW GS (Figure 2B and C) and gliadins (Figure 2D and E) were the major groups, accounting for between about 45% and 55% and between 30% and 40% of the total gluten protein fraction, respectively, at 21 DPA. These two fractions decreased or increased, respectively, as a proportion of the total protein during grain development.

The significance (p-values) of terms in the model fitted using REML are given in Table 2. For gliadins, the interactions between cultivar and time point and between N level and time point were significant (p < 0.001, F-test), but the interaction between cultivar and N level was not significant (p = 0.153, F-test), indicating that each cultivar responded in a similar way to increased N fertilization. During development the proportion of gliadins increased (means are presented in Figure 2D and E), with the increase being greater in Cordiale, Marksman, and Xi19 than in the other three cultivars. For all cultivars, there was a small increase between 28 and 35 DPA compared to rapid changes between 21 and 28 DPA (particularly at 200 kg N/ha) and between 35 and 42 DPA. Malacca contained the lowest proportion of gliadins throughout development and at maturity. The proportion of gliadins was lowest at the lowest N level, with little difference between the proportions at 200 and 350 kg N/ha.

The changes observed for LMW GS were the inverse of those observed for the gliadins, which is to be expected, as these two groups together accounted for over 80% of the total fraction. Thus, the interactions between cultivar and time point and between N level and time point were significant (p < 0.001, F-test), but the interaction between cultivar and N level was not

dx.doi.org/10.1021/jf500625c | J. Agric. Food Chem. 2014, 62, 4399−4407

significant (p = 0.532, F-test). A rapid decrease occurred between 21 and 28 DPA followed by little change between 28 and 35 DPA and a further rapid decrease between 35 and 42 DPA (Figure 2B). Also, Malacca contained a much higher proportion of LMW GS compared to the other cultivars. Finally, the proportion of LMW GS was highest at the lowest N level with little difference between the 200 and 350 kg N/ha levels (Figure 2C).

Consistent differences across years and sites (data not shown) were observed between Cordiale and Marksman (high proportions of HMW GS and low proportions of LMW GS) and Malacca (high LMW GS and low gliadins).

SE-HPLC Analysis. SE-HPLC was used to separate the total grain proteins (monomers and polymers) based on their size distribution, without reduction of disulfide bonds, with five peaks being recognized.[8] The first peak to elute from the column is referred to as F1 and consists of HMW polymers enriched in HMW GS, while the F2 peak comprises LMW polymers and is enriched with LMW GS. The F3 and F4 peaks are composed principally of ω-gliadins and α-, β-, and γ-gliadins, respectively, and the F5 peak comprises LMW proteins including albumins and globulins. The total area under the trace is a measure of the total protein content of the flour and is termed AT.

The SE-HPLC data were analyzed by principal coordinates analysis. The first two PCos accounted for 86.03% (63.82 and 22.21% for PCo1 and PCo2, respectively) of the variation in the distance matrix formed from the similarities between samples, so these two were retained and the data are visualized in Figure 3, with developing and mature samples highlighted in Figure 3A and N treatments highlighted in Figure 3B. The F-statistics resulting from relating the two PCos to the variables are shown in Table 3.

F1 was most important for the separation on the PCo1 axis, followed, to a lesser extent, by F2, F3, and F5, with the mature samples being clearly separated from the immature samples (Figure 3A). F4 and total gluten protein (F1+F2+F3+F4) were important for separation on the PCo2 axis, with the coordinate generally increasing with N level for each year by site by cultivar combination (Figure 3B).

Figure 4 shows changes in the proportions of polymeric gluten proteins, calculated as F1+F2 divided by F3+F4. At all N levels and for all varieties the proportion increased as the grain developed until 28 DPA, followed by a decrease between 28 and 35 DPA and a final increase between 35 DPA and maturity. Istabraq generally had the lowest proportion of polymeric gluten proteins and Hereward the highest. The proportion of polymeric proteins decreased with increasing N level at maturity.

The protein composition also differed between varieties, and these differences were consistent across sites and years (data not shown). Averaging over the site by year combinations, Istabraq had the lowest proportion of the F1 fraction (12.2–12.5% at maturity), while the highest proportion of the F2 fraction and the lowest proportion of the F5 fraction were in Malacca (F2: 25.4–25.5%; F5: 35.7–38.5% at maturity) and Hereward (F2: 25.4–25.9%; F5: 36.4–39.3% at maturity). The lowest proportion of the F3 fraction was in Cordiale (7.1–7.5% at maturity) and Xi19 (7.1–7.4% at maturity).

Gene Expression. A total of 55 probe sets on the arrays were identifiable as corresponding to gluten protein transcripts. However, because the gluten proteins showed high polymorphism both within and between cultivars, not all of the probe sets corresponded to genes present within each cultivar. For example, six probe sets corresponded to HMW GS, for genes encoding HMW GS 1Dx3, 1Dx5, 1Bx7, 1Bx14, 1By9, and 1By16, while the HMW subunits expressed in the six cultivars are 1Ax1, 1Bx14, 1By15, 1Dx5, and 1Dy10 in Marksman, 1Bx7, 1By9, 1Dx3, and 1Dy12 in Hereward, 1Ax1, 1Bx17, 1By18, 1Dx5, and 1Dy10 in Cordiale, 1Bx17, 1By18, 1Dx2, and 1Dy12 in Malacca, 1Bx14, 1By15, 1Dx5, and 1Dy10 in Xi19, and 1Bx7, 1By9, 1Dx2, and 1Dy12 in Istabraq (Supplementary Figure S1). Similarly, a high degree of sequence identity within other families of gluten proteins would be expected to have resulted in cross-hybridization with related transcripts. Therefore, Figure 5 shows the mean expression profiles of individual transcripts related to HMW GS (six elements), LMW GS (nine elements), and gliadins (40 elements).

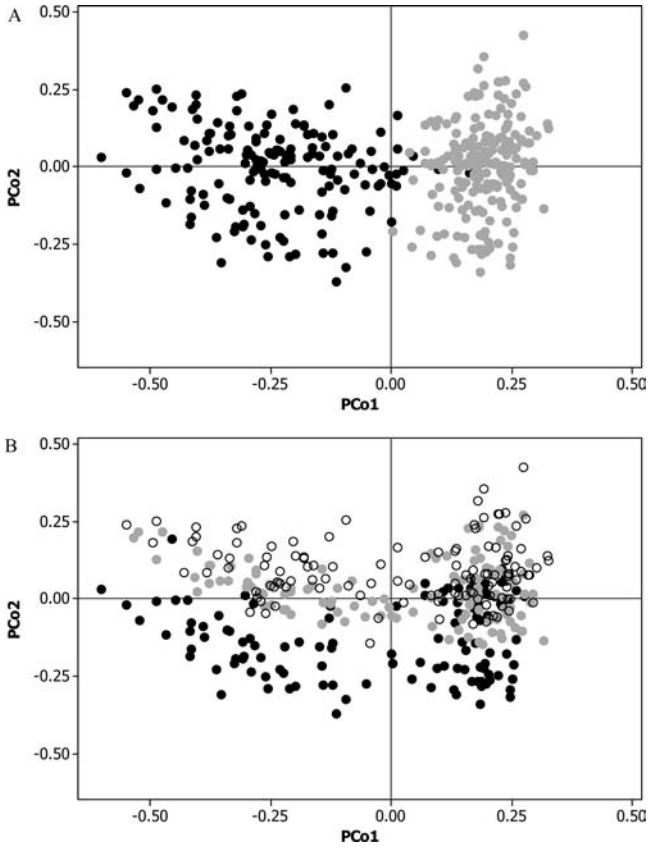

Figure 3. Coordinates for each sample determined by SE-HPLC for the first two PCos (explaining 63.82% and 22.21% of the variation in the distance matrix, respectively) showing the separation of samples according to time point (A; black = immature, gray = mature) or N level (B; black = 100 kg N/ha, gray = 200 kg N/ha, white = 350 kg N/ha).

Table 3. F Statistics from Relating the Two PCos to the ($\log_e$-Transformed) SE-HPLC Variables

variable	PCo1	PCo2
F1	3050.7	1.4
F2	1475.0	0.8
F3	1468.6	37.6
F4	9.0	979.2
F5	1065.5	80.7
gluten protein (F1+F2+F3+F4)	16.4	858.1

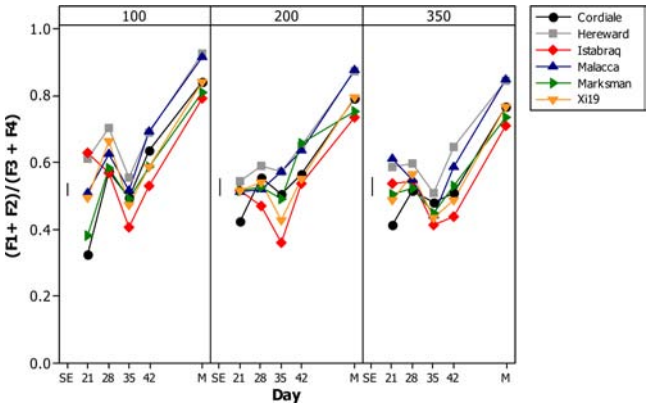

Figure 4. Ratio of polymeric (F1+F2) to monomeric (F3+F4) protein analyzed by SE-HPLC for six wheat cultivars and three levels of N fertilization (100, 200, or 350 kg N/ha). Data are means across year and site combinations. As the data are not replicated, the SEMs are based solely on the variation across years and sites (N = 354 in total, n = 11 per mean). The average SEM is shown as a vertical bar for convenience.

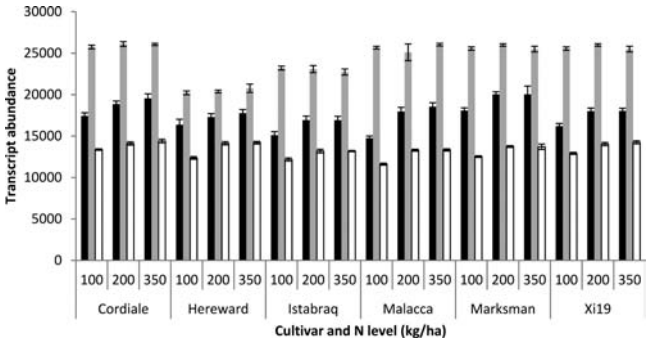

Figure 5. Gene expression values for the mean of all HMW GS (black)-, LMW GS (gray)-, and gliadin (white)-related genes for six wheat cultivars grown at one site (Rothamsted Research) only. Data are from microarray analysis and represent means of samples collected over two years with three biological replicates (N = 108 in total, n = 6 per mean). Error bars represent standard error. See Supporting Information for tables of means for statistical comparison using relevant LSD (5%) values for data on the $\log_e$-transformed scale.

The significance levels (p-values) of the main effects and the interactions between the two factors cultivar and N level are shown in Table 4 (after accounting for sources of design variation). There were independent effects of N level and cultivar (p < 0.001, F-test) for gene expression corresponding to HMW GS, which differs from the SDS-PAGE results for HMW GS, where the cultivar by N level interaction was significant. The relative levels of hybridization to the probe sets suggested that Marksman had the highest level of gene expression, but did not differ significantly (p < 0.05, LSD) from Cordiale (Supplementary Table S1). The other four cultivars appeared to have somewhat lower levels of gene expression, with Istabraq having the lowest. A trend of increasing HMW GS gene expression with increasing N was seen (Supplementary Table S1).

For LMW GS gene expression, only the main effect of cultivar was significant (p < 0.001, F-test). Cordiale, Malacca, Marksman, and Xi19 showed the highest level of LMW GS gene expression and were not significantly (p < 0.05, LSD) different from one another, while Hereward had by far the lowest level (Supplementary Table S2). There was a significant variety by N interaction (p = 0.022, F-test) for gliadin gene expression, which appeared to be lowest for Istabraq and Malacca (Supplementary Table S3). However, the validity of comparisons between cultivars can be questioned, as they may differ in the extent to which the gluten protein genes present correspond to the sequences present in the probe sets. This would result in stronger hybridization signals, indicating greater gene expression.

By contrast, comparisons of hybridization intensity within cultivars are valid, and these all showed significant increases in gene expression with increasing N. For gliadin-related gene expression, Cordiale appeared to display a more linear response with respect to increasing N than the other varieties, having the greatest hybridization intensity of all of the cultivars at 100 kg N/ha. Cordiale was also the only cultivar that showed a marked increase in gliadin gene expression between 200 and 350 kg N/ha (Supplementary Table S3).

Correlation of Gene Expression Data with Protein Composition. The proportions of gliadins measured by SDS-PAGE were significantly correlated with the corresponding data for average gliadin-related gene expression in both 2009 (r = 0.335, p = 0.013, n = 54, F-test) and 2010 (r = 0.372, p = 0.006, n = 54, F-test) (Figure 6A). In particular, the proportions of gliadin proteins and the gene expression were lowest at 100 kg N/ha, with the 200 and 350 kg N/ha samples having higher proportions of gliadin protein but more variable gliadin gene expression. Similarly, gliadin gene expression was positively correlated with the proportion of gliadin proteins measured by SE-HPLC (F4 fraction) (2009: r = 0.641, p = 0.004, n = 18, F-test; 2010: r = 0.768, p < 0.001, n = 18, F-test) (Figure 6B). No significant (p < 0.05, F-test) correlations were observed between glutenin subunit (HMW or LMW) gene expression and the proportions of the proteins determined by SDS-PAGE, but HMW subunit gene expression showed a negative correlation with the proportion of large glutenin polymers determined by SE-HPLC (Figure 6C) (2009: r = −0.387, p = 0.112, n = 18, F-test; 2010: r = −0.637, p = 0.004, n = 18, F-test), presumably because this smaller fraction, when expressed as a percentage of AT, is diluted by the increasing amounts of F4.

Table 4. Significance (F-Statistics and p-Values) of the Main Effects and Interactions between the Two Factors Cultivar and N Level for $\log_e$ Gene Expression Analysis

	source					
	HMW GS		LMW GS		gliadins

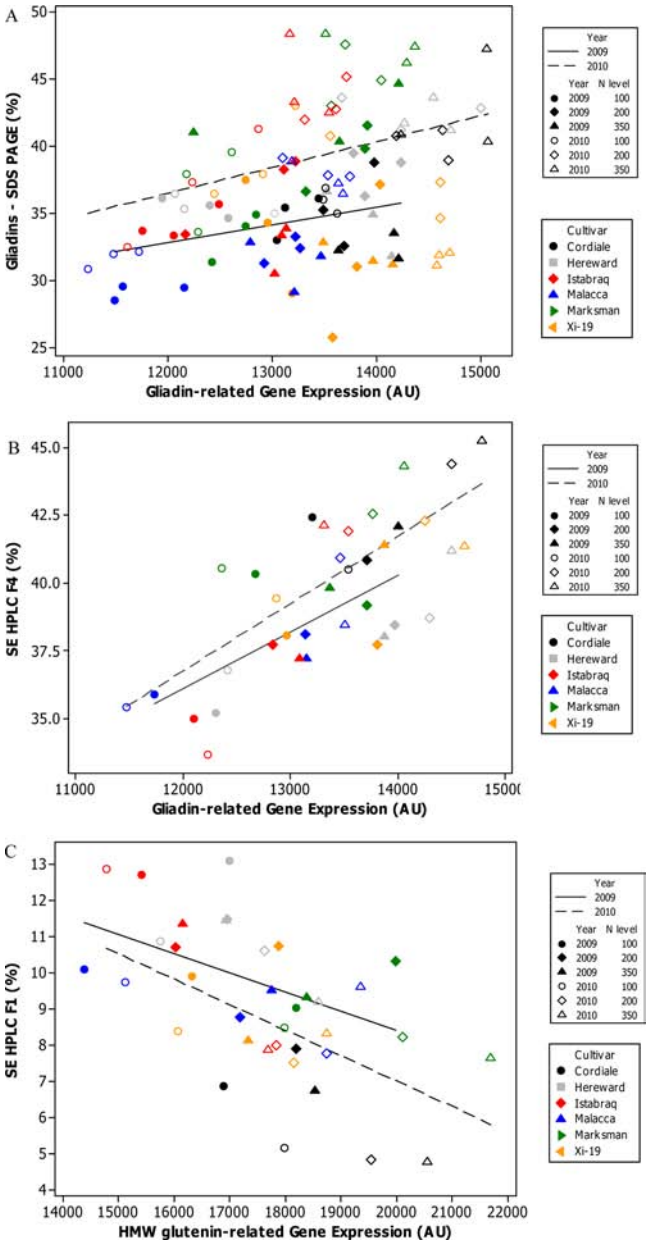

Figure 6. Correlations between gene expression values and protein contents determined by SDS-PAGE and SE-HPLC. (A) Gliadin gene expression and % gliadin proteins determined by SDS-PAGE (2009: $r = 0.335$, $p = 0.013$, $n = 54$; 2010: $r = 0.372$, $p = 0.006$, $n = 54$; for data on $\log_e$ scale). (B) Gliadin gene expression and monomeric gliadin proteins determined by SE-HPLC (F4 fraction) (2009: $r = 0.641$, $p = 0.004$, $n = 18$; 2010: $r = 0.768$, $p < 0.001$, $n = 18$; for data on $\log_e$ scale). (C) HMW subunit gene expression and large glutenin polymers (F1 fraction) measured by SE-HPLC (2009: $r = -0.387$, $p = 0.112$, $n = 18$; 2010: $r = -0.637$, $p = 0.004$, $n = 18$; for data on $\log_e$ scale). Data are for six cultivars grown at Rothamsted Research in 2009 and 2010 with three biological replicates, analyzed at 21 DPA for gene expression profiles and at maturity for protein composition.

DISCUSSION

A combination of transcriptomics and protein analysis was used to identify differences between varieties in terms of their ability to partition N into gluten proteins in response to increased N inputs. This showed a consistent and robust inverse relationship between wheat grain yield and grain %N, which is consistent with previous studies.[3,14] Although grain protein deviation (GPD) was not consistent between the two years, Marksman, Hereward, and Cordiale all tended to show positive GPD. However, both 2010 and 2011 were drier than average, particularly during the spring, which was reflected by a negative impact on N responses (on yield and/or grain N).

The relationships between genetically determined differences in gluten protein composition and grain processing properties are well established.[4,5] The most consistent effect of increased N observed in the present study was increased synthesis and accumulation of gliadins, whether determined as % gluten protein subunits by SDS-PAGE, as monomeric gluten proteins by SE-HPLC, or by gene transcript profiling. Previous studies have shown that increases in grain N result in increases in the proportions of the monomeric gliadins,[15−21] leading to increased dough extensibility. However, Pechanek et al. (1997)[22] showed that the effect of N on grain protein composition was not consistent, but varied between varieties. Our results support this conclusion, as clear statistically significant differences were observed between the six cultivars that were studied.

Less is known about the effects of nutrition on the glutenin fraction, either on the proportions of the individual subunits or on the size distribution of the glutenin polymers. Thus, both increases[23] and decreases[22] in the proportions of HMW subunits have been reported in response to N application, while Panozzo and Eagles (2000)[17] and Zhu and Khan (2001)[19] showed differential effects of N on glutenin polymers and processing properties in cultivars with different HMW subunit alleles. Our results showed that increasing grain N resulted in decreases in the % LMW GS but little effect on the % HMW GS in all cultivars, but that the absolute values and temporal patterns during development varied between the cultivars. Although these did not differ consistently between the five breadmaking cultivars and the single feed quality cultivar (Istabraq), the latter did have the lowest proportion of high molecular weight glutenin polymers (%F1 by SE-HPLC), which are known to be positively correlated with high dough strength.[24,25]

It has previously been shown that glutenin polymers increase significantly in size during the desiccation phase of seed development,[20,26,27] and the results from our study support this. Differential effects on this process could provide a mechanism for effects of the environment during the later stages of grain maturation on grain quality, but would not explain effects of the environment at earlier stages of grain development. In the present study a similar increase in gluten polymers was observed in all six wheat cultivars, with no significant difference between Hereward (which is favored by millers and bakers because it is more stable in quality between seasons), Istabraq (the feed cultivar), and the other four breadmaking wheat cultivars. Environmental effects on grain protein composition and quality that are not related to N content have also been reported by Kolster et al. (1991).[28]

In order to ensure relevance to commercial wheat production and utilization, we focused on field-grown samples of six cultivars of wheat, using material from combinations of five sites and three years (totaling 11 different environments) and three biological replicates. All cultivars showed similar trends in the relationship between N application and protein composition, but statistically significant differences were observed between the cultivars in terms of their varying trends in composition over development time. Although our data suggest that genetic differences in N utilization exist between cultivars,

dx.doi.org/10.1021/jf500625c | J. Agric. Food Chem. 2014, 62, 4399−4407

it is clear that larger scale studies are required, with more cultivar × site × year × N combinations, in order to identify and exploit genotypes that make more efficient use of applied N, in terms of efficiency of translocation to the grain and incorporation into quality-related proteins.

Characterization and Quantitation of Anthocyanins and Other Phenolics in Native Andean Potatoes

M. Monica Giusti,*[,†] Maria Fernanda Polit,[†] Huseyin Ayvaz,[†] David Tay,[‡] and Ivan Manrique[‡]

[†]Department of Food Science and Technology, The Ohio State University, 110 Parker Food Science and Technology Building, 2015 Fyffe Road, Columbus, Ohio 43210, United States

[‡]International Potato Center, Avenida La Molina 1895, La Molina Apartado Postal 1558, Lima, Peru

ABSTRACT: Andean potatoes are gaining popularity not only for their appealing colors and culinary uses but also for their potential higher content of polyphenolic compounds. The objective of this study was to identify potato varieties with increased phenolic content. This was achieved through characterization and quantitation of the phenolic composition in 20 varieties of native Andean potatoes from 4 different *Solanum* species with different colors. Major quantitative and qualitative differences among evaluated samples were more dependent on the coloration of the extracted sample rather than on the species. The most predominant anthocyanidins were petunidin-3-coumaroylrutinoside-5-glucoside and pelargonidin-3-coumaroylrutinoside-5-glucoside in purple and red potato extracts, respectively, while chlorogenic acid and its isomers were the main phenolic compund (43% of the total phenolic content). Our study suggested that the appropriate selection of native potatoes could provide new sources of polyphenolics with health promoting properties and natural pigments with increased stability for food applications.

KEYWORDS: *Andean tubers, potato, anthocyanins, polyphenols, chlorogenic acid*

INTRODUCTION

Potato is the fifth most produced crop worldwide after sugar cane, maize, wheat and rice with a production of >368 million tons in 2012.[1] Potatoes are a good source of dietary energy, carbohydrates, fiber, vitamin C, vitamin B1, niacin, vitamin B6 and minerals such as potassium, phosphorus and magnesium.[2] Besides basic nutrients, potatoes also provide a good source of phenolic compounds.

Correlation between ingesting phenolic compounds and improved health has been shown in epidemiological studies.[3−6] Phenolic compounds were shown to have antioxidant activity and other characteristics that could promote health. Among phenolics, anthocyanins are of special interest not only due to their health benefits but also due to their possible utilization as natural food pigments.[7,8]

The Andes are home to a great diversity of native potato species which have been traditionally consumed and solely grown in the Andes region by locals. Native Andean potato tubers show a wide variability in tuber shape, flesh and skin color, texture and flavor. This genetic diversity also generates substantial variability in nutritional contents.[2,9] However, very little is known about the chemical nature and identity of the bioactive compounds present in native Andean potatoes.[9]

The present study was designated to evaluate and characterize polyphenolics and anthocyanin content in native Andean potato varieties. This fits into a long-term objective of enhancing nutrition through diet and delivering health-enhancing components through stable crop commodities. For this study, the objective was to monitor and compare the phenolic content and profile of 20 different native Andean potato varieties from different species, which exhibited a variety of colors. The study included the measurement of the total phenolic, monomeric and polymeric anthocyanin content as well as the qualitative characterization of the anthocyanins and nonanthocyanin phenolics fraction. The hypothesis was that among the wide variety of native Andean potatoes, there are some that could represent important sources of phenolic components and could increase consumption of phytochemicals and antioxidants in the human diet.

MATERIALS AND METHODS

Chemicals. Reagent grade trifluoroacetic acid (TFA), certified ACS grade HCl (12N), LC−MS grade 99.9% methanol, 99.9% acetonitrile and water, certified ACS grade ethyl acetate and potassium hydroxide, HPLC grade 88% formic acid, 99.9% acetone and 99.9% chloroform were purchased from Fisher Scientific (Fair Lawn, NJ). Chlorogenic acid, caffeic acid, ferulic acid, *p*-coumaric acid and protocatechuic acid standards, reagent grade gallic acid, and Folin-Ciocalteau reagent were purchased from MP Biomedical (Aurora, OH). Sinapic acid standard (98%) was purchased from Sigma-Aldrich (St. Louis, MO). Chlorogenic acid isomers were prepared as described by Nagels.[10] Anthocyanidin standards were prepared from the acid hydrolysis of strawberries and grapes as described by Wrolstad and others.[11]

Plant Materials. A total of 20 samples (Table 1) of different colors (cream, yellow, brown, pink, red and purple) and species (*S. tuberosum*, *S. stenotonum*, *S. phureja* and *S. chaucha*) were used in this study. Potatoes were harvested by the International Potato Center (CIP), lyophilized and powdered with skin before shipping. Depending on the availability of the samples, between 150 and 500 g potato tubers were washed and cut into 1 cm^3 cubes. Cubes were then mixed and a random 100 g was weighed and placed in a polyethylene bag. Samples were immediately frozen at −20 °C and kept frozen until liophilized. Following the liophilization, native Andean potato samples

were shipped by the CIP to our laboratory. Samples were kept under dark and at −40 °C until analysis. Lyophilization with skin caused the presence of skin pieces irregularly distributed in the sample. In some of the samples, skin had darker colors and highly contributed to the sample pigment content. During the weighing step, samples were taken from different parts of the containers to have a final representative sample as homogeneous as possible.

Extraction of Anthocyanins and Other Phenolics from Potato Samples. Lyophilized potato powder (~3 g) was blended with 45 mL of acidified aqueous acetone (20:80 v/v acidified with 0.1% HCL and 0.2% TFA) for 5 min with a tissuemiser homogenizer (Fisher Scientific, Fair Lawn, NJ) over a water/ice bath to reduce enzymatic activity. The mixture was centrifuged for 5 min at 3400 g (Centrific centrifuge Model 225; Fisher Scientific, Fair Lawn, NJ) and the supernatant was filtered through a Whatman #1 filter by vacuum suction using a Buchner funnel. The residual cake was reextracted with 25 mL of aqueous acetone (20:80 v/v acidified with 0.1% HCL and 0.2% TFA). Filtrates were combined and transferred to a separatory funnel and gently mixed with 2 volumes of chloroform. Samples were stored at 4 °C for 4 h in the dark. The aqueous phase (top layer) was separated and centrifuged for 7 min (3400 g). The aqueous supernatant was recovered and residual acetone/chloroform was removed using a Büchii Rotavapor (New Castle, DE) at 40 °C under vacuum. The remaining aqueous potato extract was then taken to 5 mL on a volumetric flask with acidified water (0.01% HCl). Extraction was done in triplicate for each sample.

Solid Phase Purification of Phenolic Fraction. The aqueous potato extract was purified using a Sep-pak C_{18} Vac solid cartridge (6 cm^3, 1 g sorbent; Waters Corp., Milford, MA). The C_{18} cartridge was activated with 10 mL of methanol and washed with 10 mL of acidified water (0.01% HCl). Potato extract (1 mL) was passed through the cartridge, anthocyanins and other phenolics were bound to the C_{18} cartridge; sugars and other polar compounds were removed with 10 mL of acidified water (0.01% HCl). The phenolic fraction was eluted with 10 mL of acidified methanol (0.01% HCl). The procedure was performed twice for every sample. Methanol was removed in a Büchii rotary evaporator at 40 °C under vacuum and the phenolic fraction was taken to 5 mL on a volumetric flask with acidified water (0.01% HCl). Purified phenolic extract was filtered (0.45 μm Whatman polypropylene filter) for further HPLC analysis.

Saponification of Anthocyanins. Aqueous potato extracts (1 mL) were saponified in a screw-cap test tube with 10 mL of 20% aqueous KOH for 10 min at room temperature in the dark as described by Durst and Wrolstad.[12] The solution was neutralized with the addition of 4 N HCl until a red color was seen and applied to an activated Sep-pak C_{18} Vac solid cartridge. Column was rinsed with 10 mL of acidified water (0.01% HCl) and liberated acid groups were removed with 10 mL of ethyl acetate. Saponified anthocyanin fraction was eluted with acidified methanol (0.01% HCl) and rotoevaporated at 40 °C under vacuum. The saponified fraction was taken to 5 mL on a volumetric flask with acidified water and filtered (0.45 μm Whatman polypropylene filter) for further HPLC analysis.

Acid Hydrolysis of Anthocyanins. Saponified anthocyanin extracts (3 mL) were hydrolyzed with 10 mL of 4 N HCl in a screw-cap test tube. The test tube was flushed with nitrogen gas, sealed and placed in a boiling water bath for 60 min in the dark and then cooled in an ice bath.[7] The solution was applied to an activated Sep-pak C_{18} Vac solid cartridge. The column was rinsed with 10 mL of acidified water (0.01% HCl) and the hydrolyzed anthocyanidin fraction was collected with acidified methanol (0.01% HCl) and rotoevaporated at 40 °C under vacuum. The hydrolyzed anthocyanidin fraction was taken to 2 mL on a volumetric flask with acidified water and filtered (0.45 μm Whatman polypropylene filter) for immediate HPLC analysis.

Monomeric and Polymeric Anthocyanin Content. Monomeric anthocyanin content was determined using the pH differential method as described by Giusti and Wrolstad.[13] Each aqueous potato extract was appropriately diluted using pH 1.0 and pH 4.5 (0.4 M sodium acetate) buffers. Solutions were allowed to equilibrate for 15 min in the dark. Absorbance was read on 1 cm path length disposable cuvettes at 510 nm (for red potato extracts) or 520 nm (for purple potato extracts) and 700 nm using a UV−visible Spectrophotometer 2450 (Shimadzu Scientific Instruments, Inc., Columbia, MD). Monomeric anthocyanin content (MAC) (mg/L) was calculated using the equation given by Giusti and Wrolstad.[13] Analyses were performed for each extraction replication (n = 3).

Polymeric anthocyanin content was also determined using the method described by Giusti and Wrolstad.[13] Using the dilution factors previously determined, an aliquote (1.85 mL) of diluted sample in acidified water (0.01% HCl) was prepared in each of two cuvettes (1 cm path length); then 0.15 mL of water was added to one of the cuvettes and 0.15 mL of potassium metabisulfate solution to the other and allowed to equilibrate for 15 min before reading at 420, 510 nm (for red potato extracts) or 520 nm (for purple potato extracts) and 700 nm using a UV−visible spectrophotometer 2450 (Shimadzu Scientific Instruments, Inc., Columbia, MD). Polymeric anthocyanin content was calculated using the equations given by Giusti and Wrolstad.[13] Analyses were performed for each extraction replication (n = 3).

Total Phenolics Quantitation. Total phenolics were measured using the microscale protocol for Folin-Ciocalteau colorimetry as described by Waterhouse.[14] Aliquotes (20 μL) of aqueous potato extract, a gallic acid calibration standard and a water blank were placed into separate 1 cm path length (2 mL) plastic cuvettes. Then 1.58 mL

Table 2. Monomeric and Polymeric Anthocyanin and Total Phenolic Content in Potato Extracts[a]

[a] Section I: purple potato extracts (monomeric anthocyanin expressed as mg of cy-3-glu equivalents/100 g DW). Section II: red potato extracts (monomeric anthocyanin expressed as pg-3-glu equivalents/100 g DW). Section III: yellow potato extracts (Total phenolic content is expressed as mg of gallic acid equivalents (GAE) per 100 g of DW). Data are means ± SE (n = 3).

of water was added to each cuvette, followed by 100 μL of Folin-Ciocalteu reagent thoroughly mixed and incubated for 7 min. After incubation, 300 μL of sodium carbonate solution was added, mixed and allowed to incubate for 2 h at room temperature. Absorbance of samples, standards and blanks at 765 nm were measured on a UV−visible spectrophotometer 2450 (Shimadzu Scientific Instruments, Inc., Columbia, MD). Absorbance of the blank was subtracted from all readings and a calibration curve was created from the standards. Total phenolic content was calculated as gallic acid equivalents (GAE) based on the gallic acid calibration curve.

HPLC−MS Characterization of Samples. Samples were analyzed using a Shimadzu LCMS-2010 EV Liquid Chromatograph Mass Spectrometer (Shimadzu Scientific Instruments, Inc., Columbia, MD) equipped with LC-20AD pumps and SIL-20AC autosampler coupled with a SPDM20A photodiode array (PDA) detector and a single quadrupole electron spray ionization (ESI) mass spectrometer (MS) detector. Data was analyzed and processed using the LCMS Solutions software (Version 3, Shimadzu Scientific Instruments, Inc., Columbia, MD). Separation of anthocyanins and other phenolics in red extracts was achieved on a reverse phase Symmetry C_{18} column (3.5 um, 4.6 × 150 mm^2; Waters Corp., Milford, MA) and a Symmetry 2 micro guard column (4.6 × 22 mm^2; Waters Corp., Milford, MA). Chromatographic conditions were as follows: flow rate, 0.8 mL/min; mobile phase A, 4.5% formic acid in LCMS grade water; mobile phase B, LC−MS grade acetonitrile; gradient 0−5 min, 5% B; 5−20 min, 5−15% B; 20−30 min, 15% B; 30−40 min, 15−20% B; 40−45 min, 20−30% B; 45−48 min, 30−5% B and after each run 5 min was given to equilibrate the column to initial condition; injection volume varied according to the sample and ranged from 60 to 120 μL. Spectral data (250−700 nm) was collected during the whole run. Elution of total phenolics was monitored at wavelength 280 nm, cinnamic acids at 320 nm and anthocyanins at 510−520 nm.

Separation of anthocyanins and other phenolics in purple extracts was achieved using the following chromatographic conditions: flow rate: 0.8 mL/min; mobile phase: A, 10% formic acid in LCMS grade water; B, LC−MS grade acetonitrile; gradient: 0−5 min, 5% B; 5−16 min, 5- 13% B; 16−26 min, 13% B; 26−40 min, 13−20% B; 40−45 min, 20−30% B; 45−48 min, 30−5% B and after each run 5 min was given to equilibrate the column to initial condition; injection volume varied according to the sample and ranged from 60 to 120 μL. Spectral data (250−700 nm) was collected during the whole run. Elution of anthocyanins was monitored at wavelength 510−520 nm. Separation of anthocyanidins in hydrolyzed samples was achieved using the following chromatographic conditions: flow rate, 0.8 mL/min; mobile phase A, 4.5% formic acid in LC−MS grade water; mobile phase B, LC−MS grade acetonitrile; gradient 0−30 min, 5−35% B; 30−35 min, 35% B; 35−38 min, 35−5% B; 38−41 min, 5% B; injection volume: 120 μL. Spectral data (250−700 nm) was collected during the whole run. Elution of anthocyanins was monitored at wavelength 510−520 nm.

A 0.2 mL/min flow was diverted to the MS. Mass spectra were obtained under positive ion condition using total ion scan (SCAN) (from m/z 150 to 1300) and selective ion monitoring (SIM) modes. Eight channels including m/z 181 (caffeic acid), m/z 271 (pelargonidin), m/z 287 (cyanidin), m/z 301 (peonidin), m/z 303 (delphinidin), m/z 317 (petunidin), m/z 331 (malvidin) and m/z 355 (chlorogenic acid), were monitored in the SIM mode to detect the 6 common anthocyanin aglycone fragments and two common phenolic acids.

RESULTS AND DISCUSSION

Sample Characteristics. Detailed information about the species used in the study including water activity (aw) values of the lyophilized samples measured prior to sample extraction is shown in Table 1. All samples had aw lower than 0.086 (at ∼21 °C) except for sample 703640 which had aw of 0.209. The average moisture content in the samples was 2.07%, with sample 703640 being the only variety with moisture content higher than 4% (∼6%) (moisture data is not shown). In general the lyophilization process removed most of the moisture from the potato samples.

[a]Compound numbers and retention times refer to the numbers given in Figure 1. [b]Chlorogenic acid isomers were prepared as described by Nagels.[10]

Improvement of the Extraction. Initially, phenolic fraction of the potatoes was extracted following the procedure described by Shiroma-Kian and others.[15] However, during extraction of selected potato samples, some browning occurred and anthocyanin coloration was lost suggesting enzymatic degradation. According to Francis,[16] anthocyanins can be degraded by a number of enzymes classified as glycosidases (anthocyanases), polyphenoloxidases (PPO) and peroxidases. These enzymes are found in plant tissue and naturally occur in potatoes. Glycosidases act directly on anthocyanins hydrolyzing the pigments to sugars and anthocyanidins (aglycone).[16,17] Anthocyanidins are very unstable and degrade to colorless derivatives or condense with other phenolics to form polymeric colored compounds.[15] The action of PPO and peroxidases on anthocyanins is indirect.[11] For example, PPO oxidizes *o*-diphenols (phenolic acids, e.g., chlorogenic acid) to *o*-benzoquinone which in the presence of oxygen reacts with the anthocyanins by a nonenzymatic mechanism to form oxidized anthocyanins and degradation products.[17] In order to minimize pigment degradation, the extraction process of anthocyanins and other phenolics from potato samples was modified. The percent of acid and acetone in the aqueous acetone solution was increased and the time for the homogenization was reduced. The pH of a solution can have a marked effect on enzymatic activity. Enzymes that degrade anthocyanins have an optimum pH greater than 4.[18] The pH of 70% aqueous acetone acidified with 0.01% HCl was lower than pH 3. However, after homogenization with the potato powder, the pH of the solution was higher than pH 5. This suggested that the potato powders had high buffering capacity and were increasing the pH of the solution. In order to obtain final pH values lower than 3.5 after homogenization, the acidity of the aqueous acetone solution was increased with additional HCl and trifluoroacetic acid (TFA). A combination of 0.1% HCl and 0.2% TFA resulted on a final extract with a pH between 3−3.5 that minimized enzymatic activity and favored pigment stability.

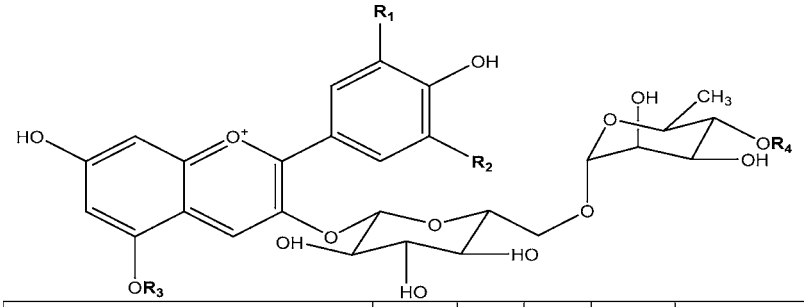
[a]Compound numbers refer to the numbers given in Table 3. [b]Tentative identification.

Another important consideration was that the extracted samples were going to be concentrated after the chloroform partitioning. High concentrations of acid could hydrolyze the phenolic compounds and anthocyanins in the sample. TFA was chosen to acidify the solution since, even though it is a strong acid, it is also more volatile than HCl and could evaporate during the concentration of the sample.

To better protect the integrity of the sample and minimize enzymatic activity, higher concentrations of acetone could be used during extraction. A small trial with different concentrations of acetone in the extraction solution was performed using 70, 80, 90 and 100% of acidified acetone. The solution with 80% aqueous acidified acetone was the most efficient and was chosen as the extracting solvent for this research.

The homogenization process was also improved using a tissuemiser homogenizer and reducing the mixing time from 10 to 5 min. The previous procedure called for homogenization on a rotamixer took longer time to extract the phenolics from the samples. In addition to decreasing the time involved in the extraction, changing to a tissumizer allowed us to incorporate a water/ice bath to reduce temperature and diminish any residual enzymatic activity. Usually when chloroform partitioning is performed in a sample, two layers are formed. The top aqueous layer contains the phenolic fraction in water and the bottom layer contains the mixture of chloroform and acetone. In our extraction procedure, an additional layer was formed between the chloroform/acetone and the aqueous layers. To separate it from the phenolic (aqueous) fraction, a centrifugation step was applied.

Total Phenolic Quantitation. Phenolic content of potato samples ranged from 113.37 to 510.20 mg of gallic acid equivalents (GAE) per 100 g of DW (Table 2). From the samples evaluated, potatoes from the species *S. tuberosum* subsp. *andigenum* and *S. Stenotomum* subsp. *stenotomum* had higher levels of phenolic compounds than the other species analyzed. Since the majority of the analyzed samples belonged to the *S. tuberosum* subsp. *andigenum* and *S. Stenotomum* subsp. *stenotomum* species (13 out of 20 samples), it can not be concluded as these species will always have higher phenolic content. More research needs to be done including more samples of different species to be able to determine if indeed samples of these two species have overall higher phenolic content than samples of other species. The sample with the highest total phenolic content ($p < 0.001$) was 703640, a *S. tuberosum* subsp. *andigenum* that exhibited a dark purple coloration in the extract with 510.2 mg of GAE/100 g DW, followed by sample 705534, a *S. stenotomum* subsp. *stenotomum*, dark purple extract and 704733, a *S. tuberosum* subsp. *andigenum*, a purple extract with 412.49 and 379.2 mg of GAE/100 g DW, respectively. Samples 706884 and 704481 both belonging to the specie *S. Stenotomum* subsp. *goniocalyx* produced yellow extracts and did not contain monomeric anthocyanins. These two samples had the lowest total phenolic content with 114.63 mg and 113.37 mg of GAE per 100 g DW, respectively. Phenolic content of the potato samples evaluated seemed to be more dependent on the coloration of the samples than on the specie, with higher phenolic content being obtained from samples exhibiting more intense colors. The values found in this research were higher than those reported by Im and others[19] in 24 regular American potatoes (including Yucon gold, Russet, red and white potatoes) bought in a local store in Berkely, California finding 4.09 mg to 281 mg of total phenolics per 100 g of DW. Only one variety studied by the authors gave higher values of phenolics, which was a Peruvian purple potato with 757 mg of total phenolics per 100g of DW.



Name of Anthocyanin	Peak No	R_1	R_2	R_3	R_4

Figure 3. Chemical structures of major anthocyanins identified in red and purple potato extracts by HPLC PDA/MS. *Compound numbers refer to the peak numbers given in Figure 4.

Monomeric and Polymeric Anthocyanin Content. Based on the anthocyanin composition, colored samples have a maximum absorbance (λ_{max}) at different wavelengths. Most of the colored potato samples analyzed had their λ_{max} either at 520 nm (purple extracts) or at 510 nm (red extracts). Purple extracts with highest absorbance at 520 nm were quantitated as cy-3-glu equivalents (Table 2 Section I) while red extracts with λ_{max} at 510 nm were quantitated as pg-3-glu equivalents (Table 2 Section II).

The monomeric anthocyanin content of the different red and purple potato varieties ranged from 8.2 to 152.7 mg/100 g DW. The cultivars with the lowest monomeric anthocyanin content were 703782, a *S. stenotomum* subsp. *stenotomum* that exhibited a light purple extract and 704133, a *S. stenotomum* subsp. *Stenotomum* exhibiting a light red extract with 8.2 and 16.8 mg/100 DW, respectively. The varieties with highest pigment content were 705534, a *S. stenotomum* subsp. *stenotomum*, dark purple extract, and 703640, a *S. tuberosum* subsp. *andigenum*, dark purple extract, with more than 145 mg cy-3-glu equivalents/100 g DW. These two samples also had high content of total phenolics. Anthocyanin content of the potato samples evaluated were more related to the coloration of the samples than on the specie, since samples with more intense colors showed higher anthocyanin content. Higher monomeric anthocyanin content has been reported for other purple potato cultivars such as Urenika with average contents 507.8 and 183.6 mg/100 g FW in the skin and flesh, respectively.[20] Rodriguez-Saona and others[7] also reported higher contents of monomeric anthocyanins (>35 mg/100 g FW) in two different red potato selections. Similarly, Campos and others[9] found higher quantities of total anthocyanin content in fresh native Andean potato tubers (8 mg to 80 mg per 100 g of fresh tuber). There might be the potential to develop a red and purple potato clones through potato breeding studies with pigment content similar to those of Urenika.[7]

In the analyzed samples, the percentage of polymeric color ranged between 12.4% and 40.3% (Table 2) with an average polymeric color of 24%. The sample with the highest percentage of polymeric color was 703782 (*S. stenotomum* subsp. *stenotomum*, red extract), which was found to contain the lowest monomeric anthocyanin content as well. Polymeric color in the potato samples could be attributed to polymerization reactions during processing/lyophilization and over storage as well as some possible residual enzymatic activity during extraction.

Anthocyanin content as a percentage of the total phenolics ranged from 5.17% to 37.02% with an average of 20% of the total phenolics content (Table 2). With the exception of sample 704733, a *S. tuberosum* subsp. *andigenum* that produced a purple extract, total phenolic and anthocyanin content showed linear correlation (R^2 = 0.841, p-value = 0.0001). The reason for sample 704733 being an outlier was the high content of phenolic compounds (379.2 mg of GAE per 100 g of DW) and low content of monomeric anthocyanins (41.1 mg of cy-3-glu

[a]Compound numbers and retention times refer to the numbers given in Figures 4 and 5. [b]All anthocyanins were identified based on the combined information on UV−vis, molecular ion, mass fragments and retention times of the anthocyanin and the anthocyanidins. Anthocyanidin identification was made using the acid hydrolysis of strawberry (for pelargonidin) and grape (for delphinidin, cyanidin, peonidin, petunidin and malvidin as references).

Figure 4. HPLC chromatograms at 520 nm for major anthocyanins of red potato extracts and their peak areas (% of total peak area at 520 nm). ND: not detected. Difference from 100 is due to the presence of minor peaks, each accounting for less than 2% of total area. *All anthocyanins were tentatively identified.

equivalents per 100 g of DW) it contained. This finding shows that even though the presence of anthocyanins increases the overall phenolic content, there might be potato varieties with high phenolic content that show little or no anthocyanin content.

Phenolic Characterization. Potato phenolics were characterized by monitoring the elution of compounds at 280 nm. Key structures for phenolics addressed are illustrated in Figure 1 and further detalied in Table 3. Three chromatograms representing purple, red and yellow extracts can be seen in Figure 2. Similar phenolic profiles were obtained for all potato samples besides the differences in the anthocyanin fractions (Figure 2).

The presence of chlorogenic, caffeic, *p*-coumaric, ferulic, sinapic, gallic and protocatechuic acid have been previously reported in potatoes.[7,20−22] Therefore, cocktails with these phenolic acid standards were injected in the HPLC−MS with the same separation method used for the potato samples. From the standards used, only chlorogenic and caffeic acid were identified among the phenolic acids in the samples. Chlorogenic acid isomers were prepared and injected in the HPLC−MS following the same method used for the potato samples and other standards. During the isomerization procedure, caffeic acid was also formed and eluted after the three isomers.

Phenolic identification was made based on UV, mass spectra and retention time comparisons to those of pure standards available. In addition to the anthocyanin peaks, 13 major phenolic peaks were found in the potato samples (Figure 2). From those peaks four compounds (**2**, **3**, **4** and **5**) have been clearly identified and two others (**1** and **6**) have been tentatively identified.

Relative proportions of the phenolic compounds (% of total peak area at 280 nm) identified were reported in Table 4. Proportions of the compound **6** (tentatively identified) were not included in Table 4 due to difficulty of quantitation since the compound coeluted with an anthocyanin peak. In average, **2**, **3** and **4** represented 43% of the total phenolic content. However, this value was lower than the 70% of total phenolic area reported by Rodriguez-Saona and others[7] in red potatoes and up to 90% of the total phenolic compounds in potato tubers analyzed by Malmberg and Theander.[23]

Anthocyanin Characterization. Anthocyanin profiles obtained were very similar among all samples within the same color (purple and red extracts). However, clear differences between anthocyanin profiles of purple and red samples were noticed from the HPLC chromatograms at 520 nm. Purple extracts had fewer peaks than the red extracts and in general, most predominant peaks in purple extracts eluted before the predominant peaks in red extracts. Due to their different profiles, both groups were characterized individually. To facilitate the identification of the anthocyanins, samples were saponified and hydrolyzed and analyzed through HPLC−MS. Anthocyanidin identification was made based on UV−vis and mass spectra and retention time comparisons to those of anthocyanidin standards obtained from the acid hydrolysis of

Figure 5. HPLC chromatogram at 520 nm for major anthocyanins in purple potato extract and their peak areas (% of total peal area at 520 nm). ND: not detected. Difference from 100 is due to the presence of minor peaks, each accounting for less than 2% of total area. *All anthocyanins were tentatively identified.

strawberry (pelargonidin) and grape (delphinidin, cyanidin, peonidin, petunidin and malvidin). Key structures of anthocyanins identified are illustrated in Figure 3 and further detailed in Table 5.

Red Potato Extracts. Three major anthocyanidins (cyanidin, pelargonidin and peonidin) were identified in red potato extracts. Among the saponified samples, four major peaks were identified based on UV−vis and mass spectra as cyanidin-3-rutinoside-5-glucoside, pelargonidin-3-rutinoside-5-glucoside, peonidin-3-rutinoside-5-glucoside, pelargonidin-3-rutinoside with pelargonidin-3-rutinoside-5-glucoside was being the most predominant peak in the saponified samples.

Seven of the nine anthocyanin major peaks in red potato extracts (Figure 4) were acylated with a cinnamic acid. Three different cinnamic acids were found acylating the anthocyanins in red potato extract: caffeic, *p*-coumaric and ferulic acid. Nine major anthocyanin peaks were identified based on UV−vis and mass spectra. Pelargonidin-3-*p*-coumaroyl-5-glucoside was the most predominant peak in red potato extracts after saponification which was in accordance with the findings of Rodriguez-Saona and others.[7] Five major peaks were pelargonidin derivatives: two nonacylated (compounds **7** and **8**) and three acylated (compounds **9**, **12** and **14**), while three pigments were acylated peonidin derivatives (compounds **10**, **13** and **15**) and only one major pigment was identified as acylated cyanidin derivative (compound **11**). Sample 704537, a *S. Chaucha specie*, presented slight differences in anthocyanin profile and therefore it was characterized individually. The main difference between sample 704537 and the other red potato extracts was the presence of compound $\mathbf{11^I}$ (Figure 4).

Relative proportions (% of total peak area at 520 nm) of the anthocyanin compounds previously identified were also shown in Figure 4. In average, compound **12** accounted for 54.6% of the total anthocyanin content. However, this value was lower than the range between 56.7 and 83.2% of total area reported by Rodriguez-Saona and others[7] in red potatoes.

Purple Potato Extracts. Five major anthocyanidins (cyanidin, petunidin, pelargonidin, peonidin and malvidin) were identified in purple potato extracts. From the six common anthocyanidins found in nature, only delphinidin was not present in purple potato extracts. Petunidin and peonidin were the most predominant anthocyanidins in purple potato extracts.

Four major peaks were found in the saponified samples of purple potato extracts. The peaks were identified based on UV−vis and mass spectra as the 3-rutinoside-5-glycoside derivatives of the five anthocyanidins found in the hydrolyzed samples. According to order of their elution, they were: cyanidin-3-rutinoside-5-glucoside, petunidin-3-rutinoside-5-glucoside, pelargonidin-3-rutinoside-5-glucoside and peonidin-3-rutinoside-5-glucoside, with petunidin and peonidin glycosides being the most predominant peaks in the saponified samples.

The separation and identification of the acylated anthocyanins in purple potato extracts was more challenging since some of the peaks coeluted making their identification more difficult. Accordingly, the HPLC separation method was improved by changing the aqueous solvent concentration to 10% formic acid and slightly modifying the solvent gradient. Even though fractioning of the molecules and MS data collection was better with lower acid concentrations, better separation of the compounds in the C_{18} column was achieved with higher acidity. The same three acylating groups (caffeic, p-coumaric and ferulic) identified in red potato extracts were also found in the purple potato extracts. Eight major acylated anthocyanin peaks (Figure 5) were identified in purple potato extracts: **11**, $\mathbf{11^I}$, **12**, **13**, **15**, **16**, **17**, **18**. Petunidin and peonidin acylated derivatives were the most predominant peaks in purple potato extracts.

Relative proportions (% of total peak area at 520 nm) of the anthocyanin compounds in purple potato extracts were also shown in Figure 5. In average, compound $\mathbf{11^I}$ accounted for 63.2% of the total anthocyanin content.

In conclusion, Andean potato samples from different species showed great variability in polyphenolic and anthocyanin content. Major quantitative and qualitative differences among evaluated samples seemed to be more dependent on the coloration of the sample after extraction rather than on the specie. Potato varieties with high anthocyanin content could be used as sources of natural pigments with increased stability for food applications. Due to the high consumption levels of potatoes around the world, selected native Andean potatoes could be be introduced into the market to deliver significant amounts of phenolic compounds with potential health promoting properties into the human diet.

Self-Emulsification of Alkaline-Dissolved Clove Bud Oil by Whey Protein, Gum Arabic, Lecithin, and Their Combinations

Yangchao Luo, Yue Zhang, Kang Pan, Faith Critzer, P. Michael Davidson, and Qixin Zhong*

Department of Food Science and Technology, University of Tennessee in Knoxville, Knoxville, Tennessee 37996, United States

ABSTRACT: Low-cost emulsification technologies using food ingredients are critical to various applications. In the present study, a novel self-emulsification technique was studied to prepare clove bud oil (CBO) emulsions, without specialized equipment or organic solvents. CBO was first dissolved in hot alkaline solutions, added at 1% v/v into neutral solutions with 1% w/v emulsifier composed of whey protein concentrate (WPC), gum arabic, lecithin, or their equal mass mixtures, and adjusted to pH 7.0. The self-emulsification process did not affect UV−vis absorption spectrum, reversed-phase HPLC chromatogram, or antimicrobial activity of CBO against *Escherichia coli* O157:H7, *Listeria monocytogenes* Scott A, and *Salmonella* Enteritidis. The entrapment efficiency after extraction by petroleum ether was determined to be about 80%. Most emulsions were stable during 7 days of storage. Emulsions prepared with WPC had smaller particles, whereas emulsions prepared with emulsifier mixtures had more stable particle dimensions. The studied self-emulsification technique may find numerous applications in the preparation of low-cost food emulsions.

KEYWORDS: *self-emulsification, clove bud oil, alkaline deprotonation, neutralization, whey protein concentrate, gum arabic*

INTRODUCTION

Essential oils (EOs) are aromatic liquids derived from plants or plant parts, including leaves, flowers, buds, fruits, barks, and seeds.[1−3] EOs are well-known for their antioxidant and antimicrobial activities and have been widely used as functional ingredients in food, pharmaceutical, and cosmetic products.[1] In recent years, the application of EOs in food products has generated particular interest because of their generally recognized as safe (GRAS) regulatory status, multiple functionalities, and wide acceptance by consumers.[2,3] Clove oils are the EOs obtained by distillation of the flower buds, stems, and leaves of the clove tree (*Syzygium aromaticum*). Among clove oils, clove bud oil (CBO) is widely used and well-known for its potent antioxidant properties and antibacterial, antifungal, and antiviral activities.[4] Eugenol, 4-allyl-2-methoxyphenol, is the primary constituent (>80%) of CBO[5] and is the major contributor of the above biological functions of CBO.[4,6,7]

The poor solubility in aqueous solutions and high volatility during processing are two major obstacles of utilizing EOs as sanitizing agents or as preservatives in food matrices. Oil-in-water emulsions carefully prepared using appropriate surfactants and emulsification processes are common choices to deliver EOs in aqueous systems. Although synthetic surfactants such as polysorbates (Tweens) have demonstrated excellent emulsifying activities, their potential toxicity and regulated use in foods limit their applications in the food industry.[8,9] Therefore, there is a paradigm shift from synthetic to naturally occurring emulsifiers.

Food biopolymers, that is, proteins and polysaccharides, with appropriate surface activity are promising candidates to prepare naturally occurring and potentially GRAS emulsions for food applications.[10,11] For instance, the combination of whey protein concentrate (WPC) and gum arabic (GA) has been shown to effectively prepare chia (*Salvia hispanica*) EO microcapsules by spray-drying, and the resultant spray-dried powder can be freely reconstituted in water, greatly improving its application in aqueous systems.[12] Furthermore, nanoemulsions, with droplets smaller than approximately 200 nm in diameter, can prevent the creaming/precipitation of EO droplets and potentially enhance their antimicrobial activity.[13] Nanoemulsions are commonly prepared by high-energy methods such as high-pressure homogenization and microfluidization, but high capital and operating costs as well as scalability raise concerns about their practicality in the food industry.[14]

Therefore, the goal of the present work was to study a low-energy self-emulsifying technique to prepare EO nanoemulsions using naturally occurring emulsifiers. CBO was used as a model EO, and WPC, GA, and soy lecithin were selected as emulsifiers. The principle was based on the deprotonation of the hydroxyl group of eugenol (Scheme 1), the major component in CBO, under aqueous alkaline conditions and the self-emulsifying process during the subsequent neutralization in the presence of the natural emulsifiers. The first objective was to study the feasibility of the proposed self-emulsifying approach and characterize physicochemical properties of CBO emulsions. The second objective was to evaluate how the emulsification process affected the antimicrobial activity of CBO

against the Gram-negative bacteria *Escherichia coli* O157:H7 and *Salmonella* Enteritidis and the Gram-positive bacterium *Listeria monocytogenes*.

MATERIALS AND METHODS

Materials. Organic-certified CBO with a purity of no less than 85% was purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). WPC-34, consisting of 3−4.5% fat, 34−36% protein, and 48−52% lactose, was provided by Grande Cheese Co. (Grande, WI, USA). The clear WPC dispersion was prepared by removing fat globules as described by Damodaran.[15] The 4% WPC was hydrated for 2 h in deionized water, and the pH was adjusted to 4.0. After standing for 2 h at room temperature (21 °C) and centrifugation at 5000*g* for 20 min (SORVALL RC5B Plus centrifuge, DuPont, Wilmington, DE, USA), the transparent supernatant was collected for emulsion preparation. GA was purchased from Fisher Scientific (Pittsburgh, PA, USA). Soy lecithin (Sunlipon 50) was generously provided by Perimondo, LLC (New York, NY, USA). Other chemicals and reagents were of analytical grade and purchased from Fisher Scientific and used as received.

Preparation of Emulsions. Deprotonation of CBO was accomplished by mixing 0.5 mL of CBO with 4.5 mL of 1−5 M NaOH in a glass vial and heating at 110 °C for 10 min in a glycerol bath until the mixture became transparent. The deprotonation of CBO was accelerated by heating, similarly to saponification in the edible oil industry. For emulsion preparation, 3 M NaOH was used as aqueous phase to dissolve CBO. Single or blends of emulsifiers were dissolved separately in water at an overall emulsifier concentration of 1% w/v, consisting of WPC only, GA only, lecithin only, or their equal mass mixtures (Table 1). Then 0.5 mL of alkaline-dissolved CBO was added to 4.5 mL of the emulsifier aqueous solution, preadjusted to pH 7.0 at room temperature, and mixed for 5 min on a magnetic stirring plate. Then, the pH of the mixture was adjusted to pH 7.0, using 3 or 0.3 M citric acid. The emulsion spontaneously formed during the acidification process. The emulsion formed was stirred for another 10 min and then stored at 4 °C until further analyses.

Table 1. Compositions Used To Prepare 1% w/v Emulsifier Aqueous Solutions

E	0	0.5	0.5
F	0.5	0	0.5
G	0.33	0.33	0.33

Structural Changes of Clove Bud Oil after Emulsification. HPLC and UV−vis absorption spectroscopy were used to study the structure of CBO before and after self-emulsification. CBO was extracted from the emulsion prepared with WPC using ethyl acetate. The solvent was then evaporated under the fume hood, and the extracted CBO was dissolved in methanol. The unprocessed CBO was directly dissolved in methanol as a control for unprocessed CBO. The absorption spectrum of each from 200 to 600 nm was determined using a UV−vis spectrophotometer (Evolution 201, Thermo Scientific, Waltham, MA, USA). For HPLC, a reversed phase system (1200 series, Agilent Technologies, Waldbronn, Germany) was used at conditions described previously.[16] The HPLC system was composed of a quaternary pump module, a degasser, an autosampler, a temperature-controlled column chamber, and an Agilent diode array and multiple wavelength detector. Chromatograms were recorded and integrated using the 1200 LC Chromatography Data System. A ZORBAX Eclipse Plus C18 HPLC column (5 μm, 150 mm × 4.6 mm, Agilent, Palo Alto, CA, USA) equipped with a ZORBAX Eclipse Plus C-18 guard column (4.6 × 12.5 mm, 5 μm) was used in the present study. A 10 μL sample was injected, and the detector was set at a wavelength of 274 nm. The mobile phase consisting of water (solvent A) and methanol (solvent B) was applied at 0.5 mL/min as follows: a linear gradient of 20−80% B from 0 to 20 min, an isocratic step with 80% B from 20 to 25 min, and a linear gradient from 80% B to 20% B from 25 to 30 min. The column chamber was controlled at 25 °C throughout the experiments.

Entrapment Efficiency. The entrapment efficiency was determined by subtracting the free oil content from the total oil content. The free oil content in the prepared emulsion was measured according to the method of Rodea-González et al.[12] with modifications. Briefly, 0.5 mL of a freshly prepared emulsion was mixed with 2 mL of petroleum ether. The mixture was gently stirred for 10 min, and then 0.1 mL of the upper organic solvent phase was transferred to a 20 mL vial, followed by resting in a fume hood for 5 min to evaporate petroleum ether. Then, 4 mL of ethanol was added to dissolve the extracted oil, and the absorbance was measured at 280 nm, using the above spectrophotometer. A standard curve was established using CBO standard solutions in ethanol to correlate the absorbance value with the oil concentration. The entrapment efficiency was then calculated using eq 1:

$$\text{entrapment efficiency}\,(\%) = \frac{\text{total oil} - \text{free oil}}{\text{total oil}} \times 100\% \quad (1)$$

Particle Size and Stability of Emulsions. The particle size of the emulsions was measured using dynamic light scattering with a Delsa Nano analyzer (Beckman Coulter, Inc., Atlanta, GA, USA) at an angle of 165°. The hydrodynamic diameter (D_h) and polydispersity index (PDI) were measured during storage at room temperature (21 °C) for 7 days.

Surface Hydrophobicity (S_0). The S_0 of individual emulsifiers and their combinations was determined using a fluorescence probe, 8-anilinonaphthalene-1-sulfonic acid (ANS), based on the method of Luo et al.,[17] with minor modifications. Briefly, individual emulsifiers or their mixtures were dispersed in 0.01 M phosphate-buffered saline (PBS, pH 7.0) at 1 mg/mL as stock solutions, which were further diluted with PBS to various concentrations in the range of 5−100 μg/mL. The diluted samples (4 mL) were mixed with 20 μL of an ANS working solution that was previously prepared at 8 mM in 0.01 M PBS (pH 7.0). The mixtures were incubated for 2 h at room temperature (21 °C) in the dark. The fluorescence intensity was then recorded at an excitation wavelength of 355 nm and an emission wavelength of 507 nm using a spectrofluorometer (model RF-1501, Shimadzu Corp.,

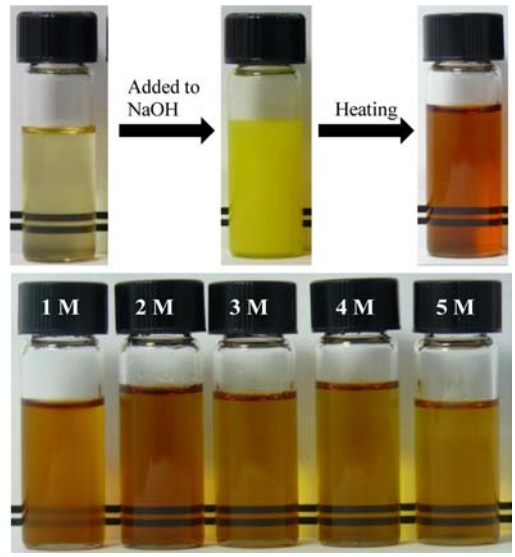

Figure 1. (a) Appearance of clove bud oil (left) after mixing at 10% v/v with 3 M NaOH (center) at 21 °C and after heating at 110 °C for 10 min (right); (b) appearance of 10% v/v clove bud oil heated at 110 °C for 10 min in 1−5 M NaOH (as labeled on vial caps).

Tokyo, Japan). The initial slope of fluorescent intensity versus sample concentration plot after linear regression with $R^2 > 0.995$ was used as an index for S_0.

Topographical Structures of Oil Droplets. The morphology of emulsion samples was studied using atomic force microscopy. The freshly prepared emulsion samples were diluted with distilled water to a final emulsifier concentration of 10 μg/mL. Ten microliters of the diluted sample was spread evenly onto freshly cleaved mica sheets mounted on a sample disk (Bruker Corp., Santa Barbara, CA, USA). A rectangular cantilever having an aluminum reflective coating on the backside and a quoted force constant of 2.80 N/m (FESPA, Bruker Corp.) and a Multimode VIII microscope (Bruker AXS, Billerica, MA, USA) were used to scan the sample. Images with a preset scan area of 10.0 × 10.0 μm were generated at a scanning speed of 1 Hz using the tapping mode.

Antimicrobial Assays. The antimicrobial activities of emulsion samples were tested against three bacterial strains in tryptic soy broth (TSB). *E. coli* O157:H7 ATCC 43895, *L. monocytogenes* Scott A, and *Salmonella* Enteritidis were obtained from the culture collection of the Department of Food Science and Technology at the University of Tennessee in Knoxville. All strains were grown in TSB and stored at −20 °C in 20% glycerol as stocks. Each strain was transferred at least twice in TSB with an interval of 24 h prior to use. Experiments were conducted at least twice for each culture, and samples were done in duplicate.

The minimum inhibitory (MIC) and minimum bactericidal (MBC) concentrations were determined using the microbroth dilution method.[18] Each culture was diluted to ca. 10^6 CFU/mL in TSB. Then, 120 μL of the diluted culture was added into wells of a 96-well microtiter plate and was mixed with 120 μL of TSB or an antimicrobial sample. Free CBO samples were prepared by dissolving 5% w/v CBO in 5% ethanol that was diluted in TSB to CBO concentrations of 250, 500, 750, 1000, 1250, 1500, 2000, or 2500 ppm. The emulsion samples were diluted in TSB directly to the same CBO concentrations. The microtiter plates were incubated at 32 °C for *L. monocytogenes* Scott A or at 37 °C for *E. coli* O157:H7 ATCC 43895 and *Salmonella* for 24 h. The absorbance at 630 nm (Abs_{630}) of each well was acquired before and after incubation using a microtiter plate reader (Titertek Multiscan MC, Labsystems, Helsinki, Finland). The MIC was defined as the lowest concentration of CBO preventing growth of the test strain, which corresponded to an Abs_{630} change of <0.05. To determine MBC, 10 μL of the mixture from negative wells (with $\Delta Abs_{630} < 0.05$) were spread-plated on tryptic soy agar (TSA) and incubated for another 24 h at temperatures referenced above. MBC was defined as the lowest concentration of CBO corresponding to no detectable colonies on TSA after incubation.

To study the growth kinetics of bacteria, 1 mL of the bacterial culture with about 10^7 CFU/mL was mixed with free CBO (predissolved in 5%) or emulsion samples and TSB to an overall volume of 10 mL, which corresponded to a population of ca. 10^6 CFU/mL. The final concentration of CBO was 750 ppm. Mixtures were incubated at 32 °C (*L. monocytogenes*) or 37 °C (*E. coli* O157:H7 and *Salmonella*). Viable bacteria were enumerated at 0, 4, 8, 24, and 48 h by spreading 0.1 mL of the mixtures on TSA plates and incubating as above for 24 h.

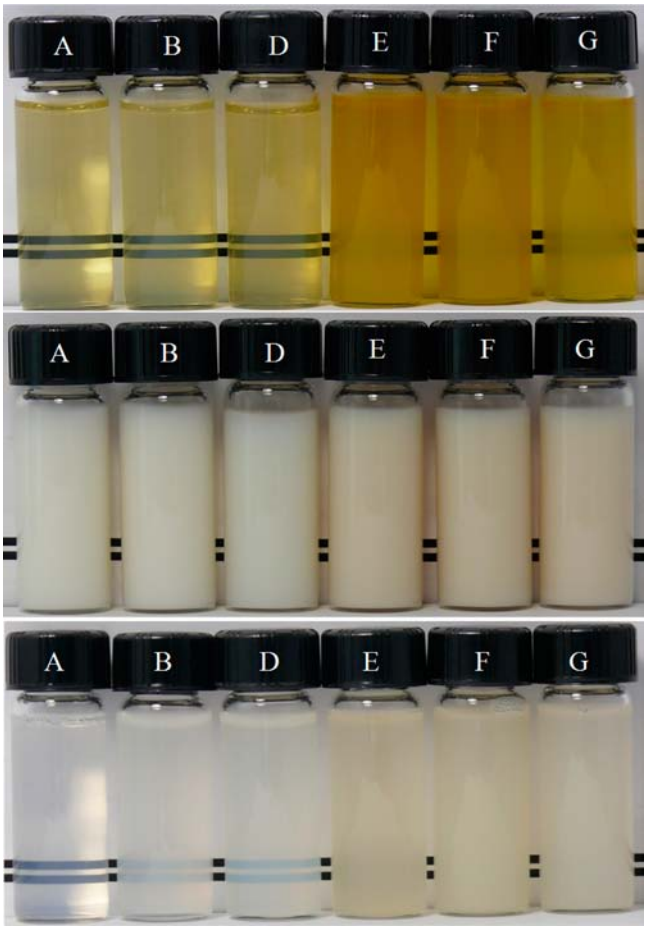

Figure 2. Appearance of samples after addition of 1% v/v alkaline-dissolved (in 3 M NaOH at 110 °C for 10 min) CBO in neutral aqueous solutions with 1% w/v emulsifier composed of (A) WPC only, (B) gum arabic only, (D) equal masses of WPC and gum arabic, (E) equal masses of gum arabic and lecithin, (F) equal masses of WPC and lecithin, and (G) equal masses of WPC, gum arabic, and lecithin (top), followed by acidification to pH 7.0 (middle), and further 5-fold dilution to 0.2% v/v oil in deionized water (bottom).

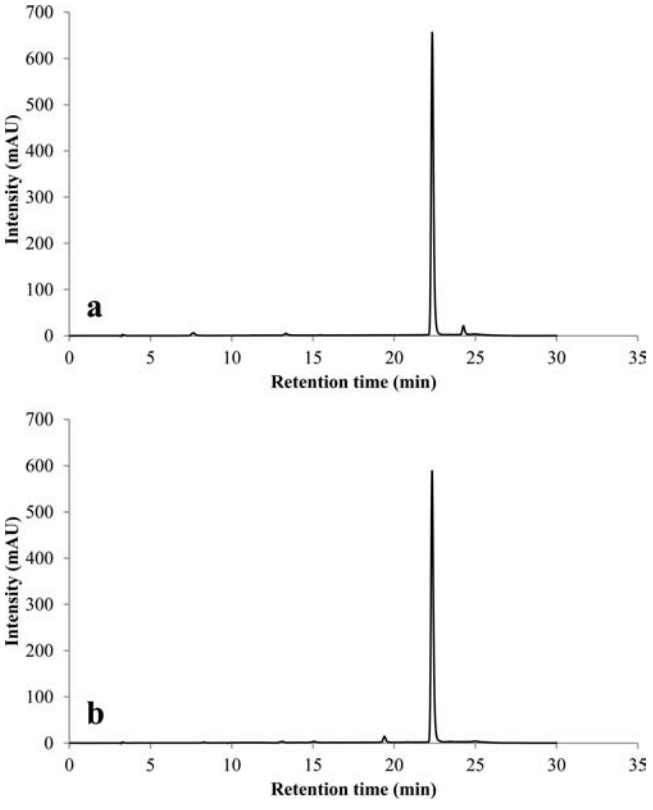

Figure 3. HPLC chromatograms of CBO before (a) and after (B) self-emulsification. The emulsion was prepared at 1% v/v CBO (predissolved in 3 M NaOH at 110 °C for 10 min) self-emulsified by 1% w/v WPC.

Statistical Analysis. The experiments of emulsion preparation and characterization were conducted in triplicate. All results were reported as means ± standard deviations. The analysis of variance (ANOVA) and Tukey's multiple-comparison tests were performed using the SPSS 13.0 software (SPSS Inc., Chicago, IL, USA) at a significance level (P) of 0.05.

RESULTS AND DISCUSSION

Alkaline Dissolution Conditions. At room temperature, the initial aqueous mixture of CBO in 3 M NaOH was turbid (Figure 1a) but gradually became transparent if stirred for a sufficient time, ca. 10 h. Transparency was due to the deprotonation of the CBO phenolic components (primarily eugenol), making them negatively charged (Scheme 1) and therefore solubilized under alkaline conditions. At elevated temperatures, the time for the reaction was significantly shortened. Preliminary tests using 10% v/v CBO in 3 M NaOH at 60−120 °C for 10 min showed that 110 °C for 10 min was sufficient to obtain a transparent sample. The transparent solution had a darker color after heating (Figure 1a), suggesting alkaline treatment caused structural changes to CBO components. The concentration of NaOH was also varied from 1 to 5 M to evaluate its influence on the reaction. It was shown that 3 M was sufficiently high to obtain a transparent solution after heating at 110 °C for 10 min (Figure 1b). The reaction conditions of heating 10% v/v CBO in 3 M NaOH at 110 °C for 10 min were used for the remainder of the research.

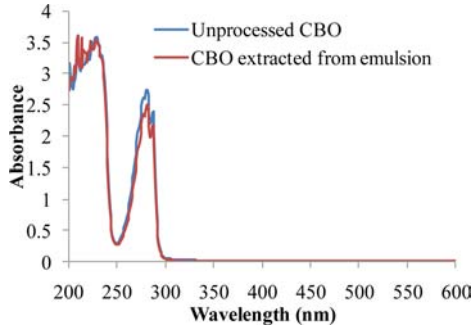

Figure 4. Comparison of UV−vis absorption spectra of CBO before and after self-emulsification. The emulsion was prepared at 1% v/v CBO (predissolved in 3 M NaOH at 110 °C for 10 min) self-emulsified by 1% w/v WPC.

Self-Emulsification of Alkaline-Dissolved CBO. The 10% v/v alkaline-dissolved CBO was mixed with a 9-fold volume of the 1% w/v emulsifier solution with compositions listed in Table 1, followed by neutralization to form emulsions containing 1% v/v CBO. When the alkaline-dissolved CBO was mixed with WPC, GA, or their blend, the mixture exhibited a lighter color than those with lecithin (Figure 2, top). This can be attributed to the color and water-insolubility of soy lecithin. When lecithin was the only emulsifier, large aggregates were observed following neutralization (data not shown), which may be due to the precipitation of lecithin by citric acid.[19] In contrast, other samples formed turbid dispersions without visible free oil or creaming, indicating successful self-emulsification (Figure 2, middle). After a 5-fold dilution to 0.2% CBO, the sample emulsified with WPC only was transparent; those with GA and WPC−GA mixture were translucent, whereas the other three samples with lecithin remained opaque, possibly due to the insoluble lecithin particles (Figure 2, bottom).

Because the self-emulsification process involved an alkaline treatment, it is essential to confirm the reversibility of the structural changes to CBO components, primarily eugenol. Therefore, HPLC was carried out to compare the retention time and peak area of eugenol in unprocessed CBO and that extracted

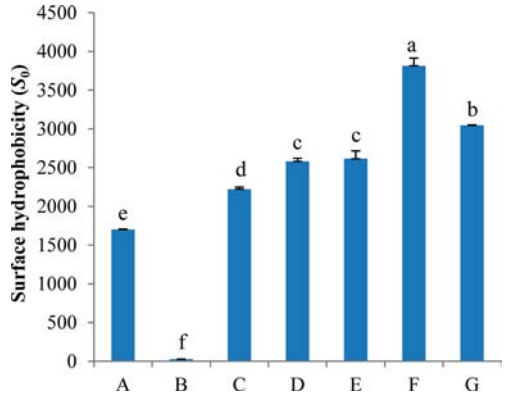

Figure 5. Surface hydrophobicity of (A) WPC only, (B) gum arabic only, (C) lecithin only, (D) equal masses of WPC and gum arabic, (E) equal masses of gum arabic and lecithin, (F) equal masses of WPC an lecithin, and (G) equal masses of WPC, gum arabic, and lecithin. Figure 6. Topographical images of CBO emulsions prepared with (A) WPC only, (B) gum arabic only, (D) equal masses of WPC and gum arabic, (E) equal masses of gum arabic and lecithin, (F) equal masses of WPC and lecithin, and (G) equal masses of WPC, gum arabic, and lecithin.

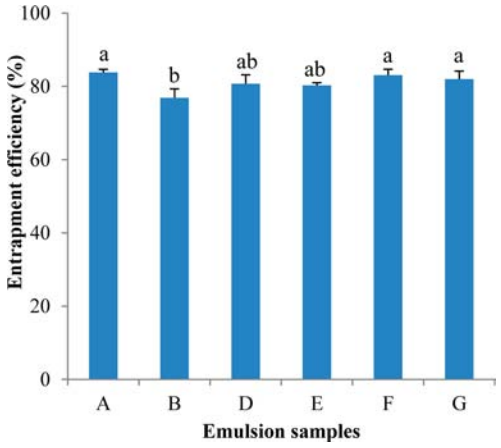

Figure 7. Entrapment efficiency of 1% v/v clove bud oil (predissolved in 3 M NaOH at 110 °C for 10 min) self-emulsified by 1% w/v emulsifier composed of (A) WPC only, (B) gum arabic only, (D) equal masses of WPC and gum arabic, (E) equal masses of gum arabic and lecithin, (F) equal masses of WPC and lecithin, and (G) equal masses of WPC, gum arabic, and lecithin. Error bars are standard deviations from three replicates. Different letters above bars indicate significant differences in the mean ($P < 0.05$).

from the emulsion. As shown in Figure 3a, the unprocessed CBO showed a sharp peak at the retention time of 22.3 min, representing eugenol.[16] The CBO extracted from the emulsion prepared with WPC (Figure 3b) had the major peak with the same retention time and peak area as the same concentration of unprocessed CBO. The same retention time revealed the same polarity of two samples, indicating that the double bond at its allyl side chain was not hydrogenated or cleaved after alkaline dissolution and neutralization. The UV−vis absorption spectra of CBO before and after emulsion preparation were also identical (Figure 4), further confirming no structural changes to CBO with the conditions studied.

Structure and Stability of Emulsions. The particle dimensions, D_h and PDI, were measured immediately after the emulsions were prepared and were monitored during the storage at ambient conditions up to 7 days (Table 2). Overall, freshly prepared emulsions exhibited D_h in the range of 160−540 nm. The sample self-emulsified with WPC alone had the smallest particles followed by the triple combination of emulsifiers and WPC−lecithin mixture, whereas that emulsified with GA alone had the largest particles. This agreed with a previous study using orange oil emulsions prepared with GA by high-pressure homogenization, which had much larger D_h than those emulsified by soy protein isolate, whey protein isolate, or sodium caseinate.[20] Compared with protein emulsifiers, the emulsification property of GA is limited by its high molecular weight and low surface hydrophobicity (Figure 5, discussed below), making it less effective in adsorbing onto the surface of oil droplets. Emulsion samples generally demonstrated good stability, showing no creaming during storage, except for the sample emulsified with GA only that demonstrated flocculated particles, which were redispersible after gentle shaking. When particle size changes were compared during storage, emulsions prepared with mixtures of emulsifiers generally showed better stability in maintaining particle size than those with individual emulsifiers. The one exception was the one emulsified with the GA−lecithin mixture, which exhibited a significant increase in particle size after 1 day of storage ($P < 0.05$). As to PDI, the emulsion prepared with GA demonstrated a significant increase in PDI ($P < 0.05$) during storage, whereas no significant changes of PDI were observed with any other emulsion. A PDI of about 0.3 indicates a relatively narrow distribution of particle sizes. Better stability of emulsions prepared with WPC−lecithin, WPC−GA, and WPC−GA−lecithin mixtures, with 8.4, 5.2, and 6.6% increases in D_h, respectively, than that of WPC

Table 3. MIC and MBC of Free and Self-Emulsified[a] Clove Bud Oil (CBO) against *E. coli* O157:H7 ATCC 43895 and *Salmonella* Enteritidis at 37 °C and against *Listeria monocytogenes* Scott A at 32 °C

[a]Emulsions were prepared with 1% v/v CBO self-emulsified with 1% w/v surfactants composed of WPC, gum arabic (GA), and lecithin individually or their combinations with equal masses. [b]Predissolved in 50% ethanol, corresponding to 2.5% ethanol in the assay mixture; the 2.5% ethanol did not show inhibition against all bacteria.

dx.doi.org/10.1021/jf500698k | J. Agric. Food Chem. 2014, 62, 4417−4424

alone (27.8% increase in D_h) agreed with the reported synergistic surface activity of β-lactoglobulin (a component of WPC) and lecithin[21] and WPC and GA.[22] Overall, emulsions prepared with WPC and its mixtures with GA and/or lecithin had smaller particles than those without WPC and had no significant change in D_h during storage ($P > 0.05$, Table 2).

To better understand potential synergistic effects among natural emulsifiers, the S_0 values of the emulsifiers and their mixtures were measured (Figure 5). Both the WPC and lecithin exhibited high S_0 values, whereas GA (a mixture of polysaccharides and glycoproteins) was very hydrophilic and hence had a low S_0. Interestingly, the combination of GA with WPC or lecithin had higher S_0 values than individual emulsifiers. As discussed above, this may indicate that the complex formation between these emulsifiers may have enhanced their emulsifying and stabilizing properties.

The topography of oil particles prepared with different emulsifiers is shown in Figure 6. The treatments self-emulsified by WPC, GA, and their combination had spherical particles, verifying self-emulsification during neutralization. In contrast, emulsions prepared in the presence of lecithin had irregular structures. This is likely due to water-insoluble lecithin particles because soybean lecithin is a complex mixture composed of both water-soluble and -insoluble substances, such as phospholipids, glycerol, and triglycerides.[23]

Entrapment Efficiency. The entrapment efficiency was about 80% for all emulsifiers (Figure 7). The treatment with GA alone had significantly lower entrapment efficiency (76.8%), possibly due to its reduced ability to emulsify CBO compared to other treatments. The efficiencies of entrapping CBO using the present self-emulsification technique were comparable to, or higher than, those of many other oil-in-water emulsion systems prepared with natural emulsifiers using high-energy methods such as high-speed homogenization,[24] high-pressure homogenization,[25] and probe-type sonication.[26]

Minimum Inhibitory and Minimum Bactericidal Concentrations of Emulsions. The MICs for free CBO were 1000, 750, and 750 ppm, whereas the MBCs were 1250, 750, and 750 ppm against *L. monocytogenes* Scott A, *E. coli* O157:H7 ATCC 43895, and *Salmonella* Enteritidis, respectively (Table 3). The results are in general agreement with other studies.[2,27] The CBO emulsions had MICs and MBCs that were similar or one to two dilutions lower than free CBO, whereas no antimicrobial activity of the emulsifiers alone was observed. Therefore, emulsification did not have a negative impact on the antimicrobial activity of CBO. Because all MICs and MBCs were below the water solubility of eugenol (1350 ppm at 21 °C and likely higher at 32 or 37 °C),[16] it can be concluded that binding between the selected emulsifiers and CBO did not interfere with the antimicrobial activity of eugenol. Conversely, higher MICs or MBCs of eugenol nanoemulsions than of free eugenol were reported when Tween 80[28] or whey protein−maltodextrin conjugates[29] were used as emulsifiers. Additionally, the emulsions prepared with GA and its mixture with other emulsifiers exhibited lower MICs and/or MBCs against *L. monocytogenes* than other treatments. It has been speculated that the strong anionic properties of GA may influence surface proteins on the cell membrane of *L. monocytogenes*, which may enhance the antimicrobial activity of EOs.[30]

Growth Kinetics of Bacteria in TSB. The three transparent/translucent emulsions (WPC alone, GA alone, and WPC−GA) with 0.2% v/v CBO (Figure 2) were evaluated for the influence on the growth kinetics of the test bacteria in TSB at a final CBO level of 750 ppm. The activity was compared with free CBO predissolved in 5% ethanol. An ethanol control (0.25% v/v, equivalent to final ethanol concentration in free CBO sample) in the TSB did not show any effect on the growth of the cultures (Figure 8). Free CBO exhibited significant inhibitory effects on the growth of three bacteria. For *L. monocytogenes* (Figure 8A), the emulsion prepared with GA exhibited a significantly better reduction ($P < 0.05$) at shorter times than the

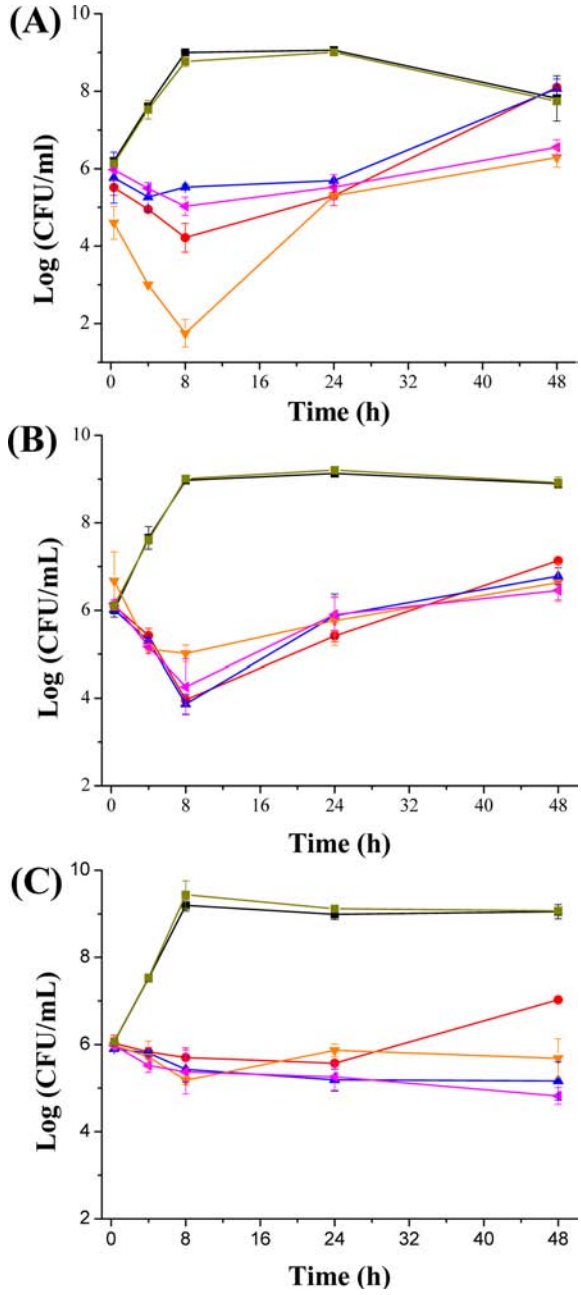

Figure 8. Growth curves of (A) *Listeria monocytogenes* Scott A at 32 °C, (B) *Escherichia coli* O157:H7 ATCC 43895 at 37 °C, and (C) *Salmonella* Enteritidis at 37 °C in TSB treated by no antimicrobials (negative control, black squares), 0.25% ethanol (positive control, as in free clove bud oil (CBO) treatment, green squares), 750 ppm free CBO (predissolved in 5% ethanol, red circles), and 750 ppm of CBO in the emulsion form prepared with WPC (blue triangles), GA (yellow triangles), and equal masses of WPC and GA (magenta triangles). Error bars are standard deviations from four replicates.

dx.doi.org/10.1021/jf500698k | J. Agric. Food Chem. 2014, 62, 4417−4424

other antimicrobial treatments, especially at 8 h, which was >2.5 log CFU/mL lower than free CBO. At 24 h, all CBO emulsions demonstrated bacteriostatic inhibition, which was 2.5−3 logs lower than the control. At the end of incubation (48 h), the antilisterial activity of WPC-emulsified sample was similar to that of free CBO and was the least effective among the three emulsions, whereas the emulsion prepared with the GA−WPC mixture exhibited significant inhibitory effects compared to the control. For *E. coli* O157:H7 (Figure 8B), all free and emulsified CBO treatments were highly inhibitory with an initial 2−2.5 log reduction in the first 8 h. After 48 h, all treatments continued to demonstrate bacteriostatic activity against the test microorganism. For *Salmonella*, no initial reduction was seen, but at the end of the incubation period, all emulsions demonstrated bacteriostatic activity, whereas the free CBO had begun to show growth (Figure 8C). Overall, at the end (48 h) of incubation, all three bacteria treated by free CBO recovered to a higher population than the three emulsion samples. Therefore, the self-emulsification technique used to prepare EO emulsions did not compromise the antimicrobial activity of CBO.

In summary, CBO emulsions were successfully prepared using a self-emulsification technique with naturally occurring food emulsifiers at ambient conditions without specialized equipment or organic solvents. The self-emulsification process (dissolving in a hot alkaline solution and neutralization) did not appear to have changed either the structure or antimicrobial activity of the major component in CBO (eugenol). WPC was effective in reducing emulsion droplet size, whereas the emulsifier mixtures were better emulsion stabilizers than single emulsifiers. Emulsions as prepared were stable during storage at room temperature and could be prepared as transparent or translucent samples upon dilution to CBO concentrations appropriate for application. Thus, the studied self-emulsification technique holds great potential in preparing EO emulsions for use as antimicrobial food preservatives or sanitizers in postharvest washing solutions for fresh produce production.

Model Studies on the Oxidation of Benzoyl Methionine in a Carbohydrate Degradation System

Michael Hellwig,* Katja Löbmann, Tom Orywol, and Annegrit Voigt

Institute of Food Chemistry, Technische Universität Dresden, D-01062 Dresden, Germany

Supporting Information

ABSTRACT: The stability of benzoyl methionine was analyzed during incubation with carbohydrate compounds such as reducing sugars, dicarbonyl compounds, reductones, and Amadori rearrangement products (ARPs). The reaction products were identified and quantified by HPLC-UV and HPLC-MS. In the presence of ARPs, >40% of benzoyl methionine was oxidized to benzoyl methionine sulfoxide after 48 h at 80 °C in acetate-buffered solution (pH 6.0), whereas <10% was oxidized in the presence of mono- and disaccharides. As an important side reaction, peptide bond cleavage through α-amidation was verified. The influence of benzoyl methionine on carbohydrate degradation reactions was assessed through analysis of vicinal dicarbonyl compounds by HPLC-UV. Glyoxal, methylglyoxal, diacetyl, and 3-deoxyglucosone were quantified as the most important derivatives. The thioether group of methionine strongly influenced carbohydrate degradation pathways: Less glyoxal was formed from reducing carbohydrates, showing that benzoyl methionine can act as a radical scavenger. However, more diacetyl was formed from ARPs and reductones, indicating that also radical-dependent pathways could be influenced by benzoyl methionine. The degradation of reducing carbohydrates should thus be an important contributor to protein oxidation in food items with low fat content.

KEYWORDS: *protein oxidation, methionine, Amadori products, reductone, dicarbonyl compounds*

INTRODUCTION

The thioether group of methionine, **1**, is very prone to oxidation by reactive oxygen species (ROS), which leads to the formation of methionine sulfoxide (MetSO), **2**, and methionine sulfone, **3** (Figure 1).[1] ROS involved in methionine oxidation are hydrogen peroxide (H_2O_2), the superoxide radical anion ($^{\bullet}O_2^-$), the hydroxyl radical ($^{\bullet}OH$), and alkoxyl radicals ($^{\bullet}OR$). They result from radiation, metal-catalyzed oxidations, and oxidase-catalyzed reactions. Oxidation reactions can also occur at other amino acid side chains and at the protein backbone.[2] Protein oxidation is generally considered to have negative consequences on food quality; however, the underlying molecular mechanisms are not yet fully understood.[3] The products **2** and **3** have only rarely been analyzed in protein model systems[4] and food samples. In soy proteins, egg white powder, and whey concentrates, up to 67% of total methionine can be oxidized to the sulfoxide **2** and up to 10% to the sulfone **3**.[5−7] Methionine oxidation was proposed to result from food processing, but this has not yet been assessed systematically. Research primarily focused on oxidation reactions caused by lipid peroxidation.[8,9] The free amino acid **1** can undergo several further degradation reactions during food processing, for example, to aroma-active aldehydes.[10,11] The sulfoxide **2** can be a source of essential methionine, but the reduction to **1** was reported to be incomplete, especially in young organisms.[12]

The formation of radicals can also be observed in carbohydrate chemistry. Exposure of carbohydrates to high-temperature and extreme pH milieus leads to their degradation via different reactions such as dehydration, β-dicarbonyl cleavage, and retro-aldol reactions.[13,14] These reactions are generally referred to as caramelization, that is, sugar degradation reactions in the absence of amino compounds. The reactions are accelerated in the presence of amino compounds (amino acids, peptides, proteins) in the course of the Maillard reaction. Enolized carbohydrates can easily be oxidized to dicarbonyl compounds by molecular oxygen, which is concomitantly reduced to superoxide and hydrogen peroxide. This reaction can be accelerated by transition metal ion catalysis during monosaccharide autoxidation.[15−17] Under physiological conditions, the formation of superoxide is fastest from osones and short-chain carbohydrates and slowest from ketoses and aldoses.[18] Amadori rearrangement products (ARPs), which enolize comparatively quickly, were reported to play a key role in the formation of hydrogen peroxide and superoxide radical anions.[19−21] The possibility of superoxide generation from ARPs in glycated protein has also been discussed with respect to diabetic complications in vivo.[22]

The high susceptibility of **1** to oxidation and the importance of redox reactions in carbohydrate degradation chemistry allow the hypothesis that **1** could significantly be oxidized by intermediates of sugar degradation. It was the aim of this study to assess the stability of benzoyl methionine, **1a**, in a model of carbohydrate degradation, to identify the reaction products and to compare different carbohydrate compounds in terms of their ability to provoke methionine oxidation. Moreover, the cleavage of a peptide bond by α-amidation in a carbohydrate degradation system and the influence of the thioether group of **1** on carbohydrate degradation reactions are reported for the first time.

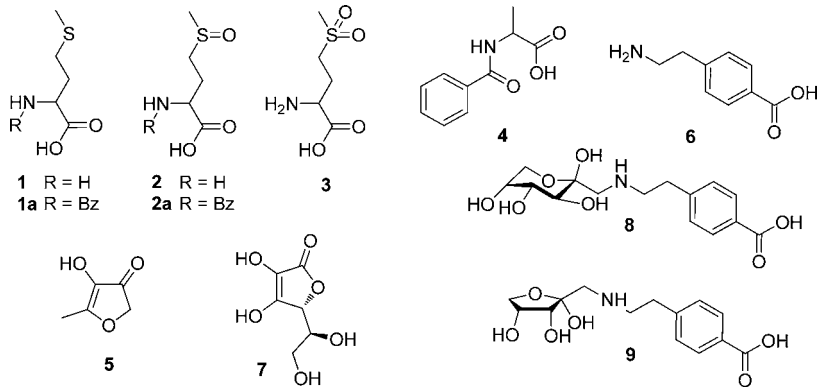

Figure 1. Chemical structures of the investigated products: **1**, methionine; **1a**, benzoyl methionine (BzMet); **2**, methionine sulfoxide (MetSO); **2a**, benzoyl methionine sulfoxide (BzMetSO); **3**, methionine sulfone; **4**, benzoyl alanine (BzAla); **5**, 4-hydroxy-5-methyl-3-furanone; **6**, 4-(2-aminoethyl)benzoic acid; **7**, ascorbic acid; **8**, 4-[2-(1-desoxyfructosyl)aminoethyl]benzoic acid; **9**, 4-[2-(1-desoxyribulosyl)aminoethyl]benzoic acid.

MATERIALS AND METHODS

Chemicals. Benzoyl succinimide (BzOSu), benzoyl methionine (BzMet, **1a**), and benzoyl alanine (BzAla, **4**) were obtained from Bachem (Bubendorf, Switzerland) and D-glucose, DL-methionine sulfoxide, and diisopropyl ethylamine (DIPEA) from Alfa Aesar (Karlsruhe, Germany). Lactose monohydrate was purchased from Roth (Karlsruhe, Germany). Fructose, lactulose, 4-hydroxy-5-methyl-3-furanone, **5**, methylglyoxal, 4-(2-aminoethyl)benzoic acid, **6**, hydrochloride (PAEBA), linolenic acid methyl ester, and ribose were obtained from Sigma-Aldrich (Steinheim, Germany). Ammonium acetate was from Grüssing (Filsum, Germany) and ascorbic acid **7** from Riedel-de-Haën (Seelze, Germany). Stearic acid methyl ester was purchased from Merck (Darmstadt, Germany). The water used for the preparation of buffers and solutions was obtained using a Purelab plus purification system (USFilter, Ransbach-Baumbach, Germany).

Synthesis of DL-Benzoylmethionine Sulfoxide, 2a. Benzoyl succinimide (1.0 g, 4.6 mmol) and 1.52 g (9.2 mmol) of DL-methionine sulfoxide, **2**, were dissolved in a mixture of 10 mL of dimethylformamide, 10 mL of dioxan, and 5 mL of water. The reaction was started by the addition of 1.56 mL (9.2 mmol) of DIPEA. The mixture was stirred for 5.5 h, evaporated to dryness in vacuo, and redissolved in 30 mL of water. The solution was extracted with ethyl acetate (4 × 20 mL). The aqueous solution was left to crystallize at 4 °C overnight. The crystals were recrystallized from water.

Analytical data: ESI-MS, positive mode, $[M + H]^+$ m/z 270.1; ^{1}H NMR (500 MHz, D_2O), δ 2.21 (m, 1H), 2.38 (m, 1H), 2.61 (s, 3H), 2.87 (m, 1H), 2.98 (m, 1H), 4.64 (m, 1H), 7.43 (m, 2H), 7.53 (m, 1H), 7.70 (m, 2H). Elemental analysis of $C_{12}H_{15}NO_4S$ (MW = 269.32) requires C, 53.52%; H, 5.61%; N, 5.20%; and S, 11.91%. Found: C, 51.95%; H, 4.71%; N, 4.98%; S, 12.11%. Content = 95.3%, based on nitrogen. Yield = 0.3 g (24.2%).

Synthesis of 4-[2-(1-Desoxyfructosyl)aminoethyl]benzoic Acid, 8. PAEBA, **6** (153.1 mg, 0.76 mmol), and 740 μL of 1 N NaOH were evaporated to dryness and redissolved in 30 mL of methanol. After the addition of 803 mg (4.5 mmol) of glucose, the mixture was heated under reflux for 4 h. The slightly brown solution was evaporated to dryness. The residue was mixed with silica gel until a fluid powder was obtained. The product was fractionated by flash chromatography on 50 g of silica gel using 350 mL of acetone/methanol (4:1, v/v), 300 mL of acetone/methanol (1:1, v/v), and 350 mL of methanol as the eluents. Fractions of 10 mL were collected manually, and product elution was monitored by spotting 1 μL of the fractions on two TLC plates and spraying either with 0.1% ninhydrin in ethanol or with 1% triphenyl tetrazolium chloride in 1 N NaOH. The product was found to elute between 510 and 690 mL. The organic solvents were removed by rotary evaporation, and the residue was lyophilized to give a slightly yellow powder, which was stored at −20 °C.

Analytical data: ESI-MS, positive mode, $[M + H]^+$ m/z 328.1; NMR data, see Table S1 in the Supporting Information. RP-HPLC content = 86.6%, calibrated with PAEBA. Yield = 185.6 mg (59.1%).

Synthesis of 4-[2-(1-Desoxyribulosyl)aminoethyl]benzoic Acid, 9. **6** (149.2 mg, 0.74 mmol) and 443.7 mg (3.0 mmol) of ribose were dissolved in 2 mL of water. The solution was slurried with 1.4 g of cellulose and lyophilized. The lyophilisate was stored at room temperature in a desiccator for 36 days in the presence of a saturated solution of calcium chloride maintaining a relative humidity of 35%.[23] The brown powder was then extracted with water (3 × 50 mL), and the combined fractions were evaporated to dryness using a rotary evaporator. The residue was dissolved in 10 mL of 0.075% acetic acid and fractionated by semipreparative HPLC using a Wellchrom high-pressure gradient system with an online degasser, a UV detector K-2501, and a fraction collector K-16 (all from Knauer, Berlin, Germany). The separation was performed at room temperature using an RP-18 column (Eurospher 100, 300 mm × 8 mm, 5 μm, Knauer) with a guard column (30 mm × 8 mm) filled with the same material. The flow rate was 1.4 mL/min, and the absorbance was read at 254 nm. Samples of 1 mL were injected manually and the eluate of the prominent peak was collected and evaporated to dryness in vacuo. Because this peak was not pure, the residue was dissolved in 75 mL of pyridinium acetate buffer, pH 3.0, and fractionated on a semi-preparative ion-exchange column in the pyridinium form (1.5 × 50 cm) as described earlier.[24] The column was eluted first with 300 mL of 0.3 M pyridinium formate buffer, pH 3.75, then with 250 mL of 0.3 M pyridinium acetate buffer, pH 4.05, and last with 500 mL of 0.4 M pyridinium acetate buffer, pH 4.35. From the collected fractions (6 mL), 1 μL was spotted on two TLC plates. Detection with ninhydrin and triphenyl tetrazolium chloride reagents revealed that the target substance eluted with 220−400 mL of the last elution buffer. The respective fractions were combined, filtered, evaporated to dryness, and finally lyophilized.

Analytical data: ESI-MS, positive mode, $[M + H]^+$ m/z 298.1; NMR data, see Table S2 in the Supporting Information. RP-HPLC content = 67.6%, calibrated with PAEBA. Yield = 28.2 mg (8.1%).

Characterization of Synthesized Products. NMR spectra were recorded on a Bruker DRX 500 instrument (Rheinstetten, Germany) at 500 MHz (^{1}H) and 125 MHz (^{13}C), respectively, using D_2O as the solvent. Chemical shifts are given in parts per million (ppm) relative to the internal HOD signal (^{1}H, 4.70 ppm), and relative to the external standard tetramethylsilane (^{13}C), respectively. Assignments of signals are based on ^{1}H−^{1}H correlation spectroscopy (COSY), distortionless enhancement by polarization transfer (DEPT) and heteronuclear single-quantum coherence (HSQC) experiments. Mass spectra were obtained on a PerSeptive Biosystems Mariner time-of-flight mass spectrometry instrument equipped with an electrospray ionization source (ESI-TOF-MS, Applied Biosystems, Stafford, TX, USA) working in the positive mode. Calibration of the mass scale was performed with a mixture of bradykinin, angiotensin I, and

neurotensin. After appropriate dilution with 1% formic acid in 50% aqueous acetonitrile, the samples were injected into the ESI source by a syringe pump. Elemental analysis was performed on a Euro EA 3000 elemental analyzer (Eurovector, Milano, Italy). Elemental analysis was used to calculate the product content of **2a**. The percentage of nitrogen in the preparation was divided by the theoretical percentage of nitrogen of the target substance and the content expressed in percent by weight. The purity and content of **8** and **9** were determined by HPLC-UV using the gradient system for benzoylated amino acids after calibration with **6**.

Incubation of Benzoylated Amino Acids with Carbohydrate Compounds. In general, benzoyl methionine (BzMet), **1a** (4 mM), was incubated with different carbohydrate compounds (sugars, dicarbonyl compounds, reductones, and ARPs, 4 mM) in 1 mL of 0.1 M sodium acetate buffer, pH 6.0, for 48 h at 80 °C in a sand bath. Stearic and linolenic acid methyl esters were dissolved in methanol before addition. The incubations were performed in screw-cap glass tubes (V = 7.5 mL). To evaluate the time course of the oxidation of **1a**, samples were prepared as above and heated for up to 6 h. For each sampling time, separate solutions were prepared, so that opening of the tubes during incubation could be avoided. In additional experiments, **1a** was substituted for 4 mM BzAla, **4**, PAEBA, **6**, or BzMetSO, **2a**. All incubations were performed in triplicate. After the incubations, the samples were cooled and stored at −20 °C until analysis. For the analysis of benzoylated amino acids, 50 μL of the incubation mixture was added to 950 μL of HPLC solvent A. The samples were centrifuged (10000 U/min, 10 min, 4 °C), transferred into HPLC vials, and measured as described below. Dicarbonyl compounds were converted to quinoxalines by incubating 500 μL of the reaction mixtures with 150 μL of 0.5 M sodium phosphate buffer, pH 7.0, and 150 μL of a solution containing 0.2% *o*-phenylenediamine and 18.5 mM DETAPAC.[25] After overnight derivatization, the samples were centrifuged (10000 U/min, 10 min, 4 °C), transferred into HPLC vials, and measured as described below.

High-Pressure Liquid Chromatography with UV Detection. HPLC-UV analyses were performed using a high-pressure gradient system from Amersham Pharmacia Biotech (Uppsala, Sweden), consisting of a pump P-900 with an online degasser (Knauer), a column oven, and a UV detector UV-900. For the analysis of benzoylated amino acids and benzamide, a stainless steel column (250 mm × 4.6 mm) filled with Eurospher-100 RP-18 material of 5 μm particle size with a guard column (5 mm × 4 mm) of the same material was used (Knauer). The mobile phases were 10 mM ammonium acetate buffer, pH 4.5 (solvent A), and methanol (solvent B). The proportion of solvent B was at 20% for 3 min, then linearly increased to 75% during 11 min, and further to 80% B during 3 min. The absorbance was read at 228 nm. The injection volume was 65 μL, and the separation was performed at room temperature and a flow rate of 0.8 mL/min. The analysis of 1,2-dicarbonyl compounds was performed as described previously.[25] For both methods, external calibration was performed. The recovery of **1a** at a concentration of 4 mM was 101% after incubation without carbohydrate compounds.

High-Pressure Liquid Chromatography with Mass Spectrometric Detection. Quinoxalines in selected incubation mixtures were analyzed with the high-pressure gradient system 1200 series (Agilent Technologies, Böblingen, Germany), consisting of a binary pump, an online degasser, a column oven, an autosampler, and a diode array detector. Samples were analyzed at room temperature on a stainless steel column (150 mm × 3 mm, 5 μm) filled with Eurospher-100 RP-18 material (Knauer, Berlin, Germany) with an integrated guard column (5 mm × 3 mm) of the same material. A solution of 0.075% acetic acid in water (solvent A) and a mixture of 80% methanol and 20% solvent A (solvent B) were used as the eluents at a flow rate of 0.3 mL/min in the gradient mode (0 min, 5% B; 30 min, 50% B; 35 min, 50% B; 39 min, 70% B; 44 min, 70% B; 46 min, 5% B; 56 min, 5% B). The injection volume was 50 μL.

The absorbance was read at 280 and 312 nm, respectively. UV spectra were recorded between 190 and 400 nm. The HPLC system was coupled to the mass spectrometer 6410 Triple Quad (Agilent Technologies), working in the positive mode with a capillary voltage of 4000 V, a source temperature of 350 °C, and a fragmentor voltage of 110 V. The mass scan (m/z 105−500) was started after 2 min. Data acquisition and evaluation were performed with the software Mass Hunter B.02.00 (Agilent).

The same device and HPLC column were used for the mass spectrometric analysis of benzoylated amino acids. As solvent A, 10 mM ammonium acetate buffer, pH 4.5 was used, whereas solvent B was methanol. Benzoylated amino acids were separated at a flow rate of 0.3 mL/min in the gradient mode (0 min, 20% B; 3 min, 20% B; 8 min, 50% B; 14 min, 65% B; 16 min, 80% B; 19 min, 20% B; 24 min, 20% B). The injection volume was 65 μL. The absorbance was read at 228 nm, and UV spectra were recorded between 190 and 400 nm. The mass scan (m/z 100−1000) was started after 2 min at a fragmentor voltage of 135 V.

RESULTS AND DDISCUSSION

Stability of Benzoyl Methionine during Sugar Degradation. The high impact of amino groups on sugar degradation reactions has long been known, but little is known about the interrelationships between other functional groups of amino acids and carbohydrate degradation. In preliminary studies on the modification of protein-bound lysine residues with 3-deoxyglucosone,[26] a certain degradation of protein-bound methionine during heating of fructosylated casein was noticed. Methionine sulfoxide formation has also been observed in glycation reactions of casein and lactose.[4] Because **1** is very susceptible to oxidation, and redox reactions are important in carbohydrate degradation chemistry, **1** should significantly be oxidized by carbohydrate degradation intermediates. To quantify the extent of oxidation reactions and to compare different carbohydrates, **1a** was utilized as a molecular probe. N-Benzoylation of methionine should suppress Maillard reactions at the amino group and enable direct analysis also of the reaction product(s) by RP-HPLC with UV detection. Hydrolysis and derivatization steps, which can favor the degradation of **2**,[12] were avoided. As carbohydrate compounds, food-relevant sugars and degradation products together with important reductones and Amadori rearrangement products (ARPs) were included in the study. Compounds **8** and **9** served as model ARPs. The need for protection of possible sites of side reactions (e.g., amino groups) led to the choice of 4-(2-aminoethyl)benzoic acid (PAEBA, **6**) as the parent amine (Figure 1). The UV-active ARPs **8** and **9** had a carboxyl group to ensure water solubility. An ethylene group was introduced between the aromatic ring and the amino group to suppress side reactions resulting from the conjugation of the amino group with the ring. NMR analysis of the ARPs **8** and **9** showed that the fructosyl residue of **8** was mainly present in the β-pyranose form, whereas the ribulosyl residue of **9** showed the α-furanose, β-furanose, and open-chain forms (data shown in Supporting Information Tables S1 and S2). Owing to the strong structural similarity of the sugar moieties of **8** and **9** to those of fructoselysine and ribuloselysine,[21,24] both products were considered suitable as ARP model compounds. The incubations were performed at equimolar concentrations (4 mM) of **1a** and carbohydrate compounds at 80 °C in sodium acetate buffer at pH 6.0. With buffer salts, traces of metals can be introduced, which are known to catalyze monosaccharide autoxidation;[15−17] however, differences between carbohydrate compounds can be assessed nevertheless. The incubation of **1a** with equimolar H_2O_2 led to the immediate and complete oxidation to **2a**. No oxidation was observed when **1a** was incubated in the absence of any carbohydrate compound. Because **2a** was stable in the presence of carbohydrate

compounds for up to 48 h, it was measured as an integral marker of the extent of oxidation. RP-HPLC allowed the separation of **1a** and **2a** (Figure 2a,b). The formation of **2a** could be followed by this method when **1a** was incubated with glucose (Figure 2c) or ribose (Figure 2d).

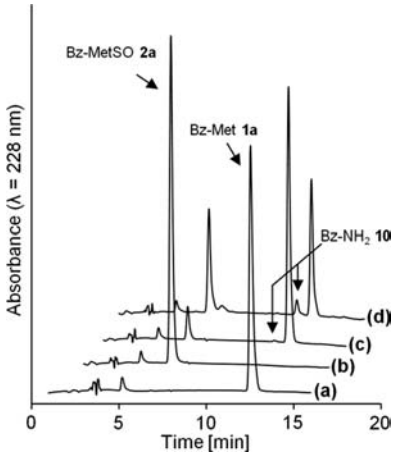

Figure 2. RP-HPLC with UV detection of (a) a standard solution of benzoyl methionine, **1a**; (b) a standard solution of benzoyl methionine sulfoxide, **2a**; (c) an incubation mixture consisting of 4 mM benzoyl methionine and 4 mM glucose after constant heating at 80 °C for 48 h; and (d) an incubation mixture consisting of 4 mM benzoyl methionine and 4 mM ribose after constant heating at 80° for 48 h.

In all incubation experiments with carbohydrate compounds, the concentration of **2a** rose in a monotone way; however, pronounced differences between compounds in their ability to induce methionine oxidation were observed both in the time course and in the extent of oxidation. Time courses for four representative carbohydrate compounds are shown in Figure 3. Aldoses and ketoses led to only very slow oxidation of **1a**. The incubation with glucose provoked no measurable oxidation in the first 4 h, and only 0.2% of **1a** had been oxidized to **2a** after 6 h (data not shown). With ribose, the oxidation of **1a** is already measurable after 1.5 h, and 8 times more **2a** is formed after 6 h (Figure 3). In contrast, dicarbonyl compounds, reductones, and ARPs showed intense initial oxidation. In the presence of **8**, 2.6% of **1a** had already been oxidized after 20 min of incubation. After the initial phase, the oxidation proceeded more slowly and linearly as indicated by the regression lines in Figure 3. This biphasic process can best be explained by a fast oxidation of the carbohydrate compounds in the first minutes by the oxygen dissolved in the solution. Assuming the production of one molecule of superoxide from one molecule of oxygen and the oxidation of one molecule of **1a** by one molecule of superoxide,[27,28] ca. 6% of **1a** can be oxidized at an oxygen solubility of 8 mg/L at 25 °C, which decreases to 2−4 mg/L at 80 °C. After the initial phase, the reaction rate is more strongly determined by the transfer of oxygen from the gas phase to the medium, which results in a linear time course. However, this effect is the same for all derivatives incubated and should not be a serious drawback.

Due to differences in the initial phase of oxidation, no reaction rates were calculated; instead, the extent of oxidation was compared through quantification of **2a** after 48 h of constant heating at 80 °C. Again, the susceptibility to oxidation of **1a** is lowest in the presence of aldoses and highest in the presence of ARPs (Table 1). Because the oxidation of **1** is a process mediated by ROS, the different carbohydrates and carbohydrate derivatives must differ in their ability to generate ROS. The differences between glucose, ribose, and methylglyoxal can be explained by their susceptibility to enolization, which precedes the oxidation of monosaccharides and

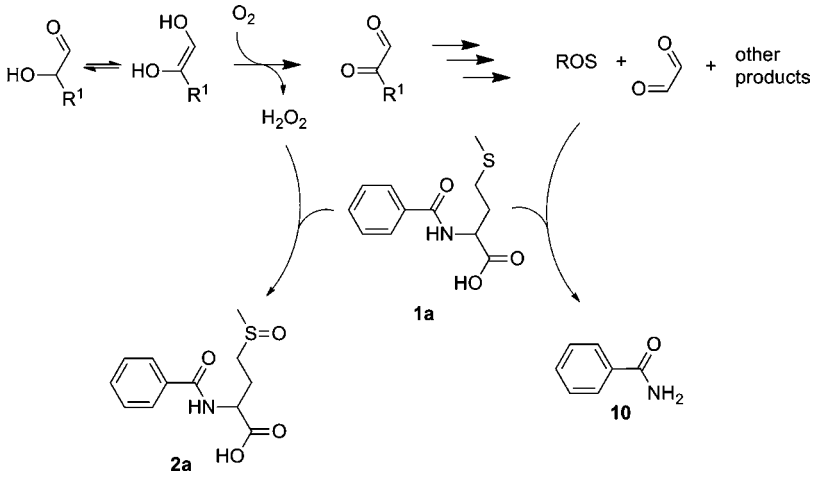

Figure 4. Proposed pathways of carbohydrate degradation, methionine oxidation, and α-amidation in heated mixtures of benzoyl methionine, **1a**, and aldoses.

correlates with the formation of superoxide radical anions.[15,21,18,27] Enolization of intact saccharides is hindered by acetal formation. Methylglyoxal cannot form ring structures and is able to enolize more easily. The low concentrations of **2a** measured after incubation of glyoxal as compared to methylglyoxal can be explained by the fact that glyoxal cannot enolize and forms stable aldehyde hydrates.

The reductones **5** and **7**, which possess an α-keto enediol structure, also invoked relatively strong oxidation. Although generally regarded as a powerful antioxidant, **7** can also act in a pro-oxidative way by generating hydrogen peroxide through autoxidation.[29] Both pro- and antioxidative properties have also been described for α-aminoketones and aminoreductones.[28,30] The antioxidative activity of aminoreductones can be at least equal to that of **7**.[30] The highest concentrations of **2a** were measured in the presence of the ARPs **8** and **9**. The 1,2-enolization of ARPs is strongly favored due to decreasing electron density at the C-1 following N-protonation under acidic conditions.[31] Moreover, aminoreductones are generated very quickly in heated solutions of carbohydrates and amino compounds as degradation products of the initially formed ARPs.[32,33] Even though aminoreductones were not measured in the present study, it can be assumed that they are responsible for the strong oxidation of **1a** in the presence of **8** and **9**. Further studies will have to show how the oxidation of the thioether group of methionine is dependent on the concentration of carbohydrate compounds and the ratio of carbohydrate compounds to methionine. Incubation of **1a** with ARPs **8** and **9** led to the same extent of oxidation as co-incubation with methyl linolenate, whereas there was no **2a** measurable on incubation with methyl stearate. The strong oxidation of methionine by intermediates of lipid peroxidation in food model systems is known from the literature.[8] A comparison of the extent of methionine oxidation in food systems caused by intermediates of lipid and carbohydrate oxidation will be part of our further studies. The fact that carbohydrate degradation products and ARPs can strongly contribute to protein oxidation should be taken into account when proteins for food applications are functionalized by glycation.[34]

Besides **2a**, a further new peak appeared during the incubation of **1a** with most of the carbohydrate compounds. This peak eluted before **1a** (Figure 2) and showed a UV spectrum similar to that of **1a**, but with a slightly hypsochromically shifted relative maximum at 225 nm. From the apparent protonated molecular ion (m/z 122.2), a relative monoisotopic molecular mass of 121.2 was calculated, leading to the assumption that the peak is caused by benzamide ($BzNH_2$, **10**). The identity of this peak as **10** was verified by comparison with a standard. In the presence of most carbohydrate compounds, **2a** and **10** are formed in a ratio of 10:1. Slightly more **10** is formed in the presence of the reductones **5** and **7**, whereas it hardly appears in incubation mixtures containing methyl linolenate. Amides such as **10** are products of the well-known α-amidation pathway, which starts by abstraction of a hydrogen radical from the α-C atom of a peptide-bound amino acid, ultimately leading to an amide (N-terminal) and a ketoacyl derivative (C-terminal).[35] Differences in the relative amounts of the reaction products **2a** and **10** could result from differences in the amounts and species of ROS produced from the different carbohydrate compounds (Figure 4).

The present study shows that oxidation reactions of carbohydrates might also strongly influence protein stability in food systems, for example, during food processing and storage. Because molecular oxygen is not able to directly oxidize **1** in solution, the role of carbohydrates in the development of the sometimes very high concentrations of **2** in food[5−7] needs to be further explored, predominantly with regard to redox, concentration, temperature, and moisture dependence.

Changes in Carbohydrate Degradation Reactions in the Presence of Benzoyl Methionine. The oxidation of carbohydrates can lead to the formation of vicinal dicarbonyl compounds.[16,17] Being the predominant products, 3-deoxyglucosone, glyoxal, methylglyoxal, and diacetyl were measured after 48 h of incubation (Figure 5). To see whether the occurrence of dicarbonyl compounds can be attributed to the thioether group of methionine, benzoyl alanine (BzAla, **4**) was incubated under the same conditions. The results are presented in Table 2. The methionine thioether group strongly alters the pattern of dicarbonyl compounds resulting from carbohydrate degradation. As a rule, mono- and disaccharides form 3−15 times more glyoxal in the presence of **4** than in the presence of **1a**. On the other hand, slightly less 3-DG is formed from fructose, lactose, and lactulose in the presence of **4** than in the presence of **1a**. As depicted in the generalized scheme in Figure 4, the enolized form of a carbohydrate compound, for example,

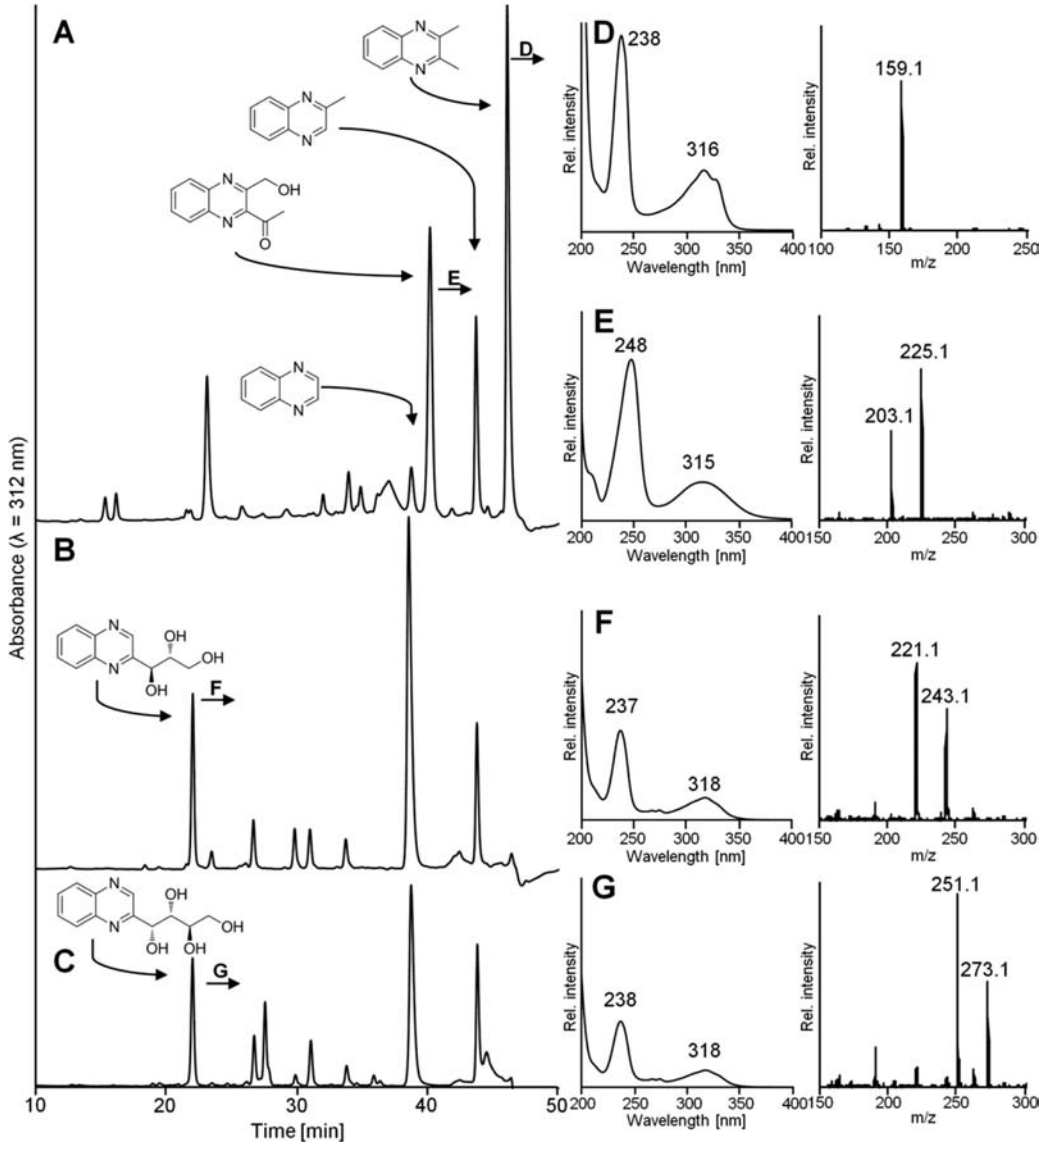

Figure 5. RP-HPLC with UV and mass spectrometric detections of incubation mixtures of benzoyl methionine (c = 4 mM), **1a**, in the presence of (A) 4-hydroxy-5-methyl-3-furanone, **5**; (B) ribose; and (C) fructose after constant heating at 80 °C for 24 h with proposed structures of quinoxalines; UV and mass spectra of quinoxalines resulting from (D) diacetyl (t_R = 46.2 min), (E) 2,3,4-trioxopentanol (t_R = 40.2 min), (F) ribosone (t_R = 22.1 min), and (G) glucosone (t_R = 22.0 min).

glucose, is oxidized to a 1,2-dicarbonyl compound, for example, glucosone, whereas molecular oxygen is reduced to hydrogen peroxide as an ROS species. Hydroperoxides have been proposed as the first intermediates in carbohydrate autoxidation.[27] In this study, the primary oxidation products 2,3,4-trioxopentanol, ribosone, and glucosone, respectively, were qualitatively identified in the reaction mixtures as the respective predominating quinoxalines resulting from the furanone **5** (Figure 5E, proposed quinoxaline structure), ribose (Figure 5F), and fructose (Figure 5G), respectively. The quinoxalines were identified on the basis of a relative UV maximum between 312 and 320 nm and their protonated molecular ions ($[M + H]^+$) or the respective sodium adducts ($[M + Na]^+$). In later stages of autoxidation, the carbohydrate chain can oxidatively be cleaved leading, for example, to the formation of glyoxal.[36−39] When **1a** is present, the reaction of ROS with the thioether group is favored. Thus, **1a** can suppress oxidative carbohydrate degradation reactions in favor of nonoxidative degradations leading, for example, to 3-deoxyglucosone or methylglyoxal.[40] In the presence of **1a**, carbohydrates behave similarly as under microaerobic conditions.[38−40]

The situation is quite diverse when ARPs and reductones are examined. In this case, glyoxal formation tends to be higher in the presence of **1a** than in the presence of **4**. Moreover, a pronounced formation of diacetyl was measured in the incubation mixtures of some carbohydrate compounds (Figure 5D). Diacetyl formation was always significantly higher when BzMet was present. Basically, diacetyl can be formed by the combination of two acetyl radicals especially at low concentrations of oxidizing agents,[41] by isomerization from 1-deoxyglucosone[42,43] and during specific glucose degradation reactions.[44] Traces of free amino groups can be formed from the ARPs **8** and **9** during the incubations. Therefore, **8** was replaced in the incubation by its parent molecules **6** and glucose as well as by **6** and fructose to assess possible interferences resulting from the early Maillard reaction. At a

[a]Data are given in μmol/L, means ± SD, $n = 3$.

concentration of 4 mM of each compound, the incubation of glucose and **6** or of fructose and **6** with **1a** did not lead to a significant change in the oxidation to **2a** or the cleavage to **10** (Table 1). Diacetyl formation was not measurable (Table 2). The role of ARP degradation by primary amines under the incubation conditions was measured through incubation of **8** only with **6** (both at 4 mM, 48 h, 80 °C). This did not lead to the same increase in the concentration of diacetyl as on incubation of **1a** and **8** (Table 2). Thus, the thioether group of methionine must be responsible for the differences in diacetyl formation. The mechanistic basis for these changes could be a decrease in the concentration of oxygen or ROS in the mixtures after reaction with **1a**, which could favor combinations of acetyl radicals to form diacetyl.[38,41] On the other hand, the radical nature of methionine oxidation might also lead to a stabilization of intermediate reductone or acetyl radicals; however, the nature of such stabilization yet needs to be further explored.

In summary, it has been shown that **1a** can be oxidized to **2a** during incubation with reducing carbohydrates, reductones, and ARPs at moderate temperatures. The presence of **1a** leads to changes in the reaction pathways of sugar degradation in such a way that oxidation reactions are suppressed, whereas certain radical reactions, for example, the combination of acetyl radicals to form diacetyl, are favored. These findings represent novel aspects of the molecular basis of protein oxidation reactions in food systems. Even in the absence of substantial amounts of lipids, food protein oxidation should occur through the action of intermediates of carbohydrate or ARP oxidation, for example, in food items such as skimmed milk or beer, and also in solid foods such as bread (crumb) or low-fat meat products without the development of a characteristic flavor resulting from lipid peroxidation products. The determination of individual protein oxidation products needs further attention.

ABSTRACT: To improve the gel strength, we attempt to introduce the microcomposite concept into the food gel system. A stable positively charged chitin microfibers (CMFs) suspension was fabricated by a facile microfluidizer approach without changing its chemical structure. The obtained CMFs bearing width of about 0.5−5 μm and length of more than 500 μm were then developed in a transglutaminase cross-linked β-conglycinin (7S) gel. The morphological and rheological characterizations of the 7S-CMF composited gels were done as a function of the protein and CMFs concentrations. Results showed that the presence of the CMFs network improved the gel strength significantly. This effect was CMFs content dependent and was related to the formation of a sponge-like porous microstructure. We inferred that the CMFs provided an initial framework for gel formation and added structural rigidity to the protein gel. The role of protein was to participate in network development as an electrostatic coating and gelation component.

KEYWORDS: *β-conglycinin, chitin, microfiber, reinforce, composite, gel*

INTRODUCTION

Foods should be understood as soft materials.[1] It is no surprise that food technologists are getting or will be getting inspiration from other scientific fields such as material science. Novel functional properties are expected to be created by high performance composite materials in polymer-based food systems. Recently, the application of the nano- or micro-structured composite concept has been observed in biopolymer-based films, hydrogels, and scaffolds.[2−6] As novel functional renewable materials, natural cellulose and chitin nano- or microfibers have received increasing interest because of their abundance, biocompatibility, and specific properties.[7] In addition to their high mechanical strength, they have several useful advantages such as high aspect ratio and facile chemical modification, showing a potential application in the material and food industry.[4]

According to previous research, the top-down method is applicable to the production of nano- or microfibers, involving physical, enzymatic, chemical, and mechanical ways.[8] Compared to other approaches, microfluidization, as a novel mechanical method, has attracted a great deal of interest in recent years because it is convenient. Lee et al.[9] reported that cellulose nanofibers can be prepared by the application of a microfluidizer at 138 MPa. Liu et al.[10] also found that the joint treatment of wet-grinding and high-pressure homogenization can effectively disassemble chitosan particles into nanofibers.

Chitin (poly-β-(1,4)-*N*-acetyl-D-glucosamine) is the second most abundant natural polysaccharide next to cellulose. As the waste products of the seafood industry, crab and shrimp shells are the main commercial sources of chitin, implying that there is a great profit if chitin can be used as a food ingredient. Chitin has shown a great deal of functional and nutritional benefits such as the reduction of plasma cholesterol and intestinal lipid absorption.[11] However, chitin is insoluble in all common solvents due to its rigid crystalline structure, which is a major problem in developing its uses. Even though it can be dissolved in some specific solvents such as saturated calcium solvent,[12] using them by this means in food industry can be challenging. Recently, for promotion of the use of chitin, fibrillar chitin provides another interesting pathway because a lot of novel functional properties have been reported after the formation of chitin and chitosan nano- or microfibers.[4,10,13−15] Araki et al.[4] reported that the presence of chitin nanowhiskers significantly enhanced the gel strength of the cross-linked chitosan hydrogel. Zhou et al.[14] found that the chitosan nanofibers played a role like a cross-linker and a reinforcing agent in the polyacrylamide hydrogel, resulting a significant increase in compression strength and storage modulus. Most recently, reports on using chitin nanofibers suspensions as metal sorbents have been first published.[15] However, as far as we know, fibrillar chitin as food compositions have seldom been investigated until now. The applications of nano- or microfibers in the above-mentioned investigations provide a novel route, and we attempt to introduce this nano- or microcomposite concept into a food system for reinforcing the food gel.

Soy proteins (SP) are the most important representative of legume proteins and have been widely used to formulate foods to improve their nutritional and functional qualities. Microbial transglutaminase (MTGase), because of its low-cost mass production and is "Generally Recognized As Safe", has been largely utilized as a food processing tool in the past few years.[16]

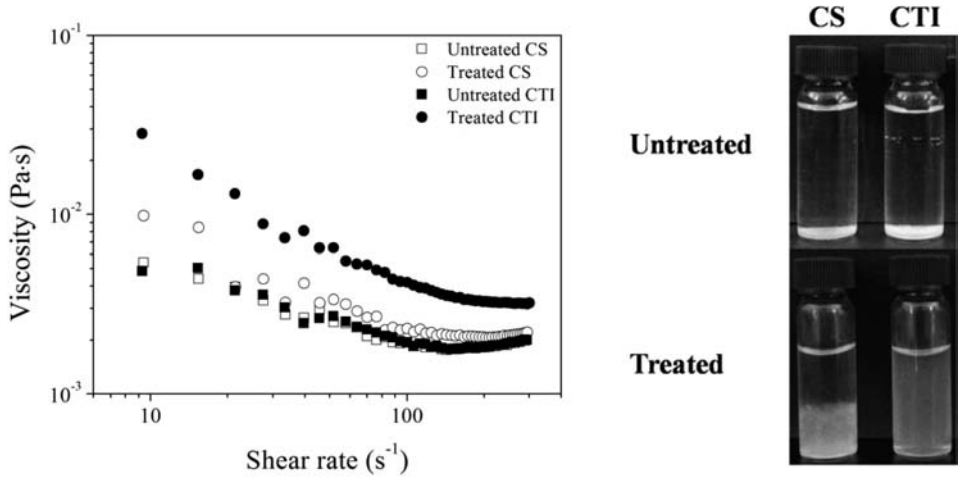

Figure 1. Observation and viscosity of the raw suspension and treated suspension of chitosan (CS) and chitin (CTI), respectively (0.1 wt % dry sample weight).

There have been several reports on the gelation of SP induced by MTGase.[17,18] Tang et al.[18] found that MTGase cross-linked glycinin-rich SP gel showed significantly higher gel strength than β-conglycinin-rich SP gel. In recent years, MTGase induced SP-polysaccharide composite gels, which showed notably improved gel strength, are attracting increased attention. Guo et al.[19] introduced a novel method regarding MTGase induced SP-based hydrogel by complexing SP with dextran sulfate. Most recently, Zhang et al.[20] investigated the combined cross-linking of MTGase and Maillard cross-linking, indicating that denser and finer networks of combined-treated gels were formed compared to those of the SP gels.

β-Conglycinin (7S), one of the main fractions of SP, is a glycoprotein, showing a great potential in delivery of hydrophilic nutrients. However, 7S gels show poor gel strength, which could limit its uses. In this study, we prepared a chitin microfibers (CMFs) network in an aqueous system by a facile mechanical top-down approach and investigated the morphology and structure of the obtained CMFs network. Subsequently, use of CMFs for reinforcement of MTGase cross-linked 7S gels was investigated to reveal its potentially attractive application in food. Small and large deformation rheological analyses were used to investigate gelation kinetics and mechanical properties. The microstructures of the gels were characterized by using scanning electron microscopy.

MATERIALS AND METHODS

Materials. Defatted soybean flakes were purchased from Shandong Xinjiahua Industrial and Commercial Co. Ltd., China. The β-conglycinin-rich SP was prepared according to Nagano's procedure.[21] Protein content of 7S lyophilized powder was 89.7 ± 0.4% determined by the Dumas method (N × 5.71) in a Rapid N Cube (Elementar France, Villeurbanne, France). The chitosan (molecular weight about 300 kDa; degree of deacetylation of 95%; moisture 8.0%; ash content 0.7%) and chitin (degree of deacetylation ≤50%; moisture 9.0%; ash content 0.9%) used for experiment were purchased from Shandong Aokang Industrial and Commercial Co. Ltd., China. MTGase was purchased from Ajinomoto Co., Japan. The activity of the enzyme product was 100 U/g as determined according to the method proposed by Folk et al.[22] All chemicals used were of analytical or better grade.

Preparation of Chitin and Chitosan Fiber Suspensions. A certain amounts of raw chitin and/or chitosan powders were suspended into distilled water to obtain a slurry with 0.1%, 0.25%, and 0.5% (w/w) dry sample weight. After 10 min of stirring, the slurries were homogenized using an Ultraturrax (T25, IKA, Staufen, Germany) at 10 000 rpm for 5 min. The obtained predispersed slurries were then passed through a homogenizer (Microfluidizers M-110 EH Processor Co., Lampertheim, Germany) under a constant pressure of 150 MPa and at a flow rate of 100 mL/min for 10 passes. The obtained chitin and chitosan fiber suspensions were stored at 4 °C prior to further analysis.

Preparation of 7S-CMF Composite Gels. The gel solutions were prepared by dissolving the 7S powders into the chitin fiber suspensions directly. A certain amount of 7S powders was dissolved into a certain amount of chitin fiber suspensions (0.1%, 0.25%, and 0.5%, w/w) under continuous stirring (200 rpm) for 3 h. The pHs of mixtures were adjusted to 7.0, and then the mixtures were stored overnight at 4 °C to allow a complete hydration. For the gelation step, a MTGase concentration of 30 unit/g of 7S was used in each reaction according to the pretest. In all mixtures, 7S reached a final concentration of 4%, 6%, and 8% (w/v), respectively. After vacuum degassing, the mixtures were incubated in a water bath (45 °C, 4 h) for gel formation.

ζ-Potential. The ζ-potentials of the samples were determined according to previous publications by using a Nanosizer ZS instrument (Malvern Instruments Ltd., Worcestershire, UK).[10,23] The electrophoretic mobility was determined by Laser Doppler Velocimetry, and the maximum working voltage on the electrode was ±160 V. The Henry equation was then applied for calculating the ζ-potential. All measurements were conducted in triplicate.

Fourier Transform Infrared Measurements (FTIR). FTIR measurements were performed on flakes of sample powder mixed with KBr. The sample quantity (about 5 mg) in KBr (200 mg) was chosen in order to optimize the flake transmittance and to obtain a well detectable absorption in the spectral region of 4000−400 cm^{-1}. All spectra were recorded at 25 °C, with a resolution of 4 cm^{-1}, using a Vector-33 interferometer (Bruker Optics, Ettlingen, Germany) working under a vacuum to avoid intense spectral components.

Low Amplitude Dynamic Oscillatory Measurements. Steady shear viscosities and dynamic rheological measurements were conducted by a HAAKE RheoStress 600 rheometer (Thermo electron GmbH, Karlsruhe, Germany) equipped with a parallel plates geometry (plate sensor PP35 Ti, 35 mm diameter, 1 mm gap) and a circulating system for temperature control. In the steady shear experiment, the apparent viscosity was measured across a range of shear rates (0.01−300 s^{-1}) at 25 °C. As for dynamic rheological analyses, time-sweep analysis was used to monitor the gelation kinetics of gel samples, which were induced by MTGase. The sample solutions were placed on the plate immediately after the addition of MTGase. Subsequently, the test at a frequency of 1 Hz and a strain of 0.5% (within linear

dx.doi.org/10.1021/jf500922n | J. Agric. Food Chem. 2014, 62, 4434−4442

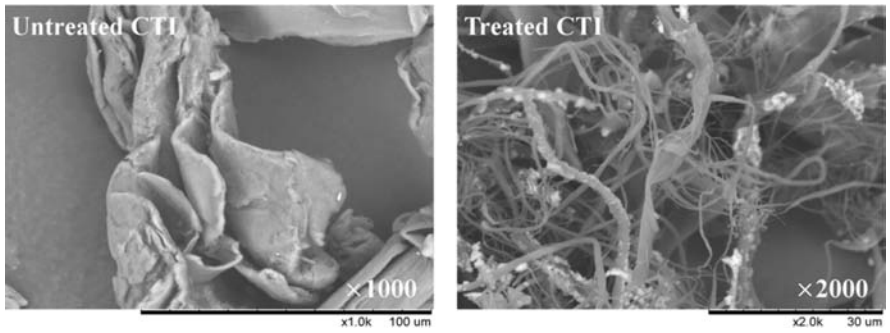

Figure 2. SEM micrographs of the raw chitin sample and high-pressure homogenized treated sample.

viscoelastic region) was started when the temperature was stable at 45 °C.

Uniaxial Compression. The gel samples (cubes with an edge length of 10 mm) were compressed between lubricated plates fitted to a TA.TX2 texture analyzer (Stable 194 Micro System, Surrey, U.K.) with a cylinder measuring probe (P/20a) which had a diameter of 20.0 mm. The breakdown pattern of the gels was observed by compressing the gels at a constant speed of 0.2 mm/s to 20% of their initial height at room temperature. Stress and strain were calculated according to the following equations: stress = $(F/A_i) \times ((L_i - \Delta L)/L_i)$; strain = $|\ln(L_i/(L_i - \Delta L))|$, where F(N) is the force measured during compression; A_i (m^2) is the initial cross sectional area of the specimen; L_i (m) is the initial specimen height; ΔL (m) is the deformation. At least two gel samples were tested per treatment, and each treatment was replicated two times.

Scanning Electron Microscopy (SEM) Observations. According to a previous publication,[18] chitin microfibers and gel samples were immersed in liquid nitrogen for 5 min to minimize the impact of ice crystals and then freeze-dried. Lyophilized samples were cut carefully and stuck onto an SEM aluminum plate through the double-sided conductive carbon tabs. Samples were coated with gold in a E-1010 ion sputter (Hitachi High-Technologies Corporation, Tokyo, Japan) before the test. The SEM images were recorded at 25 °C using a TM-3000 tabletop low vacuum scanning electron microscope (Hitachi High-Technologies Corporation, Tokyo, Japan) at an accelerating voltage of 15 kV.

Statistical Analysis. All the data were subjected to one-way analysis of variance, and correlations between the results were carried out using Statistical Analysis System Software (SAS version 9.0, SAS Institute, Cary, NC); significant differences were determined by Duncan's multiple range test and accepted at $P < 0.05$.[24]

RESULTS AND DISCUSSION

Characterization of Chitin Microfibers. Figure 1 shows the observations and viscosities of the raw suspensions and treated suspensions of chitosan and chitin, respectively. As shown in photograph, raw chitosan and chitin particles, without any treatment, both settled quickly in water (less than 2 min). After being processed by high-pressure homogenization, chitosan and chitin suspensions displayed totally different stabilities in water. Large and millimeter-scale fibers were obtained in treated chitosan suspension coupled with the settlement of these fibrils after 5 min. Treated chitin, however, was macroscopically well suspended in water and did not precipitate during 2 months of storage at 4 °C. The viscosities of these samples also can be seen in Figure 1. As a control, samples showed very low shear viscosities before high-pressure homogenization treatment. No significant increase in viscosity can be found in treated chitosan suspension. In contrast, chitin fiber suspension showed a significant increase in viscosity, suggesting that the internal structure of chitin spread out after the treatment and the increased steric hindrance effect resulted

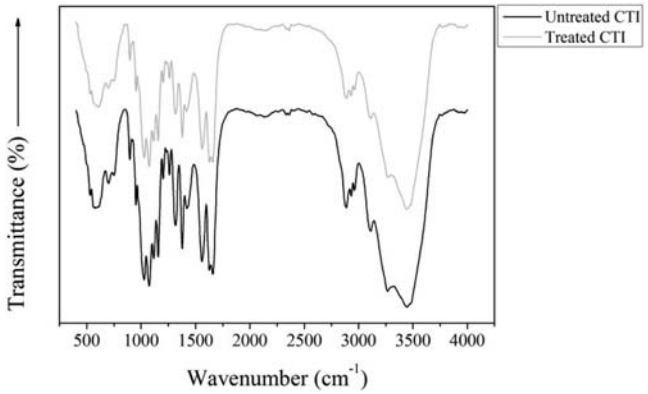

Figure 3. FTIR spectra of the raw chitin sample and its microfibers after mechanical treatment.

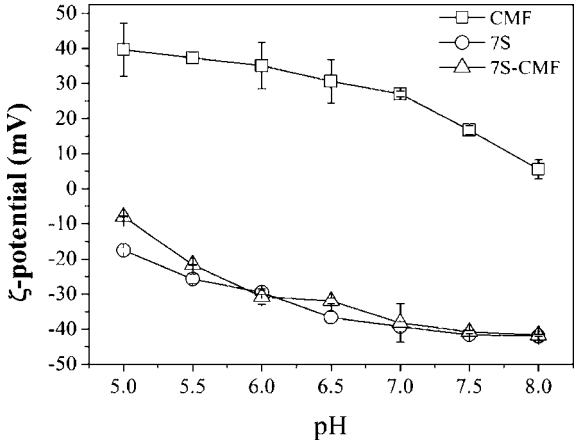

Figure 4. Effects of pH on ζ-potential of chitin microfibers (CMFs) suspension (1 mg/mL), β-conglycinin (7S) suspension (5 mg/mL), and 7S-CMFs mixture (5 mg/mL, 7S/CMFs ratio = 5/1).

in a higher viscostiy.[25] Chitin fiber suspension showed a decrease in viscosity for higher shear rates, meaning that the samples were shear thinning. It could indicate that the shear reduced the connections between chitin fibers and made the suspension flow more easily.[25,26]

Figure 2 shows the SEM micrographs of raw chitin powder and high-pressure treated chitin sample. Large and irregular-shaped particles which were millimeter sized were observed in Figure 2A. After treatment, the irregular-shaped chitin particles disassembled into chitin fibers. These fibers intertwined with each other, and the diameter of these fibers were distributed over a range from approximately 0.5 to 5 μm (Figure 2B),

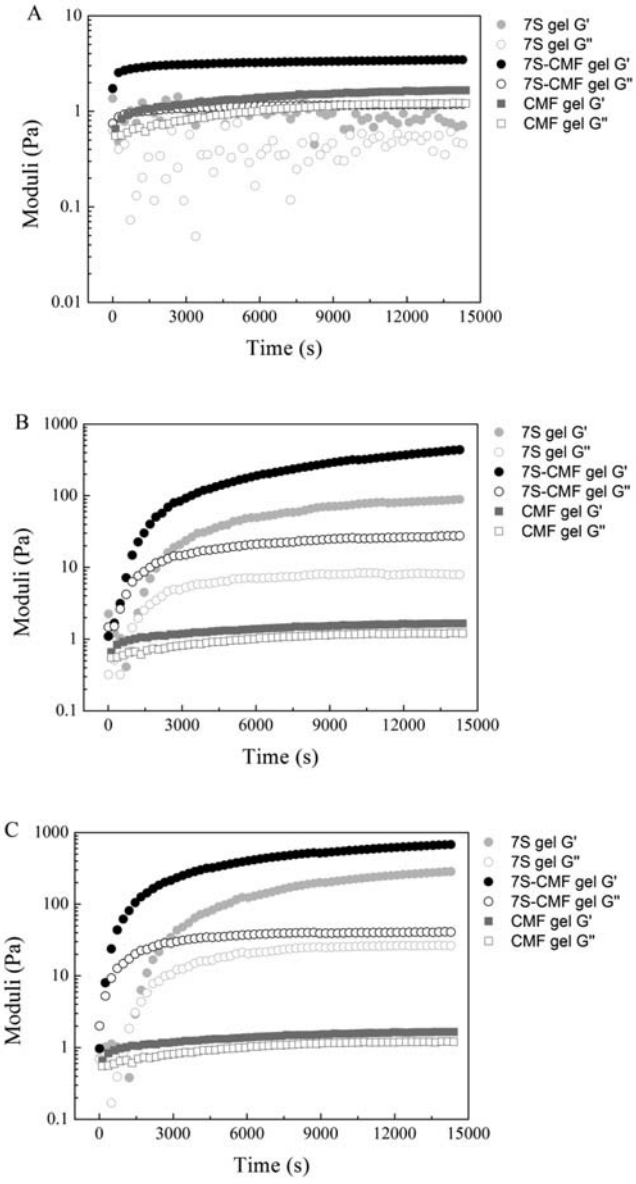

Figure 5. Time sweep rheological profiles of 7S-CMF composite gels as a function of 7S concentrations (A: 4%, B: 6%, and C: 8%).

meaning that chitin microfibers (CMFs) were obtained. Many research studies have clarified several advantages regarding high-pressure homogenization for obtaining chitin nano- or microfibers such as high mechanical strength, high aspect ratio, and adsorption of protein and metal ions.[15] Most recently, Tzoumaki et al.[27] successfully fabricated an oil-in-water Pickering emulsion which was stabilized by chitin nanocrystal. Overall, high-pressure homogenization successfully disassembled the chitin particles into stable water suspensible chitin microfibers, which could be used in food as a thickening and reinforced filler.

The chemical composition of chitin was obviously unchanged during the high-pressure homogenization treatments, which can be seen in Figure 3. The chemical composition analysis of chitin was based on the identification of bands related to the functional groups present in chitin: the OH stretching band at 3480 cm^{-1}, NH stretching band at 3270 cm^{-1}, amide band I at 1660 and 1620 cm^{-1}, and amide II band at 1560 cm^{-1}. Both the position and relative intensity of characteristic bands of the CMFs are similar to those of the raw chitin particle, indicating the original chemical and molecular structures of chitin were retained in the case of mechanical treatment. Liu et al.[10,14] also reported that the chemical compositions of both chitosan and chitin were unchanged during the mechanical treatments at neutral pH.

Stability of 7S-CMF Mixture. Electrostatic forces have been shown to have a significant effect on colloid stability in many studies regarding protein and polysaccharide interaction.[28] There appears to be no investigation on the ζ-potential of chitin colloid suspension, which is probably because measurements of ζ-potential of insoluble chitin particles are unreliable. However, the ζ-potentials were successfully measured after the chitosan and chitin particles were disassembled into micro- or nanofibers.[10,29] The ζ-potential–pH patterns of CMFs are shown in Figure 4, which show that CMFs were positively charged microfibers at all tested pHs (from pH 5.0 to 8.0). The pK_a of amino groups was reported as 6.2–7.0.[30] At a pH below the pK_a, chitin microfibers carry a positive charge due to the protonation of amino groups, and the charged groups provide electrostatic repulsion between fibers.[29] With pH elevation, the ζ-potentials of CMFs decreased from 39.6 ± 5.5 mV at pH 5.0 to 5.5 ± 1.9 mV at pH 8.0. It is noteworthy that CMFs showed high ζ-potentials above 27 mV during a long pH region from 5.0 to 7.0 and then decreased to 5.5 mV rapidly. This phenomenon was due to the deprotonation of the amino groups. Concomitantly, the suspended CMFs were stable at a long pH region and then settled down in 5 min at high pH (pH 8.0), suggesting that CMFs were also electrically stabilized and aggregates were obtained at high pH due to the decrease electrostatic repulsion.

The ζ-potential–pH patterns of 7S are shown in Figure 4 as well. It is well-known that 7S particles carry a negative charge at pH above their pI (pH 4.3). Electrostatic interaction between 7S and CMFs should occur at all tested pH values because they carry a complementary charge. The strength of the electrostatic interaction (SEI) between oppositely charged polyelectrolytes can be estimated by calculating the absolute value of the product of the measured ζ-potential of both polymers at each pH.[28] The SEI–pH curves indicated that the interactions between 7S and CMFs should be strongest at pH 6.5 and coacervates should be obtained (data not shown). However, the 7S-CMFs mixture was stable, and no coacervates were found at all tested pHs. The ζ-potential curve of 7S-CMFs mixture suggested that the charge of the mixture was protein charge dominant because it showed similar values as the 7S ζ-potential curve.

Moreover, the thermal stability of CMFs was also investigated by macroscopic observation. Macroscopic observation suggested that CMFs suspension was stable at 45 °C and became unstable at the temperature above 70 °C. This phenomenon can be ascribed to the increasing attractive interaction between the chitin fiber when increasing the system temperature.[25] As a result, cold-set MTGase cross-linked gelation method was used to form the 7S-CMF composite gel because it can effectively avoid the impact of heat treatment on the stability of the microfibers

7S-CMF Composite Gel. In this study, we attempted to investigate the effect of CMFs on gelation rate and extent of soy 7S globulin. Therefore, dynamic viscoelastic properties of the 7S-CMF composite gels were investigated by small deformation rheological measurements. Storage modulus (G') and loss modulus (G'') values represent the elastic and viscous

dx.doi.org/10.1021/jf500922n | J. Agric. Food Chem. 2014, 62, 4434–4442

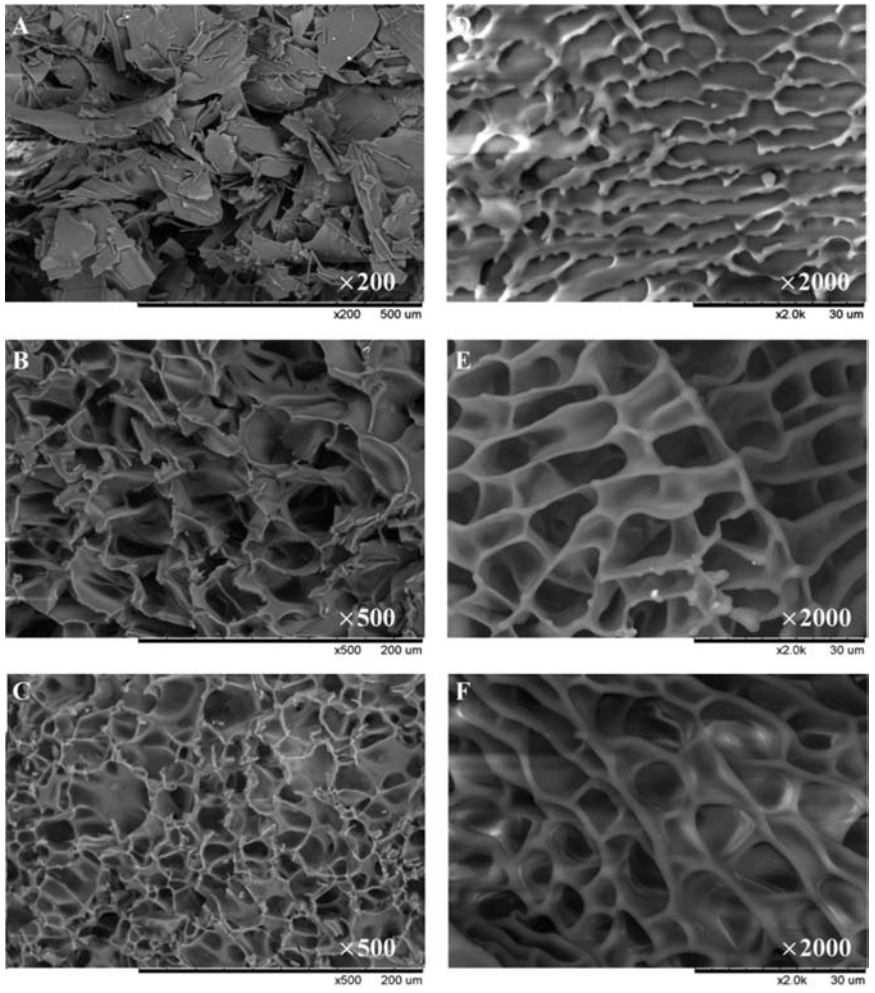

Figure 6. SEM images of 7S-CMF composite gels as a function of 7S concentrations (A and D: 4%; B and E: 6%; C and F: 8%; A, B, and C: 7S gels; D, E, and F: CMFs composited 7S gels).

components in the network.[31] As shown in Figure 5, 7S dispersion showed different rheological profiles at different protein contents. Irregular scatter diagrams were obtained at 7S concentration of 4%, suggesting that the 7S dispersion was still in the liquid state, and no gelation networks were obtained at such a low concentration. As long as the protein content (6% and 8%, w/v) exceeded the critical gelation concentration, G' and G'' of 7S dispersion developed similarly, and the G' values were significantly greater in magnitude than the G'' values. As for 7S-CMF composite gels, significant enhancements of gel strength were observed in Figure 5. As shown in Figure 5A, compared to the 7S gel, the 7S-CMF composite gel displayed a more organized pattern even though it was still liquid state in appearance. This phenomenon may be related to the presence of CMFs network that provided an initial framework and the G' values were stable around 1 Pa (CMFs gel in Figure 5). However, the lack of protein reacting sites resulted in a low elastic and viscous modulus. Significant increases of viscoelastic modulus were found at a higher protein concentration, representing an evident increase in G' values of the 7S-CMF composite gel of about 10 times compared with those of the 7S gel at both protein content of 6% and 8%. Meanwhile, the gelation time (t_{gel}), which is generally accepted as the time when the value of G' becomes greater than that of G'' and is greater than 10 Pa,[32] was significantly ($p < 0.05$) shortened in the presence of CMFs. In detail, the values of t_{gel} at protein content of 6% and 8% decreased from 2000 and 1900 s (7S gel) to 800 and 300 s (7S-CMF composite gel), respectively.

The changes in rheological and mechanical properties of gels are highly related to the changes in microstructure. One way to look at the inside of a gel is with SEM. Typically, SEM showed better resolution than confocal laser scanning microscopy (CLSM), but the sample used in SEM requires rather a severe and time-consuming sample preparation including freeze-drying.[33] The porous and cellular microstructures observed with SEM are probably induced by ice crystal formation during the freezing step in sample preparation.[34] As presented in Figure 6, the results of SEM showed that microstructural modifications occur in 7S-CMF composite gels, in particular, changes in porosity, including an increase in the amount and a decrease in size. In detail, 7S gels showed disordered and lamellar structures at 4%, while showed typical interconnected macroporous morphologies with pore sizes ranging from 10 to 40 μm at 6% and 8%, indicating that the more protein the gel had the more compact and homogeneous the microstructure was. Sponge-like pore structures were formed as seen in 7S-CMF composite gels (Figure 6D−F). The size of the pores is around 3−9 μm. Beginning with the thin and shallow networks at low protein content, thicker and smoother networks and deeper pores were observed with an increase in protein content. Such changes in microstructure could affect gel rheological properties and explain the increase in gel viscoelastic modulus.

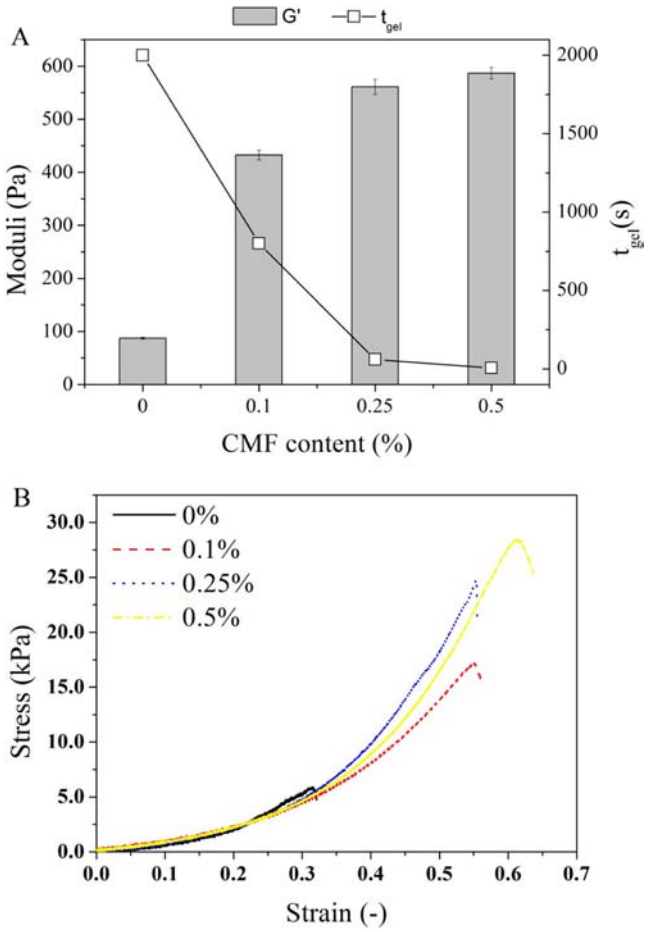

Figure 7. (A) G', t_{gel}, and (B) stress−strain curves of 7S-CMF composite gels as a function of CMFs concentrations at a 7S concentration of 6%.

Aouada et al.[5] also found a three-dimensional, well-oriented porous microstructure when they added cellulose nanofibers into a hydrogel, showing a similar decreases in pore size and increases in gel strength.

Figure 7A showed that the elastic modulus increased while the t_{gel} decreased significantly ($p < 0.05$) with increased concentrations of CMFs, suggesting that the formation of gel was significantly influenced by the CMFs content. Previous papers have clarified the effect of polysaccharide concentration on the formation of protein−polysaccharide mixed gel. Guo et al.[19] showed that the gelation of soy protein was accelerated by adding dextran sulfate, and the strengths of the formed gels were dextran sulfate amount dependent. Le et al.[35] found the β-lactoglobulin and xanthan gum ratio strongly affected gelation kinetics and was a main factor controlling the gelation process and the gel structure. Uniaxial compression measurements were performed to investigate the fracture properties (Figure 7B). 7S gel fractured at relatively low strain and stress values which coincided with previous investigations,[36] suggesting a weak and brittle gel was formed. 7S-CMF composite gel showed different stress−strain curves. As expected, increasing CMFs concentration caused an increase in both fracture stress and fracture strain. The value of the fracture stress increased from 5.8 to 17.0 kPa, 24.7 and 28.4 kPa, while the fracture strain increased from 0.315 to 0.551, 0.553, and 0.614 with CMFs content elevation. These agreed with the small deformation rheological investigations that showed a similar trend of G' values for 7S-CMF composite gels.

To further confirm the data of small and large deformation tests, SEM images of 7S-CMF composite gels were recorded as a function of CMFs contents. As shown in Figure 8, a significantly different microstructure can be found between the 7S-CMF composite gels and control sample, and then smaller and regular pores were obtained when the CMFs concentration increased. The overall data suggested that the great enhancement in gel strength may be related to the modification of gel microstructure, and this modification was ratio dependent.

General Discussion. In this work, a stable chitin microfibers suspension was obtained by passing chitin particles through a high-pressure homogenization equipment. The

obtained novel fiber material was used in 7S gel as a thickening and reinforced filler because the advantages such as high viscosity, high aspect ratio, and facile electrostatic modification (Figures 1, 2, and 4). Compared to MTGase induced 7S gel, the addition of CMFs enhanced the gel strength and modified the gel structure. To clarify a reasonable understanding of this improvement, a schematic illustration of the formation of 7S-CMF composite gel is proposed and shown in Figure 9.

β-Conglycinin is one of the main fractions of SP. MTGase induced 7S gelation has been fully investigated in past 20 years, concluding that transglutaminase catalyzed an acyl-transfer reaction between the γ-carbonyl group of a glutamine residue and the ε-amino group of a lysine residue. The resultant covalent connections between the protein molecules formed the three-dimensional networks of the gel.[16] If protein underwent a heat treatment, more groups were exposed from the hydrophobic core of the molecules, and this treatment favored the MTGase cross-linking reaction.[19] In this paper, heating cannot be used, and this type of MTGase cross-linked unheated 7S gel showed typical interconnected macroporous protein backbone and relatively weak gel strength which were proven by means of SEM and rheology technique (Figure 9A). As shown in Figures 1 and 2, high-pressure homogenization disassembled the chitin particles into stable water suspensible chitin microfibers (Figure 9B). Most interestingly, the result of ζ-potentials showed that the obtained CMFs still carried a positive charge at neutral pHs. The reason for this phenomenon is probably because the release, from within the chitin particles, of some unacetylated amino groups increased the protonation on the microfiber surfaces.[37] Liu et al.[10] reported a similar result using chitosan and chitin suspension. The adsorption of metal ions by these materials have been reported due to the microfibrous structure and electrostatic attraction.[15] Most interestingly, some researchers suggested that the presence of nano- or microfiber significantly increased the mechanical and swelling properties of biomaterial hydrogel.[38,39] From this viewpoint, a hypothesis is proposed in Figure 9C.

When a 7S-CMF mixture was obtained at neutral pH, the presence of a CMFs network provided an initial framework, and then the protein coated on the CMFs network via electrostatic attractive force because protein carried a complementary charge in this case. However, the presence of excessive protein in the aqueous phase might exist around the CMFs framework and produce a net negative charge of the whole system (Figure 4). After MTGase induced covalent cross-linking, the 7S-CMF composite gel system was achieved. The CMFs played a key role as a gel backbone, while the role of the 7S protein was to participate in network development as a coating and gelation component. Thanks to the presence of CMFs, a more organized and rigid microstructure was remodeled, resulting a shorter gelation time and stronger gel strength. This reinforced behavior indicated that CMFs in this work had a similar reinforcing effect with other nano- or microfillers such as nanoparticles and nanocrystals, which can indicate that the uniformly dispensed nano- or microfillers can transfer the load from the polymer chain to themselves and stop the growing of microcracks.[38−40] Moreover, Zhou et al.[39] suggested that the mechanical properties of composite hydrogels depend not only on the reinforced properties of fillers, but also on interactions between the filler and the matrix, resembling the electrostatic coating of SP on rthe CMFs network in this paper.

In conclusion, a stable chitin microfibers suspension was successfully fabricated by passing chitin particles through a microfluidizer. As shown in the morphology analysis, high-pressure treatment disassemble the chitin particles into chitin microfibers. As a result, the enlarged steric structure and released amino groups improved the colloidal stability by a steric stabilizing and electrostatic repulsion effect. The most interesting finding in this paper was that the presence of the CMFs network improved the gel strength of the MTGase

cross-linked 7S gel significantly. The amount of CMFs was found to be a factor that affected the gel properties as well. The more CMFs the gel contained, the faster and the tougher the gel formed. The fracture stress and fracture strain also increased as a function of CMFs content. We inferred that the presence of CMFs provided an initial framework for gel formation and added structural rigidity to the 7S gel. The role of protein was to participate in network development as an electrostatic coating and gelation component. These findings will provide a new path for application of chitin in food.

Supporting Information

ABSTRACT: The molecular structures of amylose and amylopectin have an impact on functional properties of starch-containing food. This is the first study comparing amylose size distributions from various plant sources. Chain-length distributions (CLDs) of amylose and amylopectin branches ("fine structure") are characterized using size-exclusion chromatography [sometimes termed gel permeation chromatography (GPC)] and parametrized by both biosynthesis-based and empirical fits, to understand the starch biosynthesis mechanism and identify associations with starch digestibility. All starches show bimodal amylose weight CLDs, varying with plant sources, with potato tuber and sweet potato root starch having relatively longer branches than the others. The digestograms of all starches fit first-order kinetics. Unlike what has been seen in cooked grains/flours, amylose and amylopectin fine structures have no association with the digestibility of freshly gelatinized starch. This suggests that the observed effect in cooked grains/flours arises from a secondary interaction between amylose fine structure and higher order structural features.

KEYWORDS: *starch, amylose, size-exclusion chromatography, chain-length distribution, biosynthesis, digestibility*

INTRODUCTION

Starch is the main carbohydrate reserve in plants, is a major source of energy in human diet and animal feed, and has wide applications in industry. It is a polysaccharide, wherein the D-glucose monomer units are linearly extended by α-(1 → 4) glycosidic linkages and the branches are connected by α-(1 → 6) glycosidic linkages as branching points. Starch consists of two main molecules: amylose, mostly linear with a molecular weight of 10^5−10^6 and a few long branches, and amylopectin, the main component of normal starches, which is hyper-branched with a much higher molecular weight (10^7−10^8) and a vast number of short-chain branches. Both components have broad distributions of size and molecular weight. A common means of characterizing structure is the chain-length distribution (CLD), the weight or number distribution of individual chains following enzymatic debranching. We use the term "fine structure" to describe this.

Starch is synthesized in plants in various organs, including seeds, roots, tubers, and fruits, and in a wide range of species. Its structure of starch varies with plant source, contributed by the differences in the coordinated action of a series of enzymes involved in starch biosynthesis, including starch synthases (SS), starch branching enzymes (SBE), and starch debranching enzymes (DBE).[1] The molecular structure of amylopectin and the amylose content of many starches have been widely reported. However, amylose fine structure from different botanical sources is essentially unexplored.

The molecular structure of starch has significant impacts on its nutritional properties for humans, especially digestibility.[2] Rapidly digested starch leads to a high postprandial glycemic response and is believed to be related to some chronic diseases, including insulin resistance, diabetes, and obesity. Slowing down the digestion rate of starch, on the other hand, is beneficial in preventing diet-related metabolic diseases.[3,4] Similar to other dietary fibers, resistant starch (RS), the component of a starch that is not digested in the small intestine, is associated with the reduced risk of acquiring colorectal cancer.[5]

Some relationships between starch structure and digestibility have been reported; e.g., starches with short amylopectin branches are more susceptible to enzyme digestion.[6] It has also been reported that so-called "high-amylose" starches tend to have more RS compared to normal and waxy starches.[7,8] It is noted in this context that "high-amylose" starches are in fact starches containing a significant number of long chains, which could either belong to true amylose or be long amylopectin chains. Relationships between amylose fine structure and digestibility are still lacking because of limited data on amylose, with only a few studies on the impacts of amylose molecular fine structure on starch digestibility.[9−11]

This paper is the first study comparing amylose fine structures from different plant species and botanical origins and discussing their impacts on starch digestion properties. The CLDs of amylose and amylopectin branches are characterized using size-exclusion chromatography (SEC) after enzymatic debranching. The amylopectin CLDs were fitted with a mathematical model based on starch biosynthetic processes to reduce the CLDs to a few parameters from which the entire CLD was reproduced using the model and which are based on

the underlying biosynthetic processes;[12,13] having just a few parameters rather than a whole curve greatly facilitates a statistically meaningful comparison between different starch samples. The *in vitro* enzymatic digestion of freshly cooked starch samples is investigated, and correlations between amylose fine structure and starch digestibility are investigated.

MATERIALS AND METHODS

Materials. Four varieties of sorghum grains (RTx2737, B296, ICSV400, and BTx3054) grown in Narrabri (New South Wales, Australia) were provided by Dr. Alan Cruickshank from the Department of Agriculture, Fisheries and Forestry Queensland, Warwick, Queensland, Australia. One sorghum variety (S10) grown in Liverpool (New South Wales, Australia) was supplied by Professor Ian D. Godwin, the University of Queensland, Brisbane, Queensland, Australia. Barley grains from two commercial cultivars (Shepherd and Mackay) and two breeding lines (ND18076 and ND19119-5), developed by Dr. Jerome D. Franckowiak, were grown at Hermitage Research Facility, Warwick, Queensland, Australia, and provided by Dr. Glen Fox from the University of Queensland, who also supplied commercially available barley grain (Schooner) from an alternate location (Toowoomba, Queensland, Australia). Rice grains from four breeding lines (YRI08-04-10, YRJ08-03-13, YRA08-03-10, and YRD08-05-05) were supplied by Yanco Agricultural Institute, Department of Primary Industries, Yanco, New South Wales, Australia. In addition, Nipponbare rice grain, maize grain, wheat grain, field pea, and cow pea samples were supplied by Dr. Matthew K. Morell, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australia. Potato tuber and sweet potato root samples were purchased from a grocery store in Brisbane, Queensland, Australia.

Protease from *Streptomyces griseus* (type XIV), pancreatin from porcine pancreas, and LiBr (ReagentPlus) were purchased from Sigma-Aldrich Pty. Ltd. (Castle Hill, New South Wales, Australia). Isoamylase (from *Pseudomonas* sp.), amyloglucosidase (from *Aspergillus niger*), and D-glucose (GOPOD Format) kit were purchased from Megazyme International, Ltd. (Bray Co., Wicklow, Ireland). A series of pullulan standards with peak molecular weights ranging from 342 to 2.35×10^6 were purchased from Polymer Standards Service (PSS) GmbH (Mainz, Germany). Dimethyl sulfoxide [DMSO, guaranteed reagent (GR) grade for analysis] was purchased from Merck Co., Inc. (Kilsyth, Victoria, Australia). All other chemicals were reagent-grade and used as received.

Extraction, Dissolution, and Debranching of Starch Molecules for Structural Analysis. All starch samples were extracted and dissolved in DMSO solution with 0.5% (w/w) LiBr (DMSO/LiBr), following a method described elsewhere,[14,15] with minor modifications. Legume seeds were used as harvested; cereal grains were manually dehulled; while potato tubers and sweet potato roots were manually peeled, cut into smaller cubes, and then freeze-dried. Each sample was then ground into fine flour using a cryo-mill (Freezer/Mill 6850 SPEX, Metuchen, NJ) in a liquid nitrogen bath. Milling was for 5 min at 10 s^{-1}. Each milled flour was treated with protease and sodium bisulfite solution, followed by centrifugation to remove protein. The treated flour was dissolved in DMSO/LiBr solution and precipitated using ethanol (each treatment followed by centrifugation) to remove insoluble and soluble non-starch components, respectively. The precipitate (extracted starch) was debranched using isoamylase, following the method by Hasjim et al.,[16] neutralized to pH ~7 using 0.1 M NaOH, heated in a water bath at 80 °C for 2 h, freeze-dried, and then dissolved in DMSO/LiBr solution for subsequent analysis by SEC.

SEC. The SEC weight distribution of debranched starch was analyzed in duplicate using an Agilent 1100 series SEC system (Agilent Technologies, Waldbronn, Germany) equipped with a refractive index detector (RID, ShimadzuRID-10A, Shimadzu Corp., Kyoto, Japan), as described elsewhere.[25,26] The background theory for the following treatment has been given in detail by Castro et al.[27] A series of SEC columns (GRAM precolumn and GRAM 100 and GRAM 1000 columns, PSS) placed in an oven at 80 °C were used to separate the debranched starch molecules. DMSO/LiBr solution was used as the mobile phase with a flow rate of 0.6 mL/min. Pullulan standards were used for calibration to convert from the SEC elution volume to the hydrodynamic volume V_h or the corresponding radius R_h using the Mark–Houwink equation. The Mark–Houwink parameters K and α of pullulan in DMSO/LiBr solution at 80 °C are 2.424×10^{-4} dL g^{-1} and 0.68, respectively.[25] This relation was also used to calculate the degree of polymerization (DP) of debranched starch molecules from R_h. The Mark–Houwink parameters K and α for linear starch in DMSO/LiBr at 80 °C are 0.0150 mL g^{-1} and 0.743, respectively.[28] For linear polymers (such as debranched starch), the number distribution, $N(X)$, can be obtained from the corresponding weight distribution obtained from the RID using the relation[26,27] $w(\log X) = X^2N(X)$.

Fitting Amylopectin Number CLDs with a Biosynthesis Model. The number CLD of amylopectin as a function of DP can be used to understand the enzymatic biosynthetic processes of amylopectin molecules in the plants. Each number CLD of amylopectin branches was fitted with a model of amylopectin biosynthesis,[12,13] using a publicly available code.[29] The model considers the activities of the three core starch biosynthetic enzymes: soluble starch synthases that elongates glucan chains of amylopectin [termed SS, a role for amylose taken by granule-bound starch synthase (GBSS)], SBE (which introduces branches), and DBE (which trims excess branches). By fitting the number CLD of amylopectin with this model, a series of parameters can be obtained characterizing the enzymatic processes of the amylopectin biosynthesis. The activity ratios of SBE/SS and DBE/SS are denoted β and γ, respectively. From the mathematical development, each value of γ is associated with a value of β, so that γ is eliminated from the fitting.[12] In addition, SBE can only form branches with lengths longer than a certain minimum DP, X_{min}, and the length of moiety retained after branching must be more than a certain minimum DP, X_0. X_{min} and X_0 are also used as parameters to describe the enzymatic processes. It has been shown[30] that the CLD of amylopectin branches with DP $\lesssim$ 70 obtained using SEC is contributed by two enzyme sets, denoted enzyme sets i and ii, and the relative contribution of each is termed $h_{(ii,i)}$. In actuality, more enzyme sets are involved, but the band broadening in SEC is such that the components of the chains confined to a single lamella arising from two enzyme sets[30] cannot be distinguished. Thus, the parameters characterizing the single-lamellar SEC CLDs are in fact averages over those for the two underlying enzyme sets.

Isolation of Starch Granules by Wet Milling. Starch granules were isolated from cryo-milled flours by wet milling, following the slightly modified method by Syahariza et al.[15] Each flour sample (2 g) was steeped in 6 mL of sodium bisulfite solution (0.45% sodium metabisulfite, w/v) overnight and then milled using a homogenizer (T-25 ULTRA-TURRAX, IKA, Wilmington, NC) for 3 min. The homogenized slurry was filtered through a 53 μm screen. The flour particles that remained on the screen were homogenized and filtered, and this process was repeated 3 times or more, until no flour particles were visible on the screen. All filtrate fractions were combined and mixed with NaCl solution (0.1 M) and toluene at a ratio of 9:1 to remove proteins and lipids. The mixture was stirred for 1 h and then allowed to stand until the starch granules settled at the bottom. The toluene layer and most of the NaCl solution layer were siphoned off, and the NaCl solution/toluene steps were repeated several times until the toluene layer seemed clear, indicating no proteins or lipids. The isolated starch granules were washed repeatedly with water and ethanol, followed by air-drying at room temperature for 1 day.

***In Vitro* Starch Digestibility.** Isolated starch granules (50 mg, dry weight basis) were suspended in 2 mL of distilled water and gelatinized in a boiling water bath for 30 min with stirring and occasional vortex mixing. Each freshly gelatinized starch sample was dissolved with 7.5 mL of sodium acetate buffer (0.2 M, pH 6.0, containing 0.49 mM $MgCl_2$, 200 mM $CaCl_2$, and 0.02% NaN_3) and equilibrated at 37 °C for 15 min. An enzyme solution (0.5 mL) containing 25 μg of pancreatin and 12.5 μL of amyloglucosidase in sodium acetate buffer solution was added to the starch suspension, and the mixture incubated in a water bath at 37 °C with stirring at 200

rpm. Starch digesta (0.1 mL) were collected at 0, 10, 20, 40, 60, 90, 120, 180, 240, and 300 min, and the digestion was stopped by adding 0.9 mL of absolute ethanol. The digestibility of freshly gelatinized starch (g/100 g of dry starch) was determined from the amount of glucose released in the supernatant, tested using the Megazyme D-glucose kit, with a conversion factor of 0.9 (the ratio of the molecular weight of the anhydroglucose monomer unit in starch to that of glucose). The digestogram, for C = concentration of digested starch at time t, was fitted to first-order kinetics[31]

$$\ln(dC/dt) = \ln(C_\infty k) - kt \quad (1)$$

where k is the digestion rate coefficient and C_∞ is the concentration at long times.

Statistical Analysis. Each analysis was carried out in duplicate. Mean value and standard deviation were analyzed by Minitab 16 (Minitab, Inc., State College, PA) using analysis of variance (ANOVA) with the general linear model and Tukey's pairwise comparisons. Significant differences of the mean values were determined at $p < 0.05$. Box plots were also performed using Minitab 16 to compare the structural differences among barley, sorghum, and rice starches. Pearson's and Spearman's rank correlations were conducted using SPSS version 21 software (SPSS, Inc., Chicago, IL).

RESULTS AND DISCUSSION

CLDs. The amylose fine structural features of particular interest in the present paper are the SEC weight distribution and number distribution (termed SEC weight CLD and number CLD) of glucan chains from debranched starch as a function of the DP, X, denoted $w(\log X)$ and $N(X)$ (see Figures 1 and 2). There are a number of experimental points in this regard. Amylose branches readily retrograde (reassociate into a double helical structure) in water because of the long linear structure[17] and become less soluble, resulting in overestimation of their molecular size. Aqueous solutions with some additional treatments, including alkaline pH, high temperature, microwave, and autoclave, have been used to improve the solubility of amylose in water.[18−21] However, degradation of starch molecules may happen under these harsh conditions. Dissolution in DMSO with lithium salts has been shown to dissolve starch molecules completely without significant degradation and retrogradation.[15,22] Finally, the amylose CLD here is obtained using SEC. While fluorophore-assisted carbohydrate electrophoresis (FACE) gives very accurate CLDs for amylopectin chains,[23] this method is inapplicable to the longer chains in amylose, a problem that does not exist with SEC. However, SEC suffers from inaccuracies arising from band broadening and from calibration to relate the DP to elution volume.[24] The latter problem cannot be overcome using light-scattering detection for smaller chains, because of signal/noise limitations. These two problems are fortunately not significant for the semi-quantitative objectives of the present paper.

The CLDs of debranched starches from several sorghum, barley, and rice varieties are presented in Figure 1, and those from other botanical sources are presented in Figure 2. All starch samples show typical SEC weight and number CLDs of debranched starch. The components with $X < 100$ are amylopectin chains, while those with $X \geq 100$ are amylose chains. The SEC weight CLDs of debranched starches from all samples show four peaks or shoulders (panels A−C of Figure 1 and Figure 2A). The first peak (denoted by AP1) is the global maximum, which comprises the shorter amylopectin branches with lengths up to DP of 30, normally confined to one amorphous/crystalline lamella. The second peak or shoulder (denoted by AP2) represents the longer amylopectin branches with DPs ranging from 30 to 100, which span more than one crystalline lamella. There are also two peaks for amylose CLDs, the shorter and longer amylose branches, AM1 (X = 100−700) and AM2 (X = 700−40 000). This implies that these arise from potentially discrete enzymatic starch biosynthetic processes,[9] whose nature is unknown. For instance, one possibility is that the branches belonging to AM1 and AM2 originate from different isoforms of GBSS, the main enzyme synthesizing amylose; however, further investigations are needed to verify such speculation and to unveil the nature of the underlying mechanism.

Both SEC weight (panels A−C of Figure 1) and number (panels of Figure 1D-F) CLDs of debranched starches from cereal grains of different varieties within the same plant species generally show small differences. To compare this fine structure between starches, a set of empirical parameters was defined and obtained from the SEC weight CLDs.[9,10] These are the DP at the maximum of each peak, donated by X_{AP1}, X_{AP2}, X_{AM1}, and X_{AM2}, and the height of the each maximum relative to that of AP1, $h_{AP2/AP1}$, $h_{AM1/AP1}$, and $h_{AM2/AP1}$. The DP at the maximum of each peak reflects the relative size of chains in each group of branches, while the height ratio of each peak maximum to AP1 represents the relative amount of chains in each group of branches. As noted, because of band broadening, the two peaks/shoulders from the shorter and longer amylopectin branches and the two peaks/shoulders from the shorter and longer amylose branches are overlapping. The amylose content was calculated by the ratio of the area under the curve (AUC) of amylose branches to that of the overall SEC weight CLD of debranched starch.[32]

Structural parameters of starches from sorghum, barley, and rice varieties are compared in Figure 3. There are small differences in the parameters among the starches from different varieties within the same species (see Table S1 of the Supporting Information); however, some significant differences are observed among the starches from sorghum, barley, and rice grains (Figure 3). The X_{AM1} and $h_{AM1/AP1}$ values of barley starches cannot be obtained because the AM1 peak in the SEC weight CLDs of debranched barley starches is too small and broad; therefore, structural parameters of barley starches are not included in the comparison. Rice starches have higher X_{AM1} than sorghum starches, but the opposite trend is observed for $h_{AM1/AP1}$ values. The X_{AM2} values of barley starches are significantly higher than those of sorghum and rice starches. Barley starches have the largest amylose contents and $h_{AM2/AP1}$ values among the starches from the three cereal grains, whereas rice starches have the lowest. The X_{AP1} values show a similar trend to amylose content and $h_{AM2/AP1}$ values, suggesting that there are probably interrelationships between amylopectin and amylose CLDs. Rice starches also have significantly smaller X_{AP2} than barley and sorghum starches. On the other hand, the $h_{AP2/AP1}$ values are not significantly different among the starches from the three cereal grains.

