HPLC Analysis. The high-performance liquid chromatography (HPLC) method[9] with minor modification was employed to determine the content of isoflavones. The HPLC used was equipped with a C18 column (4.6 mm × 250 mm, YMC-Pack ODS-AM, S-5 μm, YMC Co., Tokyo, Japan), a UV−vis detector (UV-2075 Plus, Jasco, Tokyo, Japan), and a chromatography data processor (EC 2000, Analab Co., Taipei, Taiwan). Linear concentration gradient in mobile phase was conducted by using two solutions: (A) 0.1% glacial acetic acid in deionized H_2O and (B) 0.1% glacial acetic acid in acetonitrile. After a 20 μL sample was injected into the column, a percentage of solvent B was increased from 15% to 20% in 20 min, successively increased to 24% in 10 min, and held for 4 min then further increased to 35% in 10 min and held for 8 min, and finally reduced to 15% in 5 min and held for 3 min. The total time was 60 min. The flow rate of the mobile phase was 1.0 mL/min.

Statistical Analysis. Data were reported as the mean of measurements in triplicate. One-way analysis of variance (ANOVA)

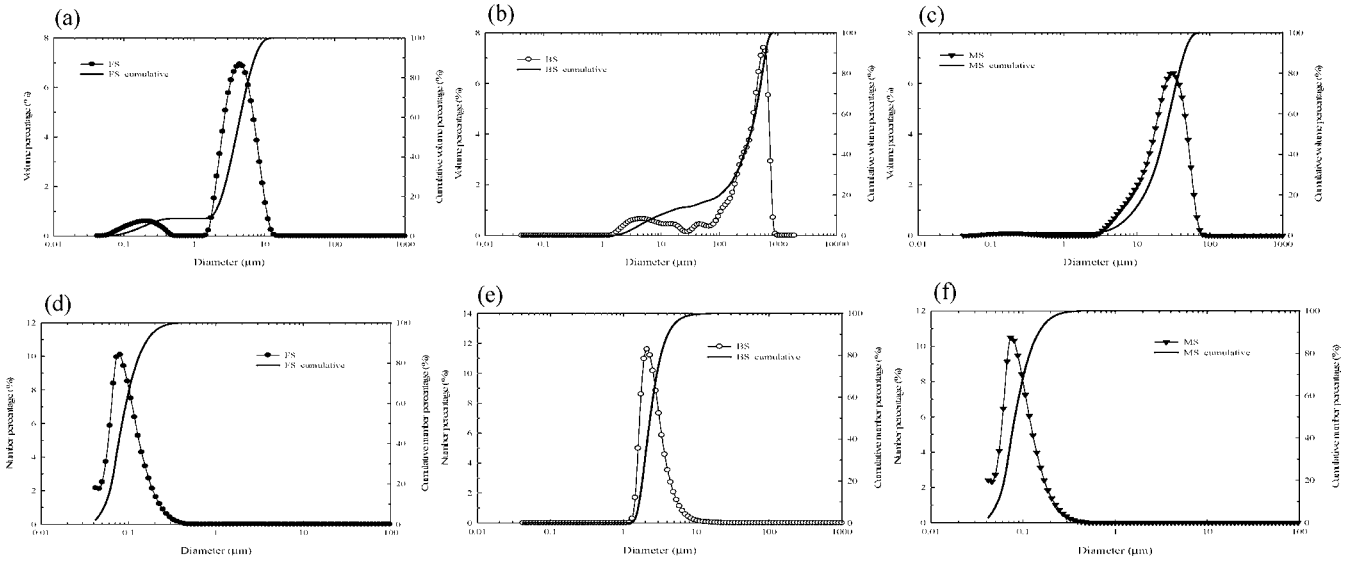

Figure 1. Particle size distribution: (a−c) volume and (d−f) number of (a,d) filtered (FS), (b,e) blended (BS), and (c,f) media-milled (MS) soymilk.

was used to determine the significance of treatment using the Statistical Analysis System (SAS version 9.1; SAS Institute Inc., Cary, NC), followed by a Duncan's new multiple range test. Differences were considered as statistically significant when the P value was <0.05.

RESULTS AND DISCUSSION

Particle Size Distribution (PSD). FS exhibited a bimodal distribution in terms of volume with a volume-mean diameter of 4.40 ± 2.39 μm and largest particle of 16.4 μm (Figure 1a), which was similar to the data in the literature.[14,29] Small particles ranged from 0.042 to 0.571 μm, and large particles ranged from 1.321 to 16.4 μm. The percentage of small particles was 8.8%. The presence of a two particle range might induce instability of soymilk. The particle size distribution in terms of number provided the evidence that almost all the particles (99.93%) were smaller than 1 μm with a number-mean diameter of 0.103 ± 0.086 μm. The percentage of the number of particles smaller than 0.1 μm was about 65% (Figure 1d). The grinding generated ultrafine particles, and the removal of large particles by filtration resulted in high percentage of nanoparticles. That was similar to commercial soymilk in Taiwan. BS exhibited similar bimodal size distribution (in volume) but with a much greater volume-mean diameter of 348 ± 227 μm (Figure 1b) and with most of particles ranging from 100 to 1000 μm. Because of fast precipitation, particles greater than 1000 μm were not detected during size measurement. The largest particle was about 905 μm, and there were no particles smaller than 1 μm (Figure 1e). Media-milling resulted in a skewed particle size distribution in terms of volume (Figure 1c) with a volume-mean diameter of 26.6 ± 14.6 μm. Apparently, there existed very few particles smaller than 1 μm. Thus, the size distribution was monomodal. Most of the particles ranged from 2.313 to 87.9 μm. The presence of larger particles in MS was due to greater content in fiber. The monomodal size distribution might let the product exhibit reasonable stability. Nevertheless, the size distribution (Figure 1f) in terms of number was similar to that of FS with most of particles (99.97%) smaller than 1 μm. The number-mean diameter was 0.099 ± 0.095 μm with 68% of particles smaller than 0.1 μm. The data indicated that media-milling resulted in a soymilk similar to FS in terms of particle size.

Morphology. FS appeared to be well dispersed (Figure 2a) due to the removal of coarse particles by filtration. Nonetheless, there existed unbroken cell walls or fibers (about 200−300 μm)

dx.doi.org/10.1021/jf404465w | J. Agric. Food Chem. 2014, 62, 742−749

in BS (Figure 2b). The force exerted by the high-speed blender was not adequate to break the fibrillar structure. Media-milling did break soybean structure down to the nano/submicrometer scale (Figure 2c). There was no precipitation observed for FS and MS (Figure 2d), but precipitation occurred remarkably in BS. The morphology of three samples were further examined by using a scanning electron microscope (SEM). Both FS (Figure 3a,b) and MS (Figure 3e,f) exhibited similar

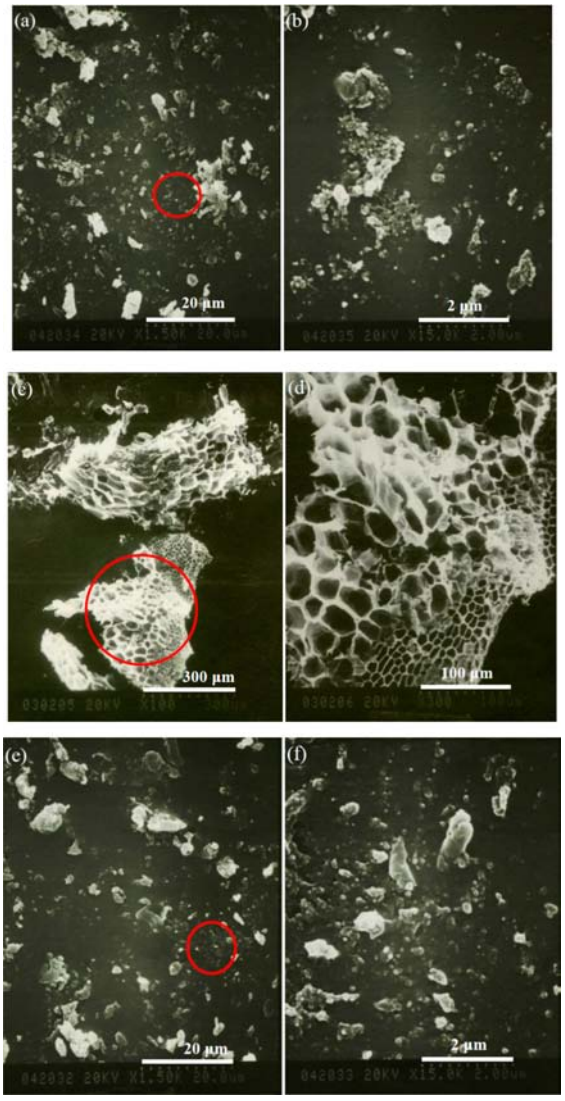

Figure 3. SEM micrographs of (a) filtered, (c) blended, and (e) media-milled soymilk. (b,d,f) Enlargement of circle portion in (a), (c), and (e), respectively.

morphology and particle size. Although there were some particles greater than 1 μm, most particles were smaller than 1 μm (Figure 3b,f). In BS, there were large particles (greater than 300 μm) which appeared to be cell walls (Figure 3c,d). SEM confirmed the presence of nano/submicrometer particles in FS and MS.

Physical Properties. As described previously, a constant percentage (10.89% db) of soybean was used to prepare all soymilk samples. The solid contents in BS (10.61%) and MS (10.72%) were similar due to retaining the whole soybean with minimum okara. The solid content in FS was 8.24%, indicating a solid loss more than 20%. The filtration resulted in more okara and low solid recovery (75.67 ± 0.74%), which was close to that (74.48%) reported by Wang and Murphy.[10] The viscosity (160.59 ± 4.26 cps) of MS was about 38-fold of that (4.22 ± 0.02 cps) of FS, probably due to greater content in solid and fiber, which have been shown to exhibit high swelling power[30] and water retention capacities[31] as well as viscosity. Because of fast precipitation, the viscosity of BS was not determined. The solid content did affect the viscosity of MS (Figure 4). The viscosity of MS was increased linearly with

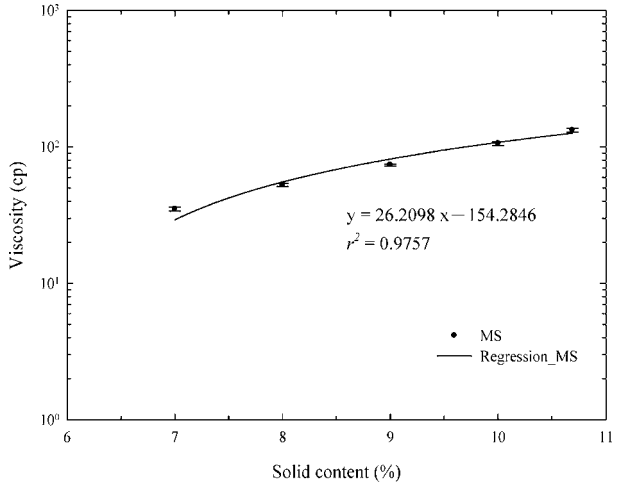

Figure 4. Viscosity versus solid content of media-milled (MS) soymilk.

solid content with a coefficient of determination (r^2) of 0.98. Calculated from Figure 4, the viscosity of MS at 8.24% solid was 61.68 cps, which was much greater than that of FS. The data indicated that the presence of fiber resulted in high viscosity. Via media-milling, less soybean was needed to achieve similar viscosity of FS.

Heating or autoclaving are required in commercial processes. To minimize the effect of solid content on the properties measured, the solid contents of all the samples were adjusted to about 7% before autoclaving. Both solid content and pH were not significantly altered by autoclaving (Table 1). The viscosity

Table 1. Solid Content, Viscosity, and pH[a] of Filtered (FS), Blended (BS), and Media-Milled (MS) Soymilk[b] before and after Autoclaving

sample	autoclaving[c]	solid content (%)	viscosity[d] (cp)	pH
FS	before	7.04 ± 0.02a	2.91 ± 0.08c	6.44 ± 0.03b

	after	7.05 ± 0.07a	38.97 ± 1.50a	6.50 ± 0.01ab

[a]Mean ± standard deviation (n = 3). Values in the same column with different lowercase letters (in a, b ,and c) were significantly different by Duncan's new multiple range test (p < 0.05). [b]The concentration of soybean slurry using to soymilk production was 10.89%. [c]Soymilks were adjusted to 7% (w/w) before autoclaving for minimizing the effect of solid content. [d]Viscosity was measured at shear rate 100 s^{-1}. [e]NA, not available. Viscosity of blended sample was undetectable due to fast precipitation.

dx.doi.org/10.1021/jf404465w | J. Agric. Food Chem. 2014, 62, 742−749

of both FS and MS were increased after autoclaving, probably due to denaturation of protein. After autoclaving, FS exhibited a viscosity of 4.26 cps, which was close to that of heated soymilk (3.56 cps) measured by Toda et al.[14] and were greater than those (1.77−2.55 cps) of soymilks produced from six soybean cultivar.[32] The viscosity of MS (38.97 ± 1.50 cP) was much greater than that of FS due to higher content of dietary fibers.

The stability of soymilk was elucidated by the change in the backscattered-light intensity difference ($\Delta I_{t\text{-}0\ min}$) with time (Figure 5). Without heat treatment, there existed a rapid increase in $\Delta I_{t\text{-}0\ min}$ (Figure 5a) for BS during 95 min, which indicated the occurrence of fast precipitation. Then, $\Delta I_{t\text{-}0\ min}$ reached a plateau, probably due to the completion of precipitation. Nevertheless, autoclaving resulted in a continuous increase in $\Delta I_{t\text{-}0\ min}$ (Figure 5b) showing slow precipitation. The data illustrated that BS was not stable and was not appropriate for commercial use. FS was more stable than BS. The $\Delta I_{t\text{-}0\ min}$ of FS slightly decreased at the beginning, then increased gradually, but increased remarkably after 500 min (Figure 5a) due to precipitation. MS appeared to be the most stable among three samples. There existed a slight decrease in $\Delta I_{t\text{-}0\ min}$ in 300 min. Afterward, the change in $\Delta I_{t\text{-}0\ min}$ was minimum, which indicated the stability of MS due to high viscosity and fine particles. Autoclaving reduced the floating and made both FS and MS be more stable. Heating has been shown to improve the stability of soymilk.[29]

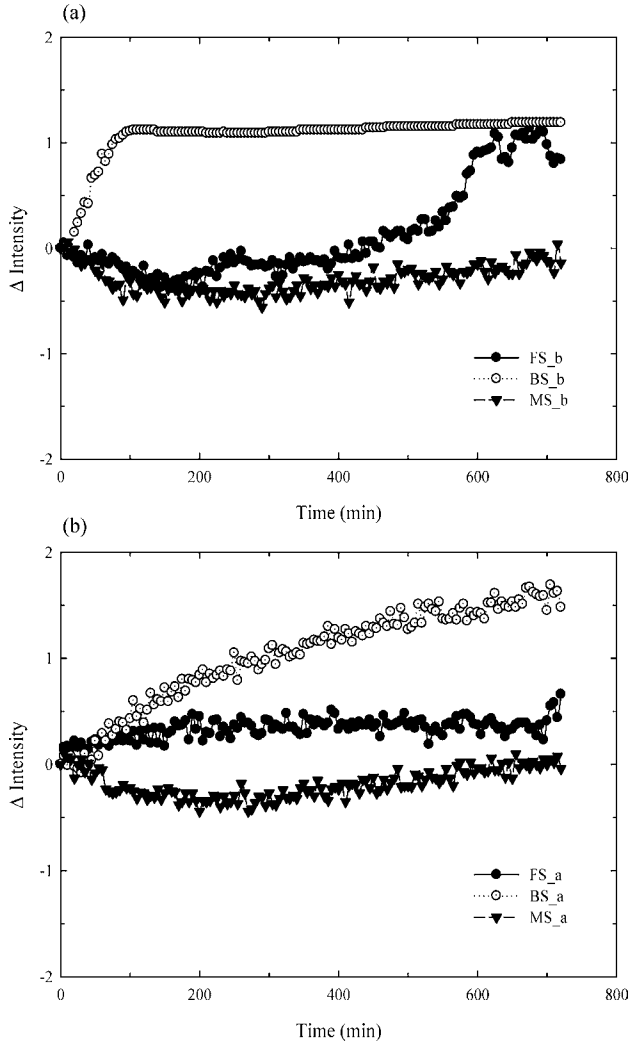

Figure 5. Stability of filtered (FS), blended (BS), and media-milled (MS) soymilk (a) before and (b) after autoclaving.

Composition Analysis. There was no okara during processing, and the compositions of BS and MS were similar to those of soybean flour in terms of crude protein, total dietary fiber, and ash (Table 2). The data of total dietary fiber were close to those (21.1−23.2%) reported by Van der Riet et al.,[17] who pointed out that the dietary fiber content in okara ranged from 52.8 to 58.1% (composed by 40.2−43.6% of insoluble dietary fiber). FS was high in crude fat but low in total dietary fiber (including insoluble and soluble fiber). Compared with soybean flour, MS appeared to have higher content of soluble dietary fiber (4.65 ± 0.79%), probably due to intensive shearing forces during media-milling.

Total Polyphenol Content. The total polyphenol content in soybean flour was 3.30 ± 0.12 mg GAE/g dry solid. In other words, there were 35.94 mg GAE in a 100 g mixture of water and soybean flour. The measurements were slightly greater than literature data (2.15−2.99 mg GAE/g).[33,34] On the basis of the weight of dry solid, FS exhibits the most total polyphenol content among three samples (Table 3). Most of phenolic compounds were not removed by filtration and were reserved in the product.[33,34] Thus, it was reasonable to obtain a high amount of polyphenol in FS. Although BS and MS exhibited similar composition and solid content, MS had higher total polyphenol content than BS. Autoclaving resulted in 7−11% (including three samples) loss of polyphenol due to thermal effect.[33,34] However, on the basis of 100 g of soymilk for general consumption, MS had the highest total polyphenol content among three samples due to highest solid content. Compared with soybean flour, media-milling resulted in the greatest recovery of total polyphenol due to no okara produced and full breakage of the fibrous structure of soybeans by shearing forces. The results were similar to the impact of severe processes (such as steam explosion and high-pressure steam-

ing) generating considerable breakdown of lignocelluloses structure, depolymerization of lignin (a category of phenolic derivates), and defibration and increasing in water-soluble phenolic compounds.[33,35,36]

Isoflavone Content. Isoflavone is a major bioactive compound in soybeans and related products. There were almost no aglycone and low acetylglucoside in soybean flour (Table 4). Processes resulted in the loss of total isoflavone. Compared with soybean flour, the contents of glucoside, malonylglucoside, and acetylglucoside in FS, BS, and MS were significantly decreased. Nevertheless, the content of aglycone in three samples increased and MS yielded the most aglycone. Grinding might raise the activity of β-glucosidase(glucan endo-1,6-β-glucosidase)[37,38] and thus resulted in an increase in unconjugated aglycone (daidzein, genistein, and glycitein). As reported in the literature,[11,33] heating resulted in the loss of isoflavone. After autoclaving, the loss of total isoflavone contents in three samples ranged from 10 to 13%. Autoclaving affected the profile of four categories of isoflavone. Malonylglucoside and aglycone were reduced, but glucoside was increased. Acetylglucoside was not affected significantly. The phenomena were similar to those reported in the literature.[10,33,34,39,40] Among three samples, the percentage of loss of aglycone in FS was the highest (about 65%). This might be the reason why the content of aglycone in commerical soymilk was low. The content of aglycone in MS was the greatest one among three samples, which would be beneficial to human health.

As the price of crops has appreciated in recent years, yield would be a key factor on choosing appropriate process. The total isoflavone conserved in autoclaved FS, BS, and MS from the starting materials was 44.95, 61.09, and 65.83%, respectively. The low recovery of isoflavone in FS was due to the discarding of okara in which there was about one-third of total isoflavone of soybeans and a high proportion of aglycone,[11] probably due to low solubility of aglycone (about 3 μM for geistein and 10 μM for daidzein) in pure water.[41] High recovery of agyclone in MS indicated that media-milling could preserve resources.

Aglycone has been found to exhibit the highest bioavailability among isoflavones.[42,43] Genistein has been found to exhibit more antioxidation capacity than daidzein.[12] In addition, it is the major compound for the chemopreventive efficacy of soy[44] and has been found to exhibit anticancer effects via in vitro and in vivo studies.[8,45] The rise in the content of genistein in MS might increase the health benefits of the product. To decrease serum cholesterol levels and to prevent coronary heart disease (CVD), the USFDA has recommended a daily intake of 25 g of soy protein[46] with about 87.5 mg of isoflavones,[47−51] which is near the daily isoflavones consumption (40−80 mg/day) by Asian people.[52] To achieve a similar purpose, the daily consumption of three soymilks would be 311.72 mL of FS, 229.24 mL of BS, or 212.43 mL of MS. It appeared that the utilization of media-milling could save the use of soybean and thus reduce the cost of production.

ABSTRACT: Fatty liver may have implications for metabolic syndrome, such as obesity, hypertension, and diabetes. Therefore, the development of pharmacological or natural agents to reduce fat accumulation in the liver is an important effort. The *Sechium edule* shoots have already been verified to decrease serum lipids and cholesterol and prevent atherosclerosis. However, how *Sechium edule* shoots modulate hepatic lipid metabolism is unclear. This study was designed to investigate the effects and mechanisms of polyphenol extracts (SPE) of *Sechium edule* shoots in reducing lipid accumulation in oleic acid-treated HepG2 cells. We found that water extracts (SWE) of *Sechium edule* shoots could decrease serum and hepatic lipid contents (e.g., triacylglycerol and cholesterol). Furthermore, SWE and SPE through the AMPK (AMP-activating protein kinase) signaling pathway could decrease lipogenic relative enzymes, such as FAS (fatty acid synthase), HMGCoR (HMG-CoA reductase), and SREBPs (sterol regulatory element binding proteins), and increase the expression of CPT-I (carnitine palmitoyltransferase I) and PPARα (peroxisome proliferators activated receptor α), which are critical regulators of hepatic lipid metabolism. These observations suggested that *Sechium edule* shoots have potential for developing health foods for preventing and remedying fatty liver.

KEYWORDS: *SPE (polyphenol extracts of Sechium edule shoots), SWE (water extracts of Sechium edule shoots), AMPK, FAS, HMGCoR, SREBPs*

INTRODUCTION

Excessive lipid may accumulate in liver,[1] leading to obesity-associated fatty liver disease (FLD).[2] Fatty liver is closely associated with life-style-related diseases such as hyperlipidemia, hypertension, arteriosclerosis, type 2 diabetes mellitus, and cancer.[3,4] Fatty liver has a strong positive relationship to outbreaks of hepatitis, cirrhosis, and cancer.[5] The fat that accumulates can cause inflammation and scarring in the liver. At its most severe, nonalcoholic fatty liver disease (NAFLD) can progress to liver failure.[6] Therefore, prevention and treatment of lipid accumulation in liver are relevant to health promotion.

Previous research showed that the hepatic TG (triacylglycerol) content is significantly correlated with plasma TG levels and fat mass in humans.[7] As we know, the hepatic TG availability is controlled by the balance between FAS and oxidation in the liver.[8] The underlying cause of fat accumulation in NAFLD is mostly due to the synthesis of fatty acids and inhibition of fatty acid oxidation.[9] Several recent studies have demonstrated transcriptional regulation of the gene for the enzymes of synthesis of fatty acids, including FAS (fatty acid synthase) and glycerol-3-phosphate acyltransferase (GPAT), by sterol regulatory element binding proteins (SREBPs).[10,11] Activation of FAS through modulation of SREBP-1 has been reported in human breast cancer.[12] The transcription factor peroxisome proliferators activated receptor (PPAR) is expressed at very low levels in the liver, and overexpression of this transcription factor in the liver leads to hepatic adipose accumulation with the expression of several adipogenic genes in the liver.[13] SREBP-1 can modulate the enzymes of lipid production, such as FAS and GPAT, and can affect the formation of fatty acids and TG. In addition, SREBP-1 not only regulates the formation rate of TG but also determines whether TG can be released from the liver.[14,15] SREBP-2 regulates the generation of cholesterol metabolism-related proteins such as HMG-CoA reductase (HMGCoR) and low density lipoprotein receptor (LDLR).[16,17] SREBP plays an important role in the process of controlling the formation of fatty liver. PPARs are the sensors of in vivo lipids. They control the related gene, carnitine palmitoyltransferase (CPT), in lipid oxidation and thus play a role in regulating lipid metabolism, which controls

almost all aspects in fatty acid metabolism.[18] AMP-activating protein kinase (AMPK) phosphorylates and inactivates a number of metabolic enzymes involved in ATP-consuming cellular events including fatty acid and cholesterol synthesis, involving FAS[19] and HMGCoR.[20] The activation of the AMPK pathway is necessary to prevent fat accumulation.

The *Sechium edule* shoots contain many nutritional components including flavonoids, which are known as a powerful polyphenol and antioxidant.[21] It is useful as a complementary treatment for arteriosclerosis and hypertension and as a diuretic and anti-inflammatory remedy.[22,23] It has already been verified to decrease serum lipid and cholesterol and prevent atherosclerosis.[22] However, how components of *Sechium edule* shoots modulate hepatic lipid metabolism is unclear.

We examined the effect of the SWE and SPE on hepatic hypolipidemia. Human HepG2 cells were treated with indicated concentrations of SWE and SPE in the presence of OA for 24 h. We used this model to elucidate whether SWE and SPE prevents lipid accumulation in hepatic cells.

MATERIALS AND METHODS

Materials. Leaves of fresh *Sechium edule* shoots were collected in Nantou County, located in central Taiwan. The 3-(4, 5-dimethylthiazol-zyl)-2, 5-diphenylterazolium bromide (MTT) and oleic acid were purchased from Sigma-Aldrich (St. Louis, MO, U.S.A.). GPx, SOD, and SREBP antibodies were obtained from Santa Cruz Biotechnology (CA, U.S.A.). Anti-pThr172-AMPK and anti-AMPK antibodies were purchased from Cell Signaling Technology (Beverly, MA, U.S.A). Anti-β-actin, anti-FAS, anti-SREBP-1, anti-GPAT, anti-HMGCoR, SREBP-2, anti-LDLR, and anti-catalase antibodies were purchased from Sigma-Aldrich.

Preparation of SWE and SPE. Fresh leaves were chopped and air-dried under shade and milled to a coarse powder. The powder was used for the preparation of water extracts (SWE) and phenolic extracts (SPE). The powder (20 g) was then subjected to maceration with sufficient volume of distilled water (1000 mL) for 4 °C for 24 h. Then the aqueous extract was filtered and lypophilized to get the yield of 17.24%. For preparation of the SPE, 100 g of dried powder of *Sechium edule* was submerged in 300 mL of ethanol and heated at 50 °C for 3 h. The extract was filtered and thereafter lyophilized under reduced pressure at room temperature. The powder was then resuspended in 500 mL of 50 °C distilled water, followed by extraction with 180 mL of ethyl acetate three times, redissolved in 250 mL of distilled water, stored at 70 °C overnight, and lyophilized. The presence and proportion of the main constituents of SPE were then analyzed by HPLC.

HPLC (High Performance Liquid Chromatography) Analysis. HPLC was performed with a Hitachi HPLC system (Hitachi, Danbury, CT, USA), which consisted of a pump (L-6200A), an ultraviolet detector (L-4250), and the Hitachi D-7000 HPLC System Manager program. A reported procedure was used for analyzing the phenolic acids, using a Mightysil RP-18 GP 250 column (Kanto, Tokyo, Japan) and two mobile phase solvent: solvent A, acetic acid/water (2:98, v/v), and solvent B, 0.5% acetic acid in water/acetonitrile (50:50, v/v). The flow rate was 1 mL/min. The gradient for the separation was 100% solvent A at 0 min, 70% solvent A and 30% solvent B at 5 min, 65% solvent A and 35% solvent B at 50 min, 60% solvent A and 40% solvent B at 55 min, 0% solvent A and 100% solvent B at 60 min, followed by a 5 min postrun with HPLC grade water. Phenolic acids were detected at 260 nm.

Cell Culture. Human HepG2 cells obtained from the American Type Culture Collection were maintained in DMEM supplemented with 10% fetal calf serum, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM L-glutamine and kept at 37 °C in a humidified atmosphere of 5% CO_2. Cells were grown to 70% confluence and then incubated in serum-free medium for 24 h before treatments. To induce FA (fatty acid) overloading, HepG2 cells at 70% confluence were exposed to a long-chain oleic acid (OA). OA/BSA complex was prepared as reported previously.[24] Stock solutions of 1 M OA prepared in culture medium containing 1% BSA were diluted in culture medium to obtain the desired final concentrations. The OA/BSA complex solution was sterile-filtered through a 0.22 μm pore membrane filter and stored at −20 °C.

Cytotoxicity Assay. HepG2 cells were seeded at a density of 1×10^6 cells/mL in 24-well plates and incubated with oleic acid, SPE, and SWE at various concentrations for 24 h. Thereafter, the medium was removed and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, 0.5 mg/mL) was added to incubate for 4 h. The viable cells were directly proportional to the production of formazan. Following dissolution in isopropanol, the absorbance was read at 563 nm with a spectrophotometer (Beckman DU640).

Nile Red Stain. HepG2 cells were seeded in 6-well plates (3×10^6 cells/mL) and treated with 0.6 mM oleic acid and different concentrations of SPE and SWE for 24 h. After the cells were washed twice with PBS, they were fixed with 4% formaldehyde for 30 min and then stained with 40 μg of Nile red solution for 30 min at room temperature. Lipid-bound Nile red fluorescence was observated using inverted fluorescence microscopy.

Preparation of Protein Extract of HepG2 Cells. The proteins of cells were harvested in cold RIPA (radioimmunoprecipitation assay) buffer [1% NP-40 (nonyl phenoxypolyethoxylethanol), 50 mM Tris-base, 0.1% SDS, 0.5% deoxycholic acid, 150 mM NaCl, pH 7.5] containing leupeptin (17 μg/mL) and sodium orthovanadate (10 μg/mL). The cell mixture was vortexed at 4 °C for 4 h. All mixtures were then centrifuged at 12 000 rpm at 4 °C for 10 min, and the protein contents of the supernatants were determined with the Coomassie blue total protein reagent (Kenlor Industries, Inc., USA) using bovine serum albumin as the standard.

Western Blot Analysis. Equal amounts of protein samples (50 μg) were subjected to SDS−polyacrylamide gel electrophoresis and electrotransferred to nitrocellulose membranes (Millipore, Bedford, MA, USA). Membranes were blocked with 5% nonfat milk powder with 0.05% Tween 20 in PBS and then incubated with the first antibody at 4 °C overnight. Thereafter, membranes were washed three times with 0.05% Tween 20 in PBS and incubated with the anti-mouse secondary antibody conjugated to horseradish peroxidase (GE Healthcare, Little Chalfont, Buckinghamshire, U.K.). Bands were detected and revealed by enhanced chemiluminescence using ECL Western blotting detection reagents and exposed ECL hyperfilm in FUJFILM Las-3000 (Tokyo, Japan). Protein quantitation was determined by densitometry using the FUJFILM-Multi Gauge V2.2 software.

Statistical Analysis. Results are reported as the mean ± standard deviation of three independent experiments and statistical comparisons were evaluated by one-way analysis of variance (ANOVA). *P* values less than 0.05 were considered statistically significant.

RESULTS

SWE and SPE Content Assay. The single-ring type of polyphenol compounds (gallic acid, GA) were used to determine the standard content of total polyphenol. The results show (Table 1) that in SWE, the single-ring polyphenol compounds were 4.41% ± 0.02% polyphenol (using gallic acid as the standard), 3.32% ± 0.17% flavonoids (using quercetin and naringenin as the standard), 26.73% ± 2.18% carbohydrate, 4.67% ± 1.46% protein, and 3.25% ± 1.611% lipid.

The analysis of SPE revealed that it contained 17.74% ± 0.05% total polyphenol (using gallic acid as the standard) and 21.10% ± 0.28% flavonoids (using quercetin and naringenin as the standard). The presence and proportion of the main constituents of SPE were then analyzed by HPLC (Figure 1). For the standardization of SPE, the presence of protocatechuic acid (3.56% ± 0.14%), gallocatechin gallate (11.06% ± 0.18%), caffeic acid (4.42% ± 0.25%), rutin (1.14% ± 0.13%), quercetin

dx.doi.org/10.1021/jf404611a | J. Agric. Food Chem. 2014, 62, 750−759

Table 1. Components of SWE and SPE (polyphenol extracts) of *Sechium edule* Shoots

	SWE (%)	SPE (%)
polyphenol (gallic acid as STD)	4.41 ± 0.02	17.74 ± 0.05
flavonoid	3.32 ± 0.17	21.10 ± 0.28
flavone and flavonol	1.54 ± 0.07	4.52 ± 0.07
flavanone and flavanonol	1.78 ± 0.10	16.58 ± 0.21
carbohydrate	26.73 ± 2.18	
protein	4.67 ± 1.46	
lipid	3.25 ± 1.11	

(3.71% ± 0.32%), and naringenin (11.28% ± 1.12%) was confirmed in the SPE.

The Effect of SWE and SPE on Cell Viability of HepG2 Cells. Using different concentrations of SWE and SPE to treat HepG2 cells, after 24 h, we analyzed cell viability. Figure 2A,B showed that from the result of MTT, the drug lethal dose (IC_{50}) of SWE was more than 5 mg/mL and that of SPE was 2.32 mg/mL respectively. This experiment focuses on the premise that intracellular lipid accumulation will not cause any damage to cells. So the follow-up experiment used concentrations of 1 and 5 mg/mL SWE and 0.5 and 1 mg/mL SPE for treatment of HepG2 cells.

Inhibition of OA-Induced Lipid Accumulation by SWE and SPE in HepG2 Cells. The above results showed that the cell growth condition was good, and cell survival rates remained at 100%. Our preliminary work has demonstrated that cell viability is unaffected at a concentration of 0.6 mM OA. Thus, we used 0.6 mM OA and SWE (1 and 5 mg/mL) and SPE (0.5 and 1 mg/mL) to culture HepG2 cells in order to observe the fat accumulation. Figure 3A is the result of using Nile red fluorescent staining to show that fat accumulation altered the red fluorescence with change in fat in cytoplasm in a dose dependent manner. Next, using Nile red staining and flow cytometric analysis to detect the intensity of fluorescence (Figure 3B), we found that the intensity of fluorescence was proportional to fat content. Then, we quantified the intracellular fat content (Figure 3C). The fat content of HepG2 was 2.1 times higher ($*p < 0.05$) than the control group after exposure to OA. SWE treatment of cells at doses of 1 or 5 mg/mL resulted in a reduction of lipid content (92.1% and 84.25%) compared with the OA group ($*p < 0.05$). Treatment with SPE, also reduced lipid content about 88.1% and 83.21% ($*p < 0.05$) compared with the OA group. These results showed that SWE and SPE had the effect of inhibiting intracellular fat accumulation. SPE was more efficient than SWE in causing this effect.

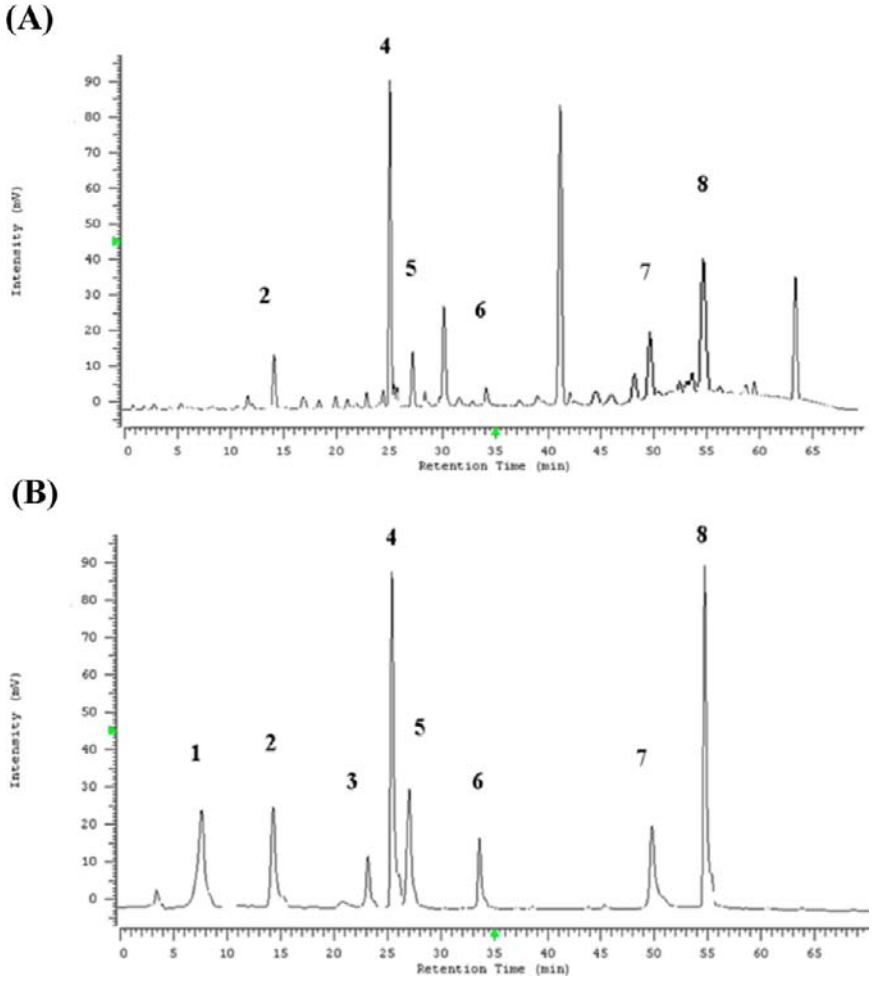

Figure 1. The HPLC chromatogram of SPE (polyphenol extracts of *Sechium edule* shoots). (A) HPLC chromatogram of free polyphenols from SPE (10 mg/mL, 10 μL). (B) HPLC chromatogram of eight kinds of standard polyphenols (1 mg/mL; 10 μL). Peaks: (1) gallic acid; (2) protocatechuic acid; (3) catechin; (4) gallocatechin gallate; (5) caffeic acid; (6) rutin; (7) quercetin; (8) naringenin.

dx.doi.org/10.1021/jf404611a | J. Agric. Food Chem. 2014, 62, 750−759

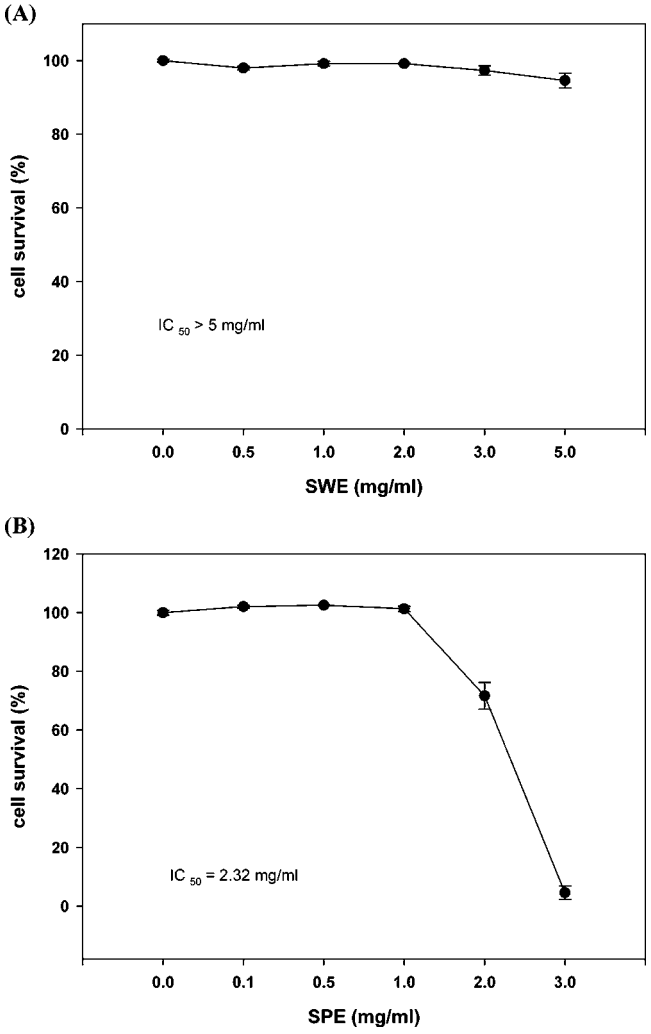

Figure 2. The cytotoxicity effects of SWE (water extracts of *Sechium edule* shoots) and SPE (polyphenol extracts of *Sechium edule* shoots) on human hepatocarcinoma cell line. HepG2 cells were treated with various concentrations of SWE (A) or SPE (B) for 24 h. Viability of HepG2 cells was determined by the MTT assay. The results are presented as mean ± SD of two independent experiments.

Effect of SWE and SPE on the Expression of TG Synthesis Related Proteins. Figure 4A shows that cells that were induced by OA had 1.24 times the expression of FAS. When compared with the control group, in cells that were exposed to 1 or 5 mg/mL SWE, the expression of FAS was 1.08 and 1.03 times, respectively. Figure 4A shows that cells that were induced by OA had 1.28 times the expression of SREBP-1. When compared with the control group, after exposure to 1 or 5 mg/mL SWE, the expression of SREBP-1 was 1.21 and 1.11 times, respectively. GPAT is the rate-determining enzyme of triglyceride synthesis. Figure 4A also reveals that the expression of GPAT induced by OA was 1.25 times. When compared with the control group, after cells were exposure to 1 or 5 mg/mL SWE, the expression of GPAT was 1.22 and 1.03 times, respectively. Figure 4B shows that cells induced by OA had the expression of FAS 1.26 times. After exposure to 0.5 or 1.0 mg/mL SPE, the expression of FAS was 1.09 and 0.687 times, respectively. SWE and SPE reduced the expression of FAS in HepG2 cells in a dose dependent manner after induction by OA.

Figure 4B shows that cells induced by OA had 1.31 times the expression of SREBP-1. After exposure to 0.5 or 1.0 mg/mL SPE, the expression of SREBP-1 was 1.17 and 1.13 times, respectively. SWE and SPE reduced the expression of FAS in HepG2 cells in a dose-dependent manner after induction by OA. Figure 4B also reveals that the expression of GPAT was induced 1.29 times by OA. When compared with the control group, after cells were exposed to 0.5 or 1 mg/mL SPE, the expression of GPAT was 0.98 and 0.91 times respective. Both SWE and SPE reduced the expression of GPAT in HepG2 cells after induced by OA, and the response was dose-dependent. From those data, we can validate that, through the inhibition of those transcription factors, SWE and SPE may regulate the synthesis of triglycerides.

Effect of SWE and SPE on the Expression of Cholesterol Synthesis Related Proteins. HMGCoR is the rate-determining enzyme of cholesterol synthesis. To test whether the reduction of lipid accumulation in both SWE- and SPE-treated HepG2 cells is accompanied by changes in cholesterol biosynthesis, Western Blots were performed. As seen in Figure 5A,B, the expression of HMGCoR, SREBP-2, and LDL-R were remarkably decreased by SWE (1 or 5 mg/mL) or SPE (0.5 or 1 mg/mL) treatment compared with the OA-treated group. From those data, we can validate that, through the inhibition of those transcription factors and LDLR, SWE and SPE may regulate the synthesis of cholesterol (Figure 5).

Effect of SWE and SPE on the Expression of Fatty Acid Oxidation Related Proteins. CPT-1 is an enzyme in the body that helps change fat to energy. In this study, the results have shown that SWE or SPE treatment increases the expression of PPARα and CPT-1 compared with that in the OA group in HepG2 cells (Figure 6). Thus, through the stimulation of those transcription factors, SWE and SPE were shown to increase the oxidation of fatty acids.

Effect of SWE and SPE on the Phosphorylation of AMPK. AMPK is an important regulator in the metabolism mechanism for sugar and fat. In Figure 7A, when cells were treated with 1 or 5 mg/mL SWE, the expression of p-AMPK was significantly increased 1.33- and 1.40-fold respectively, compared with that in the OA group. We further observed that the ratio of AMPK/p-AMPK was increased ($*p < 0.05$, $**p < 0.001$), indicating that SWE can activate AMPK. In Figure 7B, the expression of p-AMPK was significantly increased 1.29- and 1.32-fold after treatment with 0.5 or 1 mg/mL SPE in HepG2 cells. We also observed that the p-AMPK/AMPK ratio had an upward trend. With those results, we prove that SWE and SPE can activate AMPK and, hence, reduce lipid synthesis in cells.

DISCUSSION

The liver plays an essential role in lipid metabolism via regulating lipogenesis and oxidative stress.[23] Excessive lipid accumulation in liver may progress to steatohepatitis.[2] The mechanism study is well-known in oleic acid-induced human hepatoma HepG2 cells model. Here, we attempted to examine the hypolipidemia effect and possible mechanism of SWE or SPE on hepatic lipid metabolism. Previous reports indicated that a regulation of hepatic LDLR and HMGCoR activity could be observed in HepG2 cells.[25,26] The fat accumulation in NAFLD is mostly due to the synthesis of fatty acids and inhibition of fatty acid oxidation.[27] Generally, hepatic hypolipidemic mechanisms are highly associated with expression of lipogenic enzymes, cholesterol biosynthesis, fatty

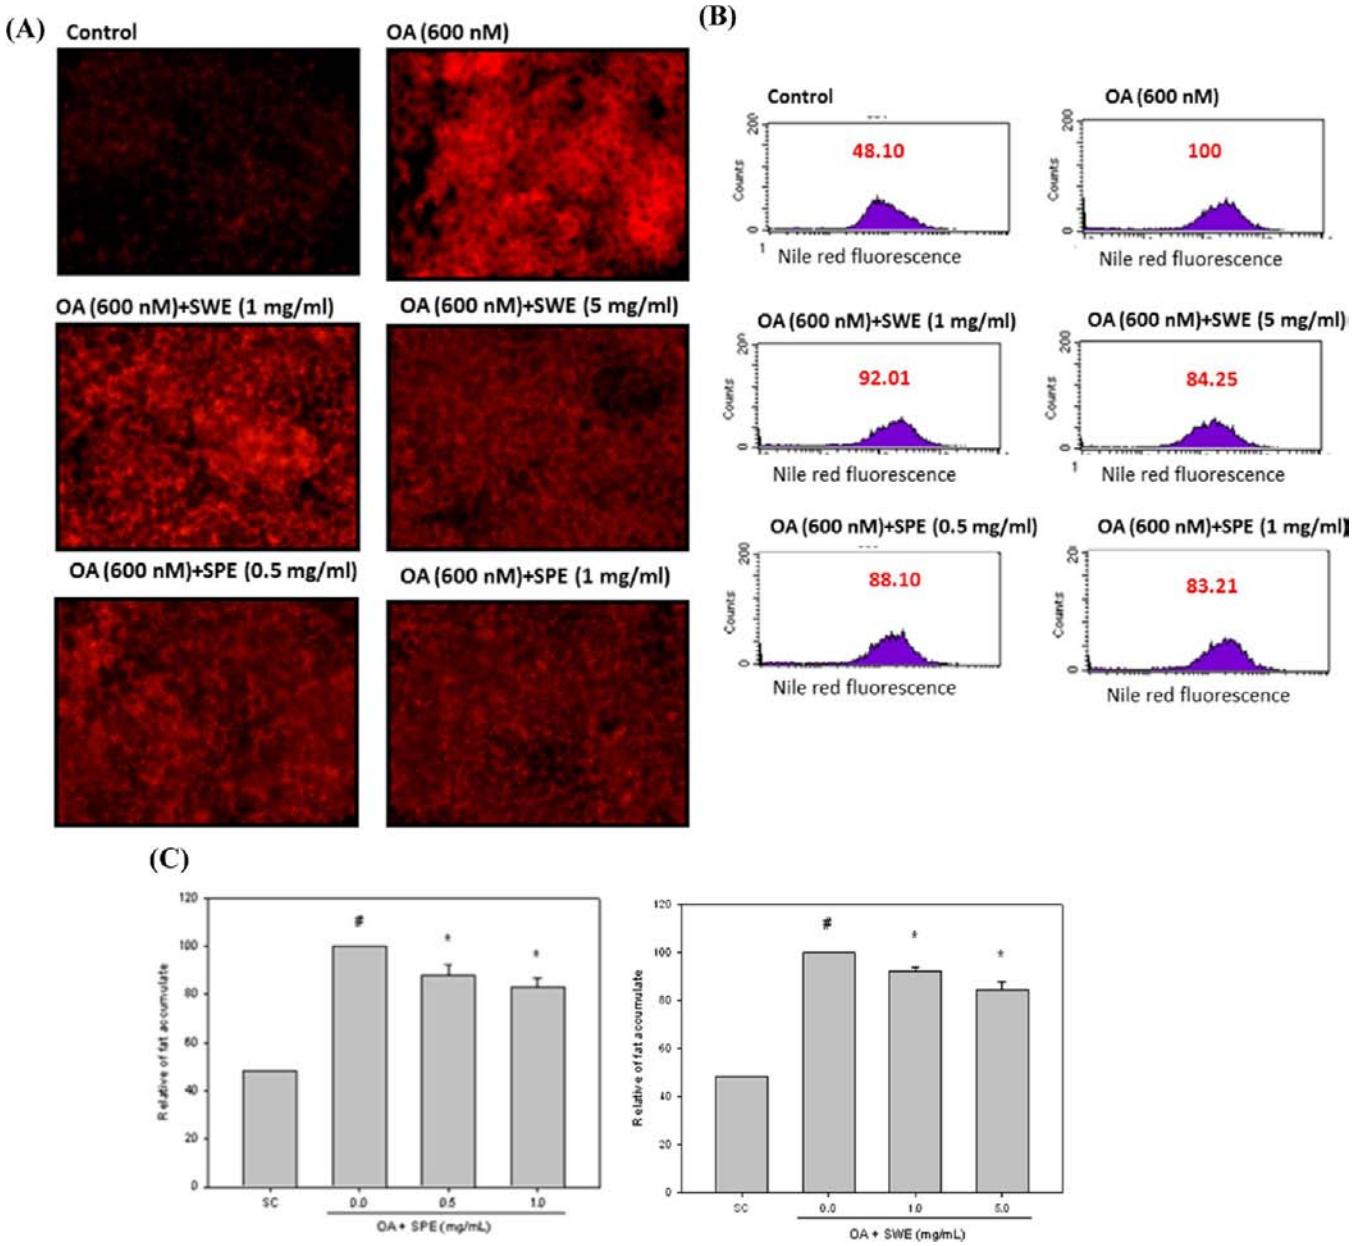

Figure 3. Effects of SWE (water extracts of *Sechium edule* shoots) or SPE (polyphenol extracts *of Sechium edule* shoots) on intracellular lipid accumulation in HepG2 cells. Cells are cotreated with oleic acid (OA) 0.6 mM and various concentrations of SWE or SPE for 24 h. (A) After culturing, cells were fixed with formalin and stained with Nile red and (B) analyzed by flow cytometry. (C) Quantitative assessment of the percentage of lipid accumulation; data represent the average of three independent experiments ± SD. SC indicates an internal control of cell stained with Nile red; 0 indicates an induced control of cells treated with oleic acid only. #$p < 0.05$ compared with the SC group; *$p < 0.05$ compared with the OA-induced group.

acid β-oxidation, and TG biosynthesis in HepG2 cells. In our present study, the hypolipidemic mechanisms of SWE and SPE were related to expression of lipogenic enzymes (SREBP-1 and FAS), cholesterol biosynthesis (HMGCoR, SREBP-2, and LDL-R), fatty acid β-oxidation (PPAR-α and CPT-1), and TG biosynthesis (GPAT) in OA-induced HepG2 cells.

AMPK is a multisubunit enzyme recognized as a major regulator of lipid biosynthetic pathways due to its role in the phosphorylation and inactivation of key enzymes such as FAS.[28] Studies demonstrated that polyphenolic extracts from plants can activate AMPK and inhibit FAS expression by preventing SREBP-1 translocation to the nuclei.[29−31]

Polyphenols are widely found in *Sechium edule* shoots.[32] In this study, we found that both SWE and SPE contained total polyphenols about 7.73% and 38.84%, respectively. These concentrations were sufficient to lower lipid levels in the liver.[33] Therefore, both SWE and SPE have great ability to activate AMPK and then reduce protein expression of SREBP-1, leading to inhibition of hepatic lipogenesis. Our data showed that AMPK plays a pivotal role in the hypolipid effect, and both SWE and SPE can augment AMPK activation (Figure 7). SREBP-1 is a key lipogenic transcription factor regulating the gene expression of lipogenic enzymes and is dedicated to the synthesis and uptake of fatty acids and triacylglycerol.[31,34] Our data showed that the expression of SREBP-1 and its

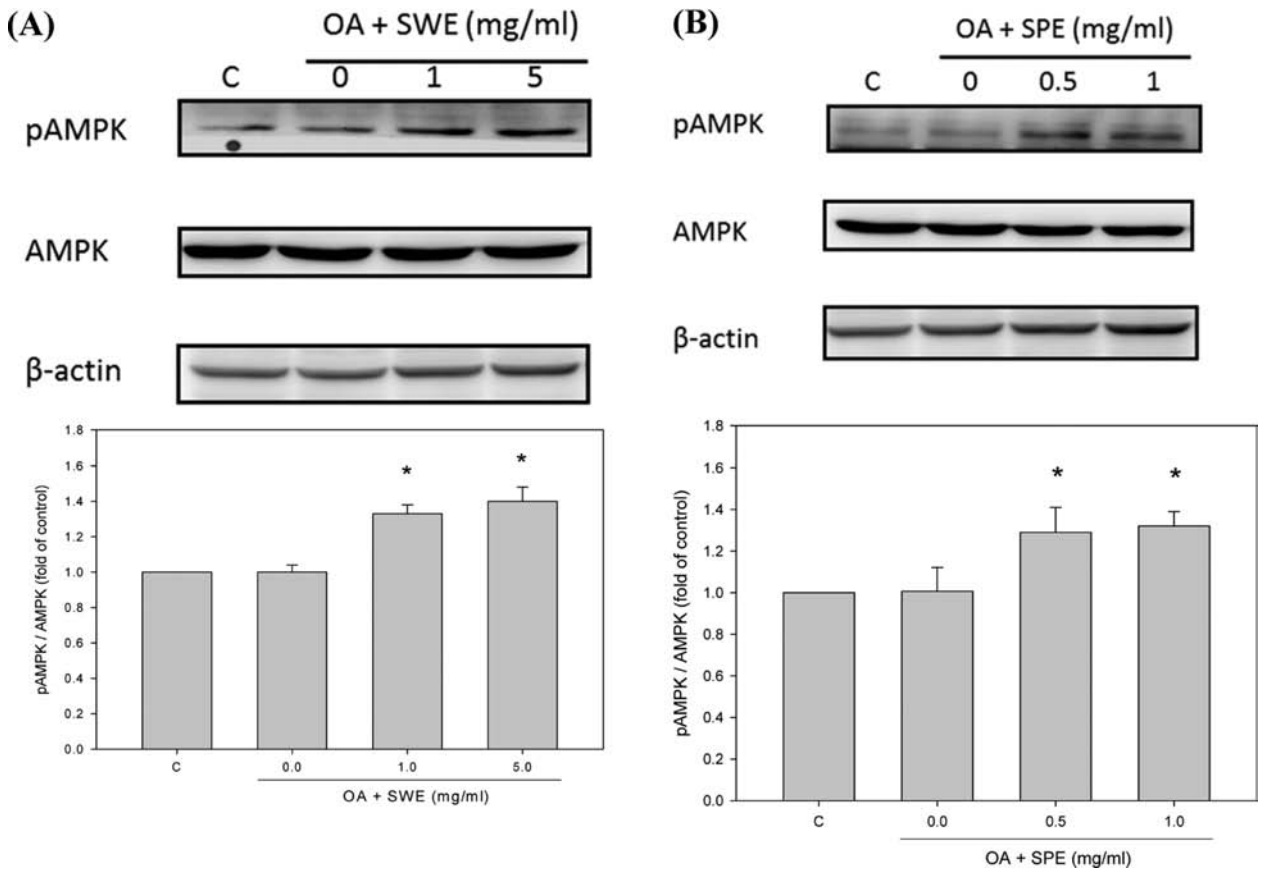

Figure 7. Treatment of SWE (water extracts of *Sechium edule* shoots) and SPE (polyphenol extracts of *Sechium edule* shoots) increased AMP-activated protein kinase (AMPK) phosphorylation protein expression in OA (oleic acid)-induced HepG2 cell. Cells were coexposed to OA (0.6 mM) and various doses of SWE (A) or SPE (B) for 24 h. AMPK phosphorylation (pThr172-AMPK) was detected by Western blot analysis under the same conditions. The numbers below the panels represent quantification of the immunoblot by densitometry. *$p < 0.05$ compared with OA-induced group.

downstream factors, FAS and GAPT, were reduced in response to SWE or SPE treatment in HepG2 cells (Figure 4). Another recent study suggests that AMPK mediates a decrease in SREBP-1 expression.[29] Consequently, our data suggest that the ability of SWE and SPE to decrease FAS and GAPT expression may occur through AMPK activation and SREBP-1 suppression.

In addition increase of hepatic lipogenesis by activation of SREBP-1 may contribute to the development of chemically induced fatty liver.[35] AMPK phosphorylates and inhibits SREBP-1 activity to attenuate hepatic steatosis,[36] whereas SREBP-2 primarily controls cholesterol homeostasis by activating genes required for cholesterol synthesis and uptake.[37] Our data corroborated these results (Figure 5 and Figure 7). Similarly, AMPK inhibits in vitro lipogenesis in hepatocytes through the downregulation of the cleavage processing and transcriptional activity of SREBP.[36] PPAR-α is highly expressed in the liver where it activates genes involved in β-oxidation of fatty acids.[38] In our study, both SWE and SPE treatment result in an increased expression of PPAR-α in OA-induced lipid accumulation cells.

In conclusion, the current study identifies that SWE and SPE can reduce lipid accumulation. We also propose that AMPK is pivotal in closing the anabolic pathway and promoting catabolism by down regulating the activity of key enzymes in lipid metabolism, such as HMGCoR and FAS. Both SWE and SPE can suppress fat accumulation of the liver and could be developed as a potential therapeutic treatment in order to reduce the formation of a fatty liver.

Supporting Information

ABSTRACT: After heating in excess water under little or no shear, starch granules do not dissolve completely but persist as highly swollen fragile forms, commonly termed granule "ghosts". The macromolecular architecture of these ghosts has not been defined, despite their importance in determining characteristic properties of starches. In this study, amylase digestion of isolated granule ghosts from maize and potato starches is used as a probe to study the mechanism of ghost formation, through microstructural, mesoscopic, and molecular scale analyses of structure before and after digestion. Digestion profiles showed that neither integral nor surface proteins/lipids were crucial for control of either ghost digestion or integrity. On the basis of the molecular composition and conformation of enzyme-resistant fractions, it was concluded that the condensed polymeric surface structure of ghost particles is mainly composed of nonordered but entangled amylopectin (and some amylose) molecules, with limited reinforcement through partially ordered enzyme-resistant structures based on amylose (for maize starch; V-type order) or amylopectin (for potato starch; B-type order). The high level of branching and large molecular size of amylopectin is proposed to be the origin for the unusual stability of a solid structure based primarily on temporary entanglements.

KEYWORDS: *starch granule ghosts, gelatinization, α-amylase, enzyme-resistant fraction, glucan conformation, polymer entanglement*

INTRODUCTION

Many agriculture and food biopolymers are assembled in an ordered or crystalline form in nature to confer stability and minimize hydration-driven swelling in the native environment. However, once these molecules or assemblies are heated above the relevant melting temperature, most become soluble, at least initially. Examples include many proteins and polysaccharides. Starch, however, is an exception, as when native semicrystalline granules are heated above their characteristic melting temperature under little or no shear, they swell and release some lower molecular weight components, but do not dissolve completely. Most applications of starch in food and industrial processes involve a heating step in the presence of water, which disrupts the ordered arrangement of polymers within granules (termed gelatinization). Gelatinized starches typically contain a mixture of solubilized polymers (mainly leached amylose and amylopectin molecules with low molecular weight) and residual granular structure (also termed (fragments of) granule "ghosts").[1] The importance of starch granule ghosts in determining the properties of cooked starches is often underestimated in studies that treat gelatinized starch as a fully dissolved polymer solution, like other biopolymer solutions such as agar and gelatin.[2,3] The presence of the large (10−200 μm) macromolecular architecture of granule ghosts within an otherwise homogeneous polymer system can affect molecular processes, such as phase separation, and contribute to functional properties of starches that play important roles in texture and mouthfeel (e.g., viscosity, rheology, and tribology).[2]

Numerous studies of the structural changes associated with starch gelatinization have been reported,[4−8] but the factors that contribute to the stability of granule ghost structures are still not clear. Various approaches have been used to understand the robustness of granule ghosts, including selective extraction of surface nonpolysaccharide components, treatment of ghosts with protein-degrading enzymes, and the study of waxy maize mutants with variable (low) amylose contents.[2,9] On the basis of these studies, it has been hypothesized that ghost formation is due to the cross-linking of amylose chains and/or long amylopectin branches (previously presumed to be by double helices), modulated by surface nonpolysaccharide components.[2,9] However, direct experimental testing of this hypothesis has not been reported yet. Due to the lack of detectable ordered structure in granule ghosts[1] (e.g., crystallinity from X-ray diffraction, helical order, or regularity of amylopectin clusters from small-angle X-ray scattering), physical techniques used to study the intermolecular interaction of biopolymers, such as wide- and small-angle X-ray scattering, differential scanning calorimetry (DSC), ^{13}C nuclear magnetic resonance (NMR), and Fourier transform infrared (FTIR) spectrometry, may provide limited insight into the mechanism of ghost formation and stabilization. We have recently shown, however, that there is a fraction of granule ghosts that is relatively resistant to enzymatic digestion.[10] In this work we hypothesize that such enzyme-resistant fractions may be important in providing stabilizing structure to granule ghosts. We have therefore studied the susceptibility of granule ghosts toward enzymatic hydrolysis and investigated the macromolecular and ordered structures present in undigested residues as a probe of local structures that may be important in the formation and structure of ghosts.

Although there is some enzyme-resistant material present in granule ghosts formed under low shear cooking conditions from both maize and potato starches, high shear cooked starches are almost 100% digested, suggesting that granule ghosts are structurally different from high shear cooked starches.[10] In this study, amylase digestion is used as a probe to investigate the structure of granule ghosts isolated from maize and potato, two commonly used commercial starches with different ghost profiles (e.g., size and integrity), as exemplars. On the basis of the concept that the enzyme-resistant fraction is important for maintaining ghost integrity, at least three hypotheses for the underlying structural basis for enzyme resistance can be proposed: (a) the multimicrometer structure of granule ghosts acts as a barrier to limit enzyme access; (b) cross-linking or dense entanglement of amylose and/or amylopectin branches limits enzyme action; or (c) proteins and lipids associated with the granule may contribute to either barrier or local cross-linking mechanisms. To test these hypotheses, in this study morphological parameters of ghosts and digested remnants have been studied with different microscopic techniques, the molecular structure evolution during amylase digestion of granule ghosts has been monitored by ^{1}H NMR spectroscopy and size exclusion chromatography (SEC), and the conformation of polymers within ghosts and enzyme-resistant residues has been determined by ^{13}C CP/MAS NMR. On the basis of the data obtained, mechanisms for starch granule ghost formation and stability are discussed.

EXPERIMENTAL PROCEDURES

Materials. Maize starch (MS) was purchased from Penford Australia Ltd. (Lane Cove, NSW, Australia), and potato starch (PS) was from Sigma-Aldrich. (St. Louis, MO, USA). Porcine pancreatic α-amylase (A3176, activity = 23 unit/mg) and other chemicals were obtained from Sigma-Aldrich.

Depletion of Proteins and Lipids from Granule Surfaces. Treatment of starch granule slurries (20% w/v) with sodium dodecyl sulfate (SDS, 2% w/v) at 20 °C for 30 min was used to extract surface proteins and lipids.[9] Extracted granules were isolated by centrifugation and washed with >10 volumes of cold deionized water until no foaming was observed in the washings. Despite the extensive washing, some SDS was retained by the granules as shown by the increase in sodium and sulfur contents after treatment (Supporting Information, Table S1).

Preparation of Cooked Starch and Granule Ghosts. Starch granule aqueous slurry (10 mL, 0.5% w/v) in a 50 mL centrifuge tube (with a magnetic stirrer, 3 mm × 8 mm) was heated to 100 °C on a hot plate stirrer at a stirring rate of 1500 rpm for 30 min ("high shear cooking") and designated "cooked starch". Granule ghosts were isolated from maize and potato starches following an adaptation of a method reported previously.[1,2] Starch (200 mg) was suspended in a small amount of cold water and then poured into hot water (95 °C, 40 mL). The dilute suspension (0.5% w/v starch) was kept at 95 °C for 30 min at a low stirring rate (250 rpm, "low shear cooking") and then centrifuged (30 °C, 2000*g* for 15 min). The supernatant was removed, and the spun ghosts were washed twice by resuspension in hot water (90 °C) with gentle manual stirring followed by centrifugation. Ghost yield was defined as the weight ratio of freeze-dried pellet to initial starch. The washed ghosts were finally resuspended in excess water for microscopy and in vitro digestion. For SEC, NMR, and scanning electron microscopy (SEM) measurements, starch samples were precipitated by absolute ethanol and dried under pressured nitrogen gas overnight.

Microscopy. Light microscopy was performed using a Zeiss Axio microscope (Oberkochen, Germany). One drop of fresh granule ghost suspension was placed on a glass slide and stained with 2% iodine solution, and the images were recorded by AxioCam ERc5s camera (Zeiss). For confocal microscopy, the staining procedure of fresh granule ghosts with Nile Blue was adapted from the method described by Schirmer et al.[11] Aqueous suspensions of granule ghosts (0.5 mL) and 40 μL of aqueous Nile Blue solution (0.1 g/100 mL; N0766, Sigma-Aldrich) were transferred into 2 mL microcentrifuge tubes. After thorough mixing by repeated pipetting up and down, the stained solutions were incubated at 20 °C for 3 h. For confocal microscopic observation, the stained suspensions were dropped into the cavity of glass slides, sealed with a coverslip, and then observed using an LSM 700 confocal laser scanning microscope (CLSM, Zeiss). Excitation was at 639 nm with a diode laser operating at 2% of power capacity, and the emitted light was detected at an interval wavelength of 640−700 nm. Images of optical sections of granule ghosts were recorded with ZEN 2011 software (Zeiss). For SEM, ethanol-dried samples were thinly spread onto circular metal stubs covered with double-sided adhesive carbon tape and then platinum coated in a sputter coater. Images of the granule ghosts were acquired with a JEOL 6300 scanning electron microscope (JEOL Ltd., Tokyo, Japan) under an accelerating voltage of 5 kV.

Particle Size Distribution. Particle size analysis was carried out using a Malvern Mastersizer Hydro 2000MU (Malvern Instruments Ltd., Malvern, UK) following the method of Dhital et al.[12] A refractive index of 1.34 was used for granule ghost size calculation. The starch samples were added to circulating water until an obscuration of >10% was recorded.

In Vitro Starch Digestion. In vitro starch digestion was performed with porcine pancreatic α-amylase, from the method described by Zhang, Dhital, and Gidley[10] with slight modifications. Starch samples (50 mg, dry basis) were digested with 2.5 units of α-amylase in 30 mL of sodium acetate buffer (0.2 M, pH 6.0) in a shaking water bath at 37 °C. Aliquots (0.2 mL) were removed at different intervals, mixed with 1.0 mL of 95 °C water, and then boiled for 10 min to inactivate enzymes. The reducing sugar value was measured by the Nelson−Somogyi method.[13] The maltose equivalent released (%) was calculated using the following equation (eq 1). Results were expressed as means with standard deviations of at least duplicate measurements.

$$\text{maltose equivalent released (\%)} = \frac{\text{total wt of equivalent maltose in supernatant}}{\text{dry wt of starch}} \times 100 \quad (1)$$

Size Exclusion Chromatography. The fully branched and debranched size distribution of starch molecules during the course of in vitro digestion was obtained from an SEC system (Agilent 1100, Agilent Technologies, Waldbronn, Germany) equipped with a refractive index detector (RID-10A, Shimadzu, Kyoto, Japan) following the methods of Cave et al.[14] and Hasjim et al.[15] SEC samples were prepared following the method described elsewhere[15] and then injected into the following series of columns: precolumn, Gram30, Gram3000 (PSS, Mainz, Germany) for the fully branched distribution, and precolumn, Gram100, Gram 1000 for debranched distribution. The molecular size distribution data were plotted as SEC weight distribution, $w(\log V_h)$, against the hydrodynamic radius (R_h/nm). For linear polymers of uniform geometry, the size and molecular weight (or equivalently the degree of polymerization, DP) are uniquely related, and hence the size distribution can be processed to a molecular weight distribution using the Mark−Houwink equation.[14,16] SEC calibration was performed using pullulan standards with molecular weights ranging from 342 to 1.66 × 10^6 Da (PSS, Mainz, Germany). The standards were dissolved in the SEC eluent and injected into the branched and debranched SEC setups to provide universal calibration curves to relate elution volume with R_h. Because of the calibration range, the R_h values above the upper limit of the standards available (~50 nm) are only semiquantitative. The amylose content can also be calculated as the ratio of the area under the curve (AUC) of the debranched SEC distribution curves for the larger branches to the total AUC for all branches.[17] The amylose contents of maize and potato starches determined in this way were 23.3 ± 1.0 and 18.3 ± 0.4% respectively.

^{1}H Nuclear Magnetic Resonance Spectroscopy. The degree of branching (DB) of starch molecules during the course of in vitro digestion was measured on a Bruker Avance NMR spectrometer (Bruker Biospin, Rheinstetten, Germany), operating at a Larmor

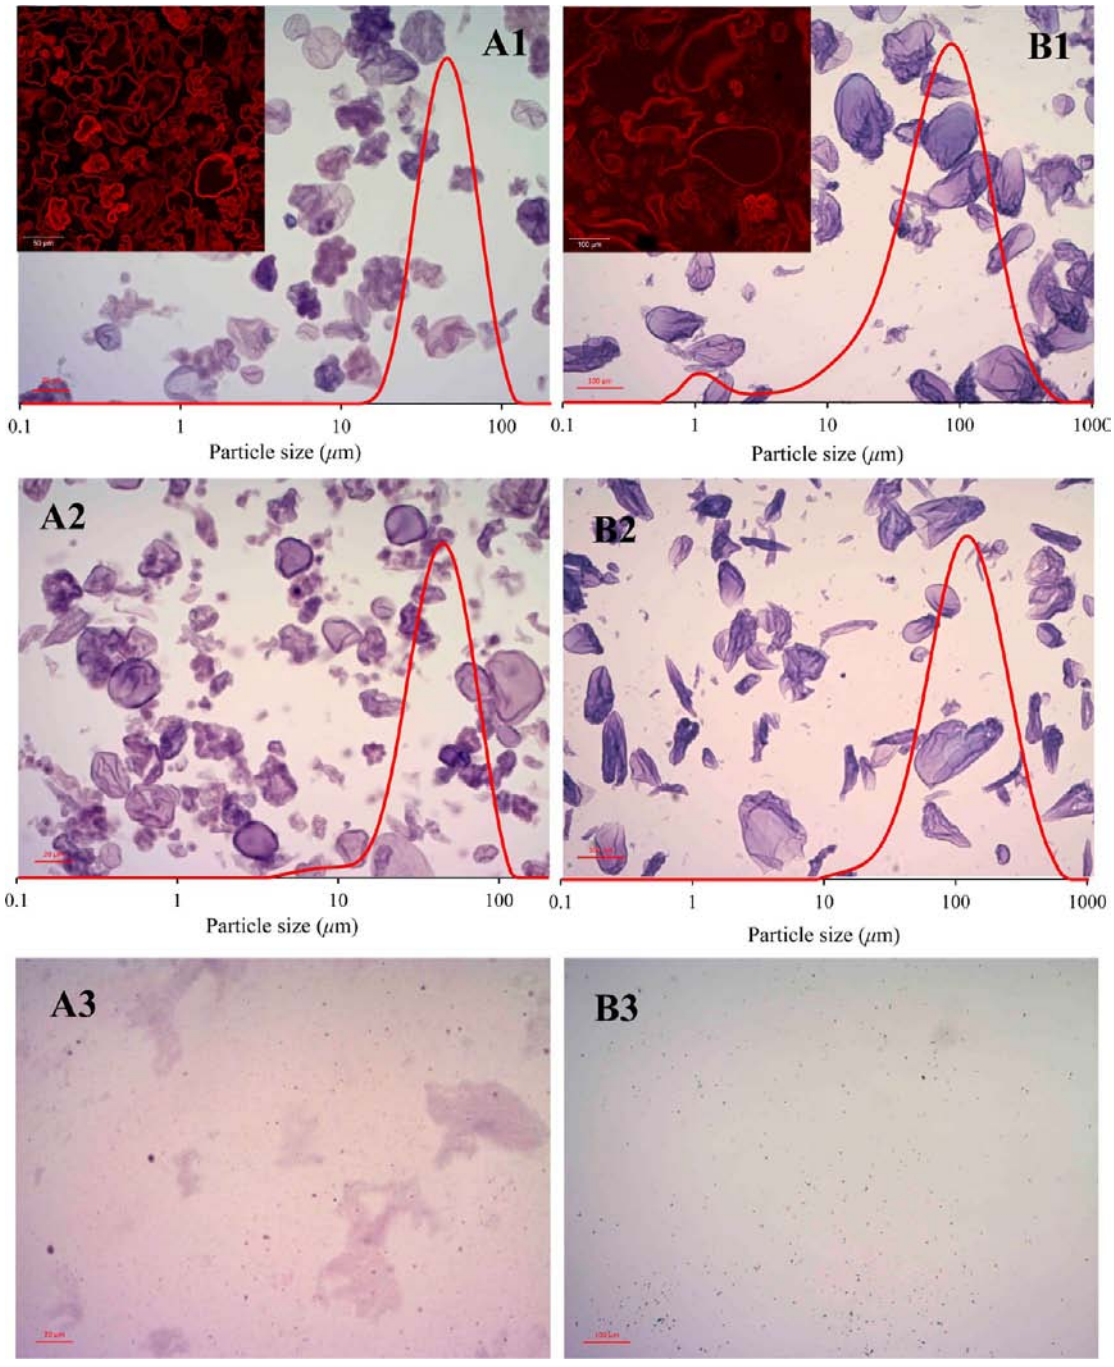

Figure 1. Light micrographs and particle size distribution of fresh granule ghosts (A, maize, scale bar = 20 μm; B, potato, scale bar = 100 μm) with/without SDS pretreatment or high shear force (1, without any treatment; 2, with SDS pretreatment; 3, with high shear force treatment after ghost formation). Insets in panels A1 and B1 are confocal microscopy images after staining with Nile Blue.

frequency of 750 MHz for ^{1}H, equipped with a TXI5z probe following the method of Tizzotti et al.[18] ^{1}H NMR spectra were recorded at 333 K with an 8 μs 90° pulse, a repetition time of 15.98 s (composed of an acquisition time of 3.98 s and a relaxation delay of 12 s), and 128 scans. The addition of a very low amount of TFA-d_1 to the medium causes the exchangeable protons of the starch hydroxyl groups and of the residual water to shift to higher frequency, leading to clear and well-defined ^{1}H NMR spectra.[18] DB is obtained using eq 2

$$\mathrm{DB}\ (\%) = \frac{I_{\alpha\text{-}(1,6)}}{I_{\alpha\text{-}(1,4)} + I_{\alpha\text{-}(1,6)}} \times 100 \qquad (2)$$

where $I_{\alpha\text{-}(1,4)}$ and $I_{\alpha\text{-}(1,6)}$ are the ^{1}H NMR integrals of internal α-(1,4) and α-(1,6) linkages at ∼5.12 and ∼4.78 ppm, respectively.

^{13}C CP/MAS Nuclear Magnetic Resonance Spectroscopy. Starch samples were examined using a solid-state ^{13}C CP/MAS NMR spectrometer (Bruker MSL-300, Rheinstetten, Germany) at a ^{13}C frequency of 75.46 MHz. Approximately 200 mg of sample was packed in a 4 mm diameter, cylindrical, partially stabilized zirconium oxide rotor with a KelF end-cap. The rotor was spun at 5 kHz at the magic angle (54.7°). The 90° pulse width was 5 μs, and a contact time of 1 ms was used for all samples with a recycle delay of 3 s. The spectral width was 38 kHz; acquisition time, 50 ms; time domain points, 2L; transform size, 4K; and line broadening, 50 Hz. At least 2400 scans were accumulated for each spectrum. In the case of the 3 h digestion residues of maize and potato ghosts, it was necessary to collect 20000 scans, as only 50 mg was available. Spectra were referenced to external adamantine and were

analyzed by resolving the spectra into ordered and amorphous subspectra and calculating the relative areas as described previously.[19] When percentage order is calculated, freeze-dried starches are compared with freeze-dried amorphous standards, and samples precipitated with ethanol are compared with ethanol-precipitated amorphous standards.

RESULTS AND DISCUSSION

Microscopic Structure of Granule Ghosts. Fresh granule ghosts from maize and potato starches were isolated by centrifugation following the method reported by Debet and Gidley.[2] This method ensures full gelatinization and maximum swelling (for most normal starches) when starch is heated at 95 °C for 30 min in excess water. The risks of retrogradation from leached amylose and shear degradation are minimized by the low starch concentration (<1% w/v) and low stirring rate during ghost preparation respectively.[20] Light microscopy and particularly confocal microscopy suggest that ghost particles are essentially hollow with a surface "skin" composed of apparently densely packed starch (Figure 1A1,B1). Granule ghosts have characteristic microscopic features depending on their botanical and genetic origins.[21] Fresh maize ghosts showed complex shapes and surface folds, but appeared overall fairly spherical, typically with a particle size between 15 and 35 μm (Figure 1A1). In contrast, potato ghosts have a wide range of particle sizes (typically 50–150 μm) with more ellipsoidal shapes and significant amounts of granule fragments (Figure 1B1). Expansion is so extensive that the resultant potato ghosts (ca. 4 times expansion in original diameter, i.e., ca. 64-fold increase in granular volume) are more fragile and sensitive to shear force, compared with maize ghosts (increasing only ca. 2 times in diameter) even under the low shear conditions used in ghost preparation. This is not surprising because potato starch contains an appreciable amount of phosphate monoester groups,[22] which are negatively charged and linked to potato amylopectin molecules. The resulting charge repulsion effect helps to untangle the individual branches and extends the degree of granule swelling.[23] Maize ghosts frequently appeared to have more localized regions of folds and wrinkles (Figure 1A1,B1, insets), which may trap undispersed starch polymers.[3]

The morphology of granule ghosts was also investigated using CLSM after being stained by Nile Blue, a water-soluble basic oxazine dye, which is one of the most suitable fluorescent staining agents for both granular and gelatinized starches in the absence of

dx.doi.org/10.1021/jf404697v | J. Agric. Food Chem. 2014, 62, 760–771

proteins.[11] CLSM micrographs of granule ghosts show isolated balloon-like structures, lacking their original contents (Figure 1A1,B1 insets). The skins of maize ghosts appear to be thicker and more substantial and do not show much deterioration or collapse, compared with potato ghosts (Figure 1A1,B1 insets).

To visualize structure at higher resolution, fresh ghosts were precipitated with absolute ethanol, dried with N_2 gas, and examined by SEM. Although syneresis occurring during ethanol precipitation can reduce the roughness of surfaces,[24] the sizes of granule ghosts visualized by electron microscopy (Figure 2) are in agreement with the fresh ghosts (Figure 1) observed by light microscopy. Walls of the ghosts, especially those from maize, did not show much deterioration or collapse, which is consistent with CLSM images (Figure 1A1). Surface pinholes were visible in some ethanol-precipitated ghost particles (Figure 2C) and were of approximately the same size as before cooking (0.1−0.3 μm).[25] Potato ghosts (Figure 2E,F) showed a spongier and more open structure and evidence for deterioration/fracture, probably due to the comparatively thinner walls of these more expanded hollow particles.

Starch granules, in addition to amylose and amylopectin, contain small quantities of minor components, such as lipids and proteins. The proportion of these components depends on the botanical origin and the degree of purification during extraction.[21] SDS can be used to solubilize at least some proteins and lipids from the surface of starch granules (see Supporting Information, Table S1).[9] The extraction of lipids/proteins from the granule interior is difficult, requiring more disruptive methods such as stringent extractions at higher temperatures, chaotropic agents, or starch-degrading enzymes.[9] SDS washing of granules prior to ghost formation resulted in reduced ghost integrity (or robustness), especially for potato (Figure 1A2,B2). As granule ghosts with SDS pretreatment have more irregular shapes (some rod-like shapes for potato), it is not appropriate to assess the particle size by laser scatting techniques. These results are consistent with a previous study in which surface proteins and lipids were found to be a determinant of ghost robustness rather than ghost formation.[2] Shearing results in fragmentation of heated starch granules and facilitates the development of a homogeneous matrix.[26] The multimicrometer structure of ghosts can be efficiently disrupted by Ultraturrax homogenization (20000 rpm for 1 min), resulting in a dispersion of smaller particles and dissolved polymer molecules (Figure 1A3,B3).

α-Amylase Digestion. For the range of starches examined here and previously, both surface nonpolysaccharide material and polysaccharide chains themselves appear to be linked with ghost formation and/or resultant integrity.[1,2,9] The roles of the multimicrometer structure (hypothesis a) and surface proteins/lipids (hypothesis c) during ghost formation were tested by breaking down the ghost particles by high-speed homogenization or extracting surface components by SDS at room temperature, respectively, with enzyme digestion being used as a structure/function probe. According to our previous findings, there is some enzyme-resistant fraction present in granule ghosts after α-amylase and amyloglucosidase digestion, individually and in combination, compared with high-shear-cooked starch.[10] We suggest that the most enzyme-resistant fractions may play an important role in maintaining ghost integrity.

The kinetic profiles of granule ghost digestion were monitored by measuring the reducing sugar released at specific intervals during digestion with a low amount of α-amylase (Figure 3). In addition, the influence of maltose on the kinetics of α-amylase was also investigated (see the Supporting Information, Figure S1), to confirm that the end products (i.e., malto-oligosaccharides) do not inhibit further α-amylase digestion under the conditions used.[27] For both maize and potato ghost samples, pretreatment with SDS or post treatment by shearing did not change digestion behaviors markedly, but cooking with high shearing to prevent ghost formation resulted in a small increase in digestibility, particularly after 3 h of digestion (Figure 3A,B). When the yield of enzyme-resistant fraction was quantified by weight, the high-shear-cooked starches were found to be almost completely digested after 3 h, particularly for potato (isolated yields of 2.1 ± 0.3% for cooked maize and 0.2 ± 0.2% for cooked potato). Starch gelatinization disrupts structural features (e.g., semicrystalline structure, original surface organization) that otherwise slow down enzyme action, and can cause surface rupture at stress points.[3] Digestion profiles suggest that SDS-extractable proteins/lipids are not crucial for control of either ghost digestion or ghost integrity. The skins of many ghosts appear incomplete, with cracks and openings on the micrometer scale and additional small (~20 nm) pores (particularly for maize starch) and fine particles (~400 nm, particularly for potato starch)[3,28] Therefore, we propose that the formation of enzyme−substrate complexes, rather than the access of the enzyme to the granule ghost skin, primarily determines the rate-limiting step of enzyme digestion. Evidence that surface nonpolysaccharide components alone are not sufficient to restrict swelling and affect resultant ghost formation also comes from a previous comparison of swelling profiles for a wide range of starches from different botanical origins.[9] This is logical, as starch polymers are the dominant components in ghosts.[2]

For maize and potato starches, temperatures of structural disorganization (as monitored by loss of birefringence or DSC)

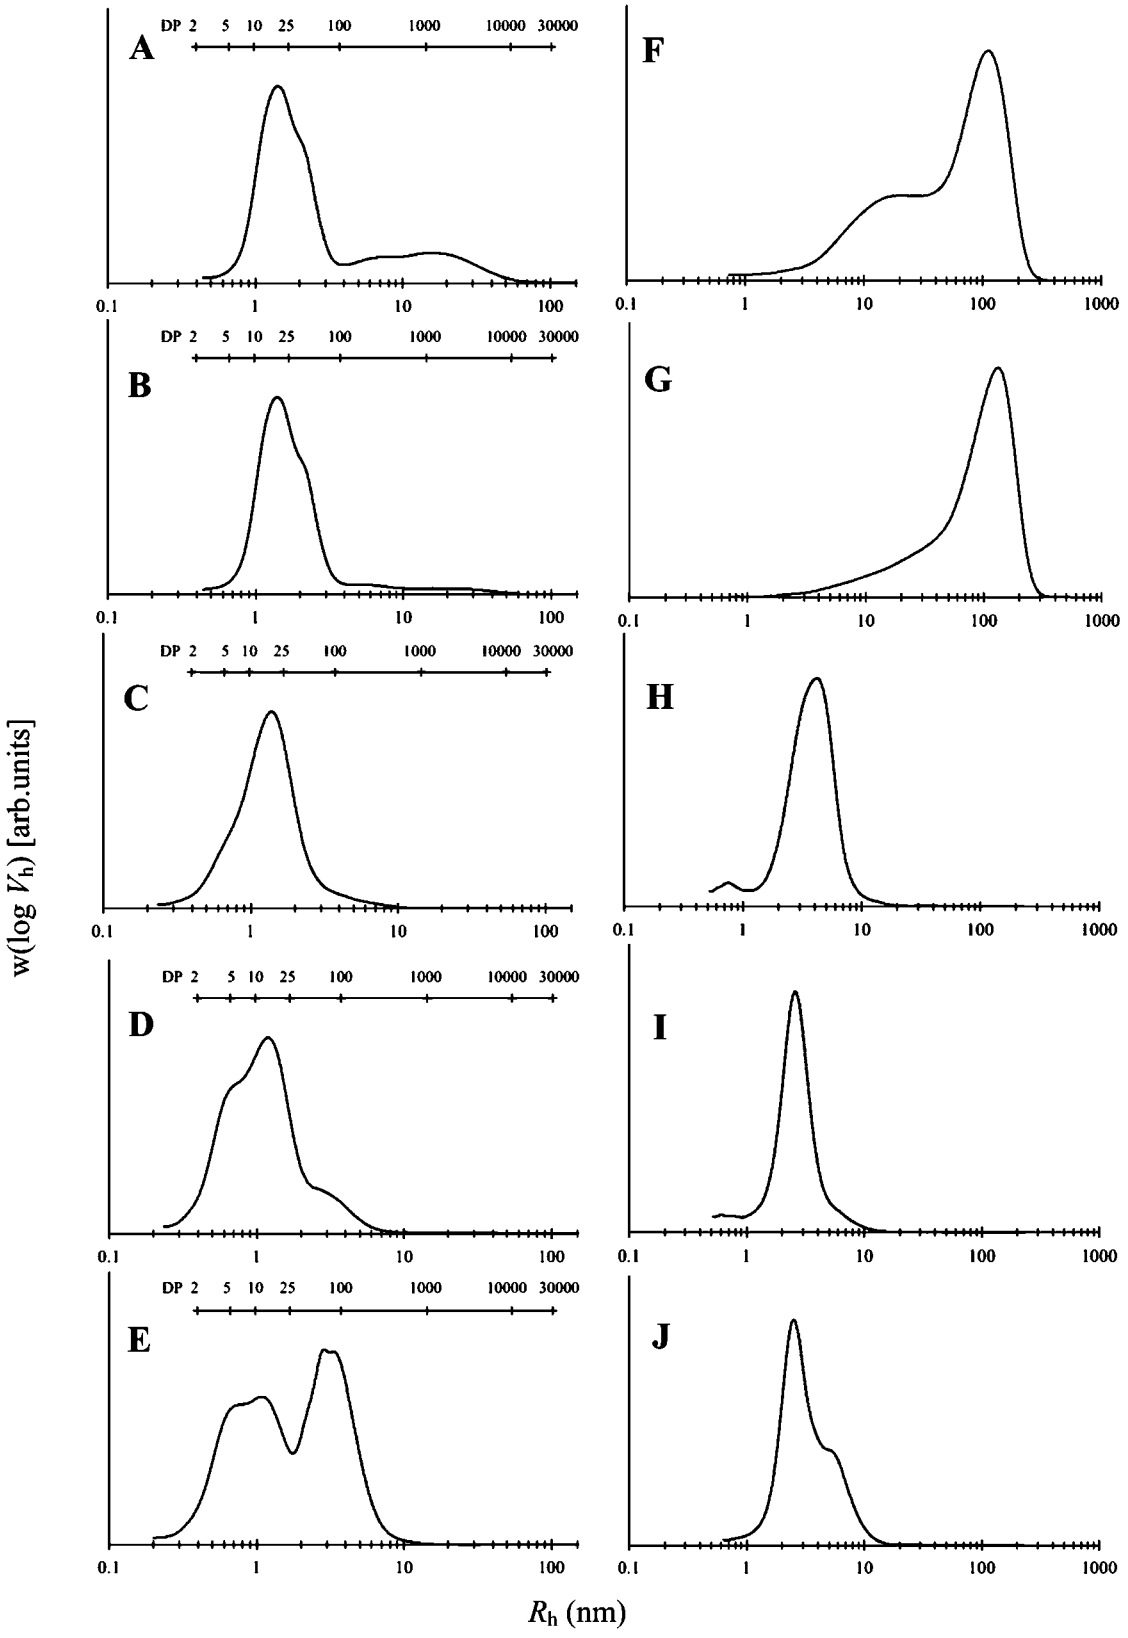

Figure 4. Size distributions of debranched (A–E) and whole (F–J) molecules from maize starch (A and F) and granule ghosts (B and G) after α-amylase hydrolysis for (C and H) 20, (D and I) 60, and (E and J) 180 min.

are relatively similar, yet swelling profiles show major differences.[29] However, once swollen, the digestibilities of potato and maize granule ghosts are comparable (Figure 3), but in both cases for starch cooked under shear, the maltose equivalents released are ca. 10% higher than for ghost samples after 3 h of hydrolysis, suggesting some structural differences between high-shear-cooked starch and granule ghosts. Up to now,[1] no direct evidence of any carbohydrate ordered structure has been found

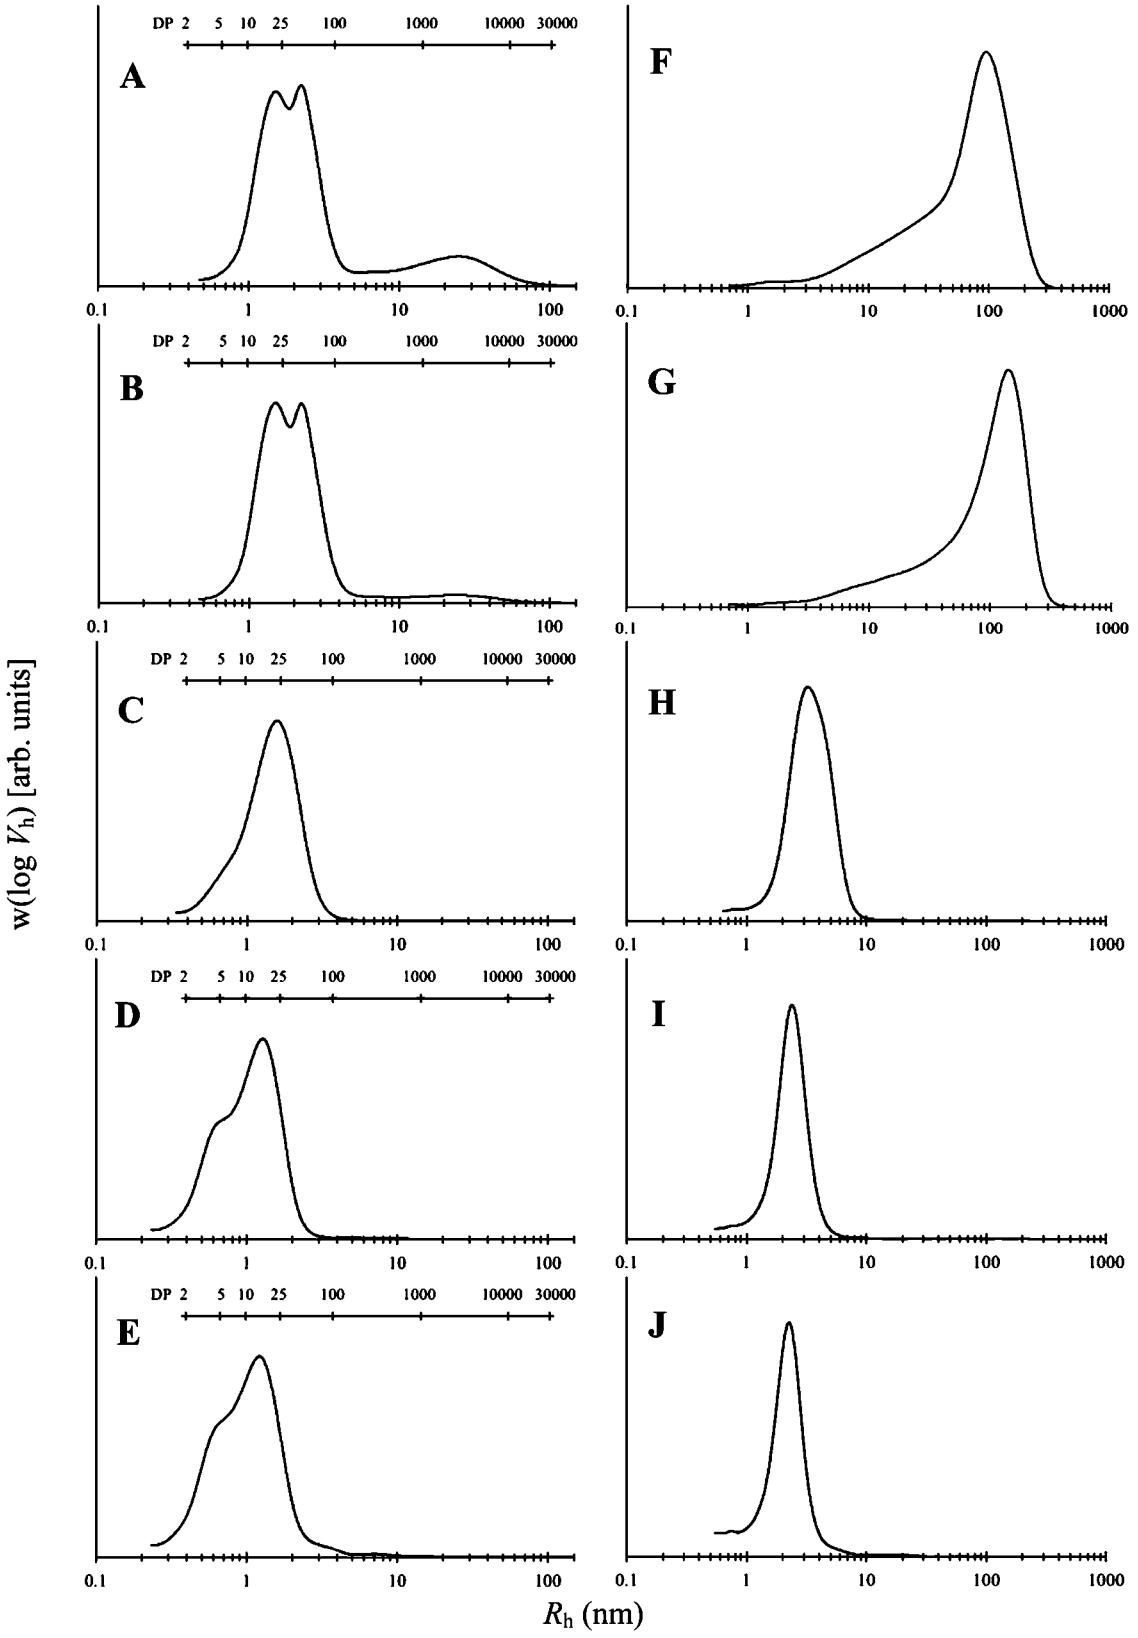

Figure 5. Size distributions of debranched (A–E) and whole (F–J) molecules from potato starch (A and F) and granule ghosts (B and G) after α-amylase hydrolysis for (C and H) 20, (D and I) 60, and (E and J) 180 min.

for ghosts by X-ray scattering/diffraction, ^{13}C NMR, or DSC (e.g., Supporting Information Figure S2). For starch that has been solubilized and then become insoluble by retrogradation, the driving force is typically double-helix formation and subsequent crystallization, but there is currently no evidence that these structures exist in granule ghosts, which have never been solubilized. The possible reasons could be that either the double-helical order is present within ghosts but lower than the

dx.doi.org/10.1021/jf404697v | J. Agric. Food Chem. 2014, 62, 760–771

detection limit of measurement techniques or the polymer chains are just physically entangled without any fixed conformation in the skins of ghosts.

Molecular Structures Present in Granule Ghosts and Their Evolution during Amylase Digestion. Molecular size distribution of whole maize and potato starch molecules (Figures 4F and 5F, respectively) and chain length distributions of enzymatically debranched maize and potato starch samples (Figures 4A and 5A) were characterized using SEC. The fully branched SEC weight distribution of the whole molecules of the two starches showed an amylopectin peak (R_h between 40 and 300 nm, peak R_h = ∼100 nm) and a shoulder for amylose molecules stretching from R_h of 1 to 40 nm. However, some hybrid components could also be present, such as molecules that are highly branched like amylopectin but with molecular size similar to that of amylose and also amylopectin molecules with extra-long branches.[30] The debranched SEC weight distribution can be empirically divided into two regions representing amylopectin branches (single-lamella branches, peak R_h ∼1.5 nm or DP ∼12; trans-lamella branches, peak R_h ∼2.5 nm or DP ∼50) and amylose branches (R_h ∼3.5−80 nm, DP ∼100−30000).[15,31] Amylose molecules are typically smaller than amylopectin and tend to leach out from granules during swelling, as shown by amylose contents of maize (8.4%) and potato (6.7%) ghosts, which are much lower than the starting starches (Figures 4B and 5B). Comparison of Figures 4F/5F with Figures 4G/5G shows that ghost formation is accompanied by loss of the lower molecular size molecules, again consistent with the amylose content results. During ghost formation, 15.1 and 38.8% of amylopectin (calculated from the amylose content of both granules and ghosts and the isolated yields of ghosts, see the Supporting Information) is leached out of maize and potato granules, respectively, suggesting that either a proportion of ghosts do not survive the cooking process or that amylopectin molecules are leached alongside amylose. Despite differences in particle size and robustness, ghosts from maize and potato starch have similar fully branched and debranched molecular size distributions (Figures 4B,G and 5B,G).

The debranched and fully branched SEC weight distributions of maize and potato ghosts and their evolution during amylase digestion are shown in Figures 4 and 5, and DB values calculated from ^{1}H NMR spectra are summarized in Table 1. DB values increase with digestion time, consistent with branched residues being less susceptible to digestion than nonbranched residues, and potato DB values reach higher levels, suggesting a difference in the relative enzyme susceptibility of nonbranched residues between maize and potato ghosts. The size distribution of whole starch molecules reveals that both amylose and amylopectin were quickly degraded to smaller molecules with a single R_h peak (∼4 nm for maize; ∼3 nm for potato) apparent within 20 min of digestion. The remnant small molecules were mainly degraded amylopectin and possibly contain some linear polymers, consistent with the fact that α-amylase is an endoacting enzyme and likely to cleave α-1,4 linkages largely at random locations and also in line with the increased DB values during digestion (Table 1). The corresponding chain length distributions showed fewer changes of the degraded amylopectin together with a clear loss of longer amylose branches (R_h >10 nm, DP >500) (Figures 4C and 5C), suggesting that α-amylase tends to cleave amylopectin molecules into clusters (which provide a barrier to enzyme access and hence prevent preferential digestion of intercluster amylopectin molecules[32]) and that digestion within clusters occurs at random. At the beginning of digestion (20 min), there was a gradual degradation of starch molecules as the peaks of both whole and debranched distributions were slightly shifted to lower R_h regions (Figures 4 and 5D,F,I,J). In addition, it is noteworthy that the debranched chain distributions of 3-h-digested maize ghosts had bimodal peaks, whereas those from potato ghosts showed only one peak at R_h ∼1.5 nm with a shoulder that diminishes in size without changing shape (Figures 4E and 5E). The bimodal peaks of maize ghost residues are designated highly branched α-limit dextrin (peak observed at R_h ∼1 nm) and longer chain polymers (R_h peak ∼3.4 nm) respectively, which are consistent with their whole molecule distributions and DB values (Figures 4E,J; Table 1). Clusters of branching points within starch molecules will slow the amylase action because of steric hindrance. It is noteworthy that some long-chain polymers (DP >100) survived, presumably from degraded amylose in original maize ghost particles. Cuevas et al.[33] also found that the hot-water-insoluble fractions in waxy rice starch contained DP ≥100 chains, which were absent in the hot-water-soluble fractions. However, these long-chain components were not found for the potato ghosts with the same digestion time and similar digestion extents (Figure 3), in agreement with the higher DB values, compared with that of maize residues (Table 1). Furthermore, the α-limit dextrin peak indicates that whole amylopectin present in the ghosts is reduced in size by α-amylase to ∼2.5 nm remnant molecules, which is consistent with previous results.[15,31]

Conformation of Ghost Residues after Enzyme Digestion. The macromolecular architecture of an apparently amorphous matrix such as granule ghosts is critical to their formation and stability. For starch granules, Biliaderis et al.[34] proposed a three-phase model incorporating two distinct types of amorphous materials, that is, nonordered intercrystalline and bulk amorphous matrix, together with the crystalline domains of amylopectin clusters, accounting for order−disorder phase transitions of starch gelatinization. However, there is no reason to suppose that the same amorphous structures exist after gelatinization. As a probe of molecular conformation, molecular order (single helices, double helices) at short distance scale solid-state CP/MAS NMR spectra were recorded before and after enzyme digestion.

The ^{13}C CP/MAS NMR spectra of maize and potato ghosts prepared by freeze-drying or ethanol precipitation produce distinct NMR spectra (Figure 6A). Regardless of the botanical origin of starch, when the starches from the two drying methods are intensity matched at 84 ppm (Figure 6A), there is a difference in intensity between 92 and 100 ppm. By instead matching the intensity of a freeze-dried ghost spectrum, and an ethanol-precipitated ghost spectrum in the 92−100 ppm region, and then

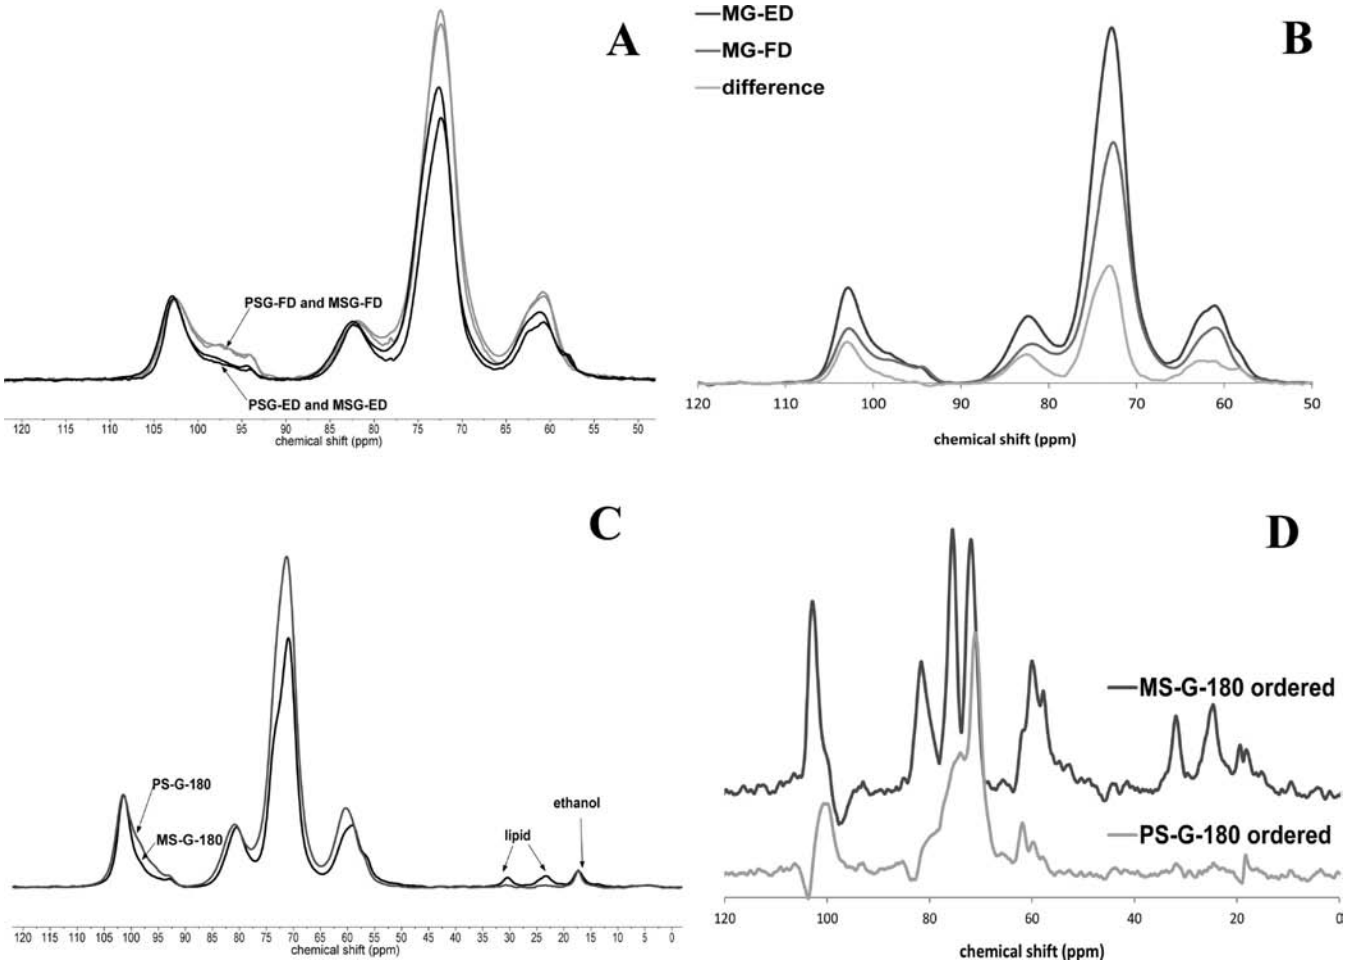

Figure 6. ^{13}C NMR spectra: (A) maize and potato ghosts with freeze-drying (FD) or ethanol-drying (ED); (B) maize ghosts with freeze- or ethanol-drying; (C) digestion residues from maize and potato ghosts. Separation of ^{13}C NMR spectra into ordered subspectra: (D) digestion residues from maize and potato ghosts. MS, maize starch; PS, potato starch; G-180, granule ghost hydrolysis for 180 min.

subtracting the two spectra, a spectrum of V-type helices is revealed (Figure 6B). Spectra of all ethanol-precipitated ghosts clearly indicated the presence of V-type helices with peaks for C1 at 102.9 ppm and C4 at 81.5 ppm.[35] After 3 h of enzyme digestion, the resistant material was recovered by ethanol precipitation to separate it from the large amount of low molecular weight digestion products. NMR spectra (Figure 6C) therefore showed intensity consistent with V-type helices with peaks at 102.9 and 81.5 ppm. The ordered subspectra (Figure 6D) were obtained by matching the intensity at 84 ppm of the 3 h digestion residues and an ethanol-dried amorphous maize starch standard and subtracting one from the other. Although there is no obvious order present when the total spectrum of 3-h-digested potato ghost is compared with the amorphous standard, upon subtraction of the two spectra it becomes apparent that a small amount of B-type double helices (13 ± 2%) is found for the potato ghost digestion residue with peaks at 100.3 and 99.5 ppm.[35−38] In contrast, the spectrum of the 3 h digestion residue from maize ghosts shows more V-type (19 ± 2%) than the standard and the starting ghost material. As shown in Figure 6A,B, ghosts (residues) isolated by ethanol precipitation have some V-type character. Consistent with this, digestion residues from both maize and potato starch ghosts have a signal for ethanol in the NMR spectrum (Figure 6C, 17 ppm). However, there are clearly also signals for lipids in the 3 h digestion residue from maize ghosts (Figure 6C, 33 and 23 ppm), and similar levels of ethanol peaks for both maize and potato 3 h digestion residues (Figure 6C, 17 ppm) can be detected.[39] We therefore propose that the enzyme-resistant V-type helices found in the digestion residue from maize ghosts are due to amylose−lipid complexes either present in the starting granule or formed during gelatinization and/or digestion processes.[40]

Proposed Mechanism for Granule Ghost Formation. At the early stage of heat/moisture-induced starch swelling, even at lower temperatures than those required for crystallite melting, amylose and a small amount of amylopectin molecules can leach out of granules.[41] Crystallite melting,[4] driven by double-helix dissociation,[5] causes granule swelling essentially by replacing hydrogen bonds between amylopectin chains with hydrogen bonds to water molecules,[42] thereby allowing swelling of high molecular weight amylopectin. Swelling behavior is primarily a property of amylopectin,[43] a main molecular component of ghosts, whereas amylose acts both as a diluent and as an inhibitor of swelling, especially in the presence of lipids/proteins, which can form insoluble complexes with amylose.[42,44] An intact amylopectin surface is thought to form a continuous layer surrounding internal starch granule components.[3,28] At certain critical stress points of granules, swelling eventually ruptures the envelope (e.g., Figure 2F), presumably by breakdown of the molecular interactions that holds the granule surface together. On the basis of the high level of enrichment of high molecular size amylopectin, we suggest that molecular interaction between

amylopectin units is responsible for the surface integrity of ghost particles. It has previously been shown by both small-angle and wide-angle X-ray scattering that there is no detectable crystalline or lamellar order in barley starch ghosts.[1] This lack of detectable organizational structure was further extended in this study through both DSC, which showed no detectable melting endotherms (Supporting Information, Figure S2), and solid state ^{13}C NMR, which showed only amorphous features for both maize and potato freeze-dried ghost samples (Figure 6A). However, it is possible that a small amount of cross-linking through, for example, double helices could be present below detection levels of the X-ray, NMR, and DSC techniques. The finding that there is a small amount of an enzyme-resistant fraction in maize (3.8 ± 0.3%, calculated by weight of 3 h digestion residue) and potato (1.5 ± 0.4%) starch ghosts suggests the possibility that this fraction provides a cross-linking or other stabilizing function in otherwise amorphous granule ghost structures.

From NMR (Figure 6) and SEC (Figures 4 and 5) results, the enzyme-resistant fraction of maize ghosts is enriched in amylose with 19% of the sample in a lipid-complexed single-helical form, and the enzyme-resistant portion of potato ghosts is enriched in amylopectin branches/clusters with 13% of the sample present as B-type double helices. In the case of maize, no evidence has been found for the presence of any potentially cross-linking double helices within ghosts, suggesting that double helices are not necessary to provide structure to ghost particles. Although the V-type helices from amylose−lipid complexes are not responsible for cross-linking starch chains as they involve only a single starch chain, they may help to rigidify segments of amylose within maize ghosts. Potato ghosts are more highly swollen and more sensitive to shear than maize ghosts, probably due to the repulsion effect from negatively charged phosphate groups during swelling. Despite similar amylose contents and enzyme digestibility to maize starch ghosts, the enzyme-resistant fraction from potato ghosts is qualitatively different, being based on amylopectin and containing at least some double helices. Normally, B-type double helices would be expected to be formed more readily from amylose and thereby potentially act to cross-link starch polymers. SEC data (Figure 5E,J) for potato ghost enzyme-resistant residue, however, show that it contains predominantly amylopectin, consistent with largely intra-amylopectin double helices formed from adjacent branches, although cross-linking between amylopectin molecules cannot be ruled out. The presence of double helices in enzyme-resistant fractions of potato but not maize starch ghosts is consistent with the fact that the chain length distribution of amylopectin from potato is longer than that of maize (Figures 4A and 5A), and the absence of V-type helices is consistent with the much lower lipid content of potato compared to maize starch.[45] However, it should be noted that the amount of double helices is low (~13% calculated for the 3 h digestion residue, corresponding to ~0.2% based on total starch ghost explaining why it cannot be detected in non-enzyme-treated ghosts) and, therefore, not likely to be a primary mechanism for ghost formation.

On the basis of the lack of detectable ordered structure in intact ghosts, and the low level of order within the small fraction of ghosts that are enzyme resistant, it is apparent that the stable structure of ghosts is derived primarily from simple entanglement of nonordered polymers, particularly amylopectin. The highly branched primary structure and very high molecular size of amylopectin (Figure 5) mean that each molecule can be involved in a large number of temporary entanglements, the sum of which can result in an effectively permanent multimicrometer structure. Small amounts of amylose molecules may also be important to hold amylopectin molecules together by physical entanglements (e.g., maize and potato ghosts) and strengthen the cross-linking entanglements between amylopectin molecules. For example, starches from waxy maize lines with variable low levels of amylose formed granule ghosts with yield and integrity dependent on amylose content.[2] Surface proteins and lipids can also affect ghost properties. For those starches (e.g., wheat and maize) that have restricted swelling due to surface proteins/lipids,[9] ghosts prepared from SDS-treated granules show greater expansion due to the removal of constraining proteins and lipids, leading to a greater extent of swelling before sufficient cross-linking interactions occur to prevent dissolution.

In conclusion, the high molecular weight and highly branched primary structure of amylopectin will lead to many dynamic entanglements, which in combination seem to be sufficient to retain a stable ghost structure. The formation of ghosts as a consequence of extensive swelling of granules following gelatinization suggests that entanglements are formed during the swelling process, explaining why stable hydrated nonordered starch structures starting from preisolated amylopectin have not been reported. The proposed mechanism for granule ghost formation not only confirms that double helices are not necessary to strengthen ghost structure but also raises the question as to how enzyme-resistant fractions could be formed from an essentially amorphous (entangled) starch matrix. Crystallinity alone does not always lead to an increase in enzyme resistance, and almost amorphous high-amylose starches can provide high yields of resistant fraction, although it has generally been accepted that crystallinity must play some role in determining enzyme resistance.[46−48]

Volatile Compounds as Markers of Tofu (Soybean Curd) Freshness during Storage

Seonmi Lee, Heera Cho, and Kwang-Geun Lee*

Department of Food Science and Biotechnology, Dongguk University—Seoul, 26, 3-Ga, Pil-dong, Chung-gu, Seoul 100-715, Republic of Korea

ABSTRACT: Volatile compounds in packed and unpacked commercial tofu were extracted by solid phase microextraction fibers and analyzed by gas chromatography−mass spectrometry. The tofu samples were stored at 4 °C for 15 days to measure freshness and quality changes during storage. Totals of 41 and 35 volatile compounds were identified from packed tofu and unpacked tofu, respectively. Peak area ratio (PAR) of hexanal in packed tofu increased from 11.44 (day 0) to 496.30 (day 9) and finally decreased to 11.06 on day 15 of storage. PAR of ethanol and 1-hexanol increased from 5.41 and 0.76 (day 1) to 66.93 (day 9) and 47.46 (day 15), respectively. Changes in these volatiles in unpacked tofu were similar to those in packed tofu. The results show that hexanal, ethanol, and 1-hexanol are characteristic volatile compounds for providing quantitative and qualitative information regarding deterioration of tofu.

KEYWORDS: *volatile compounds, tofu, storage, freshness, HS-SPME, GC-MS*

INTRODUCTION

Tofu (soybean curd) is a healthy, popular, and traditional soy food in Asian diets, as it is rich in protein, calcium, B-vitamins, iron, and magnesium.[1] Tofu is becoming more popular in other countries because isoflavones in soybean are very beneficial to human health.[2] However, tofu is very perishable and has a short shelf life of 2−3 days.[3] Tofu is very sensitive to microbial growth even under refrigeration due to its high moisture content (>80%) and neutral pH (5.8−6.2).[4−6] Mass production of tofu is currently carried out in Korea through a pasteurizing process at a low temperature and packaging in sealed containers. Tofu is distributed by a cold-chain system. Sales of tofu increased rapidly from $336 million (2004) to $414 million (2008) in Korea. The cold-chain system provides easy handling of tofu and improves its storability.[7] Nevertheless, the only way to check the freshness of leftover tofu is to look at the expiration date on the label or smell the tofu. A few studies have investigated the development of a freshness indicator for tofu.[8]

Many studies have been conducted on the volatile compounds in fermented tofu and other soybean products. However, these studies were restricted to volatile compounds of fermented soybean products such as Thai thua nao, Chinese sufu, and Korean doenjang.[9−13] Among the volatiles, hexanal, ethanol, and 1-hexanol are found in all fermented tofu. In particular, hexanal contributes a disagreeable green grass-like aroma to tofu and soy milk.[14,15] The content of hexanal in the nonfermented tofu is higher than that in fermented tofu. This phenomenon suggests that fermentation may remove the undesirable green grass flavor from soybean products[16,17] and indicates that volatile compounds in tofu could be a durable index chemical to determine the quality of tofu during storage.

The typical methods for extracting volatile compounds from tofu are simultaneous distillation extraction, supercritical fluid extraction, and solid phase microextraction (SPME).[13,18,19] SPME has recently replaced older techniques for volatile analysis as it is fast and less labor intensive.[20] In addition, the SPME method is a solvent-free technique and is relatively inexpensive.[21] SPME coupled with gas chromatography−mass spectrometry (GC-MS) was adopted in this study.

Few studies have investigated changes in volatile compounds of fresh commercial tofu during storage.[18,22] The objective of our study was to investigate the changes in volatile compounds in commercial tofu using the SPME method and GC-MS during storage. Analyses of volatiles and microbial contamination were carried out to evaluated the freshness and quality change in tofu. The relationship between tofu freshness and volatile compounds was determined.

MATERIALS AND METHODS

Materials. Two types of tofu, a packed tofu and an unpacked tofu, were purchased at a commercial market in Korea. In Korea the market for tofu is divided into packed and unpacked tofu. The packed tofu selected in this study is the first in market share in Korea. The unpacked tofu was also selected due to higher market share in Korean traditional market. Petri film was used for microbiological analysis (3M, St. Paul, MN, USA). The C_8−C_{20} alkanes for calculating the retention indices (RI) were purchased from Aldrich Chemical Co. (St. Louis, MO, USA). Three kinds of SPME fibers with different coats were purchased from Supelco Inc. (Bellefonte, PA, USA); they were polydimethylsiloxane (PDMS, 100 μm film thickness), Carboxen−polydimethylsiloxane (CAR-PDMS, 75 μm film thickness), and polydimethylsiloxane−divinylbenzene (PDMS-DVB, 65 μm film thickness).

Sample Preparation and Storage Condition. The tofu was cut into cubed samples (5 cm ×5 cm ×3 cm) and placed in a plastic container with 160 mL of sterile purified water. Tofu was classified according to temperature and storage day. The samples were stored at 4 °C for 15 days.

Microbiological Analysis. Ten grams of sample was mixed with 90 mL of buffered peptone water (0.1%) in a sterile stomacher bag.

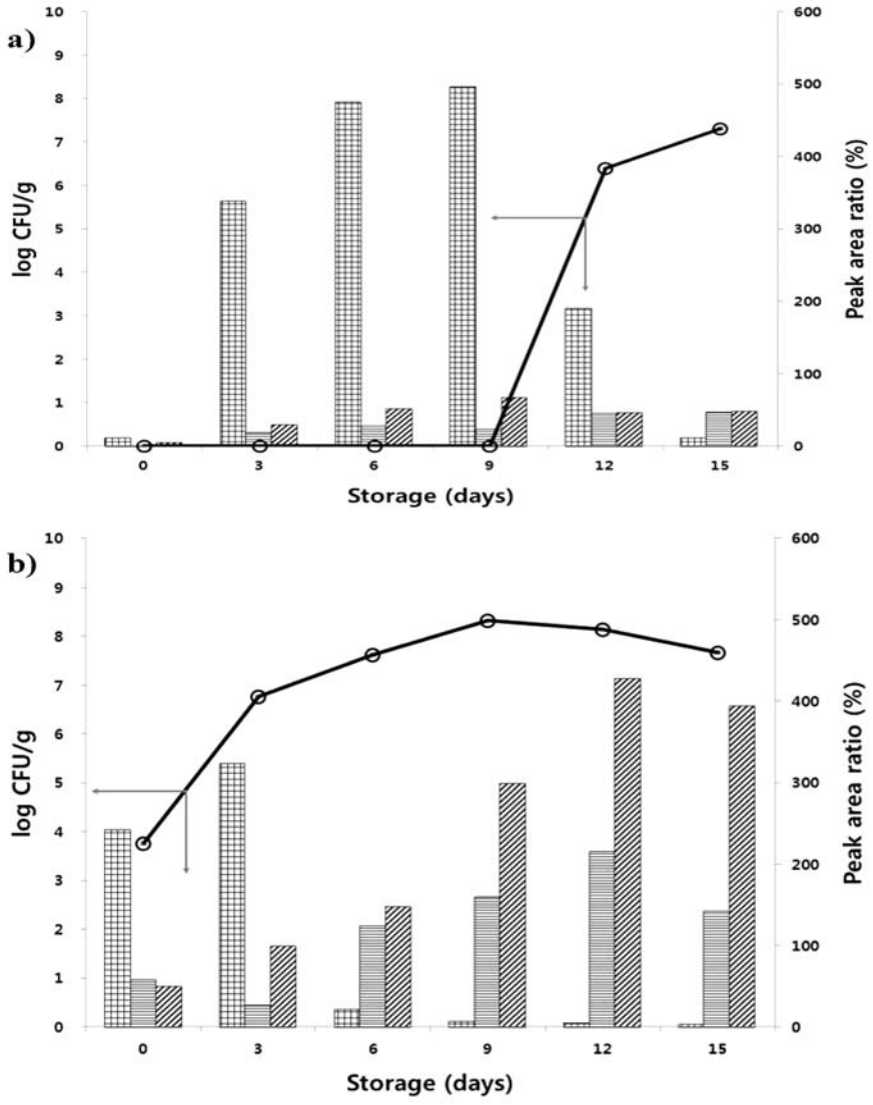

Figure 1. Relationship between microbial growth and peak area ratio of volatile compounds in packed tofu (a) and unpacked tofu (b) during storage at 4 °C. Bars represent, from left to right in each group, hexanal, 1-hexanol, and ethanol.

The mixture was blended for 1 min using a Stomacher Lab Blender (Bag mixer model, Inter Science), serially (1:10) diluted with buffered peptone water (0.1%), and plated on Petri film (3M). The Petri film was incubated at 37 °C for 48 h, and total bacterial counts were carried out.

Volatile Compound Analysis. The ground samples (2.5 g) were mixed with 2.5 mL of tofu soaking water, and the mixtures were placed into a 15 mL headspace vials (Supelco). The headspace vials were sealed with a polypropylene hole cap and PTFE/silicone septa (Supelco). Then they were pre-equilibrated for 21 min at 46 °C in a thermostatic bath. Before the volatile compound extraction, 20 μL (1 ppm) of internal standard (1,2-dichlorobenzene) was added to the sample solution. Samples were analyzed using headspace-SPME-GC-MS.

Three fibers were tested and compared: PDMS (100 μm film thickness), CAR-PDMS (75 μm film thickness), and PDMS-DVB (65 μm film thickness). Each fiber was preconditioned in the injector of the GC system according to the conditions provided by the manufacturer.

The selected fiber (CAR-PDMS (75 μm film thickness) fiber) was pushed through the vial septum of the prepared sample. The fiber was pushed out of the housing and exposed to the headspace (3 cm in depth) at 46 °C for 14 min. After extraction, the fiber was pulled into the housing, and the SPME device was removed from the vial and inserted into the injection port of a gas chromatograph (GC) for thermal desorption of the analysis (4 cm in depth). The fiber was desorbed for 10 min at 230 °C to eliminate any residual volatile compounds.

GC-MS analysis was performed using an Agilent 6890 gas chromatograph with a 5975 mass spectrometry detector (Agilent Technologies Inc., Palo Alto, CA, USA) equipped with a DB-WAX column (30 m length × 0.32 mm i.d × 0.25 μm film thickness; J&W Scientific, Folsom, CA, USA). The analytical conditions were as follows: inlet temperature, 220 °C; column head pressure, 14.14 psi; splitless time, 1 min; helium carrier gas flow rate, 1.3 mL/min; oven temperature, held at 40 °C for 4 min, raised at 5 °C/min to 185 °C, and held for 20 min. Mass spectra were generated in the electron impact mode (MSEI) at 70 eV and an ion source temperature of 230 °C. The total ion chromatograms acquired via GC-MS was used for peak area integration. Agilent MSD Chemstation software (G1701BA ver.D.02.00) was used for data acquisition.

Compound Identification and Quantification. The volatile compounds were positively identified by comparing Kovats retention indices (KI)[23] and the MS fragmentation patterns with those of reference compounds or with mass spectra in the Wiley 275 mass spectral database (Hewlett-Packard, Palo Alto, CA, USA) and previously reported KIs. The KIs of the unknown compounds were determined via sample injection with a homologous series of alkanes (C_8−C_{20}). The GC-MS conditions were the same as described above. To quantify volatiles, the samples were run in duplicate, and the integrated areas based on the total ion chromatograms were normalized to the areas of the internal standard and averaged. The relative volatile concentrations

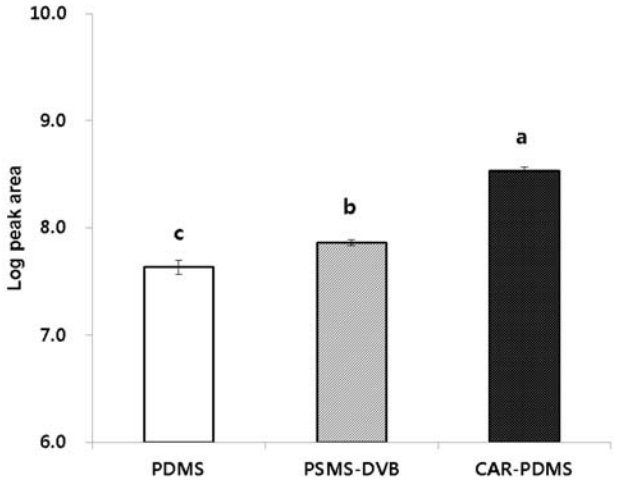

Figure 2. Effect of the SPME fiber on extraction of total volatile compounds from tofu (values sharing a common letter are not significantly different; $p \leq 0.05$).

in the tofu samples were determined by comparison with the concentration of the internal standard (1,2-dichlorobenzene), assuming a response factor of 1.

Statistical Analysis. SPME fiber screening statistics were conducted using the Statistical Analysis System (SAS) software ver. 9.2 (SAS Institute, Cary, NC, USA).

RESULTS AND DISCUSSION

Microbiological Analysis. Figure 1 shows the microbial population and volatiles of packed and unpacked tofu during the storage period at 4 °C. The initial colony-forming units (CFUs) of aerobic mesophilic microorganisms (total bacterial count) of packed tofu and unpacked tofu were different. No microorganisms were detected until storage day 9 for packed tofu. Then, their level reached 7.29 log CFU/g at day 15. The initial number of microbial flora in unpacked tofu was 3.76 log CFU/g, which was much higher than that of packed tofu. The number of microbial flora ranged from 3.76 to 7.67 log CFU/g in unpacked tofu for all storage days. The maximum log CFU/g in unpacked tofu was found after 9 days of storage. The unpacked tofu had rapidly growing microbial flora compared with that in the packed tofu because it was exposed to air without any packaging material. In Korea the microbial (aerobic mesophilic microorganisms) count exceeding the safe level is approximately 6−7 log CFU/g.[8] However, coli form should be <1 log CFU/g in tofu.[24]

Selection of SPME Fiber. Three fibers, PDMS (100 μm film thickness), PDMS-DVB (65 μm film thickness), and CAR-PDMS (75 μm film thickness), were evaluated to analyze total volatiles in tofu. The effects of the various PDMS, PDMS-DVB, and CAR-PDMS fibers on extraction of the volatile compounds in packed tofu are shown in Figure 2. The sum of peak area of each volatile was significantly higher in CAR-PDMS than that in

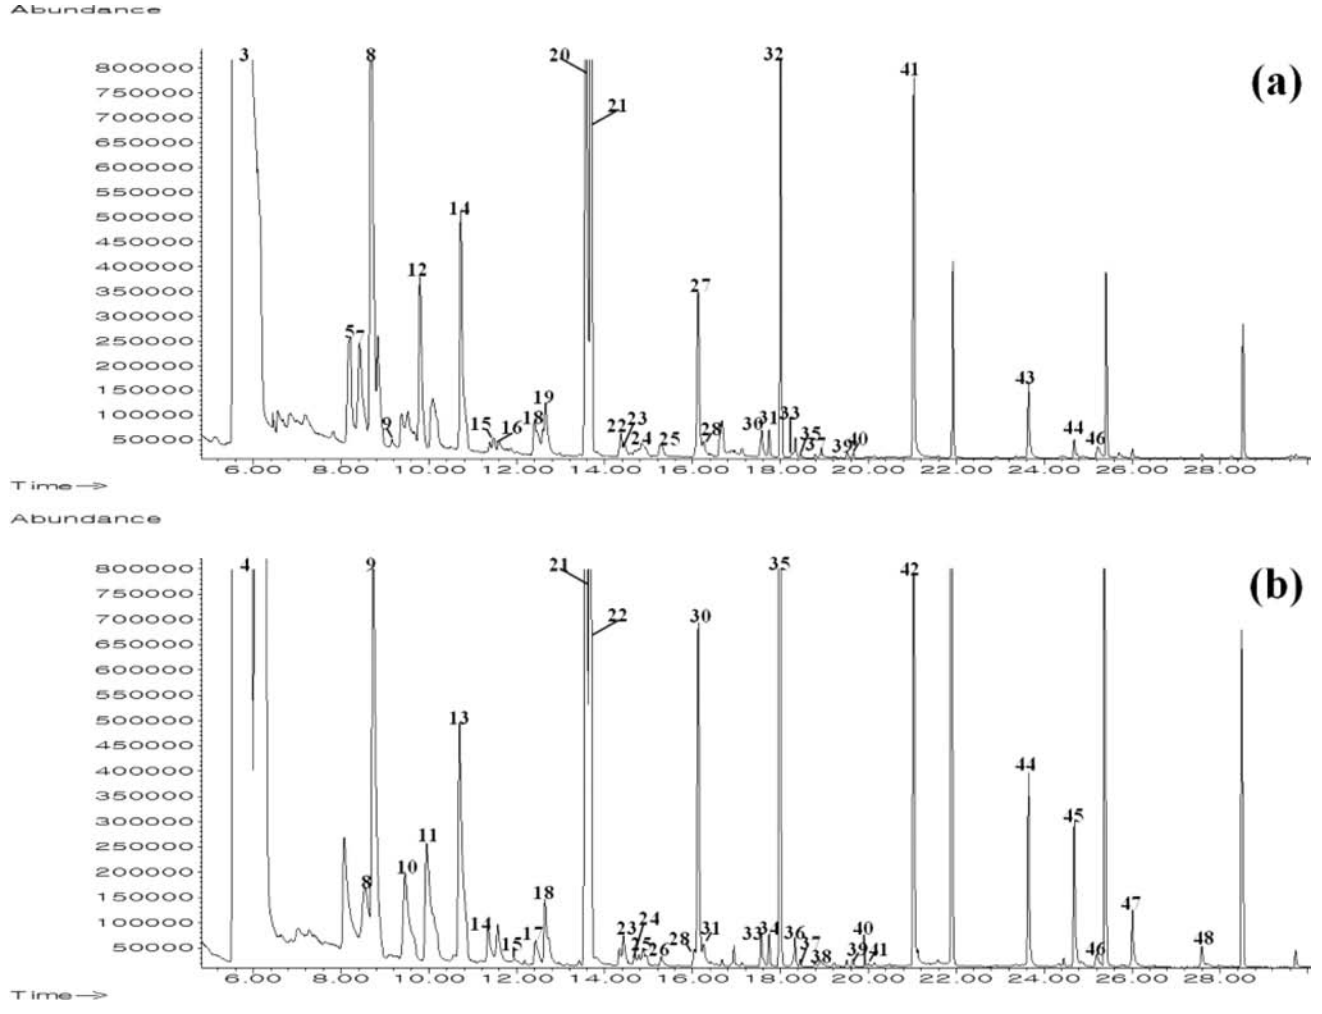

Figure 3. Gas chromatography−mass spectrometry chromatogram of packed tofu (a) and unpacked tofu (b) on day 0 at 4 °C.

dx.doi.org/10.1021/jf404847g | J. Agric. Food Chem. 2014, 62, 772−779

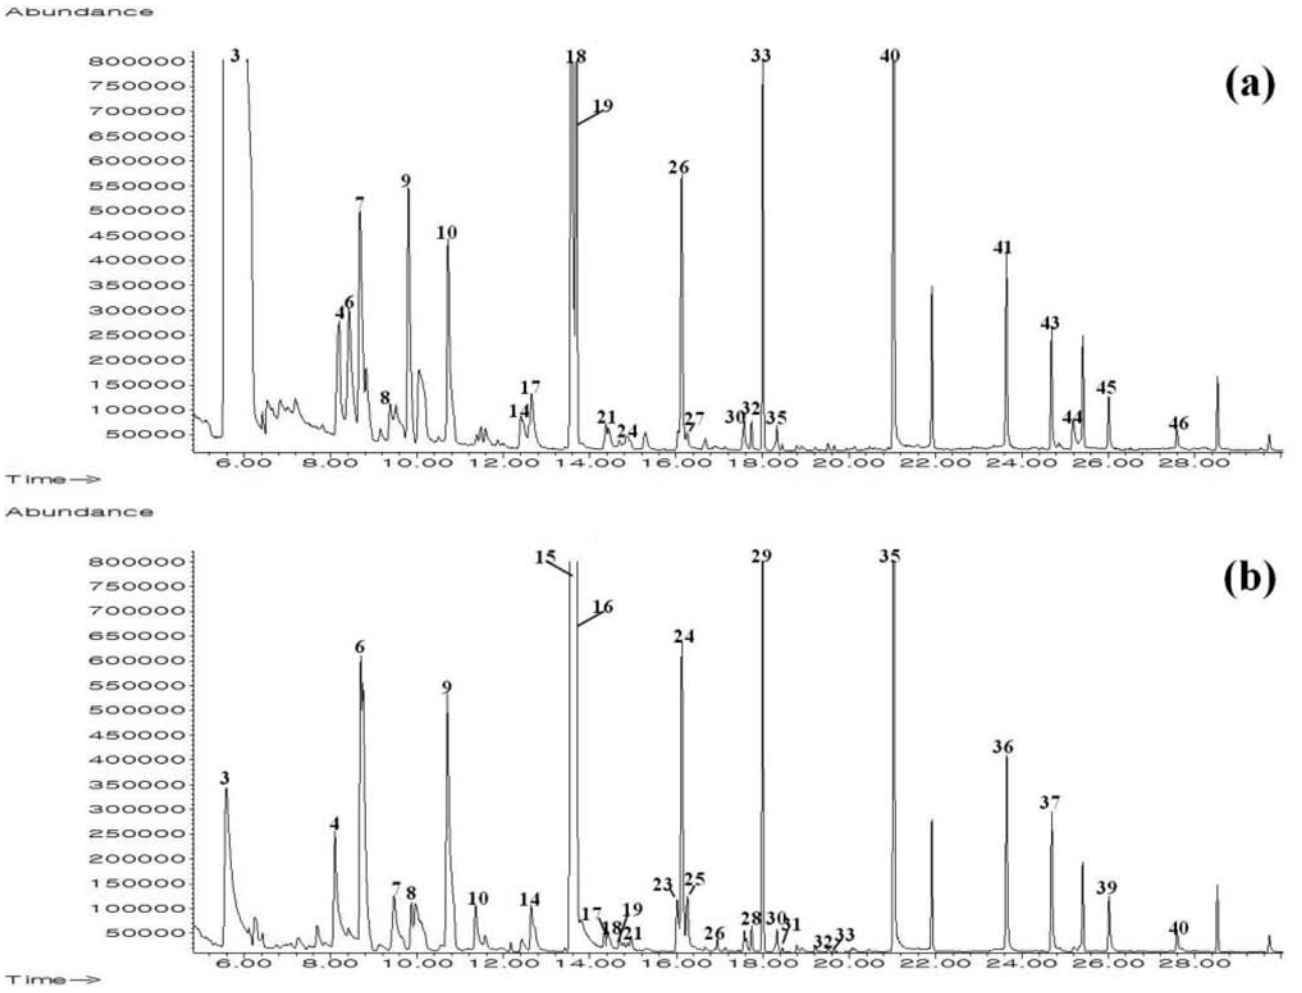

Figure 4. Gas chromatography−mass spectrometry chromatogram of packed tofu (a) and unpacked tofu (b) on day 6 at 4 °C.

the other fibers ($p \leq 0.05$). Thus, CAR-PDMS was selected to analyze the tofu volatiles.

Changes in Tofu Volatile Compounds. Volatile compounds were analyzed by GC-MS using a SPME method to measure freshness and quality changes in the packed and unpacked tofu. Figures 3, and 4, 5 show GC-MS chromatograms in the two types of tofu at days 0, 6, 15 (4 °C), respectively. Volatile chemicals in the GC-MS chromatograms were clearly separated in the packed and unpacked tofu. The major peaks in tofu were hexanal (peak 3 in both tofus) and 1-hexanol (peak 18 in the packed and peak 15 in the unpacked) (Figure 4). As shown in Table 1, 42 volatile compounds were identified in packed tofu during storage for 15 days at 4 °C, including 6 acids, 17 alcohols, 9 aldehydes, 1 alkane, 1 aromatic compound, 2 furans, 3 ketones, and 3 miscellaneous compounds. Thirty-five volatile compounds were identified in unpacked tofu, including 5 acids, 16 alcohols, 6 aldehydes, 1 alkane, 1 aromatic compound, 2 furans, 2 ketones, and 2 miscellaneous compounds during storage for 15 days at 4 °C (Table 2).

Alcohols were the largest class of volatile compounds in both packed and unpacked tofu. Seventeen and 16 alcohols were identified in packed and unpacked tofu, respectively, including ethanol, 1-penten-3-ol, 3-methyl-1-butanol, 1-pentanol, (*Z*)-2-penten-1-ol, 1-hexanol, (*Z*)-3-hexen-1-ol, 3-octanol, (*E*)-2-hexen-1-ol, 1-octen-3-ol, 1-heptanol, benzenemethanol, 2,3-butanediol, 1-octanol, 1,2-propanediol, and 1*H*-indol-5-ol. 1-Hexanol and 1-octen-3-ol were key compounds that yield a green bean flavor.[24] The peak area ratio (PAR) of 1-hexanol increased from 0.76 to 47.46 in packed tofu and from 58.05 to 215.24 in unpacked tofu as the storage was extended. The PAR of 1-octen-3-ol increased from 0.21 to 10.16 in packed tofu and from 8.67 to 14.24 in unpacked tofu, but it was not dramatically increased compared to that of hexanol.

Ethanol increased steadily in accordance with increasing storage. The PAR of ethanol increased from 5.41 to 66.93 in packed tofu during 9 storage days. However, the PAR of ethanol in unpacked tofu was 49.46 and increased to 428.18 at storage day 12. In contrast, pleasant odors such as 1-octanol (rosy-like odor) and 3-octanol (melon, herbaceous, nutty, citrus-like odor) in packed tofu were detected until storage day 3, but they were not detected after day 6. 1-Octanol and 3-octanol were detected in unpacked tofu until storage days 9 and 15, respectively. The PARs of 1-octanol and 3-octanol were 0.36 and 0.71, respectively, at days 9 and 15 of storage. The trend in the change in alcohols in the two types of tofu was different during storage. The PARs of nine alcohols increased in packed tofu. However, those of the other eight alcohols decreased and were not detected at day 3 or later. The PARs of the 14 alcohols increased during storage in the unpacked tofu, but 3 alcohols, 1-octanol, benzenemethanol, and 1,2-propanediol, were not detected at days 12, 15, and 3, respectively.

Six acids, including benzeneacetic acid, acetic acid, butanoic acid, propionic acid, hexanoic acid, and benzoic acid, were identified in packed and unpacked tofu except for propionic acid.

dx.doi.org/10.1021/jf404847g | *J. Agric. Food Chem.* 2014, 62, 772−779

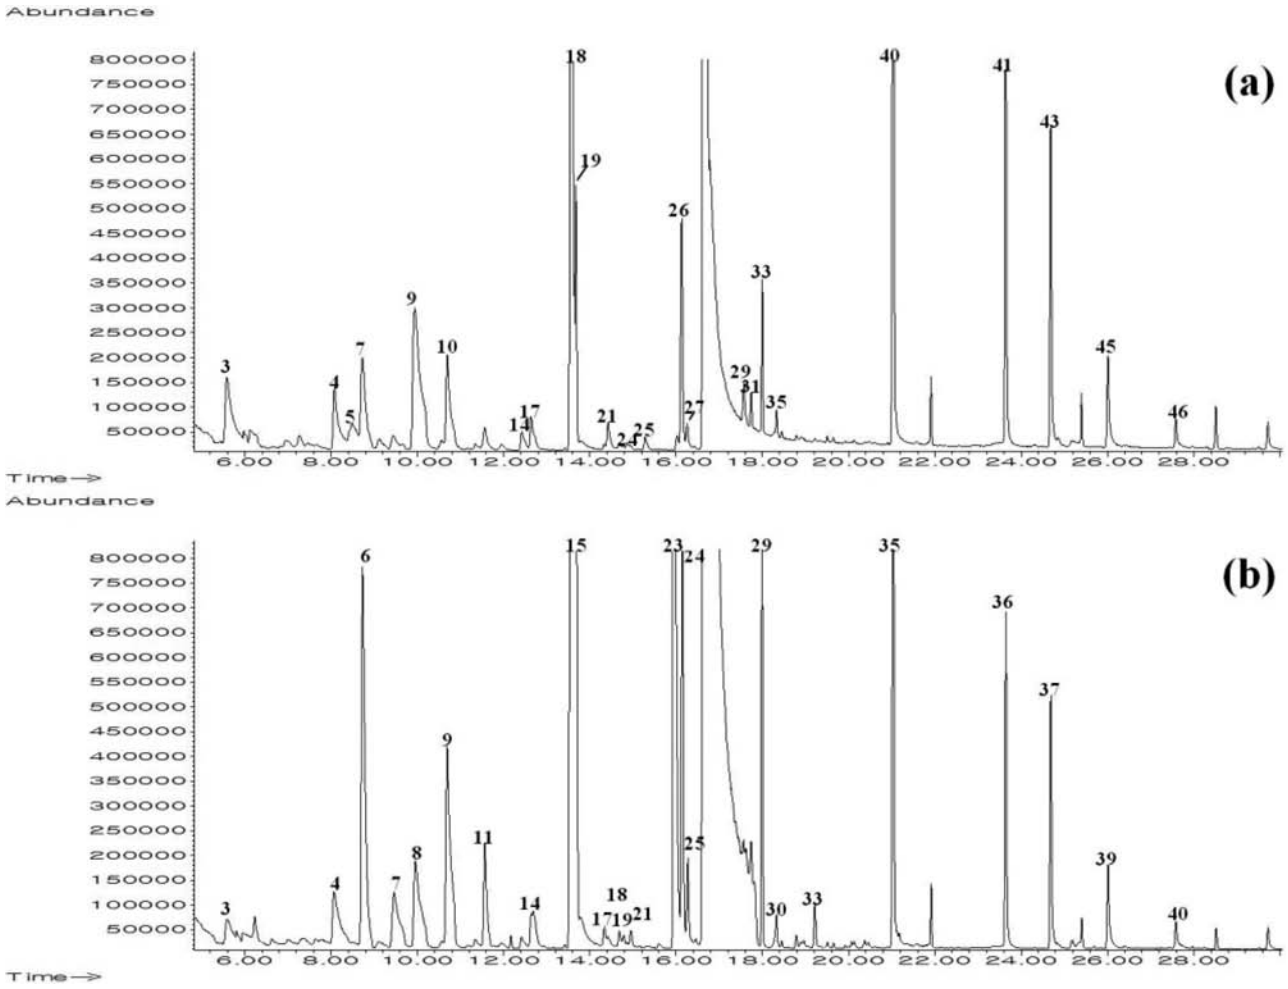

Figure 5. Gas chromatography−mass spectrometry chromatogram of packed tofu (a) and unpacked tofu (b) on day 15 at 4 °C.

The benzeneacetic acid and butanoic acid levels were relatively high among acids in both tofus. In accordance with a previous study, hexanoic acid was found in mold-fermented sufu, soybean milk, and soybean paste. This acid is derived from the oxidation of hexanal.[12,25,26] However, in our study, hexanoic acid was detected in both tofus only during early storage. Butanoic acid and acetic acid result from hydrolysis of soybean lipids.[27] Several acids have been described as having a cheesy odor, including butanoic acid (cheesy, sweaty, sharp, sour, rancid) and hexanoic acid (cheesy, pungent, rancid, sour, sweaty, fatty).[9] The various acids were observed more in fermented or deteriorated tofu than those in fresh tofu. In particular, unpacked tofu had higher levels of benzeneacetic acid and acetic acid than packed tofu.

Nine aldehydes, including hexanal, heptanal, (*E*)-2-hexanal, octanal, (*E*)-2-heptenal, nonanal, (*E*)-2-octenal, benzaldehyde, and 2, 4-decadienal, were identified in packed tofu. Six aldehydes, including hexanal, heptanal, (*E*)-2-heptenal, nonanal, 3-hydroxybutanal, and benzaldehyde, were also found in unpacked tofu. Benzaldehyde (cherry or almond-like odor) and 2,4-decadienal (potato chip-like odor) are favorable odors of aldehyde compounds.[28,29] Hexanal is one of the important volatile compounds of tofu, but it contributes a disagreeable green grass-like odor to tofu.[14] It was reported that the content of hexanal in tofu decreased markedly during storage,[16] and fermented soybean pastes and tofu had large amounts of hexanoic acid, a derivative of hexanal.[12] In accordance with those early studies, it is inferred that hexanal can be used as a freshness indicator of tofu. A high concentration of hexanal was found in the fresh tofu, indicating that it had not deteriorated. The PAR of hexanal increased from 11.44 (initial day) to 496.30 (day 9) and finally decreased to 11.06 (day 15) in packed tofu. It increased from 242.27 (initial day) to 324.04 (day 9) in unpacked tofu and then decreased to 2.87 (day 15). Previous study reported that hexanal contributes to the green and grassy odor of the raw material of tofu.[17] From these results, we assumed that the undesirable green grass-like flavor decreased during deterioration.

2-Ethylfuran and 2-pentylfuran were identified in both packed tofu and unpacked tofu. 2-Pentylfuran has been recognized to have a grassy or green bean aroma.[30] Formation of furan is due to sugar dehydration of fragmentation in the Maillard reaction.[30] Three ketones, including 2-heptanone, 3-hydroxy-2-butanone, and 2,3-octanedione, were identified from packed tofu. Among them, 2-heptanone, which possesses a spicy, fruity, cinnamon-like odor, has been reported in mold-fermented sufu, cooked soybean, fermented soybean paste, soybean milk, chungkuk-jang, and natto.[9,26,28,31] However, 2-heptanone was not found in unpacked tofu.

In conclusion, the objectives of the present study were to analyze the profile of the volatile compounds in packed and unpacked tofu during storage at 4 °C. Among the SPME fibers, the CAR-PDMS fiber was the most suitable to extract the volatile compounds in tofu; 42 and 40 volatile compounds were identified from packed and unpacked tofu, respectively.

Hexanal, ethanol, and 1-hexanol were characteristic volatile compounds that provided quantitative and qualitative information regarding the deterioration of tofu. Volatile compounds could be a useful indicator to determine the overall edibility of food such as tofu. Currently, this approach is being applied to more diverse foods to determine their edibility.

Topoisomerase II-Targeting Properties of a Grapevine-Shoot Extract and Resveratrol Oligomers

Simone A. Baechler,[†] Anika Schroeter,[†] Martina Dicker,[†] Pablo Steinberg,[§] and Doris Marko*[,†]

[†]Department of Food Chemistry and Toxicology, University of Vienna, Waehringerstrasse 38, A-1090 Vienna, Austria

ABSTRACT: Grapevine-shoot extracts (GSE), containing *trans*-resveratrol and resveratrol oligomers, are commercially available as food supplements. Considering the topoisomerase-targeting properties of *trans*-resveratrol, the question of whether GSE affect these enzymes, thereby potentially causing DNA damage, was addressed. In a decatenation assay, GSE potently suppressed the catalytic activity of topoisomerase IIα ($\geq$5 μg/mL). The resveratrol oligomers ϵ-viniferin, r2-viniferin, and hopeaphenol, isolated from GSE, were also identified as topoisomerase IIα inhibitors. In the in vivo complexes of enzyme to DNA (ICE) bioassay, neither GSE, r2-viniferin, nor hopeaphenol affected the level of enzyme–DNA intermediates in A431 cells, thus representing catalytic inhibitors rather than topoisomerase poisons. GSE caused moderate DNA strand breaks ($\geq$25 μg/mL) in the comet assay. Taken together, GSE presumably acts as a catalytic inhibitor of topoisomerase II with r2-viniferin and hopeaphenol as potentially contributing constituents. However, the increase of FPG-sensitive sites points to an additional mechanism that may contribute to the DNA-damaging properties of GSE constituents.

KEYWORDS: *grapevine-shoot extract, resveratrol oligomers, topoisomerase II, DNA damage*

INTRODUCTION

Resveratrol (*trans*-3,5,4′-trihydroxystilbene) is a natural polyphenol found in grapes (*Vitis vinifera*), berries, peanuts, and red wine.[1,2] This plant phytoalexin has been associated with health benefits due to its antioxidant, anti-inflammatory, and antitumorigenic properties.[2−5] These activities are mediated through its interaction with multiple cell signaling pathways including several receptors, kinases, and cyclooxygenases.[5,6] Recently, topoisomerase II has been identified as another target for *trans*-resveratrol.[7,8] Due to the claimed beneficial health effects of resveratrol such as cardioprotection and cancer prevention,[5,9] the intake of dietary supplements consisting of grape-derived complex mixtures is increasing.[5]

The grapevine-shoot extract (GSE) used in this study contains high amounts of *trans*-resveratrol (7.7%) and resveratrol oligomers (29.4%) such as ϵ-viniferin, r2-viniferin, and hopeaphenol (Figure 1; see Materials and Methods), which are biosynthesized by the plants via oxidative coupling.[10,11] GSE has been shown to exert antiproliferative, pro-apoptotic, and antioxidant properties, partially exceeding the effects expected for *trans*-resveratrol.[11−13] Thus, it might be presumed that individual polyphenols present in the extract act synergistically.[11] Although data regarding the biological activity of resveratrol oligomers are quite limited, it has been reported that hopeaphenol, r2-viniferin, and ϵ-viniferin possess potent antiproliferative effects in different tumor cell lines.[14−17] Furthermore, these resveratrol oligomers have been identified, besides *trans*-resveratrol and miyabenol C, as growth-inhibiting compounds present in GSE in an activity-guided isolation.[10] Because *trans*-resveratrol has been shown to interact with human topoisomerase II,[7,8] the question arises whether GSE, rich in stilbenes, exhibits topoisomerase-II-inhibiting activity, thereby potentially contributing to its antiproliferative effects.

Topoisomerases are ubiquitous enzymes maintaining the topology of DNA within the cell.[18] Thus, they are essential during replication, transcription, chromosome segregation, and cell division, because these processes demand an alteration of DNA topology.[19−21] During their catalytic cycle, they generate transient DNA strand breaks by forming a covalent enzyme–DNA intermediate, called a "cleavable complex", to release torsional stress.[22] Two distinct topoisomerase II isozymes, α and β, are present in mammals. Despite their high sequence homology, they are encoded on different genes and exhibit differences in their cellular expression and function. Expression of topoisomerase IIα is tightly linked to cell proliferation, whereas IIβ is constitutively expressed.[23,24] Because topoisomerases are essential for cell proliferation, they are important targets of clinically used anticancer and antibacterial drugs.[22,23,25] However, in the present work we focused exclusively on the inhibition of human topoisomerase II. Two classes of inhibitors are distinguished by their mode of action. Topoisomerase poisons are able to stabilize the covalent enzyme–DNA intermediate and by doing so enhance the levels of cleavable complexes, whereas catalytic inhibitors act on many different steps in the catalytic cycle of topoisomerases.[19,22,25,26] Topoisomerase poisons exert cytotoxic properties by causing DNA strand breaks after collision of replication or transcription machineries with the stabilized cleavable complex. In contrast, catalytic inhibitors block the overall catalytic activity of the enzyme, leading to inhibition of tumor cell proliferation.[19,27]

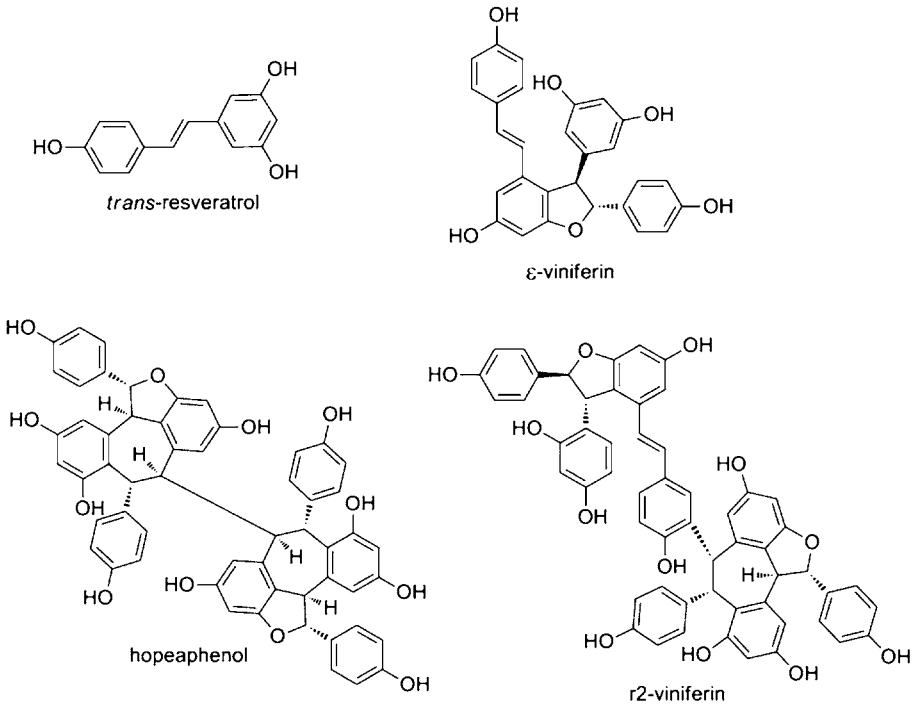

Figure 1. Chemical structures of *trans*-resveratrol and the resveratrol oligomers tested in this study.

In the present study, the question of whether GSE and several of its resveratrol oligomers possess topoisomerase II inhibitory properties, leading to DNA damage, was addressed. Because topoisomerase inhibitors mediate antiproliferative effects, possible therapeutic benefits in chemotherapy should be revealed. Therefore, we determined the ability of GSE to interact with human topoisomerase II in a cell-free decatenation assay and compared it with that of its constituents resveratrol, *ε*-viniferin, r2-viniferin, and hopeaphenol. By measuring the ability of topoisomerase II to decatenate circulated kinetoplast DNA, both classes of topoisomerase inhibitors are detected in a decatenation assay. Therefore, an ICE bioassay was additionally performed in human epidermoid carcinoma cells, which selectively detects topoisomerase poisons by separating cleavable complexes from free enzyme. Because inhibition of these essential enzymes might lead to an enhanced DNA strand break rate, the impact of GSE and its resveratrol oligomers on DNA integrity was measured via single-cell gel electrophoresis (comet assay).

MATERIALS AND METHODS

Chemicals and Recombinant Enzymes. The GSE vineatrol30 was kindly provided by Breko GmbH (Bremen, Germany) and Actichem (Montauban, France), which develop and produce this extract in cooperation. Vineatrol30 included 7.7% resveratrol, 14.6% *ε*-viniferin, 3.4% ampelopsin A, 1.8% hopeaphenol, 2.4% iso-*trans*-*ε*-viniferin, 1.6% vitisin A (r2-viniferin), 2.5% vitisin B (r-viniferin), 0.6% piceatannol, and 2.5% miyabenol C. Taken together, 37.1% of vineatrol30 consists of resveratrol and resveratrol oligomers. According to the manufacturer Actichem, at the present time the identities of compounds making up 62.9% of the extract remain unknown, but the presence of further polyphenols can definitely be discarded. *ε*-Viniferin (90% purity), r2-viniferin (>93% purity), and hopeaphenol (95% purity) were kindly provided by Actichem. Resveratrol and etoposide (ETO) were purchased from Sigma-Aldrich Chemie GmbH (Taufkirchen, Germany) and cell culture media and supplements from GIBCO Invitrogen Life Technologies (Karlsruhe, Germany), Sigma-Aldrich Chemie GmbH, and SARSTEDT AG & Co. (Nuembrecht, Germany). Recombinant topoisomerase II*α* was generously provided by Prof. Boege (Duesseldorf, Germany).

Cell Culture and Incubation. The human epidermoid carcinoma cell line A431 was obtained from the German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig, Germany). A431 cells were cultivated in minimum essential medium (MEM, 4.5 g/L glucose, without sodium pyruvate), containing 10% (v/v) heat-inactivated fetal calf serum (FCS), 1% (v/v) penicillin/streptomycin, and 1% (v/v) L-glutamine. Cells were cultured at 37 °C in a humidified 5% CO_2 atmosphere and routinely tested for mycoplasma contamination. Cell passages between 10 and 25 were used to perform the experiments.

GSE was dissolved in dimethyl sulfoxide, whereas solutions of resveratrol, r2-viniferin, *ε*-viniferin, and hopeaphenol were prepared with 70% (v/v) ethanol on ice. Aliquots of the stock solutions were stored at −80 °C and added to the incubation media just before the experiments, thus resulting in the corresponding final concentrations of the test compounds and 1% (v/v) DMSO and ethanol. However, final concentrations of the solvents of 3.3% were present in the decatenation assay. All tests were carried out in the presence of catalase (100 U/mL) to prevent hydrogen peroxide generation in the cell culture media.

Decatenation Assay. The catalytic activity of topoisomerase II was measured with kinetoplast DNA from *Crithidia fasciculata* (kDNA) (TopoGen, Port Orange, FL, USA). kDNA (250 ng) was incubated at 37 °C for 60 min in a final volume of 30 μL topoisomerase II assay buffer (50 mM Tris-HCl, pH 7.9, 120 mM KCl, 10 mM $MgCl_2$, 1 mM ATP, 0.5 mM DTT, 0.5 mM EDTA, and 0.03 mg/mL BSA) in the presence or absence of 40 ng of topoisomerase II*α*. The reaction was stopped by the addition of $^1/_{10}$ volume of 1 mg/mL proteinase K in 10% (w/v) SDS and incubated for 30 min at 37 °C. Gel electrophoresis was conducted at 4.5 V/cm in 1% (w/v) agarose gels with a Tris acetate/EDTA buffer (40 mM Tris, 1 mM EDTA, pH 8.5, 20 mM acetic acid). The gel was stained with ethidium bromide solution (10 μg/mL) for 20 min. The fluorescence of ethidium bromide was measured with a LAS4000 digital imaging system (Fujifilm, Duesseldorf, Germany).

Isolating in Vivo Complexes of Enzyme to DNA (ICE) Bioassay. The ICE bioassay was performed with slight modifications as previously described.[28] Three million A431 cells were seeded in

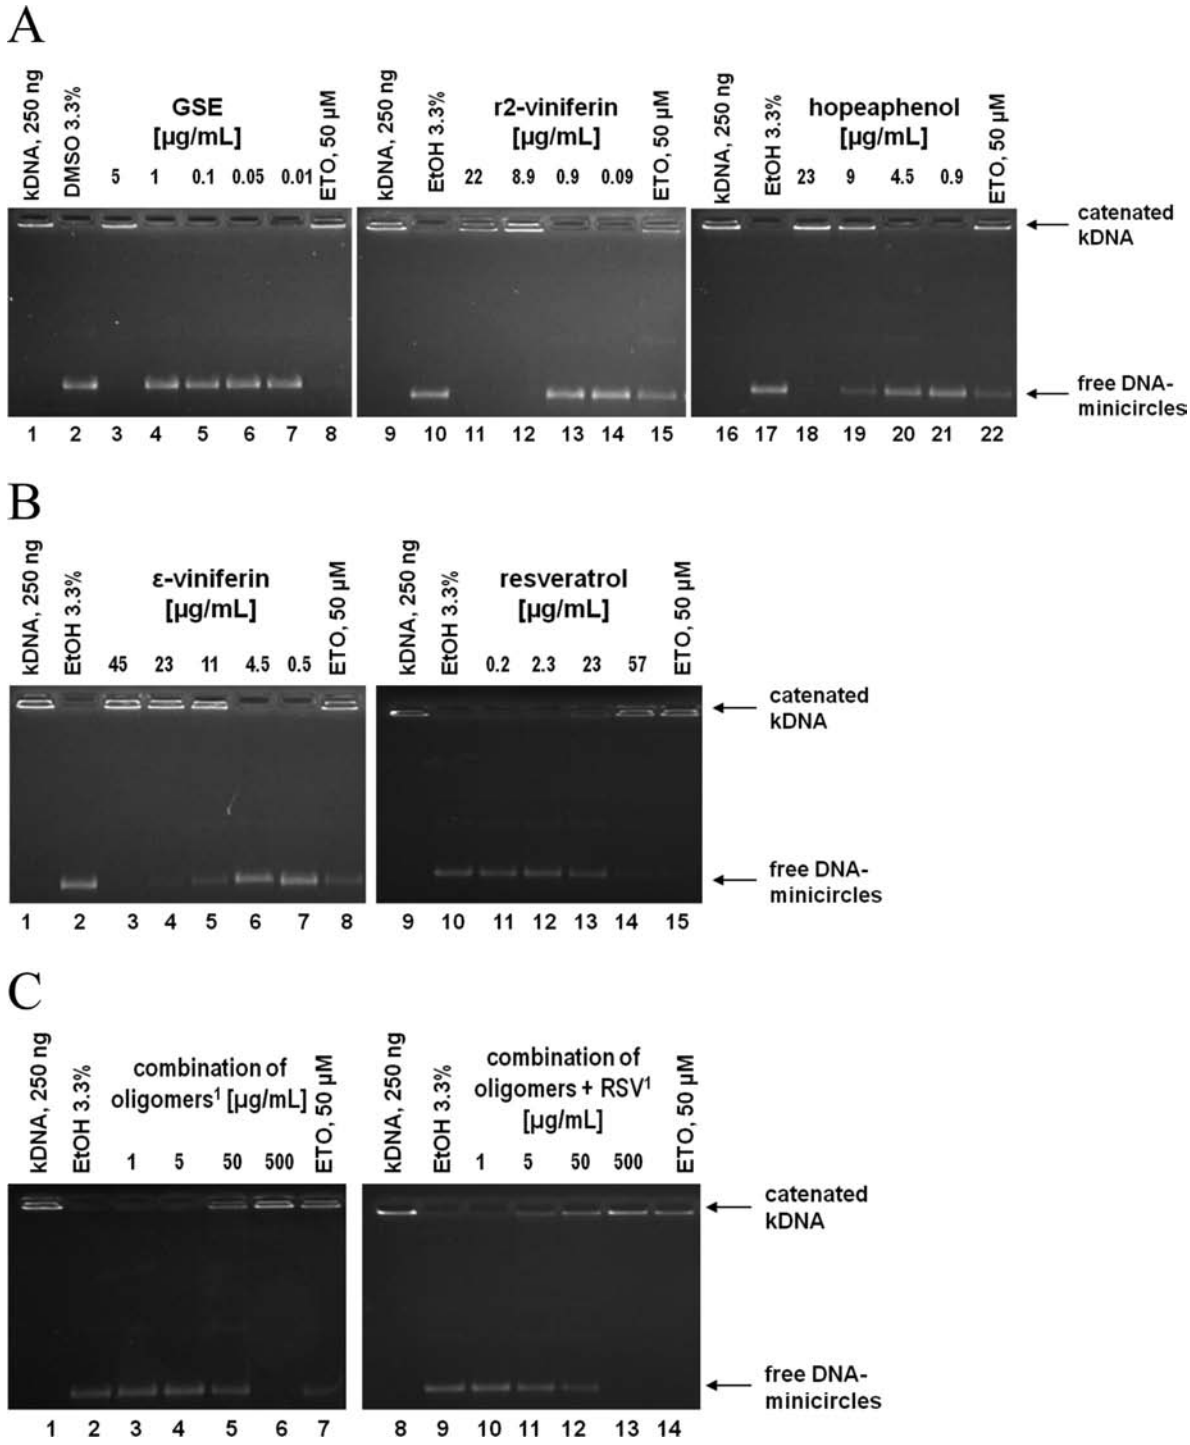

Figure 2. Impact of GSE and resveratrol oligomers on the catalytic activity of topoisomerase IIα using a decatenation assay. Topoisomerase IIα was exposed to increasing concentrations of the compounds for 60 min at 37 °C. A representative gel of three experiments with similar outcomes is shown. The topoisomerase II poison etoposide (ETO) was used as positive control. (A) Lanes: 1, 9, and 16, kDNA (250 ng); 2, 10, and 17, kDNA + topoisomerase IIα + respective solvent control (3.3%); 3−7, 11−14, and 18−21, kDNA + topoisomerase IIα + test compound; 8, 15, and 22, kDNA + topoisomerase IIα + ETO. (B) Lanes: 1 and 9, kDNA (250 ng); 2 and 10, kDNA + topoisomerase IIα + EtOH (3.3%); 3−7 and 11−14, kDNA + topoisomerase IIα + test compound; 8 and 15, kDNA + topoisomerase IIα + ETO. (C) Lanes: 1 and 8, kDNA (250 ng); 2 and 9, kDNA + topoisomerase IIα + EtOH (3.3%); 3−6 and 10−13, kDNA + topoisomerase IIα + test compounds; 7 and 14, kDNA + topoisomerase IIα + ETO.

Petri dishes (diameter = 15 cm) and allowed to grow for 72 h to achieve a cell confluence of ∼80%. Cells were incubated with the solvent control or the test compounds for 1 h under serum-free conditions. The topoisomerase II poison etoposide (ETO), which is clinically used as a chemotherapeutic drug, was included as a positive control. Thereafter, cells were harvested and lysed in 6 mL of TE buffer (10 mM Tris, pH 8.0, 1 mM EDTA, 1% (w/v) *N*-laurylsarcosyl sodium salt). Cell lysates (4 mL) were layered onto a cesium chloride gradient in polyallomer tubes (14 mL; SW40, Beckman Coulter GmbH, Krefeld, Germany). After centrifugation at 100000*g* for 24 h at 20 °C, the gradient was fractionated and slot-blotted onto nitrocellulose membranes. Immunodetection was performed by using

dx.doi.org/10.1021/jf4046182 | *J. Agric. Food Chem.* 2014, 62, 780−788

specific polyclonal antibodies (Santa Cruz Biotechnology, Heidelberg, Germany). Chemoluminescent signals (LumiGLO, Cell Signaling Technology, Beverly, MA, USA) were analyzed with a LAS4000 digital imaging system (Fujifilm). The DNA content of the single fractions was measured with a NanoDrop2000 spectrophotometer (PeqLab Biotechnologie GmbH, Erlangen, Germany). The intensity of the chemoluminescent signals was integrated using the software Multi Gauge V3.2 (Fujifilm). The resulting arbitrary light units of the DNA-containing fractions were normalized to the respective DNA content and plotted as test over control (T/C, %).

Comet Assay. Single-cell gel electrophoresis was performed according to the method of Gedik et al.[29] as previously described by Pelka et al.[30] Three hundred thousand A431 cells were seeded in Petri dishes (diameter = 5.5 cm) and allowed to grow for 48 h prior to drug treatment (cell confluence = ∼60−70%). Cells were exposed to the corresponding solvent controls (DMSO or ethanol (70%, v/v) or the test compounds for 1 h in serum-free medium. Irradiation with UV light for 2 min was included in the testing as a positive control. Cells were harvested, and cell viability was determined by trypan blue exclusion. An equivalent volume of trypan blue solution (0.4%; Sigma-Aldrich Chemie GmbH) was added to 50 μL of cell solution. Whereas viable cells are able to exclude the dye, dead cells are stained dark blue. Cell viability was determined as percentage of total viable cells (unstained) per total cells (stained and unstained). After centrifugation of aliquots containing 30000 cells at 425*g* for 10 min, the pellet was resuspended in 65 μL of low-melting agarose and layered onto microscope slides. After the solidification of agarose, the slides were immersed overnight at 4 °C in lysis solution (89 mL of lysis buffer [2.5 mM NaCl, 100 mM EDTA, and 10 mM Tris-HCl, pH 10, 1% (w/v) *N*-laurylsarcosyl sodium salt], 10 mL of DMSO, and 1 mL of Triton X-100).

Treatment with the enzyme formamidopyrimidine-DNA-glycosylase (FPG) was conducted to detect FPG-sensitive base modifications. Samples were incubated with a 1:3000 dilution of the enzyme (New England Biolabs, Vienna, Austria) in FPG buffer (40 mM HEPES, 0.1 M KCl, 0.5 mM EDTA, pH 8, 0.2 mg/mL BSA) for 30 min at 37 °C. Alkaline treatment (300 mM NaOH, 1 mM EDTA, pH 13.5) was performed for 20 min at 4 °C and was followed by a horizontal gel electrophoresis (25 V, 300 mA) for another 20 min at 4 °C. After neutralization, samples were stained with ethidium bromide. Fluorescence was detected with a Zeiss Axioskop (λ_{ex} = 546 ± 12 nm; λ_{em} > 590 nm), and tail intensity (intensity of the DNA in the comet tail calculated as a percentage of overall DNA intensity) was analyzed by scoring 50 images per slide with CometIV software (Perceptive Instruments, Suffolk, UK).

Statistical Analysis. Data were expressed as the mean ± SD. After analysis of the variance of the results (ANOVA), differences between single groups were determined by Student's *t* test using the software Origin 9 (OriginLab, Northampton, MA, USA).

RESULTS

Topoisomerase II-Targeting Properties of GSE and Several of Its Constituents. In preliminary experiments r2-viniferin, ε-viniferin, and hopeaphenol were tested in the concentration ranges 0.9−18, 0.5−44.5, and 0.9−18 μg/mL, respectively, whereby the growth-inhibiting effect of r2-viniferin and hopeaphenol became statistically significant after 48 h at a concentration ≥4.5 μg/mL and that of ε-viniferin at a concentration ≥27 μg/mL (E. Nevo-Koch, unpublished observations). To elucidate the molecular mode of action leading to the observed antiproliferative effects of GSE and the resveratrol oligomers, the impact of these compounds on topoisomerase II activity was investigated within the same concentration range using a decatenation assay. Resveratrol was also included in the testing for comparison reasons (Figure 2). Whereas kDNA in its catenated form cannot enter an agarose gel (Figure 2A, lanes 1, 9, and 16), single DNA minicircles released from the catenated network by catalytically active topoisomerase II will migrate into the gel (Figure 2A, lanes 2, 10, and 17). GSE showed potent topoisomerase II-inhibiting properties, completely blocking the enzyme at a concentration of 5 μg/mL, as no migrating minicircles were detected. This inhibitory concentration of the extract contains 0.7 μg/mL ε-viniferin, 0.4 μg/mL *trans*-resveratrol, 0.09 μg/mL hopeaphenol, and 0.08 μg/mL r2-viniferin. A possible contribution of these single compounds to the topoisomerase-II-inhibiting properties of the extract was further determined in the decatenation assay. All tested resveratrol oligomers were found to inhibit the catalytic activity of topoisomerase IIα. The resveratrol tetramer r2-viniferin possessed the strongest inhibiting properties entirely suppressing enzyme activity at concentrations ≥8.9 μg/mL. Hopeaphenol also exhibited a moderate topoisomerase II-targeting potency and inhibited the enzyme at concentrations ≥4.5 μg/mL. Exposure to 23 μg/mL hopeaphenol led to a complete inhibition of the catalytic activity of topoisomerase IIα. The resveratrol dimer ε-viniferin exerted the lowest inhibitory properties of all resveratrol oligomers tested by equimolar comparison, slightly affecting the catalytic activity of topoisomerase IIα at a 11 μg/mL concentration and reaching entire suppression of enzyme activity at 45 μg/mL (Figure 2B,D). Resveratrol itself caused almost complete inhibition of the catalytic activity of topoisomerase IIα at a concentration of 57 μg/mL. The topoisomerase poison ETO (50 μM) was used as a positive control (Figure 2A, lanes 8, 15, and 22).

Possible additive or synergistic effects of resveratrol and its oligomers were further investigated by combination experiments (Figure 2C). Concentrations of the single oligomers in the combination were chosen equivalent to their amounts in the extract. Indicated concentrations refer to the combination of oligomers present in 1, 5, 50, or 500 μg/mL GSE. The combination of r2-viniferin, hopeaphenol, and ε-viniferin showed an inhibition of topoisomerase II activity in concentrations equivalent to 50−500 μg/mL GSE. Addition of resveratrol increased the inhibitory properties of the combination, slightly inhibiting enzyme activity at concentrations equivalent to 5 μg/mL. Although the combination experiments revealed that resveratrol as well as its oligomers contribute to the effects of the GSE, neither of the two combinations reached the strong inhibitory effect of the extract.

To investigate whether the topoisomerase II targeting properties of GSE and its constituents also unfold within human epidermoid carcinoma cells, the ICE bioassay was performed (Figure 3). This technique allows identification of topoisomerase poisons, as the enzyme is detected while being covalently linked to DNA. Incubation of A431 cells with increasing concentrations of GSE for 1 h did not enhance the level of stabilized topoisomerase IIα−DNA intermediates, as no topoisomerase IIα signal was detected in the DNA-rich fractions (Figure 3A). In contrast, a strong signal for topoisomerase IIα was observed for the topoisomerase II poison ETO (50 μM), used as a positive control.

The tetramers r2-viniferin and hopeaphenol, which led to a potent inhibition of catalytic activity of topoisomerase II in the cell-free system, as well as resveratrol, were also tested in the ICE bioassay. As it showed only weak inhibitory effects on topoisomerase IIα, the resveratrol dimer ε-viniferin was not included in the cellular testing. The immunoblots of the DNA-containing fractions and the results of the quantification (Figure 3B) indicate that none of the constituents were able to increase the amount of covalent topoisomerase II−DNA

dx.doi.org/10.1021/jf4046182 | J. Agric. Food Chem. 2014, 62, 780−788

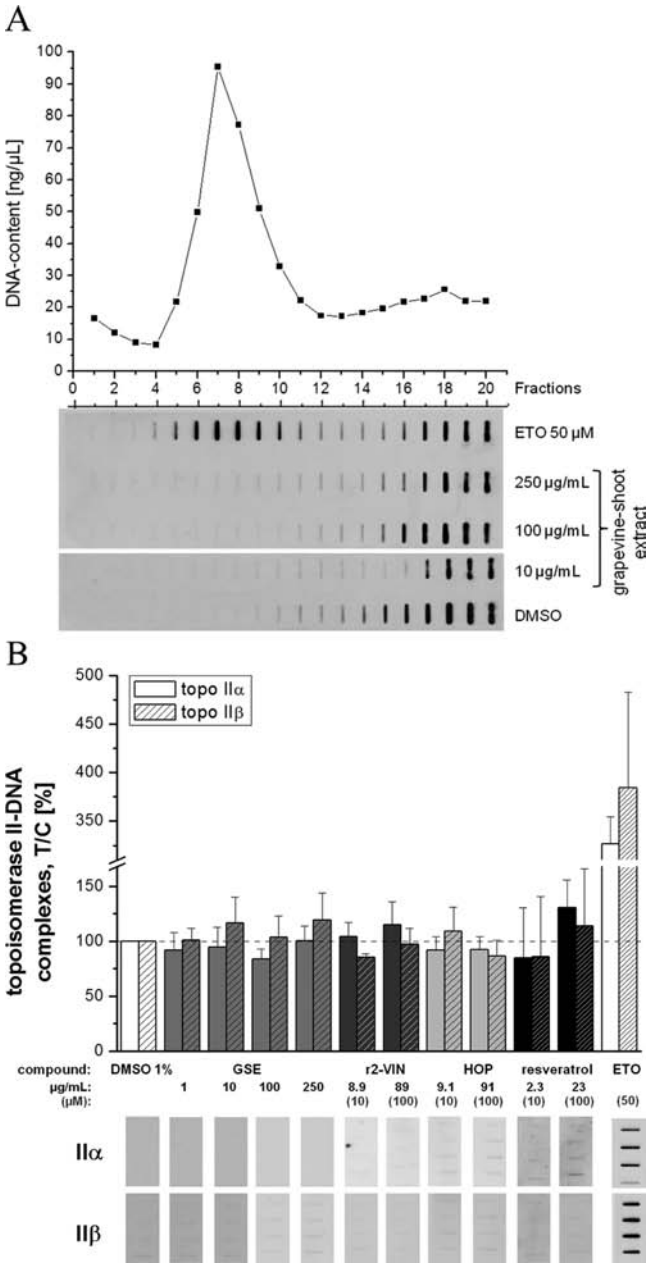

Figure 3. Effect of the GSE on the stabilization of covalent topoisomerase II–DNA intermediates in A431 cells. (A) Using the ICE bioassay, free enzyme was separated from DNA-linked protein via ultracentrifugation in a cesium chloride gradient. DNA content of the single fractions is exemplarily plotted for the positive control etoposide (ETO). On the bottom, representative immunoblots after detection of topoisomerase IIα of three independent experiments with similar outcome are shown. (B) Quantification of the amount of stabilized topoisomerase II–DNA intermediates in the DNA-containing fractions. Results are calculated as test over control with respect to DNA content × 100 (T/C, %) and represent the mean ± SD of three independent experiments. Representative immunoblots of the DNA-containing fractions used for quantification are shown for both topoisomerase II isoforms.

complexes. Thus, the level of cleavable complexes was not significantly increased after incubation of A431 cells with the GSE, resveratrol, r2-viniferin, and hopeaphenol, even at the highest tested concentrations of 250, 23, 89, and 91 μg/mL, respectively, when compared to the solvent control. Moreover, no differences could be observed between the topoisomerase isoforms IIα and IIβ. However, a slight, yet not significant, increase of covalent topoisomerase IIα–DNA complexes was observed after incubation with 23 μg/mL resveratrol, possibly indicating weak topoisomerase II poisoning activities.

Induction of DNA Strand Breaks by GSE and Several of Its Constituents. Because topoisomerase inhibitors might cause torsional stress within cells, they could affect DNA integrity. Thus, the DNA strand-breaking potential of GSE and resveratrol oligomers was investigated in A431 cells by single-cell gel electrophoresis under alkaline conditions (Figure 4A). Treatment with the DNA repair enzyme FPG was included in the testing to detect FPG-sensitive sites, which are indicative of oxidative DNA damage. Cell viability exceeded 80% throughout the experiment (Figure 4B).

The incubation of A431 cells with GSE for 1 h was found to significantly enhance the level of DNA strand breaks in the cells. At the highest tested concentration of 25 μg/mL GSE, a tail intensity of ∼2.5% was reached. In contrast, resveratrol, r2-viniferin, and hopeaphenol showed no impact on DNA integrity in A431 cells after this incubation period. FPG treatment led to an increased DNA strand break rate for the GSE and the tetramers at the highest tested concentration (GSE, 25 μg/mL; r2-viniferin and hopeaphenol, 45 μg/mL). In the case of GSE and hopeaphenol, the FPG-sensitive sites were significantly increased when compared to the samples not exposed to FPG. Furthermore, a tail intensity of almost 6% was reached after a FPG treatment by GSE, whereas the effects after incubation with r2-viniferin (3.5%) and hopeaphenol (4.5%) were less pronounced. In contrast, resveratrol did not increase the level of FPG-sensitive sites.

DISCUSSION

The potential health-enhancing properties of *trans*-resveratrol have prompted numerous studies to identify the cellular mechanisms and potential target molecules involved.[2,4,5] Several studies showed topoisomerase I- and II-inhibiting properties of this stilbene possibly contributing to its antiproliferative effects.[31−33] Recently, it has been reported to act as a topoisomerase II poison in human carcinoma cells, affecting chromosome segregation during mitosis.[8,34] Whereas topoisomerase poisons trap the enzyme when it is covalently bound to DNA, catalytic topoisomerase inhibitors interact with the enzymes in a noncovalent bound state.[26] Thus, *trans*-resveratrol has been reported to induce micronuclei and affect chromosome segregation in proliferating cells, probably due to its topoisomerase-poisoning effects.[34] GSE has been shown to possess biological properties similar to those of *trans*-resveratrol, as antiproliferative, pro-apoptotic, and antioxidant effects have been described.[11−13] Because GSE was shown to be more potent regarding cell growth inhibition than *trans*-resveratrol itself, it was suggested that *trans*-resveratrol and its oligomers may act synergistically.[12,35] In the present study we investigated whether GSE possesses topoisomerase-II-inhibitory properties similar to those of *trans*-resveratrol resulting in DNA damage and thereby contributing to its antiproliferative effects. A431 cells were used because in a preliminary screening of human tumor cells the antiproliferative effect of the resveratrol oligomers was significant in this cell line (E. Nevo-Koch, unpublished observations). Therefore, A431 cells were considered to be particularly adequate to study the mechanisms underlying the growth-inhibiting effects of these compounds.

dx.doi.org/10.1021/jf4046182 | J. Agric. Food Chem. 2014, 62, 780−788

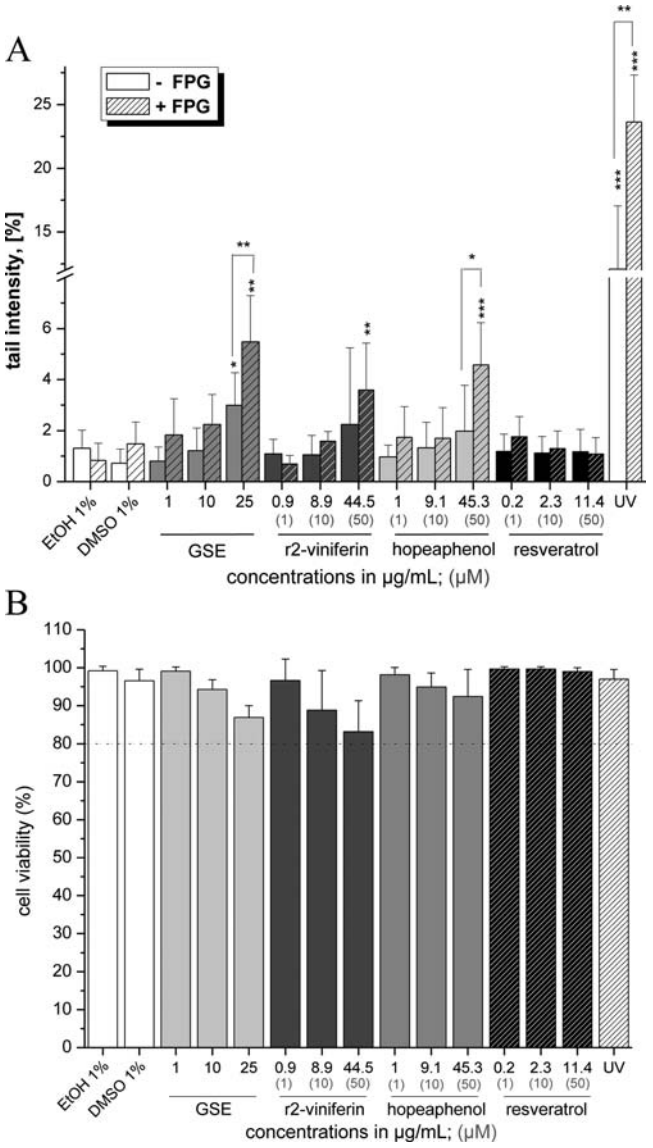

Figure 4. Impact of the GSE and resveratrol oligomers on DNA integrity in A431 cells determined by single-cell gel electrophoresis (comet assay). Cells were treated with the extract or the single compounds for 1 h in serum-free medium. (A) Results are given as the mean ± SD of tail intensities (%) from at least three separate experiments, each performed in duplicate. Dashed bars display additional treatment with the enzyme FPG to detect FPG-sensitive sites indicative for oxidative stress. Irradiation with UV light was used as a positive control. Significances are calculated by Student's *t* test (∗, $p < 0.05$; ∗ ∗, $p < 0.01$; ∗∗∗, $p < 0.001$) and either refer to the corresponding solvent control or indicate significant differences between FPG-treated and untreated samples. (B) Cell viability was determined by trypan blue exclusion. Results were calculated as the number of vital cells over total cell number, and data are presented as the mean ± SD.

GSE was found to be a potent catalytic inhibitor of topoisomerase IIα, suppressing enzyme activity at a concentration of 5 μg/mL. Thus, GSE, containing 0.4 μg/mL *trans*-resveratrol, exhibits stronger topoisomerase II-targeting effects than the stilbene, which showed almost complete inhibition of topoisomerase IIα activity at 23 μg/mL. These results are in line with previous studies, which reported an IC_{50} value for topoisomerase II inhibition by resveratrol of 15.0 μg/mL,[36] whereas complete suppression of enzyme activity was observed with 27.4 μg/mL.[7] The higher potency of GSE in inhibiting topoisomerase II activity could be due to additive or synergistic effects of *trans*-resveratrol and the individual resveratrol oligomers present in the extract. The resveratrol oligomers ε-viniferin, r2-viniferin, and hopeaphenol have been identified as biologically active constituents of GSE, contributing to its antiproliferative effect in A431 cells.[10] To elucidate whether these oligomers might be responsible for the topoisomerase II inhibition by GSE, their potential to inhibit this enzyme was investigated. All tested resveratrol oligomers inhibited the catalytic activity of purified topoisomerase II, whereas the tetramers r2-viniferin and hopeaphenol exhibited a stronger inhibitory potency than the resveratrol dimer ε-viniferin at equimolar concentrations. This is in accordance with previous findings showing that ε-viniferin exhibits only a limited inhibitory activity on tumor cell progression in the cell cycle and apoptotic death compared to *trans*-resveratrol.[13,35] Yet, none of the tested oligomers alone seems to be responsible for the entire effect of the GSE, because much higher concentrations than those present in the extract were needed to block topoisomerase II activity. Furthermore, we addressed the question of whether topoisomerase II inhibition by GSE might be due to additive or synergistic effects of *trans*-resveratrol and its active resveratrol oligomers. A combination of the oligomers corresponding to their amounts present in the extract revealed that r2-viniferin, hopeaphenol, and ε-viniferin are not exclusively responsible for the topoisomerase II inhibition by GSE. When resveratrol was included in the combination experiment, enzyme activity was suppressed at lower concentrations, suggesting that resveratrol has a considerable impact on the topoisomerase II-inhibitory properties of GSE. Nevertheless, the potent suppression of enzyme activity by GSE cannot be explained by resveratrol and the herein tested resveratrol oligomers alone. Therefore, we suggest that other constituents, which have not been identified up to now, may substantially contribute to the strong topoisomerase II-targeting effects of GSE. In this context it should be noted that the identity of compounds making up 62.9% of the extract remain unknown and that no further polyphenols besides resveratrol and its oligomers listed under Materials and Methods are present in GSE.

Depending on their mode of action, topoisomerase inhibitors can be divided into two classes. Whereas catalytic inhibitors of topoisomerase II may prevent the enzyme from binding to DNA or block ATP binding prior to DNA cleavage, topoisomerase poisons stabilize the covalent enzyme−DNA intermediate.[26] In a further approach, we investigated whether GSE or the resveratrol oligomers act as a topoisomerase II poison in human tumor cells. Neither the GSE, resveratrol nor the tetramers r2-viniferin and hopeaphenol significantly increased the amount of topoisomerase II−DNA intermediates in human epidermoid carcinoma cells. This indicates that GSE rather acts as a pure catalytic inhibitor of topoisomerase II and not as a topoisomerase II poison. Although *trans*-resveratrol has previously been reported to poison topoisomerase II,[8] the level of cleavable complexes was not significantly increased under our conditions. However, a slight, yet not significant increase of covalent topoisomerase IIα−DNA complexes was observed at the highest tested concentration of 23 μg/mL. These controversial findings might be due to differences in the concentration range as well as variation between the used cell lines. Thus, the resveratrol concentration present in the GSE (~19 μg/mL in 250 μg/mL GSE) seems to be insufficient to

dx.doi.org/10.1021/jf4046182 | J. Agric. Food Chem. 2014, 62, 780−788

stabilize covalent topoisomerase II−DNA intermediates in human epidermoid cancer cells. However, the lack of topoisomerase poisoning of GSE despite containing *trans*-resveratrol could also be explained by other constituents of the extract acting as catalytic inhibitors. Because the resveratrol oligomers r2-viniferin and hopeaphenol did not poison topoisomerase II, they might present catalytic inhibitors, possibly restraining topoisomerase II poisons in the GSE from stabilizing the cleavable complex. This is the case of anthocyanins and anthocyanin-rich extracts, which are known to suppress the stabilization of topoisomerase−DNA complexes of chemotherapeutics by acting as catalytic topoisomerase inhibitors.[37,38] It also has to be considered that other extract constituents might exhibit a higher binding affinity to topoisomerases, thereby blocking the active site of the enzyme.

So far, we cannot rule out that the lack of topoisomerase poisoning in A431 cells is due to the fact that resveratrol or its tetramers are quickly biotransformed into inactive metabolites. Furthermore, the tetramers might not reach the nucleus in concentrations necessary to stabilize the cleavable complex. Thus, the bioactivity of resveratrol metabolites and cellular uptake of resveratrol tetramers are subjects of our ongoing studies.

As expected for catalytic inhibitors of topoisomerase II, only weak DNA strand-breaking properties were observed for GSE. Resveratrol has been reported to increase phosphorylation of H2AX by topoisomerase II poisoning after a long incubation time.[7] H2AX becomes rapidly phosphorylated at DNA strand break sites to form γH2AX foci and holds a key position in DNA repair processes. Thus, phosphorylation of H2AX presents a sensitive marker for DNA double-strand breaks.[39] However, the effects of GSE may not be explained by *trans*-resveratrol, as no increase of DNA strand break rate was observed by *trans*-resveratrol after a short incubation time. In addition to the enhanced DNA strand break rate, FPG-sensitive sites were detected after GSE treatment. Because r2-viniferin and hopeaphenol also increased the level of FPG-sensitive sites, it might be assumed that they account for the oxidative DNA damage observed with GSE. These results suggest that mechanisms other than topoisomerase inhibition are likely to be responsible for the detected DNA strand-breaking properties of GSE and the resveratrol tetramers. Thus, the resveratrol tetramers as well as the GSE might cause a shift towards pro-oxidative processes regarding the intracellular redox balance. The detection of FPG-sensitive sites was unexpected, as GSE and r2-viniferin have been reported to exhibit antioxidant rather than pro-oxidant properties.[11,40,41] However, *trans*-resveratrol has been shown to act as a pro-oxidant in the presence of copper ions, which has been proposed to be an important mechanism underlying its anticancer properties.[42,43] Besides *trans*-resveratrol, other pro-oxidant compounds might be present in the extract, causing oxidative stress and oxidative DNA damage.[11]

Inhibition of the catalytic activity of topoisomerase II might cause a delay in cell cycle progression, mainly in the S phase, resulting in cell cycle arrest or cell death.[36,44,45] Resveratrol is known to inhibit cell cycle progression of different cancer cells by blocking cells in the S phase.[7,13,46] Moreover, GSE has been demonstrated to affect cell cycle progression by causing a delay in the early S phase.[13,47] The accumulation of cells in the S phase could be topoisomerase-mediated, as has been shown for *trans*-resveratrol.[8] Thus, topoisomerase inhibition may account (at least in part) for the reported antiproliferative effects of *trans*-resveratrol[48,49] and GSE.[11,12]

Taken together, our results show that GSE has potent topoisomerase-II-inhibiting properties, acting as a catalytic inhibitor rather than a poison. Thus, inhibition of topoisomerase II might possibly contribute to the antiproliferative effects of the GSE. No study regarding the bioavailability of the individual resveratrol oligomers in laboratory animals or humans has been published up to now. On the basis of their structure, it is probable that they will reach a biologically relevant concentration only in the epithelium of the gastrointestinal tract. Because they can exert a pronounced antiproliferative effect in tumor cell lines in the lower micromolar concentration range, they may be useful in combination with cytostatic agents to treat gastrointestinal tumors such as colorectal carcinomas.

ABSTRACT: Anthocyanidins and anthocyanins are pharmacologically active constituents of various berry fruits, such as blueberry and cranberry. These compounds are also contained in massively used nutritional supplements based on extracts or dry matter from berry fruits. The current study evaluated the effects of anthocyanidins and anthocyanins on the expression and catalytic activity of major drug-metabolizing enzymes CYP2C9, CYP2A6, CYP2B6, and CYP3A4 in primary cultures of human hepatocytes and human liver microsomes. Expression of mRNA was quantified by qRT-PCR. Expression of proteins was evaluated by Western blotting and immunochemiluminescence. The catalytic activity of CYP enzymes was measured by HPLC using specific enzyme substrates. Tested anthocyanidins (6) and anthocyanins (21) did not induce the expression of mRNA and protein of CYP2C9, CYP2A6, CYP2B6, and CYP3A4 genes in human hepatocytes. Catalytic activities of CYP2C9, CYP2A6, CYP2B6, and CYP3A4 enzymes were inhibited by all anthocyanidins to different extents (e.g., delphinidin inhibits CYP3A4 by >90% at 100 μM with IC_{50} = 32 μM). Of 21 anthocyanins tested, only cyanidin-3-*O*-rhamnoside (CYP3A4 by >75% at 100 μM with IC_{50} = 44 μM) and two glycosides of delphinidin significantly inhibited examined cytochromes P450. It may be concluded that in the ranges of common ingestion of either food or dietary supplement an induction or significant inhibition of CYP2C9, CYP2A6, CYP2B6, and CYP3A4 activity is most probably not expected.

KEYWORDS: *anthocyans, cytochrome P450, food−drug interactions, human hepatocytes, xenobiotics*

INTRODUCTION

The anthocyans (in Greek *anthos* means flower and *kyanos* means blue) are widespread natural flavonoids that occur in all tissues of higher plants (flowers, leaves, roots, stems, fruits, and vegetables) as water-soluble vacuolar pigments. They have significant roles in the animal kingdom in pollination and seed dispersal.[1] The stability and color of anthocyans depend on the pH and the occurrence of chelating metal ions.[2] The structural differences between anthocyans are the number of the hydroxyl groups; the degree of methylation of −OH groups; the number, nature, and position of sugar attachments; and the number and nature of aliphatic or aromatic acids fixed to sugars in the molecule.[3] The most common sugars are glucose, galactose, and rhamnose.[4] Anthocyans comprise two types of compounds, that is, anthocyanins and anthocyanidins, which are aglycon (sugar-free) backbones of anthocyanins (for structures see Table 1). Anthocyanins are found in plant foods including cereals, tubers, roots, pulses, etc., and also in beverages and dietary supplements.[5] The most common anthocyanidins in higher plants include cyanidin, delphinidin, malvidin, pelargonidin, peonidin, and petunidin.[1,5] The anthocyans are important for their various health benefits.[4,6] They play an important role in obesity and diabetes control, neuronal and cardiovascular disease prevention, and improvement of visual and brain functions.[5] Anthocyans display a plethora of biological effects, including antiproliferative,[7] antiapoptotic,[8] antitumor,[9] antimutagenic,[10] antioxidant,[11] antiradical,[12] and nitric oxide inhibitory effects.[13]

Despite numerous studies of anthocyan biological activities, a systematic study focused on the interactions between anthocyans and drug-metabolizing cytochromes P450 was not carried out yet. Because common foods, beverages, and food supplements contain various natural or synthetic xenobiotics, including anthocyans, a phenomenon of food−drug interactions emerged. Dietary xenobiotics can interfere with drug-metabolizing enzymes and may cause their inhibition or induction. Indeed, we recently described the activation of the aryl hydrocarbon receptor (AhR) and induction of drug-metabolizing CYP1A1 in human cancer cell lines and human hepatocytes by anthocyanidin pelargonidin[14] and by anthocyanins pelargonidin-3-*O*-rutinoside and cyanidin-3,5-*O*-diglucoside.[15] In the current study, we have evaluated the effects of 21 anthocyanins and 6 anthocyanidins on the main drug-metabolizing cytochromes P450, those being CYP2A6,

CYP2B6, CYP2C9, and CYP3A4. We measured (i) induction = expression of CYPs at the levels of mRNA and protein in primary cultures of human hepatocytes and (ii) inhibition = catalytic activity of CYPs in human liver microsomes. Tested anthocyanins did not induce CYP2A6, CYP2B6, CYP2C9, and CYP3A4 in primary human hepatocytes. On the other hand, CYP3A4 activity was inhibited by all anthocyanidins tested (with delphinidin at a concentration of 100 μM down to 8% of the original activity). The inhibition of CYP2C9 by anthocyanidins was prominent with pelargonidin and peonidin only, whereas CYP2A6 and CYP2B6 were not inhibited. Of the anthocyanins tested, only cyanidin-3-*O*-rhamnoside inhibited activities of all CYP isoforms examined, with the strongest effect on CYP3A4 activity (inhibition down to 25% of the control).

MATERIALS AND METHODS

Compounds and Reagents. Dimethyl sulfoxide (DMSO), rifampicin (RIF), and hygromycin B were purchased from Sigma-Aldrich (Prague, Czech Republic). The following anthocyanins and anthocyanidins were purchased from Extrasynthese (Lyon, France): peonidin-3-*O*-glucoside chloride (PEO-1), peonidin-3-*O*-rutinoside chloride (PEO-2), pelargonidin-3,5-di-*O*-glucoside chloride (PEL-1), pelargonidin-3-*O*-rutinoside chloride (PEL-2), delphinidin-3-*O*-glucoside chloride (DEL-1), delphinidin-3-*O*-rutinoside chloride (DEL-2), delphinidin-3,5-di-*O*-glucoside chloride (DEL-3), delphinidin-3-*O*-sambubioside chloride (DEL-4), delphinidin-3-*O*-rhamnoside chloride (DEL-5), malvidin-3-*O*-glucoside chloride (MAL-1), malvidin-3,5-di-*O*-glucoside chloride (MAL-2), malvidin-3-*O*-galactoside chloride (MAL-3), cyanidin-3-*O*-glucoside chloride (CYA-1), cyanidin-3-*O*-rutinoside chloride (CYA-2), cyanidin-3,5-di-*O*-glucoside chloride (CYA-3), cyanidin-3-*O*-sophoroside chloride (CYA-4), cyanidin-3-*O*-arabinoside chloride (CYA-5), cyanidin-3-*O*-rhamnoside chloride (CYA-6), cyanidin-3-*O*-galactoside chloride (CYA-7), cyanidin-3-*O*-sambubioside chloride (CYA-8), cyanidin-3-*O*-lathyroside chloride (CYA-9), cyanidin chloride (CYA), delphinidin chloride (DEL), malvidin chloride (MAL), peonidin chloride (PEO), petunidin chloride (PET), and pelargonidin chloride (PEL). Luciferase lysis buffer and P450-Glo CYP1A1 assay were from Promega (www.promega.com; Hercules, CA, USA). Oligonucleotide primers used in RT-PCR reactions were from Invitrogen. LightCycler FastStart DNA Master^{PLUS} SYBR Green I was from Roche Diagnostic Corp. (Intes Bohemia, Czech Republic). Cryopreserved human liver microsomes (pooled) were purchased from Biopredic International (Rennes, France). Microsomes were obtained under approval of the local ethics committee and in accordance with the ethic regulations of the country of origin (France). They were from 20 males and 6 females with a protein content of 25 mg/mL; the CYP1A1/2, CYP2A6, CYP2B6, CYP2C9, CYP2C19, CYP2E1, and CYP3A4/5 enzyme activities were verified prior to the experiment.

For determination of CYP activities, testosterone (CYP3A4), coumarin (CYP2A6), 7-ethoxy-4-(trifluoromethyl)coumarin (CYP2B6), and diclofenac (CYP2C9) as well as respective metabolites

dx.doi.org/10.1021/jf404643w | J. Agric. Food Chem. 2014, 62, 789−797

7-hydroxy-4-(trifluoromethyl)coumarin and 7-hydroxycoumarin were supplied by Sigma-Aldrich; 6β-hydroxytestosterone was from Ultrafine (Manchester, UK), and 4-hydroxydiclofenac was supplied by BD Biosciences (San Jose, CA, USA).

All other chemicals were of the highest quality commercially available.

Human Hepatocytes. Human hepatocytes (six different primary cultures) were obtained from two sources: (i) human liver obtained from multiorgan donors LH44 (F, 57 years), LH45 (M, 46 years), LH46 (M, 37 years), LH47 (M, 47 years), and LH49 (M, 38 years); tissue acquisition protocol was in accordance with the requirements issued by the local ethical commission in the Czech Republic; (ii) long-term human hepatocytes in monolayer batch HEP220670 (F, 64 years) (Biopredic International, Rennes, France). Hepatocytes were treated in a serum-free medium for 24 or 48 h with the tested compounds, RIF (10 μM), and/or vehicle (DMSO; 0.1% v/v). Cultures were maintained at 37 °C and 5% CO_2 in a humidified incubator.

Quantitative Reverse Transcriptase Polymerase Chain Reaction (qRT-PCR). Total RNA was isolated using TRI reagent, and cDNA was synthesized according to the common protocol, using M-MLV reverse transcriptase F-572 (Finnzymes) and random hexamers 3801 (Takara). qRT-PCR was carried out on a Light Cycler apparatus 480 II (Roche Diagnostic Corp., Prague, Czech Republic). The levels of CYP2A6, CYP2B6, CYP2C9, CYP3A4, and GAPDH mRNAs were determined as described elsewhere.[16] The measurements were performed in triplicates. Gene expression levels were normalized to glyceraldehyde-3-phosphate dehydrogenase (GAPDH), a housekeeping gene. Data were processed according to the delta−delta method.

Protein Detection and Western Blotting. Total protein extracts were prepared, and they were subjected to SDS-PAGE separation and Western blot transfer. The blots were probed with antibodies against CYP2A6 (mouse monoclonal; sc-53615, F16 P2 D8), CYP2B6 (rabbit polyclonal; sc-67224, H-110), CYP2C9 (goat polyclonal; sc-23436, C-21), CYP3A4 (mouse monoclonal; sc-53850, HL3), and β-actin (goat polyclonal; sc-1616, I-19), all purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Chemiluminescent detection was performed using horseradish peroxidase-conjugated secondary antibody and an Amersham (GE Healthcare) ECL kit.

Enzyme Activities of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 in Human Liver Microsomes. Activities of individual CYP isoforms were measured according to published protocols.[17] The following microsomal CYP activities were tested: CYP3A4, testosterone 6β-hydroxylation; CYP2A6, coumarin 7-hydroxylation; CYP2B6, 7-ethoxy-4-(trifluoromethyl)-coumarin 7-deethylation; and CYP2C9 activity, diclofenac 4′-hydroxylation.

Reaction mixtures of individual determinations contained, for determination of CYP2A6, CYP2B6, or CYP2C9 activity, 35 pmol P450 and for determination of CYP3A4 activity, the amount of microsomal fraction with 100 pmol of P450. All reaction mixtures were buffered by 100 mM K/PO_4 (pH 7.4) and contained a NADPH generating system consisting of isocitrate dehydrogenase (9 U/mlL), $NADP^+$ (0.5 mM), isocitric acid (4 mM), and $MgSO_4$ (5 mM). Final concentrations of substrates in the corresponding reaction mixtures were as follows: CYP2A6, coumarin (10 μM); CYP2B6, 7-ethoxy-4-(trifluoromethyl)coumarin (15 μM); CYP2C9, diclofenac (16 μM); CYP3A4, testosterone (100 μM). Aqueous stock solutions of anthocyanins were 1 mM (pH 6.7); anthocyanidins of the same concentration were dissolved in aqueous solution of pH 3.5. For detailed description of the incubations, see the previous papers.[14,15] For each enzyme assay, a preliminary experiment was done to determine the K_M and V_{max} for a given enzyme reaction and to obtain the values of substrate concentrations suitable for the inhibition experiments. Inhibition experiments were routinely performed with six concentrations of the tested compound (0, 10, 20, 40, 80, and 100 μM in the reaction mixture). All determinations were done in triplicates. The effects of anthocyans on CYP activities were determined according to methods indicated above by HPLC using the Prominence system (Shimadzu, Kyoto, Japan). Sigma Plot v. 10.0 (Systat, Chicago, IL, USA) was used for plotting the results. The inhibition was expressed as the relative activity (control, 100%) remaining after addition of the respective inhibitor.

RESULTS

Effects of Anthocyanidins on the Expression of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 in Human Hepatocytes. Six major anthocyanidins (i.e., cyanidin, peonidin, petunidin, pelargonidin, delphinidin, malvidin) were examined in three different primary cultures of human hepatocytes (i.e., LH44, LH45, HEP220670). Cells were incubated with tested compounds (50 μM), model panel CYP2/3 inducer rifampicin (RIF; 10 μM), and DMSO (0.1% v/v) as vehicle for control. The duration of the treatments was 24 and 48 h for mRNA and protein analyses, respectively. Rifampicin strongly induced CYP3A4 mRNA in all human hepatocyte cultures, LH44 (117-fold), LH45 (55-fold), and HEP220670 (45-fold). Consistently, CYP3A4 protein was strongly induced by rifampicin in all human hepatocyte cultures. None of the anthocyanidins tested induced the expression of CYP3A4 mRNA (Figure 1) or protein (Figure 2) in any of the three cultures used. Similarly, no induction of CYP2B6 mRNA and protein was observed for tested anthocyanidins. Strong induction of CYP2B6 protein and mRNA was achieved by rifampicin, yielding the inductions of mRNA by factors of 9-, 15-, and 22-fold, in cultures LH44, LH45, and HEP220670, respectively (Figures 1 and 2). The expression of CYP2C9 mRNA was increased by rifampicin by factors of 3-, 2-, and 48-fold, in cultures LH44, LH45, and HEP220670 (Figure 1), respectively, whereas the level of CYP2C9 protein was not significantly increased by rifampicin (Figure 2). The lack of CYP2C9 protein induction and weak CYP2C9 mRNA induction (LH44, LH45) by rifampicin is probably due to high constitutive levels of CYP2C9 in human hepatocytes. None of the anthocyanidins tested induced the expression of CYP2C9 mRNA (Figure 1) or protein (Figure 2) in any human hepatocyte culture. Rifampicin induced CYP2A6 mRNA in all human hepatocyte cultures, LH44 (3-fold), LH45 (4-fold), and HEP220670 (18-fold). Cyanidin, malvidin, delphinidin, and petunidin increased CYP2A6 mRNA levels, but the effects were not systematic in all hepatocyte cultures and occurred rather randomly, perhaps due to interindividual metabolic profiles (Figure 1). Rifampicin also induced CYP2A6 protein, whereas the tested anthocyanins had no systematic effects on CYP2A6 protein level in human hepatocyte cultures (Figure 2).

Effects of Anthocyanins on the Expression of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 in Human Hepatocytes. In the next series of experiments, the effects of 21 anthocyanins (for details see Materials and Methods) were tested in four different human hepatocyte cultures (LH45, LH46, LH47, LH49). For this purpose, hepatocytes were incubated for 24 and 48 h with tested compounds (50 μM), rifampicin (RIF; 10 μM), and vehicle (DMSO; 0.1% v/v). Rifampicin significantly induced CYP2A6 (3-, 4-, 8-, 5-fold), CYP2B6 (9-, 15-, 25-, 14-fold), CYP2C9 (3-, 2-, 5-, 2-fold), and CYP3A4 (117-, 55-, 121-, 13-fold) mRNAs in all human hepatocyte cultures. None of the anthocyanins tested induced CYP2B6, CYP2C9, or CYP3A4 mRNAs. Similarly as in the case of anthocyanidins, the expression of CYP2A6 mRNA was increased by some anthocyanins, but these effects were not reproducible between individual human hepatocyte cultures (Figure 3). The data from Western blot analyses of CYP3A4 and CYP2B6 proteins were consistent with those at mRNA level. Whereas rifampicin strongly induced CYP3A4 and CYP2B6 proteins, the tested anthocyanins had no effects (Figure 4). Rifampicin strongly induced CYP2A6 protein, but the tested anthocyanins had no

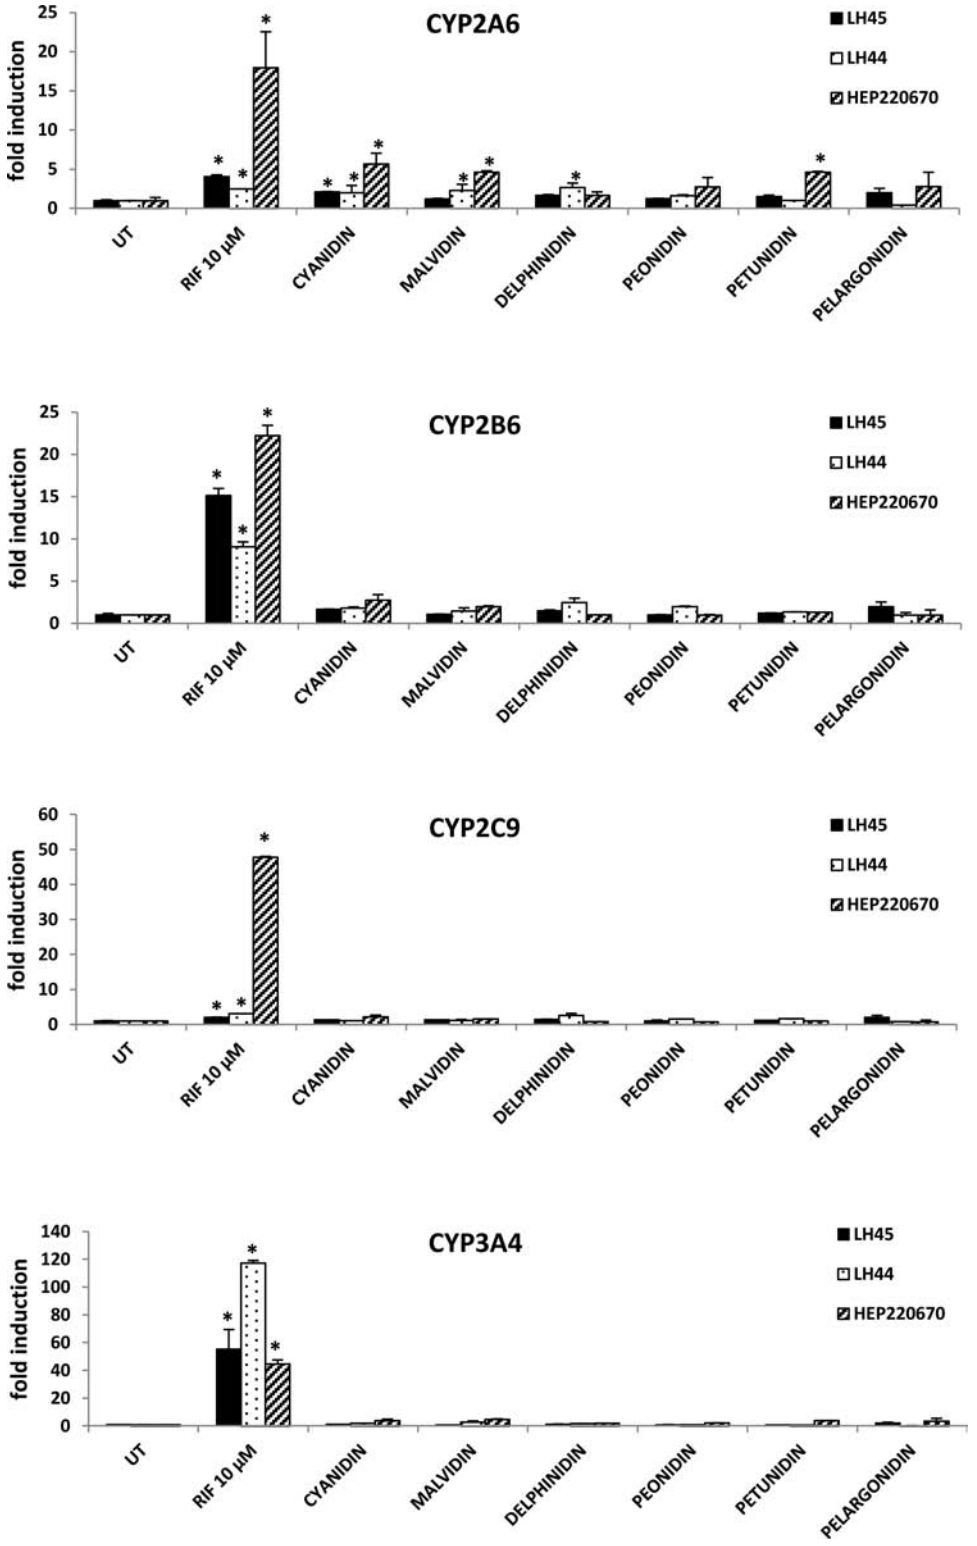

Figure 1. Effects of anthocyanidins on the expression of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 mRNAs in human hepatocytes. Primary human hepatocyte cultures (LH44, LH45, HEP220670) were incubated for 24 h with cyanidin (50 μM), peonidin (50 μM), petunidin (50 μM), pelargonidin (50 μM), delphinidin (50 μM), malvidin (50 μM), rifampicin (10 μM), and DMSO (0.1% v/v) as a vehicle for control. Bar graphs show RT-PCR analyses of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 mRNAs. The data are the mean from triplicate measurements and are expressed as a fold-induction as compared to DMSO-treated cells. The data were normalized per GAPDH mRNA levels. ∗, value is significantly different from DMSO-treated cells ($p < 0.05$) as determined by Student's t test.

effects, and CYP2A6 protein was not detectable in cells incubated with anthocyanins. The levels of CYP2C9 protein were not significantly and systematically altered either by rifampicin or by tested anthocyanins (Figure 4).

Effects of Anthocyanidins and Anthocyanins on Catalytic Activities of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 in Human Liver Microsomes. Enzyme activities were examined with anthocyanidins (and anthocyanins) in

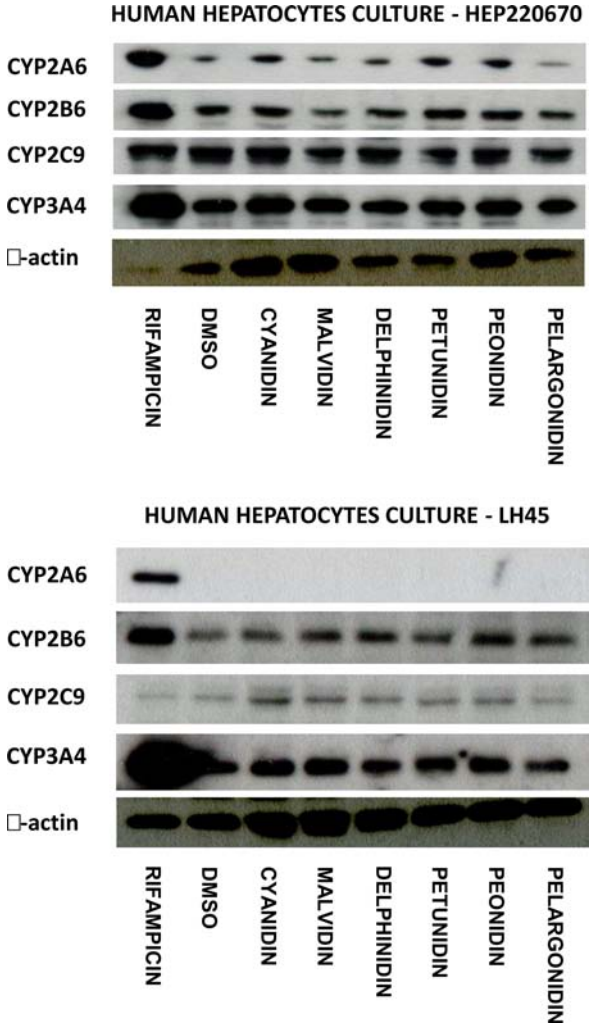

Figure 2. Effects of anthocyanidins on the expression of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 proteins in human hepatocytes. Primary human hepatocytes cultures (LH44, LH45, HEP220670) were incubated for 48 h with cyanidin (50 μM), peonidin (50 μM), petunidin (50 μM), pelargonidin (50 μM), delphinidin (50 μM), malvidin (50 μM), rifampicin (10 μM), and DMSO (0.1% v/v) as a vehicle for control. Western blots show analyses of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 proteins. As a loading control, the blots were probed to β-actin (data not shown).

concentrations of 0, 10, 20, 40, 80, and 100 μM. The most prominent inhibitions of CYP activities were observed for CYP3A4 (testosterone 6-β-hydroxylation) and CYP2C9 (diclofenac 4′-hydroxylation). The enzyme activity of CYP3A4 was inhibited by at least down to 50% with all six anthocyanidins tested. The most prominent inhibitory effects were observed with delphinidin (down to 9% of the control value by 100 μM delphinidin with IC_{50} = 32 μM) and petunidin and peonidin (down to about 20% of the control at 100 μM; the IC_{50} values reached 31 μM for petunidin and 36 μM for peonidin). Pelargonidin inhibited this activity down to 35% at 100 μM concentration with IC_{50} = 55 μM. Inhibition of CYP3A4 activity by malvidin and cyanidin did not reach 50% of control value (Figure 5; top left).

Significant inhibition of CYP2C9 was attained by pelargonidin, peonidin (down to 25−30% of the control value with 100 μM, IC_{50} = 25 and 21 μM) and petunidin (100 μM, IC_{50} = 61 μM), whereas cyanidin did not inhibit CYP2C9 enzyme activity (Figure 5; top right). All anthocyanidins tested inhibited the CYP2A6 enzyme activity (coumarin 4-hydroxylation), albeit to different extents. The strongest inhibition was attained by delphinidin, where the activity was inhibited down to 75% at the 100 μM concentration (Figure 5; bottom left). All other anthocyanidins exhibited concentration-dependent, however much lower, degrees of inhibition. Concentration-dependent inhibition of CYP2B6 activity (7-ethoxy-4-(trifluoromethyl) coumarin O-deethylation) was observed with all anthocyanidins. On the other hand, the extent of inhibition was not greater than 20% only (Figure 5; bottom right).

Interestingly, among the anthocyanins (i.e., the respective glycosides of anthocyanidins) CYA-6 (cyanidin-3-*O*-rhamnoside chloride) inhibited activities of all CYP isoforms examined with the strongest effects on the CYP3A4 activity (down to 25% of the control at 100 μM with IC_{50} = 44 μM). The CYP2C9, CYP2A6, and CYP2B6 activities were inhibited by CYA-6 down to 40% of the initial enzyme activity (Figure 6). Besides CYA-6, the CYP3A4 activity was inhibited also by DEL-2 (delphinidin-3-*O*-rutinoside; down to 35% at 100 μM, IC_{50} = 67 μM), whereas other anthocyanins inhibited the CYP activities to lower extents; a more prominent decrease in the enzyme activity was observed for CYP2B6 and CYA-2 (to 45% at 100 μM) and for CYP2C9 with DEL-1 (to 55% at 100 μM concentration).

DISCUSSION

Metabolism of xenobiotics, including drugs, may be influenced by the presence of second xenobiotic, producing a phenomenon of drug−drug interaction. Because many natural and synthetic xenobiotics originate from food, a phenomenon of food−drug interactions was established. A mechanistic base for food−drug interaction may be either inhibition or induction of drug-metabolizing enzymes by xenobiotics. Therefore, in the current study, we have examined the effects of common dietary anthocyanidins (6) and anthocyanins (21) on the expression and catalytic activity of cytochromes P450 CYP2A6, CYP2B6, CYP2C9, and CYP3A4. The major findings of the study are that (i) tested anthocyans (i.e., both the anthocyanidins and anthocyanins) do not induce CYP2A6, CYP2B6, CYP2C9, and CYP3A4 mRNAs and proteins in primary human hepatocytes and that (ii) all of the anthocyanidins did inhibit the CYP3A4 activity; among anthocyanins, the enzyme activity of this isoform was also inhibited the most, although not so largely as with the anthocyanidin aglycons.

Xenobiotic-mediated induction of cytochromes P450 CYP2A6, CYP2B6, CYP2C9, and CYP3A4 is controlled by various transcriptional regulators, including xenoreceptors (e.g., pregnane X receptor, PXR; constitutive androstane receptor, CAR), nuclear receptors (e.g., retinoic acid receptors, RARs; retinoid X receptors, RXRs; liver X receptor, LXR; farnesoid X receptor, FXR; vitamin D receptor, VDR), and receptors for steroid hormones (e.g., glucocorticoid receptor, GR; estrogen receptor, ER).[18] The activators of listed receptors are therefore usually inducers of CYP2 and CYP3 genes, and vice versa. Importantly, xenoreceptors and steroid and nuclear receptors are important transcriptional regulators of many genes, involved in energy metabolism, cells growth, differenciation, immunity, etc. Activation of these receptors by xenobiotics often leads to so-called endocrine disruption, besides from CYP gene induction. In addition, induction of drug-metabolizing CYPs by xenobiotics may cause chemically induced cell damage or carcinogenesis. Overall, the finding that 27 dietary anthocyans are not inducers of human CYP2A6, CYP2B6,

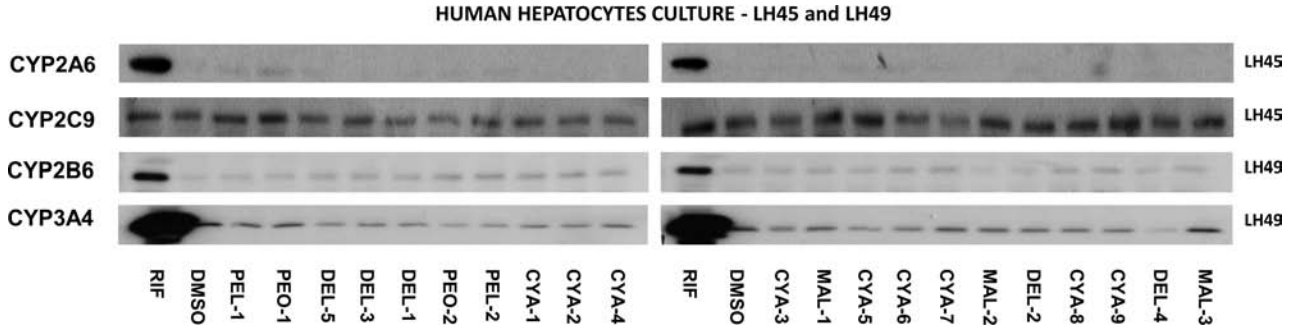

Figure 4. Effects of anthocyanins on the expression of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 proteins in human hepatocytes. Primary human hepatocytes cultures (LH44, LH45, LH47, LH49) were incubated for 48 h with 21 different anthocyanins (for details see Materials and Methods), each at a concentration of 50 μM, rifampicin (10 μM), and DMSO (0.1% v/v) as a vehicle for control. Representative Western blots show analyses of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 proteins in human hepatocytes cultures LH45 and LH49. Similar profiles were observed in cultures LH44 and LH47. As a loading control, the blots were probed to β-actin (data not shown).

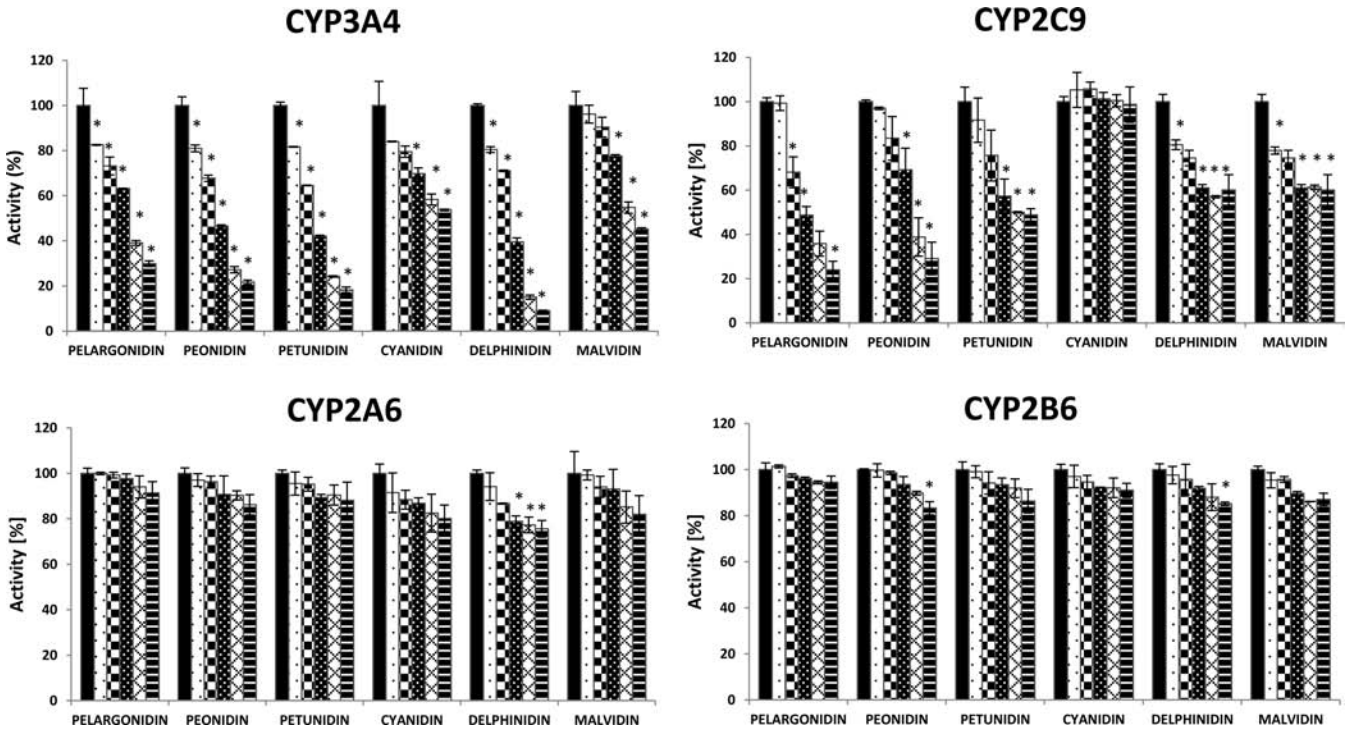

Figure 5. Effects of anthocyanidins on catalytic activities of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 proteins in human liver microsomes. Inhibition of catalytic activities is expressed as the activity remaining relative to control (100%, without anthocyanidin) in percent. Concentration of respective anthocyanidins in the reaction mixture was 0, 10, 20, 40, 80, and 100 μM. For experimental details, see Materials and Methods. *, value significantly different from control ($p < 0.05$).

CYP2C9, and CYP3A4 is of positive value, with regard to massive use of anthocyan-containing foods and products in alimentation and herbal medicine.

However, the anthocyans were able to inhibit the marker activities of CYP enzymes to a significant extent. In particular, CYP3A4 activity was inhibited by all anthocyanidins tested and at least with two anthocyanins (CYA-6 and DEL-2) to 25 and 35% at 100 μM, respectively. In other cases, the decrease of enzyme activity has exceed 50% only exceptionally, as in case of CYP2C9 with pelargonidin and peonidin (25−30% at 100 μM) and to 40% with cyanidin glycoside (CYA-6).

Interestingly, the ability of anthocyanidins to inhibit an enzyme activity is not directly reflected in properties of corresponding anthocyanins. For example, it is the delphinidin that inhibits the CYP3A4 enzyme activity the most (Figure 5), but the most prominent inhibition of the same activity was observed with a cyanidin glycoside (CYA-6). However, cyanidin aglycon (i.e., the anthocyanidin) inhibited the CYP to a much lesser extent (Figure 5). Hence, it seems that the ability of an anthocyanin to inhibit a particular CYP enzyme is given by the molecule as a whole; in other words, it cannot be simply derived from the property of the respective aglycon (anthocyanidin). The fact that it is the activity of CYP3A4 that is influenced the most by an interaction with an anthocyan molecule is clearly in line with the relative openness, accessibility, and flexibility of the active site of this enzyme, which is known to accommodate molecules with different sizes and properties.[19−21] The most important question is the relevance of these interactions to human nutrition. The concentrations of anthocyans and anthocyanidins as well as anthocyanins in plasma may reach the micromolar range after ingestion of tens of milligrams of fruit. However, the level may

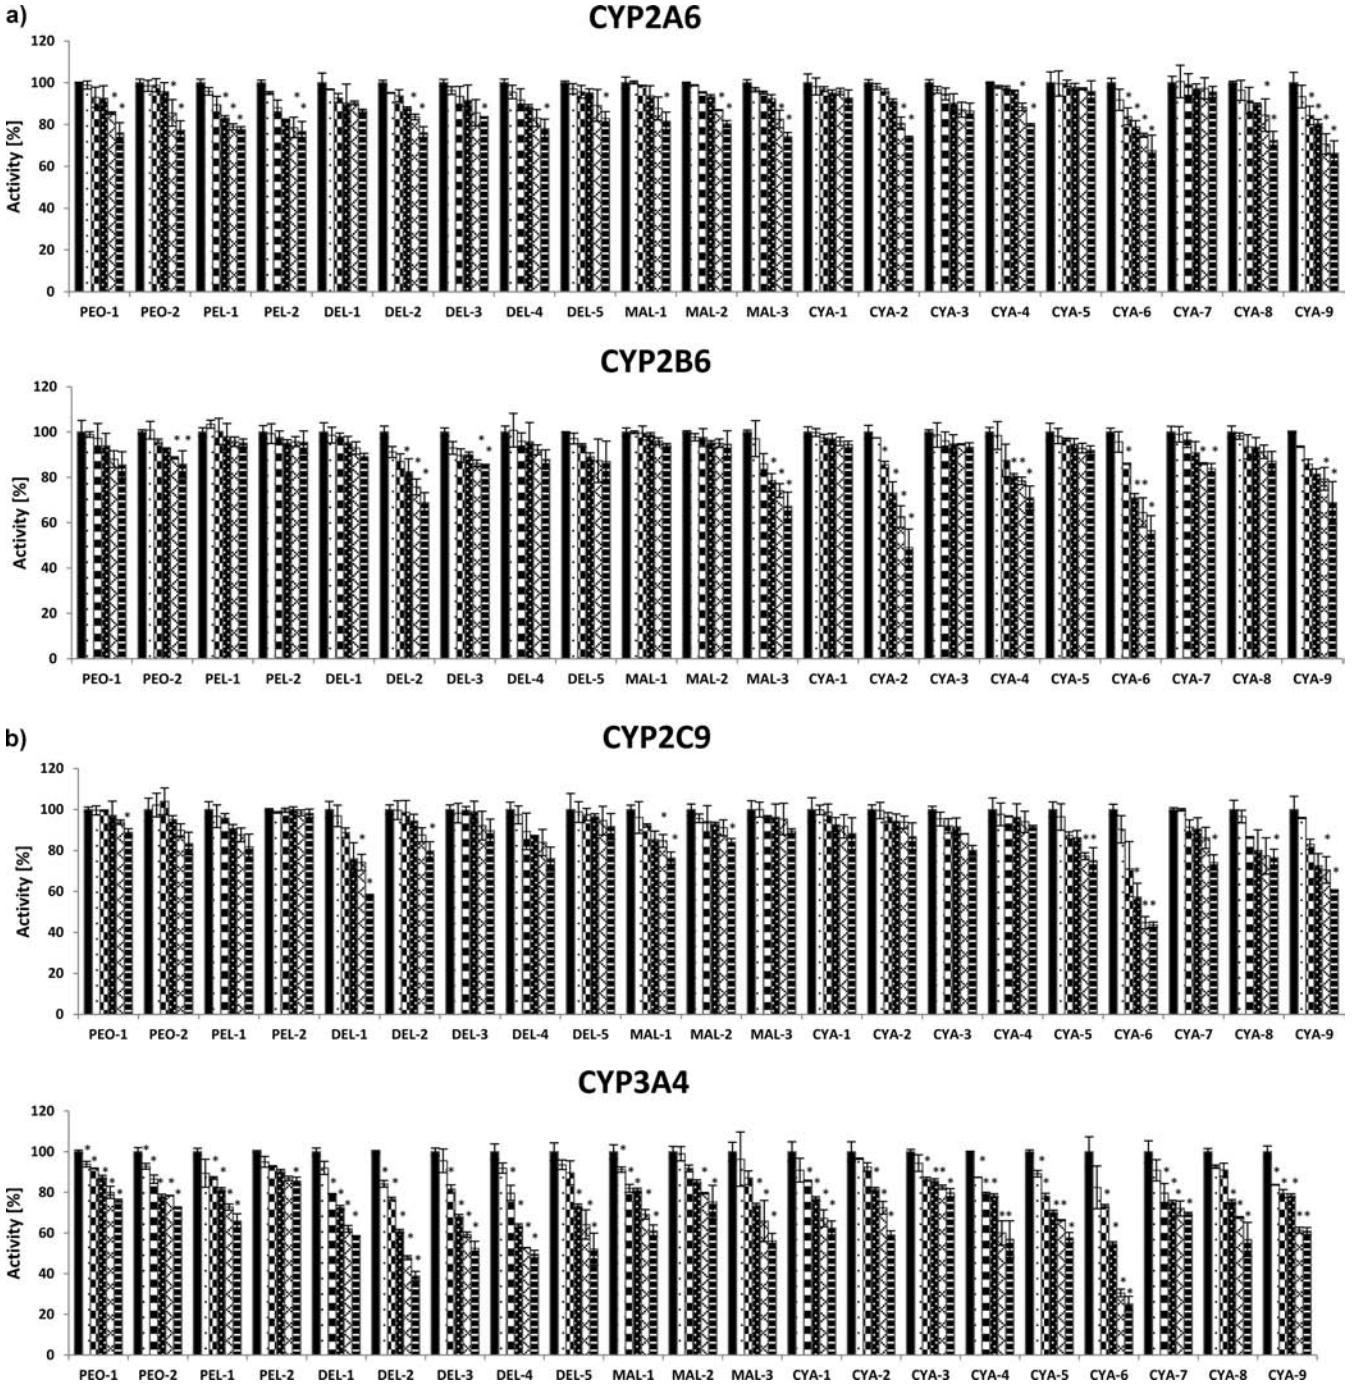

Figure 6. Effects of anthocyanins on catalytic activities of CYP2A6, CYP2B6, CYP2C9, and CYP3A4 proteins in human liver microsomes. Inhibition is expressed as in Figure 5; for abbreviations, see Compounds and Reagents. Anthocyanin concentrations were 0, 10, 20, 40, 80, and 100 μM. $*$, value significantly different from control ($p < 0.05$).

be much higher when a dietary supplement is taken or, more generally, at the site of action. However, it may be concluded that, in the ranges of common ingestion of either food or a dietary supplement, an induction or significant inhibition of, for example, CYP3A4 activity is most probably not expected.

ABSTRACT: Our previous study showed that *trans*-fatty acids can cause apoptosis of endothelial cells through the caspase pathway and the mitochondrial pathway. The objective of this study was to explore how *trans*-fatty acids activate the caspase pathway, whether there exist specific receptors induced apoptosis by comparing normal cells and non-rafts cells treated with elaidic acid (9*t*18:1) and oleic acid (9*c*18:1), respectively. Compared to normal cells treated with 9*t*18:1, the cell viability increased by 13% and the number of apoptotic cells decreased by 3% in non-rafts cells treated with 9*t*18:1 ($p < 0.05$), and the expression levels of pro-apoptotic proteins such as caspase-3, -8, -9, Bax, and Bid decreased, and expression of antiapoptotic protein Bcl-2 increased ($p < 0.05$). In addition, *Fas*/*FasL* expression in cell membrane decreased significantly ($p < 0.05$). In conclusion, the lipid rafts and *Fas*/*FasL* pathway may involve in 9*t*18:1-induced apoptosis of human umbilical vein endothelial cells.

KEYWORDS: *trans-fatty acid, lipid raft, human umbilical vein endothelial cells, receptor, apoptosis*

INTRODUCTION

trans-Fatty acids (TFAs) have been reported to promote vascular diseases mainly by promoting apoptosis and inflammation of vascular endothelial cells (ECs).[1] Excessive apoptosis of ECs is the start of endothelial dysfunction and the development of cardiovascular disease. Epidemiological and animal studies have shown that a high intake of TFAs raise the level of serum low-density lipoprotein (LDL) and triglyceride (TG) and cause vascular endothelial injury. It can also increase expression of the soluble intercellular adhesion molecule (SICAM)-1, soluble vascular cell adhesion molecule (SVCAM)-1, and E-selectin, which are important mediators in the process of inflammation.[2] TFAs induce endothelial cell apoptosis through the caspase pathway[3] and promote release of endothelial inflammatory cytokines.[1] However, it is unknown how the pathway is activated and whether there exist specific receptors at the cell membranes.

Over the past decade, many studies have shown the existence of particular microdomains at the cell membranes: lipid rafts, which are rich in cholesterol and sphingolipids and play many important roles in cell signal transduction.[4,5] Apoptosis is a genetically controlled mechanism of cell death and can be mediated by the death receptor pathway as well as the mitochondrial pathway.[6] There are a number of membrane receptors and channels located in lipid rafts which promote apoptosis when activated.[7] Caveolin-1 is a main protein which exhibits several functional domains in which the caveolin scaffolding domain involves in signaling pathways by the interaction with proteins.[8]

There have been few references about the relationship between lipid rafts and TFAs based on our knowledge. However, several studies have shown that polyunsaturated fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), can change the component of lipid rafts.[9−11] DHA was also found to change the lipid rafts regulation of interleukin receptor signaling pathway.[12,13] n-3 polyunsaturated fatty acids regulated downstream signaling, activation of T cells, activation of transcription, and secretion of cytokines by changing the structure of lipid rafts, which provided evidence for n-3 polyunsaturated fatty acids in the prevention of colon cancer.[14] Iwona et al.[15] reported that 9*c*11*t*-conjugated linoleic acid (CLA) changed cell membrane structure and then interfered with intracellular transport of epidermal growth factor receptor and its related signaling pathway, both functionally associated with lipid raft properties. Therefore, we supposed that TFAs as a kind of fatty acids might have similar connection with lipid rafts. It is interesting to know if TFAs alter vascular cell lipid rafts and stimulate cell membrane receptor proteins and activate downstream signaling pathways in the process of cell dysfunction. The aim of this study was to determine whether lipid rafts play a key role in cell dysfunction caused by TFAs and its receptor proteins activate caspase pathway.

MATERIALS AND METHODS

Chemicals and Reagents. Dulbecco Modified Eagles Medium (DMEM) and fetal bovine serum (FBS) were obtained from Gibco Life Technologies (Carlsbad, USA). Anti-p21, anti-cyclin-dependent kinase (CDK) 4, anti-CDK2, anti-cyclinD1, and anticaspase-3, -8, and -9 antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, USA). Anti-p53, anti-Bax, and anti-Bcl-2 antibodies were obtained from Anbo Biotechnology (California, USA). Methyl-β-

cyclodextrin (MβCD) was from Aladdin (Shanghai, China). Elaidic and oleic acid (98.5% purity) were purchased from Sigma (Boston, USA). All other chemicals were of reagent grade or better.

Cell Culture and TFA Treatment. Human umbilical vein endothelial cells (HUVECs, College of Medical Sciences, Nanchang University) were maintained in DMEM supplemented with 10% fetal bovine serum, 1% penicillin, and 1% streptomycin at 37 °C in a humidified atmosphere of 5% CO_2 and 90% air. The cells were divided into six groups: control group (treated with 0.1 M PBS), elaidic acid group (treated with 100 μmol/L 9*t*18:1 for 24 h), oleic acid group (treated with 100 μmol/L 9*c*18:1 for 24 h), MβCD group (treated with 10 mmol/L MβCD), MβCD + elaidic acid group (incubated with 100 μmol/L9*t*18:1 for 24 h after treated with 10 mmol/L MβCD), and MβCD + oleic acid group (incubated with 100 μmol/L 9*c*18:1 for 24 h after treated with 10 mmol/L MβCD).

Cytotoxicity Assay of MβCD. HUVECs in logarithm period were seeded at a density of 2×10^4–5×10^4 cells/ml into 96-well microculture plates after centrifugation and were cultured at 37 °C in humidified air with 5% CO_2. HUVECs were treated with 10 mmol/L MβCD for 10, 20, 30, 40, 45, 50, 55, 60, and 65 min, respectively, and then 20 μL methyl thiazol tetrazolium (MTT) solution (5 mg/mL) was added to each well and incubated at 37 °C in humidified air with 5% CO_2 for 4 h. Afterward, the medium with MTT was removed, 150 μL dimethyl sulfoxide (DMSO) was added into each well, and after shaking the plates for about 10 min, the cell pellet was resuspended. Detection and quantification of the formazan crystals was performed by a micro plate reader (Thermo, Finland) at 490 nm.

Assay of Cholesterol Efflux. To investigate the effect of 10 mmol/L MβCD on cholesterol level in cell membranes, a cholesterol assay kit (Ke Da Hong Wei, Beijing, China) was used to detect the cholesterol level in cell membranes after being treated with MβCD for different times following the instruction of the manufacturer. Cholesterol ester was decomposed into free cholesterol by cholesterol esterase, and free cholesterol was oxidized by cholesterol oxidase. Hydrogen peroxide was generated during the reaction and catalyzed by peroxidase. Chromogenic substance has a maximum absorption peak at 550 nm.

Observation of HUVECs with Transmission Electron Microscope. After HUVECs were treated with 10 mmol/L MβCD for 10, 60, and 90 min, respectively. Cells were collected and fixed with 2.5% glutaraldehyde overnight. After washed in 0.1 M PBS (3 × 5 min), the cells were post fixed with 1% OsO4 for 1 h, followed by dehydration with a graded acetone series (30, 70, 90, and 2 × 100%, each for 30 min). The specimens were then embedded in resin and polymerized at 35 °C for 24 h and 60 °C for 12 h. The specimens were cut by an ultrathin microtome. The sections were collected on copper grids, stained with 0.5% lead citrate for 10 min, and rinsed with water. The

images of these sections were made by transmission electron microscope.

Cell Viability Assay. Briefly, at the end of the incubation, the media were removed and MTT added in each well for 4 h incubation. Then DMSO was added and shaken gently for 10 min so that the precipitation was completely dissolved. Absorbance was recorded at 490 nm using a micro plate reader (Spectra max190, Molecular Devices, California).

Apoptosis Detection by Flow Cytometry. Cells were collected from each group and 100 μL of binding buffer added to suspend the cells. The cells were then collected by centrifugation and washed twice with PBS. Then 5 μL of fluorescein isothiocyanate (FITC) and 5 μL of propidium iodide (PI) were added to the mixture and incubated in the

dark for 10−15 min at room temperature. Apoptosis of the cells was detected by flow cytometry within 1 h after the addition of 500 μL of binding buffer.

Western Blot Analysis of Apoptosis-Related Proteins. Total cell lysates were extracted by RIPA buffer on ice. After centrifugation at 20000*g* for 15 min, supernatant was taken and stored at −70 °C until use. Protein (80 μg) was mixed with loading buffer and denatured by boiling for 5 min. The proteins were separated by SDS-PAGE and then transferred to a nitrocellulose membrane. After blocking with 5% nonfat milk, membranes were then incubated with anticaspase-3, -8, and -9, anti-Bcl_2, anti-Bax, and anti-Bid antibodies overnight at 4 °C, followed by incubation with horseradish peroxidase-conjugated secondary antibodies at room temperature for 1 h. Finally, protein bands were visualized by enhanced chemiluminescence (ECL) detection system (Kang Wei, Beijing, China).

Immunofluorescence of Fas. Briefly, cells were fixed with 4% paraformaldehyde for 15 min and 0.5% Triton X-100 in PBS for 20 min. Cells were blocked with goat serum for 1 h and then incubated overnight at 4 °C with anti-Fas antibody (1:100). Subsequently, cells were incubated with goat antirabbit FITC antibody (1:200) for 1 h at room temperature and incubated with 40, 6-diamidino-2-phenylindole (DAPI), to label nuclei, for 5 min in a dark space. Images were acquired with a fluorescence microscope (Olympus, Japan).

Measurement of Cytochrome C Level. Treated cells were washed with cold PBS twice and homogenized in cold lysis buffer containing 1 mmol/L DTT and 0.5 mmol/L PMSF on ice for 40 min and then centrifuged at 10000 rpm at 4 °C for 2 min. The supernatants were used for the measurement of cytochrome C using ELISA kit (Senxiong Biotechnology, Shanghai, China).

Determination of Fatty Acids by Gas Chromatography. Total lipids were extracted from $4-6 \times 10^7$ cells using chloroform/methanol (1:1, v:v). Fatty acids were then methylated using sodium methoxide and analyzed by a gas chromatograph equipped with a flame ionization detector (model 6890 N, Agilent Technologies, Shanghai, China). Peaks were identified by their retention times relative to standards FAME mixture (no. 463).

Statistical Analysis. Data are expressed as mean ± SD. Statistical analysis was performed by one-way ANOVA followed by Student's *t*-test using SPSS.15.0 software. $p < 0.05$ was indicative of significant difference.

RESULTS

Treatment Time of M*β*CD in HUVECs. M*β*CD is a time-dependent reagent which could extract cholesterol of cell and perturb the function of lipid rafts. The reasonable treatment time of M*β*CD (10 mmol/L) in HUVECs without cytotoxicity should be determined. As shown in Figure 1 A, cell viability decreased by 30% within 65 min treatment. Cholesterol levels (Figure 1B) dropped to 60% after treatment with M*β*CD for 1 h. Although the longer the treatment time with M*β*CD and the better extract efficiency of cholesterol, cells membranes were more seriously damaged with the increased treatment time. As shown in Figure 1C, there was almost no injury to the cells when the treatment times were less than 60 min, but obvious damages were found after 60 min, such as morphological changes, cytoplasm leakage, and increased cavities. To ensure the normal physiological conditions of cells, the reasonable

treatment time of M*β*CD should be within 60 min. We also examined the effect of M*β*CD on lipid rafts in 50 min by determining the expression of cavelin-1, one of important makers of lipid rafts. A significant decrease in cavelin-1 expression was observed (Figure 1D). The results suggest that M*β*CD may interrupt the function of lipid rafts.

Effect of M*β*CD on TFA-Induced Apoptosis of HUVECs. MTT assay and flow cytometry were performed to examine the effect of TFA on cell viability and apoptosis of HUVECs. The cell viability rate in M*β*CD + elaidic acid group increased significantly (from 70% to 84%), and the M*β*CD + oleic acid group had no obvious changes (Figure 2A). In the M*β*CD treated groups, the number of apoptotic cells which incubated with 9*t*18:1 dropped significantly by nearly 3% (the early apoptosis decreased from 5.11% to 4.50% and late apoptosis dropped to 1.5%), while the apoptotic cells of 9*c*18:1 group slightly increased when compared with non-M*β*CD treated group (Figure 2B).

To determine whether lipid rafts play an important role in cell apoptosis after TFA supplementation, we compared the expression levels of apoptosis-related proteins between M*β*CD treated and nontreated cells. In the M*β*CD + elaidic acid group,

the expression of caspase-3, -8, -9, and Bax was down-regulated and Bcl-2 was up-regulated when compared with elaidic acid group and control group (Figure 2C). Furthermore, the release of cytochrome C from the mitochondria to cytosol decreased (Figure 2D), perhaps due to the down-regulated expression of Bid. The expression levels of pro-apoptotic proteins decreased significantly in MβCD + oleic acid group compared with control group, while expression levels of some proteins including Bax, Bcl-2, and caspase-9 almost unchanged between the MβCD + oleic acid group and the oleic acid group (Figure 2C). These results indicate that lipid rafts had greater impact on the elaidic acid group than on the oleic acid group.

Effect of MβCD on TFA-Induced Cell Cycle Changes in HUVECs. As shown in Figure 3, in non-MβCD treated groups, elaidic acid significantly increased the expression of p53, p21, and p27 in comparison with other groups. The expression levels of p21 and p27 also increased in 9*c*18:1 group compared with control group. It has been reported that p21 and p27 could induce cell cycle arrest in G1 phase and G2/M phase through inhibition of CDK4-cyclin D1 and CDK2-cyclin E activity (18, 19). However, the expression of CDK4 and cyclin D1 increased significantly ($p < 0.05$) and CDK2 expression did not change significantly ($p > 0.05$).

In MβCD treated HUVECs, 9*t*18:1 supplementation resulted in a down-regulation of p53, p21, p27, and CDK4-cyclin D1 compared with 9*t*18:1 group. It should be pointed out that expression of p53 decreased significantly compared with control group, but CDK2 had no significant changes compared with other groups. Similar data were obtained with 9*c*18:1.

Effect of MβCD on TFA-Induced Expression of Apoptosis Receptors. As shown in Figure 4A, Fas and TNFR1, two apoptosis receptors located in lipid rafts, were investigated. The expressions of Fas and its ligand (FasL) were significantly increased in the elaidic acid group and unchanged in the oleic acid group, while they returned to normal levels in the MβCD + elaidic acid group and slightly increased in the MβCD + oleic acid group. The expression of TNFR1 had no significant change in each group ($p < 0.05$).

As shown in Figure 4B, both Fas and its ligand (FasL) were highly expressed on the cell membranes of 9*t*18:1 stimulated HUVECs The death domain with each other together formed tripolymers and activated the apoptosis pathway.

Effect of MβCD on Absorption of Fatty Acids in HUVECs. The levels of 9*t*18:1 in elaidic acid group and 9*c*18:1 in the oleic acid group significantly increased in comparison with control group ($p < 0.05$, Table 1). The results showed that the cells had obvious absorption of fatty acids. However, there were no significant differences between control and MβCD groups or between elaidic acid and MβCD + elaidic acid groups. Only did 9c18:1 level decrease in the MβCD + oleic acid group compared with the oleic acid group. The results indicated that lipid rafts had little effect on elaidic acid absorption but a slight effect on oleic acid absorption.

DISCUSSION

Lipid Rafts Could Involve in Elaidic Acid-Induced Apoptosis of HUVECs. TFAs resulted in systemic inflammation, insulin resistance, and adiposity resistance. Both randomized trials and observational studies demonstrated that TFAs consumption led to endothelial dysfunction.[16] Previous studies have shown that several dietary fatty acids had an effect on both cell membranes and gene transcription.[17,18] Qiu et al.[3] showed that TFAs led to endothelial cell apoptosis through the caspase pathway and the mitochondria. However, they did not report how TFAs activated the caspase pathway. It remains unknown whether there are specific receptor-induced apoptosis or what roles cell membranes play during this process. Apoptosis was a genetically controlled mechanism of cell death with a number of specific biochemical and morphological changes, including membrane blebbing, chromatin condensation, cytoplasmic condensation, and internucleosomal fragmentation of DNA. It could be mediated by death receptor pathway as well as the mitochondria pathway.[19]

Lipid rafts were specific membrane microdomains which were rich in cholesterols and sphingolipids.[4] Lipid rafts appeared to be involved in many biological events such as synthetic traffic, cell skeletal reconstruction, and signal transduction.[5] MβCD was the most common drug that interferes with lipid rafts; its mechanism of action was to remove or disturb the specificity of membrane cholesterol. Treatment with 10 mmol/L of MβCD within 60 min did not cause significant changes in both morphology (Figure 1C) and physiology (Figure 1A) of HUVECs. The content of cholesterol and expression level of cavelin-1 in cell membrane decreased significantly (Figure 1B,D). These results indicated that treatment with 10 mmol/L of MβCD within 60 min successfully destroy lipid rafts on cell membrane. The 9*t*18:1 treatment decreased cell viability, increased apoptosis, and resulted in down-regulation of Bcl-2 and up-regulation of the pro-apoptotic proteins such as Bax, Bid, caspase-3, caspase-8, and caspase-9. However, when lipid rafts of the endothelial cells were destroyed, the expression levels of these pro-apoptotic proteins were decreased and antiapoptotic protein (Bcl-2) was increased in 9*t*18:1-induced apoptosis. These results have for

dx.doi.org/10.1021/jf404834e | J. Agric. Food Chem. 2014, 62, 798−807

the first time demonstrated that lipid rafts could influence on 9*t*18:1-induced apoptosis of HUVECs.

Taken together, we have for the first time shown that fatty acids especially TFAs act on HUVECs by affecting lipid rafts. However, whether apoptotic receptors were destroyed or fatty acids were less absorbed remained unclear. Therefore, we conducted fatty acids composition analysis in the study. It was found that there was no significant difference in the level of fatty acids between elaidic acid group and MβCD + elaidic acid group, but the level of 9c18:1 in MβCD + oleic acid group decreased significantly ($p < 0.05$). We proposed that the absorption of 9t18:1 was not affected by lipid rafts, and the apoptotic receptor was the key point of apoptosis. The decreased absorption of 9c18:1 in MβCD + oleic acid group might be due to the decline of fatty acid translocase, a receptor localized in lipid rafts and nonraft plasma membrane, with an ability to help the uptake of required long-chain fatty acids for normal biological function of cells.[20]

Fas/FasL Pathway May Involve in 9*t*18:1-Induced Apoptosis of HUVECs. Two apoptosis receptors, Fas and tumor necrosis factor receptor (TNFR) 1, were located in lipid rafts. Fas (also known as CD95 or APO-1) was a type I glycosylated 45 kD membrane protein that belonged to the TNF family and transmitted a suicide signal to the cell upon binding of its ligand (FasL), a highly conserved, 40 kD glycoprotein.[21] TNFR1 was also a kind of apoptotic receptor.[22] Fas/FasL system was a critical signal pathway involved in apoptosis regulation in several cell types[23] and could be activated by many factors, such as drugs,[24] oxidative stress,[25] and other stimuli. Loss of integrity of lipid rafts by drugs could diminish CD95-mediated caspase-8 activation and apoptosis.[26,27] The activation of CD95 linked with its translocation into the lipid rafts. Lang et al.[28] reported that CD95 signaling was triggered by the interaction between active/inactive CD95 species and lipid rafts. A number of studies have demonstrated the importance of formation and internalization of CD95-containing raft in CD95-induced apoptosis of different kinds of human cells.[29,30] Zhang et al.[31] using a reconstituted system, found that the Fas/FasL interaction between membranes creates submicrometer membrane microdomains, and the cells then reveal various apoptosis features.

Treatment of elaidic acid increased the apoptosis of HUVECs. The result of immunofluorescence analysis (Figure 4B) showed that Fas clustered on lipid rafts when HUVECs were stimulated by 9*t*18:1. However, the expression levels of Fas and FasL significantly decreased in nonrafts cells after 9*t*18:1 treatment where cell apoptosis was inhibited. These results indicated that the Fas/FasL pathway might be involved in elaidic acid-induced apoptosis of HUVECs.

In conclusion, we proposed a possible molecular mechanism involved in 9*t*18:1-induced apoptosis and cell-cycle arrest in HUVECs (Figure 5). Lipid rafts and Fas/FasL pathway could play an important role in 9*t*18:1-induced apoptosis. Fas receptor and its ligand clustered in the lipid raft and then started the apoptosis program after 9*t*18:1 stimulated HUVECs. Then caspase-8 was activated when the signal was received that the apoptosis receptor (Fas/FasL) transmitted. The high expression of caspase-8 could increase the expression of Bid and Bax and decrease the expression of Bcl-2 and lead to release of mitochondrial cytochrome C. The mitochondrial cytochrome C which released to the cytoplasm would activate caspase-9 and then activate its downstream protein caspase-3. In addition, p53 as a critical pro-apoptotic protein and cell cycle

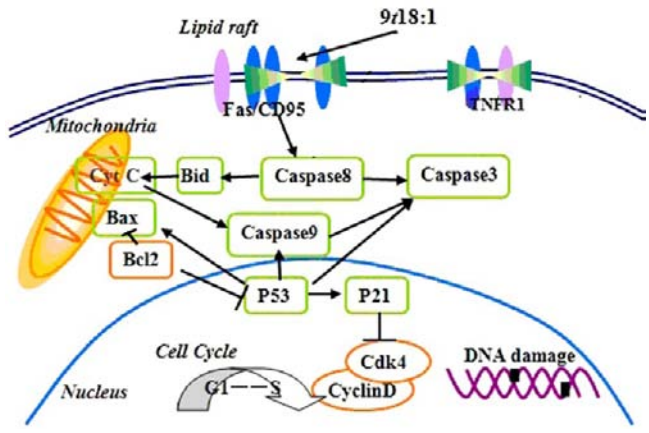

Figure 5. The proposed molecular mechanisms involved in 9*t*18:1-induced apoptosis and cell-cycle arrest in HUVECs.

protein was highly expressed after being treated with 9*t*18:1. The high expression of p53 increased the caspase-9 and other pro-apoptotic protein like Bax. p53 could also activate the expression of p21 and then interfere with the cell cycle.

9*t*18:1 Affects G1/S Phase in Cell Cycle. Cells in the long term evolution have developed detection mechanisms to ensure correct DNA replication and cell cycle distribution, and these critical control stages were often called cell cycle checkpoints or restriction points. There were three major cell cycle checkpoints, namely G1/S phase, G2/M phase, and the spindle assembly checkpoint. In the process of cell cycle regulation, the control point of G1/S phase was the key point of signal transmission and integration into the nucleus and the process of cell proliferation.

The human tumor suppressor protein p53 was critical for the transcriptional activation of a series of proteins involved in cell cycle control and apoptosis. p53 played its control on the cell cycle primarily through the G1/S checkpoint [32] and also regulated the G2/M checkpoint.[33] Activation of p53 in response to a variety of stimuli was associated with an increase in its protein levels and post-translational modifications, which induced the activation of a number of genes like p21 and p27, leading to cell cycle arrest.[34] CDK4 as a checkpoint regulates cell cycle in G1/S phase. In general, increased expression of p21 could enhance the inhibitory effect on CDKs and weaken CDK4-cyclinD1 regulation in the G1/S phase, resulting in G1 arrest and incomplete cell mitosis.[35] Compared to the control, 9*t*18:1 induced significant increases in the expression levels of p53, p21, and p27 ($p < 0.05$) and the expression level of CDK4-cyclinD1 increased in 9*t*18:1 group. When nonraft cells were exposed to 9*t*18:1, p53, p21, and p27 protein levels decreased and CDK4-cyclinD1 level also decreased compared with that in the 9*t*18:1 group, but they were still higher than that of the control. Whether this phenomenon is the result of self-regulation or of other mechanisms needs to be further investigated.

Characterization of the Surface Properties of Wheat Spikelet Components Grown under Different Regimens and the Biocontrol Yeast *Cryptococcus flavescens*

Christopher A. Dunlap* and David A. Schisler

Crop Bioprotection Research Unit, National Center for Agricultural Utilization Research, Agricultural Research Service, U.S. Department of Agriculture, 1815 North University Street, Peoria, Illinois 61604, United States

Supporting Information

ABSTRACT: Surface properties play an important role in plant−microbe interactions and determine if microbial propagules adhere to the surface of a plant. Fusarium head blight is an important disease of wheat that is initiated by the pathogen colonizing the wheat head. To better understand how surface properties of wheat may affect disease development and spray applications, the surface properties of wheat (*Triticum aestivum* L.) spikelet components were characterized under different environmental growing regimes. In addition, the surface properties of the biocontrol yeast *Cryptococcus flavescens* OH 182.9, which has been shown to effective in managing Fusarium head blight, were characterized. Wheat samples grown in a greenhouse environment were compared with samples produced in the field for two wheat cultivars. The results show changes occurring in the surface energy parameters and estimates of roughness during this period between the two cultivars. In general, the greenhouse samples were more hydrophobic than those grown in the field. The surface properties of the biocontrol yeast *C. flavescens* OH 182.9 were determined from contact angles on microbial lawns and revealed the cells were hydrophobic with a free energy of aggregation of −86.3 mJ/m^2 in water.

KEYWORDS: *wheat, spikelet, greenhouse, field, anthesis, Cryptococcus*

INTRODUCTION

The surfaces of the aerial parts of terrestrial plants frequently are covered by a waxy cuticle, which mediates the interactions between the plant and the environment. The chemical and physical properties of these surfaces determine the nature of these interactions. These properties play an important role in plant−microorganism interactions by influencing the likelihood of a microbial propagule adhering to the plant and subsequently colonizing the surface. In the case of the wheat disease Fusarium head blight (FHB), these propagules are ascospores and macroconidia of *Gibberella zeae*, the primary causal agent of FHB in North America. In addition, it is also important to understand how propagules of some beneficial microorganisms interact and adhere to the plant surface, such as applied biological control agents.

In previous work, our laboratory isolated the basidiomycetous yeast *Cryptococcus flavescens* OH 182.9 (NRRL Y-30216) from anthers of flowering wheat heads.[1] Research has demonstrated the yeast's efficacy in reducing FHB and its associated mycotoxin production in greenhouse and field settings[2,3] when assayed alone or in combination with other biocontrol agents.[4,5] Wheat is primarily vulnerable to FHB when favorable (warm and wet) weather conditions coincide with the period of anthesis when wheat florets open for flowering.[6] Little is known about the surface properties of wheat heads during this period when the pathogen must adhere and colonize the plant. Understanding the physicochemical properties of the wheathead are important, because adhering to the plant surface is the first step in the infection process both for the plant pathogen and for the beneficial biocontrol organism.

Although several studies have characterized the surface properties of the leaves of wheat,[7−9] no studies could be found that characterized the surface properties of the wheat spikelet. The wheat spikelet is the prevalent location for infection onset,[10,11] and the glume and lemma make up the bulk of the surface area (see Figure 1). It is also not known if any significant surface property alterations occur during the period of anthesis, which may make the plant more vulnerable to colonization. In addition, no studies have examined the impact of growing regimen on the surface properties of wheat spikelets grown in a greenhouse versus field-grown plants. This is important because many crop protection products are first tested in the greenhouse before taken to the field.

Knowledge of these physicochemical properties of the spikelet surface is also important for developing formulations of sprayable pest control products. Understanding how a spray droplet interacts with the target surface can help in guiding formulation decisions. These surface properties are also needed as parameters for accurate spray droplet adhesion models such as the model of Forster, which incorporates spray droplet size, velocity, surface angle, dynamic surface tension, and leaf contact angle measurements.[12] These models can help guide decisions

when developing new formulations or application technology for a specific crop system.

The goal of this study was to characterize the surface properties of the wheat spikelet components around the period of anthesis under greenhouse- and field-growing regimens. An additional goal was to characterize the surface properties of the biocontrol yeast antagonist *C. flavescens* OH 182.9.

MATERIALS AND METHODS

Wheat Samples. Field trials were conducted in Peoria, IL, USA, in 2009. Soft red winter wheat cultivar Freedom (moderately resistant to FHB) and Pioneer Brand 2545 (susceptible to FHB) were grown using standard agronomic conditions.[13] Whole wheat heads were cut from plots at split boot (early Feekes 10.1), out of boot (Feekes 10.5), and flowering (Feekes 10.5.1) and at 4, 8, and 12 days after flowering. Heads were stored in zip-lock bags on ice until analysis. For greenhouse growth of wheat seedlings, experiments were conducted in a climate-controlled greenhouse with temperatures that ranged from 17 to 20 °C at night and from 25 to 28 °C during the day. Natural sunlight was supplemented with high-pressure sodium lights for 14 h/day. Each experimental unit consisted of two plants of the chosen cultivar grown in a 19 cm diameter plastic pot. Each pot contained air-steam pasteurized (60 °C for 30 min) potting mix (Terra-lite Redi-earth mix, W. R. Grace, Cambridge, MA, USA), and plants were grown in a growth chamber (25 °C, 14 h photoperiod, 600 μmol/[m^2/s]) for 7−8 weeks prior to transfer to greenhouse benches. Pots were fertilized after 1 week and weekly thereafter with 50 mL of a solution containing 1.25 g/L Peters 20−20−20 (Grace-Sierra Horticultural Products, Milpitas, CA, USA) and 0.079 g/L iron chelate (Sprint 330, Becker Underwood, Inc., Ames, IA, USA). From approximately 1 week to 3 weeks after transferring plants to the greenhouse, wheat heads were harvested at the same physiologic stage of development as used for the field-grown wheat.

Contact Angle Measurements on Wheat Tissues. To determine the contact angle of glume or lemma tissues, samples were removed from a wheat spikelet and affixed to a microscope slide using double-sided tape. The location on the wheat head of spikelet samples was randomly chosen with at least three samples from each of the top, middle, or bottom third of the head. Four liquids were tested on each type of sample: deionized water, formamide, methyleneiodide, and acetone/water (1:1). Acetone, formamide, and methyleneiodide were obtained from Sigma-Aldrich (St. Louis, MO, USA) in the highest purity available. The water was provided by a Barnstead Easypure II reverse osmosis system. Contact angles were determined using an FTA4000 video drop shape analysis system (First Ten Angstroms, Portsmouth, VA, USA). A droplet of 5 μL was deposited onto the sample and the image recorded every 100 ms for 15 s. Under this time regimen, the droplets reached equilibrium. The droplet images were analyzed using software provided by the instrument manufacturer. The images were fit to a nonspherical model. A minimum of 10 replicate samples was tested for each sample and each liquid.

Production of *C. flavescens* OH 182.9. A pure culture of *C. flavescens* OH 182.9 (NRRL Y-30216) was initiated on one-fifth strength tryptic soy broth agar (TSBA, Difco Laboratories, Detroit, MI, USA) from a 10% glycerol stock stored at −80 °C. After growth at 25 °C for 24 h, cells from a plate were used to inoculate starter cultures of the strain. Starter cultures were produced in nonbaffled, 125 mL Erlenmeyer flasks containing 25 mL of liquid medium (SDCL)[14] that was incubated at 250 rpm, 2.5 cm orbit, and 25 °C for 24 h. A test culture was then initiated by inoculating it to an initial optical density (OD) of approximately 0.100 at 620 nm wavelength light (A620) using starter culture cells. Test cultures were incubated as described for starter cultures and harvested after 48 h of growth.

Contact Angle Measurements on *C. flavescens* OH 182.9. A microbial lawn of *C. flavescens* OH 182.9 was produced using a modified version of a previously described procedure.[15] Briefly, a 5 mL suspension of the production culture containing (~1 × 10^8 cfu/mL) was filtered in a 15 mL vacuum filtration unit utilizing a 25 mm, 0.22 μm pore, GVWP membrane, both from Millipore Inc. (Billerica, MA, USA). The membranes are hydrophilic and low protein binding and made of polyvinylidene fluoride. The membrane was prewetted and rinsed with deionized water. The sample was added to the filter, vacuum was initiated, and the solution was allowed to remain on the filtering apparatus for 30 min. Under these conditions, the microbial lawn/membrane would clog the filtering process and only about 1 mL of water would have been removed. The remaining liquid was carefully removed with a pipet. The membrane was allowed to slowly dry for 3 h in a Petri dish before measurements were conducted. The membrane was secured to a microscope slide using double-sided tape to provide a stable platform. Contact angles were determined and analyzed as previously described for the wheat components.

Filtering Experiments. To determine the propensity of *C. flavescens* OH 182.9 to clog a filter membrane, we measured the time needed to clog or completely filter a solution of *C. flavescens* OH 182.9 cells. Three solutions were prepared using 8 mL of cell suspension (~1 × 10^8 cfu/mL) in spent culture media combined with either 2 mL of water or 2 mL of 100 mM ethylene glycol bis(2-aminoethylether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA), pH 8.0, or 2 mL of 100 mM 2-({2-[bis(carboxymethyl)amino]ethyl}(carboxymethyl)-amino) acetic acid (EDTA), pH 8.0. The solution was filtered in a 15 mL vacuum filtration unit utilizing a 25 mm, 0.22 μm pore, GVWP membrane, both from Millipore Inc. The vacuum pressure was provided by a building-wide system and averaged ~95 mbar. The membrane was prewetted with deionized water. The sample was added to the filter, vacuum was initiated, and the time to complete clogging or until all of the water was removed was assessed visually. The tests were run on three individual cultures with two or more technical replicates of each.

Microscopy. Photomicrographs of cells of *C. flavescens* in culture were taken using an Olympus BX60 system light microscope equipped with Nomarski optics and an Olympus DP70 digital camera (Melville, NY, USA).

RESULTS AND DISCUSSION

Contact Angle Measurements on Greenhouse-Grown Wheat Spikelets. The contact angles of three liquids were determined for the wheat spikelet components (glume and lemma) for samples immediately before and after anthesis for two wheat cultivars grown under a greenhouse-growing regimen. The measurements were conducted on two different wheat cultivars, Freedom and Pioneer Brand 2545 (Table S1 in the Supporting Information). The choice of these two wheat

varieties is based on the cultivar Freedom being moderately resistant to FHB and Pioneer Brand 2545 being susceptible to FHB. Both tissue types have been identified as potential infection sites of the FHB pathogen.[10,16] The results are reported in Figure 2A. The results show no significant differences between the two wheat cultivars under these conditions. In addition, for each cultivar, the glume and lemma show no significant differences among themselves under these conditions. Observing the change in water contact angle as a function of time, the means trend toward higher contact angles from the split boot stage to day 8 (post anthesis). The most notable difference from the time course is observed in the lemma from the Freedom strain at the split boot stage and day 8 (post anthesis) and is statistically significant ($P < 0.05$).

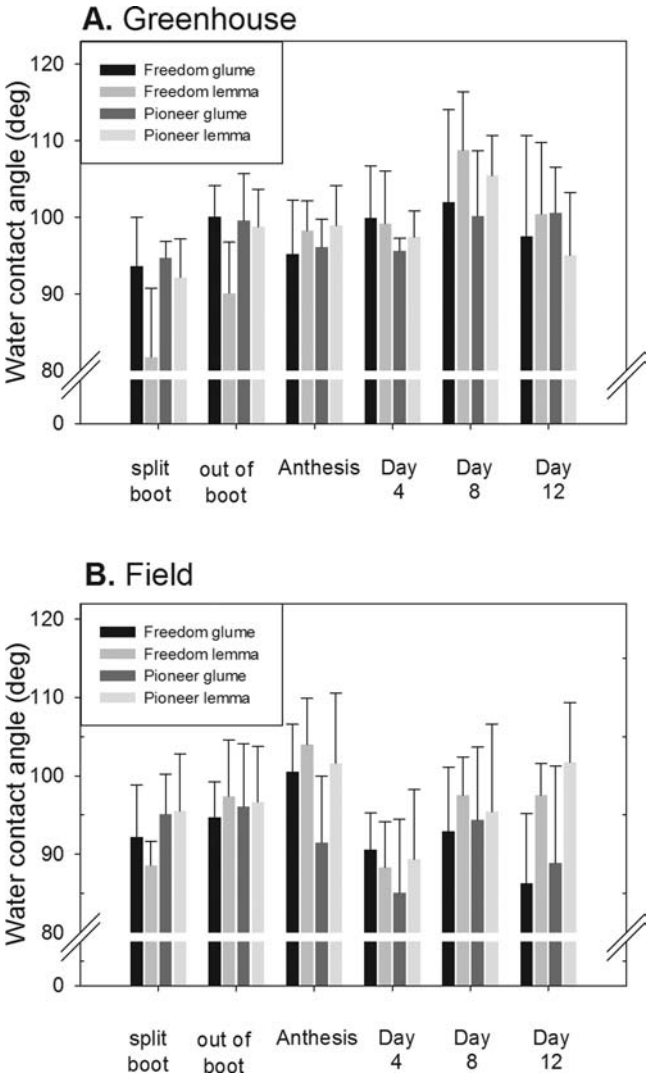

Figure 2. (A) Water contact angles of the glume and lemma of two wheat varieties (Freedom and Pioneer) grown (A) in a greenhouse and (B) in the field at different stages of growth. Error bars are ±1 SD.

Contact Angle Measurements on Field-Grown Wheat Spikelets. The contact angles were determined for the wheat spikelet components for the two wheat varieties grown in field plots (Table S2 in the Supporting Information). The field-grown samples exhibited much more variation and differences between the strains. The only significant difference ($P < 0.05$) between the strains for a specific tissue and time was between the lemma at the split boot stage. Comparisons of tissue type for a specific strain and time showed three significant differences. These include the Pioneer cultivar at anthesis and day 12 and Freedom at day 12. From an analysis of the time course, the most notable difference is that all of the conditions, except Pioneer lemma, are significantly different between anthesis and day 4 (post anthesis). Weather during the field trials was uneventful with two moderate precipitation events occurring on day 2 (post anthesis, 29 mm) and the evening of day 8 (post anthesis, 24 mm), daily temperature highs and lows are included in supplemental Figure S1. Previous studies on wheat leaves reported a much higher water contact angle than we observed on the wheat head. Early studies report wheat leaves have a water contact angle in excess of 130°,[8] whereas a more recent study reported a wheat leaf water contact angle of 165°.[9]

Comparing the results between greenhouse- and field-grown plants shows the field-grown plants tend to be less hydrophobic than the greenhouse plants. In cereals, a variety of agronomic traits have been identified to be altered when produced in greenhouse versus the field environment,[17−19] but only limited studies could be found that identify changes in surface properties or ultrastructure of plant surfaces under these regimens.[20,21] These results suggest surface properties may affect studies comparing greenhouse- and field-grown plant traits. This may be one of the causes of the variation in performance microbial biocontrol products in greenhouse environments versus field environments.[3,22]

Surface Energy Calculations for Wheat Spikelet Components. The contact angles were used to calculate the surface free energy using the Owens−Wendt method (geometric mean),[23] which uses the contact angle of a polar (water) and apolar (methyleneiodide) liquid to calculate the dispersive and polar components of surface energy. The results for the greenhouse-grown plants are reported in Figure 3A. The two wheat varieties show a distinct difference in surface energy for the post anthesis time points. The results for the field-grown plants are reported in Figure 3B. The field results do not reveal any distinct patterns; the largest change occurs in the Pioneer glume sample between anthesis and day 4 with a change of 5.1 dyn/cm ($P < 0.05$).

Water/Acetone Contact Angle Measurements. The contact angle of a acetone/water, 1:1 (v/v), solution has been used to estimate the surface roughness of various leaves.[24] This measurement is also required as a parameter in the spray droplet adhesion model.[12] The results for the greenhouse-grown samples are reported in Figure 4A. The contact angles range in value from 68° to 84°. The results identify differences between individual samples, but there are no clear trends in the data. The acetone/water contact angles of the field-grown samples are reported in Figure 4B. As before, the field-grown samples show a greater diversity in the observed contact angles, which range in value from 73° to 95°. There are no significant differences between the tissue types, although both surfaces show changes occurring at or immediately after anthesis. The two cultivars show significant differences before anthesis and become comparable post anthesis. One possible attribute in plants that could produce differences in roughness is variation in the trichomes. Trichomes are small fine outgrowths on the surface plant parts. Variation in trichome distribution has been reported in pigeonpeas (*Cajanus* spp.) for plants grown in the greenhouse versus field-grown plants.[20] Alternatively, wax

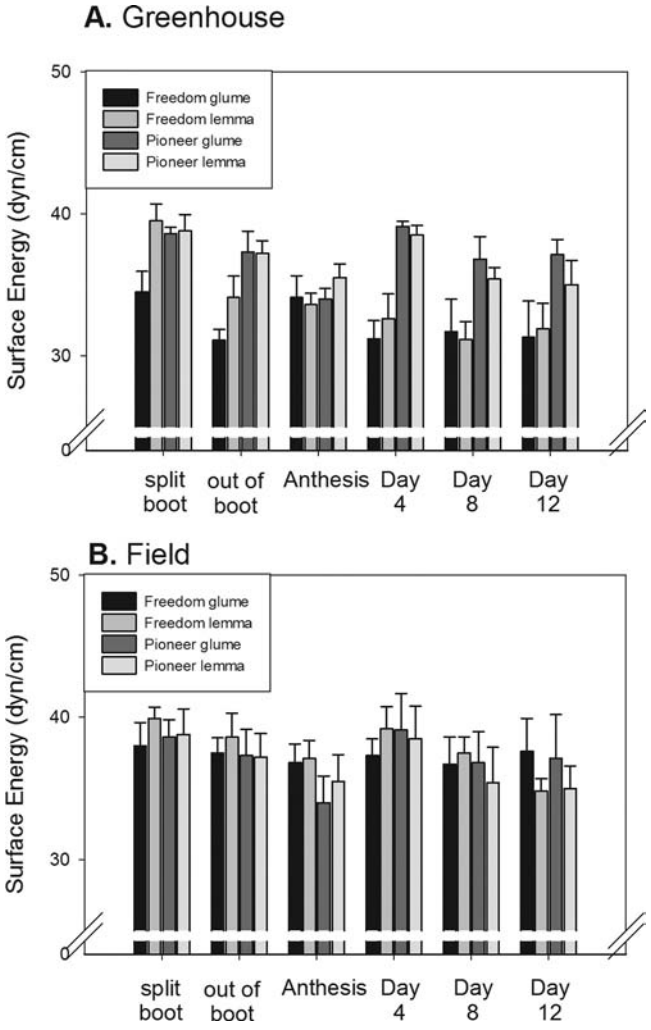

Figure 3. Surface energy of the glume and lemma of two wheat varieties (Freedom and Pioneer) grown (A) in a greenhouse and (B) in the field at different stages of growth. Surface energy was calculated from water and methyleneiodide contact angles using the Owens–Wendt method (geometric mean).[23] Error bars are ±1 SD.

morphology and ultrastructure have been correlated with surface roughness on wheat leaves.[8]

Contact Angle Measurements on *Cryptococcus flavescens* OH 182.9. To determine the surface properties of microorganisms, they are typically prepared by capturing them on a filter membrane and drying them to a uniform state.[25] This method was used to generate samples for our biocontrol antagonist *C. flavescens*. The contact angles were determined for three liquids, two polar (water and formamide) and one apolar (methyleneiodide). The contact angles are reported in Table 1.

The contact angles were then used to derive the surface energy parameters for the *C. flavescens* lawn. The contact angles were used to calculate the surface free energy using the Owens–Wendt method (geometric mean),[23] which uses the contact angle of a polar and an apolar liquid to calculate the dispersive and polar components of surface energy. In addition, surface free energy was determined using the VCG method,[26] which requires two polar liquids and one apolar liquid. The VCG method also calculates the dispersive and polar components of surface energy, but further refines the estimate by separating the polar fraction into Lewis acid and base

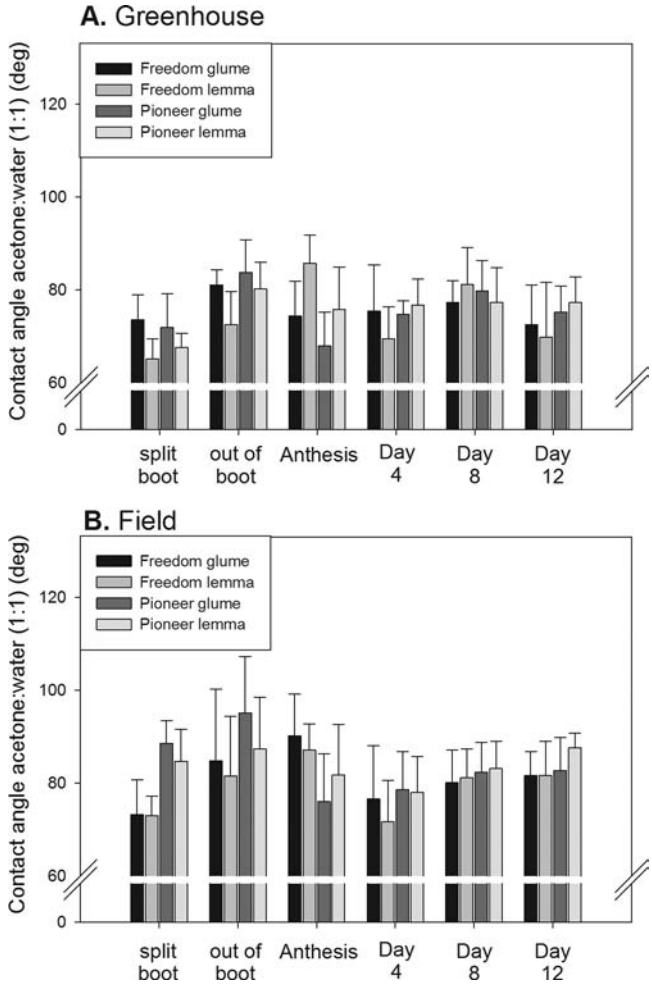

Figure 4. Acetone/water (1:1) contact angles of the glume and lemma of two wheat varieties (Freedom and Pioneer) grown (A) in a greenhouse amd (B) in the field at different stages of growth. Error bars are ±1 SD.

components. The calculated results for the surface energy parameters are reported in Table 1. The calculated surface energy parameters for *C. flavescens* are at the high end of the range reportedly observed in microorganisms.[27]

Microbial surface hydrophilicity or hydrophobicity can be described by calculating the free energy of aggregation (ΔG_{mwm}) in aqueous solution, where m is microbe and w is

dx.doi.org/10.1021/jf404181f | J. Agric. Food Chem. 2014, 62, 809–815

water.[28−30] The free energy of aggregation is a measure of the interactions between two of the same particles (two cells of *C. flavescens*), immersed in a liquid (water). A microbial surface is characterized as hydrophobic when ΔG_{mwm} is <0 or as hydrophilic when ΔG_{mwm} is >0. If the change in free energy is positive ($\Delta G_{mwm} > 0$), it is energetically unfavorable to bring the particles together and the particles do not aggregate in aqueous solution. Likewise, if the change in free energy is negative ($\Delta G_{mwm} < 0$), it is energetically favorable to bring the particles together and the particles readily aggregate in aqueous solution. The free energy of aggregation is the sum of the Lifschitz−van der Waals interaction free energy and polar interaction free energy, which can be written in terms of their component surface tensions.

$$\Delta G_{mwm} = -2\left(\sqrt{\gamma_m^{LW}} - \sqrt{\gamma_w^{LW}}\right)^2 - 4\left(\sqrt{\gamma_m^+\gamma_m^-} + \sqrt{\gamma_w^+\gamma_w^-} - \sqrt{\gamma_m^+\gamma_w^-} - \sqrt{\gamma_m^-\gamma_w^+}\right) \quad (1)$$

Calculation of the free energy of aggregation for cells of *C. flavescens* in aqueous solution yielded a value of −86.3 mJ/m^2. This would classify the surfaces of these cells as hydrophobic, because the interaction between cells is energetically favorable. Interestingly, this is inconsistent with observations in our laboratory that the cells do not readily aggregate in aqueous solution. Figure 5 shows the yeast cells at the typical harvest

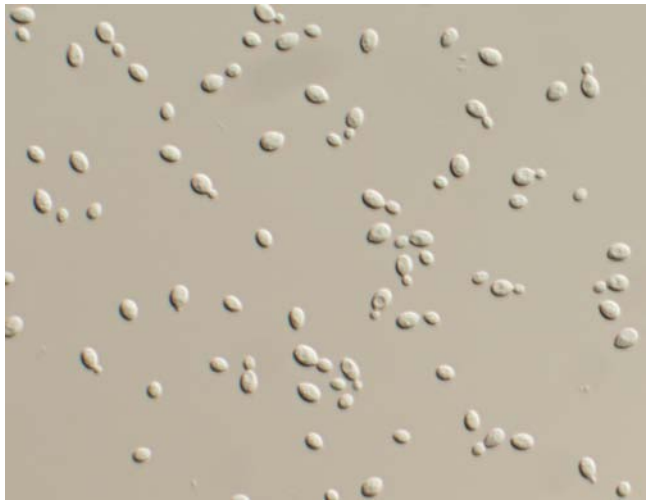

Figure 5. Micrograph of cells of *C. flavescens* OH 189.2 at the time of harvest.

time (early stationary phase), and they demonstrate no inclination to aggregate. It is important to note that this treatment of free energy of aggregation does not account for electrostatic interactions. Therefore, one possible explanation for the difference in calculated versus observed properties is that electrostatic interactions are an important contribution to surface free energy and that the repulsive nature of like charges (same charge on each cell) is able to keep the cells from aggregating.

Another possible explanation for the inconsistent results between the measured surface properties of the microbial lawn and their behavior in solution is the cells in the microbial lawn are in a different state from the cells in solution. One observation supporting this possibility is the previously reported ability of the cells to rapidly clog a filter membrane.[31] This suggests cells have the ability change properties during the filtering of the solution. Although it is tempting to speculate this maybe the result of a quorum sensing or concentration-dependent phenomenon, there are no laboratory observations to support this theory. The cells can be highly concentrated through centrifugation, and they are still readily dispersible back into solution. Scanning electron micrographs of the microbial lawns on a filter membrane show the cells have an extracellular polymer connecting each other.[31] Given the rapid rate of filter clogging (∼30 s), it is not feasible for the cells to produce the compound quickly enough to respond to the changes in environmental conditions. This suggests the compound is already made and excreted when needed or is already made and activated/altered with another small molecule when needed.

It has long been known that multivalent cations, specifically calcium, can promote cell to cell aggregation via bridging of anionic cell surface polymers.[32,33] To explore if multivalent ions could play a role in the current system, we used divalent chelators during filtration to reduce the bioavailability of divalent ions in the culture supernatant. The common divalent chelators EDTA and EGTA have been used study cell to cell aggregation in other systems.[34] To determine if divalent ions played a role in preventing filtration, we added EDTA or EGTA to a final concentration of 20 mM before filtering. The results of the experiment are somewhat qualitative given the nature of the experiment. The control sample with *C. flavescens* only quickly clogged the filter (∼1 min) and allowed only ∼1 mL of a total of 6 mL of the water to be removed. Allowing the material to stay under vacuum overnight (∼16 h) yielded no additional water removal. Whereas both the EGTA- and EDTA-amended solutions stopped noticeable filtering in (∼1 min) also, an extended period of time (8−16 h) on the vacuum resulted in complete water removal. These results suggest calcium or other divalent ions play a role in the phenomena, but are not the sole determining variable.

This is the first study to characterize the surface of wheat spikelets under different environmental growth regimens and to do so through the important period of anthesis. Overall, these results suggest the surface properties and surface ultrastructure of the glume and lemma are experiencing only minor changes during anthesis for these cultivars, because only some are statistically significant. However, small changes have the potential to alter the ability of microorganisms to adhere to these surfaces.[35] It has previously been shown that these properties can alter the binding of pathogen conidia to wheat surface.[9,36] In addition, these properties also play a role in preharvest sprouting, by regulating ear wetting through water repellency.[7] These data can also be used to optimize pest control formulations for improved delivery and retention to the wheat head. This is accomplished by incorporating these parameters into spray droplet adhesion models, such as the model of Forster, which incorporates spray droplet size, velocity, surface angle, dynamic surface tension, and leaf contact angle measurements.[12] These models allow the user to predict the size of spray droplets needed to ensure adhesion to the target.

Supporting Information

ABSTRACT: Pharmaceuticals have been detected in the soil environment where there is the potential for uptake into crops. This study explored the fate and uptake of pharmaceuticals (carbamazepine, diclofenac, fluoxetine, propranolol, sulfamethazine) and a personal care product (triclosan) in soil–plant systems using radish (*Raphanus sativus*) and ryegrass (*Lolium perenne*). Five of the six chemicals were detected in plant tissue. Carbamazepine was taken up to the greatest extent in both the radish (52 μg/g) and ryegrass (33 μg/g), whereas sulfamethazine uptake was below the limit of quantitation (LOQ) (<0.01 μg/g). In the soil, concentrations of diclofenac and sulfamethazine dropped below the LOQ after 7 days. However, all pharmaceuticals were still detectable in the pore water at the end of the experiment. The results demonstrate the ability of plant species to accumulate pharmaceuticals from soils with uptake apparently specific to both plant species and chemical. Results can be partly explained by the hydrophobicity and extent of ionization of each chemical in the soil.

KEYWORDS: *plant uptake, pharmaceuticals, fate, soil, bioavailability, carbamazepine, diclofenac, fluoxetine, propranolol, sulfamethazine, triclosan*

INTRODUCTION

Worldwide, pharmaceutical use has been on the increase for the past century[1−3] and will continue to increase into the future with the development of new medicines to cure recently discovered diseases as well as previously untreatable conditions. Following use by the patient, active pharmaceutical ingredients (APIs) and their metabolites are excreted to the sewerage system. They are then typically transported to a wastewater treatment works, where, depending on their molecular structure and physicochemical properties, they can be either degraded by biological treatment processes or released to the environment in effluents or sorb to sludge.[4−8] The soil environment will therefore be exposed to APIs and their metabolites when sludge from treatment processes is applied to land as an agricultural fertilizer or when soil is irrigated with reclaimed wastewater effluent.[9−13] While only a few studies have explored the occurrence of APIs in the soil environment, available data indicate that a range of API classes, including nonsteroidal anti-inflammatory drugs, antidepressants, anticonvulsants, and antibacterial agents do occur in soils in concentrations up to the low mg/kg level.[9−15]

Because of detection of pharmaceuticals in soils, concerns have been raised over the potential for these substances to be taken up into human food items and to pose a risk to human health.[16,17] A number of studies have demonstrated the uptake of pharmaceuticals used in human and veterinary medicine into plants.[16−24] Studies have explored the uptake and translocation of a variety of APIs with a particular focus on the antidepressant drug fluoxetine and antibacterial chemicals including sulfamethazine, sulfamethoxazole, and trimethoprim into numerous plant species including root and shoot crops such as soybean, lettuce, and carrot.

Many of the previous plant uptake studies have been done at unrealistic exposure concentrations. Studies typically have looked at uptake only with no attempt being made to understand the temporal fate of the pharmaceutical in soil matrices. Without understanding the dynamics of the distribution and fate of the pharmaceuticals in the soil, it is difficult to establish relationships between the properties of pharmaceuticals and uptake. This study was therefore initiated to explore the fate, distribution, and uptake of a range of pharmaceuticals in soil–plant systems. This work consisted of a fate study (with no plants) and an uptake study performed on two crop species with five pharmaceuticals and an antimicrobial personal care product. The compounds were selected to cover a diverse range of physicochemical properties (Table 1).

MATERIALS AND METHODS

Analytical grade carbamazepine (>98% purity), diclofenac (>98% purity), fluoxetine (>98% purity), propranolol (>99% purity), sulfamethazine (>99% purity), and triclosan (>97% purity) were obtained from Sigma-Aldrich (Sydney, Australia). Deuterated forms of selected study compounds (carbamazepine-d_{10} (99.8% purity), diclofenac-d_4 (98.5% purity), fluoxetine-d_5 (99.4% purity), propranolol-d_7 (99.6% purity), and triclosan-d_3 (98.6% purity) were purchased

triclosan	antimicrobial	$C_{12}H_7Cl_3O_2$	289.54	8.1	4.8	4.80

[a]Un-ionized form of the drugs; [b]at pH 6.25.

from TLC Pharmachem (Vaughan, Canada) for use as internal standards in the chemical analyses.

Tepko soil (obtained from near Tepko township in South Australia) was used for both the plant uptake and fate studies (pH 6.25, EC 0.09 dS/cm, OC 1%, CEC 5.2 cmol(+)/kg, 0.6% moisture, clay 8%, 3% silt and 89% sand). The soil was not cropped and had not previously received biosolid or wastewater applications. Test soil was obtained from the top 10 cm depth and prior to testing was air-dried and then sieved to 2 mm to ensure homogeneity.

Ryegrass seeds (*Lolium perenne*, Guard variety) were obtained from Seed Services (SARDI, South Australian Research and Development Institute) and radish seeds (*Raphanus sativus*, Cherry belle variety) were from Mr Fothergills (Sydney, Australia).

Fate Study. For each study chemical, duplicate pots of soil (200 ± 5 g) were spiked with aliquots of 1 g/L (in acetone) solution to give a nominal concentration of test compound of 10 mg/kg. This concentration, which is higher than concentrations expected in the environment, was chosen to enable detection of the study compounds in the soil pore water. Following spiking, soil was mixed by hand to ensure a homogeneous distribution of the test chemicals; pots were then left for 2 h in a fume cupboard to evaporate off any solvent. Blank control pots were also prepared. Plants were omitted from fate study pots because previous research has demonstrated that the presence of plants results in no significant differences in compound dissipation in soils either by uptake or enhanced degradation and therefore would not significantly influence our fate study.[17] Pots were then kept in controlled conditions (14 h light (23 °C) 10 h dark (15 °C)) until time of sampling. Moisture content adjustments were made on a daily basis, by addition of deionized water (DI), to ensure levels remained at 60% of the soil maximum water holding capacity (MWHC) (for methods see Supporting Information, section 1.1). Sampling points were 0 h, 1, 3, 7, 14, 40 days. At each sampling point, duplicate pots were removed, and the soil pore water was extracted. Extractions were done by taking 2 × 25 g portions of soil from each pot and placing these on top of a glass wool insert in 2 × 25 mL disposable plastic syringes. Syringes were placed in plastic centrifuge tubes and centrifuged at 3500 rpm for 45 min. The resulting pore water collected in the two centrifuge tubes for each single sample was combined into one sample and centrifuged again at 15 000 rpm for an additional 30 min and then transferred to vials ready for analysis. Soil samples (sampled directly from the fate pots) were also taken and stored at −20 °C for later analysis.

Uptake of Pharmaceuticals into Plants. Plastic pots containing 500 ± 5 g and 200 ± 5 g were prepared for use in uptake studies with radish and ryegrass respectively. Pots were prepared in triplicate for each pharmaceutical and plant type and spiked as per the fate study to give a final soil concentration of 1 mg/kg. This concentration, which is at the high end of reported concentrations for pharmaceuticals in soil and at the lower end of concentrations used in previous uptake studies, was chosen to maximize the likelihood of detection in plant tissue while maintaining a degree of realism. Solvent and blank controls were also prepared in triplicate. Soils were then left for 48 h to equilibrate before a total of 6 and 16 seeds were initially added to each pot for radish and ryegrass respectively, which were then lightly covered in test soil.

Plants were left to grow for 6 weeks in a growth chamber under the same conditions as the pots in the fate study. Pots were arranged in a randomized order (specific positions were determined based on a random number generator in Microsoft Excel). A similar watering regime to that used in the fate study was adopted to maintain moisture levels at 60% of the MWHC. After 50% germination (when the seedling was visible through the soil), plants were fed Ruakura nutrient solution, where 5 mL was applied per 250 g soil twice weekly (for three weeks) instead of the DI water. After 3 weeks, addition of nutrient solution continued with one 5 mL application of nutrient solution per 250 g of soil per week (for nutrient solution preparation, see Supporting Information, section 1.2). When 80−90% of plants had germinated (approximately day 11), the radish plants were thinned to leave behind three seedlings. This was to ensure maximum for growth potential in order to gather enough biomass for the chemical analysis.

At harvest, loose soil was removed from around the radish plant to allow for the intact removal of the whole radish. The radish plant was thoroughly rinsed in deionized water to remove any soil residues, patted dry with paper towel, weighed, and divided up into root and above ground biomass, and these were then reweighed separately. For the ryegrass, after the maximum height of the plants from each treatment was measured, the above ground plant material was cut away, rinsed in DI water, patted dry, and then weighed. All plant samples were cut into smaller pieces and then freeze-dried and stored at −20 °C until extraction for residue analysis. Soil was also taken from the plant pots, at the end of the uptake study, for analysis.

Pharmaceutical Analysis. *Extraction from Soil and Plant Material.* Pharmaceutical compounds were extracted from soils and plants using validated methods chosen for their high percentage recoveries (Supporting Information, section 1.3). Prior to plant and soil extractions, 1 mg/g of deuterated stable isotope standard was added to their respective samples (100 μg/L stock solution in acetone). Since stable isotopes were unavailable for sulfamethazine, control plants and control soil samples were spiked with a known amount of sulfamethazine to determine recoveries. For the soil extraction (i.e., soil taken directly from the pots), 5 mL of methanol was added to 1 g of soil (wet weight) and 1 g of sand. After addition of the solvent, the test tubes were vortexed for 1 min and then ultrasonicated for 15 min. Lastly, the tubes were centrifuged for 30 min at 1500 rpm, and the supernatant was removed. The extraction process was repeated with a further addition of 5 mL of methanol and then 5 mL of acetone. The supernatants from the three extractions were combined and then evaporated to dryness before being reconstituted in 1 mL of methanol, sonicated for 5 min and then transferred into LC-MS/MS vials for analysis.

For the plant extractions, sand (1 g) was added to 1 ± 0.1 g of plant material for each of the samples and 5 mL of extraction solvent (70:30 acetonitrile/Milli-Q water solution) was then added to the test tube. After addition of the solvent, the test tubes were vortexed for 1 min and then ultrasonicated for 15 min. The samples were then centrifuged for 30 min at 1500 rpm, and the supernatant was removed and the process was repeated for two further extractions. The combined extracts (15 mL) were diluted with Milli-Q to make a maximum solvent concentration of 10%, and the extract was then applied to an Oasis HLB (Waters Corporation) 6 mL 200 mg solid phase extraction (SPE) cartridge that had been preconditioned with Milli-Q water and methanol. The cartridges were left to dry under a vacuum, washed with 10% methanol in Milli-Q water, and eluted with 2× methanol (3 mL) and 1× dichloromethane (3 mL). The eluates were combined and evaporated to dryness under a nitrogen stream and reconstituted in 1

mL of methanol. Lastly, the test tubes were sonicated for 5 min ready for the extract to be transferred into LC-MS/MS vials.

LC-MS/MS Analysis. Cleaned-up extracts were analyzed for the pharmaceuticals by LC-MS/MS using a ThermoFinnigan TSQ Quantum Discovery Max (Thermo Electron Corporation). HPLC separation was performed with a Kinetex C18 100 × 2.1 mm i.d. (2.6 μm particle size) column (Phenomenex, USA) with a mobile phase flow rate of 0.3 mL/min. The mobile phase composition consisted of two eluents which were (A) formic acid (0.1%) and (B) acetonitrile using a binary gradient program over 12 min. The relative flow of 0.1% formic acid was 95% for 2 min, 20% after 3 min, 2% at 4 min, and held for 3 min until 7 min before returning to 95% by 9.5 min. MS/MS analysis was undertaken using atmospheric pressure electrospray ionization (ESI) in both positive and negative ionization modes. Spray voltage was 5000 V, and source collision induced dissociation was −12 V in positive ESI and −4000 and 10 V for negative ESI, with the ESI capillary line maintained at 350 °C and collision gas (Ar) pressure set at 1.5 mTorr. More details of the analytical method pertaining to each compound are summarized in Supporting Information, section 1.4. Qualitative and quantitative analysis of compounds was based on retention time, multiple reaction monitoring (MRM) of two product ions, and the ratios between the product ions.

Isotopes were used to account for recovery (loss of analytes during sample preparation and matrix effects); however, isotopes were unavailable for sulfamethazine. Sulfamethazine spiked matrix samples were extracted and run throughout the analysis and compared with sulfamethazine standards in a clean matrix to determine the extent of ion suppression or enhancement. Lower limits of quantitation (LOQs) were derived using guidelines proposed by the USEPA.[25]

Data Analysis. *Soil Degradation.* Concentrations of pharmaceuticals in soil and pore water were plotted against time of sampling. Where there was a significant difference in concentration to that measured at 0 days (for methods see Statistical Analysis section), three kinetic models were used to fit the data: a simple first-order degradation kinetic (SFO; eq 1) model, a first-order multicompartment model (FOMC; eq 2),[26] and a biexponential first-order model (BFO; eq 3).[27] Model parameters were optimized according to recommendations by FOCUS using the least-squares method with Microsoft Excel Add-Inn Solver.[27]

$$C_t = C_0 e^{-kt} \quad (1)$$

$$C_t = C_0(1 + \beta t)^{-\alpha} \quad (2)$$

$$C_t = C_{t1} + C_{t2} = C_{01} e^{(-k1t)} + C_{02} e^{(-k2t)} \quad (3)$$

where C_t is the concentration of pharmaceutical remaining in soil (μg/g) after t (days), C_0 is the initial concentration of pharmaceutical (μg/g), k is the rate of degradation (day^{-1}), β is the location parameter, α is a shape parameter determined by coefficient of variation k values. For eq 3, $C_{t1} + C_{t2}$ is the total amount of pharmaceutical applied at time t = 0 (in two compartments), C_{01} and C_{02} is the amount of chemical applied to compartment 1 and 2 respectively, and k_1 and k_2 are independent decay rate constants for compartments 1 and 2 respectively. Models used specific to each pharmaceutical, parameter, and measurement to assess the goodness of fit for the optimized parameters are outlined in Supporting Information, section 1.5. For SFO and FOMC model fits, the time it took for a 50 or 90% decline in the concentration of the pharmaceutical (DT_{50}, DT_{90}) could then be calculated from the model fits (Supporting Information, section 1.5.1). For BFO models, no analytical solution exists to calculate degradation end points.

Uptake Factors. Measured concentrations for each of the pharmaceuticals taken up by the radish and ryegrass were used to calculate soil and pore water-based uptake factors (UFs). UFs were derived using concentrations in the soil, pore water, and plant material (eqs 4−6).

$$UF_{soil} = \frac{C_p}{C_s} \quad (4)$$

$$UF_{pore\ water} = \frac{UF_{soil}}{K_d} \quad (5)$$

$$K_d = \frac{C_s}{C_{pw}} \quad (6)$$

where UF_{soil} is the soil-based UF, $UF_{pore\ water}$ is the soil pore water-based UF, C_p is the concentration in plant material, C_s is the concentration associated with the soil particles (i.e., total soil concentration corrected for the concentration in the pore water), C_{pw} is the concentration in the pore water, and K_d is the average soil sorption coefficient for each pharmaceutical calculated across seven sampling points in the fate study.

Statistical Analysis. Statistical analysis of the data was performed using Sigma Plot (v.11.0). A one-way ANOVA (significance level 0.05) was employed to assess differences in plant biomass (dry weight) between plants grown under treated soil and controls. Additionally, a one-way ANOVA (p = 0.05) was employed to assess any differences in concentration of the pharmaceuticals in the soil and pore water over 40 day exposures, with additional comparisons between sampling points assessed by Holm−Sidak pairwise comparison. To determine which pharmaceuticals showed a significant difference in concentration between radish leaf and ryegrass, t test's were performed. Prior to all tests, the data were tested for normality and equal variance by performing a Shapiro−Wilk and Levene−Mediane test, respectively.

RESULTS AND DISCUSSION

Fate Study. Over 40 days, average K_d values ranged from 0.99 to 121.88 L/kg and increased in the order of sulfamethazine < carbamazepine < fluoxetine < diclofenac < propranolol < triclosan (Table 2). Some of the study compounds persisted in the soil throughout the 40 day uptake period, while others were readily dissipated (Figure 2; Table 3). There was no significant difference between measured concentrations at 0 and 40 days for carbamazepine (p = 0.026), fluoxetine (p = 0.162), and propranolol (p = 0.757). Triclosan dissipated from the soil after 14 days (p = 0.004). Concentrations of diclofenac (p = 0.032) and sulfamethazine (p = 0.013) significantly decreased after 1 day and were undetectable after 3 days. The dissipation rates of these three compounds was fast (0.06−1.4 day^{-1}; Table 3); compound degradation followed single first-order kinetics, and corresponding DT_{50} values were 0.5, 0.99, and 11.55 days for diclofenac, sulfamethazine, and triclosan respectively.

The persistent nature of carbamazepine, fluoxetine, and propranolol is consistent with previous research findings.[9,28−30] The observed degradation of triclosan is also consistent with previous research which has suggested a half-life of 18 days.[31] Results presented in this study show that in less than 40 days only 10% of the applied triclosan remained in the soil (Supporting Information, section 1.5). This is probably due to the transformation of triclosan to methyl triclosan.[13,32] Previous fate studies have also shown that diclofenac is not persistent and readily biodegradable from soils as a result of chemical mineralization.[15,33] The half-life observed in this study (0.5 days) is therefore comparable to previous findings of <5 days[33] and considerably faster than observations by Xu et al.,[34] who reported DT_{50}'s ranging from 3.1 days (loamy sand) to 20.4 days (silty loam) (Table 3). Dissipation of sulfamethazine has been observed in previous research, although the average half-life was longer at 18.6 days than reported in this study (Table 3).[35]

Even though diclofenac and sulfamethazine were not detectable in whole soil extracts after 3 days, detectable concentrations of these chemicals in the pore water were seen

[a]More detailed table including model fit provided in Supporting Information, section 1.5. [b]No significant difference between 0 and 40 day measured concentrations; therefore, data were not modeled to determine degradation rates.

for the full duration of the fate study (Figure 2). By 40 days, concentrations of all test chemicals remaining in the pore water decreased in the order carbamazepine > fluoxetine > sulfamethazine > propranolol > triclosan > diclofenac (Figure 2). With the exception of sulfamethazine on 0 days, carbamazepine concentrations were consistently the highest in the pore water (1321–3129 μg/L) over 40 days (Figure 2). Sulfamethazine concentrations were initially high (2932–6502 μg/L); however after 1 day, concentrations dropped to 832–2683 μg/L, after which they decreased at a slower rate. Unlike soil dissipation, pore water dissipation did not follow first-order kinetics. Models instead included first-order multicompartment model (FOMC; eq 2)[26] and a biexponential first-order model (BFO; eq 3) (Table 3). Pore water concentrations decreased significantly in the diclofenac ($p = 0.016$) and sulfamethazine studies ($p = < 0.001$) resulting in DT_{50}'s < 20 days (Table 3) in comparison to DT_{50}'s for the remaining compounds of >40 days. While triclosan dissipated rapidly from the soil, pore water concentrations were not significantly different at any of the sampling points over 40 days ($p = 0.266$).

Plant Uptake. Plants contain ion channels and enzymes which could also be potentially targeted by pharmaceuticals and may initiate a response such as inhibition in the transport of essential elements required for plant growth for example.[36] Previous research has highlighted the potential for pharmaceuticals to induce toxic effects on plants.[22] Dose response relationships with plants grown under triclosan treatment have been noted starting at 0.44 mg/L in hydroponic studies[24] and low observed effect concentrations (LOECs) seen at 0.74 mg/kg after plant growth in quartz sand.[37] In this study, however, no observed effect on plant growth was noted for any of the treatments in comparison to the controls ($p = 0.08–0.966$) for both radish and ryegrass, probably due to the more realistic exposure concentrations that were used. This is in support of previous research where concentrations of carbamazepine in root tissue ranging between 202–426 μg/kg yielded no observed effect on ryegrass aerial plant growth (Supporting Information, section 1.6).[38]

Previous research has demonstrated metabolism of carbamazepine within the bean and leaf.[17,39] Therefore, in our study it is possible there may have been some transformation of parent compounds; however potential metabolite products were not quantified, and the results presented focus on the parent compounds. Five of the six test chemicals were taken up in detectable quantities into radish and ryegrass (Table 2; Figure 1). The degree of uptake varied across pharmaceuticals and plant species. With the exception of propranolol, greater uptake into radish was seen after combining the concentrations in the bulb and leafy parts compared to ryegrass. For both radish and ryegrass, carbamazepine was taken up to the greatest extent with measured concentrations of up to 52 μg/g dwt in radish leaf (Figure 1). While sulfamethazine was taken up by both plants, this was consistently below the LOQ (Supporting Information, section 1.4.1). Therefore, both radish leaf and radish bulb accumulated chemicals in the order of carbamazepine > triclosan > diclofenac > propranolol > fluoxetine, whereas chemicals accumulated in the ryegrass in the order of carbamazepine > propranolol > triclosan > fluoxetine > diclofenac (Figure 1).

In the propranolol exposure, there was very high uptake into the ryegrass, but this was not mirrored in the radish leaf where concentrations were some 16 times lower ($t_{(4)} = 6.38$, $p = 0.003$) (Figure 1). For the remaining pharmaceuticals, concentrations in the radish leaf and ryegrass were not significantly different (carbamazepine $t_{(4)} = 2.28$, $p = 0.09$;

dx.doi.org/10.1021/jf404282y | J. Agric. Food Chem. 2014, 62, 816–825

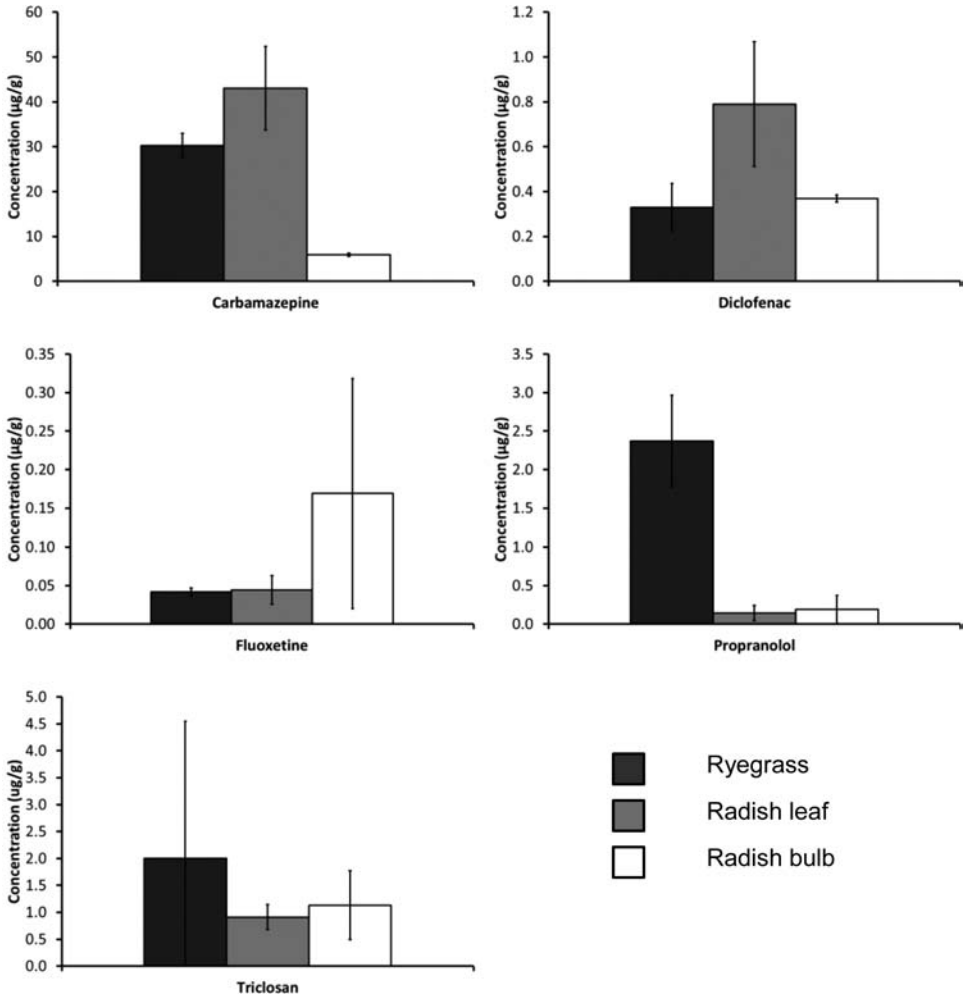

Figure 1. Uptake of carbamazepine, diclofenac, fluoxetine, propranolol, and triclosan into ryegrass, radish leaf, and radish bulb after plants were grown from seed in pharmaceutically spiked soil for 40 days. Average concentrations (dry weight) provided with error bars representing the standard error. Sulfamethazine uptake was below LOQ.

diclofenac $t_{(4)} = 2.69$, $p = 0.06$; fluoxetine $t_{(4)} = 0.24$, $p = 0.82$; triclosan $t_{(4)} = 0.34$, $p = 0.75$).

Greater fluoxetine uptake into the roots was observed in this study (170 ng/g dwt) in comparison to research by Wu et al.[17] where fluoxetine root concentrations were <22.2 ± 5.3 ng/g after exposure via biosolids application. The amended soil concentration in the Wu et al.[17] study was lower (0.07 mg/kg) than the current study, whereas in an earlier study Redshaw and colleagues saw fluoxetine uptake by *Brassicaceae* tissue cultures from a hydroponic setup comparable to the results from our study at 0.26−0.49 µg/g.[23]

Uptake Factors. The greatest UF_{soil} values for the ryegrass, radish leaf, and radish bulb were obtained in the carbamazepine treatments, with values of 65.3, 60.6, and 8.28, respectively (Table 2). In comparison, relatively small UF_{soil} values were found for fluoxetine (0.08−0.36) (Figure 1). Calculated $UF_{pore\ water}$ range between 0.01−8.31, 0.0008−7.71, and 0.001−1.05 for the ryegrass, radish leaf, and radish bulb respectively (Table 2). Similar to UF_{soil} carbamazepine exposure resulted in the highest $UF_{pore\ water}$ in the ryegrass, radish leaf, and radish bulb. Triclosan had the lowest $UF_{pore\ water}$ in the radish leaf (0.0008) and bulb (0.001), whereas fluoxetine had the lowest $UF_{pore\ water}$ in ryegrass (0.01).

In comparison to results generated from field experiments (via biosolid application) for carbamazepine uptake into roots and shoots, the results presented in this study are just over double those observed in the field study.[21] Specifically for triclosan, work by Karnjanapiboonwong et al.[40] found greater UFs between the soil and the root in the pinto bean (*Phaseolus vulgaris*), which ranged between 9 and 12, in comparison to UF_{soil} (0.12) and $UF_{pore\ water}$ (0.001) values generated in this study for the radish root. However, in the ryegrass exposure the triclosan UF_{soil} is considerably larger in the present study at 37.6, demonstrating that plant uptake is dependent on both species and compound; such factors are discussed in more detail below.

Potential Factors Influencing the Uptake of Pharmaceuticals. Plant uptake is thought to be heavily dependent on the physicochemical characteristics of the chemical, including Henry's Law constant, water solubility, and octanol−water partition coefficient.[41−44] Dissociation constants are important because they can describe whether a chemical is neutral or ionizable at environmentally relevant pH values. A clear distinction has been made between the plant uptake of neutral chemicals and chemicals that are ionized (electrically charged), and separate models exist to predict uptake of chemicals in both these forms.[45] However, it is important to note the total

dx.doi.org/10.1021/jf404282y | J. Agric. Food Chem. 2014, 62, 816−825

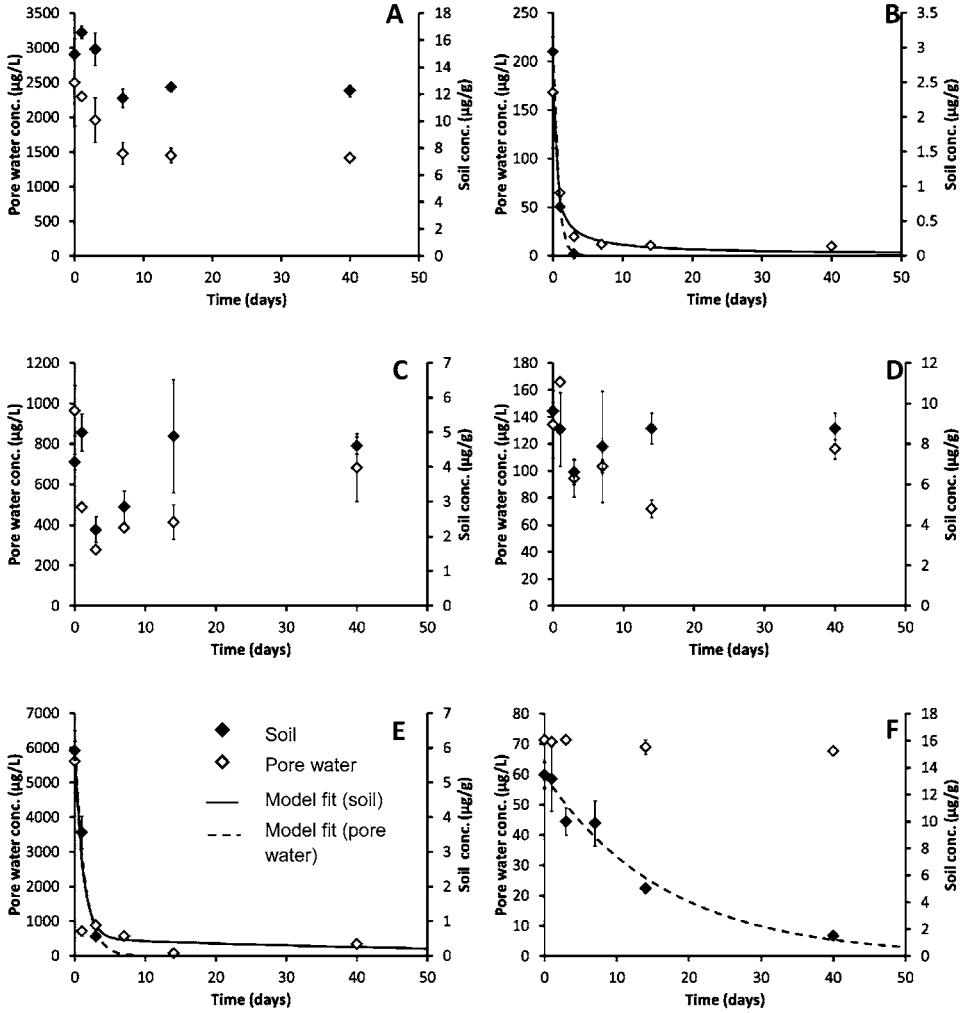

Figure 2. Average measured soil (closed) and pore water (open) concentrations during fate study (40 days) for test pharmaceuticals: carbamazepine (A), diclofenac (B), fluoxetine (C), propranolol (D), sulfamethazine (E), and triclosan (F). Best model fit provided by dashed line for soil and a solid line for pore water where necessary and error bars represent standard error of mean.

concentration in a plant cell comprises neutral, ionic, and complexed forms of a compound.[45] In this study, carbamazepine was the only neutral chemical, whereas the remaining pharmaceuticals were ionizable (Table 1).

For neutral chemicals, hydrophobicity (usually expressed as log K_{ow}) has been postulated to be the most important property involved in the uptake of chemicals into a plant from the soil medium[46] as the degree of uptake appears to be proportional to the octanol–water partition coefficient.[47,48] Briggs et al.[47] proposed that plant uptake of neutral chemicals can be represented by a Gaussian distribution (bell-shaped curve) where maximum translocation of chemicals can be seen at a log K_{ow} ~1.78 in comparison to particularly hydrophobic (high log K_{ow}) and hydrophilic (low log K_{ow}) chemicals which are taken up to a lesser extent.

Carbamazepine is hydrophilic in nature preferring to reside in the aqueous phase rather than attached to the soil particles as demonstrated by the low K_d values discussed above (Table 2). The high concentrations in pore water for the carbamazepine exposure may have played a crucial role in the large amount of uptake observed. However, the consistently high carbamazepine uptake into leafy parts of the plants (<52 μg/g) can more likely be attributable to the log K_{ow} of this neural compound which is similar to the K_{ow} values where maximum uptake of neutral organics is observed.[47] Greater carbamazepine concentrations were noted in the leaf material in comparison to the roots (Figure 1; Table 2) which is in agreement with previous research findings.[17,19,21,38] It appears that the uptake of carbamazepine is passive and not restricted by root membranes. The relatively low hydrophobicity of carbamazepine enables it to be transported by mass flow from the roots and concentrate in the mature and older leaves.[19]

Even though triclosan is slightly ionized at the test soil pH of 6.19 (1.2%), most of the compound will be in the nonionized form. The un-ionized molecule has a log K_{ow} of 4.80, so the low observed uptake for triclosan can be also explained by the fact that it falls on the upper tail of the Gaussian distribution.[47] Small radish $UF_{pore\ water}$ (0.0008–0.001) and UF_{soil} (0.10–0.12) values for triclosan uptake demonstrate that particularly hydrophobic chemicals are not taken up to a great extent in the plant material.

Similar to triclosan, only a small proportion of sulfamethazine (5.8%) would be in the ionized form. On the basis of the Gaussian distribution,[47] the neutral form of sulfamethazine (log K_{ow} of 0.9) would not be expected to enter the root system; it is therefore not surprising that concentrations of sulfamethazine were below the LOQ and that UFs could not be calculated. The rapid dissipation from the soil in the first of the study 3 days

dx.doi.org/10.1021/jf404282y | J. Agric. Food Chem. 2014, 62, 816–825

may have also contributed to the lack of detection of sulfamethazine in plant tissue (Figure 2).

Diclofenac, fluoxetine, and propranolol are expected to be extensively ionized in the test soil (>99%). Previous research demonstrates that plant uptake of the dissociated species of an ionizable compound is lower compared to the un-ionized species.[49,50] As demonstrated in Figure 1, there was up to 600 times less uptake of diclofenac, fluoxetine, and propranolol in the ryegrass in comparison to the neutral pharmaceutical carbamazepine. Specifically for diclofenac, the large ionization combined with the results from the fate study which show extensive dissipation from both the soil and pore water and low measured concentrations can probably explain the minimal uptake of diclofenac into the radish and ryegrass.

Previous research findings demonstrate that some pharmaceuticals have a tendency to accumulate in the roots with the roots acting as a sink for hydrophobic neutral compounds.[17,24] In general, organic chemicals with log K_{ow} > 4 are expected to have high potential for root retention and low translocation capacity.[44] Even though diclofenac and fluoxetine have log K_{ow} > 4 (Table 1), this is in their un-ionized form. As both diclofenac and fluoxetine are extensively ionized at test soil pH log K_{ow} is not applicable and thus cannot explain plant uptake. However log D_{ow} (pH corrected log K_{ow}) could be a better descriptor for ionized chemicals as our results show a general increase in log D_{ow} corresponds to an increase in $UF_{pore\ water}$ and UF_{soil}. For example, fluoxetine and propranolol have low log D_{ow} values (Table 1) and smaller $UF_{pore\ water}$ (<0.14) than diclofenac ($UF_{porewater}$ < 0.93) at log D_{ow} 2.3.

Similar to other studies, our results found differences in uptake between the two crop species.[16,21] Differences may be explained by factors such as degree of root growth, transpiration rates, and the size and shape of the leaf material. Differences in plant lipid contents may also be important as this can affect the sorption of hydrophobic chemicals.[51,52] The reported lipid content of perennial ryegrass ranges between 2−4%,[53] whereas radish bulbs only contain trace amounts of lipid which may explain the lower observed uptake of carbamazepine, diclofenac, and propranolol in the radish (Figure 1). However, similarly to results in the Wu et al.[21] study, differences in plant uptake behavior could not be solely attributable to differences in lipid content between plants.

On the basis of the results presented, the factors that affect the uptake of pharmaceuticals into plants include physicochemical properties of the pharmaceuticals, species type including lipid content, and distribution between above and below ground plant. Previous work has also highlighted that plant uptake can vary between a mixture and single compound exposure,[54] and additional research has also demonstrated that soil properties and the application of biosolids or wastewater irrigation can also affect plant uptake.[17,21,55−57] Interestingly, the persistence of pharmaceuticals in soil can also be influenced by the presence of biosolids, which can ultimately affect plant uptake as well.[29] Therefore to conclude, the uptake of chemicals into plants is a complex process governed by a combination of soil, plant, and chemical factors. However on the whole, the uptake behavior observed in this study makes sense based on the knowledge from previous research.

Human Exposure. Uptake into plants, especially edible crops, may represent an important exposure pathway of these chemicals into the food chain and thus present a risk to humans and livestock which feed on them.[16,58−60] An acceptable daily intake (ADI) value can be used to calculate the amount of a substance, for example, pharmaceuticals, that can be consumed by a human without resulting in appreciable risk to health. For a full explanation of calculated methods to determine the risk to humans from consuming contaminated crops from results in the present study see Supporting Information, section 1.7.

Results show that if all crops consumed were grown in soil containing the selected pharmaceuticals, then humans would not consume levels greater than the ADI for any of the pharmaceuticals in this study (Table 4). It should also be noted that all crops eaten must be grown in the contaminated soil as our analysis assumed radish leaf and bulb to be representative of all above and below ground crops consumed, which is not currently the case. A safety factor of 100 was also applied to the minimum therapeutic dose to calculate the ADI, and for a large proportion of the population this is not needed, which would make the actual ADI higher than the current threshold.

Table 4. Results from a Comparison of Acceptable Daily Intake (ADI) Values for Study Chemicals and Theoretical Crop Concentration (Based on Measured Soil Concentrations and UF_{soil} Calculated in This Study) Shown As a Percentage of ADI[a]

		ryegrass	radish
	soil (mg/kg)	% of ADI in 359.5 g crop	% of ADI in 159 g crop
carbamazepine	0.0065[b]	3.81	0.21
diclofenac	0.00054[c]	0.18	0.06
fluoxetine	0.0067[c]	0.09	0.19
propranolol	0.0004[d]	0.20	0.01
triclosan	0.019[b]	83.80	0.12

[a]With exception of sulfamethazine as plant concentrations were below LOQ. Ryegrass was used as a representative above ground crop species and radish as a representative below ground crop species. [b]Measured soil concentration reference = Duran-Alverez et al., 2009. [c]Measured soil concentration reference = Dalkmann et al., 2012. [d]Measured soil concentration reference = Vazquez-Roig et al., 2012.[10,14,15]

To date, the health risks from pharmaceuticals in drinking water have been reviewed, and several papers have also computed levels in crops fit for human consumption.[16,61,62] For fluoxetine, a comparison of measured concentrations in drinking water and predicted no effect concentrations in children yielded a ratio of 2.8×10^{-4}, which would infer the risk to humans drinking water contaminated with fluoxetine would be minimal. Indeed, for all APIs evaluated, approximate margins of safety for potential exposures ranged from 30 to 38000.[61] Presently, the risk to humans in terms of contaminated crops is therefore similar to drinking water exposures, in that it is highly unlikely.

However, an important note for the future is that with the growing demand for alternative irrigation resources in water stressed regions and projected increases in the application of sewage sludge on land, pharmaceutical loadings in soil will inevitably increase. The threat posed by pharmaceuticals taken up into crops may therefore be of more concern in the future than based on current exposure levels.

In conclusion, radish and ryegrass can take up a variety of pharmaceuticals and personal care products from spiked soil. On the basis of current exposure levels, however, this uptake does not pose a risk to humans consuming crop grown in contaminated soil. Using a combination of fate study and plant uptake data, it is clear that relationships between plant uptake

and the available fraction of the chemical are key. While a chemical may have a log K_{ow} that fits within the Gaussian distribution correlating with a high propensity for uptake, this clearly is not the only property influencing uptake into plants. The ionizable state of the chemical together with its potential for degradation may result in diminishing concentrations in the soil matrix. The fraction available for uptake may therefore be very small, and, correspondingly, the measured concentrations in the plant material will also be minimal. Interestingly, fate studies data show that while a chemical may dissipate from the soil it can still remain in the pore water. This may hold wider implications for risk assessments and screening techniques as chemicals present in the pore water may still be bioavailable for uptake into an organism.

Our results demonstrate that in some circumstances uptake and distribution of pharmaceuticals and personal care products in a plant can be related to hydrophobicity (K_{ow}) and generally follows a Gaussian distribution, although this is not always the case. The results presented here would suggest that there are different drivers responsible for the uptake between different plant species. It is instructive to note that pharmaceuticals are predominantly ionizable organic chemicals, and in contrast to neutral organics, this is a characteristic that is likely to affect their partitioning behavior in terms of bioavailability, plant uptake, and molecular interaction with soil matrices of variable pH. It therefore may be important to question previous assumptions on plant uptake, and specific models may be required to accurately predict plant uptake which account for species differences, distribution of chemicals in the plant, chemical properties, and the fate of the pharmaceutical in different soil matrices.

Supporting Information

ABSTRACT: Minor polar compounds of 88 extra virgin olive oils were analyzed by HPLC-DAD-MS (high-performance liquid chromatography—diode array detector—mass spectrometry) and by the Folin-Ciocalteu (FC) spectrophotometric method, to validate and evaluate, for olive oils, the linear association between FC and HPLC data. The Pearson correlation coefficients were calculated between HPLC and FC results. The highest, positive R were related with deacetoxyoleuropein aglycone (R = 0.93) and oleuropein aglycone (R = 0.93) as single compounds and with the sum of orthodiphenols (R = 0.94) and the sum of all compounds (R = 0.95), showing that both estimations of total phenols content are reliably correlated, regardless for the absolute contents and are independent of the relative composition of the phenolic fraction. On the other hand the HPLC quantifications of apigenin and lignans showed no significant correlation with FC. These results, supported also by principal component analysis, may suggest caution about the interpretation of FC results to compare olive oils with very different phenolic profiles.

KEYWORDS: *polyphenols quantification in olive oils, biophenolic minor polar compounds, analytical methods, secoiridoids, lignans*

INTRODUCTION

The definition of quality of extra virgin olive oil (EVOO) is currently based on commodity specifications and on the assessment of its organoleptic characteristics and health properties. These properties are mainly due to the presence of antioxidants, among them minor polar compounds (MPCs). Both simple and complex phenolic antioxidants are detectable in the minor polar fraction of EVOO: 5-hydroxytyrosol, tyrosol derivatives,[1−3] secoiridoids, and lignans.[4,5] Single biophenols, such as hydroxytyrosol and oleuropein aglycone, are endowed with potent antioxidant and cardioprotective activity.[6−9] Either in vitro[10−12] or in animal models,[13] olive oil phenolic compounds inhibit low-density lipoprotein (LDL) oxidation in a concentration-dependent way, and an extract of EVOO containing phenolic compounds can inhibit NF-kB (nuclear factor κ-light-chain-enhancer of activated B cells) activation, reducing the risk of coronary heart diseases.[14]

The phenolic compound concentration in EVOO depends on several factors such as cultivar[15−17] and agronomic and technological aspects of production.[18−20] Phenolic compounds are correlated to the olive oil stability.[21,22] Molecules containing an orthodiphenolic group (e.g., oleuropein aglycone and derivatives) are thought to be the main responsible for the olive oil resistance to oxidations,[23] and a method of assessing oil stability is based on the evaluation of biophenols over time.[24]

Currently, the two most commonly used methods to evaluate polyphenolic content of olive oil are the well-known Folin-Ciocalteu (FC) colorimetric assay[25−28] and high-performance liquid chromatography (HPLC). FC is a simple and highly efficient procedure, but it is limited by a low specificity.[27,28] HPLC is sensitive and specific, but it is very time-consuming and requires special expertise and a laboratory.[29−31] Recently, also the correlation of polyphenolic content with the extinction coefficient at 225 nm (K 225) was studied, mainly to estimate the sensorial attribute of bitterness[32,33] or bitterness and pungent[34] on a chemical basis.

The FC spectrophotometric method quantifies the total content of polyphenols as gallic acid.[9,35] For wine and other water-based systems FC is well-established and was deeply discussed and compared with different methods.[36,37] On the contrary, in the scientific literature specifically concerning olive oil analysis, to date there are no papers comparing the FC result with the evaluation of phenol content by chromatographic separation followed by their quantification, although both kinds of result may be reported and indirectly correlated.[38−41]

Furthermore this reagent has been considered by some authors[27,28] as nonspecific to phenolic compounds, because it can be reduced by nonphenolic compounds,[42] and this analytical method has been proposed as more appropriate to evaluate the reducing capacity than to determine the total phenolic content.

Therefore, consistent information about FC validation by reliable analytical protocols is currently lacking for olive oil quality assessment. The International Olive Oil Council (IOC)

[a]In the first section of the table (1.1) all data are considered, while in the following sections three subsets are separately analyzed: (1.2) oils from typical Tuscan varieties, traditionally mixed together; (1.3) oils from Seggianese variety; and (1.4) oils from Taggiasca variety. In column 1 the single compounds and the sums of chemically related compounds are listed. The mean, the standard deviation, and the number of observations are reported in Columns 2−4, respectively. Column 5 shows the *F* values of the homogeneity-of-slopes test. Column 6 shows the Pearson correlation coefficients between each HPLC-DAD and the FC value, followed by Column 7, where the corresponding significance test is reported. Many samples show values under the detection limit for apigenin and make the homogeneity of slopes test unreliable.

itself adopts the HPLC method[43] but gives also a provisional approval[44] to a method for the colorimetric determination of *o*-diphenols, based on sodium molibdate dehydrate and 370 nm absorbance,[45] thus confirming the need of both analytical approaches and the importance of making them as interchangeable as possible.

The purpose of this work is to evaluate, in EVOO analysis, the correlation of FC's results with the results by HPLC-DAD-MS (high-performance liquid chromatography−diode array detector−mass spectrometry), focusing also on the relationship between the single molecules or classes of MPCs quantified by HPLC, and the corresponding FC results, and aiming to a consistent interpretation of FC results, for olive oils characterized by very different phenolic profiles.

MATERIALS AND METHODS

Sampling. Eighty-eight commercial EVOOs were selected and analyzed. They were crushed during the years 2002, 2003, 2004, 2005, 2006, and 2008 at the technological maturity of the olives and derived from the following Italian cultivars and provinces or homogeneous mixtures of cultivars, according to the tradition of their cultivation area: Carboncella (Rieti), Frantoio (Livorno), Leccino (Rieti), Leccio del Corno (Florence), Madonna dell'Impruneta (Florence), Mignolo (Livorno), Moraiolo (Livorno), Pendolino (Firenze), Seggianese (Grosseto), Taggiasca (Imperia), a mixture from Siena of Frantoio, Moraiolo, Leccino, and Pendolino, a mixture from Florence of Frantoio, Moraiolo, Leccino, and Correggiolo, and a mixture of Frantoio, Moraiolo, and Leccino. The observations were distributed as shown in the reported graphs. All oils were stored at room temperature in bottles capped with nitrogen after crushing and were analyzed within one month.

The cultivars Frantoio, Moraiolo, Leccino, Leccio del Corno, Pendolino, and Seggianese are known to be characterized by high contents of secoiridoidic derivatives.[15−17,46] On the contrary Taggiasca, a Ligurian cultivar of extreme interest, and Carboncella, a cultivar from the Lazio Region, are characterized by high levels of lignans and low levels of total MPCs.[47] For this reason, a subset of 41 observations, including mainly the cultivars of the first group, was more deeply analyzed, and oleocanthal, one of the secoiridoidic derivatives, was also quantified.

Sample Preparation and Chemical Analyses. A volume of 50 mL of each sample was extracted with 150 mL of EtOH−H_2O (70:30 v/v), where the water was acidified with formic acid (pH = 2.5). Defatting with *n*-hexane was carried out to remove the lipid fraction. The hydroalcholic extract was concentrated under reduced pressure (around 0.25 atm) to dryness with a Rotavapor (BÜCHI Labortechnik AG), dissolved with 2 mL of extraction solvent, and analyzed by HPLC using an HP-1100 liquid chromatograph equipped with a DAD detector and an HP 1100 MSD quadrupole mass spectrometer with an API-electrospray interface (Agilent Technologies, Palo Alto, CA, USA).

Reagents, Standards, and Solvents. Solvents for the HPLC-DAD-MS analyses were of analytical grade and were purchased from Sigma (St. Louis, MO, USA). Water was purified by a Milli-Q Plus system from Millipore (Milford, MA, USA). The following commercial compounds were used: tyrosol, oleuropein, luteolin, and apigenin (Extrasynthèse, France) and 5-hydroxytyrosol (Cayman Chemical Ltd., United States). FC reagent was purchased from Sigma (St. Louis, MO).

HPLC-DAD-MS. The adopted HPLC method was similar to the method previously reported.[22] It is more time-consuming than the SSOG (Stazione Sperimentale Oli e Grassi) method in terms of sample preparation and time analysis but is more detailed, allowing the determination at different wavelengths (240, 280, and 350 nm) of single molecules belonging to different subclasses. In detail, the LiChrosorb RP18 (Merk Hibar) column, 250 mm × 4.6 mm (5 μm), was used. The eluents were H_2O at pH 3.2 by formic acid (0.035% v/v) (A) and acetonitrile (B). The analyses were performed by a multistep linear solvent gradient as follows: 0−23 min, gradient 0−11% B; 23−33 min, isocratic 11% B; 33−45 min, gradient 11−13% B; 45−49 min, isocratic 13% B; 49−59 min, gradient 13−20% B; 59−72 min, isocratic 20% B; 72−74 min, gradient 20−25% B; 74−79 min, isocratic 25% B; 79−89 min, gradient 25−35% B; 89−92 min, isocratic 35% B; 92−100 min, gradient 35−45% B; 100−103 min, isocratic 45% B; 103−107 min, gradient 45−100% B; 107−110 min, isocratic 100% B. Total time of analysis 110 min, oven temperature 26 °C; flow rate 0.8 mL min^{-1}. The operative conditions of the electrospray ionization/mass spectrometry (ESI-MS) detector were: capillary voltage from 3000 to 3500 V, working in negative ionization, with a variable fragmentor potential in the range of 80−150 V. MS spectra were acquired from m/z 100−800. MPCs (minor polar compounds) were identified by comparison with pure standards, isolated compounds, UV spectra, relative retention time, and mass spectra in ESI. A detailed presentation of the method of identification is provided (see the Supporting Information). Lignans were identified and analyzed as described in Mulinacci et al.[47] For a subset of 41 observations oleocanthal was also quantified according to Beauchamp et al.[8] The single compounds were quantified with HPLC-DAD using a four-point regression curve constructed with the following standards: tyrosol, luteolin, and oleuropein (Extrasynthèse, France), 5-hydroxytyrosol (Cayman Chemical Ltd., United States). Calibration curves with a $r^2 \geq 0.9998$ were used. Tyrosol and lignans concentrations were calculated at 280 nm using tyrosol as the reference compound. 5-Hydroxytyrosol was calculated at 280 nm using a 5-hydroxytyrosol standard. The flavonoids were evaluated at 350 nm and using luteolin as an external standard. The secoiridoids were calculated at 280 nm using oleuropein as the reference compound; elenolic acid and elenolic acid derivatives were evaluated at 240 nm using oleuropein as the

reference compound at the same wavelength. In all cases actual concentrations of derivatives were calculated after applying corrections for changes in molecular weight: knowing the molecular weight of each compound (MW_x), their actual concentration was obtained by applying a multiplication factor of MW_x/MW_y, where MW_y is the molecular weight of the specific reference compound. The compounds evaluated by HPLC-DAD-MS were 5-hydroxytyrosol, tyrosol, deacetoxyoleuropein aglycone, oleocanthal, lignans as acetoxypinoresinol, oleuropein aglycone, a group of other secoiridoidic derivatives, luteolin, apigenin, and elenolic acid. Elenolic acid is not a phenolic compound, but it is a hydrolysis product of its polyphenols esters; therefore it was included. Biophenols were extracted and fractionated aiming at the total recovery of all MPCs, thus pointing to a reliable estimate of their total content. All of the samples were analyzed in triplicate, and the standard deviation was <5%. The limits of detection (LOD) were found to be 0.20 mg kg^{-1} for luteolin and 0.33 mg kg^{-1} for tyrosol, oleuropein, and 5-hydroxytyrosol. A signal-to-noise ratio of 3:1 was used for the calculation of the LOD.

The MPCs that were identified and quantified (Table 1) belong to five classes characterized by different functional groups: simple phenols (tyrosol, 5-hydroxytyrosol), ortho-diphenols (oleuropein aglycone, deacetoxyoleuropein aglycone), oleocanthal and other secoiridoidic derivatives, lignans (acetoxypinoresinol and pinoresinol, hereafter referred to as "lignans"), flavonoids (luteolin and apigenin, hereafter referred to as "flavonoids"), and molecules without the phenolic group (elenolic acid and its derivatives). For this reason the relationship of the FC value with two groups of compounds was also considered, and the sum of the flavonoids (luteolin and apigenin) and of the orthodiphenols (oleuropein aglycone and deacetoxyoleuropein aglycone) was calculated, together with the total sum.

Folin-Ciocalteu Assay. The total phenolic content by the FC method was determined according to the analytical protocol described by Singleton et al.[26] The method was adapted for oils as follows: 2.5 g of EVOO was diluted with 5 mL of *n*-hexane and extracted two times by 2 min of vortex and 5 min of centrifugation (4500 rpm) with 5 mL of CH_3OH-H_2O (80:20 v/v). A portion of 1 mL of the extract was added to 0.25 mL of FC reagent, 1.5 mL of Na_2CO_3 (20% w/v), in a 10 mL volumetric flask reaching the final volume with purified water. Each sample was stored for 45 min at the controlled temperature of 25 °C, and the spectrophotometric analysis was performed at λ = 725 nm. The final result, expressed in mg/kg of gallic acid, was obtained through a calibration curve with range from 1 to 15 μg mL^{-1} (R^2 = 0.9985).

Statistical Analysis. The Pearson correlation coefficient and its corresponding significance was calculated between every single HPLC determination and the total phenolic content quantified by FC (FC in tables and graphs) and discussed. The same was done for the sums of compounds described formerly.

Correlation analysis was applied to the whole data set and to every Cultivar*Year subset. The variable labeled "Cultivar" included also the mixtures of cultivars described formerly. The Cultivar*Year subsets of data were included in calculation as replications. The consistency of the correlations was evaluated by the homogeneity-of-slopes analysis. For this reason two linear models were adopted and tested. The models included each HPLC result as a response variable, the Cultivar*Year combination as grouping variable, the FC result as covariate or as regressor, and contributor to the continuous-by-class effects (to test the homogeneity of slopes). Least squares means (LS-means) were computed for each Cultivar*Year subset, and the data were adjusted accordingly, before calculating again and evaluating correlations, to minimize the Cultivar*Year variations. Data belonging to Cultivar*Year subsets with less than four oils are shown in graphs but were not included in statistical calculations. Data were also explored by principal component analysis (PCA).

The programs for the statistical and graphical processing were developed in SAS 9.3 executing on the Linux 3.9.10-100.fc17.x86_64 platform.

RESULTS AND DISCUSSION

MPCs are present in very different quantities in the oils under study (Table 1, Columns 2 and 3, Figures 1−4). This is consistent with the expected profiles of the cultivar that were considered.[15−17,46,47]

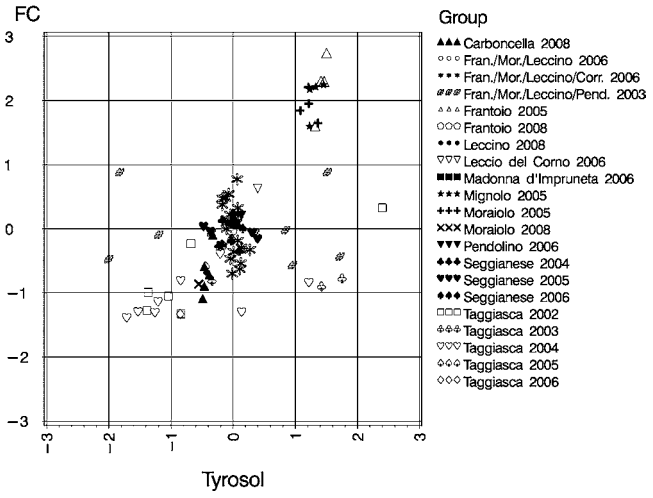

Figure 1. Correlation between the concentration of total polyphenols by the Folin-Ciocalteu (FC) spectrophotometric method (mg/kg of gallic acid) and the concentration of tyrosol (mg/kg) determined by HPLC-DAD-MS. All values are standardized. The values of the *X*-axis variable are adjusted for the Cultivar*Year group: the least-squares means were computed for each Cultivar*Year subset, and the data were adjusted accordingly.

Secoiridoidic derivatives showed a UV−vis spectrum similar to that of oleuropein, and the MS spectrum recorded in the negative ion mode exhibited the signal at 377 *m*/*z*, corresponding to the quasi-molecular ion of the aglycone of oleuropein.

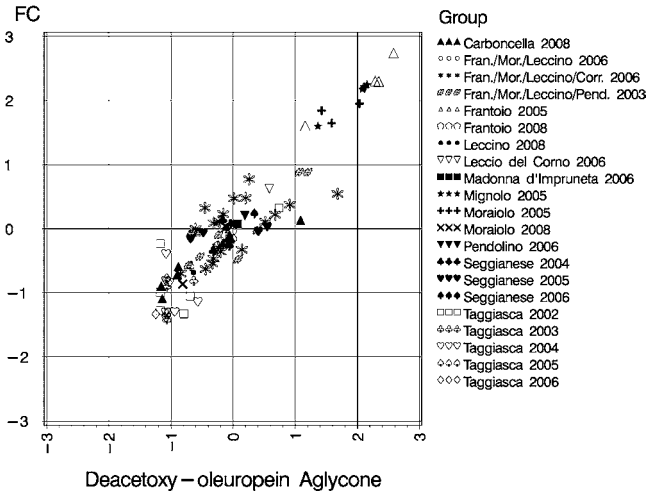

Figure 2. Correlation between the concentration of total polyphenols by the FC spectrophotometric method (mg/kg of gallic acid) and the corrected concentration of deacetoxyoleuropein aglycone (mg/kg) determined by HPLC-DAD-MS. All values are standardized. The values of the *X*-axis variable are adjusted for the Cultivar*Year group: the least-squares means were computed or each Cultivar*Year group, and the data were adjusted accordingly.

dx.doi.org/10.1021/jf403104a | J. Agric. Food Chem. 2014, 62, 826−835

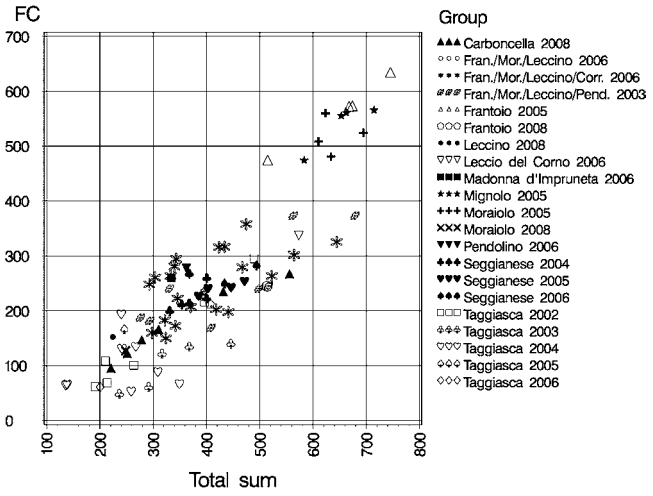

Figure 3. Correlation between the concentration of total polyphenols by the FC spectrophotometric method (mg/kg of gallic acid) and the sum of corrected concentrations (mg/kg) of all compounds determined by HPLC-DAD-MS. Values are not standardized nor corrected for the Cultivar*Year group.

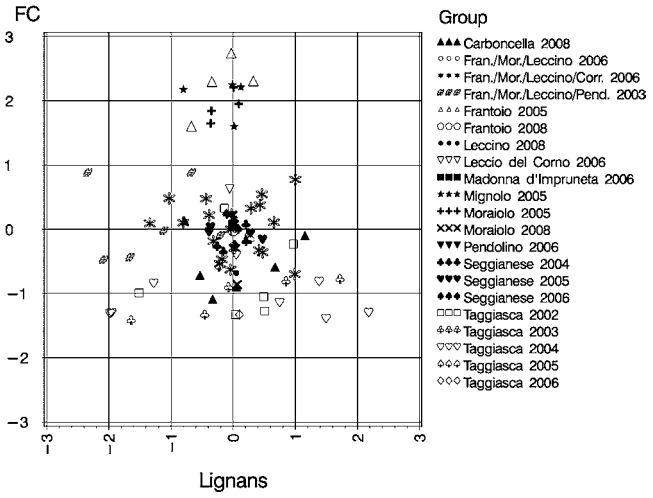

Figure 4. Correlation between the concentration of total polyphenols by the FC spectrophotometric method (mg/kg of gallic acid) and the corrected concentration (mg/kg) of lignans determined by HPLC-DAD-MS. All values are standardized. The values of the *X*-axis variable are adjusted for the Cultivar*Year group: the least-squares means were computed for each Cultivar*Year group, and the data were adjusted accordingly.

The homogeneity-of-slopes results show that 5-hydroxytyrosol, tyrosol, and the secoiridoidic derivatives (oleocanthal included), are not reliably correlated with FC (Table 1 Column 5); that is, the linear relationships between these variables and FC are significantly different in the different Cultivar*Year subsets. This kind of relationship is made clear by the tyrosol graph (Figure 1) where the scatters of the single Cultivar*Year subsets have very different shapes and orientations. The apigenin contents are generally too low to be detected by the method adopted, but, in those cultivars with appreciable apigenin contents (Moraiolo 2005, Frantoio 2005, and the three mixtures of Tuscan cultivars) apigenin shows no reliable (nor significant) linear relationship (data not shown) between its HPLC-DAD and FC quantifications (Table 1). The detection limit, evaluated for apigenin in all analyzed extracts, is 0.2 mg/kg. The estimate of the detection limits were based on a signal-to-noise ratio of 3:1 of the minor component.

All of the remaining variables show opposite results (Table 1, Column 5) and, from this point of view, perform reliably and can be divided in four groups (Table 1, Columns 6 and 7): those having a highly significant and strong positive correlation ($R > 0.90$) with FC, those having a significant but weaker correlation ($0.71 \geq R > 0.65$), those showing an intermediate position ($0.90 \geq R > 0.70$), and those having no significant correlation with FC or a Pearson correlation coefficient significant but less or equal than 0.65.

The highest significant correlations were scored by the ortho-diphenols deacetoxyoleuropein aglycone ($R = 0.93$, Figure 2) and oleuropein aglycone ($R = 0.93$) as single compounds and by the their sum ($R = 0.94$), and by the sum of all compounds ($R = 0.95$, Figure 3) .

By contrast the lowest correlation ($R = -0.08$, non-significant) was related to lignans (Figure 4), followed by the sum of flavonoids ($R = 0.56$), luteolin aglycone ($R = 0.60$), and elenolic acid derivatives ($R = 0.61$). The fact that lignans reliably show no significant linear relationship between the HPLC and the FC values could mean that these molecules do not react properly with the Folin reagent, due to the absence of functional groups, like the catechol group, that can more effectively exchange with the reagent.

The inconsistency of hydroxytyrosol and tyrosol (Figure 1, Table 1, part 1.1 Column 5, parts 1.2−1.4 Columns 6 and 7), is possibly related to the variation of their concentration due to their antioxidant capacity and to the opportunity to be easily produced by hydrolysis from the secoiridoidic molecules containing them. They play a transient role as intermediate products between the reserve of secoiridoidic compounds and the redox systems where their antioxidative power may be spent. This makes the quantification of hydroxytyrosol and tyrosol less meaningful than the quantification of their source-compounds.

Oleocanthal, shows a constant, positive ($R = 0.68$) correlation with the FC result within the subset of data where it was quantified.

These results can be better explained if we consider also the eigenvalues and the eigenvectors (Table 2) derived from the PCA. The first principal component explains about 58% of the total variance, the second principal component explains about 12%, and the third principal component explains about 10%. The eigenvalues indicate that three to five components provide a good summary of the data, with three components accounting for about 81% of the total variance and five components explaining about 92%.

The first component reflects the overall performance of almost all variables since the first eigenvector shows approximately equal loadings on almost all of them, with two remarkable exceptions: lignans and apigenin (Table 2, part 2.2, and Figure 5, top left graph). Notably, the highest positive loadings involve FC, deacetoxyoleuropein aglycone and oleuropein aglycone. The second eigenvector, on the contrary has the highest loadings on the variables lignans (positive) and flavonoids (negative). Here FC and diphenols (deacetoxyoleuropein aglycone and oleuropein aglycone) shows extremely low loadings. The third eigenvector has a very high positive loading on lignans and flavonoids, but low and negative loadings on FC and diphenols. The loadings on the first three components of the secoiridoidic derivatives are similar to those of diphenols and FC.

[a]Sections 2.1.1 and 2.2.1: all data; Sections 2.1.2 and 2.2.2: oils from typical Tuscan varieties, mixed together according to tradition; Sections 2.1.3 and 2.2.3: oils from Seggianese variety; Sections 2.1.4 and 2.2.4: oils from Taggiasca variety.

In short, the first component (58% of the variance) is the only one having a high positive loading on FC and shows that the compounds under study can be considered as positively correlated with the FC variable, though with major quantitative differences (apigenin) and with a clear exception: lignans. The second and the third component, accounting for 23% of variance, are not correlated with FC and show mainly the relationship between lignans and flavonoids.

The statistical analysis was repeated including only the typical Tuscan mixture of Frantoio, Correggiolo, Leccino, and Moraiolo cultivar (Table 1 part 1.2, Table 2 parts 2.1.2 and 2.2.2, and Figure 5, top right graph), the Seggianese cultivar (Table 1 part 1.3, Table 2 parts 2.1.3 and 2.2.3, and Figure 5, bottom left graph) and Taggiasca cultivar (Table 1 part 1.4, Table 2 parts 2.1.4 and 2.2.4, and Figure 5, bottom right graph).

If the results including only the mixture of Frantoio, Correggiolo, Leccino, and Moraiolo are compared with those of the whole data set, they show weaker correlation (20 observations scoring $R = 0.56$ between FC and total phenol content by HPLC) but similar trends. This subset of oils shows an estimated total phenols content of 250 mg/kg by FC and 400 mg/kg by HPLC, with lignans contributing for 27% (107 mg/kg, vs 103 mg/kg of the whole data set) and deacetoxyoleuropein aglycone and oleuropein aglycone for 30% (119 mg/kg, vs 120 mg/kg of the whole data set). The results of PCA also suggest that this subset of data closely resembles the whole data set: in the space of the first two components, accounting for 67% of total variance, almost all HPLC variables are grouped together with FC except lignans and flavonoids that show opposite loadings along the second component.

Also for the Taggiasca subset (22 observations) in the space of the first two components (58% of total variance) FC, diphenols and phenols are grouped together but not with lignans and flavonoids.

This pattern is less clear in the Seggianese subset, including only 12 observations, where anyway oleuropein aglycone can be seen close to FC, while lignans and apigenin show an opposite trend.

The total phenol content of the Seggianese cultivar was estimated as 240 mg/kg by FC and 405 mg/kg by HPLC-DAD, with lignans contributing for 12% (50 mg/kg) and deacetoxyoleuropein aglycone and oleuropein aglycone for 41% (164 mg/kg).

The total phenol content of the Taggiasca cultivar was estimated 119 mg/kg by FC and 282 mg/kg by HPLC-DAD, with lignans contributing for 46% (131 mg/kg) and deacetoxyoleuropein aglycone and oleuropein aglycone for 10% (27 mg/kg). Interestingly, the correlations between the two results (FC and total by HPLC) were $R = 0.72$ for Seggianese and $R = 0.79$ for Taggiasca.

This suggests that the FC and HPLC-DAD estimations of total phenols content are reliably correlated, regardless for the absolute contents, and are independent of the relative composition of the phenolic fraction. The FC reagent seems to react poorly with lignans and flavonoids, while an opposite behavior is shown with stable orthodiphenols. The strong specific reactivity of FC reagent with catechol group in oils, and a weaker reactivity with other functional groups, typical of the polyphenols family, suggests caution about interpretation of FC results for olive oils characterized by very different phenolic profiles.

Considering the complexity of MPCs in olive oil, the current, single FC assay may not be the best choice to characterize the phenolic composition of an oil sample. Choosing an appropriate phenolic assay depends on what kind of information is required. For example the total phenol content estimated by the FC assay may be useful to determine the approximate actual content of phenolics, but this amount may be do not correspond directly to the organoleptic property of bitterness, or to specific health properties such as the total antioxidant power, both of them so important to oil qualification. Furthermore the total antioxidant power depends also on compounds that, according to our findings, are not properly intercepted by the FC assay. Therefore RP-HPLC and the identification and quantification of single MPC currently cannot be easily replaced by any simpler test. On the other

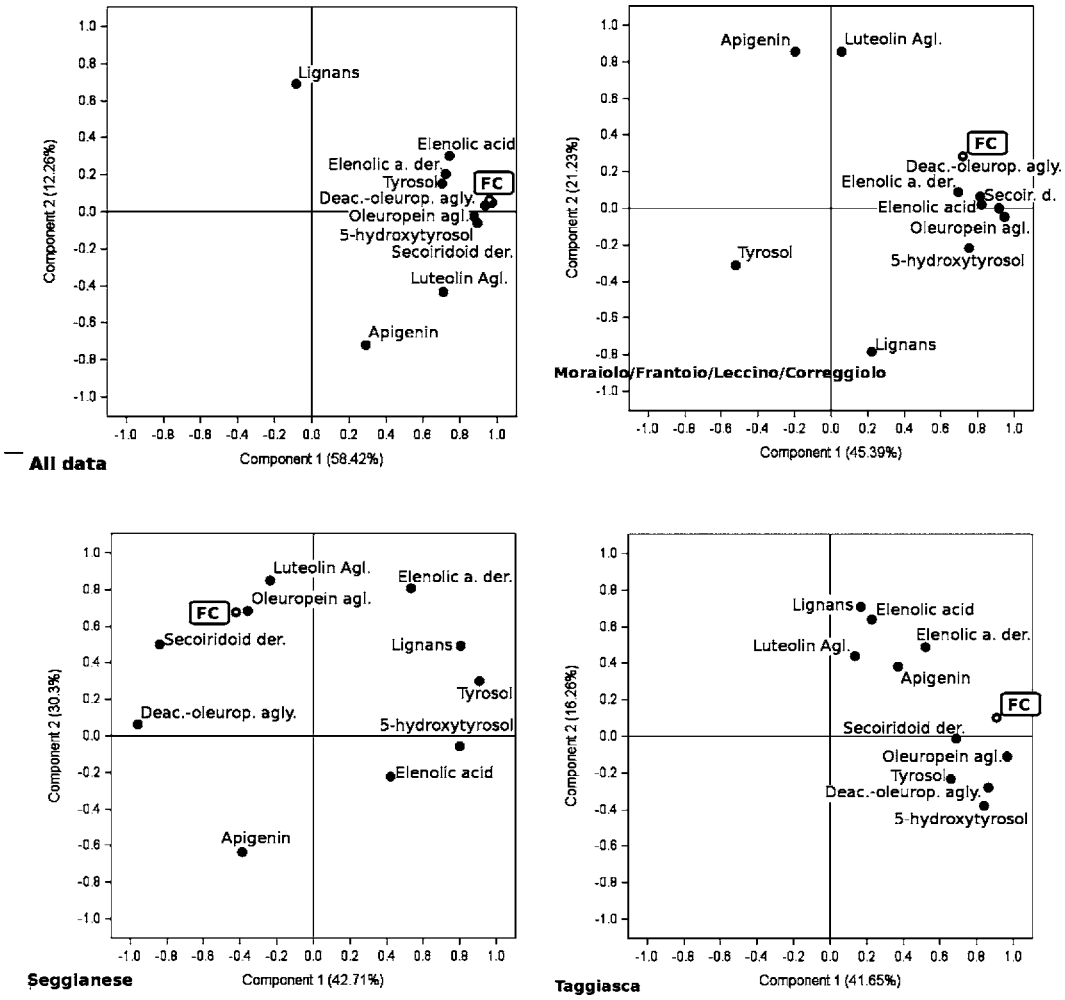

Figure 5. Loading plots of the concentrations of total polyphenols by FC spectrophotometric method and of the single compounds determined by HPLC-DAD-MS, in the space defined by the first two principal components. Top left graph: the whole data set is considered (88 observations, 71% of total variance explained). Top right graph: the principal component analysis is limited to a subset of data, including only a typical Tuscan mixture of varieties (20 observations, 67% of total variance explained). Bottom left graph: the principal component analysis is limited to a subset of data, including only Seggianese variety (12 observations, 73% of total variance explained). Bottom right graph: the principal component analysis is limited to a subset of data, including only Taggiasca variety (22 observations, 58% of total variance explained). FC stands for Folin-Ciocalteu.

hand there is a strong need for simple and reliable methods for olive oil quality assessing.

Supporting Information

ABSTRACT: The loquat, *Eriobotrya japonica* Lindl. (Rosaceae), is a small tree native to Japan and China that is widely cultivated for its succulent fruit. Its leaves are used as an ingredient of a tasty tea called "Biwa cha" in Japanese. The anti-osteoporosis effects of the leaves of loquat in vitro and in vivo have been investigated. After 15 days of feeding normal diet or diet supplemented with 5% loquat leaves, the body weight, viscera weights, and bone mineral density (BMD) of both groups of eight ovariectomized (OVX) mice were compared. The result showed that the loss of BMD in loquat-fed mice was significantly prevented in three parts of the body, especially in the trabecular bone of the head ($P < 0.05$), abdomen ($P < 0.01$), and lumbar ($P < 0.05$) compared to the control group. No hypertrophy in the uterus by the loquat leaves diet was observed. The effect of the extract (447.25 g) prepared from the dried leaves of loquat (2.36 kg) was further studied on RANKL-induced osteoclast differentiation and cell viability. The extract suppressed the differentiation of osteoclasts under 50, 125, 250, and 500 μg/mL. Through bioactivity-guided fractionation, ursolic acid (**1**) was isolated and inhibited osteoclast differentiation under 4 and 10 μg/mL. It was concluded that loquat leaves possess the potential to suppress ovariectomy-induced bone mineral density deterioration.

KEYWORDS: *tea, osteoporosis, Eriobotrya japonica, osteoclast differentiation, ursolic acid*

INTRODUCTION

Biwa (Japanese) is a flowering plant known as loquat, *Eriobotrya japonica*, and belongs to the Rosaceae family. It probably had its origin in southeastern China and has been cultivated in Japan since ancient times. It is widely cultivated for its succulent fruit. Its leaves are used as the ingredient of tasty teas called as "Biwa cha" in Japanese. It has been reported that the extracts of the leaves from *E. japonica* exerted an antiobesity effect through regulation of plasma lipid and adiponectin levels in mice and adipogenic transcription factors PPARγ and C/EBPα in 3T3-L1 adipocytes.[1] Also, the leaves of *E. japonica* were reported to have a potent inhibitory effect on the inflammatory mediator via the attenuation of NF-κB translocation to the nucleus.[2] *E. japonica* significantly delayed carcinogenesis induced by peroxynitrite (initiator) and TPA (promoter), and its potency was comparable to that of a green tea polyphenol, (−)-epigallocatechin 3-*O*-gallate, in the same assay.[3]

Osteoporosis is a growing public health problem, affecting millions of people worldwide.[4] It is a major growing health problem for elderly women associated with ovarian hormone deficiency following menopause and is by far the most common cause of age-related bone loss in women.[5] Decreased bone density and the resulting bone dysfunction greatly affect the quality of life, because the bone is a supporting organ, hematopoietic tissue, and immune tissue.[6] This imbalance of bone remodeling is caused by excess osteoclast activity. Osteoclasts are large multinucleated cells, which can resorb bone. These multinucleated cells express known markers, including tartrate-resistant acid phosphatase (TRAP),[7] a glycosylated monomeric metalloenzyme expressed in mammals, that is highly expressed in osteoclasts associated with osteoblast migration to bone resorption sites. This initiates osteoblast differentiation, proliferation, and activation.[8]

Hormone replacement therapy (HRT) is a treatment for the prevention of bone loss and for restoring the rate of bone resorption and formation.[9] However, long-term HRT may increase a patient's risk of developing breast cancer, endometrial cancer, thromboembolic events, or vaginal

bleeding.[10] Therefore, because of women's reluctance to comply with HRT, safer ingredients originating from foods or beverages such as tea are needed for the treatment or prevention of menopausal symptoms, such as osteoporosis.

As far as we know, the antiosteoporosis effect of the leaves of *E. japonica* has not yet been investigated. The objective of this study was to investigate the effect of the leaves of *E. japonica* on the bone mineral density (BMD) of ovariectomized mice and RANKL-induced osteoclast differentiation and to identify the active substance.

MATERIALS AND METHODS

Chemicals. *E. japonica* (Thunb.) Lindl. (Rosaceae) was obtained from Japan in 2010, and a voucher specimen (No. EJ001) has been deposited in the Laboratory of Systematic Forest and Forest Products Sciences (Kyushu University, Fukuoka, Japan). All leaves were air-dried and powdered mechanically. Methanol and water extracts of the leaves of loquat were prepared with three times extraction at room temperature. Mice (C57BL/6JJc1) used for the experiment were purchased from Clea Co. (Osaka, Japan). RAW 264.7 macrophage cells were purchased from the Riken Bioresource Center Cell Bank (Tsukuba, Japan). Minimal essential medium, alpha modification (α-MEM medium), was from Gibco BRL (Grand Island, NY, USA); fetal bovine serum (FBS) and antibiotics—antimycotics were obtained from Gibco and Invitrogen (Carlsbad, CA, USA), respectively. Receptor activator of NF-κB (RANKL) from *Escherichia coli* was purchased from PeproTech EC (London, UK), and tumor necrosis factor alpha (TNF-α) was obtained from Roche Molecular Biochemicals (Mannheim, Germany). TRAP staining kit 387-A was obtained from Sigma-Aldrich (St. Louis, MO, USA). Oleic acid was obtained from Wako (Osaka, Japan). Dimethyl sulfoxide (DMSO) was also obtained from Wako.

Animals and Diets. Sixteen 12-week-old female mice were bilaterally ovariectomized at 11 weeks of age. Groups of four mice were randomly housed in one animal cage. The animal room was conditioned at 23 ± 1 °C and illuminated according to a 12 h light/dark cycle (light on at 8:00 a.m. and off at 8:00 p.m.). All animals were allowed free access to distilled water and fed ad libitum. AIN-76 diets with (loquat group) or without the leaves of loquat (control group) were used on the basis of the diet reported by the American Institute of Nutrition Ad Hoc Committee on Standards for Nutritional Studies.[11] This diet was composed on the basis of the average energy intake for Japanese 40−49-year-old women with a slight modification of protein, fat, and carbohydrate weight.[12] The total calorie count in both groups' diets was the same. The main diet ingredients were vitamins, minerals, DL-glutamin, choline bitartrate, cellulose, casein, safflower oil, starch, and sucrose (Table 1).

Animal Experiment Protocol. At the beginning of the experiment, the mice were acclimated for 6 days by feeding the control diets to both groups. Then the 16 mice were randomly divided into two groups (n = 8 each), and (1) the control group was fed the modified AIN-76 diet and (2) the loquat group was fed the modified AIN-76 diet incorporating 5% leaves of loquat. The treatment continued to the 22nd day, and then the mice were sacrificed and dissected. The body weights and food intakes of all animals were measured every day. The handling and sacrificing of all animals were carried out in accordance with nationally prescribed guidelines, and ethical approval for the studies was granted by the Animal Care and Use Committee of Kyushu University (Authorization A22-234-0).

Table 1. Compositions of the AIN-76 Diet in the Control Group and Loquat Group

composition	percentage (%)	
	control group	loquat group
vitamins	1.0	1.0
minerals	3.5	3.5
DL-glutamine	0.3	0.3
choline bitartrate	0.2	0.2
cellulose	5.0	2.69
casein	20.6	20.29
safflower oil	12.71	12.53
corn starch	15.49	15.56
leaves of loquat powder	0	5.0
sucrose	41.15	38.93

X-ray CT Scan. On the 21st day of the diet regimen, each mouse underwent a computed tomography (CT) scan. BMD was measured by a computerized tomography scanner (X-ray CT) (La Theta, Aloka Co. Tokyo) at a scan pitch of 5 mm for mouse body parts. The BMD of the head, chest, abdomen, and lumbar (including the trabecular bone, cortical bone, and whole) were analyzed.

Anatomy. At the end of the experiment, the mice were euthanized with pentobarbital sodium at 50 mg/kg body weight, and the liver, uterus, kidney, spleen, brain, and fat mass (fat around the kidney and fat around the uterus) were carefully removed and weighed.

Cell Cultures. Cells of the murine macrophage cell line RAW 264.7 were maintained in α-MEM with 10% FBS and 1% antibiotics. For the osteoclastogenesis experiments, cells were cultured in a 96-well plate at the density of 6×10^3 cells/well, and after 24 h, the adherent cells were cocultured with an additional α-MEM medium + 10% FBS + 1% antibiotics containing cytokines (40 ng/mL RANKL and 10 ng/mL TNF-α). Samples at appropriate concentrations were dissolved into DMSO (v/v, 0.1% in each well) and added into each well. The cells were then cultured for 4 days.

Assay for Osteoclastic TRAP Activity. The protocol for the assay of osteoclastic TRAP activity was as follows. After the cell culture period, the media were removed and adherent cells were fixed in 37% formaldehyde mixed with acetone and citrate solution (8:65:25, v/v/v) for 3 min and then washed with water. The cells were then stained for TRAP with the TRAP staining kit 387-A according to the manufacturer's instructions: the cells were stained with a fast garnet GBC base solution mixed with sodium nitrite solution, naphthol AS-BI phosphoric solution, acetate solution, and tartrate solution. After 1 h of staining in the dark, the stained cells were washed with water and colored by hematoxylin solution for 2 min and then rinsed with 0.1 N NaOH. The number of TRAP-positive multinucleated cells in each well was counted. Oleic acid was used as a positive control based on reference.[13]

Assay for Cell Proliferation. Cell viability was evaluated using a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay. RAW cells (1×10^5 cells/well) were seeded into 96-well plates for 24 h. Samples at appropriate concentrations were dissolved in DMSO (v/v, 0.1% in each well) and added into each well for another 24 h. After culturing, the cells were treated with 5 μL of MTT (final concentration = 5 mg/mL dissolved in phosphate buffer solution) for 4 h, and the precipitated dye was solubilized by isopropanol (with 0.04 N HCl). The absorbance at 570 nm was measured.

Extraction and Isolation. For the extraction and isolation of bioactive principles, 5.10 kg of fresh leaves of loquat was freeze-dried and ground into powder, and the resulting 2.36 kg of the dried leaves of loquat were extracted with methanol (35 L) and evaporated. Then, 447.25 g of methanol extract was obtained (yield = 18.95%). First, a part of the methanol extract (234.22 g) was separated by silica gel column chromatography (20 cm i.d. × 50 cm, 4.49 kg of Wakogel C-200) and eluted with an n-hexane/EtOAc solvent system [10:0 (11 L), 9.8:0.2 (2 L), 9.7:0.3 (2 L), 9.6:0.4 (2 L), 9.5:0.5 (2 L), 9:1 (2 L), 8.5:1.5 (11 L), 8:2 (8 L), 7:3 (5 L), 6.5:3.5 (12 L), 6:4 (5 L), 5.5:4.5 (2.5 L), 5:5 (6.5 L), 4:6 (3 L), 3:7 (3 L), 2:8 (2 L), 0:10 (2 L), and methanol 100% (13 L)] to yield 14 fractions. The remaining part of the methanol extract (213.03 g) was applied to column chromatography again (20 cm i.d. × 50 cm, 4.21 kg of Wakogel C-200) and eluted with an n-hexane/EtOAc solvent system [10:0 (10 L), 9:1 (5 L), 8.5:1.5 (5 L), 8:1.5 (5 L), 8:2 (7 L), 7.5:2.5 (6 L), 7:3 (5 L), 6.5:3.5 (5 L), 6:4 (5 L), 5.5:4.5 (5 L), 5:5 (5 L), 4:6 (5 L), 3:7 (5 L), 2:8 (5 L), 1:9 (5 L), 0:10 (14 L), and methanol 100% (10 L)] to yield 14 fractions. On the basis of the TLC results, twice-separated fractions were combined into nine fractions [Fr. 1 (17.58 g), Fr. 2 (8.37 g), Fr. 3

dx.doi.org/10.1021/jf402735u | J. Agric. Food Chem. 2014, 62, 836−841

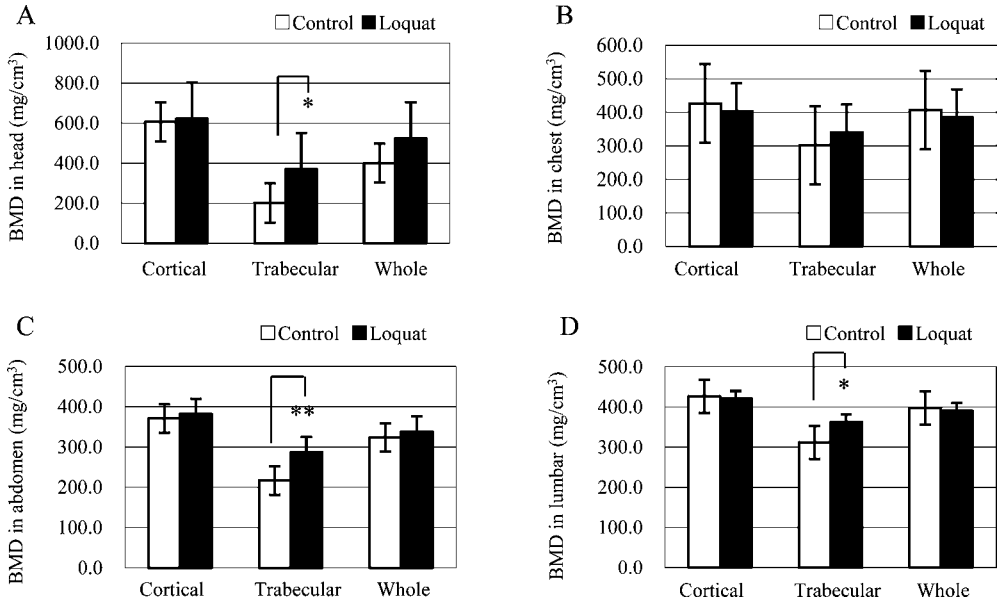

Figure 1. Effect of diet with or without the leaves of loquat on the bone mineral density (BMD) of the head (A), chest (B), abdomen (C), and lumbar (D) in OVX mice. Data showed ± SD (n = 8); Student's t test: (*) $P < 0.05$; (**) $P < 0.01$.

(4.86 g), Fr. 4 (7.55 g), Fr. 5 (12.46 g), Fr. 6 (13.34 g), Fr. 7 (14.44 g), Fr. 8 (14.03 g), and Fr. 9 (366.45 g)]. On the basis of bioactivity-guided fractionation on osteoclastic TRAP activity, Fr. 4 (7.10 g) was subjected to further separation. Fraction 4 was applied to silica gel column chromatography (6 cm i.d. × 120 cm, 963 g of Wakogel C-200) and eluted with an *n*-hexane/EtOAc solvent system [10:0 (1 L), 9:1 (1.5 L), 8:2 (1.5 L), 7:3 (1.5 L), 6.8:3.2 (1 L), 6.5:3.5 (1 L), 6.2:3.8 (1 L), 6:4 (1 L), 5:5 (1 L), 2.5:8.5 (1 L), and methanol 100% (2 L)] to give eight fractions. The amount of each fraction was shown as Fr. 4-1 (74.11 mg), Fr. 4-2 (3.79 mg), Fr. 4-3 (17.52 mg), Fr. 4-4 (74.16 mg), Fr. 4-5 (85.29 mg), Fr. 4-6 (1.18 g), Fr. 4-7 (1.04 g), and Fr. 4-8 (4.79 g). Further fractionation procedures were applied only to Fr. 4-7, due to its highest osteoclastic TRAP inhibitory activity. Fraction 4-7 (989.1 mg) was applied to a Sephadex LH 20 column (5 cm i.d. × 50 cm, Sephadex amount = 100 g) and eluted with MeOH/$CHCl_3$ (500 mL) to give eight fractions: Fr. 4-7-1, Fr. 4-7-2, Fr. 4-7-3, Fr. 4-7-4, Fr. 4-7-5, Fr. 4-7-6, Fr. 4-7-7, and Fr. 4-7-8. The 15 mg of fraction 4-7-6 (see the HPLC chromatogram in the Supporting Information, Figure S1) dissolved in methanol was separated by recycling preparative HPLC (LC- 9204, Japan Analytical Industry Co., Tokyo, Japan). The total injection amount was 3 mL, with the flow rate at 5 mL/min; mobile phase was methanol 95% + water 5%, and the column was an Inertsil ODS-3 (20 × 250 mm, GL Science, Toyko, Japan) with detection for absorbance at 210 nm to give compound **1** (6.27 mg) (see the Supporting Information, Figure S2). To verify the purity, the isolated compound **1** was confirmed by HPLC (see the Supporting Information, Figure S3). HPLC chromatograms for individual fractions (Fr. 1−9, Fr. 4-1, 4-3−4-8, Fr. 4-7-1−4-7-8) and methanol extract were also studied (see the Supporting Information, Figure S4).

GC-MS and NMR Identification. For the gas chromatography−mass spectrometry (GC-MS), compound **1** (white solid) was treated with trimethylsilyldiazomethane (Tokyo Chemical Industry, Tokyo, Japan) in a solution of benzene (20% ethanol) for 30 min at room temperature and then subjected to a GC-MS analysis. Conditions were as follows: column temperature, 260 °C for 60 min; injection temperature, 250 °C; detector temperature, 300 °C; column, DB-5 capillary column, 0.25 mm i.d. × 30 m; helium rate, 1.4 mL/min; injection volume, 1 μL; split ratio, 5:1; m/z range, 50−600. EI/MS m/z (relative intensity %): 470 (3), 412 (3), 262 (100), 233 (6), 203 (97), 189 (24), 133 (75), 119 (27). Then compound **1** was dissolved in DMSO-d_6 and identified by ^{1}H NMR and ^{13}C NMR as ursolic acid (**1**) (optical rotation $[\alpha]_D^{24}$ +31.3 (methanol, c 0.117). The above data were compared with the literature[14] (see the Supporting Information, Figure S5).

Statistical Analysis. All values are expressed as means ± SD. The significance of differences between means for two groups was determined by Student's t test. Differences were considered significant at (*)$P < 0.05$ and (**)$P < 0.01$.

RESULTS

Effect of the Leaves of Loquat on Body Weight and the Weight of Each Organ. The two groups of mice showed no significant difference in body weight or viscera weights; notably, their uterine weights were the same. This outcome suggests that the leaves of loquat did not influence the actions of estrogen or its receptors; it also indicates that there is no potential side effect caused by unexpected estrogenic activity.

Effect of the Leaves of Loquat on BMD of Various Body Parts. We investigated the effect of the leaves of loquat on the BMD of various body parts of mice and found that the loss of BMD in the trabecular cells of head, abdomen, and lumbar parts was inhibited after treatment with the diet containing the leaves of loquat compared to the control group. As shown in Figure 1, the BMD of the loquat group was significantly higher in the trabecular bone of the head, abdomen, and lumbar.

Effect of the Extracts Prepared from the Leaves of Loquat on Osteoclast Differentiation. To determine the effect of the extracts prepared from the leaves of loquat on osteoclast differentiation, we applied water extract or methanol extract with various concentrations to RAW 264.7 cells. As shown in Figure 2, the multinucleated osteoclast-like cells were significantly inhibited by the methanol extract in a dose-dependent manner (**, $P < 0.01$). Under these concentrations, the methanol extract did not affect the cell viability of RAW 264.7 cells, suggesting that the methanol extract of the leaves of loquat inhibited osteoclast differentiation specifically without any cytotoxicity. It should be noted that the water extract showed no influence on osteoclast differentiation up to 500 μg/mL.

dx.doi.org/10.1021/jf402735u | J. Agric. Food Chem. 2014, 62, 836−841

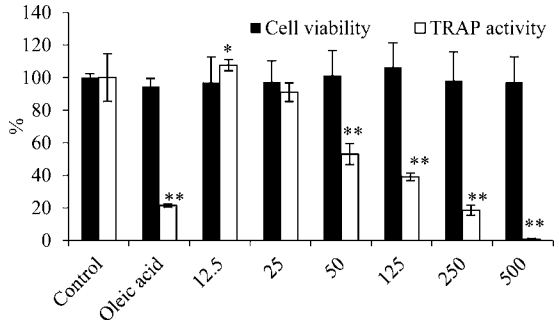

Figure 2. Effect of methanol extract of the leaves of loquat on osteoclast differentiation and cell viability of each concentration on RAW 264.7 cells. Oleic acid (50 μg/mL) was used as a positive control. The concentrations of methanol extract of the leaves of loquat were 12.5, 25, 50, 125, 250, and 500 μg/mL. Data showed ± SD (n = 3). Student's t test against control: (*) $P < 0.05$; (**) $P < 0.01$.

Effect of Subfractions Prepared from Methanol Extract of the Leaves of Loquat by Chromatography on Osteoclast Differentiation. We examined the effects of the nine fractions separated from the methanol extract on osteoclast differentiation. Under the concentration of 20 μg/mL, Fr. 4 showed significant osteoclast differentiation inhibitory activity with less cytotoxicity (Figure 3A), so it was further fractionated into eight fractions (Fr. 4-1−4-8), and their effects on osteoclast differentiation activity under 20 μg/mL were examined. As shown in Figure 3B, fraction 4-7 significantly inhibited the osteoclast differentiation; other fractions had less effect. In light of the search for bioactive principles, we applied Fr. 4-7 to further fractionation procedures and evaluated their effects on osteoclast differentiation. Among the eight fractions (Fr. 4-7-1−4-7-8), Fr. 4-7-6 showed significant inhibitory activity Figure 3C).

Effect of an Isolated Compound on Osteoclast Differentiation. Fraction 4-7-6 was further separated by recycling preparative HPLC to give compound **1**. Compound **1** was identified as ursolic acid (**1**) (Figure 4B). Ursolic acid (**1**) inhibited osteoclast differentiation in a dose-dependent manner shown in Figure 4A. We concluded that ursolic acid (**1**) should be the major principle for antiosteoclast activity of the leaves of loquat.

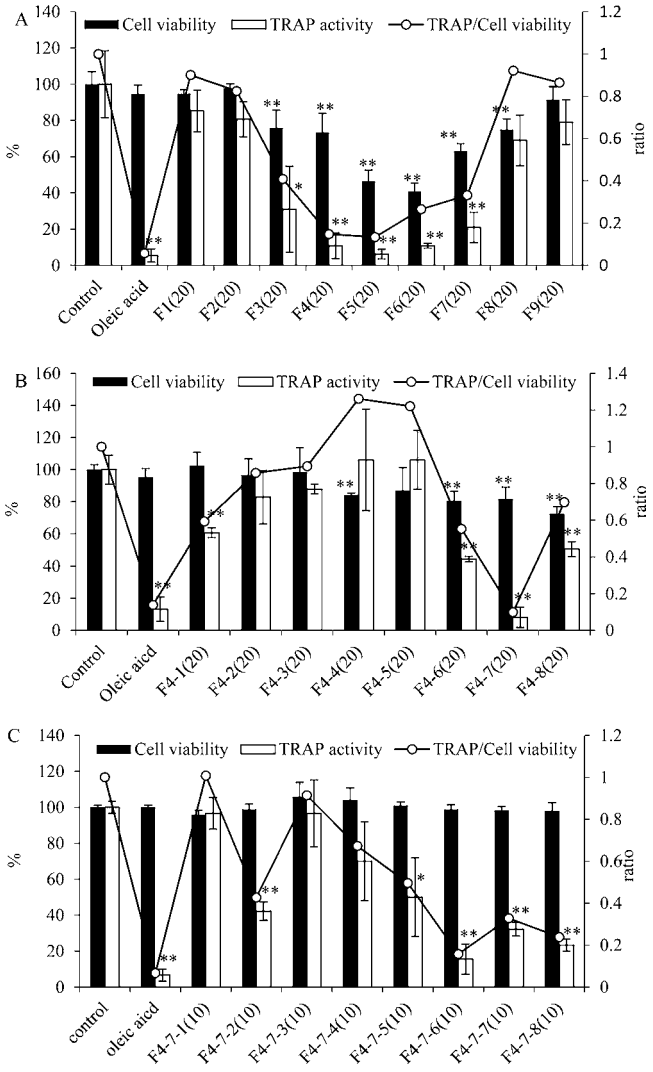

Figure 3. Effect of subfractions separated from methanol extract (A), Fr. 4 (B) and Fr. 4-7 (C) on osteoclast differentiation and cell viability on RAW 264.7 cells. Oleic acid (50 μg/mL) was used as a positive control. The concentration of subfractions separated from methanol extract and Fr. 4 was 20 μg/mL, and the concentration of subfractions separated from Fr. 4-7 was 10 μg/mL. Data showed means ± SD (n = 3). Student's t test against control: (*) $P < 0.05$; (**) $P < 0.01$.

DISCUSSION

Ovariectomized animal models (OVX) have been widely used to study preventive treatments for postmenopausal osteoporosis with estrogen insufficiency.[15] In OVX animals, as in postmenopausal women, bone loss induced by ovarian deficiency results mainly from trabecular bone loss.[15] In the present study, the administration of the leaves of loquat had a significant preventive effect against BMD loss of trabecular bone in OVX mouse compared to the control, especially in the head, abdomen, and lumbar. However, there is no obvious effect on the weight of the uterus and other organs in ovariectomized mice, indicating that the mechanism of the preventive effect of bone loss is not related to estrogenic activity.[7]

The loss of bone mass and the deterioration of bone microstructure have been linked to an imbalance between bone formation and bone resorption.[16] Here we found that the methanol extract of the leaves of loquat significantly inhibited the expression of multinucleated osteoclast cells, which are responsible for bone resorption, by evaluating the TRAP activity of osteoclast cells. Dose-dependent inhibitory effects of the extract on the differentiation of the osteoclasts without any cytotoxicity were observed.

The leaves of loquat exhibit significant in vivo and in vitro bone preventive activity; thus, it will be of interest to further investigate bioactive compounds. By using a bioactivity-guided fractionation judged by bioassay using RAW 264.7 cells, the effects of subfractions prepared from methanol extract on osteoclast differentiation at different concentrations were screened; the most significant bioactive fractions were tracked and further fractionated. One bioactive compound separated from bioactive fractions, ursolic acid (**1**), showed osteoclast differentiation inhibitory activity dose-dependently. On the basis of previous study on the leaves of loquat, pentacyclic triterpene acids make up the greatest percentage of secondary metabolites. Ursolic acid (**1**) accounted for >50% of the quantified triterpene fraction.[17] The yield of ursolic acid (**1**) extracted by methanol is higher than that by water due to its

dx.doi.org/10.1021/jf402735u | J. Agric. Food Chem. 2014, 62, 836−841

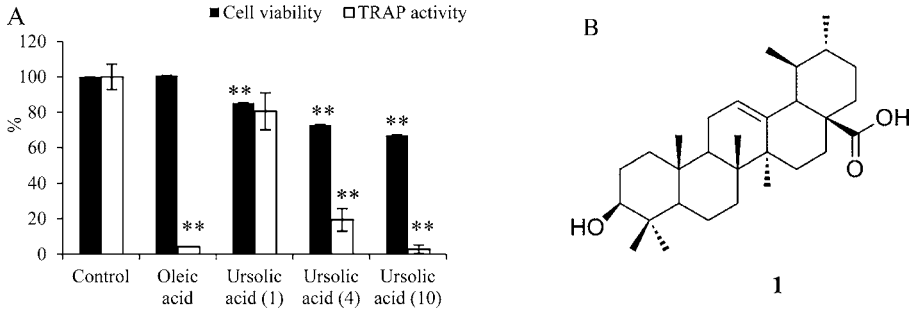

Figure 4. Effect of ursolic acid (**1**) on osteoclast differentiation and cell viability on RAW 264.7 cells (A) and chemical structure of ursolic acid (**1**) (B). Oleic acid (50 μg/mL) was used as a positive control. The concentrations were 1 μg/mL (2.19 μM), 4 μg/mL (8.77 μM), and 10 μg/mL (21.9 μM). Data showed ± SD (n = 3). Student's t test against control: (*) $P < 0.05$; (**) $P < 0.01$.

relatively low polarities.[18] In our study, through quantified study by HPLC, the percentage of ursolic acid in methanol extract of loquat leaves is nearly 33%, and the percentage of ursolic acid in the dried loquat leaves is 6.25% (see the Supporting Information Figure S4 and Table 1). A number of studies have demonstrated ursolic acid (**1**) can indeed suppress multiple molecular targets that play a pivotal role in anticancer potential, anti-inflammatory in vitro, and in vivo human clinical trials.[19−21] However, more detailed investigations are needed to completely understand its exact mode of action against different diseases. There are few reports of ursolic acid (**1**) in the study of osteoporosis diseases. Lee et al. observed that ursolic acid (**1**) has bone-forming activity in an in vivo mouse calvarial bone formation model. Also, ursolic acid (**1**) stimulates osteoblast differentiation and mineralization with the induction of osteoblast-specific gene expressions.[22] However, no study focused on the inhibitory activity of ursolic acid (**1**) on osteoclast differentiation. We found that ursolic acid (**1**) inhibited osteoclast differentiation with an IC_{50} value of 3.49 μM.