The same analysis was performed for a series of starches extracted from a range of plant species and organs, including maize grain, wheat grain, cow pea, field pea, potato tuber, and sweet potato root. Because all samples are normal starches, the effects of varieties within the same species are less significant and, hence, only one variety of each sorghum, barley, and rice (ICSV400, ND19119-5, and YRD08-05-05, respectively), with structural parameters near the average among all varieties within each cereal grain, was chosen as the representative for comparison to the starches from other botanical sources. The weight and number CLDs of these starch samples are presented

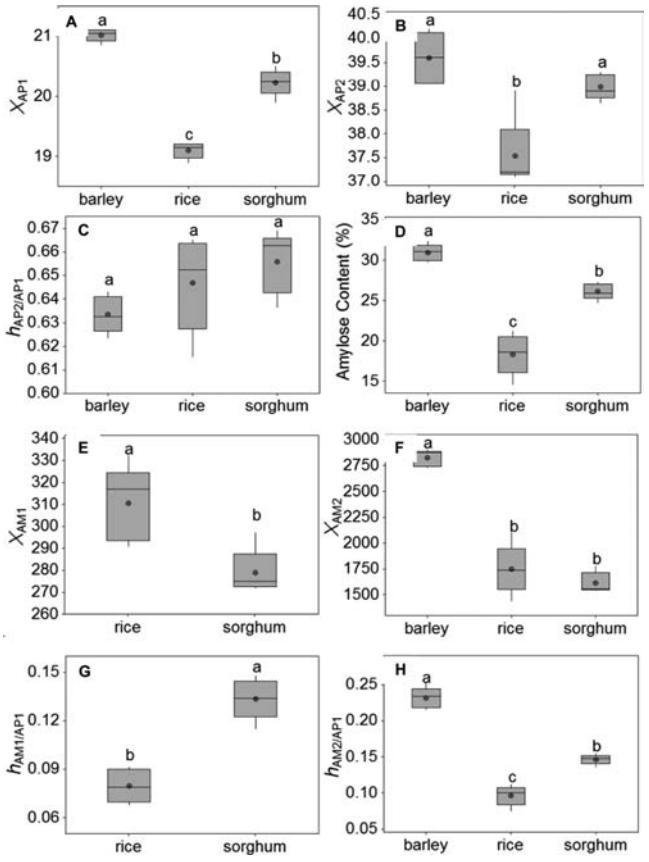

Figure 3. Comparison of the structural parameters from SEC weight CLDs among the starches extracted from sorghum, barley, and rice: (A) X_{AP1}, (B) X_{AP2}, (C) $h_{AP2/AP1}$, (D) amylose content, (E) X_{AM1}, (F) X_{AM2}, (G) $h_{AM1/AP1}$, and (H) $h_{AM2/AP1}$. Panels A, B, and C, amylopectin chains; panels E, F, G, and H, amylose chains. Samples with different letters above the boxes are significantly different at $p < 0.05$.

in Figure 2. The structural parameters are given in Table 1. Although some differences can be observed among the CLDs of starches from different botanical sources presented as number distributions $N(X)$ (Figure 2C), more details in the differences are apparent in the weight CLDs $w(\log X)$ (panels A and B of Figure 2). Differences in amylopectin CLDs among samples can also be seen from the number CLDs of amylopectin branches (Figure 2D). Presenting the same data in different ways can emphasize the different features of the CLD. The weight CLD shows the variations in the structure of amylose branches better than the number CLD.

The amylose contents vary substantially among the starch samples from different botanical sources (Table 1). This is a well-known observation and will only be briefly discussed here; all results are consistent with the literature. Legume seed starches contain the highest amylose,[33] whereas potato tuber and sweet potato root starches have the lowest.[34] The amylose contents of the starches in cereal grains are widely distributed, from barley starch having similar amylose content to legume seed starches to rice starch similar to potato tuber and sweet potato root starches. The amylose content of potato starch was reported to vary from 23 to 31%,[33−35] and that of wheat starch in the literature ranges from 19.3 to 32.7%.[34,36,37] Different values of the amylose content in rice and maize starches have also been reported, e.g., by Fitzgerald et al.[38] In addition the differences in the genetic background of the plant sources,

multiple methods were used to test the amylose content in the literature and different methods measure different properties of starch that are then converted to the amylose content.[38,39]

The fine structures of amylose molecules and their relationships with amylopectin fine structure and starch properties are largely unexplored. The AM1 peaks of potato tuber and barley grain starches, as mentioned above, appear only as the shoulders of the AM2 peaks; therefore, the X_{AM1} and $h_{AM1/AP1}$ values of potato tuber and barley grain starches cannot be determined. With this exception, sweet potato root starch shows the highest X_{AM1} value but the lowest $h_{AM1/AP1}$ value among all starches. The X_{AM1} values of the other starches are quite similar, ranging from 270 to 354. Sorghum grain, maize grain, wheat grain, and field pea starches show similar $h_{AM1/AP1}$ values (around 0.13), while those for sweet potato root, rice grain, and cow pea starches are significantly lower. The X_{AM2} of potato tuber starch is the highest, followed by cow pea, barley grain, and sweet potato root starches in decreasing order, all of which are above 2600; on the other hand, those of wheat grain, field pea, rice grain, sorghum grain, and maize grain starches are markedly lower (between 1550 and 1965). The $h_{AM2/AP1}$ values of the AM2 peaks differ significantly among all samples, ranging from 0.101 to 0.236 and without clear distinctions among cereal grain, legume seed, tuber, and root starches. These results imply that the amylose molecules of potato tuber and sweet potato root starches have relatively longer branches than most cereal grain and legume seed starches, although their amylose contents are smaller.

In general, potato tuber and sweet potato root starches have the highest values of X_{AP1}, and cereal grains starches have the lowest values; although the differences are statistically significant ($p < 0.05$), the difference is only three monomer units between the largest and smallest X_{AP1}. On the other hand, both X_{AP2} and $h_{AP2/AP1}$ of potato tuber and sweet potato root starches are significantly and substantially higher than the other starches (from three to eight monomer units larger for X_{AP2} and 115−145% higher for $h_{AP2/AP1}$), with less significant differences among cereal grain and legume seed starches. That is, the amylopectin chains of potato tuber and sweet potato root starches are relatively longer than those of cereal grain (barley, sorghum, rice, maize, and wheat) and legume seed (cow pea and field pea). This might be related to the crystalline structure of starch. The crystalline structure of native starch granules can be grouped into three polymorphisms: A-, B-, and C-type polymorphs. The A-type polymorphic starch has a crystalline structure with monoclinic unit cells, whereas the B-type polymorphic starch has a crystalline structure with hexagonal unit cells and a water channel in the middle of each unit cell. The B-type starches, for instance, potato tuber starch, have longer average amylopectin chains and greater proportions of longer amylopectin chains than the A-type starches (barley, sorghum, rice, maize, and wheat).[40,41] This is probably because the larger proportion of long amylopectin branches requires more space, which is satisfied by the water channel in the unit cells of the B-type crystalline structure aligning into a stable crystalline structure. Because the C-type polymorph is a mixture of A- and B-type polymorphs, the average chain lengths of amylopectin chains of the C-type starches (cow pea, field pea, and sweet potato root starches) are in between those of A- and B-type polymorphic starches.[42−44]

Treating Amylopectin CLD with the Biosynthesis Model. Fitting the number CLDs of amylopectin (Figure 2D) with the amylopectin biosynthesis model[12,13] provides information on the activities of the core starch synthesizing enzymes and gives key insights into starch biosynthesis, the mechanism of which is still largely unclear. It also provides predictions for studies on enzymatic requirements for producing starch with targeted structure. Furthermore, the fitted parameters thus obtained, along with the structural parameters in Table 1, can be used to obtain the interrelationship between amylose and amylopectin fine structures. The fitted number CLD quantitatively reproduces the significant features of the experimental SEC number CLD of amylopectin branches (see Figure S1 of the Supporting Information). The $X_{0(i)}$ and $X_{0(ii)}$ values were set to 4 and 1, respectively, for all starch samples, as reported by Wu and Gilbert.[12] The $X_{min(i)}$ and $X_{min(ii)}$ values are similar among all starch samples (10−12 and 7−8, respectively), and in some cases, the fitting was not dramatically changed by altering X_{min} slightly. Hence, $X_{min(i)}$ and $X_{min(ii)}$ were excluded for the comparison among different starch samples. As discussed, SEC band broadening hides subtler features in the amylopectin CLD. There are extensive literature discussions on fine-structure features (e.g., by Jane et al.[40] and Cuevas et al.[45]).

Significant differences are observed in the fitted enzymatic activities among the three cereal grain (sorghum, barley, and rice) starches (Figure 4), suggesting that there are systematical differences in the enzymatic processes of starch biosynthesis in different plant species. Slight differences are also present in the fitting parameters among different varieties within the same species, reflecting the effects of genetic variations and/or environmental conditions in starch biosynthesis (see Table S2

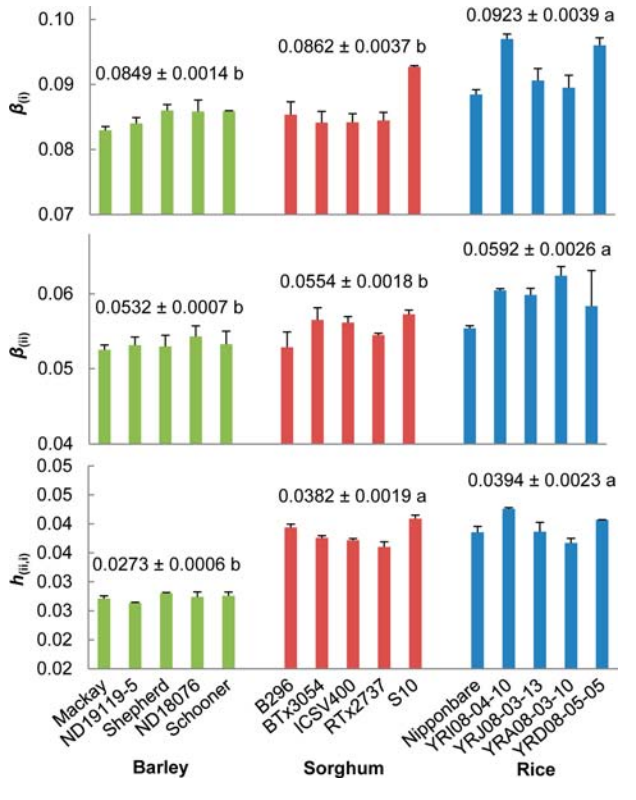

Figure 4. Parameters obtained from fitting the number CLD of barley (green), sorghum (red), and rice (blue) starches to the mathematical model: $\beta_{(i)}$, $\beta_{(ii)}$, and $h_{(ii,i)}$. Mean ± standard deviation is calculated from the five varieties of each plant species. Values with different letters are significantly different at $p < 0.05$.

[a]Correlation is significant at the 0.05 level. [b]Correlation is significant at the 0.01 level.

of the Supporting Information). These show that fitting the SEC number CLDs to this model not only allows for a quantitative comparison of the differences in the enzymatic processes in amylopectin biosynthesis among different species but also shows the small variations among different varieties within the same species.

Similar to the previous section, one variety of each of the sorghum, barley, and rice grain starches (ICSV400, ND19119-5, and YRD08-05-05, respectively) is compared to those from other botanical sources (maize grain, wheat grain, cow pea, field pea, potato tuber, and sweet potato root). The fitting parameters are summarized in Table 2. The $\beta_{(i)}$ values of cereal grain starches are significantly higher than those of the potato tuber and sweet potato root starches, and those of legume seed starches lie in between the other two groups. That is, the activity of SBE in relative to that of SS during amylopectin biosynthesis is higher (or equivalently there is a greater relative branching rate) in cereal grains than in potato tuber or sweet potato root, producing a greater fraction of single-lamella amylopectin branches and/or shorter length of amylopectin chains in cereal grains. This is consistent with the trends of X_{AP1}, X_{AP2}, and $h_{AP2/AP1}$ values (Table 1). The $\beta_{(ii)}$ values compared to the $\beta_{(i)}$ values show no clear trends among the different starch samples, whereas the $h_{(ii,i)}$ values show the opposite trend to the $\beta_{(i)}$ values. The effects of the enzyme set i on the number CLD are more significant than those of enzyme set ii, indicating that the differences in the proportion of longer amylopectin branches among all starch samples, as observed from the SEC weight CLDs (Figure 2A), are mainly due to the differences in the reaction rates of enzyme set i.

Understanding Starch Biosynthesis through Parametrization. The coefficients from Pearson's and Spearman's

dx.doi.org/10.1021/jf5011676 | J. Agric. Food Chem. 2014, 62, 4443−4453

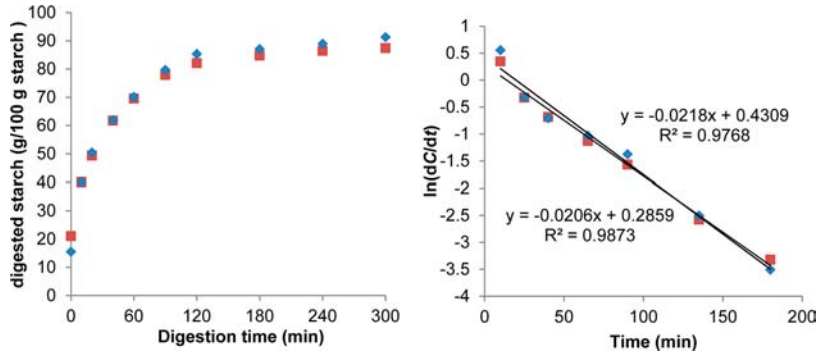

Figure 5. Digestogram of freshly cooked barley starch (shepherd) in duplicates, and the fitting of these digestograms to first-order kinetics.

rank correlation tests among the starch structural and fitting parameters are summarized in Table 3. Pearson's correlation test detects linear relations, while Spearman's rank correlation test is also able to reveal non-linear relations.

In general, the amylose content has little or no significant correlation with DPs at local peak maxima and $h_{AP2/AP1}$ of amylopectin, suggesting that the increased biosynthesis of amylose has only minor effects on amylopectin fine structure. The amylose content is positively and significantly correlated with $h_{AM1/AP1}$ and $h_{AM2/AP1}$, simply because these contribute to the amylose content. In addition, the amylose content, $h_{AM1/AP1}$, and $h_{AM2/AP1}$ are strongly and negatively correlated with $h_{(ii,i)}$, implying a competitive relationship between the biosynthesis of longer amylopectin chains and those of amylose. This is consistent with a proposed mechanism where amylopectin chains are elongated by GBSS, then cleaved from amylopectin molecules, and become amylose molecules when a sufficient size is reached.[46]

The X_{AP1}, X_{AP2}, X_{AM2}, $h_{AM2/AP1}$, $\beta_{(i)}$, and $\beta_{(ii)}$ are significantly and positively correlated and are correlated with X_{AM1} and $h_{AP2/AP1}$. It has been hypothesized that shorter amylopectin chains are elongated by SSI and SSII, longer amylopectin branches are elongated by SSIII, and amylose is elongated by GBSS. SBE isoforms introduce new branches on starch molecules, while DBE isoforms trim excess branches during amylopectin biosynthesis. The correlations might indicate that some of these enzymes (or enzyme isoforms) share the same pool of substrates and/or are in complex formation with one another (for example, SSIIa, SSIII, SBEIIa, and SBEIIb have been found in the same complex[47]).

It is noteworthy that $\beta_{(i)}$ and $\beta_{(ii)}$ are negatively correlated with X_{AM2}, meaning that the decreased SBE activity and/or increased SS activity leads to an increase in the length of longer amylose chains. SS is believed to be responsible for synthesizing amylopectin and not associated with amylose synthesis. SBE, on the other hand, acts on both amylose and amylopectin. Thus, it is more likely that the length of longer amylose chains is negatively associated with SBE activity. Because amylose is synthesized in starch granules by GBSS,[46] this relationship between the length of longer amylose chains and SBE activity provides evidence for the presence of SBE within starch granules, although SBE is found mainly as a soluble form in plastid stroma.[48] In contrast to what is seen for X_{AM2}, X_{AM1} has no significant correlation with either $\beta_{(i)}$ or $\beta_{(ii)}$, indicating that SBE does not participate in the synthesis of short amylose chains. The explanation of this phenomenon might be because GBSS and SBE activities become low in the late stage of starch synthesis.[49] In this point of starch biosynthesis, GBSS probably tends to synthesize short amylose chains, while SBE activity within starch granules becomes too low to act on these short amylose chains. As a result, the length of short amylose chains is not affected by SBE activity. However, the amylose synthesis process during starch development is still unclear, requiring further study.

In addition, the relationships among X_{AP1}, X_{AP2}, X_{AM1}, and X_{AM2} suggest that the elongation of each group of branches is not strictly by one type of enzyme; one such example is the contribution of enzyme set i to longer amylopectin chains, although enzyme set i mainly contributes to short amylopectin chains (see Figure S1 of the Supporting Information). Hence, if enzyme set i favors elongation to branching ($\beta < 1$), it will increase both X_{AP1} and X_{AP2}. This is the first study that has shown the chain-length dependency between amylopectin and amylose chains. Further studies are needed to understand the mechanism behind this observation.

***In Vitro* Digestibility and Its Correlations with Starch Structure.** In human diet, starch-containing foods are normally consumed after cooking, where starch granules have been gelatinized. During gelatinization, starch granules swell and the amylose molecules leach out into the supernatant and form a network surrounding the swollen granules, which inhibits further swelling of starch granules. At the same time, the semi-crystalline ordered structure of starch is disrupted, leading to an amorphous structure.[41] The swelling of starch granules and the melting of the crystalline structure after gelatinization increase the accessibility of starch molecules for enzymatic digestion, leading to a higher digestion rate. The granular architecture of native starch granules, on the other hand, provides a physical barrier to the diffusion of the enzymes and results in a lower digestion rate.[50,51] In addition, the starch molecules in a double helical crystalline structure, such as native starch granules and retrograded starch, are more restricted and bind less readily with amylolytic enzymes.[52]

To simulate the digestion process of starch in foods, starch samples were enzymatically digested using an *in vitro* method, after being thoroughly cooked in sufficient water. The typical digestogram of freshly gelatinized starches is present in Figure 5, showing duplicates of a barley starch as an example of repeatability. All digestograms are well-fitted by first-order kinetics (exemplified for barley starch in Figure 5), and the digestion rate coefficients k are listed in Table S3 of the Supporting Information. Pearson's and Spearman's rank correlation analyses were performed to obtain the linear and non-linear relationships, respectively, between the starch digestion rate and starch structural parameters, and the correlation coefficients are summarized in Table 3.

dx.doi.org/10.1021/jf5011676 | J. Agric. Food Chem. 2014, 62, 4443−4453

Both Pearson's and Spearman's rank correlation tests show that there are no significant correlations between the digestion rate of freshly gelatinized starch and starch structural parameters, suggesting that the digestion rate of freshly gelatinized starch is not affected by the amylose content and amylopectin and amylose fine structures. These results contrast those for cooked rice grains and sorghum flours, showing that the digestion rate was positively correlated with X_{AM2} but negatively correlated with $h_{AM2/AP1}$ and $h_{AP2/AP1}$.[9−11] The plant cell wall, protein, and lipids in grains and flours can greatly influence starch digestibility, such as creating a physical barrier and/or molecular interaction that prevents starch granules from swelling and starch molecules from leaching out during gelatinization or cooking. The presence of a plant cell wall and protein in grains and flours can also restrict water penetration and heat diffusion, increasing the resistance of starch granules to gelatinization and retaining some of the native granular structure after cooking.[53] Most of these non-starch components have been removed during isolation of starch granules, and thus, the starch granules have more freedom to swell and to be completely gelatinized during cooking. The digestion profiles of freshly gelatinized starch from the current study are also different from those of native starch granules[41,54] and retrograded starch,[6,8] showing that, in general, a higher proportion of long amylopectin branches and/or higher amylose content decreases starch digestibility. This is due to the presence of the crystalline structure in native starch granules and retrograded starch, which is enhanced or stabilized by long amylopectin chains and amylose, restricting the ability of the starch molecules to bind with amylolytic enzymes. Freshly gelatinized starch has lost almost all of the crystalline structure, and thus, the effects of long amylopectin chains and amylose are less apparent. This implies that the observed correlation between amylose fine structure in rice and sorghum flour/cooked grain can be ascribed to a secondary interaction between this fine structure and higher order structural features, as discussed above.

In conclusion, this study examines, for the first time, the fine molecular structure of amylose extracted from different plant sources. Two amylose peaks are observed on the SEC weight CLDs of all starch samples. In comparison to the SEC number CLD, the SEC weight CLD is better in exhibiting the structural features of amylose molecules. The amylose CLD differs dramatically with plant source, showing biosynthetic enzyme activities among different plant sources. Fitting the amylopectin number CLDs to a biosynthesis model gives new insight into the enzymatic processes involved in amylopectin biosynthesis. The fitted parameters obtained vary to different extents depending upon the plant sources. Enzyme set i plays a more dominant role than enzyme set ii in controlling amylopectin CLD. Correlations among starch structural and amylopectin fitting parameters suggest that amylopectin is probably the primer of amylose biosynthesis, and multiple enzymes might share the same substrate pool or work in the same complexes. *In vitro* digestion results show that the digestion rate of thoroughly cooked starch-containing food is not attributed to the fine molecular structure of amylose and amylopectin; instead, a secondary interaction between starch fine structure and higher order structural features might be a key factor.

Supporting Information

ABSTRACT: ε-Poly-L-lysine (ε-PL), a naturally occurring amino acid homopolymer, has been widely used as a food preservative. However, its antimicrobial mechanism has not been fully understood. This study investigated the antimicrobial mode of action of ε-PL on a yeast, *Saccharomyces cerevisiae*. When treated with ε-PL at the concentration of 500 μg/mL, cell mortality was close to 100% and the phospholipid bilayer curvature, pores, and micelles on the surface of *S. cerevisiae* were clearly observed by scanning electron microscopy (SEM). At the level of 200 μg/mL, ε-PL significantly inhibited the cell growth of *S. cerevisiae*. When treated with 50 μg/mL ε-PL, the yeast cell was able to grow but the cell cycle was prolonged. A significant increase in cell membrane permeability was induced by ε-PL at higher concentrations. Metabolomics analysis revealed that the ε-PL stress led to the inhibition of primary metabolic pathways through the suppression of the tricarboxylic acid cycle and glycolysis. It is therefore proposed that the microbiostatic effect of ε-PL at lower levels on *S. cerevisiae* is achieved by inducing intracellular metabolic imbalance via disruption of cell membrane functions. Moreover, the results suggested that the antimicrobial mechanism of ε-PL on *S. cerevisiae* can in fact change from microbiostatic to microbicidal when the concentration of ε-PL increased, and the mechanisms of these two modes of action were completely different.

KEYWORDS: *ε-poly-L-lysine, Saccharomyces cerevisiae, antimicrobial mechanism, microbicidal, microbiostatic, metabolomics*

INTRODUCTION

ε-PL is a linear L-lysine homopolymer biosynthesized by actinomyces, and it has a unique structure linking ε-amino and α-carboxylic acid functional groups. It is a polycationic peptide, containing 25−35 amino acid residues. ε-PL was first discovered as a secreted product from a strain of *Streptomyces albulus* no. 346, now designated *S. albulus* NBRC 14147.[1]

Currently, ε-PL has been widely applied to food preservation because of its strong antimicrobial activity,[2] safety, and high thermostability. The antimicrobial activity of ε-PL was not affected after heat treatment at 120 °C for 20 min.[3] ε-PL has been approved by agencies of the United States, Japan, and Korea as a preservative in food.[4,5] In addition to food applications, ε-PL has a good potential application in the medical field due to some of its unique capabilities, such as selectively removing endotoxins to reduce cell toxicity, improving cell adhesion, inhibiting pancreatic lipase activity, and inhibiting the production of oral bacterial toxin.[4]

ε-PL exhibits antimicrobial activities against a wide spectrum of microorganisms including Gram-positive and Gram-negative bacteria, yeasts, and molds.[2] Research has shown that the α-amino groups of ε-PL are very important for its antimicrobial activity. However, the antimicrobial activity of ε-PL is greatly affected by pH, ionic strength, and the presence of anionic compounds. Muto[6] found that ε-PL induced the leakage of cytoplasmic malate dehydrogenase (MDH) from *Escherichia coli* cells, and such leakage had a good correlation with the decrease in cell survival rate. The microbicidal activities of ε-PL was dependent on microbial cell size, rather than the microbial species. Yamanaka and Hamano[4] reported that the antimicrobial activity of ε-PL was caused by a physical action on the cytoplasmic membrane, and the antimicrobial mechanism of ε-PL was electrostatic interaction with the microbial cell surface, followed by disorganization of the membrane and abnormal distribution of the cytoplasm, ultimately leading to physiological damage of the microbial cells. Up to now, the detailed antimicrobial mechanism of ε-PL remains unclear.

Metabolomics aims to systematically analyze the entire small molecule metabolite composition and dynamic response in microorganisms.[7] Metabolomics analysis also assess the last step in the series of changes under an external stress[8] or a pathological insult,[9] and the composition of metabolites directly reveals the phenotypic changes in a living system. We can understand the impact of ε-PL on microbial metabolism through the study of variation of intracellular metabolites, and it is important for further understanding of the antimicrobial mechanism of ε-PL.

Saccharomyces cerevisiae has also proven to be a good model eukaryote to study the inhibition effects of and the cellular responses to antimicrobial preservatives. After more than a decade of postgenomic research in our laboratory, *S. cerevisiae* has turned out to be a powerful model microbial system to study the effects and targets of many antimicrobial drugs. In this study, a common yeast strain of *S. cerevisiae*, AS2399, was treated with ε-PL at different concentrations, and the

antimicrobial activity and mechanisms of ε-PL were analyzed. *S. cerevisiae* cells in the ε-PL-treated groups and the control group were compared by scanning electron microscopy (SEM). The membrane permeability was investigated by propidium iodide (PI) assay. A GC-MS-based metabolomics approach and a multivariate analysis were then utilized to compare the global metabolite profiles of *S. cerevisiae* in response to ε-PL at different levels. It was surprisingly found that the antimicrobial mechanism of ε-PL on *S. cerevisiae* seemed to be more complicated than in previous studies; it actually changed depending on the concentration of ε-PL. At lower concentrations, ε-PL mainly exhibited a microbiostatic effect; at higher concentrations it clearly showed a microbicidal effect.

MATERIALS AND METHODS

Microorganism, Media, and Incubation Conditions. *S. cerevisiae* AS2399 was precultured in YPD liquid medium (2% glucose, 1% yeast extract, 2% peptone, w/v, pH 6.0) with a rotary speed of 180 rpm at 28 °C for 12 h. Then, the precultured yeast cells were transferred to a fresh YPD liquid medium, and the initial cell density was adjusted to 0.3−0.4 measured by a 722S visible spectrophotometer (Shanghai Precision Scientific Instrument Co. Ltd., Shanghai, China) at 600 nm. The cells were cultivated at 28 °C on a rotary shaker at 180 rpm in 500 mL cotton-plugged flasks containing 100 mL of YPD liquid medium either with or without ε-PL. The ε-PL used in this study was a powder provided by Silver Elephant Bioengineering Corp. (Zhejiang, China), and it had 25−35 residues with an isoelectric point of 9.0. The ε-PL solution was prepared with deionized water. For the ε-PL-treated cells, ε-PL was added to the liquid medium before cultivation at final concentrations of 50, 200, and 500 μg/mL, respectively. The experiments were conducted in triplicates.

Dose−Response Assay and Cell Fatality Rate and Viability Determination. The dose−response curve of the yeast cells was determined by measuring cellular OD_{600}. The cell fatality rate was determined using a methylene blue staining method.[10] The plate count method was used to determine yeast cell viability.

Scanning Electron Microscopy. SEM was used to observe *S. cerevisiae* cells according to a modified method of Shimada et al.[11] In brief, after ε-PL treatment, *S. cerevisiae* cells were harvested by centrifugation at 3000*g* for 3 min and washed with 0.1 M phosphate buffer. Then, cells were resuspended in 1 mL of 2.5% (v/v) glutaraldehyde (pH 7.1) at 4 °C for 2 h. After centrifugation, the cells were washed with 0.1 M phosphate buffer and then dehydrated in a progressive ethanol solution and were finally dried. Cells were then sputter-coated with gold (Hitachi E-1010) and observed with a Hitachi SU1510 microscope.

Determination of Membrane-Disrupting Activity of ε-PL (PI Assay). The membrane-disrupting activity of ε-PL was determined by measuring the fluorescence enhancement of PI (Sigma Corp., USA) in ε-PL-treated cells according to a modified method of Veerman et al.[12] It was based on the principle that the PI enters only membrane-compromised cells, after which the fluorescence of this probe is enhanced by 20−30-fold due to its binding to nucleic acids. Cells were harvested by centrifugation at 3000*g* for 3 min and washed twice with phosphate buffer saline (PBS). Cells were then resuspended in PBS, and the final cell density was adjusted to OD_{600} 0.3−0.5. One hundred microliters of the cell suspension was mixed with 100 μL of PI (initial concentration was 12 μg/mL) and was then incubated at room temperature for 5 min. The fluorescence intensity was measured at excitation and emission wavelengths of 535 and 617 nm, respectively, by a SYNERGY4 multifunctional enzyme mark instrument (Bioteck). Each experiment was conducted in triplicate.

$$\text{membrane-disrupting activity} = \frac{\text{fluorescence intensity}}{OD_{600}} \quad (1)$$

Extraction of Intracellular Metabolites. Cell samples were collected at 4, 8, and 12 h either with or without ε-PL. Yeast cells were quenched and extracted as described previously[13] with some modifications. Four biological replicates were performed for each sample. First, cell suspensions were immediately quenched at −40 °C for 5 min with 40% (v/v) methanol in water. The quenching solution was prechilled at −40 °C and used at a ratio of 4:1 (v/v) of quenching solution to cell suspension. Then cells were harvested by centrifugation at 5000*g* for 5 min and washed with PBS twice to remove the residual culture medium, followed by washing with ultrapure water to remove the salts from PBS. Then, cells were ground into fine powder in liquid nitrogen. Ground cells (50 mg) were first suspended in 1 mL of extraction buffer containing methanol/water (1:1, v/v, −40 °C) and then mixed thoroughly. The mixture was frozen in liquid nitrogen for 1 min and then was thawed, and this freeze−thaw process was repeated four times. After centrifugation at 5000*g* for 3 min, the supernatant was collected; 0.5 mL of extraction buffer was added into the precipitate for further extraction. After mixing and centrifugation at 10000*g* for 5 min, the additional supernatant extract was combined with the previously collected supernatant extract. To correct minor variations that occurred during analysis, 20 μL of internal standard solution (succinic-d_4 acid, 1.4 mg/mL, Sigma) was added to 100 μL aliquots before lyophilization.

Derivatization. Before GC-MS analysis, a two-stage chemical derivatization was carried out as described previously.[13] First, methoximation was performed by dissolving the dried metabolite samples in 50 μL of methoxamine hydrochloride (20 mg/mL in pyridine, Sigma), and the solution was incubated at 40 °C for 80 min. Then, 80 μL of *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA, Sigma) was added to the samples, which were subsequently incubated at 40 °C for 80 min for trimethylsilylation.

GC-MS Analysis. GC-MS analysis was performed by a GC-MS system (Agilent Technologies, Palo Alto, CA, USA) equipped with an HP-5 capillary column (60 m × 320 μm i.d., 0.25 μm film thickness; Agilent J&W Scientific, Folsom, CA, USA). Samples (1 μL) were injected with a split ratio of 1:10. Helium was used as the carrier gas at a constant flow of 1 mL/min. The injection, ion source, and ion source surface temperatures were set to 280, 250, and 280 °C, respectively. The GC oven temperature was set to 70 °C for 2 min, then raised to 290 °C at a rate of 5 °C/min, and maintained at 290 °C for 3 min. The electron impact ionization (70 eV) was set at a full scan mode (m/z 50−800). MSD Oroductivity ChemStation software (version E.02 01.1177, Agilent Technologies) was used to acquire mass spectrometric data. Compound identification was performed by comparing the mass spectra with a commercially available standard library, the National Institute of Standards and Technology mass spectral library 2008. The compounds were also identified by comparing their mass spectra and retention times with those of commercially available reference compounds.

Data Analysis. All of the areas of acquired peaks were normalized against the internal standard for further data processing. The generated normalized peak areas (variables) were imported into SIMCA package (ver. 11.5) (Umetrics, Umea, Sweden) for multivariate statistical analysis. Principal component analysis (PCA) and partial least-squares (PLS) analysis were applied to the data after mean-centering and orthogonal signal correction preprocessing. An unsupervised PCA was initially performed to obtain an overview of the GC-MS data from the control and different groups of ε-PL-treated *S. cerevisiae* cells, and the differences between the samples were detected in the PCA scores plots. Moreover, another unsupervised hierarchical cluster analysis (HCA) was performed using HCE 3.5 software. To identify the metabolites that were associated with ε-PL stress, a supervised PLS was subsequently carried out. On the basis of the loadings plots and variable importance in the projection (VIP) value threshold (VIP > 1) from the PLS models, variables that were responsible for distinguishing between the ε-PL-treated and control (without ε-PL) groups were selected. *T* tests were performed on specific metabolites and their ratios to assess the statistical significance of the metabolic changes.

Statistical Analysis. Data were analyzed using SPSS20.0 statistical software packages (http://www-01.ibm.com/software/analytics/spss/). Differences with a P value of <0.05 were considered statistically significant.

RESULTS

Dose−Response Curve, Fatality Rate, and Viability of *S. cerevisiae* in the Presence of ε-PL. As shown in Figure 1A, the addition of ε-PL inhibited cell growth, and the inhibition became increasingly significant as the concentration of ε-PL increased. The stationary phase of *S. cerevisiae* was delayed in the ε-PL-treated group at 50 μg/mL compared with the control group without ε-PL. The cell death rate of *S. cerevisiae* was increased slightly (Figure1B) by 50 μg/mL ε-PL, but most of the cells could still manage to survive. When the concentration of ε-PL was increased to 200 μg/mL, the cell growth was significantly inhibited, and cell mortality was increased by 30−40% (Figure1B). When the ε-PL concentration was increased to 500 μg/mL, the cell mortality rate climbed to nearly 100%. As shown in Figure 1C, *S. cerevisiae* cell viability decreased over time, especially in treatment groups with ε-PL at concentrations of 200 and 500 μg/mL.

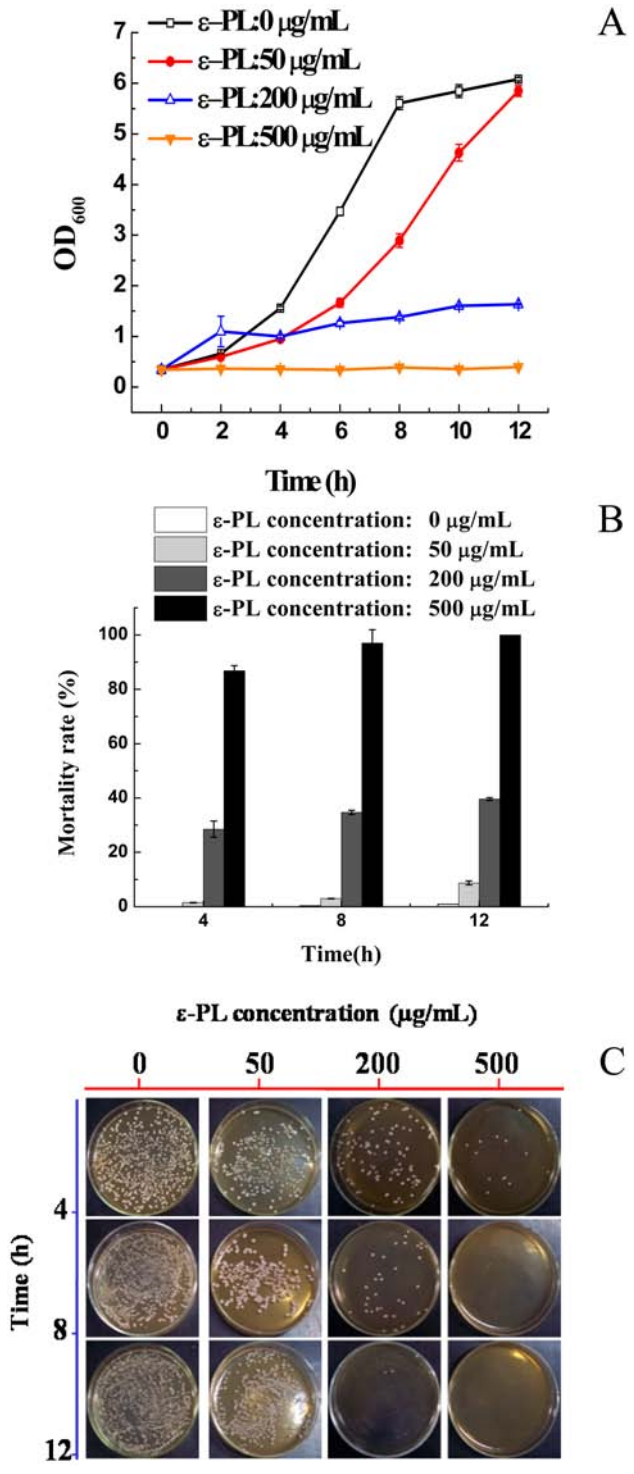

Figure 1. Effects of different concentrations of ε-PL on *S. cerevisiae*: (A) dose−response of ε-PL against *S. cerevisiae*; (B) microbicidal activities of the different concentrations of ε-PL at time points of 4, 8, and 12 h (each value is the mean of three replicates ± SD); (C) vitality of *S. cerevisiae* treated with different concentrations of ε-PL at different sampling times.

Morphological Changes in Yeast Cells Induced by ε-PL. The effect of ε-PL on *S. cerevisiae* morphology changes was investigated with SEM. In the control group a normal surface of *S. cerevisiae* was observed, and there was no apparent cellular debris (Figure 2A) on the cell surface. Compared with the control group, the size of *S. cerevisiae* cells did not change significantly for ε-PL-treated groups (Figure2B−E), but cell deformation and morphological changes became obvious as the concentration of ε-PL increased to 200 μg/mL and above. Rough and sunken surfaces were observed in some cells treated with 200 μg/mL ε-PL (Figure 2C). When the cells were treated with 500 μg/mL ε-PL, the surface of the cells was clearly rougher, and multiple pores and micelles on the surfaces could

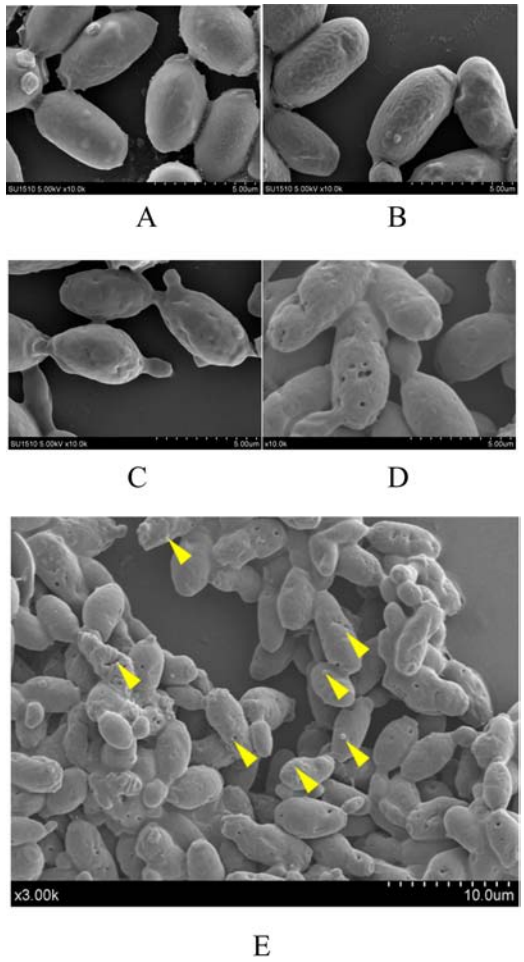

Figure 2. Scanning electron microscopy (SEM) images of *S. cerevisiae* cells without ε-PL treatment (A) treated and with ε-PL treatment at 50 μg/mL (B), 200 μg/mL (C), and 500 μg/mL (D, E) for 8 h.

dx.doi.org/10.1021/jf500505n | J. Agric. Food Chem. 2014, 62, 4454−4465

be easily seen. In addition, certain membrane disruption was observed in some cells, indicating that disruption of the bilayer curvature (Figure 2D,E) by ε-PL at higher concentrations had occurred. The pore on the cell membrane was about 0.3 μm in diameter. However, the morphology of the cells treated with 50 μg/mL ε-PL did not change significantly (Figure 2B).

Membrane-Permeabilizing Activity of ε-PL. The membrane-permeabilizing activity of ε-PL was investigated by using the PI assay. A significant increase in fluorescence intensity was observed in the ε-PL-treated groups at concentrations of 200 and 500 μg/mL for 4 h (Figure 3). In

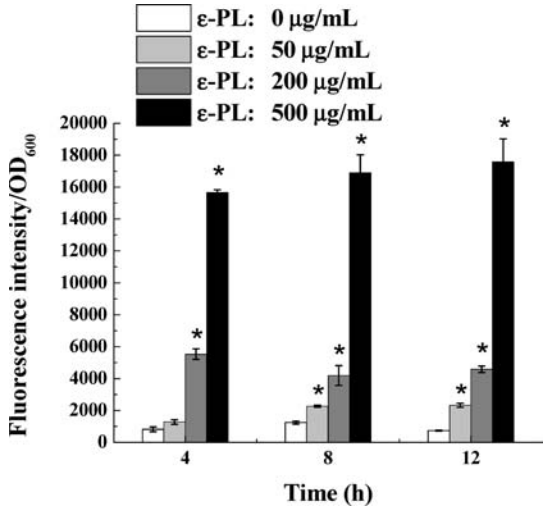

Figure 3. Membrane-permeabilizing effects of ε-PL as determined in the PI assay. Each value is the mean of three replicates ± SD. The asterisk (*) indicates significant difference from equivalent control point (t test, $P < 0.05$).

ε-PL-treated groups the fluorescence intensity increased significantly as the treatment time extended. A dramatic increase in fluorescence intensity was observed in the 500 μg/mL ε-PL treatment group.

Effect of ε-PL Treatment on Intracellular Metabolite Profiles of *S. cerevisiae*. Typical GC-MS total ion chromatograms (TIC) of the *S. cerevisiae* cells treated with various concentrations of ε-PL are shown in Figure S1 in the Supporting Information. Many fewer metabolites were found in the 500 μg/mL ε-PL treatment group than in the control and low ε-PL treatment groups. As illustrated in Figure 1, *S. cerevisiae* cells did not grow, and the cell mortality was close to 100%, probably due to the termination of metabolism of the cells by 500 μg/mL ε-PL. Therefore, the GC-MS data from the sample of 500 μg/mL ε-PL treatment group were not included in the multivariate statistical analysis.

A total of 72 metabolites were analyzed. PCA was used to investigate the metabolic differences between ε-PL-treated cells and control cells. PCA, an unsupervised clustering method, identifies and ranks major sources of variance within data sets and allows clustering of biological samples into both expected and unexpected groups on the basis of similarities and differences in the measured parameters.[14] Figure 4 shows the PCA scores plot of samples taken at different sampling time points, and the PC1/PC2 scores plot was performed to represent the sample distribution in the new multivariate space. Distinct clustering was observed among different groups at the 4 and 8 h time points (Figure 4A,B). There was no clear

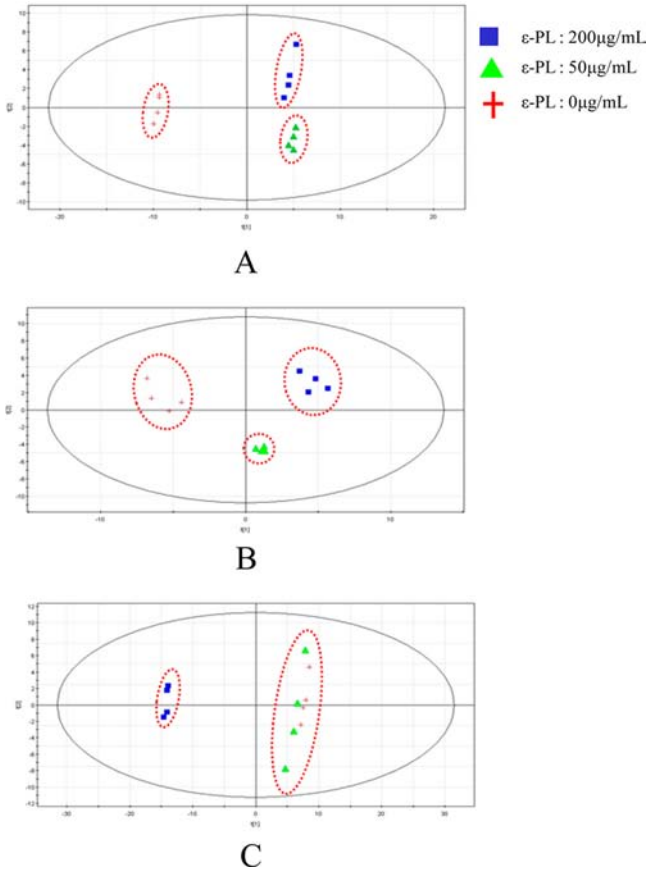

Figure 4. PCA scores plot for control group without ε-PL and ε-PL treated group. (A) sampling time at 4 h (PC1, 76.6% of total variance; PC2, 16.4% of total variance); (B) sampling time at 8 h (PC1, 50.1% of total variance; PC2, 30.8% of total variance); (C) sampling time at 12 h (PC1, 83.7% of total variance; PC2, 10.6% of total variance). In the scores plot, the confidence interval is defined by Hotelling's T2 ellipse (95% confidence interval), and observations outside the confidence ellipse are considered outliers.

difference between the 50 μg/mL treatment and the control group at the 12 h time point. The 200 μg/mL treatment group had a significantly different clustering compared with the other groups at the 12 h time point (Figure 4C). Meanwhile, multivariate data analysis was also performed by HCA. The HCA plot of the 72 differential metabolites reflected a clustering pattern that was similar to the result of the PCA (Figure 5). The ε-PL-treated groups were different from the control group at 4 and 8 h, and the ε-PL-treated group at 200 μg/mL was different from the other two groups at 12 h. The results of HCA also validated the predictive accuracy of the PCA models.

To further verify the differences and identify the metabolites that were mainly responsible for discrimination between the ε-PL-treated cells and the control cells, PLS analysis, a supervised clustering method, was performed. The clustering results were consistent with the PCA and HCA models, suggesting that the cell exposure to ε-PL might have led to systematic changes in cell metabolism pathways (Figure 6A,C,E).

Changes in Intracellular Metabolites in ε-PL-Treated Cells. The major metabolic perturbations that caused these discriminations were identified from the PLS loading plot (Figure 6B,D,F). In the PLS model, the VIP coefficient reflects the contribution of each metabolite. A higher VIP value means

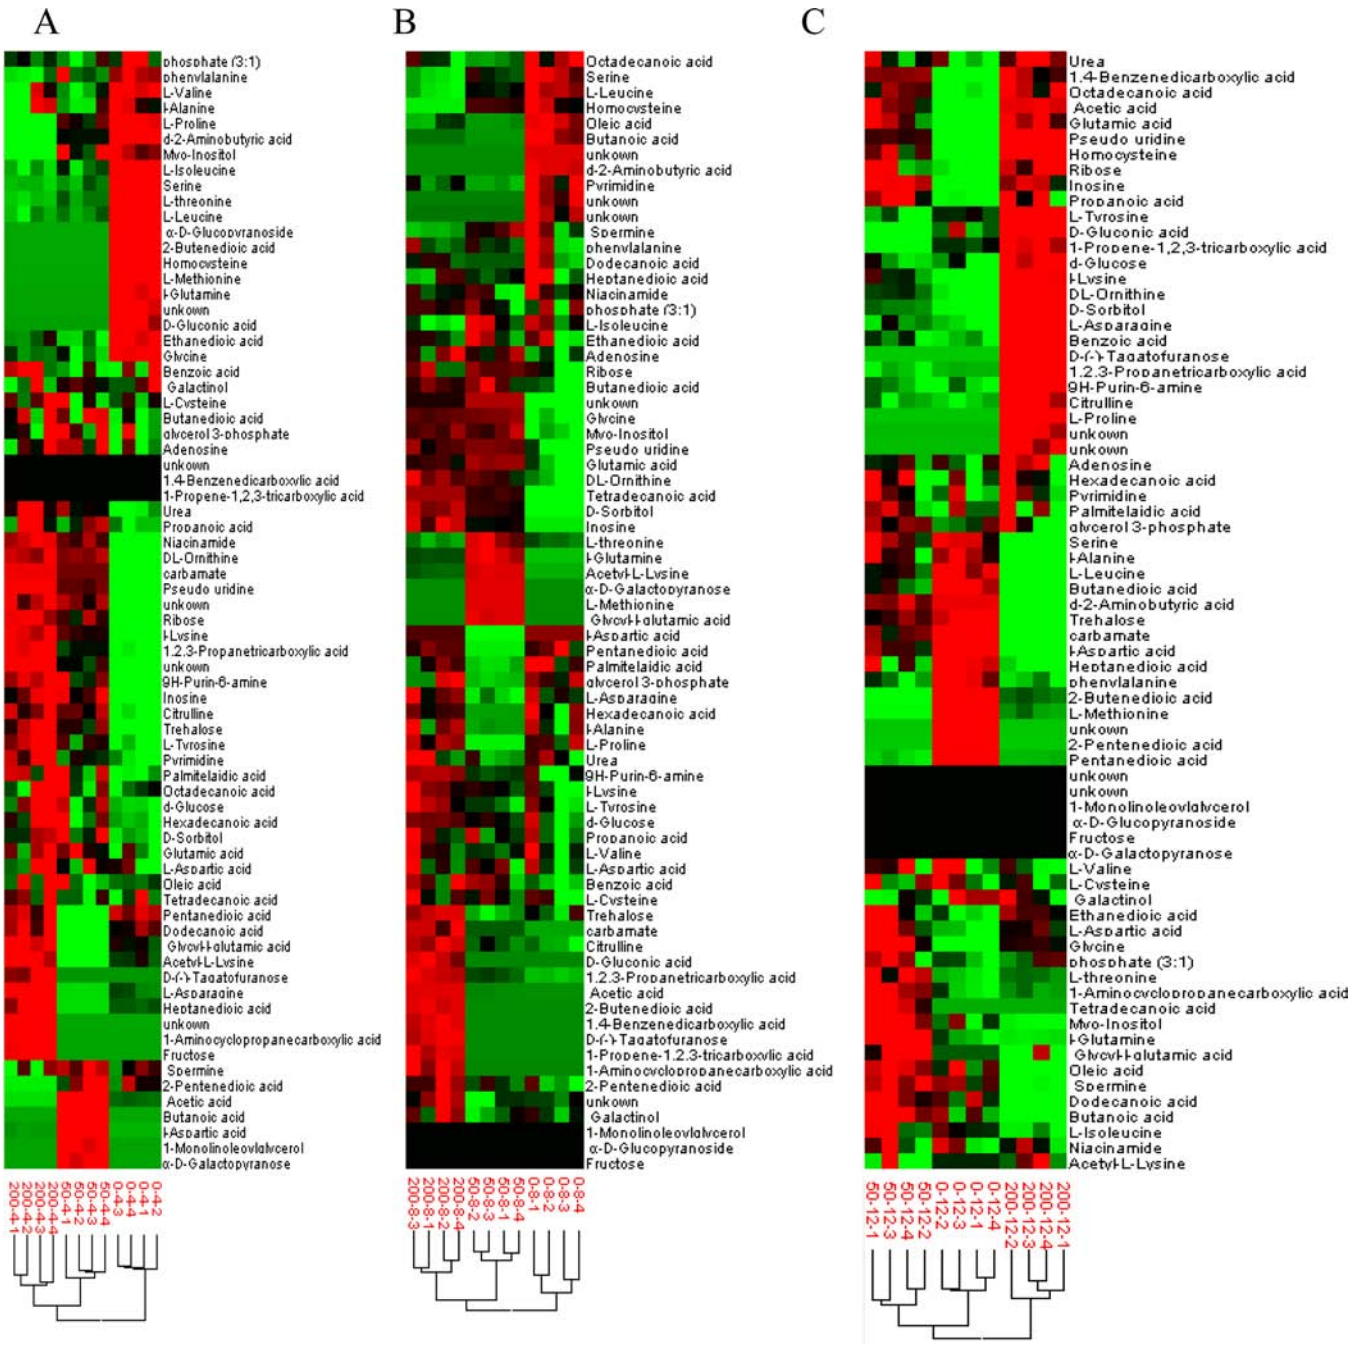

Figure 5. Hierarchical cluster analysis of the 72 identified differential metabolites: (A) sampling time at 4 h; (B) sampling time at 8 h; (C) sampling time at 12 h.

a higher contribution of the metabolite to the differentiation. A metabolite with a VIP value >1 suggests a major contribution to discriminating groups within PLS models.[15] Ornithine, phosphate, lysine, ethanedioic acid, aspartic acid, citrulline, acetic acid, citrate, glutamic acid, serine, and trehalose were found to be the most influential metabolites that were responsible for the differentiation between ε-PL-treated cells and control cells by PLS (Figure 7).

To evaluate the significant differences of metabolites in the ε-PL-treated cells compared with the control cells, a total of 30 identified typical metabolites were analyzed by *t* test (Figure8 and Table 1). These metabolites are divided into different categories based on the type of compounds and their position in the metabolic pathway, such as central carbon metabolism, urea cycle, amino acid, membrane structure, carbohydrate, and alcohols.

As illustrated in Figure 8 and Table 1, glucose is involved in glycolysis. It, as the origin of glycolysis, was found to accumulate in the ε-PL-treated groups. When compared with the control group, glucose concentration increased to 1.54- and 1.6-fold at 4 and 12 h in the 200 μg/mL ε-PL-treated group. Citrate and butanedioic acid are related to the TCA cycle. The levels of citrate compared with control increased dramatically to 3.12- and 2.75-fold at 4 and 8 h in the 50 μg/mL ε-PL-treated group and to 5.92-, 8.19-, and 4.54-fold at 4, 8, and 12 h in the 200 μg/mL ε-PL-treated group. On the contrary, when compared with the control group, the levels of butanedioic

acid markedly decreased to 0.52- and 0.25-fold at 12 h in the 50 and 200 μg/mL ε-PL-treated groups, respectively.

Ornithine, citrulline, and urea are all involved in the urea cycle. The levels of these compounds were all elevated in ε-PL-treated groups. In the 50 μg/mL ε-PL-treated group, the levels of ornithine at 4, 8, and 12 h compared with control were 3.27-, 1.85-, and 1.53-fold, respectively. In the 200 μg/mL ε-PL-treated group, the levels of ornithine at 4, 8, and 12 h compared with control were 3.54-, 2.19-, and 2.48-fold, respectively. The levels of citrulline compared with control were significantly elevated to 3.11-, 1.93-, and 2.6-fold at 4, 8, and 12 h in the 200 μg/mL ε-PL-treated group, respectively.

A total of 13 amino acids were detected, and the most notable one was glutamic acid. Glutamic acid was accumulated in ε-PL-treated groups. When compared with the control group, it notably rose to 1.13-, 1.62-, and 1.51-fold at 4, 8, and 12 h in the 200 μg/mL ε-PL-treated groups, respectively.

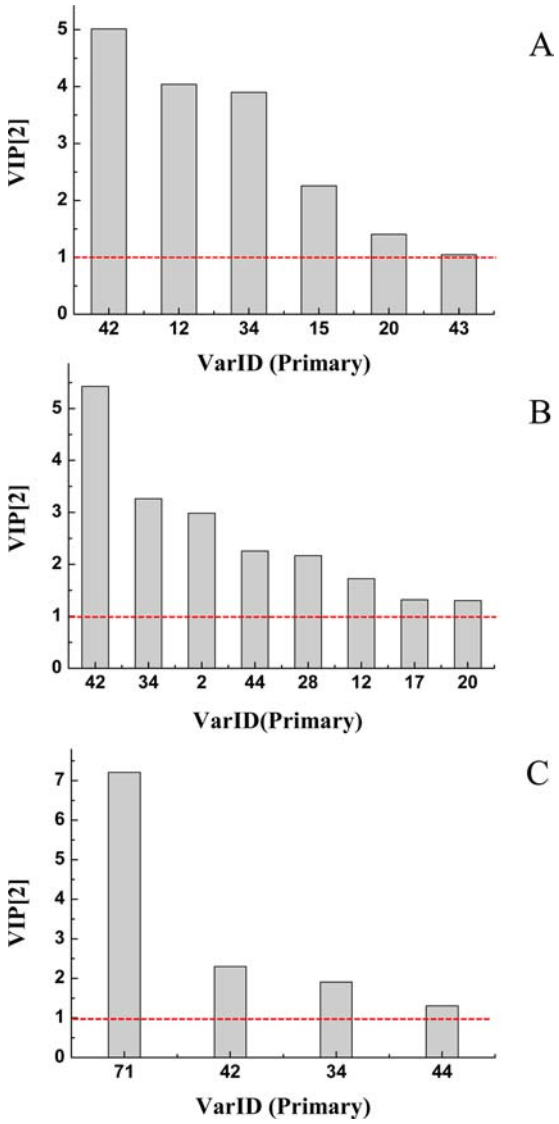

Figure 7. VIP plot generated by PLS: (A) sampling time at 4 h; (B) sampling time at 8 h; (C) sampling time at 12 h. *X*-axis represents each metabolite. 42, ornithine; 12, phosphate; 34, lysine; 15, ethanedioic acid; 20, aspartic acid; 43, citrulline; 2, acetic acid; 44, citrate; 28, glutamic acid; 17, serine; 71, trehalose.

There are two alcohols detected in *S. cerevisiae* cells. The levels of sorbitol compared with control in 50 and 200 μg/mL ε-PL-treated groups were increased to 1.86- and 4.92-fold at 12 h, respectively. The levels of inositol in 50 and 200 μg/mL ε-PL-treated groups compared with control were 2.06- and 2.01-fold at 8 h, respectively.

The detected trehalose in 50 and 200 μg/mL ε-PL-treated groups compared with control was notably decreased to 0.68- and 0.03-fold at 12 h, respectively.

DISCUSSION

The growth of cells was greatly inhibited by ε-PL. ε-PL at lower concentrations could lead to a delay in cell growth cycle of *S. cerevisiae* (Figure 1A). The cell mortality rate increased gradually, and cell viability decreased as the ε-PL concentration and treatment time increased. *S. cerevisiae* cells were killed when the ε-PL concentration reached a certain level (500 μg/mL), suggesting a fungicidal effect of ε-PL. These results indicated that the antimicrobial mode of action of ε-PL against *S. cerevisiae* was concentration-dependent. The membrane-permeabilizing activity of ε-PL was consistent with the PI assay. In the PI assay, the fluorescence intensity significantly increased as the ε-PL concentration increased (Figure 3).

Pore Formation on the Surface of *S. cerevisiae* Cells by ε-PL. The morphology of the yeast cells treated with ε-PL was also examined by SEM. Compared with the 500 μg/mL ε-PL-treated group, similar morphological alterations have been reported with *E. coli* treated with HAHp2-3-I, and micelles and pores on the surface of *E. coli* were clearly observed under SEM.[16] Currently, the antimicrobial peptides are divided into membrane disruption and nonmembrane disruption mechanism classes, depending on whether the reorientation of peptide leads to perturbation of the integrity of the cell membrane or peptide translocation into the cytoplasm.[16] The SEM observation results suggested that ε-PL at the 500 μg/mL concentration had a microbicidal activity via the membrane-damaging model. In the membrane disruption mechanism, "barrel-stave", "carpet", or "toroidal-pore" mechanisms are well studied.[16] In the barrel-stave model, peptide helices form a bundle in the membrane with a central lumen, much like a barrel composed of helical peptides as the staves. This type of transmembrane pore does not make the phospholipid bilayer curvature and is induced by hydrophobic peptides. In the toroidal-pore model, peptide can induce the phospholipid bilayer curvature, but without micelles appearing on the membrane surfaces. In the case of the carpet model, antimicrobial peptides with net charges will be attached to the membrane surface by electrostatic attraction and then accumulate on the bilayer surface like a carpet. Finally, the bilayer is disrupted in a detergent-effect manner, and phospholipid bilayer curvature, pores, and micelles are usually observed on the membrane surface.[16−18] In this study, the phospholipid bilayer curvature, pores, and micelles on the surface of *S. cerevisiae* after incubation in the medium containing 500 μg/mL ε-PL were clearly observed (Figure 2D,E). Moreover, in a previous study, Shima et al.[2] thought that ε-PL attached to the membrane surface due to electrostatic effects, which was consistent with the binding mode of antimicrobial peptides on the membrane surface in the carpet model. Thus, we presume that the microbicidal mechanism of ε-PL is more likely the carpet model. Interestingly, the *S. cerevisiae* cells could well be inhibited by low concentrations of ε-PL (<200 μg/mL), and the permeability of the cell membrane was increased, although pores or micelles on the surface of *S. cerevisiae* after incubation with low concentrations of ε-PL were not observed, and the cell shape did not change. These results also suggest that the basic mechanisms for fungicidal effect of ε-PL at higher concentrations are different from those of fungistatic effect at lower concentrations. In addition, the high concentration of antimicrobial peptides is necessary in the carpet model,[18] which also supports our speculation on the microbicidal mechanism of ε-PL.

After initial membrane binding, researchers found that peptides must locally concentrate to exert their microbiostatic activity, until they reach a concentration that enables their microbicidal action. Such a feature is commonly described as the threshold concentration concept. At this concentration, peptides begin to rearrange and alter cell membrane permeability.[17] This type of threshold concentration has been shown for some pore-forming peptides, such as Bac8c.[19] This

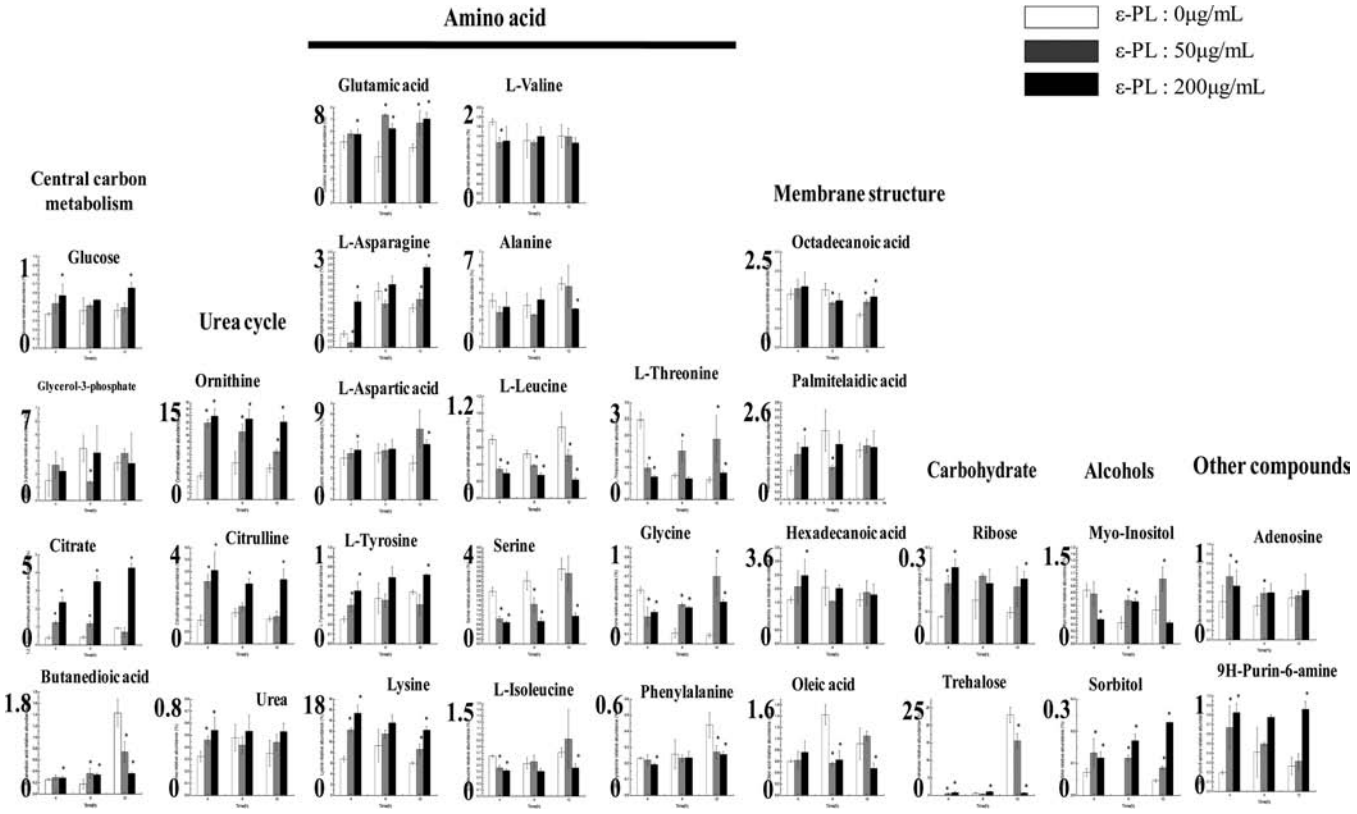

Figure 8. Variations of intracellular metabolites under the influence of ε-PL at 4, 8, and 12 h. Each value is the mean of four replicates ± SD. The asterisk (∗) indicates significant difference from equivalent control point (*t* test, $P < 0.05$).

study provides one of the best illustrations for the threshold concentration theory.

ε-PL Imposes Restrictions on Primary Metabolic Pathways. On the other hand, the microbiostatic mechanism of ε-PL has not been fully understood so far. When the concentration of ε-PL is not high enough to kill *S. cerevisiae* cells, such as at 50 and 200 μg/mL levels, it remains unclear how ε-PL inhibited the growth of the yeast. The aim of a metabolomics approach is to characterize or quantify as many as possible metabolites present in a biological sample in an unbiased manner.[20] Metabolomics analysis also assesses the last step in the series of changes that occur following an external stimulus[8] or a pathological insult,[9] and the composition of metabolites directly reveals the phenotypic changes that occur in a living system. Therefore, metabolomics studies are critical to reveal the antimicrobial mechanism of ε-PL on *S. cerevisiae*.

A perturbation in these intracellular metabolites caused by ε-PL could be detected by a GC-MS-based metabolomics approach. In this study, GC-MS combined with multivariate statistical analysis was used to investigate metabolic changes that occurred in *S. cerevisiae* as a result of exposure to different concentrations of ε-PL. The results demonstrated that there were clearly many differences at the level of intracellular metabolites among different treatment groups. Moreover, there was a clear distinction between the control and ε-PL-treated groups based on PCA, HCA, and PLS analysis. Compared with the control group, ε-PL treatment induced many metabolic changes, especially in the metabolism of carbohydrates, alcohols, lipids, and amino acids.

To investigate potential linkages between these metabolic changes and ε-PL treatment, the measured metabolite variations were mapped onto the metabolic pathways (Figure 9). As shown in Figure 9, these changes were not randomly distributed; instead, they occurred coordinately in distinct localized regions of the network. In ε-PL-treated groups, ε-PL promoted the intracellular accumulation of glucose, which indicated that glycolysis was inhibited by ε-PL. This might account for the growth inhibition of *S. cerevisiae* that was observed in the presence of ε-PL at a lower level. Furthermore, ε-PL caused decreases in the contents of serine, phenylalanine, leucine, isoleucine, and valine (Table 1). Moreover, the levels of glycine and threonine also decreased in the early stage of ε-PL treatment (Table 1). These metabolites could be converted from 3-P-glycerate and pyruvate (Figure 9), which are both metabolic intermediates of the Embden−Meyerhof−Parnas (EMP) pathway. As seen from another perspective, to some extent, the levels of metabolic intermediates of the EMP pathway decreased under ε-PL treatment. Such results also indicated the inhibition of EMP pathway by ε-PL. In the TCA cycle, the level of citric acid was increased by ε-PL (Figure 9 and Table 1). Citric acid was then transformed into α-ketoglutarate (α-KG), but α-KG might not be further involved in TCA. As shown in Figure 9, the levels of TCA cycle intermediate glutamic acid (Glu) and urea cycle intermediates ornithine, citrulline, and urea increased, whereas the level of succinate decreased upon exposure to ε-PL. The results indicated that α-KG was mainly transmuted into glutamic acid (Glu), leading to the inhibition of the TCA cycle by ε-PL. In previous studies, *S. cerevisiae* EMP pathway and TCA cycle were also inhibited by alcohol, acetic acid, and other external stimulants.[21−23]

It is our hypothesis that the central carbon metabolism of *S. cerevisiae* can be inhibited by low concentrations of ε-PL. Here are the possible explanations. First, because of ε-PL tiled on the

An asterisk (*) indicates abundance of metabolite is relative to internal standard succinic-d_4 acid; a dagger (†) indicates the metabolite corresponding to the control group was undetermined.

cell membrane, ε-PL can inhibit the membrane functions through changes in membrane fluidity and permeability. However, the cell membrane plays an important role in cell life activities, particularly in the transportation of amino acids, sugars, and ions into the *S. cerevisiae* cell through the cell membrane.[24] Thus, ε-PL can indirectly inhibit the central carbon metabolism due to the disruption of membrane functions. In addition, the plasma membrane ATPase (Pma1p) is the major protein in the plasma membrane.[24] Normally, H^+-ATPase functions to ensure the homeostasis of ions in the cytoplasm, and hence its malfunction would affect the permeability barrier of the yeast membrane; it is believed to play an important role in *S. cerevisiae* cells in response to stresses.[25,26] Inositol can increase ATPase activity to counteract the impact of ethanol on *S. cerevisiae* cell membrane permeability.[25−27] In the present study, inositol was also detected, and it was found to accumulate in the cells with prolonged action time in the ε-PL-treated groups (Figure 8). It may be a stress response in *S. cerevisiae* in the presence of ε-PL. Because ATPase activity affects the permeability of cell membrane and energy supply and there is a close relationship between inositol and ATPase activity,[28] the rise in the inositol level in *S. cerevisiae* in response to ε-PL would strongly support our hypothesis.

Second, ε-PL may induce apoptosis in yeast cells by stimulating a burst of reactive oxygen species (ROS), and thus the central carbon metabolism was indirectly inhibited. Currently, many studies have shown that the mechanism of antimicrobial peptides is very complicated, which involves their effects on multiple targets.[17,18] For instance, there are many research papers on antimicrobial peptides inducing cell apoptosis through activation of ROS, such as PAF26, coprisin, and melittin.[29−31] In our study, the levels of sorbitol and inositol in the *S. cerevisiae* cells increased by ε-PL treatment (Table 1). Sorbitol and inositol as compatible solutes are common polyhydric alcohols, which may also protect the

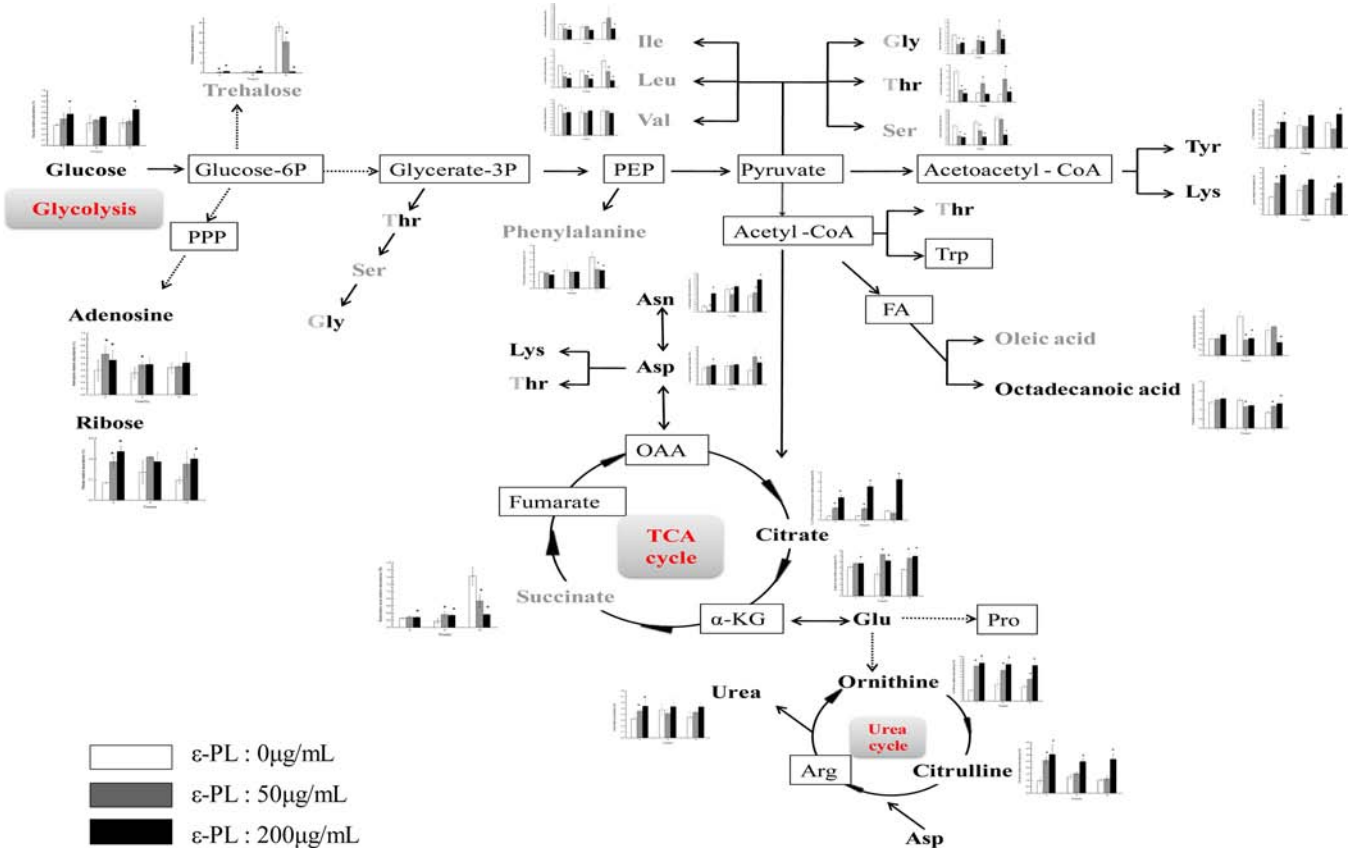

Figure 9. Schematic showing changes of metabolite abundance mapped onto the metabolic network at sampling times of 4, 8, and 12 h. Solid arrows in the network indicate a single step connecting two metabolites; dashed arrows represent multiple steps. Metabolites shown in bold black indicate a significant increase in value, bold gray indicates a significant decrease; a gray first letter only of the metabolite indicates that it is first decreased and then increased under ε-PL stress. Metabolites undetected are boxed. PPP, pentose phosphate pathway; PEP, phosphoenolpyruvate; OAA, oxaloacetate; α-KG, α-ketoglutarate; FA, fatty acid; Ile, isoleucine; Leu, leucine; Val, valine; Arg, arginine; Asn, asparagine; Asp, aspartic acid; Glu, glutamic acid; Gly, glycine; Lys, lysine; Pro, proline; Ser, serine; Thr, threonine; Trp, tryptophan; Tyr, tyrosine.

intracellular enzyme activity and cell membrane integrity through their ROS scavenging activities.[14,32] These results support our proposed ROS burst hypothesis in the *S. cerevisiae* cells.

Finally, the abnormal distribution of the cytoplasm induced by ε-PL through electrostatic interaction with the microbial cell surface may also be one of the factors responsible for the intracellular metabolic disturbances.

Variations of Protective Metabolites. Trehalose is a nonreducing disaccharide and is also commonly considered to be a protective substance of yeast cells responding to multiple external stresses.[33,34] However, trehalose is not always accumulated under external stress in the cells of *S. cerevisiae*; for example, trehalose is not accumulated in response to H_2O_2.[35,36] In the current study, trehalose was detected at 12 h in cells. However, compared with the control group, the level of trehalose did not increase in response to ε-PL treatment. This might be due to the fact that trehalose is converted from glucose-6-phosphate, an intermediate metabolite of EMP pathway.[33,36] However, the EMP pathway was inhibited by ε-PL from the beginning; therefore, the level of trehalose did not increase in the ε-PL-treated groups. The result also suggests that trehalose was unrelated to the stress induced by ε-PL.

Glutamic acid is usually considered to be a protective metabolite in cells, and it plays an important role in various stress responses; its role is largely accomplished by enhancing the stability of the cell membrane.[13,37−39] In the ε-PL-treated groups, the level of glutamic acid increased as a response tobetter protect the cells (Table 1). These results once again confirmed our hypothesis that ε-PL indirectly inhibited central carbon metabolism through disrupting the membrane functions.

Proposed Antimicrobial Mechanism of ε-PL. On the basis of our research results, we found that fungistatic and fungicidal mechanisms of ε-PL on *S. cerevisiae* cells were completely different. Thus, we are proposing two possible antimicrobial mechanisms of ε-PL as shown in Figure 10. First, ε-PL binds to anionic components of the cell membrane through electrostatic interaction. When ε-PL reached a threshold concentration, ε-PL quickly acted on the cell membrane of *S. cerevisiae* following a mode of action of the carpet model, causing micelle formation and phospholipid bilayer bending and perforation on the cell membrane, eventually leading to cell death. This is the fungicidal effect. On the other hand, when ε-PL concentration is below the threshold level, ε-PL can cause changes in the fluidity, structure, and permeability of the cell membrane. Membrane function is then disrupted due to these changes. Disruption of membrane function will lead to the inhibition of intracellular central carbon metabolism. At the same time, ε-PL may induce cell apoptosis by stimulating intracellular ROS generation. These combined actions caused by ε-PL will lead to its inhibiting the growth of *S. cerevisiae* cells, but not necessarily killing the cells.

dx.doi.org/10.1021/jf500505n | J. Agric. Food Chem. 2014, 62, 4454−4465

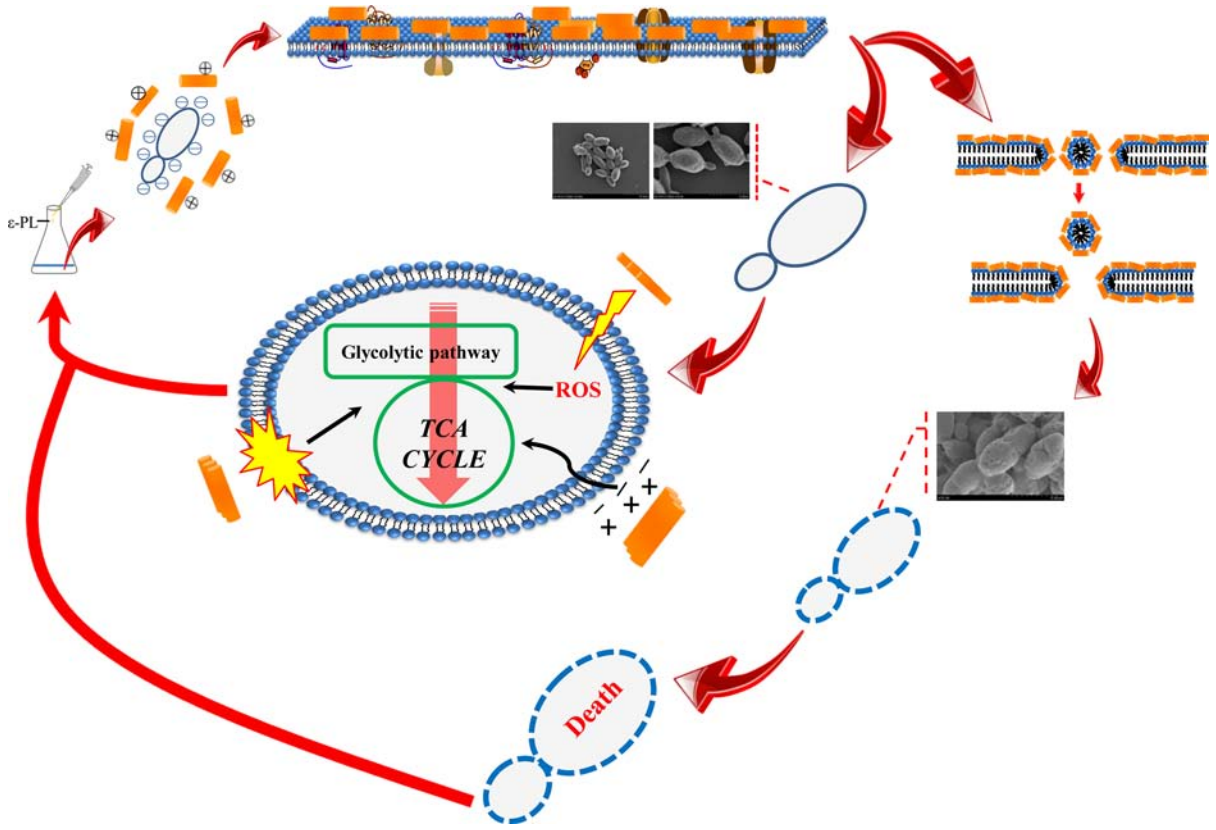

Figure 10. Possible mode of action of the ε-PL on *S. cerevisiae*.

Such mode of action is called fungistatic or a microbiostatic effect.

It is also noteworthy that most known antimicrobial peptides, or bacteriocins, generally consist of a variety of amino acids. In contrast, ε-PL is a homopolymer of a single amino acid, lysine. It also occurs in nature. In the current study, we found the action mode of ε-PL was similar to that of some other antimicrobial peptides.

In summary, this study provides a good example of antimicrobial mechanism investigation at the metabolite level with high-throughput methods. It also provides new insight into ways of understanding the modes of action of known or new antimicrobials. These results suggest that the metabolomics approach is a powerful tool to study antimicrobial mechanisms and can provide a new perspective at the molecular level on how microorganisms respond to biological preservatives including antimicrobial peptides.

Supporting Information

ABSTRACT: Rapid and sensitive surface-enhanced Raman spectroscopy (SERS) for aflatoxin detection was employed for development of the models to classify and quantify aflatoxin levels in maize at concentrations of 0 to 1,206 μg/kg. Highly effective SERS substrate (Ag nanosphere) was prepared and mixed with a sample extract for SERS measurement. Strong Raman bands associated with aflatoxins and changes in maize kernels induced by aflatoxin contamination were observed in different SERS spectroscopic regions. The *k*-nearest neighbors (KNN) classification model yielded high classification accuracy and lower prediction error with no misclassification of contaminated samples as aflatoxin negative. The multiple linear regression (MLR) models showed a higher predictive accuracy with stronger correlation coefficients (r = 0.939−0.967) and a higher sensitivity with lower limits of detection (13−36 μg/kg) and quantitation (44−121 μg/kg) over other quantification models. Paired sample *t* test exhibited no statistically significant difference between the reference values and the predicted values of SERS in most chemometric models. The proposed SERS method would be a more effective and efficient analytical tool with a higher accuracy and lower constraints for aflatoxin analysis in maize compared to other existing spectroscopic methods and conventional Raman spectroscopy.

KEYWORDS: *aflatoxin, surface-enhanced Raman spectroscopy (SERS), nanostructure, chemometrics, food safety*

INTRODUCTION

Aflatoxins as secondary metabolites produced by the *Aspergillus* strains have been causing a major problem for agriculture in many countries. Aflatoxins in contaminated food and feed products are carcinogens as recognized by the International Agency for Research on Cancer (IARC) as well as other health hazards for animals and humans, leading to substantial economic losses to relevant industries.[1] Like fumonisins and other mycotoxins, maximum levels for aflatoxins in grains and oilseeds destined for animal and human consumptions have been set by the Food and Drug Administration (FDA) and European Commission (EC).[2]

The aflatoxin detection methods currently available in laboratory and nonlaboratory sites such as high performance liquid chromatography (HPLC) and enzyme-linked immunosorbent assay (ELISA) are highly selective, very accurate, and precise with good detection limits.[3] However, these methods are not practical and convenient for a real-time response due to long analysis time, low cost-effectiveness, analysis complexity, and requirement of trained personnel. Therefore, numerous studies have been continuously conducted to develop rapid, simple, and inexpensive methods with high sensitivity and specificity for early detection and identification of aflatoxins. A method employing portable equipment and nonhazardous solvents for aflatoxin analysis would be more suitable for application at the sites where the samples are collected.[4]

Spectroscopic methods are very promising and excellent tools for screening of aflatoxin contaminated samples because they are inherently rapid, specific, and possibly partially or completely computerized. Among spectroscopic methods, Raman spectroscopy is valuable due to its great possibilities and advantages in detecting mycotoxins in grains and oilseeds.[5−7] Compared to other spectroscopic methods used for mycotoxin analysis such as near-infrared spectroscopy (NIR) and Fourier-transform infrared spectroscopy (FTIR), Raman spectroscopy can provide well-resolved bands of mycotoxin molecules and allow acquisition of spectra in aqueous environments. However, conventional Raman spectroscopy has a small cross-section of Raman scattering compared to that of Rayleigh scattering, resulting in lack of sensitivity and thus requiring a longer collection time for improvement of spectral quality. Surface-enhanced Raman spectroscopy (SERS) has been considered as one of the most promising techniques to greatly improve the sensitivity of conventional Raman spectroscopy.

SERS is an advanced technique that uses nanostructural surface phenomena to enhance a weak inelastic-scattering Raman effect of molecules adsorbed on and/or at the vicinity of metal particles like silver, gold, and copper.[4,8,9] SERS can measure samples with great sensitivity and rapidity to provide comprehensive information, even on orientation of single

molecules adsorbed on nanometallic particles. However, detection ability and accuracy of target molecule are greatly influenced by a morphological variation of nanostructures and adsorption variation of the molecule where it is located.

The acceptability of SERS is largely determined by the methods to prepare SERS substrates.[10−17] A typical SERS enhancement factor reported in previous studies is about order of 10^7 and up to 10^{14} at extremely high enhancement levels enough for single molecule detection and identification. For SERS measurement, nanoparticles should agglomerate or aggregate prior to sample introduction. Previous studies showed that metallic nanoparticles are initially precipitated and their growth takes place with the progress of the reaction.[11,13,17] The size and stability of nanoparticles can be further optimized by altering the environments around the particles such as pH of reaction solutions, concentrations of reducing and stabilizing agents, and ratio of nanoparticle/molecule.[11]

Due to its high sensitivity, specificity, and rapidity, SERS has been broadly applied in biochemistry, molecular biology, environmental science, and food science for detection and discrimination of a wide variety of target agents.[4] Unfortunately, SERS methods are not readily available as a screening method for routine use and on-site analysis for aflatoxin detection due to use of costly metal substrates and technical difficulties in producing stable SERS substrate and obtaining reproducible results.[16,18] Wu et al.[18] obtained high quality SERS spectra of aflatoxins with a low detection limit and excellent differentiation ability with comparison of actual SERS spectra and theoretical Raman spectra.

The objective of this research is to employ a rapid and sensitive SERS method for detection of the level of aflatoxins in maize by extracting ground maize samples using a simple and fast one-step extraction procedure to explore the possibility of the method implementation for on-site analysis. The proposed SERS method could serve as a powerful tool for a high-throughput analysis with a great accuracy and convenience for aflatoxin detection at many sample collection points requiring rapid routine analysis.

MATERIALS AND METHODS

Materials. The standards of aflatoxin B_1, B_2, G_1, and G_2 were purchased from Sigma-Aldrich (St. Louis, MO). The Aflatest immunoaffinity column used for HPLC analysis was obtained from VICAM (Watertown, MA). All chemicals, reagents, and organic solvents were of analytical grade and used without any further purification.

Sample Preparation and Extraction. Maize samples naturally contaminated with aflatoxins were obtained from Office of the Texas State Chemist regulatory samples collected by Texas Feed and Fertilizer Control Service according to the State's plan of work. A total of 132 samples with aflatoxin concentration range of 0−1,126 μg/kg were selected for HPLC analysis and SERS measurements. A ZM 200 ultra centrifugal mill (Retsch, Haan, Germany) with a 0.075 mm diameter screen was used to grind each sample of approximately 4.5 kg. The ground samples contained in a polyethylene bottle were stored in a refrigerator of 4 °C prior to use and between sample measurements. The samples with higher moisture content were dried to below 15% at 40 °C for 12 h to ensure inhibition of fungal growth in the samples. The samples were equilibrated to a room temperature at least 1 h prior to analysis.

Twenty grams of ground sample was placed in a plastic bottle to which 100 mL of methanol/water (70:30, v/v) extraction solvent was added for sample extraction by vigorously shaking for 5 min. The resultant mixture was filtered through the filter paper (Whatman #1). The sample extract was directly used for SERS measurement.

Preparation of SERS Substrate. Ag nanosphere (NS) for SERS measurements was prepared with slight modifications to the previous methods.[10,19,20] In brief, 0.5 g of $AgNO_3$, 10 mL of deionized water, 0.8 g of sodium oleate, 1 mL of oleic acid, and 5 mL of ethanol were added to a 20 mL glass vial in order under agitation. The glass vial was air-tightly sealed and placed in the oven at 150 °C for 24 h. Afterward the system was cooled down to room temperature. The products inside the vial were washed with ethanol three times and dried to form Ag nanocrystals (NC) at the bottom. The collected 4 mg of AgNC was added to 1 mL of cyclohexane. This solution was added to a solution of 28 mg of sodium dodecyl sulfate (SDS) in 1 mL of deionized water. The system containing AgNC was subjected to ultrasonic treatment for emulsification for about 1 h and subsequently heated at 70 °C with stirring until the cyclohexane was removed to manufacture AgNSs.

HPLC Analysis of Aflatoxins. Fifty grams of ground maize sample was shaken for 1 h at 200 rpm for sample extraction using a solvent of methanol:water (70:30, v/v). The resultant mixture was filtered through the folded filter paper (Whatman #1). Ten milliliters of the filtered extract was mixed with 20 mL of deionized water and 1 g of sodium chloride and filtered to obtain the clean sample extract for loading onto an Aflatest immunoaffinity column (Vicam, Watertown, MA). The eluate from the column though washing with water and methanol was diluted with 1 mL of HPLC water and injected into a Waters 2695 HPLC system (Waters, Milford, MA). The HPLC system was equipped with a Spherisorb 4.6 × 150 mm, C18 column connected with Waters Spherisorb guard column 4.6 × 10 mm. The mobile phase consisted of a mixture of water:acetonitrile:methanol (3:1:1), flowing at a rate of 1.0 mL/min. Empower software (Milford, MA) was used to obtain and analyze chromatographic data. The mixture of standard aflatoxins B_1, B_2, G_1, and G_2 was prepared to build a standard calibration curve for quantification of aflatoxins in ground maize samples.

SERS Measurement. The mixture of AgNSs and the extract at the ratio of 1:1 (v/v) in volume was prepared. A 300 μL volume of the mixture was placed on 96 wells for SERS measurements in quadruplicate using spectroscopy with a RamanStation 400F (PerkinElmer, Beaconsfield, Buckinghamshire, U.K.). The Raman system was interfaced with the Spectrum (v. 6.3) software for data acquisition and analysis and consisted of a 256 × 1024 pixel CCD detector and a near-infrared laser source of 785 nm wavelength, with 175 mW output power focused on the sample. The software-controlled motorized sample stage was operated at <2 micro step resolution in an *x*-*y*-*z* direction for optimal spectral acquisition. The spectrum collected with exposure time of 2 and 5 scans at the sample location was recorded at the spectral resolution of 4 cm^{-1} in the Raman shift range of 200 to 2,000 cm^{-1}. The spectra from 7 different spots on the sample were averaged to obtain a representative spectrum of each sample.

Scanning electron microscopy (SEM) images of the samples were also made with a JSM 7500F microscope (JEOL Ltd., Tokyo, Japan) to characterize the size and morphology of AgNS and its mixture with the extracts.

Spectral Data Preprocessing. The SERS spectrum was corrected for background at the time of its acquisition. The spectrum was further baseline-corrected and normalized to minimize the influence of instrumental and environmental changes in the laboratory on the Raman signal. The background-corrected SERS spectrum was also preprocessed by a 9-point Savitzky−Golay filtering function to obtain first and second derivatives of spectra, which eliminates baseline and linear slope effects. The deconvolution preprocessing method was applied to the normalized spectra to improve a band resolution by diminishing interference between unresolved bands.

Development and Validation of Chemometric Models. For application of statistical analyses, the preprocessed spectral data were converted to an ASCII file. Prior to the development of classification models, the samples were divided into 5 subgroups according to the level of aflatoxins in maize samples: below 20 μg/kg (regarded as negative), 20−200 μg/kg, 300−450 μg/kg, 550−700 μg/kg, and above

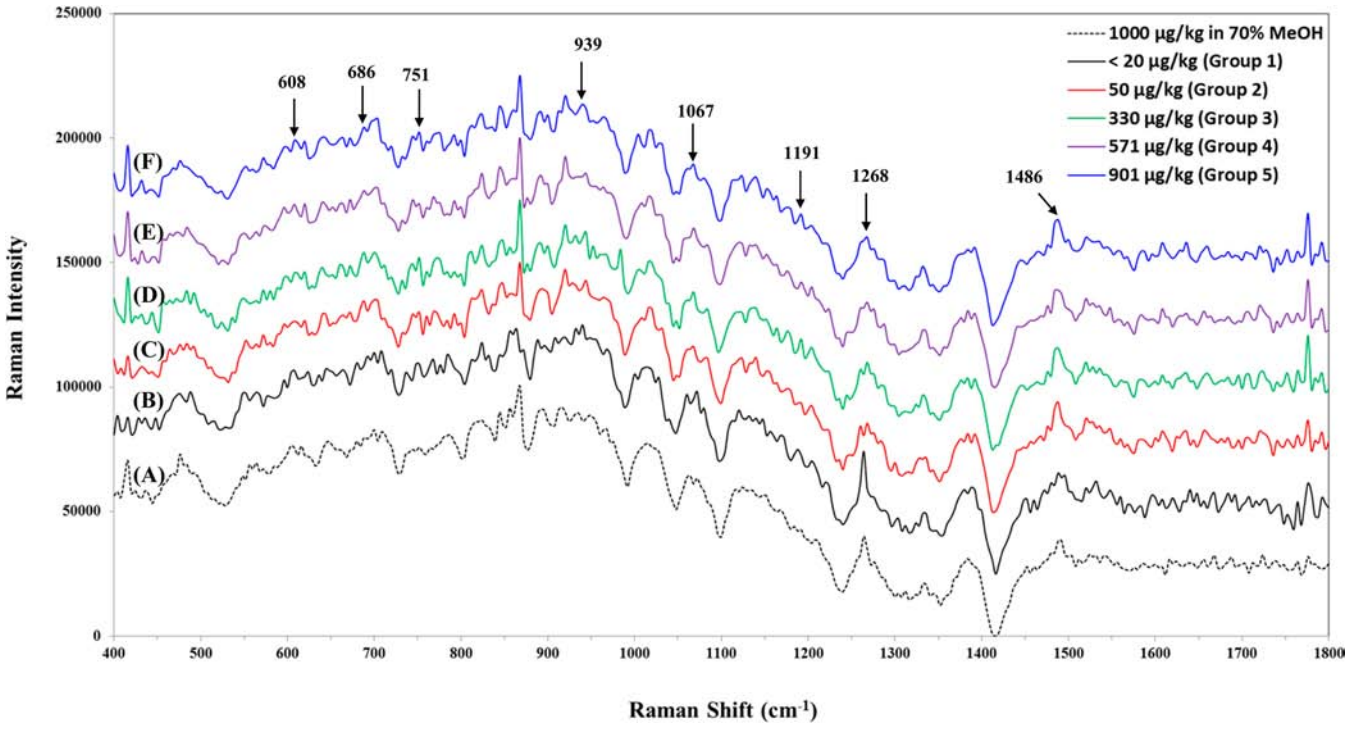

Figure 1. SERS spectra of 1,000 μg/kg pure aflatoxin in extract solvent (70% MeOH) (A) and aflatoxin contaminated sample at concentrations of (B) below 20 μg/kg (group 1), (C) 50 μg/kg (group 2), (D) 330 μg/kg (group 3), (E) 571 μg/kg (group 4), and (F) 901 μg/kg (group 5).

850 μg/kg. Principal component analysis (PCA), partial least-squares (PLS), and cluster analysis were employed to see if the samples could be well grouped into the predefined subgroups. A total of 115 spectral data were partitioned into a training data set (n = 85) for developing a calibration model and validation data set (n = 35) for testing the model. The chemometric calibration models for classification of samples by aflatoxin level were developed using two chemometric methods as proposed in previous research:[21−23] k-nearest neighbor (KNN) and linear discriminant analysis (LDA). The models were evaluated by comparing their classification accuracy and false negative error to select the model most suitable for the classification of aflatoxin contaminated maize samples.

The calibration models for aflatoxin quantification in maize were developed for the preprocessed spectral data by applying multiple linear regression (MLR), principal components regression (PCR), and partial least-squares regression (PLSR) algorithms. Prior to the chemometric application, a whole spectroscopic data set (n = 132) was randomly split into a 75% training data set and 25% validation data set. In the development of calibration models, SERS spectra were correlated with total aflatoxin concentrations (a sum of aflatoxins B_1, B_2, G_1, and G_2) in maize determined by HPLC reference methods using the chemometric methods. PCR and PLSR calibration models were cross-validated by leave-one-out validation method and evaluated based on coefficient of determination (r^2) and the predicted residual sum of squares (PRESS). The calibration models from MLR analysis using a stepwise regression option included the selected wavelengths as input variables in the equation based on partial r^2 values, partial F values, and PRESS. All chemometric models were externally validated by applying the models to predict total aflatoxin concentrations of the validation sample set and assessed by comparing the root-mean-square error of calibration (RMSEC), the root mean standard error of prediction (RMSEP), and correlation coefficient of determination (r^2). The limit of detection (LOD) and the limit of quantitation (LOQ) to assess the sensitivity of the models were determined using LOD = $3s/r$ and LOQ = $10s/r$, respectively, where s is the standard deviation of the predicted aflatoxin concentration and r is the slope of the corresponding regression equation.

Statistical Analysis. All data analyses and the development and validation of chemometric models were performed using SAS software. Statistical comparison between the SERS predicted and HPLC reference values were carried out using paired sample t test, Pearson's correlation coefficients, and the ratio of the standard deviation of the reference data to the standard error of cross-validation (RPD).[24]

RESULTS AND DISCUSSION

Spectral Data Analysis. Figure 1 shows normalized SERS spectra of ground maize sample extracts representing each aflatoxin contamination group. Common spectral features were observed among samples, but simultaneously, a distinctive change of Raman band intensities was also noticed among the sample extracts, particularly between below and above 20 μg/kg samples. Qualitative spectral differences in the normalized and derivative spectra were observed in the Raman shift ranges of 400−530 cm^{-1}, 800−980 cm^{-1}, 1100−1250 cm^{-1}, and 1500−1800 cm^{-1}. The major bands in these Raman shift regions may be associated with fungal cellular metabolites and modified cell membrane and inhibited protein and starch synthesis due to the effects of fungal and aflatoxin infection of kernels.[25]

The observed Raman bands in the SERS spectra were well assigned to the main vibrational modes associated with aflatoxin molecules according to the previously reported results.[18,26] However, shifts of some aflatoxin bands, in particular, in the aflatoxin-related Raman spectral regions, were easily observed compared to corresponding bands of conventional Raman spectroscopy. The shifts of Raman bands can be attributed to the effect of charge transfer between adsorbed aflatoxin molecules and silver metal in combination with the resonance excitation of surface plasmon.[11,27] The methyl moiety present in the extraction solution seems to add the complexity of Raman bands shift as well.[9] Nevertheless, some assignments for the major bands of interest can be tentatively determined (Table 1). The bands at 1557 and 1596 cm^{-1} corresponded to the stretching mode between carbons. The ν(C═C) mode was observed at 1486 cm^{-1}. The C−O bond at 939 cm^{-1} was

[a]SERS band assignments are made according to Wu et al.[23] and Móricz et al.[31]

significantly different between contaminated and noncontaminated samples in the spectra. Also, the C−H in-plane and out-of-plane bending modes found at 686 and 751 cm^{-1} appeared to be largely influenced by aflatoxin contamination. The vibration mode at 608 cm^{-1} is assigned to the ring deformation mode. However, Raman band intensity does not increase in proportion to aflatoxin concentration. This nonlinear relationship might be due to the variation in adsorption of aflatoxin molecules onto the SERS active sites and differences in sample matrices, silver nanoparticle concentration, and agglomerate morphology.[14]

Such irreproducibility of SERS signal can arise from several different conditions. If a SERS substrate contains uneven distribution of hot spots, only some portions of active sites may contribute to the SERS signal.[18] Different surface orientation and placement of target molecules on agglomerates of metal nanoparticles can also induce a slight change of SERS signal.[13,28] One obstacle in common applications of SERS is due to its inherent instability caused by metal nanoparticle aggregation with aging.[15] Our study revealed that the stability of metal nanoparticles can be significantly subject to the environments around the nanoparticles, such as a pH of the reacting solutions and nanoparticle/target molecule ratio as reported in previous studies.[11,28] The fungi producing aflatoxins obtain necessary nutrients from contaminated grains, diminishing protein, carbohydrates, and other micronutrients in the grains.[29] If the molecules other than target molecules, for example, in the sample extract for the present study, bind SERS active sites, SERS signal may respond to the concentration of the target molecules in a nonproportional way.[17] In the present study, the spectra obtained from Ag nanosphere (NS) displayed a good repeatability because hot spots are basically evenly distributed around the AgNSs and can yield a reproducible enhanced signal. Figure 2 shows representative SEM images of the AgNSs and their mixture with maize extract for the morphological analysis. In Figure 2, dispersed AgNC with various diameters were observed and they form blocks into

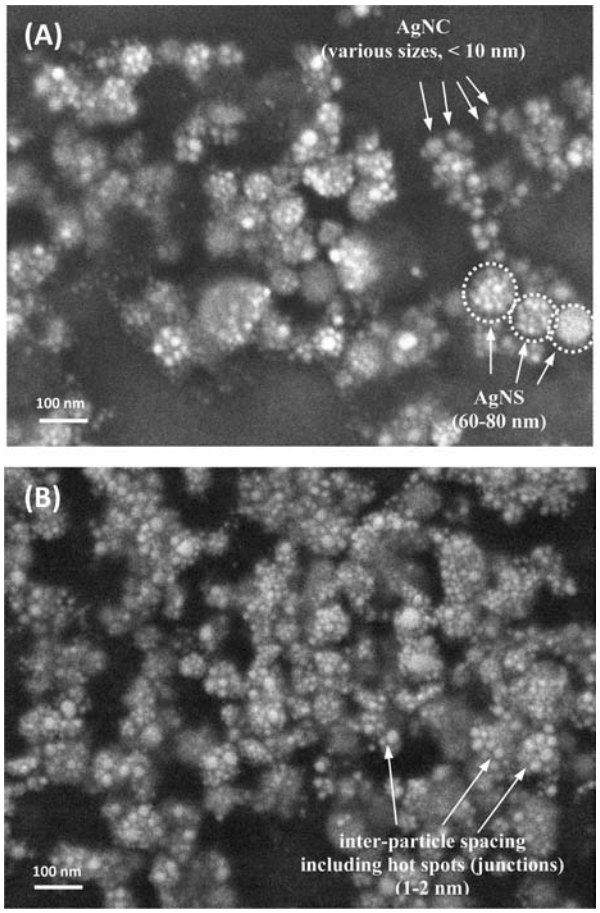

Figure 2. Scanning electron microscope (SEM) images of the mixtures of AgNSs and sample extracts at aflatoxin concentrations of (A) 50 μg/kg and (B) 901 μg/kg.

AgNSs with the diameters of 60−80 nm at an interparticle spacing of 1−2 nm. The AgNSs with the packed AgNC contain periodic hot spots or junctions which provide surface areas to adsorb aflatoxin or bioactive molecules. The previous studies reported that nanoparticles with a diameter of <10 nm produce a weak and irreproducible Raman signal due to a smaller size and the surface characteristics of nanoparticle clusters.[9,10] Meanwhile, the AgNS with a large diameter containing smaller AgNC within a microemulsion of oil droplets can produce a strong electromagnetic coupling effect for significant signal enhancement.[6,19] Further research needs to be conducted to determine the effect of structure modification of AgNSs on the spectroscopic characteristics after the sample extract introduction.

Our study shows that conventional Raman spectra obtained from the same samples were much weaker than SERS spectra and shifted in different SERS spectral regions. This indicates that aflatoxin and other extracted molecules adsorbed on the surface of nanoparticles are excited in different vibrational modes in SERS along with surface plasmon phenomenona.[9,28] In our previous studies,[30,31] a conventional Raman spectroscopy required a larger sample area and longer scanning time to obtain better spectral surface and subsurface features of ground maize samples, particularly at lower concentrations. The difference in intensity of a conventional Raman spectrum largely depended on the changes in physical, chemical, and structural properties of aflatoxin contaminated samples rather

than aflatoxin concentration.[6] Therefore, the Raman SERS method is considered as a more effective and highly efficient analytical tool for direct aflatoxin detection compared to conventional Raman spectroscopy.

Classification of Aflatoxin Contaminated Maize Samples. The classification models for aflatoxin contaminated and noncontaminated maize sample groups were developed by applying the *k*-nearest neighbors (KNN) algorithm for the four preprocessed SERS spectra in the Raman shift region of 400−1800 cm^{-1}. The KNN method was selected as a chemometric modeling technique for classification of aflatoxin contaminated maize samples because it showed outperformance over other chemometric methods such as linear discriminant analysis, partial least-squares, and principal component analysis in our previous studies.[30,31] In the present study, the KNN models exhibited stable classification accuracies from the number of neighbors greater than 5. Table 2 shows the classification accuracies of the KNN models for all preprocessed spectral data tested. As observed in Table 2, the performance of the classification models was largely determined by the mathematical pretreatment of the spectra. The correct classification rate of all calibration models was 100% for a training data set regardless of the spectral preprocessing method while rather lower classification accuracies (71.4−91.4%) were achieved when the calibration models were applied to validation data. The KNN models offering higher classification accuracy in classifying aflatoxin contaminated samples, as determined by the number of errors in an external validation data set, were obtained using normalized and deconvolution spectral data (Table 2). These two models displayed excellent classification results for maize samples with <20 μg/kg and >850 μg/kg. However, the model using the deconvolution spectra yielded higher classification accuracies for maize samples of groups 2, 3, and 4 than the model developed with normalized spectra,

dx.doi.org/10.1021/jf500854u | J. Agric. Food Chem. 2014, 62, 4466−4474

which may be attributed to the enhanced-resolution of the unresolved bands by the deconvolution pretreatment of the spectra. In these two models, no samples with greater than 20 μg/kg were misclassified as aflatoxin negative. This was in accordance with the finding in our previous study[31] with conventional Raman spectroscopy, indicating Raman spectroscopy is a promising technique to offer a rapid screening of large number of samples for aflatoxin contamination. The higher error rates were found in the models developed with first and second derivative spectra. These two KNN models displayed rather higher misclassification rate for the samples from all aflatoxin groups. This may be attributed to the excessive amplification of the noise and other extraneous peaks in the derivative spectra, resulting in a significant difference in the relative intensity of aflatoxin peaks with the original spectra despite improvement of spectroscopic resolution. However, even these models misclassified only one or two samples belong to group 2 into noncontaminated samples (group 1) considered as aflatoxin negative.

As opposed to what would be expected, the correct classification rates of the KNN models developed with the preprocessed spectra obtained from highly sensitive SERS technique were not greater and in fact were even slightly lower than those of the same chemometric models in our previous study[31] with conventional Raman spectroscopy. This can be in part explained by binding of bioactive molecules in the extracts to SERS active sites to lower SERS signal for aflatoxin molecules.[17] However, as mentioned above, the SERS method requires much smaller area and shorter scanning time than conventional Raman spectroscopy to yield equivalent results. Therefore, the calibration models can be further improved and become more robust by adding more training samples.

Because maize samples were not adequately clustered to the predefined aflatoxin group on the principal component score plot, the canonical discriminant scores derived from linear discriminant analysis of the preprocessed spectra were used to build a scatter plot (Figure 3). The canonical variable is the combination of original variables that can allow us to distinguish among the groups.[23] Figure 3 shows the actual distance between aflatoxin groups in a reduced, two-dimensional space. Maize samples within the same group are grouped closely together on the plot while the samples with very different concentrations are remotely grouped. On the whole, the grouping of the samples on the scatter plot is in agreement with the results of correct classification rates for the KNN models developed with the preprocessed spectral data (Table 2). Regions of overlap among aflatoxin groups and the degree of the overlap appear to be associated with the misclassification rate of the relevant groups. As expected, each aflatoxin group was better separated by two canonical functions for normalized and deconvolution spectra than those for first and second derivative spectra. The first two canonical variables were significant ($P < 0.001$) in all KNN models, implying its substantial contribution to discriminating aflatoxin contamination groups. The first canonical function in all models accounts for the highest percentages (62.8−71.3%) of the total variation of the groups (Figure 3). Consequently, the first and second canonical functions can explain a total of from 84.0 to 88.5% variations in the spectral data.

The PCA and PLS results also provide some additional information on the particular spectral subranges and bands corresponding to the level of aflatoxins in maize sample extracts (data not shown). Some spectral regions and wavelengths with higher loading values in PCA and with higher absolute regression coefficient value in PLS are associated with an increased level of aflatoxins and changes in maize kernels induced by aflatoxins.[25] Cluster analysis performed using all the preprocessed spectra allowed classification of aflatoxin contamination samples, which was basically configured by the aflatoxin group. However, the classification results obtained from the best clustering algorithm employed (hierarchical Ward's minimum variance method) were not as good as those from the canonical functions.

Quantification of Aflatoxins in Maize Samples. The relationships between actual aflatoxin concentrations and SERS values predicted by the models for four preprocessed spectra are shown in Table 3 and Figure 4. The chemometric methods including multiple linear regression (MLR), principal components regression (PCR), and partial least-squares regression (PLSR) algorithms, employed for development of aflatoxin quantification models, extract meaningful information from SERS spectra to correlate the spectra with aflatoxins and modified physicochemical features of maize kernels caused by aflatoxin contamination, which allows us to detect a subtle difference between aflatoxin contaminated samples for aflatoxin quantification.[6,32,33] The MLR models showed better regression quality, higher predictive accuracy, and lower error rate than other chemometric methods while the PCR models yielded far less satisfactory results compared to the MLR and PLSR models.

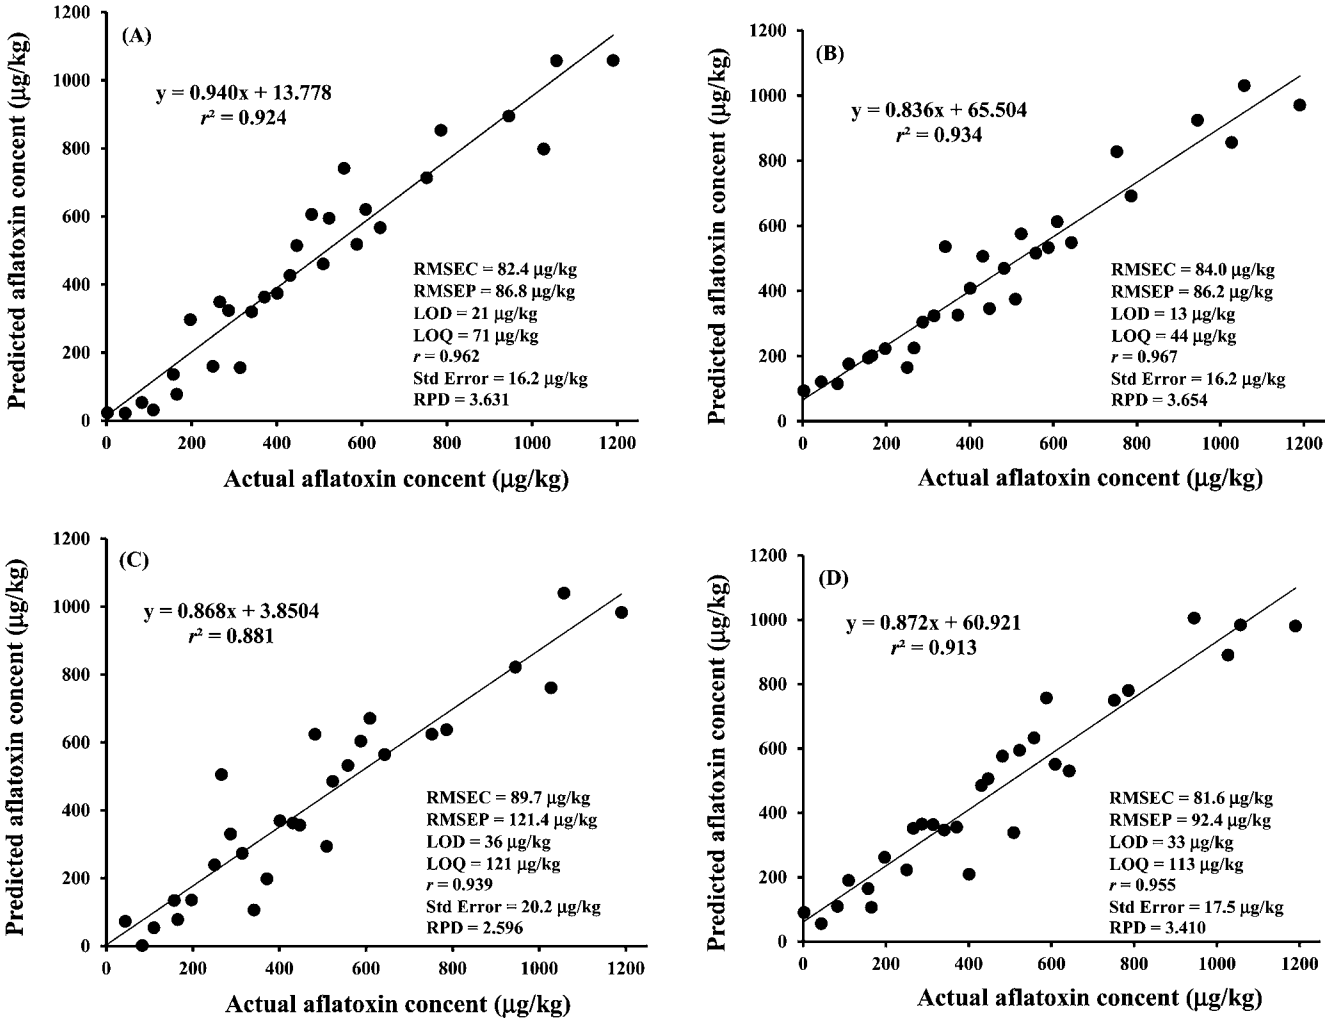

Figure 4. A linear regression plot of reference HPLC versus SERS predicted aflatoxin concentrations of the validation data set in the MLR models developed with four preprocessed spectra: (A) normalization; (B) first derivative; (C) second derivative; and (D) deconvolution.

In the MLR models, selection of optimal wavelengths was carried out using STEPWISE regression procedure and the selected wavelengths were further examined to eliminate collinearity and overfitting problems using variance inflation factor (VIF) and tolerance options. The final combination of the wavelengths was then determined by comparing with the results of the SQUARE (R^2 selection) method. All MLR models developed with the preprocessed spectra could account for more than 90% of variation in both training and validation data set, except for second derivative spectra in the validation data set (Figure 4). As would be expected, the calibration models of normalized, first derivative, and deconvolution spectra displayed better statistical performance than the model for second derivative spectra. Coefficients of determination (r^2) and predictive error rate (RMSEP) of the former three calibration models applied to the validation data set were in the range of 0.913−0.934 and 86.2−92.4 μg/kg, respectively. Meanwhile, the model for second derivative data yielded lower r^2 (0.881) and higher predictive error rate (RMSEP = 150.6 μg/kg). The slope of the linear regressions for the training data set was in the range of 0.908 to 0.923 while the calibration models applied to the validation data set produced a slightly lower slope (0.836−0.940) (Figure 4). These observations indicate a good quality of the regressions and high predictive capability of selected MLR models suitable for screening of aflatoxin contaminated samples. It appears that the MLR models include several prominent wavelengths relevant to starch molecules extracted with 70% methanol as well as aflatoxin molecules in the extract. These results enable us to carefully infer that current MLR models developed from SERS spectra may reasonably predict low and high aflatoxin concentration in extracted maize sample with the selected solvent if the models are further improved by optimized instrumental and measurement experimental conditions. However, as observed in our previous studies[30,31] with conventional Raman spectroscopy, the SERS technique was also not very accurate in predicting very low aflatoxin concentrations, particularly below the FDA action level (20 μg/kg) for aflatoxins. But the reason for inaccurate prediction of very low aflatoxin concentration with SERS might be different with conventional Raman spectroscopy. The low predictive accuracy of the SERS results may be in part explained by adsorption variation of aflatoxin molecules on or in the vicinity of the SERS active site.[8,10,14] On the other hand, conventional Raman spectroscopy could not accurately predict aflatoxin concentration due to its insufficient sensitivity and inherently weak signal to detect aflatoxin molecules as well as inhomogeneous fungal contamination and aflatoxin distribution in ground maize samples.[34,35] Therefore, it would be expected that the SERS requires less effort and attention than

conventional Raman spectroscopy in optimizing sample preparation procedure and measurement conditions to obtain reproducible and representative spectra and to improve the repeatability of the spectra.

The detailed statistical results of the PLSR models are presented in Table 3. The PLSR calibration models yielded comparable results to the MLR calibration models for the training data set, resulting in high r^2 values (0.932−0.974), lower error rate (RMSEC: 47.9−77.0 μg/kg), and a linear regression slope in the range of close to 1 (Table 3). However, the predictive accuracy of the PLSR calibration models predicting the validation samples was not as good. The PLSR calibration models applied to the validation data set produced lower r^2 values and linear regression slopes, accounting for the variation of the preprocessed spectra in the range of 82.0−91.5%. Besides, the predictive error rate (RMSEP) and quality of linear regression were not sufficiently good to use the models for predicting aflatoxin concentrations. The PCR models revealed a poor predictive performance for the training and validation samples irrespective of the preprocessing method (data not shown). The PCR calibration models applied to the validation data set yielded much lower coefficients of determinations and higher prediction errors than the MLR and PLSR models.

Paired sample t test for the validation data set showed no statistically significant difference ($p > 0.01$) between the reference HPLC values and the predicted values of SERS in all aflatoxin quantification models, except for the MLR model for second derivative spectra, but the statistical results were very subject to the chemometric and/or preprocessed methods (Table 3 and Figure 4). The MLR models showed higher p values and stronger correlation coefficients (r = 0.906−0.967) with the HPLC reference values than the PLSR and PCR models, indicating that the MLR models produced more comparable results to the HPLC method at aflatoxin levels tested. The limit of detection (LOD) and the limit of quantitation (LOQ) of the MLR models are in the ranges of 13−36 μg/kg and 44−121 μg/kg, respectively, indicating that the models are more sensitive for quantification of aflatoxins in maize. Standard errors of paired differences between the reference and predicted values were also lowest in the MLR models. According to the criterion of RPD (ratio of the standard deviation of the reference data to the standard error of cross-validation) values described in previous literature,[24,36] the MLR models may be effective for screening of aflatoxin contaminated samples. Despite the chemometric models developed by conventional Raman spectroscopy showing a slightly higher predictive accuracy than those of SERS at aflatoxin concentrations tested in this study,[31] the effectiveness and efficiency of the SERS would be better if more considerations were given to sensitivity, analysis speed, reproducibility of spectra, and potential improvement of SERS substrate.

In conclusion, the research results prove that SERS can be an alternative rapid and highly sensitive analytical method for classification and quantification of aflatoxins in contaminated maize samples over standard wet chemical methods. Compared to other spectroscopic techniques and conventional Raman spectroscopy, this technique seems to be able to provide more comprehensive information on the structural and electronic properties of aflatoxin molecules. However, the problem of spectral variation induced by instability of nanoparticles and differences in sampling and sample batches should be minimized or resolved prior to application of SERS for aflatoxin analysis. Besides, inexpensive nanomaterials and nanostructures that can give better Raman signal and stronger enhancement factor need to be found. It may also be useful to develop the SERS method combining automated spectral processing and statistical analysis algorithms for the on-site testing to facilitate real-time monitoring at critical locations in grain supply chains. Certainly, SERS is a promising and potentially powerful tool for detecting aflatoxins in maize and other grains which can greatly help improve the safety and quality of food and feed products.

ABSTRACT: RNA silencing or RNA interference (RNAi), which is triggered by double-stranded RNA (dsRNA), is an evolutionarily conserved process that is active in a wide variety of eukaryotic organisms. Engineering plants with hairpin construct in which the viral gene is arranged in inverted repeats (IR) renders plants resistant to plant virus infection. However, there is no report on whether biologically important changes occurred by the insertion of IR, which confer transgenic plants virus resistance. In the present study, the compositions of virus-resistant transgenic soybean seeds developed by insertion of three short IRs, each containing the specific, highly conserved sequences derived from one virus, were compared with those of nontransgenic counterparts by applying the principle of substantial equivalence to determine whether significant undesirable biological changes occurred by IR insertion. The results revealed that the nutrient components as well as antinutrient contents of these virus-resistant soybean lines are substantially equivalent to those of the nontransgenic counterparts, and the majority of the measured amounts of nutritional components and antinutrient contents are well within the range of values reported for other commercial soybean lines. The results imply that no biologically important changes occurred by the insertion of IRs in the RNAi-mediated virus-resistant transgenic soybeans. The results can serve as baseline information for developing RNAi-mediated transgenic soybean cultivars or other crops with broader spectrum virus resistance.

KEYWORDS: *inverted repeats, virus-resistant transgenic soybean, composition, substantial equivalence*

INTRODUCTION

Research during the past decade has firmly established that land plants use an RNA-targeting defense mechanism termed RNA silencing (or RNA interference, RNAi) to combat virus infections. The trigger of RNA silencing is a double-stranded RNA (dsRNA), which is processed into small interfering RNAs (siRNAs), which direct Argonaute protein silencing corresponding genes or genetic elements in a sequence-specific manner.[1,2] On the basis of RNAi machinery, engineering plants with hairpin construct in which the transgenes are arranged in inverted repeats (IR) offers a promising alternative for controlling most major virus disease problems in crops.[3]

Considering the history of traditional breeding on safety, the likelihood that safety concern might arise due to unintended compositional changes resulting from transgenes is negligible. However, compositional studies continue to be required, and regulatory requirements for composition studies are becoming increasingly complex in some regions.[4] Soybean (*Glycine max* L. Merrill) is an important staple source of vegetable protein in food and animal feed as well as for industry because the abundance and nutritional quality of seed proteins in soybean exceed those in other grain crops. To our best knowledge, there is no report on whether biologically important changes occurred by the insertion of IR that conferred transgenic plants virus resistance. The present study was designed to evaluate the composition of the RNAi-mediated virus-resistant transgenic soybeans engineered with hairpin construct and their nontransgenic counterpart through a series of chemical analyses to determine whether significant undesirable biologically changes occurred by the IR insertion in transgenic soybeans, using the concept of "substantial equivalence", which was developed by the Organisation for Economic Co-operation and Development (OECD) in 1993 and was elaborated further by FAO/WHO.[5,6] The concept suggests that if no meaningful difference from the conventional counterpart is found, then the transgenic crop is as safe and nutritious as its traditional counterpart, which is generally accepted as safe on the basis of human food use history. Substantial equivalent analysis has been studied for different events of transgenic crops, such as corn,[7,8] soybean,[9−15] rice,[16] and papaya.[17]

MATERIALS AND METHODS

Soybean Used for Analysis. The transgenic soybeans and respective nontransgenic counterparts were cultivated in cultivation pots, which were 30 cm in diameter and 23 cm in height, in the greenhouse of the Chinese Academy of Tropical Agriculture in Hainan, China. Each cultivar (one transgenic soybean line or its nontransgenic line) was composed of 10 cultivation pots of soybeans. The arrangement of soybean cultivation pots was randomly assigned. The transgenic soybean lines were T4 generation of self-crossing progenies from T0 generation of soybean transformants, which were developed through the *Agrobacterium*-mediated transformation with transgene construct dsABS.[18] The construct contains three hairpins, which derived from the highly conserved regions of replicase genes of

[a]Grams per 100 g of dry weight. [b]From ref 29.

Alfalfa mosaic virus (AMV, a member of the family Bromoviridae), *Bean pod mottle virus* (BPMV, a member of the family Secoviridae), and *Soybean mosaic virus* (SMV, a member of the family Potyviridae), respectively, and the *bar* gene isolated from *Streptomyces hygroscopicus* as a selectable marker.

Compositional Analyses. *Proximate.* Moisture content was determined gravimetrically by drying the samples in a vacuum oven at approximately 100 °C.[19] For ash determination, the samples were placed in an electric furnace at 550 °C and ignited in air. The residual ash was quantified gravimetrically.[20] The Kjeldahl method was employed to determine total nitrogen and protein of the sample. The percent nitrogen was calculated and converted to equivalent protein using a factor of 6.25.[21] The crude fat content of the soybean seed samples was determined using the Soxhlet extraction method.[22] The carbohydrates content was calculated by difference using the fresh weight-derived data according to the following equation:

$$\%\ \text{carbohydrates} = 100 - (\%\ \text{protein} + \%\ \text{fat} + \%\ \text{ash} + \%\ \text{moisture})$$

Amino Acid Profile. Protein hydrolysis was performed before ninhydrin derivatization to analyze total amino acid composition, with the exception of cysteine, methionine, and tryptophan. The samples were hydrolyzed with 1 mL of 6 M hydrochloric acid at 110 °C for 22 h under a nitrogen atmosphere. The hydrolysate was dried under reduced pressure, dissolved in 0.02 M HCl, and subjected to analysis using a UV detector and a Hitachi L-8800 automatic amino acid analyzer (Hitachi High-Technologies, Tokyo, Japan). The cystine and cysteine in the samples were oxidized to cysteic acid, and methionine was oxidized to methionine sulfone through dithiodipropionic acid treatment for 16 h at approximately 0 °C. Tryptophan is hydrolyzed from proteins by heating at approximately 110 °C in 4.2 M sodium hydroxide for 20 h. After acid hydrolysis, the sample was separated on an anion exchange column and detected with a ninhydin reaction as described in the literature.[23]

Fatty Acid Profile. Up to 20 g of ground powder of transgenic or nontransgenic soybean seeds was analyzed through gas chromatography according to the procedures from the literature.[24]

Antinutrients. Lectins were determined by measuring the agglutinating properties of soybean sample extract on rabbit red blood cells according to modified procedures from the literature.[25,26] Trypsin inhibitor activity was determined by using a modified method described previously in the literature.[27]

Isoflavones Profile. The profiles of isoflavones of soybean seeds were determined through liquid chromatography according to procedures from the literature.[28]

Statistical Analysis. After harvest, the seeds of 10 cultivation pots of each cultivar were put together. Half of each cultivar's harvested dried seeds, which were selected randomly, were milled into powder using a high-speed tissue masher for nutrient compositional analysis. All statistical data analyses were performed employing the SPSS 19.0 software package. All analytical determinations were conducted in triplicate, and results are expressed as the mean ± standard deviation. Differences between samples were tested using one-way analysis of variance (ANOVA). $P \leq 0.05$ was considered to be statistically significant.

RESULTS AND DISCUSSION

Proximate Compositions. Table 1 shows the proximate analyses, including moisture, ash content, crude protein, crude fat, and carbohydrates, of the three virus-resistant transgenic

soybean lines and their nontransgenic counterpart seeds. In terms of these compositions, with a confidence level of 95%, no statistically significant differences were observed not only between the transgenic soybean seeds and the control but also among the different transgenic soybean lines. Individual values were within the tolerance interval determined for commercial varieties and within published literature ranges.[29] These results implied that no biologically important changes occurred for the proximate compositions of the transgenic soybean lines 729-3, 729-4, and 729-5 compared with their nontransgenic counterpart.

Amino Acid Contents. Table 2 presents the content of 18 amino acids of transgenic virus-resistant soybean and nontransgenic seeds. The content of individual amino acids in soybean seeds was expressed as percentage with respect to the total protein. The contents of the majority of the measured amino acids fell within the ranges of the ILSI database,[29] except threonine and tryptophan; the contents of these were higher than the maximum values. However, no significant differences in the levels of any of the 18 amino acids measured were found between the virus-resistant soybean seeds and their nontransgenic counterparts. These results demonstrated that the amino acid contents of the transgenic soybean cultivars were substantially equivalent to those of nontransgenic counterparts.

Fatty Acids. Individual fatty acids of soybean samples were estimated by GC-MS analysis. All fatty acids were expressed as percentage with respect to the total fatty acids (Table 3). Among them, consistent with previous results,[14−20] palmitic acid (C16:0), oleic acid (C18:1), and linoleic acid (C18:3) were the most abundant fatty acids of transgenic virus-resistant soybeans and their nontransgenic counterpart. The percentage values of the majority of the measured fatty acids fell within the ranges of the ILSI database,[29] except palmitoleic and heptadecenoic; the contents of these two fatty acids were lower than the minimum values. However, with a confidence level of 95% no statistical differences were found in fatty acid composition. The contents of the fatty acids in harvested seeds of the virus-resistant soybeans 729-3, 729-4, and 729-5 were comparable to those observed in the seeds of conventional control.

Antinutrients. The results for two important antinutritional factors (lectin and trypsin inhibitors) are presented in Table 4. Both of them were generally low and did not exceed the range reported previously,[29] which might not affect the nutritional potential of soybean seeds. The contents of lectin and trypsin

inhibitor in the harvested seeds of virus-resistant transgenic soybeans were comparable with those observed in the harvested seeds of the nontransgenic control with a confidence level of 95%. These results exhibited that the antinutrient composition of the transgenic lines was substantially equivalent to that of the nontransgenic counterpart.

Isoflavones Profile. The contents of isoflavones including daidzin, glycitin, genistin, daidzein, glycitein, and genistein in the harvested seeds of virus-resistant transgenic soybeans were comparable to those observed in the harvested seeds of the conventional control (Table 5). The level of these isoflavones fell within the ranges of other commercially available soybeans reported in previous literature.[30] No significant statistical difference was observed in any of the isoflavones levels between the transgenic and nontransgenic soybean seeds.

In conclusion, the results of compositional analyses show no meaningful differences had been found in the transgenic soybean lines with glyphosate tolerance and virus resistance from the conventional counterpart with a confidence level of 95%. On the basis of the principle of substantial equivalence,[5,6] the transgenic soybean lines with glyphosate tolerance and virus resistance are substantially equivalent to those nontransgenic counterparts. The results reported herein, together with previous findings that the composition of transgenic glyphosate-tolerant soybeans with the *bar* gene is equivalent with that of conventional soybeans,[9−15] support the conclusion that no significant undesirable biological changes occurred by the insertion of IR conferring transgenic soybean with robust resistance to mixed infection of AMV, BPMV, and SMV.

RNA silencing or RNA interference (RNAi), a form of gene suppression that occurs at transcriptional and post-transcriptional levels, is an evolutionarily conserved process that is active in a wide variety of eukaryotic organisms.[1,2] One of the advantages of RNAi-mediated virus resistance is the relatively small size of the transgene required for silencing, enabling more than one short IR containing different viruses' conserved sequences to be stacked to a single construct and enabling a broader spectrum of resistance to be developed with a single transgene.[3] RNAi has been an important tool to render plants resistant to plant virus infection,[31] although there are three main factors that can determine the practical usefulness of antiviral strategies: efficiency, durability, and safety.[32] The results showed that the transgenic soybeans with IR insertion are substantially equivalent to nontransgenic counterparts. The concept of "substantial equivalence" suggests that the RNAi-mediated virus-resistant transgenic soybeans are as safe and nutritious as their traditional counterpart. The results can serve as baseline information for developing RNAi-mediated transgenic soybean cultivars or other crops with broader spectrum virus resistance.

Glucosinolates, Myrosinase Hydrolysis Products, and Flavonols Found in Rocket (*Eruca sativa* and *Diplotaxis tenuifolia*)

Luke Bell* and Carol Wagstaff

Department of Food and Nutritional Sciences and the Centre for Food Security, University of Reading, Whiteknights, Reading, Berkshire RG6 6AH, United Kingdom

ABSTRACT: Rocket species have been shown to have very high concentrations of glucosinolates and flavonols, which have numerous positive health benefits with regular consumption. This review highlights how breeders and processors of rocket species can utilize genomic and phytochemical research to improve varieties and enhance the nutritive benefits to consumers. Plant breeders are increasingly looking to new technologies such as HPLC, UPLC, LC-MS, and GC-MS to screen populations for their phytochemical content to inform plant selections. This paper collates the research that has been conducted to date in rocket and summarizes all glucosinolate and flavonol compounds identified in the species. The paper emphasizes the importance of the broad screening of populations for phytochemicals and myrosinase degradation products, as well as unique traits that may be found in underutilized gene bank resources. This review also stresses that collaboration with industrial partners is becoming essential for long-term plant breeding goals through research.

KEYWORDS: *Brassicaceae, isothiocyanates, plant breeding, indoles, nitriles*

INTRODUCTION

In recent years, several species of minor leafy crops have risen to prominence as potentially important commercial and edible species. One example is rocket, which has quickly gained popularity in the Western diet. Originally found as an obscure crop in Mediterranean and Middle Eastern countries, rocket has become popular largely due to the pungent aromas and tastes associated with it. Glucosinolates (GSLs)/isothiocyanates (ITCs) and flavonols derived from many species[1−4] have been shown to impart significant protection against cancer and heart disease.[4−11] In Western countries, diets are generally lacking in fruits and vegetables. Despite government initiatives (such as the "5-a-day" campaign in the United Kingdom and the United States), these diseases are increasingly leading to premature deaths.[12] Plant breeders aim to maximize levels of such beneficial compounds, but with little genomic information about rocket species presently available, this is a formidable task. This review will give an overview of research in rocket, an outbreeding crop, and how breeders and processors can utilize it to enhance beneficial compounds.

ROCKET SPECIES

Rocket (also known as arugula, rucola, and roquette) is a leafy vegetable crop that has gained substantial popularity across the world, particularly over the past 15 years.[13−16] Two main species are predominantly farmed as salad crops; these are *Eruca sativa* ("salad" or "cultivated" rocket; sometimes referred to as *Eruca vesicaria* subsp. *sativa*) and *Diplotaxis tenuifolia* ("wild" rocket). Both species share a peppery taste and aroma that is very distinctive.[17] They have been reported to contain high levels of vitamin C, GSLs, flavonols, and phenolics.[18−25] These are all known to have both antioxidant and anticancer properties and are also implicated in lowering the risk of cardiovascular and cognitive diseases. For excellent information on these beneficial effects and their underlying causes, see Drewnowski and Gomez-Carneros,[26] Keum et al.,[27] D'Antuono et al.,[28] Egea-Gilbert et al.,[29] Degl'Innoocenti et al.,[30] Bjorkman et al.,[31] and Jeffery et al.[32]

TAXONOMY AND DOMESTICATION

A distinction should be made that both *Eruca* and *Diplotaxis* species have overlapping characteristics and that one can be easily mistaken for the other by the untrained eye and/or before a certain level of maturity has been reached.[28] It is also arguable that *D. tenuifolia* is the least "wild" of the two species even though the common name is "wild rocket". It is featured and favored in commercial products and breeding programs and is likely to be more domesticated than *Eruca* species as a result. *Diplotaxis* varieties are generally uniform phenotypically, with *Eruca* varieties being more diverse in this respect.[23] No direct genomic evidence has been presented in the literature to suggest one species is any more or less genetically variable than the other. Variability in GSL data seems to support the hypothesis that *Diplotaxis* species are more "wild",[33] although it is not conclusive, as only a relatively small number of cultivars have been tested. This is a point that needs clarification through research and extensive breeding, as neither species can be considered fully domesticated.[29] For example, germination rates are variable, reproductive organs are typically small, seedpods shatter and disperse freely (rather than staying on the plant), and physical defenses such as leaf hairs are still present in many commercial varieties.[34]

PHYTOCHEMICALS IN *ERUCA SATIVA* AND *DIPLOTAXIS TENUIFOLIA*: TYPES AND STRUCTURES

Glucosinolates. GSLs are β-thioglucoside *N*-hydrosulfates that are responsible for the sharp and bitter-tasting flavors found in cruciferous vegetables.[35,36] In combination with the enzyme myrosinase (thioglucoside glucohydrolase, EC 3.2.1.147), GSLs are hydrolyzed to create isothiocyanates, nitriles, thiocyanates, epithionitriles, indoles, oxazolidine-2-thiones, cyanopithioalkanes, ascorbigens, goitrogens, and epithioalkanes[37−49] (see Figure 1). Many of these hydrolysis products have antibacterial, antifungal, and insect-repellant effects.[50−55] GSLs and ITCs are being increasingly used as "biofumigants" to suppress soilborne pathogens, nematodes, and weeds. Some of the volatile products have the opposite effect of attracting species that can tolerate high GSL concentrations, such as types of ovipositing insects.[56,57]

The conditions under which hydrolysis of GSLs occurs will affect the respective proportions of the chemicals produced; pH, iron ions, thiol ions, temperature, and hydration play a particularly prominent role in this process in vivo.[58] The separation of GSLs in specialist "S-cells" from myrosinase in myrosin cells means that the two components come into contact only upon tissue disruption, for example, when damaged via chewing or digestion.[59−69] It is the biological activity of the ITC hydrolysis products in humans that is of most interest in rocket.[50] GSLs can be hydrolyzed within the intestinal tract by gut microflora that are known to have specific myrosinase activity,[70−73] but the efficacy of their action is not yet well determined.

GSL concentrations can vary and change over time depending on environmental conditions and stress.[7] Other factors affecting GSL profiles include plant age, organ type, developmental stage, ambient air temperature, level of water stress, photoperiod, agronomic practice, degree of wounding, and geographical origin of the variety/species.[74−81] These can often affect the profiles of *all* phytonutrients contained within tissue, not just GSLs,[82] and they are all factors that plant breeders aim to mitigate through development of genetically advanced and uniform breeding lines.

GSLs and the ITC derivatives have been an integral part of the human diet for millennia because of their presence in the family Brassicaceae.[64−66,83−89] GSLs are evolutionarily recent secondary metabolic products, having arisen 10−15 million years ago,[90,91] acting to prevent pathogen attack and dissuade herbivory. They are known in only a few angiosperm families of the order Brassicales, which includes the Brassicaceae,[92−100] and of which *Eruca* and *Diplotaxis* are members.

A study by Pasini et al.[33] of 37 rocket accessions (*Diplotaxis* and *Eruca*) showed that GSL profiles were all very similar, regardless of the species. In total, 12 GSL compounds were found across all accessions; Table 1 illustrates all known GSL compounds identified to date in rocket. These include 4-mercaptobutyl GSL (glucosativin),[21] 4-methylthiobutyl GSL (glucoerucin),[101] and 4-methylsulfinylbutyl GSL (glucoraphanin),[28] which constitute the three most abundant GSLs in rocket.

Flavonols. Flavonols are diphenylpropanes (C_6–C_3–C_6)[102] and are another important group of chemicals found within rocket species. Flavonols in rocket are found with sugar conjugates and typically occur in relatively large quantities.[103] The aglycones found (such as quercetin and kaempferol) are glycosylated and acylated, which in turn affects their biological properties.[18] A study by Martínez-Sánchez et al.[18] identified over 50 different flavonol compounds across four different species. Watercress, mizuna, and two species of rocket were all found to accumulate very different compounds within their leaves and in varying quantities. Wild rocket showed high levels of quercetin-3,3′,4-triglucosyl (43.5 mg 100 g^{-1} fw), and salad rocket had mostly kaempferol-3,4′-diglucosyl (97.8 mg 100 g^{-1} fw). The group also showed a correlation between quercetin derivatives and high antioxidant activity, despite the significant variations seen between species.

Studies conducted on rocket tissues have identified significant concentrations of polyglycosylated flavonols. The core aglycones of these are kaempferol, quercetin, and isorhamnetin;[102] Table 2 provides an up-to-date list of all flavonol compounds identified in rocket. Martínez-Sanchez et al.[18] showed that *Eruca* species accumulate kaempferol derivatives, whereas *D. tenuifolia* accumulates predominantly quercetin instead, meaning that the two chemicals could be used as identification markers between the two species.[104] Isorhamnetin aglycones are common to both species but typically in much lower concentrations.[33] The specific aglycones also impart various degrees of antioxidant activity. For example, quercetin derivatives have a higher activity than kaempferol and isorhamnetin. The differences in structure

dx.doi.org/10.1021/jf501096x | J. Agric. Food Chem. 2014, 62, 4481−4492

(the arrangement of hydroxyl groups and glycosylation) affect antioxidant activity by allowing the molecules to act as hydrogen/electron donors, single-oxygen scavengers, or reducing agents.[105]

PHYTOCHEMICALS AND THE RELATIONSHIP WITH QUALITY: TASTE AND AROMA

It is thought that the presence of glucosativin, glucoerucin, and their hydrolysis products within rocket leaves is what gives

[x]Standard GSL molecule according to IUPAC nomenclature.

them a characteristic flavor.[44] Many of the health beneficial GSLs and ITCs are thought to be responsible for strong tastes that some consumers find repellant.[106] It seems that to many people, these compounds contribute very little to a pleasurable eating experience and are actively avoided.[83] Conversely, however, some people prefer these strong tastes and aromas and will actively seek to consume rocket when it is available. Growers in Italy often prefer the subsequent cuts because of the more intense tastes and aromas that are produced,[107] and some will even "sacrifice" the first cut in favor of the subsequent leaf growth. This highlights a divide between consumers that may be indicative of underlying genotype(s) for taste perception and preference.

The breeding process in rocket varieties to date has effectively made the species "milder" in taste when compared to plants that grow naturally in the wild. Whether this has been intentional or as a result of selecting for other unrelated traits (such as leaf morphology) is debatable. Some recent commercial varieties have been bred for a "hotter" taste, such as 'Wildfire', by Tozer Seeds (Surrey, UK).

A study by Pasini et al.[17] demonstrated how breeding for sensory traits could be achieved by highlighting which glucosinolates contribute to specific taste and aroma elements in rocket. It was found that progoitrin/epiprogoitrin is responsible for bitter taste attributes, despite being only a minor component of the overall GSL profile of rocket (4.3−11.4% of total

GSL concentration). The perceived pungency of leaves was positively related to the overall GSL content of accessions, and the levels of glucoraphanin negatively contributed to the typical "rocket" flavor. The study also highlighted an important difference between rocket and other *Brassica* sensory studies[108] in that bitterness was perceived as a favorable characteristic according to panelists. The flavonol compound kaempferol-3-(2-sinapoylglucoside)-4′-glucoside also significantly and positively contributed to flavor attributes in *Eruca* accessions. This would indicate that GSL compounds are not totally responsible for flavor in rocket. The study itself stopped short of saying how or if the information obtained would be used in breeding programs, but with study into rocket flavor components, milder (and/or stronger) varieties could be bred more efficiently once the responsible compounds are properly identified.[26]

HEALTH-PROMOTING PROPERTIES OF GLUCOSINOLATE–MYROSINASE PRODUCTS AND FLAVONOLS OF ROCKET

Isothiocyanates. ITC hydrolysis products have been identified in rocket,[45] such as 4-(methylthio)butyl ITC (erucin),[109,110] which is known to show antiproliferative activity in human lung carcinoma A549 cells, hepatoma (HepG2) cells, colon cancer cells, prostate cancer cell lines (PC3, BPH-1, and LnCap), and leukemia cells.[111] Erucin is a structurally reduced analogue of sulforaphane (which is predominantly found in broccoli) and has shown promising anticancer properties in vitro (e.g., antiproliferation of human erytroleukemic K562 cells).[112] Research into the chemopreventative and antigenotoxic nature of ITCs has shown promising results[113] (see Figure 2). Other studies involving chemically induced genotoxicity have shown very strong antigenotoxic effects of *E. sativa* extracts,[13] which is in agreement with other Brassicaceae studies.[114,115] Identifying specific cultivars of rocket with elevated levels of erucin and glucoraphanin would be an important first step in developing superior varieties from a human nutrition standpoint.

The results of GSL/ITC research prompted an investment in broccoli breeding in the past decade. A similar concerted effort could be made for rocket, which contains similar compounds that are potentially just as efficacious in humans.[116] Erucin, for example, has been shown to have a very similar, and even superior, biological activity to that of sulforaphane.[117] One paper has specifically demonstrated that the concentration of rocket ingested in an average daily diet is significant enough to impart a cancer preventative effect.[13] The metabolism of ITCs in humans via the mercapturic acid pathway has been investigated. ITCs are conjugated with glutathione and degraded by N-acetylation, initiating an increase of phase II detoxification enzymes; see Figure 3 for the detailed pathway breakdown of erucin.[113]

Nitriles. Along with ITCs, nitriles are the most abundant bioactive compounds produced by GSL hydrolysis.[116] The hydrolysis of glucoraphanin, for example, yields predominantly sulforaphane and sulforaphane nitrile. The ratio in which the two are formed depends greatly upon the environmental conditions and the plant cultivar that is used.[117] A low-pH medium tends toward the formation of nitriles, whereas high pH forms ITCs.[118,119] The presence of thiol and iron ions favors nitriles, and high temperature and hydration produce more ITCs.[120,121] This can have substantial consequences for any potential health benefits that might be imparted by the consumption of rocket.[119] The nitrile form is approximately 3 orders of magnitude less efficacious than the ITC in inducing quinone

dx.doi.org/10.1021/jf501096x | J. Agric. Food Chem. 2014, 62, 4481−4492

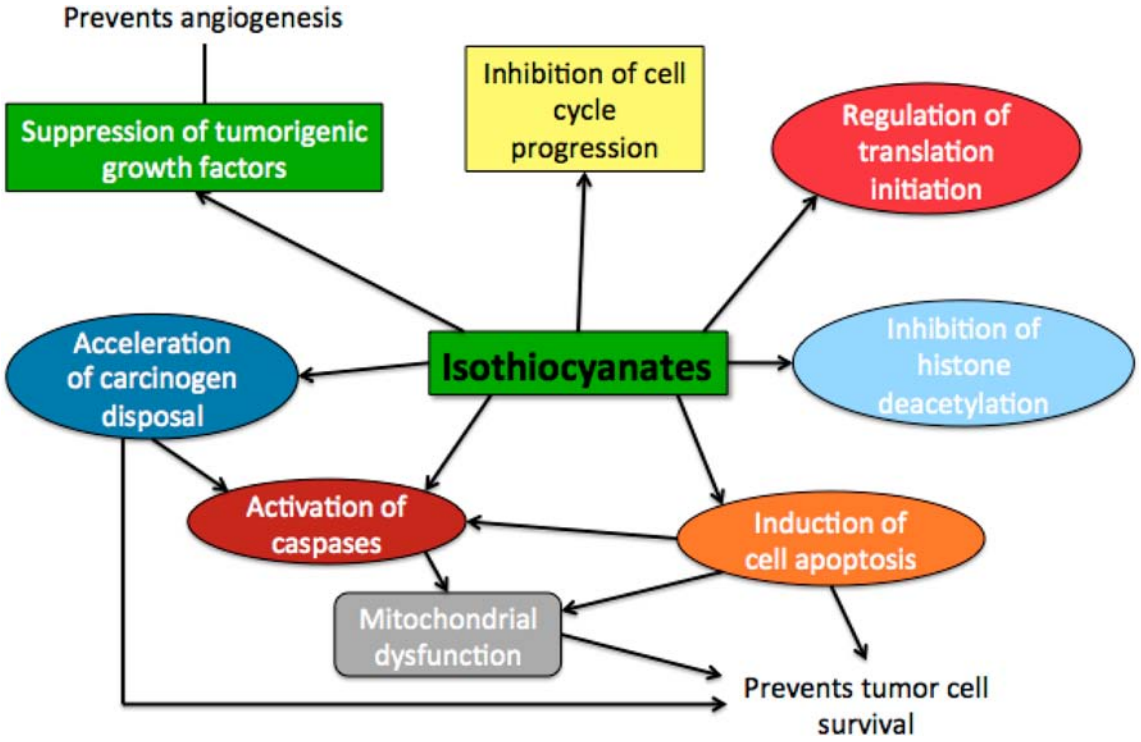

Figure 2. Pathways of documented ITC action in tumorigenic cells. See Wu et al.[113] for a detailed review of the roles ITCs play in cancer prevention.

reductase (phase II enzyme) and thus imparts a reduced enzymatic and anticarcinogenic response. Nitriles also compete with ITCs in this induction and reduce potential positive effects further.[38] As the ratio of these compounds may depend on plant variety, care must be taken in rocket breeding when plants are selected for GSL content, as this may not be reflective of the bioactives produced in subsequent hydrolysis reactions.[122] Other underlying genetic factors may influence which degradation pathway is taken.[123,124]

Indoles. Indoles are the predominant autolysis product of indole glucosinolates such as glucobrassicin, as their ITC counterparts are unstable.[85] Glucobrassicin has been detected as a minor GSL in rocket species,[33] and the predominant indole species produced is indole-3-carbinol. This compound is known to be cancer-preventative,[125,126] particularly in reproductive organs in vitro and in vivo. A condensation product of indole-3-carbinol, 3,3′-diindolymethane, is also responsible for beneficial physiological effects. Both compounds have been shown to reduce cell proliferation in breast, prostate, cervical, and colon cancer cell lines. They also show distinct differences from ITCs such as sulforaphane[127] and inhibition of tumor development in the stomach, breast, uterus, tongue, and liver of rodents.[128−135] Experiments in rodents have shown an increase in drug-metabolizing enzymes in the stomach, liver, and small intestines of individuals consuming both ITCs and indoles. This is suggestive of enhanced detoxification phase II enzymes (such as quinone reductase, glutathione reductase, and glutathione transferase)[134] and a mechanism by which these phytochemicals impart chemopreventative effects.[135,136]

Typically indoles inhibit cell proliferation through cytostatic mechanisms, whereas ITCs induce cytotoxicity within cell lines (at >12.5 μM concentrations), which ultimately leads to increased apoptosis.[137,138] This indicates that both types of compound could act and be effective at different stages of cancer development.[11] Indoles have been shown to induce programmed cell death in prostate, breast, and osteocarcinoma cell lines[139] and G_1 cell cycle arrest in breast and prostate cancer cell lines.[140,142,143] It is these cytostatic effects on cell proliferation that have been suggested as the mechanism responsible for the lack of apoptosis effects in indoles.[141]

Using information on GSL content in rocket, the ITC and indole effects can be potentially maximized in new varieties and be of greater benefit to human health when considered in tandem, rather than separately.[127]

Oxazolidine-2-thiones and Goitrogens. The hydrolysis of β-hydroxy-alkyl GSL compounds (e.g., progoitrin; a minor GSL in rocket) can produce oxazolidine-2-thiones such as goitrin (5-vinyloxazolidine-2-thione).[142−148] It is these compounds that are largely attributed to the thyroid condition of goiter in mammals,[149] but the action of microflora in the gut is thought to mediate the problems associated with high oxazolidine-2-thione intake.[150−153] That being said, oxazolidine-2-thiones interfere with thyroxine synthesis[154] and are therefore likely to have an adverse biological effect regardless of gut microflora action or bodily iodine status.[3] A study by Nishie and Daxenbilcher[155] showed that these compounds are not teratogenic or embryotoxic, however.

These molecules contribute significantly to the bitter taste of rocket that some people perceive quite strongly.[154] The detection of these compounds may be mediated in a similar genetic fashion as PROP (propylthiouracil), for example.[155,156] By using phytochemical data in rocket breeding programs these oxazolidine-2-thione components could be reduced, potentially improving consumer acceptance (depending on the target consumer) and avoiding any possible adverse health effects associated with overconsumption.

Ascorbigens. Ascorbigens are formed via the reaction of indole-3-carbinol and 3,3′-diindolymethane with ascorbic acid in the stomach during myrosinase-catalyzed degradation of indolyl-3-methyl glucosinolates.[157,158] In this manner it is

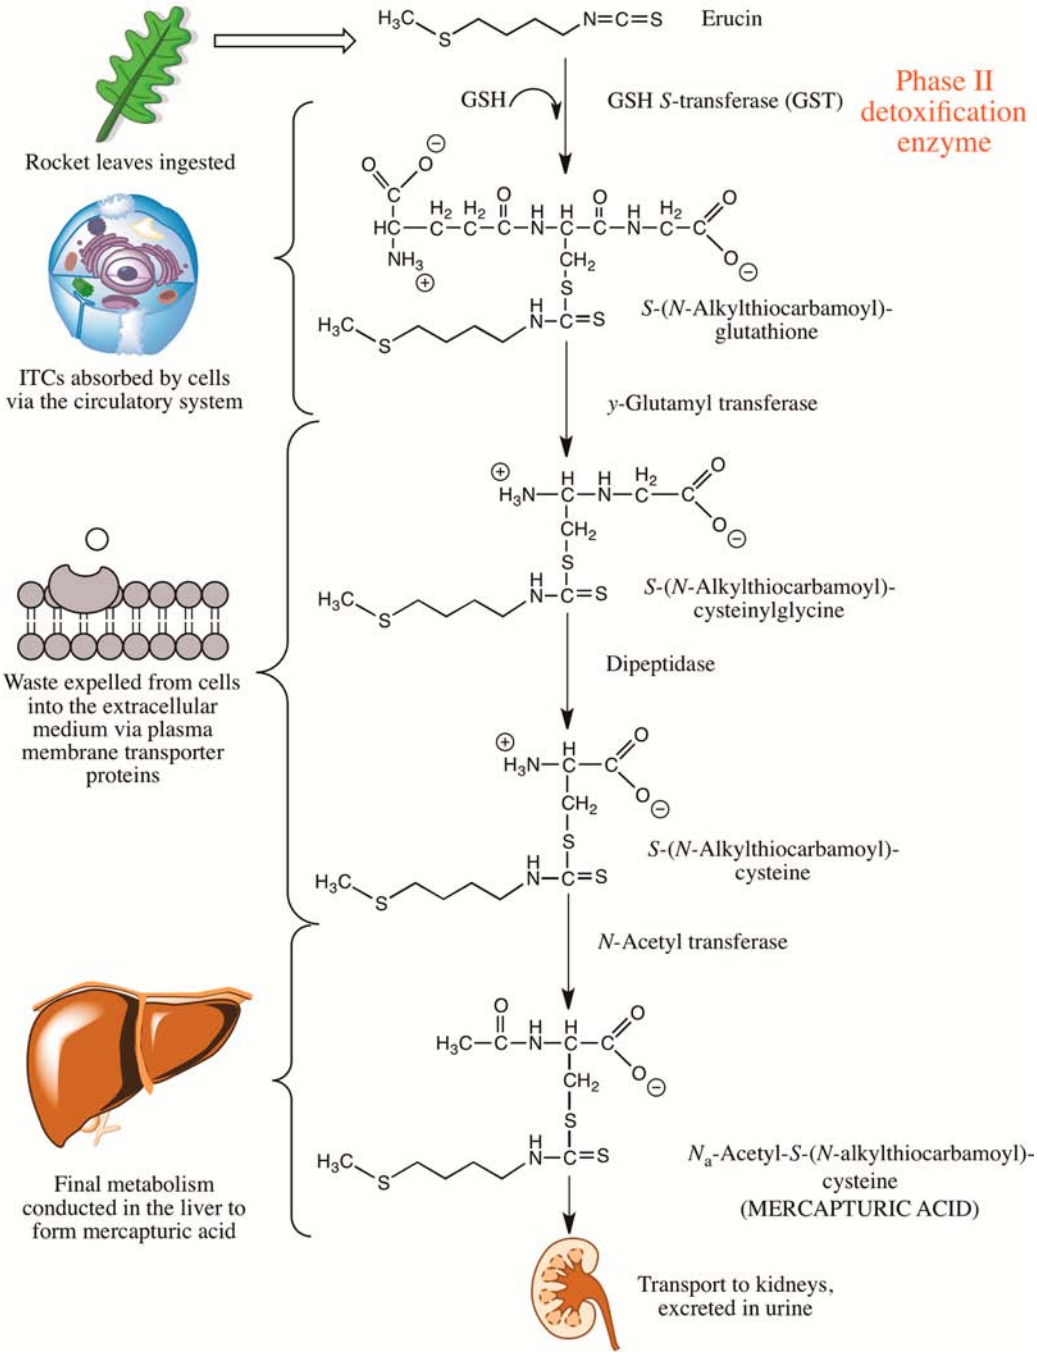

Figure 3. Mercapturic acid pathway of ITC metabolism in the human body. After ingestion of rocket leaves, glucoerucin is hydrolyzed by myrosinase to form erucin. This is released and absorbed in the ileum, where it is transported in the blood to cells around the body. ITCs initiate phase II detoxification enzymes in this pathway and are known to aid in cancer prevention. Adapted from Wu et al.[113]

thought that ascorbigens have a role in cancer modulation[159] via quinone reductase induction.[114] As has been highlighted previously, this has important implications for breeding for plant varieties with enhanced chemopreventative effects.

Epithioalkanes. Epithioalkanes are formed as part of the myrosinase reaction with GSLs at low pH with epithiospecifier protein and ferrous ions. These GSLs typically have a side chain with a double bond, such as sinigrin.[160−163] It is uncertain whether these compounds produce any significant bioactive effect in humans, but the ratio in which they are produced alongside ITCs, nitriles, and indoles may affect on these compounds' efficacy as anticarcinogens.

Flavonols. The antioxidant and anti-inflammatory function of flavonols in the human diet are well-known and include protecting the colonic epithelium from free radical damage.[164−167] They can induce the up-regulation of enzymes (such as cytochrome P450), which may lead to a decreased risk of cancer, cardiovascular disease, immune dysfunction, atherosclerosis, and chronic inflammation.[168,169]

FACTORS AFFECTING PHYTOCHEMICAL CONTENT

Breeding and Cultivation. Rocket has been consistently shown to be a good dietary source for flavonols, GSLs, and antioxidants. However, there can be large differences between

dx.doi.org/10.1021/jf501096x | J. Agric. Food Chem. 2014, 62, 4481−4492

plants of the same germplasm accession due to a combination of genetic and environmental variability. This is probably due to the outbreeding nature of the species[104] and a lack of overall uniformity in varieties. Commercial varieties cannot be considered truly domesticated because of this tendency for outcrossing, and the susceptibility of plants to inbreeding depression (a loss of genetic variability due to repeated self-pollination or crossing with a closely related individual). Development of advanced open-pollinating breeding lines (lines that are allowed to cross-pollinate freely in a population of selected individuals), or even F_1 hybrids (superior varieties produced by crossing distinctly different, elite inbred lines), could potentially minimize such variation.

Throughout the food chain there are many aspects that can have an adverse effect on GSL levels within leaves (Figure 4). These include cultivar choice, cultivation practice, climatic conditions, photoperiod, sulfur and nitrogen availability, harvest date, time spent in storage, temperature of wash water, levels of physical damage to leaves, packaging atmosphere, and food preparation methods.[30−32,170−173]

Harvesting. Rocket species have the ability to regrow their leaves repeatedly after cutting, which allows for several harvests to take place under optimal conditions.[107] In parts of southern Italy, it is not unheard of for up to seven harvests to occur from a single planting. This has obvious cost-saving benefits for growers, but multiple harvests also induce stress responses in rocket that may be detrimental to the flavor and aesthetics of the crop. Stress drives up the production of secondary metabolites such as GSLs and anthocyanins, which will produce very strong, bitter tastes. There are other detrimental effects of multiple harvests; leaves become progressively smaller and more "skeletal" in appearance with each cutting, for example. High anthocyanin levels also affect the color of leaves, turning them an undesirable pink, purple, or red. Color has been found to be one of the most important characteristics consumers look for in rocket,[174] and so the loss of fresh appearance can ultimately lead to rejection of crops by supermarkets and processors.

Industrial and Culinary Processing. There are five main influences that have been identified as affecting GSL levels during processing.[94] These are the action of myrosinase hydrolysis, myrosinase inactivation, the lysis and leaching of GSLs into wash water, thermal degradation of GSLs, and the loss of ascorbic acid, iron, and other enzyme cofactors. Myrosinase inactivation and thermal degradation of GSLs is probably less of an issue in rocket species, as the leaves are not typically cooked. The leaves are not ordinarily frozen, and so freeze−thaw hydrolysis is not likely to be a major factor either. Other factors almost certainly play a significant role in GSL and phytochemical loss in rocket. Verkerk et al.[94] highlighted four key areas that affect GSL levels before reaching the end consumer: (1) variety/cultivar used; (2) storage and packaging (postharvest, post-processing, and in shops/supermarkets); (3) industrial processing; and (4) consumer preparation methods.

If each of these areas can be mitigated through breeding superior varieties, consumers will receive an end product that is of higher nutritive quality and thus provides increased health benefits.

Postharvest Storage. Studies on both *Diplotaxis* and *Eruca* species have been conducted to determine the effects of postharvest storage conditions on chlorophyll content and respiration rates.[15] Both species of rocket have been found to have high respiration rates,[107] leading to rapidly impaired visual quality, such as stem browning, tissue yellowing, and general decay.[175] Provided initial GSL loss can be mitigated through breeding, ITC formation has been shown to increase over nitrile formation during the storage period.[176]

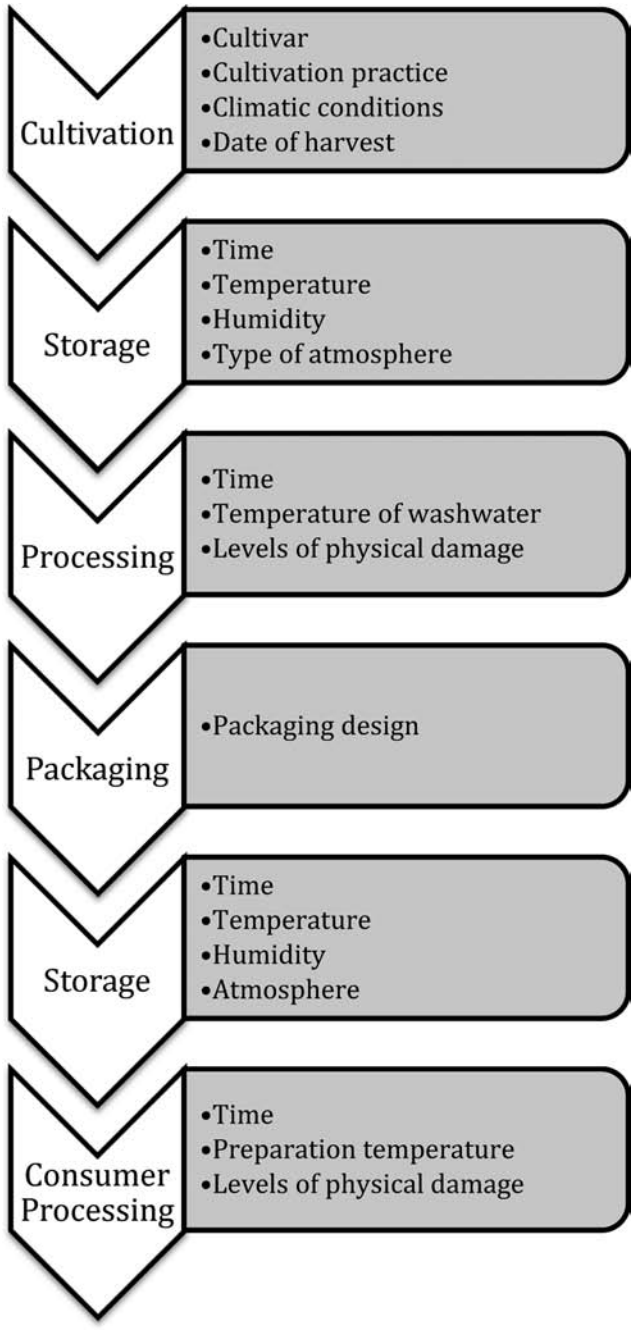

Figure 4. Factors and conditions within the commercial supply chain that affect GSL and flavonol levels within rocket leaves.

Time, temperature, humidity, and atmospheric conditions are all optimized for specific crops within the logistics chain, but these factors are often designed to prevent only visual degradation and not phytochemical breakdown.[100] Getting producers, packagers, and transporters to change their current practices to better preserve the health-promoting compounds in rocket would be a difficult task. Treatments and storage conditions are often integrated parts of protocols and procedures, and changing these would require significant testing on a commercial scale.

NEW SELECTION TOOLS FOR BREEDERS

Phytochemical Selection. It should not be forgotten that some GSLs and their breakdown products are thought to be toxic, and even carcinogenic, at high concentrations.[128] Breeders and researchers should be mindful that more of a certain compound does not necessarily mean "better".[177] Humans seem to be able to tolerate GSLs much better than pigs, rats, and rabbits, for example, but overconsumption of these compounds may have serious health consequences[64] as high-dose−effect relationships are as yet unknown in humans.[94] Few papers in GSL research (regardless of species) have acknowledged the potential for plant breeders to utilize HPLC/UPLC/LC-MS/GC-MS methods within breeding programs to "monitor" and select plants for their phytochemical content in this manner. These techniques would provide valuable information on breeding lines relatively rapidly, especially for GSL and flavonol breeding.[178] It is not common practice to select rocket plants on the basis of their phytochemical profile at present, but as interest in these compounds increases, it will be necessary for breeders to modify their selection criteria and information sources to remain competitive in the salad vegetable market.[94] This has been achieved with 'Beneforte' broccoli (Seminis Vegetable Seeds; subsidiary of Monsanto Co., St. Louis, MO, USA; www.beneforte.com) for example. It has also been indicated in hybrid varieties of *Brassica* that ITC/nitrile ratios can be selected for.[179]

Genetic Resources and Marker-Assisted Breeding. European initiatives (such as the EU GENRES project "Leafy vegetables germplasm, stimulating use"; http://documents.plant.wur.nl/cgn/pgr/leafyveg/) have included rocket species within their remit, indicating the rising prominence of the species and the desire for more work to be conducted on them. The germplasm accessions stored in gene banks are a valuable genetic resource for breeders to take advantage of.[180] The accessions contained within these collections are highly variable and have unique visual and sensory characteristics that could be introgressed into breeding lines relatively easily.[181]

Genetic information about rocket within the published literature is very scarce. Some molecular marker techniques such as random amplification of polymorphic DNA (RAPD), inter-simple sequence repeats (ISSR), and amplified fragment length polymorphisms (AFLP) have been used to analyze morphological characteristics of *E. vesicaria*.[29] ISSR and AFLP are relatively robust for screening variable populations and discriminating between cultivars,[180] but RAPD is notoriously unreliable and suffers from a lack of reproducibility and resolution. Perhaps one of the most underutilized marker types is sequence related amplified polymorphism (SRAP). The forward and reverse primers are designed to target arbitrary GC- and AT-rich sequences of the genome, respectively, and are therefore more likely to anneal to active genomic regions.[182] This could be of use in understudied crops such as rocket, as it provides a simple, repeatable, and reliable way of screening large populations.

These techniques are now for the most part, however, obsolete in advanced molecular plant breeding, as next-generation sequencing (NGS) and single-nucleotide polymorphism (SNP)/quantitative trait loci (QTL) analyses are far more specific, reliable, and cost-effective. SNPs are the most abundant marker type within genomes, and their high density is ideal for studying specific regions in detail.[183] NGS techniques are now relatively affordable, even for relatively small companies. They are widely available in academic institutions, but many companies are bypassing these in favor of dedicated private commercial services[184] or are developing their own in-house facilities. The inability of some research institutions to provide adequate customer service, cost-effectiveness, data storage, and results on time is jeopardizing how much knowledge is in the public domain. Increasingly, both large and small breeding companies are collaborating privately and advancing techniques far beyond those found in academic institutions. Future work by institutes in advanced genomics, sequencing, and genotyping is likely to be obsolete in some cases because private research is already finding new innovations, for example, for data storage and bioinformatics. Because private companies have no obligation to share their knowledge, many of these advances may be unobserved by the mainstream scientific community. Institutes and universities need to do more to attract business from industry to keep up with the pace of private advances in this area.

Transcriptome sequences are now (generally) adequate for breeders to use and make huge advances in only a few years. Linkage mapping and QTL analyses can be conducted on desktop computers, making integration into breeding companies relatively straightforward from an IT point of view, even if the actual sequencing and genotyping are outsourced. Again, this may typically be to private companies providing a dedicated service. The availability of software licenses and advanced training courses from private companies also means plant breeders do not necessarily need the expertise found in universities and research institutes to attain their goals.

SUMMARY

Of all the research papers concerning rocket species and their phytochemistry, none have directly addressed how information could be used within a working breeding population. Often it is explained or postulated purely as theory rather than actual practice or given only a cursory mention. Only very rarely is a plant breeding program reflective of theory, due to the large number of environmental factors affecting plant growth, development, and reproduction. The progressive selection of rocket plants through conventional/molecular breeding would be a valuable tool for the research community and provide an excellent incentive for breeding companies to fund research. The actual monitoring and quantification of GSL/flavonol levels through successive generations (i.e., not just one as has been the case with most studies) would not only validate the heritability of such traits in rocket but also provide a "roadmap" for how other minor crops might be developed for commercial use.

Attention must be paid to the phytochemical content of varieties within breeding populations of rocket. By focusing solely on morphological traits, important phytochemical genotypes may be inadvertently lost from populations; this could be said of all Brassicaceae species, not just rocket. The balance of glucosinolate−myrosinase degradation products does seem to have a genetic component to it and so could be selected for also. Utilizing genetic resources, the falling costs of sequencing and bioinformatics can soon produce nutritively superior varieties of rocket. Plant breeding typically takes longer than the average research project allows for, even with the use of advanced genomic selection methods. This is a situation that could be remedied by long-term industrial collaboration and sponsorship by plant-breeding firms.

Oxygen and Hydrogen Isotope Composition of Silage Water

ABSTRACT: Silage is an important dietary water source that influences the oxygen and hydrogen isotopic composition of domestic herbivores and their products. Silage sampled fresh from the silo had ^{18}O- and ^{2}H-depleted tissue water when compared with fresh pasture grass sampled around midday during the silage-making seasons. During exposure in the feed bunk, silage water became increasingly enriched in ^{18}O and ^{2}H. When $\delta^{18}O$ was plotted against $\delta^{2}H$, the slope of the regression was less during daytime than during night-time. Exposure to ^{18}O- and ^{2}H-enriched or -depleted water vapor inside sealed glass containers led to strong changes in the isotope composition of silage water. The results resembled predictions from the Craig–Gordon isotope model of evaporation. The atmospheric conditions during exposure (relative humidity, exposure time, and isotopic composition of the air vapor) in the feed bunk thus strongly affect the isotopic composition of silage water ingested by domestic herbivores.

KEYWORDS: *feedwater, labeling, evaporation, turnover, pool kinetic, water isotopes*

INTRODUCTION

Dietary water or feed moisture is an important source of water for herbivorous animals.[1] The oxygen (^{18}O) and hydrogen (^{2}H) isotope composition of ingested water is reflected in animal body water,[2] in fecal water,[3] and in tissues such as bones and teeth,[4] hair,[5,6] and milk.[7] The isotopic composition of dietary water is affected by that of precipitation (meteoric water), which is influenced by geographic features,[8] and also by local environmental conditions and vegetation characteristics.[9,10] Latitudinal, altitudinal, and seasonal variation in the isotope composition of meteoric water depends on temperature for rain and snow formation.[11] The isotopic composition of water in plant roots, tubers, and stems closely reflects that of the water taken up by roots,[12] but leaf water is isotopically enriched in comparison with source water due to isotope fractionation effects during evaporation.[13] Similarly, free surface water, such as water in puddles on pastures and dew on the leaves,[14] is subject to evaporative enrichment. Enrichment is influenced by relative humidity (RH) and the isotopic composition of water vapor.[10,13,15,16] Local humidity can also have an important effect on the oxygen isotope composition of biogenic phosphate.[17,18] Because of the above relationships there is much interest in food science, ecology, anthropology, and forensic science in using the hydrogen and oxygen stable-isotope composition of animal tissues and animal products as a tracer for the geographic origin of foodstuffs[19] as well as for the detection of adulteration of foodstuffs,[20,21] the geographic movements of animals (e.g., in birds),[8] the behavioral/nutritional ecology of herbivores,[3] and the production ecology of livestock systems.[22]

Silage is an important feedstuff in cattle production, and silage moisture can contribute a significant fraction of the total water intake of cattle.[23] Therefore, the isotopic composition of silage water affects that of body water and tissues, including milk and meat.[2] To our best knowledge, the isotopic composition of silage water has not been studied to date. Accordingly, there is no empirical knowledge on the relationship between the ^{18}O and ^{2}H of silage water and that of other water sources, such as fresh grass and drinking water, which have been studied comparatively well.[24,25] Also, there is no empirical knowledge about the main environmental controls of silage-water isotope composition. Thus, for instance, we do not know to what extent observed geographic, seasonal, and production ecology-related patterns in the ^{18}O and ^{2}H composition of milk or beef and lamb meat[7,20] are related to isotope effects emanating from silage-water consumption.

We hypothesize that silage-water isotope composition is strongly affected by RH and the isotopic composition of atmospheric humidity, as plant tissue becomes disconnected from the (liquid) soil water source when the stand is cut, and subsequent water exchange is dominated by vapor fluxes. RH may vary by 50% during a day,[26] whereas the isotopic composition in air humidity typically varies by 40‰ for hydrogen and 6‰ for oxygen during a year,[11] suggesting that RH and isotopic composition could well be a main control of silage-water isotope composition.

This study presents results derived from data collected on grassland farms in southern Germany and also the results from an experiment conducted under controlled conditions. The work addresses the following specific questions: What is the water isotope composition of silage when taken fresh from the silo? Does its isotope composition differ from that of leaf water sampled in the period of silage production? How does silage-water isotope composition change when silage is exposed to atmospheric conditions in the feed bunk? And, how does silage-water isotope composition respond to altered vapor isotope composition in controlled experiments? The observed changes of silage-water isotope composition were compared with predictions from the Craig–Gordon model. This model has been used extensively to explain the water isotope relationships during evaporation of open water bodies[27] and leaves,[28] and it provides a mechanistic treatment of evaporative fractionation, RH, and vapor isotope composition on water isotope composition at the evaporating surfaces.

THEORY

Assuming that silage water is a well-mixed reservoir, the change in water-mass per surface area (W, mol m^{-2}) over an increment of time dt is given by the rates of input (I, mol m^{-2} s^{-1}) by rain

or dew formation, and by the rate of evaporation (E, mol m^{-2} s^{-1}):

$$dW/dt = I - E \quad (1)$$

For the conditions in our feed bunk underneath a roof we can neglect I. The evaporation flux E is proportional to the vapor concentration difference between the water−air interface (evaporating surface) and the turbulent atmospheric region and, thus, to RH:[29]

$$E = C_s(1 - h)/\rho \quad (2)$$

where C_s denotes the saturation concentration of vapor (which depends on temperature), h is RH in equations, and ρ is a resistance coefficient.

The isotope composition of the evaporation flux is given by the Craig−Gordon model,[16] which accounts for the equilibrium isotope fractionation between liquid and vapor, the kinetic fractionation resulting from the diffusion across the air boundary layer, and the back flux of atmospheric moisture:[11]

$$R_E = (\alpha^* R_s - hR_a)/((1 - h)\rho_i/\rho) \quad (3)$$

R denotes the ratio of the abundances of the heavy and light isotopes (^{2}H/^{1}H or ^{18}O/^{16}O), and α^* is the temperature-dependent fractionation factor (α^*_O = 1.0095, α^*_H = 1.0804 at T = 24 °C).[30] The subscripts indicate the evaporated water (E), silage-water in our case (s), atmospheric vapor (a), and the heavy isotope (i).

Equation 3 can be translated into δ notation, the conventional notation for the natural abundance of stable isotopes.[29] Thus, δ^{18}O (or δ^2H) is given as δ^{18}O (or δ^2H) = $R_{sample}/R_{standard}$ − 1, where standard refers to the international SMOW standard. Then

$$\delta_E \approx (\delta_s - h\delta_a - \varepsilon^* - \Delta\varepsilon)/(1 - h) \quad (4)$$

where ε^* and $\Delta\varepsilon$ represent the equilibrium enrichment calculated from α^* and the kinetic enrichment in the diffusive layer under fully turbulent air (calculated from α_k; α_{kO} = 1.0189 and α_{kH} = 1.017)[31,32] that are associated with the phase change and diffusion. The change in δ_s is then given by[33]

$$d(WR_s)/dt = -ER_E \quad (5)$$

This means that for silage, the volume and isotopic ratio in the remaining water are controlled only by the evaporation rate E and the isotopic composition of the evaporation flux R_E, both of which depend on RH (eqs 2 and 3). The remaining fraction of the initial amount of water, W_0, is defined as $f = W/W_0$. Equation 5 can be rearranged to describe the change in isotopic composition of the remaining silage water, $d\delta_s$, with f:[34,35]

$$d\delta_s/d\ln f = \delta_E - \delta_s \quad (6)$$

As f approaches zero, δ_s approaches a steady state isotopic composition, δ_{steady},[33] under local atmospheric conditions due to the return from the atmosphere. The change of δ_s, $d\delta_s$, thus approaches zero, which, by integrating with respect to f, yields[35]

$$(\delta_s - \delta_{steady})/(\delta_{s0} - \delta_{steady}) = f^m \quad (7)$$

where δ_{s0} is the initial isotopic composition of silage water (at f = 1), δ_s is the isotopic composition of silage water at any instant in f < 1, and $m = (h - \varepsilon_k - \varepsilon^*)/(1 - h + \varepsilon_k)$ as defined by Welhan and Fritz,[34] Gonfiantini,[29] and Gibson et al.[35]

In the case of evaporation in completely dry air (h = 0), the so-called Rayleigh fractionation results and eq 7 reduces to[11]

$$(\delta_s + 1)/(\delta_{s0} + 1) = f^{\alpha^* - 1} \quad (8)$$

With vapor-saturated air (RH 100%), isotopic exchange between vapor and silage water would occur without evaporative water loss. Then, δ_s would approach the equilibrium with the air vapor if the air vapor reservoir is infinite.

With high humidity, when the water potential of the air is less negative than the (osmotic and matrix) water potential of the silage,[36,37] condensation may occur. In this case, the isotopic value of silage water (δ_s') is a mixture of condensed air vapor (δ_{cond}) and initial silage water (δ_s) until δ_s becomes equilibrated with air vapor and also reaches δ_{cond}. Thus

$$\delta_s = \frac{(M_s + M_{cond}) \times \delta_s' - M_{cond} \times \delta_{cond}}{M_s} \quad (9)$$

where M_s and M_{cond} represent the mass of initial silage water and the mass of condensed water. The equilibrium fractionation controls the isotopic composition of water condensed in saturated air[14] and thus δ_{cond}.

When silage becomes exposed to an infinite vapor source that is not in equilibrium with the water pool in the silage, this silage-water pool will gradually exchange and turn over until an equilibrium is reached. We used the reaction progress method to describe the turnover of O and H in silage water. An advantage of the reaction progress approach is that it provides half-life estimates for multiple pool systems.[38] In addition, results from experiments with isotopically different vapors (labeling experiments) can be combined. The reaction progress $1 - F$ depends on the fraction F of the water pool that has already been turned over. It is given by[38,39]

$$\frac{\delta_s - \delta_{eq}}{\delta_{s0} - \delta_{eq}} = 1 - F \quad (10)$$

where δ_{eq} is the isotopic composition of water that is in equilibrium with air vapor and F = 0 and F = 1 represent the beginning of the exchange reaction and its final steady state (equilibrium). The exchange of a single pool follows

$$1 - F = e^{-\lambda t} \quad (11)$$

where λ is the first-order rate constant. Equations 10 and 11 are particularly useful when expressed as

$$\ln(1 - F) = -\lambda t \quad (12)$$

which follows a straight line in the case of a single pool system, and a graph composed of several straight line segments in systems with several pools.

MATERIALS AND METHODS

Silage. Silage was obtained from the Grünschwaige Experimental Station, Germany: 48°23′ N, 11°50′ E (for details regarding the site, see Schnyder et al.[40]). All grassland was used for beef cattle husbandry with Limousin suckler cows. During the grazing season (approximately from the end of April to the end of October) all cattle were kept on permanent pastures. Meadows and surplus pasture growth were used for silage and hay production. Silage cuts were mainly taken in June and August (yielding 40 and 35% of total on-farm silage production). Silage production generally followed the practices described by Wilkinson.[41] Grass was mowed at around 10:00 a.m., followed by spreading and tedding. In the afternoon of the same day it was raked into rows, and on the following day the wilted grass (approximately 45% dry matter content) was collected using a forage harvester, cut to a length of 4−8 cm, transferred to a drive-in silo without addition of

other fermentable substrates, and consolidated. The silo was sealed not later than 5:00 p.m., and it remained closed until opening for feeding. Silage was the main feed source during the period of sward dormancy when the cattle were housed.

Fresh pasture grass was sampled at approximately biweekly intervals during the growing seasons (from April to October) of 2006 to 2012. All grass samples were collected around noon, immediately put into extraction vials, and sealed in the field.

Silage samples were taken randomly from silos on the experimental farm in March/April of 2011, 2012, and 2013. In addition, 28 samples of silage were obtained from silos of regional farms within a radius of about 20 km around the experimental farm. The samples comprised silage from 2012 and 2013, from different months (May−October), from the first to the fourth cut, and from grass−clover mixtures and seminatural grasslands to capture the range that can be expected.