To the best of our knowledge, the present study is the first to report the effect of the leaves of loquat in the treatment of osteoporosis. Our results showed that the leaves of loquat in the diet could prevent BMD loss in OVX mice. Ursolic acid (**1**) is responsible for the osteoclast differentiation inhibitory activity. In conclusion, the leaves of loquat should be a functional ingredient of tea for the prevention and treatment of osteoporosis.

ABSTRACT: Orange juice is considered a rich source of carotenoids, which are thought to have diverse biological functions. In recent years, a fermentation process has been carried out in fruits resulting in products that provide higher concentrations of bioactive compounds than their original substrates. The aim of this study was to evaluate the effect of a controlled alcoholic fermentation process (15 days) on the carotenoid composition of orange juice. Twenty-two carotenoids were identified in samples. The carotenoid profile was not modified as result of the fermentation. Total carotenoid content and provitamin A value significantly increased from day 0 (5.37 mg/L and 75.32 RAEs/L, respectively) until day 15 (6.65 mg/L and 90.57 RAEs/L, respectively), probably due to a better extractability of the carotenoids from the food matrix as a result of processing. Therefore, the novel beverage produced could provide a rich source of carotenoids and exert healthy effects similar to those of orange juice.

KEYWORDS: *orange juice, alcoholic fermentation, carotenoids, β-cryptoxanthin, provitamin A, bioactive compounds, LC-MS (APCI)*

INTRODUCTION

Orange juice is among the most consumed fruit juices worldwide. Orange juice accounts for 60% of all Western Europe consumption of fruit juices and juice-based drinks. In the United States, this juice is the most popular juice per capita, being consumed at 5 times the rate of Americans' second choice, apple juice.[1] Orange juice is considered a rich source of bioactive compounds beneficial for human health, such as ascorbic acid, flavonoids, and carotenoids. Numerous epidemiological and intervention studies have provided evidence to support that orange consumption may reduce the risk of cardiovascular diseases and cancer.[2,3]

Carotenoids are an important group of natural pigments, responsible for the coloring of most fruits and vegetables such as oranges, red peppers, watermelons, carrots, and tomatoes.[4] These compounds are minor constituents in cereal grains.[5] Nearly 750 naturally occurring carotenoids have been identified, and this number continues to rise.[6] Orange juice has one of the most complex carotenoid profiles reported in any fruit.[7] From a nutritional and physiological standpoint, orange juice carotenoids are thought to have diverse biological functions and actions, such as antioxidant capacity,[8] provitamin A activity,[9] macular protection,[10] bone health,[11] and anticarcinogenic effect.[12]

The increasing interest in these pigments has prompted the development of numerous analytical methods for characterizing carotenoids in orange juice[7] and other foods[13] and has prompted research into adequate production conditions and technological treatments to maintain or enhance carotenoid composition and subsequent application in the food industry.[14] Many studies have examined the effect of processing such as pulsed electric fields, thermal treatment, high pressure, refrigerated storage, or ultrafrozen on the carotenoid content of different types of orange juice, determining the optimal technological conditions to preserve the potential healthy effect of the resulting product.[15] It has been recently found that fermentation might improve the profile of bioactive compounds in fruits and vegetables, so a fermentation process has been carried out in fruits (pomenagrate,[16] mulberry,[17] apple[18]) and vegetables (red sorghum,[19] onion[20]), resulting in products that provide higher concentration of bioactive compound content than the substrate. Accordingly, it would be interesting to analyze the effect of a controlled fermentation process on the carotenoid composition of orange juice. On the other hand, this orange fermented product contains a moderate amount of alcohol. Numerous studies have demonstrated that moderate alcoholic consumption produces positive effects on plasma lipid profile, coagulation system, and the atherosclerotic process.[21] Therefore, healthy effects of dietary bioactive compounds and moderate alcohol consumption would also act synergistically in a potential beverage based on a controlled alcoholic fermentation of orange juice.

Therefore, the aim of this study was to evaluate the effect of the controlled alcoholic fermentation on the carotenoid composition of orange juice with a special emphasis on the provitamin A content. Furthermore, this novel orange juice beverage would suggest a new way to commercialize orange

and the possibility of providing the consumer with a new potentially healthful beverage that could extend the supply of other similar drinks with higher alcohol content, such as wine, beer, or cider.

MATERIALS AND METHODS

Samples. The company Grupo Hespérides Biotech S.L. carried out the controlled alcoholic fermentation by using a novel process (patent WO2012/066176A120120524). A commercial pasteurized orange juice made from *Citrus sinensis* L. var. Navel late (Huelva, Spain) was used as starting material. The criteria for selection of this orange juice were the compositional homogeneity, microbiological stability, and organoleptic quality. These aspects are necessary for adequate development of the fermentation process and consumer acceptance of the final product. The yeast strain *Pichia kluyveri* var. *kluyveri* (Saccharomycetaceae family), isolated by Grupo Hespérides Biotech S.L. from the natural microbiota present in the orange fruit, was used as the inoculum. This yeast was selected for producing a low alcohol percentage (0.8−1.2% v/v) in the final product. The fermentation was carried out in a PVC tank (5 L) at 20 °C for 15 days in repose. Before sample collection, the fermentation liquid was agitated and mixed by the use of magnetic agitator to promote sample homogenization. Samples were aseptically collected on alternate days throughout the fermentation period (days 0, 1, 3, 5, 7, 9, 11, 13, and 15) and immediately stored at −20 °C until analysis. Two simultaneous fermentation processes were performed under identical conditions. Table 1 summarizes the quality parameters in both orange juice and fermented product: pH, tritatable acidity (TA), total glucids (reducing and nonreducing sugar), total soluble solids (TSS) (°Brix), pulp content (%), and alcohol (% v/v).[22]

Table 1. Quality Parameters of Orange Juice before and after Fermentation

quality parameter[a]	orange juice	fermented orange juice
pH	3.48 ± 0.20	3.43 ± 0.20

[a]Values are expressed as the mean ± standard deviation. [b]TA, titratable acidity. [c]TSS, total soluble solids.

Chemicals and Reagents. HPLC grade methanol and acetone were supplied by BDH Prolabo (VWR International Eurolab, S.L., Barcelona, Spain). Diethyl ether containing 7 ppm of butylated hydroxytoluene (BHT) was purchased from Scharlau S.L. (Barcelona, Spain). HPLC grade deionized water was produced with a Milli-Q 50 system (Millipore Iberica S.A., Madrid, Spain). The remaining reagents were all of analytical grade and purchased from Sigma-Aldrich Química S.A. (Madrid, Spain).

Carotenoid Extraction. Carotenoid pigments were extracted from the nonfermented and fermented orange juice samples using the method of Mínguez-Mosquera and Hornero-Méndez[23] with some modifications. Briefly, an aliquot (10 mL) of a previously shaken sample was centrifuged at 10000*g* and 4 °C for 10 min to collect the solids in suspension. The pellet containing the carotenoid pigments was extracted with acetone (3 mL) containing 0.5% (w/v) BHT and centrifuged at 5000*g* and 4 °C for 5 min. The extraction step was repeated once, and both extracts were combined and dried under a nitrogen stream in a round-capped 15 mL polypropylene centrifuge tube. A saponification step was included to simplify the complexity of the HPLC carotenoid profiles by hydrolyzing the carotenoid acyl esters naturally present in orange juice. The dried extract was dissolved in 3 mL of diethyl ether and 0.5 mL of 20% (w/v) KOH/MeOH was added, followed by a reaction period of 20 min with intermittent agitation. After the addition of 3 mL of distilled water, samples were centrifuged at 5000*g* and 4 °C for 5 min to separate organic (upper) and aqueous (lower) phases. The supernatant was collected, dried under a nitrogen stream, and kept under the inert atmosphere at −30 °C until chromatographic analysis. Before the analysis, samples were dissolved in 0.5 mL of acetone and centrifuged at 12000*g* and 4 °C for 5 min. All operations were carried out under dimmed light to prevent isomerization and photodegradation of carotenoids.

Pigment Identification. Routine procedures were used to identify the carotenoids, using a combination of different experiments: separation and isolation of pigments by TLC and cochromatography (TLC and HPLC) with pure standards, analysis of the UV−visible and mass spectra, comparison with values in the literature,[4,24−28] and chemical test for 5,6-epoxy groups. Samples of *β*-carotene (*β*,*β*-carotene), antheraxanthin (5,6-epoxy-5,6-dihydro-*β*,*β*-carotene-3,3′-diol), *β*-cryptoxanthin (*β*,*β*-caroten-3-ol), zeaxanthin (*β*,*β*-carotene-3,3′-diol), lutein (*β*,*ε*-carotene-3,3′-diol), violaxanthin (5,6:5′,6′-diepoxy-5,6:5′,6′-tetrahydro-*β*,*β*-carotene-3,3′-diol), and neoxanthin (5′,6′-epoxy-6:7-didehydro-5,6:5′,6′-tetrahydro-*β*,*β*-carotene-3,5,3′-triol) were isolated and purified from natural sources (*Capsicum annuum* and *Mentha arvensis*).[23] 5,8-Epoxy-carotenoids, such as mutatoxanthin (5,8-epoxy-5,8-dihydro-*β*,*β*-carotene-3,3′-diol), auroxanthin (5,8:5′,8′-diepoxy-5,8:5′,8′-tetrahydro-*β*,*β*-carotene-3,3′-diol), luteoxanthin (5,6:5′,8′-diepoxy-5,6:5′,8′-tetrahydro-*β*,*β*-carotene-3,3′-diol), and neochrome (5′,8′-epoxy-6,7-didehydro-5,6:5′,8′-tetrahydro-*β*,*β*-carotene-3,5,3′-triol) were prepared from the corresponding 5,6-epoxy parent pigments (antheraxanthin, violaxanthin, and neoxanthin) by controlled treatment with diluted HCl. Latochrome (5′,8′-epoxy-5,6,5′,8′-tetrahydro-*β*,*β*-carotene-3,5,6,3′-tetrol) and karpoxanthin (5,6-dihydro-*β*,*β*-carotene-3,3′,5,6-tetrol) were only tentatively identified due to the lack of pure standards. The tentative identification of *Z* isomers of lutein and mutatoxanthin was based on the presence and relative intensity ($\%A_B/A_{II}$) of the *cis* peak at about 330−340 nm in the UV−visible spectrum; a reduced fine structure and small hypsochromic shift in λ_{max} with respect to the all-*E* counterpart; and the chromatographic behavior in the C18 HPLC column, showing a slightly greater retention of *Z* than the all-*E* isomer.[28]

Carotenoid Analysis and Quantification by HPLC. Carotenoid pigments were analyzed by reversed-phase HPLC using a method previously developed[23] with slight modifications. Briefly, the method uses a C18 reversed-phase column (Mediterranea SEA18, 20 × 0.46 cm i.d., 3 *μ*m particle size; Teknokroma S.C.L., Barcelona, Spain) and a binary gradient elution system of acetone−deionized water at a flow of 1.0 mL/min. The mobile phase started at 75% acetone and rose linearly to 95% within 10 min and continued isocratically for 7 min, then changing to 100% within 3 min and maintaining this composition for 3 min. The injection volume was 10 *μ*L, and detection was carried out simultaneously at 402, 424, and 450 nm (1.2 nm spectral resolution and 10 scan/s scanning speed), to detect and quantify the diverse family of citrus carotenoids characterized as having different chromophores. The column and sample compartment were maintained at 25 and 15 °C, respectively. HPLC analyses were performed with a Waters 2695E Alliance quaternary pump equipped with a Waters 2998 diode array detector and were controlled with Empower2 data acquisition software (Waters Corp., Milford, MA, USA). Pigments were quantified in the saponified extracts by using calibration curves (six to eight concentration levels) prepared with standard stock solutions for each carotenoid in the concentration range of 5−100 *μ*g/mL. Calibration curves were constructed by plotting the peak area at 402 nm (for auroxanthin and *ζ*-carotene), 424 nm (for neochrome and luteoxanthin), and 450 nm (for mutatoxanthin, zeaxanthin, lutein, *β*-cryptoxanthin, and *β*-carotene) versus the pigment concentration. Latochrome and karpoxanthin were quantified by using the calibration curve of neochrome and zeaxanthin, respectively. The *Z* isomers were quantified by using the calibration curve of the all-*E* isomer. Concentration values were calculated as milligrams of pigment per liter of juice.

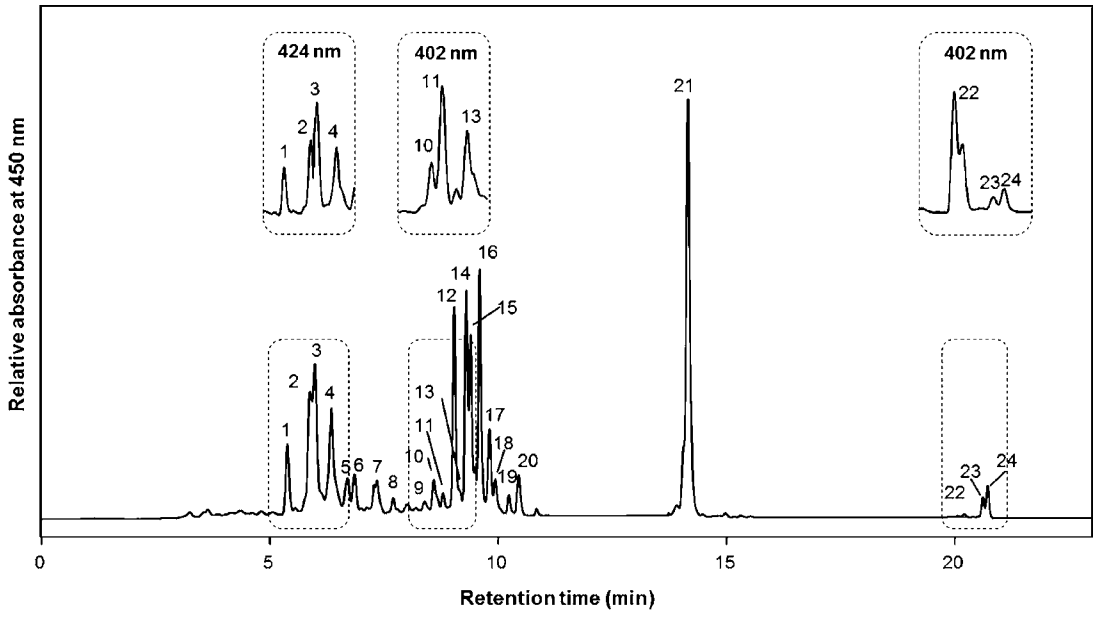

Figure 1. C18 reversed-phase HPLC chromatogram obtained for a saponified carotenoid extract prepared from the orange juice used for fermentation. See text for chromatographic conditions. Peak identification and characterization are given in Table 2.

[a]Tentative identification. [b]Britton et al.[6] [c]nd, not determined. [d]na, not available.

Provitamin A carotenoid content was expressed as retinol activity equivalents per liter of juice (RAEs/L) following the method of Scott and Rodríguez-Amaya,[29] with 1 RAE corresponding to 12 *μ*g of (all-*E*)-*β*-carotene or 24 *μ*g of *Z* isomers of *β*-carotene or any other carotenoid containing one unsubstituted *β*-ring.

Carotenoid Analysis and Quantification by Liquid Chromatography−Mass Spectrometry (LC-MS (APCI+)). LC-MS was performed by coupling a chromatographic system with a Micromass ZMD4000 mass spectrometer equipped with a single-quadrupole analyzer (Micromass Ltd., Manchester, UK) and an atmospheric

dx.doi.org/10.1021/jf404589b | J. Agric. Food Chem. 2014, 62, 842−849

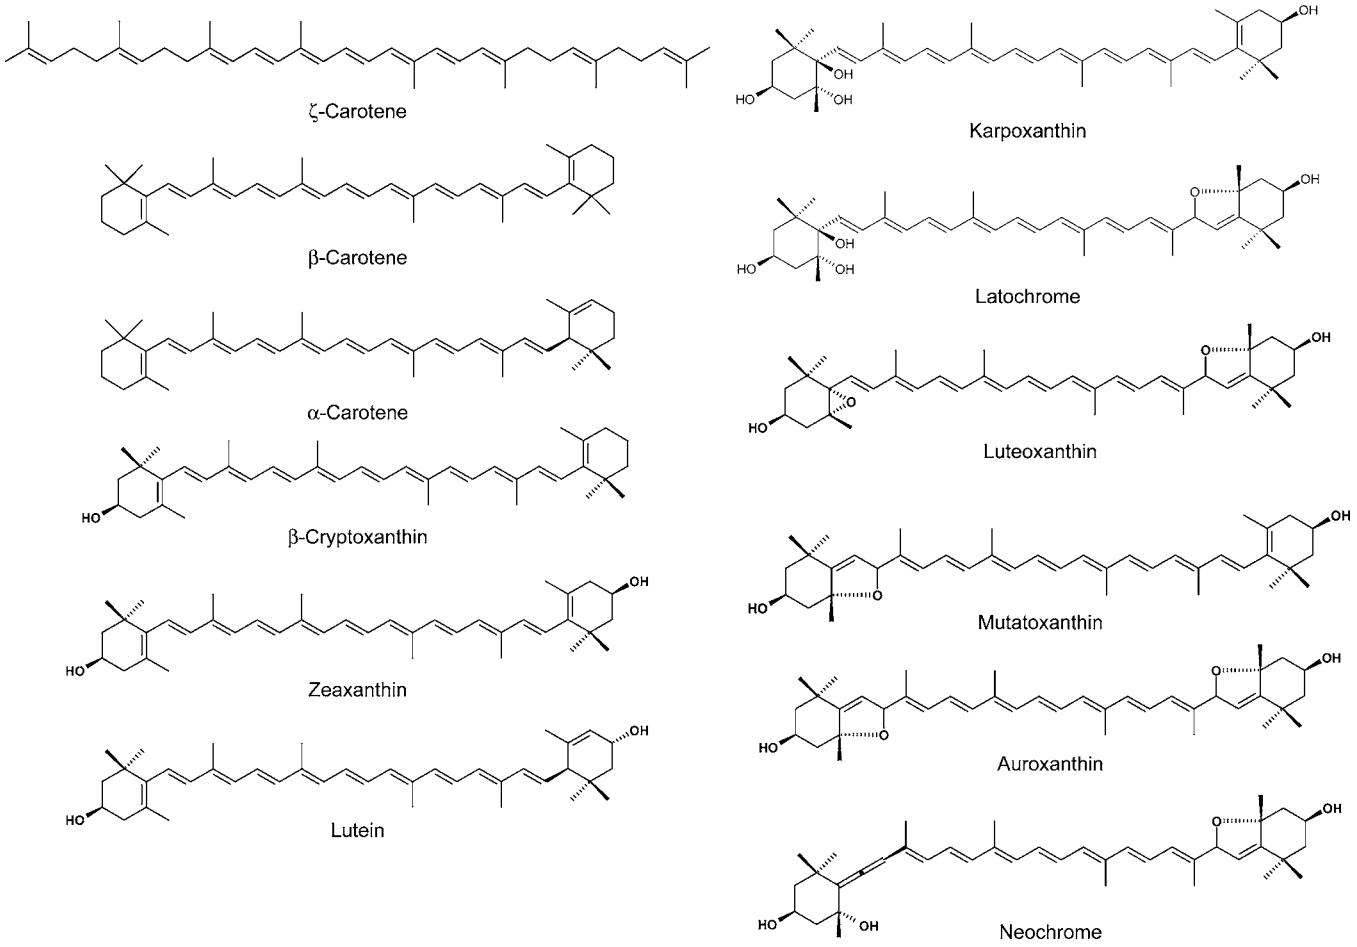

Figure 2. Chemical structures of the carotenoid pigments present in the orange juice used for fermentation.

pressure chemical ionization (APCI) probe. The system was controlled with MassLynx 3.2 software (Micromass Ltd., Manchester, UK). MS conditions were as follows: positive ion mode (APCI+); source temperature, 150 °C; probe temperature, 400 °C; corona voltage, 3.7 kV; high-voltage lens, 0.5 kV; and cone voltage, 30 V. Nitrogen was used as the desolvation and cone gas at 300 and 50 L/h, respectively. Mass spectra were acquired within the m/z 300−1200 range. The chromatographic conditions were as described above for carotenoid analysis and quantification.

Statistical Analysis. The fermentation process was performed in duplicate, and all samples were analyzed in triplicate. Results are expressed as the mean ± standard deviation. Analysis of variance (one-way ANOVA; Duncan's test) was applied to establish significant differences between the values of carotenoid and provitamin A carotenoid content obtained during the fermentation. A probability value of $p < 0.05$ was considered as the criteria for significance. These analyses were carried out by SPSS15.0 software (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Carotenoid Composition of Orange Juice Used in the Fermentation. Figure 1 depicts the chromatogram corresponding to the carotenoid profile present in the orange juice used in the fermentation process, and Table 2 summarizes the chromatographic and spectroscopic data (UV−visible and mass spectra). Twenty-two carotenoids, including some *Z* geometrical isomers, were identified in the saponified extracts of the orange juice. The carotene fraction was composed of *β*-carotene, *α*-carotene, and *ζ*-carotene, whereas the xanthophyll group was more complex, being composed of zeaxanthin, lutein, *β*-cryptoxanthin, and several carotenoids containing 5,8-epoxy groups in their structure (neochrome, mutatoxanthin, luteoxanthin, auroxanthin, and latochrome), which are respectively derived from neoxanthin, antheraxanthin, violaxanthin, and latoxanthin by the rearrangement of 5,6-epoxy groups under acidic conditions.[30] Figure 2 depicts the chemical structures of these pigments. Several geometric isomers corresponding to *Z* isomers of mutatoxanthin and lutein were also identified. Latochrome was only tentatively identified due to the lack of a pure standard. The $[M + H]^+$ value (m/z 619) was consistent with the formula $C_{40}H_{58}O_5$ (MW = 618.4284) and the presence of at least three to four hydroxy groups, explaining the higher polarity (shorter retention time) with respect to neochrome. The UV−visible absorption maxima at 401, 424, and 450 nm were in agreement with a chromophore of eight conjugated double bonds (as in the case of luteoxanthin) and with the presence of a 5,8-epoxy group, as supported by the negative results of the epoxide test. These data were in accordance with Meléndez-Martínez et al., who reported that numerous authors had erroneously identified latoxanthin (5′,6′-epoxy-5,6,5′,6′-tetrahydro-*β*,*β*-carotene-3,5,6,3′-tetrol) and its 5,8-epoxy derivative, latochrome, as neoxanthin in citrus fruit.[31] The presence of latochrome in orange juice was previously reported by Gross et al.,[32] but no further identification work has been carried out in this vegetable product. The UV−visible spectra of latoxanthin (417, 440, 468 nm, %I II/II = 95, in ethanol) and latochrome (398, 422, 448 nm, % III/II = 95, in ethanol) are highly similar to the spectra

dx.doi.org/10.1021/jf404589b | J. Agric. Food Chem. 2014, 62, 842–849

of neoxanthin (418, 442, 471 nm, % III/II = 85, in ethanol) and neochrome (398, 421, 448 nm, % III/II = 80, in ethanol), respectively. This similarity and their analogous chromatographic behaviors would likely explain the misidentification of these pigments in citrus fruit. For this reason, a complete experimental characterization is essential for their unambiguous identification. In addition, three peaks (eluting at 5.86, 6.31, and 6.87 min) with λ_{max} at 419, 443, and 472 nm (% III/II = 90) were detected, consistent with a chromophore of nine conjugated double bonds plus a β-end ring.[30] The negative epoxide test result and the shorter retention time with respect to the dihydroxylated xanthophylls (lutein and zeaxanthin) supported the tentative identification of these pigments as karpoxanthin (5,6-dihydro-β,β-carotene-3,3′,5,6-tetrol) isomers. Unfortunately, no mass spectra could be recorded for these minor chromatographic peaks. Nevertheless, given that latochrome is the 5,8-epoxy derivative of karpoxanthin, it can be conjectured that karpoxanthin was present.

Table 3 reports the carotenoid profile and content of the samples. In relation to the quantitative analysis of carotenoids in the orange juice, auroxanthin (1.39 mg/L; sum of three epimers) and β-cryptoxanthin (0.71 mg/L) were the most abundant xanthophylls among the 22 carotenoid pigments identified in this study. As mentioned before, auroxanthin derived from violaxanthin under the acidic conditions of orange juice. These observations were in agreement with previous studies reporting β-cryptoxanthin and violaxanthin as the major carotenoids in orange juice.[4,33] Luteoxanthin, the intermediate product between violaxanthin and auroxanthin, was detected in trace amounts. (all-*E*)-Zeaxanthin, ζ-carotene, and (all-*E*)-lutein were present at 0.40, 0.37, and 0.30 mg/L, respectively. Two epimers of mutatoxanthin (8*R* and 8*S*) were detected in orange juice with concentrations of 0.29 and 0.32 mg/L, which derived from antheraxanthin, their 5,6-epoxy precursor, originally present in the fresh juice. Geometric carotenoid isomers were detected in minor concentrations in orange juice, including (9*Z*)- and (13*Z*)-lutein and two (*Z*)-mutatoxanthin isomers, were found at concentrations ranging from 0.02 to 0.13 mg/L. The carotenoid composition of characterized orange juice was similar to other studies,[7] but comparisons of the carotenoid profiles of orange juices are notoriously difficult. Their composition depends on the variety of the fruit, climate, stage of maturity, industrial processing, and storage conditions, among other factors. Mouly et al. were able to use the carotenoid profile to identify the geographic origin (cultivation and/or production) of orange juice samples.[34]

Effect of Alcoholic Fermentation on the Carotenoid Composition of Orange Juice. A limited number of authors have evaluated the effect of fermentation on carotenoid composition in other fruits and vegetables, and the results reported are diverse. Fermentation of carrot slices resulted in carrot chips with higher α-carotene content.[35] Fermented sweet potatoes presented higher β-carotene concentration than the starting product.[36] Grape must showed increased neoxanthin, violaxanthin, and luteoxanthin contents and decreased α-carotene content during alcoholic fermentation.[37] Koh et al. did not find significant variation in lycopene content of tomato juice after fermentation.[38] The type of microorganism used and the duration of the fermentation process could explain these differences. In contrast, the influence of fermentation on the content of other bioactive compounds has been widely studied. Fermentation of onion led to an increase in flavononoid metabolites and its consequent biological activity enhancement.[39] Fermented chickpeas showed a higher total phenolic content than the unstarted product,[40] and fermentation of red sorghum increased the flavonoid content in the final product.[19]

Our results show that the carotenoid profile at the end of the fermentation process was similar to that of the nonfermented orange juice, with no apparent degradation and/or transformation of carotenoids associated with the processing (Table 3). Carotenoids containing 5,6-epoxy groups were already converted into the corresponding carotenoid 5,8-epoxy derivatives in the nonfermented juice due to the close contact of the pigments with the organic acids naturally present in the starting material (commercial orange juice). In addition, the fact that no increase in *Z* isomer content was observed during the fermentation suggests that the applied conditions were very smooth and did not affect the integrity of the pigment structures. Hence, the 5,8-epoxy carotenoids and *Z* isomers in the fermented orange juice would have been formed during the industrial production of the commercial orange juice, including the pasteurization. Auroxanthin (1.77 mg/L; sum of three epimers) and β-cryptoxanthin (0.85 mg/L) also were the most abundant pigments in fermented orange juice (at the end of the process). The sum of the epimers of mutatoxanthin reached a remarkable value of 0.76 mg/L. (all-*E*)-Zeaxanthin, ζ-carotene, neochrome, and (all-*E*)-lutein were quantified at similar amounts (0.47, 0.45, 0.46, and 0.36 mg/L, respectively). Karpoxanthin and one of its isomer reached a final content of 0.29 mg/L. The other pigments also were detected in minor concentrations (0.03−0.18 mg/L) in fermented orange juice, as in orange juice (Table 3).

As a general trend, the concentration of all individual carotenoids were significantly higher ($p < 0.05$) after 15 days of the fermentation processing with respect to the original juice. The total carotenoid content, expressed as the sum of individual carotenoid concentrations, showed a significantly higher value ($p < 0.05$) after the fermentation period (6.65 mg/L) when compared with the initial content (5.37 mg/L), these data being similar to those reported by Lee and Coates (5.70 mg/L).[41] Because de novo biosynthesis of carotenoids is not possible after the processing of orange juice, a feasible explanation for their apparent increase in concentration during fermentation may be due to the occurrence of some changes in the internal structure of the suspended solids, in which the pigments are integrated, enhancing their extractability during the analytical procedure. This aspect is of particular interest because it would indirectly indicate an increased bioaccessibility of the carotenoids in the fermented juice, so that further research should be carried out to confirm this hypothesis.

Carotenoids have been implicated in several biological processes including cardiovascular protection,[42] immune responses,[43] antioxidant activity,[44] or bone metabolism.[11] Humans need to acquire carotenoids through their diet because they are not able to synthesize them de novo.

According to our results, fermentation of orange juice induces an apparent increase of carotenoid content, so the fermented orange juice could be considered as a good source of these bioactive compounds and may have potentially beneficial effects already tested in orange juice. In addition, there is a remarkable presence of carotenoids with provitamin A activity (β-carotene, α-carotene, and β-cryptoxanthin) in the samples, because these compounds have also been assigned with important biological activities (antioxidant capacity, reducing the risk of atherosclerosis process).[44,45] The provitamin A value obtained in the present study for the starting orange juice

(75.32 RAEs/L) was similar to those reported by Meléndez-Martínez (9.69−94.8 RAEs/L) for different types of commercial orange juice marketed in Spain.[46] As observed for the individual carotenoids, provitamin A content was significantly higher ($p < 0.05$) in the fermented juice (at day 15 of processing) (90.57 RAEs/L) than in original substrate (75.32 RAEs/L) (Table 3). Some of the most relevant carotenoids with biological activities related with human health (lutein, β-cryptoxanthin, and β-carotene) showed a significantly higher content after fermentation, as indicated above. Consequently, the increase in the carotenoid extractability observed in the fermented orange juice should be considered as an advantage with respect to the original juice.

In summary, a potential novel beverage of fermented orange juice may be a rich source of carotenoids and provitamin A compounds, which could exert healthy effects similarly to the original orange juice. Moreover, the controlled alcoholic fermentation would be of great interest to the citrus industry due to the recent interest in the development of innovative practices to meet the demand for natural products rich in bioactive compounds by the consumer, in consonance with their increasing concern about diet and health. In vivo and intervention studies are currently being performed to evaluate the bioavailability of the bioactive compounds of this novel orange drink and its potential effects derived from both the bioactive compounds and the low alcoholic degree. Subsequently, the assessment of its sensory characteristics and consumer acceptance is also necessary.

Antioxidant Activity of Phenolics in Leaves of Three Red Pepper (*Capsicum annuum*) Cultivars

Woo-Ri Kim,[†] Eun Ok Kim,[†] Kyungsu Kang,[†] Sarangerel Oidovsambuu,[†] Sang Hoon Jung,[†] Byung Sup Kim,[‡] Chu Won Nho,[†] and Byung-Hun Um*[,†]

[†]Functional Food Center, Korea Institute of Science and Technology (KIST) Gangneung Institute, Gangneung 210-340, Korea

[‡]Department of Plant Science, Gangneung-Wonju National University, Gangneung 210-702, Korea

ABSTRACT: The antioxidant properties and phenolic profiles were first investigated in this paper on the leaves of three red pepper cultivars, Blackcuban (BCPL), Hongjinju (HPL), and Yeokgang-hongjanggun (YHPL). Of the ethanol extract of the three cultivars, BCPL showed potent antioxidant activities against the 1,1-diphenyl-2-picrylhydrazyl radical (DPPH) and the 2,2-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) radical. Nine antioxidative compounds from the red pepper leaves were isolated and identified as one polyamine phenolic conjugate, *N*-caffeoylputrescine (**1**); three chlorogenic acid derivatives, 5-*O*-caffeoylquinic acid (**2**), 5-*O*-caffeoylquinic acid methyl ester (**4**), and 5-*O*-caffeoylquinic acid butyl ester (**9**); one anthocyanin, delphinidin-3-[4-*trans*-coumaroyl-L-rhamnosyl(1→6)glucopyranoside]-5-*O*-glucopyranoside (**3**); and four flavone glycosides, luteolin-7-*O*-apiofuranosyl(1→2)glucopyranoside (**5**), luteolin-7-*O*-glucopyranoside (**6**), apigenin 7-*O*-apiofuranosyl(1→2)-glucopyranoside (**7**), apigenin-7-*O*-glucopyranoside (**8**). **1** and **3** had the greatest potential for radical-scavenging activity and HepG2 cells protecting effect against oxidative stress. BCPL exhibited the highest content of **1** and **3**. Of the three cultivars BCPL may be considered a good source of antioxidants.

KEYWORDS: *Capsicum annuum, red pepper leaves, phenolic compounds, anthocyanin, antioxidant effects*

INTRODUCTION

Recently, researchers have actively studied new sources to provide safe natural antioxidant additives for foods and cosmetics. This is, in part, because some synthetic antioxidants commonly used to preserve food and cosmetic base materials, such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), and *tert*-butylhydroquinone (TBHQ), are suspected to be toxic.[1] Thus, there is a need to identify newer antioxidants that can scavenge several free radicals and prevent multiple diseases, including cancer, atherosclerosis, diabetes, inflammation, and aging.[2,3] Natural antioxidants have become the target of many studies searching for sources of potentially safe, effective, and cheap antioxidants.[4]

Pepper (*Capcicum annuum* L.), belonging to the plant family Solanaceae, is the most highly consumed worldwide season-free vegetable. In Korea, it is the most important spice in food, as it is one of the most important ingredients in kimchi, which is a traditional fermented food.[5] The red pepper fruit contains a high amount of provitamin A (*β*-carotene and *β*-cryptoxanthin).[6] With respect to flavonoids, most studies have concentrated only on flavonoid aglycones (quercetin and luteolin) obtained after hydrolysis of red pepper fruits.[7]

Red pepper consumption and research have primarily focused on its fruits. Traditionally, however, red pepper leaves have also been eaten as cooked vegetables after blanching in hot water. Red pepper leaves can be a good source of food and cosmeceutical materials, including antioxidants. Recently, red pepper leaves have been reported to have antimutagenic, antioxidant, antimicrobial, and tyrosinase inhibitory activities.[8] In addition, two flavonoids, apigenin and apigenin 7-*O*-apiofuranosyl(1→2)glucopyranoside, have been identified in pepper leaves.[9]

The present research aimed to investigate phenolic compound profiles and antioxidant properties in the red pepper leaves of three cultivars, Blackcuban (BCPL), Hongjinju (HPL), and Yeokgang-hongjanggun (YHPL). The isolation and identification of phenolic compounds from the red pepper leaves of three cultivars, as well as the evaluation of antioxidant properties (through DPPH and ABTS radical-scavenging activity) and HepG2 cells protecting effects against *tert*-butyl hydroperoxide (*t*-BHP) induced oxidative stress are reported in this paper.

MATERIALS AND METHODS

Plant Materials. Leaves of three red pepper cultivars (BCPL, HPL, and YHPL) were obtained from the Department of Plant Science at Gangneung-Wonju National University in Gangneung, Gangwondo, Korea. Seeds of three red pepper cultivars were sowed and cultured in a glass house (20−30 °C) for 60 days. The cultured seedlings were transplanted on May 24, 2011, and cultivated in the fields under an experimental vinyl house (20−35 °C) of Gangneung-Wonju National University in Gangneung. After 90 days of cultivation, the full-grown leaves were collected. The fresh pepper leave samples were immediately stored at −20 °C until analysis.

General Procedure. 1,1-Diphenyl-2-picrylhydrazyl radical (DPPH), 2,2-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), and potassium persulfate for ABTS, as well as Folin−Ciocalteu's phenol reagent, trolox, quercetin, tannic acid, gallic acid, trifluoroacetic acid (TFA), and formic acid, were purchased from Sigma Chemicals (St. Louis, MO, USA). Analytical grade acetonitrile

and distilled HPLC grade water were purchased from Fisher Scientific (Pittsburgh, PA, USA). Column chromatography was performed over silica gel (Merck, Darmstadt, Germany), Sephadex LH-20 (Pharmacia, Uppsala, Sweden), and Amberlite XAD-7 (Sigma Chemicals). Sodium carbonate anhydrous (Na_2CO_2) and aluminum chloride ($AlCl_3$) were purchased from Shinyo Pure Chemical Co. Ltd. (Osaka, Japan).

UV−vis absorption spectra were measured on a Synergy HT Multimicroplate reader (Bio-Tek instrument, Winooski, VT, USA). The preparative HPLC separations were performed using a JASCO PU-2086 Plus pump, an MD-2015 detector, a Rheodyne injector with a 2 mL sample loop, and an FC204 fraction collector (Gilson Scientific Ltd., Luton, Bedfordshire, UK). ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were acquired on a Varian Unity INOVA 500 spectrometer for the 1D and 2D NMR experiments in CD_3OD. The chemical shifts are expressed in parts per million (ppm), and the coupling constants are in hertz (Hz). An Agilent LC-MS (Agilent Technologies, Waldbronn, Germany) equipped with UV detectors, quaternary pump, and quadrupole LC-MS 6120 was used with ChemStation as the operation system program.

Radical-Scavenging Activity (Offline Spectrophotometric $ABTS^+$ and $DPPH^+$ Assay). ABTS radical-scavenging activity of the test extracts and compounds were determined using an $ABTS^+$ decolorization assay according to the method of Argoti et al.[10] with minor modifications. To the ABTS liquid substrate system was added 2.45 mM potassium persulfate in a stoichiometric ratio of 1:0.5 (v/v). The mixture was allowed to stand in the dark at room temperature for 8 h. Then, the nine purified compounds (100 μL) were allowed to react with 100 μL of the ABTS radical solution. The reaction mixture was incubated for 5 min at room temperature in dark conditions, and the absorbance was measured at 734 nm. The change in absorbance with respect to the control (containing $ABTS^+$ solution only without the sample, expressed as 100% free radicals) was calculated as the IC_{50} value. The known antioxidants ascorbic acid and trolox were used as positive controls.

The free radical-scavenging activity of the test extracts and compounds were determined by the DPPH assay.[10] Briefly, the reaction mixture was contained in an ethanol solution of DPPH (100 μL) and purified phenolic compounds of three different concentrations (100 μL). The reaction mixture was incubated for 1 h at room temperature in dark conditions, and the absorbance was measured at 517 nm. IC_{50} values against three radical-scavenging activities were determined by regression analysis of the results obtained at three different concentrations of the sample. Ascorbic acid and trolox were used as positive controls.

Measurement of Total Phenolics and Flavonoids Content. Total phenolics was determined using the reported method.[11] A 20 μL sample aliquot of extract or gallic acid/tannic acid standard (50−500 μg/mL) was mixed with distilled water (1.58 mL) followed by 2 N Folin−Ciocalteau's reagent (20 μL). After the mixture had been vortexed and incubated at room temperature for 5 min, 20% sodium carbonate solution (100 μL) was added. Samples were vortexed and kept at room temperature for 30 min. Absorbance of the blue solution was recorded at 730 nm. The total phenolic content was expressed as milligrams of gallic acid equivalent (mg GAE/g) and tannic acid equivalent (mg TAE/g) per gram of sample.

Total flavonoid content was determined by the aluminum chloride colorimetric method using quercetin as a standard.[12] Briefly, the extracts were dissolved in EtOH. Then, the sample solution (100 μL) was mixed with an aqueous solution of 2% aluminum chloride (100 μL). After 5 min of incubation at ambient temperature, the absorbance of the supernate was measured at 435 nm. The total flavonoid content was expressed as milligrams of quercetin equivalents per gram of sample.

Screening of Antioxidant Activity with Online HPLC-ABTS System. To test the antioxidant activity of the extracts directly, the online HPLC-ABTS screening system was applied. This system consisted of an Agilent 1200 analysis HPLC system (Agilent Technologies, Santa Clara, CA, USA) fitted with an additional pump to supply the ABTS radical solution. For the ABTS radical reagent, a 2 mM ABTS stock solution containing 3.5 mM potassium persulfate was prepared in water and diluted 8-fold in HPLC grade water. This solution was incubated overnight in darkness at room temperature for radical stabilization. Antioxidant capacity was measured according to the previous method.[13]

Briefly, 10 μL of three cultivars of pepper leaf extract solutions was injected into the online HPLC-ABTS system. The individual compounds were separated with a column (Kromasil 100-5 C18, 250 × 4.6 mm, 5 μm) in the solvent system of 0.1% TFA in acetonitrile (A) and 0.1% TFA in water (B) with a 1 mL/min flow rate. The gradient conditions were as follows: 0−10 min, 20% A; 10−30 min, 20−50% A; and then returning to the initial conditions. The column was kept at 25 °C during the entire sequence. The ABTS radical solution was supplied with a flow rate of 0.5 mL/min. The chromatogram was recorded at 330 and 530 nm as a positive peak, and the visible detector was set at 734 nm to measure the decrease of ABTS radicals as a negative peak. The data were analyzed by ChemStation software (Agilent Technology).

Extraction and Isolation of Anthocyanin and Phenolics from Red Pepper Leaves. The leaves (1 kg) of three different red pepper cultivars were extracted three times with EtOH containing 0.1% HCl in a dark environment during 24 h at room temperature. The acidic ethanol solvent was evaporated under reduced pressure to afford the BCPL (76.10 g), HPL (49.99 g); and YHPL (45.27 g) extracts.

The BCPL extract was resuspended in water containing 0.1% HCl and was partitioned with *n*-hexane (*n*-Hex), methylene chloride (CH_2Cl_2), ethyl acetate (EtOAc), *n*-butanol (*n*-BuOH), and water (H_2O). All fractions were then concentrated in vacuo (*n*-Hex fraction, 11.1 g; CH_2Cl_2 fraction, 3.06 g; EtOAc fraction, 3.56 g; *n*-BuOH fraction, 29.69 g; H_2O fraction, 24.77 g). The EtOAc fraction was chromatographed by a preparative HPLC system (Waters prep-HPLC, Hydrosphere C18 column (250 × 20 mm, 5 μm)) eluting with an ACN/0.1% FA in H_2O (10:0 to 100:0, v/v) gradient condition. Three fractions were obtained as follows: A (0.31 g), B (0.16 g), and C (0.27 g). The A and B fractions were purified by the preparative HPLC system (JASCO PU-2086 Plus pump, MD-2015 detector); compound **4** (1.62 mg) and compound **9** (5.80 mg) were obtained, respectively. The C fraction was chromatographed by the preparative HPLC system to yield three subfractions (EA-C-1−EA-C-3). Subfractions EA-C-1 (60 mg), EA-C-2 (27.5 mg), and EA-C-3 (86.95 mg) were further chromatographed by the same purification procedure on preparative HPLC and yielded a pure compound **7** (3.37 mg) and compound **8** (80 mg). The purple *n*-BuOH fraction (3 g) was chromatographed for anthocyanin by Amberlite XAD-7 column chromatography eluting with acidic MeOH containing 0.1% HCl/H_2O (40:60 to 70:30) to yield two fractions (Bu-A and Bu-B). The Bu-B fraction (1.2 g) was chromatographed by the preparative HPLC system to yield two subfractions (Bu-B-1 and Bu-B-2). Subfraction Bu-B-1 (84.2 mg) was rechromatographed by Sephadex LH-20 column chromatography eluting with MeOH containing 0.1% TFA, and a pure compound **1** (21.76 mg) and compound **3** (32 mg) were separated.

The extracts of HPL and YHPL were not isolated as the same chemical components from the HPLC chromatogram, and the LC-MS data of HPL and YHPL as BCPL are presented in Figure 2. The YHPL extract was resuspended to isolate the compounds except for the same chemical components of BCPL in water. It was partitioned three times with *n*-Hex, CH_2Cl_2, EtOAc, *n*-BuOH, and H_2O. All fractions were then concentrated in vacuo (*n*-Hex fraction, 16.14 g; CH_2Cl_2 fraction, 5.76 g; EtOAc fraction, 1.7 g; *n*-BuOH fraction, 10.26 g; H_2O fraction, 14.0 g). The EtOAc fraction was purified by the preparative HPLC system, and compound **2** (56.66 mg) and compound **5** (7.83 mg) were obtained. The H_2O fraction (2 g) was fractionated using vacuum liquid chromatography with silica-C18. Elution was carried out successively with solvents of increasing nonpolar MeOH/H_2O (5:95 to 100:0, v/v) to afford compound **6** (4.08 mg).

Cell Culture and Cell Viability Assay. Human hepatoma HepG2 cells were obtained from the American Type Culture Collection (Manassas, VA, USA). HepG2 cells were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS, Hyclone, Logan, UT, USA), 100 units/mL penicillin, and 100 μg/mL streptomycin. The cells were cultured in a

humidified atmosphere of 5% CO_2 at 37 °C. For chemical treatments, HepG2 cells were cultured in DMEM without FBS to reduce direct interaction between the phytochemicals and FBS. Protective activities of the isolated compounds from the three pepper cultivar leaves against *t*-BHP-induced cell death were measured using the cell viability assay as previous described.[14]

Briefly, HepG2 cells (1×10^4 cells/well) were plated in 96-well plates and incubated for 24 h. Cells were then preincubated with the isolated (10−20 μg/mL) compounds from three pepper cultivar leaves and epigallocatechin gallate (EGCG, 10 μM) in serum-free DMEM for 24 h. Cells were washed with Dulbecco's phosphate-buffered saline (DPBS) and treated with *t*-BHP (250 μM) in serum-free DMEM for 3 h. Then, cell viability was measured using the EZ-Cytox Cell Viability Assay Kit (Daeil Lab Service, Seoul, Korea).

Quantification of Phenolics by HPLC. The nine phenolic compounds isolated from red pepper leaves of the three different cultivars were quantified by an HPLC method. HPLC analysis was performed with an Agilent 1200 HPLC system consisting of a binary pump (G1312A), autosampler (G1367B), diode array detector (G1315D), and degasser (D1379B). The separation of each compound was carried out on a Kromasil 100-5 C18 column (250 × 4.6 mm, 5 μm) with 1 mL/min flow rate in a solvent system of acetonitrile containing 0.1% TFA (A) and water containing 0.1% TFA (B). The gradient condition used was as follows: 0−10 min, 20% A; 10−30 min, 20−50% A; and then returning to the initial conditions. The chromatogram was detected at 330 nm. Calibration curves were constructed with each compound in a range of 0.1−1000 μg/mL. A high linearity ($r^2 > 0.999$) was obtained for each standard curve.

Statistical Analysis. Data were expressed as the mean ± standard deviation (SD). Statistical analysis included one-way analysis of variance (ANOVA) followed by Tukey's Honestly Significant Difference (HSD) test, and Pearson correlation test for correlation between variables were performed using IBM SPSS statistics 21. p values <0.05 were considered statistically significant.

RESULTS AND DISCUSSION

Radical Scavenging Activity of the Extracts of Three Red Pepper Cultivar Leaves. The antioxidative activities of the ethanol extracts from the pepper leaves of three different cultivars (BCPL, HPL, and YHPL) were evaluated by DPPH and ABTS assay with ascorbic acid and trolox as standards. As shown in Table 1, the DPPH radical-scavenging activity (IC_{50}) of BCPL was 49.2 ± 6.1 μg/mL, lower than that of YHPL (54.3 ± 4.5 μg/mL) or HPL (62.2 ± 3.4 μg/mL). Similarly, the ABTS radical-scavenging activity (IC_{50}) of BCPL was 26.2 ± 3.2 μg/mL, lower than that of YHPL (33.7 ± 3.9 μg/mL) or HPL (41.9 ± 3.1 μg/mL). Therefore, the order of antioxidant effects by radical-scavenging activity of the three red pepper leaves was BCPL > YHPL > HPL.

Table 1. Radical-Scavenging Activity of the Extracts of Three Pepper Cultivar Leaves[a]

	radical-scavenging activity IC_{50} (μg/mL)	
extract	DPPH	$ABTS^+$
BCPL	49.2 ± 6.1b	26.2 ± 3.2b
HPL	62.2 ± 3.4a	41.9 ± 3.1a
YHPL	54.3 ± 4.5ab	33.7 ± 3.9ab
ascorbic acid	1.3 ± 0.2c	0.3 ± 0.1c
trolox	1.6 ± 0.6c	0.3 ± 0.0c

[a]Values represent the means ± SD from triplicate experiments. Different letters in the same column denote a significant difference according to Tukey's test, $p < 0.05$.

Content of Total Phenolics and Total Flavonoids. Folin−Ciocalteu's assay is a frequently used screening method for the measurement of the antioxidant capacity of food products and dietary supplements. The total phenolic content of ethanol extracts from three red pepper leaves was assayed by the Folin-Ciocalteu method using gallic acid and tannic acid as standards, and the result is presented in Figure 1A. Total phenolic content of BCPL was the highest, 6.5 ± 0.8 mg GAE/g (6.4 ± 0.6 mg TAE/g), for fresh weight. HPL was found to be 4.4 ± 0.1 mg GAE/g (4.3 ± 0.1 mg TAE/g), and YHPL had the lowest at 4.3 ± 0.1 mg GAE/g (4.1 ± 0.1 mg TAE/g). Ku et al.[8] recently reported that the total phenolic content in pepper leaves of 13 commercial cultivars ranged from 2.31 ± 0.07 to 5.16 ± 0.09 mg GAE/g. These data are consistent with our results.

The total flavonoid content of three pepper leaves was evaluated by aluminum chloride colorimetric assay. The content was expressed as milligrams of quercetin equivalents (mg/g) of fresh weight. As shown in Figure 1B, total flavonoid content ranged from 2.4 ± 0.1 mg/g in HPL to 2.7 ± 0.2 mg/g in YHPL. However, no significant difference was observed among the three cultivars studied (BCPL, HPL, and YHPL). Thus, the order of total phenolics content of three red pepper leaves was found to be BCPL > HPL > YHPL. On the other hand, the order of total flavonoid content was found to be YHPL > BCPL > HPL.

Online HPLC−$ABTS^+$ Assays as Activity Guide. To investigate the major compounds and to measure their ABTS radical-scavenging activity, the ethanol extracts of the three red pepper cultivar leaves were subjected to the online HPLC−$ABTS^+$ screening system.[15] This methodology allows rapid pinpointing of antioxidants in complex mixtures through postcolumn mixing of separated analytes with radical solutions. The resulting reduction signal was detected as a negative peak by an absorbance detector (at 734 nm for $ABTS^+$ scavenging activity). After this online radical-scavenging screening of the extracts, it was easy to detect the active components present in each extract. Without isolation by the online HPLC−$ABTS^+$ assay system, peaks 1, 2, and 4 would have been easily overlooked because of their small quantity (Figure 2). These compounds were negligible in HPLC chromatogram at 330 nm, but it was very active in the online HPLC-$ABTS^+$ assay system. Hence, the online ABTS assay system was an efficient method for the purification of antioxidants based on activity-guided chromatographic separation and isolation from natural resources. As shown in Figure 2, the BCPL chemical components were almost similar to HPL, but YHPL was different from BCPL and HPL. In addition, the anthocyanin from the chromatogram at 530 nm existed only for BCPL. Therefore, this indicated that major and minor antioxidants (peaks 1−9) were isolated using preparative HPLC and open column chromatography.

Isolation and Identification of Anthocyanin and Phenolic Compounds. To identify peaks 1, 3, 4, and 7−9 of the HPLC chromatogram of the BCPL extract and peaks 1, 2, 5, and 6 of the HPLC chromatogram of the YHPL extract, we partitioned with *n*-Hex, CH_2Cl_2, EtOAc, *n*-BuOH, and H_2O. The EtOAc and *n*-BuOH fractions of BCPL and EtOAc and H_2O fraction of YHPL were subjected to silica gel RP-C18 chromatography and reverse phase preparative-HPLC. The resulting compounds **1**−**9** were isolated from BCPL and YHPL (Figure 3). Compounds **1**−**9** were characterized and identified by UV and ESI-MS, as well as 1D and 2D NMR. The spectral data of compounds **1**−**9** agreed with earlier published data: compound **1**,[16] compound **2**,[15] compound **3**,[17] compound **4**,[18]

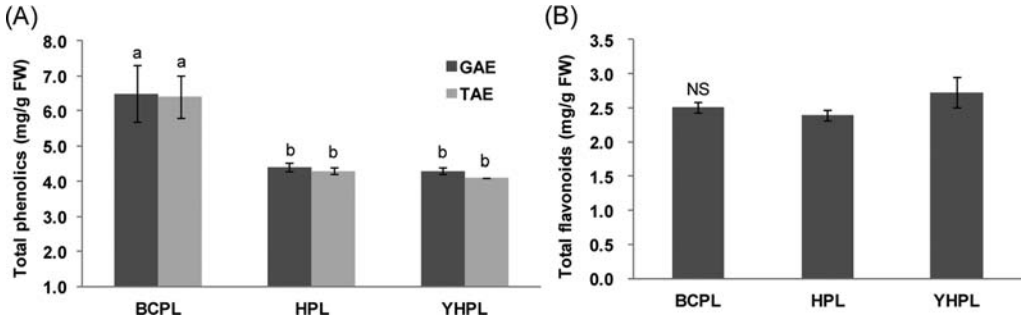

Figure 1. Total phenolic (A) and flavonoid contents (B) of three red pepper cultivar leaves. The total phenolic content was expressed as gallic acid equivalent (GAE) and tannic acid equivalent (TAE). The total flavonoid content was expressed as quercetin equivalents. BCPL, Blackcuban; HPL, Hongjinju; YHPL, Yeokgang-hongjanggun; FW, fresh weight. Each bar represent the mean ± SD from triplicate experiments. Different letters in the bar denote a significant difference according to Tukey's test, $p < 0.05$.

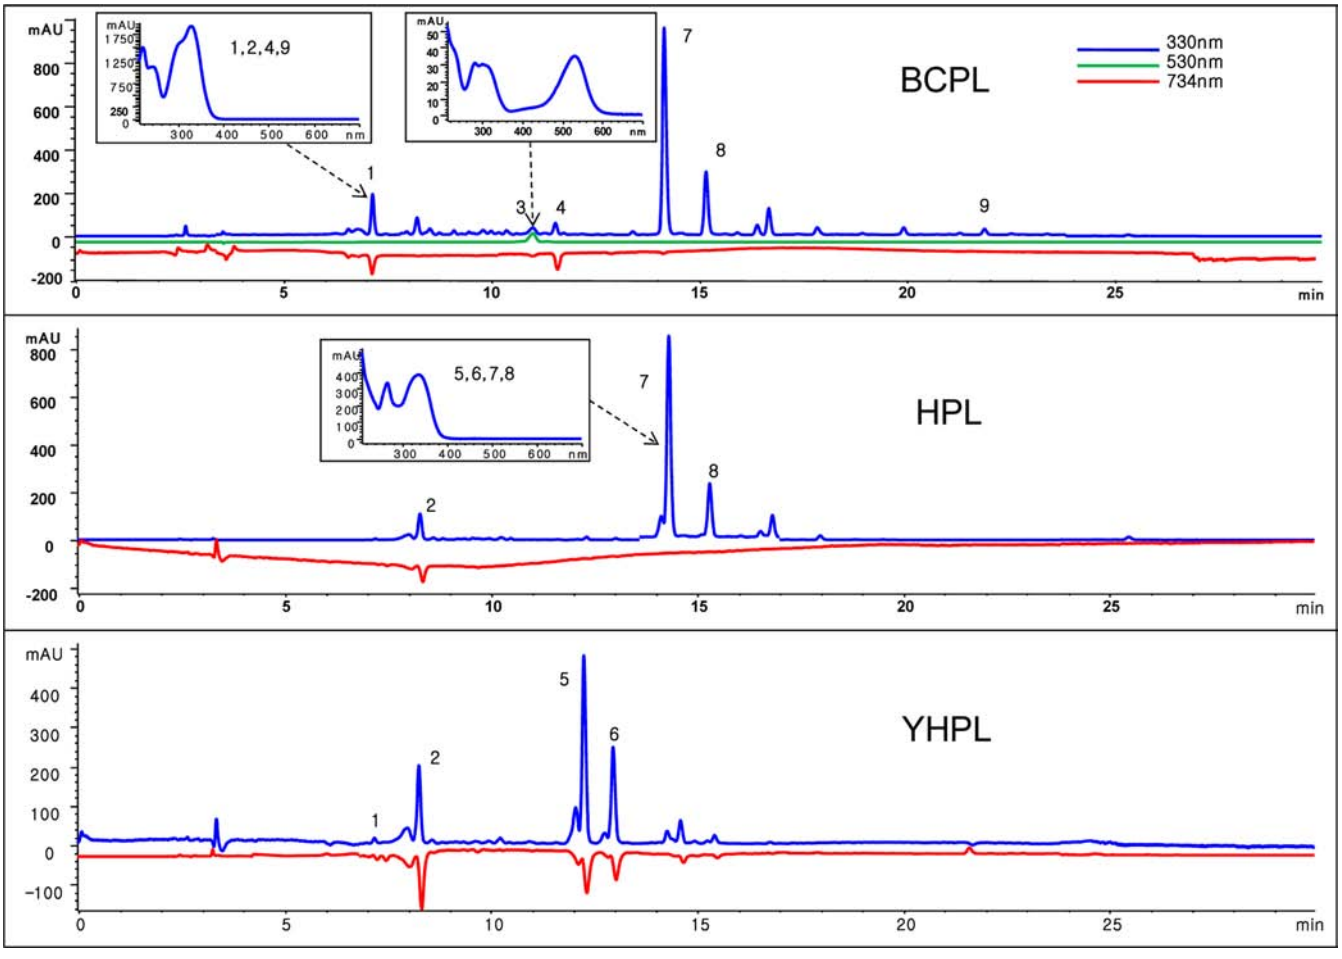

Figure 2. Chromatogram and UV spectrum of the online HPLC-DAD-ABTS screening system. The ethanol extracts from red pepper leaves of three different cultivars, Blackcuban (BCPL), Hongjinju (HPL), and Yeokgang-hongjanggun (YHPL), were analyzed with an HPLC system, and the eluates from the HPLC column were reacted with ABTS radical reagent. The analytes were detected at 330 and 530 nm as a positive peak, and their ABTS radical-scavenging activity was recorded at 734 nm as a negative peak.

compound **5**,[19,20] compound **6**,[21] compound **7**,[22] compound **8**,[13] and compound **9**.[21] The structural characteristics of isolated phenolics **1**−**9** are detailed below.

*N-Caffeoylputrescine (**1**):* apricot powder; ESI-MS *m*/*z* 251 $[M + H]^+$; ^{1}H NMR (500 MHz, CD_3OD) δ 7.39 (1H, d, J = 15.6 Hz, H-7), 7.00 (1H, d, J = 1.9 Hz, H-6), 6.90 (1H, dd, J = 8.2 Hz, 1.9 Hz, H-2), 6.76 (1H, d, J = 8.1 Hz, H-3), 6.37 (1H, d, J = 15.6 Hz, H-8), 3.34 (2H, d, J = 6.4 Hz, H-11), 2.96 (1H, t, J = 7.2 Hz, 7.2 Hz, H-14), 1.70 (2H, m, H-13), 1.63 (2H, m, H-12); ^{13}C NMR (125 MHz, CD_3OD) δ 169.6 (C-9), 148.9 (C-4), 146.8 (C-5), 142.4 (C-7), 128.1 (C-1), 122.2 (C-2), 118.2 (C-8), 116.4 (C-3), 115.0 (C-6), 40.5 (C-14), 39.6 (C-11), 27.6 (C-12), 25.9 (C-13).

*5-O-Caffeoylquinic acid butyl ester (**9**):* pale yellow powder; ESI-MS m/z 411 $[M + H]^+$; ^{1}H NMR (500 MHz, CD_3OD) δ 7.52 (1H, d, J = 15.9 Hz, H-7′), 7.04 (1H, d, J = 2.0 Hz, H-5′), 6.95 (1H, dd, J = 8.2 Hz, 2.0 Hz, H-6′), 6.78 (1H, d, J = 8.2 Hz, H-2′), 6.21 (1H, d, J = 15.9 Hz, H-8′), 5.26 (1H, m, H-3), 4.14 (1H, m, H-5), 3.75 (1H, dd, J = 7.0 Hz, 2.7 Hz, H-4), 2.22 (2H, d, J = 5.4, H-2), 2.17 (2H, m, H-9), 1.99 (2H, m, H-6), 1.61 (2H, m, H-11), 1.34 (2H, m, H-12), 0.89 (3H, t, J = 7.4 Hz, 7.4 Hz, H-13); ^{13}C NMR (125 MHz, CD_3OD) δ 175.0 (C-7), 168.1 (C-9′), 149.7 (C-4′), 147.3 (C-7′), 146.9 (C-3′), 127.6 (C-1′), 123.0 (C-6′), 116.5 (C-2′), 115.0 (C-5′), 114.9 (C-8′), 75.5 (C-1), 72.4 (C-4), 72.1 (C-3), 70.1 (C-5), 38.0 (C-2), 37.9 (C-6), 37.6 (C-9), 31.6 (C-10), 20.0 (C-11), 14.1 (C-12).

All of these compounds (**1**–**9**) were identified for the first time in this paper as constituents of pepper leaves, except for compound **7**.[9] Compound **1** has been found in the leaves of *Nicotiana tabacum* and yellow bell pepper,[16,23] and compounds **2**, **4**, and **8** have been isolated from *Ligularia fischeri* var. *spiciformis* Nakai, *Lonicera confuse*, *B. parviflora*, *Euphorbia ebracteolata*, and leaves of *Lonicera japonica*, *Erigeron breviscapus*, and *Sarcandra glabra*.[13,18] Compound **3** has been isolated from eggplant.[17] In addition, compound **5** has been isolated from celery seeds, celery husk, *Campanula patula*, *Centaurea cyanus*, hot pepper fruits, *Astragalus eremophilys*, and *Astragalus vogelii*,[24,25] and compound **7** has been isolated from *Crotalaria podocarpa*, *Conocaryum calleryanum*, and *Artabotrys hexapetalus* and leaves of *Capsicum annuum*.[9,22,26] Finally, compounds **6** and **9** have been isolated from the leaves of *Codonopsis nervosa* and *Elsholtzia rugulosa*, flowers of *Ligustrum lucidum*, and leaves of *Callicarpa nudiflora*.[21,27−30]

Antioxidant Activities of Anthocyanin and Phenolic Compounds Isolated from Three Red Pepper Cultivar Leaves. The antioxidant activities of the isolated compounds **1**−**9** were assayed using the different assay systems: (1) scavenging activity of free radicals based on chemical trapping using DPPH and ABTS assay methods; (2) protective activity of compounds against *t*-BHP-induced HepG2 cell death.

The free radical chain reaction is widely accepted as a common mechanism of lipid peroxidation. Radical scavengers may directly quench and react with peroxide radicals to terminate peroxidation chain reactions. Assays based upon the use of DPPH and $ABTS^+$ are the most popular spectrophotometric methods for the determination of the antioxidant capacity of foods, beverages, and vegetable extracts.[31] In the DPPH assay, the stable DPPH in alcoholic solution reduces to the yellow diphenylpicrylhydrazine due to the formation of the nonradical from DPPH by accepting an electron or hydrogen radical in the presence of an antioxidant. The DPPH radical-scavenging activities of nine phenolic compounds isolated from red pepper leaves are shown in Table 2. Most of the phenolic compounds significantly scavenged the DPPH radical in a dose-dependent manner. Among the nine phenolics, compounds **3** (IC_{50} = 3.5 ± 0.4 μM) and **1** (IC_{50} = 4.8 ± 0.0 μM) showed the highest DPPH free radical-scavenging activity, of which

Table 2. Radical-Scavenging Activity of the Phenolic Compounds Isolated from Red Pepper Leaves[a]

		radical-scavenging activity IC_{50} (μM)	
no.	compound	$DPPH^+$	$ABTS^+$
1	*N*-caffeoylputrescine	4.8 ± 0.0f	9.2 ± 0.8f
2	5-*O*-caffeoylquinic acid	37.0 ± 3.4d	68.1 ± 1.7bc
3	delphinidin-3-[4-(*trans*-coumaroyl)-L-rhamnosyl-(1→6) glucopyranoside]-5-*O*-glucopyranoside	3.5 ± 0.4f	4.4 ± 0.3f
4	5-*O*-caffeoylquinic acid methyl ester	20.4 ± 1.1e	38.0 ± 0.8e
5	luteolin-7-*O*-apiofuranosyl-(1→2)-glucopyranoside	18.8 ± 1.5e	76.2 ± 8.6b
6	luteolin-7-*O*-glucopyranoside	39.5 ± 4.7cd	61.4 ± 8.7cd
7	apigenin-7-*O*-apiofuranosyl(1→2) glucopyranoside	>200a	133.9 ± 3.0a
8	apigenin-7-*O*-glucopyranoside	153.7 ± 13.2b	63.9 ± 4.4cd
9	5-*O*-caffeoylquinic acid butyl ester	51.7 ± 0.7c	55.6 ± 0.5d
	ascorbic acid	7.4 ± 1.1f	1.7 ± 0.6g
	trolox	6.4 ± 2.4f	1.2 ± 0.0g

[a]Values represent means ± SD from triplicate experiments. Different alphabet letters in the same column denote a significant difference according to Tukey's test, $p < 0.05$.

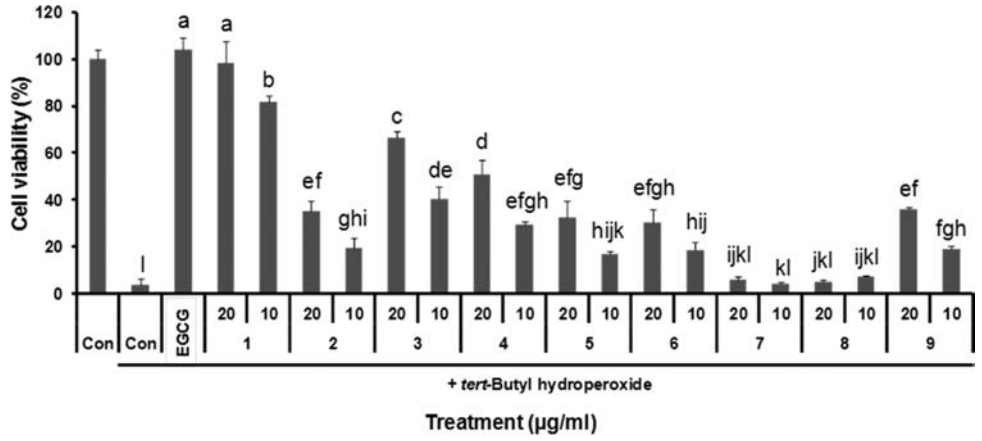

Figure 4. Protective effects of the compounds from pepper leaves against HepG2 cell death induced by *tert*-butyl hydroperoxide (*t*-BHP). Each bar represents the mean ± SD from triplicate experiments. Different letters over the bars denote a significant difference according to Tukey's test, $p < 0.05$. **1**, *N*-caffeoylputrescine; **2**, 5-*O*-caffeoylquinic acid; **3**, delphinidin-3-[4-(*trans*-coumaroyl)-L-rhamnosyl(1→6)glucopyranoside]-5-*O*-glucopyranoside; **4**, 5-*O*-caffeoylquinic acid methyl ester; **5**, luteolin-7-*O*-apiofuranosyl(1→2)glucopyranoside; **6**, luteolin-7-*O*-glucopyranoside; **7**, apigenin-7-*O*-apiofuranosyl(1→2)glucopyranoside; **8**, apigenin-7-*O*-glucopyranoside; **9**, 5-*O*-caffeoylquinic acid butyl ester.

activities were stronger than that of ascorbic acid (IC_{50} = 7.4 ± 1.1 μM) and trolox (IC_{50} = 6.4 ± 2.4 μM), but was not statistically significant. The scavenging activities of the remaining compounds were in the following order: **5** > **4** > **2** ≥ **6** ≥ **9** > **8** > **7**. The scavenging effects on the ABTS radical also showed marked differences according to the compounds (Table 2). Among them, the highest inhibition effects on the ABTS radical cation were found in compounds **3** (IC_{50} = 4.4 ± 0.3 μM) and **1** (IC_{50} = 9.2 ± 0.8 μM), similar to the results obtained from the DPPH assay. Meanwhile, the antioxidant effects for the ABTS radical scavenging of two phenolic compounds were lower than those of ascorbic acid (IC_{50} =1.7 ± 0.6 μM) and trolox (IC_{50} = 1.2 ± 0.0 μM), a well-known antioxidant. The scavenging activities of the remaining compounds were in the following order: **4** > **9** ≥ **6** ≥ **8** ≥ **2** ≥ **5** > **7**. In previous research, the radical-scavenging activities by DPPH assay of compounds **2**,[10] **6**,[11] and **8**[32] have been similarly reported with results of compounds isolated from pepper leaves as 54.8 ± 1.4, 37.9 ± 1.6, and 44.7 μM, respectively.

The in vitro ability to protect HepG2 cells from oxidative damage was evaluated for the isolated nine compounds (Figure 4). The protective effects of the compounds against oxidative stress were evaluated; *t*-BHP treatment for 3 h significantly decreased cell viability (3.8 ± 2.4%) compared to the control (100 ± 4.0%). Pretreatments using the compounds (10 and 20 μg/mL) increased cell viability in a dose-dependent manner. Particularly, compounds **1**, **3**, and **4** enhanced cell viability up to 98.3 ± 9.2, 66.4 ± 2.9, and 50.8 ± 6.1% at a concentration of 20 μg/mL, respectively. Table 3 summarizes the correlation between DPPH and ABTS radical-scavenging activity and HepG2 cells protective effect. A positive correlation ($p < 0.05$) was observed between DPPH and ABTS radical-scavenging activity, whereas a negative correlation ($p < 0.01$) was observed between DPPH and ABTS radical-scavenging activity and the protective effect of the compounds in the cell culture system. These results suggest that the cell protective effect was exerted through a radical-scavenging mechanism. Most of the phenolic compounds expected from compounds **7** and **8** isolated from red pepper leaves had potent protective effects against *t*-BHP-induced HepG2 cell death, as well as scavenging activity on DPPH and ABTS radicals. Therefore, **1** and **3** of the phenolic compounds included in red pepper leaves are potent free radical scavengers and may be considered an excellent source of antioxidants.

Table 3. Correlation of Bioactivities of Each Compound[a]

	correlation coefficient (*r*)		
	DPPH	ABTS	cell protective effect
DPPH		0.774*	−0.772**
ABTS			−0.832**
cell protective effect			

[a]Correlation is significant at (*) $p < 0.05$ level or (**) $p < 0.01$ level.

Phenolic Contents in Three Red Pepper Cultivar Leaves. The content of nine phenolic compounds in three red pepper cultivar leaves was determined by HPLC analysis. As shown in Table 4, red pepper leaves of different cultivars contain different ratios and types of polyphenols. The sums of identified phenolic compounds **1**−**9** of BCPL, HPL, and YHPL are 6.23 ± 0.68, 4.16 ± 0.15, and 2.76 ± 0.13 mg/g, respectively (Table 4), which correspond to the total phenolic contents of the three extracts (Figure 1). The most abundant phenolic compound found in BCPL was compound **7** (3.53 ± 0.28 mg/g fresh weight), representing approximately 57% of the total phenolics composition, followed by **3** (0.86 ± 0.01 mg/g) > **1** (0.77 ± 0.05 mg/g) > **4** (0.34 ± 0.16 mg/g) > **6** (0.04 ± 0.01 mg/g) > **5** (0.02 ± 0.00 mg/g), and **9** (0.02 ± 0.01 mg/g). Furthermore, the main phenolic compounds in HPL were **7** (3.28 ± 0.09 mg/g), **2** (0.36 ± 0.02 mg/g), and **8** (0.26 ± 0.01 mg/g), representing approximately 79, 8.7, and 6.3% of the total phenolic composition, respectively. In contrast to BCPL and HPL, the major phenolic compounds of YHPL were **5** (1.83 ± 0.09 mg/g) and **6** (0.37 ± 0.01 mg/g), representing 66 and 13.3% of the total phenolics, respectively, followed by **2** (0.26 ± 0.01 mg/g) and **1** (0.26 ± 0.02 mg/g) > **7** (0.06 ± 0.00 mg/g). Therefore, flavonoid **7** was the main component in BCPL and HPL, whereas flavonoids **5** and **6** were the predominant constituents in YHPL. Anthocyanin **3** was found only in BCPL.

Compound **3** was identified for the first time from pepper leaves. Anthocyanins have been categorized as the most important group of water-soluble natural pigment in crops

Table 4. Content of Phenolic Compounds in the Leaves of Three Red Pepper Cultivars[a]

cultivar	content (mg/g FW)									
	1	2	3	4	5	6	7	8	9	sum[b]
BCPL	0.77 ± 0.05a	nd	0.86 ± 0.01	0.34 ± 0.16	0.02 ± 0.00b	0.04 ± 0.01b	3.53 ± 0.28a	0.65 ± 0.16	0.02 ± 0.01	6.23 ± 0.68a
HPL	0.12 ± 0.02c	0.36 ± 0.02	nd	0.01 ± 0.00	0.10 ± 0.01b	0.03 ± 0.00b	3.28 ± 0.09a	0.26 ± 0.01	nd	4.16 ± 0.15b
YHPL	0.26 ± 0.02b	0.26 ± 0.01	nd	nd	1.83 ± 0.09a	0.37 ± 0.01a	0.06 ± 0.00b	nd	nd	2.78 ± 0.13c

[a]Values represent the mean ± SD from triplicate experiments. Different letters in the same column denote a significant difference according to Tukey's test, $p < 0.05$. FW, fresh weight; total, sum of nine compound contents; nd, not detected. **1**, *N*-caffeoylputrescine; **2**, 5-*O*-caffeoylquinic acid; **3**, delphinidin-3-[4-(*trans*-coumaroyl)-L-rhamnosyl(1→6)glucopyranoside]-5-*O*-glucopyranoside; **4**, 5-*O*-caffeoylquinic acid methyl ester; **5**, luteolin-7-*O*-apiofuranosyl(1→2)glucopyranoside; **6**, luteolin-7-*O*-glucopyranoside; **7**, apigenin-7-*O*-apiofuranosyl(1→2)glucopyranoside; **8**, apigenin-7-*O*-glucopyranoside; **9**, 5-*O*-caffeoylquinic acid butyl ester. [b]Values represent the sum of the phenolic components 1−9.

such as fruits, vegetables, and flowers.[33−35] These natural pigments are beneficial to the food industry due to their good properties as food colorants and beneficial human health effects, such as antioxidant, anti-inflammatory, anticancer, antidiabetic, and antiartherogenic properties.[11,33] Compound **2** is well-known as a treatment material for its antihistamine, antiviral, antioxidative activity, and DNA-protective activity.[13,36,37] Compound **6** is reported on for its antiproliferative, anti-LDL oxidative, and cytotoxic activity, as well as its gelatinase and collagenase inhibition, antifeedant activity, and anti-HBV activity.[38−43] Compound **7** is well-known as a treatment material for its anticomplement, anti-inflammatory, liver protection, and antibacterial activities.[44−46] Compound **8** is well-known as a treatment material as an antifungal, cytotoxic, antibacterial, and anti-HIV agent.[47−49] Finally, compound **9** is well-known as a treatment material due to its antibacterial nature.[50] Thus, they represent an effective antioxidant source for commercial food and pharmaceutical uses due to their content, disease treatment, and strong radical-scavenging activities.

Individual and total phenolic compounds showed significant differences in cultivars, and BCPL was observed to have the highest phenolic content for compounds **1** and **3**, as well as the highest antioxidant capacity (DPPH, IC_{50} = 49.2 ± 6.1 μg/mL; and ABTS, IC_{50} = 26.2 ± 3.2 μg/mL). On the basis of the above findings, it is suggested that strong antioxidant activities of BCPL of red pepper leaves were related with high contents of compounds **1** and **3**. These results indicate that compounds **1** and **3** may be important factors for the quality of red pepper leaves. Future studies are required to evaluate the various beneficial health effects of phenolic compounds isolated, as well as for red pepper leaves in vitro and in vivo.

ABSTRACT: The present study was conducted to evaluate the effects of early administration of *Lactobacillus fermentum* I5007 on intestinal development and microbial composition in the gastrointestinal tract using a neonatal piglet model. Full-term 4 day old piglets, fed with milk replacer, were divided into a control group (given placebo of 0.1% peptone water) and a *L. fermentum* I5007 group (dosed daily with 6×10^9 CFU/mL *L. fermentum* I5007). The experiment lasted 14 days. On day 14, a significant increase in the jejunum villous height (583 ± 33 vs 526 ± 18) and increases in the concentrations of butyrate (7.55 ± 0.55 vs 5.33 ± 0.39) and branched chain fatty acids in the colonic digesta were observed in piglets in the *L. fermentum* I5007 treatment ($P < 0.05$). mRNA expression of IL-1β (1.29 ± 0.29 vs. 0.62 ± 0.07) in the ileum were lower after 14 days of treatment with *L. fermentum* I5007. Denaturing gradient gel electrophoresis (DGGE) revealed that *L. fermentum* I5007 affected the colonic microbial communities on day 14 and, in particular, reduced numbers of *Clostridium sp.* *L. fermentum* I5007 play a positive role in gut development in neonatal piglets by modulating microbial composition, intestinal development, and immune status. *L. fermentum* I5007 may be useful as a probiotic for application in neonatal piglets.

KEYWORDS: *intestinal metabolism, Lactobacillus fermentum I5007, gut microbiota, neonatal piglets*

INTRODUCTION

Before birth, the gastrointestinal tract of the fetus is sterile, and during the initiation of the birth process and thereafter, acquisition of microbes is ongoing and time-dependent.[1,2] Many factors affect the composition of the microbiota in the intestinal tract before the gut finally gets a dense and stable population as an adult.[3] Early colonization with beneficial bacteria could help establish an effective ecosystem and bring about maturity in the physical structure of the gut.[4,5]

Probiotic and prebiotic administration during the neonatal period can improve gut function by improving the intestinal immune status and maintaining microbial balance during gastrointestinal disturbances.[5,6] Although progress has been made in disclosing the mechanisms through which probiotics act on the intestinal immunity and microbial composition of clinical models, knowledge about the interaction between probiotics and intestinal microbial metabolism, as well as microbial composition in healthy animals and humans, is lacking.

Lactobacilli are normal inhabitants of the gastrointestinal tract in humans and other mammals, and have been intensively studied during the past decades for their probiotic properties in both clinical and animal models.[7−9] *Lactobacillus fermentum* I5007 was initially isolated in our lab from the colonic mucosa of healthy weaning piglets, identified by the Institute of Microbiology Chinese Academy of Sciences (Beijing, China), and was shown to possess many characteristics of an excellent probiotic, including gastric acid and bile tolerance, high adhesion to CaCo-2 cells, competitive exclusion against pathogen invasion, and alleviation of weaning stress in piglets.[10−12] Our previous study has conferred the optimum dosage (about 10^{10} CFU/d *L. fermentum* I5007) for improving growth performance and diarrhea incidence in the neonatal period in piglets (data not published). However, the exact role of these lactobacilli in the intestine during the neonatal period in vivo is still unknown.

In contrast to rodent models, the size of the newborn piglet easily allows for clinically relevant nutritional interventions, and the ontogeny and anatomy of the gastrointestinal tract are more similar to those of human infants.[13,14] The present study evaluated the effects of an early introduction of an exogenous *L. fermentum* I5007 strain to gut metabolism and maturation, as well as the indigenous microbiota and their metabolic products, which will determine any implications of *L. fermentum* I5007 for pediatric nutrition.

MATERIALS AND METHODS

Chemicals. Rogosa Sharpe medium, Luria−Bertani agar, ampicillin, metaphosphoric acid, and peptone were all purchased from ZSGB-Bio Company (Beijing, China) while Agarose was provided from Gene Company LTD (Hong Kong, China). Skim milk, phosphate buffer saline, ampule, and hematoxylin−eosin were purchased from Huaxing-Bio Company (Beijing, China). Polyacrylamide gels, Tris-acetate-

EDTA buffer, formamide, and urea were obtained from Premedical Lab (Beijing, China).

Ethics Statement. The experimental protocol was approved by the China Agriculture University Institutional Animal Care and Use Ethical Committee (Beijing, China).

Bacterial Strain, Growth, and Storage Conditions. *L. fermentum* I5007 was cultured on sterile Man Rogosa Sharpe medium at 37 °C for 24 h in an anaerobic environment, followed by centrifugation at 5000*g* for 10 min at 4 °C. The cells were resuspended in reconstituted skim milk (20% w/v) and immediately freeze-dried. The freeze-dried powder containing 6×10^9 colony forming units (CFU)/g was stored in sealed packets at a temperature of 4 °C until used.

Piglets and Treatment. A total of thirty-six, full-term crossbred (Large White sires × Landrace dams) piglets obtained from four litters were used in this study. The piglets were delivered vaginally at the Langzhong Bei Pig Husbandry Training Farm (Beijing, China) and allowed colostrum for 48 h after birth. After colostrum consumption, the piglets were individually housed in stainless steel pens located over a totally slotted floor in a temperature (33 ± 1 °C) and relative humidity (65−70%) controlled room programmed to deliver a light:dark cycle of 16:8 h. On the third day of life, piglets were trained to suckle from bottles filled with milk replacer (Rosalac Instant, Bonilait Proteins, France, dry matter 89%, lactose 45%, protein 21.5%, fat 18.7%, ash 9.8%, lysine 1.7%; vitamins and minerals meet the nutrient requirements), and the milk replacer was dissolved in warm boiled water (w/v 1:4.5) to provide the same level of nutrients as sow-reared piglets. The fresh liquid milk replacer was fed to piglets individually from the feeder six times daily (2, 6, 10, 14, 18, and 22 h). The feeders were cleaned each time before adding the new fresh milk replacer, and the remaining milk was measured. The formula did not contain any antibiotics or other medicine.

On day 4 (equivalent to the first day of the experiment), piglets were allocated to one of two treatments (the *L. fermentum* I5007 group and the control group) balanced for litter of origin and body weight (initial body weight of 2.00 ± 0.31 kg). Each piglet in the *L. fermentum* I5007 group was orally administered 6×10^9 CFU *L. fermentum* I5007 dissolved in 3 mL of 0.1% of peptone water once a day for 14 days while the piglets in the control group were given the same volume of 0.1% peptone water.

Sample Collection. The health status was recorded for each piglet, and the occurrence of diarrhea was visually assessed each afternoon according to the method of Hart and Dobb.[15] Scores were 0 = normal, firm feces; 1 = possible slight diarrhea; 2 = definitely unformed, moderately fluid feces; or 3 = very watery and frothy diarrhea. The occurrence of diarrhea was defined as maintaining score of 3 for one day (monitor time: 10:00 a.m. and 16:00 p.m.). Diarrhea incidence was calculated according to the equation where diarrhea incidence (%) = n (numbers piglets of diarrhea) × days (the diarrhea duration)/n (the total number of experiment piglets) × days (the whole experiment days) × 100%.

After being weighed on the morning of the days 7 and 14 of the experiment (equivalent to 11 and 18 days of age), 6 healthy piglets closest to the average body weight balanced for litter of origin from each treatment were euthanized with electricity and their abdominal cavities were opened to remove the gastrointestinal tract. The small intestine was carefully dissected from the mesentery, and 2 cm segments were obtained from the jejunum (the middle of the small intestine). The intestinal segments were placed in neutral formalin for histological analysis. Additional segments 15 cm long, taken from the jejunum, were rinsed with cold 0.01 M sterile PBS (pH 7.4) and blotted dry on filter paper. Jejunal mucosa from the jejunum was obtained by gently scraping the mucosal layer using a glass microscope slide, 0.5 g of mucosal scrapings from each piglet was collected into a sterile Eppendorf tube (Axygen Inc., Union City, California), and 1 mL of 0.01 M PBS containing 2 mg/mL protease inhibitor supplied by the Huaxingbochuang Institute (Beijing, China) was added to each tube. Each sample was centrifuged at 3500*g* for 10 min at 4 °C after being homogenized (T10, IKA Works, Staufen, Germany). The supernatant was harvested and stored at −20 °C for analysis of disaccharidase activities. The colonic digesta were used for pH measurements and then gently squeezed into sterile Eppendorf tubes, frozen in liquid nitrogen, and subsequently stored at −80 °C until processing. Two digesta samples per treatment ($n = 6$) were randomly selected and pooled as three new samples (with equal wet weight) until needed for further genomic DNA isolation.

Intestinal Morphology and Enzyme Activities. Samples from jejunal segment were embedded in paraffin and cut into serial sections (5 μm). Five nonsuccessive sections of each sample were selected and stained with hematoxylin−eosin for identification. Five well oriented villi (determined as the distance between the crypt openings and the end of the villi) and their associated crypt (measured from the crypt-villous junction to the base of the crypt) per section were selected and measured under an Olympus Light Microscope (CK-40, Olympus, Tokyo, Japan) at 40× magnification. The means of these measurements were calculated to yield a single value per piglet. These procedures were conducted by an observer unaware of the treatment assignment. Myeloperoxidase (MPO), as an indicator of neutrophil infiltration, was determined in ileal segment on day 14. The activities of the disaccharidase (lactase, maltase, sucrase) and MPO were determined according to assay kit instructions (Nanjingjiancheng, Nanjing, China). One unit of specific MPO activity was defined as that degrading 1 μmol of hydrogen peroxide per min, and data were expressed as units of MPO per gram of tissue. The disaccharidase activities were expressed as units per milligram of protein, and the amount of protein of samples was determined using a commercially available bicinchoninic acid kit (Thermo, Rockford, IL, USA).

RNA Isolation and RT-PCR. Total RNA was isolated from the ileal segments using a RNeasy Mini Kit (Qiagen, Hilden, Germany). The purity was determined by the ratio of A_{260}:A_{280} using a NanoDrop spectrophotometer (P330, Implen, Germany), and then the quality was checked with 1% agarose gel electophoresis. The extracted RNA was converted into first-strand cDNA by reverse transcription of 1 μg of total RNA using a PrimeScript First Strand cDNA Synthesis Kit (Takara, Dalian, China) according to the manufacturer's protocol and stored at −80 °C. Real-time PCR was performed on an Applied Biosystems 7500 Real-Time PCR System (Applied Biosystems, Singapore) using SYBR Green PCR Master Mix (Takara, Dalian, China). The sequences of PCR primer for target genes were as follows: forward 5′-CCTCCTCCCAGGCCTTCTGT-3′, reverse 5′-GGGCCAGCCAGCACTAGAGA-3′ for IL-1β;[16] forward 5′-AGT-TTTCCTGCTTTCTGCAGC T-3′, reverse 5′-TGGCATCGAAGT-TCTGCACT-3′ for IL-8;[17] forward 5′-ATGGGCGACTTGTTG-CTGAC-3′, reverse 5′-CACAGGGCAGAAATTGATGACA-3′ for IL-10;[18] forward 5′-CCCAAGGACTCAGATCATCG-3′, reverse 5′-ATACCCACTCTGCCATTGGA-3′ for TNF-α;[16] forward 5′-CAT-CACCATCGGCAACGA-3′, reverse 5′-GCGTAGAGGTCCTTC-CTGATGT-3′ for β-actin.[19] Quantification of target mRNA was conducted using a relative standard curve generated by a serial dilution (1:10) covering the appropriate concentration range. The reaction was conducted in a total volume of 10 μL, and the process included predenaturation for 30 s at 95 °C, and then 40 cycles of 5 s at 95 °C, 30 s at 60 °C, and 40 s at 72 °C for the target genes. For the porcine β-actin gene, the annealing temperature was set at 58 °C. The relative gene expression was determined for the two treatments on day 14. All reactions were performed in triplicate. The mRNA expression is expressed as the ratio between the target gene and β-actin gene expression.

Colonic Short Chain Fatty Acid Concentrations and pH Value. The pH in the colonic digesta was determined for each sample, and the concentrations of short chain fatty acids were determined by a gas chromatographic method following the procedures of Franklin et al.[20] with modification. About 1.5 g of thawed digesta was suspended in 1.5 mL of distilled water in a screw-capped tube (Axygen Inc., Union City, CA). The entire sample was centrifuged at 15000*g* at 4 °C for 10 min. After that, 1 mL of suspernatant was transferred into an ampule and mixed with 200 μL of metaphosphoric acid (HPO_3). The ampules were placed in an ice bath for 30 min and then centrifuged again for 10 min. The sample was injected into a HP 6890 series gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a HP

19091N-213 column 30.0 m × 0.32 mm i.d. (Agilent, Palo Alto, CA. The injector and detector temperatures were 185 and 210 °C, respectively.

DNA Isolation, PCR-Denaturing Gradient Gel Electrophoresis (DGGE), and Identification of Fragments Extracted from the Gels. The extraction of DNA from colonic digesta for denaturing gradient gel electrophoresis was performed using a QIAamp Stool Mini-Kit (Qiagen, Hilden, Germany). The concentration of extracted DNA was measured using a NanoDrop spectrophotometer (P330, Implen, Germany). The bacterial universal V3 region of the 16S rDNA gene was amplified according to Muyzer et al.[21] The PCR products were analyzed by electrophoresis on 1.2% (w/v) agarose gel in SYBR Green I (Sigma, St. Louis, MO) to verify that a single product of the expected size was obtained.

DGGE was performed for separation of PCR amplicons in 8% (w/v) polyacrylamide gels with a vertical gradient of denaturants between 35 and 60% (100% denaturing solution was defined as 40% (v/v) formamide and 7 M urea). For each sample, the same concentration of DNA was loaded to one lane of the gel. Electrophoresis was initiated by prerunning for 5 min at 200 V and then for 16 h at 85 V in 0.5× Tris-acetate-EDTA buffer at a constant temperature of 60 °C in a DCode System Apparatus (Bio-Rad, Hercules, CA). The DGGE gel was stained by SYBR green I (Sigma, St. Louis, MO) for 15 min at room temperature, photographed with a Gel Doc XR$^+$ System (Bio-Rad, Hercules, CA), and analyzed with Quantity One Basic 4.6.6 Software for Windows (Bio-Rad, Hercules, CA).

Interesting bands in the DGGE profiles were excised with a sterile needle, reamplified, and purified with a Takara Mini Best DNA Fragment Purification Kit (Takara, Dalian, China) according to the manufacturer's protocol. The PCR products were cloned into the vector pMD-19T according to the manufacturer's instructions and transformed into *Escherichia coli* DH5α cells via chemical transformation. The transformants were grown on Luria−Bertani agar in the presence of 100 μg/mL ampicillin. The positive recombinants were screened and identified by PCR and sent for sequencing. Homology searches were performed using the BLAST program in the NCBI database (http://blast.ncbi.nlm.nih.gov/).

Statistical Analysis. Statistical analyses were performed using the Analysis of Variance (ANOVA) procedures of the Statistical Analysis Systems Statistical Software Package Version 8.02 (SAS Institute, Cary, NC). Each piglet served as an experimental unit. Differences at $P < 0.05$ were considered significant, and $P < 0.1$ was considered to be indicative of a trend.

RESULTS

Performance, Jejunum Morphology, and Enzyme Activities. The average daily weight gain during days 8 to 14 and the whole experiment period was 26.9% and 24.3% higher for piglets in the *L. fermentum* I5007 treatment compared with the control ($P < 0.05$, Table 1). Diarrhea incidence was lower in piglets fed *L. fermentum* I5007 compared with the control (1.19 vs 2.98%). During the second week, two piglets in the control treatment died on days 10 and 13 separately due to serious diarrhea.

Maturation of the intestine was assessed by changes in intestinal morphology and the activity ofthe disaccharidases, lactase, sucrase, and maltase in the jejunum (Table 2). In jejunum, villous height on day 14 was higher in *L. fermentum* I5007 piglets compared with the control piglets ($P < 0.05$), while disaccharidase activities on either day 7 or 14 did not differ due to treatment as well as the MPO activity in ileal segment on day 14.

Digesta Metabolites. Table 3 shows the concentrations of short chain fatty acids and pH values determined in the colonic digesta. Short chain fatty acid concentrations were not different between the two treatments measured on day 7. However, on day 14, the concentrations of branched chain fatty acids (isobutyric acid and isovaleric acid) and butyric acid were

higher in piglets fed *L. fermentum* I5007 than the control treatment ($P < 0.05$). Piglets treated with the *L. fermentum* I5007 tended to exhibited a lower pH ($P = 0.06$) on day 14 (6.27 vs 6.41).

Cytokine Expression. Both inflammatory and anti-inflammatory cytokines in the intestinal tissue were measured at the end of the experiment to assess the effects of feeding *L. fermentum* I5007 on modulations of the immune response (Figure 1). The expression of the inflammatory cytokine IL-1β

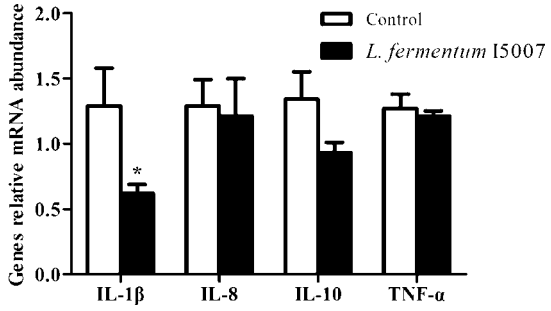

Figure 1. mRNA expression of relevant cytokines in ileal segments. Effects of the *L. fermentum* I5007 on IL-1β, IL-8, IL-10, and TNF-α mRNA expression in the ileal segment of piglets on day 14. Data are means ± SEM ($n = 6$). Significant differences between control and *L. fermentum* I5007 treated piglets: * $p < 0.05$.

mRNA was observed to be lower in piglets in the *L. fermentum* I5007 treatment compared with the control treatment ($P = 0.05$) on day 14. The expression of the anti-inflammatory cytokine IL-10 also tended to be lower in *L. fermentum* I5007 treated piglets ($P = 0.09$), while IL-8 and TNF-α mRNA expression did not differ between the two treatments (Figure 1).

Colon Microbiota Profiles Generated by PCR-DGGE and Sequence Analysis of DGGE Bands. Analysis of the DGGE fingerprints revealed no significant differences between the treatments in band numbers on day 7 or 14 of the experiment (Table 4). Simpson's index of diversity and Dice's

coefficient of similarity were not different on day 7. In contrast, Simpson's index of diversity and Dice's coefficient of similarity were increased in piglets in the *L. fermentum* I5007 treatment compared with the control treatment on day 14 ($P < 0.05$ Table 4). The bands which differed between the two groups were excised from the gels and their species identified by sequence analysis. The sequences of excised DGGE bands are available in the EMBL database under accession numbers HF559182−HF559188. These are summarized in Table 5. On

7	uncultured bacterium	98

day 7, high individual variation was observed compared with the profile shown on day 14 and the microbial populations became more similar within groups over time. Different bands between two treatments on day 14 were excised from the profile, and a relative decrease of the *Clostridium*-like phenotype was observed in the *L. fermentum* I5007 group. The *L. fermentum* I5007 strain could only be detected in the *L. fermentum* I5007 group (99% indentity with pure *L. fermentum* I5007 strain) and was not present in control piglets on either day 7 or 14 (bands 6, 8, Figure 2).

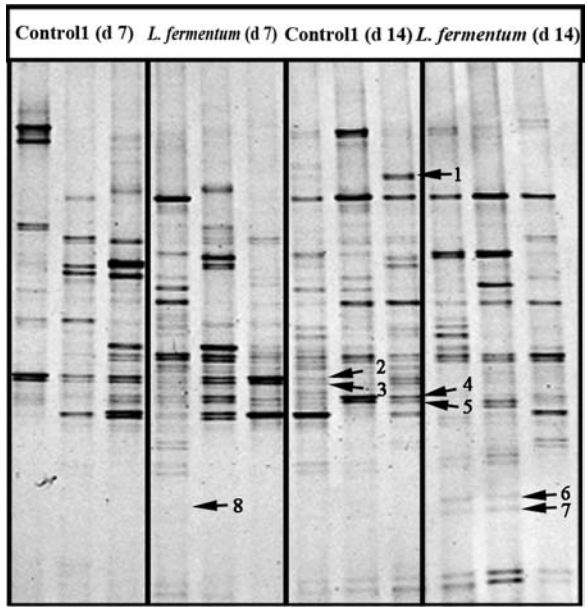

Figure 2. Bacterial diversity of the colonic microbiota of *L. fermentum* I5007 treated piglets and the control. DGGE fingerprints of PCR products of the V3 region of 16S rDNA from colonic digesta from piglets. Arrows (1 to 8) indicate excised bands that were different between the treated group and the control, followed by being reamplified (see Table 5); $n = 3$.

DISCUSSION

In the present study, neonatal piglets were selected as the model and the effects of *L. fermentum* I5007 were evaluated during a two-week intervention period. A significant increase in villous height in the jejunum was observed on day 14, indicating a certain rapid maturation of the intestines. The increase in villous height demonstrated improved architecture

dx.doi.org/10.1021/jf403288r | J. Agric. Food Chem. 2014, 62, 860−866

and active sites between the luminal digesta and the epithelium, which might result in an increased digestive and absorptive ability.[22] Siggers et al.[5] observed that a combination of probiotics supplemented into neonate formulas could increase the villous height. This result was also supported by the work conducted by Wang et al.,[12] which revealed that *L. fermentum* I5007 enhanced the level of mucosal proteins involved in energy metabolism, cell structure, and mobility in the jejunum in weaning piglets. The jejunum is the main organ for nutrient absorption, and therefore it is reasonable that the beneficial effects of *L. fermentum* I5007 could be mediated via improving the physiological structure of the jejunum. In the present study, lactase, maltase, and sucrase activities were not affected by *L. fermentum* I5007. Siggers et al.[5] also observed that a combination of probiotics supplemented into neonate formulas did not increase disaccharidase activities compared with the control. Our findings show that intervening with desirable microbes at an early age and shifting the microbiota toward a more beneficial composition is a good strategy to maintain a healthy gut and impact later succession of microbiota.[23,24]

To further illuminate whether the effects of *L. fermentum* I5007 were mediated through immune regulation, both pro-inflammatory and anti-inflammatory cytokine mRNA abundance were determined in ileum. IL-1β, mostly considered as a sensitive pro-inflammatory cytokine as the occurrence of host lesions,[25] was observed to have lower mRNA expression after 14 days of *L. fermentum* I5007 administration compared with piglets in the control group. However, myeloperoxidase, which has been considered related to inflammatory response, was not observed significantly different between the two treatments, which indicated that *L. fermentum* I5007 introduction did not irrigate disturbance in intestine. IL-10 is associated with T_{H2} cell or T_{reg} cell stimulation and usually is used as a marker for anti-inflammatory effects,[26] and it tended to be lower in the *L. fermentum* I5007 treatment, which was in accordance with the IL-1β expression, while IL-8 and TNF-α expression were not changed. Thus, the beneficial effects of exogenous strain of *L. fermentum* I5007 could be at least partly mediated via effects on immune modulation. In addition, our results were strengthened by some recent research related to the pathogen invasion in piglets that have been challenged.[27,28]

Short chain fatty acids are the major end products from the fermentation processes of gut microbiota in the large intestine and play an important role in the maintenance of colonic function such as improving barrier function, inhibiting adherence of pathogens, and contributing to energy utilization.[29−32] It is known that changes in the concentration and proportion of individual short chain fatty acids are consistent with changes in bacterial populations.[33−37] Our results showed that oral administration of *L. fermentum* I5007 not only increased the concentration of butyrate and the branched chain fatty acids but also decreased *Clostridium* strains accompanied by a lowered pH in the colonic digesta, which were consistent with the findings conducted by Hu et al.,[35] who found that increase in butyrate-producing bacteria or probiotics as *L. fermentum* can be related to the reduction of *Clostridiales sp*. Butyrate has been proved associated with positive effects on pathogen control and gut barrier function,[38,39] especially colonic energy utilization, cell proliferation in the gastrointestinal tract, and stabilization of the luminal pH in rodent animals.[36,38−41] Recently, via in vivo experiments, it also has been reported that butyrate is capable of reducing the incidence of *Clostridium spp.* and coliform induced opportunistic infection, and the reduction of these opportunistic putrefactive bacteria has been suspected of reducing the probability of pathophysiology disorders.[38,42] Thus, it is reasonable to assume that the growth performance and intestinal health were also improved via impact on intestinal metabolism. However, the exact role and its pathway of the branched chain fatty acids are still poorly understood.

The microbial ecosystem in the colon is complex and sophisticated.[33] *L. fermentum* I5007 administration increased Simpson's index of diversity measured using DGGE analysis. This revealed that the population got more complex and diverse by supplementation of the *L. fermentum* I5007 strain. A more diverse population could allow a more stable ecology when facing environmental disruptions.[43,44] This may be the potential reason for the low incidence of diarrhea in the *L. fermentum* I5007 treatment. In addition, the increase in Dice's coefficient of similarity within the *L. fermentum* I5007 treatment in the second week indicated that the microbial profile within this group tended to be more uniform. However, the whole profile revealed that administered *L. fermentum* I5007 could only make a minor change in the total microbial population. These findings were supported by the work conducted by Fuentes et al.[45] and Rauch and Lynch,[6] both of whom observed that administration of lactobacilli could shape the gastrointestinal niche and facilitate colonization by a diversity of beneficial bacterial species, but not alter the overall bacteria structure.

After *L. fermentum* I5007 was introduced, no statistical differences were observed between the two groups for any parameters measured during the first week. We speculated that it would take more than one week for the introduction of the exogenous strain to fully interact with the bacterial community for the newborn piglets. The development of the gut microbiota after intervention should be regarded as a gradual and complex process, not only as a succession in the ecological sense but influenced by microbial and host interactions, including strain adhesion, colonization, and proliferation as well as bacterial-host communication.[3,46] In addition, due to the immature gut in neonates, the intestinal environment may have undergone turbulence and high dynamics while establishing a new and steady profile. Here the results showed that the profiles were more uniform on day 14 compared with day 7, and the microbiota and concentrations of metabolic products in piglets in the *L. fermentum* I5007 treatment were significantly different from those in the control on day 14. Furthermore, *L. fermentum* I5007 was found in the treated group on days 7 and 14 in colonic digesta, which demonstrated that *L. fermentum* I5007 can tolerate the gastric acid and bile from the small intestine and inhabit the lower gastrointestinal tract. The above-mentioned findings suggest that *L. fermentum* I5007 exerts its function promptly after initial introduction, but the significant changes in microbial composition and metabolism were time dependent and occur during the following week.

In conclusion, our study indicated that after early introduction of *L. fermentum* I5007, the structure of the neonatal piglets' microbial composition and their metabolism as well as immune status could be manipulated, while promoting communities more resilient and putatively beneficial to gut homeostasis. The effects are exerted at an early stage following introduction, which suggests that *L. fermentum* I5007 could be used as a probiotic for application in the neonatal period in piglets. As for the limitations of the study, in our opinion, increased amount of experimental animals will help to reduce

the impact of individual differences among animals; in addition, further research will be performed to reveal the mechanism of *L. fermentum* I5007 favors on intestinal development.

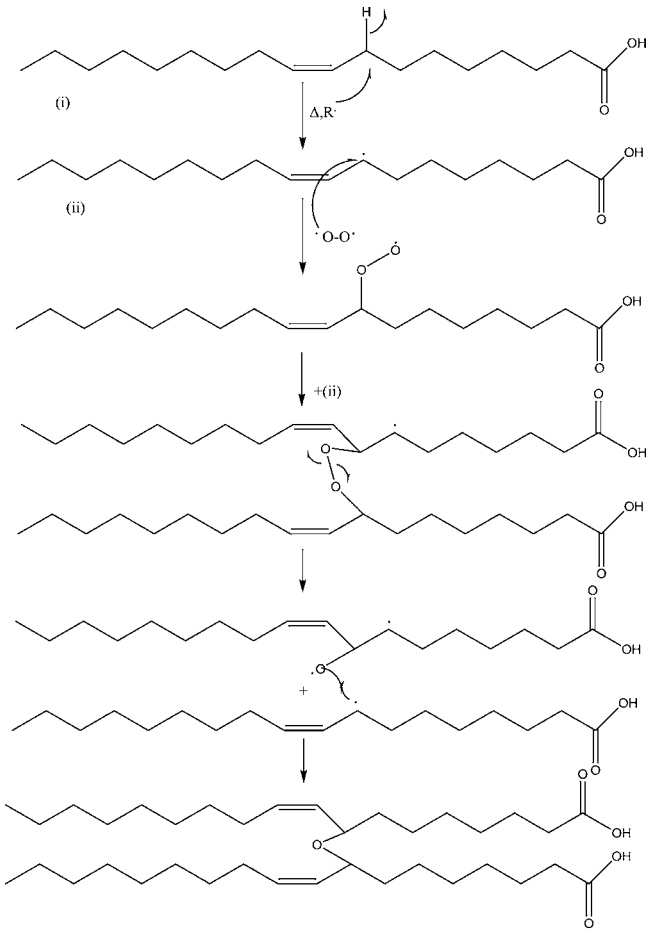
termination process can involve combination reactions of the resulting free radicals including production of ether dimers.

Oleic acid (OA), a monounsaturated 18-carbon fatty acid, is the major ingredient of virgin olive oil or any other type of olive oil, and a free radical mechanism for thermal dimerization/oligomerization is very plausible when OA is the starting material. An example of a possible autoxidation mechanism is shown below, with an ether linkaged dimer (PM1) as an end product.



PM1

Many different structural isomers are possible as a result of head-to-head or head-to-tail alignment of the starting material, as well as many possible positional and geometrical isomers of the double bond.[10]

It has previously been shown that virgin olive oil becomes a strong hemagglutinin against human red blood cells when heated open in air. The dimer of oleic acid has been characterized as one of the major molecules responsible for the effect.[7,9] In this paper an effort is made to investigate if any other byproduct molecules, formed as a result of the virgin olive oil heating process, are associated with hemagglutination abilities and to characterize them structurally.

MATERIALS AND METHODS

Materials. HPLC grade solvents and fatty acids were obtained from Sigma (St. Louis, MO, USA). The lipid standards were obtained from Larodan Fine Chemicals (Malmo, Sweden).

Hemagglutination Assays. Human red blood cells (RBCs) were washed twice with 1 mM phosphate-buffered saline (0.85%)−0.01% sodium azide (pH 7.4). The hemagglutination assays were performed as previously discussed by Patrikios et al.[9] The plates were read at half-hour intervals by observing the bottoms of the wells. The first row of wells served as control. Hemagglutination activity was recognized as the settling of cells in contrast to flowing in the control wells. Titer is expressed as the highest dilution of test samples that still gives agglutination. Specific titer is defined as titer per milligram lipid per milliliter.

Thin-Layer Chromatography. Silica gel G plates (20 × 20 cm) (Macherey-Nagel, GmbH & Co., Germany) were prewashed in the developing solvent system (heptane/diethyl ether/acetic acid, 55:45:1, v/v/v) and activated by heating for 1 h at 120 °C under vacuum (15 mm). Sample (20−30 μg, 0.5 mg/mL in chloroform/methanol (1: 1 v/v)) was spotted onto silica gel plates using 2 mL Microcap pipets (Blaubrand, Germany). The plates were dried using a hand-dryer (cool setting) for 5 min before development. The chromatography chamber was saturated with solvent system vapor for 30 min before development of plates. The plates were developed until the solvent front was about 2 cm from the top, removed and air-dried for 30 min, and visualized in iodine vapor. For sample extraction from the plates the bands were visualized by a strip exposed to iodine. Each band was scraped off and eluted with chloroform/methanol (1:1 v/v).[11]

Heated Extra Virgin Olive Oil Preparation. Virgin olive oil was heated at 130 °C (an average cooking temperature) for 24 h in a metal heating block (USA/Scientific, Olala, FL, USA) in glass tubes open to air. Standard oleic (OA) and ricinoleic acid (RA) (Sigma) were also treated as above.

Preparation of Extra Virgin Olive Oil Dispersions. Dispersions were prepared by diluting the samples to 0.5 mg/mL PBS-N. The lipid extract dispersions were filtered through LC PVDF Acrodisc membranes (0.2 μm, Gelman) to remove particulate matter.

Table 1. R_f Values of the Components of OA, RA, and Virgin Olive Oil, Unheated and Heated (24 h at 130 °C), on Silica Gel TLC Plates in Isooctane/Isopropyl Alcohol/Acetic Acid (95:5:1, v/v/v)

	R_f values of components[a]

		0.31		7.5×10^2
		0.25		7.3×10^2
			0.19	1.0×10^3

[a]Identification of the components of the fractions was by comparison with R_f values of the components of standard commercial monomer, linear dimer, and trimer (Emery). [b]The concentration was approximately 0.5 mg/mL. Specific titer is defined as titer per mg lipid per mL. [c]The R_f value of the heated OA monomer differs from the R_f value of the nonheated OA monomer because the molecular structure is affected during heating at 130 °C for 24 h (mostly at the double-bond position in the fatty acid chain), probably due to formation of positional and/or geometrical isomers.

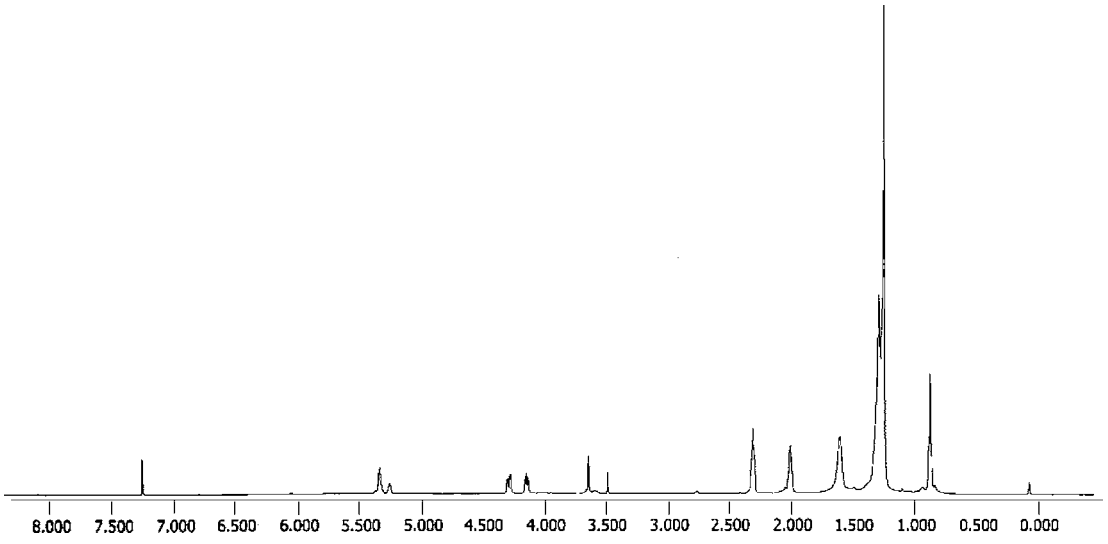

Figure 1. ^{1}H NMR spectrum of virgin olive oil sample heated at 130 °C for 24 h open in air and esterified with CH_2N_2. The ester was obtained in $CDCl_3$ solvent at ambient temperature using an INOVA Varian 600 MHz spectrometer.

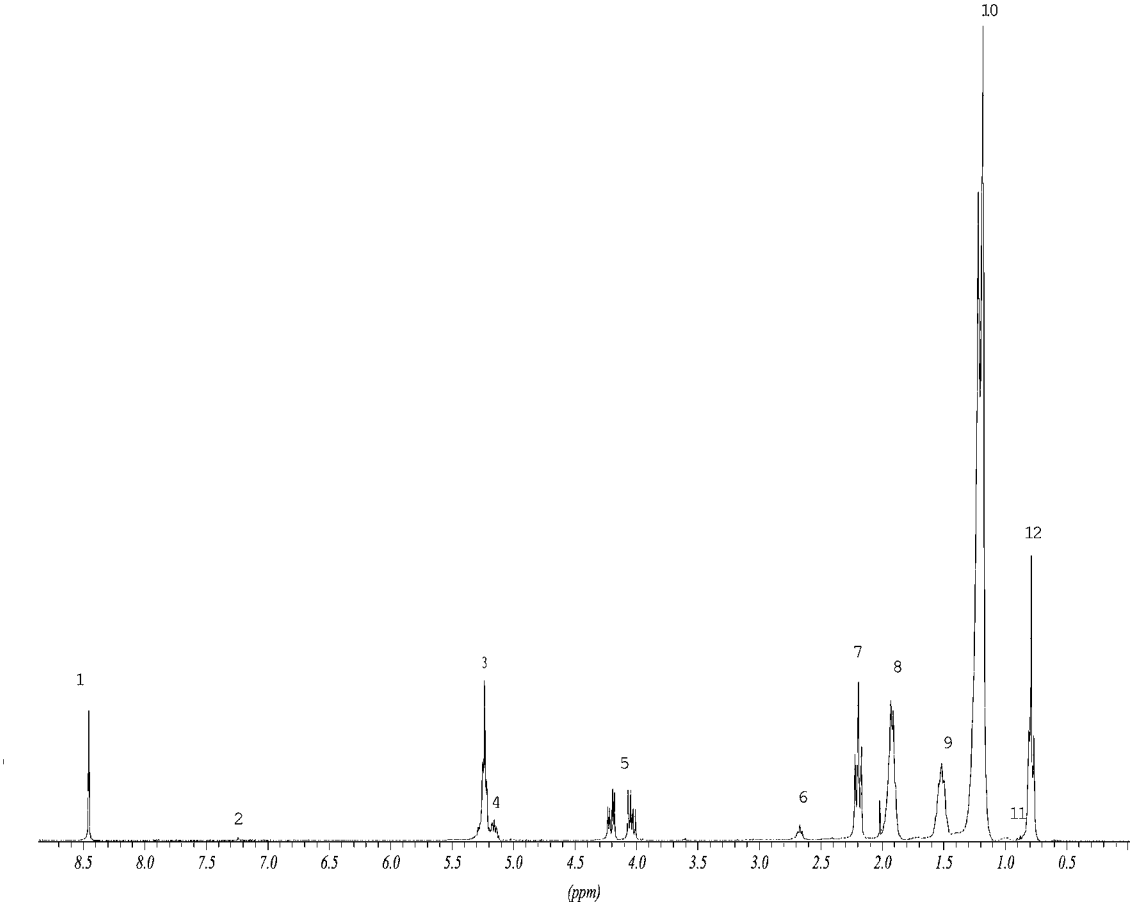

Figure 2. ^{1}H NMR spectrum of refined virgin olive oil in $CDCl_3$ solvent. The spectrum was obtained at ambient temperature using a Bruker 300 MHz spectrometer.

Synthesis of Fatty Acid Methyl Esters. The methyl esters were prepared according to a standard protocol.[9]

Light Microscopy. A Cytovision Analyzer (Applied Image Co) was used for photographs, attached to a microscope (Zeiss Axioskop). Agglutinated cells were taken from microtiter plates that were titered and allowed to develop for approximately 30 min. The following preparations were used: (1) untreated human RBCs; (2) active lipid extract from heated virgin olive oil (1 mg/mL); (3) unheated virgin olive oil preparations (1 mg/mL). All samples were dissolved in PBS-N. Fresh human RBCs were washed once with citrate because the cells retain their shape much better in citrate than in PBS and, therefore, allow better photographs to be taken. It should be noted that cells washed in citrate will maintain their integrity for only approximately 2 h.

Nuclear Magnetic Resonance Spectroscopy. $CDCl_3$ (99.5%) ampules were purchased from Merck (Darmstadt, Germany) and ultraprecision NMR tubes from Peypin (France) and Wilmad 535-5 mm

(Spintec-Rototec). The high-resolution spectra in $CDCl_3$ were obtained using Bruker 300 AC and Varian INOVA 600 instruments. All data were collected using pulse sequences and phase cycling routines provided in the Bruker and Varian libraries of pulse programs. ^{1}H NMR spectra in the Bruker instrument were recorded using the following acquisition parameters: pulse width (PW), 3.0 μs; spectral width (SW), 2513 Hz; data size (TD), 32K; recycling delay (RD), 1.0 s; number of transients (NS), 16; and digital resolution, 0.076 Hz pt^{-1}. DQF-COSY and ^{1}H−^{13}C HSQC spectra experiments were performed with gradients at 600 MHz. The ^{1}H sweep width was 9820 at 600 MHz. Typically homonuclear proton spectra were acquired with 4096 data points in t_2, 16−64 scans, 256−512 complex points in t_1, and relaxation delay of 1−1.5 s. Data were processed and analyzed with the v-NMR software package from Varian. Spectra were zero-filled two times and apodized with a square sine-bell function shifted by $\pi/2$ in both dimensions. The ^{1}H−^{13}C HSQC spectrum was recorded with 1024 data points in t_2, 16 scans per increment, 128 complex points in t_1, and a relaxation delay of 1 s. The ^{13}C spectral width was 20000 Hz.

Mass Spectrometry. Mass spectra were obtained with a TSQ 7000 Finnigan MAT spectrometer using electron spin ionization (ESI) and spray voltage (4.5 kV). The sheath gas pressure (N_2) during the experiment was 35 psi and the capillary temperature, 200 °C. Samples were dissolved in a mixture of $CH_3OH/CHCl_3$.

RESULTS AND DISCUSSION

The approach by which oils and foodstuffs in general are manufactured, processed, cooked, and used affects their nutritional value and safety.

Many studies in the literature have discussed the oxidation products of olive oil. In 2002 Patrikios and in 2003 Patrikios et al. reported the hemaglutinating properties of oxidation and thermal degradation products of lipid extracts isolated from heat-processed foodstuffs including virgin olive oil.[8,9] In the present study we focused on the molecular structure of another possible specific molecule that is possibly formed in the virgin olive oils under the above conditions and which promotes hemagglutinating activity with human RBCs.

Thin-layer chromatography on silica gel, in a system that discriminates by the number of carboxyl groups (free fatty acids are released from glycerol after the sample heating preparation process), was used to resolve the components of the heated virgin olive oil (Table 1). Bands were cut out, eluted, and titered against human RBCs. The identification of the components of the fraction was carried out by comparison with R_f values of the components of a heated sample of oleic acid, ricinoleic acid (RA), and standard commercial monomer, dimer and trimer (Emery). A portion of byproducts in the heated virgin olive oil sample showed the same R_f values as the corresponding R_f values of the monomeric, oligomeric, and polymeric byproducts of the heated sample of OA, RA, and the commercial oligomers. As reported by Patrikios, this might be the result of hydrolysis, which can take place under heat processing in air, of the triacylglycerols,

releasing oleic acid, which after free radical formation and oxidation can result in dimerization, oligomerization, and polymerization.[9] The TLC shows two spots with slightly different R_f values for dimers. One of the dimer molecules with

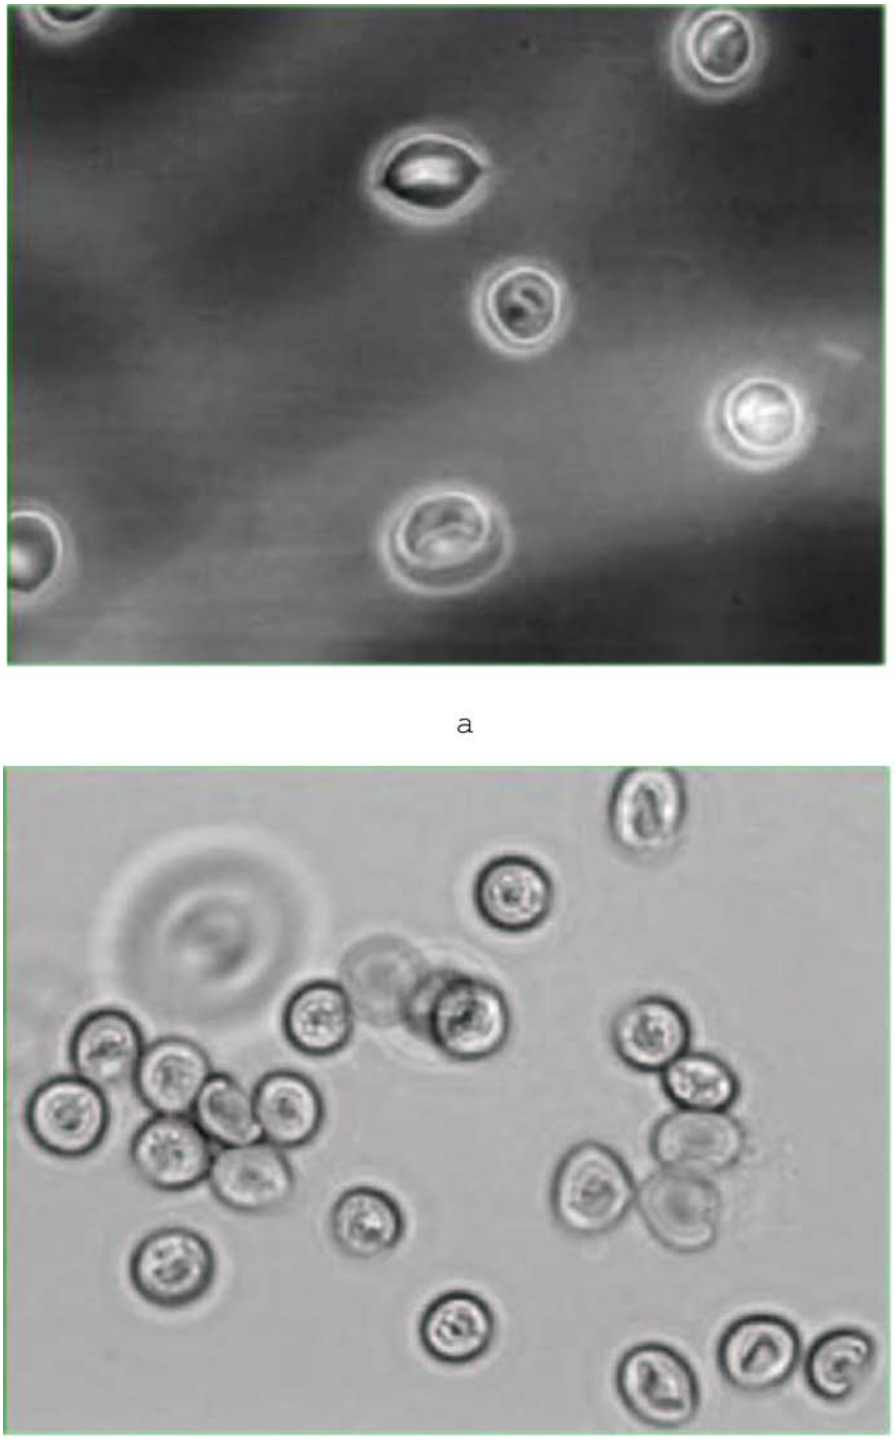

Figure 5. Light micrographs of human erythrocytes in citrate buffer (pH 7.4): (a) with unheated virgin olive oil; (b) with the isolated virgin olive oil oligomer preparation (1.0 mg/mL).

R_f 0.31 was characterized by Patrikos et al. as a linear dimer of oleic acid (dioleyl), dimerized by −C−C− linkage.[9] This dimer was shown to be associated with strong hemagglutinating properties against human RBCs. The second dimer formed with R_f 0.25 is now characterized as an ether-linked unsaturated dimer and is also shown to be associated with hemagglutinating properties against human RBC.

A spot with about the same R_f is observed when commercial RA was treated under the same conditions (Table 1). The ^{1}H NMR spectrum of the compound is shown in Figure 1. To characterize it, several ^{1}H NMR spectra from virgin olive oil samples originated from different countries were obtained. A representative one is shown in Figure 2. The sample was run in $CDCl_3$ and using a known amount of pyrazine in case a

PM2

quantitative result was necessary. This method was developed in two previous publications by Mavromoustakos et al.[12,13]

As can be observed in the representative spectrum shown in Figure 2, the peaks are almost identical with those reported by Sacchi et al. and are shown in Table 2.[14] All olive oils analyzed were missing the peaks in the region of 3.5−3.7 ppm observed for the sample under investigation. We made an effort to characterize these peaks. First, we have drawn several plausible structures and used NMR databases to simulate the spectrum. A compound that gave a ^{1}H NMR spectrum similar to the experimental was PM2 (esterified).

The peak at 3.5 ppm corresponds to a methoxy group, whereas the peak at 3.65−3.7 ppm corresponds to C<u>H</u>−O−CH. HSQC experiment is in agreement with this assignment. C−H correlation between the two critical peaks at the region of 3.5−3.7 ppm and the corresponding peaks centered at 50 ppm were observed in HSQC spectrum (Figure 3). ^{13}C NMR spectra of virgin olive oils are lacking peaks in the region of 50 ppm (Figure 4 and Table 3), in agreement with data obtained by Sacchi.[14] The 2D COSY spectrum showed a correlation between the assigned peaks as C<u>H</u>−O−C<u>H</u> with C<u>H$_2$</u> as expected.

Panels a and b of Figure 5 show human RBCs that were mixed with unheated virgin olive oil and with the isolated oligomer preparation, respectively. As seen in Figure 5b, mixtures of chains and rosettes were observed by light microscopy (LM), but no lysis or fusion was apparent. Agglutination was found to involve cell clumping and to be time-dependent. The agglutination activity, which we observed, most likely is due to a partial insertion of the dimer/oligomer formed into red cell membrane in a way that links red cell without affecting membrane dynamics and permeability properties.

ESI mass spectroscopy of the oligomer isolated from the heated sample of virgin olive oil after methylation suggests the possible existence of the proposed dimer, an acyclic "hydro" dimer that contains two *cis* and/or *trans* double bonds and ether linkages at the 8, 9, 10, and 11 carbons between two aliphatic (hydrocarbon) chains. The interpretations of all major peaks in the Figure 6 mass spectrum are shown in Table 4. In particular, the peak at 637.5 has a molecular weight very close to that of PM1 + CH_3OH (CH_3OH was used as a dilution solvent along with $CHCl_3$). The peak at 549.5 is 88 units smaller and may correspond to a dimer without two positively charged ions of m/e 88 $2[CH_3C{=}OH]^+$. Interestingly, the most intense peaks observed in the spectrum differ from the ones with higher m/e by 44.

dx.doi.org/10.1021/jf403745x | J. Agric. Food Chem. 2014, 62, 867−874

We concluded that virgin olive oil can undergo oligomerization through free radical mechanism of the oleic acid and autoxidation when heated at 130 °C for 24 h open in air. Subsequently, dioleyl or oligomers are formed by a direct linkage of the accumulated free radicals or by an intermediated peroxy radical formation (through autoxidation reaction).[7] Thus, when virgin olive oil is consistently heated open in air it can possibly undergo nutritional damage with a possible direct but as yet unknown effect on human health.

AUTHOR INFORMATION

Corresponding Author

*(I.S.P.) Mail: School of Medicine, European University Cyprus, 6 Diogenes Street, 2404 Engomi, P.O. Box 22006, 1516 Nicosia, Cyprus. Phone: 00-357-99097856. E-mail: i.patrikios@euc.ac.cy.

Author Contributions

Both authors interpreted the data. I.S.P. drafted the report tables and figures, and all authors critically revised and approved the final version. I.S.P. was responsible for the laboratory experiments, and T.M. was responsible for the NMR and GC-MS experiments. Both I.S.P. and T.M. performed the literature search, and both contributed to the structural elucidation of the active molecule and the rationale of the involved biochemical mechanisms. Both authors vouch for the accuracy and completeness of the data, and both authors read and approved the final manuscript.

Funding

This work was supported by a grant from the Research Promotion Foundation of Cyprus, RPF 06/99.

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

We thank the Cyprus Institute of Neurology and Genetics for hosting the project. We also acknowledge E. Siapi for obtaining MS spectrum and Simona Golic Grdadolnik, who obtained some of NMR spectra. We especially thank Elsa Tsartsidou for her contribution in the preparation of the tables.

The mammalian target of rapamycin (mTOR) is one of the major growth regulatory pathways controlled by AMPK. The mTOR pathway plays a major role in proliferation, angiogenesis, and metastasis of NSCLC and other cancers. The target on mTOR signaling pathways is extensively investigated for cancer chemotherapy including NSCLC.[10] Moreover, AMPK controlled lipid metabolism at transcriptional and post-translational levels. AMPK phosphorylates and inactivates metabolic enzyme acetyl-CoA carboxylase (ACC) that is involved in regulating de novo biosynthesis of fatty acid and cholesterol. Phosphorylated ACC led to the decrease of malonyl-CoA levels, thus stimulating mitochondrial carnitine palmitoyltransferase 1 (CPT1) and promoting fatty acid oxidation. Moreover, AMPK inhibits transcription factor SREBP1c, which controls the entire fatty acid synthetic pathway or directly inhibits the expression of fatty acid synthase (FASN).[11]

Rhododendron formosanum Hemsl. (Ericaceae) is an evergreen broad-leafed tree native to Taiwan and ubiquitously distributed from 800 to 2000 m. The vegetation exhibits a unique pattern and forms pure dominant vegetation.[12,13] We studied whether *R. formosanum* exhibited pharmacological activities for NSCLC and investigated its bioactive phytochemical constituents. Our results indicated that treatment of NSCLC cells with *R. formosanum* had a very potent inhibitory effect on cellular growth.

MATERIALS AND METHODS

Materials. The leaves of *R. formosanum* were collected after flowering in April 2010 and July 2010 at the Dasyueshan site (24°14′6.49″ N, 120°57′7.29″ E at 1911 m asl). Ursolic acid, oleanolic acid, betulinic acid, 4′,6-diamidino-2-phenylindole (DAPI), 3-[4,5-dimethylthylthiazol-2-yl]-2,5-diphenyltetrazolium (MTT), and propidium iodide (PI) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). The antibody for LKB1 was purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Primary antibody against phospho-AMPK (Thr 172), AMPK, Bcl-2, Bax, caspase-9, caspase-3, FASN, phospho-ACC (Ser 79), mTOR, phospho-mTOR (Ser 2448), and phospho-p70S6k (Thr 389) were purchased from Cell Signaling Technology (Beverly, MA, USA). β-Actin antibody was purchased from Sigma Chemical Co. HRP-conjugated goat anti-rabbit IgG and goat anti-mouse IgG were obtained from Millipore (Billerica, MA, USA). Methanol (MeOH), *n*-hexane, dichloromethane (DCM), *n*-butanol (BuOH), and ethyl acetate (EA) were purchased form Seedchem Co. (Melbourne, Australia). Silica gel 60 was purchased from Merck KGaA (Darmstadt, Germany).

Plant Collection, Chemical Extraction, and Isolation. The leaves of *R. formosanum* were air-dried for chemical analysis. The air-dried and powdered leaves of *R. formosanum* (5.5 kg) were extracted with MeOH for 3 days at room temperature (three times), and the combined extracts were concentrated in vacuo (under 35 °C) to obtain a dark green gum (1540 g), which was suspended in H_2O and partitioned sequentially with DCM, EA, and BuOH. The EA extract (3.5 g) was subjected to column chromatography on silica gel using *n*-hexane, *n*-hexane−EA, and EA−MeOH mixtures of increasing polarity for elution to furnish 10 fractions.

Quantification of Ursolic Acid, Oleanolic Acid, and Betulinic Acid in RFL-EA-2 and RFL-EA-3 Fractions. The EA fractions of *R. formosanum* were prepared at concentration of 1 mg/mL in MeOH. The samples were passed through 0.22 μm filters (Millipore) and placed in sample vials for liquid chromatography (LC) analysis. LC mass analysis for the quantification of betulinic acid, oleanolic acid, and ursolic acid was carried out with an Atlantis T3 RP-18 column (150 × 2.1 mm; 3 μm; Waters, Milford, MA, USA). In each case the injection volume was 5 mL. The column was eluted with buffer A (distilled water/acetonitrile/formic acid; 95/5/0.1, v/v/v) and buffer B (acetonitrile/formic acid; 100/0.1, v/v) at a flow rate of 0.25 mL/min at 25 °C. The column was eluted initially with 100% buffer A, followed by a linear increase in buffer B to 30% from 0 to 5 min, and maintained in 30% buffer B for another 5 min. From 10 to 20 min, a linear increase in buffer B to 80% was carried out, and the column was maintained in 80% buffer B for another 10 min. The column was further eluted with a linear increase in buffer B to 95% from 30 to 40 min. The column was finally equilibrated with buffer A for 10 min. Quantification of the triterpenoids in EA fraction was performed in the ion monitoring mode selected. Both positive and negative ionization mode MS analyses were undertaken. The molecular ion peaks and mass spectra recorded were compared to those of reference substances. Analysis was carried out using data-dependent MS/MS scanning from m/z 100 to 1000. The temperature of the ion source was maintained at 100 °C, the dry temperature was 365 °C, and the desolvation gas, N_2, had a flow rate of 12 L/min. Product ion scans for mass were performed by low-energy collision (20 eV) using argon as the collision gas. All liquid chromatography−electrospray ionization−tandem mass spectrometry (LC-ESI-MS/MS) data were processed by Bruker Daltonics data analysis software (version 4.0). All chemicals were prepared at a concentration range of 0.01−1000 μg/mL. Quantification of triterpenoids was performed with the selected ion monitoring (SIM) mode. The separated $[M - H]^-$ ion chromatogram was selected at m/z 455 for the specific parent ion of triterpenoids. The linearity of the calibration curves was demonstrated by the good determination of coefficients (r^2) obtained for the regression line. Good linearity was achieved over the calibration range, with all coefficients of correlation >0.995. All samples were freshly prepared. The mean values for the regression equation were $y = 6 \times 10^7x + 1 \times 10^7$ ($r^2 = 0.9997$) for betulinic acid, $y = 552577x + 5 \times 10^7$ ($r^2 = 0.9983$) for oleanolic acid, and $y = 353895x + 3 \times 10^7$ ($r^2 = 0.9985$) for ursolic acid. The limits of quantification (LOQ) and determination (LOD), defined as signal-to-noise ratios of 3:1 and 10:1, were in the ranges 0.01−0.1 and 0.1 mg/mL, respectively.

Cell Lines and Cell Culture. Both A549 cells (human lung adenocarcinoma cell line) and H460 cells (human non-small-cell lung cancer cell line) were used in the study and were acquired from the American Type Culture Collection. A549 cells were cultured in DMEM (Invitrogen, Carlsbad, CA, USA), and H460 cells were cultured in RPMI-1640 (Invitrogen) supplemented with 10% fetal bovine serum (FBS, 10%) (Invitrogen), streptomycin (100 μg/mL), and penicillin (100 IU/mL) (Invitrogen) in a humidified incubator at 37 °C with 5% CO_2.

Cell Viability Assay. To measure the cell viability, A549 cells or H460 cells were incubated on the 96-well cell culture cluster (1×10^4 cells/well). MTT stock solution was prepared at a conentration of 5 mg/mL in PBS, and working solution (500 μg/mL) was diluted from stock solution. The medium was removed from each well, and 100 μL of MTT working solution was added for 1 h at 37 °C. When the crystals had formed, the solution was removed and 80 μL of DMSO was aded to dissolve the crystals. Finally, OD 570 nm was used to detect the absorbance by the ELISA reader. MTT assay was done as described previously.[14]

Western Blot Analysis. Cells (2×10^6) were seeded onto the 10 cm cell culture dish overnight and treated with ursolic acid (30 μM) for 0, 12, 24, and 48 h. After treatment, cells were collected in a 1.5 mL eppendorf and lysed in the lysis buffer (0.1% SDS, 1% NP-40, 10 g/mL leupeptin, 1% sodium deoxycholate, 1 mM PMSF, 10 mM Tris-HCl, pH 7.5, 150 mM NaCl, and 10 g/mL aprotinin). Each protein sample was extracted and quantified by using a Bio-Rad protein assay kit, and each group took 50 μg of total proteins to run SDS-PAGE, following transfer to the PVDF membrane. Western Blot was done as described previously.[15] The results were analyzed and quantified by using Image J software.

Cell Cycle and Apoptosis Analysis. A549 cells (5×10^5) were cultured in a 6 cm cell culture dish for 24 h and then treated with ursolic acid (10−30 μM) for 24 and 48 h. After treatment, cells were harvested in a 15 mL tube, washed with PBS, resuspended in PBS, and fixed in 2 mL of 70% ethanol at 20 °C overnight. The cell cycle state and apoptosis was determined by using PI staining as reported previously.[15]

Fluorescence Microscopy. After treatment with ursolic acid (30 μM) for 48 h, A549 cells were fixed by 70% ethanol at −4 °C for 6 h or overnight. Cells were stained with DAPI (1 μg/mL DAPI, 0.1% Triton X-100) at room temperature for 15 min. The morphology of cell nuclei

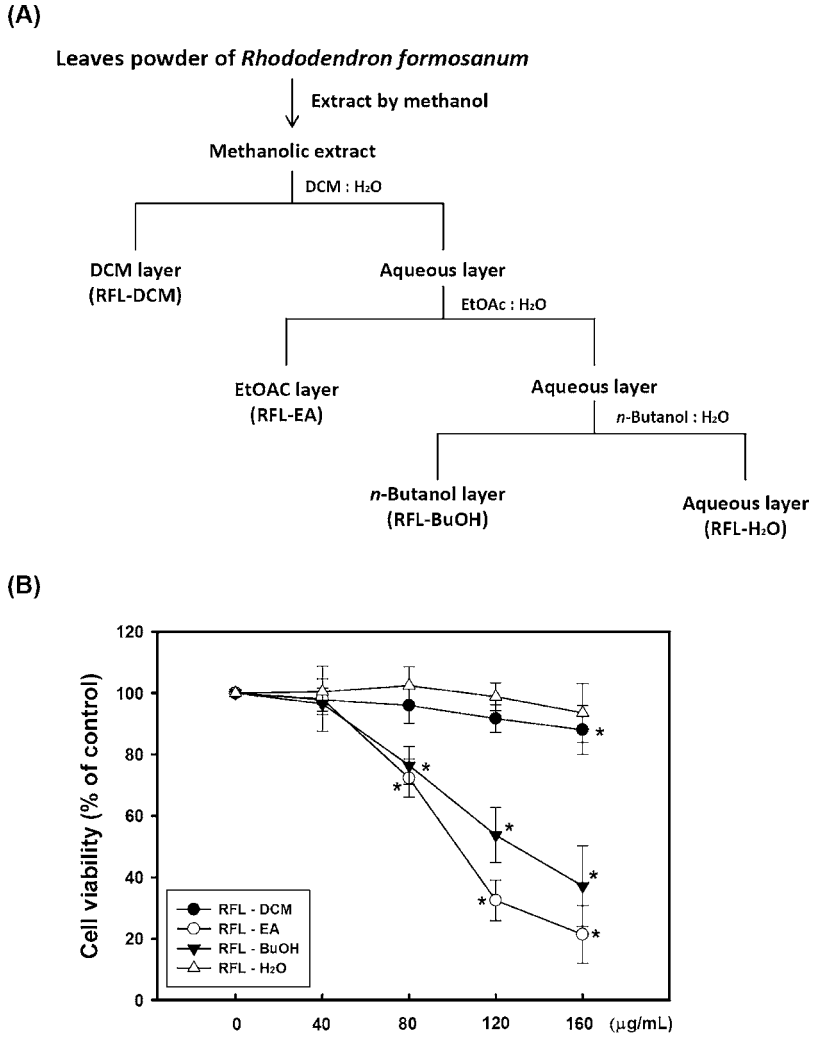

Figure 1. Antiproliferation activities of different fractions from *R. formosanum*. (A) Leaf powder of *R. formosanum* was extracted by methanol and partitioned into four fractions including dichloromethane, ethyl acetate, *n*-butanol, and water to get RFL-DCM, RFL-EA, RFL-BuOH, and RFL-H_2O fractions. (B) A549 cells were treated with the four fractions (40−160 μg/mL) for 24 h. Cell viability was then determined using the MTT assay. This experiment was repeated three times. The data represent the mean ± SD. Values were significantly different from the control group: ∗, $P < 0.05$.

was observed by Nikon TE2000-U fluorescence microscope at 400× magnification. Fluorescence microscopy was done as described previously.[16]

RNA Interference Suppression of LKB1. A549 cells were transfected with LKB1 small interfering RNA (siRNA) using siRNA transfection reagent (Santa Cruz Biotechnology) and incubated for 6 h. The LKB1 siRNA was obtained from Santa Cruz Biotechnology (sc-25816).

Statistical Analysis. Data were presented as the mean ± SD of at least three independent experiments. For statistical analysis, the independent Student's *t* test was used to compare the continuous variables between two groups, and the chi-squared test was applied for comparison of the dichotomous variables. An asterisk indicates that the values were significantly different from the control (∗, $P < 0.05$).

RESULTS

***R. formosanum* Induced NSCLC A549 Cell Growth Inhibition.** To evaluate the bioactive phytochemical constituents of *R. formosanum*, we extracted with methanol and separated the methanol extract into dichloromethane (RFL-DCM), ethyl acetate (RFL-EA), *n*-butanol (RFL-BuOH), and water (RFL-H_2O) fractions (Figure 1A). We next examined the antiproliferative activity of *R. formosanum* extracts on NSCLC A549 cells. Among these *R. formosanum* extracts, RFL-EA was the most effective in our assay (Figure 1B). Further fractionation of the RFL-EA by column chromatography was used to analyze the detailed bioactive phytochemical constituents (Figure 2A). Our study demonstrated that fractions 2 and 3 from the RFL-EA extract (RFL-EA-2, RFL-EA-3) possessed the strongest antiproliferative activity against A549 cells (Figure 2B). The morphology variations of *R. formosanum*-treated A549 cells were investigated by microscopic inspection. After treatment with different concentrations of RFL-EA-2 or RFL-EA-3 for 48 h, apoptotic bodies were observed in A549 cells (Figure 2C). These results may provide a rationale for the potential use of *R. formosanum* against NSCLC.

Comparative Study of the Phytochemical Constituents of RFL-EA-2 and RFL-EA-3. The HPLC fingerprint chromatogram was established to analyze the detailed phytochemical constituents of RFL-EA-2 and RFL-EA-3. Figure 3A shows the HPLC fingerprint chromatogram for the mixture of ursolic acid, oleanolic acid, and betulinic acid. As shown in Figure 3B, RFL-EA-3 contains ursolic acid, oleanolic acid, and betulinic acid. Interestingly, our results revealed that ursolic acid was the most abundant constituent in RFL-EA-2 and RFL-EA-3 (Table 1).

dx.doi.org/10.1021/jf404243p | J. Agric. Food Chem. 2014, 62, 875−884

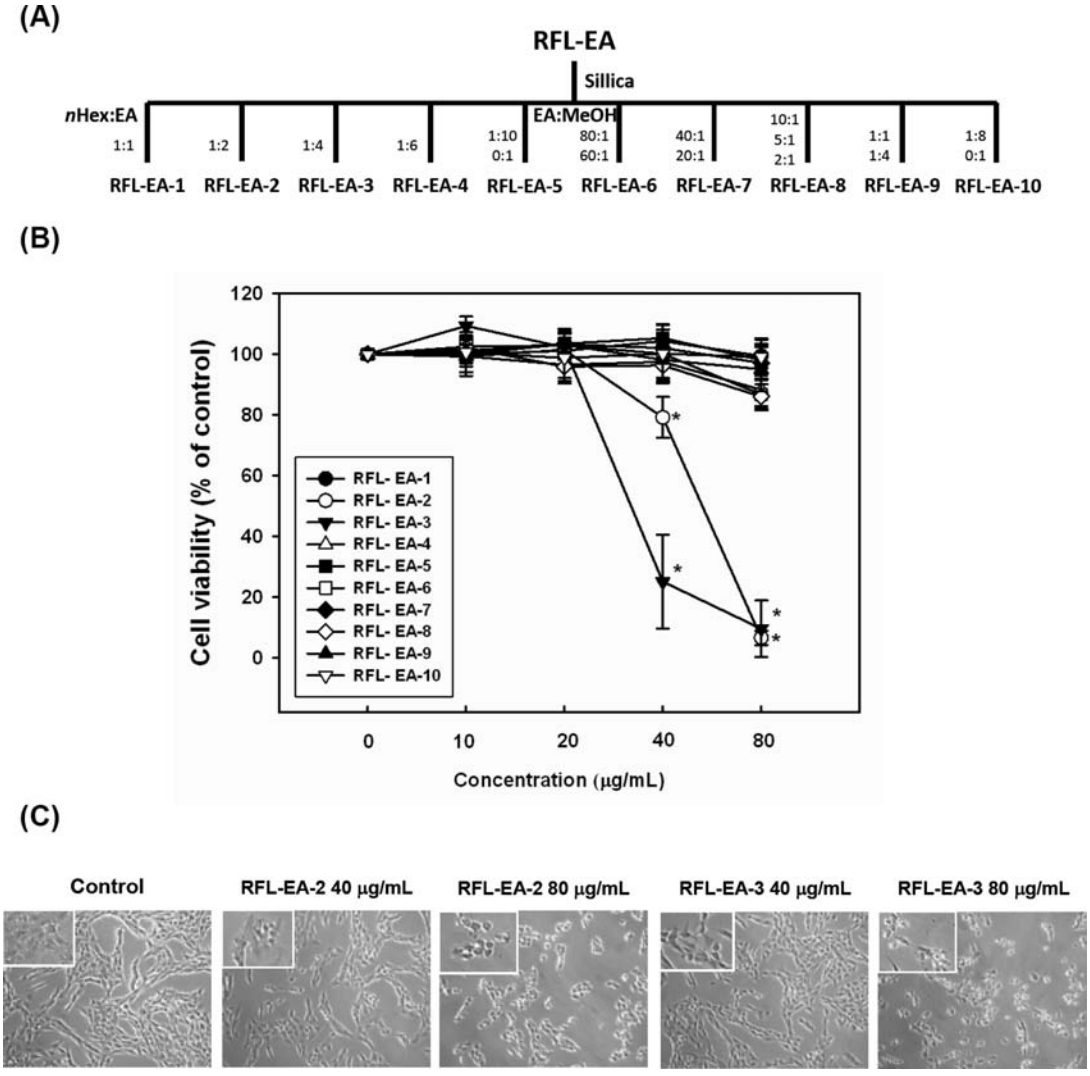

Figure 2. Antiproliferation activities of different RFL-EA fractions against NSCLC A549 cells. (A) RFL-EA was injected into a silica column and eluted with *n*-hexane, ethyl actate, and methanol at different combination rates to get 10 fractions. (B) A549 cells were treated with the 10 fractions (10−80 μg/mL) for 24 h. Cell viability was then determined using the MTT assay. This experiment was repeated three times. The data represent the mean ± SD. Values were significantly different from the control group: ∗, $P < 0.05$. (C) A549 cells were treated with RFL-EA-2 (40−80 μg/mL) and RFL-EA-3 (40−80 μg/mL) for 24 h, and cell morphology was observed by photomicroscope.

Effect of Oleanolic Acid, Ursolic Acid, and Betulinic Acid on NSCLC Cell Proliferation. The potential antiproliferative activities of oleanolic acid, ursolic acid, and betulinic acid were evaluated using the MTT assay. A549 and H460 cells were treated with various concentrations of ursolic acid (Figure 4A), oleanolic acid (Figure 4B), and betulinic acid (Figure 4C) for 24 and 48 h. Among these constituents, ursolic acid and betulinic acid exhibited potent cytotoxic effects on NSCLC cells (Figure 4). Because ursolic acid was the most abundant constituent and exhibited potent cytotoxic effects, we chose ursolic acid for the subsequent experiments.

Ursolic Acid Induces NSCLC Cell Apoptosis. To test whether ursolic acid could induce apoptosis, apoptosis and morphology variations were investigated by microscopic inspection. After treatment with different concentrations of ursolic acid for 48 h, apoptotic bodies were observed in A549 cells (Figure 5A). We next elucidated whether ursolic acid induced chromatin condensation in A549 cells. After 30 μM ursolic acid treatment, chromatin condensation was seen in A549 cells, as evidenced by staining with DAPI (Figure 5B). To further confirm ursolic acid-induced A549 cell apoptosis, flow cytometric analysis was performed. After treatment with various concentrations of ursolic acid for 24 and 48 h, A549 cells underwent apoptosis (Figure 5C). Apoptosis-related modulators were studied by Western blot analysis. Treatment with 30 μM ursolic acid increased the cleavages of caspase-3 and caspase-9 (Figure 5D). Moreover, there was a marked increase of pro-apoptotic protein Bax and a marked decrease of anti-apoptotic protein Bcl-2 in ursolic acid-treated A549 cells (Figure 5E). These results indicated that ursolic acid induced apoptosis in NSCLC cells.

Ursolic Acid Decreases Protein Synthesis via the Up-regulation of AMPK Activity in NSCLC Cells. Abnormalities in the AMPK function have emerged as an important pathway implicated in cancer development.[9] We examined whether ursolic acid was involved in the regulation of AMPK. Figure 6A indicates that ursolic acid stimulated AMPK phosphorylation in a time-dependent manner, whereas AMPK activation resulted in marked inhibition of mTOR and p70S6K in a time-dependent manner (Figure 6B). Our studies suggest that the phosphor-

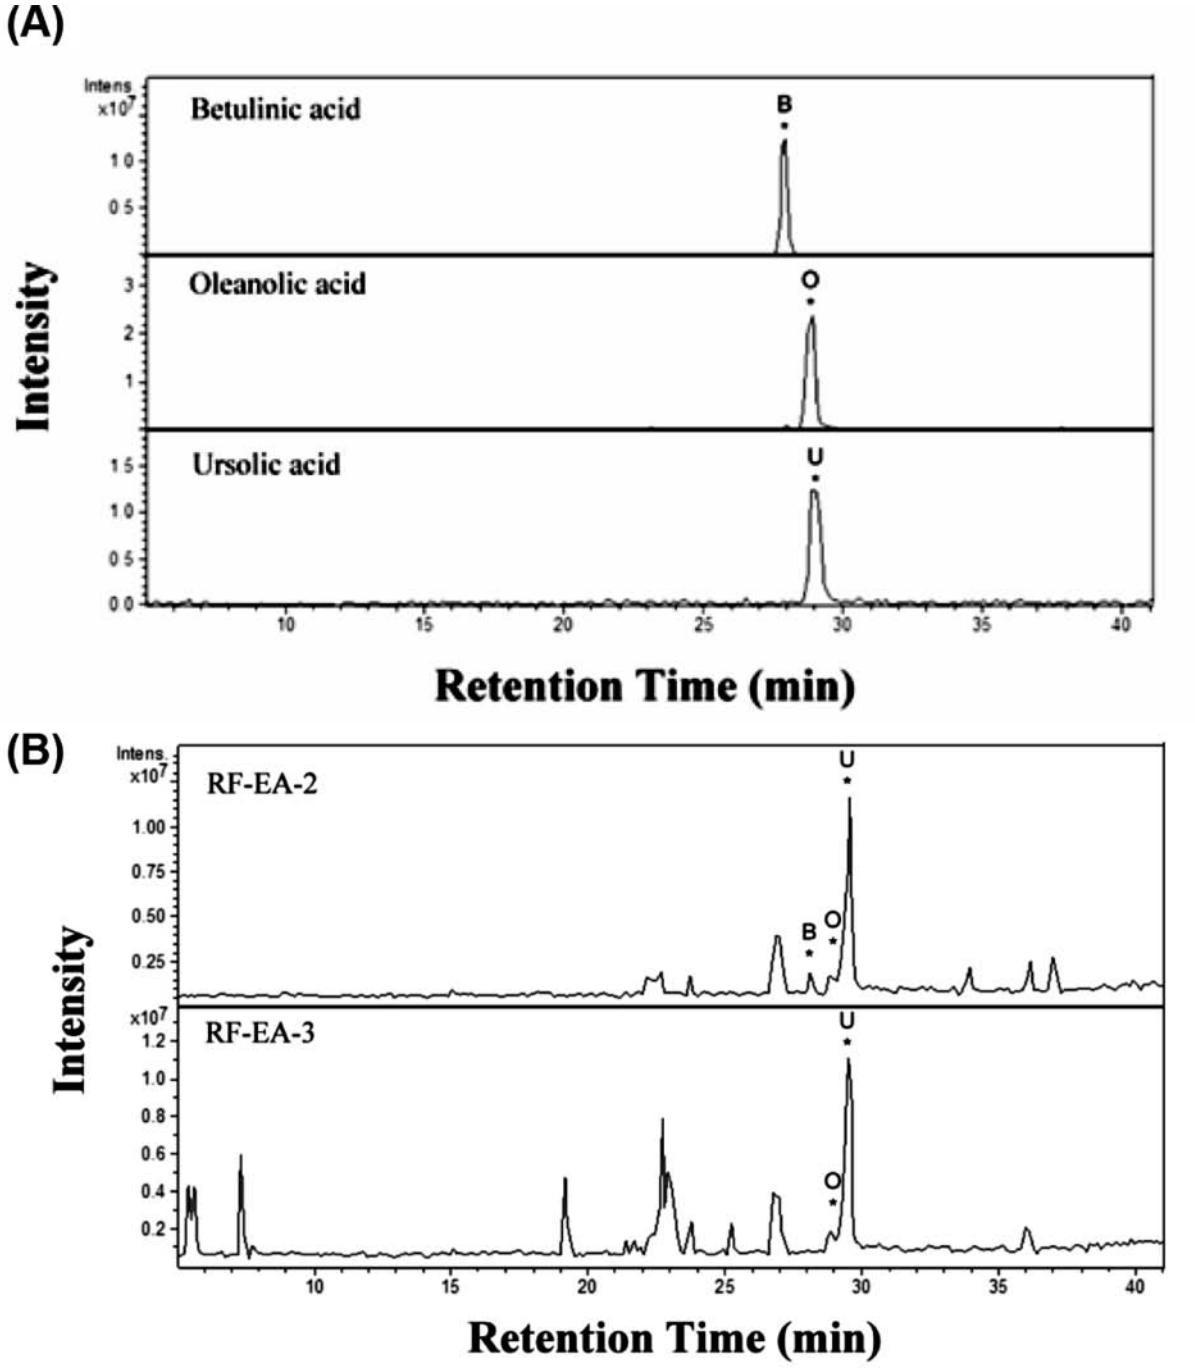

Figure 3. Quantification of triterpenoids by LC-ESI-MS/MS analysis. (A) Individual standard triterpenoids including betulinic acid (B), oleanolic acid (O), and ursolic acid (U) were subjected to LC-ESI-MS/MS analysis for chemical identification and quantification. Panel B shows quantification of the betulinic acid, oleanolic acid, and ursolic acid from RFL-EA-2 and RFL-EA-3 fractions.

Table 1. Concentration of Betulinic, Oleanolic, and Ursolic Acid in the Fractions RF-EA-2 and RF-EA-3

	concentration (μg/mg)	
	RF-EA-2	RF-EA-3
betulinic acid	0.37	<0.1
oleanolic acid	2.55	1.88
ursolic acid	550.2	528.2

ylation of AMPK is required for ursolic acid to decrease protein synthesis in NSCLC cells.

Ursolic Acid Inhibits Lipogenesis through Activation of AMPK in NSCLC Cells. AMPK negatively regulated the activities of lipogenic enzymes FASN and ACC. We next examined reduction of FASN expression and ACC activity in ursolic acid-treated A549 cells. Our result indicated that ursolic acid decreased the expression of FASN and increased ACC phosphorylation in a time-dependent manner (Figure 6C). Our results suggested that ursolic acid suppressed lipogenesis through modulation of AMPK activity.

Ursolic Acid Induces AMPK Phosphorylation via an LKB1-Dependent Pathway. The canonical target of LKB1 is AMPK.[6] To further investigate whether ursolic acid induced

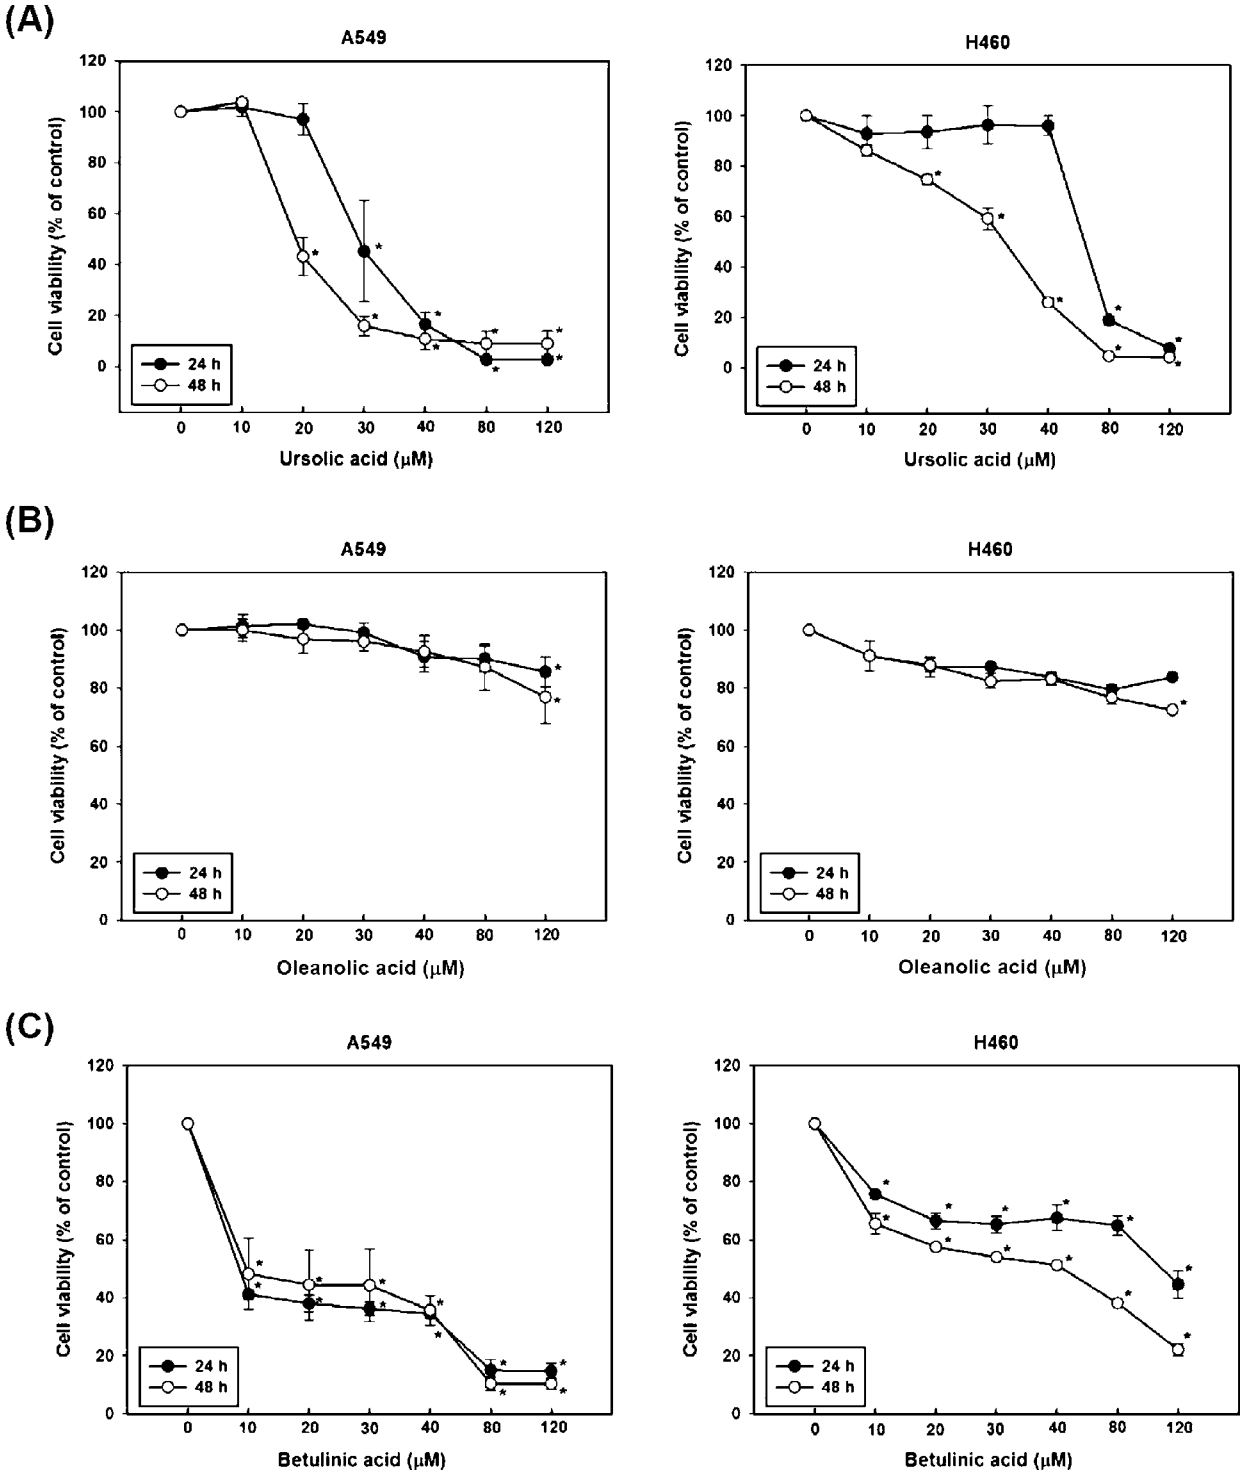

Figure 4. Antiproliferation effect of ursolic acid, oleanolic acid, and betulinic acid against NSCLC cells. A549 cells and H460 cells were treated with (A) ursolic acid, (B) oleanolic acid, and (C) betulinic acid at concentrations of 10−160 μM for 24 or 48 h. Cell viability was then determined using the MTT assay. This experiment was repeated three times. The data represent the mean ± SD. Values were significantly different from the control group: ∗, $P < 0.05$.

AMPK phosphorylation via an LKB1-dependent pathway, LKB1 siRNA was used to inhibit LKB1 expression in A549 cells. After treatment with ursolic acid, an increasing level of phosphorylated AMPK was observed; however, under LKB1 siRNA transfection, despite the addition of ursolic acid, AMPK phosphorylation was reduced (Figure 6D). Our results showed that the activation of AMPK by ursolic acid treatment might occur via an LKB1-dependent pathway.

DISCUSSION

The present study has clearly evaluated the bioactive constituents of *R. formosanum* and investigated the antiproliferative activity on NSCLC. We extracted *R. formosanum* with dichloromethane

dx.doi.org/10.1021/jf404243p | J. Agric. Food Chem. 2014, 62, 875−884

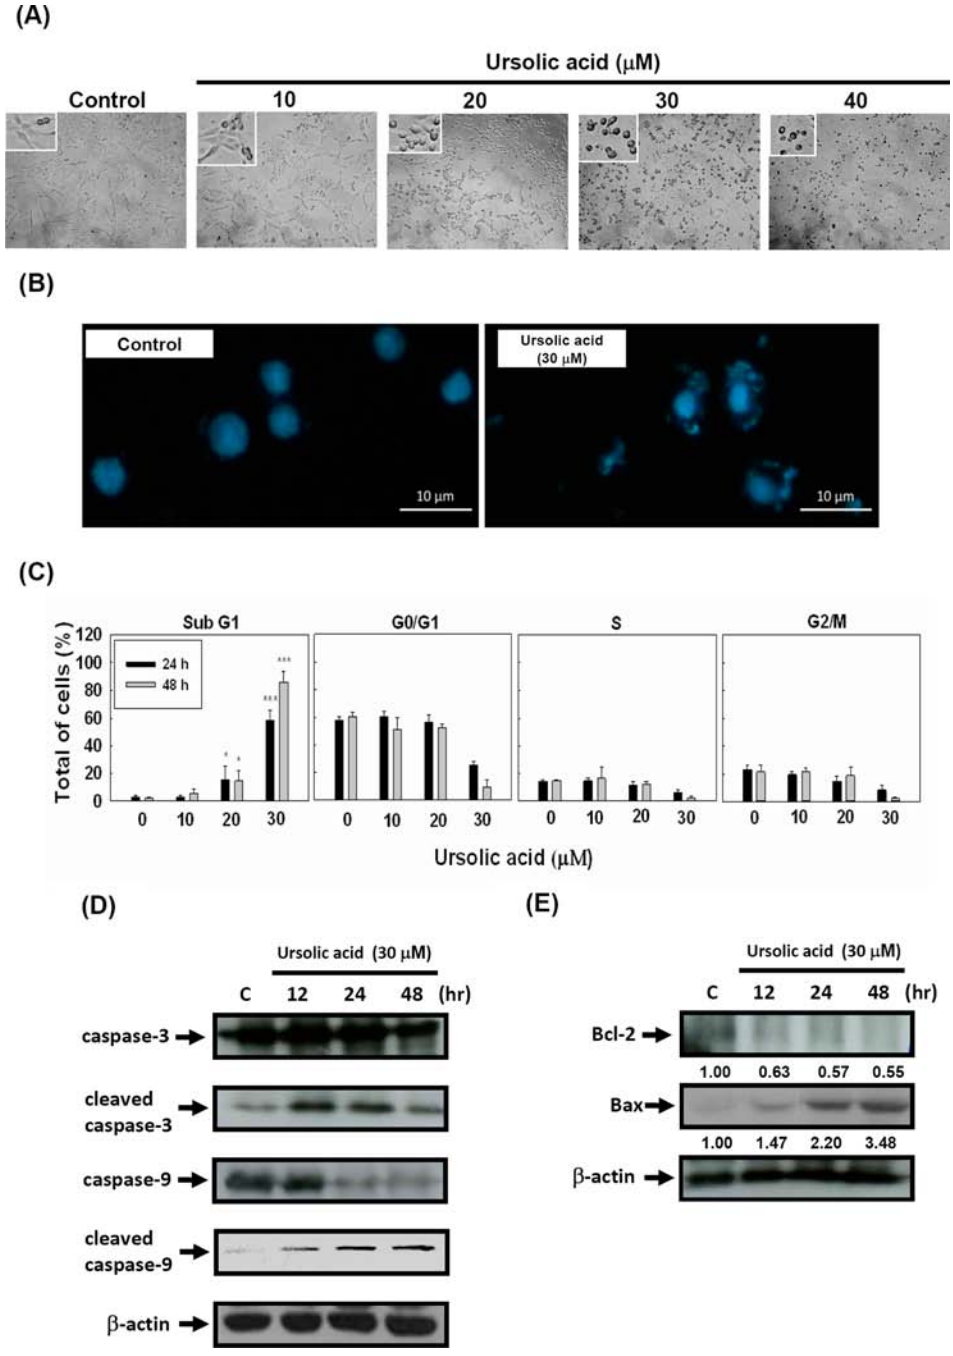

Figure 5. Ursolic acid induced A549 cell apoptosis. (A) A549 cells were incubated with ursolic acid (10−40 μM) for 24 h, and morphology was observed by photomicroscope; (B) the morphology of cell nuclei was observed by fluorescence microscope. (C) To observe cell cycle statements and apoptosis levels, cell were stained with PI and measured by flow cytometry. (D) A549 cells were treated with ursolic acid (30 μM) for the indicated time. Cells were then harvested and lysed for the detection of caspase-3, cleaved caspase-3, caspase-9, cleaved caspase-9, and β-actin. (E) A549 cells were treated with ursolic acid (30 μM) for the indicated times. Cells were then harvested and lysed for the detection of Bcl-2, Bax, and β-actin. Western blot data presented are representative of those obtained in at least three separate experiments. The values below the figures represent change in protein expression of the bands normalized to β-actin.

(RFL-DCM), ethyl acetate (RFL-EA), *n*-butanol (RFL-BuOH), and water (RFL-H_2O). RFL-EA possesses the most effective bioactivity in our cell viability assay. Moreover, our study also demonstrated that fractions 2 and 3 from the RFL-EA extract (RFL-EA-2, RFL-EA-3) showed the greatest antiproliferative effect on NSCLC cells. In our previous study, 18 known compounds were isolated from the 6 fractions obtained by column chromatography from the methanolic extract of *R. formosanum* leaves.[13] In this study, the major components of RFL-EA-2 and RFL-EA-3 were ursolic acid, oleanolic acid, and betulinic acid. Among the three constituents, ursolic acid was the most abundant compound in RFL-EA-2 and RFL-EA-3. Interestingly, our results also revealed that ursolic acid possessed the most efficient antiproliferative effect on NSCLC cells.

Ursolic acid is a natural pentacyclic triterpene acid, which exists in elder flower, apples, lavender, peppermint rosemary, basil, bilberries, cranberries, thyme, oregano, hawthorn, prunes, and medicinal herbs. Because ursolic acid is relatively nontoxic,

dx.doi.org/10.1021/jf404243p | J. Agric. Food Chem. 2014, 62, 875−884

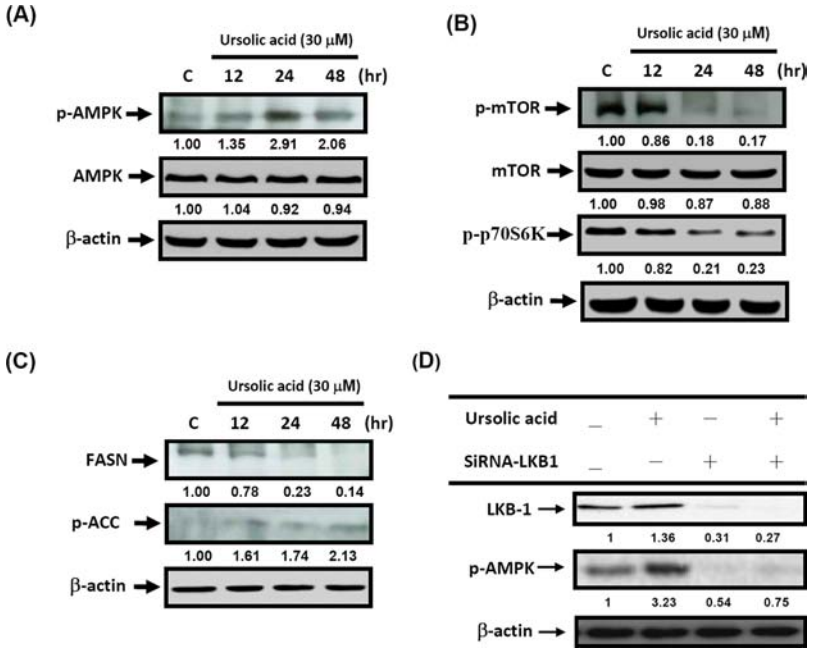

Figure 6. Ursolic acid decreases general mRNA translation and the activity of fatty acid synthesis via activation of AMPK. (A) A549 cells were treated with ursolic acid (30 μM) for the indicated times. Cells were then harvested and lysed for the detection of phosphorylated AMPK (Thr 172), AMPK, and β-actin. (B) A549 cells were treated with ursolic acid (30 μM) for the indicated times. Cells were then harvested and lysed for the detection of phosphorylated mTOR (Ser 2448), mTOR, phosphorylated p70S6K, and β-actin. (C) A549 cells were treated with ursolic acid (30 μM) for the indicated times. Cells were then harvested and lysed for the detection of FASN, phospho-ACC (Ser79), and β-actin. (D) A549 cells were transfected with 50 nmol/L LKB1-siRNA using Oligofectamine. A total of 24 h after transfection, cells were treated with ursolic acid (30 μM) for 24 h. After harvesting, cells were lysed and prepared for Western blotting analysis using antibodies against LKB-1, phosphorylated AMPK (Thr 172), and β-actin. Western blot data presented are representative of those obtained in at least three separate experiments. The values below the figures represent change in protein expression of the bands normalized to β-actin.

there is a growing interest in the elucidation of the pharmacological activities. Several papers reported that ursolic acid has many health benefits including hepatoprotective, anti-inflammatory, and anticancer effects.[17−19] Ursolic acid possesses strong anticancer activity against several cancers of the prostate,[20] breast,[21] lung,[22] pancreas,[23] ovary,[24] colon,[25] and bladder.[26] In the present study, we focused on the antineoplastic effect of ursolic acid on NSCLC cells. These findings suggested that ursolic acid is a potent anticancer agent.

Induction of cell apoptosis is thought to be the principal mechanism by which anticancer drugs kill cells. Ursolic acid has been reported to induce apoptosis through calcium-dependent activation of sphingomyelinase.[27,28] To confirm whether the cytotoxic effect of ursolic acid was due to apoptosis in NSCLC cells, phenotypic characteristics, cell cycle analysis, and Western blotting were used in the present study. Our results indicate that ursolic acid induced cleavages of caspase-9 and caspase-3 and also attenuated the expression of Bcl-2, indicating that ursolic acid induced apoptosis via a caspase-dependent pathway. The Bcl-2 family of proteins plays a crucial role in the mitochondrial pathway of apoptosis. The ratio between Bcl-2 and Bax proteins has been suggested as a primary event in determining the sensitivity to the mitochondrial pathway of apoptosis. Bax translocation to the mitochondria and insertion into the membrane induces cytochrome *c* and other apoptogenic factor release that subsequently activates caspase-3, leading to downstream apoptotic responses.[29] From the above results, we suggest that the enhancement of Bax and the attenuation of Bcl-2 a might be the important molecular pathway that is involved in ursolic acid-induced apoptosis in A549 cells.

Recent studies have focused on the potential of targeting cellular metabolic pathways that may be altered during NSCLC tumorigenesis and progression. AMPK has recently been considered as a critical energy-sensing serine/threonine kinase in the regulation of cellular metabolism. The activation of AMPK switches on catabolic pathways that generate ATP while switching off ATP-consuming processes. Recently, our group and others have reported that sustained AMPK activation inhibits cancer cell growth and proliferation and induces cancer cell apoptosis.[15,30] These findings are given that cancer cell DNA replication, mitosis, cell growth, and proliferation are all ATP-consuming processes. In this study, ursolic acid induced growth inhibition and apoptosis in NSCLC A549 cells, and activation of AMPK may contribute to the process. Similarly, Zheng et al. suggested that activation of AMPK by ursolic acid contributes to growth inhibition and apoptosis in human bladder cancer T24 cells.[31] Son et al. reported that ursolic acid induced apoptosis in HepG2 cells via AMPK activation and GSK3β phosphorylation.[32] Lee et al. found that ursolic acid potentiated cell cycle arrest and UVR-induced apoptosis in skin melanoma cells via AMPK activation.[33] These studies are consistent with our findings here that AMPK activation by ursolic acid induced A549 cell apoptosis. However, how AMPK activation induces A549 cell apoptosis needs further study. Our study provides evidence that ursolic acid may be a potential cancer chemopreventive agent for NSCLC, and AMPK might be the key mechanism for its action.

Targeting the mTOR pathway may lead to the development of novel drugs for cancers. Many laboratories and pharmaceutical companies have focused intensely on developing approaches to block the mTOR pathway. particularly due to the fact that the

mTOR pathway plays such a crucial role in cancer biology. The intervention of some target proteins will lower mTOR activity; for example, activation of AMPK results in decreased mTOR signaling and, in turn, inhibition of protein synthesis and cellular growth.[14,15,34] The present data show that ursolic acid inhibits protein synthesis via the AMPK−mTOR pathway.

In conclusion, *R. formosanum* is an endemic species distributed widely in Taiwan. The pharmacological activities of *R. formosanum* have not yet been fully explained. To the best of our knowledge, the antineoplastic activity of *R. formosanum* has not been explored in previous studies. In this study, we have investigated the chemical constituents and antineoplastic activity of *R. formosanum* against NSCLC cells. On the basis of these studies, it is tempting to propose that *R. formosanum* could be developed as an antineoplastic agent for NSCLC.

serum (FBS), antibiotic−antimycotic 100X, bovine serum albumin (BSA) were supplied by Equitech-bio (Kerrville, TX, USA), Invitrogen (Grand Island, NY, USA) and Jackson ImmunoResearch Laboratories (West Grove, PA, USA), respectively. All the reagents in the study were of analytical grade.

Ultrafast Liquid Chromatography (UFLC). A Shimadzu UFLC system equipped with two LC-20AD pumps and a SPD-M20A detector was used to analyze test samples. The analysis was performed on a Shim-pack XR ODS column, 2.2 μm (3.0 mm i.d. × 100.0 mm). The mobile phase was composed of (A) 20% methanolic solution containing 0.5% TFA and (B) 70% methanolic solution containing 0.5% TFA. The injection volume was 1 μL, and the analytical temperature was set at 40 °C.The UFLC elution conditions were as follows: 0.0% B (0−0.50 min); 0 → 30.0% B (0.50−1.00 min); 30.0 → 50.0% B (1.00−6.00 min); 50.0 → 70.0% B (6.00−11.50 min); 70.0 → 100.0% B (11.50−13.00 min); holding 100% B for further 2.00 min. The flow rate was 0.50 mL/min.

Preparation of *Perilla* Leaf Extract. The red *Perilla* leaves, 2.4 kg, harvested in September 2012, were first smashed by a muller. They were then immersed in 5 L of 10% acetic acid solution and extracted by a modified extractor. After extraction in triplicate with 5 L of 10% acetic acid, the total extraction solution arrived at 15.6 L. Amberlite XAD-7 resin (46.7 cm × 5.7 cm inner diameter) was filled with the above solution. Three liters of 1% TFA−80% methanol eluent was collected and evaporated to dryness (11.1 g).

The *Perilla* leaf extract obtained above was analyzed by UFLC. As shown in Figure 1A main six peaks were distributed in the UFLC chromatogram at a wavelength of 280 nm. Peaks 5 and 6 were also detected at a wavelength of 520 nm and determined as anthocyanins (S and MS, Figure 1B) (see also Table 1). These six peaks isolated were identified as the following compounds by UV spectra, mass spectra, and previous literature. (1) Caffeic acid:[16−18] λ_{max} = 322 nm, m/z 179 ($[M - H]^-$). (2) Luteolin 7-*O*-diglucuronide:[16] λ_{max} = 347 nm, 265 nm, m/z 639 ($[M + H]^+$). (3) Apigenin 7-*O*-diglucuronide:[16] λ_{max} = 336 nm, 266 nm, m/z 623 ($[M + H]^+$). (4) Rosmarinic acid:[16−18] λ_{max} = 329 nm, m/z 359 ($[M - H]^-$). (5) Shisonin:[16] λ_{max} = 523 nm, m/z 757 ($[M + H]^+$). (6) Malonylshisonin:[16,19] λ_{max} = 524 nm, 278 nm, m/z 843 ($[M + H]^+$).

Supramolecular Formation and Rosmarinic Acid Extract Isolation. Figure 2 shows the process of supramolecular formation and RA extraction from *Perilla* leaf. *Perilla* leaf extract (2.0 g), dissolved by 50% aqueous methanol solution (10.0 mL), was neutralized with $NH_3 \cdot H_2O$ (2.0 mL). After the solution was dried by a vacuum, flavocommelin (Fc; 612.0 mg/12.0 mL) and magnesium acetate aqueous solution (Mg^{2+}; 714.0 mg/5.0 mL) were added into the above residue. The reaction solution was mixed thoroughly for 20 min. After the solution was evaporated with a rotary evaporator, 8.0 mL of water and 56.0 mL of ethanol were added in order to form a precipitate at −20 °C overnight. The precipitation step was repeated two times. The supernatant and precipitate were separated by centrifugation (3000 rpm × 10 min) and evaporated to dryness. Both the dried supernatant and precipitate were kept in a desiccator with $CaCl_2$ for several days, yielding 1.7 and 1.5 g, respectively.

The supernatant described above (50.3 mg) was dissolved in 12.0 mL of 1% TFA aqueous solution, followed by the addition of 4.0 mL of ethyl acetate for extraction. The extraction procedure was repeated three times (12.0 mL of ethyl acetate extract). The ethyl acetate layer and water layer were evaporated to dryness in a vacuum, yielding 10.5 ± 0.5 mg and 44.3 ± 2.9 mg, respectively.

Table 1. Identification of UFLC Peaks of *Perilla* Leaf Extract Using a PDA Detector of UFLC and Mass Spetra Analysis[a]

peak no.	t_R (min)	UV λ_{max} (nm)	molecular ion (m/z)	compound identification	refs
1	3.2	322	179 $[M - H]^-$	caffeic acid	19−21
2	5.5	347, 265	639 $[M + H]^+$	luteolin 7-*O*-diglucuronide	19
3	6.8	336, 266	623 $[M + H]^+$	apigenin 7-*O*-diglucuronide	19
4	9.2	329	359 $[M - H]^-$	rosmarinic acid	19−21
5	11.6	523	757 $[M + H]^+$	shisonin	19
6	12.4	524, 278	843 $[M + H]^+$	malonylshisonin	19, 22

[a]Liquid chromatography/electrospray ionization quadrupole time-of-flight mass spectrometry (LC/ESI-Q-TOF-MS) analysis was conducted using an Acquity UPLC/Xevo QTof MS system (Waters Corporation).

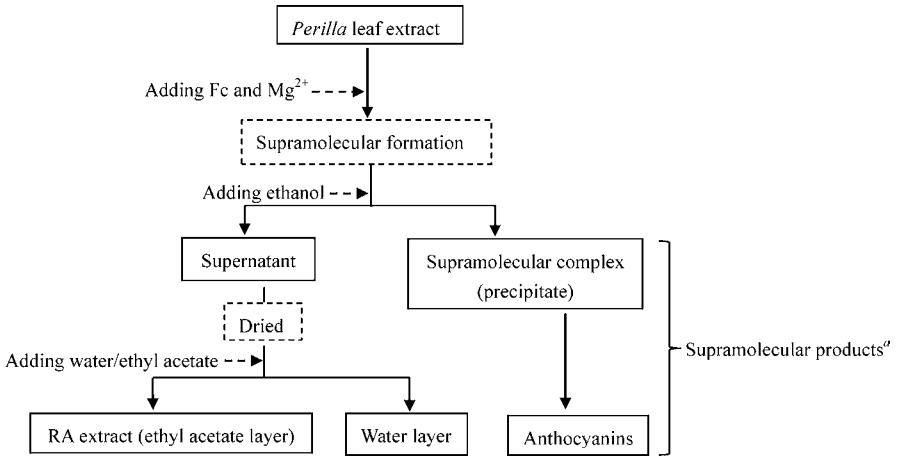

Figure 2. Rosmarinic acid extract and anthocyanins isolated from *Perilla* leaf extract by supramolecular formation. [a]Supramolecular products are supernatant and supramolecular complex obtained by supramolecluar formation, and the related extracts such as RA extract, water layer, and anthocyanins described above.

Total Phenolics (TP). TP was determined by a previous method reported by Cheplick et al.[20] Absorbance was monitored at 725 nm. Gallic acid (10, 25, 40, 60, 80 μg/mL) was used to establish a standard curve. TP was expressed as gallic acid equivalent (GAE) of a test sample.

DPPH Radical Scavenging Activity (DRSA). DRSA was determined using a previously reported method.[18] A sample solution (0.25 mL) was added into a tube with 0.10 M acetic acid buffer (0.25 mL, pH 5.5). The above solution was mixed with methanol (0.25 mL) and DPPH (0.25 mL, 0.4 mM in methanol). The reaction stood for 30 min in a dark place. DPPH absorbance was measured at 517 nm. Trolox and BHT were used as the standard chemicals. The calculation of DPPH radical scavenging activity (%) was carried out according to eq 1.

$$\text{scavenging activity}(\%) = (A_{\text{control}} - A_{\text{sample}})/A_{\text{control}} \times 100 \quad (1)$$

The SC_{50} value which represents the concentration of sample that caused 50% scavenging was determined by GraphPad PRISM 5 from the obtained scavenging activity values.

β-Hexosaminidase Release from the RBL-2H3 Cell Line. β-Hexosaminidase release from the RBL-2H3 cell line (supplied by RIKEN BioResource Center Cell Bank, Ibaraki, Japan) was determined using a previous method with some modifications.[21] The RBL-2H3 cells in a base medium (D-MEM containing 10% FBS and 1% antibiotic−antimycotic 100X) were dispensed into a 24−well plate (2.5×10^5 cells/well), followed by an incubation at 37 °C in 5% CO_2 atmosphere for one night. The cells were washed by PBS (1 mL) and incubated with 500 μL of antibody solution (mouse monoclonal anti-dinitrophenyl antibody, 50 ng/mL in base medium) for 2 h sensitization. A test sample solution of 490 μL was added to each well after washing two times with 500 μL of modified Tyrode's buffer (MT buffer, Tyrode's salt solution containing 1 g/L BSA and 4.76 g/L HEPES). The MT buffer instead of the sample was added into the well as the control. The test samples, dissolved in DMSO, were diluted with MT buffer (final DMSO concentration = 0.1%). After 10 min incubation, albumin dinitrophenyl (10 μL, final concentration = 50 ng/mL) was added to each well. The cells evoked allergic reactions for 30 min (degranulation). The microplate was cooled at 0 °C for 10 min to terminate the reactions. After transference of supernatant (50 μL) into a 96-well plate, 100 μL of *p*-nitrophenyl-2-acetamide-2-deoxy-β-D-glucopyranoside (3.3 mM) in 0.1 M citric acid buffer (pH 4.5) was added into each well with an incubation at 37 °C for 25 min. Finally, 100 μL of glycine buffer (pH 10.0, 2 M) was added and β-hexosaminidase release was quantitatively calculated by the amount of *p*-nitorophenol release from the substrate with a microplate reader at 405 nm. The calculation was carried out using eqs 2 and 3 below. In "blank", spontaneous β-hexosaminidase release from cells was checked in the condition without antibody or samples. In "total", total amount of β-hexosaminidase release from the cells was confirmed by lysing the cells with 0.1% TritonX-100 in MT buffer. In "control", the amount of β-hexosaminidase released from cells was determined in the condition without a sample. In "sample", the amount of β-hexosaminidase released from cells was determined in the condition with a sample added.

$$\text{ratio of } \beta\text{-hexosaminidase release } (\%) = \frac{(\text{OD}_{\text{control}} \text{ or } \text{OD}_{\text{sample}} - \text{OD}_{\text{blank}})}{(\text{OD}_{\text{total}} - \text{OD}_{\text{blank}})} \times 100 \quad (2)$$

$$\beta\text{-hexosaminidase release } (\%) = \frac{\text{OD}_{\text{sample}} - \text{OD}_{\text{blank}}}{\text{OD}_{\text{control}} - \text{OD}_{\text{blank}}} \times 100 \quad (3)$$

The ratio of β-hexosaminidase release (%) of "control" was between 25% and 38%.

α-Glucosidase Activity. α-Glucosidase activity was assessed according to a previous report.[11] A sample solution (50 μL) was mixed with α-glucosidase solution (100 μL, 1 U/mL) in a 96-well plate. After preincubation at 25 °C for 10 min, the reaction was initiated by adding 50 μL of *p*-nitrophenyl-α-D-glucopyranoside (5 mM) in 0.1 M PBS (pH 6.9). The mixed solution was shook at 25 °C for 5 min. At the beginning and the end of the reaction, absorbance at 405 nm was measured by a microplate reader. In control, PBS instead of the sample was added into the well. The α-glucosidase inhibition (%) was calculated by eq 4.

$$\text{inhibition } (\%) = (\triangle A_{\text{control}} - \triangle A_{\text{sample}})/\triangle A_{\text{control}} \times 100 \quad (4)$$

The sample concentration that causes 50% inhibition (IC_{50} value) was calculated from α-glucosidase inhibition by GraphPad PRISM 5.

Statistical Analysis. Statistical analysis was carried out by GraphPad PRISM 5 with Newman−Keuls test (one-way ANOVA). The value represents mean ± standard deviation (SD) in triplicate at least. Significant differences of values were statistically $p < 0.05$.

RESULTS AND DISCUSSION

Separation of RA Extract by Supramolecular Formation. There are many resources of RA in nature as biologically active substances. So, isolation techniques have been developed so far. For example, RA was purified up to 38.8%, yielding 43.8% from 1 g of the crude sample by a Sephadex LH-20[22] column, after response surface optimized

dx.doi.org/10.1021/jf404318j | J. Agric. Food Chem. 2014, 62, 885−892

Table 2. RA Extract and Anthocyanins Separated from *Perilla* Leaf Extract by Supramolecular Formation[a]

		purity (%)		yield (%)	
sample	weight (g)	RA	anthocyanins	RA	anthocyanins
Perilla leaf extract	2.0[b]	21.2	27.5		
supernatant	1.7	16.3	6.5	79.5	18.9
RA extract	10.5 ± 0.5[c]	62.9 ± 4.5	1.2 ± 0.2	82.9 ± 5.6	3.9 ± 0.3
water layer	44.3 ± 2.9[c]	1.0 ± 0.1	5.9 ± 0.6	1.6 ± 0.1	79.9 ± 1.8
supramolecular complex	1.5	1.5	18.7	7.4	71.4
anthocyanins	15.6 ± 1.2[d]	ND[e]	95.5 ± 2.5	ND	83.9 ± 2.3

[a]Each value represents mean ± SD in triplicate. [b]Weight of *Perilla* leaf extract for supramolecular formation. [c]Amount of sample (mg) was obtained by water/ethyl acetate extraction from 50.3 mg of supernatant. [d]Amount of anthocyanin (mg) obtained from 94.9 mg of supramolecular complex. [e]Not detected.

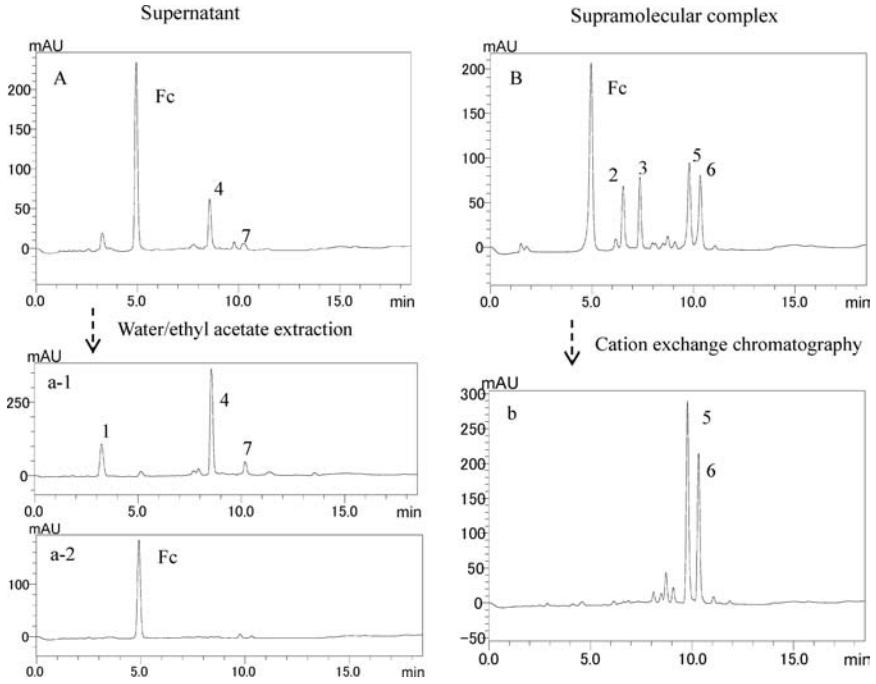

Figure 3. UFLC chromatograpms of rosmarinic acid extract from supernatant and anthocyanin from supramolecular complex after supramolecular formation (280 nm): (A) supernatant; (B) supramolecular complex; (a-1) RA extract; (a-2) water layer; (b) anthocyanins. (1) Caffeic acid. (2) Luteolin 7-*O*-diglucuronide. (3) Apigenin 7-*O*-diglucuronide. (4) Rosmarinic acid. (5) Shisonin. (6) Malonylshisonin. (7) Rosmarinic acid methyl ester.

extraction from *Melissa officinalis* leaves. Phenolics and RA were purified with macroporous resins (HP-20 and Amberlite XAD-7HP)[23] from *Rabdosia serra* (MAXIM.) HARA leaf, yielding highly concentrated RA (112.5 mg with 62.9% purity for HP-20 and 95.7 mg with 58.8% purity for Amberlite XAD-7HP).

In this experiment, crude extracts (11.1 g) of *Perilla* leaves immersed in 10% acetic acid contained anthocyanins (27.5% purity, MS and S mainly) and RA (21.2% purity) with caffeic acid, luteolin 7-*O*-diglucuronide, and apigenin 7-*O*-diglucuronide (Figure 1A). Figure 2 shows the scheme of practical separation of RA extract and *Perilla* anthocyanins by applying the supramolecular formation technique. Through supramolecular formation of anthocyanins in *Perilla* leaf extract (2.0 g) and adding Fc (612.0 mg) and Mg^{2+} (714.0 mg), RA-containing supernatant (1.7 g) was excluded from the supramolecular complex (precipitate, 1.5 g). Thus, purity of RA in the supernatant was 16.3%, including excess amount of Fc in the supernatant. If Fc content is omitted from the calculation of the purity, purity of RA would be 53.4%, compared with the initial purity of RA (21.2%). RA extract (yield 10.5 ± 0.5 mg, purity 62.9 ± 4.5%) was easily purified and isolated from an ethyl acetate layer through partitioning of water and ethyl acetate from 50.3 mg of supernatant by excluding Fc (Table 2) because RA was able to dissolve in ethyl acetate but Fc could not be dissolved in it at all. With the solubility difference between RA and Fc in ethyl acetate, RA extract, 390.4 mg (purity of 60.9%), could be isolated in ethyl acetate layer with a fairly high purity from 1.5 g of supernatant as a typical example of large scale of purification. Moreover, Fc could be recycled after usage in the experiment.