Experiment A: Isotopic Composition of Silage Water in the Feed Bunk. This experiment assessed the variation of the isotopic composition of silage water after distribution in a feed bunk during a day. During the period of sward dormancy when cattle were housed, the daily requirement of silage was distributed on the cleaned feed bunk in the open-front stall once every morning. Silage was sampled on three consecutive days (April 25, 26, and 27, 2012) immediately after distribution in the feed bunk and at 0.5, 1, 2, 4, and 24 h thereafter. On a given day, the last sample (of the 24 h period) was collected on the next day just before the leftovers were removed and new silage was provided. A handful of silage was sampled from the upper layer of silage in the feed bunk where the cattle tended to consume. Each sample was conserved in a self-sealing bag and kept at −4 °C until water extraction started.

Weather data, including RH and air temperature, which exhibited clear diurnal cycles (Figure 1), were obtained from a meteorological station in Freising (distance = 7 km; http://www.lfl.bayern.de/agm/daten.php?statnr=8).

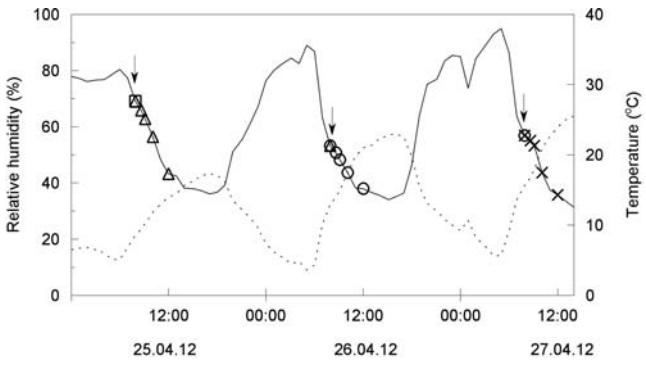

Figure 1. Weather conditions (RH, solid line; air temperature, dashed line) for four consecutive days during the feed bunk experiment. The arrows indicate the removal of leftovers from the previous day and the distribution of fresh silage in the feed bunk when 0-h and 24-h samples were taken. Markers show sampling after 0, 0.5, 1, 2, 4, and 24 h since distribution in the morning (8:00 a.m.) on April 24 (□), 25 (△), 26 (○), and 27 (×) of 2012, respectively.

Additionally, air vapor was sampled by cryogenic distillation in April (from 2006 to 2011) to assess its variation in $\delta^{18}O$ and $\delta^{2}H$ during this time of the year. Rain was sampled and measured every month from 2006 to 2011 for construction of the local meteoric water line (LMWL).

Experiment B: Vapor Labeling of Silage Water. The second experiment analyzed how the isotopic composition of air vapor influences the isotopic composition of silage water. Silage, which had been produced the year before, was collected from the silo of the experimental farm using a silage corer on March 31, 2011, and then kept in a self-seal bag at 4 °C until placement in a closed container (an exsiccator vessel with drying agent removed). To allow quick sampling from the container during the experiment, about 2 g of silage was allocated to each of six or eight aluminum trays per container as individual samples (see below). The container was then closed for about 12 h to effect a homogenization of moisture content and isotopic composition in all of the samples.

The silage samples were placed on the perforated shelf of the (exsiccator) container. Under the shelf, 40 mL of labeling water was placed in a plate of 10 cm diameter. To promote air mixing, a fan was installed in the headspace of the container. The labeling water and silage samples were quickly placed in the container and the lid was closed. Thus, the initial conditions in the container were the same as in the room with temperature, RH, $\delta^{18}O$, and $\delta^{2}H$ around 24 °C, 40%, −18‰, and −130‰, respectively.

The experiment was divided into two groups, with different sampling intervals. Each group had two containers with differing isotope composition of the labeling water. The labeling water was either enriched (in ^{18}O and ^{2}H) or depleted (heavy or light water) relative to silage water. In the first group with short time intervals between openings, six samples were exposed to the labeling atmosphere and two were removed randomly after 1, 2, and 4 h from each container. In the second group with long intervals between openings, each container contained eight samples and two samples were collected after 8, 24, 48, and 96 h. In each case, one of the duplicate samples was used to measure the isotopic composition of water and the other was used to measure relative moisture content (g/g, water mass in fresh mass of silage). The labeling water in each container was sampled at the beginning and end of the labeling experiment.

In a preliminary experiment, air-tightness of the containers was verified by filling the containers with N_2 and measuring CO_2 and humidity changes using a LiCor LI-6262 infrared gas analyzer. The evolution of humidity inside containers was examined after placing a dish of water in the container. Humidity increased rapidly from an initial 48 to 100% with a half-life of 1.8 min (r^2 = 0.96 with n = 233). The measurements were not repeated during the experiments with silage, because it would have required additional fittings, hoses, pumps, and instruments, increasing the probability of leaks and failure.

Extraction and Measurement of Silage Water. Silage water was extracted by cryogenic vacuum distillation. For the regional samples and for experiment A, $\delta^{2}H$ and $\delta^{18}O$ were measured using a L2120-*i* Analyzer (Picarro, Santa Clara, CA, USA). Mean analytical uncertainties quantified as SD of about four replicate measurements for each sample were ±0.1‰ for $\delta^{18}O$ and ±0.5‰ for $\delta^{2}H$. To examine whether the measurements using the L2120 are biased by organic volatiles in the water extracts, we compared the measurements of the L2120 with measurements of an IsoPrime isotope ratio mass spectrometer that was interfaced to a multiflow equilibration unit (both GVI, Manchester, UK). This comparison was made for a large number of samples (n = 177 for O and n = 58 for H) of differing origins. We found no indication that water samples extracted from plants or soil were subject to a larger error than pure water (rain, tap water, groundwater, air humidity). The mean bias (difference) between both instruments for 55 plant samples (O, 1.1‰; H, 1.6‰) and 51 soil samples (O, 0.0‰; H, −2.4‰) did not differ from the mean bias of 70 pure water samples (O, 0.4‰; H, −1.4‰). Also, the scatter between both measurement methods as quantified by the root mean squared error did not differ between plant samples (O, 1.4‰; H, 5.8‰), soil samples (O, 0.2‰; H, 2.5‰), and pure water samples (O, 0.6‰; H, 3.5‰).

For experiment B, which was more sensitive to such bias by organic volatiles, ^{2}H and ^{18}O values were determined by IRMS with a Thermo Finnigan DELTA^{plus} XL with TC/EA converter (Finnigan MAT, Bremen, Germany). Analytical uncertainties were ±0.5‰ for $\delta^{18}O$ and ±2‰ for $\delta^{2}H$ in this case.

All three measurement systems were calibrated using secondary isotope standards (i.e., V-SMOW, SLAP, and GISP) and checked at regular intervals using previously calibrated (again against secondary isotope standards) laboratory water standards for possible instrument drift. These laboratory standards were produced from local deionized tap water by evaporation/condensation, so that their isotope range spanned the range of samples.

RESULTS

Comparison of Fresh Grass and Silage. The water isotope composition of fresh grass sampled in June and August, the two main periods of silage making, differed slightly (about 1.2‰ in ^{18}O), reflecting the differences in weather conditions between the two periods. In contrast, for silage there was a pronounced depletion by about 14‰ in ^{18}O and 60‰ in ^{2}H relative to fresh grass (Table 1). In the feed bunk, the silage became less depleted but, on average, the effect was small (about 1‰ in ^{18}O).

Table 1. Oxygen and Hydrogen Isotopic Composition ($\delta^{18}O$ and $\delta^{2}H$) of Water in Silage of Regional Farms and on the Experimental Farm and in Fresh Grass[a]

		$\delta^{18}O$ (‰)		$\delta^{2}H$ (‰)	
	n	mean	SD	mean	SD
regional farms					
silage from silo	28	−12.9	5.4	−109.1	51.5
experimental farm					
silage from silo	24	−9.1	2.8	−80.0	23.0
silage from feed bunk	36	−8.1	1.7	−71.5	12.4
fresh grass in June	23	2.8	3.7	−22.7	16.2
fresh grass in August	32	4.0	1.9	−11.6	10.0

[a]Silage was directly taken from either the silo or the feed bunk. Fresh grass was collected at around noon in the months when grass was cut for silage production (June and August).

The silage from the regional farms, on average, was even more depleted than the silage of the experimental farm. The standard deviation was large, and the range included the silage of the experimental farm. A pattern caused by the year or month of production or by the cut or the type of silage was not evident.

Experiment A: Feed Bunk Experiment. The isotope composition of silage water changed in a similar way on the three consecutive days. After distribution in the feed bunk, it became increasingly enriched in ^{18}O and ^{2}H (Figure 2). At 1 day after distribution, $\delta^{18}O$ and $\delta^{2}H$ of silage water had increased by 4‰ and 30‰, but was still depleted relative to the fresh grass (Table 1).

The silage water extracted from samples taken fresh from the silo in April lay at the right side of the LMWL. On average, air vapor in April had a $\delta^{18}O$ of −18 ‰ (SD 2‰) and a $\delta^{2}H$ of −132‰ (SD 16‰), respectively, whereas the water estimated from air vapor and equilibrium fractionation was very close to the LMWL and exhibited almost identical $\delta^{18}O$ but higher $\delta^{2}H$ than the water of silage taken fresh from the silo. The silage-water samples from the feed bunk were divided into two groups according to the RH of the air (Figure 3). During the morning hours (8:00 a.m. to 12:00 p.m.) the RH was relatively low and decreasing (from about 60 to 40%; Figure 1), thereby accelerating evaporation. Samples taken in this time fitted an evaporation line with a slope of 5.95 (standard error of the slope, 0.45, $r^2 = 0.76$; Figure 3a). During the night-time the RH increased to about 80% and remained at this level for several hours (Figure 1). The slope of the $\delta^{2}H$ versus $\delta^{18}O$ regression for samples taken at daily intervals, between 8:00 a.m. of 1 day and 8:00 a.m. of the next day, was significantly steeper (7.61 with a standard error of 0.55, $r^2 = 0.96$; Figure 3b).

Experiment B: Vapor Labeling Experiment. The moisture content of the silage decreased in the sealed glass containers with short opening intervals of 1, 2, and 4 h ($y = -0.03x^{0.5} + 0.47$, $r^2 = 0.46$), probably due to exchange of vapor-saturated air with vapor-depleted air when the container was opened frequently (Figure 4). In contrast, when the container was opened infrequently, silage moisture content increased with time due to condensation ($y = 0.41x^{0.06}$, $r^2 = 0.45$).

The water from silage sampled before exposure to the labeling water did not fall on the LMWL (Figures 5 and 6), as had been observed in experiment A (Figure 3). With the exception of the samples taken after 1 h, the successive samples showed a gradual exchange of the initial silage water with vapor derived from the labeling water (Figure 5). Thus, silage water became gradually enriched when exposed to heavy labeling water and depleted when exposed to light labeling water.

The gradual exchange of silage water with labeling water via vapor fluxes was especially evident when plotted as a function of labeling duration (Figure 6). A different isotopic trend of silage water was apparent, however, in the container with short intervals between openings compared with the container with long intervals between openings (compare panels a and b of Figure 6 and panels c and d of Figure 6). During the first hour,

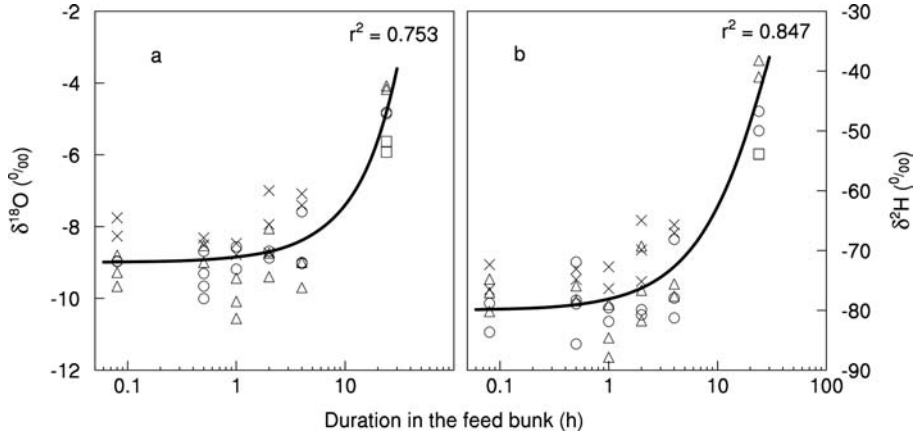

Figure 2. Changes in oxygen (a) and hydrogen (b) isotopic composition of silage water following distribution in the feed bunk at 8:00 a.m. Samples were taken immediately after distribution of silage in the feed bunk (~5 min after distribution, $n = 7$) on April 24 (□), 25 (△), 26 (○), and 27 (×) and at 0.5 h ($n = 8$), 1 h ($n = 7$), 2 h ($n = 8$), 4 h ($n = 7$), and 24 h ($n = 6$) after distribution. *x*-axes are log scaled. Lines denote second-order polynomial regressions.

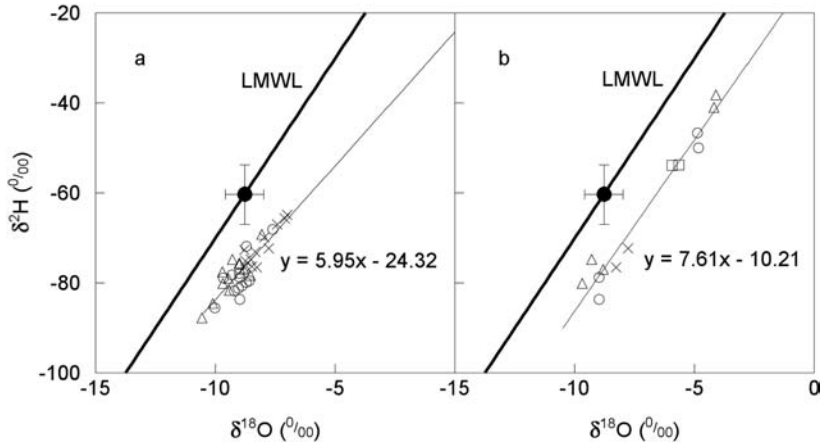

Figure 3. Relationship between $\delta^{18}O$ and $\delta^{2}H$ (evaporation line) of silage water. (a) Samples were taken immediately after distribution in the feed bunk at about 8:00 a.m. and 0.5, 1, 2, and 4 h later (n = 37). (b) Samples were taken immediately after distribution and 24 h later (n = 13). Explanation of symbols is given in Figure 2. The isotopic composition of water at 22 °C that would be in equilibrium with the measured air vapor is shown as a solid circle (●) with standard errors. The bold line represents the local meteoric water line (LMWL) derived from monthly rainwater samples between 2006 and 2011 (n = 73, r^2 = 0.99). The thin lines are regression lines for the silage water.

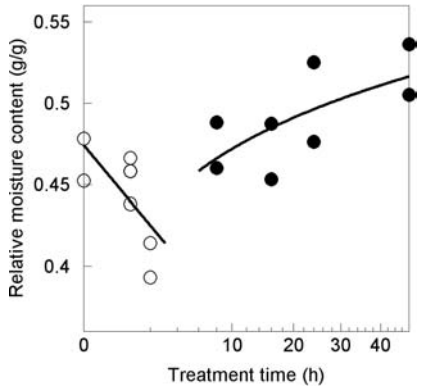

Figure 4. Moisture content of the silage as a function of time since the start of labeling: (○) data from short intervals between openings of the sealed glass containers; (●) data from long intervals between openings of the glass containers. The time axis is square-root scaled.

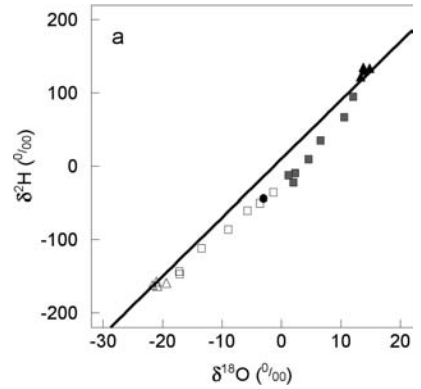

Figure 5. $\delta^{2}H$ versus $\delta^{18}O$ plot of the silage water extracted from silage exposed to heavy water and light water for 1−96 h. The black circle (●) denotes the initial silage water, triangles indicate the heavy (▲) and the light (△) labeling water. Gray and white squares represent the water in silage exposed to heavy and light labeling water, respectively. The line is the local meteoric water line (LMWL).

the silage water became enriched in ^{18}O by on average 3‰ and in ^{2}H by on average 17‰ (Figure 6a,c). However, the initial enrichment was less (only about one-third) when the labeling water was isotopically depleted (Figure 6a,c). With longer exposure time, the silage water approached the corresponding labeling water (Figure 6a,c). In the second group, where the first sample from the sealed containers was taken after 8 h, the silage water exponentially approached the corresponding labeling water (Figure 6b,c) and almost attained the value of labeling water after 48 h in the case of light labeling water. Conversely, a notable change still occurred with the heavy labeling water due to the larger isotopic spacing between silage water and heavy labeling water.

For the containers with long opening intervals and long exposure times, it was assumed that the disturbance due to the opening was very small and, hence, did not affect the estimation of reaction progress (Figure 7). The effect of condensation, however, had to be considered, as this was evident from the increasing moisture content (Figure 4). After exclusion of this effect (eq 9), the transformed data fell on one straight line during the first 48 h (Figure 7). The slope of the regression line was −0.035 (standard error 0.002, r^2 = 0.957), which corresponds to a half-life of approximately 20 h. The measurements after 96 h of exposure time fell clearly outside the range that could be expected from the prediction interval of the regression. Following the reaction progress approach, the intercept of the regression for the slow pool indicated that approximately 10% of the total silage water had a half-life longer than 20 h.

Model Simulations. Under zero humidity, the δ values follow a Rayleigh line when plotted against the remaining fraction of silage water (Figure 8). With RH increasing up to 50%, the convexity of the line decreased as compared to the Rayleigh line until a straight line was reached at RH = 50%, with a positive slope in the case of labeling water being heavier than the silage water and a negative slope in the opposite case (Figure 8a,b). With RH > 50%, the silage water approached a constant value during drying. This constant value was lower and was reached earlier at higher RH. At 100% humidity the water in the silage approached the isotopic composition of the labeling water.

The influence of RH on the pattern of slopes for the relationship between $\delta^{2}H$ versus $\delta^{18}O$ (evaporation line) depended on the relation of the initial composition of silage

dx.doi.org/10.1021/jf405703g | J. Agric. Food Chem. 2014, 62, 4493−4501

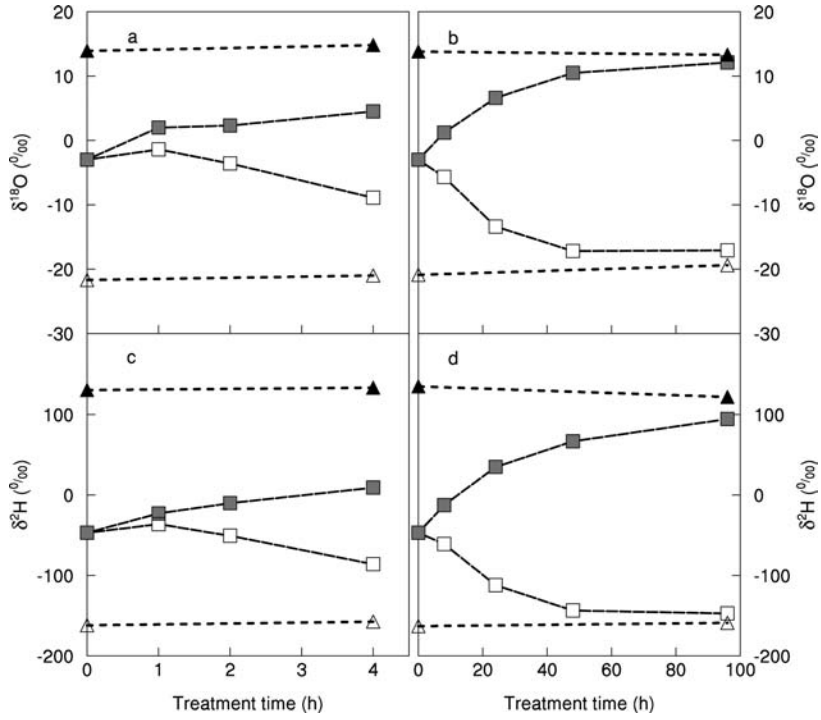

Figure 6. Time course of oxygen and hydrogen isotopic composition ($\delta^{18}O$ and $\delta^{2}H$) of silage water (squares) and labeling water (triangles) for up to 4 h (a, c) and for up to 96 h (b, d). Solid and open symbols indicate heavy and light labeling water, respectively; variation of $\delta^{18}O$ and $\delta^{2}H$ of silage water for up to 4 h and labeling water are represented by dashed lines connecting the data points, whereas the silage water for up to 96 h is represented by solid lines with exponential functions.

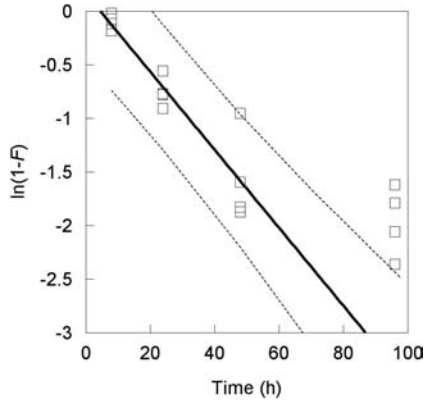

Figure 7. Reaction progress variable ($\ln(1 - F)$) calculated from data obtained from the container with long opening intervals and long labeling time after exclusion of the effect of condensation. Dashed lines represent the 95% prediction intervals of the regression (solid line, $y = 0.2 - 0.02x$; $r^2 = 0.785$; the intercept is not significant) as calculated from the measurements after 8, 24, and 48 h of labeling.

water and the isotopic composition of the vapor (Figure 8c,d). When the water in equilibrium with air vapor was isotopically heavier than the silage water, the slopes increased with RH (Figure 8c). In contrast, the $\delta^{2}H$ versus $\delta^{18}O$ line of remaining water rotated clockwise as RH increased if the silage became exposed to vapor, resulting in equilibrium water that was more depleted than the silage water (Figure 8d). For the isotopic composition chosen for Figure 8c, the line became almost vertical at about 60% RH, indicating that under this condition only $\delta^{2}H$ would change while $\delta^{18}O$ would remain constant.

DISCUSSION

This work presents the first analysis of silage-water isotope composition. It demonstrates a large contrast to the isotopic composition of fresh grass and a dominant role of RH and atmospheric water-vapor isotope composition on the isotopic composition of silage water. The changes in the isotope composition of silage water behaved similarly with the expectations from the simulation with the Craig–Gordon evaporative model, a classical mechanistic framework which has been applied extensively in empirical studies of the water isotope composition of open bodies of water and leaf water.[11]

Silage water, extracted from silage removed fresh from the silo, was strongly depleted in ^{18}O and ^{2}H relative to water extracted from fresh grass that was collected at about the same time of day as grass mowing for silage production took place, even though the moisture content of fresh grass (approximately 80%) was much higher than that of silage (about 50%). Thus, silage water must have become depleted in ^{18}O and ^{2}H at one or more stages of the production process between mowing and storage. Such processes may have involved vapor exchange with soil and atmosphere and condensation–evaporation cycles involving dew rise (vapor flux from the soil) and dew fall (atmosphere) during diurnal periods between mowing and carting of silage to the silo. Both atmospheric vapor and soil water are depleted in ^{18}O and ^{2}H relative to leaf water collected at noon.[42] Also, leaf water follows strong diurnal cycles,[42] with predawn values of $\delta^{18}O$ approximately 10‰ depleted relative to leaf water collected at noon (Inga Schleip, Ulrike Gamnitzer, Hans Schnyder, unpublished data). Certainly, additional empirical studies of diurnal vapor exchange fluxes, and related condensation–evaporation phenomena on silage water $\delta\ ^{18}O$ and $\delta\ ^{2}H$ between mowing and closing of the silo are needed.

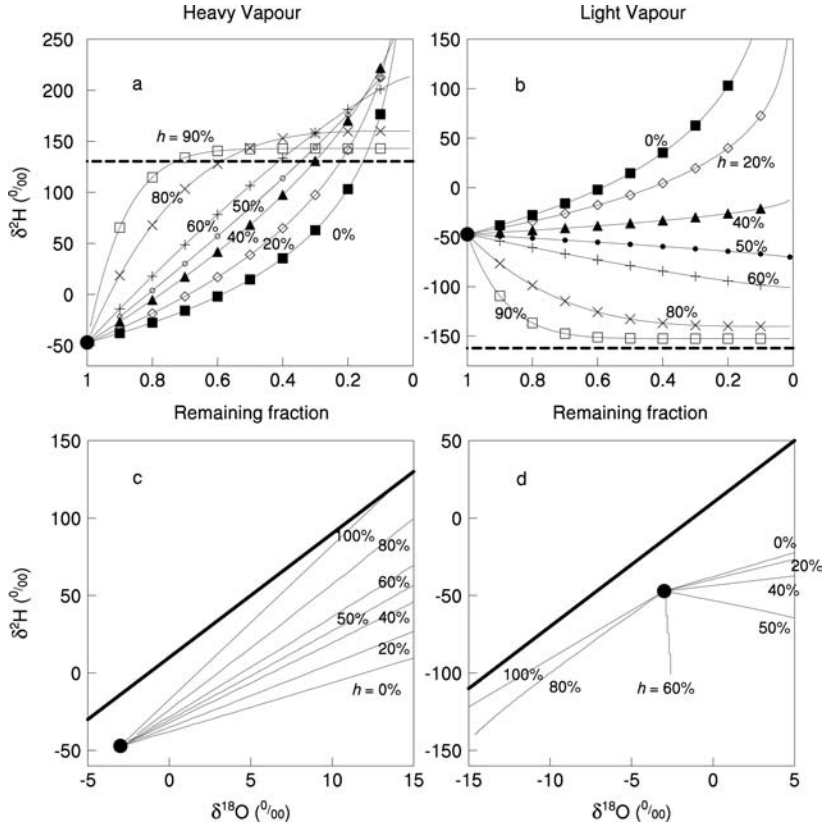

Figure 8. Effect of relative humidity (h) and isotopic composition of air vapor on the change of the hydrogen isotopic composition of silage water (δ^2H_s) (a, b) and on the slope of the δ^2H–$\delta^{18}O$ relationship (c, d) during drying. The air vapor was assumed to be in equilibrium with either heavy water (heavy vapor, $\delta^{18}O_a$ = 4.2‰, δ^2H_a = 42.9‰; a, c) or light water (light vapor, $\delta^{18}O_a$ = −31.1‰, δ^2H_a = −226.9‰; b, d) of experiment B. All calculations assume T = 24 °C, initial $\delta^{18}O_s$ = −3.0‰, initial δ^2H_s = −47.1‰, and kinetic fractionation α_{kO} = 1.0189 and α_{kH} = 1.017 (see refs 31 and 32). Dashed lines in panels a and b represent the labeling water, which was also the equilibrated state for silage water at h = 100%. Solid lines in panels c and d represent the local meteoric water line. The solid circle represents the same initial silage water in all panels.

After removal from the silo, the isotopic composition changed depending on the moisture conditions of the surrounding air, including its isotopic composition and the duration of exposure. In a vapor-labeling experiment, initial drying led to a transient enrichment but, with continuing exposure to the high humidity environment, exchange reactions became predominant (Figure 6). The Craig–Gordon model accounts for the effects of RH and isotopic composition of the vapor (Figure 8), and it was able to explain the results of all experiments. For instance, the silage in the feed bunk followed a steeper trend during the night, when RH was high, than during the daytime when humidity was low, in agreement with the prediction of the Craig–Gordon model (Figure 8). Also, in experiment B, the data points at 1 h cannot be explained as a pure exchange with vapor, but considering drying, they conformed to expectations from the Craig–Gordon model (Figure 8).

Depending on the amount and the isotopic composition of the air vapor and the degree of drying of the silage after removal from the silo, a large variation of silage water is possible. This variation may span >200‰ for δ^2H, as suggested by the simulations with the Craig–Gordon model (Figure 8). Under more realistic scenarios, where the atmospheric vapor did not differ strongly from the equilibrium vapor of silage water and drying on the feed bunk was limited, the observed variation of silage-water isotope composition in the feed bunk was much smaller (approximately 40‰ for δ^2H; Figure 2).

Vapor labeling and pool modeling indicated that the bulk of silage water comprised a pool that could be exchanged rapidly with the surrounding vapor. With a half-life of 20 h, 75% of the water inside this pool was exchanged within about 1.7 days. The fast change of the isotopic composition after exposure of the silage to an environment with altered vapor isotope composition is not unexpected given that the tissue/cell structures of the leaf are weakened or disrupted due to the mechanical and chemical modifications of the production process.[36] The vapor-labeling study also suggested that a minor fraction of the silage water (corresponding to approximately 10% of total silage water or 5% of the initial amount of tissue water in the cut grass if it is assumed that moisture decreases from an initial 80 to 40% during silage production) was included in a less rapidly exchanging water pool. We do not know the actual physical identity of this pool. Numerically it is similar in size to the water content of air-dry grass (hay),[43] which is probably associated with the bound-water fraction of cell walls.

The increase in silage moisture in the sealed containers is likely to have been due to condensation induced by the more negative osmotic and matrix potential of the silage water, relative to that of the deionized labeling water of zero potential[36,37] but not to dew formation, which was excluded in the isothermal containers. Dew could possibly provide air humidity much more rapidly to the leaves. This may explain the much shorter (apparent) half-life (1–3 h) of leaf water in intact leaves under pronounced dew formation.[44] Dew formation is

dx.doi.org/10.1021/jf405703g | J. Agric. Food Chem. 2014, 62, 4493–4501

likely to occur during the wilting phase of silage production, especially at night-time, but may also occur in open feed lots.

In each case, the silage water was found to be considerably more depleted in ^{18}O and ^{2}H than the water in fresh leaves (Table 1; Figure 2). The use of water isotopes as an indicator of the geographical origin, which has been well demonstrated in wildlife,[45] may be useful in domestic animals only if the type of feed is known (i.e., fresh grass vs silage). In domestic animals, water isotopes are better suited to indicate the type of feeding: A small seasonal variation can be expected when silage is fed throughout the year, whereas water isotopes in feed will show pronounced variation with season in the case of summer-grazed animals. In turn, the isotopic composition of the body water of an animal also changes when the diet is switched, for example, as occurs between the grazing period and the stall-feeding period in late autumn. Thus, barn-fed and pasture-fed lambs from the United Kingdom differed more than pasture-fed lambs from the United Kingdom and from Sicily in $\delta^{2}H$,[46] and the isotope composition of milk water changed significantly between winter and summer.[47] Large seasonal changes in $\delta^{18}O$ and $\delta^{2}H$ related to a diet switch were also found in cow hair[48] and beef.[20] A change in feed moisture content may also influence body-water isotope composition via a changed requirement and intake of drinking water.[49] However, both factors, the changed isotopic composition and an altered drinking water requirement, would probably change the isotopic composition of body water in the same direction as silage water, as drinking water is isotopically depleted relative to leaf water. Also, silage-water isotope composition plotted close to the LMWL. Drinking water should also plot on this line if it is derived from local meteoric water. In accordance with this, we also expect that the lower water requirements of animals during winter than during summer, due to lower temperature,[50,51] would not modify the picture.

In summary, our study demonstrated that silage water differs markedly from leaf water, and it can change during the feeding process. Thus, body water in domestic animals will differ depending on whether the feed is silage or fresh grass. This feeding pattern will overlay the geographic pattern. Given that this is the first study on silage water, more information would be useful about the influence of the production process on isotope composition of silage water.

Supporting Information

ABSTRACT: This research was conducted to evaluate the effects of selenium-enriched probiotics (SP) on growth performance, antioxidant status, immune function, and selenoprotein gene expression of piglets under natural high ambient temperature in summer. Forty-eight crossbred weanling piglets randomly allocated to four groups were fed for 42 days ad libitum a basal diet without (Con, 0.16 mg Se/kg) and with supplementation of probiotics (P, 0.16 mg Se/kg), sodium selenite (SS, 0.46 mg Se/kg), and SP (0.46 mg Se/kg). From each group, three piglets were randomly selected for blood collection on days 0, 14, 28, and 42 and tissue collection on day 42. The SP improved growth performance of piglets. Both SS and SP increased blood glutathione peroxidase activity and tissue thioredoxin reductase 1 mRNA expression, with SP being higher than SS. All P, SS, and SP supplementation increased the superoxide dismutase activity (40.1, 53.0, and 64.5%), glutathione content (84.6, 104, and 165%), TCR-induced T lymphocyte proliferation (20.8, 26.4, and 50.0%), and IL-2 concentration (24.9, 27.2, and 46.2%) and decreased malondialdehyde content (25.1, 26.3, and 49.3%), respectively. The greatest effects of SP supplementation suggest that SP may serve as a better feed additive than P or SS for piglets under high-temperature environments.

KEYWORDS: *selenium-enriched probiotics, antioxidant status, immune function, high-temperature environment, piglet*

INTRODUCTION

High ambient temperature, which can cause heat stress to pigs, especially during the summer in southern China, is a major detrimental factor that negatively affects pig health and production performance.[1] The global warming climate change as recently claimed may exacerbate this situation. A major health problem caused by heat stress in pigs is the reduction in their antioxidant capacity and immunity,[2] which could result in enormous economic losses to the swine industry.[3]

It is known that the activities of glutathione peroxidase (GPX) and superoxide dismutase (SOD) and the content of glutathione (GSH) represent the competence of animal antioxidant status because these proteins participate in the clearing of superoxide anion free radicals in cells to protect cells from being injured.[4] The malondialdehyde (MDA) content manifests the level of lipid peroxidation and indirectly represents the level of cell or tissue damage.[4] T lymphocyte proliferation and interleukin 2 (IL-2) secretion play important roles in animal immune function.[5] IL-2, a cytokine secreted by activated T lymphocytes, is an essential factor for the growth, proliferation, and differentiation of regulatory T cells.[6]

As an essential trace element nutrient for mammalian animals, selenium (Se) plays a key role in redox regulation, antioxidant defense, and immune function through GPX enzymes that catalyze the removal of the excess potentially damaging radicals produced during stress situation.[7,8] The biological effects of Se are mainly exerted through its incorporation into selenocysteine (a special amino acid) and further into selenoproteins,[9] of which some function as antioxidant enzymes with selenocysteine in the catalytic centers.[10] Selenoproteins such as glutathione peroxidase 1 (GPx1), GPx4, and thioredoxin reductase 1 (TR1) are thought to play important roles in animal antioxidant status and immune responses via the altered physiological Se status.[11] Dietary Se supplementation has been reported to increase the GPX and SOD activities, decrease MDA levels,[12] improve immunocompetence[13] of broilers under heat stress, and enhance GPx1 and TR1 selenoprotein gene expression in livers of young pigs.[14] A better effect of organic Se than inorganic Se has been reported in improving animal growth performance, as well as antioxidant and immune functions.[15−17] However, little research has been conducted to explore the effects of Se on the antioxidant status, immune function, and selenoprotein gene expression of young piglets under high ambient temperature.

Probiotics (P) are nonpathogenic microorganisms that can resist host small intestinal digestion and reach the colon alive, where they perform beneficial effects for the health of the host animals.[18] Previous studies of probiotic lactobacillus bacteria and yeasts have demonstrated that either *Lactobacillus acidophilus* or *Saccharomyces cerevisiae* has strong effects on animal

antioxidant status and immunity and can inhibit lipid peroxidation in pigs under normal conditions.[19,20] Likewise, a previous study in poultry also indicated that probiotics can reduce the adverse effects of heat stress.[21] However, similar studies have scarcely been conducted in pigs under high ambient temperature.

To combine the beneficial effects of both Se and probiotics, we have newly developed a feed additive product called Se-enriched probiotics (SP) in our laboratory (Chinese patent no. ZL 2005 1 0040990.2).[21] The probiotic *L. acidophilus* and *S. cerevisiae* strains we used are very efficient in transforming inorganic Se to organic Se.[22,23] Previous studies have demonstrated that dietary SP supplementation has beneficial effects on inhibiting heat shock protein (hsp) mRNA expression in piglets[24] and improving blood lipid profile in mice.[25]

The objective of this study was to investigate the potential effects of SP on the growth performance, antioxidant status, immune function, and selenoprotein gene expression of piglets raised under a high-temperature environment.

MATERIALS AND METHODS

Chemicals. The antioxidant assay kits were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). Both the WST-8 Cell Counting Kit-8 and the total protein assay kit were purchased from Biyuntian Institute (Nanjing, China). Lymphocyte Separation Medium was purchased from Tianjin Hematology Institute, Chinese Academy of Medical Sciences (Tianjin, China). The interleukin-2 (IL-2) assay kit was obtained from YuanYe Biotechnology Co., Ltd. (Shanghai, China). The inorganic sodium selenite (SS) used in this study was purchased from Sigma (Shanghai, China). The stock solution of sodium selenite as a Se standard [GBW(E) 080215] and the certified Se reference material, pork liver (GBW 08551), were provided by the National Research Center for Standard Materials (Beijing, China) and the Institute of Food Examination of the Ministry of Commerce (Beijing, China), respectively. Reagents used for real-time PCR were purchased from TaKaRa (Dalian, China). All reagents for the Se assay were of analytical grade.

P, SS, and SP Products. Both P and SP products used were obtained from our own laboratory in Nanjing Agricultural University (Jiangsu, China) and contain two probiotic strains, *L. acidophilus* and *S. cerevisiae*. The colony-forming units (CFU) of *L. acidophilus* and *S. cerevisiae* strains in both products were approximately 10^{11} and 10^{9} CFU/mL, respectively. The total Se content in SS stock solution was 100 mg/L. The total Se content in SP was 10.0 mg/L, with >90% being organic Se and >75% being selenomethionine (Se-Met).[23]

Experimental Design and Animal Trial. According to a completely randomized experimental design, 48 crossbred [(Landrace × Yorkshire) × Duroc] weanling barrows (4 weeks old, body weight = 7.9 ± 0.5 kg) were randomly divided into four groups of 12 in each. Piglets in each group were further allotted into three feeding pens (as three replicates) with four piglets in each pen or replicate. All piglets received a basal diet that contained 0.16 mg Se/kg for 2 weeks prior to the feeding trial. The ingredient composition of the basal diet has been previously reported.[24]

Piglets of the four treatment groups were fed the basal diet without or with supplementation of P, SS, or SP product. The SP product provided 0.3 mg total Se/kg diet, and so did the SS product. The final calculated total Se concentration in either the SS- or the SP-supplemented diet was 0.46 mg/kg. The P product provided *L. acidophilus* and *S. cerevisiae* to the diet at doses equivalent to that provided by the SP product with the total cell counts of *L. acidophilus* and *S. cerevisiae* being 3×10^{11} and 3×10^{9} CFU/kg, respectively.

The animal feeding trial lasted for a total of 6 weeks (42 days, from June 19 to July 30, 2011) and was conducted at Bangcheng Swine Farm located in Xinghua (32°93′ N latitude and 119°82′ E longitude), Jiangsu, China. During the first 33 days, the daytime temperature in the pig shed (with natural ventilation) ranged from 25 to 38 °C, and during the last 9 days, the daytime temperature ranged from 31 to 40 °C.

All of the diets for the piglets were replenished daily, and fresh water was accessible at all times throughout the trial. Each pig was weighed at the beginning and the end of the feeding trial. Feed intake was recorded daily. Average daily gain (ADG), average daily feed intake (ADFI), and feed/gain (F/G) ratio were calculated for each group and each pig.

All experimental protocols were approved by the Committee for the Care and Use of Experimental Animals of Nanjing Agriculture University, and the Animal Ethical Number granted was SYXK (Su) 2011-0036.

Sample Collection and Preparation. From each of four treatment groups three piglets were randomly selected for blood sample collection at 2:00 to 4:00 p.m. on days 0, 14, 28, and 42 from the precaval vein. From each piglet approximately 5 mL of blood was collected in a syringe primed with EDTA, and another 5 mL of blood was collected in a syringe without EDTA. Both blood samples with and without EDTA were gently ejected into 10 mL Eppendorf tubes, respectively.

Approximately 2 mL of EDTA-primed blood samples was directly stored at −20 °C until analysis of GPX activity. To prepare erythrocyte lysates, 1 mL EDTA-primed whole blood samples were centrifuged at 700*g* for 10 min, and the resulting red blood cells were washed three times with physiological saline, resuspended in 4 mL of ice-cold distilled water, shaken vigorously to force hemolysis, and then centrifuged at 700*g* for 10 min. The resulting supernatant was the erythrocyte lysate sample required and stored at −20 °C until analysis of GSH content.

To obtain serum samples, 5 mL of whole blood sample (without EDTA) was kept in a slanting position at 37 °C for 2 h and then at 4 °C overnight, followed by centrifugation at 700*g* for 15 min. The resulting supernatant was the serum sample required and stored at −20 °C until analysis of SOD activity, MDA content, and IL-2 concentration.

At the end of the experiment (on day 42), three piglets from each of the four treatment groups were randomly selected and euthanized. Half of the spleen from each pig was harvested and stored at 37 °C until isolation of primary porcine splenocytes for analysis T lymphocyte proliferation. One-fourth of each liver, kidney, and spleen tissue was rapidly excised and rinsed with ice-cold isotonic saline, then snap-frozen in liquid nitrogen, and stored at −70 °C until analysis of GPx1, GPx4, and TR1 mRNA expression.

Analysis of GPX and SOD Activities and GSH and MDA Contents. The GPX activity in whole blood, the GSH content in erythrocyte, the SOD activity, and MDA contents in serum were respectively determined using the commercial kits in accordance with the manufacturers' instructions. GPX activity, SOD activity, and GSH and MDA contents were expressed as U/L, U/mL, μmol/g protein, and nmol/mL, respectively.

TCR-Induced T Lymphocyte Proliferation Assay. The lymphocytes of peripheral blood and spleen were collected by using a commercial Lymphocyte Separation Medium (Tianjin Hematology Institute). The T lymphocyte proliferation induced by T-cell receptor (TCR) was analyzed using a WST-8 Cell Counting Kit-8 (Beyotime) according to the manufacturer's instructions as previously described by Zhang and Sun.[26] Briefly, 5.0×10^{5} cells suspended in RPMI-1640 medium (100 μL) containing 10% fatal bovine serum were seeded in 96-well plates and treated in the absence (control) or presence of 2 μg/mL stimulatory anti-pig-CD3 mAb (clone PPT3; Abcam). After incubation for 44 h, CCK-8 solution (10 μL) was added to each well, and the cells were incubated at 37 °C for 4 h with 5% CO_2. At the end, the cells in each well were measured by Vis spectrophotometer at 450 nm.

Determination of IL-2 Concentrations in Serum. The IL-2 concentrations in the serum samples were measured by using a commercial porcine IL-2 enzyme-linked immunosorbent assay (ELISA) kit in accordance with the manufacturer's protocol (YuanYe

Biotechnology Co., Ltd.). The concentration units were expressed as pg/mL.

Determination of Selenoprotein mRNA Expression. Real-time quantitative PCR method was employed for selenoprotein mRNA detection. The PCR primers (Table 1) for two selenoprotein genes (GPx4 and TR1) and one reference gene (β-actin) were designed using Primer Premier Software (PREMIER Biosoft International, Palo Alto, CA, USA) on the basis of the known porcine sequences reported in the NCBI database (http://www.ncbi.nlm.nih.gov).

Table 1. Primers Used for Real-Time Quantitative PCR

gene	accession no.[a]	primer sequence (5′−3′)	product (bp)
β-actin	DQ845171.1	forward: CTGCGGCATCCACGAAACT reverse: AGGGCCGTGATCTCCTTCTG	147

TR1	NM_214 154	forward: CCCTGGTGACAAAGAGTA reverse: GTCCTGGTCAAATCCTCT	184

[a]For retrieving the corresponding cDNA or gene sequences from the GenBank database (http://www.ncbi.nlm.nih.gov).

Total RNA was isolated from the frozen tissue samples using the RNAiso Plus (TaKaRa) reagent according to the manufacturer's protocol. The isolated RNA pellets were resuspended in 30 μL of diethyl pyrocarbonate-treated water, quantified by measurement of the absorbance ratio at 260/280 nm, and then stored at −70 °C prior to cDNA synthesis. First-strand cDNA was synthesized from 1 μg of total RNA using Oligo dT primers and M-MLV reverse transcriptase (TaKaRa) according to the manufacturer' instructions. Real-time PCR was performed on an ABI PRISM 7300 detection system (Applied Biosystems, USA). Reactions were performed in a 25 μL reaction mixture containing 12.5 μL of 2× SYBR Green I PCR Master Mix (TaKaRa), 10 μL of cDNA, 1 μL of each primer (10 μM), and 0.5 μL of PCR-grade water. The PCR procedure consisted of a 95 °C step for 30 s followed by 40 cycles consisting of 95 °C for 5 s and 60 °C for 31 s. A dissociation curve was run for each plate to confirm the production of a single product. A nontemplate reaction served as the negative control.

The relative levels of selenoprotein mRNA were determined using the Δ cycle threshold (ΔCt) method with β-actin serving as a reference gene. For each of the target selenoprotein genes, the ΔΔCt values of all the samples were calculated by subtracting the average ΔCt of the Con group from the average ΔCt of the P, SS, or SP group. The ΔΔCt values were converted to fold differences by raising 2 to the power of $-\Delta\Delta Ct$ (i.e., $2^{-\Delta\Delta Ct}$).

Statistical Analysis. Data were analyzed by the one-way ANOVA model followed by Duncan's multiple-range tests to separate the means using the SPSS computer program for Windows (version 17.0). Data for each treatment group are presented as means ± SE, and the statistical significance was set at $P < 0.05$.

RESULTS

Animal Growth Performance. The initial body weight (BW) and final BW, ADG, ADFI, and F/G in different groups of pigs are shown in Table 2. As expected, there was no difference in initial BW among the four treatment groups. Among the Con, P, and SS treatment groups, there were no differences in all of the growth performance parameters including ADFI, ADG, final BW, and F/G. Although there was no difference in ADFI when the SP group was compared with the other three groups, the SP group had higher ($P < 0.05$) final BW and ADG and lower ($P < 0.05$) F/G.

GPX Activity of Whole Blood. The GPX activities of whole blood from the four treatment groups are shown in Table 3. As expected, on day 0 there was no difference in GPX activities among the four treatment groups. On days 14, 28, and 42, the GPX activities in the P group were not higher than that in the Con group, but significant increases ($P < 0.05$) were observed in the SS and SP groups when compared to the P or Con group. Furthermore, the SP group was even higher ($P < 0.05$) than the SS group in GPX activities by approximately 23.8, 21.3, and 17.8% on days 14, 28, and 42, respectively.

Table 3. GPX Activity of Whole Blood of Piglets[a]

	GPX activity (U/L)			
group	day 0	day 14	day 28	day 42
Con	117 ± 3.22a	112 ± 2.36a	109 ± 5.43a	111 ± 4.72a
P	114 ± 4.47a	117 ± 3.89a	121 ± 3.22a	121 ± 2.68a
SS	115 ± 4.09a	147 ± 3.09b	155 ± 4.73b	163 ± 5.58b
SP	116 ± 4.97a	182 ± 2.68c	188 ± 4.64c	192 ± 3.57c

Data presented are means ± SE ($n = 3$). Within a column means followed by different letters are significantly different ($P < 0.05$).

Table 4. GSH Content of Erythrocytes of Piglets[a]

	GSH content (μmol/g protein)			
group	day 0	day 14	day 28	day 42
Con	17.4 ± 1.93a	18.5 ± 1.95a	20.2 ± 1.85a	21.2 ± 1.97a
P	16.0 ± 2.30a	31.3 ± 2.05b	39.1 ± 2.30b	40.5 ± 2.55b
SS	18.4 ± 1.90a	33.5 ± 1.59b	43.6 ± 2.75b	45.4 ± 1.92b
SP	17.3 ± 2.06a	44.9 ± 1.97c	56.6 ± 2.10c	57.9 ± 2.14c

[a]The GSH contents in erythrocytes (μmol/g protein) of piglets fed the normal basal diet (Con group), the basal diet supplemented with probiotics (P group), the basal diet supplemented with sodium selenite (SS group), and the basal diet supplemented with selenium-enriched probiotics (SP group). Data presented are means ± SE (n = 3). Within a column means followed by different letters are significantly different (P < 0.05).

between the SS and P groups, either the SS or P group was higher (P < 0.05) than the Con group on days 14, 28, and 42. Furthermore, the SP group was even higher (P < 0.05) than the SS or the P group in erythrocyte GSH contents by approximately 38.5, 36.7, and 34.7% on days 14, 28, and 42, respectively.

SOD Activity of Serum. The SOD activities of serum from the four treatment groups are shown in Table 5. As expected, on day 0, there were no differences in SOD activities among the four treatment groups. Although there were no differences between the SS and P groups and between the SP and SS groups, either the P or SS group was higher (P < 0.05) than the Con group in SOD activities on days 14, 28, and 42. Furthermore, the SP group was even higher (P < 0.05) than the P group by approximately 18.3, 19.7, and 14.5% on days 14, 28, and 42, respectively.

MDA Content of Serum. The MDA contents of serum from four treatment groups are shown in Table 6. As expected, on day 0, there was no difference in MDA contents among the four groups. Although there were no differences between the SS and P groups, either the SS or P group was lower (P < 0.05) than the Con group on days 14, 28, and 42. Furthermore, the SP group was even lower (P < 0.05) than the SS or P group by approximately 34.3, 32.4, and 29.0% on days 14, 28, and 42, respectively.

TCR-Induced T Lmphocyte Proliferation. The TCR-induced T lymphocyte proliferation in the peripheral blood lymphocytes and the splenocytes collected from the four treatment groups on day 42 postfeeding are shown in Figure 1. When compared to the Con group, significant promotions (P < 0.05) were observed in the TCR-induced T lymphocyte proliferations in both tissues in the P, SS, and SP groups. Although there was no difference in promoting T lymphocyte proliferation between the P and SS groups in both tissues, a

Table 6. MDA Content in Serum of Piglets[a]

Data presented are means ± SE (n = 3). Within a column means followed by different letters are significantly different (P < 0.05).

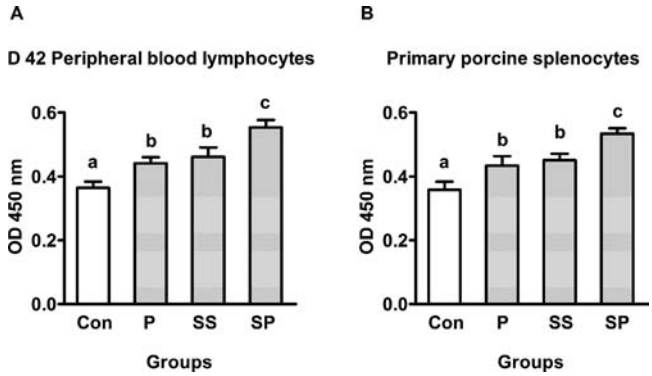

Figure 1. TCR-induced T lymphocyte proliferation in the peripheral blood lymphocytes (A) and splenocytes (B) of piglets fed the normal basal diet (Con group), the basal diet supplemented with probiotics (P group), the basal diet supplemented with sodium selenite (SS group), and the basal diet supplemented with selenium-enriched probiotics (SP group). Data presented are means ± SE (n = 3). Within a panel bars labeled with different letters differ (P < 0.05).

significant promotion (P < 0.05) was observed in the SP group when compared to the P or SS group in either tissue. In the peripheral blood lymphocytes (Figure 1A), the magnitudes of promotion were 25.0 and 19.6% for the P and SS groups, respectively. In the splenocytes (Figure 1B), the magnitudes of promotion were 23.3 and 17.8% for the P and SS groups, respectively.

IL-2 Concentration in Serum. The IL-2 concentrations in serum from four treatment groups are shown in Table 7. As expected, on day 0, there were no differences in IL-2 concentrations among the four groups. Although there were no differences between the SS and P groups, either the SS or P group was higher (P < 0.05) than the Con group on days 14–42. Furthermore, the SP group was even higher (P < 0.05) than

Table 5. SOD Activity in Serum of Piglets[a]

	SOD activity (U/mL)			
group	day 0	day 14	day 28	day 42
Con	106 ± 4.61a	96.3 ± 4.44a	105 ± 2.54a	102 ± 4.24a
P	108 ± 5.03a	131 ± 6.27b	142 ± 5.71b	152 ± 5.89b
SS	107 ± 3.66a	143 ± 3.96bc	155 ± 5.63bc	166 ± 3.38bc
SP	106 ± 3.52a	155 ± 3.56c	170 ± 3.22c	174 ± 3.26c

[a]The SOD activities in serum (U/mL) of piglets fed with the normal basal diet (Con group), the basal diet supplemented with probiotics (P group), the basal diet supplemented with sodium selenite (SS group), and the basal diet supplemented with selenium-enriched probiotics (SP group). Data presented are means ± SE (n = 3). Within a column means followed by different letters are significantly different (P < 0.05).

Table 7. IL-2 Concentration in Serum of Piglets[a]

	IL-2 concentration (pg/mL)			
group	day 0	day 14	day 28	day 42
Con	102 ± 4.28a	99.3 ± 3.23a	100 ± 2.85a	101 ± 3.33a
P	103 ± 3.54a	122 ± 2.47b	126 ± 3.61b	127 ± 2.47b
SS	97.2 ± 2.93a	124 ± 3.73b	128 ± 3.17b	130 ± 3.06b
SP	100 ± 3.52a	139 ± 3.54c	147 ± 3.07c	153 ± 3.73c

[a]The IL-2 concentrations in serum (pg/mL) of piglets fed with the normal basal diet (Con group), the basal diet supplemented with probiotics (P group), the basal diet supplemented with sodium selenite (SS group), and the basal diet supplemented with selenium-enriched probiotics (SP group). Data presented are means ± SE (n = 3). Within a column means followed by different letters are significantly different (P < 0.05).

the SS or P group in serum IL-2 concentrations by approximately 13.0, 15.7, and 19.5% on days 14, 28, and 42, respectively.

GPx4 mRNA Expression. The expression levels of GPx4 mRNA in liver, kidney, and spleen tissues from four treatment groups on day 42 postfeeding are shown in Figure S1 (see the Supporting Information). Although some numerical increases in the GPx4 mRNA expression levels can be seen for the SS and SP groups in all three tissues, there were no statistically significant increases found in these tissues.

TR1 mRNA Expression. The expression levels of TR1 mRNA in liver, kidney, and spleen tissues collected from four different treatment groups on day 42 postfeeding are shown in Figure 2. There were no differences in terms of TR1 mRNA expression levels between the P and Con groups in any of the three tissues. However, significant increases (P < 0.05) of TR1 mRNA expression were observed for the SS and SP groups in all three tissues. When compared to the SS group, the SP group showed further increases (P < 0.05) in TR1 mRNA expression by 51.4, 23.5, and 27.5% in liver, kidney, and spleen tissues, respectively.

DISCUSSION

Earlier studies demonstrated that high-temperature environments could decrease egg production and compromise the immune function of poultry, pigs, and dairy calves,[3,27,28] and supplementation of vitamin E, vitamin C, amino acids, or Se can reduce the negative effects such as immune and physiological responses of high temperature on poultry and sheep.[13,29,30] It has been reported that probiotics can also relieve the adverse effects in poultry such as decreased growth performance and immune response under heat stress.[21] Another SP product, also developed in our laboratory, was reported to have additive beneficial effect of P and Se in terms of hens' egg-laying performance.[22] However, there is very limited knowledge concerning the effects of SP on piglets exposed to high-temperature environments.

Previous studies found no difference in ADG, ADFI, and F/G between control pigs and the pigs fed extra probiotics or inorganic Se at 0.3 mg/kg diet, whereas decreased F/G was observed with the pigs fed organic Se at 0.3 mg/kg diet.[31,32] Consistent with those data obtained from normal temperature conditions, the P or SS supplementation did not affect final BW, ADG, ADFI, and F/G in the current study under high-temperature condition; however, SP supplementation improved final BW and ADG and decreased F/G of these piglets. This discrepancy is not easily explained. One may hypothesize that the improved growth performance resulting from SP supplementation is due to the organic Se in the SP product because organic Se could affect thyroid hormone (TH) secretion, which directly or indirectly leads to a decreased F/G. Although TH was not determined in this study, it was reported that thyroxine (T4) and tri-iodothyronine (T3) could be responsible for anabolic metabolism of nutrients in lambs, with T3 being the most active form, and the Se-dependent enzyme, type I deiodinase, is needed when T4 is deiodinated to the active T3.[33] Supplemental Se caused a decrease in T4 and an increase in T3, and organic Se may be superior to inorganic Se in facilitating the T4 to T3 conversion through the action of selenoenzyme,[15] because sodium selenite had no effects on T3, T4, and T4/T3 ratio.[34]

The present study of piglets raised under high ambient temperature showed that dietary P supplementation increased GSH content and SOD activity and decreased MDA content, which is consistent with previous results on pigs raised under normal temperature conditions.[35,36] Besides these GSH, SOD, and MDA parameters, dietary SS and SP supplementation additionally increased GPX activity. Although the mechanism of probiotics on increasing GSH content and SOD activity is still unclear, the reduced MDA content may be associated with the increased GSH content and SOD activity and is further evidence of the role of probiotics (*L. acidophilus*) in improving the function of swine antioxidant defense system.[35] The effects of SS on GPX and SOD activities and GSH and MDA contents

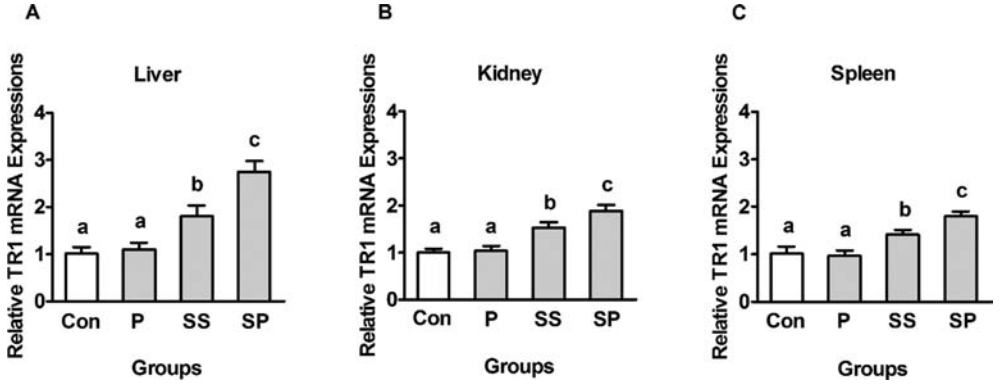

Figure 2. TR1 mRNA expression in the liver (A), kidney (B), and spleen (C) from the piglets fed with the normal basal diet (Con group), the basal diet supplemented with probiotics (P group), the basal diet supplemented with sodium selenite (SS group), and the basal diet supplemented with selenium-enriched probiotics (SP group). Data presented are means ± SE (n = 3). Within a panel bars labeled with different letters differ (P < 0.05).

in pigs raised under high-temperature conditions have not been reported until this study. It is known that the GPX activity in which Se plays a crucial role is strongly associated with animal antioxidant status,[10] as previous studies indicated that Se can elevate the antioxidant status of pigs under normal temperature conditions.[36]

That the SP supplementation further increased GPX and SOD activities and GSH content and reduced MDA content in this study strongly suggests that the SP used has more robust beneficial effects in terms of improving animal antioxidant status than P or SS alone. Our previous study also demonstrated that SP could improve murine blood lipid profile of mice and that the beneficial effects of SP are more robust than that of P or SS used alone.[25]

The effects of Se on promoting T lymphocyte proliferation and increasing IL-2 concentration in pigs raised under a high-temperature condition have not been reported either until this study. The data obtained from this study showed that dietary supplementation of P, SS, or SP promoted TCR-induced T lymphocyte proliferation in both blood and spleen and increased serum IL-2 concentrations, which are consistent with some previous studies under normal temperature conditions.[9,37] Although the mechanism is not very clear, these positive effects were thought to be due to the effects of Se on increasing Ca^{2+} flux[38] and involving cellular free thiols.[39] Furthermore, this study also showed that the effects of SP supplementation in increasing lymphocyte number and IL-2 secretion were more dramatic than that of P or SS supplementation alone, suggesting that SP is more effective in boosting pig immune function than P or SS used alone. The reason may be because there was a synergistic effect of Se and P in T lymphocyte proliferation and IL-2 secretion. It was reported that a probiotics of *L. acidophilus* increased lymphocyte number and IL-2 secretion in pigs raised under normal temperature conditions.[40,41]

The results of this study showed that TR1, but not GPx4, mRNA expressions were up-regulated by dietary supplementations of SS or SP for piglets. The mechanism of Se regulation on the expression of selenoprotein mRNA is not very clear. However, it is known that this is due to neither the transcriptional regulation nor the mRNA processing and exports from the nucleus.[42] On the other hand, it has been suggested that the explanation of Se affecting mRNA expression is that selenoprotein transcripts are affected via nonsense-mediated mRNA decay mechanism.[43]

This study found that SP supplementation has a more dramatic effect in up-regulation of TR1 mRNA expressions than SS supplementation, which may be due to the better bioavailability of the organic Se in the SP product than that of the inorganic Se in the SS product.[43] That the GPx4 mRNA expression was not affected by dietary SS or SP supplementation, as found in this study, is also consistent with previous research results.[14] But why the GPx4 mRNA expression is not sensitive to dietary Se supplementation is unknown.

In summary, the present study indicated that dietary supplementation of SP improved animal growth performance, antioxidant status, immune function, and some selenoprotein mRNA expression in piglets raised under high ambient temperature, suggesting that this SP product is a feasible dietary supplementation for piglets during hot seasons. The more robust beneficial effects of the SP product than the P or SS product used alone may be explained by two possible reasons: (i) there is an additivity or a synergistic effect between probiotics and Se in these beneficial effects, and (ii) the more robust antioxidant effects of the SP product may be due to the organic Se it contained relative to the inorganic Se contained in the SS.

ABSTRACT: The attention of researchers is burgeoning toward oilseed press-cake valorization for its high protein content. Protein removal from oil-cakes generates large quantities of fibrous residue (oil-and-protein spent meal) as a byproduct, which currently has very limited practical utility. In the wake of increasing awareness in waste recycling, a simple environmentally benign hydrothermal carbonization process to convert this "end-of-pipe" waste (spent meal) into antioxidative, hemocompatible, fluorescent carbonaceous nanoparticles (FCDs) has been described. In the present investigation, an interesting application of FCDs in fabricating low-cost rapeseed protein-based fluorescent film, with improved antioxidant potential (17.5−19.3-fold) and thermal stability has been demonstrated. The nanocomposite film could also be used as forgery-proof packaging due to its photoluminescence property. For assessing the feasibility of antioxidative FCDs in real food systems, a comparative investigation was further undertaken to examine the effect of such nanocarbon-loaded composite film on the oxidative shelf life of rapeseed oil. Oil samples packed in nanocomposite film sachets showed significant delay in oxidative rancidity compared to those packed in pristine protein-film sachet (free fatty acids, peroxide value, and thiobarbituric acid-reactive substances reduced up to 1.4-, 2-, and 1.2-fold, respectively). The work presents a new concept of biobased fluorescent packaging and avenues for harnessing this potent waste.

KEYWORDS: *rapeseed press-cake, carbon nanodots, hydrothermal carbonization, nanocomposite film, rapeseed protein*

INTRODUCTION

Currently, fluorescent nanoparticles (NPs) (also known as quantum dots (QDs) due to their typical sizes below 10 nm), a young smart member of the nanomaterial family, is gaining attention, especially in the fields of optoelectronics, bioimaging, biomedicines, etc. Unfortunately, application of NPs in foods[1−5] and their packaging materials is still in its infancy. The reason behind this seems to be the raised toxicity concern and environmental hazard of the fluorescent semiconductor QDs, which are based on metallic elements and heavy metals (elements from the periodic groups II−IV, III−V, and IV−VI). Alternatively, fluorescent carbon NPs (called fluorescent carbon dots or FCDs or C-dots or simply CNPs) can become an exciting option, because they are greener for the environment and show aqueous dispersibility, numerous possible applications in nanobiotechnology, and far less toxicicty to living organisms. Recently, Sk et al.[6] reported the presence of FCDs in regular carbohydrate-based food items such as bread, jaggery, sugar caramel, cornflakes, and biscuits and also showed their biocompatibility. This novel discovery alleviated the misapprehension that all fluorescent NPs are toxic and revealed that humans have been consuming fluorescent nanomaterials in the form of food caramels for centuries, and thus they can be considered safe.

Recently, procurement of novel C-dots from greener sources such as egg,[7] orange juice,[8] banana juice,[9] soy milk,[10] glucose, sucrose, starch,[11] citric acid,[12] chitosan,[13] etc., has been the center of attraction. Although they are the current state of the art, most of these methods suffer to some degree from certain drawbacks such as the requirement of sophisticated and expensive equipment such as a laser beam, microwave, or high-power autoclave; neat chemicals as precursors for synthesis; or even multisteps of operation along with surface passivation to improve the water solubility and photoluminescent properties of C-dots. Moreover, use of such food/feed or other edible stuffs as raw materials for FCD preparation is expensive for bulk use, and in the long run would create undue strains on the food resource system and food security scheme. This is a major drawback to the commercial synthesis of NPs from these edible resources, which is unlikely to be extended in the near future. This motivated us to search for a simple economical technique for the production of FCDs from industrial or agricultural byproducts. This is a challenging but worthy concept as the use of waste materials is one of the most attractive options to reduce the raw material cost and also seems benign from an ecological point of view. In this context, very few papers are available. Lu et al.[14] reported such an endeavor from pomelo peel, and the resulting CNP was used for the detection of mercury ions in water. Wang et al.[15]

prepared C-dots from egg-shell membrane and used it for designing a fluorescent probe for glutathione detection. In a closely related work, FCDs were prepared from used coffee grounds,[16] and their practicality in cell imaging and detection of angiotensin I and insulin was assessed. Most reported C-dots have been prepared for bioimaging, which limits their application in other fields. As such, it has become urgent to develop effective routes to create functional C-dots as well as expand their applications.[10] Explicitly, the role of FCDs in the food packaging domain is unexplored to date.

Industrially, mechanical pressing of the oilseeds produces the oil (main product) and the press-cake (byproduct). Due to the high quantity of protein, the oil-cake or meal is being used mainly as animal feed. Recently, owing to the high nutritive value of the meal protein, techniques are now being devised to harness it. After the extraction of meal protein, the residual fibrous waste material (protein spent meal) is discarded and is not extensively used in industries. At present there are very few possibilities for the utilization of this waste; usually the residue is disposed of as landfill and, hence, is as an "end-of-pipe" waste. In this work, the synthesis of green fluorescent quantum-sized carbonaceous NPs from "oil-and-protein spent" rapeseed meal by a facile hydrothermal process has been reported for the first time. These NPs are referred to as "carbogenic" because of their high oxygen content along with carbon.[12]

Undeniably, the most active area of food nanoscience research and development is "packaging". This is likely connected to the fact that the public has been shown in some studies to be more willing to embrace nanotechnology in "out-of-food" applications than those in which NPs are directly added to food.[17] Therefore, the practicality of the synthesized FCDs for making green-fluorescent edible biopackaging material was investigated in this study, thereby expanding the potential application of C-dots. Synthetic plastic packaging is beginning to be replaced by biodegradable ones because of environmental concerns. Films made of carbohydrates and protein are long and have empirically been used to make food grade biodegradable packaging materials. A recent approach to this technology involves the use of vegetable protein from different types of oil-cakes such as cottonseed,[18] pumpkin seed,[19] soybean,[20] and rapeseed/canola.[21] In this milieu, edible films using rapeseed protein were developed in the current investigation, because this biopolymer can be obtained as a value-added product from the underutilized meal. As such, the study was extended to evaluate the effect of such a nanoadditive on the physicochemical properties of rapeseed protein film.

Mostly, consumers have to rely on holograms and other displays on the packets to segregate authentic products from their duplicate inferior counterparts. Often, fluorescent dyes are incorporated into the packaging to help customers easily detect authentic products (e.g., erythrosine); however, many of these dyes have been shown to be cytotoxic to a variety of mammalian cell types.[22] The unique "green" photoluminescence property of the here-in synthesized carbogenic NPs, along with high antioxidative potential and hemocompatibility, offer a solution to this problem. It is envisioned that FCD-incorporated edible films would not only be useful for quality control to ensure that consumers are able to purchase authenticated products, but would also improve the oxidative stability of the produce/commodity. To justify this possibility, further study was conducted to see the effect of FCD−protein composite film on the oxidative shelf life of an oil sample. For simplicity, the preparative protocol along with the summarization of the complete investigation is depicted pictorially in Supplementary Figure S1 in the Supporting Information.

MATERIALS AND METHODS

Chemicals. All solvents and reagents were obtained from E. Merck (India), of either high-performance liquid chromatography (HPLC) grade or analytical reagent grade, and were used without further purification.

Materials and Sample Preparation. Cold-pressed rapeseed oil and press-cake were obtained from Assam Khadi and Village Industries Board, Guwahati, India. Press-cake was detoxified prior to protein extraction according to the reported procedure[23] and then stored at −20 °C until use.

Protein Extraction from Detoxified Meal. Aqueous suspension of detoxified meal was prepared with water (30:1 v/w), followed by the addition of 0.1 M NaCl and 0.4% sodium sulfite. The pH of the suspension was adjusted to 11 ± 0.1 with 1 N NaOH solution; the suspension was mixed (200 rpm) for 1 h at 25 °C in the orbital shaker (Sartorius Stedin Biotech, CERTOMAT IS), followed by centrifugation (Sigma 3-18K centrifuge) at 7000 rpm for 20 min at 4 °C. The solid residue (oil-and-protein spent meal) was vacuum-dried (lab companion model OV-12, Jeiotech Co., Korea) for 48 h at 40 °C, ground to pass through a sieve having 250 μm pores, and then stored at −20 °C for further use. On the other hand, the protein-rich supernatant was filtered through Whatman filter no. 41, and then ammonium sulfate was added up to 85% saturation. The mixture was kept in an ice bath for 3 h with gentle stirring and then centrifuged at 10000 rpm for 20 min at 4 °C. The obtained protein precipitate was redispersed in Milli-Q water (Millipore Water Purification System, Model-Elix, USA), neutralized to pH 7, dialyzed against water at 4 °C, and finally freeze-dried, which was subsequently used for making the composite film.

Synthesis of C−Dots from Oil-and-Protein Spent Meal. FCDs were synthesized by hydrothermal carbonization (HTC) of spent meal using the reported protocols[8,24] with slight modification. In a typical procedure, oil-and-protein spent meal (10 g) was dispersed in 1 N NaOH solution (solvent) at a solvent/meal ratio of 463:1 (v/w). The suspension was refluxed in an oil bath under magnetic stirring at 180 °C for 3 h (details of the optimal production of FCDs using response surface methodology are given in supplementary section 1 in the Supporting Information). After the reaction is over, the resultant black solution was allowed to cool and then centrifuged at 3000 rpm for 10 min to separate the unreacted residue. The brownish supernatant was washed with dichloromethane to remove the unreacted organic moieties. Subsequently, the aqueous phase was mixed with acetone (water/acetone ratio =1:3 v/v), and the acetonic extract was finally reduced to dryness under vacuum. The residue was dispersed in Milli-Q water, dialyzed against water (using 1 kDa membrane, Himedia, India), and finally dried under vacuum at 40 °C to obtain FCDs (≈0.942 g).

Characterization of C−Dots. High-resolution transmission electron microscopy (HRTEM; JEOL, JEMCXII) images along with the selected-area electron diffraction (SAED) pattern were obtained at an accelerating voltage of 200 kV, and the sample was prepared by drop casting 2 μL of NP solution (0.25 mg/mL) on a 300 mesh carbon-coated copper grid and subsequent air-drying before analysis.

X-ray diffraction (XRD) measurement was carried out in thin film mode of powdered sample using a Rigaku Miniflex model (Japan), operated at 30 kV voltage and a current of 15 mA with Cu Kα radiation source (λ = 1.54 Å) at a scan rate of 5° (2θ) min^{-1} over the range of 10−70°.

Thermogravimetric analysis (TGA) curves were collected on a TG 50 model (Shimadzu, Japan). The samples were combusted under nitrogen flow (10 mL/min, to avoid thermo-oxidative reactions) at temperatures ranging from 25 to 600 °C, at a rate of 3 °C/min.

Fourier transform infrared (FTIR) spectra were obtained on a FTIR Nicolet Magna 5PC spectrometer (Impact-410, Madison, WI, USA), coupled to a PC with Omnic analysis software and having a deuterated triglycine sulfate (DTGS) detector and Nernst filament as the IR light

source. The sample was ground with KBr powder to form well-defined pellets for IR measurement, with 32 scans from 4000 to 400 cm^{-1} at a resolution of 4 cm^{-1}.

Micrographs of the sample were obtained using a JSM-6390LV scanning electron microscope (SEM; JEOL, Japan) at an accelerating voltage of 15 kV. Prior to SEM observation, samples were mounted on stubs with double-sided adhesive tape, followed by coating the samples with a thin layer of gold. For determining the elemental composition and purity, sample was prepared on a carbon-coated copper grid and kept under vacuum desiccation for 3 h before they were loaded onto a specimen holder. Elemental analysis on single particles was carried out using electron dispersive an X-ray spectroscopy (EDX, JSM-6390LV) attachment equipped with SEM.

^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were detected at 400 MHz by a JEOL NMR system (Japan), using the inbuilt DELTA (δ) software (version G4.3.6, Japan) provided by the manufacturer.

The ultraviolet−visible (UV−vis) absorption spectrum of aqueous NP solution (0.1 mg/mL) was recorded on a UV−vis spectrophotometer (CECIL 7400, 7000 series, Aquarius).

The photoluminescence (PL) spectrum of aqueous NP solution (0.1 mg/mL) was measured on a photoluminescent spectrophotometer (model LS 55, PerkinElmer, Singapore PTE Ltd., Singapore). Illumination of the aqueous NP dispersion for detecting its fluorescence property was done inside a UV cabinet (BD-198 model, Test Master, Kolkata, India).

Quantum yield (QY) of C-dots was measured in reference to quinine sulfate in 0.1 M H_2SO_4 (QY = 58% at 354 nm excitation).[6,25] The formula used for QY is

$$(QY)_{Sm} = (QY)_{St} \times [(PL\ area/OD)_{Sm}/(PL\ area/OD)_{St}] \times \eta_{Sm}^2/\eta_{St}^2 \quad (1)$$

where Sm indicates the sample, St indicates the standard, η is the refractive index of the solvent, and PL area and OD are the fluorescence area and absorbance value, respectively. For aqueous solutions $\eta_{sm}/\eta_{st} = 1$ was chosen.[6]

Antioxidant activity was measured by using the modified 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical method.[26] Briefly, 3 mL of sample solution was mixed with 1 mL of 1 mM methanolic solution of DPPH. The mixture was then vortexed and incubated in the dark at ambient temperature for 30 min. The absorbance was measured at 517 nm in a UV−vis spectrophotometer. In the case of FCDs or ascorbic acid (as standard), the amount was varied from 10 to 180 μg/mL of reaction mixture,[27] whereas for film samples, 25 mg of each film was dissolved in 3 mL of Milli-Q water.[26] The DPPH scavenging percentage was calculated using the formula

$$\text{scavenging activity}(\%) = \{(A_D - A_S) \times 100\}/A_D \quad (2)$$

where A_D and A_S are the absorbance of the DPPH solution and the standard/sample, respectively.

The hemolytic activity assay was performed according to the reported procedure.[23] Briefly, fresh goat blood from a slaughterhouse was collected in a centrifuge tube containing anticoagulant, trisodium citrate (3.2%), and was centrifuged at 3000 rpm for 10 min. The supernatant was discarded, and only the red blood corpuscles (RBCs or erythrocytes) were collected. RBCs were further washed three times with phosphate buffer solution (PBS, pH 7.4). A 10% (v/v) suspension of erythrocytes in PBS was prepared, and 1.9 mL of this erythrocyte solution was placed in a 2 mL centrifuge tube; 0.1 mL of FCDs in PBS was added to it. The tubes were then incubated for 1 h at 37 °C. For comparison, Triton X-100 (0.2%) and PBS were taken as positive and negative controls, respectively. After incubation, the tubes were subjected to centrifugation at 3000 rpm for 10 min, and finally the absorbance of the supernatant was taken at 570 nm in the UV−visible spectrophotometer.

Cell labeling with FCDs was done according to the procedure of Chandra et al.[28] The erythrocytes enriched fraction was centrifuged twice (3000 rpm, 15 min) at 4 °C to remove the residual plasma and buffy coat. RBCs were washed three times with PBS (pH 7.4) and resuspended in the same buffer to make a packed cell volume of ≈10% (w/v) as stock. Then, cell labeling was carried out by mixing different aliquots of the above RBC stock suspension with different volumes of FCDs (30.4, 45.5, 60.8, and 75.8 μL) from its stock solution (660 mg/mL) for making the final concentrations of FCDs as 20, 30, 40, and 50 mg/mL by addition of PBS in each set of experiments. Afterward, the erythrocytes were incubated for 4 h at room temperature, centrifuged (3000 rpm, 15 min) at 4 °C, and then washed three timeswith PBS. Finally, 20 μL of the cell suspension was taken and used to prepare a smear on glass slides, which were viewed under a fluorescent microscope (LEICA DM 3000, power = ebq 50 qc, USA) attached to a LEICA DFC 450C camera.

Preparation of Rapeseed Protein−FCD Composite Film and Its Application for Oil Packaging. Rapeseed protein film solution was prepared by using the methodology reported by Cho and Rhee.[20] Freeze-dried rapeseed protein powder (8 g) and glycerol (4 g) were dissolved in 100 mL of Milli-Q water. The suspension was heated on a hot-plate magnetic stirrer for 10 min at 80 °C until a homogeneous clear solution was obtained. FCDs (20 or 30 mg) were added to the mixture, and blending was further continued for 15 min at 80 °C. The mixture (40 mL each) was cast onto glass Petri plates and then dried in an oven at 35 °C for 48 h. Films were conditioned in an environmental chamber (plant growth chamber HB 303DH, K&K Scientific Supplier, India) set at 25 °C with 50% relative humidity (RH) for 48 h. The composite films with 20 and 30 mg of FCDs/100 mL of film-forming solution were accordingly coded F1 and F2, respectively. Film without FCDs served as control and was designated F0.

Films were drawn into small rectangular sachets/pouches (5 cm × 3.5 cm), each of which was filled with 4 mL of cold-pressed rapeseed oil, and then sealed after the headspace had been flushed with nitrogen gas. Oil-containing sachets were stored for 28 days in the environmental chamber (25 °C, 50% RH), and the oil samples were analyzed after every 7 days. Oil samples packed in F0, F1, and F2 were accordingly labeled S0 (control), S1, and S2, respectively.

Characterization of the Composite Films. Film thickness was measured at five random positions with a micrometer (Mitutoyo Corp., Japan). The mean thickness was used to calculate the mechanical and barrier properties of films.

For moisture content determination, film samples were weighed into aluminum pans and dried at 105 °C in an oven for 24 h (until the equilibrium weight). The weight loss of the sample was determined, from which the moisture content was calculated.

Water vapor permeability (WVP) was determined gravimetrically following the standard method of the American Society for Testing and Materials (ASTM).[26] Conditioned film samples were sealed to glass cups (4.7 cm diameter) containing water. The film-covered cups were placed in the environmental chamber (25 °C, 75% RH). Cups were weighed periodically using an analytical balance (Denver Instrument, Bohemia, NY, USA), until steady state was reached (±0.0001 g). Once the steady state was reached, the water vapor transmission rate (WVTR, ng/m^2 s) of the film (eq 3) was determined from the slope obtained from the regression analysis of moisture weight gain (Δw) transferred through the film area (A) during a definite time (Δt). WVTR was then used to calculate WVP using eq 4.

$$WVTR = \Delta w/A(\Delta t) \quad (3)$$

$$WVP = WVTR(x/\Delta p) \quad (4)$$

x is the average thickness of the film, and Δp is the partial water vapor pressure between the two sides of the film.

Oxygen permeability of the films was determined by using the wet chemical procedure of Ayranci and Tunc.[29]

Tensile strength (TS, in MPa) and *Elongation at break* (EB, %) of the film was measured according to ASTM D-882-91.[30] For evaluating *puncture strength* (PS, given as force in Newton (N)), film was punctured with a 2 mm probe in a Texture Analyzer (TA HD Plus, Stable Micro Systems, UK).

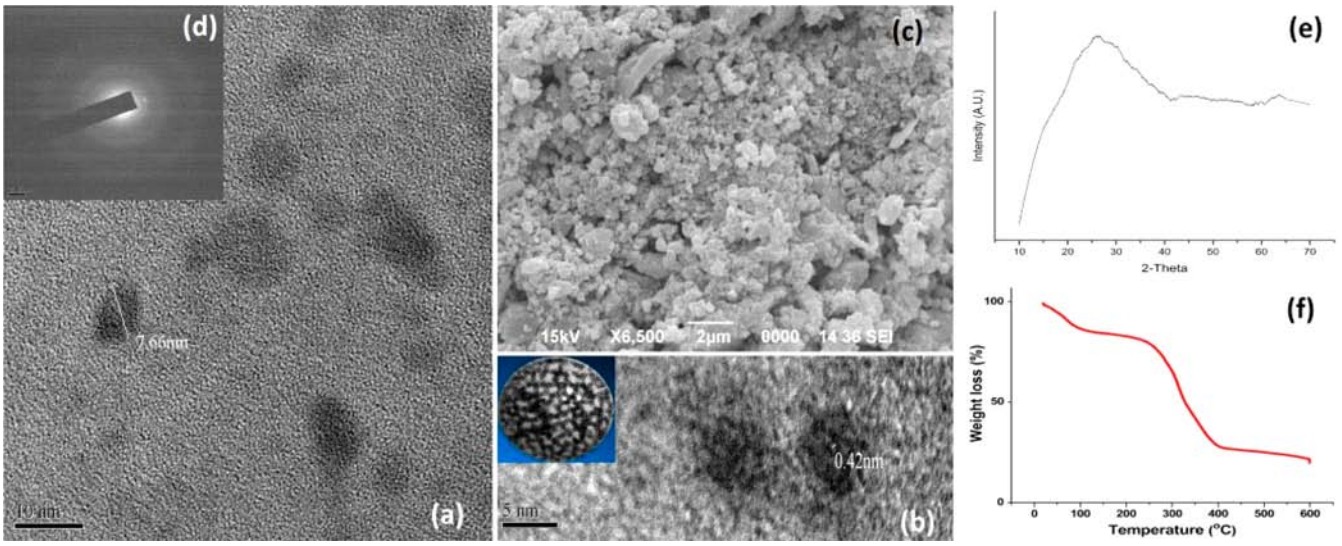

Figure 1. (a) TEM image of FCDs thus formed; (b) corresponding HRTEM image of two nanoparticles (inset, pictorial representation of the morphology of one nanoparticle); (c) SEM image of the clusters of nanoparticles obtained after drying; (d) SAED image; (e) XRD pattern; (f) TGA curve of FCDs.

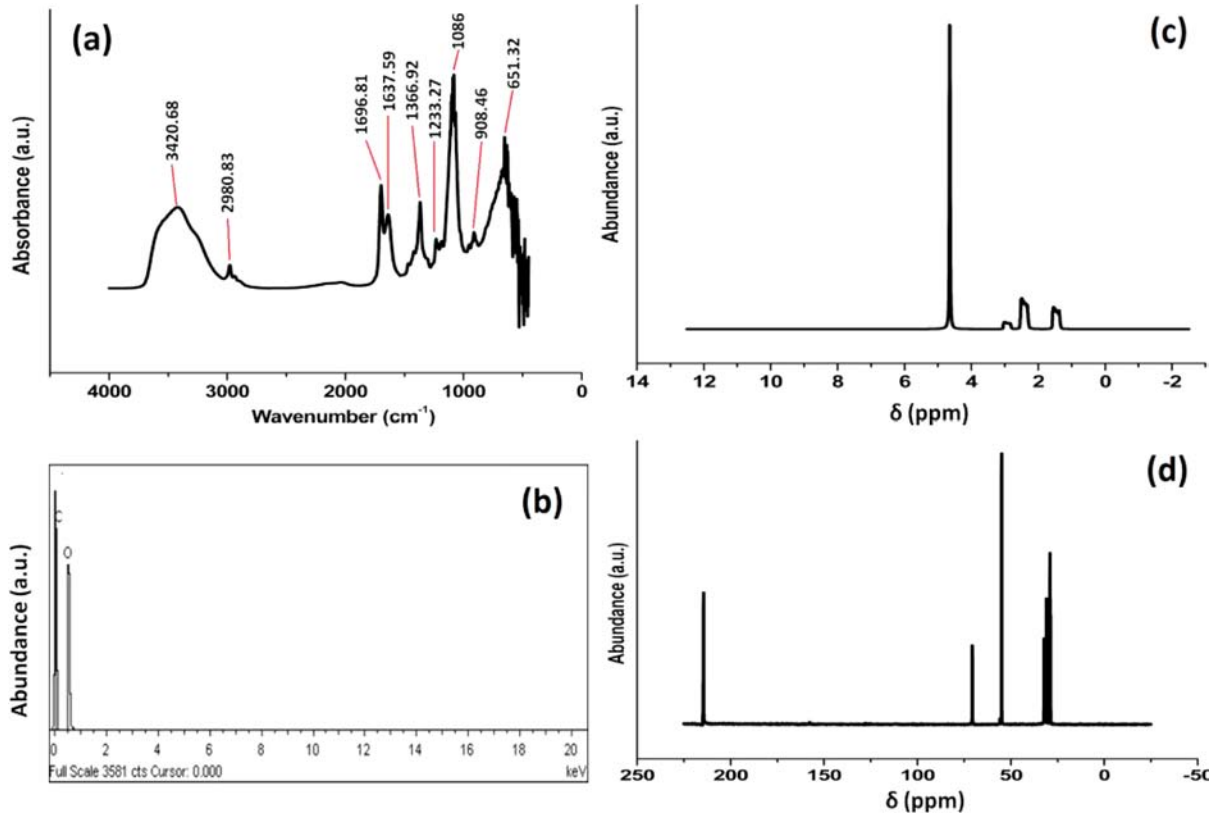

Figure 2. (a) FTIR spectrum, (b) EDX data, (c) ^{1}H NMR, and (d) ^{13}C NMR of FCDs.

Color intensity of the film was measured using a Hunter Lab Colorimeter (Ultrascan, VIS-Hunter Associates Lab., USA), fitted with a large area port (2.5 cm diameter aperture). The instrument (including 65°/0° geometry, D25 optical sensor, 10° observer, specular light) was calibrated using white and black reference tiles provided by the manufacturer.

For determining *opacity*, film absorbance was measured at 600 nm using a UV−vis spectrophotometer.[26] The sample was cut into a rectangle piece and directly placed in a spectrophotometer test cell, using an empty test cell as the reference. The opacity index of the film was calculated by using the equation

$$\text{opacity} = \text{Abs}_{600}/x \quad (5)$$

where Abs_{600} is the absorbance at 600 nm and x is the average film thickness (mm).

Analytical Tests for Oil Sample. *Free fatty acid* (FFA) and *peroxide value* (PV) were determined according to the method of Chaijan et al.[31] and expressed as grams per 100 g of lipid and milliequivalents (mequiv) of free iodine per kilogram of lipid, respectively.

Conjugated diene (CD) was estimated from the absorbance value at 233 nm using cyclohexane as the solvent blank.[32]

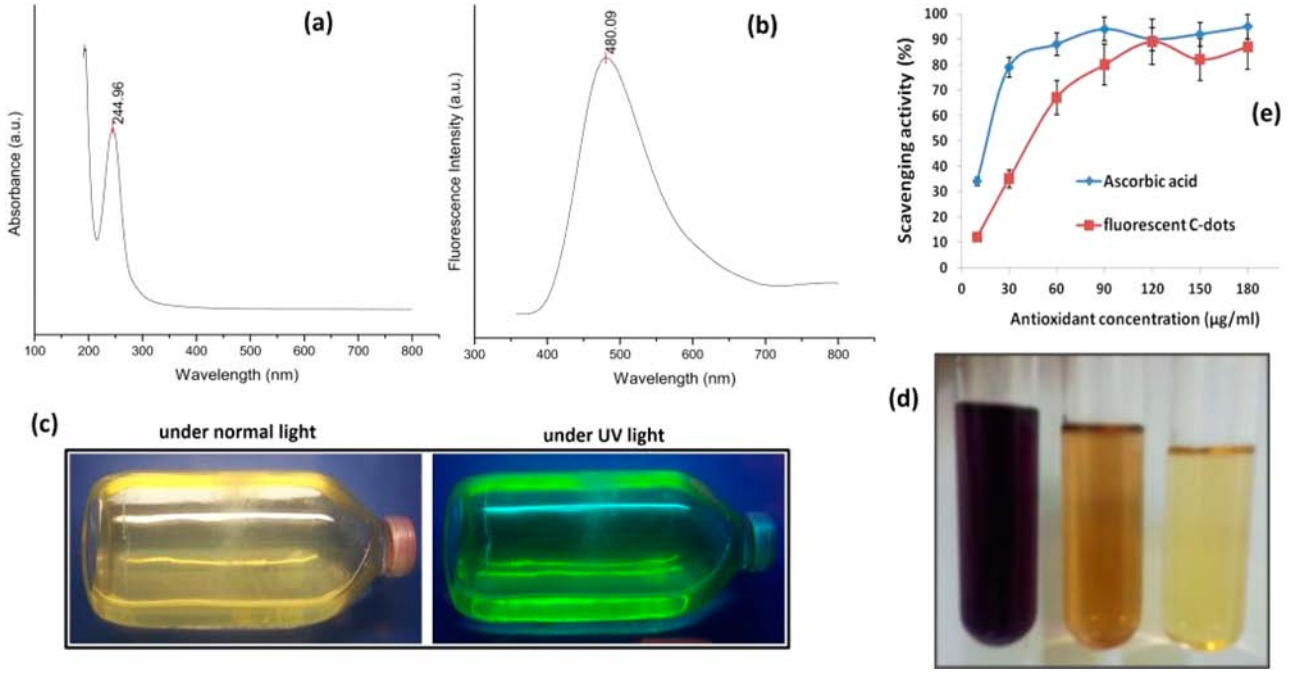

Figure 3. (a) UV−vis spectrum; (b) PL spectrum of aqueous dispersion of FCDs (0.1 mg/mL); (c) photographs of aqueous FCD dispersion (0.25 mg/mL) observed under white light and the same under UV light; (d) gradual bleaching of DPPH solution by FCDs; (e) DPPH scavenging activity of FCDs in comparison to that of ascorbic acid.

For *thiobarbituric acid-reactive substances (TBARS) assay*,[31,33,34] oil sample (0.5 g) was mixed with 2.5 mL of a solution containing 0.375% thiobarbituric acid, 15% trichloroacetic acid, and 0.25 N HCl. The mixture was heated in a boiling water bath (95−100 °C) for 10 min to develop a pink color, cooled with running tap water, and then centrifuged (3600*g*) at 25 °C for 20 min. The absorbance value of the supernatant at 532 nm was expressed as the result (A_{532}).

Statistical Analysis. All analyses were performed in triplicate, and the mean value was calculated. Analysis of variance (ANOVA) and separation of means were carried out by Tukey test, using SPSS software (version 16.0, SPSS Inc., Chicago, IL, USA) and considered significantly different at $p < 0.05$.

RESULTS AND DISCUSSION

Characterization of FCDs. The formation of C-dots was confirmed by TEM measurement (Figure 1a). HRTEM images clearly revealed that the NPs are spherical in shape; their diameters mainly lay in the range of 4.71−10.77 nm with maximum population at 7.66 nm. It can be seen that there are holes or crevices on the surface of C-dots, giving them an appearance of a puffer-like hollow ball (Figure 1b). The average diameter of these surface holes was calculated to be 0.42 nm (approximately). SEM image (Figure 1c) indicates that dried FCD powder is an aggregate of small carbon grains hundreds of nanometers in size. The entities appear to be nonhomogeneous in size and shape. This asymmetry is probably due to the effect of drying, because of which the NPs formed clusters of various sizes and shapes.[24]

The absence of any discernible lattice fringes in the HRTEM image suggests an amorphous nature of the as-prepared NPs. Concomitantly, the SAED pattern of the C-dots showed diffused rings (Figure 1d), revealing an amorphous carbon phase,[7] which agrees well with the HRTEM analysis. Furthermore, the XRD pattern (Figure 1e) presented a broad hump-like peak near 25.8°, which is attributed to amorphous carbon.[11]

The thermal behavior of FCDs was investigated by TGA. The thermogram (Figure 1f) exhibited a two-step degradation pattern with the initial degradation (<100 °C) ascribed to the loss of moisture and volatile products, whereas the final degradation (286.24−358.21 °C) was associated with the decomposition of oxygen-containing groups.[35]

The FTIR spectrum was acquired to gain further structural insights and the surface state of the synthesized FCDs. In this spectrum (Figure 2a), the stretching frequencies observed at 651, 908, 1086, 1233, 1367, 1638, 1697, 2981, and 3421 cm^{-1} indicate the presence of olefinic C−H (out-of-plane), epoxy ring, C−O or C−O—C, carboxylate group, C−N, C═O, C−H, and hydroxyl (−OH) stretch, respectively.[9] The different oxygenous functional groups as evident from FTIR prove that the surface of the FCD is partially oxidized. The origin of these functional groups can be ascribed to the degradation of the carbohydrates, crude fibers, and residual protein present in the spent meal through hydrothermal treatment.[10,14] Additionally, the presence of these hydrophilic functional groups imparts excellent water solubility to the C-dots without further chemical modification, which in turn promotes the environmental friendliness of the product.[9]

EDX data (Figure 2b) further confirm the fact that the as-prepared NPs mainly consist of carbon (47.81 wt %) and oxygen (52.18 wt %).

NMR spectra highlighted the presence of two different kinds of chemical environments or regions, which are discussed as follows. In the ^{1}H NMR spectrum (Figure 2c), the regions found are δ 1−3 (for sp^3 C−H protons) and δ 3−6 (for protons attached with hydroxyl, ether, and carbonyl groups).[9] Also, in the ^{13}C NMR spectrum (Figure 2d), similar regions were found; namely, δ 20−100 (for sp^3 carbons and for carbons attached with a hydroxyl group or ether linkage) and δ 214−215 (for keto, −C═O carbon atoms).[9] Specifically, the peaks within δ 28−33 depict the presence of methyl groups in the

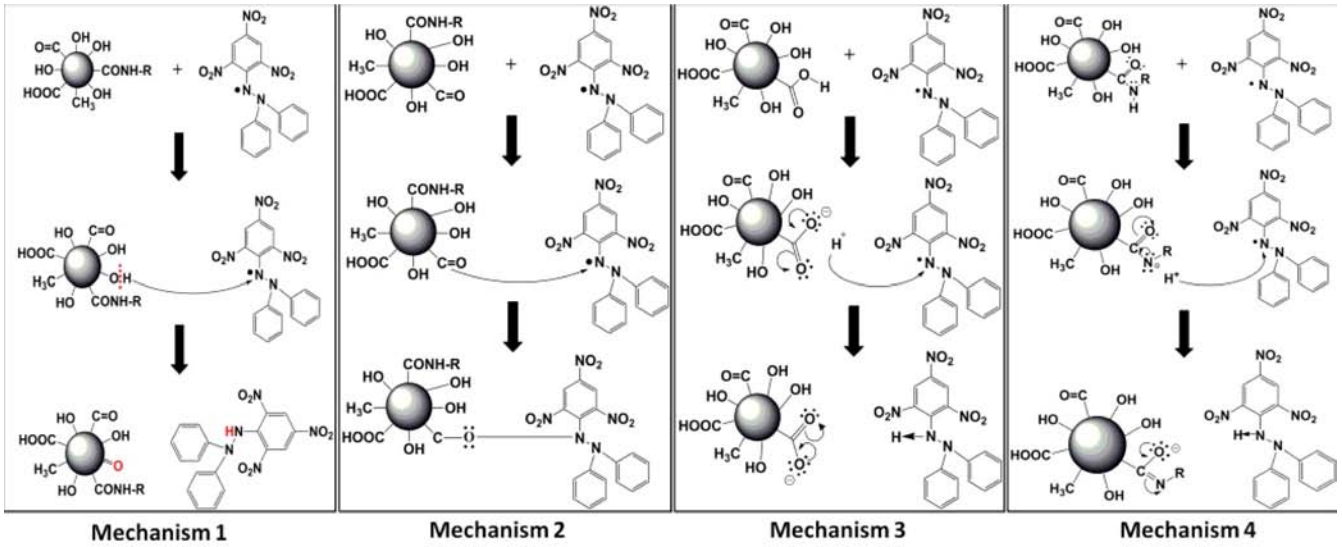

Figure 4. Plausible mechanism for the DPPH scavenging activity of FCDs.

surface functional moieties, and the singlet peak at δ 70.67 indicates the occurrence of carbohydrate units in FCDs.[6]

To explore the optical properties of FCDs, UV−vis absorption (Figure 3a) and PL studies were carried out. FCDs showed maximum UV absorption peak at 244.96 nm, which is likely to have originated from the formation of multiple polyaromatic groups where $\pi-\pi^*$ transitions of the aromatic C−C bond occur.[8] Most C-dots are excited in the UV region (330−420 nm) and yield photoluminescence in the wavelength range of 400−600 nm depending on the size of the C-dots.[16] Figure 3b shows the PL emission peak of FCDs centered at 480.09 nm, with excitation at 350 nm. This is consistent with the literature. From the fundamental as well as application viewpoint, fluorescence is one of the most fascinating behaviors of C-dots. The aqueous solution of FCDs is bright yellow and transparent in normal light but changes to an intense green color under UV light (Figure 3c), signifying the NPs to be fluorescent. It is worth noting that the origin of fluorescence from the obtained dispersion could be attributed only to the presence of C-dots because the preparatory ingredients (spent rapeseed meal, water, and NaOH) are known to be nonfluorescent materials (i.e., nonemissive under UV light), further confirming the formation of luminescent NPs. QY measured using quinine sulfate as a reference was found to be 9.2%, which is comparable with those of the reported luminescent C-dots. The fundamental mechanism of fluorescence of C-dots is still an open question; however, it is thought that the presence of quantum size and different surface trap sites could be the main factors. It is believed that radiative recombination between electrons and holes (excitons) take place at the particle surface, under the illumination of excitation light, and thus fluorescence emission occurs.[36]

With the aim of detecting the radical scavenging activity of FCDs, the DPPH assay was performed. As known, a freshly prepared DPPH solution exhibits a deep purple color with an absorption maximum at 517 nm. This purple color generally fades/disappears as soon as an antioxidant is added into the medium, resulting in a decrease in absorbance at 517 nm. Interestingly, it was found that unlike other antioxidants, FCDs first turned the purple color of fresh DPPH solution into a reddish-brown color and then gradually into a colorless (bleached) product (Figure 3d). Compared to ascorbic acid, the reaction of DPPH with FCDs proceeded at a slower rate. Nevertheless, the decrease in absorbance is detectable within minutes of reaction. This observation corroborates the DPPH radical scavenging activity of carbonaceous fullerenes (C_{60}).[37] As shown in Figure 3e, the scavenging activity of ascorbic acid and FCDs increased in a dose-dependent manner up to 94% at the dose level of 90 μg/mL and to 89% at the dose level of 120 μg/mL, respectively. The EC_{50} value was determined from the plotted graph of scavenging activity versus the concentration of sample/standard, which is defined as the amount of antioxidant necessary to decrease the initial DPPH radical concentration by 50%. EC_{50} values of ascorbic acid and FCDs were found to be 35.83 $\pm$ 4.17 and 56.16 $\pm$ 2.97 μg/mL, respectively ($p < 0.05$), confirming that the scavenging potential of FCDs was lower than that of ascorbic acid. Nonetheless, this noble facet of FCDs raises the prospects of its incorporation into oxidation-prone food models. Indeed, the nanochemistry involved in radical scavenging property of C-dots needs further investigation; however, from the knowledge gained so far, it could be explained that the quenching behavior of FCDs may be attributed to its quantum size with increased surface-to-volume ratio, providing more available reaction sites, and also to the presence of different functional moieties on the surface (−OH, C═O, −CONR, −COOH, etc.), which tends to interact with and reduce DPPH species. It has been reported that among the water-soluble fullerenes, nanomaterials of C_{60} $(C(COOH)_2)_2$, $C_{60}(OH)_{22}$, and metallofullerenes possess high antioxidative function and can wipe out different types of reactive oxygen species (ROS) depending on surface modification.[36] Amino acid-functionalized multiwalled carbon nanotubes were found to be more potent antioxidants than butylated hydroxyanisole and reduced glutathione.[38] A schematic illustrating the probable mechanism(s) is proposed in Figure 4. Data from the literature suggest that similar to fullerenes, ROS or free radicals may be "grafted" or adsorbed at the surface of C-dots by radical addition to the carbon framework, which is due to their high electron affinity.[37,39] Thus, the mechanism of scavenging reaction is not straightforward in the case of NPs, and a generalized inference can be drawn that the organic

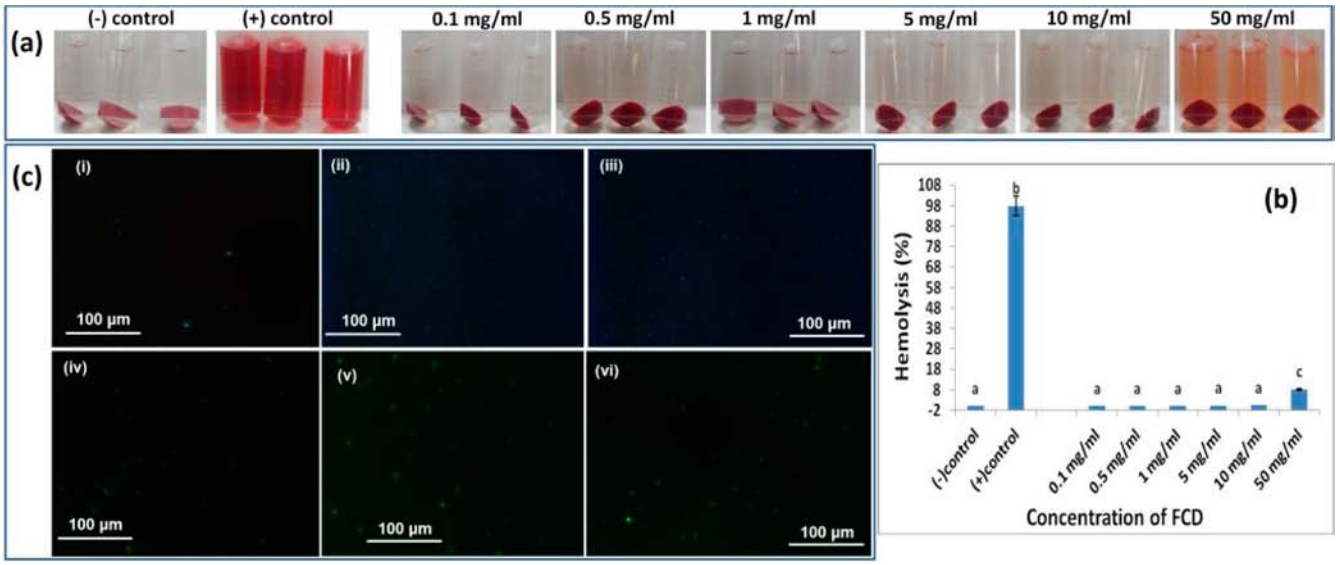

Figure 5. (a) Photographs of RBCs treated with FCDs at different concentrations. The released hemoglobin from the damaged cells in the supernatant can be seen in the photographs. (b) Hemolysis percentages of FCDs at different concentrations; (c) RBCs treated with various concentrations of FCDs observed under fluorescence microscope by excitation at 405 nm (i−(iii) and 488 nm (iv−vi).

functionalities of NPs can quench DPPH radicals (perhaps by providing hydrogen atom or by electron donation, conceivably via a free radical attack on the DPPH molecule, or by grafting/linking of radicals to C-dot's surface) and convert them to a colorless/bleached product (i.e., 2,2-diphenyl-1-picrylhydrazine, or a substituted analogous hydrazine).

Hemocompatibility. A hemolysis test was used to determine the toxicity of FCDs on mammalian RBCs. Because there are concerns about the health implication of NPs, it is important to understand how FCDs interact specifically with RBCs, as it would eventually come in direct/indirect contact with blood as soon they are exposed to the host's body. Hemolytic activity of NPs is usually determined by measuring the absorption peak of hemoglobin at 570 nm, which is released to the solution from hemolyzed cells.[40] Photographs showing precipitated RBCs at the end of the hemolysis experiment are given in Figure 5a. The red color of the released hemoglobin from damaged cells is clearly observable for positive control and 50 mg/mL concentration of FCDs. For the rest of the samples (negative control and 0.1−10 mg/mL of FCDs), the supernatants are almost colorless, confirming the intactness of the RBC membrane in these cases. This result is in conformity with that of Figure 5b. According to ASTM E2524-08 standard (standard test method for analysis of hemolytic products of NPs), hemolysis >5% indicates that the test material causes damage to RBCs; this criterion was exceeded at the FCD concentration of 50 mg/mL. Hence, FCDs were found to exhibit hemolytic activity only at higher concentration (≥50 mg/mL), which is much lower than that reported for their other counterparts (fullerenes, carbon nanotubes, etc.) and several similar NPs.[41] This benevolent feature may be due to the presence of congenial surface functional groups, making FCDs tolerable at low concentration. Yildirim et al.[40] also found that surface functionalization of nanostructures can render them completely nonhemotoxic.

To get a closer insight into the FCD-induced biological effect on RBC, the uptake of FCDs by the RBCs was examined by fluorescence microscope (Figure 5c). With increasing dosages (20, 30, and 40 mg/mL), no marked changes in the morphological shape of RBCs was detected; however, higher concentration (50 mg/mL) caused dramatic hemolysis, showing ruptured cell membranes and patches of released cell content (Supporting Information Supplementary Figure S9). It is possible that mechanical pressure exerted by excess permeation and accumulation of FCDs inside the cells caused lysis, especially at higher dosage. Thus, FCDs were found to be biocompatible in a dose-dependent manner, with no detectable hemotoxic effect up to 40 mg/mL. The C-dots were likely internalized into the RBCs through endocytosis,[16] and even after entering into the cells, the C-dots retained their fluorescence property and turned bright green under UV excitation (488 nm). In addition, when the laser excitation was changed to 405 nm, a fluorescent blue color was observed. A similar observation was obtained by Sahu et al.[8] in the case of orange juice-derived CNP. All of these preludes demonstrate that the FCDs obtained from spent rapeseed meal can serve as a potential substitute for organic dyes or semiconductor QDs in bioimaging applications.

Characterization of Rapeseed Protein Film, with (F1 and F2) or without (F0) Added FCDs. Having established the biocompatibility, we introduced the FCDs into a biopolymer matrix (rapeseed protein) in a pursuit to make fluorescent biopackaging material. One of the most important and difficult tasks in the incorporation of active compounds and new materials in a matrix is understanding if they will be miscible with the matrix and if they will not influence the processability and their structure.[42] In this study, the preliminary experiments allowed the determination of FCD concentrations that when added to the protein-based matrix do not affect significantly their appearance and processability (Supporting Information Supplementary section 3). Accordingly, composite films having 20 or 30 mg FCDs/100 mL of film-forming solution were prepared for further analyses.

On the basis of visual inspection, all of the examined films (F0, F1, and F2) showed similar homogeneity, transparency, and flexibility, with the exception of color. The color of the film changed from slightly yellow to dark brown-yellow when FCDs were added (Figure 6a−c). Generally, CNPs are blackish-

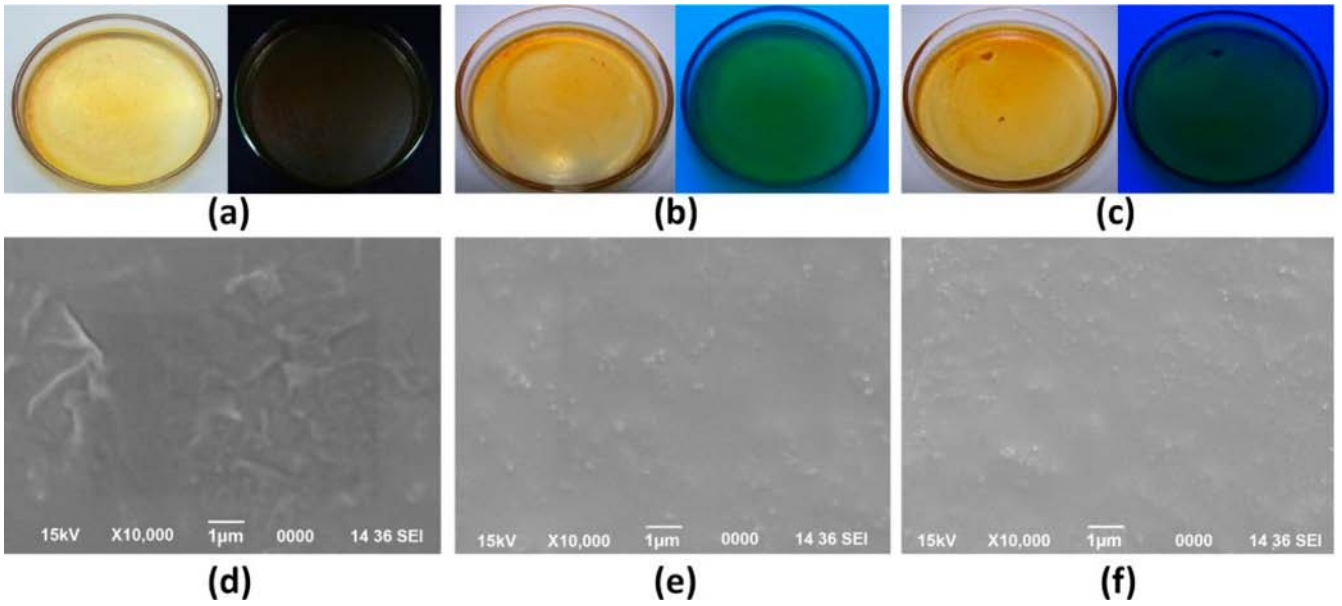

Figure 6. Photograph showing the pristine protein film and the nanocomposite films under normal light (on left) and UV light (on right) (F0 (a), F1 (b), F2 (c)) and their corresponding SEM images (F0 (d), F1 (e), F2 (f)).

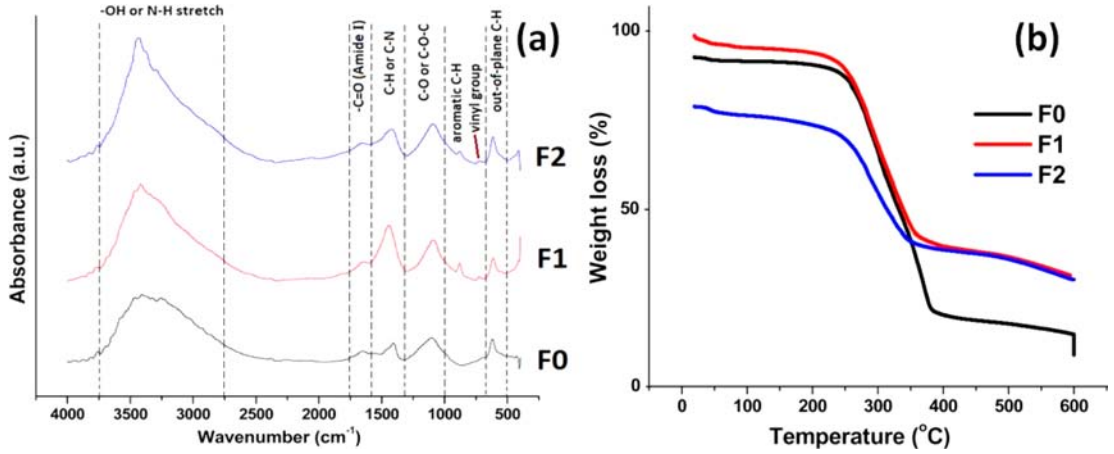

Figure 7. (a) FTIR spectra and (b) TGA curves of F0, F1, and F2.

brown, which might be the cause for dark coloration. As anticipated, F0 did not show any green glow under UV light, whereas under the same condition, F1 and F2 appeared as intense green-light-emitting films. From this it is clear that a homogeneous dispersion of the nanocomponent in the film matrix is obtained, without the presence of any visible green-colored fluorescent patches or clusters. Thus, we were successful in fabricating fluorescent glowing edible films based on the luminescent C-dots, which is envisioned to be used in forgery-proof packaging. It is expected that such packaging would benefit consumers, industry stakeholders, and food regulators. At this point, one of the objectives in this work was accomplished, and the comparative study of the physicochemical properties of these films was undertaken.

SEM was used to characterize the topography and morphology of the films (Figure 6d–f). The microstructure of F0 presented rough ridge-like protrusions on the surface, typical of protein films, as has been also reported for films prepared with soy protein,[43] rapeseed protein,[21] and pumpkin seed protein.[19] Surprisingly, F1 and F2 did not show any such ridge structures; rather, a good distribution of the additive (FCDs) in the matrix was found. FCDs appeared to be embedded on the polymeric matrix and exhibited a heterogeneous size distribution most likely due to some agglomeration. Such problems of agglomeration of nanomaterials in composite films have often been reported.[44] Agglomeration usually occurs when a relatively high loading of the nanomaterial is added to the matrix, as is the case here. Apparently, such tiny clustering did not affect the green fluorescence of the films.

The effect of the addition of FCDs into protein film was initially evaluated by FTIR. When different compounds are mixed, physical bonds and chemical interactions are reflected by changes in characteristic spectral peaks.[42] FTIR spectra of F0, F1, and F2 are shown in Figure 7a. The main broad peaks are maintained, the spectra of the films with FCDs being similar to that of the control. Special mention should be made of the peaks between 3500 and 3000 cm^{-1}, corresponding to the hydroxyl groups or hydrogen bonds or to the N–H group, that are weaker in F0 when compared to F1 or F2. This stretch appeared to be more recognizable with increasing FCD concentration. This indicates higher amounts of O–H or N–

dx.doi.org/10.1021/jf500138f | J. Agric. Food Chem. 2014, 62, 4509–4520

H groups in F1 and F2 than in F0. Derived from this fact, it is feasible to believe that FCDs, with hydrophilic surface moieties, may form hydrogen bonding between themselves or with amino groups of protein, especially when the protein is partially unfolded (denatured) during heating of a film-forming solution. This might be one of the possible reasons that F1 and F2 had more compact, uniform, and homogeneous surface morphologies compared to F0, as viewed under SEM (Figure 6d–f), mainly due to high compatibility of FCDs in the protein matrix. Addition of FCDs led to the emergence of a few new peaks in the region of 717–727 cm^{-1} (ascribable to out-of-plane C–H bending in aromatic substitution) and 878–881 cm^{-1} (correlating to the presence of vinyl groups). Moreover, in F1 and F2, the intensity of C–H or C–N stretching at 1400–1450 cm^{-1} increased and seemed to be more distinguishable than that in F0. All of these facets signify the possibility of new interactions and cross-links between FCDs and polymeric matrix.

The thermal stability of the composite films was tested by TGA. The thermograms in Figure 7b show that all of the film samples follow a similar degradation pattern, indicating uniform dispersion and high interactions of FCDs with the film (polymer) matrix.[45] Surprisingly, in all three samples, no significant mass loss was noted up to ∼260 °C, beyond which decomposition of glycerol and protein occurred.[18] The char yield is the nonvolatile carbonaceous material generated on pyrolysis, which is indicated by the residual weight after the decomposition step. It is worth mentioning that the increase of the residual yield (the char) with the increase of FCD concentration was detected, which points to the thermo-insulating nature of the C-dots as a nanofiller for the polymer matrix, a property similar to that of carbon nanotubes.[46] After degradation, the net weight loss of F0 was found to be ∼80.58%, whereas those of F1 and F2 were ∼59.73 and ∼45.65%, respectively. Thus, with the increase in FCD content, significant ($p < 0.05$) reduction in weight loss was observed, thereby proving FCDs as potent thermo-insulators for proteinaceous films, a desirous property for high-temperature processing.

Adding FCDs to the film matrix had little or no influence on film thickness ($p > 0.05$) (Table 1). This might be due to their small size. Although the same amount of film-forming solution was used, the slightly higher thickness of F0 may be due to its ridges-like rough outgrowths on its surface, as seen under SEM. The presence of FCDs led to an increase of water affinity of edible films, showing that moisture content increases in F1 and F2 significantly ($p < 0.05$) as compared to F0 (Table 1). This may be due to the hydrophilic behavior of the –OH groups in FCDs, which probably influenced WVP, increasing the adsorption of water molecules[42] in FCD-incorporated films when compared with F0. As a consequence, the water vapor barrier property of F1 and F2 is less than that of F0 (Table 1). The opposite behavior was observed for O_2 permeability, leading to a significant decrease ($p < 0.05$) of the values for FCD-containing films when these were compared with F0. Usually it is perceived that higher WVP would render higher O_2 permeability;[42] however, in this case, the radical scavenging functional groups of FCDs probably created additional sites in the film favoring the removal of oxygen, thereby minimizing the influence of adsorbed moisture in the film's transport properties. Thus, the oxygen barrier property is improved due to the presence of FCDs.

Table 1. Physicochemical Properties of Pristine Protein (F0) and Nanocomposite Films (F1 and F2)[a]

property	F0	F1	F2
thickness (μm)	54.1 ± 0.2a	48.8 ± 0.15a	49.7 ± 0.09a
moisture content (% dry basis)	28.26 ± 1.64a	35.84 ± 1.09b	36.91 ± 1.38c
WVP (ng m/m^2 s Pa)	1.43 ± 0.62a	2.47 ± 1.56b	2.85 ± 1.42b
oxygen permeability (ng day^{-1} Pa^{-1} m^{-1})	8.6 ± 0.3a	4.7 ± 0.2b	2.9 ± 0.2c
tensile strength, TS (MPa)	3.55 ± 0.51a	2.10 ± 1.78b	2.12 ± 1.15b
puncture strength, PS (N)	1.18 ± 0.03a	0.87 ± 0.01b	0.53 ± 0.09c
elongation at break, EB (%)	9.64 ± 0.02a	17.78 ± 0.69b	16.09 ± 1.03b
Hunter *L*	81.00 ± 0.13a	78.17 ± 0.16b	77.24 ± 0.09b
Hunter *a*	0.34 ± 0.01a	1.24 ± 0.03b	1.58 ± 0.05c
Hunter *b*	11.98 ± 0.12a	10.92 ± 0.07b	8.60 ± 0.04c
opacity	2.39 ± 0.17a	2.45 ± 0.13b	2.56 ± 0.02b
DPPH scavenging activity (%)	3.72 ± 1.61a	64.91 ± 2.83b	71.73 ± 4.01c

[a]Results are the mean ± standard deviation of three replicates. Values followed by same letter within a row are not significantly different ($p > 0.05$).

TS, PS, and EB of a material are used to study their resistance to tensile stress, to determine the breaking force, and to express the percentage of increase in length that occurs before the sample breaks (i.e., film's ability to stretch), respectively. The presence of FCDs in F1 and F2 influences their mechanical properties, decreasing the values of TS and PS ($p < 0.05$); on the other hand, an increase of EB values was observed. The reason behind the decreases in TS and PS by the addition of FCDs was the hydrophilic nature of C-dots, which favors the interaction with water molecules,[42] as explained by the higher moisture content of the films. Due to its small size, FCDs fit easily into the polymer chains. Due to the hydrophilic groups of FCDs (especially –OH), it is likely to be strongly bonded by hydrogen bridges with glycerol and protein molecules especially at amine, amide, carboxyl, and hydroxyl sites.[47] As a result, protein–protein interaction decreases and polymer segmental mobility increases (flexibility or EB enhances).

Good optical properties of film are extremely important in food packaging for ensuring that consumers can clearly see the food product. The darkness of the FCD-loaded films was significantly higher ($p < 0.05$), as evidenced by the lower Hunter *L* values compared to the control. Meanwhile, in comparison with F0, increase in FCD concentration increased Hunter *a* (indicator of the tendency toward redness) and decreased Hunter *b* (indicator of the reduction of yellowness) values. F0 was more transparent (lower opacity value) than F1 and F2 (Table 1). The opacity of the film samples significantly increased ($p < 0.05$) with increasing FCD concentration. This observation could be explained by the fact that a higher amount of added FCDs hinders light passage through the film. This result accords with several published studies in which addition of antioxidants, polyphenols, plant extracts, or other additives to film matrices has been found to affect the optical properties severely.

As the level of FCDs increased in the film formulation, so did the expected antioxidant character of the composite film (Table 1). In relation to F0, the DPPH scavenging activity increased by 17.5- and 19.3-fold in F1 and F2, respectively. F0 also showed

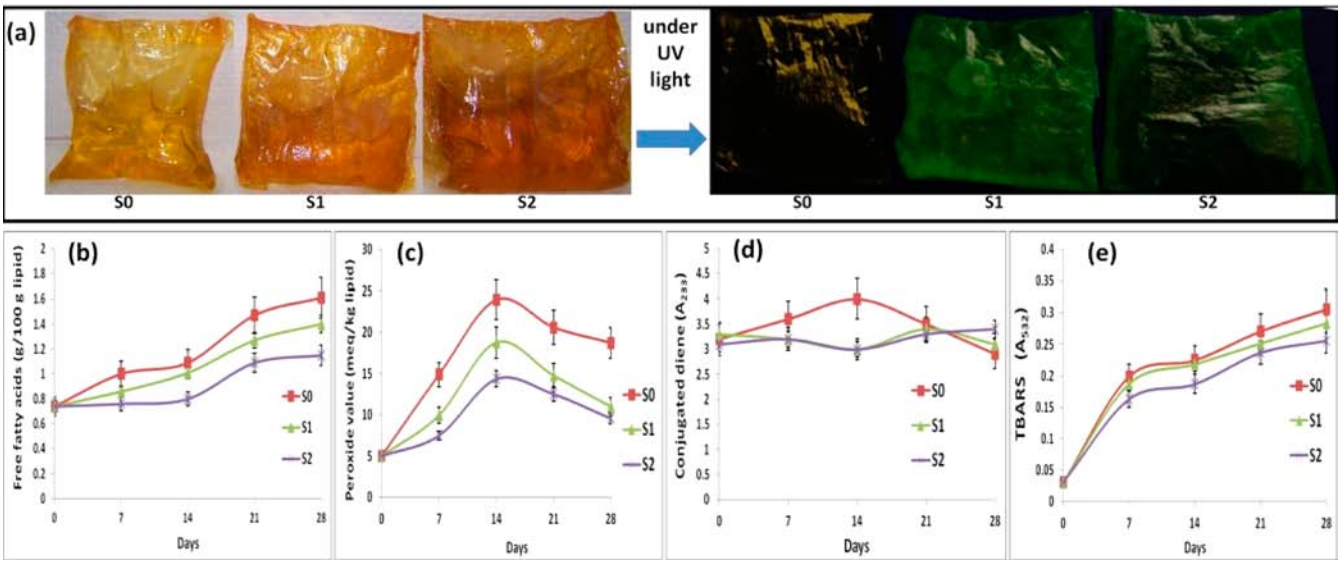

Figure 8. (a) Oil sample packed in F0, F1, and F2, as viewed under normal white light and UV light; changes in (b) free fatty acids (FFA), (c) peroxide value (PV), (d) conjugated dienes (CD), and (e) TBARS values of S0, S1, and S2 during storage.

some scavenging activity on DPPH. This is related to the fact that free radicals can react with the residual free amino ($-NH_2$) groups to form stable macromolecular radicals, and the $-NH_2$ groups can form ammonium (NH_3^+) groups by absorbing a hydrogen ion from the solution.[26] It should be noted that although a high amount of FCDs was incorporated into the film, the FCDs in the protein film showed much lower antioxidant capacity than in the free form (aqueous dispersion) at much lower concentration (Figure 3e). This could be due to interaction between FCDs and the film matrix formed via hydrogen bonds and other cross-links, thereby reducing the availability of free structural factors such as hydroxyl, keto, and carboxylic groups,[48] which imparts a scavenging feature to FCDs.

Oxidative Stability Analyses of Rapeseed Oil Packed in Nanocomposite Films. On the basis of the above results, it was presumed that the use of FCD-incorporated composite packaging could be helpful in improving the oxidative shelf life of lipid food items during storage. As such, rapeseed oil, packed in small pouches made of either nanocomposite films (F1 and F2) or pristine protein film (F0), was monitored over time to assess the antioxidative effect of these films on a real food system. The samples packaged in nanocomposite film (S1 and S2) can easily be segregated from the control (S0) under UV light, on the basis of the inherent green luminescence of C-dots (Figure 8a). To consider the complexity of the lipid oxidation process, both the primary and secondary oxidation products have been assessed.

Within the first 14 days of storage, FFA content increased perpetually in both S0 and S1 ($p < 0.05$); however, S2 showed negligible changes as compared to day 0 ($p > 0.05$) (Figure 8b). Subsequently, a gradual increase was found up to 21 days, and the highest FFA value was obtained on day 28. Possibly, lipid hydrolysis, catalyzed by lipases, occurred to a greater extent at the end of the storage period. On day 28, the respective FFA values of S1 and S2 were ~1.2- and ~1.4-fold less than that of S0. A small amount of FFA is usually noticeable in cold-pressed oil due to the release of enzymes from crushed seeds along with the oil. Alternatively, the accumulation of FFA could be attributable to the lipases from micro-organisms, which was probably enhanced with extended storage.[31]

Unsaturated fatty acids react with molecular oxygen, usually via a free radical mechanism, to form hydroperoxides, the primary oxidation products.[49] A marked increase in PV was observed in all of the tested samples for up to 14 days ($p < 0.05$) (Figure 8c). Thereafter, a decrease in PV was noticeable with extended storage ($p < 0.05$), which was presumed to be due to degradation of hydroperoxides, yielding a wide variety of secondary decomposition products including aldehydes. On day 28, the PV of S0 was almost 2 times higher than those of S1 and S2, which indicates the higher deterioration rate of S0 compared to the other samples.

During oxidation of PUFAs containing methylene-substituted dienes and polyenes, there is a shift in the position of the double bond due to isomerization and conjugate bond formation (conjugated dienes).[32] This is accompanied by increased UV absorption at 233 nm. It is an indicator of autoxidation and is reported to increase with uptake of oxygen and formation of peroxides, during the early stages of oxidation. Chaijan et al.[31] reported that almost immediately after peroxides are formed, the nonconjugated double bonds (C═C−C—C═C) that are present in natural unsaturated lipids are converted to conjugated double bonds (C═C−C═C). Thus, conjugated dienes are the primary oxidation products formed. A_{233} of S0 increased slightly up to 14 days of storage, after which its value showed a decreasing trend (Figure 8d). S1 and S2 exhibited similar profiles up to 21 days. From day 21 onward, A_{233} of S1 decreased and that of S2 continued to increase, until the end of the storage period ($p < 0.05$). This decrease probably occurred because of their decomposition into secondary oxidation products.

Secondary lipid oxidation was studied by the TBARS value. Traditionally, the absorbance at 532 nm of the pink pigment formed in the reaction is measured. In all of the samples, the TBARS value increased sharply throughout the storage ($p < 0.05$) (Figure 8e). The marked increase in TBARS during 14−28 days of storage was coincidental with the decrease in PV (Figure 8c). This was probably due to the destruction of hydroperoxides into relatively polar secondary products,

dx.doi.org/10.1021/jf500138f | J. Agric. Food Chem. 2014, 62, 4509−4520

especially aldehydes in the later stages of lipid oxidation. It was most likely that a higher rate of lipid oxidation might be taking place at the end of the storage period (days 14−28). Additionally, the loss in natural antioxidants (such as tocopherol, polyphenols, etc.) of rapeseed oil during extended storage might contribute to the increased lipid oxidation.

On the basis of the available data, it can be interpreted that the antioxidative FCDs in F1 and F2 retarded the lipid oxidation rate in S1 and S2 by quenching the free radicals. The formation of free radicals, which precedes lipid hydroperoxides, is the initial step in lipid oxidation.[34] Abstraction of hydrogen atoms from allylic carbon atoms in unsaturated lipids generates a lipid radical, which in turn has the potential to initiate the chain reactions of the autoxidation cycle.[49] The cycle is terminated either through a recombination of two radicals or by a reaction of the radical with antioxidant, leading to the formation of more stable radicals. The chain-breaking antioxidant, therefore, interrupts the oxidation chain reaction to enhance stability. Thus, FCD-incorporated packaging materials showed a profound impact on the oxidative shelf life of lipid product. Further studies need to be undertaken to improve the antioxidative and antimicrobial properties of these composite films.

From this work it is concluded that high-value CNP can be easily synthesized from spent rapeseed meal by a simple green hydrothermal route. The obtained NP was found to be multifunctional, such as water solubility, high reductive potential, photoluminescence, and biocompatibility. This is due to the rich functionalities attached to the nanocarbons. The literature enumerates biopolymer-based films as good vehicles for the incorporation of active compounds; however, inclusion of fluorescent carbon nanostructures has rarely been evaluated. The present investigation shows the incorporation of FCDs into rapeseed protein film matrix, which adds new features to the film, for instance, photoluminescence, enhancement in antioxidant potential, and thermal stability. Moreover, oil samples packed in sachets made of FCD−protein composite film are able to resist oxidation better than those stored in pristine protein-based sachets. The work opens up new possibilities for agricultural residues as a valuable precursor of useful nanomaterials and can subsequently give rise to a new concept of biobased edible fluorescent food packaging, suggesting new scalable and simple approaches to improve environmental sustainability in industrial processes. Further studies should be undertaken to analyze the release behavior of FCDs from the film into different food model systems, their effect on organoleptic properties and the gastrointestinal tract, and toxicological assessment using in vitro and in vivo models.

Synthesis of Rotenone-*O*-monosaccharide Derivatives and Their Phloem Mobility

Pei-Wen Qin,[†,‡,§] Jie Wang,[†,‡,§] Hao Wang,[†,‡] Ying-Jie Wen,[†,‡] Meng-Ling Lu,[†,‡] Yu-Feng Li,[†,‡] Yue-Shuo Xu,[†,‡] and Han-Hong Xu*[,†,‡]

ABSTRACT: Six monosaccharide derivatives of rotenone were designed and synthesized to assess whether rotenone could become phloem mobile by the addition of a monosaccharide group. Phloem mobility experiments showed that only D-glucose conjugates exhibit phloem transport properties in castor bean (*Ricinus communis* L.) seedlings. Two D-glucose conjugates, 2-*O*-*β*-D-glucopyranosyldemethylrotenone and 6′-*O*-*β*-D-glucopyranosyldalpanol, had significantly obtained systemicity compared with that of rotenone, and 6′-*O*-*β*-D-glucopyranosyldalpanol was more mobile than 2-*O*-*β*-D-glucopyranosyldemethylrotenone. Coupling with a monosaccharide core is a reasonable method for conferring phloem mobility on insecticides, but phloem mobility is also affected by the parent molecule and the position of the monosaccharide.

KEYWORDS: *rotenone, monosaccharide, glycosylation reaction, phloem-mobility*

INTRODUCTION

Phloem-mobile insecticides are both economical and efficient,[1−3] but there are only a few phloem systemic insecticides obtained because the development of new pesticides with that systemicity is often expensive and complicated. Two strategies have been adopted for conferring phloem mobility to nonsystemic insecticides. One strategy consists of introducing a carboxyl group to a nonsystemic pesticide. For example, after conjugating oxamyl with glucuronic acid, the oxamyl derivative exhibits an improved phloem mobility higher than that of the parent compound in transgenic tobacco.[4] The other strategy is using the endogenous plant transporters to confer phloem mobility on nonphloem-mobile insecticides or to confer a phloem mobility different from that of the parent compound.[5−7]

In plants, sugar-transport proteins play a key role not only in long-distance transportation but also in cell-to-cell distribution of sugars throughout the plant.[8] Recently, researchers found that a plant hexose-transporter bound in plasmalemma was involved in the transportation of the 2-deoxyglucose-NBD conjugate in *E. coli*.[9] Moreover, we have reported the synthesis of a novel fipronil-glucose conjugate (GTF) and demonstrated that linking glucose can change fipronil into a phloem systemicity type, which was mediated by monosaccharide transporters.[2,10] In addition, 10 kinds of fipronil-monosaccharide derivatives were synthesized in our previous work (Figure 1).[11] Most of these derivatives have been verified as having phloem systemicity. These studies revealed that conjugating glucose or another monosaccharide can confer phloem mobility on a nonphloem-mobile insecticide.

It remains to investigate whether any nonmobile insecticide can be converted into a phloem-mobile one by the coupling of a glucose group or other monosaccharide in the same manner as that done to fipronil. Therefore, this study focuses on rotenone, a natural product of the isoflavone family and a botanical insecticide obtained from the root extracts of some leguminous plants such as *Derris* and *Lonchocarpus*.[12−15] Rotenone was linked with five kinds of monosaccharides (glucose, galactose, mannose, xylose, and arabinose) to obtain

six rotenone-glucosides linked with an *O*-glycosidic bond, including a natural product, dalpanol-*O*-glucoside.[16] Their phloem mobilities were tested in a *Ricinus* system.

MATERIALS AND METHODS

General Methods. TLC was taken on a silica gel plate (GF_{254}, Qingdao, China). Silica gel (200−300 mesh) was used for flash column chromatography. The ^1H and ^{13}C NMR spectra were provided by a Bruker AVANCE III 600 (Brunker Corporation, Switzerland) spectrometer with tetramethylsilane (TMS) as the internal standard, and chemical shifts were recorded. The mass spectrographic analysis was recorded on a Waters ZQ4000 (Waters, MA, USA) with electron-spray ionization.

Materials. The seeds of castor bean No. 9, provided by the Agricultural Science Academy of Zibo (Zibo, China), and the cultivation of seedlings were followed by a previous method.[17] Then, six day-old seedlings (the hypocotyl was about 20 mm length) were selected for further experiments.

General procedure for the Preparation of Compounds (2a−2f). Trichloroacetimidate donors[18] (Figure 2), 2-de-*O*-methylrotenone[19,20] and dalpanol[21] (Figure 1) were synthesized as previously described.

The trichloroacetimidate donor (1.2 mmol), activated 4 Å molecular sieve, and 2-de-*O*-methylrotenone (1 mmol), or dalpanol (1 mmol) were added in anhydrous CH_2Cl_2 (10 mL) under nitrogen atmosphere. The mixtures were carried out at 25 °C for 0.5 h, then cooled to −30 °C. Next, boron trifluoride etherate ($BF_3{\cdot}OEt_2$, 0.05 mL) was injected into the solution containing 2-de-*O*-methylrotenone to produce compounds **2a**−**2e** (Scheme 1). Trimethylsilyl trifluoromethanesulfonate (TMSOTf, 0.05 mL) was injected to the solution containing dalpanol to produce compound **2f** (Scheme 2). The mixtures were kept in this condition for 4 h and stirred another 1 h at 25 °C. After filtering the suspension, the filtrate was collected and

dried in vacuo, followed by chromatography (chloroform−methanol, 99:1) to produce compounds **2a−2f** as solids.

*6′-O-(2,3,4,6-Tetra-O-acetyl)-β-D-glucopyranosyldalpanol (**2f**).* White solid; yield 87%. ^{1}H NMR ($CDCl_3$) δ: 7.77 (d, J = 8.4 Hz, 1H), 6.72 (s, 1H), 6.42 (s, 1H), 6.41 (d, J = 9.0 Hz, 1H), 5.16 (t, J = 9.6 Hz, 1H), 4.98 (t, J = 9.6 Hz, 1H), 4.92−4.88 (m, 2H), 4.76 (d, J = 7.8 Hz, 1H), 4.66 (t, J = 9.0 Hz, 1H), 4.58 (dd, J = 12.0, 2.4 Hz, 1H), 4.17 (dd, J = 12.0, 10.0 Hz, 1H), 4.15 (d, J = 12.0 Hz, 1H), 4.09 (dd, J = 12.0, 2.4 Hz, 1H), 3.81 (d, J = 3.6 Hz, 1H), 3.77 (s, 3H), 3.72 (s, 3H), 3.67 (ddd, J = 9.6, 6.0, 2.4 Hz, 1H), 3.07 (d, J = 9.0 Hz, 2H), 2.00, 1.99, 1.95, and 1.80 (both s, 3H, Ac), 1.28 (s, 3H), 1.27(s, 3H). ^{13}C NMR ($CDCl_3$) δ: 189.20, 170.75, 170.44, 169.67, 169.22, 167.42, 158.08, 149.69, 147.63, 144.03, 129.97, 113.61, 113.54, 110.55, 104.95, 104.82, 101.14, 95.83, 90.62, 78.62, 73.08, 72.38, 71.83, 71.55, 68.97, 66.46, 62.53, 56.53, 56.05, 44.80, 27.52, 24.09, 21.43, 20.83, 20.79(2C) 20.56. EI-MS, m/z: 743.7 $[M + 1]^+$, 765.7 $[M + Na]^+$.

General Procedure for the Preparation of Title Compounds (3a−3f). The solid (**2a−2f**, 1 mmol) in a mixture of acetyl chloride (0.1 mL) in anhydrous methanol (10 mL) was left to stand for 4 h at 25 °C, then concentrated to dryness at 25 °C (Schemes 1 and 2). The solid was chromatographed on a silica gel column (chloroform−methanol, 15:1), and after removing solvents and washing with cooled methanol, the desired products **3a−3f** were obtained.

*2-O-β-D-Glucopyranosyldemethylrotenone (**3a**).* White solid; yield 37%. ^{1}H NMR (DMSO) δ: 7.71 (d, J = 8.4 Hz, 1H), 6.82 (s, 1H), 6.57 (d, J = 8.4 Hz, 1H), 6.51 (s, 1H), 5.33 (t, J = 9.0 Hz, 1H), 5.15−5.14 (m, 1H), 5.12 (d, J = 5.4 Hz, 1H), 5.05−5.02 (m, 2H), 4.94 (d, J = 5.4 Hz, 1H), 4.92 (s, 1H), 4.51 (dd, J = 12.0, 3.0 Hz, 1H), 4.51 (d, J = 7.8 Hz, 1H, G_1H), 4.41 (t, J = 5.4 Hz, 1H), 4.24 (d, J = 12.0 Hz, 1H), 3.92 (d, J = 3.6 Hz, 1H), 3.70 (s, 3H), 3.66−3.62 (m, 1H), 3.53 (m, 1H), 3.27 (dd, J = 15.6, 9.6 Hz, 1H), 3.23−3.13 (m, 3H), 3.08−3.05 (m, 1H), 2.88 (dd, J = 15.6, 7.8 Hz, 1H), 1.71 (s, 3H). ^{13}C NMR (DMSO) δ: 188.60, 166.51, 157.58, 149.78, 148.51, 143.12, 140.71, 129.25, 115.01, 113.18, 112.78, 112.36, 105.49, 104.34, 101.59, 101.54, 87.18, 76.93, 76.85, 73.15, 71.69, 69.31, 65.76, 60.32, 55.78, 43.54, 30.52, 16.91. Figure 5. Membrane potential of protoplasts treated with conjugates **3a**−**3f** at 6 h. (A) Fluorescent intensity histogram. (B) Mean relative fluorescence. Protoplasts in buffer (pH 5.8) with conjugates **3a**−**3f** and rotenone (100 μM) were suspended for 6 h. Cont = control, without any treatment; Rot = rotenone. The letters on tops the columns show that there were not significant differences between treatment and the control by Duncan's multiple range test ($P > 0.05$). Mean ± SE; $n = 3$.

Table 1. Analysis of Phloem Sap

compds	incubation medium (μM)	phloem sap[a] (μM)	compds	incubation medium (μM)	phloem sap[b] (μM)
3a	100	4.90 ± 0.58	**4a**	100	23.0 ± 1.9
3b	100	ND	**4b**	100	ND
3c	100	ND	**4c**	100	7.6 ± 1.6
3d	100	ND	**4d**	100	21.8 ± 1.9
3e	100	ND	**4e**	100	15.3 ± 2.2
3f	100	14.71 ± 0.77			
rotenone	100	ND			

[a]The collection of phloem sap started from 2 h to the end of 6 h (mean ± SE; $n = 3$). ND represents not detected. [b]Data are from Yuan et al.,[11] and the phloem sap collection of monosaccharide-fipronil conjugates lasted for 2 h.

250 mm × 4.6 mm i.d.) was used at 25 °C for separation. The eluting solvent was composed of CH_3CN and H_2O (40/60, v/v). The method of standard curve was employed to determine the concentrations of 2-*O*-β-D-glucopyranosyldemethylrotenone (**3a**) and 6′-*O*-β-D-glucopyranosyldalpanol (**3f**). The linear equations of **3a** and **3f** were $y = 24.153x + 4.3533$ ($r = 0.9997$) and $y = 19.078x + 2.1597$ ($r = 0.9996$), respectively.

The conjugates **3a** of **3f** in phloem sap were identified by a previously reported method with some modifications.[10] The eluting solvent was composed of CH_3CN and H_2O (5/95, v/v, at 0.5 min; 80/20, v/v, at 3 min; and 5/95, v/v, at 4.5 min). The optimized parameters were as follows: capillary voltage, 300 kV; cone voltage, 35 V; desolvation temperatures, 350 °C; and source temperatures, 105 °C. At last, the molecule ion peaks of compounds **3a** and **3f** were determined as 541.7 and 573 (Figure 3), and those of the fragment ion peak were 379 and 393, respectively.

RESULTS AND DISCUSSION

Synthesis and Characterization. The trichloroacetimidate method[22] was adopted to couple monosaccharide with rotenone producing the conjugates **2a**−**2f** in yields of over 80%. A widely used catalyst, $BF_3{\cdot}OEt_2$, was used to prepare compounds **2a**−**2e**, but it was not efficient enough to obtain conjugate **2f** because the hydroxyl group of dalpanol is less active than that of 2-de-*O*-methylrotenone. Therefore, a more effective catalyst, TMSOTf, was introduced to the condensation of dalpanol with glucose, resulting in a yield of 87%. A classic reaction system of acetyl deprotection, NaOMe/MeOH, was attempted in the preparation of compounds **3a**−**3f**; however, it was unsuccessful because rotenone is unstable under strong alkaline conditions. Therefore, an unusual system, AcCl/MeOH, was used to prepare the desired products, with a yield of 23−37%. Finally, a series of rotenone-*O*-monosaccharide derivatives with *O*-glycosidic linkage (**3a**−**3f**, Figure 4) was obtained.

The structures of conjugates **2a**−**2f** and **3a**−**3f** were confirmed by mass spectrometry, ^1H and ^{13}C NMR. The characteristic signal of the acetyl groups could be observed in the ^1H and ^{13}C NMR spectra of compounds **2a**−**2f**. The ^1H NMR spectrum of conjugate **2a** showed signals of the acetyl groups at 2.14, 2.04, 2.03, and 2.01 ppm, and the ^{13}C NMR spectrum showed them at 171.09, 170.46, 169.62, 169.57, 20.98, 20.83, and 20.80 ppm. Compared with compounds **2a**−**2f**, there were no peaks corresponding to acetyl groups in the ^1H NMR and ^{13}C NMR spectra in compounds **3a**−**3f**. This demonstrates that the acetyl groups were totally removed in the desired products. The characteristic signal of G_1H was also confirmed in ^1H NMR spectra. For example, in compound **3a**, the signal of G_1H was observed at 4.51 ppm with $J = 7.8$ Hz, indicating that the glucosidic linkage is in the β configuration.

Phloem Mobility. Phloem mobility of conjugates **3a**−**3f** was measured using the castor bean system. The previously reported method[2] was used to measure the membrane potential of the protoplast after treatment with conjugates **3a**−**3f**. Each treatment was repeated three times, each repetetition was taken twice, and then the data were analyzed by the Duncan's multiple range test (Figure 5). Figure 5B indicates that there is no significant difference in relative fluorescence within the treatment period compared to that of the control. Consequently, they can be used to test their phloem mobility using the *Ricinus* system.

The detection results in Table 1 showed that only **3a** (4.90 ± 0.58 μM at 6h) and **3f** (14.71 ± 0.77 μM at 6 h) exhibited phloem mobility, whereas the other conjugates were not found

[a]The physicochemical properties of tested compounds were predicted by ACD Laboratories Perceptaprogram, version 14.0. log $K_{o/w}$ and pK_a values were classic values.

in the phloem sap. The mobility of **3f** was about three times that of **3a**, proving that the position of glucose coupling with rotenone significantly affected the phloem mobility of conjugates. Both **3a** and **3f** are D-glucose-rotenone conjugates, indicating that D-glucose is better as a substrate for conferring phloem mobility on rotenone than the other monosaccharides. However, in our previous work,[11] almost any kind of monosaccharide-fipronil conjugate exhibited phloem mobility. The wide discrepancy of phloem mobility between monosaccharide-fipronil and monosaccharide-rotenone suggests that the parent compound is involved in phloem mobility. Furthermore, fipronil is transported in the sunflower xylem,[23] while there are no reports of rotenone xylem mobility in any plant. Therefore, the results above demonstrate that phloem mobility can be acquired by a molecule by coupling it with a monosaccharide but that the extent of phloem mobility is affected by the parent molecule. Whether the influence of the parent molecule could be weakened by conjugating another monosaccharide needs further research.

"Rule of Five" was widely employed to predict whether the endogenous compounds or xenobiotics can cross membranes.[24−26] Given the physicochemical properties of tested compounds **3a−3f**, rotenone, and dalpanol in Table 2, the tested compounds are predicted to exhibit a very poor diffusion through the membranes. The Kleier model is widely utilized to predict the phloem mobility of a xenobiotic based on its physicochemical properties (pK_a and log $K_{o/w}$).[10,27] Most of the tested xenobiotics fit well, except for several xenobiotics whose transport is carrier-mediated.[5,27] Taking the physicochemical properties (pK_a and log $K_{o/w}$) of tested compounds into consideration (Table 2), compounds **3a−3f**, rotenone and dalpanol were predicted to be nonphloem mobile in terms of the Kleier Model (Figure 6). However, both **3a** and **3f** were demonstrated to be phloem mobile using the *Ricinus* system and therefore violate both this model (Figure 6) and "Rule of Five" (Table 2). The phloem mobility of some small xenobiotics were proved to involve active carrier processes, which can recognize and load these compounds into phloem sieve tubes.[28,29] Therefore, it is likely that an active carrier-mediated mechanism is also involved in glucose-rotenone conjugate uptake as well as in the systemicity of glucose-fipronil conjugates.[10] The carrier-mediated mechanisms of these large xenobiotics deserved further research.

In summary, six conjugates containing both rotenone or dalpanol and monosaccharide moieties were obtained. The tests of phloem systemicity demonstrate that conjugates with different monosaccharides have different phloem mobility and that only D-glucose-type conjugates exhibit phloem systemicity. By contrast, conjugating hexoses, pentoses, and deoxysugars to fipronil can confer phloem transport (Table 1).[11] The data suggest that this mobility is affected by the parent compound.

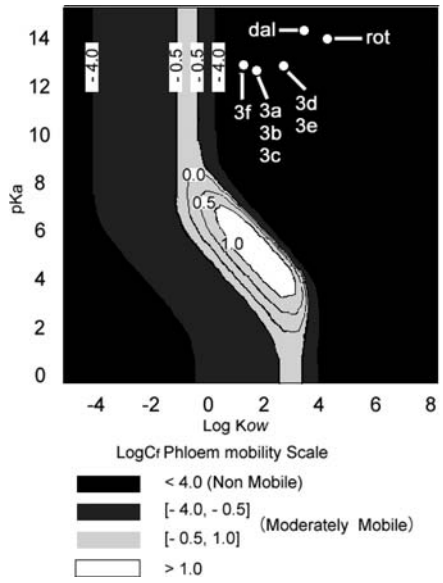

Figure 6. Prediction of phloem mobility of the tested compounds (**3a−3f**, rotenone and dalpanol) using the Kleier model.[30] Log $K_{o/w}$ and pK_a in Table 2. rot = rotenone; dal = dalpanol.

The current article offers examples of successful conversions of nonphloem-transport natural pesticide molecules into phloem-transport ones and presents useful data for developing novel insecticides with phloem mobility.

Characterization of the Key Aroma Compounds in Shiraz Wine by Quantitation, Aroma Reconstitution, and Omission Studies

Christine M. Mayr,[†] Jason P. Geue,[§] Helen E. Holt, Wes P. Pearson, David W. Jeffery,[‡] and I. Leigh Francis*

The Australian Wine Research Institute, P.O. Box 197, Glen Osmond (Adelaide), South Australia 5064, Australia

ABSTRACT: The key aroma compounds of premium Australian Shiraz wines from the warm Barossa Valley and cooler Margaret River regions were characterized. GC−Olfactometry was conducted to determine the most important volatile compounds, which were then quantitated. The wine from the Barossa Valley had higher concentrations of ethyl propanoate, dimethyl sulfide (DMS), and oak-derived compounds, whereas the Margaret River wine contained above threshold concentrations of the 'cheesy' compounds 2- and 3-methylbutanoic acid, as well as rotundone, the 'pepper'-smelling compound. The aromas were reconstituted by combining 44 aroma compounds, and sensory descriptive analysis was used to investigate the importance of the omission of several compounds, including DMS, rotundone, fatty acids, and β-damascenone, and the influence of nonvolatiles was also assessed. The study showed that the aroma of the Shiraz wines could be reconstituted in both cases, with the changes in the nonvolatile fraction having a large influence.

KEYWORDS: *Shiraz, wine, omission tests, aroma reconstitution, sensory descriptive analysis, nonvolatiles*

INTRODUCTION

Shiraz is one of the most important grape varieties in Australia and accounts for about 40% of all red wines made each year. This variety is also important to wines from several regions in France and is of growing significance worldwide. The flavor of Shiraz, also known as Syrah, is commonly described as 'spicy', 'dark fruit'- and 'berry'-like, with different styles produced depending on the region of origin and winemaking and viticultural decisions. Despite the importance of Shiraz to the world wine industry, little is known about the volatile compounds that are the key contributors to its aroma.

Of the >800 volatiles in wine,[1] only a relatively small number of specific key aroma active compounds have been identified by sensory analysis.[2,3] Guth was among the first who comprehensively determined the important flavor compounds in wine, studying the white wine varieties Scheurebe and Gewürztraminer and reconstituting their aroma.[4] The success of gas chromatography−olfactometry (GC-O), often using aroma extract dilution analysis (AEDA), coupled with careful quantitative analysis of the aroma active compounds and knowledge of aroma threshold values, has allowed significant advances in understanding of the often subtle differences in aroma between wine types. Performing a reconstitution study is an important step in modern flavor research, to confirm the identification and quantitation experiments and, therefore, to verify that all important compounds have been detected.[5] Subsequently, the key aroma compounds of another white wine (from Maccabeo) have been investigated in detail, alongside reconstitution experiments,[6] and the same group also conducted thorough studies on a Grenache rosé[7] as well as on red wine from Rioja.[8] Recently the key flavor and taste compounds of the red wine variety Dornfelder were decoded and a full reconstitution was successfully conducted.[9] For each of these studies reporting detailed and comprehensive examination of the key aroma compounds, a common finding has been that a relatively small number of yeast metabolism-derived fatty acid ethyl esters, acetate esters, fatty acids, alcohols, and the grape-derived norisoprenoid β-damascenone are of notable importance to wine aroma. For some individual wine types, the sulfur-containing compounds 3-mercaptohexanol, 3-mercaptohexyl acetate, and dimethyl sulfide, the monoterpenes *cis*-rose oxide and linalool, oak volatiles such as *cis*-oak lactone and vanillin, and the nitrogen-containing isobutylmethoxypyrazine can also have a strong influence on aroma.

Despite its importance for the wine industry, information on the aroma compounds of wines made from Shiraz grapes is very limited.[10] It is known that Shiraz wines do not contain an appreciable concentration of methoxypyrazines,[11] a characteristic that sets this variety apart from some other highly valued grape varieties such as Cabernet Sauvignon, Merlot, and Cabernet Franc, and some Shiraz wines can have sensorially important levels of rotundone, which gives a distinctive 'spicy'/'peppercorn' flavor.[12] To our knowledge no comprehensive characterization of Shiraz wine flavor has been conducted. The objective of this study was to determine the key aroma compounds of two ultrapremium (highly priced, high reputation for quality) Australian Shiraz wines, representative of two different styles: one from a relatively cooler climate in Western Australia and the other from a warmer grape-growing region in South Australia. Reconstitution studies were performed, and the reconstitutions were compared to the real wines by means of sensory descriptive analysis. In the sensory study the relative influence of the aroma compounds dimethyl sulfide, β-damascenone, linalool, and rotundone, as well as the

role of oak-derived compounds, fatty acids, and nonvolatiles, was investigated via omission experiments.

MATERIALS AND METHODS

Wine. Two ultrapremium commercial 2006 vintage Shiraz wines from Margaret River, Western Australia (AUD$40), and Barossa Valley, South Australia (AUD$80), were selected in 2010 following an informal blind tasting with expert technical staff of the AWRI with extensive wine assessment experience, where a range of potential wines of long-standing reputation were considered, and selected on the basis of having characteristic sensory properties expected of wines of their respective regions. The basic composition of the wines was as follows: Barossa Valley Shiraz, pH 3.50, titratable acidity (TA, as tartaric acid) 6.8 g/L, alcohol 14.6% v/v, glucose + fructose (G + F) 0.7 g/L, volatile acidity (VA, as acetic acid) 0.68 g/L, free SO_2 14 mg/L, total SO_2 64 mg/L; Margaret River Shiraz, pH 3.50, TA 6.3 g/L, alcohol 14.2% v/v, G + F 0.6 g/L, VA 0.51 g/L, free SO_2 22 mg/L, total SO_2 91 mg/L.

Chemicals. All chemicals were of analytical reagent grade unless otherwise stated, and water was obtained from a Milli-Q purification system (Millipore, North Ryde, NSW, Australia). Ethyl propanoate, ethyl 2-methylpropanoate, ethyl butanoate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, 2-methylpropyl acetate, 2-methylbutyl acetate, 3-methylbutyl acetate, 2-methyl-1-butanol, 3-methyl-1-butanol, ethyl hexanoate, hexyl acetate, ethyl lactate, 1-hexanol, propanoic acid, ethyl decanoate, ethyl dodecanoate, butanoic acid, 2-methylbutanoic acid, 3-methylbutanoic acid, 2-phenylethanol, decanoic acid, linalool, acetic acid, guaiacol, 4-ethylphenol, 5-methylfurfural, furfural, carbon disulfide, α-terpineol, β-damascenone, *cis*- and *trans*-oak lactone, vanillin, eugenol, sotolon, methionol, and methional were supplied by Sigma-Aldrich (Castle Hill, NSW, Australia). Ethyl acetate, 1-butanol, β-ionone, and 2-phenylethyl acetate were supplied by Merck (Kilsyth, Victoria, Australia). 2-Methyl-1-propanol was supplied by Riedel-de Haën (Seelze, Germany). Ethyl octanoate, hexanoic acid, and octanoic acid were supplied by Hopkin and Williams (London, UK). 4-Ethylguaiacol and dimethyl sulfide were supplied by Apin Chemicals (Abingdon, UK). Due to the difficulties of working with gaseous hydrogen sulfide and methanethiol, a suitable alternative employed the sodium salts of these analytes (sodium hydrosulfide hydrate, purity > 71%, and sodium thiomethoxide, purity > 96.4%, both supplied by Sigma-Aldrich), which were dissolved in cooled water and used immediately.

Basic Wine Composition. The basic chemical composition of all wines was determined by AWRI Commercial Services using methods as detailed in Iland et al.[13] TA, VA, pH, G + F, and alcohol were measured using FTIR WineScan (FOSS, Hillerød, Denmark).

Gas Chromatography−Olfactometry. GC-O was performed using an Agilent 6890 GC, equipped with a Gerstel MPS2 multipurpose sampler and coupled to an Agilent 5973N mass selective detector. The GC was also fitted with a Gerstel olfactory detection port (ODP series 1), and the flow was split between MS and ODP in a 1:1 ratio. The instrument was controlled with Agilent G1701DA ChemStation software with Maestro software integrated version 1.3.3.51/3.3. For GC analysis and GC-O DB-Wax and DB-5MS columns (both Agilent, dimensions of 60 m × 0.25 mm, 0.25 μm film) were used. The mass spectrometer quadrupole temperature was set at 150 °C, and the source was set at 230 °C. Positive ion electron impact spectra at 70 eV were recorded in the range of m/z 35−350. The carrier gas was helium (ultra high purity, BOC, Adelaide, Australia), and constant pressure mode set to 31.1 psi (nominal initial flow 2.1 mL/min) was used. For liquid injection, the samples (2 μL) were applied by splitless injection technique; the oven was held at 40 °C for 2 min and heated at 6 °C/min to 240 °C.

GC-O−Dynamic Headspace (Purge-Trap) Technique. Dynamic headspace analysis was used to analyze flavor compounds by means of GC-O as well as for identification by GC-MS. A 10 mL aliquot of wine was used in a 20 mL amber glass headspace vial, and the sample was equilibrated at 30 °C for 1 min. The volatiles were purged with helium for 20 min at 30 °C at a flow rate of 60 mL/min and 500 rpm agitation. A Tenax-TA trap was used, and its temperature was held at 30 °C during purging. After the sample purging was completed, the trap was dry-purged for 10 min at 50 mL/min to remove condensed water on the trap. The sample was then desorbed from the trap at 280 °C for 5 min to the splitless injection port using a Gerstel MPS2 multipurpose sampler of the gas chromatograph. Columns and temperature program were as described for the liquid injections.

Isolation of Volatiles for Liquid Injection. The volatiles were extracted from wine samples (500 mL) by liquid−liquid extraction with 3 × 250 mL of diethyl ether using a separation funnel and shaking vigorously for 10 min at room temperature. The combined organic phases were washed with brine and dried over anhydrous sodium sulfate. After filtration and concentration on a Vigreux column to approximately 200 mL, the volatiles were isolated by means of the solvent-assisted flavor evaporation technique (SAFE).[14] The SAFE extract was concentrated to about 1 mL at 40 °C using a Vigreaux column.

Identification of Volatiles and Aroma Extract Dilution Analysis. GC-O was conducted on the headspace samples as well as on the liquid extracts, and the odor active regions were evaluated by 15 (Margaret River wine) or 17 (Barossa Valley wine) panelists using both DB-Wax and DB-5MS columns. The wine headspace sample was then diluted stepwise (1:10) with 14% v/v aqueous ethanol/saturated potassium hydrogen tartrate, and each dilution was investigated by GC-O by three panelists using the DB-Wax column only. Identification was performed by comparing a compound's mass spectra, linear retention indices (LRI) using the n-alkane C_{5-30} series, and the odor quality with those of reference compounds.

Quantitation of Volatiles. The fermentation-derived volatile ethyl esters (ethyl acetate, ethyl lactate, ethyl hexanoate, ethyl octanoate, ethyl decanoate, ethyl 3-methylbutanoate, ethyl 2-methylbutanoate, ethyl butanoate, ethyl 2-methylpropanoate, ethyl propanoate), acetates (2-methylbutyl acetate, 3-methylbutyl acetate, 2-methylpropyl acetate, 2-phenylethyl acetate, hexyl acetate), acids (butanoic acid, hexanoic acid, octanoic acid, decanoic acid, 2-methylpropanoic acid, 2-methylbutanoic acid, 3-methylbutanoic acid), and alcohols (2-methyl-1-propanol, 1-butanol, 2-methy-1-lbutanol, 3-methyl-1-butanol, 1-hexanol) were quantitated as described previously.[15] The analysis of the monoterpenes linalool and α-terpineol was as described,[16] and the sesquiterpene rotundone was quantitated as described by Siebert et al.[17] The norisoprenoids β-damascenone and β-ionone were analyzed according to the method of Ugliano et al.[18] The low-molecular-weight sulfur compounds hydrogen sulfide, dimethyl sulfide, and methanethiol were determined as described by Siebert et al.[19] Quantitation of the volatiles acetic acid, 4-ethylguaiacol, guaiacol, 4-ethylphenol, 5-methylfurfural, furfural, *cis*- and *trans*-oak lactone, eugenol, and vanillin was according to the method of Pollnitz et al.[20] conducted by AWRI Commercial Services.

Sotolon, methionol, and methional were quantitated by means of stable isotope dilution assays as follows. After the addition of the respective labeled standard (synthesized in-house as described elsewhere, Mayr et al. in preparation) to wine samples (300 mL), the samples were equilibrated for 30 min and then extracted with diethyl ether (3 × 150 mL). The combined organic phases were washed with brine and finally dried over anhydrous sodium sulfate. After filtration and concentration on a Vigreaux column to 200 mL, the volatiles were isolated by SAFE. The SAFE extract was concentrated to about 1 mL at 40 °C using a Vigreaux column and analyzed by two-dimensional GC-MS using the following conditions. GC/GC-MS was performed using a gas chromatograph type Agilent 7890A, equipped with a Gerstel MPS2 XL multipurpose sampler and coupled to an Agilent 5975C mass selective detector (MSD). The instrument was controlled with Agilent G1701EA ChemStation software in conjunction with Gerstel Maestro software (version 1.4.8.14). For quantitation, a DB-5MS column and a DB-Wax column (both Agilent, dimensions of 30 m × 0.25 mm, 0.25 μm film) were used. Heart-cutting was performed by means of a Deans switch microfluidic plate with a flame ionization detector. The SAFE extracts were injected (2 μL) by splitless injection technique; the oven temperature was held at 40 °C for 2 min and heated at 6 °C/min to 240 °C. The carrier gas was helium (ultrahigh purity, BOC, Adelaide,

dx.doi.org/10.1021/jf405731v | J. Agric. Food Chem. 2014, 62, 4528−4536

Australia), in constant pressure mode with the 1D column head pressure at 46.5 psi and the 2D column at 34.95 psi. The Agilent GC split/splitless inlet was fitted with a resilanized borosilicate glass SPME inlet liner (Supelco) and was held at 250 °C. The MS transfer line was held at 250 °C. The cryotrap (Gerstel cryotrap system CTS2) was cooled to 0 °C with liquid N_2 and held at 0 °C as the 0.6 min heart-cut from the 1D column was transferred to the retention gap of the 2D column and while the oven was cooled to 130 °C, and then the cryotrap temperature was increased to 300 °C at 20 °C/s and held at 300 °C for 1 min.

Aroma Reconstitution. For sensory experiments the quantitated aroma compounds of the two wines were spiked into a winelike matrix according to their respective occurring concentrations. The model system of ethanol/water at the ethanol concentrations of the respective wines (14.2 and 14.6% v/v) was saturated with potassium hydrogen tartrate and adjusted to pH 3.50 using aqueous tartaric acid (40% w/v). To imitate more closely the nonvolatile matrix acids, fructose, glucose, glycerol, succinic acid, malic acid, lactic acid, sodium chloride, potassium hydrogen phosphate, and potassium thiosulfate were added, in the concentrations measured in the wines, as shown in Table 1. Organic acids were quantitated as published recently.[21]

Table 1. Major Organic Acid, Sugar, and Salt Concentrations in the Two Wine Samples

	concentration (g/L)	
compound	Barossa Valley Shiraz	Margaret River Shiraz
glycerol	12.4	8.8
glucose	nd[a]	0.18
fructose	0.59	0.25
lactic acid	1.6	1.9
succinic acid	3.9	5.2
NaCl	0.1	0.1
K_2HPO_4	1.0	1.0
$K_2S_2O_3$	0.02	0.02

[a]Not detected.

Sensory Descriptive Analysis. Eleven panelists were recruited (nine females, two males, ages 32−61 years), all of whom were part of the AWRI trained descriptive analysis panel. All panelists attended four training sessions to generate and refine appropriate aroma descriptors, their definitions, and reference standards, for rating in the formal sessions. The assessors rated 12 aroma attributes (shown in Table 2). The intensity of each aroma attribute was rated using an unstructured 15 cm line scale, with indented anchor points of "low" to "high" placed at 10 and 90%, respectively.

Samples were presented to panelists in 30 mL aliquots in three-digit-coded, covered, International Organization for Standardization black wine glasses at 22−24 °C, in isolated booths under daylight lighting, with randomized presentation order within each tray of samples across judges, except in the practice sessions, when there was a constant presentation order. In practice booth sessions the panelists assessed nine samples in duplicate, which were presented as six trays of three wines per tray. For both practice and formal testing sessions, assessors were forced to take a 60 s rest between samples. There was a 10 min rest between trays, during which assessors were requested to leave the booths. For the formal sensory sessions assessors were presented with six trays of three wines per tray each day for three days of assessment by aroma only. Eighteen samples were assessed each day in a complete randomized block design, presented to assessors three times on separate days. FIZZ software (version 2.46, Biosystemes, France) were used for the collection of all data.

Data Analysis. Sensory descriptive data for each attribute were analyzed using an analysis of variance (ANOVA) (JMP 7.0, SAS Institute, 2007) testing for the effects of sample, judge, replicate, and their interactions treating judge as a random effect, using sample by judge as the error term for the sample effect in a mixed model. Principal component analyses (PCAs) were conducted on the mean values averaged over panelists and replicates, using the correlation matrix. PCA was conducted using The Unscrambler software (CAMO Inc., Oslo, Norway).

Table 2. Aroma Descriptors and Definitions Used in the Sensory Analysis

attribute	description (reference standard composition[a])
overall fruit	overall intensity of fruit aroma of the wine
red fruit	aroma of red fruit (3 fresh raspberries, Sara Lee)
dark fruit	aroma of dark fruit (1 fresh blueberry, 2 fresh blackberries, Sara Lee)
oaky	aroma of oak (1 tsp French oak wood shavings)
smoky/ bacon	aroma of smoke, bacon (5 drops, Liquid Smoke hickory flavor)
chocolate	aroma of dark chocolate (1/3 of a square 70% cocoa chocolate, Lindt & Sprüngli)
pepper	aroma of black pepper, peppercorns (1/5 tsp freshly ground black pepper)
cooked vegetable	aroma of cooked/tinned vegetables, vegetable water (1/2 tsp water from canned green beans)
plastic	aroma of plastic, glue (4 μg/L 2,6-dichlorophenol)
green	aroma of green wood, pine, grass (freshly cut pine wood, 4 cm × 1 cm, 10 × 1 cm piece cut grass, no wine)
spices	aroma of sweet spices (equal parts aniseed, cinnamon, cloves, mixed spice; total 1/5 tsp)
nail polish remover	aroma of solvent, nail polish remover (150 μg/L ethyl acetate)
geranium	aroma of geranium (3 × 3 cm piece geranium leaf)

[a]All standards made up in 30 mL of neutral dry red wine unless otherwise stated. tsp, teaspoon.

RESULTS AND DISCUSSION

Identification and Quantitative Analysis. Aroma compounds in the concentrated liquid extracts as well as the headspace of both wines were analyzed by GC-O. Table 3 shows data from the dynamic headspace analysis. Odor active regions that could be detected in diluted samples were further identified by their mass spectra, retention time, and odor quality in comparison to reference compounds. Approximately 100 odorants could be detected, but those for which <20% of assessors reported an aroma are not listed in Table 3. Comparison of the identification by the assessors of odor active compounds in the two different wines, as indicated by GC-O, showed only slight differences and almost all identified compounds could be detected in both wines, with exception of hexyl acetate, methionol, 2,3-butanediol, 5-methylfurfural, α-terpineol, 2-phenylethyl acetate, and ethyl 4-methylpentanoate. To gain insight into the aroma differences of the two Shiraz wines, 48 of the most important compounds, from the GC-O data of the two GC column types and also evaluation of the liquid extract GC-O data (data not shown), were quantitated and the odor activity values (OAVs) were calculated by dividing actual concentrations with the published odor detection threshold concentration. Table 4 shows the concentration levels, odor thresholds in wine or model wine, and the resulting OAVs of both wines.

Of the 48 quantitated compounds, in the Barossa Valley Shiraz 28 compounds were found with an OAV >1, whereas in the Shiraz from Margaret River 27 compounds reached concentrations higher than their odor threshold. As expected, the highest concentrations in both wines were found for acetic acid (680 mg/L for BV and 510 mg/L for MR), followed by ethyl lactate (366 mg/L for BV and 247 mg/L for MR) and ethyl acetate (164 mg/L for BV and 103 mg/L for MR). fermentation alcohols 2- and 3-methylbutanol, 2-methylpropanol, and 2-phenylethanol were found in concentrations in the milligrams per liter range, and in the Shiraz from Margaret River those compounds were at a higher concentration. As the odor thresholds of those compounds are between 14 and 65 mg/L, the high concentration in which they occur does not necessarily reflect their importance for the overall flavor. Taking the odor threshold into account, the highest OAV in the Shiraz from the Barossa Valley was determined for the fruity-smelling ethyl octanoate, which was 76 times the threshold concentration, followed by β-damascenone (OAV 44), which has an apple-like aroma. The fruity esters 3-methylbutyl acetate (OAV 17), ethyl hexanoate (OAV 26), and ethyl 3-methylbutanoate (OAV 18) also had high OAVs and are therefore important contributors to the overall flavor. Phenolic compounds, such as the primarily oak-derived compounds guaiacol (OAV 1.5), vanillin (OAV 1.5), and eugenol (OAV 6.8), were also found in concentrations above their threshold.

The compounds with the highest OAVs in the Shiraz from Margaret River were similar to those of the Barossa Valley Shiraz. Ethyl octanoate (OAV 88) had the highest odor activity value, followed by the other esters including ethyl hexanoate (OAV 28), ethyl propanoate (OAV 24), ethyl 3-methylbutanoate (OAV 33), and β-damascenone (OAV 24). The BV Shiraz was much higher in the concentration of ethyl propanoate. Considering other acetate esters and ethyl esters, which are important for fruity characters,[22,23] there were no significant concentration differences between the two Shiraz wines. Unlike the BV Shiraz, in the wine from Margaret River the 'cheesy', 'sweaty'-like isomers 2- and 3-methylbutanoic acid were found with high OAVs around 28. The Barossa Valley wine was higher in oak-derived compounds such as *cis*-oak lactone and eugenol and notably higher in dimethyl sulfide. The sesquiterpene rotundone, which was reported to be responsible for the 'pepper' flavor in Shiraz,[12] was detected in an above threshold concentration only in the cooler climate Shiraz.

Reconstitution Test. To confirm that the compounds were indeed key aroma compounds in Shiraz wine, they were recombined and compared with the corresponding real wine. For each wine different reconstitutions were prepared in a wine-like matrix, always adding 44 of the quantitated compounds in the amount in which they appear in Table 4, excluding those compounds occurring in concentrations far below their odor threshold (notably furfural, α-terpineol, and hexyl acetate).

The reconstitutions were first evaluated in informal blind tastings by eight expert panelists, with initial assessment of the samples presented in black glasses in silence followed by open discussion of the characteristics of the samples. The aroma of the reconstituted samples containing 44 aroma compounds in a wine-like matrix (containing ethanol, water, and tartaric acid and also organic acids, salts, and glycerol as described above) was considered in good agreement with the real wine. The overall aroma of the Barossa Valley Shiraz reconstitution was judged more wine-like by these experts than the Margaret River reconstitution. As shown below, the descriptive analyses confirmed this observation as most sensory attributes were better modeled in the BV samples.

Omission Tests. The relative sensory importance of the aroma compounds rotundone, dimethyl sulfide, β-damascenone, linalool, fatty acids, and oak-derived compounds, as well as nonvolatile compounds, was investigated by omission experiments. These compounds were selected on the basis of the differences in concentration between the two wines, as well as from bench tastings, which were used to assess different aroma compounds. Table 5 shows the different combinations of the reconstituted wines and the codes used.

From the ANOVA of the sensory descriptive study results there were significant differences ($P<0.05$) across the samples for all attributes with the exceptions of 'plastic' and 'pepper'. For the 'pepper' attribute, considering this is caused by a compound for which approximately 20% of the population are anosmic,[12] the ANOVA was rerun treating judge as a fixed effect; with this approach the pepper aroma was then rated significantly different across the samples.

The results of the descriptive study for the 16 reconstitution samples, excluding the real wines, are shown in Figure 1 in the form of a PCA plot to show the differences between the two wine types. The real wines were not included in the PCA as they were generally rated higher in several attributes, notably 'dark fruit', which dominated the PCA, making the differences among the reconstituted samples less clear. The sensory profiles of the two wines had been studied in an earlier sensory descriptive analysis.[24]

The Barossa Valley wine reconstitution samples were rated higher than the Margaret River samples in the fruity attributes 'overall fruit' and 'dark fruit', and the mean ratings for 'oaky' and 'chocolate' were also higher in this wine. For the samples mimicking the Margaret River wine the attributes 'green' and 'geranium' were more important. In both sample sets the reconstitutions without nonvolatiles (BV-NV, MR-NV) were clearly separated from their counterparts with nonvolatiles and showed a higher 'chocolate' and 'dark fruit' aroma, with lower 'green' and 'pepper' ratings. The higher rating for 'dark fruit' in the Barossa Valley wine in comparison to the wine from the Margaret River could be caused by higher concentrations of

[a]Odor threshold; reference given. In aqueous ethanol except for refs 24 29, in water, and ref 28 30, in wine. [b]Calculated as the mean value of two different workups. [c]Concentration/threshold concentration.

esters and also DMS, as the removal of DMS (BV-DMS) shifted the rating toward 'green', with lower fruit ratings. That the wine from the Barossa valley was rated more 'oaky' was also reflected in higher concentrations for *cis*-oak lactone and eugenol. There were only relatively small effects of omitting several of the compounds tested, and these will be discussed below.

Comparing the Reconstitution and the Real Wines. To assess in more detail the effects of the omissions, data from the two wines are presented separately for the most important attributes for each wine based on the PCA and the attributes that showed significant differences (Figures 2 and 3). Of all the aroma attributes, the highest rating for the real wine sample of the Barossa Valley was given for the attribute 'overall fruit' (Figure 2), which was significantly higher than the reconstituted samples. The omission of 'oaky' compounds decreased the rating significantly, as well as the omission of dimethyl sulfide. Dimethyl sulfide had a concentration of 130

[a]BV, Barossa Valley Shiraz; MR, Margaret River Shiraz. [b]Ethanol, water, tartaric acid, glycerol, fructose, glucose, succinic acid, malic acid, lactic acid, NaCl, K_2HPO_4, $K_2S_2O_3$ concentrations shown in Table 1; aroma compounds as shown in Tables 4 and 5. [c]Matrix consisting only of ethanol, water, and tartaric acid.

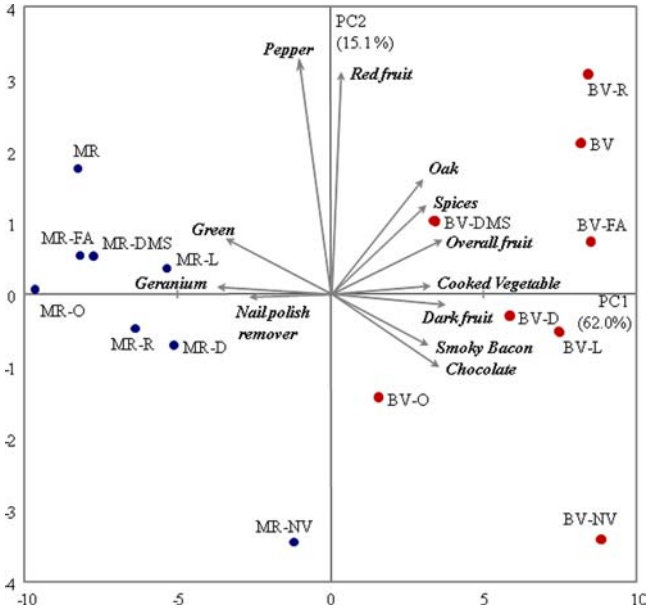

Figure 1. PCA scores and loadings biplot of all samples in the Shiraz reconstitution and omission study. Abbreviations for reconstitution treatments are as listed in Table 5.

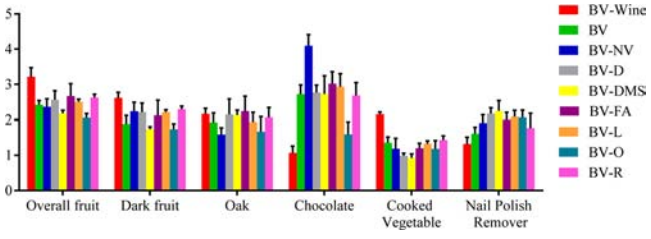

Figure 2. Mean ratings of important aroma attributes in Barossa Valley Shiraz reconstitution samples. Abbreviations for reconstitution treatments are as listed in Table 5. Error bars are one standard error.

μg/L in this wine and was well above the odor threshold. Its aroma can be described as 'cabbage-like', 'corn', and 'asparagus', depending on the matrix as well as the concentration. Our study shows that dimethyl sulfide also contributes to or enhances the fruit flavor, which is in agreement with findings of

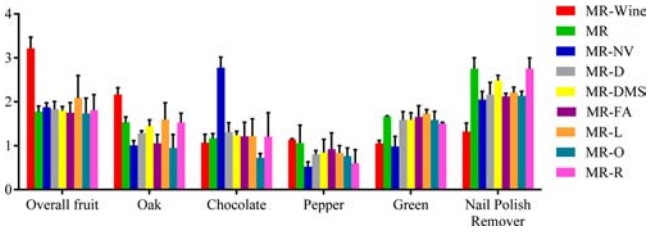

Figure 3. Mean ratings of important aroma attributes in Margaret River Shiraz reconstitution samples. Abbreviations for reconstitution treatments are as listed in Table 5. Error bars are one standard error.

others.[22,25] Although the concentration of β-damascenone is 44 times above the odor threshold and we would therefore expect that it has an influence on the fruity flavor, it does not seem to contribute substantially to the 'overall fruit' flavor as the omission of this compound led to only a marginal increase. In contrast, Pineau et al.[26] found an indirect effect of β-damascenone on fruit flavor, and Escudero et al.[22] showed that β-damascenone and β-ionone also enhance the fruitiness of wines.

Besides 'overall fruit', the attribute 'dark fruit' was an important descriptor for the BV reconstitutions and the real wine. In particular, the mean rating of the reconstitution without the nonvolatiles (BV-NV) is very similar to the real wine sample, whereas the full reconstitution (BV) has a lower intensity in 'dark fruit'. Surprisingly, the subtraction of DMS (BV-DMS) does not change the rating, whereas the reconstitution without β-damascenone (BV-D) increased the rating for the 'dark fruit' character. The omission of either linalool or rotundone led to a higher rating in this attribute, likely caused by a masking effect of these compounds on the dark fruit character.

The rating of 'oaky' is in good agreement within all samples, without any significant differences. Only the sample without nonvolatiles (BV-NV) and, as expected, the omission of oaky compounds (BV-O) were rated lower in 'oaky'. Interestingly, as discussed above, the rating for the 'chocolate' character showed significant differences and especially the sample with the omission of the nonvolatiles (BV-NV) had a very high rating in this attribute. The real wine was rated significantly lower in 'chocolate', and also the omission of 'oaky' compounds resulted in a rating similar to that of the real wine.

In contrast to this, the real wine sample (BV-wine) was rated significantly higher in the 'cooked vegetable' attribute, and the omission of either dimethyl sulfide or β-damascenone decreased the intensity for this attribute in comparison to all other reconstitutions. That dimethyl sulfide contributes to the 'cooked vegetable' character was not surprising. 'Nail polish remover' was an attribute used to describe the aroma of ethyl acetate, which is generally an undesirable character of wine. As Figure 2 shows, all reconstituted samples showed a much higher rating for this attribute than the original wine sample. The attribute 'geranium' was rated a low intensity in all samples, and the differences between the reconstitutions and the original wine sample were not significant.

The mean ratings for important sensory attributes for the reconstitutions of the wine from Margaret River are shown in Figure 3. Similarly to the wine from the Barossa Valley, 'overall fruit' was an important flavor attribute and rated highly in the real wine. The reconstituted samples were all scored significantly lower for this attribute, with only a marginal increase of the rating for the omission of linalool. Whereas the

dx.doi.org/10.1021/jf405731v | J. Agric. Food Chem. 2014, 62, 4528−4536

'oaky' character was very well modeled in the BV samples, for the MR sample set there were significant differences. The real wine was rated higher than all other samples, and the omission of nonvolatiles (MR-NV) and 'oaky' compounds (MR-O) resulted in the lowest rating. The sample without fatty acids (MR-FA) also showed a lower rating for the 'oaky' attribute. The 'chocolate' attribute for the reconstitution was in good agreement with the score for the real wine with only the omission of nonvolatiles (MR-NV) showing a significant increase for this rating. The same effect was seen for the Barossa Valley Shiraz samples; the nonvolatiles seem to have an important influence on the aroma perception of the compounds responsible for the 'chocolate' character.

The attribute 'pepper' in the wine from Margaret River was rated higher than in the BV Shiraz, which is reflected in the concentrations of the pepper-smelling compound rotundone. In the MR Shiraz rotundone was found at 38 ng/L, a concentration well above the odor threshold,[24] whereas the concentration in the BV Shiraz was only 1 ng/L. For this attribute, the rating of the full reconstitution (MR) is in good agreement with the real wine (MR-Wine). As for other attributes the fraction of nonvolatiles has a significant influence on the rating for 'pepper', which was in this case decreased. Also, the omission of rotundone led to a lower mean rating for the 'pepper' attribute. Considering the 'green' aroma descriptor, the omission of nonvolatiles (MR-NV) resulted in a rating very similar to that of the real wine; all other samples showed a higher rating.