On the other hand, as supramolecular formation, supramolecular complex (Figure 3B) including anthocyanins (MS and S mainly) and unexpected flavonoids (luteolin 7-*O*-diglucuronide and apigenin 7-*O*-diglucuronide) was precipitated by ethanol, which is supported by the report on the alumina complex formation published by Asada et al.[15] In the supramolecular complex, 15.6 mg of anthocyanins (Figure 3b, 95.5 ± 2.5% purity) has been successfully isolated from the supramolecular complex (94.9 mg), after excluding neutral

chemicals such as Fc and flavonoids (Table 2). Thus, by supramolecular technique, both rosmarinic acid and anthocyanins could be easily isolated from *Perilla* leaf extract.

With supramolecular technology, fairly pure rosmarinic acid (60.9%) and highly pure malonylshisonin and shisonin (95.5%), which have various biological activities,[2−9] as well as RA extract are possible for large scale purifications to supply the extracts and the pure chemicals to the food industry.

Antioxidant Activities of Supramolecular Products. Polyphenols possess biologically beneficial activities and are frequently utilized as antioxidant,[18] antiallergic,[24] and antidiabetic[20] reagents. Phenolics in *Perilla* leaves are well-known compounds, owing to their potent antioxidant activities and other bioactivities.[4−9] In our study, *Perilla* leaf extract, Fc, and supramolecular products (Figure 2) were tested for antioxidant and other biological activities. Total phenolics (TPs) as an antioxidant activity were 433.9 ± 58.6 mg/g gallic acid equivalent (GAE) for RA extract, 116.9 ± 2.7 mg/g GAE for supernatant, 170.7 ± 8.2 mg/g GAE for supramolecular complex, and 4.1 ± 1.3 mg/g GAE for Fc (Table 3). Fc, with only one hydroxyl group on the A-ring, hardly contributed to high TP. RA extract exhibited the highest TP, more than two times higher than *Perilla* leaf extract (215.2 ± 2.9 mg/g GAE). It is suggested that TP of RA extract isolated from *Perilla* leaf extract using the supramolecular technique showed the greatest TP. Moreover, the TP of standard RA (711.8 ± 5.3 mg/g GAE) was higher than that of RA extract. The TP of RA extract was calculated to be 61.0% of standard RA. Therefore TP of RA extract was interpreted by the purity of RA (62.9 ± 4.5%) in the extract. Compared with the previous report, RA extract and *Perilla* leaf extract have a higher TP than the extracts of oregano, chocolate mint, and other Lamiaceae family herbs.[11]

Table 3. Total Phenolics of *Perilla* Leaf Extract, Fc, and Supramolecular Products[a]

sample	total phenolics (mg/g GAE)[b]
Perilla leaf extract	215.2 ± 2.9
Fc	4.1 ± 1.3
supernatant	116.9 ± 2.7
RA extract	433.9 ± 58.6
water layer	47.6 ± 1.6
supramolecular complex	170.7 ± 8.2
anthocyanins	189.8 ± 9.8
standard RA	711.8 ± 5.3

[a]Each value represents mean ± SD in triplicate. [b]Total phenolics expressed as gallic acid equivalent (GAE).

DPPH radical scavenging activity (DRSA) is widely applied in assessment of antioxidant activities of plant extracts. A dose-dependent capability of DRSA was observed for *Perilla* leaf extract and supramolecular products (Table 4). RA extract exhibited DRSA at 88.3 ± 0.7% at a concentration of 10 μg/mL while the other supramolecular products exhibited scavenging activity below 50%. RA extract exhibited the highest DRSA with an SC_{50} value of 5.5 ± 0.2 μg/mL (concentration of sample that causes 50% scavenging of free radicals as shown in eq 1), which was more than two times higher DRSA than *Perilla* leaf extract (SC_{50} value, 10.8 ± 0.1 μg/mL) and supernatant (SC_{50} value, 21.7 ± 0.3 μg/mL). Standard RA (SC_{50} value, 4.6 ± 0.2 μg/mL) exhibited higher DRSA than RA extract (SC_{50} value, 5.5 ± 0.2 μg/mL), which is consistent with the results for TP. It has been reported that polyphenols are good antioxidants because phenolic hydroxyl groups are able to provide hydrogen to hydroxyl radical, superoxide radical, and other reactive free radicals.[25] Comparing DRSA of RA extract with those of the reference chemicals it demonstrated that RA extract exhibited similar DRSA to Trolox and higher than BHT (Table 4).

As many inflammations (induced by TNF-α, IL-6, and other sources) of animal cells including human are triggers of diabetes and cancer,[26] anti-inflammatory activities, which can be linked with free radical scavenging activity, of polyphenols including flavonoids and phenylpropanoids have been reported.[24] Polyphenolic compounds also provide anticarcinogenic, antimutagenic, and cardioprotective activities, as a consequence of their strong antioxidant properties.[27] Polyphenols could be good resources for suppressing allergy[24] and treating hyperglycemia associated with type 2 diabetes.[20] Because of the observation of high total phenolics, as well as strong DPPH radical elimination ability, among supramolecular products, we expected that effective antiallergic activity would be observed and hyperglycemia could be suppressed by α-glucosidase inhibition.

Antiallergic Activities of Supramolecular Products on the Suppression of β-Hexosaminidase Release from the RBL-2H3 Cell Line. The lower release of β-hexosaminidase, biomarkers of the RBL-2H3 cell line, is necessary to elicit an antiallergenic response while the RBL-2H3 cell line is applied as a typical model for the research on mast cell excretion and screening for antiallergic phytochemicals.[28] Shimoda et al.[21]

Table 4. DPPH Radical Scavenging Activity of *Perilla* Leaf extract, Fc, and Supramolecular Products[a]

	scavenging activity (%)					
sample (μg/mL)	2.5	5	10	15	20	SC_{50}[b] (μg/mL)
Perilla leaf extract	10.7 ± 1.2	23.4 ± 2.0	48.8 ± 0.2 e	71.7 ± 1.6	87.0 ± 0.3	10.8 ± 0.1 c
Fc	NI[c]	NI	NI	NI	NI	>25
supernatant	NI	10.2 ± 0.9	23.5 ± 0.9 f	35.9 ± 0.1	50.5 ± 0.6	21.7 ± 0.3 e

BHT	14.0 ± 0.6	41.5 ± 2.9	76.2 ± 0.9 d	84.5 ± 0.6	87.0 ± 0.4	6.6 ± 0.3 b

[a]Each value represents mean ± SD in triplicate. Means with different letters are significantly different ($p < 0.05$). [b]SC_{50} value which represents the concentration of sample that caused 50% scavenging was calculated from scavenging activity values. [c]No inhibition detected.

reported β-hexosaminidase release suppression by extracts of *Perilla* leaf (*Perilla frutescens*), Japanese butterbur (*Petasites japonicas*, Compositae), and tien-cha (*Rubus suavissimus*). These extracts have a potency for the prevention of pollennosis, seasonal allergic rhinitis, and other allergic reactions.[29−31] Therefore, *Perilla* leaf extract is becoming more popular in the Japanese market as a folk medicine. However, they did not show the efficient extraction technique of RA extract with great activities.

In this paper, the antiallergic activities of *Perilla* leaf extract, Fc, and supramolecular products, such as supramolecular complex, supernatant, RA extract, anthocyanins, and water layer, were assessed by β-hexosaminidase release suppression of RBL-2H3 cells (Figure 4). The concentrations of 50% β-

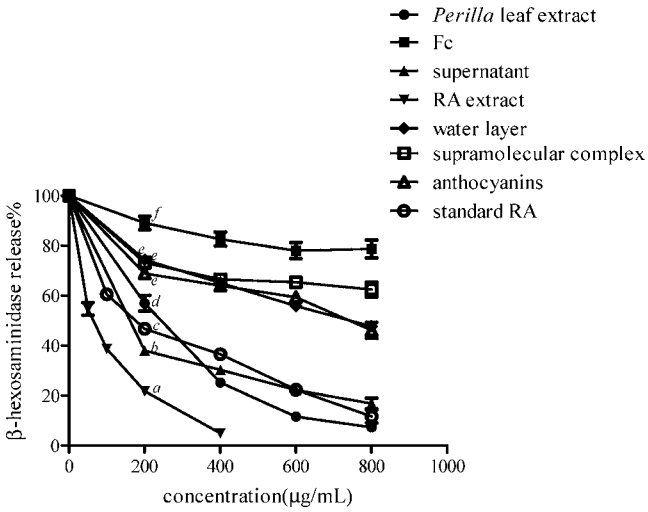

Figure 4. Antiallergic activities of supramolecular products on β-hexosaminidase release suppression from the RBL-2H3 cell line. Each value represents mean ± SD in quadruplicate.

hexosaminidase release inhibition of standard RA, *Perilla* leaf extract, supernatant, and RA extract were mainly 136.7 ± 12.6 μg/mL, 208.4 ± 20.0 μg/mL, 81.1 ± 23.3 μg/mL, and 52.9 ± 6.7 μg/mL (IC_{50} values), respectively. The suppression of β-hexosaminidase release was dose-dependent. In our study, RA extract suppressed β-hexosaminidase release 3.9 times and 2.6 times more than *Perilla* leaf extract and standard RA, respectively, and exhibited the highest antiallergic activity among the supramolecular products. Also, it is suggested that other compounds as well as RA in RA extract may contribute to antiallergic activity.

RA is reported to possess anti-inflammatory and antiallergic effect and inhibit seasonal allergic rhinoconjunctivitis.[31,32] RA suppresses inflammatory activity by the decrease of IgE and COX-2 levels.[5] Therefore, efficient isolation of pure RA and RA extract that has higher antiallergic activity than RA itself is desired in current food and drug markets. Supramolecular formation and solvent partition technique may offer the possibility of the development of new drugs.

In the UFLC chromatogram (Figure 3a-1), caffeic acid (t_R = 3.2 min) and rosmarinic acid methyl ester (RA-me, t_R = 10.2 min) were found in RA extract as minor components besides RA. The β-hexosaminidase release inhibitory result gave IC_{50} values of caffeic acid and RA-me (synthesized by us) of 132.0 ± 3.6 μg/mL and 9.9 ± 0.8 μg/mL, respectively. This result showed that RA-me exhibited higher inhibitory activity than standard RA. In RA extract the content of RA and RA-me was 62.9% and 6.9% respectively. At IC_{50} of RA extract (52.9 μg/mL), it was calculated as 33.3 μg/mL for RA and 3.7 μg/mL for RA-me, respectively, which contributed to 43% β-hexosaminidase release inhibition as an additive effect. Therefore, RA-me, as a component in RA extract, contributed to high β-hexosaminidase release inhibitory activity besides RA. We found the greatest activity of RA-me in RA extract and supernatant as a minor component. So, although the purity of RA (16.3%) in supernatant is a bit lower than that of RA in leaf extract (21.2%), supernatant showed greater values of IC_{50} than that of leaf extract because of not only increasing of Fc in supernatant as the impurity but also increasing of RA-me by the selective isolation with supramolecular technique and solvent partition technique.

Yun et al.[24] reported that curcumin, with the highest potential to suppress β-hexosaminidase release among 25 polyphenols, was around 4 times greater than RA. In contrast, RA-me found in RA extract was 13.8 times higher than RA. Therefore, RA-me can suppress β-hexosaminidase release more effectively than curcumin.

In conclusion, RA extract isolated by supramolecular technique showed effective antiallergic activity. We clarified that RA-me, as a minor component in RA extract, contributed to high antialleric activity with RA as an additive effect.

α-Glucosidase Inhibitory Activities of Supramolecular Products. α-Glucosidase inhibitors, alleviating postprandial hyperglycemia, would have potential to manage diabetes. *Perilla* leaf extract, Fc, and supramolecular products were examined for inhibition effects of α-glucosidase. RA extract inhibited the greatest α-glucosidase activity (IC_{50} of 0.23 ± 0.01 mg/mL) among the supramolecular products (Table 5). Furthermore,

Table 5. α-Glucosidase Inhibitory Activity of *Perilla* Leaf Extract, Fc, and Supramolecular Products

sample	IC_{50}[a] (mg/mL)
Perilla leaf extract	0.42 ± 0.01 a
Fc	5.60 ± 0.23 e
supernatant	0.42 ± 0.01 a
RA extract	0.23 ± 0.01 a
water layer	2.74 ± 0.21 d
supramolecular complex	1.54 ± 0.04 b
anthocyanins	1.99 ± 0.01 c
standard RA	0.95 ± 0.01 b

[a]IC_{50} values were calculated from dose−response curves of α-glucosidase inhibition. Each value represents mean ± SD in triplicate. Means with different letters are significantly different ($p < 0.05$).

RA extract inhibited α-glucosidase activity 4.1 times and 1.8 times higher than standard RA (IC_{50} value, 0.95 ± 0.01 mg/mL) and *Perilla* leaf extract (IC_{50} value, 0.42 ± 0.01 mg/mL), respectively, while RA is reported to be a better research target on α-glucosidase inhibitory activity.[11] Moreover, RA extract exhibited α-glucosidase inhibitory activity higher than 4,5-dicaffeoylquinic acid (IC_{50}, 0.46 mg/mL), as an effective α-glucosidase inhibitor, isolated from flower buds of *Tussilago farfara* L.[33] and coffee bean.[34] Therefore, RA extract has potential to suppress hyperglycemia by inhibiting α-glucosidase activity.

The α-glucosidase inhibitory activity result showed that IC_{50} values of caffeic acid and RA-me were 3.46 ± 0.18 mg/mL and 0.44 ± 0.01 mg/mL, respectively. It showed that RA-me

exhibited greater α-glucosidase inhibitory activity than standard RA. We concluded that RA extract containing RA-me and other minor components as unknown compounds besides RA contributed to high α-glucosidase inhibitory activity, especially unknown compounds might highly contribute to the activity. We found that RA-me and other minor compounds with high α-glucosidase inhibitory activity were contained in RA extract and supernatant. So, although the purity of RA (16.3%) in supernatant was a bit lower than that of RA in leaf extract (21.2%), supernatant showed the same IC_{50} value of α-glucosidase inhibitory activity with that of leaf extract because of not only increasing of Fc in supernatant as the impurity but also increasing of RA-me and other minor compounds by the selective isolation with supramolecular technique and solvent partition technique (Table 5).

Moreover, in the *Perilla* leaf extracted by 10% acetic acid, RA-me was not detected in our experiment though Kang et al.[17] characterized RA-me as one phenolic phytochemical in *Perilla frutescens*. Therefore, we surmise it to be an artificial compound in *Perilla* leaf extract. The generated RA-me and other minor components in RA extract potently contributed to antiobesity activity by inhibiting α-glucosidase activity. Clarification of the minor components contributing to α-glucosidase inhibitory activity is under investigation.

Through supramolecular formation, RA-containing supernatant was excluded by supramolecular complex and RA extract (62.9 ± 4.5% purity) with potent biological activities was obtained. The obtained RA extract had exhibited the three great activities of DPPH radical scavenging, antiallergy effects, and α-glucosidase inhibition. Antiallergic activity and α-glucosidase inhibition of RA extract were greater than those of standard RA. This study shows that RA and other minor components in RA extract contributed both activities of antiallergy effects and α-glucosidase inhibition. We will discuss molecular mechanisms of the activities in detail by linking with the interaction of biologically important chemicals after identification of these active compounds. In conclusion, the RA extract isolated from *Perilla* leaf extract by supramolecular formation and solvent extraction has potential applications in managing diabetes mellitus and other chronic and degenerative diseases. This is the first report on RA extract with potent antioxidant, antiallergic, and α-glucosidase inhibitory activity separated from *Perilla* leaf extract using the supramolecular formation and partition technique.

MO). Vanillic acid (purity > 96%) was purchased from Wako Pure Chemicals (Osaka, Japan). Kaempferol (purity > 97%) and taxifolin (purity > 96%) were obtained from Funakoshi (Tokyo, Japan). All solvents [extra pure grade or high-performance liquid chromatography (HPLC) grade] were obtained from Nacalai Tesque. Nuclear magnetic resonance (NMR) spectra were obtained from an ECS-400 spectrometer (JEOL, Tokyo, Japan) using the pulse sequences of the manufacturer. High-resolution mass spectrometric data were obtained using a XEVO QtofMS spectrometer (Waters Japan, Tokyo, Japan) in negative electrospray ionization (ESI) mode. A PU-2089 low-pressure gradient system (JASCO, Tokyo, Japan) equipped with a MD-2018 photodiode array (PDA) detector was employed for analytical HPLC. PDA data were analyzed using ChromNAV, version 1.8 (JASCO). A LC-6AD system (Shimadzu, Kyoto, Japan) equipped with a UV-970 detector (JASCO) was used for preparative HPLC.

Preparation of MbO_2 and MetMb. MbO_2 was prepared using the method reported previously.[9] MetMb solution was prepared from a stock solution of MbO_2. Potassium hexacyanoferrate (III) (2 mg) was added to a solution of MbO_2 (120 μmol/L) in a phosphate buffer (pH 7.4, 3 mL) at 23 °C. After gentle stirring for 0.5 min, the solution was desalted 3 times at 14000*g* for 6 min at 4 °C with an Amicon Ultra-0.5, Ultracel-10 ultrafiltration membrane (Merck Millipore, Cork, Ireland) using phosphate buffer. The final residual solution (ca. 0.5 mL) was diluted with buffer, yielding 120 μmol/L MetMb solution (3 mL). The purity and concentration of the MetMb solution were confirmed with a UVmini 1240 ultraviolet−visible (UV−vis) spectrometer (Shimadzu).[17]

Measurement of MetMb Reduction and MbO_2 Oxidation. To a 96-well microplate, 50 mmol/L phosphate buffer (pH 7.4, 140 μL), 120 μmol/L MetMb or MbO_2 in the same buffer (150 μL), and an appropriate amount of test samples (polyphenols, their products, or L-

dx.doi.org/10.1021/jf404357h | J. Agric. Food Chem. 2014, 62, 893−901

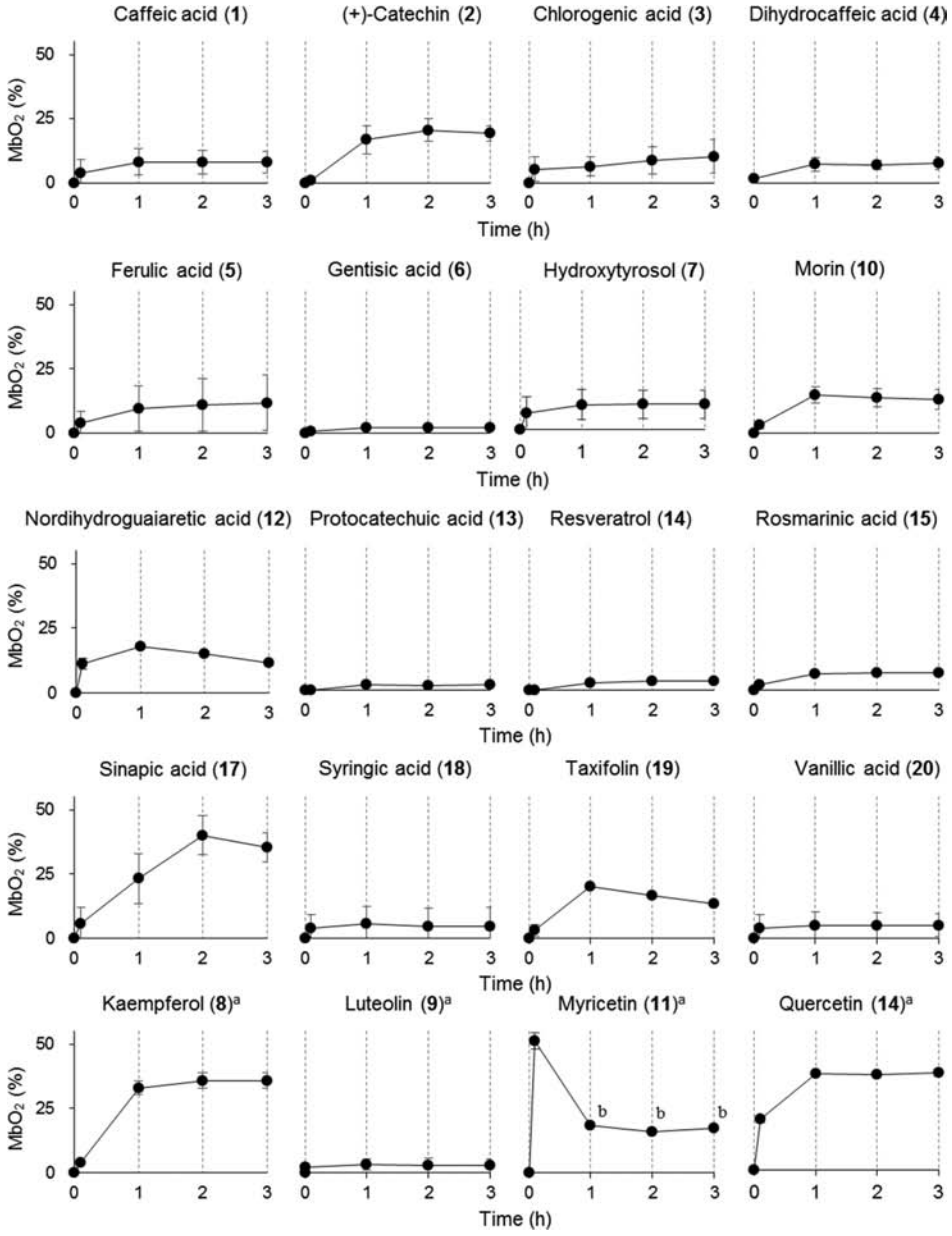

Figure 2. Effects of phenols (600 or 300 μmol L^{-1}) on MetMb reduction. Results are expressed as the mean ± standard deviation (SD) (n = 6). (a) Activity of kaempferol, luteolin, myricetin, and quercetin was measured at 300 μmo/L because their solubilities are below 600 μmol/L. (b) Data on myricetin after 1 h are low of accuracy because of the dark brown color of the solution mixture.

ascorbic acid) in dimethyl sulfoxide (DMSO) (10 μL) were subsequently added. The microplate was incubated at 37 °C in a Multiskan GO microplate reader (Thermo Fisher Scientific, Yokohama, Japan) for 3 h, and absorbance at 500 and 582 nm was measured at 1 h intervals. At the beginning and end of the experiment, visible spectra (450−650 nm) were obtained with the same microplate reader. MbO_2 and MetMb concentrations in the well were calculated by the following equation based on the absorption spectra of 60 μmol/L pure MbO_2 or MetMb: MbO_2 (μmol/L) = $(89.7A_{582}) - (32.9A_{500})$, where A_{500} and A_{582} refer to absorbance at 500 and 582 nm, respectively. Redox conversion efficiency between MetMb and MbO_2 was expressed as a percentage calculated by the MbO_2 concentration relative to the initial concentrations (60 μmol/L) of each MbO_2 and MetMb.

HPLC and Liquid Chromatography−Mass Spectrometry (LC−MS) Analyses of Quercetin Products during MetMb Reduction. At 1 h intervals, an aliquot (5 μL) was removed from the above-mentioned reaction with quercetin (300 μmol/L) and the reaction products were analyzed under the following conditions: column, a 250 × 4.6 mm inner diameter, 5 μm, Cosmosil $5C_{18}$-AR-II (Nacalai Tesque); flow rate, 1.0 mL/min; solvent A, 1% acetic acid in water; solvent B, acetonitrile; gradient conditions, linear gradient from 5 to 100% solvent B (40 min); and detection, absorbance at 280 nm. The concentration of each product in the reaction mixture was calculated using the following calibration equations: quercetin, Y (μmol/L) = $0.70X \times 10^{-3} + 0.15$ (range for Y, 50−300 μmol/L); product I, Y (μmol/L) = $3.62X \times 10^{-4} + 2.39$ (range for Y, 1−1000 μmol/L); product II, Y (μmol/L) = $1.02X \times 10^{-3} + 1.64$ (range for Y, 10−1000 μmol/L); product III, Y (μmol/L) = $3.59X \times 10^{-4} + 8.94$ (range for Y, 10−1000 μmol/L), where X represents the peak area at 280 nm. The MS data for each product was obtained by LC−MS. An additional aliquot (5 μL) was also taken after 1 and 3 h for the analysis of products I−III, and the analyses were carried out under the following conditions: separation conditions, column, a 250 × 4.6 mm inner diameter, 5 μm, Cosmosil $5C_{18}$-AR-II (Nacalai Tesque); flow rate, 0.5 mL/min; solvent A, 1% acetic acid in ultrapure water, solvent

dx.doi.org/10.1021/jf404357h | J. Agric. Food Chem. 2014, 62, 893−901

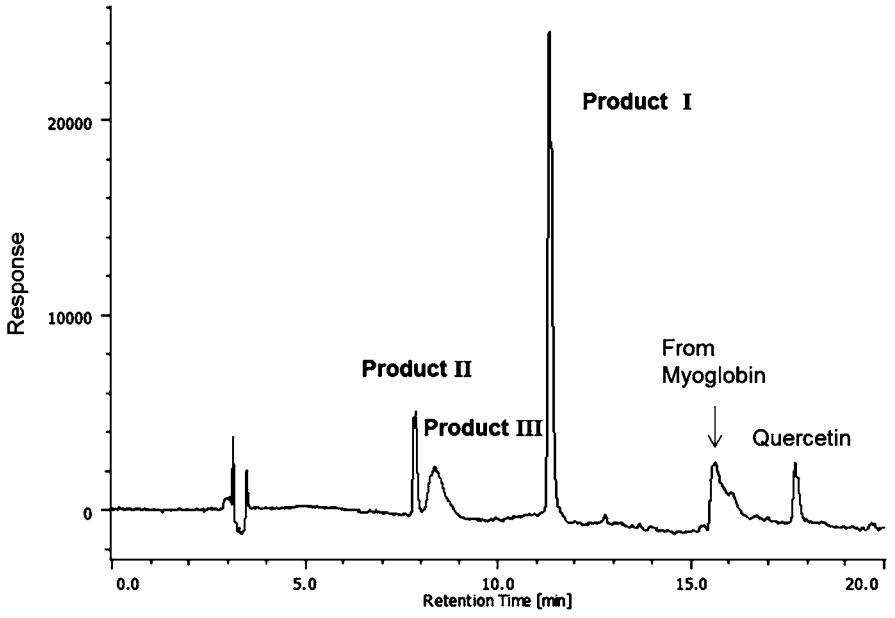

Figure 3. HPLC profile for the reaction of quercetin and MetMb at 2 h.

B, acetonitrile (LC−MS grade, Merck, Darmstadt, Germany); gradient conditions, linear gradient from 5 to 100% solvent B (80 min); and MS conditions, mode, negative ESI; capillary voltage, 2.4 kV; cone voltage, 40 V; source temperature, 150 °C; desolvation temperature, 500 °C; cone gas flow rate, 50 L/h; desolvation gas flow rate, 1000 L/h, MS^E low collision energy, 6 V; and MS^E high collision energy, 20−30 V. The elemental composition of each peak compound was calculated from the high-resolution MS data of the deprotonated molecular ion using MassLynx software, version 4.1 (Waters).

Preparation and Structure Elucidation of Quercetin Oxidation Products I−III. To a solution of quercetin (50 mg) in acetonitrile (50 mL) and water (50 mL) was added 90 mg of $FeCl_3 \cdot 6H_2O$ and the solution was stirred at 37 °C for 1 h. The solution was passed through a short column of Chelex100 (10 g), and the eluate was evaporated *in vacuo*. The residue obtained was purified by preparative HPLC under the following conditions: column, a 250 × 20 mm inner diameter, 5 μm, Cosmosil $5C_{18}$-AR-II (Nacalai Tesque); flow rate, 9.0 mL/min; solvent, 0.1% trifluoroacetic acid in 85:15 (v/v) water/acetonitrile. All eluates from 18−24 min were collected and evaporated to give product I (**21**, 40 mg). Product I (**21**): HR-ESIMS (m/z) $[M - H]^-$, calcd for $C_{15}H_9O_8$, 317.0297; found, 317.0284. UV λ_{max} (acetonitrile/H_2O/acetic acid), 325 (sh), 292 nm. ^1H NMR (acetone-d_6) δ: 7.64 (1H, d, J = 2.4 Hz), 7.57 (1H, dd, J = 8.1 and 1.8 Hz), 6.92 (1H, d, J = 8.1 Hz), 6.13 (1H, brd, J = 1.2 Hz), 6.12 (1H, brd, J = 1.2 Hz) [6.13 (2H, brs)]. Products II (**22**, 1 mg) and III (**23**, 7 mg) were also isolated after oxidizing quercetin (55 mg) for 2 h with $FeCl_3 \cdot 6H_2O$ (99 mg) in acetonitrile−water [1:1 (v/v), 100 mL] at room temperature. Purification was carried out as follows: The reaction solution was passed through a Chelex100 column (10 g), and the eluate was purified by preparative HPLC after evaporation. Two peaks (14−16 and 22−25 min) were collected and evaporated to give products II (**22**) and III (**23**), respectively. Product II (**22**) (protocatechuic acid): ESIMS (m/z) 153 $[M - H]^-$ (100%). UV λ_{max} (acetonitrile/H_2O/acetic acid), 292, 260 nm. ^1H NMR (DMSO-d_6) δ: 8.30 (1H, br s), 7.31 (1H, d, J = 1.8 Hz), 7.26 (1H, J = 8.2 and 1.8 Hz), 6.76 (1H, J = 8.2 Hz). Product III (**23**) (2,4,6-trihydroxyphenylglyoxylic acid): ESIMS (m/z), 193 $[M - H]^-$ (40%), 195 (40%), 177 (50%), 153 (100%). UV λ_{max} (acetonitrile/H_2O/acetic acid), 292 nm. ^1H NMR (DMSO-d_6) δ: 5.62 (2H, s).

HPLC Analysis of the Reactions of Products I−III with MetMb. To each well of a microplate, 140 μL of 50 mmol/L phosphate buffer (pH 7.4), 10 μL of the appropriate concentration of each product in DMSO, and 150 μL of 120 μmol/L of MetMb or MbO_2 in the same buffer were added. The plate was incubated at 37 °C, and absorption at 582 and 500 nm was obtained at 1 h intervals. At the same intervals, aliquots (5 μL) were taken and injected into the HPLC unit. Analysis of the reaction products I−III was carried out under the following conditions: column, a 250 × 4.6 mm inner diameter, 5 mm, Cosmosil $5C_{18}$-AR-II (Nacalai Tesque); flow rate, 1.0 mL/min; solvent A, 1% acetic acid in water; solvent B, acetonitrile; linear gradient from 5 to 100% solvent B (40 min); and detection, absorbance at 280 nm. The concentration of each product in the reaction mixture was calculated using the above-mentioned equations.

RESULTS AND DISCUSSION

MetMb Reduction by Polyphenols. Ascorbic acid is known to potently reduce MetMb; however, the precise concentration required for this reduction *in vitro* has not yet been reported. First, we examined the effect of the ascorbic acid concentration (60−2400 μmol/L) on MetMb (60 μmol/L) in pH 7.4 phosphate buffer. The results obtained showed that 600 μmol/L ascorbic acid reduced MetMb gradually, forming MbO_2 equivalent to 80% of the initial amount of MetMb after 3 h at 37 °C. Therefore, these conditions were employed in experiments using 20 kinds of polyphenols and related phenolic compounds (Figure 1). Figure 2 shows the MetMb reduction

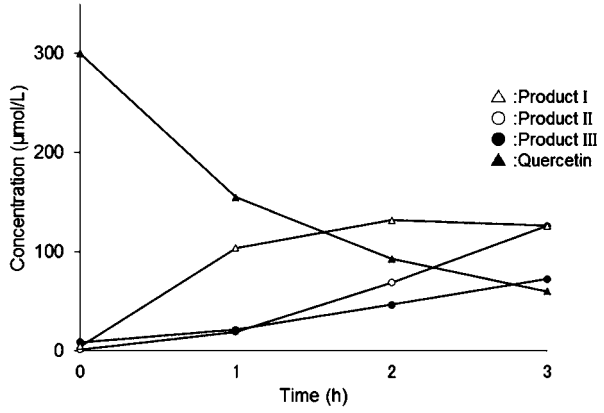

Figure 4. Time-course analytical data for products I−III in the reaction of quercetin and MetMb.

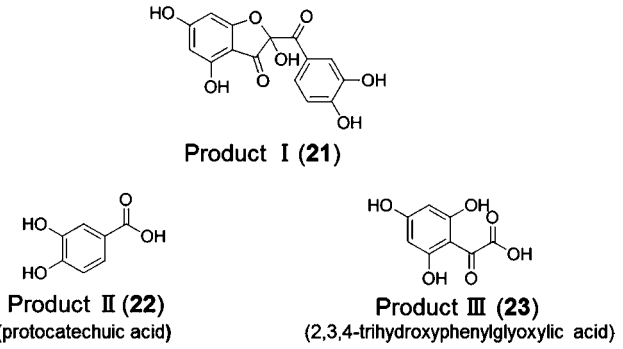

Figure 5. Chemical structures of products I–III.

and MbO_2 formation by the polyphenols. The data are shown in percentage of MbO_2 in total myoglobins, which was calculated on the basis of absorbance at 500 and 582 nm of each 60 μmol/L pure MbO_2 and MetMb.[18] Although most polyphenols showed weak reducing activity as reductants, sinapic acid (**17**) (600 μmol/L) exhibited apparent potency, followed by catechin (**2**), nordihydroguaiaretic acid (**12**), taxifolin (**19**), morin (**10**), and ferulic acid (**5**). Unfortunately, the activity of some flavonoid polyphenols could not be measured at this concentration because of insolubility. Therefore, the activity of 300 μmol/L of these flavonoids [kaempferol (**8**), luteolin (**9**), myricetin (**11**), and quercetin (**14**)] was measured; the results are illustrated in the lower part of Figure 2. As shown there, kaempferol (**8**), quercetin (**14**),

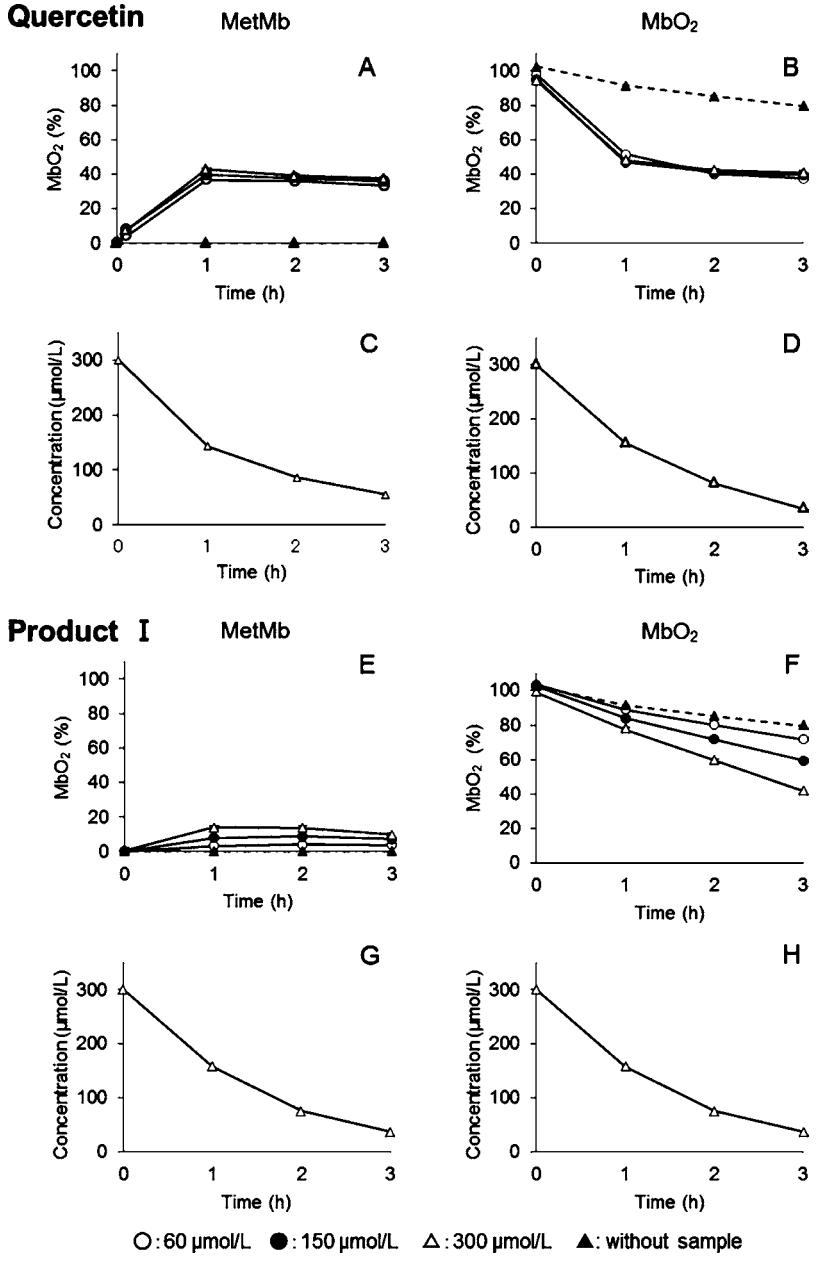

Figure 6. MetMb reduction andMbO_2 oxidation of quercetin and product I and changes in concentrations of quercetin and product I in the reaction solutions. Panels A and E refer to MetMb reduction. Panels B and F refer to MbO_2 oxidation. Panels C and G express concentration changes during MetMb reduction. Panels D and H express concentration changes during MbO_2 oxidation to MetMb. Data are expressed as the mean ± SD; note that most SD values are smaller than the symbols used in the graph.

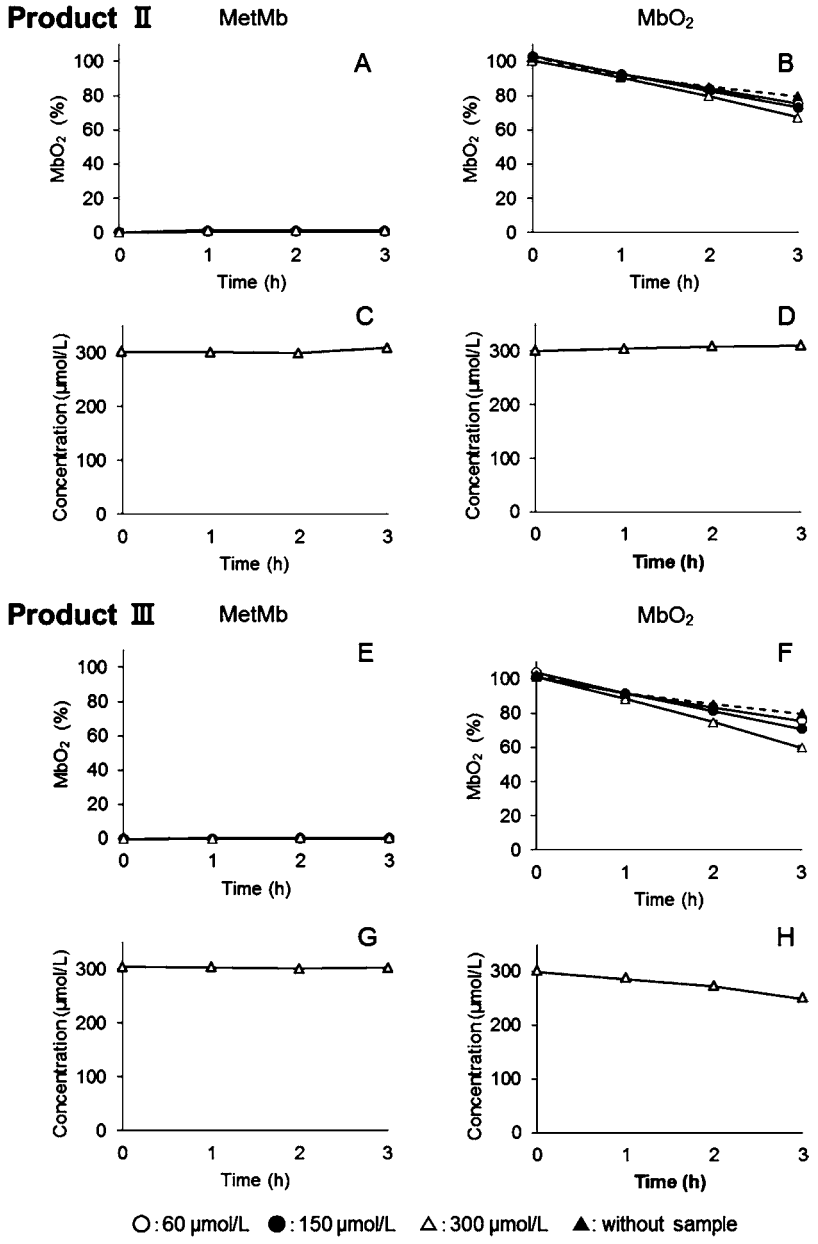

Figure 7. MetMb reduction and MbO_2 oxidation of products II and III and changes in concentrations of products II and III in the reaction solutions. Panels A and E refer to MetMb reduction. Panels B and F refer to MbO_2 oxidation. Panels C and G express concentration changes during MetMb reduction. Panels D and H express concentration changes during MbO_2 oxidation to MetMb. Data are expressed as the mean ± SD; note that most SD values are smaller than the symbols used in the graph.

and myricetin (**11**) showed apprant reducing activity even at this lower concentration. These compounds are flavonols, and flavonols are known to be potent antioxidants[19] with low reduction potential[20] relative to other flavonoids. Next, we undertook a chemical investigation of the high reducing activity of the flavonol, quercetin (**14**).

HPLC Analysis of Quercetin Products during MetMb Reduction. On the basis of redox principles, quercetin should be oxidized during MetMb reduction. We carried out a time-course analysis of the MetMb reducing reaction of quercetin by HPLC. Figure 3 shows analytical results at 2 h. In the HPLC profile, three noticeable peaks were observed at retention times of 7.8, 8.3, and 11.3 min, in addition to quercetin (17.8 min). The time course of the formation of these reaction products is summarized in Figure 4. Figure 4 shows three new compounds (products I–III) coinciding with the decrease in quercetin levels during the reaction. The formation of product I was faster than that of products II and III, indicating that product I was the first oxidation product from quercetin and that products II and III were secondary products, possibly derived from product I. The MetMb reduction was completed by 1 h, and the produced MbO_2 remained at the same concentration (the bottom–right panel of Figure 2). Product I reached a plateau after 2 h, while products II and III continued to increase and quercetin decreased over 3 h. These results suggested that quercetin was largely responsible for MetMb reduction, while the other products probably contributed to the maintenance of MbO_2 levels.

Identification of Products I–III from Quercetin. To identify the structures of products I–III, we applied various

dx.doi.org/10.1021/jf404357h | J. Agric. Food Chem. 2014, 62, 893–901

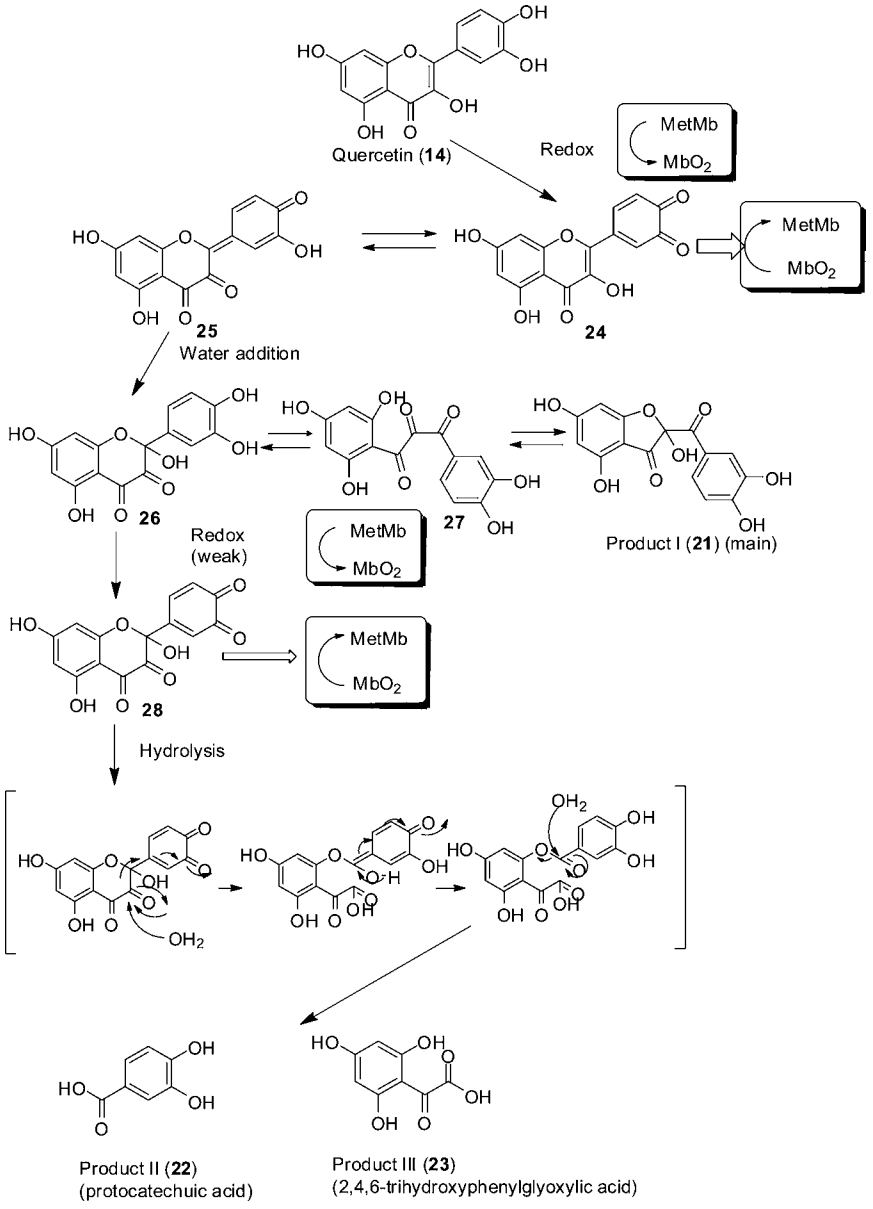

Figure 8. Proposed mechanism for MbO_2 production from MetMb by quercetin.

chemical reagents to quercetin. We found that oxidation by ferric chloride afforded better results than other oxidation reagents. Treatment of quercetin with ferric chloride in acetonitrile and water gave a mixture of the same products as observed in the MetMb reduction. The products were purified by preparative HPLC using an ODS column to give products I–III. ^{1}H NMR, UV, and MS analysis of these products revealed that they are products of oxidation and oxidative degradation of quercetin. The structures of these products are shown in Figure 5. Products II (**22**) (protocatechuic acid) and III (**23**) (2,4,6-trihydroxyphenylglyoxylic acid) were previously identified from peroxidase oxidation of quercetin, and their UV spectra were identical with the reported values.[21] Although product I was also identified previously from the oxidation of quercetin[22−24] and the structure is tentatively identified as product I (**21**) in Figure 5, it may exist as a tautomer because HPLC of product I showed two slightly split peaks; however, the corresponding pure forms could not be isolated under the analytical conditions because of their rapid conversion to each other. Also, the chemical shifts of the ^{1}H NMR signals for 6 and 8 positions were observed at slightly different values depending up the on concentration. Tautomerism in product I has been reported by several groups,[22,23,25−27] but the observed UV spectrum of product I suggested that it exists mainly as structure I (**21**) (Figure 5).

Effect of Quercetin and Its Oxidation Products on the Redox State of Mb. The effects of three isolated quercetin oxidation products on the redox state of Mb were examined and compared to quercetin. Results for the change in the concentration of MbO_2 in the presence of 60−300 μmol/L quercetin are shown in Figure 6. Panels A and B of Figure 6 show that quercetin oxidizes MbO_2 and reduces the MetMb concentration independently; both reactions converged to ca. 40% MbO_2. Although quercetin and Mb seemed to be under redox equilibrium, quantitative analysis of the reaction mixture (panels C and D of Figure 6) showed that quercetin decreased continuously after reaching equilibrium. These results indicate that the oxidation products identified also influence the redox

dx.doi.org/10.1021/jf404357h | J. Agric. Food Chem. 2014, 62, 893−901

state of Mb. Panels E−H of Figure 6 and panels A−H of Figure 7 show the redox activity of these products toward MbO_2 and MetMb, and their concentration changes during the reaction. As shown in panels E and F of Figure 6, product I also oxidizes MbO_2 and reduces MetMb, but efficiency is much lower than quercetin in both cases. Products II and III have negligible oxidative activity toward MbO_2 and no reductant activity toward MetMb (panels A, B, E, and F of Figure 7). These results for the redox relation between myoglobins and these products were confirmed by HPLC analysis of products I−III in the reaction mixture (panels G and H of Figure 6 and panels C, D, G, and H of Figure 7). As shown in panels G and H of Figure 6, the concentration of product I (300 μmol/L) was decreased with myoglobins, revealing that product I influences the redox reactions with myoglobins. On the other hand, treatment of products II and III with MetMb and MbO_2 shows a negligible change in the concentration, indicating that products II and III are stable under these reaction conditions and do not strongly influence the redox state of Mb.

Proposed Mechanism for MetMb Reduction by Quercetin. We proposed a mechanism for MetMb reduction by quercetin *in vitro* (Figure 8). First, quercetin reduces MetMb to produce bright red MbO_2; however, oxidized quercetin drivatives, including the B-ring quinone (**24**), enhance MbO_2 oxidation. It has been found that electrophilic compounds, such as α,β-unsaturated aldehydes enhanced MbO_2 oxidation.[28] These electrophiles were indicated to react with Mb at nucleophilic amino acid residues, destabilizing MbO_2.[29] Quinone derivatives of polyphenols also have the same electrophilic tendency[30,31] to alter the tertiary structure of proteins, such as MbO_2, which is rich in nucleophilic amino acid residues, such as histidine and lysine.[32] Polyphenols are potent antioxidants bearing catechol moieties, which during oxidation afford *ortho*-quinone derivatives, and some polyphenols afford quinone derivatives that accumulate in the system.[33,34] To date, no quinone derivative has been isolated from quercetin or related flavonols, but several water adducts have been identified.[24,35,36] These results suggested that water addition to the oxidized flavonols is fast and quickly yields phenolic compounds that prevent quinone−protein interactions. As illustrated in Figure 8, one molecule of water is added to a tautomer of the quinone (**25**) and affords product I (**21**) via water adducts **26** and **27**, which has a catechol moiety that can reduce MetMb. Although reduction by product I (**21**) also produces another quinone derivative **28** that may oxidize MbO_2, its efficiency is much lower than that of quercetin. In addition to its low redox activity, product I (**21**) is converted to products II (**22**) and III (**23**) via oxidation and subsequent hydrolysis. Thus, products II (**22**) and III (**23**) exhibit almost no redox activity toward MetMb or MbO_2. These properties are also supported by the higher reduction potential of product II (E_7 of 0.60 V)[37] and that of quercetin (E_7 of 0.33 V).[38] From the results of this investigation, we propose that most of the predominant MetMb-reducing activity of quercetin and related flavonols is because of their high propensity to reduce MetMb combined with the rapid conversion of their oxidized products, which destabilize MbO_2, to redox-stable compounds.

The results of this investigation showed that some polyphenols were applicable to reduce MetMb to bright red MbO_2. The bright red color is very important to maintain the freshness and quality of meat and meat-derived foods. The proposed reduction mechanism of one of polyphenols, quercetin, have revealed high potential for application of polyphenols to maintain the fresh meat color as reductants and also to develop a new color-maintaining technique for meat foods based on the redox chemistry of polyphenols.

300 HR was obtained from Amersham Biosciences. Other chemicals and reagents were of analytical grade.

Extraction and Purification. The pulp tissues of *L. chinensis* (500 g) were defatted with ethanol for 8 h and then extracted with water (1:20, w/v) at 85 °C for 3 h. This process was repeated three times. After centrifugation at 3018*g* for 10 min, the supernatant was concentrated and precipitated with 95% ethanol (2 times volume) at 4 °C for 12 h. The precipitate was then dissolved in distilled water and intensively dialyzed for 2 days against distilled water (cutoff M_w 3500 Da). After concentration, the solution was deproteinized with Sevag reagent ($CHCl_3$/BuOH = 4:1, v/v) for 15 min, and the procedure was repeated seven times. Finally, the extracts were centrifuged to remove insoluble material, and the supernatant was lyophilized as the crude polysaccharide (LCP50).

The crude polysaccharide was dissolved in distilled water and fractionated on a DEAE-cellulose-52 column (5.0 × 70.0 cm) equilibrated with distilled water with a linear gradient from 0 to 1.0 M NaCl at a flow rate of 0.7 mL/min. All of the fractions were assayed for carbohydrate content by using the phenol−sulfuric acid method, and one sharp peak was pooled, dialyzed, concentrated, and further purified by a Sephadex G-100 column (1.6 × 80.0 cm) and Sephacryl S-300 HR (1.2 × 100.0 cm) eluting with water, to afford a purified polysaccharide (LCP50W).

General Analysis. The carbohydrate content was determined according to the phenol−sulfuric acid method using glucose as a standard.[14] Sulfate content was measured according to the referenced method.[15] Uronic acid content was determined by the carbazole−sulfuric acid method using glucuronic acid as a standard.[16] Fourier transform infrared (FT-IR) spectroscopy was recorded using a Tensor 27 Bruker instrument. The sample was ground with KBr powder and then pressed into pellets for FT-IR measurement in the frequency range of 4000−500 cm^{-1}.[6] Optical rotation was measured using a Jasco Polarimeter model P-1020 at 23 °C.

Determination of Homogeneity and Number-Average Molecular Weight. The homogeneity and number-average molecular weight of LCP50W were determined on a Waters Acquity UPLC system equipped with a TSK-SW4000 column and an evaporative light scattering detector (ELSD). The sample solution (10 mL, 1.0 mg/mL) was injected each run, with water as the mobile phase at a flow rate of 0.3 mL/min. The linear regression was calibrated with T-series dextran standards (M_w = 5 × 10^6, 2 × 10^5, 7 × 10^4, 1 × 10^4, and 3 × 10^3 Da).[17]

Chemical Composition Determination. LCP50W (5 mg) was hydrolyzed for 6 h at 110 °C with 2 mL of 2 M TFA. Excess acid was removed through codistillation with MeOH. High-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD) was used for identification and quantification of the monosaccharides. The diluted sample was passed through a 0.45 μm filter and injected into the HPAEC-PAD system (Dionex-5500, Dionex Corp., Canada).[18] LCP50W (30 mg) was partially hydrolyzed with 0.05 M TFA at 100 °C for 6 h, and TFA was removed by evaporation. The hydrolysate was dialyzed against distilled water for 48 h in a dialysis bag with a 3500 Da cutoff. The fraction outside the dialysis bag was collected and evaporated to dryness (fraction 1). The fraction in the dialysis bag was dried by evaporation under reduced pressure and then hydrolyzed with 0.5 M TFA. The hydrolysate was also dialyzed against distilled water for 48 h. The fraction out of the dialysis bag (fraction 2) and the fraction in the dialysis bag (fraction 3) were collected and evaporated to dryness, respectively. Fractions 1, 2, and 3 were hydrolyzed with 2 M TFA at 110 °C for 6 h and then analyzed by HPAEC-PAD.[6]

Periodate Oxidation and Smith Degradation Analysis. LCP50W (15 mg) was dissolved in distilled water, and then 15 mM $NaIO_4$ (25 mL) was added into the solution. Thirty milliliters of the solution was drawn at 6 h intervals in the dark 4 °C and then diluted to 5 mL with the water and measured in a spectrophotometer at 223 nm.[19] The reaction was completed after 84 h, and ethylene glycol (0.2 mL) was added to the solution to decompose the excess reagent. Consumption of HIO_4 was measured according to a spectrophotometric method,[20] and the production of formic acid was determined by titration with 0.060 M NaOH. The reaction mixture was dialyzed against distilled water, and the nondialysate was reduced with $NaBH_4$ (30 mg) for 24 h. The pH was adjusted to 6.0 with 0.1 M HOAc, and then the solution was dialyzed. The nondialysate was lyophilized and hydrolyzed with 2 M TFA at 110 °C for 6 h. Finally, the products were acetylated and analyzed by GC.[7]

Methylation and GC-MS Analysis. LCP50W (20 mg) was methylated six times according to the method described by Hakomori.[21] Complete methylation was confirmed by the disappearance of the OH band (3200−3700 cm^{-1}) in the IR spectrum. The methylated products were hydrolyzed, reduced, and acetylated. The resulting alditol acetates were analyzed by GC-MS.[22] Linkages were identified according to the relative retention time and fragmentation patterns. The monosaccharide molar ratio was calibrated using the peak areas and response factor in GC.

NMR Spectroscopy. LCP50W (60 mg) was dried in a vacuum oven (70 °C) for 6 h, and then the dried sample was dissolved in 2 mL of D_2O and lyophilized. This procedure was repeated three times to completely replace H with D, and the sample was finally dissolved in D_2O for 3 h before NMR analysis. ^{13}C NMR and ^{1}H NMR spectra were recorded on a Bruker AMX 500 FT spectrometer (Bruker, Germany).

Ultrastructure of LCP50W. A scanning electron microscope (SEM) image of LCP50W was obtained by means of an environmental scanning electron microscope (ESEM, Philips XL-30, Philips-FEI Co., Eindhoven, The Netherlands). The dried powder sample was placed on a specimen holder fixed with double-side adhesive tapes and then sputtered with gold powder using a sputter coater. The sample was observed with 1000-, 5000-, 10000-, and 30000-fold magnification at an accelerating potential of 5.0 kV under a high-vacuum condition.

Animals and Cells. Kunming mice (grade II, SCXK 2011-2015, 20−25 g, 6−8 weeks old) were obtained from the Experimental Animal Center, Sun Yat-sen University, China. Animals were acclimatized for at least 7 days prior to use and maintained in a temperature-controlled environment (22 ± 2 °C) with a 12 h light−dark cycle and with free access to water and standard rodent chow.

YAC-1 lymphoma cell line was obtained from The Cell Bank of Type Culture Collection of Chinese Academy of Sciences (Shanghai, China). It was maintained in RPMI 1640 medium supplemented with 100 IU/mL penicillin, 100 μg/mL streptomycin, and 10% FBS at 37 °C under humidified air with 5% CO_2.

Splenic Lymphocyte Proliferation Assay. The assay for splenic lymphocyte proliferation was performed by MTT method.[23] Briefly, spleens were aseptically removed from sacrificed mice with scissors and forceps in cold phosphate-buffered saline (PBS) and then minced in aseptic PBS. The splenocytes were obtained by pressing spleen tissue through nylon mesh filters. The removal of blood cells in the splenocyte suspension was carried out by washing the cells with Tris-NH_4Cl three times. The isolated splenocytes were counted by trypan blue exclusion with viability of >95%, and then they were placed into the 96-well flat-bottom microplates at 5 × 10^6 cells/mL in RPMI 1640 medium with or without LCP50W. The groups that combined with Con A were cotreated with Con A (5 μg/mL), whereas the negative control was treated with RPMI 1640 medium only. Each group was repeated in three wells. The cells were incubated at 37 °C under 5% CO_2 for 48 h, and then 20 μL of MTT (5 mg/mL) was added to each well, with further incubation for another 4 h. After removal of MTT by centrifugation at 1811*g* for 5 min at 4 °C, the formazan precipitate was solubilized in DMSO (200 μL/well). Splenic lymphocyte proliferation was measured by determining the optical density (OD) at 570 nm using multifunctional microplate reader (Boteng, USA).

Natural Killer (NK) Cell Cytotoxicity Assay. Lymphocytes from each mouse were prepared as effector cells, whereas YAC-1 cells were used as target cells. In brief, the effector cells (1 × 10^7 cells/mL) were incubated for 48 h with LCP50W ranging from 3.9 to 250 μg/mL. Then the same volume of YAC-1 cells (2 × 10^5 cells/mL, effector cells/target cells = 50:1) was added to the wells of 96-well round-bottom microwell plates in the sample group. In addition, the wells that had only added effector cells or target cells were respectively taken as effector and target cells control groups. Each group was repeated in three wells. After 4 h of incubation, the MTT method was used to

detect NK cell activity. The OD value at 570 nm for each well was measured using a multifunctional microplate reader (Boteng, USA). The percentage of NK cell cytotoxicity was calculated from the formula

$$\text{NK cell cytotoxicity} = [1 - (OD_S - OD_E)/OD_T] \times 100\%$$

where OD_S refers to the OD value of test sample, OD_E refers to the OD value of effector cell control, and OD_T refers to the OD value of target cell control.[24]

Measurement of Th1/Th2 Cytokines. The levels of cytokines IFN-γ and IL-4 (especially secreted by Th1 and Th2 cells, respectively) were determined using sandwich ELISA kits. Briefly, lymphocytes from each mouse were prepared as described above, and then they were placed into the 24-well flat-bottom microplates at 5×10^6 cells/mL in RPMI 1640 medium with or without LCP50W, in which concentrations were 3.9, 15.6, and 62.5 μg/mL respectively. Meanwhile, all wells were in the presence of Con A (5 μg/mL). Each group was repeated in three wells. After incubation for 48 h, the lymphocyte supernatant was collected by centrifugation at 906*g* for 15 min. The cytokine concentrations were assayed according to the cytokine ELISA protocol from the manufacturer's instructions.[25]

Determination of Th1/Th2 Specific Transcription Factors.[26] Lymphocytes were prepared as described above, and then they were placed into the 6-well flat-bottom microplates at 5×10^6 cells/mL in RPMI 1640 medium with or without LCP50W, in which concentrations were 3.9, 15.6, and 62.5 μg/mL, respectively. All wells were in the presence of Con A (5 μg/mL). Each group was repeated in three wells. After incubation for 48 h, the lymphocytes were collected by centrifugation at 1811*g* for 5 min. The collected lymphocytes were homogenized using Trizol reagent, and then chloroform was added to remove proteins. Isopropanol was used to precipitate total RNA. RNA pellets were dissolved in 20 μL of diethylpyrocarbonate (DEPC)-treated water. Total RNA was converted into cDNA using a Veriti 96-well thermal cycler (Applied Biosystems), and cDNA was amplified by PrimeScript One Step RT-PCR kit ver. 2. Primers were designed and synthesized by Shanghai Sangon Biotech. The sequences of specific primers are listed in Table 1.

Table 1. Primers Used in This Study

primer	sequence (5′−3′)	product size (bp)
mouse T-bet forward	GCCAGGGGAACCGCTTATATG	136
mouse T-bet reverse	GACGATCATCTGGGTCACATTGT	
mouse GATA-3 forward	TCTGGAGGAGGAACGCTAATGG	408
mouse GATA-3 reverse	GAACTCTTCGCACACTTGGAGACTC	
mouse β-actin forward	ATGTTTGAGACCTTCAACAC	491
mouse β-actin reverse	CACGTCACTTCATGATGG	

The reaction conditions were as follows: 50 °C/30 min for reverse transcription, 94 °C/2 min for initial denaturation, amplification for 30 cycles (94 °C/30 s for denaturation, 58 °C/30 s for annealing, and 72 °C/40 s for extension), and hold at 4 °C. PCR products (5 μL) were analyzed by electrophoresis in a 1.5% agarose gel for 30 min. Then the electrophoresis bands were observed by gel imager (Bio-Rad Corp., Hercules, CA USA), and photographs were taken. Image analysis software (Image J) was applied to analyze the DNA bands. The gray value of β-actin was taken as the standard one, and the results were represented by the ratios of gray values of transcription factor T-bet or GATA-3 to β-actin.

Determination of Cell Cycle Distribution. Lymphocytes from each mouse were prepared as described above, and then they were placed into the 24-well flat-bottom microplates at 5×10^6 cells/well in RPMI 1640 media with or without LCP50W, in which concentrations were 7.8, 31.2, and 125 μg/mL, respectively. The positive control was treated with Con A (5 μg/mL), whereas the negative control was treated with RPMI 1640 only. Each group was repeated in three wells. After incubation for 48 h, the lymphocytes were collected by centrifugation at 1811*g* for 5 min. The collected lymphocytes were fixed by cold 70% ethanol (10% FBS) at 4 °C for 8 h. The fixed cells were rinsed by PBS and then dyed by PI dye solution for 15 min. The dyed cells were filtered through 300 mesh nylon mesh and finally analyzed by a FACScan Flow cytometer (BD) with ModFit LT 4.0 software.

Statistical Analysis. The results are expressed as the means ± SD of data obtained from triplicate experiments. Statistical analysis was performed by independent *t* test in Statistical Analysis software SPSS 11.5, and $P < 0.05$ was regarded as statistically significant.

RESULTS AND DISCUSSION

Isolation, Purification, Determination of Molecular Weight, and Composition of LCP50W. After hot water extraction and ethanol precipitation, the crude polysaccharide (8.54 g) was obtained from pulp tissues of *L. chinensis*. After purification via DEAE-cellulose 52, Sephadex G-100, and Sephacryl S-300 HR column chromatography, the profile of LCP50W appeared as a single and symmetrical sharp peak, which was detected by the phenol−sulfuric acid method. The yield of LCP50W from the crude polysaccharide was calculated to be 55.6%. It also exhibited a single and symmetrical peak in HPLC-GPC analysis, which showed its homogeneity based on the distribution of molecular weight. Its molecular weight was determined as 4.72×10^4 Da according to the retention time. The total carbohydrate content of LCP50W was measured to be 98.2% (w/w), and the *m*-hydroxybiphenyl colorimetric test

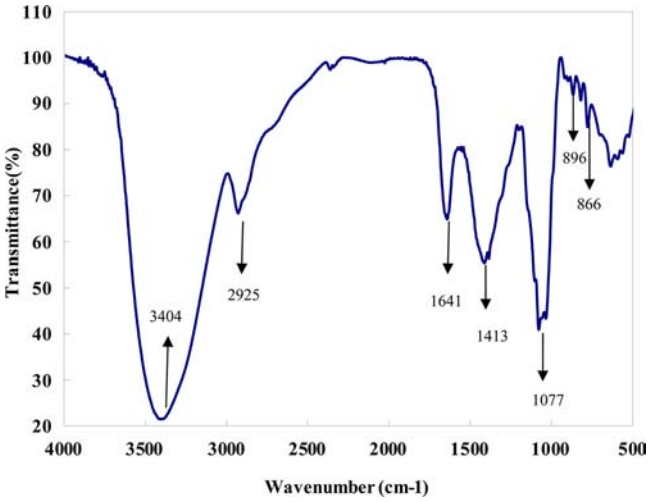

Figure 1. FI-IR spectrum of LCP50W.

was negative. LCP50W did not contain any sulfate esters. The uronic acid content of LCP50W was below the detection limit. The optical rotation of LCP50W was $[\alpha]_D^{20} = -35°$ (c 1.0, 23 °C, H_2O).

Structural Characterization of LCP50W. The monosaccharide composition of LCP50W is presented in Table 2. Five monosaccharides, rhamnose, arabinose, galactose, glucose, and mannose, were identified in the hydrolysate of LCP50W, and their ratios were 2.45:5.78:1.00:4.58:1.32 by HPAEC-PAD analysis. The component of fraction 3 in Table 2 showed that rhamnose and glucose may be the backbone of the structure of LCP50W. The analysis results of fractions 1 and 2 indicated that the branched structure of LCP50W was composed of rhamnose, galactose, and mannose and terminated with arabinose. The periodate-oxidized products were fully hydrolyzed and analyzed by HPAEC-PAD after periodate oxidation. The results shown in Table 2 indicate that there were rhamnose, galactose, and mannose in the oxidation products. The presence of rhamnose, galactose, and mannose revealed that some residues of rhamnose, galactose, and mannose were (1→3)-linked, (1→2,3)-linked, (1→2,4)-linked, (1→3,4)-linked, or (1→2,3,4)-linked, which could not be oxidized, respectively. There was no arabinose or glucose in the oxidation products (Table 2). It could be inferred that linkages of arabinose and glucose were (1→), (1→2), (1→6), and (1→2,6), which might be oxidized to produce glycerol.[27,28]

Methylation and GC-MS Analysis of LCP50W. Methylation analysis by GC-MS was used to provide more structural information for LCP50W. Seven homogeneous peaks of the fully methylated alditol acetates were obtained from GC-MS analysis. The results showed the presence of seven components, namely, 2,3,5-Me_3-Ara, 3,4-Me_2-Rha, 2,4-Me_2-Rha, 2,4,6-Me_3-Man, 2,3,4-Me_3-Glc, 2,4,6-Me_3-Gal, and 3,4-Me_2-Glc in a molar ratio of 3.17:0.96:0.98:1.25:1.13:1.09:3.03 (Table 3). According to their retention times, by comparison with mass spectrum patterns from the literature, and on the basis of the standard data in the CCRC Spectral Database for PMAAs, the linkages of D-galactose and L-mannose were deduced as (1→3), the linkage of L-arabinose was deduced as (1→), the linkages of D-glucose were deduced as (1→2) and (1→2,6), and the linkages of L-rhamnose were deduced as (1→2) and (1→3). These results showed a good correlation between terminal and branched residues. The molar ratio of these residues agreed overall with the monosaccharide composition of LCP50W described as above.

IR Spectroscopy and NMR Analysis. The infrared spectrum of LCP50W revealed the purified product's major functional groups and the chemical bonds (Figure 1). In the FT-IR spectrum, the characteristic bands in the regions of 3404, 2925, and 1641 cm^{-1} belonged to O−H bending, C−H bending, and associated water, respectively. The band at 1413 cm^{-1} was due to C−O bending; the bands at 1024−1154 cm^{-1} indicated pyranose. The characteristic absorptions at 866 and 896 cm^{-1} indicated that α- and β-configurations present simultaneously. Any signals corresponding to sulfate ester were not found in FT-IR spectrum of LCP50W. There was no absorption at 1740 cm^{-1}, indicating no existence of uronic acid in the polysaccharide structure.[14,29]

The spectra of ^{13}C NMR and ^{1}H NMR of LCP50W are shown in Figure 2. Signals of LCP50W in ^{13}C NMR and ^{1}H NMR spectra were assigned on the basis of the monosaccharide analysis, linkage analysis, and chemical shifts.[6,19,30−34] The resonances in the region of 95.0−110.0 ppm in ^{13}C NMR were attributed to the anomeric carbon atoms of D-galactose, D-glucose, L-rhamnose, L-mannose, and L-arabinose. The peaks at 95.9 ppm corresponded to C-1 of (1→3)-linked α-L-Man unit, 97.5 ppm corresponded to C-1 of (1→6)-linked α-D-Glc unit, 98.5 ppm corresponded to C-1 of (1→2)-linked α-LRha unit, 99.7 ppm corresponded to C-1 of (1→3)-linked α-D-Gal unit, 101.6 ppm corresponded to C-1 of (1→2,6)-linked α-D-Glc unit, 107.5 ppm corresponded to C-1 of (1→3)-linked β-L-Rha unit, and 109.2 ppm corresponded to C-1 of (1→)-linked α-L-Ara unit. The ^{1}H NMR spectrum contained seven signals at δ 5.23, 5.17, 5.13, 5.09, 5.07, 4.99, and 4.85 for the anomeric protons, indicating that seven residues, designated (1→)-linked α-L-Ara, (1→3)-linked α-L-Man, (1→3)-linked α-D-Gal, (1→2)-linked α-L-Rha, (1→2,6)-linked α-D-Glc, (1→6)-linked α-D-Glc, and (1→3)-linked β-L-Rha units, respectively, were present in LCP50W (Table 4). The results also indicated that the backbone was composed of (1→2,6)-linked α-D-glucopyranosyl residues, which branched at O-6. By means of ^{13}C and ^{1}H NMR spectra, the entire assignment of the ^{13}C and ^{1}H chemical shifts of LCP50W was achieved and is presented in Table 4.

On the basis of the results of HPAEC-PAD, GC-MS and NMR, the backbone of LCP50W should contain (1→3)-linked β-L-rhamnopyranosyl residues, (1→6)-linked α-D-glucopyranosyl residues, and (1→2,6)-linked α-D-glucopyranosyl residues, which branched at O-6. The three branches consisted of (1→2)-linked α-L-rhamnopyranosyl residues, (1→3)-linked α-D-galactopyranosyl residues, and (1→3)-linked α-L-mannopyranosyl residues, terminated with (1→)-linked α-L-arabinopyranosyl residues, respectively. From the aforementioned results, the repeating structural unit of LCP50W could be as shown in Figure 3.

Ultrastructure. Figure 4 presents scanning electron micrographs (SEM) of LCP50W at magnifications of 1000, 5000, 10000, and 30000. SEM observations revealed that the ultrastructure of LCP50W was mainly composed of a surface with a sheet-like appearance and randomly distributed ovoid-shape particles, with diameters of approximately 2.5 μm. These might be due to the branches and network structures of the polysaccharide.

Effect of LCP50W on Splenic Lymphocyte Proliferation. The spleen combines the innate and adaptive immune system in a uniquely organized way, which has become the most important organ for antibacterial and antifungal immune

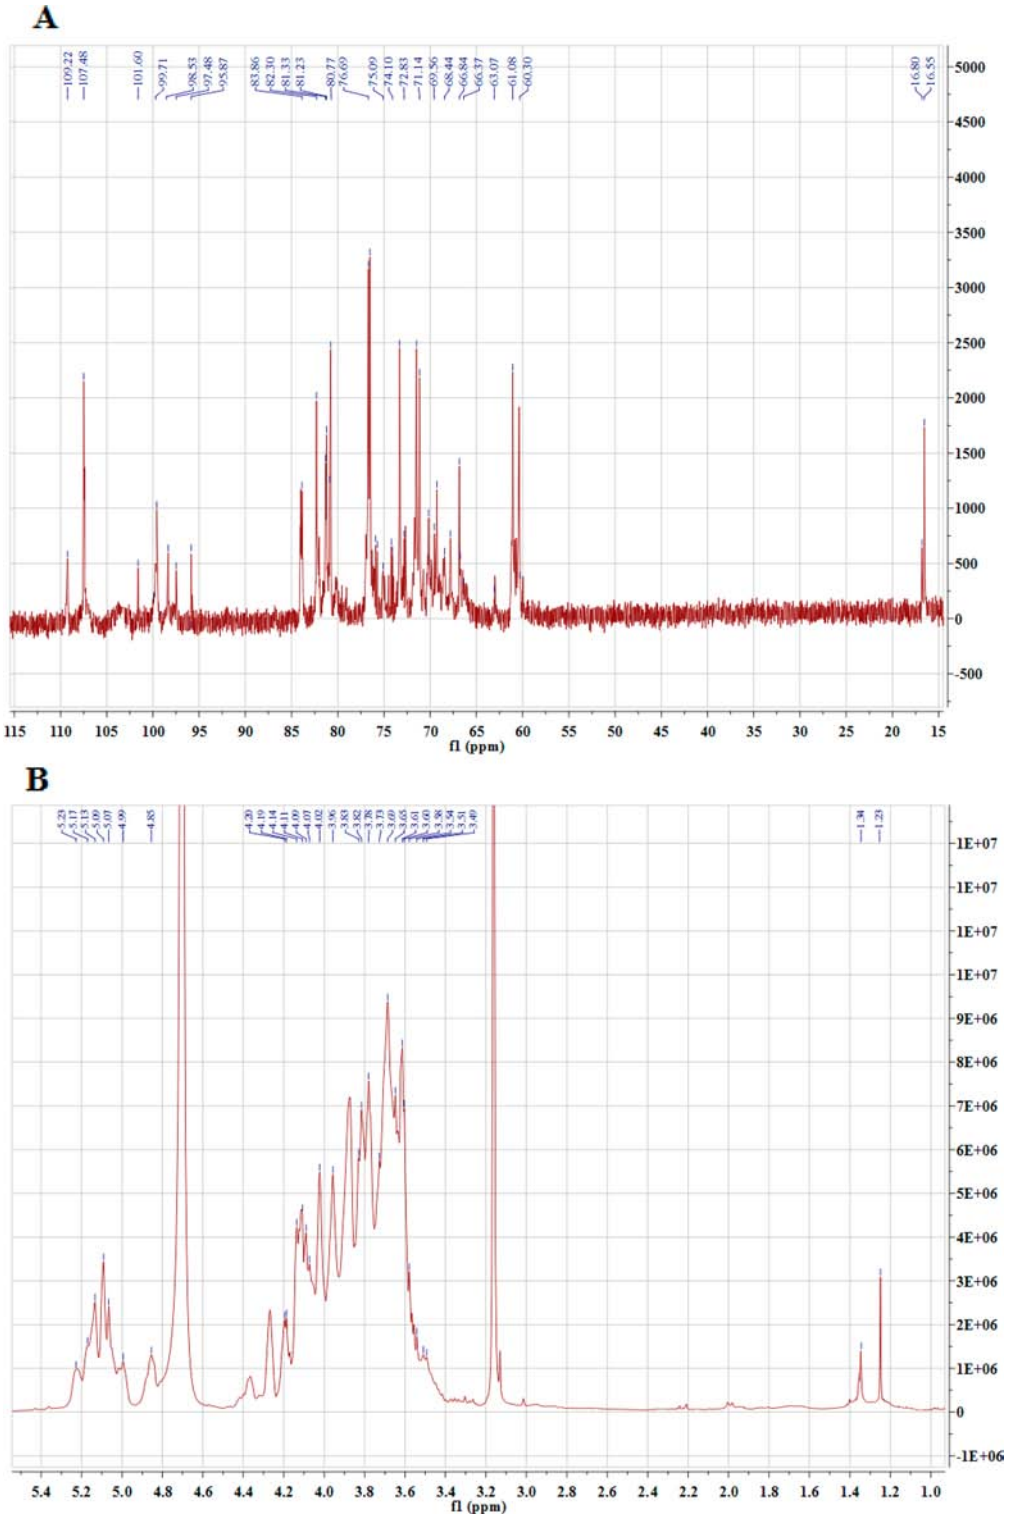

Figure 2. (A) ^{13}C NMR spectrum and (B) ^{1}H NMR spectrum of LCP50W.

reactivity. Therefore, the spleen has been an ideal tissue to be studied in immune research.[35] To investigate the general activity of LCP50W on immune cells, the effect on splenic lymphocyte proliferation was investigated, and the results are presented as Figure 5. LCP50W (3.9−125 μg/mL) significantly promoted the proliferation of splenic lymphocytes in a concentration-dependent manner. When used in combination with Con A, LCP50W also caused a significant stimulation of the proliferation of splenic lymphocytes. These results indicated that LCP50W had the potential of promoting the lymphocyte proliferation alone or along with Con A.

Effect of LCP50W on NK Cell Cytotoxicity. NK cells are another important group of immune cells, serving as effector lymphocytes of the innate immune system that control several types of tumors and microbial infections by limiting their spread and subsequent tissue damage.[36] In Figure 6, we could find that LCP50W promoted the cytotoxicity of NK cells at

concentrations of 3.9−250 μg/mL, which showed a concentration-dependent manner.

Effect of LCP50W on Secretion of Cytokines IFN-γ and IL-4. From the results of LCP50W on the proliferation of lymphocytes and cytotoxicity of NK cells, we could get the initial conclusion that LCP50W had the potential of immune enhancement. To further explore its immunomodulatory mechanism, we investigated the secretion levels of IFN-γ and IL-4, which are hallmark cytokines of Th1 and Th2 cells, respectively.[37] The two cytokines are often mutually exclusive in immune response. IFN-γ secreted by Th1 cells could inhibit the proliferation of Th2 cells, whereas IL-4 secreted by Th2 cells in turn may suppress the proliferation of Th1 cells. As shown in Figure 7A, LCP50W (3.9−62.5 μg/mL) boosted the secretion of IFN-γ but significantly inhibited that of IL-4 (Figure 7B) in a concentration-dependent manner.

Effect of LCP50W on Expression of Transcription Factors T-bet and GATA-3. The effect of LCP50W on the release of IFN-γ and IL-4 suggested that its stimulation of mice immune function might be mediated by influencing Th1/Th2 balance. For exploring the mechanism, the transcription factors T-bet and GATA-3, which are specific transcription factors of Th1 and Th2 cells, were further investigated. T-bet, which belongs to the Tbr1 subfamily of the T box gene family, is a 530 amino acid protein with a 189 amino acid T box DNA-binding domain. T-bet is a Th1-specific transcription factor that plays a central role in Th1 development, which transactivates the IFN-γ gene, induces IFN-γ production, and redirects polarized Th2 cells into the Th1 pathway.[38] GATA-3 belongs to the GATA family of zinc finger proteins, which was selectively expressed in differentiating and effector Th2 cells. GATA-3 is required for

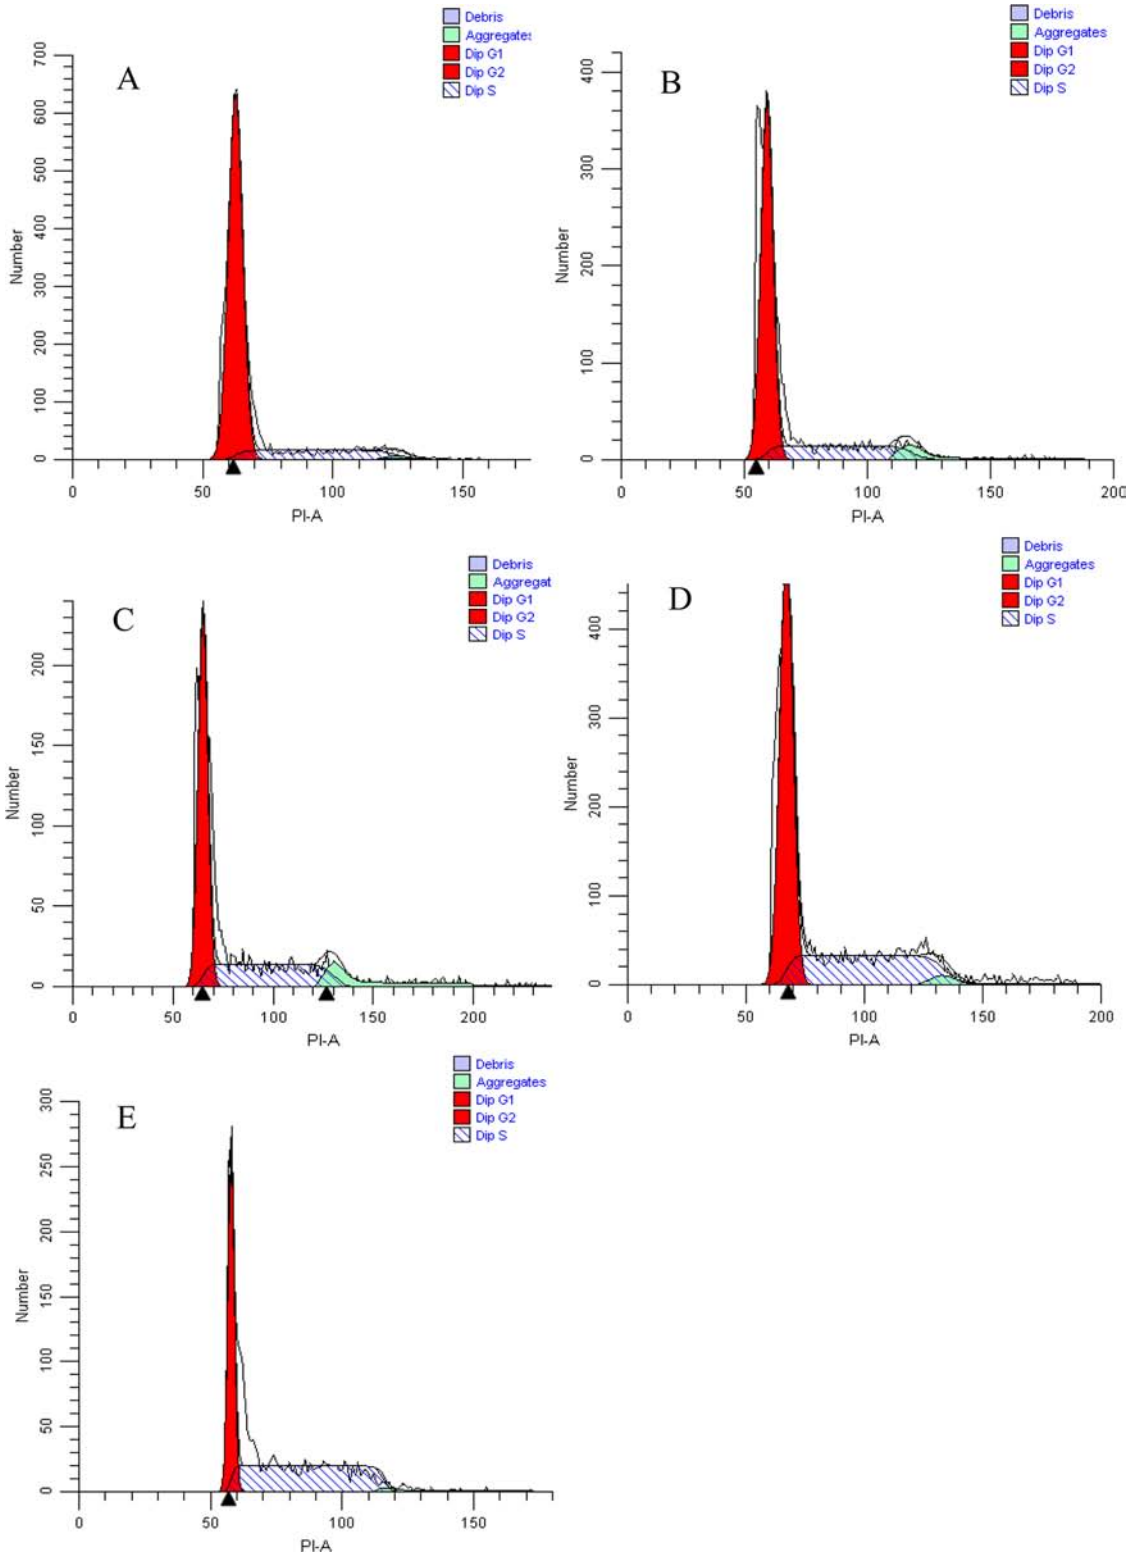

Figure 9. Effect of LCP50W on lymphocyte cell cycle: (A) 0 μg/mL; (B) 7.8 μg/mL; (C) 31.2 μg/mL; (D) 125 μg/mL; (E) Con A 5 μg/mL. Data were analyzed by a BD FACScan Flow with ModFit LT 4.0 software.

the transcription of all Th2 cytokine genes, and the loss of Th2 cytokine gene expression in Th1 cells is at least in part a consequence of the down-regulation of GATA-3. GATA-3 appears therefore to be a potent transactivator of the IL-4 promoter.[39] The results shown in Figure 8 indicated that LCP50W (3.9−62.5 μg/mL) inhibited the expression of GATA-3 but enhanced that of T-bet. The DNA bands were further analyzed by image analysis software Image J, and results are represented in Table 5 by the ratios of gray values of transcription factor T-bet or GATA-3 to β-actin. LCP50W showed significant up-regulation of T-bet at concentrations of 15.6 and 62.5 μg/mL and noticeable down-regulation of

GATA-3 at 3.9, 15.6, and 62.5 μg/mL, respectively, when compared to the negative control.

Effect of LCP50W on Lymphocyte Cell Cycle. For analysis at DNA level, flow cytometry was used to analyze lymphocyte cell cycle distribution. The results obtained by ModFit LT 4.0 software demonstrated that LCP50W promoted spleen cells into the S phase (Figure 9). Data were further performed by independent t test in Statistical Analysis software SPSS 11.5, which are presented in Table 6. LCP50W (7.8, 31.2, and 125 μg/mL) significantly promoted spleen cells into the S phase in a concentration-dependent manner, which was consistent with the results in Figure 5A.

In conclusion, a novel water-soluble polysaccharide (LCP50W) isolated from the pulp tissues of *L. chinensis* contained five monosaccharides, D-galactose, D-glucose, L-rhamnose, L-mannose, and L-arabinose. Particularly, our research proposes for the first time the mechanism of immunomodulation of *L. chinensis* polysaccharide (LCP50W). This novel polysaccharide in vitro could promote the proliferation of lymphocytes, NK cell cytotoxicity, and the development of cell cycle toward the S phase. LCP50W boosted the secretion of Th1 cytokine IFN-γ but inhibited the secretion of Th2 cytokine IL-4; it enhanced the expression of T-bet but inhibited the expression of GATA-3. In addition, in vitro study demonstrated that LCP50W had the potential of enhancing the immune functions of mice, which may be mediated by influencing Th1/Th2 balance. Further research is necessary to elucidate the mechanism of LCP50W's immunomodulation on subpopulations of Th1/Th2 cells.

protein, was provided by Shanghai Science Peptide Biological Technology Corp. The purity and molecular mass of the synthesized peptide were verified by HPLC and mass spectrometry, respectively. All the products used were dissolved in 0.9% saline to be administered to the rats.

In Vitro ACE Inhibitory Activity Assay. The assay was conducted using a previously reported HPLC method.[7]

Animal Ware. This study was carried out in strict accordance with the recommendations from the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. The protocol was approved by the Committee on the Ethics of Animal Experiments of Jilin University. All surgery was performed under ether, and all efforts were made to minimize suffering. The protocol conformed to guidelines for the humane care of animals.[14] A total of 30 male SHRs (purchased from Vital River Laboratories), aged 9−10 weeks and weighing 220−270 g, were used in the course of this study. The SHRs were housed in temperature-controlled rooms (22 ± 2 °C) with 12 h light/dark cycles, where spontaneously hypertensive rats could consume tap water and standard diets ad libitum. All SHRs were acclimatized for 3 days with diet before the experiment. The 30 SHRs were assigned to 5 groups: 0.9% saline for the negative group, 10 mg/kg of body mass of captopril for the positive group, and three treatment groups, i.e., 2 mg/kg of body mass of RVPSL for low dose, 10 mg/kg of body mass of RVPSL for medium dose, and 50 mg/kg of body mass of RVPSL for high dose. The rats from the negative group, positive group, and treatment groups were orally administered 1 mL of the corresponding solution from 7:30 a.m. to 8:00 a.m. every day for 4 weeks.

Blood Pressure Measurement. The blood pressure of the SHRs was measured by the tail-cuff method.[15] Before measurement, the rats were kept at 39 °C for 2−3 min to make the pulsation of the tail artery detectable using a blood pressure monitor (model BP-2010A, Softron Co., Tokyo, Japan). The tail cuff was connected to a cylinder of compressed air through an arrangement of inlet and outlet valves that permitted inflation and deflation of the cuff at a constant rate. The systolic blood pressure (SBP) and the diastolic blood pressure (DBP) of the rats were measured by the tail-cuff method before administration and also 5, 10, 15, and 20 h postadministration. Moreover, to guarantee the reliability of the measurements, we established a training period of 4 days before the actual trial time, and during this period the rats were accustomed to the procedure. All measurements were performed by the same person in a quiet environment.

Isolation of RNA from the Rats' Kidneys. Kidney tissues of the spontaneously hypertensive rats that were stored in an ultra-low-temperature freezer at −80 °C (Haier, Beijing, China) were homogenized with a tissue homogenizer under liquid nitrogen conditions. The total RNA of the SHRs' kidneys was isolated using the SV total RNA isolation system Z3105 according to the manufacturer's product instructions (Promega Corp., Beijing, China). The RNA purity and concentration were determined by the A260/A280 ratio (UV2550, Shimadzu, Japan).

Single-Strand cDNA Synthesis. Transcriptor first-strand cDNA was synthesized from 1 μg of RNA using the First Strand cDNA synthesis kit for RT-PCR. A 1 μg portion of total RNA was added to a thin-wall PCR tube on ice, and then 2 μL of 60 μM random hexamer primers was added. RNA-free water was added to a total volume of 13 μL. A 40 μL aliquot of transcriptor reverse transcriptase reaction buffer, 0.5 μL of protector ribonuclease (RNase) inhibitor, 2 μL of deoxynucleotide mix, and 0.5 μL of transcriptor reverse transcriptase were added subsequently to the thin-wall tube, and the contents were incubated at 25 °C for 10 min followed by 55 °C for another 30 min. The reaction was stopped by heating at 85 °C for 5 min. The reaction tube was placed on ice and then stored at −20 °C for an RT-PCR study.

RT-PCR. Real-time PCR was performed for renin, Ang, ACE, AT1 receptor, AT2 receptor, and the housekeeping gene glyceraldehyde 3-phosphate dehydrogenase (GAPDH) using the Premix Ex Taq kits on an ABI 7500 real-time PCR system. The primers were ordered from Takara China (Dalian, Liaoning, China). The results are shown in Table 1. PCR reactions were carried out in a 20 μL solution consisting of 2 μL of cDNA template (50 ng), 10 μL of Premix Ex Taq (Probe qPCR), 0.4 μL of forward primer (10 μM), 0.4 μL of reverse primer (10 μM), 0.8 μL of probe solution, 0.4 μL of ROX reference dye II, and 6.0 μL of PCR water. Thermal cycling was initiated with 30 s of denaturation at 95 °C and then by 40 repeats of 5 s at 95 °C and 30 s at 60 °C for melting curve analysis and cooling. The entire process was performed according to the guidelines of the ABI 7500 instrument (Life Technologies Corp., Grand Island, NY). The quantification of a target gene was expressed as the relative expression ratio of the target gene (i.e., ACE, renin, Ang, AT1 receptor, and AT2 receptor) in a sample versus that of a control in contrast to the housekeeping gene GAPDH.

Assay of Serum Ang and Aldosterone Concentrations. The serum Ang I, Ang II, and aldosterone concentrations were determined with the iodine angiotensin I radioimmunoassay kit, iodine angiotensin II radioimmunoassay kit, and iodine aldosterone radioimmunoassay kit, respectively. The above-mentioned samples were measured with an SN-6105 γ RIA counter (Beijing Tayasaf Science & Technology Co., Ltd., Beijing, China) within 20 min after the reaction was stopped. Test samples and standards were measured in duplicate. All of the

processes were implemented according to the aforementioned guidelines of the manufacturers.

Statistical Analysis. Values are expressed as the means ± SD. Statistical comparisons between groups were performed using one-way analysis of variance (ANOVA) followed by Student's *t* test. *p* values of <0.05 were considered significant.

RESULTS AND DISCUSSION

Effects of RVPSL on the SBP and DBP of the SHRs in 4 Weeks. There were no mortalities and no significant differences in the final body mass among the experimental SHRs during the 4 weeks. The results demonstrated that the oral administration of saline to SHRs did not lower the values of the SBP and DBP (Figure 1). On the contrary, the SBPs of

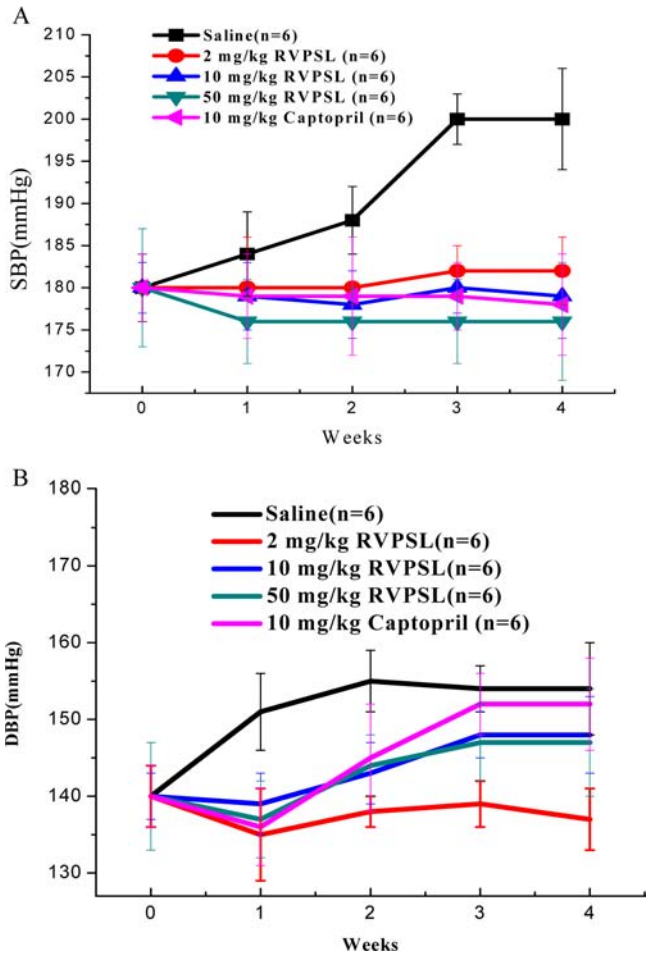

Figure 1. Antihypertensive effects of RVPSL in SHRs: (A) change in the SBP after administration for 4 weeks and (B) change in the DBP after administration for 4 weeks. Each value is expressed as the mean ± SD. A *p* value of <0.05 (*) is considered statistically significant by one-way ANOVA.

SHRs administered saline as the negative group increased from 180 ± 7 to 200 ± 9 mmHg. However, the SBPs of SHRs administered different concentrations of RVPSL as the treatment groups decreased. RVPSL caused a significant dose-dependent decrease in SBP in these animals from the first week until the fourth week. Moreover, the greatest decreases of SBP were obtained when the SHRs were administered 50 mg/kg RVPSL. From the third week after the oral administration with peptide RVPSL, the SBP of the positive control group and that of the treatment groups were significantly lower than that of the negative group.

However, the reduction of DBP in the treatment groups was not significantly higher than that of the negative group from the first week to the fourth week. Some researchers suggested that orally administered bioactive peptide decreased the blood pressure of the SHRs[16] and also demonstrated that the antihypertensive activity of bioactive peptide was blocked by a CCK1 antagonist. In this context, we performed further studies to evaluate the mechanism of antihypertensive peptide derived from egg protein.

Effects of RVPSL on Renin mRNA Expression of the Kidney. Relative renin mRNA levels of the kidney were detected by real-time PCR and quantified as shown in Figure 2A in contrast to GAPDH, which remained stable in comparison to *β*-actin in our study. The expression was analyzed on the fourth week, when a decrease in the treatment group with oral administration of RVPSL (50 mg/kg) and in the positive control group (captopril) was found in contrast to the negative control group (saline). Renin can cleave the substrate angiotensinogen to form Ang I, which is later converted to Ang II. Ang II raises blood pressure by a number of actions: the most important ones being vasoconstriction, sympathetic nervous stimulation, increased aldosterone biosynthesis, and renal actions. Angiotensin II-converting enzyme inhibitors presumably stimulate renin secretion by interrupting angiotensin II feedback inhibition. To some extent, the decrease of renin may contribute to the low production of Ang I and Ang II.

Effects of RVPSL on ACE mRNA Expression of the Kidney. Relative ACE mRNA levels of the kidney were detected by real-time PCR and quantified as shown in Figure 2B in comparison to GAPDH. The expression was also analyzed on the fourth week. A significant decrease in the treatment group with oral administration of RVPSL (50 mg/kg) and in the positive group was found compared to the negative group, but there was no significant difference between the treatment group and the positive group. The results demonstrated that captopril and egg white peptide RVPSL exhibited high activity against ACE in vivo. The antihypertensive effects of captopril and RVPSL were thought to be correlated with their inhibition of ACE activity, which was reflected in our study by the decrease in the mRNA expression of ACE in the kidney for the positive group and RVPSL-treated groups. Consequently, the production of Ang II converted by ACE from Ang I was decreased by the effects of the captopril and/or RVPSL administration. The captopril and the peptide RVPSL are potent inhibitors of angiotensin I-converting enzyme, which is responsible for the conversion of angiotensin I to angiotensin II.

Effects of RVPSL on AT1 and AT2 Receptor mRNA Expression of the Kidney. Relative AT1 receptor and AT2 receptor mRNA levels of the kidney were measured by real-time PCR as shown in parts C and D, respectively, of Figure 2 and compared to the housekeeping gene GAPDH. On the basis of the expression analysis after oral administration for 4 weeks, the results revealed that a significant decrease of AT1 in the treatment group and the positive control group occurred in comparison with the negative control group. However, the AT2 receptor was highly expressed in the treatment group and positive group in contrast to the negative control group. The AT1 receptor seemed to have functions opposite those of the AT2 receptor. Some researchers also demonstrated that the

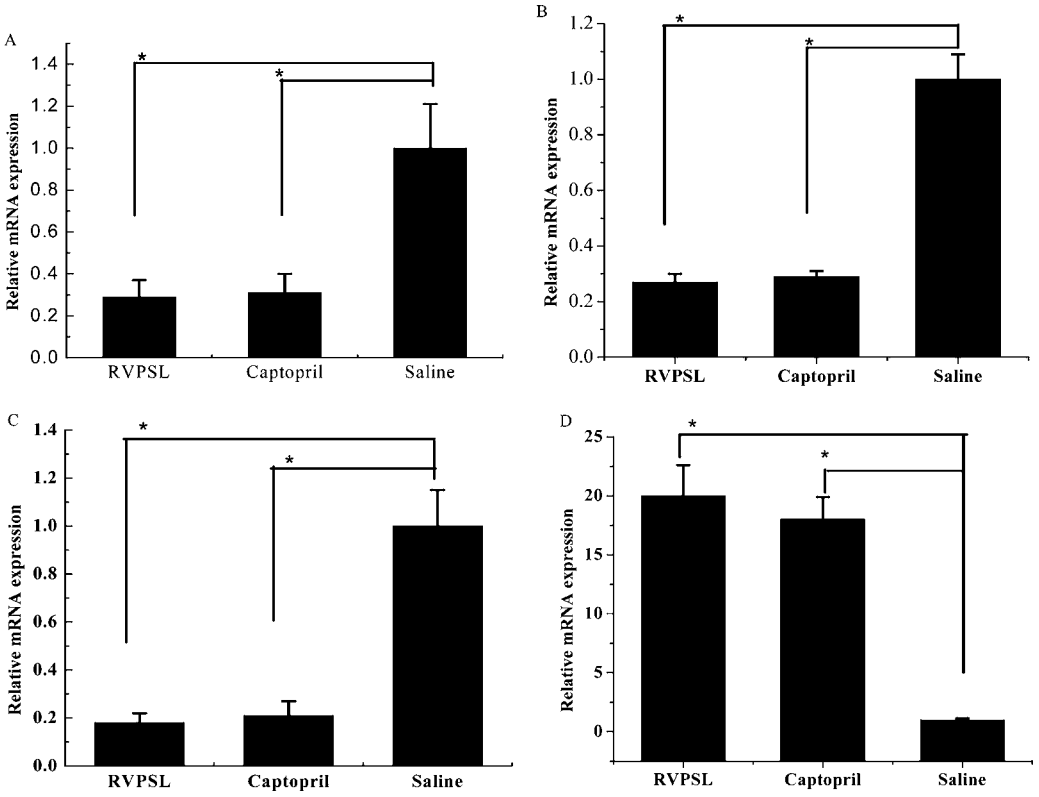

Figure 2. Effect of RVPSL on major RAS components in the SHR kidney: (A) change in relative renin mRNA levels, (B) change in relative ACE mRNA levels, (C) change in relative mRNA levels of the AT1 receptor, and (D) change in the relative mRNA levels of the AT2 receptor . Each value is expressed as the mean ± SD. A p value of <0.05 (*) is considered statistically significant by one-way ANOVA.

AT2 receptors appeared to antagonize the actions of the AT1 receptor.[17]

Effects of RVPSL on the Concentrations of RAS Components of the Serum. The concentrations of serum Ang I, renin, Ang II, and aldosterone were investigated and quantified with an RIA counter and are shown in Figure 3. Compared to the negative group, the serum renin levels of the positive group and high-dose treatment group (50 mg/kg) were significantly lower by 37% and 44% (Figure 3A), respectively. Ang II levels and aldosterone levels of the positive group and high-dose treatment group also declined significantly (Figure 3B,C) in comparison with the negative group. Thus, the peptide RVPSL reduced the blood pressure in combination with the ACE inhibitor or/and renin inhibitor. Although the expression levels of the serum renin of the positive and high-dose treatment groups decreased, the Ang I levels of the positive group and treatment group were not reduced significantly (Figure 3D). Our study on the SHRs gave results similar to those described in another report.[1] In addition, there was no significant difference between the positive group and the high-dose treatment group in the serum Ang I, renin, aldosterone, and Ang II concentrations. In our earlier work, the peptide from egg white protein was shown to have an in vitro ACE inhibition activity with an IC_{50} value of 20 μM,[7] which prompted us to further investigate the in vivo antihypertensive effect of the peptide and explore the corresponding expression of major RAS components in the SHRs. We found that the peptide RVPSL (50 mg/kg) from egg white protein significantly decreased the SBPs of SHRs by 24 mmHg in comparison to the negative group. Miguel[15,18] also evaluated the effects of the hydrolysate of egg white on the short- and long-term arterial blood pressure and suggested that the hydrolysis of egg white with pepsin may be a practical procedure to produce functional bioactive peptides with antihypertensive activity. Ovokinin, a peptide that was hydrolyzed by chymotrypsin from OA 359-364, was found to be able to significantly lower the systolic blood pressure in the SHRs in a dose-dependent manner, when administered orally.[11] Besides, three novel peptides, IQW, IRW, and LKP purified from the ovotransferrin, also exhibited potent activity against ACE based on the quantitative structure−activity relationship of tri- and dipeptides with angiotensin-converting enzyme inhibitory activity.[19] Moreover, IQW was stable against the digestive enzymes.[20] Since the process and pathological characteristics of the SHRs' hypertension are very similar to those of human hypertension,[1] SHRs have generally been used to conduct initial studies on in vivo antihypertensive effects of bioactive peptides. While much is known about diet and physical activity linked to high blood pressure, less is known about the effects of the gene expression level on individual components of RAS in tissues that are responsible for predisposition to cardiovascular disease.[21−24] In this context, we evaluated the mRNA levels of renin, ACE, and AT1 receptor in the rat kidney and found they were significantly reduced. On the contrary, the mRNA level of AT2 receptor in the kidney was upregulated in the treatment group (50 mg/kg) and positive control group compared to the negative group. For the AT1 receptor, the mRNA levels of the positive group and high-dose treatment group (50 mg/kg RVPSL) were decreased significantly. In comparison to that of the negative group, mRNA levels of the AT2 receptor were significantly increased by 20- and 16-fold for the positive group and treatment group (50 mg/kg), respectively. In addition, the

dx.doi.org/10.1021/jf405189y | J. Agric. Food Chem. 2014, 62, 912−917

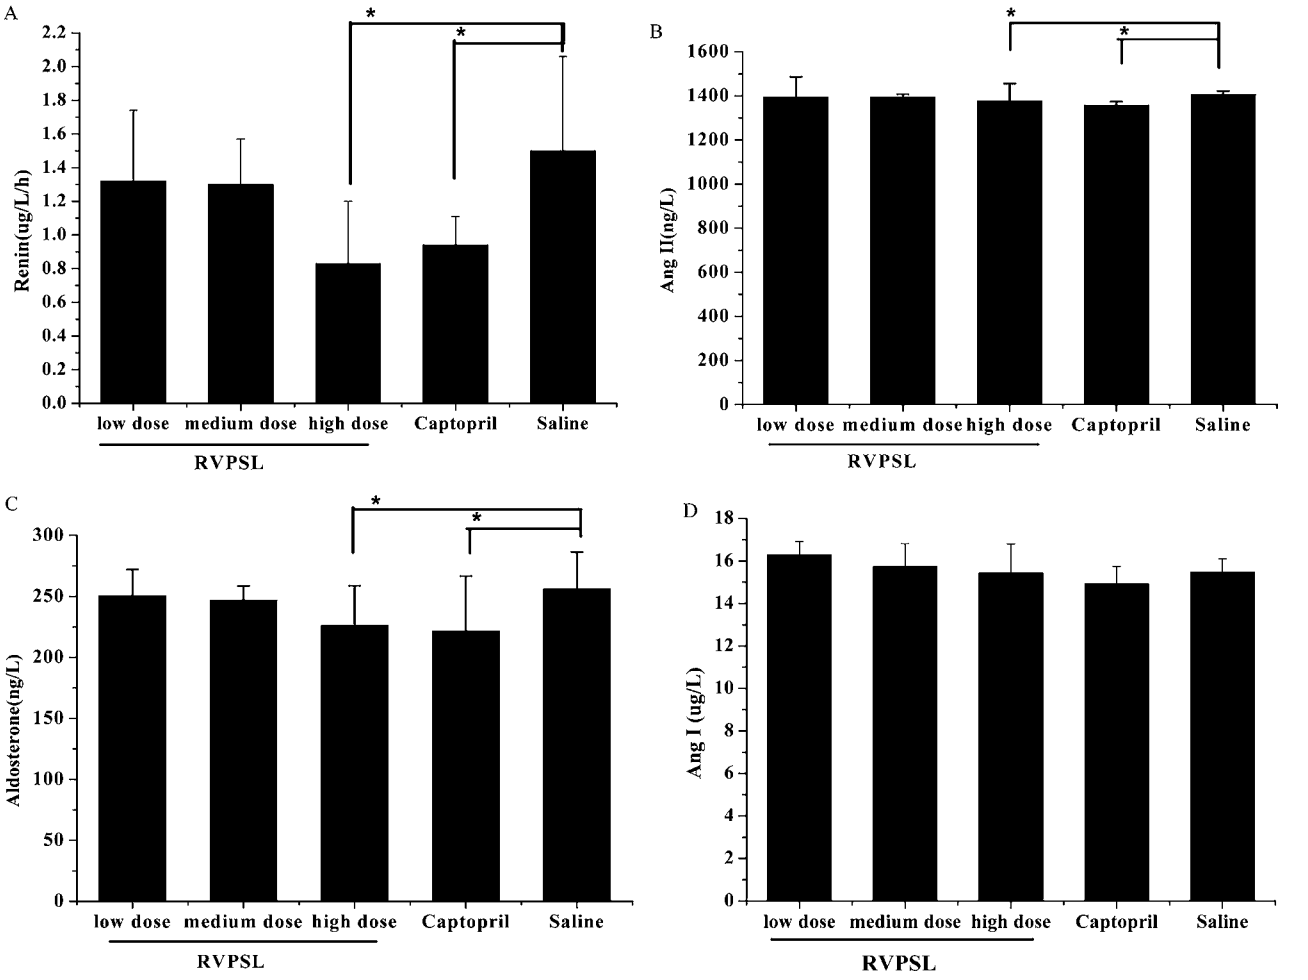

Figure 3. Effects of RVPSL on major RAS components in the serum of SHRs: (A) change in serum renin concentrations, (B) change in serum Ang I concentrations, (C) change in serum Ang II concentrations, and (D) change in serum aldosterone concentrations. Each value is expressed as the mean ± SD. A p value of <0.05 (*) is considered statistically significant by one-way ANOVA.

concentrations of renin, Ang II, and aldosterone in the serum increased significantly in comparison to those of the negative group.

In summary, the current work demonstrated clearly, for the first time, that the peptide RVPSL derived from the egg white significantly decreased the SBP of SHRs in 4 weeks. Also, our results indicated that the peptide RVPSL affected the expression of major RAS components by downregulating the renin, ACE, Ang II, and AT1 receptor while upregulating the AT2 receptor in the kidney or serum of SHRs.

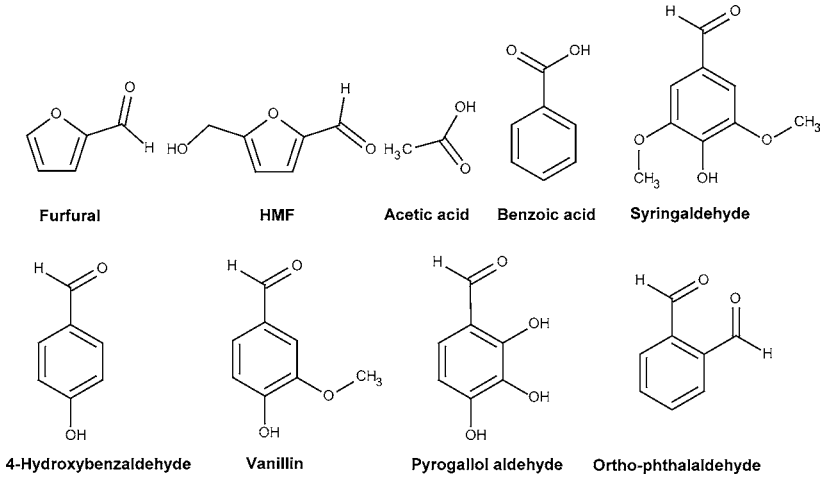

Figure 1. Carbonyl compounds tested for their inhibitory activity on alcoholic fermentation by *Saccharomyces cerevisiae*.

correlation between the structural features of carbonyl compounds and their biological activities will help to understand inhibition of biofuel production. Therefore, we are using QSAR modeling to assess this inhibition on ethanolic fermentation in our research.

In this study, the inhibitory effects of selected aldehydes and acids (Figure 1) on ethanolic fermentation by *Saccharomyces cerevisiae* were investigated. The objective of this study was to identify the specific molecular descriptors that correlate the molecular structure of carbonyl compounds to their inhibitory activity. The quantitative information on carbonyl inhibition was evaluated on the basis of the initial rate of glucose consumption and the final ethanol yield. The alcohol dehydrogenase (ADH) activity in response to vanillin inhibition was determined from the batch fermentation results. Effects of acetic acid and benzoic acid on alcoholic fermentation were also studied with and without pH control. Using those data, the correlation between the inhibition efficiency and carbonyl molecular descriptors was established.

MATERIALS AND METHODS

Chemicals. Glycerol, 4-hydroxybenzaldehyde, 4-hydroxy-3-methoxybenzaldehyde (vanillin), and 2,3,4-trihydroxybenzaldehyde (pyrogallol aldehyde) were purchased from Acros Organics (Morris Plains, NJ, USA). 3,5-Dimethoxy-4-hydroxybenzaldehyde (syringaldehyde) was purchased from Aldrich (Milwaukee, WI, USA). *o*-Phthalaldehyde was purchased from Pickering Laboratories (Mountain View, CA, USA). Benzoic acid and glucose (anhydrous) were purchased from Alfa Aesar (Ward Hill, MA, USA). Vanillyl alcohol and vanillic acid were purchased from Fluka (Milwaukee, WI, USA). Acetic acid, NaOAc, NaCl, KCl, $MgCl_2$, and $CaCl_2$ were purchased from Fisher Scientific (Fair Lawn, NJ, USA). All chemical reagents were of chromatographic grade. Stock solutions of aldehydes (1.0 M) were prepared in ethanol (Sigma-Aldrich, St. Louis, MO, USA), and stock solutions of carboxylic acids (1.0 M) were prepared in deionized water. All stocks were kept at 4 °C before use.

Calculation of Physicochemical Descriptor. The physicochemical properties of model inhibitory compounds were calculated using open software MarvinSketch for the hydrophobicity (log *P*), steric parameter, and molecular refractivity. The E_{LUMO}, E_{HOMO} and dipole moment (u), were calculated using PM6 semiempirical methods (GaussView 5.0). Together, the molecular electrophilicity index (ω) was calculated by using the equation[15,18]

$$\omega = \frac{\mu^2}{2\eta} = \frac{E_{HOMO}{}^2 + 2E_{HOMO}E_{LUMO} + E_{LUMO}{}^2}{4(E_{LUMO} - E_{HOMO})}$$

where μ is the molecular chemical potential and η is the molecular hardness.

Yeast Strain, Culture, and Fermentation. *S. cerevisiae* (baker's yeast, Fleischmann's) was precultured in a YPG liquid medium composed of 10 g/L yeast extract, 20 g/L peptone, and 20 g/L glucose at 30 °C. After 12−15 h, the yeast was harvested and concentrated by centrifugation. The harvested yeast was washed at least twice with sterile water before it was inoculated for batch fermentation. The initial yeast innoculation was 2.0 g/L in fermentation. Batch fermentation was performed in 125 mL serum bottles with 60 mL of 2% (w/w) glucose only at 30 °C, with an initial pH at 6.0 and a shaking speed at 165 rpm for 48 h. No additional nutrients were added in the fermentation medium. The glucose solution was sterilized by filtration through a 0.2 μm sterile filter (VWR, Suwanee, GA, USA). Carbonyl compounds or salts were added into the glucose solution individually from their stock solutions or powders before sterilization. Samples were taken from the fermentation at various time points (1, 3, 6, 9, 12, 24, and 48 h) and centrifuged to collect the supernantant for identification and quantitation by HPLC. Yeast biomass concentration of each data point was measured by UV−vis spectrophotometry at 600 nm. All fermentations were carried out in duplicate. To examine the pH effects of acetic acid and benzoic acid on fermentation, acids were added to the glucose solution from their stock soltuions, and the pH was adjusted with 10% NaOH before sterilization. The resulting pH of the fermentation medium for individual carbonyl compounds was 5.3 (5.0 mM *o*-phthalaldehyde), 4.8 (5.0 mM pyrogallol aldehyde), 5.0 (5.0 mM syringaldehyde), 5.2 (5.0 mM 4-hydroxybenzaldehyde), 5.0 (5.0 mM vanillin), and 5.9 (glucose control), respectively. To examine the effects of inorganic and organic salts on fermentation, we added 27.5 mM NaCl, KCl, $MgCl_2$, and $CaCl_2$ and 50 mM NaOAc individually to 2% glucose solution for batch fermentation. No additional nutrients were added to the fermentation medium. The fermentation conditions were kept the same as above.

The initial consumption rate of glucose (R_S) was calculated on the basis of the sugar consumed in the first 3 h of fermentation [$R_S = (C_0 - C_t)/t$)], where C_0 and C_t were the sugar concentrations at 0 and *t* h, respectively.

The inhibition efficiency *E* (%) of carbonyl compound on fermentation was calculated using the decreased gluocse consumption rate

$$E\ (\%) = \frac{R_{SC} - R_S}{R_{SC}} \times 100$$

where R_{SC} is the initial glucose consumption rate without inhibitor.

HPLC Analysis. Glucose, ethanol, and glycerol were quantitated with a Shimadzu (LC-20A) HPLC system consisting of an autosampler, LC-20AD pump, and RID-10A detector, with a 300 mm × 7.8 mm i.d., 9 μm, Aminex HPX-87P column and a 30 mm × 4.6 mm i.d. guard column of the same material (Bio-Rad, Hercules,

dx.doi.org/10.1021/jf405711f | J. Agric. Food Chem. 2014, 62, 918−926

CA, USA). The mobile phase was composed of 5 mM sulfuric acid running isocratic at 0.6 mL/min. The temperature of the column was maintained at 45 °C throughout the run.

Vanillin, vanillyl alcohol, and vanillic acid were separated and quantitated on the same HPLC system mentioned above with a diode array detector at 254 nm (SPD-M20A). The column for separation was a 250 mm × 4.6 mm i.d., 5 μm, C30 Carotenoid column (Waters, Milford, MA, USA). The mobile phase was acetonitrile/water/formic acid (20:80:1, v/v/v) at 0.6 mL/min, and the temperature of the column was maintained at 30 °C.

Yeast Alcohol Dehydrogenase Activity Assay. To examine the alcohol dehydrogenase (ADH) enzyme activity in response to vanillin inhibition during the batch fermentation, yeast cells were collected at 0, 6, and 9 h of fermentation time with the addition of 0, 2.5, 5.0, 10, and 25 mM vanillin. Samples in 5 mL aliquots were first centrifuged at 2100 rpm for 10 min and then washed with deionized water and centrifuged in an Eppendorf centrifuge 5415R at 13000 rpm for 5 min. The cell pellets were then resuspended in a Y-PER yeast protein extraction reagent (Thermo Fisher Scientific, Rockford, IL, USA) and lysed at room temperature for 20 min with a gentle vortex. The Halt protease inhibitor cocktail (Thermo Fisher Scientific) was added to the lysed solution to prevent protein degradation. The lysed cells were centrifuged in an Eppendorf centrifuge 5415R at 13,000 rpm for 10 min to remove the cell debris, and the supernatant was collected for ADH enzyme activity assays.

The total protein concentration of the supernatant was determined using the Quick Start Bradford dye reagent (Bio-Rad), measuring at 595 nm using bovine serum albumin (BSA) as the reference standard. The ADH enzyme activity was measured on the basis of method described previously by Vallee and Hoch.[19] Briefly, 1.3 mL of 50 mM, pH 8.8, sodium pyrophosphate buffer, 0.1 mL of 95% ethanol, and 1.5 mL of 15 mM cofactor nicotinamide adenine dinucleotide (NAD+) (Sigma-Aldrich) were mixed fresh. The reaction was started by adding 0.1 mL of cell extract (lysate) to the solution. The reaction rate was then measured for 6 min at 340 nm for the change of NAD^+. One unit of ADH activity was defined as the amount of enzyme required to catalyze the conversion of 1.0 μmol of ethanol to acetaldehyde per minute, at pH 8.8 and 25 °C.

Statistical Analysis and Structure−Inhibition Relationships. The data results of carbonyl compound inhibition on glucose consumption and ethanol production were analyzed using one-way analysis of variance (ANOVA) (Excel 2007, Microsoft Office). A p value of <0.05 was considered to be significant. Statistical calculation of correlations between physicochemical parameters and inhibiton efficiency was carried out by regression analysis using Excel 2007 (Microsoft Office). The statistical values include n, the number of observations; s, the stardard error of the estimate; r^2, the coefficient of determination; F, the Fisher statistic; and p, the signficance. A value of $p < 0.05$ indicated that the correlation was significant.

RESULTS AND DISCUSSION

Effects of Aldehydes on Alcoholic Fermentation. The inhibitory effects of different carbonyl compounds on alcoholic fermentation were observed when vanillin, syringaldehyde, 4-hydroxybenzaldehyde, pyrogallol aldehyde, and *o*-phthalaldehyde (all 5.0 mM) were added to the yeast fermentation using glucose as the substrate. Syringaldehyde, pyrogallol aldehyde, and *o*-phthalaldehyde showed significant inhibition on both the glucose consumption rate and ethanol productivity, whereas furfural, HMF, and 4-hydroxybenzaldehyde showed no inhibition on the final ethanol yields. Specifically, pyrogallol aldehyde and *o*-phthalaldehyde reduced the initial glucose consumption rate by 60 and 89%, respectively, and also decreased the final ethanol yield by 60 and 99%, respectively (Figure 2). Although syringaldehyde did not reduce the final ethanol yield (0.40 g/g), it decreased the initial glucose consumption rate by 31%. Interestingly, it was observed that vanillin, syringaldehyde, and 4-hydroxybenzaldehyde could

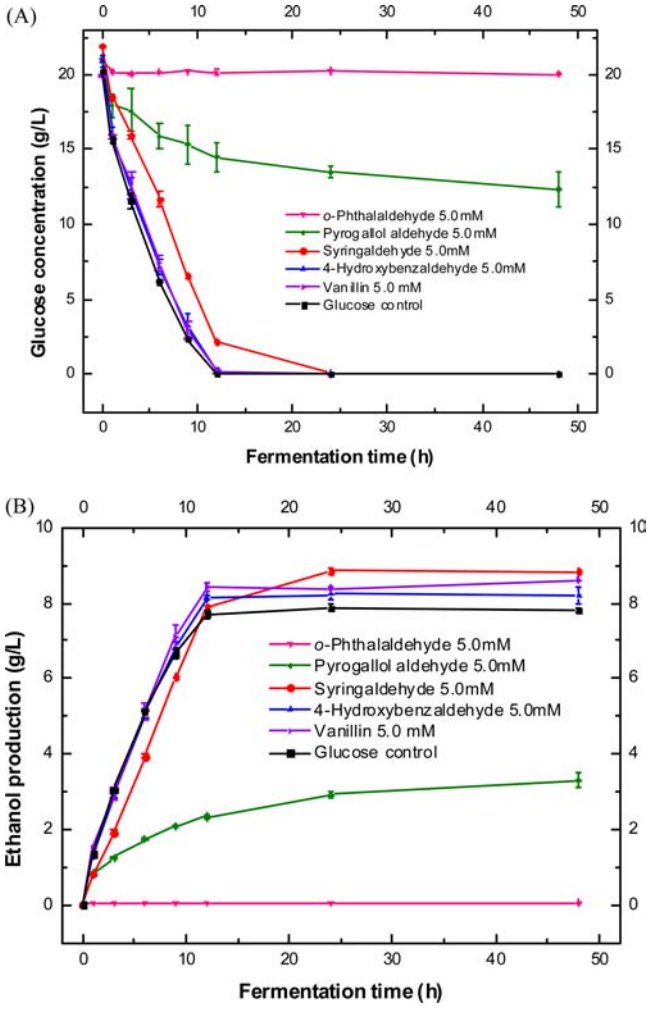

Figure 2. Effects of aldehydes on (A) glucose consumption and (B) ethanol production by *S. cerevisiae*.

increase the ethanol yields by 11, 4, and 1%, respectively, which are similar to those by furfural and HMF in our previous study.[20] These results were in good agreement with reports in the literature that ethanol or butanol yields could be improved by the addition of weak inhibitors.[21−24]

Glucose was completely consumed at 12 h with the addition of vanillin and 4-hydroxybenzaldehyde, similar to the control (without addition of any selected compounds). The addition of *o*-phthalaldehyde and pyrogallol aldehyde resulted in partial consumption of glucose even at 48 h. With the addition of syringaldehyde, the glucose uptake was delayed but completed at 24 h. The initial glucose consumption rates (0.32, 1.15, and 1.98 g/L/h) with the addition of *o*-phthalaldehyde, pyrogallol aldehyde, and syringaldehyde were closely matched to their volumetric ethanol productivity (0.02, 0.42, and 0.42 g/L/h). We performed an ANOVA for both glucose consumption rates and ethanol yields. Statistical analysis showed significant inhibition from *o*-phthalaldehyde, pyrogallol aldehyde, and syringaldehyde. Judging from the initial glucose consumption rate, the inhibitory activity on yeast fermentation was ranked as *o*-phthalaldehyde > pyrogallol aldehyde > syringaldehyde > furfural, HMF, vanillin > 4-hydroxybenzaldehyde.

We believe that the inhibitory activity of these aldehydes is related to the chemical environment of their reactive carbonyl groups (C═O). Previously, various molecular descriptors have

been widely used to characterize chemical reactivity of quinones, unsaturated esters, and phenols.[25−27] These molecular descriptors typically include hydrophobicity (log P, octanol/water partition coefficient), molar refractivity, dipole moment, energy of the lowest unoccupied molecular orbital (E_{LUMO}), energy of the highest occupied molecular orbital (E_{HOMO}), and electrophilicity index (ω).[15,16]

Carbonyl Reactivity and Quantitative Structure−Inhibition Relationship (QSIR). The inhibition efficiency of carbonyl compounds on yeast fermentation was correlated with several molecular descriptors as summarized in Table 1. Significant correlation (r^2 = 0.74, p = 0.013) has been found between E_{LUMO} and the inhibition efficiency (E) of aldehydes (eq 1). E_{LUMO} is a global parameter that indicates the electrophilic reactivity of a molecule.[25,28] The E_{LUMO} of *o*-phthalaldehyde showed the most negative value of −1.50 eV; *o*-phthalaldehyde also was the most inhibitory compound to yeast fermentation (Table 1). Linear regression analysis found the dipole moment and ω were weakly correlated to the inhibitory efficiency (eqs 2 and 3, Table 2). The dipole moment is a measure of the polarity of the molecule.[29] Pyrogallol aldehyde showed the highest dipole moments (5.66 D), and it was the second most inhibitory compound among the tested carbonyl compounds. The electrophilicity index (ω) is defined by the square of its electronegativity divided by its chemical hardness.[18] *o*-Phthalaldehyde showed the highest electrophilicity index (3.73), but its overall weak correlation with inhibitory efficiency (E) was probably due to the E_{HOMO} value. No correlation was found between E_{HOMO} and inhibitory efficiency. Another global parameter, log P, which measured the hydrophobicity of a molecule,[28] showed a poor correlation to inhibitory efficiency in regression eq 4 (Table 2). Previously, Zaldivar et al.[30,31] reported that the toxicity of aldehydes and organic acids on ethanolic fermentation by *Escherichia coli* LY01 was directly related to hydrophobicity. However, the difference may come from the use of a different microorganism and a difference in calculation methods; we used sugar consumption instead of bacterial growth in calculating inhibition.

Studies in the literature have proposed that the chemical reactivity of aldehydes contributed to the inhibition.[31] This hypothesis was supported by the observation that the addition of bisulfite reduced the toxicity of acid hydrolysates.[32] However, few studies have quantitated the chemical reactivity of aldehydes or correlated their reactivity to fermentation inhibition. Here, we quantitated the carbonyl reactivity by calculating their molecular descriptors and correlating the electrophilicity to the inhibitory activity of carbonyl compounds. Table 1 summarizes the inhibitory effects and physicochemical descriptors of carbonyl compounds; the E_{LUMO} correlated best with the inhibition efficiency (E), which could be described as a QSAR model:

$$E = -0.541 - 0.979E_{LUMO}$$

This indicates that carbonyl compounds with higher negative E_{LUMO} values would have higher inhibitory effects. E_{LUMO} typically serves as one of the reactivity parameters for molecular electrophilicity.[26] Carbonyl compounds, as electrophiles, could react with biological macromolecules (protein and DNA) by Michael addition[15] or Schiff base formation,[33] and their inhibitory effects have been related to strong electrophilic reactivity.[34] Our results support using E_{LUMO} to indicate the inhibitory effects of carbonyl compounds on alcoholic fermentation. Consequently, we have identified E_{LUMO}, one of the molecular descriptors, as a reliable, perhaps global parameter that correlates carbonyl compound electrophilicity to inhibition. Obviously, more work to build the QSAR model with a larger number of carbonyl compounds on ethanol and butanol fermentation in *S. cerevisiae* and *Clostridium acetobutylicum* will fine-tune the model and make it more accurate in predicting the structure−inhibitory activity of carbonyl compounds in biomass hydrolysate.

The fact that pyrogallol aldehyde and *o*-phthalaldehyde exhibited inhibition on the final ethanol yield was probably attributed to their strong electrophilic reactivity toward the biological nucleophilic sites. However, the addition of weak inhibitors including furfural, HMF, 4-hydroxybenzaldehyde, vanillin, and syringaldehyde indeed enhanced the final ethanol yield; in particular, vanillin had the highest enhancement. Thus, we used vanillin as a model compound to further examine the effect of weak inhibitors on ethanol (as well as glycerol) production with *S. cerevisiae*.

Effects of Vanillin Concentration on Alcoholic Fermentation. To examine the tolerance of yeast to vanillin, we added various amounts of vanillin (2.5, 5.0, 10, 25 mM) to yeast fermentation (Figure 3). The pH of the medium decreased to 5.3, 5.0, 4.8, and 4.7, respectively. The results showed that vanillin at 25 mM significantly inhibited the final ethanol yield by 63%, whereas at 2.5, 5, and 10 mM it increased

dx.doi.org/10.1021/jf405711f | J. Agric. Food Chem. 2014, 62, 918−926

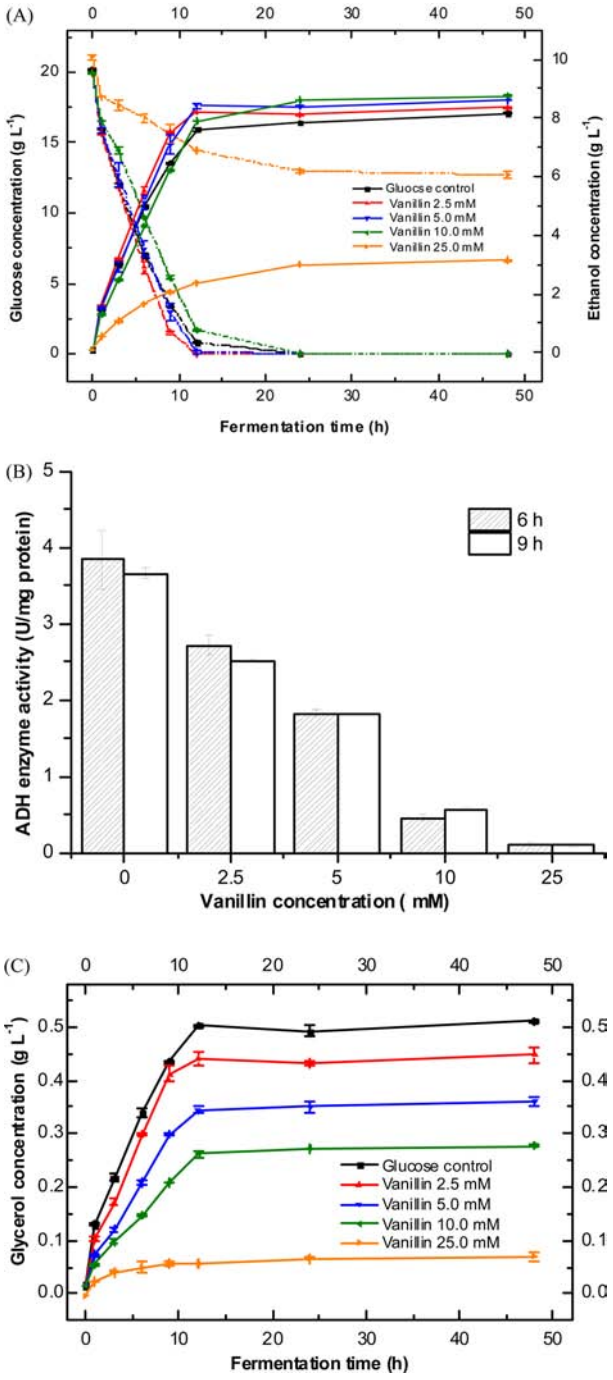

Figure 3. Effects of vanillin on (A) glucose consumption, (B) ADH enzyme specific activity, and (C) glycerol production in fermentation by *S. cerevisiae*.

the final ethanol yield by 3.2, 6.7, and 8.7%, respectively. This indicated a concentration-dependent activity: At low concentrations (2.5, 5, and 10 mM) there was nearly complete glucose consumption within 12 h. However, high concentration (25 mM) inhibited glucose consumption significantly and stopped glucose usage at 24 h. Previously, it was reported that the less inhibitory activities of furfural and HMF were from detoxification by microbes that converted them to alcohols.[35,36] In this study, we observed that vanillin could be reduced to vanillyl alcohol (major product) and oxidized to vanillic acid (minor product) at the same time under the tested conditions. The conversion yields were also dose-dependent; at low concentration (2.5 mM), the yield of vanillyl alcohol was 96.6% and that of vanillic acid, 3.4%. At high concentration (5.0 and 10 mM), the yields of vanillyl alcohol were 71.4 and 59.5%, respectively, and the yields of vanillin acid were 1.4 and 0.7%, respectively. The enzymes responsible for converting vanillin to vanillyl alcohol and vanillic acid probably were alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH).[37] The higher conversion yield (95% at 2.5 mM vanillin) of vanillyl alcohol was related to higher ADH enzyme activity in the anaerobic conditions, because the NAD^+-dependent ADH activity was typically 10-fold higher than ALDH activity in aerobic condition.[38] The increase of vanillin concentration would decrease the ADH and ALDH enzyme activities, which probably explains why both vanillyl alcohol and vanillic acid yields decreased with increasing vanillin concentration. Consequently, we examined the ADH activity in cell extract at 6 and 9 h of fermentation with various amounts of added vanillin (Figure 3B). The results showed ADH activity decreased significantly with the increase of vanillin concentration. The ADH activity dropped significantly at 6 h of fermentation from 3.85 U/mg to 2.72, 1.83, 0.46, and 0.11 U/g, respectively, with vanillin at 0, 2.5, 5.0, 10.0, and 25.0 mM. A positive correlation has been found between the vanillyl conversion yield and ADH activity ($y = 0.0569x - 2.6473$, $r^2 = 0.90$). At 9 h of fermentation, the ADH activity dropped similarly with increasing vanillin concentration (Figure 3B).

Addition of vanillin decreased the glycerol yield in yeast fermentation as compared to the control (Figure 3C). The glycerol yield decreased by 12.3, 29.6, 45.7, and 82.7%, respectively, with vanillin at 2.5, 5.0, 10.0, and 25 mM. Glycerol, another major byproduct in yeast fermentation, is produced by the reduction of dihydroxyacetone phosphate to glycerol 3-phosphate (G3P) and then dephosphorylation to glycerol.[39,40] The formation of glycerol maintains the redox balance and removes the extra NADP and NAD.[39] The decrease of glycerol yield was probably related to the reducing activities of the yeast cells, which acted as an alternative redox sink for reoxidizing NADH/NADPH. As a result, the ethanol yield increased in the presence of low concentrations of vanillin (2.5, 5.0, and 10 mM) (Figure 3C). The addition of vanillin also decreased the pH of the fermentation medium (5.3−4.7). This could also potentially contribute to the increase in ethanol yield and the decrease in glycerol yield.[41] However, the control experiments did not show a pH effect on glycerol yield within the pH range examined.

Effects of Acetic Acid and Benzoic Acid on Alcoholic Fermentation. Acetic acid and benzoic acid have been implicated as potential inhibitors from lignocellulosic biomass pretreatment.[42,43] To examine whether acids or their salts play a role in the fermentation inhibition, we first added various amounts of acetic acid into yeast fermentation with the initial pH adjusted at 6 (Figure 4A). The results showed that acetate (25, 50, 100, and 150 mM) did not inhibit ethanol production and glucose consumption at pH 6; contrarily, the final ethanol yield increased by 3%, and the glucose consumption rate increased by 20%. On the other hand, acetate (25, 50, 100, and 150 mM) inhibited the yeast growth and reduced the final biomass by 10, 20, 30, and 38% (Figure 4B). Interestingly, the beginning of the stationary phase was shifted earlier, from 12 h (the control) to 6 h. Glycerol production was also inhibited by acetate; the final glycerol concentration was reduced from 0.53 to 0.3, 0.25, 0.22, and 0.22 g/L, respectively.

dx.doi.org/10.1021/jf405711f | J. Agric. Food Chem. 2014, 62, 918−926

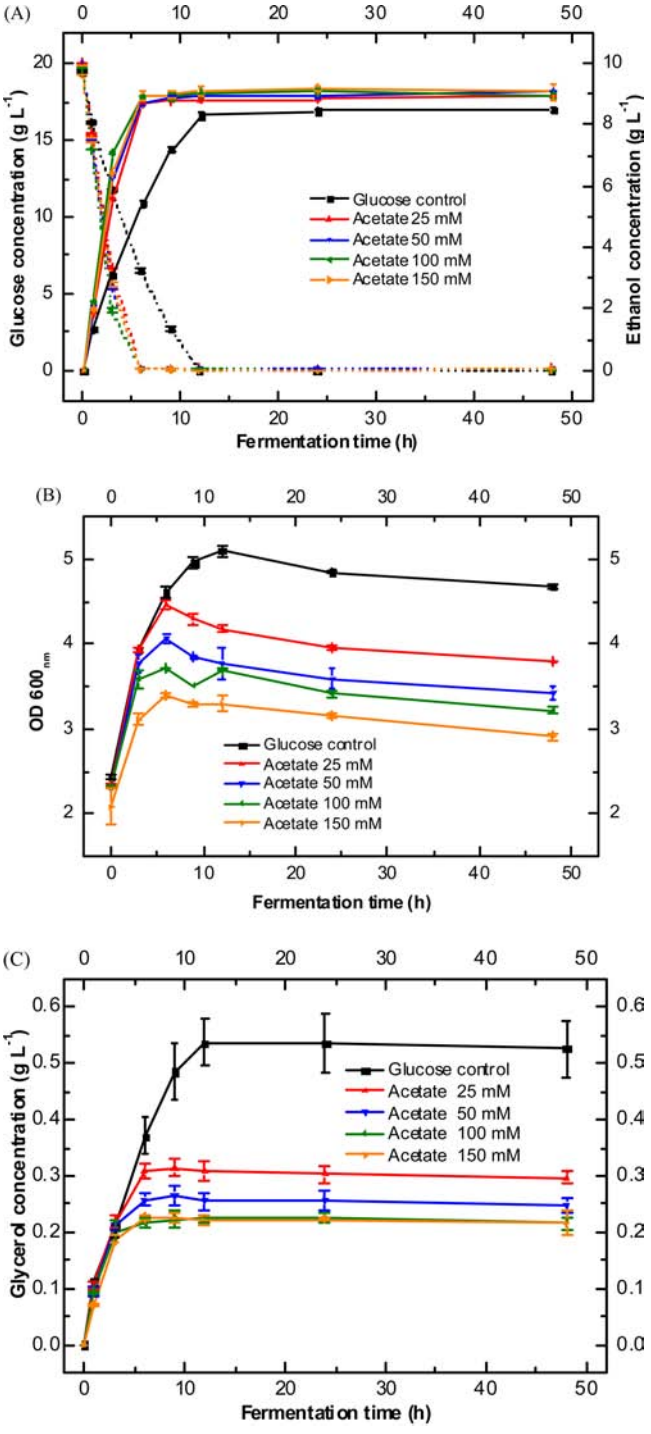

Figure 4. Effects of acetate on ethanol yields, yeast biomass, and glycerol production in fermentation by *S. cerevisiae*.

Acetic or benzoic acid inhibition was found to be pH-dependent. Without pH adjustment, the addition of 5.0 mM benzoic acid resulted in pH 3.3 in the fermentation medium. The glucose consumption was significantly inhibited, and the final ethanol yield was reduced by 89% when compared to the glucose control (Figure 5). The addition of 50 mM acetic acid resulted in pH 3.0, the glucose consumption was significantly inhibited, and the ethanol final yield was reduced by 94% when compared to the control. At pH 4.0, the acetic acid inhibited the volumetric ethanol productivity, but not the final ethanol yield. The volumetric ethanol productivity was reduced from

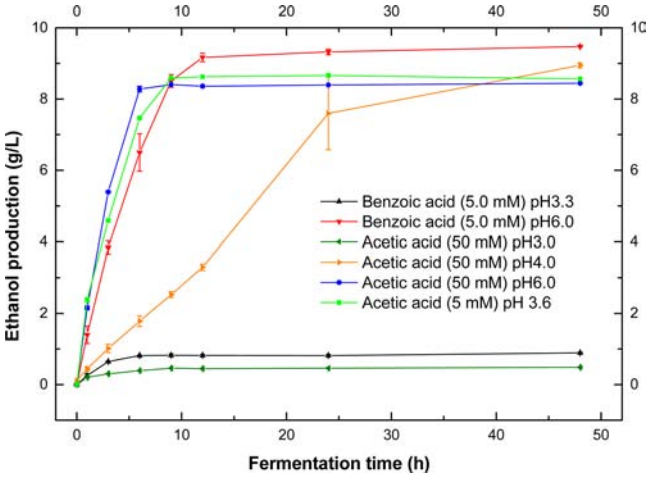

Figure 5. Effect of acetic acid and benzoic acid with and without pH control on fermentation by *S. cerevisiae*.

1.04 to 0.31 g/L/h. When the pH was adjusted to 6, the acetic acid and benzoic acid changed to their corresponding salts (acetate and benzoate). Both appeared to have no inhibitory activity on the final ethanol yield (Figure 5). Actually at pH 6.0, benzoate and acetate increased the final ethanol yields by 16 and 3%, respectively.

These results suggest that the inhibitory effect of acetic acid and benzoic acid are pH-dependent. The inhibition by these weak organic acids at low pH probably came from their undissociated forms. It is believed that the addition of weak organic acids has a significant impact on the growth energetics of fermenting microorganisms.[24,44] When a weak acid was present in the fermentation medium, a low medium pH value (especially lower than the pK_a value of the acids added) increased the fraction of undissociated forms of the acids, which diffused into the cells and decreased the intracellular pH. To maintain a constant pH, the cell must pump out the proton using a plasma membrane ATPase. Consequently, if the diffusion rate exceeded the transport capacity of the plasma membrane, acidification of the cells occurred, which led to the inhibition of both cell growth and ethanol production. Benzoic acid and acetic acid have pK_a values of 4.2 and 4.8, respectively. At a medium pH of 3.0, both acids were present in their undissociated forms; this could cause significant inhibition on fermentation. The pH dependence of weak acid inhibition was also reported on cofermentation of glucose and xylose by genetically engineered *S. cerevisiae*,[43] where the inhibition by acetic acid could be removed by adjusting the pH.

To examine if lowering the medium pH affected the fermentation, we also compared the effect of 5 and 50 mM acetic acid on fermentation without pH control (Figure 5). Addition of 5 mM acetic acid decreased the medium pH to 3.6, whereas it showed no inhibition on either glucose consumption or final ethanol yield. This indicated that it was the concentration of the undissociated form of acetic acid, rather than the medium pH, which led to the inhibition. A similar result was observed before, in which the specific growth rate of *S. cerevisiae* in batch culture did not decrease as the medium pH decreased from 5 to 3.[24]

To examine whether the beneficial effect of acetate on glucose consumption rate was specifically related to acetate or to commonly used inorganic or organic salts, we added 27.5 mM NaCl, KCl, $MgCl_2$, and $CaCl_2$ and 50 mM NaOAc to the

dx.doi.org/10.1021/jf405711f | J. Agric. Food Chem. 2014, 62, 918−926

fermentation. The results showed that all added salts improved the final ethanol yields slightly (Figure 6). The addition of KCl

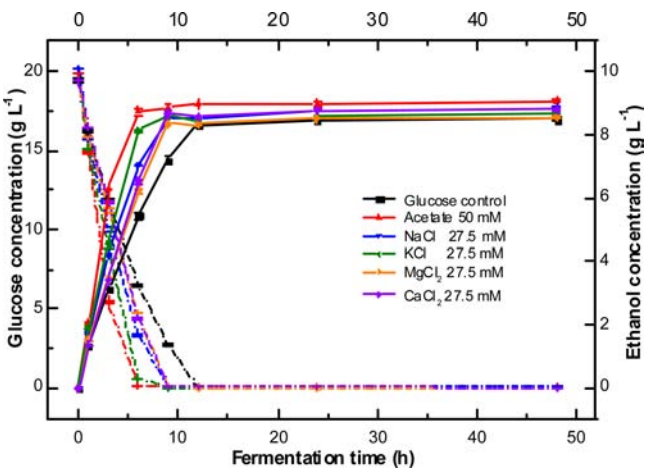

Figure 6. Effects of various salts on ethanol production by *S. cerevisiae*.

and $CaCl_2$ increased the ethanol yields by 2.0 and 3.5%, respectively, whereas NaCl and $MgCl_2$ increased the ethanol yield by <1%. More interestingly, the glucose consumption rates were increased significantly as compared to the control; addition of NaOAc, NaCl, KCl, $MgCl_2$, and $CaCl_2$ increased the glucose initial consumption rates by 88, 33, 39, 7, and 1%, respectively. It was likely that acetate activated the cell membrane permeability and increased glucose consumption.[45,46] Consequently, the time for complete glucose consumption was reduced from 12 to 9 h. A similar observation was reported on ethanolic fermentation by *Zymomonas mobilis*, where chloride salts enhanced ethanol production.[46] The improvement of glucose consumption with inorganic or organic salts could be valuable in the fermentation of biomass hydrolysate, because it would eliminate the requirement to remove the salts generated from biomass pretreatment in hydrolysate conditioning stages, and the presence of salts in biomass hydrolysate could be beneficial to alcoholic fermentation.

Glucose Respiration and Anaerobic Fermentation. In yeast metabolism, glucose consumption takes place via respiration or anaerobic fermentation. The culture conditions typically control the prevailing pathways. Repression of respiration under high glucose concentration resulting in aerobic fermentation, is known as the Crabtree effect. However, we carried out all of the fermentation experiments under facultative anaerobic conditions in 125 mL serum bottles; the Crabtree effect, therefore, was not expected to be significant in our study. Statistical analysis of the results indicated that furfural, HMF, syringaldehyde, pyrogallol aldehyde, and *o*-phthalaldehyde showed significant inhibition ($p < 0.05$) on volumetric ethanol productivity (Q_{EtOH}), which indirectly suggests that these carbonyl compounds inhibit anaerobic fermentation. The analysis also showed a significant inhibitory effect of syringaldehyde, pyrogallol aldehyde, and *o*-phthalaldehyde on the glucose consumption rate (R_S), which was related to both respiration and anaerobic fermentation. However, the exact effect of carbonyl compounds on glucose respiration could not be estimated in this study. As for the effect of acetate on alcoholic fermentation, the volumetric ethanol productivity increased by >79%, but the yeast biomass decreased by 10–38%. This suggested that acetate had a stimulatory effect on anaerobic fermentation and an inhibitory effect on respiration (biomass yield typically was related to sugar respiration).

In summary, effects of aldehydes and carboxylic acids on ethanolic fermentation have been quantitated on the basis of glucose consumption rate and final ethanol yield. With an attempt to build a structure–inhibition relationship of carbonyl compounds on fermentation, we have identified that E_{LUMO} is a very good global parameter to correlate the molecular structure of carbonyl compounds to their inhibitory effects. The study also revealed that the addition of vanillin (<10 mM) changed the glycerol pathway to an ethanol pathway and decreased glycerol yields in fermentation. In addition, fermentation inhibition by acetic and benzoic acids was found to be pH-dependent. The inorganic and organic salts showed the potential to enhance glucose consumption rates and final ethanol yields by activating the membrane permeability of yeast. Future work will be focused on building the QSAR model for ethanol and butanol fermentation with a larger number of carbonyl compounds.

89Grx is therefore potentially useful for biotechnological applications.

MATERIALS AND METHODS

Materials. *C. sorokiniana* T-89 (isolated from the paddy field of Chiayi, Taiwan) was provided by Dr. Tan-Chi Huang. The restriction enzymes, *Nde*I and *Xho*I, were purchased from NEB (New England BioLabs, U.S.A.). β-Hydroxyethylene disulfide [HED, $(HOCH_2CH_2)_2S_2$], as a low molecular weight substrate, was purchased from Sigma-Aldrich-Fluka (St. Louis, MO). Glutathione reductase (GR), NADPH, and glutathione (GSH) were obtained from Sigma (St. Louis, MO). The High-speed Plasmid Mini Kit and Gel/PCR DNA Fragments Extraction Kit were purchased from Geneaid (Geneaid Biotech, Bade City, Taiwan). Protein molecular mass markers were obtained from Fermentas (Canada).

RNA Extraction and cDNA Synthesis. Total RNA of *C. sorokiniana* T-89 was prepared using RNAzol RT (Molecular Research Center). The mRNA was then purified using Oligotex mRNA Mini kit (Qiagen, U.S.A.). The cDNA was carried out using the 5′/3′ RACE kit (Roche, Germany).

Cloning of *C. sorokiniana* T-89 Grx Gene and Its Mutant Forms. After total RNA was extracted from *C. sorokiniana* T-89, the cDNA was synthesized for sequencing analysis. Gene-specific primers of CsT-89Grx were designed on the basis of the RNA sequencing analysis information of *C. sorokiniana* T-89. The full length Grx gene from *C. sorokiniana* T-89 was amplified by polymerase chain reaction (PCR) using gene-specific primers, and the CsT-89 Grx gene was obtained using *C. sorokiniana* T-89 cDNA as a template. The forward primer Grx-F (5′-GGAATTC*CATATG*AGCGCGGCCAAG-CAGCTGG-3′) and the reverse primer Grx-R (5′-CCGC*TCGAG*GAGCACGCCGGCATTGCGCAGCAT-3′) were incorporated with the cloning sites of *Nde*I and *Xho*I (in italics), respectively. After digestion with *Nde*I and *Xho*I, the CsT-89Grx DNA fragment was ligated into a pET-20b(+) expression vector (Novagen, Germany), which was previously treated with the same restriction enzymes. Consequently, the recombinant pET-20b_CsT-89Grx plasmid was transformed into the cloning host *E. coli* DH5α (GeneMark, Taiwan). The site-directed mutagenesis of CsT-89Grx active sites (C25A and C28A) were constructed using the QuikChange Site-Directed Mutagenesis Kit (Agilent Technologies, U.S.A.). The mutant primers were designed to replace cysteine by alaline (in italics) as follows: CsT-89GrxC25A-F (5′- AGCAAGACC-TAC*GC*GCCTTACTGCGTG-3′), CsT-89GrxC25A-R (5′-CACGCAGTAAGG*CGC*GTAGGTCTTGCT-3′); CsT-89Grx C28A-F (5′-TACTGCCCTTAC*GC*GGTGAAGGGCAAG-3′), CsT-89GrxC28A-R (5′-CTTGCCCTTCAC*CGC*GTAAGGG-CAGTA-3′); and CsT-89GrxC25,28A-F (5′-TTTAGCAA-GACCTC*GC*GCCTTAC*GC*GGTGAAGGGCAAGCGG-3′), CsT-89Grx C25,28A-R (5′-CCGCTTGCCCTTCAC*CGC*G-TAAGG*CGC*GTAGGTCTTGCTAA A-3′).

Bioinformatic Analysis of CsT-89Grx. The protein sequence of CsT-89Grx was analyzed using protein−protein BLAST in NCBI (http://www.ncbi.nlm.nih.gov/). The molecular mass and pI of the encoded protein were computed using ExPASy (http://www.expasy.ch/tools/protparam.html). The multiple amino acid sequence alignment of CsT-89Grx was compared using ClustalW2 (http://www.ebi.ac.uk/Tools/clustalw2/index.html).

Expression and Purification of Recombinant CsT-89Grx. For recombinant CsT-89Grx (rCsT-89Grx) expression, *E. coli* BL21(DE3) (Novagen, Germany) was used as the expression host. The BL21(DE3) containing pET-20b_CsT-89Grx was grown until OD_{600} 0.4 at 37 °C in LB broth with ampicillin (100 μg/mL). Thereafter, the recombinant protein was induced by adding isopropyl thio-β-D-galactoside (IPTG) to a final concentration of 0.4 mM. Protein induction was performed at 28 °C for 4 h before cell harvesting. The cells were lysed in BugBuster Protein Extraction Reagent (Novagen, Germany). The crude protein lysate was obtained after 10 000*g* centrifugation for 15 min. The rCsT-89Grx was purified using BD TALON Superflow Resin, which was used for the purification of polyhistidine-tagged protein (BD Biosciences Clontech, U.S.A.). The purified enzyme was desalted using a Protein Desalting Spin Column following affinity purification (Pierce, U.S.A.). The recombinant protein was analyzed using 16% Tricine sodium dodecyl sulfate polyacrylamide gel electrophoresis (Tricine SDS-PAGE).[28]

Protein Quantitation and Enzyme Activity Assay. Protein concentrations were quantified according to Bradford's [29] method using bovine serum albumin as the standard. Grx activity was assayed using the HED method.[30] The reaction mixture consisted of 50 mM of Tris-Cl (pH 7.4), 0.6 μg of GR, 0.3 mM of HED, 0.2 mM of NADPH, 0.8 mM of GSH, and 0.1 μg of rCsT-89Grx in a total volume of 500 μL. Briefly, the disulfide bond was spontaneously formed between HED and GSH within 2 min, and the reaction was subsequently commenced by adding 0.1 μg of rCsT-89Grx. Activity was monitored on the basis of the decrease in NADPH absorbance at 340 nm. One unit of activity was defined as the enzyme necessary to deplete 1 μmol of NADPH per minute. The value was calculated by $(\Delta A340 \times V)/(\min \times 6.2)$, where V indicates the cuvette volume in milliliters, and 6.2 is the millimolar extinction coefficient for NADPH.[30]

Biochemical Characterization of the Recombinant CsT-89Grx. The activities of CsT-89Grx under various conditions were studied using the described HED assay. The optimal pH and temperature, stability of pH and temperature, kinetic analysis as well as the effects of metal ions, chemical reagents, and inhibitors were studied. For the optimal pH of CsT-89Grx, the activity of the enzyme over the pH range of 3.0 to 11.0 was measured using a 50 mM acetate buffer (pH 3.0−6.0), a 50 mM Tris-HCl buffer pH (pH 7.0−9.0), and a 50 mM glycine-NaOH buffer (pH 10.0−11.0) at 30 °C. Optimal enzyme activities were also tested at various temperatures (15 to 60 °C) at pH 8.5 in 50 mM Tris-HCl buffer. To analyze thermal tolerance, the enzyme was incubated at various temperatures from 4 to 100 °C for 1 h, and residual activity was analyzed in 50 mM Tris-HCl buffer (pH 8.5) at 50 °C. The pH stability of CsT-89Grx was investigated at different pH values (pH 3, 5, 7, 9, and 11) and at optimum pH and temperature. The kinetic analyses of the purified CsT-89Grx with different concentrations of HED (0.06 mM to 0.2 mM) were conducted under the optimum pH and temperature conditions. To study the effects of various metal ions (NaCl, $MgCl_2$, $MnCl_2$, $CaCl_2$, $CoCl_2$, $CuSO_4$, $ZnCl_2$, and $FeCl_3$) on the enzyme, 1 or 10 mM of the metal ions and CsT-89Grx was preincubated in 50 mM Tris-HCl (pH 8.5) at 37 °C for 30 min. The mixture was then analyzed for enzyme activity under optimal conditions. The effects of chemical reagents and inhibitors on enzyme activity were measured. Chemical reagents and inhibitors, including urea, ethylenediaminetetraacetic acid (EDTA), sodium dodecyl disulfate (SDS), dithiotheretiol (DTT), phenylmethanesulfony fluoride

(PMSF), and iodoactamide, were incubated with the enzyme for 30 min at 37 °C in 50 mM Tris-HCl (pH 8.5). Residual activity was determined at 50 °C in 50 mM Tris-HCl buffer (pH 8.5). Enzyme activity without treatment was defined as 100%.

RESULTS AND DISCUSSION

Cloning of Grx Gene from *C. sorokiniana* T-89 and Sequence Analysis. *C. sorokiniana* T-89 isolated from a paddy field in Chiayi, Taiwan, belonged to the heat-tolerant *Chlorella species* because it could grow well up to 38 °C.[31] Cultures of *C. sorokiniana* T-89 at different growth stages were used for RNA extraction, and mRNA was converted to cDNA for sequence analysis. The contig data of sequences were obtained using the Illuina sequencing system. Contigs were predicted for their function via sequence alignment using NCBI BLAST. Among the sequence data, Grx was identified. The forward and reverse specific primers of CsT-89Grx were designed on the basis of sequence alignment using NCBI BLAST. Using *C. sorokiniana* T-89 cDNA as template, the 321 bp DNA fragment encoding the Grx protein was amplified by PCR. CsT-89Grx was further constructed into pET-20b(+) and was confirmed to have the correct sequence by DNA sequencing.

Using the ExPASy Compute pI/MW program, the theoretical molecular mass and pI of CsT-89Grx were computed as 11.4 and 8.97 kDa, respectively. The bioinformatics of CsT-89Grx was analyzed using the NCBI protein-BLAST program. According to the data analysis, the predicted active sites of CsT-89Grx were Cys^{25} and Cys^{28}, and the conserved redox active site CPYC motif suggested that CsT-89Grx belonged to the dithiol superfamily.[26,32,33] The residues of Lys^{22}, Cys^{25}, Tyr^{27}, Arg^{69}~Pro^{72}, and Gly^{83}~Asp^{86} were predicted to be the putative GSH binding sites (Figure 1).

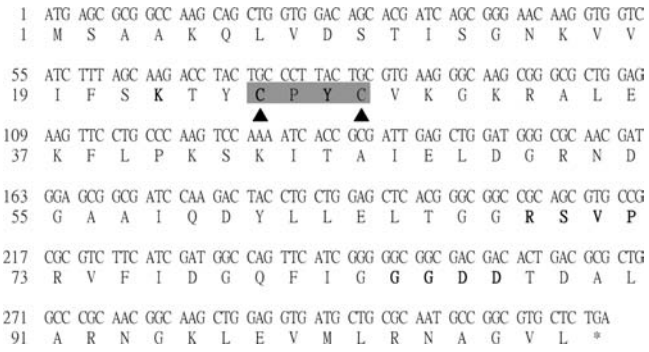

Figure 1. Deduced nucleotide and amino acid sequence of *C. sorokiniana* T-89 glutaredoxin (CsT-89Grx). The stop codon is shown in asterisks. The predicted active sites of CsT-89Grx, Cys^{25}, and Cys^{28} are shown as black triangles, and the putative conserved CPYC motif is indicated by a gray block. The putative GSH-binding sites are composed of Lys^{22}, Cys^{25}, Tyr^{27}, Arg^{69}~Pro^{72}, and Gly^{83}~Asp^{86}, as presented by bold letters.

Moreover, multiple amino acid sequence alignments of Grx containing *C. sorokiniana* T-89 (in this study), *Aspergillus fumigates* Af293 (XP_750359.1), *Chlamydomonas reinhardtii* (XP_001694001.1), *E. coli* (AAA23936.1), *Homo sapiens* (NP_002055.1), *Saccharomyces cerevisiae* S288c (NP_009895.1), and *Taiwanofungus camphorates* (ABY58974.1) were also conducted. Despite low sequence similarity (CsT-89Grx shared 53% identity with CrGrx, 44% with AfGrx, 43% with TcGrx, 36% with HsGrx and ScGrx, and 27% with EcGrx), the active site (CPYC motif) and GSH-binding sites were highly conserved (Figure 2).

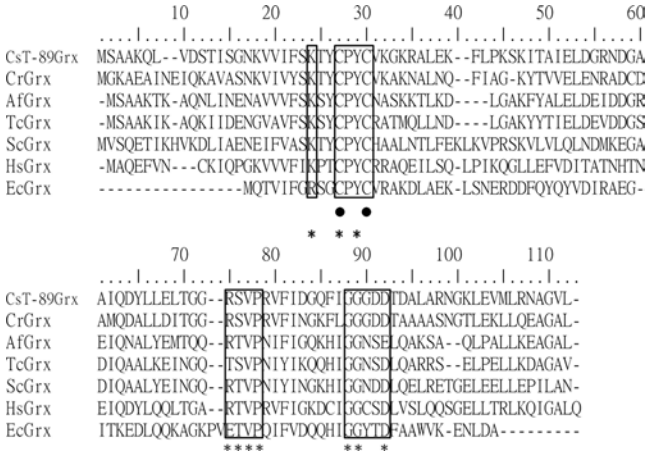

Figure 2. Multiple amino acid sequence alignments of CsT-89Grx with diverse organisms using the ClustalW2 program. Accession numbers and abbreviations of the sequences: *Chlorella sorokiniana* T-89 (CsT-89Grx, this study), *Chlorella variabilis* (CvGrx, EFN57573.1), *Aspergillus fumigates* Af293 (AfGrx, XP_750359.1), *Chlamydomonas reinhardtii* (CrGrx, XP_001694001.1), *Escherichia coli* (EcGrx, AAA23936.1), *Homo sapiens* (HsGrx, NP_002055.1), *Saccharomyces cerevisiae* S288c (ScGrx, NP_009895.1), and *Taiwanofungus camphorates* (TcGrx, ABY58974.1). The conserved residual amino acids are displayed in the black box.

Expression and Purification of Recombinant CsT-89Grx. The DNA fragment of 321 bp of CsT-89Grx was amplified by PCR using the specific primers (Grx-F/Grx-R) and cloned into the pET-20b(+) expression vector, as described in the Materials and Methods. The result was analyzed by 16% Tricine SDS-PAGE (Figure 3). After induction by IPTG, the rCsT-89Grx containing the 6-His tag was overexpressed in *E.*

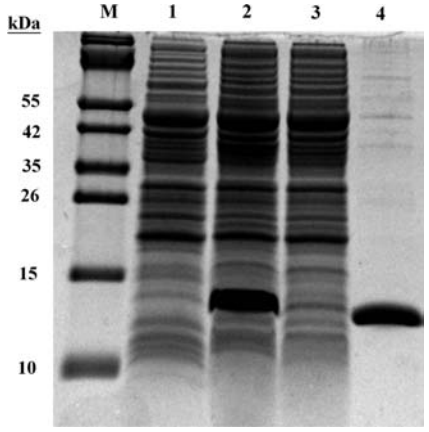

Figure 3. Expression and purification of the recombinant CsT-89Grx in the *E. coli* expression system. The total protein and purified enzyme were analyzed with 16% Tricine SDS-PAGE followed by Coomassie blue staining. Lane 1, crude soluble extract from Bl21(DE3) with pET-20b(+); lane 2, crude soluble extract from Bl21(DE3) expressing CsT-89Grx containing the 6-His tag; lane 3, pass-through protein from TALON Co^{2+} column; lane 4, the purified CsT-89Grx by TALON Co^{2+} column; and lane M is a PageRuler Prestained protein marker (Fermentas).

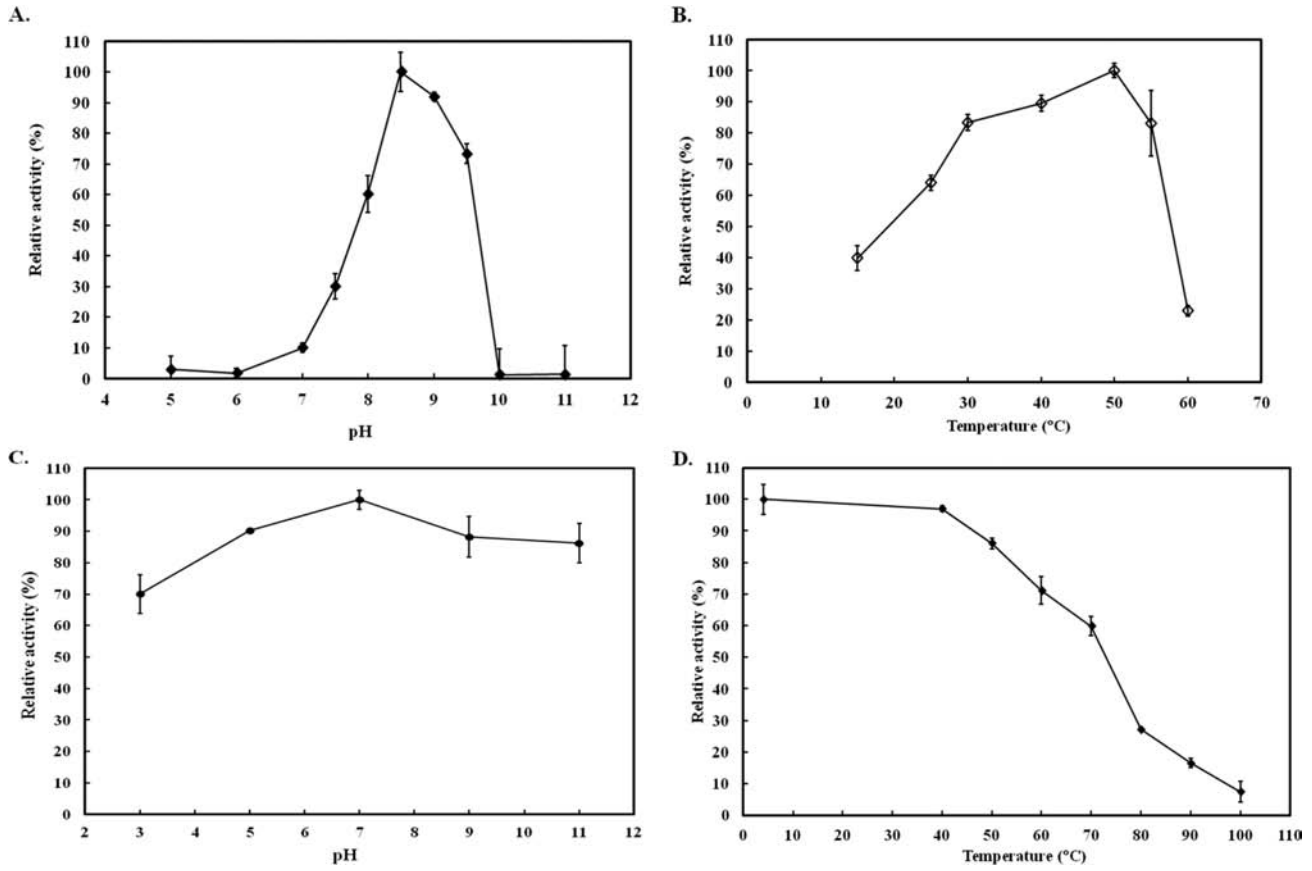

Figure 4. Effect of pH and temperature on purified CsT-89Grx using HED assay. (A) Optimal pH of CsT-89Grx measured at different pH values (pH 5 to 11). Activity at pH 8.5 corresponds to 100%. (B) Optimal temperature of CsT-89Grx measured from 15 to 60 °C. Activity at 50 °C corresponds to 100%. (C) Effect of pH on the stability of CsT-89Grx. Purified CsT-89Grx was incubated at 37 °C from 50 mM acetate buffer (pH 3, 5), 50 mM Tris-HCl (pH 7, 9), and 50 mM glycine-NaOH (pH 11) for 1 h. (D) Thermal stability of the purified CsT-89Grx. Enzyme was incubated at pH 7.4, 50 mM Tris-HCl buffer at different temperatures (4 to 100 °C) for 1 h. Grx activity was monitored on the basis of the decrease in NADPH absorbance at 340 nm.

Table 1. Kinetic Parameters of CsT-89Grx and the Published Grxs from Other Organisms

		CsT-89Grx	EcGrx1[a]	ScGrx1[b]	CrGrx1[c]	HsGrx1[d]	TcGrx[e]

	k_{cat} (min^{-1})	3566.8 ± 269.94	6900	132	1800	490	1633.0
	k_{cat}/K_m	20982 ± 390.26	2300	1100	5294	458	2864.9

[a] The reaction mixture, 100 mM Tris-Cl, pH 8.0, 6 mg/mL yeast glutathione reductase (GR), 1 mM GSH, 0.7 mM HED, 0.2 mM NADPH, 0.1 mg/mL bovine serum albumin (BSA), and 2 mM EDTA, was incubated at 25 °C for the enzyme activity measurements.[35] [b] The reaction mixture, 100 mM Tris−HCl, pH 7.4, 6 μg/mL GR, 1 mM GSH, HED (0.03 to 2.2 mM), 0.2 mM NADPH, 0.1 mg/mL BSA, and 2 mM EDTA, was incubated at 30 °C for 3 min for the enzyme activity measurements.[36] [c] The reaction mixture contained: 50 μmol Tris-Cl, pH 8.0, 1 μmol EDTA, 0.5 μmol GSH, 3.8 μg yeast GR, 0.2 μmol NADPH, 50 μg BSA, (0.1−2 mM) HED, in a final volume of 0.5 mL.[37] [d] The reaction mixture contained: 100 mM potassium phosphate, pH 7.0, 1 mM EDTA, 1 mM GSH, 6 μg/mL yeast GR, 240 μM NADPH, 0.1 mg/mL BSA, and 0.1−3 mM HED.[38] [e]The reaction mixture, 100 mM Tris-Cl, pH 7.4, 0.8 mM GSH, 0.6 μg GR, 0.2 mM NADPH, and 0.3 mM to 2.4 mM HED in a final volume of 100 μL, was incubated at 25 °C for 2 min for the enzyme activity measurements.[32]

coli BL21(DE3) (Figure 3, lane 2). A molecular mass of approximately 12 kDa of the purified rCsT-89Grx was also shown in the gel and was consistent with the expected size of rCsT-89Grx, including the 6-His tag (Figure 3, lane 4).

Effects of pH and Temperature on the Purified CsT-89Grx. The effects of pH and temperature on the purified rCsT-89Grx were evaluated using the HED assay. The optimal pH of rCsT-89Grx was determined at pH 8.5. High activity was observed in a broad temperature range from 30 to 55 °C (>80% relative activity of maximum activity), and the optimum activity was observed at 50 °C (Figure 4A,B). Meanwhile, the stability of pH and temperature on the rCsT-89Grx was investigated. After preincubation under different pH conditions for 1 h, over 70% residual activity of CsT-89Grx was detected in a broad pH range from 3 to 11, which suggested stability at a broad pH range (Figure 4C). Analysis of the stability of CsT-89Grx at the temperature range of 4 to 100 °C showed relative stability below 70 °C (>50% of residual activity) and even at 80 °C for 1 h, with approximately 30% of CsT-89Grx activity retained (Figure 4D). Ken et al. [32] reported that the residual activity of TcGrx remained at approximately 50% at 100 °C for 8.5 min. The Grx from *Ipomoea batatas* maintained 60% activity after heating at 80 °C for 16 min.[34] Compared with TcGrx and *Ipomoea batatas* glutaredoxin, CsT-89Grx retained 70% activity

dx.doi.org/10.1021/jf405213h | J. Agric. Food Chem. 2014, 62, 927−933

under 100 °C for 8.5 min and 80 °C for 30 min (data not shown). These results suggested that the recombinant CsT-89Grx is the most heat-stable Grx reported.

Kinetic Parameters of the Purified CsT-89Grx. The kinetic analysis of rCsT-89Grx was illustrated with the Lineweaver−Burk plot. The kinetic parameters K_m (0.17 mM), k_{cat} (3566.9 min^{-1}), and k_{cat}/K_m (20 982 min^{-1} mM^{-1}) were calculated. The kinetic parameters of CsT-89Grx were compared with those of Grx from other organisms, including *E. coli*,[35] *Saccharomyces cerevisiae*,[36] *Chlamydomonas reinhardtii*,[37] *Taiwanofungus camphorates*,[32] and *Homo sapiens*.[38] The rCsT-89Grx showed that a relatively lower K_m corresponds to a higher k_{cat} value, and the highest k_{cat}/K_m value compared with Grx from other organisms. These results suggested that rCsT-89Grx had the highest catalytic efficiency in reducing the disulfide bond (Table 1).

Effects of Metal Ions and Chemical Reagents on the Purified CsT-89Grx. The effects of metal ions and chemical reagents on the activities of rCsT-89Grx are presented in Table 2. Metal ions, such as Na^+, Mg^{2+}, Mn^{2+}, and Ca^{2+}, displayed no significant effect on enzyme activity. The activity was slightly decreased by 1 mM Co^{2+} (retaining 89% relative activity) and was significantly inhibited by 10 mM Co^{2+} (loss of 65.4% relative activity). The activity of rCsT-89Grx was sharply reduced by treatment with Cu^{2+}, Zn^{2+}, and Fe^{3+}. Meanwhile, the activity of rCsT-89Grx was unaffected by 1 or 5 mM of EDTA, which suggested that rCsT-89Grx was not a metalloenzyme (Table 3).

Table 2. Effects of Metal Ions on the Activities of the Purified CsT-89Grx

metal ions	concentration	relative activity (%)
none		100
Na^+	1 mM	93.2 ± 3.3
	10 mM	104.6 ± 6.2
Mg^{2+}	1 mM	84.0 ± 3.6
	10 mM	99.3 ± 4.5
Mn^{2+}	1 mM	92.4 ± 8.0
	10 mM	109.1 ± 4.7
Ca^{2+}	1 mM	81.2 ± 6.2
	10 mM	109.5 ± 4.0
Co^{2+}	1 mM	89.1 ± 14.2
	10 mM	34.6 ± 2.7
Cu^{2+}	1 mM	9.4 ± 9.0
	10 mM	7.7 ± 3.9
Zn^{2+}	1 mM	5.0 ± 3.9
	10 mM	2.4 ± 1.6
Fe^{3+}	1 mM	21.0 ± 7.0
	10 mM	1.5 ± 1.7

Recombinant CsT-89Grx was incubated with different chemical reagents to investigate their effects on its activity. Residual activity was measured following the HED assay. As shown in Table 3, the activity of rCsT-89Grx was significantly reduced by 1 or 5 mM SDS treatment. After treatment with 1 and 4 M urea, enzyme activity was reduced to approximately 23.3 and 60%, respectively. DTT is a strong reducing agent frequently used to reduce the disulfide bonds of proteins.[39] Unexpectedly, CsT-89Grx activity was slightly decreased following preincubation with 5 mM DTT. This result suggested that DTT might affect either the activity of GR or GSSG (glutathione, oxidized form).[40,41] Indeed, DTT did not influence the activity of rCsT-89Grx after being removed from the reaction. PMSF, an irreversible inhibitor, slightly affected the activity of CsT-89Grx at 5 mM. The result suggested that PMSF might influence serine, which is a GSH-binding site, thus causing part of the charge change for serine.

Table 3. Effects of Chemicals on the Activities of the Purified CsT-89Grx

chemicals	concentration	relative activity (%)
none		100
EDTA	1 mM	103.1 ± 7.0
	5 mM	100 ± 6.3
SDS	1 mM	37.1 ± 4.2
	5 mM	23.8 ± 11.8
Urea	1 M	76.7 ± 7.6
	4 M	40.0 ± 5.2
iodoacetamide	1 mM	68.1 ± 0.9
	5 mM	49.3 ± 4.1
PMSF	1 mM	96.4 ± 6.7
	5 mM	89.8 ± 5.7
DTT	1 mM	94.0 ± 12.3
	5 mM	68.9 ± 3.0
removing DTT[a]	1 mM	101.1 ± 4.4
	5 mM	98.7 ± 4.8

[a]The purified CsT-89Grx was preincubated with DTT for 30 min at 37 °C in 50 mM Tris-HCl (pH 8.5). DTT was then removed from the reaction solution by a protein desalting spin column. The residual activity was determined at 50 °C in 50 mM Tris-HCl buffer (pH 8.5).

Active Site Identification by Site-Directed Mutagenesis. According to the sequence analyses, only two cysteine (putative active sites, Cys^{25} and Cys^{28}) appeared in CsT-89Grx. Moreover, CsT-89Grx belonged to the dithiol superfamily, and its reaction mechanism is presumably catalyzed by dithiol−disulfide exchange via the coupling of −SH groups to GR and NADPH.[20,42] This finding suggested that no disulfide bond appeared in the active site of CsT-89Grx. On the basis of the bioinformatics analysis, the active site of CsT-89Grx was predicted to be the Cys^{25} and Cys^{28}. As expected, the CsT-89Grx activity was destroyed by iodoacetamide (Table 3). The CsT-89Grx retained 68.1 and 49.3% activity in 1 and 5 mM iodoacetamide, respectively. To confirm the active sites, site-directed mutagenesis of the putative active sites Cys^{25} and Cys^{28} was performed (Supplemental Data). The single mutation C25A and C28A and the double mutation C25,28A retained 1.63, 12.87, and 1.5% activity, respectively (Table 4). The above analyses suggested that the Cys25 and Cys28 of CsT-89Grx acted as active sites and served an important function in the antioxidant activity of rCsT-89Grx.

In conclusion, we obtained a novel, highly active recombinant Grx enzyme with strong antioxidation capacity

Table 4. Specific Activity of rCsT-89Grx and Mutant Forms

protein	specific activity[a] (unit/mg)	relative activity (%)
rCsT-89Grx	259.3 ± 6.35	100
rCsT-89Grx ^{C25A}	4.23 ± 7.75	1.63 ± 2.99
rCsT-89Grx ^{C28A}	33.37 ± 3.48	12.87 ± 1.34
rCsT-89Grx ^{C25,28A}	3.88 ± 2.81	1.50 ± 1.08

[a]Since the enzyme activities of mutant forms were not detected under the same condition of wild type, the specific activity analyses were carried out with 100 ng rCsT-89Grx and 1 μg mutant forms, respectively.

from *C. sorokiniana* T-89. The thiol/disulfide oxidoreductase, Grx, from *C. sorokiniana* T-89 was successfully expressed in the *E. coli* expression system. On the basis of the biochemical analyses, CsT-89Grx exhibited the highest activity at 50 °C and pH 8.5. CsT-89Grx displayed high heat stability and can adapt to a broader pH range for catalytic reactions. These biochemical properties suggest that the recombinant CsT-89Grx is potentially useful for biotechnological applications such as natural foods and pharmaceuticals. CsT-89Grx presented the highest catalytic efficiency (k_{cat}/K_m) in reducing the disulfide bond compared with Grx from other organisms. The above conclusions are possible reasons why *C. sorokiniana* T-89 can grow well at temperatures up to 38 °C, thus aiding in the scavenging of oxidative stress. Moreover, *C. sorokiniana* T-89 can be useful as a functional food.

form.[15] However, there were no reports on how antibacterial and antioxidant activities of tea polyphenols changed after nanoliposomal encapsulation. In addition, chitosan−tripolyphosphate nanoparticles could improve the stability of (−)-epigallocatechin gallate in alkaline solution.[16] However, the changes in the stability of tea polyphenol encapsulated in nanoliposomal were not clear when exposed to an alkaline solution.

To improve alkaline media stability of tea polyphenols, the methodology of combining ethanol injection methods with DHPM was adopted to prepare TPN. The physicochemical characteristics of TPN under optimal conditions were described in detail, such as morphology, particle size, size distribution, zeta potential, entrapment efficiency, and sustaining release. The stability under alkaline environment and release profiles of tea polyphenol encapsulated in nanoliposome was studied. Besides, biological activities (in vitro antioxidant activity (DPPH free radical scavenging assay and ferric reducing/antioxidant power) and in vitro antibacterial activity) of TPN were also investigated.

MATERIALS AND METHODS

Materials. Tea polyphenol (98%) was purchased from Hangzhou Gosun Biotechnologies Co., Ltd. (Hangzhou, China). The main compositions of tea polyphenol were flavanols (EGCG (50.44%), EGC (13.76%), DL-C (4.56%), EC (4.98%), GCG (2.02%), and ECG (13.84%)), anthocyanins, flavonoids and phenolic acids. Phospholipid 90G (phosphatidylcholine content = 96.6%) was provided by Lipoid GmbH (Ludwigshafen, Germany). Cholesterol (MKBF1936 V) was obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA) Ethanol, Tween 80, methanol, and other reagent chemicals were all of analytical grade.

Preparation of TPN by Ethanol Injection−DHPM Method. First, according to the method of Fan et al.[17] with modifications, TPN was prepared by an ethanol injection method under the optimum conditions as follows. Phospholipid, cholesterol, Tween 80, and tea polyphenols were mixed in a mass ratio of 8:1.2:2:1. The mixture (40 mg/mL phospholipid) was well dissolved in absolute ethanol and quickly injected into the same volume of phosphate-buffered saline (PBS; pH 6.0, 0.05 M). Then, it was stirred vigorously and kept for half an hour. The aqueous phase immediately became milky, which is a result of liposome formation (20 mg/mL phospholipid). Then, the liposomal system was transferred to a rotary evaporator and lowered into a 45 °C water bath. Ethanol was removed under reduced pressure during the hydration reaction.

Second, according to our previous method,[12−14,18] tea polyphenol liposomes (40 mg/mL phospholipid) obtained were applied to a microfluidizer (M-110, Microfluidic Corp., Newton, MA, USA) at room temperature, which works on the principle of dividing a pressurized stream into two parts, passing each part through a fine orifice and impacting or colliding the parts against each other in the interaction chamber, at a pressure of 120 MPa for one cycle, and then TPN (40 mg/mL phospholipid) was obtained. TPN was used for the following experiments without further purification.

Physicochemical Characterizations and Morphology of TPN. Physicochemical characterizations of TPN, including determination of tea polyphenol content, entrapment efficiency, particle size, size distribution, and zeta potential, were determined as follows.

Preparation of standard curve was conducted according to the method of Lu et al.[2] The reference standard of tea polyphenol was weighed precisely and dissolved in absolute ethanol to form 5, 10, 15, 20, 30, 40, 50, and 60 μg/mL standard solutions. The absorbances of these solutions were determined at 275 nm by taking ethanol as a blank. The linear regression of absorbance on concentration was made, and the regression equation was calculated; the standard curve was $y = 0.0228x + 0.0317$, $R^2 = 0.9999$.

Determination of entrapment efficiency was conducted according to the methods of Yang et al.[12] and Fan et al.[17] with few modifications. The encapsulation efficiency of nanoliposome was determined by using the dialysis technique to separate the nonentrapped tea polyphenol from liposomes. Five milliliters of tea polyphenol liposomal dispersion was placed into a dialysis bag of cellulose membrane (MW cutoff 10000, Shanghai Huamei Biochemistry Ltd., Shanghai, China) and immersed in 100 mL of PBS (pH 6.0, 0.05 M) for 8 h, with mild stirring, and phosphate buffer was refreshed every 2 h. The rest of the dispersion remaining in the dialysis bag after 8 h was placed into a 500 mL brown capacity bottle and diluted with absolute ethanol. After 30 min of sonication, aiming to break down the nanoliposome, the sample was cooled to room temperature, and then the tea polyphenol content was determined using a spectrophotometer at 275 nm and calculated according to a calibration curve. The entrapment efficiency (EE) was calculated from eq 1:

$$\mathrm{EE}\,(\%) = (W_{\mathrm{en}}/W_{\mathrm{total}}) \times 100\% \quad (1)$$

W_{en} is the weight of tea polyphenol encapsulated in nanoliposomes, and W_{total} is the initial weight of tea polyphenol added in the preparation.

The size distribution of TPN was measured by a dynamic laser light scattering method at 25 °C using a Nicomp 380 ZLS (Santa Barbara, CA, USA), according to our previous method.[18] The intensity was detected at an angle of 90°. Samples were diluted 10-fold with Milli-Q water before measurement. Mean particle sizes were calculated as the average of at least triplicate measurements.

The zeta potential values of TPN were measured using the Nicomp 380 ZLS according to our previous method.[18] Samples were diluted 10-fold in Milli-Q water before analysis. Zeta potentials were calculated as the average of at least triplicate measurements. Each individual zeta potential measurement was calculated from the mean of at least 10 readings from each sample.

According to our previous method[18] with modifications, the morphology observations were performed with an AFM (Agilent 5500, Agilent Technologies, Santa Clara, CA, USA). The TPN was diluted and made to a final lipid concentration (8 μg/mL). Diluted sample (10 uL) was deposited onto a freshly cleaved mica surface and subsequently dried in a desiccator.

In Vitro Antioxidation. The free radical scavenging capacity was determined according to the method of our previous work[12] with minor modifications. The free radical scavenging activities of TPN and tea polyphenol solution were assayed using a relatively stable free radical, DPPH. An amount of 0.1 mL of the test samples (50, 75, 100, and 125 μg/mL of TPN and pure tea polyphenol solution) was added into 2.3 mL of anhydrous ethanol. After they had been mixed vigorously, 1.6 mL of 60 μg/mL DPPH solution was added. The redox reaction was carried out at room temperature for 20 min, and the free radical scavenging activities of TPN and tea polyphenol solution were quantified by determining the change of absorbance at 517 nm. The control solution contained the same amount of blank nanoliposome and DPPH radical. The blank solution included the same amount of blank nanoliposome and 3.9 mL of anhydrous ethanol. DPPH radical scavenging activity was evaluated by using eq 2:

$$\text{radical scavenging activity}\,(\%) = (A - B)/(A - C) \times 100\% \quad (2)$$

A is the absorbance of control solution after reaction, B is the absorbance of the samples after the reaction, and C is the absorbance of the blank solution.

The FRAP of TPN was determined according to the methods of Benzie and Strain[19] and Patel et al.[20] with modifications. Briefly, 4.8 mL of FRAP reagent, prepared freshly and warmed at 37 °C, was mixed with 0.2 mL of the samples at different dilute times. FRAP reagent contained 2.5 mL of a 10 mmol/L 2,4,6-tris(2-pyridyl)-s-triazine (TPTZ) solution in 40 mmol/L HCl plus 2.5 mL of 20 mmol/L $FeCl_3 \cdot 6H_2O$ and 25 mL of 0.3 mol/L acetate buffer of pH 3.6. The reaction took place at a temperature of 37 °C for 10 min. Once the reaction was completed, the value of absorbance in a UV−vis spectrophotometer was recorded at 593 nm against blank. A blank

solution contained 4.8 mL of FRAP reagent solution and an appropriate volume of blank nanoliposome, and it was incubated under the same conditions as the rest of the samples. Aqueous solutions of gallic acid (0.2 mL) with concentrations in the range of 10−80 μg/mL were combined in a test tube with 4.8 mL of reagent solution, and they were incubated under the same conditions as the rest of the samples. The absorbance of gallic acid solutions was then determined at 593 nm, respectively, with PBS as blank. The linear regression of absorbance on concentration was made and its equation was calculated. The regression equation of the standard curve was $y = 0.0197x - 0.0348$, $R^2 = 0.9998$. The FRAP of TPN was expressed as the equivalent content of gallic acid, using above regression equation of the standard curve.

Antimicrobial Activity. It was found in our preliminary experiment that the turbidity of liposomes prepared by ethanol injection was much higher than that of nanoliposomes prepared by ethanol injection in combination with DHPM, which was not suitable for in vitro antibacterial activity experiments. Consequently, the antibacterial activity of TPN was conducted in this study, by taking tea polyphenol solution as a control group. The inhibition zone of tea polyphenol before and after nanoliposome encapsulation was determined by diffusion technique (disc method), according to method of Liolios et al.[21] with few modifications. The tests were conducted against four common food pathogenic bacteria: *Staphylococcus aureus* (ATCC6538), *Escherichia coli* (ATCC8739), *Salmonella typhimurium* (ATCC14028), and *Listeria monocytogenes* (ATCC19115). The experiments were repeated three times, and the results (mm of zone of inhibition) were expressed as average values.

Minimum inhibitory concentration and minimum bactericidal concentration determinations were conducted according to Wattanasatcha et al.'s[22] method. Four food pathogenic bacteria were grown in LB at 37 °C until a total bacterial count of 10^8 cfu/mL was reached. Then, the obtained bacterial suspension was used for evaluating the minimum inhibitory concentration and minimum bactericidal concentration of each test compound.

The minimum inhibitory concentrations of tea polyphenol solution and TPN were determined by using the broth dilution method. To each test, 1.5 mL of tea polyphenol solution and TPN (concentration range of 39−5000 μg/mL) was added in 1.5 mL of sterile (121 °C for 15 min) broth in the test tubes, respectively. Then, the tubes were inoculated with 200 μL of the above bacterial suspension, mixed, and incubated at 37 °C for 24 h before the turbidity of the broth recorded at 600 nm. The lowest concentration at which no growth occurred in either tube was taken as the MIC. After the MIC was determined, the tubes that did not show an increase in turbidity at 24 h were streaked on LB agar plates and incubated for 24 h at 37 °C to check for bacterial growth/survival. Each experiment was performed in triplicate.

In Vitro Drug Release. In vitro drug release from TPN was performed in 50 mM PBS (pH 6.0), which was used in the preparation of TPN, according to Lu et al.'s[2] method with slight modifications, by taking tea polyphenol solution as a control group. An amount of 2 mL of TPNs was loaded in a dialysis bag with the cutoff size of 10 kDa before being placed into 200 mL of PBS (kept constant at 37 ± 0.5 °C and stirred at 100 rpm). At predetermined time intervals (0.5, 1, 2, 4, 6, 8, 10, 12, and 24 h), the content of tea polyphenol in the samples were determined as described above.

Stability in Alkaline Solution. Tea polyphenol is unstable in alkali solution, and its half-life would significantly decrease due to the alkaline environment. The stability of TPN under alkaline conditions (pH 7.4) could mimic the pH environment present in intestinal or other fluids such as plasma. Therefore, a stability study, under alkaline conditions (pH 7.4), could provide a useful guide for oral administration application of TPN. The detailed process of alkali stability was conducted according to Dube et al.'s[16] method with modifications. A suspension of TPN in 50 mM potassium hydrogen phosphate buffer (pH 7.4) was prepared. The final concentration of tea polyphenol present in the suspensions was 200 μg/mL, and then it was incubated at 37 °C for a set period. The absorbance of TPN in alkaline solution (pH 7.4) was determined at 430 nm to determine oxidation contents of tea polyphenol.[23] Free tea polyphenol without being encapsulated, at a similar concentration of 200 μg/mL, was used as a control in parallel experiments and was subjected to the same treatment as the nanoliposome preparations.

Statistical Analysis. All experiments were done in at least triplicate. The values are expressed as means ± standard deviation (SD). Data were subjected to statistical analysis using SPSS software version 18.0. Differences were considered significant at $p < 0.05$.

RESULTS AND DISCUSSION

Characterization and Morphology of TPN. Characterizations of TPN, including entrapment efficiency, particle size, polydispersity index, and zeta potential, will be discussed in detail in this work. The surface morphology of TPN was observed by atomic force microscope. The entrapment efficiency and drug load values are key points for potential applications of the liposomal system. The entrapment efficiency and drug load of TPN under the optimum conditions were 78.5 ± 5 and 8.5 ± 0.5%, respectively. The entrapment efficiency of tea polyphenol nanolipsome in this work was different from that in previous papers.[2,7,8] Gulseren and Corredig[7] reported that the entrapment efficiency of tea polyphenol-bearing nanoliposome using high-pressure homogenization was 58.3%. The entrapment efficiency of TPN prepared by the thin film ultrasonic dispersion method was 60.3%.[2] Tea polyphenols and vitamin E-loaded nanoscale complex liposome using reverse-phase evaporation method exhibited 50.81% entrapment efficiency.[8] In addition, the drug load of tea polyphenol nanolipsome in this work was similar to that of Lu et al.[2] (6.0%).

To determine the particle size of TPNs, their mean particle size and polydispersity index were measured by using a dynamic laser light scattering method. Tea polyphenol nanolipsome exhibited smaller size (66.8 ± 7.6 nm) than previous results[2,7−9] and had a narrow polydispersity index (0.213 ± 0.046). TPN prepared with milk fat globule membrane phospholipids, using a high-pressure homogenizer, showed lager mean sizes (>100 nm);[7] TPN obtained by thin film ultrasonic dispersion method were 160.4 nm with a polydispersity index of 0.28;[2] and the tea polyphenol nanoscale complex liposome showed 202.8 nm (mean sizes) and 0.296 (polydispersity index).[8] In a preliminary experiment, a thin film dispersion method was also attempted to prepare tea polyphenol liposome, but it was difficult to wash membrane from the wall of the rotary flask and difficult to spontaneously form liposome when the tea polyphenol was 5 mg/mL. Hence, an ethanol injection method, without the membrane washing off process, was used to prepare tea polyphenol liposome. The mean particle size of tea polyphenol liposome prepared by the ethanol injection method was 496 nm, which was not in nanoscale. In our previous research, we also found that DHPM treatment containing strong mechanical forces could significantly reduce the particle size of liposome.[12,24] In addition, the zeta potential of TPN under the optimum conditions was −6.16 mv (pH 6.0), which was lower than those of Gulseren and Corredig[7] (−12 mv, pH 5.0) and Lu et al.[2] (−67.2 mv, pH 6.62). Liposomes are mainly composed of cholesterol and phospholipids. The different value of zeta potential of liposome was probably attributed to variations in competence and property of phospholipids. There are two main viewpoints on whether the zeta potential value could directly decide its shelf life. The suspension with greater zeta potential is more likely to be stable, which was due to the charged particles repelling one another and thus overcoming the natural tendency to

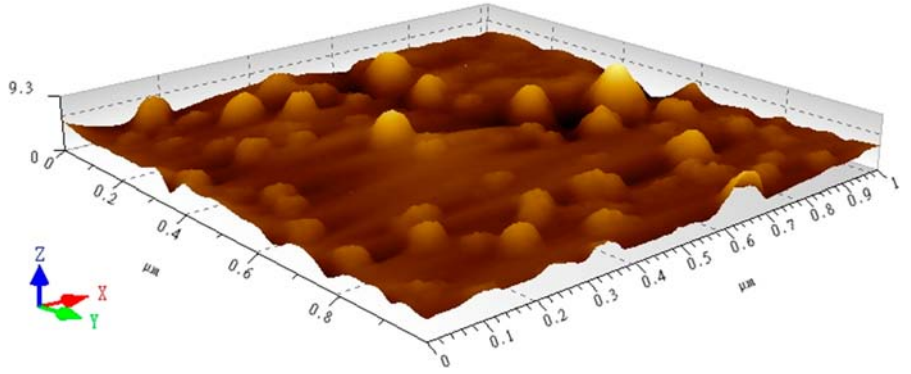

Figure 1. AFM micrograph of tea polyphenol nanoliposome.