As seen for the reconstitution of the BV samples, the attribute 'nail polish remover' was rated much higher in all samples. In this case, especially the full reconstitution (MR) and the samples MR-DMS and MR-R had increased ratings in this attribute. The perception of this flavor compound seems to be increased in reconstituted samples, presumably due to the lack of masking aroma compounds such as DMS. It is also possible that the equilibration between acetic acid and ethanol is different in the model wine from that in the real wine matrix or that different SO_2 levels contribute to the intensity of the attribute 'nail polish remover'.

This study has found that by mixing 44 aroma compounds in concentrations measured in Shiraz, the aroma of two different Australian Shiraz wines could be reconstituted. A relatively small number of critical compounds were found, providing optimism that predictive models can be developed to relate wine composition to flavor attribute intensities. Different omission experiments were analyzed by sensory descriptive analysis, and the greatest differences related to the omission of nonvolatiles. Compounds such as β-damascenone, linalool, and fatty acids had only small effects on aroma, highlighting the complexity of the behavior of mixtures of odorants even when present well above detection threshold. The omission of the mixture of organic acids, sugars, minerals, and glycerol increased the rating for the 'chocolate' character in both sample sets significantly and decreased the 'pepper' and 'green' attributes of the wine from the cooler region. Further research is needed to investigate which component of the nonvolatile fraction is the main cause of this effect, which may be of great importance in understanding and controlling undesirable 'green' flavors in wines.

Aroma Active Volatiles in Four Southern Highbush Blueberry Cultivars Determined by Gas Chromatography−Olfactometry (GC-O) and Gas Chromatography−Mass Spectrometry (GC-MS)

Xiaofen Du and Russell Rouseff*

Citrus Research and Education Center, University of Florida, 700 Experiment Station Road, Lake Alfred, Florida 33850, United States

ABSTRACT: Aroma active volatiles in four southern highbush blueberry cultivars ('Prima Dona', 'Jewel', 'Snow Chaser', and 'Kestrel') were determined using solid phase microextraction (SPME) in combination with gas chromatography−olfactometry (GC-O) and identified via GC-PFPD and GC-MS using retention indices of reference compounds and mass spectral data. The aromas of total, unseparated SPME extracts evaluated using GC-O were rated 8.2−9.0/10 for the four cultivars in terms of similarity to the original blueberry homogenates. In terms of GC-O aroma similarity, those aroma active volatile groups characterized as green, fruity, and floral were most intense. Of the 43 volatiles found to have aroma activity, 38 were identified and 13 had not been previously reported in blueberries. Although linalool and (*E*)-2-hexenal were common major aroma impact volatiles, dominant aroma-active volatiles were different for each cultivar. Principal component analysis confirmed that each cultivar possessed a unique aroma active profile as each cultivar was clustered into a separate score plot quadrant.

KEYWORDS: *southern highbush blueberry, blueberry aroma, GC-O, SPME*

INTRODUCTION

Next to strawberries, blueberries are the second most important berry crop in the United States.[1] The cultivated blueberry market has more than tripled since the 1970s. It has increased at a rate of 10−20% annually since 2000. The U.S. 2012 crop was worth $781.8 million.[2] The rapid increase in blueberry consumption is mainly driven by its reported nutraceutical functions, health benefits, and unique flavor.[3]

Blueberry is a plant native to North America. It is in the genus *Vaccinium*, section Cyanococcus. In this section, there are three main commercialized blueberries: highbush (*Vaccinium corymbosum*), lowbush (*Vaccinium angustifolium*), and rabbiteye (*Vaccinium ashei*). Highbush blueberry is the major planted cultivar, which accounts for approximately 95% of the total commercial production in the United States. Highbush blueberry can be further divided into northern highbush and southern highbush blueberry. Northern highbush is a high-chill blueberry, which has been optimized for high-chill zones. High-chill zones are those climates that experience a minimum of 800 h below 7.2 °C. Southern highbush is a hybrid between the northern highbush and various low-chill Cyanococcus species.[4] The northern highbush blueberry is the predominant cultivar grown in the major blueberry production areas in the northern United States: Maryland, Michigan, New Jersey, North Carolina, and Washington. The southern highbush blueberry is primarily grown in California and Florida.

Florida's southern highbush blueberries ripen earlier than blueberries in other growing areas and are the major producers of U.S. blueberries from the middle of April to late May. The early-market fruit commands a high price, and this has led to the expansion of Florida's blueberry acreage.[5] To be competitive in the blueberry market the fruit should be early ripening and of good quality. Flavor and aroma are two of the most important fruit quality characteristics and ultimately determine consumer acceptability and purchase decision. However, to the best of our knowledge, there is no study that evaluates the aroma volatiles of Florida southern highbush blueberry.

The study of blueberry flavor has been quite limited. A few of the major volatiles have been identified in various blueberry types. In highbush blueberries, the major volatile compounds were reported as ethyl acetate, (*E*)-2-hexenal, (*E*)-2-hexenol, hexanal, (*Z*)-3-hexenol, linalool, and geraniol.[6−8] Other compounds such as citronellol, α-terpineol, 2-phenylethanol, and vanillin have also been suggested to contribute to the typical aroma of highbush blueberries.[9] Few studies have examined the aroma composition in lowbush blueberries. Acetaldehyde, methyl acetate, ethyl acetate, methyl 2-methylbutanoate, methyl 3-methylbutanoate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, methyl butanoate, and linalool were reported as the major aroma compounds.[10−12] A greater number of esters have been reported in lowbush compared to highbush blueberries. Studies on rabbiteye blueberry aroma are also very limited. The major volatiles identified in rabbiteye blueberry are ethyl acetate, *p*-cymene, hexanol, (*Z*)-2-hexenol, heptanol, cinerolone, β-ionone, terpene-4-ol, 2-undecanone, α-terpineol, carveol, nerol, and eugenol.[13−15] A combination of (*E*)-2-hexenal, (*E*)-2-hexenol, (*Z*)-3-hexenol, and linalool has been reported as being responsible for the characteristic blueberry flavor.[14]

Because the identification of blueberry aroma active volatiles is limited and conflicting, especially because there seem to be no studies on the aroma composition of southern highbush blueberry, the object of this study was to investigate the aroma active compounds in two common and two new Florida

southern highbush blueberry cultivars using a combination of SPME, GC-O, and GC-MS. A secondary goal was to evaluate the aroma active volatiles of these cultivars using GC-O to determine how similar or different the aroma profiles of these four cultivars were.

MATERIALS AND METHODS

Chemicals. Pure standards of ethyl propionate, methyl 2-methylbutanoate, methyl 3-methylbutanoate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, (*Z*)-3-hexenyl acetate, (*E*)-2-hexenyl acetate, linalool, citronellol, nerol, geranylacetone, hexanal, (*Z*)-3-hexenal, (*E*)-2-hexenal, (*E*,*E*)-2,4-hexadienal, (*E*,*Z*)-2,6-nonedienal, (*E*,*E*)-2,4-nonedienal, (*Z*)-3-hexenol, 2-heptanol, 2-heptanone, 1-octen-3-one, 2-methylbutanoic acid, hexanoic acid, methional, Furaneol, *p*-cresol, and eugenol were purchased from Aldrich Chemical Co. Inc. (Milwaukee, WI, USA). Geranyl acetate, 1,8-cineole, α-terpineol, octanal, and decanal were supplied from Sunpure (Lakeland, FL, USA). Geraniol, pentanal, and dimethyl disulfide were purchased from Acros Organics (Fair Lawn, NJ, USA). 2-Nonanone was from Eastman Chemical Co. (Kingsport, TN, USA), whereas β-damascenone was from Givaudan Roure Corp. (Whippany, NJ, USA). Sodium fluoride (ACS grade) were obtained from Acros Organics. Sodium chloride and methanol were purchased from Fisher Scientific (Fair Lawn, NJ, USA).

Blueberry Samples. Highbush blueberry plants 'Jewel' and 'Prima Dona' were grown at a local blueberry farm in Haines City, FL, USA, whereas 'Snow Chaser' and 'Kestrel' were grown at a blueberry breeding center at the University of Florida, Gainesville, FL, USA. Blueberry samples were hand-harvested on April 27 (for 'Jewel' and 'Prima Dona') and May 10 (for 'Snow Chaser' and 'Kestrel') of 2011. All blueberries were grown in mounded pine bark and received similar fertilization. To obtain equal levels of fruit maturity, the berries were harvested in the more northern location (Gainesville) 2 weeks later than the berries grown in Haines City.

Blueberry samples were washed with distilled water and gently dried with tissue paper. Two hundred grams of distilled water and 200 g of berries were homogenized along with sodium chloride and sodium fluoride (final concentrations 20 and 1%, respectively) in a glass blender (Waring Products Div., Dynamics Corp. of America, New Hartford, CT, USA). Samples were blended in a high-speed pulse mode for 20 s. The puree was used for analysis.

SPME Blueberry Volatiles. SPME has been successfully coupled with GC-O to identify aroma active volatiles in foods for approximately 15 years now.[16] In this study 10 g of blueberry puree was added into a 40 mL vial and a 4 mm stir bar, which was flushed with nitrogen before sealing with a septum screw top. It was found that gentle stirring of the sample reduced equilibrium times and improved analytical precision. Samples were equilibrated at 40 °C in a water bath for 20 min. After equilibration, a 2 cm fiber coated with divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS, Supelco, Bellefonte, PA, USA) was exposed to the headspace of the vial for 40 min at the same temperature. The three-phase fiber was chosen as it consistently produced the most representative collection of headspace volatiles compared to other fiber types. Forty minutes was chosen as an extraction time as it produced the largest amounts of volatiles and at the same time produced the most consistent results. The fiber was then introduced into the GC injection port for a 3 min desorption.

Direct GC-O. A 1 m deactivated silica column (0.32 mm i.d.) was installed on an Agilent 6890N gas chromatograph system (Palo Alto, CA, USA) directly from the injector to a high volume sniffing port (Datu, Geneva, NY, USA). The flow rate of the helium carrier gas was 20 mL/min. The injection port temperature was 220 °C, and the oven temperature was 150 °C (isothermal). The configuration allows for the evaluation of global odor of the extracts without chromatographic separation, and the entire analysis was completed in <30 s. Two trained panelists smelled the odor of the unseparated SPME extract at the GC sniffing port. Then, panelists opened a 40 mL vial to smell the original blended blueberry puree. Panelists rated the similarity between the unseparated SPME extract and the original puree odors using an 11-point scale ranging from 0 (far from the sample) to 10 (identical to the original sample). Each panelist had been screened from a larger pool of potential panelists using a set of 15 common fruit aroma active volatiles. Accepted panelists demonstrated that they could detect all separated volatiles in the training set and could reproduce the intensity of each volatile. Training time was approximately 3 weeks.

Time−Intensity GC-O Procedure. GC-O analysis was conducted using an Agilent 6890N gas chromatograph system equipped with a flame ionization detector (FID) with the previously described olfactometer. Samples were separated using a DB-Wax column (30 m × 0.32 mm i.d. cross-linked poly(ethylene glycol), 0.50 μm film thickness, J&W Scientific, Folsom, CA, USA). The column effluent was split 1:2 (by volume) into the FID and a heated sniffing port block, where the flow was mixed with humidified air. The column flow rate was 2.0 mL/min (helium) with injection in the splitless mode. Injector and detector temperatures were 220 and 250 °C. The initial oven temperature was 35 °C and held for 1 min before increasing to 190 °C at 4 °C/min and then to 240 °C at a rate of 8 °C/min, and holding at 240 °C for 5 min before cooling back to 35 °C.

Olfactometry analyses were performed by two trained panelists. Assessors rated aroma intensity continuously throughout the chromatographic run using a linear potentiometer from which output was recorded and quantified using Chromperfect software (Justice Innovations, Palo Alto, CA, USA). Retention times and verbal descriptors were recorded to permit aroma descriptors to be coupled with computerized aroma time−intensity plots. Triplicate analyses were performed for each sample by each panelist. Volatiles were not considered to be aroma active unless detected during at least half of the total sniffing trials. The intensity was the average from all panelists when an aroma was registered. Compound identification was based on matching retention times and aroma character with authentic pure standards, retention indices (RIs) that were determined using a series of standard linear alkanes C_5−C_{25}, GC-MS, or GC-PFPD (pulsed flame photometric detector).

GC-MS Identification Aroma Active Compounds. GC-MS analyses were performed using a PerkinElmer Clarus 500 gas chromatograph and a quadropole mass spectrometer (PerkinElmer, Waltham, MA, USA). Compound separation was achieved with a DB-WAX column (60 m × 0.25 mm i.d. cross-linked poly(ethylene glycol), 0.50 μm film thickness, J&W Scientific, Agilent Technique, Foster City, CA, USA). Column flow rate (helium) was 1.5 mL/min. Initial oven temperature was 35 °C. After holding for 1 min, the oven temperature was increased to 190 °C at 4 °C/min and then to 240 °C at 8 °C/min. The oven was maintained at 240 °C for 5 min before returning to 35 °C. Injection, MS transfer line, and ion source temperatures were 230, 240, and 180 °C, respectively. Fragmentation data from m/z 25 to 300 were collected in the scan mode. Compound identifications were made by comparing mass spectral data from the Wiley 275.L (G1035) database and confirmed by authentic pure standards and reported linear retention index (LRI; Kovats) values found in the literature.

GC-PFPD Identification of Sulfur Compounds. Sulfur volatile analyses were achieved using an Agilent 7890A gas chromatograph system equipped with a sulfur-specific detector: a PFPD (model 5380, OI Analytical Co., College Station, TX, USA). Volatiles were separated using a Stable-WAX column (30 m × 0.32 mm i.d. cross-linked poly(ethylene glycol), 0.50 μm film thickness, Restek, Bellefonte, PA, USA). Column flow was 1.5 mL/min (helium). Initial oven temperature was 35 °C. After holding for 1 min, the oven temperature was increased to 65 °C at a rate of 3 °C/min, then increased to 170 °C at a rate of 6 °C/min, and finally to 240 °C at a rate of 10 °C/min with a 5 min hold. The GC injection temperature was 200 °C, and the detector temperature was 250 °C. Sulfur gate time was 6−24.9 ms, and pulse frequency was approximately 3 pulses/s. Sulfur peaks from the PFPD detector were integrated using Chromperfect software version 5.0 (Justin Innovations, Inc., CA). Compound identification was based on matching LRI values from authentic sulfur standards and LRIs reported in the literature with those observed in the samples.

Multivariate Statistics. The aroma active volatile data set used average intensity ratings from the olfactory panel. Principal component

analysis (PCA) was carried out using Unscrambler version 10 from Camo (Woodbridge, NJ, USA). All 43 aroma active volatile values were used in the calculations. Graphical score and loading plots were superimposed into a single figure using the Unscrambler biplot graphing feature.

RESULTS AND DISCUSSION

Global Blueberry Aroma Using SPME. Although blueberry volatile composition has been studied by several groups, there is some disagreement, some of which can be attributed to volatile extraction and identification techniques employed. Traditional techniques such as distillation, liquid−liquid extraction, and headspace sampling are frequently used for volatile isolation in berry fruit.[17] However, most of these techniques are labor-intensive and can produce artifacts. All aroma extraction techniques produce extracts favoring some chemical classes and minimizing others or (in the case of solvent extraction) extract volatiles that have very little volatility at room temperatures but are 100% volatilized in the GC injector. Thus, GC-O results need to be interpreted with care. Static headspace solid phase microextraction (SPME) is an alternative volatile extraction technique that employs a fused silica fiber coated with an appropriate sorbent stationary phase which collects and concentrates only volatiles. The main advantages of SPME are speed, simplicity of operation, and lack of a solvent peak to obscure highly volatile components from the sample. SPME has been widely used to extract volatiles in a wide range of food samples.[18] However, not all SPME fibers produce the same results. The three-phase fiber was used in this study as we have found it to produce the most representative extracts.

When static headspace volatile collection is employed, berry samples can be present as whole fruit, sliced fruit, or blended puree. Blending is more commonly employed for berries because blending can increase volatile release from the berry matrix. However, the reaction of native enzyme activity can distort the original aroma by converting nonvolatiles into aroma active volatiles. In this study, 20% sodium chloride and 1% sodium fluoride (w/w) were added as part of the blending mixture to prevent or reduce this effect. Sodium chloride was used to inhibit lipoxygenase activity, whereas sodium fluoride was used to inhibit polyphenol oxidase activity and microbial growth during equilibrium and volatile extraction. Preliminary experiments indicated that when these salts were not employed, blueberry purees had more than 200 times the total "green volatiles" (hexanal, (*Z*)-2-hexenal, (*E*)-2-hexenal, hexanol, (*Z*)-3-hexenol, and (*E*)-2-hexenol). The rate of formation for each "green compound" appeared to be cultivar and time dependent. Informal sensory evaluations of these samples (blended with or without salts) indicated that berry purees with no added salt had much stronger "green" flavor than those with the added salt. Therefore, salts were added to the berries during blending to prevent the distortion of the native aroma profile.

After blending, blueberry puree volatiles were extracted in the static headspace mode using a 2 cm, triphase SPME fiber (DVB/CAR/PDMS). This fiber was chosen because it had been found to extract the most representative strawberry volatiles.[19] To confirm the representativeness of the SPME extracts, the global aromas of the extracts were evaluated using the unseparated GC-O method and compared to the original blended samples. The global aroma of the extracts and aroma description of the original blended samples including 'Jewel', 'Prima Dona', 'Snow Chaser', and 'Kestrel' are presented in Table 1. Overall, the aroma of the homogenized blueberry samples could be described as "fresh green", "grassy", "fruity", "floral", "blueberry-like", and "tea-like". However, the top aroma impression for each blueberry cultivar was different. 'Jewel' gave the strongest aroma notes of "grassy" and "fresh green", whereas 'Snow Chaser' had the highest level of "floral" note. 'Prima Dona' had the top aroma notes of "fresh green" and "fruity". 'Kestrel' had a similar top aroma of "fresh green" and "fruity"; however, its intensity was much higher than that of 'Prima Dona'. Overall, the global aroma of SPME extracts was quite similar to that of the original blueberry homogenates (Table 1). Compared to the reference purees, the global aroma of SPME extracts had average rates of 8.5, 9.0, 8.2, and 8.9 for 'Jewel', 'Prima Dona', 'Snow Chaser', and 'Kestrel', respectively (Table 1). The results suggested that collected SPME volatiles generated an odor that was representative of the original sample.

Table 1. Global Aroma of SPME Headspace Extracts of Four Florida Southern Highbush Blueberries Scores Compared to Aroma of Original Blended Samples

cultivar	aroma of original blended sample	global aroma of SPME extract	score
Jewel	grassy, fresh green, fruity, blueberry-like	grassy, green, fruity, blueberry-like, red tea-like	8.5
Prima Dona	fresh green, fruity, blueberry-like, green tea-like	fresh green, blueberry-like, fruity, red tea-like	9.0
Snow Chaser	floral, fruity, fresh green, blueberry-like	rosy, fresh green, floral, fruity	8.2
Kestrel	fresh green, fruity, floral, green tea-like, blueberry-like	fresh green, fruity, blueberry-like, floral, red tea-like	8.9

GC-O Analysis. Shown in Figure 1 are the average aromagrams from 'Prima Dona' and 'Kestrel' southern highbush blueberry cultivars. The 'Kestrel' aromagram is inverted for comparison purposes. Both qualitative (missing aroma volatiles) and quantitative (aroma intensity) differences are apparent. One of the more obvious features is the high number

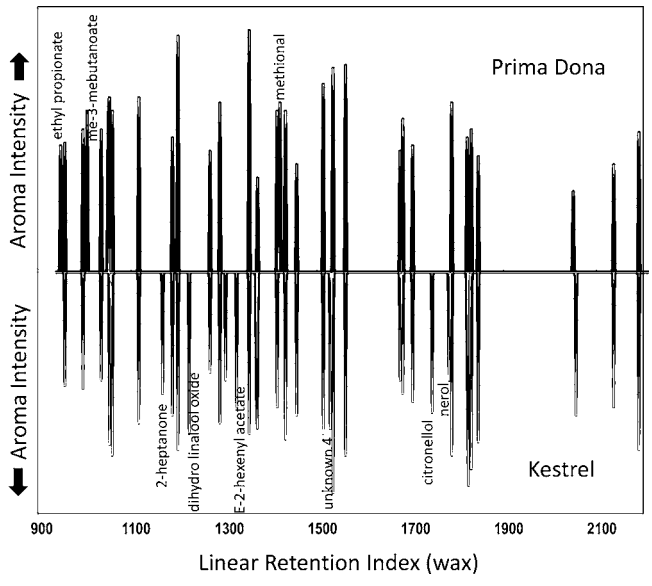

Figure 1. Aromagrams of average aroma intensities from 'Prima Dona' (upper) and 'Kestrel' (lower and inverted).

[a]RI, retention index; Std, standard; AD, aroma description. [b]Tentatively identified.

(28) of shared aroma active volatiles. It is also worth noting that the aroma strengths of these aroma active volatiles are quite different. For example, the most intense odorant in the 'Kestrel' cultivar was linalool, whereas the most intense odorant for 'Prima Dona' was an unknown described as having a sulfurous, grassy aroma and eluted at a wax LRI of 1353. There were, however, nine volatiles that were found in only one cultivar and not the other. The relatively new 'Kestrel' cultivar contained six aroma active volatiles that were not observed in the more established 'Prima Dona' cultivar. This is not to say that the six aroma active volatiles labeled in Figure 1 were not present in 'Prima Dona'; it means only if they were present, their concentrations were below their respective thresholds. Conversely, the 'Prima Dona' cultivar contained three aroma active volatiles not observed in the 'Kestrel' cultivar. These peaks are labeled as well.

Aroma Volatiles in Southern Highbush Blueberry. A summary of aroma active volatile from all four southern highbush blueberry cultivars is shown in Table 2. A total of 43 aroma active volatiles are observed in the GC-O experiments. Thirty-eight of these aroma active compounds were identified using the techniques listed in the last column in the table. Five aroma active volatiles remain unidentified/unknown. There were nine aldehydes, eight esters, seven terpenes, five ketones, two alcohols, two acids, two sulfurs, and three miscellaneous compounds.

Aldehydes are the most abundant chemical group with aroma activity found in southern highbush blueberry. Hexanal, (*Z*)-3-hexenal, (*E*)-2-hexenal, (*E*,*Z*)-2,6-nonadienal, and (*E*,*E*)-2,4-

nonedienal contributed "fresh green", "grassy", and "fruity" aroma notes, whereas pentanal, octanal, (*E*,*E*)-2,4-hexadienal, and decanal contributed "fatty" and "citrus" aroma notes (Table 2). Unsaturated aldehydes such as (*Z*)-3-hexenal, (*E*,*E*)-2,4-hexadienal, (*E*,*Z*)-2,6-nonadienal, and (*E*,*E*)-2,4-nonedienal have not been previously reported in blueberries. These unsaturated aldehydes are generally considered as the oxidized products of unsaturated fatty acids and should be considered as natural in vivo products of blueberry maturation as the added salt should have inhibited enzyme activity during and after sample blending. Aldehydes as a group make a major contribution to blueberry aroma, in agreement with previous results.[14]

Esters are the next most abundant group, including ethyl propanoate, methyl 2-methylbutanoate, methyl 3-methylbutanoate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, (*Z*)-3-hexyl acetate, (*E*)-2-hexyl acetate, and geranyl acetate contributing "green", "sweet", "fruity", "apple", "banana", "pear", and "floral" aroma notes (Table 2). Ethyl propanoate, methyl 2-methylbutanoate, (*E*)-2-hexyl acetate, and geranyl acetate have not been previously reported in blueberry. Ethyl 2-methylbutanoate has been identified in northern highbush and lowbush blueberry,[6,10] whereas methyl 3-methylbutanoate, ethyl 3-methylbutanoate, and (*Z*)-3-hexyl acetate have been reported in lowbush blueberries.[10] Generally, esters are the major aroma components of fruits such as strawberry,[20] apple, and banana.[21] However, few esters have been identified in highbush blueberry. Esters are not considered as important as aldehydes to the aroma in northern highbush blueberries. They have been identified as important volatiles in some lowbush blueberries.[10] In terms of ester composition, the southern highbush blueberry is more similar to lowbush blueberry than to the northern highbush blueberry.

Terpenes such as linalool, citronellol, nerol, and geraniol contributed "sweet", "floral", "fruity", "citrus", and "berry-like" aroma notes. 1,8-Cineole, dihydrolinalool oxide, and α-terpineol contributed "woody", "herbaceous", and "piney" aroma notes (Table 2). Except for dihydrolinalool oxide, all of the other six terpenes had been previously reported in various blueberry types.[6,7,10,14] Linalool was a major aroma active volatile in all four southern highbush blueberry cultivars examined. This is consistent with literature data.[14] Geraniol was a major aroma volatile only in 'Snow Chaser' and 'Kestrel'.

Only two alcohols, including (*Z*)-3-hexenol and 2-heptanol, were aroma active (Table 2). We confirmed earlier reports that 2-heptanol contributed a "musty", "moldy" aroma to southern highbush blueberries. (*Z*)-3-Hexenol had been reported as one of the major "green compounds" in blueberries. However, in this study, it was observed in only a single cultivar ('Kestrel)' and only at midlevel intensity.

Only three ketones were found to have aroma activity. They included 2-heptanone, 1-octen-3-one, and 2-nonanone. They contributed "fruity" "mushroom", "earthy", and "cheese-like" aroma. These carbonyl compounds have not been previously reported as contributing to blueberry aroma. Acids such as hexanoic acid and 2-methylbuanoic acid contributed "cheesy" and "sour" sensory attributes and have been previously reported in blueberry.[7]

Sulfur compounds were identified using a special sulfur-specific detector, a PFPD. Using this highly sensitive and selective detector, several sulfur volatiles were tentatively identified using retention index matching. Identified volatiles included hydrogen sulfide, methanethiol, dimethyl sulfide, dimethyl disulfide, and methional. However, only dimethyl disulfide and methional were found to possess aroma actively in parallel GC-O studies. They were described as possessing "sulfurous rotten egg" and "cooked potato" aromas, respectively (Table 2). Methional had not been previously reported in blueberries, but dimethyl sulfide had been reported in some wild blueberries.[22]

Furaneol was tentatively identified in two southern highbush blueberries ('Jewel' and 'Prima Dona', Table 2). Furaneol has "sweet", "candy", and "caramel" aroma notes, with a very low organoleptic threshold, 10 μg/kg in water.[23] Furaneol has been reported in fruits such as strawberry,[23] pineapple,[24] and blackberry.[25] However, it has not been previously identified in blueberry. Two phenolic compounds, including *p*-cresol and eugenol, contributed "fecal" and "clove" aroma attributes to southern highbush blueberries. Both of these two compounds have been previously reported in blueberries.[7]

Comparison of Chemical Groups and Total Intensities. Not surprisingly, the four southern highbush blueberry cultivars share many common aroma volatiles. Of the 43 aroma active volatiles, 33 were common to at least three of the four cultivars. There were a total of 37 aroma volatiles in 'Kestrel', 36 in 'Jewel', 33 in 'Snow Chaser', and 32 in 'Prima Dona'. Aldehydes (9) were the most abundant volatile group, closely followed by esters (8) and terpenes (7). There was more variation within the terpene group than in any other chemical group. Only three aroma active terpenes were observed in 'Prima Dona', but seven terpenes were observed in 'Kestrel'.

Not only did the number of aroma active compounds vary among the four cultivars, but the aroma intensities also varied. 'Jewel' and 'Kestrel' had the highest total aroma intensities from all aroma active volatiles (both identified and unknown) of 209 and 204, respectively. In contrast, the total aroma intensities due to 'Prima Dona' and 'Snow Chaser' were only 180 and 179, respectively. The major contributors to total aroma intensity were aldehydes, esters, and terpenes. The aldehyde and terpene intensity values observed in this study were in agreement with literature reports that aldehydes and terpenes are considered the major volatiles contributing to blueberry aroma.[14]

Aroma Profiles of 'Jewel', 'Prima Dona', 'Snow Chaser', and 'Kestrel'. No single aroma active volatile was that much more intense than all the others. Only linalool and (*E*)-2-hexenal had aroma intensity >7.5 in all four cultivars. It has been previously reported that an aroma recombination of (*E*)-2-hexenal, (*E*)-2-hexenol, (*Z*)-3-hexenol, and linalool conveys the characteristic blueberry flavor.[14] In the current study (*E*)-2-hexenol was not detected and (*Z*)-3-hexenol was observed only as a midlevel aroma active volatile in a single cultivar ('Kestrel').

Shown in Figure 2 is a summary of the total aroma intensities of all 43 aroma active volatiles grouped into eight groups based on aroma similarities. It can be seen that green, fruity, and floral aroma characters are the major contributors to blueberry aroma. Sulfury and moldy/musty are midlevel aroma attributes with the remaining three aroma categories contributing to background blueberry aroma. Therefore, blueberry aroma is more complex than a single aldehyde and a few 6- and 10-carbon alcohols.

The relative aroma strengths of these eight aroma categories varied somewhat between the four cultivars. 'Jewel' and 'Kestrel' possessed similar aroma strengths in the five strongest aroma categories. However, 'Jewel' contained relatively greater intensities in the low-level aroma categories of sweet and

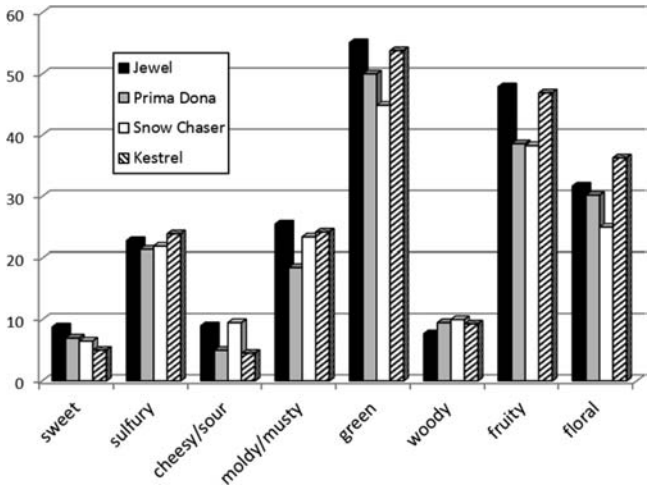

Figure 2. Comparison of GC-O aroma group profiles of four southern highbush blueberry cultivars grown in Florida.

cheese/sour than 'Kestral'. In a similar fashion, the aroma profile of 'Prima Dona' was similar to that of 'Snow Chaser", but 'Prima Dona' exhibited higher total levels in the major green and floral aroma categories.

Principal Component Analysis. To determine if there were appreciable differences in the aroma profiles of the four cultivars used in this study, the aroma volatile data were analyzed using PCA. Shown in Figure 3 are the score and

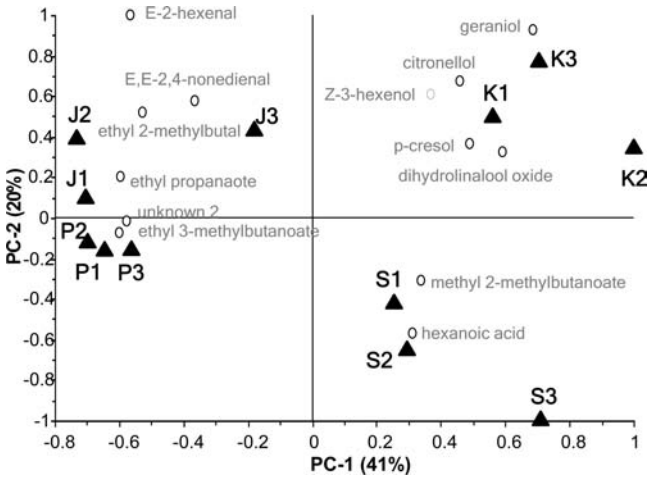

Figure 3. PCA biplot of eigenvalue score values (open triangles) and major loading values (solid circles). P, 'Prima Dona'; J, 'Jewel'; K, 'Kestrel'; S, 'Snow Chaser'.

loading plots of triplicate results for the four blueberry cultivars examined in this study. The first two principal components described 61% of the total variance. Furthermore, each of the four cultivars was clustered in the score plot with no overlap. This indicated that each of the four cultivars possessed a unique aroma profile. PC-1 cleanly separated 'Kestrel' and 'Snow Chaser' on the right-hand (+) side from the more commercially common 'Jewel' and 'Prima Dona' cultivars. The PC-1 axis was defined primarily by geraniol and dihydrolinalool oxide load values on the positive side and ethyl-3-methylbutanoate and unknown 2 loading values on the negative side. PC-2 completely separated 'Kestrel' from 'Snow Chaser' and 'Jewel' from 'Prima Dona'. However, as shown in Figure 3, the degree of separation in the latter case was not as profound. PC-2 was defined primarily but not exclusively by the loading values of citronellol, (*Z*)-3-hexenol, and *p*-cresol on the positive side and by hexanoic acid and methyl-2-methylbutanoate on the negative side. It should be kept in mind that the eigenvector values shown in the score plots were the results of many other variables with smaller loading values. Nevertheless, the complete separation of all four cultivars indicated that each possessed a unique aroma profile and that the close proximity (but not overlapping) of the 'Jewel' and 'Prima Dona' clusters indicated that their overall aroma profiles were similar but still distinct.

ABSTRACT: The aroma-active compounds present in tree-ripened fruits of the five mango (*Mangifera indica* L.) cultivars Haden, White Alfonso, Praya Sowoy, Royal Special, and Malindi were isolated by solvent extraction followed by solvent-assisted flavor evaporation (SAFE) and analyzed by gas chromatography−olfactometery (GC-O). Application of a comparative aroma extract dilution analysis (cAEDA) afforded 54 aroma-active compounds in the flavor dilution (FD) factor range from 4 to ≥2048, 16 of which are reported for the first time in mango. The results of the identification experiments in combination with the FD factors revealed 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone as an important aroma compound in all cultivars analyzed. Twenty-seven aroma-active compounds were present in at least one mango cultivar at an FD factor ≥128. Clear differences in the FD factors of these odorants between each of the mango cultivars suggested that they contributed to the unique sensory profiles of the individual cultivars.

KEYWORDS: *mango, Mangifera indica, aroma extract dilution analysis, 4-hydroxy-2,5-dimethyl-3(2H)-furanone*

INTRODUCTION

Mangoes are the fruits of *Mangifera indica* L., a tropical tree native to South Asia and a member of the sumac family (Anacardiaceae). Mango cultivation is said to have started more than 4000 years ago in the region of eastern India. Today, mango trees are grown throughout the tropical and selected subtropical parts of the world, and mangoes are among the most important fruit crops of the tropics with the major producers being India, China, Thailand, and Pakistan.[1−3]

Mango fruits grow at the end of a long, string-like stem. They are drupes, consisting of a leathery exocarp, a fleshy, juicy mesocarp representing the edible part, and a stony endocarp encasing a single large, flat, oblong seed. The pulp normally sticks to the pit, as fibers extend from the endocarp into the flesh. Size, shape, skin color, skin smoothness, and flesh color strongly depend upon the cultivar. Today, several hundred different mango cultivars are known, over 350 of which are propagated in commercial nurseries. In general, mangoes are between 6 and 25 cm long and weigh up to 2 kg. Typically, the shape is slightly kidney-like and somewhat flattened, with a beak at the apex, but sometimes also nearly round, oval, or ovoid-oblong. The immature fruit has a green skin that gradually turns yellow, orange, red, or purple as the fruit matures. Combinations of several colors in one fruit also occur. The skin surface may be velvety or smooth and waxy. The flesh color ranges from whitish yellow to orange. Mangoes are usually picked before they are fully ripe to prevent them from falling and being damaged. After the fruits have ripened, they can be stored under refrigeration for up to 3 weeks. Mangoes are mainly consumed as fresh fruits. A minor percentage is processed to preserves, juice, dried fruit, or chutney. The mango flesh consists of ∼80% water and up to 20% sugar. It is a rich source of dietary fiber, vitamin C, and β-carotene.[1,2]

A major factor contributing to the popularity of mango is its flavor. In Western countries, mangoes are generally considered high in quality if they combine a low fiber content with a strong sweet taste, a balanced acidity, and an aroma profile high in fruity and low in terpeny notes. Similar to phenotypical traits such as fruit size, shape, and color, the flavor properties of mangoes are strongly influenced by the cultivar.[3]

Numerous studies have been conducted on mango volatiles of different cultivars,[3,4] which has led to the identification of several hundred compounds to date.[4] It has been demonstrated that besides the cultivar,[3,5−26] the maturity,[3,18,22,23] and the geographic origin[26] have an influence on the volatile profile of fresh mangoes.

Despite the large number of investigations on mango volatiles, studies aimed at evaluating the contribution of individual volatile compounds to mango aroma are surprisingly scarce.[15−17,20,25] Application of an aroma extract dilution analysis (AEDA)[27,28] to headspace extracts obtained from mangoes of different cultivars grown in Brazil, (Carlota, Haden, Espada, Coração de Boi, Rubi, and Tommy Atkins) revealed the fruity-smelling ethyl butanoate as an important aroma-active compound in all samples investigated, whereas the

importance of ethyl 2- and 3-methylbutanoates, δ-3-carene, and α-pinene clearly depended on the cultivar.[15] On the basis of odor activity values (OAVs; ratio of concentration to odor threshold), hexanal, (*E*)-2-hexenal, (*Z*)-3-hexenal, (*E*)-2-decenal, γ-terpinene, and (*E*)-β-ocimene were suggested as key aroma compounds in Thai Khieo Sawoei mangoes[16] and β-damascenone, terpinolene, ethyl hexanoate, (*E*,*Z*)-2,6-nonadienal, 4-methoxy-2,5-dimethyl-3(2*H*)-furanone (MDMF), (*R*)-linalool, and ethyl butanoate were proposed as characteristic aroma components in yellow Thai Keaw mango fruits.[17] A detailed study including the analysis of 20 mango cultivars followed by OAV calculation resulted in the identification of ethyl 2-methylpropanoate, ethyl butanoate, (*E*,*Z*)-2,6-nonadienal, (*E*)-2-nonenal, methyl benzoate, (*E*)-β-ionone, decanal, and MDMF as potentially most important mango aroma compounds.[20] A more recent study on odor-active compounds in Corazón mangoes showed high OAVs for β-damascenone, ethyl butanoate, (*E*,*Z*)-2,6-nonadienal, ethyl 2-methylpropanoate, (*E*)-2-nonenal, (*E*)-β-ionone, and terpinolene.[25]

A major deficiency in the body of previously published work on aroma-active compounds in mango is the application of simultaneous distillation−extraction (SDE) for the isolation of the volatile fraction.[16,17,20,25] The elevated temperatures acting on the fruit material during the SDE procedure are known to lead to compound degradation and artifact formation.[29] The use of mild volatile compound isolation techniques, such as solvent-assisted flavor evaporation (SAFE),[30] therefore, is an important factor in the identification of the authentic aroma-active compounds present in the fruits.

The aim of the present study was to apply a comparative AEDA (cAEDA) on the volatiles obtained by SAFE distillation from fresh, tree-ripened mangoes of different cultivars. To our knowledge, there are no reports on the aroma-active compounds in fresh mango fruit that employ the SAFE isolation technique to date. To gain insight into the compounds contributing to the specific sensory profiles of different mango cultivars, five cultivars exhibiting clear organoleptic differences were chosen for this investigation, namely, Haden, White Alfonso, Praya Sowoy, Royal Special, and Malindi.

The cultivar Haden was initially introduced in Florida in 1910 and inspired the creation of the large-scale mango industry in southern Florida. Haden is a seedling of the Indian cultivar Mulgoba and probably resulted from Mulgoba × Turpentine. Haden is the seed parent of numerous other U.S. cultivars.[31] Haden mango fruits are ∼10 × 8 cm in size and weigh up to 500 g. The skin is thick and tough, yellow in color, with crimson blush and numerous whitish-yellow glands. The fruit shape is egg-like with a depressed beak. The flesh is yellowish-orange, firm, and juicy, with a moderate fiber content and a pleasant aroma.[2]

Alfonso, also known as Appus, Badami, Gundu, Haphus, Kagdi, Khader, and Khader Pasand, is a small and traditional Indian cultivar dating back to the early 16th century. It is considered one of the finest dessert mangoes. The cultivar White Alfonso, also referred to as Safeda Afoos, originated in India, too, as a descendant of Alfonso and was collected in 1908 close to Mumbai. White Alfonso mangoes are large, with a weight up to 2 kg. They are yellow with a red blush skin, which is thick and tough. The orange colored flesh is sweet, firm, and juicy with minimal fiber.

Praya Sowoy is a typical Southeast Asian mango cultivar originating in Thailand. Fruits are big, weighing up to 1 kg, and have an oblong shape. The skin is yellow and thin, and the flesh is firm with little fiber.

Royal Special is a lesser known Indian mango cultivar that is mainly used for mango products such as pickles, dried mangoes, and canned juice.[32] The skin is thick and tough, and the flesh is juicy and fibrous.

The cultivar Malindi is a chance seedling of unknown parentage from the Kenyan coastline. It is also known as apple mango due to the round fruit shape resembling an apple. Malindi mangoes grow to approximately 1 kg. The skin is smooth and thin and the flesh yellow, juicy, and low in fiber.

MATERIALS AND METHODS

Mango Fruits. All samples were provided by the USDA ARS Station in Miami, FL, USA. Fruits were harvested by hand when fully ripe. State of ripeness was estimated by experienced ARS personnel through sensory evaluation of color, firmness, taste, and aroma. Fruits were shipped overnight by air freight to the Mars Global Chocolate Science and Technology Laboratory (Hackettstown, NJ, USA). Sensory analyses and preparation of aroma isolates were performed on the day of arrival.

Reference Aroma Compounds. The following reference aroma compounds were purchased from the commercial vendors given in parentheses: **1**−**2**, **4**−**8**, **10**−**16**, **19**−**24**, **26**−**36**, **38**−**45**, **47**, **49**−**54** (Sigma-Aldrich, St. Louis, MO, USA); **37** (Penta Manufacturing Company, Livingston, NJ, USA). Compounds **3**,[33] **9**,[34] **17**,[35] **18**,[36] **46**,[37] and **48**[37] were synthesized as described in the literature.

Miscellaneous Chemicals and Reagents. Diethyl ether and pentane were freshly distilled before use. Mercurated agarose gel was prepared from Affi-Gel 10 (Bio-Rad, Munich, Germany) using a procedure provided by Bio-Rad.

Sensory Analyses. Fresh mango samples (15 g) were cut into cubes (2 cm) and placed into 20 mL borosilicate glass scintillation vials (Thermo Fisher Scientific, Fair Lawn, NJ, USA). Each sample was orthonasally evaluated by free choice profiling and in a quantitative descriptive analysis (QDA) by 12 trained sensory panelists. The descriptors used in the QDA were defined on the basis of the odor of a reference compound dissolved in water at a concentration of 100 times above the respective threshold value or using a standard reference material. Reference odorants used in the sensory experiments were ethyl butanoate (fruity), 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (HDMF) (caramel, sweet), butanoic acid (sweaty), linalool (floral, citrus), (*Z*)-3-hexenal (green), myrcene (terpeny), γ-octalactone (coconut), and 4-mercapto-4-methyl-2-pentanone (tropical). The standard sensory reference materials used in the study were fresh pineapple cubes (2 cm) (pineapple) and fresh raspberries (raspberry). Panelists rated the descriptor for each of the samples on a seven-point scale in 0.5 increments from 0 to 3, with 0 = not detectable, 1 = weak, 2 = moderate, and 3 = strong.

Preparation of the Aroma Isolates. Fresh ripe mangoes (3 fruits) were peeled, seeds were removed, and the flesh was cut into sections (4 cm). The sections were immediately frozen in liquid nitrogen and ground into a fine powder with a laboratory mill. A portion of the powder (25 g) was sequentially extracted with freshly distilled diethyl ether (1 × 100 mL, 1 × 50 mL) on an autoshaker at ambient temperature for 10 min. After centrifugation (5000 rpm; 5 min), the supernatants were combined and the residue was discarded. The organic layer was isolated in a separatory funnel, and the aqueous layer was discarded. The ether extract was then subjected to high-vacuum distillation using SAFE.[30] The distillation apparatus was thermostated at 40 °C and kept under high vacuum (10^{-3} Pa). The sample was dropped into the evaporation flask of the device over 40 min. After an additional 30 min, the vacuum was broken, and the distillate was thawed at room temperature and dried over anhydrous sodium sulfate. The sample was then concentrated to approximately 2 mL using a Vigreux column (50 × 1 cm) and finally to 200 μL under a gentle stream of nitrogen. The aroma profile of the isolate was then

evaluated to ensure that it closely matched the profile of the fresh ripe mango flesh.

Gas Chromatography–Olfactometry (GC-O). A 6890 series GC system (Agilent Technologies, Santa Clara, CA, USA) was equipped with a DB-5 or an HP-FFAP capillary (each 30 m × 0.32 mm, 0.25 μm film thickness) (Agilent). The samples (1 μL) were injected cold-on-column at 35 °C using helium as the carrier gas. The flow rate was set to 1.0 mL/min. After 1 min at 35 °C, the oven temperature was increased at 60 °C/min to 60 °C, then increased at 6 °C/min to 230 °C, and held for 10 min. The effluent was split 1:1 by volume at the end of the capillary by a Y-type splitter into two 50 cm sections of uncoated deactivated fused silica capillaries. One section was directed to the flame ionization detector (FID) held at 250 °C and the other part to a heated sniffing port held at 180 °C. The sniffing port was mounted on the front FID detector base and consisted of a custom-machined aluminum cylindrical cone (80 mm × 25 mm i.d.) housing the capillary. During GC-O analysis, the odor of the effluent from the sniffing port was evaluated by a panelist. As an odor was detected, the retention time and the odor quality were recorded. Linear retention indices (RI) were calculated from these retention times and the retention times of adjacent *n*-alkanes by linear interpolation.

Comparative Aroma Extract Dilution Analysis. Aroma isolates were diluted to obtain serial dilutions of 1:2, 1:4, 1:8, ..., 1:2048. Dilutions 1:4, 1:8, 1:32, 1:128, 1:512, and 1:2048 were additionally analyzed by GC-O using the FFAP column and the conditions described above. For best comparison, corresponding dilutions of each cultivar were analyzed consecutively. For each cultivar, each aroma-active region was assigned an FD factor corresponding to the dilution factor of the highest diluted sample in which the odor was detectable.[27,28]

Fractionation of the Mango Aroma Isolates. Samples prepared as described above were concentrated to 1 mL with the use of a Vigreux column and applied to a silica gel solid phase extraction (SPE) cartridge (Phenomenex, Torrance, CA, USA) that was conditioned sequentially with pentane (5 mL), diethyl ether (5 mL), and a second portion of pentane (5 mL). Elution was performed with pentane (5 mL; fraction A) followed by pentane/diethyl ether (98:2, v/v; 5 mL; fraction B), pentane/diethyl ether (95:5, v/v; 5 mL; fraction C), pentane/diethyl ether (9:1, v/v; 5 mL; fraction D), pentane/diethyl ether (1:1, v/v; 5 mL; fraction E), and finally diethyl ether (5 mL; fraction F). Each fraction was then concentrated, first to 2 mL using a Vigreux column and finally to 200 μL under a gentle stream of nitrogen prior to analysis.

The volatile thiol fraction (fraction T) of each mango cultivar was isolated from a SAFE distillate obtained from 25 g of fruit pulp by affinity chromatography.[38] The SAFE distillate was concentrated (Vigreux column; 5 mL) and applied onto mercurated agarose gel (1 g) in a glass column (0.5 cm i.d.). After the column had been rinsed with dichloromethane (50 mL), the thiols were eluted with dithiothreitol (10 mmol/L) in dichloromethane (50 mL). The excess of dithiothreitol was removed by SAFE distillation, and the distillate was concentrated to 200 μL using a Vigreux column (60 cm) and a microdistillation device.[39]

The odorants detected during AEDA were localized in fractions A–F and T by GC-O, and mass spectra were recorded by gas chromatography-mass spectrometry (GC-MS) or two-dimensional heart-cut gas chromatography–olfactometry/mass spectrometry (GC-O/GC-O/MS).

Gas Chromatography–Mass Spectrometry. An Agilent 6890 series GC system equipped with an HP-FFAP column (30 m × 0.25 mm, 0.25 μm film thickness) (Agilent) was coupled via a heated (250 °C) transfer line to an Agilent 5973 mass spectrometer detector. Helium at 1 mL/min constant flow was used as the carrier gas. One minute after on-column injection at 35 °C, the oven temperature was increased at 60 °C/min to 60 °C and then at 6 °C/min to 230 °C. The final temperature was held for 10 min. The mass spectrometer was operated in electron impact (EI) ionization mode at 70 eV and a scan range of *m*/*z* 50–550.

Two-Dimensional Heart-Cut Gas Chromatography-Olfactometry/Mass Spectrometry. A gas chromatograph Mega 2 (Fisons Instruments, Mainz, Germany), equipped with a cold-on-column injector, a column DB-FFAP (30 m × 0.32 mm, 0.25 μm film thickness) (Agilent Technologies, Waldbronn, Germany), a moving column stream switching system (MCSS), and an FID plus a sniffing port as monitor detectors, was coupled via a heated (250 °C) deactivated fused silica capillary serving as transfer line to a CP 3800 gas chromatograph (Varian, Darmstadt, Germany) equipped with a cold trap and a column DB-5 (30 m × 0.25 mm, 0.25 μm film thickness) (Agilent). The column end was connected via a Y-shaped glass splitter and deactivated fused silica capillaries to a sniffing port and a Saturn 2000 mass spectrometer (Varian) operated in the EI mode. The sniffing ports each consisted of a cylindrical aluminum device with a beveled top and a central drill hole for the capillary and were mounted on a heated detector base of the GC. The tailor-made trap consisted of a piece of steel tubing housing the capillary and, when active, was cooled (−100 °C) by means of liquid nitrogen. The length and diameter of the splitting capillaries in the second oven were adjusted to ensure simultaneous detection of eluted compounds at the sniffing port and in the MS, which was confirmed by the analysis of test odorants.

For the structural assignment of compounds **3** and **9**, in a first run, the mango fractions containing the target compounds were separated on the first column while the MCSS conveyed the eluate to the monitor detectors. The retention times of the target compounds were determined by sniffing the eluate at the sniffing port. In a second run, during the elution of the target compounds, the eluate of the first column was transferred to the precooled trap where the heart-cut was condensed. After trap cooling had been turned off, the second oven was started. The eluate was monitored by sniffing, and when the target compound was detected at the sniffing port, the mass spectrum was recorded.

RESULTS AND DISCUSSION

Sensory Characteristics of the Mango Cultivars. Freshly cut pieces of the flesh of tree-ripened fruits of each of the five mango cultivars were evaluated by trained panelists, first using free-choice profiling (Table 1) and subsequently a QDA (Figure 1). Results showed distinct differences between the cultivars. The aroma of Haden mangoes was characterized as typical sweet mango-like with strong fruity, tropical, coconut-like notes. White Alfonso also showed a characteristic sweet mango-type aroma, but was less fruity than Haden, instead showing a pronounced terpeny note that distinguished it from all other varieties investigated. The sensory profile of Praya Sowoy was clearly dominated by a strong green, grassy odor note, whereas the scores of the other aroma notes were rather low in this cultivar. The overall aroma of Royal Special mangoes included the characteristic sweet mango-like note, a pronounced fruity note, pineapple-like and floral notes, and, in

Table 1. Sensory Characterization of the Five Mango Cultivars by Orthonasal Free-Choice Profiling (12 Experienced Panelists)

cultivar	aroma description
Haden	sweet mango aroma with fruity, tropical, coconut, and pineapple notes
White Alfonso	sweet mango aroma with terpeny, green, and coconut notes
Praya Sowoy	mildest sweet mango aroma with green and mild fruity notes
Royal Special	sweet mango aroma with some terpeny, fruity, and raspberry notes
Malindi	sweet mango aroma with some mild terpeny, green, pineapple, and tropical notes

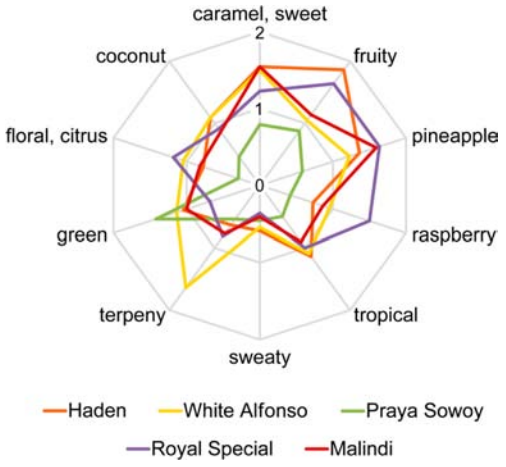

Figure 1. Aroma profiles of fresh fruit flesh obtained from five mango cultivars. Panelists rated the intensity of each attribute on a scale from 0 to 3 in 0.5 increments, with 0 = not detectable, 1 = weak, 2 = moderate, and 3 = strong.

particular, an intense and unique raspberry note. The aroma of Malindi was characterized as having a very balanced sweet mango aroma profile with pineapple-like, fruity, green, tropical, and mild terpeny notes, but lacking any special note.

Screening the Mango Volatiles for Aroma-Active Compounds. Tree-ripened mango fruits of each cultivar were peeled, the seeds were removed, and the flesh was cut into small sections. To stop enzymatic reactions, the sections were immediately frozen in liquid nitrogen and ground into a fine powder, which was subsequently extracted with diethyl ether. Nonvolatile compounds were removed from the extracts by SAFE,[30] and the distillates were concentrated. Elevated temperatures were avoided throughout the entire workup to avoid artifact formation and compound degradation. In particular, the extraction was performed at ambient temperature, and SAFE was carried out at 40 °C. As a result, the smell of the aroma isolates still clearly represented the typical aroma characteristics of the fresh flesh of the corresponding mango cultivars. Aroma isolates were submitted to a cAEDA,[27,28] which resulted in 54 aroma-active compounds in the FD factor range from 4 to ≥2048 (Table 2).

To assign the structures of the odorous compounds, their RIs, odor characteristics, and mass spectra were compared to data obtained from authentic reference substances. To separate aroma-active compounds from coeluted components and to aid in their identification by GC-MS, each of the aroma isolates was fractionated over silica gel to afford six fractions (A−F). Further aroma isolates of each cultivar were submitted to affinity chromatography[38] on mercurated agarose gel to selectively enrich thiols (fraction T). All fractions were subsequently analyzed by GC-O to localize the odorants and then by GC-MS to obtain their mass spectra. This procedure allowed for the structural assignment of 42 of the 54 aroma-active compounds (Table 2). When mass spectra could not be obtained using this procedure, due to either insufficient selectivity or sensitivity of the approach, fractions were further concentrated and analyzed by two-dimensional GC-O with heart-cutting and MS detection. This GC-O/GC-O/MS approach led to the structural identification of two further compounds, namely, compounds **3** and **9**. For nine compounds (**16**, **18**, **20**, **24**, **28**, **46**, **48**, **52**, and **53**) sufficiently pure mass spectra for identification could not be obtained, but unequivocal structural assignments were achieved on the basis of the comparison of RIs and odor characteristics as determined by GC-O on two capillaries of different polarities (FFAP, DB-5) with data of reference compounds analyzed in parallel. No reference compound was available for (*E*,*Z*,*Z*)-1,3,5,8-undecatetraene (**25**); thus, its structure was tentatively assigned by comparing RIs, odor characteristics, and mass spectra with published data.[40−42]

The results of the identification experiments in combination with the FD factors revealed the 27 compounds depicted in Figure 2 as the most potent aroma-active compounds in the five mango cultivars, all of which exhibited an FD factor of ≥128 in at least one of the samples analyzed. Among them, sweet, caramel-like-smelling HDMF (**47**) exhibited the highest FD factor (≥2048) in all five mango cultivars. HDMF, therefore, might be a major contributor to the characteristic sweet mango aroma note common to all cultivars investigated. HDMF has been reported in mangoes before[43] but has never been recognized as a major aroma-active compound yet. This might be associated with the volatile isolation techniques applied in previous GC-O studies. Hot steam distillation procedures such as SDE not only imply the problem of artifact formation and compound deterioration but also give rise to low recovery of rather polar odorants such as HDMF.[30] For the same reason, most probably, 4-hydroxy-3-methoxybenzaldehyde (vanillin, **54**), had never been identified in mangoes before.

High FD factors were further determined for some fruity-smelling esters including ethyl butanoate (**5**), ethyl 3-methylbutanoate (**7**), ethyl 2-methylpropanoate (**1**), and ethyl 2-methylbutanoate (**6**). These compounds most probably accounted for the general fruity note in the mango aroma profiles. All of these have already been reported as potent aroma-active compounds in mango,[15,20,25] and particularly the importance of ethyl butanoate for the aroma of Haden has been suggested before.[15] Similarly, lactones such as γ-octalactone (**43**) and δ-octalactone (**45**) have already been held responsible for the coconut-like odor note in mangoes.[20,25]

The particular pineapple-like aroma note clearly detected in Haden, White Alfonso, Royal Special, and Malindi corresponded quite well to high FD factors of the pineapple-like-smelling odorants (*E*,*Z*)-1,3,5-undecatriene (**21**) and/or (*E*,*Z*,*Z*)-1,3,5,8-undecatetraene (**25**) in these cultivars. A peculiar raspberry note perceived in the sensory profile of Royal Special might be explained by high FD factors of violet-like-smelling aroma compounds β-ionone (**44**, FD 512) and dihydro-β-ionone (**40**, FD 128). Whereas β-ionone is known to be an important contributor to the aroma of raspberries[44] and has already been reported as an aroma-active compound in mangoes,[20,25] dihydro-β-ionone is reported here for the first time in *M. indica*.

Although β-ionone was also detected as a potent odorant in White Alfonso (FD 512), no such strong raspberry note was present in the sensory profile of this cultivar, probably due to a dominating terpeny odor note. This note might most likely be caused by the terpeny-smelling compounds (*Z*)-β-ocimene (**14**) and (*E*)-β-ocimene (**15**), which were present in high amounts (FD 512 and 128) in White Alfonso, but rather low (FD ≤32 and ≤4) in the other four cultivars. (*E*)-β-Ocimene had already been shown to contribute to the aroma of Thai Khieo Sawoei mangoes.[16] The tropical aroma note detected in the mango samples might be associated with the tropical, passionfruit-like-smelling 4-mercapto-4-methyl-2-pentanone

Table 2. continued

was based on remaining criteria as indicated above. [i]Reference compound was not available. The structure was tentatively assigned by comparing retention indices, mass spectra, and odor characteristics with literature data.[40−42] [j]Odorants not separated on either GC column.

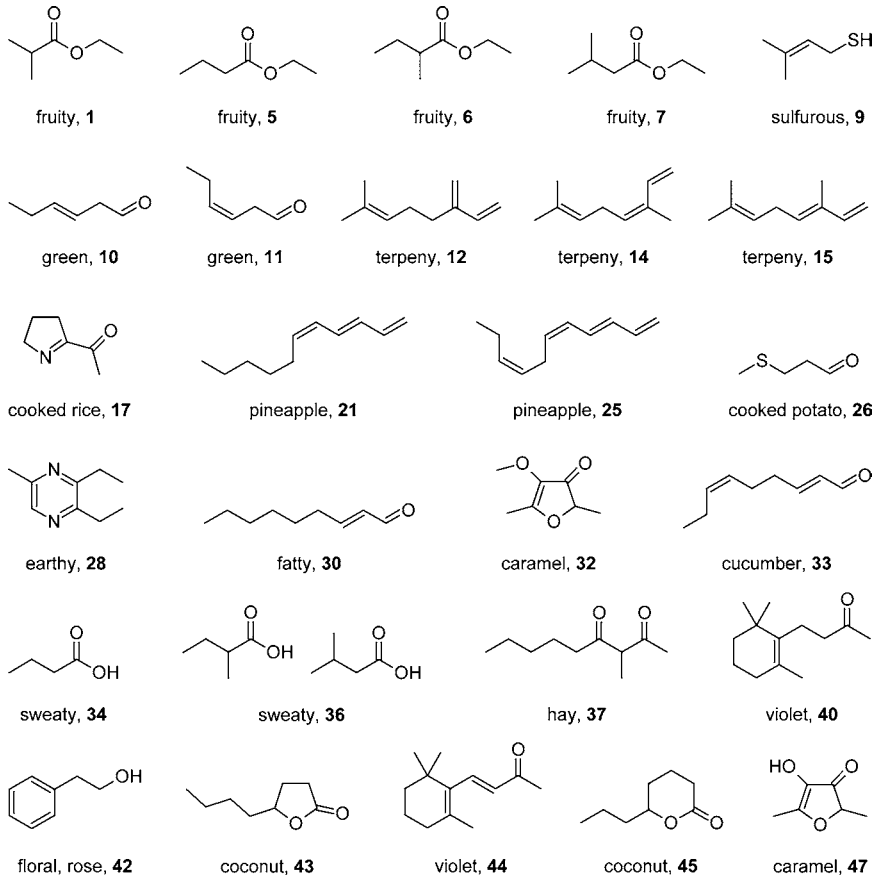

Figure 2. Aroma-active compounds with an FD factor ≥128 in at least one of the five mango cultivars analyzed.

(**20**). In Haden, however, sulfurous, skunk-like-smelling compounds (*E*)-2-butene-1-thiol (**3**) and 3-methyl-2-butene-1-thiol (**9**), previously unknown in mango, might further contribute to this specific odor character.

In good agreement with the dominating green, grassy odor note associated with Praya Sowoy mangoes, considerably high FD factors were determined for the green, grassy-smelling (*E*)-3-hexenal (**10**, FD 512) and (*Z*)-3-hexenal (**11**, FD 128). Cucumber-like-smelling (*E*,*Z*)-2,6-nonadienal (**33**, FD 128), fatty-smelling (*E*)-2-nonenal (**30**, FD 128), and hay-like-smelling 3-methyl-2,4-nonanedione (**37**, FD 128) might further contribute to the unique odor properties of Praya Sowoy. On the other hand, the sweaty, rancid-smelling butanoic acid (**34**) and 2-/3-methylbutanoic acid (**36**), although also present in rather high amounts (FD 128) compared to the other four varieties (FD ≤32), obviously did not have a vital influence on the overall aroma profile of Praya Sowoy.

In summary, the application of the cAEDA on the five mango cultivars resulted in 54 odor-active compounds, among which, to the best of our knowledge, 16 substances (**3**, **9**, **17**, **18**, **20**, **21**, **26**, **37**, **40**, **46**, **48**, **52**−**54**) are reported here for the first time as mango constituents. The FD factors provided useful ideas on the compounds responsible for the typical olfactory profile of mangoes in general and the compounds accounting for the aroma characteristics of individual cultivars. Nevertheless, the role of some odorants detected with high FD factors during cAEDA, such as the cooked rice-like-smelling 2-acetyl-1-pyrroline (**17**, FD ≤512), cooked potato-like-smelling 3-(methylthio)propanal (**26**, FD 512 in Haden), earthy-smelling 2,3-diethyl-5-methylpyrazine (**28**, FD 128 in Royal Special), and hay-like-smelling 3-methyl-2,4-nonanedione (**37**, FD 128 in Praya Sowoy), all of which had not been reported in mangoes before, is yet unclear. To fill this gap and to unequivocally confirm the hypotheses discussed before, further studies are required. Investigations on the role of individual odorants in the aroma of the five different mango cultivars, including exact quantitation of odor-active compounds by stable isotope dilution assays, aroma reconstitution experiments, and omission tests,[28] are currently under way.

Supporting Information

ABSTRACT: In this work, a novel electrochemical sensor for 3-chloro-1,2-propandiol (3-MCPD) detection based on a gold nanoparticle-modified glassy carbon electrode (AuNP/GCE) coated with a molecular imprinted polymer (MIP) film was constructed. *p*-Aminothiophenol (*p*-ATP) and 3-MCPD were self-assembled on a AuNP/GCE surface, and then a MIP film was formed by electropolymerization. The 3-MCPD template combined with *p*-ATP during self-assembly and electropolymerization, and the cavities matching 3-MCPD remained after the removal of the template. The MIP sensor was characterized by cyclic voltammetry (CV), differential pulse voltammetry (DPV) and scanning electron microscopy (SEM). Many factors that affected the performance of the MIP membrane were discussed and optimized. Under optimal conditions, the DPV current was linear with the log of the 3-MCPD concentration in the range from 1.0×10^{-17} to 1.0×10^{-13} mol L^{-1} ($R^2 = 0.9939$), and the detection limit was 3.8×10^{-18} mol L^{-1} ($S/N = 3$). The average recovery rate of 3-MCPD from spiked soy sauce samples ranged from 95.0% to 106.4% (RSD < 3.49%). Practically, the sensor showed high sensitivity, good selectivity, excellent reproducibility, and stability during the quantitative determination of 3-MCPD.

KEYWORDS: *molecularly imprinted polymer, electropolymerization, polyaminothiophenol, gold nanoparticles, 3-MCPD*

INTRODUCTION

3-Chloro-1,2-propandiol (3-MCPD) belongs to the chloropropanol chemicals that are formed by the reaction between hydrochloric acid and residual vegetable fat in the process of producing acid hydrolyzed vegetable protein (HVP).[1] Chloropropanols do not exist in the natural brew sauce produced by microbial fermentation. In recent years, HVP as a common savory ingredient is widely added to soy sauce and various composite seasonings. Therefore, 3-MCPD has been detected in a wide range of blended soy sauces.[2] However, there have been many studies on the toxicity of 3-MCPD such as neurotoxicity,[3] nephrotoxicity,[4] genotoxicity,[5] immunotoxicity,[6] and reproductive toxicity. Recently, 3-MCPD was classified by the IARC as group 2B and is thus "probably carcinogenic to humans".[7] The European Union (EU) established a limit level of 20 μg kg^{-1} for 3-MCPD in HVP and soy sauce.[8]

It is thus necessary to establish a simple and rapid analytical method for the trace detection of 3-MCPD. Several conventional techniques such as capillary electrophoresis with electrochemical detection,[9] gas chromatography combined with mass spectrometry (GC-MS),[10−12] and GC with electron capture detection (GC-ECD)[13] have been developed to detect 3-MCPD. Nevertheless, these methods are usually expensive and require highly trained technical personnel and complex sample pretreatment. In contrast, molecularly imprinted polymer (MIP) based electrochemical sensors have advantages such as rapid response, time savings, low cost, and high sensitivity and selectivity.

MIP sensors are currently widely used for the recognition and detection of template molecules.[14−17] In electrochemical sensors, MIPs can either accumulate the template molecules on the surface of the electrode, which makes the sensor more sensitive, or separate the template molecules from other analytes to improve the selectivity of the sensor. These advantages of MIPs make them ideal recognition elements for sensors. For the preparation of MIP sensors, electropolymerization can be used to directly synthesize MIP films in situ on the surface of the electrode.[18] The constructed imprinted films are stable and their thickness is easily controlled. And the quantity of effective recognition cavities on the surface of the sensor determines the sensitivity of MIP sensors. It is well-known that more binding cavities form with increasing MIP film thickness, but thick MIP films can make communication inefficient between the imprinted cavities and the transducer and result in slow analyte diffusion to the binding cavities.[19] Au nanoparticles (AuNPs) have been used to obtain higher surface area electrodes and thus increase the amount of effective imprinted sites.[18] This occurs by electrodeposition of AuNPs onto the electrode surface, which presents important advantages such as a large number of reactive sites, catalytic properties, large surface area, and high conductivity.[16,20] Self-

assembled monolayer (SAM) based chemically modified electrodes can also improve the performance of the solid electrodes. SAMs can be produced by strong chemisorption between organic molecules and a substrate. Moreover, SAMs have excellent stability, can be integrated with biomolecular electronic devices, and are widely used in sensors.[21−23]

In this study, self-assembly and electropolymerization were combined to prepare a MIP sensor for the determination of 3-MCPD. AuNPs were first electrodeposited onto a glassy carbon electrode (GCE) surface to obtain a higher surface area electrode to increase the number of effective binding cavities. Subsequently, *p*-aminothiophenol (*p*-ATP) was self-assembled onto the AuNP/GCE surface by the formation of Au−S bonds between gold and the thiol groups (-SH) of the *p*-ATP molecules. The 3-MCPD template was then further assembled onto the monolayer of *p*-ATP through hydrogen bonding between the amino groups of *p*-ATP and the hydroxyls of 3-MCPD. Finally, a MIP film was formed on the surface of the AuNP/GCE with *p*-ATP and 3-MCPD assembly by electropolymerization in an ethanol solution with *p*-ATP, 3-MCPD template, and tetrabutylammonium perchlorate (TBAP). A novel MIP sensor was thus obtained after removing the 3-MCPD template. The electrochemical behavior of the imprinted sensor was characterized by cyclic voltammetry (CV) and differential pulse voltammetry (DPV). The electrochemical experimental results indicate that the MIP sensor has high sensitivity and excellent selectivity toward 3-MCPD. And the MIP sensor was successfully used to detect trace amounts of 3-MCPD in real soy sauce, and it showed good reproducibility, stability, and recovery. This study provides a promising approach for preparing sensors and makes the fabricated sensor an ideal candidate for 3-MCPD detection.

MATERIALS AND METHODS

Reagents and Chemicals. 3-MCPD (97%), 1,3-dichloro-2-propanol (1,3-DCP, 97%), 2,3-dichloro-1-propanol (2,3-DCP, 97%), glycerol (99%), and 1,2-propanediol (99%) were purchased from J&K Chemical. Tetrabutylammonium perchlorate (TBAP, 99%) and *p*-ATP (97%) were obtained from Sigma (Aldrich, Spain). Tetrachloroaurate-(III) acid ($HAuCl_4$), potassium ferricyanide, and potassium ferrocyanide ($K_3[Fe(CN)_6]$ and $K_4[Fe(CN)_6]$, 99.5%) were provided by Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). All other reagents were chromatography analytical grade and prepared with ultrapure water. Ultrapure water was used throughout this work. Stock solutions of 100 mM analytes were prepared and kept in brown bottles at 4 °C. Soy sauce was purchased from a local supermarket.

Instruments. CV and DPV experiments were carried out with a CHI-760C electrochemical workstation (CH Inc., Shanghai, China). The conventional three-electrode system was employed with a modified glass carbon electrode (GCE, Φ2 mm) as working electrode, a platinum wire as auxiliary electrode, and a saturated calomel electrode (SCE) as reference one. The morphology of the modified GCE surface was observed using a scanning electron microscope (SEM) (Hitachi S-4800, Japan). All experiments were performed at ambient temperature.

Fabrication of a AuNP Modified GCE. Before electrode modification, a bare GCE was immersed in a fresh piranha solution of H_2SO_4/30% H_2O_2 (3:1, v/v) for 15 min and then rished with redistilled water. The GCE was polished to a mirror-finish with a slurry of alumina (0.30 and 0.05 μm), washed with ultrapure water, and then ultrasonicated in ethanol and ultrapure water for 2 min. The polished GCE was then dipped in 2.43 mmol L^{-1} aqueous $HAuCl_4$ solution with 0.1 mol L^{-1} H_2SO_4 and treated at −0.2 V constant potential for 200 s. After being rinsed several times with ultrapure water and absolute ethanol, the modified GCE was immersed in H_2SO_4/30% H_2O_2 (3:1, v/v) solution for 5 min, washed with ultrapure water, and then dried under nitrogen flow at room temperature.

***p*-ATP and 3-MCPD Self-Assembly on the AuNP/GCE.** The *p*-ATP-modified electrode was prepared according to the reported methods.[19,24,25] The prepared AuNP/GCE was immersed in an ethanol solution containing 5 mM *p*-ATP for 24 h at room temperature, removed, and then washed with ethanol and redistilled water to remove physically absorbed *p*-ATP. Then, the *p*-ATP-modified AuNP/GCE was immersed in an ethanol solution with 1 mmol L^{-1} 3-MCPD for 4 h. The electrode was removed, rinsed with ethanol and redistilled water to remove physically absorbed 3-MCPD, and then dried under nitrogen gas at ambient temperature.

Fabrication of Imprinted PATP−AuNP/GCE. The *p*-ATP−3-MCPD modified AuNP/GCE was immersed in an ethanol solution containing 0.1 mmol L^{-1} *p*-ATP, 0.05 mmol L^{-1} 3-MCPD, and 50 mmol L^{-1} TBAP. After the polymer solution was deoxygenated under nitrogen flow for 15 min, electropolymerization was carried out by 10 CV scannings between −0.3 V and +1.2 V (scan rate 50 mV s^{-1}). Then, the imprinted PATP−AuNP/GCE was immersed in methanol/water (2:1) solution containing 4 mol L^{-1} HNO_3 for 25 min to remove the 3-MCPD template. For comparison, a nonimprinted PATP−AuNP/GCE was fabricated and treated in the same way without adding the 3-MCPD template.

Electrochemical Measurements. CV and DPV measurements were carried out to evaluate the current response of the modified electrodes immersed in a solution of 2.5 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ with 0.1 mol L^{-1} KCl as the supporting electrolyte over an applied potential range from −0.2 to +0.6 V. All measurements were carried out at ambient temperature. Cyclic voltammograms (CVs) of the MIP film were performed by scanning the potential between −0.3 and +1.2 V at a scan rate of 50 mV s^{-1}.

Detection of 3-MCPD in Real Soy Sauce Samples. Soy sauce samples provided by a local market were used to evaluate the developed MIP sensor. All samples were determined to be free of 3-MCPD by GC-ECD detection before performing spiking and recovery studies. Soy sauce samples (1.0 mL) were spiked with a 3-MCPD standard solution at concentration levels of 10^{-16}, 10^{-15} and 10^{-14} mol L^{-1}. After mixing with a vortex mixer, the samples were centrifuged at 4000 rpm for 10 min at room temperature. The supernatants were ultrasonicated with ethyl acetate (3 mL) three times for 15 min each. After keeping steady for 10 min, the resulting extractants were collected, dried under nitrogen flow at room temperature, and then dissolved in 1 mL of ethanol solution. The mixture was then centrifuged at 4000 rpm for 10 min, and the clear solution was analyzed using the MIP sensor.

RESULTS AND DISCUSSION

Fabrication of the AuNP Modified GCE. During electrodeposition of AuNPs onto the GCE surface, efficient coverage of AuNPs was obtained by controlling the deposition time. The deposition time was optimized by testing the DPV signals of the AuNP/GCE in 2.5 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$

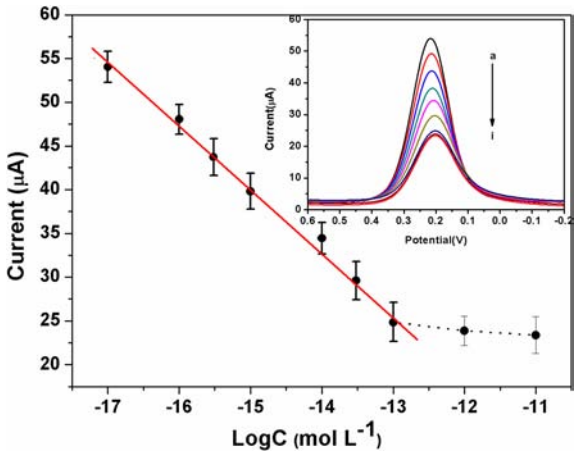

Figure 4. DPV of the PATP−AuNP/GCE incubated using different concentrations of 3-MCPD: (a−i) 10^{-17}, 10^{-16}, 10^{-15}, 10^{-14}, 10^{-13}, 10^{-12}, or 10^{-11} mol L^{-1} 3-MCPD in an aqueous solution for 6 min.

with 0.1 mol L^{-1} KCl. As shown in Figure s1A, Supporting Information, the DPV response of $[Fe(CN)_6]^{3-/4-}$ reached the maximum at 1400 s and then decreased. Although the number of AuNPs on the electrode surface increased with the longer deposition time, the further accumulation of AuNPs would decrease the surface area of the AuNPs, which would reduce the current response of the modified electrode. The obtained SEM images showed that the AuNPs had a uniform dispertion on the electrode surface (Figure s1B, Supporting Information). Since the current response of $[Fe(CN)_6]^{3-/4-}$ slightly increased

from 200 to 1400 s, a deposition time of 200 s was selected to fabricate the AuNP modified GCE.

Fabrication of Imprinted PATP−AuNP/GCE. Scheme 1 shows the preparation procedure used to produce the imprinted PATP−AuNP/GCE. The preparation procedure can be summarized in four steps: *p*-ATP self-assembly on the AuNP/GCE surface; hydrogen bonding adsorption of 3-MCPD template onto the *p*-ATP−AuNP/GCE surface; electropolymerization of PATP on the AuNP/GCE surface with *p*-ATP and 3-MCPD assembly; removal of 3-MCPD template from the MIP film. Before electropolymerization, the AuNP/GCE was immersed in a *p*-ATP solution for 24 h. A SAM of *p*-ATP molecules was formed on the surface of AuNP/GCE by Au−S bonds between the gold particles and the thiol groups (-SH) of the *p*-ATP molecules. Then, the *p*-ATP monolayer was chemisorbed onto the AuNP/GCE surface, and this exposed an array of amino groups to the solution. Subsequently, the *p*-ATP−AuNP/GCE was immersed in the 3-MCPD solution for 4 h. The 3-MCPD template assembled on the *p*-ATP−AuNP/GCE surface through hydrogen bonding between the amino groups ($-NH_2$) of *p*-ATP and the hydroxyls of 3-MCPD. The self-assembly of 3-MCPD increased the number of the binding sites in the MIP film and enhanced the sensitivity of the sensor. Furthermore, the SAM formed by *p*-ATP and 3-MCPD served as an initial polymerizable monolayer to drive selective electropolymerization on the AuNP/GCE surface.[26]

The imprinted PATP membrane was electrodeposited onto the surface of AuNP/GCE followed by *p*-ATP and 3-MCPD assembly in an ethanol solution with 0.1 mmol L^{-1} *p*-ATP, 0.05 mmol L^{-1} 3-MCPD, and 50 mmol L^{-1} TBAP by ten CV scannings over the potential range of −0.3 and +1.2 V with a scan rate of 50 mV s^{-1}. Figure 1A showed the representative CV response of the electropolymerization process that was used to form a PATP membrane on the surface of AuNP/GCE. During electropolymerization, radical anions were produced at a certain scan potential, and they initiated the polymerization of *p*-ATP. The CV behavior of *p*-ATP showed that it undergoes an entirely irreversible oxidation process. The oxidation peak of *p*-ATP was clearly observed at a 0.658 V potential on the first scanning. The peak current gradually reduced with increasing the scan cycles, and it eventually reached a steady state after 10 scan cycles. The oxidation peak potential of *p*-ATP slightly shifted to more anodic potential from 0.658 to 0.747 V. The results showed that a polymeric PATP membrane was formed on the AuNP/GCE surface. The decrease in the current response seemed to be related to the continuous formation of the PATP film, which suppressed the oxidation reaction of *p*-ATP. The morphology of the PATP−AuNP/GCE surface was observed using SEM, as shown in Figure 1B. The roughness of the PATP−AuNP/GCE surface increased obviously compared with the surface of the AuNP/GCE, indicating that the polymer membrane was successfully deposited onto the surface of the electrode. To evaluate the hydrophilic property of the MIP film, a contact angle experiment was provided. The contact angle θ was 98.5°, which indicated that the MIP film was hydrophobic (Figure s2, Supporting Information).

The cyclic voltammograms of the film formed with and without 3-MCPD were similar, which indicated that 3-MCPD did not have any effect on the electroactivity on the AuNP/GCE in the polymerization potential window range. Therefore, the structure of 3-MCPD was not electrochemically changed during the polymerization process.

Characterization of the Electrochemical Behavior of the MIP Sensor. The CV responses of the bare and modified electrodes were recorded in 2.5 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ with 0.1 mol L^{-1} KCl to confirm whether 3-MCPD was embedded in the MIP membrane, where the redox current of $[Fe(CN)_6]^{3-/4-}$ was used to evaluate the procedure. Figure 2 showed the relationship between the surface modification conditions of the GCE and the peak current. The bare electrode showed a couple of redox peaks with a peak potential separation (ΔE_p) of 93 mV and an I_p ratio of about 1:1 in curve a. After covering with AuNPs, a decrease in the ΔE_p (75 mV) and an increase in the I_p were obtained, as shown in curve b. This could be attributed to an increase in electrocatalytic effect and the effective surface area of the AuNPs, which could greatly increase the electron transfer rate of $[Fe(CN)_6]^{3-/4-}$. Curve c

dx.doi.org/10.1021/jf4055159 | J. Agric. Food Chem. 2014, 62, 4552−4557

shows the current response of the MIP sensor before the removal of 3-MCPD. By comparison with the current response of the AuNP/GCE, almost no redox peak was observed, which indicated that the MIP film had been formed on the AuNP/GCE surface. After removing 3-MCPD (curve d), a decrease in ΔE_p (129 mV) and an obvious increase in I_p were observed. A possible reason was that the cavities after 3-MCPD removal enhanced the diffusion of $[Fe(CN)_6]^{3-/4-}$ through the MIP film and promoted the redox reaction of $[Fe(CN)_6]^{3-/4-}$ on the sensor. The emergence of curve e can be ascribed to the limited access of $[Fe(CN)_6]^{3-/4-}$ to the imprinted membrane after recombining 3-MCPD. This can be explained by the interaction between 3-MCPD and the imprinted membrane, which determines the electron transfer properties of $[Fe(CN)_6]^{3-/4-}$ on the surface of the electrode. In contrast, for the NIP sensor after template removal (curve f), almost no electrochemical response was obtained because the PATP membrane covered the GCE surface polymerized in the absence of 3-MCPD, which caused that no cavities with binding sites to be available. The eluted nonpolymerized *p*-ATP in the NIP film lead to a minor change in redox current, which was negligible after template removal. This indicates that the NIP sensor is nonselective and fails to recognize 3-MCPD.[27]

Optimization of the Incubation and Elution Time. The incubation time is an important factor that influences the adsorption of the targets on the sensor. To determine the optimum incubation time for the detection of 3-MCPD, the imprinted PATP−AuNP/GCE was incubated over different times in 2×10^{-15} mol L^{-1} 3-MCPD. As shown in Figure 3A, the current decreased significantly with an increase in incubation time and reached a stable response after 6 min, which indicated that an adsorption equilibrium was obtained. Therefore, the optimum incubation time for 3-MCPD determination was 6 min.

After electropolymerization, the PATP membrane modified GCE was immersed in a methanol/water (2:1) solution containing 4 mol L^{-1} HNO_3, which was used to remove the template. As shown in Figure 3B, the current gradually increased and reached a maximum at about 25 min, and it remained stable over 15 min, which means that the template was completely removed at about 25 min in this elution solution. As a result, an adsorption time of 6 min and an elution time of 25 min were selected in the following sections.

Electrochemical Detection of 3-MCPD. To detect 3-MCPD, the proposed PATP−AuNP/GCE was immersed in different concentrations of 3-MCPD solution from 1×10^{-17} to 1×10^{-11} mol L^{-1}, and a significant decrease in peak current was observed as shown in the inset of Figure 4. This indicated that when 3-MCPD was recombined, a compact film appeared on the electrode surface, which prevented $[Fe(CN)_6]^{3-/4-}$ from accessing the electrode surface. The formed PATP film resulted in a lower electrochemical response for the $[Fe(CN)_6]^{3-/4-}$ probe.

For quantitative analysis, the proposed PATP−AuNP/GCE was incubated at different concentrations of 3-MCPD for 6 min. DPVs of the sensor were recorded in a 2.5 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ solution containing 0.1 mol L^{-1} KCl. After a 6 min preconcentration, because the binding sites in the membrane were occupied by 3-MCPD template, the redox peak current decreased with an increase in 3-MCPD concentration. As shown in Figure 4, the decrease in DPV signals is directly related to the increase of 3-MCPD concentration. A linear behavior between the DPV current and the log of the 3-MCPD concentration was obtained from 1×10^{-17} to 1×10^{-13} mol L^{-1} (R^2 = 0.9939). The lowest detectable concentration was 3.8×10^{-18} mol L^{-1}, which was more sensitive than most available 3-MCPD detection methods (Table 1).

The Adsorption Characteristics of the MIP Sensor. The adsorption curves of the MIP and NIP sensor for 3-MCPD were plotted in Figure s3, Supporting Information. With the increase of concentration of 3-MCPD, the adsorption capacity of the MIP sensor gradually increased and reached the stability. It showed that the MIP sensor had an excellent adsorption for 3-MCPD and the NIP sensor had almost no adsorption.

The selectivity of the MIP sensor, based on the specific interaction between the template and the binding cavities, is an important factor to be considered. The selectivity of the MIP sensor toward 3-MCPD was evaluated by determining its DPV signals in the presence of analogues including glycerol, 1,2-propanediol, 1,3-DCP, and 2,3-DCP. It was calculated using the peak current ratio (I_m/I_o) where I_m and I_o are the anodic peak current of $[Fe(CN)_6]^{3-/4-}$ at about 0.2 V potential with and without structural analogues. A 10-fold excess of glycerol, 1,2-propanediol, 1,3-DCP, and 2,3-DCP in the presence of 3-MCPD hardly changed the peak current of $[Fe(CN)_6]^{3-/4-}$, as shown in Figure 5. The I_m/I_o only varied slightly between 0.91 and 0.98 (inset of Figure 5). The results indicated that the proposed sensor had a higher recognition selectivity for 3-MCPD than for analogues. This may be explained by the fact that the delicate binding cavities of the 3-MCPD template in the MIP film are able to recognize the template molecules through their shape, size, and functional group distribution, which can be used to detect 3-MCPD from a complex matrix without separation.

The Reproducibility and Stability of the MIP Sensor. To evaluate the reproducibility and repeatability of the MIP sensor, experiments were carried out in 10^{-15} mol L^{-1} 3-MCPD solution. The MIP sensor was regenerated with a peak current RSD of 3.12% using four different GCE electrodes. The excellent reproducibility was obtained with a relative standard deviation of 2.93% after 20 washes and measurements. Therefore, the MIP sensor has good reversibility. Moreover, the good stability of the sensor is a key factor for the 3-MCPD detection. To evaluate its stability, the MIP sensor was stored at room temperature for 10 days, and the peak current did not significantly change. After a month, it decreased to 92%. All measurements indicate that the MIP sensor possesses excellent stability.

Application to Real Soy Sauce Samples. The proposed method was used to determine the amount of 3-MCPD in soy sauce samples. The soy sauce samples were directly spiked with 10^{-16}, 10^{-15}, and 10^{-14} mol L^{-1} 3-MCPD, respectively. The result showed that the average recovery of 3-MCPD from the soy sauce samples was excellent and ranged from 95.0% to 106.4% with less RSD (<3.49%) in Table 2. Therefore, the established method can be used to detect the trace content of 3-MCPD in soy sauce without sample pretreatment.

Supporting Information

ABSTRACT: Cabernet Sauvignon and Shiraz grapes were sourced from different regions within Australia, and microvinified with a skin contact period of 6 days. Grape samples were extracted using two protocols: a 15% v/v ethanol, 10 g/L tartaric acid extract of gently crushed berries (wine-like, WL) and a 50% v/v ethanol, pH 2 extract of grape berry homogenate. It was found that in WL extracts, grape tannin and anthocyanin concentrations were strongly related to wine tannin, anthocyanin and color density achieved during the skin contact period. No relationship was observed for grape tannin concentration analyzed in homogenate extracts and wine tannin, but a strong, positive relationship was found for anthocyanin concentration. When the data obtained from homogenate extraction was treated separately by grape variety, a stronger relationship between grape and wine tannin concentration was observed. Tannin compositional analysis in wines indicated that higher tannin concentrations were due to the extraction of tannin of higher molecular mass during fermentation, most likely from grape skins.

INTRODUCTION

In the production of red wines, it is crucial to optimize the extraction of grape-derived phenolic compounds, primarily anthocyanin and condensed tannin (proanthocyanidin) in order to ensure the development of stable wine color and desirable textural properties. Tannins extracted during wine-making potentially originate from grape skins, seeds and pulp[1] while in most commercially-produced grape varieties, anthocyanins occur only in the grape skins. The extraction of phenolics from these respective grape components during fermentation differs significantly, with anthocyanin and skin tannin being extracted early,[2,3] and seed tannin being extracted later. While a significant amount of tannin is present in grape pulp, this appears to remain nonextractable during fermentation, potentially due to a strong association with pulp cell wall constituents.[1] Interactions between tannin and cell wall constituents may also occur in grape skins (and potentially seeds), which limits tannin extraction into the wine.[1] Apart from exerting a limiting effect on tannin extractability, cell wall constituents from grape and yeast cells which become suspended during fermentation can bind, and remove tannin and anthocyanin as these settle to form wine lees.[1,4,5]

There are only a limited number of published studies which have directly explored the relationship between grape phenolic concentration and wine composition. Studies which have attempted to draw correlations between an exhaustive extract of homogenized grape samples (50% v/v ethanol) and the corresponding wines[6,7] have shown positive relationships for grape anthocyanin analysis and wine color indices. However, for tannin analysis in 50% v/v ethanol extracts of whole-grape homogenates, the relationship between grape and wine tannin has been found to be weak[7] or absent.[6] Some studies have explored the relationship between only grape skin tannin concentration and wine tannin concentration.[8−12] These have shown a strong relationship, in which higher grape skin tannin concentrations were correlated with higher wine tannin concentrations. Interestingly, a cocorrelation between higher grape skin tannin concentration, grape anthocyanin concentration and wine color density was a common observation by these authors.[8−12]

Color, as well as anthocyanin and tannin concentrations in wine, have been shown to be positively associated with market value grade, and they are therefore useful as objective markers for wine quality.[13,14] Higher wine tannin, anthocyanin and polymeric pigment concentrations have been shown to be strongly correlated with wine color density and overall quality score as defined by a sensory panel.[10] Yet, despite this clear indication that the strategic management of wine tannin and anthocyanin is important, a rapid analytical method to predict wine phenolic profile from grapes has not yet been developed.

Various factors may have hindered progress in this area. Foremost, rapid, high-throughput analysis methods which are specific for tannin have only recently been developed.[15−18] Another important consideration is that most analytical methods aim to achieve as close to an exhaustive extraction as possible, and this is evident in techniques applied for grape tannin and anthocyanin.[15,16] Wine, on the other hand,

represents a partial extraction from the grape solids. As a result, using an exhaustive extraction method might not capture information regarding the intrinsic variability in the kinetics of tannin and anthocyanin extraction during fermentation, as well as potential back-binding events to cell wall constituents. In light of this, a desirable, commercially relevant outcome for wine industry producers would be a procedure for the prediction of anthocyanin and tannin concentrations achievable during fermentation, specifically, the stage during which skin tannin extraction approaches a plateau and is proportionally higher than tannin extraction from seeds.[2,3,19] In addition, considering that certain winemaking techniques may increase extraction of tannin from the grape solids,[20] a measure of total grape tannin (i.e., exhaustive extraction) is also of relevance for decision-making in the winery. Both measures could inform producers how best to approach processing, e.g. guiding pressing decisions or for benchmarking winemaking procedures. Conceptually, the idea of an "extractability" assay is not new, and methods have been proposed by other authors to represent phenolics extractable under aqueous conditions, in comparison with a harsh, high-solvent extraction.[21−23] However, this has yet to be demonstrated as relevant across a sufficiently wide range of grape and wine phenolic compositions. There exists a significant knowledge gap in understanding the grape to wine relationship: in terms of both tannin and anthocyanin extractability, their retention in wine and the development of wine color.

The current study aimed to validate an extraction protocol which mimics the conditions of fermentation, and apply it to grape samples representing a wide a wide range of phenolic composition. To do this, a large sample set from two commercial grape varieties at different ripeness grades were sourced across a number of grape-growing regions within South Australia. Grape batches were subjected to extraction in dilute 15% v/v alcohol (wine-like extract, WL), as well as to a more exhaustive extraction protocol using homogenized grapes and 50% v/v ethanol, and were microvinified. Tannin and anthocyanin concentrations in grape extracts and wines were compared, and they provide a proof of concept that grape compositional parameters can be measured to predict wine phenolic outcomes. This indicates the scope for the development of a commercially-relevant analytical approach.

MATERIALS AND METHODS

Grape Sampling and Processing. A total of 39 batches of fruit (approximately 8 kg) were sourced from two grape varieties in the 2012−2013 growing season: 20 samples of Cabernet Sauvignon grapes and 19 samples of Shiraz grapes. Grape regions and vineyards were selected by a commercial wine producer (Accolade Wines, Reynella, SA, Australia). Grapes were harvested at commercial ripeness from five growing regions within South Australia: Riverland, McLaren Vale, Clare, Padthaway, and Langhorne Creek. The temperature and rainfall data for these regions for the 2012−2013 growing season are shown as S1 in the Supporting Information. Following harvesting, batches of fresh fruit were stored sealed, and they were then immediately transported to Adelaide, South Australia. On arrival, fruit batches were stored at 4 °C for no more than 6 days. In order to facilitate sample processing and small-scale winemaking, no more than 10 batches of grapes were processed within a week. Fruit batches were therefore processed at five time points over a period of 2 months, for which the dates of sample preparation are shown in Table 1. Grape batches were completely destemmed by hand, and thereafter, subsamples were taken for analysis and winemaking. For analysis of average berry weight, juice pH, titratable acidity (TA) and total soluble solids (as °Brix), a 200-berry sample was collected and weighed. This was then transferred to a plastic bag equipped with a resealable zipper and gently crushed by hand. Expressed juice was collected through a 0.5 mm sieve, and then centrifuged at 1730*g* for 5 min. Juice °Brix was determined using a digital refractometer. TA and pH were determined using a pH meter and combination electrode. The TA was determined by titrating with 0.33 M sodium hydroxide solution to a pH end-point of 8.2, and expressed in g/L of tartaric acid equivalents. From each destemmed grape berry sample, triplicate 50 g (±0.5 g) and 200 g batches were sampled and the weight recorded, and these were then transferred to plastic bags equipped with a resealable zipper or in screw-cap polypropylene containers, respectively. The triplicate 50 and 200 g samples were stored at 4 °C and processed fresh within 3 h, as described below. For certain grape samples, further triplicate batches of 50 and 200 g were collected as described above, but they were immediately frozen at −20 °C. These grape batches were stored for either 24 h, 1 month or 3 months in order to determine the effect of freezing on anthocyanin and tannin concentration measured by different analytical methodologies. Finally, triplicate 1 kg samples were collected from each destemmed grape batch and transferred to sealed plastic bags. Care was taken to minimize grape crushing, and samples were stored at 4 °C overnight, before being processed for microvinification, as described below.

Extraction of Whole Berry Samples under Wine-like Conditions. To simulate the extraction of tannin and anthocyanin from gently crushed grapes under wine-like conditions, a WL extraction protocol in model wine solution was developed. The extraction solvent was prepared containing 400 mL/L absolute ethanol and 10 g/L tartaric acid, pH 3.4. Frozen 50 g berry samples were brought to room temperature by placing them sealed, within a 25 °C water bath for 1 h. Defrosted or fresh triplicate 50 g berry samples, retained in a plastic bag equipped with a resealable zipper, were gently crushed by hand. Crushed grape berries and juice were transferred to a 70 mL polypropylene jar, and 15 mL of extraction solvent was added, to each sample. This addition was based on an approximate juice yield of 0.5 mL per g of fruit, in order to extract in 15% v/v ethanol. Samples were sealed under screw cap and extracted on a platform shaker at 25 °C in the dark for 40 h. After extraction, samples were pressed by hand through a 0.5 mm sieve and the volume of recovered extract recorded. For the sample set studied, the percentage standard deviation of the average recovered extraction volume was 7%. The grape skin and seed residue were recovered and re-extracted in 30 mL of 50% v/v aqueous ethanol pH 2 (with HCl) for a further 18 h. The 50% ethanol extract was recovered as described above, but the volume was not recorded. The WL and 50% ethanol extracts were centrifuged at 1730*g* for 5 min, and thereafter aliquots were removed for the analysis of tannin and anthocyanin as described below.

Optimization of Extraction Volume and Time for Model Wine Extracts. Before the main experiment was commenced, the effect of extraction volume and the length of the extraction on tannin concentration per unit berry fresh mass were investigated for a single Cabernet Sauvignon grape sample obtained from a vineyard located at the Waite Campus, University of Adelaide. Grape samples were prepared as outlined above, but the extraction volume per 50 g sample was adjusted between 35 and 75 mL, maintaining the ethanol concentration at 15% v/v. Extractions were performed in triplicate, and tannin and anthocyanin concentrations were monitored at five time points over a 64 h period and then analyzed as outlined below (Supporting Information S2).

Extraction of Grape Berry Homogenates. Homogenate extractions were performed according to a published protocol.[5,15,16] The selection of a 200 g grape sample for homogenization was required for the type of homogenizer used, which was a Retsch Grindomix GM200 (Retsch GmbH & Co., Germany). Frozen 200 g berry samples were defrosted by placing them at 4 °C for 18 h. Both fresh and defrosted triplicate 200 g samples were homogenized cold (<10 °C) and analyzed on the day of homogenization. Berry samples were homogenized in at 8000 rpm for 20 s. A 1 g portion of homogenate was weighed into a pretared centrifuge tube and the mass recorded. The homogenate was then extracted in 10 mL of 50% v/v, aqueous ethanol, pH 2. Tubes were capped and extractions carried out

on a suspension mixer for 1 h at room temperature. The tube was then centrifuged at 1730*g* for 10 min, and the supernatant analyzed as described below.

Microvinification. The triplicate 1 kg grape batches were retained in the plastic bag equipped with a resealable zipper which had been used for storage at 4 °C overnight, and crushed by hand, ensuring that no leakage of juice occurred. All grape juice and solids (skin, seeds) were transferred to sterile 1.5 L glass French Press coffee plungers (Bodum, Triengen, Switzerland) using a glass funnel. A standard addition of 50 mg potassium metabisulfite (PMS) (Enartis Pacific Pty Ltd., Nuriootpa, South Australia) was made per 1 kg ferment. The ferments were adjusted to a pH of 3.5 by the addition of tartaric acid (Australian Tartaric Products Pty Ltd., Red Cliffs, Victoria, Australia). *Saccharomyces cerevisiae* PDM yeast (Maurivin, Sydney, Australia) and diammonium phosphate (DAP) were added at a rate of 300 mg/kg must. Each ferment, including the glass French Press and plunger, was weighed. Fermentation was initiated at a constant temperature of 25 °C, and the progress of fermentation was monitored daily by the reduction in ferment weight. On a daily basis the plunger was gently lifted to mix the wine, and thereafter the fermentation cap was resubmerged leaving approximately 1 cm of wine above the plunger surface. After 6 days of fermentation the plunger was lowered to press off the wine from the grape solids. Wine was carefully transferred to a 500 mL bottle equipped with an oxygen trap and kept at 25 °C for a further 24 h. For the first sample series undergoing fermentation, 5 out of 6 grape batches had completed fermentation within the 7-day period, with residual glucose and fructose levels below 0.5 g/L (Table 2). In order to prevent oxidation or film yeast growth, and well as to retain consistency in processing between the various fermentation experiments, all ferments were stopped at 7 days. This was also an important consideration to prevent the introduction of skin contact time as an additional variable in the study. To stop fermentation, an 80 mg addition of total SO_2 as PMS (as a 10% w/v solution in water) was added to each ferment, stirred, and allowed to equilibrate for 2 h. Wine was decanted into sterile 100 and 200 mL glass bottles, sealed under screw-cap with no ullage, and stored for 4 weeks at 4 °C. Thereafter, wine was sampled for analysis of pH and TA as described above. Residual sugar in each wine was determined as glucose and fructose equivalents using an automated analyzer (Daytona) with the enzymatic method of Randox (Randox Laboratories, Crumlin, United Kingdom). Volatile acidity was measured using a multispectral wine analyzer (Microdom, Taverny, France) and was between 0.2 and 0.7 g/L across the wine sample range. Wine tannin, anthocyanin and color were analyzed as described below. A further 10 mL aliquot of each wine was frozen at −80 °C for later analysis of tannin composition. The decision to freeze wine samples for analysis was based on the previous observation that tannin concentration in both WL grape extracts and wines are stable within 18 months (Supporting Information S3).

Analysis of Anthocyanin, Tannin and Wine Color Properties. Tannin, anthocyanin and color properties in triplicate grape extracts and wines were analyzed using a standard high-throughput method.[16] Each analysis was performed in duplicate. Briefly, tannin concentration was analyzed following precipitation by methyl cellulose (MCP) in 1.1 mL 96-well plate. A 25 μL sample of grape extract or wine was combined with 300 μL of 0.04% (w/v) methyl cellulose (Sigma-Aldrich, St. Louis, MO, USA) solution, mixed on an automated plate shaker and left to stand for 3 min. A sample control was included where water was added in place of the methyl cellulose solution. A 200 μL aliquot of saturated ammonium sulfate (Sigma-Aldrich, St. Louis, MO, USA) was added, followed by 475 μL water. Where tannin concentration was below detection limit, the sample was increased up to 100 μL and the volume of water adjusted accordingly to give a final volume of 1 mL. Samples were mixed on an automated plate shaker and left to stand for 10 min. Centrifugation was performed for 5 min at maximum speed on a Hettich Universal 32 R centrifuge equipped with a Hettich 1645 rotor for 96-well plates (Adelab Scientific). A 300 μL aliquot of supernatant from the methyl-cellulose treated and control samples were transferred into a 370 μL 96-well UV plate and the 280 nm absorbance measured using a SpectraMax M2Microplate Reader (Molecular Devices, Australia). Quantification was performed by analyzing the difference in 280 nm absorbance between control and MCP-treated samples, using (−)-epicatechin (Sigma-Aldrich, St. Louis, MO, USA) as the quantitative standard. To ensure standardization of the tannin analysis across the staggered time points at which grape and wine sampling and extraction took place, a purified commercial seed extract (Tarac Technologies, Nuriootpa, Australia) was included for each 96-well plate assayed.

For the measurement of grape and wine color, the procedure was as follows. For total anthocyanin, a 20 μL of wine or a 50 μL aliquot of grape extract was added to 1 M HCL to a final volume of 1 mL, and mixed. Samples were left to stand in the dark for 1 h. The 1 h period was modified from the original method stipulating 3 h,[16] as we had demonstrated that maximal ionization of anthocyanins was achievable within this period (data not shown). For wine analyses only, a further 100 μL of wine was added to 900 μL of buffer solution containing 0.5% (w/v) tartaric acid and 12% (v/v) ethanol (pH 3.4), mixed and analyzed immediately. Buffer solution was also prepared containing 0.1% (v/v) acetaldehyde or 0.375% (w/v) sodium metabisulfite, and 900 μL of the respective solutions were combined with 100 μL wine, mixed, left to stand in the dark for 1 h, and then analyzed. For spectral analysis of color measures, a 300 μL aliquot was transferred to a 370 μL 96-well UV plate and the 420 and 520 nm absorbances measured using a SpectraMax M2Microplate Reader (Molecular Devices, Australia), corrected using an appropriate sample blank and a water constant correct function to approximate a 1 cm path length. Estimates of wine anthocyanin, modified wine color density and nonbleachable (bisulfite-resistant) pigment were determined from spectral data according to the calculations outlined in the published method.[16] The estimate of grape anthocyanin was also according to the published method[16] but without correction for bisulfite.

Following the analysis of tannin concentration in wines, a subsample of 8 high-concentration and 8 low-concentration wines (a single replicate of a triplicate ferment batch) were identified for subsequent tannin compositional analysis, of which equal proportions were from the Shiraz and Cabernet Sauvignon grape varieties. The 10 mL frozen (−80 °C) aliquots of each of the 16 wines identified were rapidly defrosted in a water bath at room temperature, and centrifuged at 1730*g* for 5 min. Duplicate analyses of wine aliquots were performed. Total tannin (approximately 1 mg based on MCP analysis) was isolated using solid-phase extraction with the modifications outlined in Kassara et al. (2011).[14] Purified tannin was reconstituted in 100 μL methanol and analyzed by high-throughput phloroglucinolysis[24] and high-performance liquid chromatography (HPLC), as described previously.[25,26] For HPLC, an Agilent model 1100 (Agilent Technologies Australia Pty Ltd., Melbourne, Australia) was used, equipped with Chemstation software. For phloroglucinolysis, (−)-epicatechin (Sigma-Aldrich, St. Louis, MO, USA) was the quantitative standard.

Statistical Analysis. Significant differences between samples and treatments were determined by one-way analysis of variance (ANOVA) or Student's *t*-test. For analysis of unbalanced sample numbers, the weighted mean was used. For these analyses the JMP 5.0.1 (SAS, Cary, NC, USA) and Graph Pad Prism 6.02 (GraphPad Software, Inc., La Jolla, CA, USA) software packages were used. For linear regression and multiple linear regression analysis, Unscrambler X 10.2.0 (CAMO Software, Oslo, Norway) or Microsoft Excel 2007 was used.

RESULTS AND DISCUSSION

Effect of Extraction Volume and Time on Tannin and Anthocyanin Concentration in Model Wine Extracts. The effect of extraction volume and the length of the extraction on tannin and anthocyanin concentration in WL extracts were investigated for a single Cabernet Sauvignon grape sample. The extraction volume was between 35 and 75 mL, maintaining the ethanol concentration at 15% v/v, sampled five times during 64 h (Supporting Information S2). For all extraction volumes

[a]Wine-like tannin extract corrected for differences in extraction volume recovery. [b]ANOVA, $n = 39$, different superscripted letters after the mean within a column indicate significant differences by a post-hoc Student's t-test, ns = not significant.

tested, tannin concentration increased up to the 40 h time point. At the 40 h time point the standard error of the triplicate extractions was low, and differences in tannin quantity between extracts of different volumes were negligible. Before and after the 40 h time point, higher extraction volumes (65 or 75 mL) were found to have lower tannin concentrations when normalized for differences in total solvent volume. However, it was also observed that at the 45 and 64 h assay time points, there was a large increase in the standard error for the tannin assay triplicates. Thus, the estimated tannin quantity at these time points was found to be more variable for the different extraction volumes tested, either increasing, decreasing or reaching a plateau. Since this may have reflected instability or oxidation of the extract at the 45 and 64 h time points, a 40 h

dx.doi.org/10.1021/jf5002777 | J. Agric. Food Chem. 2014, 62, 4558−4570

extraction period was selected as optimal to maximize tannin extraction but prevent extract instability. For the extract volumes tested, the 40 mL volume extract was more stable across sampling time points, and standard error was low across all time points evaluated. Therefore, a 40 mL extraction volume (15 mL addition of solvent, as outlined above) was selected to optimize for tannin extraction. It should be noted, however, that this gave a slightly lower estimated anthocyanin concentration than the higher extraction volumes evaluated (Supporting Information S2). The estimated anthocyanin quantity was found to be directly related to extract volume, and it decreased as solvent volume decreased. Losses of anthocyanin at lower solvent volumes may have been due to a greater adsorption of anthocyanin to grape constituents, or potentially oxidation, but this was not investigated further. Anthocyanin in all extract volumes tested was found to decline after a 40 h extraction time, which confirmed that this was an optimal extraction period to ensure extract stability.

Compositional Variation in Grape and Wine Samples. Since the objective of the research was to source grapes with a diverse range of phenolic compositions on which extraction protocols could be validated, it was considered that regional and maturity differences might introduce significant variability. Differences in phenolics by grape variety were a further important consideration, and two principal commercial grape varieties were selected for the study.

To better define the regions within South Australia from which grapes were sourced, seasonal minimum and maximum temperatures, and rainfall data for the 2012−2013 growing season are shown as S1 of the Supporting Information. It was evident that the regions selected for the study had differences in the maximum and minimum temperatures during the growing season. In particular, McLaren Vale was characterized by higher minimum temperatures during the ripening period, which was noted anecdotally to be associated with a compression of the ripening period, which may account for the higher average °Brix levels for the region, and higher residual sugar levels in wines due to only a partial completion of fermentation in the 7-day period (Tables 1 and 2).

The Padthaway region had lower minimum temperatures than the other regions studied throughout grape development, but this was not associated with measurable differences in juice composition. Similarly, differences in maximum temperature during the grape development period were not associated with regional differences in juice composition. Only the Riverland and Langhorne Creek regions differed in maximum daily temperature from the other regions sampled, being higher and lower, respectively. All the regions sampled received intermittent rain events during the grape development period, but only Clare, Riverland and Padthaway had high rainfall during the ripening phase. Riverland had the lowest total seasonal rainfall of the regions, and Clare the highest. Albeit from a low sample number, Clare grape samples were characterized by lower juice titratable acidity, but they had no difference in pH. Small differences in general grape and wine composition were found by grape variety, with Shiraz having slightly lower juice pH, higher berry weight, and higher juice titratable acidity than Cabernet Sauvignon (Table 1), but no significant difference was found in juice °Brix. Due to acid adjustment prior to winemaking, titratable acidity was not significantly different between varieties, but it was found that after vinification, Shiraz wines had a slightly higher average pH than Cabernet Sauvignon wines.

For the range of grape and wine samples analyzed, the variation in measured tannin and anthocyanin concentration was greater than the variation in juice compositional properties (pH, titratable acidity, °Brix) or berry weight (Tables 1 and 2). For tannin determined in WL extracts, the difference between the maximum and minimum concentrations across all samples varied by a factor of 3.5. For homogenate extracts and wines, this factor was 5.5. For anthocyanin concentration determined in WL extracts, homogenate extracts and wines, maximum and minimum values differed by a factor of 3 across the whole range of samples (Tables 1 and 2). As might be expected, the concentration of tannin and anthocyanin determined using the homogenate extraction procedure was higher than the corresponding analysis using WL extracts.

There were no significant differences observed in the averages by grape variety for tannin and anthocyanin concentrations determined using WL extraction. However, for homogenate extracts, the average tannin concentration for Cabernet Sauvignon grapes was higher than that in Shiraz, but no difference was found by variety in terms of anthocyanin concentration. Grape tannin and anthocyanin concentrations determined using both the WL and homogenate extraction protocols showed regional variation, and grape samples with the lowest concentrations were from the Riverland compared with all other regions (Table 1).

In comparing the anthocyanin and tannin concentrations of the corresponding wines, regional differences were consistent with what was observed in the grape extracts: the lowest concentrations for both parameters were found in Riverland wines, and the highest in McLaren Vale wines (Table 2). A consideration in interpreting this result is that the McLaren Vale sample was composed of grapes of a higher average °Brix, and the corresponding wines contained higher residual sugar, a natural result of stopping the fermentation 24 h after the 6-day skin contact period. The possibility that higher grape maturity could be related to higher concentrations of phenolics in WL extracts and wines cannot be excluded, and this will be discussed later. It would not be expected that the presence of higher sugar concentrations in WL extracts, or higher residual sugar in the ferments, might have influenced either tannin or anthocyanin concentration by altering the sample matrix, and this is supported by our observations that wine tannin concentration does not change significantly after press (unpublished data, see Supporting Information S4).

Since collecting data regarding the management practices of each vineyard from which the grapes were sourced was not practicable, it is not possible to suggest any causative effect for the observed regional differences. The Riverland is a highly irrigated region, with greater water application and therefore potentially a higher vineyard vigor, which could have reduced grape anthocyanin, and possibly tannin.[27,28] However, it is noteworthy that the average berry weight for Riverland fruit was not significantly greater than the berry weights from the other regions, and it would be expected that this would increase in response to irrigation.[29,30] As noted previously, the main climatic variable which distinguished the Riverland region from the others was higher maximum daily temperatures during the developmental period (Supporting Information S1). Higher temperatures during berry development are well-known to be associated with lowered grape anthocyanin concentration[31] but an effect on tannin is less clear, and might be expected to result in higher grape tannin concentration.[32] The regional effect is

nonetheless evident, and it most likely reflects the interaction of climate, cultural practices, and possibly grape maturity.

Correlation of Grape and Wine Compositional Parameters. The primary aim of this study was to observe whether a relationship could be found between a grape-based measure of tannin or anthocyanin and the corresponding analysis in wine. Since most anthocyanin not only remains in the monomeric form in wine but also forms colored derivatives,[33] analyzing only wine anthocyanin concentration might not capture the range of colored products which were

[b]Analysis of tannin in wine-like extracts assuming a constant juice yield per unit berry fresh mass. [c]Analysis of tannin or anthocyanin in wine-like extracts corrected for differences in final extraction volume. [d]Wine color compositional measures determined as absorbance units. [e]Wine tannin concentration determined by methyl cellulose precipitation. [f]Grape must total soluble solids preferment determined as °Brix.

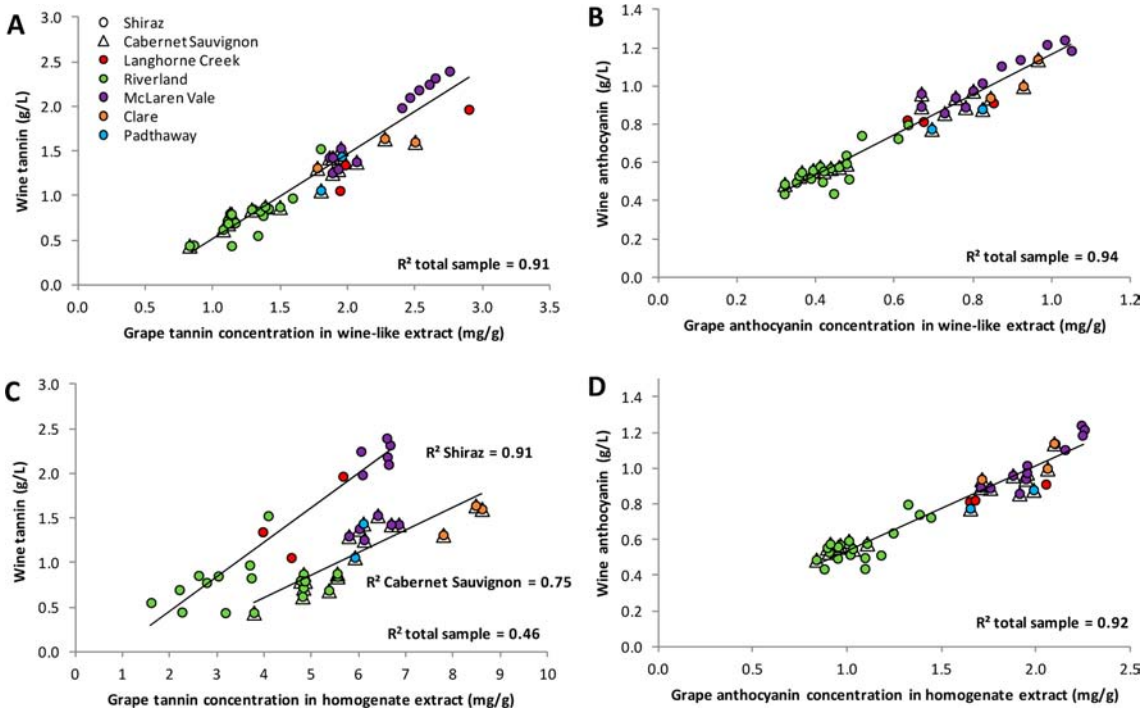

Figure 1. Linear regression analysis showing distribution of data by grape variety and region of (A) wine-like grape tannin and wine tannin; (B) wine-like grape anthocyanin and wine anthocyanin; (C) homogenate grape tannin and wine tannin; (D) homogenate grape anthocyanin and wine anthocyanin.

formed during fermentation. Therefore, the relationships of grape-based measures of tannin and anthocyanin to a range of wine parameters were investigated: tannin, monomeric anthocyanin, modified wine color density[16] and nonbleachable pigments.[16] The wine color properties of the sample series are shown in Table 2. A summary table of key significant relationships between measured grape and wine parameters obtained following linear regression analysis is presented as *R*-squared (R^2) values (Table 3), and for reference, the full correlation table is provided as S5 of the Supporting Information.

In the development of the WL extraction protocol, an important consideration was that some variability in juice yield might exist between grape samples, which could influence the dilution of tannin extracted, as well as the alcohol concentration of the extraction medium, since the addition of ethanol was kept constant. Therefore, tannin concentration (as mg/g berry fresh weight) was expressed as a volume-corrected measure, as well as an uncorrected measure which assumed a constant juice yield per gram of grapes. Strong relationships were found using linear regression analysis for corrected and uncorrected tannin concentration determined across the whole range of grape samples ($R^2 \geq 0.95$) (Table 3), and both these analytical measures were strongly related to wine tannin concentration ($R^2 > 0.9$). The calculated root-mean-square error (RMSE) of prediction of wine tannin concentration from the WL assays was 0.18 g/L for the volume-corrected corrected assay, and 0.15 g/L for the uncorrected assay. This is of relevance, since in

dx.doi.org/10.1021/jf5002777 | J. Agric. Food Chem. 2014, 62, 4558–4570

a commercial application of the WL extraction protocol, the estimate of juice volume or recovered extract volume would be tedious and time-consuming, and possibly hinder its uptake. The current results indicate that this volume correction step may not be necessary in order to compare compositional differences between grape samples. The relationship between grape tannin concentration determined using the WL tannin protocol and wine tannin concentration is shown graphically (Figure 1A), and it demonstrates the distribution of samples by grape variety, maturity and regional origin, as discussed previously.

Re-extraction of the WL extract residues with 50% v/v ethanol increased the estimate of total grape tannin concentration by 52% (±13%) but reduced the strength of the relationship with wine tannin slightly to give an R^2 value of 0.86 (Supporting Information S5). With sample homogenization and extraction in 50% v/v ethanol, the grape tannin concentration was on average 204% (±92%) higher than that determined in the WL extracts. Interestingly, a poor relationship was observed between grape tannin concentration determined from homogenate extracts and wine tannin concentration (R^2 = 0.46 for total sample) (Figure 1C, Supporting Information S5). A "tannin extractability" estimate was calculated as follows: [WL tannin ×100] ÷ [homogenate tannin]. This measure expresses the extractable grape tannin concentration as a proportion of total grape tannin, and we considered that this might correlate with wine tannin concentration. However, no relationship was found with the "tannin extractability" estimate and wine tannin concentration (data not shown, see Supporting Information S5).

From the scatter-plot shown in Figure 1C, a separation of tannin data by grape variety could be observed, which indicates that there may be different responses for grape tannin concentration determined in homogenate extracts for the Shiraz and Cabernet Sauvignon varieties. Indeed, separation of the samples by variety brought an improvement in the R^2 values for grape tannin determined in homogenate extracts and wine tannin following linear regression, and this was better modeled for Shiraz (R^2 > 0.9) than for Cabernet Sauvignon (R^2 = 0.75). It is likely that at high ethanol concentration (50% v/v) and with homogenization, a significantly increased seed tannin was extracted than can be expected with WL extraction. Since seed tannin is not readily extracted during the early stages of fermentation[2,19] (Supporting Information S6), it is unlikely that seed tannin was significantly extracted in the wines, and this will be discussed in more detail at a later stage. The WL extraction protocol is therefore more accurate in predicting the concentration of grape tannin that is extractable during primary fermentation, in this case during a set 6-day skin contact period.

Differences in the concentration and proportional distribution of tannin within the grape berry (skin versus seed) may account for somewhat higher concentrations of homogenate-extract grape tannin in the Cabernet Sauvignon samples, possibly reflecting a higher seed tannin concentration. The relatively strong relationship found for homogenate-extracted tannin concentration and wine tannin concentration for the respective grape varieties treated as distinct sample sets shows that this extraction protocol may still have relevance for the prediction of wine-extractable tannin, but only when the calibration is determined for a given variety.

For grape anthocyanin, the homogenate extraction, corrected WL (Table 3) and uncorrected WL protocols (Supporting Information S5) were strongly correlated to one another. Both grape-based measures were strongly related to wine anthocyanin concentration ($R^2 \geq 0.9$) and wine color density (R^2 > 0.85) (Table 3, Figure 1B, D). A weaker relationship was found for the grape-based measures of anthocyanin and nonbleachable wine pigments, with WL and homogenate extracts giving R^2 = 0.7 (Table 3) and 0.65, respectively.

Rather, a stronger relationship was found for wine tannin concentration and nonbleachable pigments (R^2 > 0.85). Nonbleachable pigment and wine tannin concentration also strongly contributed to wine color density, as evidenced by similarly high R^2 values. Since wine color was analyzed in young wines, a significant proportion of anthocyanin was still in the monomeric form (Table 2), and it had not yet undergone the reactions associated with aging which significantly increase nonbleachable pigments.[34] Hence, the greatest contribution of nonbleachable pigments in young wines was potentially from anthocyanin-tannin condensation products (polymeric pigments) formed during fermentation[35] as opposed to smaller, anthocyanin-derived pigments. Since both anthocyanin and tannin are required for the formation of stable wine color, their analysis in WL extracts may be a good predictor of wine color density, as well as nonbleachable pigments. Multiple linear regression analysis revealed an improvement of the R^2 of prediction for both wine color density and nonbleachable pigments to 0.87 when both WL tannin and anthocyanin concentration measures were used (data not shown).

A further important consideration was how basic grape compositional differences in terms of either ripeness or berry weight were related to measured color and tannin in grapes or wine. It was found that the degree of grape sugar ripeness (as juice °Brix) was related (R^2 > 0.7) (Table 3) to uncorrected WL tannin concentration, wine tannin concentration, wine color density and nonbleachable pigments. Interestingly, juice °Brix had a weaker relationship with concentrations of corrected WL tannin, grape anthocyanin and wine anthocyanin (Supporting Information S5). No relationship was found for juice °Brix and the recovered volume of WL extracts, so the strong relationship to uncorrected WL tannin concentration is not accounted for simply by changes in juice volume. A further important observation was that no correlation was found between berry weight and any measure of grape or wine tannin and color (data not shown). This is of particular relevance for grapes of the Shiraz variety,[36] since shrivel in the later stages of ripening may increase the relative concentration of tannin and sugar per unit fresh mass.

As discussed previously, both the corrected and uncorrected measures of grape WL tannin concentration were strongly related to wine tannin concentration, but the R^2 value was slightly higher for the uncorrected measure (0.94 compared to 0.91). Therefore, the correlation between wine tannin and °Brix may simply indicate that increases in grape ripeness may have been associated with increased extractability of tannin.

Since all ferments were pressed off skins before the completion of alcoholic fermentation, and wines made from higher °Brix grapes had high residual sugar levels, ethanol concentration was unlikely to have influenced tannin extraction. The relationship between grape ripeness (°Brix) and tannin concentration in grapes is unclear, and reports in the literature are variable, showing that tannin can increase, remain constant or decrease during ripening.[26,37−43] While our results do not demonstrate a causative effect, the current data indicate that changes in grape composition associated with ripening may

[f]Molecular mass as determined by phloroglucinolysis. [g]Mean degree of polymerization in epicatechin units. [h]Molar proportion of extension (−)-epigallocatechin subunits. [i]Molar proportion of (−)-epigallocatechin subunits of extension (EXT) subunits only. [j]Molar proportion of terminal and extension (−)-epicatechin-3-*O*-gallate subunits. [k]ANOVA, $n = 16$, different letters after the mean within a column indicate significant differences determined by a post-hoc Student's *t*-test.

influence the extraction of grape tannin into wine during fermentation, and this warrants ongoing investigation.

Compositional Differences between High- and Low-Tannin Wines. A subset of wine samples were analyzed for subunit compositional analysis following solid-phase extraction[14] and phloroglucinolysis[24] to determine whether differences in wine tannin concentration observed using the MCP tannin assay could be (1) confirmed using an alternative method of quantification and (2) associated with changes in tannin subunit composition or molecular mass. A subset of wine samples from both grape varieties studied were selected, having high- or low-tannin concentration based on the MCP assay. The Shiraz wines had higher tannin concentration, as measured by MCP, than Cabernet Sauvignon wines (Table 4). However, when tannin concentration was determined by phloroglucinolysis for these samples, high-tannin Shiraz and Cabernet Sauvignon wines showed similar concentrations based on subunit yield. On the other hand, for the low-tannin samples, the Cabernet Sauvignon wines had a somewhat higher subunit yield by phloroglucinolysis than Shiraz wines. Nevertheless, it was evident that differences in high and low wine tannin concentrations determined using the MCP tannin assay were confirmed by the phloroglucinolysis assay.

The differences in the phloroglucinolysis yield point to varietal differences in the extent to which the tannin could be cleaved to its component subunits by acid-catalyzed depolymerization (tannin mass conversion). It is well-known that wine tannin mass conversion can vary by grape variety, ripeness[1,26,38,44−47] and decreases during winemaking,[1,45] following oxidation[48] or during wine aging.[47] This consequently affects wine tannin concentration as determined by subunit yield. It was evident that tannin mass conversion was similar by variety for both low- and high-tannin wines (Table 4), and was higher in Cabernet Sauvignon wines than in Shiraz wines. Varietal differences in tannin mass conversion may not necessarily be incurred during winemaking, and they can be found in tannin extracts from grape.[1,26,45,46] The differences in phloroglucinolysis yield between high- and low-tannin wines may therefore be a varietal effect. Varietal differences in tannin composition were also observed for the degree of tannin galloylation ((−)-epicatechin-*O*-gallate), which was significantly higher for Shiraz wines. Since seed tannins contain proportionally higher levels of epicatechin gallate than skin tannin,[40,44] this could be considered to reflect a greater extraction of seed tannin in Shiraz wines. However, this is unlikely to be the case, since our work to date with Shiraz grapes has shown minimal extraction of seed tannin during a similar skin contact period to that used in the current study (Supporting Information S6). Furthermore, the degree of galloylation in skin tannin can be up to 10% in Shiraz grapes,[1,44,47] but it is generally low in ripe Cabernet Sauvignon grapes[26,43,49] (also see Supporting Information S7).

Tannin molecular mass, which gives similar information to the mean degree of polymerization (mDP) increased as wine tannin concentration increased, and this was associated with a minor increase in the proportion of prodelphinidin ((−)-epigallocatechin) of total tannin subunits. However, when prodelphinidin was expressed as a proportion of extension

dx.doi.org/10.1021/jf5002777 | J. Agric. Food Chem. 2014, 62, 4558−4570

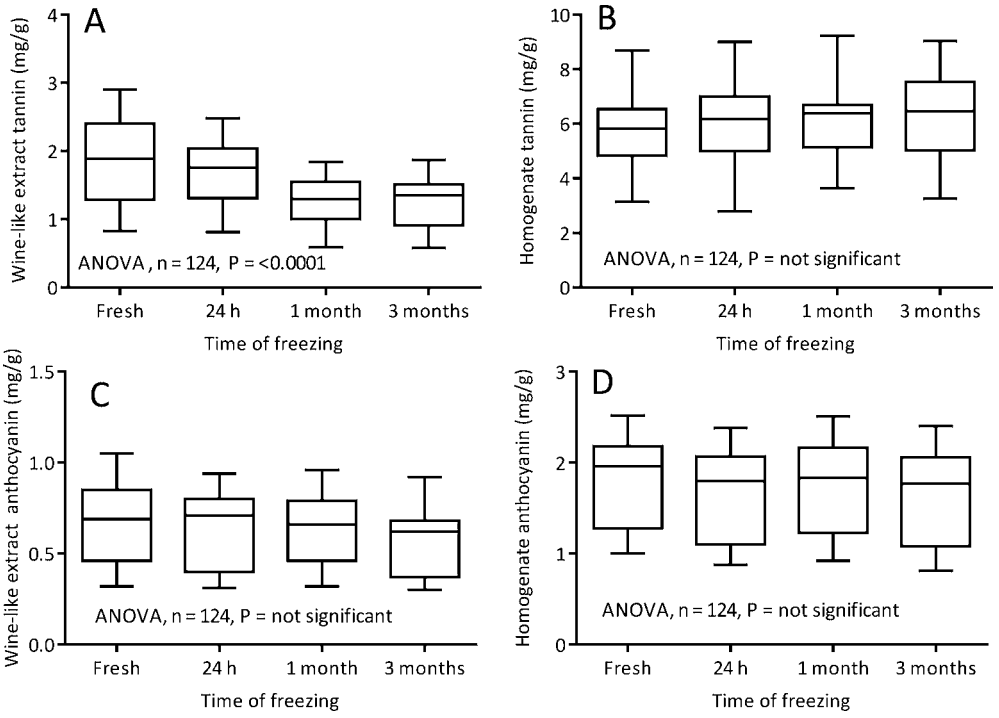

Figure 2. Effect of a 3 month freezing period at −20 °C on grape composition determined by one-way ANOVA (n = 124) showing the distribution of samples as box and whisker plots (mean, maximum, minimum): (A) tannin concentration determined following wine-like extraction; (B) tannin concentration determined following homogenate extraction; (C) anthocyanin concentration determined following wine-like extraction; (D) anthocyanin concentration determined following homogenate extraction.

units only, this was unchanged by either grape variety or tannin concentration. The proportion of prodelphinidin as a proportion of extension units can range considerably in skin tannins, and it is quite variable by season and grape variety[1,26,42−45,49] (Supporting Information S7). For the current wine sample set, therefore, the high values for prodelphinidin as a proportion of tannin extension units, together with a low percent galloylation are strong evidence that the wine tannin extracted during the 6-day skin contact period was primarily derived from the grape skins. This is expected based on published work[2] as well as our unpublished data (Supporting Information S6), which indicate that skin tannin extraction predominates within the early skin contact period.

Effect of Freezing on the Analysis of Grape Tannin and Anthocyanin. The effect of storing grape samples at low temperature is an important consideration when samples are collected at a faster rate than analytical capacity and throughput allow, such as in a commercial or research context. Previous studies have shown that grape samples can be frozen at −20 °C for up to 3 months without measuring a loss in anthocyanin, when this was determined following a homogenate extraction protocol.[50] At the outset of the current study, the effect of freezing grapes on tannin concentration was unknown.

The analysis of tannin and anthocyanin in homogenate and WL extracts was performed on a subset of grape samples that had been frozen at −20 °C for 24 h, 1 month and 3 months (Figure 2). Due to the previous observations that anthocyanin concentration declines after 3 months of freezing,[50] the storage period was not extended further. It was found that freezing grape samples for 24 h brought about a small reduction in grape tannin concentration measured using the WL extraction protocol, and this decreased further by 1 month and 3 months (Figure 2A). In observing the distribution of measured WL tannin concentration at 24 h of freezing, the most significant decreases (14% loss) in tannin concentration were found for the grape samples with the highest tannin, while samples with lower tannin were unchanged. After 1 month and 3 months of freezing, losses in measured tannin concentration measured in WL extracts were consistent for both high- and low-tannin grape samples, between 34% and 37%.

Unlike the WL extraction protocol, frozen grape samples analyzed using the homogenate extraction procedure showed no significant loss in measured grape tannin concentration (Figure 2B). This indicates that the effect on tannin concentration in WL extracts was not likely to be due to tannin degradation, but rather due to changes in tannin extractability brought about by freezing. This is also supported by the observation that tannin concentration is stable in frozen extracts (and wines) at −20 °C (Supporting Information S2). Speculatively, freezing of grapes may increase the adsorption of tannin by grape cell walls,[1] since breakdown of subcellular compartments during freezing and defrosting may occur. In contrast to the effect on WL tannin, no impact of freezing was found for WL anthocyanin extracts (Figure 2C). Similar to a previously published study,[50] freezing up to 3 months caused no reduction in measured anthocyanin concentration in homogenate extracts. This indicates that following limited time periods of frozen storage, the homogenization extraction protocol can be used for grape tannin and anthocyanin analysis, but the WL extraction protocol is acceptable only for anthocyanin analysis.

Implications of the Results for Commercial Wine-making Practice. The reported results have shown that for fresh grape samples, the application of a WL extraction provides a good indication of tannin and anthocyanin concentrations extractable during fermentation (in this study during a 6-day

dx.doi.org/10.1021/jf5002777 | J. Agric. Food Chem. 2014, 62, 4558−4570

skin contact period). It was found that there was no benefit in correcting tannin or anthocyanin concentration in WL extracts for variation in juice (extract) volume. This means that extractions and analyses could be implemented in situations which demand high sample throughput, such as commercial or research laboratories. A limitation of the WL extraction protocol for tannin analysis, however, was that grape samples could not be frozen. It is therefore recommended that where delays in sample analysis occur, whole grape bunches are sealed and stored short-term at 4 °C before being destemmed. Alternatively, if WL extractions can be immediately conducted on fresh grapes, the extract appears to be stable at −20 °C, enabling the tannin analysis to be performed later (Supporting Information S3).

The use of a homogenate extraction protocol was also found to be of value for predicting wine anthocyanin concentration, and when the calibration is adjusted for a particular cultivar, it could be used to predict wine tannin concentration. The benefit found for the use of the homogenate extraction protocol was that samples could be frozen before analysis. A further advantage of homogenate extraction is that this method has been used to develop calibrations for rapid analytical methods such as near-infrared spectroscopy[51] and UV−visible spectroscopy.[52]

The WL and homogenate extraction techniques were shown to be of value in the prediction of tannin and anthocyanin concentrations extractable during the fermentation period. However, it is important to note that in commercial winemaking practice, different winemaking approaches can increase tannin concentration[20] beyond that extracted during fermentation. Some studies have shown that skin tannin concentration tends to reach a maximum during primary ferment,[2,3] but others have shown that it can increase continuously during both fermentation[49,53] and extended maceration.[39] On the other hand, seed tannin is poorly extracted during primary fermentation, but a late, rapid increase in extraction is observed after approximately 6 days, suggested to be facilitated by hydration of the seeds rather than an increase in wine ethanol concentration.[19,54] Hence, seed tannin extraction could potentially increase until maceration is stopped, but it has been observed that a maximum in total wine tannin concentration is generally reached by 20 days of maceration.[39,55]

Given this variability in the kinetics of tannin extraction, a key question is whether the magnitude of the effect of a winemaking technique on final wine tannin concentration is in fact dependent upon grape tannin composition and extractability. In collating data from a limited number of studies which have explored the effect of extended maceration on wine tannin extraction,[20,39,49,55−57] it was found that a strong positive relationship exists between tannin extracted during fermentation and the maximum tannin extracted following extended maceration (Supporting Information S8).

Based on this, it appears viable that in a commercial context, decision-making regarding the optimal winemaking approach for particular grape batches could be enhanced by knowledge of the tannin and anthocyanin extractable during fermentation. For example, for high-tannin grapes, adequate extraction of phenolics may be obtained during a short skin contact period, whereas for low-tannin grapes extending maceration time or applying thermovinification[20] may be required. The benchmarking of grape samples for their predicted wine tannin, anthocyanin, and color could facilitate comparisons by season, region, vineyard, grape variety or management practices, and it would be of great advantage in commercial winemaking.

Funding

The Australian Wine Research Institute, a member of the Wine Innovation Cluster in Adelaide, is supported by Australian grape-growers and winemakers through their investment body, the Grape and Wine Research and Development Corporation, with matching funds from the Australian Government.

Notes

The authors declare no competing financial interest.

■ ACKNOWLEDGMENTS

The authors would like to thank Accolade Wines, Reynella, South Australia for the donation of grape samples. Chris Bevin, formerly of Accolade Wines, coordinated the logistics of vineyard selection, harvesting and transport of grape samples. Bob Dambergs is recognized for conceptualizing and developing the small-scale “French Press” winemaking method. Michael Coode is acknowledged for small-scale winemaking, and Ruchita Shah, for technical support in both the laboratory and winery. Ross Kolouch, Michael McBryde and Jennifer Baldock assisted in the preparation and handling of grape and wine samples. Eric Wilkes and Peter Godden of the AWRI are thanked for proof-reading the manuscript.

Assessment of the Degree of Interference of Polyphenolic Compounds on Glucose Oxidation/Peroxidase Assay

Adeline Ik Chian Wong[†] and Dejian Huang*[,†,‡]

[†]Food Science and Technology Program, Department of Chemistry, National University of Singapore, 3 Science Drive 3, Singapore 117543, Singapore

[‡]National University of Singapore (Suzhou) Research Institute, 377 Lin Quan Street, Suzhou Industrial Park, Jiangsu 215123, China

ABSTRACT: The glucose oxidase/peroxidase assay (GOP) is a coupled enzymatic assay commonly used in measuring glucose concentrations in biological sciences and food chemistry, particularly for quantification of α-glucosidase activity. However, we found that the GOP assay is prone to interference, especially from reducing substances such as polyphenolic compounds, which are commonly found in botanical materials. To establish the scope and limitation of the assay in measuring α-glucosidase inhibition activity, we systematically investigated the structural features of the polyphenolic compounds that can lead to false positives. Utilizing sodium dodecyl sulfate (SDS) as surrogate for the meriquinone intermediate formed during the reaction, we measured the reactivity of this redox active intermediate toward common flavonoids. Our results show that flavonoids with *o*-dihydroxy groups in the B-ring cause strong interference and that compounds with little DPPH scavenging activity do not have interference. Our results highlight the need for checking the suitability of the GOP assay first before it is applied in measuring α-glucosidase inhibition activity. In addition, when the literature data on α-glucosidase inhibition activity of botanical extracts or polyphenolic compounds using GOP assay are interpreted, potential false positives due to interference on the assay will need to be taken into consideration.

KEYWORDS: *α-glucosidase, glucose oxidase/peroxidase assay, o-dianisidine, flavonoids*

INTRODUCTION

Due to the increasing global population of type II diabetes patients, research on finding ways to mitigate this dreadful disease have intensified in recent years.[1] One way to control hyperglycemia is through starch hydrolase inhibitors from edible plants, which contain structurally diverse α-glucosidase inhibitors including sugar mimics[2] and polyphenolic compounds.[3,4] To uncover novel α-glucosidase inhibitors from plants, particularly edible plants, the *p*-nitrophenyl glucopyranose (*p*NPG) assay and coupled glucose oxidase/peroxidase (GOP) bienzyme assay are widely applied as convenient guides to fractionation and purification of inhibitors. Whereas the *p*NPG assay uses a synthetic probe that may not be truly reflective of natural substrates of the enzymes, the GOP assay was developed initially to quantitate the amount of D-glucose in human fluids.[5] Principally, this assay uses glucose oxidase to oxidize β-D-glucose by molecular oxygen to D-glucono-δ-lactone and hydrogen peroxide. In the presence of peroxidase (e.g., horseradish peroxidase), hydrogen peroxide reacts with colorless chromogenic molecules to form colorful dyes that can be quantified conveniently by colorimeters. Many chromogenic compounds have been used as substrates for horseradish peroxidase.[6] Among them, *o*-dianisidine has been more widely applied than others. In acidic conditions, the oxidized *o*-dianisidine becomes rose-pink with absorbance maximum at 540 nm (Figure 1).[7] Due to its convenience, the GOP assay has been applied in many other systems including measurement of α-glucosidase activity and screening for its inhibitors.

Although the GOP assay is highly substrate specific and relatively convenient to use, it is highly susceptible to various interferences.[8,9] The GOP assay utilizes two oxidases and involves complicated redox reaction mechanisms; as such, any compounds that can inhibit the two enzymes or react with the reactive intermediates of reaction will cause interferences.[10] Indeed, there are scattered reports on the interference issue of the GOP assay. Using 4-aminoantipyrine and 3-hydroxybenzoic acid as chromogenic substrates in the GOP assay, Shaukat and co-workers recently found that green tea polyphenolic compounds cause interferences and lead to false-negative results in blood serum glucose concentrations, and the interference was suggested to be due to the radical scavenging activity of the polyphenolic compounds.[11] In another study, polyphenols were also found to interfere because of their reducing activity.[12] Despite the number of studies addressing the issue of interferences, the GOP assay continues to be applied in the quantification of α-glucosidase inhibitory activity of natural products due to its convenience and selectivity of glucose.[13] Because natural products often contain polyphenolic compounds, it is important to systematically address the scope and limitations of the GOP assay in quantifying botanical samples on α-glucosidase inhibitory activity. Therefore, we investigated the interference of common polyphenolic compounds found in the plant kingdom on the degree of interference on GOP assays by adding sodium dodecyl sulfate (SDS) to stabilize meriquinone intermediates formed during the oxidation of *o*-dianisidine by peroxidase. Our results reported herein will help researchers in using the GOP assay in plant extracts to assess the suitability of

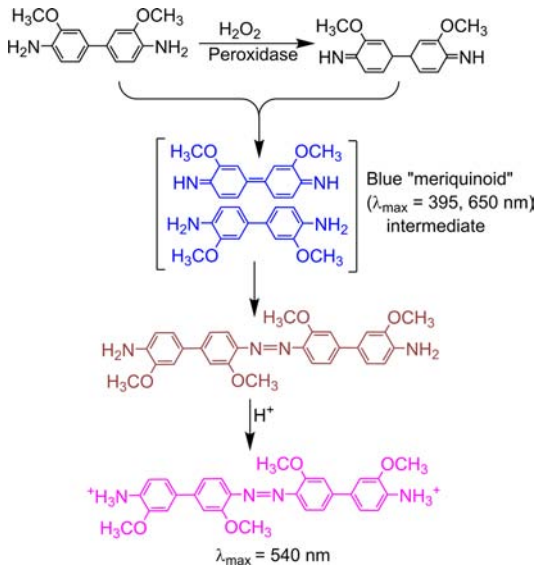

Figure 1. Reaction scheme of *o*-dianisidine oxidation. Hydrogen peroxide reacts with colorless reduced *o*-dianisidine in the presence of peroxidase to form the dianisidine quinonediimine intermediate. Application of SDS suspends the meriquinoid complex intermediate (λ_{max}= 395; 650 nm). Irreversible coupling reaction with two quinonediimines forms the brown bisazobiphenyl product. Bisazobiphenyl product reacts with H_2SO_4 to form a more stable pink product (λ_{max}= 540 nm).

the assays and provide a guide for avoiding unnecessary false results.

MATERIALS AND METHODS

Reagents and Instruments. Chemical reagents were obtained from commercial sources. These compounds include caffeic acid, ferulic acid, rutin, apigenin, chrysin, coumaric acid, gallic acid, hesperedin, hesperetin, kaempferol, luteolin, morin, naringin, quercetin, hydrogen peroxide solution, *o*-dianisidine dihydrochloride, glucose oxidase, and peroxidase from horseradish, sodium dodecyl sulfate, (-)-Epigallocatechin gallate, (-)-Epigallocatechin, (-)-Epicatechin, Quinic acid (Sigma-Aldrich, Singapore); 3,5-dihydroxyflavone, 3,7-dihydroxyflavone, 3′,3,4-trihydroxyflavone, 5,3′,4′-trihydroxyflavone, 5,7,3′,4′,5′-pentahydroxyflavone, 7,3′,4′-trihydroxyflavone, 7,8-dihydroxyflavone, fisetin, galangin, gossypetin, and myricetin (Indofine Chem. Co., Hillsborough, NJ, USA); tannic acid (Merck, Germany); and ascorbic acid, chlorogenic acid (Spectrum Chemical Co., Singapore). A microplate reader (Bio-Tek Instruments Inc., Winooski, VT, USA) was used to measure the spectrophotometric readings.

Generation of the Meriquinone Intermediate and Its Reactivity with Polyphenolic Compounds. *o*-Dianisidine (0.1 mM), SDS (1.0 mM), H_2O_2 (0.1 mM), and peroxidase (0.25 units) in citrate buffer (pH 4) were reacted for 1 min to generate the meriquinone intermediate, which was quantified by UV absorbance at 395 nm. Polyphenolic compounds with various concentrations were reacted with meriquinone. The decrease of the UV absorbance over time was monitored for selected compounds including vitamin C, coumaric acid, caffeic acid, gallic acid, and EGCG. For the rest of the samples, end point readings were carried out at 650 nm. The final concentrations of the polyphenolic compounds were kept at 100 μM. The absorbance readings were taken after 5 min of reaction. The degree of interference was quantified through the equation

$$\%\ \text{interference} = 100(A_{blk} - A_s)/A_{blk}$$

where A_s is the absorbance of the reaction mixture of the sample with meriquinone at 650 nm and A_{blk} is the absorbance of blank (water). All measurements were performed in triplicates, and the results were expressed as mean ± standard deviation.

RESULTS AND DISCUSSION

During the quantification of α-glucosidase activity and measurment of the activity of inhibitors, maltose or sucrose was hydrolyzed into glucose (and fructose in the case of sucrose). The α-glucosidase activity was measured by the generated glucose by the GOP assay. The commonly used chromophore in GOP assay is *o*-dianisidine, which is oxidized by peroxidase to give brown azo dye via a blue charge transfer complex, meriquinone (Figure 1). The polyphenolic compounds may interfere with the assay by reacting with meriquinone, which will lead to false negatives of the glucose or false positives in α-glucosidase inhibitory activity. To assess the severity of interference by different polyphenolic compounds by reducing meriquinone intermediate, we applied SDS at pH 4 according to literature studies to stabilize the positively charged meriquinone intermediates through electrostatic interaction with the negatively charged surfactant.[14,15]

Ascorbic Acid. When ascorbic acid was added to the meriquinone solution at concentrations of 25 and 50 μM (1:4 and 1:2 ratios with reference to H_2O_2), there was an initial marked decrease in absorbance but also a regain of the blue color from 10 to 250 s (Figure 2A). Apparently, the ascorbic acid is consumed

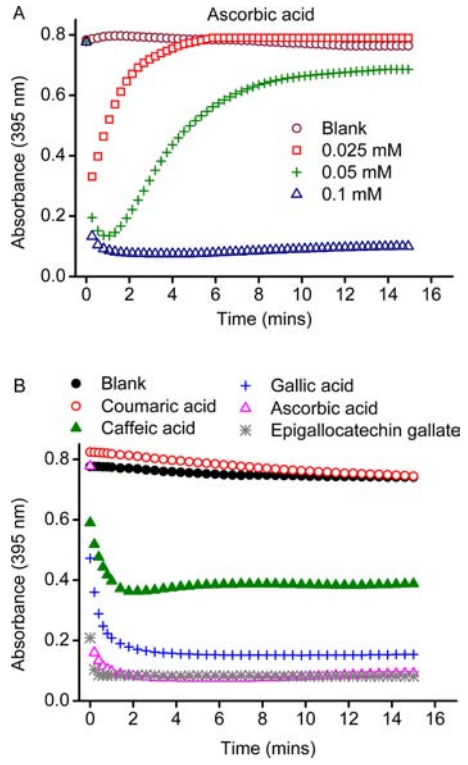

Figure 2. (A) Reduction kinetics of the meriquinone structure monitored at 395 nm for 15 min at various stoichiometries of H_2O_2 concentration to ascorbic acid (ratios of 4:1, 2:1, and 1:1). (B) Reduction kinetics (monitored at 395 nm for 15 min) of the meriquinone structure of coumaric acid, caffeic acid, gallic acid, ascorbic acid, and EGCG at a stoichiometric ratio of 1:1 H_2O_2/sample concentration.

quickly by oxidation with meriquinone, leading to the fading of blue color. The increase in absorbance is due to the regeneration of meriquinone intermediates formed by enzymatically catalyzed oxidation of *o*-dianisidine as there was a surplus of H_2O_2. When ascorbic acid was added at a ratio of 1:1 with H_2O_2 (100 μM), there was a dramatic reduction in the meriquinone solution to a colorless solution without any regain of color. This finding

dx.doi.org/10.1021/jf500431z | J. Agric. Food Chem. 2014, 62, 4571−4576

suggests that vitamin C reacts only with meriquinone but does not inhibit peroxidase.

We further monitored the reduction kinetics of the meriquinone intermediate reaction with coumaric acid, caffeic acid, gallic acid, and epigallocatechin gallate with concentration equal to that of H_2O_2 (Figure 2B). Coumaric acid with only one hydroxy group (OH) did not show much reactivity, whereas caffeic acid can lead to 50% interference at steady state throughout the remaining time. A further addition of an OH group in gallic acid was shown to reduce 75% of the absorbance values, from 0.8 to 0.2. The dependence on the number of OH groups in the phenolic acid is consistent with the increasing reducing activity from mono- to tri-OH moieties. These preliminary results prompted us to systematically evaluate the interference of common polyphenolic compounds.

Reduction of Meriquinone Intermediate by Polyphenolic Compounds. To delineate the structure−activity relationship, we measured 31 commonly found polyphenolic compounds, and the results are shown in Figures 3 and 4 arranged by their structural groups. We will discuss each class of compounds, respectively.

Flavones. As shown in Figure 3A, chrysin and apigenin have no interference ($p < 0.05$) indicating that the A ring OH groups at the 5- and 7-positions do not enable reduction of meriquinone. In contrast, apigenin isomer, 7(or 5),3′,4′-trihydroxyflavone, exhibits significant activity. This plus the fact that luteolin has a similar activity suggests that the catecholic unit is sufficient for the reduction of meriquinone. In agreement with this, 7,8-dihydroxyflavone also has a comparable activity, although it has only two OH groups. In this series, pentahydroxyflavone possesses the strongest activity because it has three *o*-OH groups at the B ring.

Flavanones. The common flavanones naringin, hesperetin, and its glycoside counterpart hesperedin all showed intermediate interference activity as shown in Figure 3B. The reason was that the B rings of the tested flavones do not contain catecholic units. Apparently, methoxylation of the catechol unit will lead to a reduced activity. In addition, there was no difference between hesperidin and hesperetin, suggesting that the OH group in the C-7 position of the A ring does not contribute to the activity of reducing meriquinones. These flavanones do possess some antioxidant activity, although the activity is much weaker compared with those of many other flavonoids.[16,17] Similar to the case of rutin, the glycosylation of hesperedin did not influence the interference percentage ($p > 0.05$).

Phenolic Acids. Coumaric acid shows a partial interference even though it has only one OH group; this is very different from that of isoflavones, which have multiple OH groups but have only very weak interferences (Figure 3C). In addition, ferulic acid and caffeic acid show stronger interferences that are comparable to that of chlorogenic acid. Gallic acid also exhibits strong interference. Therefore, it is reasonable to conclude that hydrolyzable tannins, which are the major group of polyphenolic compounds in the plant kingdom, will also have strong interference because gallates are the main moiety in hydrolyzable tannins. Indeed, tannic acid shows a strong interference. Similarly, caffeic acid has two OH groups arranged in the ortho position and was shown to have a percent interference of 88.91 ± 2.35, which was comparatively high. The percent interference of caffeic acid was not significantly different ($p > 0.05$) from those of gallic acid (due to the additional OH group) and ferulic acid (due to the CH_3O group). In the case of ferulic acid, one methoxy substitution at the ortho position relative to the hydroxyl group slightly decreased the interference (84.89 ± 2.8), but the decrease was not significant ($p > 0.05$). Ortho substitution with an electron donor of a methoxy group stabilizes the aryloxyl radical and thus its antioxidative action. However, the impact of a methoxy group is far from being equivalent to the addition of a hydroxy group. The removal of either the methoxy or hydroxy group from the phenolic ring resulted in a sharp decrease in the percent interference as seen by the coumaric acid structure. Monophenols are known to be less efficient in antioxidant activity.[19]

Flavan-3-ols. Similar to previous results, we found that all flavan-3-ols (catechins) exhibit strong interferences (Figure 3D). At the tested concentration, there was no difference among the catechins. The catecholic units in the B ring and/or the *o*-trihydroxy groups in the B ring and galloyl units are certainly potent in reducing meriquinones.[20]

Flavonols. With 11 compounds, this group is the largest category, and all of them exhibit a certain degree of interference (Figure 3E). The degree of interference is roughly correlated to the number of OH groups except rutin, which has four OH groups, but the interference activity is much weaker than that of its aglycone quercetin. Therefore, the 3-OH group contributes significantly to the activity. In this series, the *o*-OH group at the B ring increases the activity as is apparent by comparing the values of kaempferol and quercetin. 3,5-Dihydroxyflavone, 3,7-dihydroxyflavone, and galangin showed intermediate interference. These three compounds have a similar feature in that they lack any hydroxy group in the B ring of its structure but differ in the OH group present in the A and C rings. The hydroxy position of 3,7-dihydroxyflavone showed a significantly stronger interference compared to 3,5-dihydroxyflavone. Galangin, which has OH groups on the 3-, 5-, and 7-positions, did not significantly increase interference compared to 3,7-dihydroxyflavone. The addition of a hydroxyl group (monohydroxyl substitution) in the B ring as seen in kaempferol increased the percent interference significantly ($p < 0.05$). It has been proposed that the single 4′-hydroxy group in the B ring has the potential to conjugate with the 3-hydroxy group through conjugation of the C ring. The phenoxyl radical formed could abstract an electron from the radical cation to generate a dication and the phenolate.[18] The addition of another hydroxyl group in the 5′-position of the B ring as seen in myricetin did not significantly ($p > 0.05$) alter the interference as compared to quercetin. This is on par with other studies, which have shown that the presence of a third hydroxy group in the B ring at the C-5 position did not enhance the effectiveness of myricetin compared to quercetin.[19] The stabilizing effect of the extra radical is provided by only one of the two hydroxyls ortho to the hydrogen-donating hydroxyl group.[20] Studies have also suggested that a hydrogen atom is most likely donated from the 3-OH, which leads to a more stable radical tautomer.[21,22]

In a broad stroke, there seems to be an overall structure−activity relationship between the compound and its ability to reduce the meriquinone radical. Within the "high interference" category, the compounds generally possess a larger number of hydroxy groups (OH). The radical scavenging property of flavonoids has been attributed to the number of OH groups that are present in the ring structure.[23,24] In addition, the configuration of the H-donating hydroxy groups is also one of the main structural features, which influences the antioxidant capacity of phenolics.[25] Furthermore, compounds in the "high interference" group possess many OH groups that are in the ortho position. The ortho arrangement of OH groups causes the development of an intramolecular hydrogen bond (IHB), which is able to stabilize the radical, leading to a lower O−H bond dissociation enthalpy (BDE). The BDE governs the ability of a particular flavonoid to

donate hydrogen atoms, and the lower the BDE value, the higher the ability of a flavonoid to donate hydrogen.[26]

Correlation of Degree of Interference and Antioxidant Activity Measured by DPPH Radical Scavenging Activity. Because meriquinone is an oxidant, its reaction with polyphenolic compounds has some similarity to the reaction used in measuring the antioxidant activity with the DPPH assay. If there is a good correlation of interference and the DPPH assay, one might be able to apply the DPPH assay to conveniently distinguish the likelihood of interference of any given plant extract. Therefore, we attempted to correlate the degree of the interference and the IC_{50} of the polyphenolic compounds for DPPH assay, and the results are shown in Figure 4. In general,

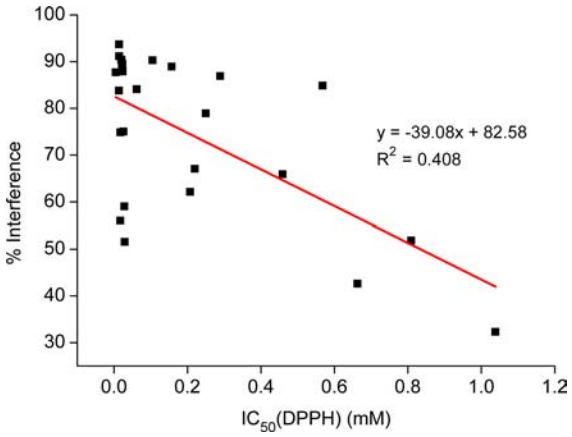

Figure 4. Correlation between percent interference of compounds and the IC_{50} of DPPH (mM).

those compounds with a high interference also had a high antioxidant activity (i.e., low IC_{50} of DPPH assay), but there was no linear correlation. Therefore, DPPH may be qualitatively applied to judge the potential interference of the GOP assay. Measuring the turbidity decrease during enzymatic starch hydrolysis is an accurate way to test enzyme activity, and it is not subject to interference due to reducing activity of the phenolic compounds. We applied this method to evaluate the inhibitory activity of α-glucosidase and found that these compounds have no measurable activity. These results highlighted the limitation of the GOP assay in natural products.

In conclusion, we have illustrated that the majority of polyphenolic compounds found in the plant kingdom have a significant interference in the GOP assay. Because the reaction with the free radical intermediate is likely to be a reduction reaction, it is reasonable to assume that radical scavengers will have a false-positive interaction. This effectively makes the GOP assay not useful in measuring the α-glucosidase inhibition activity of botanical extracts. It is essential to test the interference first before the GOP assay is applied for quantification of α-glucosidase activity. Recently, our group developed a high-throughput method for screening α-glucosidase and α-amylase inhibition activity of natural products using turbidity changes.[27] In this assay, natural starch was applied as the substrate and acarbose was used as a reference standard. Because turbidity is a physical parameter of the starch solution, one would expect that it would be more resistant to the interference of chemical reactions.

ABSTRACT: An earlier study explored the possibility of analyzing the distribution of branches directly in native, whole starch without isolating the amylopectin component. The aim of this study was to explore if this approach can be extended to include starch mutants. Whole starches from *du1* maize mutants deficient in starch synthase III (SSIII) with amylose content of ∼30−40% were characterized and compared with the wild type of the common genetic background W64A. Clusters were produced from whole starch by hydrolysis with α-amylase of *Bacillus amyloliquefaciens*. Their compositions of building blocks and chains were analyzed further by complete α-amylolysis and by debranching, respectively, whereafter the products were subjected to gel permeation and anion exchange chromatography. The size and structure of the clusters were compared with those of their isolated amylopectin component. Whereas the whole starch of the wild type sample had a branched structure similar to that of its amylopectin component, the results showed that the *du1* mutation resulted in more singly branched building blocks in the whole starch compared to the isolated amylopectin. This suggested that amylose and/or intermediate materials in whole *du1* starches likely contributed to the composition of branches. This study explored an alternative procedure to characterize the composition of branches in the whole starch without fractionating the components.

KEYWORDS: *whole starch, starch synthase III, structure, cluster, building block*

INTRODUCTION

Starch is a complex mixture of diverse biopolymers of glucose ranging from linear to branched molecules.[1] However, separation of these components in mutant starches can be a challenge. One of the most commonly employed methods for normal starches is based on butanol precipitation as originally developed by Schoch.[2] By this method the starch components are fractionated into a butanol-precipitated fraction, referred to as amylose, and a butanol-non-precipitated fraction, commonly known as amylopectin. Variations in the butanol precipitation based methods have been developed over the years. For example, Klucinec and Thompson used a mixture of isoamyl alcohol and butanol to obtain a precipitate consisting of amylose and intermediate material, whereas the supernatant consisted of amylopectin.[3] The amylose was then separated from the intermediate material by precipitation in butanol. When research is conducted on different mutant samples, however, the definitions and the isolation of the different starch components become more confounding.

Analysis of starch samples from mutant plants with detailed genetics presents an opportunity to understand biosynthesis−structure relationships. However, the analysis of the branched structure of the starch components down to the cluster and building block levels[4] requires a relatively large amount of sample. Whereas starches from plants most often are available in comparatively large amounts, starches from organisms such as algae or leaves[5,6] are available only in small quantities and do not in practice permit a separation into amylopectin and other components. This seriously hinders further exploration of the structure of starch from interesting mutants or pursuing other research questions. A possible alternative could be to analyze whole starch samples ("whole" denotes the native starch isolated from flour as opposed to the fractionated starch components) without separating the amylose and amylopectin. In a previous study with normal and waxy maize,[7] we explored the opportunity to understand starch structure without separating the amylose and amylopectin fractions from whole starch. We showed that the branching pattern in whole normal maize starch was comparable to that of waxy maize starch. One of the critiques of that research, however, was that the comparison of the whole normal starch was not with the amylopectin component from the same normal starch. In this study we therefore isolated the amylopectin component and compared it with the same whole maize starch of the genetic background W64A. We further used *du1* mutants of maize with the same genetic background that are deficient in starch synthase III (SSIII)[8,9] as a test material to study if analyses of the branching pattern in mutant whole starches are useful for the understanding of the effect of the mutation. The mutations were detailed by Lin et al.,[10] and the molecular structure of the starches was reported previously by Zhu et al.[11] Further studies on the cluster and building block structure of amylopectin from the same samples were also presented.[12] It was shown that the *du1* mutation altered the structure of starch and its amylopectin component and that it also increased the apparent amylose content. This study compares the cluster and building block structure of whole *du1* maize starches with the data for clusters and building blocks in amylopectin presented previously.[12]

MATERIALS AND METHODS

Starches and Enzymes. The maize samples including one wild type (W64A) and two single *dull1* mutants (*du1-Ref* and *du1-M3*) were the same specimens used in a previous study.[10] They were of the W64A inbred genetic background. Both *dull1* mutations caused complete loss of SSIII enzyme activity, but *du1-Ref* expressed the protein at low level, whereas *du1-M3* produced no protein.[10] The molecular structure of the starches and the cluster and building block structure of amylopectins were reported previously.[11,12]

α-Amylase of *Bacillus amyloliquefaciens* (EC 3.2.1.1), β-amylase of barley (EC 3.2.1.2, specific activity = 705 U/mg), isoamylase of *Pseudomonas amyloderamosa* (EC 3.2.1.68, specific activity = 210 U/mg), and pullulanase of *Klebsiella pneumoniae* (EC 3.2.1.41, specific activity = 699 U/mg) were from Megazyme (Wicklow, Ireland). The activity of the α-amylase (413 U/mL at pH 6.5, 25 °C) was determined on the basis of a previous description.[13] The given activities of other enzymes were according to the supplier.

Time Course Analysis of α-Amylolysis for Cluster Production from Whole Starch. Whole starch (20 mg) was dissolved in 400 μL of 90% dimethyl sulfoxide (DMSO) by gentle heating and then constant stirring for 3 days at room temperature (~22 °C) to ensure the complete dissolution of starch before hot double-distilled water (1.4 mL) was added. After cooling, α-amylase (200 μL, 0.9 U/mL) in NaOAc buffer (0.01 M, pH 6.5) was added to start the reaction in a water bath (25 °C) with magnetic stirring. The concentrations for substrate and α-amylase in the reaction system were 10 mg/mL and 0.09 U/mL. Samples (200 μL) were taken from 20 to 150 min. If not analyzed immediately, NaOH solution (4 μL, 5.0 M) was added and mixed to destroy the α-amylase, and then the sample was stored at −18 °C. Before analysis, the sample was diluted in water (200 μL), conditioned by NaOH solution (40 μL, 5.0 M), and analyzed by GPC

on Sepharose CL 6B as described below under Chromatographic Techniques.

Production and Characterization of α-Dextrins and β-Limit Dextrins of Clusters from Whole Starch. Whole starch (160 mg) was dissolved in 3.2 mL of 90% DMSO by gentle heating and then constant stirring for 3 days at room temperature (~22 °C) to ensure the complete dissolution of starch. Hot double-distilled water (11.2 mL) was added and, after cooling, α-amylase (1.6 mL, 0.9 U/mL) in NaOAc buffer (0.01 M, pH 6.5) was added to start the reaction in a water bath (25 °C) with magnetic stirring. The reaction was continued for 90 min before being stopped by the addition of NaOH (320 μL, 5.0 M) and standing at room temperature for 2 h to destroy the α-amylase. Pure methanol (80 mL) was added to precipitate the α-dextrins of clusters. The sample was left at 4 °C for 3 h before the precipitate was recovered by centrifugation (4000*g*, 20 min) at room temperature. The precipitate was washed twice with pure methanol (10 mL) and allowed to stand in a fume hood to remove the methanol through evaporation.

The external chain segments of α-dextrins of clusters were removed by β-amylase to obtain the β-limit dextrins of clusters as previously described.[7] Briefly, α-dextrins were dissolved in hot water to a carbohydrate concentration of 10 mg/mL and mixed with NaOAc buffer (0.01 M, pH 6.0) and β-amylase (1 μL/10 mg of dextrins). The β-amylolysis reaction was conducted at room temperature overnight, then boiled for 5 min, condensed by rotary evaporation at 50 °C, and purified through two coupled PD-10 columns (GE Healthcare Life Sciences, Piscataway, NJ, USA) to remove maltose and buffer salt. The β-amylolysis was repeated, and the resulting hydrolysate solution was run twice through the PD-10 columns to completely remove maltose and buffer salt from the β-LDs. The solution of β-LDs of clusters was condensed to a smaller volume for a suitable concentration for further analysis and stored in a freezer (−30 °C) before use.

Debranching. Solutions of β-LDs and building blocks with a carbohydrate amount of 1 mg were diluted in hot water to make up a volume (225 μL). After cooling, NaOAc buffer (25 μL, 0.01 M, pH 5.5), pullulanase (1 μL), and isoamylase (1 μL) were added. The reaction was at room temperature for 20 h with stirring to completely break the α-(1,6)-linkages before analysis by high-performance anion exchange chromatography (HPAEC). The reaction was terminated by boiling for 10 min.

Chromatographic Techniques. The molecular weight distributions of the clusters and building blocks were analyzed by gel permeation chromatography (GPC) of Sepharose CL 6B (Pharmacia, Uppsala, Sweden) and of Superdex 30 (Pharmacia), respectively, as described previously.[12] The column was calibrated as described previously.[14] The building block mixtures and also the debranched samples were analyzed by HPAEC as described previously.[12]

Statistical Analysis. Tests were conducted in triplicate and analyzed using SPSS version 19.0 software (IBM Corp., Armonk, NY, USA). Differences between means of data were compared by least significant difference at a significance level of $p < 0.05$.

RESULTS

Time Course Analysis of α-Amylolysis of Whole Starch. Hydrolysis kinetics of whole starches treated with α-amylase of *B. amyloliquefaciens* by using GPC is presented in Figure 1 (W64A) and Figure 2 (*du1-M3*). The hydrolysis profile for *du1-Ref* was similar to that of *du1-M3*. The fractions prior to 125 are primarily branched dextrins, whereas those after that are mostly linear dextrins.[15] These latter dextrins were likely the product of both amylose and the external and intercluster segments of amylopectin or intermediate materials. Figure 3 shows the kinetics of starch degradation over time. The hydrolysis was rapid in the initial stage and then became slower. The average DP of the branched dextrins leveled off around DP 150. On the basis of these observations, 90 min of α-amylolysis was chosen for large-scale cluster production for all whole maize starches.

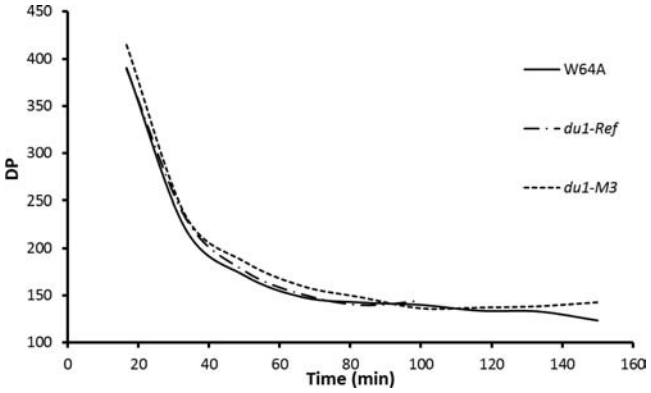

Figure 3. Development of average DP (degree of polymerization) of branched dextrins as a function of time during α-amylolysis.

Characterization of Clusters. Isolated clusters from whole starch were subjected to β-amylolysis to remove external chains that remained after α-amylolysis. The molecular weight distribution of the resulting β-limit dextrins (β-LDs) is shown in Figure 4. The average DP of clusters from W64A (64.6) was

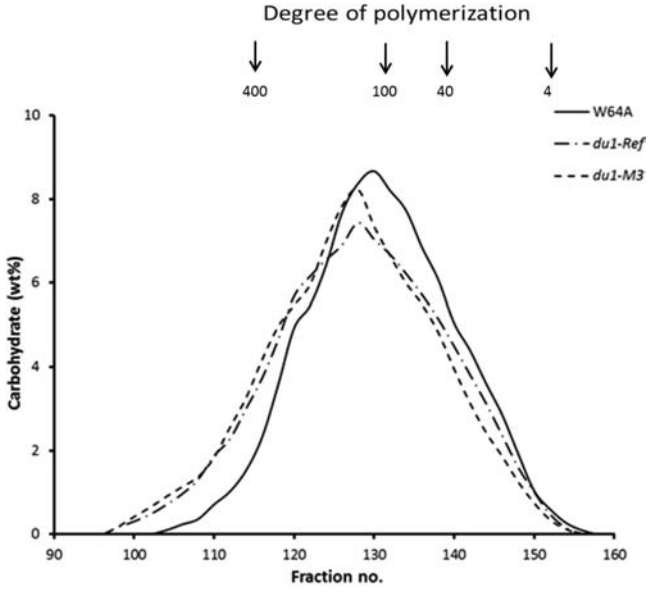

Figure 4. Molecular weight distribution obtained by GPC on Sepharose CL 6B of β-limit dextrins of clusters. wt %, weight-based percentage.

smaller than that of *du1-Ref* (78.3) and *du1-M3* (86.9) (Table 1). The same trend was also found for the peak DP (120 for W64A and 140 for *du1* mutants). *du1* mutant samples had a higher average number of chains per cluster (NC 13.2−15.2) than W64A (NC 10.9). Average chain length (CL 5.7−5.9), internal chain length (ICL 3.0−3.3), and total internal chain length (TICL 9.9−10.3) were similar for all genotypes.

Unit chains of clusters can be categorized into a- (carrying no other chains) and b-chains (carrying other chains).[16] These chains are different from "A" and "B" chains typically designated in amylopectin molecules.[17] The a-chains are completely external chains and have DP 2 and 3 in the β-LDs,[18] whereas the b-chains represent the internal unit chain profiles of the clusters and are presented in Figure 5. The b-chains can be further divided into different categories according

Table 1. Characterization of β-Limit Dextrins of Clusters from Whole Maize Starches[a]

genotype	DP	peak-DP	NC	peak-NC	CL	ICL	TICL
W64A	64.6c	120b	10.9c	20.2b	5.9a	3.3a	10.3a
du1-Ref	78.3b	140a	13.2b	23.7a	5.9a	3.2ab	10.1ab
du1-M3	86.9a	140a	15.2a	24.4a	5.7a	3.0b	9.9b

[a]DP, average degree of polymerization (DP) estimated by GPC; NC, number of chains estimated as DP/CL; CL, average chain length estimated by HPAEC; ICL, internal chain length = (CL − ECL) × NC/(NC − 1) − 1, in which ECL is 2 for β-limit dextrin; TICL, total internal chain length = CL of b-chains in β-LD − 1.5. Different lower case letters within a column indicate significant differences ($p < 0.05$).

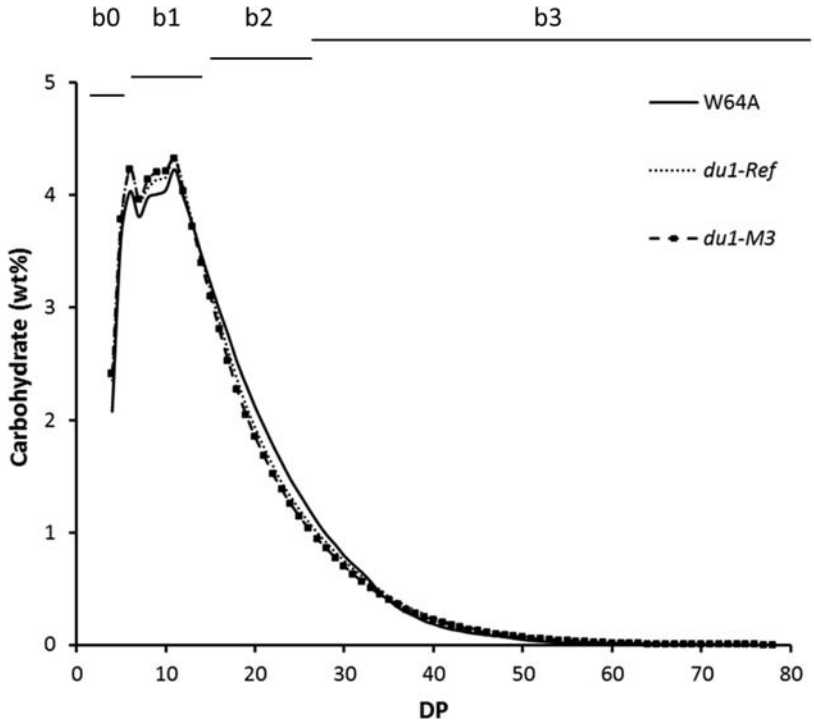

Figure 5. Fractionation by HPAEC of unit chains of debranched β-limit dextrins of clusters from whole starches. b0 = 4−6, b1 = 7−18, b2 = 19−27, b3 ≥ 28. wt %, weight-based percentage.

to their length and on the basis of their possible function as a part of the cluster structure (Table 2).[16] The amounts of a-chains in the clusters of whole starch of all different genotypes were similar (59.6−60.3%), and this was also the case for b1- and b3-chains. However, *du1* mutant samples had somewhat lower amounts of b2-chains (3.3−3.6%) and higher amount of b0-chains (11.8−12.2%) than W64A (b2 = 4% and b0 = 11.4%).

Table 2. Relative Molar Composition (Percent) of Chain Categories in β-Limit Dextrins of Clusters from Whole Maize Starches in Comparison with That from the Amylopectin[a]

genotype	a	b0	b1	b2	b3
W64A	60.3a	11.4b	22.8a	4.0a	1.4a
du1-Ref	59.6a	12.2a	23.0a	3.6b	1.5a
du1-M3	61.0a	11.8ab	22.3b	3.3b	1.3a
$W64A_{AP}$	51.4	10.2	19.6	3.5	1.4
$du1\text{-}Ref_{AP}$	51.7	9.0	19.2	4.5	2.1
$du1\text{-}M3_{AP}$	52.5	9.5	19.4	4.4	2.3

[a]For the whole starch of W64A, *du1-Ref*, and *du1-M3*, the DP range of *a* = 2−3, b0 = 4−6, b1 = 7−18, b2 = 19−27, and b3 ≥28 for β-LDs; for the amylopectin ($W64A_{AP}$, $du1\text{-}Ref_{AP}$, and $du1\text{-}M3_{AP}$), the composition was from the φ,β-LDs as detailed previously, the DP range of a = 2, b0 = 4−6, b1 = 7−18, b2 = 19−27, b3 ≥28 for φ,β-LDs.[12] Different lower case letters within a column of whole starches (W64A, *du1-Ref*, and *du1-M3*) indicate significant differences ($p < 0.05$).

Characterization of Building Blocks in Clusters. To further understand the organization of chains in clusters, the clusters were subjected to extensive hydrolysis to release the small and tightly branched building blocks. As expected, the building block profile exhibited two distinguishable peaks with the one around fraction 123 (DP ∼ 8) representing singly branched building blocks and the one around fraction 136 (DP ∼ 2) representing linear dextrins (Figure 6). The branched building blocks can generally be categorized into five groups (groups 2−6), of which groups 2−4 have a corresponding number of chains and groups 5 and 6 are more heterogeneous with ≥5 chains per block.[19,20] The molecular structure of building blocks is presented in Table 3. The branched building blocks had an average DP of 11.0−11.2 and the NC ranged from 2.8 to 3.0 for all genotypes. The chain length parameters of the building blocks were also very similar.

From the structures of clusters and their building blocks, the interconnection and composition of branched building blocks in clusters were calculated (Table 4). The interblock chain length (IB-CL) was similar for all of the genotypes (6.5−6.6). The number of blocks per cluster ranged from 5.5 (*du1-M3*) to

dx.doi.org/10.1021/jf500697g | J. Agric. Food Chem. 2014, 62, 4577−4583

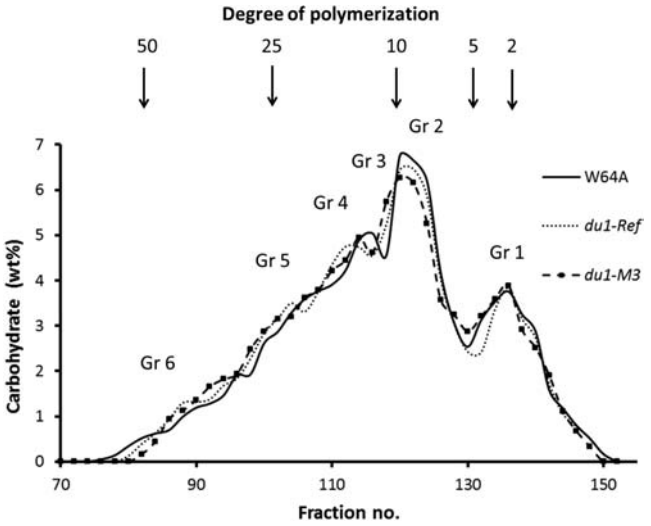

Figure 6. Fractionation of building blocks in β-limit dextrins of clusters of whole maize starches on Superdex 30. Groups (Gr) of building blocks are shown. wt %, weight-based percentage.

4.2 (W64A). All genotypes had a density of blocks per cluster around 6.4−6.5. Clusters in the *du1* mutant samples had somewhat less of group 2 blocks (57.6−58.0%) compared with W64A (60.4%), but more of groups 3−6 blocks.

DISCUSSION

In a previous study, we highlighted that the cluster and building block attributes were similar between whole normal and waxy maize starches.[7] Results from this study, in which the amylopectin was isolated from normal starch (W64A) and compared with the same starch, confirmed that the cluster and building block data from whole normal starch are reflective of the structure of the corresponding amylopectin (Figure 7). This study also takes this approach further with mutant starch that affects the structure of the amylopectin component. Results in this study will be compared with the fine structure of amylopectin from these same samples reported in a previous publication.[12]

The pattern of α-amylolysis of samples in this study agreed with the previous result for normal maize starch with an apparent amylose content of 23%.[7] However, there remained large dextrins (fractions 45−70) toward the end of hydrolysis (Figures 1 and 2) that are typically not observed with pure amylopectin samples[7,15] and even from these samples[12] as compared in Figure 8. This may therefore be attributed to the amylose and/or the intermediate components of starch. Hayashi et al.[21] reported that amylose could reassociate and precipitate when whole starch in DMSO solution is diluted in water and cooled. In this aggregated physical form it would become resistant to α-amylolysis. Nevertheless, these remnants were hydrolyzed by subsequent dissolution and β-amylolysis as shown by their absence in the purified cluster fractions (Figure 4). Another noticeable difference was the larger amount of dextrins produced by the α-amylase at the boundary between the branched and linear dextrins[15] (fractions 120−125) with whole starches compared to amylopectin, especially for the *du1-M3* sample toward later stages of α-amylolysis (Figure 2). This may be attributed to extensive hydrolysis of both amylose and intermediate fractions[22] to DP ~40. The large production of this material from the *du1* samples may be attributed to the higher amounts of amylose (36.5 and 40.5% for mutants vs 29.6% for normal maize) with altered molecular structure as a result of SSIII deficiency as shown previously.[11]

The external chain segments that remain in the clusters after the action of α-amylase can largely be removed either with β-amylase or sequentially with phosphorylase *a* and then β-amylase.[23] The external chain lengths (ECL) of a- and b-chains in β-LDs are slightly different from that of φ,β-LDs: In β-LDs a-chains have DP 2 or 3 and the ECL of the b-chains is 1 or 2, whereas in φ,β-LDs all a-chains have DP 2 and the ECL of all b-chains is 1.[23] The internal structure of the LDs is, however, identical in β-LDs and φ,β-LDs. In this study, β-LDs of the clusters were produced as opposed to φ,β-LDs in our previous study on the purified amylopectin,[12] as this saves 2 days of analysis time. A comparison of the clusters from the two protocols is presented in Figures 7 and 9. The differences in the profiles in the region of the short chains (<DP 15) are due to minor differences in ECL of the LDs rather than differences in the internal chain distributions. The profiles of the b-chains at DP >15 (where the small differences in ECL of β-LDs and φ,β-LDs diminish) of clusters from whole normal maize were very

Table 4. Composition of Building Blocks in β-Limit Dextrins of Clusters of Whole Maize Starches[a]

				distribution of block categories (%)			
genotype	IB-CL	DBbl	NBbl	Gr 2	Gr 3	Gr 4	Gr 5 and Gr 6
W64A	6.6a	6.5a	4.2b	60.4a	21.3b	8.8b	9.5b
du1-Ref	6.5a	6.5a	5.1a	58.0b	22.3a	9.1a	10.6a
du1-M3	6.5a	6.4a	5.5a	57.6b	22.7a	9.1a	10.5a

[a]IB-CL, interblock chain length per cluster = mol $\%_{linear} \times DP_{linear}$/mol $\%_{branched}$ + 4; DBbl, density of building blocks per cluster = NBbl/$DP_{cltr} \times 100$, in which DP_{cltr} is the average DP of φ,β-LDs of clusters; NBbl, number of building blocks per cluster = wt $\%_{Bbl}/100 \times DP_{cluter}/DP_{Bbl}$, in which wt $\%_{Bbl}$ is the weight percent of branched building blocks. Categorization of groups 2−6 of building blocks is based on their number of chains per block. Different lower case letters within a column indicate significant differences ($p < 0.05$).

Table 3. Characterization of Building Blocks in β-Limit Dextrins of Clusters from Whole Maize Starches[a]

	linear		branched						
genotype	mol %	DP	wt %	mol %	DP	CL	ICL	TICL	NC
W64A	56.4a	2.0a	80.8b	43.6b	11.0a	3.8ab	1.7b	4.3ab	3.0a

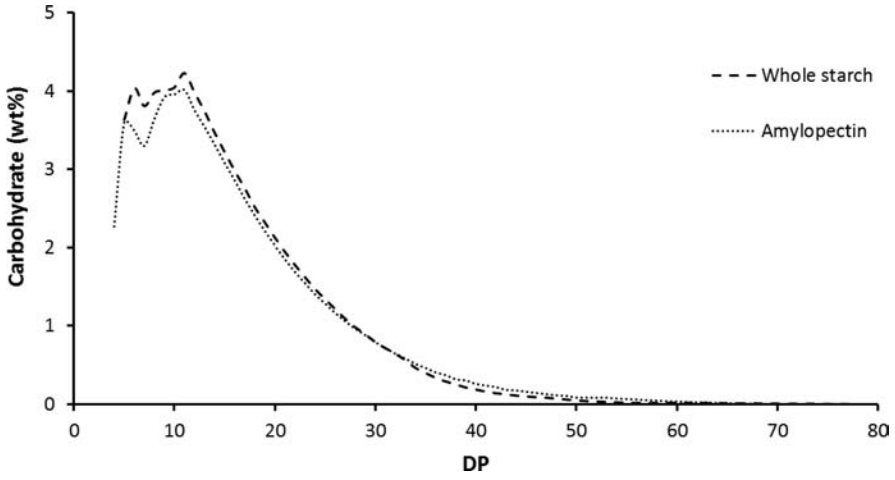

Figure 7. Unit chain length distribution comparison of clusters from whole starch (β-limit dextrins) and its amylopectin (φ,β-limit dextrins) of W64A. Data for amylopectin are from a previous paper.[12] wt %, weight-based percentage.

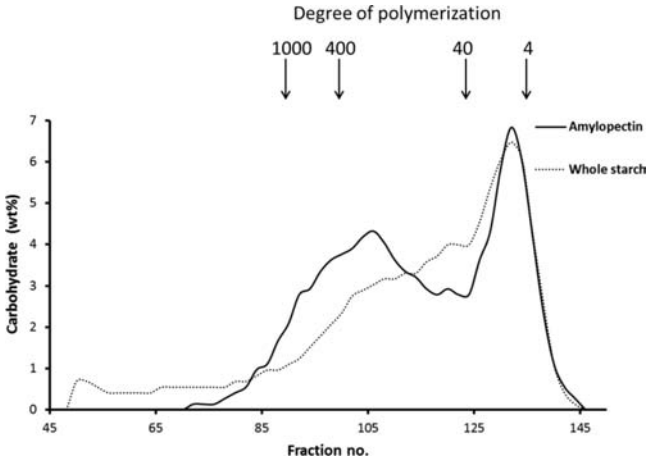

Figure 8. Comparison of α-dextrins of whole starch and its amylopectin from *du1-M3* during α-amylolysis at 120 min. Data for amylopectin are from a previous paper.[12] wt %, weight-based percentage.

similar to those of the clusters from amylopectin isolated from the same starch (Figure 7).

The amounts of a-chains in the clusters of whole starch of different genotypes were, however, significantly higher than the amount of a-chains in clusters of amylopectin (Table 2). This can be attributed to the fact that chains with DP 3 in the β-LDs are mixtures of a- and b-chains[24] and therefore overestimate the number of a-chains in the β-LDs, whereas in the φ,β-LDs, all a-chains have DP 2. In general, the *du1* mutation resulted in an elevated amount of shorter b-chains around DP 5−15 and a decreased amount of intermediate-length b-chains around DP 15−30 (Figure 9). This did not agree with the previous results on the cluster structure of amylopectin of the same samples (Table 2).

The effect of *du1* mutation on the cluster size and NC (Table 1) was consistent with the previous result on the φ,β-LDs of clusters from amylopectin,[12] although minor differences in the exact values for the *du1* mutant starches were noted. The pattern of the influence of *du1* mutation on the CL, ICL, and TICL of whole starch clusters was partially inconsistent with the results of amylopectin.[12] Apparently, this might be attributed to clusters from branched components in either

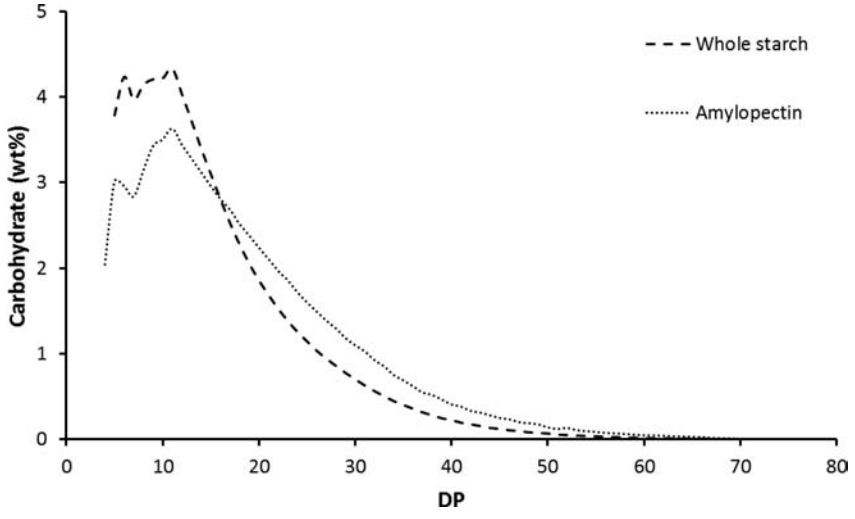

Figure 9. Unit chain length distribution comparison of clusters from whole starch (WS) (β-limit dextrins) and its amylopectin (φ,β-limit dextrins) of *du1-M3*. Data for amylopectin are from a previous paper.[12] wt %, weight-based percentage.

intermediate materials or branched amylose molecules, which likely had relatively higher amounts of shorter chains.

When the building blocks from whole starch (Table 3) were compared to those from amylopectin,[12] their structures were similar, but there were compositional differences in the small building blocks. Group 2 building blocks was more abundant in whole starch compared to clusters from purified amylopectin, and group 3 building blocks were correspondingly lower.

The difference in the composition and structure of clusters and building blocks from whole starch and isolated amylopectin, although small, do reflect the influence of amylose and intermediate components. The deficiency in SSIII probably resulted in altered levels of other enzymes related to biosynthesis of amylose, as suggested by Fujita et al. and Szydlowski et al.[25,26] This likely influenced the branching pattern of several starch components, which ultimately gave rise to different structural characteristics of the clusters when whole starch was analyzed as test material.

In conclusion, the cluster and building block structures of whole starches deficient in starch synthase III were compared with those of isolated amylopectin from a previous study. Structural and compositional similarities were observed but with some minor differences. The structural differences included a higher proportion of singly branched building blocks (group 2) in clusters of whole starch with a corresponding reduction of group 3 building blocks compared to isolated amylopectin. This difference was likely due to changes in the structural features in the amylose and/or intermediate components as affected by the deficiency in SSIII. On the basis of these results, it is apparent that the use of whole starches to explore branching patterns cannot replace the analysis of purified amylopectins, especially in mutant samples. However, it could be used as a complement and will provide useful information in the analysis of samples obtained in only small quantities like from leaf starches, from which purified amylopectin cannot be obtained in large enough quantities.

ABSTRACT: Isothiocyanates (ITCs) hydrolyzed from glucosinolates (GSLs) in Brassicaceae tissue are toxic to soil organisms. In this study, the effect of aliphatic and aromatic ITCs from hydrated dry Brassicaceae shoot tissues on the mycelium and oospores of the pea root rot pathogen *Aphanomyces euteiches* was investigated. The profile and concentrations of GSLs in two test Brassicaceae species, *Sinapis alba* and *Brassica juncea*, and the ITCs from the dominant hydrolyzed parent GSLs were monitored. The concentrations of dominant ITCs and pathogen exposure time were evaluated in in vitro experiments. The greatest effect on the pathogen was observed from aliphatic ITCs hydrolyzed from *B. juncea* tissue, and the effect depended on the ITC concentration and exposure time. ITCs were more effectively hydrolyzed from *B. juncea* GSLs than from *S. alba* GSLs; i.e., the ITC/GSL ratio was higher in *B. juncea* than in *S. alba* tissue, giving a different release pattern. The release of phenylethyl isothiocyanate, which was common to both species, followed a pattern similar to that of the dominant ITC in each crop species. This suggests that traits other than GSL content, e.g., plant cell structure, may affect the release of ITCs and should therefore influence the choice of species used for biofumigation purposes.

KEYWORDS: *Brassicaceae, glucosinolate, isothiocyanate, Aphanomyces euteiches, pea root rot*

INTRODUCTION

Pea root rot caused by the pathogen *Aphanomyces euteiches* Drechs is a serious problem in pea production worldwide.[1−3] The pathogen can persist in the soil for long periods without a host plant due to the thick protective cell walls of the *Aphanomyces* oospores. When oospores are stimulated to germinate by pea root exudates,[4] a short mycelium strand and a sporangium are produced. The sporangium releases zoospores that attack the pea roots.[5] Pea root rot is difficult to control as there are no available pea cultivars with an acceptable level of resistance.[6] Furthermore, synthetic fungicides may have a negative environmental impact, and certain agents have been prohibited, for example, within the European Union.[7] The commonly recommended way to control *A. euteiches* is therefore to leave intervals (6−8 years) between pea crops in the rotation.[8]

Many plants of the family Brassicaceae (brassica) can suppress soil-borne organisms when grown as cover crops or when added as plant residues to infested soil.[9−11] In field studies, *Sinapis alba* (white mustard) reduced the development of *Aphanomyces* pea root rot when used as green manure. This reduction was enhanced when white mustard was used for a second consecutive year.[12] Studies under greenhouse conditions showed that incorporating cabbage tissue after growth in contaminated soil gave close to a 10-fold reduction in pea root rot disease severity.[13] Suppressive effects of brassica tissues are associated with the glucosinolate class of chemicals (GSLs) present in the tissues.[10] The biofumigation concept in agricultural systems was introduced by Australian scientists in the 1990s and includes practices to relieve the pressure of soil pests and pathogens by the use of brassica crops.[14] The concept is based on the toxic volatile compounds produced from hydrolyzed GSLs.[10,13,15,16] When brassica crop tissues are damaged, GSLs are hydrolyzed by myrosinase to form volatile isothiocyanates (ITCs), thiocyanates, water-soluble nitriles, and epithionitriles.[10,17] The composition and quantity of the produced substances depend on the parent GSL. The type and concentration of GSLs vary between brassica species, cultivars, and vegetative parts and are also influenced by the plant development stage.[16,18,19] The GSLs are classified as aliphatic, aromatic, or indolyl on the basis of their chemical structure.[10,20] Isothiocyanates suppress a wide range of organisms, including the soil-borne pathogen *A. euteiches*.[21] A study has demonstrated that volatile compounds from decomposing cabbage tissues inhibit hyphal growth of *A. euteiches* and that the pathogen is unable to grow further when placed in fresh air after exposure, although the active substance was not specified.[9] The suppressive effects depend on the composition and concentration of ITCs.[22] The chemical structure of ITCs influences their mode of action, meaning that different ITCs may show varying levels of toxicity at the

same concentration.[23−25] An aliphatic structural group attached to the nitrogen in the basic ITC structure generally confers greater toxicity than an aromatic structure.[26] Generally, the toxicity of ITCs decreases as the size of the organic group increases.[27,28] Aliphatic ITCs bind directly with protein molecules inside cells and inhibit their activity, whereas aromatic ITCs first interact with the cell membrane, changing its electrophilic properties, before entering the cell[23] and reducing cell activity.[29]

Many different brassica-derived materials have been used to study aspects of biofumigation, such as fresh plant tissues, rape seed meal, freeze-dried plant tissues, and oil extracts, but pure ITCs have also been used.[18,30−32] Shoot tissue comprises the greater part of the brassica plant material when it is used for biofumigation in practice. Here, we evaluate a simple, reproducible system for studying shoot tissue effects on a plant pathogen in vitro using low-temperature drying of the plant material.[13,33]

Our overall aim was to discover how brassica plant tissues can be used for biofumigation to reduce the occurrence of root rot on peas caused by *A. euteiches*. Our specific objectives were to compare crop species with different GSL compositions to generate knowledge on the choice of brassica crop for biofumigation in the control of pea root rot. We tested the hypotheses that (1) ITCs from hydrolyzed aliphatic GSLs in *Brassica juncea* shoot tissue are more effective than ITCs from aromatic GSLs in *S. alba* shoot tissue at reducing the ability of *A. euteiches* oospores to cause pea root rot, (2) the lethal effect of aliphatic ITCs from shoot tissues on the growth of *A. euteiches* depends on the concentration of ITCs and time of pathogen exposure, and (3) the release patterns of ITCs from *B. juncea* and *S. alba* are different and influence the suppressive effects on *A. euteiches*.

MATERIALS AND METHODS

Plant Materials. Air-dried shoot tissues of two GSL-containing plant species, *B. juncea* (cv. Pacific Gold) and *S. alba* (cv. Architect), a non-GSL plant species, *Secale cereale* (cv. Amilo), and a water control were compared for their effect on the oospores and mycelium of *A. euteiches*. The effect of volatile compounds produced from hydrated shoot tissues was studied in in vitro experiments. The most effective plant species was chosen for dose and exposure-time experiments, compared with the effect of chemical solutions of the dominant ITCs from the two brassica species. The composition of GSLs in *B. juncea* and *S. alba* dry shoot tissues and of ITCs produced from hydrated tissues were analyzed.

Shoot Tissue Production. Three cover crops, *S. alba*, *B. juncea*, and *Se. cereale*, were grown in garden soil (Hasselfors Garden AB, Sweden) in the greenhouse. A complete nutrient solution (Cederroth International AB, Sweden) was applied at regular intervals together with additional $(NH_4)_2SO_4$ to enhance GSL production. Shoot tissues were harvested at soil level when *B. juncea* and *S. alba* reached the flowering stage. The tissues were dried at 35 °C for 72 h and then ground separately four times at 6000 rpm to a fine powder. The ground shoot tissues were stored in airtight containers and kept in a dark and dry place until use.

***A. euteiches* Inoculum.** *A. euteiches* strain 5035:2A was used in all experiments (obtained from F. Heyman, Department of Forest Mycology and Plant Pathology, Swedish University of Agricultural Sciences, Uppsala, Sweden). The strain was maintained on corn meal agar (CMA) (Oxoid Ltd., United Kingdom) at 6 °C and was used for soil inoculation.[34,35] For the production of oospore inoculum, the *A. euteiches* strain was cultured in oat meal broth for 4 weeks. It was homogenized, the oospore concentration was calculated, and then it was mixed with talcum powder (VWR International AB, Sweden) and dried. The dry inoculum material was sieved through a 1 mm mesh net and stored at 4 °C until use.

Field Soil. Soil was collected from an agricultural field in Giresta, Enköping, Sweden, and tested for the absence of *A. euteiches*. The soil consisted of 46% clay, 48% silt, 2% sand, and 4% organic matter. The organic matter content was estimated by loss on ignition. The soil contained 1.5 mg of N/mL, and the pH (H_2O) was 7.7. The soil was sieved through a 0.6 cm mesh and stored at 4 °C with the soil moisture content maintained at 21% during storage. For some experiments the soil was sterilized by autoclaving twice at 121 °C for 30 min.

Oospore Volatile Exposure and Bioassay. A 1 g mass of dry shoot tissue of *B. juncea*, *S. alba*, and *Se. cereale* was transferred separately to 220 mL plastic cups (8.9 cm diameter). A 4 g mass of talcum powder containing about 2.8×10^4 oospores was spread homogeneously on a filter paper placed in a 9 cm diameter sieve (1 mm mesh) and placed on top of the cup. At the start of the experiment 5 mL of sterilized deionized water was added to the tissue, and another plastic cup was immediately placed upside down on top of the sieve as a lid. The container was sealed with several layers of Parafilm (Sigma-Aldrich Sweden AB) and placed in the dark at 24 °C for 10 days. Sterilized deionized water was used as the control, and three replicates per treatment were performed.

After 10 days of incubation, the oospore−talcum powder mixture was removed from the container, and 0.8 g of the 4 g of treated powder was mixed with 80 mL of sterilized and nonsterilized soil. Four subsamples, 20 mL each, of the two infested soils were transferred to 85 mL pots. One pea seed (cv. Clare) was sown on top of the infested soils in each pot and was covered with an additional 5 mL of noninfested soil. The pots were placed in a greenhouse with a light/dark period of 14 h/10 h at a temperature of 24/19 ± 2 °C and relative humidity (RH) of 85 ± 5%. The soil moisture was adjusted daily to field levels to obtain optimal infection conditions. All pea seedling roots were evaluated for root rot disease severity 3 weeks after sowing. Each pea seedling was assigned a DSI (disease severity index) value on the basis of the mean disease symptoms of the individual pea seedlings in the four tubes representing each experimental unit. The scale for DSI ranges from 0% to 100%, but each individual plant can only be assigned one of five scores for disease severity: 0%, healthy plant; 25%, root slightly discolored; 50%, root extensively discolored but not shrunken; 75%, root extensively discolored and shrunken; 100%, root partly or completely rotted or plant dead.[36]

In Vitro Exposure of the Mycelium to Volatiles: Effect of Dose. Dry shoot tissue, 60, 100, and 140 mg, of *B. juncea*, *S. alba*, and *Se. cereale* was transferred separately to 220 mL plastic cups and mixed with 5 mL of sterilized, deionized water. A water control was included, and all treatments had three replicates. The doses were determined after a pilot study with *B. juncea* shoot tissues in which a 140 mg dose completely inhibited pathogen growth. A plug (7 mm diameter) from actively growing *A. euteiches* culture was placed in the center of a 9 cm CMA dish and placed as a lid on the top of the cup immediately after water was added to the dry plant tissues. The cup and dish were sealed with Parafilm and incubated in a growth cabinet at 24 °C for 4 days. The colony diameter of *A. euteiches* was measured on the lid daily using a measuring scale. After 4 days, the culture dish lids were removed from the cups, placed in the same growth cabinet at 24 °C, and observed for further growth of *A. euteiches*.

In Vitro Exposure of the Mycelium to Volatiles: Effect of Exposure Time. Hydrated *B. juncea* shoot tissue (140 mg) was used to produce volatile compounds which were exposed to an actively growing *A. euteiches* plug (7 mm diameter) put on fresh CMA dishes as in the dose experiment described above. Three exposure times were used, 40, 80, and 120 min, with three replicates of each. After exposure, the dishes were incubated at 24 °C, and the colony diameter of *A. euteiches* was measured daily using a measuring scale on the lid. After 4 days, the culture dish lids were removed from the cups, placed in the same growth cabinet at 24 °C, and observed for further growth of *A. euteiches*.

Exposure with ITC Chemical Standards. An in vitro experiment was performed using authentic chemical standards (CSs) of volatile

compounds produced from *B. juncea* and *S. alba* tissues, identified as described below. Standard solution mixtures were designed to give concentrations of volatile compounds that closely resembled those recorded from hydrated dry shoot tissue by collecting volatile compounds from plant tissue and CSs under the same conditions and quantifying the major components by gas chromatography (Table 1). The *B. juncea* chemical standard mixture (B.juncea-CS) contained allyl isothiocyanate (40 μg/μL, >98% purity, Sigma-Aldrich Sweden AB) and phenylethyl isothiocyanate (2 μg/μL, 99% purity, Sigma-Aldrich Sweden AB). The *S. alba* chemical standard mixture (S.alba-CS) contained benzyl isothiocyanate (30 μg/μL, 98% purity, Sigma-Aldrich Sweden AB), phenylethyl isothiocyanate (5 μg/μL) and allyl isothiocyanate (0.2 μg/μL). All chemical standard mixtures were dissolved in hexane.

A 1 μL volume of each B.juncea-CS and S.alba-CS standard mixture was placed in the center of a filter paper in a sealed plastic cup containing an actively growing *A. euteiches* mycelium (7 mm plug) placed on a fresh CMA dish and incubated in the dark at 22 °C. Hyphal growth was measured daily for 4 days using a measuring scale. The growth was compared with the growth of an *A. euteiches* volatile-exposed culture where the volatiles originated from 140 mg of hydrated dried tissues of *B. juncea* and *S. alba* using water and hexane as control treatments. For details of ITC analyses, see below.

Glucosinolate Analysis. Glucosinolates were extracted from ground shoot tissue.[37] In brief, GLSs were extracted from 100 mg of dry shoot tissue by 70% MeOH which was heated to 90 °C to deactivate myrosinase and therefore avoid degradation of the GSLs. The extracts were transferred to a DEAE-Sephadex 25 column (Sigma, St. Louis, MO) before desulfating. Desulfoglucosinolates were separated and identified using HPLC with an acetonitrile/Milli-Q water gradient. GSL detection was performed with a photodiode array detector with 229 nm wavelength. The correction factors at 229 nm to calculate the concentrations of GSLs were followed.[38,39] The peaks of desulfoglucosinolates were identified by comparison with standards on the basis of retention times and ultraviolet spectra. Different concentrations of sinigrin (2-propenyl) (Acros Organics, Fair Lawn, NJ) were used as an external standard and extracted following the same procedure as that for the shoot tissue. The levels of GSLs were calculated on the basis of the dry weight of the tissues.

Isothiocyanate Analysis. Ground shoot tissue (140 mg) was placed in a glass dish and moistened with 5 mL of Milli-Q water. The suspension was immediately placed under a bell-shaped glass vessel (380 mL) with two openings and sealed with bulldog clips at 24 ± 2 °C in the dark. Volatile compounds were collected by pulling air from the outlet of the jar through a glass liner containing Tenax TA (50 mg, 60/80 mesh, Supelco, Bellefont, PA).

A positive pressure push−pull system was used, with charcoal-filtered air pushed through an inlet into the vessel at 500 mL/min and pulled out through the adsorbent at 350 mL/min. The greater push rate prevented entry of contaminating volatiles. All glassware and Teflon tubes (connecting air flow tubes) were washed with detergent, distilled water, and acetone and baked in an oven at 175 °C for at least 16 h prior to the entrainment. Charcoal filters and glass liners with Tenax TA were baked at 175 and 220 °C, respectively, under N_2 flow for 16 h. Volatiles were collected for periods of 10 min at 0−10, 30−40, 60−70, and 120−130 min after addition of water to the tissue. The rest of the time the outlet of the glass vessel was open, preventing the buildup of released volatiles.

Concentrations of ITCs arising from the dosing of CS solutions as described above were determined by analyzing 1 μL of either B.juncea-CS or S.alba-CS mixture put on a filter paper placed inside a sealed plastic cup (220 mL). A glass liner (with Tenax TA) was inserted through a hole in the plastic cup, and air was pulled from the cup at a flow rate of 350 mL/min. The aim was to sample at the peak concentration of the major ITCs, which was after 60−70 min of incubation for B.juncea-CS and 0−10 min of incubation for S.alba-CS as indicated by previous analysis of volatiles from *B. juncea* and *S. alba* plant tissues. Volatiles were collected for 10 min and analyzed by gas chromatography as described below.

For quantification, collected volatiles were analyzed by gas chromatography (GC) on an Agilent 6890N with a flame ionization detector equipped with an HP-1 column (100% dimethylpolysiloxane, 50 m, 0.32 mm i.d., 0.52 μm film thickness, J&W Scientific, Folsom, CA) and fitted with an Optic 3 thermal desorption system (Atas GL International, Veldhoven, The Netherlands). An internal standard, 50 ng of decane, was injected onto the glass liner containing the sample prior to desorption. The liner containing the Tenax with absorbed volatiles was placed directly into the injector, and volatiles were thermally desorbed starting at 30 °C for 0.5 min and rising at 16 °C/s to 250 °C. The GC temperature program was 30 °C for 3 min, 5 °C/min to 150 °C for 0.1 min, and then 10 °C/min to 250 °C for 15 min using hydrogen as the carrier. The amount of each compound was calculated relative to the internal standard.

For tentative compound identification, volatile samples from the treatments, *B. juncea* hydrated plant tissue, B.juncea-CS mixture, *S. alba* hydrated plant tissue, and S.alba-CS mixture, were collected as described above and analyzed by coupled GC−mass spectrometry using an Agilent 7890N gas chromatograph coupled to an Agilent 5975C mass-selective detector (electron impact 70 eV) fitted with an Optic 3 thermal desorption system (Atas GL International). The thermal desorption and GC oven temperature programs were as described above. The carrier gas was helium with a flow rate of 1.3 mL/min. Volatile compounds were identified by comparison against a commercially available library (National Institute of Standards and Technology, NIST 08, Gaithersburg, MD) and by comparison of mass spectra and retention indices with commercially available authentic standards where available (Sigma-Aldrich Sweden AB). Where standards were unavailable, in some cases the retention index (Kovats Index, KI) of the substance could be matched with a previously published KI for the compound on the type of GC column used in the current study (HP-1) (Figure 5).

ITC/GSL Ratios. ITC/GSL ratios were calculated for selected GSLs. 2-Propenyl glucosinolate was the dominant GSL in *B. juncea* shoot tissues, and *p*-hydroxybenzyl glucosinolate was dominant in *S. alba* shoot tissues. 2-Phenylethyl was detected in both plant tissues as a common GSL. The detected GSLs were recorded as micromoles per gram of dry tissue in the GC analysis (Table 2) and converted to micrograms for the selected GSLs using their molecular weights. Estimated amounts of ITCs produced from their parent GSLs in hydrated plant tissues during the initial 130 min were calculated (Figure 5). Total amounts of each ITC (μg) produced in the initial 130 min of hydrolysis from 1 g of hydrated dry tissue was divided by

the amount of each GSL (μg) in 1 g of dry tissue and multiplied by 100 to determine the ITC/GSL ratios.

Statistical Analysis. The mean DSI and radial growth of hyphae were transformed to their natural logarithms. The experiments were generally analyzed in accordance with their completely randomized design. However, the soil treatment (sterilized vs nonsterilized) in the test of disease development on peas after oospore exposure to ITC volatile compounds was treated as a subplot factor and the cover crops were treated as the main plot factor in a split plot design. The effect of the cover crop, dose of cover crops, and time of exposure to the volatile and cover crop/chemical were treated as fixed factors in all experiments, and each replicate was treated as a random factor. Analyses of variances were made using the procedure linear model, and least-squares means were compared using Tukey's test with a $P \leq 0.05$ significance limit in R version 2.15.1 (The R Foundation, 2012).

RESULTS

Effects of Volatile Compounds on Oospores. Volatile compounds from hydrated *B. juncea* dry tissue strongly reduced the inoculum potential of *A. euteiches* oospores, shown by a significant reduction in pea root rot symptoms compared to that of control shoot tissues from the other species ($P < 0.001$, SE ± 0.120; Figure 1). The other cover crops or soil sterilization before the experiment started had no significant effect on disease development.

Effect of Volatile Compounds on Hyphal Growth: Effect of Dose. *B. juncea* shoot tissue suppressed the hyphal growth of *A. euteiches* more efficiently than tissue from the other species ($P < 0.001$) (Figure 2). The hyphal growth of *A. euteiches* was more affected by shoot tissue dose with *B. juncea* than with *S. alba* (dose × cover crop interaction, $P < 0.001$). The highest dose of *B. juncea* shoot tissue completely inhibited growth, and no further growth was registered when these cultures were placed in fresh air. The volatile compounds produced from the lower doses of *B. juncea* and the highest dose of *S. alba* also reduced the hyphal growth of *A. euteiches*

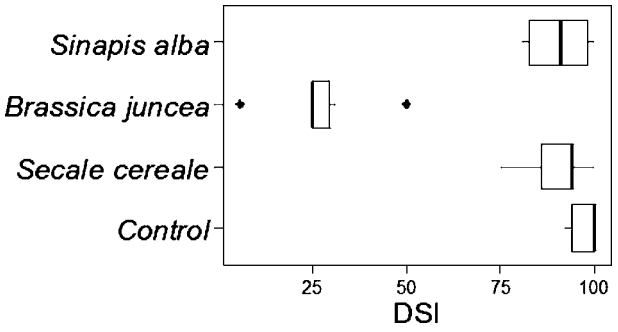

Figure 1. Pea root rot symptoms registered in a bioassay depending on pretreatment of *Aphanomyces* oospores with volatile compounds from hydrated dry plant tissues. Pea seedlings were rated for pea root rot 3 weeks after pea seed sowing. The scale for disease severity index (DSI) is 0−100%: 0%, healthy plant; 25%, root slightly discolored; 50%, root extensively discolored but not shrunken; 75%, root extensively discolored and shrunken; 100%, root partly or completely rotted or plant dead.[36] The value of DSI is back-transformed from the natural logarithm. Control = water.

significantly compared with the water control. No effect was found in the *Se. cereale* tissue treatment.

Effect of Volatile Compounds on Hyphal Growth: Effect of Exposure Time. The hyphal growth of *A. euteiches* was affected by the time of exposure to volatile compounds produced from hydrolyzed *B. juncea* shoot tissue ($P = 0.002$). The volatile compounds from the 140 mg dose of hydrated *B. juncea* shoot tissue completely inhibited the growth of *A. euteiches* after exposure for 120 min (Figure 3). No further growth was observed during the following days when the cultures were placed in fresh air.

Effects of Chemical Standard Mixtures. Volatile compounds arising from the chemical standard mixtures suppressed the growth of *A. euteiches* in vitro ($P < 0.001$). Volatile compounds from hydrated *B. juncea* dried shoot tissue and both chemical standard mixtures, B.juncea-CS and S.alba-CS, completely inhibited the growth of *A. euteiches* (Figure 4). There was no further growth in the following days when the cultures were placed in fresh air. Volatile compounds from hydrated *S. alba* tissue also caused some reduction of hyphal growth compared to the water control. No inhibition of pathogen growth was observed when exposed to the solvent hexane.

Glucosinolates in *B. juncea* and *S. alba* Shoot Tissues. Both species contained aliphatic, aromatic, and indolyl GSLs. Total extracted GSL concentrations in *S. alba* were higher than the concentration of GSLs in *B. juncea*. *S. alba* contained one more GSL compound than *B. juncea*. The aliphatic 2-propenyl glucosinolate dominated in *B. juncea*, and the aromatic *p*-hydroxybenzyl glucosinolate dominated in the *S. alba* tissue (Table 2).

Isothiocyanates from *B. juncea* and *S. alba*. *S. alba* shoot tissue produced more volatile compounds and a greater total amount of ITCs than *B. juncea*. *S. alba* and *B. juncea* were dominated by aromatic benzyl isothiocyanate hydrolyzed from *p*-hydroxybenzyl and benzyl glucosinolates and aliphatic allyl isothiocyanate from 2-propenyl glucosinolate, respectively. Both plant species produced the aromatic phenylethyl isothiocyanate (Table 3).

Pattern of ITC Release from *B. juncea* and *S. alba* Hydrated Tissues. ITCs were released faster from the GSLs in *S. alba* than from the GSLs in *B. juncea* tissue at the

beginning of hydrolysis (Figure 5). The GSLs of *B. juncea* produced ITCs over a longer time with increasing rate compared to ITCs from *S. alba* tissue. The estimated ITC/GSL ratio of the dominant aliphatic 2-propenyl producing allyl isothiocyanate in *B. juncea* was 1.82. The ITC/GSL ratio for the dominant aromatic *p*-hydroxybenzyl and benzyl producing benzyl isothiocyanate in *S. alba* was 0.56. The ratio of the aromatic 2-phenylethyl glucosinolate producing phenylethyl isothiocyanate, which was common to both species, was 11.51 for *B. juncea* and 15.51 for *S. alba*.

The release patterns of phenylethyl isothiocyanate were different for the two species, even though the originating 2-phenylethyl glucosinolate was the same in both species. Instead, it followed the same pattern as the dominant allyl isothiocyanate in *B. juncea* and benzyl isothiocyanate in *S. alba* (Figure 5).

dx.doi.org/10.1021/jf501776c | J. Agric. Food Chem. 2014, 62, 4584−4591

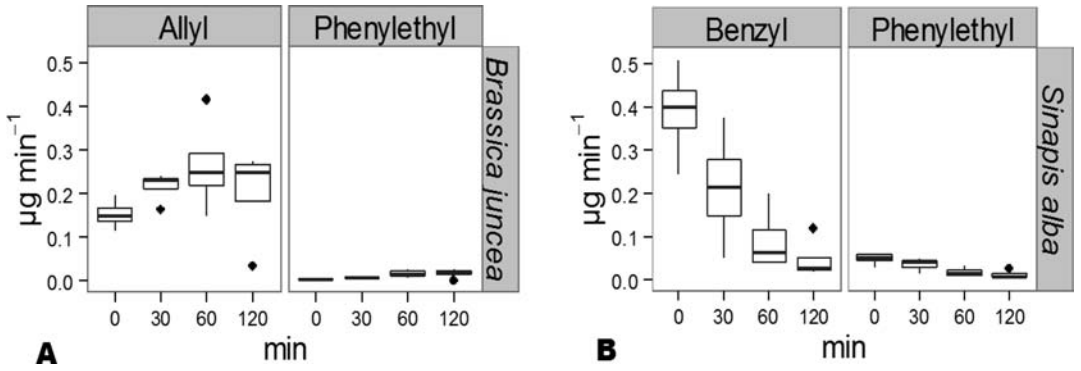

Figure 5. Release pattern and concentration of allyl, benzyl, and phenylethyl isothiocyanates at different time (min) points after addition of water to 1 g of dry shoot tissue of (A) *B. juncea* (cv. Pacific Gold) and (B) *S. alba* (cv. Architect).

DISCUSSION

This study shows that volatile compounds produced by brassica shoot tissue have a strong inhibitory effect on *A. euteiches*. However, the results also highlight the importance of understanding the mechanisms behind the suppression when designing systems where plants containing GSLs are used to control soil-borne pathogens. We show that the brassica species, dose of ITC, and time of exposure interact in determining the effect of the volatile compounds on the *A. euteiches* mycelium or oospores.

We used shoot tissues from two brassica species with different GSL profiles. Although we used cultivars different from those in earlier investigations, produced the plant tissue under greenhouse conditions, partly with artificial light, and dried the material to standardized dosages, the variety and concentration of GSLs in *B. juncea* and *S. alba* shoot tissues were similar to those found in earlier studies.[10,15,42−45] This indicates that the GSL composition remains consistent in the plant species despite differences in cultivar, growing conditions, and low-temperature drying of the plant material. As a consequence of the composition of GSLs, we found that the volatile compounds produced from *B. juncea* and *S. alba* were dominated by allyl and benzyl isothiocyanates, respectively, which is in line with earlier studies.[10] The thick-walled, long-lived oospores of *A. euteiches* are structures very different from the thin-walled *A. euteiches* hyphae. Nevertheless, suppression by direct exposure to volatile compounds was shown for both these reproductive structures. For both mycelium and oospore exposures, volatiles hydrolyzed from *B. juncea* tissue were more effective than volatiles from *S. alba* tissue. Previous investigations comparing the effects of aliphatic and aromatic ITCs tested the survival of weevil larvae.[30] The conclusion was that the aliphatic allyl isothiocyanate is likely to have greater biological activity than the aromatic ITCs, which is in line with the biological responses observed in the current study.

The in vitro data from the current study show that the amount of *B. juncea* tissue used was lethal to *A. euteiches*, whereas the equivalent amount of *S. alba* tissue did not completely prevent pathogen growth. This indicates that the highest dose of *S. alba* dry shoot tissue did not produce a high enough concentration of volatile compounds to prevent pathogen growth. However, in the experiment with chemical standards, the volatile compounds released from the *S. alba* chemical mixture completely prevented hyphal growth. The analysis of collected volatile compounds showed that the *S. alba* chemical mixture produced 10 times more ITCs than *S. alba* hydrated dry shoot tissue. It can be assumed that the concentration of ITCs contributes to their suppressive effects.

Our ITC analysis revealed differences in the pattern of ITC release between *B. juncea* and *S. alba* hydrated dry tissues. The calculated ITC/GSL ratios indicate that 2-propenyl glucosinolate is more efficient than *p*-hydroxybenzyl and benzyl glucosinolates at producing ITCs. The chemical structure and size of GSLs mainly regulate their efficiency of conversion into ITCs.[25,48] Our chemical analysis also shows the hydrated dry shoot tissue of *S. alba* released volatile compounds more rapidly, with the highest concentration recorded within a much shorter time than for *B. juncea*. The dominant ITC released by *B. juncea* tissue, allyl isothiocyanate, has a lower molecular weight and lower boiling point than benzyl isothiocyanate, the dominant compound released by *S. alba*. However, despite the expected higher volatility of allyl isothiocyanate, its concentration in the headspace of hydrolyzed powder of the respective plants was comparable to that of benzyl isothiocyanate. Although it is likely that the volatility of these ITCs does influence their toxicity, our results suggest that other factors inherent to the dry powders themselves are also important.

The hydrolysis process for the dominant aliphatic GSL in *B. juncea* shoot tissue seemed to follow a longer time course than that for the dominant aromatic GSL in *S. alba*. Furthermore, we observed that the release pattern of phenylethyl isothiocyanate differed between plant species, following the same pattern as the dominant ITC for each species. The ITC/GSL ratio (indicating the efficiency of production) of the species' common aromatic phenylethyl isothiocyanate from the parent 2-phenylethyl glucosinolate was lower in *B. juncea* tissue than in *S. alba*. This suggests that other traits inherent to the dry powders, such as plant cell structure or water-absorbing capacity, influence GSL hydrolysis and ITC release. These factors probably interact with the characteristics of the chemicals themselves, such as volatility, to determine the eventual ITRC release.[48] These factors, however, require further investigation.

Toxic effects from incorporated *B. juncea* plant tissue in *A. euteiches* contaminated soil have been shown to reduce the development of pea root rot, but an effect of ITCs has not always been established.[12,46] In a closed system, volatile ITCs can easily interact directly with the exposed pathogen. We show that the degree of detrimental effects from ITCs was enhanced as the time of pathogen exposure increased. For *A. euteiches* growing on CMA agar medium, the lethal dose of ITCs from *B. juncea* was reached after 2 h of exposure, showing the importance of keeping the concentration of effective ITCs

dx.doi.org/10.1021/jf501776c | J. Agric. Food Chem. 2014, 62, 4584−4591

high for this period. For an optimal effect in a biofumigation process, this suggests the use of a cover after incorporation of plant biomass to minimize evaporation of volatiles. This measure was also suggested in earlier studies.[47]

The current study shows that brassica plant tissue, its dominant ITCs, their concentration and release pattern, and exposure time are important factors for the suppression of *A. euteiches*. The results highlight the importance of choosing plant species with the most effective production ratio but also high biomass production to reach optimal concentration levels when GSL-containing plants are used for biofumigation. The results support the use of a cover to minimize dispersal of ITCs, which should allow the ITCs to interact directly with the pathogen for a longer period. However, the findings from this study need further verification under field conditions.

Supporting Information

ABSTRACT: Strawberry leaves contain high amounts of diverse phenolic compounds potentially possessing defensive activities against microbial pathogens and beneficial properties for human health. In this work, young strawberry plants were treated with two plant activators, *S*-methylbenzo-1,2,3-thaidiazole-7-carbothiate (BTH) and birch wood distillate. Phenolic compounds from activator-treated and control leaves were subjected to quantitative analyses by HPLC-DAD, HPLC-ESI-MS, and microQTOF ESI-MS. Thirty-two different phenolic compounds were detected and characterized, and 21 different ellagitannins constituted the largest group of compounds in the strawberry leaves (37.88−45.82 mg/g dry weight, 47.0−54.3% of total phenolics). Treatment with BTH resulted in higher levels of individual ellagitannins, whereas treatment with birch wood distillate strongly increased the levels of chlorogenic acid in strawberry leaves compared with the control. The results suggest that different plant activators may be useful tools for the activation of different branches in the phenylpropanoid biosynthesis in strawberry.

KEYWORDS: *polyphenols, strawberry (Fragaria × ananassa), leaves, BTH, activators*

INTRODUCTION

During the evolutionary history of terrestrial plants, plant surfaces have been continuously exposed to abiotic and biotic stresses caused by environmental factors such as ultraviolet-B (UV-B) radiation, ozone, and numerous plant pathogens and insects. In agriculture, pesticides are extensively used to control diseases, insects, and weeds to protect and improve yields and might be considered a necessity of modern farming.[1−3] Despite the benefits of pesticides to crop yields, these chemicals can additionally cause some health hazards to pesticide-manufacturing workers and farmers, and also consumers and workers in the food industry are exposed daily to plant pesticides and pesticide residues via plants or food of plant origin.[1−3] In the future, changing climatic variables, such as altered wind patterns and rising temperatures, may further increase pest outbreaks and the need for pesticide application and directly or indirectly alter the behavior of pesticides, for example, fungicides, in agricultural lands and plant surfaces.[4−6] Altogether, application of pesticides can also cause some external, delayed costs from damage to the environment, human health, and other production sectors.[3,5] Apart from better awareness and safety practices, there is likely a growing need and demand for inexpensive and effective but at the same time more natural pesticides. Phenolic compounds, a large class of plant secondary metabolites, are an important component of plants' natural defense against pathogens. Elicitor molecules are exogenous or endogenous compounds that can activate defense compounds, secondary metabolites, or their synthesis in an organism. Elicitors that induce pathways enhancing the accumulation of phenolic compounds can be utilized to protect plants from infections.[7]

Polyphenolic compounds have been, and still are, important mediators in the adaptation and survival responses of plants in acute and chronic challenges. Polyphenols, such as ellagitannins, appear to play an important role in plant defense against insect pests[8] and plant pathogens.[9] Also, plants growing naturally in high latitudes,[10] high temperature, and high light conditions[11] or under low nitrogen and phosphorus availability[12,13] may contain relatively high concentrations of phenolic compounds. UV-B radiation[14] and ozone-induced stress[15,16] are capable of causing variable changes in polyphenol profiles. Polyphenols also act in plants regulating cell growth, differentiation, pollen fertility, and nodulation and thus may contribute some vital features of plant fitness.[17,18] The concentration of polyphenols in plants varies widely during plant development and in different plant organs.[19] The concentration of antimicrobial polyphenols can be increased by exposing plants to mild microbial infection or infection mimicking treatment, that is, by application of elicitor-active compounds capable of activation of defensive pathways. For example, *S*-methylbenzo-1,2,3-thaidiazole-7-carbothiate (BTH) is successfully used in numerous plants to activate plant defense systems, increasing concentrations of different polyphenols.[20]

Recently it has been found that leaves of berry plants are rich in bioactive polyphenols. High concentrations of polyphenols have been measured from black currant (*Ribes nigrum*),[21] raspberry (*Rubus ideaus*),[22] bilberry (*Vaccinium myrtillus*),[10]

saskatoon (*Amelanchier alnifolia*),[23] and strawberry (*Fragaria* × *ananassa*)[24] leaves. Strawberries are extensively grown horticultural crop plants possessing a wide range of bioactive compounds. In strawberry, antioxidant capacity in leaves has been found higher than in berries,[19] and the extract made from wild strawberry leaves has demonstrated a direct, endothelium-dependent vasodilator activity.[25] Potentially beneficial health effects of strawberry polyphenols against, for example, cancer,[26] cardiovascular diseases,[27] inflammation-related diseases,[28] and Alzheimer's disease,[29] have been reported. These observations suggest that strawberry leaves may be a promising bioresource for diverse health-related applications; this could increase the level of utilization and the value of the plant material. Although polyphenols from strawberry fruits have been extensively analyzed from different cultivars during the past few years, little is known about the individual phenolic compounds occurring in strawberry leaves.[30,31] We previously analyzed some of the phenolic compounds in greenhouse-grown strawberry leaves.[32] We also detected improved resistance of strawberry leaves to powdery mildew (*Sphaerotheca macularis* Wall. ex. Fr) after BTH exposure.[32]

Byproducts of a slow thermal conversion process, also known as pyrolysis of wood material, have been used in Asian countries for centuries as growth stimulants, fertilizers, fungicides, herbivore repellents, and herbicides, and today they are marketed globally as biological control agents.[33,34] Birch wood distillate is a byproduct of birch wood processing formed during pyrolysis,[33] and its tar-free fraction contains mainly acetic acid, methanol, hydroxypropanone, furfural, and acetone.[34] Fractions of birch wood distillate may act as plant-based biological control agents that can possibly be used as a commercial plant-protecting agent of low environmental risk.[34,35]

In the present study, extensive analysis using powerful liquid chromatography coupled to diode array detection and electrospray ionization mass spectrometry (HPLC-DAD, HPLC-ESI-MS, and microQTOF ESI-MS) was conducted to further identify and characterize the induced polyphenols from BTH- and birch wood distillate-treated strawberry leaves to clarify the potential of strawberry leaves as a source of health-beneficial compounds and BTH and birch wood distillate as plant-protecting agents.

MATERIALS AND METHODS

Plant Material. Strawberries (cv. Polka) were grown at the MTT AgriFood Research Finland (Jokioinen, Finland) greenhouses in 7 cm pots in a peat−sand mixture (3:1) and fertilized weekly with Superflex-9 fertilizer (19% N, 5% P, 20% K). The following growth conditions were used: relative humidity, 50−70% (night−day); daylight, 16 h; and temperature, 19−22 °C (night−day). Plants were grown until they had at least four fully developed leaves before the treatments were begun.

Two hundred strawberry plants were randomly divided into three groups of 40−80 plants. One group was sprayed with 0.5 g/L active BTH (Bion 50 WG, Syngenta, ca. 5 mL per plant) according to our previous work.[32] One group was sprayed with 10% birch wood distillate (ca. 5 mL per plant) containing, for example, acids, ether-solubles, ether-insolubles ("wood syrup"), and polycyclic aromatic hydrocarbons.[34] Further composition of the distillate is described in Fagernäs et al.[34] The control group was sprayed with water until runoff (ca. 5 mL per plant). Samples for chemical analysis were collected from control plants immediately after treatment (day 0) and from control and BTH- and birch wood distillate-treated plants 7 days after treatment (day 7).[32] All samples were collected at the same time of day (at 12−2 p.m.) under uniform light conditions. For each treatment/sampling date combination, we randomly selected 10 plants and destructively harvested leaves for chemical analyses. From these 10 plants, leaves from 2−3 plants were pooled, creating four unique sample replicates per treatment/sampling date combination. Samples were immediately frozen with liquid nitrogen and stored at −80 °C until they were freeze-dried.

Sample Preparation, Extraction, and Fractionation. Freeze-dried samples were homogenized into a fine powder using a ball grinder (Retsch MM200, Haan, Germany) and stored in a −20 °C freezer until the chemical analyses were conducted. Our analytic workflow was as follows: (1) initial sample screening; (2) preparative scale extraction, fractionation, and MRM method development; (3) quantitative analysis of phenolic compounds by UPLC-DAD-MS/MS; and (4) qualitative analysis of phenolics by HPLC-ESI-QTOF-MS.

Initial Sample Screening. For initial screening and subsequent quantitative analysis, analytical scale extractions were used: samples of 10 mg were extracted with 2 × 1400 μL of acetone/water (80:20, v/v). The extracts were concentrated into water phase with a vacuum concentrator (Eppendorf concentrator 5301, Hamburg, Germany), freeze-dried (Christ Alpha 2-4, Osterode, Germany), redissolved into 1 mL of water, and filtered through 0.20 μm PTFE filters (VWR International, Darmstadt, Germany). We first conducted preliminary analyses to identify the major phenolic compounds present in all samples using UPLC-MS/MS (see experimental methods below).

Preparative Scale Extraction, Fractionation, and MRM Method Development. For preparative scale extractions, 8 g of ground leaf material was extracted with 5 × 200 mL acetone/water (80:20, v/v). Acetone was evaporated from the pooled extracts by rotary evaporation and the water phase freeze-dried. Two grams of the freeze-dried extract was dissolved into 30 mL of water and fractionated with Sephadex LH-20 (Pharmacia, Uppsala, Sweden) gel chromatography as described by Salminen and Karonen.[36] The Sephadex fractions containing the polyphenols were further fractionated by semipreparative HPLC using a Waters Delta 600 (Waters, Milford, MA, USA) system equipped with Fraction Collector III. The column used was Phenomenex Gemini C18 (10 μm, 150 × 21.2 mm, Phenomenex, Torrance, CA, USA) with 0.1% formic acid and acetonitrile as eluents. These purified compounds were used by direct infusion with a Waters XEVO triple-quadrupole mass spectrometer to develop compound-specific multiple reaction monitoring (MRM) methods and quantitative calibration curves for the specific measurement of each major metabolite in our samples (Table 1).[37] Isomeric compound pairs with the same molecular masses were quantified using the same calibration curve for both of the compounds.

Quantitative Analysis of Phenolic Compounds by UPLC-DAD-MS/MS. For quantitative analyses, phenolic extracts from each sample (after 30× dilution with water) were analyzed using ultraperformance liquid chromatography with an electrospray triple-quadrupole mass spectrometry detector (UPLC-MS/MS) and compound-specific MRM methods. The Waters Acquity Xevo UPLC-MS/MS (Waters, Milford, MA, USA) system utilized a Waters Acquity UPLC BEH Phenyl column (1.7 μm, 2.1 × 100 mm, Waters, Dublin, Ireland) column with acetonitrile (A) and 0.1% formic acid (B) as eluents. The gradient was as follows: 0−0.5 min, 0.1% A (isocratic); 0.5−5 min, 0.1−30% A in B (linear gradient); 5−5.1 min, 30−90% A in B (linear gradient); 5.1−7.1 min, 90% A (isocratic); 7.1−7.2 min, 90−0.1% A in B (linear gradient); 7.2−8.5 min, 0.1% A (isocratic). The flow rate was 0.500 mL/min. Five microliters of the sample extract was injected into the UPLC column. Phenolic concentrations were calculated as milligrams per gram dry weight.

Qualitative Analysis of Phenolics by HPLC-ESI-QTOF-MS. All fractions and extracts were analyzed by the HPLC-DAD-ESI-QTOF-MS system consisting of an Agilent 1200 series HPLC equipped with a diode array detector (Agilent Technologies, Waldbronn, Germany) and micrOTOF-Q ESI-mass spectrometer (Bruker Daltonics, Bremen, Germany). Chromatographic separations were performed using a Waters Acquity UPLC BEH C18 column (1.7 μm, 50 mm × 2.1 mm, Waters, Dublin, Ireland). The binary mobile phase consisted of acetonitrile (A) and 0.1% formic acid (B). The elution profile was as follows: 0−0.1 min, 0% A (isocratic); 0.1−5 min, 0−30% A in B

[a]Isomeric compounds with the same molecular mass that were quantified with the same calibration curves are denoted in their identifying code (e.g. E6a, E6b). Compounds with multiple reported retention times are known epimers (e.g., tellimagrandin I) or other isomers that were detected in samples but below the limits of quantification (in parentheses, e.g., 1-*O*-galloylglucose). Ellagitannin and galloyl derivative characterization based on Moilanen, Sinkkonen, and Salminen, 2013. GA, gallic acid; G, galloyl; Q, quinic acid; GLUC, glucose; HHDP, hexahydroxydiphenoyl.

(linear gradient); 5−6 min, 30−70% A in B (linear gradient); 6−8 min, 70% A in B (isocratic). The flow rate was 0.45 mL/min, and the injection volume was 5 μL. Chromatograms were recorded at 280 nm. The HPLC system was controlled by Hystar software (version 3.2., Bruker BioSpin, Rheinstetten, Germany). The mass spectrometer was controlled by Compass micrOTOF control software (Bruker Daltonics) and operated in negative ion mode. The capillary voltage was maintained at +4000 V with the end plate offset at −500 V. The pressure for the nebulizer gas (N_2) was set at 1.6 bar, and the drying gas (N_2) flow rate was 12.0 L/min and temperature, 200 °C. The full scan mass ranged from m/z 100 to 3000. Calibration with 5 mM sodium formate injected via a six-port valve was used at the end of the LC-MS experiment to provide high-accuracy mass measurements. The data were handled by Compass DataAnalysis software (version 4.0, Bruker Daltonics).

Data Handling. The phenolic chemical data set contained both quantitative variation (in the total concentrations of phenolics in a sample) and qualitative variation (relative amounts of different chemical in comparison to the total concentration). To distinguish between these two effects, for each sample we divided the concentration of each individual compound by the total concentration of phenolics in the sample (the sum of all compounds combined). These values were used in further analysis as measures of qualitative variation in the phenolic profile of each sample. In addition to this, we included the total concentration of phenolics as a measure of quantitative variation between samples.

Statistical Analysis. Our data set contained a large number of response variables (concentrations of individual chemicals), with strong positive and negative correlations between individual traits. This correlated data structure precluded the use of multiple univariate analysis of variance (ANOVA) analyses. Similarly, because the number of response variables (P = 33) exceeded our sample size (N = 16), we did not have the statistical power to utilize standard statistical methods such as MANOVA. Thus, we opted to utilize principal component analysis (PCA) to explain observed variation between samples in phenolic profiles. PCA uses orthogonal transformation to generate linearly uncorrelated principal components.[38] We used the PRINCOMP procedure in SAS to perform a PCA with all of our treatment levels together. We selected the optimum number of principal component axes using a scree plot,[38] which resulted in two axes (Supporting Information Table S1).

To test whether groups of samples separated in the PCA were significantly different, from one another we used the GLM procedure in SAS to perform ANOVA. We used our treatment levels as predictor variables and the two PC axes as response variables. We used the LSMEANS statement to test for differences between treatments, correcting for multiple comparisons using the Tukey adjustment.

RESULTS AND DISCUSSION

Identification and Characterization of Strawberry Leaf Phenolics. The phenolic compounds from strawberry leaves were characterized and tentatively identified according to their characteristic UV spectra, molecular masses, and MS fragmentation patterns. In total, 32 phenolic compounds were quantified using sensitive and compound-specific MRM methods that were separately developed for each compound (Figure 1; Table 1). Isomeric compounds with the same molecular mass were treated as unique compounds, but separate analyses pooling these compounds resulted in qualitatively similar results (results not shown). Strawberry leaves contained a diverse suite of polyphenols, including gallic acid derivatives (6), ellagitannins (21), flavonoids (5), proanthocyanidins (3), and chlorogenic acids (2).

The total amounts and percentages of different groups of phenolic compounds in different treatment groups are presented in Table 2. Twenty-one different ellagitannins constituted the largest group of the compounds in the leaves,

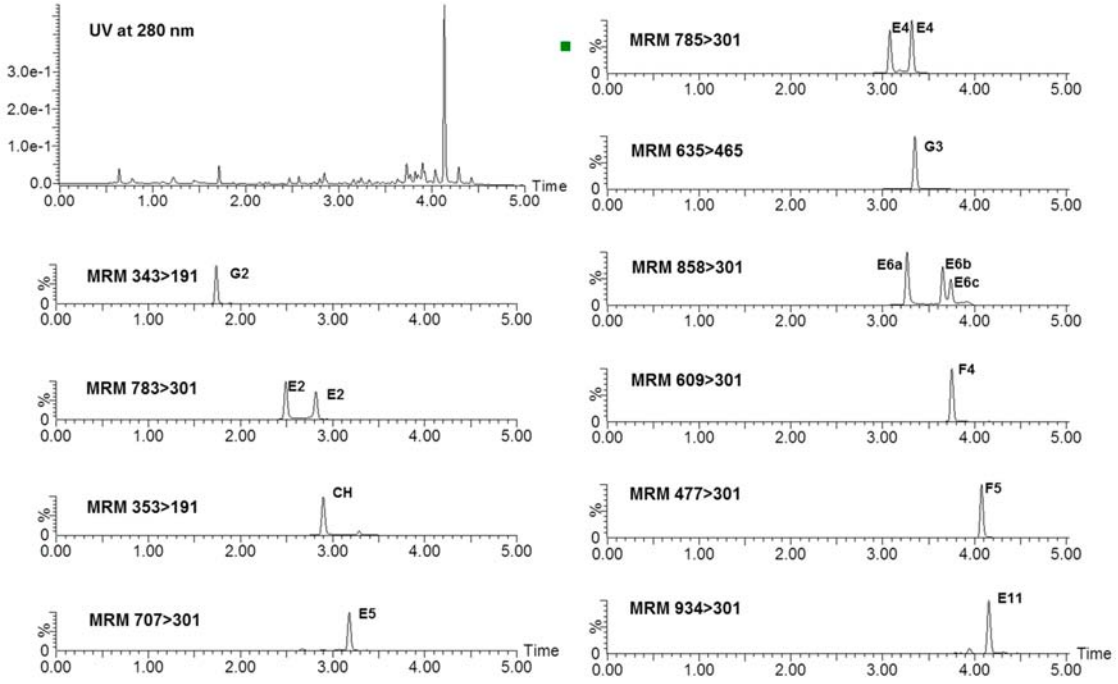

Figure 1. Representative UV and compound-specific MRM chromatograms. The use of MRM allowed the highly sensitive and selective quantification of a number of phenolic compounds simultaneously. Pictures are selected MRM chomtograms, with individual measured compounds identified.

representing 47.0−54.3% of the total phenolic compounds in differently treated strawberry leaves. Ellagitannins occur in high levels also in strawberry fruits (9.7−22.9 mg/100 g).[30] Sanguiin H-6, lambertianin C, galloyl bis-hexahydroxydiphenic acid (HHDP) glucose,[30] agrimoniin, and five other ellagitannins[31] were recently detected in fruits of different strawberry cultivars. In this work, agrimoniin (Table 2, code E9b) was the most abundant compound in the strawberry leaves, supporting the previous findings[32] and agrimoniin was also recently found to be the main ellagitannin in both wild and cultivated strawberry fruits.[31,39]

In the present study, flavonoids were found to be the second largest group of polyphenols in strawberry leaves, and their percentage of the total phenolic compounds in different treatment groups was 36.4−41.4%. However, Oszmiański et al.[22] found quercetin derivatives as the most abundant group of phenolic compounds in the strawberry leaves.

Proanthocyanidins are the most abundant phenolic compounds in strawberry fruits; the concentrations vary among cultivars between 53.9 and 163.2 mg/100 g.[30] Proanthocyanidins have also been detected in strawberry leaves[32] and in the leaves of white strawberry.[24] In the present study, proanthocyanidins represented the third largest group of phenolic compounds in strawberry leaves (4.7−8.0% of total, Table 2). Galloyl derivatives and chlorogenic acids were the other phenolic compounds identified from the strawberry leaf samples, and their percentages of total phenolic compounds altered between 0.9 and 3.1%.

When compared to the recent information about polyphenols analyzed from the leaves of other berries, strawberry appears to be a rich source of different ellagitannins. For example, leaves of bilberry contain mainly quercetin-3-*O*-glucuronide, *trans*-chlorogenic acid, *cis*-chlorogenic acid, cinchonain, and some other minor phenolics, whereas the main compound in the lingonberry leaves seems to be quercetin-3-*O*-glucuronide, and these leaves contain also many other quercetin drivatives and other flavonols.[40] The saskatoon leaves consisted mainly of quercetin- and kaempferol-derived glycosides (41% of the phenols), hydroxycinnamic acids (36%), and minor amounts of catechins and neolignans.[23]

In general, we observed strong positive correlations between the concentrations of gallic acid derivatives and ellagitannins (Supporting Information Table S2). This was expected, because these compounds are formed along the same hydrolyzable tannin biosynthetic pathway that uses the metabolic flux of one branch of the shikimate pathway.[36] In contrast, all of the hydrolyzable tannins showed negative correlations with the concentrations of flavonoids, proanthocyanidins, and chlorogenic acids. This finding is in agreement with flavonoids, proanthocyanidins, and chlorogenic acids needing the metabolic flux of the shikimate pathway that is not directed toward hydrolyzable tannins. Similarly, we found strong positive correlations between the relative concentrations of flavonoids, proanthocyanidins, and chlorogenic acids as they all need the shikimate pathway for their biosynthesis. However, flavonoids and proanthocyanidins were more strongly correlated with each other than with chlorogenic acids, because they utilize also the acetate/malonate pathway that is not needed for the biosynthesis of chlorogenic acids. Among the correlations between individual compounds there were three exceptions that did not fit well with the general pattern: HHDP-glucose (E1), ellagitannin 2038 Da (E13), and flavonoid glycoside 594 Da (F3). Of these, only the pattern observed with HHDP-glucose and other HTs is explained by HHDP-glucose being the catabolic product of ellagitannins.[41] To explain the patterns observed with E13 and F3 would need further investigation of the specific structures.

The PCA and subsequent ANOVA were able to detect significant differences in the polyphenolic profiles of different treatments (Figure 2). The first two PCA axes were able to

[a]Values are presented as the mean ± standard deviation with percent concentration in parentheses. Sample size for each treatment was 4. BTH, BTH-treated leaves; Birch, birch wood distillate-treated leaves.

summarize 77% of the variance in the data set (Supporting Information Table S1). These principal components were able to separate samples into unique clusters corresponding to different treatments (Figure 2A). ANOVA and Tukey's pairwise comparisons revealed these clusters formed significantly different groups. The first principal component (PC1) separated samples into three clusters, corresponding to different treatments. All treatments were differentiated in PC1 except for control day 7 and birch wood distillate-treated day 7 (Figure 2A, *x*-axis). The second principal component (PC2) further differentiated groups on the basis of their combined phenolic profiles. Here, control day 7 and birch wood distillate-treated day 7 were differentiated (Figure 2A, *y*-axis). The individual traits with the highest and lowest loading values contributed most to these differences (Figure 2B; Supporting Information Table S1).

Impact of BTH Treatment on Strawberry Leaf Phenolics. The total amount of phenolic compounds in untreated control leaves was not much altered in 7 days, but in the BTH-treated leaves the concentration of total phenolic compounds was increased 7 days after the BTH exposure (Table 2). Interestingly, in a previous work[32] using strawberry cultivar 'Jonsok', the concentration of phenolics in BTH-treated plants was found to be reduced to the same level as in control plants within 7 days even if the concentration was higher in treated than in untreated plants after 2 days of exposure. This is in line with the recent data demonstrating that majority of the phenolic compounds accumulated in plants in a genotype-dependent manner[42] because a different cultivar (cv. 'Polka') was used in the present study.

The total amount of ellagitannins in BTH-treated strawberry leaves was found to increase within the 7 days after BTH exposure, but the total content of galloyl derivatives was not much altered in BTH-treated plants over the test period. In control plants, the total contents of both ellagitannins and galloyl derivatives were somewhat decreased during the 7 day experiment. Instead, the total amount of proanthocyanidins was increased in all leaf samples within the 7 day test period, but the increase was more pronounced in control samples than in BTH-exposed samples.

In our previous work[32] we found that the most significant early accumulation of strawberry leaf phenolic compounds after BTH application occurred in the ellagitannin group but that the increased total ellagitannin content of BTH-treated plants did not persist over 7 days. However, the total amounts of tannin groups do not indicate any specific biological activities in a

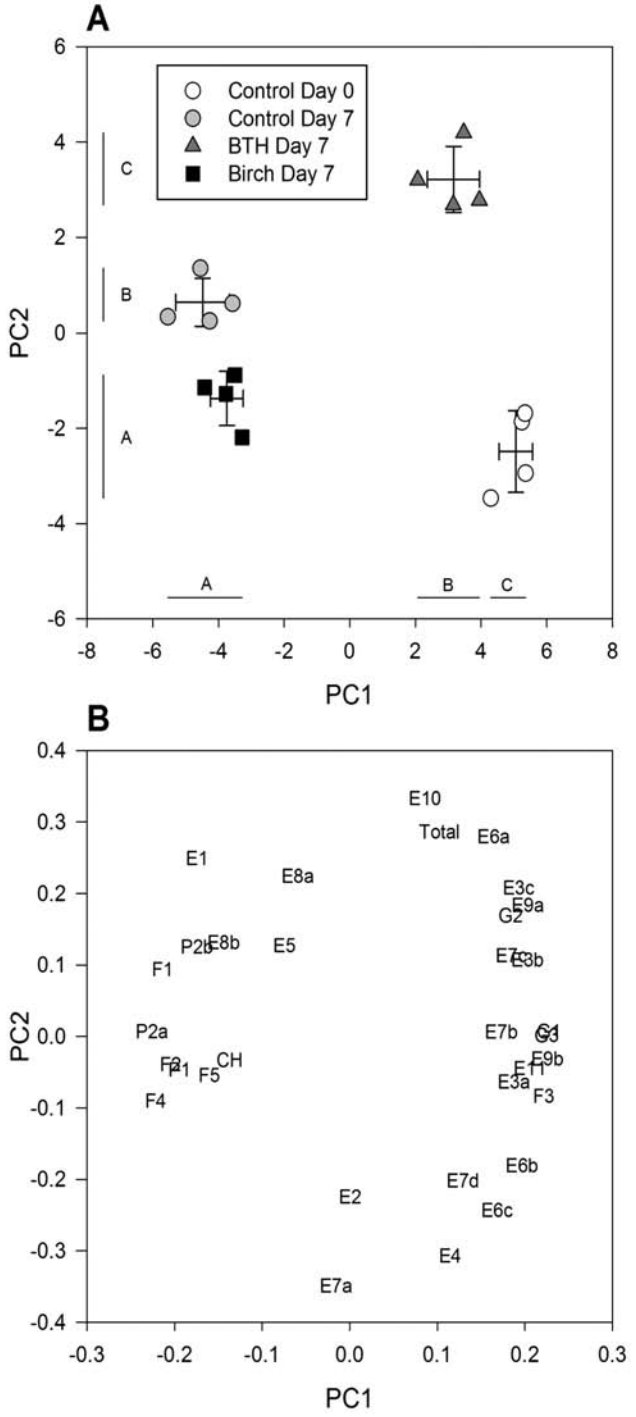

Figure 2. Results of principal component analysis. Panel A shows the sample scores on PC1 and PC2 from PCA. Bars and letters on each PC axis show the results of ANOVA analyses, groups with different letters were significantly different at α = 0.05. BTH, BTH-treated strawberry leaves; Birch, birch wood distillate-treated strawberry leaves. Panel B shows the loading values of response values (phenolic compound concentrations and total phenolics) on the same PCA axes.

plant sample because the activity of an individual tannin compound is affected by its chemical structure and the contents of different active and nonactive compound forms may vary.[41] It is known that the contents of individual phenolics in tree leaves can change during leaf development and in a season-dependent manner, even though the total amount of phenolic compounds is not necessarily altered.[41]

Salicylic acid (SA), a 2-hydroxyl derivative of benzoic acid, is an important player not only in plant innate immunity but also in systemic-acquired resistance (SAR), and both SA and its analogue BTH as well as incompatible microbial interaction are known to induce rapid oxidative burst (OB) in plants.[43,44] OB is a plant defense mechanism causing rapid and extensive production of reactive oxygen species, mainly superoxide radical ($^{\bullet}O_2^-$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($^{\bullet}OH$), which destroy invading pathogens and act as signal molecules in further stress-related reactions in plant cells; however, they can also damage plant tissues and organelles.[45,46] Proanthocyanidins, ellagitannins, and galloyl-glucose esters are strong radical scavengers.[43] For example, in sugar cane (*Saccharum* spp.), exposure to H_2O_2 has been shown to cause up-regulation of phenylpropanoid pathways and, hence, increase the production of phenolic metabolites in the plants 24 h after the H_2O_2 treatment.[46] Ellagitannins generally play protective roles in plants against microbial pathogens and insects pests.[8,9] It was recently found that a penta-esterified ellagitannin, identified as 1-*O*-galloyl-2,3;4,6-bis-hexahydroxydiphenoyl-β-D-glucopyranose, is strongly accumulated in strawberry leaves as a result of infection by nonvirulent *Colletotrichum fragariae*;[47] this ellagitannin may have properties of common plant defense molecule and capability of activating defense cascades perhaps via the transcription factor WRKY1 following elicitor treatment or pathogen infection.[48] In addition, (+)-catechin previously isolated from strawberry leaves was shown to contribute the induced resistance against fungal diseases.[49] Proanthocyanidins are oligomers and polymers of flavan-3-ol units, such as (+)-catechin, and flavan-3-ols are products of the flavonoid biosynthesis pathway.[50] Like total proanthocyanidins, total flavonoid compounds in the control and BTH-treated plants were increased 7 days after the exposure, but the flavonoid level in the BTH-exposed samples stayed lower than in the control plants. In a previous study,[32] the amount of catechin was not altered upon BTH application. Stress factors, such as competition, herbivory, and diseases, can cause changes in allocation patterns in plants and plant leaves, and these changes are often dependent on both plant genotype and resource availability.[51]

Effect of Birch Wood Distillate on Leaf Phenolics. To examine if plant-derived natural elicitors are capable of activation of the phenolic defense compound production in strawberry, leaves were treated with birch wood distillate. Interestingly, our data clearly indicate that birch wood distillate exposure increased the concentrations of chlorogenic acids in strawberry leaves. Chlorogenic acids were increased in control plants as well, but the increase in distillate-treated plants was much more pronounced (Table 2). The other phenolic compounds exhibited no changes in response to birch wood distillate treatment.

In plants, chlorogenic acid has been demonstrated to play an important role in plant resistance to fungal diseases.[52] The strong antibacterial activity of chlorogenic acid appears to be based on its ability to modulate outer and plasma membrane permeability, resulting in the loss of the important barrier function.[53] In peach (*Prunus persica*), another member of the Rosaceae family, neochlorogenic acid, an isomer of chlorogenic acid, has been found to inhibit brown rot (*Monilinia laxa*) infections, and also chlorogenic acid has a reducing effect on melanin production and, hence, on the growth of the fungus.[54]

Collectively, our data demonstrate that strawberry leaves possess a substantial amount of ellagitannins and that the accumulation of specific ellagitannins in young strawberry leaves can be further increased by elicitor treatments such as BTH application. Our data also suggest that plant-derived activators such as birch wood distillate can activate different branches in the strawberry phenylpropanoid biosynthetic pathway from synthetic ones (such as BTH); treatments of young plants in greenhouses with different types of plant activators may, hence, hold great potential for enhancing specific compounds in plants for the production of valuable biomaterial for industrial applications, for example, cosmetics, dietary supplements, pharmaceuticals, and animal feed. Consequently, young greenhouse-grown strawberry plants provide a homogeneous and inexpensive material for the production of specific ellagitannins. BTH treatments have also been found to improve resistance in grape plants to gray mold and in strawberry to powdery mildew.[32,55] In addition, some studies support the idea of using pyrolysis byproducts as environmentally and economically sustainable plant-protecting agents.[33] Hence, more extensive study on the application and mechanisms of action of BTH and wood-derived biological activators in protecting plants from fungal diseases could also be worthwhile.

Supporting Information

ABSTRACT: In this research, the chemical composition and biological activities of various extracts obtained from whole parts of *Sedum sediforme* (Jacq.) Pau were compared. The amounts of total phenolic and flavonoid components in crude extracts were determined by expression as pyrocatechol and quercetin equivalents, respectively. All of the extracts (petroleum ether, acetone, methanol, and water) obtained from *S. sediforme* showed strong antioxidant activity in four tested methods. Particularly, the IC_{50} values of the methanol extract, which was the richest in terms of total phenolic and flavonoid contents, were found to be lower than those of α-tocopherol and BHT in β-carotene bleaching (9.78 ± 0.06 μg/mL), DPPH free radical scavenging (9.07 ± 0.07 μg/mL), and ABTS cation radical scavenging (5.87 ± 0.03 μg/mL) methods. Furthermore, the methanol extract of *S. sediforme* showed higher inhibition activity than galanthamine against acetyl- and butyryl-cholinesterase enzymes. Also, acetone and methanol extracts exhibited moderate antimicrobial activity against *Candida albicans*. The main constituents of fatty acid and essential oil were identified as palmitic acid (C16:0) (28.8%) and α-selinene (20.4%), respectively, by GC-MS. In the methanol extract of *S. sediforme*, quercetin, rutin, naringenin, and protocatechuic, *p*-coumaric, caffeic, and chlorogenic acids were detected and quantified by LC-MS/MS. Results of the current study showed that the methanol extract of *S. sediforme* may also be used as a food supplement.

KEYWORDS: *Sedum sediforme, phenolic content, essential oil, fatty acid, antioxidant, anticholinesterase, antimicrobial, quercetin, LC-MS/MS, GC-MS*

INTRODUCTION

Belonging to the Crassulaceae family, the genus *Sedum* L. comprises approximately 348 species in the world and 33 species in Turkey. Additionally, it is named Kayakoruğu and Damkoruğu in Anatolia.[1,2] *Sedum* species have been known as both vegetables and folk medicines. They are used for the treatment of many diseases such as wounds, hemorrhoids, constipation, and foot fungi and as a laxative and diuretic.[3−5] Being a Mediterranean element, *Sedum sediforme* (Jacq.) Pau is named Altın otu (goldherb) due to its yellow flowers and is used as a food[4−6] and ornamental globally.[7]

Previous phytochemical studies indicated that *Sedum* species contained different natural compounds such as new isoflavone derivatives sedacins A and B,[8] arbutin and hydroquinone,[9] phenolic acids and flavonoids,[10] flavonol glycosides and sarmenosides V−VII,[11] and alkaloids.[12] In addition, several studies exhibited that *Sedum* species had strong antioxidant potential.[5,8,10,13,14]

Several papers can be found on *S. sediforme* in the literature. In the study of Sakar et al., it is reported that two new compounds, the structures of which were elucidated by spectroscopic means as (2*R*,3*R*)-7,4′-dihydroxy-5,3′,5′-trimethoxyflavan 3-*O*-gallate and 1-β-D-glucopyranosyloxy-3-methoxy-5-hydroxybenzene, were isolated from *S. sediforme* flowers.[15] They were accompanied by limocitrin 3-glucoside, 1-β-D-glucopyranosyloxy-3,5-dihydroxybenzene, kaempferol 3-rhamnoside, quercetin 3-rhamnoside, (−)-epicatechin 3-gallate, (−)-epigallocatechin 3-gallate, myricetin 3-rhamnoside, and gallic acid.[15]

In a former study, an HPLC method was established to determine quercetin, which is a common hydrolysate of the flavonoid glycosides in *Sedum sarmentosum*, *Sedum lineare*, and *Sedum erythrostictum*.[16] Besides, Romojaro et al. reported that *S. sediforme* had a high phenol content and hydrophilic total antioxidant activity.[5] These aforementioned studies triggered us

to focus on *S. sediforme*, which is an edible species. The high phenolic content of *S. sediforme* and the quercetin content of *Sedum* species show that chemical and biological activities of these species are worth studying deeply. It is a known fact that phenolic compounds, especially quercetin, show high antioxidant and anticholinesterase activities.[17−19] Thus, we aimed to investigate the relationship between the chemical composition and biological activities of *S. sediforme*.

To the best of our knowledge, there are no studies on the essential oil, fatty acid, and phenolic profiles and antioxidant (β-carotene−linoleic acid test system, DPPH free radical scavenging activity, and cupric reducing antioxidant capacity (CUPRAC)), anticholinesterase and antimicrobial activities of *S. sediforme* in the literature. At the beginning, the fatty acid and essential oil compositions of *S. sediforme* were determined by using GC-MS in the current study. In the next step, related antioxidant, anticholinesterase, and antimicrobial activities and total phenolic and flavonoid contents were analyzed. Moreover, the phenolic and flavonoid contents of *S. sediforme* methanol extract was also determined using UHPLC-ESI-MS/MS for quantitative and qualitative purposes.

MATERIALS AND METHODS

Chemicals and Instruments. The phenolic content and fatty acid composition of *S. sediforme* were determined by using LC-ESI-MS/MS (Shimadzu, Kyoto, Japan) and GC-MS (Thermo Scientific Polaris Q) instruments, respectively. A Shimadzu UV spectrophotometer and a BioTek Power Wave XS microplate reader (USA) were used for the activity assays. 2,2′-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) (purity = 97.5%) and butylated hydroxytoluene (BHT) (≥99%) were purchased from Merck (Darmstadt, Germany); quercetin (95%), protocatechuic acid (97%), chrysin (97%), rutin (94%), hesperetin (95%), naringenin (95%), rosmarinic acid (96%), vanillin (99%), *p*-coumaric acid (98%), caffeic acid (98%), chlorogenic acid (95%), formic acid (≤100%), 2,2-diphenyl-1-picrylhydrazyl (DPPH) (≥95%), β-carotene (≥93%), linoleic acid (≥99%), Tween 40, pyrocathecol (≥99%), 5,5-dithiobis-(2-nitrobenzoic acid) (DTNB) (≥98%), copper(II) chloride dihydrate ($CuCl_2 \cdot 2H_2O$) (≥99%), neocuproine (2,9-dimethyl-1,10-phenanthroline) (≥98%), ethylenediaminetetraacetic acid (EDTA) (≥98%), acetylcholinesterase (AChE) (type VI-S, EC 3.1.1.7, 425.84 U/mg), and butyrylcholinesterase (BChE) (EC 3.1.1.8, 11.4 U/mg) were obtained from Sigma (Germany); α-tocopherol (≥95.5%) and acetylthiocholine iodide (≥98%) were from Aldrich (Germany); galanthamine hydrobromide (≥94%) was from Sigma-Aldrich (Germany); Folin−Ciocalteu phenol reagent was from Applichem (Germany); butyrylthiocholine iodide (≥99%) was from Fluka (Germany).

Plant Material. *S. sediforme* (Jacq.) Pau was collected by Dr. A. Ertaş from western Turkey (Istanbul) in May 2012 and characterized by Dr. Y. Yeşil (Department of Pharmaceutical Botany, Faculty of Pharmacy, Istanbul University). Voucher specimens have been strored in the Herbarium of Istanbul University, Faculty of Pharmacy (ISTE: 9805).

Identification and Quantitation of Phenolic Compounds. *Instruments and Chromatographic Conditions.* LC-ESI-MS/MS analysis of the methanol extract was performed by using a Shimadzu UHPLC instrument coupled to a tandem MS instrument. The liquid chromatograph was equipped with LC-30AD binary pumps, a DGU-20A3R degasser, a CTO-10ASvp column oven, and an SIL-30AC autosampler.

For the chromatographic separation, a C18 reversed-phase Inertsil ODS-4 (100 mm × 2.1 mm i.d., 2 μm) analytical column was used. The column temperature was fixed at 40 °C. The elution gradient consisted of mobile phases (A) water (5 mM ammonium acetate and 0.1% formic acid) and (B) acetonitrile (0.1% formic acid). The following gradient was used: at $t = 0.00$ min, 20% B; at $t = 3.00$ min, 20% B; at $t = 3.01$ min, 50% B; at $t = 8.99$ min, 50% B; at $t = 9.01$ min, 90% B; at $t = 11.99$ min, 90% B; at $t = 12.00$ min, 20% B; at $t = 14.99$ min, 20% B. The solvent flow rate was maintained at 0.5 mL/min, and the injection volume was settled as 10 μL.

MS Instrumentation. MS detection was performed using a Shimadzu LCMS 8040 model triple-quadrupole mass spectrometer equipped with an ESI source operating in negative ion mode. LC-ESI-MS/MS data were collected and processed by LabSolutions software (Shimadzu). The multiple reaction monitoring (MRM) mode was used to quantify the analytes: the assay of phenolic compounds was performed following two or three transitions per compound, the first one for quantitative purposes and the second and/or third one for confirmation.

Optimization of LC-ESI-MS/MS Method. Subsequent to several combinations of trials, a gradient acetonitrile (0.1% formic acid, 5 mM ammonium acetate) and water (0.1% formic acid) system was concluded to be the best mobile phase solution. For rich ionization and the separation of the molecules, the mentioned mobile phase proved to be the best of all. ESI source was chosen instead of atmospheric pressure chemical ionization (APCI) and atmospheric pressure photoionization (APPI) sources as the phenolic compounds were small and relatively polar molecules. Tandem mass spectrometry was chosen to be used for the current study because this system is commonly used for its fragmented ion stability.[17] The working conditions were determined as interface temperature, 350 °C; DL temperature, 250 °C; heat block temperature, 400 °C; nebulizing gas flow (nitrogen), 3 L/min; and drying gas flow (nitrogen), 15 L/min.

Method Validation Parameters. In the current study, 11 phenolic compounds (quercetin, protocatechuic acid, chrysin, rutin, hesperetin, naringenin, rosmarinic acid, vanillin, *p*-coumaric acid, caffeic acid, and chlorogenic acid) were quantified in *S. sediforme*. In the chromatographic analysis of phenolic compounds, gradient separation was

applied. Linear regression equations of the phenolic compound standards are represented in Table 1. The linearity of the LC-MS/MS conditions for phenolic compounds was affirmed in the range from 0.025 to 1 mg/L by the high coefficient of determination ($R^2 > 0.999$) obtained. The limit of detection (LOD) and limit of quantitation (LOQ) of the method reported in this study were dependent on the calibration curve established from six measurements. The LOD and LOQ of the method were determined by using the equations 3S/N and 10S/N, respectively (S/N refers to the signal to noise ratio) (Table 1). For different compounds, LOD ranged from 0.53 to 0.93 μg/L and LOQ ranged from 1.59 to 2.86 μg/L (Table 1). Furthermore, the recovery of the phenolic compound standards ranged from 91.2 to 102.3%.

Estimation of Uncertainty. *Identification of Uncertainty Sources.* The sources of the uncertainty for the applied method were evaluated and calculated using EURACHEM Guide, 2004.[17,20,21]

The following parameters were used for the calculations of uncertainties: (1) calibration curve (cal); (2) purity of reference standards (pur); (3) stock solutions (Css); (4) weighing of samples (m_{sample}); (5) repeatabilitity (rep); (6) recovery (rec).

Standard combined uncertainty is a function of the individual uncertainties of each parameter and calculated by using eq 1:

$$u(C) = \sqrt{u^2(\text{cal}) + u^2(\text{pur}) + u^2(\text{Css}) + u^2(\text{w}) + u^2(\text{rep}) + u^2(\text{rec})} \quad (1)$$

Main uncertainty sources are defined as purity of standards and calibration curve. Standard combined uncertainties are multiplied by 2 for the calculation of expanded uncertainties by accepting a 95% confidence level. Calculated uncertainties are shown in Table 1.

Preparation of Plant Extracts for LC-ESI-MS/MS. For sample preparation, initially, the whole parts of the dried and powdered plants (10 g) were extracted by MeOH (3 × 50 mL) in 24 h at room temperature (extraction yield, 8.3%). The extract was subsequently filtered and evaporated under reduced pressure. Then, dry filtrate was diluted until 250 mg/L and passed through the 0.2 μm microfiber filter for LC-ESI-MS/MS.

Esterification of Total Fatty Acids and GC-MS Conditions. Esterification of petroleum ether extract (100 mg) of *S. sediforme* was performed according to the report of Kılıc et al.[22] In this study, Thermo Scientific Polaris Q GC-MS was used. GC-MS study conditions and comparison of identification and quantification of the compounds were done in exactly same manner according to Kılıc et al.[22]

Preparation of Plant Extracts for Biological Activities and GC-MS. In this analysis, primarily, whole plant material was dried and powdered, and 100 g of plant material was sequentially macerated with petroleum ether (3 × 250 mL), acetone (3 × 250 mL), methanol (3 × 250 mL), and water (3 × 250 mL) for 24 h at room temperature. Subsequent to filtration, the solvents were evaporated to handle the crude extracts.

Preparation of Essential Oil and GC-MS Conditions. Essential oil was obtained using a Clevenger apparatus from the whole parts of plant (100 g), which was crumbled into small pieces and soaked in distilled water (500 mL) for 3 h. The obtained essential oil was dried over anhydrous Na_2SO_4 and stored at 4 °C for a sufficient period of time. The essential oil was diluted using CH_2Cl_2 (1:3 v/v) prior to gas chromatography–flame ionization detector (GC-FID) and GC-MS analysis. GC-FID analysis was performed using a Thermo Electron Trace GC-FID detector, and GC-MS analysis was performed using the same GC and Thermo Electron DSQ MS.

The following GC conditions were applied for both GC-MS and GC-FID analyses. The GC oven temperature was kept at 60 °C for 10 min and programmed to 280 °C at a rate of 4 °C/min and then kept constant at 280 °C for 10 min. A nonpolar Phenomenex DB5 fused silica column (30 m × 0.32 mm, 0.25 μm film thickness) was used with helium at 1 mL/min (20 psi) as a carrier gas. The split ratio was adjusted to 1:50, the injection volume was 0.1 μL, and EI/MS was recorded at 70 eV ionization energy. The mass range was m/z 35–500 amu. Alkanes (C8–C24) were used as reference points in the calculation of Kovats indices (KI) by the same conditions.[23,24]

Identification of the compounds was based on comparing their retention times and mass spectra with those obtained from authentic samples and/or the NIST and Wiley spectra as well as data from the published literature. GC-FID and GC-MS analyses were replicated three times (mean RSD% < 0.1).

Determination of Total Phenolic and Flavonoid Contents. Total phenolic and flavonoid amounts in the crude extracts expressed as pyrocatechol and quercetin equivalents, respectively, were calculated according to the following equations:[25,26]

$$\text{absorbance} = 0.0126\ \text{pyrocatechol}\ (\mu\text{g}) + 0.0314\ (R^2 = 0.9936)$$

$$\text{absorbance} = 0.1495\ \text{quercetin}\ (\mu\text{g}) - 0.0958\ (R^2 = 0.9994)$$

Antioxidant Activity of the Extracts. To determine the antioxidant activity, the following tests were applied: β-carotene–linoleic acid test system, DPPH free radical and ABTS cation radical scavenging activity, and cupric reducing antioxidant capacity (CUPRAC) methods.[27−30]

Anticholinesterase Activity of the Extracts. A spectrophotometric method developed by Ellman et al. was used to indicate the acetyl- and butyryl-cholinesterase inhibitory activities.[31]

Determination of Antimicrobial Activity and Minimum Inhibitory Concentration (MIC). Five different microorganisms including Gram-positive bacteria (*Streptococcus pyogenes* ATCC19615 and *Staphylococcus aureus* ATCC 25923), Gram-negative bacteria (*Pseudomonas aeruginosa* ATCC 27853, *Escherichia coli* ATCC 25922), and yeast (*Candida albicans* ATCC10231), which were purchased from Refik Saydam Sanitation Center (Turkey), were used for detecting the antimicrobial activity of the samples. The disc diffusion method was employed for this purpose.[32] The minimum inhibitory concentration was determined by the broth macrodilution method according to NCCLS.[33] Ampicillin and fluconazole were used as positive controls for bacteria and yeast, respectively.

Statistical Analysis. The results of the antioxidant and anticholinesterase activity assays were represented as means ± SD. The results were evaluated using an unpaired t test and ANOVA variance analysis with the NCSS statistical computer package. The differences were considered statistically significant at $p < 0.05$.

RESULTS AND DISCUSSION

Quantitative Analysis of Phenolic and Flavonoid Compounds by UHPLC-ESI (QqQ)/MS/MS. Having the same general structure with an aromatic hydroxyl nucleus, almost 8000 phenolic compounds exist in nature.[17] Phenolic compounds that exist in plants constitute one of the most important groups acting as free radical terminators and primary antioxidants. Plant polyphenols are multifunctional in that they act as reducing agents, hydrogen atom donors, and singlet oxygen scavengers. Besides being the most diverse and prevalent natural compounds, flavonoids are the most important phenolics. Being members of the polyphenol family, flavonoids have more than 4000 species that exist in the roots, flowers, and leaves of plants.[17]

A literature survey reveals several studies on the use of liquid chromatography electrospray ionization tandem mass spectrometry to perform quantitative analyses.[17,34] Therefore, for quantitative purpose, the analyses of 11 phenolic and flavonoid compounds in the methanol extract of *S. sediforme* were done by an accurate method on a mass spectrometer equipped with a triple-quadrupole analyzer. Due to the fact that negative ionization mode was more sensitive and selective for phenolics and flavonoids, it was preferred in the current study.

The specific fragmentation reactions were selected to monitor the aforesaid phenolic and flavonoid compounds by

MRM. Eleven compounds, which were five flavonoids, five phenolic acids, and one phenolic aldehyde, were monitored by the transition from the specific deprotonated molecular ions to the corresponding fragment ions. Molecular ions, fragments observed in MS/MS, related collision energies for these fragments, and the quantified result for *S. sediforme* are presented in Table 2.

Table 2. Identification and Quantification of Phenolic Compounds of Methanol Extract of *S. sediforme* by UHPLC-ESI-MS/MS

compound	parent ion (m/z)[a]	MS^2(CE)[b]	quantification[c] (μg analyte/g extract)
quercetin	**300.90**	**151.0 (22), 121.0 (26), 107.0 (29)**	**1813.51 ± 137.82**
protocatechuic acid	152.90	108.9 (15), 90.9 (25)	71.23 ± 7.22

[a]Molecular ions of the standard compounds (mass to charge ratio). [b]MRM fragments for the related molecular ions (CE refers to related collision energies of the fragment ions). [c]Values in μg/g (w/w) of plant methanol extract. [d]Not detected.

Quercetin, rutin, and naringenin were detected and quantified of five flavonoids; however, chrysin, hesperetin, and vanillin were not found. Furthermore, four phenolic acids (protocatechuic acid, *p*-coumaric acid, caffeic acid, and chlorogenic acid) were characterized in *S. sediforme* (Table 2; Figure 1; Figure S1 in the Supporting Information). Quercetin was found to be the most abundant flavonoid compound (1813.51 ± 137.82 μg/g extract) in the methanol extract of *S. sediforme* (Table 2; Figure 1). Besides, caffeic acid (151.25 ± 8.93 μg/g extract) was found to be the most plentiful phenolic acid in *S. sediforme* (Table 2; Figure 1).

In the literature, there are few studies on phenolic and flavonoid compounds of *Sedum* species by HPLC and LC-MS techniques.[16,35] Xu et al. reported a HPLC methodology that was established to determine quercetin, which is a common hydrolysate of the flavonoid glycosides in *S. sarmentosum*, *S. lineare*, and *S. erythrostictum*.[16]

Fatty Acid and Essential Oil Composition by GC-MS. GC-MS analysis was used to determine the fatty acid composition of the petroleum ether extract. As represented in Table 3, 10 components were identified, constituting 100.0% of the petroleum ether extract of *S. sediforme*, and the major

constituents were characterized as palmitic acid (C16:0) (28.8%), stearic acid (C18:0) (24.6%), and linolenic acid (C18:3 omega-3) (12.9%). This is the first report on the fatty acid composition of *S. sediforme*. The amount of saturated fatty acids was found to be greater than the amount of unsaturated fatty acid in the present study. There have been no reports regarding direct fatty acid analysis of *Sedum* species by GC-MS, except the lipophilic extract obtained from *Sedum hispanicum*.[36] However, in this study, 0.89% of the fatty acid content was identified in the lipophilic extract of *S. hispanicum*. In that sense,

dx.doi.org/10.1021/jf500067q | J. Agric. Food Chem. 2014, 62, 4601−4609

it could be said that the current study is the first report on the fatty acid composition of *Sedum* species.

The essential oil composition was examined by GC-MS analysis. Twenty-four components were determined, constituting 91.6% of the essential oil composition of *S. sediforme*. The main components of the essential oil of *S. sediforme* were identified as α-selinene (20.4%), 2,5-di-*tert*-octyl-*p*-benzoquinone (13.1%), valencene (6.3%), and carvone oxide (4.3%) (Table 4). There have been few papers regarding GC-MS analysis of essential oil composition of *Sedum* species.[37,38] Yaylı et al. reported that 38 and 35 components were identified in the essential oils of *S. pallidum* var. *bithynicum* and *S. spurium*, respectively. Besides, in their study, the main components of these species were found to be caryophyllene oxide for *S. pallidum* var. *bithynicum* and hexahydrofarnesyl acetone for *S. spurium* in the ratios of 12.8 and 15.7%, respectively.[38]

Antioxidant Activity and Total Phenolic and Flavonoid Content. The antioxidant activity studies of the petroleum ether (SSP), acetone (SSA), methanol (SSM), and water (SSW) extracts prepared from the whole plant of *S. sediforme* were carried out by β-carotene bleaching, DPPH free radical scavenging, ABTS cation radical decolorisation, and CUPRAC assays. The SSM extract showed the highest extraction yield, but no significant differences in the extraction yields of other extracts were observed.

In the crude extracts, total phenolic and flavonoid amounts were determined and expressed as pyrocatechol and quercetin equivalents, respectively (y = 0.0126 pyrocatechol (μg) + 0.0314, R^2 = 0.9936 and y = 0.1495 quercetin (μg) − 0.0958, R^2 = 0.9994). The phenolic and flavonoid amounts of the SSM extract were identified to be the richest. The amounts of total phenolic and flavonoid from SSM were 335.71 ± 4.81 and 26.66 ± 0.75 μg/mg extract, respectively. The amount of phenolic components was seen to be higher than that of flavonoid components. The results are shown in Table 5. In the literature, total phenolic and flavonoid contents in the examined *Sedum acre* extracts were expressed in terms of gallic acid and rutin equivalents, respectively.[14] Moreover, Stankovic et al. reported that the total phenolic and flavonoid amounts in the examined acetone extract of *S. acre* were 181.75 and 173.42 mg/g, respectively.[14] Additionally, in the study of Romojaro et al. *S. sediforme* showed high levels of total phenolic content, 191.53 mg/100 g fresh weight (gallic acid equivalent).[5] In this regard, the richness of *Sedum* species in terms of phenolic and flavonoid compounds, which are known for their important pharmacological properties, increases the importance of these species.

As indicated in Table 6, the SSP and SSA extracts showed moderate lipid peroxidation activity (IC_{50} = 51.34 ± 0.92 and

54.61 ± 0.31 μg/mL, respectively) and the SSW extract showed weak lipid peroxidation activity (153.05 ± 1.71 μg/mL) in the β-carotene bleaching method. However, the SSM extract showed very strong lipid peroxidation activity (9.78 ± 0.06 μg/mL) in the β-carotene bleaching method. Furthermore, the SSM extract exhibited higher activity than α-tocopherol (15.54 ± 0.21 μg/mL) and BHT (10.35 ± 0.03 μg/mL), which were used as standards in the β-carotene bleaching method. As seen in Table 6, the SSP and SSW extracts showed weak and moderate activity (174.55 ± 0.91 and 104.45 ± 1.28 μg/mL) in DPPH free radical scavenging activity, respectively. On the other hand, the SSA and SSM extracts exhibited very strong DPPH free radical scavenging activity. Besides, the SSA (17.20 ± 0.33 μg/mL) and SSM (9.07 ± 0.07 μg/mL) extracts showed higher activity than α-tocopherol (18.76 ± 0.31 μg/mL) and BHT (48.86 ± 0.09 μg/mL). In previous studies, Mavi et al. reported that *S. sempervivoides* showed very strong activity (88.9 and 86.0% inhibition, respectively) in the DPPH free radical scavenging assay and lipid peroxidation−thiobarbituric acid method at 200 μg/mL concentration.[13] In addition, Stankovic et al. reported that the acetone extract of *S. acre* exhibited very strong activity in the DPPH free radical scavenging assay.[14] The largest capacity to neutralize DPPH radicals was found for the acetone extract, which neutralized 50% of free radicals at the concentration of 29.57 μg/mL.[14] Morover, in the study of Thuong et al., the MeOH-, EtOAc-, and BuOH-soluble fractions exhibited significant scavenging activities against free radicals (DPPH and superoxide) as well as remarkable inhibitory effects on lipid peroxidation.[10]

As shown in Table 6, the SSP extract indicated moderate activity (75.03 ± 0.45 μg/mL) in the ABTS cation radical scavenging assay. However, the SSA, SSM, and SSW extracts exhibited very strong effects in the ABTS cation radical scavenging assay. In addition to that, the SSA (8.76 ± 0.52 μg/mL), SSM (5.87 ± 0.03 μg/mL), and SSW (9.01 ± 0.29 μg/mL) extracts showed higher activity than α-tocopherol (9.88 ± 0.08 μg/mL) and BHT (10.67 ± 0.11 μg/mL). According to Romojaro et al., *S. sediforme* showed very strong effects in hydrophilic and lipophilic total antioxidant activities, with 588.87 ± 35.52 mg of Trolox equivalent 100 g^{-1} FW.[5] Morover, *S. sediforme* showed good activity (81.60% inhibition) in peroxyl radical (H_2O_2) scavenging potential assay.[5] The SSM extract and α-tocopherol indicated 1.73 and 1.62 absorbance in CUPRAC at 100 μg/mL, respectively (Figure 2). According to our literature survey this is the first study about the cupric reducing antioxidant capacity of *Sedum* species. Therefore, this study is important in this field.

When we look at the antioxidant results of the four tested extracts, we can see the parallelism between antioxidant activities and total phenolic content. In particular, looking at the quantitative phenolic analysis of the methanol extract by LC-MS/MS, it can be deduced that this high activity may be related to the quercetin content. Quercetin is known to have various pharmacological effects.[17−19] Particularly, flavonoids are present in plant sources as flavonoid glycosides. Therefore, this high activity also might be said to arise from quercetin gycosides. If we were to express this in a different way, this high activity can be attributed to the synergic effect between quercetin, quercetin glycosides, and other phenolic compounds.[39] In further studies, our group plans to purify, structurally determine, and quantify the secondary metabolites, especially flavonoid glycosides of *Sedum* species. Furthermore, we also aim to study in vivo pharmacological effects of the purified compounds.

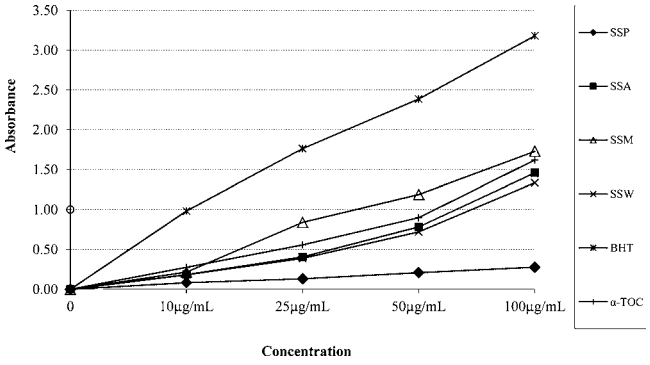

Figure 2. Cupric reducing antioxidant capacity of *S. sediforme*, α-tocopherol, and BHT.

Anticholinesterase Activity. As demonstrated in Table 5, the SSA extract exhibited good inhibitory activity (65.69% inhibition) against butyrylcholinesterase enzyme. The SSW extract showed moderate inhibitory activity (40.61% inhibition) against acetylcholinesterase enzyme, at 200 μg/mL. On the other hand, the SSM extract showed 85.09 and 89.57% inhibition activities, which are higher than galanthamine inhibitory activity against acetyl- and butyryl-cholinesterase enzymes at 200 μg/mL, respectively.

The anticholinesterase activity of the SSM extract shows parallelism to its high total phenolic and flavonoid contents. This high activity of the SSM extract might be related not only to its high total phenolic and flavonoid contents but also to its quercetin content directly or to the synergic effect of quercetin with other phenolic compounds.[39] When previous studies are examined, it can be seen that quercetin has strong antioxidant properties as well as an anticholinesterase effect.[17−19] Additionally, Min et al. reported that quercetin had shown potential inhibitory activity against AChE.[18] Furthermore, Choi et al. reported that quercetin might improve cognitive ability against TMT-induced neuronal deficit and also had an inhibitory action against AChE.[19] To our knowledge, there are no reports about the anticholinesterase activity of *Sedum* species. Because our results were higher than those for galanthamine and there has been no such study about *Sedum* species, the anticholinesterase activity results of *S. sediforme* will be important data in this field.

Antimicrobial Activity. The antimicrobial activities of *S. sediforme* extracts against different microorganisms were measured by using the disc diffusion method, and the results were assessed according to inhibition zone diameter. Results are presented in Table 7. No antimicrobial activity of the water extract against the five tested microorganisms was detected (data not shown). However, the petroleum ether, acetone, and methanol extracts were active on tested microorganisms, and the sensitivity of active extracts was found not to differ significantly among tested microorganisms. Whereas the petroleum ether extract exhibited weak antimicrobial activity (inhibition zone < 12) against all tested microorganisms, the acetone and methanol extracts showed moderate antimicrobial activity against *C. albicans* (inhibition zone < 20−12) and weak antimicrobial activity against Gram-positive and -negative bacteria. The highest activities were exhibited by acetone and methanol extracts against *C. albicans*, with 18 ± 0 and 15 ± 0.1 mm inhibition zone diameters, respectively.

[a]Inhibition zone in diameter (mm) around the disks (6 mm) impregnated with 30 mg/mL of plant extracts. [b]Inhibition zone in diameter (mm) of positive controls that are ampicillin for bacteria and fluconazole for yeast. Minimum inhibitory concentration (MIC) values are given as mg/mL for plant extracts and as μg/mL for antibiotics. [c]Not active.

For a more reliable assessment of antimicrobial activity, a broth dilution assay was carried out. The sensitivity of the test microorganisms against active extracts was evaluated, and results are shown as MIC (Table 7). Values ranged from 8 to 19 mg/mL for the petroleum ether extract, from 1 to 17 mg/mL for the acetone extracts, and from 1 to 9 mg/mL for the methanol extracts. The MIC results indicate that the methanol extract was found to be the most active extract. The lowest MIC value was recorded by the acetone and methanol extracts against *C. albicans* (1 mg/mL). This is the first study dealing with the antimicrobial activity of *S. sediforme*. On the other hand, in a previous paper, the methanol, acetone, and ethyl acetate extracts of *S. acre* revealed high antibacterial activity against Gram-positive bacteria and low to moderate antifungal activity.[14] Besides, the essential oils of *S. pallidum* Bieb. var. *bithynicum* and *S. spurium* showed low antimicrobial activity against Gram-negative and -positive bacteria and yeast-like fungi,[38] and *S. sormentosum* Bunge showed weak inhibitory activity against *B. subtilis* and *S. aureus*.[40]

The present study concluded that the methanol extract of *S. sediforme* showed very strong antioxidant and anticholinesterase activities. These properties of the methanol extract of *S. sediforme* were parallel to the total phenolic content. On the basis of our results, quercetin was found to be the most abundant phenolic compound in *S. sediforme*. Many studies in the literature showed that quercetin and its glycosides had potent biological properties, in particular antioxidant and anticholinesterase activities. Thus, these high activities of *S. sediforme* may be related to either high total phenolic or quercetin contents.[17−19,41] From a broader perspective, these high activities of *S. sediforme* might be related not only to its high total phenolic and flavonoid contents but also directly to its quercetin content or to the synergic effect of quercetin with other phenolic compounds.[39]

Furthermore, protocatechuic, *p*-coumaric, and chlorogenic acids were found for the first time in *Sedum* species. Although the total phenolic content was found as very rich in *S. sediforme*, phenolic constituents were detected in low amounts. Therefore, these results could be the effect of some other phenolic constituents such as flavonoid glycosides that we have not studied yet.

In conclusion, it is found that *S. sediforme* had very high antioxidant and anticholinesterase activities. Therefore, the results of the current study showed that the methanol extract of *S. sediforme* can also be used as a food source because of its high quercetin amount, total phenolic content, strong antioxidant, and anticholinesterase properties.

All in all, the rich total phenolic content and high antioxidant and anticholinesterase capacities of the methanol extract of *S. sediforme* indicated that more future studies should be done in this field.

In Vitro Inhibitory Effect on Digestive Enzymes and Antioxidant Potential of Commonly Consumed Fruits

Anna Podsędek,* Iwona Majewska, Małgorzata Redzynia, Dorota Sosnowska, and Maria Koziołkiewicz

Institute of Technical Biochemistry, Department of Biotechnology and Food Sciences, Lodz University of Technology, Stefanowskiego 4/10, 90-924 Łódź, Poland

ABSTRACT: Dietary inhibitors of fats and carbohydrates degrading enzymes can reduce obesity and type 2 diabetes. In this study, we screened crude extracts from 30 commonly consumed fruits to test their in vitro inhibitory effect against key enzymes relevant for obesity (pancreatic lipase) and type 2 diabetes (α-glucosidase and α-amylase), total phenolic content (Folin–Ciocalteu method), and antioxidant capacity (ABTS and FRAP). The IC_{50} values of the fruits tested varied from 39.91 to >400 mg/mL, from 1.04 to >80 mg/mL, and from 0.72 to 135.07 mg/mL against α-glucosidase, α-amylase, and pancreatic lipase, respectively. Antioxidant capacity ranged from 0.66 to 124.66 μmol of TE/g of fruit and strongly correlated with phenolic content, while the enzyme inhibition was poorly correlated with total phenolic and antioxidant capacity. Among fruits tested, blue honeysuckle and red gooseberry exhibited the highest inhibitory activity with respect to the carbohydrate degrading enzymes, while lingonberry had the strongest anti-lipase activity.

KEYWORDS: *fruits, enzyme inhibition, pancreatic lipase, α-glucosidase, α-amylase, antioxidant capacity, phenolic compounds*

INTRODUCTION

Overweight and obesity are the fifth leading risk of global deaths. In addition, 44% of the diabetes burden, 23% of the ischemic heart disease burden, and between 7% and 41% of certain cancer burdens are attributable to overweight and obesity (http://www.who.int). According to the World Health Organization (WHO) overweight and obesity as well as their related diseases can be reduced by limiting energy intake from total fats and sugars, engaging in regular physical activity, and increasing consumption of fruits, vegetables, legumes, whole grains, and nuts. Dietary intervention seems to be a reasonable option for treatment of obesity and type 2 diabetes.

Inhibition of dietary fat and sugar absorption from the intestine seems to be an effective way to prevent obesity and type 2 diabetes. In the continuing search for novel effective antiobesity and antidiabetes agents, medicinal plants or inedible parts of plants have been screened for potential lipase, α-amylase, or α-glucosidase inhibitory activities.[1−5] Pancreatic lipase (EC 3.1.1.3; triacylglycerol acyl hydrolase) produced by the pancreatic acinar cells hydrolyzes triglycerides mainly into 2-monoacylglycerols and free fatty acids, and it is responsible for the hydrolysis of 50−70% of total dietary fats in the intestinal lumen.[1,6] The plant derived pancreatic lipase inhibitors are classified into the following classes of chemical compounds: saponins, terpenes, and phenolics.[1] However, it is increasingly recognized that among different classes of phytochemicals phenolic compounds are the most active lipase inhibitors. Consistently with this statement, several in vitro studies have shown that white, green, oolong, and black tea polyphenols[7−9] as well as green coffee and cocoa polyphenols[10,11] inhibit pancreatic lipase.

Phenolic compounds affect also digestive enzymes involved in the hydrolysis of dietary carbohydrates. The inhibition of α-amylase and α-glucosidase by polyphenolic-rich plant extracts or isolated phenolic compounds may offer a natural dietary approach to preventing type 2 diabetes. Pancreatic α-amylase [EC 3.2.1.1; α-1,4-glucan-4-glucanohydrolase] is an endoglucosidase that is delivered into the intestinal lumen as a constituent of pancreatic juices and catalyzes the hydrolysis of starch to maltose and maltotriose.[12] α-Glucosidase [EC 3.2.1.20] is a membrane-bound enzyme located in the epithelium of the small intestine, and it catalyzes the cleavage of glycosidic bonds and releases of glucose from disaccharides and oligosaccharides.[13] The inhibitory activity of plant origin phenolic compounds against carbohydrate degrading enzymes is being increasingly documented. For example, cocoa,[11] colored grains[14] and almond seed skin[15] as well as herbal polyphenolic-rich fractions[16] have shown inhibitory effects on α-amylase and/or α-glucosidase activities in vitro. It is reasonable to hypothesize that a phenolic-rich diet may reduce absorption of fats and sugars via an inhibition of the enzymes degrading these substrates. For this reason the interest in studying the inhibition of digestive enzymes by these phytochemicals has recently increased.

It is well-known that fruits are very important components of the human diet as well as the sources of dietary phenolics. There is some evidence that polyphenols from fruits and fruit products can also inhibit digestive enzymes. McDoughall et al.[17] reviewed that berry anthocyanins, ellagitannins, and proanthocyanidins inhibit α-glucosidase, α-amylase, and pancreatic lipase, respectively. Additionally, strawberry, raspberry, blueberry, rowanberry, blackcurrant, and red grape extracts showed inhibitory effects on carbohydrate degrading enzymes.[18−23] Some information is also available about anti-lipase potential of fruit extracts, because such inhibitory activity

was demonstrated for blueberry,[24] lingonberry, Arctic bramble, cloudberry, strawberry, raspberry,[25] and Cornelian cherries.[4]

Therefore, it is reasonable to hypothesize that consumption of fruits may decrease α-glucosidase, α-amylase, and/or pancreatic lipase activities and may be an important support in the management of postprandial hyperglycemia and obesity. The objective of this study was to screen the different fruits commonly consumed in Poland as well as all over the world for their pancreatic lipase, α-glucosidase, and α-amylase inhibitory activities and determine the correlation of the inhibitory effect to antioxidant capacity and phenolic content.

MATERIALS AND METHODS

Materials. The list of fruits used in this study is given in Table 1. Gallic acid, intestinal acetone powder from rat source of α-glucosidase (EC 3.2.1.20), α-amylase (from porcine pancreas type VI-B, lipase (EC 3.1.1.3) from porcine pancreas type II, *p*-nitrophenyl-α-D-glucopyranoside (pNPG), *p*-nitrophenyl acetate, 4-methylumbelliferyl oleate, *p*-nitrophenyl-α-D-glucopiranoside, 2,2′-azinobis(3-ethyl-benzthiazoline-6-sulfonic acid) (ABTS), 2,4,6-tris-2-pyridyl-*s*-triazine (TPTZ), potassium persulfate, trolox, TRIS-base, dimethyl sulfoxide (DMSO), and acetonitrile were obtained from Sigma-Aldrich. Acetone and sodium carbonate were purchased from Chempur (Piekary Śląskie, Poland). Folin−Ciocalteu reagent, potato starch, hydrochloric acid, sodium chloride, calcium chloride, and ferric chloride of analytical grade were purchased from POCH (Gliwice, Poland). Ultrapurity water was prepared in the laboratory using a Simplicity Water Purification System (Millipore, Marlborough, MA, USA).

Table 1. Popular Name, Scientific Name, Origin, and Purchased Place of Fruits Tested

fruit sample	scientific name	origin	place of purchase
apple cv. Golden Delicious	*Malus domestica*	Poland	local farmers
banana	*Musa*	not known	local supermarket
bilberry	*Vaccinium myrtillus*	Poland	local market
black currant	*Ribes nigrum*	Poland	local market
blackberry	*Rubus fruticosus*	Poland	local farmers
blueberry cv. Toro	*Vaccinium corymbosum*	Poland	Research Institute of Horticulture
blue honeysuckle cv. Wojtek	*Lonicera caerulea* var..*kamtschatica*	Poland	Research Institute of Horticulture
cranberry	*Vaccinium oxycoccus*	Poland	local market
chokeberry	*Aronia melanocarpa*	Poland	local market
gooseberry green	*Ribes uva-crispa*	Poland	local market
gooseberry red	*Ribes uva-crispa*	Poland	local market
grape pink	*Vitis vinifera*	Chile	local supermarket
grapefruit red	*Citrus paradis*	not known	local supermarket
kiwi	*Actinidia chinensis*	Chile	local supermarket
lingonberry	*Vaccinium vitis-idaea*	Poland	local market

plum cv. Węgierka Zwykła	*Prunus domestica*	Poland	local market
pomegranate	*Punica granatum*	Tunisia	local supermarket
pomelo	*Citrus maxima*	not known	local supermarket
raspberry cv. Polka	*Rubus idaeus*	Poland	local farmers
red currant	*Ribes rubrum*	Poland	local market
sour cherry	*Prunus cerasus*	Poland	local farmers
strawberry cv. Onebor	*Fragaria x ananassa*	Poland	local farmers
sweet cherry cv. Regina	*Prunus avium*	Poland	local farmers

Preparation of Fruit Extracts. Extraction from the edible, mixed part of fruits (20 g) was done with 70% acetone (200 mL) at room temperature for 60 min with constant stirring. After centrifuging at 4000 rpm for 10 min, and filtration through Munktell filter AB, the supernatants were concentrated at 40 °C (vacuum rotary evaporator RII, Büchi, Switzerland) to remove the acetone and the aqueous phase was diluted to 25 mL with water. For further analytical and biological activity assays, a gradient of concentrations was prepared via serial dilution of the fruit extracts in pure water. Finally, 1 mL of extract corresponded to 0.8 mg of fruit.

Pancreatic Lipase Inhibition in Vitro Assay. The inhibition of lipase activity was determined by measuring the release of 4-methylumbelliferone from 4-methylumbelliferyl oleate or *p*-nitrophenol from *p*-nitrophenyl acetate by using a fluorimetric or spectrophotometric method, respectively. The amount of the inhibitor (expressed as mg of fruit per 1 mL of reaction mixture under assay conditions) required to inhibit 50% of the enzyme activity is defined as the IC_{50} value. The IC_{50} of the fruits tested was obtained from the line of the plot of the fruit concentration in 1 mL of reaction mixture versus the % inhibition. All samples were assayed in triplicate.

Fluorimetric assay using 4-methylumbeliferyl oleate as substrate (4-MUO) was carried out according to previous papers[26,27] with some modification. Lipase from porcine pancreas type II was dissolved in buffer consisting of 20 mM Tris-base, 150 mM NaCl, and 1.3 mM $CaCl_2$ (pH 7.4) at 1 mg/mL, and then the supernatant was used after centrifugation at 13 000 rpm for 5 min. The 0.1 mM substrate solution was prepared by dissolving 1.1 mg of 4-MUO in 0.5 mL of DMSO and diluting 50-fold with the above Tris buffer. For the pancreatic lipase assay, in a 96-well plate 25 μL of the varying concentrations of the fruit extracts were combined with 25 μL of enzyme solution, mixed, and incubated at 37 °C for 5 min. Then, 50 μL of 0.1 mM 4-MUO solution was added, mixed, and incubated at 37 °C for 20 min. The amount of 4-methylumbelliferone released by lipase was measured with a microplate reader (Synergy2, BioTek Instruments Inc.) at an excitation wavelength of 360 nm and at an emission wavelength of 460 nm. The sample blank and the control blank (without substrate) were performed in the same way. The inhibition (%) was calculated by using the following formula:

$$\text{inhibition (\%)} = \frac{(F_{\text{control}} - F_{\text{control blank}}) - (F_{\text{sample}} - F_{\text{sample blank}})}{(F_{\text{control}} - F_{\text{control blank}})} \times 100$$

where F_{control} and $F_{\text{control blank}}$ are a fluorescence value of the solvent control with and without 4-MUO, respectively; F_{sample} and $F_{\text{sample blank}}$ are a fluorescence value of the extract with and without 4-MUO, respectively.

The procedure of Umezawa et al.[28] for lipase activity determination using *p*-nitrophenyl acetate as substrate was modified. The 50 mM stock solution of *p*-nitrophenyl acetate in DMSO was prepared. Pure water was added to reach a final concentration of 10 mM. Lipase from porcine pancreas type II was dissolved in water at 10 mg/mL, and then centrifuged at 13 000 rpm for 5 min. The composition of the reaction mixture was as follows: 0.2 mL of fruit extract, 0.2 mL of lipase solution, 1.4 mL of 0.1 M Tris buffer (pH 7.4), and 0.2 mL of 10 mM *p*-nitrophenyl acetate solution. The absorbance at 400 nm was read immediately against water after incubation at 37 °C for 10 min. In the control sample, the extract was replaced with 0.2 mL of water. A blank

[a]Values are means ± standard deviations. Mean values with different letters within the same column are statistically different ($p < 0.05$). [b]4-Methylumbelliferyl oleate based assay. [c]*p*-Nitrophenyl acetate based assay.

sample without the *p*-nitrophenyl acetate was measured for each extract. The results were expressed as inhibition (%) of lipase activity according to the following formula:

$$\text{inhibition (\%)} = \frac{A_{\text{control}} - (A_{\text{sample}} - A_{\text{sample blank}})}{A_{\text{control}}} \times 100$$

Alpha-Glucosidase Inhibition Assay. The inhibition of α-glucosidase activity was determined by measuring the amount of glucose hydrolyzed from *p*-nitrophenyl-α-D-glucopyranoside. An α-glucosidase enzyme solution was prepared by dissolving 0.5 g of intestinal acetone powder from rat in 10 mL of saline (0.9% w/v) and sonicated 12 times at regular intervals (30 s sonications and 30 s off) in an ice bath. After centrifugation at 3000 rpm for 30 min at 4 °C, the resulting supernatant was diluted two times with 0.1 M potassium phosphate buffer (pH 6.9) and was used as the enzyme solution. For the α-glucosidase assay, in a 96-well plate 50 μL of the fruit extract was combined with 50 μL of a fresh prepared enzyme solution and incubated for 10 min. The enzyme reaction was initiated by adding 50 μL of 5 mM *p*-nitrophenyl-α-D-glucopyranoside solution in the above buffer (pH 6.9). The mixtures were incubated at 37 °C for 20 min. Finally, 100 μL of 0.1 M sodium carbonate solution was added and the absorbance (A_A) was read at 405 nm (Synergy2, BioTek Instruments Inc.). Blank and α-glucosidase controls were also included. α-Glucosidase control (A_C) consisted of buffer, substrate, and enzyme. Blank (A_B) consisted of the fruit extract, substrate, and enzyme added after stopping of the reaction with 0.1 M sodium carbonate solution. Blank to control (A_D) consisted of the buffer, substrate, and enzyme added after stopping of the reaction with 0.1 M sodium carbonate solution. All samples were assayed in triplicate.

The rate of α-glucosidase inhibition activity was calculated as a percentage of the control by the following equation:

$$\text{inhibition (\%)} = 100 \times \left[1 - \frac{(A_A - A_B)}{(A_C - A_D)}\right]$$

where A_C, A_A, A_B, and A_D were the absorbance of control, sample, blank sample, and blank control, respectively. The inhibitory activity was expressed as the IC_{50} value.

Alpha-Amylase Inhibition Assay. The α-amylase inhibitory effect of the fruit extracts was assayed according to the procedure described previously by Xiao et al.,[29] with slight modifications. Briefly, 40 μL of 0.2% (w/v) potato starch solution, 20 μL of the fruit extract, or 0.1 M phosphate buffer containing 6 mM $CaCl_2$ (pH 6.9) (control) was mixed with 20 μL of α-amylase from porcine pancreas type VI-B dissolved in the above buffer in a 96-well plate to start the enzyme reaction. After incubation at 37 °C for 10 min, the reaction was stopped by the addition 80 μL of 0.4 M HCl. After that, 100 μL of 5 mM I_2 in 5 mM KI was added, and the absorbance was read at 600 nm (Synergy2, BioTek Instruments Inc.). All samples were assayed in triplicate. The α-amylase inhibitory activity was calculated as follows:

$$\text{inhibition (\%)} = 100 \times \left[1 - \frac{(A_B - A_A)}{(A_D - A_C)}\right]$$

where A_A and A_B were the absorbance of incubated mixture containing fruit extract and starch with or without amylase, respectively. A_C and

A_D were the absorbance of incubated mixture containing starch and amylase or only starch. The inhibitory activity was expressed as the IC_{50} value.

Determination of Antioxidant Capacity. The fruit extracts were assessed for antioxidant capacity by the following two methods: 2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonic acid) radical scavenging activity (ABTS method) and ferric reducing antioxidant power (FRAP method). In both methods, trolox (6-hydroxy-2,5,7,8-tetramethychroman-2-carboxylic acid) was used as a standard and the antioxidant capacity was expressed as μmol of trolox equivalents (TE) per 1 g fresh weight of fruit. All samples were assayed in triplicate.

ABTS Method. $ABTS^{\bullet+}$ radical cation scavenging activity was determined according to the procedure described by Re et al.[30] 2,2′-Azinobis(3-ethylbenzthiazoline-6-sulfonic acid) radical cation ($ABTS^{\bullet+}$) was produced by the reacting of 7 mM ABTS water solution with 2.45 mM potassium persulfate (final concentration) followed by an incubation of the mixture in the dark for 12−16 h at room temperature. Stock solution of $ABTS^{\bullet+}$ was diluted with methanol until an absorbance of 0.76 ± 0.02 at 734 nm was reached. Then, 20 μL of fruit extract or water (control) was mixed with 1 mL of diluted $ABTS^{\bullet+}$ solution, and after 6 min at 30 °C absorbance of this mixture was measured at 734 nm.

FRAP Method. The FRAP assay developed by Benzie and Strain[31] was performed with some modification. Briefly, 2.7 mL of FRAP reagent, prepared freshly and warmed to 30 °C, was mixed with water (0.27 mL) and the fruit extract (0.09 mL). The FRAP reagent was prepared by mixing 2.5 mL of a 10 mM solution of 2,4,6-tris-2-pyridyl-*s*-triazine (TPTZ) in 40 mM HCl with 2.5 mL of 20 mM $FeCl_3$ and diluting with 25 mL of 0.3 mM acetate buffer (pH 3.6). Absorbance at 593 nm was recorded after 10 min incubation of the solution at 30 °C.

Total Phenolic Content. The content of the total phenolics was evaluated by using the Folin−Ciocalteu method. Each fruit extract (0.1−1.0 mL) was mixed with 25 mL of distilled water followed by 0.5 mL of Folin−Ciocalteu reagent and 5 mL of 20% (w/w) Na_2CO_3. The volume of reaction mixture was adjusted to 50 mL with distilled water. The absorbance was then measured at 760 nm after incubation at room temperature for 20 min. Total phenolic content was expressed as mg of gallic acid equivalent (GAE) per 100 g of fresh weight of fruit. All samples were assayed in triplicate.

Phenolic Profile. Phenolic profiles were determined using a high-performance liquid chromatography system (Waters, Milford, MA) that consisted of a gradient pump (1525), photodiode array detector (2998), autoinjector (2707) and Breeze 2 system controller equipped with a 250 × 4.6 mm i.d., 5 μm Symmetry C18 column (Waters). The mobile phase was a binary gradient with A, water/formic acid (90:10, v/v), and B, water/acetonitrile/formic acid (40:50:10, v/v/v), with a flow rate of 1 mL/min.[32] The binary gradient was as follows: 12% B (0 min), 12−30% B (0−26 min), 30−100% B (26−40 min); 100% B (40−43 min), 12% B (43−48 min), and 12% B (48−50 min). Phenolics were qualified into one of the four subclasses and quantified on the base of maximum of UV−vis absorption and spectra recorded from 200 to 600 nm. The hydroxybenzoic acid derivatives and flavanols were quantified at 280 nm and expressed as gallic acid equivalents, hydroxycinnamic acids at 320 nm as chlorogenic acid equivalents, flavonols at 360 nm as rutin equivalents, and anthocyanins at 520 nm as cyanidin 3-glucoside equivalents. The results were expressed as mg/100 g fresh weight of fruit. All samples were assayed in triplicate.

Statistical Analysis. The results are given as the means ± standard deviations. Data were analyzed by means of a one-way ANOVA using Statistica Ver. 6.0 (USA), and Duncan's post hoc test was used to assess the differences between the means with significance level $p < 0.05$. Pearson's correlation coefficients were determined using Microsoft Excel XP.

RESULTS AND DISCUSSION

Pancreatic Lipase Inhibitory Activity. Pancreatic lipase is the most important enzyme responsible for digestion of dietary fat, so its inhibition can lead to beneficial effects on overweight and obesity. In the present work the anti-lipase activity of fruits was investigated using *p*-nitrophenyl acetate (spectrophotometric method) and 4-methylumbelliferyl oleate (fluorimetric method) as substrates. Significant differences ($p < 0.05$) were found among the analyzed fruits in the inhibitory activities toward pancreatic lipase type II (Table 2). The IC_{50} values varied from 0.72 to 135.07 mg of fruit/mL in the fluorimetric method and from 4.07 to more than 80 mg of fruit/mL in the spectrophotometric method. Among the 30 fruits examined, only lingonberry and red currant strongly inhibited pancreatic lipase activity in both methods. They showed IC_{50} values less than 0.8 mg/mL in the fluorimetric assay, and less than 10 mg/mL in the spectrophotometric assay. In addition, bilberry, pink grape, raspberry, cranberry, chokeberry, blueberry, red gooseberry, and black currant showed a relatively high inhibitory effect with their IC_{50} values less than 2 mg/mL in the fluorimetric assay. Black currant and cranberry showed also high inhibitory activity with IC_{50} less than 10 mg/mL in the assay of *p*-nitrophenol release. On the other hand, seven fruits used at 80 mg/mL concentration (the maximum dose of fruit extract in the assay condition) inhibited in this assay pancreatic lipase activity less than 50%.

Few reports have been published about pancreatic lipase inhibitory activity of crude fruit extracts in vitro. Slanc et al.[33] reported that 20 mg/mL of blueberry and apple fruits provided 70% inhibitory activity, while raspberry and banana extracts provided between 40 and 70% inhibitory activity against pancreatic lipase, measured with *p*-nitrophenyl palmitate. Methanolic extract of the Carols muscadine inhibited pancreatic lipase activity with IC_{50} 34.41 mg/mL.[34] Roh and Jung[4] demonstrated a relatively high anti-lipase activity (34.8%) for Cornelian cherries at a concentration of 0.1 mg/mL when *p*-nitrophenyl butyrate was used as a substrate. On the other hand, seven raspberry cultivars examined by Zhang et al.[23] did not show anti-lipase activity measured by fluorimetric assay. Other in vitro studies also demonstrated that lipase activity was effectively inhibited by phenolic-rich extracts of raspberry, strawberry, cloudberry, and Arctic bramble, while black currant and rowanberry extracts had no effect in *p*-nitrophenyl laurate-based assay.[25] These opposite effects can result from the use of different analytical methods (different type and concentration of synthetic substrate, concentration of lipase) and type of extraction solvent. For this reason, there is a need to standardize the method, and further studies with the use of dietary lipids as substrates should be carried out to compare and/or confirm anti-lipase activity of fruit extracts evaluated using artificial substrates.

α-Glucosidase and α-Amylase Inhibitory Activity. In human, dietary carbohydrates are hydrolyzed by pancreatic α-amylase and intestinal α-glucosidase enzymes responsible for the breakdown of oligosaccharides and disaccharides into monosaccharides suitable for absorption.[3] The inhibition of these enzymes is specifically useful for the treatment of non-insulin-dependent diabetes because it will slow down the release of glucose in the blood. In the present work the anti-glucosidase or anti-amylase activity of fruits was investigated using *p*-nitrophenyl-α-D-glucopyranoside or potato starch as substrates, respectively. Significant differences ($p < 0.05$) were found among the analyzed fruits in the inhibitory activities toward α-glucosidase and α-amylase (Table 2). The inhibition of α-glucosidase was in a wide range with the IC_{50} values from 39.91 to more than 400 mg fruit/mL. Blue honeysuckle showed

[a]Values are means ± standard deviations. Mean values with different letters within the same column are statistically different ($p < 0.05$).

the strongest α-glucosidase inhibitory activity with an IC_{50} value of 39.91 mg/mL, and the order of the most potent α-glucosidase inhibitors was as follows: blue honeysuckle > green gooseberry >blueberry > bilberry > black currant > sweet cherry > pink grape > red gooseberry.

Although the fruits tested appeared to have anti-α-glucosidase activities, our experiments have shown that they are weak inhibitors of pancreatic α-amylase. Among 30 fruits tested, half of them at concentration 200 mg/mL inhibited α-amylase activity below 50%. The findings showed that red and green gooseberries, chokeberry, and red currant were the most effective inhibitors of this enzyme with IC_{50} values less than 2 mg/mL.

α-Amylase and/or α-glucosidase inhibitory activities of raspberry, strawberry, lingonberry, black currant, pomegranate, and blueberry extracts have been confirmed by other authors,[18,22] although the inhibitory effect ranks are different from those obtained in our experiments. Similarly to our results, Da Silva Pinto et al.[35] reported red and black currants and red and green gooseberries as the good inhibitors of α-glucosidase and α-amylase, while red currant was the strongest inhibitor of both enzymes. In the present study red currant has indicated very high α-amylase inhibitory activity, but a moderate inhibitory effect against α-glucosidase. Zhang and co-workers[23] observed strong α-glucosidase inhibitory effect for the phenol-rich extracts from raspberries, while none of the seven extracts showed detectable inhibitory effect against pancreatic α-amylase. Contrarily, in our study raspberry crude extract inhibited activity of both enzymes at the moderate level. This observation is consistent with the report of McDougall et al.[18] that the raspberry extract inhibited activity of pancreatic α-amylase. In addition, α-glucosidase inhibitory activity was also demonstrated for Carols muscadine[34] and apple,[36] while α-amylase inhibitory effect was demonstrated for rowanberry, cloudberry, and Arctic bramble.[22]

Antioxidant Capacity. The contribution of fruits to health improvement has been partly attributed to their antioxidant capacity. Antioxidant properties of fruits tested were estimated as scavenging potential toward $ABTS^{\bullet+}$ radical cation and the potential to reduce ferric to ferrous ion (FRAP), and were expressed as trolox (soluble analogue of vitamin E) equivalents (TE): Table 3. Significant differences ($p < 0.05$) were found among the analyzed fruits in the antioxidant capacity. The trolox equivalents (TE) values varied from 0.84 to 124.66 μmol/g of fresh fruit and from 0.66 to 94.24 μmol/g in ABTS and FRAP methods, respectively. Chokeberry had the highest antioxidant capacity, while plum Renkloda showed the lowest TE values, regardless of assay method. Antioxidant capacities of the fruits have been studied in vitro by many authors,[37−39] and our results are consistent with published data.

Total Phenolic Content and Phenolic Profile. The health benefits of fruits are mainly attributed to their vitamins, carotenoids, and phenolic compounds. Phenolic compounds range from simple, low molecular weight, single aromatic

ringed compounds to large and complex flavonoids and tannins, with a wide range of biological activities. In this study, the total extractable phenolic contents of 30 different fruits were determined by colorimetric method with Folin−Ciocalteu reagent, and expressed as gallic acid equivalents (GAE). Although the Folin−Ciocalteu reagent is nonspecific to phenolic compounds, and can react with a wide range of thiol derivatives, some vitamins, especially vitamin C, and aromatic amino acids, it is still the most widely used reagent to determine total phenolic content.[40] Moreover, the responses of phenolic compounds to this assay were affected by both the position and degree of hydroxylation in the phenolic molecule. In the present study significant differences ($p < 0.05$) were found among the analyzed fruits in the total phenolic content. The phenolic contents for the fruits studied ranged from 22.78 to 1423.74 mg of GAE/100 g fresh weight (Table 3). Among the fruits, chokeberry contained the highest amount of phenolics followed by blue honeysuckle, bilberry, black currant, and lingonberry, whereas the lowest levels (less than 30 mg of GAE/100 g) were found in plum Renkloda, pears Lukasówka and Nashi, and peach. In general, the present findings are consistent with literature data,[39,41−43] wherein phenolic content in fruits may be affected by a large number of factors such as climatic conditions, agrotechnical processes, cultivars, harvest time, and storage conditions.

Evaluation of Parameters across Tests. In the present study a highly positive correlation between phenolic content and antioxidant capacities measured by ABTS and FRAP assays was reported with a Pearson's correlation coefficient of $r \geq 0.97$ when used for 30 fruit extracts (Table 4). Others researchers also noticed good correlation between total phenolic content and antioxidant potential of fruits as well as a strong correlation between ABTS and FRAP assays.[38,44−46] Some authors postulated that the Folin−Ciocalteu (FC) assay should not be viewed as a measure of total phenolic content, but rather a measure of overall antioxidant capacity.[46] Therefore, it could be expected to find excellent linear correlations between the total phenolic content obtained by the FC method and the antioxidant activity determined by FRAP and ABTS assays. We also observed a high positive correlation between antioxidant capacities measured by ABTS and FRAP assays with a Pearson's correlation coefficient of $r \geq 0.992$.

In contrast to the high correlation between phenolic content and antioxidant capacity, a weaker correlation was observed between phenolic content and inhibition of pancreatic lipase, α-glucosidase, or α-amylase ($r < -0.530$), as well as between antioxidant capacity and the inhibitory effect ($r < -0.473$); Table 4. Our results are consistent with the data for blueberry anthocyanin extract for which α-amylase inhibitory activity correlated poorly with both total phenolic content and FRAP.[24] Lack of correlation between α-glucosidase inhibitory activity and antioxidant activity and total phenolic content has been reported for the phenol-rich extracts from seven raspberry cultivars.[23] In contrast, Wang and co-workers[20] noted a positive correlation (averaging $r = 0.89$) between α-glucosidase inhibitory activity and scavenging activity for peroxyl and hydroxyl radicals as well as for hydrogen peroxide and singlet oxygen in blueberry peel tissue. Flores et al.[24] also observed high correlation between α-glucosidase inhibition by blueberry anthocyanin extract and both its total phenolic content and FRAP.

Results of the present and previous studies suggest that the type of phenolics is more important for the inhibitory effects against digestive enzyme than total phenolic amounts. Moreover, phenolic compounds present in the crude extracts may show synergistic and/or antagonist effects which can influence results of measurements in the assay system. Remarkable differences not only in content but also in composition of phenolic compounds for fruits affect their biological activity. Moreover, a large diversity in the structure between the different subclasses of phenolic compounds as well as within the group influences their stability, solubility, and bonding ability with the digestive enzymes. For example, significant differences in anti-lipase activity were dependent upon the procyanidin degree of polymerization.[47] Previous study also demonstrated that anthocyanidin has much stronger anti-lipase and anti-glucosidase activities than the glycoside form.[48] Among nine phenolic acids tested by Zhang et al.[23] only

ellagic acid inhibited α-glucosidase activity, and according to You et al.[34] ellagic acid was a stronger inhibitor of this enzyme than catechin and quercetin. Therefore, phenolic composition may have a significant importance for inhibition of digestive enzymes by fruits.

For the above-mentioned reason, the three extracts with the highest inhibitory activity against enzymes tested were analyzed for the phenolic profile by HPLC (Table 5). The most abundant phenolic compounds found in the blue honeysuckle extract (the highest α-glucosidase inhibitory activity) were anthocyanins. The inhibitory effectiveness of anthocynins against α-glucosidase has also been reported for other colored fruits such as black currant, strawberry, raspberry, and blueberry fruit extracts.[18,20] This may suggest that anthocyanins are important constituents regarding anti-glucosidase activity. Although chokeberries are known as the most rich source of anthocyanins among fruits[49] in the present study they showed higher IC_{50} value compared to blue honeysuckle. This difference in the IC_{50} values may result from different anthocyanin profile for these two fruits. The major anthocyanin in chokeberry is cyanidin 3-galactoside (66.7% of total anthocyanins),[42,49] while cyanidin 3-glucoside dominates in the blue honeysuckle fruit (71−89% of total anthocyanins).[50] According to Bräunlich et al.[51] cyanidin-3-galactoside possessed 1.8-fold lower α-glucosidase inhibitory activity than cyanidin-3-glucoside. So, inhibitory activity of anthocyanins is strongly influenced by the sugar units linked to the anthocyanidin.

Phenolics with maximum at 280 nm, i.e., flavanols and/or hydroxybenzoic acids, are the main phenolic compounds in red gooseberries which exhibited the highest α-amylase inhibitory activity (Tables 2 and 5). According to literature data[52] proanthocyanidins are important phenolics in gooseberry fruit. α-Amylase inhibitory activity of strawberry and red raspberry was associated with tannins, especially ellagitannins.[35,53] However, a high level of ellagitannins in yellow raspberries did not increase amylase inhibition.[22] Probably the presence of anthocyanins potentiated the enzyme inhibition by ellagitannins. The authors also suggested that high α-amylase inhibitory activity of rowanberry is related to proanthocyanidins.

The high pancreatic lipase inhibitory activity of lingonberries may be caused by proanthocyanidins.[25] In the present study the flavanols were the main phenolic compounds in these berries (Table 5). Sugiyama et al.[54] suggested that the oligomeric procyanidins present in apple polyphenol extract inhibited triglyceride absorption by inhibiting pancreatic lipase activity in mice and humans.

ABSTRACT: This study aimed to identify the bioactive compounds and evaluate the anti-cold-stress function of the sorghum distillery residue (SDR) using tilapia as an alternative animal model. The highest contents of water-soluble bioactive compounds in SDR were polyphenols, followed by tannins, anthocyanins, and flavonoids. SDR was extracted with double-distilled water, 95% ethanol, and ethyl acetate, separately. The ethanol extract (SDR−E) yielded the highest polyphenol content [15.03 mg/g of SDR dry weight (dw)], of which the EC_{50} value of *R*,*R*-diphenyl-*β*-picrylhydrazyl (DPPH) radical scavenging efficiency was 0.56 ± 0.04 mg/mL. The SDR−E suppressed the oxidation of low-density lipoproteins (LDLs) more efficiently than that of other extracts. Tilapia fed a diet containing 3.6% SDR−E decreased accumulative mortality during cold stress, of 46.2%. The accumulative morality of the control was 92.9%. The phenolic acids identified in SDR included gallic acid (0.36 ± 0.08 mg/g of SDR dw), 3,4-dihydroxybenzoic acid (0.16 ± 0.12 mg/g of SDR dw), and 4-hydroxybenzoic acid (0.49 ± 0.23 mg/g of SDR dw). Diets supplemented with 0.5% 4-hydroxybenzoic acid fed to tilapia showed a lower mortality rate than that fed 1.0% 4-hydroxybenzoic acid, comparable to that of the tilapia fed 20% SDR. The latter showed lower mortality than that of the control. These results suggested that 4-hydroxybenzoic acid is one of the major anti-cold-stress compounds in SDR.

KEYWORDS: *sorghum distillery residue, phenolic acids, 4-hydroxybenzoic acid, tilapia, anti-cold stress*

INTRODUCTION

Sorghum distillery residue (SDR), a byproduct of sorghum liquor production, has not been used to add value to it. Sorghum contains high levels of flavonoids, anthocyanins, and phenolic acids.[1,2] The antioxidant activity significantly correlates to the total phenolic content of sorghum.[3] The antioxidative properties of polyphenols allow them to suppress low-density lipoprotein (LDL) oxidation and scavenge free radicals.[4,5] Polyphenols demonstrate antioxidative activities better than vitamin C and vitamin E[4]. Grey mullet (*Mugil cephalus*) fed SDR improved blood fluidity and cold adaptation during winter.[6] A grey mullet fed diet containing 20% SDR resulted in significantly increased total antioxidant capacity of blood plasma and prolonged the lag phase of *ex vivo* tilapia LDL oxidation compared to those fed the control diet.[5] SDR extracts were found to have free-radical-scavenging and tyrosinase-inhibiting effects.[5,7] Both *in vitro* and *ex vivo* LDL oxidation of tilapia were inhibited by the hot-water extract of freshwater clam in a similar dose-dependent pattern. Therefore, the *in vitro* study could serve as a quick screening test to predict the *in vivo* protective effect on LDL oxidation.[8,9]

This research targeted the identity of the natural-occurring antioxidants present in SDR. Different solvents were used to extract polyphenols from SDR to obtain the highest yield and to identify the bioactive compounds extracted. *R*,*R*-Diphenyl-*β*-picrylhydrazyl (DPPH) free-radical-scavenging activity and prolongation of the lag phase of LDL oxidation may be used as bioindicators to evaluate the antioxidative properties of the SDR. Tilapia was used as an alternative animal model to assess the anti-cold-stress activity of SDR when the fish were exposed to cold stress.

MATERIALS AND METHODS

SDR. SDR collected from the Kinmen Distillery was dried at 145 °C at 5 rpm with a double drum dryer (Sung-Hsing Enterprise, Taiwan). The moisture content of SDR reached less than 10%. The dried SDR was ground at room temperature (Yuan Tai Chi dump-style mill, Yu Chi Machinery, Taiwan) and sieved to 60 mesh.

SDR Extracts. SDR was added with 10 times double-distilled (dd) H_2O (w/v) (SDR−W), 95% ethanol (SDR−E), and ethyl acetate (SDR−EA), separately. The SDR extracts were then heated at the boiling point of the solvent for 2 h. The extract was filtered with Advantec 5C filter paper. The residue was extracted repeatedly. Each extract was collected and combined. The solvents were removed under vacuum, while the concentrate was freeze-dried (Kingmech Co., Ltd., Taiwan) and stored at −20 °C for later use.

Chemical. DPPH, gallic acid, 3,4-dihydroxybenzoic acid, 4-hydroxybenzoic acid (4-HB), caffeic acid, cyanidin, quercetin, and epigallocatechin-3-gallate (EGCG) were purchased from Sigma Chemical Co. (St. Louis, MO). All solvents/chemicals used were of analytical grade and obtained from Merck, Taiwan, Ltd. [Taipei, Taiwan, Republic of China (ROC)].

DPPH Free-Radical-Scavenging Properties. The method by Shimada et al.[10] was applied. SDR−W and SDR−EA were dissolved in 200 μL of ddH_2O and dimethyl sulfoxide (DMSO), respectively, and the volume was adjusted to 1000 μL by adding methanol. SDR−E was dissolved in 1000 μL of methanol. A total of 50 μL of each sample or

Trolox as the positive control was taken to a 96-well microplate. The volume was adjusted to 150 μL by adding methanol. A total of 50 μL of 100 mM methanolic solution of DPPH was added to these wells and shaken vigorously. The wells were placed at room temperature for 30 min in the dark prior to being detected at 517 nm using an enzyme-linked immunosorbent assay (ELISA) reader (Spectramax 190, Maxline Microplate Reader System Devices, Sunnyvale, CA). Samples of lower absorbance at 517 nm ($A_{517\ nm}$) indicate higher DPPH scavenging activity.

Total Phenolic Content. A volume of 500 μL of SDR methanolic extract (1 mg/mL) was added to 1 mL of 1:10 (v/v) diluted Folin–Ciocalteu phenol reagent to react at 25 °C for 5 min. Na_2CO_3 was added to the mixture solution to adjust the pH to 9.70–9.85 and allowed to stand for 2 h at 25 °C. Absorbance at 675 nm was measured. The results were expressed as milligrams of gallic acid equivalent per gram of SDR dry weight (dw).[11]

Total Anthocyanin Content. A total of 5.0 g of SDR was added to 50 mL of 0.1% HCl methanol, shaken for 1 h in the dark, and then filtered (Whatman No. 4 filter paper). Residues were extracted repeatedly until the red color disappeared. The solvent extracts were combined, of which 20 mL was taken, and its pH was adjusted to 1.0 and 4.5 with HCl and NaOH, respectively. The sample was analyzed at 520 nm. Cyanidin was used to calibrate the standard curve.[12]

The non-anthocyanin compounds did not absorb at 520 nm, as shown in Figure 2.

Total Flavonoids. A sample of 5.0 g was added to 100 mL of methanol, shaken for 1 h, and then filtered. Residues were extracted twice. The two aliquots were mixed, of which 1 mL was added to 1 mL of 2% methanolic $AlCl_3{\cdot}6H_2O$. The conjugation of Al^{3+} and flavonoids stabilized the color appearance and produced the bathochromic shift for identification. Absorbance was measured at 430 nm, 10 min later. The results were expressed as milligrams of quercetin equivalent per gram of SDR dw.[13]

Tannins. A total of 0.2 g of SDR was added to 10 mL of 1% HCl methanol and shaken for 24 h at room temperature. The mixture was centrifuged at 2200*g* for 10 min. A total of 100 μL of crude extract was added to 5 mL of vanillin reagent (Sigma, St. Louis, MO). The color of the mixture developed after 20 min. The absorbance was read at 500 nm. A standard curve of epigallocatechin-3-gallate (EGCG) in milligrams per milliliter (Sigma) was prepared for quantification. Concentrations were calculated as EGCG (milligrams of equivalent per gram of dw) from the standard curve.[13,14]

Quantification of Phenolic Acids. A sample of 5.0 g was added to 400 mL of 50% aqueous acetone,[15] ultrasonicated (Ultrasonic Cleaner, model D200H, 40 kHz, power at 200 W, heater at 250 W, Delta Co., Taipei, Taiwan) for extraction at 45 °C for 1 h, and then filtered (Whatman No. 4 filter paper). Residues were extracted twice. The extracts were mixed and evaporated at 60 °C using a rotary evaporator. The concentrate was added to 200 mL of butanol and ultasonicated for 2 min, and then the butanol fraction was allowed to separate from the aqueous fraction. Butanol was removed from the butanol extract under vacuum and then dissolved in methanol to 100 mL. High-performance liquid chromatography (HPLC) analysis was carried out after filtering the sample through a 0.45 μm nylon filter. A total of 10 μL of the filtrate was injected into a Luna C18 column (25 cm × 4.6 mm, 5 μm particles, Phenomenex, Torrance, CA), eluted with mobile phase A (2:98, v/v, acetic acid/water) and mobile phase B (8:92, v/v, butanol/methanol) using a gradient program: 0–10 min (95:5, v/v, A/B), 10–17.5 min (85:15, v/v, A/B), 17.6–30.5 min (85:15, v/v, A/B), and 30.6–40 min (50:50, v/v, A/B). The flow rate was 1.0 mL/min. The UV absorbance was monitored at 254 nm (Thermo UV 6000 LP, Finnigan Spectra System, Riviera Beach, FL).[16]

Isolation and Cu^{2+}-Induced Oxidation of LDL. LDL was obtained by ultracentrifugation of human blood plasma from a density range of $1.019 < d < 1.063$ adjusted with NaBr.[17] LDL was dialyzed for 24 h against 5 mM phosphate-buffered saline (PBS) containing 125 mM NaCl (pH 7.4) at 4 °C. The concentration of the dialyzed LDL was determined enzymatically using a commercial kit (Randox Laboratories, San Francisco, CA) and adjusted to 0.15 mg of cholesterol/mL. A total of 100 μL of LDL was added to SDR extract in each well, of which the volume was adjusted to 240 μL with PBS. Then, 10 μL of 125 μM $CuSO_4$ solution was added to make a final volume of 250 μL in each well. The time course of LDL oxidation was monitored, as indicated by the increased absorbance at 232 nm in the 96-well quartz microliter plate (Spectramax 190, Maxline Microplate Reader System Devices, Sunnyvale, CA) at 25 °C for 12 h. The LDL oxidation lag phase was calculated.[5,8]

Cold-Stress Trials. *SDR Feeding Trial.* Tilapia (*Oreochromis mossambicus*) were transferred from a fish farm to the laboratory and acclimated for 2 weeks. Each fish was hand-collected from aquaria with a net onto a plastic tray. The eye of the fish was covered with a piece of cheesecloth and weighed. Seven fish of similar sizes were kept in each of four glass aquaria (92 × 56 × 61 cm) with constant-aerated fresh water of 24 °C. Commercial eel powder (Tai Roum Co., Taichung, Taiwan, ROC) was used as the control diet, which contained 44% protein, 25% carbohydrates, 6% lipid, and 12.0% ash. Dextrin was added in the control diet to balance the 3.6% SDR–E–poly(ethylene glycol) (PEG) diet (Table 1). Both diets were isocaloric and of equal protein content. After acclimation, tilapia were divided into two groups in duplicated aquaria with six fish per aquarium. For 3 months, the two groups of tilapia were fed with the control diet or test diet at 1% body weight per day. The latter contained 3.6% SDR–E–PEG (on a dw basis), which was the SDR–E treated with PEG to counteract the inhibitory effect of the tannins in SDR.[14] The control diet and 4-HB diet did not contain tannin; thus, PEG was not added to them. All groups of fish were exposed to a temperature drop from 24.5 to 13 °C within 10 h, then maintained for 5 days at 13 °C, followed by readjustment of the water temperature to 24 °C, and held for 2 days.

Table 1. Formulation of Tilapia Feed in the SDR–E Feeding Trial

component	control	SDR–E–PEG
formulation (g)		
SDR–E		3.6
PEG[a]		0.1
eel powder	100.0	96.3
dextrin	3.7	
composition		
protein (%)	42.3	42.3
gross energy (kcal/g)	3.8	3.8

[a]PEG = poly(ethylene glycol).

4-HB Feeding Trial. Tilapia were separated into three groups, with each of them consisting of 16 fish/glass aquarium, and fed a diet at 1% body weight per day. The 20% SDR–PEG diet was used as a positive control, in which casein was added for adjusting the diet to isocaloric and of equal protein content with the test diets (Table 2). SDR itself contained 27% crude protein. The test diet contained 0.5% authentic 4-HB or 1.0% 4-HB, separately.

Table 2. Formulation of Tilapia Feed in the 4-HB Feeding Trial

component	20% SDR–PEG	0.5% 4-HB	1.0% 4-HB
formulation (g)			
SDR	20.0		
4-HB[a]		0.5	1.0
PEG[b]	0.1		
eel powder	73.0	99.5	99.5
casein	7.0		0.5
composition			
protein (%)	44.0	44.0	44.0
gross energy (kcal/g)	3.8	3.8	3.8

[a]4-HB = 4-hydroxybenzoic acid. [b]PEG = poly(ethylene glycol).

Statistical Analysis. All values are presented as the mean ± standard deviation (SD). Analysis of variance (ANOVA) was used for comparison of multiple samples. A least significant difference (LSD) test was applied for significant analysis at the 95% level. Sigma 9.0 for Windows was used for statistical analysis of data.

RESULTS AND DISCUSSION

Bioactive Compounds of SDR. The antioxidant compounds in SDR were identified, as shown in Table 3.

Table 3. Bioactive Compounds of SDR in Comparison to Sorghum[a]

compound	sorghum (mg of equivalent/g of dw)	SDR (mg of equivalent/g of dw)
polyphenols as gallic acid	6.51 ± 1.55 b	3.13 ± 0.62 a
anthocyanins as cyanidin	0.07 ± 0.05 a	0.05 ± 0.03 a
flavonoids as quercetin	0.04 ± 0.02 a	0.06 ± 0.01 b
tannins as EGCG	1.60 ± 0.13 b	1.25 ± 0.38 a

[a]All data are shown as the mean ± SD (n = 3).

Polyphenols contributed the highest content, followed by tannins in sorghum and SDR. Anthocyanins and flavonoids were much lower in content, each of which contributed only 20% of the polyphenols. In comparison to the bioactive compounds of sorghum, the SDR was significantly ($p < 0.05$) lower in polyphenols and tannins than sorghum. No significant ($p > 0.05$) difference in anthocyanin content was found between sorghum and SDR.

Yield of Total Polyphenols Varied with Extraction Solvents. Polyphenols were extracted from SDR with water, ethanol, or ethyl acetate, separately, as shown in Table 4. The water extract showed the highest yield, followed by the ethanol extract and then the ethyl acetate extract. However, the ethanol extract contained the highest amount of polyphenols. A recent study on SDR also showed that the water extract had a higher yield than the ethanol extract (SDR−E).[7] Their phenolic content in SDR−E was 19.20 ± 3.22 mg of gallic acid equivalent (GAE)/g of extract, while ours was 15.03 mg of GAE/g of extract (Table 4). Both results were in a similar range.

Table 4. Yield and Polyphenol Content Extracted from Sdr Water, 95% Ethanol, Or Ethyl Acetate Extracted from Sdr

extract[a]	yield[b] (% dw)	SDR extract (mg of GAE/g)[c]	SDR dw (mg of GAE/g)[c]
SDR−W	30.8	4.74	1.46
SDR−E	18.6	15.03	2.80
SDR−EA	9.8	10.07	0.99

[a]SDR, sorghum distillery residue; W, double-distilled water; E, ethanol; and EA, ethyl acetate. [b]Yield (%) = (dry weight of SDR extract/SDR dry weight) × 100. [c]The polyphenol content was expressed as gallic acid equivalent (GAE).

Inhibition of LDL Oxidation and DPPH Scavenging Activity. Cu^{2+}-induced oxidation of human LDL was used for evaluation of the LDL protective effect. The *in vitro* model showed that all of the extracts of SDR prolonged the lag phase of LDL oxidation, being 2−13 times the control, 69.9 ± 11.0 min (Table 5), and reduced the oxidation rate at the propagation stage in a dose-dependent manner (Figure 1). At the same concentration (0.04 mg/mL) of the SDR extract, SDR−E had the longest lag time for human *in vitro* LDL oxidation (903.6 ± 21.2 min), followed by SDR−EA (894.5 ± 24.2 min). Both were significantly ($p < 0.05$) higher than that of Trolox, the positive control (624.9 ± 25.3 min), as shown in Table 5. The lag time of LDL oxidation increased with the total polyphenols of SDR−E (15.03 mg of GAE/g of SDR dw) in comparison to that of SDR−W (4.74 mg of GAE/g of SDR dw), as shown in Table 4, and its lag time was only 135.3 ± 56.7 min, as shown in Table 5.

Table 5. *In Vitro* Effects of the SDR Extract on the Lag Time of Human LDL Oxidation and DPPH Scavenging Activity

treatment[a]	lag time (min)[b]	DPPH scavenging, EC_{50} (mg/mL)
control	69.9 ± 11.0 a	
SDR−W	135.3 ± 56.7 b	1.22 ± 0.06 c
SDR−E	903.6 ± 21.2 d	0.56 ± 0.04 b
SDR−EA	894.5 ± 24.2 d	2.67 ± 0.06 d
Trolox	624.9 ± 25.3 c	0.03 ± 0.00 a

[a]SDR, sorghum distillery residue; W, double-distilled water; E, ethanol; and EA, ethyl acetate. [b]A comparison was made at an equal concentration of 0.04 mg/mL extract. Values in the same column with different letters are significantly different ($p < 0.05$), as analyzed with Duncan's test.

Trolox is able to protect the endogenous antioxidants of LDL from oxidation and prolong the oxidation lag phase[18] and, thus, was used as positive control in this study. SDR−W contained mainly water-soluble substances and resulted in a lag phase 2 times the control, while SDR−E extended the lag phase 12.9-fold that of the control and 1.45-fold that of Trolox.

The antioxidative effect of SDR−E on LDL oxidation was significantly stronger than that of SDR−W, indicative of the fact that the 95% ethanol extract contained more active compounds or the polarity was lower than the water-soluble compounds in SDR. SDR−E was similar in polarity and efficiency to SDR−EA to protect the LDL from oxidation. The SDR−E and SDR−EA extracts are comparatively nonpolar and can readily enter into the core of the LDL to protect the LDL endogenous antioxidants, such as α-tocopherol.[8] From the oxidation lag time, SDR−E and SDR−EA both showed higher antioxidative activity on LDL than that of Trolox.

SDR−E showed the lowest EC_{50} or the higher DPPH free-radical-scavenging activity than SDR−W and SDR−EA (Table 5). SDR−E demonstrated the highest efficacy in both prolonging the oxidation lag time and the DPPH free-radical-scavenging ability. A high content of polyphenol in SDR−E (Table 4) seemed to contribute to the antioxidative activity in prolonging the LDL oxidation lag time and free-radical-scavenging effect. However, no significant correlation was found between the lag time of LDL oxidation and free-radical-scavenging activity (Table 5), indicative of the fact that the antioxidative activity of sorghum involved in retarding the initiation of LDL oxidation[3] came from mechanisms other than scavenging free radicals.

Phenolic Acids of SDR. The phenolic acids of SDR were identified using reversed-phase high-pressure liquid chromatography equipped with a photodiode array detector (RP-HPLC−PDA), as shown in Figure 2A. The chromatogram of the 4-HB standard is shown in Figure 2B, and the chromatogram of the mixture of authentic phenolic acids, including gallic acid, 3,4-dihydroxybenzoic acid, and caffeic acid, is shown in Figure 2C.

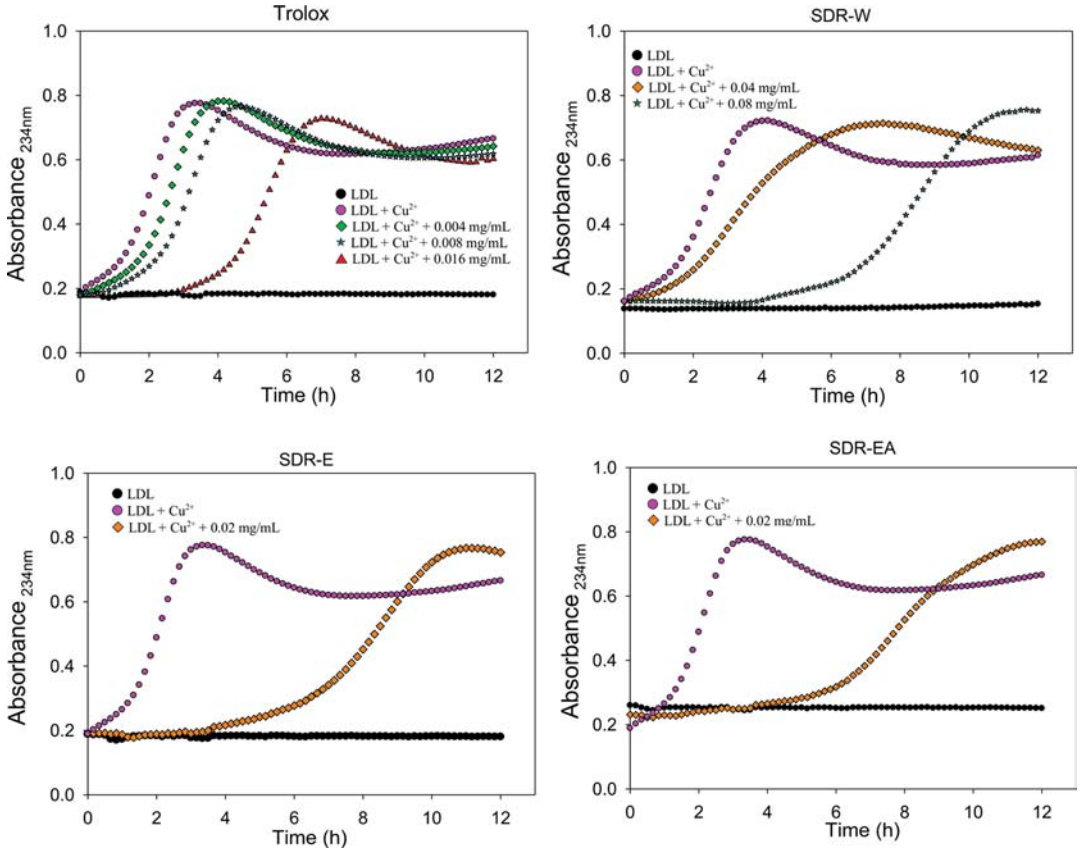

Figure 1. *In vitro* oxidation of human LDL treated with SDR extracts in comparison to Trolox.

The compound in each peak was identified by comparing the retention time and absorption spectrum to those of the authentic standards. Gallic acid (5.308 min), 3,4-dihydroxybenzoic acid (11.172 min), and 4-HB (17.71 min) were verified as present in SDR. An unknown compound was observed at 20.78 min, to be identified. SDR showed a pronounced increase in 4-HB after fermentation of the cooked sorghum. The highest content of phenolic acid in SDR was 4-HB (0.49 ± 0.23 mg/g of dw), followed by gallic acid (0.36 ± 0.08 mg/g of dw) and 3,4-dihydroxybenzoic acid (0.16 ± 0.12 mg/g of dw), as shown in Table 6.

Sorghum of white, lemon yellow, red, and brown varieties contains phenolic acids, which are located in the pericarp, testa, aleurone layer, and endosperm. A total of 10 phenolic acids, including 4-HB and gallic acid, were identified from sorghum.[19] These two phenolic acids were both found in SDR but not in cooked sorghum before fermentation (Table 6). The phenolic acids in sorghum are present mostly in the bound form.[20] Bilberry (European blueberry) fermented with *Lentinus edodes* having β-glycosidase activity also increased in phenolic content, including gallic acid, 4-HB, chlorogenic acid, and *p*-coumaric acid.[21]

The anti-inflammatory activity of sorghum bran correlated with their phenolic content and antioxidant activity.[22] 4-HB showed antimicrobial[23] and antifungal activity[24] and inhibited pre-adipocyte growth.[25] Fermentation of sorghum is a way to produce phenolic acids for enhancing its bioactivities.

Tilapia Fed SDR−E−PEG Reduced Mortality after Cold Stress. Because a fish diet containing 20% SDR−PEG fed to grey mullet (*Mugil cephalus*) prolonged the lag phase of LDL oxidation,[5] tilapia were tested by feeding the diet equivalent to the 20% SDR−PEG diet. The yield of SDR−E in the SDR was 18.6% (Table 4). The test diet fed to tilapia was adjusted to contain 3.6% SDR−E−PEG in comparison to feeding with the control diet made of commercial eel powder. Both diet groups were fed for 3 months at 24.5 °C. During the cold-stress trial, the water temperature was monitored to 13 °C, held for 5 days, and then recovered to 24 °C for 2 days. The accumulative mortality of tilapia is shown in Figure 3. When the water temperature stayed at 13 °C for 5 days, the accumulative mortality of the SDR−E−PEG group was 38.4%, which was much lower than that of the control group (64.3%). As the temperature returned to 24 °C for 2 days, the accumulative morality of the SDR−E−PEG group increased to 46.2%, significantly different ($p < 0.05$) from the control group (92.9%), indicating that SDR−E fed to tilapia improved the adaptability of the fish to temperature fluctuation.

4-HB as an Anti-Cold-Stress Component of SDR. To reduce the consumption of ethanol during preparation of the bioactive feed for practical application, SDR−PEG was used for feeding trials at a level of 0.5 or 1% (w/w) 4-HB of feed. The bioactive compound of SDR responsible for the anti-cold-stress effect in fish was assessed. The highest content of phenolic acids in SDR was 4-HB; therefore, it was speculated to be the major contributor of the anti-cold-stress activity. Tilapia were fed diets containing 20% SDR−PEG,[14] 0.5% 4-HB, or 1.0% 4-HB for 37 days at 25 °C, and then the water temperature was dropped to 13 °C, maintained for 13 days, and followed by recovering to 25 °C. The accumulative mortality is shown in Figure 4. Tilapia fed with 0.5 and 1.0% 4-HB started to die after days 6 and 7, while the accumulated mortality increased to 25 and 37.5%, respectively. Tilapia fed with 20% SDR−PEG

Table 6. Phenolic Acid Content of Cooked Sorghum Seed and SDR (mg/g of dw)[a]

compound	cooked sorghum seed	SDR
gallic acid		0.36 ± 0.08
3,4-dihydroxybenzoic acid	0.05 ± 0.04	0.16 ± 0.12
4-HB		0.49 ± 0.23

[a]The data are shown as the mean ± SD (n = 3).

started to die after day 10, and the final accumulative mortality was 18.75%, indicated that SDR was stronger in anti-cold-stress capacity than that of 0.5 or 1.0% 4-HB.

The diet containing 0.5% 4-HB was less effective to fish with regard to anti-cold-stress capacity than the diet containing 20% SDR−PEG (Figure 4). While the bioactive content of SDR−PEG was comparable to that of SDR−E−PEG, which showed lower accumulative mortality than those fed the control diet (Figure 3), we summarized that SDR, SDR−E, and 0.5% 4-HB could all improve fish survivability during cold stress. However,

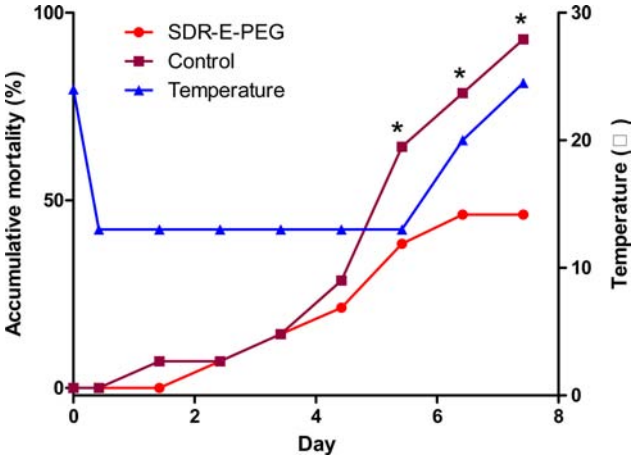

Figure 3. Mortality of tilapia fed for 3 months between September and November with diet containing 95% SDR–E–PEG, followed by exposure of tilapia to cold stress at 13 °C for 5 days and then recovered to 24.5 °C. (*) Values significantly different ($p < 0.05$) between the control and test groups.

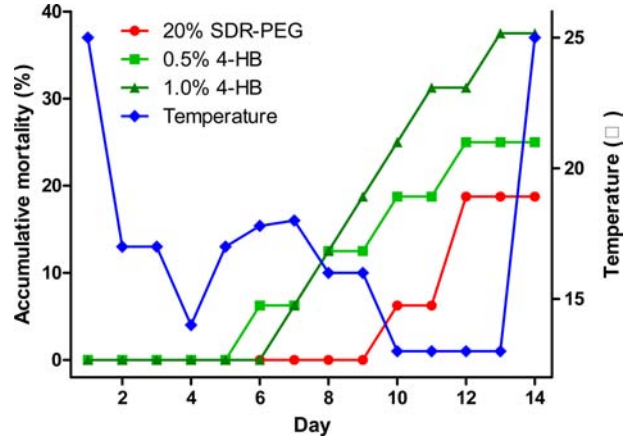

Figure 4. Accumulative mortality of the tilapia fed diet containing 20% SDR–PEG, 0.5% 4-HB, and 1.0% 4-HB for 37 days, followed by exposure to cold stress.

there could be other effective components present in SDR to better enhance the anti-cold-stress effect than 0.5% 4-HB alone. This is our ongoing study to identify these other anti-cold-stress compounds and possibly the mechanism of this effect.

Consumption of cranberry juice increased the concentration of 2-hydroxybenzoic acid (salicylic acid) in plasma[26] and urine of human volunteers.[27] The phytochemical constituents of the cranberry extract showed antiproliferative and synergistic effects against human tumor cell lines.[28] The phenolic acids demostrated anti-inflammatary[29] and antioxidant[30] activities and enhanced gut health.[31]

This study is the first investigation to elucidate the potential applicability of SDR–E to be used as a feed additive to enhance the cold adaptability of cultured tropical fish. It is indicated that the mortality occurred mainly when the temperature was recovered from cold stress, while 4-HB in SDR enhanced the cold adaptability of fish. It seemed that there are bioactive compounds other than 4-HB present in SDR that amplified the efficacy of 4-HB, which deserve further investigation.

ABSTRACT: Effects of asiatic acid (AA) at 10 or 20 mg/kg/day upon hepatic steatosis in mice consuming a high-fat diet (HFD) were examined. AA intake decreased body weight, water intake, feed intake, epididymal fat, and plasma and hepatic triglyceride levels in HFD-treated mice ($P < 0.05$). HFD enhanced 2.85-fold acetyl coenzyme A carboxylase (ACC1), 3.34-fold fatty acid synthase (FAS), 3.71-fold stearoyl CoA desaturase (SCD)-1, 3.62-fold 3-hydroxy-3-methylglutaryl coenzyme A reductase, 2.91-fold sterol regulatory element-binding protein (SREBP)-1c, and 2.75-fold SREBP-2 expression in liver ($P < 0.05$). Compared with HFD groups, AA intake at two doses reduced 18.9−45.7% ACC1, 25.1−49.8% FAS, 24.7−57.1% SCD-1, and 21.8−53.3% SREBP-1c protein expression ($P < 0.05$). Histological results indicated AA intake at two doses reduced hepatic lipid accumulation and inflammatory infiltrate. HFD increased hepatic production of reactive oxygen species, interleukin (IL)-1β, IL-6, and tumor necrosis factor-α, as well as decreased hepatic glutathione content and glutathione peroxidase and catalase activities ($P < 0.05$). AA intake at two doses reversed these alterations ($P < 0.05$). AA intake suppressed 32.4−58.8% nuclear factor kappa (NF-κ)B p65 and 24.2−56.7% p-p38 expression ($P < 0.05$) and at high dose down-regulated 29.1% NF-κB p50 and 40.7% p-JNK expression in livers from HFD-treated mice. AA intake at two doses lowered plasma insulin secretion and HOMR-IR ($P < 0.05$). These results suggest that AA is a potent hepatic protective agent against HFD-induced hepatic injury.

KEYWORDS: *asiatic acid, high-fat diet, hepatic steatosis, insulin resistance*

INTRODUCTION

Hepatic steatosis, hyperlipidemia, and obesity due to lipid accumulation are risk factors associated with the prevalence of cardiovascular diseases and metabolic disorders,[1,2] in which both oxidative and inflammatory reactions are involved.[3] Enhanced lipogenesis is a major contributor to lipid accumulation in the liver and other organs. Thus, any agent with antilipogenic, antioxidative, and anti-inflammatory effects may improve lipid metabolism disorders and alleviate hepatic steatosis and related injury.

Asiatic acid (AA, Figure 1) is a pentacyclic triterpene naturally occurring in many vegetables and fruits such as basil (*Ocimum basilicum*), brown mustard (*Brassica juncea*), and centella (*Centella asiatica* L.).[4,5] It has been reported that this triterpene could provide antioxidative and anti-inflammatory protection for mouse liver against D-galactosamine or lipopolysaccharide-induced acute liver injury.[6,7] Wei et al.[8] observed that AA intragastrical administration protected liver against ethanol-induced hepatotoxicity through attenuating oxidative stress. Pakdeechote et al.[9] indicated that 3 weeks of AA intake at 10 or 20 mg/kg/day improved high-carbohydrate and high-fat diet induced metabolic abnormalities including glucose intolerance, hypertension, and circulating oxidative and inflammatory stress in rats. However, it remains unknown whether AA could suppress high-fat diet caused hepatic lipogenesis or oxidative and inflammatory injury.

Acetyl coenzyme A carboxylase (ACC), fatty acid synthase (FAS), stearoyl CoA desaturase (SCD)-1, and 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase are lipogenic enzymes and involved in the biosynthesis of triglyceride and cholesterol in the liver and adipose tissue.[10,11]

[a]Values are means ± SD, $n = 10$. Means in a row without a common letter differ, $P < 0.05$.

Sterol regulatory element-binding protein (SREBP)-1c and SREBP-2 are important transcription factors responsible for the expression of genes encoded for fatty acid and cholesterol biosynthesis, respectively.[12,13] In addition, hormones such as insulin, leptin, and adiponectin also affect lipid metabolism. Abnormal levels of these hormones in circulation due to a high-fat diet enhance lipogenesis.[14] So far, less information is available regarding the influence of AA upon these lipogenic enzymes, SREPBs, and hormones. It is reported that a high-fat diet promoted hepatic oxidative and inflammatory stress by activating nuclear factor kappa (NF-κ)B and mitogen-activated protein kinase (MAPK) pathways.[15,16] Our previous study found that a high-fat diet decreased hepatic glutathione (GSH) content, lowered catalase and glutathione peroxidase (GPx) activities, and increased cytokine release.[17] If AA could alleviate high-fat diet caused oxidative and inflammatory injury, it may protect the liver against the development of steatohepatitis.

The major purpose of this study was to investigate the effects of AA at 10 or 20 mg/kg/day on lipid deposit and protein expression of lipogenic enzymes and SREBPs in livers from high-fat diet treated mice. The influence of this triterpene upon hepatic oxidative and inflammatory stress, as well as the variation of insulin, leptin, adiponectin, and ghrelin in circulation, was also evaluated.

MATERIALS AND METHODS

Materials. Asiatic acid (AA, 98%) was purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). High-fat diet (HFD) containing 60% of calories as fat was purchased from Research Diets Co. (New Brunswick, NJ, USA), in which saturated fat and monounsaturated fat were 55 and 35% of total fat, respectively.

Animals and Diets. Male 3-week-old C57BL/6 mice were obtained from the National Laboratory Animal Center (National Science Council, Taipei City, Taiwan). Use of the mice was reviewed and approved by the China Medical University animal care committee. After 1 week of acclimation, mice were used for experiments.

Experimental Design. Mice were divided into four groups: normal group (normal diet); HFD group (high-fat diet); AA-low group (high-fat diet plus AA at 10 mg/kg/day); AA-high group (high-fat diet plus AA at 20 mg/kg/day). AA, suspended in 1.2% methyl cellulose (MC), was administered daily by oral gavage. After 7 weeks, mice were killed with carbon dioxide. Blood, liver, and epididymal fat from each mouse were collected and weighed. Protein concentration of tissue homogenate was determined by a commercial assay kit (Pierce Biotechnology Inc., Rockford, IL, USA) with bovine serum albumin as standard. Our preliminary study found that there was no significant difference in all measurements between mice consuming the normal diet and normal diet plus AA-high or between mice consuming the high-fat diet and the high-fat diet plus vehicle (1.2% MC). Thus, two groups, normal diet plus AA-high and high-fat diet plus vehicle were omitted in the present study.

Blood Analysis. Triglyceride (TG) and total cholesterol (TC) levels in plasma were assayed by kits purchased from Wako Pure Chemical Co. (Osaka, Japan). Plasma activity of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) was determined by commercial kits (Randox Laboratories Ltd., Crumlin, UK). Plasma levels of glucose (mmol/L) and insulin (nmol/L) were measured by using a glucose HK kit (Sigma Chemical Co., St. Louis, MO, USA) and mouse ultrasensitive ELISA kit (DRG Instruments GmbH, Marburg, Germany), respectively. Insulin resistance, expressed as homeostasis model assessment-insulin resistance (HOMA-IR), was calculated via the formula [glucose (mmol/L) × insulin (mU/L)]/22.5. Plasma leptin and adiponectin levels were measured using a Mouse Leptin Quantikine ELISA kit (R&D Systems, Minneapolis, MN, USA) and a Rat/mouse Adiponectin ELISA kit (Phoenix Europe GmbH, Karlsruhe, Germany), respectively. Plasma immunoreactive ghrelin concentration was measured using a radioimmunoassay kit (Phoenix Pharmaceuticals, Belmont, CA, USA).

Hepatic TG and TC. Liver homogenate, 1 mL, was mixed with 2.5 mL of chloroform/methanol (2:1, v/v). The chloroform layer was collected and concentrated. After mixing with 10% Triton X-100 in isopropanol, the sample was assayed by using Wako Triglyceride E-Test and Total Cholesterol E-Test kits (Wako Pure Chemical).

Fecal Lipid Analysis. Feces, at 0.5 g, were mixed with 3.5 mL of deionized water. After sitting at 4 °C overnight, feces were homogenized by vortexing. The fecal lipid was extracted with methanol/chloroform (2:1, v/v) using a method described in Tsujita et al.[18] The lipophilic layer was collected and dried under a nitrogen stream.

Measurement of Oxidative and Inflammatory Factors in Liver. Liver tissue was homogenized with cold phosphate-buffered saline containing 0.05% Tween 20 and 1 mM EDTA. After centrifuging, the supernatants were used for measurements. Sample was mixed with 25 mM 2′,7′-dichlorofluorescein diacetate. After 30 min of incubation at room temperature, reactive oxygen species (ROS) level was determined by monitoring fluorescence change at an excitation wavelength of 488 nm and an emission wavelength of 515 nm. GSH content was measured by using a commercial kit (OxisResearch, Portland, OR, USA). The activities of GPX and catalase were assayed by GPX and catalase kits (Calbiochem, EMD Biosciences, Inc., San Diego, CA, USA). Levels of interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)-α were determined using ELISA kits (R&D Systems).

Western Blot Analysis. Liver tissue was homogenized in buffer containing 0.5% Triton X-100 and protease-inhibitor cocktail (1:1000, Sigma-Aldrich Chemical Co.). This homogenate was further mixed with buffer (60 mM Tris-HCl, 2% SDS, and 2% β-mercaptoethanol, pH 7.2) and boiled for 5 min. Sample at 40 μg protein was applied to 10% SDS−polyacrylamide gel electrophoresis and transferred to a nitrocellulose membrane (Millipore, Bedford, MA, USA) for 1 h. After blocking with a solution containing 5% nonfat milk for 1 h to prevent nonspecific binding of antibody, membrane was incubated with mouse anti-ACC1, anti-FAS, anti-SCD-1 (1:1000), anti-HMG-CoA reductase, anti-SREBP-1c, anti-SREBP-2 (1:2000), and anti-NF-κB and anti-MAPK (1:1000) monoclonal antibodies (Boehringer-Mannheim, Indianapolis, IN, USA) at 4 °C overnight and followed by reaction with horseradish peroxidase-conjugated antibody for 3.5 h at room temperature. The detected bands were quantified by an image analyzer (ATTO, Tokyo, Japan), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as a loading control. The blot was quantified by densitometric analysis. Results were normalized to GAPDH and given as arbitrary units (AU).

Table 2. Plasma Levels of ALT, AST, TG, and TC, Hepatic Levels of TG and TC, and Fecal Lipid Level in Mice Treated with Normal Diet (ND), High-Fat Diet (HFD), or HFD with AA-Low or AA-High for 7 Weeks[a]

	ND	HFD	HFD + AA-low	HFD + AA-high
plasma				
ALT (U/L)	33 ± 3a	118 ± 10d	91 ± 5c	60 ± 6b
AST (U/L)	36 ± 4a	104 ± 8d	82 ± 7c	51 ± 4b
TG (g/L)	2.24 ± 0.08a	5.76 ± 0.21d	5.01 ± 0.13c	3.98 ± 0.10b
TC (g/L)	1.28 ± 0.05a	3.90 ± 0.11c	3.56 ± 0.06c	2.94 ± 0.07b
hepatic				
TG (mg/g wet wt)	25.9 ± 1.2a	64.5 ± 2.5d	51.1 ± 1.6c	38.2 ± 0.9b

fecal				
lipid (mg/g feces)	8.3 ± 0.5a	13.6 ± 0.4b	14.0 ± 0.6b	15.7 ± 0.5c

[a]Values are means ± SD, $n = 10$. Means in a row without a common letter differ, $P < 0.05$.

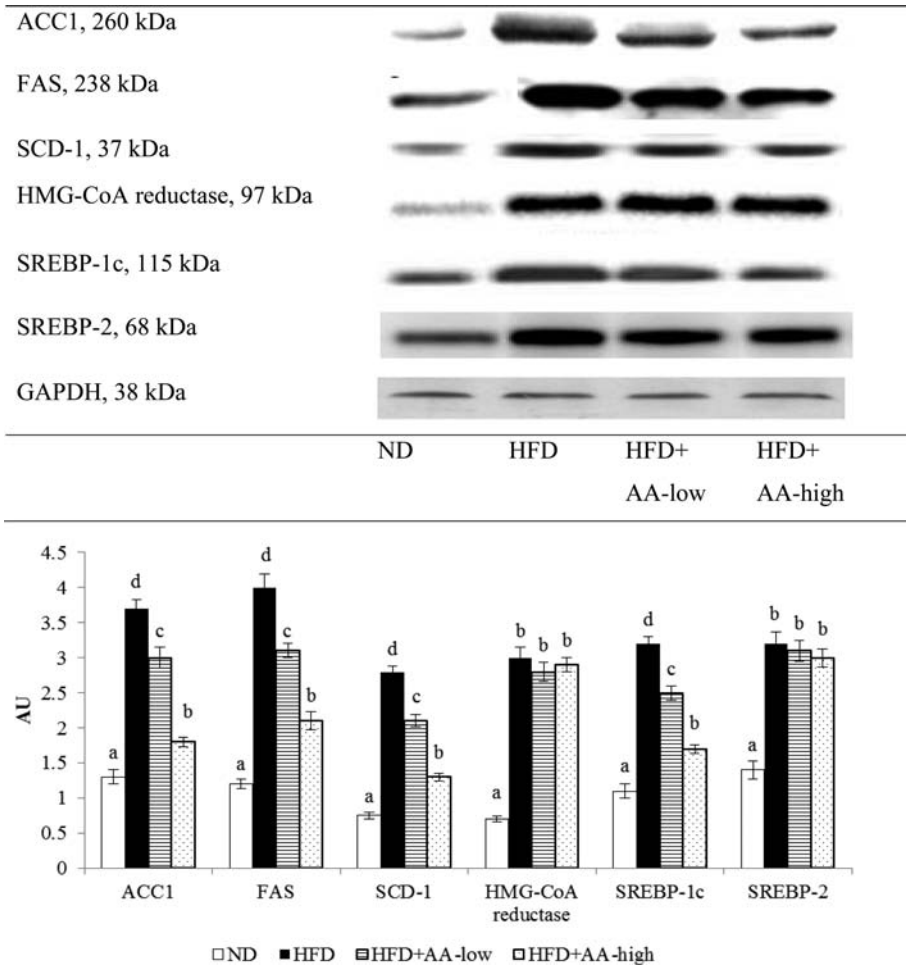

Figure 2. Hepatic protein expression of ACC1, FAS, SCD-1, HMG-CoA reductase, SREBP-1c, and SREBP-2 in mice treated with normal diet (ND), high-fat diet (HFD), or HFD with AA-low or AA-high for 7 weeks. Values are means ± SD, $n = 10$. Means among bars without a common letter differ, $P < 0.05$.

Histological Analysis. Partial liver tissue from each mouse was fixed in 10% phosphate-buffered formalin and embedded in paraffin. Paraffin section at 5 μm thickness was cut and stained with Oil Red O (ORO) stain and hematoxylin-eosin (H&E) stain, and followed by examination under a light microscope for histological analysis.

Statistical Analysis. The effect of each treatment was analyzed from 10 mice ($n = 10$) in each group. All data were expressed as the mean ± standard deviation (SD). Statistical analysis was done using one-way analysis of variance, and post-hoc comparisons were carried out using Dunnet's t test. Statistical significance was considered at $P < 0.05$.

RESULTS

Effects of AA on Body Weight. HFD increased mouse body weight, water intake, feed intake, liver weight, and epididymal fat (Table 1, $P < 0.05$). Compared with HFD groups, AA intake at low and high doses decreased body weight, water intake, feed intake, and epididymal fat in HFD-treated mice ($P < 0.05$). AA intake only at high dose lowered liver weight of mice treated with HFD ($P < 0.05$).

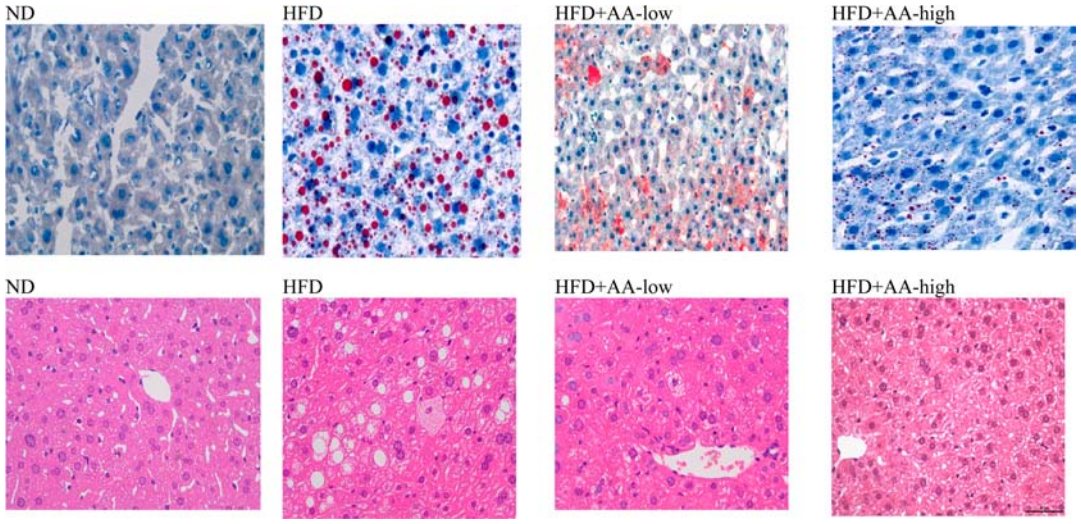

Figure 3. Effects of AA upon hepatic lipid accumulation (upper row), determined by ORO statin; hepatic inflammation (lower row), determined by H&E stain in mice treated with normal diet (ND), high-fat diet (HFD), or HFD with AA-low or AA-high for 7 weeks. Magnification: 200×.