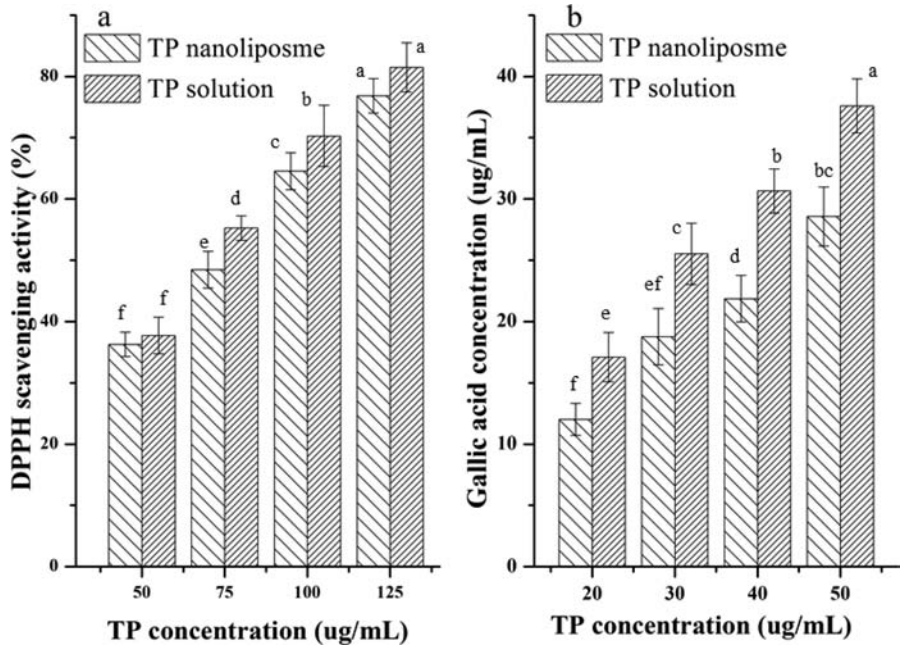

Figure 2. (a) DPPH free radical scavenging capacity and (b) ferric reducing/antioxidant power (FRAP) of tea polyphenol solution and nanoliposme at various concentrations.

aggregate.[25] However, it was also deemed in some studies that even at low zeta potential values (i.e., close to 0), liposomes might remain stable.[26] According to the research studies of Lu et al.[2] and Makino et al.,[26] it can be concluded that the zeta potential value was not a direct indicator of the stability of liposome. Consequently, the shelf life of liposome depended not just on its zeta potential value. In this work, two vital indicators of liposome (entrapment efficiency and particle size) indicated that DPHM combined with ethanol injection methods was suitable for preparing TPN.

As presented in Figure 1, 1 μm × 1 μm scans were captured, showing the morphology of TPN was mainly spherical defined shapes (indicated by the arrows). TPNs maintained a spherical and well-defined shape (common characteristic of nanoliposome), which was in agreement with the morphology observed by transmission electron microscopy.[2] According to AFM photographs, most of the TPN was well distributed, which is in agreement with a narrow size distribution obtained by DLS (shown in Figure S1 in the Supporting Information). Furthermore, the sizes of nanoliposomes obtained through AFM were close to mean sizes measured by a dynamic laser light scattering method, which was consistent with results of Maherani et al.[27]

Nanoliposome is a new technology for the encapsulation and delivery of bioactive agents. It is generally acknowledged that the performance of bioactive agents could be enhanced by nanoliposomes, improving their solubility and bioavailability and in vitro and in vivo stability, as well as preventing their unwanted interactions with other molecules.[28] In addition, their smaller mean diameters could be helpful in enhancing their bioavailability.[12] This study examined how the bioactivity of TPN varied. In vitro antibacterial activity and in vitro antioxidant activity of TPN will be discussed in detail in the following text.

In Vitro Antioxidation. To date, it is still not clear how the in vitro antioxidant activity of tea polyphenols after nanoliposome encapsulation changed. There are different types of antioxidant methods used to estimate in vitro antioxidant activity of tea polyphenols before and after nanoliposome encapsulation. The DPPH free radical scavenging capacity assay and ferric reducing/antioxidant power (FRAP) assay were chosen to represent organic solvent and aqueous phase environments, respectively.

dx.doi.org/10.1021/jf402886s | J. Agric. Food Chem. 2014, 62, 934−941

The stable DPPH radical is a widely used scavenging model for evaluating the free radical scavenging ability of natural compounds. The effect of antioxidants on DPPH radical scavenging was attributed to their hydrogen-donating ability. It is shown in Figure 2a that both tea polyphenol solution and TPN had concentration-dependent antioxidant activities toward DPPH free radical scavenging capacity. No significant differences in DPPH free radical scavenging capacity of the same concentration of tea polyphenol were found before and after nanoliposome encapsulation. The DPPH scavenging activities of the tea polyphenol solution in 50, 75, 100, and 125 μg/mL were 37.7 ± 3.0, 55.2 ± 1.9, 70.2 ± 5.2, and 81.4 ± 4.0%, respectively, with an equal or higher DPPH scavenging power of TPN (36.2 ± 2.0, 48.4 ± 3.1, 64.5 ± 3.0, and 76.8 ± 2.8%, respectively).

Alterations in DPPH radical scavenging activity of antioxidants were reported by other authors after gum arabic–maltodextrin particle,[29] liposome,[30] and placebo chitosan microsphere[31] encapsulation. Peres et al.[29] demonstrated that free catechin and gum arabic–maltodextrin particles loaded with catechin exhibited similar DPPH quenching abilities in all tested concentrations and deemed that the loading method preserved the original antioxidant properties of the catechin. Niu et al.[30] reported that the DPPH radical scavenging activity of liposomal curcumin was higher than that of free curcumin. It was ascribed to the polarity of different environments. Curcumin is a hydrophobic core material, so it would be entrapped in the liposomal bilayer, the polarity of which is much lower than that of sodium phosphate buffer, and the DPPH molecule has a highly hydrophobic nature; it is likely that the DPPH radical is scavenged by curcumin inside liposome.[30] Weerakody et al.[31] reported that lipoic acid encapsulated in placebo chitosan microspheres exhibited lower DPPH radical scavenging activity as compared to free lipoic acid, which could be attributed to an incomplete extraction of the encapsulated lipoic acid due to structural interactions. In this work, nanoliposome encapsulation did not reduce the DPPH radical scavenging capacity of tea polyphenol. It was probably explained by the main reagent in the DPPH radical scavenging system being alcohol. Nanoliposome would be demulsified by high concentrations of alcohol. Tea polyphenol encapsulated in liposome aqueous phase was exposed homogeneously into the DPPH system, after alcohol demulsification. Therefore, compared with tea polyphenol solution, TPN exhibited an equal or lower DPPH radical scavenging activity. In our previous study, it was also found that the DPPH radical scavenging activity of vitamin C was not significantly altered by nanoliposome encapsulations.[12]

The FRAP assay was developed to measure reducing power in plasma,[19] but the assay has been adapted to measure antioxidant activity of tea polyphenols.[32] The FRAP assay is quick and simple to perform, and the reaction is reproducible and linearly related to the molar concentration of the antioxidant present.[19] It is based on the reduction, which is monitored by measuring the change of absorbance at 593 nm. At low pH, a colorless ferric complex (Fe^{3+}–tripyridyltriazine) changes to a blue ferrous complex (Fe^{2+}–tripyridyltriazine) by the action of electron-donating antioxidants.[19] Figure 2b shows that both tea polyphenol solution and TPN have concentration-dependent antioxidant activity toward ferric reducing/antioxidant assay. Nevertheless, the ferric reducing/antioxidant power of tea polyphenol was reduced by nanoliposome encapsulations. In the current study, we found that the ferric reducing/antioxidant power of TPN was significantly lower than that of tea polyphenol solution. The FRAP values of the tea polyphenol solution at 20, 30, 40, and 50 μg/mL were equivalent to 17.1 ± 2.0, 25.5 ± 2.5, 30.6 ± 1.8, and 37.6 ± 2.2 μg/mL gallic acid, respectively, which are higher FRAP values than those of TPN (12.0 ± 1.3, 18.7 ± 2.3, 21.9 ± 1.9, and 28.6 ± 2.4 μg/mL gallic acid, respectively).

It was reported by some researchers that the antioxidant activity measured by the FRAP assay was reduced by many encapsulations (solid lipid matrix, chitosan microspheres, novel polymer–polyphenol beads).[20,31,33] Patel et al.[20] reported that the lower FRAP value of epigallocatechin gallate in the novel polymer–polyphenol beads at an initial stage of 2 h was probably hindered by bead encapsulation, compared with free epigallocatechin gallate. Weerakody et al.[31] also found that the antioxidant activity by FRAP assay of lipoic acid encapsulated in chitosan microspheres was much lower than the same concentration of free lipoic acid, which was probably due to structural interaction between chitosan matrix and lipoic acid. Donsì et al.[33] reported that the antioxidant activities by FRAP assay of the encapsulated resveratrol and curcumin in a solid lipid matrix were much lower than those of resveratrol and curcumin that were not encapsulated. In this study, the FRAP assay of tea polyphenol was decreased by nanoliposome encapsulation. This was probably due to the fact that most of the tea polyphenol was encapsulated in the nanoliposome aqueous phase. Therefore, donating electron capacity of tea polyphenol encapsulated in nanoliposome would be influenced by phospholipid bilayer membranes, which resulted in a low antioxidant activity that was evaluated by the FRAP value of TPN.

In Vitro Antibacterial Activity of TPN. It was not clear how the in vitro antibacterial activity of tea polyphenol changed after nanoliposome encapsulation. To evaluate the variation in antibacterial activity of tea polyphenol after nanoliposome encapusulation, four common food pathogenic bacteria (*S. aureus*, *E. coli*, *S. typhimurium*, and *L. monocytogenes*) were used to determine the antimicrobial activities of tea polyphenol before and after encapsulation of nanoliposomes. The inhibition zones of tea polyphenol solution and nanoliposome are shown in Figure 3. The inhibition zones of tea polyphenol solution for *S. aureus*, *E. coli*, *S. typhimurium*, and *L. monocytogenes* were 21.3 ± 1.3, 19.7 ± 0.5, 19.7 ± 1.2, and 19.3 ± 0.9 mm, respectively, whereas TPN exhibited smaller inhibition zones for *S. aureus*, *E. coli*, *S. typhimurium*, and *L.*

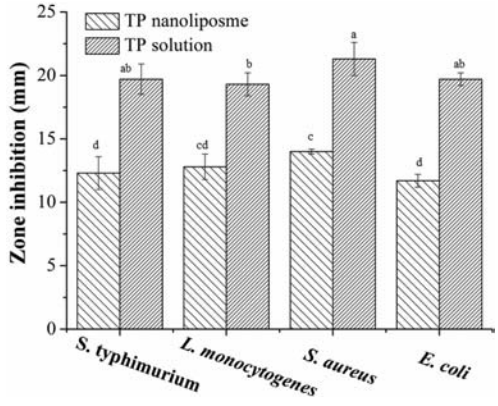

Figure 3. Antimicrobial activities (mm of zone inhibition) of tea polyphenol solution and nanoliposme.

monocytogenes (14.0 ± 0.2, 11.7 ± 0.5, 12.3 ± 1.3, and 12.8 ± 1.0 mm, respectively). The minimum inhibitory concentrations of tea polyphenol solution for *S. aureus*, *E. coli*, *S. typhimurium*, and *L. monocytogenes* were 0.078, 0.312, 0.078, and 0.039 mg/mL, respectively, and minimum bactericidal concentrations were 0.312, 0.312, 0.312, and 0.312 mg/mL, respectively. Compared with tea polyphenol solution, TPN exhibited higher minimum inhibitory concentrations (1.25, 1.25, 1.25, and 0.625 mg/mL, respectively) and minimum bactericidal concentrations (2.5, >2.5, 2.5, and 2.5 mg/mL, respectively). It could be concluded from the above that the antibacterial activity of tea polyphenol was decreased by nanoliposome encapsulation.

Low antibacterial activity of tea polyphenol nanoliposome in this work could be explained by the photograph of tea polyphenol solution and TPN incubated in a broth for 24 h (Figure S2 in the Supporting Information). With the concentration increasing from 0.078 to 2.5 mg/mL, the color of both tea polyphenol solution and nanolipsome in the broth became deeper and deeper. However, the color of tea polyphenol solution in the broth was much deeper than that of TPN in broth. Red sediments were found in tea polyphenol solution in the broth, and they became larger with increasing concentration (indicated by the arrows). Red circles were also formed on the walls of the test tube, which was due to the red sediments in the broth. However, no red sediments and circles were observed in all various concentrations of TPN samples. The cause for the sediment phenomenon could be probably attributed to the tea polyphenol. Catechins as the main components in tea polyphenol would react with proteins present in the broth and form various complexes with protein, thus resulting in the formation of sediments.[34] TPN possessing high entrapment efficiency (78.5%) could prevent tea polyphenol incorporated into the aqueous cores from being released into the broth, interacting with proteins in the broth solution and forming sediments. Tea polyphenol solution could interact with the protein (in the broth) and form sediment, but there were large portions of antibacterial compositions still in the broth. The nonencapsulated portion of tea polyphenol in nanoliposome would also interact with protein, but the nonencapsulated portion in nanoliposome was too small to form obvious sediment. In addition, the content of encapsulated tea polyphenol released from nanoliposome during 24 h of incubation in broth was very low, which was also confirmed by the following sustained release profiles of TPN. Resident antibacterial ingredients remaining in broth in the TPN sample were much lower than that in the control group (tea polyphenol solution). Consequently, liposomal encapsulation could reduce the antibacterial activity of tea polyphenols.

There have been some reports on encapsulation technologies that could alter the antibacterial activity of biological agents, but there were no uniform viewpoints on how the antibacterial activity of biological agents varied after encapsulation. According to previous papers, there were no consensus opinions on whether encapsulation technology could enhance or reduce the antibacterial activity of biological substances.[21,22] In Liolios et al.'s[21] study, all tested compounds from the essential oil presented enhanced antimicrobial activity after the liposomal encapsulation, even only 4.16% entrapment efficiency. According to Liolios et al.,[21] the dramatically increased antimicrobial activity by liposomal encapsulation was probably due to PC−liposomes interacting with cells in many ways (intermembrane transfer, contact release, absorption, fusion, phagocytosis); the mechanism of interaction depends on the cell type (cell wall/membrane composition), as well as the liposome membrane physicochemical characteristics; the use of liposomal formulation improves the cellular transport and releases the active component inside the cell. However, Wattanasatcha et al.[22] reported that minimum inhibitory concentration and minimum bactericidal concentration of *P. aeruginosa* were increased by nanosphere encapsulation, which means that the action of thymol toward this bacterial strain is somewhat retarded when the material is encapsulated. Wattanasatcha et al.[22] deemed that it was probably due to the ethylcellulose/methylcellulose shell being nondegradable under the experimental condition, and it is speculated that diffusion of the hydrophobic thymol molecules from the spheres is prior to their action on the bacteria. In the present study, we found that nanoliposome encapsulation reduced the antibacterial activity of tea polyphenols. This was probably due to the high viscidity, which made it difficult for tea polyphenols to diffuse into the agar. In addition, slight amounts of tea polyphenols released from the nanolipsome after encapsulation also result in lower antibacterial activity.

In Vitro Drug Release of TPN. Liposomes have the property of prolonging the residence time of the drugs in the blood, releasing the drugs slowly in vivo. An in vitro release model in this work was expected to partly reflect properties of prolonging the residence time in vivo of liposome, which was an important factor of liposome potential applications. The in vitro drug release profiles of tea polyphenol solution and TPN were obtained and are shown in Figure 4. Rapid tea polyphenol

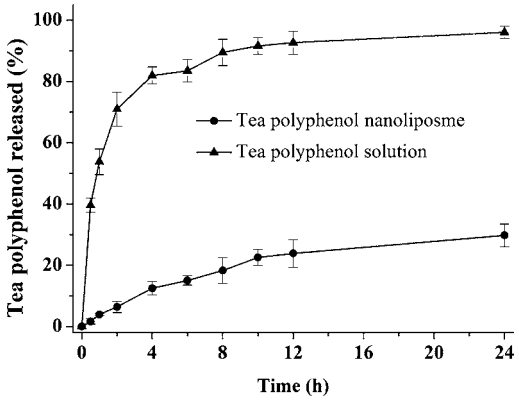

Figure 4. In vitro release of tea polyphenol from tea polyphenol solution and nanoliposme.

diffusion was observed in tea polyphenol solution before 2 h, and nearly 70% of tea polyphenol diffuses across the dialysis membrane. After that, the tea polyphenol diffusion rate from tea polyphenol solution dropped, and reached a maximum content of 92.6 ± 3.8% at 12 h. This was similar to Zhou et al.'s[5] result that 81% of tea polyphenol solution diffused across the dialysis membrane after 4 h and reached a maximum content (near 95%) at 12 h. Compared with tea polyphenol solution, nanoliposome obviously slowed the release of tea polyphenol. TPNs had a continued release rate, with only 6.4 ± 1.9% of tea polyphenol released in 2 h and reaching a maximum content of 23.9 ± 4.5% in 12 h. Then they exhibited a very slow release of 29.8 ± 3.7% after 24 h. It could be concluded from the above that TPN has a sustained release profile.

There were some reports that encapsulation methods or carrier systems such as nanoliposomes prepared by the thin film ultrasonic dispersion method,[2] chitosan-coated nanoparticles,[3]

high-pressure antisolvent coprecipitation,[4] and complex coacervation core micelles[5] could enhance the sustained release profile of tea polyphenols. Various carrier systems exhibited different sustained release capacities of tea polyphenols. In the Lu et al.[2] study, TPN also exhibited a sustained profile, but the sustained capacity was lower than that in this work. The sustained release rate reached nearly 25% after 2 h, and within 12 h, the cumulative release increased to about 70%.[2] The burst effect of tea polyphenols from chitosan-coated tea polyphenols nanoparticles was observed in 6 h, in which 30−40% of the drug was released from nanoparticles.[3] Sosa et al.'s[4] results showed that green tea encapsulation using high-pressure antisolvent coprecipitation exhibited a release of nearly 30% of the drug in 20 h, and no significant release was observed from 20 to 90 h. Zhou et al.[5] demonstrated that complex coacervation core micelles had a sustained release capacity, and the complex coacervation core micelles continuously released tea polyphenol, until it was completely released at 14 h (97%). In this work, the sustained release behavior of nanoliposomes is presumably due to the high probability of tea polyphenols being incorporated into the aqueous cores inside the bilayers, which overcomes a burst release, whereas the variant sustained capacity of liposomes was probably attributed to their difference in entrapment efficiency, encapsulation method, and membrane structure.

Stability under Alkaline Solution. Tea catechins incubating at slightly alkaline pH, similar to the small intestine, showed a rapid decline in the concentrations of tea catechins,[35] and their half-life was significantly reduced by alkaline media.[36] Consequently, the stability experiment of TPN under alkaline pH (pH 7.4), which mimics the environment present in the intestinal tract or other fluids such as plasma, is necessary to carry out. Tea polyphenols are easily oxidized, which is due to their abundance of various sensitive ingredients such as chemically unstable catechins and theaflavins. Tea catechins readily undergo oxidation and form quinone oxidized products,[16] and their oxidation products are a brown color possessing a peak area at 430 nm.[23] Therefore, the stability of tea polyphenol solutions and tea polyphenol encapsulated in nanoliposome could be measured by the absorbance of oxidation products.

Changes in absorbance at 430 nm of 200 μg/mL tea polyphenol solution and tea polyphenol in nanoliposome in PBS (50 mM 7.4) were recorded with increasing time from 0 to 24 h. The variations in absorbance and color of tea polyphenol solution and TPN are shown in Figure 5. Both tea polyphenol solution and TPN at 0 h showed low absorbance at 430 nm (0.083 ± 0.01 and 0.062 ± 0.01), and then the absorbance increased to 1.304 ± 0.075 and 0.827 ± 0.068, respectively, at 24 h, whereas the absorbance of TPN at the same incubation time was much lower than that of tea polyphenol solution. For example, after incubation for 4 h, the absorbances at 430 nm of tea polyphenol solution and TPN were 0.613 ± 0.061 and 0.357 ± 0.044, respectively. In addition, the absorbance differences between the two samples were increasing. The difference was 0.138 at 1 h and increased to 0.477 at 24 h. In addition, we could observe that both tea polyphenol solution and TPN became browner over time. The brown color of tea polyphenol solution at the same incubation time was much darker than that of TPN. This was consistent with absorbance alteration. Both absorbance and color alteration reflected that nanoliposome encapsulation could decrease the degradation rate of tea polyphenol and improve the stability of tea

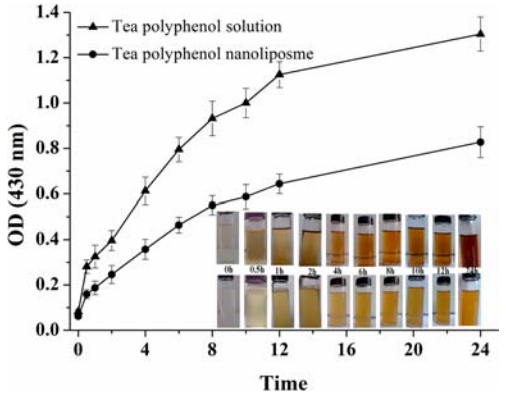

Figure 5. Stability profiles of tea polyphenol solution and nanoliposome in 50 mM potassium hydrogenphosphate buffer, pH 7.4 (37 °C), at an initial concentration of 200 μg/mL. (Inset) Photograph of tea polyphenol solution and nanoliposome incubated at 50 mM potassium hydrogenphosphate buffer, pH 7.4 (37 °C), for a set period.

polyphenols in an alkaline solution. This was similar to Fang et al.'s[15] report that liposomes could provide stable retention of epigallocatechin gallate in the medium. Encapsulation of tea catechins in chitosan−tripolyphosphate nanoparticles enhanced their stability in potassium hydrogen phosphate buffer (pH 7.4), which was also observed.[16]

Several factors, including pH, oxygen level, and concentration of epigallocatechin gallate, could affect the stability of epigallocatechin gallate.[37] It was reported that tea catechins became much less stable[38] and tea polyphenol became more sensitive to degradation with reducing concentrations[37] and when the pH increased from an acid pH to an alkaline pH. In this work, nanoliposome encapsulations' ability to protect tea polyphenols was probably attributed to hindering two important factors (oxygen levels and concentration of tea polyphenol), which could obviously affect the stability of tea polyphenols. Tea polyphenols encapsulated in nanoliposome were isolated with extra membrane environments, so little oxygen could interact with tea polyphenol. In addition, due to the slow release ratio of tea polyphenols, the concentration of tea polyphenols in nanoliposome might remain at a high value and the degradation rate of tea polyphenols was much slower than that of tea polyphenol solution. In this study, the stability of tea polyphenols against alkaline media was significantly improved by nanoliposome using a combination ethanol injection method with DHPM. Although the antioxidant and antimicrobial activities of TPN were not improved after encapsulation of polyphenol in the liposome, the sustaining property was obviously enhanced.

without any detectable regeneration of β-carotene from its radical cation.[8]

It is accordingly of interest to study ET to carotenoid radical cations from a series of plant phenolates, with decreasing reduction potentials resulting in increasing driving force for ET. Such a kinetic study should further explore whether the fundamental ET reaction of eq 4 in an antioxidant interaction in membranes will enter the inverted region for increasing driving force where the rate of ET according to the Marcus theory decreases. Such an inverted region for the rate of ET now has been recognized for other types of bimolecular ET reactions and may for antioxidant regeneration have important biological consequences for controlling oxidative stress and also for design of functional foods with sensitive nutrients.[9−19] We have selected β-carotene, lycopene, zeaxanthin, astaxanthin, and canthaxanthin as a series of carotenoids of general food interest for our studies together with the selection of plant phenols shown in Figure 1, all of which are known to be important plant-based antioxidants in human nutrition or used for antioxidant protection of food emulsions. A large difference in antioxidative activity has been noted for rather small changes in molecular structure in homologue series of natural plant phenols also with a positive effect on human health as taylored by increasing hydrophobicity.[20,21]

2. MATERIALS AND METHODS

2.1. Chemicals. *all-trans*-β-Carotene (β-Car) was purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). *all-trans*-Lycopene was extracted from tomato juice and purified according to the procedure described by Zhang et al.[22] Astaxanthin, canthaxanthin, and zeaxanthin sealed in ampules under argon were supplied by Roche A/S (Hvidovre, Denmark). *m*-Hydroxybenzoic acid (≥99%), vanillic acid (≥97%), *p*-coumaric acid (≥98%), syringic acid (≥95%), caffeic acid (≥98%), and rutin (≥94%) were also purchased from Sigma-Aldrich. Quercetin (≥98%) was purchased from Fluka Biochemika (Buchs, Switzerland). Methanol of high-performance liquid chromatography (HPLC) grade (J&K Scientific Ltd., Beijing, China) was used as received. Chloroform (>99.0%, Beijing Chemical Works, Beijing, China) was purified before use by being passed through an alumina column (AR, Tianjin Fuchen Chemical Plant, Tianjin, China). Solutions of phenolates were prepared by addition 1 or 2 equiv of tetramethylammonium hydroxide (97%, Sigma-Aldrich) to the phenols dissolved in neutral chloroform/methanol (9:1, v/v) solutions.

2.2. Laser Flash Photolysis. The laser flash photolysis apparatus has been described elsewhere.[8] Briefly, the excitation laser pulses at 532 nm (4 mJ/pulse, 7 ns, 10 Hz) were supplied by a Nd^{3+}:YAG laser (Quanta-Ray PRO-230; Spectra Physics, Santa Clara, CA), and the probe light was provided by a xenon lamp (CW 300 W). The optical path length of the flow cuvette (~30 mL) used for laser flash photolysis was 5 mm. The near-infrared kinetics probed at 900 nm for β-carotene radical cation (β-$Car^{\bullet+}$) was detected with a photodiode (model S3071, Hamamatsu Photonics, Hamamatsu, Japan) attached to a Trivista spectrograph monochromator (Princeton Instruments, Trenton, NJ), and the kinetic traces were stored and averaged with a digital storage oscilloscope (bandwidth 600 MHz; Teledyne LeCroy WaveSurfer 64Xs, Chestnut Ridge, NY) connected to a personal computer. For kinetic analyses, the time evolution profiles of the optical density change (ΔOD) upon pulsed excitation were fitted to a two- or three-exponential model function as previously described.[2,8] The concentration of β-carotene was 50 μM. Solution samples were used immediately after preparation under reduced light conditions. All of the measurements were carried out in a thermostated room (23 ± 1 °C). The decay kinetics for carotenoid radical cations was found independent of dissolved oxygen upon a comparison between air-saturated and degassed solutions.

3. RESULTS AND DISSCUSSION

Carotenoids modulate oxidative stress in membranes and cellular structures through ET to oxidizing radicals.[3] The fate of carotenoid radical cations formed under such conditions of oxidative stress have previously been followed in real time kinetic studies using fast spectroscopic techniques for homogeneous solutions, and their effect on lipid oxidation

[a] $E = E^{\ominus}_{\text{Car}^{\bullet+}} - E^{\ominus}_{\text{phenol}}$ with $E^{\ominus}_{\text{phenol}}$ based on ref 16 and $E^{\ominus}_{\text{Car}^{\bullet+}}$ based on ref 17.

have been evaluated in liposomes as a model for membranes.[2,7] Carotenoids have thus been found to form an antioxidant network according to their tendency of reduction of their one-electron-oxidized forms but also to undergo regeneration reactions by other antioxidants such as polyphenols when available as electron donors, leading to antioxidant synergism between different carotenoids and between carotenoids and polyphenols.[7,14]

Carotenoid radical cations were generated as in our previous studies using laser flash photolysis in homogeneous chloroform/methanol (9:1, v/v) as an electron-withdrawing solvent.[2] The fate of the β-carotene radical cation was followed using transient absorption spectroscopy at 900 nm in the absence or presence of one of the plant phenols shown in Figure 1 with and without base added as shown in Figure 2 for caffeic acid and syringic acid. The β-carotene radical decays only slowly even in the presence of a plant phenol in the absence of base. However, addition of 1 or 2 equiv of base in the presence of a plant phenol induces rapid decay, which for 1 equiv of base is described by a biexponential decay curve and for 2 equiv of base requires a triexponential fitting as can be seen in Figure 2. Similar results were obtained for the other plant phenols investigated (data not shown), and an analysis of the numerical values for the multiexponential decay curves showed in all cases that one exponential term dominated with a larger amplitude contribution. Other minor components in the exponential decay curves may be due to interference from the laser or to parallel or sequential reactions as previously noted for reactions of β-carotene radical cations with (iso)flavonoids and their glycosides.[2] The rate constant for the dominant decay reaction of β-carotene radical cations by each of the seven plant phenols investigated can be found in Table 1 for conditions with both 1 and 2 equiv of base added after conversion to second-order rate constants. Similar results were obtained for lycopene and zeaxanthin, for which the second-order rate constants are also presented in Table 1. For none of these carotenoids did the decay of the radical cation induced by base alone interfere with the reduction of the radical cation by the plant phenolate. In contrast, under alkaline conditions, the radical cation of astaxanthin and canthaxanthin decayed rapidly. The first-order rate constants for decay of carotenoid radical cations formed by laser flash photolysis in the absence of phenolates are for all five carotenoids collected in Table 2. For astaxanthin and canthaxanthin, the observed first-order rate constants are

astaxanthin	5.9×10^5	1.5×10^6

larger by more than a factor of 10 than for zeaxanthin, lycopene, and especially β-carotene. Accordingly, under the actual experimental conditions, the reaction of the radical cations of the two ketocarotenoids with the plant phenols became slower than the reaction with the solvent. This observation of a rapid reduction of these carotenoid radicals by the alkaline solvent is in agreement with the previous identification of the keto group as important for electron transfer to astaxanthin and canthaxanthin radical cations.[7]

The first-order rate constants for decay of the carotenoid radical cations were assigned to the reaction of eq 4 in which a carotenoid is regenerated by ET from the phenolate.[2,7] Notably, the phenolate (≥100 μM) was for all experimental conditions in large excess compared to the radical cations, which were only formed as a minor fraction of the total concentration of the carotenoid (50 μM) during laser flash photolysis. This large excess provides pseudo-first-order conditions for the reactions with phenolates following the laser flash photolysis. The pseudo-first-order rate constants determined as shown in Figure 2 for β-carotene by exponential fitting were found to depend linearly on the concentration of excess plant phenol, in agreement with a second-order reaction as shown in Figure 3 for caffeic acid and syringic acid reacting

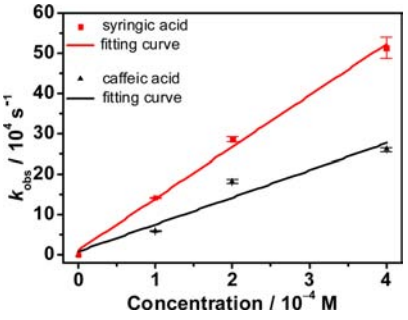

Figure 3. Dependence of the observed first-order rate constant for reduction of β-carotene (50 μM) radical cation on the concentration of caffeic acid and syringic acid in the presence of 1 equiv of base in chloroform/methanol (9:1, v/v) solution at 23 °C. Linear regression for up to 4.0×10^{-4} M provides the second-order rate constants of Table 1.

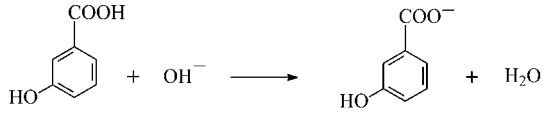
with β-carotene for up to 400 μM phenolate. For a higher concentration of plant phenolate, deviations from this simple second-order reaction were noted with indications of rate saturation at higher phenol concentrations (data not shown), as also noted previously for the puerarin dianion reacting with carotenoid radical cations.[7] The pseudo-first-order rate constants determined for lycopene and zeaxanthin by the same procedure as for β-carotene were likewise converted to second-order rate constants and are included in Table 1 for further discussion. The second-order rate constants calculated from the observed pseudo-first-order rate constants and included in Table 1 for further discussion are all based on the conditions used for the experiment of Figure 2.

The plant phenols were found not to react directly with the β-carotene radical cation despite a large driving force. The values of E of Table 1 are based on the reduction potentials determined in aqueous solution of pH 7.0[16]

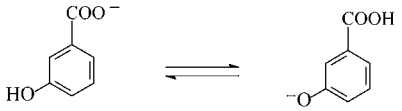
$$\varphi\text{-}O^{\bullet} + e^- + H^+ \rightarrow \varphi\text{-}OH \quad (5)$$

and $E^{\ominus}$ = 1.06 V for reduction of the radical cation of β-carotene, 0.98 V for lycopene, and 1.03 V for zeaxanthin as determined for aqueous conditions.[17] However, deprotonation of the plant phenols studied (Figure 1) resulted in each case in a rapid reaction even following reaction with only 1 equiv of base as for *m*-hydroxybenzoic acid:



(6)

The deprotonation of the neutral phenols is suggested to facilitate formation of an encounter complex with the radical cation. The deprotonation of the plant phenol will mainly occur at the more acidic carboxylic group ($pK_a \approx 3$) rather than at the phenol group ($pK_a \approx 8$). However, the equilibrium, although shifted to the left



(7)

may be important for ET to the radical cation in the encounter complex.

The values of the second-order rate constants for ET from the plant phenol to the radical cation of β-carotene, lycopene, and zeaxanthin increase in the chloroform/methanol binary solvent for increasing driving force to a certain rate close to the diffusion limit for bimolecular reactions;[18] see Figure 4 for β-carotene, Figure 5 for lycopene, and Figure 6 for zeaxanthin. However, for a continuing increase in driving force, the rate constants decrease for all these carotenoid radical cations. Such a bell-shaped dependence on the driving force for the rate of ET was predicted by the Marcus theory for ET[9] and was later confirmed experimentally for a number of processes, including

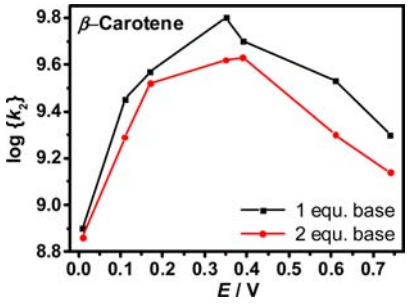


Figure 4. Logarithm of the second-order rate constant for electron transfer to β-carotene radical cation from plant phenolate in the presence of 1 or 2 equiv of base in chloroform/methanol (9:1, v/v) at 23 °C as a function of the driving force for ET ($E = E^{\ominus}_{\beta\text{-Car}^{\bullet+}} - E^{\ominus}_{\text{phenol}}$). For identification of phenols, see Table 1.

dx.doi.org/10.1021/jf404725v | J. Agric. Food Chem. 2014, 62, 942−949

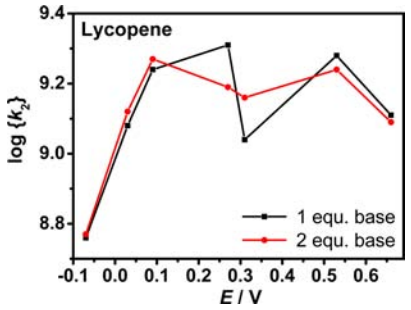

Figure 5. Logarithm of the second-order rate constant for electron transfer to lycopene radical cation from plant phenolate in the presence of 1 or 2 equiv of base in chloroform/methanol (9:1, v/v) at 23 °C as a function of the driving force for ET ($E = E^{\ominus}_{\beta\text{-Car}^{\bullet+}} - E^{\ominus}_{\text{phenol}}$). For identification of phenols, see Table 1.

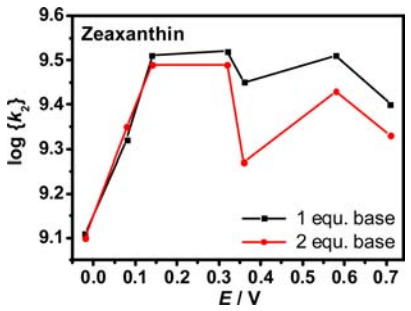

Figure 6. Logarithm of the second-order rate constant for electron transfer to zeaxanthin radical cation from plant phenolate in the presence of 1 or 2 equiv of base in chloroform/methanol (9:1, v/v) at 23 °C as a function of the driving force for ET ($E = E^{\ominus}_{\text{Zea}^{\bullet+}} - E^{\ominus}_{\text{phenol}}$). For identification of phenols, see Table 1.

ET from phenolate ions.[10−14] Accordingly, we analyzed the rate data on the basis of the Marcus theory.[9,14] The rate of ET is controlled by the driving force ($-\Delta G^{\circ}_{\text{ET}}$), a matrix coupling element (V), and the reorganization energy (λ) for the reaction:[14,19]

$$k_{\text{ET}} = \sqrt{\frac{4\pi^3}{h^2\lambda RT}}\, V^2 \exp -\left\{\frac{(\Delta G^{\circ} + \lambda)^2}{4\lambda RT}\right\} \tag{8}$$

The plot of Figure 7 is based on a reorganization of eq 8 and yields $\lambda = 0.41 \pm 0.03$ and 0.40 ± 0.03 eV from the slope of the linear regression lines for the reorganization energy for ET from the plant phenols to the β-carotene radical cation in the presence of 1 or 2 equiv of base, respectively.[23] The matrix coupling element has the value $V = 5.85$ cm^{-1} for the plant phenols with 1 equiv of base added and $V = 5.10$ cm^{-1} for 2 equiv of base. For lycopene, similar plots gave $\lambda = 0.33 \pm 0.04$ eV and $V = 4.53$ cm^{-1} and $\lambda = 0.34 \pm 0.05$ eV and $V = 4.40$ cm^{-1} for 1 and 2 equiv of base, respectively. For zeaxanthin the values were $\lambda = 0.39 \pm 0.04$ eV and $V = 6.03$ cm^{-1} and $\lambda = 0.38 \pm 0.04$ eV and $V = 5.24$ cm^{-1} for 1 and 2 equiv of base, respectively. The values for the relative coupling elements represent the coupling between each of the carotenoid radical cations and the plant phenolates investigated. For the three carotenoids, the driving force, $-\Delta G^{\circ}_{\text{ET}}$, increases for the same series of phenolates reacting with radical cations as β-carotene > zeaxanthin > lycopene, in agreement with the increasing maximal rate for ET observed in experiments (β-carotene > zeaxanthin > lycopene) and an increasing calculated reorganization energy, λ, in agreement with the Marcus theory. λ

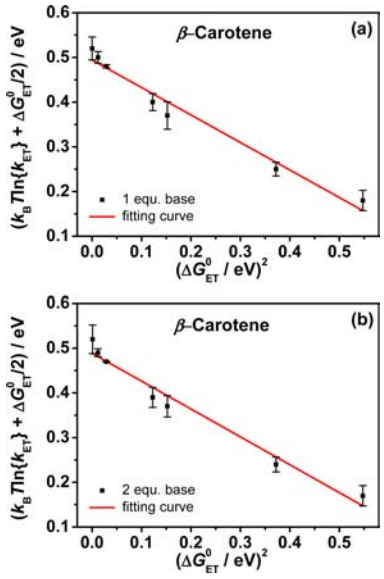

Figure 7. Marcus plot for reduction of β-carotene radical cation by plant phenolate in chloroform/methanol (9:1, v/v) at 23 °C in the presence of 1 (a) and 2 (b) equiv of base.

decreases for decreasing $E^{\ominus}$ for the carotenoid, but is independent of the charge on the phenolate. In contrast, V decreases with increasing charge on the phenolate.

The regeneration of β-carotene following laser flash photolysis shows a pattern similar to the bell-shaped relationship seen in Figure 4 for the rate of ET. The highest degree of protection of the β-carotene, defined as

$$\text{protection} = \frac{\Delta\text{OD(absence of phenol)} - \Delta\text{OD(presence of phenol)}}{\Delta\text{OD(absence of phenol)}} \times 100 \tag{9}$$

in which ΔOD is the relative steady-state absorbance at 500 nm following bleaching of β-carotene, is found for caffeic acid and syringic acid, as can be seen in Figures 8 and 9. Both for less

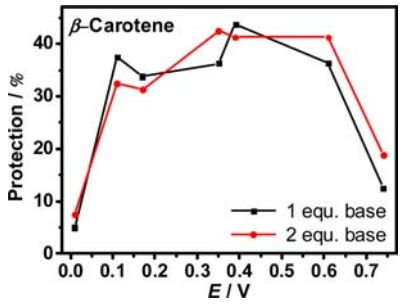

Figure 8. Fraction of β-carotene regenerated by plant phenol in the presence of 1 or 2 equiv of base for 50 μM β-carotene and 100 μM phenol in chloroform/methanol (9:1, v/v) following 7 ns flash photolysis at 532 nm and 23 °C as a function of the driving force for ET ($E = E^{\ominus}_{\beta\text{-Car}^{\bullet+}} - E^{\ominus}_{\text{phenol}}$). For identification of phenols, see Table 1.

reducing and for more reducing plant phenol than caffeic acid and syringic acid, the degree of protection decreases. For both lycopene and zeaxanthin, the same similarity between the dependence of protection of carotenoid and rate of regeneration of carotenoid was found. This dependence of protection of β-carotene through regeneration of β-carotene

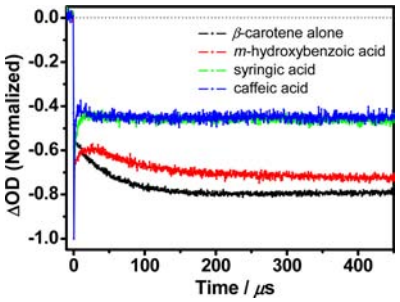

Figure 9. Slow bleaching of β-carotene in chloroform/methanol (9:1, v/v) at 23 °C following laser flash photolysis at 532 nm as monitored at 500 nm in the absence or presence of plant phenol and 2 equiv of base.

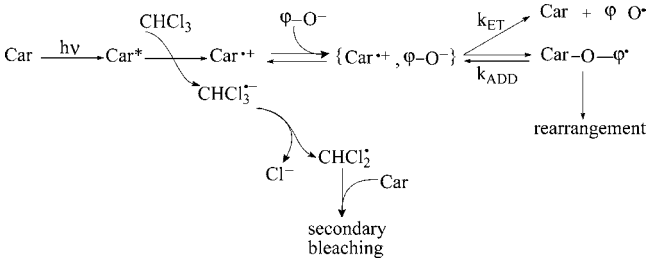
through ET according to eq 4 was further confirmed by inspection of the spectral changes of the β-carotene/phenolate solutions subjected to photolysis; see Figure 10. β-Carotene is bleached by irradiation at 532 nm, a wavelength where none of the plant phenols absorb light, to a certain degree depending on the nature of the plant phenol present in reactions providing no spectral evidence for formation of β-carotene/phenol adducts as was seen for catechins.[8] The recovery of β-carotene following photolysis as followed by transient absorption at 500 nm (Figure 10 d) is seen to occur on a time scale similar to that of the decay of the radical cation (Figure 2) with a half-life around 1 μs corresponding to $k \approx 10^6$ s^{-1}. The fast regeneration of β-carotene is, however, followed by a slower bleaching as is evident in Figure 9, in agreement with previous findings.[24]

The maximal protection of β-carotene approaches 50% as is seen for caffeic acid and syringic acid. The protection of lycopene by the same plant phenols was found to be slightly better, while the protection of zeaxanthin was found to be comparable to the protection of β-carotene. This observation is in agreement with the detection of a slow secondary bleaching of β-carotene in electron-withdrawing solvents initiated by a solvent radical formed in the initial photobleaching of β-carotene in a 1:1 ratio.[24] For the chloroform/methanol mixture as solvent, $CHCl_3^{\bullet-}$ as the initially formed solvent radical was previously found to be converted to $CHCl_2^{\bullet}$ prior to reaction with β-carotene, resulting in the secondary and slower bleaching.[24]

The reactions of Scheme 1 show the coupling between the primary photobleaching and the slower bleaching of β-carotene

Scheme 1



in chloroform/methanol in the presence of plant phenolates. The maximal protection against photobleaching of β-carotene provided by the plant phenolates reacting most efficiently in ET reactions only approaches 50% as is seen in Figure 8. This observation seems to indicate that the plant phenolates are not involved in the secondary bleaching, but only in the primary bleaching. The β-carotene radical cation formed in the primary bleaching reaction may react with a plant phenolate to form a precursor complex for further reaction. Such precursor complexes are often indicated in ET reactions, and their formation may, for some combinations of electron donors and electron acceptors, be rate determining, while, for other combinations, the subsequent reaction of the encounter complex controls the rate.[19] For the ET from the plant phenolate to the carotenoid radical cations, the reaction of the encounter complex seems to be rate determining; see Figures

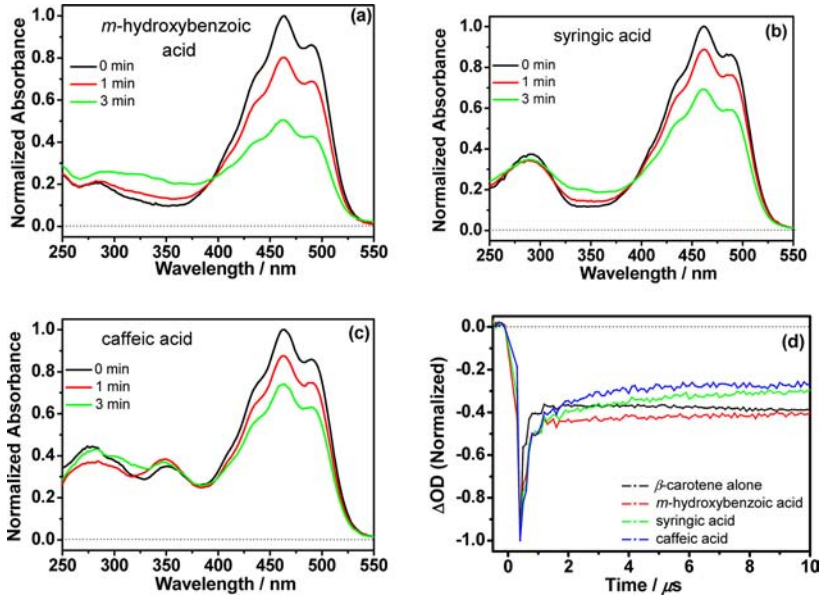


Figure 10. Steady-state absorption spectra of β-carotene (50 μM) in the presence of 100 μM *m*-hydroxybenzoic acid (a), syringic acid (b), or caffeic acid (c) in chloroform/methanol (9:1, v/v) at 23 °C in the presence of 2 equiv of base before and after laser flash photolysis at 532 nm for the indicated time. (d) Normalized recovery of β-carotene bleaching followed at 500 nm for 10 μs in the presence of *m*-hydroxybenzoic acid, syringic acid, and caffeic acid each in the presence of 2 equiv of base.

dx.doi.org/10.1021/jf404725v | J. Agric. Food Chem. 2014, 62, 942−949

4−6, since the rate depends on the driving force for ET and does not level off for increasing driving force, but continues to decrease. Other factors such as an increasing edge-to-edge distance of the encounter complex may, however, also contribute to the decreasing rate for the increasing driving force for the actual series of plant phenols.

A reaction competitive with ET from the phenolate in the encounter complex to the radical cation formed during the primary bleaching may explain the correlation between k_{ET} and the degree of protection of β-carotene. Such a competing reaction may involve a reversible adduct formation as shown in Scheme 1, which for some strongly reducing plant phenols may involve further rearrangements as was seen for the tea catechins and β-carotene.[8] For the plant phenolates investigated in the present study, adducts formed with carotenoids may not react further as they are not seen as stable products. However, it remains unexplained why the phenolate dianion reacts with a rate comparable to or even slower than the phenolate monoanion; see Table 1. However, a single negative charge seems to facilitate formation of the encounter complex, and intramolecular proton transfer equilibria as shown in eq 7 may be involved. Such equilibria may specifically be involved for caffeic acid as a simple plant phenol with two phenol groups in the *ortho* position, decreasing the rate for the reactions of the cations of lycopene and zeaxanthin with the anions of caffeic acid. The small difference in the matrix coupling constant corresponds to a large difference in rates between the reaction of monoanions and dianions. Notably, the rates are comparable for a driving force below the reorganization energy for the two series of phenolates for all three carotenoids, while the difference increases above the reorganization energy, with the monoanion reacting faster; see Figure 4.

Regeneration of lipophilic carotenoids from their radical cations as formed in membranes during oxidative stress by hydrophilic plant phenolates seems to involve an encounter complex, the formation of which depends on electrostatic forces. This encounter complex may react through at least two reaction channels. One reaction involves ET and leads to immediate regeneration of the carotenoids, while the other leads to adduct formation and for some polyphenols to further degradation of the carotenoids. The ET channel is fast, but for increasing driving force above the reorganization energy for ET, inverted region effects as described by the Marcus theory are recognized. As a consequence, the most reducing phenolic antioxidants may not be the most efficient in regeneration of carotenoids and may even show antioxidant antagonism.[1,21] This aspect may also be worth considering when foods or beverages colored by carotenoids need an antioxidant protection agent against light-induced bleaching.

MATERIALS AND METHODS

Dynamic in Vitro Gastrointestinal Model. TIM-1, a dynamic in vitro gastrointestinal model, was originally described by Minekus et al.[5,6] For a schematic diagram of TIM-1, see Verwei et al.[15] This gastric small-intestinal model comprises four connected compartments that represent the stomach, duodenum, jejunum, and ileum, respectively. Each compartment consists of a glass outer wall with a flexible inner wall. The flexible wall is surrounded by water at 37 °C, which is used to squeeze the flexible walls and mix the chyme, simulating peristaltic movements in the gastrointestinal tract. The jejunal and ileal compartments are connected with semipermeable hollow-fiber membranes to remove digested products and especially fat-soluble compounds that were incorporated into mixed micelles.[6−8] The pH values, as well as the gastric emptying and small-intestinal passage of the food, are computer-controlled according to preset curves based on information on human in vivo conditions.[6]

TIM-1 Experimental Design. Two diets that had already been tested in vivo[14] were each evaluated using TIM-1. The difference between the two diets was the food matrix where the β-carotene was incorporated, with one diet containing vegetables high in β-carotene (mixed diet) and the second diet containing vegetables low in β-carotene but supplemented with β-carotene in salad dressing oil (oil diet). The frozen diets were defrosted at 4 °C for ∼16 h before the experiment and were homogenized to mimic the process of chewing by human teeth, to increase experimental consistency and to minimize mixing errors as only a limited amount could be introduced in the gastric compartment. A portion of the diet was put into the gastric compartment of TIM-1. During digestion, the total filtrate (bioaccessible fraction) was collected in 30-min fractions during the first 2 h and hourly fractions until the end of the experiment at 6 h. The total ileal efflux was collected hourly during the 6 h experiment. At the end of the experiment, the residues from the gastric, jejunal, and ileal compartments were collected. The ileal efflux and residues were analyzed to determine the non-bioaccessible fraction. Possibly present β-carotene content in the bile and pancreatic solutions was also analyzed. The samples were stored at −20 °C until β-carotene analysis by HPLC.

Feeding Sample. The feeding sample consisted of 120.0 g of the homogenized diet and was introduced into the gastric compartment together with 50.0 g of gastric juice, 5 g of amylase, and 37 g of water.[6,8] The 120.0 g of the mixed diet contained 498 μg of β-carotene (90% as *trans*-β-carotene), and 120.0 g of the oil diet contained 220 μg of β-carotene (98% as *trans*-β-carotene) (Table 1). A capsule containing 47.0 μg of [$^{13}C_{10}$]β-carotene was introduced into TIM-1 immediately after putting the feeding sample in the gastric compartment.

The β-carotene in the oil diet originated from supplemental β-carotene (85%) and from vegetables and fruits (15%). The supplemental β-carotene in the oil suspension was added to salad dressing for the oil diet (all-*trans* β-carotene, 30% suspension in vegetable oil, Hoffmann-La Roche, Switzerland). Both diets were typical Western diets with respect to the contribution of carbohydrates, proteins, and fats to the energy intake (57%, 13%, and 30%, respectively). Both diets were prepared as duplicate diets during a previously conducted diet-controlled study in humans.[14] Each of the duplicate diets was pooled, homogenized, mixed thoroughly with 2.5 mL of 20% butylhydroquinone (t-BHQ) per kilogram of food, and stored at −20 °C until analysis.

Table 1. Values of Energy, Macronutrients, Fiber, Retinol, and Carotenoids of Two Diets per 100 g Wet Weight[a]

	mixed diet	oil diet
energy (kJ)	584	570
fat (g)	4.7	4.3
protein (g)	4.9	4.8
carbohydrates (g)	17.5	18.2
fiber (g)	1.7	1.6
retinol (μg)	12	13
total β-carotene in salad dressing oil (μg)	<1	156
total β-carotene in vegetables and fruits (μg)	415	28
trans-β-carotene (μg)	373	180
cis-β-carotene (μg)	42	4
α-carotene (μg)	75	3
β-cryptoxanthin (μg)	8	12
lutein (μg)	84	37
zeaxanthin (μg)	8	8

[a]Values of energy and carbohydrates were calculated. The mixed diet contained vegetables high in β-carotene, and the oil diet contained vegetables low in β-carotene supplemented with synthetic β-carotene in salad dressing oil. For the in vitro study, the feeding sample consisted of 120.0 g of the homogenized diet.

Chemical Analysis of β-Carotene in the Feeding Sample. Samples of each homogenized diet (4.0 g each) were extracted in duplicate using a mixture of methanol, tetrahydrofuran (THF), and dichloromethane (45:45:10 v/v/v). The resulting extract was saponified at room temperature overnight using a 1.5 mol/L potassium hydroxide ethanolic solution supplemented with sodium ascorbate, disodium sulfide, and glycerol. Then the mixture was extracted using diisopropyl ether, which was subsequently washed three times with water. Part of the resulting extract was evaporated to dryness and redissolved in HPLC mobile phase. The resulting solution was analyzed for β-carotene using reversed-phase HPLC with diode array detection.[16,17] These analyses were performed for quality control at two laboratories (Food Analysis Laboratory at TNO, Zeist and at Human Nutrition, Wageningen University). Results from both analyses were similar.

Chemical Analysis of β-Carotene in Jejunal and Ileal Filtrates. Samples of 1000 μL each were vortex mixed with an equal volume of ethanol containing tocol as an internal standard (IS). This mixture was extracted with a 2-fold volume of hexane using vortex mixing for 2 min. Part of the resulting extract was evaporated to dryness and redissolved in eluent. The resulting solution was analyzed for β-carotene and IS using reversed-phase HPLC-diode array detection.[16] The limit of precision of the known value of IS was 5%. These analyses were performed at the Food Analysis Laboratory at TNO, Zeist.

Chemical Analysis of β-Carotene in Ileal Efflux and Residues. The ileal efflux and residues had more complex and less dissoluble matrices than the filtrates and consisted of supernatants and pellets. The concentrations of carotenoids in the ileal efflux and residues were measured at the division of Human Nutrition, Wageningen University. The supernatants of both ileal efflux and residues were treated according to the procedure described by Khan et al.[17] Briefly, the pellets of both ileal efflux and residues were extracted in duplicate in the presence of anhydrous sodium sulfate (4.0 g) and calcium

dx.doi.org/10.1021/jf403312v | J. Agric. Food Chem. 2014, 62, 950−955

carbonate (0.5 g), with 20 mL of THF containing 0.01% t-BHT after using a tissue grinder. The extract was filtered through a glass funnel fitted with Whatman paper no. 54. The residue was twice re-extracted with 20 mL of THF. The extract was evaporated to dryness, redissolved in methanol/THF (1:1 v/v %) containing 0.01% t-BHT, transferred into a 25.0 mL volumetric flask, and made up to volume. An amount of 25 μL was injected into the HPLC system for analysis. Within-run and between-run coefficients of variation for β-carotene were 2.6% and 7.1%, respectively.

Labeled β-Carotene in the Capsule and Measurement of Isotopic Enrichment in Filtrates. The concentration of β-carotene in the capsules was analyzed by HPLC with absorbance detection according to the method described by Khan et al.[17] The capsule contained 47.0 (±0.8) μg [12,13,14,15,20,12′,13′,14′,15′,20′-$^{13}C_{10}$]-β-carotene in sunflower oil (>82% oleic acid and >9% linoleic acid; Hozol; Contined BV, Bennekom, The Netherlands). The $^{13}C_{10}$-labeled β-carotene was synthesized at ARC Laboratories (Apeldoorn, The Netherlands) as described previously[18] (isotopic incorporation >99%, isomeric purity >93% all-*trans*, chemical purity >98%). The capsules were designed for oil solutions and were made from bovine gelatin (Capsugel, Bornem, Belgium).

The first experiment of each diet was analyzed for isotopic enrichment in the filtrates. The degree of isotopic enrichment of β-carotene with [$^{13}C_{10}$]β-carotene in filtrates was measured by using liquid chromatography-atmospheric pressure chemical ionization-mass spectrometry (APCI LC−MS) as described previously.[19,20] β-Carotene and [$^{13}C_{10}$]β-carotene were monitored in negative ion mode at mass-to-charge ratios (m/z) 536 and 546, respectively.[20] Isotopic enrichment of β-carotene in the filtrates was the proportion of labeled β-carotene to total β-carotene. These analyses were performed at the University of Illinois.

Calculations. The β-carotene bioaccessibility, the amount of bioaccessible β-carotene in μg per 100 μg of β-carotene available for digestion, was expressed as a fraction of β-carotene feeding and was calculated by the formula

$$\frac{\mu g\ \beta\text{-carotene}_{filtrates}}{\mu g\ \beta\text{-carotene}_{feeding} + \beta\text{-carotene}_{endogenous}} \times 100$$

where β-carotene$_{filtrates}$ is the total β-carotene in the jejunal and ileal filtrate, β-carotene$_{feeding}$ is the β-carotene in the feeding sample and comprises the β-carotene in 120.0 g of the diet and a capsule with 47 μg of labeled β-carotene, and β-carotene$_{endogenous}$ is the β-carotene content in the bile and pancreatic solutions secreted into the duodenal compartment.

The recovery (%) (mass balance) of β-carotene was calculated by the formula

$$\frac{\beta\text{-carotene}_{filtrates} + \beta\text{-carotene}_{ileal\ efflux} + \beta\text{-carotene}_{residues}}{\beta\text{-carotene}_{feeding} + \beta\text{-carotene}_{endogenous}} \times 100$$

where β-carotene$_{ileal\ efflux}$ is the β-carotene content in the total material delivered from the ileal compartment, and β-carotene$_{residues}$ is the total β-carotene in the residues of stomach, duodenum, and ileum.

The proportion of isotopic enrichment (IE) of β-carotene with [$^{13}C_{10}$]β-carotene was calculated by IE in filtrates divided by IE in feeding sample and multiplied by 100.

RESULTS

The endogenous β-carotene content of the bile and pancreatic juice used in TIM-1 was below the detection limit in all runs. There were no other sources of β-carotene than the feeding samples. The results with the mixed diet are based on triplicate experiments. The results with the oil diet are based on duplicate experiments since one experiment failed due to a defective hollow-fiber membrane unit. Because of the high recovery in both oil diet runs and similar bioaccessibilities, these duplicate runs were regarded as representative.

The bioaccessibility of β-carotene, determined by collection of all the filtrates, was 28.2 μg/100 μg β-carotene from the mixed diet and 53.4 μg/100 μg β-carotene from the oil diet (Table 2 and Figure 1). The recovery of β-carotene was 92% and 105% in the two runs with the oil diet and 88%, 94%, and 104% in the three runs with the mixed diet (Table 2).

Table 2. β-Carotene Amounts, Bioaccessibility of β-Carotene, and the Recovery of β-Carotene with the Two Diets in TIM-1 over 6 h[a]

	β-carotene in mixed diet			β-carotene in oil diet	
	run 1	run 2	run 3	run 1	run 2
feeding					
diet (μg)	498	498	498	220	220
capsule (μg)	47	47	47	47	47
endogenous (μg)	nd	nd	nd	nd	nd
filtrates					
jejunal filtrate (μg)	95.6	83.5	80.3	76.3	80.5
ileal filtrate (μg)	73.7	73.0	55.5	65.4	62.8
ileal efflux (μg)	264.2	312.0	233.6	34.8	44.9
residues					
residue of stomach and duodenum (μg)	31.7	27.4	67.9	44.0	62.9
residue of jejunum and ileum (μg)	48.2	69.7	40.1	25.8	29.7
bioaccessibility (μg β-carotene/100 μg β-carotene)[b]	31.1	28.7	24.9	53.1	53.7
recovery (%)[c]	94.2	103.8	87.6	92.3	105.2

[a]The mixed diet contained vegetables high in β-carotene, and the oil diet contained vegetables low in β-carotene supplemented with synthetic β-carotene in salad dressing oil. nd = not detected. [b]The β-carotene bioaccessibility is the amount bioaccessible β-carotene in μg per 100 μg of β-carotene available for digestion and is calculated as (μg β-carotene in filtrates)/(μg β-carotene from feeding + endogenous) × 100. [c]Recovery (%) = (β-carotene in filtrates + ileal efflux + residues)/(β-carotene from feeding + endogenous) × 100.

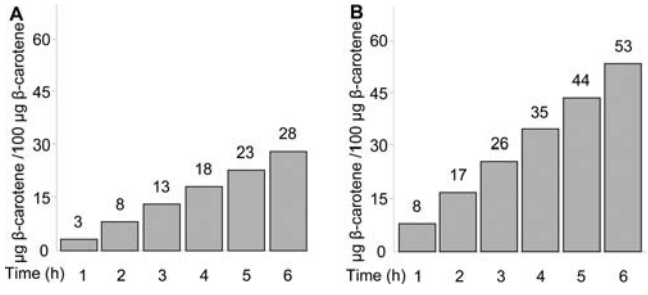

Figure 1. Cumulative β-carotene in filtrates expressed as a percentage of feeding to time after the runs (n = 3) with the mixed diet (A) and with the oil diet (B) after the runs (n = 2) in TIM-1 during 6 h.

dx.doi.org/10.1021/jf403312v | J. Agric. Food Chem. 2014, 62, 950−955

The isotopic enrichments of β-carotene in the feeding sample compared with the isotopic enrichment of β-carotene in the filtrates varied over time from 85% to 122% in the jejunal filtrates and from 79% to 139% in the ileal filtrates (Table 3).

Table 3. Proportion of Isotopic Enrichment of β-Carotene with [$^{13}C_{10}$]β-Carotene in Filtrates Compared with That of the Feeding Sample for the Two Diets in TIM-1 over 6 h

	mixed diet (%)	oil diet (%)
jejunal filtrate 0−3 h	85	106
jejunal filtrate 3−6 h	111	122
ileal filtrate 0−3 h	112	79
ileal filtrate 3−6 h	139	85
weighted average filtrate 0−6 h[a]	113	99

[a]The measured β-carotene levels in jejunal filtrates were slightly higher than in ileal filtrates (Table 2).

Averaged over 6 h, the isotopic enrichment of β-carotene in the filtrate for the oil diet was closer to the theoretical value of 100% than for the mixed diet (99% v 113%). This difference in isotopic enrichment was expected because the oil diet with supplemental β-carotene was more comparable with the matrix of labeled β-carotene in the feeding sample than was the β-carotene in vegetables in the mixed diet. In the TIM-1 run with the mixed diet, the isotopic enrichment in the jejunal filtrate was lower than in the ileal filtrate, which indicates that micellarization of labeled β-carotene in the jejunal compartment lagged behind that in the ileal compartment. In contrast, the opposite was seen in the TIM-1 run with the oil diet, where micellarization of labeled β-carotene was faster in the jejunal compartment than in the ileal compartment. The isotopic enrichment increased over time in both jejunal and ileal filtrates, which means that the labeled β-carotene was not equally distributed over time in the bioaccessible fractions. Labeled β-carotene either did not fully equilibrate with the β-carotene in the food matrix or else followed a different micellarization pattern.

DISCUSSION

This in vitro gastrointestinal model appears useful for determination of the effects of food matrices on the bioaccessibility of β-carotene from foods, especially when fat-soluble nutrients compete for uptake in mixed micelles.

Comparing the Bioaccessibilities of β-Carotene from Both Diets. The mixed diet represented a healthy diet with high amounts of cooked vegetables and fruits. The oil diet was representative of a diet low in vegetables and fruits but high in food items fortified with β-carotene, such as those regularly consumed in industrialized societies (e.g., margarine). The oil diet and the mixed diet contained β-carotene in the physiological dose range and were designed according to the guidelines of 'good nutrition' from the Dutch Nutrition Board in The Hague, The Netherlands. Both diets were typical western diets with respect to the contribution of carbohydrates, proteins, and fats to the energy intake (57%, 13%, and 30%, respectively). The β-carotene amount in the oil diet was not the same as in the mixed diet; however, this was also the situation in the in vivo study.[14] The absorption efficiency of β-carotene is regarded constant as long as the β-carotene consumption is within physiological ranges.[1,2,21] Furthermore, the mixed diet contained a higher amount of β-carotene than the oil diet but had a lower amount bioaccessible β-carotene compared to the oil diet; in contrast, the oil diet contained a lower amount of β-carotene than the mixed diet but had a higher amount bioaccessible β-carotene compared to the mixed diet.

Bioaccessibility of β-carotene was 28 μg/100 μg β-carotene (or 28%) from the mixed diet and 53 μg/100 μg β-carotene (or 53%) from the oil diet. So, the bioaccessibility of labeled and dietary β-carotene from the oil diet was 1.9-fold higher than from the mixed diet. This 1.9-fold enhancement in apparent absorption between two diets was also found in the in vivo study.[14]

Although in absolute terms results of β-carotene bioaccessibility using TIM-1 are not strictly comparable with in vivo experiments, the differences in β-carotene bioaccessibilities between food matrices are still comparable with absorption estimates in humans. Thus, TIM-1 cannot be used for predicting absorption in vivo, but the system is a useful tool for measuring differences in bioaccessibility of β-carotene between various food matrices.

Comparing the Bioaccessibilities of β-Carotene Measured Using Other Models. Bioaccessibility of β-carotene from various meals, fruits, and vegetables have been reported using other in vitro digestion models. Garrett et al.[22] developed an in vitro digestion model based on the method of Miller et al.,[23] which simulates human gastric and pancreatic digestion as static duo-compartments. Our result of 28% bioaccessibility of β-carotene from the mixed diet is slightly higher than the reported bioaccessibility of β-carotene from meals. For example, the micellarization of β-carotene was 12−18% from a baby food meal of carrots, spinach, and chicken,[22] 16% from a meal of mango and chicken,[24] 16% from stir-fried meal of spinach, carrots, and tomato paste,[25] and 18% from a salad meal of spinach, tomato, carrot, and lettuce.[26]

Several other studies have used the same in vitro method for single fruits or vegetables. From orange and kiwi, the micellarization of β-carotene was 34% and 47%, respectively.[27] From mango, the micellarization of β-carotene was 25−39%; from mango with milk and sugar, 37−48%; from papaya, 31−34%; and from papaya with milk and sugar, 41−44%.[28] The micellarization of β-carotene from carrot was 14% for carrot juice,[29] 17% from processed carrots,[30] 20% from raw carrots,[31] and 33% from stir-fried carrots.[31] From other vegetables, the micellarization of β-carotene was 17% from maize,[32] 17% from boiled spinach,[29] 30% from spinach puree,[33] 30% from spinach,[27] 29% from tomatoes,[34] 30% from boiled cassava,[35,36] 45% from sweet potato,[27] 54% from broccoli,[27] and 57% from courgette.[34] Our result of 28% is comparable to these as our study included a mix of different cooked vegetables and fruits.

Hedrén et al.[37] developed a similar static duo-compartmental in vitro model, which estimates the maximum amount of carotenoids released, but not necessarily micellarized. Using this other in vitro model, the percentages of accessible β-carotene in homogenized, raw carrots were 21% and 30% and from cooked carrots were 27% and 39%, without and with addition of oil, respectively.[37] Another study by Hedrén et al.[38] showed accessible β-carotene was 39% from sweet potato, 64% from pumpkin, and 47% from cassava, which were all cooked with sunflower oil. Three other studies with this method showed a bioaccessibility of β-carotene of 19% from boiled pumpkin,[39] 74% from boiled carrot,[39] and when cooked with vegetable oil, 11−22% from various processed sweet potato,[40] 21% from sweet potato, and 39% from pumpkin.[41] Our results of 28% and 53% are also comparable with the results from this in vitro method.

Although these other models are temperature- and pH-controlled, they are not representative of the continuously changing variables during passage through the stomach and the small intestine. For general prediction of micellarization of β-carotene, these models are adequate. However, TIM-1 allows for the closest simulation to date of in vivo dynamic physiological processes occurring within the lumen of the stomach, duodenum, jejunum, and ileum of humans. Furthermore, TIM-1 has as major advantage that the model allows for the collection of samples during the process of digestion without disturbing or temporarily stopping the experiment and thereby allows studying the digestion process in time.

Extrinsic Labeled β-Carotene vs Time of Both Diets. When using any extrinsic labeling technique in absorption studies, the assumption must be made that the label fully mixes with the compound and equally distributes in the lumen of the small intestine. This means that in each time period of the digestion process, the isotopic enrichment of β-carotene in the filtrates should be the same as in the diet. However, during the 6 h of the TIM-1 experiment, the isotopic enrichments of β-carotene in the ileal filtrate in mixed diet runs increased and in oil diet runs decreased compared with the jejunal filtrate, which indicates discrimination for micellarization. This enrichment pattern can be explained by retarded equilibration in the mixed diet run, where the labeled β-carotene is bound and captured by the complex matrix and available later in time for digestion than in the oil diet. The isotopic enrichment of β-carotene with [$^{13}C_{10}$]β-carotene in filtrates was not constant over time. This implies that the labeled β-carotene behaved differently from the β-carotene incorporated into the matrices of vegetables and fruits high in β-carotene and behaved differently from the matrix of supplemental β-carotene in oil. The labeled β-carotene dissolved in oil was not equally distributed over time in the bioaccessible fractions, which means that during the experiment, it did not fully mix with dietary β-carotene. As suggested by the average filtrate over 6 h for the oil diet, which was 99%, the extrinsic labeling technique could be used to measure absorption in vivo if the matrix of the homogenized diet were comparable with the oily matrix of extrinsic labeled β-carotene. However, the different isotopic enrichments of β-carotene in the ileal filtrate and jejunal filtrate in the oil diet suggested different micellarization patterns for dietary β-carotene in oil and labeled β-carotene in oil.

Additional experiments are required to confirm and explain this result, which may be influenced by dissolving of the capsule, and to investigate the reproducibility of the measured isotopic enrichments in these samples with very low amounts of labeled and unlabeled β-carotene.

The advantage of this TIM-1 dynamic model is that it can address mixing effects and partitioning effects of labeled fat-soluble compounds during the digestion process. Therefore, this in vitro model could provide significant value for checking assumptions in distribution of labeled compounds in in vivo labeling studies.

In summary, the food matrix effects on bioaccessibility of β-carotene could be measured using TIM-1 and were consistent with in vivo data. The labeled β-carotene either did not fully equilibrate with the β-carotene in the food matrix or else followed a different micellarization pattern. The application of extrinsically labeled β-carotene was not confirmed.

mobilization, are synthesized only after seed germination,[24,25] revealing that P34 may possess different biological activity. Structurally, the thiol proteases of the papain family possessed highly conserved catalytic triad (Cys-His-Asn) residues and three disulfide bonds.[26] Compared with these thiol proteases, a Gly37 replaced the highly conserved catalytic Cys in P34; of the three disulfides, two were present in P34 (Cys68-Cys108 and Cys171-Cys224). However, one of the three disulfides in other thiol proteases existed as Cys34 and Asn77 in P34, so it was suggested that the Cys34 near Gly37 should be a free thiol and act as the active-site residue.[23,24] Until now, only one protein was reported to be similar to P34, which was a 31 kDa thiol protease (SPE31) isolated from the seeds of a legume plant (*Pachyrizhus erosus*), and they were considered to form a unique subfamily within the papain family.[27] However, the substrates of P34 and SPE31 were not clear yet.

Several members of the papain protease family have been reported in allergenic reaction, such as fecal dust mite allergen Der 1p[28] and archtype papain thiol protease.[29] And it was considered that the destructive proteolytic activity of these thiol proteases might be a significant factor in the allergenicity.[30] Bd 30K (257 AARs), an allergenic soybean protein, was first identified by Ogawa et al., and considered as similar protein to P34 owing to their identical N-terminal amino acid sequences and amino acid compositions.[31,32] However, the Arg46, Ser75, Gln80, and Phe203 of P34 were replaced by the Ser46, Cys75, His80, and Glu203 of Bd 30K (NCBI database). Two studies reported that there were two spots for P34 and Bd 30K on the two-dimensional electrophoresis gel,[30,33] revealing that P34 and Bd 30K might be two different proteins with similar biological activities. Many studies reported that P34/Bd 30K had high specificity to interact with soybean OBs,[5,12,22−24,34] very similar to the interaction between protease and its substrate. The interaction between P34/Bd 30K and soybean OBs was clarified as the disulfide bond between P34/Bd 30K and 24 kDa oleosin.[5]

In fact, the best way to confirm one protease is directly mixing it with its substrate. Sewekow et al. reported a method for the purification of P34 by hydrophobic interaction chromatography, and a key buffer of 0.1 M sodium carbonate (pH > 11.0) was used.[35] Ogawa et al. reported a method for the purification of Bd 30K, and sodium dodecylsulfate (SDS, 4%) and heat treatment (98 °C, 10 min) were used.[32] According to the present study, P34 and Bd 30K (assumed as the proteases) are already denatured at pH 11.0 and also denatured when exposed to SDS and/or high temperature. It is considered that a method for bioactive P34/Bd 30K purification is a great challenge at the present stage. In this study, some properties (specificity, optimal pH, and temperature) of the proteases of 24 and 18 kDa oleosins, and oleosin hydrolysis in soybean germination were examined, and the high relationship between the proteases and P34/Bd 30K was also discussed. It is considered that this study is very meaningful for designing better processing methods for the soybean OB extraction and the enzyme-assisted aqueous extraction of soybean oil.

MATERIALS AND METHODS

Materials. Soybean Nannong 88−31 (moisture content, 9%), harvested in August, 2011, was used. It was stored at 4 °C until use. This study was conducted from March, 2012 to June, 2013, and the behaviors of oleosin hydrolysis were consistent in this period. One study reported that the structure of glycinin, which was purified from soybean stored at 4 °C for 18 months, did not show significant changes compared to the purified glycinin from soybean stored in a −20 °C freezer.[36] These showed that the data in the study should be acceptable. All reagents were purchased from Sigma-Aldrich Trading Co., Ltd. or of analytical reagent grade. Precision Plus Protein All Blue (Bio-Rad, USA), including 250, 150, 100, 75, 50, 37, 25, 15, and 10 kDa proteins, was used as the protein marker.

Raw Soymilk Preparation. Soybean (20 g) was soaked in deionized (DI) water at 4 °C for 18 h. The soaking water was poured off, and the soaked soybeans were washed with fresh DI water three times. DI water, precooled in 4 °C refrigerator, was added to make the total weight of 200 g. This mixture was ground in a Waring blender (18 000 rpm, MJ-60BE01B, Midea) for 2 min and filtered through four layers of gauze to obtain raw soymilk (about pH 6.8).

Oil Bodies (OBs) Extracted by pH 6.8, 8.0, 9.5, and 11.0 at 4 °C. This was conducted with the method by Chen and Ono[34] with the modification that the temperature was controlled at 4 °C. Sucrose was added into raw soymilk to make the concentration of 20% (w/w) and mixed well in 4 °C refrigerator. A total of 40 g of raw soymilk (20% sucrose) was added into the first centrifuge tube. The residual raw soymilk was adjusted to pH 8.0 by 2 M NaOH, and 40 g was added into the second centrifuge tube. The residual raw soymilk was adjusted to pH 9.5, and 40 g was added into the third centrifuge tube. The residual raw soymilk was adjusted to pH 11.0, and 40 g was added into the fourth centrifuge tube. Then they were treated by centrifugation (25,000*g*, 30 min; 4 °C). The supernatant of pH 6.8 system was collected (termed pH 6.8 supernatant), stored in 4 °C refrigerator and used for the experiment below. The floating fractions were collected, dispersed into 39 g of sucrose solution (20%, w/w), and adjusted to corresponding pH, respectively. They were mixed well and treated by centrifugation (25,000*g*, 30 min; 4 °C). Then the collection of floating fraction, dispersion into sucrose solution (20%, w/w), pH adjustment, and centrifugation as above was repeated twice. The floating fractions obtained were dispersed into DI water with oil concentrations of 40 mg/mL. The four suspensions were all adjusted to pH 6.5. Each suspension (7 mL) was incubated in 35 °C water bath for 0, 0.5, 1, 3, 6, and 9 h, and 1 mL of suspension was collected and cooled in one ice water bath, respectively. The obtained OB suspensions (1 mL) were defatted by diethyl ether with the method by Tzen et al.[37] Briefly, three milliliters of diethyl ether (4 °C) was added, thoroughly mixed for 30 min and centrifuged (15,000*g*, 5 min; 4 °C). The upper diethyl ether was removed, and the procedure was repeated one more time. The residual diethyl ether was allowed to evaporate in a hood combined with fan blowing, which was conducted in ice water bath. The residual aqueous solution was well mixed. The protein concentration of pH 6.8 extracted OBs was determined by the micro-Kjeldahl method, and 0.5 mL of the defatted sample (well mixed) was diluted with Tricine-SDS-PAGE sample buffer to make the protein concentration of 2 mg/mL. The other three defatted samples (pH 8.0, 9.5 and 11.0), which had lower protein concentrations, were mixed with the same volume of sample buffer above. This method, different from the traditional method, was beneficial for examining the protein release behaviors from OBs.

Effect of pH 6.8 Supernatant on pH 11.0 Extracted OBs. A total of 7 mL of the pH 11.0 extracted OB suspension (pH 6.5, 4 °C) was added into 30 mL of pH 6.8 supernatant obtained above. They were stirred in ice water bath for 30 min and centrifuged (25,000*g*, 30 min; 4 °C). The floating fraction was carefully collected and dispersed well into 7 mL of DI water, and stored in 4 °C refrigerator (termed the first OBs). The supernatant was collected carefully with syringe and mixed in ice water bath for 30 min with another 7 mL of fresh pH 11.0 extracted OB suspension. It was treated by centrifugation (25,000*g*, 30 min; 4 °C). Then the collection of supernatant fraction, and its mixing with 7 mL of fresh pH 11.0 extracted OB suspension followed by centrifugation was repeated three more times, and floating fraction (OBs) and supernatant (termed the fifth supernatant) were obtained by the last centrifugation. The floating fraction was dispersed into 7 mL of DI water (4 °C) and termed the fifth OBs. The protein concentrations of the fifth supernatant and pH 6.8 supernatant were determined by bicinchoninic acid assay with bovine serum albumin as standard, and diluted with SDS-PAGE sample buffer to make the

concentrations of 20 mg/mL. The first and fifth OBs were incubated in 35 °C water bath for 0, 0.5, 1, 3, 6, and 9 h, and 1 mL of suspension was collected and cooled in an ice water bath. Then they were treated as above for Tricine-SDS-PAGE analysis.

Soybean Germination. In order to simulate the natural soybean germination, 20 g of soybeans was washed and soaked in tap water for 9 h at room temperature. A food-grade plastic container, without cover, was used for the soybean germination, and there were many holes on its bottom and walls. The tap water was poured off, and the soybeans were uniformly placed on the container bottom. The boiled tap water (room temperature) was sprayed on the soybean for about 2 min, and a preservative film (with artificially small holes) was used to cover the container for germination (1, 2, 4, 6, and 8 days). Everyday the soybeans was sprayed with boiled tap water (room temperature) four times (at 8:00, 12:00, 16:00, and 20:00). In the soybean germination, the room temperature was within the range of 21−33 °C. DI water, precooled in 4 °C refrigerator, was added into the germinated soybeans to make total weight of 200 g. It was ground for 2 min and filtered through four layers of gauze to obtain raw germinated soymilk. Sucrose was added into raw germinated soymilk to make a concentration of 25% (w/w) and mixed well. Raw germinated soymilk (6.5 mL; 25% sucrose, w/w) was added into the first ultracentrifuge tube. The residual raw germinated soymilk was adjusted to pH 8.0, and 6.5 mL was added into the second ultracentrifuge tube. The residual was adjusted to pH 9.5, and 6.5 mL was added into the third ultracentrifuge tube. The three tubes were all preplaced in the ice water bath. Then 3 mL of 20% (w/w) sucrose solution was carefully layered on the top of the raw germinated soymilk in the three tubes. These were treated by ultracentrifugation (197,000*g*, 1 h; 4 °C), and solid OB pad was formed on the top of 20% sucrose solution. The OB pad was carefully taken out and rinsed by DI water (4 °C). The residual DI water was carefully absorbed by filter paper. The OB pad was weighed, and 5-fold of DI water (4 °C) was added to disperse it well. Then it was defatted as above. The protein concentration of the defatted sample (pH 6.8 extracted OBs from 1 d germinated soybean) was determined by the micro-Kjeldahl method, and 0.5 mL of the defatted sample was diluted with Tricine-SDS-PAGE sample buffer to make the protein concentration of 2 mg/mL. The other defatted samples (pH 8.0, pH 9.5; 2, 4, 6, and 8 d germinated soybean), which had lower protein concentrations, were all diluted with the same volume of sample buffer above and used for Tricine-SDS-PAGE analysis.

Effects of Temperature and pH on Oleosin Hydrolysis. pH 6.8 extracted OB suspension (pH 6.5), without repeated washing as above, was used to examine the effect of temperature on oleosin hydrolysis. A total of 15 mL of suspension was incubated in 20, 30, 35, 40, 50, and 60 °C water baths, respectively. After 0, 0.5, 1, 3, 6, and 9 h, 1 mL of suspension was collected and cooled in ice water bath. In addition, 15 mL of pH 6.8 extracted OB suspension was respectively adjusted to pH 4.0, 5.0, 6.0, 6.5, 7.0, 8.0, 9.0, 10.0, and 11.0, and all incubated in 35 °C water bath. After 0, 0.5, 1, 3, 6, and 9 h, 1 mL of suspension was collected and cooled in ice water bath. The obtained OB suspensions (1 mL) were treated as above for Tricine-SDS-PAGE analysis. These experiments were conducted two times and showed the same trend.

SDS-PAGE. SDS-PAGE was conducted with the method by Laemmli with the concentrations of the stacking and separating gels being 5% and 12.5%, respectively.[38] 2-Mercaptoethanol was added into the samples (pH 6.8 supernatant and the fifth supernatant) to the concentration of 2% (v/v) and heated for 3 min in a boiling water bath. Then 10 μL of each sample was loaded into a sample well. SDS-PAGE was performed at 15 mA for about 2 h. The gel was stained by using Coomassie Brilliant Blue G-250.

Tricine-SDS-PAGE. Tricine-SDS-PAGE was conducted according to the method by Schagger.[39] The concentrations of stacking and separating gels were 4% and 16%, respectively. 2-Mercaptoethanol (no 2-mercaptoethanol for nonreducing Tricine-SDS-PAGE) was added into the samples above to the concentration of 2% (v/v), and samples were heated for 3 min in a boiling water bath. Then 20 μL of each sample was loaded into a sample well, and the samples were electrophoresed at constant voltage of 30 mV until all samples entered into the stacking gel and then at constant voltage of 100 mV until end. The gel was stained using Coomassie Brilliant Blue G-250.

Two-Dimensional Electrophoresis. The pH 6.8 and 8.0 extracted OB suspensions obtained without strict temperature control were desalted by dialysis against DI water (4 °C) and lyophilized. The lyophilized OBs were extracted with acetone at 4 °C. After stirred for 30 min, the homogenate was filtered through one layer of filter paper, and the protein fraction was recovered. This was repeated two more times to remove neutral lipids. Then it was further defatted by chloroform/methanol (2/1, v/v) three times. Finally, the protein obtained was placed in the hood to allow the organic solvent evaporated.

The two-dimensional electrophoresis was performed according to the Bio-Rad manufacturer's instructions. One hundred and fifty micrograms of protein obtained above was thoroughly dissolved in 125 μL of 2-D electrophoresis sample preparation solution (7 M urea, 2 M thiourea, 2% (w/v) CHAPS, 75 mM DTT, 0.2% (w/v) ampholyte 3−10, 0.001% bromophenol blue), assisted by vortexing and ultrasonic treatment. It was loaded onto a linear IPG gel strip (pH 3−10, 7 cm, Bio-Rad, USA) and allowed to hydrate for 16 h at 20 °C. The first dimensional isoelectric focusing (IEF) was conducted at 40 kVh using Protean IEF Cell (Bio-Rad Laboratories). After IEF, the IPG strip was reduced and alkylated with DTT (20 mg/mL) and iodoacetamide (25 mg/mL) in equilibration buffer (6 M urea, 2% (w/v) SDS, 0.375 M Tris-HCl, pH 8.8 and 20% (w/v) glycerol) for 15 min. After rinsed by SDS-PAGE electrode buffer, it was transferred onto the SDS-PAGE separating gel, covered with low melting point agarose and subjected to the second dimensional SDS-PAGE. The gel was stained by Coomassie Brilliant Blue G-250.

MALDI-TOF/TOF MS. The protein spots were excised from the Coomassie Brilliant Blue G-250 stained gel, washed in distilled water, and destained completely in a 30% acetonitrile (v/v) containing 100 mM NH_4HCO_3. After a 100% acetonitrile washing, the destained gel piece was placed into reducing solution (10 μL of 100 mM DTT, 90 μL of 100 mM NH_4HCO_3) for 30 min at 56 °C. After a 100% acetonitrile washing, 70 μL of 100 mM NH_4HCO_3 and 30 μL of 200 mM iodoacetic acid were added and incubated for 20 min in dark. After a 100% acetonitrile washing again, 5 μL (10 μg/mL) of trypsin (Promega, V5111) was added and put into 4 °C refrigerator for 30 min. Then 25 mM NH_4HCO_3 solution was added. The peptides were generated after 20 h incubation at 37 °C. The solution containing peptides was collected and concentrated at 30 °C to get dry powder. A total of 3 μL of 0.1% trifluoroacetic acid (v/v) was used to dissolve dry powder. In the final step before MALDI-TOF/TOF analysis, the sample was prepared by mixing 0.7 μL of the sample and 0.7 μL of 4-hydroxy-α-cyanocinnamic acid (matrix) on a MALDI target and air-dried. All mass spectra were obtained with an ultrafleXtreme MALDI-TOF/TOF (Bruker Daltonics, Germany) and were analyzed by flexAnalysis software provided by Bruker Daltonics Corp. Protein identification was performed by searching plant proteins in the latest version of the NCBInr database.

RESULTS AND DISCUSSION

Oleosin Hydrolysis of pH 6.8 Extracted OBs. The pH 6.8 extracted OB suspension (pH 6.5) was incubated in a 35 °C water bath for 0, 0.5, 1, 3, 6, and 9 h. Figure 1 reveals that 24 kDa oleosin shows an apparent molecular weight (MW) of 24 kDa, 18 kDa oleosin shows an apparent MW of 16 kDa, and 16 kDa oleosins (two bands) show apparent MWs of 13−14 kDa on Tricine-SDS-PAGE gel. The bands of 24 and 18 kDa oleosins gradually became weak with increasing incubation time, while the bands of lipoxygenase, β-conglycinin, γ-conglycinin, β-amylase, glycinin, Bd 30K, and P34 did not change. The band of 16 kDa oleosin 1 gradually became dense with increasing incubation time and merged with the band of 16 kDa oleosin 2. Band 1 already appeared in the freshly extracted OBs, gradually became dense before 3 h, and became

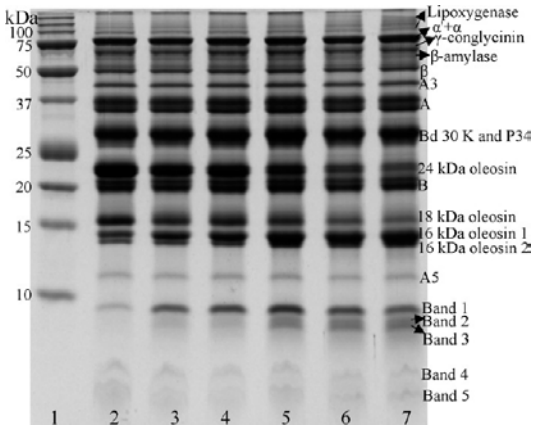

Figure 1. 24 and 18 kDa oleosin hydrolysis in the pH 6.8 extracted OB suspension (pH 6.5) incubated at 35 °C. Lane 1, marker; lanes 2−7, OB suspension incubated for 0, 0.5, 1, 3, 6, and 9 h, respectively. α', α, and β are the subunits of β-conglycinin; A3, A, and A5 are acidic polypeptides of glycinin; and B is the basic polypeptides of glycinin.

weak after 3 h. Bands 2 and 3 weakly appeared after 0.5−1 h and gradually became dense after 1 h. Bands 4−5 already appeared in the freshly extracted OBs (similar to band 1) and did not show a clear trend with increasing incubation time. The total intensities of 24, 16, and 13−14 kDa band and bands 1−5 on lanes 2−7 were analyzed by Image Lab Software (Bio-Rad, USA), and they were almost the same; 13−14 kDa band on lane 7 was matched to 24 kDa oleosins (P29530 and P29531), 18 kDa oleosin (C3VHQ8), and 16 kDa oleosins (C6SZ13 and gil35657640) by MALDI-TOF/TOF MS. The apparent MWs of bands 1−3 and bands 4−5 were respectively determined as around 9 and 3−4 kDa by Image Lab Software with the standard on lane 1, indicating that bands 1−3 should be the small hydrolyzed products of 24 kDa oleosins (P29530 and P29531), while bands 4−5 might be the small hydrolyzed products of 18 kDa oleosin (C3VHQ8). Different from bands 1−3, bands 4−5 did not show a clear trend with increasing incubation time, and it was considered that this should result from the smaller MWs of bands 4−5, which were highly possible to be removed in the gel treatment (fixing, staining and destaining). These results clearly showed: (1) the proteases, which had high specificities for 24 and 18 kDa oleosins, were existed in the pH 6.8 extracted OBs; (2) the proteases did not hydrolyze the extrinsic proteins and also were unlikely to hydrolyze 16 kDa oleosins 1 and 2; (3) the large hydrolyzed products of 24 and 18 kDa oleosins contributed to the 13−14 kDa band by the incubation of pH 6.8 extracted OB suspension (pH 6.5); (4) bands 1−3 (around 9 kDa) should be the small hydrolyzed products of 24 kDa oleosin, while bands 4−5 might be the small hydrolyzed products of 18 kDa oleosin; (5) the proteases should cleave specific peptide bonds of 24 and 18 kDa oleosins to form limited hydrolyzed products (13−14 kDa band and bands 1−5, Figure 1).

The results above showed that the proteases of 24 and 18 kDa oleosins exactly existed of the pH 6.8 extracted OBs, which contained many OB extrinsic proteins as well as OB intrinsic proteins. On one hand, it was very hard to consider that lipoxygenase (enzyme for lipid), β-conglycinin (storage protein), γ-conglycinin (storage protein), β-amylase (enzyme for amylose), and glycinin (storage protein) could hydrolyze oleosins. On the other hand, it was reported that oleosin could act as a bifunctional enzyme that had both monoacylglycerol acyltrasferase and phospholipase activities,[40] caleosin could act as peroxygenase to produce peroxidized polyunsaturated fatty acids,[41] and steroleosin, also named as sterol dehydrogenase, could dehydrogenate phytosterol into its ketone-containing derivative,[42] indicating that OB intrinsic proteins had enzymatic activities on different lipid species, but not on protein. Therefore, it was considered that P34 and Bd 30K (or some Tricine-SDS-PAGE undetectable proteins) might be the proteases of 24 and 18 kDa oleosins.

Effect of pH 6.8 Supernatant on pH 11.0 Extracted OBs. It was highly possible that the proteases were the OB extrinsic proteins. As stated above, pH 6.8 extracted OBs were obtained as a floating fraction from raw soymilk by centrifugation. It was considered that some of the proteases might still remain in the pH 6.8 supernatant. In addition, it was reported that soybean OBs without extrinsic proteins could be obtained by pH 11.0 extraction. Therefore, an experiment was designed to eliminate the possibility that OB intrinsic proteins, lipoxygenase, β-conglycinin, γ-conglycinin, β-amylase, and glycinin could hydrolyze 24 and 18 kDa oleosins. The protein in 30 mL of pH 6.8 supernatant was absorbed by the pH 11.0 extracted OB suspension (pH 6.5, 4 °C) five times (7 mL each time), and the first and fifth OBs were obtained.

Figure 2 shows the protein compositions of the pH 6.8 supernatant (lane 2) and the fifth supernatant (lane 3). For the

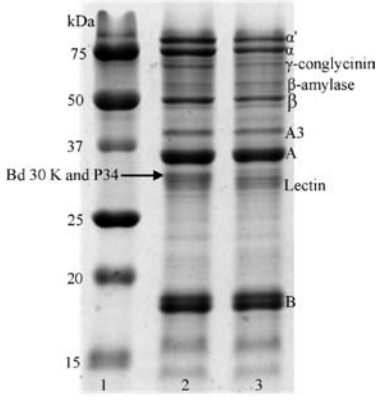

Figure 2. SDS-PAGE profiles of the pH 6.8 supernatant and the fifth supernatant. Lane 1, marker; lane 2, the pH 6.8 supernatant; lane 3, the fifth supernatant.

detectable protein bands, it is found that the band indicated by an arrow (lane 2), identified as P34 and Bd 30K by MALDI-TOF/TOF MS, is almost disappeared for the fifth supernatant (lane 3). For the first OBs, 24 and 18 kDa oleosins are respectively hydrolyzed to about 48% and 64% by 9 h incubation (Figure 3a,c). For the fifth OBs, 24 and 18 kDa oleosins are not hydrolyzed (Figure 3b,d). The detectable protein composition of the fifth OBs (Figure 3b) is almost the same as that of the first OBs (Figure 3a). However, the band indicated by an arrow in Figure 3a is obviously denser than the corresponding one in Figure 3b. The band in Figure 3a is matched to P34, Bd 30K, and caleosin, while the one in Figure 3b is matched to caleosin by MALDI-TOF/TOF MS. These results clearly revealed: (1) the proteases of 24 and 18 kDa oleosins were the OB extrinsic proteins; (2) 24 and 18 kDa oleosins still could be hydrolyzed even after exposed to pH 11.0; (3) the hydrolysis of 24 and 18 kDa oleosins was not happened in the absence of P34 and Bd 30K (or some Tricine-SDS-PAGE undetectable proteins). These results also made us

(d) The effect of incubation time on the hydrolysis of 24 and 18 kDa oleosins in the fifth OBs.

realize that it was the OB extrinsic proteins, not the microbial spoilage, that was responsible for the oleosin hydrolysis.

Oleosin Hydrolysis in the pH 6.8, 8.0, 9.5, and 11.0 Extracted OBs. The results above exactly revealed that the proteases were the OB extrinsic proteins. Chen and Ono reported that more and more extrinsic proteins were released from OBs with increasing alkaline pH.[34] It was considered that the proteases might also show the similar trend. And it is well-known that protease must keep its natural conformation to possess its proteolytic activity and must contact its substrate to express its proteolytic activity. Therefore, OBs were obtained by pH 6.8, 8.0, 9.5, and 11.0 extractions, respectively. Lanes 2 in Figure 4a−d show the protein compositions of pH 6.8, 8.0, 9.5, and 11.0 extracted OBs before incubation. Different from the other extrinsic proteins, considerable amounts of Bd 30 K/P34 are remained in the pH 8.0 (lane 2, Figure 4b) and pH 9.5 (lane 2, Figure 4c) extracted OBs. There are two bands near the position of P34 and Bd 30K for the pH 11.0 extracted OBs (lane 2, Figure 4d), and they are matched to caleosins by MALDI-TOF/TOF MS.[5]

pH 6.8, 8.0, 9.5, and 11.0 extracted OBs were dispersed into DI water, respectively. All of them were adjusted to pH 6.5, and incubated in 35 °C water bath for 0, 0.5, 1, 3, 6, and 9 h (Figure 4a−d). The band intensities of 24 and 18 kDa oleosins were analyzed by Image Lab Software (Bio-Rad, USA). Figure 4e shows that the residual 24 kDa oleosin of pH 6.8 extracted OBs is decreased to 43% by 9 h incubation, followed by pH 8.0 (53%) and 9.5 (74%) extracted OBs, and the 24 kDa oleosin of pH 11.0 extracted OBs is unlikely to be hydrolyzed. Figure 4f shows that the residual 18 kDa oleosin of pH 6.8 extracted OBs is decreased to 45% by 9 h incubation, while the 18 kDa oleosin of pH 8.0, 9.5, and 11.0 extracted OBs is slightly or unlikely to be hydrolyzed. It was interesting that high proteolytic activity of 24 kDa oleosin-hydrolyzing protease was remained, but very low proteolytic activity of 18 kDa oleosin-hydrolyzing protease was remained in the suspension (pH 6.5) of pH 8.0 extracted OBs. In addition, obvious proteolytic activity of 24 kDa oleosin-hydrolyzing protease was still remained in the suspension (pH 6.5) of pH 9.5 extracted OBs. These clearly revealed that the interaction between 24 kDa oleosin and its protease was strong to alkaline pH. In our previous research, it was confirmed that all of P34 and Bd 30K were bound to 24 kDa oleosin by disulfide bonds (SS).[5] Together with the P34 and Bd 30K behavior in the pH 6.8, 8.0, 9.5, and 11.0 extracted OBs, it showed: (1) some of the disulfide bonds were weak to alkaline pH, but some of the disulfide bonds were strong to alkaline pH; (2) P34 and Bd 30K had high relationship with the proteases of 24 kDa and 18 kDa oleosins. In addition, it was considered that P34 and Bd 30K were different proteins owing to their four different amino acid residues (NCBI database) and their behaviors on the two-dimensional electrophoresis gel.[30,33] Therefore, it was considered that P34 and Bd 30K might be bound to 24 kDa oleosin through disulfide bonds with different bond energies. In order to confirm this hypothesis, two-dimensional electrophoresis was conducted for the proteins of pH 6.8 and 8.0 extracted OBs. Figure 5 shows that there are two spots (PX1 and PX2) resolved for the P34 and Bd 30K.[30,33] This further made us realize that P34 and Bd 30K should be different proteins. Unluckily, both of PX1 and PX2 were matched to P34 and Bd 30K by MALDI-TOF/TOF MS, which should be resulted from their high homologies with each other. According to their amino acid sequences (NCBI

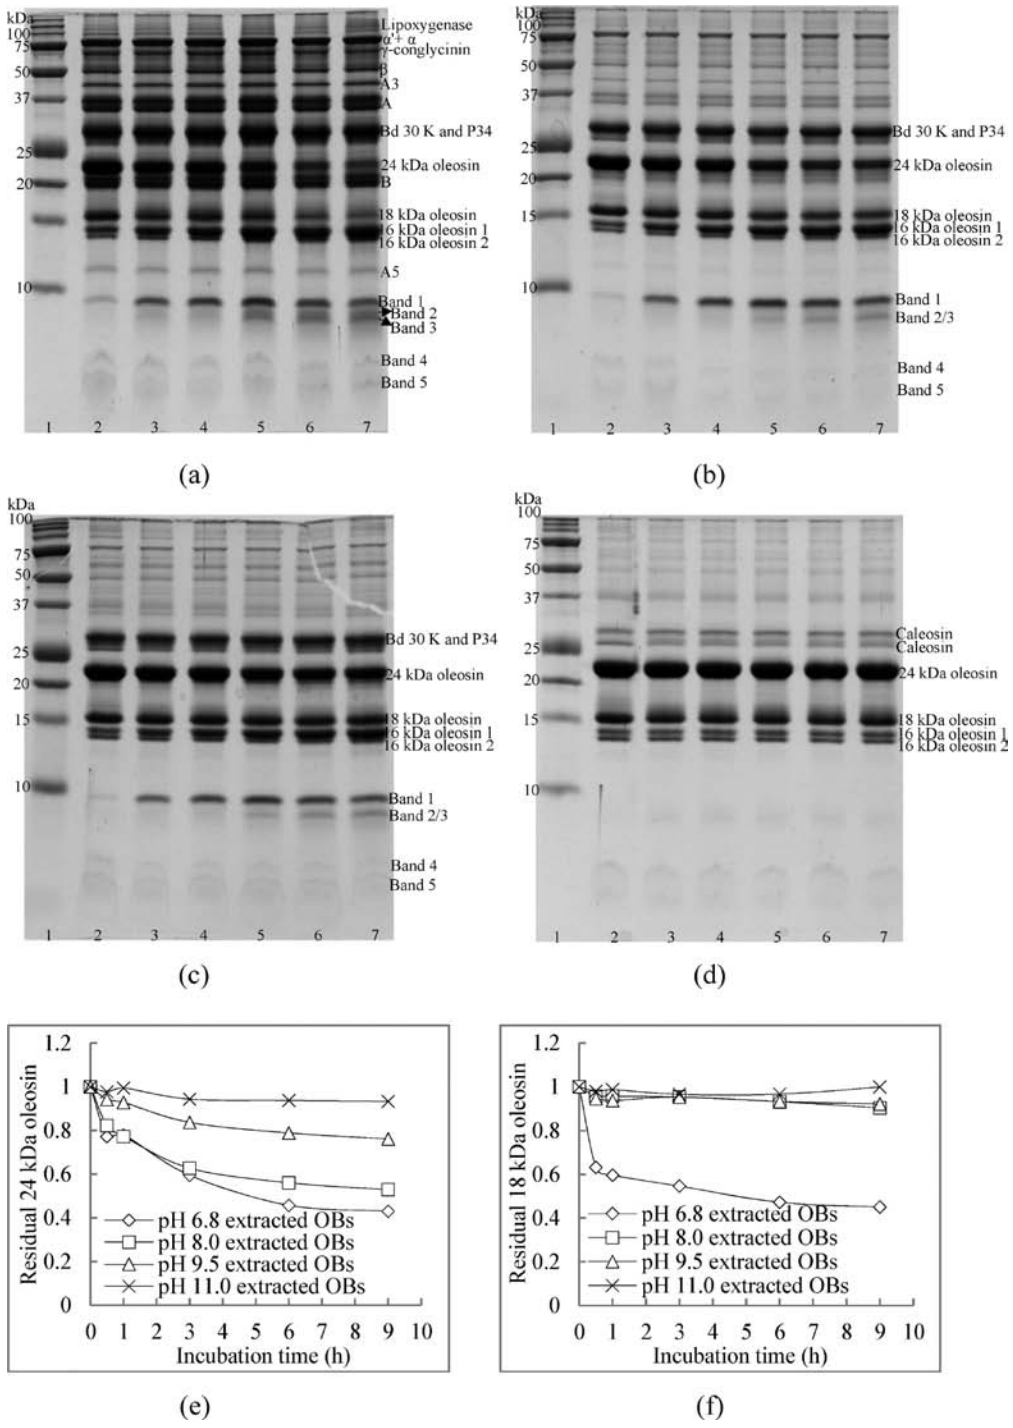

Figure 4. Tricine-SDS-PAGE profile of pH 6.8 (a), 8.0 (b), 9.5 (c), and 11.0 (d) extracted OB suspensions (pH 6.5) incubated at 35 °C. Lane 1, marker; lanes 2−7, OB suspension incubated for 0, 0.5, 1, 3, 6, and 9 h, respectively. (e) The 24 kDa oleosin hydrolysis in pH 6.8, 8.0, 9.5, and 11.0 extracted OB suspensions (pH 6.5) incubated for 0, 0.5, 1, 3, 6, and 9 h. (f) The 18 kDa oleosin hydrolysis in pH 6.8, 8.0, 9.5, and 11.0 extracted OB suspensions (pH 6.5) incubated for 0, 0.5, 1, 3, 6, and 9 h.

database), Bd 30K was more acidic than P34. Therefore, PX1 and PX2 could be preliminarily matched to P34 and Bd 30K, respectively. It is found that the PX2/PX1 intensity ratio of pH 8.0 extracted OBs is obviously larger than that of pH 6.8 extracted OBs (Figure 5), exactly revealing that PX1 (possibly P34) has weak resistance to alkaline pH, while PX2 (possibly Bd 30K) has strong resistance to alkaline pH. This is greatly consistent with the protease behaviors on the hydrolysis of 24 and 18 kDa oleosins.

Because both P34 and Bd 30K were interacted with 24 kDa oleosin by disulfide bonds, the behavior of the interaction in the incubation of pH 6.8 extracted OBs could be examined by nonreducing Tricine-SDS-PAGE (Figure 6a) combined with its corresponding reducing Tricine-SDS-PAGE (Figure 6b). The band intensities (24 kDa oleosin; 18 kDa oleosin; 16 kDa oleosin 1 + 16 kDa oleosin 2 + large hydrolyzed products of 24 and 18 kDa oleosins; band 1) were analyzed by Image Lab Software (Bio-Rad, USA). It was found that 24 kDa oleosin

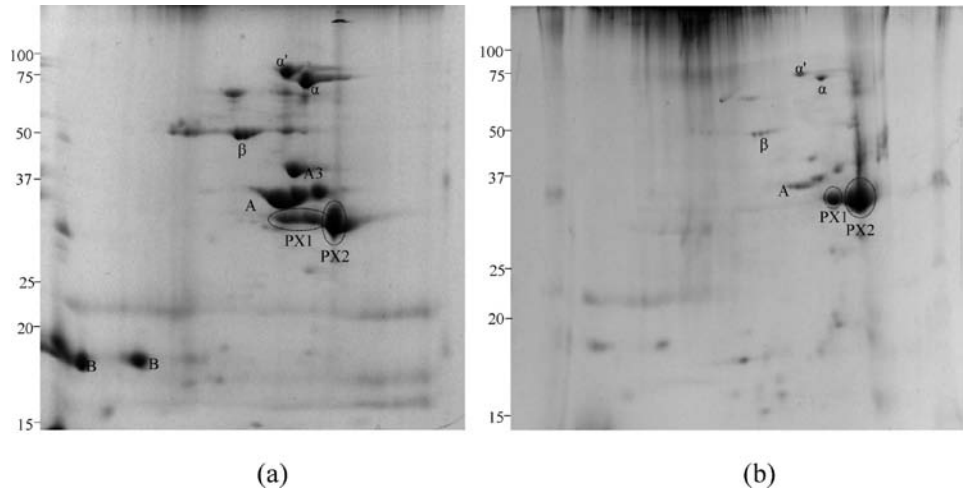

Figure 5. Protein profiles of pH 6.8 (a) and 8.0 (b) extracted OBs by two-dimensional electrophoresis. Both of PX1 and PX2 were matched to Bd 30K and P34 by MALDI-TOF/TOF MS.

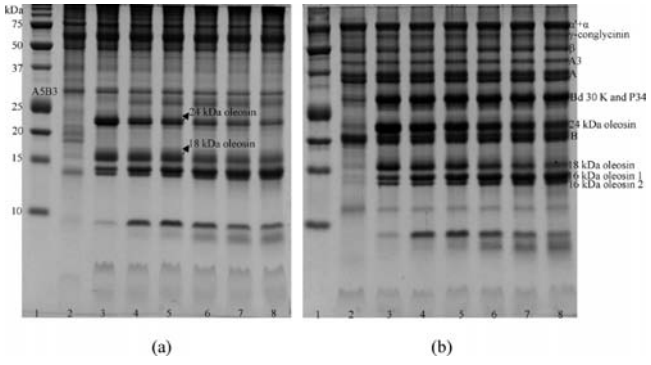

Figure 6. Nonreducing (a) and reducing (b) tricine-SDS-PAGE profiles of pH 6.8 extracted OB suspension (pH 6.5) incubated at 40 °C. Lane 1, marker; lane 2, raw soymilk; lanes 3−8, OB suspension incubated for 0, 0.5, 1, 3, 6, and 9 h, respectively.

bands in the nonreducing condition were weaker than their corresponding ones in the reducing condition, while the other three were almost the same as each other. Figure 6a shows that a thin band is located at the position of P34 and Bd 30K, and it is matched to one subunit of glycinin and caleosin by MALDI-TOF/TOF MS. These revealed that P34 and Bd 30K were always bound to 24 kDa oleosin by disulfide bonds in the incubation, very similar to the interaction between enzyme and its substrate in the reaction system that enzyme was less than its substrate. In addition, if Bd 30K and P34 were not the proteases, the Bd 30K/P34-SS-polypeptides (13−14 kDa) or the Bd 30K/P34-SS-polypeptides (around 9 kDa) might be produced in the incubation, meaning that the 13−14 kDa band or the band around 9 kDa in the nonreducing condition (Figure 6a) should be less than the corresponding one in the reducing condition (Figure 6b). However, this is unlikely happened in Figure 6.

Therefore, one hypothesis was suggested as below: PX1 (the protease of 18 kDa oleosin) was not only bound to 24 kDa oleosin by disulfide bond, but also interacted with 18 kDa oleosin by noncovalent molecular interactions for hydrolyzing 18 kDa oleosin, which might be able to weaken bond energy of the disulfide bond above; PX2 (the protease of 24 kDa oleosin) was just bound to 24 kDa oleosin without interaction with 18 kDa oleosin. As a result, PX1 was easily removed from OBs, while PX2 was difficult to remove by alkaline pH.

According to the UniProtKB database, 24 kDa oleosin (P29530) is divided into three parts: N-terminal (76 AARs), hydrophobic central domain (54 AARs) and C-terminal (96 AARs); 24 kDa oleosin (P29531) is also divided into three parts: N-terminal (57 AARs), hydrophobic central domain (72 AARs), and C-terminal (94 AARs). The hydrophobic central domain is buried in the TAGs matrix of OBs, while N- and C-terminals are exposed to the exterior. Both of P34 and Bd 30K have 257 AARs, so it is highly possible that P34/Bd 30K can interact with 18 kDa oleosin by noncovalent molecular interactions in addition to the disulfide bond with 24 kDa oleosin. Therefore, it was considered that the hypothesis above was reasonable and acceptable.

Oleosin in Germinated Soybean. If 24 kDa oleosin was hydrolyzed in soybean germination, it meant that its protease must be bound to OBs for the 24 kDa oleosin hydrolysis. In addition, the results above clearly showed that 24 kDa oleosin-hydrolyzing protease was still bound to OBs even at pH 8.0 and 9.5. Therefore, it was considered that the pH 6.8, 8.0, and 9.5 extracted OBs from germinated soybean should contain the 24 kDa oleosin-hydrolyzing protease if the assumption above was correct.

Soybean was naturally germinated for 1, 2, 4, 6, and 8 d, and OBs of each germinated soybean were extracted by pH 6.8, 8.0, and 9.5, respectively. Figure 7 shows that almost all of the 24 kDa oleosin is hydrolyzed by 4 d germination. If 24 kDa oleosin-hydrolyzing protease was detectable protein by Tricine-SDS-PAGE, it should appear not only in Figure 7, but also in Figures 1−6. As a result, P34/Bd 30K should be the most possible protein as the protease of 24 kDa oleosin.

Figure 7e shows that four protein bands (6−9) remained for the OBs of 8 d germinated soybean. By MALDI-TOF/TOF MS, band 6 was matched to several lipoxygenase isoforms, band 7 was not matched to any proteins, band 8 was matched to P34, Bd 30K, and caleosin, and band 9 was matched to 24 kDa oleosins (P29530 and P29531). These results revealed (1) 24, 18, and 16 kDa oleosins were all hydrolyzed in soybean germination, showing a different trend from the extracted OBs of ungerminated soybean; (2) Bd 30K and P34 were always bound to the extracted OBs from germinated soybean even when all oleosins were hydrolyzed. The mechanism for the 16

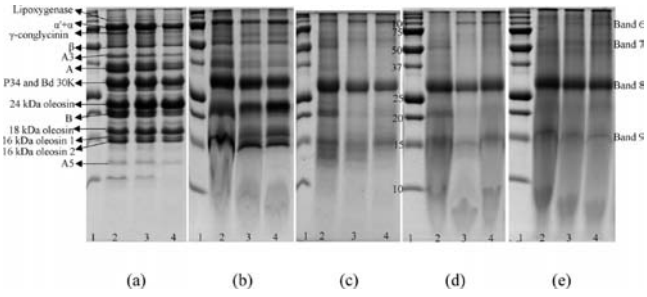

Figure 7. Protein profiles of pH 6.8, 8.0, and 9.5 extracted OBs from germinated soybean by Tricine-SDS-PAGE. (a) 1 d germinated soybean. (b) 2 d germinated soybean. (c) 4 d germinated soybean. (d) 6 d germinated soybean. (e) 8 d germinated soybean. Lane 1, marker; lanes 2–4, pH 6.8, 8.0, and 9.5 extracted OBs, respectively.

kDa oleosin hydrolysis needed further researches, which should be closely correlated with the germination.

Effects of Temperature and pH on Oleosin Hydrolysis. The pH 6.8 extracted OB suspensions (pH 6.5) were respectively put into 20, 30, 35, 40, 50, and 60 °C water baths and incubated for 0, 0.5, 1, 3, 6, and 9 h. The hydrolysis behaviors of 24 and 18 kDa oleosins (analyzed by Image Lab Software) at different temperatures are shown in Figure 8a,b, clearly revealing that 35–50 °C is the optimal temperature range for the hydrolysis of 24 and 18 kDa oleosins, while 60 °C can denature the proteases. This showed that the proteases of 24 and 18 kDa oleosins had the similar resistances to temperature.

The pH 6.8 extracted OB suspensions were respectively adjusted to pH 4.0, 5.0, 6.0, 6.5, 7.0, 8.0, 9.0, 10.0, and 11.0, and incubated in 35 °C water bath for 0, 0.5, 1, 3, 6, and 9 h. Figure 8c,d show that pH 6.0–6.5 is the optimal pH range for the hydrolysis of 24 and 18 kDa oleosins. The hydrolysis of 24 kDa oleosin was gradually slowed down from pH 6.5 to 10.0 and almost completely inhibit at pH 11.0. Different from 24 kDa oleosin, the hydrolysis of 18 kDa oleosin was greatly inhibited at pH ≥8.0, agreeing with the results in Figure 4. Therefore, it was considered that pH ≥11.0 or ≥60 °C might be better for the extraction of soybean OBs, while the combination of pH 6.0–6.5 and 35–50 °C might be better for the enzyme-assisted aqueous extraction of soybean oil.

In all, this study showed that the proteases (OB extrinsic proteins) in the pH 6.8 extracted OBs had high specificity to hydrolyze 24 and 18 kDa oleosins, and they should cleave specific peptide bonds to form limited hydrolyzed products (13–14 kDa band and bands 1–5, Figure 1). In addition, the optimal temperature and pH of the proteases were respectively

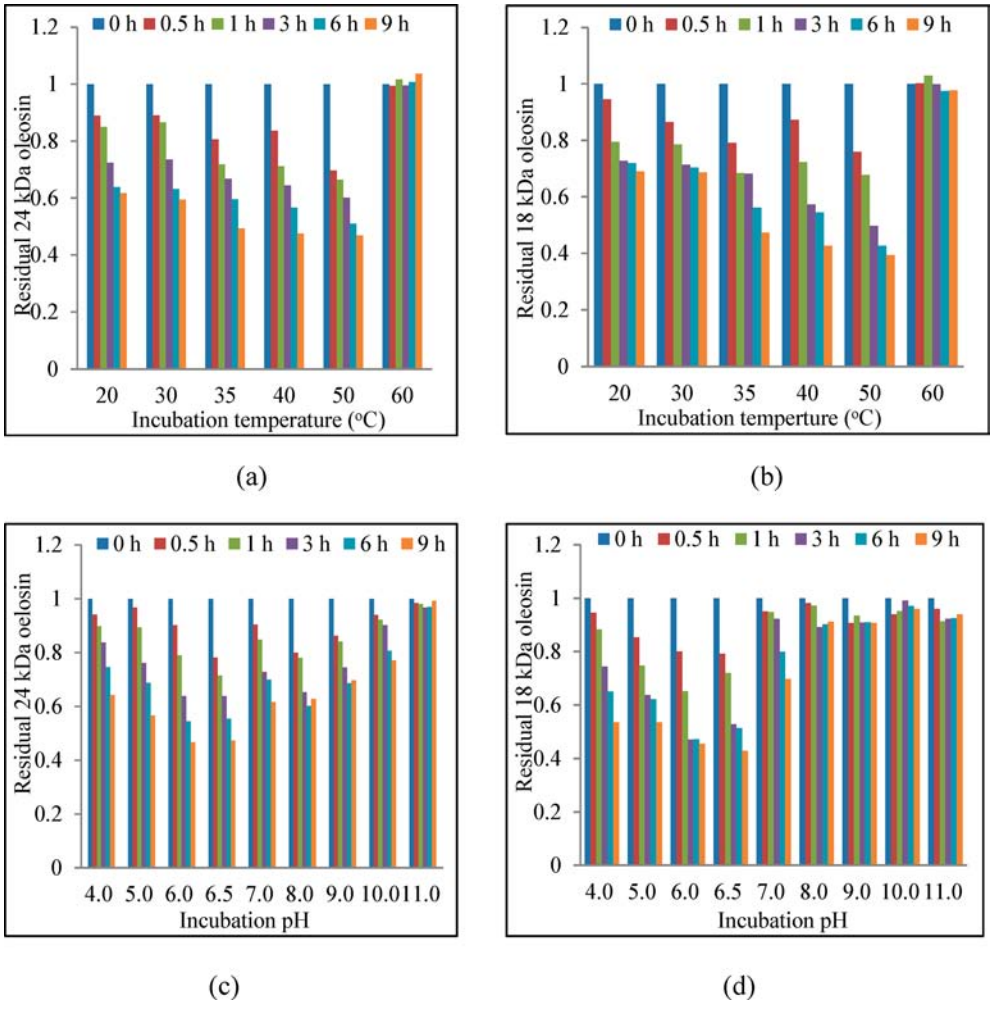

Figure 8. Effects of temperature (a, b) and pH (c, d) on the hydrolysis of 24 (a, c) and 18 kDa (b, d) oleosins in the pH 6.8 extracted OB suspensions.

dx.doi.org/10.1021/jf405382w | J. Agric. Food Chem. 2014, 62, 956–965

clarified as in the ranges of 35−50 °C and 6.0−6.5, and 60 °C or pH 11.0 could denature them. Different from the extracted OBs from ungerminated soybean, 16 kDa oleosin was also hydrolyzed in soybean germination in addition to 24 and 18 kDa oleosins. Although this study did not show direct evidence for confirming the proteases, all results in this study showed a high possibility that P34 and Bd 30K were the proteases of 24 and 18 kDa oleosins. For further research, it is considered that the respective purification of the bioactive Bd 30K and P34 (a great challenge at present stage) and their effects on oleosin hydrolysis should be examined. At last, it is suggested that some Tricine-SDS-PAGE undetectable proteins should be also considered in further studies.

[a] Bold and underlined are the second transition that is used for quantification.
[b] Collision energy (bold and underlined) was attenuated to avoid the saturation of the detector at the highest concentration level of the calibration curve. Transitions in the corresponding row were used for quantification.
[c] Retention time may vary from column-to-column. Bold and underlined are pesticides whose retention time drifted within a batch run.
[d] Bold and underlined are pesticides with recoveries not in the range of 81 to 110 %.
[e] Bold and underlined are pesticides intermediate precision > 20 %.
[f] Bold and underlined are pesticides MU > 50 %.
[g] Column number.
[h] Method performance was based on two spike levels, i.e. 240.0 and 400.0 μg/kg due to its poor sensitivity.
[i] Method performance was based on three spike levels, i.e. 90.0, 240.0 and 400.0 μg/kg due to its poor sensitivity.
[j] Pesticides have a relatively low solubility in methanol. Stock solution was prepared in 1000.0 μg /mL.
[k] Pesticides have a relatively low solubility in methanol. Stock solution was prepared in 2000.0 μg /mL.
[l] An Ion with Cl^{37} was selected as a precursor ion.

MATERIALS AND METHODS

Materials and Reagents. For the pesticide residue transfer rate study, 44 dried tea leaf samples, which had tested positive for one or more pesticides, were obtained from a 2011 targeted survey program under the Food Safety Action Plan in Canada. All samples (50 g per samples) were well blended in CFIA contract laboratories prior to shipment to the Calgary Laboratory for the study. For method development and validation, blank samples of tea leaves (pesticide free), including Earl Grey, oolong, green tea, herbal tea and orange pekoe, were obtained from local markets. Tea bags were cut and emptied into mixing bowls, then mixed to create a composite. Loose tea leaf samples (200−500 g per sample) were blended using a food blender. All samples were stored at room temperature.

Ammonium acetate (reagent grade and LC-MS grade) and LC-MS acetonitrile (Chromasolv, 2.5 L) were purchased from Sigma-Aldrich Corp. (Canada). ENVIRO CLEAN extraction columns (6.0 g of anhydrous magnesium sulfate ($MgSO_4$) and 1.5 g of sodium acetate, 50 mL centrifuge tubes) and ENVIRO CLEAN extraction columns ((900 mg of $MgSO_4$, 150 mg C_{18}, and 300 mg of primary−secondary amine (PSA), 15 mL centrifuge tubes) or (900 mg of $MgSO_4$, 150 mg of graphitized black carbon, and 300 mg of PSA, 15 mL centrifuge tubes)) were obtained from United Chemical Technologies, Inc. (Bristol, PA, USA). Acetic acid (glacial acetic acid, reagent grade, 99.7%), acetonitrile (distilled in glass), and methanol (distilled in glass) were obtained from Caledon Laboratories Ltd. (Canada). Water (18.2 MΩ·Cm) used for reagent and sample preparation was from a Barnstead Nanopure system (Thermo Scientific, USA). Pesticide standards (Table 1, column 1) were obtained from EQ Laboratories Inc. (USA), Riedel-de Haen AG (Germany), or Chem Service (USA). Internal standards carbendazim-d_4 and carbofuran-d_3 were purchased from EQ Laboratories Inc. (USA), and thiabendazole-d_4 was from Chemical Synthesis Services (Northern Ireland). LC vials were Mini-UniPrep syringeless filter devices with polypropylene housing and PVDF 0.45 μm membrane (Whatman Inc., USA).

UHPLC/ESI-MS/MS Parameters. The LC/ESI-MS/MS system utilized was an Agilent 1200 SL (Agilent, Germany) coupled with an API 5000 LC/MS/MS system (Applied Biosystem, Canada). The system was controlled using Analyst 1.5 software.

Mobile phase B was acetonitrile, and mobile phase A was 10 mM ammonium acetate with 2% acetonitrile in water. The column oven temperature was set at 35 °C, and the autosampler temperature was set at 5 °C.

Core−Shell Particles Column. The core−shell particles or UHPLC column utilized was a Kinetex C_{18}, 100 mm × 2.1 mm, 2.6 μm column (Phenomenex, USA). Injection volume was 3 μL, and total run time was 12 min. The UHPLC gradient profile is shown in Table 2.

MS/MS Conditions. The ion source was a TurboIonSpray or Turbo V electrospray ion source in positive mode. Pause time between mass ranges was 5 ms. Specific mass spectrometric parameters such as dwell time, declustering potential (DP), entrance potential (EP), collision energy (CE), collision cell exit potential (CXP), and multiple reaction monitoring transitions (MRM or Q1 and Q3) are listed in Table 1. Parameters including DP, EP, CE, and CXP were optimized using the Quantitative Optimization bundled with the Analyst software by infusing each individual pesticide standard (10 or 50 μg/L) into the mass spectrometer. The syringe pump (Harvard Apparatus, USA) flow rate was set at 10 μL/min for infusion. Scheduled MRM was set according to the retention time of pesticides using a MRM detection window of 100 s. The total scan time was 1.6211 s, and the duration was 11 min. Other general mass spectrometric parameters are shown in Table 2.

Table 2. UHPLC Gradient Profiles and MS Parameters

Kinetex C_{18}, 2.6 μm			
Total time	Flow rate (μl/min)	A (%)	B (%)
0.0	300	92	8
4.0	300	10	90
8.0	300	10	90

Collision gas (CAD)	7
Curtain gas (CUR)	25
Ion source gas 1 (GS1)	60
Ion source gas 2 (GS2)	60
IonSpray voltage (IS)	5000
Temperature	550

Preparation of Standard Solutions. Individual pesticide standard stock solutions were generally prepared at a concentration of 4000.0 μg/mL in methanol. Due to its poor solubility in methanol, carbendazim was prepared at 200.0 μg/mL, and a few pesticides were prepared at 1000.0 or 2000.0 μg/mL (Table 1, column 1). Internal standard stock solution including carbofuran-d_3, carbendazim-d_4, and

					40.0	μg/L	
					Brewed tea (μg/L)		

thiabendazole-d_4 was prepared at 100.0 μg/mL. Intermediate pesticide standard mix working solutions were prepared at 10.0 μg/mL. Stock and intermediate solutions were stored at −20 °C.

Dried Tea Leaves. A six-level pesticide standard mix working solution was prepared by transferring 0.1, 0.5, 2.0, 4.0, 6.0, and 10.0 mL of 10.0 μg/mL intermediate working solution into six separate 50 mL volumetric flasks and making up to volume with methanol. This resulted in 0.02, 0.1, 0.4, 0.8, 1.2, and 2.0 μg/mL standard solutions, which were used to construct matrix-matched standard calibration curves. Internal standard working solution (2.0 μg/mL) was prepared from their respective stock in a mixture of acetonitrile and methanol (50:50, v/v). All working solutions were stored at 4 °C.

Brewed Tea. A six-level pesticide standard mix working solution was prepared by transferring 0.1, 0.5, 2.0, 4.0, 6.0, and 10.0 mL of 10.0 μg/mL intermediate working solution into six separate 50 mL volumetric flasks and making up to volume with methanol. This resulted in 0.02, 0.1, 0.4, 0.8, 1.2, and 2.0 μg/mL standard solutions, which were used to construct matrix-matched standard calibration curves. Four-level sample spike pesticide standard working solutions were prepared by transferring 2.0, 6.0, 10.0, and 16.0 mL of 10.0 μg/mL intermediate working solution into separate 50 mL volumetric flasks and making up to volume with methanol. This resulted in 0.4, 1.2, 2.0, and 3.2 μg/mL standard solutions, which were used for sample fortification. Internal standard working solution (0.8 μg/mL) was prepared from their stock in a mixture of acetonitrile and methanol (50:50, v/v). All working solutions were stored at 4 °C.

Preparation of Reagent Solutions. Acetonitrile/acetic acid (99 + 1, v/v) was prepared by mixing 990 mL of acetonitrile with 10 mL of acetic acid. Ammonium acetate solution (0.1 M) was prepared by weighing 7.7 g of ammonium acetate and dissolving in 800 mL of water. After transfer into a 1000 mL volumetric flask, the solution was made up to volume with water. Solvent buffer was a mixture of 0.1 M ammonium acetate and methanol (50 + 50, v/v).

Sample Preparation and Extraction Procedure. *Dried Tea Leaves.* Sample extraction and cleanup procedures followed the buffered QuEChERS method.[7] An incurred tea sample (5.0 g/sample) was weighed into individual 50 mL polypropylene centrifuge tubes (VWR International, Canada). To each tube was added 250 μL of 2.0 μg/mL internal standard working solution (100.0 μg/kg equivalent in samples) and 15 mL of water. Tubes were capped, and the contents were mixed and allowed to stand for the purpose of hydration. After 30 min of hydration at room temperature, 15 mL of acetonitrile/acetic acid (99 + 1, v/v) was added to individual samples and mixed, followed by the addition of 1.5 g of sodium acetate anhydrous and 6.0 g of magnesium sulfate anhydrous. The centrifuge tubes were capped, and all samples were shaken for 1 min using a Geno/Grinder 2010 at 1500 rpm (SPEX SamplePrep, USA) and then were centrifuged at 3000 rpm (~2100*g*) for 3 min using an Allegra 6 centrifuge (Beckman Coulter Inc., USA). Supernatants were transferred (7 mL/sample) into individual 15 mL polypropylene centrifuge tubes that contained 900 mg of $MgSO_4$, 150 mg of graphitized black carbon, and 300 mg of PSA. The centrifuge tubes were capped, shaken for 45 s by hand, and centrifuged at 3000 rpm (~2100*g*) for 3 min. Three milliliters of supernatant (1 g sample/3 mL) was transferred into individual 5 mL Pyrex brand centrifuge tubes, precalibrated with 1 mL volume accuracy (VWR International, Canada). Each of the sample extracts was evaporated to 0.1−0.2 mL, which took approximately 45 min, using an N-EVAP nitrogen evaporator (Organomation Associates Inc., USA) at 30 °C under a stream of nitrogen. The extracts were made up to 0.5 mL with methanol, vortexed for 30 s, and then made up to 1.0 mL with 0.1 M ammonium acetate and vortexed again for 30 s. One hundred microliters of each extract was transferred into a Mini-UniPrep vial (Whatman Inc., USA), and 500 μL of solvent buffer (a mixture of 0.1 M ammonium acetate/methanol, 50 + 50, v/v) was added. The vials were capped, vortexed for 30 s, and pressed to filter. Sample extracts were injected to the UHPLC/ESI-MS/MS. All dried tea leaves (incurred samples) were analyzed in duplicate.

Brewed Tea. Dried tea leaves were brewed as follows. Five grams of dried tea leaves were weighed into a 250 mL Erlenmeyer flask, to which 150 mL of boiling water (distilled) was added. The sample was swirled to mix after 3 and 6 min with a total brewing time of 10 min. After the brewing process, the brewed tea samples were cooled by immersing the flask in cold water (~7 °C) for 20 min. Then, 10 mL of brewed tea was subsampled into individual 50 mL polypropylene centrifuge tubes (VWR International, Canada) for the QuEChERS extraction and cleanup. For the fortification experiment, 100 μL of each four-level sample spike pesticide standard working solution was added into four centrifuge tubes to provide 4.0, 12.0, 20.0, and 32.0 μg/L pesticide equivalents in samples. To each tube was added 100 μL of 0.8 μg/mL internal standard working solution (8.0 μg/kg equivalent in samples). After 10 min at room temperature, 10 mL of acetonitrile/acetic acid (99 + 1, v/v) was added to individual samples and mixed for 45 s, followed by the addition of 1.5 g of sodium acetate anhydrous and 6.0 g of magnesium sulfate anhydrous. Four to six samples were processed at a time and shaken immediately by hand to avoid clumping. All samples were then shaken for 1 min using Geno/Grinder 2010 at 1500 rpm (SPEX SamplePrep, USA) and were centrifuged at 3000 rpm (~2100*g*) for 3 min using an Allegra 6 centrifuge (Beckman Coulter Inc., USA). Supernatants were transferred (5 mL/sample) into individual 15 mL polypropylene centrifuge tubes (VWR International, Canada) that contained 900 mg of $MgSO_4$, 150 mg of C_{18}, and 300 mg of PSA. The centrifuge tubes were capped, shaken for 45 s by hand, and centrifuged at 3000 rpm (~2100*g*) for 3 min. Two and half milliliters of supernatant was transferred into individual 5 mL Pyrex brand centrifuge tubes, precalibrated with 1 mL volume accuracy (VWR International, Canada). Each of the sample extracts was evaporated to 0.1 − 0.2 mL, which took approximately 30−45 min, using an N-EVAP nitrogen evaporator (Organomation Associates Inc., USA) at 30 °C under a stream of nitrogen. The extracts were made up to 0.5 mL with methanol, vortexed for 30 s, and then made up to 1.0 mL with 0.1 M ammonium acetate and vortexed again for 30 s. Five hundred microliters of each extract was transferred into a Mini-UniPrep vial (Whatman Inc., USA), and the vials were capped, vortexed for 30 s, and pressed to filter. Sample extracts were injected on an UHPLC/ESI-MS/MS system. All brewed tea (incurred) were analyzed in duplicate.

Preparation of Matrix-Matched Calibration Standards and Calculation. *Dried Tea Leaves.* Matrix-matched calibration standards were prepared by adding standards and internal standards to blank sample extracts after sample extraction and cleanup. A blank tea sample (5.0 g/sample) was weighed into a 50 mL centrifuge tube, and the

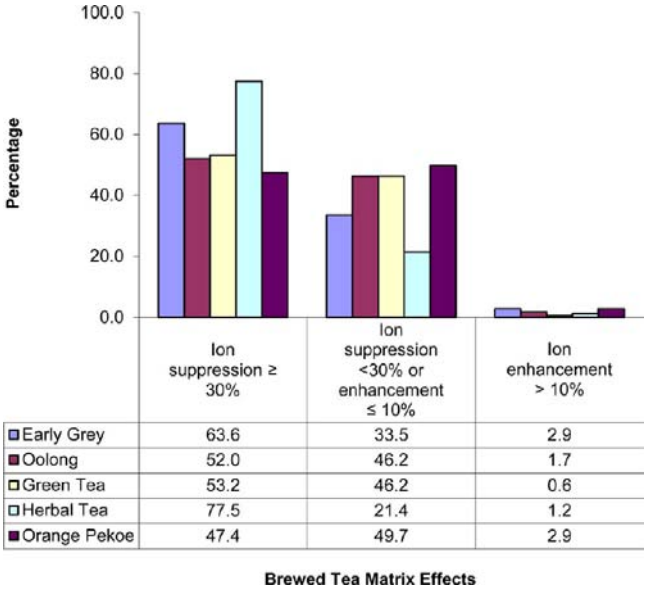

Figure 1. UHPLC/ESI-MS/MS matrix effects. The 172 pesticides were prepared in matrix extracts (a total of 5 brewed tea matrices) and solvent buffer at a concentration of 8.0 μg/kg equivalent in sample.

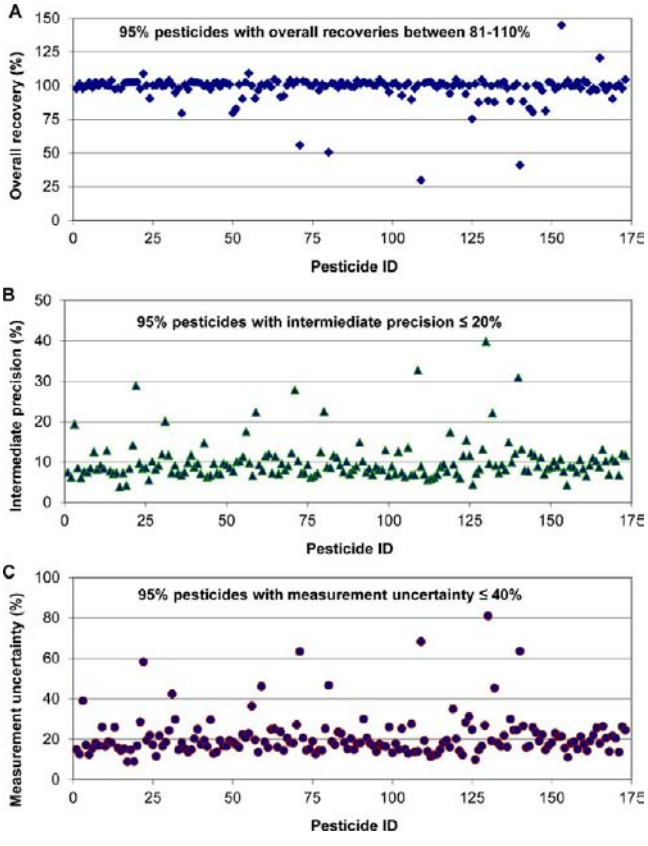

Figure 2. UHPLC/ESI-MS/MS method performance for analysis of 172 pesticides in brewed tea: (A) overall recovery; (B) intermediate precision; (C) measurement uncertainty.

sample was processed through the extraction procedure as described above for dried tea leaves. Two hundred and fifty microliters of each six-level pesticide standard mix working solution was added into each of six blank sample extracts, providing 5.0, 25.0, 100.0, 200.0, 300.0, and 500.0 μg/kg per standard equivalent in samples. Then, 50 μL of 2.0 μg/mL internal working solution was added to each sample

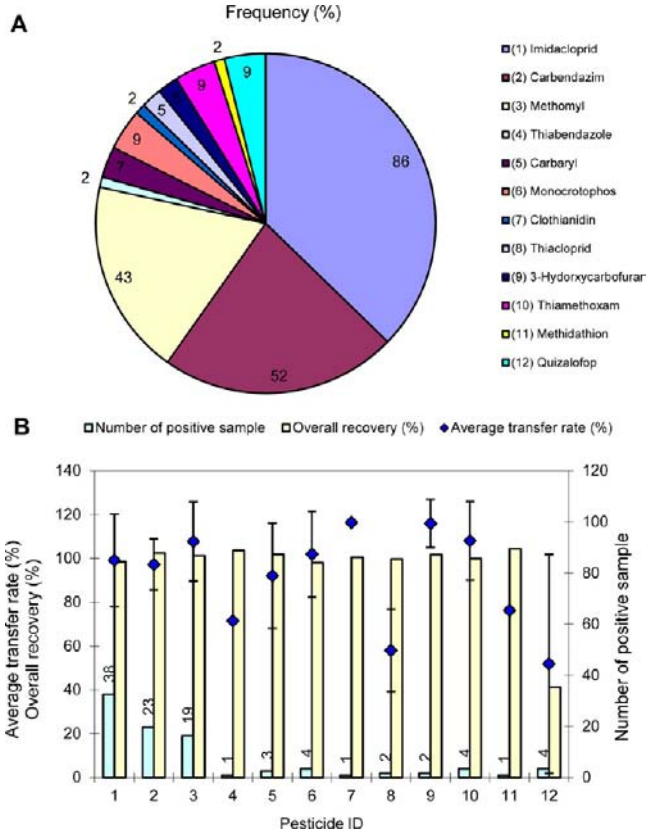

Figure 3. (A) Frequency (%) of 12 pesticides found in 44 incurred samples. (B) Number of positive samples, average transfer rate (%), and overall recovery in brewed tea (%). Pesticides: (1) imidacloprid; (2) methomyl; (3) carbendazim; (4) thiabendazole; (5) carbaryl; (6) monocrotophos; (7) clothianidin; (8) thiacloprid; (9) 3-hydroxycarbofuran; (10) thiamethoxam; (11) methidathion; (12) quizalofop.

(100.0 μg/kg equivalent in samples). The extracts were made up to 0.5 mL with methanol, vortexed for 30 s, made up to 1.0 mL volume with 0.1 M ammonium acetate and then vortexed again for 30 s. The extracts were diluted six times using the solvent buffer prior to UHPLC/ESI-MS/MS injection.

Brewed Tea. Matrix-matched calibration standards were prepared by adding standards and internal standards to blank sample extracts after sample extraction and cleanup. A blank brewed tea sample (10.0 mL/sample) was weighed into a 50 mL centrifuge tube, and the sample was processed through the extraction procedure as described above for brewed tea. Fifty microliters of each six-level pesticide standard mix working solution was transferred into six separate blank sample extracts, providing 0.4, 2.0, 8.0, 16.0, 24.0, and 40.0 μg/L per standard equivalent in samples. Then, 25 μL of 0.8 μg/mL internal working solution was added to each sample (8.0 μg/L equivalent in samples). The extracts were made up to 0.5 mL with methanol, vortexed for 30 s, made up volume to 1.0 mL with 0.1 M ammonium acetate, and then vortexed again for 30 s. Five hundred microliters of each extract was transferred into a Mini-UniPrep vial (Whatman Inc., USA), and the vials were capped, vortexed for 30 s, and pressed to filter. Sample extracts were analyzed using UHPLC/ESI-MS/MS.

To compensate for matrix effects, the oolong tea was used as the standard matrix to prepare matrix-matched calibration standards in both dried tea leaves and brewed tea.

Matrix-matched standard calibration curves for each individual pesticide were constructed using MultiQuant. Concentration, (μg/kg or μg/L (ppb)) versus the ratio (analyte area/IS area) of each individual pesticide was plotted. Deuterium-labeled standards carbendazim-d_4, carbofuran-d_3, and thiabendazole-d_4 were used as internal standards for their respective native compounds for quantification. Other pesticides

used carbofuran-d_3 as an internal standard for quantification. In general, the quadratic function was applied to the calibration curves based on the line of best fit. $1/x$ weighting was used to improve the accuracy for quantification of pesticide residues at low concentration. Responses for the unknown concentration or fortified samples were compared to the curves to calculate the amount of pesticide residues (μg/kg or μg/L (ppb)) in samples. Matrix-matched calibration standards were prepared fresh for each batch of samples.

Method Validation. The method for brewed tea was validated by a nested experimental design, described elsewhere.[8] The main factors of variances associated with method performance or measurement uncertainties of an in-house validated method are concentrations or

spike levels of analytes, matrix effects, day-to-day variation, and within-day variation of the method. The last two factors are designated the intermediate precision. In this study, there were a total of five brewed teas, that is, Earl Grey, oolong, green tea, herbal tea, and orange pekoe. For each matrix, samples were spiked at four levels, that is, 4.0, 12.0, 20.0, and 32.0 μg/L, in triplicate. Spike experiments were repeated on two different days or by each of two analysts. Overall recovery, intermediate precision, and measurement uncertainty were calculated using a combined algorithm that consisted of SAS codes (SAS software release 9.1, SAS Institute Inc., USA) along with a Microsoft Excel (Microsoft Office 2002) workbook.

RESULTS AND DISCUSSION

Experimental Design. To study pesticide residue transfer rates from dried tea leaves to brewed tea, a two-stage experiment was deliberately designed. First, tea leaves were brewed, and then the resulting tea was analyzed for pesticide residues. Five grams of dried tea leaves and 150 mL of hot water were used in the brewing process. Data from a few preliminary experiments showed this combination increased method sensitivity or decreased detection limits to low parts per billion. This allowed us to use a 10 mL subsample of brewed tea, a typical QuEChERs sample size, to quantify a pesticide at a concentration as low as 12.0 μg/kg in dried tea leaves. The thermohydrolysis, which may induce the loss of certain pesticides, was not investigated in the current study because we were concerned with the concentrations or amounts of pesticides in brewed tea after the brewing process. The study on thermohydrolysis would be of value, especially for investigation of the production of additional pesticide metabolites.

In general, the amounts of incurred pesticides in dried tea leaves, including green tea, oolong tea, and black tea, ranged from 5.0 to 500.0 μg/kg (ppb), as being confirmed by the previous year's monitoring program results, and some residues were as high as a few millligram per kilogram (ppm). The challenge was to quantify pesticides at parts per billion concentration levels in both dried tea leaves and brewed tea, especially after the brewing process. Some published studies have reported transfer rates for a few pesticides from tea leaves to brewed tea.[4−6] These studies were performed at relatively high residue concentrations, that is, parts per million levels, and for a very limited number of pesticides. In the current study, we utilized a highly sensitive UHPLC/ESI-MS/MS system with an appropriate experiment design to analyze up to 172 pesticides at parts per billion concentration levels to understand the transfer rates of a broad spectrum of pesticide residues. The API 5000 LC/MS/MS system used had an analytical range from 1.0 to 100.0 μg/L in solvent buffer (concentration in vials) for most pesticides studied, which was equivalent to 0.4 μg/L to 40.0 μg/kg in brewed tea as a result of a factor of 2.5 times concentration from brewed tea to final sample extracts.

Assuming a pesticide residue will transfer with a rate between 20 and 100%, Table 3 presents four scenarios of the lowest or highest concentration of an incurred pesticide that could possibly be detected in tea leaves or brewed tea when following the procedure described under Materials and Methods. For example, if a pesticide has a transfer rate of 20%, the lowest concentration of a pesticide in tea leaves that can be detected in brewed tea (Table 3A) is 60 μg/kg; and a transfer rate of 100% leads to as low as 12.0 μg/kg in tea leaves (Table 3B). In these cases, when the amount of a pesticide in dried tea leaves happens to be over 40 μg/L in brewed tea (Table 3D), the sample size (tea leaves) can be reduced to fit its level in the range of 0.4−40.0 μg/kg for quantification. Basically, the experiment was designed to detect pesticides in a range from 12.0 to 1200.0 μg/kg in tea leaves when a 100% transfer rate was assumed.

QuEChERS. Pesticides were extracted from dried tea leaves (5 g/sample) and brewed tea (10.0 mL/sample) following the buffered QuEChERS method[7] or AOAC Official Method 2007.01.[9] The complete procedure consisted of three steps including the first step, extraction with acetonitrile containing 1% acetic acid, $MgSO_4$, and sodium acetate; and the second step, cleanup by dispersive solid-phase extraction (d-SPE) using $MgSO_4$, PSA, and graphitized black carbon for dried tea leaves or $MgSO_4$, PSA, and C_{18} for brewed tea. Graphitized black carbon helps to remove some pigments such as catechins and chlorophyll from tea leaves while leaving polar pesticides behind in the acetonitrile extract. It should be mentioned that the final extracts were still relatively dark in color, especially for black tea. The third step comprised concentration, reconstitution, and filtration. Concentration and reconstitution served as an additional cleanup step to remove particles or pigments, which were precipitated out during the process. Extracts were diluted six times for tea leaves, and no dilution was used for brewed tea (filtered to remove particles) prior to UHPLC/ESI-MS/MS injections. The QuEChERS method proved to be a practical extraction procedure for UHPLC/ESI-MS/MS analysis of pesticide residues in tea.

Matrix Effects. The matrix could either enhance or suppress ionization of pesticides during the electrospray process. Its effects might vary from sample to sample and ultimately affect the UHPLC/ESI-MS/MS quantitative results. Previous experiments indicated that the matrix effects were significant in tea leaves,

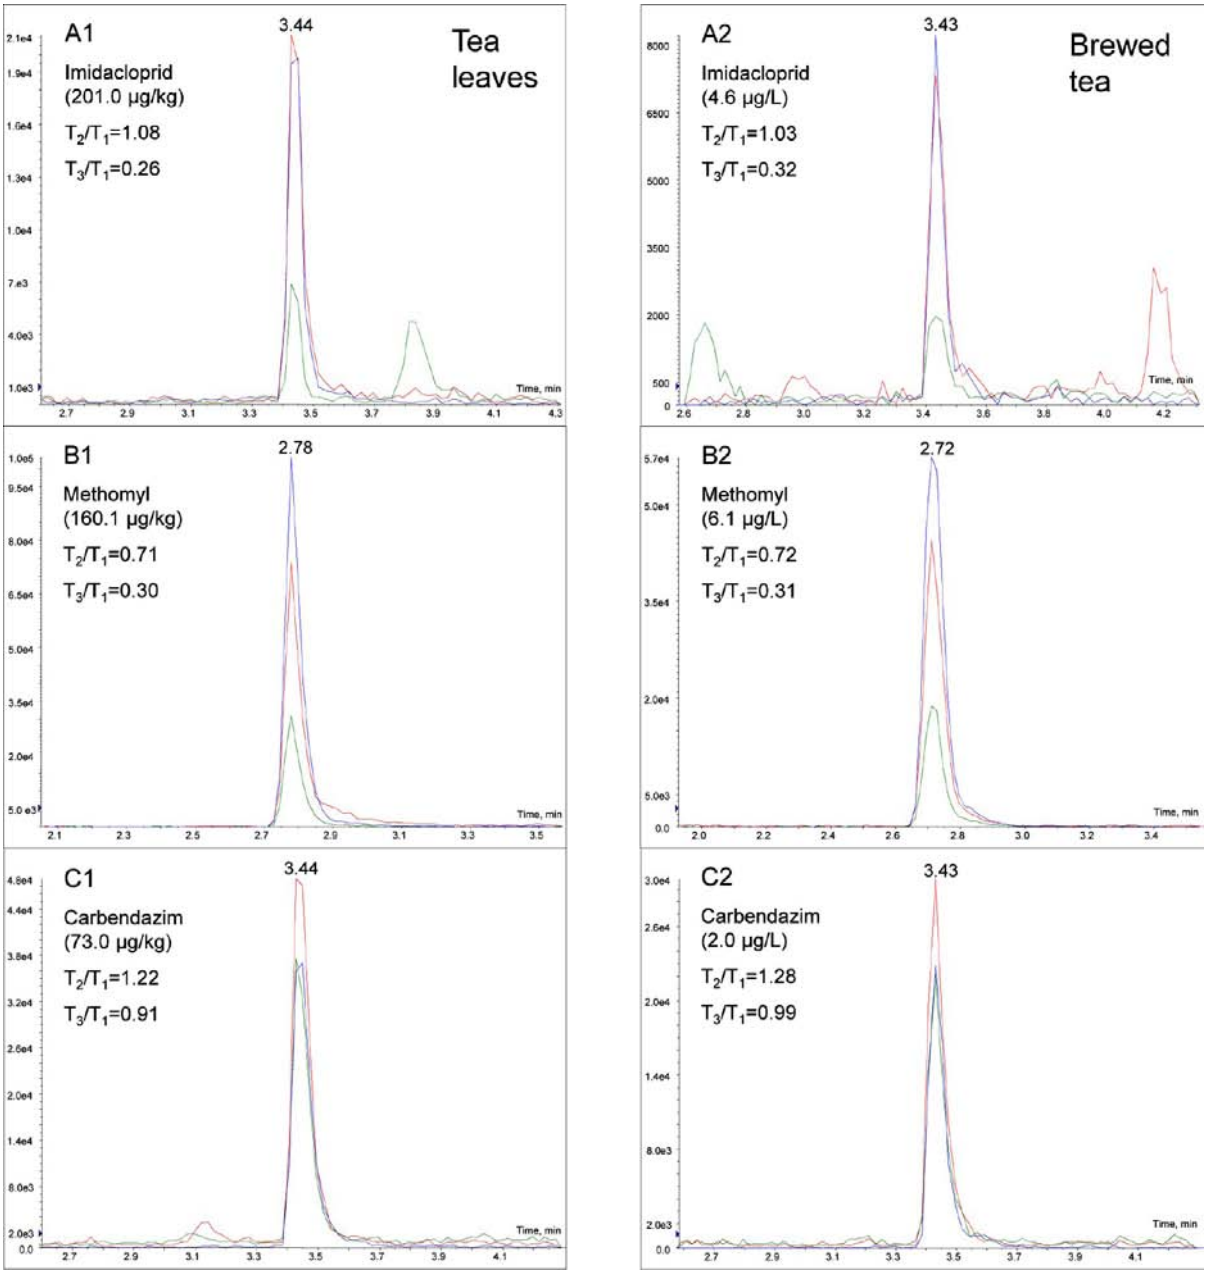

Figure 4. Examples of UHPLC/ESI-MS/MS chromatograms of three common incurred pesticides from one tea and its corresponding brew tea for quantification and confirmation. Imidacloprid transitions: 256.1→209.1 (T_1), 256.1→174.9 (T_2), and 256.1→84.0 (T_3). Methomyl transitions: 163.1→87.9 (T_1), 163.1→106.0 (T_2), and 163.1→58.0 (T_3). Carbendazim transitions: 192.1→160.2 (T_1), 192.1→132.0 (T_2), and 192.1→104.9 (T_3).

and only 8−16% of the pesticides showed ion suppression of <30% or enhancement ≤10%.[7] Matrix effects in brewed tea were evaluated by comparing the responses of pesticides in sample extracts to those pesticide standards prepared in solvent buffer at the same concentration, for example, 8.0 μg/L equivalent in samples. Between 21.4 and 49.7% of the pesticides in brewed tea showed ion suppression of <30% or enhancement ≤10% in brewed tea (Figure 1). Therefore, to quantify pesticides in both tea leaves and brewed tea for the purpose of studying the transfer rates, oolong tea was chosen as a standard or reference matrix for all samples to prepare matrix-matched standard calibration curves to compensate for matrix effects during quantification or to cancel out matrix effects when pesticide transfer rates were calculated.

Quantification and Method Performance. LC/ESI-MS/MS analysis of pesticide residues in tea leaves has been reported elsewhere,[7] and the UHPLC/ESI-MS/MS method was revalidated when a core−shell column replaced the conventional C_{18} column in this study (data not shown). With the core−shell column method for dried tea leaves, 87% of the pesticides had recoveries between 81 and 110%, 94% had an intermediate precision ≤20%, and 89% showed measurement uncertainty ≤40%. The method performance of UHPLC/ESI-MS/MS was very comparable to that of LC/ESI-MS/MS, which was published in 2011.[7]

The UHPLC/ESI-MS/MS analysis of pesticides in brewed tea was a newly developed method and was therefore fully validated according to a nested design[10] to evaluate method performance characteristics including accuracy expressed as overall recovery, intermediate precision, and measurement uncertainty (MU). Four factors, that is, concentrations or spike levels of pesticides,

dx.doi.org/10.1021/jf404123h | J. Agric. Food Chem. 2014, 62, 966−983

matrix effects, day-to-day variation, and within-day variation, were included in the evaluation. Method performance results are summarized in Table 1 and are illustrated in Figure 2. About 95% of the pesticides had recoveries between 81 and 110%, intermediate precision ≤20%, and measurement uncertainty ≤40%. In general, 97% of the pesticides demonstrated MU ≤ 50%, which was a recommended default value in European Union (EU) Document SANCO/12495/2011 for pesticide analysis and enforcement decisions (MRL exceedances).[11] Therefore, the UHPLC/ESI-MS/MS along with QuEChERs served as a practical tool for quantifying pesticide residues in brewed tea.

Pesticide Transfer Rates. Among the 172 pesticides studied, 12 were detected in 44 known-incurred dried tea leaves. Of these pesticides, imidacloprid, carbendazim, and methomyl were the three most frequently found pesticides (Figure 3A). Most of the incurred samples had concentrations of <100 μg/kg in tea leaves, but in one sample imidacloprid concentrations reached as high as 6012 μg/kg (Table 4). The results for quizalofop were not quantitative because of its large measurement uncertainty (>50%). The 12 identified pesticides represented different classes of pesticides such as insecticides, fungicides, and acaricides. All pesticides, in both tea leaves and brewed tea, were confirmed according to the criteria of ion ratios and retention times (Tables 1 and 5) in 2002/657/EC.[12] Because the method recoveries of 11 pesticides (quizalofop not included) in tea leaves and brewed tea were around 100% (Figure 3B and Table 4) and a standard matrix (i.e., oolong tea) was used to overcome matrix effects, the transfer rates presented in Table 4 should reflect accurate percentages for those pesticides that were transferred from dried tea leaves to brewed tea after the brewing process. The variations in transfer rates are most likely as a result of the differences in tea samples. For example, the transfer rate of imidacloprid ranged from 51.6 to 125.0% (average = 84.9%), that for carbendazim ranged from 73.8 to 112.8% (average = 83.4%), and that for methomyl ranged from 63.3 to 118.9% (average = 92.4%) depending on individual samples of the type of tea (Table 4). The overall average transfer rates of 11 pesticides (quizalofop not included) ranged from 49.7 to 99.8%. The 11 identified pesticides were LC-amenable pesticides; therefore, their physicochemical properties might be attributed to their relatively high transfer rates.

Conclusion. This paper presented a practical approach to study pesticide residue transfer rates from dried tea leaves to brewed tea. UHPLC/ESI-MS/MS with a core−shell column was demonstrated to be a fast tool (12 min analytical run time) to analyze 172 pesticides in both tea leaves and brewed tea. Twelve pesticides were detected in 44 known incurred tea samples. Imidacloprid, carbendazim, and methomyl were the three most frequently found pesticides among 12 pesticides. Transfer rates of 11 pesticides (quizalofop not included) ranged from 49.7 to 99.8%. The pesticide residues were likely transferred from tea leaves to brewed tea during the brewing process and may therefore pose a risk to consumers. This study has underscored the importance of establishing an adequate monitoring program for pesticide residues in dried tea leaves with appropriate maximum residue limits.

NOTE ADDED AFTER ASAP PUBLICATION

After this paper was published ASAP on January 15, 2014, an error under Sample Preparation and Extraction Procedure, Brewed Tea, was noted. The equivalency of the internal standard working solution has been changed with the posting of January 16, 2014.

Drug Administration,[20] and therefore they represent a suitable alternative as chemical preservatives to be used on fruits and other food products.

Methyl cinnamate (MC), a methyl ester of cinnamic acid, is one of the major volatile components of strawberry aroma produced and released during fruit maturation.[21,22] Its antimicrobial activity against common phytopathogenic fungi has been tested under in vitro conditions.[23,24] Most recently, the successful incorporation of MC into edible films has been reported.[25] In the present work MC was used in combination with carvacrol (C; the major component of EOs from oregano and thyme), for which antibacterial and antifungal properties have been widely studied. Therefore, the development of an alginate coating containing MC in combination with C has been proposed in this study to improve the antimicrobial activity of C as well as to overcome the negative impact of the strong odor of C on the sensory properties of strawberries. However, although EOs have a positive effect on extending fruit shelf life, the concentrations needed in edible coatings to have an effective antimicrobial property may have a negative effect on barrier-mechanical and optical properties of the coating and therefore affect its performance and acceptability.

The aim of this work was to optimize the antimicrobial and physical properties of alginate coatings containing C and MC for their potential application on fresh strawberries and other perishable fruits. Response surface methodology (RSM) was used as an effective statistical technique for simultaneously investigating and optimizing the response variables.

MATERIALS AND METHODS

Materials and Preparation of Alginate Coating Solution. Food grade sodium alginate (Keltone LV, ISP, San Diego, CA, USA) was the primary ingredient use in the edible coating formulations. Glycerol (Starwest Botanicals Inc., Rancho Cordova, CA, USA) was added as plasticizer to provide good flexibility to the coatings. C and MC were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Coating solutions were prepared by dissolving sodium alginate powder (2% w/v) in distilled water while heating on a stirring hot plate for 15 min at 70 °C until the mixture became clear. Then, 1.5% (w/v) glycerol was added to the solution and stirred for 5 min. Finally, C and MC (active compounds) were incorporated into the solution a little at the time and homogenized with a Polytron 3000 (Kinematica, Luzern, Switzerland) for 10 min at 4000 rpm. Because of the insolubility of MC in water, MC was previously dissolved in ethanol (40% w/w) at 40 °C under stirring at 220 rpm for 5 min.

Antimicrobial Properties of Coating Solutions. An overlay diffusion[26] test was performed as a qualitative test for antimicrobial activity of coatings against *E. coli* and *B. cinerea*. Frozen cultures of *E. coli* O157:H7 (strain RM 1484, original designation SEA13B88), obtained from the U.S. Food and Drug Administration, were streaked on tryptic soy agar (TSA) plate and incubated overnight at 37 °C. One isolated colony was restreaked on TSA and then incubated at 37 °C for 24 h. This was followed by inoculating one isolated colony into 5 mL of trypticase soy broth (TSB) and incubating it at 37 °C for 24 h, under agitation. The microbial broth was then serially diluted (10×) in 0.1% peptone water. Afterward, 100 μL of 10^5 colony-forming units (CFU/mL) was uniformly spread onto TSA plates and left to dry for 5 min at room temperature. Plates were divided into three or four even areas on the basis of the compound concentrations, and a 10 mm diameter filter paper, aseptically cut in the shape of a disk, was placed at the center of each area. Then, 20 μL of each solution was placed on top of the filter paper. The plates were incubated at 37 °C for 24 h. The inhibition radius around the filter paper (colony-free perimeter) was measured in triplicate with a digital caliper (Neiko Tools, Ontario, CA, USA), and the inhibition area was then calculated in square millimeters.

Botrytis cinerea was isolated from small pieces of surface tissue cut from molded strawberries. The molded pieces were placed in a 500 mL flask, and 0.05% Tween 80 was added until the pieces were completely covered. The flask was cupped and shaken for 10 min; after that, the solution was serially diluted (10×) with 0.05% v/v Tween 80. Aa aliquot of 100 μL was spread onto potato dextrose agar (PDA, with 100 mg of chloramphenicol in 1 L media plates) plates and stored for 3−5 days at room temperature. Cultures were then restreaked into PDA plates and incubated at room temperature for 6 days. Spores from day 6 cultures were harvested in 10 mL of 0.05% Tween 80 solution, which was vortexed for several minutes until uniform spore suspension was obtained. The inoculum's concentration was adjusted to 10^5 spores/mL using a hemocytometer. Then, 100 μL of the final inoculum was plated and evenly spread onto PDA plates and left to dry for 5 min. The plates, in triplicate, were divided into three and four areas; at the center of each area, 20 μL of each coating solution were placed on top of a 10 mm diameter filter paper. The inhibition radius and area around the filter paper were measured and calculated, as those for the overlay test on *E. coli*, after 4 days at room temperature.

Viscosity. The viscosity of the solutions was measured using a Brookfield Digital Rheometer (model DV − III+, Brookfield Engineering Laboratories, Middleboro, MA, USA) with a SC4-21 spindle (0.66 mm diameter, 1.23 mm long) set at 125 rpm constant rotation speed. Eight milliliters of solution at 40 °C was used for the measurement, immediately after the incorporation of EOs. Five viscosity readings were made for each coating solution from 1 to 5 min at constant shear rate (116.25 1/s) and temperature (40 °C).

Turbidity. Turbidity studies of the solution, previously warmed at 40 °C, were determined with an HI 88703 turbidity meter (Hanna Instruments, Carrollton, TX, USA). Ten milliliters of each solution was placed into transparent glass cuvettes for this assay, and measurements unit were expressed as nephelometric turbidity units (NTU).

Whitish Index (W_i). The color of the alginate coating solution was measured using a Konica Minolta spectrophotometer (CM508D, Konica−Minolta Inc., Ramsey, NJ, USA) under a standard white reflector plate. CIE L^*, a^*, b^* color coordinates, obtained from the reflection spectra of the samples using a D65 illuminant/10° observer angle, were used to calculate the whitish index as $W_i = 100 - [(100 - L^*)^2 + a^{*2} + b^{*2}]^{1/2}$.[27]

Experimental Design. To optimize the antimicrobial and physical properties of alginate coating, a full factorial design (FFD) was used as a first step to determine which independent variables, between C and MC, influenced the most the antimicrobial activity against *B. cinerea* and *E. coli* (responses). Levels of C and MC, ranging from 0.25 to 1.25% (w/w) (Table 1), were selected on the basis of preliminary tests

Table 1. Levels of the Variables Used in FFD 2^2

	levels % (w/w)		
independent variable	−1	0	+1
carvacrol	0.25	0.75	1.25
methyl cinnamate	0.25	0.75	1.25

on antimicrobial activity. A 2^2 factorial design was replicated three times to obtain more precise estimates of the effects as well as to analyze the variation at each treatment combination.

After the concentrations of the variables had been selected, on the basis of their effect on antimicrobial activity, a RSM was run for evaluating the antimicrobial activity against *E. coli* and *B. cinerea*, viscosity, turbidity, and whitish index (W_i) of the coating, to determine the concentrations of the independent factors that optimize coating characteristic for its potential application on fresh strawberries. A central composite design (CCD), characterized by 11 experimental points (4 star points, 4 cube points, and 3 central points), was selected for this purpose. Three replicates of each experimental condition were carried out, and the mean values were stated as observed responses. Experimental runs were randomized to minimize the effects of unexpected variability in the observed responses. It was assumed that a

dx.doi.org/10.1021/jf4042886 | J. Agric. Food Chem. 2014, 62, 984−990

second-order response function was fitted for relating the responses to the independent variables:

$$Y = \beta_0 + \sum \beta_i x_i + \sum \beta_{ii} x_i^2 + \sum \beta_{ij} x_i x_j$$

Y is the dependent variable and, β_0, β_i, β_{ii}, and β_{ij} are constant coefficients of intercept, linear, quadratic, and interaction terms, respectively. X_i, X_i^2, and X_{ij} represent linear, quadratic, and interactive effects of independent factors, respectively. The coefficients of the independent variables in the model were estimated by multiple regressions and evaluated by analysis of variance (ANOVA).

ANOVA was used to compare the control (alginate-based coating without antimicrobial) with the coating formulations (with antimicrobials) generated by the CCD for viscosity, turbidity, and W_i.

Tukey's means-comparison test was applied at a significance level of 0.05 to determine differences among treatments. The Minitab 14 statistical package was used to perform data analysis, experimental design matrix, and optimization procedure (Minitab Inc., USA).

Multiple Responses Optimization. After the elaboration of response surface models, a multicriteria methodology was used for the simultaneous optimization of the significant response variables. The Derringer function (desirability function) is the most currently used methodology to find optimal compromises between the total number of responses taken into account.[28,29] Each estimated response variable was transformed into a dimensionless individual desirability value (d_i) using the desirability function of the statistical program. The desirability function included the minimum and maximum acceptable values of each response. The values of d_i vary in the interval $0 \leq d_i \leq 1$, increasing as the desirability of the corresponding response increases. This transformation makes it possible to combine the results obtained from responses localized in different regions because they were measured on different orders of magnitude.

The individual desirabilities were then combined to give an overall desirability (D) by using a geometric mean equation

$$D = \sqrt[m]{d_1 d_2 \ldots d_m}$$

where m is the number of responses studied in the optimization process.

The simultaneous optimization process aimed to find the levels of the factors that demonstrated the maximum overall desirability.

RESULTS AND DISCUSSION

Full Factorial Design (FFD). Five combinations of C and MC were generated from the FFD. A preliminary antifungal test against *B. cinerea* was made for the five solutions (containing the five combinations of active compounds) with and without the addition of calcium chloride. Indeed, as a coating agent, alginate is commonly used in combination with $CaCl_2$ because of its ability to form strong gels upon cross-linking reaction.

Results indicated that solutions with $CaCl_2$ had poor inhibition of fungus growth (Table 2). It was previously reported that the physical properties of the gel adversely affected the release of low molecular weight compounds.[31] The calcium alginate gel is characterized by a typical egg-box structure in which the guluronic acid of alginate molecule can be linked to a similar region in another alginate molecule by means of calcium ions.[30] Therefore, the poor antifungal activity of alginate gels containing $CaCl_2$ could be related to the limited release of C and MC from the gel structure. On the basis of this result, a sodium alginate solution without $CaCl_2$ was selected as coating material for future studies.

Experimental data presented in Table 3 are the inhibition of *E. coli* and *B. cinerea* by combined concentrations of C and MC in alginate edible coatings.

The highest value (as the average of the three replicates) for antimicrobial activity against *E. coli* and *B. cinerea* was obtained by the combination of 1.25% (w/w) C and MC. It was also observed that the inhibition of both pathogens was mainly dependent on carvacrol concentration. The statistical analysis results of the FFD (Table 4) showed that only C had a significant ($p \leq 0.1$) effect on both microorganisms. These results also suggested that the MC range from 0.25 to 1.25% (w/w) was probably too low to achieve significant antimicrobial activity. Therefore, in the following central composite design, higher concentrations of MC, ranging from 0.5 to 2.5% (w/w), were selected, whereas the concentrations of C remained the same in the range of 0.25−1.25% (w/w).

experimental result without any significant lack of fit ($p > 0.05$). The main effect of C was found to be significant ($p < 0.05$), and the positive regression coefficient (Table 7) indicated that the antimicrobial activity of the coating increased when C was added into the solution. On the other hand, as in previous results, MC did not show any significant activity on *E. coli*. However, it did have a strong linear effect against *B. cinerea* ($p < 0.001$) (Table 6). On the basis of the regression coefficient terms (Table 7), the linear (499.34) and quadratic (94.92) terms of MC showed the largest antimicrobial effect against *B. cinerea*, followed by the linear effect of C (80.56). These results indicated that the increased concentration of MC in the coating significantly increased the antimicrobial activity of this compound, although no significant interaction between the

two variables was observed (Table 6). The positive quadratic term of MC indicated that the antimicrobial activity of the coating increased quadratically when this compound was incorporated. The significant p value of regression ($p < 0.001$) and the nonsignificant lack of fit ($p > 0.05$) in the ANOVA proved that the proposed second-order polynomial model was fitted to represent the relationship between the two variables and the experimental results on antimicrobial activity against *B. cinerea*. This relationship can be better understood by examining the surface plots depicted in Figure 1, in which the

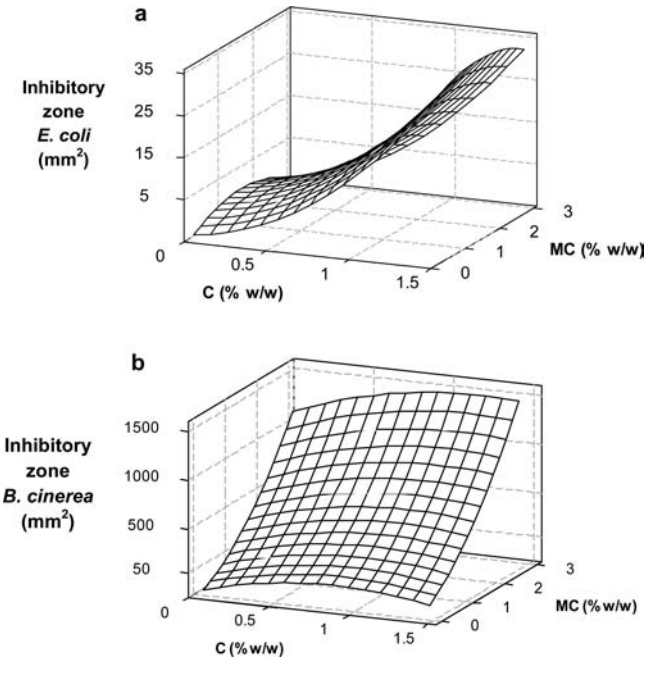

Figure 1. Response surface of antimicrobial activity against (a) *E. coli* and (b) *B. cinerea* as a function of carvacrol and methyl cinnamate (% w/w).

effects of the independent variables (C and MC) on the inactivation of selected microorganisms (*E. coli* and *B. cinerea*) were evaluated. Figure 1a shows that the inhibitory action of C on *E. coli* was very effective and directly proportional with its concentration, whereas MC did not exert a significant antimicrobial activity against this foodborne pathogen within the range of concentration studied. Conversely, in Figure 1b, we observe a highly linear increase in the inhibitory action of

dx.doi.org/10.1021/jf4042886 | J. Agric. Food Chem. 2014, 62, 984−990

MC on *B. cinerea* growth, with an increase in MC concentration in the coating, whereas C was not effective in deterring *B. cinerea* growth under the indicated concentrations range. The efficacy of C incorporated into edible films against *E. coli* O157:H7 was previously reported by Du[32] and Rojas-Grau.[33] They indicated that the addition of carvacrol into tomato-based edible films and apple puree edible films caused inactivation of *E. coli* and that the inactivation was directly related to the increase of C levels in the films. Carvacrol is considered a broad-spectrum antimicrobial, because it is effective against bacteria, yeasts, and fungi.[34] The biocidal mode of carvacrol on bacteria occurs via membrane damage resulting in an increase in membrane permeability to protons and potassium ions, depletion of the intracellular ATP pool, and disruption of the proton-motive force, ultimately leading to cell death.[35] The antifungal activity of C was reported in previous works[36,37] where spore germination and mycelium growth of *B. cinerea* were reduced when exposed to carvacrol's vapor, and the reduction was significantly greater as carvacrol concentration in the vapor increased, showing a high potential to improve the shelf life and safety of perishable foods. The antifungal properties of C against a wide range of foodborne fungi have been previously documented[38,39] and compared with those of other naturally occurring compounds, showing a high potential application against important phytopathogic fungi affecting food products.[40] The antifungal effectiveness of C could be further amplified by exploiting the high antifungal properties of MC. However, the combination of the two compounds did not show any synergistic effect on either foodborne pathogen (Table 6); the incorporation of C and MC exerted high antimicrobial activity. C (X_1) significantly ($p < 0.05$) inhibited *E. coli* and *B. cinerea*, whereas MC (X_2) significantly ($p < 0.001$) inhibited *B. cinerea*.

Effect of Carvacrol and Methyl Cinnamate on Turbidity. The results from ANOVA (Table 6) showed the significant fitting of the turbidity experimental data to the quadratic model presented a determination coefficient (R^2) of 0.985. This implied that 98.5% of the variations could be explained by the fitted model.[41] The turbidity of the coating solutions was negatively affected ($p < 0.05$) by the addition of the antimicrobial compounds. A strong linear effect ($p < 0.001$) was observed for both antimicrobial compounds and their interaction ($p < 0.05$). However, a higher positive regression coefficient was observed for MC, which suggested that it had a stronger effect on the turbidity of the coating compared to C. This fact is further supported by the response surface shown in Figure 2, where an upsurge in turbidity with an increase in MC concentration was observed but only a slight rising trend was observed as C concentration increased. Alginate coating without antimicrobial compounds served as control in the statistical comparison with the antimicrobial alginate solutions to determine if the addition of C and MC affected the turbidity of the coatings. The control alginate coating presented a significantly lower value ($p < 0.05$) of turbidity (144.3 ± 4.04) compared to all antimicrobial solutions containing C and/or MC. Turbidity is an optical property of liquids defined as the measurement of the scattered light that results from the interaction of incident light with suspended solids in the liquid.[42] The presence of particulate material in all antimicrobial solutions increased the turbidity values of the coating. Those particulates in the solutions were probably formed due to the water-insoluble property of MC. Moreover, the production of oil in water emulsions, due to the presence of C in water-based alginate solution, could have also increased the turbidity of the coating.[43]

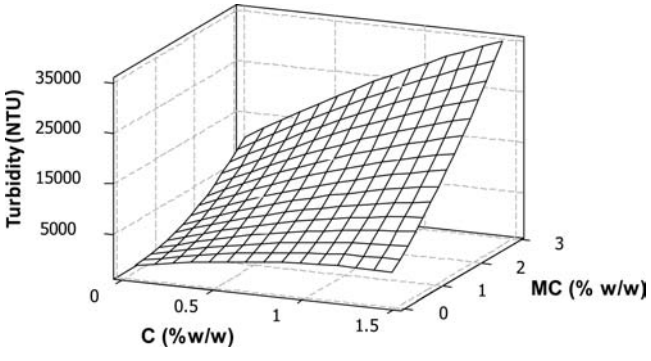

Figure 2. Response surface of turbidity (NTU) as a function of carvacrol and methyl cinnamate (% w/w).

Effect of Carvacrol and Methyl Cinnamate on W_i. With regard to visual characteristics, an edible coating for fruit applications should improve the appearance of the product and impart a natural aspect at the same time. Color is an important property to be considered when a new coating is developed. In this study, W_i was calculated because the incorporation of antimicrobial compounds led to a change of the color from transparent to white, compared to the control (Figure 3). Table 6 shows the results of ANOVA, in which carvacrol presented the highest significant effect ($p < 0.001$), achieving a negative impact on coating transparency. Additionally, the data show that the quadratic term of C, the linear and quadratic terms of MC, and the linear interaction between the two active compounds were also significant ($p < 0.05$), even when the quadratic and interaction terms of the regression coefficient of the variables were negative (Table 7). The regression model was highly significant with a determination coefficient (R^2) of 0.990, which indicated that almost the total variation was explained by the model. The value of the adjusted R^2 (0.977) confirmed that the model was highly significant on the W_i. The fitness of the quadratic model was further confirmed by the significant regression p value ($p < 0.05$) and no significant ($p > 0.05$) lack of fit (Table 6).

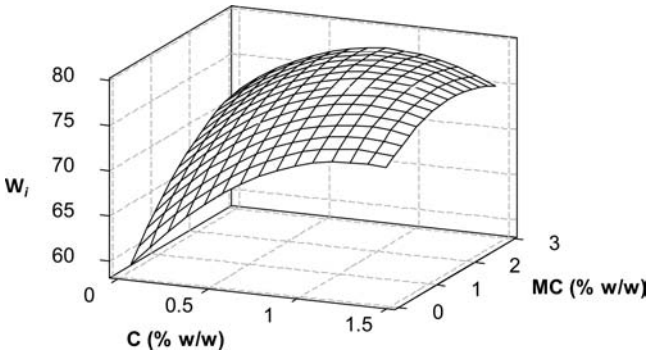

Figure 3. Response surface of whitish index (W_i) as a function of carvacrol and methyl cinnamate (% w/w).

Effect of Carvacrol and Methyl Cinnamate on Viscosity. Alginate was used as primary ingredient in edible coating solution due to its unique property of increased viscosity upon hydration. Aqueous solutions of alginate are considered non-Newtonian fluids, being characterized by shear-

dx.doi.org/10.1021/jf4042886 | J. Agric. Food Chem. 2014, 62, 984−990

thinning characteristic, meaning that the viscosity decreases as the shear rate increases.[44] Therefore, in this study the shear rate was maintained constant at 125 rpm. The effect of the addition of antimicrobial compounds was studied on the viscosity of the fluid to identify whether their incorporation would affect the fluid characteristic of the coating solution and eventually compromise further coating process application. Considering the coating and strawberry physical characteristics, preliminary studies indicated a decrease in coating performance at viscosity values above 83 cP. Hence, viscosity values lower than 83 cP were used as a target for the optimization of the solution. Table 7 shows the results of ANOVA for the fitting model of the viscosity experimental data to a second-order function, which was found to describe the experimental response influenced by the antimicrobial variables without any significant ($p > 0.05$) lack of fit (Table 6). Because the full model was not able to predict viscosity responses based on antimicrobial variables, the model was reduced by excluding the nonsignificant linear and quadratic terms of MC, as well as the interaction between C and MC, to adequately correlate the quadratic relationship between the concentrations of the antimicrobial compounds and viscosity of the fluid. The results showed that only the linear and quadratic effect of C significantly ($p < 0.05$) affected the viscosity of the coating solution (Table 6). However, the positive linear term (+6.20) and the negative quadratic term of the regression coefficient (−4.59) indicated that increasing C concentrations led to an increase in viscosity until a turning point was reached at 0.68% (w/w) C. Concentrations of C above this value tend to decrease the viscosity of the coating solution, probably due to the plasticizer action of C. It has been reported that C reduces the intermolecular forces in polymer chains, thus decreasing the viscosity of the coatings.[45] Similar results were observed when different concentrations of essential oils, above 1.5% (w/w), were added into apple and tomato edible films.[46,47]

Multiple Responses Optimization. On the basis of the findings of each response surface model, an overall optimization study was performed to obtain an antimicrobial coating with physical properties suitable for strawberry application. The optimum condition for alginate coatings with the most desirable characteristics, obtained by the overall desirability function, was at 0.98% (w/w) carvacrol and 1.45% (w/w) methyl cinnamate concentrations.

electrophoresis was determined to further evaluate the effect of SSA on the plasmid DNA structure. Moreover, theoretical docking was carried out to visualize the position and preferential docking sites of SSA in ctDNA. This study may provide insight into the binding mechanism of SSA with ctDNA at the molecular level and potential hazards of the sweetener.

MATERIALS AND METHODS

Materials. The stock solution (4.87×10^{-3} mol L^{-1}) of SSA (Aladdin Chemical Co. Shanghai, China) was prepared in ultrapure water. A highly polymerized fibrous form of ctDNA was purchased from Sigma-Aldrich Co. (St. Louis, MO, USA), and its stock solution was prepared by dissolving the required amount of ctDNA in 0.1 mol L^{-1} NaCl solution and stored at 4 °C. The concentration of ctDNA in stock solution was 3.61×10^{-3} mol L^{-1} determined by UV−vis absorption at 260 nm using the molar absorption coefficient ε_{260} = 6600 L mol^{-1} cm^{-1}.[15] The purity of ctDNA was determined by the ratio of the absorbance at 260 nm to that at 280 nm. The ctDNA solution gave a ratio of $A_{260}/A_{280} > 1.8$, suggesting that the ctDNA was sufficiently free from proteins.[16,17] Supercoiled pUC18 plasmid DNA was obtained from Beijing Solarbio Science and Technology Ltd. (Beijing, China). All stock solutions were diluted to the required concentrations with 0.05 mol L^{-1} Tris-HCl buffer, pH 7.4. All chemicals were of analytical reagent grade, and ultrapure water (18.2 MΩ cm) was used throughout the experiment.

Fluorescence Measurements. The fluorescence spectral titrations were performed on a spectrofluorometer (model F-4500, Hitachi, Japan) with a DC-2006 thermostat bath (Ningbo Xinyi Ultrasonic Instrument Co., Ningbo, China). Three milliliters of SSA (8.12×10^{-5} mol L^{-1}) was first added to a 1.0 cm quartz cell, and various concentrations of ctDNA were then gradually titrated to the cell using a micropipet. The fluorescence emission spectra were measured at 292, 298, 304, and 310 K over a wavelength range of 340−540 nm with an exciting wavelength at 277 nm. All solutions were under conditions of stirring and allowed to equilibrate for 5 min before measurements were conducted. To eliminate the possible reabsorption and inner filter effect arising from UV−vis absorption of ctDNA, the fluorescence data of SSA were corrected for absorption of excitation and emitted light according to the relationship[18]

$$F_c = F_m\, e^{(A_1+A_2)/2} \quad (1)$$

where F_c and F_m are the corrected and measured fluorescence, respectively, and A_1 and A_2 are the absorbance of the ctDNA solutions at 277 and 430 nm, respectively.

Iodide quenching experiments were performed by adding different amounts of potassium iodide solution ($(0-1.09) \times 10^{-2}$ mol L^{-1}) to SSA and SSA−ctDNA complex solutions, respectively. The single-strand ctDNA (ss ctDNA) solution was prepared by heating native double-stranded ctDNA (ds ctDNA) solution in a boiling water bath for 10 min, followed by rapid cooling in an ice−water bath. When the temperature was gradually increased to 298 K, ds ctDNA became ss ctDNA.[19] A comparison of the quenching effects of ss ctDNA and ds ctDNA was carried out by progressively adding ss ctDNA or ds ctDNA solution to SSA solution at a constant concentration of 8.12×10^{-5} mol L^{-1}. The corresponding fluorescence intensity was recorded, and then the quenching constants were calculated.

The effect of NaCl on the fluorescence of the SSA−ctDNA system was determined by gradually adding various amounts of NaCl ($(0-2.67) \times 10^{-2}$ mol L^{-1}) to the fixed amount of SSA and SSA−DNA complex solutions to measure the changes in fluorescence intensity.

Deveplopment of the Expanded Data Matrix for MCR−ALS. The UV−vis absorption spectra were measured on a Shimadzu UV-2450 spectrophotometer equipped with a controlled cell holder matched with 1.0 cm quartz cells. To determine the interaction between SSA and ctDNA, two separate experiments were carried out by fluorescence and UV−vis absorption spectra titrations in Tris-HCl buffer (pH 7.4) at room temperature, following methods standardized in our laboratory to get the expanding data matrix for MCR−ALS.[20] For experiment 1, the concentration of SSA was kept constant at 8.12×10^{-5} mol L^{-1}, and different amounts of ctDNA were added progressively to the solution. For experiment 2, the concentration of ctDNA was fixed at 6.00×10^{-5} mol L^{-1}, and various amounts of SSA were added to the solution. All of the samples were allowed to stand for 5 min before the spectroscopic measurements. The UV−vis absorption spectra (220−320 nm) and fluorescence spectra (340−540 nm) were both collected every 1 nm. Therefore, four data matrices, $\boldsymbol{D}_F^{SSA}$ (31 × 201) and $\boldsymbol{D}_{UV}^{SSA}$ (31 × 101) from experiment 1 and $\boldsymbol{D}_F^{ctDNA}$ (31 × 201) and $\boldsymbol{D}_{UV}^{ctDNA}$ (31 × 101) from experiment 2, were obtained, and these data matrices for two different experiments were combined and an expanded data matrix was established.

DNA Melting Studies. In a typical DNA melting experiment, the absorbance change at 260 nm of ctDNA and SSA−ctDNA complex was investigated as a function of temperature ranging from 20 to 100 °C. The values of melting temperature (T_m) were obtained from the transition midpoint of the melting curves based on f_{ss} versus temperature (T), where $f_{ss} = (A - A_0)/(A_f - A_0)$, A_0, A, and A_f being the initial absorbance, the absorbance corresponding to different temperatures, and the final absorbance, respectively.[10]

Viscosity Measurements. The viscosity measurements were made on an Ubbelohde viscometer (Φ 0.7−0.8 mm, Shanghai Qianfeng Rubber and Glass Co., Shanghai, China) maintained at 25 ± 0.1 °C by an electronic thermostat water bath (Shanghai Yuejin Medical Instrument Co., Shanghai, China). The concentration of ctDNA was kept at 4.81×10^{-5} mol L^{-1}, and aliquots of SSA solution were added directly into the viscometer. The solutions were mixed thoroughly, and the flow times of ctDNA alone and its mixtures with different ratios of SSA to ctDNA ([SSA]/[ctDNA]) through the capillary were then measured in five replicates using a digital stopwatch with an accuracy of ±0.20 s. The data were presented as $(\eta/\eta_0)^{1/3}$ versus the molar ratios,[21] where η_0 and η are the specific viscosities of ctDNA alone and the SSA−ctDNA complex. Viscosity values were determined from the observed flow time of DNA-containing solutions (t) and corrected for buffer solution (t_0), $\eta = (t - t_0)/t_0$.[13]

CD Measurements. CD spectra of ctDNA in the absence and presence of different amounts of SSA were recorded at a wavelength range of 220−320 nm under constant nitrogen flush by a Bio-Logic MOS 450 CD spectrometer (Bio-Logic, Claix, France) equipped with a 1.0 mm path length quartz cuvette. The CD measurements were carried out in pH 7.4 Tris-HCl buffer at room temperature, and all observed CD profiles were corrected for the buffer signal.

FT-IR Analyses. A FT-IR spectrometer (Thermo Nicolet-5700) equipped with a germanium attenuated total reflection (ATR) accessory was used to measure infrared spectra as reported earlier.[10,20] All spectra were recorded on OMNIC software via the ATR method over the spectral range of 1800−800 cm^{-1} with a resolution of 4 cm^{-1} and 64 scans after 2 h of incubation of SSA with the ctDNA solution. Due to sugar C−C and C−O stretching vibrations, the band of DNA at 968 cm^{-1} exhibited no spectral change upon ligand−DNA complexation.[22] Thus, this band was generally used as an internal reference in the different spectra ([ctDNA solution + SSA solution] − [SSA solution]). The intensity ratios (R) of the bands due to several ctDNA in-plane vibrations related to base pairs and the PO_2 stretching vibrations versus the SSA concentrations were obtained after peak standardization using $R_i = I_i/I_{968}$, where I_i is the intensity of absorption peak at i cm^{-1} for free ctDNA and the SSA−ctDNA complex at different concentrations of SSA and I_{968} is the intensity of the 968 cm^{-1} peak (internal reference).[23]

Molecular Modeling. The following molecular docking studies were implemented with the software package AutoDock version 4.2. The crystal structure of the B-DNA with identifier 425D[24] was downloaded from the Protein Data Bank (http://www.rcsb.org/pdb). The 3D structure of the ligand SSA was constructed in Sybyl ×1.1 (Tripos Inc., St. Louis, MO, USA), and its energy-minimized conformation was obtained with the MMFF94 force field.[20] In the process of docking preparation, all of the water molecules were removed, whereas Gasteiger charges and essential hydrogen atoms were added with the aid of AutoDock tools. The grid spacing was set

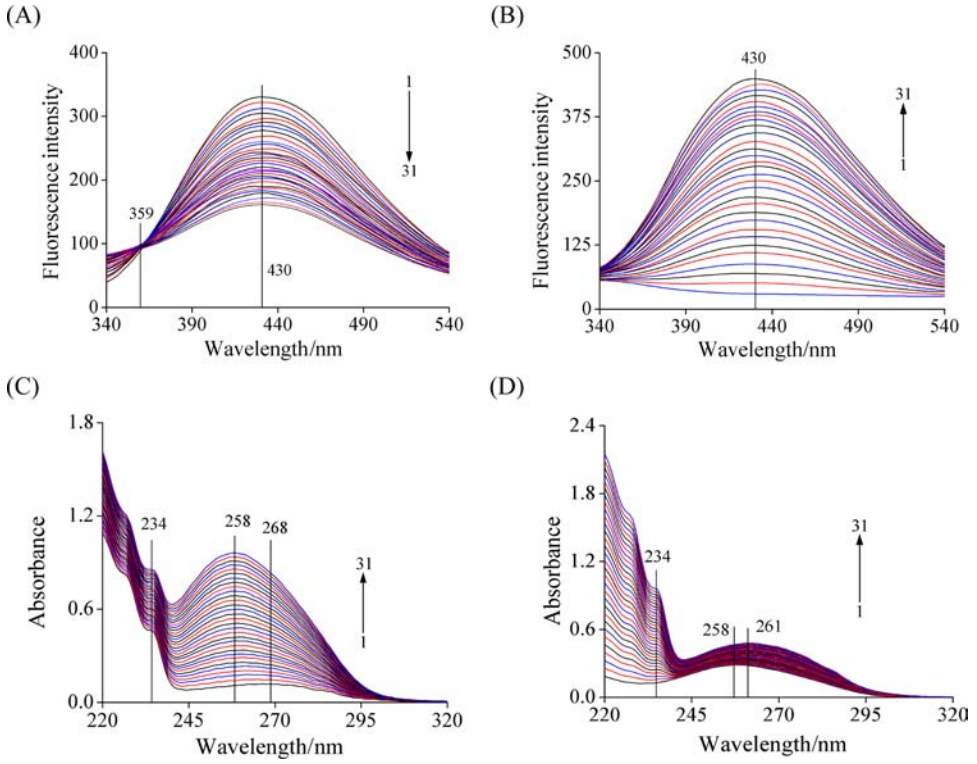

Figure 2. Spectra obtained from different experiments. Experiment 1: (A) fluorescence (D_F^{SSA}) and (C) UV−vis (D_{UV}^{SSA}), c(SSA) = 8.12 × 10^{-5} mol L^{-1}, and c(ctDNA) = 0, 0.60, 1.20, ..., 18.0 × 10^{-5} mol L^{-1} for curves 1−31, respectively. Experiment 2: (B) fluorescence (D_F^{ctDNA}) and (D) UV−vis (D_{UV}^{ctDNA}), c(ctDNA) = 6.0 × 10^{-5} mol L^{-1}, and c(SSA) = 0, 0.49, 0.98, ..., 14.70 × 10^{-5} mol L^{-1} for curves 1−31, respectively.

to be 0.375 Å with a dimension of 118 Å × 74 Å × 118 Å to encompass the whole DNA molecule. After the docking procedure was run successfully, the binding site and the possible conformation of the complex were generated from the reaction between SSA and DNA.

Gel Electrophoresis. Supercoiled pUC18 plasmid DNA (5 μL, 450 μg mL^{-1}) was treated with different concentrations of SSA followed by dilution with Tris-HCl buffer (0.05 mol L^{-1}) containing 0.05 mol L^{-1} NaCl (pH 7.4) to a total volume of 15 μL. The samples of DNA and SSA−DNA complex were incubated for 24 h at 37 °C. A loading buffer (5 μL) containing 0.03% bromophenol blue, 0.03% xylene cyanol, and 30% glycerol was added and electrophoresis performed at 80 V for 1.0 h in 1× Tris−acetate−EDTA (TAE) buffer using 1.0% agarose gel containing 1.0 μg mL^{-1} ethidium bromide. After the electrophoresis, the gel was visualized and photographed by a UV illuminator.

Chemometrics Methods. MCR−ALS has often been used to estimate an optimal concentration and spectra profiles of the species during the chemical reaction.[25,26] Resolution of these chemical species can be largely enhanced when several runs of different spectrophotometric titrations of the same chemical reaction system are resolved simultaneously.[27] Mathematically, the experimental data matrix, $\boldsymbol{D}$, was decomposed into the two smaller factor matrices, $\boldsymbol{C}$ and $\boldsymbol{S}^T$, according to the algebraic model

$$\mathbf{D}(m \times n) = \mathbf{C}(m \times f) \times \mathbf{S}^T(f \times n) + \mathbf{E}(m \times n) \quad (2)$$

where $\boldsymbol{D}$ is the experimental data matrix with dimensions m (spectral objects) × n (wavelengths); $\boldsymbol{C}$ ($m \times f$) is the concentration profile matrix of pure species in the samples; $\boldsymbol{S}^T$ ($f \times n$) is the transposed matrix consisting of, for example, the emission spectra; the f rows of this matrix contain the pure spectra associated with the f species in the samples; and $\boldsymbol{E}$ ($m \times n$) is the residuals matrix. The MCR−ALS algorithm was performed in the following several steps. First, the number of components, f, involved in the chemical reaction process was estimated. This determination was implemented by rank analysis, singular value decomposition (SVD),[28] based on the assumption that the singular values related to chemical components are larger than those associated with errors and noise in the experiment. Second, the constrained alternating least-squares (ALS) regression procedure was utilized to iteratively optimize the initial estimates of $\boldsymbol{S}^T$ or $\boldsymbol{C}$, which are created by evolving factor analysis (EFA).[29] Once the number of species, f, has been extracted, the initial concentration profiles and pure spectra of all the contributing species can be established by the MCR−ALS method.