Table 3. Plasma Level of Glucose, Insulin, HOMA-IR, Leptin, Adiponectin, and Ghrelin in Mice Treated with Normal Diet (ND), High Fat Diet (HFD), or HFD with AA-Low or AA-High for 7 Weeks[a]

	ND	HFD	HFD + AA-low	HFD + AA-high
glucose (mmol/L)	7.2 ± 0.3a	7.8 ± 0.5a	7.6 ± 0.2a	7.5 ± 0.4a
insulin (nmol/L)	14.2 ± 0.6a	25.8 ± 1.8d	22.5 ± 1.1c	17.8 ± 0.9b
HOMA-IR	4.3 ± 0.8a	33.4 ± 2.1d	26.1 ± 1.7c	15.0 ± 1.0b
leptin (ng/mL)	1.21 ± 0.20a	2.19 ± 0.17b	2.10 ± 0.11b	1.98 ± 0.08b
adiponectin (μg/mL)	8.3 ± 0.5b	4.7 ± 0.2a	4.8 ± 0.4a	5.1 ± 4a
ghrelin (fmol/mL)	152 ± 13b	96 ± 7a	101 ± 6a	105 ± 9a

[a]Values are means ± SD, n = 10. Means in a row without a common letter differ, $P < 0.05$.

Table 4. Hepatic Levels of ROS and GSH, Activities of Catalase and GPX, and Levels of IL-1β, IL-6, and TNF-α in Mice Treated with Normal Diet (ND), High-Fat Diet (HFD), or HFD with AA-Low or AA-High for 7 Weeks[a]

	ND	HFD	HFD + AA-low	HFD + AA-high
ROS (RFU/mg protein)	0.26 ± 0.04a	1.30 ± 0.12d	1.02 ± 0.10c	0.66 ± 0.08b
GSH (nmol/mg protein)	12.4 ± 0.6d	7.3 ± 0.4a	8.4 ± 0.5b	10.1 ± 0.7c
GPX (U/mg protein)	18.6 ± 0.5d	12.5 ± 0.3a	14.1 ± 0.4b	15.5 ± 0.5c
catalase (U/mg protein)	17.1 ± 0.7d	11.3 ± 0.4a	12.5 ± 0.6b	14.3 ± 0.6c
IL-1β (pg/mg protein)	19 ± 3a	108 ± 10d	87 ± 8c	60 ± 5b
IL-6 (pg/mg protein)	15 ± 2a	94 ± 7d	77 ± 5c	52 ± 4b
TNF-α (pg/mg protein)	18 ± 4a	103 ± 11d	85 ± 9c	56 ± 5b

[a]Values are means ± SD, n = 10. Means in a row without a common letter differ, $P < 0.05$.

Effects of AA on Lipid Levels. HFD raised plasma ALT, AST, TG, and TC levels; hepatic TG and TC levels; and fecal lipid content (Table 2, $P < 0.05$). Compared with HFD groups, AA intake at two doses decreased plasma ALT, 22.9−48.5%; AST, 21.2−50.1%; and TG levels, 12.4−30.4%; and lowered hepatic TG level, 20.8−41.3% ($P < 0.05$). Plasma TC level and hepatic TC level were reduced by AA intake at high dose ($P < 0.05$). AA intake only at high dose increased fecal lipid content ($P < 0.05$).

Effects of AA on Hepatic Lipogenesis. As shown in Figure 2, HFD enhanced 2.85-fold ACC1, 3.34-fold FAS, 3.71-fold SCD-1, 3.62-fold HMG-CoA reductase, 2.91-fold SREBP-1c, and 2.75-fold SREBP-2 expression in liver ($P < 0.05$). Compared with HFD groups, AA intake at two doses reduced ACC1, 18.9−45.7%; FAS, 25.1−49.8%; SCD-1, 24.7−57.1%; and SREBP-1c, 21.8−53.3%, protein expression ($P < 0.05$). AA intake did not affect hepatic protein expression of HMG-CoA reductase and SREBP-2 ($P > 0.05$). As shown in Figure 3, HFD led to a great amount of fat deposition in liver, determined by ORO stain (upper row), and caused obvious foci of inflammatory cell infiltration in liver, determined by H&E stain (lower row). AA intake at two doses decreased hepatic lipid droplets and inflammatory infiltration. HFD increased plasma levels of insulin, leptin, and HOMA-IR and decreased adiponectin and ghrelin levels (Table 3, $P < 0.05$). AA intake at two doses lowered plasma insulin secretion and HOMR-IR ($P < 0.05$) but did not affect plasma glucose, leptin, ghrelin, or adiponectin levels ($P > 0.05$).

Effects of AA on Hepatic Oxidative and Inflammatory Stress. HFD increased hepatic production of ROS, IL-1β, IL-6, and TNF-α as well as decreased hepatic GSH content and GPX and catalase activities (Table 4, $P < 0.05$). Compared with HFD

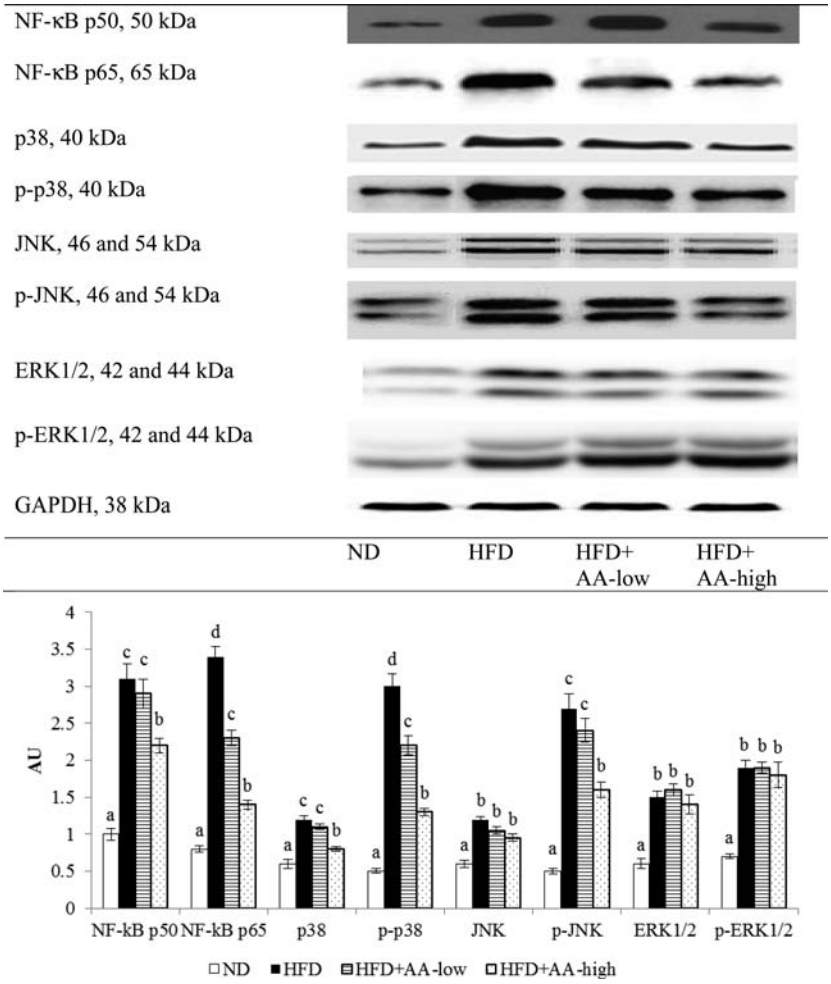

Figure 4. Hepatic protein expression of NF-κB and MAPK in mice treated with normal diet (ND), high-fat diet (HFD), or HFD with AA-low or AA-high for 7 weeks. Values are means ± SD, $n = 10$. Means among bars without a common letter differ, $P < 0.05$.

groups, AA intake at two doses lowered hepatic ROS, 21.5−49.2%; IL-1β, 19.4−44.3%; IL-6, 18.1−44.7%; and TNF-α, 17.5−45.6%, levels but retained 15.1−38.4% GSH content and maintained 12.8−24.1% GPX and 10.6−26.5% catalase activities ($P < 0.05$). As shown in Figure 4, HFD up-regulated hepatic NF-κB and MAPK expression ($P < 0.05$). AA intake dose-dependently suppressed NF-κB p65, 32.4−58.8%, and p-p38, 24.2−56.7%, expression ($P < 0.05$) and at high dose down-regulated NF-κB p50, 29.1%, and p-JNK, 40.7%, expression. AA intake did not affect ERK1/2 and p-ERK1/2 expression ($P > 0.05$).

DISCUSSION

The high-fat diet we used enhanced hepatic protein expression of lipogenic enzymes and factors including ACC1, FAS, SCD-1, HMG-CoA reductase, SREBP-1c, and SREBP-2, which clearly explained the observed lipid accumulation in liver, circulation, and epididymal white adipose tissue. We further found that the intake of AA markedly attenuated high-fat diet caused hyperlipidemia, hepatic steatosis, and epididymal fat deposit. Our Western blot data revealed that AA intake effectively suppressed hepatic expression of ACC1, FAS, SCD-1, and SREBP-1c. Our histological data indicated that AA intake reduced fat deposits in hepatocytes. Furthermore, AA intake alleviated high-fat diet induced insulin resistance and hepatic oxidative and inflammatory stress. These findings supported that AA could protect liver via antilipogenic, antioxidative, and anti-inflammatory activities to improve high-fat diet caused injury.

ACC1 mediates the initial step of fatty acid synthesis via converting acetyl-CoA to malonyl-CoA.[11] FAS is responsible for the last step in fatty acid biosynthesis and plays a determinant role for hepatic fatty acid generation in de novo lipogenesis.[10] SCD-1 catalyzes the rate-limiting step in the cellular biosynthesis of monounsaturated fatty acids, primarily oleate and palmitoleate, which could be incorporated into and stored as triglyceride in liver.[19] SREBP-1c is the major upstream transcription factor involved in hepatic triglyceride biosynthesis and modulates the expression of downstream targets including FAS, ACC1, and SCD-1.[20−22] Thus, the suppression on the expression of these enzymes and SREBP-1c could inhibit hepatic lipogenesis and lower fat accumulation in liver. Our present study found that AA treatments effectively down-regulated hepatic expression of ACC1, FAS, SCD-1, and SREBP-1c, which subsequently decreased triglyceride biosynthesis and deposit in liver, adipose tissue, and circulation and finally attenuated hepatic steatosis and lowered body weight. These findings indicated that AA was an effective agent against triglyceride biosynthesis. Obviously, the antilipogenic activities of AA could be mainly ascribed to its suppression upon hepatic SREBP-1c, an upstream lipogenic factor, and the less available SREBP-1c subsequently declined the expression of downstream

factors, ACC1, FAS, and SCD-1 in the liver. On the other hand, HMG-CoA reductase, regulated by SREBP-2, is responsible for cholesterol biosynthesis.[23] Our present study found AA intake did not affect hepatic SREBP-2 and HMG-CoA reductase expression. SREBP-1c is produced from a single gene, *SREBF-1*, located on chromosome 17p11.2, but SREBP-2 is generated from another gene, *SREBF-2*, located on chromosome 22q13.[24] It is speculated that AA had less affinity to chromosome 22q13 and/or less interference with gene *SREBF-2*, which caused failure in regulating SREBP-2 in HFD-treated mice liver. However, it is interesting to find that AA at high dose lowered hepatic and circulating cholesterol levels. It is likely that AA at high dose mildly mediated other factor(s) involved in cholesterol biosynthesis. These results implied that AA was a weak inhibitor against cholesterol biosynthesis. In addition, our data revealed AA intake at high dose increased fecal lipid content. Thus, the lipid-lowering effect of this triterpene was slightly due to an increase in lipid excretion.

Other studies[25,26] and our present study found that a high-fat diet altered circulating levels of several hormones. Our data indicated that AA intake substantially alleviated hyperinsulinemia. It is highly possible that this triterpene suppressed hepatic lipogenesis and reduced lipid accumulation in liver and adipose tissue, which in turn restored insulin sensitivity and lowered the requirement for insulin. The reduction of HOMA-IR in AA-treated mice we observed also agreed with this agent improving high-fat diet induced insulin resistance. In addition, a high-fat diet stimulates the release of inflammatory cytokines such as IL-1β and TNF-α, which blocks adipocyte insulin action and contributes to the development of obesity-related insulin resistance.[27,28] Thus, the improved insulin resistance in AA-treated mice could partially result from the diminished hepatic release of these inflammatory cytokines. AA treatments did not affect high-fat diet induced hyper-leptinemia, hypo-adiponectinemia, and hypo-ghrelinemia in our present study. Obviously, AA was not able to mediate these hormones.

It is reported that excessive energy from a high-fat diet promoted oxidative enzyme activities, disturbed tricarboxylic acid cycle electron transport chain, and impaired mitochondrial respiratory capability in liver and other organs such as the heart, which led to the overproduction of ROS and enhanced oxidative stress and consequently activated MAPK and NF-κB pathways.[29,30] The activation of these two pathways further augmented hepatic oxidative and inflammatory stress and contributed to the progression of liver disorders including steatohepatitis.[30,31] The results of our present study agreed with those previous studies because our molecular analyses data revealed that a high-fat diet enhanced hepatic expression of NF-κB p50, NF-κB p65, p38, JNK, and ERK1/2, which in turn evoked the generation of ROS and inflammatory cytokines including IL-6 and TNF-α. Furthermore, we found that AA intake limited phosphorylation of NF-κB p50, NF-κB p65, p38, and JNK in liver, which subsequently decreased the activation of NF-κB and MAPK. Because both NF-κB and MAPK pathways have been suppressed, the lower formation of ROS and inflammatory cytokines in livers from AA-treated mice could be explained. Our histological results indicated that AA intake ameliorated lobular inflammation and diffuse ballooning degeneration in hepatocytes. The restored antioxidative defenses such as GPX and catalase activities and lowered plasma ALT and AST levels in AA-treated mice also indicated that hepatic oxidative and inflammatory stress had been mitigated. These findings showed that dietary AA could be absorbed and exerted its hepatic protection through regulating hepatic NF-κB and MAPK pathways.

AA is a triterpene naturally occurring in many plant foods and herbs. Ramachandran and Saravanan[32] reported that AA intake at 10 or 20 mg/kg body weight altered hepatic enzyme activities of carbohydrate metabolism in diabetic rats. In our present study, AA intake also at 10 or 20 mg/kg body weight markedly protected THE liver against high-fat diet induced injury in mice. On the basis of its natural property and support from other studies and our data, the application of this compound seems safe. The doses used in our present study were approximately equal to 0.7 or 1.4 g/day for a 70 kg man. Our previous study found that gynura (*Gynura bicolor* DC), brown mustard (*Brassica juncea*), and daylily (*Hemerocallis fulva* L.) contained AA in the range of 55−102 mg/g dry weight.[4] Thus, the consumption of these vegetables, rich in AA, might also benefit the prevention of diet-induced lipid disorders. On the other hand, we noted that AA intake lowered mouse feed intake. It seems that this agent, a tasteless compound, was able to affect appetite and contributed to decreased body weight.

In conclusion, high-fat diet caused hyperlipidemia, hepatic steatosis, and insulin resistance. The intake of asiatic acid markedly lowered lipid accumulation in the circulation, liver, and adipose tissue via suppressing the protein expression of ACC1, FAS, SCD-1, and SREBP-1c. This triterpene also improved insulin resistance and attenuated hepatic oxidative and inflammatory injury. These results suggest that asiatic acid is a potent hepatic protective agent against high-fat diet induced steatohepatitis.

ABSTRACT: Shogaols, the major constituents of thermally processed ginger, have been proven to be highly effective anticancer agents. Our group has identified cysteine-conjugated shogaols (M2, M2′, and M2″) as the major metabolites of [6]-, [8]-, and [10]-shogaol in human and found that M2 is a carrier of its parent molecule [6]-shogaol in cancer cells and in mice, while being less toxic to normal colon fibroblast cells. The objectives of this study are to determine whether M2′ and M2″ behave in a similar manner to M2, in both metabolism and efficacy as anticancer agents, and to further explore the biological pro-apoptotic mechanisms of the cysteine-conjugated shogaols against human colon cancer cells HCT-116 and HT-29. Our results show that [8]- and [10]-shogaol have similar metabolic profiles to [6]-shogaol and exhibit similar toxicity toward human colon cancer cells. M2′ and M2″ both show low toxicity against normal colon cells but retain potency against colon cancer cells, suggesting that they have similar activity to M2. We further demonstrate that the cysteine-conjugated shogaols can cause cancer cell death through the activation of the mitochondrial apoptotic pathway. Our results show that oxidative stress activates a p53 pathway that ultimately leads to p53 up-regulated modulator of apoptosis (PUMA) induction and down-regulation of B-cell lymphoma 2 (Bcl-2), followed by cytochrome *c* release, perturbation of inhibitory interactions of X-linked inhibitor of apoptosis protein (XIAP) with caspases, and finally caspase 9 and 3 activation and cleavage. A brief screen of the markers attenuated by the proapoptotic activity of M2 revealed similar results for [8]- and [10]-shogaol and their respective cysteine-conjugated metabolites M2′ and M2″. This study highlights the cysteine-conjugated metabolites of shogaols as novel dietary colon cancer preventive agents.

KEYWORDS: *ginger, cysteine-conjugated metabolites, shogaols, colon cancer, apoptosis*

INTRODUCTION

Ginger, the rhizome of *Zingiber officinale*, has been cultivated as both a ubiquitous spice and a traditional medicinal food for thousands of years.[1] Its many curative properties include treatment of nausea and dyspepsia, ameliorating symptoms of arthritis via anti-inflammation, and therapeutic activity against asthma, respiratory disorders, and rheumatic ailments.[2−5] Most recently, pharmacologically active components of ginger have been implicated in chemoprevention via numerous mechanisms. Gingerols and shogaols have been identified as the most active ingredients in ginger. Shogaols, the products of ginger thermal processing, consistently show greater anticarcinogenic activity than gingerols, with [6]-shogaol (6S) being the most abundant one followed by [10]- and [8]-shogaol (10S and 8S) (Figure 1A).[6−10] In particular, 6S has repeatedly shown strong chemopreventive activity against colorectal cancer, the third most common cancer diagnosed in the United States.[11−15]

Therapeutics with high anticancer potency often come under scrutiny for their accompanying toxicity against noncancerous cells in the viable organism. Consequently, there is escalating interest in employing dietary components and their metabolic constituents as less noxious treatments toward chemoprevention.[16−18] Our group has recently established that the reactive ginger component 6S is extensively metabolized in mice and in cancer cells[19,20] and that redox transformation and a phase II mercapturic acid pathway (MAP) are its major metabolic routes.[19,20] As previously reported, an initial reaction between the α,β-unsaturated ketone functional group of 6S and the cysteine sulfhydryl component of GSH takes place in the MAP, giving rise to the corresponding conjugates. The conjugates then undergo series of enzymatic modifications on the GSH moiety, forming cysteinylglycine, cysteine, and finally *N*-acetylcysteine conjugates. Additional studies show that both 8S and 10S are also metabolized in humans through the MAP and the cysteine-conjugated metabolites, M2′ and M2″, respectively (Figure 1B), were identified as their major metabolites in human urine.[21] Phase II metabolism products such as thiol conjugates are more water-soluble and often less toxic and pungent than their parent compounds, making them preferable for chemoprevention trials.[22] Our group recently investigated the bioactivity of the cysteine-conjugated metabolite of [6]-shogaol (M2) and its putative mode of action as a hydrophilic carrier of the parent molecule to its site of efficacy. We established that cysteine-conjugation reduced the toxicity of 6S against normal human colon and lung fibroblast cells while

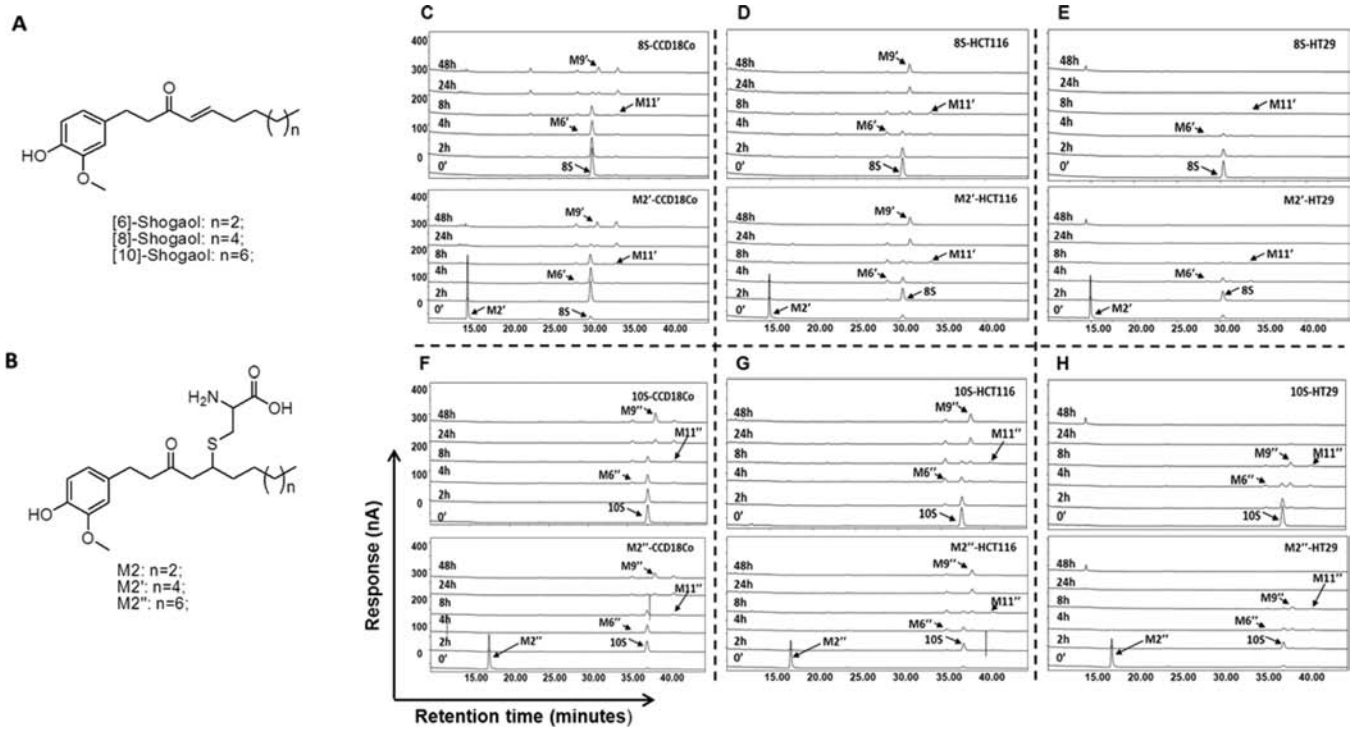

Figure 1. M2′ and M2″ serve as a carrier to their parent compounds [8]- and [10]-shogaol (8S and 10S), respectively. Chemical structures of shogaols (A) and their cysteine-conjugated metabolites (B); HPLC-ECD chromatograms representing the metabolic profiles of 8S, M2′, 10S, and M2″ in human colon normal cells, CCD-18Co (C, F), and human colon cancer cells, HCT-116 (D, G) and HT-29 (E, H).

still retaining efficacy against human colon and lung cancer cells.[13] Through a series of chemical stability and biological assays, we demonstrated the function of M2 as a carrier of 6S to its active site, wherein the parent compound is rendered less toxic but regains potency and similar bioactivity upon deconjugation.[23] It is still unknown whether M2′ and M2″ behave in a similar manner to M2, in both efficacy as anticancer agents and metabolically. As an expansion of our proposed chemical mechanism for cysteine conjugates as carriers of their parent molecule shogaols, we investigated whether M2′ and M2″ are the respective carriers of 8S and 10S in cancer cells and can induce apoptosis through a mechanism similar to M2.

Although we have established the functionality and importance of M2, its mechanism of action against colon cancer cells has not been completely elucidated. There have been studies implicating 6S as a pro-apoptotic agent, via reactive oxygen species (ROS) production and subsequent growth arrest and DNA damage (GADD)-inducible transcription factor 153 (GADD153) expression in COLO 205 cells,[15] an inducer of G_2/M arrest and aberrant mitotic cell death associated with tubulin aggregation in HCT-116 colon carcinoma cells,[14] and an inhibitor of colon cancer cell proliferation through activation of peroxisomal proliferator activated receptor γ (PPARγ).[12] Given the significance of M2 as a potential therapeutic with selective toxicity toward cancerous cells, the impetus of this study is also to determine the mechanistic role M2 plays in promoting apoptosis in human colon cancer cells HCT-116 and HT-29. In particular, examining the impact of M2 in colon cancer cells containing wild-type *p53* (HCT-116) and mutant *p53* (HT-29) will be emphasized. The progressive loss or inactivation of *p53* is well associated with the corresponding advancement of cancer to more aggressive stages, and is one of the most prevalent genetic defects in human malignancies that often correlates to chemotherapeutic resistance.[24−26] Thus, determining whether the bioactivity of M2, M2′, or M2″ is dependent upon *p53* status is of critical concern in terms of cancer prevention, since usable compounds must be able to exert their activity through the early mutations stages of cancer.

MATERIALS AND METHODS

Cell Culture. HCT-116 and HT-29 human colon cancer cells, CCD-18Co human fibroblast cells derived from colon, and Eagle's minimum essential media (EMEM) were obtained from American Type Tissue Culture (Manassas, VA). McCoy's 5A medium was purchased from Thermo Fisher Scientific (Waltham, MA). Supplements of fetal bovine serum (FBS) and penicillin/streptomycin were purchased from Gemini Bio-Products (West Sacramento, CA).

Reagents. 6S, 8S, and 10S were purified from ginger extract in our laboratory.[10] M2 was synthesized in our laboratory, as previously reported.[13] HPLC-grade solvents and other reagents were obtained from VWR International (South Plainfield, NJ). LC/MS grade solvents and other reagents were obtained from Thermo Fisher Scientific (Rockford, IL). Glutathione was obtained from Sigma-Aldrich (St. Louis, MN). Crystal violet, glutaraldehyde, MTT [3-(4,5-dimethylthiaxol-2-yl)-2,5-diphenyltetrazolium bromide], and propidium iodide were procured from Thermo Fisher Scientific (Waltham, MA). Primary antibodies against β-actin, B-cell lymphoma 2 (Bcl-2), caspase 9, caspase 3, cytochrome *c*, PUMA (p53 up-regulated modulator of apoptosis), p53, XIAP (X-linked inhibitor of apoptosis protein), as well as secondary antibodies conjugated to HRP (horseradish peroxidase) against mouse and rabbit were purchased from Cell Signaling Technology (Beverly, MA).

HPLC-ECD Analysis. A high-performance liquid chromatrography/ESA electrochemical detector (HPLC-ECD) (ESA, Chelmsford, MA) consisting of an ESA model 584 HPLC pump, an ESA model 542 autosampler, an ESA organizer, and an ESA electrochemical detector (ECD) coupled with two ESA model 6210 four sensor cells was used. A Gemini C18 column (150 mm × 4.6 mm, 5 μm; Phenomenex, Torrance, CA) was used for chromatographic analysis at

a flow rate of 1.0 mL/min. The mobile phases consisted of solvent A (30 mM sodium phosphate buffer containing 1.75% ACN and 0.125% THF, pH 3.35) and solvent B (15 mM sodium phosphate buffer containing 58.5% ACN and 12.5% THF, pH 3.45). The gradient elution had the following profile: 20% B from 0 to 3 min; 20−55% B from 3 to 11 min; 55−60% B from 11 to 12 min; 60−65% B from 12 to 13 min; 65−100% B from 13 to 40 min; 100% B from 40 to 45 min; then 20% B from 45.1 to 50 min. The cells were then cleaned at a potential of 1000 mV for 1 min. The injection volume of the sample was 10 μL. The eluent was monitored by the Coulochem electrode array system (CEAS) with potential settings at 200, 250, 300, 350, 400, 450, and 500 mV. Data for Figure 1 were from the channel set at 350 mV of the CEAS.

LC/MS Analysis. LC/MS analysis was carried out with a Thermo-Finnigan Spectra System, which consisted of an Accela high-speed MS pump, an Accela refrigerated autosampler, and an LTQ Velos ion trap mass detector (Thermo Electron, San Jose, CA) incorporated with heated electrospray ionization (H-ESI) interfaces. A Gemini C_{18} column (50 mm × 2.0 mm i.d., 3 μm; Phenomenex, Torrance, CA) was used for separation at a flow rate of 0.2 mL/min. The column was eluted from 100% solvent A (5% aqueous methanol with 0.2% acetic acid) for 3 min, followed by linear increases in B (95% aqueous methanol with 0.2% acetic acid) to 40% from 3 to 15 min, to 91% from 15 to 49 min, and to 100% from 49 to 50 min, and then with 100% B from 50 to 55 min. The column was then re-equilibrated with 100% A for 5 min. The LC eluent was introduced into the H-ESI interface. The positive ion polarity mode was set for the H-ESI source with the voltage on the H-ESI interface maintained at approximately 4.5 kV. Nitrogen gas was used as the sheath gas and auxiliary gas. Optimized source parameters, including ESI capillary temperature (300 °C), capillary voltage (50 V), ion spray voltage (3.6 kV), sheath gas flow rate (30 units), auxiliary gas flow rate (5 units), and tube lens (120 V), were tuned using authentic 6S. The collision-induced dissociation (CID) was conducted with an isolation width of 2 Da and normalized collision energy of 35 for MS^2 and MS^3. Default automated gain control target ion values were used for $MS-MS^3$ analyses. The mass range was measured from 50 to 1000 m/z. Data acquisition was performed with Xcalibur 2.0 version (Thermo Electron, San Jose, CA).

Chemical Synthesis of M2′ and M2″. The experimental procedure to synthesize M2′ and M2″ was similar to that of M2.[13] In brief, a catalytic amount of $NaHCO_3$ (1.3 mg, 0.015 mmol) was added to a mixture of 8S (91.2 mg, 0.3 mmol) and cysteine (54 mg, 0.45 mmol) in methanol/water (6 mL, 1:1, v/v). The mixture was stirred at room temperature for 24 h, and adjusted to pH 6 with a diluted acetic acid solution (0.1 M). The mixture was then purified by preparative HPLC to give M2′ as a white solid (70 mg, yield 55%). Shogaol 10S (100 mg, 0.3 mmol) instead of 8S was used in the above reaction to give M2″ (73 mg, yield 54%).

Purification of M2′ or M2″ Using Preparative HPLC. Waters preparative HPLC systems with 2545 binary gradient module, Waters 2767 sample manager, Waters 2487 autopurification flow cell, Waters fraction collector III, dual injector module, and 2489 UV/Visible detector were used to separate M2′ or M2″ from the reaction mixture. A Phenomenex Gemini-NX C_{18} column (250 mm × 30.0 mm i.d., 5 μm) was used with a flow rate of 20.0 mL/min. The wavelength of the UV detector was set at 280 nm. The injection volume was 1.0 mL for each run. The mobile phase consisted of solvent A (H_2O + 0.1% formic acid) and solvent B (MeOH + 0.1% formic acid). The reaction mixture of M2′ was injected to the preparative column and eluted with a gradient solvent system (75% to 87% B from 0 to 12 min; to 75% B from 12 to 12.5 min; then 75% B from 12.5 to 15 min). A total of six runs resulted in 70 mg of M2′ (t_R 9.45 min). Similarly, reaction mixture of M2″ was injected to the preparative column and eluted with a gradient solvent system (85% to 100% B from 0 to 15 min; then

dx.doi.org/10.1021/jf501351r | J. Agric. Food Chem. 2014, 62, 4632−4642

100% B from 15 to 16 min; to 85% B from 16 to 16.5 min; then 85% B from 16.5 to 20 min). A total of seven runs resulted in 73 mg of M2″ (t_R 8.13 min).

Nuclear Magnetic Resonance (NMR). ^{1}H (600 MHz), and ^{13}C (150 MHz) NMR spectra of M2′ and M2″ in CD_3OD were acquired on a Bruker AVANCE 600 MHz NMR spectrometer (Bruker, Inc., Silberstreifen, Rheinstetten, Germany). The ^{1}H and ^{13}C NMR data of M2′ and M2″ are listed in Table 1.

Metabolism of 8S, 10S, M2′, and M2″ in Human Colon Cancer Cells. Cells (1.0×10^6) were plated in six-well culture plates and were allowed to attach for 24 h at 37 °C in 5% CO_2 incubator. Shogaol 8S or 10S in DMSO or the corresponding cysteine-conjugated metabolites M2′ and M2″ were diluted in McCoy's 5A medium (containing 10% fetal bovine serum, 1% penicillin/streptomycin, and 1% glutamine) to reach a final concentration of 10 μM and were incubated with different colon cancer cell lines (HCT-116 or HT-29). At different time points (0, 2, 4, 8, 24, and 48 h), 190 μL samples of supernatant were taken and transferred to vials containing 10 μL of 2% acetic acid to stabilize these compounds and their respective metabolites. An equal volume of acetonitrile was added to the samples before centrifugation. The supernatant was harvested, and the samples were then analyzed by HPLC-ECD.

Evaluation of Toxicity in Human Colon Cancer and Normal Colon Cells. Cell viability was determined by an MTT colorimetric assay as described previously.[27] Briefly, human colon fibroblast cells, CCD-18Co, or human colon cancer cells, HCT-116 or HT-29, were plated in 96-well microtiter plates with 3000 cells/well and allowed to attach for 24 h at 37 °C and 5% CO_2. The test compounds (in DMSO) were added to cell culture medium to desired final concentrations (final DMSO concentrations for control and treatments were 0.1%). After the cells were cultured for 24 h, the medium was aspirated, and cells were treated with 200 μL of fresh medium containing 2.41 mmol/L MTT. After incubation for 3 h at 37 °C, the medium containing MTT was aspirated, 100 μL of DMSO was added to solubilize the formazan precipitate, and the plates were shaken gently for an hour at room temperature. Absorbance values were derived from the plate reading at 550 nm on a Biotek (Winooski, VT) microtiter plate reader. The reading reflected the number of viable cells and was expressed as a percentage of viable cells in the control. CCD-18Co cells were grown in EMEM. Both HCT-116 and HT-29 cells were cultured in McCoy's 5A medium. All of the above media were supplemented with 10% fetal bovine serum, 1% penicillin/streptomycin, and 1% glutamine, and the cells were kept in a 37 °C incubator with 95% humidity and 5% CO_2.

Apoptosis Analysis. Apoptosis was determined by FACS analysis of propidium iodide (PI)-stained cells. In brief, cells were trypsinized, washed with cold phosphate-buffered saline (PBS), fixed in ice-cold 70% ethanol for 1 h, and then resuspended in 2 mL of PBS supplemented with 10 μL of RNase (100 mg/mL) and incubated at 37 °C for 30 min. After incubation, DNA was stained with 1 mg/mL PI in PBS. Cell staining was analyzed using a Cell Lab QuantaTM SC flow cytometer (Beckman Coulter, Danvers, MA), and data were processed using FCS Express software (DeNovo Software, Los Angeles, CA). The percentage of apoptotic cells in each sample was determined based on the sub-G_0 peaks detected in monoparametric histograms.

Measurement of Reactive Oxygen Species. This assay employed the cell-permeable fluorogenic probe 2′,7′-dichlorodihydrofluorescein diacetate [DCFH-DA] (Sigma-Aldrich, St. Louis, MO) to measure the relative changes in O_2^- and H_2O_2 levels in HCT-116 or HT-29 cells after treatment with 5, 10, and 20 μM 6S or M2 (or DMSO) over 0, 2, 4, 8, and 24 h. In brief, DCFH-DA is diffused into cells and is deacetylated by cellular esterases to nonfluorescent 2′,7′-dichlorodihydrofluorescein (DCFH), which is rapidly oxidized to highly fluorescent 2′,7′-dichlorofluorescein (DCF) by intracellular hydrogen peroxide or other low molecular weight peroxides.[13,28] Measured fluorescence intensity is thus proportional to the amount of such peroxides in the cell at a given time. Human colon cancer cells HCT-116 or HT-29 were seeded in 96-well black-sided, clear-bottomed culture plates, with 5000 cells/well and were allowed to adhere for 24 h in a 37 °C incubator with 5% CO_2. Media was aspirated, and 5, 10, or 20 μM M2, 6S, or DMSO diluted in media was added to designated wells, which were run in triplicate. After desired incubation times of 0, 2, 4, 8, or 24 h, media and test compounds were aspirated. Cells were washed three times with 200 μL of PBS before addition of 100 μL of 1 mM DCFH-DA. The fluorogenic probe permeated cell membranes and was processed to DCF for 1 h at 37 °C. After incubation, plates were immediately placed in a Biotek microplate reader to measure fluorescence at wavelengths of 485 (excitation) and 528 (emission). Raw values were normalized to DMSO control for each time point and are presented as fold induction versus 0 h time point (n = 3).

Western Blot Analysis. Cell lysates were prepared in ice-cold RIPA lysis buffer [25 mM Tris-HCl (pH 7.6), 150 mM NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% SDS, Thermo Fisher Scientific] supplemented with a protease inhibitor cocktail (AEBSF, aprotinin, bestatin, E-64, leupeptin, and pepstatin A in DMSO with EDTA, Thermo Fisher Scientific). Protein content was measured by a Pierce BCA Assay Kit (Thermo Fisher Scientific). Protein contents of cell lysates (30 μg of protein/lane) were resolved by SDS-PAGE. Proteins were then electro-transferred onto PVDF membranes, and blots were blocked for 1 h at room temperature in 1 × TBS with 1% casein (Bio-Rad Laboratories, Berkeley, CA). Blots were then incubated overnight at 4 °C with the desired primary antibody diluted in TBS with 0.5% Tween-20. Blots were then washed with TBS-Tween 20 and probed for 1 h with the appropriate secondary antibody (1:1000). Protein bands were visualized with chemiluminescence using West Femto maximum detection substrate (Thermo Fisher Scientific). To confirm equal protein loading in each lane, immunoblots were stripped and reprobed for β-actin. Protein fold-induction was calculated by normalizing the intensity of the band of interest to β-actin first and then to DMSO control lanes.

Colony Formation Assay. Human colon cancer cells HCT-116 or HT-29 (1000 cells per well) were seeded in 6-well culture plates for 24 h and then incubated with M2 (0, 1, 5, 10, 20, or 40 μM) in DMSO in a 37 °C incubator with 5% CO_2. After 2 weeks, colonies were washed with phosphate-buffered saline (PBS), then stained with a mixture of 6.0% glutaradehyde and 0.5% crystal violet for 30 min at room temperature, rinsed in water, air-dried, and then photographed.

Statistical Analysis. Student's t-test or two-way analysis of variance (ANOVA) with the Bonferroni post-test were used to determine the statistical significance of data, which was performed on GraphPad Prism version 5.00 for Windows (GraphPad Software, San Diego, CA).

RESULTS

Synthesis and Structure Elucidation of M2′ and M2″. A similar experimental procedure was used for the syntheses of M2′ and M2″ as the previous protocol used for M2.[13] M2′ showed the molecular formula $C_{22}H_{35}NO_5S$ on the basis of positive ESI-MS at m/z 426 $[M + H]^+$ and its ^{1}H and ^{13}C NMR data. The molecular weight of M2′ was 121 mass units more than that of 8S (MW 304), indicating that M2′ was the cysteine-conjugated 8S, which is an expected result from the reaction between 8S and L-cysteine. This was also supported by the observation of the absence of a double bond in the ^{1}H and ^{13}C NMR spectra of M2′. Therefore, M2′ was confirmed to be 5-cysteinyl-8S. In the same way, M2″ was identified as 5-cysteinyl-10S, based on its positive ESI-MS at m/z 454 $[M + H]^+$ and its ^{1}H and ^{13}C NMR data (Table 1).

M2′ and M2″ Give Similar Metabolic Profiles as Their Parent Compounds 8S and 10S. Recent work in our group has focused on the biotransformation of the cysteine-conjugated metabolite of 6S, M2. The metabolic profiles of M2 in cancer cells HCT-116 and H-1299 resembled those of 6S, indicating that its biotransformation route was initiated by deconjugation.[23] Evidence supporting the identification of M2′ and M2″ as carriers of their respective shogaols is presented in

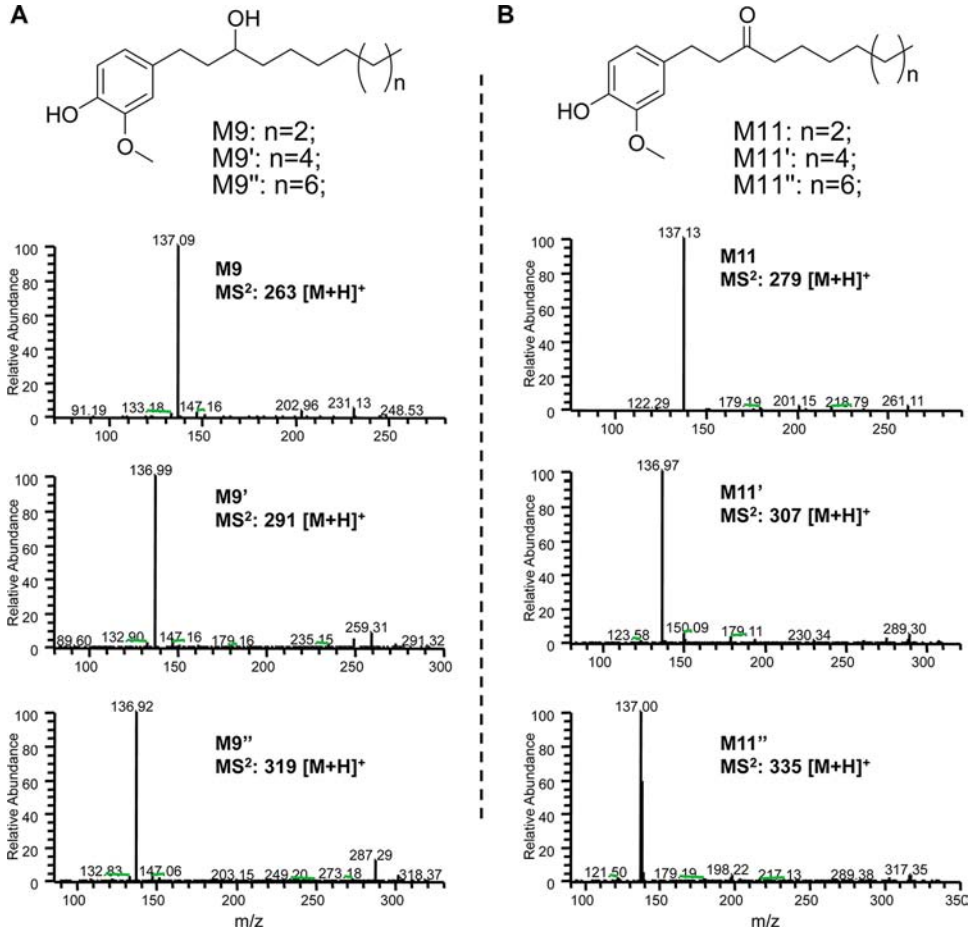

Figure 2. Chemical structures and MS/MS spectra of M9, M9′, and M9″ (A) and M11, M11′, and M11″ (B).

Figure 1, in which the metabolic profiles of 8S and 10S in human colon fibroblast cells CCD18Co (Figure 1C,F) or human colon cancer cells HCT-116 (Figure 1D,G) and HT-29 (Figure 1E,H) are compared with the profiles of M2′ and M2″ in the same respective cell lines. Upon removal of the cysteine residue, which occurs after less than 2 h of treatment, M2′ and M2″ are metabolized in an almost identical fashion as their parent shogaols. We have reported that M9 and M11 are the major metabolites of 6S in cancer cells; M11 is the double bond reduced metabolite of 6S, and M9 is the ketone group reduced metabolite of M11.[19] In the present study, reduced products were also identified as the major metabolites of 8S and 10S in human colon fibroblast cells and cancer cells, M9′ and M11′ for 8S and M9″ and M11″ for 10S. Their structures were confirmed by comparing their MS/MS spectra with those of M9 and M11 (Figure 2).

M2′ and M2″ Exert Similar Bioactivities as Their Parent Compounds 8S and 10S. We have reported that M2 has low toxicity in normal human fibroblast colon and lung cells while still remaining toxic against colon cancer and lung cancer cells.[13] As the structure of the cysteine-conjugated metabolites of 8S and 10S only differ from 6S by their respective increases in side chain length, we hypothesized that M2′ and M2″ should have similar activities compared with their parent molecules as M2 has compared with 6S.

Our results from measurement of cell viability by MTT assay show that 8S and 10S and their respective cysteine-conjugated metabolites M2′ and M2″ have low toxicity in normal colon cells CCD-18Co (Figure 3A), with IC_{50} values of 104.66 and 135.53 μM for 8S and 10S, respectively, and IC_{50} values greater than 200 μM for M2′ and M2″. All compounds were highly potent against human colon cancer cells HCT-116 (Figure 3B) and HT-29 (Figure 3C), with slightly different efficacy profiles between the two types of cells. M2′ and M2″ show higher activity against HCT-116 than their parent molecules, with IC_{50} values of 15.21 and 13.28 μM, respectively, versus values of 22.8 and 25.09 μM for 8S and 10S, respectively. Similar results were observed in the *p53* mutant HT-29 cell line, albeit slightly more resistant to treatment from all compounds. The IC_{50} values for 8S and 10S, 27.88 and 23.92 μM, were about 10−16% lower than those for M2′ and M2″, at 31.15 and 28.75 μM, respectively.

M2 Induces Apoptosis in Human Colon Cancer Cells HCT-116 and HT-29. In order to compare the biological similarities of M2, M2′, and M2″, we first needed to acquire a more accurate view of the mechanisms of action of M2. To study the impact of M2 on induction of apoptosis in both HCT-116 and HT-29 colon cancer cells, the percent of apoptotic cells were quantified after 24 h treatment of increasing doses of M2 (Figure 3D). A dose-dependent effect of M2 was observed with HCT-116 cells being notably more sensitive to M2 treatment than HT-29 cells. Treatment with 40 μM M2 gave the greatest induction of apoptosis in HCT-116 and HT-29 cells, with 26.34% or 14.38% apoptotic cells, respectively. The 10 and 20 μM treatments also yielded twice as many apoptotic HCT-116 cells compared with HT-29 cells (Figure 3D).

dx.doi.org/10.1021/jf501351r | J. Agric. Food Chem. 2014, 62, 4632−4642

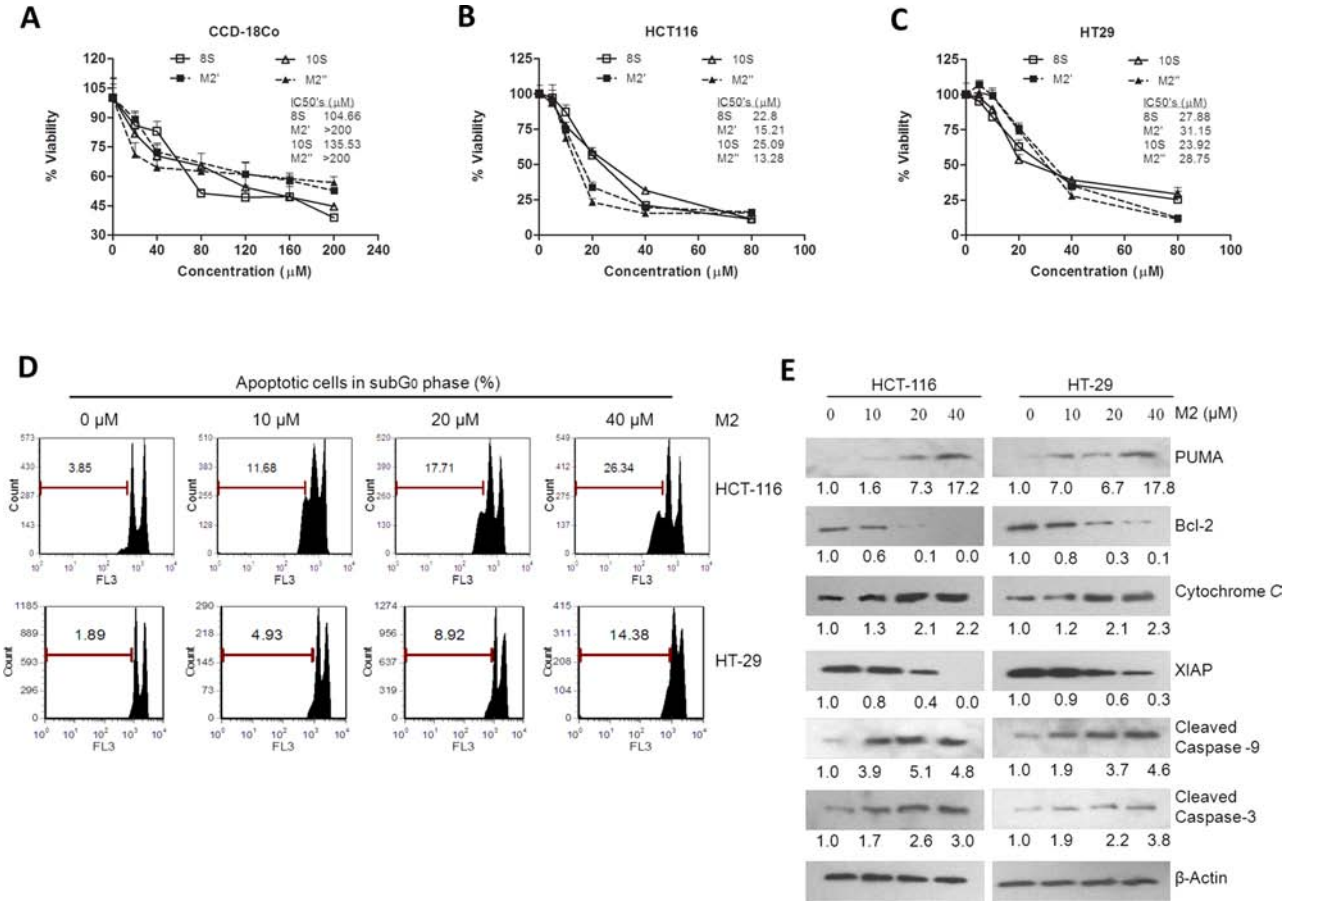

Figure 3. M2′ and M2″ remain bioactive to human colon cancer cells but less toxic to human normal colon cells than 8S and 10S and M2 induces apoptosis on HCT-116 and HT-29 human colon cancer cells. Growth inhibitory effects of 8S, M2′, 10S, and M2″ against human normal colon cells CCD-18Co (A) and human colon cancer cells HCT-116 (B) and HT-29 (C) treated with 8S, M2′, 10S, or M2″ for 24 h at different doses (n = 6) (measured by MTT assay). (D) Effect of M2 on apoptosis in human colon cancer cells HCT-116 and HT-29 treated with M2 (0, 10, 20, and 40 μM) for 24 h measured by PI staining; data represent mean ± SD. (E) Western blot analysis of HCT-116 and HT-29 cell extracts treated with DMSO, 10, 20, and 40 μM of M2 for 24 h. Fold induction for each marker compared with DMSO is indicated under the corresponding line.

Induction of apoptosis was further confirmed by Western blot analysis of markers of the intrinsic mitochondrial apoptosis pathway (Figure 3E). Increasing doses of M2 led to PUMA induction (up to ∼17-fold increase in both cell lines when treated with 40 μM M2) and progressive reduction of Bcl-2 levels (undetectable in HCT-116 and ∼0.1-fold in HT-29 cells when treated with 40 μM M2). We detected a progressive increase in cytochrome c release with increasing doses of M2 (up to ∼2.2-fold increase in both cell lines when treated with 40 μM M2). We also observed a clear, progressive reduction in XIAP expression with increasing doses of M2 (undetectable in HCT-116 and ∼0.3-fold in HT-29 cells when treated with 40 μM M2). Finally, increasing concentration of the cleaved forms of caspase 9 (up to ∼4.6-fold increase in both cell lines when treated with 40 μM M2) and caspase 3 (∼3−4-fold increase in both cell lines when treated with 40 μM M2) were detected with increasing doses of M2. Overall, these results show that markers of the mitochondrial pathway (PUMA, Bcl-2) of apoptosis were activated upon exposure to M2 and ultimately led to the release of the corresponding apoptosis markers (cytochrome c, cleaved caspases 3 and 9).

8S, 10S, M2′, and M2″ Activate Apoptosis. Our results on M2′ and M2″ are consistent with our previous observation that M2 has low toxicity in normal colon cells while still retaining strikingly similar potency to 6S in cancer cell growth inhibition.[13] Thus, we could tentatively propose that M2′ and M2″ have similar biological roles as the function we previously proposed for M2, as low toxicity carriers of parent molecular 8S and 10S to active sites, where function is restored upon removal of the cysteine group.[23] To verify this hypothesis, we studied the apoptotic markers modulated by M2 (described Figure 3E) in HCT-116 and HT-29 cells treated with 8S, M2′, 10S, or M2″ for 24 h. We chose a dose of 20 μM since it is close to the IC_{50} values of all compounds.

Screening of the markers modulated by the pro-apoptotic activity of M2 gave similar results for 8S and 10S and their respective cysteine-conjugated metabolites M2′ and M2″(Figure 4A). In other words, PUMA and cleaved caspase-3 were up-regulated, with concomitant down-regulation of Bcl-2. The changes in marker expression was observed in both cell lines in a nearly identical amplitude between the parent compound and its corresponding metabolite.

Shogaols and Their Cysteine-Conjugated Metabolites Affect Wild-Type and Mutant *p53* Expression in Human Colon Cancer Cells HCT-116 and HT-29. Since we established that the cysteine-conjugated shogaols could activate apoptosis through the same pathway, we wanted to further study their mechanisms of action using 6S and its metabolite M2 as a model. We established that PUMA, a transcriptional target of p53, accumulated almost identically in *p53* wild-type

dx.doi.org/10.1021/jf501351r | J. Agric. Food Chem. 2014, 62, 4632−4642

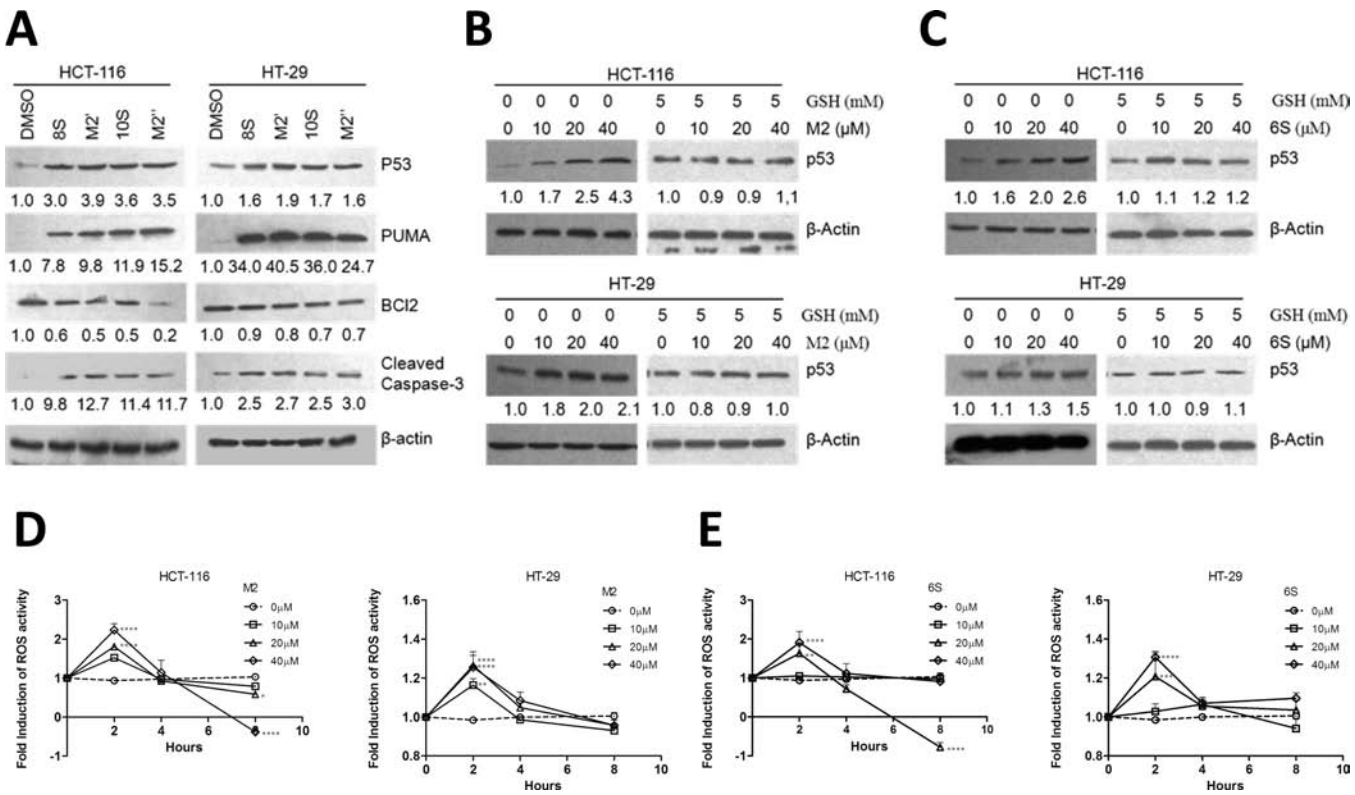

Figure 4. Cysteine conjugated shogaols induce apoptosis via oxidative stress-mediated p53 pathway. Western blot analysis of HCT-116 or HT-29 cell extracts treated with DMSO or 20 μM of 8S, M2′, 10S, or M2″ for 24 h on apoptosis-related protein (A) or with 0, 10, 20, and 40 μM of M2 or 6S on p53 expression with or without the presence of GSH (5 mM) (B and C). Protein levels were relatively quantitated by densitometric analysis using β-actin as a loading control. Fold induction for each marker compared with DMSO is indicated under the corresponding line. (D, E) Induction of ROS by M2 or 6S. HCT-116 and HT-29 cells were treated with indicated concentrations of 6S or M2 for different time periods, and the intracellular ROS levels were determined as described under Materials and Methods. (*$p < 0.05$, **$p < 0.01$, ***$p < 0.001$, and ****$p < 0.0001$).

HCT-116 and *p53* mutant HT-29 cell lines, with both showing greater than 17-fold induction of PUMA after 24 h treatment with 40 μM M2 (Figure 3E). To study the impact of M2 on p53 regulation in human colon cancer cells and its dependency on p53 integrity, *p53* wild-type HCT-116 or *p53* mutant HT-29 cells were cultured with M2 or 6S for 24 h at concentrations of 10, 20, or 40 μM. The p53 response in colon cancer cells to 6S treatment (10, 20, or 40 μM for 24 h) was observed in HCT-116 and HT-29. After M2 or 6S treatment, a dose-dependent up-regulation of p53 is noted in both wild-type and mutant cancer cell lines (Figure 4B,C), indicating that M2 or 6S regulation of p53 does not require a wild-type gene, although induction of p53 expression by M2 or 6S is dramatic in HCT-116 cells and slightly less striking (but still significant) in HT-29 cells (Figure 4B,C). Consistent with our premise, we then studied p53 expression in HCT-116 and HT-29 cells after exposure to 20 μM of 8S, M2′, 10S, or M2″. We observed an increase in p53 accumulation for all compounds (Figure 4A). The cysteine-conjugated metabolites were able to increase p53 accumulation in a similar manner to their parent compound.

6S and Its Cysteine-Conjugated Metabolite M2 Affect Reactive Oxygen Species Generation in Human Colon Cancer Cells HCT-116 and HT-29. Our observations up to this point indicated that M2 induces apoptosis in colon cancer cells through modulation of p53 expression and subsequent activation of the mitochondrial apoptotic pathway through PUMA and Bcl-2. However, the mechanism triggering the p53 accumulation was still unclear. Because overabundance of reactive oxygen species has been implicated as a genotoxic stressor and trigger for p53 activation,[29−33] we observed the production of ROS by M2 (compared with parent compound 6S for reference) in HCT-116 and HT-29 cells. As shown in Figure 4D,E, the trends of ROS induction by both M2 and 6S are strikingly similar, with the greatest peak at 2 h after treatment and a steady decline thereafter, which is consistent with the changes of glutathione levels in cancer cells that we reported previously.[23] In this case, treatment of HCT-116 cells with 40 μM M2 produced the greatest ROS activity after 2 h, with greater than 2-fold induction (with statistical significance, $p < 0.0001$). The scales of induction of ROS by M2 or 6S are parallel to the p53 induction response in the two respective cell lines. That is, in HCT-116 cells, ROS activity is induced 2-fold or greater by M2 or 6S treatment, while in HT-29 cells, ROS activity is induced less than 1.5-fold.

To demonstrate that ROS induction was indeed the trigger to p53 accumulation, we treated HCT-116 and HT-29 cells for 24 h with M2 or 6S (10, 20, or 40 μM) and supplemented with 5 mM GSH in order to suppress ROS accumulation in the cells. As shown on Figure 4B,C, addition of GSH suppressed p53 induction in both cell lines for all concentrations of M2 or 6S, establishing that p53 does not accumulate if there is no ROS generation.

M2 Inhibits Colony Formation in Human Colon Cancer Cells HCT-116 and HT-29. While we established that the cysteine conjugate of 6S can activate apoptosis, it is possible that other mechanisms leading to cancer cell death are triggered, especially in light of the specific activation of the multiacting p53. Since p53 is one of the major regulators of the

dx.doi.org/10.1021/jf501351r | J. Agric. Food Chem. 2014, 62, 4632−4642

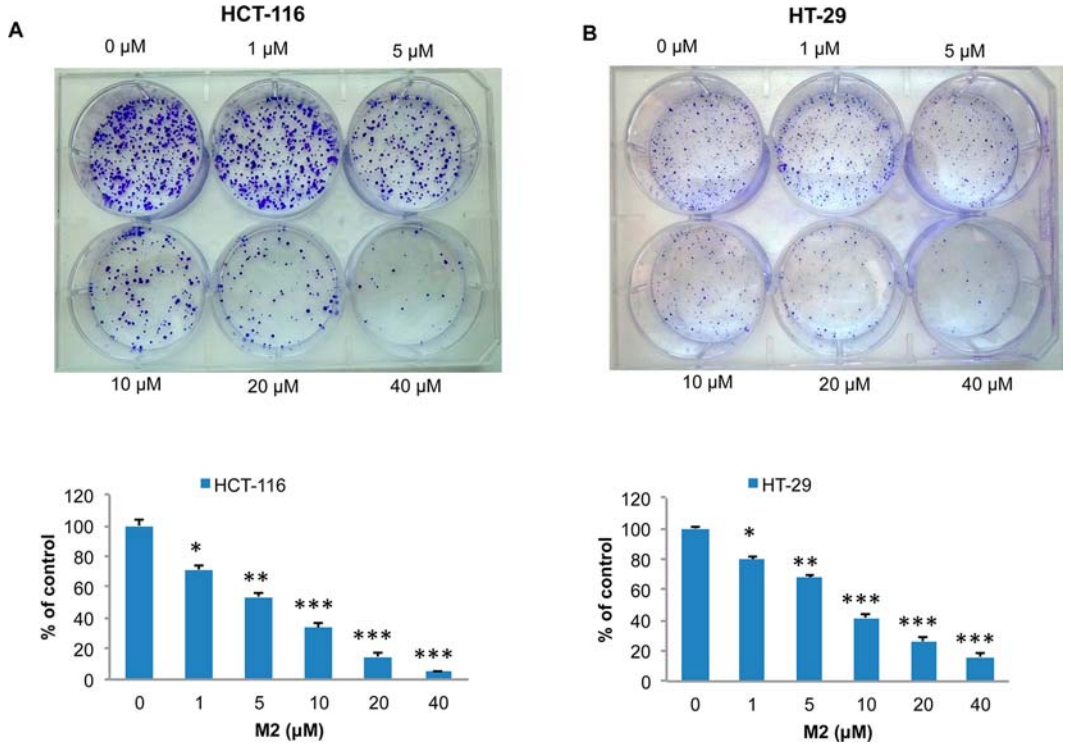

Figure 5. Dose dependent inhibition of human colon cancer cell colony formation by M2 in HCT-116 (A) and HT-29 (B) cells. HCT-116 (A) and HT-29 (B) cells were treated with M2 (0, 1, 5, 10, 20, and 40 μM) and incubated in 6-well plates for 2 weeks, and the cells were then stained with crystal violet and counted for colony formation. Each column represents a mean ± SD (n = 3; *p < 0.05; **p < 0.01; ***p < 0.001).

cell cycle, we further investigated the potential of our cysteine conjugated metabolites to inhibit cancer cell proliferation, using a colony assay and M2 as a model. Human colon cancer cells HCT-116 (Figure 5A) and HT-29 (Figure 5B) were treated with M2 with doses ranging from 0 to 40 μM for 2 weeks. Inhibition of colony formation was observed in a dose-dependent manner in both cell lines, with 50% inhibition between 5 and 10 μM treatments. Following a trend underlined previously, HCT-116 cells are slightly more sensitive to M2 than HT-29 cells.

DISCUSSION

There is currently considerable interest in developing cancer therapeutics and preventive agents from dietary sources, with extensive research over the past few decades focusing on plant derivatives.[34−38] Ginger has been comprehensively studied in recent years for its chemopreventive properties, particularly against colorectal cancer.[39−42] Our group and others have identified active constituents of ginger, with our most recent focus on shogaols, especially 6S.[12,13,19,20,23,39,43,44] The metabolism and biotransformation of 6S was investigated thoroughly, providing further insight into its means of exerting bioactivity.[19] Upon testing the efficacy of the major metabolites of 6S, we found that 5-cysteinyl-conjugated 6S (M2) exerted strong antiproliferative activity against human colon cancer cells, while having significantly lessened toxicity in normal human colon cells.[13] Further, M2 was shown to act as a carrier of parent molecule 6S.[23] The discovery of M2 was via correlation of 6S metabolism as a highly electrophilic xenobiotic through the detoxifying mercapturic acid pathway (MAP). We also found that increased chain length of shogaols does not cause a departure from the MAP. M2′ and M2″ were identified as the major metabolites of 8S and 10S, respectively, from humans upon consumption of ginger tea.[21] The current study shows that M2′ and M2″ are the carriers of 8S and 10S, respectively, and have similar antiproliferative activity against human colon cancer cells and less toxicity in normal human colon cells to their respective parent compounds. Our results clearly indicate that this portion of phase II metabolism transforms electrophiles to less reactive and more water-soluble intermediates, thus aiding in their mobility and decreasing their toxicity en route.[45]

It has already been established through many studies that 6S induces apoptosis in cancer cells via several pathways,[12−15] and thus our focus was to identify the pathway that encompasses the mode of activity of M2. We demonstrated that M2 treatment could induce ROS generation, which in turn up-regulated p53 expression and induced apoptosis through the mitochondrial pathway. This proposed mechanism is summarized in Figure 6. Since tumor suppressor gene *p53* is one of the most frequent mutations in cancers, leading to resistance to pharmacological interventions and more aggressive progression,[46−49] we were interested in testing the efficacy of M2 in wild-type *p53* HCT-116 human colon cancer cells as well as mutant *p53* HT-29 human colon cancer cells. In what could be a fortunate outcome for the putative roles of ginger constituents and metabolites toward chemoprevention, M2 induced apoptosis in both cell lines. It is notable that although the p53 pro-apoptotic pathway was exploited for at least some of M2's bioactivity and that we observed a general trend of superior bioactivity in HCT-116 cells, the metabolite's efficacy was ultimately not compromised by *p53* mutation. This is particularly attractive in terms of cancer chemoprevention, since it suggests that the cysteine-conjugated metabolite of 6S would still be able to activate a p53 apoptotic response even in cancer cells containing mutations of the *p53* gene.

dx.doi.org/10.1021/jf501351r | J. Agric. Food Chem. 2014, 62, 4632−4642

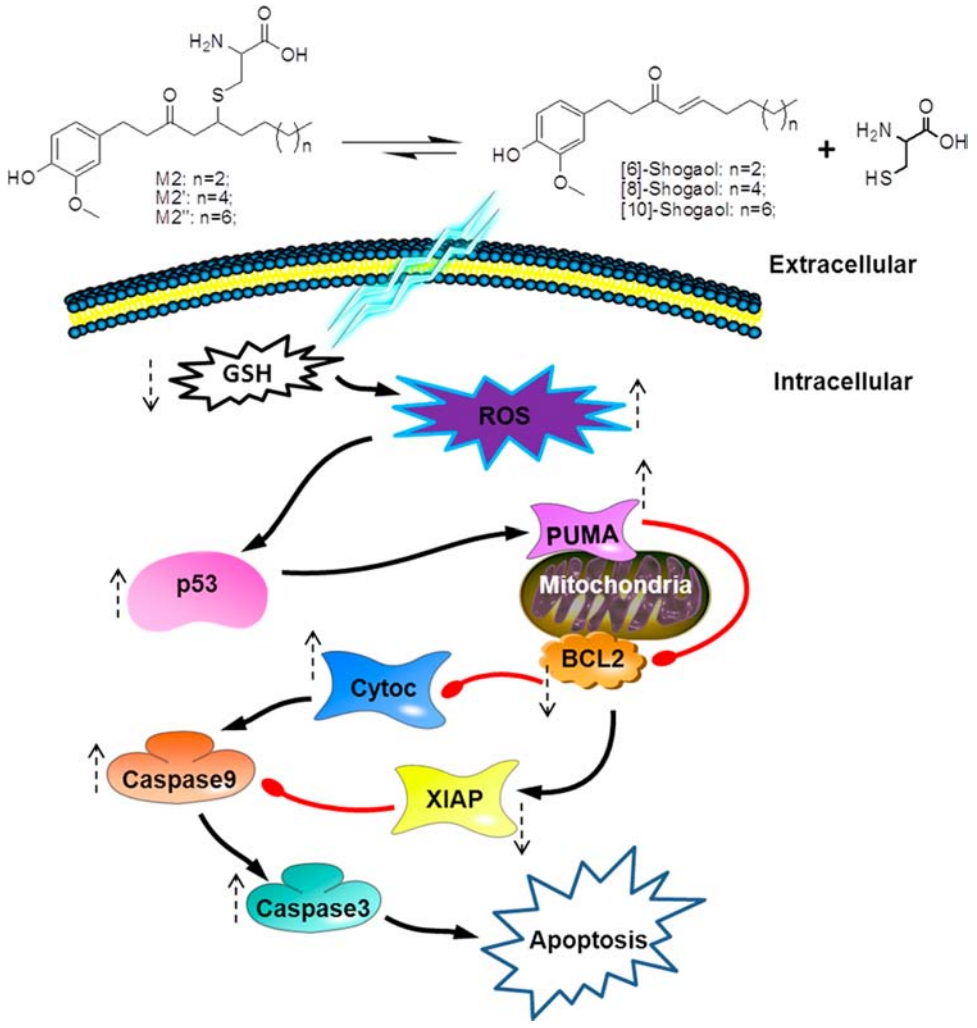

Figure 6. Schematic representation of the mechanisms of action of shogaols and their cysteine-conjugated metabolites in regulating apoptosis by p53 induction, activation of PUMA via p53 translocation to the mitochrondrial surface, Bcl-2 down-regulation, cytochrome *c* release, XIAP inhibition, and finally caspases 9 and 3 activation and cleavage.

A commonly proposed p53-induced apoptosis mechanism involves direct interaction with Bcl-2 family members and down-regulation of antiapoptotic genes, such as Bcl-2, which was also noted in the current study.[47,50−52] Both HCT-116 and HT-29 human colon cancer cells experienced a dramatic down-regulation of Bcl-2 after M2 treatment. Interestingly, PUMA, a transcriptional target of p53,[53] was also up-regulated in both colon cancer cell lines after treatment with M2. Upon a transcriptionally induced signal from p53, PUMA assists in promoting apoptosis by disrupting the association restraints Bcl-xL exerts on p53, thus liberating the molecule to exert pro-apoptotic activity, but binding to Bcl-xL in the process.[54] This evidence supports the strong role of M2 as a chemopreventive agent against colon cancer cells that induces p53 expression and downstream regulation.

Treatment of colon cancer cells HCT-116 and HT-29 with M2 in this study lead to apoptosis, through early production of reactive oxygen species. Overabundance of ROS combined with a cancer cell's reduced detoxification ability can often lead to oxidative stress sufficient to induce programmed cell death.[55] Apoptosis induced by p53 is at least partially dependent upon accumulation of ROS,[56] and we demonstrated this to be also true in our model. Therefore, we can conclude that M2 causes p53 induction of apoptosis via ROS production in both HCT-116 and HT-29 human colon cancer cells. Since we demonstrated that the other metabolites M2′ and M2″ activate similar markers of apoptosis (Figure 4A) and contain the same chemical reactivity as M2, it is reasonable to conclude that these metabolites would behave in a similar way and could also activate cancer cell apoptosis through ROS induction and the subsequent p53 accumulation. In addition, we also demonstrated that M2 does not exclusively induce cancer cell death through apoptosis and can also influence other major mechanisms such as cell proliferation (Figure 5); it follows that other cysteine conjugated metabolites originating from the same MAP have that potential as well. These compounds are worthy of further investigation, and further studies could examine commonly consumed ginger mixtures containing these compounds for more direct translation of these data to *in vivo* dietary models.

Ginger components are highly lauded for their vast and varied chemopreventive properties. Because shogaols have been proven as highly effective anticancer agents, the continued study of their mechanisms of activity can allow us to discover novel anticancer targets. Further, investigation of the metabolic products of shogaols can provide new therapeutic routes that are less toxic, while retaining high efficacy. This study has shown that cysteine-conjugated shogaols are novel compounds

with a putative role as natural pharmaceuticals with low-toxicity, high-potency, and at least partial indifference to *p53* integrity in colon cancer cells.

ABSTRACT: Pomelo peel is an abundant pectin-rich biomass waste in China and has the potential to serve as a source of fuels and chemicals. This study reports a promising way to deal with pomelo peel waste and to utilize it as raw material for ethanol production via simultaneous saccharification and fermentation (SSF). An integrated strategy, incorporating hydrothermal treatment, multienzyme formulation, and fed-batch operation, was further developed to enhance the ethanol production. The results show that hydrothermal treatment (120 °C, 15 min) could significantly reduce the use of cellulase (from 7 to 3.8 FPU g^{-1}) and pectinase (from 20 to 10 U g^{-1}). A multienzyme complex, which consists of cellulase, pectinase, β-glucosidase, and xylanase, was also proven to be effective to improve the hydrolysis of pretreated pomelo peel, leading to higher concentrations of fermentative sugars (36 vs 14 g L^{-1}) and galacturonic acid (23 vs 9 g L^{-1}) than those with the use of a single enzyme. Furthermore, to increase the final ethanol concentration, fed-batch operation by adding fresh substrate was employed in the SSF process. A final solid loading of 25% (w/v), which is achieved by adding 15% fresh substrate to the SSF system at an initial solid loading of 10%, produced 36 g L^{-1} ethanol product in good yield (73.5%). The ethanol concentration is about 1.73-fold that at the maximum solid loading of 14% for batch operation, whereas both of them have a closed ethanol yield. The results indicate that the use of the fed-batch mode could alleviate the decrease in ethanol yield at high solid loading, which is caused by significant mass transfer limitation and increased inhibition of toxic compounds in the SSF process. The integrated strategy demonstrated in this work could open a new avenue for dealing with pectin-rich biomass wastes and utilization of the wastes to produce ethanol.

KEYWORDS: *pomelo peel, ethanol, cellulase, pectinase, enzymatic hydrolysis, SSF*

INTRODUCTION

Citrus production and consumption worldwide have grown strongly over the past few decades. According to the statistical data from the Food and Agriculture Organization of the United Nations (FAOSTAT), the world production of citrus fruits in 2010 was over 100 million tons.[1] With the heavy consumption of these fruits (e.g., juice/sugar production), a large amount of citrus waste is generated, which accounts for about 50% of the fruit weight. The wastes include fruit peel, membrane residues, and other byproducts.[2] Traditionally, the wastes are disposed of through a burning process or used as raw material for active substance extraction and animal feed manufacturing.[3−6] However, these means are not satisfactory as the market demand may be limited or secondary contamination and low-value products result. Up to now, the majority of citrus wastes are still deposited or disposed of simply as mentioned before, leading to serious environmental pollution and great wastage of resources. Therefore, it is highly desirable to develop green and economical ways to deal with citrus wastes, as well as to utilize the wastes to produce staple or value-added products.

Citrus wastes mainly consist of soluble mono- and disaccharides (e.g., glucose, fructose, sucrose), insoluble polysaccharides (e.g., cellulose, hemicellulose, pectin), and lignin.[7] This chemical composition renders the wastes to be a potential candidate for the production of biofuels and other sugar-based chemicals.[2,8] Ethanol, being one of the most promising biofuels, has received great attention with the increasing fuel demand and environmental concerns globally. In recent years, much effort has been invested to develop second-generation ethanol fuel from nonfood crops. Most of this research focuses on the use of recalcitrant lignocellulosic biomass, such as corn cobs,[9,10] corn stover,[11−13] wood chips,[14,15] switchgrass,[16] and rice straw,[17] due to their large-scale availability and low raw material cost. In these cases, the high content of lignin and the recalcitrant structure of these feedstocks greatly hinder enzymatic hydrolysis and fermentation. Generally, harsh pretreatment and high enzyme loading are required in ethanol production. In comparison with recalcitrant lignocellulosic biomass, citrus wastes, such as citrus peel, contain less lignin and more pectin, which enable a facile hydrolysis of the wastes into fermentable sugars by the use of several hydrolytic enzymes in combination.[18,19] With the large sugar content generated from highly degradable polysaccharides and the elimination of harsh pretreatment, citrus wastes could prove to be an attractive source of bioethanol.[20] This

pomelo peel (this work)	16.50	6.86	35.42	3.16	12.62	4.14

study aims to provide a practical approach to utilize citrus wastes as biomass source for ethanol production.

In previous studies, citrus wastes from orange (*Citrus sinensis*),[21−25] Kinnow mandarins (*Citrus reticulata*),[26−28] and grapefruit (*Citrus paradisi*)[29] have been successfully used to produce ethanol via enzymatic hydrolysis and fermentation. As we know, the technological package (e.g., pretreatment, enzymatic hydrolysis, fermentation) utilized in ethanol production is generally specific to the feedstocks, due to the significant structural differences among various biomass materials. The technology, together with the properties of the feedstock (e.g., degradability, availability, locality, price), determine the economic feasibility of ethanol production. Pomelo (*Citrus maxima*), a characteristic fruit of China, has a large annual production of >2 million tons (pomelo and grapefruit production are estimated at 3.6 million tons in 2011 from FAOSTAT, with China being the largest producer). Pomelo has more peel and segment membrane than most other citrus fruits, generating a significant quantity of pomelo waste in China. However, to date, no report has discussed the utilization of these wastes for ethanol production.

Pomelo peel has a higher pectin content than other citrus wastes (see Table 1). Although pectin can be easily hydrolyzed, the high pectin content could still limit the hydrolysis of cellulose and hemicellulose because it acts as a physical barrier to restrict the access of enzymes to the substrate.[30] Furthermore, pectin can increase the viscosity of substrate slurry and limit mass transfer during hydrolysis and fermentation. The lower sugar content (~36%, including cellulose, hemicellulose, and soluble sugars) in pomelo peel as compared to other citrus wastes could also result in a lower final ethanol concentration. Therefore, to focus on using pomelo peel as the feedstock for ethanol production, it is essential to develop efficient and economic approaches to improve the hydrolysis efficiency and increase the final ethanol concentration.

Herein, we report a green and economical way to deal with pomelo peel waste and utilize it for ethanol production via a simultaneous saccharification and fermentation (SSF) process. An integrated strategy, incorporating hydrothermal treatment, multienzyme formulation, and fed-batch operation, was proposed to enhance ethanol production. Specifically, to reduce the enzyme dosage in the process, we introduced a simple hydrothermal treatment at a high temperature (120 °C) before performing SSF. Multienzyme formulation and fed-batch operation were further employed to improve the hydrolysis efficiency and increase the final ethanol concentration. In addition, the effects of the initial D-limonene concentration, pH value, and dry yeast concentration on ethanol production were also investigated.

MATERIALS AND METHODS

Chemicals, Enzymes, and Yeast. Glucose (>99.5%), cellobiose (>99%), sucrose (>99.5%), fructose (>99%), xylose (>99%), galactose (>99%), arabinose (>99%), rhamnose (>99%), and galacturonic acid (>97%) were purchased from Sigma. D-Limonene (>97%) was obtained from Aladdin Industrial Corp. (Shanghai, China). Cellulase (GC220, 123 FPU mL^{-1}) was purchased from Genencor International (Palo Alto, CA, USA) in 2009. Pectinase (Multifect pectinase, 597 U mL^{-1}) was graciously provided by Genencor International in 2009. Commercial ethanol instant active dry yeast powder (*Saccharomyces cerevisiae*, yeast cells concentration ~ 20 billion cells/g, water content ~ 6%) was purchased from Angel Yeast Co., Ltd. (Wuhan, China). All of the other chemicals, such as ethanol, sulfuric acid, hydrochloric acid, and oxalate ammonium, were of analytical grade and were obtained from commercial sources.

Sample Preparation. Mature yellow pomelos (*C. maxima*) were collected from a local fruit market in Tianjin, China. Pomelo peels were manually separated and washed with deionized water to remove any extraneous matter. Then the peels were cut into small pieces (~1 cm) and dried in a hot-air oven at 70 °C to a constant weight. The dried pomelo peels were ground to a fine powder (500−600 μm) using an electric mill and stored in an enclosed container for subsequent use.

Hydrothermal Treatment. To facilitate the operation of pretreatment and subsequent enzymatic hydrolysis or SSF, as well as to enhance the break of biomass structure, sodium acetate buffer (50 mM, pH 4.8) was chosen as acidic medium to pretreat pomelo peels. In a typical experiment, 10 g of dried pomelo peels was placed in a screw-capped laboratory bottle (Pyrex bottles) and mixed with sodium acetate buffer (50 mM, pH 4.8) solution at a final concentration of 10% (w/v). The solid/liquid slurry was then put into a stainless steel autoclave at 120 °C for 15 min. After cooling, the treated pomelo peels were directly used for subsequent enzymatic hydrolysis or SSF processing. To prepare the sample for compositional analysis, the solid residue after hydrothermal treatment was separated by filtering, washed with deionized water, and dried in a hot-air oven at 70 °C to a constant weight.

Enzymatic Hydrolysis by Multienzyme Complex. The pomelo peels were first treated under different solid loadings, 5, 7, 10, and 14% (w/v), according to the procedure mentioned above. After hydrothermal treatment, two commercial enzymes, GC220 and Multifect pectinase, were added into the resulting pomelo peel samples over loading ranges of 0−4.6 FPU g^{-1} dry matter (DM) and 0−25 U g^{-1} DM, respectively. Digestive reactions were carried out in an air-bath shaker at 150 rpm and 50 °C for the appropriate time. Five hundred microliter aliquots were taken out at different time points for high-performance liquid chromatography (HPLC) analysis. To investigate the effect of hydrothermal treatment on sugar release, raw pomelo peels without pretreatment were used as a control sample for enzymatic hydrolysis.

Ethanol Production via SSF Process. All of the SSF experiments with a loading volume of 30 mL were carried out in 100 mL glass bottles. The pomelo peels was mixed with sodium acetate buffer (50 mM, pH 4.8) containing 1 g L^{-1} $(NH_4)_2HPO_4$, 1 g L^{-1} $MgSO_4 \cdot 7H_2O$, and 2.0 g L^{-1} yeast extract at the desired initial DM concentrations (5−14%, w/v, based on the dry weight of raw pomelo peels). After hydrothermal treatment, GC220 (3.8 FPU g^{-1} DM) and Multifect pectinase (15 U g^{-1} DM) were added into the treated pomelo peel samples and then incubated at 50 °C for 10 h with continuous shaking

at 150 rpm. After prehydrolysis, the temperature was reduced to 30 °C, and the pH of the medium was controlled at 5.0. The initial pH of the prehydrolyzed medium was between 4.0 and 4.3, and sodium hydroxide was added to the mixture to adjust the pH. The SSF experiments were started by adding 2−6 g L^{-1} dry yeast at 30 °C and 150 rpm. The time of yeast addition was referred to as time zero. The experiments were run for another 48 h. Five hundred microliter aliquots were taken out at different time points for HPLC analysis (e.g., ethanol, sugars, galacturonic acid). After SSF processing, the residue solid was washed, filtered, dried, and weighed. Ethanol volumetric productivity (grams per liter per hour, g L^{-1} h^{-1}) was calculated as the ratio of the final ethanol concentration (g L^{-1}) to the fermentation time (h).

The fed-batch SSF experiments were started with an initial 10% solid loading. Another 10 or 15% dry matter was added during the SSF process, giving a final solid loading of 20 or 25%. The final solid loading of 20% is achieved by adding 0.6 g (3%, w/v), 0.6 g (3%), 0.6 g (3%), and 0.2 g (1%) of fresh pretreated pomelo peel at 8, 18, 24, and 30 h, respectively. The final solid loading of 25% is achieved by adding 0.6 g (3%, w/v), 0.6 g (3%), 0.6 g (3%), 0.5 g (2.5%) 0.5 g (2.5%), and 0.2 g (1%) fresh pretreated pomelo peel at 8, 18, 24, 30 , 36, and 42 h, respectively. The fermentation conditions, enzyme loadings, and nutrient concentrations were the same as in the batch experiments.

Analytical Methods. The ethanol-soluble fraction was extracted by using repeated extractions of pomelo peels at 10% solid-to-liquid ratio using 80% ethanol at 80 °C. All of the filtrate was collected and centrifuged at 13000 rpm for 10 min and then analyzed for sugars by using HPLC. The contents of cellulose, hemicellulose, lignin, and ash in pomelo peels were determined in accordance with the standardized methods of the National Renewable Energy Laboratory (NREL, Golden, CO, USA).[31] Pectin content was determined by sequential extraction of water (60 °C, 2 h, two times), 0.5% oxalate ammonium (60 °C, 2 h, two times), and 0.05 M HCl (80 °C, 1 h).[32] The extracts were recovered by filtration and precipitated by ethanol with 4 times volume, respectively. The resulting pectin were then dried and weighed. D-Limonene content in pomelo peels was estimated using the Scott oil method.[33]

Sugars, such as glucose, xylose, galactose, and arabinose, were quantified by a HPLC system (Agilent, USA) using a refractive index detector and Aminex HPX-87P column (Bio-Rad, Hercules, CA, USA) at 85 °C with ultrapure water as the mobile phase at a flow rate of 0.8 mL min^{-1}. Peaks were detected and quantified on the basis of the area and retention time of the sugar standards (e.g., sucrose, glucose, fructose, arabinose, galactose, xylose, and rhamnose). Ethanol and galacturonic acid were determined by HPLC equipped with a refractive index detector on an Aminex HPX-87H column (Bio-Rad) at 65 °C. The mobile phase was 0.005 mol L^{-1} sulfuric acid, and the flow rate was 0.6 mL min^{-1}. All of the samples were centrifuged and filtered through 0.45 μm membranes.

The activities of GC220 and Multifect pectinase were determined on the basis of the different substrates because both of them contain many different enzymes. Cellulase and β-glucosidase activities of enzymes were determined using filter paper and cellobiose as substrate, respectively, according to the methods suggested by Ghose.[34] Xylanase and pectinase activities (U mL^{-1}, 1 U = 1 μmol min^{-1} of substrate converted) of enzymes were assayed using birchwood xylan and polygalacturonic acid as substrate, respectively, as previously described.[35,36] The protein content in enzyme solution was measured using Bradford's method with bovine serum albumin as the standard.[37] Each datum was represented as the mean of three replicate analyses. Especially, cellulase activity (FPU mL^{-1}) and β-glucosidase activity (CBU mL^{-1}) were given by[34]

$$\text{cellulase activity} = \frac{0.37}{[\text{enzyme}]\ \text{releasing 2.0 mg of glucose}}\ \text{FPU mL}^{-1} \quad (1)$$

$$\beta\text{-glucosidase activity} = \frac{0.0926}{[\text{enzyme}]\ \text{releasing 1.0 mg of glucose}}\ \text{CBU mL}^{-1} \quad (2)$$

where [enzyme] represents the proportion of original enzyme solution present in the directly tested enzyme dilution.

RESULTS AND DISCUSSION

Chemical Composition of Pomelo Peel. We have determined the chemical composition of raw pomelo peel and its compositional changes after hydrothermal treatment. As shown in Figure 1, raw pomelo peel consists of cellulose

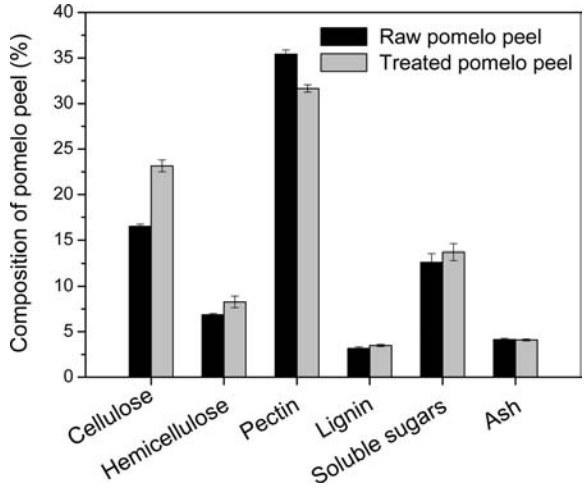

Figure 1. Compositional change of pomelo peel after hydrothermal treatment. Treatment conditions: solid loading 10% (w/v), 50 mM sodium acetate buffer (pH 4.8), 120 °C, 15 min.

(16.5%, based on dry matter), hemicellulose (6.86%), pectin (35.42%), lignin (3.16%), soluble sugars (12.62%), and ash (4.14%). Especially, the soluble sugars in ethanol extract are mainly composed of glucose (5.6% of dry matter) and fructose (6.9%). After treatment, the overall weight loss of solid components is 29.88%. Compositional analysis shows that the pectin content decreased to 31.65%, indicating the partial hydrolysis of pectin during the treatment. On the basis of the change in soluble sugars contents (12.62 vs 13.71%, Figure 1) and overall weight loss of solid components, we found that 23.8% of soluble sugars were released from solid fractions to liquid phase. In addition, cellulose and hemicellulose, generally, are difficult to be degraded during the treatment process (120 °C, 15 min). Their content in residual solid increased to 23.14 and 8.27% after treatment, respectively, remaining 98.2 and 84.4% of their initial weight in raw materials. In general, no significant change in chemical composition of pomelo peel was found during the hydrothermal treatment.

Enzymatic Hydrolysis of Pomelo Peel via Multi-enzyme Complex. In this study, two commercial enzymes, namely, GC220 and Multifect pectinase, were used to hydrolyze the pomelo peel waste. Protein concentrations and specific activities of the enzymes are presented in Table 2. GC220 has a high cellulase activity of 123 FPU mL^{-1}, and Multifect pectinase has a high pectinase activity of 597.4 U mL^{-1}. Both of them have β-glucosidase and xylanase activities, which are sufficient to degrade cellobiose and xylan, making the addition of β-glucosidase and xylanase for this hydrolysis process unnecessary. When the cellulase and pectinase loadings

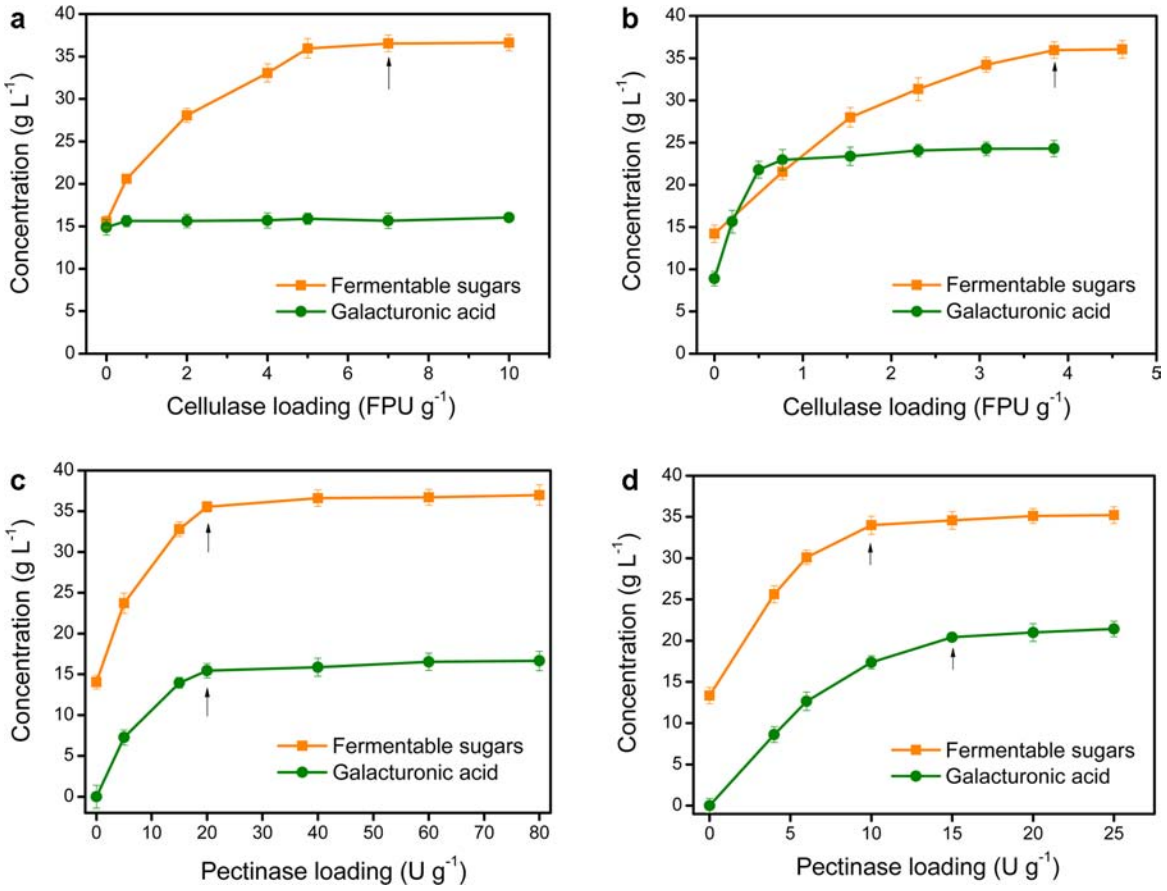

Figure 2. (a, b) Effect of cellulase loading on the release of fermentable sugars and galacturonic acid from raw pomelo peel (a) and treated pomelo peel (b) at 10% (w/v) solid concentration. Other default conditions unless otherwise noted: pectinase 20 U g^{-1}, pH 4.8, 50 °C, 150 rpm, 24 h. (c, d) Effect of pectinase loading on the release of fermentable sugars and galacturonic acid from raw pomelo peel (c) and treated pomelo peel (d) at 10% (w/v) solid concentration. Other default conditions unless otherwise noted: cellulase 3.8 FPU g^{-1}, pH 4.8, 50 °C, 150 rpm, 24 h.

were 3.8 FPU g^{-1} and 15 U g^{-1}, respectively, the hydrolysate after 24 h of reaction at 5% solid loading contained glucose (13.7 g L^{-1}), fructose (5.9 g L^{-1}), galactose (2.6 g L^{-1}), rhamnose (1.0 g L^{-1}), xylose (1.0 g L^{-1}), arabinose (1.3 g L^{-1}), and galacturonic acid (10.8 g L^{-1}). To calculate the sugars content for ethanol production, we defined the sum of glucose, fructose, galactose, and rhamnose as fermentable sugars, which can be transformed into ethanol by *S. cerevisiae*.

Figure 2 shows the effect of cellulase and pectinase loading on the release of fermentable sugars and galacturonic acid from pomelo peel at a 10% solid concentration. When the pectinase loading was 20 U g^{-1}, the concentrations of fermentable sugars increased with increasing cellulase loading for both untreated and treated pomelo peel (Figure 2a,b). The sugars concentration was measured at about 15 g L^{-1} only by using pectinase alone (zero points in Figure 2a,b). The increased fermentable sugars after cellulase addition are mainly attributed to the release of glucose from cellulose chains on the basis of the HPLC results (data not shown). In the case of treated pomelo peel, 3.8 FPU g^{-1} cellulase loading can produce a high sugar concentration (~36 g L^{-1}), and this loading is lower than that for raw pomelo peel (~7 FPU g^{-1}) to produce the same sugar concentration. In addition, the treated pomelo peel has a higher galacturonic acid concentration than raw pomelo peel (23 vs 15 g L^{-1}) at a low cellulase loading (e.g., 1 FPU g^{-1}). Generally, galacturonic acid is localized in pectic fractions of citrus peels.[38] Higher galacturonic acid concentration suggests that hydrothermal treatment together with cellulose degradation may allow pectinase to become more accessible to pectin and thus improve its hydrolysis.

The changes in the concentration of fermentative sugars and galacturonic acid with increasing pectinase loading are shown in Figure 2c,d, and the cellulase loading was kept at 3.8 FPU g^{-1}. When cellulase was used alone, the sugars concentration was about 14 g L^{-1} (zero points in Figure 2c,d), which mainly resulted from cellulose and hemicellulose. As the pectinase loading was increased to 20 U g^{-1}, the sugar concentration for raw pomelo peel increased to about 35 g L^{-1} (Figure 2c). It is noted that the same concentration can be reached using a lower enzyme loading of 10 U g^{-1} for pretreated pomelo peel sample (Figure 2d). The higher sugar concentration after pectinase addition is attributed to the release of glucose and galactose in pectin-branched chains, as well as the enhanced hydrolysis of cellulose and hemicellulose. On the other hand, the

concentration of galacturonic acid was directly correlated with pectinase loading. For raw and pretreated pomelo peel, the saturated pectinase dosages were 20 and 15 U g^{-1} respectively. These results indicate that the application of hydrothermal treatment could significantly reduce the use of cellulase (from 7 to 3.8 FPU g^{-1}) and pectinase (from 20 to 10 U g^{-1}). This treatment process, combined with a multienzyme complex, could further improve the hydrolysis of pectin and cellulose, leading to high concentrations of fermentative sugars (from 14 to 36 g L^{-1}) and galacturonic acid (from 9 to 23 g L^{-1}).

Enzymatic Hydrolysis of Pomelo Peel at High Solid Loadings. High concentrations of fermentable sugars are often required to obtain high ethanol concentrations. A promising approach to increase sugar concentrations involves the operation of enzymatic hydrolysis at high solid loadings. For pomelo peel, when the solid loading exceeded 14%, almost all of the buffer solution was absorbed. The high viscosity will prevent efficient mixing and mass transfer, resulting in more power consumption, poor solid and enzyme distribution, and localized product buildup. In this work, we investigated the enzymatic hydrolysis of pretreated pomelo peel over the solid loading range of 5−14%. As shown in Figure 3, the final

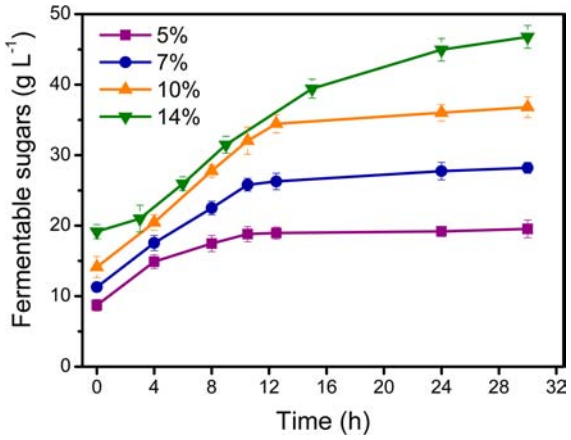

Figure 3. Time course of the release of fermentable sugars from pretreated pomelo peel at different solid loadings. Conditions: cellulase 3.8 FPU g^{-1}, pectinase 15 U g^{-1}, pH 4.8, 50 °C, 150 rpm.

concentrations of fermentable sugar obtained after 24 h of hydrolysis could reach 19, 28, 36, and 44 g L^{-1} at solid loadings of 5, 7, 10, and 14%, respectively. The hydrolysis rates were notably higher within the first 12 h of hydrolysis than at the later stage. The enzymatic hydrolysis could be nearly finished within 12 h when the solid loading was <10%. However, efficiency was reduced when the solid loading was at 14%, and >30 h was necessary for the entire hydrolysis reaction. The results suggest that high solid loading (e.g., 14%) could cause significant mass transfer limitation, leading to decreased hydrolysis efficiency. Therefore, in this case, a solid loading of 10% is appropriate for enzymatic hydrolysis of pomelo peel.

Ethanol Production from Pomelo Peel via a SSF Process. SSF is a promising process for ethanol production from lignocellulosic biomass due to its reduced catabolite repression, simplicity of operation, low capital investment, and improved process economics. In this study, we therefore employed SSF to produce ethanol using pectin-rich pomelo peel as substrate. Prior to the SSF process, a prehydrolysis operation was performed at 50 °C for 10 h with 3.8 FPU g^{-1} cellulase and 15 U g^{-1} pectinase loadings; the temperature was then reduced to 30 °C, and the yeast was added to initiate SSF process.

Previous studies had demonstrated that D-limonene in citrus wastes was toxic to yeast cells and thus reduced the alcoholic fermentation ability.[22] Therefore, citrus wastes are often required to remove D-limonene below inhibitory levels for yeasts prior to SSF. For example, steam explosion can be used to remove >90% of the D-limonene in citrus waste because it is highly volatile.[22] In this work, the hydrothermally treated pomelo peel contains 0.045% (v/w, of dry matter) D-limonene, which could lead to a maximum concentration of 0.0045% during the SSF process at a 10% solid loading. To determine the inhibition threshold amount of D-limonene to *S. cerevisiae*, we investigated the effect of initial concentration of D-limonene on ethanol production. The commercial D-limonene (97%) was added to pomelo peel at the beginning of SSF to achieve different D-limonene concentrations, ranging from 0.01 to 0.15% (v/v). As shown in Figure 4a, ethanol concentrations in fermentations decreased for initial D-limonene concentrations >0.06% (v/v). Because the D-limonene concentration in pomelo peel slurry (0.0045%) is much lower the critical value (0.06%), additional removal of D-limonene is not required in further study.

To obtain high alcoholic fermentation ability, two key operating parameters, the initial pH value and the yeast concentration, were optimized in this study. As shown in Figure 4b, the initial pH had a significant effect on both ethanol and galacturonic acid concentrations. Alcoholic fermentation at an initial pH of 4.5 produced the least ethanol. In this case, the final pH at the end of fermentation was 4.2. The result indicated that pH 4.2−4.5 greatly repressed yeast vitality and thus reduced the ethanol production. When the initial pH increased to 5.0 or 5.5, the final pH values in fermentation broth were 4.71 and 5.05, respectively. In both cases, we could obtain high ethanol concentrations within the pH range of 4.7−5.5. However, further increase of initial pH to ≥6.0 could reduce the ethanol yield. Meanwhile, we found that the galacturonic acid concentrations decreased as the pH increased, because pectinase is more effective at a lower pH (e.g., pH 4.5). Therefore, the initial pH of 5.0 is ideal for both *S. cerevisiae* and pectinase and was used in the following study.

A series of SSF experiments were further carried out using different dry yeast inoculations to determine the most appropriate yeast concentration. As shown in Figure 4c, when the yeast concentration was 2 g L^{-1}, 9.83 g L^{-1} ethanol was produced after 36 h of SSF process using 3.8 FPU g^{-1} cellulase and 15 U g^{-1} pectinase loadings. Final ethanol levels increased with increasing yeast concentration up to 5 g L^{-1}. When using 5 g L^{-1} yeast, we obtained 17.3 g L^{-1} ethanol product after 36 h of SSF. Nevertheless, as the yeast amount reached 6 g L^{-1}, the production rate and concentration of ethanol decreased. This finding can be explained by increased sugar consumption for cell growth under an oxygen circumstance and a large amount of seed.

During the SSF process, glucose, fructose, and galactose can be fermented to ethanol by *S. cerevisiae* cells (no sucrose was detected in the samples). The glucose consumption rate is higher than that of fructose and galactose.[26] The maximum concentration of fermentable sugars was 38.4 g L^{-1} at a 10% solid loading. A theoretical ethanol concentration of 19.6 g L^{-1} could be obtained if all fermentable sugars were fermented to ethanol. Using the optimized parameters as described before,

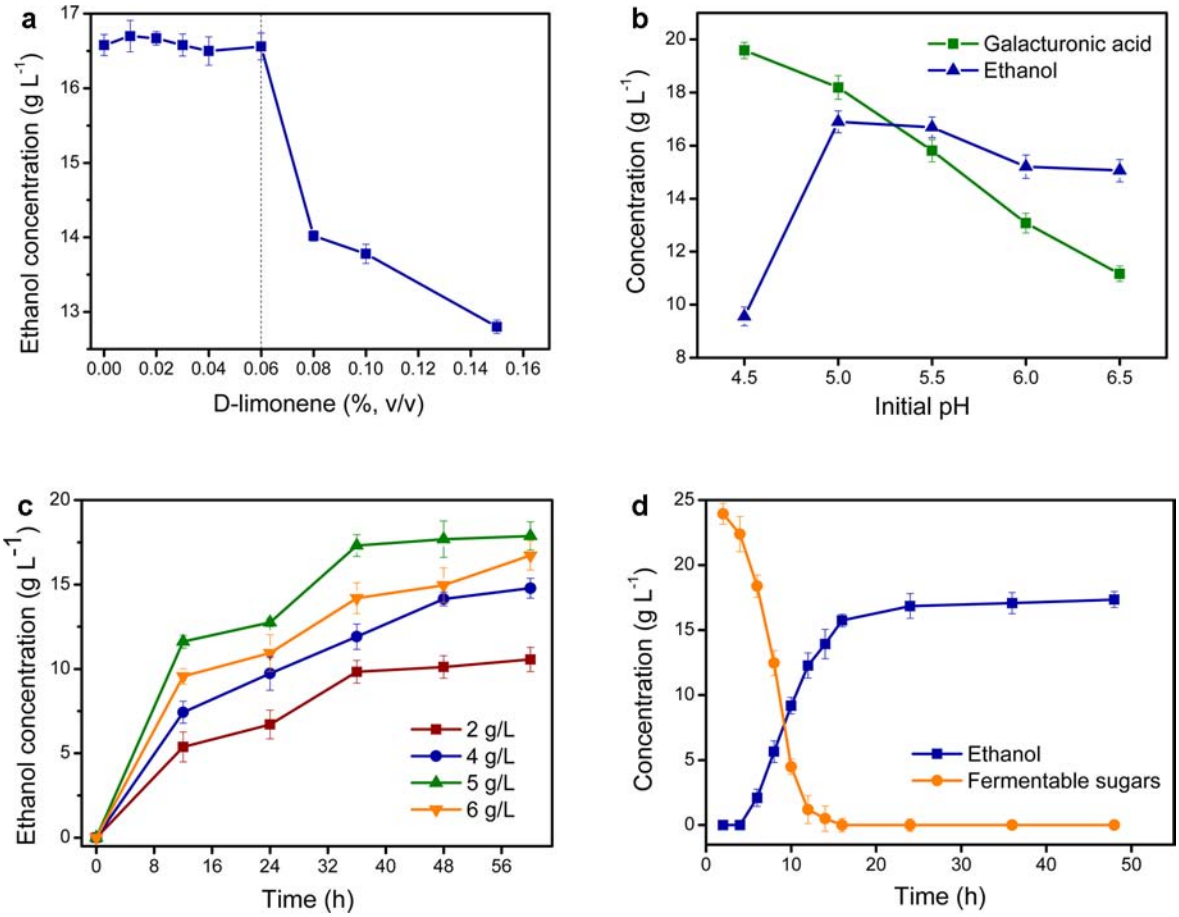

Figure 4. (a–c) Effects of initial D-limonene concentrations (a), pH values (b), and yeast concentrations (c) on ethanol production in the SSF process. (d) Time course of ethanol production and sugars consumption in the SSF process. Default conditions unless otherwise noted: (1) prehydrolysis conditions: cellulase 3.8 FPU g^{-1}, pectinase 15 U g^{-1}, pH 4.8, 50 °C, 150 rpm, 10 h; (2) SSF conditions: solid loading 10%, yeast 5 g L^{-1}, pH 5.0, 30 °C, 150 rpm, 48 h.

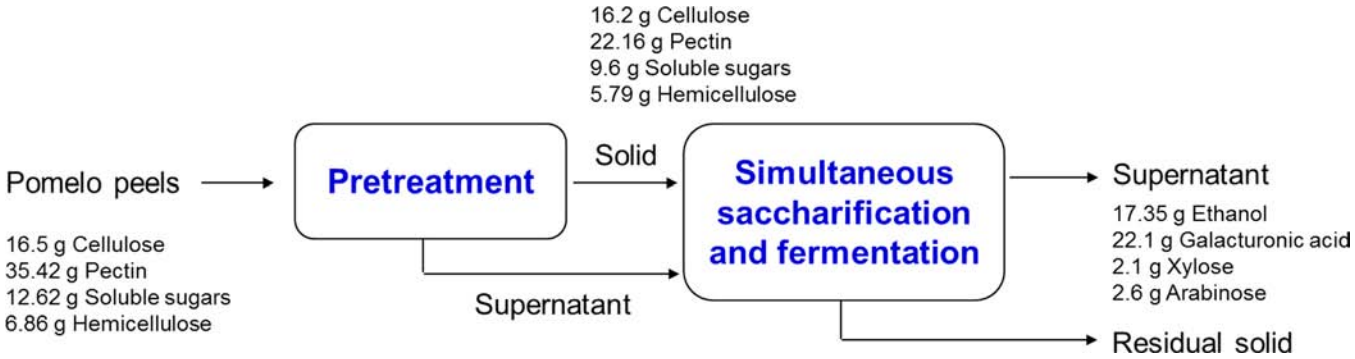

Figure 5. Mass flow for key components of pomelo peels during the hydrothermal pretreatment and SSF process. Pretreatment conditions: solid loading 10% (w/v), 50 mM sodium acetate buffer (pH 4.8), 120 °C, 15 min. SSF conditions: (1) prehydrolysis: 10% solid loading, cellulase 3.8 FPU g^{-1}, pectinase 15 U g^{-1}, pH 4.8, 50 °C, 150 rpm, 10 h; (2) SSF: yeast 5 g L^{-1}, pH 5.0, 30 °C, 150 rpm, 48 h.

17.35 g L^{-1} ethanol was obtained after 48 h of SSF (Figure 4d), accounting for 88.4% of the theoretical yield. Within the first 16 h, >90% of the total ethanol could be produced (the volumetric ethanol productivity is 0.98 g L^{-1} h^{-1}), which suggests that yeast cells may have utilized most of the sugars at this stage and then switched into stationary mode due to nutrient exhaustion and changes in environmental conditions in the medium. Figure 5 shows the mass flow for key components of pomelo peels during the hydrothermal pretreatment and SSF process. As shown in Figure 5, the main products are ethanol (17.35 g, equivalent to 34.02 fermentable sugars) and galacturonic acid (22.1 g), indicating that approximately 80.5% of the original components (cellulose, pectin, and soluble sugars) was transferred to product.

Ethanol Production via SSF with Batch and Fed-Batch Operation. For ethanol production, an important objective is to increase the final ethanol concentration, thus reducing the costs of downstream processing. Generally, operating SSF at high solid loadings is a promising way to increase ethanol concentrations. In this work, we investigated the ethanol

dx.doi.org/10.1021/jf405172a | J. Agric. Food Chem. 2014, 62, 4643–4651

production with batch operation at different solid loadings. As described before, the maximum solid loading for batch operation is 14% due to the high viscosity of pomelo peel slurry. The ethanol concentrations and yields at the solid loadings of 5−14% are shown in Figure 6. When the initial solid

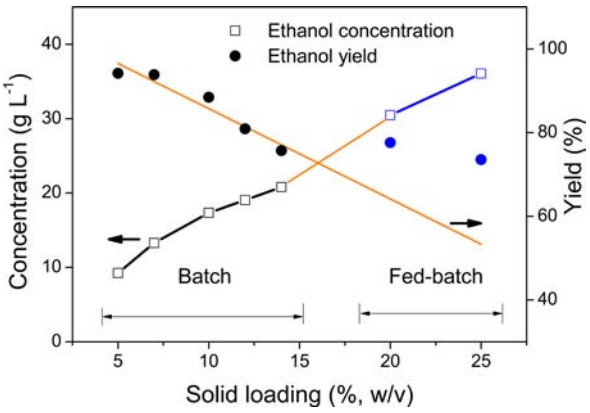

Figure 6. Final ethanol concentrations and yields in the batch (5−14% solid loading) and fed-batch SSF process. Final solid loadings of 20 and 25% were achieved by adding another 10 and 15% to the SSF system with an initial solid loading of 10%, as described under Materials and Methods. Other default conditions unless otherwise noted: (1) prehydrolysis: cellulase 3.8 FPU g^{-1}, pectinase 15 U g^{-1}, pH 4.8, 50 °C, 150 rpm, 10 h; (2) SSF: yeast 5 g L^{-1}, pH 5.0, 30 °C, 150 rpm, 48 h.

concentration is 5% (w/v), the ethanol concentration reached 9.24 g L^{-1}, being 94.2% of the theoretical concentration. At the highest solid loading (14%), we can obtain 20.8 g L^{-1} ethanol product. However, the ethanol yield decreased significantly from 94.2 to 75.7% with increasing solid loadings. The yields would further decrease if the solid loading was increased under batch operation. The worsened performance of yeast and enzymes should be mainly attributed to the lowered mass transfer efficiency (high viscosity). Additionally, the accumulation of yeast inhibitors, such as ethanol,[39,40] and D-limonene (Figure 4a),[22] at high solid loading could also limit the ethanol production.

To further increase the final ethanol concentration while avoiding an increase in viscosity, fed-batch operation by adding fresh substrate was used in the SSF process. As shown in Figure 6, on the basis of the initial solid concentration of 10%, an additional 10% of fresh substrate was added during the first 30 h. The final ethanol concentrations after 48 h increased to 30.45 g L^{-1}, which is nearly 2 times higher than that at 10% solid loading (17.35 g L^{-1}, Figure 6). The concentration could further increase to 36.06 g L^{-1} (the volumetric ethanol productivity is 0.75 g L^{-1} h^{-1}) at a 25% final solid loading via fed-batch operation. In these cases, the yields can reached 77.6 and 73.5%, respectively, which is close to that at 14% solid loading and much higher than the predicted value (at 25% solid loading) under batch operation. Our results demonstrated that use of the fed-batch mode could alleviate the technical problem, as mentioned before, which is caused by high loading of pomelo peel in the SSF process.

Previous studies had employed separate hydrolysis and fermentation (SHF) to produce ethanol from citrus wastes (e.g., orange peel[41,42]) hydrolysate. Although SHF could achieve high ethanol concentration, it has low volumetric ethanol productivity (e.g., 37−40 g L^{-1}, 0.50−0.55 g L^{-1} h^{-1};[41] 35−38 g L^{-1}, 0.42−0.8 g L^{-1} h^{-1}[42]). In this study, SSF with batch operation could obtain higher volumetric ethanol productivity (0.98 g L^{-1} h^{-1}) compared with the SHF process. However, batch SSF produces only 17.35 g L^{-1} ethanol due to the low sugar content in pomelo peel. Other citrus wastes and the mixed fruit wastes have higher sugar content and lower pectin content (Table 1); therefore, simple batch SSF could be used for ethanol production, achieving high ethanol concentration and high ethanol productivity (e.g., Kinnow waste and banana peel, 26.84 g L^{-1}, 0.56 g L^{-1} h^{-1};[43] citrus peel, 38.68 g L^{-1}, 1.61 g L^{-1} h^{-1};[22] Kinnow mandarin peel, 33.87 g L^{-1}, 2.82 g L^{-1} h^{-1};[27] Kinnow waste, 42 g L^{-1}, 3.5 g L^{-1} h^{-1}[26]). For pomelo peel, however, it is difficult to obtain high ethanol concentration in the batch SSF process, as mentioned before, due to the high viscosity at high solid loading. Here, we proposed fed-batch SSF strategy, combined with hydrothermal treatment and multienzyme formulation, to enhance the ethanol production, obtaining 36 g L^{-1} ethanol product as close to that from other citrus peels. Additionally, the fed-batch SSF had an ethanol productivity of 0.75 g L^{-1} h^{-1} within 48 h, which is higher than that in batch-SSF with 14 wt % solid loading (0.43 g L^{-1} h^{-1}, within 48 h).

In this study, *S. cerevisiae*, a robust yeast strain, was used to produce ethanol from pomelo peel. It presents many advantages, including high ethanol tolerance and favorable performance at relatively low pH and oxygen levels. However, *S. cerevisiae* has no ability to naturally ferment galacturonic acid and pentose sugars.[44] Citrus wastes, such as pomelo peel in this work, contain significantly large amounts of galacturonic acid. If galacturonic acid can be converted to ethanol, it would further increase the final ethanol concentration and thus increase the feasibility of these feedstocks for large-scale ethanol production. Whereas engineering *S. cerevisiae* to utilize galacturonic acid is a solution, it is still currently a challenge to develop efficiently engineered *S. cerevisiae* for ethanol production from galacturonic acid.[45] However, successful attempts have been made to ferment galacturonic acid to ethanol using recombinant bacteria, such as *Escherichia coli* KO11.[19,46] Therefore, these strains can be employed to utilize the galacturonic acid in the residual fermentation broth after SSF process.

In summary, we have developed an integrated strategy, incorporating hydrothermal treatment, multienzyme formulation, and fed-batch operation, to enhance ethanol production from pomelo peel. Hydrothermal treatment helped in partial hydrolysis of pectin and helped in reducing the use of cellulase and pectinase. Multienzyme complex was also proven to be effective in improving the hydrolysis of pretreated pomelo peel to fermentative sugars and galacturonic acid. Moreover, to overcome the drawback of low ethanol concentration, we employed fed-batch SFF to produce ethanol from pomelo peel, achieving 36 g L^{-1} ethanol product in good yield (73.5%) and ethanol productivity (0.75 g L^{-1} h^{-1}). The strategy demonstrated in our work, combined with subsequent galacturonic acid conversion, could open a new avenue for utilization of the abundant pectin-rich biomass available to produce ethanol.

Synthesis and Evaluation of Novel Acyl Derivatives from Jatropha Oil as Potential Lubricant Basestocks

Arukali Sammaiah, Korlipara V. Padmaja, and Rachapudi B. N. Prasad*

Centre for Lipid Research, CSIR−Indian Institute of Chemical Technology, Hyderabad 500007, Andhra Pradesh, India

ABSTRACT: A novel class of jatropha oil-based acylated derivatives from hydroxy alkyl esters of jatropha fatty acids (C_1, C_3, C_4, and C_8) and various anhydrides (C_2, C_3, C_4, and C_6) were synthesized and their physicochemical and lubricant properties reported. Jatropha fatty acid alkyl esters were dihydroxylated using the in situ performic acid method and further acylated with different anhydrides to produce acylated derivatives. Acylated derivatives of dihydroxy jatropha fatty acid alkyl esters were charaterized by NMR, FTIR, GC, and GC-MS analysis and were evaluated for their viscosity, viscosity index, pour and flash points, and oxidation stability. Most of the derivatives are either in ISO VG 22 or 32 viscosity grade with good viscosity index. It was observed that increase in acyl chain length and branching in the end-chain ester improved the pour point of the diacyl derivatives. All of the hexanoylated esters exhibited better oxidation stability compared to other acylated products, and their pour points are comparable to those of synthetic esters such as TMP trioleates. In general, isoalcohol esters with longer acyl chains showed promise as potential candidates for hydraulic fluids and metal-working fluids in ISO VG 22 and 32 viscosity range.

KEYWORDS: *jatropha oil, hydroxy fatty acid alkyl esters, acylated derivatives, viscosity index, pour point, oxidation stability*

INTRODUCTION

With increasing oil prices, global warming, and other environmental problems, the field of lubricants derived from nonpetrochemical feedstock has recently attracted a great deal of interest. Vegetable oils are considered to be one of the cheapest and most abundant biological sources available.[1] The use of vegetable oils as platform chemicals for biolubricant synthesis has numerous advantages, including inherent biodegradability and limited toxicity. In this context, increasing efforts have been focused on the use of vegetable oils as platform chemicals for the development of lubricant basestocks. On the other hand, vegetable oils exhibit poor oxidative stability[2,3] due to the presence of unsaturation. These active sites are highly susceptible to radical attack, and subsequently the molecules undergo oxidative degradation and form polar oxy compounds, which results in insoluble deposits and increase in oil acidity and viscosity. The functionalization at unsaturation with hydroxyl moieties through reactions involving the C−C double bonds is the most used methodology for the preparation of plant oil-derived lubricant basestocks.[4−14] Most of the work reported on acylated derivatives is based on edible oils such as soy and corn or nonedible oils such as milkweed, which are high-viscous fluids. Biolubricant basestocks have more demand for lower viscosity grades such as ISO VG 32 and 64. Therefore, with a view to develop lower viscosity grade base fluids, we have chosen a nonedible oil, namely, jatropha oil, as feedstock. *Jatropha curcus* (Linnaeus), a tropical, oilseed-bearing tree belonging to the Euphorbiaceae family, has attracted considerable attention as a potential source for biodiesel production. Jatropha oil is looked upon as one of the most appropriate renewable alternative sources not only for biodiesel but also for biolubricants.[15−17] In this study, we report the synthesis of different acylated derivatives of dihydroxy fatty acid alkyl esters (C_1−C_8; Scheme 1) from jatropha oil utilizing various acid anhydrides for acylation to study the effect of branching on the lubricant properties of the products.

MATERIALS AND METHODS

Materials. Jatropha oil (JO, iodine value = 92 mg I_2/g) was purchased from M/s Sanjeevani Herbal Heath Society (Hyderabad, India). Sodium hydroxide, hydrochloric acid (HCl), sulfuric acid, *p*-toluenesulfonic acid (*p*-TSA), propan-2-ol, butan-1-ol, 2-methylpropan-1-ol, 2-ethylhexan-1-ol, dimethylaminopyridine (DMAP), xylene, aqueous hydrogen peroxide (30%), formic acid (85%), acetic acid, acetic anhydride, sodium bicarbonate, and sodium sulfate were purchased from s.d.Fine-Chem Ltd. (Mumbai, India). Propionic, butyric, and hexanoic anhydrides were procured from Sigma-Aldrich (St. Louis, MO, USA). Hexane, methanol, and ethyl acetate were purchased from Industrial Solvents and Chemicals Pvt. Ltd. (Mumbai, India).

Methods. *Instrumental Analysis.* ^{1}H NMR spectra were obtained using a Bruker AR X 400 spectrometer (500, 300 MHz), and TMS was used as an internal standard. ^{13}C NMR spectra were recorded in $CDCl_3$ on a Varian spectrometer (75 MHz). IR spectra were recorded in chloroform on a PerkinElmer (Norwalk, CT, USA) model Spectrum BX FTIR spectrometer neat as thin film. The spectrum was recorded in absorbance mode.

The fatty acid composition was analyzed by using gas chromatograph 6890N series of Agilent making using an HP-1 column (30 m × 0.25 mm × 0.5 μm). The injector and flame ionization detector were at 300 °C. The oven temperature was programmed at 150 °C for 2 min and then increased to 300 °C at 10 °C/min. The carrier gas used was nitrogen at a flow rate of 1.5 mL/min. The GC-MS analysis was performed using an Agilent 6890 gas chromatograph with an HP-1 MS capillary column (30 m × 0.25 mm × 0.5 μm) connected to an Agilent 5973 mass spectrophotometer at 70 eV (*m*/*z* 50−600; source at 230 °C, and quadruple at 150 °C) in the EI mode. The oven temperature

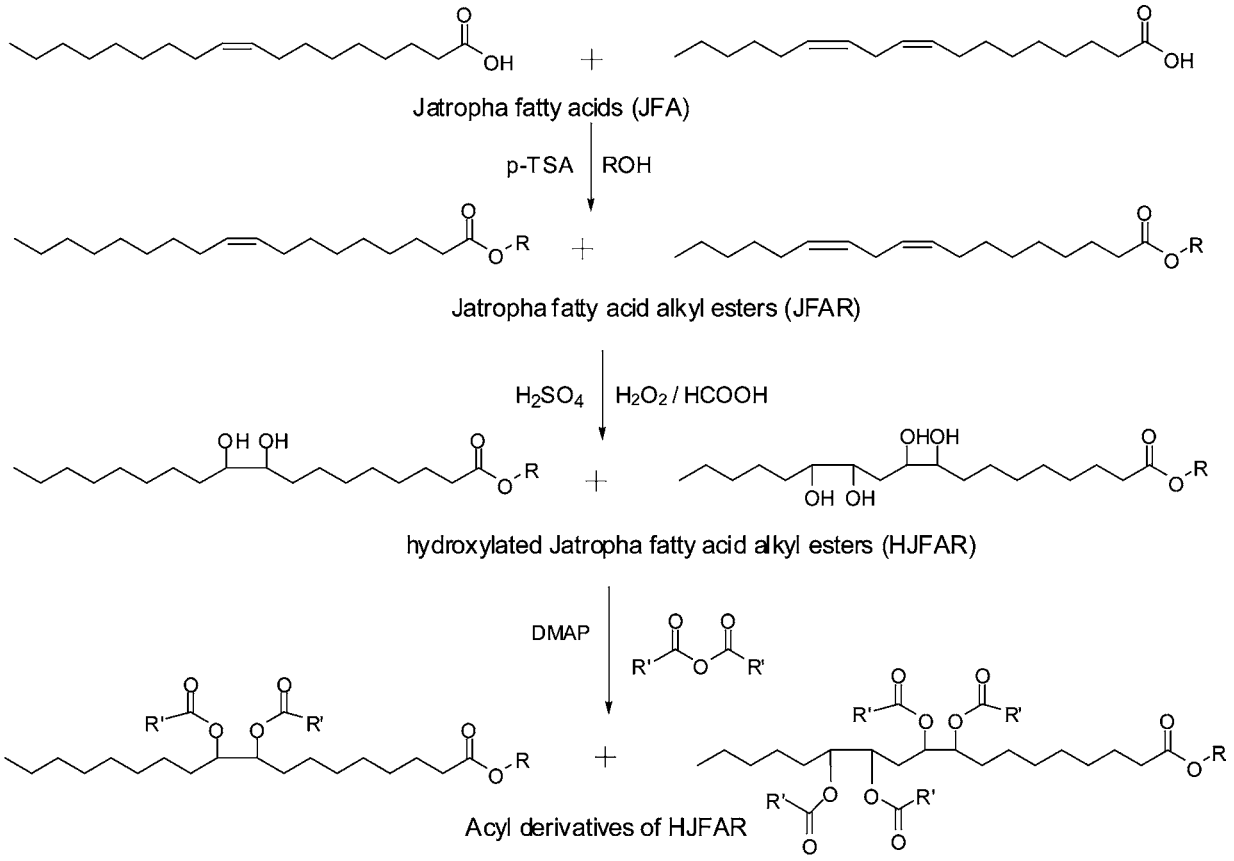
Scheme 1. Synthesis of Acylated Derivatives of Dihydroxy Jatropha Fatty Acid Alkyl Esters



was programmed at 150 °C for 2 min, raised at 10 °C/min to 300 °C, and held for 20 min at 300 °C. The carrier gas used was helium at a flow rate of 1.0 mL/min.

The hydroxyl values of hydroxy and acylated jatropha fatty acid alkyl esters were determined as per the AOCS Cd 13-60 standard method. The iodine and acid values of products were determined as per the AOCS Cd 1-25 and Cd 3d-63 standard methods. Quantitative analysis was always carried out in three replicants.

Hydrolysis of Jatropha Oil. Jatropha oil (107.20 g, 0.12 mol) and sodium hydroxide (19.2 g, 0.48 mol) dissolved in 215 mL of distilled water were stirred mechanically for 6 h. The substrate and reagent were taken in 1:4 mol/mol ratio, and substrate to water was taken in 1:2 vol/vol ratio. The course of the reaction was monitored by TLC using the solvent system hexane/ethylacetae (90:10 v/v) until the complete disappearance of triglyceride. After completion of the reaction, the reaction mixture was acidified with concentrated HCl. The product was extracted in ethyl acetate and washed with water to remove excess HCl, and the solvent was evaporated to obtain 101.2 g of product.

Preparation of Jatropha Fatty Acid Alkyl Esters. Jatropha fatty acids (JFAs; 100 g, 0.37 mol), alcohol (0.74 mol), *p*-TSA (1 g based on 1% weight of JFA), and 150 mL of xylene were stirred at reflux under nitrogen atmosphere until a theoretical amount of water was collected. The crude product was distilled at 60−150 °C and 5 mmHg to remove excess alcohol and xylene. The resultant product was dissolved in hexane, washed with $NaHCO_3$ solution, filtered over Na_2SO_4, concentrated in vacuo, and dried under vacuum to afford alkyl esters of jatropha fatty acids. Short-chain alcohols were esterified without using xylene, H_2SO_4 for methyl esters and *p*-TSA for 2-propyl esters. The product was passed over basic alumina using hexane to recover the product having an acid value of <0.1.

Hydroxylation of Jatropha Fatty Acid Alkyl Esters. Jatropha fatty acid alkyl esters (110 g, 0.388 mol), formic acid (0.582 mol), and concentrated sulfuric acid (2% weight of formic acid and hydrogen peroxide) were taken into a three-necked round-bottom flask, and the temperature of the medium was maintained at 15 °C. Hydrogen peroxide solution, 30% concentration (1.164 mol), was added slowly to the contents under mechanical stirring at 15 °C for 1 h. After addition, the contents were stirred at 85 °C for 15 h. The final product was extracted with ethyl acetate and washed with water until it was acid free. The reaction was monitored hourly by oxirane value, hydroxyl value, and IR and gas chromatography studies. The formation of hydroxyl product was confirmed by IR, ^{1}H NMR, ^{13}C NMR, and GC and GC-MS studies after silylation of the hydroxyl product.

Hydroxy Jatropha Fatty Acid Methyl Esters. ^{1}H NMR ($CDCl_3$) δ 0.89 (t, $-CH_2-C\underline{H}_3$), 1.24−1.4 (m, $-C\underline{H}_2-CH_3$), 1.55−1.65 (m, $C\underline{H}_2-CH_2-CO-$), 2.27 (t, $-C\underline{H}_2-C{=}O$), 3.2−3.4 (m, $-C\underline{H}-OH$), 3.65 (s, $O-CH_3$); ^{13}C NMR ($CDCl_3$) δ 14 ($\underline{C}H_3-CH_2-$), 22−32.2 ($-CH_2-$), 34.3 ($-\underline{C}H_2-C{=}O$), 51.5 ($\underline{C}H_3O-C{=}O$), 74.2 ($-\underline{C}H-OH$), 174.5 ($-COO-$); IR (neat, cm^{-1}) 3445 (−OH), 2925 (C−H), 1743 (C=O), 1168 (C−C (=O)−O).

Acylation of Hydroxy Jatropha Fatty Acid Alkyl Esters. Hydroxylated jatropha fatty acid alkyl esters (100.1 g, 0.32 mol), alkanoic anhydride (0.8 mol), DMAP (0.1 g, 0.1% DMAP based on weight of hydroxylated jatropha fatty acid alkyl esters), and xylene (150 mL) were taken in a three-necked round-bottom flask and stirred at 140−150 °C for 6−8 h. The reaction was monitored by TLC using as solvent system hexane/ethyl acetae (90:10 v/v) and IR. The crude product was distilled at 140 °C and 5 mmHg to remove excess alkanoic anhydride and xylene. The residue was extracted with ethyl acetate and washed with water, filtered over Na_2SO_4, and concentrated in vacuo to obtain diacyl jatropha fatty acid alkyl esters. The product was further purified to remove traces of alkanoic acid by passage through a basic alumina column to obtain diacyl jatropha fatty acid alkyl esters with an acid value of <0.1. The product was confirmed by IR, ^{1}H NMR, ^{13}C NMR, and GC and GC-MS studies.

Hexanoylated Esters of Jatropha Fatty Acid 2-Ethyl-1-hexyl Esters (HOJFAEHE). ^{1}H NMR ($CDCl_3$) δ 0.90 (t, −CH$_2$−C<u>H</u>$_3$), 1.24−1.38 (m, −C<u>H</u>$_2$−CH$_3$), 1.43−1.65 (m, C<u>H</u>$_2$−CH$_2$−CO−), 2.24−2.35 (m, −C<u>H</u>$_2$−C=O), 3.95 (d, −C<u>H</u>$_2$−O−C=O), 4.92−4.98 (m, −C<u>H</u>−O−C=O); ^{13}C NMR ($CDCl_3$) δ 10.8 (<u>C</u>H$_3$−CH$_2$−), 14 (<u>C</u>H$_3$−CH$_2$−), 22.7−32.02 (−CH$_2$−), 34.2−38.4 (−<u>C</u>H$_2$−C=O), 66.6 (−<u>C</u>HO−C=O), 73.35−74.8 (−<u>C</u>H−O−C=O), 173.2 (CH$_3$−<u>C</u>OO−), 173.8 (−<u>C</u>OO−); IR (neat, cm^{-1}) 2930 (C−H), 1729 (C=O), 1174 (C−C (=O)−O).

Density. The density of the hydroxy products was measured following ASTM method D-4052. The measurements were carried out at 25 °C by using an Anton Paar DMA 4500 M density meter, and distilled water was used to verify the exact volume. The measurements were conducted three times for each sample, and the results were averaged.

Kinematic Viscosity. The kinematic viscosities were determined on a Cannon Constant Temperature Viscosity Bath (Cannon Instrument Co., State College, PA, USA) at 40 and 100 °C using a Cannon Fenske viscometer tubes per ASTM method D-445. The viscosity index (VI) was calculated from the kinematic viscosity data at 40 and 100 °C using ASTM method D-2270. Triplicate measurements were made, and the average values were reported.

Pour Point. The pour points of acylated products were measured per ASTM method D-97 with an accuracy of ±3 °C using on Automatic Pour Point Tester manufactured by Dott. Gianni Scavini & Co., Italy. Pour points were measured in 3 °C increments, and all the runs were carried out in duplicate.

Flash Point. Flash point of the products was measured per ASTM D-93 method using a Koehler Inc. apparatus. Duplicate measurements were made, and the average values were reported.

Rotating Pressurized Vessel Oxidation Test (RPVOT). Oxidation stability of acylated products was determined with RPVOT tests per ASTM test method D-2272. The experiments were carried out in the presence of copper catalyst at 150 °C and 5.0 mL of reagent grade water, and the vessel was sealed and charged with oxygen to 90 psi pressure.

RESULTS AND DISCUSSION

Jatropha oil containing oleic (45.7%) and linoleic (33%) acids as major fatty acids was converted into its corresponding fatty acids by a saponification route. Jatropha fatty acids (acid value, 193 mg KOH/g) were esterified with different alcohols, namely, methanol, propan-2-ol, butan-1-ol, 2-methylpropan-1-ol, and 2-ethylhexan-1-ol using H_2SO_4 for methyl esters and *p*-TSA for the other esters. The fatty acid esters were hydroxylated by using Prilezhaev dihydroxylation using in situ generated performic acid from hydrogen peroxide and formic acid. Synthesis of dihydroxy jatropha fatty acid alkyl esters was done in a single step, without isolating the intermediate epoxide, and they were analyzed for their physicochemical characteristics and chromatographic (GC, GC-MS) and spectral data. The low iodine value (1.2−1.8 g I_2/100 g) and higher hydroxyl values (195−220 mg KOH/g) of the esters indicated almost complete hydroxylation of fatty acid esters. Hydroxy alkyl esters were characterized using GC after silylation with *N*,*O*-bis(trimethylsilyl)trifluoroacetamide. The formation of the hydroxyl group was observed in the FTIR

dx.doi.org/10.1021/jf501388d | J. Agric. Food Chem. 2014, 62, 4652−4660

absorption at 3445−3463 cm^{-1} wavenumbers. The double-bond carbon was no longer detected at 3004 cm^{-1} in the products. ^{1}H NMR spectra of products exhibited the following peaks: 3.2−3.4 (−C<u>H</u>−OH), 2.25 ($-CH_2-C{=}O$), 1.60−1.2($-CH_2-$), and 0.85−0.93 ppm (CH_3). ^{13}C NMR confirmed the presence of the following groups: carbonyl at around 173−174.5 ppm, C_9 and C_{10} hydroxyl carbons at 74.2 and 75.5 ppm, $-CH_2-$ carbon over the range from 21.5 to 34.5 ppm, and terminal methyl carbon at 11−14 ppm.

The density and kinematic viscosities of the oil's hydroxylated esters from which the VI values were calculated are summarized in Table 1. Density and viscosity values were low for esters with branched alcohols and high for esters with straight-chain alcohols.

Table 1. Physicochemical Properties of Hydroxy Jatropha Fatty Acid Alkyl Esters

	hydroxy JFA esters				
	methyl	*n*-butyl	isopropyl	isobutyl	2-ethylhexyl
hydroxyl values (mg KOH/g)	220.13	224.46	220.46	222.52	195.37
iodine value	1.3	1.8	1.2	1.5	1.5
density 25 °C	0.9638	0.9367	0.9380	0.9374	0.9244
kinematic viscosity (cSt)					
40 °C	167.88	84.62	51.22	58.85	67.34
100 °C	15.02	9.86	6.94	7.66	8.81
viscosity index	87	95	89	92	103

In the second step, hydroxy alkyl esters were acylated with acetic, propionic, butyric, and hexanoic anhydrides. Reaction progress was monitored using FTIR for checking the disappearance of the O−H stretching band in the region of 3700−3100 cm^{-1} and by determination of the hydroxyl number. The prominent alkyl and carbonyl frequencies around 2940−2850 and 1740 cm^{-1}, respectively, indicated the substituent moieties' contributions to the spectra. The completion of reaction was confirmed by hydroxyl value (<2) of the products and also by their respective ^{1}H NMR and ^{13}C NMR spectra. New peaks at 4.91−4.98 ppm (protons at the point of substitution −CH−O−CO−R in the FA chain) appeared in all acylated products.

The FTIR spectra of the acylated products (Figure 1) did not exhibit hydroxy bands at 3447 cm^{-1} and a corresponding increase in the ester carbonyl at ∼1739 cm^{-1}, confirming more ester structures in the products. The FTIR spectra (Figure 1) of all these products have some common peaks at 2928 and 2856 cm^{-1} (methylene asymmetric stretching), 1465 cm^{-1} (CH_2 bending vibration), 1372 cm^{-1} (CH_3 symmetrical bending vibration), and 722 cm^{-1} (CH_2 rocking vibrations) and additional peaks at 1234, 1174, and 1106 cm^{-1} due to stretching vibrations of the C−O group in esters. Formation of the acylated products was also confirmed by the increase in peak intensity ratio 1465:1372 cm^{-1}. Also, the intensities of peaks such as 1739 (ester carbonyl) and 1174 cm^{-1} (C−O stretching of esters) relative to that of the 2928 cm^{-1} peak have increased in acylated products compared to starting materials (Figure 1). This is due to the increase in ester functionalities in the products. This trend was observed in spectra of all acylated

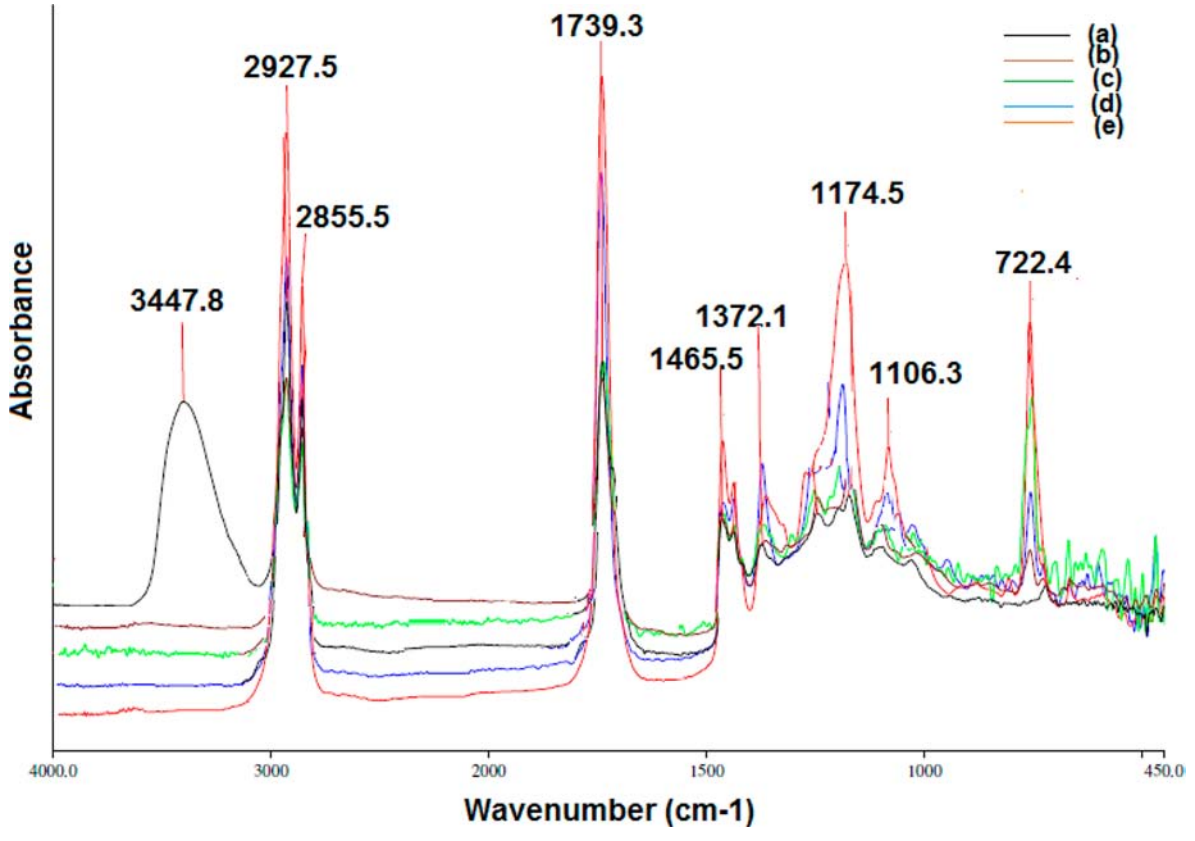

Figure 1. IR spectra of (a) hydroxy jatropha fatty acid methyl esters, (b) acetylated jatropha fatty acid methyl esters, (c) propionylated jatropha fatty acid methyl esters, (d) butanoylated jatropha fatty acid methyl esters, and (e) hexanoylated jatropha fatty acid methyl esters.

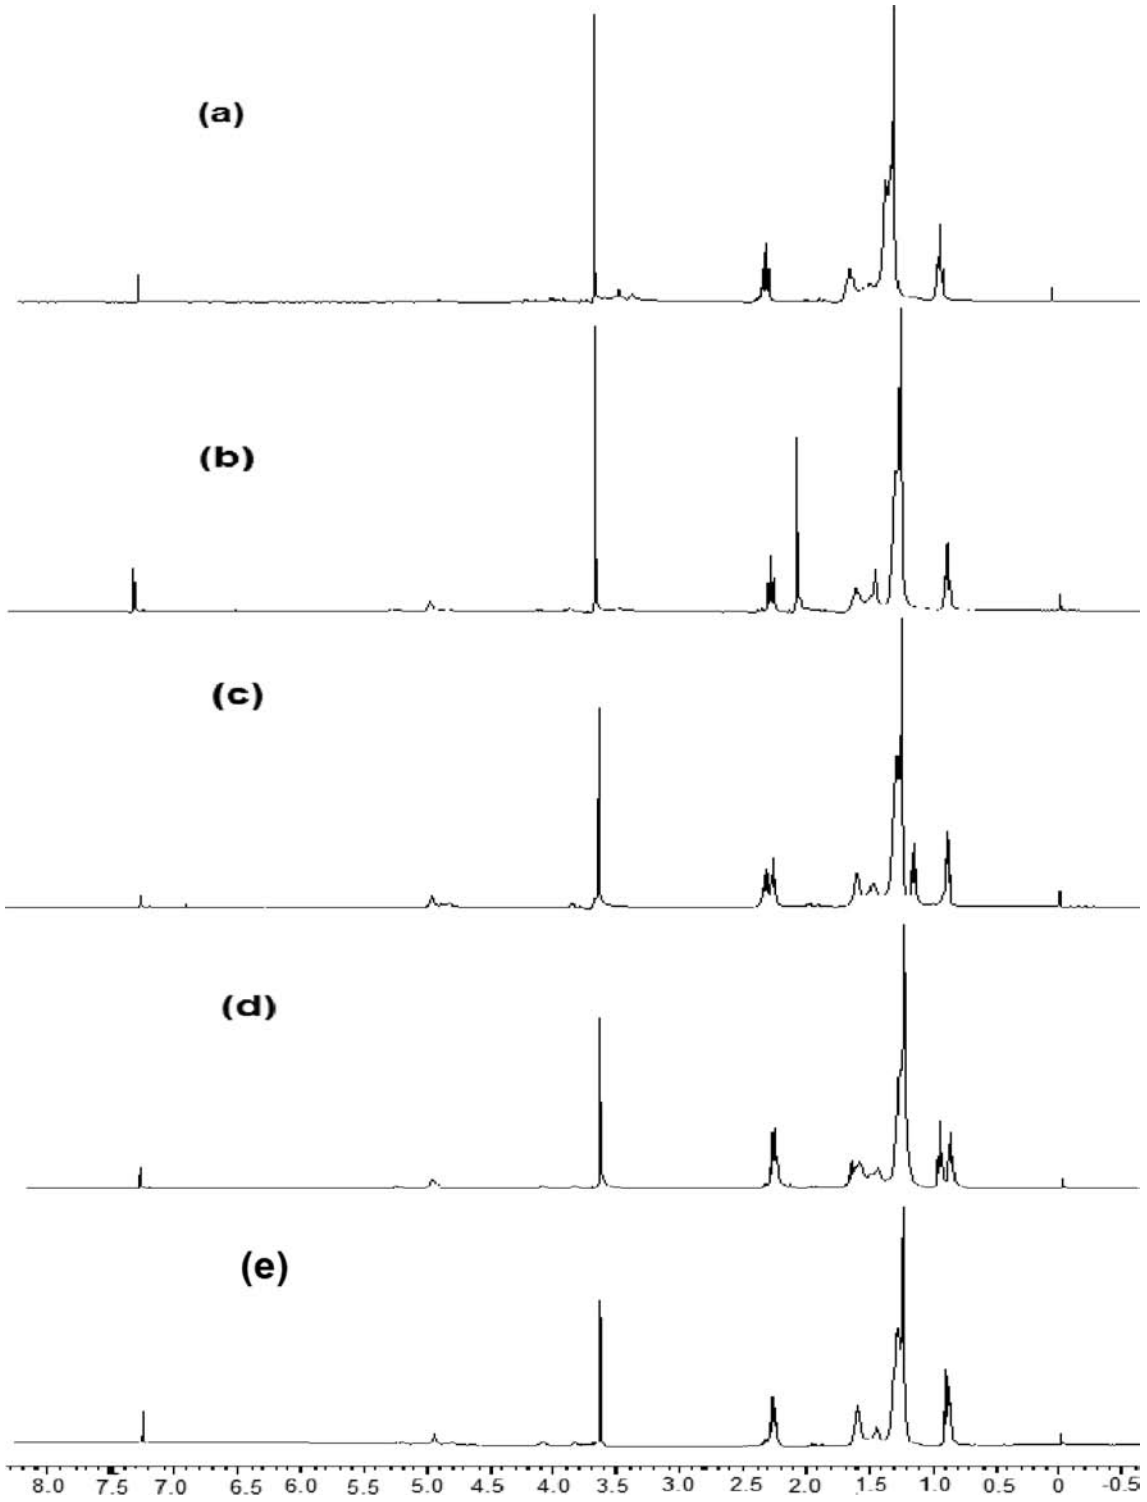

Figure 2. ^{1}H NMR spectra of (a) hydroxy jatropha fatty acid methyl esters, (b) acetylated jatropha fatty acid methyl esters, (c) propionylated jatropha fatty acid methyl esters, (d) butanoylated jatropha fatty acid methyl esters, and (e) hexanoylated jatropha fatty acid methyl esters.

products, confirming the formation of the acyl group in all of the products.

In the ^{1}H NMR spectra (Figure 2) the presence of additional peaks in acetylated products at 2.07 ppm is due to methyl protons of the $-COCH_3$ group and corresponding methyl carbons at 21.2 ppm, and carbonyl carbons at 170.3 ppm in ^{13}C NMR (Figure 3) confirm the formation of the acetoxy groups. Additional peaks also appeared at 2.23−2.36 ppm due to the $-CH_2$ protons α to the carbonyl group. The formation of propionylated products is confirmed by an increase in the area of the peak at 2.25−2.36 ppm due to CH_2 protons α to the carboxy group of the acyl side chain, the appearance of a new peak at 1.14−1.18 ppm due to methyl protons on the end of the acyl side chain, and the corresponding methyl carbon peak at 9.3 ppm in the ^{13}C NMR spectrum. The butanoylated products are confirmed by an increase in area of the peak at

dx.doi.org/10.1021/jf501388d | J. Agric. Food Chem. 2014, 62, 4652−4660

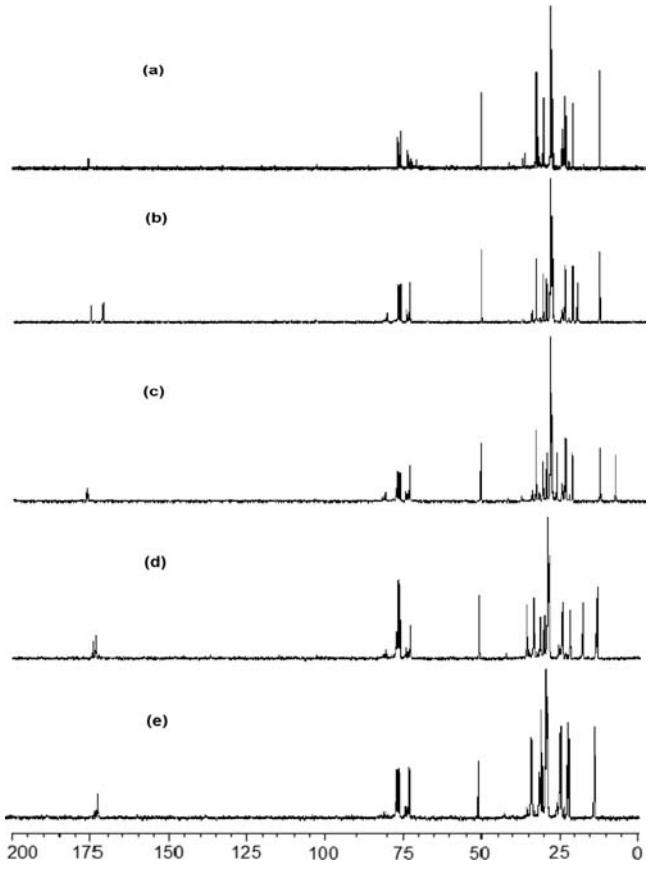

Figure 3. ^{13}C NMR spectra of (a) hydroxyl jatropha fatty acid methyl esters, (b) acetylated jatropha fatty acid methyl esters, (c) propionylated jatropha fatty acid methyl esters, (d) butanoylated jatropha fatty acid methyl esters, and (e) hexanoylated jatropha fatty acid methyl esters.

2.37−2.21 ppm due to CH_2 protons α to the carboxy group of the acyl side chain, the appearance of a new peak at 0.93−0.98 ppm due to CH_3 protons of the acyl side chain, and a new peak at 18.2 ppm in the ^{13}C NMR spectrum due to the CH_2 carbon α to the end carbon of the acyl side chain. The hexanyolated products are confirmed by an increase in the area of peaks at 2.25−2.32 ppm due to CH_2 protons α to carboxy group of acyl side chain and 0.93−0.98 ppm due to CH_3 protons of acyl side chain in their ^1H NMR spectra. In the ^{13}C NMR spectra, the appearance of a new peak at 34.4 ppm due to the CH_2 carbon α to the carboxy group of the acyl side chain confirms their formation. The peaks at 3.2−3.4 ppm in hydroxy products due to hydroxy protons in the −CHOH group are not present in acylated derivatives. Both the NMR and the infrared spectra of these acyl derivatives indicated the absence of residual hydroxyl groups in the acylated derivatives. The GC-MS spectra also indicated the absence of hydroxylated products indicating complete acylation of hydroxyl groups. Acylated derivatives were evaluated for their lubricant properties such as viscosity, viscosity index, pour and flash points, and oxidation stability by RPVOT test. The results are summarized in Table 2.

Kinematic Viscosity. Acylation of dihydroxylated products resulted in a reduction of kinematic viscosity at both 40 and 100 °C. The kinematic viscosity of acylated derivatives was found to be in the ranges of 19.45−30.06 cSt at 40 °C and 4.24−5.92 cSt at 100 °C as shown in Table 2. These ranges are lower than that of the original oil because of the difference in molecular size. Most of the acylated derivatives are found to be in the range of either ISO VG 22 or 32 viscosity grade and of hydraulic base fluids. Among the alkyl acylated derivatives 2-ethylhexyl esters with the longest chain length exhibited the highest observed viscosity relative to the other products. Viscosity attenuation was observed with an increase in chain length of the acyl chain up to C_4. This is due to the effect of branching in the chain, which tends to introduce sphericity in the molecule, causing attenuation in the viscosity.[14] Increase in viscosity in hexanoylated esters is in accord with the expectation that materials with longer chain lengths generally exhibit higher viscosities because of their extended sweep in the medium. Similar observations of the effect of branching on viscosity had been reported in branched polysaccharides,[18] branched synthetic polymers[19,20] and oligomerized estolides of oleic acid.[21] The viscosity index of hydroxylated jatropha fatty acid alkyl esters varied from 87 to 103. The VI value is increased (104−150) in the acylated derivatives. The VI of acylated products increased with increasing chain length of the acyl group. Even though the VI increased with the molecular weight of the acyl group, it decreased with branching. A similar trend was reported by Yao et al.[22] for ricinoleic acid-based acylated products. The VI values of the reported acylated derivatives are comparable to those of synthetic oils and superior to those of mineral oils.[23,24]

Pour Point. Pour point measurement provides a good estimate of low-temperature fluidity of the lubricants. The pour points of acylated products were found to be in the range from 9 to −15 °C (Table 2). Acylated products esterified with straight-chain alcohols (methyl and *n*-butyl) exhibited higher pour points (from 9 to 0 °C). The basestocks with higher pour points are suitable for high-temperature and radiation resistance applications.[25] The pour point improved in the case of esters with isoalcohols such as 2-propyl, 2-methyl-1-propyl, and 2-

dx.doi.org/10.1021/jf501388d | J. Agric. Food Chem. 2014, 62, 4652−4660

ethyl-1-hexyl (from 0 to −15 °C) due to the presence of branching. The basestocks with low pour points are useful for machine tool and hydraulic systems applications.[25] All acylated products of 2-ethylhexyl esters exhibited low pour points. A similar trend was also reported by Erhan et al.[26] In general, isoalcohol esters with longer acyl chain lengths exhibited lower pour points.

Flash Point. Flash point measurement provides a good estimate of volatility and fire resistance of the lubricants. The flash point of acylated products was found to be in the range of 202−254 °C, which is observed to be much higher than that of the JO (Table 2). The flash points increased with increasing chain length of the end-chain ester group and the acyl group. All of the acylated products with flash point ≥165 °C lie well within the range of hydraulic oils.[27] High flash point ensures greater safety in the handling and storage of the fuel, which is a desirable requirement for lubricants.

Oxidation Stability. Oxidation stability is another important property that determines the lubricant's stability. The oxidation stability of acylated derivatives and JO obtained using the RPVOT method was found to be in the range of 5−15 min (Table 2). Acetylated, propionylated, and butanoylated methyl esters exhibited lower oxidation stability values (5 min) similar to that of JO, and hexanoylated derivatives exhibited higher values (15 min). No significant change was observed with increasing chain length of the end-chain ester group from C_3 to C_8. The oxidative stability of hexanoylated esters was found to be similar to that of synthetic esters such as TMP trioleate.[24]

In conclusion, we have synthesized a series of novel acyl derivatives from jatropha oil in two simple steps. In the first step we prepared different hydroxylated jatropha fatty acid alkyl esters by in situ generated performic acid method followed by their acylation with anhydrides of different chain lengths to prepare their acyl derivatives. Preliminary investigations on these products have shown that these are promising candidates for low-viscosity grade applications either as such or after formulations.

Supporting Information

ABSTRACT: A combined deacetylation and PFI refining pretreatment was applied to corn cob for the improvement of a two-stage enzymatic hydrolysis. In stage 1, the pretreated corn cob was first hydrolyzed by xylanase to produce xylo-oligosaccharides (XOS). In stage 2, the solid residue isolated from stage 1 was further hydrolyzed by cellulase and β-glucosidase. NaOH, Na_2CO_3, and $Ca(OH)_2$ were tested to remove acetyl groups in the process of deacetylation, and it was found that $Ca(OH)_2$ could be the most suitable alkali for deacetylation in this work. After deacetylation using 0.8 mmol of $Ca(OH)_2$/g of substrate and PFI refining, 50.5% xylan in the raw material could be hydrolyzed into XOS. The corresponding xylan yield of stage 1, the glucan yield of stage 2, and the total sugar yield (all sugars released in the hydrolyzate) after the two-stage enzymatic hydrolysis were 0.306, 0.305, and 0.661 g/g of corn cob, respectively.

KEYWORDS: *corn cob, deacetylation, PFI refining, enzymatic hydrolysis, pretreatment, xylo-oligosaccharides (XOS)*

INTRODUCTION

Xylo-oligosaccharides (XOS) are widely used as food and feed additives, which are considered soluble dietary fibers that have prebiotic activity, favoring the improvement of bowel and immune functions and having antimicrobial and other health benefits.[1] Currently, XOS are usually produced from the separated xylan or pretreated xylan-rich biomass through acidic or enzymatic hydrolysis.[2−7] Corn cob is an inexpensive and widely available resource of hemicellulose, which is usually chosen to produce XOS.[2−4,6] In comparison to the chemical technologies (e.g., acid hydrolysis), the enzymatic hydrolysis is a better route for the food industries, because no toxic and undesired byproducts, such as furfural, are generated during the enzymatic process.[1] However, the enzymatic substrates are mostly prepared by severe processes, which would not be friendly to the environment. Furthermore, the cellulose in the xylan-deprived corn cob residue should be used in a more economical and environmentally benign method.

For enzymatic hydrolysis of biomass, pretreatment is an important technology to alter the structure of cellulosic biomass to make cellulose/hemicellulose more accessible to enzymes.[8] Nowadays, most commercially promising pretreatment processes [e.g., dilute acid/alkali pretreatment,[9,10] steam explosion,[11] sulfite pretreatment to overcome recalcitrance of lignocellulose (SPORL) method,[12] etc.] are mainly aimed to remove the lignin or hemicellulose through severe chemical reactions or mechanical treatment with respect to the properties of feedstock and the goal of end use. For corn cob, which has a high hemicellulose (32−39%) and low lignin content (9−14%),[3,4,6] the acetyl groups on hemicellulose would be the main recalcitrance barrier, because the steric hindrance of acetyl groups could lower the activity of xylanase.[13] Thus, the selective removal of acetyl groups from the backbone of xylan in feedstock by deacetylation can significantly improve the xylan digestibility and cellulose enzymatic hydrolysis.[14] Acetyl xylan esterase,[15,16] hydroxylamine solutions,[17] and dilute alkali[13] can be used for deacetylation, and the conditions of deacetylation are usually milder compared to the traditional pretreatments, because acetyl groups are more reactive than the other enzymatic hydrolysis hinders (e.g., lignin).[18] Furthermore, deacetylation could reduce the acetic acid generated during pretreatment and enzymatic hydrolysis, which could restrain the growth of microbes in the ethanol fermentation.[19,20]

On the other hand, many mechanical refining technologies that have been widely applied in the pulp industry were used to increase enzymatic hydrolysis of various pretreated biomass. The applied technologies included disk-mill,[12,21,22] PFI mill,[22−24] food processor blender,[22] extruder,[22,25,26] Szego mill,[23] etc. It was reported that all of the refining technologies could improve the biomass digestibility by 10−20%.[22] Among them, the PFI mill was a commonly used laboratory mechanical refiner, which could provide accurate control and induce homogeneous refining effects on the substrate.[27] As a lab equipment, the PFI mill could refine a small quantity of biomass and be easily handled. Also, the PFI mill was usually used to simulate a disc refiner, which could be used at a large scale, although the refining of the PFI mill differed from disc and conical refiners (PFI mill imposed a greater proportion of compressive to shear forces). It has been know that the PFI mill is a high-energy and low-intensity refiner and normally uses 10 times the energy typically consumed in industrial refiners.[27]

[a]Measured as Na_2O.

Therefore, in this work, to improve the XOS yield and efficiently use cellulose from corn cob, a combined deacetylation and PFI refining pretreatment process was established and a two-stage enzymatic hydrolysis for the pretreated corn cob were carried out. The two-stage enzymatic hydrolysis was also used to evaluate the effectiveness of the combined pretreatment method. In the first stage of enzymatic hydrolysis (stage 1), just xylanase was added to release XOS, while in the second stage of hydrolysis (stage 2), both cellulase and β-glucosidase were used to digest the solid residue obtained from stage 1, aiming for the full utilization of the corn cob.

MATERIALS AND METHODS

Materials. The corn cob was harvested in 2012, in Shandong province (China), further milled by an agriculture use hammer mill, and screened to obtain the fraction with a particle size between the meshes of 20 and 80 (i.e., 0.18−0.85 mm). The screened corn cob was stored in sealed plastic bags at room temperature to be ready for the component analysis and pretreatment. The solid content of the prepared corn cob was 93.9%.

Xylanase was generously provided by Habio Enzyme (Mianyang, Sichuan province, China), and its activity was 38 international units (IU)/mL. Celluclast 1.5 L (cellulase) and Novozyme 188 (β-glucosidase) were bought from Sigma-Aldrich (St. Louis, MO). The activities of cellulase and β-glucosidase were 121 filter paper units (FPU)/mL and 741 IU/mL, respectively. All of the enzyme activities were measured using the methods reported by Ghose.[28] Other chemicals were of analytical quality and were bought from Sinopharm Chemical Reagent Co., Ltd. All of the enzymes and chemicals were used as received.

Deacetylation Treatment. The deacetylation treatment of corn cob was carried out following the previous procedure,[14] with slight modifications. Briefly, 10 g of screened dry corn cob was put into a 250 mL bottle with 120 mL of alkali solution of different alkali charge. The alkali charge ranged from 0.2 to 0.8 mmol/g of oven-dried (od) substrate. Then, the bottle was placed in an incubator shaker with 160 rpm at 70 °C for 3 h. After deacetylation, the corn cob was filtered and washed with tap water 4 times through a 300-mesh nylon cloth until neutrality. For each time, the ratio of washing water/deacetylated corn cob was 3:1 (w/w). Finally, the solid samples were collected and weighed for further analysis and tests. As a control, the corn cob was treated in water at 70 °C for 3 h. In deacetylation treatment, two weak bases Na_2CO_3 and $Ca(OH)_2$ and one strong base NaOH were used. The alkali charges of NaOH and Na_2CO_3 were measured as Na_2O (mmol/g of od substrate), and the alkali charges of $Ca(OH)_2$ (mmol/g of od substrate) were considered to be the same as that of Na_2O in this work, because although the solubility of $Ca(OH)_2$ is low (about 1.4×10^{-3} mmol/L in 70 °C), the ionization degree is high ($k_1 = 3.72 \times 10^{-3}$, and $k_2 = 3.98 \times 10^{-2}$). For example, 0.6 mmol of NaOH or Na_2CO_3 (as Na_2O)/g of substrate and 0.6 mmol of $Ca(OH)_2$/g of substrate could be considered to have the same alkali charge.

Mechanical Refining. To further increase enzymatic digestibility, the deacetylated and washed corn cob was modified by a PFI beating machine (mode PL11-00, Xianyang TEST Equipment Co., Ltd., Xianyang, China). The beating conditions were as follows: beating revolution was 4000 according to the studies by Chen et al.[14] and Jones et al.[23]; beating consistency was 10 wt %; revolution speed was 1400 rpm; and beating gap was 0.24 mm.

Enzymatic Hydrolysis. The corn cob was hydrolyzed in two stages. In stage 1, the corn cob was first hydrolyzed by xylanase. A total of 20 mL of a mixture of substrate (with 2% solid loading), sodium citrate buffer (0.1 M, pH 4.8), and xylanase was added in a 50 mL bottle for the National Renewable Energy Laboratory (NREL) procedure.[29] The xylanase dose was 66 IU/g of od biomass. The xylanase hydrolysis was carried out at 50 °C with the agitation at 120 rpm for 24 h. Upon completion, the hydrolyzate was separated by filtration, and the solid residue was washed and further hydrolyzed by cellulase and β-glucosidase in stage 2. All hydrolyzed residues were added together with sodium citrate buffer (0.1 M, pH 4.8), cellulase, and β-glucosidase to a 50 mL bottle. Then, the slurry was diluted to 20 mL. The cellulase and β-glucosidase doses were 18 FPU/g and 9 IU/g of od biomass, respectively, on the basis of the corn cob added in stage 1. The other conditions were the same as stage 1. After 48 h of hydrolysis, the hydrolyzate was collected by filtration to be ready for sugar analysis.

Analytical Methods. Glucan, xylan, acetyl, and lignin contents of biomass were determined using the NREL procedure.[30] The oligosaccharide and monosaccharide in the hydrolyzate were examined by high-performance liquid chromatography (HPLC, model 1200, Agilent, Santa Clara, CA) on a carbohydrate analysis column (Waters SunFire, 4.6 × 250 mm, 5 μm) with 50 mg/L ethylenediaminetetraacetic acid (EDTA) calcium salts as the mobile phase. A 10 μL sample of the hydrolyzate was injected into the column, and XOS were detected by a refractive index detector. Glucose, xylose, arabinose (Sigma, St. Louis, MO), xylobiose, xylotriose, and xylotetraose (Suntory Co., Ltd., Kyoto, Japan), with retention times of 9.7, 10.8, 12.2, 8.9, 7.7, and 7.0 min, respectively, were used as standards.

The crystallinities of corn cobs were measured using a Bruker D8 ADVANCE X-ray diffractometer (Bruker Co., Germany). The specimen was prepared by placing approximately 0.1 g of the freeze-dried and milled biomass sample on a glass sample holder and then placing a drop of acetone on the sample to fix it on the holder. The specimen was scanned at 2°/min from $2\theta = 10-26°$ with a step size of 0.05°.

RESULTS AND DISCUSSION

Effect of the Pretreatment on Structural Features of Corn Cob. Table 1 shows the compositions of native and deacetylated corn cobs, as well as the recovery or removal rate of the corresponding component. In most cases, the deacetylation process could not efficiently remove the lignin, which was a main barrier of enzymatic hydrolysis, except using NaOH at an alkali charge of 0.8 mmol/g of substrate. A total of 63% delignification was achieved when using 0.8 mmol of NaOH/g of substrate, while the lignin removal at other conditions was just 20−32%. This was probably due to the fact that the acetyl groups were easier to remove compared to lignin. A lower dosage of NaOH (e.g., 0.6 mmol/g of substrate) could only sufficiently remove acetyl groups, while a higher dosage of NaOH (e.g., 0.8 mmol/g of substrate) could also provide enough alkali to remove much more lignin during deacetylation. Under these relatively mild alkaline conditions, the recovery rates of glucan and xylan after deacetylation were all higher than 92 and 84%, respectively (Table 1), because there was only a small amount of carbohydrates degraded in deacetylation (particularly for glucan). The glucan and xylan compositions of the samples were all improved by the removal of ash, lignin, soluble sugars, and other water-soluble extractives. Also, as shown in Table 2, after deacetylation, there was a slight increase (1−2%) of the crystallinity index of corn cob. This was because of the removal of amorphous components (i.e., acetyl groups and lignin) in deacetylated corn cob.[24] However, the decrease of cellulose crystallinity after deacetylation was due to the increase of the cellulose content in the deacetylated corn cob (Table 1). After PFI refining, both the crystallinity index and cellulose crystallinity of deacetylated corn cob were decreased (Table 2). This was mainly due to the destruction of the crystalline region in cellulose caused by the compression and shear forces during PFI refining.[18]

Table 2. Crystallinity Index of Corn Cob before and after Deacetylation and PFI Refining

	raw corn cob	deacetylated corn cob[a]	deacetylated and PFI refined corn cob[a]
crystallinity index (CrI) (%)	35.7	37.1	34.3
cellulose crystallinity (CCr) (%)	102.3	94.5	87.3

[a]Deacetylation condition: $Ca(OH)_2$ of 0.4 mmol/g of substrate alkali charge.

Unlike the delignification and crystallinity, the deacetylation increased significantly with the increase of alkali charge. For example, when the alkali charge was increased from 0.2 to 0.8 mmol/g of substrate using Na_2CO_3, the degree of deacetylation was increased from 23 to 74%. For the two weak alkali [Na_2CO_3 and $Ca(OH)_2$], the effect of $Ca(OH)_2$ on deacetylation was closer to that of NaOH compared to Na_2CO_3, because of the higher pH derived from $Ca(OH)_2$ at the same alkali charge. For instance, 96% deacetylation could be achieved after $Ca(OH)_2$ treatment with the alkali charge of 0.8 mmol/g of substrate at 70 °C for 3 h, suggesting that the mild process could efficiently remove the acetyl groups in corn cob.

Two-Stage Enzymatic Hydrolysis of Deacetylated Corn Cob. Low solids (2%) enzymatic hydrolysis was performed to test the digestibility of deacetylated corn cob in the near-ideal conditions, in which the mass transfer limitations between enzymes and substrate as well as the inhibition from products could be negligible. Figures 1 and 2 show the effect of the alkali charge on the percentage of enzymatic hydrolysis and the sugar yields of the two-stage hydrolysis of corn cobs, which were deacetylated by NaOH, Na_2CO_3, and $Ca(OH)_2$, respectively. Both the percentage of enzymatic hydrolysis and the sugar yields were increased with the increase of the alkali charge. When the corn cobs were deacetylated by NaOH, Na_2CO_3, and $Ca(OH)_2$ at the alkali charge of 0.8 mmol/g of substrate, the hydrolysis percentages of xylan in stage 1 were 93, 71, and 85%, respectively. The hydrolysis percentages of glucan in stage 2 were 86, 58, and 74%, respectively. For the case of $Ca(OH)_2$, although the enzymatic hydrolysis percentage of xylan was lower than that for NaOH, the sugar yield (0.293 g/g of corn cob at 0.8 mmol/g of substrate) was similar to the sugar yield using NaOH (0.300 g/g of corn cob at 0.8 mmol/g of substrate) because of the high recovery of xylan after the

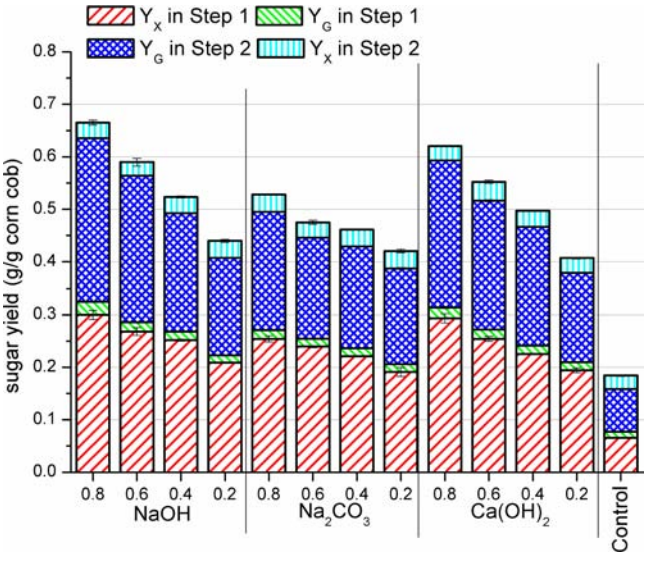

Figure 2. Sugar yields (Y_G and Y_X) of the two-stage hydrolysis of corn cob deacetylated by different bases and alkali charges. Values of 0.8–0.2, samples deacetylated with the alkali charge of 0.8–0.2 mmol/g of substrate (NaOH and Na_2CO_3 were calculated as Na_2O); control, water-treated sample.

deacetylation process using $Ca(OH)_2$. In comparison to other cellulosic material (such as corn stover[14] and aspen wood[31]), the corn cob could be highly digested in enzymatic hydrolysis after mild deacetylation treatment without any severe pretreatment (such as acid-assisted steam explosion[11] and acidified sodium chloride delignification[12,21]) because of the low lignin and high hemicellulose contents. In the two-stage hydrolysis, most xylan was separated in stage 1 by xylanase, leaving most of the glucan in the hydrolyzed solid residue because of the selectivity of xylanase. All of the proportions of sugars in the hydrolyzates after stage 1 were similar to the proportion deacetylated by $Ca(OH)_2$ with the alkali charge of 0.8 mmol/g of substrate (Table 3). XOS accounted for about 50% soluble

[d]On the basis of xylan or glucan in the raw corn cob.

sugar in the hydrolyzate. The comparatively low percentage of XOS could be caused by the long hydrolysis time, which could obtain a higher xylan yield because XOS could be further hydrolyzed into xylose by β-xylosidase in crude xylanase. The enzymatic digestions of the solid residues (stage 2) obtained from xylanase hydrolysis had a trend similar to stage 1. Because most of the digestible xylan was removed in stage 1 by xylanase, the percent of xylose in the hydrolyzate of stage 2 was much lower than the hydrolyzate directly obtained from the traditional one-stage enzymatic hydrolysis without the xylan-removing process. As presented in Table 4, the final sugar

[a]Hydrolysis substrate: PFI refined corn cob [deacetylated by $Ca(OH)_2$ at the alkali charge of 0.8 mmol/g of substrate]. [b]The total yield of two-stage hydrolysis (Y_G or Y_X) was calculated as follows: $Y_G = Y_{G1} + Y_{G2}$; $Y_X = Y_{X1} + Y_{X2}$. [c]Enzyme doses: cellulase, 18 FPU/g of od biomass; β-glucosidase, 9 IU/g of od biomass; and xylanase, 66 IU/g of od biomass.

yields obtained from the two-stage enzymatic hydrolysis were somewhat lower compared to the traditional one-stage hydrolysis. This was likely because used cellulase and β-glucosidase contained some xylanases, which had the ability to hydrolyze xyloligomers into xylose, thus removing the inhibition from xyloligomers during hydrolysis. This was in agreement with the fact that there were no xyloligomers detected in the hydrolyzate after one-stage hydrolysis. On the other hand, in the one-stage hydrolysis, three enzymes (cellulase, β-glucosidase, and xylanase) were added together, and the addition of xylanase may reduce the ineffective adsorption of cellulase to xylan and lignin, thus leading to the relative increase of cellulase activity.[18,32−34] Therefore, a higher final sugar yield could be achieved by the one-stage enzymatic hydrolysis. However, in stage 1 of the two-stage enzymatic hydrolysis, used xylanase had a lower ability to hydrolyze xyloligomers to xylose. Thus, many xyloligomers could be obtained after the hydrolysis of stage 1. Furthermore, in stage 2, the glucan yield was lower compared to the one-stage hydrolysis. This was possibly due to the relatively increased proportion of lignin in the xylan-deprived corn cob residue. The increased proportion of lignin might increase the ineffective adsorption of cellulase to lignin, thus lowering the glucan yield. However, although the sugar yields from the two-stage hydrolysis were lower than the one-stage hydrolysis, using xylanase and cellulase to "tailor" the deacetylated corn cob in two separated processes could make the component of the product more simplified, which is good for the further microbial or chemical utilizations. In addition, the optimization of enzymatic hydrolysis and the study of the inhibition of the XOS product in high solid loading (≥15%) hydrolysis will be conducted in the future.

Impact of Refining on the Enzymatic Hydrolysis. As shown in Figures 3 and 4, the enzymatic hydrolysis percentages of xylan (E_X) in stage 1, the enzymatic hydrolysis percentages of glucan (E_G) in stage 2, and the total sugar yields (Y_S) were all increased after PFI refining. The increased extents of sugar yields ranged from 0.023 to 0.212 g/g of corn cob (Figure 4), which were comparable to the previous reports.[18] However, the increased extents of hydrolysis percentages and sugar yields for the samples treated at hash conditions were lower than that for the samples treated with mild conditions. For example, as shown in Figure 4A, 9.7% improvement of the enzymatic hydrolysis percentage of xylan could be obtained for the samples treated with 0.2 g of $Ca(OH)_2$/g of substrate, while only 3.6% improvement could be achieved for the samples treated with 0.8 g of $Ca(OH)_2$/g of substrate. Also, for the

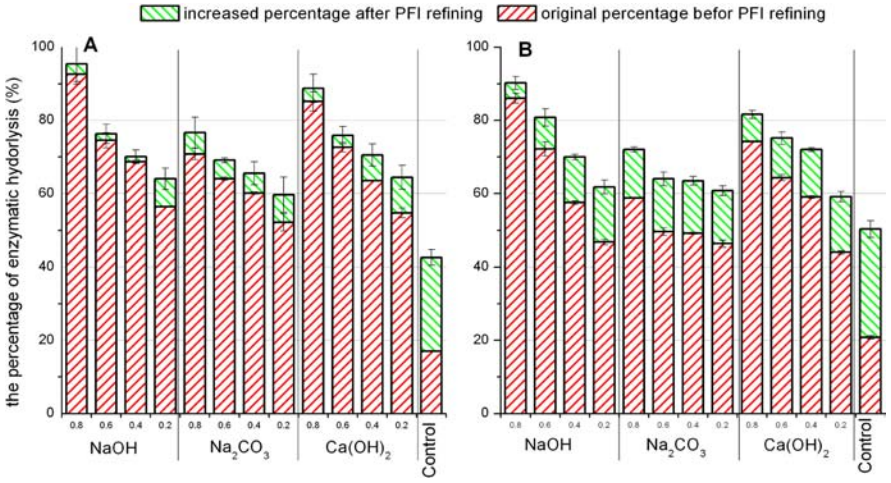

Figure 3. Effect of PFI refining on the rates of enzymatic hydrolysis (E_G and E_X) of the two-stage hydrolysis of deacetylated corn cob. (A) E_X of stage 1 (xylanase hydrolysis). (B) E_G of stage 2 (cellulase and β-glucosidase hydrolysis) Values of 0.8−0.2, samples deacetylated with the alkali charge of 0.8−0.2 mmol/g of substrate (NaOH and Na_2CO_3 were calculated as Na_2O); control, water-treated sample.

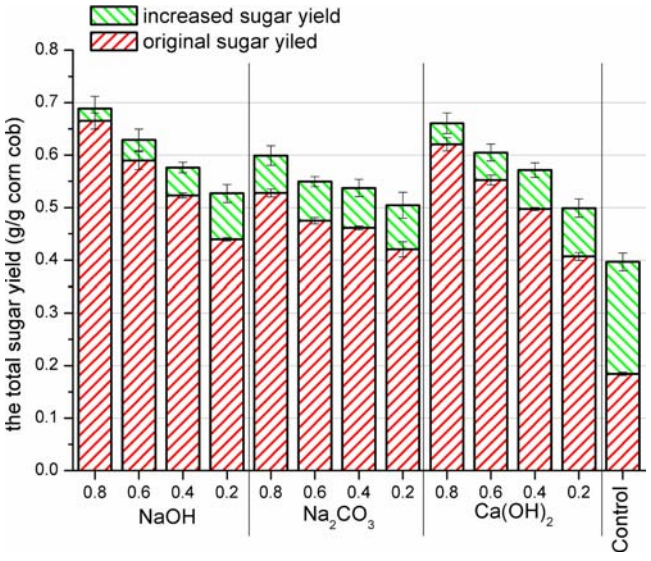

Figure 4. Effect of PFI refining on the total sugar yields (all of the sugars in hydrolyzate) obtained from the two-stage hydrolysis of deacetylated corn cob. Values of 0.8−0.2, samples deacetylated with the alkali charge of 0.8−0.2 mmol/g of substrate (NaOH and Na_2CO_3 were calculated as Na_2O); control, water-treated sample.

control sample, the total sugar yield was 0.212 g/g of corn cob, while after PFI refining, the total sugar yield could be 2.7 times higher than that of the unrefined sample (Figure 4). This was because the size reduction that resulted from the PFI refining increased the reactive surface area for enzymes, thus leading to an increase of xylan and glucan yields.[18] On the other hand, the decrease of crystallinity of cellulose (Table 2) caused by the compression and shear force of the PFI mill could also make cellulose more digestible.[13] In addition, as presented in Figure 4, a total sugar yield of 0.661 g/g of corn cob could be obtained from the samples treated by 0.8 mmol of $Ca(OH)_2$/g of substrate, which was comparable to the yield (0.688 g/g of corn cob) obtained from the sample treated by NaOH with the same alkali charge. This was due to the fact that higher sugar recovery could be achieved in the deacetylation process by the use of $Ca(OH)_2$. Therefore, it can be concluded that $Ca(OH)_2$ is the more appropriate alkali for deacetylation and the suitable alkali charge is 0.8 mmol/g of substrate based on the results obtained in this study. Other benefits using $Ca(OH)_2$ are that (1) $Ca(OH)_2$ is an inexpensive and milder base compared to NaOH and (2) $Ca(OH)_2$ can be easily recovered. Although some calcium ions may precipitate as calcium salts, precipitated calcium could be removed by sufficient washing (e.g., using vacuum washing equipment at large-scale production) after deacetylation. Another possible solution to avoid the precipitation of calcium is to add a small amount of chelating agent (e.g., EDTA) before deacetylation, so that the released calcium ions could be chelated and then removed during washing.