In the study, two-way fluorescence and the UV−vis spectral expanded data matrix, $\boldsymbol{D}$, were built up by placing the individual data matrices corresponding to the two types of spectra side by side. The related bilinear model for MCR−ALS analysis could be expressed by the following equation:

$$[\mathbf{D}_{UV}\mathbf{D}_F] = \mathbf{C} \times [\mathbf{S}_{UV}^T\mathbf{S}_F^T] + [\mathbf{E}_{UV}\mathbf{E}_F] \quad (3)$$

$\boldsymbol{D}_{UV}$ and $\boldsymbol{D}_F$ are the measurements for the same experiment obtained with two different spectroscopic techniques. Thus, a single-concentration profile matrix, $\boldsymbol{C}$, and a row-wise augmented matrix of pure spectra, $\boldsymbol{S}^T$, can be resolved by the MCR−ALS algorithm.

RESULTS AND DISCUSSION

Fluorescence and Absorption Spectra of Interaction between SSA and ctDNA. Figure 2A shows the emission spectra of SSA in the presence of various concentrations of ctDNA. It was found that the fluorescence intensity of SSA at 430 nm decreased regularly without any significant shift of the peak with the increasing concentration of ctDNA (curves from 1 to 31). A weak fluorescence spectrum of ctDNA could be seen in Figure 2B;with the gradual addition of SSA solution, the fluorescence signal of ctDNA was enhanced (curves from 1 to 31), and a new peak at 430 nm was observed. The UV−vis absorption spectra of SSA exhibited two absorption bands at 234 and 268 nm, and upon the addition of ctDNA, the absorption intensity of SSA at 268 nm increased gradually with a significant blue shift (from 268 to 258 nm, corresponding to

dx.doi.org/10.1021/jf405085g | J. Agric. Food Chem. 2014, 62, 991−1000

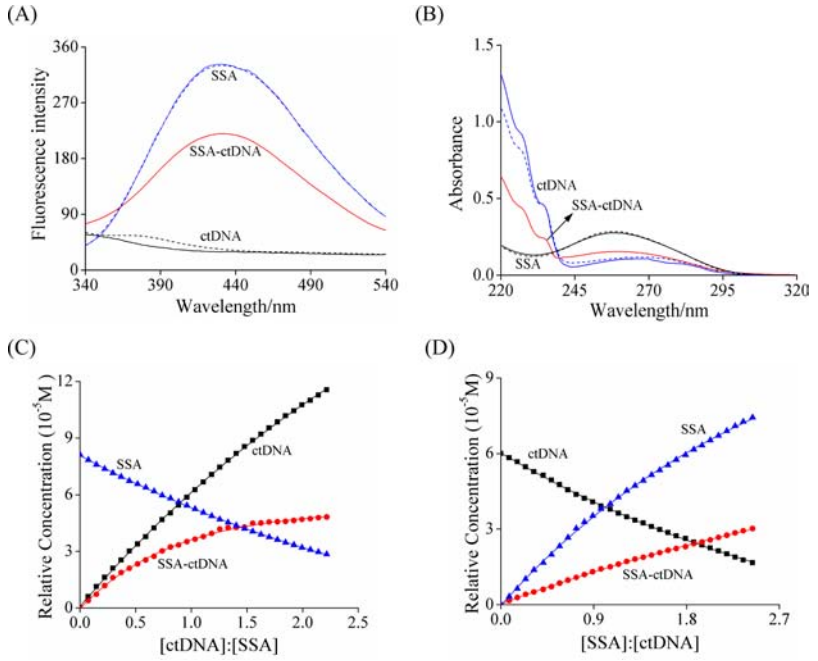

Figure 3. Results obtained from the simultaneous analysis of the UV−vis and fluorescence data of the two experiments by MCR−ALS: (A) recovered fluorescence spectra; (B) recovered UV−vis spectra (solid line, recovered spectra; dashed line, measured spectra); recovered concentration profiles for experiment 1 (C) and experiment 2 (D).

curves from 1 to 31, Figure 2C). On the other hand, with increasing amounts of SSA, the absorption peak of ctDNA at 258 nm, which resulted from the strong absorption of purine and pyrimidine bases in ctDNA, showed a gradual increase accompanied by a significant red shift (from 258 to 261 nm, corresponding to curves from 1 to 31, Figure 2D).

As the collected spectral profiles were highly spectrally overlapped and complicated, it was difficult to deduce the concentration changes of reaction components and gain the spectrum of the SSA−ctDNA complex by the conventional fluorescence and UV−vis absorption methods. Furthermore, no quantitative and qualitative information was available from these profiles.[25] Therefore, in the study, the expanded spectroscopic data matrix obtained from SSA−ctDNA mixtures was simultaneously resolved by the MCR−ALS to extract useful information of the SSA−ctDNA reaction system, such as the concentration profiles and the pure spectra for each species so as to determine the SSA−ctDNA interaction.

Decomposition of the Expanded Fluorescence and UV−Vis Data Matrix by MCR−ALS. The expanded fluorescence and UV−vis data matrix, $[\boldsymbol{D}_F, \boldsymbol{D}_{UV}]$ was analyzed using the SVD model, and the number of significant factors related to the chemical species was evaluated. The extracted first four eigenvalues were determined to be 102.32, 31.62, 10.23, and 1.99, indicating that three significant factors for the prediction of three separate chemical components existed in the system, namely, SSA, ctDNA, and SSA−ctDNA complex. As the spectra of these three components in the mixtures significantly overlapped, a powerful chemometics method, MCR−ALS, was applied to resolve the combined fluorescence and UV−vis absorption data matrix to obtain the concentrations and pure spectra of the three species. Panels A and B of Figure 3 display the pure fluorescence and UV−vis spectra recovered for different species, which correspond to $\boldsymbol{S}_F^T$ and $\boldsymbol{S}_{UV}^T$, respectively. The resolved spectra (solid line) of the free SSA and ctDNA kept good consistency and prediction with the measured counterparts (dashed line). The consistency between the predicted and measured spectral profiles of SSA and ctDNA suggested that the concentration profiles were correctly resolved. Moreover, the fluorescence and UV−vis spectra of the SSA−ctDNA complex (Figure 3A,B) were extracted with the aid of MCR−ALS, which were difficult to be observed by conventional methods. The obtained concentration profiles of SSA, ctDNA, and SSA−ctDNA complex by MCR−ALS analysis showed that the concentration of SSA−ctDNA complex increased gradually along with the decrease of the concentration of SSA upon the addition of ctDNA (Figure 3C), and some superfluous free ctDNA existed in the reaction system. A similar increasing tendency of the concentration of the SSA−ctDNA complex accompanied by a decreasing tendency of ctDNA concentration with increase in concentration of SSA was observed from Figure 3D. It was thus concluded that SSA bound to ctDNA, and a SSA−ctDNA complex was formed.

Fluorescence Quenching Assays. At the excitation wavelength of 277 nm, SSA exhibited a strong fluorescence emission peak at 430 nm (Figure 4A). When different amounts of ctDNA were titrated into a fixed concentration of SSA, the fluorescence intensity of SSA decreased regularly, indicating that an interaction between SSA and ctDNA existed.[30]

The possible quenching mechanism can be made clear by the well-known Stern−Volmer equation

$$\frac{F_0}{F} = 1 + K_{SV}[Q] = 1 + K_q\tau_0[Q] \quad (4)$$

where F_0 and F are the fluorescence intensities of SSA in the absence and in the presence of ctDNA, respectively. [Q] is the concentration of ctDNA. K_{SV} and K_q are the Stern−Volmer quenching constant and the bimolecular quenching constant, repectively, and K_q equals K_{SV}/τ_0. τ_0 denotes the average lifetime of the fluorophore in the absence of quencher, the value of τ_0 of the biopolymer is 10^{-8} s.[31]

dx.doi.org/10.1021/jf405085g | J. Agric. Food Chem. 2014, 62, 991−1000

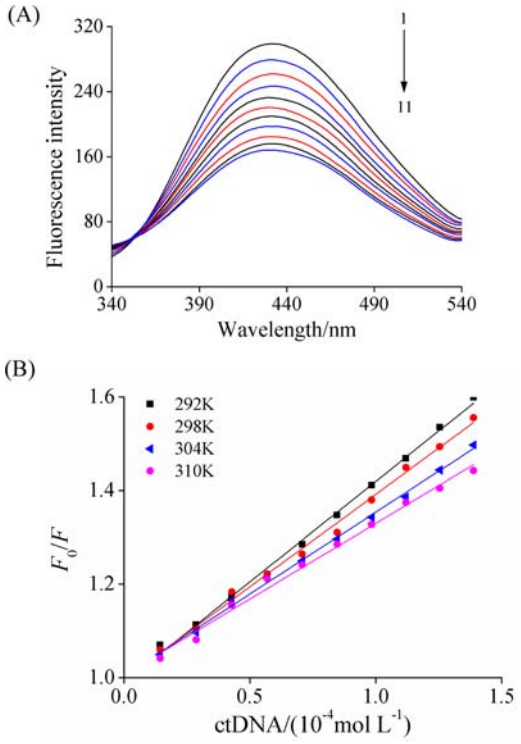

Figure 4. (A) Effect of ctDNA on fluorescence spectra of SSA (T = 298 K, pH 7.4, λ_{ex} = 277 nm, λ_{em} = 430 nm); c(SSA) = 8.12 × 10^{-5} mol L^{-1}; and c(ctDNA) = 0, 1.44, 2.87, 4.28, 5.69, 7.08, 8.46, 9.83, 11.19, 12.54, and 13.88 × 10^{-5} mol L^{-1}, for curves 1−11, respectively. (B) Stern−Volmer plots for the fluorescence quenching of SSA by ctDNA at different temperatures.

The fluorescence data at different temperatures (292, 298, 304, and 310 K) were fitted by Stern−Volmer plots (Figure 4B), and the corresponding K_{SV} values for the interaction between SSA and ctDNA are shown in Table 1. The results clearly showed that the K_{SV} was inversely correlated with temperature, and the calculated K_q values were 4.31 × 10^{11}, 3.96 × 10^{11}, 3.50 × 10^{11}, and 3.23 × 10^{11} L mol^{-1} s^{-1} at 292, 298, 304, and 310 K, respectively, which were higher than the maximum scatter collision quenching constant of various quenchers with biopolymers, 2.0 × 10^{10} L mol^{-1} s^{-1}.[31] These results suggested that the probable quenching mechanism of SSA by ctDNA was static quenching.[32]

The modified Stern−Volmer equation used in the static quenching to calculate the association constant of SSA−ctDNA interaction was[33]

$$\frac{F_0}{F_0 - F} = \frac{1}{f_a K_a}\frac{1}{[Q]} + \frac{1}{f_a} \quad (5)$$

where f_a is the fraction of accessible fluorescence, and K_a is the modified Stern−Volmer association constant for the accessible fluorophores, which equals the quotient of an ordinate $1/f_a$ and slope $1/f_aK_a$. The dependence of $F_0/(F_0 - F)$ on the reciprocal value of the quencher concentration $1/[Q]$ is linear. As shown in Table 1, the values of K_a tended to a decreased trend with increasing temperature. This observation could be because the stability of the SSA−ctDNA complex was reduced. It should be noted that the K_a value obtained here was lower than that reported for classical intercalators, such as ethidium bromide (2.6 × 10^6 L mol^{-1}) and acridine orange (4.0 × 10^5 L mol^{-1}),[34] but corresponded to the groove binders of DNA.[35,36]

Thermodynamic Parameters and Binding Forces. Essentially, interaction forces, including hydrogen bonds, van der Waals forces, electrostatic forces, and hydrophobic interaction forces, play major roles in the interaction between DNA and ligands.[37] The estimated thermodynamic parameters such as enthalpy change ($\Delta H°$) and entropy change ($\Delta S°$) for DNA reactions can determine the main factor contributing to binding affinity and specificity. Thus, to further characterize the interaction forces between SSA and ctDNA, the relevant thermodynamic parameters dependent on temperatures were analyzed by the van't Hoff equation

$$\log K_a = -\frac{\Delta H°}{2.303RT} + \frac{\Delta S°}{2.303R} \quad (6)$$

where R is the gas constant (8.314 J mol^{-1} K^{-1}). Four different temperatures of 292, 298, 304, and 310 K were used. The values of $\Delta H°$ and $\Delta S°$ were obtained from the slope and intercept of the linear van't Hoff plot based on log K_a versus $1/T$. The free energy change ($\Delta G°$) could be calculated from the following equation:

$$\Delta G° = \Delta H° - T\Delta S° \quad (7)$$

The negative $\Delta H°$ and $\Delta S°$ values (Table 1) showed that the binding of SSA to ctDNA was driven mainly by hydrogen bond and van der Waals forces,[38] and the negative $\Delta G°$ indicated that the interaction process was spontaneous. The formation of SSA−ctDNA complex, which was exothermic and enthalpy-favored according to obtained thermodynamic data, led to a more ordered state, possibly due to the freezing of the motional freedom of both SSA and ctDNA molecules.[35]

Melting Studies. The thermal behavior of DNA in the presence of small molecules could provide information about its interaction mode with ligands. Interaction of small molecules with DNA could influence the melting temperature (T_m), the temperature at which the double helix denatures into single-stranded nucleic acid.[39] It was reported that intercalative binding increased the stability of DNA helix, and the T_m was increased by about 5−8 °C, but nonintercalative binding, like groove binding mode or electrostatic, led to no obvious

Table 1. Quenching Constants (K_{SV}), Association Constants (K_a), and Thermodynamic Parameters for the Interaction of ctDNA with SSA at Four Temperatures

T (K)	K_{SV} (×10^3 L mol^{-1})	R^a	K_a (×10^3 L mol^{-1})	R^b	$\Delta H°$ (kJ mol^{-1})	$\Delta S°$ (J mol^{-1} K^{-1})	$\Delta G°$ (kJ mol^{-1})	R^c
292	4.31	0.9964	7.62	0.9928			−21.92	
298	3.96	0.9946	5.01	0.9941	−63.19	−141.73	−20.91	0.9914
304	3.50	0.9969	2.92	0.9975			−19.90	
310	3.23	0.9909	1.72	0.9949			−18.90	

[a] R is the correlation coefficient for K_{SV} values. [b] R is the correlation coefficient for K_a values. [c] R is the correlation coefficient for the thermodynamic parameters.

increase in the T_m.[13,40] Thus, melting measurement can be used as an approach to investigating the binding properties of SSA to ctDNA. As shown in Figure 5A, the T_m of ctDNA increased from 74.8 to 75.6 °C after binding with SSA. That is, SSA provides lower accessibility for DNA binding than the intercalating bound molecules.

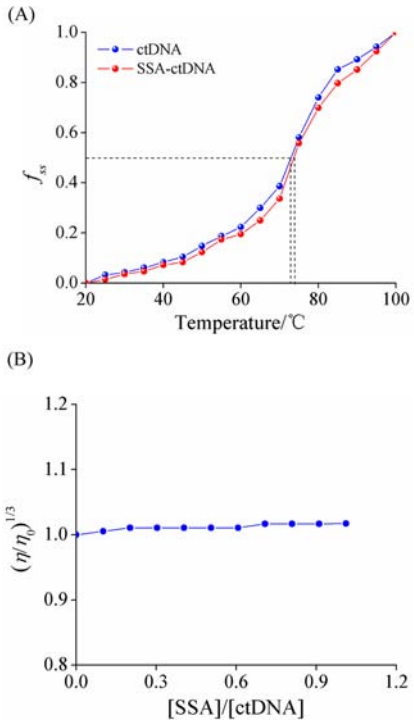

Figure 5. (A) Melting curves of ctDNA in the absence and presence of SSA at pH 7.4. c(SSA) = 8.12 × 10^{-5} mol L^{-1}, and c(ctDNA) = 1.17 × 10^{-4} mol L^{-1}. (B) Effect of increasing amounts of SSA on the relative viscosity of ctDNA at 298 K. c(ctDNA) = 4.81 × 10^{-5} mol L^{-1}.

Viscosity Investigation. An extraordinary feature of the classic intercalative binding mode first proposed by Lerman was the lengthening of the DNA helix as the base pairs were separated to bind the ligand, which resulted in a significant increment in DNA viscosity.[41] In contrast, there was little effect on the viscosity of DNA if groove or electrostatic binding occurred in the binding process.[42] As shown in Figure 5B, the relative viscosity of ctDNA showed no significant change with the continuous addition of SSA, indicating that the binding mode of SSA with ctDNA was not intercalation but groove or electrostatic binding.

Ionic Strength Effect. Probing the effect of the ionic strength on the interaction is an efficient way to investigate the electrostatic interaction of small molecules to DNA. Although NaCl is not an anionic quencher of DNA,[43] it could compete for phosphate anion. Addition of NaCl solution was reported to impair electrostatic interaction between DNA and small molecules.[44] The effect of the sodium ion strength on the interaction between SSA and ctDNA was investigated with different concentrations of NaCl in the absence and presence of ctDNA. The results (Figure 6A) showed that the addition of NaCl had no obvious effect on the fluorescence of SSA and SSA−ctDNA, suggesting that the electrostatic binding of SSA to ctDNA could be excluded.

Iodide Quenching Effect. Iodide quenching experiments could provide evidence for the groove binding of SSA to DNA.

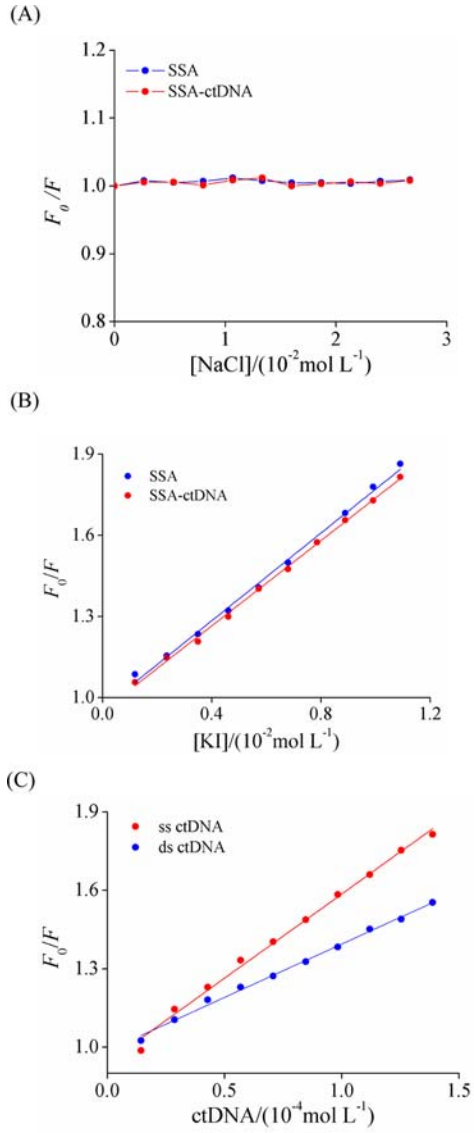

Figure 6. (A) Effect of ionic strength on the fluorescence of SSA and SSA−ctDNA system. c(SSA) = 8.12 × 10^{-5} mol L^{-1}, and c(ctDNA) = 1.17 × 10^{-4} mol L^{-1}. (B) Fluorescence quenching plots of SSA by KI in the absence and presence of ctDNA at pH 7.4. c(SSA) = 8.12 × 10^{-5} mol L^{-1}, and c(ctDNA) = 1.17 × 10^{-4} mol L^{-1}. (C) Fluorescence quenching plots of SSA by ds ctDNA and ss ctDNA at pH 7.4. c(SSA) = 8.12 × 10^{-5} mol L^{-1}.

Negatively charged I^- was chosen for the important purpose: a highly negatively charged quencher will be repelled by the negatively charged phosphate backbone of DNA, and an intercalator should be prevented from being quenched by anionic quencher.[45] However, the groove binders should be quenched easily by anionic quenchers. The quenching constants (K_{SV}) for SSA and SSA−ctDNA were determined from the Stern−Volmer equation. The K_{SV} values of free SSA and SSA−ctDNA by I^- ion were 81.1 and 78.8 L mol^{-1}, respectively (Figure 6B). There was only a small change in iodide quenching interactions after SSA−ctDNA interaction, which indicated that the bound SSA molecules did not intercalate into the base pairs of ctDNA. In other words, SSA molecules bound to ctDNA through groove binding.

Effects of SSA on ss ctDNA and ds ctDNA. Further support for the groove binding of SSA to DNA was obtained

dx.doi.org/10.1021/jf405085g | J. Agric. Food Chem. 2014, 62, 991−1000

through comparison of the effects of SSA on ss ctDNA and ds ctDNA because the groove mode may lead to a greater quenching effect of ss ctDNA than ds ctDNA. By contrast, intercalation mode should cause a weaker quenching effect of ss ctDNA than that of ds ctDNA.[42] As shown in Figure 6C, ss ctDNA exhibited a higher slope than ds ctDNA. The values of K_{SV} for ds ctDNA and ss ctDNA were calculated to be 4.09×10^3 and 6.45×10^3 L mol^{-1}, respectively. The results further confirmed that there was a groove binding mode between SSA and ctDNA.

CD Spectra. To explore the possible influence of SSA binding with ctDNA on the secondary structure of ctDNA, CD measurements were performed in the presence and absence of SSA at different concentrations. It was reported that the CD spectrum of ctDNA exhibited a positive band at 275 nm due to base stacking and a negative band at 245 nm caused by helicity, which are characteristics of DNA in right-handed B form.[46,47] If a small molecule binds to DNA through intercalation, the intensity of positive and negative bands will decrease significantly, whereas groove binders do not significantly unwind DNA base pairs.[48]

As shown in Figure 7, with increasing concentration of SSA, the negative band decreased and the positive band increased

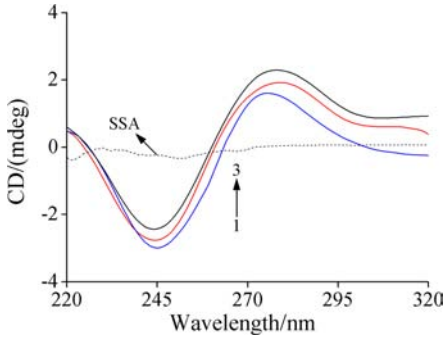

Figure 7. (A) Circular dichroism spectra of ctDNA in the presence of increasing amounts of SSA at pH 7.4. c(ctDNA) = 3.61×10^{-4} mol L^{-1}. The molar ratios of SSA to ctDNA were 0:1, 4:1, and 8:1 for curves 1−3, respectively. c(SSA) = 4.87×10^{-4} mol L^{-1} (dashed line).

remarkably. There was an inconspicuous wavelength shift detected in the negative band but a significant red shift was observed in the positive band. Similar results were reported,[49−51] and this type of change in the CD spectra was deemed as a transformation from B-like DNA structure to A-like conformation in groove binding mode.

FT-IR Studies. The FT-IR spectra of free ctDNA and SSA−ctDNA complex at different molar ratios are shown in Figure 8A. The characteristic spectrum of B-form DNA mainly consists of six peaks at 1717 cm^{-1} (guanine), 1667 cm^{-1} (thymine), 1610 cm^{-1} (adenine), 1490 cm^{-1} (cytosine), 1222 cm^{-1} (PO_2 asymmetric vibrations), and 1088 cm^{-1} (PO_2 symmetric vibrations).[20,52]

According to changes in the intensity and position of these peaks (Figure 8), some information about the interaction of SSA with the nitrogenous bases of ctDNA can be obtained. As shown in Figure 8A, the band of guanine at 1717 cm^{-1} shifted toward a higher frequency at 1727 cm^{-1} (by 10 cm^{-1}) for SSA−ctDNA complex, whereas the effects on the cytosine band at 1490 cm^{-1}, the thymine band at 1667 cm^{-1}, the adenine band at 1610 cm^{-1}, and the $-PO_2$ bands at 1222 and 1088 cm^{-1} were mild (shifted by 2−3 cm^{-1}). These observations

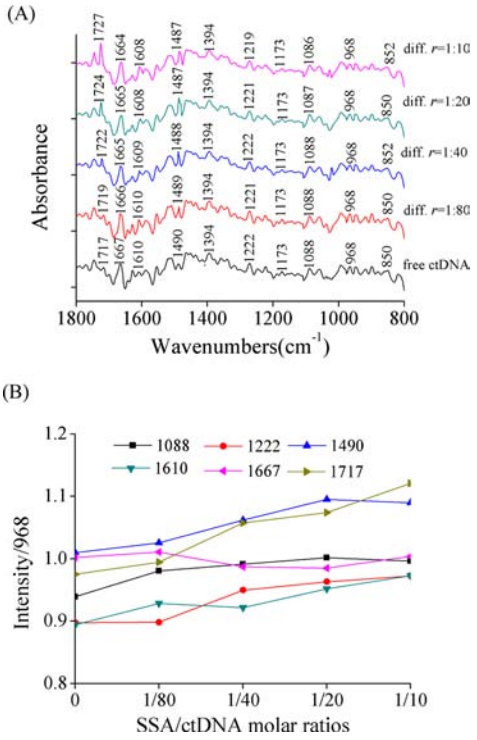

Figure 8. (A) FT-IR spectra and difference spectra [(ctDNA + SSA) solution − SSA solution] in the region of 1800−800 cm^{-1} for free ctDNA and SSA−ctDNA complex in an aqueous solution. (B) Intensity ratio variations of several ctDNA vibrations as a function of different SSA/ctDNA molar ratios. c(ctDNA) = 3.61×10^{-3} mol L^{-1}.

could be because the SSA bound to guanine bases of ctDNA directly.[53] Moreover, a significant increase in the intensity of the band at 1717 cm^{-1} was also observed when the SSA concentration was increased (Figure 8B). Compared with the former, the intensity change at 1667 cm^{-1} and those at 1610, 1490, 1222, and 1088 cm^{-1} were weaker. Small changes in peak position and intensity of the $-PO_2$ bands and cytosine, thymine, and adenine bands indicated that SSA affected their stability to some degree. The results suggested that SSA preferentially bound to guanine, and the binding caused a slight perturbation to the ctDNA molecule.

Computational Docking Simulation of SSA Binding to ctDNA. The molecular modeling method can offer the visual representation of the binding characteristics of small ligands to DNA, which is helpful to complement and substantiate the experimental results.[47]

After the 100 docking runs were successfully performed, a total of 19 multimember conformational clusters were formed. Cluster analysis was carried out using a rmsd tolerance of 2.0 Å, and the binding energy of the distributed conformations is shown in Figure 9A. The highest populated cluster contained 17 of the 100 analyzed conformations and possessed an estimated binding energy of −4.99 kcal mol^{-1}. However, the most populated cluster was not the most energetically favorable cluster. Thus, the predicted binding model with the lowest docking energy was then selected for binding orientation analysis.[54]

As exhibited in Figure 9B, the SSA molecule bound to the DNA minor groove with the lowest binding energy (−6.78 kcal mol^{-1}). Moreover, two hydrogen bonds were formed between SSA and guanine. One hydrogen bond was built by the oxygen atom O-5 linked S-4 of SSA with the H-22 hydrogen atom

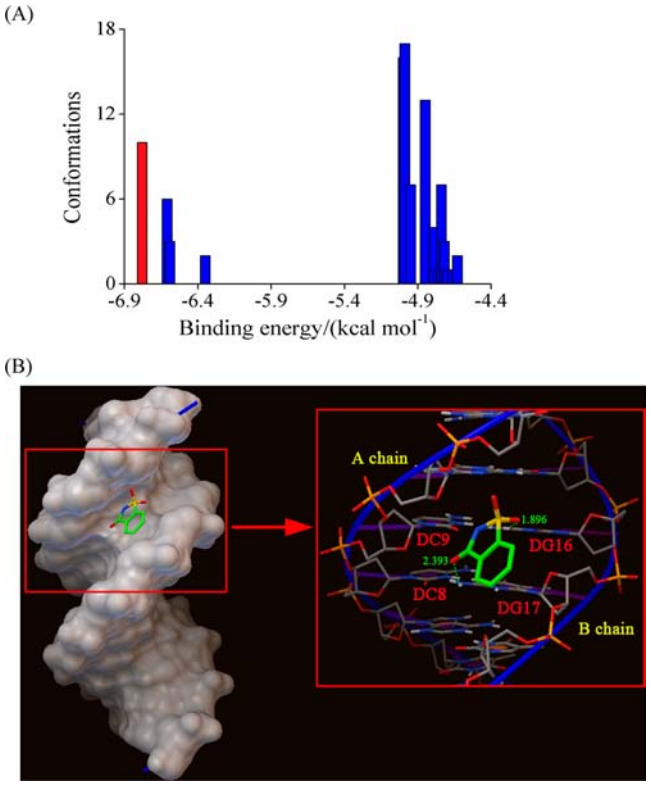

Figure 9. (A) Cluster analyses of the AutoDock docking runs of SSA with DNA. (B) Molecular modeling results of the energy-minimized structure of the SSA−DNA system. The green dashed lines stand for hydrogen bonds.

associated with N-2 of guanine (DG16 of the B chain). The other one was formed between the oxygen atom O-2 linked C-1 of SSA and the H-22 hydrogen atom associated with N-2 of guanine (DG17 of the B chain); their lengths were 1.896 and 2.393 Å, respectively. These docking results have shown that SSA was prone to bind to the guanine base of ctDNA and implied that hydrogen bond forces played an important role in SSA interaction with ctDNA. The docking results were consistent with the experimental results shown above.

DNA Cleavage Activity of SSA. DNA cleavage activity of SSA was analyzed by agarose gel electrophoresis using supercoiled pUC18 plasmid DNA. When circular plasmid DNA is run on electrophoresis, three forms of plasmid DNA may be observed: form I, an intact supercoiled form; form II, an open circular form or nicking form; and form III, a linear form. Their migration speeds were expected to be in the order form I > form III > form II.[55] As shown in Figure 10, the migration of form I was unchanged with increasing concentration of SSA, and both forms II and III cannot be observed. These results indicated that SSA did not have any significant cleavage activity of plasmid DNA.[56,57] These findings along with CD and FT-IR results support the assumption that SSA does not damage but perturbs the DNA structure.

In summary, the binding interaction of SSA with ctDNA in physiological buffer was investigated by multispectroscopic techniques, as well as viscosity measurements, DNA melting analysis, and molecular modeling studies. The mode of binding interaction of SSA with ctDNA has been found to be principally groove binding, and hydrogen bonds and van der Waals forces played major roles in the binding process. The FT-IR analysis implied that SSA was prone to bind to guanine of ctDNA,

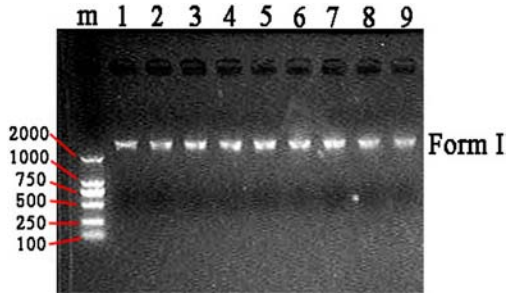

Figure 10. Gel electrophoresis of plasmid pUC18 supercoiled DNA (112.5 μg mL^{-1}) in the presence of increasing amounts of SSA after 24 h of incubation at 37 °C. Lanes: M, DNA marker; 1, supercoiled plasmid DNA; 2−9, SSA + plasmid DNA, and c(SSA) = 2.44, 4.87, 7.31, 9.74, 12.18, 14.61, 17.05, and 19.48 × 10^{-4} mol L^{-1}, respectively.

which was consistent with modeling studies. The results of CD spectra revealed that the binding of SSA to ctDNA resulted in a slight perturbation in ctDNA double-helix conformation. Gel electrophoresis studies showed that this binding did not induce significant DNA cleavage. Moreover, MCR−ALS was applied to resolve the combined fluorescence and UV−vis data matrix to evaluate the progress of SSA interaction with ctDNA. Significantly, the spectra of pure SSA, ctDNA, and especially the SSA−ctDNA complex along with their concentration profiles were successfully obtained.

This study presented binding characteristics of the minor groove interaction of SSA with ctDNA, which further advanced our knowledge of the interaction of small molecules with ctDNA and could be useful in assessing the toxicologic effects of this food sweetener. It should be noted that the maximum residue level (MRL) of SSA in different foods was set from 80 to 2500 mg L^{-1}.[2] The SSA concentration used in this study (8.12 × 10^{-5} mol L^{-1}, i.e., 16.41 mg L^{-1}) is comparable to the amount currently used as a food additive.

amounts of such enzymes,[14] and their ability to perform aryl hydroxylation has been shown.[15] Furthermore, horseradish is a root vegetable. If cultivated in contaminated soil, its edible parts are in direct and permanent contact with environmental contaminants and are likely to incorporate them to a certain extent as was shown for the edible root parts of carrot plants.[4] This makes horseradish suitable for studies on the uptake of environmental contaminants and on metabolite elucidation in the context of agricultural and environmental research.

UPLC high-resolution mass spectrometry using MS^E was proven to be an outstanding method for the analysis of metabolites enabling both their sensitive detection and deducing their elemental composition from their exact masses.[16] Due to interfering matrix compounds, coextracted from the plant tissue, the visual discovery of metabolites in total ion current chromatograms will be restricted to very abundant signals. Common strategies to search for metabolites are neutral loss scans and precursor ion scans using a QqQ mass spectrometer. However, these approaches can be too selective as they exclude unexpected metabolites. In general, methods of multivariate data analysis are promising to investigate the metabolism of xenobiotics in plant cells to handle the large quantities of obtained chromatographic and mass spectrometric data and to evaluate them in an unbiased and comprehensive manner. Principal component analysis (PCA) in combination with orthogonal projection to latent structures discriminant analysis (OPLS-DA) is increasingly applied to handle the large amount of data in metabolomics studies, whereas their application in environmental or contaminant metabolism research is rarely reported. In the following study the advantages of the above-mentioned method for the elucidation of metabolites of xenobiotica in plants are presented using the example of triclosan applied to a hairy root culture of horseradish (*Armoracia rusticana*).

EXPERIMENTAL PROCEDURES

Chemicals. Triclosan (5-chloro-2-(2,4-dichlorophenoxy)phenol, >97.0%) was provided by Fluka (Buchs, Switzerland) and methanol (Hypergrade) by Merck (Darmstadt, Germany). Acetonitrile, ammonium acetate, and acetic acid (all of ULC/MS grade) were provided by Biosolve (Valkenswaard, The Netherlands).

Root Culture Treatment and Sample Processing. A hairy root culture of horseradish (*A. rusticana*) was cultivated in 100 mL of MS culture medium in Erlenmeyer flasks as described elsewhere.[17] Ten days after subcultivation, triclosan was dissolved in methanol and applied to the culture medium to a concentration of 0.6 μg mL^{-1} (2 μM). The incubation was terminated at day 1, 2, or 5 of exposure to detect and identify triclosan metabolites in plant material.

The plant material was separated from the culture medium by suction filtration, immediately frozen in liquid nitrogen, and stored at −20 °C prior to further sample processing. The plant material was ground under liquid nitrogen using a mortar and pestle and transferred to 45 mL glass centrifuge tubes with a magnetic stir bar. The plant material was extracted three times with 8 mL of water/acetonitrile 1:1 (v/v) with 5 mM ammonium acetate and 0.5% glacial acetic acid by stirring at room temperature and centrifuged for 5 min at 4500 rpm. The three biological replicates of each sampling day were combined to obtain a higher concentration of metabolites in the extract. The supernatants were collected and concentrated to a volume of 1 mL by removing acetonitrile using a rotary evaporator followed by water removal employing lyophilization. The samples were filtered through syringe filters (0.45 μm) prior to liquid chromatographic−mass spectrometric analysis.

UPLC-QToF-MS Analysis. The analysis was performed on a Waters Acquity UPLC system connected to Synapt G2S QToF mass spectrometer equipped with an electrospray ionization source (Waters, Milford, MA, USA). An aliquot of 10 μL of each sample was injected onto the column. UPLC separation was achieved using an Acquity UPLC HSS-T3 column (100 × 2.1 mm, 1.7 μm particle size) at a flow rate of 0.6 mL min^{-1} and a column temperature of 60 °C. The mobile phase consisted of (A) water and (B) ACN, both with 5 mM NH_4OAc and 0.05% acetic acid. The gradient applied was as follows: 0 min, 5% B; 7 min, 95% B; 8 min, 95% B; 8.1 min, 5% B; 10 min, 5% B. Electrospray ionization was carried out in separate analyses under negative and positive polarity by applying capillary voltages of −0.7 and +0.7 kV, respectively. The source temperature was set to 140 °C and the desolvation temperature to 550 °C. The sampling cone voltage was set to 35 V and source offset at 50 V. Nitrogen and argon were used as cone and collision gases, respectively. The desolvation gas flow was 950 L h^{-1}.

The mass spectrometric data were collected from m/z 50 to 1200 in centroid mode with a 0.15 s scan time. To ensure m/z accuracy, leucine enkephaline was infused via the reference probe as lockspray and a two-point calibration was applied. Two sets of data were collected in parallel using MS^E acquisition. One data set contains low collision energy data (4 eV, MS, effectively the accurate mass of molecular ions) and the second data set the elevated collision energy data (15−35 eV, MS^E, all of the fragment ions).

Each sample was measured three times in a randomized order.

Data Processing. Centroid raw mass spectrometric data obtained under low collision energy were processed using MarkerLynx application manager for MassLynx 4.1 software (Waters). The parameters used were as follows: retention time ranging from 0 to 8 min, m/z ranging from 50 to 1200, retention time tolerance 0.05 min, a m/z tolerance of 0.01 Da, and a marker intensity threshold of 500.

The intensity of each ion was normalized with respect to the total ion count to generate a data matrix that consisted of the retention time, m/z value, and normalized peak area using MarkerLynx software. The data matrix was reduced by applying a mass defect filtering of ±0.150 u of triclosan and processed by EZinfo software (Waters). The unsupervised segregation of control and exposed cell extract was checked by PCA using pareto-scaled data. The S-plot of the supervised partial least-squares-discriminant analysis (PLS-DA) and orthogonal projection to latent structures (OPLS) enabled the selection of analytes that are responsible for the distinction of control and exposed cell extract ($|p(corr)| > 0.5$ on S-plot). These analytes are subsequently analyzed for chlorine pattern, that is, two signals with a m/z difference of 1.9970 u (±0.0030 u), by applying an isotopic pattern filter (Macro for Microsoft Excel). The m/z values of potential candidates were arranged according to their retention time and peak profile to align the signals of molecular ions, adducts, and fragment ions.

The assignment of the chemical formula was accomplished according to the following criteria: The deviation for ion mass was set to ≤5 ppm and the following element limits: C (0−100), H (0−100), O (0−30), N (0−4), S (0−4), Cl (0−6), and P (0−2). The chlorine number was restricted further according to the observed isotopic pattern.

RESULTS AND DISCUSSION

To overcome the limitations of a targeted analysis, in which a limited set of probable and predictable metabolites has to be defined before analysis, a more unbiased approach was chosen. A screening by recording high-resolution full scan mass spectra combined with their treatment by multivariate statistics and data filter techniques was performed to include possible unexpected and minor abundant metabolites in this study, as well. Therefore, the extracts of control and triclosan-exposed horseradish hairy root tissues were analyzed by UPLC−high-resolution mass spectrometry applying the MS^E mode. Abundant triclosan metabolites with high signal intensities became apparent by comparing base peak chromatograms of extracts of control and exposed root tissues (Figure 1). In contrast, less abundant metabolites are difficult to discover in

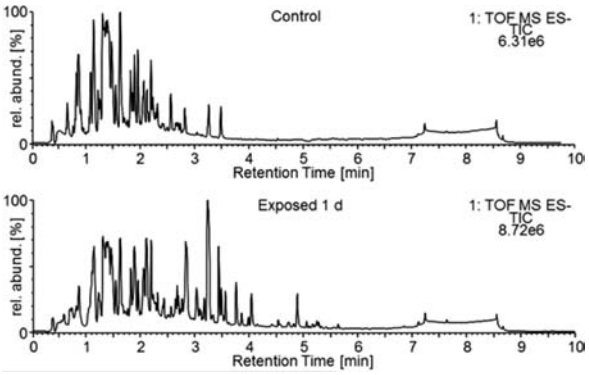

Figure 1. Low collision energy total ion current chromatograms (ESI neg) of extracts of control (top) and triclosan-exposed (bottom) horseradish root tissues.

the presence of intense signals of the biogenic plant matrix. This requires the use of multivariate data analysis.

In addition, two filter techniques were applied, which consider likely mass spectrometric features of the triclosan metabolites and discriminate them from matrix compounds. The application of the mass defect filter results from the knowledge that mass defect values of a parent compound and its metabolites are quite similar and enable the discrimination of matrix ions that arise from endogenous compounds. Compared to others,[18−20] we applied a rather broad filter of ±0.150 u for mass defect filtering to account for extensively conjugated metabolites. The mass defect filter was applied to the raw data set and reduced the number of candidate signals from 6939 to 3867.

These signals were further processed via PCA. PCA provided a clear separation of the extracts of control and treated hairy root tissues (Figure 2a). By using OPLS-DA of the untreated horseradish sample and the triclosan-treated horseradish samples (different treatment periods (1, 2, and 5 days) now considered as replicates), the number of signals representing potential metabolites was further reduced to 572 ($|p(\mathrm{corr})| > 0.5$ on S-plot, Figure 2b). Differentiation within the S-plot occurs because of concentration differences, and metabolites with a higher intensity yield a better separation from the background ions.

The reduced data matrix was treated with a second filter method, with the assumption that metabolites contain at least one chlorine atom of the three originally present in the triclosan molecule. This isotopic pattern filter utilizes the isotopic pattern of chlorinated organic compounds, that is, two signals with $\Delta m/z$ of 1.9970 u (±0.0030 u) and a relative intensity of $m + 2/m$ of at least 32%. Dehalogenation might occur during the plant metabolism of organic contaminants,[21−23] but it is unlikely that all three chlorine atoms are removed at once. It was essential to reduce the data matrix by mass defect filter and multivariate statistics prior to the application of the isotopic pattern filter. Otherwise, due to the complex mixture of coeluting matrix compounds, the sole application of the isotopic filter would have led to a large number of false positives because molecular ions of coeluting compounds appear as an isotopic pattern of chlorinated compounds.

The final step of the data processing was to arrange the m/z values according to their retention time and peak shape. This led to a further reduction of the number of potential triclosan metabolites, because several m/z values could be assigned as

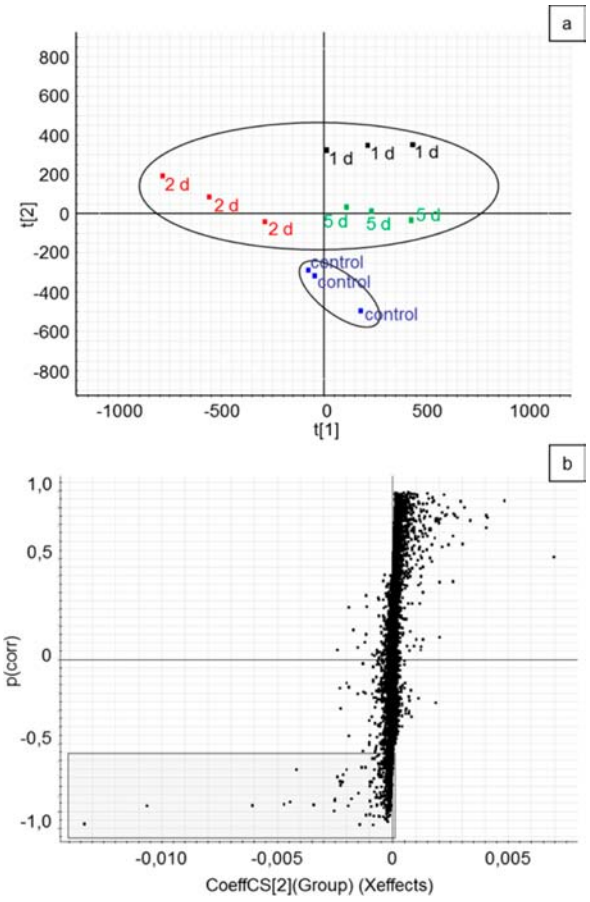

Figure 2. Score plot (a) of the principal component analysis of the acquired data set and S-plot (b) comparing the data from control and exposed (1, 2, and 5 days) horseradish cultures via orthogonal projection to latent structures discriminant analysis. The rectangle includes data that contribute significantly ($|p(\mathrm{corr})| > 0.5$) to the differentiation between extracts of control and treated cultures.

molecular ion, fragment ions, and adduct ions of one compound. Thirty-three potential triclosan metabolites were considered for structure elucidation. The same procedure was applied to the mass spectrometric data generated by positive ionization. However, the ion intensities of the triclosan metabolites obtained in positive mode were generally low, so that only abundant metabolites were visible and no additional metabolites were detected. Therefore, only data generated in negative mode are considered here.

Structure Elucidation. According to the fragmentation behavior of their molecular anions, these 33 metabolites were categorized into four groups.

Triclosan Sulfosaccharides (Group 1). The signal that contributes most to the differentiation between the extracts of exposed and control tissue cultures was detected at a retention time of 3.22 min (M9). The low collision energy mass spectrum of this compound shows a signal at m/z 694.9100 (Figure 3a) with the characteristic isotopic pattern of a trichlorinated compound and a mass 407.6967 u heavier than the parent triclosan. For this m/z a sum formula of $C_{21}H_{18}Cl_3O_{16}S_2$ was derived. The intensity of the molecular anion is very low, whereas the fragment ion at m/z 614.9544 is far more abundant. This fragment ion ($C_{21}H_{18}Cl_3O_{13}S$) arises from a neutral loss of 79.9556 u, corresponding to the loss of

SO_3 from a sulfate moiety of $[M - H]^-$. This is confirmed by a product ion at m/z of 96.9592 (HSO_4^-).

As visible from the high collision energy mass spectrum (Figure 3b), collision-induced fragmentation gave rise to a number of further fragment ions, of which some showed the trichloro isotopic pattern. The most intense fragment ion without chlorine substituent (m/z 327.0020; $C_9H_{11}O_{11}S$) arises from the neutral loss of triclosan (287.9524 u) from the $[M - HSO_3]^-$ ion. The corresponding triclosan fragment ion (m/z 286.9426) was also recorded, although with a very low relative intensity. This suggests that this metabolite was transformed solely at the phenolic moiety of triclosan. Further ions detected at m/z 283.0121 ($C_8H_{11}O_9S$) and 241.0019 ($C_6H_9O_8S$) are formed by the successive neutral losses of 43.9901 u ($-CO_2$) and 42.0109 u (− ketene, C_2H_2O). They point to a malonyl moiety. The remaining $C_6H_9O_8S$ fragment ion was assumed to be a sulfohexopyranose. The formation of a fragment ion of m/z 152.9854 via a retro-Diels−Alder cleavage suggests that C5 of the hexopyranose is sulfated. Therefore, this metabolite was tentatively identified as triclosan (malonylhexopyranosyl) disulfate, the suggested fragmentation pathway of which is given in Figure 4. Additionally, trichlorinated fragment ions were detected at m/z 570.9643 ($C_{20}H_{18}Cl_3O_{11}S$) and 528.9534 ($C_{18}H_{16}Cl_3O_{10}S$). These are formed by losses of 43.9901 and 42.0109 u from $[M - HSO_3]^-$, respectively, as has been analogously observed for the $C_9H_{11}O_{11}S$ fragment ion. Besides the very low abundant $[M - H]^-$ at m/z 694.9100, no further hints for the presence of two sulfate groups were detected. For comparison, the fragmentation behavior of the reference compound D-glucosamine 3,6-disulfate was studied. In agreement with the fragmentation pathway of M9, a very facile loss of SO_3 was observed already in the low collision energy mass spectrum of D-glucosamine 3,6-disulfate. This led to a molecular anion of low abundance but a rather prominent $[M - H - SO_3]^-$.

Analogous to this example, a total four sulfo- and disulfosaccharide conjugates of triclosan were tentatively identified by their mass spectra (Table 1). Among the most intensive ones was the triclosan hexopyranosyl sulfate (M18) as another example of a sulfated monosaccharide, eluting at 3.76 min.

Conjugation of organic contaminants with sulfate is very important for the animal xenobiotic metabolism. For plants, only a few studies exist on the formation of 2-*O*-sulfate glucosides and 6-*O*-sulfate glucosides.[24,25] Disulfated carbohydrate conjugates, however, have not been described so far. This may partly be due to their lability, which leads to the facile loss of one of the sulfate groups upon ionization.

Triclosan Saccharide and Sulfate Conjugates (Group 2). Besides the triclosan sulfosaccharide conjugates, which formed predominately fragment ions of the glycon moiety, an additional group of metabolites has been detected. Contrary to the sulfosaccharides, the collision-induced dissociation of their molecular anions gave rise almost exclusively to the triclosan fragment ion at m/z 286.9433 (calcd). One of these seven metabolites is M19, which eluted after 3.98 min and gave rise to a series of trichlorinated ions in its low collision energy mass spectrum (Figure 5a). Whereas the signal m/z 448.9952 ($C_{18}H_{16}Cl_3O_7$) was assigned to the molecular ion, m/z 484.9724, 495.0013, and 509.0170 were assigned to its chloride, formate, and acetate adducts, respectively. The molecular formula and mass gain of 162.0519 u compared to triclosan suggest that an anhydrohexose moiety was added, and M19 therefore is the triclosan hexoside. The preferred loss of the anhydrohexose moiety and formation of the aglycon (triclosan) anion is typical for glycoside conjugates.[26] In comparison to the metabolites of group 1, the hexoside lacks a sulfate group to stabilize the negative charge at the glycon moiety. The conjugation with hexose plays a central role in the proposed pathway of triclosan metabolism in the hairy root culture of horseradish and is crucial for the formation of almost all further metabolites (Figure 6).

By analogy, the molecular anions of the metabolites M10 and M14 were detected at m/z 611.0493 ($C_{24}H_{26}Cl_3O_{12}$) and m/z 595.0547 ($C_{24}H_{26}Cl_3O_{11}$), respectively. These point to additional hexose and desoxyhexose moieties and thus to the metabolites triclosan hexosyl hexoside (M10) and triclosan desoxyhexosyl hexoside (M14), respectively.

The molecular anion of M13 was detected at 3.44 min in the low collision energy mass spectrum at m/z 534.9968 ($C_{21}H_{18}Cl_3O_{10}$). This is 86.0016 u higher than that of the

[a]Metabolites are numbered according to their elution order. Metabolites that are supposed to be isomers are labeled with the adjuncts a–d. [b]Molecular anions and fragment ions whose detected m/z values led to no or more than one possible sum formula could not assigned.

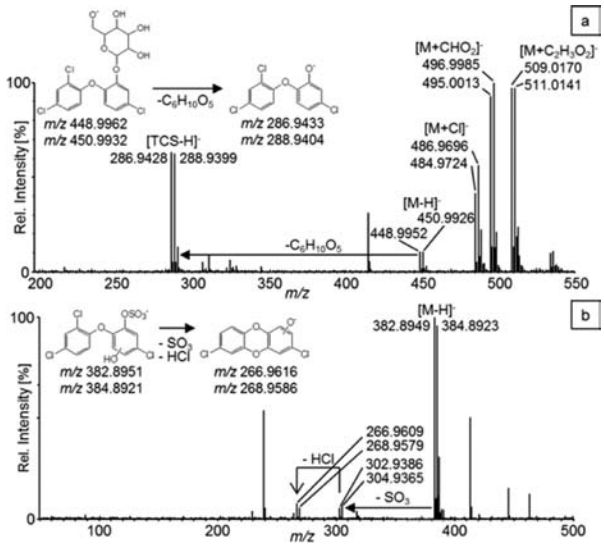

Figure 5. Low collision energy mass spectra (ESI neg) and proposed structure of (a) metabolite M19 tentatively identified as triclosan hexopyranoside and of (b) metabolite M22 tentatively identified as OH-triclosan sulfate.

triclosan hexoside. Additionally, an abundant signal of its dimeric anion $[2M-H]^-$ at m/z 1071.0035 was observed. The $[M-H]^-$ ion underwent a neutral loss of 43.9905 u (CO_2) to a fragment ion m/z 491.0063 ($C_{20}H_{18}Cl_3O_8$). Metabolite M13 was therefore tentatively identified as triclosan malonylhexoside. One metabolite that does not contain a carbohydrate moiety was M20 and eluted after 4.04 min. Its molecular anion at m/z 366.9006 corresponds to a sum formula of $C_{12}H_6Cl_3O_5S$ and gave rise also to the triclosan fragment ion. M20 was therefore assigned as triclosan sulfate and is one of two detected metabolites that are not conjugated with a hexose (Figure 6).

Hydroxytriclosan Conjugates (Group 3). In contrast to the previous two groups of metabolites, the mass spectra of a number of additional transformation products showed neither the triclosan fragment ion nor the neutral loss of triclosan. Rather, the fragmentation of most of these metabolites gave rise to only one fragment ion at m/z 266.9609 ($C_{12}H_5Cl_2O_3$) with the corresponding Cl_2 isotopic pattern. Because the molecular formulas and isotopic patterns of all corresponding molecular anions indicated trichlorinated metabolites, the fragment ion at m/z 266.9609 ($C_{12}H_5Cl_2O_3$) was interpreted as the dichlorodibenzodioxinol fragment ion, which was, likely, formed from

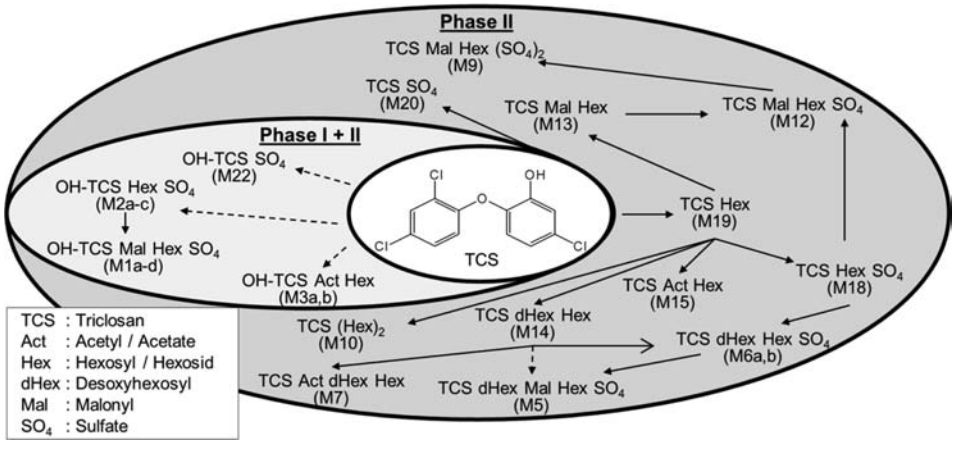

Figure 6. Proposed pathway of triclosan metabolization in hairy root cultures of horseradish. Dashed arrows represent multistep processes.

dx.doi.org/10.1021/jf404784q | J. Agric. Food Chem. 2014, 62, 1001–1009

the conjugates of hydroxylated triclosan (OH-triclosan) (Figure 5b). The likely precursor of this fragment ion, that is, the hydroxytriclosan fragment ion itself, was detected at m/z 302.9386 only for hydroxytriclosan sulfate (M22). Whereas the triclosan conjugates would also allow for ring closure upon HCl elimination, they would lack the additional hydroxy moiety to stabilize the negative charge of the anion.

Another fragmentation behavior of hydroxylated metabolites is observed for the metabolites M2 and M4, which form m/z 301.9306 ($C_{12}H_5Cl_3O_3$). This formula is consistent with a resonance-stabilized triclosan quinone radical anion. This nicely illustrates the diversity in mass spectrometric fragmentation behavior, which would have impeded the detection of all hydroxylated metabolites by a precursor ion scan. In sum, 11 hydroxylated triclosan metabolites with four different elemental compositions were detected and tentatively identified. Because their mass spectra show only a few diagnostic ions, the support for the proposed structures is low and no additional structural information can be obtained by formed fragment ions for more complex metabolites such as the OH-triclosan malonyl hexosyl sulfate M1. The introduction of an additional hydroxy group is expected to increase the polarity and, hence, to decrease the retention time during reversed phase chromatography of metabolites in comparison to nonhydroxylated ones. In contrast, the OH-triclosan sulfate eluted later than its nonhydroxylated equivalent.

The comparison of the peak intensities of hydroxylated and nonhydroxylated metabolites suggests that only a small portion of triclosan was subjected to phase I metabolism prior to conjugation. The ability of the horseradish culture to form hydroxylated species was already observed recently and can be ascribed to the existence of P450 monooxygenase in plant cells.[15] Except for the hydroxylated sulfate metabolite, several isomers (up to four) were formed for saccharide conjugates of OH-triclosan. However, with the fragment ions observed it was not possible to assign the sites of hydroxylation.

Despite this intensive study of the mass spectra generated at low and high collision energies, a total of 10 of the compounds recognized as triclosan metabolites could not be identified (Table 1, *group 4*). According to the m/z values and sum formula, respectively, three of these compounds contained nitrogen. As cysteine and glutathione conjugates might be formed during the plant metabolism, the sum formulas were examined to match respective structures, but no proper structure could be derived. For five of these unidentified compounds no sum formulas were determined from the exact m/z values of the molecular anions, because more than one probable sum formula was derived by the MassLynx 4.1 software.

Proposed Pathway of Triclosan Metabolism in Horseradish Hairy Root Cultures. A possible metabolic pathway for the formation of these 23 metabolites is provided in Figure 6. The detected metabolites are mainly pure phase II metabolites, that is, conjugates with endogenous compounds at the phenolic OH-group of triclosan. The conjugation of this OH-group with a hexose, probably β-D-glucose,[27] plays a central role, because the resulting triclosan hexoside (M19) is an intermediate for the formation of a number of further metabolites. The malonylation, acetylation, and sulfation of one OH-group of the glycon part gave rise to the malonylhexoside (M13), acetylhexoside (M15), and sulfohexoside (M18), respectively. Disaccharide conjugates such as M10 and M14 are formed by the glycosylation with one further hexose or desoxyhexose, respectively. Furthermore, products formed by combinations of these reactions were observed, such as the triclosan malonylsulfohexoside (M12), which upon further sulfation gives rise to triclosan malonyldisulfohexoside (M9). Even though the formation of sulfohexosides of contaminants was reported before, disulfation of hexose conjugates has not been observed, so far. Besides these metabolites, the triclosan sulfate (M20) is formed by the direct sulfation of the phenolic OH-group of triclosan and is one of the few metabolites that does not require the previous glycosylation. Besides this large number of metabolites, which are formed exclusively by a combination of phase II reactions, four conjugates of the phase I metabolite OH-triclosan were detected. Three of the OH-triclosan conjugates form two to four structural isomers as the detection of identical m/z values at several retention times indicates. In sum, the OH-triclosan conjugates had comparatively low signal intensities, and the phase I metabolite OH-triclosan itself was not detected. The phase I reactions seem to play a minor role in the entire metabolism of triclosan by the hairy root culture of horseradish. This may indicate that the conjugation reactions of triclosan with sulfate or a hexose are faster than the hydroxylation in the phase I metabolism. Nevertheless, this is the first report on the phase I metabolism of triclosan in plants.

The combination of phase I and II metabolism in plants may give rise to a complex mixture of structurally diverse metabolites of environmental contaminants of high and very low signal intensities. This emphasizes the need and usefulness of the reported strategy of an unbiased and comprehensive approach for sample analysis using UPLC-QToF-MS^E and data processing using statistical means. It reduces the risk of overlooking a part of the metabolites formed in a plant. Even though structure proposals could be derived for 23 of the 33 detected triclosan metabolites, about one-third remained unidentified. Further analytical effort would be required for their identification. The inclusion of this and similar analytical approaches to detect and identify metabolites into uptake studies of environmental contaminants into plants would provide a more comprehensive view on this issue. An important next challenge poses the quantification of these metabolites, as reference compounds are usually not available.

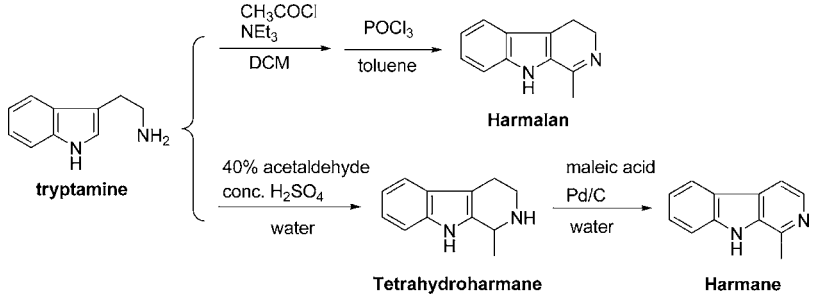
Scheme 1. Synthesis of Harmalan, Tetrahydroharmane, and Harmane



for 5 h. Then the mixture was washed with a saturated aqueous solution of $NaHCO_3$, dried over anhydrous Na_2SO_4, and filtered, and the solvent was removed under reduced pressure. The crude was dissolved in toluene (20 mL) and chloroform (20 mL), phosphorus oxychloride (3 mL) was added dropwise to the above solution, and then the mixture was heated at reflux for 7 h. The mixture was adjusted to pH 9 with a saturated aqueous solution of Na_2CO_3 after it was cooled to room temperature. The resulting solution was extracted with dichloromethane (3 × 20 mL), the combined organic phases were washed with brine (50 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo and purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 10:1) as eluent to give harmalan as a brown solid (0.35 g, 60%): mp = 180−183 °C (lit.[17] mp = 182−183 °C); ^{1}H NMR (400 MHz, $CDCl_3$) δ 9.47 (s, 1H, NH), 7.60 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.48 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 7.31 (t, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.16 (t, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 3.88 (t, $^3J_{HH}$ = 8.4 Hz, 2H, CH_2), 2.95 (t, $^3J_{HH}$ = 8.8 Hz, 2H, CH_2), 2.53 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{12}H_{13}N_2$ $(M + H)^+$ 185.1073, found 185.1077.

Synthesis of Tetrahydroharmane (1-Methyl-2,3,4,9-tetrahydro-1*H*-pyrido[3,4-*b*]indole).[18] To a solution of 40% aqueous solution of acetaldehyde (8.1 mL, 43.75 mmol) in water (250 mL) was added concentrated H_2SO_4 (5 drops), the mixture was stirred at room temperature for 0.5 h. Then tryptamine (3.50 g, 21.88 mmol) was added, and the mixture was heated at reflux for 7 h. The mixture was adjusted to pH 10 with an aqueous solution of NaOH after it was cooled to room temperature. The resulting solution was extracted with dichloromethane (3 × 100 mL), and the combined organic phase was washed with brine (200 mL), dried over anhydrous Na_2SO_4, filtered, concentrated in vacuo, and then purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 5:1) as eluent to give tetrahydroharmane as a brown solid (2.53 g, 62%): mp = 173−175 °C (lit.[19] mp = 177−178 °C); ^{1}H NMR (400 MHz, DMSO-d_6) δ 10.68 (s, 1H, NH), 7.35 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.27 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 6.98−7.02 (m, 1H, Ar−H), 6.91−6.95 (m, 1H, Ar−H), 3.99−4.04 (m, 1H, CHNH), 3.33 (s, 1H, CHNH), 3.14−3.19 (m, 1H, CH_2NH), 2.81−2.87 (m, 1H, CH_2NH), 2.51−2.62 (m, 2H, CH_2CH_2), 1.36 (d, $^3J_{HH}$ = 6.8 Hz, 3H, CH_3CH); HRMS (ESI) calcd for $C_{12}H_{15}N_2$ $(M + H)^+$ 187.1230, found 187.1231.

Synthesis of Harmane (1-Methyl-9*H*-pyrido[3,4-*b*]indole).[20] To a stirred solution of maleic acid (0.53 g, 4.57 mmol) in water at room temperature was added 1-methyl-2,3,4,9-tetrahydro-1*H*-pyrido-[3,4-*b*]indole (0.85 g, 4.57 mmol), and the mixture was stirred until the solid dissolved in water (120 mL); then Pd/C (0.85 g) was added, and the mixture was heated at reflux for 8 h. Then the mixture was cooled and filtered, and the filtered solid was washed carefully with water. The combined filtrates were adjusted to pH 9 with aqueous NaOH and then extracted with dichloromethane (3 × 50 mL), and the combined organic phases were washed with brine (100 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo to give harmane as a white solid (0.50 g, 60%): mp = 244−245 °C (lit.[21] mp = 235−238 °C); ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.41 (s, 1H, NH), 8.37 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 8.12 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.83 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 7.52−7.57 (m, 2H, Ar−H), 7.26−7.32 (m, 1H, Ar−H), 2.84 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{12}H_{11}N_2$ $(M + H)^+$ 183.0917, found 183.0915.

Synthesis of Quaternary Ammonium Salts 1. To a solution of harmine (0.50 g, 2.36 mmol) in ethyl acetate (120 mL) was added benzyl bromide (0.48 g, 2.83 mmol), and the mixture was heated at reflux for 12 h. Then the mixture was cooled and filtered, and the filter cake was washed with ethyl acetate and dried to give **1** as a white solid (0.67 g, 74%): mp = 276−277 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.78 (s, 1H, NH), 8.74 (d, $^3J_{HH}$ = 6.4 Hz, 1H, Ar−H), 8.58 (d, $^3J_{HH}$ = 6.8 Hz, 1H, Ar−H), 8.37 (d, $^3J_{HH}$ = 8.8 Hz, 1H, Ar−H), 7.35−7.44

dx.doi.org/10.1021/jf404840x | J. Agric. Food Chem. 2014, 62, 1010−1018

(m, 3H, Ar−H), 7.23 (d, $^3J_{HH}$ = 7.2 Hz, 2H, Ar−H), 7.12 (d, $^4J_{HH}$ = 1.0 Hz, 1H, Ar−H), 7.08 (dd, $^3J_{HH}$ = 8.8 Hz, $^4J_{HH}$ = 1.0 Hz, 1H, Ar−H), 5.98 (s, 2H, CH_2), 3.95 (s, 3H, OCH_3), 2.98 (s, 3H, CH_3).

Synthesis of 2-Benzyl-7-methoxy-1-methyl-2,3,4,9-tetrahydro-1*H*-pyrido[3,4-*b*]indole (2). To a solution of **1** (0.67 g, 1.75 mmol) in methanol (150 mL) was added dropwise sodium borohydride (0.53 g, 14.00 mmol) in methanol (30 mL), and then the mixture was heated at reflux for 15 h. The solvent was distilled off, and the residue was diluted with dichloromethane (2 × 50 mL) and water (50 mL); the combined organic phase was washed with brine (50 mL), dried over anhydrous Na_2SO_4, filtered, concentrated in vacuo, and purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 5:1) as eluent to give **2** as a brown oil (0.47 g, 88%): ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.68 (s, 1H, NH), 7.50−7.52 (m, 2H, Ar−H), 7.43−7.47 (m, 3H, Ar−H), 7.36−7.40 (m, 1H, Ar−H), 6.90 (dd, $^3J_{HH}$ = 8.8 Hz, $^4J_{HH}$ = 2.4 Hz, 1H, Ar−H), 6.83 (d, $^4J_{HH}$ = 2.4 Hz, 1H, Ar−H), 3.97 (d, $^2J_{HH}$ = 13.6 Hz, 1H, $CH_2C_6H_5$), 3.81 (q, $^3J_{HH}$ = 6.8 Hz, 1H, $CHCH_3$), 3.77 (d, $^2J_{HH}$ = 13.6 Hz, 1H, $CH_2C_6H_5$), 3.22−3.29 (m, 1H, CH_2CH_2), 2.85−2.95 (m, 2H, CH_2CH_2), 2.68−2.74 (m, 1H, CH_2CH_2), 1.61 (d, $^3J_{HH}$ = 6.8 Hz, 1H, $CHCH_3$).

Synthesis of 7-Methoxy-1-methyl-2,3,4,4a,9,9a-hexahydro-1*H*-pyrido[3,4-*b*]indole (3).[22] To a solution of **2** (0.70 g, 2.29 mmol) in 2,2,2-trifluoroethanol (120 mL) was added Pd/C (0.70 g), and then the reaction system was evacuated and purged with hydrogen three times; the mixture was stirred in a hydrogen atmosphere overnight at room temperature. The mixture was concentrated in vacuo and purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 10:1) as eluent to give **3** as a pale yellow solid (0.37 g, 74%): mp = 158−160 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 6.93 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 6.31 (dd, $^3J_{HH}$ = 8.0 Hz, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 6.26 (d, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 3.76 (s, 3H, OCH_3), 3.49 (s, 1H, NH), 3.39−3.45 (m, 1H, $CHCH_3$), 3.35 (t, $^3J_{HH}$ = 8.4 Hz, 1H, CH), 2.97−3.02 (m, 1H, CH), 2.69−2.72 (m, 1H, CH_2), 2.53−2.60 (m, 1H, CH_2), 2.08−2.20 (m, 2H, CH_2NH), 1.26 (s, 1H, NH), 1.23 (d, $^3J_{HH}$ = 6.4 Hz, 3H, CH_3); HRMS (ESI) calcd for $C_{13}H_{19}N_2O$ $(M + H)^+$ 219.1492, found 219.1494.

Data for 7-Methoxy-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole (Tetrahydroharmine). The compound was synthesized using a similar procedure as for compound **3**; the mixture was stirred for 3 h to give tetrahydroharmine as a white solid (0.56 g, 80%): mp = 195−197 °C (lit.[23] mp = 198−200 °C); ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.64 (s, 1H, NH), 7.35 (d, $^3J_{HH}$ = 8.8 Hz, 1H, Ar−H), 6.85 (d, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 6.77 (dd, $^3J_{HH}$ = 8.4 Hz, $^4J_{HH}$ = 2.4 Hz, 1H, Ar−H), 4.14−4.19 (m, 1H, $CHCH_3$), 3.84 (s, 3H, OCH_3), 3.33−3.39 (m, 1H, CH_2CH_2), 3.01−3.07 (m, 1H, CH_2CH_2), 2.66−2.78 (m, 2H, CH_2CH_2), 1.65 (s, 1H, NH), 1.44 (d, $^3J_{HH}$ = 6.8 Hz, 3H, CH_3); HRMS (ESI) calcd for $C_{13}H_{17}N_2O$ $(M + H)^+$ 217.1335, found 217.1337.

Synthesis of Compounds 4 and 5.[24] To a solution of harmane (0.20 g, 1.10 mmol) in glacial acetic acid (10 mL) was added NBS (0.20 g, 1.10 mmol) at room temperature, and the mixture was stirred at room temperature for 6 h. Then the mixture was concentrated under reduced pressure and adjusted to pH 10 with an aqueous solution of $NaHCO_3$, and the aqueous solution was extracted with dichloromethane (20 mL × 4). The combined organic layer was dried over anhydrous Na_2SO_4 and then was concentrated in vacuo and purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 40:1→20:1) as eluent to give **4** (0.24 g) and **5** (0.05 g).

6-Bromo-1-methyl-9H-pyrido[3,4-b]indole (4). This compound was obtained as a white solid in 83% yield: mp = 256−257 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.44 (s, 1H, NH), 8.39 (d, $^3J_{HH}$ = 5.6 Hz, 1H, Ar−H), 8.24 (d, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 7.78 (d, $^3J_{HH}$ = 5.6 Hz, 1H, Ar−H), 7.63 (dd, $^3J_{HH}$ = 8.4 Hz, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 7.42 (d, $^3J_{HH}$ = 8.8 Hz, 1H, Ar−H), 2.83 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{12}H_{10}BrN_2$ $(M + H)^+$ 261.0022, found 261.0026.

8-Bromo-1-methyl-9H-pyrido[3,4-b]indole (5). This compound was obtained as a yellow solid in 17% yield: mp = 201−204 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.36−8.49 (m, 2H, NH and Ar−H), 8.05 (d, $^3J_{HH}$ = 6.4 Hz, 1H, Ar−H), 7.80 (s, 1H, Ar−H), 7.70 (d, $^3J_{HH}$ = 6.4 Hz, 1H, Ar−H), 7.18 (t, $^3J_{HH}$ = 6.4 Hz, 1H, Ar−H), 2.88 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{12}H_{10}BrN_2$ $(M + H)^+$ 261.0022, found 261.0025.

Synthesis of Compounds 6 and 7.[25] To a mixture of harmane (0.40 g, 2.20 mmol) and sodium nitrate (0.93 g, 10.99 mmol) was added dropwise trifluoroacetic acid (20 mmol) at 0 °C, and then the mixture was stirred overnight at room temperature. The mixture was adjusted to pH 10−11 with an aqueous solution of $NaHCO_3$ in an ice bath and then was extracted by dichloromethane (20 mL × 3). The combined organic phase was concentrated in vacuo and purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 20:1) as eluent to give **6** (0.24 g) and **7** (0.06 g) .

1-Methyl-6-nitro-9H-pyrido[3,4-b]indole (6). This compound was obtained as a pale yellow solid in 72% yield: mp > 300 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.36 (s, 1H, NH), 9.30 (d, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 8.41 (dd, $^3J_{HH}$ = 8.8 Hz, $^4J_{HH}$ = 3.0 Hz, 1H, Ar−H), 8.33 (d, $^3J_{HH}$ = 5.6 Hz, 1H, Ar−H), 8.20 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 7.73 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 2.79 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{12}H_{10}N_3O_2$ $(M + H)^+$ 228.0768, found 228.0767.

1-Methyl-8-nitro-9H-pyrido[3,4-b]indole (7). This compound was obtained as a yellow solid in 12% yield: mp = 207−210 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.77 (s, 1H, NH), 8.77 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 8.50 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 8.38 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 8.11 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 7.48 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 2.92 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{12}H_{10}N_3O_2$ $(M + H)^+$ 228.0768, found 228.0772.

Synthesis of Harmol (1-Methyl-9*H*-pyrido[3,4-*b*]indol-7-ol). A solution of harmine (0.50 g, 2.36 mmol) in glacial acetic acid (18 mL) and 40% hydrobromic acid solution (18 mL) was stirred at room temperature for 1 h, and then the mixture was heated at reflux for 10 h. After cooling to room temperature, the mixture was adjusted to pH 8 with a saturated aqueous solution of $NaHCO_3$. The yellow slurry was filtered, and the cake was washed with water to afford harmol as a yellow solid (0.46 g, 98%): mp > 300 °C (lit.[26] mp = 304−307 °C); ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.24 (s, 1H, NH), 9.72 (s, 1H, OH), 8.11 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 7.94 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.75 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 6.90 (d, $^4J_{HH}$ = 1.2 Hz, 1H, Ar−H), 6.69 (dd, $^3J_{HH}$ = 8.4 Hz, $^4J_{HH}$ = 1.6 Hz, 1H, Ar−H), 2.69 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{12}H_{11}N_2O$ $(M + H)^+$ 199.0866, found 199.0867.

Synthesis of 1-Methyl-9*H*-pyrido[3,4-*b*]indol-7-yl isopropylcarbamate (8).[27] To a solution of harmol (0.50 g, 2.53 mmol) in DMF (50 mL) was added isopropyl isocyanate via syringe over 5 min, the mixture was stirred at room temperature for 2 h, then triethylamine (0.08 g, 0.758 mmol) was added, and the mixture was stirred overnight at room temperature. Then brine (100 mL) was added, the aqueous solution was extracted with ethyl acetate (20 mL × 4), and the combined organic layer was dried over anhydrous Na_2SO_4, concentrated in vacuo, and purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 20:1) as eluent to give **8** as a pale white solid (0.50 g, 70%): mp > 300 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.58 (s, 1H, NH), 8.20 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 8.16 (d, $^3J_{HH}$ = 8.8 Hz, 1H, Ar−H), 7.90 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 7.76 (d, $^3J_{HH}$ = 8.0 Hz, 1H, NHCO), 7.27 (d, $^4J_{HH}$ = 1.6 Hz, 1H, Ar−H), 6.95 (dd, $^3J_{HH}$ = 8.4 Hz, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 3.65−3.73 (m, 1H, CH), 2.75 (s, 3H, CH_3), 1.16 (d, $^3J_{HH}$ = 6.4 Hz, 6H, $(CH_3)_2CH$); HRMS (ESI) calcd for $C_{16}H_{18}N_3O_2$ $(M + H)^+$ 284.1394, found 284.1399.

Synthesis of 1-Methyl-9*H*-pyrido[3,4-*b*]indol-7-yl dimethylcarbamate (9). To a solution of harmol (0.40 g, 2.02 mmol) in THF (150 mL) was added triethylamine (0.31 g, 3.03 mmol), and the mixture was stirred for 0.5 h. Then dimethylcarbamic chloride was added dropwise, and the mixture was stirred overnight at room temperature. Then water (20 mL) and dichloromethane (20 mL) were added. The separated organic layer was dried over anhydrous Na_2SO_4, filtered, concentrated in vacuo, and then purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 10:1) as eluent to give **9** as a pale white solid (0.48 g, 89%): mp = 225−227 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.63 (s, 1H, NH),

8.20 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 8.17 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 7.91 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 7.30 (d, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 6.97 (dd, $^3J_{HH}$ = 8.4 Hz, $^4J_{HH}$ = 2.0 Hz, 1H, Ar−H), 3.10 (s, 3H, CH_3), 2.94 (s, 3H, CH_3), 2.75 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{15}H_{16}N_3O_2$ (M + H)$^+$ 270.1237, found 270.1240.

Compounds **10** and **11** were synthesized using a procedure similar to that used for compound **9**.

Data for 1-Methyl-9H-pyrido[3,4-b]indol-7-yl acetate (10). This compound was obtained as a white solid in 50% yield: mp = 237−240 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.90 (s, 1H, NH), 8.23 (d, $^3J_{HH}$ = 2.4 Hz, 1H, Ar−H), 7.78 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 7.70 (d, $^3J_{HH}$ = 2.0 Hz, 1H, Ar−H), 7.16 (s, 1H, Ar−H), 6.93 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 2.76 (s, 3H, CH_3), 2.42 (s, 3H, CH_3CO); HRMS (ESI) calcd for $C_{14}H_{13}N_2O_2$ (M + H)$^+$ 241.2647, found 241.2650.

Data for Synthesis of 1-Methyl-9H-pyrido[3,4-b]indol-7-yl pivalate (11). This compound was obtained as a white solid in 85% yield: mp = 221−222 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.68 (s, 1H, NH), 8.30 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 7.75 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 7.54 (d, $^3J_{HH}$ = 4.8 Hz, 1H, Ar−H), 7.09 (s, 1H, Ar−H), 6.86 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 2.73 (s, 3H, CH_3), 1.45 (s, 9H, $C(CH_3)_3$); HRMS (ESI) calcd for $C_{17}H_{19}N_2O_2$ (M + H)$^+$ 283.1441, found 283.1446.

Synthesis of (*S*)-1-Methyl-9*H*-pyrido[3,4-*b*]indol-7-yl-2-(benzyloxycarbonylamino)-3-methylbutanoate (12). To a solution of amino acid (0.80 g, 3.03 mmol) in dichloromethane (150 mL) was added triethylamine (0.41 g, 4.04 mmol), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDCI) (0.76 g, 4.04 mmol), and DMAP (0.50 g, 4.04 mmol), and then the mixture was stirred overnight at room temperature. The mixture was washed with a saturated aqueous solution of NH_4Cl (50 mL × 2) and a saturated aqueous solution of $NaHCO_3$ (50 mL) successively, dried over anhydrous Na_2SO_4, filtered, concentrated in vacuo, and then purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 20:1) as eluent to give **12** as a pale white solid (0.80 g, 90%): mp = 69−71 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.54 (s, 1H, NH), 8.34 (d, $^3J_{HH}$ = 5.2 Hz, 1H, Ar−H), 7.92 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 7.66 (d, $^3J_{HH}$ = 4.8 Hz, 1H, Ar−H), 7.35−7.38 (m, 5H, Ar−H), 7.19 (s, 1H, Ar−H), 6.94 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 5.39 (d, $^3J_{HH}$ = 8.4 Hz, 1H, NHCO), 5.17 (s, 2H, CH_2), 4.54−4.66 (m, 1H, CHNH), 2.77 (s, 3H, CH_3), 2.38−2.50 (m, 1H, $CH(CH_3)_2$), 1.14 (d, $^3J_{HH}$ = 6.8 Hz, 3H, $CH(CH_3)_2$), 1.09 (d, $^3J_{HH}$ = 6.8 Hz, 3H, $CH(CH_3)_2$); HRMS (ESI) calcd for $C_{25}H_{26}N_3O_4$ (M + H)$^+$ 432.1918, found 432.1920.

Synthesis of (1*S*,3*S*)-1-Methyl-2,3,4,9-tetrahydro-1*H*-pyrido-[3,4-*b*]indole-3-carboxylic acid (13).[28] To a solution of L-tryptophan (20.00 g, 98.0 mmol) in water (500 mL) were added concentrated H_2SO_4 (2 mL) and a 40% aqueous solution of acetaldehyde (20 mL) successively, and the mixture was stirred overnight at room temperature. Then the mixture was adjusted to pH 6−7 with ammonia solution (25−28%, w/w), and a white solid precipitated. The white slurry was filtered, and the cake was washed with water to afford **13** as a white solid (16.7 g, 74%): mp = 278−280 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.11 (s, 1H, COOH), 7.45 (d, $^3J_{HH}$ = 7.8 Hz, 1H, Ar−H), 7.34 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.09 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.00 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 4.52 (q, $^3J_{HH}$ = 6.4 Hz, 1H, CH), 3.61 (dd, $^3J_{HH}$ = 11.6 Hz, $^3J_{HH}$ = 4.4 Hz, 1H, CH), 3.16 (dd, $^2J_{HH}$ = 16.0 Hz, $^3J_{HH}$ = 4.0 Hz, 1H, CH_2), 2.74−2.81 (m, 1H, CH_2), 1.62 (d, $^3J_{HH}$ = 6.4 Hz, 3H, CH_3); (dr = 11.7:1); HRMS (ESI) calcd for $C_{13}H_{15}N_2O_2$ (M + H)$^+$ 231.1128, found 231.1132.

Synthesis of Ethyl (1*S*,3*S*)-1-Methyl-2,3,4,9-tetrahydro-1*H*-pyrido[3,4-*b*]indole-3-carboxylate (14). To a solution of acid **13** (16.0 g, 69.0 mmol) in ethanol (500 mL) was added dropwise thionyl chloride in an ice bath, and then the mixture was heated at reflux for 5 h. The solvent was distilled off, the residue was dissolved in water (250 mL), and then the mixture was adjusted to pH 9 with an aqueous solution of $NaHCO_3$. The aqueous was extracted by ethyl acetate (150 mL × 3), the combined organic phase was washed with brine and dried over anhydrous Na_2SO_4, and then the mixture was concentrated in vacuo to give **14** as a light yellow solid (16.40 g, 92%): mp = 136−137 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.86 (s, 1H, NH), 7.49 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.33 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.17 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.11 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 4.26−4.31 (m, 3H, CH and OCH_2), 3.81 (dd, $^3J_{HH}$ = 11.2 Hz, $^3J_{HH}$ = 4.4 Hz, 1H, CH), 3.13 (dd, $^2J_{HH}$ = 15.2 Hz, $^3J_{HH}$ = 4.0 Hz, 1H, CH_2), 2.79−2.86 (m, 1H, CH_2), 1.52 (d, $^3J_{HH}$ = 6.4 Hz, 3H, CH_3), 1.35 (t, $^3J_{HH}$ = 7.2 Hz, 3H, OCH_2CH_3); HRMS (ESI) calcd for $C_{15}H_{19}N_2O_2$ (M + H)$^+$ 259.1441, found 259.1443.

Synthesis of Ethyl 1-Methyl-9*H*-pyrido[3,4-*b*]indole-3-carboxylate (15).[29] A mixture of **14** (12.4 g, 47.7 mmol) and sulfur (3.10 g, 95.4 mmol) in xylene (150 mL) was heated at reflux for 12 h. Then the mixture was cooled to 0 °C and kept for 1 h, dichloromethane (10 mL) was added to the mixture, and pink solid was precipitated. The mixture was filtered, and the cake was washed with toluene to afford **15** as a brown solid (8.40 g, 69%): mp = 217−219 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 9.60 (s, 1H, NH), 8.79 (s, 1H, Ar−H), 8.18(d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.54−7.60 (m, 2H, Ar−H), 7.32−7.36 (m, 1H, Ar−H), 4.50 (d, $^3J_{HH}$ = 6.8 Hz, 2H, OCH_2), 2.79 (s, 3H, CH_3), 1.41 (t, $^3J_{HH}$ = 7.2 Hz, 3H, OCH_2CH_3); HRMS (ESI) calcd for $C_{15}H_{15}N_2O_2$ (M + H)$^+$ 255.1128, found 255.1131.

Synthesis of 1-Methyl-9*H*-pyrido[3,4-*b*]indole-3-carboxylic acid (16). To a solution of ester **15** (2.00 g, 7.87 mmol) in alcohol (60 mL) was added NaOH (0.47 g, 11.81 mmol) in portions, and then the mixture was heated at reflux for 6 h. Then the mixture was concentrated under reduced pressure, the residue was dissolved in water (50 mL), and the aqueous solution was extracted by diethyl ether (50 mL × 2). Then the solution was adjusted to pH 5−6 with an aqueous solution of diluted hydrochloric acid (3 M), the slight yellow slurry was filtered, and the cake was washed with water to afford **16** as a yellow solid (1.46 g, 82%): mp > 300 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.04 (s, 1H, COOH), 8.77 (s, 1H, Ar−H), 8.36 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.66 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.60 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.30 (d, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.31 (d, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 2.82 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{13}H_{11}N_2O_2$ (M + H)$^+$ 227.0815, found 227.0811.

Synthesis of (1-Methyl-9*H*-pyrido[3,4-*b*]indol-3-yl)methanol (17). To a solution of ester **15** (2.00 g, 7.40 mmol) in THF (300 mL) was added $LiAlH_4$ (0.60 g, 15.7 mmol) in portions at 0 °C, and then the mixture was stirred overnight at room temperature. Then the reaction was quenched by water, and methanol (100 mL) was added. After the mixture had been stirred at room temperature for 2 h, the slurry was filtered, the cake was washed with dichloromethane, the filtrate was concentrated to afford **17** as a yellow solid (1.58 g, 95%): mp = 195−197 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.46 (s, 1H, NH), 8.19 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.95 (s, 1H, Ar−H), 7.56 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.49−7.53 (m, 1H, Ar−H), 7.18−7.22 (m, 1H, Ar−H), 5.30 (t, $^3J_{HH}$ = 6.0 Hz, 1H, OH), 4.67 (d, $^3J_{HH}$ = 6.0 Hz, 2H, CH_2OH), 2.73 (s, 3H, CH_3).

Synthesis of 1-Methyl-9*H*-pyrido[3,4-*b*]indole-3-carbaldehyde (18). The mixture of alcohol **17** (1.16 g, 5.47 mmol) and IBX (3.04 g, 10.93 mmol) in DMSO (60 mL) was stirred overnight at room temperature. After water (200 mL) and dichloromethane (50 mL × 3) were added, the separated organic layer was dried over anhydrous Na_2SO_4, filtered, concentrated in vacuo, and purified by flash chromatography on silica gel using dichloromethane and methanol (v/v = 10:1) as eluent to give **18** as a white solid (0.46 g, 40%): mp = 194−196 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.17 (s, 1H, NH), 10.07 (s, 1H, CHO), 8.68 (s, 1H, Ar−H), 8.38 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.68 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.61 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.33 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 2.87 (s, 3H, CH_3).

Synthesis of (*E*)-3-(1-Methyl-9*H*-pyrido[3,4-*b*]indol-3-yl)-acrylic acid (19). To a solution of aldehyde **18** (0.45 g, 2.14 mmol) and piperidine (3 drops) in pyridine was added malonic acid (0.33 g, 3.21 mmol), and the reaction mixture was heated at 120 °C for 4 h. Then the mixture was concentrated in vacuo, water was added (50 mL), the pH was adjusted to 11−12 with an aqueous solution of NaOH, and then the mixture was extracted with diethyl ether. The aqueous phase was adjusted to pH 5−6 with dilute hydrochloric acid (3 M), the yellow slurry was filtered, and the cake was washed with water to afford **19** as a yellow solid (0.51 g, 94%): mp = 220−223 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.22 (s, 1H, NH), 11.85 (s, 1H, COOH), 8.31 (s, 1H,

Ar−H), 8.21 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.72 (d, $^3J_{HH}$ = 15.2 Hz, 1H, CHCH), 7.62 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.56 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.28 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 6.78 (d, $^3J_{HH}$ = 15.6 Hz, 1H, CHCH), 2.80 (s, 3H, CH_3); HRMS (ESI) calcd for $C_{15}H_{13}N_2O_2$ $(M + H)^+$ 253.0972, found 253.0975.

Compounds **20** and **21** were synthesized using a procedure similar to that used for compound **19**.

*Data for (E)-3-(1-(Thiophen-2-yl)-9H-pyrido[3,4-b]indol-3-yl)-acrylic acid (**20**).* This compound was obtained as a yellow solid in 85% yield: mp = 248−250 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.43 (s, 1H, NH), 12.10 (s, 1H, COOH), 8.47 (s, 1H, Ar−H), 8.28 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 8.17 (d, $^3J_{HH}$ = 3.2 Hz, 1H, Ar−H), 7.80 (d, $^3J_{HH}$ = 4.8 Hz, 1H, Ar−H), 7.77−7.80 (m, 2H, Ar−H), 7.62 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.33−7.38 (m, 2H, Ar−H and CHCH), 6.88 (d, $^3J_{HH}$ = 15.6 Hz, 1H, CHCH), 6.93 (d, $^3J_{HH}$ = 15.6 Hz, 1H, CHCH); HRMS (ESI) calcd for $C_{18}H_{13}N_2O_2S$ $(M + H)^+$ 321.0692, found 321.0694.

*Data for (E)-3-(1-(Pyridin-3-yl)-9H-pyrido[3,4-b]indol-3-yl)acrylic acid (**21**).* This compound was obtained as a yellow solid in 50% yield: mp > 300 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.43 (s, 1H, NH), 12.10 (s, 1H, COOH), 9.31 (d, $^4J_{HH}$ = 1.6 Hz, 1H, Ar−H), 8.81 (dd, $^3J_{HH}$ = 4.8 Hz, $^4J_{HH}$ = 1.2 Hz, 1H, Ar−H), 8.61 (s, 1H, Ar−H), 8.56−8.59 (m, 1H, Ar−H), 8.31 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.84 (d, $^3J_{HH}$ = 15.6 Hz, 1H, CHCH), 7.76 (dd, $^3J_{HH}$ = 7.6 Hz, $^4J_{HH}$ = 4.8 Hz, 1H, Ar−H), 7.70 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.62 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.35 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 6.93 (d, $^3J_{HH}$ = 15.6 Hz, 1H, CHCH); HRMS (ESI) calcd for $C_{19}H_{14}N_3O_2$ $(M + H)^+$ 316.1081, found 316.1079.

Biological Assay. The anti-TMV and fungicidal activities of the synthesized compounds were tested using our previously reported methods.[30,31]

RESULTS AND DISCUSSION

Synthesis. Harmalan and tetrahydroharmane were obtained from tryptamine by Bischler−Napieralski and Pictet−Spengler reaction, respectively. Tetrahydroharmane was oxidized using the Pd/C−maleic acid system in water to give harmane in 60% yield (Scheme 1).

In the synthesis of Tetrahydroharmine, harmine was used as starting material. First, harmine was reacted with benzyl bromide to give a quaternary ammonium salt **1** in 74% yield, then it was reduced by sodium borohydride to give tetrahydrocarboline **2** in 88% yield, and finally tetrahydroharmine was obtained from **2** by debenzylation using palladium−carbon and hydrogen. The reaction time of debenzylation should be controlled at <3 h. Otherwise, the product will be over-reduced to give hexahydro-1*H*-pyridoindole **3**. When the reaction time was extended to 12 h, the product was converted into **3** completely (Scheme 2). In Scheme 3, the bromination and nitration products were synthesized from harmane using the reported methods.[22−24]

Harmol can be obtained from harmnine by a demethylation reaction (Scheme 4). It was reported that the demethylation reaction of harmine could be processed by BBr_3 in chloroform, but the reaction yield was low (<30%).[32] This was because of the poor solubility of harmine in conventional demethylation solvent (dichloromethane, chlorobenzene, etc.); thus, the demethylation reaction was very slow and incomplete. Therefore, in our trial on the demethylation of harmine, glacial acetic acid and 40% (m/m) aqueous hydrobromic acid (v/v = 1:1) were used instead of chloroform, and harmol was obtained in 98% yield, which was used in the synthesis of *O*-substituent derivatives **8**−**12** at the 7-position.

To investigate the influence of the degree of unsaturation of the C ring and the substituents at 3-position on the anti-TMV

activities, compounds **13−16** and **19−21** were synthesized using the method showed in Scheme 5.

Antiviral Activities. Most of the tested compounds displayed good antiviral activity in vitro, of which harmane, harmalan, tetrahydroharmane, tetrahydroharmine, and **14** exhibited higher inhibition than Ribavirin (Table 1). When the C ring (Figure 3) was dihydropyridine or tetrahydropyridine, the activities of these compounds were obviously higher than that of the compounds containing a pyridine moiety. For instance, the activities of harmalan, tetrahydroharmane, and tetrahydroharmine were 58.6, 63.7, and 58.2%, respectively, at 500 μg/mL, which were much higher than that of Ribavirin (40% at 500 μg/mL), whereas the activity of harmine was 44.6% at 500 μg/mL. The activity of tetrahydro-β-carboline **14** was 46.5%

at 500 μg/mL, whereas the activity of the corresponding β-carboline compound **15** was 33.3% at the same concentration. When tetrahydroharmine was further reduced to hexahydroharmine (**3**), the activity (41.9%, 500 μg/mL) was also reduced.

When the skeleton was β-carboline (C ring was pyridine) (Figure 3), it was detrimental to anti-TMV activity when a substituent was introduced to the benzene ring (A ring). For example, the in vitro activity of compound with no substituent on the benzene ring (harmane) was 54.5% at 500 μg/mL, whereas the activity was reduced to 44.6 and 32.6% when a methoxy (harmine) or a hydroxy (harmol) group was introduced to the 7-position. The derivatives of harmol (**8**−**11**) exhibited the same or lower activities against TMV compared with harmol. For the compound containing a carbamate moiety, the substituents on the nitrogen of amide had an obvious effect on the activity; the activity of a compound containing isopropylamino (**8**) (31.3%, 500 μg/mL) was better than that of a compound containing dimethylamino (**9**) (12.6%, 500 μg/mL). For the compounds containing an ester structure, the spatial arrangement of the substituents might have an impact on anti-TMV activity of the compounds, as the activity of compound containing acetyl (**10**) was 30% at 500 μg/mL, whereas when the substituent was changed to pivaloyl (**11**), the compound exhibited no activity against TMV. The activity of compound containing a bromo at 6-position (**4**) was equivalent to that of Ribavirin (40% at 500 μg/mL); when the substituent was changed to nitro at 6- or 8-position (**6** and **7**), the activities were reduced to 15.7 and 30% at 500 μg/mL, respectively.

The substituents on the 3-position of the β-carbolines or tetrahydro-β-carbolines played an important role in the activities. The activities of compounds containing ethyl formate (**14**) at the 3-position were better than that of compounds containing carboxylic acid (**13** and **16**) and acroleic acid (**19**−**21**). Among **19**−**21**, the substituents on the 1-position also had different effects on the antiviral activity; the 2-thienyl compound (**20**) was better than the methyl (**19**) and 3-pyridyl (**21**) compounds.

Further bioassay was conducted to investigate their inactivation, curative, and protection effects in vivo (Table 2). The result showed that most of the compounds exhibited good to excellent antiviral activity and similar structure−activity relationships to the activity in vitro. Harmane, harmalan, tetrahydroharmane, tetrahydroharmine, **3**, **4**, and **14** exhibited higher activities than Ribavirin; especially the activities of compounds harmalan (62.3, 55.1, and 60.3% at 500 μg/mL) and tetrahydroharmane (64.2, 57.2, and 59.5% at 500 μg/mL)

[a]*F.C, Fusarium oxysporium* f. sp.*cucumeris*; *C.H, Cercospora arachidicola* Hori; *P.P, Physalospora piricola*; *A.S, Alternaria solani*; *F.G, Fusarium graminearum*; *F.M, Fusarium moniliforme*; *S.S, Sclerotinia sclerotiorum*; *P.C, Phytophthora capsici*; *R.C, Rhizoctonia cerealis*; *B.M, Bipolaris maydis*; *W.A,* watermelon anthracnose; P.I, *Phytophthora infestans*; *R.S, Rhizoctonia solani*; *B.C, Botrytis cinerea*.

were much higher than that of Ribavirin (37.4, 36.2, and 38.5% at 500 μg/mL); harmine, harmol, **7**, and **20** showed activities comparable to that of Ribavirin. It was interesting that the compound containing an ester on the 3-position (**14**) exhibited obviously higher activities (50.4, 43.9, and 47.9% at 500 μg/mL) than compounds having other substituents on the 3-position. In consideration of the better solubility and stability of compound **14**, it can be used as a new lead structure for further development of anti-TMV reagents.

Fungicidal Activities. These alkaloids and their derivatives also exhibited good fungicidal activities against 14 kinds of plant fungi (Table 3). When the C ring was pyridine, the compounds exhibited higher activities than those with dihydropyridine or tetrahydropyridine as the C ring. When the skeleton was β-carboline (C ring was pyridine), the types and positions of the substituents on the benzene ring (A ring) had a significant influence on the fungicidal activities. For instance, compound **7** (1-methyl-8-nitro-9*H*-pyrido[3,4-*b*]indole) exhibited excellent fungicidal activity against most of the tested fungi, whereas compound **6** (1-methyl-6-nitro-9*H*-pyrido[3,4-*b*]indole) exhibited only moderate activity; compound **11**, containing a pivaloyloxy group, exhibited higher fungicidal activity than the compound containing acetoxy (**10**). Some of these compounds selectively exhibited fungicidal activities to certain fungi. For example, the activities of harmane (against *Cercospora arachidicola* Hori) and compound **3** (against *Physalospora piricola*) were >90%, which was much higher than that against other fungi.

In summary, 6 known β-carboline, dihydro-β-carboline, or tetrahydro-β-carboline alkaloids and a series of their derivatives were designed, synthesized, and first assayed for their anti-TMV activities both in vitro and in vivo and for their fungicidal activity against 14 fungi. All of the compounds exhibited good to excellent anti-TMV activities. Especially, the inactivation, curative, and protection activities of compounds harmalan (62.3, 55.1, and 60.3%, respectively, at 500 μg/mL) and tetrahydroharmane (64.2, 57.2, and 59.5% at 500 μg/mL) in vivo were much higher than those of Ribavirin (37.4, 36.2, and 38.5% at 500 μg/mL). Compound **14** also exhibited obviously higher activities in vivo (50.4, 50.0, and 57.8% at 500 μg/mL) than Ribavirin and other derivatives, and its solubility and stability were better than those of the natural products, so it can be used as a lead structure for the development of anti-TMV drugs. Moreover, some of these compounds, especially compounds **4**, **7**, and **11**, exhibited good fungicidal activity against 14 kinds of fungi. Further studies on structural optimization are in progress in our laboratory.

The goals of this study were first to directly compare the isoxazoline toxicological profiles of the [^{3}H]fluralaner binding site with that of [^{3}H]EBOB and [^{3}H]AVE in the *Musca* receptor and second to examine the relationship in *Musca* and honeybee (*Apis mellifera*) between binding site specificity and pest toxicity. The action of fluralaner in mammalian brain was also considered.

MATERIALS AND METHODS

Chemicals and Radioligands. Three radioligands were used: [^{3}H]fluralaner (14 Ci/mmol),[19] [^{3}H]EBOB (26 Ci/mmol),[10] and [^{3}H]AVE (11 Ci/mmol).[17] Fluralaner (**1**) was prepared as described,[19] and isoxazolines **2**–**15** (Figure 2) were provided by DuPont Crop Protection (Newark, DE). Other compounds were obtained from commercial sources.

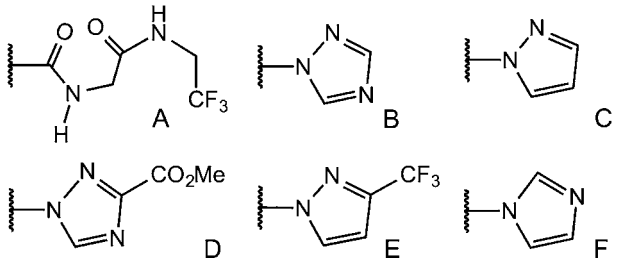

Figure 2. Structures of isoxazolines studied. Insecticidal activities are reported by Lahm et al.[6] for all compounds except **1**, **4**, **10**, **11**, and **12**.

Toxicity to Insects. Adult *Musca* (about 25 mg each) 3–5 days after emergence from the pupae (obtained from Benzon Research Inc., Carlisle, PA) were treated by intrathoracic injection with 0.03 μg of isoxazoline in 0.2 μL of DMSO–water (1:3), and the toxicity was determined at 24 h. Poisoning signs of this 1.2 μg/g isoxazoline dose were rated for each fly in groups of 40 as 0 (no effect), 1 (unable to walk or fly), and 2 (no response to prodding) following the reported method.[20,21] The assay was repeated two more times and averaged on a percentage basis. The values were calculated as follows: number of impaired flies (score 1) plus twice the number of dead flies (score 2); i.e., all impaired was scored 50, and complete mortality was scored 100.

The insecticidal activity of nine isoxazolines studied here was previously reported as ppm LC_{50} with four pest species, i.e., fall armyworm (*Spodoptera frugiperda*), corn earworm (*Helicoverpa zea*), potato leafhopper (*Empoasca fabae*), and western flower thrips (*Frankliniella occidentalis*).[6] Potency values for these pests were expressed as $1/LC_{50}$.

Membrane Receptor Preparation. *Musca* adults were frozen in liquid nitrogen and the heads recovered by shaking and sieving with a yield of about 1.0 g of heads per 1000 flies. The heads (1.0 g) were homogenized in 10 mL of ice-cold buffer A (250 mM sucrose, 10 mM Tris–HCl, pH 7.5) containing Haltphosphatase inhibitor cocktail (Thermo Scientific, Rockford, MA) (1%, v/v). The homogenate was filtered through four layers of nylon mesh (64 μm) and centrifuged at 700*g* for 30 min and the supernatant filtered again through four layers of nylon mesh. The membranes were then recovered by centrifugation at 25000*g* for 30 min. The pellet was resuspended in buffer A, kept on ice for 10 min, and then centrifuged again at 25000*g* for 30 min. The final membrane pellet was resuspended in buffer B [300 mM NaCl and 10 mM phosphate-buffered pH 7.5 saline (PBS)], filtered through four layers of nylon screen to remove particles, and employed for the binding assay after protein determination.[22] The same procedure was used to prepare *Apis* brain membranes from bees obtained at a local apiary.

Binding Assays. The receptor binding assays were based on our original studies with *Musca* for three radioligands, [^{3}H]fluralaner,[19] [^{3}H]EBOB,[10] and [^{3}H]AVE.[17] The binding assays consisted of sequential addition to incubation tubes (13 × 100 mm) of candidate inhibitor in DMSO (0.5 μL) and membrane preparation (200 μg of *Musca* or *Apis* protein) in PBS (1.0 mL). The radioligand [final concentration 0.1 nM [^{3}H]fluralaner, 0.5 nM [^{3}H]EBOB, or 0.5 nM [^{3}H]AVE] was introduced into 10 μL of buffer B with mixing. Incubations were for 70 min at 22 °C followed by addition of ice-cold PBS (5 mL) and filtration with GF/B glass-fiber filters and then two 5 mL rinse washes of cold PBS. Radioactivity on the filters was counted with 10 mL of scintillation fluid Safety-Solve cocktail (Research Products International Corp., Elk Grove, IL) after the filters were allowed to stand in the dark overnight. Nonspecific binding was determined with 5 μM fluralaner for [^{3}H]fluralaner, 5 μM fipronil for [^{3}H]EBOB, and 5 μM AVM for [^{3}H]AVE. Each experiment was repeated 3–5 times, and the results reported are the means with standard errors.

Mammalian GABA-R preparations and assays were as previously reported for rat brain membranes[23] and recombinant β_3 homopentamer.[24,25]

RESULTS

***Musca* and *Apis* [^{3}H]Fluralaner Binding Assays.** Optimization of the [^{3}H]fluralaner binding assay proved to be a challenge because of relatively high levels of nonspecific binding and possibly multiple binding sites.[8,19] The method described is acceptable but still far from ideal using 0.1 nM [^{3}H]fluralaner to give an adequate level of specific binding. Total and specific binding and percent specific binding for *Musca* averaged 2000 ± 100 dpm, 600 ± 100 dpm, and about 30%, respectively. The corresponding values for *Apis* averaged 1650 ± 100 dpm, 800 ± 50 dpm, and about 45%, respectively. [^{3}H]EBOB and [^{3}H]AVE were assayed with the same *Musca* preparation and method as for [^{3}H]fluralaner except with 0.5 nM radioligand. Total, nonspecific, and specific binding for *Musca* with [^{3}H]EBOB were 1200 ± 100 dpm, 600 ± 50 dpm, and about 50%, respectively, and with [^{3}H]AVE they were 2700 ± 100 dpm, 2100 ± 100 dpm, and about 75%, respectively.

Binding Site Profiles. *Musca [^{3}H]Fluralaner, [^{3}H]EBOB, and [^{3}H]AVE Binding Sites. Four Insecticide Chemotypes (Figure 3).* The four representative inhibitors used were isoxazoline (fluralaner), phenylpyrazole (fipronil), organochlorine (α-endosulfan), and macrocyclic lactone (AVE) tested at 0.1, 1, 10, 100, and 5000 nM (final concentration). The *Musca* [^{3}H]fluralaner site is highly sensitive to fluralaner and AVE with IC_{50} values of about 0.4 and 3 nM, respectively, but not to fipronil or α-endosulfan.[19] The [^{3}H]EBOB site is sensitive to fluralaner, fipronil, and α-endosulfan (IC_{50} values of

dx.doi.org/10.1021/jf4050809 | J. Agric. Food Chem. 2014, 62, 1019–1024

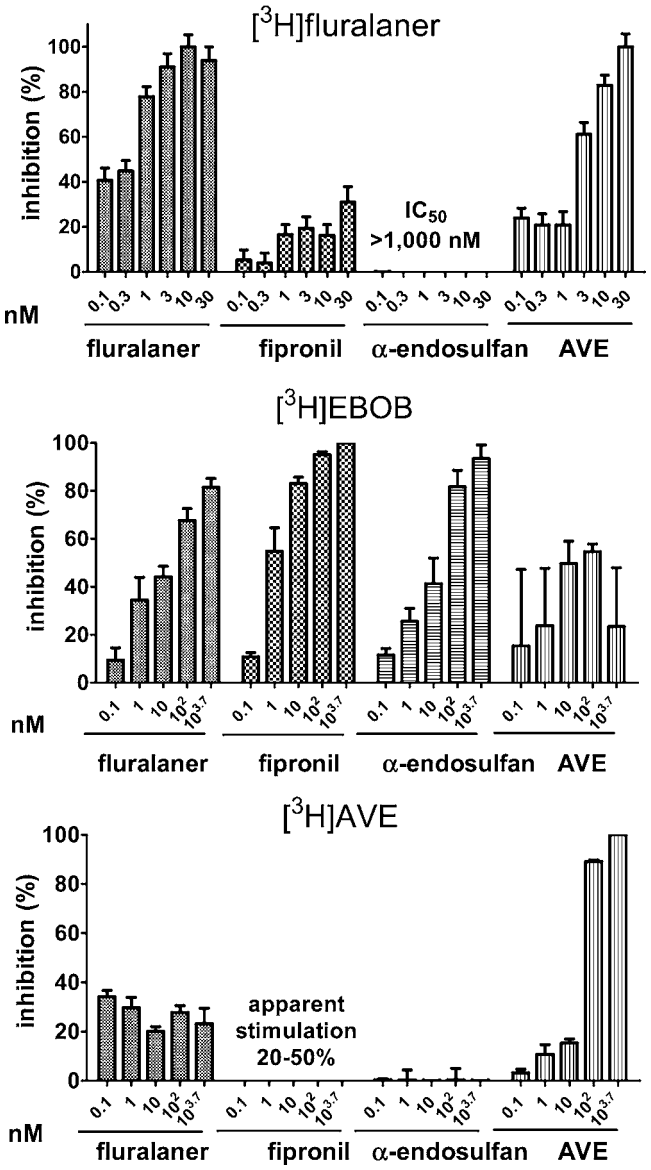

Figure 3. Effect in *Musca* of fluralaner, fipronil, α-endosulfan, and AVE on binding of [^{3}H]fluralaner, [^{3}H]EBOB, and [^{3}H]AVE. A concentration of 5000 nM is shown as $10^{3.7}$.

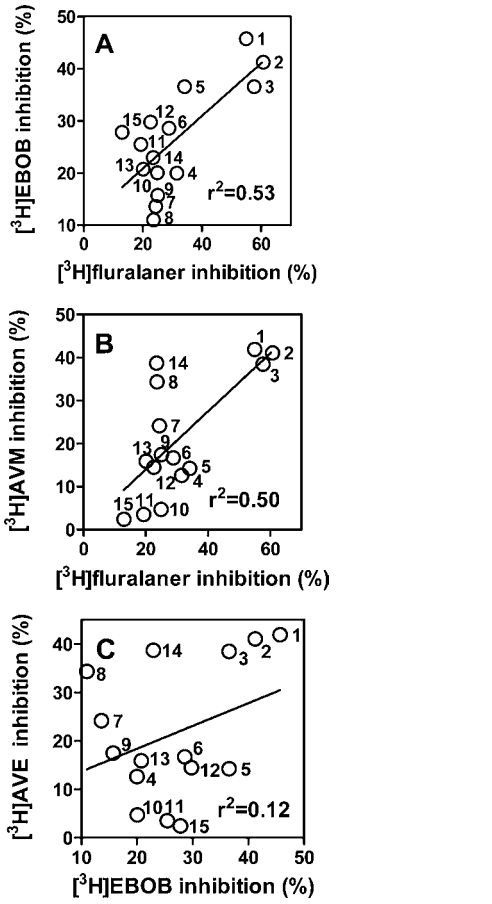

Figure 4. Potency relationships in *Musca* of 15 isoxazolines at 10 nM as inhibitors of [^{3}H]fluralaner versus [^{3}H]EBOB (A), [^{3}H]fluralaner versus [^{3}H]AVE (B), and [^{3}H]EBOB versus [^{3}H]AVE (C) binding.

39−41 nM) but much less so to AVE. The [^{3}H]AVE site is poorly sensitive to fluralaner, apparently stimulated to a small degree (20−50%) by fipronil, insensitive to α-endosulfan, and highly sensitive to AVE ($IC_{50} \approx 20$ nM).

Fifteen Isoxazolines (Figure 4). Fifteen isoxazolines were examined for their inhibitory activity to [^{3}H]fluralaner, [^{3}H]EBOB, and [^{3}H]AVE binding. The most active compounds were isoxazolines **1** (fluralaner), **2**, and **3**. The others were much weaker inhibitors. The binding site profiles for [^{3}H]fluralaner relative to [^{3}H]EBOB give a correlation coefficient of 0.53, about the same as that for [^{3}H]fluralaner versus [^{3}H]AVE (r^2 = 0.50) and much better than that for [^{3}H]EBOB versus [^{3}H]AVE (r^2 = 0.12). There are clearly common features of the target or coupled binding sites but not identity for isoxazolines interacting in the three radioligand assays.

Apis [^{3}H]Fluralaner Binding Site with 15 Isoxazolines (Figure 5A). The specificity of 15 isoxazolines for inhibition of [^{3}H]fluralaner binding was similar (r^2 = 0.55) for *Apis* and *Musca*.

Toxicity to Musca and Four Pest Species Relative to Musca and Apis [^{3}H]Fluralaner Binding Affinity. Musca (Figure 6). The set of 15 isoxazolines was assayed for toxicity to *Musca* adults by intrathoracic injection of a standard 1.2 μg/g dose. Only three of the isoxazolines (**1**−**3**) showed high toxicity, and they were the same ones most effective as inhibitors of [^{3}H]fluralaner binding and among the better inhibitors of [^{3}H]EBOB and [^{3}H]AVE binding.

Pest Species. The findings on toxicity to *Musca* and four pest species were compared with each other (Figure 7) and with the structure−activity relationships for inhibition in *Apis* of [^{3}H]fluralaner binding (Figure 5B−E). Isoxazoline poisoning of *Musca* was at best a moderate predictor of toxicity to *Spodoptera* and *Helicoverpa* and even poorer with *Frankliniella* and *Empoasca*. Compounds **2**, **3**, **7**, and **8** were highly active on all species, whereas **5** and **14** were intermediate in toxicity and **6**, **9**, and **13** had the lowest activity. The correlation of receptor binding with toxicity was always better for *Apis* (Figure 5 B−E) (r^2 = 0.75−0.84) than for *Musca* (r^2 = 0.30−0.68) (Supporting Information). The best correlation was for *Apis* [^{3}H]fluralaner binding inhibition with *Empoasca* toxicity (r^2 = 0.84).

Mammalian $GABA_A$-R (Figure 8). Fluralaner, fipronil, and heptachlor epoxide were compared for potency in the [^{3}H]EBOB binding assay with rat brain membranes and recombinant human β_3 homopentamer. Fluralaner gave 37% inhibition at 10^4 nM with rat brain membrane, consistent with

dx.doi.org/10.1021/jf4050809 | J. Agric. Food Chem. 2014, 62, 1019−1024

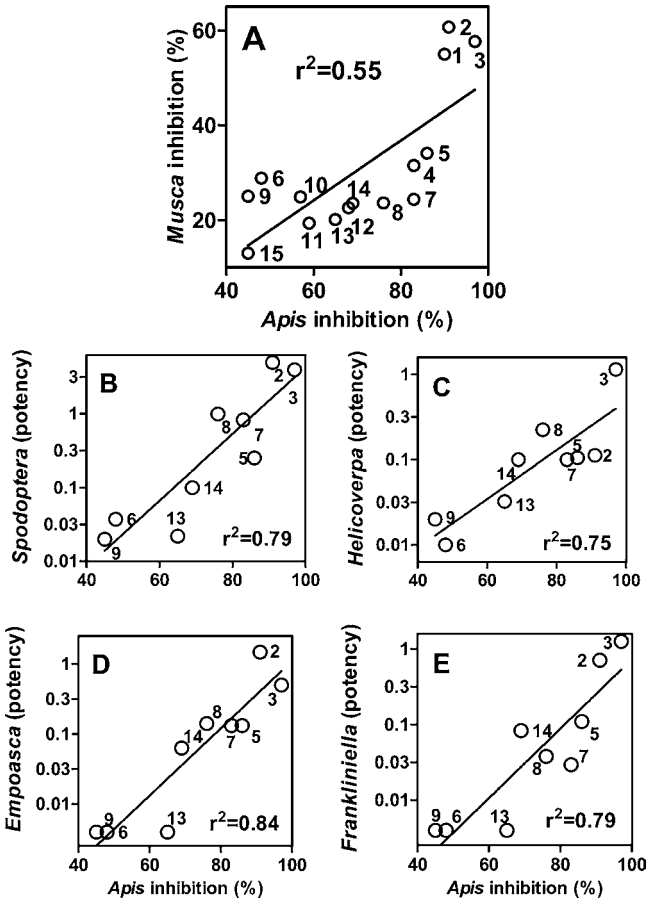

Figure 5. Potency relationships in *Apis* and *Musca* of 15 isoxazolines at 10 nM as inhibitors of [^{3}H]fluralaner binding (A) and for 9 isoxazolines relative to toxicity in four pest insects (B–E). The corresponding r^2 values for *Musca* were 0.56 for *Spodoptera*, 0.30 for *Helicoverpa*, 0.52 for *Empoasca*, and 0.68 for *Frankliniella* (see the Supporting Information).

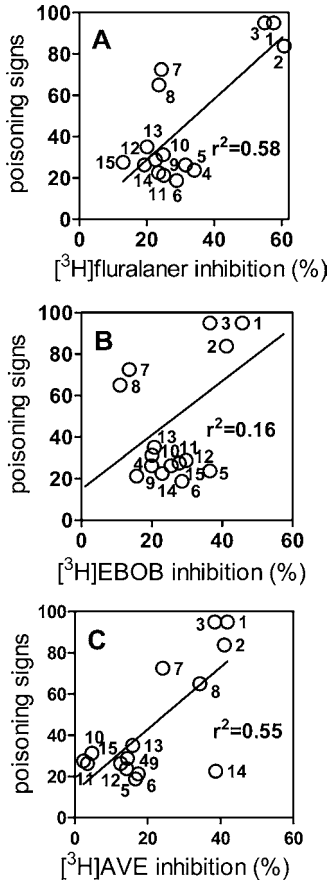

Figure 6. Potency in *Musca* of 15 isoxazolines at 10 nM as inhibitors of [^{3}H]fluralaner (A), [^{3}H]EBOB (B), and [^{3}H]AVE (C) binding relative to their toxicity.

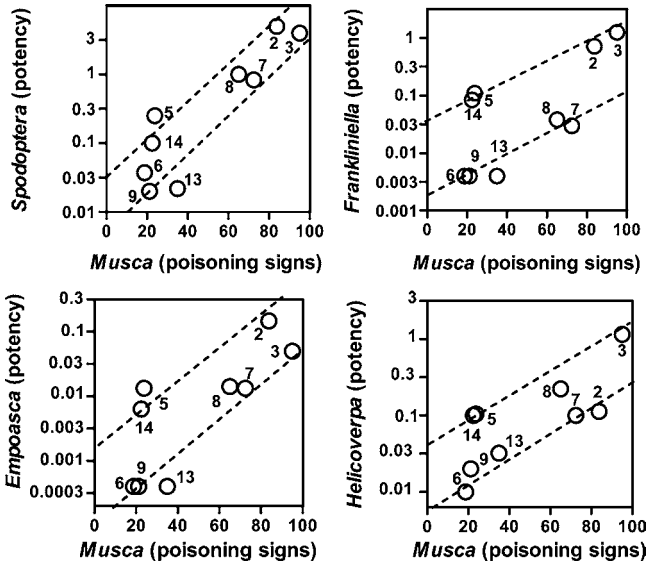

Figure 7. Toxicity of nine isoxazolines to *Musca* relative to four pest species.

an earlier report, [8] but it had almost no effect on the recombinant β_3 homopentamer. Heptachlor epoxide and fipronil showed high affinity for rat brain membranes with IC_{50} values of 200 and 800 nM, respectively, and even higher affinity for the recombinant human β_3 subunit with IC_{50} values of 5.4 and 3.4 nM, respectively.

DISCUSSION

The GABA receptor is the target for the isoxazoline insecticides based on several types of evidence. The most complete studies were for fluralaner acting on insect ligand-gated ion channels using MdGBCl and MdGluCl cDNAs, which encode the subunits of *Musca* GABA- and glutamate-gated chloride channels, respectively.[8] Two-electrode voltage clamp electrophysiology was used to confirm that fluralaner blocks GABA- and glutamate-induced chloride currents in *Xenopus* oocytes expressing MdGBCl or MdGluCl channels, with IC_{50} values of 5.3 and 80 nM, respectively. Blockade by fluralaner was observed in A2′S-MdGBCl and S2′A-MdGluCl mutant channels at levels similar to those of the respective wild types, and *Musca* expressing A2′S-MdGBCl channels were as susceptible to fluralaner as standard house flies. These findings indicated that fluralaner is a novel and specific blocker of insect ligand-gated chloride channels.[8]

The present study confirms the potency of fluralaner as a high-affinity inhibitor of the *Musca* [^{3}H]EBOB site[8] and shows directly the subnanomolar affinity of [^{3}H]fluralaner for *Musca*[19] and *Apis* GABA-R. The ecological impact of the isoxazoline-sensitive GABA-R site not only in target pests but also in *Apis* remains to be determined. The *Apis* GABA-R assay is better

dx.doi.org/10.1021/jf4050809 | J. Agric. Food Chem. 2014, 62, 1019–1024

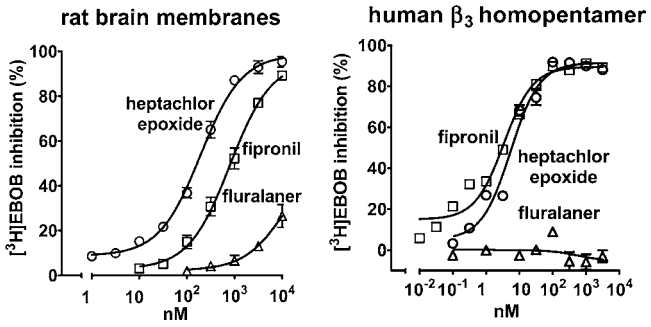

Figure 8. Potency in rat brain membranes and the recombinant human GABA-R β_3 homopentamer of fluralaner, fipronil, and heptachlor epoxide as inhibitors of [^{3}H]EBOB binding.

than the *Musca* GABA-R assay as a predictor of insecticidal activity, a finding rationalized as a higher ratio of the most relevant isoxazoline high-affinity binding site in the *Apis* assay. A marked difference is observed in the inhibitor specificity of the *Musca* [^{3}H]fluralaner and [^{3}H]EBOB sites, establishing that they are distinct but coupled. The AVE agonist site is coupled to both the fluralaner and EBOB sites but each in a unique way. The three distinct and coupled sites are all targets for insecticide action, but the isoxazoline site provides two unique features. It is much more important in insects than mammals, providing a high level of selective toxicity. The sites have no features in common that confer cross-resistance. This is an exciting observation stimulating interest in isoxazolines as possibly the next generation of GABAergic insecticides.

■ ACKNOWLEDGMENTS

We are greatly indebted to George P. Lahm, James D. Barry, and Thomas F. Pahutski of DuPont Crop Protection Stine Haskell Research Center (Newark, DE) for providing a set of 14 isoxazolines critical for the validating experiments on in vitro structure–activity relationships relative to insecticidal activity. C.Z. thanks Professor Lihong Qiu of the China Agricultural University for academic counsel and Berkeley laboratory colleagues Amanda Ly, Breanna Ford-Morris, Madhur Garg, and Stephen Lantz for assistance and advice. We thank Vincent Salgado and Brecht London of BASF Corp. (Research Triangle Park, NC) for helpful suggestions on preparing *Musca* membranes for [^{3}H]EBOB binding assays.

■ ABBREVIATIONS USED

AVE, avermectin B_{1a}; [^{3}H]EBOB, the radioligand 4′-ethynyl-4-*n*-propylbicycloorthobenzoate; fluralaner or A1443, 4-[5-(3,5-dichlorophenyl)-4,5-dihydro-5-(trifluoromethyl)-3-isoxazolyl]-2-methyl-*N*-[2-oxo-2-(phenylamino)ethyl]benzamide; GABA-R, γ-aminobutyric acid receptor; PBS, phosphate-buffered saline; [^{3}H]TBOB, the radioligand *tert*-butylbicycloorthobenzoate; [^{35}S]TBPS, the radioligand *tert*-butylbicyclophosphorothionate

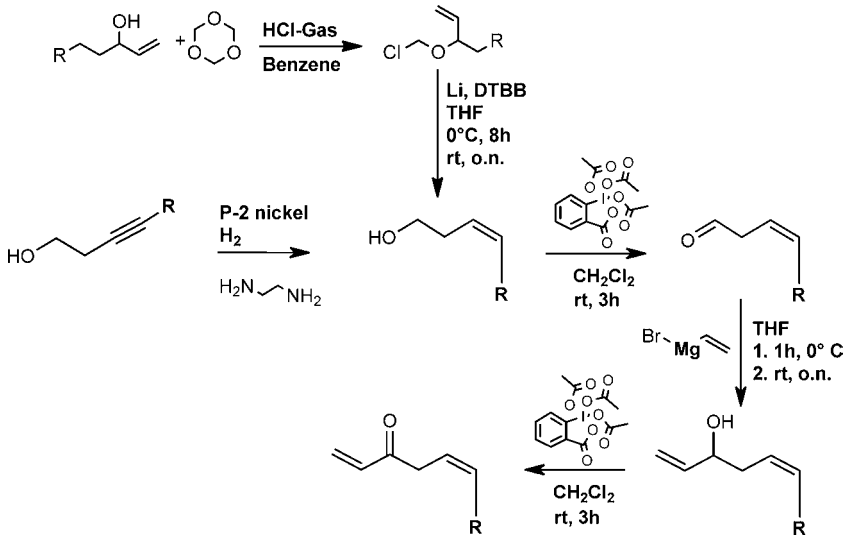

Figure 1. Synthetic routes leading to the (*Z*)-alka-1,5-dien-3-oxo compounds.

determination. A way to avoid such bias is to apply determination by gas chromatography−olfactometry, thereby involving an additional separation step so that odor threshold determination can be focused solely on the substance of interest. This methodology has been used for odor threshold determination in a series of studies in conjunction with[20,21] or without[22] an internal odorous standard, for example, (*E*)-dec-2-enal,[20,21] to correct for potential interindividual variations in sensitivity or odorant delivery. The latter has been used in a series of determinations until today and, accordingly, serves as a reference technique that allows for comparison of odor properties between substances and also between determinations in different laboratories.[23−25]

Accordingly, the following study has been based on this approach for elaborating the respective odor properties of the compounds investigated within this study.

MATERIALS AND METHODS

Chemicals. The following chemicals were purchased from the suppliers given in parentheses: octanal, nonanal, decanal, undecanal, undec-1-en-3-ol, dodec-1-en-3-ol, but-1-en-3-one, hex-1-en-3-ol, hept-1-en-3-ol, oct-1-en-3-ol, pent-1-en-3-one, hexa-1,5-dien-3-ol, (*Z*)-hex-3-en-1-ol, (*E*)-hex-3-en-1-ol, (*Z*)-non-3-en-1-ol, (*E*)-pent-3-enoic acid, (*E*)-hept-3-enoic acid, (*E*)-oct-3-enoic acid, (*E*)-non-3-enoic acid, (*E*)-dec-3-enoic acid, pent-3-in-1-ol, dec-3-in-1-ol, Dess−Martin periodinane, malonic acid, s-trioxane, vinylic magnesiumbromide (Aldrich, Steinheim, Germany); pent-1-en-3-ol, non-1-en-3-ol, oct-1-en-3-one, (*Z*)-oct-3-en-1-ol, hept-3-yn-1-ol (Lancaster, Mühlheim, Germany).

Syntheses. The identity of all intermediates and synthetic products was determined by MS/EI, as well as their retention indices on at least two capillary columns of different polarities (FFAP, SE-54 (DB5), and OV-1701) (data available in Supporting Information Tables S1−S6). Linear retention indices (RI) of the compounds were calculated as previously described.[26] Purity and concentration of all synthetic products were determined according to the method described by Milo,[27] using methyl octanoate or any other ester of high GC purity and a compound with the same effective carbon number as the substance to be determined.[28−30]

Hex-1-en-3-one and (*Z*)-octa-1,5-dien-3-one were synthesized according to the literature: Blank et al.,[23] Ullrich and Grosch.[9]

Hexa-1,5-dien-3-one, Hept-1-en-3-one, Non-1-en-3-one. Hexa-1,5-dien-3-one (Figure 1), hept-1-en-3-one, and non-1-en-3-one (Figure 2) were synthesized by a Dess−Martin oxidation of the corresponding alcohols using Dess−Martin periodinane.[31,32]

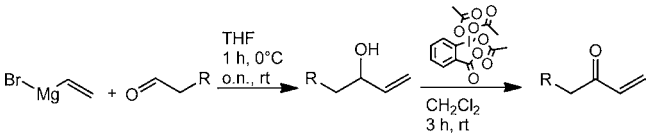

Figure 2. Synthetic route leading to the alk-1-en-3-oxo compounds.

(*Z*)-Hepta-1,5-dien-3-ol, (*Z*)-Nona-1,5-dien-3-ol, (*Z*)-Dodeca-1,5-dien-3-ol, (*Z*)-Hepta-1,5-dien-3-one, (*Z*)-Nona-1,5-dien-3-one, (*Z*)-Dodeca-1,5-dien-3-one. The target compounds were synthesized by stereospecific reduction of pent-3-yn-1-ol, hept-3-yn-1-ol, or dec-3-yn-1-ol, respectively, as described previously for the synthesis of (*Z*)-hex-3-en-1-ol,[33,34] followed by oxidation of the resulting (*Z*)-alk-3-en-1-ols to the corresponding (*Z*)-alk-3-enals using Dess−Martin periodinane.[31,32] A subsequent Grignard-type reaction of the aldehydes with vinylmagnesium bromide gave the (*Z*)-alka-1,5-dien-3-ols; their oxidation using Dess−Martin periodinane revealed the corresponding dienone (Figure 1).

(*Z*)-Deca-1,5-dien-3-ol, (*Z*)-Undeca-1,5-dien-3-ol, (*Z*)-Deca-1,5-dien-3-one, (*Z*)-Undeca-1,5-dien-3-one. (*Z*)-Deca-1,5-dien-3-one and (*Z*)-undeca-1,5-dien-3-one were synthesized by oxidation of (*Z*)-oct-3-en-1-ol or (*Z*)-non-3-en-1-ol using Dess−Martin periodinane[31,32] followed by a Grignard-type reaction of the obtained aldehydes with vinylmagnesium bromide to yield (*Z*)-deca-1,5-dien-3-ol or (*Z*)-undeca-1,5-dien-3-ol. Subsequent oxidation with Dess−Martin periodinane gave the corresponding ketones (Figure 1).

(*Z*)-Trideca-1,5-dien-3-ol, (*Z*)-Tetradeca-1,5-dien-3-ol, (*Z*)-Trideca-1,5-dien-3-one, (*Z*)-Tetradeca-1,5-dien-3-one. (*Z*)-Trideca-1,5-dien-3-ol and (*Z*)-tetradeca-1,5-dien-3-ol were synthesized by reaction of s-trioxane with undec-1-en-3-ol or dodec-1-en-3-ol[35] followed by a Wittig rearrangement[36] to form the (*Z*)-undec-3-en-1-ol or (*Z*)-dodec-3-en-1-ol. The latter compounds were oxidized using Dess−Martin periodinane[31,32] followed by a Grignard-type reaction of the obtained aldehydes with vinylmagnesium bromide to yield (*Z*)-trideca-1,5-dien-3-ol or (*Z*)-tetradeca-1,5-dien-3-ol. Dess−Martin periodinane gave the corresponding ketones (Figure 1).

Dec-1-en-3-ol, Undec-1-en-3-ol, Dodec-1-en-3-ol, Tridec-1-en-3-ol, Tetradec-1-en-3-ol, Dec-1-en-3-one, Undec-1-en-3-one, Dodec-1-en-3-one, Tridec-1-en-3-one, Tetradec-1-en-3-one. A Grignard-type reaction of octanal, nonanal, decanal, undecanal, or dodecanal, respectively, with vinylmagnesium bromide gave the alk-1-en-3-ols, and subsequent oxidation using Dess−Martin periodinane yielded the corresponding alk-1-en-3-ones (Figure 2).

(*E*)-Hepta-1,5-dien-3-ol, (*E*)-Octa-1,5-dien-3-ol, (*E*)-Nona-1,5-dien-3-ol, (*E*)-Deca-1,5-dien-3-ol, (*E*)-Undeca-1,5-dien-3-ol, (*E*)-Dodeca-1,5-dien-3-ol, (*E*)-Hepta-1,5-dien-3-one, (*E*)-Octa-1,5-dien-3-one, (*E*)-Nona-1,5-dien-3-one, (*E*)-Deca-1,5-dien-3-one,

dx.doi.org/10.1021/jf404885j | J. Agric. Food Chem. 2014, 62, 1025−1031

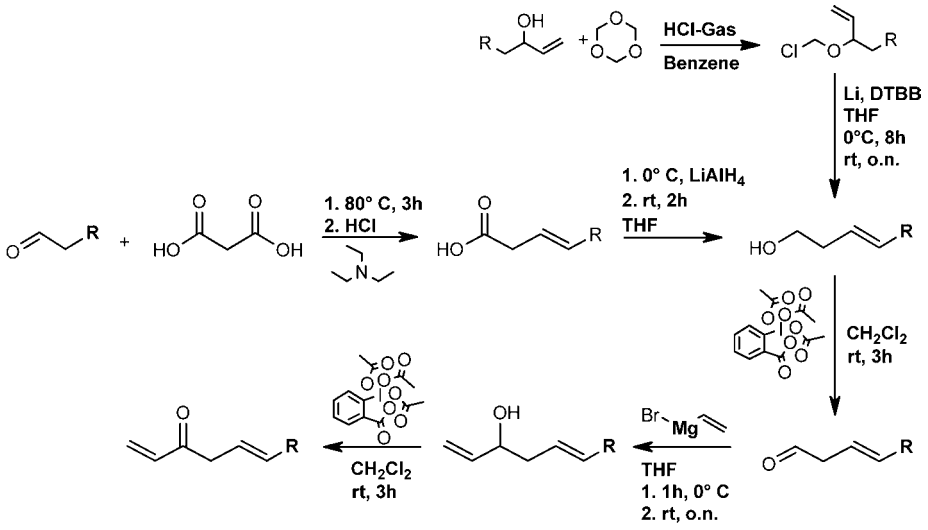

Figure 3. Synthetic routes leading to the (*E*)-alka-1,5-dien-3-oxo compounds.

Table 1. Odor Qualities and Odor Thresholds of Homologous (*Z*)-Alka-1,5-dien-3-ones

		threshold in air[a] (ng/L)		
odorant	odor quality[b]	by GC-O	data from lit.[c]	previously identified in food[c]
hexa-1,5-dien-3-one	geranium-, vegetable-like, metallic	0.01	nr	nr
(*Z*)-hepta-1,5-dien-3-one	geranium-like, metallic	0.0006	nr	nr
(*Z*)-octa-1,5-dien-3-one	geranium-like, metallic	0.003	0.003−0.006[3]	mushrooms,[3] soybean oil,[24] olive oil[40]
(*Z*)-nona-1,5-dien-3-one	herb-, mushroom-like	0.06	nr	nr
(*Z*)-deca-1,5-dien-3-one	herb-, mushroom-like	0.12	nr	nr
(*Z*)-undeca-1,5-dien-3-one	herb-, mushroom-like	0.18	nr	nr
(*Z*)-dodeca-1,5-dien-3-one	herb-, mushroom-like	1.1	nr	nr
(*Z*)-trideca-1,5-dien-3-one	herb-like, fresh	126	nr	nr
(*Z*)-tetradeca-1,5-dien-3-one	fresh, green, sweet	353	nr	nr

[a]Odor thresholds in air were determined as described by Ullrich and Grosch.[20] [b]Odor quality as perceived at the sniffing port. [c]nr, compound or odor threshold was not reported previously.

(*E*)-Undeca-1,5-dien-3-one, (*E*)-Dodeca-1,5-dien-3-one. (*E*)-Pent-3-enoic, (*E*)-hept-3-enoic, (*E*)-oct-3-enoic, (*E*)-non-3-enoic, and (*E*)-dec-3-enoic acid were reduced to the corresponding (*E*)-alk-3-en-1-ols[37] (Figure 3). Those and (*E*)-hex-3-en-1-ol were oxidized using Dess−Martin periodinane[31,32] followed by a Grignard-type reaction of the obtained aldehydes with vinylmagnesium bromide to yield (*E*)-hepta-1,5-dien-3-ol, (*E*)-octa-1,5-dien-3-ol, (*E*)-nona-1,5-dien-3-ol, (*E*)-deca-1,5-dien-3-ol, (*E*)-undeca-1,5-dien-3-ol, and (*E*)-dodeca-1,5-dien-3-ol. Dess−Martin periodinane gave the corresponding ketones.

(*E*)-Trideca-1,5-dien-3-ol, (*E*)-Tetradeca-1,5-dien-3-ol, (*E*)-Trideca-1,5-dien-3-one, (*E*)-Tetradeca-1,5-dien-3-one. (*E*)-Trideca-1,5-dien-3-ol, (*E*)-tetradeca-1,5-dien-3-ol, (*E*)-trideca-1,5-dien-3-one, and (*E*)-tetradeca-1,5-dien-3-one were synthesized following two different routes (Figure 3): The first route is identical with synthesis of the corresponding (*Z*)-compounds. (*E*)-Trideca-1,5-dien-3-ol and (*E*)-tetradeca-1,5-dien-3-ol were synthesized by reaction of s-trioxane with undec-1-en-3-ol or dodec-1-en-3-ol[35] followed by a Wittig rearrangement[36] to form the (*E*)-undec-3-en-1-ol or (*E*)-dodec-3-en-1-ol. The obtained compounds were oxidized using Dess−Martin periodinane[31,32] followed by a Grignard-type reaction of the obtained aldehydes with vinylmagnesium bromide to yield (*E*)-trideca-1,5-dien-3-ol or (*E*)-tetradeca-1,5-dien-3-ol. Dess−Martin periodinane gave the corresponding ketones. The second route starts with a Knoevenagel condensation of malonic acid with nonanal or decanal to form (*E*)-undec-3-enoic acid or (*E*)-dodec-3-enoic acid.[38] After reduction of the (*E*)-alk-3-enoic acid to the corresponding (*E*)-alk-3-en-1-ol, route 2 follows the same path as route 1.

High-Resolution Gas Chromatography−Olfactometry (HRGC-O) and HRGC−Mass Spectrometry (HRGC-MS). HRGC analyses were performed with a type 8000 gas chromatograph (Fisons Instruments, Mainz, Germany) and a Trace GC Ultra (Thermo Fisher Scientific GmbH, Dreieich, Germany) by using the following capillaries: FFAP (30 m × 0.32 mm fused silica capillary, free fatty acid phase FFAP, 0.25 μm; Chrompack, Mühlheim, Germany), SE-54 (DB5) (30 m × 0.32 mm fused silica capillary DB-5, 0.25 μm; J&W Scientific, Fisons Instruments), and OV-1701 (30 m × 0.32 mm fused silica capillary, DB-1701, 0.25 μm; Chrompack). The (*Z*)-alka-1,5-dien-3-oxo and alk-1-en-3-oxo samples were applied by the on-column injection technique at 35 °C (Supporting Information Tables S1, S3, S4, and S6). After 2 min, the temperature of the oven was raised at 40 °C/min to 50 °C (SE-54, OV-1701) or 60 °C (FFAP), respectively, held for 2 min isothermally, then raised at 6 °C/min to 180 °C, and finally raised at 10 °C/min to 230 °C and held for 10 min. The flow rate of the carrier gas helium was 2.5 mL/min. The (*E*)-alka-1,5-dien-3-oxo compounds were applied by the column injection technique at 40 °C (Supporting Information Tables S2 and S5). After 2 min, the temperature of the oven was raised at 10 °C/min to 240 °C, then raised at 40 °C/min to 280 °C (SE-54 (DB5)) or at 10 °C/min to 240 °C (FFAP), respectively, and held for 5 min. The flow rate of the carrier gas helium was 2.5 mL/min (DB5) or 1.3 mL/min (FFAP). At the end of the capillary, the effluent was split in a ratio 1:1 (by vol) into an FID and a sniffing port using two deactivated but uncoated fused silica capillaries (50 cm × 0.32 mm). The FID and the sniffing port were held at 220 and 240 °C, respectively. S analyses were performed with an MS-95 S (Finnigan, Bremen, Germany) in tandem, an Agilent MSD 5975C (Agilent Technologies, Waldbronn,

[a]Odor thresholds in air were determined as described by Ullrich and Grosch.[20] [b]Odor quality as perceived at the sniffing port. [c]nr, compound or odor threshold was not reported previously.

Germany), and a Thermo ITQ 900 (Thermo Fisher Scientific, Dreieich, Germany) with the capillaries described above. Mass spectra in the electron impact mode (MS/EI) were generated at 70 eV. Panelists were trained volunteers from the University of Erlangen (Erlangen, Germany), exhibiting no known illness at the time of examination and with audited olfactory function. In preceding weekly training sessions the assessors were trained for at least half a year in recognizing orthonasally about 90 selected known odorants at different concentrations according to their odor qualities and in naming these according to an in-house developed flavor language.

Odor Threshold Values. Thresholds in air were determined by GC-O with (*E*)-2-decenal as internal standard[20] (Tables 1−6). The thresholds were determined by two panelists. HRGC was performed on capillary SE-54 (DB5) and capillary FFAP as already described.

Odor Quality Determination. The odor qualities were determined during GC-O evaluation and were related to odor qualities of commercially available reference compounds, such as *Z*-octa-1,5-dien-3-one (geranium like) or pent-1-en-3-ol (pungent) and pent-1-en-3-one (pungent, fish-like).

RESULTS AND DISCUSSION

The odor threshold values in air and the odor qualities of the homologous (*Z*)-alka-1,5-dien-3-ones, (*E*)-alka-1,5-dien-3-ones, and alk-1-en-3-ones are given in Tables 1, 2, and 3. The data of the corresponding alcohols are given in Tables 4, 5, and 6. With regard to the bis-unsaturated compounds, we found a very low odor threshold minimum with 0.6 mg/L air for the seven-carbon compound of the (*Z*)-alka-1,5-dien-3-ones, thus being

[a]Odor thresholds in air were determined as described by Ullrich and Grosch.[20] [b]Odor quality as perceived at the sniffing port. [c]nr, compound or odor threshold was not reported previously.

the most odor-active compound of all odorants under investigation. All (*Z*)-alka-1,5-dien-3-ones elicited a geranium-like odor quality, with the short-chain compounds possessing a merely metallic odor note, whereas an increase of the chain length results in a more herb- and mushroom-like odor quality. This change in odor qualities went along with an increase in the odor thresholds up to a factor of about 10^3. The same change in odor quality was observed for the homologous (*Z*)-alka-1,5-dien-3-ols. However, the minimum in the odor thresholds was not so pronounced for the seven-carbon compound. Generally, the most odor-active alkadienols in this series were the odorants with 7−10 carbon atoms with odor thresholds from 1 to 10 ng/L air. The odor thresholds then increased by a factor of about 10^2 from (*Z*)-deca-1,5-dien-3-ol to (*Z*)-dodeca-1,5-dien-3-ol.

Also, all (*E*)-alka-1,5-dien-3-ones elicited a geranium leaf-like odor quality. The short-chain compounds possessed a pungent and green odor note. An increase in the chain length resulted in a more citrus- and plastic-like odor. As in the case of the (*Z*)-compounds, this change was accompanied with an increase in the odor thresholds. The same changes in odor quality were observed for the homologous (*E*)-alka-1,5-dien-3-ols.

Whereas the overall geranium-like odor of the (*Z*)- and (*E*)-alka-1,5-dien-3-oxo compounds varied only slightly between homologues, the odor qualities of the alk-1-en-3-oxo compounds changed significantly with increasing chain length. The five- and six-carbon compounds were mainly described as pungent and glue-like but not mushroom-like. An increase of the chain length first led to a change to a metallic odor quality and then to the characteristic mushroom-like smells for the odorants with eight and nine carbon atoms. This change went along with two minima in the odor thresholds. The first one was observed for the pungent six-carbon compounds, followed by an increase in the odor threshold for hept-1-ene- odorants, and then a second minimum for the mushroom-like smelling eight- and nine-carbon compounds, respectively. A further increase of the chain length resulted in an increasing citrus-like, soapy, and herb-like odor quality as well as a significant increase in their odor thresholds by a factor of about 10^3 in both homologous series. Generally, the odor thresholds in air of the alk-1-ene and alka-1,5-diene carbonyl compounds were significantly lower than those of their corresponding alcohols.

Overall, most of the odor thresholds determined within the present study are in very close agreement with others previously reported for compounds that had been already investigated, for example, oct-1-en-3-one (Table 3). However, we observed a notable deviation from some reported values, for example, pent-1-en-3-one and oct-1-en-3-ol (Tables 3 and 6). In the case of these substances, odor thresholds provided by Koszinowski and Piringer[39] were higher by a factor of about 100−120, which may arise from the fact that in the previous study another approach of odor threshold determination was used based on GC-O but not utilizing an internal referencing substance such as (*E*)-2-decenal.

Overall, the results show that most of the investigated compounds in the homologous series of the (*Z*)-alka-1,5-dien-3-ones, (*E*)-alka-1,5-dien-3-ones, and alk-1-en-3-ones as well as their corresponding alcohols exhibit very low odor thresholds or very high odor potencies, respectively. Therefore, some of these compounds are possibly naturally occurring odorants but

were not yet identified in food materials perhaps due to their low concentrations. Our investigations now provide analytical data on these compounds such as retention indices as well as an evaluation of their odor qualities and odor thresholds, which can aid at their future analysis.

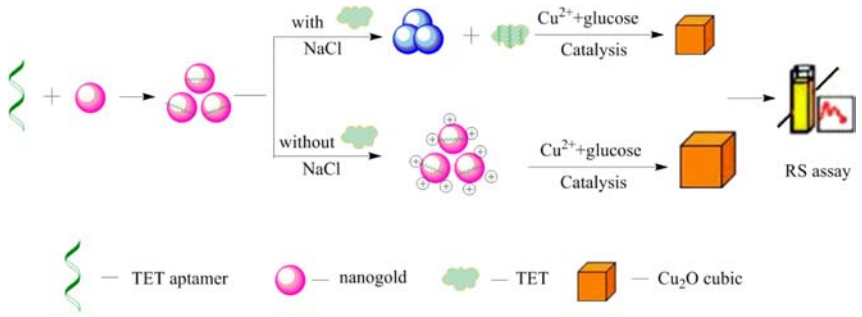

Figure 1. Principle of the ACNG catalytic RS assay for TET.

their high affinity to target substances and low cost of *in vitro* synthesis, aptamers have been increasingly applied in biochemical analysis and environmental monitoring.[22,30] In 2008, Niazi et al.[31] successfully selected the TET aptamer using the *in vitro* method. This TET aptamer has high affinity to the target TET and has already been used to analyze TET in real samples with satisfactory results. For example, Zhou and his coworkers developed an electrochemical aptasensor to detect TET with a limit of detection of 5 nM.[32] However, reports involving the catalytic activity of nanogold and RS method to detect TET are still limited.

MATERIALS AND METHODS

Chemicals. Standard TET, thiamphenine, kanamycin, aztreonam, glucose, L-tyrosine, L-valine, and L-lysine were obtained from Sigma-Aldrich (St. Louis, MO). NaCl, NaOH, $CuSO_4$, sodium potassium tartrate tetrahydrate, trisodium citrate, trichloroacetic acid, chloroauric acid ($HAuCl_4$), and *N*-(2-hydroxyethyl)piperazine-*N*-2-ethanesulfonic acid (HEPES) were obtained from Shanghai Chemical Reagent Company (Shanghai, China). The aptamer sequence of tetracycline is 5′-CGTACGGAATTCGCTAGCCCCCCGGCAGGCCACGGCTTGGGTTGGTCCCACTGCGCGTGGATCCGAGCTCCACGTG-3′,[31] and it was synthesized by Invitrogen Co., Ltd. (Shanghai, China). The tetracycline aptamer sample was dissolved in a 50 mM HEPES buffer solution and stored at 4 °C for use. Ultrapure water (Milli-Q, Millipore system) was used for the preparation of all aqueous solutions. Unless otherwise stated, all chemicals are of analytical reagent grade and were used without further purification.

Apparatus. A model F-4500 fluorescence spectrophotometer (Hitachi, Japan) was used to record the RS intensity. A nanoparticle size analyzer (NANOS, Nanos/ZS90, Malvern, U.K.) was used to obtain the Cu_2O cubic size in the system. Scanning electron microscopy (SEM, Siron 200, U.S.A.) was used to observe the Cu_2O shape. X-ray diffraction (XRD, D8 ADVANCE, Bruker, Germany) was used to confirm the catalytic products.

Preparation of Nanogold Particles. The method of nanogold particle preparation via sodium citrate reduction of $HAuCl_4$ was followed by a literature procedure.[33] All glassware used in this procedure were cleaned in a bath of freshly prepared 3:1 (v/v) HNO_3/HCl, then rinsed thoroughly in ultrapure water, and air-dried. Nanogold particles were prepared by adding 3.5 mL of 1% (w/v) trisodium citrate to a boiling solution of $HAuCl_4$ (100 mL, 0.01%, w/w) and stirred for 30 min. Within that time, the color of the solution changed from light gray, blue, purple, to wine red. After that, the mixture was stirred for an additional 15 min after removal from the heater. Finally, the cooled solution was filtrated in a 0.2 μm ultrafiltration membrane [polyvinylidene fluoride (PVDF)] to remove aggregated particles and then stored in dark glass bottles at 4 °C for further use.

Pretreatment of the Milk Sample. All of the milk sampsles were purchased from a local supermarket. They were pretreated with trichloroacetic acid to remove the proteins according to the procedure described by Tan and Chen,[34] with a slight modification. A 2% trichloroacetic acid solution and milk sample were added together into a centrifuge tube, mixed well, and ultrasonicated for 30 min.[35,36] The mixture was centrifuged at 10 000 rpm for 8 min, and the supernatant was filtered through a 0.2 μm ultrafiltration membrane (PVDF) to remove lipids. After the pH was adjusted to neutral with NaOH, the filtrate was stored at 4 °C for further detection.

Procedure for TET Determination. A total of 6 μL of 5 μM TET aptamer and 5 μL of TET solution with varying concentration were added to a plastic tube, mixed well, and then incubated in a 25 °C thermostatic incubator. The blank sample was added to 5 μL of ultrapure water instead of TET solution. After 15 min, 100 μL of nanogold solution was added to it, mixed thoroughly, and incubated for another 15 min under the same conditions. After the first two steps were finished, 7 μL of 500 mmol/L NaCl solution was added to it and diluted to 500 μL with ultrapure water.

A total of 100 μL of 6.25 mol/L NaOH solution, 10 μL of 0.028 mol/L $CuSO_4$ solution, 200 μL of 1.23 mol/L $KNaC_4H_4O_6$ solution, 50 μL of 10 mg/mL glucose solution, and 500 μL of the aptamer mixture were successively added to a centrifuge tube, diluted to 1000 μL with ultrapure water, and mixed well. Then, the tube was placed in a 60 °C thermostatic incubator for 6 min. The reaction was stopped by the tap water cooling.

A total of 500 μL of the catalytic reaction solution was transferred to a quartz cell. The RS intensity was recorded using a F-4500 fluorescence spectrophotometer with settings as follows: volt, 700 V; excited slit, 5 nm; emission slit, 2.5 nm; and synchronous scanning wavelength range, from 500 to 700 nm. The RS spectrum, the RS intensity at 620 nm ($I_{620\ nm}$), and the $(I_{620\ nm})_b$ of blank solutions without TET were recorded. The values for $\Delta I_{620\ nm} = (I_{620\ nm})_b - I_{620\ nm}$ were calculated.

RESULTS AND DISCUSSION

Principle of the ACNG Catalytic RS Assay. Single-stranded oligonucleotide (ssDNA) can coat on the surface of nanogold particles through van der Waals and intermolecular forces in proper conditions. This keeps nanogold against aggregation when the salt concentration is proper.[37] In addition, Fehling reactions barely happened at room temperature and happened indeed at 60 °C. Upon the addition of a nanocatalyst, such as ACNG, the reaction occurred apparently and Cu_2O cubic was produced quickly. In this paper, the aptamer was used to modify nanogold to obtain the catalytic ACNG, which could catalyze the Fehling reaction, yielding Cu_2O cubic at 60 °C. In the absence of TET, the aptamer absorbed on the surface of the nanogold and kept the nanogold distributing evenly in solution. Under this condition, enough ACNG could catalyze the Fehling reaction to yield a bigger Cu_2O cubic and obtain a higher RS signal. In the presence of TET, owing to the high affinities between TET and aptamers, the nanogold surface became naked and aggregated under proper NaCl concentration existence. At this time, less ACNG

dx.doi.org/10.1021/jf403566e | J. Agric. Food Chem. 2014, 62, 1032−1037

catalyzes the Fehling reaction, yielding a smaller Cu_2O cubic and obtaining a lower RS signal. Therefore, the amount of TET was negatively proportional to the amount of ACNG and, in turn, was negative to the RS signal intensity. As a results, by measuring the RS signal intensity, it is possible to determine the amount of TET. The schematic diagram is shown in Figure 1.

Aggregation of Nanogold Particles by NaCl. According to the study by Brook et al., the mechanisms of nanogold aggregations caused by salts is called the non-cross-linking pattern. The aggregation is induced by electrostatic and electrostatic stabilization without any interparticle bonds. Under this mechanism, nanogold aggregated rapidly and kept steady in appropriate conditions.[38] NaCl was chosen as an efficient cation to disturb the electronic equilibrium of nanogold surface charges to obtain aggregation in most cases.[39−41] The aggregated nanogolds induced a significant RS signal change, and the intensities were linear to the diameter of particles.[39,41−43] According to our previous reports,[42,43] aggregated nanogold has a strong RS peak at 550 nm wavelength and was chosen for use. For the nanogold aggregation reaction, the volume of aptamer, TET, NaCl, and nanogold on $I_{550\ nm}$ through RS detection was considered. In the aggregation experiments, the $\Delta I_{550\ nm}$ increased as the NaCl concentration changed from 0 to 8 mM (see Figure S1 of the Supporting Information). Moreover, when the NaCl concentrations surpassed 8 mM, the $\Delta I_{550\ nm}$ was nearly unchanged. This meant that NaCl in this system was saturated. Thus, 8 mM NaCl and 30 nM aptamer were chosen for the optimal nanogold aggregation concentration. When the volume of aptamer was 6 μL, the volume of TET was 5 μL, the volume of nanogold was 100 μL and the volume of NaCl was 8 μL, the $\Delta I_{550\ nm}$ values were the largest. The effects of the reaction time and the order of adding solutions were also investigated. The results demonstrated that $\Delta I_{550\ nm}$ attained maximum values when the reaction time was 15 min and the solution addition order was aptamer, TET, nanogold, and NaCl.

Catalytic Reaction between the Fehling Reagent and Glucose. The Fehling reaction is wildly used in the determination of reducing sugar. However, the reaction only occurs at 100 °C in a water bath for minutes when there are no catalysts. In 2010, Tao and his co-workers[19] found that 10 nm nanogold particles have a strong catalytic activity on the Fehling reaction and can reduce the Cu^{2+}−glucose system to yield Cu_2O cubic, which makes the RS intensity at 620 nm increase with an increasing nanocatalytic concentration. Here, we control the concentration of nanogold catalyst through TET dosage, which means that the catalytic capability of the nanogold has a negative correlation with the concentration of TET. The catalytic reaction conditions, such as reagent concentration, reaction time, and temperature, were optimized. The results showed the largest $\Delta I_{620\ nm}$ value when 28 nM $CuSO_4$, 625 mM NaOH, 246 nM $KNaC_4H_4O_6$, and 0.5 μg/L glucose were added, then incubated at 60 °C using a thermostatic incubator for 6 min, and chosen for use. The products of the ACNG catalytic system were obtained and used for XRD with a scanning range of 10.0−80.0° (2θ), a step size of 0.02° (2θ), a scanning step time of 0.6 s, an anode material of Cu, a current of 40 mA, and a voltage of 40 kV. According to the standard XRD spectrum of Cu_2O (see Figure S9b of the Supporting Information), the characteristic peaks are at 29.51°, 36.36°, 42.24°, 61.30°, 73.42°, and 77.27°. Our catalytic product pattern (Figure S9a of the Supporting Information) indicated that there was only Cu_2O cubic in the products. The products were also analyzed by SEM (Figure S10 of the Supporting Information). SEM showed that Cu_2O particles were cubic with a side length of about 0.5 μm, which was in agreement with the results of XRD and laser scattering image (LSI) (discussed later).

Transformation of RS Spectra. The study demonstrated that diameters of particles were the crucial factors for the RS values, but the site of the RS peak was determined by three factors: the light source of the apparatus, the absorption of the free molecule, and the RS effect of particles.[23] Results showed that the scattering peak at 620 nm was only characteristic to Cu_2O particles and chosen for analysis. Figure S12 of the Supporting Information shows that the RS values increased as the TET concentrations in solution decrease, which means that some large particles formed during catalytic reaction. From the LSI obtained by NaNo-ZS90 particle size and ζ potentiometer analyzer, the particle size distribution was in agreement with the RS value and SEM observation between the different TET concentrations. The results (see Figure S11 of the Supporting Information) show the LSI of the blank and 0.2 μM TET in solution. The average sizes were 294 and 451 nm, respectively. Therefore, the larger Cu_2O particle products were the reason for the change of the RS value.

Sensitivity of the Biosensor for TET Detection. Different concentrations of TET from 0 to 2500 nM were added to evaluate the sensitivity of the present biosensor, and the signals of RS intensity at 620 nm were recorded. As shown in Figure S12 of the Supporting Information, RS values gradually decreased with an increasing concentration of TET. To quantify the detection limit of the present biosensor, the variations of RS intensity (ΔI) at 620 nm were plotted and the calibration curve (Figure 2) looked like a sigmoid shape. It can

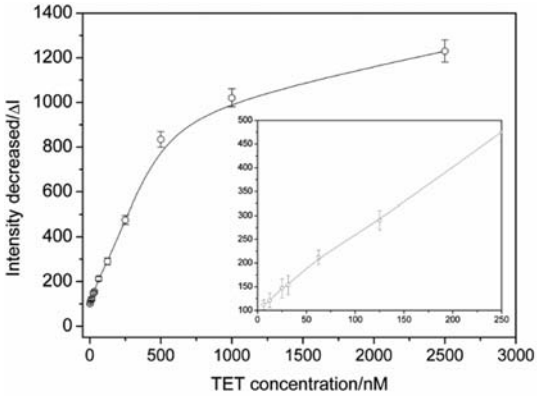

Figure 2. Calibration curve of the ACNG catalytic RS assay. The curve was fitted to a sigmoid shape with a correlation coefficient of 0.998. (Inset) RS intensity increased values at low TET concentration.

be observed that the RS intensity changed slightly when the concentrations of TET were over 625 nM in detection solutions, which indicated that the binding interaction between the aptamer and TET had reached balance and saturation. The $\Delta I_{620\ nm}$ at low TET concentrations was fitted to a linear expression with the equation of $\Delta I_{620\ nm} = 1.4793C_{TET} + 107.69$ ($R^2 = 0.998$). According to our previous research,[13,20] 3σ/slope was used to determine the detection limit of the biosensor and calculated as 11.6 nM, which is much lower than the EU-defined MRL (225 nM) and the MRL in U.S. animal products. The present biosensor is more sensitive than the detection methods reported before (Table 1), and the advantage was

Table 1. Comparison of TET Detection Analytic Methods

analyte	method	LOD	matrix	reference
TET	CE	1.8 μM	milk	45
TET	electrochemical biosensor	200 nM	water	46
TET	HPLC	99 nM	milk	9
TET	colorimetric biosensor	45.8 nM	milk	47
TET	RS	11.6 nM	milk	this paper

applying the catalytic activity of nanogold. This difference in sensitivity may be ascribed to the strong catalytic activity of nanogold to catalyze the Fehling reaction to produce a bigger Cu_2O cubic, which would lead to a high RS signal in the detection of TET. The assay could be used to detect trace levels of TET in milk samples with a comparable sensitivity. In comparison to the detection methods of TET reported before, the experimental results shown here offer the possibility of a rapid and high sensitive monitoring method for TET.

Selectivity of the Biosensor for TET Detection. The selectivity of the biosensor for TET detection was also investigated. A variety of foreign substances, such as antibiotics and organic molecules, including thiamphenine, kanamycin, aztreonam, L-tyrosine, L-valine, and L-lysine, were individually added to the reaction solutions, and the $\Delta I_{620\ nm}$ was calculated. Figure 3 showed that the RS assay had a slight change to these substances, which demonstrated that this method had high selectivity to TET detection.

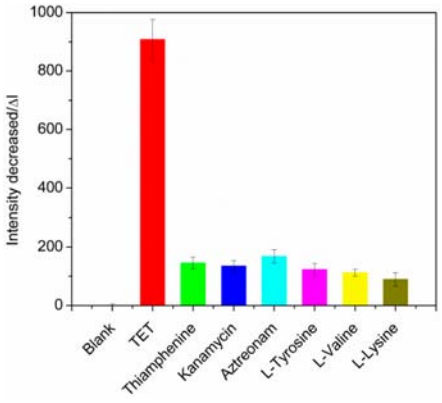

Figure 3. Specificity of the ACNG catalitc RS assay for TET detection. The concentrations of foreign substances were all 0.5 μM.

Application in the Milk Sample. At first, four analyzed milk samples with different concentrations of TET were made by adding different amounts of standard TET.[5,44] Then, they were treated and detected according to the method and procedure described before and repeated 5 times. The results are shown in Table 2. The recoveries were in the range of 105−109%, and the relative standard deviation was in the range of 1.9−4.2%. These indicated that this method had a relatively stable precision and satisfactory reproducibility.

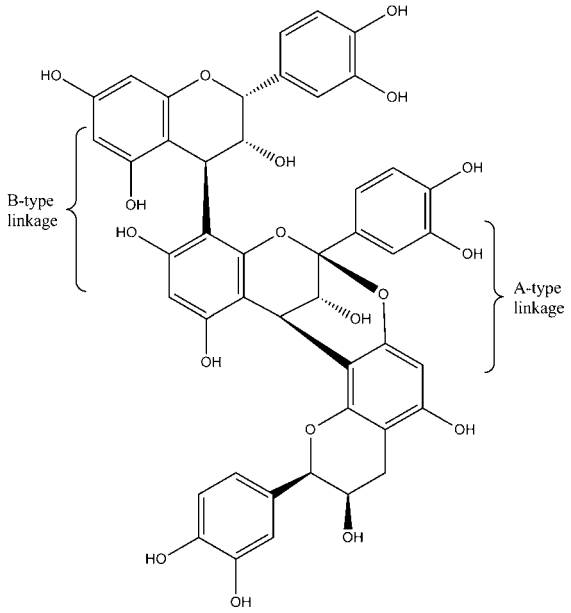

Figure 1. Representative structure of a trimeric proantocyanidin with both A-type and B-type linkages.

phase separation conditions using water and methanol[9,19,21,22] or acetonitrile[3,12,18,23] as mobile phases were used. Regarding quantitative aspects, HPLC proved to be useful for the determination of B-type proanthocyanidins in several food products. However, the red-berry product analyses were less effective due to the presence of both A-type and B-type proanthocyanidins and the lack of adequate standards.[24] The structural diversity of proanthocyanidins in red berry products led to complex profiles with poor chromatographic resolution. Furthermore, their analysis resulted in a great challenge due to the variety and quantity of proanthocyanidin-polymerized compounds.[9,21] High resolution mass spectrometry (HRMS) has also been proposed for the characterization of polyphenols in fruit products. Rockenbach et al.[18] used Fourier-transform ion cyclotron resonance mass spectrometry (FTICR-MS) to characterize and assign the elemental composition of 251 different flavan-3-ol compounds in grapes. Regarding cranberry-based products, Iswaldi et al.[12] proposed the use of time-of-flight mass spectrometry (TOF-MS) for the characterization of the phenolic fraction in cranberry syrup.

Capillary electrophoresis (CE) also appeared as an alternative technique for the analysis and characterization of polyphenolic compounds in fruit-based products.[25−29] There are, however, only a few studies that apply these techniques to the analysis of red berry fruits.[14,15] Because of the strong absorption of proanthocyanidins at 545 nm, simple colorimetric assays are still employed for the quantitative analysis of proanthocyanidins in cranberry-based products. The assay relying on the reaction of proanthocyanidins with 4-dimethylaminocinnamaldehyde is one of the most popular.[21,24]

Characterization and classification of fruit-based products can be tackled from compositional profiles as a source of analytical information. Polyphenols, as well as other low molecular weight organic acids, alcohols, esters, etc., have been found to be efficient descriptors of some climatic, agricultural, and technological features. It has also been found that the variability of compounds will depend strongly on the fruit of origin. Therefore, polyphenolic profile can be a useful platform for reliable discrimination between fruit-based products via chemometric methods such as principal component analysis (PCA). Information recovered mathematically may be essential in order to prevent misuses in the production of commercial fruit-based extracts with health-promoting properties.

The aim of this work was the development of straightforward methods for the characterization of fruit products based on polyphenolic composition. The resulting instrumental profiles were exploited to carry out the authentication of natural extracts according to the fruit of origin. For that purpose, the potentiality of capillary zone electrophoresis (CZE) and HPLC, combined with several sample extraction and treatment procedures, was evaluated in order to obtain compositional data with high discriminant ability. Different kinds of samples were analyzed including fruits (cranberry, blueberry, grapes, and raisins), fruit-based products such as grape-juice and cranberry-juice, as well as commercial cranberry-based products such as pharmaceutical natural extracts, powder capsules, syrup, and sachets. CZE and HPLC data from each method were considered as a source of potential descriptors for the authentication of fruit-based products.

MATERIALS AND METHODS

Reagents and Solutions. Unless otherwise stated, all reagents were of analytical grade. Acetic acid, formic acid, sodium tetraborate, Sephadex LH-20 and HPLC gradient grade acetone were obtained from Sigma-Aldrich (Steinhein, Germany). HPLC gradient grade acetonitrile and methanol were purchased from Panreac (Barcelona, Spain). Hydrochloric acid was from Merck (Darmstadt, Germany) and sodium hydroxide from Fluka (Steinhein, Germany).

Background electrolyte (BGE) for CE was prepared daily by diluting a 100 mM sodium tetraborate aqueous solution and by adding a 5% (v/v) of methanol. BGE solutions were filtered through 0.45 μm nylon filters (Whatman, Clifton, NJ) and sonicated before being used. Mobile phases for LC were prepared daily by adding 1% (v/v) acetic acid or 0.1% (v/v) formic acid to water, methanol, or acetonitrile.

Water was purified using an Elix 3 coupled to a Mili-Q system (Millipore, Bedford, MA) and filtered through a 0.22 μm nylon filter integrated into the Milli-Q system.

Fruit Products. Different kinds of fruits (cranberries, blueberries, grapes, and raisins) and 6 juices (3 based on cranberry and 3 based on grapes) were purchased from Barcelona markets. In addition, a total of 10 raw extract materials and commercial cranberry products, presented as powder capsules, syrup, sachets, and natural extracts were provided by Deiters, S.L. Company (Badalona, Spain). Prior to sample treatment, fruits and liquid samples (juices and cranberry pharmaceutical syrup) were freeze-dried to achieve a fully lyophilized product with a texture similar to that of natural extracts and commercial pharmaceutical samples (powder samples). So, samples remained 24 h inside a lyophilizer from −80 °C to room temperature, and then were kept for 6.5 h at 40 °C.

Sample Treatment. In order to extract phenolic compounds from fruit products different sample extraction procedures were evaluated as follows:

Sample Extraction Method 1.1: A 0.5-g portion of sample was dispersed in 10 mL of MeOH:H_2O (10:90 v/v) with 0.2% HCl. Then, the mixture was sonicated for 30 min and centrifuged for 15 min at 3500 rpm.[3]

Sample Extraction Method 1.2: Same as sample extraction method 1.1 with an additional SPE step after centrifugation. SPE was carried out using two g-bed C18 cartridges (Scharlab, Barcelona, Spain) previously conditioned with 10 mL of methanol and 10 mL of water. After loading the extract, the cartridge was washed with 10 mL of water and, finally, phenolic compounds were eluted with 10 mL of methanol.[30]

Sample Extraction Method 2.1: A 0.5-g portion of sample were dispersed in 10 mL of MeOH/H_2O (85:15 v/v). Then, the mixture was sonicated for 30 min and centrifuged for 15 min at 3500 rpm.[31]

dx.doi.org/10.1021/jf404776d | J. Agric. Food Chem. 2014, 62, 1038−1046

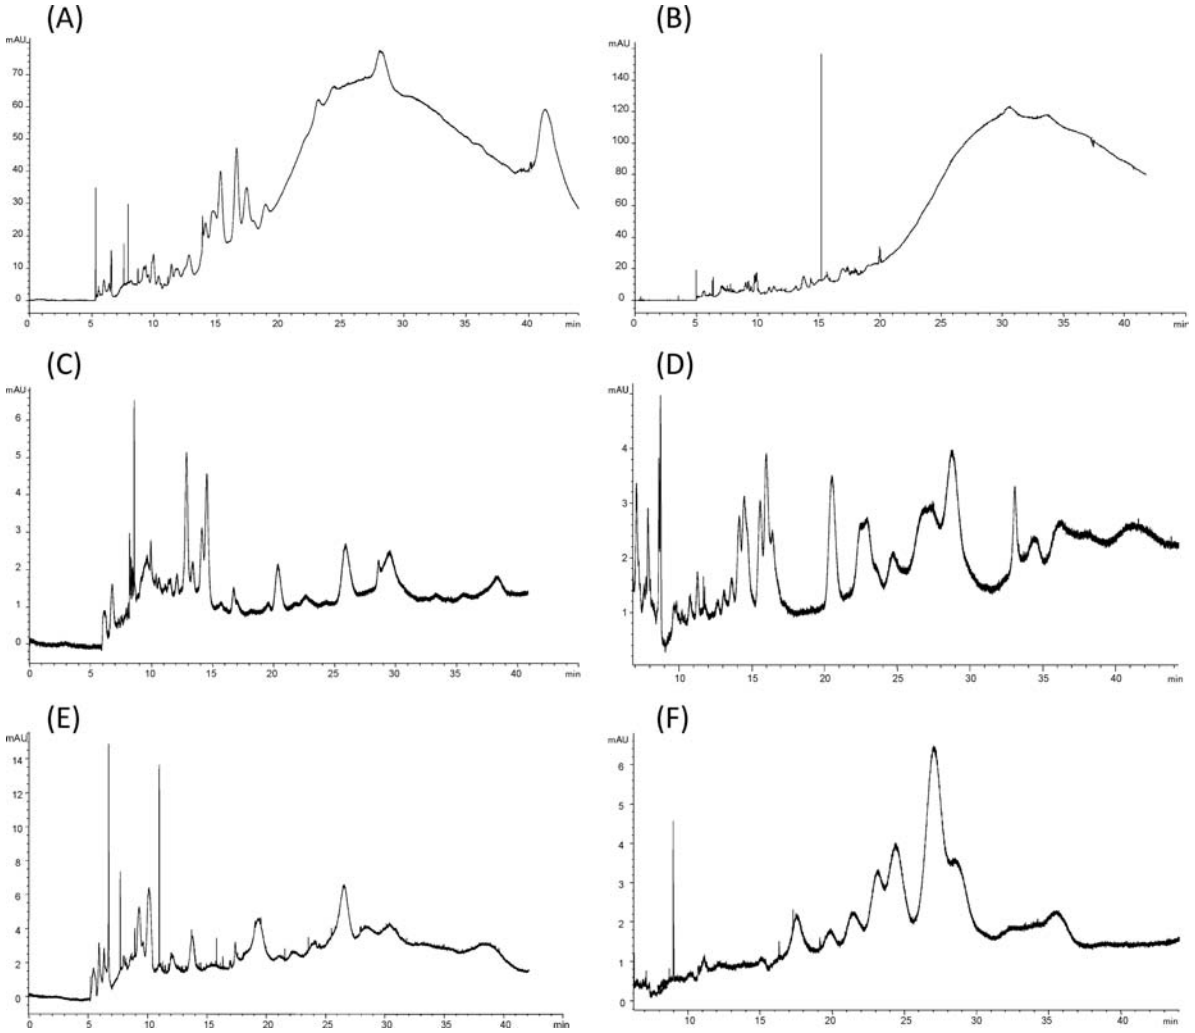

Figure 2. Electrophoretic polyphenolic profiles of a natural cranberry extract obtained after applying sample extraction methods 1.1 (A), 1.2 (B), 2.1 (C), 2.2 (D), 2.3 (E), and 3 (F). Electropherograms registered at 280 nm.

Sample Extraction Method 2.2: Same as sample extraction method 2.1, except from the extraction solvent, which in this case was acetone/MeOH/H_2O (40:40:20 v/v/v).[31]

Sample Extraction Method 2.3: Same as sample extraction method 2.1, except from the extraction solvent, which in this case was MeOH/H_2O/acetic acid (85:14.5:0.5 v/v/v).[31]

Sample Extraction Method 3: A 0.1-g portion of sample were dispersed in 10 mL of acetone/H_2O/HCl (70:29.9:0.1 v/v/v) and sonicated for 30 min. After that, the mixture was centrifugated for 15 min at 3500 rpm. The supernatant was then concentrated and semipurified using a 3 g Sephadex LH-20 cartridge (Sigma-Aldrich) preconditioned overnight in 30% methanol solution. After sample loading, the cartridge was washed with 10 mL of the 30% methanol solution and eluted with 10 mL of acetone/H_2O/HCl (70:29.9:0.1 v/v/v).[9,13]

All of the extracts were stored at −4 °C until analyzed. Before injection extracts were filtered through 0.45 μm nylon filters (Whatman).

Apparatus. *Capillary Zone Electrophoresis.* CZE experiments were performed in an Agilent HP 3D-CE system (Santa Clara, CA) equipped with a diode-array detector. The electrophoretic separation was carried out using fused-silica capillaries with a total length of 60 cm (effective length of 50 cm), and a 75 μm i.d. Background electrolyte (BGE) consisted of a 35-mM sodium tetraborate aqueous solution (pH 9.4) containing 5% (v/v) methanol. Capillary temperature was held at 25 °C. The BGE was degassed by sonication before use. Samples were loaded by pressure-assisted hydrodynamic injection (10 s, 3.5 kPa). Electrophoretic separations were performed by applying a capillary voltage of +25 kV. Analyses were carried out for 40 min and direct UV absorption was recorded from 190 to 310 nm. Electrophoretic data were processed at 280 nm.

New capillaries for CE were pretreated with 0.1 M hydrochloric acid for 60 min, water for 60 min, 0.1 M sodium hydroxide for 60 min, and finally they were washed with water for 60 min. At the beginning of each working session, the capillary was rinsed with 0.1 M sodium hydroxide for 30 min, water for 30 min, and with the BGE for 60 min. The capillary was rinsed with BGE for 5 min between runs. At the end of each session, the capillary was stored after rinsing with water.

Liquid Chromatography. LC experiments were performed on an Agilent LC 1100 System (Santa Clara, CA) equipped with a diode array detection system. Separation was carried out on a 100 × 4.6 mm^2 i.d., 2.6 μm, Kinetex C18 reversed-phase column, with a 4.0 × 3.0 mm^2 i.d. guard column of the same material (Phenomenex, Torrance, CA). The injection volume was 10 μL and UV absorption was recorded from 191 to 780 nm. Chromatographic data were processed at 280 nm. Three different gradient profiles were considered for the separation of polyphenolic fractions as follows:

Gradient Method A. Gradient method A was created from solvent A (H_2O with 0.1% formic acid) and solvent B (MeOH) as follows: 0−3 min, linear gradient from 5 to 25% B; 3−6 min isocratic step at 25% B; 6−9 min linear gradient from 25 to 37% B; 9−13 min isocratic step at 37% B; 13−18 min linear gradient from 37 to 54% B; 18−22 min isocratic step at 54% B; 22−26 min linear gradient from 54 to 95% B; 26−29 min isocratic step at 95% B; 29−29.15 min back to initial

conditions at 5% B; and from 29.15 to 36 min isocratic step at 5% B. The flow rate was 1 mL/min.

Gradient Method B. Gradient method B was created from solvent A (H_2O with 1% acetic acid) and solvent B (acetonitrile with 1% acetic acid) as follows: 0−2 min linear gradient from 0 to 5% B; 2−4 min isocratic step at 5% B; 4−30 min linear gradient from 5 to 100% B; 30−35 min isocratic step at 100% B; and from 35 to 40 min back to initial conditions at 0% B. The flow rate was 1 mL/min.

Gradient Method C. Gradient method C created from solvent A (H_2O with 1% acetic acid) and solvent B (acetonitrile with 1% acetic acid) as follows: 0−20 min linear gradient from 0 to 8% B; 20−24 min linear gradient from 8 to 15% B; 24−44 min linear gradient from 15 to 40% B; 44−45 min linear gradient from 40 to 100% B; and from 45 to 46 min back to initial conditions at 0% B. The flow rate was 1 mL/min.

Data Analysis. MATLAB (Version 6.5) was used for calculations. Principal component analysis (PCA) was from the PLS-Toolbox.[32] A detailed description of this method is given elsewhere.[33]

The plot of scores showing the distribution of the samples on the principal components (PCs) revealed patterns that may be correlated to sample characteristics, which in this case, was the fruit of origin. The study of the distribution of variables from the so-called loading plot provided information dealing with their correlations as well as dependences of proanthocyanidins and polyphenolic compounds on fruit product properties.

Data matrices to be treated were generated as a function of the separation technique, separation method and sample treatment procedure. Separation techniques were coded by CE for the CZE method, and by A, B, C for the three HPLC methods. Extraction procedures were coded numerically as 1.1, 1.2, etc. in the same way as described in the sample treatment section. As a result, data matrices were referred to as CE.1.1, CE.1.2, ..., A.1.1, ..., B.1.1, C.1.1, and so on. Dimensions of these matrices were number of samples × number of time (or area) points.

HRMS (Orbitrap) Analysis. In order to identify and confirm the presence of proanthocyanidins in commercial natural extracts accurate mass measurements were carried out with an LTQ Orbitrap Velos mass spectrometer (Thermo Scientific, Hemel Hempstead, UK) equipped with an ESI source in negative mode. Mass spectra were acquired in profile mode with a setting resolution of 30 000 at m/z 400. Operation parameters were as follows: source voltage, 3.5 kV; sheath gas flow rate, 40 arbitrary units (a.u.); auxiliary gas flow rate, 10 au; sweep gas flow rate, 10 au; and capillary temperature, 320 °C. Default values were used for other acquisition parameters [Fourier transform (FT) Automatic gain control (AGC) target 10^6 for MS mode]. Maximum injection time was set to 100 ms with two microscans for MS analysis. Full scan mass range was from m/z 100 to 2000. XCalibur software was used for data acquisition and analysis.

HPLC method A was employed for LC-ESI-LTQ-Orbitrap-MS analysis by using an Accela chromatograph (Thermo Scientific) equipped with a quaternary pump, a photodiode-array detector and a thermostatted autosampler. Commercial natural extracts analyzed by LC-ESI-LTQ-Orbitrap-MS were treated with sample extraction method 3. MS data were processed by ExactFinder 2.0 software (ThermoFisher) by applying a user target database list of polyphenolic compounds including proanthocyanidins. Several parameters such as retention time, accurate mass errors, and isotopic pattern matches were used to confirm the identity of compounds.

RESULTS AND DISCUSSION

Capillary Zone Electrophoresis. In this study, both methanol and isopropanol were evaluated as organic modifiers to obtain better electrophoretic separations of polyphenolic profiles of cranberries products. For preliminary assays, a natural cranberry extract sample was homogenized and extracted according to method 1.1. The extract was then analyzed by CZE using a 35 mM sodium tetraborate solution containing 5% of each organic solvent. Electropherograms obtained using methanol provided more peak signals, with better resolution and peak efficiency than those obtained with isopropanol. As a result, 35 mM sodium tetraborate buffer with 5% methanol was selected as the optimum BGE, and it was used in further CZE studies.

The sample treatment procedures were investigated in term of capacity of classification/discrimination of fruit samples considering the polyphenolic profiles as the analytical information. Figure 2 shows, as an example, the electropherograms corresponding to each extraction procedure. Methods 1.1 and 1.2 were focused on obtaining a general polyphenolic profile with data of various families of compounds and they were adapted from refs 3, 20, and 30 dealing with the analysis of phenolic compounds in berries. In sample extraction method 1.2 an additional SPE cleanup and preconcentration step using C18 cartridges was added. As it can be seen in electropherograms 2A and 2B, a high absorption pattern was observed from 20 to 45 min, which was attributed to the presence of some plant pigments such as anthocyanins.

Sample treatments 2.1, 2.2, and 2.3 differed in the polarity of solvents that were used. These procedures were adapted from those previously described in the literature.[31,34] Sample extraction method 2.1 employed a methanol/water 85:15 v/v solution, and it was focused on the recovery of the most polar fractions of compounds. Extraction method 2.2 used acetone/methanol/water 40:40:20 v/v/v solution for the extraction of less polar compounds occurring in cranberries. Additionally, methanol/water/acetic acid 85:14.5:0.5 v/v/v solution was used in method 2.3 to obtain the anthocyanin fraction of fruits. The corresponding electropherograms (Figures 2C−E) showed complex profiles with multiple peaks throughout the migration time.

Finally, sample extraction method 3 was developed for a more specific recovery of proanthocyanidins from cranberry products.[9,13,21,35] For that purpose, after an extraction using acetone:water:hydrochloric acid 70:29.9:0.1 v/v/v solution, sonication and centrifugation, the supernatant was concentrated and purified using a lipophilic inorganic resin (Sephadex LH-20 cartridges). Electrophoretic profiles (Figure 2F) contained more characteristic information concerning proanthocyanidins as various broad peaks corresponding to these compounds were obtained.

Principal Component Analysis of Electrophoretic Data. Sample extracts resulting from the 6 treatment procedures were analyzed by the proposed CZE-UV method. The resulting electrophoretic profiles were used as a source of information for tackling characterization and classification of fruit products. An important issue in this study was finding which procedure was able to provide the most discriminant profiles for sample featuring.

In preliminary studies, analytical data to be treated consisted of the raw electrophoretic profiles at 280 nm recorded for the set of samples. In all of the cases, electropherograms showed noticeable differences depending on the sample type. For instance, pharmaceutical products (syrup, capsules, and sachets) displayed more intense signals than those of fruit and juice samples. This finding was attributed to the high contents of polyphenols in the pharmaceuticals.

Raw electropherograms displayed some imperfections such as baseline drifts and peak shifts that may hinder the interpretation of PCA results. When raw data were analyzed PCA models were highly complex. Furthermore, the first PCs were focused on modeling the electrophoretic variability while

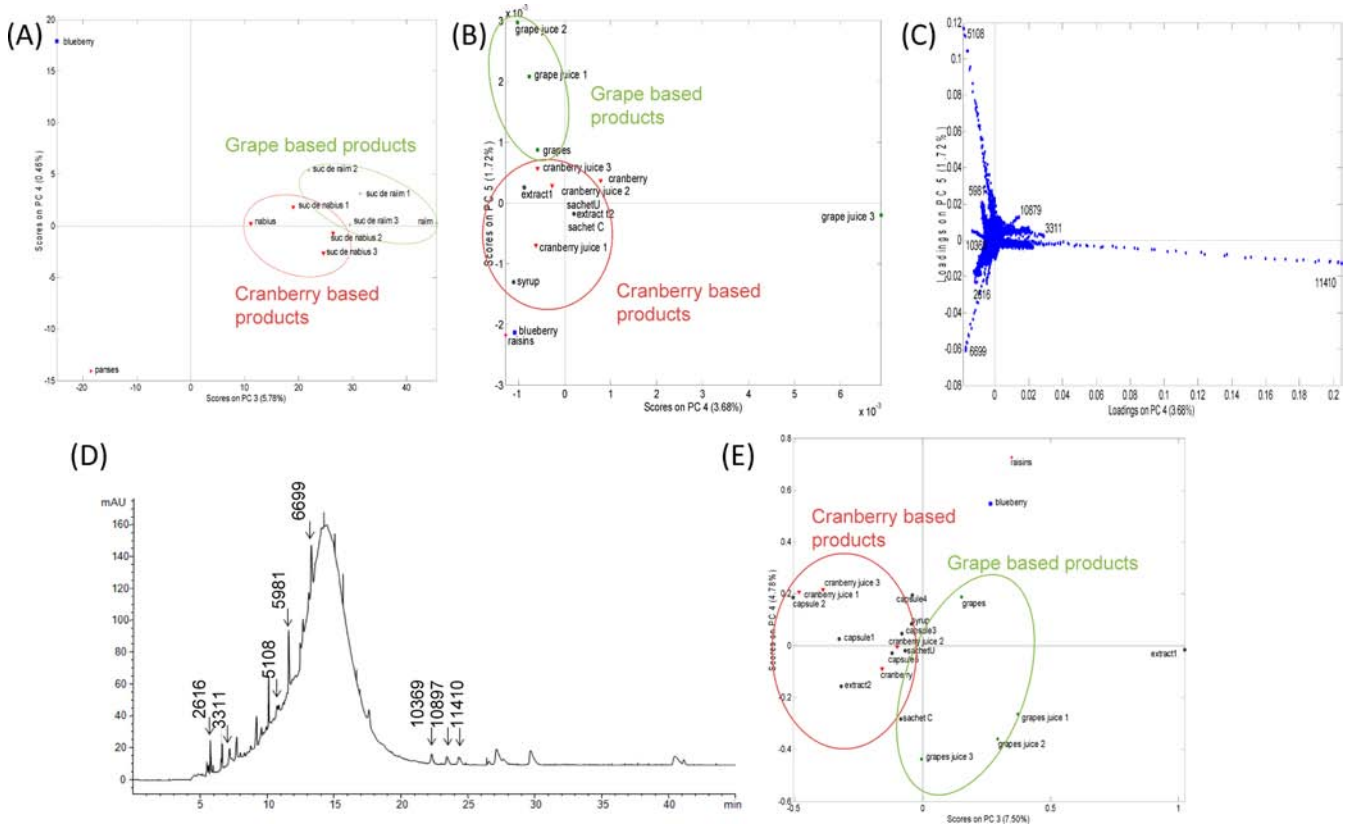

Figure 3. (A) PCA result (PC3 vs PC4 score plot) using electrophoretic polyphenolic profiles obtained with sample extraction method 1.2 for fruits and juice samples; (B) PCA results (PC4 vs PC5 score plot) using electrophoretic polyphenolic profiles obtained with sample extraction method 2.1 for all samples except pharmaceutical capsules. (C) Loading plot using peak signal areas and sample extraction method 2.1. (D) Electropherogram obtained for a cranberry commercial capsule using sample extraction method 2.1. Discriminant peak signals are indicated with an arrow. (E) PCA result (PC3 vs PC4 score plot) using eight discriminant peak signal areas and sample extraction method 2.1.

descriptive information regarding samples was hidden in further PCs. In these circumstances, the assessment of solid conclusions on the sample characteristics and classifications was hindered.

PCA was preliminarily applied to electropherogram profiles of fruits and juice samples. As an example, results showed that PC1 and PC2 for data matrix CE.1.2. were mainly focused on the description of the type of product (juice or fruit), and variance dealing with fruit of origin (cranberry or grapes) was captured by PC3 and PC4 (Figure 3A). As a result, fruits and juices were classified according to the kind of fruit that they contained. Similar results were obtained when using the other sample extraction methods.

For the simultaneous evaluation of pharmaceutical and fruit products, it was found that electrophoretic profiles of pharmaceuticals were much more intense that those obtained for fruits and juices, so data normalization was needed. Only the scatter plot of scores of PC4 versus PC5 generated with data from sample extraction method 2.1 (see Figure 3B) showed the same groups of samples than the ones achieved with the model built only with fruits and juices when considering also data related to cranberry syrup, sachets, and natural extract, whereas the model completely changed when the electropherograms of cranberry commercial capsules were considered and then no groups were observed.

Up to this point, the results obtained by PCA using raw electrophoretic polyphenolic profiles indicated that none of the data sets was capable of characterizing all of the targeted samples according to their fruit of origin. This drawback was solved using the peak areas of the most relevant peaks as a source of analytical information, thus avoiding variability of migration times and baseline drifts. For that purpose, loading plots were evaluated for choosing the most discriminant peak signals as shown in Figure 3C regarding CE.2.1 data set. After analyzing these results, eight peaks were selected as relevant ones. As an example, Figure 3D depicts the electropherogram of a cranberry commercial capsule where the eight discriminant peak signals selected are marked with an arrow. It should be mentioned that again normalization was applied to compensate differences in intensities between fruit or juice samples and commercial products.

Characterization models using the selected peaks indicated that information of the fruit of origin was captured by PC3 and PC4. The best descriptive models were obtained from the treatment of data set CE.2.1 (see the corresponding scatter plot in Figure 3E). As can be seen, grape-based products were located on the right part, whereas cranberry-based products appeared on the left side, grouped independently of the kind of product (fruit, juice, syrup, natural extract, capsules, or sachets). Sample products belonging to other fruits, such as blueberry and raisins, were plotted far away from the two main groups corresponding to grape- or cranberry-based products.

After analyzing these results, it was observed that cranberry extract 1 was not located in the area corresponding to cranberry-based products. This natural extract, used on the production of pharmaceutical products to reduce urinary tract

infections, was supposed to be elaborated from cranberries. However, our results suggested that the fruit of origin could be suspicious and, in general, it was more similar to grape products. This assumption was studied thoroughly to try to confirm the authenticity of this natural extract by high resolution mass spectrometry (HRMS).

These results show that the combination of CZE with sample extraction method 2.1 and PCA analysis using eight discriminant peak signal areas is a good strategy for the characterization of food products based on their fruit of origin and could be proposed for the authentication of commercial natural and pharmaceutical products.

Liquid Chromatography. Chromatograms corresponding to polyphenolic fractions were exploited in order to tackle the classification and authentication of cranberry-based natural extracts. For that purpose, three reversed-phase HPLC methods, which differed in the elution gradient program, were applied to obtain the compositional profiles. As an example, Figure 4 shows the chromatograms of a cranberry natural extract analyzed with each HPLC method. For HPLC method A (Figure 4A), previously developed in our research group for the characterization of wines and fruits, the chromatographic profile was complex. In the time range from 4 to 28 min, the elution of most of phenolic acids and flavonoids was produced so this data could be useful for the fruit product characterization. HPLC method B provided also complex chromatograms with a high number of peak signals that could be useful for characterization purposes (Figure 4B). In contrast, chromatograms from HPLC method C (Figure 4C) were simpler, at least in terms of peak signals, but it provided important information of proanthocyanidins composition.

Sample extracts of a cranberry juice according to the six sample treatment procedures are compared in Figure 5. As can be seen, very different chromatographic profiles were obtained depending on the sample extraction. However, in general, more peak signals were here observed than in the case of CZE. Chromatograms (A), (C), and (E) were similar in shape and corresponded to methods focused on the overall recovery of polyphenols of different families. In general, it was found that the extraction of polyphenols was better in the case (E). Conversely, chromatograms (B), (D), and (F) concerned the

dx.doi.org/10.1021/jf404776d | J. Agric. Food Chem. 2014, 62, 1038−1046

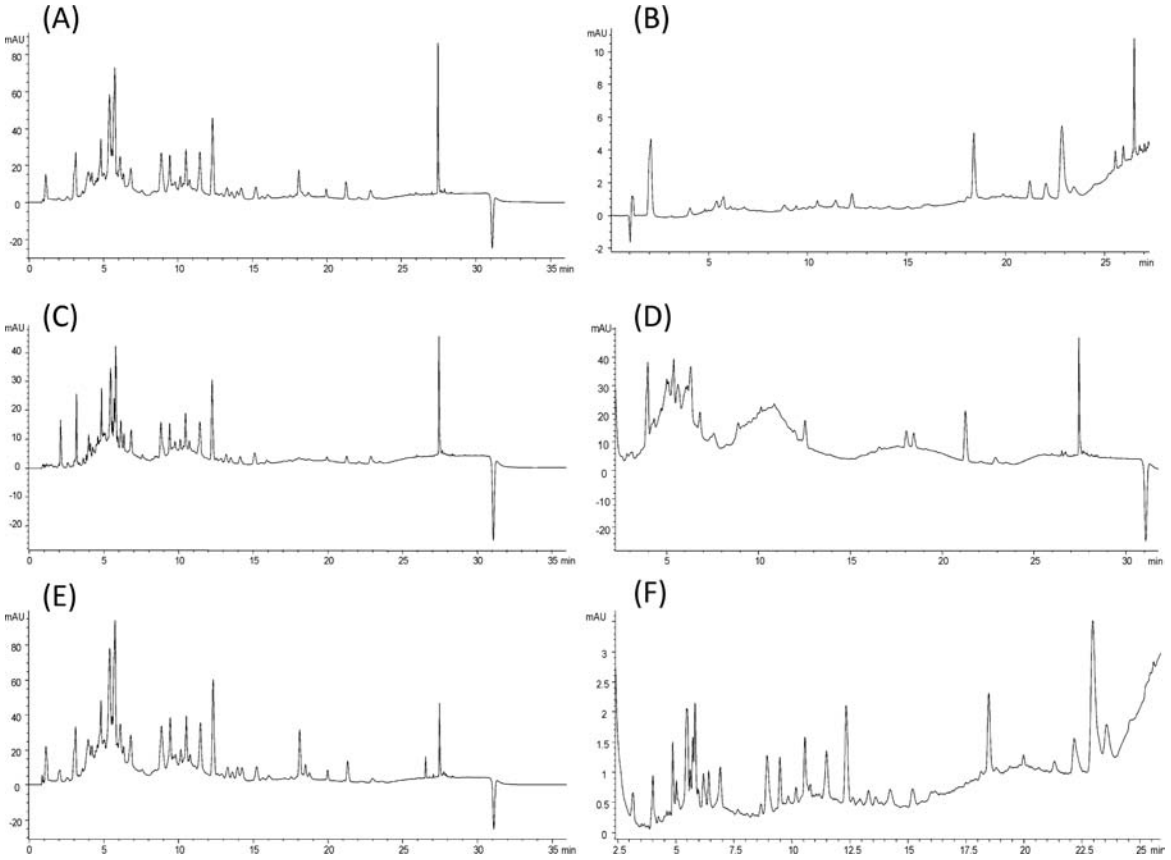

Figure 5. Chromatographic polyphenolic profiles of a cranberry juice sample obtained using HPLC method A after applying sample extraction methods 1.1 (A), 1.2 (B), 2.1 (C), 2.2 (D), 2.3 (E), and 3 (F). Chromatograms registered at 280 nm.

most extraction of polyphenols of some families. Amounts recovered from simple phenolic acids and flavonoids were lower so that more characteristic peaks related to complex polyphenols such as proanthocyanidins were observed.

Principal Component Analysis of Chromatographic Data. Analytical data to be treated by PCA consisted of raw chromatograms recorded at 280 nm. Data sets were arranged in matrix structures corresponding to each HPLC method/sample extraction combination. For more efficient modeling, specific time ranges were selected to work with the most discriminant zones of chromatograms, while avoiding disturbing variance from nonretained components and cleaning steps. In particular, time ranges dealing with high influence of proanthocyanidins were chosen. Here, these chromatographic zones were established from the injection of cranberry-based pharmaceutical products, which reasonably contained high concentrations of proanthocyanidins. Since proanthocyanidin absorption was almost selective at 520 nm,[19,21] corresponding to the detection of colored components, the elution range of the proanthocyanidins fraction was deduced from chromatograms recorded at this specific wavelength. As a result, time ranges chosen were as follows: HPLC Method A from 7 to 15 min, HPLC Method B from 6 to 15 min, and HPLC Method C from 12 to 20 min. Another drawback to be considered was that chromatograms showed noticeable differences on signal intensities depending on the sample type. In this study, data were preprocessed by normalization to equalize the influence of each sample in the PCA model for a more effective comparison of product features.

The results obtained by PCA for all data matrices indicated that PC1, PC2, and PC3 were mainly focused on the description of the type of product regardless the nature of the fruit of origin (i.e., fruit, juice, natural extract, sachet, capsule, and syrup) since this was a main contribution to the variance. In contrast, information dealing with the fruit of origin, if existent, was captured by further PCs. In particular, for matrices A.1.1, A.1.2, A.2.1, A.2.3, B.1.1, B.3, C.2.1, and C.2.3, PC4 and PC5 showed a noticeable sample organization as a function of the fruit of origin. Such a correlation was not observed for the rest of the matrices. The most favorable data set to tackle the description and classification of fruit product was achieved with HPLC method A and sample extraction procedure 3 which combined a high chromatographic resolution with a more specific recovery of proanthocyanidins. In the PCA results corresponding to matrix A.1.1. (Figure 6), grape-based products were located on the top, whereas cranberry-based products appeared below. In addition, sample products belonging to raisins and blueberry were plotted far from grape- and cranberry-based products areas.

One cranberry natural extract (referred to as extract 1), was classified as a grape-based product. In order to confirm the authenticity of this extract, HRMS experiments were carried out comparing the supposedly wrong with genuine samples.

High Resolution Mass Spectrometry (Orbitrap) Study. As described in the Introduction section, cranberries are characterized for their high content of A-type proanthocyanidins. Sample extract 1 was analyzed by UHPLC-HRMS using an LTQ-Orbitrap mass analyzer. For comparison purposes, commercial sample extract 2, which was correctly assigned as a

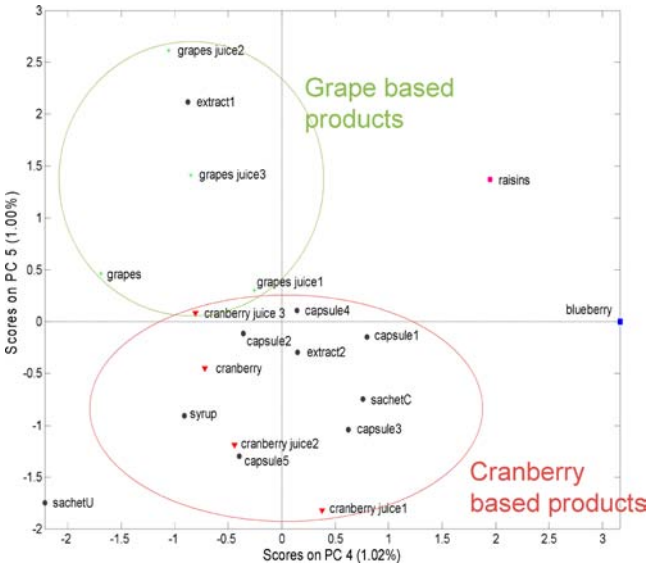

Figure 6. PCA results (PC4 vs PC5 score plot) using chromatographic polyphenolic profiles obtained using HPLC method C and sample extraction 3.

cranberry-based product with both CZE and HPLC methodologies, was also analyzed by UHPLC-HRMS as a reference of genuine products. Results obtained regarding the presence of procyanidins and proanthocyanidins are shown in Table 1. It should be pointed out that many other polyphenolic compounds such as catechin, epicatechin, protocatechuic acid, 2,5-dihydroxybenzoic acid, 4-hydroxybenzoic acid, caffeic acid, coumaric acid, cinnamic acid, vanillic acid, and quercetin, among others, were confirmed by HRMS in this kind of samples.

Table 1 shows the list of procyanidin and proanthocyanidin compounds detected and identified by HRMS Orbitrap MS analyzer. Experimental m/z values and mass errors observed (always lower than 3.4 ppm) are also indicated. A- and B-type procyanidins were found in both commercial extracts whereas C-type procyanidins were only detected and confirmed in commercial extract sample 2. Regarding proanthocyanidins, only trimer BA was detected in both samples, while the presence of higher polymeric proanthocyanidin compounds with A-type bonds, such as trimer AA and tetramer BAA, were only detected and confirmed in commercial extract sample 2. The HRMS analysis reporting the lack of presence of A-type proanthocyanidin compounds in commercial sample extract 1 allowed us to confirm that this sample was not mainly cranberry-based extract, as suspected.

The results obtained in this work proved that both CZE and HPLC combined with PCA analysis (selecting the most relevant peak signals in CZE, and using the polyphenolic chromatographic data within a delimited time range in HPLC) resulted in cheap, straightforward, and useful strategies for authentication of natural extracts according to the food of origin. PCA results from both CZE and HPLC showed that sample extract 1 was not a cranberry-based product, which was confirmed by HRMS analysis. By means of these results, the suitability of the proposed methods for the characterization of fruit-based products has been validated and demonstrated. So the information recovered with the proposed methods could be used to easily detect adulterations and prevent misuse.

21	Harberts Renette	43	Riesenboikenapfel	L211	Gewürzluiken	F210	Weißer Winterkalvill
22	Hausapfel	44	Roter Boskoop	L206	Hallauer Maienapfel	F208	Winterzitrone

This holds true especially for noncommercial, old varieties that are only grown in restricted geographic regions.

In this study the phytochemical composition of apple juices derived from 88 mostly noncommercial old varieties of apples cultivated in Upper Austria was determined. Information on the vast majority of the analyzed juices, especially concerning the polyphenolic content, is still lacking. The results of our study will help to identify available local apple varieties that are of particular interest for the development of apple-based food with a strong focus on health beneficial effects.

MATERIALS AND METHODS

Materials and Reagents. (+)-Catechin, α-amylase from porcine pancreas, AAPH (2,2′-azobis(amidinopropane) dihydrochloride), ABTS (2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonic acid), acetonitrile, AG1478, bovine catalase, epidermal growth factor (EGF), fluorescein sodium salt, Folin−Ciocalteu reagent, in vitro toxicology assay kit, methanosulfonic acid, phenolphthalein, potassium persulfate, potassium phosphate, nitric acid, rosmarinic acid, sodium bicarbonate, sodium hydroxide, trifluoroacetic acid (TFA), and Trolox [(±)-6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid] were purchased from Sigma Aldrich (Taufkirchen, Germany). Standards for K^+, Mg^{2+}, and Ca^{2+} (Certipur, cation multielement standard III) and antimony tartrate solution were from Merck-Millipore (Vienna, Austria). Potassium dihydrogen orthophosphate, ascorbic acid, methanol, and ammonium molybdate were purchased from VWR (Vienna, Austria). Sulfuric acid was obtained from Fisher Scientific (Vienna, Austria). Chlorogenic acid, epicatechin, epigallocatechin, epigallocatechin gallate, epicatechin gallate, procyanidin B1, procyanidin B2, and phloridzin were purchased from Extrasynthese (Genay, France). 96-Well plates were from Greiner Bio-One (Kremsmünster, Austria). Fetal calf serum, penicillin/streptomycin, and DMEM high glucose medium were purchased from PAA (Pasching, Austria). A protein phosphorylation analysis kit termed "cell-based Delfia assay" including a europium-labeled anti-phosphotyrosine-antibody was obtained from Perkin-Elmer (Rodgau, Germany). The Syto62 cell stain reagent was from Life Technologies (Darmstadt, Germany).

Apple Variety Selection and Preparation. All apple varieties were grown under organic conditions in the Eferding region of Upper Austria. This region termed Eferdinger Becken is a plain landscape area near the Danube river and has the most moderate climate in Upper Austria. The soil in this region consists mainly of loose or clayey sediments and is low or free of lime. The apples were collected in September and October 2010 and immediately processed to apple juice. Apples were washed and the juice was pressed out using a conventional juice maker (Kenwood JE 850 XXL). At least 10 apples harvested from three to five individual trees were processed to generate a combined juice for each variety to account for differences within apples from the same variety. The samples were stored at <−60 °C without addition of ascorbic acid. Analyzed apple varieties are shown in Table 1.

Total Phenolic Content (TPC). Total phenolic content was determined using Folin−Ciocalteu reagent as described previously[13] with small modifications. In short, apple juice was centrifuged at 10,000 rpm for 10 min and only the supernatant was used for total phenolic quantitation, since the cloudiness of apple juice has been reported to influence the obtained TPC values.[14] Deionized water (1.4 mL) was mixed with 16.7 μL of apple juice supernatant and 83.3 μL of Folin−Ciocalteu reagent. The mixture was allowed to stand for 3−6 min at room temperature followed by addition of 167 μL of sodium bicarbonate solution (200 g/L). After 70−75 min incubation at room temperature in the dark absorbance was measured at 750 nm. Total phenolic content was expressed as (+)-catechin equivalents in mg/L apple juice. Each juice was measured in triplicate.

Trolox Equivalent Antioxidant Capacity (TEAC). Total antioxidant capacity of different apple juices was measured using the ABTS decolorization assay.[15] Apple juices were diluted 1:10 with deionized water and analyzed by mixing 500 μL of diluted ABTS radical solution with 10 μL of diluted juice. After 5 min incubation at 30 °C the absorbance was measured at 734 nm. Results were quantitated based on a dilution series of Trolox ranging from 6.25 μM to 1 mM. Each juice was measured in triplicate.

Oxygen Radical Absorbance Capacity (ORAC) Measurements. The ORAC assay was performed as described previously with slight modifications.[16] Apple juices were centrifuged (5 min; 10,000 rpm) prior to measurement. Supernatant was further diluted (1:200) with phosphate buffer (10 mM, pH 7.4). In short, 150 μL of fluorescein (10 nM) was pipetted into each well and 25 μL of the standard (Trolox) or diluted apple juice was added. The plate was incubated at 37 °C for 30 min in the dark followed by addition of 25 μL of AAPH solution (240 mM) per well. The decrease in fluorescence of fluorescein was determined by collecting readings at

excitation of 485 nm and emission of 520 nm every minute for 90 min on a plate reader (POLARstar omega, BMG LABTECH, Ortenberg, Germany). The ORAC value was calculated using the ORAC plugin of the Omega MARS plate reader software. Each juice was measured in triplicate.

Mineral Nutrients, Phosphate, and Trace Elements. The minerals K^+, Mg^{2+}, and Ca^{2+} were quantitated by ion chromatography (Dionex ICS1000, Thermo Fisher Scientific, Vienna, Austria). An Ionpac CS 12A 4 mm column was used for the separation of the different cations. The mobile phase consisted of 20 mM methanosulfonic acid, the flow rate was 1 mL/min, and sample injection volume was 25 μL.

Phosphate concentrations were measured using a phosphomolybdate method.[17] The apple juices were passed through a 0.45 μm filter. 500 μL of apple juice, 2 mL of ddH_2O water, 100 μL of ascorbic acid solution (10 g of ascorbic acid in 100 mL of ddH_2O), and 200 μL of ammonium molybdate solution were mixed and filled up to 5 mL with ddH_2O. As a phosphate standard, potassium dihydrogen orthophosphate was used. Absorbance was measured at 880 nm.

The trace elements Mn^{2+}, Cu^{2+}, and Fe^{2+} were quantitated by inductively coupled plasma mass spectrometry (ICP-MS). Prior to measurement 1 mL of apple juice was mixed with 3 mL of HNO_3 and microwave-digested using the MLS Ultraclave-IV. The resulting clear solution was diluted 1:10 with ddH_2O. ICP-MS measurements were performed using an Agilent ICP-MS 7500 cx spectrometer (Agilent Technologies, Santa Clara, CA, USA) operated in He mode (Mn^{2+} and Cu^{2+}) or H_2 mode (Fe^{2+}). Each juice was measured in triplicate.

Identification and Quantitation of Polyphenols by HPLC. RPC-MS analysis was performed on an Agilent 1100 HPLC system equipped with a vacuum degasser, a quaternary pump, an autosampler, and a UV−vis diode array detector (all from Agilent Technologies, Santa Clara, CA, USA). Separations were carried out using an ODS Hypersil column (250 mm × 4.6 mm inner diameter; 1.8 μm particle size; Thermo Fisher Scientific, Austria). Analytes were separated by gradient elution with 0.1% (v/v) formic acid (A) and acetonitrile containing 0.1% (v/v) formic acid (B) at a flow rate of 1 mL/min. The linear gradient elution program was as follows: starting conditions 97.5% A and 2.5% B; the proportion of B was increased to 10% at 20 min, 20% at 32 min, 50% at 45 min, and 80% at 50 min. The column was thermostatted at 40 °C, and the injection volume was 20 μL.

MS measurements were done on a 6520 quadrupole/time-of-flight (Q-TOF) instrument equipped with an electrospray ionization source (Agilent Technologies, Santa Clara, CA, USA). Results were obtained using the following settings: MS capillary voltage 3750 V, fragmentor voltage 180 V, drying-gas (nitrogen) flow rate 12 L/min, drying-gas temperature 350 °C, and nebulizer pressure 60 psi. Scanning mass range was from m/z 70 to 3200 with an acquisition rate of 1.0 spectra/s in the negative MS mode.

Quantitation of identified polyphenols was done using UV absorption by reference substances of known concentrations prepared in deionized water. For reversed phase chromatography (RPC) analysis a Jasco LC-2000 Plus Series system comprising a quaternary pump with build-in degasser, an autosampler, a temperature controlled column compartment, and a diode array detector (DAD) equipped with Chrompass software (all from Jasco Corporation, Tokyo, Japan) was used. Separation was performed on a Hypersil ODS C18 column (250 mm × 4.6 mm inner diameter, 5 μm particle size; Thermo Fisher Scientific, Vienna, Austria). Column temperature was set to 40 °C, and elution was carried out at 1 mL/min. The injection volume for all samples was 20 μL, and eluted substances were detected using multiple UV wavelengths from 200 to 350 nm. The following conditions were used for RPC analysis: Mobile phase A contained 0.1% TFA in water. Mobile phase B contained acetonitrile, water, and TFA in the ratio 50:50:0.1 (%). Mobile phase C contained 0.1% TFA in acetonitrile. The starting conditions were 95% A and 5% B. Elution was performed with a linear gradient: The proportion of B was increased to 20% at 20 min, 40% at 32 min, and 100% at 45 min. Limit of detection (LOD) was defined as signal-to-noise ratio of 2:1 and limit of quantitation (LOQ) as 4:1. For flavan-3-ols LOD of 0.1 mg/L and LOQ of 0.4 mg/L were defined with a linear range of 1−500 mg/L. For hydroxycinnamic acids LOD of 0.05 mg/L and LOQ of 0.2 mg/L were defined with a linear range of 1−1,000 mg/L. For quercetin derivates LOD of 0.1 mg/L and LOQ of 0.3 mg/L were defined with a linear range of 0.1−100 mg/L. Apple juice samples were centrifuged for 10 min at 15,000 rpm followed by 0.1 μm filtration to remove any remaining solids before analysis.

Quantitation of Acid Content by HPLC. Malic and citric acid content was quantitated for each sample using a RPC method described previously.[18] Quantitation was done using purified malic and citric acid dissolved in deionized water. For RPC analysis a Jasco LC-2000 Plus Series system was used as described above. Separation was performed on a Sorbax SB-C18 column (75 mm × 4.6 mm inner diameter, 3.5 μm particle size; Agilent Technologies, Santa Clara, CA, USA). Column temperature was set to 35 °C, and isocratic elution was carried out at 0.5 mL/min. A 50 mM potassium phosphate buffer adjusted to pH 2.8 was used as mobile phase. Apple juice samples were centrifuged for 10 min at 15,000 rpm followed by 0.1 μm filtration to remove any remaining solids before analysis. The injection volume for all samples was 2 μL, and eluted substances were detected at 215 nm. Limit of detection (LOD) was defined as signal-to-noise ratio of 2:1 and limit of quantification (LOQ) as 4:1. For citric acid a LOD of 20 mg/L and LOQ of 50 mg/L were defined with a linear range of 20−1,000 mg/L. For malic acid the LOD was defined at 50 mg/L and the LOQ at 100 mg/L with a linear range of 0.1−20 g/L.

Quantitation of Fruit Acids by Titration. Total acid content was determined using the acidic titration method described in an OECD guideline for food production, which can be found on the OECD Web site (www.oecd.org/agriculture). In short, apple juice was diluted 1:10 with deionized water, mixed with 3 μL of phenolphthalein, and titrated with 0.1 M sodium hydroxide until the point of neutrality was reached (indicator changes from colorless to pink). Results were expressed as g/L of malic acid.

Quantitation of Anthocyanin Pigment Content. The anthocyanin content of apple juices was determined using a pH differential method.[19] In brief, apple juices were diluted 1:5 either in pH = 1.0 buffer (0.025 M potassium chloride) or in pH = 4.5 buffer (0.4 M sodium acetate) adjusted with HCl and transferred to 10 mm cuvettes. Absorbance (A) of each diluted sample was determined at 520 and 700 nm within 15 min after preparation for both pH values. The anthocyanin pigment concentration was calculated as cyanidin-3-glucoside equivalent. The quantitation limit for this method was determined to be 0.1 mg/L. Each juice was measured in triplicate.

Sugar Content Measurements. The sugar content of analyzed apple juice samples was measured using a RHB-55 refractometer (PCE-group, Meschede, Germany). In short, a single drop of undiluted apple juice was loaded onto the prism and the °Brix value was read from the graduation.

Amylase Activity. Inhibition of amylase activity by various apple juices was analyzed using a modified commercial amylase assay (Abcam, Cambridge, U.K.). The nitrophenol included in the assay was used to generate a standard curve. The apple juice samples were incubated with 1 mg/mL α-amylase for varying time periods in 96-well plates. For α-amylase activity measurements, double distilled water was used as a reagent blank, and rosmarinic acid (1.5 mg/mL), a known α-amylase inhibitor,[20] served as a positive control. 50 μL of the individual samples (apple juice diluted 1:10 in ddH_2O) was mixed with 100 μL of reaction reagent composed of 50 μL of assay buffer and 50 μL of substrate mix (containing substrate and α-glucosidase). Absorption was measured using a plate reader (POLARstar omega, BMG LABTECH, Ortenberg, Germany) at 405 nm (absorption mode) at 1 min timed intervals. Each juice was measured in triplicate.

Cytotoxicity. Cytotoxicity was analyzed using a resazurin-based assay. Human adenocarcinoma HeLa (DSMZ, Braunschweig, Germany) and human hepatocarcinoma HuH-7 cells (kind gift from John McLauchlan, University of Glasgow) were seeded in 96-well plates (30,000 cells/well) in 200 μL of DMEM high glucose medium supplemented with 10% fetal calf serum and 100 μg/mL penicillin/streptomycin. Cells were grown to 90% confluency in a humidified atmosphere at 37 °C and 5% CO_2. Test substances were added at varying concentration followed by incubation at 37 °C for different

Table 2. Ripeness Parameters (°Brix, Titratable Acidity, Malic Acid, Citric Acid) of Apple Juice Prepared from 88 Apple Varieties

time periods. Catalase was added for some experiments. The cells were washed once with medium and incubated with 10% resazurin solution in cell culture medium for two hours at 37 °C and 5% CO_2. Finally, fluorescence intensity (544 nm excitation, 590 nm emission) was measured using a plate reader (POLARstar omega, BMG LABTECH, Ortenberg, Germany). Data analysis was done using the OmegaMARS Data analysis software package (BMG Labtech, Ortenberg, Germany). Each juice was measured in triplicate.

EGFR Activity. The epidermoid carcinoma cell line A431 (DSMZ, Braunschweig, Germany) was grown in DMEM high glucose culture medium in 96-well plates for 16 h (50,000 cells/well). Complete cell culture medium was removed, and cells were starved (DMEM + 0.1% BSA without FBS) for 3 h followed by incubation with different apple juices or a known inhibitor of EGFR phosphorylation (AG1478) for 6 h. Cells were then washed once with PBS and treated with EGF (170 nM) for 5 min. Immediately afterward cells were fixed and permeabilized by addition of 100 μL of −20 °C cold methanol for 10 min. After an additional PBS washing step 100 μL of Delfia-Eu-anti-phosphotyrosine-antibody was added at a concentration of 300 ng/mL (diluted in Delfia Assay Buffer supplemented with 0.5% BSA). The plate was incubated for 2 h at room temperature and then washed four times with Delfia Wash Solution. 200 μL/well Delfia Enhancement solution was added for 5 min, and the fluorescence intensity was measured using the time-resolved fluorescence protocol on a POLARstar Omega plate reader (BMG Labtech, Ortenberg, Germany) with the following settings: start time 400 μs, cycle time 1 ms, excitation 355 nm, and emission 620 nm. Results were normalized to the total cell number per well using Syto62 cell staining. Each juice was measured in triplicate.

RESULTS AND DISCUSSION

Physicochemical Properties of Investigated Apple Varieties. It is a common sense that different maturity of fruits affects the accumulation of phytochemicals.[8] Thus the ripeness of the investigated apple varieties by quantitation of the sugar content (°Brix value) and the sample acidity (titratable acidity (TA), malic and citric acid) was determined. As shown in Table 2 a mean °Brix value of 12.9 ranging from 8.0 to 18.9, and a mean titratable acidity of 0.8 (% as malic acid) ranging from 0.27 to 1.95 was found. These results indicate a high sugar:acid ratio being consistent with a ripe state as specified by the FAO. The values for the analyzed apple juices can be found in Supplementary Table 1 in the Supporting Information. All samples are characterized by high sugar levels, and the vast majority have been found to have low acidity. Some apple juice varieties, e.g., Zuccalmaglios Renette or Geheimrat Oldenburg, have been demonstrated to have rather high, variety-specific acidity levels. Nevertheless, those samples were included in our study since the obtained °Brix values are within an acceptable range. Taken together, collected data confirm a sufficient maturity of the apples at the time of harvesting.

Quantitation of Polyphenols. A high variability for TPC was found ranging from only 103.2 mg/L up to 2.3 g/L in some varieties (Table 3). For the full list see Supplementary Table 1 in the Supporting Information. The mean TPC of all 88 analyzed varieties was determined to be 777.7 mg/L. A large standard deviation of 447.2 mg/L emphasizes the significant differences of the polyphenol content among the apple varieties. Our results clearly showed that the TPC levels of certain, popular apple varieties are relatively low: For example, the TPC content of juice prepared from Royal Gala (F204) or Topaz (F216) apples grown in the Eferding region was found to be only 185.8 and 257.4 mg/L, respectively. Gala apples are among the most common sold apple varieties worldwide (number 2 on the US market), and Topaz apples are highly popular especially in Central Europe. The great majority of the apple varieties (~60%) that were investigated within this study are used as dessert apples, 25% for the production of nonalcoholic or alcoholic beverages, and 15% as industrial apples that can be, e.g., utilized for food production. However, the economic significance of most of these apple varieties is rather low and limited to the region of Eferding in Upper Austria. Thus, attempts for a broader distribution of selected dessert apple varieties with high TPC levels as characterized in this study (e.g., Harberts Renette, Odenwälder, and Zuccalmaglios Renette) should be made to tap the full potential of these varieties.

A drawback of the FC method is that other reducing reagents present in the apple juice supernatant, such as ascorbic acid, might lead to an overestimation of obtained TPC values.[21] In addition, being a major feature of this study, the assay is not sufficient to predict the antioxidant effect of apple juice, since biological effects are to be expected from different polyphenols. To address this question, the exact composition of the polyphenol components has to be unraveled. Importantly, using the Phenol-Explorer,[22] information on the polyphenolic content could only be extracted for two apple varieties that are included in this study, namely *Royal Gala* and *Grüner Boskoop*. However, a direct comparison to our results appears difficult due to application of juice extracts for these studies rather than analyzing untreated apple juice.[23,24]

Fifteen polyphenolic compounds belonging to four different major polyphenolic groups were identified in the apple juices prepared from each variety: chlorogenic, caffeic, and 4-*p*-coumaroylquinic acid (hydroxycinnamic acids), phloretin-2′-*O*-xyloglucoside and phloridzin (dihydrochalcone derivates),

Table 4. Single Polyphenol Content (mg/L) of Apple Juices under Study

procyanidin B1 and B2, (−)-epicatechin, epigallocatechin, and epicatechingallate (flavan-3-ols), and five quercetin derivates (flavonols). A representative HPLC-DAD diagram, indicating retention times and maximal wavelengths of each compound, is shown in Supplementary Figure 1 in the Supporting Information. Table 4 summarizes the content of selected polyphenolics of all 88 apple juice samples. In addition, obtained values for each variety can be found in Supplementary Table 2 in the Supporting Information. Among the five investigated polyphenolic groups, the hydroxycinnamic acid group was found to be the most abundant one, with chlorogenic acid being the main compound in this polyphenol group. The ratio between chlorogenic acid and *p*-coumaroylquinic acid content in different varieties has been reported to vary between 1.2 and 37.1.[25] Those ratio limits are in good agreement with the mean ratio of 20.3 of the apple juice samples presented in this study. However, for some samples much higher ratios up to 104.1 (L203) or 181.5 (L214) were found, which was mainly caused by high levels of chlorogenic acid and at the same time a very low concentration of *p*-coumaroylquinic acid being detected in these varieties. The low amounts of caffeic acid found in most samples are in good agreement with other studies.[26]

Flavan-3-ols represent the second largest group of polyphenols detected in the investigated apple juices. Procyanidin B2 and epicatechin were the most abundant polyphenolic substances in this group with a mean concentration of 40.1 and 13.3 mg/L, respectively. Similar amounts were reported in a previous study analyzing untreated apple juices.[9] Two dihydrochalcone derivates were found in most apple juices: With a mean content of 6.8 mg/L phloridzin and 12.8 mg/L phloretin-2′-*O*-xyloglucoside, our results are within the range of a previous study (∼1−25 mg/L each).[27] Our measurements also confirmed the presence of flavonols. However, this polyphenol group was found in very low concentrations (∼2% of total polyphenol amount). Anthocyanin pigments were found only in a few juice samples at low concentrations ranging from 0.13 to 6.79 mg/L. This is in line with the presence of these phytochemicals exclusively in apples characterized by a red skin.[28]

In agreement with the results from TPC measurements, RPC analysis unraveled great differences in the polyphenol content and composition of apple juices from different apple varieties. For example, the amount of chlorogenic acid for some varieties ranged from 1.79 mg/L (Royal Gala, F204) up to 1209.7 mg/L (Harberts Renette). In general, the estimated TPC values correlate with the concentration of polyphenols found by HPLC measurements. However, a high TPC level does not necessarily correlate with the detected amounts of the analyzed single polyphenols. For example, the varieties F213, L202, and L203 are all characterized by a similar TPC value of about 1.000 mg/L. However, the concentration of chlorogenic acid was found to vary between 76.4, 149.73, and 145.89 mg/L, respectively. Thus, our results clearly showed that juices prepared from various apple varieties are highly diverse in their content of total polyphenols and show great variations in their individual polyphenol composition. Furthermore, when comparing different apple varieties grafted on the same tree (F and L series, respectively), it could be observed that these varieties retain their individual polyphenolic profile. The described differences are likely to depend mainly on genetic factors, which is consistent with a study analyzing the genetic variability of apples.[29] In conclusion, grafting proves to be a superior tool for a fast growth of selected apple varieties with varying phytochemical concentration, without the need for the time-consuming cultivation of the whole tree.

Quantitation of Total Antioxidant Capacity. Several studies have shown that apples possess a strong antioxidant capacity.[6,30] Here two different methods (TEAC and ORAC) were used to measure the total antioxidant capacity of the different apple juices. Table 3 summarizes the TEAC and ORAC values derived from all samples. The antioxidant capacity of these juices ranged from 0.8 to 7.8 mM (TEAC) and 3.0 to 58.9 mM (ORAC), which is in good agreement with similar studies.[31] The full list of TEAC and ORAC values from all apple juice samples can be found in Supplementary Table 1 in the Supporting Information. Our results indicate the general dependence of the antioxidant capacity on the total polyphenolic concentration as can be seen by the linear regression and correlation analysis. The coefficients of determination (R^2) are given in Figure 1. All R values (correlation coefficients) were positive at the $P < 0.0001$ significance level, indicating that the values of antioxidant capacities, assayed by the two different methods, were highly correlated (R values for TPC/ORAC, 0.69; TPC/TEAC, 0.87; ORAC/TEAC, 0.63). The regression coefficient value obtained for TPC and ORAC assay was lower compared with TEAC assay, but significant in both systems. These results indicated that the two assays were suitable and reliable for assessing total antioxidant capacities. Thus, despite the aforementioned limitations of the FC method to determine the TPC, it can possibly be considered as a first indicator of antioxidant capacity of apple juice.

It was observed that some varieties contained equal (TPC of Lesans Kalvill similar to Samareiner Rosmarien) or even more total polyphenols than others (TPC Riesenboikenapfel > Glasapfel), but lower antioxidant capacity as determined by both TEAC and ORAC measurements. This effect can be explained by the different antioxidant activity of individual polyphenols as reported in previous studies.[32] Consequently, the antioxidant capacity is dependent on the phenolic composition of an individual juice.

The low TEAC and ORAC values of juice prepared from certain apple varieties, including Topaz, is consistent with other studies analyzing the antioxidant capacity of a number of old and new apple varieties in Poland.[33] The Topaz apple is a good example of a new apple variety (introduced in the 1980s), which offers several advantages for agriculture including resistance to apple scab, high yields, and good storage properties. It is also a common apple variety for organic farming. However, the low level of phenolic substances in these varieties has not been taken into consideration so far. Consequently, the distribution of apple varieties with a higher content of polyphenols should be supported to promote their positive effects on human health.

Analysis of Minerals, Phosphate, and Trace Elements. The mean and range values of the major minerals K^+, Mg^{2+}, and Ca^{2+} are indicated in Table 5, and results for individual varieties can be found in Supplementary Table 1 in the Supporting Information. The potassium concentration ranged from 620.4 (Retina) to 2064.0 mg/L (Grüner Boskoop) with large variations between individual varieties. Compared to potassium, the concentration of magnesium and calcium was significantly lower, ranging from 8.4 to 64.4 (Mg^{2+}) and 6.7 to 57.5 (Ca^{2+}) mg/L, respectively. Similar to the potassium concentration, remarkable variations for calcium and magnesium between the different varieties could be observed. Collected data, especially for potassium and copper, are in good agreement with other studies analyzing minerals and trace elements of different apple varieties.[26,34]

The PO_4^{3-} concentration of juice prepared from 56 apple varieties was found to range between 90.0 and 420.0 mg/L (Table 5), which is consistent with the work of Eisele et al., who reported PO_4^{3-} values ranging from 86.0 to 459.0 mg/L.[26] The variation between individual apple varieties was found to be in a similar range as observed for potassium.

Finally, 52 apple juice samples were analyzed for their copper and manganese content and 27 (F and L series) for iron, respectively. The observed variations between individual samples, especially those for Mn^{2+} and Fe^{2+}, were highly pronounced for these elements. The mean and range values for the Cu^{2+}, Mn^{2+}, and Fe^{2+} content are summarized in Table 5.

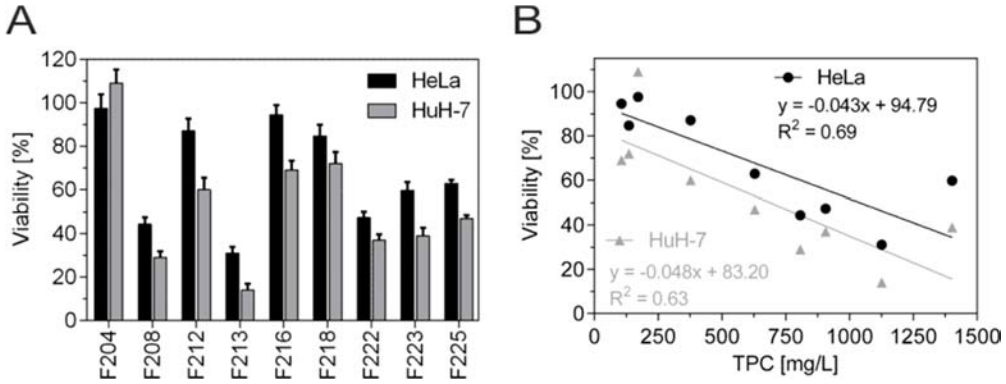

Figure 2. Cytotoxicity of selected apple juice varieties. (A) Resazurin based cytotoxicity test. HeLa or HuH-7 cells were grown to 90% confluency in 96-well plates and incubated with apple juice diluted in cell culture medium (1:5 dilution) for 6 h. Cell viability is normalized to a nontreated sample. Error bars are based on the standard error of the mean (n = 4). (B) Linear correlation regression analysis between TPC and viability. Correlation analysis reveals a significant interrelation of the total phenolic content (TPC) and the cell viability.

Taken together, our results show large variations between the different apple varieties, which is in good agreement with a previous study analyzing the concentration of various minerals in juice prepared from 175 apple varieties.[26] These variations can also be observed for various apple varieties grafted on a single tree (F and L series). Thus, apples harvested from grafted trees retain not only their polyphenolic profiles but also their characteristic mineral, trace element, and phosphate concentrations. From this point of view an intensified cultivation of selected apple varieties identified in this work should be considered. However, the availability of many of the varieties that possess these positive compositions for large scale cultivation remains a limiting factor. Engrafting turned out to be an excellent way to enhance growth rates and provide resistance to bacterial or fungal infections. By engrafting 27 different apple varieties on two trees grown close to each other, it could be shown that the apple fruits in fact remain their primary ingredient characteristics. This fact is clearly of key importance for the promotion of selected apple varieties.

Biological Effects of Selected Apple Juice Varieties. Different assays were used to determine several biological effects of apple juice varieties that were preselected by a pronounced variation of different ingredients including polyphenolics, minerals, and trace elements. Juices from nine apple varieties grafted on a single tree (F series) were used for these analyses. First, the cytotoxic effects of apple juice were determined on two different human cancer cell lines using a resazurin based assay. Apple juice has been reported to be a strong cancer chemopreventive.[35] Several studies have already shown the inhibitory effect on cell proliferation of cultured cancer cell lines.[36] Two human cell lines were used for investigation of the growth inhibition of selected apple juices. As shown in Figure 2A a strong reduction of cell viability could be observed in both cell lines for several apple juices at a 1:5 dilution. The observed inhibitory effect was clearly dependent on the apple juice concentration: no reduction in cell viability could be observed at higher dilution rates >1:50 (Supplementary Figure 1 in the Supporting Information). Using apple juice in cell culture medium might lead to H_2O_2 formation and pronounced cytotoxic effects.[37] Addition of catalase (100 U/mL) to prevent the formation of H_2O_2 further slightly reduced these cytotoxic effects (data not shown). Interestingly, a clear correlation between TPC levels and the described cytotoxic effects was found (Figure 2B). Our results show that certain apple juices reduce the viability of the analyzed human cancer cell lines in a TPC dependent manner. Interestingly, Veeriah et al. showed that native apple extracts were about twice as potent as a composed mixture of low molecular weight apple polyphenols in inhibiting cancer cell growth.[36] This indicates that other constituents, such as oligomeric procyanidines, substantially contribute to the potent antiproliferative properties of polyphenol-rich apple juices. Thus, the usage of apple juices instead of extract appears straightforward.

In a second experiment a putative apple juice dependent inhibition of human α-amylase, a major digestive enzyme that breaks down long-chain carbohydrates, was evaluated. Salivary and pancreatic α-amylases lead to the formation of maltose and other related oligomers by catalyzing the hydrolysis of α-1,4-linked glucose chains.[38] Several studies indicated a beneficial health effect of bioactive substances from apples, e.g., a reduced risk of chronic diseases including type 2 diabetes. In this regard the inhibition of α-amylase activity by these substances is of particular importance.[39] As shown in Figure 3 a 30−40% inhibition of α-amylase activity was observed when rosmarinic acid (1.5 mg/mL) was added, confirming the inhibitory potential of this substance. All tested apple juices of the F series also showed an incubation-time-dependent inhibition of α-amylase activity between ∼80% (24 h incubation) and ∼50%

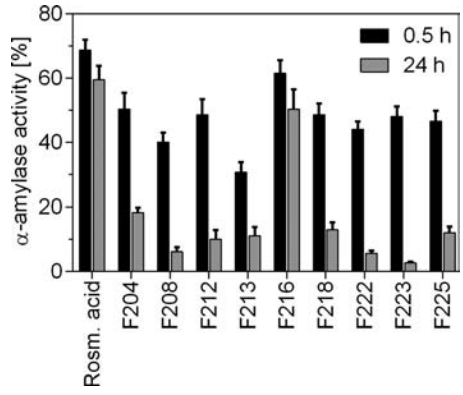

Figure 3. Inhibition of α-amylase activity by selected apple juice varieties. Rosmarinic acid (Rosm. acid; 1.5 mg/mL) or different apple juice samples diluted 1:10 were incubated with 1 mg/mL α-amylase for 30 min or 24 h, respectively. Inhibition was measured by the use of a commercial amylase activity assay containing α-glucosidase. Error bars are based on the standard error of the mean (n = 3).

dx.doi.org/10.1021/jf4051232 | J. Agric. Food Chem. 2014, 62, 1047−1056

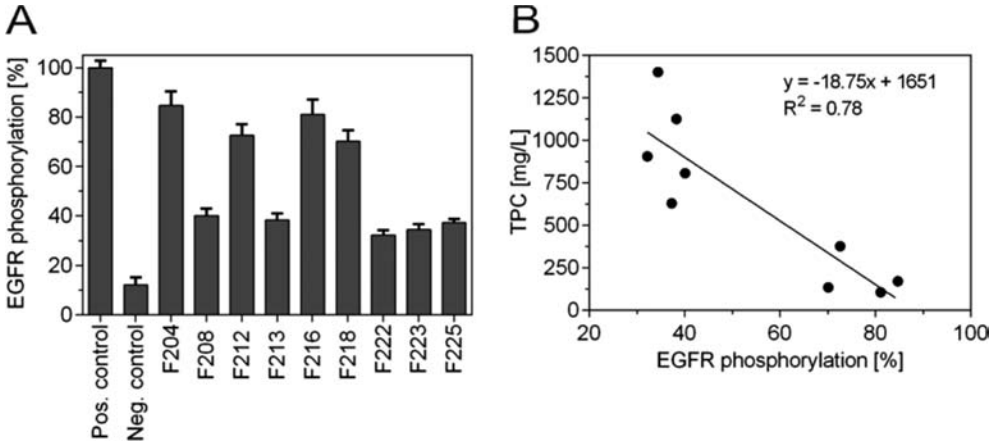

Figure 4. Epidermal growth factor receptor (EGFR) activity test. (A) HeLa cells endogenously expressing high levels of EGFR were grown to 90% confluency in 96-well plates and starved in cell culture medium without serum for 3 h, followed by incubation with the EGFR inhibitor AG1478 or selected apple juice varieties (diluted 1:20 in starving medium) for a further 6 h. After addition of 170 nM EGF, receptor phosphorylation was measured by the use of a fluorescent antibody in combination with time-resolved fluorescence. Results were normalized to EGF treated cells (positive control). AG1478 served as a negative control. Error bars are based on the standard error of the mean (n = 3). (B) Linear correlation regression analysis reveals a significant interrelation of the total phenolic content (TPC) and the EGFR phosphorylation level.

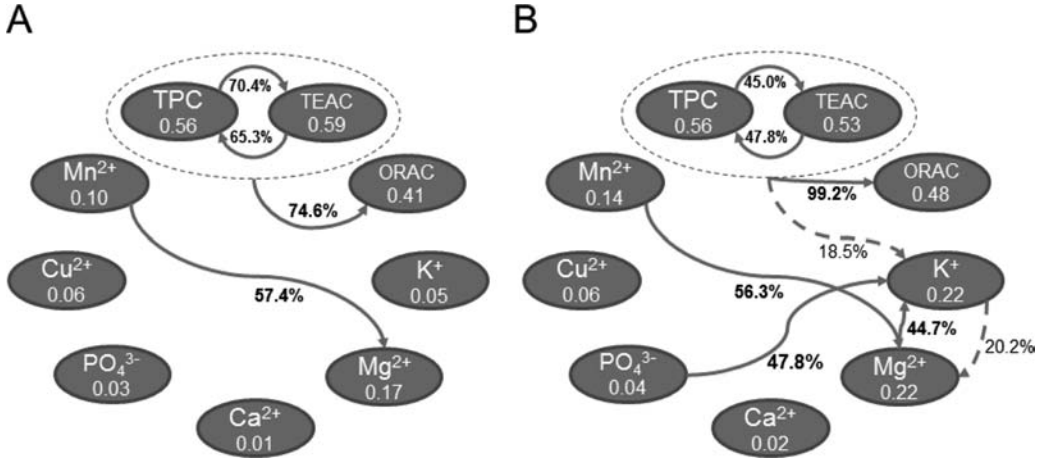

Figure 5. Graphical representation of modeling results and variable interactions using linear regression and random forests. All variables were modeled using linear regression (LR) and random forest regression (RF, 50 trees). Each node represents a variable, and the number given below a variable indicates the average quality (R^2) of the models. In order to estimate the influence of the variables on each other, all variables are mutually excluded from the modeling process, and the resulting modeling quality decrease is calculated. If the exclusion of a variable a leads to a significant decrease of the modeling quality for variable b, then a directed edge is shown; continuous lines indicate modeling influences of at least 40%, dashed lines indicate modeling influences of at least 15%, and weaker influences are not shown. As TPC and TEAC are very strongly correlated (correlation R^2 0.7125), these two variables are always excluded from the modeling process in combination, which is indicated by the dashed circles around these two variables.

(30 min incubation). In these experiments differences between individual varieties ranging from 40 to 70% (30 min) and 50 to 98% (24 h) inhibition of α-amylase activity could be observed. In contrast to the antioxidant capacity, the observed inhibitory effect was not dependent on the TPC levels of the apple juice varieties as statistical analysis determining Kendall's and Spearman's rank correlation coefficient did not reveal any significant correlation (data not shown). These results are in good agreement with a recent study excluding a positive correlation between α-amylase inhibitory activity and total phenolic content.[39] However, single polyphenols that have been shown to inhibit this enzyme (e.g., chlorogenic acid)[40] are found at high concentrations in our apple varieties.

Finally, the effects of different apple juice varieties on the activity of the epidermal growth factor receptor (EGFR) were analyzed. The EGFR plays a major role in cellular signaling: insufficient signaling may lead to the development of neurodegenerative diseases,[41] while excessive EGFR signaling is associated with the development of a wide variety of tumors. Highly elevated EGFR signaling seems to be a critical factor in the development and malignancy of these tumors.[42] Several studies have indicated that apple polyphenols inhibit EGFR activity in various cell lines.[43−45] Thus, apples rich in polyphenols are thought to prevent the formation of various cancer types in the human body. In total nine apple juice varieties of the F series were analyzed for a potential phosphorylation inhibition of the EGFR. As shown in Figure 4A the applied time-resolved-fluorescence based ELISA-assay is well-suited to detect phosphorylation of the EGFR upon stimulation. AG1478 pretreatment for 4 h clearly inhibited the phosphorylation upon EGF stimulation. When cells were incubated for 4 h with juice from different apple varieties (1:20;

dx.doi.org/10.1021/jf4051232 | J. Agric. Food Chem. 2014, 62, 1047−1056

in the presence of catalase), a pronounced inhibition of EGFR phosphorylation could be observed. Our experiments indicated remarkable differences in the degree of phosphorylation inhibition depending on the used apple varieties. Further analysis showed that the observed inhibitory effects significantly correlated with the respective TPC levels (Figure 4B), which is consistent with similar studies. Individual polyphenols such as the procyanidin dimers B1 and B2 or phloretin and phloretin-2′-*O*-xylogucoside have been found to specifically affect the EGFR activity.[43−45] Accordingly, apple juice varieties that inhibited the EGFR activity to the highest extent (F208, F213, and F223) were especially rich in these polyphenols.

In-Depth in Silico Analysis. The described dependence of the antioxidant capacity on the TPC levels is in agreement with previous studies.[6] This research was extended by the use of mathematical modeling that allowed us to identify variable interaction networks based on the analysis of apple component data. Regression models that approximate selected target variables using other available parameters in this data set have been identified. The relevance of a variable in this context can be defined via the frequency of its occurrence in models identified by evolutionary machine learning methods or via the decrease in modeling quality after removing it from the data set.[46] The following algorithms have been applied for the data set generated in this study including the results for TPC, TEAC, ORAC, Mn^{2+}, Mg^{2+}, Ca^{2+}, Cu^{2+}, K^+, and PO_4^{3-}: linear regression and random forests.[47] As shown in Figure 5A, linear regression confirms the relationship of the antioxidant capacity (TEAC and ORAC) and the TPC level. In addition, a significant interrelationship of Mg^{2+} and Mn^{2+} was found. These findings were confirmed when nonlinear modeling using random forest was applied (Figure 5B). The latter model also indicated a strong relevance of PO_4^{3-} and Mg^{2+} on the modeling of K^+. Even though importance in regression and correlation do not imply causality, this analysis implies that apples that are rich in Mg^{2+} by trend also contain higher levels of Mn^{2+}. The same assumption holds true for K^+ and PO_4^{3-}. Mn^{2+} and Mg^{2+} are abundant elements and essential to all living cells. For example Mg^{2+} plays a major role in manipulating biological compounds including DNA, RNA, and ATP. In addition, a great number of enzymes require Mg^{2+} for their function. The same is true for Mn^{2+} ions, which are essential cofactors for many enzymes. However, many of these enzymes can use Mg^{2+} as a replacement of Mn^{2+}.[48] Of special interest is the function of Mn^{2+} enzymes to detoxify superoxide free radicals in mitochondria.[49] In analogy copper and zinc bound enzymes are necessary for detoxification in the cytosol.[50] Thus, similar to polyphenols, Mn^{2+} and Cu^{2+} ions play a key role in preventing the human organism from oxidative damage.

necessary for tyrosinase to contain two copper ions in the active site, catalyzing colorful pigments or melanin by the above oxidations. One of the major protocols for treating these pigmentation-related dermatological disorders is to inhibit tyrosinase activity.

Human skin is under daily oxidative stress from both external and internal sources, such as free radicals, reactive oxygen species, or ultraviolet (UV) radiation.[6] It has been well reported that skin exposure to oxidative stress or UV radiation is the cause for skin aging or tumorigenesis. At present, the main lethal reason of ineffective treatment is tumor proliferation, which may lead to death. Within the past several decades, these are etiological factors responsible for producing melanoma, which is a form of malignant tumor of uncontrollable melanocytes and is among the most fatal of skin cancers.[7] Melanoma is one of the most aggressive cancers, resistant to medical treatments such as surgery, radiotherapy, or chemotherapy.[8] Treatments these days for melanoma are not effective enough to reduce mortalities and enhance survival rate of patients with melanoma because of a lack of therapeutic remedy. For this reason, to improve the efficacy of cancer treatment, it is essential to develop novel natural medicinal compounds for anticancer therapies. The purpose of biological aspects of this study was therefore to elucidate the antioxidative, tyrosinase-inhibitory, and anticancer properties of *C. philippinense* compounds. We further analyzed the cytotoxicity of isophilippinolide A in a human skin melanoma cancer cell line, A375.S2, to discuss the apoptotic genetic and molecular mechanisms.

MATERIALS AND METHODS

Plant Material. The roots of *C. philippinense* were collected from Taipei County, in May 2008. A voucher specimen was identified by Dr. Yen-Ray Hsui of the Chungpu Research Center, Taiwan Forestry Research Institute, and deposited in the Department of Medical Laboratory Science and Biotechnology, School of Medical and Health Sciences, Fooyin University, Kaohsiung, Taiwan.

Reagents. 2,2′-Azinobis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS), butylated hydroxyanisole (BHA), 2,2-diphenyl-1-(2,4,6-trinitrophenyl)hydrazyl (DPPH), dimethyl sulfoxide (DMSO), ethylenediaminetetraacetic acid (EDTA), ferrozine, $FeCl_3$, $FeCl_2{\cdot}4H_2O$, kojic acid, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT), mushroom tyrosinase, vitamin C, peroxidase type I from horseradish (HRPase), potassium ferricyanide [$K_3Fe(CN)_6$], propidium iodide (PI), trichloroacetic acid, and L-tyrosine were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Fetal bovine serum (FBS), minimum essential medium (MEM), and Dulbecco's modified Eagle's medium (DMEM) were obtained from GIBCO BRL (Gaithersburg, MD, USA). An Annexin V/Dead Cell Apoptosis Kit was purchased from Invitrogen (Carlsbad, CA, USA). All buffers and other reagents were of the highest purity commercially available.

Instruments. Melting points were determined using a Yanagimoto micromelting point apparatus and are uncorrected. Optical rotations were measured with a JASCO DIP-370 digital polarimeter. UV spectra were obtained on a JASCO V-530 spectrophotometer in MeCN. IR spectra were measured on a Hitachi 260-30 spectrophotometer (Hitachi, Tokyo, Japan). ^{1}H (400 MHz, using $CDCl_3$ as solvent for measurement), ^{13}C (100 MHz), DEPT, HETCOR, COSY, NOESY, and HMBC spectra were obtained on a Varian (Unity Plus) NMR spectrometer. Low-resolution FABMS and ESIMS spectra were obtained on an API 3000 (Applied Biosystems) and high-resolution FABMS and ESIMS spectra on a Bruker Daltonics APEX II 30e spectrometer (Bruker, Bremen, Germany). Silica gel 60 (Merck, 70–230 mesh, 230–400 mesh) was used for column chromatography. Precoated silica gel plates (Merck, Kieselgel 60 F-254), 0.20 and 0.50 mm, were used for analytical TLC and preparative TLC, respectively, and visualized with 50% H_2SO_4. Flow cytometry analysis was done by a Coulter Epics XL-MCL (Beckman Coulter, CA, USA) flow cytometer. Labeling dyes, such as PI, were used to investigate the events involved in apoptosis.

Extraction and Isolation. The roots (3.7 kg) of *C. philippinense* were air-dried and extracted repeatedly with MeOH (5 L × 6) at room temperature. The combined MeOH extracts (54.3 g) were obtained by concentration under reduced pressure and partitioned to yield $CHCl_3$ (34.4 g) and H_2O (8.8 g) extracts. The concentrated $CHCl_3$ extract (34.4 g) was chromatographed over silica gel using *n*-hexane–EtOAc–MeOH as eluent to produce six fractions. Fraction 1 (6.33 g) was separated by silica gel CC with increasingly polar mixtures of *n*-hexane–EtOAc to give 10 fractions (1-1 to 1-10). Fraction 1-1 (2.15 g) was resubjected to silica gel CC, eluting with *n*-hexane–EtOAc (60:1) and enriched gradually with EtOAc to obtain five fractions (1-1-1 to 1-1-5). Fraction 1-1-2 (0.85 g) was further purified by another silica gel CC using *n*-hexane–EtOAc to obtain philippinolide B (16 mg). Fraction 1–-2 (1.85 g) was further separated by silica gel CC (*n*-hexane–EtOAc (60:1)) and preparative TLC (*n*-hexane–EtOAc (100:1)), giving philippinolide A (24 mg) and isophilippinolide A (37 mg). Fraction 2 (4.93 g) was separated by silica gel CC with increasingly polar mixtures of *n*-hexane–EtOAc to give five fractions (2-1 to 2-5). Fraction 2-1 (2.52 g) was resubjected to silica gel CC, eluted with $CHCl_3$–MeOH (100:1), and gradually enriched with MeOH to obtain 10 fractions (2-1-1 to 2-1-10). Fraction 2-1-1 (0.11 g) was resubjected to silica gel CC and purified by preparative TLC to yield cinnaretamine (5 mg). Three new compound structures (see Figure 1) were identified as the following.

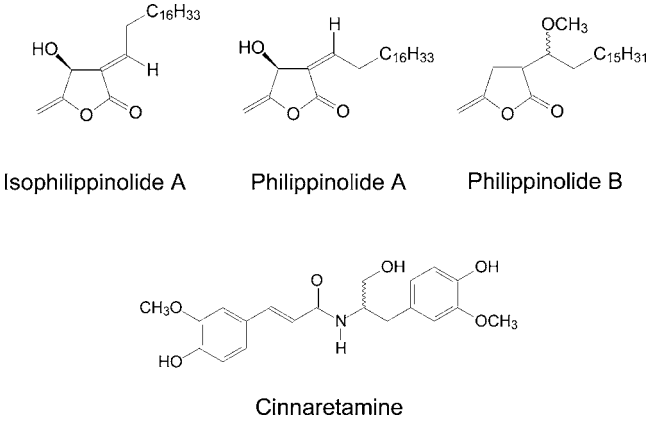

Figure 1. Chemical structures of four compounds from *C. philippinense*.

Isophilippinolide A: pale yellowish liquid; $[\alpha]^{25}_D$ −24.6 (*c* 0.05, $CHCl_3$); UV λ_{max} (MeCN) (log ε) 225 (4.12) nm; IR (neat) ν_{max} 3450 (br, OH), 1770, 1670 (α,β-unsaturated γ-lactone), 1465, 1360, 1090 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.88 (3H, t, J = 6.8 Hz, H-18′), 1.25 (28H, br s, H-4′–17′), 1.52 (2H, m, H-3′), 2.45 (2H, m, H-2′), 4.72 (1H, dd, J = 2.8, 1.2 Hz, H-6a), 4.94, (1H, dd, J = 2.8, 1.2 Hz, H-6b), 5.24 (1H, br s, H-4), 7.07 (1H, td, J = 7.6, 2.4 Hz, H-1′); ^{13}C NMR (100 MHz, $CDCl_3$) δ 14.0 (C-18′), 22.8 (C-17′), 28.2–29.7 (C-2′–15′), 32.0 (C-16′), 66.6 (C-4), 91.5 (C-6), 127.2 (C-3), 150.2 (C-1′), 157.7 (C-5), 165.5 (C-2); FABMS m/z 365 [M + H]$^+$, 211 (15), 167, 149 (16), 139 (14), 125 (33), 111 (100), 97 (70), 83 (81), 69 (90); HRFABMS m/z 365.3055 [M + H]$^+$ (calcd for $C_{23}H_{41}O_3$, 365.3056).

Philippinolide A: pale yellowish liquid; $[\alpha]^{25}_D$ −22.3 (*c* 0.05, $CHCl_3$); UV λ_{max} (MeCN) (log ε) 225 (4.11) nm; IR (neat) ν_{max} 3450 (br, OH), 1770, 1670 (α,β-unsaturated γ-lactone), 1465, 1365, 1090 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.88 (3H, t, J = 7.2 Hz, H-18′), 1.25 (28H, br s, H-4′–17′), 1.48 (2H, m, H-3′), 2.77 (2H, m, H-2′), 4.67 (1H, dd, J = 2.8, 1.6 Hz, H-6a), 4.89, (1H, dd, J = 2.8, 1.6 Hz, H-6b), 5.11 (1H, br s, H-4), 6.68 (1H, td, J = 7.6, 2.0 Hz, H-1′); ^{13}C NMR (100 MHz, $CDCl_3$) δ 14.0 (C-18′), 22.6 (C-17′), 28.3–29.8

(C-2′−15′), 31.9 (C-16′), 68.8 (C-4), 90.4 (C-6), 126.7 (C-3), 151.3 (C-1′), 157.5 (C-5), 165.5 (C-2); FABMS m/z 365 $[M + H]^+$ (5), 211 (21), 149 (11), 139 (13), 125 (46), 111 (100), 97 (75), 83 (80), 69 (92); HRFABMS m/z 365.3053 $[M + H]^+$ (calcd for $C_{23}H_{41}O_3$, 365.3056).

Philippinolide B: colorless oil; $[\alpha]^{25}_D$ −21.8 (c 0.05, $CHCl_3$); UV λ_{max} (MeCN) (log ε) 265 (4.05) nm; IR (neat) ν_{max} 3500 (br, OH), 1780, 1680 (α,β-unsaturated γ-lactone), 1290 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 0.87 (3H, t, J = 6.8 Hz, H-17′), 1.25 (26H, br s, H-4′−16′), 1.60−1.77 (4H, m, H-2′, 3′), 3.34 (3H, s, OMe-1′), 4.11 (1H, dd, J = 7.4, 4.8 Hz, H-1′), 4.87, 5.19 (each 1H, d, J = 2.4 Hz, H-6a, b), 7.21 (1H, br s, H-4); ^{13}C NMR (100 MHz, $CDCl_3$) δ 14.2 (C-17′), 22.6 (C-16′), 25.5 (C-3′), 29.1−30.3 (C-4′−14′), 31.6 (C-15′), 35.1 (C-2′), 57.5 (OMe-1′), 77.4 (C-1′), 98.0 (C-6), 137.7 (C-4), 137.7 (C-3), 155.0 (C-5), 169.8 (C-2); HRESIMS m/z 387.2877 $[M + Na]^+$ (calcd for $C_{23}H_{40}O_3Na$, 387.2875).

DPPH• Radical Scavenging Capacity Assay. The antioxidant activity of the tested compounds was determined as their ability to donate hydrogen or remove radicals by utilizing the stable DPPH• method.[9] Briefly, various concentrations of *C. philippinense* compounds were added to 0.1 mL of aqueous stable DPPH• (60 μM) solution. When DPPH• reacts with an antioxidant compound that can donate hydrogen, it is reduced, resulting in a decrease in the absorbance at 517 nm. The analyzed time interval was 10 min per point, totaling up to 30 min, using a UV−vis spectrophotometer (BioTek Co., Winooski, VT, USA). Vitamin C acted as a positive control. According to the preliminary investigations, the antioxidative results of using four compounds failed to reach high inhibitions toward the values of IC_{50}. We presented the inhibitory data at suitable concentrations in all of the antioxidative assays. The DPPH• radical scavenging activity (%) was determined as

$$\text{scavenging activity (\%)} = \frac{(A_{\text{control}} - A_{\text{sample}})}{A_{\text{control}}} \times 100\% \quad (1)$$

Metal-Chelating Activity. The ferrous ion chelating potentials of all compounds were probed according to the method described previously.[10] In short, various tested concentrations of samples dissolved in DMSO were added to a solution of 2 mM $FeCl_2 \cdot 4H_2O$ (0.01 mL). Ferrozine (5 mM; 0.02 mL) was added to the reaction, and the mixture was strongly shaken and left standing at room temperature for 10 min. The absorbance of the mixture was read at 562 nm against a blank. EDTA was used as a positive control, and the formula for calculation of the chelating activity was similar to eq 1.

Reducing Power Assay. The reducing power of the four compounds was measured on the basis of the previous method.[10] Briefly, different concentrations of each test sample were mixed with 0.085 mL of 67 mM phosphate buffer (pH 6.8) and 2.5 μL of 20% potassium ferricyanide ($K_3Fe(CN)_6$). The mixture was incubated at 50 °C for 20 min, and 0.16 mL of trichloroacetic acid (10%) was then added to the mixture, which was then centrifuged for 10 min at 3000g. The upper layer of the solution (75 μL) was mixed with 2% $FeCl_3$ (25 μL), and the absorbance was measured at 700 nm. BHA was used as a positive control. In this assay, a higher absorbance demonstrated a higher reductive capability.

Inhibition of Mushroom Tyrosinase Activity. Tyrosinase activity inhibition was determined spectrophotometrically according to the previously described method, with minor modifications.[10] Assays were carried out with an optics plate reader used to determine the absorbance at 475 nm. Kojic acid was used as a positive control for the tyrosinase inhibitory assay. The substances tested were dissolved in aqueous DMSO and incubated with L-tyrosine (2.5 mg/mL) in a 50 mM phosphate buffer (pH 6.8). All samples were dissolved in DMSO, because DMSO did not affect tyrosinase activity when <1% of the total volume. Then, 25 U/mL of mushroom tyrosinase in the same buffer was added, and the mixture was incubated at 37 °C for 30 min. Tyrosinase inhibitory activity was measured by the following equation:

$$\text{tyrosinase inhibition activity (\%)} = \frac{[(A - B) - (C - D)]}{(A - B)} \times 100\% \quad (2)$$

In this equation, A is the optical density (OD_{475}) without the tested substance, B is the OD_{475} without the tested substance, but with tyrosinase, C is the OD_{475} with the tested substance, and D is the OD_{475} with the tested substance, but without tyrosinase.

Cell Cultures. The A375.S2 (Bioresource Collection and Research Center, BCRC no. 60039, ROC) human melanoma cell line was maintained in monolayer culture within MEM supplemented with 10% fetal bovine serum and 100 U/mL penicillin, 100 mg/mL streptomycin, and 0.25 μg/mL amphotericin B. Neonatal foreskin primary human epidermal melanocytes were bought from Cascade Biologics and cultured in Medium 254 (Cascade Biologics, Life Technologies, Portland, OR, USA) supplemented with human melanocyte growth supplement. Human skin fibroblasts were grown from foreskin primary culture that was obtained from Chung-Ho Memorial Hospital, Kaohsiung Medical University. All of the cell types were incubated at 37 °C under a humidified atmosphere of 5% CO_2 in air and routine passage by trypsinization.[11,12]

Cell Cytotoxicity Assays. The effects of compounds on cell growth were evaluated using a MTT assay.[13] In short, cells were seeded in 96-well plates at a density of 7×10^3 cells/well. The medium was changed, and cells were maintained either in medium by themselves (control cells) or in the presence of the indicated drug concentrations in a final volume of 100 μL in 10% FBS culture medium. The testing samples were dissolved in sterile DMSO to create a working concentration of 1, 10, 25, 50, 100, or 200 μM. After 24 h of incubation, the medium was substituted with 100 μL of fresh medium including 0.5 mg/mL MTT. The plate was then cultured in a 37 °C incubator filled with 5% CO_2 for 2 h. Each precipitate in a specific well was treated with 100 μL of DMSO to dissolve the purple formazan crystals. After the dishes were gently shaken for 10 min in the dark to ensure maximal dissolution of the formazan crystals, the absorbance (A) values of the supernatant were measured at 595 nm. Cell viability was calculated as

$$\text{cell viabilty (\%)} = \frac{(A_{\text{sample}} - A_{\text{blank}})}{(A_{\text{control}} - A_{\text{blank}})} \times 100\% \quad (3)$$

Cell Cycle Analysis by Flow Cytometry. To determine phase distribution of DNA content in A375.S2 cells, PI staining was performed as previously described.[14,15] In short, cells were treated with vehicle (medium containing 0.05% DMSO, as the control) or eq 2 at desired final concentrations for 24 h. After treatments, the floating and trypsin-detached A375.S2 cells were collected and washed twice with ice-cold PBS and then fixed in 70% cold ethanol. The cells were stained in PBS containing 10 μL/ml PI, 10 μg/mL RNase A, and 0.05% Triton X-100 for 15 min at room temperature in the dark. The DNA content of A375.S2 cells was analyzed with a FACScan flow cytometer (Becton-Dickinson, Mansfield, MA, USA). At least 10000 events were analyzed for each test sample. Data analyses were performed with Cell-Quest and Modfit software (Becton-Dickinson).

Annexin V and PI Double Staining. We followed published protocols with minor modifications,[16] In brief, 1.3×10^5 A375.S2 cells in a 6-well microplate (at 70−80% confluency) were treated with vehicle or component for 24 h, subsequently trypsinized and washed with PBS, and then marked with annexin V−FITC (10 μg/mL)/PI (10 μg/mL); the percentage of four quadrants on treated cells was analyzed by flow cytometry. The left lower quadrant means normal cells, the lower and upper right quadrants refer to the early and late apoptotic cells, and the left upper quadrant means necrotic cells, respectively.

Western Blot Analysis. A total of 1×10^6 cells were treated with isophilippinolide A or vehicle control for 24 h. The cells were washed two times with ice-cold phosphate-buffered saline, harvested, and disrupted in lysis buffer (50 mM Tris-HCl, pH 7.5, 137 mM sodium chloride, 1 mM EDTA, 1% Nonidet P-40, 10% glycerol, 0.1 mM sodium orthovanadate, 10 mM sodium pyrophosphate, 20 mM β-

[a]Data are expressed as means ± SD of three independent experiments. ns, not significant; –, not tested. [b]Vitamin C was used as a positive control on DPPH assay at 100 μM. [c]EDTA was used as a positive control on metal chelating ability at 100 μM. [d]BHA was used as a positive control on reducing power at 100 μM. [e]Kojic acid was used as a positive control of mushroom tyrosinase assay at 100 μM.

glycerophosphate, 50 mM sodium fluoride, 1 mM phenylmethanesulfonyl fluoride, 2 μM leupeptin, and 2 μg/mL aprotinin).[6,12] The cell lysate was centrifuged at 10000*g* for 30 min at 4 °C, and the protein concentration in the supernatant was determined with the bicinchoninic acid protein assay kit (Pierce, Rockford, IL, USA). In short, equal amounts of protein were separated by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) and then electrotransferred onto polyvinylidene fluoride (PVDF, PALL Life Science, Ann Arbor, MI, USA). The membrane was clogged for 1 h with 5% nonfat milk in PBS-T buffer (phosphate-buffered saline containing 0.1% Tween 20). The membranes were incubated with corresponding primary antibodies, washed two times with PBS, and incubated with secondary antibodies against the corresponding primary antibodies. The signals were visualized utilizing enhanced chemiluminescence substrate (PerkinElmer, Boston, MA, USA). The signal intensities of proteins were analyzed by the software Gel-Pro v 3.0 (Media Cybernetics, Carlsbad, CA, USA).

Statistical Analysis. All data values are presented as the mean values (±SD) of at least three independent experiments. When appropriate, data were analyzed by Student's *t* test. Statistical significance was assumed of a p value of <0.05.

RESULTS AND DISCUSSION

Structure Elucidation of the New Butanolides. Isophilippinolide A, a pale yellowish liquid, also had the molecular formula $C_{23}H_{40}O_3$, as deduced from HRFABMS, and its spectroscopic data (IR, UV, and ^1H and ^{13}C NMR) were similar to those of philippinolide A. However, differences in chemical shift of H-1′ and its coupling constant supported an *E* configuration for $\Delta^{3(1')}$ in philippinolide A. The ^1H NMR spectrum of philippinolide A was similar to that of isotenuifolide A,[17] indicating that it has the same β-hydroxy-γ-methylene-α,β-unsaturated γ-lactone skeleton and the same *E* geometry of the trisubstituted double bond. The structure of isotenuifolide A is similar to that of philippinolide A, just different in the lipid long chain.[17] A broad singlet at δ 1.25 was again attributed to the 28 protons in the aliphatic chain in philippinolide A. The exocyclic olefinic protons appeared at δ 4.72 and 4.94, and a hydroxymethine proton resonated at δ 5.24. Philippinolide A was shown to be levorotatory, indicating the configuration at C-4 to be *S* by comparison with reported compounds.[18] Thus, the structure of isophilippinolide A was elucidated as (4*S*,3*E*)-4-hydroxy-5-methylene-3-octadecylidene-dihydrofuran-2-one.

Philippinolide A was isolated as a pale yellowish liquid and its molecular formula, $C_{23}H_{40}O_3$, was established by HRFABMS. The UV absorption at 225 nm was similar to that of tenuifolide A, consistent with the presence of an α,β-conjugated γ-lactone moiety.[17] The IR spectrum showed absorption bands for a hydroxy group at 3440 cm^{-1} and an α,β-unsaturated γ-lactone moiety at 1770 and 1670 cm^{-1}. The ^1H NMR spectrum of isophilippinolide A was similar to that of tenuifolide A,[17] indicating that philippinolide A has the same β-hydroxy-γ-methylene-α,β-unsaturated γ-lactone skeleton and the same *Z* geometry of the trisubstituted double bond. The structure of tenuifolide A is similar to that of isophilippinolide A, just different in the lipid long chain.[17] The presence of a broad singlet at δ 1.25 was attributed to protons in an aliphatic chain in isophilippinolide A. The exocyclic olefinic protons appeared at δ 4.67 and 4.89, and one hydroxymethine proton was located at δ 5.11. Isophilippinolide A was found to be levorotatory, which indicated an *S* configuration at C-4.[19] Thus, the structure assigned for philippinolide A was (4*S*,3*Z*)-4-hydroxy-5-methylene-3-octadecylidene-dihydrofuran-2-one.

Philippinolide B was isolated as a colorless oil, and the molecular formula was determined to be $C_{23}H_{40}O_3$ by ESIMS ($[M + Na]^+$, m/z 387) and HRESIMS. The presence of an α,β-unsaturated γ-lactone moiety was apparent from a UV absorption maximum at 265 nm.[20] The IR peaks at 1780 and 1680 cm^{-1} supported the presence of an α,β-unsaturated γ-lactone moiety. The ^1H NMR spectrum of philippinolide B indicated the presence of an exomethylene group and an alkene proton, which was located on the β-carbon of the unsaturated lactone, as deduced from its downfield chemical shift. In addition, signals corresponding to a methoxy functionality at δ 3.34, an oxymethine proton at δ 4.11, and long-chain aliphatic protons at δ 1.25 (26H, br s) and 1.60–1.77 (4H, m) were evident. Furthermore, the data of philippinolide B were found to be similar to those of the known butanolide, 3-(1-methoxyeicosyl)-5-methylene-5*H*-furan-2-one.[17] Thus, the structure of philippinolide B was elucidated as 3-(1-methoxyheptadecyl)-5-methylene-5*H*-furan-2-one. The configuration at C-1′ remains undefined, because the specific rotation could not be correlated to any known compound.

Free Radical Scavenging Activities of *C. philippinense* Compounds. It is well-known that the accumulation of free radicals can result in the growth of tumor or cancer cells and speed the oxidation of lipids in cosmetics and manufactured foods. Natural antioxidants, particularly free radical removing properties, are therefore necessary in skin care products and functional foods.[21,22] The inhibitory data for four compounds to 1,1-diphenyl-2-picrylhydrazyl (DPPH) at 100 and 200 μM are listed in Table 1. In this assay, antioxidants lessen the stable DPPH radicals to diphenylpicrylhydrazine, which is yellow. On the basis of this information, cinnaretamine might function as a chain-breaking agent or radical ion neutralizer inhibiting the

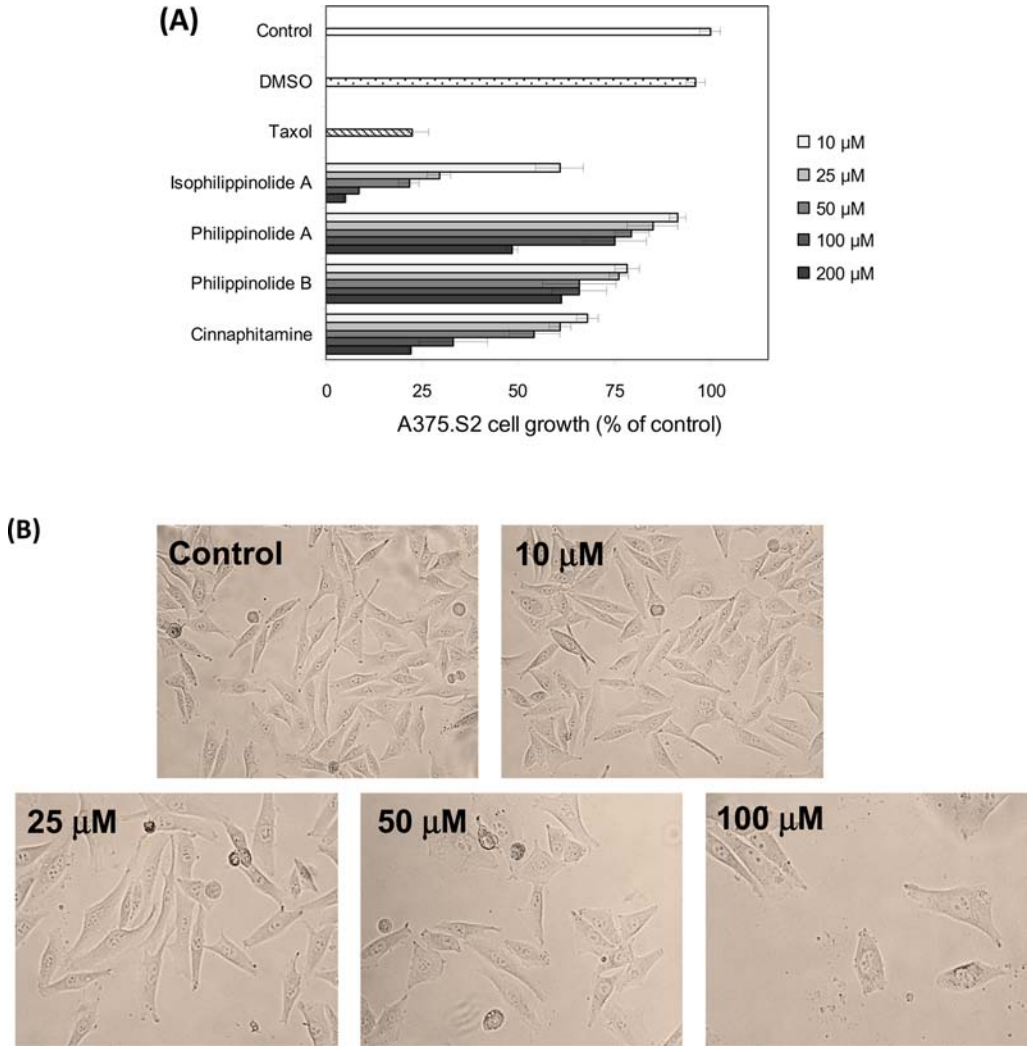

Figure 2. Antiproliferative effects of four compounds after 24 h. Data are expressed as means ± SD of three independent experiments. (A) Control, no treatment; DMSO, 0.5%; taxol, 1.0 μM. Tested compounds: from top to bottom, 10, 25, 50, 100, and 200 μM, respectively. Control had no testing sample. Bars, SD; *, $p < 0.05$. (B) Isophilippinolide A suppressed cellular proliferation and induced cytotoxicity in A375.S2 cells. Cell images were captured using a FLoid Cell Imaging Station REF: 4471136 microscope at 100×.

accumulation of harmful free radicals compared to vitamin C at the same concentration (100 μM).

Studies in the past have declared the reducing power and the chelating ability to metal ions by a biochemical agent might be major signs of its possible antioxidative aptitude. The ferrous ion chelating data for four compounds are presented in Table 1, where 100 μM EDTA was utilized as a positive control. The reagent used is ferrozine, which is capable of forming complexes with Fe(II) that are dark red in color. When this reaction is disrupted, the degree of disruption can be quantified spectrophotometrically. It was observed that all tested compounds, at doses of 100 and 200 μM, exhibited minor Fe(II) chelating properties.

The reducing power examination is an uncomplicated, fast, and dependable assay to measure reducing power with a Fe(III)−ferricyanide complex reaction. The color of the solution changes from light yellow to various shades ranging from dark green to blue, depending on tested antioxidant qualities. As reported in Table 1, cinnaretamine's reducing power was similar to the antioxidative power of BHA at the same doses.

Mushroom Tyrosinase Inhibitory Properties of *C. philippinense* Compounds. Our previous studies showed that the oxidative stress accumulation with UV exposure might induce skin darkening and the increase in reactive oxygen species in carcinogenesis.[4−7,14,21,22] For skin whitening and hyperpigmentation prevention, we examined the inhibitory properties of *C. philippinense* compounds on in vitro mushroom tyrosinase inhibition. The inhibitory effects of four compounds show only minor inhibitions to mushroom tyrosinase activity at 200 μM (Table 1). It was possible that these compounds might be useful in an assisting role and were still prime candidate factors for use in cosmetics and pharmaceuticals because of their other beneficial properties.

Antiproliferative Properties of *C. philippinense* Compounds on A375.S2 Cell. The cytotoxic properties of four compounds from *C. philippinense* were examined. The MTT assay is used to determine the cytotoxicities of *C. philippinense* compounds against human skin cancer melanoma cell line, A375.S2. Melanoma cells were incubated in the company of different concentrations of tested compounds (10, 25, 50, 100, and 200 μM), and cell growth was measured in every concentration (Figure 2A). The anticancer drug Taxol

dx.doi.org/10.1021/jf403730z | J. Agric. Food Chem. 2014, 62, 1057−1065

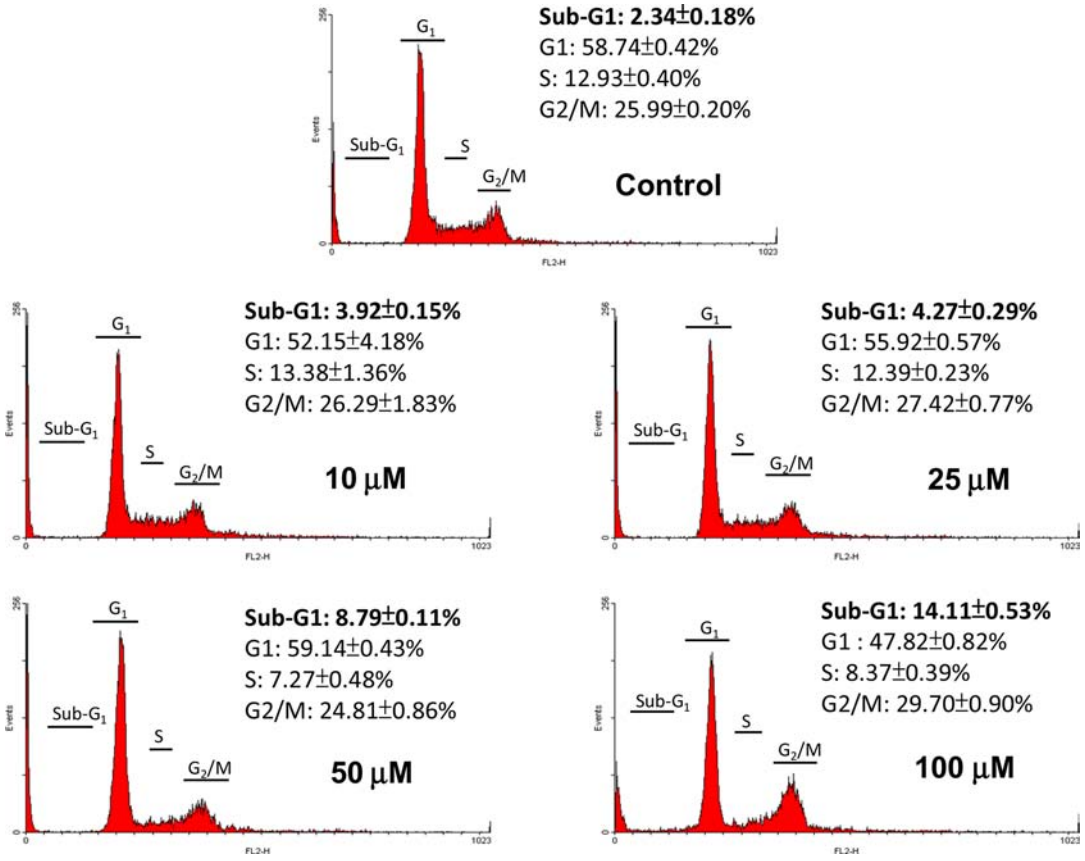

Figure 3. Isophilippinolide A induced sub-G1 cell apoptosis of A375.S2 cells. A375.S2 cells were treated at 0, 10, 25, 50, and 100 μM for 24 h, respectively. Values were obtained from three independent experiments, and representative histograms are shown. Data analyses and quantification were performed with Cell-Quest and Modfit software.

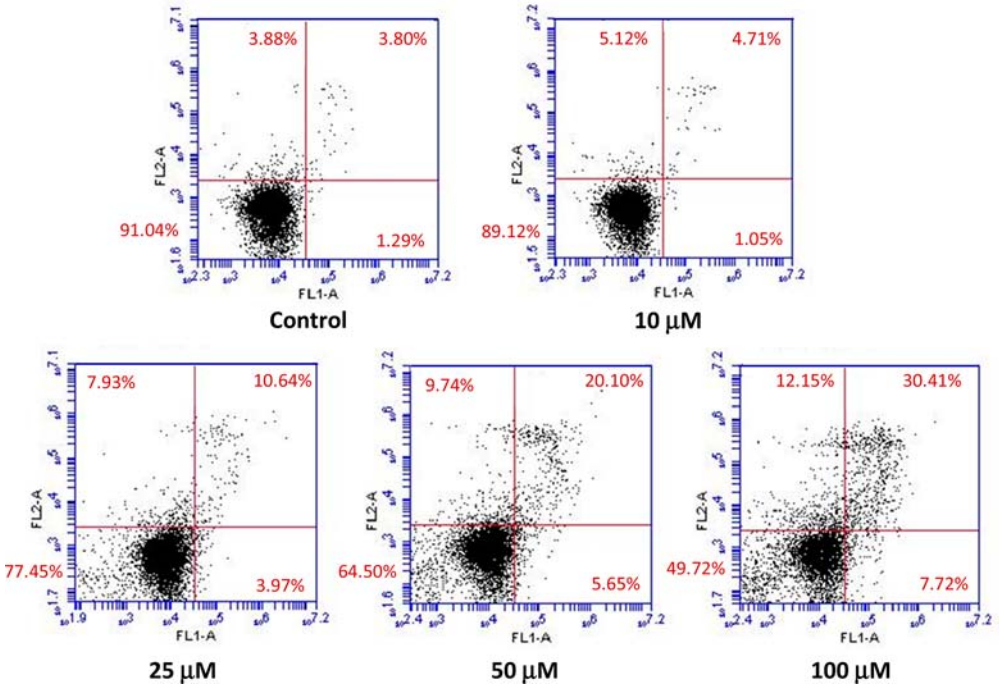

Figure 4. Isophilippinolide A induced A375.S2 cell apoptotic responses. Apoptosis was analyzed by flow cytometry after exposure to isophilippinolide A from 0 to 100 μM at 24 h and staining with annexin-V/PI.

(Paclitaxel) has been shown to cause defects in chromosome segregation, mitotic spindle assembly, and cell division to stabilize the microtubule polymer and keep it from disassembly within cells. It obstructs the progression of mitosis to prolong

dx.doi.org/10.1021/jf403730z | J. Agric. Food Chem. 2014, 62, 1057−1065

the activation of the mitotic checkpoint and to induce cell cycle arrest in various human cancer cell lines.[6] Consequently, we applied Taxol as a positive control in this study. Multiplication of A375.S2 cells was found to be suppressed by the four compounds in a dose-dependent manner from 10 to 200 μM. Isophilippinolide A exhibited an influential mean IC_{50} value of 26.7 μM after a 24 h treatment, and the other three compounds showed moderate antiproliferative activities. Morphological changes of treated isophilippinolide A were surveyed with a bright field microscope, and the magnification was 200× without staining (Figure 2B). We further investigated the detailed cellular proliferative suppression and cytotoxic mechanisms of isophilippinolide A in human melanoma.

Evaluations of Cell Cycle Arrest and Sub-G1 Accumulation of Isophilippinolide A. One parameter for assessing responsible degrees of DNA damage and consequences of cell cycle arrest distribution of treated A375.S2 cells, flow cytometry, was analyzed. Cells were processed with isophilippinolide A at 0, 10, 25, 50, and 100 μM for 24 h, respectively, followed by PI staining prior to being subjected into flow cytometric analysis (Figure 3). In cell cycle analysis, the pronounced sub-G1 population represented an indicative sign for apoptotic cells due to treatments with agents. Compared to the vehicle control group, the target compound induced apoptosis in sub-G1 phase at 2.34, 3.92, 4.27, 8.79, and 14.11% in a dose-liable way from 0 to 100 μM. It had a noticeable variation over 6-fold at 100 μM compared to the vehicle control group on sub-G1 phase, which meant the cells carried through apoptosis and that the DNA was split into bits. DNA impairment is a potential mechanism for antiproliferation effectivenesses of this agent, and more studies are required to examine the antimelanoma mechanism. Moreover, possible clinical use of isophilippinolide A shall not begin before it is proved safe to normal human cells.

Annexin V/PI Staining To Uncover Apoptotic Mechanism of Isophilippinolide A in A375.S2 Cells. A375.S2 cell pellets were mixed well with annexin V−FITC/PI (annexin V was applied as a probe to identify the event of apoptosis cells, which expressed phosphatidylserine (PS) on the cellular membrane surface with calcium buffer; PI is a cellular membrane fluorescent impermeant dye that binds with nucleic acids and is normally excluded from healthy cells) and incubated for 15 min at 25 °C and gently shaken every 30 s (as stated by the manufacturer's protocols). Unattached annexin V−FITC and PI dyes were gotten rid of by rinsing the cells with complete medium. Single-layer fluorescent marked cells were replanted into the slide and then fluorescent images were taken, respectively. A375.S2 cells were exposed to isophilippinolide A for 24 h, and there was an obvious apoptotic performance between cells treated with experimental groups and the vehicle control group (Figure 4). An augmentative increase to 30.41% at the stage of late apoptosis was found in the indicated group treated with 100 μM, compared with 3.80% of the control one. Isophilippinolide A triggered apoptosis on A375.S2 cells in dose-dependent apoptotic features from 0 to 100 μM. A375.S2 cells were all gradually withered under the existence of isophilippinolide A, which was verified to benefit the anticancer cellular proliferation that was acknowledged earlier.

Effects of Apoptotic Related Proteins in Isophilippinolide A Treated A375.S2 Cells. The activations of caspase associate proteins are indispensable to carry out apoptosis by various apoptotic stimuli. As a result, to understand the roles played by caspases in apoptotic effects caused by isophilippinolide A in human melanoma A375.S2 cells, Western blots were inspected after 24 h (Figure 5). These molecular proteins

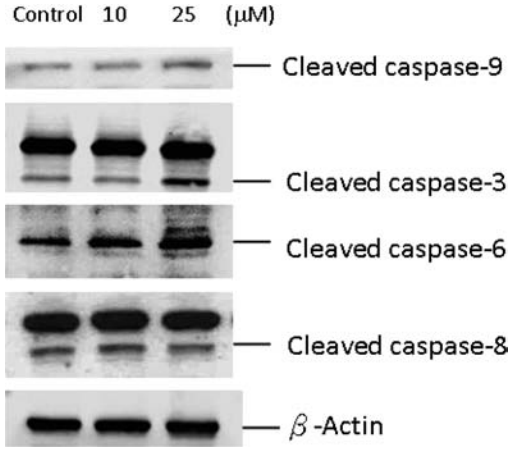

Figure 5. Western blotting was performed to compare caspase expressions in A375.S2 with and without addition of isophilippinolide A at concentrations of 10 and 25 μM for 24 h.

associated with apoptosis presented alterations, including enhanced proteolytically activated forms of caspase-9, caspase-3, and caspase-6. These cellular proteins were known to respond to apoptotic nuclear DNA damage/repair or assist organelle decomposition. We inferred that isophilippinolide A could bring about the proteolytic activations of various caspase proteins to obstruct the physiological behavior of A375.S2 cells. Additionally, to examine whether the extrinsic apoptotic pathway was activated by isophilippinolide A, the Western blot for caspase-8, the hallmark of extrinsic apoptotic pathway, was carried out. As presented in Figure 5, the cleaved form of caspase-8 was not detected as significantly changed. These results were confirmed by the cell cycle arrest in sub-G1 accumulation (Figure 3) and annexin V/PI staining in apoptotic phase (Figure 4). Accordingly, the above results suggested that isophilippinolide A induced a mitochondria-mediated apoptosis and caused sub-G1 cell cycle accumulation. However, we cannot rule out the possibility for the involvement of autophagy or necrosis, and it needs to be further investigated in the future.

The biological activities of pure chemical compounds are hugely influenced by functional groups of the compound's geometric structures. On the basis of our previous studies, it was discovered that the antiproliferation of isokotomolide A was more potent than the antiproliferation of kotomolide A.[23,24] In this study, we discovered that isophilippinolide A inhibited cellular proliferation compared to philippinolide A. We believe that the alkylidene side chain of isokotomolide A and isophilippinolide A were *trans* to the carbonyl groups, which was the key point of anticancer proliferation.

Cellular Cytotoxicities of *C. philippinense* Compounds of Normal Human Skin Cells. As natural compounds are being developed for cosmetic or therapeutic applications, safety measures, such as tests for allergies, sensitivities, or toxicities, are needed to be implemented.[13,25] We illustrated the cellular viabilities of human normal skin melanocytes (epidermal, Figure 6A) and fibroblasts (dermal, Figure 6B) after being treated for 24 h with various concentrations of *C. philippinense* compounds. Considering DMSO's likely antiproliferative

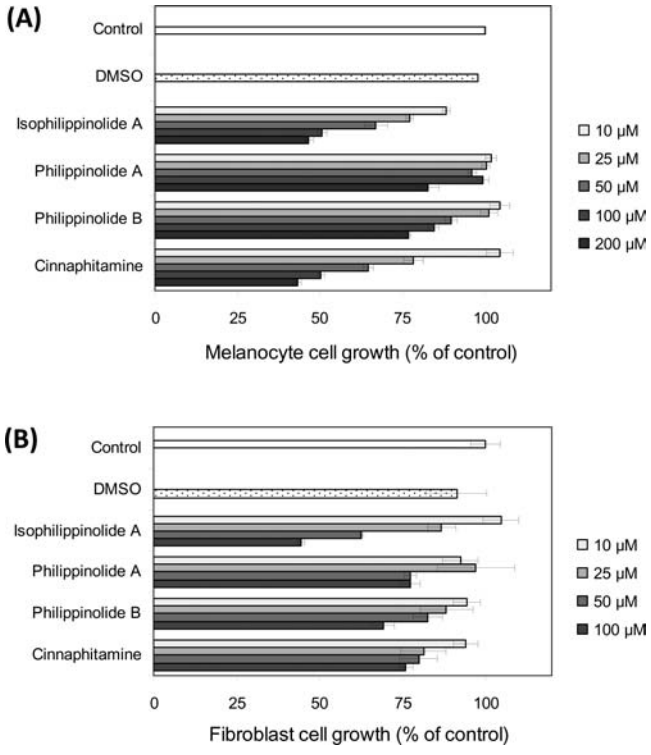

Figure 6. Human melanocyte (A) and fibroblast (B) cell growth with four compounds at various concentrations after 24 h treatments. Data are expressed as means ± SD of three independent experiments. Symbols are similar to those in Figure 2.

effects, we added a maximal amount (0.5%) of DMSO to cultures and took them as positive controls. DMSO with this maximal dose was observed not to affect the growth of human epidermal and dermal cells. These data indicated isophilippinolide A and cinnaretamine had reductions in two cell growths to illustrate cytotoxicities. Philippinolide A and philippinolide B had very little discernible toxicities toward normal human skin cells, suggesting that they will not produce cytotoxic side effects in cells.

Taken together, our present work demonstrated the potential anticancer compound, isophilippinolide A, on human melanoma A375.S2 cells via regulating DNA cell cycle arrest in sub-G1 phase and triggering apoptotic caspase protein expressions with less cytotoxicity to human normal skin cells (Figure 7). Accordingly, isophilippinolide A could inhibit human skin cancer cellular growth, bringing hope to melanoma treatment at the level of a better understanding of the molecular mechanism.

At the eighth week of treatment, the rats were fasted overnight and an oral glucose tolerance test (OGTT) was performed. Briefly, 2 g of glucose/kg of bw was dissolved in water and administered by oral gavage, and tail blood samples were taken at 0, 15, 30, and 120 min after the administration of the glucose load. The plasma glucose and insulin levels were measured.

At the ninth week of treatment, the rats were fasted overnight, tail blood samples were taken, and insulin levels were measured.

After 12 weeks of GSPE treatment, the overnight fasted animals were anesthetized with 50 mg of pentobarbital/kg of bw and sacrificed by bleeding. The blood was collected and treated with a commercial DPP4 inhibitor (Millipore, Madrid, Spain) and a serine protease inhibitor, Pefabloc SC (Roche, Barcelona, Spain), to prevent the inactivation of active GLP-1 and ghrelin, respectively. The animal tissue specimens were immediately frozen in liquid nitrogen and stored at −80 °C until further analysis.

All of the procedures were approved by the Experimental Animal Ethics Committee of the Universitat Rovira i Virgili (permission number 4250).

Intestinal GLP-1 Extraction. Active GLP-1 was extracted from the colon as previously described.[17] Briefly, colon samples were homogenized using an ethanol/acid solution (100% ethanol/sterile water/12 M HCl, 74:25:1), placed for 24 h at 4 °C, and centrifuged at 2000*g* for 20 min at 4 °C. Supernatants were collected, diluted in 1× PBS, and stored at −80 °C until further analysis. Active GLP-1 was measured following the instructions of the manufacturer.

Measurement of DPP4 Activity. DPP4 was extracted from rat intestine as previously described.[6] Briefly, intestine samples were homogenized using lysis buffer [phosphate-buffered saline (PBS) containing 100 Kallikrein inhibitor units (KIU)/mL aprotinin and 1% Triton X-100], centrifuged at 1000*g* at 4 °C for 10 min to eliminate the cellular debris, and centrifuged twice at 20000*g* at 4 °C for 10 min. The supernatants were stored at −80 °C until further analysis.

To determine the activity of DPP4 in the intestinal lysates and the rat plasma samples, the specimens were incubated with 0.2 mM *H*-glycylprolyl-pnitroanilide *p*-tosyalte in Tris−HCl buffer at 37 °C and the release of *p*-nitroanilide absorbance was measured every minute at 405 nm for 30 min.

Western Blot. Protein was extracted from the intestine using radioimmunoprecipitation assay (RIPA) lysis buffer [15 mM Tris−HCl, 1% Triton X-100, 0,1% sodium dodecyl sulfate (SDS), 167 mM NaCl, and 0.5% Na−deoxycholate] with a protease inhibitor cocktail (diluted 1:1000, Sigma-Aldrich) and 1 mM phenylmethanesulfonyl fluoride (PMSF). The total protein levels of the lysates were determined using the Bradford method.[18] The proteins were loaded and run on 10% SDS−polyacrylamide gels. The samples were transferred onto polyvinylidene difluoride (PVDF) membranes (Bio-Rad Laboratories, Hercules, CA), blocked at room temperature using 5% (w/v) non-fat milk in Tris-buffered saline with 0.2% (v/v) Tween-20 (TBST) buffer, and incubated overnight at 4 °C with rabbit anti-*β*-actin antibody (Sigma-Aldrich) or anti-CD26 (Abcam, Cambridge, U.K.). After washing with TBST, the blots were incubated at room temperature with peroxidase-conjugated anti-rabbit secondary antibody (GE Healthcare, Buckinghamshire, U.K.). The blots were washed thoroughly in TBST, followed by Tris-buffered saline (TBS) after immunoblotting, and the immunoreactive proteins were visualized using the ECL Plus western blotting detection system (GE Healthcare). Densitometric analysis of the immunoblots was performed using ImageJ 1.44p software; all proteins were quantified relative to the loading control.

Quantitative Reverse Transcription Polymerase Chain Reaction (RT-PCR). The total RNA from the hypothalamus was extracted using a RNAeasy kit (Qiagen, Hilden, Germany), and the total RNA from the duodenum and colon was extracted using the TRIzol reagent following the protocols of the manufacturers. cDNA was generated using a high-capacity cDNA reverse transcription kit (Applied Biosystems, Madrid, Spain). Quantitative PCR amplification and detection were performed using the following TaqMan assay-on-demand probes (Applied Biosystems): Rn00562910_m1 for DPP4, Rn00571500_m1 for GIP, Rn00562293_m1 for proglucagon, Rn01460420_g1 for PYY, Rn00572200_m1 for chromogranin A (CgA), and Rn00562406_m1 for GLP-1 receptor (GLP-1R). *β*-Actin was used as the reference gene (Rn00667869_m1). The relative mRNA expression levels were calculated using the $\Delta\Delta C_t$ method.

Data Analyses. The area under the curve (AUC) and homeostatic model assessment-estimated insulin resistance (HOMA-IR) were calculated as previously described by Ou et al. and Matthews et al., respectively.[19,20]

The results are expressed as the mean values ± standard error of the mean (SEM). The effects were assessed by analysis of variation (ANOVA) and Student's *t* test. All calculations were performed using SPSS software (SPSS, Chicago, IL).

RESULTS

GSPE Limits the Cafeteria-Diet-Induced Decrease in Intestinal GLP-1 Biosynthesis. To analyze whether a preventive treatment with procyanidins modulates the incretin levels in cafeteria-diet-fed rats, basal GIP and GLP-1 levels in plasma were assessed in rats fed a cafeteria diet for 12 weeks simultaneously with 25 mg of GSPE/kg of bw. As shown in Figure 1A, cafeteria-fed rats exhibited reduced plasma levels of active GLP-1. GSPE did not alter the active GLP-1 levels compared to the vehicle-treated cafeteria-fed rats. Total GIP levels were modified by neither the cafeteria diet nor the GSPE treatment (Figure 1B).

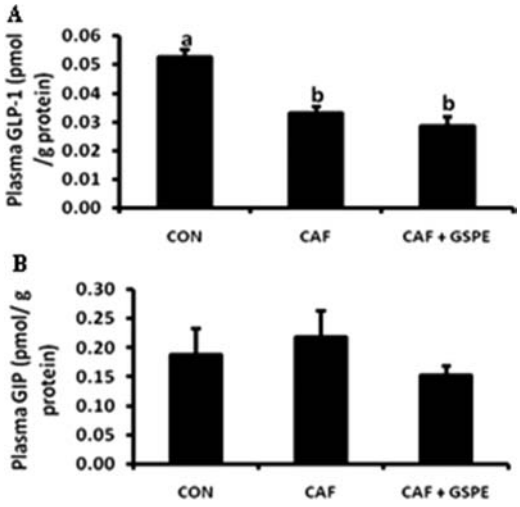

Figure 1. Effect of the cafeteria diet and GSPE on incretin plasma levels. Effects on (A) plasma-active GLP-1 levels and (B) total GIP levels were assayed after 12 weeks of cafeteria diet and preventive treatment with 25 mg of GSPE/kg of bw. The data are displayed as the mean ± SEM, with a and b as statistically significant differences at $p < 0.05$.

To assess the effect of the cafeteria diet and GSPE treatment on incretin biosynthesis, we measured the GLP-1 levels and proglucagon gene expression in the colon as well as GIP gene expression in the duodenum. As shown in Figure 2, the colon levels of GLP-1 were decreased by the cafeteria diet by approximately 30% compared to the control diet (Figure 2A), a reduction that was accompanied by a significant down-regulation of the proglucagon gene expression (Figure 2B). The GSPE treatment prevented the decrease in colon levels of GLP-1 produced by the cafeteria diet, although it did not reach control levels (Figure 2A). This effect was also observed for the expression of the proglucagon gene, as shown in Figure 2B. GIP gene expression in the duodenum was unaffected by either the cafeteria diet or the GSPE treatment [0.93 ± 0.17 and 0.89

dx.doi.org/10.1021/jf405239p | J. Agric. Food Chem. 2014, 62, 1066−1072

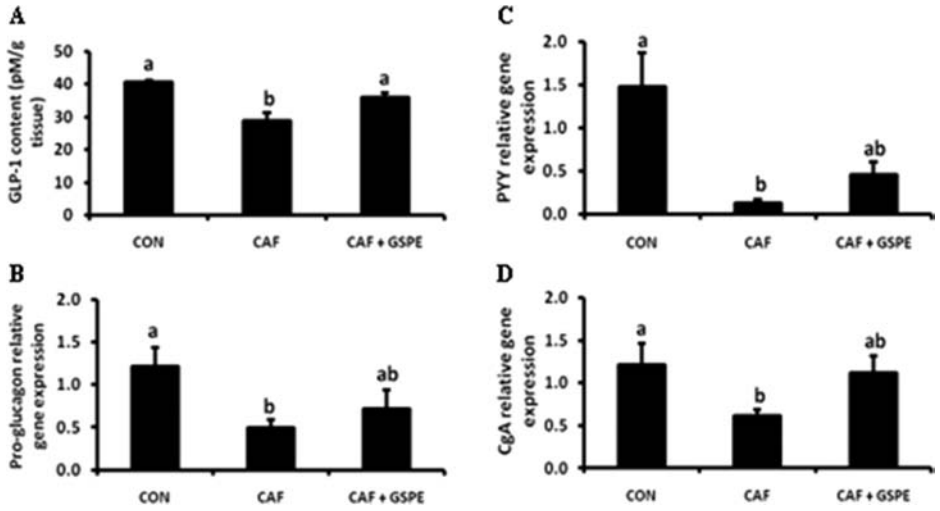

Figure 2. Effect of the cafeteria diet and GSPE on hormone production and CgA gene expression in the colon. Effects on (A) colon-active GLP-1 content and gene expression of (B) proglucagon, (C) PYY, and (D) CgA were determined after 12 weeks of cafeteria diet and simultaneous treatment with 25 mg of GSPE/kg of bw. The data are displayed as the mean ± SEM, with a, b and c as statistically significant differences at $p < 0.05$.

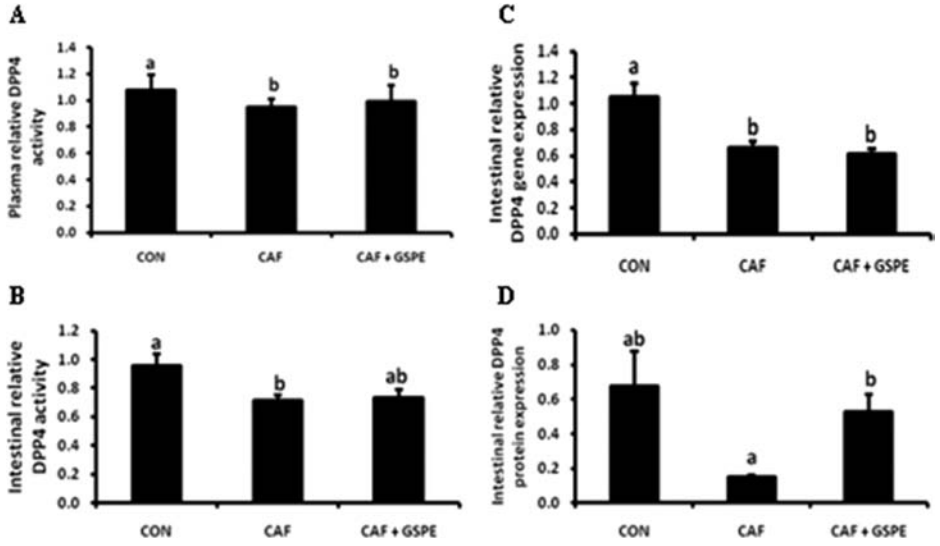

Figure 3. Effect of the cafeteria diet and GSPE on DPP4. After 12 weeks of cafeteria diet and simultaneous treatment with 25 mg of GSPE/kg of bw, DPP4 activity was determined in (A) plasma and (B) intestine. Intestinal DPP4 (C) gene expression and (D) protein expression were also assessed by RT-PCR and western blot, respectively. The data are displayed as the mean ± SEM, with a, b and c as statistically significant differences at $p < 0.05$.

± 0.10, respectively, versus the control (1.03 ± 0.09) ($p > 0.05$)].

GSPE Prevents the Cafeteria-Diet-Induced Decrease of Enteroendocrine Cells in the Colon. To determine whether the reduction in GLP-1 is due to a modulation of GLP-1 gene expression or a general effect on GLP-1-producing cells, we tested the effects of the cafeteria diet and GSPE on PYY, another hormone that is also secreted by intestinal L cells. We evaluated PYY gene expression, and as shown in Figure 2C, it was significantly downregulated as a result of the cafeteria diet, whereas GSPE treatment partially blocked this effect.

Next, we analyzed the gene expression of CgA, a marker of endocrine differentiation. Figure 2D shows that the expression of the CgA gene in the colon was significantly decreased in the CAF group, whereas GSPE treatment prevented the effect of the cafeteria diet, similar to the effect observed for GLP-1 and PYY. The expression of the CgA gene in the duodenum was also assessed, but it was unaffected by the cafeteria diet or the GSPE treatment [0.88 ± 0.11 and 1.13 ± 0.27, respectively, versus the control (1.16 ± 0.22) ($p > 0.05$)].

GSPE Modulates Intestinal DPP4. To assess whether the cafeteria diet and the GSPE treatment could also modify the enzyme responsible for incretin degradation, DPP4, the plasma and intestinal levels of DPP4 activity were measured at the end of the treatment. As shown in Figure 3A, plasma DPP4 activity was slightly but significantly decreased by the cafeteria diet, whereas it was unaffected by the GSPE treatment. Intestinal DPP4 activity was also reduced by the cafeteria diet, whereas in contrast to the effects in plasma, the simultaneous GSPE treatment prevented this decrease (Figure 3B). To analyze whether the preventive effect elicited by GSPE was due to a modulation of DPP4 production, its gene and protein expression were also evaluated in the intestine. As shown in panels C and D of Figure 3, DPP4 gene expression and protein

levels were reduced by the cafeteria diet, which is consistent with what was observed in terms of its activity. GSPE prevented the cafeteria-induced decrease in DPP4 protein expression but elicited no effect at the gene expression level.

GSPE Treatment Modulates the Expression of GLP-1 and GLP-1 Receptor Genes in the Hypothalamus. To evaluate the systemic preventive effects of GSPE on GLP-1 production, proglucagon gene expression was also assessed in the hypothalamus. As shown in Figure 4A, the cafeteria diet

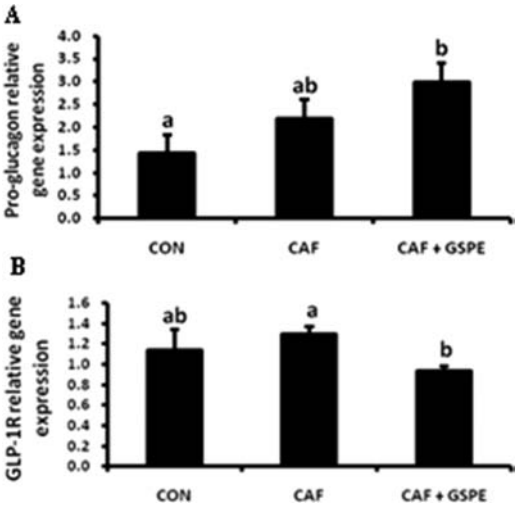

Figure 4. Effect of the cafeteria diet and GSPE on hypothalamic GLP-1 and GLP-1R. Effects on hypothalamic gene expression of (A) proglucagon and (B) GLP-1R were assessed after 12 weeks of cafeteria diet and preventive treatment with 25 mg of GSPE/kg of bw. The data are displayed as the mean ± SEM, with a and b as statistically significant differences at $p < 0.05$.

tended to upregulate proglucagon expression and GSPE treatment further enhanced this effect. We also evaluated the sensitivity to GLP-1 by assaying GLP-1R gene expression and found that its expression was unaffected by the cafeteria diet, whereas it was downregulated by the GSPE treatment compared to cafeteria-fed rats treated with the vehicle (Figure 4B).

GSPE Modulates Insulinemia after 9 Weeks of Treatment. To assess whether a preventive GSPE treatment can modulate insulinemia, an OGTT of 2 h was performed at the eighth week of treatment. As shown in Figure 5, insulin AUC was increased in cafeteria-diet-fed rats, whereas a preventive GSPE treatment prevented this effect.

Moreover, fasting plasma insulin and glucose levels were measured after 9 and 12 weeks, to test whether preventive GSPE treatment affects insulin resistance induced by the cafeteria diet. As shown in Figure 6A, HOMA-IR was significantly increased after 9 weeks of cafeteria diet, whereas a simultaneous treatment with 25 mg of GSPE/kg of bw prevented this effect, resulting in a healthier HOMA-IR. However, after 12 weeks, GSPE treatment was unable to prevent the increase in HOMA-IR induced by the cafeteria diet (Figure 6B).

DISCUSSION

Procyanidins from grape seed have been shown to improve insulin resistance, eliciting a corrective effect when the glucose homeostasis of the animal has been slightly disturbed by a

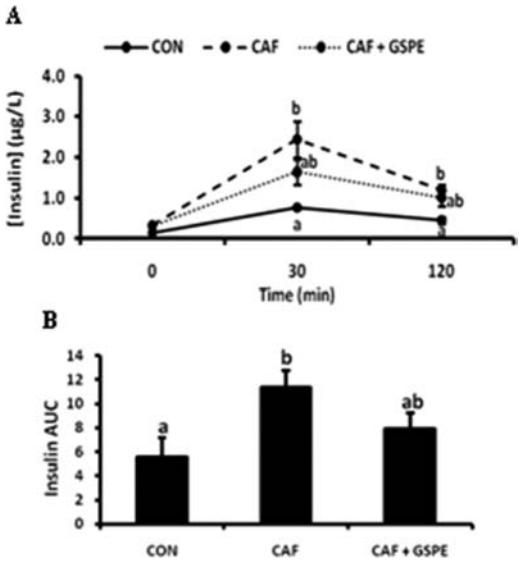

Figure 5. Effect of the cafeteria diet and GSPE on insulinemia. After 8 weeks of cafeteria diet and a preventive treatment with 25 mg of GSPE/kg of bw, a 2 h OGTT was performed, (A) insulin was analyzed at time 0, 30, and 120 min, and (B) AUC was calculated. The data are displayed as the mean ± SEM, with a and b as statistically significant differences at $p < 0.05$.

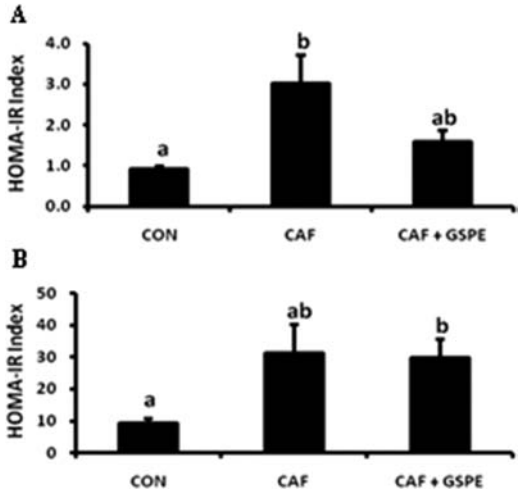

Figure 6. Effect of the cafeteria diet and GSPE on insulin resistance. Plasma glucose and insulin levels were measured, and HOMA-IR was calculated after (A) 9 weeks and (B) 12 weeks of cafeteria diet and preventive treatment with 25 mg of GSPE/kg of bw. The data are displayed as the mean ± SEM, with a and b as statistically significant differences at $p < 0.05$.

cafeteria diet.[1,2,5,21] However, whether GSPE can act in a preventive way has not yet been described. Moreover, GSPE has been shown to elicit an incretin-like effect in healthy rats.[6] However, our understanding of the effects of GSPE on the incretin system in animals with disturbed glucose homeostasis remains limited. In this study, we developed a 12-week cafeteria diet-fed model that caused a decrease in GLP-1 plasma levels and production in the intestine, with no effects on GLP-1 production and detection in the hypothalamus. The cafeteria diet also caused a decrease in the amount of DPP4 enzyme at the plasma level and in the intestine, and the HOMA-IR clearly revealed the induction of insulin resistance. We found that

dx.doi.org/10.1021/jf405239p | J. Agric. Food Chem. 2014, 62, 1066−1072

procyanidins were able to counteract several of these effects, which were predominantly found in the intestine.

With regard to GLP-1 production, the CAF + GSPE animals exhibited an increased amount of GLP-1 in colonic cells, with a simultaneous increase in GLP-1 mRNA. Similarly, Dao et al. reported that resveratrol increased the colon levels of active GLP-1, together with an increase in proglucagon gene expression, in mice fed with a HFD.[10] Dao et al. also suggested that the increase in GLP-1 production by resveratrol might explain its preventive effects on plasma levels of GLP-1, which are reduced in the vehicle-treated HFD-fed mice after the administration of an oral glucose load but are increased in the resveratrol-treated HFD-fed animals.[10] Actually, an acute dose of GSPE has also been found to effectively improve glucose-stimulated GLP-1 secretion in healthy rats (submitted results). Besides, some other proanthocyanidins (i.e., berry purees[22] and the tetrameric procyanidin cinnamtannin A2[23]) have been shown to elicit this effect.

Our results showed that treatment with GSPE also upregulated the colon expression of the PYY gene, a hormone that has been reported to be co-expressed with GLP-1 in enteroendocrine L cells.[24] Enteroendocrine cells actively self-renew and differentiate throughout the life of an animal,[25] and procyanidins are known to modify cell proliferation.[21,26,27] Therefore, we assessed whether GSPE modulated CgA levels, a marker of endocrine cells.[28,29] We found that GSPE again counteracted the effects of the cafeteria diet. Our results suggest that the modulation on GLP-1 production is due to not only a direct modulation of its gene expression but also changes in the amount of enteroendocrine cells, which were reduced by the cafeteria diet. There are no previous studies that have analyzed the effects of a cafeteria diet on the number of enteroendocrine cells. A HFD was suggested to increase the proliferation of L cells, causing a dysfunction and reducing GLP-1 secretion.[30] The different results might be attributed to differences in experimental conditions (type of diet, animal gender, and length of the study) between studies. Moreover, that study analyzed the effects within the duodenum, whereas we found effects that were limited to the colon, the predominant location for GLP-1 production.[31] In contrast, we found that the expression of CgA and GIP genes in the duodenum, where GIP-producing cells are predominantly found,[32] was unchanged in our experiment, which is consistent with the unaltered plasma levels of GIP.

The effects of GSPE on DPP4 are consistent with our previous results, which demonstrated the sensitivity of intestinal DPP4 to GSPE and a lack of GSPE effects on plasma DPP4.[6] In this study, we found that GSPE prevents the decrease in intestinal DPP4 activity and protein caused by a cafeteria diet. These results differ from previous observations because we had shown an inhibitory effect of 25 mg of GSPE/kg of bw after 45 days of treatment in healthy animals or after 30 days in animals with cafeteria-diet-induced insulin resistance.[6] The effect that a cafeteria diet elicited on DPP4 is unclear. Several authors have reported an increase in circulating DPP4 activity in humans with obesity or type 2 diabetes[33−35] and in rats with type 1 diabetes or impaired glucose tolerance.[36,37] However, limited studies in humans have shown decreased plasma DPP4 activity in diabetic subjects[38] and unchanged activity in obese, diabetic, and impaired-glucose tolerance subjects.[34,39] Taken together, these data indicate that a severe degree of hyperglycemia is required to induce an increase on circulating DPP4 activity, whereas mild hyperglycemia is insufficient to induce its increase.[34,39] Our model supports this conclusion because the cafeteria diet did not affect glycemia, which is consistent with the lack of increased DPP4. In contrast, we found a decrease that is partially prevented by GSPE. In a completely different context, the flavonoid apigenin has been reported to counteract the decrease in DPP4 activity caused by cancer in a colorectal carcinoma cell line, an observation that is in line with the effects on DPP4 observed in our study.[40] However, there is limited information regarding DPP4 activity in the intestine. Thus, it is difficult to make further conclusions. Considering that this is the first preventive study on GSPE effects, further studies are warranted to fully assess the implications of the DPP4 inhibition in the cafeteria-diet-fed model and the opposing effects elicited by GSPE.

To evaluate the systemic preventive effects of GSPE on GLP-1, we analyzed GLP-1 and its receptor in the hypothalamus, where they are also expressed.[41,42] Previous studies have shown that brain proglucagon gene expression is upregulated by a HFD.[43,44] We observed a tendency to increase hypothalamic proglucagon gene expression. However, we found that GLP-1 expression was stimulated in CAF + GSPE rats. This stimulation is consistent with the reduced expression of the GLP-1R gene. Knauf et al. found that blockade of brain GLP-1R in HF-fed mice improves insulin resistance and enhances glucose use by muscles.[43] The available evidence suggests that enteric glucose absorption activates GLP-1R-sensitive central nervous system (CNS) networks that promote enhanced glucose disposal. Furthermore, brain GLP-1R signaling controls peripheral blood flow and insulin sensitivity predominantly under hyperinsulinemic/hyperglycemic conditions. The relative importance of central versus peripheral GLP-1 action for the control of glucose homeostasis remains unclear.[42]

All of these results demonstrate that GSPE interacts with the GLP-1 system, predominantly preventing the negative effects induced by a cafeteria diet. Therefore, the CAF + GSPE animals were expected to show an improved glucose metabolism compared to the CAF group. At the eighth week, we performed an OGTT and found that the GSPE treatment corrected the glucose-induced increase in insulin AUC as expected. Indeed, these results are consistent with the action of a GSPE corrective treatment of 4 weeks, which was previously shown to improve peripheral insulin resistance at the same dose.[2] This effect was maintained at 9 weeks, when we observed an improved HOMA-IR as a result of GSPE pretreatment. However, surprisingly, after 12 weeks, our results do not show a clear improvement in HOMA-IR by the GSPE treatment. This might be due to the dose of GSPE, because we previously described high variability on the insulin levels after different GSPE doses. Working with healthy animals, we have previously shown that this variability is not dose-dependent.[45] In fact, higher GSPE doses for a longer time showed an improved insulinemia and glycemia in type 2 diabetic rats.[46,47] This was accompanied by an improved functionality of β cells related to the GSPE treatment, as we have previously found with lower doses.[5,27]

In conclusion, we have found that a cafeteria diet induces a decrease in active GLP-1 levels by decreasing GLP-1 production in the colon, which might be attributed to a loss of enteroendocrine cells, an effect that is prevented by simultaneous treatment with GPSE. GSPE treatment also increased hypothalamic GLP-1 production and downregulated GLP-1R, opposing the effects of the cafeteria diet. This

preventive action also impacts intestinal DPP4, predominantly by preventing the decrease in its activity and protein levels.

Daltonics Inc., Bremen, Germany). Optical rotation was acquired on a Perkin-Elmer (Waltham, MA) 343 polarimeter. Ultraviolet (UV) radiation was recorded on a Perkin-Elmer Lambda 650 UV–vis spectrophotometer (Perkin-Elmer). Infrared (IR) radiation was obtained on a WQF-520 FT-IR spectrometer (Beijing Rayleigh Analytic Instrument Co., Beijing, China).

Plant Material. Fresh ripe litchi fruits, cv. 'Heiye', were collected from the Fruit Tree Research Institute, Guangdong Academy of Agricultural Sciences (Guangzhou, China) in June 2012, and the pericarps were manually separated from the fruits.

Extraction and Isolation. The fresh pericarps (5.0 kg) were immersed in 85% aqueous ethanol, chopped with a multifood processor, transferred to flasks, and then heated at 50 °C for 2 h. Twenty liters of 85% aqueous ethanol was used each time, and the extraction was repeated three times. The solution was filtered and evaporated under vacuum to give an ethanolic extract (320 g). The extract (315 g) was dissolved in 2.0 L of water and then sequentially fractionated with ethyl acetate (1.5 L × 5) and *n*-butanol (1.2 L × 7) to afford ethyl acetate-soluble (109.35 g) and *n*-butanol-soluble (79.30 g) fractions after being taken to dryness under reduced pressure. The ethyl acetate-soluble fraction (107.35 g) was subjected to silica gel (2330 g, 100–200 mesh) column [545 mm × 120 mm (inside diameter)] chromatography and eluted with a chloroform ($CHCl_3$)/methanol (MeOH) mixture (v/v, 10:0, 38 L → 98:2, 24 L → 95:5, 19 L → 9:1, 33 L → 85:15, 38 L → 8:2, 25 L → 7:3, 25 L → 6:4, 9 L → 0:10, 9 L) to furnish fractions E1–E15 after they had been pooled according to their TLC profiles. Fraction E10 (10.7 g) was further subjected to silica gel (440 g, 200–300 mesh) column [720 mm × 44 mm (inside diameter)] chromatography and eluted with a $CHCl_3$/MeOH mixture (v/v, 95:5, 2.75 L → 9:1, 8.75 L → 85:15, 6.25 L) to yield fractions E10-1–E10-4. Fraction E10-4 was separated by MPLC and eluted with a MeOH/H_2O mixture (v/v, 2:8, 3:7, 4:6, 5:5, 6:4, and 7:3, each 2.4 L) at a flow rate of 10 mL/min to produce fractions E10-4-1–10-4-4. Fractions E10-4-1 and E10-4-2 were individually separated by silica gel (200–300 mesh) column chromatography to afford compounds **1** (15 mg) and **5** (11 mg), respectively. Fraction

E10-4-3 was purified by preparative HPLC using a MeOH/H_2O mixture (46:54, v/v) as the mobile phase at a flow rate of 5 mL/min to give compound **2** [retention time (t_R) of 53.4 min, 25 mg]. Fraction E11 (13.88 g) was passed through a MCI gel column [259 mm × 26 mm (inside diameter)] for depigmentation, and the obtained MeOH eluate (7.20 g) was separated by MPLC and purified by preparative HPLC using an acetonitrile/H_2O/acetic acid (AcOH) mixture (15:85:0.1, v/v/v) as the mobile phase at a flow rate of 5 mL/min to yield compounds **3** (t_R of 60.7 min, 32 mg) and **4** (t_R of 90.5 min, 30 mg). The *n*-butanol-soluble fraction (79.3 g) was subjected to silica gel (1310 g, 100−200 mesh) column [800 mm × 75 mm (inside diameter)] chromatography and eluted with a $CHCl_3$/MeOH mixture (v/v, 9:1, 5.6 L → 85:15, 18.2 L → 8:2, 14.7 L → 7:3, 10.5 L → 0:10, 5.3 L) to furnish fractions B1−B7. Fraction B4 (12.4 g) was separated by silica gel (200−300 mesh) column chromatography, MPLC, and Sephadex LH-20 column [1215 mm × 14 mm (inside diameter)] chromatography that was eluted with MeOH to afford compound **6** (8 mg). Fraction B6 (2.8 g) was separated by MPLC to give fractions B6-1−B6-7. Fraction B6-1 was further separated by Sephadex LH-20 column chromatography and purified by preparative HPLC using a MeOH/H_2O mixture (13:87, v/v) as the mobile phase at a flow rate of 5 mL/min to yield compound **7** (t_R of 95.4 min, 4 mg). Fraction B6-6 was separated by Sephadex LH-20 column chromatography and purified by preparative HPLC using a MeOH/H_2O/AcOH mixture (42:58:0.1, v/v/v) as the mobile phase at a flow rate of 5 mL/min to obtain compounds **8** (t_R of 46.2 min, 15 mg) and **9** (t_R of 44.5 min, 22 mg).

Bis(8-epicatechinyl)methane (1). Off-white amorphous powder: $[\alpha]_D^{20}$ −103.7 (*c* 0.138, MeOH); UV (MeOH) λ_{max} (nm) (log ε) 281 (3.65); IR (KBr) ν_{max} 3377, 1618, 1524, 1454, 1284, 1113 cm^{-1}; HR-ESI-MS positive *m/z* 593.1651 $[M + H]^+$ (calcd for $C_{31}H_{29}O_{12}^+$, 593.1654, error of 0.5 ppm), 615.1474 $[M + Na]^+$ (calcd for $C_{31}H_{28}O_{12}Na^+$, 615.1473, error of −0.1 ppm); ESI-MS positive *m/z* 593 $[M + H]^+$, 615 $[M + Na]^+$, negative *m/z* 591 $[M - H]^-$; ^1H NMR (400 MHz, CD_3OD) and ^{13}C NMR (100 MHz, CD_3OD) data in Table 1.

Dehydrodiepicatechin A (2). Yellowish amorphous powder: $[\alpha]_D^{20}$ 373.8 (*c* 0.064, MeOH); ESI-MS positive *m/z* 577 $[M + H]^+$, 599 $[M + Na]^+$, negative *m/z* 575 $[M - H]^-$; ^1H NMR (400 MHz, CD_3OD) and ^{13}C NMR (100 MHz, CD_3OD) data in Table 2.

8-(2-Pyrrolidinone-5-yl)-(−)-epicatechin (6). White amorphous powder: $[\alpha]_D^{20}$ −14.5 (*c* 0.345, MeOH); ESI-MS positive *m/z* 374 $[M + H]^+$, 396 $[M + Na]^+$, negative *m/z* 372 $[M - H]^-$, 408 $[M + Cl]^-$; ^1H NMR (400 MHz, CD_3OD) and ^{13}C NMR (100 MHz, CD_3OD) data in Table 1.

FRAP Assay. Ferric reducing ability of the compounds was determined following the procedures as previously described.[5] FRAP reagent was made freshly by mixing 300 mM acetate buffer (pH 3.6), a 10 mM TPTZ solution in 40 mM hydrochloric acid, and a 20 mM aqueous ferric chloride ($FeCl_3$) solution in a 10:1:1 (v/v/v) ratio. The TPTZ solution was prepared on the same day. Test compounds were dissolved in methanol and diluted 2-fold to six concentrations. Twenty microliters of the compound solution and 180 μL of FRAP reagent were mixed in 96-well plates. L-Ascorbic acid was dissolved in methanol and used as a positive reference. Each treatment was conducted in quadruplicate. The plates were incubated at 37 °C for 30 min in the dark. The absorbance of the product (ferrous TPTZ complex) in each well was read at 595 nm using a Genios microplate reader (Tecan Group, Männedorf, Switzerland). One milliliter of ferrous sulfate ($FeSO_4$) at six different concentrations and 1 mL of 10 mM TPTZ and 10 mL of 300 mM acetate buffer (pH 3.6) were used for a calibration curve. FRAP values were calculated and expressed as means ± the standard deviation (SD) in millimoles of Fe(II) per gram.

DPPH Radical Scavenging Assay. The DPPH radical scavenging ability of the compounds was evaluated according to the method as previously described.[5] DPPH was freshly prepared in methanol at a concentration of 0.1 mM. Test compounds were dissolved in methanol and diluted 2-fold to six concentrations. Twenty microliters of the compound solution and 180 μL of the DPPH solution were mixed in 96-well plates. L-Ascorbic acid was dissolved in methanol and used as a positive reference. The control contained methanol instead of the compound solution, and the blank contained methanol in place of the DPPH solution. Each treatment was conducted in quadruplicate. The plates were incubated at 37 °C for 30 min in the dark. The absorbance (OD) in each well was read at 515 nm on a Genios microplate reader (Tecan). The inhibitory rates of DPPH radicals were calculated according to the formula

$$\text{inhibition}\,(\%) = [1 - (OD_{treated} - OD_{blank})/OD_{control}] \times 100$$

SC_{50} values (the concentrations required to scavenge 50% DPPH radicals present in the test solution) were calculated and expressed as means ± SD in micromolar.

ABTS Radical Cation Decolorization Assay. The ABTS radical cation ($ABTS^{\bullet+}$) scavenging activity of the compounds was determined according to the method described previously.[6,7] ABTS was dissolved in deionized water to a concentration of 7 mM. $ABTS^{\bullet+}$ was produced by reacting the ABTS solution with 2.45 mM (final concentration) potassium persulfate, and the mixture was kept at room temperature for 12−16 h in the dark before being used. The $ABTS^{\bullet+}$ solution was diluted with phosphate-buffered saline (PBS, pH 7.4) to an absorbance of 0.70 ± 0.02 at 734 nm. Test compounds were dissolved in dimethyl sulfoxide (DMSO) and diluted to 400, 200, 100, 50, 25, and 12.5 μg/mL. Ten microliters of the compound solution and 200 μL of the diluted $ABTS^{\bullet+}$ solution were mixed in 96-well

plates. L-Ascorbic acid was used as a positive reference. The control contained DMSO instead of the compound solution. Each treatment was conducted in triplicate. After a mixing time of 10 s and an incubation period of 6 min at 37 °C in the dark, the absorbance (OD) in each well was read at 415 nm on a Varioskan Flash microplate reader (Thermo Scientific). The inhibitory rates of $ABTS^{\bullet+}$ were calculated according to the formula

$$\text{inhibition}\,(\%) = (1 - OD_{treated}/OD_{control}) \times 100$$

IC_{50} values were calculated and expressed as means ± SD in micromolar.

RESULTS AND DISCUSSION

Compound **1** was obtained as an off-white amorphous powder and deduced to have the molecular formula $C_{31}H_{28}O_{12}$ from the positive ESI-MS ion peaks at m/z 593 $[M + H]^+$ and 615 $[M + Na]^+$ as well as their HR-ESI-MS data. The IR spectrum displayed absorptions of the hydroxyl group at 3377 cm^{-1} and the phenyl moiety at 1618, 1523, and 1454 cm^{-1}. The ^1H NMR (Table 1) spectrum demonstrated eight aromatic protons at δ 6.73 (4H, br s), 6.96 (2H, br s), and 5.96 (2H, s), four protons at δ 4.76 (2H, br s, H-2) and 4.10 (2H, br dd, J = 4.7, 3.7 Hz, H-3) connected to oxygenated carbons, and four aliphatic protons at δ 2.83 (2H, dd, J = 16.6, 4.7 Hz, H-4) and 2.69 (2H, dd, J = 16.6, 3.7 Hz, H-4) that can be attributed to two methylenes. These signals suggested the presence of two epicatechinyl moieties in a symmetric state.[5] Moreover, the ^1H NMR spectrum exhibited a signal of two protons at δ 3.88 (s, H_2-11) that were readily recognized for an additional methylene. The ^{13}C NMR and DEPT (Table 1) spectra showed signals of 31 carbons, including a methylene carbon at δ 16.8 (C-11), among which the carbons at the same positions of two symmetric epicatechinyl moieties were overlapped. With the aid of the HSQC spectrum, all the protons were assigned to their corresponding carbons. In the HMBC spectrum (Figure 2), the correlations from H_2-11 to δ 155.2 (C-7), 106.7 (C-8), and 153.6 (C-9), δ 4.76 (H-2) to C-9 and C-4 (δ 29.0), and δ 2.83 and 2.69 (H_2-4) to C-9 and C-5 (δ 155.8) ascertained the connection of the methylene to C-8 of two epicatechinyl moieties. Consequently, compound **1** was determined to be bis(8-epicatechinyl)methane. Bis(8-catechinyl)methane was previously obtained from several plants such as *Rhopalocnemis phalloides* (Balanophoraceae)[8] and *Baccaurea ramiflora* (Euphorbiaceae)[9] and synthesized by hydrogenation of substituted aromatic aldehyde.[10] The differences between these two compounds were shown by coupling constants $J_{2,3}$ and $J_{4,3}$, which were 7.5 Hz and 8.8 or 5.4 Hz, respectively,[8,10] rather different from those of compound **1**.

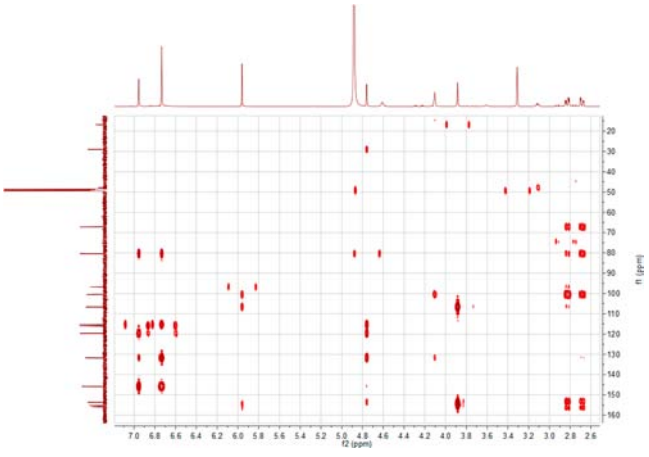

Figure 2. HMBC spectrum of compound **1**.

Compound **2** was deduced to have a molecular weight of 576 from the ESI-MS positive and negative ion peaks at m/z 577 $[M + H]^+$, 599 $[M + Na]^+$, and 575 $[M - H]^-$. The ^1H NMR (Table 2) spectrum exhibited three ABX-type aromatic protons at δ 7.04 (1H, br s, H-2‴), 6.81 (1H, d, J = 8.0 Hz, H-5‴), and 6.86 (1H, br d, J = 8.0 Hz, H-6‴), two *meta*-coupled aromatic protons at δ 5.92 (1H, d, J = 2.0 Hz, H-6) and 5.94 (1H, d, J = 2.0 Hz, H-8), two singlet aromatic protons at δ 6.55 (1H, H-5′) and 6.17 (1H, H-6″), four protons at δ 5.03 (1H, br s, H-2″), 4.45 (1H, br d, J = 4.8 Hz, H-3), 4.30 (1H, br d, J = 3.9 Hz, H-3″), and 3.82 (1H, br s, H-2) connected to oxygenated carbons, and six aliphatic protons from δ 2.65 to 2.94. The ^{13}C NMR (Table 2) spectrum displayed signals of a total of 30 carbons, including a carboxyl carbon at δ 193.8 (C-4′), four oxygenated carbons at δ 80.8 (C-2″), 72.9 (C-2), 66.4 (C-3″), and 65.1 (C-3), and three aliphatic carbons at δ 40.5 (C-2′), 29.5 (C-4″), and 25.0 (C-4). Careful analysis of the HMBC spectrum (Figure 3) such as the correlations from H-2 to C-2′ and C-6′ (δ 164.7), H-3 to C-3′ (δ 95.5), H-5′ to C-1′ (δ 91.8), C-3′, and C-8″ (δ 104.7), and H-6″ to C-8″ led us to elucidate it as dehydrodiepicatechin A. This compound was originally obtained from (−)-epicatechin by biotransformation with crude extracellular enzymes of wood rotting fungi, *Coriolus versicolor* and *Pycnoporus coccineus*,[11] and later from tea epicatechin by oxidation with peroxyl radicals generated by thermolysis of the initiator azo-bisisobutyrylnitrile.[12] This was the first report of it as a natural product.

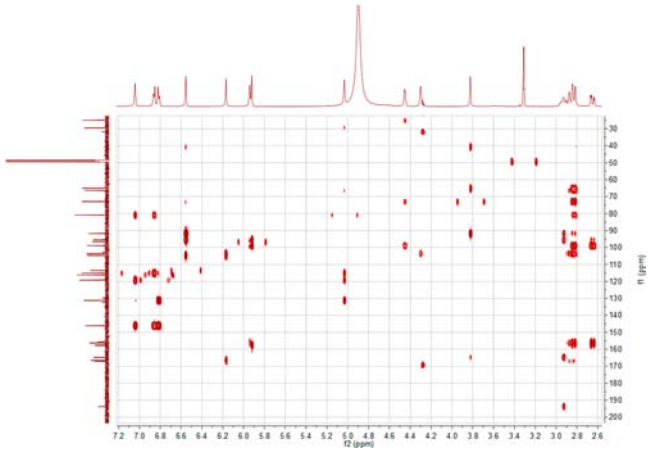

Figure 3. HMBC spectrum of compound **2**.

Compound **6** was deduced to have a molecular weight of 373 from the ESI-MS ion peaks of m/z 374 $[M + H]^+$, 396 $[M + Na]^+$, 372 $[M - H]^-$, and 408 $[M + Cl]^-$, which indicated the presence of an odd-numbered nitrogen atom. The ^1H and ^{13}C NMR spectra showed signals readily assigned for an epicatechinyl moiety as compound **1** (Table 1). In the HMBC spectrum, the correlations from δ 5.42 (1H, dd, J = 9.2, 5.3 Hz, H-1″) to δ 156.3 (C-7), 107.7 (C-8), 155.5 (C-9), and 181.3 (C-4″), δ 2.45 and 2.38 (each 1H, m, H_2-2″) to C-8 and C-4″, and δ 4.84 (1H, br s, H-2) to C-9 were observed, which suggested the presence of a pyrrolidin-2-one moiety[13] and its connection to C-8. Hence, compound **6** was identified as 8-(2-pyrrolidinone-5-yl)-(−)-epicatechin. Jang et al.[14] obtained a 2:1 mixture of two diastereomers of this compound

dx.doi.org/10.1021/jf405750p | J. Agric. Food Chem. 2014, 62, 1073−1078

from the roots of *Actinidia arguta* for the first time, which showed two sets of ^{1}H and ^{13}C NMR data. However, compound **6** exhibited only one set of ^{1}H and ^{13}C NMR data, which were in good agreement with those of the major isomer. It was the first report of this compound as a single stereoisomer.

The other known compounds were identified as proanthocyanidin A1 (**3**),[15] proanthocyanidin A2 (**4**),[15] (−)-epicatechin (**5**),[16] (−)-epicatechin 8-*C*-*β*-D-glucopyranoside (**7**),[17] naringenin 7-*O*-(2,6-di-*O*-*α*-L-rhamnopyranosyl)-*β*-D-glucopyranoside (**8**),[18] and rutin (**9**)[19] by analyses of their ^{1}H and ^{13}C NMR and ESI-MS data in combination with the comparison of their data with the reported values. Among them, compounds **2** and **6**−**8** were reported from this species for the first time.

Compounds **1**, **2**, and **6**−**8** were evaluated for antioxidant activity by FRAP, DPPH radical, and ABTS$^{\bullet+}$ scavenging assays. As shown in Table 3, the FRAP values of compounds **1** and **6** were 10.6 ± 0.3 and 8.3 ± 0.1 mmol of Fe(II)/g, respectively, which were comparable to that of the positive reference, L-ascorbic acid (11.6 ± 0.5), and their IC_{50} values toward DPPH radicals and ABTS$^{\bullet+}$ were lower than those of three other test compounds and L-ascorbic acid. Compounds **2** and **7** exhibited potent DPPH radical and ABTS$^{\bullet+}$ scavenging activity and moderate FRAP values, while compound **8** was very weak in FRAP and DPPH radical scavenging assays. It was noteworthy that we reported the potent antioxidant activity of proanthocyanidin A1 (**3**), proanthocyanidin A2 (**4**), and (−)-epicatechin (**5**) from the seeds of *L. chinensis* by FRAP and DPPH radical scavenging assays in a previous report.[5] In addition, the *in vitro* antioxidant properties of rutin (**9**), including strong DPPH radical scavenging activity and effective inhibition of lipid oxidation, were also reported previously.[20]

Table 3. Antioxidant Activities of Compounds 1, 2, and 6−8[a]

compd	FRAP (mmol/g)	DPPH (SC_{50}, μM)	ABTS (IC_{50}, μM)
1	10.6 ± 0.3	10.0 ± 0.4	9.7 ± 0.1
2	3.1 ± 0.1	16.4 ± 0.9	12.4 ± 0.4
6	8.3 ± 0.1	11.7 ± 0.1	9.1 ± 0.2
7	4.5 ± 0.1	28.0 ± 0.9	27.6 ± 0.4
8	0.5 ± 0.0	>100	20.3 ± 0.6
L-ascorbic acid	11.6 ± 0.5	35.6 ± 0.3	36.8 ± 0.2

[a]Values represent means ± SD.

This study reveals the structures of nine flavonoids; five of them were reported from litchi for the first time. Bioassay results in this study and previous reports revealed that these flavonoids were important antioxidants present in litchi pericarps.

monosaccharides, would greatly increase the biorefinery opportunities for sugar beet pulp. Thus far, little has been reported on the prebiotic potential and fermentation characteristics of the complex mixture of oligosaccharides, which is obtained after enzymatic saccharification of sugar beet pulp.

Therefore, the aim of this work was to study the *in vitro* fermentation characteristics of the oligosaccharides obtained after enzymatic saccharification of sugar beet pulp using fecal inocula from humans and pigs. Moreover, the fate of the different types of oligosaccharides and the changes in human fecal bacterial populations during *in vitro* fermentation were studied. Fructo-oligosaccharides (FOS) were selected as a reference substrate for the *in vitro* fermentation experiments, because these are one of the most frequently described prebiotic oligosaccharides and much is already known about their *in vitro* fermentation behavior.

MATERIALS AND METHODS

Chemicals. All chemicals used in this study were at least of analytical grade.

Substrates. FOS (Frutalose OFP) were obtained from Sensus (Roosendaal, Netherlands), and sugar beet pectic oligosaccharides (SBPOS) were obtained from Cosun Biobased Products (Breda, Netherlands).

Culture Medium. The culture medium was based on the modified standard ileal efflux medium (SIEM) as described before.[15] All medium components were obtained from Tritium Microbiology (Veldhoven, Netherlands). The pH of the medium was adjusted to 6.0 using 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer.

Fecal Inoculum. *Human Fecal Inoculum.* A standardized pool of adult fecal inoculum was prepared as described and validated before.[15,16] The fecal samples used to produce the standardized inoculum were pooled and obtained from 10 healthy European adults, who did not receive antibiotics in the 2 months before donation. The ratio of males to females in the human subject pool was 4:1. Their mean age was 44.7 years, with a standard error of the mean of 3.54 years. Their mean body mass index (BMI) was 23.3 kg/m^2, with a standard error of the mean of 0.85 kg/m^2.

Pig Fecal Inoculum. Three multiparous non-lactating sows (Dutch Landrace, aged 4 years) were used in this study. Their mean body weight was 233.0 kg, with a standard error of the mean of 10.02 kg. The sows did not receive any antibiotics for at least 2 months prior to feces collection. The sows were individually housed in pens at the experimental facilities of Wageningen University. The sows were fed twice daily a commercial pelleted maize- and wheat-based maintenance diet (AgruniekRijnvallei, Lienden, Netherlands). Immediately after defecation, feces were collected in a plastic container prefilled with CO_2. Extra CO_2 was decanted into the container with feces to ensure anaerobic storage conditions. The container with feces was closed and immediately placed in an insulated box containing crushed ice. After pooling, the feces were diluted 6 times (w/v) with sterilized 0.9% (w/v) NaCl solution and, subsequently, homogenized and filtered using a filter bag (type BA6041/STR, Seward, Worthing, U.K.) and a stomacher (model Classic 400, Seward). The filtered fecal solution was subsequently added to the culture medium with a ratio of 5:82 (v/v) to obtain the final inoculum. All liquids were kept at 39 °C under anaerobic conditions. Inoculum was prepared within 60 min after feces collection. All experimental procedures were performed in compliance with the appropriate rules and institutional guidelines and were approved by Wageningen University.

***In Vitro* Fermentations.** Substrates (100 mg) were weighed into 20 mL flasks. Next, 9 mL of prewarmed culture medium and 1 mL of inoculum was added to the flasks. Control samples without added substrate were used to monitor the background fermentation. All handling was performed in an anaerobic cabinet (gas phase: 96% N_2 and 4% H_2) to maintain anaerobic conditions. Flasks were closed with rubber stoppers and aluminum caps and were put in an incubator shaker (Innova 4000, New Brunswick Scientific, Enfield, CT) at 100 rpm and 37 °C (human inoculum) or 39 °C (pig inoculum). After different time points of incubation, the flasks were opened and the liquid was divided over two test tubes. One of these tubes was immediately frozen in liquid nitrogen and stored at −80 °C to preserve the sample for microbiological analysis (only for samples with human inoculum). The other tube was put into a boiling water bath for 5−10 min. This sample was used for analysis of pH, SCFA, lactate, and oligosaccharide degradation. The experiments with human inoculum and pig inoculum were performed on separate days. Both *in vitro* fermentations were run in duplicate.

Analytical Methods. *Constituent Monosaccharide Composition.* The constituent monosaccharide composition of the carbohydrates present in the substrates was analyzed as described previously.[10]

SCFA and Lactate. Acetate, propionate, butyrate, and lactate were measured in triplicate using a high-performance liquid chromatography (HPLC) system with conductivity detection equipped with an Aminex HPX-87H analytical column (7.8 × 300 mm; Bio-Rad Laboratories, Hercules, CA). An anion micromembrane suppressor (AMMS-ICE300, Thermo Scientific, Waltham, MA; 10 mM NH_4OH) was used to reduce the background conductivity. The column temperature was maintained at 45 °C, and the flow rate was 0.6 mL/min. The injection volume was 50 μL. The mobile phase was composed of 1.6 mM heptafluorobutyric acid, and elution was performed isocratically. An electrochemical detector (ED40, Thermo Scientific) was used in conductivity mode and set at a range of 200 μS. The data were processed using Empower software (Waters Corporation, Milford, MA).

Oligosaccharide Characterization. Hydrophilic interaction chromatography with mass spectrometry detection (HILIC−MS) was used to obtain information on the amount and type of oligosaccharides that were present at different time points during the *in vitro* fermentations. Chromatographic separation was performed on an Acquity UPLC BEH Amide column (1.7 μm, 2.1 × 150 mm; Waters Corporation) in combination with an Acquity UPLC BEH Amide VanGuard precolumn (1.7 μm, 2.1 × 5 mm; Waters Corporation). Analysis was performed as described previously,[17] using adapted gradient and MS settings. The mobile phase was composed of (A) H_2O, (B) acetonitrile, and (C) 200 mM ammonium formate with 2% (v/v) formic acid. The eluent profile was as follows: 0−30 min, linear from 15% A, 80% B, and 5% C to 45% A, 50% B, and 5% C; 30−32 min, linear to 75% A, 20% B, and 5% C; 32−37 min, isocratic 75% A, 20% B, and 5% C; 37−39 min, linear to 15% A, 80% B, and 5% C; and 39−45 min, isocratic 15% A, 80% B, and 5% C. A Velos Pro ion trap MS was used (Thermo Scientific). MS detection was performed in negative mode, with the ion source voltage set to −4.5 kV, the capillary voltage set to −5 V, a capillary temperature of 350 °C, a heated electrospray ionization (ESI) source temperature of 225 °C, a sheath gas flow rate of 40 (arbitrary units), an auxiliary gas flow rate of 12 (arbitrary units), and a sweep gas flow rate of 2 (arbitrary units).

Molecular Techniques. DNA from the *in vitro* fermentation samples was isolated using the AGOWA mag mini DNA isolation kit (AGOWA, Berlin, Germany), according to the instructions of the manufacturer. Approximately 100 pg of DNA template was used for polymerase chain reaction (PCR). Generation of the PCR amplicon library was performed by amplification of V5−V7 hypervariable region of the small subunit rDNA gene (16S rDNA). Amplification was performed using the forward primer 785F (5′-GGATTAGATACCCBRGTAGTC-3′) and reverse primer 1175R (5′-ACGTCRTCCCCDCCTTCCTC-3′). The primers were fitted with the 454 Life Sciences Adapter A (forward primer) and B (reverse primer), fused to the 5′ end of the 16S rDNA bacterial primer sequences. The forward primer also included a unique barcode. The amplification mix contained 2 units of Pfu Ultra II Fusion HS DNA polymerase (Stratagene, La Jolla, CA) and 1× PfuUltra II reaction buffer (Stratagene), 200 μM dNTP PurePeak DNA polymerase mix (Pierce Nucleic Acid Technologies, Milwaukee, WI), and 0.2 μM of each primer. After an initial denaturation (94 °C for 2 min), 30 PCR cycles were performed that consisted of denaturation (94 °C for 30 s), annealing (50 °C for 40 s), and extension (72 °C for 80 s). Samples with DNA recovery of equal or less than 10 pg/μL DNA were cycled

Table 1. Constituent Monosaccharide Composition and Total Sugar Levels of Substrates Used for *in Vitro* Fermentations[a]

substrate	glc	fru	ara	gal	rha	xyl	man	fuc	galA	glcA	total
SBPOS	5	0	16	17	12	1	1	1	43	4	90
FOS	10	90	0	0	0	0	0	0	0	0	95

[a]Sugar annotation: glc, glucose; fru, fructose; ara, arabinose; gal, galactose; rha, rhamnose; xyl, xylose; man, mannose; fuc, fucose; galA, galacturonic acid; and glcA, glucuronic acid. Values are expressed as mol % of the total sugar content of substrate samples. The total sugar content is expressed as w/w % of substrate samples.

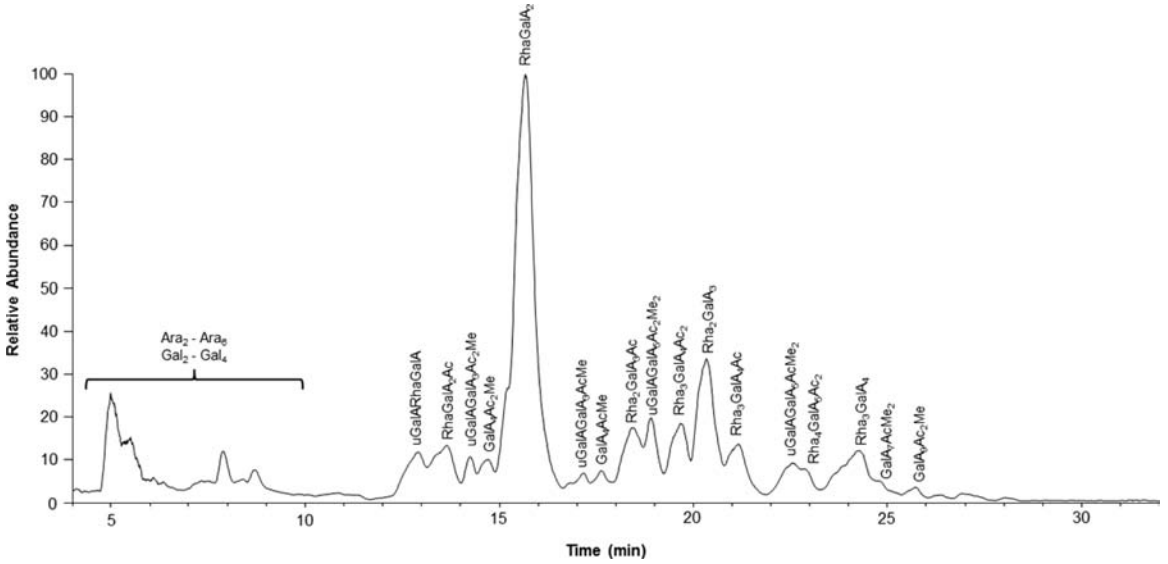

Figure 1. HILIC elution pattern of SBPOS. Peak annotation: Ara, arabinose; Gal, galactose; GalA, galacturonic acid; uGalA, unsaturated galacturonic acid; Rha, rhamnose; Ac, acetyl group; and Me, methyl ester.

35 times using the same protocol. Amplicons were size-checked and quantified by gel electrophoresis and Quant-iT Picogreen dsDNA assay (Invitrogen, Carlsbad, CA) on an Infinite M200 (Tecan, Männedorf, Switzerland). Amplicons of the individual samples were pooled equimolar and purified from agarose gel by means of QIAquick Gel Extraction Kit Protocol (Qiagen, Hilden, Germany). The library was sequenced unidirectionally in the forward direction (A adapter) in one run in the 454 GS-FLX titanium sequencer (Roche, Branford, CT) by Keygene (Wageningen, Netherlands).

Sequence Processing and Analyses. FASTA-formatted sequences and corresponding quality scores were extracted from the .sff data file generated by the GS-FLX titanium sequencer using the GS Amplicon software package (Roche, Branford, CT). GS-FLX titanium sequencing data were processed using modules implemented in the Mothur version 1.20.0 software platform module.[18] Because of the unique barcodes, sequences were initially binned by sample of origin. For further downstream analyses, sequences were trimmed. In brief, barcodes, primer sequences, and low-quality data [containing ambiguous base calls (N) in the sequence, more than eight homopolymers anywhere in the sequence, shorter than 50 nucleotides (nt) after trimming with a window average below 35 or a length of >500 or <200 base pairs (bp)] were removed. The data set was simplified using the "unique.seqs" command to generate a non-redundant (unique) set of sequences. Unique sequences were aligned using the "align.seqs" command and an adaptation of the Bacterial SILVA SEED database as a template (http://www.mothur.org/wiki/Alignment_database). Alignment was performed using the RDP template. To ensure that comparable regions of the 16S rDNA gene were analyzed across all reads, sequences that started before the 2.5 percentile or ended after the 97.5 percentile in the alignment were filtered. Sequences were denoised using the "pre.cluster" command. This command applies a pseudo-single linkage algorithm with the goal of removing sequences that are likely due to pyrosequencing errors.[19] A total of 16 814 potentially chimeric sequences were detected and removed using the "chimera.uchime" command.[20] High-quality aligned sequences were classified using the RDP-II naïve Bayesian Classifier database. Aligned sequences were clustered into operation taxonomic units (OTUs; defined by 97% similarity) and were calculated by the average linkage clustering commando method. Unclassified sequences were also grouped in OTUs and were represented with a random number to distinguish them from the different OTUs found within the same phyla.

RESULTS AND DISCUSSION

Constituent Monosaccharide Composition and Structure of SBPOS and FOS. To characterize the substrates used in this study, their constituent monosaccharide composition was analyzed and oligosaccharide structures were identified. The constituent monosaccharide composition of SBPOS and FOS is given in Table 1. SBPOS were mainly composed of uronic acids (galacturonic and glucuronic acid in a ratio of 10:1), galactose, arabinose, rhamnose, and to a lesser extent, glucose, xylose, mannose, and fucose. Approximately 15% (w/w) of these saccharides were present as mono- or disaccharides (results not shown). The different oligosaccharide structures that were present in the SBPOS mixture were identified using HILIC−MS (Figure 1). It was revealed that SBPOS were composed of several classes of oligosaccharides, which mainly consisted of rhamnogalacturonan oligosaccharides, mostly containing a terminal galacturonic acid residue at both reducing and non-reducing ends (Rha_nGalA_{n+1}), acetylated rhamnogalacturonan oligosaccharides ($Rha_nGalA_{n+1}Ac_x$), partially methyl-esterified and/or acetylated homogalacturonan oligosaccharides ($GalA_nAc_xMe_y$), and partially methyl-esterified and/or acetylated homogalacturonan oligosaccharides containing an unsaturated galacturonic acid residue at the non-reducing end ($uGalAGalA_nAc_xMe_y$). Precise structural details of these classes

[a]Values are means of triplicate measurements, with standard deviation in parentheses. SCFA and lactate results are expressed as mmol/g organic matter.

dx.doi.org/10.1021/jf4049676 | J. Agric. Food Chem. 2014, 62, 1079−1087

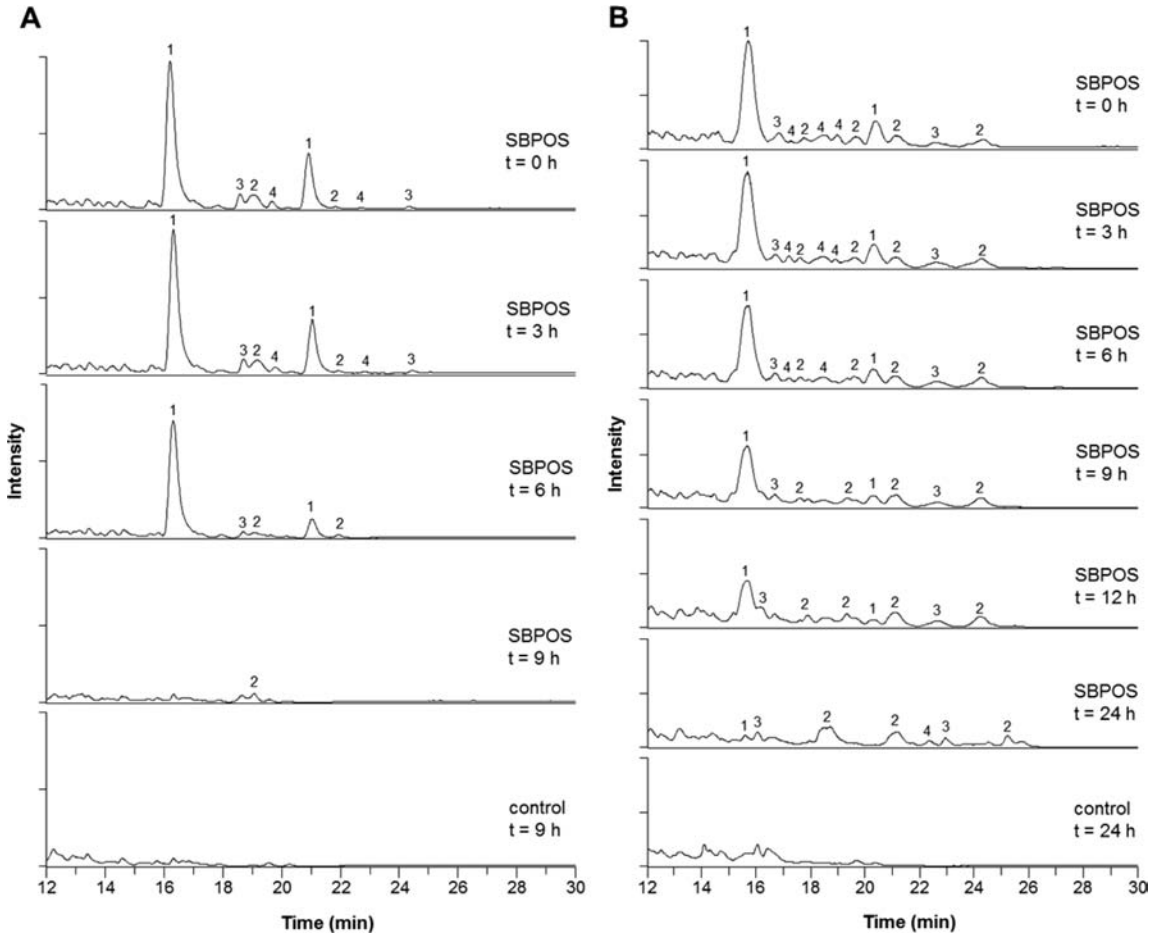

Figure 2. HILIC elution patterns obtained after several time points during *in vitro* fermentation of SBPOS using (A) human or (B) pig fecal inoculum. HILIC elution patterns obtained after 9 h (human fecal inoculum) and 24 h (pig fecal inoculum) of *in vitro* fermentation of the control sample are presented to show which peaks correspond to the medium components. Peak annotation: 1, Rha_nGalA_{n+1}; 2, $Rha_nGalA_{n+1}Ac_x$; 3, $GalA_nAc_xMe_y$; and 4, $uGalAGalA_nAc_xMe_y$.

of pectic oligosaccharides have been described elsewhere.[10] These special classes of oligosaccharides are distinct from the classes of SBPOS that have been used for *in vitro* fermentation studies previously.[4−6] Besides these classes of oligosaccharides, smaller amounts of arabinan and galactan oligosaccharides were present. The average degree of polymerization of the SBPOS was around 5.

FOS were composed of fructose and glucose residues in a ratio of 9:1. Approximately 8% (w/w) of the fructose and glucose in FOS was present as mono- or disaccharides (results not shown). FOS are obtained by partial enzymatic hydrolysis of inulin and are composed of a mixture of linear oligofructose chains, which can be terminated by a glucose residue. The fructose molecules are linked to each other by β-(2,1)-glycosidic bonds. The average degree of polymerization of FOS was 4−5 (according to the specification of the supplier).

Changes in pH. The pH was measured to monitor the course of the *in vitro* fermentations. Table 2 shows the pH after 0, 3, 6, 9, 12, 24, and 48 h of *in vitro* fermentation. For both SBPOS and FOS, the pH initially decreased. For SBPOS, the pH increased again after 12 h (human fecal inoculum) and 6 h (pig fecal inoculum). For FOS, the pH increased again after 9 h (in the case of both human and pig fecal inoculum). The decrease in pH is the result of the initially high carbohydrate availability, which results in saccharolytic fermentation and subsequent formation of SCFA and lactate, thereby lowering the pH. The decrease in pH was largest for FOS. It is likely that this was caused by the formation of lactic acid, which has a lower pK_a (3.73) compared to acetic, propionic, and butyric acid (4.76, 4.87, and 4.82, respectively). The observed increase in pH after a certain time point may be partly due to a shift to a more proteolytic fermentation.[21] The protein degradation products (e.g., ammonia) will increase the pH. For FOS, the decrease in lactate concentration (e.g., after 12−24 h) will also have contributed to the observed pH increase during the end of the *in vitro* fermentations. The gradual increase of the pH of the control samples (medium without added substrate) is most likely caused by early protein degradation because of the lack of available carbohydrates.[21] For SBPOS, the pH at t = 0 was lower compared to FOS and the control, because of the acidic nature of SBPOS.

Formation of SCFA and Lactate. The SCFA and lactate formation during *in vitro* fermentation is often used as an indicator of fiber fermentability. In our study, an increase in acetate, propionate, butyrate, and lactate was measured (Table 2). Other metabolites, such as valerate and succinate, were also analyzed and were present only in minor amounts (results not shown). The total SCFA content at the end of the fermentation was higher for SBPOS than for FOS, both when human and pig fecal inocula were used (Table 2). Substantial amounts of lactate were produced during the first stage of fermentation of FOS, by both human and pig fecal microbiota. The ratios

dx.doi.org/10.1021/jf4049676 | J. Agric. Food Chem. 2014, 62, 1079−1087

acetate/propionate/butyrate/lactate for SBPOS were generally different compared to the ratios for FOS. Acetate and propionate were mainly produced during *in vitro* fermentation of SBPOS, while for FOS, lactate and acetate were the most dominant SCFA. Total SCFA concentrations were higher when using human fecal inoculum compared to pig fecal inoculum, for both SBPOS and FOS, which is in accordance with previous work.[12]

However, more lactate was produced by pig fecal microbiota. This was especially the case for FOS but also for SBPOS. The proportion of butyrate considerably increased after 24−48 h of fermentation using human fecal inoculum and after 12−24 h using pig fecal inoculum. An increased butyrate production and, subsequently, higher butyrate proportion during the second stage of *in vitro* fermentation of pectic oligosaccharides and FOS were reported previously.[22,23]

For pig fecal microbiota, lactate was the major metabolite during the first 12 h of fermentation of FOS. The formation of lactate during *in vitro* fermentation of FOS is in accordance with previous studies.[12,24] Lactate is an intermediary product of carbohydrate fermentation and can be converted into acetate, propionate, and butyrate by common intestinal bacteria.[25] This explains the decrease of lactate and the large increase of butyrate during the second stage of fermentation of FOS (i.e., between 24 and 48 h for human fecal inoculum and between 12 and 24 h for pig fecal inoculum). Part of the butyrate may also have been formed from acetate because butyrate producing bacteria can be net utilizers of acetate.[26]

Oligosaccharide Degradation. The degradation of SBPOS during *in vitro* fermentations was monitored by HILIC−MS and is shown in Figure 2. The SBPOS were used after 9 h of *in vitro* fermentation by human fecal microbiota (Figure 2A). The increase in pH after this time corroborates that the microbiota switched to proteolytic fermentation, because all available carbohydrates were used up. Figure 2B illustrates that the degradation pattern of SBPOS during *in vitro* fermentation using pig fecal inoculum is quite different compared to the human fecal inoculum. Using pig fecal inoculum, most of the SBPOS were still clearly detectable after 12 h and some of the SBPOS were even detectable after 24 h of *in vitro* fermentation. Previously, it was demonstrated that pig fecal microbiota had limited ability to ferment citrus and soy pectin compared to human fecal microbiota.[12] Therefore, it can be expected that SBPOS are also degraded slower by pig fecal microbiota compared to human fecal microbiota.

HILIC−MS analysis also enabled us to plot the degradation rate of the different classes of oligosaccharides that were present after different fermentation times. Figure 3 shows the results for the first 24 h of *in vitro* fermentation. Using human fecal inoculum, the degradation rate of the rhamnogalacturonan oligosaccharides (Rha_nGalA_{n+1} and $Rha_nGalA_{n+1}Ac_x$) and partially methyl-esterified and/or acetylated homogalacturonan oligosaccharides ($GalA_nAc_xMe_y$) tended to be a bit slower during the first 6 h of *in vitro* fermentation compared to the other classes of oligosaccharides (Figure 3A). Nevertheless, most of the oligosaccharides were fermented after 9 h of fermentation. For comparison, the degradation of FOS during the first 6 h of *in vitro* fermentation appeared to be faster than most of the SBPOS classes (Figure 3A).

Figure 3B illustrates that the class $Rha_nGalA_{n+1}Ac_x$ was degraded slower by pig fecal microbiota than the other three SBPOS classes. The degradation rate of all classes of SBPOS by

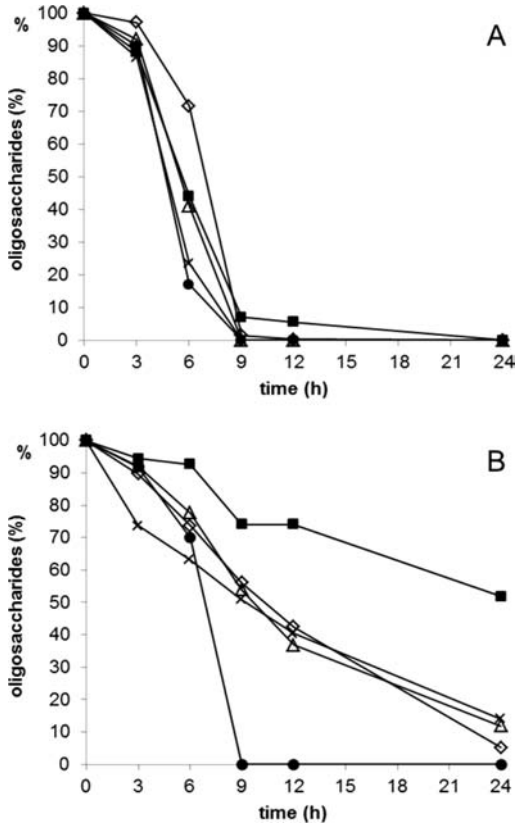

Figure 3. Degradation rate, expressed as a decrease in the percentage of the initial content of different classes of oligosaccharides during 24 h of *in vitro* fermentation by (A) human or (B) pig fecal inoculum. Legend: ◇, Rha_nGalA_{n+1}; ■, $Rha_nGalA_{n+1}Ac_x$; △, $GalA_nAc_xMe_y$; ×, $uGalAGalA_nAc_xMe_y$; and ●, FOS.

pig fecal microbiota was lower compared to human fecal microbiota. $Rha_nGalA_{n+1}Ac_x$ was shown to be the most recalcitrant class of oligosaccharides, because approximately half of the initial amount was still detectable after 24 h. For comparison, FOS were completely used up after 9 h of *in vitro* fermentation. Nevertheless, FOS was fermented slower by pig fecal microbiota compared to human fecal microbiota.

It was demonstrated previously that the degree of methyl esterification of pectic oligosaccharides influences the degradation rate *in vitro*.[11] Our study shows that acetylation of rhamnogalacturonan oligosaccharides also hinders the degradation by pig fecal microbiota but not by human fecal microbiota. The latter differs from results on xylooligosaccharides,[27] where acetylated xylooligosaccharides were degraded more slowly by human fecal microbiota compared to non-substituted xylooligosaccharides.

All classes of SBPOS were used up after 48 h (data not shown), thereby showing that both human and pig fecal microbiota possess the appropriate enzymes to fully degrade the SBPOS. The slower degradation of pectin compared to FOS by pig fecal microbiota is in accordance with previous findings.[12] Most likely, pig fecal microbiota were not very well adapted to the use of pectic oligosaccharides, because the diet of the pigs used in our study was mainly maize- and wheat-based, therefore containing low amounts of pectin.[28] Human fecal microbiota are much more adapted to pectic oligosaccharides because the human diet usually contains pectin-rich fruits or vegetables.[29]

Changes in Microbiota Composition. Figure 4 shows the human fecal microbiota composition on the genus level at

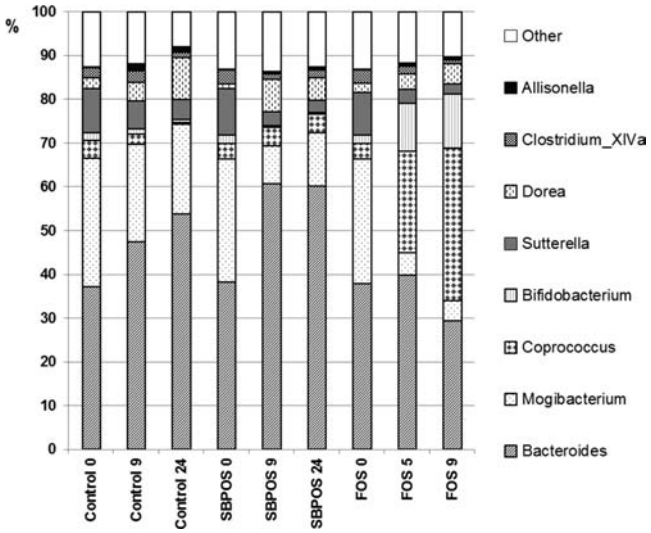

Figure 4. Human fecal microbiota composition (genus level) during *in vitro* fermentations of SBPOS and FOS.

different time points of *in vitro* fermentation of SBPOS compared to FOS and the control. The initial microbiota composition was rather similar for the different fermentations, as expected.

Bacteroides were mainly stimulated during *in vitro* fermentation of SBPOS (Figure 4). No bifidogenic effect was noticed for SBPOS, because no increase in the population of *Bifidobacterium* was observed during *in vitro* fermentation of SBPOS. By contrast, a considerable increase in the population of *Bifidobacterium* was observed after 5 and 9 h of *in vitro* fermentation of FOS. Our findings are in agreement with previous studies,[13,30] showing the limited bifidogenic effect of pectic oligosaccharides compared to FOS. It was also described previously that *Bacteroides* spp. were able to metabolize rhamnogalacturonan oligosaccharides, whereas *Bifidobacterium* strains were not able to metabolize galacturonan oligosaccharides.[31]

To highlight other interesting changes in bacterial populations, the changes in microbial genera composition were calculated after 9 and 24 h of *in vitro* fermentation compared to the control incubation (Table 3). It is shown that *Bifidobacterium* spp. were relatively decreased when SBPOS was added as a substrate. The growth of several other groups of bacteria was increased during *in vitro* fermentation of SBPOS. *Blautia* spp. increased after 9 and 24 h of *in vitro* fermentation (6- and 33-fold, respectively). These bacteria were found to be reduced in patients with colorectal cancer.[32] Some species, such as *Blautia hydrogenotrophica*, have been shown to boost the efficiency of the fermentation of dietary carbohydrates.[33] A 10-fold increase in *Coprococcus* spp. was also noticed after 24 h of *in vitro* fermentation of SBPOS. As a comparison, the increase in *Coprococcus* spp. was even higher for FOS (i.e., 18-fold increase after 9 h of *in vitro* fermentation). *Coprococcus* spp. have been recognized previously to produce high amounts of butyrate *in vitro*.[34] Furthermore, it has been hypothesized that when the growth of this group of bacteria together with *Dorea* spp. is suppressed, it may lead to the flourishing of other groups, such as clostridia, which are linked to inflammation.[35]

Table 3. Fold Changes in Microbiotal Genera after 9 and 24 h of *in Vitro* Fermentation of SBPOS and 9 h of *in Vitro* Fermentation of FOS Using Human Fecal Inoculum[a]

	SBPOS		FOS
genus	t = 9 h	t = 24 h	t = 9 h
Bifidobacterium	0.17	0.30	8.17
Slackia	0.12	0.76	0.51

Erysipelotrichaceae_incertae_sedis	1.66	1.90	5.44
Phascolarctobacterium	4.20	1.13	0.47
Allisonella	0.24	0.41	0.39
Dialister	1.94	4.96	3.64

[a]For each substrate, the ratio between a sampling time point and t = 0 was calculated (e.g., $t9/t0$ and $t24/t0$). The ratio for this value and the corresponding control was then determined to obtain fold changes. A value equal to 1 indicates no change; a value of >1 indicates an increase; and a value of <1 indicates a decrease of the respective microbiotal genera.

In addition, an increase in *Butyricicoccus* spp. was observed. It has been described previously that patients with inflammatory bowel disease had lower numbers of *Butyricicoccus* spp. in their stools than healthy subjects and oral administration of *Butyricicoccus pullicecorum* improved the epithelial barrier function.[36] *Faecalibacterium* spp. also increased, and members of this group are known by their anti-inflammatory properties. Their decrease is associated with ulcerative colitis.[37]

Besides the stimulation of certain groups of bacteria that can be associated with host health, a decrease of several groups of bacteria that may have adverse effects on host health and well-being was also noticeable. *Sutterella* spp. decreased after 9 and 24 h of *in vitro* fermentation of SBPOS. Members of this group have been isolated from individuals suffering from ulcerative colitis and Crohn's disease and are abundant in children with gastrointestinal dysfunction and autism.[38] *Alistipes* spp. and *Allisonella* spp. also decreased after 9 and 24 h of *in vitro* fermentation of SBPOS. Several species of *Alistipes* are mostly correlated with the frequency of abdominal pain in patients with irritable bowel syndrome.[39] Proportions of *Allisonella* spp. are high in patients with irritable bowel syndrome with diarrhea−constipation episodes.[40]

In conclusion, this study provides new information on the *in vitro* fermentation characteristics of SBPOS. It was shown that SBPOS can be completely fermented by human and pig fecal

dx.doi.org/10.1021/jf4049676 | J. Agric. Food Chem. 2014, 62, 1079−1087

microbiota, thereby producing butyrate yet mainly acetate and propionate. The degradation rate of SBPOS by pig fecal microbiota was lower compared to human fecal microbiota. In general, rhamnogalacturonan oligosaccharides were more slowly degraded than homogalacturonan oligosaccharides. Acetylation of rhamnogalacturonan oligosaccharides lowered the degradation rate by pig fecal microbiota but not by human fecal microbiota. A classic prebiotic effect could not be demonstrated for SBPOS, because no increase in bifidobacteria or lactobacilli was observed. However, several other potentially beneficial modifications in the microbiota composition were observed during *in vitro* fermentation of SBPOS using human fecal inoculum. Further *in vivo* work is needed to ultimately confirm these specific prebiotic properties of SBPOS. Because SBPOS are produced as a sidestream of the production of monosaccharides from sugar beet pulp, they are available in large quantities. This makes it feasible to conduct future *in vivo* experiments with SBPOS.

pressures of ~1000 atm, and heating and cooling rates above 10^{10} K/s.[14] The acoustic cavitations could generate a mechanical effect from shear force caused by rapid collapsing of the cavitation bubbles and free radicals from dissociation of the water. These two effects would degrade the huge polysaccharides into small particals.[14−16]

However, most of the research about ultrasonic degradation of sulfated polysaccharides has focused on heterostructural polysaccharides from sea algae, which induced difficulties in investigating the structural changes such as chain linkage and sulfation pattern during the degradation reaction, thus cause difficulty in eliciting the degradation mechanism of the ultrasonic degradation. To our best knowledge, there have been only a few reports on ultrasonic degradation of marine sulfated polysaccharides with well-repeated units, and investigations on the structural and bioactivity changes during the ultrasonication of the polysaccharides are even fewer. In the present study, we applied ultrasound to control degradation of the previously reported fucoidan from the sea cucumber, which was a linear sulfated polysaccharide with well-repeating tetrasaccharide units.[7] Changes in the structures and antioxidant activities of the degraded products were also examined to investigate the degradation mechanism.

MATERIALS AND METHODS

Materials and Chemicals. Standard monosaccharides, dextran, and Trolox were purchased from Sigma Chemical Co. (St. Louis, MO, USA). 1-Phenyl-3-methyl-5-pyrazolone (PMP), 1,1-diphenyl-2-picrylhydrazyl (DPPH), fluorescein (FL) sodium salt, azodiisobutyramidine dihydrochloride (AAPH), sodium chloride, and HPLC-grade potassium bromide were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). A TSK-G4000 PWxl column (30 cm × 7.8 mm, i.d. 13 μm, 500A, optimum separation range of polysaccharides is 1−700 kDa) was acquired from TOSOH Biosep (Tokyo, Japan). A Compact IC 761 (Metrohm, Herisau, Switzerland) was equipped with a separation column (Shodex IC SI-90E, 250 mm × 4.6 mm). Fucoidan was extracted from *I. badionotus* after papain digestion as we previously described.[7]

Ultrasonic Treatment. Ultrasound process was administered with an ultrasonic processor (Scientz-IID, Ningbo Scientz Biotechnology Co., Ningbo, Zhejiang, China) equipped with a 10 mm horn microtip. The ultrasonic processor had a maximum power of 950 W and operated at the frequency of 21−25 kHz. The sample was dissolved in 20 mL of nanopure water in a glass tube (diameter = 3 cm, height = 10 cm), which was immersed into a water bath (DC-1006, Safe Corp., Ningbo, Zhejiang, China) to maintain a stable temperature. The ultrasonic probe was submerged into the solution 1 cm from the top surface of the suspension.

The effects of the following ultrasonic parameters were investigated: duration (0−220 min), temperature (5, 15, 25, 35, and 45 °C), sample concentration (0.1, 1, 5, and 10 mg/mL), and input power level (5, 15, 25, 35, and 45% of the total input power). The general ultrasound conditions of all treatments were as follows: extraction temperature at 5 °C, input power level of 35%, extraction time of 20 min, and pulse mode (2 s on and 2 s off).

The intensity of the ultrasonic power that dissipated from the microtip with a radius of 10 mm was calculated according to the formula $I = P/(\pi r^2)$, where I is the ultrasound intensity, P is the input power, and r is the radius of the ultrasound probe.[17] The input power levels were set at 5, 15, 25, 35, and 45% of the total input power, which corresponded to ultrasonic powers of 61, 182, 303, 424, and 545 W/cm^2, respectively.

Degradation Kinetics Models. The kinetic models of degradation under ultrasound with different temperatures were obtained by graphical analysis. A trial-and-error procedure was applied to find the best fit reaction order. The zero-order, first-order, second-order models are as follows:

$$M_{wt} - M_{w0} = kt \quad (0)$$

$$\mathrm{Ln}(M_{wt}/M_{w0}) = kt \quad (1)$$

$$1/M_{wt} - 1/M_{w0} = kt \quad (2)$$

k is the rate constant (mol/g min) of M_w degradation during sonolysis; t is the sonolysis time (min); M_{wt} and M_{w0} are the weight-average molar mass at time t and at time 0 (Da), respectively. The model with the best correlation coefficient (R^2) was selected to predict the ultrasonic degradation.

Optimization by Response Surface Methodology (RSM). The three-level−two-factor central composite design (CCD) was employed to optimize the ultrasonic degradation conditions. Temperature (X) and ultrasonic intensity (Y) were studied at three levels (−1, 0, +1). The complete experimental plan with respect to each value in actual and coded forms is shown in the Supporting Information (Supplementary Table 1). A set of 13 experiments was carried out. The response variable was fitted into a quadratic model as follows: $Z = a + Bx + cY + dX^2 + eY^2 + fXY$, where Z is the response calculated by the model, X represents temperature (°C), Y represents ultrasonic intensity (W/cm^2), a is the intercept, b and c are linear coefficients, d and e are squared coefficients,and f is the interaction coefficient. The coefficients of the full regression model and their statistical significance were determined and evaluated using Minitab software. Statistical analysis of the model was performed to evaluate the analysis of variance (ANOVA).

Determination of the Average Molecular Weight and Molecular Weight Distribution. The average molecular weight (average M_w) and polydispersity index were determined by GPC according to the method described by Houben[18] with some modifications. The average M_w determination was carried out on a Waters 1525 HPLC system (Waters, Milford, MA, USA) with a TSK-GEL 4000 column (Tosoh Bioscience, Tokyo, Japan). Twenty microliters of the sample solution was injected and eluted with 0.2 M NaCl at 40 °C for 25 min at a flow rate of 0.5 mL/min. The eluent was monitored with a Waters 2414 refractive index detector. The results were analyzed by the GPC software. The standard dextran (Sigma) with different molecular weights was used to obtain the calibration curves each time.

Determination of Monosaccharide Composition. Monosaccharide compositions were determined using the PMP-HPLC method as described previously.[19] In brief, 2 mg of fucoidan was hydrolyzed with 2 M trifluoroacetic acid at 110 °C for 8 h. The hydrolyzed samples were dissolved into 0.3 M NaOH (450 μL) and 0.5 M methanol solution of PMP (450 μL) at 70 °C for 30 min. Lactose was added as an internal standard to each sample before derivatization. The mixture was neutralized with 450 μL of HCl (0.3 M) after cooling to room temperature and extracted with 1 mL of chloroform three times. HPLC analyses were performed on an Agilent ZORBAX Eclipse XDB-C18 column (Agilent, Santa Clara, CA, USA; 5 μm, 4.6 mm × 150 mm) at 25 °C with UV detection at 250 nm. The mobile phase was aqueous 0.05 M KH_2PO_4 (pH 6.9) with 15% (solvent A) and 40% (solvent B) acetonitrile, respectively. A gradient of B (8−19%) within a period of 25 min was applied.

Determination of Sulfate Content. Sulfate content was determined by ion chromatography.[20] Two milligrams of fucoidan fraction was hydrolyzed with 2 M TFA at 110 °C under nitrogen for 8 h. The hydrolysate was dried under vacuum before dissolving in water prior to ion chromatography. The chromatographic system used was a Compact IC 761 (Metrohm) equipped with a separation column (Shodex IC SI-90E, 250 mm × 4.6 mm) and a suppressor system. The eluent for the ion chromatographic determination was 1 mM Na_2CO_3 + 4 mM $NaHCO_3$ with 2.5% acetone at the flow rate of 1.2 mL min^{-1}. The standard curve was obtained according to the peak area and known concentration of the standard sulfate. The sulfate contents of the samples were determined from the conductivity signal after the injection of 20 μL of sample.

FTIR and NMR. Fucoidan samples (0.5 mg) were mixed with KBr (50 mg) and pressed into KBr pellets. FTIR spectra were collected by a Nicolet 5700 (Thermo Fisher Scientific, USA) at the absorbance

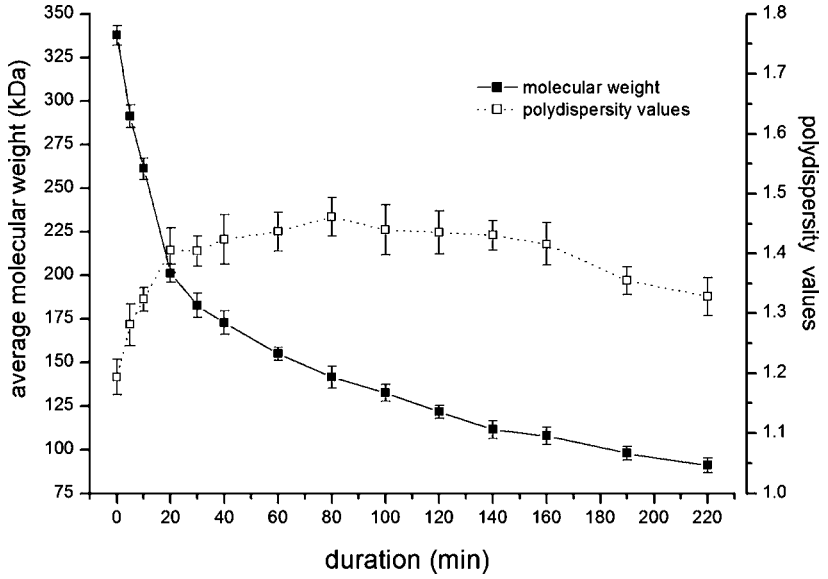

Figure 1. Effects of ultrasonic duration on the average M_w and polydispersity values of fucoidan. Ultrasound treatment conditions: temperature, 5 °C; ultrasonic intensity, 424 W/cm^2; concentration, 1 mg/mL.

mode in the frequency range of 4000−400 cm^{-1}, with a resolution of 4 cm^{-1}.

For NMR analysis, fucoidan fractions (50 mg) were coevaporated with 500 μL of D_2O (99.8%) twice via lyophilization before final dissolution in 500 μL of high-quality D_2O (99.96%) containing 0.1 μL of acetone. Both ^{13}C NMR and ^{1}H NMR spectra were obtained by a Bruker AVIII 600 M (Switzerland) at room temperature. The observed ^{1}H and ^{13}C chemical shifts were corrected by internal acetone standard (2.23 and 33.1 ppm, respectively). The number of scans (ns) in each experiment was dependent on the sample concentration.

DPPH Radical Scavenging Activity Assay. Three milliliters of sample solution (1 mg/mL), 0.6 mL of DPPH solution (0.4 mM prepared in ethanol), and 6 mL of deionized water were mixed in test tube. The absorbance was determined at 515 nm after 30 min at room temperature. All samples were run in triplicate. A standard curve was prepared using different concentrations of Trolox. The DPPH scavenging effect was calculated as

$$\text{scavenging effect } (\%) = [A_0 - (A - A_b)/A_0] \times 100\%$$

where A_0 is the absorbance of DPPH without sample, A is the absorbance of sample and DPPH, and A_b is the absorbance of sample without DPPH.

The inhibition percentage of absorbance was plotted versus the amount of fucoidan sample to obtain a regression line. The Trolox equivalent antioxidant activity (TEAC) was calculated by the ratio between the slopes of the sample and Trolox.

Oxygen Radical Absorbance Capacity (ORAC) Assay. ORAC analyses were carried out in a Fluoroskan Ascent microplate reader (Thermo Electron Corp., Vantaa, Finland) using 96-well plates. The ORAC value was determined as previously described.[21] The reaction was carried out in 75 mM phosphate buffer (pH 7.4). Twenty-five microliters of FL (504 nmol/L) and 25 μL of sample solution placed in the microplate were preincubated for 15 min at 37 °C, and then 150 μL of AAPH solution (17.07 mmol/L) was rapidly added. The fluorescence was recorded every 2 min for 180 min, with an excitation wavelength of 485 nm and an emission filter of 538 nm. The final results were calculated using the differences in areas under the FL decay curves between the blank and the sample. The results were expressed as TEAC values.

Statistical Analysis. Each treatment was repeated three times. All data were expressed as the mean ± SD and statistically evaluated with SPSS/16.00 software. Duncan's multiple-range tests were used to evaluate differences among groups.

RESULTS AND DISCUSSION

Effects of Different Ultrasonic Factors on the Molecular Properties of Fucoidan. *Duration.* The duration-dependent effects of ultrasound on changes in average M_w of the degraded fucoidan fractions are shown in Figure 1. No foam was formatted during the ultrasonic process. The average M_w decreased rapidly in the initial 30 min from 338 to 182 kDa and then gradually tended to a constant value of 91 kDa after 220 min. The polydispersity values, which indicate M_w distribution, increased quickly from 1.193 to 1.461 during the first 80 min of treatments and dropped gradually to 1.328 by the end of 220 min.

It has been reported that fracture of the polysaccharide molecule by ultrasound was mainly caused by shear force produced from the rapid collapse of cavitation bubbles.[22,23] Large polymers with longer chains are preferentially broken by shear force, whereas small molecules with shorter chains are not sensitive to it.[11] Thus, the average M_w of the sample decreased obviously in the first 30 min, and then the rate slowed as most of the fucoidans fractured into small particles. The increase of PDI values in the first 80 min was because both native and fractured fucoidan molecules were present in the solution, which led to the solution changing from a homogeneous to an inhomogeneous state. After further ultrasonic treatment, more native fucoidans were fractured and shifted to the lower molecular weight region, thus leading to a narrow M_w distribution.

Ultrasonic Intensity. Ultrasonic intensity is one of the most important factors affecting the distinct stages of acoustic cavitations, namely, nucleation, bubble growth, and collapse. The effect of ultrasound intensity on the average M_w of degraded fucoidan fractions is shown in Figure 2a. The average M_w decreased from 338 to 166, 142, 130, 124, and 122 kDa under ultrasonic intensities of 61, 182, 303, 424, and 545 W/cm^2, respectively, in 100 min. A significant increase in degradation efficiency was observed with the increase of ultrasonic intensity, indicating the importance of ultrasonic intensity on fucoidan sonolysis ($P < 0.05$).

Table 2. Reaction Rate Constants k and Half-Life Periods ($t_{1/2}$) of Fucoidan under Ultrasonic Treatment

temperature (°C)	k (mol/g min) × 10^{-8}	$t1/2$ (min)
5	5.400	54.83
15	4.299	66.84
25	3.932	75.30
35	3.372	87.80
45	3.104	95.39

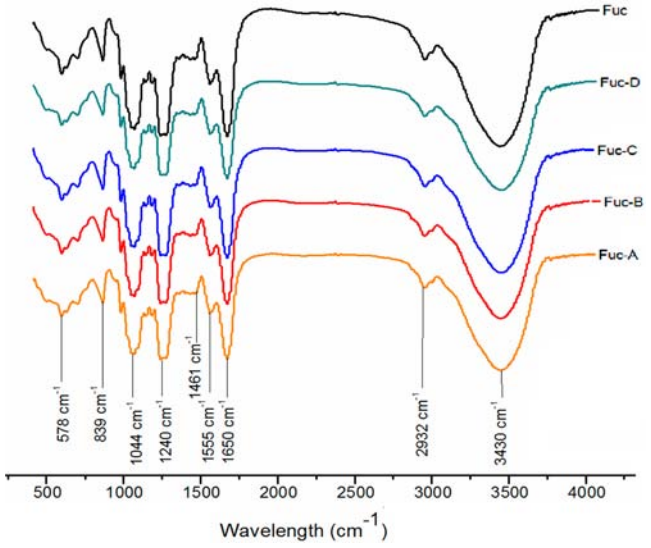

Figure 4. FTIR spectra of native fucoidan and ultrasonic degraded fucoidan fractions. Fuc-A, Fuc-B, Fuc-C, and Fuc-D were assigned to degraded fucoidan fractions prepared by ultrasonication for 30, 60, 120, and 200 min, respectively.

In a certain range, higher ultrasonic intensity could increase the energy of cavitation, lower the threshold of cavitation, and enhance the quantity of the cavitation bubbles.[24] This can explain the sharp decrease of average M_w from 166 to 124 kDa as the ultrasonic intensity increased from 61 to 424 W/cm^2. However, as the ultrasonic intensity continued to rise, more cavitation bubbles were produced around the acoustic source, which dampened the efficiency of energy transmission into the reaction medium and hampered the propagation of the ultrasound wave.[8,25] Thus, no obvious change of average M_w was observed when the ultrasonic intensity increased from 424 to 545 W/cm^2.

dx.doi.org/10.1021/jf404717y | J. Agric. Food Chem. 2014, 62, 1088−1095

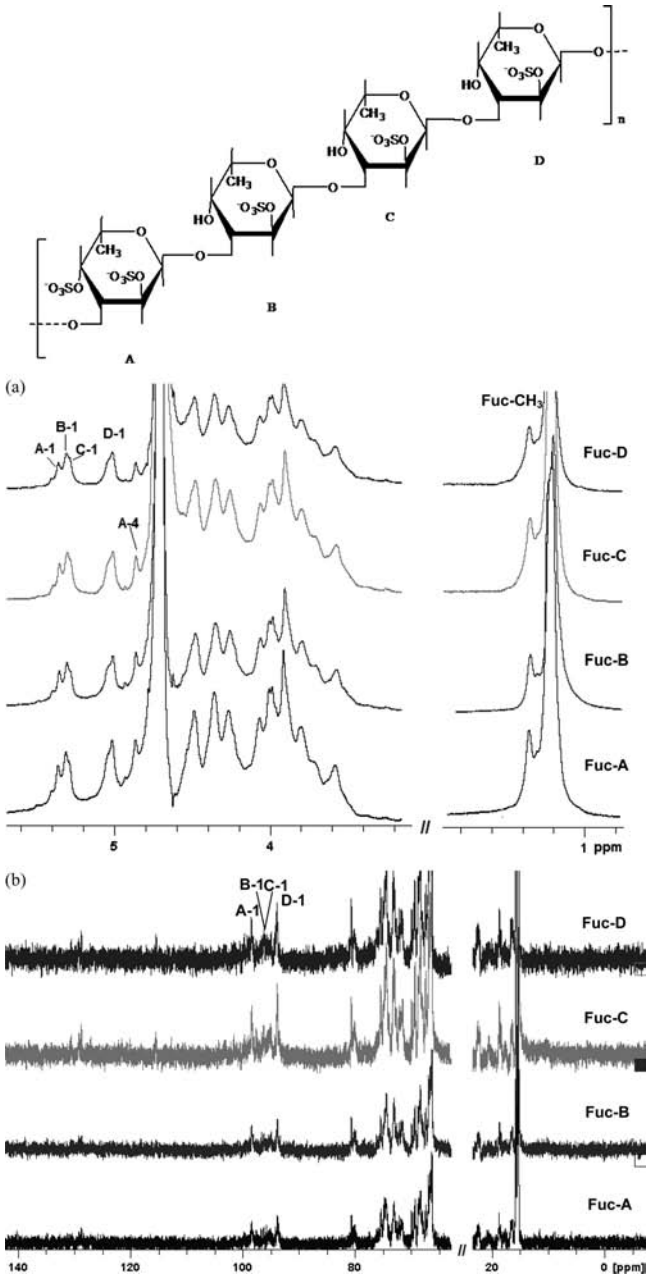

Figure 5. NMR spectra of ultrasonic degraded fucoidan fractions: (a) ^{1}H NMR; (b) ^{13}C NMR. Fuc-A, Fuc-B, Fuc-Cm and Fuc-D were assigned to degraded fucoidan fractions prepared by ultrasonication for 30, 60, 120, and 200 min, respectively.