Mass Balance Analysis. The overall process and mass balance for the combined deacetylation [on the basis of $Ca(OH)_2$] and PFI refining pretreatment of corn cob plus the two-stage enzymatic hydrolysis are presented in Figure 5. For theoretical calculation, the sugar loss in PFI refining was neglected. As demonstrated in Figure 5, after $Ca(OH)_2$ deacetylation (with the alkali charge of 0.8 mmol/g of substrate) and PFI refining, 79.8% xylan was hydrolyzed in

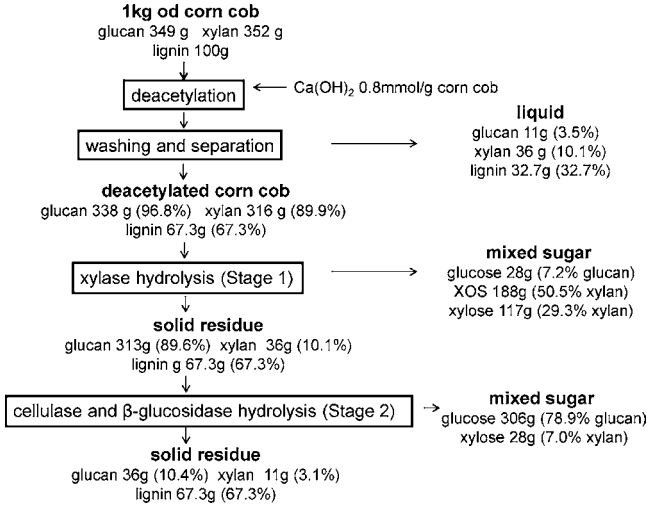

Figure 5. Mass balance of the overall process (deacetylation + PFI refining + two-stage hydrolysis).

stage 1 of enzymatic hydrolysis and 50.5% hemicellulose was converted to XOS. The cellulose in the solid residue separated from stage 1 could be highly digested by cellulase and β-glucosidase in stage 2. In total, 86.8% xylan and 86.1% glucan in the raw corn cob were hydrolyzed in the two-stage enzymatic hydrolysis, indicating that the combined $Ca(OH)_2$ deacetylation and PFI refining pretreatment process was a relatively effective method to improve the enzymatic digestion of corn cob. In addition, in comparison to the traditional one-stage enzymatic hydrolysis, the two-stage hydrolysis can make the resulting sugar products simpler and easier to be used in the downstream processes.

ABSTRACT: Starch grafted with four different methacrylates was compression molded to form thermoplastic films with good strength and water stability. Starch is an inexpensive and biodegradable polymer but is nonthermoplastic and needs to be chemically modified to make starch suitable for various applications. In this research, starch was grafted with four methacrylates (methyl, ethyl, butyl, and hexyl), and the effect of the length of the alkyl ester group on grafting parameters, thermoplasticity, and properties of thermoplastic films developed have been studied. Influence of grafting conditions on % grafting efficiency, % homopolymers, and % monomer conversion were studied, and the grafted starch was characterized using thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), and nuclear magnetic resonance (^{1}H NMR). At similar grafting ratios, butyl methacrylate (BMA) provided better strength and elongation to the starch films than the other three methacrylates. Grafting of methacrylates appears to be an economical approach to develop thermoplastic products from starch.

KEYWORDS: *starch, thermoplastics, methacrylates, grafting*

INTRODUCTION

Starch is one of the most widely used biopolymers for food and nonfood applications. Large availability, low cost, and easy biodegradability are some of the major features that make starch attractive for various applications. Starch is found in several sources, including cereal grains, vegetables, and fruits, but the basic structure and properties of starch are the same. Nonfood applications of starch include paper, pharmaceutical, biofuel, textile, and packaging, in addition to many others. Although ethanol production, paper, and other applications use starch in its native form, many types of physical and/or chemical modifications are done to make starch suitable for processing and to develop products. Modifications are also necessary to improve the properties, such as increasing its tensile strength and hydrophobicity, and to obtain starch-based products with desired features.[1] Modified or unmodified starches are made into products mainly by the wet or dry approach. Wet processing of starch includes dissolving or dispersing starch and casting the solution, mainly to form films. Dry processing of starch includes extrusion, injection, and compression molding to form foams, sheets, films, and other products.

Although dry processing of starch is preferred over wet processing, native starch is nonthermoplastic, and it is necessary to modify starch to produce thermoplastic products.[2] Thermoplastic starch, commonly referred to as TPS, is made by mixing starch with water and plasticizers under heat and can be extruded or processed into products.[3,4] TPS could be used to manufacture films for food packing, extrudates for secondary packing, and micro and nanofibers for textile and medical applications. Similarly, TPS could be used as a resin, and natural fibers could be used as reinforcement to obtain completely degradable composites. However, thermoplastic starch has several limitations. For instance, TPS is mostly water-soluble and provides products with poor strength.[3,5] Blending of synthetic polymers, inorganic materials, and additives such as lignin and nanoclay have been used to improve the properties of products developed from thermoplastic starch.[6] Cross-linking is another approach that has been commonly used to improve the properties of starch products.[7] It was previously shown that solution cast starch films, after being cross-linked with citric acid, had much higher tensile strength and water stability.[7]

Chemical modifications, such as acetylation, hydroxypropylation, and grafting, have also been used to modify starch and develop thermoplastic products.[8,9] Starch acetates have been produced on a commercial scale and used in pharmaceutical, food, and other industries. Although acetylation makes starch thermoplastic and provides products with good tensile

properties and water stability, acetylation is expensive and not affordable to develop commodity products such as films. Recently, acylation of starch using enzymes has been done to avoid the harsh conditions necessary during other chemical modifications.[1] Grafting of polymers is another approach that has been commonly used to develop products from starch. Both natural and synthetic polymers have been grafted onto starch to impart desired properties to starch.[9] A multitude of synthetic monomers such as acrylamide, polyurethane, polystyrene, acrylonitrile, and vinyl monomers have been grafted onto starch, and the thermal behavior of the grafted materials have been compared to the unmodified starch.[9−11]

Among the various types of monomers grafted onto starch, acrylic monomers such as methyl, ethyl, and butyl acrylates, and the corresponding methacrylates, are preferred due to their lower cost and ability to provide good performance properties.[12] Grafting of acrylic monomers onto starch and other biopolymers has been extensively studied, and the influence of catalysts, initiators, and monomers on the grafting parameters and properties of the products obtained has also been investigated. For example, methyl methacrylate (MMA) was grafted onto sago starch in aqueous media using different initiators of ceric ammonium nitrate and potassium persulfate under nitrogen atmosphere.[12] On the basis of FTIR studies, it was suggested that MMA was successfully grafted onto starch and that the grafted starch was suitable for developing thermoplastic products.[12] In another study, cassava starch was grafted with poly(methyl methacrylate) using benzoyl peroxide as initiator.[13] Starch with 37.2% grafting ratio, 95.5% yield, and 54.3% homopolymer was obtained after the reaction. Ethyl acrylate and acrylamide were grafted onto starch by copolymerization using potassium permanganate-citric acid as initiator, and the reaction conditions were optimized. Grafting of the copolymers onto starch was proven using FTIR.[9] In another study, corn starch was first alkenylsuccinylated to different degrees of substitutions and was later graft-copolymerized with acrylic acid.[14] Alkenylsuccinylation resulted in higher grafting efficiency and stronger films.

The influence of the alkyl chain length on the grafting efficiency was studied using three vinyl monomers [methyl methacrylate (MMA), ethyl methacrylate (EMA), and butyl methacrylate (BMA)] using ceric ammonium nitrate as the initiator. Optimum grafting conditions were developed, and it was found that the reactivity of the methacrylates increased with increasing alkyl group length.[15] It was also suggested that the monomers were grafted onto the amorphous and crystalline regions. Crystallinity and thermal stability of the grafted starch were found to decrease after grafting. Starch was graft copolymerized with methacrylonitrile and MMA, EMA, BMA, and HMA. Among the four methacrylates studied, HMA was found to have considerably lower % grafting, which was inferred to result from the lesser accessibility of HMA to the active sites of the carbohydrate.[16]

Efforts have also been made to develop thermoplastics from grafted starch.[17] Starch grafted with methyl acrylates and methacrylates has been injection molded into ribbons, and the properties of the extruded ribbons have been investigated.[18,19] Films with tensile values ranging from 8 to 17 MN/mm^2 and with elongations from 2% to 150% were obtained, depending on the level of grafting and the aging time.[18] In other research, starch-*g*-PMA with PMA contents between 59% and 67% provided films with tensile strengths ranging from 9 to 24 MN/m^2 and elongations of 30−265%.[19] Bagley et al. grafted methyl acrylate, methyl methacrylate, and a mixture of methyl and butyl acrylate and extruded them into ribbons.[20] Plastics obtained from starch-*g*-methyl methacrylate were described as being brittle, but those grafted with methyl acrylate and butyl acrylate were flexible and leathery.[20] As seen from the literature discussed above, limited study has been done on developing thermoplastics products from grafted starch, and only a few monomers have been studied. The influence of different acrylic monomers, their structures, and chain lengths, and the amount of homopolymers on the tensile properties of compression-molded films is not known. More importantly, the resistance of the films to water and high humidity and the suitability of the starch films for various applications have not been investigated. In this research, a series of vinyl monomers with increasing alkyl chain lengths were grafted onto starch. Grafting conditions were optimized, and the grafted starch was characterized for thermal behavior and structural changes. Grafted starch was compression molded into thermoplastic films, and the influences of % homopolymers on the dry and wet tensile properties were studied. The ability of the different monomers to improve the strength and water stability were also investigated.

MATERIALS AND METHODS

Materials. Corn starch (regular) was purchased from the National Starch Company and used as received. Four vinyl monomers (MMA, EMA, BMA, and HMA) were selected for grafting onto starch based on our previous studies on grafting vinyl monomers onto chicken feathers and camelina meal.[21,22] Monomers, potassium persulfate used as initiator, sodium bisulfite used as reductant, and other chemicals required for the study were reagent grade.

Methods. *Grafting.* Starch was first dispersed in water, and the required ratios of monomers were added into a four-necked flask along with the initiator and reductant. Oxygen in the flask was removed by displacing it with nitrogen, and the entire reaction was performed under nitrogen atmosphere. Grafting conditions such as monomer concentration to starch (30−140%), reaction time (0.5 to 4 h), and reaction temperature were varied to obtain the optimum grafting conditions. After the required grafting time, the reaction was stopped by adding 2% paradioxybenzene. Grafted starch was thoroughly washed in water to remove unreacted monomers and inorganic salts and later dried and collected. Grafting parameters, such as grafting efficiency, molar grafting ratio (mol/g), monomer conversion (%), and % homopolymers were calculated using equations reported in our previous researches.[21]

Thermal Analysis. Grafted starch was analyzed to determine the thermal behavior using differential scanning calorimeter (DSC) and thermogravimetric analysis (TGA). DSC studies were done on a Mettler Toledo calorimeter (Model D822e; Mettler Toledo, Columbus, OH) under nitrogen atmosphere with temperatures ranging from 25 °C to 250 °C. Three scans were done for each sample, and the average data were used to draw the melting curves. TGA studies were done on a Sigma T300 analyzer with 10 mg of sample, and three samples were analyzed under nitrogen for each condition. An average of the three samples were used to plot the thermal degradation curves.

Fourier Transform Infrared (FTIR). Grafted and ungrafted starch samples were analyzed on a Fourier Transform Infrared Spectrophotometer (Thermo Scientific Model: iS10; Thermo Scientific, Waltham, MA) on an attenuated total reflectance mode using a diamond cell. Samples were scanned 32 times from 500 to 4000 cm^{-1} at a resolution of 8 cm^{-1}. Three spectras were collected for each sample, and the average values were used for comparison.

^{1}H NMR. Nuclear magnetic resonance studies were conducted to confirm grafting of the monomers onto starch. For the NMR analysis, samples were dissolved in acetone (1 wt %) and scanned on a Avance 600 MHz Digital NMR spectrometer (Bruker Co. Ltd. Switzerland). A

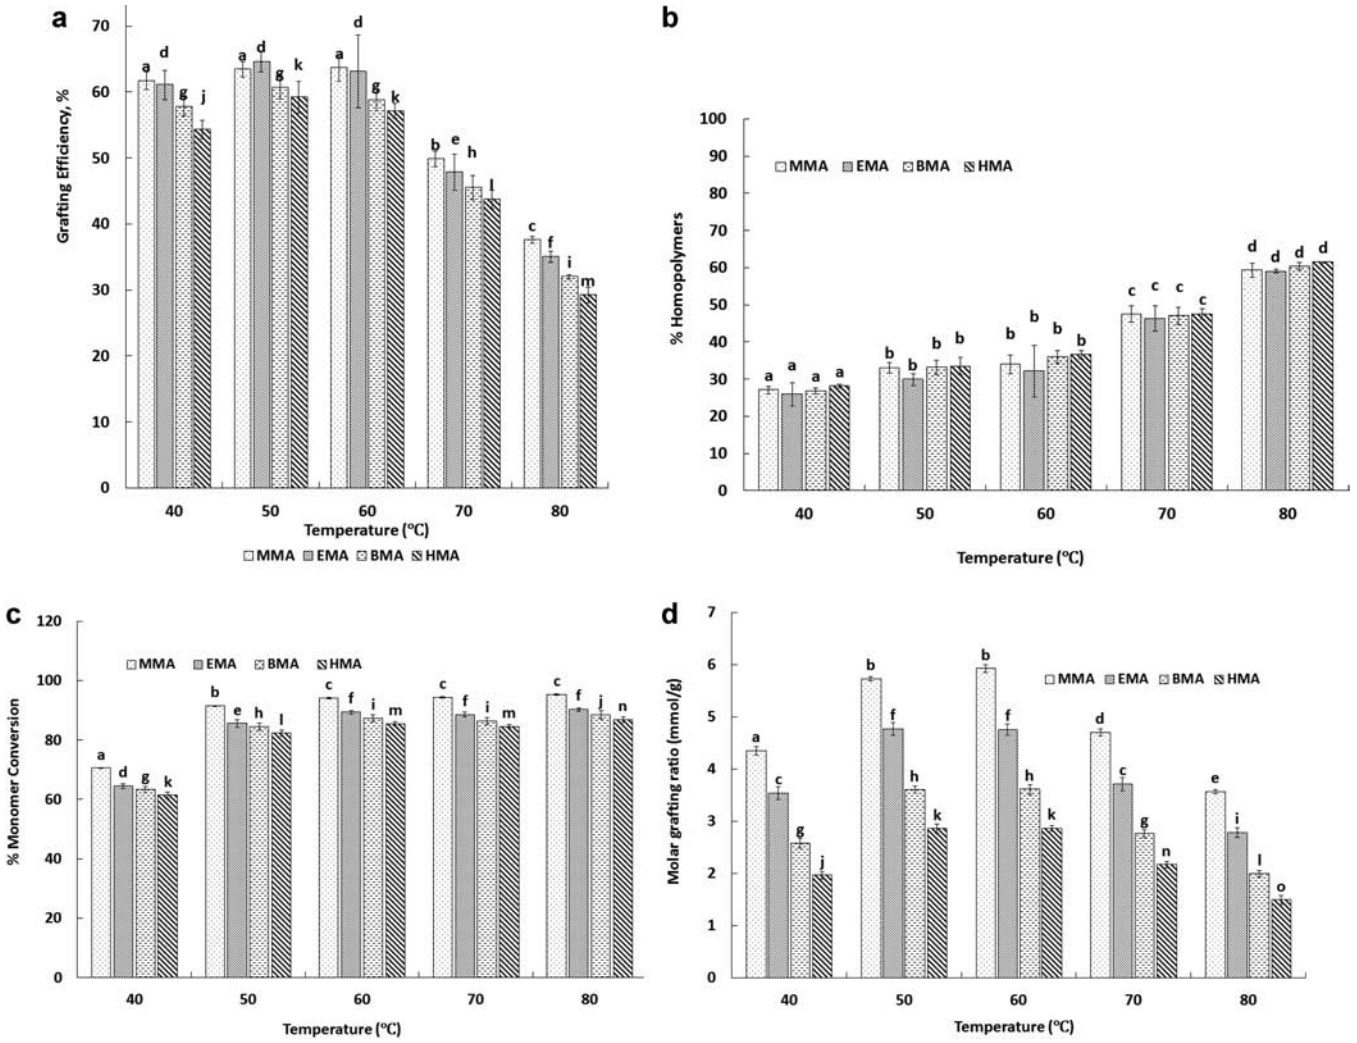

Figure 1. Influence of grafting temperature on % grafting efficiency (a), % homopolymers (b), % monomer conversion (c), and molar grafting ratio (d). Grafting was performed using 100% of monomers based on weight of starch for 180 min at various temperatures. For each monomer, data points with the different letters indicate statistically significant difference.

basic proton pulse sequence (zg30) was used with a relaxation delay of 1 s and acquisition time of 3 s and operated at 600 MHz. Spectra were phase corrected interactively using TOPSPIN. Baseline correction was carried out manually using the appropriate factors.

Influence of Homopolymers. Homopolymers formed by the reaction between the monomers will affect the thermal behavior and properties of the thermoplastic films developed. To understand the influence of homopolymers, starch was treated (Soxhlet extracted for 24 h) using acetone to remove the homopolymers. The amount of homopolymers in the grafted starch was determined based on the weight differences before and after extraction. A known amount of homopolymers (25−75%) was first dissolved in acetone, and the grafted samples were later added into the solution. Acetone was evaporated, and the samples containing homopolymers were dried and later powdered in a Wiley mill (20 mesh) before being compression molded into films.

Developing Thermoplastics. Grafted starch with and without a known amount of homopolymers was compression molded to form films. Samples (about 10−12 g) were placed between two aluminum foils and compression molded on a carver press at different temperatures for 5 min at a pressure of 20 000−40 000 PSI. The different compression conditions were because of the varying thermoplasticities of the grafted samples. After compression, the press was cooled by running cold water, and samples were collected for further analysis.

Dry and Wet Tensile Properties. Compression-molded films were first conditioned at 21 °C and 65% relative humidity for at least 48 h before being tested. To determine the stability under wet conditions, samples were conditioned at 90% humidity for 24 h in a Caron environmental chamber and then immediately tested. Tensile tests to determine the strength, elongation, and modulus were done on an MTS tensile tester (Model Qtest 10, MTS Corporation, Duluth, MN) according to ASTM standard D 882. The gauge length was 5 cm, and the crosshead speed was 10 mm/min. At least 20 samples from three different films were tested, and the average and standard deviations of the strength, elongation, and modulus were reported.

STATISTICS

Data obtained was analyzed using SAS by the Tukey's pairwise comparison method. The significance level was set at 95% with α = 0.05, and a P value of less than 5% were considered insignificant.

RESULTS AND DISCUSSION

Effect of Grafting Conditions on Grafting Parameters.

Effect of Grafting Temperature. Figure 1a,d shows the influence of temperature on grafting parameters. Increasing the temperature decreased the % grafting efficiency for all four monomers studied, as seen from Figure 1a. There was no

dx.doi.org/10.1021/jf5013709 | J. Agric. Food Chem. 2014, 62, 4668−4676

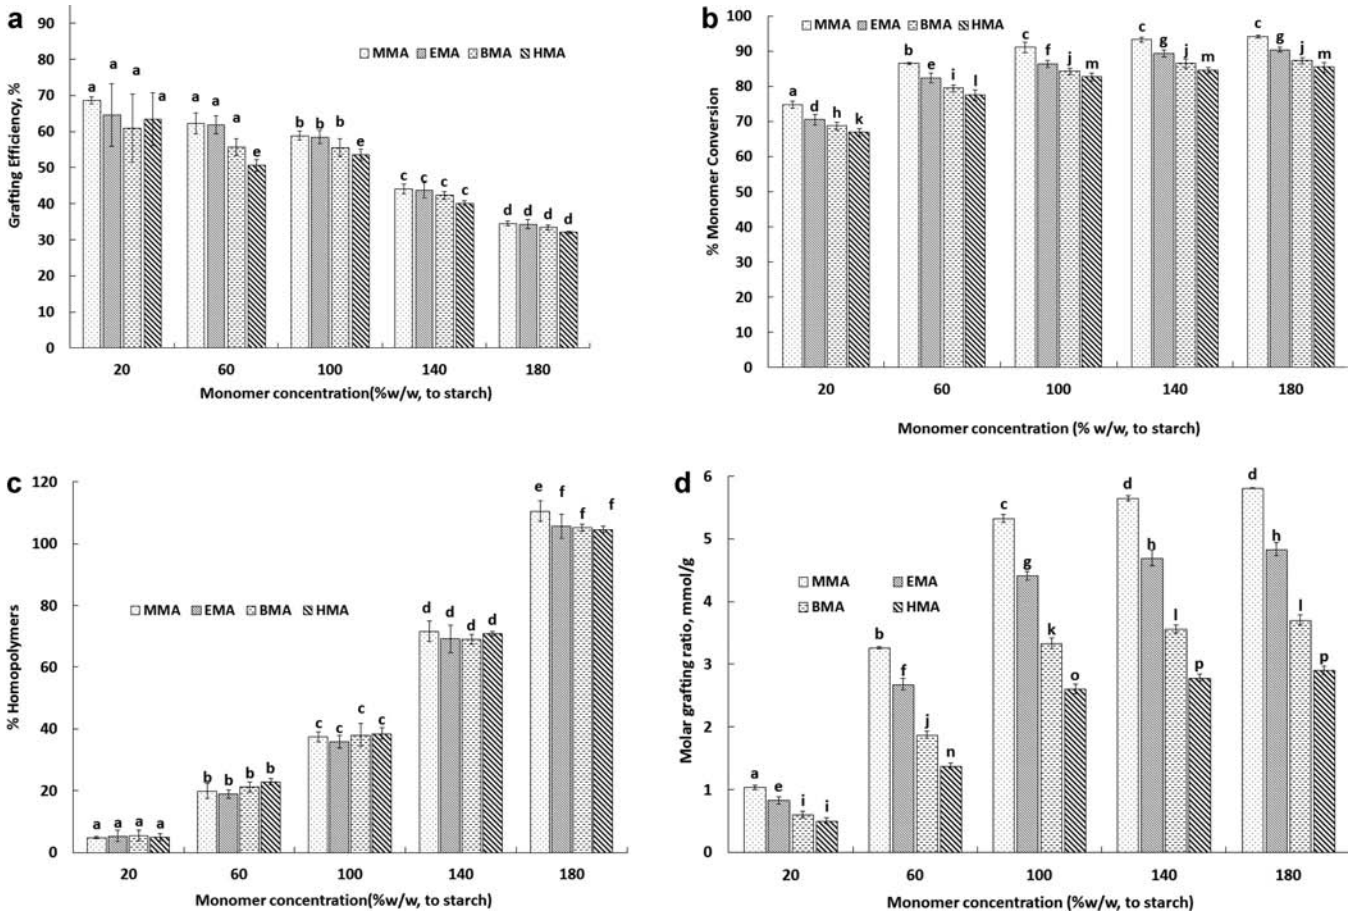

Figure 2. Influence of monomer concentration during grafting on % grafting efficiency (a), % homopolymers (b), % monomer conversion (c), and molar grafting ratio (d). Grafting was performed at 60 °C for 60 min using different concentrations of monomers. For each monomer, data points with the different letters indicate statistically significant difference.

significant change in the grafting efficiency when the temperature was between 40 °C and 60 °C, but the grafting efficiency decreased at 70 °C and 80 °C. Increasing the length of alkyl chain from 2 to 6 (MMA to HMA) decreased the % grafting efficiency at all temperatures studied. Previous studies on the grafting of starch with methacrylates have also shown that increasing temperature increased the grafting efficiency up to a certain temperature, and the % grafting efficiency (GE%) decreased at high temperature.[15] Therefore, a decrease in % GE at high temperatures was attributed to the increase in termination rate of the starch grafted polymeric chain or due to chain transfer to monomer molecules.[15] A decrease in the % GE leads to an increase in % homopolymers when the grafting temperature was 70 °C and 80 °C as seen from Figure 1b. At high temperatures, the monomers move faster and more readily react with each other and form the homopolymers. The % monomer conversion was considerably lower when the temperature was 40 °C, but increased to above 70% for all the monomers when the temperature was 80 °C or higher. Increasing the length of the alkyl chain decreased the % monomer conversion at all temperatures studied, as seen from Figure 1c due to the steric hindrance as the length of the carbon chain increases.[16] This is more evident when the molar grafting ratio is considered for the different monomers. Increasing the temperature increased the molar grafting ratio for all the monomers, as seen from Figure 1d. More interestingly, the grafting ratios decreased as the length of the alkyl chain increased, although the grafting conditions were similar. At a temperature of 60 °C, MMA had a grafting ratio of 5.9 mmol/g, compared to 2.9 mmol/g for HMA. MMA, being a much smaller molecule than HMA, was more easily accessible to starch and was easily grafted and provided higher % grafting. A temperature of 60 °C was found to provide the most optimum grafting for all four monomers studied.

Effect of Monomer Concentration. Increasing monomer concentration continually decreased the % grafting efficiency and increased the % homopolymers, as seen from Figure 2a,b. The % homopolymers were less than 5% for all the monomers when the monomer concentration was 20%. Increasing the monomer concentration leads to a substantial increase in % homopolymers up to about 105−110% when the monomer concentration is 180%. When the monomer concentration was increased above 20%, a higher number of monomer molecules are available for reaction, and therefore, higher numbers of monomers were grafted onto starch. When the monomer concentration increased above an optimum level, the monomers collide with each other and form homopolymers because the growing poly(methacrylate) chain has greater compatibility with the monomer molecules.[15,16] At low monomer concentrations (20%), the % monomer conversion is significantly lower (Figure 2c) because there are fewer molecules in solution that can react and form grafted chains or homopolymers. The molar grafting ratio increased with increasing monomer concentration for all the monomers, as

dx.doi.org/10.1021/jf5013709 | J. Agric. Food Chem. 2014, 62, 4668−4676

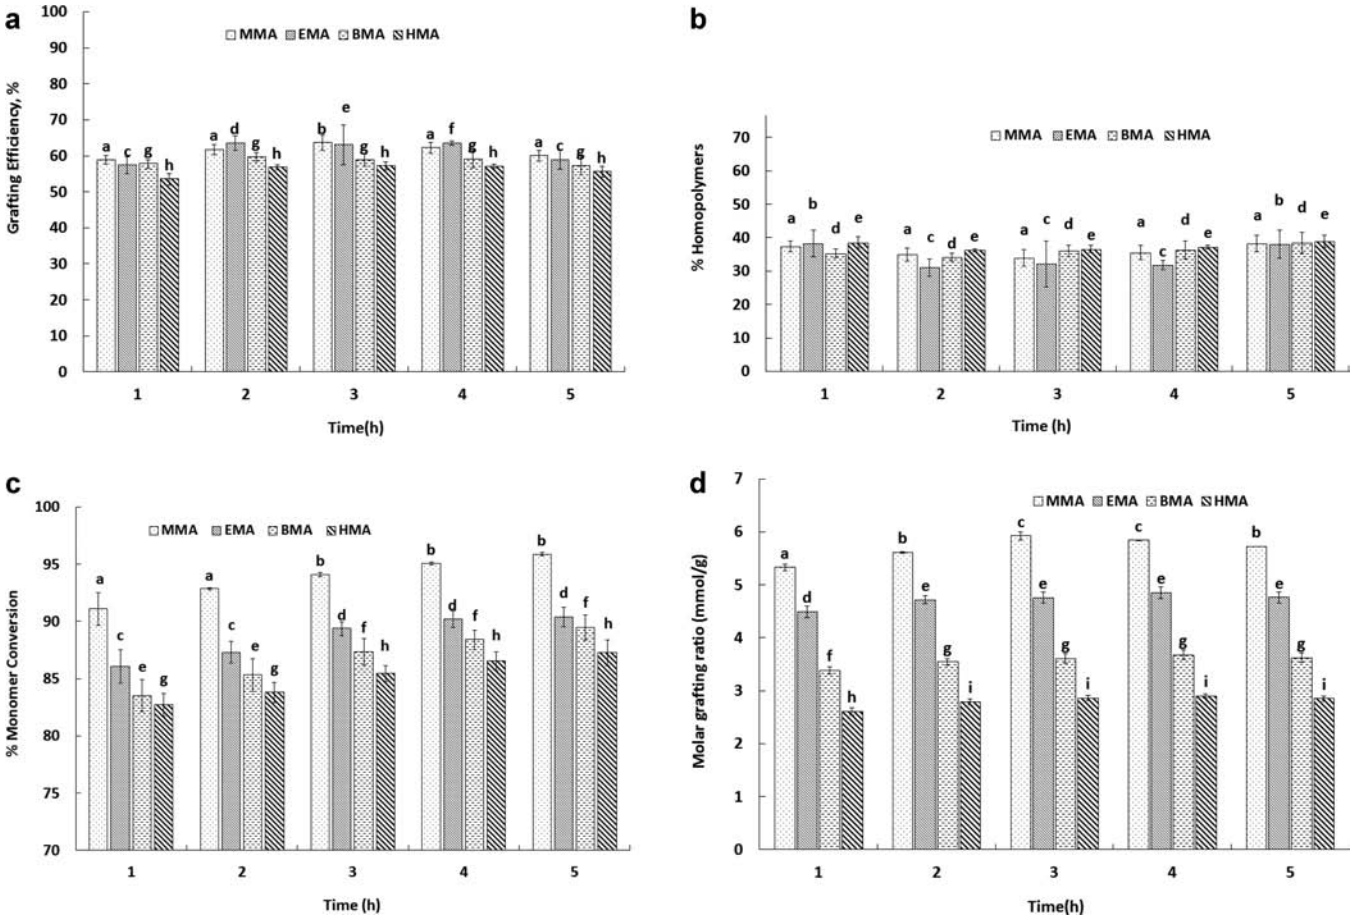

Figure 3. Influence of reaction time on % grafting efficiency (a), % homopolymers (b), % monomer conversion (c), and molar grafting ratio (d). Grafting was performed at 60 °C with 1:1 ratio of monomer to starch. For each monomer, data points with the different letters indicate statistically significant difference.

seen from Figure 2d. However, the grafting ratio decreased substantially with increasing length of the alkyl chain due to steric hindrance of the longer chain monomers and subsequent difficulty in being grafted onto starch.

Effect of Grafting Time. Grafting time did not show a major effect on % grafting efficiency, as seen from Figure 3a. Similarly, the % homopolymers (Figure 3b) also did not show any significant change with increasing reaction time. However, monomer conversion marginally increased with increasing reaction time, as seen from Figure 3c. Previous studies had shown that increasing reaction time from 30 to 60 min significantly increased % GE for MMA, EMA, and BMA. In our reaction, we added the monomers gradually for almost 30 min, and we therefore did not study a reaction time lower than 1 h. Most of the monomers have either been grafted or converted into homopolymers within 1 h, and we therefore do not observe any major change in grafting parameters with increasing reaction time. As observed before, higher alkyl chain length decreased the grafting ratio, and reaction time did not affect the grafting ratio, as seen from Figure 3d.

Characterizing the Grafted Starch. *Fourier Transform Infrared Spectroscopy.* The characteristic carbonyl group in the methacrylates that appears as C═O stretching at about 1730 cm^{-1} is seen in Figure 4 for all four spectra for the grafted starch. The intensity of this peak is highest for HMA, similar for EMA and MMA, and considerably lower for BMA. Presence of the additional peak in the grafted samples that belongs to the

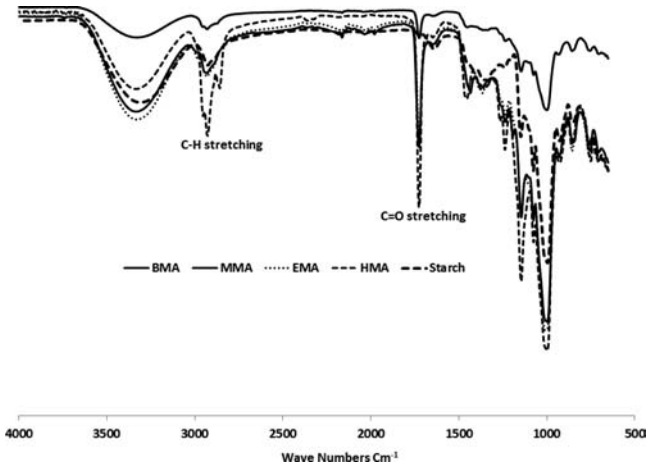

Figure 4. FTIR spectrum of the unmodified and grafted starch depicting the characteristic peaks belonging to the carbonyl group in the monomers. The spectrum was recorded after extracting the homopolymers from the grafted samples.

methacrylates confirms grafting of the monomers onto starch.[9,13] Broad peaks seen between 3500 and 3100 cm^{-1} are due to the hydroxyl groups in starch and the sharp peaks at about 2900 cm^{-1} are due to the C−H stretching from the grafted polymers, also suggesting successful grafting.[12,13]

dx.doi.org/10.1021/jf5013709 | J. Agric. Food Chem. 2014, 62, 4668−4676

Thermal Behavior. Thermal degradations of the grafted starch samples were similar as seen from Figures 5 and 6. A

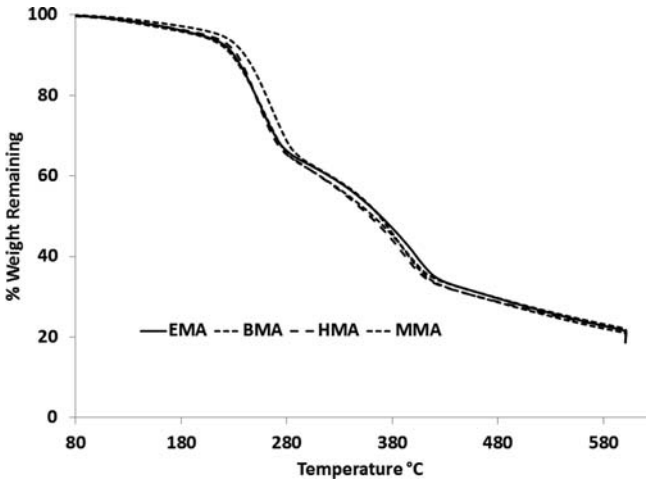

Figure 5. Thermal degradation (% weight loss) of the grafted starch samples when heated to 580 °C.

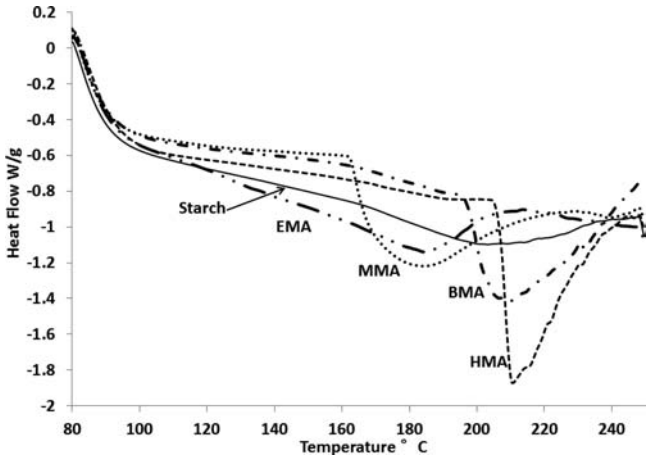

Figure 6. DSC thermograms illustrating that the starches grafted with higher lengths of alkyl chains had better melting when heated to 250 °C.

sharp decrease in the curve is seen around 220 °C, suggesting the start of degradation. MMA showed a slightly lower weight loss than the other samples up to about 300 °C, whereas HMA and EMA showed lower weight loss between 300 °C and 400 °C. An overall weight loss of about 80% was obtained after heating to 600 °C. DSC thermograms clearly show that starch grafted with longer lengths of alkyl esters (BMA and HMA) melted at higher temperatures and had sharper peaks compared to the starch grafted with MMA and EMA. Among the four monomers studied, EMA-grafted starch had a relatively lower melting enthalpy of about 12.6 J/g compared to 50−53 J/g for the other three monomers. As seen from Figure 6, HMA had a sharp and large melting peak at about 210 °C, whereas MMA and EMA produced broad melting peaks ranging from 160 °C to 200 °C. BMA and HMA are more thermally stable than MMA and EMA and therefore melt at higher temperatures. The sharp melting peaks for HMA and BMA suggest that these two polymers may provide better thermoplastic products but need higher processing temperatures. Although the melting peaks for the grafted starch were between 160 °C and 200 °C, the grafted starch could be compression molded into films at 165 °C under pressure, thereby preventing excessive thermal damage to starch at high temperatures.

^{1}H NMR. Grafting of the poly(acrylates) onto starch was evident from the NMR spectra in Figure 7a−d below. As shown in Figure 7a, the H NMR resonances at 3.2−3.8 (protons 2,3,4,5,6), 4.3 (proton 7) and 5.0−5.3 (proton 1) were the characteristic signals from starch. The resonances at 3 and 2.5 ppm were from water and DMSO, respectively. Figure 7b−e illustrated that the H NMR spectrum for the MMA-, EMA-, BMA-, and HMA-grafted starch, respectively. It could be seen that polyacrylates and starch moieties were present in the spectrum. After grafting with acrylates, resonances at 0.9−2.0 ppm appeared, which were the signals of CH_3, CH_2, and CH groups in the polyacrylate. The resonance of 4.3 ppm (proton 7) decreased or disappeared in the spectra, which clearly confirmed the grafting of polyacrylates onto the hydroxyl group of starch. The signal of $COOCH_3$ group of polyacrylate overlapped with protons 2−6 of the starch, which made the resonance at 3.2−3.8 ppm more complicated.

Tensile Properties of Compression Molded Starch Films. Table 1 provides a comparison of the tensile strength of the starch films grafted with the four different monomers and containing different levels of homopolymers. On the basis of the tensile strength in Table 1, it can be observed that increasing the length of alkyl chains from 2 to 4 increased the strength of the films when there was no homopolymer but HMA grafted starch films had considerably lower strength than BMA-grafted films. BMA had strength of 1 MPa compared to 0.2 and 0.3 MPa for MMA and EMA, respectively, whereas HMA-grafted films have a strength of 0.5 MPa. Addition of homopolymers continually increased the strength for all the monomers. With 50% homopolymers, the strength of the MMA- and EMA-grafted films were nearly 10 times higher, 3 times higher for BMA films, and twice higher for HMA films. Films made from the 100% homopolymers showed that increasing the length of the alkyl chain considerably decreased the tensile strength. For instance, MMA-homopolymer films had a strength of 12.8 MPa, compared to 3 MPa for HMA-homopolymer films. MMA- and EMA-grafted films showed considerably lower elongation than BMA and HMA films, especially with the addition of homopolymers. With 50% homopolymers, BMA films had the highest strength, although HMA-grafted films showed higher elongation than the films containing the other monomers.

Although MMA and EMA provided films with good dry tensile properties, the films containing up to 75% homopolymers were unstable in water, became too weak, and could not be tested even after conditioning at 90% humidity for 24 h at 21 °C. BMA- and HMA-grafted films showed good stability to moisture, especially in the presence of homopolymers, as seen from Table 1. In fact, the wet strength of the films grafted with HMA and containing 50% and 75% homopolymers is similar to or higher than the dry strength of the films. Tensile properties of the grafted starch films will depend on the extent of grafting, amount of homopolymers, and the inherent properties of the monomers and homopolymers. BMA provides better thermoplasticity, melts the starch and therefore provides the films with good tensile strength. In addition, increasing the alkyl chain length decreased the hydrophilicity, and therefore, BMA- and HMA-grafted films had better water stability than MMA and EMA films.

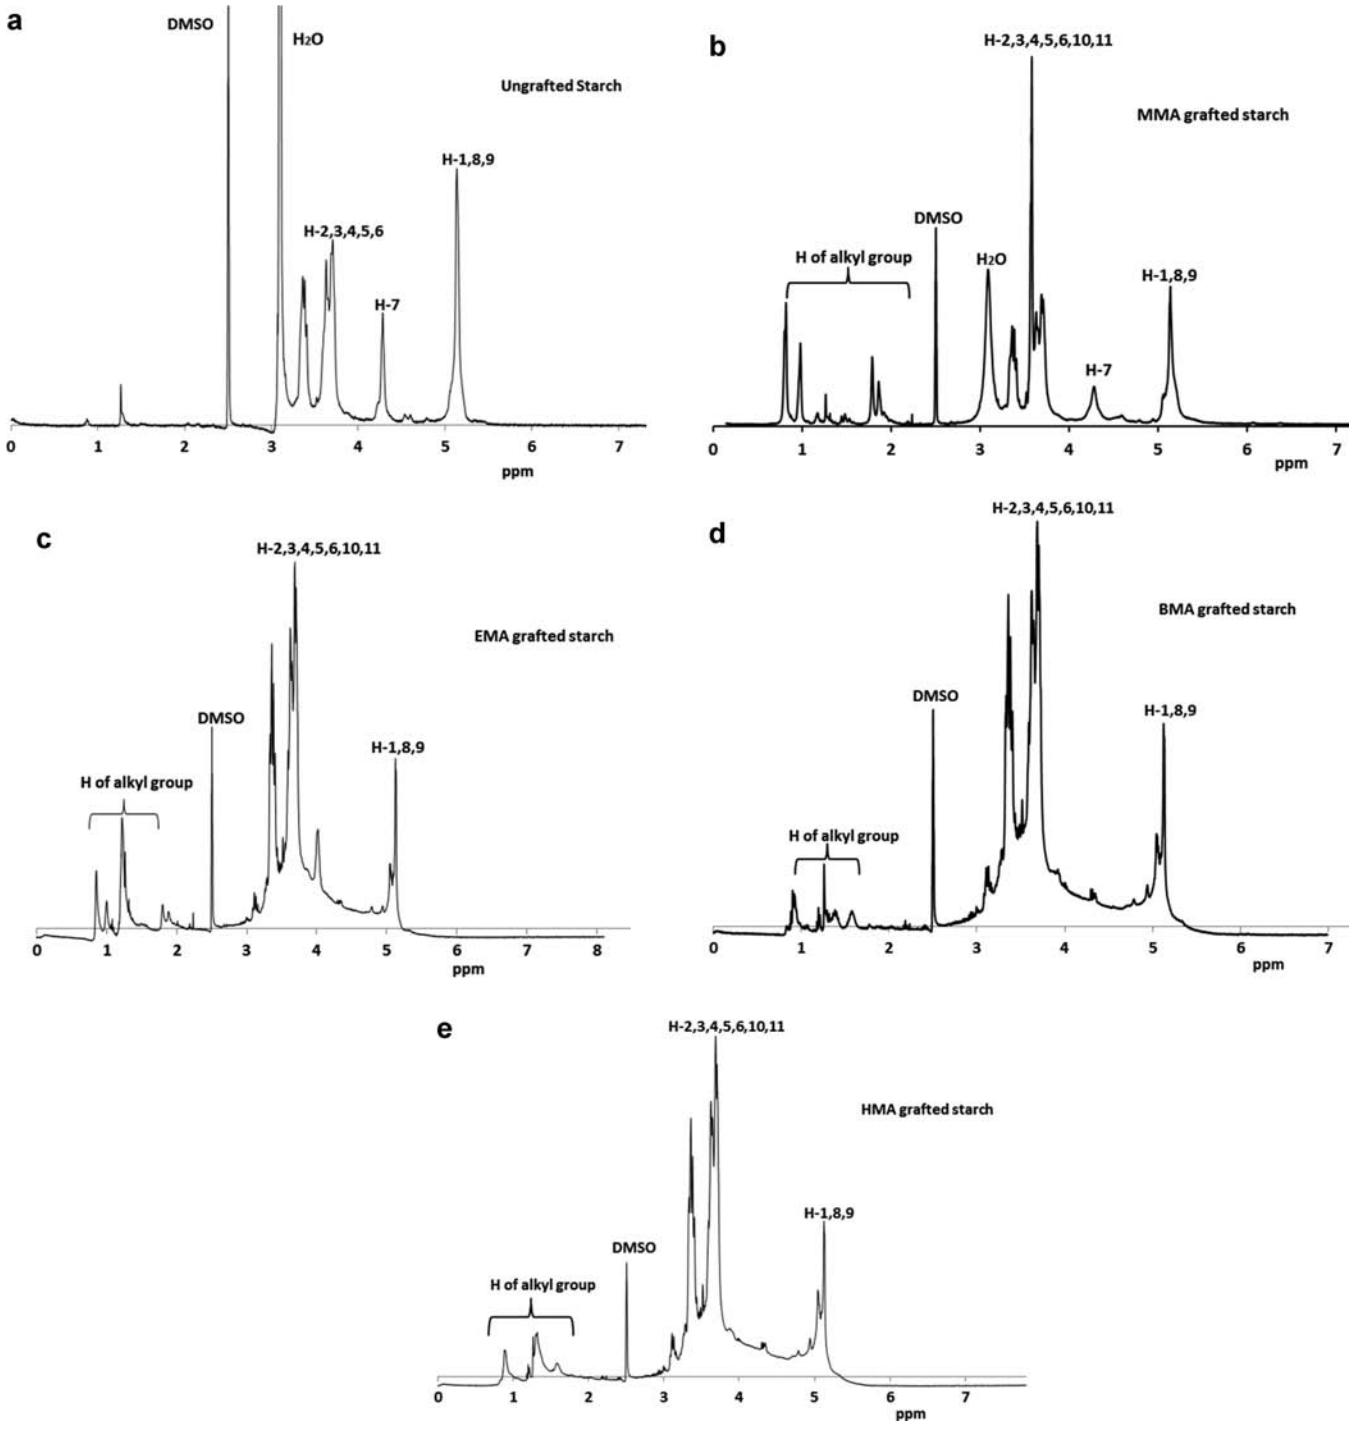

Figure 7. [1]H NMR spectra of the ungrafted starch (a), MMA-grafted starch (b), EMA-grafted starch (c), BMA-grafted starch (d), and HMA-grafted starch (e) with the position of the various hydrogen atoms.

Elongation of the films also showed that increasing the alkyl chain length and amount of monomers increases elongation. Without any homopolymers, MMA had an elongation of 2.8%, compared to 3.2% for HMA. Starch films grafted with HMA were considerably softer and therefore had lower strength but higher elongation (than BMA containing films). Increasing the length of alkyl chains increases the flexibility of the side chains, and therefore, the elongation of the films with BMA and HMA was higher than those of MMA- and EMA-containing homopolymers. Addition of homopolymers did not show an increase in the elongation of MMA- or EMA-grafted films, but the elongation of the BMA- and HMA-grafted films increased up to 10 times. BMA-grafted films without homopolymers had an elongation of 3.1%, compared to 8.5% when 50% homopolymers were added. HMA-grafted films without any homopolymers had an elongation of 3.2%, compared to 10.4% when the homopolymer content was 50%. Increase in elongation for the BMA and HMA films should be due to the high elongation of the BMA (71%) and HMA (111%) homopolymers. Wet elongation of the BMA- and HMA-grafted films also showed a similar trend with elongations of 8.6 and

16.4% for the BMA and HMA films containing 50% homopolymers.

On the basis of the strength and elongation of starch films grafted with various monomers, BMA was found to be more suitable to obtain films with good strength and elongation. A digital picture of a film made by compression molding starch grafted with BMA is shown in Figure 8. The film is transparent,

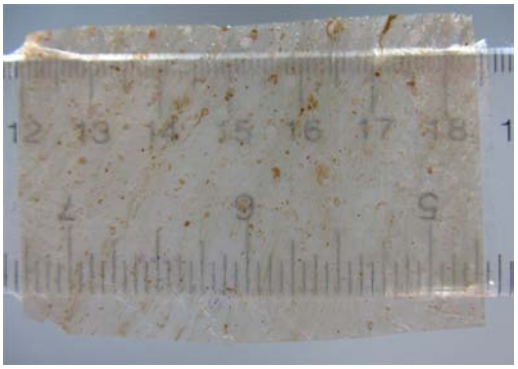

Figure 8. A digital picture of a film made by compression molding starch grafted with BMA.

indicating that the grafted starch could be melted and made into thermoplastic products. Further studies were done to develop films from BMA with different grafting ratios and study the dry and wet tensile properties, since films grafted with MMA and EMA were weak and could not be tested after conditioning at 90% humidity for 24 h.

Increasing the % grafting from 2.1 to 4.2 mmol/g (30% to 60% grafting) substantially increased the strength and elongation of the BMA grafted starch films from 1 to 3.2 MPa. There was also a considerable increase in the wet strength of the films (from 0.4 to 1.8 MPa) because of the increase in the amount of the hydrophobic polymer with increasing % grafting. When the grafting was 50%, the wet strength of the films was about 30% of the dry strength. Elongation of the films also increased from 3% to 12% when the grafting ratio was increased from 2.1 to 4.2 mmol/g. The corresponding increase in the wet elongation was from 6.7% to 25%. Strength and elongation of the films increased with increasing % grafting, since the grafted starch became more thermoplastic and formed better films. In addition, the grafted polymer had better strength and elongation than starch, and increasing the % of the grafted polymer therefore increased the tensile properties. Stability of the films under high humidities and in water is important for various applications, especially for food packaging. BMA-grafted films showed good dry and wet tensile properties even when the grafting was 30%. Therefore, BMA grafted starch films could be useful for food and other applications.

Starch grafted with BMA provided thermoplastic films with good strength and water stability. At similar grafting ratios, although increasing the length of the alkyl esters provided higher thermoplasticity and increased water stability, HMA homopolymers were considerably softer and decreased the strength of the starch films. Increasing the chain length also decreased the grafting ratio due to stearic hindrance from the monomers with longer side chains. Homopolymers considerably affected the tensile properties and water stability. Increasing the % of homopolymers generally increased the tensile strength and elongation. Films grafted with EMA were considerably brittle with elongation of 1−3%, whereas films grafted with BMA and HMA had elongations between 5% and 35%, depending on the amount of homopolymers. Overall, BMA was found to be more suitable for developing thermoplastic starch products with good tensile properties and water stability.

Supporting Information

ABSTRACT: Polyphenols normally have strong binding affinity with proteins, which may lead to protein precipitation. Glycosylation of protein via Maillard reaction in mild condition may inhibit the precipitation. This study prepared nanocomplexes of epigallocatechin-3-gallate (EGCG) and protein, and their stability against environmental stress was investigated. Subsequently, these findings were correlated with the interactions between EGCG and casein. Results showed that glycosylated casein displayed strong encapsulating and retaining capacity to EGCG, and no obvious aggregation or fusion appeared in the concentration range of 0.25−5.00 mg/mL during storage. The in vitro release demonstrated that casein, especially glycosylated casein, could effectively protect EGCG from degradation in alkaline pH and displayed a slow and sustained release in intestinal fluid, which may be attributed to the inhibiting effects of casein binding on the motion freedom of EGCG. Fluorescence quenching spectra demonstrated that the steric hindrance induced by dextran could inhibit the interaction between casein and EGCG. These findings demonstrated that glycosylated casein could be used as a promising and effective nanocarrier for EGCG.

INTRODUCTION

Tea polyphenols are being consumed by over two-thirds of the world's population and have shown versatile beneficial bioactivities.[1,2] The typical polyphenols in green tea include epigallocatechin-3-gallate (EGCG), epigallocatechin (EGC), epicatechin (EC), and epicatechin-3-gallate (ECG). Among these ingredients, EGCG is the most abundant and effective one.[3] However, EGCG is sensitive to pH, temperature, and oxygen, which limits its commercial applications in the food industry.[4] The lack of stability presents a significant challenge to design a vehicle that can protect EGCG from oxidation and degradation and thereby expand its industrial application.[1,3]

Encapsulation has been recognized as an effective approach to enhance the stability of EGCG against pro-oxidant elements.[5] So far, several delivery carriers have been applied to encapsulate EGCG, including liposomes,[6] polysaccharides,[7] proteins, and denatured protein.[8] Among these carriers, protein molecules can cross-link to each other, forming colloidal particles to encapsulate tea polyphenols effectively. EGCG binds to a wide variety of proteins, especially to those having random coil conformations (e.g., casein with 30−35% random coil) with a high content of proline.[9] The phenolic groups and associated aromatic rings in protein structure enable EGCG to build bridges between protein molecules.[10] Milk proteins have been mainly reported as possible carriers for bioactive compounds. It was proposed that EGCG may associate with heated β-lactoglobulin through hydrophobic interactions and hydrogen bonds, leading to the formation of visible microfibrilar structures.[8] Recently, casein has become rapidly recognized due to its unique unfolded structure under native conditions from the family of unstructured proteins. Fluorescence quenching,[11] single-molecule force microscopy,[10] dynamic laser light scattering,[12] small-angle X-ray scattering,[12] and some other biophysical techniques have demonstrated that EGCG has a strong binding affinity with α-casein and β-casein. Thus, casein seemed to be a promising carrier for EGCG.

Nevertheless, casein is sensitive to the variations of the ionic strength and pH in the aqueous phase. In protein-based cases, it is difficult to control the size and colloidal stability of the protein−polyphenol nanoparticles with a high loading capacity of polyphenols.[13] The precipitation of polyphenols at high loading capacity with proteins can be partly inhibited by polysaccharides through the formation of ternary protein−polyphenol−carbohydrate complexes and/or blocking of the interactions between polyphenols and proteins.[14] However, the combination of hydrophilic polysaccharide and protein creates mostly noncovalent interactions, which are sensitive to environment conditions. Accordingly, the aggregation or phase separation might take place arising from the binding at high EGCG loading capacity. Additionally, delivery systems with average sizes smaller than 100 nm and high loading capacity have scarcely been reported, and an effective system for the delivery of EGCG in clear aqueous system is still being probed. The Maillard reaction via conjugation with polysaccharide is one of the most effective methods that can obviously improve protein properties, such as emulsifying ability, solubility, stability, and antioxidation.[15] In addition, it is noted that the high hydration capacity and the presence of uncharged polysaccharide exert contrasting effects on these functional properties of casein, probably

depending on the anchorage of the hydrophobic residues of protein molecule and the orientation of the polysaccharide moiety to the aqueous layer.[13,16] Glycosylated proteins have been devoted to the encapsulated application of anthocyanin[17] and drug molecules[18] and have provided a good reference for an intestinal-targeted delivery system of vulnerable functional ingredients. Many research studies have been carried out on the interaction between proline-rich salivary glycoprotein[19] and polyphenols, but fewer papers concern the interaction between polyphenols and glycosylated proteins obtained via Maillard reaction.

In this work, EGCG nanocarrier was developed on the basis of glycosylated casein (casein−dextran conjugate) via Maillard reaction aiming to improving the stability of EGCG in the food industry, especially in clear beverages. The encapsulating properties of native and glycosylated casein were compared by using dynamic light scattering (DLS) and transmission electron microscopy (TEM). The entrapment efficiency and in vitro release behavior of EGCG were determined by high-performance liquid chromatography (HPLC). To gain insights into the influence of glycosylation, the interactions between EGCG and protein (native and glycosylated casein) were investigated by means of fluorescence spectroscopy. Some important pieces of information such as the binding constants and binding site values were compared.

MATERIALS AND METHODS

Materials. EGCG (98% purity) was purchased from Shanghai Qiangsheng Biochemical Ltd. (Shanghai, China). Casein (molecular mass 25−30 kDa, 99% purity) and dextran (molecular mass 20 kDa) were purchased from Sino-pharm Chemical Reagent Co., Ltd. (Shanghai, China). Methanol and acetonitrile were of HPLC grade (Sino-pharm Chemical Reagent Co., Ltd.). *o*-Phthaldialdehyde (OPA) of chemical grade was obtained from Sino-pharm Chemical Reagent Co., Ltd. Sodium chloride, hydrochloric acid, sodium hydroxide, monopotassium phosphate, and cholate were purchased from Sino-pharm Chemical Reagent Co., Ltd. Pepsin (activity 3000−3500 U mg^{-1}) and pancreatin consisting of protease (activity 285 U mg^{-1}), amylase (activity 288 U mg^{-1}), and lipase (activity 56 U mg^{-1}) were purchased from Sangong Biotech Co., Ltd. (Shanghai, China). Other reagents used were of analytical grade. All aqueous solutions were prepared using deionized water.

Synthesis of Casein−Dextran Conjugates. Casein−dextran (20 kDa) conjugates were synthesized via Maillard reaction as reported by Nakamura et. al with minor modification.[20] Research showed that dextran of 20 kDa supported a higher grafted degree than monosaccharide with a small molecule weight and more moderate viscosity than macromolecular polysaccharide.[21] Specifically, casein and dextran at the fixed mass ratio of 1:7 (corresponding to a molar ratio 1:6) were dissolved together in phosphate buffer solution (0.2 mol/L) at room temperature, and the pH of the mixture was adjusted to 7.0. After continuous stirring for 12 h, the solution was freeze-dried for 2 days at −50 °C. The lyophilized powder was heated at 60 °C for 20 h under 79% relative humidity in a desiccator containing saturated KBr solution. Samples were stored at −20 °C in the dark. The related mixtures were then dispersed in distilled water to a concentration of 0.5 mg/mL. To obtain the pure glycosylated casein, the sample was conducted with a 50 mL Microsep Advance Centrifugal Device (molecular weight cutoff of 100 K; Pall Corp., Port Washington, NY, USA) at 7000 rpm for 30 min until 15 mL of the initial volume remained followed by the addition of deionized water to the original volume. These procedures were repeated three times, and then the retentates were freeze-dried and stored at 4 °C.

OPA Assay. The grafting degree of casein−dextran conjugate was analyzed through an OPA assay, which was expressed as the changes in free amino group contents per gram of casein after Maillard reaction as previously reported.[22] Four milliliters of free OPA reagent was added in 200 μL of casein−dextran conjugate solutio,n and the mixture was incubated at 35 °C for 2 min. Then, the absorbance of the mixture was measured at 340 nm immediately using a spectrophotometer (UV-1600, Mapada Instruments Co., Ltd., China). The OPA reagent was used as the blank. The L-lysine curve was measured as a standard.

Molecular Weight Determination of Glycosylated Casein. The weight-average molecular weight ($\bar{M}_w$) and number-average molecular weight ($\bar{M}_n$) of glycosylated casein after modification were analyzed by aqueous high-performance size exclusion chromatography (HPSEC)[23,24] with a multiangle laser light scattering (MALLS) setup (Wyatt Technology Corp., Santa Barbara, CA, USA). The refractive index increment (dn/dc) of glycosylated casein and its molecular fraction determined experimentally was used. $\bar{M}_w$, $\bar{M}_n$, and radius of gyration (R_g) were calculated by Astra 1.4 software (MALLS). Glycosylated casein and its molecular fraction were analyzed with a SEC protein column (5 μm, 300 Å, 7.8 × 300 nm). The mobile phase was determined using 0.1 mol/L NaCl containing 0.04% NaN_3 with a flow rate of 0.4 mL/min, and the injection volume was determined at 200 μL. Each sample was analyzed at least three times.

Preparation of EGCG Nanocomplexes Composed of Casein and Glycosylated Casein. Casein−EGCG and glycosylated casein−EGCG nanocomplexes were prepared according to a previous paper with a slight modification.[25] Briefly, casein and glycosylated casein were dissolved in the 0.2 mol/L phosphate buffer at pH 7.0 and stirred overnight at room temperature. The weight concentration of casein was adjusted to 1.0 mg/mL. EGCG solution was prepared using acetate buffer (0.2 mol/L, pH 4.5). EGCG solution was mixed with the two kinds of proteins (1:19, v/v) respectively at room temperature to obtain different weight concentrations according to EGCG/protein molar ratios (0:1, 1:1, 2:1, 6:1, 10:1, 16:1, 32:1, 64:1, 128:1, 256:1). Samples were stored at 4 °C under N_2 atmosphere in a dark environment.

Size Measurement. The *z*-average diameter and size distribution of casein−EGCG and glycosylated casein−EGCG complexes were carried out at 25 ± 0.1 °C using a Nano-ZS90 particle size analyzer (Malvern Instruments Ltd., Malvern, UK) with a He/Ne laser (λ = 633 nm), scattering angle 90°. Aliquots of 1 mL of sample were diluted to 10 mL with the same buffer solution to avoid multiple scattering phenomena due to interparticle interaction.[26] Immediately, the diluted sample was transferred into the polystyrene curet for size determination, and then the *z*-average diameter (D_z) and particle size distribution (polydispersity index, PDI) were recorded by DLS.

Entrapment Efficiency. Aliquots of protein−EGCG complex solution (2 mL) were transferred into an Amicon Ultra-3K centrifugal filter device (Pall Corp.). After centrifugation at 4000 rpm for 30 min, free EGCG penetrated through the Ultracel membrane into the centrifuge tube, which was determined by HPLC. The elution was carried out on a C_{18} column (5 μm, 39 × 150 mm, Atlantis, Waters, Milford, MA, USA), the mobile phase was methanol/water (99.9:0.1, v/v), the injection volume was 5 μL, and the wavelength was set at 280 nm. EGCG standard curve was $Y = 10^7X - 15669$ (R^2 = 0.9985) in the concentration range of 0.01−0.1 mg/mL and $Y = 10^7X - 90217$ (R^2 = 0.9984) in the concentration range of 0.1−1.0 mg/mL, where X is the concentration and Y is the peak area. The entrapment efficiency was determined using the following equation:

$$\text{entrapment efficiency (\%)} = \frac{\text{amount of entrapped EGCG}}{\text{total amount of EGCG}} \times 100$$

Storage Stability. During the 10 days of storage at 4 °C under N_2 atmosphere in a dark environment, an aliquot of samples was used for size and retention rate measurements. The retention rate and change of *z*-average diameter (ΔD_Z) were determined respectively using the following equations:

$$\text{retention rate (\%)} = \frac{\text{amount of entrapped EGCG after storage}}{\text{amount of entrapped EGCG initially prepared}} \times 100$$

$$\Delta D_z\ (\%) = \frac{D_z \text{ after incubation at predetermined time} - D_z \text{ initially prepared}}{D_z \text{ initially prepared}} \times 100$$

After 15 days storage, the samples of EGCG−casein (mole ratio 64:1), direct mixture of EGCG/casein/dextran (64:1:6), and EGCG−glycosylated casein (64:1) were taken out to observe the state of suspension.

In Vitro Release. The simulated gastric fluid (SGF) or intestinal fluids (SIF) were prepared according to a previous study.[27] SGF consisted of sodium chloride (2 g/L), hydrochloric acid 37% (0.008 L/L), and pepsin (3.2 g/L). The pH was adjusted to 1.3 using hydrochloric acid. SIF consisted of sodium hydroxide (1.81 g/L), potassium dihydrogen phosphate (8.09 g/L), pancreatin (4.76 g/L), and bile salts (5.16 g/L). The pH was adjusted to 7.5 using sodium hydroxide. The release profile of EGCG from protein was assessed using a dialysis method (cutoff molecular weight of 8000 Da). A solution of 10.0 mL of EGCG−casein and EGCG−glycosylated casein nanocomplexes with EGCG/protein molar ratio 10:1 was transferred into a dialysis bag and dialyzed against 40 mL of SGF or SIF. Then the release medium was incubated at 37 °C in a multipoint stirrer (SKY-110WX, Shanghai, China) equipped with a water bath. At a predetermined sampling time, 200 μL of release medium was drawn out and replenished with 200 μL of fresh buffer. All of the samples were protected from light. The amount of released EGCG was measured by HPLC as described above. The cumulative release rate was determined by using the calculation[28]

$$\text{cumulative release percentage}_t\ (\%) = \frac{\sum_{i=1}^{i=t-1} c_i V_i + c_t V_t}{\text{total EGCG (mg)}} \times 100$$

#tab;where c_i and c_t are the concentrations of EGCG in the release medium at times i and t, respectively. V_i is the withdrawn volume from release medium at time i. V_t is the release medium volume at time t.

Transmission Electron Microscopy. TEM micrographs were conducted on a Hitachi-7650 at an accelerating voltage of 200 kV. The samples were prepared with a casein concentration of 1.0 mg/mL, and the EGCG/casein molar ratios were 0:1 and 4:1, respectively. An aqueous suspension of the samples was deposited upon a carbon-coated copper grid, followed by air-drying for 1 min. Then, the sample was instantly stained with 1 wt % ammonium molybdate.[29]

Fluorescence Quenching of Protein by EGCG. To investigate the interaction between EGCG and casein, a fluorescence quenching method was used with a fluorescence spectrometer (Hitachi F-7000, Japan). The fluorescence spectra of casein, glycosylated casein, and their EGCG complexes at different EGCG/casein molar ratios (0:1, 0.5:1, 1:1, 2:1, 6:1, 10:1, 16:1, 32:1) were scanned, respectively. All measurements were performed at 15 °C. Emission spectra were recorded from 285 to 500 nm with an excitation wavelength of 280 nm and from 290 to 500 nm with an excitation wavelength of 295 nm, employing excitation slit widths of 2.5 nm and emission slit widths of 5.0 nm.

Statistical Analysis. In this study all samples were prepared and analyzed in triplicate. The data are presented as means ± standard deviation of three determinations. Statistical significance ($p < 0.05$) was determined with the analysis of variance (one-way ANOVA) using SPSS 16.0 (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Synthesis of Casein−Dextran Conjugate. The Maillard reaction is a chemical reaction that involves linking polysaccharide and peptides or proteins by reducing end carbonyl groups and amino groups.[30] Herein, casein and dextran were used to prepare Maillard reaction products (MRPs), which were confirmed by the grafting degree (GD) assessed via OPA assay. It was found that the GD was about 22.97 ± 2.01% in the casein−dextran conjugate at the mass ratio of 1:7 (molar ratio of 1:6). Rival and his co-workers have demonstrated with a fluorometric method that casein consisted of four principal proteins, α_{s1}-casein, α_{s2}-casein, β-casein, and κ-casein, in the weight ratio of 3:0.8:3:1, corresponding with lysine residue numbers of 14, 24, 11, and 9, respectively.[31] According to the calibration and calculations of the molecular weight of casein and free lysine, the milligrams of lysine to milligrams of casein factor is $F = \sum((R_L W_L)/(W_C R_P)) = 0.08484$, where R_L is residues of lysine in each casein, $W_C = 5$, and W_L is the molecular weight of lysine.[32] This implied that the average number of free lysine residues of casein was up to 13.[33] After Maillard reaction, 3.2 ± 0.05 free amino groups were consumed. The decrease in average number of free lysine residues directly proved that these dextran molecules were grafted to casein molecules.[24]

The weight-average ($\bar{M}_w$) and number-average weights ($\bar{M}_n$) of casein and glycosylated casein had been determined by HPSEC, which demonstrated that the molecular weight of casein via Maillard reaction had changed and also gave information about the effects of modification indirectly. This presented that the weight-average molecular weights of casein and glycosylated casein were $(2.8045 \pm 0.2758) \times 10^4$ and $(2.5665 \pm 0.3855) \times 10^5$ g/mol, respectively. The number-average molecule weights were $(2.5794 \pm 0.3740) \times 10^4$ and $(2.1388 \pm 0.3212) \times 10^5$ g/mol, respectively, and the refractive index increment was $dn/dc = 1.20 \pm 0.17$. The obvious change of molecular weight further demonstrated that glycosylated casein became a bigger and more complicated micelle in solution than native casein.

Influence of Casein Glycosylation on Their Aggregation and Binding Capability with EGCG. The effects of different mixing molar ratios on EGCG−casein and EGCG−glycosylated casein were studied at pH 7.0 by DLS and HPLC (Table 1). It was found that casein and glycosylated casein displayed strongest encapsulating ability on EGCG at the ratios of 10:1 and 128:1, respectively, corresponding to EE values of 85.63 ± 0.88 and 89.36 ± 4.28%. The higher encapsulation efficiency and concentration of glycosylated casein indicated that glycosylation can improve the binding capacity of casein to EGCG. On the other hand, when the molar ratio of EGCG−casein was up to 32:1, the particle size greatly increased and cloud could be observed. When the molar ratio was further increased to the threshold of 64:1, aggregation took place and phase separation happened 4 h later. This may be due to a direct

bridging of unstructured casein by EGCG-coated proteins at higher EGCG−protein ratios.[34] When the molar ratio increased to 256:1, the system of EGCG−glycosylated casein nanocomplex was still transparent and colloidally stable. This is related to the dextran grafted on the surface of casein, which shields the casein surface from EGCG bridging by forming a steric hindrance effect.[14]

To further evaluate the stability of EGCG−casein and EGCG−glycosylated casein nanocomplexes, *z*-average diameter and retention rate during storage were compared, respectively. From Figure 1, it was observed that both *z*-average diameter and retention rate of EGCG−glycosylated casein nanocomplex became more stable than those of EGCG−casein nanocomplex. When the EGCG−casein molar ratio increased to 32:1, the retention rate of EGCG−casein nanocomplex decreased to <60%, whereas that of the EGCG−glycosylated casein nanocomplex decreased to 70%. This result indicated that casein protected EGCG from degradation. Previous study also demonstrated that the glycosylated casein played a positive role in inhibiting oxidation due to their shell structure.[35,36] As shown in Figure 2, the cloud appeared when EGCG−casein and EGCG−casein/dextran mixtures were initially prepared, whereas the EGCG−glycosylated casein nanocomplex remained clear as the same EGCG−casein molar ratio of 64:1. After 15 days of storage, the aggregation and phase separation were apparent for the EGCG−casein and EGCG−casein/dextran mixtures, whereas the EGCG−glycosylated casein nanocomplex was transparent as initially prepared.

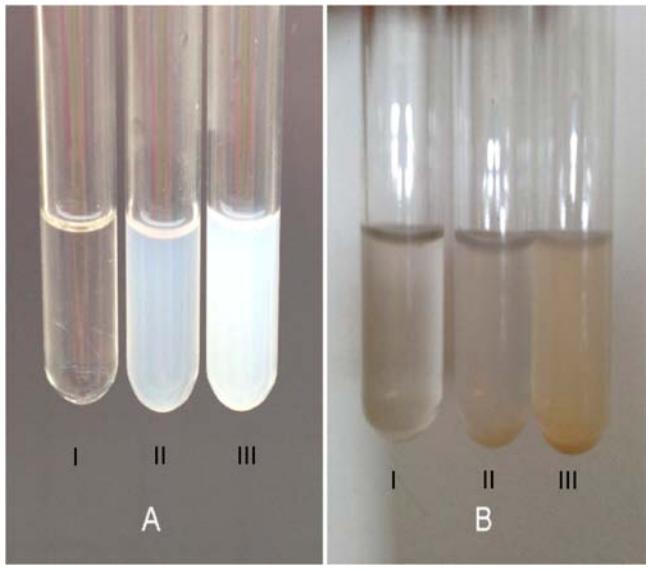

Figure 2. Photographs of the EGCG−casein complex initially prepared (A) and after 15 days of storage at 4 °C in the dark (B). (I) EGCG−glycosylated casein; (II) EGCG−casein/dextran mixture; (III) EGCG−casein nanocomplex. The samples were prepared at pH 7.0, casein concentration = 1.0 mg/mL, molar ratio of EGCG/casein 64:1.

The stabilizing role of casein to EGCG was highly concentration dependent upon the EGCG−casein molar ratio.

dx.doi.org/10.1021/jf405157x | J. Agric. Food Chem. 2014, 62, 4677−4684

Polyphenols are multidentate ligands that are able to bind simultaneously, via different phenolic groups. Upon addition of EGCG, casein binding to EGCG on more than one binding site causes intermolecular cross-linking, particle contraction, and then diameter decreasing.[22] Moreover, a higher EGCG−casein molar ratio may lead to aggregation and precipitation. Herein, the glycosylation effectively suppressed the aggregation and precipitation behavior of casein in the presence of EGCG. Thus, the steric hindrance through covalent attachment of dextran played an important role in colloidal stability. Pascal and his co-workers[37] also confirmed that the location of glycosyl moieties in salivary glycoprotein, which were strongly hydrophilic with regard to the interaction site and created steric hindrance. This property limited the extent of protein affinity to EGCG, and thereby a much higher EGCG concentration was used to cause protein aggregation. Moreover, glycosyl moieties must remain exposed to the aqueous phase at the outer surface of aggregation, and this could limit the size of the aggregates.

In Vitro Release. Due to the chemical degradation at the intestinal pH and microbial metabolism in the gastrointestinal tract, EGCG always exhibited low bioavailability.[38] One of the approaches to improve bioavailability is to encapsulate the EGCG in a carrier matrix[39] or bind it to form insoluble complexes.[40] In the present study, the effects of casein and glycosylated casein binding on the EGCG release in both SGF andSIF were investigated. Figure 3A shows that the free EGCG underwent a burst release within 0.5 h in SGF and the release rate reached 45% after 4 h of incubation. After binding with casein and glycosylated casein, the release of EGCG was inhibited, with release rates of 38 and 32% after 4 h, respectively. Obviously, the decreased release was attributed to their interaction with casein through hydrogen binding. Furthermore, this effect was more pronounced in the case of glycosylated casein. It can be elucidated in terms of earlier conclusion that casein was less susceptible to gastric enzyme degradation after glycosylation.[31]

When incubating in SIF, free EGCG exhibited a rapid release process within 1 h (Figure 3B). Note that the EGCG bound with casein or glycosylated casein exhibited a relatively slow and sustained release, and the release rates were around 65 and 58% after 5 h, respectively. Besides the inhibition of molecular mobility of EGCG, another probable reason was that the glycosylation brought steric hindrance and covered the binding sites of enzyme on protein, thus leading to a low degree of hydrolysis.[41] These results confirmed that the sustained release of EGCG from the nanocomplexes may lead to the minimization of its chemical degradation in the gut conditions. Thus, the capacity of the casein nanocomplexes (especially glycosylated casein) to stabilize EGCG suggested that much more EGCG can be delivered to the human digestive system.[22]

Morphology of EGCG−Casein Nanocomplexes at Different Molar Ratios. TEM image shows that the shapes of EGCG−casein and −glycosylated casein nanocomplexes are both spherical (Figure 4). Most of the casein and EGCG−casein nanocomplexes had a diameter of <200 nm, and the diameters decreased with the addition of EGCG. The decrease of diameter was probably due to the fact that the interactions between EGCG and casein led to the conformation transition of proline-rich casein so that the linear molecules were compact,[42] which was in agreement with the DLS data. In addition, the particle size of the EGCG−glycosylated casein nanocomplex was much smaller than that of the EGCG−casein nanocomplex, which also indicated that the glycosylation of casein had an influence on

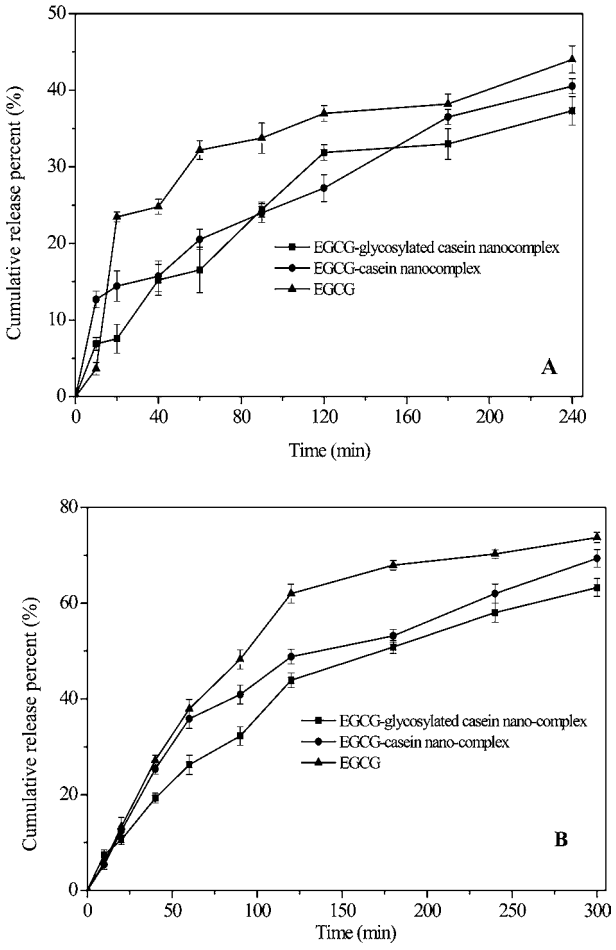

Figure 3. In vitro release of EGCG from EGCG−casein nanocomplexes in SGF (A) and SIF (B) over 4 h of incubation. The protein concentration was 1.0 mg/mL, and EGCG/casein molar ratio was 10:1.

the interaction between EGCG and casein, leading the system to be more colloidally stable.

Fluorescence Quenching of Casein by EGCG. The intrinsic fluorescence contributed by tyrosine (Tyr) and tryptophan (Trp) is an effective tool for investigating the interaction and binding of polyphenol and protein in an attempt to characterize the nature of tea polyphenol complexion. Herein, we mainly compared the binding affinities of EGCG to casein, as well as glycosylated casein. As is well-known, tryptophan has intrinsic fluorescence residues when exciting at 280 nm and tyrosine has intrinsic fluorescence residues when exciting at 295 nm in casein protein.[8] As shown in Figure 5, the fluorescence quenching of casein and glycosylated casein was induced by EGCG, which also suggested that when other molecules interacted with casein, Trp and Tyr fluorescence may change depending on the impact of such interaction on the casein conformation.[11] With increasing concentration of EGCG, the fluorescence intensity of two kinds of proteins decreased gradually upon excitement at both 280 and 295 nm, whereas the fluorescence quantum yield of Tyr at 295 nm was much smaller than that of Trp at 280 nm, which was probably because Trp residues were located on casein surfaces.

Quencher molecules produce two kinds of quenching effects, static and dynamic quenching. Static quenching frequently results in encountering pair formation between quencher and fluorophore molecules, whereas dynamic quenching requires

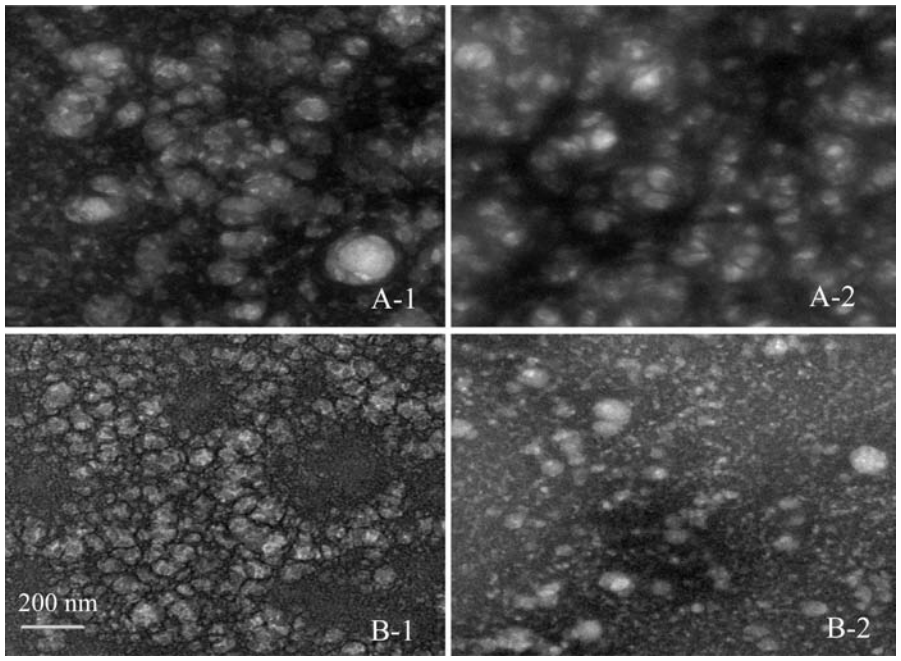

Figure 4. TEM images of EGCG−casein complexes: EGCG−casein nanocomplex (A); EGCG−glycosylated casein nanocomplex (B); EGCG/protein molar ratio 0:1 (1); EGCG/protein molar ratio 4:1 (2). The casein concentration was 1.0 mg/mL.

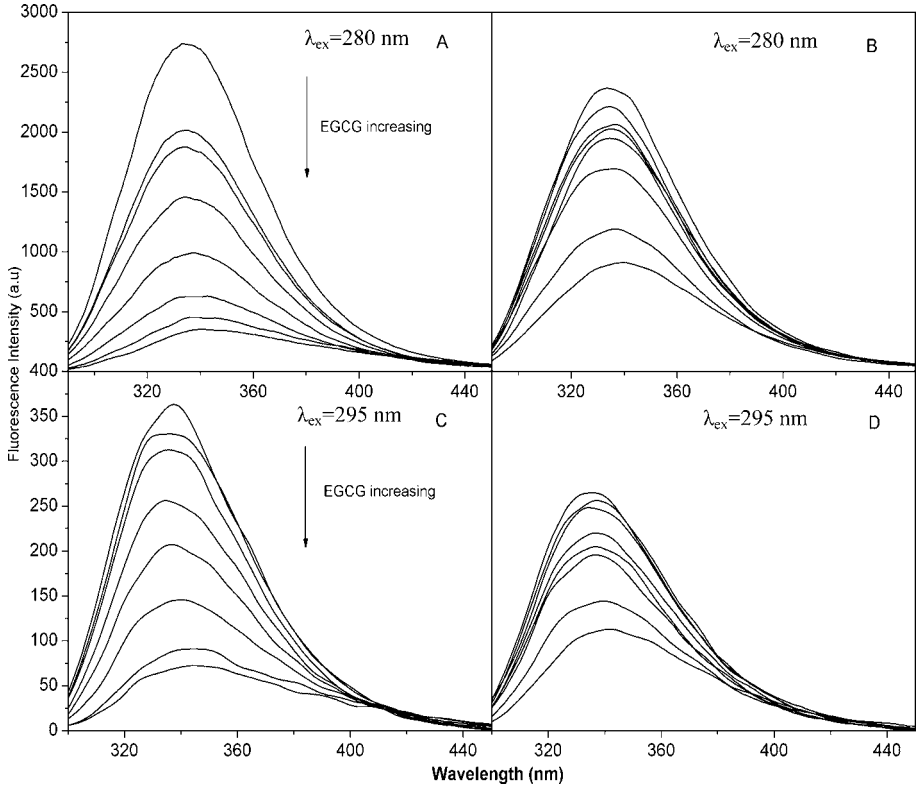

Figure 5. Quenching effect of EGCG on casein (A, C) and glycosylated casein (B, D) fluorescence intensity. The EGCG/casein molar ratios were 0:1, 0.5:1, 1:1, 2:1, 6:1, 10:1, 16:1, and 32:1 (from the top down). Casein concentration was 0.2 mg/mL.

bimolecular collisions.[43] Fluorescence quenching can be often described by the Stern−Volumer equation[8]

$$\frac{F_0}{F} = 1 + K_{sv}[Q]$$

where F_0 and F are the fluorescence intensities before and after the addition of quencher, respectively. K_{sv} is the Stern−Volumer quenching constant, and [Q] is the concentration of the quencher. The value of K_{sv} is compared with 2×10^{10} L mol^{-1} s^{-1} to determine whether the quenching type is dynamic or static quenching through the above equation. We therefore calculated that no matter Tyr or Trp, casein or casein−dextran conjugate, the K_{sv} was always $>2 \times 10^{10}$ L mol^{-1} s^{-1}, which meant it was

static quenching that decided the binding affinity between EGCG and casein.

Results from fluorescence measurements can be used to estimate the binding constant of polyphenol−protein complex from followed equation:

$$\mathrm{Lg}[(F_0 - F)/F] = \mathrm{Lg}\, K_a + n\, \mathrm{Lg}\,[\mathrm{Q}]$$

According to this equation, the binding constants and binding sites between EGCG and casein (including native and glycosylated casein) are shown in Table 2. The binding constants gave information about the molecular environment in the vicinity of the chromophore molecule, suggesting a strong affinity of EGCG with casein, which might be attributed to the presence of more OH groups in EGCG than in other catechins.[44] At 280 and 295 nm excitation wavelengths, the binding constants and binding sites of EGCG−casein were larger than those of EGCG−glycosylated casein, which suggested that EGCG had a lower affinity with glycosylated casein due to the presence of dextran grafted. With dextran grafting via Maillard reaction, little shift of emission maximum wavelength of tryptophan and tyrosine was observed in the glycosylated casein, suggesting that there was little change about the interior hydrophobic environment of protein. However, the fluorescence intensity of glycosylated casein was weakened compared with that of the native casein. Thus, it was considered that the grafting of dextran on the surface of the casein molecule presented a shielding effect on the fluorescence of casein. The tightening of casein protein structure through intramolecular interactions, such as hydrogen bonds, seemed to bury Trp and Tyr in a more hydrophobic environment, which was related to unfolding of casein structure and displayed the gradually decreasing z-average diameters in DLS measurement.

Supporting Information

ABSTRACT: Nitrilases have recently received considerable attention as the biocatalysts for stereospecific production of carboxylic acids. To improve the activity, the nitrilase from *Alcaligenes faecalis* was selected for further modification by the gene site saturation mutagenesis method (GSSM), based on homology modeling and previous reports about mutations. After mutagenesis, the positive mutants were selected using a convenient two-step high-throughput screening method based on product formation and pH indicator combined with the HPLC method. After three rounds of GSSM, Mut3 (Gln196Ser/Ala284Ile) with the highest activity and ability of tolerance to the substrate was selected. As compared to the wild-type *A. faecalis* nitrilase, Mut3 showed 154% higher specific activity. Mut3 could retain 91.6% of its residual activity after incubation at pH 6.5 for 6 h. In a fed-batch reaction with 800 mM mandelonitrile as the substrate, the cumulative production of (*R*)-(−)-mandelic acid after 7.5 h of conversion reached 693 mM with an enantiomeric excess of 99%, and the space-time productivity of Mut3 was 21.50-fold higher than that of wild-type nitrilase. The K_m, V_{max}, and k_{cat} of wild-type and Mut3 for mandelonitrile were 20.64 mM, 33.74 μmol mg^{-1} min^{-1}, 24.45 s^{-1}, and 9.24 mM, 47.68 μmol mg^{-1} min^{-1}, and 34.55 s^{-1}, respectively. A homology modeling and molecular docking study showed that the diameter of the catalytic tunnel of Mut3 became longer and that the tunnel volume was smaller. These structural changes are proposed to improve the hydrolytic activity and pH stability of Mut3. Mut3 has the potential for industrial applications in the upscale production of (*R*)-(−)-mandelic acid.

INTRODUCTION

Nitrilases (EC 3.5.5.1) are important industrial enzymes used to convert nitriles directly into corresponding carboxylic acids and ammonia in a single step with mild conditions.[1,2] Occurrences, catalytic mechanisms, applicabilities, and molecular modifications of nitrilases have been widely reported.[3−5] By far, all known nitrilases can be classified as aromatic nitrilases, aliphatic nitrilases, and arylacetonitrilases according to substrate specificity.[6] Nitrilases are found in many plants and microorganisms, and their applications have been widely explored.[6] Recently, screening new nitrilases, exploring their applications, and the molecular modification of nitrilases are becoming hot issues because of the important application of nitrilases.[4,5,7−10]

It was reported that one of the important industrial applications of nitrilases is the conversion of (*R*,*S*)-mandelonitrile to (*R*)-(−)-mandelic acid.[11] This reaction exhibits excellent enantioselectivity, low-cost starting material, and most especially the possibility of performing a dynamic kinetic resolution of racemic substrate which provides theoretically 100% yield of the product.[11,12] (*R*)-(−)-mandelic acid has been used as an important intermediate for the production of pharmaceuticals such as semisynthetic penicillins, cephalosporins, antitumor agents, antiobesity agents, and chiral resolving agent for the resolution of racemic alcohols and amines.[12,13] (*R*)-(−)-mandelic acid can be produced by two routes including chemical and biosynthetic methods.[14] Biocatalytic synthesis of (*R*)-(−)-mandelic acid has been widespread because of its industrial development and application prospects.[11,12,15,16] The production of (*R*)-(−)-mandelic acid by nitrilases has the most potential for the industrial application.[11,15,17] There are several reported strains with abilities for the bioproduction of (*R*)-(−)-mandelic acid, including *Alcaligenes* sp. ECU0401,[18] *Pseudomonas putida* MTCC 5110[7,19] *A. faecalis* ZJUTB10,[5,11] *A. faecalis* ATCC 8750,[20] *P. fluorescens* EBC191,[8] *A. faecalis* JM3,[21] *Bradyrhizobium japonicum* USDA110,[22] and *Burkholderia cenocepacia* J2315.[23] However, the reported nitrilases still cannot meet the requirement for the industrial production of (*R*)-(−)-mandelic acid because of their poor activity and lower stability under low pH. To resolve this problem, nitrilases from different origins have been modified by various approaches.[3,5,24]

The gene site saturation mutagenesis method (GSSM) is widely used in the modification of proteins based on the PCR method, which has made a series of high-profile achievements on nitrilases.[25] Yeom et al. had mentioned that a positively charged amino acid at position 129 in nitrilase from *Rhodococcus rhodochrous* ATCC 33278 was an essential residue for the activity with meta-substituted benzonitriles by the

GSSM.[26] Wu et al. obtained a mutant nitrilase with increased activity, specificity, and stability by modification at sites Thr210 and Leu201 located in α6, and Phe168 at the junction of the β10 helix and α6.[27,28] Nolan et al. found that the active sites for cyanide hydratase and nitrilase activity in the protein were the same by the GSSM.[29] The cyanide dihydratase completely lost its activity by the replacement of Cys163 to Ser, and the replacement of Tyr53 to Phe caused an increase of the K_m value of the enzyme for cyanide when the conserved amino acid residues in the cyanide dihydratase from *P. stutzeri* AK61 were altered by GSSM.[30]

In this study, the recombinant nitrilase from *A. faecalis* was selected to improve activity by using GSSM. On the basis of the secondary and three-dimensional structures, interactions between the substrate and nitrilase, and previous reports,[5,31,32] three sites in the α-helix (Leu175, Ala197, and Val305) and one site in the β-sheet (Ala284) located after Cys163 were selected for further mutagenesis. The site Gln196 was also selected using the software HotSpot Wizard to identify the point that plays an important role in enzyme catalysis and substrate specificity. After mutagenesis, the mutants were screened by a two-step screening method based on bromocresol purple as the pH indicator combined with liquid chromatography, and the best mutant Mut3 with serendipitously improved activity and pH stability was obtained. The characteristics of purified wild-type and Mut3 were studied and compared. The homology modeling and molecular docking were further studied to elucidate the interactions between substrate and nitrilase. Finally, the potential application in the kinetic resolution of racemic mandelonitrile to prepare *R*-(−)-mandelic acid was evaluated as well.

MATERIALS AND METHODS

Strains, Plasmids, and Medium. *E. coli* BL21 (DE3) (F-ompT gal dcm lon, hsdSB (rB- mB-) λ (DE3 (lacI lacUV5-T7 gene 1 ind1 sam7 nin5))) (Invitrogen, Karlsruhe, Germany) was used for heterologous expression. *E. coli* and recombinant *E. coli* strains were grown in Luria−Bertani (LB) medium (tryptone 10 g/L, yeast extract 5 g/L, and NaCl 10 g/L). The pET28b-NIT plasmid and recombinant nitrilase from *A. faecalis* was constructed and stored in our laboratory.[5] *Dpn* I and PrimeSTAR HS DNA polymerase were provided by the TaKaRa company (Dalian, China). (*R,S*)-mandelonitrile, (*R*)-(−)-mandelic acid, and (*S*)-(−)-mandelic acid were purchased from Sigma (St. Louis, MO). All other reagents and chemicals were commercially available and of analytic grade.

Gene Site Saturation Mutagenesis. Random mutations were introduced to the nitrilase gene by GSSM at positions of Leu175, Ala197, Val305, Ala284, and Gln196 using PrimeSTAR HS DNA polymerase (Takara) and pET28b-NIT plasmid as a template. The five pairs of primers carrying mutations are listed in Table 1. The plasmids with positive mutations from the previous round of mutations were used as a template for the next step of mutation. The PCR reaction mixture consisted of 200 μM for each dNTP, 0.2 μM primers, 10 μL of 5× PrimeSTAR Buffer (Mg^{2+} plus), and 1.25 U PrimeSTAR HS DNA polymerase (Takara) in 50 μL. The reaction was carried out at 94 °C for 5 min, followed by 30 cycles of 98 °C for 10 s, 55 °C for 15 s for amplifying the nitrilase gene, 72 °C for 8 min, and then 72 °C for 10 min in a PCR thermocycler (Biometra, Göttingen, Germany). PCR products were subjected to 0.9% agarose electrophoresis and then purified by a PCR purification kit (Simgen, Hangzhou, China). After purification, the DNA fragment was digested with *Dpn* I at 37 °C for 3 h to remove the template plasmid containing the methylation sites. The plasmid pET28b-NIT_{mut} was then transformed into *E. coli* BL21 (DE3) by the heat-shock method.[33]

Screening Method. A two-step screening method which was constructed to screen the mutants was described below: Each single colony was picked from the plate with 50 mg/mL kanamycin (Kan) to 96-well plates with LB broth and incubated overnight with vigorous shaking (500 rpm) at 37 °C. One part of the culture was transferred to the new 96-well plates with 50 mg/mL Kan, 0.1 mM isopropyl-β-D-thiogalactoside (IPTG), 100 mM (*R,S*)-mandelonitrile, and LB medium, and then thermomixed for 8−10 h at 30 °C. (*R,S*)-Mandelonitrile would be catalyzed to (*R*)-(−)-mandelic acid by nitrilase expressed by IPTG induction. The final concentration of 0.01% (w/v) bromocresol purple solution was added for high-throughput and rapid screening. The pH of the medium in the 96-well plate was kept at 7.0, and the screening method was based on the formation of yellow caused by mandelic acid as a result of hydrolysis by positive mutants. When the pH became lower and lower with the hydrolysis process of the (*R,S*)-mandelonitrile to produce mandelic acid, the medium with purple background would change the color to yellow. Finally, the positive mutants were selected by the formation of yellow. At the same time, the mutants which made the color of bromocresol purple solution change from purple to yellow were picked from the corresponding plates and grown at 37 °C in 50 mL of LB media containing 50 μL of 50 mg/mL Kan for further tests. The nitrilase was induced by the addition of 0.1 mM IPTG when optical density (OD) at 600 nm of the culture broth reached between 0.6 and 0.8. The cells were then incubated at 28 °C for 12 h and harvested by centrifugation at 9000 rpm for 10 min. The reaction was carried out with free cells in 1 mL of pure water at 40 °C, 500 rpm for 10 min. After reaction, the reaction mixture was centrifuged at 12000 rpm for 5 min, and then the amount of (*R*)-(−)-mandelic acid in the supernatant was subsequently determined by high-performance liquid chromatography (HPLC) mentioned below to further confirm the positive mutants with improved nitrilase activity.

Nitrilase Purification and Sodium Dodecyl Dulfate−Polyacrylamide Gel Electrophoresis (SDS−PAGE). After being induced by 0.1 mM IPTG, the cells harboring recombinant nitrilases were collected by centrifugation and then were resuspended in 30 mL of pure water and lysed by sonication with a Vibra-Cell VC 505 ultrasonic processor (Sonics and Materials Inc., Newtown, CT) at 400 W for 15 min. The resulting slurry was centrifuged at 12000 rpm for 20 min, and the supernatant was loaded to a nickel-NTA superflow column, which has been equilibrated with buffer (20 mM NaH_2PO_4 and 300 mM NaCl; and pH 8.0). Unbound proteins were washed out from the column with buffer (20 mM NaH_2PO_4, 300 mM NaCl, 50 mM imidazole, and pH 8.0). The active enzyme was eluted with buffer by a linear gradient from 50 to 500 mM imidazole at a flow rate of 1 mL/min. The purified enzymes were analyzed using 12% SDS−PAGE.

Enzyme Assays and Protein Assay. The standard activity assay was carried out using (*R*,*S*)-mandelonitrile (100 mM) as substrate and 0.2 mg/mL of purified enzyme mixed in potassium phosphate buffer (100 mM and pH 8.0). The reaction mixture (total volume 10 mL) was incubated at 45 °C for 10 min and stopped by HCl solution (final 2 M). Then, 200 μL of the mixture was centrifuged at 12000 rpm for 20 min, and the supernatant was subjected to HPLC analysis as described below for assaying the nitrilase activity. The amount of (*R*)-(−)-mandelic acid was determined by a LC-20AD prominence liquid chromatography instrument (Shimadzu, Kyoto, Japan) using a C18 column (5 μm × 250 nm × 4.6 nm, Elite Analytical Instruments Co., Ltd., Dalian, China) and equipped with a SPD-2A prominence UV/vis detector. Each sample (20 μL) was eluted at 30 °C with 0.01 M $(NH_4)H_2PO_4/CH_3OH$ = 13:7 (v/v, 1 mL/min) as the mobile phase, and absorbance at 228 nm was measured. The retention time for (*R*)-(−)-mandelic acid was 3.2 min. The optical purity of (*R*)-(−)-mandelic acid was determined by an analysis of the enantiomers on a CHIRALEL-OD-H column (250 × 4.6 mm) (Daicel Chemical Industries, Shinzaike, Japan) at a flow rate of 0.8 mL/min with a mobile phase containing hexane, 2-propanol, and trifluoroacetic acid (90:10:0.1, v/v) at a wavelength of 228 nm.

One unit of nitrilase activity was defined as the amount of enzyme that produces 1 μmol of (*R*)-(−)-mandelic acid per minute under the conditions described above. Protein quantitative analysis was conducted using the Bradford method[34] with bovine serum albumin as a standard.

Optimum pH and pH Stability. To investigate the optimal pH and the effect of pH on the activity of nitrilase, four buffers including citrate buffer (pH 3.0−6.0), phosphate buffer (pH 6.0−8.5), Tris-HCl buffer (pH 7.0−8.5), and glycine-NaOH buffer (pH 8.5−10.0) with a concentration of 100 mM were used, and the reactions were performed at 45 °C using 100 mM (*R*,*S*)-mandelonitrile as substrate. To investigate pH stability, the enzyme was dissolved in buffers of pHs ranging from 6.5 to 8.5 and incubated at 0 °C from 0.5 to 6 h, and then the relative activities were performed with standard assay conditions. Activity without treatment obtained at pH 8.0 was used as a blank and regarded as 100%.

Optimum Temperature and Thermal Stability. The optimal temperature of the enzyme was determined by assaying enzyme activities at temperatures ranging from 25 to 65 °C. Thermal stability was investigated by incubating enzymes at temperatures ranging from 30 to 60 °C. The enzyme was incubated in a heat-block at the specified temperature for a certain time. The relative activities were examined at 45 °C for 10 min.

Circular Dichroism (CD) Measurements. CD spectra were recorded on a JASCO J-815 Spectropolarimeter (JASCO Inc., Easton, MD) with Spectra Manager 228 software. The temperature was controlled from 10 to 60 °C using a Fisher Isotemp Model 3016S water bath (Fisher Scientific, Waltham, MA). A lyophilized powder (purity >95%, w/w) was prepared. A stock solution of 0.02 mg/mL nitrilase was generated in ddH_2O. The spectra were recorded from 190 to 250 nm.

Homology Modeling and Molecular Docking. The three-dimensional homology model of nitrilase was constructed using Build Homology Models (MODELER) in Discovery studio (DS) 2.1 (Accelrys Software, San Diego) and the crystal structure of a hypothetical protein PH0642 (PDB accession code 1J31) was used as the template. The catalytic tunnel size was analyzed using software HotSpot Wizard to identify the residues essential for protein function, enzyme activity, and substrate specificity. Autodock 4.0 was used to study the interaction between substrate and nitrilase, and to predict the spatial structure and catalytic mechanism of the nitrilase.

Time Course of (*R*,*S*)-Mandelonitrile Hydrolysis. The reaction mixture (10 mL) contained 0.1 g of wet cells of wild-type or evolved nitrilase suspended in 100 mM potassium phosphate buffer (pH 8.0) containing 100 mM (*R*,*S*)-mandelonitrile. These reactions were carried out at 40 °C in a reciprocal shaker at 150 rpm. Samples were removed at predetermined times, and the yield was determined by HPLC.

Fed-Batch Production of (*R*)-(−)-Mandelic Acid Using Mut3 as the Catalyst. The fed-batch reaction was performed at 40 °C and 150 rpm in 200 mL reaction volume. The reaction mixture contained 100 mM potassium phosphate buffer (pH 8.0), 100 mM (*R*,*S*)-mandelonitrile, and 5% wet cells of Mut3. (*R*,*S*)-mandelonitrile (100 mM) was fed in the subsequent 7 batches (total 800 mM) once an hour. The reaction mixture (100 μL) was periodically withdrawn and analyzed by HPLC.

Isolation and Identification of (*R*)-(−)-Mandelic Acid. The isolation procedure of (*R*)-(−)-mandelic acid was performed according to the following procedure: 2% (w/v) activated carbon was added into the fed-batch reaction mixture (200 mL) to remove the cells. After filtration, the filtrate adjusted to pH 9.0−10.0 with 2 M NaOH was extracted with an equal volume of ethyl acetate twice to obtain the aqueous phase, which was acidified to pH 1.0−2.0 with 2 M HCl. The aqueous phase suffered from vacuum filtration (SHB-III, Zhengzhou trade Co., LTD, China) to remove the proteins in the solvent, and then the filtrate was extracted with isopyknic ethyl acetate three times. After the organic extract was dried by anhydrous sodium sulfate, the solvent was removed through vacuum distillation (Adyantag ML, Heidolph, Germany) in a rotary evaporator, and the crystal of (*R*)-mandelic acid was subsequently obtained.

The ^{13}C and ^{1}H nuclear magnetic resonance (NMR) spectra of (*R*)-(−)-mandelic acid were obtained on a NMR spectrometer (AVANCE 500 MHz, Bruker, Fallanden, Switzerland) with DMSO as the solvent, using 500 and 125 MHz for carbon and proton determinations, respectively. The FTIR spectrum for (*R*)-(−)-mandelic acid was recorded on a Fourier transform infrared spectrometer (Nicolet 6700; Thermo, Waltham, MA) with a Contimμm FTIR Micro system in the region of 4000−400 cm^{-1} using KBr pellets. The LC-MS spectrum for (*R*)-mandelic acid was recorded on a high performance liquid chromatography−time-of-flight mass spectrometer (Agilent Technologies 1200 Series, 6210 Time-of-Flight MS spectrometer) (Agilent Technologies, Waldbronn, Germany), and the experimental parameters were used as follows: ionization mode, ESI scan; gas temperature, 300 °C; fragmentor, 80 V; drying gas, 3.5 L/min; skimmer, 65 V; nebulizer, 20 psig; OCTIRFV pp, 250 V; and Vcap, 3000 V.

Statistical Analysis. If not specifically noted, all experiments in this study were performed in triplicate. Analysis of variance (ANOVA) was carried out using the SAS program, version 8.1 (SAS Institute Inc., Cary, NC). Least significant differences (LSD) were computed at $P < 0.05$.

RESULTS

Construction and Screening of Mutant Libraries. The PCR products of GSSM were purified and digested by *Dpn* I to remove the template plasmid containing the methylation sites and to create the recombination library of pET28b-NIT_{mut}. Single colonies of positive mutants were picked from LB agar plates containing Kan resistance to 96-well plates with 200 μL of LB broth supplemented with 50 mg/mL of Kan and incubated overnight with vigorous shaking (500 rpm) at 37 °C. Ten microliters of the culture was transferred to the new 96-

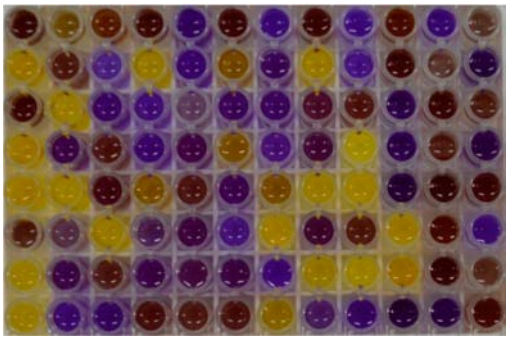

Figure 1. Mutant library screening for the high activity of nitrilases in a 96-well plate.

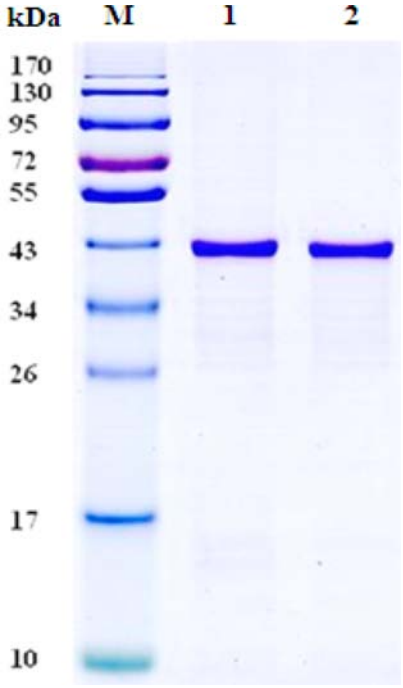

Figure 2. SDS−PAGE analysis of purified nitrilases. Gels with 30% polyacrylamide were subjected to protein analysis, and the protein bands were stained with Coomassie blue R250. Lanes 1 and 2 stand for Mut3 and the wild-type nitrilase, respectively.

well plates with 50 mg/mL Kan and 500 μL of LB medium, and then was incubated at 37 °C until the OD at 600 nm of the culture broth reached between 0.6 and 0.8 for retesting the activity and pH stability. In addition, plates containing both 100 mM (*R*,*S*)-mandelonitrile and 0.1 mM IPTG were incubated for 10 h at 28 °C. The final concentration of 0.01% (w/v) bromocresol purple solution was added for screening. The wells containing positive colonies with improved properties could become yellow and the negative mutants remain in the purple background (Figure 1 and Figure S1 in the Supporting Information). Over 6300 colonies in total were screened, and 55 clones could make the wells turn yellow. Among these clones, 10 better ones were retested using HPLC, and the clone with the greatest improvement in activity was selected (Table S1 in the Supporting Information). At the same time, selected variants were sequenced, and their amino acid substitutions are listed in Table S1 (Supporting Information). After three rounds of GSSM followed by screening, a best mutant Mut3 (Gln196Ser/Ala284Ile), with 200% relative activity than the wild-type, was selected as the targeted evolved nitrilase for further studies.

Expression and Purification of Nitrilases. The wild-type and evolved nitrilases were subjected to Nickel-NTA affinity chromatography. As shown in SDS−PAGE (Figure 2), there is only one pure band with a molecular weight of around 43 kDa observed for both of the purified wild-type and evolved nitrilases, which is consistent with the predicted molecular weight.

Influences of pH Values on the Activites of Nitrilases. It is well-known that the pH values affect the ionic environment of the enzyme, thus acting on its interaction between substrate and enzyme activity. To investigate the effect of pH on nitrilase activity, the reaction was performed in buffers including citrate buffer (pH 3.0−6.0), phosphate buffer (pH 6.0−8.5), Tris-HCl buffer (pH 7.0−8.5), and glycine-NaOH buffer (pH 8.5−10.0) with a concentration of 100 mM at 45 °C. As shown in Figure 3A, both wild-type nitrilase and Mut3 showed almost the same trends of activities under different pH conditions. The maximum specific activity of the evolved and wild-type nitrilases was observed at pH 8.0. Compared to wild-type nitrilase, the activity of Mut3 has increased significantly ranging from pH 3.0 to 10.0. Moreover, at pH 8.0, the specific activity of Mut3 (42.77 U/mg) was improved 154% compared to that of wild-type nitrilase (27.79 U/mg).

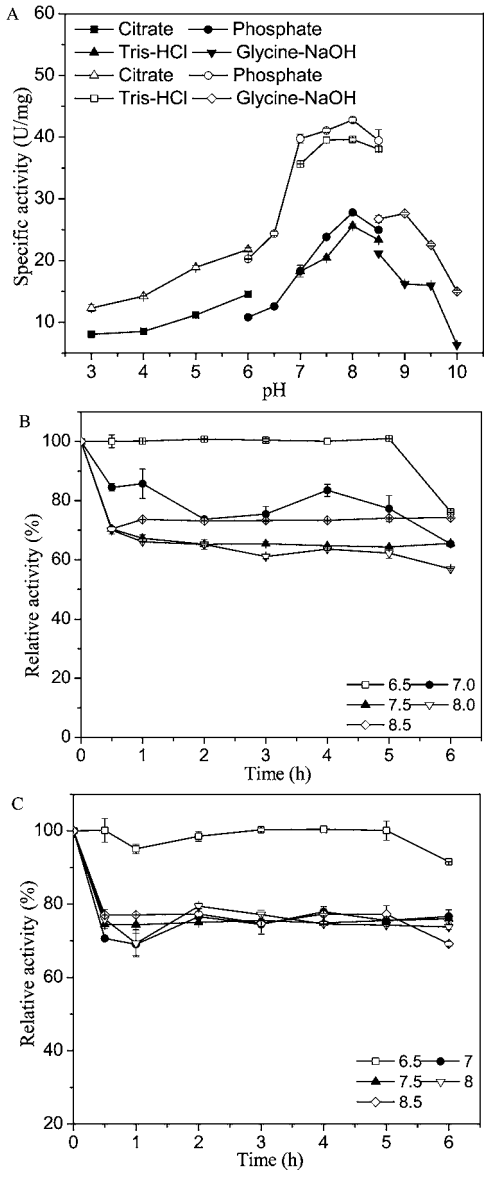

Figure 3. Influence of pH on the activity of nitrilases and stability. (A) Reactions were performed at 45 °C with different buffers. Hollow and solid represent the mutant Mut3 and the wild-type nitrilase, respectively. (B) pH stability was investigated by dissolving the wild-type nitrilase in phosphate buffers of pHs ranging from 6.5 to 8.5 and incubated at 0 °C from 0.5 to 6 h. (C) pH stability was investigated by dissolving Mut3 in phosphate buffers of pHs ranging from 6.5 to 8.5 and incubated at 0 °C from 0.5 to 6 h.

The pH stability study (Figure 3B and C) showed that Mut3 was more stable at pH 6.5 with about 90% residual activity after 6 h than the wild-type nitrilase with only 76% residual activity.

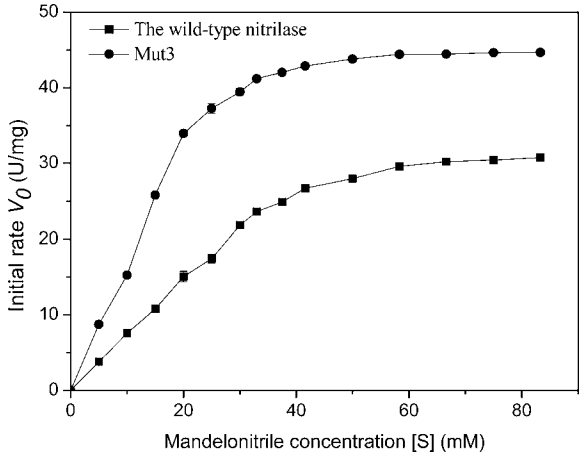

Figure 6. Reaction rate at different mandelonitrile concentrations. Reactions were performed at 45 °C, 150 rpm, with 100 mM potassium phosphate buffer (pH 8.0).

Effects of Temperatures on the Activities. The effects of temperatures on nitrilase activities of the wild-type and Mut3 were investigated. Enzyme (0.2 mg/mL) was dissolved in 100 mM phosphate buffer (pH 8.0) and incubated for 5 min at a temperature ranging from 25 to 65 °C before reaction. The reaction was started by adding 100 mM (*R*,*S*)-mandelonitrile under the corresponding temperature at 150 rpm for 10 min in a reciprocal shaker. As shown in Figure 4A, the optimum temperatures were 45 °C for both the wild-type and Mut3. The activities of nitrilases decreased significantly when the temperature was above 45 °C, and the specific activity of Mut3 was about 154% higher as compared to the wild-type nitrilase under the optimal temperature and pH.

The study of thermostability showed that the activity of wild-type nitrilase maintained about 60% incubation after 16 h, while the residual activity of Mut3 was 75% at 30 °C. After incubation for 1 h at 50 and 60 °C, the relative activity of wild-type nitrilase was sharply reduced to 4.40% and 1.03%, and Mut3 was 6.30% and 1.92%, respectively. Mut3 was unstable at higher temperature as revealed by a half-life of 54 h at 30 °C, 1.9 h at 40 °C, and 0.4 h at 50 °C, which was better than that of the wild-type nitrilase with half-lives of 21 h at 30 °C, 1.8 h at 40 °C, and 0.2 h at 50 °C (Figure 4B and C). The results corresponded to the circular dichroism data, indicating the

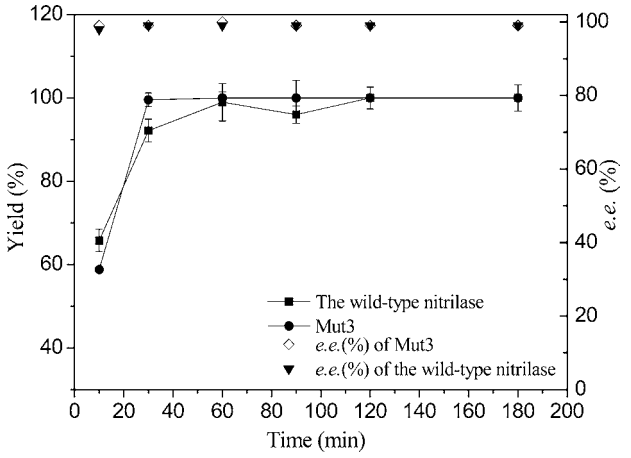

Figure 7. Time course analysis of (*R*,*S*)-mandelonitrile biotransformation by wild-type nitrilase and Mut3 under optimal conditions with a pH of 8.0, a temperature of 40 °C, and a concentration of (*R*,*S*)-mandelonitrile of 100 mM.

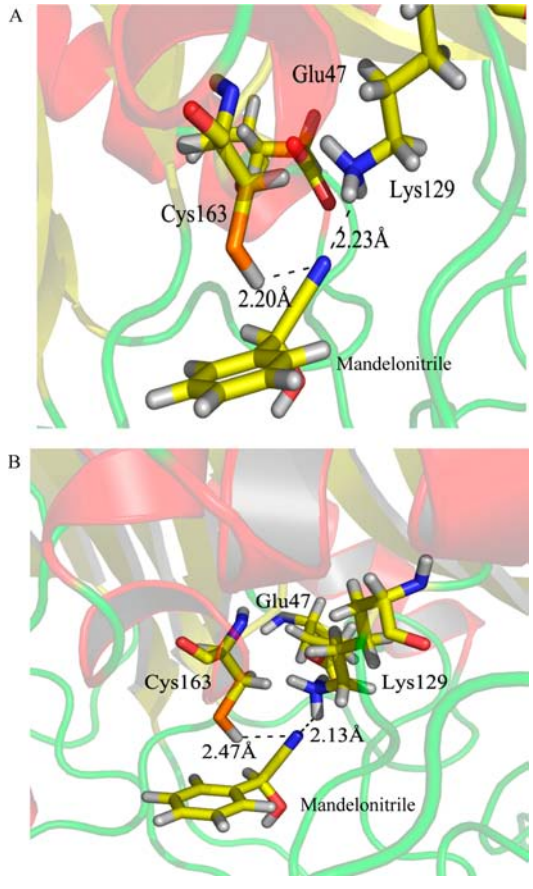

Figure 8. Homology modeling and docking analysis of nitrilases with mandelonitrile docking into the active site of the wild-type nitrilase (A) and Mut3 (B).

nitrilases were sensitive to heat (Figure 5 and Table S2, Supporting Information).

Kinetic Analysis of Wild-Type and Evolved Nitrilase. To determine the kinetics of reaction catalyzed by nitrilases, the initial rate V_0 was investigated at different concentrations (0–100 mM) of (*R*,*S*)-mandelonitrile (Figure 6). The experimental data were fitted to the Michaelis–Menten equation ($V_0 = (V_{max}[S])/(K_m + [S])$), and the values of K_m and V_{max} were

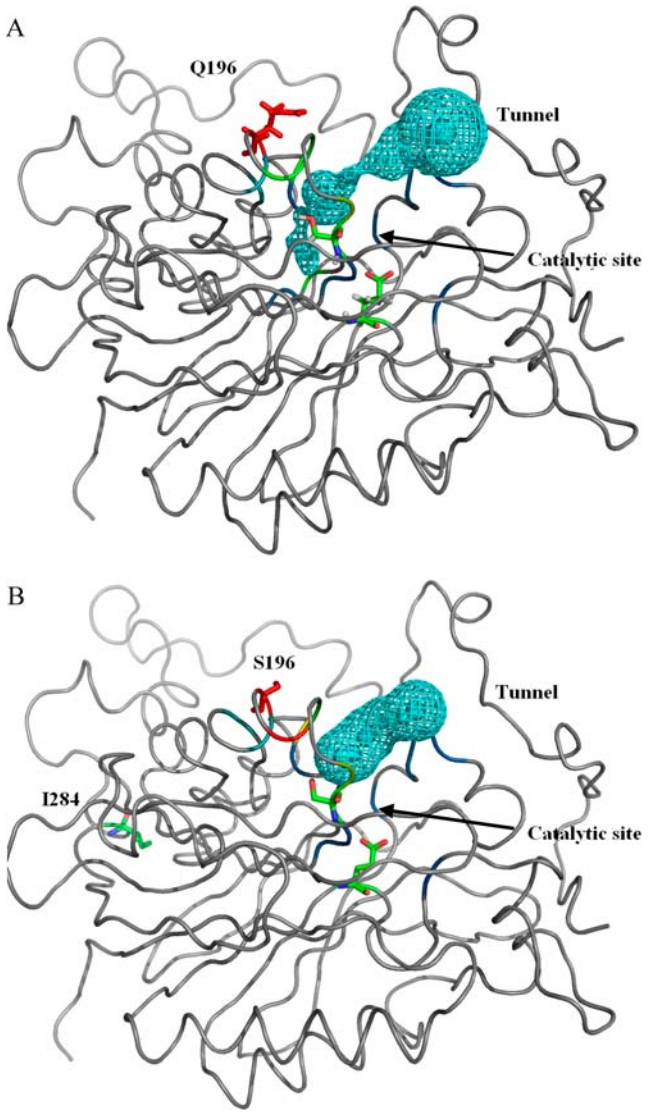

Figure 9. Tunnel analyses of wild-type nitrilase (A) and Mut3 (B).

calculated according to the Lineweaver–Burk plots. The values of K_m, V_{max}, and k_{cat} were calculated to be 20.64 mM, 33.74 μmol mg^{-1} min^{-1}, and 24.45 s^{-1} for wild-type nitrilase, while they were 9.24 mM, 47.68 μmol mg^{-1} min^{-1}, and 34.55 s^{-1} for Mut3, respectively.

Time Course of (*R*,*S*)-Mandelonitrile Hydrolysis. Wet cells of wild-type or Mut3 (0.1 g) was suspended in the 10 mL reaction mixture containing 100 mM potassium phosphate buffer (pH 8.0) and 100 mM (*R*,*S*)-mandelonitrile. The reactions were carried out at 40 °C in a reciprocal shaker at 150 rpm. Samples were removed at predetermined times, and the yield was determined by HPLC analysis. As shown in Figure 7, the yield of Mut3 could reach 100% in 0.5 h which was higher than that of the wild-type, and the enantiomeric excess (e.e.) of (*R*)-(−)-mandelic acid was >99%.

Fed-Batch Production of (*R*)-(−)-Mandelic Acid. To obtain efficient production of (*R*)-(−)-mandelic acid and reduce the potential inhibition on enzyme at high substrate concentration, a fed-batch reaction was performed using Mut3 as catalyst. (*R*,*S*)-Mandelonitrile (100 mM) was fed to the subsequent 7 batches (total concentration of substrate: 800 mM) once an hour. The accumulative concentration of (*R*)-

dx.doi.org/10.1021/jf405683f | J. Agric. Food Chem. 2014, 62, 4685–4694

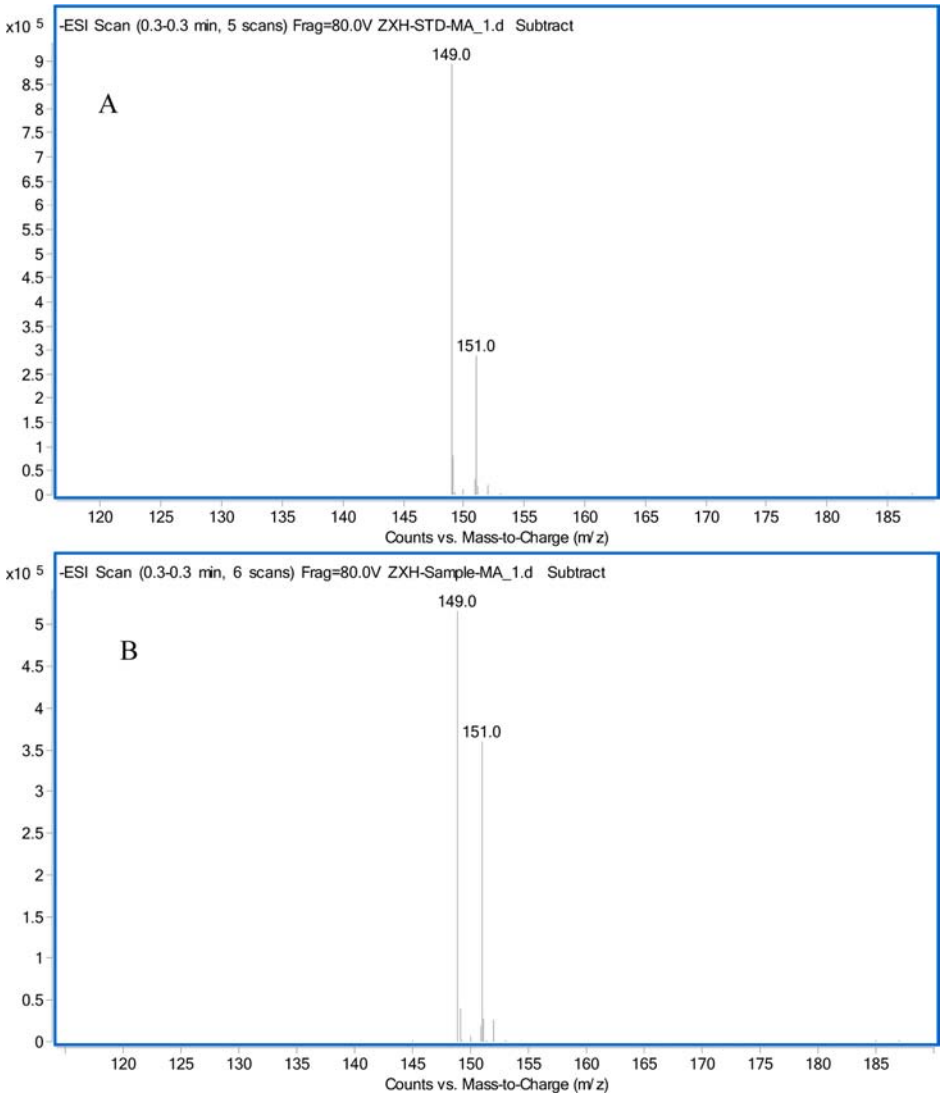

Figure 10. Identification of (*R*)-(−)-mandelic acid. LC-MS spectrum of (*R*)-(−)-mandelic acid, standard (*R*)-(−)-mandelic acid (A), and separated (*R*)-(−)-mandelic acid (B).

(−)-mandelic acid reached 585 mM after 5.5 h of biotransformation (Figure S2, Supporting Information). Compared to the previous report,[35] 693 mM of (*R*)-(−)-mandelic acid concentration at 7.5 h in this work displayed the highest productivity in terms of the nitrilase catalyzing asymmetric hydrolysis of (*R,S*)-mandelonitrile, and the optical purity of the (*R*)-(−)-mandelic acid was maintained above 99% during the reaction process. In addition, considering the cost of industrial application, Mut3 with excellent tolerance against high product concentration is more favorable for applications because the separation cost of product will be reduced substantially. Taking the volumetric productivity and product concentration tolerance into account, the mutant Mut3 was potential for industrial application.

Isolation and Identification of (*R*)-Mandelic Acid. After isolation and purification of (*R*)-(−)-mandelic acid according to the method described in Materials and Methods, (*R*)-(−)-mandelic acid with 99% purity was obtained (Figure S3, Supporting Information). The LC-MS spectrum of the separated (*R*)-(−)-mandelic acid was presented in Figure 10A and B, LC-MS showed that the molecular ion peak of (*R*)-(−)-mandelic acid was *m/z* 151.0, which was in accordance with the mass of (*R*)-(−)-mandelic acid. The FTIR spectrum of the separated (*R*)-(−)-mandelic acid is presented in Figure 11A and B; the two sharp peaks presented at 3448 and 1724 cm^{-1} could be assigned to the O−H and C═O stretching vibrations, respectively. The two peak absorption bands at 1495 and 1455 cm^{-1} were due to the C═C stretching vibration on the phenyl group. When ^{13}C NMR was performed, the isolated product gave one signal at 174 ppm, which referred to the C positions of the carboxyl group. The absorption bands between 126 and 140 ppm were due to the C positions on the phenyl group (Figure S4, A and B, Supporting Information). Figure S5, A and B (Supporting Information) shows four different kinds of H atoms, which corresponded to the structure of (*R*)-(−)-mandelic acid, one peak at chemical shift δ = 12.6356 ppm representing one H atom at the carboxyl group. The split peaks at chemical shifts between δ = 7.2797 ppm and δ = 7.4522 ppm represented the H positions on the phenyl group, and the peak at chemical shift δ = 2.50 ppm referred to the H position of the hydroxyl group. Accordingly, it was concluded that the isolated product was (*R*)-(−)-mandelic acid.

DISCUSSION

Nitrilases have recently drawn considerable attention due to their ability to transform nitriles to carboxylic acids with chemo-, region-, and enantioselectivity.[36,37] Nitrilases, as important industrial enzymes, have more significant improvements than traditional chemical catalysts,[38] which have mediated the industrial conversion of aliphatic, arylaliphatic, aromatic, and heterocyclic nitriles.[6,37] One of the important industrial applications of nitrilases is the conversion of (*R*,*S*)-mandelonitrile to (*R*)-(−)-mandelic acid with high enantioselectivity, low cost, and almost 100% yield.[5,11,12] The goal of this study is to improve the nitrilase from *A. faecalis* to meet the requirement of an upscale production of (*R*)-(−)-mandelic acid.

On the basis of the secondary structure, relationships between substrate and the nitrilase, and previous reports,[5,31,32] five sites (Leu175, Ala197, Val305, Ala284, and Gln196) were selected to carry out mutations for improving activity of nitrilase. After screening by a two step screening method, the best mutant Mut3 was selected. Mut3 displayed dramatic improvement in activity, pH stability, and tolerance to the

substrate. In a fed-batch reaction with 800 mM (*R*,*S*)-mandelonitrile as the substrate, the cumulative concentration of (*R*)-(−)-mandelic acid in the reaction mixture after 5.5 h of biotransformation reached 585 mM with an e.e. of 99%, which was higher than that in a previous report with 520 mM after 18 h. At the same time, the space-time productivity of Mut3 (10.64 mmol L^{-1} h^{-1} g^{-1}) was 7.40-fold higher than that in a previous report (1.44 mmol L^{-1} h^{-1} g^{-1}).[35]

CD results confirmed that these nitrilases are sensitive to heat and that the thermostability of Mut3 was better than that of wild-type nitrilase. The nitrilase activites of both wild-type and Mut3 shared almost the same trends under different pH conditions. The specific activity of Mut3 (42.77 U/mg) was 154% higher than that of wild-type nitrilase (27.79 U/mg) at pH 8.0. The analysis of the time course of (*R*,*S*)-mandelonitrile hydrolysis indicated that the yield of Mut3 could reach 100% in 0.5 h, which was shorter than that of wild-type nitrilase with 1 h. Especially, the time-space productivity of (*R*)-(−)-mandelic acid by Mut3 was superior to those in previous reports (Table 2).[35,39]

Homology modeling and molecular docking analysis can predict spatial structure and the catalytic mechanism of nitrilase (Figure 8). Modeling and mutation studies showed that conserved catalytic residues Cys163, Glu47, and Lys129 are the catalytic triad of the nitrilase. Cys163 attacks cyano as affinity reagents with hydrogen bonds, Lys129 has a stabilizing effect on the triplet complex with hydrogen bonds, and Glu47 plays a leading role in catalysis.[5] The tunnel analysis indicated that the diameter of the catalytic tunnel and tunnel volume for Mut3 were 1.70 and 16.0 $Å^3$ compared with 0.43 and 23.0 $Å^3$ for the wild-type (Figure 9). The larger catalytic tunnel and smaller tunnel volume can improve the nitrilase to hold and selectively catalyze the substrate.[30,32]

In summary, we genetically engineered the nitrilase originated from *A. faecalis* nitrilase by GSSM for the production of (*R*)-(−)-mandelic acid. A mutant, Mut3 with high activity, enantioselectivity, and stability in high concentrations of substrate or product, had been obtained. The thermostability of Mut3 was better than that of wild-type nitrilase. After mutation, Mut3 achieved the highest space-time productivity (10.64 mmol L^{-1} h^{-1} g^{-1}). The results in this work indicated that Mut3 was a promising biocatalyst for the production of (*R*)-(−)-mandelic acid in industrial applications. This study paved a foundation for the large-scale biotransformation of (*R*,*S*)-mandelonitrile to (*R*)-(−)-mandelic acid. Further studies will focus on the upscale production of (*R*)-(−)-mandelic acid using Mut3 as the biocatalyst and are underway in our laboratory.

ABSTRACT: Drying and denaturation kinetics of aqueous droplets of α-lactalbumin (α-lac), β-lactoglobulin (β-lg), and bovine serum albumin (BSA) were measured in a convective drying environment. Single droplets having an initial droplet diameter of 2 ± 0.1 mm and containing 10% (w/v) protein concentration were dried using conditioned air (65 and 80 °C, 2−3% RH, 0.5 m/s velocity) for 600 s. The denaturation of these proteins was measured by using reversed-phase HPLC. At the end of 600 s of drying 13.3 and 19.4% α-lac was found to be lost due to denaturation at 65 and 80 °C, respectively. Up to 31.0% of β-lg was found to be denatured, whereas BSA was not found to be significantly ($p > 0.05$) denatured in these drying conditions. The formation and strength of skin and the associated morphological features were found to be linked with the degree of denaturation of these proteins. The secondary structure of these proteins was significantly ($p < 0.05$) affected and altered by the drying stresses. The β-sheet and random coil contents were increased in α-lac by 6.5 and 4.0%, respectively, whereas the α-helix and β-turn contents decreased by 5.5 and 5.0%, respectively. The β-sheet and random coil contents in β-lg were increased by 7.5 and 2.0%, respectively, whereas the α-helix and β-turn contents decreased by 3.5 and 6.0%, respectively. In the case of BSA the β-sheet, α-helix, and random coil contents were found to increase, whereas the β-turn content decreased.

INTRODUCTION

Whey is a heterogeneous mix of proteins. Among these proteins, α-lactalbumin (α-lac, 20%), β-lactoglobulin (β-lg, 65%), and bovine serum albumin (BSA, 8%) are the major constituents and comprise >90% of total whey protein. There are numerous studies in the literature reporting the denaturation of whey protein during thermal processing including drying.[1−3] However, these studies do not provide the drying and denaturation kinetics of individual whey protein fractions. A limited number of works are reported in the literature that provide the extent of denaturation of individual whey proteins (when they are treated separately), especially during isothermal heat treatment and high-pressure treatment processes.[4−6] There is little, if any, published work in the literature quantifying and analyzing the denaturation kinetics of individual whey protein components at the droplet level during convective drying. The quantification and understanding of drying and denaturation kinetics of individual whey protein components can help minimize the denaturation of individual whey proteins during powder formation and also help in designing better spray-dryers.

The spray-drying process involves atomization of a solution into droplets in a drying chamber and subsequent removal of the solvent through evaporation and finally formation of powder product. The formation of particles from a solution in the convective drying process such as spray-drying involves both equilibrium thermodynamic and kinetic processes. The vapor pressure and temperature gradients within a drying droplet and the drying medium are the key driving forces for the mass transfer from, and heat transfer to, the droplet. In an actual drying process, unique and complex evolution of particle shape and morphology takes place, which affects the mass and heat transport process. On the other hand, the magnitude of the vapor pressure and temperature gradients and the resultant heat and mass transfer fluxes also greatly affect the development of morphology in drying droplets.

In the spray-drying process, the operating parameters (or even the design of dryer to less extent) have to be judiciously selected to control the particle morphology. This is because the characteristics of the product such as particle density, particle size distribution, and residual final moisture content are greatly affected by the morphology of dried particles.[7] During spray-drying, the particle morphology is greatly affected by the drying conditions as well as by the nature and concentration of feed and the mode of atomization used. For example, the skin-forming and crust-forming materials develop quite different

morphological features.[8] Hence, the monitoring and analysis of the evolution of morphology during the particle formation process can provide very important information. However, it is not yet technologically feasible to capture the evolution of morphology during the particle formation process in situ during spray-drying. To date, the morphological features of spray-dried powders are acquired and analyzed using final powder particles.[9] However, these morphological features cannot be used to explain the evolution of morphology during the particle formation process. Thus, the relationships among the drying kinetics, morphology, physicochemical characteristics, and denaturation of protein are poorly understood. Single-droplet drying experiments are commonly carried out to capture the evolution of morphological features in drying droplets in convective drying processes.[10] Despite some limitations such as much larger droplet size and much longer drying time, single droplet drying experiments provide very important information regarding the development of morphological features during the convective drying process which is a much simplified and idealized model of spray-drying.[11−14]

Reversed-phase high-performance liquid chromatography (RP-HPLC) is an effective tool to separate denatured and native proteins. The chemical resin in the stationary phase of this column (i.e., presence of C8, C18) successfully retards migration of the denatured protein.[3,15] The strong affinity of these chemicals toward the hydrophobic portion of denatured proteins helps to separate the denatured and native proteins.

The functionality of protein predominantly depends on its specific molecular composition and structure. The polypeptide chains acquire a folded form to perform their biological functions. However, the stress generated during processing such as spray-drying can alter the structure of protein. Fourier transform infrared (FTIR) spectroscopy has been commonly used to identify and explain the structural characteristics of proteins. It is used to quantify the change in the secondary structure of proteins.[16] The polypeptide and protein repeat units give raise to nine characteristic IR absorption bands, namely, amides A and B and amides I−VII. The amide I region ranging between 1600 and 1700 cm^{-1} is commonly chosen to measure qualitative and quantitative changes in secondary structure of proteins because of its very high signal-to-noise ratio.[17,18] Furthermore, the absorption at this band is able to give considerable variation in IR signal even at small alterations in the molecular configuration of analytes.[19]

Although the IR spectra obtained are intrinsic and complex, mathematical tools such as derivatization and Fourier self-deconvolution (FSD) analyses are available to determine the unique structural features such as α-helix, β-sheets, β-turns, and random coils of a protein.[20,21] The derivatization and FSD can be applied to quantify alteration in structural features of proteins due to processing stresses.[16,17]

In this context, the key aim of this study was to measure the denaturation and drying kinetics of major whey proteins (α-lac, β-lg, and BSA) in convective air-drying environments. FTIR spectroscopy was used to quantify and explain the alteration in the secondary structure of these proteins caused by drying-induced stresses. The evolution of droplet morphology was captured and analyzed using single-droplet drying experiments.

EXPERIMENTAL PROCEDURES

Materials. The protein samples (α-lac, β-lg, and BSA) with high purity (≥95% pure) were purchased from Sigma-Aldrich (New South Wales, Australia). The HPLC solvents acetonitrile and trifluoroacetic acid (TFA) were purchased from Sigma-Aldrich and Fisher Scientific (Victoria, Australia), respectively. Deuterium oxide (D_2O) was purchased from Sigma-Aldrich. All proteins and chemicals were used as received without further purification.

Methods. *Single-Droplet Drying (SDD).* Details of the SDD instrument and its working procedure are provided elsewhere.[22,23] Aqueous droplets of 5 ± 0.1 μL initial volume (2 ± 0.1 mm initial droplet diameter) containing 10% (w/v) protein were suspended on the tip of a glass filament with a 0.2 ± 0.01 mm diameter. This droplet-suspending filament was supported by a droplet suspension system made up of a bored Teflon cylinder. The droplets were then subjected to conditioned drying air. The drying air was cleaned and heated by passing through a series of columns containing dried molecular sieve and dried silica gel. The temperature of the drying air was controlled by a proportional-integral-derivative (PID) controller. The droplets were dried at two different air temperatures (65 and 80 °C) at a constant velocity of 0.5 m/s. The relative humidity of the drying air was measured by using an EL-USB relative humidity data logger (Lascar Electronics, UK) and was found to be 2.5 ± 0.5% at these two drying temperatures. The wet bulb temperatures corresponding to air temperatures of 65 and 80 °C were 26 and 30 °C, respectively. The droplets were dried for 600 s, and the denaturation was measured at every 60 s interval. The temperature and mass loss histories were recorded in a computer. Images of the droplets during drying were captured at every 50 s interval using a digital camera (EOS 60D, Canon, NSW, Australia) at 40−50× magnification.

Determination of Denaturation of Proteins. The convectively dried droplets were diluted to 100 μg/mL with deionized water. Then, the pH of the diluted protein solutions was lowered to 4.6 by adding 0.1 M HCl to assist in separating the native and denatured proteins.[23,24] After the pH of protein solutions was adjusted, they were kept for 30 min and centrifuged at 11500g for 10 min. The supernatant was collected and injected onto the RP-HPLC column to separate the denatured and undenatured proteins. A control sample without drying was treated in the same way including pH treatment and centrifugation. The supernatant of the control sample was also subjected to RP-HPLC separation in the same way as dried protein. Residual native protein content was calculated using the ratio between the area under the peak of the treated protein and the area under the peak of untreated (control) protein (100%), as suggested by Parris and Baginski.[3]

The experiments were carried out in triplicate, and the average values are reported in the ensuing sections. The statistical analyses were carried out by using data analysis tools, Microsoft Office Excel 2010. The significance difference between two mean values was determined using one-way analysis of variance at 95% confidence level ($p < 0.05$). The inbuilt program in Microsoft Excel was used for this purpose.

Acquiring the IR Spectra. The IR spectra were acquired using a PerkinElmer Frontier FT-IR instrument operated by CPU32 M software. The SDD samples subjected to single-droplet drying and control samples were diluted to 5 mg/mL concentration using deuterium oxide (D_2O) containing 100 mM sodium chloride (NaCl).[18] The samples used in these tests were collected after 500 s of drying at both drying (air) temperatures. This time of sample collection (500 s) was chosen on the basis of the fact that both WPI (as a whole) and its major component β-lg were found to reach their maximum levels of denaturation at this time at both drying temperatures.[25] The samples were scanned within 650−4000 cm^{-1} using triglycine sulfate (TGS) detector. A total of four scans at 4 cm^{-1} resolution were accumulated at 0.2 cm/s scanning speed.

Analysis of IR Spectra. The blank spectrum (D_2O + NaCl) was subtracted from the spectrum of each sample. The baseline-subtracted protein spectra were analyzed by using PerkinElmer's proprietary software (version 10.03.06) and OPUS 6.5.92 (Bruker Biosciences Pty Ltd., Victoria, Australia). A 9-point second-derivative analysis using the PerkinElmer software was used to locate the peak position in the spectra. The OPUS software was used for quantitative analysis of secondary structure of protein by Fourier self-deconvolution. The original spectra (of amide region I, 1600−1700 cm^{-1}) without any

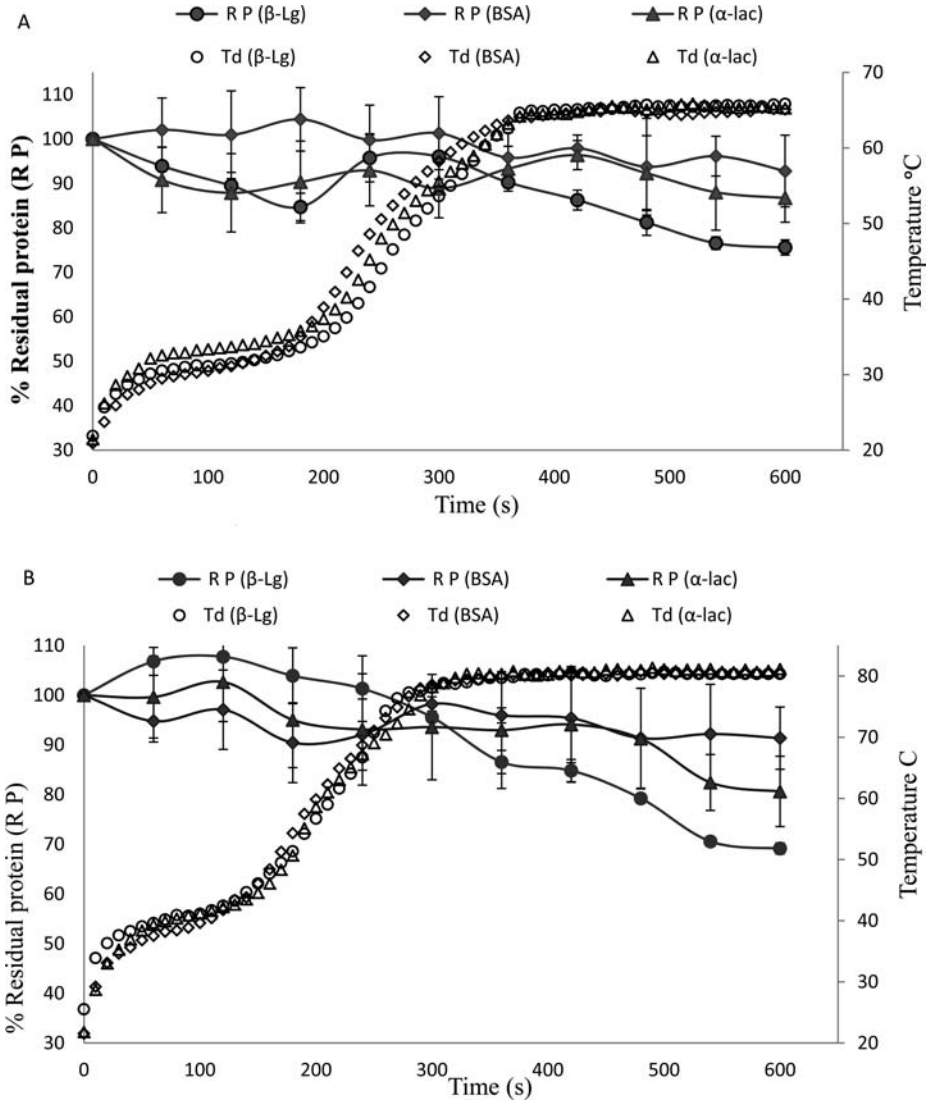

Figure 1. Denaturation of BSA, α-lac, and β-lg with drop temperature increment during drying at (A) 65 and (B) 80 °C air temperatures. The error bars show the standard deviation (SD) of experimental values.

smoothing were deconvoluted by gamma factor 2. The FSD curves were fitted with Gaussian shape and were analyzed by local least-squares (LLS) algorithm. Percentage of secondary structures (α-helix, β-sheets, β-turns, and random coils) was estimated using eq 1[16,26]

$$\text{secondary structure (\%)} = A_{\text{ind}}/A_{\text{total}} \times 100 \quad (1)$$

where A_{ind} = sum of area of individual secondary structure in amide I band and A_{total} = sum of area of total secondary structure in amide I band.

The position or location of bands for each secondary structure (β-sheets, α-helix, and β-turns) of tested proteins in D_2O were determined as suggested in the literature.[19,27,28] The bands from 1620 to 1640 cm^{-1} and from 1674 to 1680 cm^{-1} were assigned to β-sheets. The bands from 1641 to 1647 cm^{-1} were assigned to random coil. The bands within 1648−1660 cm^{-1} were assigned to α-helix. Similarly, the bands appearing at and in the vicinity of 1663, 1671, 1683, 1688, and 1694 cm^{-1} were assigned to β-turns.

RESULTS AND DISCUSSION

Denaturation of BSA, β-Lg, and α-Lac during Convective Drying. The denaturation kinetics of BSA, β-lg, and α-lac due to convective drying at droplet level were measured by RP-HPLC. As presented in Figure 1, a different extent of denaturation was observed in these whey protein fractions. Among these three proteins, BSA showed the highest stability as determined by the highest level of residual protein. β-Lg showed the least stability, that is, the lowest level of residual protein during drying. The stability of α-lac against denaturation remained between those of BSA and β-lg at both 65 and 80 °C (Figure 1). There was no significant ($p > 0.05$) loss of BSA and α-lac when dried at 65 and 80 °C for up to 480 s. At the end of 600 s, 13.26 and 19.37% of α-lac was found to be denatured at 65 and 80 °C, respectively. When the solution of β-lg was dried at these two drying temperatures, 24.40 and 30.85% of this protein was found to be denatured at 65 and 80 °C drying temperatures, respectively, when dried for 600 s. The difference in molecular configuration of these protein fractions might have played an important role for these differences in the observed denaturation. Specifically, the difference in the number of cysteine (amino acid) molecules and sulfur bridges in the structure of these proteins can be attributed to the variation in the denaturation. β-Lg starts to show significant ($p < 0.05$) loss due to denaturation (Figure 1B) when it reaches a state of irreversible denaturation (for example, 240 s at 80 °C). Before this state of irreversible denaturation is reached,

	BSA	$1.6e^{08}$	$2.00e^{-5}$	0.0078	0.9728	

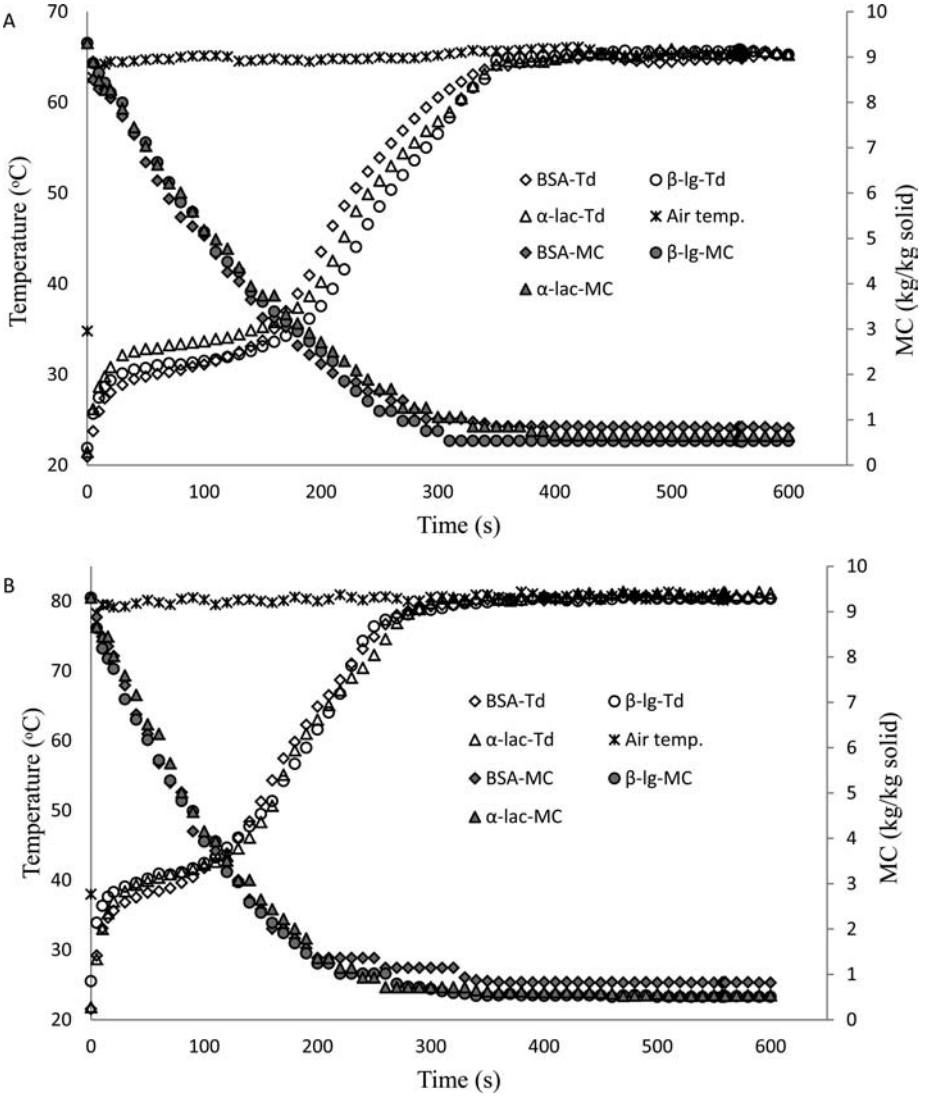

Figure 2. Moisture content and temperature profiles of BSA, α-lac, and β-lg during drying at (A) 65 and (B) 80 °C drying temperature. MC, moisture content; Td, drop temperature.

reversible denaturation occurs, and it involves excitation (due to the affinity of reaction of the thiol group of free cysteine with the adjacent sulfur bonds) of free cysteine molecules present in the β-lg and BSA structures. Due to prolonged drying stress, the peptides of β-lg are exposed to such an extent that they start to aggregate. On the other hand, the presence of 17 sulfur bridges helps to keep BSA relatively stable. Due to the absence of any free cysteine in α-lac structure, this protein is comparatively less excited or perturbed when it is subjected to dehydration stresses and it is less affected by thiol−disulfide interaction.[29] A more detailed explanation of the factors causing different extents of denaturation of these whey protein constituents during convective drying is presented elsewhere.[25]

Drying Kinetics and Its Relationship with Protein Denaturation. It is shown in Figure 1 that all of the denaturation−time curves exhibit some degree of fluctuation or perturbation from the very beginning of the drying process. When the droplet temperature was about 40 ± 5 °C, the denaturation--time curves started to fluctuate due to the impact of drying on the surface hydrophobicity. β-lg started to be lost

dx.doi.org/10.1021/jf405603c | J. Agric. Food Chem. 2014, 62, 4695−4706

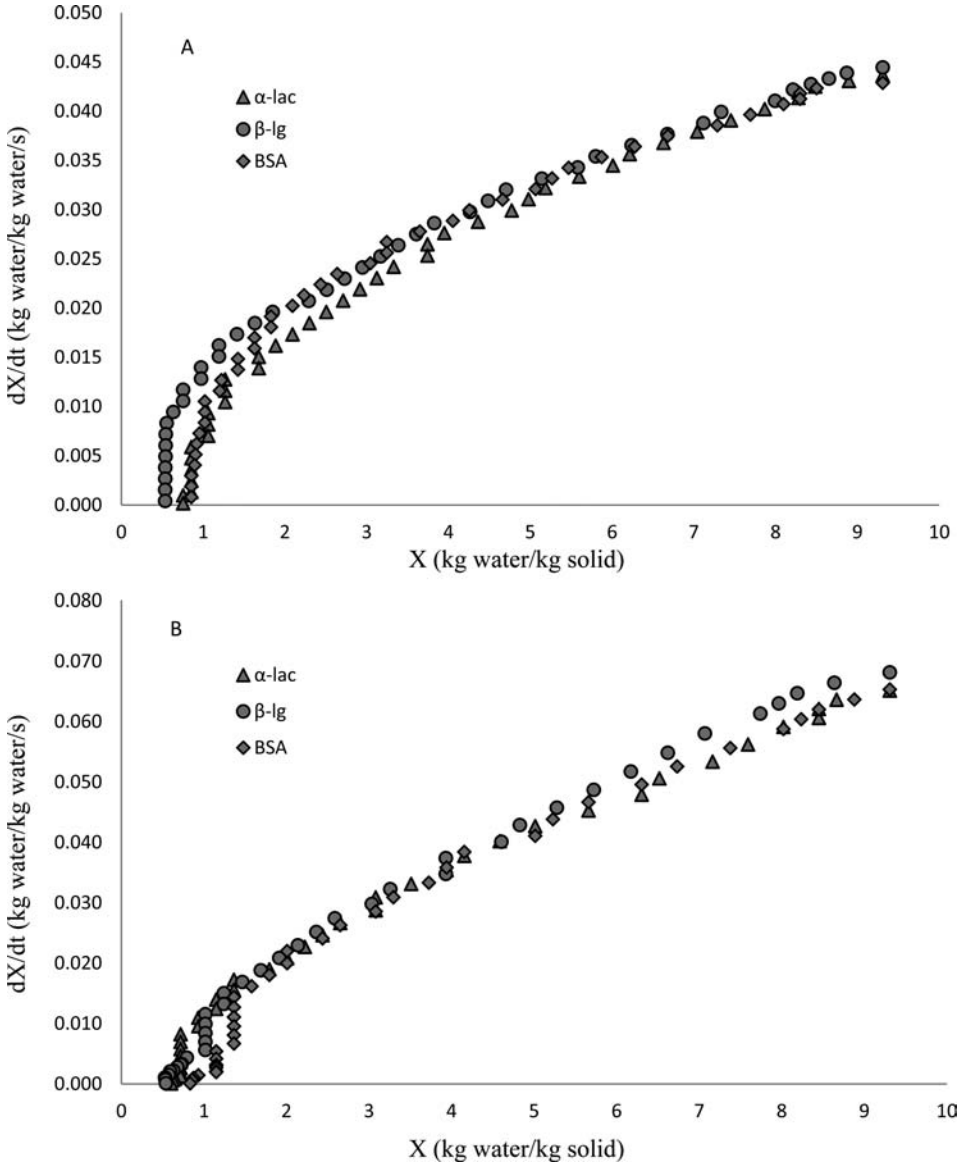

Figure 3. Evaporation rate profiles as a function of water content during drying of α-lac, β-lg, and BSA droplets at (A) 65 and (B) 80 °C air temperature.

due to irreversible denaturation and subsequent coagulation when the droplet temperature reached 55 ± 5 °C (Figure 1A). This irreversible denaturation started becoming prominent at 290 and 240 s of drying at 65 and 80 °C, respectively. We had previously reported the relationship between denaturation and droplet temperature in the case of WPI.[25] A similar trend in the relationship between denaturation and drying temperature was observed in this study only in the case of β-lg. The trends in the relationship between drying temperature and denaturation in the case of BSA and α-lac are quite different. In our earlier study,[25] WPI was dried and the individual fractions of WPI (α-lac, β-lg, and BSA) were dried as a part of whole. In the current study, intact and native individual proteins (α-lac, β-lg, and BSA) were dried individually as starting materials and the denaturation kinetics of one is not affected by the presence of the others.

To better understand the effect of drying rate on the protein denaturation, we determined the drying rate (dX_t/dt) from the experimental moisture loss versus time data. Polynomial models were fitted with the experimental moisture ratio (MR), and the drying rate was determined as shown by eqs 3 and 5 below.

For 65 °C drying temperature:

$$\mathrm{MR} = \frac{X_t - X_\infty}{X_0 - X_\infty} = At^2 - Bt + C \tag{2}$$

$$\frac{dX_t}{dt} = (X_0 - X_\infty)(2At - B) \tag{3}$$

For 80 °C drying temperature:

$$\mathrm{MR} = \frac{X_t - X_\infty}{X_0 - X_\infty} = -At^3 + Bt^2 - Ct + D \tag{4}$$

$$\frac{dX_t}{dt} = (X_0 - X_\infty)(-3At^2 + 2Bt - C) \tag{5}$$

X_t = moisture content of the droplet being dried at a given time (kg/kg solid), X_∞ = final moisture content of the dried droplet at the end of drying (kg/kg solid), and X_0 = initial moisture

dx.doi.org/10.1021/jf405603c | J. Agric. Food Chem. 2014, 62, 4695−4706

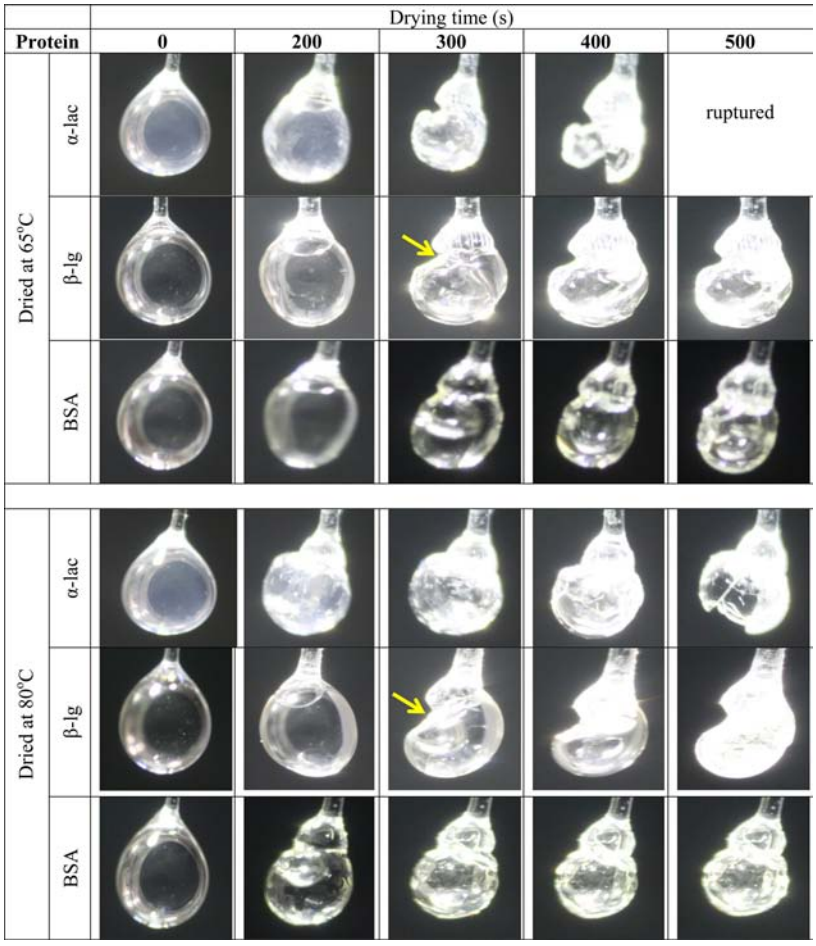

Figure 4. Development of morphological features in α-lac, β-lg, and BSA during single droplet drying at 65 and 80 °C. The arrows show partial loss of spherical shape.

content of the droplet being dried (kg/kg solid). Similarly, t = drying time (s), and A, B, C and D are the model constants. After fitting the moisture ratio curves with acceptable R^2 values, the drying rates (dX_t/dt) for all of the protein samples were calculated as shown by eqs 3 and 5. The estimated model constants along with the R^2 values are listed in Table 1.

The drying kinetics (moisture content and temperature histories) of BSA, β-lg, and α-lac are presented in Figures 2 and 3. It can be seen from Figures 2A and 3A that the BSA and β-lg tended to show higher rate of moisture loss (0.0218 and 0.0213 kg water/kg dry solid/s, respectively) than α-lac (0.0200 kg water/kg dry solid/s), and their droplet temperature remained close to the wet bulb temperature up to around 200 s. It also appears that an increase in BSA concentration offers greater resistance to moisture removal. The difference in the drying kinetics between these two proteins is observed after 200 s, and the drying rate of BSA became lower than that of β-lg (Figure 3A). After about 390 s of drying at 65 °C, the moisture content of both proteins did not decrease further and the droplet temperatures also reached very close to the drying air temperature. After the transition period of 200 s, the trends in the droplet temperature histories of these two proteins also changed remarkably. The temperature of the BSA droplet increased more rapidly than that of β-lg. In the case of α-lac the drop temperature started to increase more quickly than those of BSA and β-lg. The α-lac also showed similar reversible−irreversible transition at 200 s while drying at 65 °C. After this point, the droplet temperature of α-lac increased very rapidly and reached close to the drying air temperature. The rate of increase in droplet temperature in α-lac was faster than that of β-lg but slower than that of BSA.

These transitions in the temperature history curves (Figure 2A) of these proteins stem from the increased "drop side resistance" to the outward diffusion of moisture content.[8] The increased resistance to outward moisture diffusion gives rise to the "profile reversal", which means that the droplet temperature of the usually slower drying droplet is higher. Before the profile reversal, the drop temperature of β-lg droplet is slightly higher than that of BSA. After the profile reversal, the temperature of the BSA droplet is higher than that of the β-lg droplet. This phenomenon is more prominent in the cases of α-lac and BSA. The morphological changes of these protein droplets during convective drying, to some extent, might also be responsible for these interesting features observed in the drying profiles.

The morphological features of droplets of BSA, β-lg, and α-lac while drying at 65 and 80 °C are presented in Figure 4. It can be seen from this figure that the original spherical shape of the droplet remained more or less intact up to 200 s in all of the protein droplets. It has to be pointed out here that so long as the moisture content of the droplet is high and the droplet temperature is not too close to the drying air temperature (Figures 2 and 3), the morphology of the droplet remains more or less spherical (Figure 4). The morphology of these protein droplets showed different trends after 200 s. The BSA was

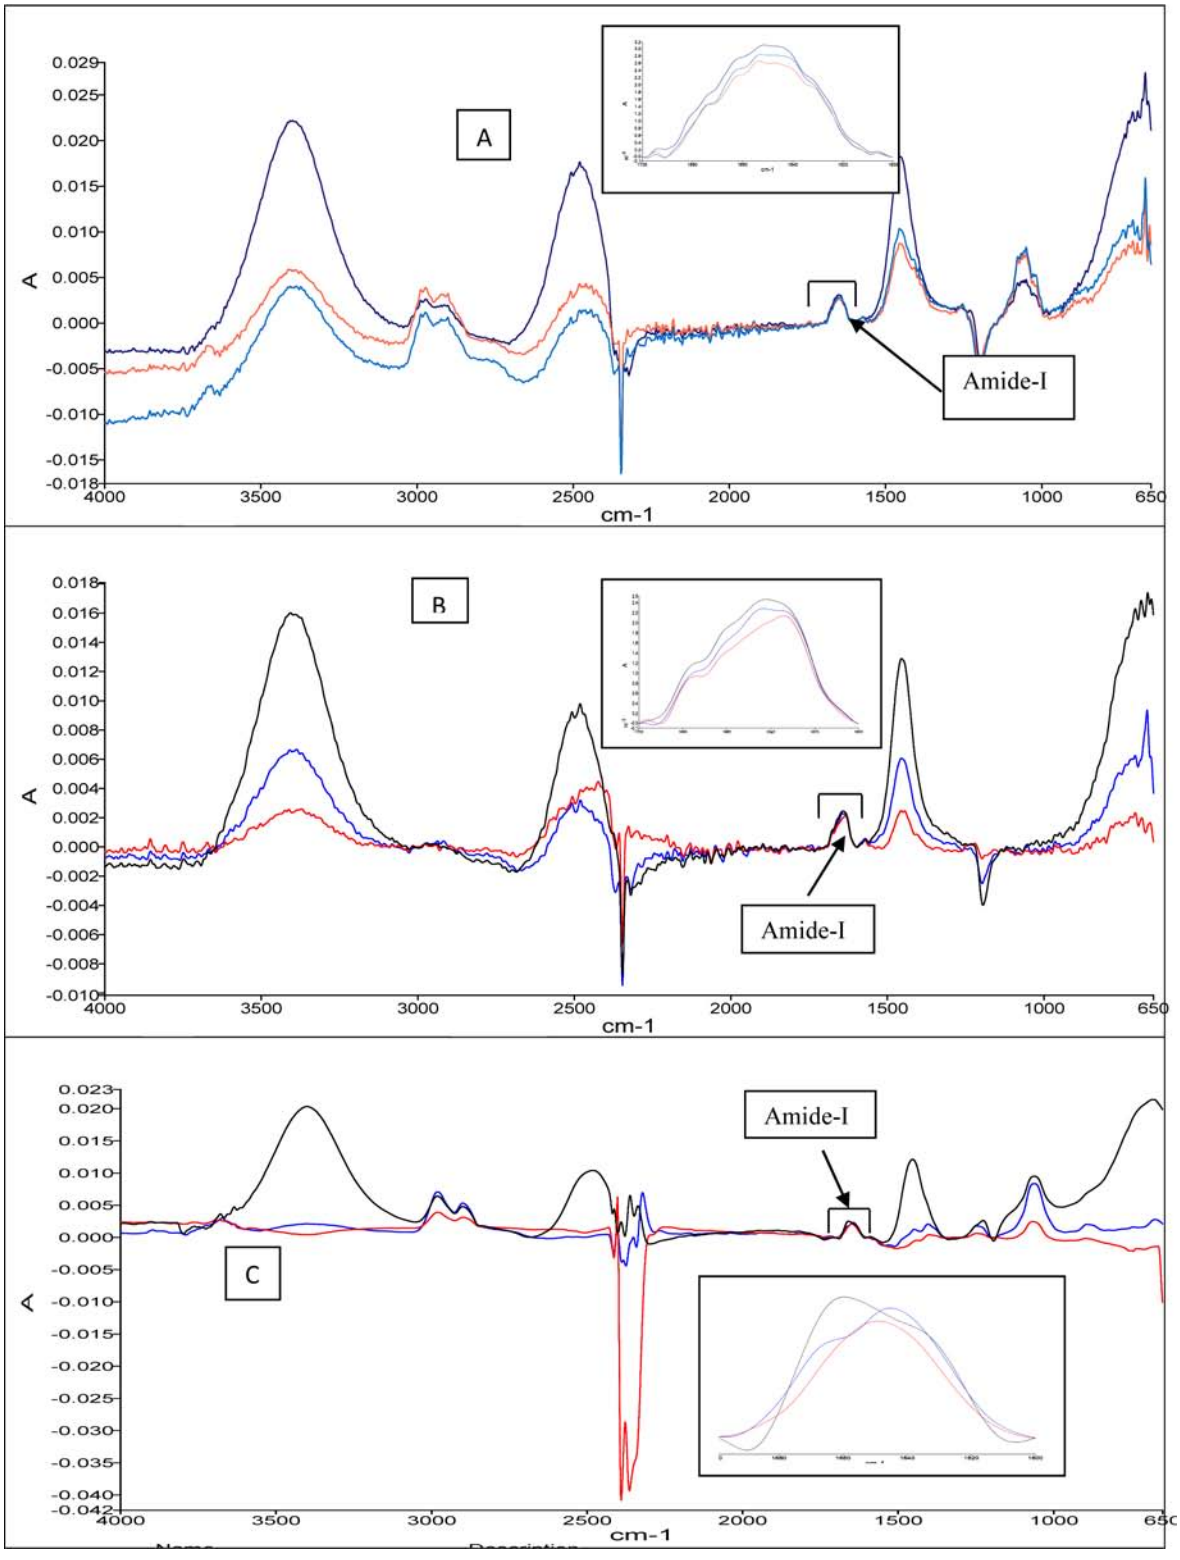

Figure 5. Absorbance spectra from FTIR of original and dried (A) α-lac, (B) β-lg, and (C) BSA (black, blue, and red lines indicate native and 65 and 80 °C treated spectra, respectively). Amide I regions are zoomed in the insets.

capable of retaining more moisture in its matrix and exhibited a sharper increase in droplet temperature. It is commonly accepted that a droplet with a lower drying rate (retains more moisture content) shows faster increase in droplet temperature due to a lesser degree of evaporative cooling. One of the interesting features associated with the morphology and drying kinetics was that the protein (BSA) containing more water in droplet for longer time was found to retain its spherical shape longer. In addition, the entrapped water inside the drying droplet of this protein caused a buildup of vapor pressure, which developed wrinkles and troughs or uneven surface morphology.[30] The interplay between the force generated by

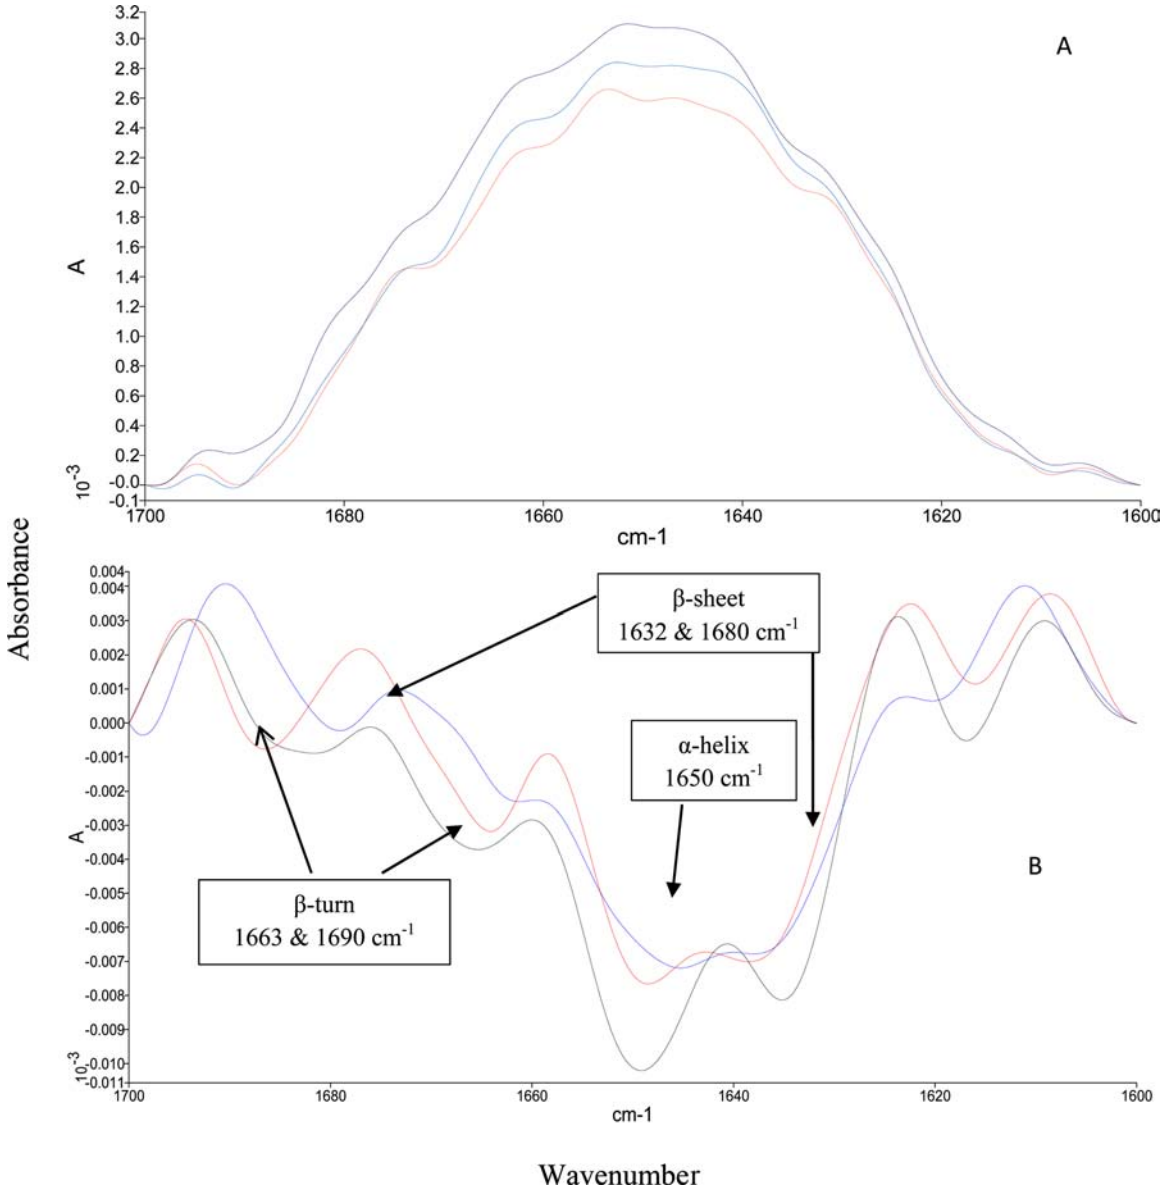

Figure 6. (A) Absorbance and (B) second-derivative spectra of amide I region of the native and single droplet dried α-lac (black, blue, and red lines indicate native and 65 and 80 °C treated spectra, respectively).

this vapor built up within the droplet, and the thermoplastic nature of the protein skin is the one of the main causes giving rise to the wrinkled morphology in BSA. A similar trend regarding the relationship between the surface morphology and drying kinetics was observed in these proteins at 80 °C as well. The only difference was that the development of morphological features occurred much mor rapidly while drying at 80 °C. After 360 s of drying at 80 °C, the moisture loss of all three proteins was almost ceased.

Denaturation of BSA, α-Lac, and β-Lg and Droplet Morphology. The evolution of morphology in BSA, α-lac, and β-lg droplets when dried at 65 and 80 °C is presented in Figure 4. As can be seen from this figure, these three proteins produced three different types of morphological features. The surface of the BSA droplet showed the ability to resist the stress exerted by the drying process and, hence, maintained spherical feature and resisted surface folding and wrinkling to a greater extent at both temperatures until the end of drying. β-Lg was least capable of resisting the deformation of droplet/particle surface during drying at both temperatures. β-Lg partially lost its spherical shape after 300 and 200 s when dried at 65 and 80 °C, respectively, and resulted in a buckled particle. α-Lac maintained its spherical shape during the early stage of drying. However, it started becoming increasingly fragile, and the particle surface was ruptured when the drying progressed.

The whey protein BSA acquired a rigid structure immediately after the start of drying (Figure 4), which might be responsible for much slower moisture evaporation in this protein. The rigidity of the BSA droplet surface during drying might be explained by its large molecular mass. BSA has a higher molecular mass (66.27 kDa) than those of α-lac (14.18 kDa) and β-lg monomer (18.28 kDa). Besides, the high number of sulfur bridges present in the BSA structure might provide greater resistance against outward moisture diffusion and maintain a moist interior. The preservation of its spherical shape by α-lac in the early stage of drying can also be attributed to its skin-forming behavior. The subsequent rupture of the α-lac particle suggests that this protein forms a thinner skin. The

dx.doi.org/10.1021/jf405603c | J. Agric. Food Chem. 2014, 62, 4695−4706

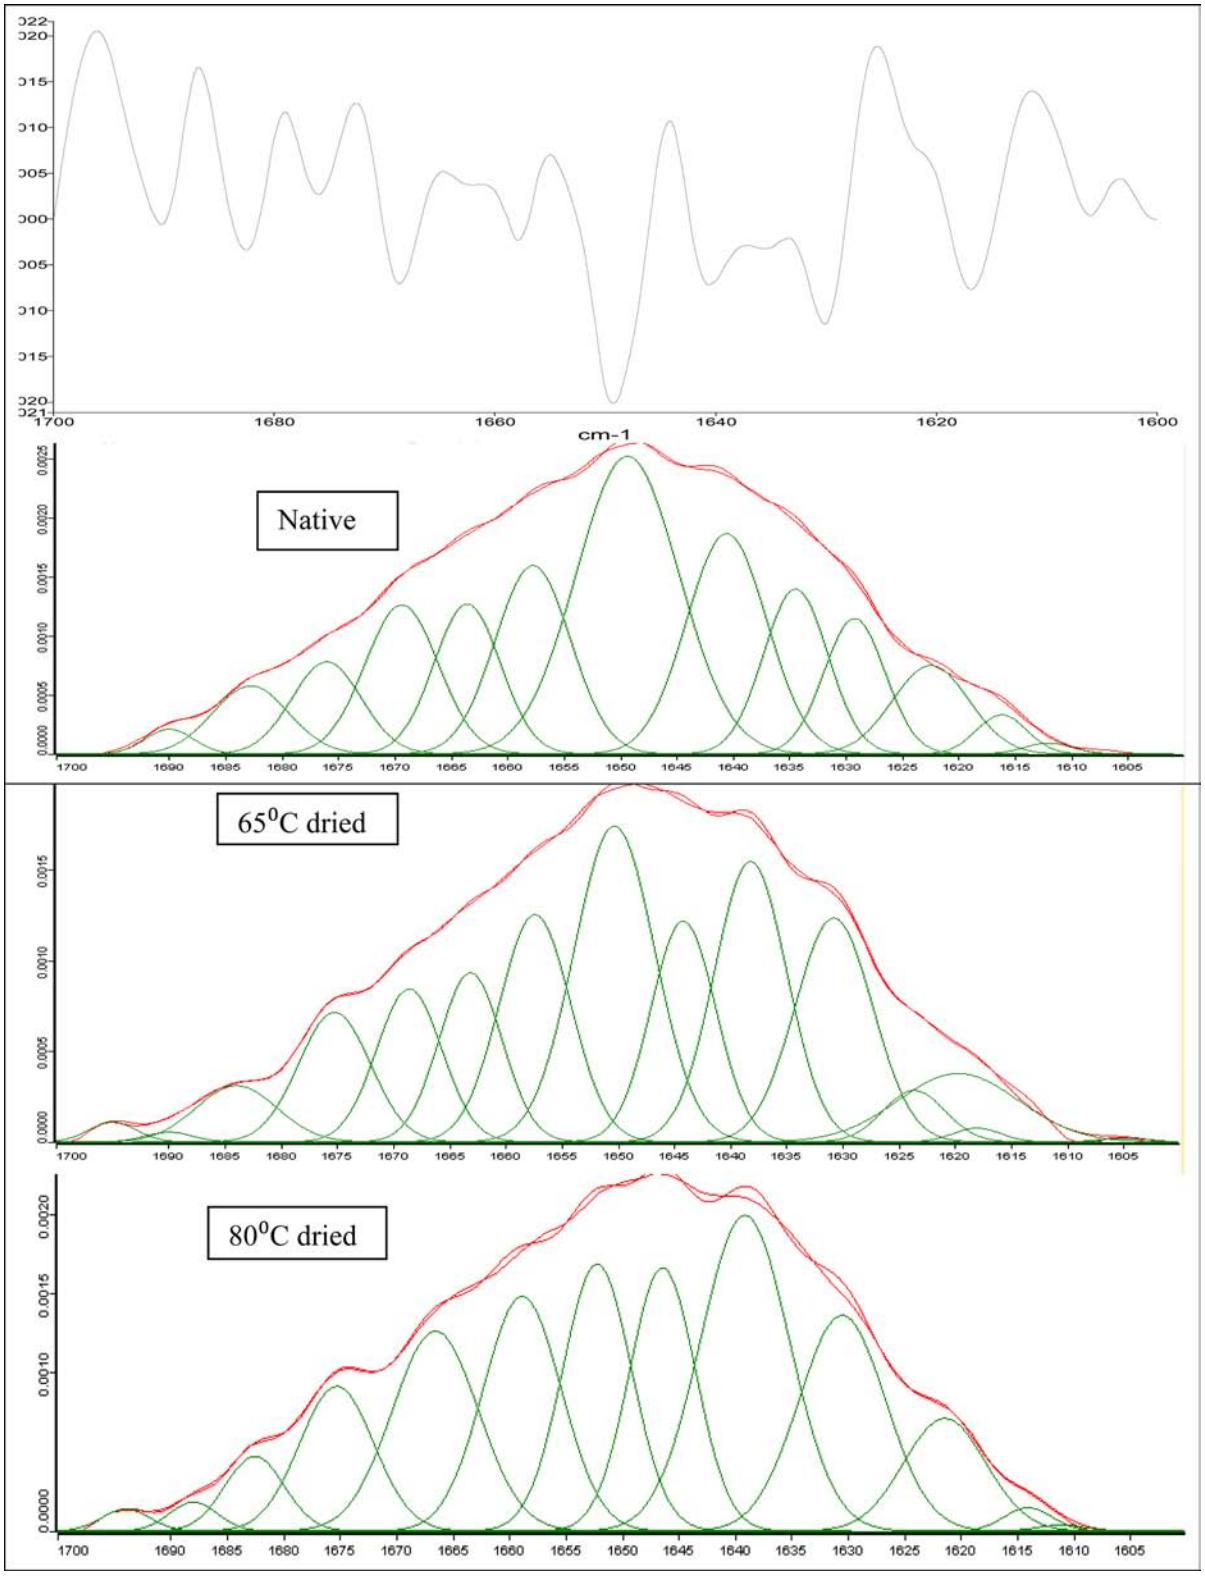

Figure 7. Fitted spectra of native and dried α-lac (a sample of second-derivative spectra of native α-lac is at the top).

irreversible denaturation of proteins and their agglomerates is capable of forming a thick skin at the outer surface of droplets being dried.[9] It can be observed from Figure 1 that α-lac denatured only marginally at 500 s when the skin was ruptured due to drying (a 65 °C). This lack of denaturation and, hence, the lack of formation of a rigid wall (or skin) produced α-lac particles with a hollow crust. The dried particles with a hollow crust are known to collapse or shrivel quite easily.[9] This is why the particles of α-lac ruptured quite easily at both drying temperatures. On the other hand, β-lg experienced significant ($p < 0.05$) denaturation at both drying temperatures and the denaturation and aggregation occurred as early as 250 s of drying. Because the denatured proteins conveniently form a rigid skin, the formation of skin in this protein also started after

dx.doi.org/10.1021/jf405603c | J. Agric. Food Chem. 2014, 62, 4695−4706

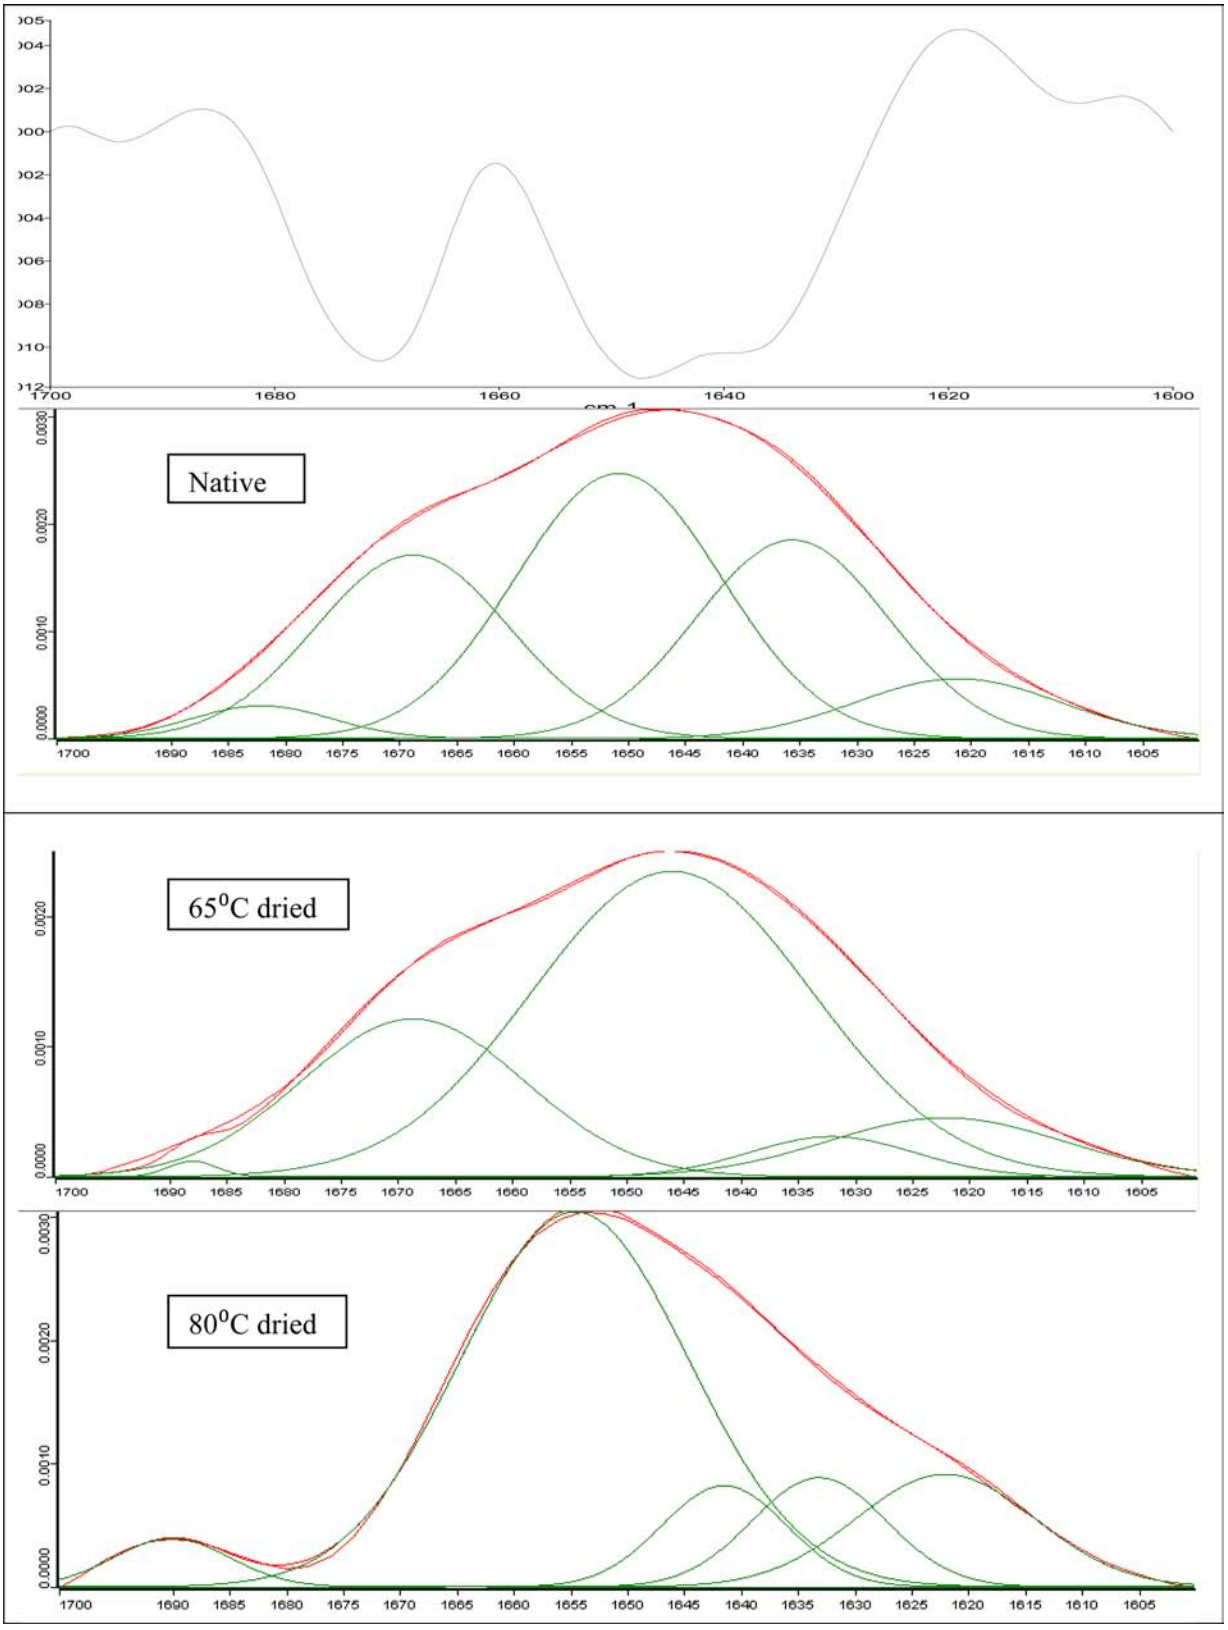

Figure 8. Fitted spectra of native and dried BSA (a sample of second-derivative spectra of native BSA is at the top).

200 s. This explains why the partial wrinkling appeared on the surface of this protein after 200 s. The better stability of α-lac droplet/particle (lack of rupture) at 80 °C compared to 65 °C (Figure 4, 500 s) can be attributed to the significantly ($p <$ 0.05) higher extent of denaturation of α-lac at 80 °C than at 65 °C.

Alteration in Secondary Structure of BSA, α-Lac, and β-Lg. Figure 5 shows the IR spectra of native and dried BSA, α-lac, and β-lg. The second derivatives of the IR spectra were

dx.doi.org/10.1021/jf405603c | J. Agric. Food Chem. 2014, 62, 4695−4706

used to identify the individual structural features of these proteins. For example, the derivative spectra (Figure 6B) derived from intrinsic absorbance spectra (Figure 6A) are able to clearly assign some specific bands in both native and dried proteins. The derivative spectra are also able to quantify the magnitude and direction of change occurring in a specific band due to drying-related stresses. For example, when α-lac was dried at 65 °C for 500 s (Figure 6B), the proportion of its β-sheet increased (around 1680 cm^{-1}), and this increase was compensated by the decrease in α-helix (around 1650 cm^{-1}) and β-turn (around 1663 and 1690 cm^{-1}). After assigning the bands using nine-point second-derivative analysis, the FTIR spectra were deconvoluted and fitted with OPUS software to quantify the individual peaks (Figures 7 and 8). The derivative spectrum of each untreated (or not dried) protein was overlaid on top of the corresponding dried protein. The assignment of each band to the secondary structural features after deconvolution is provided in Table 2. The peaks between

Table 2. Peak Assignments for Secondary Structure of Protein in D_2O of Deconvoluted Spectra in Amide I Region

component	wavenumber (cm^{-1})
β-sheet (low frequency)	1620−1640
random coil	1641−1647

Thirteen bands were required to produce best fitting to α-lac and β-lg's IR spectra (Figure 7). On the other hand, BSA produced only five major bands in both native and dried states in the amides I region (Figure 8). Although the band numbers are similar in both native and dried proteins, they showed differences in magnitude and the location of the bands. Through the band fitting and quantification, it was found that the secondary structures of α-lac and β-lg are dominated by β structure, whereas the secondary structure of BSA is dominated by helix structure (Table 3). The observed composition of secondary structural features of BSA, α-lac, and β-lg is in agreement with earlier studies.[17,27,32] It has been reported that α-lac contains 41.0% β structure and 33.0% helix structure and that β-lg contains 50.0% β structure and 10.0% helix structure.[27] Similarly, BSA contains 24.0% β-sheet and 57.0% helix in its structure.[17,32] Our observations suggest that the secondary structural properties of BSA, α-lac, and β-lg were affected by the convective drying quite differently. The drying process increased the β-sheet and random coil contents in β-lg by 7.5 and 2.0%, respectively. At the same time, the α-helix and β-turn contents decreased by 3.5 and 6.0%, respectively. In the case of α-lac, the drying stress decreased the α-helix content by 5.5% and the β-turn content by 5.0%. These decreased secondary structural contents were compensated by increases in β-sheet by 6.5% and random coil by 4.0%. The β-sheet, helix, and coil contents of BSA were found to increase (up to 2.0, 8.5, and 3.0%, respectively), whereas the β-turn content decreased (up to 13.5%).

In conclusion, the kinetics of major whey proteins revealed that at the end of 600 s of convective drying 13.3 and 19.4% α-lac was found to denature at 65 and 80 °C, respectively, whereas up to 31.0% of β-lg was denatured. No significant ($p > 0.05$) amount of BSA was found to be lost by denaturation under these drying conditions. The secondary structural properties of all the studied proteins were found to be significantly ($p < 0.05$) affected and altered by the drying stresses. In the case of α-lac and β-lg, the β-sheet and random coil contents were found to increase, which were compensated by the decrease in α-helix and β-turn. On the other hand, β-sheet, helix, and coil contents were found to increase in the case of BSA, whereas the β-turn content decreased. A highly wrinkled skin was formed on the surface of BSA, whereas a hollow fragile skin was formed on the surface of α-lac. The whey protein β-lg droplet lost its spherical shape initially but developed a firm outer surface skin afterward. The correlations among denaturation kinetics, drying kinetics, and particle morphology during drying at droplet level reported in this study will be important in producing structurally intact and functionally superior milk protein powders through spray-drying. The fundamental information on the denaturation kinetics of bovine serum albumin, α-lactalbumin, and β-lactoglobulin presented in this study will broaden the application of these proteins as nutritional and functional ingredients, especially in food and pharmaceutical applications.

Effects of Storage Temperature, Storage Duration, and Subsequent Ripening on the Physicochemical Characteristics, Volatile Compounds, and Phytochemicals of Western Red Nectarine (*Prunus persica* L. Batsch)

Christophe Aubert,* Philippe Bony, Guillaume Chalot, Pierre Landry, and Sebastien Lurol

Centre Technique Interprofessionnel des Fruits et Légumes, route de Mollégès, 13210 Saint-Rémy-de-Provence, France

ABSTRACT: Western Red nectarines, harvested at commercial maturity, were stored for up to 20 days at 1, 4, or 8 °C and then transferred to 25 °C for 0 or 4 days. The main physicochemical attributes, phytochemicals, and volatile compounds were then determined. During storage and ripening, firmness, titratable acidity, organic acids, and C_6 volatile compounds decreased, whereas ethylene production, lactones, and C_{13} norisoprenoids greatly increased. Soluble solids content, sugars, and polyphenols remained quite constant during both stages. During storage, vitamin C decreased and carotenoids did not significantly change, whereas both greatly increased during ripening. Increased time of low-temperature storage has been found to decrease lactones and C_{13} norisoprenoids in nectarine and, consequently, to limit its aroma during maturation. Finally, Western Red nectarine was found hardly chilling injury sensitive, and trends for sugars, polyphenols and lactones observed in this study were contrary to those generally reported in the literature for chilling-injured fruit.

KEYWORDS: *Prunus persica, nectarine, volatile compounds, carotenoids, polyphenolic compounds, vitamin C, shelf life, cold storage*

INTRODUCTION

Nowadays, there is a wide consensus that a greater consumption of fruits and vegetables contributes to improved health and well-being by reducing the risk of diseases such as cardiovascular diseases and some forms of cancer.[1,2] The health benefits of fruits and vegetables have been attributed to their specific chemical composition, particularly phytochemicals such as vitamin C, carotenoids, and polyphenolics, which act as antioxidants by scavenging harmful free radicals, which are implicated in most degenerative diseases.[3] On the basis of this evidence, in 2003 the Joint FAO/WHO (Food and Agriculture Organization of the United Nations/World Health Organization) report on diet, nutrition, and the prevention of chronic diseases recommended the intake of a minimum of 400 g of fruits and vegetables per day, ideally 800 g, for the prevention of chronic diseases such as cancer, diabetes, heart diseases, and obesity.

In peaches and nectarines, the major phenolic compounds are catechin, epicatechin, and caffeoylquinic acids, whereas predominant carotenoids are α- and β-carotene, zeaxanthin, and lutein. Chlorogenic acid (5-caffeoylquinic acid) and neochlorogenic acid (3-caffeoylquinic acid) have been found to be chemopreventive against breast cancer, whereas β-carotene has been suggested to have preventive benefits against lung and colorectal cancer.[4−6] Peaches and nectarines are also sources of vitamin C and vitamin A precursors. Because humans are unable to synthesize their own vitamin C, unlike most animals, this compound is considered the most important vitamin in fruits and vegetables for human nutrition, and >90% of the vitamin C in human diets is supplied by fruits and vegetables.[7] Among carotenoids, β-carotene (primarily), α-carotene, and β-cryptoxanthin are vitamin A precursors. Vitamin A is essential for normal growth, reproduction, and resistance to infection. It also plays a role in vision, and a severe deficiency can lead to irreversible blindness.[8]

Although peaches and nectarines are an important source of fibers, vitamins, and other phytochemical compounds with beneficial effects on health, these fruits are mainly appreciated by consumers for their sweetness, juiciness, and characteristic flavor. Aroma is one of the essential factors contributing to peach quality, and peach volatiles have been thoroughly investigated. More than 100 compounds have been identified, and among them, some lactones (mainly γ- and δ-decalactone, γ-dodecalactone, γ-octalactone, and γ-jasmolactone), some C_{13} norisoprenoids (β-damascenone, β-ionone, and 8,9-dehydrothea-spirone), and some C_6 aldehydes ((*Z*)-3-hexenal and (*E*)-2-hexenal) have been reported to be important compounds in peach aroma.[9,10]

Because they soften quickly at room temperature, peaches and nectarines have a short shelf life, and low-temperature storage is the most common current method for delaying ripening after harvest and extending their commercial life. However, several physiological disorders, collectively known as chilling injury (CI), can develop under low temperature during storage and affect fruit quality. These disorders, particularly lack of juiciness and flesh browning, mainly develop during fruit ripening after cold storage and are of commercial importance because the problem is not noticed until the fruit reaches consumers.[11]

Levels of phytochemicals in fruits and vegetables are known to be influenced by numerous pre- and postharvest factors such

as genetic background, maturity, environmental factors, and culture practices, as well as by storage conditions.[7,12,13] Variability of volatiles in peaches and nectarines has likewise been reported to depend on cultivar, maturity, and storage conditions.[14−23] Even though changes in volatiles during low-temperature storage have been the subject of some studies, those on carotenoids, polyphenols, or vitamin C in nectarines are relatively scarce.[24−28]

Despite their importance for the overall quality of nectarine, to our best knowledge, to date no study carried out on the evolution of both volatiles and phytochemicals during storage has been reported in the literature. The aim of this work was to evaluate the effects of different storage conditions (3 temperatures × 5 durations) followed or not by 4 days of ripening at 25 °C on several nectarine quality attributes, such as sugars, organic acids, volatile compounds, carotenoids, polyphenolics, and vitamin C. Firmness, ethylene production, soluble solids content, and titratable acidity have also been determined.

MATERIALS AND METHODS

Chemicals. Chloroform (99.9%), ethyl acetate (99.8%), ethanol (99.8%), 2-octanol (98%), formic acid (96%), KH_2PO_4 (99.5%), H_3PO_4 (33.5−36.5%), tris(2-carboxyethyl)phosphine (TCEP; 98%), $(NH_4)_2SO_4$ (≥99%), and *n*-alkane standards (C_8−C_{40}) were obtained from Sigma-Aldrich (Saint-Quentin-Fallavier, France). Acetonitrile (99.99%), hexane (99.99%), acetone (99.98%), dichloromethane (99.9%), and methanol (99.99%) were all of HPLC gradient grade (Fisher Chemical, Leicestershire, UK). Reference compounds were obtained from Sigma-Aldrich (sucrose, glucose, fructose, citric acid, malic acid, quinic acid, ascorbic acid, (*Z*)-3-hexenyl acetate, (*Z*)-3-hexenal, hexanal, (*E*)-2-hexenal, (*E*)-2-hexenol, benzaldehyde, linalool, 2,4-hexadienal, 6-pentyl-α-pyrone, γ-octalactone, γ-decalactone, γ-jasmolactone, β-carotene, 3-caffeoylquinic acid, 4-caffeoylquinic acid, 5-caffeoylquinic acid, (+)-catechin, procyanidin dimer B2, quercetin-3-*O*-galactoside, quercetin-3-*O*-glucoside, and quercetin-3-*O*-rutinoside), Interchim (Montluçon, France) (hotrienol, γ-hexalactone, γ-heptalactone, δ-octalactone, and δ-decalactone), and Extrasynthese (Lyon, France) (β-cryptoxanthin, cyanidin-3-glucoside, and procyanidin dimer B1). Deionized water (0.050 $\mu S \cdot cm^{-1}$) used in all experiments was obtained from a Purelab Flex system (ELGA Labwater, Antony, France).

Samples. Yellow-fleshed nectarines (*Prunus persica* L. Batsch cv. Western Red) were hand-harvested at commercial ripeness stage on August 24, 2012, from the experimental orchard of the Ctifl of Balandran (Gard, France). Commercial ripeness represented fruit harvested with firmness of about 50 N to withstand handling, transport, and storage conditions. Immediately after harvest, fruits (~350 kg) were transported to the laboratory and healthy fruits were then selected on the basis of skin color, uniformity, and size and randomly placed in trays of 30 fruit. Three batches of ~100 kg (~600 fruit) were then made. Two of them were stored at temperatures outside the "killing temperature zone",[11] respectively at 1 and 8 °C, and the third was stored at 4 °C to induce development of CI symptoms. The fruit were stored at these temperatures for up to 3 weeks (3, 6, 10, 13, and 20 days). After storage, samples were then transferred to 25 °C and analyses were carried out after 0 (SL0) or 4 days (SL4). All measurements were performed on 30 fruits (3 replications of 10 fruits) at harvest and for each combination of factors (5 storage durations × 3 cold storage durations × 2 shelf life durations).

Ethylene Production (EP). Whole nectarines were weighed and placed in 10 L jars (3 jars per treatment containing 10 fruits each) hermetically sealed for 60 min before measurements using a gas chromatograph equipped with a flame ionization detector (FID-GC). Five hundred microliter gas samples were collected from the outlet port of each jar and directly injected into a Varian 3800 gas chromatograph fitted with a CP-PoraPLOT Q-HT column (0.53 mm × 10 m × 20 μm) (Varian). Oven, injector, and FID temperatures were 30, 50, and 250 °C, respectively.

Evaluation of Fruit and Physicochemical Analyses. Flesh firmness was determined on two opposite sides of each fruit after the removal of a 1 mm thick slice of skin using a fruit texture analyzer (FTA GS-15, Güss Ltd.) fitted with an 8 mm diameter plunger tip. The results were expressed in newtons (N). Fruits were then cut into two halves through the suture plane, and flesh browning was immediately evaluated on the mesocarp and the area around the pit. The score of CI was then calculated according to the method of Zhang et al.[19] Fruits were then freed from the stone, cut in small cubes (~1 cm^3), immediately frozen in liquid nitrogen and reduced to powder using a mortar grinder (Pulverisette 2, Fritsch) with liquid nitrogen. The frozen powders were then stored at −80 °C until analysis. About 15 g of frozen tissue (−80 °C) was thawed for ~30 min at room temperature, homogenized in a blender (Waring, USA), and then centrifuged (8500*g*, 5 min, 4 °C). Soluble solids content (SSC) was determined from the supernatant with an Atago PR-32 digital refractometer. The results were expressed in °Brix. Titratable acidity (TA) was determined by diluting 5 mL of supernatant with 30 mL of deionized water and titrating to pH 8.1 with 0.1 N NaOH using a Titroline 7000 automatic titrator with autosampler (SI Analytics). Results were given as grams of malic acid per 100 g of fresh weight (FW).

Determination of Sugars and Organic Acids. The levels of individual sugars (glucose, fructose, sucrose, and sorbitol) and organic acids (malic, citric, and quinic acid) were simultaneously determined by HPLC. One gram of frozen powder added to 20 mL of deionized water was homogenized for 60 s using an Ultra-Turrax (T25, Ika). After centrifugation (14000*g*, 10 min, 4 °C), the supernatant was filtered (RC 0.2 μm Phenex; Phenomenex, Le Pecq, France) and directly injected into HPLC. A Waters Acquity UPLC H-Class liquid chromatograph was used with a photodiode array detector (PDA) and a refractive index (RI) detector connected in series. The PDA was set at 210 nm. The RI temperature was set at 34 °C. Ten microliters of each sample was injected using a sample manager on a 300 mm × 7.8 mm i.d. ion-exclusion Rezex ROA-Organic H+ column equipped with a Carbo-H guard column (Phenomenex). The column oven temperature was set at 27 °C. The flow of mobile phase (0.005 N H_2SO_4) was 0.4 mL/min. Identifications were performed by comparing retention times (t_R) with those of standards and by spiking samples with pure compounds. Quantifications were carried out using calibration curves based on different injected amounts of standards.

Determination of Vitamin C. One gram of frozen powder added to 10 mL of metaphosphoric acid (MPA, 6%) was homogenized for 60 s at 20000 rpm with an Ultra-Turrax (T25, Ika). After centrifugation (10000*g*, 5 min, 4 °C), the supernatant was filtered (RC 0.2 μm Phenex; Phenomenex). Ascorbic acid (AA) was determined by direct injection in HPLC (see conditions below) of 500 μL of extract added to 500 μL of MPA (6%). Total vitamin C was determined by HPLC after 3 h of reduction under agitation at room temperature of 500 μL of extract added to 500 μL of TCEP (10 mM) in MPA (6%).[29] Dehydroascorbic acid (DHA) was then calculated by subtracting AA determined in the absence of reducing agent from total vitamin C content. A Varian ProStar 230 liquid chromatograph was used with a photodiode area detector (Varian PDA detector 330). The PDA was set at 245 nm. Ten microliters of each sample was injected using a Varian 410 autosampler on a 250 mm × 4.6 mm i.d. (5 μm) Supelcosil C18 column (Sigma-Aldrich). The column oven temperature was set at 25 °C. The flow of mobile phase (0.2 M KH_2PO_4; pH adjusted to 3.0 with H_3PO_4) was 1 mL/min. Identifications were performed by comparing retention times (t_R) with those of standards and by spiking samples with pure compounds. Quantifications were carried out using calibration curves based on different injected amounts of standards.

Determination of Carotenoids. Two grams of frozen powder and 40 mL of a mixture of hexane/acetone/ethanol (40:20:40 v/v/v) were homogenized for 30 s at 20000 rpm using an Ultra-Turrax (T25, Ika). After the addition of 6 mL of deionized water, agitation, and centrifugation (10000*g*, 5 min, 4 °C), 10 mL of hexanic extract was concentrated to dryness under vacuum directly into a 2 mL HPLC autosampler vial using an evaporator−concentrator (Rocket, Genevac Ltd.). After the addition of 1 mL of CH_2Cl_2/MeOH (50:50 v/v) and solubilization, the carotenoid extract was directly injected into UPLC.

Separation and characterization of carotenoid compounds were carried out using a Waters Acquity UPLC equipped with a photodiode array detector (detection at 475 nm) and a Phenomenex Kinetex C18 column (100 mm × 2.1 mm i.d., 1.7 μm) protected by a precolumn filter (Phenomenex). The column oven temperature was set at 15 °C. A binary solvent system was used at a 0.5 mL/min flow rate with solvent A (acetonitrile/water; 96:4 v/v) and solvent B (ethyl acetate). The elution gradient was as follows: 0−2.5 min, isocratic 0% B; 2.5−11 min, linear 0−51% B; 11−16 min, isocratic 51% B. The volume of injection was 2 μL. Identifications were performed by comparing retention times (t_R) with those of standards and by spiking samples with pure compounds. Quantifications were carried out using calibration curves based on different injected amounts of standards.

Determination of Polyphenols. Four grams of frozen powder and 20 mL of a mixture of MeOH/H_2O/formic acid (60:38:2 v/v/v) were homogenized for 60 s at 20000 rpm with an Ultra-Turrax (T25, Ika) and centrifuged (10000*g*, 5 min, 4 °C). Ten milliliters of supernatant was concentrated to dryness under vacuum directly into a 2 mL HPLC autosampler vial using an evaporator−concentrator (Rocket, Genevac Ltd.). After the addition of 1 mL of mixture of MeOH/formic acid (95:5 v/v) and solubilization, the polyphenolic extract was directly injected into UPLC and UPLC-MS as described below. Separation and characterization of phenolic compounds were carried out using a Waters Acquity UPLC equipped with a photodiode array detector (detection at 280, 330, and 520 nm) and a Waters Acquity HSS T3 column (100 mm × 2.1 mm i.d., 1.8 μm) protected by a precolumn filter (Waters), in a 45 °C heated oven. A binary solvent system was used at a 0.4 mL/min flow rate with solvent A (water/formic acid; 98.5:1.5 v/v) and solvent B (methanol). The elution gradient was as follows: 0−6 min, linear 1−21% B; 6−14.5 min, linear 21−70% B; 14.5−19 min, isocratic 95%; 19−24 min, isocratic 1% B. The volume of injection was 1 μL. The hydroxycinnamic acids and flavanols were detected at 280 nm, flavonols at 330 nm, and anthocyanins at 530 nm. Compound identification was achieved by comparing the retention times (t_R) and their UV−vis spectra from 200 to 600 nm with those of standards and by spiking samples with pure compounds whenever possible. The identification of the phenolic compounds was also achieved through the coupling of a Waters Acquity UPLC with an ion trap mass spectrometer Bruker Daltonics HCT ultra equipped with an electrospray ionization source. Chromatographic conditions were the same as above. A capillary voltage of 2 kV was used in the negative and positive ion modes for polyphenol and anthocyanin characterization, respectively. Nitrogen was used as drying and nebulizing gas with a flow rate of 9 L/min. The desolvation temperature was set at 365 °C and the nebulization pressure at 40 psi. The ion trap was operated in the Ultrascan mode from m/z 150 to 1200. The volume of injection was 1 μL. Quantification was achieved according to the concentrations of a corresponding external standard. For the compounds lacking reference compounds, related compounds were used as standards for the quantification. Therefore, *p*-coumaroylquinic acid and caffeoylquinic acid derivative were quantified in equivalents of 5-caffeoylquinic acid. Levels of phenolic compounds were expressed as milligrams per 100 g of FW.

Isolation of Volatiles. Samples were analyzed according to the liquid−liquid microextraction (LLME) method previously described[30] with some modifications. Briefly ∼20 g of frozen powder, 20 mL of $(NH_4)_2SO_4$ saturated solution, and 20 μL of 2-octanol (411.6 μg/mL) (internal standard) were homogenized at 20000 rpm with an Ultra-Turrax (T25, Ika) and centrifuged (13000*g*, 5 min, 4 °C). The supernatant was then transferred into a 50 mL screw-capped conical centrifuge tube (34 × 98 mm glass borosilicate) containing a magnetic stir bar (15 × 6 mm). Two hundred microliters of $CHCl_3$ was added, and the mixture was extracted for 60 min under magnetic stirring at room temperature. After removal of the magnetic stir bar, the tube was sonicated for 1 min in a Branson Ultrasonic Cleaner 5510 and centrifuged (1000*g*, 5 min, 4 °C). Chloroform extract was then recovered with a 50 μL syringe, transferred to a 100 μL vial, and immediately injected into GC-MS and GC-FID. Separation of volatile compounds was carried out using a Varian 3800 gas chromatograph equipped with an Rtx-Wax (Restek) capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness). The flow of hydrogen 5.7 carrier gas was 1 mL/min. The oven temperature was kept at 40 °C for 3 min, then programmed to 250 °C at 5 °C/min, and kept at 250 °C for 15 min. Injections (1 μL) were performed at 220 °C in splitless mode (1.5 min) using a CombiPAL autosampler equipped with a Peltier cooling rack at 4 °C (CTC Analytics). The FID was kept at 250 °C. The levels of the volatile compounds were expressed as 2-octanol equivalent (assuming all of the response factors were 1). The concentrations are to be considered as relative data because recovery after extraction and calibration factors related to the standard were not determined. Identification of volatiles was achieved using GC-MS. A PerkinElmer Clarus 680 gas chromatograph was used with the same capillary column as above. Injections (1 μL) were performed at 220 °C in splitless mode (1.5 min) using a 108-vial integrated liquid autosampler (PerkinElmer). The oven temperature program was as above. A PerkinElmer Clarus SQ8C mass spectrometer was used. Mass spectra were acquired over the 30−350 amu range at 1 scan/s, with an ionizing electron energy of 70 eV and ion source at 220 °C. The transfer line temperature was set at 250 °C, and the flow of helium 6.0 carrier gas was 1 mL/min. Compounds were first identified using NIST/EPA/NIH MS Search 2.0 and our own mass spectra libraries. Identities of most of them were then confirmed by comparison of their linear retention indices and EI mass spectra with those of reference compounds.

Statistical Analysis. Analyses of variance and principal component analysis (PCA) were performed using Statbox 7.2.2 (FBC Software).

RESULTS AND DISCUSSION

The effects of different cold storage conditions and subsequent shelf life on the physicochemical attributes and the levels of the main phytochemicals and volatile compounds of a yellow-fleshed nectarine were investigated in this study. The fruits, harvested at commercial ripeness stage, were stored for up to 3 weeks in cold chambers at 1, 4, or 8 °C and then subjected to a postharvest ripening at 25 °C and 80−90% relative humidity in a ripening chamber for 0 (SL0) or 4 days (SL4). Fruit evaluation, firmness, SSC, TA, EP, and the levels of the main sugars (sucrose, glucose, fructose, and sorbitol) and organic acids (malic, citric, and quinic acid) have been determined. A total of 25 volatile compounds including 4 C_6-compounds, 9 lactones, 6 C_{13} norisoprenoids, 3 terpenols, 2 carbonyl compounds, and 1 ester were extracted using LLME and analyzed by GC-FID and GC-MS. Among phytochemicals, both forms of vitamin C (ascorbic and dehydroascorbic acid), 2 carotenoids (β-carotene and β-cryptoxanthin), and 12 polyphenolic compounds, including 5 hydroxycinnamic acids, 1 anthocyanin, 3 flavan-3-ols, and 3 flavonols, have been determined by HPLC, UPLC, and UPLC-MS.

A PCA was performed to graphically summarize the distribution of the 50 variables (11 physicochemical attributes, 39 volatiles and phytochemicals) within the different samples of nectarines (31 samples) (Figure 1). As shown in Figure 1A, 57% of the total variance was explained by the first two axes. The first axis (PC1), with 41% of the variance explained, mainly discriminates SL0 from SL4 samples, whereas the second axis (PC2), with 16% of the variance explained, mainly discriminates samples according to the duration of storage. The distribution of the variables is shown in Figure 1B, and most of them are well correlated on the first two axes (60% of the variables showed a squared factor loading >0.50). As shown, SL4 samples positively located on PC1 are particularly characterized by high levels of lactones and C_{13} norisoprenoids. With an average squared factor loading of ∼0.92, the nine lactones were highly positively correlated on PC1, particularly 7-decen-5-olide (L8; 0.943), γ-octalactone (L3; 0.937), γ-heptalactone (L2; 0.935), hexalactone (L1; 0.934), δ-octalactone (L4; 0.928), and γ-decalactone

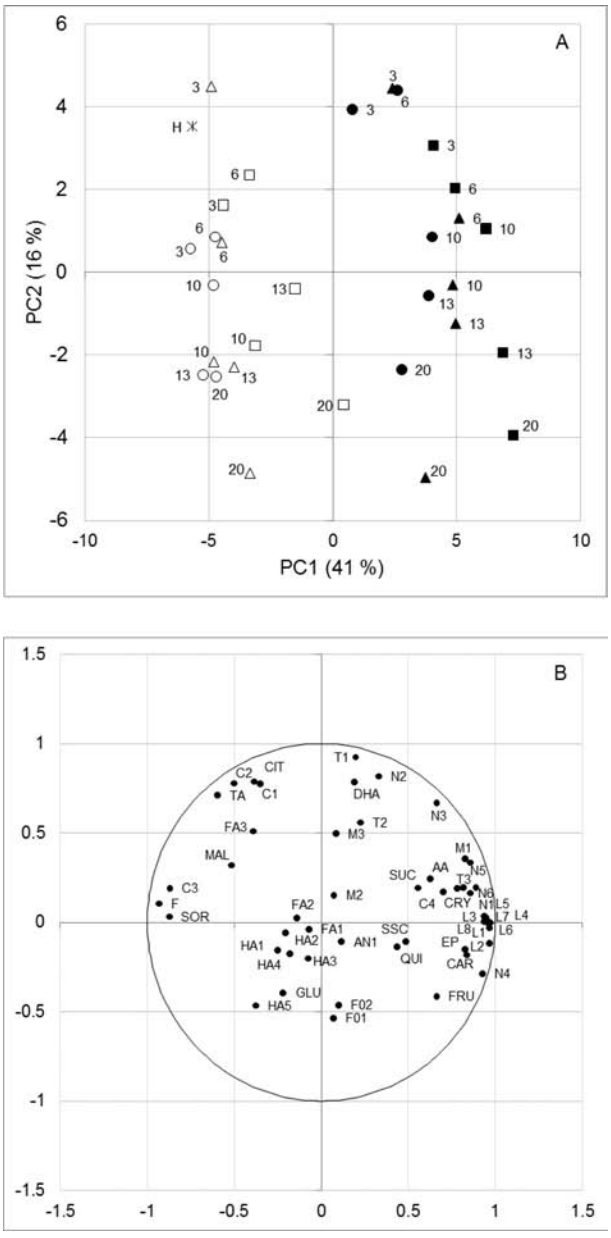

Figure 1. Results from PCA: (A) projection of the samples at harvest (H) and during storage at 1 °C (○, ●), 4 °C (△, ▲), or 8 °C (□, ■) (numbers represent days of cold storage, after 0 days at 25 °C (open symbols) or 4 days at 25 °C (solid symbols); (B) factor loadings of variables (EP, ethylene production; F, firmness; SSC, soluble solids; TA, titratable acidity; for other codes see Tables 1−4).

(L5; 0.902). Most of the C_{13} norisoprenoids were also highly correlated on PC1, in particular, 3-hydroxy-β-ionone (N4, 0.859), dehydrovomifoliol (N6; 0.791), 8,9-dehydrotheaspirone (N1, 0.733), and 3-hydroxy-5,6-epoxy-β-ionone (N5; 0.686). Among other variables, (*Z*)-3-hexenyl acetate (M1; 0.733), β-carotene (CAR; 0.701), EP (0.682), 3,7-dimethyl-1,5-octadien-3,7-diol (T3; 0.665), and β-cryptoxanthin (CRY; 0.608) were also well positively correlated on PC1. SL0 samples, negatively located on the first axis, are mainly defined by high levels of firmness (F; 0.868), sorbitol (SOR, 0.764), and (*E*)-2-hexenal (C3, 0.756). Samples at harvest and those stored for 3 or 6 days, positively located on PC2, are mainly discriminated from those stored for 20 days by higher levels of linalool (T1; 0.856), 3-hydroxy-7,8-dihydro-β-ionone (N2; 0.669), citric acid (CIT; 0.622), dehydroascorbic acid (DHA; 0.616), (*Z*)-3-hexenal (C2; 0.606), hexanal (C1; 0.602), and TA (0.506).

Fruit Evaluation, Firmness, Ethylene Production, Soluble Solids Content, Titratable Acidity, Sugars, and Organic Acids. Up to 13 days of storage, whatever the temperature, no flesh browning was detected in our samples at both SL0 and SL4. For longer storage, a slight internal browning appeared in a limited number of fruits after ripening. After 20 days of storage and 4 days at 25 °C, the CI scores for the samples stored at 1, 4, or 8 °C were between 4 and 6% and were found very low in comparison to those generally reported in the literature for CI-sensitive peaches.[19,20,27,28] In a previous work, Red Diamond nectarine and May Diamond nectarine, respectively the seed parent and the pollen parent of Western Red nectarine (U.S. Plant Patent 8,196), have been found to not develop any symptoms of CI after 5 weeks of storage at 0 or 5 °C.[31] The effects of storage and/or postharvest ripening on the main physicochemical attributes and the levels of predominant sugars and organic acids of Western Red nectarines are given in Table 1 and Figure 2. As shown, the variations of firmness and EP are the most important changes observed in response to the different treatments. Globally, the effects are characterized by opposite changes in these two parameters. With increasing storage time and temperature, flesh firmness decreased while EP increased at the same time. For up to 2 weeks, firmness was generally maintained at 1 and 4 °C, whereas it decreased drastically after 10 days of storage at 8 °C. These results indicate that as the fruit softened there was a typical ethylene climacteric rise, which is in agreement with previous works.[19,20] The rate of softening of nectarines during cold storage was found to be very similar for lower temperatures (Figure 2). For storage at 1 and 4 °C, the average decrease of firmness was about ∼0.3 N per day over the 3 weeks, whereas it was 6 times higher (∼1.8 N per day) during storage at 8 °C. After 13 and 20 days of storage at this temperature, the loss of firmness was respectively about 45 and 70%, and, according to Crisosto,[32] the corresponding nectarines are to be considered respectively as "ready to buy" (26.6 N) and "ready to eat" (13.5 N). The firmness of fruit after cold storage followed by 4 days at 25 °C ranged from 2.7 to 11.9 N and, as expected, overall firmness decreased with days at 25 °C. The rate of softening of nectarines during postharvest ripening at 25 °C was found to be very similar for fruits cold-stored at 1 or 4 °C. The results also indicated that the longer the samples are prestored at 1 or 4 °C, the greater the decrease of firmness during the phase of ripening at 25 °C (up to ∼11 N per day for 20 days of storage).

As presented in Figure 2, EP increased as the fruit softened, particularly during storage at 8 °C or postharvest ripening at 25 °C. No significant difference was observed for EP in the nectarines maintained at 1 or 4 °C for up to 3 weeks of storage, whereas it markedly increased in fruits stored at 8 °C even after only 3 days of storage. For 13 and 20 days of storage, the levels of EP were 50−65-fold higher in fruits stored at 8 °C than in fruits stored at lower temperatures. After 4 days at 25 °C, levels of EP significantly increased whatever the temperature of prestorage. Levels of EP were significantly higher in fruits prestored at 8 °C than in those maintained at 1 or 4 °C, but in comparison the increases were markedly more important for prestored fruits at these latter temperatures.

SSC ranged from 11.5 to 13.4 °Brix with a mean of 12.3 °Brix, which is greater than the minimum (8 °Brix) established by the European Union to market peaches and nectarines (R-CE no. 1861/2004), although most previous findings

[a]Means within the same days of cold storage + days at 25 °C followed by different capital letters are significantly different (SNK test, $p < 0.05$). [b]Means within the same temperature of cold storage followed by different small letters are significantly different (SNK test, $p < 0.05$).

considered that a mean value of SSC over 10 °Brix is the minimum value for consumer acceptance.[33] No significant change was observed for SSC during storage and/or postharvest ripening at 25 °C, and the levels in samples were found to be overall similar to those observed at harvest (Figure 2). These results are consistent with those observed by Robertson et al.[17] and Cano-Salazar et al.[21−23] Sucrose was found as the major soluble sugar, ranging from 49 to 59% of the total sugar content, followed by reducing sugars, fructose (16−22%) and glucose (15−19%), and sorbitol (6−14%). As shown in Table 1, the level of total sugar contents was not affected by storage and shelf life. Some significant differences have been observed for the levels of sucrose and reducing sugars during storage and/or shelf life, but on average their levels have been found to be very similar to those observed at harvest (Table 1). In contrast, although the levels of sorbitol did not change significantly during storage, a significant decrease of about 30−50% was observed during shelf life at 25 °C. Sorbitol, a polyalcohol sugar, has been previously reported to play an important role in the texture and flavor of peach and nectarine fruits and also in terms of nutrition for special dietary purposes, such as diet control and dental health.[34] Because the levels of CI were very low in our samples, our results differ from those recently reported by Wang et al.,[28] who observed, after 28 days of storage at 5 °C, significant changes in the levels of sucrose and reducing sugars in peaches exhibiting severe internal browning symptoms. As previously mentioned,[28] our results support that probably close relationships between soluble carbohydrate metabolism and CI exist in peaches exposed to cold stresses.

The levels of TA ranged from 0.51 to 0.76 g malic acid/100 g. These levels have been found to be lower than the maximum limit (0.9%) generally admitted between peaches with low and high levels of acidity.[33] The average level of TA found in ripened Western Red nectarine (SL4) was about 0.64 g malic acid/100 g and was consistent with most of those previously reported in the literature for other yellow-flesh nectarines.[21−23,33−35] The main organic acids detected in Western Red nectarines were citric and malic acid, which each represent about 40% of the total organic acids, and quinic acid. The results were consistent with those previously reported,[34] but shikimic acid was not detected in our sample. As shown in Figure 2 and Table 1, TA, total organic acids, and malic and citric acid significantly decreased during storage and shelf life at 25 °C, whereas levels of quinic acid were not affected by postharvest treatments and were found similar to those observed at harvest. As previously observed for Californian and Chilean yellow flesh peaches,[33] approximately 30% of the harvest titratable acidity (HTA) in mature fruit has been lost during ripening. These results also agree with those previously reported by Robertson et al.[16] and Cano-Salazar et al.[21−23]

Phytochemical Compounds. Total vitamin C content ranged from 2.9 to 6.5 mg/100 g and ascorbic acid (AA) was predominant (81−90%). The average level of vitamin C in ripened samples (SL4) was about 5.6 mg/100 g. Similar levels have been previously found in different cultivars of yellow-fleshed nectarines from California.[35] As indicated in Table 2, regardless of the temperature, the levels of AA, and consequently those of vitamin C, decreased significantly with days of storage, but losses were significantly more important at 1 or 4 °C. For 20 days of storage, the levels of vitamin C observed in nectarines stored at 8 °C were about 18% lower than those observed at harvest, but the levels were, respectively, 46 and 40% lower for samples prestored at 1 or 4 °C. These results are consistent with those previously reported by Dalla Valle et al.,[24] who observed a

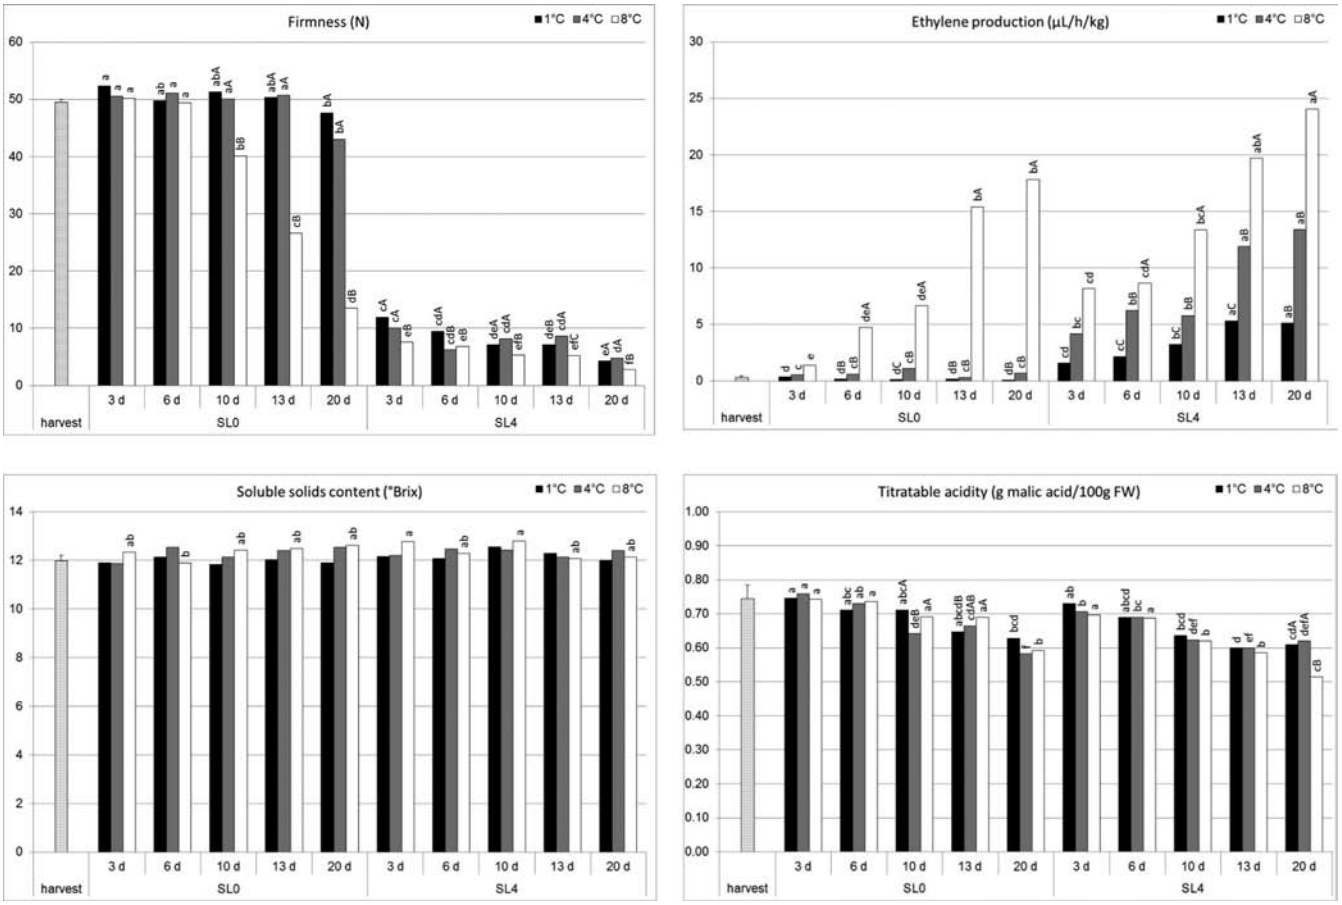

Figure 2. Physicochemical attributes in nectarine samples at harvest and after 3, 6, 10, 13, or 20 days of cold storage followed by 0 (SL0) or 4 (SL4) days at 25 °C. Similar vertical bars followed by different small letters are significantly different (SNK test, $p < 0.05$). Vertical bars within the same days of storage + days at 25 °C followed by different capital letters are significantly different (SNK test, $p < 0.05$).

significant decrease in the levels of vitamin C in three different peach cultivars stored for up to a week at 4 °C after harvest. Recently, significant lower levels of AA in peaches stored at 0 °C have been also reported in comparison to the levels observed in fruits stored at 5 °C.[27] These results also confirm that although low-temperature storage is the most important tool to extend shelf life and maintain fruit quality, freshly harvested fruits contain more vitamin C than those held in cold storage.[7] Our results also indicated that levels of AA increased significantly during postharvest ripening. After 4 days at 25 °C, vitamin C levels in the nectarines were on average 22% higher than those observed in the corresponding samples before ripening. After 20 days of storage, these values were 80 and 60% higher for samples prestored at 1 or 4 °C, respectively. Peaches and nectarines are climacteric fruit and therefore may ripen either on- or off-tree. Although it is generally admitted that maturity is one of the major factors determining the compositional quality of fruit, and consequently influences the content of AA in fruit, its accumulation during ripening depends on the type of fruit. Our results are in agreement with Lee and Kader,[7] who previously reported that AA content decreased with ripening in apple and mango, but increased in papaya, apricot, and peach. They also reported that fruit accumulated AA during ripening on or off the plant, even if the increase was much greater in the fruit left on the plant. Our results also confirm that, sometimes, fruits stored at room temperature after cold storage may improve their nutritional attributes such as vitamin C content. Similar results have been observed in kiwifruit maintained for a week at 25 °C after a cold storage during 2−6 months at 0 °C.[36] Toor and Savage[37] also observed a slight accumulation of AA in tomatoes stored at 7, 15, or 25 °C for up to 10 days.

As indicated in Table 2, total carotenoid content ranged from 126 to 197 μg/100 g; β-carotene was predominant and accounted for 95−97% of the total carotenoid content in our samples. These levels are consistent with those previously observed in different cultivars of yellow-fleshed nectarines from California.[35] No significant change was observed for carotenoid content during cold storage, but in contrast they increased significantly during the postharvest ripening at 25 °C, with a more pronounced effect for samples prestored at 4 or 8 °C. On average, the levels of carotenoids in samples after 4 days at 25 °C were 13, 21, and 32% higher than those observed at harvest in the nectarines prestored at 1, 4, and 8 °C, respectively. The changes in carotenoid levels during cold storage have not been studied much, but similar results have been observed in two cultivars of yellow nectarines,[25] in carrots,[38] or in mangoes.[39] With regard to evolution of carotenoids during shelf life, increases of β-carotene and β-cryptoxanthin in peaches held in air at 20 °C for 8 days after harvest were already observed by Caprioli et al.[26] Similar results have also been described previously for kiwifruit stored for 2 months at 0 °C and maintained for 7 days at 25 °C.[36]

As shown in Table 3, total polyphenol content ranged from 8.6 to 10.4 mg/100 g. Hydroxycinnamic acids, accounting for

75−82% of the total polyphenol content, were found to be predominant, followed by anthocyanins (8−16%), flavanols (4−7%), and flavonols (4−5%). Among hydroxycinnamic acids, 5- and 3-caffeoylquinic acids, and cyanidin-3-glucoside (anthocyanin) accounted, respectively, for 42−47, 29−34, and 8−15% of the total polyphenol content. In all samples, the amount of chlorogenic acid was larger than that of neochlorogenic acid. These results are consistent with those previously reported by Tomás-Barberán et al.[40] and confirm that this compound is the main hydroxycinnamate of peaches. Cryptochlorogenic (4-caffeoylquinic) acid was also detected in our samples. Catechin was found as the main monomeric flavanol as previously mentioned. Procyanidins B1 and B2 have also been detected in our samples, but not epicatechin, gallocatechin, and epigallocatechin. Among flavonols, quercetin 3-glucoside, 3-galactoside, and 3-rutinoside have been quantified in our samples but no kaempferol derivatives have been detected. As previously mentioned,[40] cyanidin 3-glucoside was found as the main anthocyanin pigment, but anthocyanin 3-rutinoside was not found in our extracts. As shown in Table 3, although some individual polyphenol results were statistically different between samples, the changes observed during storage and/or postharvest ripening were relatively weak and the levels in samples were found to be overall similar to those observed at harvest. These results are consistent with those previously reported by Asami et al.[41] in peaches stored during 2 weeks at 4 °C, but differ from those reported by Tsantili et al.,[27] who reported significant changes in total phenolic and flavonoid concentrations in peaches stored at 5 °C for 2 or 4 weeks. Because this latter work supports a possible role of polyphenols in cell wall metabolism in chilling-injured peaches, it is not surprising, given the CI scores observed in our samples, that no significant change was found for these compounds.

Volatile Compounds. As indicated in Table 4, the effects of storage and/or postharvest ripening on Western Red volatiles are mainly characterized by opposite changes in two major groups of volatiles, the first group consisting of C_6 compounds and the second of lactones and C_{13} norisoprenoids. Except for 20 days of storage at 8 °C, C_6 compounds, aldehydes, and alcohols, products of enzymatic breakdown of unsaturated fatty acids, are the main compounds isolated in unripened nectarines (SL0), from 44% in samples stored for 13 days at 8 °C to 86% in nectarines at harvest (Figure 3). During storage and/or postharvest ripening, the relative proportions of these so-called green components, in particular those of (*Z*)-3-hexenal and (*E*)-2-hexenal (Table 4), decreased drastically by up to ∼8% in samples stored for 20 days at 8 °C with 4 days of ripening at 25 °C. These results agree with those previously reported in peaches by Zhang et al.[19] With decreasing concentrations of C_6 compounds during storage and/or ripening, lactones and C_{13} norisoprenoids increase during the same time and become the major volatiles in "ready to eat" nectarines. Whereas the levels of lactones and C_{13} norisoprenoids in the samples stored at 1 or 4 °C have been found to be very similar to those observed at harvest, they significantly increased during storage at 8 °C and after ripening, with a much more marked effect during this latter stage (Table 4). After 4 days of ripening at 25 °C, the relative proportions of lactones and C_{13} norisoprenoids were, respectively, 76 and 13% in samples prestored for 20 days at 8 °C (Figure 3). Among lactones, γ-hexalactone, γ- and δ-octalactone, γ- and δ-hexalactone, γ-jasmolactone, 6-pentyl-α-pyrone, and (*Z*)-7-decen-5-olide, previously reported to be major contributors to peach aroma,[9,10] are the ones that mainly increased during postharvest ripening, reaching their highest amounts in samples stored for 13 or 20 days at 8 °C followed by 4 days at 25 °C. These results are consistent with those previously reported by Raffo et al.[18] and confirm that increasing times of low-temperature storage (2−3 weeks, 1−4 °C) significantly reduce the fruit's ability to perform lactone accumulation and, consequently, to develop its aroma after being exposed to ripening temperature. These results also indicated that storage at a moderate temperature (8 °C) does not decrease the fruit's ability to ripen normally when they are removed from storage and exposed to a ripening temperature. Previous works reported significantly lower levels of volatiles, especially lactones, in chilling-injured peaches during the shelf life period after transfer from low temperature.[19,20] Our results indicate that in lack of CI, or at least in the case of very low levels of development, the levels of lactones do not drastically decrease during shelf life. As recently proposed by Xi et al.,[20] these results support that loss of fruity aromas in peaches and nectarines during cold storage is a symptom of CI. In agreement with the results previously reported by Engel et al.,[14] γ-hexalactone was already present at high levels in fruits at harvest and increased steadily during maturation, whereas γ- and δ-decalactone, present at very low levels in unripened fruit, mainly increased during the last stages of ripening (SL4).

A similar trend was observed for C_{13} norisoprenoids, and particularly for 8,9-dehydrotheaspirone, 3-hydroxy-β-ionone, 3-hydroxy-5,6-epoxy-β-ionone, and dehydrovomifoliol. These compounds, generally considered to be derived from carotenoids by oxidative degradations, are important aroma constituents, and most of those reported in this study have been previously identified in numerous natural products.[42] Oxygenated carotenoids, neoxanthin (an allenic xanthophyll), violaxanthin (an epoxy xanthophyll), and lutein (a nonepoxy xanthophyll) have been previously identified in nectarines,[43] and partial characterization of carotenoid cleavage enzymes in nectarine[44] has been shown. The occurrence of free and glycosidically bound C_{13} norisoprenoid compounds has been previously described in peaches and nectarines.[9,14,16,45−47] Several authors have pointed out the importance of these compounds for the aroma of peaches and nectarines. 8,9-Dehydrotheaspirone has been previously reported as a major constituent in white-fleshed nectarines. The importance of this spirocyclic C_{13} ether, and those of β-ionone and β-damascenone for the specific flavor of these cultivars, has been clearly demonstrated by Takeoka et al.[48] and Knapp et al.[49] Except in the research done by Raffo et al.[18] on peach, to our best knowledge no data about the impact of low-temperature storage and/or postharvest ripening on the levels of C_{13} norisoprenoids in nectarines have been reported. As shown in Table 4, no significant change was observed for C_{13} norisoprenoids content during cold storage, but in contrast they increased significantly during the postharvest ripening at 25 °C, with a more pronounced effect for samples prestored at 4 or 8 °C.

Regardless of temperature, the levels of linalool significantly decreased with increasing duration of storage, whereas they increased when fruit were transferred to 25 °C. After 13 days of storage at 1 or 4 °C, the concentrations of linalool were under the limits of detection, and only very low levels of this compound were detected after ripening at 25 °C. These results were in agreement with those previously reported in peaches.[17,18] Lastly, with the exception of the increase of (*Z*)-3-hexenyl acetate when fruits were transferred to 25 °C, the changes of other compounds during storage and/or ripening

Table 4. Levels[a] of Volatile Compounds in Nectarine Samples at Harvest and after 3, 6, 10, 13, or 20 Days of Cold Storage followed by 0 (SL0) or 4 (SL4) Days at 25 °C

[a]Values expressed in μg/kg equivalent of 2-octanol. [b]Linear retention index calculated using a series of *n*-hydrocarbons. [c]A, identities confirmed by comparing mass spectra and retention time with those of authentic standards; B, identities tentatively assigned by comparing mass spectra with those obtained from the literature numbered and italicized within parentheses. [d]Means within the same temperature of cold storage followed by different small letters are significantly different (SNK test, $p < 0.05$). [e]Means within the same days of cold storage + days at 25 °C followed by different capital letters are significantly different (SNK test, $p < 0.05$). [f]Not detected.

dx.doi.org/10.1021/jf405755s | J. Agric. Food Chem. 2014, 62, 4707−4724

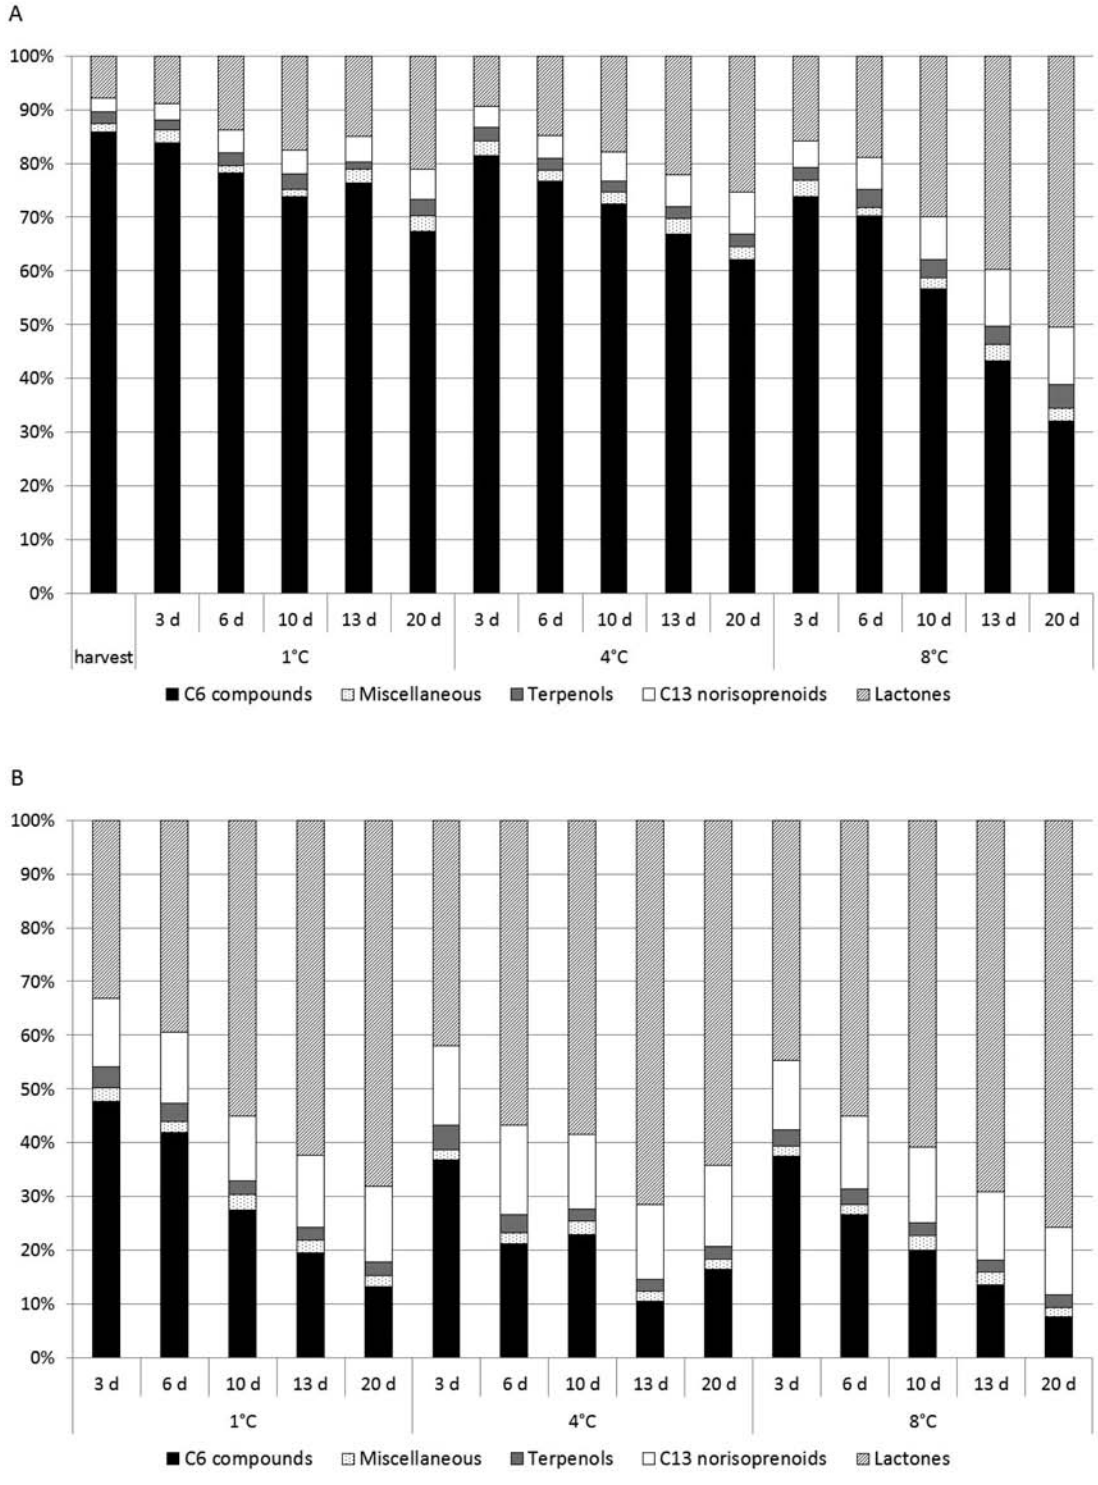

Figure 3. Relative proportions (percent) of the main classes of volatile compounds in nectarine samples at harvest and after 3, 6, 10, 13, or 20 days of cold storage followed by 0 (A) or 4 (B) days at 25 °C.

have been found to be erratic, and no univocal trends have been observed.

In this study, great numbers of data have been obtained under different storage conditions of Western Red nectarine and/or subsequent ripening. The results showed that the most significant changes, those being significant decreases of firmness, TA, organic acids, and C_6 volatile compounds and a significant increase of EP, lactones, and C_{13} norisoprenoids, took place during storage and postharvest maturation, whereas SSC, sugars, and polyphenolic compounds remained quite constant during the same time. This study also clearly indicates that in the case of a very low level of CI development, the trends observed for the levels of sucrose, reducing sugars, polyphenols, and lactones are different from those generally observed in chilling-injured nectarines. As previously mentioned by other studies, the present results tend to confirm that there are close relationships between soluble carbohydrate metabolism and CI in peach fruit exposed to cold stresses.

dx.doi.org/10.1021/jf4057555 | J. Agric. Food Chem. 2014, 62, 4707−4724

They also support a possible role of phenolics in cell wall metabolism in chilling-injured peaches. Lastly, they confirm that the decrease of lactones and the loss of fruity aromas generally observed during shelf life after removal from cold storage are symptoms of CI in peach fruit.

Toward an Understanding of Mechanisms Involved in Non-Polyphenol Oxidase (Non-PPO) Darkening in Yellow Alkaline Noodles (YAN)

Robert E. Asenstorfer,*[,†] Marie J. Appelbee,[‡,§] Christine A. Kusznir,[†] and Daryl J. Mares[†]

ABSTRACT: Asian noodles prepared from bread wheat flour darken over time due to a combination of polyphenol oxidase (PPO) activity and non-PPO effects. Although the enzymatic mechanism associated with the PPO reaction is well established, the non-PPO component consists of both physical (e.g., changes in surface properties) and chemical reactions. Variations in pH and solvents were used to gain a quantitative estimate of the contribution of physical and chemical components to non-PPO darkening in yellow alkaline noodles (YAN). In a set of five common high-PPO Australian wheat cultivars it was estimated that on average non-PPO darkening accounted for 69% of total darkening, with approximately two-thirds of this due to physical darkening and one-third had a chemical origin. Data from the chemical portion of non-PPO darkening is consistent with the presence of a PPO-like enzyme that oxidizes tyrosine, has a pH maximum of 8.1, and is inhibited by 50% methanol or ethanol but in the noodle is insensitive to PPO inhibitors such as tropolone. Therefore, with low-PPO and PPO-free wheat varieties becoming available, it may be possible to further reduce darkening in YAN by breeding for wheat varieties with low or zero levels of this PPO-like enzyme.

KEYWORDS: *yellow alkaline noodle (YAN), polyphenol oxidase (PPO), non-PPO darkening*

INTRODUCTION

Yellow alkaline noodles (YAN) are made from bread wheat (*Triticum aestivum* L.) flour treated with alkaline salts. A bright yellow color free from dark specks is highly desirable. YAN are usually sold as a fresh product, although they can be parboiled and refrigerated to extend storage time. Fresh YAN darken over time, which decreases their marketability. Polyphenol oxidase (PPO), which is inhibited by tropolone and salicylhydroxamic acid, causes about one-third to half of the darkening.[1] It is, however, possible to reduce PPO darkening by the selection of wheat varieties with low or zero PPO activity.[2,3] The remaining darkening is non-PPO darkening and results from both physical and chemical factors.[1] The physical component of non-PPO darkening involves changes in the noodle matrix, which alter the reflectance properties of the noodle surface, whereas the chemical component of non-PPO darkening is thought to arise from oxidation of tyrosine to yield black pigments.[4]

In previous studies, non-PPO darkening as measured by a change in the CIE-*Lab L** value was described using two time periods, 0−4 and 4−24 h.[1,4] Non-PPO darkening during the first time period was correlated with protein content[1] and was related to physical changes in the noodle.[1] Non-PPO darkening in the second time period (4−24 h) was independent of total protein content and was thought to be predominantly due to chemical oxidation rather than physical changes in the noodle. Oxidation of tyrosine groups within the glutenin and gliadin proteins with subsequent polymerization provides a possible mechanism for darkening during the 4−24 h time period.[1] Possible evidence for this was the addition of *n*-propanol extracts (containing predominantly gliadin and traces of unpolymerized glutenin), tyrosine, or the peptide GQQGYYPTS (an analogue of the consensus motifs GYYPTS(L/G)QQ) to YAN increased darkening during the 4−24 h time period.[1] Because a lack of specific inhibitors for non-PPO darkening,[5] it has been difficult to determine the contribution of the chemical component to total non-PPO darkening in YAN. The aim of this paper is to gain an estimate of the proportion of physical and chemical components of non-PPO darkening and to examine the origin of the chemical portion of non-PPO darkening.

MATERIALS AND METHODS

Materials. A hard white bread wheat with high-PPO activity (*Triticum aestivum* L. cv. Tasman) and a durum wheat with a near-zero PPO activity (*Triticum durum* Desf. cv. Kamilaroi) were selected. Grains of both cultivars were produced in field trials at the Waite Campus of the University of Adelaide.[1,4] Four hard white high-PPO bread wheat cultivars (Lark, Sunvale, Janz, and Yitpi) and a hard white low-PPO bread wheat (Axe) produced in field trials at the Waite Campus of the University of Adelaide were also examined for chemical and physical components of non-PPO darkening. PPO activities for the cultivars as determined according to the method of Bernier and Howes[2,6,7] were measured as an increase in absorbance of a tyrosine solution at 415 nm after 3 h: Tasman, 0.27 ± 0.05; Kamilaroi, 0.02 ± 0.01; Lark, 0.15 ± 0.02; Sunvale, 0.20 ± 0.01; Janz, 0.15 ± 0.09; Yitpi, 0.15 ± 0.02; Axe, 0.06 ± 0.01. Absorbance for Kamilaroi was not significantly different from control (solution with no grains), and indeed there was no visible change in color of the incubation solution or the grain coat.

Flour Milling and Noodle Sheet Preparation. Grain was conditioned overnight to 15% moisture and milled on a Bühler experimental mill (Bühler AG, Uzwil, Switzerland). The break and reduction flour streams were combined. The pollard stream was resieved on a shaker, and the recovered flour was added to the combined streams from the mill. Different batches of grain gave slightly different color responses, and therefore the same batch was used for each experiment and, when possible, for the different experiments. Flour (10 g) and 3.6 mL of 2% sodium carbonate solution, with or without the PPO inhibitor tropolone (0.01 mol L^{-1}), were mixed into a dough in a cylindrical mixing bowl using a drill press with a modified mixing paddle. The dough was mixed for 105 s with intermittent pauses to clean dough adhering to the paddle. The dough was rolled into a ball and made into a noodle sheet using a domestic pasta maker (Atlas 150, Marcato S.P.A., Campodarego, Italy). The noodle sheet was then placed in a resealable plastic bag to prevent drying and to make noodle handling easier. Processing and storage were at room temperature (22 °C).

Darkening Rates. CIE-*Lab* color measurements of raw noodles were made using a Dataflash 100 (Datacolor International, Lawrenceville, NJ, USA) reflectance spectrophotometer. Each data point represents the average of two noodle sheets, each of which was measured twice. The rates of darkening for the two time periods were determined from the L^* value of the noodle sheets measured at 2, 5, 10, 15, 20, 30, 40, 50, 60, 90, 120, 150, 180, 210, 240, and 1440 min. Mixed-order rate equations ($\Delta L^* = kt^n + c$, where ΔL^* is the change in darkening between time 2 min and time t of darkening, k is the rate, t is time in h, and n and c are constants) were fitted to the noodle darkening and standard errors estimated using WinCurveFit.[8]

pH Analysis. Noodles from near-zero-PPO Kamilaroi flour were made in a series of buffers: 2% HCl, 0.2 mol L^{-1} sodium citrate (pH 4.0, 5.0, 6.0); 0.2 mol L^{-1} Tris (pH 7.0, 8.0, 9.0, 10.0); 0.2 mol L^{-1} $NaCO_3$; 1% NaOH; 1.5% NaOH; 2% NaOH. The L^* values were measured at 0, 2, 4, and 24 h. Noodles (1 g) were extracted in 2 mL of water and centrifuged, and the pH was measured. A curve[9]

$$\Delta L^* = \frac{a + b10^{(\mathrm{pH}-\mathrm{p}K_{a1})} + c10^{(2\mathrm{pH}-\mathrm{p}K_{a1}-\mathrm{p}K_{a1})}}{1 + 10^{(\mathrm{pH}-\mathrm{p}K_{a1})} + 10^{(\mathrm{pH}-\mathrm{p}K_{a1}-\mathrm{p}K_{a2})}}$$

where a represents the ΔL^* plateau at low pH, b is the theoretical maximum ΔL^* value, and c represents the plateau at high pH, was fitted to the change in darkening (ΔL^*) using WinCurveFit,[8] which allowed estimation of pK_a (acid dissociation constant) values and maximum and minimum ΔL^* values.

Incorporation of Solvents into Noodle Preparation. The 2% sodium carbonate solution used to prepare the noodles was made up with different nonaqueous solvents. These were glycerol (Merck Pty Ltd., Kilsyth, VIC, Australia), ethylene glycol (Ajax Chemicals Pty Ltd., Sydney, Australia), methanol (Chem-Supply, Gilman, SA, Australia), ethanol (Chem-Supply), *n*-propanol (Scharlab S.L., Sentimenat, Spain), and dimethyl sulfoxide (Merck Pty Ltd.). The rates of darkening were measured using the method described above.

Mid-infrared (Mid-IR) Spectroscopy. Mid-IR frequencies used to examine changes in the protein quaternary structure were the amide I band (1580−1720 cm^{-1}; 80% C−O stretch, 10% C−N bend, and 10% N−H bend) and amide II band (1480−1580 cm^{-1}; 60% N−H bend and 40% C−N stretch).[10,11] The spectrum of noodle sheets was obtained using a PerkinElmer (Waltham, MA, USA) Spectrum One FT-IR spectrometer equipped with a Pike Technologies (Madison, WI, USA) diffuse reflectance autosampler. The data were transferred to GRAMS/AI[12] software, and the areas of the amide bands were determined manually.

***n*-Propanol Extract Fractionation.** Initial separation was based on the Osborne method.[13] Flour (200 g) was extracted with water (1.5 L) for 30 min at 60 °C and then centrifuged at 1500*g* for 10 min to give an albumin fraction. A globulin fraction was obtained by extracting the precipitate with a 0.2 mol L^{-1} NaCl solution (750 mL) for 30 min at 60 °C and then centrifuged at 1500*g* for 10 min. To the precipitate was added 30% ethanol (750 mL), and the mixture was extracted for 30 min at 60 ° and , then centrifuged at 1500*g* for 10 min to give gliadin fraction (A). The 50% propanol fraction (gliadin fraction B) was obtained by adding *n*-propanol (750 mL) to the precipitate and extracting for 30 min at 60 °C. This extract was centrifuged at 1500*g* for 10 min and the supernatant retained (if dried by rotary evaporation this yielded ≈10−12 g). In preference to drying, different amounts of water or propanol were added, and the precipitates and supernatants were analyzed for noodle darkening activity. A fraction with the highest activity was obtained by diluting the supernatant to 9% propanol and allowed to stand for 72 h. The supernatant was decanted, and both supernatant and precipitate were dried by rotary evaporation (yields: precipitate, ≈1.5 g; supernatant, ≈9 g). The precipitate was washed with 200 mL of chloroform to give two fractions, chloroform soluble (≈0.7 g) and chloroform insoluble (≈0.7 g), which were dried by rotary evaporation. The chloroform-insoluble material was subsequently redissolved in warm 20% propanol (50 mL) and fractioned using a C18 column (90 mm × 20 mm dia., Bodesil-C18 40 μm, Varian, Palo Alto, CA, USA), collecting the elution with 100 mL of 20% propanol fraction (≈0.3 g) and then eluting with 50% propanol (100 mL) to obtain a 50% propanol fraction (≈0.4 g). Both fractions were dried by rotary evaporation.

PPO Analysis. PPO analyses of protein extracts were based on the 96-well method of Bernier and Howes.[6] A tyrosine solution (100 mL) was made with 0.01 mol L^{-1} tyrosine in 0.1 mol L^{-1} Tris base buffer (pH 9) with ≈40 μL of Tween 20 added. Protein extract (2 mg) was dissolved in 300 μL of tyrosine solution per microplate well and incubated for 3 h at 37 °C. Portions (100 μL) from each well were transferred into a new microplate, and the optical density was read by a microplate reader.

Polyacrylamide Gel Electrophoresis (PAGE). SDS-PAGE separation was achieved byusing the method of Singh et al.[14] with minor modifications.[15] Acid-PAGE was performed according to the method of Clements.[16] Gliadins were extracted from *T. aestivum* cv. Chinese Spring, Gabo, Cheyenne, and Tasman as reference standards.

RESULTS AND DISCUSSION

Effect of pH on YAN Non-PPO Darkening. It was necessary to establish the amount of physical and chemical components of non-PPO darkening. A higher proportion of chemical than physical darkening occurred during the 4−24 h time period.[4] The pH data (Figure 1) indicated that there are

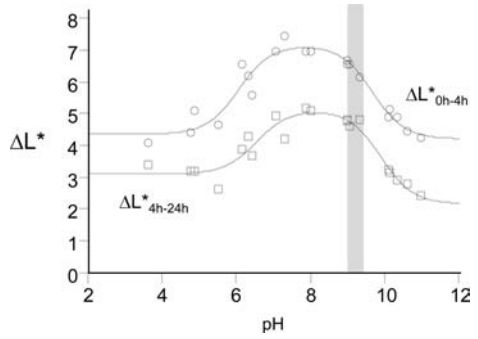

Figure 1. Effect of pH on darkening during the 4−24 h time period in noodles made from near-zero-PPO Kamilaroi durum flour (gray area indicates the approximate pH of YAN).

both pH-dependent and pH-independent components to non-PPO darkening during the 4−24 h time period. The maximum darkening of noodles made from Kamilaroi flour occurs at pH 8.1, which is slightly lower than the pH of normal YAN (pH ≈9−9.2) but similar to the pH of maximum PPO activity in noodles (pH ≈8.2).[4] Plateaus associated with minima of non-PPO darkening were observed at pH values <5 and >11. These plateaus represent the pH-independent component of non-PPO darkening associated with physical darkening, whereas the pH-dependent portion is associated with chemical darkening. In YAN, the chemical portion of non-PPO darkening was estimated

Table 1. Maximum and Minimum (Plateaus pH <5 and >11) Darkening (ΔL^*) Values and pK_a Values for Non-PPO Darkening in Noodles Made with Near-Zero-PPO Kamlaroi Durum with a Range of pH Values for Three Time Periods (0−4, 4−24, and 0−24 h)

		ΔL^*_{min}		pK_a values	
time period	ΔL^*_{max} (pH)	pH <5	pH >11	pK_{a1}	pK_{a2}
0−4 h	7.07 (7.86)	4.35 ± 0.21	4.20 ± 0.30	6.07 ± 0.18	9.67 ± 0.21
4−24 h	5.02 (8.14)	3.10 ± 0.17	2.16 ± 0.36	6.54 ± 0.22	9.91 ± 0.22
0−24 h	12.09 (7.99)	7.49 ± 0.28	6.34 ± 0.48	6.27 ± 0.13	9.81 ± 0.16

by calculating the difference between maximum and minimum darkening, whereas the physical portion of non-PPO darkening was estimated by the difference between the minimum and zero darkening. Both of these were expressed as a percentage of maximum darkening. Without knowing the actual baseline darkening at alkaline noodle pH (9−9.2), two preliminary estimates for the chemical portion of non-PPO darkening were calculated by comparing maximum darkening at pH 8.1 with each of the plateaus. On the basis of the low-pH plateau, 38% of non-PPO darkening, or on the basis of the high-pH plateau, 57% of non-PPO darkening, was due to chemical processes during the 4−24 h time period. A similar analysis of the 0−4 and 0−24 h time periods suggested chemical darkening was responsible for approximately 38% (low-pH plateau) to 41% (high-pH plateau) and 38% (low-pH plateau) to 47% (high-pH plateau) of total non-PPO darkening, respectively (Table 1).

pK_a (acid dissociation constant) values were used to measure the midpoints between maximum and minimum darkening in YAN relative to pH (Figure 1; Table 1). The maximum for non-PPO darkening at pH 8.1 was flanked by a pK_a measured for chemical darkening on the low-pH side of the peak (pK_{a1} = 6.54 ± 0.22) and one on the high-pH side of the peak (pK_{a2} = 9.91 ± 0.22), which are similar to the pK_a values reported for PPO darkening in YAN made from Tasman flour (pK_{a1} = 7.0; pK_{a2} = 9.8).[4] This suggests the chemical component of non-PPO darkening may be due to an enzyme.

Effect of Solvents on YAN Non-PPO Darkening. In preliminary investigations, it was noted that different solvents have an effect on YAN darkening. The solvents investigated can be divided into two groups according to their effects on darkening in noodles made from Kamilaroi flour during the 4−24 h time period (Figure 2). Methanol, ethanol, and propanol show a linear inhibition of darkening with higher concentration until a critical concentration of solute was reached. This coincided with a concentration at which there is inadequate water to make a noodle. Dimethyl sulfoxide (DMSO) and ethylene glycol both showed a lower rate of inhibition until a critical concentration, when the inhibition of darkening increased rapidly (Figure 2). Glycerol at 10% showed a slight enhancement of darkening, and at lower concentrations a curve similar to DMSO and ethylene glycol could be fitted.

In YAN made with near-zero-PPO Kamilaroi flour, the maximum inhibition of darkening by methanol or ethanol (50% solution) indicated that 61−64% of darkening during the 4−24 h time period (Figure 2A) and 33−39% of total darkening for the 0−24 h time period were due to non-PPO chemical reaction (Table 2). Whereas the estimate for the chemical portion of non-PPO darkening achieved by methanol/ethanol addition for the 4−24 h time period was slightly higher than the estimate derived from the pH data for the same period (38−57%), the estimates obtained for the 0−24 h time period by 50% methanol/ethanol addition and by pH (38−47%) method were in reasonable agreement. For the 4−24 h time period, the level of

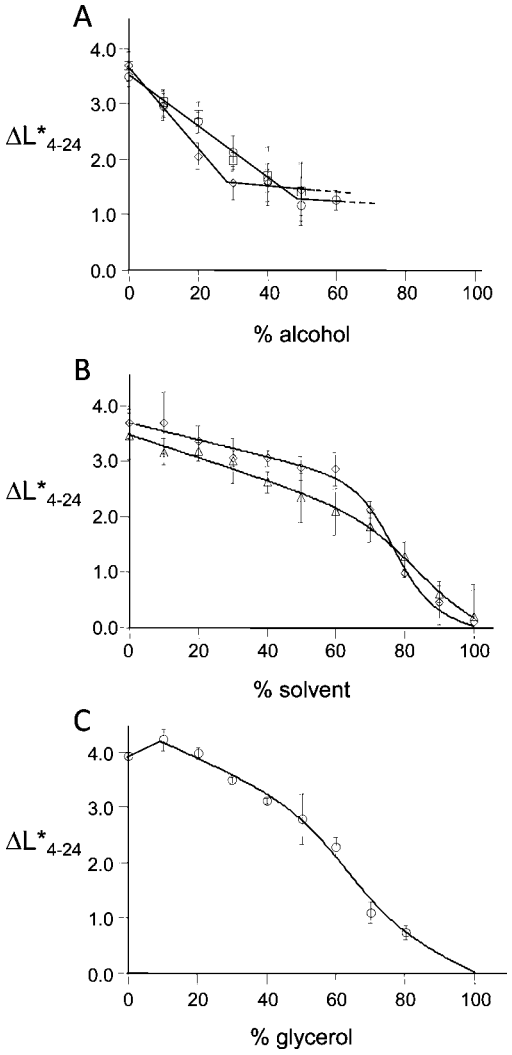

Figure 2. Effects of different solvents on YAN darkening in noodles made from near-zero-PPO Kamilaroi durum flour during the 4−24 h time period: (A) methanol (circles), ethanol (squares), propanol (diamonds); (B) ethylene glycol (diamonds) and dimethyl sulfoxide (triangles); (C) glycerol; panels B and C are fitted with modified logistic curves (bars represent standard error of the mean).

non-PPO darkening inhibited by 50% methanol or ethanol was similar to the high range for the pH data, indicating the plateau at high pH was a more appropriate baseline for physical non-PPO darkening than the low-pH plateau. Contrary to previous suggestions,[1] a considerable amount of physical darkening occurred during the 4−24 h time period.

Addition of nonaqueous solvents can displace water from the surface of the protein and cause changes in protein structure, which should be detected by IR spectroscopy.[17−19] Whereas the amide II band is strongly influenced by hydration,[19,20] no

60%	mixed					

differences were observed in the band areas of either the amide I or the amide II bands between 50% methanol or 50% ethanol and the control (data not shown), suggesting conformational changes in gluten structure were not involved in non-PPO darkening but rather a chemical reaction was involved. Noodles made with very high concentrations of DMSO, ethylene glycol, and glycerol showed little or no darkening, which clearly indicated that there is a requirement for water for both the physical and chemical components of non-PPO darkening to proceed.

By calculating the difference in darkening between the control noodle (0% alcohol) and the noodle made with an inhibitor (or organic solvent), it is possible to estimate the rate of inhibition of darkening. For example, Figure 3A shows that the control noodle exhibits darkening at a faster rate and amount than the noodle made with 50% methanol. The difference between these curves indicates the effects of 50% methanol only. This curve fits a first-order rate equation ($\Delta L^* = a \exp(-kt)$, where k is the rate, t is time in hours, and a is a constant), and from this it is possible to estimate the rate of darkening (0.07 ± 0.02 h^{-1}). These difference rate data suggest that although there is sufficient water to make a noodle, methanol or ethanol inhibit first-order or pseudo-first-order reactions at all concentrations (Table 3). The rates of darkening for methanol and ethanol are similar. Additional darkening attributed to PPO, which was estimated by difference in the darkening of Tasman noodles made with and without 0.01 mol L^{-1} tropolone (a PPO inhibitor; Figure 3B), indicated that PPO darkening also follows a first- or pseudo-first-order reaction, and the rate is similar to that for inhibition by methanol and ethanol (0.11 ± 0.01 h^{-1}). A first-order or pseudo-first-order reaction is often indicative of an enzyme-catalyzed reaction.

dx.doi.org/10.1021/jf500206e | J. Agric. Food Chem. 2014, 62, 4725−4730

Ethanol and methanol have the potential to alter enzyme conformation, leading to inhibition. Whereas the chemical portion of non-PPO darkening is inhibited by ethanol and methanol, PPO activity is only partially inhibited by both methanol and ethanol in noodles made from Tasman flour (Figure 3B). It is known that wheat PPO is resistant to inactivation by quite high levels of methanol and ethanol.[21] By using a combination of 50% methanol and tropolone it is possible to estimate the contribution of the different processes to YAN darkening. For example, YAN made from Tasman flour with 0.01 mol L^{-1} tropolone compared (ΔL^* = 9.26) with the control (ΔL^* = 15.7) gave an estimate that 41% of darkening was due to PPO. Any darkening in YAN not inhibited by 50% methanol and 0.01 mol L^{-1} tropolone gives an estimate of the physical portion of non-PPO darkening (ΔL^* = 6.36), which is about 41% in Tasman. The remaining darkening (18%) is due to the chemical portion of non-PPO darkening (Figure 3B).

In this way, YAN made from five common high-PPO wheat varieties (including Tasman) and a low-PPO variety (Axe) were measured and compared with the near-zero-PPO Kamilaroi to give an estimate of the contribution of the PPO and the physical and chemical portions of non-PPO darkening in YAN (Table 2). There was no significant difference in noodle darkening in the presence or absence of the PPO inhibitor, tropolone. The relative contribution of the chemical portion of non-PPO darkening to total non-PPO darkening was similar in the high-PPO wheat varieties and Kamilaroi but not in the low-PPO wheat variety, Axe (Table 2).

Other Possible Methods for Estimating the Chemical Portion of YAN Non-PPO Darkening. Asenstorfer et al.[5] published the effects of a variety of enzyme inhibitors on noodle darkening, and although no specific non-PPO inhibitor was identified, the enzyme inhibitor phenylhydrazine (0.01 mol L^{-1}) decreased darkening in Kamilaroi by an amount similar to the chemical portion of non-PPO darkening (ΔL_{0-24} = 4.16) and in Tasman by an amount similar to the combined contributions of PPO darkening and the chemical portion of non-PPO darkening (ΔL_{0-24} = 8.84). Phenylhydrazine is a PPO inhibitor;[22] however, it appears to be inhibiting an enzyme in addition to PPO. This was further evidence that the chemical portion of non-PPO darkening is catalyzed by an enzyme, possibly an enzyme with PPO-like activity but which is insensitive to the PPO inhibitor, tropolone. Phenylhydrazine (or a less toxic alternative) may provide another method of estimating the contribution of the enzymatic (PPO and non-PPO) to YAN darkening.

Extraction of YAN Darkening Components. Initial results suggested that gliadins and glutenins were involved in the chemical portion of non-PPO darkening.[1] When the gliadin-rich extracts from *Triticum durum* cv. Kamilaroi were dried and added back to YAN, there was an increase in non-PPO darkening. The fraction with the highest YAN darkening activity was derived from a 50% propanol extract of Tasman flour. This 50% propanol extract was subsequently further fractionated by C18 chromatography with 20% propanol and 50% propanol. The fraction obtained from the 20% propanol was active with a ΔL^*_{0-24} value of 3.10 ± 0.46, whereas the fraction obtained from the 50% propanol was inactive with a ΔL^*_{0-24} value of −0.82 ± 0.52 (Table 4). These two propanol fractions were also analyzed for tyrosine darkening using the PPO assay. The 20% propanol fraction oxidized some tyrosine, whereas the 50% propanol fraction showed no darkening. Subsequent work confirmed the relationship between tyrosine darkening, as measured by the PPO assay, and the amount of noodle darkening (Figure 4) and therefore indicated that the active fractions contained enzyme(s) rather than substrate.

Table 4. Comparison of Fractions Obtained from *T. aestivum* cv. Tasman Flour on the Darkening (ΔL^*_{0-24}) of Yellow Alkaline Noodles (YAN) Made with Near-Zero-PPO Kamilaroi Flour (Adjusted to 0.1 g/10 g equiv) and the Oxidation of Tyrosine As Measured at 415 nm

20% propanol	3.10 ± 0.46	14.0 ± 2.5

[a]Not determined.

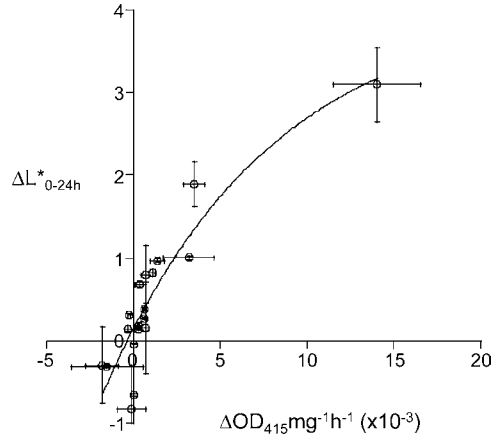

Figure 4. Darkening of YAN (ΔL^*_{0-24}) made from zero-PPO Kamilaroi flour with a range of propanol extracts from Tasman flour added (adjusted to 0.1 g/10 g equiv) compared with the oxidation of tyrosine (ΔOD_{415}) by the same extracts (bars represent standard error of the mean).

Analysis by SDS-PAGE and acid-PAGE showed that the 20% propanol fraction contained a higher proportion of α/β-gliadins than the 50% propanol fraction (data not shown). Mass spectrometry of the 20% propanol fraction revealed that the main constituents of this fraction were proteins with mass 30000−35000 (m/z), which was consistent with the presence of gliadins[23] (data not shown). Typically wheat PPO enzymes are associated with the water-soluble (albumin/globulin) fraction[24] and not the gliadin fraction. The active fractions appeared to contain an enzyme inhibited both by tropolone and by methanol (Table 5). In agreement with previous studies,[21] PPO in YAN made from Tasman flour was only slightly inhibited by methanol (Figure 3B). However, partial purification of the unknown enzyme involved in non-PPO darkening may have increased its sensitivity to tropolone inhibition. It is therefore possible that this enzyme is a type of PPO. Anderson et al.[25] reported a tropolone-insensitive PPO in immature wheat kernels. However, if this enzyme is indeed a PPO, it belongs to a different class of PPO enzymes than previously described in wheat bran.[25,26]

Data presented here are consistent with the suggestion that the chemical component of non-PPO darkening involves the presence of a PPO-like enzyme with a hydrophobicity similar to that of gliadin which is able to oxidize tyrosine, has a pH maximum of 8.1, and is sensitive to 50% methanol, ethanol, and

expected methanol + extract	−1.81

[a]Tropolone (PPO inhibitor) and 50% methanol were added to noodles containing the extract and compared with control noodles made with and without 50% methanol.

phenylhydrazine but is insensitive to tropolone in situ. With low-PPO and PPO-free wheat varieties becoming available, it may be possible to further reduce darkening in YAN by breeding for wheat varieties with low or zero levels of this PPO-like enzyme.

ABSTRACT: The antimicrobial effects of red wine and its inherent components on oral microbiota were studied by using a 5-species biofilm model of the supragingival plaque that includes *Actinomyces oris*, *Fusobacterium nucleatum*, *Streptococcus oralis*, *Streptococcus mutans* and *Veillonella dispar*. Microbiological analysis (CFU counting and confocal laser scanning microscopy) of the biofilms after the application of red wine, dealcoholized red wine, and red wine extract solutions spiked or not with grape seed and inactive dry yeast extracts showed that the solutions spiked with seed extract were effective against *F. nucleatum*, *S. oralis* and *A. oris*. Also, red wine and dealcoholized wine had an antimicrobial effect against *F. nucleatum* and *S. oralis*. Additional experiments showed almost complete and early degradation of flavan-3-ol precursors [(+)-catechin and procyanidin B2] when incubating biofilms with the red wine extract. To our knowledge, this is the first study of antimicrobial properties of wine in an oral biofilm model.

KEYWORDS: *wine, polyphenols, oral bacteria biofilm, antimicrobials*

INTRODUCTION

The oral cavity is an enormously complex habitat with several hundred commensal microbial species colonizing it, and furthermore, it is unique in the human body in possessing nonshedding surfaces, the teeth, allowing microorganisms to adhere to the surface of teeth for long periods of time, embedded in a self-produced matrix of extracellular polymeric substances,[1] and thus leading to extensive biofilm formation, dental plaque,[2] which is more resistant than planktonic cells to mechanical stress or antibiotic treatment.[3] The microorganisms of dental plaque live with one another in a commensal or mutualistic symbiotic relationship, allowing a mixture of aerobic and anaerobic bacteria to live in the same environment. Some of these oral bacteria, such as streptococci or lactobacilli, are able to produce high levels of organic acids following fermentation of dietary sugars. Acids released from dental plaque lead to demineralization of the tooth surface and consequently to dental caries, periodontal disease or tooth loss,[4] which are the most prevalent oral diseases in humans, affecting up to 60−90% of the world population.[5]

Even using mechanical removal, dental biofilms cannot be eliminated completely. Antimicrobial agents are complementarily used to control dental plaque.[6−8] Until now, several substances have been tested for the control of oral biofilms, including essential oils, amine fluoride, triclosan, etc., but one of the most widely used and effective antibiofilm agents is chlorhexidine.[9] However, chlorhexidine has been associated with some secondary effects, namely the reduction of human taste perception and the pigmentation of oral tissues, which limits its application. Therefore, the search for new antimicrobials has arisen, and natural products are preferable due to the lack of secondary effects and, therefore, the potential for long-term usage in the oral cavity.

The inherent matrix of the biofilm, such as extracellular polymeric substances that reduce penetration of antimicrobial agents and the presence of persistent cells surviving at low metabolic rates, contributes to the widely described phenomenon of reduced sensitivity to antimicrobial agents.[10] Because of this, biofilm models including bacteria and fungi from different species, have proven both useful and reliable in predicting *in vivo* efficacy of antimicrobials. In this sense, most experimental models for short-term studies involve a solid surface for the adhesion of bacteria.[11]

Although there is substantial literature reporting the antimicrobial properties of phenolic compounds or polyphenols against bacteria isolates,[12−14] information about their effect on oral pathogens is still scarce.[15] Studies carried out with tea and cranberry polyphenols have shown an inhibitory effect on biofilm formation by oral pathogens such as *Streptococcus mutans*, *Streptococcus oralis*, *Streptococcus sobrinus* and *Porphyromonas gingivalis*.[16] Grapes and wines are good dietary sources of polyphenolic compounds, including hydroxybenzoic and hydroxycinnamic acids, phenolic alcohols, flavan-3-ol monomers, oligomeric and polymeric procyanidins, flavonols, stilbenes and anthocyanins (only present in red varieties).[17] Recently, it has been found that wine and grape phenolic extracts, as well as pomace phenolic extracts, were able to inhibit the growth of different *Streptococcus* spp. strains associated with dental caries.[18,19]

On the other hand, interactions between wine phenolics and oral microbiota can also include a possible bacterial catabolism

of wine phenolics into less complex phenolic metabolite structures, as seems to happen with flavonol glycosides.[15] With regard to anthocyanins, their degradation in human saliva at 37 °C has been described, being structure-dependent, largely mediated by oral microbiota, and partially suppressed after oral rinsing with antibacterial chlorhexidine.[8]

With the final aim of seeking natural products that could be used in oral hygiene and to ascertain interactions between wine components and oral microbiota, in this study the antimicrobial effects of red wine and dealcoholized red wine were investigated using a biofilm model of the supragingival plaque that integrates five bacteria species commonly associated with oral disease. A wine phenolic extract (Provinols), especially rich in anthocyanins, was also tested using the same model, and in both the absence and presence of other enological extracts from grape seeds (Vitaflavan) and yeast (inactive dry yeast, IDY). Additional experiments were carried out to determine any possible phenolic metabolism during the formation of the bacterial biofilm.

MATERIALS AND METHODS

Red Wines. The red wine used in this study was a young red wine (var. Pinot Noir, vintage 2010), kindly provided by Bodegas Miguel Torres S.A. (Catalonia, Spain). The wine was elaborated following the winery's own winemaking procedures and was selected because of its relatively high phenolic content: total polyphenols = 1758 mg of gallic acid equiv/L, total anthocyanins = 447 mg of malvidin-3-glucoside/L, and total catechins = 1612 mg of (+)-catechin/L. The main individual phenolic compounds found in this wine included anthocyanins, flavan-3-ols, flavonols, alcohols, stilbenes and hydroxycinnamic acids[20] (Table 1).

For the preparation of dealcoholized red wine, ethanol was removed using a rotary evaporator and then distilled water was added until the original volume was reached.

Oenological Extracts. A wine extract, Provinols, was kindly supplied by Safic-Alcan Especialidades S.A.U. (Barcelona, Spain). A grape seed extract, Vitaflavan, was kindly provided by Piriou (Les Dérivés Resiniques & Terpéniques S.A., France). The total phenolic content of the extracts was 474 mg of gallic acid equiv/g for Provinols and 629 mg of gallic acid equiv/g for Vitaflavan. The main phenolic compounds identified in both extracts are reported in Table 1. Also, two inactive dry yeast (IDY) commercial preparations (*Saccharomyces cerevisiae*), IDY 1 and IDY 2, rich in mannoproteins, amino acids and peptides, respectively, were kindly provided by Lallemand S.A. (Blagnac, France) and Agrovin S.A. (Alcázar de San Juan, Ciudad Real, Spain).

The wine extract was dissolved in distilled water containing 2.5% DMSO (v/v), at a concentration of 1.6 g/L. The wine extract solution was fortified in grape seed polyphenols by adding 2.5 g of grape seed extract to 100 mL of the wine solution. Also, the wine extract solution was enriched in wine matrix components (mainly polysaccharides and nitrogen compounds) by adding the IDY preparations to the wine extract solution at a final concentration of 0.4 g/L.

Bacterial Strains and Culture (Growth) Conditions. *Actinomyces oris* OMZ 745, *Fusobacterium nucleatum* OMZ 598, *Streptococcus oralis* OMZ 607, *Streptococcus mutans* UA159 (OMZ 918) and *Veillonella dispar* ATCC 17748^T (OMZ 493) were obtained from the culture collection of the Institute of Oral Biology, University of Zürich. Prior to the experiment, precultures were prepared by transferring the strains on Columbia Blood Agar plates and incubating them for 96 h at 37 °C under anaerobic conditions. After this time, the strains were transferred from the Columbia Blood Agar plates to broth cultures (1 × 9 mL of modified fluid universal medium (mFUM) + 0.3% glucose) (OMZ 493 + 1% sodium lactate) and incubated overnight at 37 °C. After incubation, 200 μL of bacteria from each working culture was individually inoculated in 5 mL of fresh mFUM and incubated at 37 °C anaerobically (7 h maximum). In order to obtain an inoculum

containing cultures in the exponential growth phase of approximately 10^7 CFU/mL, a microbial suspension with equal volumes and densities of each strain was prepared.

Saliva Processing. Saliva was collected from five volunteers and processed according to the protocol of Guggenheim et al.[21] Briefly, whole unstimulated saliva was collected for 1 h each morning, over several days, at least 1.5 h after eating, drinking, or teeth cleaning. Saliva samples were collected in sterile 50 mL polypropylene tubes, chilled in an ice bath or frozen at −20 °C. After 500 mL of saliva had been collected, it was pooled and centrifuged (30 min, 4 °C, 27,000*g*); the supernatant was pasteurized (60 °C, 30 min) and recentrifuged in sterile tubes. The resulting supernatant was stored in sterile 50 mL polypropylene tubes at −80 °C. The efficiency of the process was assessed by plating the processed saliva samples onto CBA agar; after 72 h at 37 °C, no CFUs were observed on the incubated plates. A sterile 1:1 dilution in H_2O + 25% physiological NaCl was used for the biofilm formation and throughout the experimentation.

In Vitro Biofilm Experiments. Figure 1 shows a sequence chart regarding the biofilm formation prior to assays for determining changes in the microbial population of the biofilm and for assessing phenolic metabolism in the biofilm.

Biofilm Formation. Biofilms were grown using the slightly modified protocol described by Guggenheim et al.[21] and Thurnheer et al.[22] In brief, the 5-species biofilms were grown in 24-well polystyrene cell-culture plates on hydroxyapatite (HA) discs of 9 mm Ø (Clarkson Chromatography Products, South Williamsport, USA) previously preconditioned in 800 μL of whole unstimulated pooled saliva (as described in the previous section) during 4 h at room temperature, with shaking (95 rpm) in order to promote pellicle formation. To initiate the biofilm formation, the discs were covered for 45 min with 1.6 mL of a mixture comprising 30% saliva, 70% mFUM and 200 μL of the bacterial inoculum described above. mFUM corresponds to a well-established tryptone yeast-based broth medium designated as FUM[23] and modified by supplementing 67 mM Sørensen's buffer (final pH 7.2). The carbohydrate concentration in mFUM was 0.3% (w/v) and consisted of glucose for the first 16 h and from then on of a 1:1 (w/w) mixture of glucose and sucrose.

After this first incubation, discs were subjected to three consecutive 1 min dip-washes in 2 mL 0.9% NaCl to remove growth medium and free-floating cells but not microorganisms adhering firmly to the HA discs. Then, they were incubated anaerobically for 16.5 h at 37 °C in preconditioned and processed saliva to form the biofilm (Figure 1).

Assay for Determining Changes in the Microbial Population of the Biofilm. Once the biofilm was formed, discs were maintained in a 24-well plate with preconditioned and processed saliva in anaerobic conditions for 7 days. Twice a day, and with 7 h of difference in between, discs were "fed" by immersing them into a preconditioned fresh growth medium (30% saliva, 70% mFUM (v/v) containing 0.15% glucose and 0.15% sucrose) for 45 min, at 37 °C, under anaerobic conditions, After each "feeding", discs were dipped in the different test solutions (1 mL) for 2 min and while being gently shaken by hand. After this time, the discs were dipped once in the preconditioned-processed saliva in order to clean any remains of the test solutions. Immediately after, discs were returned to the "old" 24-well plate with preconditioned and processed saliva and incubated anaerobically until the next "feeding" (Figure 1). After 7 days, biofilms were either stained for confocal laser scanning microscopy (see below) or harvested, at room temperature, in 1 mL of 0.9% NaCl by scratching with a special odontological instrument. Cell viability was tested using a Live/Dead BacLight Viability Kit (Molecular Probes Inc.) The total CFU, streptococci and all taxa were assessed by anaerobic culture (37 °C) using selective (Mitis Salivarious for *Streptococcus oralis* and *Streptococcus mutans*; Fastidious Anaerobe Agar for *Fusobacterium nucleatum*) and nonselective media (Columbia Blood Agar for *Actinomyces oris*, *Veillonella dispar* and total CFU) and colonies were counted.

Distilled water was used as the negative antimicrobial control, and 0.2% chlorhexidine-gluconate solution (Sigma-Aldrich, Steinheim, Germany) in water was the positive antimicrobial control. In order to discard a possible antimicrobial effect of the alcohol, a 12%-ethanol-in-water solution was also tested. For both, test solutions and controls, experiments were carried out in triplicate.

Assay for Assessing Phenolic Metabolism in the Biofilm. After initiating biofilm formation as described above, the 70:30 saliva:mFUM media was enriched with the wine extract (1.6 g/L) in the absence of the presence of grape seed extract (10 g/L) and added into the wells containing the discs (Figure 1). Then, plates were incubated at 37 °C under anaerobic conditions and aliquots of enriched media were taken at 0, 2, 4, 6, 8, and 24 h.

Analysis of Wine Compounds and Bacterial/Microbial Metabolites. Phenolic compounds were analyzed using an UPLC-ESI-MS/MS following a previously reported method.[20] The liquid chromatographic system was a Waters Acquity UPLC (Milford, MA) equipped with a binary pump, an autosampler thermostated at 10 °C, and a heated column compartment (40 °C). The column employed was a BEH-C18, 2.1 × 100 mm and 1.7 μm particle size from Waters (Milford, MA). The mobile phases were 2% acetic acid in water (A) and 2% acetic acid in acetonitrile (B). The gradient program was as follows: 0 min, 0.1% B; 1.5 min, 0.1% B; 11.17 min, 16.3% B; 11.5 min, 18.4% B; 14 min, 18.4% B; 14.1 min, 99.9% B; 15.5 min, 99.9% B; 15.6 min, 0.1% B. Equilibrium time was 2.4 min resulting in a total runtime of 18 min. The flow rate was set constant at 0.5 mL/min and injection volume was 2 μL.

The LC effluent was pumped to an Acquity TQD tandem quadrupole mass spectrometer equipped with a Z-spray electrospray ionization (ESI) source operated in negative polarity mode. The ESI parameters were set as follows: capillary voltage, 3 kV; source temperature, 130 °C; desolvation temperature, 400 °C; desolvation gas (N_2) flow rate, 750 L/h; cone gas (N_2) flow rate, 60 L/h. The ESI was operated in negative ionization mode. For quantification purposes, data were collected in the multiple reaction monitoring (MRM) mode, tracking the transition of parent and product ions specific to each compound. The MS/MS parameters (cone voltage, collision energy and MRM transition) of the 60 phenolic compounds targeted in the present study (mandelic acids, benzoic acids, phenols, hippuric acids, phenylacetic acids, phenylpropionic acids, cinnamic acids, 4-hydrox-

[a]Significant differences (Dunnett's test) in the population in comparison to the negative control (water).

yvaleric acids and valerolactones) were previously reported.[24] Data acquisition and processing was realized with MassLynx 4.1 software.

Staining of Biofilms and Confocal Laser Scanning Microscopy (CLSM). For CLSM, treated as well as untreated, biofilms were stained using the LIVE/DEAD BacLight bacterial viability assay (Invitrogen, Zug, Switzerland) according to the instructions of the manufacturer. After 20 min staining, excess dye was gently aspirated from the discs without touching the biofilms. They were embedded upside-down in 20 μL of Mowiol[25] and stored at room temperature in the dark for at least 6 h prior to microscopic examination.

Stained biofilms were examined by CLSM at randomly selected positions using a Leica TCS SP5 (Leica Microsystems, Heidelberg GmbH, Germany) with a ×20/0.8 numerical aperture (NA) and a ×63/1.4 NA oil immersion objective lens in conjunction with 488 nm laser excitation and 530 nm emission filters for Syto 9 (live stain) and 561 nm laser excitation, and 640 nm emission filters for propidium iodide (dead stain). Image acquisition was done in 8-line average mode, and the data were processed using Imaris 7.2.2 (Bitplane AG, Zurich, Switzerland).

Statistical Analysis. Means and standard deviations were calculated using Microsoft Excel 2007. Statistical analyses were performed through Statistica©. To compare the antimicrobial effects of the different treatments with the control (water), the Dunnett test was applied. Graphs were performed with Microsoft Excel 2007.

RESULTS AND DISCUSSION

Antimicrobial Properties of Red Wine on the Biofilm. The effects of a red wine and the same wine without ethanol on a biofilm model composed of five representative species commonly encountered in supragingival plaque, including Gram-positive (*A. oris, S. mutans, S. oralis*) as well as Gram-negative (*F. nucleatum, V. dispar*) bacteria,[21] were investigated. Among these bacteria were the so-called early colonizers, *A. oris*, *S. oralis* and *V. dispar*, and late colonizers, *S. mutans* and *F. nucleatum*, the latter also designated as a bridging organism due to its capability to coaggregate with a wide range of early and late colonizers.[26] In comparison to the control biofilm (Figure 2A), when biofilms were dipped into red wine (Figure 2B) and dealcoholized red wine, some decrease in cell viability of the whole biofilm was visually estimated. However, no visually changes were observed when applying the wine extract solution (Figure 2C). CFU values for the five bacteria comprising the biofilm indicated an important reduction in *F. nucleatum* and *S. oralis* population when applying red wine and dealcoholized red wine to the biofilm, in comparison to the negative control (distilled water) (Table 2). The Dunnett test confirmed

[a]Significant differences (Dunnetts test) in the population in comparison to the negative control (water + 2.5% DMSO).

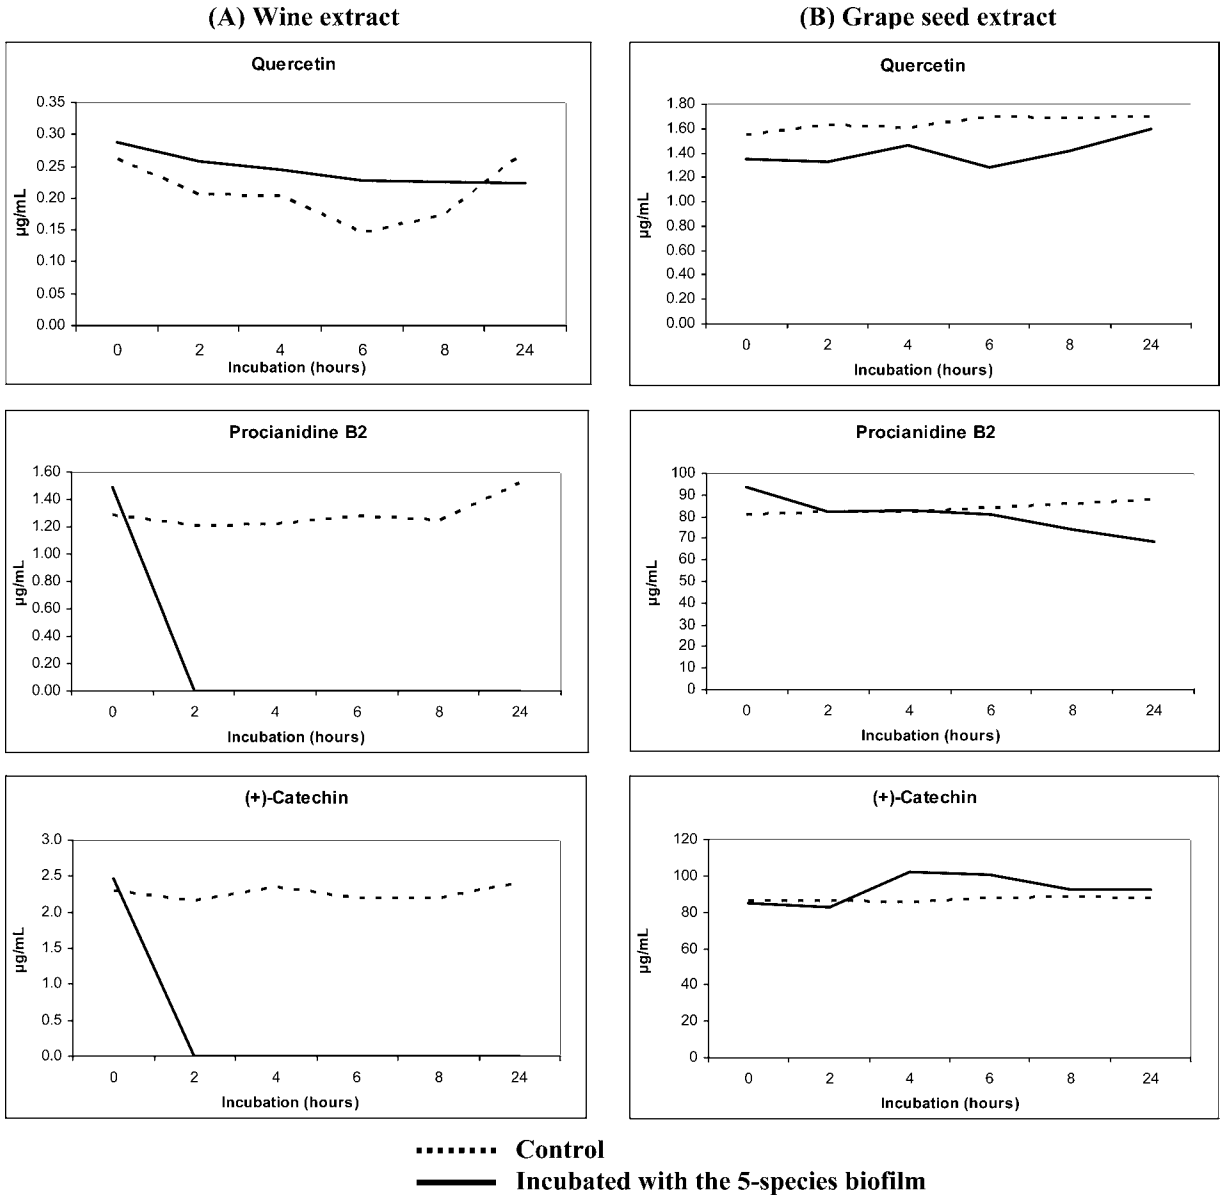

Figure 3. Metabolism of precursors (+)-catechin, quercetin and procyanidin B2 after 0, 2, 4, 6, 8, and 24 h of incubation in FUM media enriched with (A) wine extract (Provinols) and (B) grape seed extract (Vitaflavan, 1%) in wine extract solution.

significant differences in the population of these two strains after the treatment with wine and dealcoholized wine. Generally, wines contain between 10 and 12% of ethanol, which have antimicrobial properties. To understand the action mechanism of red wines in more depth, the effects of ethanol of the bacteria biofilm were investigated. The treatment with 12% ethanol resulted in a significant decrease in the population of *F. nucleatum* (Table 2). However, since treatments of the biofilm with both wine and dealcoholized wine inhibited *F. nucleatum* growth, it was likely that other wine components—apart from ethanol—had antimicrobial properties against this bacteria species. As expected, all the strains were eradicated after the treatment with the positive control (0.2% chlorexidine-gluconate solution) (Table 2).

In an intervention study with 75 volunteers, Signoretto et al.[27] analyzed the microbial population of supragingival and

dx.doi.org/10.1021/jf501768p | J. Agric. Food Chem. 2014, 62, 4731−4737

subgingival plaque using PCR-DGGE and found that *F. nucleatum* was less frequent in wine drinkers compared with water drinkers. Other authors, such as Daglia et al.,[28] have also shown antimicrobial properties of dealcoholized wine against oral streptococci. Both studies were consistent with our results in that wine selectively inhibited the growth of *F. nucleatum* and *S. oralis* in the presence of other species, such as *S. mutans*, *A. oris* and *V. dispar* in an oral biofilm model.

Given the antimicrobial effects of wine observed in the first experiment, the next step was to study the influence of some wine-specific components, such as polyphenols, including flavan-3-ols, peptides or yeast polysaccharides. For that purpose, a red wine extract solution spiked with different extracts rich in those specific components of wine (grape seed extract rich in flavan-3-ols, and two inactive dry yeasts rich in peptides and mannoproteins, respectively) was used. Table 3 reports the CFU values of the five bacteria species of the tested biofilm after treatments with wine extract and wine extract solution spiked with different extracts (grape seed extract, IDY1 and IDY2). Dunnett's test showed significant differences in *F. nucleatum, S. oralis and A. oris* with the application of the wine extract spiked with the grape seed extract rich in flavan-3-ols.[17] However, wine extract solutions spiked with IDY1 and IDY2 did not show any effect in the populations of the five-strain biofilm. Notably, a great decrease in the viability of the cell was visually appreciated in the biofilm recovered from the discs that were dipped in the grape seed extract solution (Figure 2D). Cueva et al.[29] reported significant inhibition in the growth of some oral streptococci, such as *Streptococcus mutans* and *Streptococcus sobrinus*, when incubating planktonic cultures with flavan-3-ols precursors, (+)-catechin and (−)-epicatechin, in which grape seed extract is particularly rich. Moreover, they showed that extracts from grape seed, especially Vitaflavan and its oligomeric fraction, exerted higher antimicrobial activity against various oral pathogens than the rest of the extracts tested (red wine extract and grape pomace extract). Similarly, Rotava et al.[30] and Baydar et al.[31] reported antimicrobial effects of grape seed extracts against pathogenic bacteria such as *S. aureus* and *E. coli*. It has been suggested that the high concentration of flavonoids and their derivatives in grape seeds could be responsible for the antimicrobial activity of grape seed extracts.[32] These observations raise the question of how the hydroxyl groups (structure) of flavonoids affect oral bacterial biofilm.

The search for new antimicrobial agents to control the formation of dental plaque requires appropriate screening models that include orally relevant organisms. The mode used in this study is not only useful for investigating ecological shifts in plaque composition in response to plaque composition but also for testing the efficacy of antimicrobial agents under conditions of repeated short-term exposure.[11] Other oral biofilm models that use flow chamber systems or in-mouth dispositives have also been used. Among these, flow chamber systems allowing biofilm formation/maturation under hydrodynamic conditions, and careful control and easy changes of the environment, are very useful for analysis of structural biofilm formation. In-mouth dispositives allow *in vivo* formation of the biofilm including the endogenous microbiota of the volunteer. Although these models are the most realistic in miming oral biofilms, the high interindividual variability in the composition of the biofilms may provoke high deviations in the results.

Changes in Wine Phenolic Metabolism. Because wine and its polyphenols diminished bacteria population in the oral biofilm, a new assay was performed in order to gain a deeper understanding about microbial metabolism of polyphenols in the tested extracts.

First, the wine extract solution was added to the growth media and the progress of the phenolic metabolism by the five-species biofilm was studied by monitoring changes in the main phenolic compounds present in the wine extract (Table 1): flavan-3-ols monomers ((+)-catechin, (−)-epicatechin and (−)-epicatechin-3-*O*-gallate), dimeric procyanidins (B1, B2, B3, B4, B5, B7, B2-3-*O*-gallate and B2-3-*O*-gallate), trimeric procyanidins (C1 and other trimers) and flavonols (quercetin, myricetin, kaempherol, quercetin-3-*O*-glucoside and quercetin-3-*O*-galactoside). As a brief example, Figure 3A shows the differences in the degradation by the five-strain biofilm of three of the analyzed precursors, (+)-catechin, procyanidin B2 and quercetin, when growing in media enriched with the wine extract solution (1.6 g/L). The UPLC-MS analysis of these three compounds showed high degradation rates, almost completely during the first 2 h of incubation, in the flavan-3-ol precursors, (+)-catechin and procyanidin B2, probably because of their low concentration in the media, which permitted the bacteria of the biofilm to ues them as a carbon source. However, no degradation of the precursor quercetin was observed during the incubation period.

To gain further knowledge about the metabolism of grape polyphenols, specifically in flavan-3-ols metabolism, the growing media was enriched by adding, to the red wine extract solution, a concentration of 10 g/L of grape seed extract, which is especially rich in flavan-3-ol precursors (Figure 3B). Despite the greater concentration of flavan-3-ol precursors, no degradation of the flavan-3-ol precursors was observed. Nor was degradation of precursor quercetin observed during the incubation period.

The emergence of antibiotic resistance by some oral bacteria biofilm species presents a worldwide problem, and thus, novel strategies are required. The use of natural antimicrobials may contribute to controlling the disordered growth of oral microbiota; thus, overcoming problems caused by species resistant to conventional antimicrobials.[33] To our knowledge, this is the first report on the antimicrobial properties of wine in an oral biofilm model. Our results show that red wine, at moderate concentration, inhibits the growth of some pathogenic species in an oral biofilm model. These findings contribute to existing knowledge about the beneficial effects of red wines (one of the most important products of agriculture and food industries) on human health. Moreover, the promising results concerning grape seed extract, which showed the highest antimicrobial activity, open promising ways toward a natural ingredient in the formulation of oral care products specifically indicated for the prevention of caries, due to its antimicrobial properties.

Supporting Information

ABSTRACT: Increasing nitrogen supply can increase Fe and Zn concentrations in wheat grain, but the underlying mechanisms remain unclear. Size-exclusion chromatography coupled with inductively coupled plasma mass spectrometry was used to determine Fe and Zn speciation in the soluble extracts of grain pearling fractions of two wheat cultivars grown at two N rates (100 and 350 kg of N ha^{-1}). Increasing N supply increased the concentrations of total Fe and Zn and the portions of Fe and Zn unextractable with a Tris−HCl buffer and decreased the concentrations of Tris−HCl-extractable (soluble) Fe and Zn. Within the soluble fraction, Fe and Zn bound to low molecular weight compounds, likely to be Fe−nicotianamine and Fe−deoxymugineic acid or Zn−nicotianamine, were decreased by 5−12% and 4−37%, respectively, by the high N treatment, whereas Fe and Zn bound to soluble high molecular weight or soluble phytate fractions were less affected. The positive effect of N on grain Fe and Zn concentrations was attributed to an increased sink in the grain, probably in the form of water-insoluble proteins.

KEYWORDS: *wheat, iron, zinc, speciation, distribution*

INTRODUCTION

Iron and zinc deficiencies are widespread nutritional disorders, affecting over two billion people in the world.[1,2] Insufficient dietary intakes of Fe and Zn and limited dietary diversity are thought to be responsible for human micronutrient deficiencies, especially in developing countries, where high proportions of cereal grains with inherently low concentrations of Fe and Zn, such as wheat and rice, are consumed as staple foods.[1,3] The bioavailability of Fe and Zn in cereal grains is also relatively low due to the presence of antinutritional compounds such as phytic acid and phenolic compounds.[1] Additionally, milling of wheat grain into white flour further results in reduced concentrations of Fe and Zn, because they are enriched in the outer parts of the grains, consisting mainly of the aleurone layer, embryo, pericarp, and testa.[4−6] Therefore, increasing Fe and Zn concentrations and/or their bioavailability in white flour is desirable for tackling the problem of micronutrient malnutrition.

Recent studies have shown that nitrogen supply is an important factor affecting the concentrations of Fe and Zn in wheat grain. For example, under both field and glasshouse conditions, increasing N supply generally enhances Fe and Zn concentrations in wheat grain.[5,7−9] It has been reported that N increases Zn uptake by roots, Zn translocation from roots to shoots and Zn remobilization from leaves to grain in wheat,[4,10] but the mechanisms are not well understood.

Nicotianamine (NA), a nonprotein amino acid, is an important nitrogenous compound involved in Fe and Zn transport via the phloem and subsequent loading into seeds.[11−15] Increasing NA concentration in the rice seed by overexpression of the rice NA synthase genes (*OsNAS*) was found to enhance not only Fe and Zn concentrations in the seed but also their bioavailability.[16−18] The increased Fe and Zn concentrations in the endosperm of the transgenic rice seed were mainly present as complexes with NA and deoxymugineic acid (DMA).[12,16] DMA is synthesized from NA and is involved not only in the acquisition of Fe from the rhizosphere but also in the phloem transport of Fe.[19,20] There is evidence that DMA is the major Fe chelate in rice phloem sap.[21] Therefore, it is possible that the beneficial effect of N results from an increased synthesis of NA and/or DMA facilitating the transport of Fe and Zn to the grain via the phloem. Another possible explanation is that increased N supply may create a larger sink in the grain for Fe and Zn, as there is evidence of positive correlations between protein and Fe and Zn concentrations among diverse wheat cultivars.[22−24]

The bioavailability of a given element is determined by both its total concentration and its distribution among various chemical species;[25] both the concentration and speciation may vary among different tissues or milling fractions of cereal grains. The effects of N on the total concentrations of Fe and Zn in

different milling fractions of wheat grain have been studied, with the results showing generally positive effects in different grain fractions such as in the embryo, endosperm, and bran.[5,8,26] However, little is known about the effect of the N supply on the chemical speciation of Fe and Zn in different wheat grain fractions. This information could provide an important clue to understanding the effect of N on Fe and Zn distribution in the grain. Recently, size-exclusion chromatography coupled with inductively coupled plasma mass spectrometry (SEC−ICP-MS) has been used to identify the soluble forms of Fe complexed with soluble phytate and Zn bound to peptides in barley embryos,[27] Fe and Zn bound to NA and DMA in rice endosperm,[12,16] and Fe and Zn bound to NA/DMA, soluble phytate, and high molecular weight compounds in wheat flour.[28] If increasing N supply increases the transport of NA- or DMA-chelated forms of Fe and Zn to the grain, one may expect increased levels of these complexes in wheat grain.

The objective of the present study was therefore to investigate how the N supply affects the chemical speciation of Fe and Zn in the soluble extracts of whole wheat grain and fractions prepared by sequential pearling of the grain.

MATERIALS AND METHODS

Field Experiment. Two wheat cultivars (*Triticum aestivum* cv. Hereward and Paragon) were grown in the Wheat Genetic Improvement Network (WGIN) trial at Rothamsted, United Kingdom, in October 2008. Hereward is a winter wheat, and Paragon is a spring wheat, both being hard wheat with good bread-making properties.[29] The information about the experimental site, climate, and crop husbandry for the experiment has been previously described.[30] The soil was a clay loam with a pH of 8.1, a total Zn concentration of 88.8 mg kg^{-1}, and a DTPA-extractable Zn concentration of 1.6 mg kg^{-1}. Each cultivar was sown in three replicate plots (each 3 × 10 m) with two N application rates (100 and 350 kg of N ha^{-1}, recorded as N100 and N350, respectively). A completely randomized block design was used for the experiment. Nitrogen fertilizer, as ammonium nitrate, was applied in split top dressings in March (nominal growth stage (GS) 24), April (GS 31), and May (GS 32) 2009.[31] In addition, 145 kg of P_2O_5 ha^{-1} and 120 kg of K_2O ha^{-1} as potassium dihydrogen phosphate were applied in March 2009. All plots received 111 kg of sulfate ha^{-1} as kieserite in March 2009.

Pearling of Wheat Grain. The grain was harvested at crop maturity and air-dried to 12% moisture content before pearling. Wholemeal was produced using a ball mill (Glen Creston, Stanmore, England). Pearling was carried out as described by Tosi et al.[32] using a Streckel and Schrader (Hamburg, Germany) pearling mill. This gave fractions 1−6 corresponding to 7%, 6%, 7%, 10%, 10%, and 10% of the grain weight. Previous studies have shown that these fractions are enriched in the pericarp tissue (bran), the aleurone layer, the subaleurone layer, and three progressively more central areas of the starchy endosperm, respectively.[32] The grain remaining after pearling, representing the core endosperm and accounting for about 50% of the total grain weight, was ground in a ball mill and called fraction 7. Between 95% and 97% of the initial mass was recovered in the seven fractions after pearling.

Chemical Analysis. Whole grain (WG) and grain pearling fractions (oven-dried at 50 °C for 10 h) were digested with HNO_3/$HClO_4$ (87/13, v/v) in a heating block.[33] Total Fe, Zn, and P concentrations in digested solutions were determined by inductively coupled plasma optical emission spectrometry (ICP-OES; PerkinElmer Optima 7500 DV, Waltham, MA). Two blanks and a certified reference material (NIST1567a, wheat flour) were included in each batch of digestion to ensure analytical quality. Repeated analysis (n = 7) of NIST 1567a gave mean values (±SD) of 14.1 ± 1.7 mg of Fe kg^{-1}, 11.7 ± 0.5 mg of Zn kg^{-1}, and 1.33 ± 0.03 g of P kg^{-1}, which are in good agreement with the certified values of 14.1 ± 0.5 mg of Fe kg^{-1}, 11.6 ± 0.4 mg of Zn kg^{-1}, and 1.34 ± 0.06 g of P kg^{-1}, respectively. The nitrogen concentration in the samples was determined with the American Society for Testing and Materials (ASTM) standard protocol E1019 using a LECO combustion analysis system based on the Dumas method.[31] Phytate P in the samples was determined according to the method of Haug and Lantzsch.[34]

Wholemeal and three selected grain pearling fractions (fractions 3, 5, and 7, corresponding to the subaleurone layer, central endosperm, and core endosperm, respectively) of both cultivars with two N treatments were extracted according to Eagling et al.[28] Approximately 70 mg (subaleurone layer), 100 mg (whole grain flour), and 140 mg (endosperm) of the selected fractions were extracted with 7 mL of 50 mM Tris−HCl buffer (pH 7.5) in sterile vials. The extracts were incubated at 37 °C for 18 h with shaking at 120 rpm. At the end of the incubation period, the extracts were centrifuged (21000g, 13 °C, 10 min) and the supernatant was filtered through a 0.2 μm filter (Minisart). Total Fe and Zn concentrations in the soluble extracts were determined using ICP-MS (Agilent 7500ce, Agilent Technologies, Palo Alto, CA). Fe and Zn speciation in the soluble extracts was analyzed using SEC−ICP-MS. A Superdex 75 10/300 GL size-exclusion column (glass, 10 × 300 mm, 13 μm cross-linked agarose/dextran, Amersham Biosciences, United States) was used to obtain an optimum separation range between 0.7 and 70 kDa. Tris−HCl buffer (50 mM, pH 7.5) was used as the mobile phase with a flow rate of 0.47 mL min^{-1} at a controlled temperature of 18 °C. The volume of the sample injected was 100 μL. SEC−ICP-MS analyses were performed on a high-performance liquid chromatograph (Agilent 1100 series, Agilent Technologies, Waltham, MA) coupled to an ICP mass spectrometer with the following conditions: rf power, 1.5 kW; carrier gas flow rate, 0.85 L min^{-1}; nebulizer pump speed, 0.2 L min^{-1}; collision/reaction gas, H_2 (3 mL min^{-1}) and He (2 mL min^{-1}). A mixture of He and H_2 was used as the collision/reaction gas to minimize polyatomic interferences on the isotope signals.

Molecular size calibration was performed using a UV detector (Agilent Technologies, Palo Alto, CA) at 214 nm and the standards apoprotein (6.6 kDa), cytochrome c (12.4 kDa), vitamin B12 (1.35 kDa), triglycine (0.19 kDa), and glycine (0.075 kDa) (all from Sigma-Aldrich). A log-linear regression curve was constructed from molecular size versus retention time. A 100 μL volume of 20 mM EDTA/50 mM Tris−HCl buffer (pH 7.5) was injected between flour samples to remove residual metals adsorbed to the column. The column was rinsed twice after bran samples due to the higher levels of Fe and Zn. To remove any residual metals retained by the column, it was cleaned rigorously between batches with 100 μL of pepsin (1 mg mL^{-1}), phytase (2 mg mL^{-1}), NaCl (0.5 M), and acetic acid (10%) (all from Sigma-Aldrich) at a flow rate of 0.2 mL min^{-1} at 36 °C. EDTA (10 mM)/Tris−HCl (50 mM) buffer (pH 7.5) was injected through the column for 1 h each day.

As Tris−HCl provided a pH buffer only, Tris−HCl-extractable Fe and Zn can be considered to represent the water-soluble fraction. Insoluble Fe and Zn concentrations were estimated by the difference between the total and soluble concentrations. The concentrations of Fe and Zn bound to the individual peaks in the Tris--HCl-extractable fractions were estimated by multiplying the relative peak areas by the soluble concentrations of these elements in the extracts.

Statistical Analysis. The significance of the effects of N application rates, cultivars, and pearling fractions and their interactions on Fe and Zn concentrations was evaluated by analysis of variance (ANOVA). Significant differences between treatment means were determined using Tukey's honest significant difference (HSD) test at the 5% level (P < 0.05) using GenStat, 14th ed. (VSN International, Hemel Hempstead, U.K.).

RESULTS

Grain Yields. Increasing the N dose from 100 to 350 kg ha^{-1} increased the grain yield by 33% and 27% in the cultivars Hereward and Paragon, respectively (P < 0.001; Supplementary Figure 1, Supporting Information). There was no significant

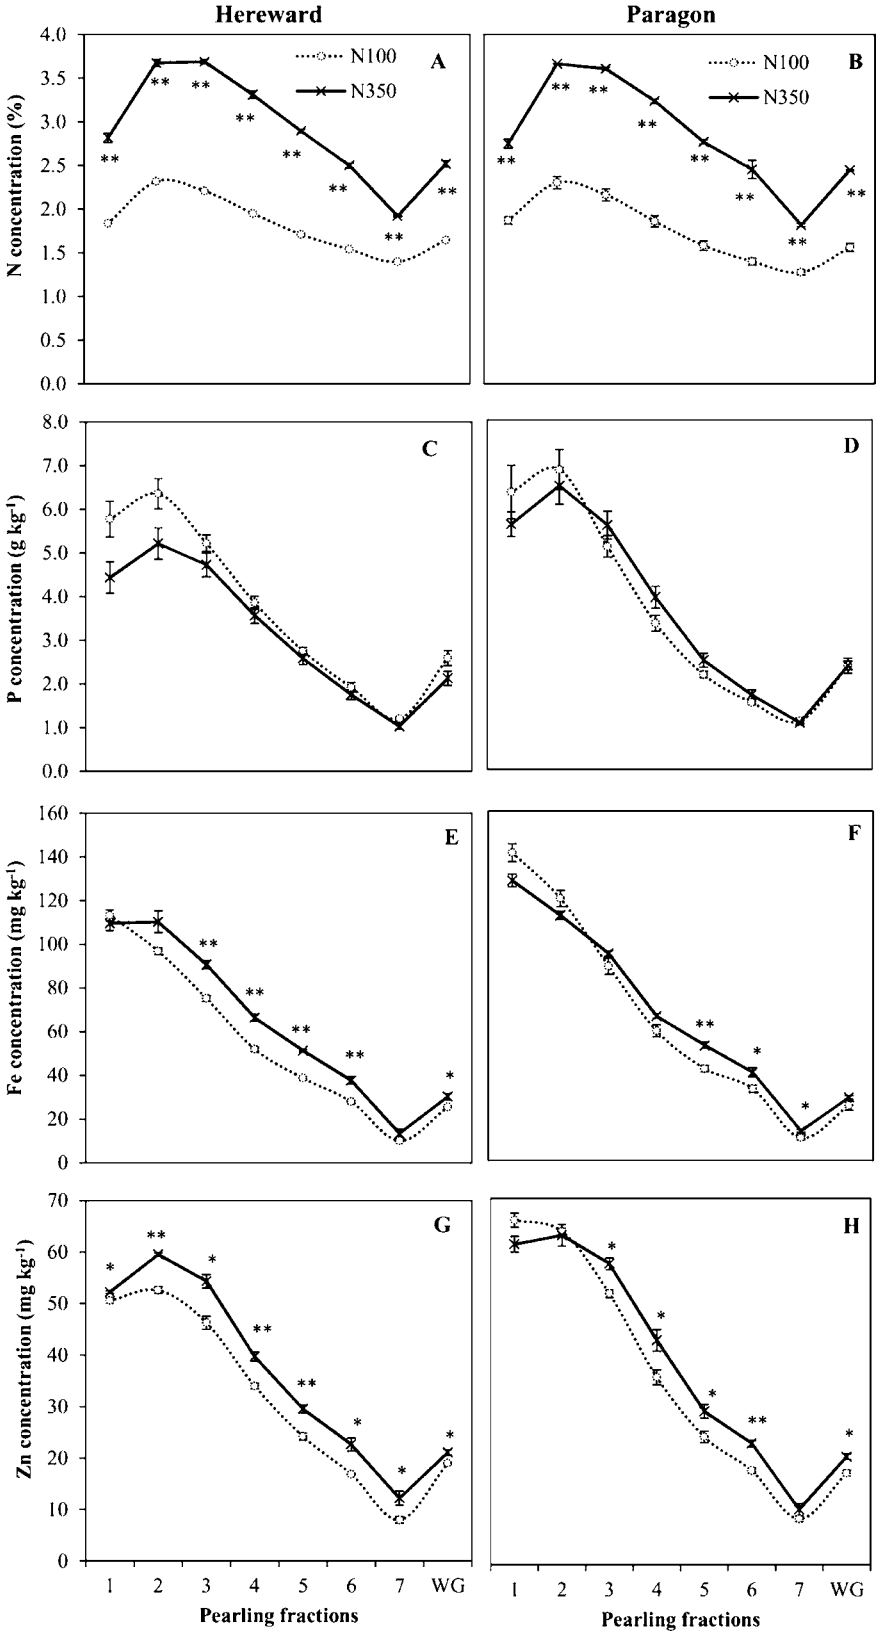

Figure 1. Effects of N treatments (low N, 100 kg of N ha^{-1}; high N, 350 kg of N ha^{-1}) on the N, P, Fe, and Zn concentrations in the pearling fractions and whole grain of the wheat cultivars Hereward and Paragon. Data are means ± SE of three independent replications. One and two asterisks indicate significant differences between the two N treatments for the same pearling fraction at $P < 0.05$ and $P < 0.01$, respectively. Key: fraction 1, bran; fraction 2, aleurone layer; fraction 3, subaleurone layer; fractions 4–6, three progressively more central areas of the starchy endosperm; fraction 7, core endosperm; WG, whole grain.

dx.doi.org/10.1021/jf500273x | J. Agric. Food Chem. 2014, 62, 4738–4746

difference between the two cultivars in grain yield at either level of N treatment.

Distributions of Fe and Zn in Different Pearling Fractions. Figure 1 shows the effects of the N supply on the total concentrations of N, P, Fe, and Zn in WG and pearling fractions of the two wheat cultivars. Two-way ANOVA revealed significant effects of the N supply on the N, P, Fe, and Zn concentrations and significant effects of the cultivar on the N and Zn concentrations of WG (Supplementary Table 1, Supporting Information). The interactions between N supply and cultivar were also significant for the P and phytate P concentrations of WG. Three-way ANOVA showed significant effects of the interactions of N supply, cultivar, and pearling fraction on the Fe and Zn concentrations with the exception of the nonsignificant effect of the interaction between N and cultivar on the Zn concentration (Supplementary Table 1). The high N treatment (350 kg of N ha^{-1}) significantly increased the N concentrations in all pearling fractions and WG of both cultivars, the effect being more pronounced in the outer layers (pearling fractions 2 and 3) than in the core endosperm (Figure 1A,B). There was no significant difference in the P concentration of WG or pearling fractions between the two N treatments (Figure 1C,D). The high N treatment significantly decreased the phytate P concentration in the core endosperm (fraction 7) in Hereward, but had no significant effects in Paragon (Figure 2). The high N treatment significantly increased the total Zn concentration in WG of both cultivars and the total Fe concentration in Hereward (Figure 1E–H). There were also significant and positive effects of the N supply on the Fe and Zn concentrations in most of the pearling fractions of Hereward (Figure 1E–G). In Paragon N decreased the Fe and Zn concentrations in the bran and/or aleurone layer but increased their concentrations in the inner fractions (Figure 1F,H). In general, the effect of N was larger and more consistent in Hereward than in Paragon.

There was a progressive decrease in the concentrations of N, P, Fe, and Zn from the outer to the inner part of the grain (Figure 1). For example, the highest concentrations of N, P, Fe, and Zn in the outermost bran or aleurone layer (fraction 1 or 2) were 0.7-, 4.3-, 10.4-, and 5.6-fold higher than those in the inner core endosperm (fraction 7) in the low N treatment, while the corresponding values were 0.9-, 4.1-, 7.2-, and 3.9-fold higher in the high N treatment, respectively, in Hereward. Similar results were also found in Paragon.

Supplementary Table 2 (Supporting Information) presents the effects of the two N treatments on the distributions of Fe and Zn in different pearling fractions. In Hereward, the outermost three layers (bran, aleurone layer, and subaleurone layer) constituted about 20% of the grain mass, but accounted for 54% and 47%, respectively, of the total Fe and Zn contents in the low N treatment. In the high N treatment, these outer layers accounted for slightly less of the grain Fe (48%) and Zn (41%) than in the low N treatment. By contrast, the remaining core endosperm, constituting about 50% of the grain mass, contained only 14–16% and 19–24%, respectively, of the total Fe and Zn contents (Supplementary Tables 2 and 3, Supporting Information). Similar results were also found in Paragon.

Fe and Zn Speciation in Grain Pearling Fractions. Figures 3 and 4 show SEC–ICP-MS analysis of the Fe and Zn species in the Tris–HCl extracts of wholemeal (Figures 3A,B and 4A,B) and pearling fractions 3 (Figures 3C,D and 4C,D), 5 (Figures 3E,F and 4E,F), and 7 (Figures 3G,H and 4G,H). Due to the long run time for each sample, the samples of the two cultivars were analyzed in two separate batches. For this reason, the absolute peak heights or peak areas were not comparable between the two cultivars.

For Fe speciation, the extracts of all samples contained a low molecular weight (LMW; 1.5 ± 0.1 kDa) complex which eluted at ~36 min. Our previous study[28] showed that this LMW peak probably contains a mixture of Fe–DMA and Fe–NA. Similarly, the LMW peak has been shown to contain a mixture of Fe–DMA and Fe–NA in rice extracts.[12,16] The wheat extracts also contained one or two high molecular weight (HMW) forms of Fe at retention times of ~16 and 18 min (corresponding to >70 ± 0.4 and 20 ± 0.4 kDa, respectively). The identities of these HMW peaks are unknown, but could be soluble proteins.[28] Additionally, the extracts from some fractions, such as the subaleurone layer and the central endosperm of Hereward and the subaleurone layer of Paragon, showed the presence of a medium molecular weight (MMW) complex at a retention time of ~29 min (corresponding to 5.0 ± 0.1 kDa) (Figure 3C–E). The study by Eagling et al.[28] showed that this peak coeluted with P, suggesting that it is a soluble iron phytate. Persson et al.[27] identified a similar MMW peak in the extracts of barley embryo as a soluble iron phytate oligomer.

For Zn speciation, the extracts of all samples contained an HMW complex (>70 kDa) at a retention time of ~16 min and an LMW complex at a retention time of ~35 min (1.9 ± 0.2 kDa) (Figure 4); the latter has been identified as a mixture of Zn–NA and Zn–DMA complexes in rice endosperm.[12] A

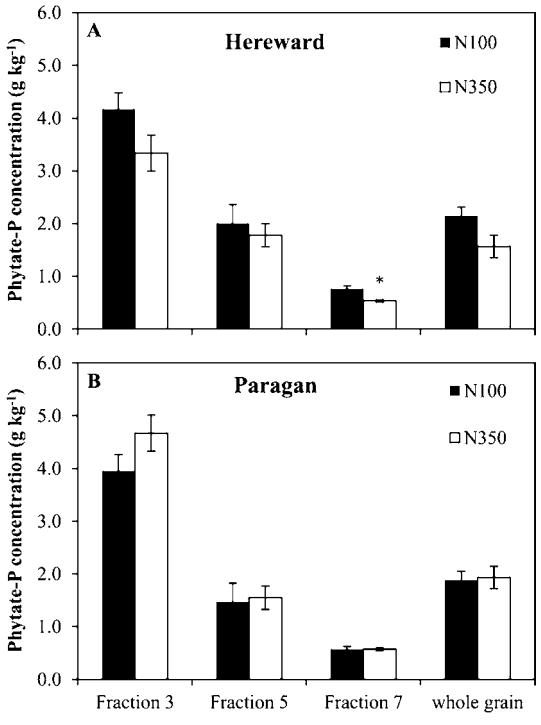

Figure 2. Effects of N treatments (low N, 100 kg of N ha^{-1}; high N, 350 kg of N ha^{-1}) on the phytate P concentrations in the selected pearling fractions and wholemeal flour of the wheat cultivars Hereward and Paragon. Data are means ± SE of three independent replications. An asterisk indicates a significant difference between the two N treatments for the same pearling fraction at $P < 0.05$. Key: fraction 3, subaleurone layer; fraction 5, central endosperm; fraction 7, core endosperm.

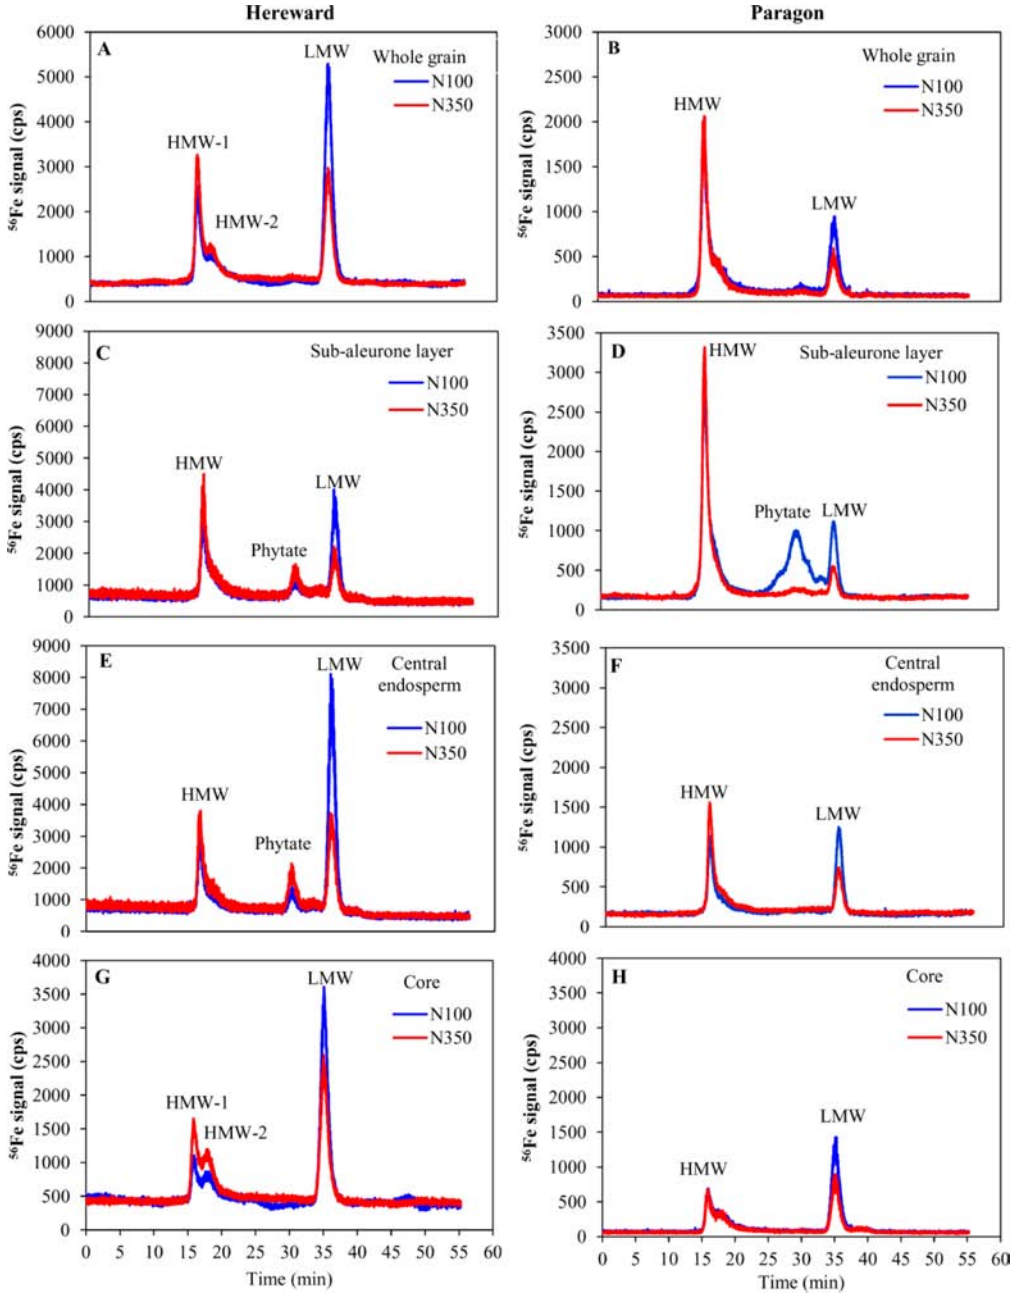

Figure 3. Chromatograms of Fe speciation in the 50 mM Tris−HCl buffer (pH 7.5) extracts of wheat fractions (wholemeal flour, subaleurone layer, central endosperm, and core endosperm) as determined by SEC−ICP-MS.

comparison with the Zn−NA and Zn−DMA standards suggests that the LMW peak in wheat extract is more likely to be only Zn−NA.[28]

The nitrogen supply had a distinct effect on Fe species in the soluble extracts. The high N treatment significantly enhanced the peak area of HMW Fe, but decreased that of LMW Fe in both cultivars, as well as that of the soluble iron phytate (MMW) in the subaluerone layer of Paragon (Figure 3). Generally, the effect of N on Zn species was similar to that for Fe species, although less pronounced (Figure 4).

Tables 1 and 2 present the concentrations and percentage distributions of Fe and Zn species, respectively, in the selected samples of both cultivars. The nitrogen supply had opposite effects on the soluble (extracted in 50 mM Tris−HCl buffer, pH 7.5) and insoluble fractions of Fe and Zn. In the wholemeal and all pearling fractions except the core endosperm of Hereward, the concentrations of soluble Fe were significantly lower in the high N than in the low N treatment. Similar but less pronounced results were also found for the soluble Zn concentration. By contrast, the insoluble fractions of Fe and Zn were significantly increased by the high N treatment. In the wholemeal of Hereward, soluble Fe represented 33.5% and 21.6% of the total Fe concentrations in the low and high N treatments, respectively, with the remainder being the insoluble fractions. For Zn, the soluble fraction accounted for 46.2% and 35.3%, respectively, in the low and high N treatments. There was a general trend of increasing percentage of soluble Fe and Zn from the subaleurone/central endosperm layer to the inner core endosperm. For Paragon, the effects of N on insoluble and soluble Fe and Zn concentrations were similar to those

dx.doi.org/10.1021/jf500273x | J. Agric. Food Chem. 2014, 62, 4738−4746

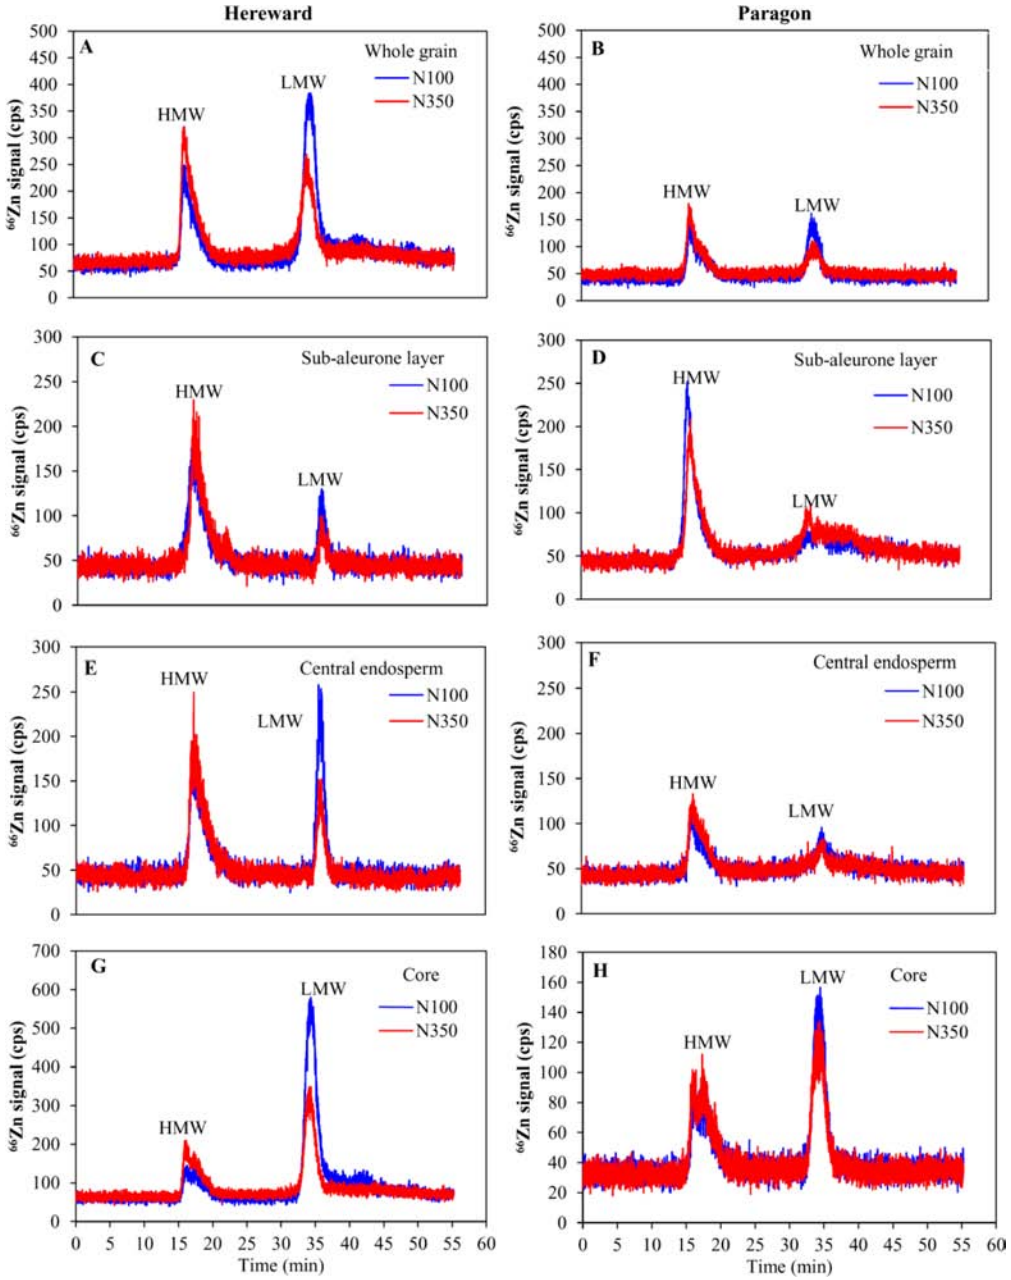

Figure 4. Chromatograms of Zn speciation in the 50 mM Tris−HCl buffer (pH 7.5) extracts of wheat fractions (wholemeal flour, subaleurone layer, central endosperm, and core endosperm) as determined by SEC−ICP-MS.

observed in Hereward with the exception of the wholemeal, where the soluble Zn concentration was significantly increased by the high N treatment. In general, the effects of N were more significant and consistent in Hereward than in Paragon.

Among the soluble species, the concentrations of LMW Fe (likely Fe−NA and Fe−DMA complexes) and LMW Zn (likely Zn−NA) were lower in the high N than in the low N treatment, the differences being significant in most of the pearling fractions and the wholemeals of both cultivars (Tables 1 and 2). Among all pearling fractions of the two cultivars, soluble LMW Fe accounted for 1.5−24.8% of the total Fe concentration; this percentage was the highest in the core endosperm and was significantly decreased by the high N treatment in most pearling fractions. Soluble LMW Zn accounted for 4.8−58.4% of the total Zn concentration, which was also significantly decreased by the high N treatment in most pearling fractions. The effects of N on other soluble species of Fe or Zn (i.e., those associated with HMW and soluble phytate) were not significant.

DISCUSSION

The present study has shown that increasing the N application rate from 100 to 350 kg ha^{-1} generally increased the concentrations of Fe and Zn in wheat grain, although there were some subtle differences between the two wheat cultivars and between the different pearling fractions (Figure 1). The positive effect of N is generally consistent with other studies,[5,8] although the extent of increase was relatively small in the present study possibly due to a dilution effect of increased yield and limited availability of Zn and Fe in the soil with a high pH. Similar to previous studies,[26,35] both Fe and Zn concentrations were found to decrease from the outer layer of the grain to the

central endosperm, a pattern that reflects the localization of the phytate granules in the aleurone layer and their role in sequestering Fe and Zn.[36] It should be noted that, due to the presence of a crease in the wheat grain, the pearling method used may not completely remove the bran and the aleurone layer from the central endosperm fraction, thus explaining the presence of some soluble phytate P in this fraction (Figure 3E). However, the positive effect of the N supply on the Fe and Zn concentrations was not related to phytate, because its concentration was unaffected or even slightly decreased by

dx.doi.org/10.1021/jf500273x | J. Agric. Food Chem. 2014, 62, 4738−4746

the high N treatment (Figure 2). Small concentrations of soluble iron phytate complexes were found in some of the pearling fractions, but they were not significantly affected by N treatments.

It has been shown that Fe and Zn are likely to be complexed with NA and/or DMA during their transport in the phloem, an important process for the translocation of these minerals from leaves to grains.[13,15,19,20] A high N supply may enhance NA and/or DMA biosynthesis and therefore its availability for the phloem transport of Fe and Zn.[4,10,37] However, contrary to this hypothesis, we found that the concentrations of LMW Fe (likely Fe−NA/Fe−DMA) and LMW Zn (likely Zn−NA) in the different pearling fractions and in the whole grain were significantly decreased by the high N treatment (Figures 3 and 4, Tables 1 and 2). Mainly due to this negative effect, N also significantly decreased the concentrations and percentages of soluble Fe and Zn. These results suggest that enhanced NA and/or DMA availability is not the reason for the positive effect of N on Fe and Zn accumulation in wheat grain. Alternatively, it is possible that elevated NA and/or DMA are responsible for the Fe and Zn transport into the grain but that Fe and Zn are then sequestered in other forms.

Interestingly, insoluble forms of Fe and Zn were significantly increased by the high N treatment, especially in Hereward (Tables 1 and 2). This effect was much larger than the negative effect of N on the soluble Fe and Zn, resulting in an overall increase in the total concentrations (Figure 1). This N effect may be explained by an increased content of protein (Figure 1A,B), which may bind Fe and Zn in the grain. A recent study using high-resolution secondary ion mass spectrometry (NanoSIMS) showed that Fe in the wheat endosperm is associated with the protein matrix surrounding the starch granules and the protein bodies.[38] The identities of the proteins that bind Fe and Zn in the endosperm are not known, but the lack of Fe signals inside the protein bodies in the NanoSIMS images suggests that they are not storage proteins. Ferritins are Fe storage proteins, but they are soluble[39] and represent only a small proportion of the total Fe in cereals such as wheat.[40,41] Other compounds such as tannins and certain types of insoluble fiber may also interact with Fe and Zn,[42] but may not explain the effect of N. Taken together, the results of the present study suggest that a high N supply provides a larger protein sink for the storage of Fe and Zn in the wheat grain. This larger sink may also sequester Fe and Zn at the expense of the soluble forms, including Fe and Zn complexes with NA/DMA, resulting in lower concentrations of the soluble Fe and Zn.

The effect of N in influencing the distribution of Fe and Zn between the soluble species and the insoluble fraction on their bioavailability to humans remains to be investigated. Previous studies have shown that the Fe−NA and Zn−NA complexes in rice are bioavailable using an in vitro digestion/Caco-2 cell culture model and mouse feeding experiments.[12,16,18] Therefore, decreased NA−Fe and NA−Zn may have negative effects on Fe and Zn bioavailability. However, Fe and Zn bound to insoluble proteins may become bioavailable during gastrointestinal digestion processes. Additionally, the positive effect of N was not associated with an increased phytate level, which may be favorable to Fe and Zn bioavailability.

Lettucenin Sesquiterpenes Contribute Significantly to the Browning of Lettuce

Franziska Mai and Marcus A. Glomb*

Institute of Chemistry, Food Chemistry, Martin-Luther-University Halle-Wittenberg, Kurt-Mothes-Straße 2, 06120 Halle, Germany

ABSTRACT: Wound-induced changes in the composition of secondary plant compounds cause the browning of processed lettuce. Cut tissues near the lettuce butt end clearly exhibit increased formation of yellow−brown pigments. This browning reaction is typically been attributed to the oxidation of polyphenols by the enzyme polyphenol oxidase (PPO). However, in our previous study on Iceberg lettuce, we showed that, besides the enzymatic polyphenol browning, other reactions must be involved in the formation of colored structures. With the present study for the first time, we isolated yellow sesquiterpenes by multilayer countercurrent chromatography (MLCCC), followed by preparative high-performance liquid chromatography (HPLC). Further analyses by nuclear magnetic resonance (NMR) and mass spectrometry (MS) techniques identified lettucenin A and three novel derivatives. We call these compounds lettucenins A1, B, and B1. Color-dilution analyses revealed these lettucenins as key chromophores in the browning of Iceberg lettuce. A time formation curve showed the accumulation of lettucenins A and B within 40 h after cutting. Thereafter, these structures were degraded to unknown colored compounds. Lettucenin A was verified in five varieties of *Lactuca*. In contrast to that, lettucenin A was present only at trace levels in five varieties of *Cichorium*. Therefore, lettucenin A might be used as a chemosystematic marker of the genus *Lactuca*.

KEYWORDS: *Iceberg lettuce, Lactuca sativa, multilayer countercurrent chromatography (MLCCC), enzymatic browning, lettucenin, color-dilution analyses*

INTRODUCTION

Besides tomato, potato, and carrot, lettuce (*Lactuca sativa* L.) is one of the most popular vegetables in the world.[1] Favorite species are Butterhead, Romaine, and most importantly, Iceberg lettuce. In 2010, the consumption per private household in Germany amounted to 2.8 kg.[1]

Browning is one of the main causes of quality loss during the postharvest storage of lettuce and minimally processed lettuce.[2] In general, lettuce tends toward very rapid browning specifically on the lettuce butt end after harvesting.[3] Yellowish brown pigments are usually formed on bruises and cut surfaces. The huge economic loss encouraged researchers to conduct studies to understand lettuce-browning mechanisms. Numerous studies have focused on the typical enzymatic browning triggered by polyphenol oxidase (PPO). Furthermore, extensive investigations were carried out to describe beneficial effects of specific physical or chemical treatments on the prevention of discoloration.[3,4] However, for lettuce and also other kinds of fruits or vegetables, no precise relationship was found between browning potential, PPO activity, and total or individual phenol accumulation or degradation.[5−7] Besides the chemistry of black tea fermentation, specific products of enzymatic browning have hardly been scientifically researched.

In our recent study, the relationship between discoloration of Iceberg lettuce and enzymatic browning was thoroughly investigated.[8] This was based on literature that described enzymatic browning as the reaction between phenolic substances and enzymes.[4,9,10] Unexpectedly, the total concentration of polyphenols and the activity of PPO were not directly related to the browning processes. Model incubation experiments of plant extract solutions supported the argument that, in addition to the typical enzymatic browning induced by PPOs, further mechanisms must be considered to explain total browning of lettuce.[8]

Post-infectious defense induces the formation of antimicrobial substances in plants. The German plant pathologist K. O. Müller established the term "phytoalexin" in 1940.[11] The induction of the secondary metabolites is often caused by biotic (microorganisms) and abiotic agents, such as heavy metals (e.g., cupric chloride), but also physical injuries (such as cutting or brushing).[13]

Lettucenin A was first reported to be a sesquiterpenoid phytoalexin of lettuce by Takasugi et al. and found to be produced by lettuce and dandelion leaves in response to stress induced by pathogenic fungus or cupric chlorid.[12,13] Another fungitoxin was isolated and identified as costunolid from lettuce infected with *Pseudomonas cichorii*.[12] In addition, lettucenin A showed strong bioactivity against different pathogenic fungi *in vivo*.[14]

Monde et al. and Ahmad et al. described non-colored phytoalexins from *Cichorium intybus* and *Taraxacum wallichii*.[15,16] Bennet et al. hypothesized further phytoalexins of the sesquiterpenoid group to be involved in defense reactions in Iceberg lettuce but were not able to show any specific structures.[14] Up until now, lettucenin A is the only colored structure that might be responsible for the discoloration of lettuce.

With the present work, we were able to isolate colored sesquiterpenes from lettuce and correlate the intensive tissue

browning to the formation of phytoalexins. The formation of lettucenin A and three novel derivatives was induced solely by mechanical injury. With color-dilution analyses, we established the significance of lettucenins in the browning of lettuce. Finally, lettucenin A was quantitated in different varieties of Cichorieae.

MATERIALS AND METHODS

Chemicals. Chemicals of the highest quality available were obtained from Roth (Karlsruhe, Germany), unless otherwise indicated. High-performance liquid chromatography (HPLC)-grade methanol was purchased from Sigma-Aldrich (Taufenkirchen, Germany). Deuterated $CDCl_3$ was obtained from Chemotrade (Leipzig, Germany). For all experiments, ultrapure water was used.

Plant Materials. Commercial varities of lettuce (*L. sativa* L., Romaine, Butterhead, Iceberg, Lollo Rosso, and Lollo Bionda; *C. intybus* L., Radicchio, Sugar Loaf, and Chicory; and *Cichorium endivia* L., Endive and Frisee) were obtained from local markets in Germany. The lettuce heads were prepared for further processing by removing and discarding wrapper leaves and brown spots. For some experiments, the fresh lettuce head was separated into four tissue types: green leaves, yellow leaves, leaf panicles, and butt end. Each lot was cut into squares (1 × 1 cm) using a sharp ceramic knife and mixed thoroughly. For browning, the processed plant materials were packed into Petri dishes and kept at room temperature for 24 and 48 h, respectively. The brown material was stored in freeze bags, freeze-dried, and stored at −20 °C until used.

Extraction of Plant Material. For isolation of colored structures, 100 g of the freeze-dried mix of the entire head of Iceberg was extracted with acetone/water (7:3, v/v, 1.5 L) at 5 °C for 24 h under an argon atmosphere. The filtrates were concentrated under reduced pressure (<30 °C) until complete evaporation of acetone. The residual aqueous solution was successively extracted with diethyl ether (2 × 200 mL) and ethyl acetate (2 × 200 mL). The diethyl ether and ethyl acetate extracts were evaporated to dryness, and the residues (1500 mg of diethyl ether extract and 600 mg of ethyl acetate extract) were used for multilayer countercurrent chromatography (MLCCC).

For comparative studies on browning, 1 g of freeze-dried material of 24 and 40 h aged sliced tissue types of Iceberg lettuce was extracted with 10 mL of acetone/water (7:3, v/v) at 5 °C under an argon atmosphere. After 24 h, the samples were centrifuged at 4500 rpm for 10 min. A 1 mL aliquot of the clarified supernatant was dried under argon stream. The residue was extracted 2 times with 2 mL of diethyl ether. The combined diethyl ether phases were dried under an argon stream.

Analytical HPLC−Diode Array Detection (DAD)−Mass Spectrometry (MS). A Jasco system (Jasco, Gross-Umstadt, Germany) with a quaternary gradient unit PU 2080, a degasser DG 2080-54, an autosampler AS 2055, a column oven (Jasco Jetstream II), and a multiwavelength detector MD 2015 was used. Alternatively, the detector was coupled to an API 4000 triple quadruple mass spectrometer (Applied Biosystems, Foster City, CA). Chromatographic separations were performed on stainless-steel columns (Vydac CRT, 218TP54, 250 × 4.0 mm, RP-18, 5 μm, Hesperia, CA) using a flow rate of 1.0 mL/min. The mobile phase consisted of water (solvent A) and MeOH/water (7:3, v/v, solvent B). To both solvents (A and B), 0.8 mL/L of formic acid was added. Samples were analyzed using a gradient system: samples were injected at 50% B and held for 10 min. The gradient was changed linear to 100% B in 60 min and held at 100% B for 10 min. The column temperature was always 25 °C. The effluent was monitored at 280 and 420 nm.

MS ionization was achieved using the turbospray ionization source operated in positive-ion mode. Turbospray settings were as follows: curtain gas (N_2) at 40 psi, ion source gas 1 at 50 psi, ion source gas 2 at 60 psi, source temperature at 500 °C, and ion spray voltage at 4500 V. The total ion current (TIC) chromatogram with a scan range between m/z 100 and 700 and mass spectral data on precursor ions were detected. Declustering potential, entrance potential, collision energy, and cell exit potential were optimized for each analyte. For evaluation, we used Analyst software and Borwin−PDA software.

Quantitation of Lettucenins A and B. For quantitation, the samples were analyzed with HPLC using DAD, as described above. The phytoalexins eluted with a retention time of 22.8 min (lettucenin B) and 27.0 min (lettucenin A). Standard solutions were prepared in methanol. The amounts of lettucenins A and A1 were calculated on the basis of the published molar extinction coefficient of lettucenin A.[12] For quantitation of lettucenins B and B1, the authentic isolated standards were used.

MLCCC. The MLCCC system (Ito, multilayer separator−extractor model, P.C., Inc., Potomac, MD) was equipped with a constant flow pump (Waters 6000 A, Waters Corporation, Milford, MA), a Kontron spectrophotometer (Kontron 432, Kontron-Instruments, Rossdorf, Germany) operating at 420 nm, and a sample injection valve with a 10 mL sample loop. Eluted liquids were collected in fractions of 8 mL with a fraction collector (LKB Ultrorac 7000, LKB-Producter AB, Stockholm-Bromma, Sweden). Chromatograms were recorded on a plotter (Servogor 200, GMC, Nürnberg, Germany). The multilayer coil was prepared from a 1.6 mm inner diameter polytetrafluoroethylene (PTFE) tubing. The total capacity was 290 mL. MLCCC was run at a revolution speed of 790 rpm and a flow rate of 2 mL/min in head-to-tail modus.

Samples of 500 mg of dried extract were dissolved in a 1:1 mixture of light and heavy phase (10 mL) and injected into the system. Diethyl ether extracts were separated using *n*-hexane/ethyl acetate/methanol/water (3:5:3:5, v/v/v/v, solvent system A), and ethyl acetate extracts were isolated using *n*-hexane/ethyl acetate/methanol/water (4:5:4:5, v/v/v/v, solvent system B). The purified materials (fractions 35−40) were evaporated to dryness, and the residues (5−15 mg) were used for preparative HPLC−ultraviolet (UV).

Preparative HPLC−UV. A Besta HD 2-200 pump (Besta, Wilhelmsfeld, Germany) was used at a flow rate of 15 mL/min. Elution of materials was monitored by an UV detector set at 420 nm (Jasco UV-2075, Gross-Umstadt, Germany). Up to 20 mg of the above material from MLCCC was injected. Chromatographic separations were performed on a stainless-steel column (Vydac CRT, 218TP1022, 250 × 23 mm inner diameter, RP-18, 10 μm, Hesperia, CA). The mobile phases used were solvents A and B, identical to the analytical HPLC−DAD system. An isocratic method was chosen according to the characteristics of the target structures. From the individual chromatographic fractions, solvents were removed under reduced pressure. After the addition of diethyl ether, combined solutions of lettucenins were dried under argon stream.

Accurate Mass Determination [High-Resolution Mass Spectrometry (HRMS)]. The high-resolution positive- and negative-ion electrospray ionization (ESI) mass spectra were obtained from a Bruker Apex III Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer (Bruker Daltonics, Billerica, MA) equipped with an infinity cell, a 7.0 T superconducting magnet (Bruker, Karlsruhe, Germany), a radio frequency (RF)-only hexapole ion guide, and an external electrospray ion source (APOLLO, Agilent, off-axis spray). Nitrogen was used as the drying gas at 150 °C. The samples were dissolved in methanol, and the solutions were introduced continuously via a syringe pump at a flow rate of 120 μL/h. The data were acquired with 256 000 data points and zero-filled to 1 024 000 by averaging 32 scans.

Nuclear Magnetic Resonance (NMR) Spectroscopy. NMR experiments were performed on a Bruker Avance III 800 NMR spectrometer (Bruker, Rheinstetten, Germany) operating at 800 MHz for ^1H and 200 MHz for ^{13}C, respectively. Samples were dissolved in $CDCl_3$, and all spectra were run at 27 °C. Chemical shifts are given relative to external Me_4Si and were referenced to internal $CDCl_3$ (^1H, δ = 7.260 ppm; ^{13}C, δ = 77.160 ppm).

Color-Dilution Analysis. An aliquot (50 μL) of diethyl ether extract was analyzed by HPLC−DAD for determination of the color-dilution factor (CD factor). Fractions (1 mL) with material exhibiting absorption maxima at 420 nm were then stepwise 1:1 diluted with solvent B. The test was carried out in daylight against a white background. Each dilution was visually judged until the color

difference between the diluted fraction and two blanks of solvent B could just be visually detected using a triangle test. This dilution was defined as the CD factor. The CD factors evaluated by five different panelists in two independent sessions were averaged. For assignment of the total color-dilution factor (CD_{total} factor), 50 μL of diethyl ether extract was diluted to 1 mL and treated as described above.[19]

RESULTS AND DISCUSSION

Browning of Lettuce Tissues. For the following studies, conventional Iceberg lettuce was sliced and browned at room temperature. After 24 h, the sliced and bruised areas of the plant material showed significant discoloration. To explain the discoloration, 24 h aged sliced Iceberg lettuce was compared to fresh sliced Iceberg lettuce. For this purpose, freeze-dried plant material was extracted as described above. The final diethyl ether extracts were screened for colored structures by analytical HPLC–DAD (Figure 1). A direct comparison of chromatograms A and B at 420 nm shows that, in browned lettuce, different visible absorbing compounds were detected. Because of the absorption maxima between 400 and 440 nm, these structures are indeed responsible for the discoloration (Figure 2). In the context of enzymatic browning, yellow structures with similar UV/vis spectra were previously presented in the literature but structural analysis was not performed.[17] For structure elucidation, the brown soluble compounds were isolated from the diethyl ether and ethyl acetate extracts of Iceberg lettuce.

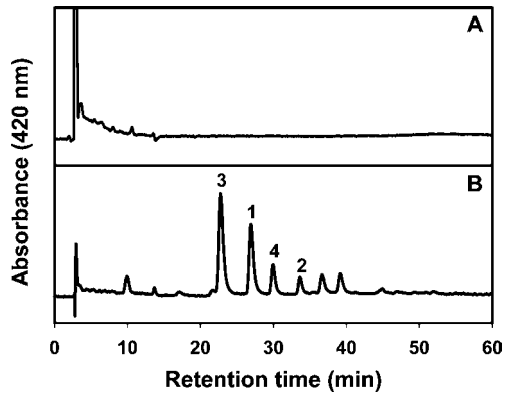

Figure 1. HPLC–DAD chromatogram of (A) acetone/water extract from fresh sliced Iceberg lettuce at λ = 420 nm and (B) acetone/water extract from 24 h aged sliced Iceberg lettuce at λ = 420 nm. Retention times are given in parentheses: (**1**) lettucenin A (27.0 min), (**2**) lettucenin A1 (33.7 min), (**3**) lettucenin B (22.8 min), and (**4**) lettucenin B1 (30.0 min).

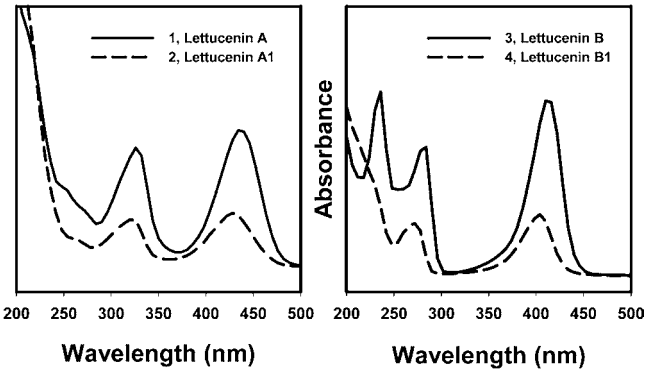

Figure 2. UV/vis spectra of (**1**) lettucenin A, (**2**) lettucenin A1, (**3**) lettucenin B, and (**4**) lettucenin B1.

Isolation and Elucidation of Colored Compounds. The first step of purification was separation by MLCCC using solvent system A for ethyl acetate extracts and solvent system B for *n*-butanol extracts. Afterward, fractions containing the yellowish brown material were separated by preparative HPLC to isolate pure substances. The final structural evidence was achieved by ^{1}H and ^{13}C NMR measurements, as well as heteronuclear single-quantum coherence (HSQC), heteronuclear multiple-bond correlation (HMBC), and homonuclear correlation spectroscopy (H,H COSY) techniques.

Four structures were verified (Figure 1): lettucenin A (**1**) and three derivatives A1 (**2**), B (**3**), and B1 (**4**). Thus far, only compound **1** has been isolated from Iceberg lettuce. NMR data of compound **1** were in line with the study by Takasugi et al. Lettucenin A is a phytoalexin that was identified in Iceberg lettuce for the first time in 1985,[12] but no other structures have yet been published.

Compounds **1**–**4** were isolated as unstable yellowish crystalline substances with concentrations ranging between 0.1 and 6.0 μg/g of fresh weight (FW) as determined by HPLC–DAD. HPLC/ESI–MS delivered for compound **1** a pseudo-molecular ion of m/z 241.2 $[M + H]^+$. This finding was confirmed by HRMS (found, m/z 241.08608 $[M + H]^+$; calculated, m/z 241.08592 $[M + H]^+$, for $C_{15}H_{13}O_3$). In comparison, HRMS gave a pseudo-molecular ion of m/z 243.2 $[M + H]^+$ for compound **3** (found, m/z 243.10157 $[M + H]^+$; calculated, m/z 243.10157 $[M + H]^+$ for $C_{15}H_{15}O_3$). HPLC/ESI(+)–tandem mass spectrometry (MS^2) experiments verified a dominant CO loss of 28 mass units for both compounds $[M + H - 28]^+$ (Table 1). The degree of unsaturation (DU) was calculated from the molecular formulas. The DUs of compounds **1** and **3** were 10 and 9, respectively. The absence of a double bond in compound **3** was also reflected in the UV/vis spectrum. The absorption maximum shifted from 440 nm for compound **1** to 416 nm for compound **3** (Figure 2). ^{1}H NMR experiments of compounds **1** and **3** confirmed the difference of a double bond between C-4 and C-15. For compound **3**, at position C-4, an additional proton was detected and, at position C-15, a methyl group was identified, which coupled with the proton at C-4 to give a doublet (1.35 ppm, d; Table 2). This was different from lettucenin A, which clearly showed a methylene signal for H-15 (5.92 ppm, m; 6.67 ppm, m). The remaining signals of compound **3** corresponded to the pattern of lettucenin A.

With regard to all results, compound **3** boasts the same basic ring structure as lettucenin A with the difference of saturation between C-4 and C-15 (Figure 3) and was unequivocally assigned to 2,7,8,9-tetrahydro-6,9-dimethyl-2-oxo-azuleno[4,5-*b*]furan-3-carboxaldehyde. We have named compound **3** lettucenin B because of the structural similarity to lettucenin A.

HPLC/ESI–MS delivered for compounds **2** and **4** pseudo-molecular ions of m/z 271.1 and 273.1 $[M + H]^+$, respectively. These findings were confirmed by HRMS (found for compound **2**, m/z 271.09649 $[M + H]^+$; calculated, m/z 271.09649 $[M + H]^+$, for $C_{16}H_{15}O_4$; found for compound **4**, m/z 273.11214 $[M + H]^+$; calculated, m/z 273.11214 $[M + H]^+$, for $C_{16}H_{17}O_4$; Table 1). In parallel to compounds **1** and **3**, compounds **2** and **4** also showed a difference of m/z 2 to indicate an absent double bond. HPLC/ESI(+)–MS^2 experiments verified parallel losses of 14 and 32 mass units for both

[a]All spectra were recorded at 800 MHz in $CDCl_3$ in ppm. δ, chemical shift; J, coupling constant. Hydrogen/carbon assignments were verified by HMBC, HSQC, H,H COSY, and attached proton test (APT) measurements.

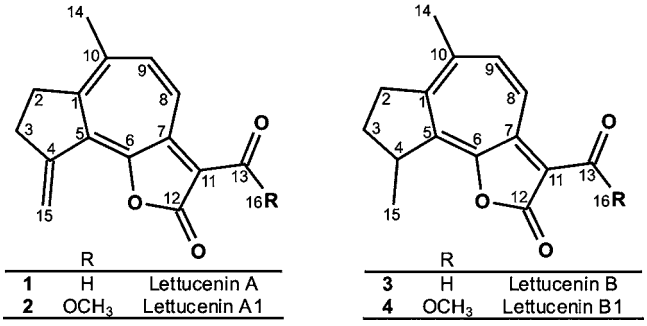

Figure 3. Isolated chromophores from processed Iceberg lettuce.

compounds **2** and **4** (Table 1). $[M + H - 32]^+$ is a characteristic fragment of methyl esters.[18]

Indeed, a methoxy group was verified for compound **4** by ^{1}H and ^{13}C NMR experiments downfield at 3.93 and 51.7 ppm, respectively, in addition to the ^{1}H and ^{13}C NMR signal pattern of lettucenin B (Tables 2 and 3). A simultaneous high-field shift of C-13 from 186.0 to 165.0 ppm and HMBC correlations between C-16 and C-13 as well as C-11 unequivocally established the proposed methyl ester and was assigned to 2,7,8,9-tetrahydro-6,9-dimethyl-2-oxo-azuleno[4,5-*b*]furan-3-carboxylic acid methyl ester. Therefore, we call compound **4** lettucenin B1.

Because of the low quantities of compound **2** found in processed lettuce, it was not possible to isolate enough material for NMR studies. Nevertheless, in comparison of the UV/vis spectra of compound **1** to compound **3** and compound **2** to compound **4**, the absorption maxima shift from 440 to 416 nm and from 428 to 404 nm, respectively; i.e., there was the same difference of 24 nm in both pairs (Figure 2). In parallel to compound **1**, this indicated an extra double bond for compound **2**. In comparison of compound **1** to compound **2** and compound **3** to compound **4**, each with an identical UV/vis pattern, compounds **2** and **4** showed a hypsochromic shift of 12 nm. These parallels together with the HRMS, MS^2, and UV/

vis data strongly proposed compound **2** as the methyl ester of lettucenin A, as shown in Figure 3.

Influence of Lettucenins to Discoloration. To determine the contribution of lettucenins to the overall color of browned Iceberg lettuce, color-dilution analysis was performed (Figure 4).[19,20] CD factors were analyzed in the diethyl ether

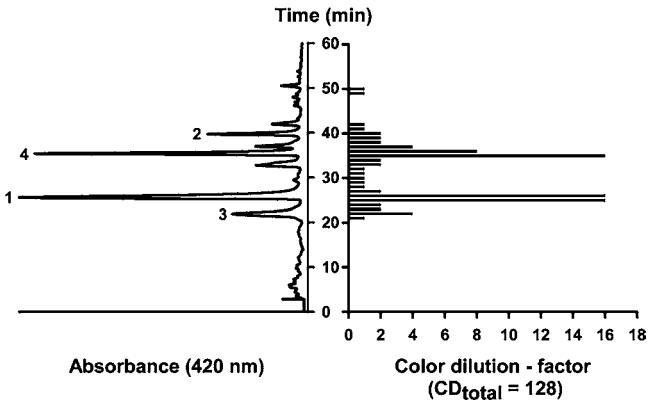

Figure 4. HPLC–DAD chromatogram (λ = 420 nm; left side) and color-dilution chromatogram (right side) of the diethyl ether extract of 24 h aged sliced Iceberg lettuce.

extract by a panel of five people. At 420 nm, chromophores were detected, which accounted for more than 50% of the total color of the diethyl ether extract. The structurally identified compounds **1**–**4** contributed 40% to the overall color (with the lead compound lettucenin A even at 25%). This means that the difference of 10% was related to the remaining unknown signals. In addition, in the total water/acetone extract, compounds **1**–**4** explained 25% of the overall color. This means that lettucenins are important coloring agents in the browning of Iceberg lettuce.