Temperature. Figure 2b shows the effect of temperature on ultrasonic degradation efficiency. The result indicated higher temperature would lead to a lower degradation efficiency. The average M_w of the sample treated under 5, 15, 25, 35, and 45 °C was decreased from the initial 338 kDa to 130, 144, 155, 167, and 168 kDa after 100 min of treatment, respectively. This trend was due to the increasing reaction temperature allowing cavitation to be achieved with lower acoustic intensity, which was a direct consequence of the rising vapor pressure associated with the heated liquid.[26]

Initial Solution Concentration. The effect of concentration on degradation efficiency was investigated as shown in Figure 2c. The average M_w values of fucoidan after the ultrasonic processes were 131, 138, 151, and 160 kDa as the

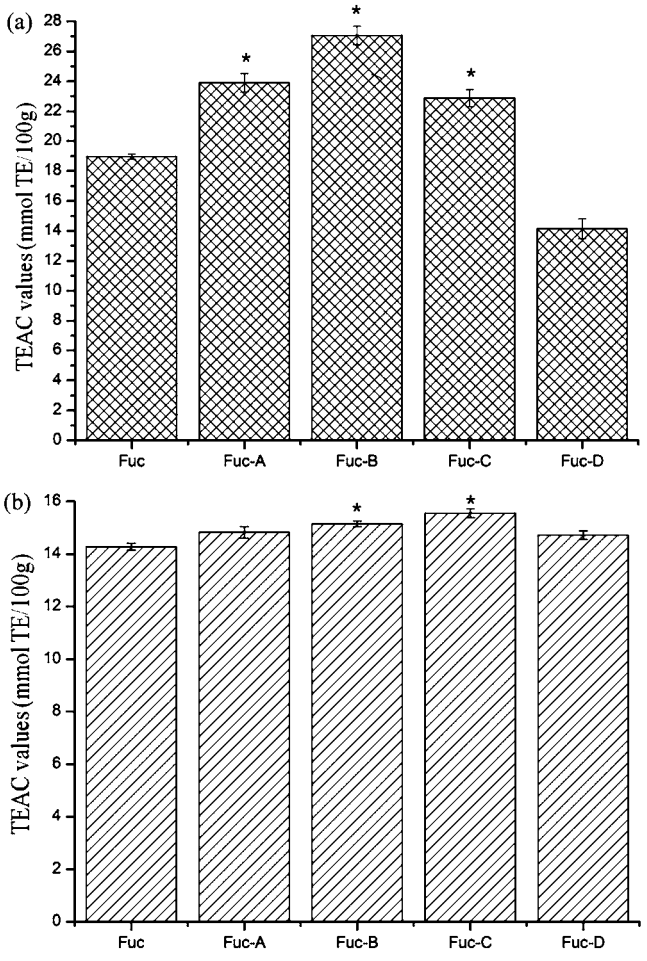

Figure 6. Antioxidant activities of native fucoidan and degraded fucoidian fractions: (a) DPPH radical scavenging activity; (b) oxygen radical absorbance capacity. The results were expressed by TEAC (Trolox equivalent antioxidant activity) values. Fuc-A, Fuc-B, Fuc-C, and Fuc-D were assigned to degraded fucoidan fractions prepared by ultrasonication for 30, 60, 120, and 200 min, respectively. An asterisk (*) indicates significant differences ($p < 0.05$).

concentration rose from 0.1 to 10 mg/mL. This trend could be explained by more diluted concentration leading to less intense entanglement between the polysaccharide chains in solution. Thus, the random coiled structure of the molecule extended more freely and became more vulnerable to the attack of shear force.[27] Moreover, the velocity gradients around the collapsing bubbles are higher in more diluted solutions, which would also benefit the ultrasonic degradation.[28]

Degradation Kinetics of Fucoidan under Ultrasound Treatment. To further predict the degradation efficiency of ultrasonic treatment on fucoidan from the sea cucumber, the correlation coefficients (R^2) among ($M_{wt} - M_{w0}$), ($\ln M_{wt}/M_{w0}$), ($1/M_{wt} - 1/M_{w0}$), and time at different temperatures are summarized in Table 1. The degradation kinetics model of fucoidan under ultrasonic treatments was best fitted to a second-order kinetic equation: $1/M_{wt} - 1/M_{w0} = kt$. Similar results can be found in ultrasound degradation on pectin,[13] dextran,[29] agarose, and carrageenans.[12]

The kinetic curves under different temperatures are presented in Figure 3 by plotting ($1/M_{wt} - 1/M_{w0}$) of each sample versus time of ultrasonication (t). The reaction rate constants (k) and half-life periods ($t_{1/2}$) were calculated

dx.doi.org/10.1021/jf404717y | J. Agric. Food Chem. 2014, 62, 1088−1095

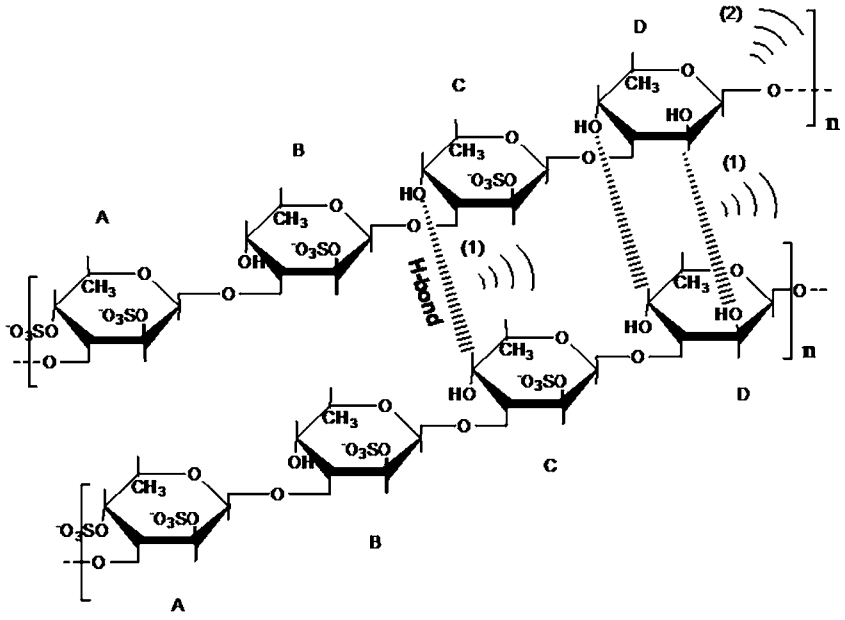

Figure 7. Possible mechanism of ultrasonic action on the fucoidan: (1) mechanical effect broke the hydrogen bonds among the fucoidan molecules; (2) free radicals produced by ultrasonic treatment acted on the nonsulfated fucose in the backbone.

according to the second-order reaction model (Table 2). The k value was much higher at lower temperatures. As the temperature increased from 5 to 45 °C, the k value dropped from 5.4×10^{-8} to 3.104×10^{-8} mol/g min while $t_{1/2}$ increased from 54.83 to 95.39 min. The retarded depolymerization effect was attributed to the loss of cavitation energy, because the energy escaped more easily from the cavitation bubbles at a higher temperature. As a consequence, the degradation efficiency dropped continuously as the temperature increased from 5 to 45 °C.

Optimization by Response Surface Methodology (RSM). On the basis of single-factor analysis, the relationship between response (average M_w) and variables (temperature and ultrasonic intensity) was further optimized by RSM. The results at each design point are shown in Supplementary Table 1 in the Supporting Information. The regression equation in terms of the coded value of the variables was calculated as $Z = 243.12 + 2.954X - 17.785Y + 1.164X^2 - 3.532Y^2 - 5.135XY$, which represents the average M_w of the degradation products (Z) as a function of temperature (X) and ultrasonic intensity (Y). The determination coefficient R^2 of 0.9411 for average M_w of the degradation products suggested that the fitted model could explain 94.11% of the total variation, indicating that the regression model was reliable in predicting the average M_w changes of fucoidan during ultrasonic process by the model.

ANOVA was conducted to assess the significance and adequacy of the model. As shown in Supplementary Table 2, the ANOVA of the quadratic regression model showed the model F value was 22.38, and a low value of "probability >F" ($P < 0.001$) demonstrated that the model was highly significant. XY is a significant model term ($P < 0.05$); the intercept and Y are highly significant model terms ($P < 0.01$). The "lack of fit F value" of 0.335 implied the lack of fit is significant.

On the basis of the regression equation, the optimum temperature and ultrasonic intensity were calculated to be 12 °C and 508 W/cm^2, respectively. The minimum average M_w of fucoidan was predicted to be 207 kDa under the optimized condition. To confirm the prediction, ultrasound degradation was performed under optimum conditions, and the average M_w of the degradation product was tested to be 208 kDa, which was quite close to the predicted value.

Structure Analysis of Degraded Fucoidan Fractions. The structure of the fucoidan from the sea cucumber *I. badionotus* has been identified as a simple linear backbone with well-repeated units of tetrasaccharides (Figure 5). These features facilitated our investigation on the structural changes of the sample during ultrasonication treatments and the possible mechanism of degradation.

Low M_w fucoidan fractions were prepared for further analyses of structure and antioxidant activity. The fractions treated under the optimum ultrasonic conditions for 30, 60, 120, and 200 min were named Fuc-A, Fuc-B, Fuc-C, and Fuc-D, respectively.

Monosaccharide Composition and Sulfate Content. Monosaccharide composition analysis showed that fucose was the only monosaccharide detected in all fucoidan fractions. The sulfate contents of the native fucoidan and the degraded fucoidan fractions (Fuc-A, Fuc-B, Fuc-C, Fuc-D) were 31.22, 32.08, 33.42, 34.11, and 34.74%, respectively. The sulfate content was slightly increased with prolonged ultrasonic duration. This trend indicated that, on the one hand, the polysaccharide chain might have suffered minor destruction; on the other hand, the sulfate group, which was critical to the bioactivity, was not severely damaged throughout the ultrasound process.

FTIR Spectra. The structures of the ultrasonic-treated fucoidan fractions were investigated by FTIR spectra, and the results are shown in Figure 4. The characteristic absorption peaks of the samples are assigned as follows:[30,31] major absorption bands around 3430 cm^{-1} were attributed to O—H stretching; the signal at 2932 cm^{-1} was due to C—H stretching of CH_2 groups; an absorption at 1650 arose from stretching vibration of C═O, C═N; the feature at 1555 cm^{-1} was due to the bending vibration of −NH; an absorption at 1461 cm^{-1} was the stretching vibration of C═O from carboxyl group and the bending vibration of −OH; the signal at 1240 cm^{-1} was caused

by S═O stretching; bands around 1044 cm^{-1} were assigned to C−O stretching vibrations (C—O—H, C—O—C); absorption at 839 cm^{-1} was attributed to COS bending vibration; and the feature at 578 cm^{-1} was assigned to the asymmetric and symmetric O═S═O deformation of sulfates.

The similarity of the IR spectra between degraded and native focuidan indicated the main repeated units of the fucoidan chain were not destroyed by ultrasonication. Moreover, there was no obvious changing in the characteristic peaks at 1240 and 839 cm^{-1} caused by S═O stretching and C—O—S bending vibration,[7] indicating that there was no obvious desulfation during the ultrasonic treatment.

NMR Spectroscopy. The detailed structure, especially the chain linkage and sulfation pattern change, was further investigated by 1D NMR, and the results are shown in Figure 5. The assignment of the proton signals was based on our previous research, which gave in detail assignments of the signals based on mass spectra and 2D NMR.[7] In the ^{1}H NMR spectra (Figure 5a), all four samples showed very similar spectra: anomeric signals at 5.22 ppm (J = 3.92, A-α), 5.26 ppm (J = 3.60, B-α), 5.20 ppm (J = 3.81, C-α), and 5.00 ppm (J = 3.22, D-α) all appeared, and they were attributed to the anomeric proton of fucose residues A, B, C, and D, respectively, in Figure 5. The signals among 3.5−4.5 ppm were attributed to the cross-ring protons; those at 1.23 ppm were attributed to the methyl of the fucose units. No signal was obviously changed during the ultrasonic prosess, indicating that the unique repeated units of tetrasaccharides of the fucoidan remained.

However, there were some minor changes after ultrasonic treatment. The strength of the anomeric signals at 5.00 ppm (unit D, the nonsulfated fucose in the tetrasaccharide repeat) of the ultrasonic-treated samples decreased slightly as the time increased. The proportions of D-1 at 5.00 ppm to the total anomeric proton (A1 to D-1), in Fuc-A, Fuc-B, Fuc-C, and Fuc-D, are 0.315, 0.306, 0.298, and 0.278, respectively. The slight decrease in proton of unit D indicated the nonsulfated fucose might be liable to destruction during ultrasonic treatment, which was a coincidence with the slight increase in the sulfate content. As the mechanical effect of the ultrasonic was usually acted on the hydrogen bond of the polysaccharides molecules, the destruction of unit D may have caused the free radicals produced during the ultrasonic treatment. A similar trend was identified during the acid hydrolysis of this fucodian in our previous research;[7] the acid was also more likely to act on the middle nonsulfated fucose (unit D).

^{13}C NMR (Figure 5b) showed similar spectra for the four fractions. Although limited by the low resolution of the signals in the experimental conditions, we can still observe there were no obvious differences in the nonsulfated fucose anomeric carbon signals. Thus, we further confirmed the main backbone structure was not changed.

Antioxidant Activities Change. The antioxidant activities of the degraded fucoidan fractions were evaluated by DPPH and ORAC assays, and the data are shown in Figure 6. Both of the experiments indicated that the antioxidant activity of the degraded sample increased rapidly during the first period of the ultrasonication and then showed a decreasing trend as the ultrasonication continued. The increase in the antioxidant activity in the first stage may due to the following reasons: First, lower M_w polysaccharides with a mild effect of intramolecular hydrogen bonds would have more free hydroxyl and amino groups.[32] Second, lower M_w polysaccharides have higher contents of reducing sugars at the same mass concentration level.[33]

However, in the second stage, the reduction of the average M_w became slower, and the destruction of the polysaccharide structure was more severe as more free radicals were produced, which resulted in the reduction of the antioxidant activity. Thus, it is important to control the ultrasonic time to control the molecular size as well as to improve its antioxidant activity.

Mechanism of Ultrasonic Degradation of Fucoidan. The ultrasonic process is a mild, effective, and environmentally friendly method to degrade polysaccharides. It is widely acknowledged that the ultrasonic wave could yield the shear force and $H^•$ and $HO^•$ radicals.[15] The current opinion on the mechanism in the ultrasonic degradation of polysaccharides, for example, the sulfated polysaccharide from a red algae, may be explained more by mechanical and less by radical effects.[34] On the basis of the results of the structure analysis and the antioxidant activity, we speculated the possible ultrasonic mechanism acting on the fucoidan may be a combination a mechanical and free radical degradation (Figure 7).

During the initial stage, the average M_w of fucodian decreased sharply and no obvious structure change was observed. Meanwhile, the antioxidant activities of the degraded fractions were significantly improved. Thus, we speculated that the degradation was mainly due to the mechanical effect on dissociated aggregate polymer rather than the chemical reaction. The active groups for the antioxidant activity were not damaged. Therefore, the broken hydrogen bonds among the fucoidan molecules was the main reason causing the average M_w to decrease during this stage. As the ultrasonication continues, the M_w could hardly decrease anymore because the polysaccharide chains have been broken to be a single chain and become harder and harder to fracture. At the same time, the decreasing antioxidant activity is an indication of the destruction of some chemical groups. Thus, it is difficult for the mechanical effect to act on the chain, and the degradation might be due to the free radicals that attacked the nonsulfated fucose in the backbone. However, the specific degradation bonds should be further confirmed by other analysis tools.

Our research was based on a homogeneous fucoidan from the sea cucumber *I. badionotus* with well-defined tetrasaccharide repeating units, which showed excellent anticoagulant, antithrombotic, and antioxidant activities. Applying the ultrasonic process to obtain low molecular fuodian will not only improve its oral absorption and utilization rate but also help to understand the mechanism of ultrasonication on marine polysaccharides and further optimize the processing condition. The low M_w fucoidans prepared deserve further development as a marine antithrombotic drug.

24 kDa. Caseinates are flexible proteins that readily adsorb to lipid surfaces with coverage of 1 mg protein/m^2. β-Lactoglobulin, the major protein component of WPI, has a molecular weight of about 18 kDa. Although β-lactoglobulin and caseinates have similar interfacial energy lowering properties,[14] globulins are more compact and slower to reorganize upon adsorption resulting in a higher amount for surface coverage, 2−3 mg/m^2. SPI is also a globulin but much larger, 200−350 kDa. The surface charge upon adsorption is highly dependent on pH. At acidic and neutral pH encountered in the digestive system, dairy and SPI proteins are highly cationic or anionic, respectively. The release of protein encapsulated lipids may also be assisted by digestive enzymes. *In vitro* digestion by gastric pepsin did not significantly increase release of lipids encapsulated by SPI, WPI, or β-lactoferrin, but intestinal pancreatin significantly accelerated release of emulsion stabilized by β-lactoglobulin and WPI.[15] Differences in size, conformation, hydrophobic amino acid content, and ionic amino content contribute to different emulsion size, protein layer thickness, stability to aggregation, and stabilization of the lipid core to oxidation. Proteins (like SC, WPI, and SPI) are thought to be able to better protect BC and lipids against oxidation and degradation in encapsulated systems[3,16] compared to small molecule surfactants (like Tween 20), because of the free radical scavenging and metal chelating properties of cysteine, tyrosine, tryptophan, phenylalanine, and histidine.[17]

Although protein emulsifiers are GRAS, there are concerns regarding the safety and potential cytotoxicity of nanosystems because they may be inhaled or absorbed via pinocytosis by the intestinal epithelial cells.[18] Hu et al. investigated the cytotoxicity of chitosan−caseinophosphopeptide nanocomplexes by MTT assay and found no significant toxicity.[19] He et al. showed that the viability of cells exposed to food protein stabilized nanoemulsions was greater than 85% at 3 mg/mL concentration, while other traditional emulsifiers (like Tween 80) caused a significant decrease in cell viability.[15] To date, there have been no reports about the cellular cytotoxicity and *in vitro* uptake of BC loaded nanoparticles with Caco-2 cells.

In the present study, SC, WPI, and SPI were used as emulsifiers to develop food-grade, relatively stable nano- and microparticles for oral delivery of BC. The effects of emulsifiers and the concentrations on physicochemical stability of BC loaded nanoparticles during storage were evaluated. We hypothesize that although the residual BC of the nanoparticles prepared by the solvent evaporation is likely to be a solid, uptake by Caco-2 cells will still occur because of the high surface area. The cytotoxicity and cellular uptake of prepared BC loaded nanoparticles in an *in vitro* digestive system were also investigated.

MATERIALS AND METHODS

Materials. BC (≥97.0%, UV) was purchased from Sigma-Aldrich (St. Louis, MO). Sodium caseinate (SC) powder (protein content >95% and 1.0% fat on dry basis by manufacturer) was obtained from Fonterra Co-operative Group (Auckland, New Zealand). Whey protein isolate (WPI; Hilmar 9410, 93.0% protein, 0.2% lactose, 1.0% fat, and 2.0% ash, on a dry basis, and 4.5% water) was obtained from Hilmar Food International, Inc., Livingston, CA). SPI was extracted in our laboratory from dehulled and defatted soybean meal by the alkali-solution and acid-isolation method (protein content >93% and 0.96% fat content on dry basis by measurement).[20] Dulbecco's modified Eagle's medium (DMEM) (containing 4.5 g/L D-glucose and GlutaMAX), penicillin and streptomycin (100×), fetal bovine serum (FBS), TrypLE Select, Hanks' balanced salt solution (HBSS), and phosphate buffer solution (PBS) (10×) were purchased from GIBCO (Grand Island, NY). The human colon carcinoma cell lines (Caco-2 cells, ATCC, Manassas, VA) were grown in DMEM. Cells after 25−40 passages were used in the uptake study. All other chemicals and reagents used were HPLC-grade and obtained from Sigma-Aldrich (St. Louis, MO).

Methods. *BC Loaded Nanoparticle Preparation.* SC, WPI, and SPI were dispersed (0.10−1.50%, w/w) separately in 5 mM phosphate buffer pH 7.0 containing 0.02 wt % sodium azide antimicrobial agent. The dispersions were stirred for 2 h and refrigerated overnight to maximize dissolution. Then, 0.1% β-carotene (BC) (w/w) solutions were prepared in ethyl acetate. BC loaded nanoparticles were prepared according to the method described by Tan and Nakajima[10] with minor changes. Water, 100 mL, was saturated with 8.3 g of ethyl acetate[21] prior to formulating the protein solution in order to prevent precipitation of BC during homogenization. The BC in ethyl acetate solution was combined with the ethyl acetate saturated protein solution at a ratio of 1:9. The mixtures were homogenized for 10 min at 8000 rpm using an Ultra-Turrax homogenizer (T25, Ika-Werke, Staufen, Germany) to form a coarse emulsion before additional homogenization using a two-stage valve homogenizer (APV-1000 high-pressure homogenizer, Wilmington, MA) for one cycle at 70 MPa. After the homogenization, ethyl acetate was removed from the emulsions on a rotary evaporator at 40 °C. The residual ethyl acetate was determined by headspace gas chromatography and found to be less than 0.001% (data not shown), less than that reported by other investigators.[22] Samples of 5 mL of each nanoparticles were stored in 10 mL amber glass vials flushed with nitrogen at 4 and 25 °C for analysis of BC retention during 30 d storage.

Measurement of Surface Tension and CMC. Surface tension was measured using the pendant plate method with the DataPhysics DCAT21 dynamic contact angle meter and tensiometer (DataPhysics Instruments, Germany) according to the method described by Mao et al.[16] The critical micelle concentration (CMC) of SC in this study was determined by using DataPhysics DCAT21 similar to the method previously described.[23] Briefly, several concentrations of protein nanoparticles were prepared by dilution of the protein stock solution (20 mg mL^{-1}) with sterile ultrapure water. The CMC is the point at which the surface tension no longer increases with increasing protein concentration. Temperature was kept constant at 25.0 ± 0.2 °C with a circulating water bath system.

Particle Diameter and ζ-Potential Analysis. The characteristics of BC loaded nanoparticle solutions were determined by measuring the mean particle diameter, diameter distribution, and ζ-potential of nanoparticles by dynamic light scattering technique using a Malvern Zetasizer (Nano-ZS; Malvern Instruments, Worcestershire, U.K.). Refractive indices of 1.47 for BC and 1.33 for phosphate buffers were used. To reduce multiple scattering effects, the nanoparticles dispersions were diluted 100 times with 5 mM phosphate buffer pH 7.0 prior to the measurements that were performed in triplicate.

Particle diameter measurements to determine the effect of storage on BC loaded nanoparticle solutions stabilized by the three proteins were conducted at 0, 16, and 30 d at 4 and 25 °C.

Color Evaluation. The color of nanoparticles of BC and its isomers depends on their concentration, stability, and particle diameter. The color parameters (L^*, a^*, b^*) were determined using a tristimulus colorimeter Ultra Scan PRO (Hunterlab, Japan). L^* values are a measure of lightness, a^* indicates degree of greenness (for negative a^* values) and degree of redness (for positive a^* values), and b^* also ranges from negative to positive values indicating degree of blueness to yellowness, respectively. The color of the nanoparticle samples all prepared with 1.0% (w/w) proteins was determined by measuring the reflectance from the surface of a transparent flat-faced quartz cuvette. All measurements were repeated three times. Color changes (color differences) were calculated using the following formula:

$$\Delta E^* = [(L^* - L_0)^2 + (a^* - a_0)^2 + (b^* - b_0)^2]^{1/2} \quad (2)$$

Here, subscript 0 indicates color at start of storage period.

dx.doi.org/10.1021/jf404073c | J. Agric. Food Chem. 2014, 62, 1096−1104

Transmission Electron Microscopy (TEM) Analysis. TEM was used to observe differences in internal structure of the nanoparticles and to confirm diameter by dynamic light scattering. Samples were prepared by the conventional negative-staining method. Nanoparticles were placed on copper grids and negatively stained with 2% (w/v) phosphotungstic acid for several minutes at room temperature. Grids bearing nanoparticles were analyzed with a Hitachi H-700 transmission electron microscope (Hitachi, Tokyo, Japan).

Cytotoxicity of BC Loaded Nanoparticles on Caco-2 Cells. Cell viability, a commonly used indicator of *in vitro* cytotoxicity, was evaluated by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. The colorimetric MTT assay measures the activity of cellular enzymes that reduce MTT to its insoluble purple formazan form.[24] Caco-2 cells were incubated in DMEM containing 10% FBS, 1× nonessential amino acid (NAA), and 1× penicillin and streptomycin. Caco-2 cells in DMEM were seeded at a density of 1.2×10^5 cells/well onto 96-well plates and incubated (Sanyo, Osaka, Japan) at 37 °C in 90% humidity and 5% CO_2. After 48 h incubation, the media was discharged, and BC loaded nanoparticles diluted with DMEM were added to the wells. After 24 h incubation at 37 °C the nanoparticles containing media were replaced with 100 μL of DMEM containing MTT (10 μL, 5 mg/mL in 1× PBS, pH 7.2) and incubated for 2 h at 37 °C. Finally, the supernatant was removed and 100 μL of dimethyl sulfoxide (DMSO) added. The 96-well plates were analyzed with a Multilabel microplate counter (Victor,[3] PerkinElmer, Waltham, MA) at 570 nm. Cell viability was calculated by the percentage of absorbance relative to control (treated with DMEM only).

Cellular Uptake of BC Loaded Nanoparticles. Caco-2 cells were incubated in DMEM containing 10% FBS, 1× nonessential amino acid (NAA), and 1× penicillin and streptomycin at 37 °C in a 90% humidity and 5% CO_2 incubator (Sanyo, Osaka, Japan) onto 12-well plates.[25] Caco-2 cells were seeded at a density of 1.2×10^5 cells/well. The media was changed every two days. After five days, the cell monolayers were observed by optical microscopy (Leica, IL) to ensure that the cells reached about 90% confluence. Caco-2 cell monolayers were washed with DMEM three times. Both protein encapsulated BC loaded nanoparticles and BC in THF/DMSO (1:1, v/v) solution (as control) were diluted in DMEM to a final BC concentration of 5 μg/mL. A 1 mL portion of the BC encapsulated nanoparticle and control in THF/DMSO were added to separate wells containing washed Caco-2 cells. The final concentration of THF was less than 0.1%. Following 24 h incubation at 37 °C in a CO_2 incubator, the supernatants were removed, and the cell monolayers were washed three times with precooled PBS solution to stop uptake and wash the surface of cell monolayers. After that, 0.5 mL of 10% ethanolic PBS solution was added to dissociate cell monolayers. Cell suspensions were obtained with cell scrapers. A 0.4 mL portion of cell suspension was extracted with solvent and analyzed for BC content by HPLC (procedure given below), and the remaining 0.1 mL was used for protein content determination.

Protein Content Analysis. Caco-2 cell protein content was determined using the bicinchoninic acid (BCA) assay at 560 nm with bovine serum albumin as the standard.[26]

Extraction and Quantification of BC from Nanoparticles and Caco-2 Cells. The BC in nanoparticles was extracted with 3 mL of ethanol/*n*-hexane (1:2, v/v) three times. The hexane fractions were combined and brought up to 10 mL for HPLC analysis. The effect of storage on BC loaded nanoparticle dispersion stabilized by the three proteins was conducted at 0, 2, 9, 16, 23, and 30 days at both temperature conditions.

A 25 μL portion of 5 μg/mL trans-β-Apo-8′-carotenal in ethanol was added to 0.4 mL Caco-2 cell suspension as an internal standard. The cell suspensions (0.4 mL) were extracted three times with 3 mL of ethanol/*n*-hexane (1:2, v/v). Organic fractions were removed and combined with transfer pipets, and the extract was dried under a stream of nitrogen gas at 40 °C. The BC extract was dissolved in 0.1 mL of methanol/dichloromethane (1:1, v/v) containing 0.1% BHT for HPLC analysis. The recovery of trans-β-Apo-8′-carotenal from Caco-2 cells was greater than 94%.

HPLC quantification of BC was performed using an Agilent 1100 HPLC system with DAD UV−vis absorption detector (Agilent, Santa Clara, CA), according to the published method.[27] BC quantitation range (0.1 μg/mL to 100 ug/mL) was established for HPLC analysis of BC in nanoparticles and Caco-2 cells. A polymeric carotene C_{30} reverse-phase analytical column (250 mm × 4.6 mm i.d., 5 μm, YMC, Inc., Wilmington, NC) was used to separate BC with a flow rate of 1 mL/min at room temperature. The guard column was a reverse-phase C_{18} column (50 mm × 3.0 mm i.d., 5 μm, YMC, Inc.). The injection volume was 20 μL, and the detection wavelength was 450 nm. The chromatography conditions were as follows: solvent A, methanol/acetonitrile/H_2O (84:14:2, v/v/v); solvent B, dichloromethane. The solvent gradient program was 80% A/20% B at 0 min and was changed linearly to 45% A/55% B in 15 min, and maintained for 5 min, and followed by a linear return to 80% A/20% B at 25 min.

Statistics. All measurements were performed at least three times and were reported as mean ± standard deviation. The data were analyzed by the analysis of variance (ANOVA) using the SPSS 17.0 package (IBM, New York). Duncan's multiple range test was used to determine the significant differences of the mean values ($P < 0.05$).

RESULTS AND DISCUSSION

Particle Diameter. The particle diameter distributions of solid BC nanoparticles encapsulated by SC, WPI, and SPI at the concentrations resulting in the smallest mean particle diameter are shown in Figure 1, and the mean diameter and

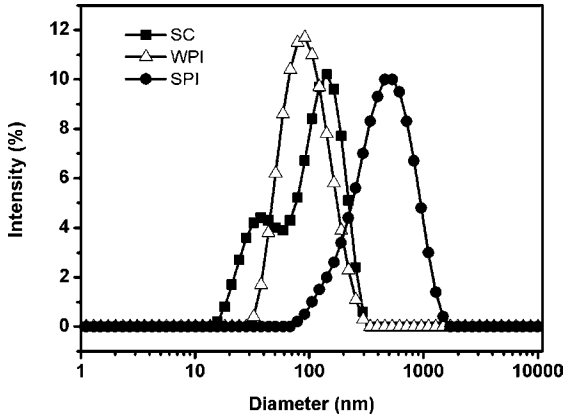

Figure 1. Particle diameter distributions of SC (1.0%, w/w), WPI (1.0%, w/w), and SPI (1.0%, w/w) encapsulated BC loaded nanoparticles.

polydispersity index determined by dynamic light scattering (DLS) are shown in Table 1. The loading capacity of BC in nanoparticles was 1.07%, 1.05%, and 1.06% for SC, WPI, and SPI, respectively. For all three different protein solid lipid nanoparticles, the efficiencies of encapsulation of BC are 99.1%, 98.8%, and 98.7%, respectively, for SC, WPI, and SPI at 1.0% (w/w), respectively, indicating BC was fully encapsulated by three proteins. Although evaporation of the solvent resulted in solid lipid nanoparticles, DSC and X-ray diffraction did not show crystalline cores (results not shown). The SC, WPI, and SPI used contained 1% residual lipids (Materials and Methods section). The ethyl acetate used to solubilize BC and saturate the protein solution most likely also extracted the residual lipids from the protein emulsifying agents. We speculate that the extracted lipids and BC formed a mixture that was not crystalline.

Lipid soluble nutrients including triglycerides and BC are reduced to nanosized mixed micelles of phospholipids and bile acids *in vivo*[28] suggesting that small diameter may be necessary

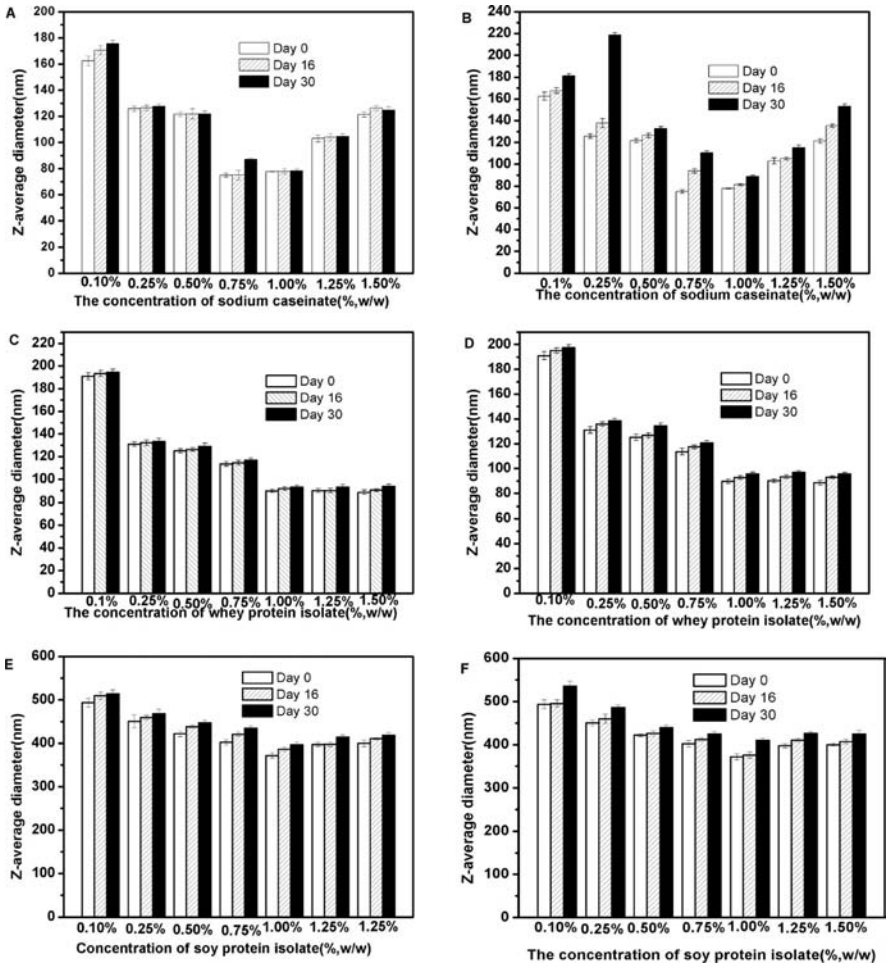

Figure 2. Change of Z-average diameters of three protein encapsulated BC loaded nanoparticles over time (30 days) under storage at 4 °C (A, C, E) and 25 °C (B, D, F). A and B refer to SC, C and D refer to WPI, and E and F refer to SPI. Data are represented as the mean ± STD ($n = 3$).

or simply facilitates uptake. Increasing the emulsifier concentration of SC, WPI, and SPI from 0.10% to 1.00% generally resulted in a significant ($P < 0.05$) decrease in particle diameter (Table 1). The Z-average particle diameter of 0.1% (w/w) SC stabilized nanoparticles was 162.4 nm (Table 1), and some unemulsified BC-lipid solids could be observed after evaporation, illustrating that BC was not fully emulsified. When SC was increased to 0.25% (w/w), the mean diameter decreased drastically ($P < 0.05$) to 125.8 nm. However, the particle distribution was now bimodal with peaks at about 100 and 30 nm. Increasing concentrations of SC increased the relative amounts of the 30 nm peak at the expense of the 100 nm. This suggests that the amount of SC limits the formation of the smaller particles due to their higher surface area. At 0.75% (w/w) SC, the particle diameter reached its minimum (75.0 nm). The critical micelle concentration (CMC) of SC in this study was determined to be 0.688%. When the concentration of SC exceeded the CMC, SC self-associated to form micelles leading to a slight ($P > 0.05$) increase in diameter of BC loaded nanoparticles to 77.8 nm at 1.0% (w/w). Continuing to increase the SC concentration to 1.5% (w/w) resulted in a significant increase of particle diameter to 121.3 nm ($P < 0.05$),

[a]Storage condition: no light, full of nitrogen.

indicating that some SC aggregated and associated into submicelles or aggregates as reported during high pressure homogenization.[29] Dickinson has also suggested that at the molecular level pressure-induced disintegration of casein micelles arises from the disruption of internal hydrophobic interactions and dissociation of colloidal calcium phosphate resulting in interparticle bridges leading to aggregation and association.[30]

The mean particle diameter of WPI nanoparticles gradually decreased from 190.9 to 89.7 nm when the concentration of WPI increased from 0.10% to 1.0% (w/w). The particle diameter of the nanoparticles did not change with increasing WPI concentration from 1.0% to 1.5% (w/w). These results suggest that the surplus WPI in solution did not form multiple adsorption layers or aggregate at the surface of droplets due to net negative charges on the free protein and adsorbed proteins.

SPI is composed of the following two major proteins: 7S and 11S with molecular weights of approximately 200 000 and 350 000 Da, respectively. When SPI was used as an emulsifier, the particle diameter of the nanoparticles was approximately two times larger than when using SC or WPI. This could be attributed to the poor emulsifying ability of SPI, and fewer hydrophobic amino acids on the surface to bind to the lipid core in comparison with milk proteins. Because SPI does not efficiently stabilize the newly formed droplets, coalescence occurs and results in larger particle diameter.

The PDI value is a measure of the variability in the distribution of particle diameter. All samples had a relatively narrow distribution with a PDI value less than 0.471. As protein concentration increased, the SC and WPI stabilized nanoparticles exhibited an increased PDI, possibly due to the formation of an increasing population of smaller particles. The PDI of the SPI encapsulated nanoparticles did not change with increasing protein concentration, and the particle size did not decrease as much as the milk proteins.

Particle Diameter of BC Loaded Nanoparticles During Storage. The diameter stability of nanoparticles is important for their utilization in foods because texture and appearance depend on structural stability. The particle diameters increased less than 10% at 4 °C, and in general, there was a greater increase in particle diameter at 25 °C (10−76%) during the 30 day storage period (Figure 2). The stability to storage is probably due to the repulsive forces due to the negative surface charges at pH 7 (ζ-potential Table 3). Yang et al.[5] also noted that the diameter increments of nanoparticles were greater at higher temperatures and attributed the temperature effect to more rapid movement at higher temperature that increased gravitational flocculation. Although the initial diameters of the particles encapsulated by SC were smaller at the start of storage, the diameter increase was greater than those

emulsifiers	SC	WPI	SPI
ζ-potential (mV)	−35.7 ± 0.4b	−29.9 ± 0.5a	−37.8 ± 0.4c

[a]Values are the mean ± STD of triplicates. Values in the same column with different letters (a−c) are significantly different ($p \leq 0.05$).

encapsulated by the globuler proteins WPI and SPI at all concentrations after 30 days. The larger WPI and SPI particles are expected to increase in diameter with storage due to their more rapid rise to the surface and subsequent aggregation or flocculation. While flocculation due to gravitational separation probably occurs, it is slow compared to other mechanisms. In the case of SC emulsions, increasing protein concentration allows for intermolecular bridging of adsorbed proteins by proteins not adsorbed to the lipid surface. In conclusion, storage temperature may be an important factor to determine nanoparticles' physical stability. There were no obvious BC lipid solids or sediments in the stored BC nanoemulsion samples indicating that they were fairly stable.

Effect of Emulsifier Type and Concentrations on BC Chemical Stability. Samples of BC dissolved in ethyl acetate were used as the control. Compared to the control samples, BC in nanoparticles showed significantly improved chemical stability and higher retentions at both temperatures (4 and 25 °C) (Figure 3), indicating nanoparticles were a good delivery system in enhancing stability of encapsulated lipophilic molecules. The order of chemical stability of BC loaded nanoparticles was the following: SC > WPI > SPI (Table 2). The chemical stability of corn oil, containing 70% polyunsaturated linoleic acid, emulsions was in the following order: SC > WPI > SPI.[13] The decrease in BC concentration was fit to a zero-order kinetic reaction model (Figure 3) as suggested by Cornacchia and Roos.[31] The rate of loss was greater at 25 °C than that at 4 °C (Table 2). The regression coefficients (R^2) are from 0.896 to 0.998 and the intercepts are from 0.919 to 1.00 (Supporting Information, Table 1S).

The oxidative stability of the BC core is affected by two predominant properties of the encapsulating protein: the binding of metal ions and the thickness of the encapsulating layer. Binding of transition metal ions by cysteine, tyrosine, tryptophan, phenylalanine, and histidine from the aqueous phase can reduce free radical oxidation; however, if the binding site is at the interfacial layer, proximity of transition metals may increase oxidation. The phosphoserine residues in casein increased stability by binding pro-oxidative iron and copper ions.[32] WPI also has about 8 mol binding sites for iron per mol of protein.[33] Hwang et al.[34] reported that there was a positive

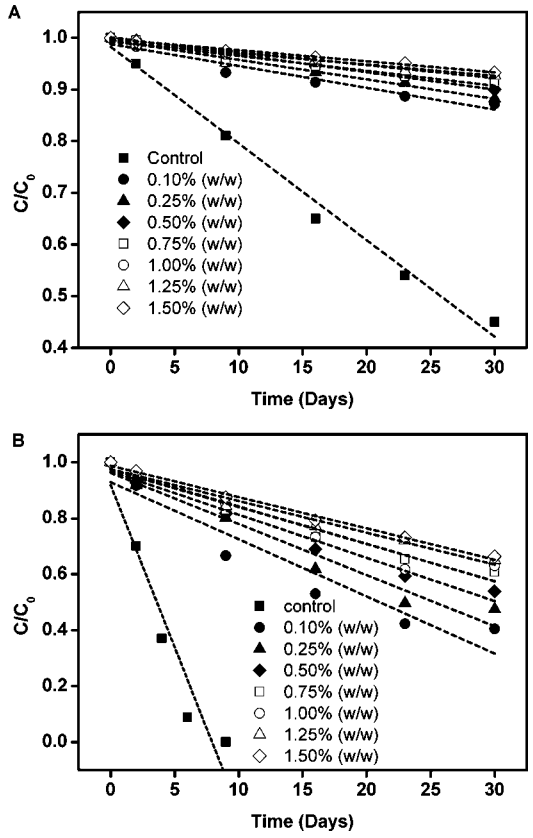

Figure 3. Kinetics of degradation of pure BC in ethyl acetate (as control) and BC loaded nanoparticles prepared with different concentrations of SC under 30 days storage at 4 °C (A) and 25 °C (B).

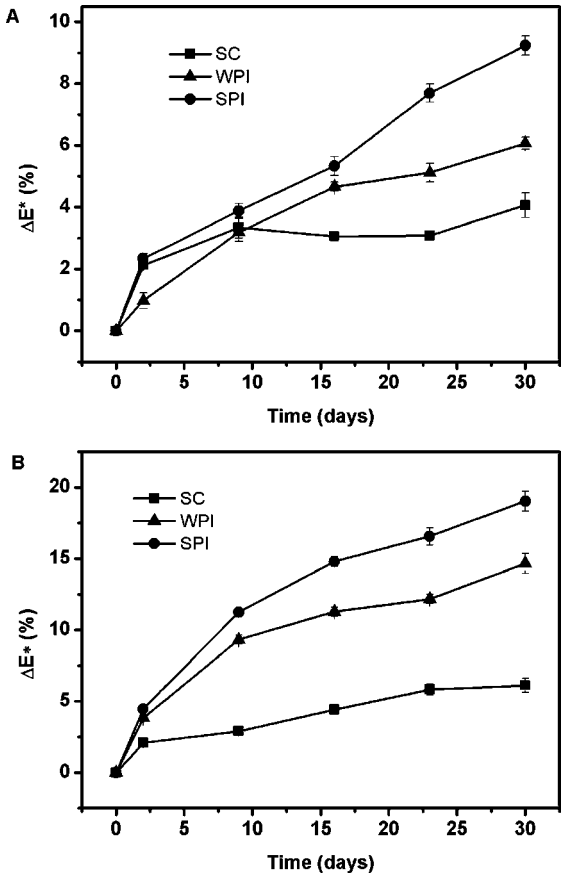

Figure 4. Influence of emulsifiers on total color evolutions (ΔE^*) during 30 days of storage of BC loaded nanoparticles under 4 °C (A) and 25 °C (B) (1.0% SC; 1.0% WPI; 1.0% SPI).

relationship between the carboxyl group content of ethylenediaminetetraacetic dianhydride (EDTAD)-modified SPI and metal-binding ability.

Casein, in excess, can form a thick interfacial layer around carrier oil droplets extending from 10 to 15 nm compared to 2−3 nm for whey proteins.[35] The greater thickness may reduce the interaction between BC and pro-oxidants in aqueous phase.

At low protein concentrations (0.1−1.0%, w/w), the BC lipid surface may not be fully covered by the emulsifier, and direct contact with metal ions, pro-oxidants, and dissolved oxygen may increase BC oxidation. Increasing the protein content (SC, WPI, SPI) in solution resulted in a decrease in the loss rate of BC (Table 2). Most likely, oxidation was initiated by dissolved oxygen during the high speed mixing step.

Impact of Emulsifiers on Total Color Change (ΔE^*). The color and appearance are important visual factors for food choice by consumers.[36] The apparent color of carotenoids varies (red/orange/yellow) with concentration, oxidation, and particle diameter. The lightness (L) of three BC nanoparticles increased during storage, an indicating the color fading and BC loss. The decrease of a value suggested the decrease of redness of BC nanoparticles, while the yellowness (b) increased with increasing storage (Supporting Information, Table 2S). The degree of total color change, as expressed by ΔE^*, with storage temperature was consistent with the decrease of BC. The color changes at 25 °C were greater than at 4 °C (Figure 4), and the order was SC < WPI < SPI at both temperatures. The BC loaded nanoparticles produced in this study had better physicochemical stability than those previously reported by Qian et al.[3] perhaps due to solid lipid cores which have been reported to have lower susceptibility to degradation than BC in solution.[37]

TEM of BC Loaded Nanoparticles. The shape of the BC nanoparticles stabilized by three proteins (SC, WPI, and SPI) was observed by transmission electron microscope (TEM). As shown in Figure 5, the three nanoparticles were spherically shaped and uniformly dispersed, suggesting BC was fully encapsulated by proteins. The TEM images of BC loaded nanoparticles prepared by the solvent displacement technique emulsified by gelatin and Tween 20[38] were also spherical.

Cell Toxicity of BC Loaded Nanoparticles. BC loaded nanoparticle toxicity was evaluated by the MTT assay which is a commonly used, sensitive colorimetric method to determine cell viability.[39] The cell viability was determined at different dilution times (DT) by the MTT assay (Figure 6). Pure β-carotene was used as a control. Pure β-carotene is insoluble in water, so β-carotene dissolved in THF/DMSO (1:1) was diluted in DMEM as control to study the toxicity of β-carotene. No cytoxicity was observed with Caco-2 cells treated with pure β-carotene at the same concentrations in nanoparticles. At DT = 0 (initial protein concentration = C_o =10 mg/mL), the cell viabilities treated with the three BC loaded nanoparticles were 84 ± 8% for SC, 80 ± 7% for WPI, and 83 ± 7% for SPI, respectively. The viabilities of Caco-2 cells when exposed to food protein (WPI and SPI) stabilized nanoemulsions at 3 mg/mL were about 85%,[15] which was similar to our finding. He et al.[15] also reported that the food proteins had a better biocompatibility, compared to egg phosphatidylcholine (EPC)

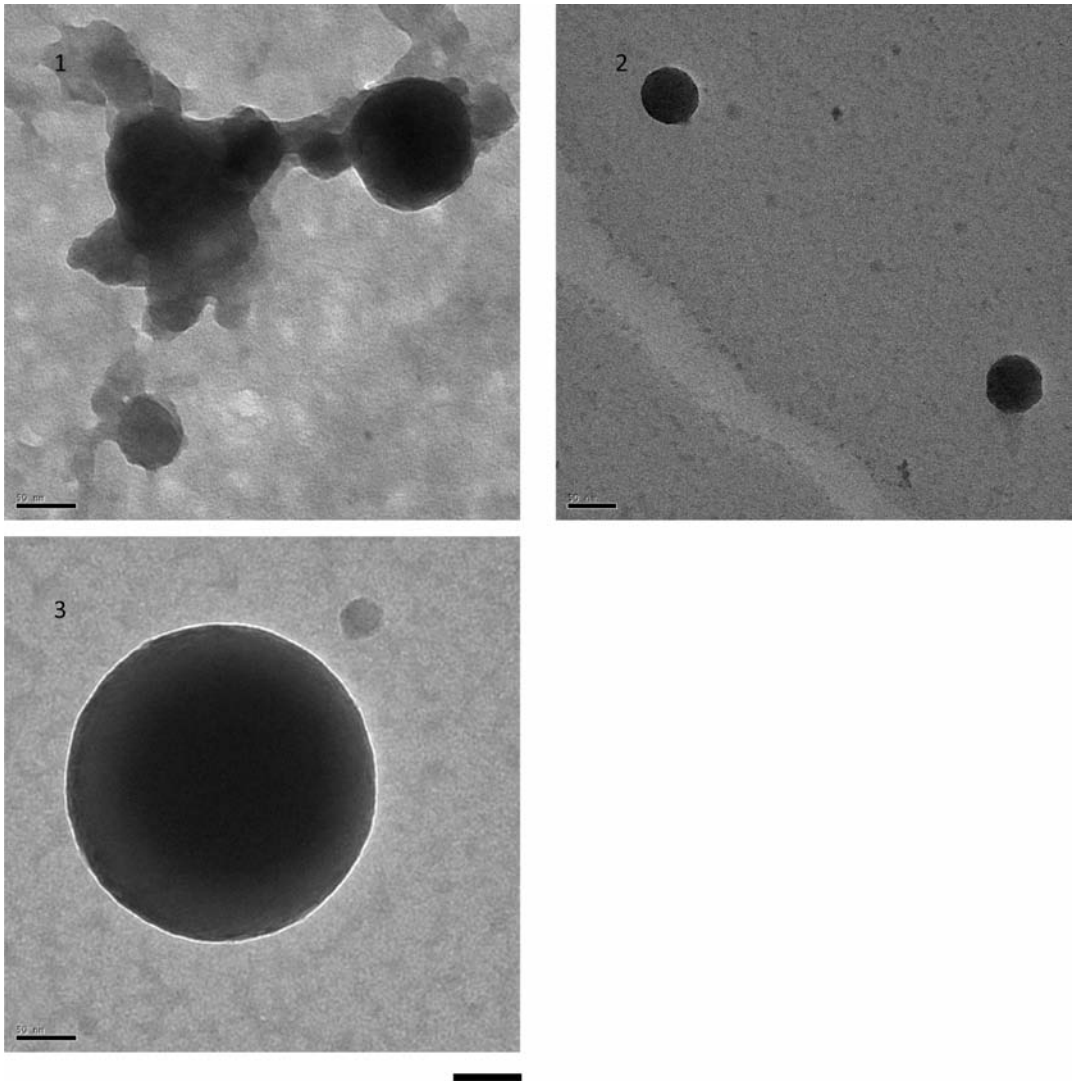

Figure 5. Transmission electron micrographs of BC loaded nanoparticles prepared with SC (1), WPI (2), and SPI (3), respectively, at a final concentration of 1% (w/w). Scale bar indicates 50 nm.

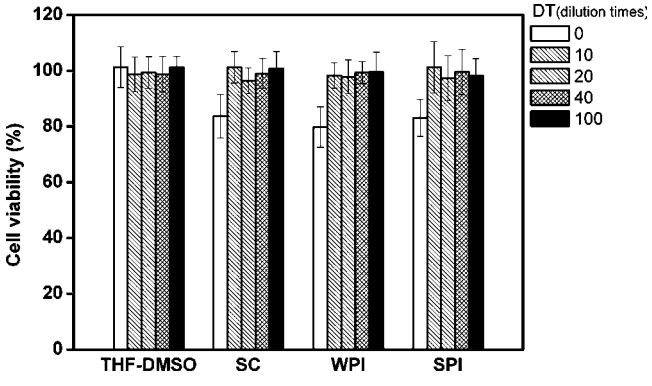

Figure 6. *In vitro* cytotoxicity of pure BC (as control) and three BC loaded nanoparticles at different dilution times (DT) on Caco-2 cells measured by MTT assay. Cell viability was expressed as mean ± STD (n = 3).

and other surfactants. In addition, at DT = 10 ($0.1 \times C_o$) or greater, all the cell viabilities were above 95% indicating that the BC loaded nanoparticles were nontoxic when the concentrations of protein emulsifiers were below 1 mg/mL. The results suggest that protein-based nanoparticles are biocompatible.

BC Loaded Nanoparticle Uptake *in Vitro*. Cellular accumulation of micellar BC was found to be proportional to up to 30 h of incubation time. A 24 h period was chosen for the uptake of BC nanoparticles with Caco-2 cells.[40] The rate and extent of nanoparticle uptake is determined by the properties of the particle, like, diameter, shape, charge, and interfacial characteristics. The uptake of BC loaded nanoparticles prepared by homogenization−solvent evaporation was greater than BC in THF/DMSO suspension (Figure 7). This was surprising since in both cases, BC nanoparticles versus BC suspension THF/DMSO at 5 μg/mL, BC was in solid form. However, BC in THF/DMSO may have precipitated in the crystalline form whereas BC in the nanoparticles, by X-ray diffraction, appears to be in an amorphous solid. We hypothesize that a mixture composed of residual lipids extracted by ethyl acetate from SC, WPI, and SPI prevented crystallization. The nanoparticles were also smaller in diameter. The cellular uptake of BC in THF/DMSO suspension was 264 ± 37 pmol/mg protein (Figure 7). While the uptake values of SC, WPI, and SPI BC loaded nanoparticles were 687 ± 69, 891 ± 142, and 452 ± 48 pmol/

dx.doi.org/10.1021/jf404073c | J. Agric. Food Chem. 2014, 62, 1096−1104

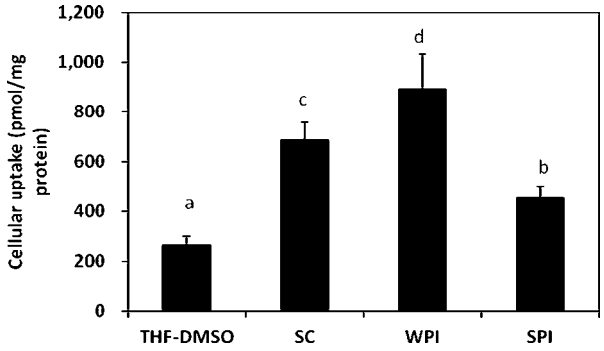

Figure 7. Uptake of BC by Caco-2 cells monolayers incubated with BC THF/DMSO suspension SC stabilized BC loaded nanoparticles, WPI stabilized BC loaded nanoparticles, and SPI stabilized BC loaded nanoparticles at BC concentration of 5 μg/mL. Values were expressed as mean ± STD (n = 3). Values with different letters (a–d) are significantly different ($p \leq 0.05$).

mg protein, respectively, which was a 2.6-, 3.4-, and 1.7-fold increase, respectively. The cellular uptake values among the three nanoparticles were significantly different ($P < 0.05$) and increased in the following order: SPI < SC < WPI. Differences in particle diameter of the BC core may be the main reason for differences in uptake. The BC core diameter is probably related to encapsulated nanoparticle diameter although there will be differences in the thickness of the adsorbed protein layers. However, the mean diameter of SPI encapsulated BC loaded nanoparticle was 372 ± 7 nm, and much larger than SC stabilized (77.8 ± 0.2 nm) or WPI stabilized BC loaded nanoparticles (89.7 ± 1.7 nm). Besides the increased surface area of smaller particles nanosized objects, the release properties of the lipid may be affected by its crystallinity and distribution within the particle.

Although transport by scavenger receptor SR-BI is believed to be the conventional means of BC absorption,[41] the literature also reports that nanosize droplets (d < 200 nm) may be directly transported across the epithelium cell layer by paracellular mechanism, passive diffusion or an "endocytosis" mechanism.[41,42] There was a significant negative correlation between BC uptake and the nanoparticles' negative surface charge (ζ-potential) ($P < 0.05$). ζ-Potential is influenced by ionic strength, and the measurements were made in 5 mM (pH 7.0) phosphate buffer while the concentration of the main sources of ions in cell culture media was about 150 mM. Therefore, our ζ-potential measurements may not be reliable although Dagliesh et al.[43] found that the ζ-potential for casein became more negative by only 1.5 mV going from 100 mM to 20 mM NaCl. Previous research has indicated that surface charge is an important factor in permeation of nanoparticles.[44] The surface of enterocytes (Caco-2 monolayers) is coated with a negatively charged mucin layer. The negative electrical charge of the surface of three protein encapsulated BC loaded nanoparticles may interact with the mucin layer through electrostatic repulsion, restricting the uptake of BC. The largest ζ-potential value of SPI nanoparticles also had the least BC uptake content. These results indicated that changing surface charge may be an effective method to improve cellular uptake.

In summary, our study shows that BC loaded nanoparticles can be prepared and stabilized by food grade proteins. The toxicity of nanoparticles appears to be low at about 10 mg BC/100 mL and insignificant when diluted 10 times or more. The evaporation method produced spherical solid BC cores probably mixed with residual protein lipids. The protein encapsulated nanoparticles had increased uptake of BC compared to BC in THF/DMSO suspension. Oxidative stability was highest in BC loaded nanoparticles stabilized by SC proteins due to the different interfacial characteristics at the droplet surface and the amino acid compositions. The intrinsic antioxidative capacity of proteins contributed to oxidative stability. This study contributes to interest in designing new delivery systems to increase stability and uptake of lipophilic nutrients in the food industry.

greater than 95%) and the rest of the reagents were provided by Sigma-Aldrich (St. Louis, MO).

Determination of the Fatty Acid Profile. *Sample Preparation.* The fatty acid profile was determinated by a gas chromatography procedure by methylation with cold methanolic solution of potassium hydroxide. In a 5 mL screw top test tube, 0.10 g of the HSO sample was weighed. A total of 3 mL of heptane and 500 μL of 2 N methanolic potassium hydroxide solution were added. The sample was shaken vigorously for 15 s, leaving it to stratify until the upper solution became clear. The upper layer containing the methyl esters was decanted.[23]

Chromatographic Conditions. The fatty acid methyl esters (FAMEs) were analyzed in a Hewlett-Packard 6890 gas chromatograph equipped with a flame ionization detector (FID), using a SP2380 silica capillary column (30 m × 0.32 mm internal diameter, 0.25 mm film). The initial column temperature was 165 °C, which was held for 10 min and programmed from 165 to 200 °C at 1.5 °C/min. The injector temperature was 210 °C, and the detector temperature was 250 °C. FAMEs were identified by retention time comparison to that of the corresponding standard peaks.

Unsaponifiable Extraction. The unsaponifiable matter of HSO was isolated following conventional procedures, and its components were analyzed following the International Union of Pure and Applied Chemistry (IUPAC) method.[24] A total of 5 g of HSO, 1 mL of internal standard (IS) solution (1 mg/mL α-colestanol and 0.5 mg/mL eicosanol in chroloform), and 50 mL of a 2 N potassium hydroxide solution in ethanol/water (80:20, v/v) were put into a 250 mL flask; saponification was carried out by boiling and stirring the sample for 1 h. After cooling, 100 mL of distilled water was added, and the sample was transferred to a separating funnel and extracted 3 times with 80 mL of ethyl ether. The ether extracts were pooled into a separating funnel (with 125 mL of distilled water) and washed with distilled water (125 mL each time), until the wash gave a neutral reaction. Then, the wash water was removed; the organic sample was dried with anhydrous sodium sulfate, filtered, and taken to dryness; and the residue was weighed.[25]

Separation of the Unsaponifiable Components. HSO unsaponifiable matter was by means of both flash and plate chromatography, providing fractions with superimposable profiles. Preparative thin-layer chromatography (TLC) was preferred over column chromatography because of its greater handiness and convenience of operation. The unsaponifiable fraction dissolved in chroloform was deposed on a 1 mm silica gel 60 F_{254} PLC plate, 20 × 20 (Merck, Darmstadt, Germany). The plate was placed into the developing chamber and eluted with hexane/diethyl ether (65:35, v/v). After development and solvent evaporation, the plate was developed with 2′,7′-dichlorofluorescein solution and important bands was evidenced.[25] The most important bands were scraped separately from the plate and extracted first with hot chloroform (10 mL) and then with ethyl ether (10 mL). The two solvent extracts were mixed and taken to dryness. The residue was finally dissolved and sylilated with 200 μL of a solution of pyridine−hexamethyldisilazane−trimethylchlorosilane to 15−30 mg of the insaponificables in glass-stoppered tubes.[20]

Chromatographic Conditions. Sterol and alcohol fractions were analyzed with a HP5890 Series II gas chromatograph (Boston, MA) equipped with a capillary column SPB5, 30 m length, 0.25 mm inner diameter, and 0.25 μm film thickness of poly(5% diphenyl/95% dimethyl siloxane) stationary phase. Carrier gas was hydrogen, with a head pressure of 110 kPa and 1:60 split ratio. The injector and detector temperature was 300 °C. The isotherm program to 255 °C was programmed to the sterol fraction for 30 min, and the oven temperature was programmed from 225 to 280 °C with a rate of 3 °C/min for the alcohol fraction for 50 min. The analysis was carried out following the amending Regulation (EC) 2568/91 on the characteristics of olive and the relevant method of analysis. The mass spectrometry (MS) analyses were performed using Kratos MS 80 mass spectrometer equipped with a NBSLIB2 data system. Scan time and mass range were 1 s and m/z 50−500, respectively. Fraction components were quantified by means of the ISs, and the total concentration in HSO was calculated as the sum of individual peak concentrations.

Determination of Hydrocarbon and Wax Contents. The wax esters, formed by the reaction of alcohols (aliphatic, triterpenic, methylsterols, and sterols) and free fatty acids, are present in seed and fruits. The usual procedure was followed by column chromatography. This method has been adopted by the European Union. A solution of lauryl arachinodate (0.1 mg/mL) and methyl heptadecanoate (0.1 mg/mL) in methanol was used as the IS. The wax esters eluted just before the triacylglycerols, thereby the addition of a colorant (Sudan I) with R_f similar to that of the triacylglycerols allows for visualization when the elution of wax esters ends. The fraction isolated contains also other minor components, such as the hydrocarbons. After isolation, this fraction was carried out by the gas chromatographic system (Agilent Technologies 6890N) equipped with an on-column injector and FID and using a short capillary-fused silica column (10 m) coated with 5% phenylmethylsilicone.[26]

Analysis of Tocopherols. The tocopherol content was analyzed by high-performance liquid chromatography (HPLC) in accordance with the IUPAC 2432 method.[27] A total of 1.5 g of HSO was dissolved in the solution (10 mL) of 0.5% isopropanol in *n*-hexane (mobile phase). The chromatographic separation was performed using a Perkin-Elmer liquid chromatograph equipped with an isocratic pump LC200 and an ultraviolet−visible (UV−vis) detector Lc295. A normal-phase column Lichrosphere Si60 (250 mm length, 4.6 mm inner diameter, and 5 μm particle size) was used with an injection volume of 20 μL and a flow rate of 1.0 mL/min. The absorbance was measured at 295 nm. The results were expressed as milligrams of tocopherol per 100 g of oil.

Statistical Analysis. All sample preparation and analyses of all of the classes of analytes (sterols, alcohols, hydrocarbons, waxes, fatty acids, phenols, and tocopherols) were performed in triplicate and were calculated with respect to respective ISs. Values are expressed as the mean, and standard error of the mean (SEM) is given. Each chromatogram is the most representative of three similar analyses.

RESULTS AND DISCUSSION

Industrial hemp is widely known to provide high-quality fibers and materials for textile, paper, or bio-building uses. Complementary products along with fibers should be taken into account in growing hemp because they might significantly enhance its competitiveness. The HSO and secondary metabolites, which can be found in the unsaponifiable fraction, are only some examples of potential complementary products that can be derived from industrial hemp.[28] The unsaponifiable fraction has received very little attention by researchers, despite the potential relevance that it may have in phytomedical technology, the discipline of studying the plant-derived pharmaceutical and nutraceutical compounds.[29]

In our analysis, the main fatty acids of HSO were linoleic acid (RT, 15.718), α- and γ-linolenic acids (RT, 18.223 and 18.323, respectively), and oleic acid (RT, 13.465), which together comprised 88% of the total fatty acids (Table 1). The fatty acid profile of HSO was similar to that reported in Canada[4,30] and for hemp cultivated in Europe with slightly higher linolenic acids.[31] The palmitic, stearic, and oleic acid contents of HSO were similar to those of evening primrose oil (EPO).[32] The PUFAs of the oil amounted to 76% of the total of fatty acids, while the monounsaturated and saturated fatty acids amounted to 12% each. The high amounts of α-linolenic acid (17%) may have favorable nutritional implications and beneficial physiological effects on the prevention of coronary heart disease and cancer.[33,34] The presence of γ-linolenic acid (3.4%) provides it with a high pharmaceutical value for degenerative chronic diseases.[35] The oil was characterized by a high polyunsaturated/saturated (P/S) ratio, which is regarded favorably for the

Table 1. Fatty Acid Profile (GC) in HSO

name	mean ± SEM (%)
palmitic acid (16:0)	5.62 ± 0.04
palmitoleic acid (16:1)	0.31 ± 0.02
estearic acid (18:0)	2.68 ± 0.12
oleic acid (18:1)	11.90 ± 0.35
linoleic acid (18:2, ω-6)	55.05 ± 0.47
eicosanoic acid (20:0)	2.50 ± 0.15
α-linolenic acid (18:3, ω-3)	16.70 ± 0.08

total sterols			2793.73 ± 124.32

reduction of serum cholesterol and atherosclerosis and prevention of heart diseases.[36] Similarly, the ratio of ω-6/ω-3 fatty acids was 3.

On other hand, little effort has been expended to study other minor compounds present in HSO. The present work has isolated and characterized the different and interesting fractions from unsaponifiable HSO. A great amount of qualitative information was generated in every analysis. A yield (1.84−1.92%) of unsaponifiable matter was obtained.

Sterols were isolated from the HSO unsaponifiable matter and represented a 15.18% from this fraction. The identification of the different phytosterols has been made by gas chromatography (GC) and GC−MS comparing their relative retention time (RR_t) values and their MS fragments to literature values. Chromatographic analyses are shown in Figure 1 and Table 2. β-Sitosterol (1905.07 ± 59.27 mg/kg of oil) and campesterol (505.69 ± 32.04 mg/kg of oil) were predominant in the phytosterol fraction (2793.73 ± 124.32 mg/kg of oil). This proportion shows that EPO is twice as rich as olive oil in these natural products.[37] Plant sterols and stanols in fat matrices effectively lower low-density lipoprotein (LDL) cholesterol levels in hypercholesterolemic and diabetic patients and healthy human volunteers. Recent studies also show that dietary intake of plant sterols is related to a lower risk of myocardial infarction, lowering LDL cholesterol even when incorporated in non-fat matrices.[38] In addition, they may reduce biomarkers of oxidative stress and inflammation and modulate the atherosclerosis development.[20,39]

Another interesting fraction is the aliphatic alcohols.[40] Phytol (167.59 ± 1.81 mg/kg of oil) and geranylgeraniol (26.06 ± 0.08 mg/kg of oil) were predominant in the aliphatic alcohol fraction (226.94 ± 2.26 mg/kg of oil), and the abundant linear aliphatic alcohol was hexacosanol (16.17 ± 0.21 mg/kg of oil) (Figure 2 and Table 3). Chemical and nutritional studies have shown that mixtures of long-chain primary alcohols extracted from waxy materials from different sources, such as beeswax, rice bran, wheat germ, sugar cane, and grain sorghum, are able to exert several beneficial physiological effects, such as reducing platelet aggregation, endothelial damage, and cholesterol-lowering effects.[40,41] On the other hand, recent investigations

performed by our group demonstrated that a similar linear alcohol fraction isolated from pomace olive oil (a byproduct of olive oil) has a protective effect on some mediators involved in the inflammatory damage development.[19] Phytol, a constituent of chlorophyll, is mainly found in human food, such as spinach, beans, raw vegetables, and asparagus, and has both anticancer and antioxidant actions.[42]

HSO did not prove be rich in squalene (Table 4), which had a presence of 80.52 mg/kg, if compared to other known plants rich in squalene (olive oil or *Amaranthus* oil).[43] The levels of saturated hydrocarbons were 451.77 ± 26.05 mg.

Tocopherols, another minor oil component, belong to a group of lipid-soluble compounds generally referred to as vitamin E, encompassing α-, β-, γ-, and δ-tocopherols. Because

Table 4. Amount of Squalene, Linear Hydrocarbons, and Waxes (GC) in the Unsaponifiable Fraction from HSO

name	mean ± SEM (mg/kg of oil)
squalene	80.52 ± 1.35
total linear hydrocarbons	451.77 ± 26.05
aliphatic waxes	0.98 ± 0.08
terpenic waxes	42.37 ± 0.61
total waxes	43.35 ± 0.69

of their ability to scavenge free radicals involving a tocopherol−tocopheryl semiquinone redox system, tocopherols are the most important natural antioxidants. Moreover, these compounds were shown to exhibit various beneficial effects on degenerative diseases, such as atherosclerosis, cardiovascular disease, Alzheimer's disease, or certain types of cancer.[44] The major tocopherol in HSO was the γ isomer at 91 ± 1.4% of the total tocopherol (Table 5). Similar results of γ-tocopherol,

Table 5. Tocopherol Contents in the Unsaponifiable Fraction from HSO (mg/100 g) by HPLC

name	mean ± SEM (mg/100 g of oil)
α-tocopherol	3.22 ± 0.65
β-tocopherol	0.81 ± 0.16
γ-tocopherol	73.38 ± 2.86
δ-tocopherol	2.87 ± 0.83
total tocopherols	80.28 ± 4.50

accounting for 90% of the total, have been reported for *C. ruderalis* L.[45] Concentrations of tocopherol isomers from HSO were in the range reported for hemp cultivars grown in Canada.[4] α-Tocopherol is considered to be the predominant antioxidant in olive oil, sunflower oil, and EPO, while γ-tocopherol prevails in rapeseed oil.[46−48]

This study is an important contribution for *C. sativa* L. valorization as a source of bioactive compounds. Finally, the extraction of high-value bioactive compounds can be perfectly integrated with the large-scale applications of hemp, contribu-

dx.doi.org/10.1021/jf404278q | J. Agric. Food Chem. 2014, 62, 1105−1110

ting to research novel applications in the food, pharmaceutical, cosmetic, and other non-food industries.

Hydrolysis of methyl ester groups from the pectin backbone by PME can occur via three different mechanisms.[16,17] The first mechanism involves a multiple chain reaction, in which PME removes one methyl ester from the pectin chain and then dissociates from the substrate, resulting in random deesterification of the chain. This is typically the mode of action of acidic fungal PME.[16,18] The second mechanism is single chain, or linear, deesterification, where PME follows along one chain and cleaves all the methoxyl groups, which results in blocks of demethylated pectin. This is generally the mode of deesterification for higher plant PME.[16,18] This would suggest that carrot PME also employs linear deesterification, although no research to date has confirmed this. The third mechanism involves multiple attacks of the enzyme on methyl esters, where only a limited number of methyl groups are removed from each pectin substrate. The mechanism by which carrot PME catalyzes deesterification of carrot pectin has not yet been determined.

Carrot Juice Cloud Stability. The rate of juice clarification is governed by two mechanisms: flocculation and sedimentation. Flocculation is the phenomenon in which particles cluster together to form aggregates, increasing the effective particle size. Sedimentation is the settling out of flocculated particles from suspension to the bottom of the container. Typically, flocculation leads to faster sedimentation in accordance with Stokes' Law. Larger particles formed from flocculation increase the rate of sedimentation and, hence, cause more rapid loss of cloud stability.

If particle size influences the rate of cloud loss and clarification, then it is worthwhile exploring how particle size increases within juices over storage time. In a suspension, particles remain separate from one another due to the presence of an energy barrier between them, which reduces their rate of collision. The energy barrier is influenced by several different contributions, including attractive van der Waals interactions (which reduce the barrier) and repulsive electrostatic forces (which increases it).[19−22] Factors that lower the energy barrier make it more likely that cloud particles will closely approach one another, at which point they can "stick" to each other and floc as a result of short-range attraction.

In juices with active enzymes, PME cleaves methoxyl groups from the pectin backbone and additional negatively charged residues are exposed. These like-charged residues would normally enhance the repulsive interparticle energy barrier; however, naturally present divalent cations such as calcium may bind to these sites, creating electrostatic attractive interactions between particles. The calcium can then cross-link pectin chains on different particles together, thereby forming insoluble calcium pectate within aggregates that are large enough to sediment out according to Stokes' Law.[1,17,20,23]

Little research has been conducted regarding the effect that residual PME levels have on cloud stability of carrot juice, which is a low-acid juice product. Therefore, the goal of this study was to observe the effects of adding PME to pasteurized carrot juice and suggest a mechanism for cloud flocculation and sedimentation.

MATERIALS AND METHODS

Material Sourcing. Sugarsnax variety carrots (*Daucus carota* L. ssp. sativa cv. 'Sugarsnax') were used to make the PME extraction, and were sourced from Bolthouse Farms in Bakersfield, CA. The average PME activity in raw carrot juice made from these carrots was found to be 0.43 U/g (range: 0.218−0.806 U/g), as measured by individually juicing 30 Sugarsnax carrots on a benchtop juicer. Commercial pasteurized Bolthouse carrot juice (pH 6.20) was purchased from a local grocery store. All containers of purchased juice were mixed together to ensure a uniform starting material. The PME activity of the commercial juice was found to be less than 5% of the average carrot juice PME.

Reagents. Sodium chloride, monobasic monohydrate sodium phosphate, dibasic anhydrous sodium phosphate, citric acid monohydrate, sodium citrate, hydrochloric acid, sodium hydroxide, sulfamic acid, and ferric ammonium sulfate were obtained from Fisher Scientific (Fair Lawn, NJ). Trizma base, Trizma hydrochloride, citrus pectin, Bradford Reagent, lauryl sulfate, bovine serum albumin (BSA), Fluoral-P, alcohol oxidase, and 3-methyl-2-benzothiazolinone hydrazine hydrochloride hydrate were obtained from Sigma Aldrich Co. (St. Louis, MO). Micro Bio-Spin desalting columns were obtained from Bio Rad (Hercules, CA), and membrane tubing was sourced from Spectrum Medical Industries, Inc. (Houston, TX). Deionized distilled water was used in all experiments.

PME Preparation and Characterization. *PME Extraction.* PME added to commercial carrot juice was prepared from an extraction of raw carrots based on the method of Ly-Nguyen et al.[24] A sample of 600−700 g of washed carrots was homogenized with 600 mL deionized water in a Vita-Mix blender set on high for 2 min (Model VM0101D, Vita-Mix Co., Cleveland, OH). The homogenate was filtered through four layers of cheesecloth, and the filtrate was discarded. The pellet was washed four times with 1 L deionized water to ensure the removal of color and organic compounds. The pellet was then mixed with 1:4 (w/v) 0.2 M Tris and 1 M NaCl (pH 8.0) for 30 min to extract PME into the supernatant, and the carrot slurry was filtered through four layers of cheesecloth. The supernatant was collected and the pellet discarded.

The supernatant was stirred with 30% ammonium sulfate for 30 min as a purification step to precipitate large proteins that were not PME. This mixture was then centrifuged at 18 000*g* for 15 min at 20 °C in a Sorvall centrifuge (Model RC5C, DuPont, Wilmington, DE). After centrifugation, the pellet was discarded and the supernatant was vacuum filtered (Whatman #4) to remove any remaining large particles.

To precipitate the PME enzyme, 80% ammonium sulfate was slowly mixed into the supernatant. The mixture was stirred for 30 min, and then centrifuged at 18 000*g* for 15 min at 20 °C. The supernatant was discarded, and the PME precipitate that collected on the side of the centrifuge tubes was redissolved in 0.05 M citric acid/sodium citrate buffer (pH 6.5). The redissolved PME was then dialyzed in membrane tubing (MWCO 3500) in the citric acid/sodium citrate buffer in two stages. In the first stage, PME was dialyzed for 1 h at 4 °C, during which time highly concentrated molecules such as salts rapidly diffuse into the surrounding buffer and slow further diffusion. Therefore, for the second stage, fresh buffer solution was added to allow for continuous rapid diffusion, and the PME was dialyzed overnight at 4 °C. Once dialysis was complete, the PME, suspended in buffer, was stored in 1 mL aliquots at −20 °C.

The specific activity of three sample replicates from the extraction was measured by the PME assay and Bradford protein determination, and these three activity values were averaged to obtain the specific activity of that batch of PME extract. This concentrated PME preparation had an activity of 116 U/mL, and a specific activity of 123 U/mg protein.

Bradford Protein Determination. The Bradford protein assay was based on the method described in the Technical Bulletin of the Bradford Reagent by Sigma-Aldrich.[25] The procedure was modified so that only one-third of the assay volume was used, in order to cut down on hazardous waste. Therefore, 0.33 mL of samples and standards was added to 1 mL Bradford reagent, and the solution was incubated at room temperature (25 °C) for 5−10 min and then measured at 595 nm in a Shimadzu spectrophotometer (Columbia, MD).

PME Assay. PME activity was determined based on the assay developed by Anthon and Barrett (2004), in which a crude extract of PME from carrot juice was added to a standard amount of pectin.[26] The methanol produced in this reaction was used to quantify the

amount of enzyme activity and, hence, the amount of enzyme present in the sample. Pectin used in the assay was dialyzed overnight in water. Assays were started by adding 5 μL of a 10-fold dilution of the carrot juice to 95 mL of the assay medium, which contained 3 mg/mL pectin and had a pH of 7.5. All samples were placed into a 30 °C water bath, and at four time points (40, 70, 100, and 130 min) after the start of the assay, 0.1 mL aliquots were removed and added to 0.1 mL of a solution containing 5 mg/mL of each ferric ammonium sulfate and sulfamic acid. After 30 min at room temperature, 0.8 mL of water was added and absorbance at 620 nm was determined using a Shimadzu spectrophotometer (Columbia, MD). Methanol concentrations were determined from a separate methanol standard curve. The amount of methanol formed was plotted and the activity was calculated from the slope of the plot.

Cloud Stability during Juice Storage. *PME Addition.* The PME extract, made as described above, was added to commercial carrot juice in 5 quantities, 0, 0.15, 0.25, 0.5, and 1 U/g, where a unit of enzyme activity (U) is defined as the number of micromoles of methanol produced in 1 min, and grams refers to the mass of carrot juice. Since different volumes of PME extract (enzyme suspended in 0.05 M citric acid/sodium citrate buffer) were added to the juice to achieve different enzyme levels, it was necessary to compensate for the subsequent changes in juice volume. The largest volume of extract added (for addition of 1 U/g) was used as a baseline, and the other samples had a combination of enzyme extract and citric acid/sodium citrate buffer added so that all samples had the same final volume. This was done to ensure each juice was diluted the same small amount and any effects of the buffer were mitigated. Final juice pH after PME addition was 6.20. To prevent microbial growth during the storage study, 0.2% sodium azide was added to the juice. Juices were stored for up to 56 days at 5 °C.

Relative Sediment Height. Relative sediment height, also known as the sedimentation test, is a measure of the quantity of visible settling that occurs in the juice.[21,27] It is the height ($H_{sediment}$) of the cloud sediment divided by the total height (H_{total}) of the juice in a vial.

Samples used for measuring the relative sediment height of the sediment were placed in 7 mL glass vials with screw caps and allowed to remain undisturbed except for gentle transportation of the vials from the refrigerator to the laboratory bench for measurements. A caliper was used to make height measurements in triplicate.

Relative Turbidity. Relative turbidity is a spectrophotometric method to determine cloud stability by comparing the turbidity in a juice sample before and after centrifugation.[21,22,28−30] For the carrot juices examined here, absorbance at 660 nm was used as the measure of juice turbidity. At this wavelength, absorbance is predominantly determined by the scattering due to the particles, rather than specific chemical absorption.[31] Relative turbidities were determined by measuring the absorbance values for the whole juice and for the supernatants obtained after centrifugation (4200*g*, 15 min, 20 °C). When absorbance values measured in standard 1 cm cuvettes were unacceptably high, shorter path length cuvettes (0.5 mm for whole juice and 5.0 mm for juice supernatants) were used. Turbidity (τ) was calculated as the absorbance divided by the path length used for measurement. Relative turbidities (expressed as %) were calculated as $\tau_{serum}/\tau_{total} \times 100$.

Particle Size Determination. Static light scattering was used to measure average particle size.[21,28,30,32−34] A laser is passed through the sample and, upon hitting a particle, diffracts and creates a light pattern against the detector that depends on the particle size. Measurements were performed using a Microtrac S3500 (Montgomeryville, PA). Results were obtained as the volume fraction of particles contained within a discrete size range (bin). The mean diameter was determined as a volume average:

$$D_{4,3} = \frac{\sum (n_I d_I^4)}{\sum (n_I d_I^3)} \quad (1)$$

Here $D_{4,3}$ is the volume mean diameter, n_i is the number of particles in bin *i*, and d_i is their diameter. Carrot juice was inverted gently 10 times to ensure even distribution of particles and then added to the instrument sample port, which was operated at a flow rate of 15% of maximum. Particles were assumed to be irregular in shape and absorbing, and a refractive index value for water of 1.333 was used. Three replicates were measured for each sample.

RESULTS

Effect of Added PME on Cloud Stability. It is generally understood that PME impacts juice cloud stability, but the time frame over which destabilization occurs and the impact of the amount of active enzyme is not known, nor is the mechanism of cloud destabilization by PME well understood. Therefore, a storage study was conducted that examined the effects of different quantities of added enzyme on the cloud stability of commercial carrot juice. Commercial pasteurized carrot juice was preferred as the starting material for these studies, rather than raw unpasteurized juice made in the laboratory, because of the former's uniform particle content and minimal active PME (see Material Sourcing in Materials and Methods). Starting with juice that lacked any PME, then adding known amounts of a partially purified carrot PME, juices with different known levels of PME activity could be obtained. The levels of PME added (0.15, 0.25, 0.5, and 1.0 U/g) were based on the level of endogenous PME measured in raw Sugarsnax carrot juice made with a benchtop juicer. This level varied widely across the juice from individual carrots, even within carrots planted and harvested at the same time and grown in the same field. For 30 individually measured carrots, the PME activity of the juice ranged from 0.218 to 0.806 U/g, with an average of 0.43 U/g.

Cloud stability was measured via relative turbidity ($\tau_{serum}/\tau_{total}$), which has been used previously by others as a method sensitive to the extent of flocculation within the cloud.[21,28,29] Flocculation creates larger particles within the suspension, which are removed more effectively by centrifugation, and leave behind a serum with a lower particle concentration and lower turbidity. Thus, smaller values of $\tau_{serum}/\tau_{total}$ indicate that more flocculation has occurred. As shown in Figure 1, at all levels of

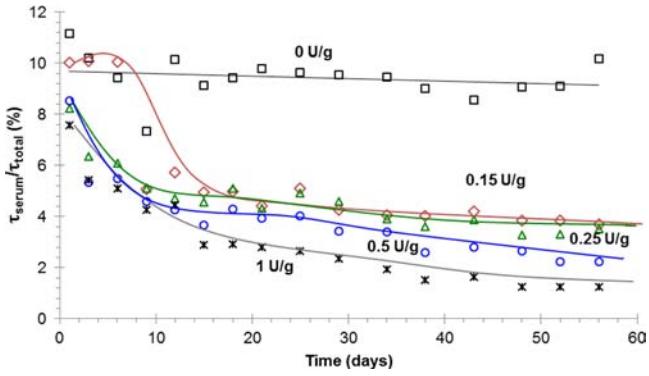

Figure 1. Relative turbidity ($\tau_{serum}/\tau_{total}$, %) of carrot samples with 0 (□), 0.15 (◇), 0.25 (△), 0.5 (○), and 1.0 (∗) U/g of added PME enzyme over the course of 56 days of storage.

added PME the cloud was less stable than in the control juice with no added enzyme. The relative turbidity of the control sample remained consistently high throughout storage, while those samples with added PME showed a large degree of clarification after centrifugation (Figure 1).When the amount of added PME was at or above 0.25 U/g, there was an inverse relationship at the 90% confidence level between the level of PME addition and the relative turbidity of the cloud at periods longer than 15 days.

dx.doi.org/10.1021/jf4043979 | J. Agric. Food Chem. 2014, 62, 1111−1118

Loss of cloud stability and juice clarification was also monitored by measuring relative sediment height ($H_{sediment}/H_{total}$). Consistent with the results for relative turbidity, much less clarification occurred in the control than in the enzyme-treated samples (Figure 2). However, the relative sediment height of the control juice increased slowly over the course of the storage period, indicating that there was natural settling occurring within the juice that is not attributable to PME activity.

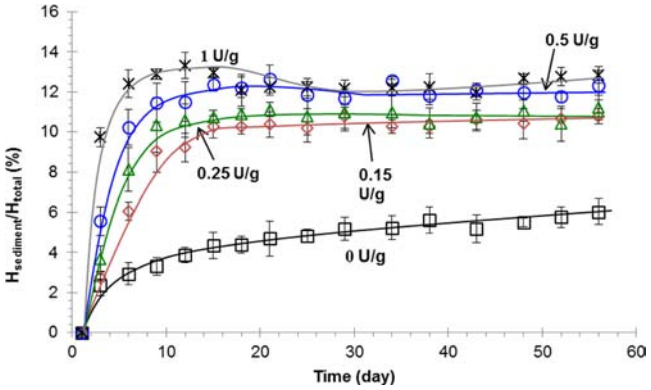

Figure 2. Relative sediment height ($H_{sediment}/H_{total}$, %) of carrot samples with 0 (□), 0.15 (◇), 0.25 (△), 0.5 (○) and 1.0 (∗) U/g of added PME over the course of 56 days of storage at 5 °C.

All samples containing active PME had an initial period (~10 d) of rapid sedimentation, after which the sediment height leveled off (Figure 2). The kinetics of this process can be represented using the empirical formula

$$\frac{H_{sediment}}{H_{total}} = \frac{t^2 H_\infty}{t^2 + T_o^2} \quad (2)$$

where t is time, H_∞ is the steady-state dimensionless plateau height, and T_o is a characteristic time of the initial, rapid sedimentation period. H_∞ and T_o could thus be obtained by a fit of eq 2 to the data in Figure 2; results for these two fit parameters are given in Table 1.

Table 1. Sediment Plateau Height and Time of Initial Height Increase From Eq 2, for the Four Levels of Added PME Enzyme

			quality of fit	
enzyme added (U/g)	H_∞ plateau height (%)	T_o (days)	R^2	χ^2
0	-	-	-	-
0.15	11	4.9	0.99	1.3
0.25	11	3.9	0.98	0.80
0.50	13	3.2	0.98	1.2
1.00	13	2.1	0.92	2.1

Carrot juice with greater amounts of added enzyme became unstable more quickly during storage, as shown by the number of days (T_o) it took for the initial rapid sedimentation period to occur (Table 1). With added enzyme, just a few days were needed for the cloud to separate visually into a sediment layer with approximately steady thickness. The thickness of that sediment layer increased slightly but significantly ($p \geq 0.05$) as more enzyme was added into individual samples.

Effects of Added PME on Particle Size. Measurements of relative turbidity and sedimentation indicated that PME addition increased both flocculation and clarification rates in the cloud. Rates of flocculation can be estimated more directly by analyzing changes in particle sizes. As discussed above, the particle size distribution of the entire juice sample was measured by gently inverting the juice samples, thus ensuring an even distribution of particle sizes throughout each sample, and then using static light scattering to determine particle diameters. Inspection of the particle size distribution profiles for each level of enzyme added showed that the carrot juice started with a trimodal distribution (Figure 3), i.e., three overlapping populations with different modes of approximately 0.7, 1.7, and 13 μm. In the absence of enzyme, this distribution did not change over time (Figure 3a). For the enzyme-containing systems, (Figure 3b–e), there was a rapid initial change occurring over the first ~9 days, during which the second modes shifted to larger diameters, leaving the size of the other two modes unaffected. As a result, the height of the first peak at smaller sizes shrank over time as that of the larger mode grew.

Examination of all enzyme levels (Figure 4a) indicated that the extent of this shift at earlier times did not strongly depend on the amount of enzyme; there was a similar increase in particle size for mode 2 at all levels of added enzyme. The first rapid shift was followed by a second, slower change in the distribution, as the second peak diameter gradually increased to merge with the third mode over ~30–40 days. This second growth process occurred more rapidly at higher enzyme concentrations at longer times. Consequently, data at day 5 exhibited little dependence on the amount of enzyme added, as long as some active enzyme was present (Figure 4a). Samples with 0.15, 0.25, and 0.5 U/g added PME also had very similar particle size distributions at 33 days of storage; it was only the sample with 1.0 U/g added PME that had a significantly greater particle size (Figure 4b). Finally, at day 43, the two highest enzyme concentrations both exhibited more significant particle growth than the other samples (Figure 4c).

The increase in particle size is an indication that flocculation was occurring within the cloud.[30,35] This is qualitatively visible in the light microscopy photos (Figure 5), as one can distinguish the individual particles that make up an aggregate. Clearly, the presence of active enzyme corresponded to the formation of flocs in the mixture, with the size of those flocs larger in the two samples with highest amounts of enzyme. Overall, the data in Figures 1–5 consistently indicates that as particles flocculated and grew in diameter, they began to settle out, causing clarification. Therefore, it can be concluded that the amount of enzyme present had a direct effect on the rate of flocculation and sedimentation. In addition, measurements of turbidity, sedimentation, and particle size distributions all indicate a process that occurred more rapidly over an initial period of ~5–10 days. This period is followed by a time of slower flocculation rates with little change in the observed sediment layer, although changes in the cloud structure were still occurring.

DISCUSSION

Adding PME to carrot juice caused juice clarification, as measured by sediment height and relative turbidity. With more added enzyme, the juice clarified more rapidly and to a greater extent. The clarification was accompanied by an increase in particle size. Although no previous research has been found on

dx.doi.org/10.1021/jf4043979 | J. Agric. Food Chem. 2014, 62, 1111–1118

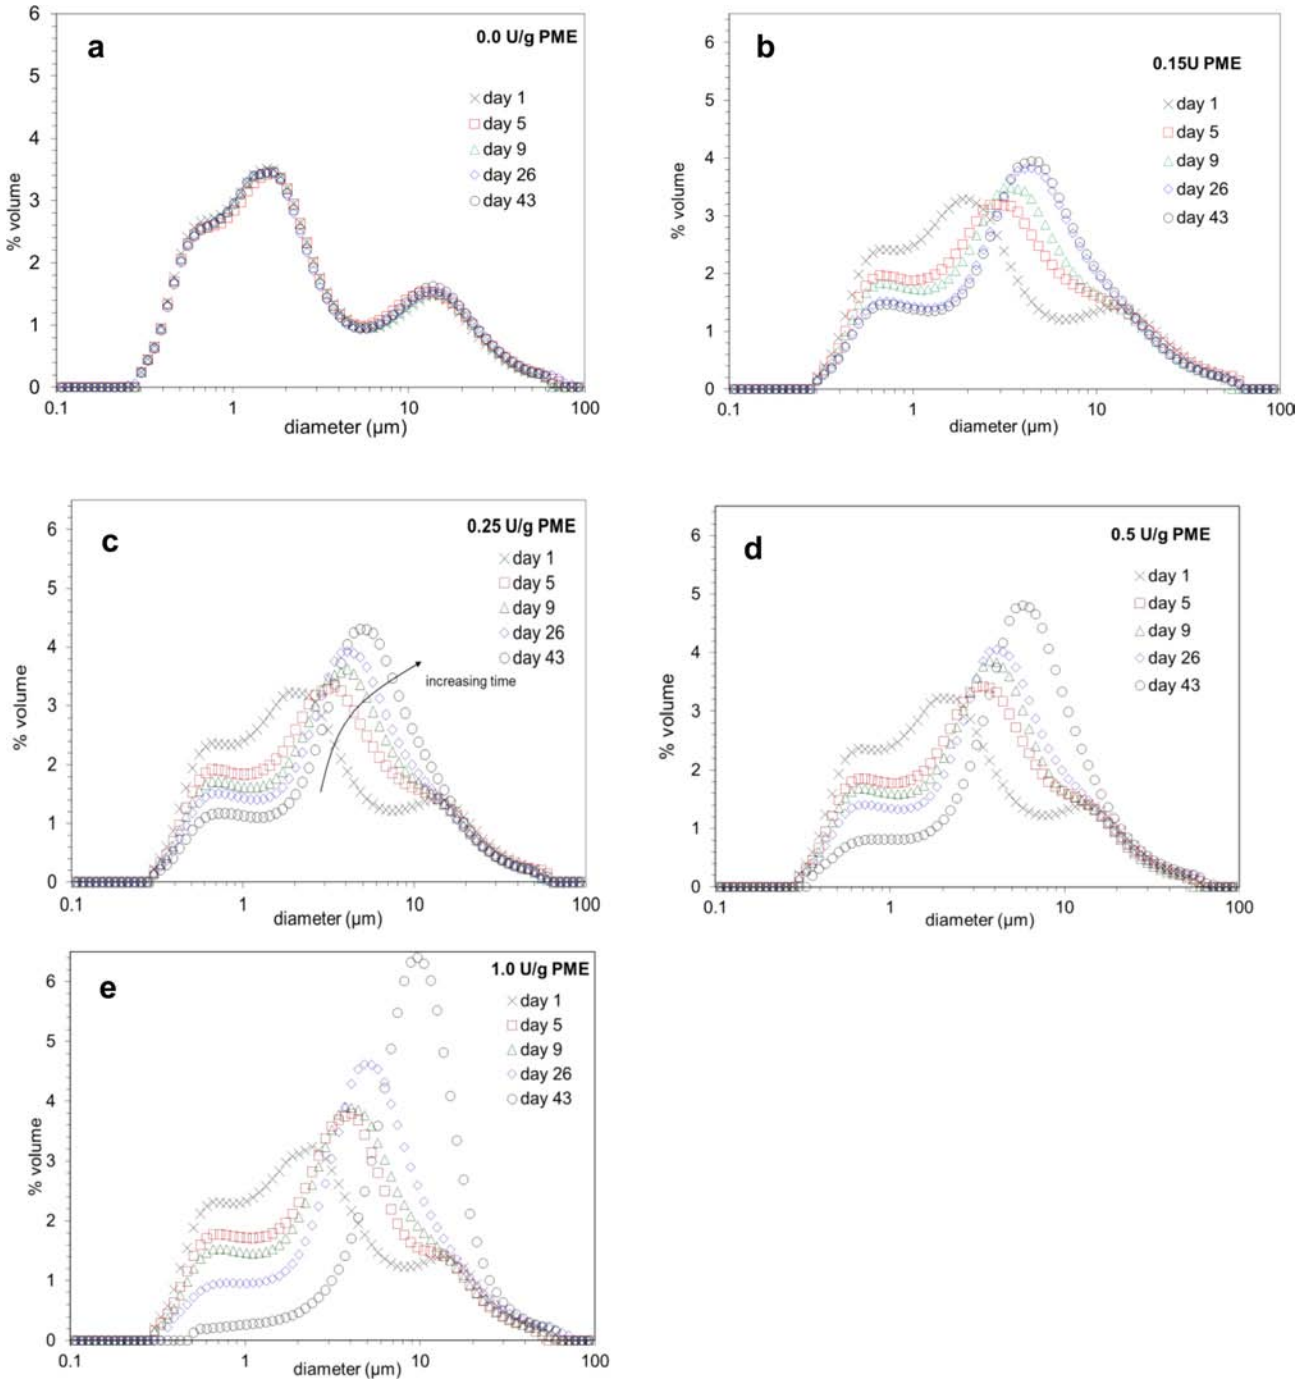

Figure 3. Particle size distribution curves for commercial carrot juice with no added PME (a) and with the following amounts of enzyme added: 0.15 (b), 0.25 (c), 0.5 (d), and 1.0 U/g (e). Though particle sizes were measured every three days for 56 days, data for only days 1, 5, 9, 26, and 43 were used to represent the size changes that occurred.

the addition of different enzyme levels back into juice, these results are consistent with those reported for native residual enzyme activity in commercial juices. In citrus and tomato juices, clarification occurred above a certain minimum threshold of PME activity.[7−9] In pineapple juice, residual PME activities of 4.1×10^{-4} U/mL did not cause complete clarification, whereas PME values 10 times greater resulted in complete clarification.[6]

Commercial juice was used instead of raw, unpasteurized juice for consistency and relevancy to the industry. However, there are important differences between commercial, pasteurized juice and raw juice that could affect the results. Preliminary work showed that juice made in the laboratory and filtered through cheesecloth had particle sizes 50 times greater than those of commercial carrot juice, with much greater variation in particle size. Additionally, our laboratory juice had 1.25 times more solid matter than commercial juice. Interestingly, when the carrots were blanched before juicing in the laboratory, the amount of solid matter became equal to that of the commercial juice, which would suggest that the heating of the carrot weakens the internal structure and allows particles to be broken down into smaller sizes and removed. This could account in

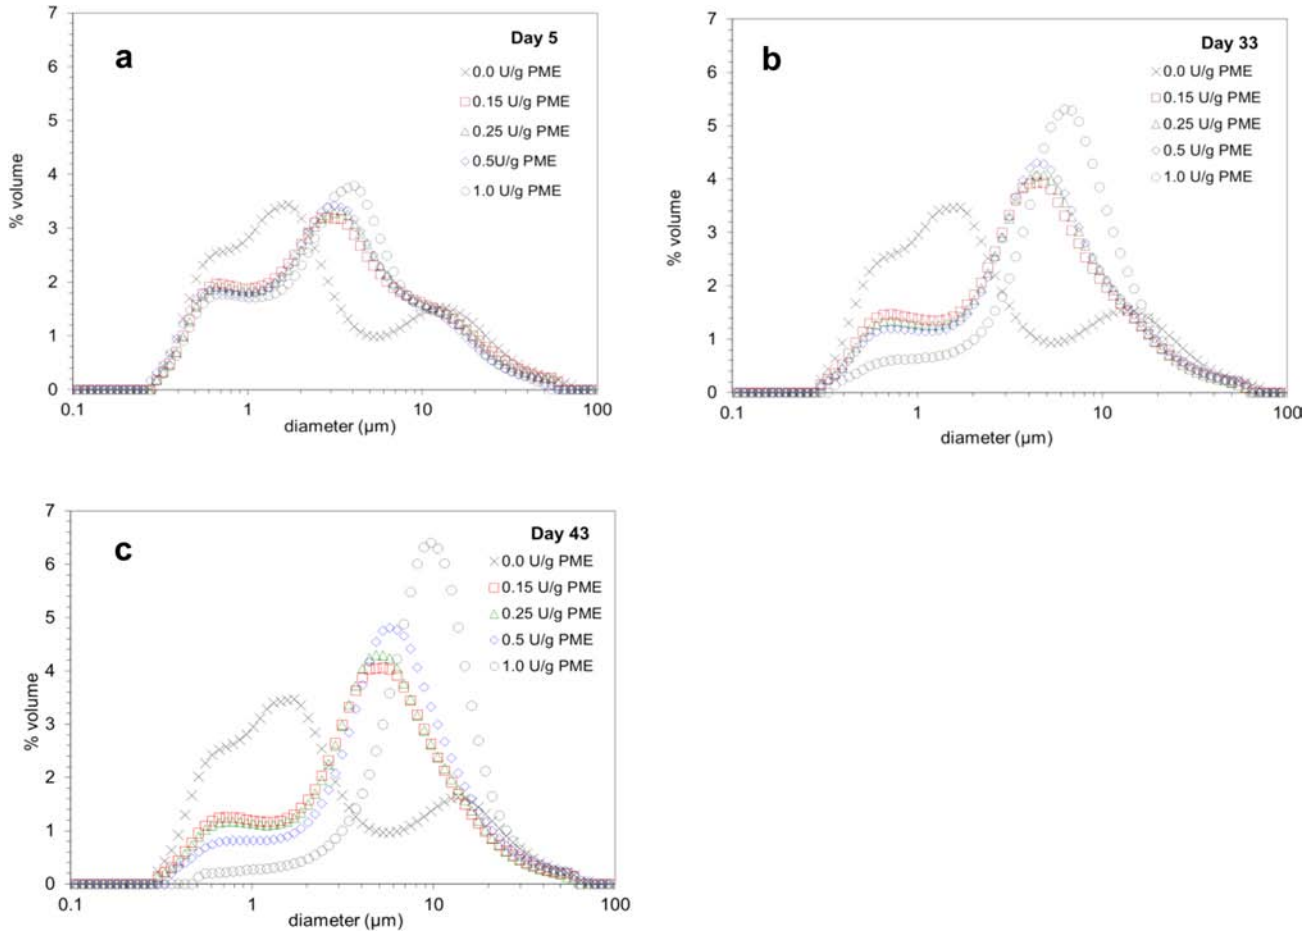

Figure 4. Comparison of particle size distribution of carrot juices with different amounts of added PME after 5 (a), 33 (b), and (c) 43 days.

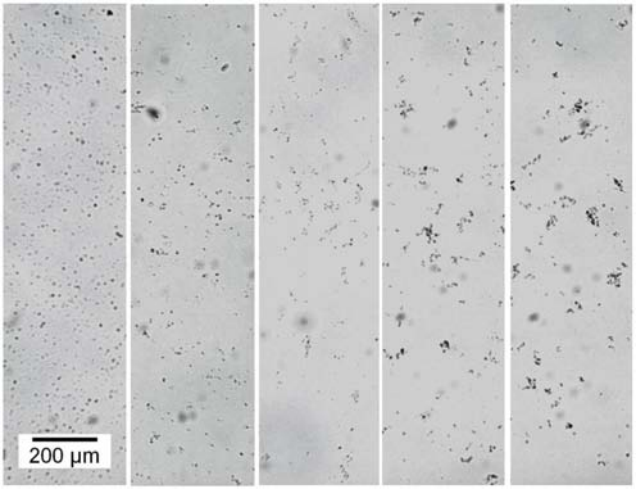

Figure 5. Commercial carrot juice with added enzyme viewed with 20× light microscopy at 56 days of storage at 5 °C. From left to right, enzyme levels are 0, 0.15, 0.25, 0.5, and 1.0 U/g.

part for the smaller particle sizes in pasteurized commercial carrot juice versus raw laboratory juice, and is supported by the work of Reiter et al. who found that pasteurized juice had smaller particle diameters than unpasteurized juice.[30] Processing techniques have a significant impact on cloud particle size; a study by Reiter et al.[30] showed the wide range of particle sizes (0.1−700 μm) for carrot juices produced with decanter technology from five different manufacturers. The commercial juice used in this study had <1% of particles >10 μm.[28] This indicates there is a wide range of processing techniques used in the juice industry that can result in different particle sizes.

The changes in sediment height and relative turbidity observed here were similar to one another in that both indicated an initially rapid destabilization process, followed by slower changes over time. Both also showed small but significant differences between juices with the three highest amounts of PME added at the later stages of the storage time course. Changes in particle size showed a similar trend. Over the first 5−10 days of storage, there was a relatively rapid increase in diameter of the population of smallest particles in the mixture. At longer times, sizes in the population of larger particles grew slowly, with the rate of this growth showing a modest dependence on enzyme concentration especially at the highest levels of added PME. By the end of the storage time course, all three measures of juice clarification, sediment height, relative turbidity, and particle size distribution, showed similar small differences between the juices with different levels of added PME. If PME induced clarification is due to enzymatic de-esterification of the juice pectins, then one might expect that clarification would occur more rapidly with more added enzyme but that all the juices would eventually reach the same end point.

Why the final states of the juices differed with differing amounts of added enzyme is not clear. One possibility is that the de-esterification of pectin by PME was only partial and that

dx.doi.org/10.1021/jf4043979 | J. Agric. Food Chem. 2014, 62, 1111−1118

the final degree of pectin esterification achieved depended on the amount of enzyme added. It is known that in the absence of high salt concentrations, PME binds strongly to de-esterified stretches of pectin, resulting in the formation of inactive PME−pectin complexes.[36] As a result, PME typically only partially de-esterifies a pectin chain before becoming inactive. It is possible that at higher levels of added PME, a higher final level of de-esterification is obtained because more pectin can be de-esterified before all the PME enzyme forms inactive PME−pectin complexes and de-esterification stops. The differences in particle size, aggregation, flocculation, and sedimentation between samples with different levels of added PME may all result from this difference in this final degree of esterification. It is even possible that all the PME catalyzed de-esterification in the juice occurred very rapidly, within the first day or two of the experiment. In that case, not only the different extents but also the different time courses for the particle sizes and sedimentation over the next 56 days could be due to the differences in final pectin esterification between the different levels of added PME, rather than being from different rates of de-esterification.

A second possibility is that particle aggregation and clarification is partially due to direct protein binding effects. Proteins (including PME) present in the high salt extract of cell wall material that was used as the source of the added PME may bind to the particulate matter in the juice, possibly affecting particle size aggregation. This is supported by the observations of Schmelter et al. who found that even thermally inactivated PME was able to cause pectin gelation in the presence of salts.[37] This ability of PME to create gels even when inactivated was taken as an indication that, in addition to its catalytic mechanism, the PME protein could participate in direct electrostatic and hydrophobic interactions with the pectin. Proteins also have the capability of interacting with each other in high acid environments (pH 4.4), and it has been argued that it is protein−protein interactions that influence cloud stability more than protein-pectin interactions.[30]

Our micrograph data and the overall kinetics in the system may indicate that particle growth is in the diffusion limited aggregation (DLA) regime. In such a regime, once a nucleation site is formed, additional particles may be added one at a time via the "hit and stick," describing a rapid, irreversible flocculation, without time for rearrangement.[38] Loose, fractal flocs are the result of such a mechanism,[35,39] consistent with what is observed in Figure 5. As more PME is added, flocculation occurs at a greater rate, creating even looser and therefore larger flocs. Such flocs have a greater effective diameter, and so sediment out more with centrifugation (Figure 1), yet they do not pack as tightly on the bottom because of their loose structure (Figure 2). Initially, in juice with a high level of added PME, it may be that particles do not have to diffuse far to encounter another particle with which they are able to flocculate. High amounts of PME create more particles of pectin that have a higher lower degree of esterification, and the PME itself can participate in flocculation. This would account for the relatively rapid increase in particle size at the beginning of storage.

MATERIALS AND METHODS

Plant Materials and Treatment. Fresh broccoli (*B. oleracea* var. *italica*) that was kindly supplied by the orchard of Anhui Academy of Agricultural Sciences, Anhui, China, and selected to avoid florets showing physical damage or microbial infection was used throughout this study. Solutions of sodium hydrosulfide ($NaHS{\cdot}3H_2O$, Sigma) were used as the hydrogen sulfide (H_2S) donor. Aqueous solutions (150 mL) of 0, 0.40, 0.80, 1.20, 1.60, 2.00, 2.40, 2.80, or 3.20 mM NaHS were prepared in sealed containers (volume 3 L). Six pieces of freshly cut broccoli florets (approximately 35 ± 2 g) from six different broccoli shoots were fumigated with H_2S in the sealed containers at 25 °C and 85−90% relative humidity. For dark-promoted senescence, the containers were stored in darkness. Treatment solutions were renewed daily and florets were observed every 24 h. Each experiment was repeated three times.

Visual Evaluation of Broccoli Senescence. The appearance of fresh-cut broccoli fumigated with H_2S gas was evaluated subjectively by 20 people using five indexes: freshness, rotting rate, yellowness, flavor, texture, and floret organization.[11] Each index was divided into four ranks and assigned scores of 2.0, 1.5, 1.0 and 0, with higher numbers assigned to better visual evaluation, and the sum of the five indexes is shown as a score from 0 to 10.

Determination of Functional Compounds in Broccoli. Chlorophyll content of broccoli florets was determined using the colorimetric method of Lichtenthaler and Wellburn with minor modifications.[12] About 0.50 ± 0.01 g of finely chopped broccoli floret samples was placed in an Erlenmeyer flask containing 5−10 mL of 80% acetone as extraction solvent. After extraction, the OD value of supernatant was recorded at 645 and 663 nm. Every analysis was repeated in triplicate, and the results were expressed as mg/g FW (fresh weight).

Carotenoid content of broccoli samples was determined by the method of Nath et al.[13] Fresh .50 ± 0.01 g sample was ground with 5−10 mL of acetone by adding 1.00 g of anhydrous Na_2SO_4. The supernatant was transferred to a beaker and the extraction step was repeated three times. The combined supernatants were transferred to a separating funnel, and 5−10 mL of petroleum ether was added and mixed thoroughly. The upper layer of petroleum ether was collected and absorbance recorded at 452 nm, and the amount of carotenoid was expressed as mg/g FW.

The following procedures were used for the assays of total phenols, flavonoids, and anthocyanin. Broccoli samples of 1.00 ± 0.01 g were homogenized with 10 mL of aqueous methanolic HCl (50% methanol, 0.05% concentrated HCl, pH 3.5), the brei was allowed to macerate for 24 h in the dark (0−4 °C), and the mixture was filtered for subsequent determination. Determination of total phenols was performed according to the method of Pirie and Mullins.[14] The content of total phenols was determined spectrophotometrically at 280 nm. A calibration curve was prepared for total phenols using gallic acid as the standard.

The determination of flavonoids was performed according to the work of Zhishen et al. with slight modification.[15] A 1.0 mL portion of filtrate was placed in a 10 mL volumetric flask, distilled water was added to make 5 mL, 0.3 mL of 5% $NaNO_2$ was added, and the solution was mixed thoroughly. After 5 min, 3 mL of 10% $Al(NO_3)_3$ was added, and the solution was mixed thoroughly. After 6 min, 2 mL of 1 M NaOH was added, the total was adjusted to 10 mL with distilled water, and the solution was mixed thoroughly again. The content of flavonoids was determined spectrophotometrically at 510 nm with rutin used as the standard for calibration.

The determination of anthocyanin was estimated according to the method of Lee and Wicker.[16] Absorption of the filtrate was recorded at 530, 620, and 650 nm. The content of anthocyanin was calculated using the formula below. One unit of anthocyanin content was expressed as a change of 0.1 OD value.

$$OD = (OD_{530} - OD_{620}) - 0.1 \times (OD_{650} - OD_{620})$$

Ascorbate was determined by the method described by Nath et al.[13] Floret samples of 2.00 ± 0.01 g were ground with 15 mL of 4% oxalic acid, and the homogenate was filtered through filter paper. The volume of filtrate was adjusted to 25 mL with 4% oxalic acid and titrated with 2,6-dichlorophenol-indophenol to a pink color.

Determination of the Contents of Reducing Sugar, Soluble Protein, Total Soluble Solids, and Free Amino Acids. For reducing sugars, broccoli samples (1.00 ± 0.01 g) were ground with 5 mL of sodium phosphate buffer (pH 7.0, 200 mM), the homogenate was centrifuged at 10 000 rpm for 30 min, and the supernatant was collected for subsequent analysis. The determination of reducing sugar was performed spectrophotometrically according to Miller's dinitrosalicylic acid method.[17] Each analysis was repeated in triplicate, and the results were expressed as mg/g FW.

Total soluble solid content was determined using a digital refractometer (Tongfang Inc., Shanghai, China) according to the method of Jiang et al.[18]

The content of soluble protein was determined by the method described by Bradford.[19] Supernatant (0.1 mL) was mixed with 0.9 mL of distilled water and 5 mL of 0.1 mg/mL Coomassie Brilliant Blue G-250. After 5 min, the OD value was recorded at 595 nm by spectrophotometer. Analyses were repeated in triplicate and the results expressed as mg/g FW.

Free amino acid content was measured according to the work of Hu et al. using an automatic amino acid analyzer (model S433D, Syknm, Germany).[8] Fresh-cut broccoli florets (0.50 ± 0.01 g) were ground with 5 mL of 80% ethanol, the homogenate was centrifuged at 10 000 rpm for 5 min, and the supernatant was heated at 80 °C to remove ethanol and to concentrate the sample to 1 mL.

Determination of Superoxide Anion ($\bullet O_2^-$), Hydrogen Peroxide (H_2O_2), and Malondialdehyde (MDA). Contents of $\bullet O_2^-$, H_2O_2, and MDA were determined according to the methods described by Hu et al.[8]

Determination of Enzyme Activities. Activities of guaiacol peroxidase (POD), ascorbate peroxidase (APX), catalase (CAT), glutathione reductase (GR), and lipoxidase (LOX) were determined by the procedures described by Hu et al.[8] Frozen broccoli floret samples (0.50 ± 0.01 g) were homogenized with 5 mL of ice-cold sodium phosphate buffer (200 mM, pH 7.8) containing 1.0 mM EDTA. The homogenate was centrifuged at 12 000 rpm (4 °C, 20 min), and the supernatant was used for activity measurement. Analysis of guaiacol POD activity was based on the oxidation of guaiacol by hydrogen peroxide. The reaction mixture contained 1.7−1.8 mL of sodium phosphate buffer (50 mM, pH 6.1), 0.1 mL of 3% H_2O_2, 1 mL of 1% guaiacol, and 100−200 μL of enzyme extract. The increase in absorbance at 420 nm was recorded. APX activity was determined in the presence of 0.5 mM ascorbate and 0.5 mM H_2O_2 by monitoring the decrease in absorbance at 290 nm. CAT activity was determined spectrophotometrically by monitoring the decrease in absorbance at 240 nm. The reaction mixture contained 2.8 mL of sodium phosphate buffer (50 mM, pH 7.0), 100 μL of 3% H_2O_2, and 100 μL of enzyme extract. The decrease of GR activity in absorbance at 340 nm was recorded. One unit of POD, APX, CAT, and GR activity was defined as an increase or decrease of 0.01 OD value per minute. The results were expressed as U/g FW.

The activity of LOX was determined in the presence of linoleic acid by monitoring the changes in absorbance at 234 nm. One unit of LOX activity was defined as a decrease of 0.01 OD value in absorbance per minute. The results were expressed as U/g FW.

The activity of polyphenol oxidase (PPO) was determined by procedures described by Benjamin and Montgomery.[20] Broccoli samples (2.00 ± 0.05 g) were homogenized with 5.0 mL of sodium phosphate buffer (50 mM, pH 6.8). After centrifugation, the supernatant was used for the activity assay using catechol as substrate. One unit of PPO activity was defined as an increase of 0.01 OD value in absorbance at 410 nm per minute. The results were expressed as U/g FW.

The activity of phenylalanine ammonia lyase (PAL) was determined by the procedures described by Beaudoin-Eagan and Thorpe.[21] One unit of PAL activity was defined as a change of 0.01 OD value in absorbance at 290 nm per minute. The results were expressed as U/g FW.

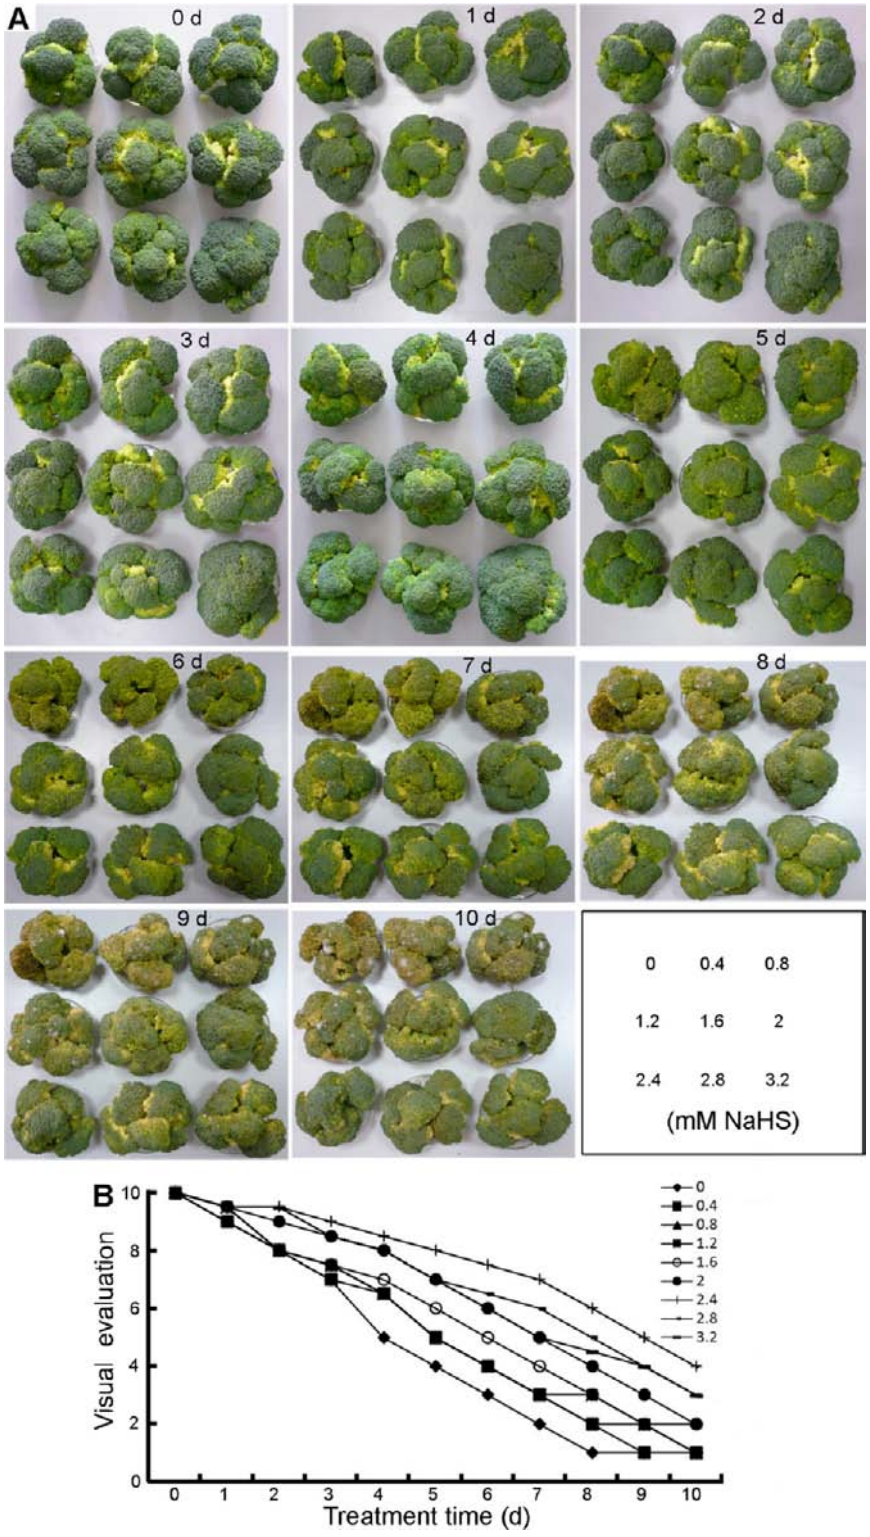

Figure 1. Effects of H_2S on the senescence and visual evaluation in postharvest broccoli. Broccoli florets were fumigated with different concentrations (0, 0.4, 0.8, 1.2, 1.6, 2.0, 2.4, 2.8, or 3.2 mM) of aqueous solutions of NaHS for 0−10 d, respectively, and the experimental treatments are shown in lower right of part A. Photographs (A) were taken from day 0 to 10, and visual evaluation (B) was recorded. The experiments and following ones were carried out at room temperature and 85−90% relative humidity.

The activity of protease was measured according to the method described by Reimerdes and Klostermeyer.[22] Broccoli florets (0.50 ± 0.01 g) were homogenized with 5 mL of ice-cold Tris-HCl buffer [50 mM, pH 7.5, included 1 mM ethylene diamine tetraacetic acid (EDTA), 15 mM β-mercaptoethanol, and 1% PVP]. The homogenate was centrifuged at 10 000 rpm (4 °C, 30 min), and the supernatant was used for activity determination. One unit of protease activity was defined as an increase of 0.01 OD value at 278 nm per hour, and the results were expressed as U/g FW.

RNA Extraction and Reversed Transcript Polymerase Chain Reaction (PCR). Fresh-cut broccoli florets were ground in liquid nitrogen, and RNA was extracted by the RNAiso Plus according to the

dx.doi.org/10.1021/jf4047122 | J. Agric. Food Chem. 2014, 62, 1119−1129

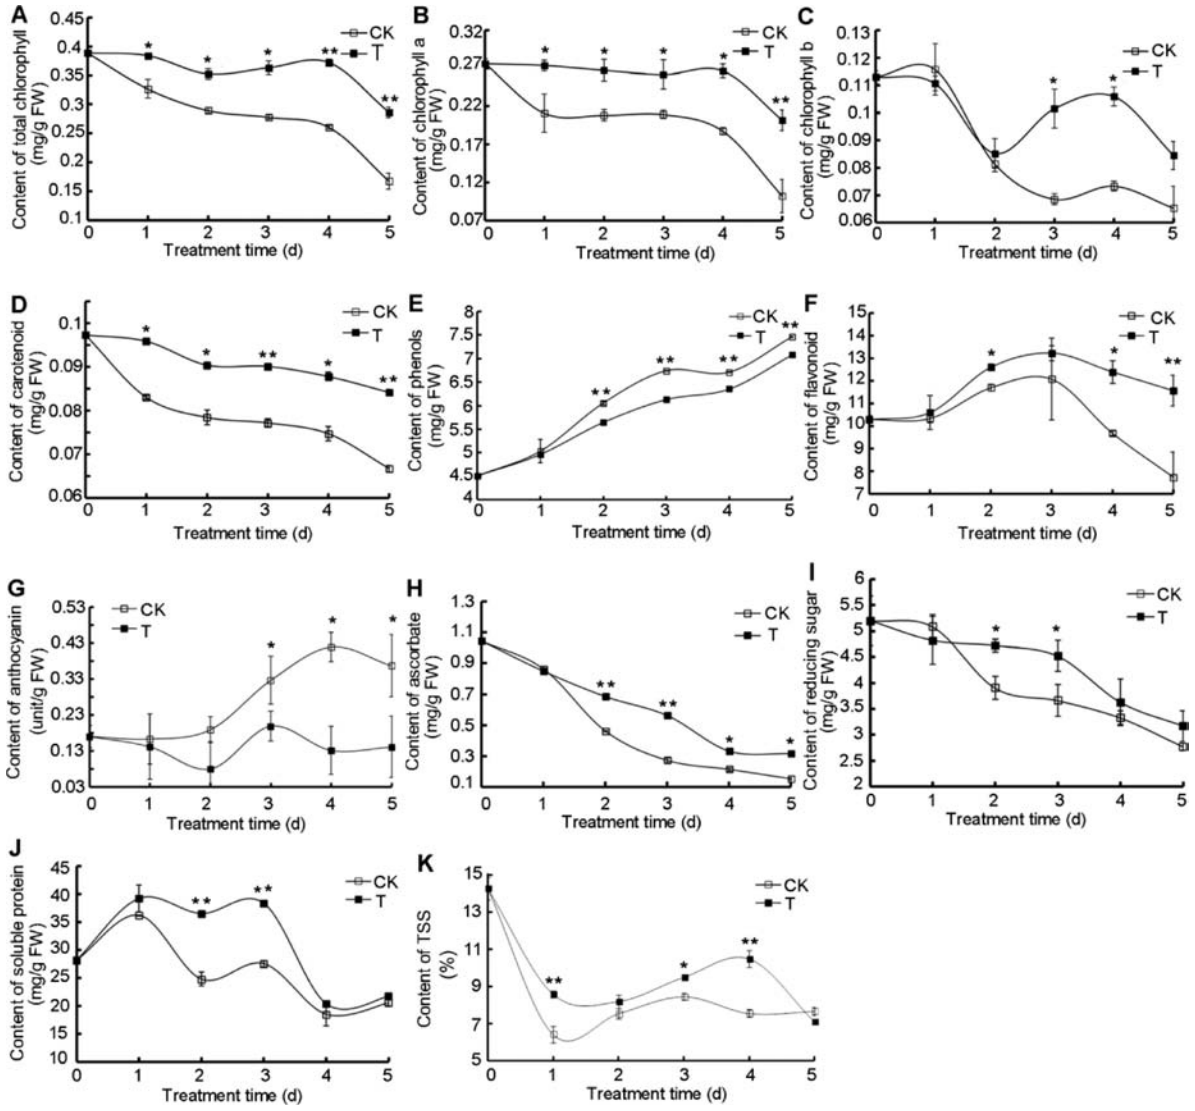

Figure 2. Effects of H_2S on the contents of total chlorophyll (A), chlorophyll *a* (B), chlorophyll *b* (C), carotenoid (D), total phenols (E), flavonoid (F), anthocyanin (G), ascorbate (H), reducing sugar (I), soluble protein (J), and total soluble solids (TSS) (K) in postharvest broccoli. Broccoli florets were fumigated with 2.4 mM H_2S donor NaHS aqueous solution (T) with water as the control groups (CK) for 0−5 d. Data are presented as means ± SD (n = 3). * and ** in this figure and following ones stand for a significant difference between CK and T at $P < 0.05$ and $P < 0.01$, respectively.

manufacturer's instructions (Takara, Kyoto, Japan), and total RNA was used for cDNA synthesis using a reverse transcription kit (Prime Script RT Master Mix, Takara, Kyoto, Japan). The resulting cDNA was applied as template for PCR using a PCR system with Easy Taq DNA Polymerase (TransGen, Beijing, China). The PCR primers used for detecting the genes *BoSGR* (stay-green protein), *BoNYC* (chlorophyll *b* reductase), *BoCLH1* (chlorophyllase 1), *BoCLH2* (chlorophyllase 2), *BoPaO* (pheophorbide *a* oxygenase), *BoPPH* (pheophytinase), *BoRCCR* (red catabolite chlorophyll reductase), and *BoACT* (actin) followed the methods of Hasperué et al.[23] The following primers were utilized to assess relative expression of *BoCP1* (cysteine protease) and *BoLOX1* (lipoxygenase 1) by PCR: *BoCP1*, 5′-CGCCGATCTG-ACCAACGAA-3′ and 5′-CCGCTCCAATCGCAGAAAA-3′; *BoLOX1*, 5′-TCTCCACGAATTTCTGGGAAACAAAG-3′ and 5′-AGTCCTCTGAGTGTGTAGCCTTTC-3′. Three independent extracts of RNA were done and similar results were obtained.

Analysis of Rubisco. Fresh-cut broccoli florets were homogenized using a chilled mortar and pestle in sodium phosphate buffer (50 mM, pH 7.5) containing 1 mM EDTA, 15 mM 2-mercaptoethanol, and 1% (v/v) PVP, and the homogenate was centrifuged at 15 000 rpm for 10 min at 4 °C. Then the supernatant was collected for Rubisco analysis. The Rubisco was visualized by nondenaturing PAGE with Coomassie Brilliant Blue R-250 staining according to the method of Ono et al.[24]

Other Vegetables and Fruits Fumigated with H_2S. Fresh-cut lotus root, potato, yams, lettuce, pumpkin, and peach, kindly supplied by the orchard of Anhui Academy of Agricultural Sciences, Anhui, China, were fumigated with different concentrations of H_2S donor NaHS and photographed.

Statistical Analysis. Statistical significance was tested by one-way analysis of variance (ANOVA), and the results are expressed as the mean values ± standard deviation (SD) of three independent experiments. Fisher's least significant differences (LSD) were calculated following a significant ($P < 0.01$ or $P < 0.05$) t test.

RESULTS

H_2S Alleviates the Senescence of Postharvest Broccoli. In our experiments, broccoli florets were fumigated with H_2S released by different concentrations of aqueous solutions of NaHS with water as the control. As shown in Figure 1A, H_2S fumigation alleviated postharvest senescence of broccoli in a dose-dependent manner. Water control broccoli

[a]Postharvest broccoli were fumigated with 2.4 mM H_2S donor NaHS aqueous solution (T) with water as the control groups (CK) for 0−2 d (CK0, CK1, CK2, T1, and T2). Data are presented as means ± SD (n = 3). The contents of free amino acids were determined by automatic amino acid analyzer (model S433D, Sykmn). Different letters indicate significant differences ($p < 0.05$) between the treatments.

matured and yellowed quickly after 3 days of storage, while different NaHS treatment alleviated the postharvest yellowing of broccoli with an optimal concentration of 2.4 mM. Visual quality was evaluated according to the freshness, rotting rate, yellowness, flavor, texture, and organization. As shown in Figure 1B, 2.4 mM NaHS treatment showed the optimal effect on the visual quality of postharvest broccoli and thus was used in subsequent experiments.

Effect of H_2S on the Contents of Chlorophyll, Carotenoid, Total Phenols, Flavonoids, Anthocyanin, Ascorbate, Reducing Sugar, Soluble Proteins, and Total Soluble Solids. To further understand how H_2S alleviated yellowing and browning of fumigated broccoli, we determined the contents of chlorophyll, carotenoid, phenols, flavonoids, anthocyanin, and ascorbate in broccoli. Chlorophyll contents (Figure 2A) were expressed as the sum of chlorophyll *a* (Figure 2B) and chlorophyll *b* (Figure 2C). As shown in Figure 2A−C, total chlorophyll content as well as the amounts of chlorophylls *a* and *b* decreased gradually during storage in water controls, while H_2S fumigation maintained a relatively stable level of total chlorophyll and chlorophyll *a* until day 4, followed by a decrease on day 5, and also a higher level of chlorophyll *b* at the late stage of storage.

Carotenoid pigments protect cellular membranes by scavenging or quenching free radicals[25] acting as an essential lipid-soluble antioxidant in plants. Changes in carotenoid content, which consist of *β*-carotene and lutein, are shown in Figure 2D. The content of carotenoid decreased rapidly in the water control, whereas H_2S fumigation significantly prevented this decrease.

Regardless of treatment, total phenols increased steadily in broccoli florets with time (Figure 2E). However, broccoli fumigated with H_2S maintained lower levels of total phenols compared with water controls after 2 d of storage. As shown in Figure 2F, flavonoid content increased gradually in both treatments until 3 d followed by a rapid decrease in water controls, while H_2S fumigation alleviated the decrease and sustained a significantly higher level of flavonoids on days 4 and 5.

The content of anthocyanin in broccoli florets increased steadily in the water control until 5 d of storage, as shown in Figure 2G, but anthocyanin content in H_2S-fumigated broccoli was maintained at a significantly lower level compared with that of water controls. As shown in Figure 2H, the content of ascorbate in broccoli florets decreased during postharvest storage in both treatments; however, H_2S fumigation significantly alleviated the decrease after 2 d of storage.

The contents of reducing sugars and soluble proteins are shown in Figure 2I,J. The content of reducing sugar decreased gradually in both H_2S-fumigated and water control tissue throughout the storage time; however, the content of reducing sugar in postharvest broccoli fumigated with H_2S was higher than that of control on days 2 and 3 of storage. As shown in Figure 2J, soluble protein levels in H_2S-fumigated broccoli increased on day 1 and remained stable until day 3 followed by a drop on day 4. A similar pattern was observed in water control, except that the soluble protein level decreased sharply on day 2 and increased slightly on day 3. H_2S fumigation sustained significantly higher level of soluble protein on days 2 and 3 relative to that of water control.

The contents of soluble solids decreased sharply after 1 day of storage in H_2S treatment and water controls; thereafter, the contents varied slightly (Figure 2K). However, H_2S application

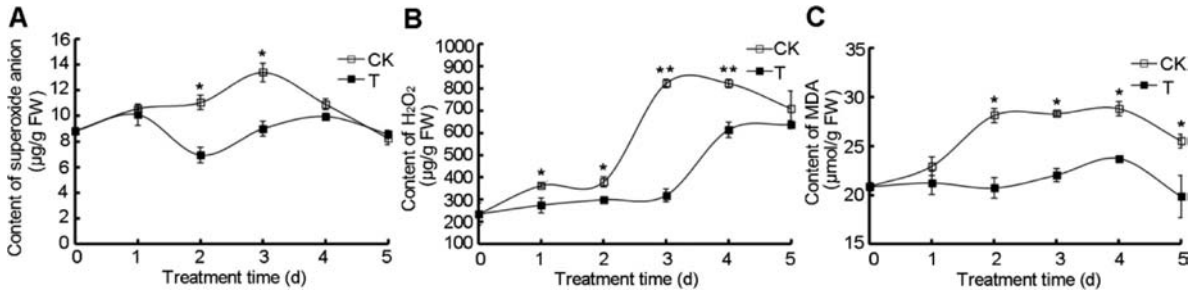

Figure 3. Effects of H_2S on the accumulation of superoxide anion ($\bullet O_2^-$) (A), hydrogen peroxide (H_2O_2) (B), and malonaldehyde (MDA) (C). Broccoli florets were fumigated with 2.4 mM H_2S donor NaHS aqueous solution (T) with water as the control groups (CK) for 0−5 d. Data are presented as means ± SD (n = 3).

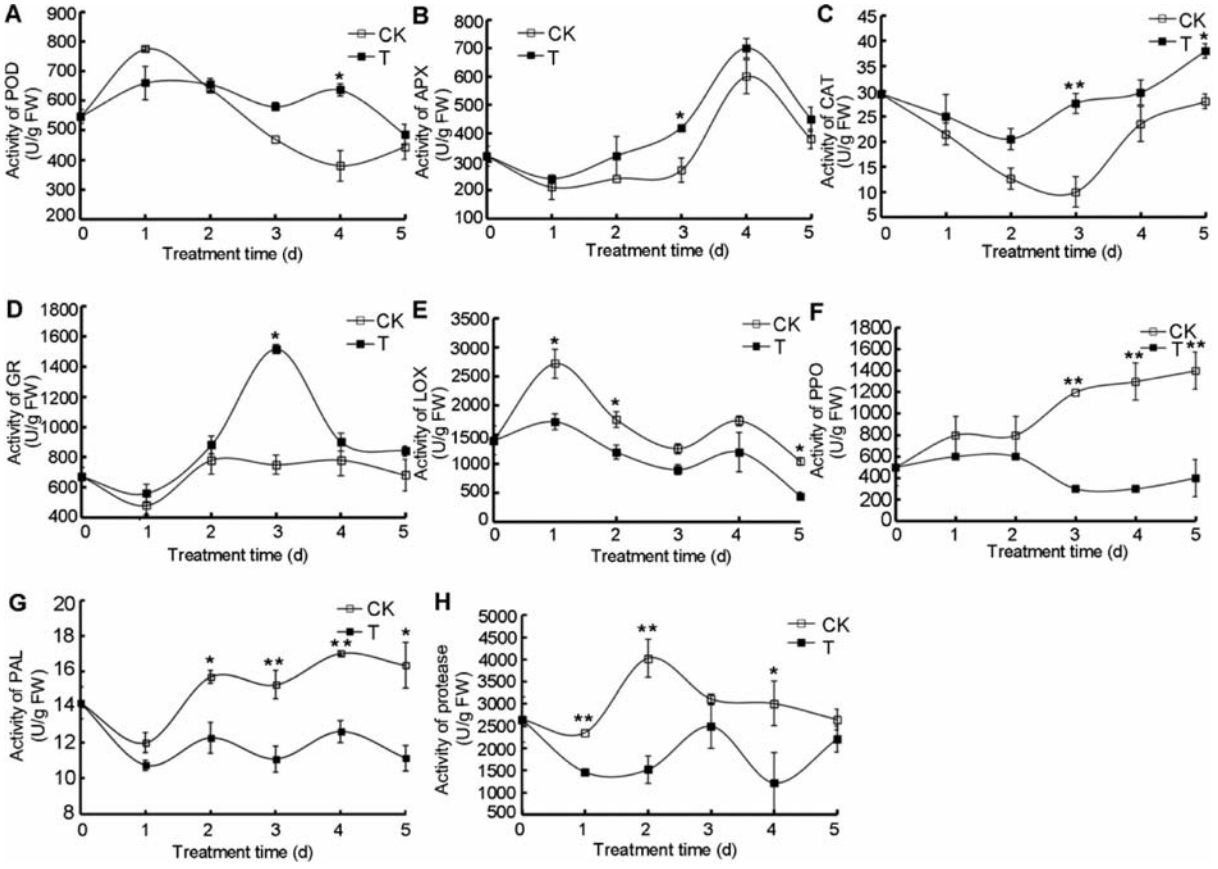

Figure 4. Role of H_2S in the regulation of the activities of guaiacol peroxidase (POD) (A), ascorbate peroxidase (APX) (B), catalase (CAT) (C), and glutathione reductase (GR) (D) and the down-regulation of lipoxygenase (LOX) (E), polyphenol oxidase (PPO) (F), phenylalanine ammonia lyase (PAL) (G), and protease (H) in postharvest broccoli florets. Postharvest broccoli florets were fumigated with 2.4 mM H_2S donor NaHS aqueous solution (T) with water as the control groups (CK) for 0−5 d. Data are presented as means ± SD (n = 3).

maintained significantly higher levels of soluble solids than water controls on days 1, 3 and 4.

Effect of H_2S on the Contents of Free Amino Acids in Postharvest Broccoli. H_2S fumigation sustained lower levels of free amino acids compared with water control (Table 1). Storage and senescence induced a rapid increase of total amino acid contents, regardless of treatment, although exposure to H_2S gas alleviated the increase. With the exception of Asp, the content of free amino acids in H_2S-fumigated and control broccoli was higher than that of freshly harvested broccoli. In addition, H_2S did not significantly affect the levels of Gly, Ala, and His on day 1, while a significant decrease of Gly and His appeared on day 2 compared with water control. Many amino acids, including Asn, Cys, Gln, Met, Pro, Thr, Trp, and Tyr, were not detected in broccoli during storage.

H_2S Decreases the Content of MDA and Reactive Oxygen Species, $\bullet O_2^-$ and H_2O_2. The contents of $\bullet O_2^-$, H_2O_2 and MDA in broccoli fumigated with H_2S and water are shown in Figure 3A−C. The overproduction of reactive oxygen species and the occurrence of oxidative damage are universal events during vegetable storage. $\bullet O_2^-$ accumulated steadily during the first 3 d of storage in water controls followed by a gradual decrease, whereas H_2S fumigation significantly alleviated $\bullet O_2^-$ accumulation at 2 and 3 d of storage (Figure 3A). H_2O_2 production in postharvest broccoli was rapidly enhanced on 3 d of storage and thereafter was maintained at a relatively higher level than that of H_2S-fumigated florets (Figure

dx.doi.org/10.1021/jf4047122 | J. Agric. Food Chem. 2014, 62, 1119−1129

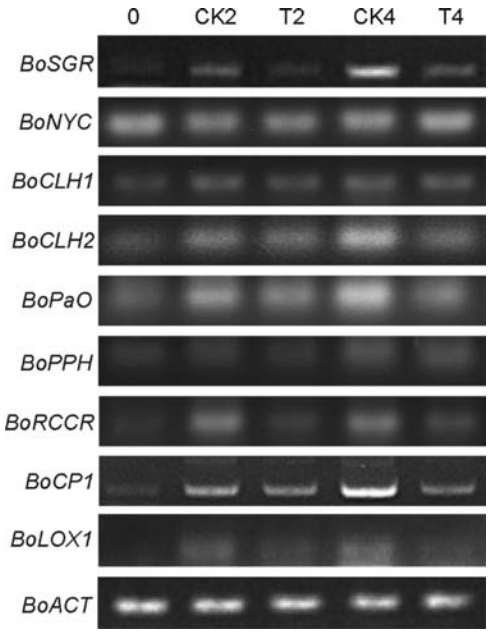

Figure 5. Effect of H_2S on the relative expression of *BoSGR* (stay-green protein), *BoNYC* (chlorophyll *b* reductase), *BoCLH1* (chlorophyllase 1), *BoCLH2* (chlorophyllase 2), *BoPaO* (pheophorbide *a* oxygenase), *BoPPH* (pheophytinase), *BoRCCR* (RCC reductase), *BoCP1* (cysteine protease), *BoLOX1* (lipoxygenase), and *BoACT* (actin, AF044573) in broccoli florets fumigated with 2.4 mM H_2S donor NaHS aqueous solution (T) and water as the control groups (CK) for 0, 2, and 4 d, respectively. *BoACT* was used as a control gene.

3B). In contrast, H_2O_2 content of H_2S-treated tissue was maintained at a low level for 3 d until a burst appeared on d 4.

As shown in Figure 3C, MDA accumulated steadily in control broccoli during the first 2 d of storage and then was maintained at a stable level until 4 d followed by a slight decline. In contrast, H_2S fumigation sustained a constant lower level of MDA during storage compared with water control (Figure 3C).

Changes in the Activities of Guaiacol Peroxidase, Ascorbate Peroxidase, Catalase, Glutathione Reductase, Lipoxygenase, Polyphenol Oxidase, and Phenylalanine Ammonia Lyase. The activities of enzymes involved in oxidative metabolism in plants, such as guaiacol peroxidase (POD), ascorbate peroxidase (APX), catalase (CAT), glutathione reductase (GR), lipoxygenase (LOX), polyphenol oxidase (PPO), and phenylalanine ammonia lyase (PAL) were measured in broccoli exposed to 2.4 mM NaHS and water (Figure 4). As shown in Figure 4A, POD activities in H_2S-treated broccoli were maintained at a higher level than those of controls after 4 d of storage and then decline. In control tissue, POD increased on day 1 and decreased steadily until 4 d of storage. Figure 4B illustrates similar changes in the activity of APX in broccoli exposed to H_2S or water. APX activity increased in both treatments after 1 d of storage and peaked on day 4 followed by a decline. The activity of APX in H_2S-fumigated broccoli was always higher than that of control during 5 d storage. The activities of CAT in postharvest broccoli under both treatments are described in Figure 4C. CAT activity in H_2S and water controls decreased gradually with the lowest level appearing on days 2 and 3, respectively. Thereafter, CAT activity increased steadily in both treatments, while H_2S fumigation always maintained higher CAT activity than water control. For instance, on day 3 of storage, H_2S fumigation induced a 3-fold increase of CAT activity compared with water control. Figure 4D showed similar variations in GR activities in both treatments, except that H_2S fumigation induced a burst of GR activity on 3 d of storage. GR activities decreased slightly during the first day of storage in both treatments, but H_2S fumigation induced a rapid increase of GR activity until day 3, followed by a sharp decline on day 4. In contrast, GR activity in water control was maintained at a relative lower and stable level compared with H_2S treatment.

LOXs belong to a large family of plant enzymes that catalyze the hydroperoxidation of polyunsaturated fatty acids. Figure 4E showed a similar change pattern in LOX activity between control and H_2S treatment, while H_2S fumigation sustained a lower level of LOX compared with water controls. LOX activity was induced greatly in the first day of storage and then fluctuated in water controls. However, LOX activity was maintained at a lower level in H_2S-treated tissue than in water controls.

Changes in the activities of PPO are illustrated in Figure 4F and show that H_2S fumigation maintained lower PPO activities compared with controls during the entire postharvest storage period. PPO activities increased gradually in control broccoli, while those of H_2S-treated florets were maintained at lower levels. Changes in PAL activity, an enzyme that catalyzes the first step in the phenylpropanoid pathway, are shown in Figure 4G. PAL activity declined during the first day of storage in both treatments. Thereafter, PAL activity increased gradually in water control broccoli, whereas the activity fluctuated at a lower level in H_2S treatment. Surface browning is frequently observed in fresh-cut vegetables and is highly related to the activities of PPO and PAL. We observed lower levels of phenols and lower PAL and PPO activities in H_2S-fumigated broccoli compared with water control, suggesting that H_2S postponed the browning process in postharvest broccoli.

The changes of protease activities are shown in Figure 4H. Consistent with the higher level of soluble protein in H_2S-fumigated broccoli (Figure 2J), the activity of protease in H_2S-fumigated broccoli was always lower than that of controls. On day 2 of storage, protease activity was enhanced greatly in water control broccoli. Consistent with the lower level of protease in H_2S-fumigated broccoli, the total free amino acids in H_2S-fumigated samples were lower than that of water controls (Table 1).

Effect of H_2S on the Relative Expressions of Senescence-Related Genes. Broccoli senescence is accompanied by chlorophyll degradation and protein degradation. Therefore, we examined the effects of H_2S fumigation on the expression of the chlorophyll degradation related genes *BoSGR*, *BoCLH2*, *BoPaO*, *BoRCCR*, cysteine protease gene *BoCP1*, and lipoxygenase gene *BoLOX1*. As shown in Figure 5, the expression of *BoSGR*, *BoCLH2*, *BoPaO*, *BoRCCR*, *BoCP1*, and *BoLOX1* were induced after 2 d of storage in water, suggesting that these genes were expressed along with senescence, while H_2S fumigation showed lower expression levels of these genes on days 2 and 4 of storage. In contrast, the expression levels of *BoNYC*, *BoCLH1*, and *BoPPH* were relatively stable during storage and H_2S fumigation showed marginal effects on the expression of these genes.

Effect of H_2S Fumigation on Dark-Promoted Senescence. Dark treatments have been used as a conventional method to induce plant senescence.[26] Thus, we examined whether H_2S fumigation could alleviate dark-promoted

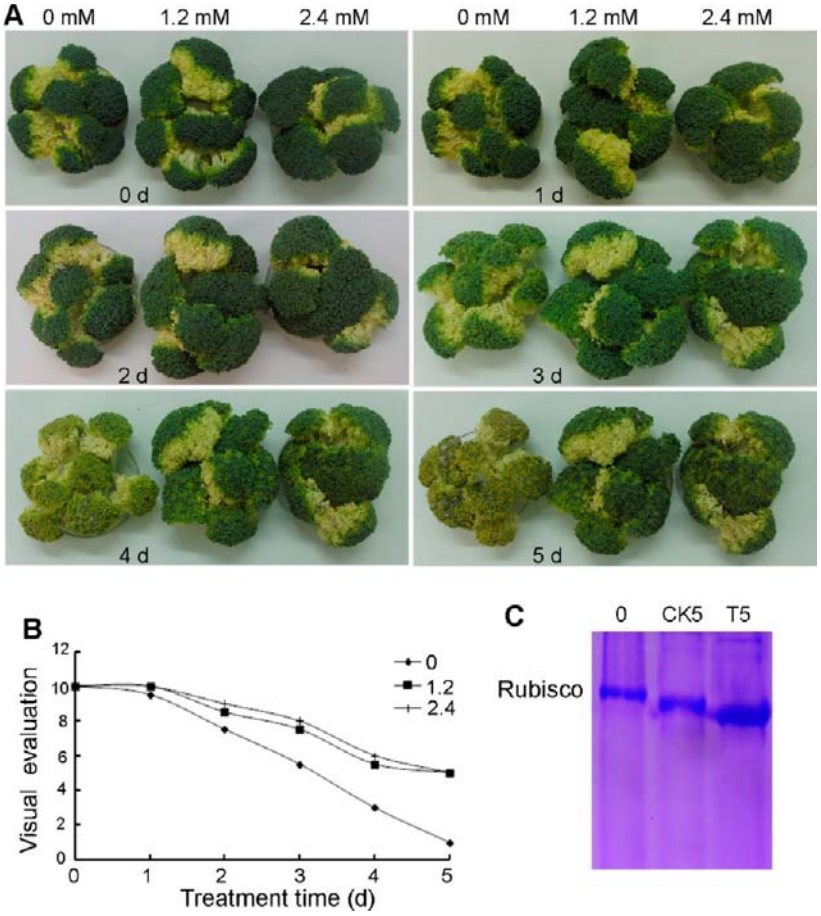

Figure 6. Effects of H_2S on dark-induced senescence, visual evaluation, and Rubisco degradation in postharvest broccoli. Broccoli florets were fumigated with different concentrations (0, 1.2, and 2.4 mM) of aqueous solutions of NaHS for 0−5 d, respectively. Photographs (A) were taken from day 0 to 5, and the visual evaluation (B) was recorded. Effect of H_2S on the degradation of Rubisco in darkness (C) in broccoli florets fumigated with 2.4 mM H_2S donor NaHS aqueous solution (T) and water as the control groups (CK) for 0−5 d. Lanes 1−3 from left to right in part B represent broccoli florets in dark-induced senescence for 0 d, 5 d (CK5), and 5 d (T5), respectively. The proteins of broccoli samples were separated by nondenaturing PAGE and then stained with Coomassie Brilliant Blue R-250.

senescence in broccoli. As shown in Figure 6A, 1.2 and 2.4 mM NaHS treatments effectively alleviated the dark-promoted senescence of postharvest broccoli. Visual evaluation showed that NaHS treatment maintained higher quality of postharvest broccoli than water controls (Figure 6B).

During leaf senescence, Rubisco is gradually degraded, and its components are recycled within the plant; therefore, we examined whether H_2S fumigation alleviated Rubisco degradation during broccoli senescence. As shown in Figure 6C, during dark-promoted senescence, H_2S fumigation maintained higher level of Rubisco compared with water treatment, suggesting the important role of H_2S in alleviating Rubisco degradation.

H_2S Alleviates the Senescence of Other Vegetables and Fruits. As shown in Figure 7, when postharvest lotus root, potato, yams, lettuce, pumpkin, and peach were fumigated with different concentrations of the H_2S donor NaHS, their shelf lives were prolonged. H_2S fumigation also prevented the surface browning of lotus root, potato, yams, lettuce, and peach. This survey of H_2S fumigation on the senescence of these postharvest vegetables and fruits also suggests that the role of H_2S in alleviating senescence might be universal in plants, probably by the activation of the antioxidant enzymes. H_2S also reduced the browning process in fumigated postharvest lotus root, potato, yam, and lettuce, further confirming a role for H_2S in regulating postharvest processes in these plants.

DISCUSSION

Due to the reduction in the content of carbohydrate, protein, vitamins, and antioxidants, broccoli florets are perishable and senescent after harvest.[1,25] As broccoli deteriorates, it undergoes chlorophyll degradation, lipid peroxidation, cell necrosis.[27] Our results show that H_2S can alleviate the senescence of postharvest broccoli under natural and dark-promoted senescence conditions (Figures 1 and 6) and maintain higher contents of nutrients (Figure 2). During postharvest storage, we observed a decrease of chlorophylls, carotenoids, flavonoids, and ascorbate, while H_2S application to postharvest broccoli can alleviate such decreases. The nonenzymatic antioxidant system in plants consists of ascorbate, carotenoids, and flavonoids and is capable of quenching ROS generated during postharvest storage.[28,29] The yellowing of plants is positively correlated to the degradation of chlorophyll.[30] The stable content of chlorophyll under H_2S fumigation, as observed in the present study (Figure 1A), strongly supports the role of H_2S in alleviating senescence. The content of anthocyanin accumulated highly in water control compared to H_2S-fumigated broccoli during storage. Anthocyanin accumulated in leaves during autumn senescence,[31] suggesting that in the present study H_2S fumigation postponed senescence in broccoli florets.

Figure 7. Effect of H_2S fumigation on the senescence of other vegetables and fruits. Fresh-cut vegetables and fruits of lotus root (A), potato (B), yams (C), lettuce (D), pumpkin (E), and peach (F) were fumigated with different concentrations of NaHS as shown in the lower part of every figure. Photographs were taken at different times, as shown in each single figure.

The reducing sugar, soluble protein, soluble solid, and free amino acids were also determined in broccoli during postharvest storage. H_2S sustained higher level of reducing sugar, soluble protein, and soluble solid than water control. In contrast, the total content of free amino acids accumulated more in water control than in H_2S-fumigated broccoli. Consistently, H_2S sustained lower level of protease activity, whose primary role in plant senescence is to remobilize the nutrients out of dying cells into actively growing tissues in the plant.[30]

Overproduction of reactive oxygen species and oxidative damage are universal events during vegetable storage. In the present study, H_2S significantly alleviated the accumulation of superoxide anion, hydrogen peroxide, and MDA. Plants have evolved the capacity to scavenge ROS by antioxidants, such as ascorbate and phenols, and antioxidative enzymes SOD, POD, APX, CAT, and GR.[32] The ascorbate−glutathione cycle maintains homeostasis of ascorbate and glutathione in plants, and consequently, we measured their levels during broccoli senescence.[28] In the present study, we observed decreased levels of H_2O_2, $\bullet O_2^-$, and MDA and enhanced activities of POD, CAT, APX, and GR, suggesting the signaling role of H_2S in activating the antioxidant enzymes.

The senescence of postharvest vegetables is accompanied with lipid peroxidation mediated mainly by LOXs (lipoxygenases). LOXs belong to a large family of plant enzymes that catalyze the hydroperoxidation of polyunsaturated fatty acids and lead to the production of MDA.[27] We found that H_2S sustained lower levels of LOX and lower expression level of *BoLOX1* compared with water control. Correspondingly, the accumulation of MDA was also reduced by H_2S, suggesting that oxidative stress in postharvest broccoli was alleviated by H_2S.

Surface browning is frequently observed in fresh-cut vegetables. Phenylalanine ammonia lyase (PAL) and polyphenol oxidase (PPO) are two key enzymes in the synthesis of free phenolics and the catalytic oxidation of phenolics to brown-colored pigments, respectively, and were found to have a strong relevance to surface browning.[33,34] We observed a lower level of phenols and lower levels of PAL and PPO activities in H_2S-fumigated broccoli compared with water control, implicating that H_2S postponed the browning process in fresh-cut broccoli. The study of H_2S on the senescence of other vegetables and fruits also suggested that the role of H_2S in alleviating senescence might be universal in plants. The reduced browning process observed in H_2S-fumigated fresh-cut lotus root, potato, yam, and lettuce further confirms a role of H_2S in browning inhibition.

H_2S can be produced endogenously in plants, and H_2S emission has been observed in plants attacked by pathogens or when under abiotic stresses as part of sulfur-induced resistance (SIR) response,[5] suggesting a signaling role of H_2S in plant growth and development. More recently, we found that

dx.doi.org/10.1021/jf4047122 | J. Agric. Food Chem. 2014, 62, 1119−1129

exogenous H_2S is involved in preventing senescence of cut flowers and strawberry.[7,8] Álvarez et al. found that the *DES1* mutation led to premature leaf senescence and induced autophagy phenotype in *Arabidopisis*, suggesting an important role of sulfide in senescence.[9,10] The underlying mechanism of hydrogen sulfide in senescence alleviation is not completely known. Here we found that the expression of chlorophyll degradation related genes *BoSGR*, *BoCLH2*, *BoPaO*, *BoRCCR*, cysteine protease gene *BoCP1*, and lipoxygenase gene *BoLOX1* was down-regulated in broccoli fumigated with H_2S during storage. During chlorophyll degradation, transformation from Chl *b* to Chl *a* is catalyzed by a Chl(ide) *b* reductase encoded by a gene named non-yellow coloring 1 (*NYC1*).[35] Dephytilation of chlorophyll by chlorophyllase (CHL) is required in chlorophyll degradation. Schelbert et al. proposed that a new enzyme, pheophytinase (PPH), is involved in dephytilation of pheophytine to generate pheophorbide.[36] Pheophorbide *a* oxygenase (PaO) catalyzes the opening of the porphyrin ring of pheophorbide and generates red chlorophyll catabolytes (RCC). This reaction is followed by the reduction of RCC by RCC reductase (RCCR). Since the photosynthetic competence of *sgr* leaves decreases normally during that period, it is classified as one of the nonfunctional type stay-green mutants. Then we tried to discover whether the delayed yellowing effect of H_2S on broccoli is a nonfunctional stay-green type. We detected the content of Rubisco in dark-promoted senescence and found that H_2S not only alleviated chlorophyll degradation but also prevented Rubisco degradation during senescence of broccoli.

In the present study, H_2S treatment maintained higher levels of metabolites and lower accumulation of ROS and MDA in broccoli compared with water control, suggesting that H_2S treatment provides a safe way to alleviate senescence during vegetable storage. Besides, H_2S could be produced endogenously in plants.[5] Our previous report showed that the levels of endogenous H_2S in fruits treated with exogenous H_2S gas are 10−20% higher than those of the water control, further suggesting its safe usage in postharvest storage.[8]

The ripening and senescence of postharvest vegetables are regulated by endogenous signaling molecules and hormones, including ethylene, jasmonic acid, ABA, H_2O_2, and NO.[8,37−40] In this work, we confirm the role of H_2S in prevention of the senescence of broccoli and other vegetables and fruits, implying that H_2S might be universal signal in endogenous maturation and senescence in plants. However, whether and how H_2S is involved in cross-talk with other hormones and signaling molecules, such as ethylene, jasmonic acid, and NO, requires further elucidation.

partitioning of skin tannin[19] compared extraction in buffered solution (pH 7.5) to tannin remaining bound to the residue following extraction, presumed to be cell wall fragments. Both the buffer-soluble extract, designated the vacuolar fraction, and the cell wall-bound fraction were further extracted using acidified methanol.[19] The experiment showed that the mean degree of polymerization (mDP) of tannin within the vacuole did not change during grape development, yet the mDP of tannins associated with the cell wall was higher and tended to increase at the end of maturation. However, in said study,[19] the mDP of tannins isolated from cell walls was markedly lower than observations from studies on the same cultivar using 70% v/v acetone extraction.[10,14,16] This may indicate that a greater fraction of tannin is desorbed from the grape cell wall using acetone. This phenomenon has been shown definitively for tannin extracted from apple using methanol or aqueous acetone, in which acetone extraction yielded tannin of higher mDP.[22] Furthermore, in that work, aqueous acetone was shown to completely desorb high mDP tannin bound to cell wall material, in a fashion similar to the application of urea. It is therefore evident that further research is needed to better understand the factors which influence partitioning of tannin to extractable and nonextractable fractions.

Recent work using model studies has demonstrated the high affinity of purified grape cell wall material for tannin and highlighted that these interactions may limit tannin extraction during vinification. This may explain some of the significant variability that is observed in wine-extractable tannin between grape cultivars and grape ripeness stages.[16,23−26] For grape skin tannin from red grapes, highly polymerized tannins had a low affinity for skin cell walls compared with tannin of intermediate molecular mass.[16] However, it was found that with the progression of ripening, changes in skin cell wall composition facilitated an enhanced adsorption of this high mDP tannin fraction.[25] Structural changes in skin cell wall polysaccharides were found to occur early in grape development, before or close to veraison, and as such the altered adsorption properties of cell wall material for tannin during late-stage ripening could not be directly linked to changes in polysaccharide composition. Rather, it was noted that the specific enhancement of high molecular mass tannin adsorption was consistent with increases in cell wall porosity. Theoretically, an enhanced porosity could enable penetration and encapsulation of high molecular mass tannins within the cell wall structure and has been observed to contribute to cell wall−tannin interactions in apple.[27−29] In ripening grapes, multiple factors may influence tannin extractability: interactions with cell walls, cell integrity, tannin concentration, tannin molecular mass, tannin structural modification, and interaction with other phenolics, including self-association.[30] As reviewed here, these factors can change simultaneously during grape ripening, rendering the system highly complex.

The work presented in the current study has sought to build on previous research using model experiments, to observe how differences at a cellular level might affect skin tannin extractability during ripening. Extraction of grape skins has been carried out in various concentrations of aqueous ethanol to determine whether differences in tannin extractability could be related to ripening stage. In certain samples, ethanolic extraction was compared to a harsh or "total" extraction in 70% v/v acetone. Whole extracts were subjected to gel permeation chromatography (GPC) to observe whether changes in tannin extractability were associated with differences in tannin molecular mass distribution. Tannin and anthocyanin solutions were combined with isolated cell walls to determine the effect of concentration on their respective adsorption affinities. In addition, scanning electron microscopy (SEM) and nitrogen adsorption isotherms were used to characterize changes in cell wall surface area (porosity) during ripening.

MATERIALS AND METHODS

Instrumentation. An Agilent model 1100 HPLC (Agilent Technologies Australia Pty Ltd., Melbourne, Australia) was used with Chemstation software for chromatographic analyses. For SEM, a Philips XL30 field emission scanning electron microscope (Philips, Eindhoven, The Netherlands) was used.

Grape Sample Preparation and Extraction. *Vitis vinifera* L. cv. Cabernet Sauvignon grape samples were obtained from a commercial vineyard in the Langhorne Creek growing region of South Australia (Pernod Ricard Australia, Orlando Wines) at different commercial ripeness stages in the 2010 season. Berry samples were collected from three rows distributed within the vineyard block to obtain a representative sample, pooled, and processed fresh. A 200 berry subsample was processed fresh, and the juice centrifuged at 1730g for 5 min and analyzed for total soluble solids (°Brix) using a digital refractometer. This data has been published previously.[3] Triplicate subsamples of 100 berries were prepared for cell wall isolation, and a further 36 subsamples of 10 berries each were prepared for phenolic extraction experiments.

The 100-berry samples were weighed, and skins were then separated from flesh and seed while kept on ice. Recovered skin material was weighed to determine the proportion of fresh skin material to total berry mass, frozen in liquid nitrogen, and stored at −80 °C until used for the isolation of cell wall material. Cell wall material was isolated from frozen grape skins as described previously.[25] For the purpose of comparing ripening-related changes in cell walls, two early-stage (preveraison and veraison) cell wall samples were retained from a previous study.[25]

The 10-berry samples were peeled, and the skins were rinsed with ice-cold 30 mM aqueous citric acid, gently blotted with a paper towel, weighed, and immediately transferred to 30 mL of extraction solvent. Four different extraction solvents were used, 10, 20, or 50% v/v ethanol and 70% v/v acetone, each containing aqueous 0.01% v/v trifluoroacetic acid (TFA). To minimize sample degradation and prevent any partial extraction during the rinsing step, a maximum number of 10 fresh berries could be processed per experiment. The ratio of solid material to solvent was 1:15, according to the optimal conditions described by Verries and co-workers,[21] to ensure that extraction efficiency was not influenced by saturation of the extraction medium, and the concentrations of tannin and anthocyanin within extracts did not exceed 1 and 0.6 g/L, respectively. Extractions were in triplicate, performed at 25 °C in the dark, under nitrogen in sealed 50 mL centrifuge tubes. To ensure continuous contact of skins and solvent, centrifuge tubes were placed flat and mixed gently using a platform shaker. All extractions were performed over 64 h to keep the conditions consistent between experiments. The extraction time was selected to optimize tannin extraction in dilute ethanol solutions (10 and 20% v/v), which was maximal at 64 h, whereas tannin extraction containing 50% v/v ethanol or 70% v/v acetone reached a plateau at 42 h (Supporting Information Figure S1). Following extraction, 50 mL tubes containing residual skin solids were centrifuged at 1730*g* for 5 min, and aliquots of the supernatant were directly analyzed as described below.

Analysis of Skin Tannin and Anthocyanin. A 500 μL aliquot of 70% v/v acetone extract was dried under a stream of nitrogen and reconstituted in the same volume of aqueous ethanol (20% v/v). Aqueous ethanol extracts were directly analyzed in duplicate. Tannin and anthocyanin concentrations in aqueous ethanolic extracts were determined in a 96-well plate format using the high-throughput method described previously.[31] Tannin concentration was expressed as (−)-epicatechin equivalents using an external standard curve (Sigma-Aldrich, St. Louis, MO, USA). To standardize tannin analysis across

the staggered time points at which grape sampling and extraction took place, a purified commercial seed extract (Tarac Technologies, Nuriootpa, Australia) was included for each 96-well plate assayed. Data were expressed on a skin weight and per berry basis. Berry weight data have been previously published.[25]

Gel Permeation Chromatography. An aliquot of each skin extract was dried under a stream of nitrogen and recovered in *N*,*N*-dimethylformamide. Samples were centrifuged at 16000*g* for 5 min and directly analyzed by GPC as describedin ref 32. Preveraison skin tannin fractions of known molecular mass (by phloroglucinolysis) were used as standards for calibration.[23] For calibration, a second-order polynomial was fitted with the tannin elution time at 50% for each standard.

Cell Wall Surface Area. The cell wall material samples were mounted on specimen stubs with carbon tabs and coated with 5 nm of platinum in a Cressington 208HR sputter coater (Cressington Scientific Instruments Ltd., Watford, UK). Samples were examined in a Philips XL30 field emission scanning electron microscope operated at an accelerating voltage of 10 kV. Specific surface areas of dry cell wall isolates were determined using an automated manometric gas adsorption apparatus[33] providing data collection for samples at 77 K and subatmospheric pressures. An accurate liquid nitrogen level control of up to ±0.2 mm was achieved and maintained throughout each measurement by a custom-built liquid nitrogen delivery system.[34] Ultrahigh-purity grade gaseous helium (>99.9%) and ultrahigh-purity grade gaseous nitrogen (>99.9%) (both from BOC Gases, Australia) were used for dead-volume and nitrogen adsorption measurements at 77 K, respectively. Duplicate analyses were performed at staggered points in the construction of nitrogen adsorption isotherms to confirm the reproducibility of measurements.

Binding Reaction of Tannin and Cell Wall Material. Skins prepared fresh from commercially ripe Cabernet Sauvignon grape samples were extracted for 18 h in either 70% v/v acetone or 15% v/v ethanol containing 0.01% v/v TFA. Tannin was purified from extracts according to a published method.[24] Tannin isolates were characterized by phloroglucinolysis,[12] which yielded mDP values of 11 units for the 15% v/v ethanol extract and 33 units for the 70% v/v acetone extract. The absence of monomeric phenolics, in particular anthocyanin, from the tannin fractions was confirmed by GPC analysis[32] (negligible material eluting later than 16.3 min). Tannin solutions were prepared in 12% v/v ethanol containing 0.01% v/v TFA. Tannin concentrations were from a minimum of 0.25 g/L and up to a maximum of 10 g/L. These were combined in 1 mL aliquots with 10 mg of a skin cell wall preparation, which corresponded to the most ripe harvest date in the current study, in 1.5 mL centrifuge tubes. Cell wall solutions were vortexed and then incubated for 1 h at 27 °C with shaking and thereafter centrifuged at 16000*g* for 20 min. For each experiment a standard blank of the respective tannin solution without cell wall material was included. Supernatants were analyzed by GPC. The loss of tannin in supernatants through interaction with cell wall material was determined by difference in GPC peak area, calibrated for the respective tannin preparations used in the study, as described previously.[26] Adsorption isotherms were fitted using the Langmuir equation,[35] modeling the quantity of tannin bound (mg/g) as a function of the concentration of tannin remaining in solution, at theoretical equilibrium. Curve fit R^2 values of 0.99 were obtained for both tannin types tested, and these results were used to derive the apparent affinity constant (K_L) and the maximum adsorption capacity N_{max} of cell wall material for each tannin type, where N represents the mass of tannin bound (mg) per gram of cell wall material.

Binding Reaction of Monoglucoside Anthocyanins with Cell Wall Material. Shiraz grapes at commercial ripeness (24 °Brix) were partially homogenized with a blender. Crude methanolic extracts (50% v/v) were prepared from the grape slurry and then concentrated under reduced pressure at 30 °C. A Toyopearl (660 mL bed volume) column equilibrated with 0.1% v/v TFA was prepared, and aqueous extracts were loaded in 100 mL batches. Water-soluble nonadsorbent compounds were eluted in 2 L of the loading solvent. The monoglucoside anthocyanin fraction was eluted with 1.5 L of 30% v/v methanol containing 0.1% v/v TFA. The column was then washed with 2 L of 2:1 v/v acetone/water and re-equilibrated with 0.1% v/v TFA. The eluate was concentrated under reduced pressure at 30 °C, frozen at −80 °C, and then lyophilized, yielding ≅200 mg of dry material, which was stored under nitrogen at −80 °C until used. Extract purity was verified by HPLC,[31] and the sample was free of acetylated or coumaroylated anthocyanins, derived pigments, and polymeric material. The extract was found to have trace quantities of early-eluting material at 280 nm, but this was below the detection limit for quantification, indicating minimal contribution of non-anthocyanin phenolics. Anthocyanin concentration was determined as the sum of individual 3-*O*-monoglucoside anthocyanins, as malvidin-3-glucoside units using a commercial standard (Polyphenols Laboratories, Norway). Anthocyanin was added to a solution of 12% v/v ethanol containing 0.01% v/v TFA at increasing concentration from 0.1 and 2 g/L either alone or combined with a 1.25 g/L solution of the 33 mDP tannin. These were combined in 1 mL aliquots with 10 mg of a skin cell wall preparation that corresponded to the most ripe harvest date in the current study, in 1.5 mL centrifuge tubes. Cell wall solutions were vortexed and then incubated for 1 h at 27 °C with shaking and thereafter centrifuged at 16000*g* for 20 min. Methyl cellulose

precipitation[31] was selected to analyze tannin concentration in supernatants. This was due to the potential interference of a high anthocyanin concentration in the phloroglucinolysis and GPC methods, which would require an additional sample purification step. Anthocyanin was analyzed as the sum of individual 3-*O*-monoglucosides, quantified by HPLC.[31] Anthocyanin adsorption isotherms were fitted using the Langmuir equation as described for tannin adsorption experiments, above.

RESULTS AND DISCUSSION

Skin Tannin and Anthocyanin Extraction in Aqueous Ethanol. The extraction of both skin tannin and anthocyanin increased with the addition of ethanol to the solvent (Table 1). For extraction using dilute, 10% v/v ethanol, significant increases in both tannin and anthocyanin content were evident only between the first sampling point (22 °Brix) and the final sampling point (26 °Brix). When 20% v/v ethanol was used as the extraction solvent, extractable tannin and anthocyanin content increased from the first to the second sampling point and thereafter remained constant. When ethanol concentration was increased to 50% v/v, it was evident that there was an increase in the extraction of both skin tannin and anthocyanin with advancing ripeness. However, for the transition from 23 to 24 °Brix, there was no increase in either anthocyanin or tannin extracted in 50% v/v ethanol from the skin samples.

Partitioning of Tannin to a Nonextractable Fraction. In the previous experiment it was reported that no differences were found in the extraction of tannin in dilute ethanol (10 and 20% v/v) between the 23, 24, and 26 °Brix samples. Extraction in 70% v/v acetone was also performed on samples from these ripeness stages and is hereafter referred to as "total" tannin, because this acetone/water ratio presents a more exhaustive extraction for tannin than the ethanol-based solvents.[17] Nevertheless, we note that some residual high molecular mass tannin remains nonextractable in 70% v/v acetone,[24,25] which was not accounted for in the current sample set.

It was found that during late-stage ripening, there was a continuous increase in total skin tannin content (Figure 1). When the tannin content extracted at different ethanol concentrations was expressed as a percentage of total tannin,

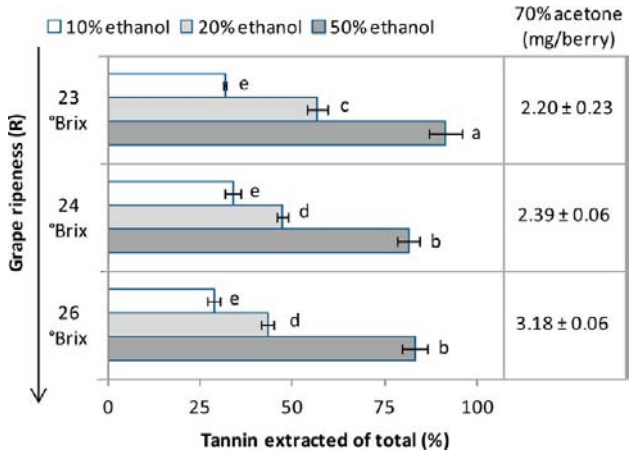

Figure 1. Ripening-related changes in tannin extracted using an increasing concentration of aqueous ethanol as a proportion (%) of total tannin extractable in aqueous acetone (data are the mean ± SE; data compared by ANOVA, $n = 27$, $P < 0.001$, followed by post-hoc Student's t test; different letters indicate statistically significant differences between means).

the proportion of tannin extractable in 10% v/v ethanol remained constant during ripening. However, at 20 and 50% v/v ethanol, it was evident that with the progression of ripening a fraction of skin tannin became nonextractable at 24 and 26 °Brix in comparison with the 23 °Brix sample. As a more hydrophobic solvent, ethanol disrupts hydrophobic interactions, potentially between tannin and cell walls, protein, or other skin phenolics,[36] thereby facilitating greater extraction. It is evident that a portion of grape skin tannin remained readily extractable in aqueous ethanol, independent of the total tannin concentration.

To characterize the size distribution of fractions extractable under the different solvent conditions, extracts were subjected to GPC analysis (Figure 2). The cumulative molecular mass distribution based on unpurified extracts represents both polymeric material and smaller molecular mass phenolics. For all of the GPC distribution data, quantitatively greater differences in molecular mass between treatments were evident at later elution by GPC (70% elution), which corresponds to the polymeric fraction (mDP ≅ 3−15). This is consistent with the observed increases in tannin concentration with increasing ethanol concentration in the solvent (Table 1). For all ethanolic extracts, the distribution was shifted toward a higher molecular mass average with advancing ripeness (Figure 2A−C). For 70% v/v acetone extracts, the curves were more closely overlaid (Figure 2D), indicating that higher total grape tannin content resulted in increases across the entire molecular mass distribution. Two effects are evident: first, that higher molecular mass tannins were increasingly extracted as solvent polarity decreased and, second, that at the latest grape sampling point, a fraction of intermediate molecular mass tannin was more extractable in ethanol. This finding points to greater complexity in the factors that drive tannin extractability of during ripening and raises questions as to whether there are (a) changes in the interaction of tannin with skin cell walls with advancing ripeness; (b) changes in tannin concentration that affect the selectivity of tannin adsorption by cell walls as a function of tannin molecular mass; and/or (c) changes in the composition of other phenolics, namely, anthocyanins, that affect the interaction of tannin with cell walls. These questions are further addressed below through cell wall characterization and model adsorption experiments.

Analysis of Grape Cell Wall Surface Characteristics with Advancing Ripeness. Previous research on the tannin adsorption properties of skin cell walls from the same grape sample series presented in the current study demonstrated that the selective adsorption of high molecular mass tannin increased in the late stages of ripening.[25] The analysis of cell wall polysaccharides indicated that major compositional changes occurred around veraison, with a preveraison loss of galacturonic acid (galacturonan) followed by losses in arabinogalactan I, consistent with published research.[37] However, compositional changes in cell wall polysaccharides in late-stage ripening were found to be minor and could not be used to qualify the changes in cell wall binding properties for tannin. These cell wall samples[25] were further characterized by SEM and for surface area using nitrogen adsorption isotherms. It is evident from scanning electron micrographs that preveraison grape cell walls display a regular, relatively smooth (Figure 3A) surface structure with defined pit fields (Figure 3B). The presence of defined pit fields was not detectable in cell walls imaged at veraison (Figure 3C), which is consistent with losses in homogalacturonan-rich regions of the cell wall,[38]

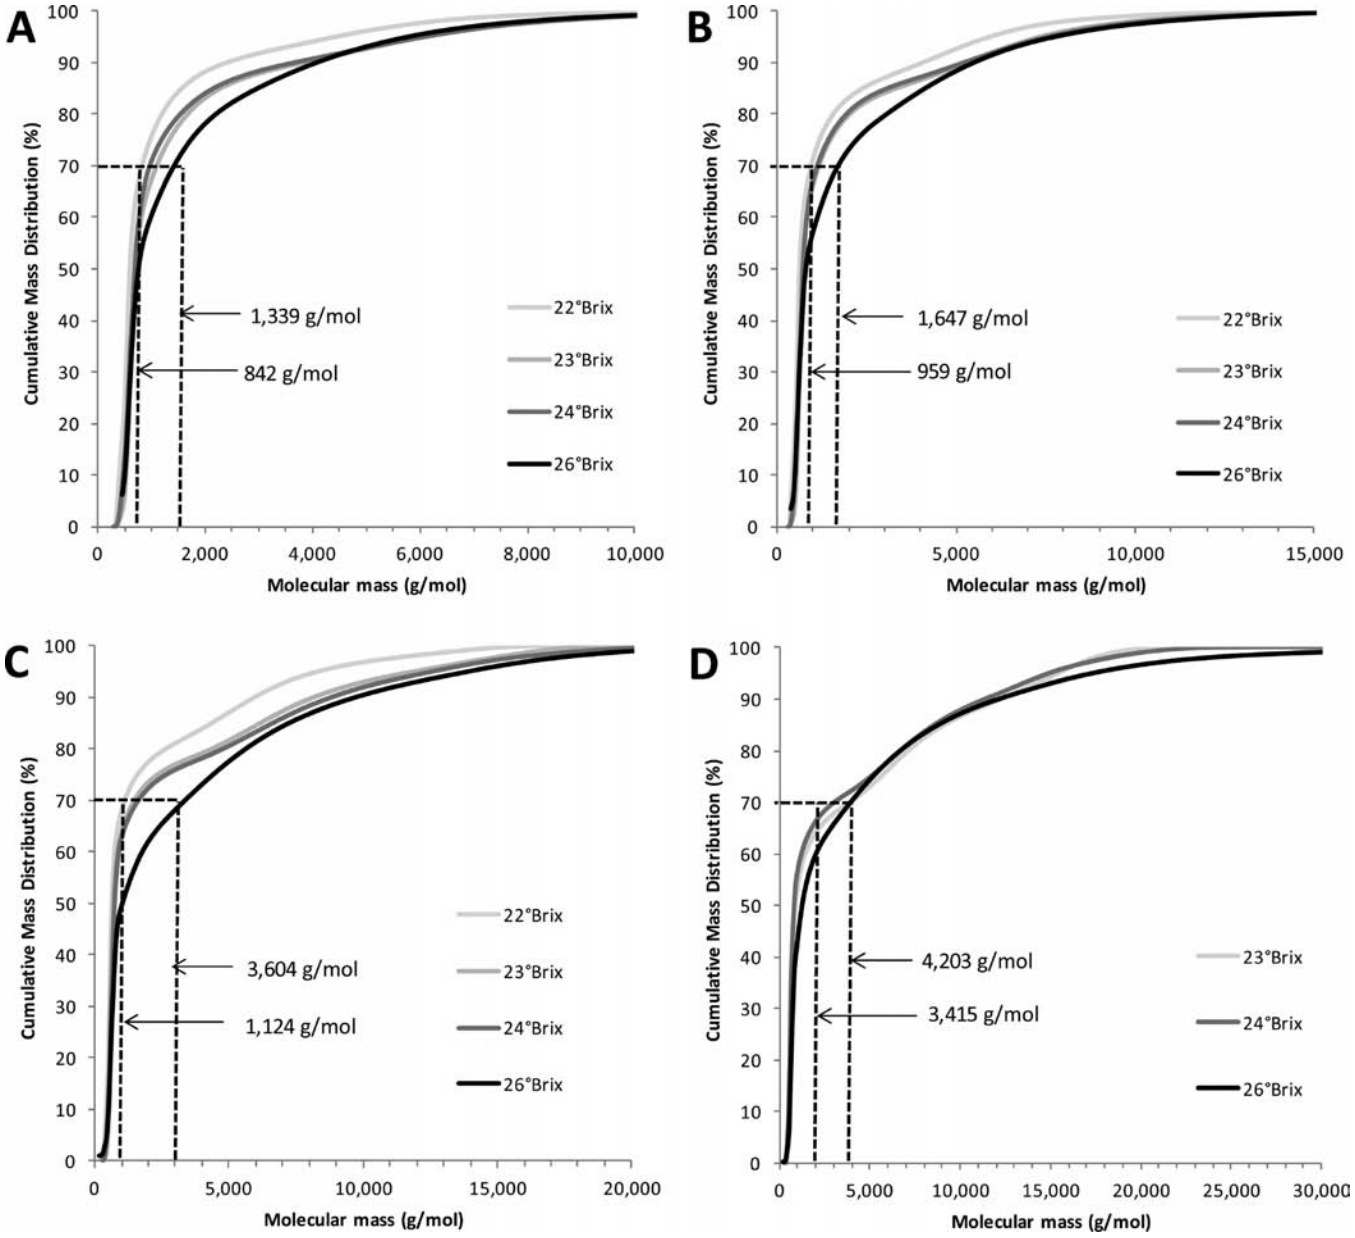

Figure 2. Cumulative molecular mass distribution of grape skin extracts at different ripeness levels according to their grape juice total soluble solids determined by gel permeation chromatography: (A) extracts in 10% v/v ethanol; (B) extracts in 20% v/v ethanol; (C) extracts in 50% v/v ethanol; (D) extracts in 70% v/v acetone.

which confirmed earlier cell wall analysis.[25] In the later stages of ripening, deepening of folds in the cell wall was evident, leading to a "wavy" appearance (Figure 3D–F). Initially, we considered that this might be a fault of the tissue preparation method, because lyophilization is noted to cause collapse of the cell wall structure and a reduction in macroporosity.[28] This effect is particularly evident in the case of harsher drying methods.[27] However, we note that this phenomenon has been documented previously in fixed tissue from ripening grape skins, using transmission electron microscopy.[39] The authors proposed that a "wavy" appearance resulted from localized swelling of the cell wall. However, it was noted that the appearance of an undulating cell wall was concomitant with degradation of the middle lamella. Therefore, it is possible that cell wall conformation was retained through the extraction and drying steps, and the SEM images may reflect true changes in cell wall structure with ripening. These observable changes in the surface structure of cell walls were of interest because previous observations related to enhanced adsorption of high molecular mass tannins at late-stage ripening were consistent with a greater cell wall porosity.[25] The working hypothesis is that a greater surface area over which tannin binds to cell walls can occur via hydrogen bonding and hydrophobic interactions within cell wall cavities. In the absence of pores, high molecular mass tannins may be excluded from the cell wall and have limited interaction.[24]

To quantify the SEM observations, and as a prerequisite for employing the unripe cell wall fraction as a reference material, specific surface areas were defined for cell wall preparation from the ripening series. Although the specific surface area of each sample was low, well-defined low-pressure isotherms were obtained with negligible uncertainty (values were approximately

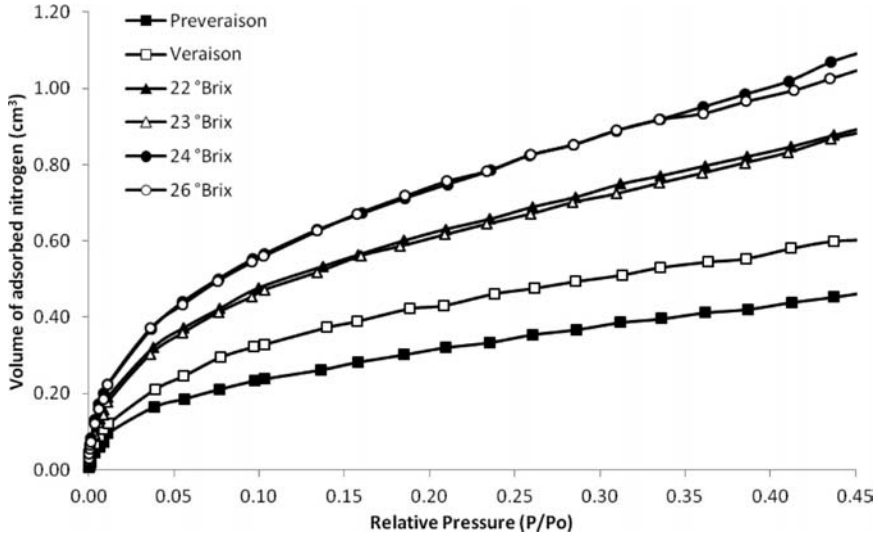

Figure 4. Nitrogen gas adsorption isotherms determined at standard temperature and pressure for isolated cell wall material from unripe and ripening Cabernet Sauvignon grape skins (P = sample cell pressure; Po = nitrogen vapour pressure at 77K; preveraison = January 15, 11 days before veraison; veraison = January 26).

the size of the symbols used) (Figure 4), leading to area values with precision suitable for three significant figures, and this data is presented in Table 2. As expected, the folds seen by SEM represent a roughened surface leading to an increased specific surface area susceptible to nitrogen gas analyses. For the sample series under investigation, two surface area categories were noted in ripening skin cell walls, corresponding to the ripeness grades 22 and 23 °Brix, as distinct from 24 and 26 °Brix, respectively. This conclusion is better defined by reference to the isotherms in Figure 4 than from the subtle, but real, differences in the specific surface areas extracted from these isotherms.

Enhancement of cell wall porosity with the progression of ripening lends support to the hypothesis that greater penetration of high molecular mass tannin within cell wall pores could occur.[25] This could result in a reduced extractability of this tannin fraction with ripening, due to greater encapsulation within pores and, therefore, adsorption by cell wall components. The measurable changes in ethanol-extractable tannin (Table 1) showed that no change in tannin extraction to dilute ethanol solution occurred, despite increases in cell wall porosity. However, when the partitioning of tannin extractable in aqueous ethanol was compared with that by 70% acetone extraction, a stronger relationship with cell wall porosity could be demonstrated (Figure 1). The highest cell wall porosity category was for samples collected at 24 and 26 °Brix (Figure 4; Table 2), and the corresponding samples demonstrated a reduction in ethanol-extractable tannin (in 20

and 50% v/v ethanol) as a proportion of acetone-extracted tannin. A possible interpretation of this result is that increased porosity in skin cell walls during late-stage ripening may facilitate sequestering of tannins as an adsorbed fraction within the cell wall. On the basis of the published cell wall–tannin interaction data for these samples,[25] it would be expected that the adsorbed tannin fraction would consist primarily of high molecular mass tannin, which is nonextractable even at increased ethanol concentration. Despite this observation, it was evident that increased total acetone-extractable tannin concentration in the final sampling date (26 °Brix) (Figure 1) resulted in two measurable phenomena: (a) enhanced tannin extraction in 50% v/v ethanol (Table 1) and (b) increased tannin molecular mass in the extract (Figure 2C). These observations may be influenced by cell wall porosity but cannot be explained by this effect alone.

Effect of Tannin Concentration and Molecular Mass on the Interaction with a Porous Skin Cell Wall Material. Binding isotherms were constructed for two purified tannins of low and high average molecular mass (mDP 11 and 33). The tannins were prepared using different extraction methods to selectively extract molecular mass classes, 15% v/v ethanol and 70% v/v acetone, and were not subjected to further fractionation. Therefore, both tannin fractions were heterogeneous in terms of their molecular mass distribution (data not shown). In particular, the 70% v/v acetone extract had a distribution of high (>15000 g/mol), intermediate, and low molecular mass material, which reflects the broad spectrum present in grape skins in situ. The dilute ethanol extract reflected the distribution of wine-extractable skin tannin (<15000 g/mol).

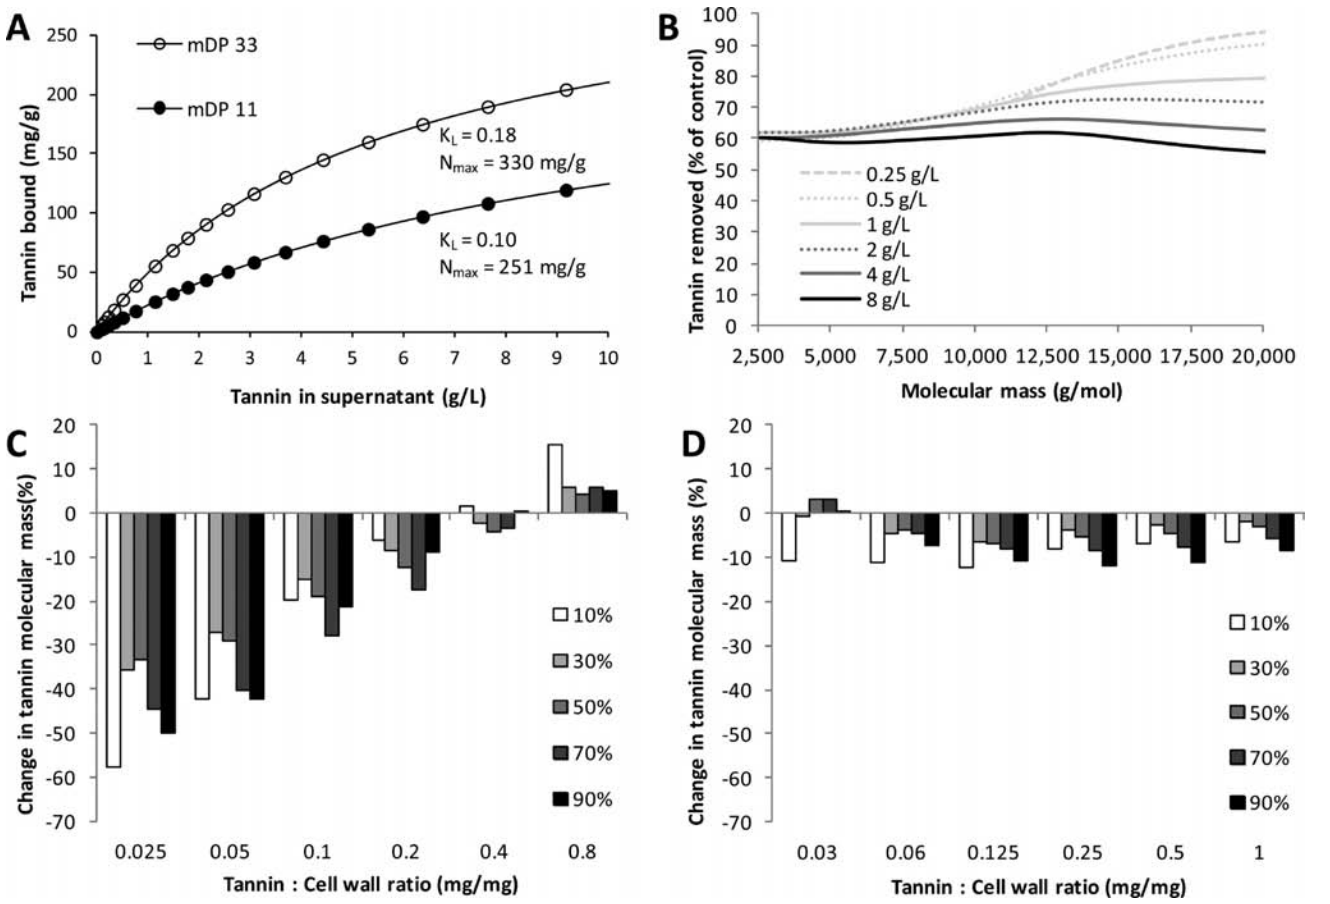

Figure 5. Effect of skin tannin concentration and mean degree of polymerization (mDP) on the binding reaction with 10 mg of porous, ripe skin cell wall material (26 °Brix), analyzed by gel permeation chromatography: (A) constructed adsorption isotherms for mDP 33 and mDP 11 tannins with estimated affinity constants (K_L) and maximum adsorption capacity (N_{max}); (B) percentage of mDP 33 tannin removed by adsorption to cell walls as a function of tannin molecular mass; (C) change in cumulative molecular mass (% elution) following adsorption of mDP 33 tannin; (D) change in cumulative molecular mass (% elution) following addition of mDP 11 tannin.

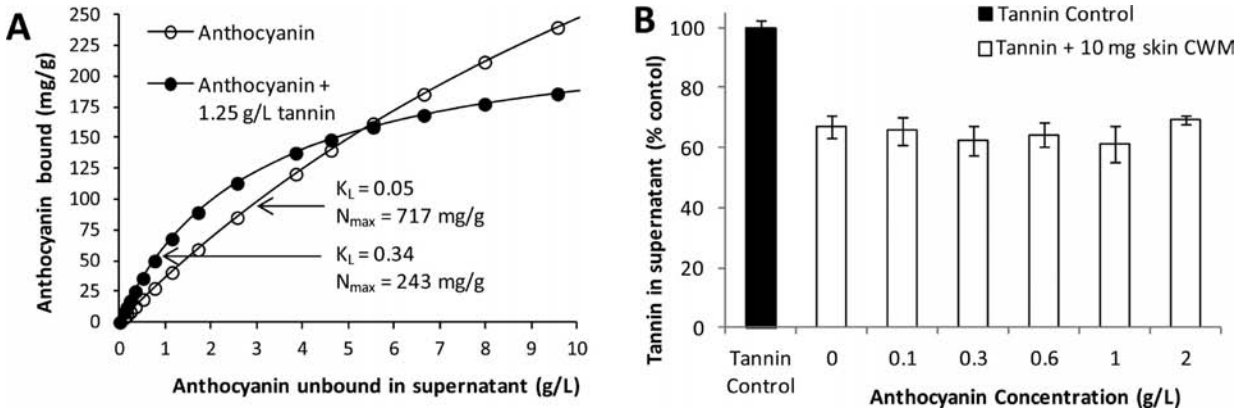

Figure 6. Binding reaction of a porous, ripe skin cell wall material (26 °Brix) with monoglucoside anthocyanin, alone or in combination with 1.25 g/L of a purified skin tannin extract (mDP 33.1): (A) adsorption isotherms showing estimated affinity constants (K_L) and maximum adsorption capacity (N_{max}) constructed using the Langmuir equation; (B) change in tannin concentration as a percentage of a 1.25 g/L control (100%) following addition of 10 mg of skin cell wall material with increasing concentration of anthocyanin (mean ± SE).

The affinity constant (K_L) and estimated saturation level (N_{max}) derived from Langmuir isotherms (Figure 5A) for tannin adsorption by skin cell walls differed as a function of tannin molecular mass. Adsorption of high molecular mass tannin by cell wall material gave higher K_L and N_{max} values by comparison with the lower molecular mass tannin sample. The binding constants calculated from the isotherms would suggest that for skin cell walls, higher molecular mass tannin was bound more effectively even at high concentrations. However, an analysis of the selectivity of binding showed that this was not the case. From the molecular mass distribution data obtained via GPC, for high molecular mass tannin applied at low concentration, adsorption in the highest molecular mass range approached 100% (Figure 5B). As the tannin concentration increased, the selective adsorption of this molecular mass fraction decreased significantly, whereas, the adsorption of the intermediate molecular mass tannins remained relatively constant at 60%. This result indicates a concentration-dependent effect, whereby the averages taken at different molecular mass cutoff points (% elution) shifted with increasing tannin concentration (Figure 5C): decreased molecular mass at low concentrations and increased molecular mass at the highest tannin concentration. Conversely, for the low molecular mass tannin fraction applied, there was less selectivity observed in binding events, and molecular mass decreased for all tannin molecular mass classes, independent of tannin concentration (Figure 5D). These results show that increases in tannin concentration may have resulted in a higher total amount of tannin adsorbed by cell walls, but also reduced adsorption of higher molecular mass tannins. For the current study, the tannin/cell wall ratio in situ would have been ≅0.2 (2 g/L tannin application) based on published data for cell wall yield.[25] This means that for even a small change in total skin tannin concentration, the molecular mass of the nonadsorbed tannin fraction could shift to a higher average as a result of a changing selectivity pattern by the cell walls.

Althought it cannot be conclusively shown from the current data, the loss of selectivity for higher molecular mass material even at low applied tannin concentrations suggests the early saturation of direct binding sites on the cell wall. The saturation constant calculated from the Langmuir equation, first, exceeds the solubility of tannin in aqueous ethanol (Figure 5A) and, second, fails to account for the selectivity of binding. Previous work[25] showed that more porous cell walls (later ripeness) more effectively adsorb higher molecular mass tannin (>15000 g/mol), and this can account in part for the observed sequestering of tannin to a nonextractable fraction in riper skins. Increased porosity may facilitate a greater surface area over which high molecular mass tannin can bind. Hence, it might be expected that the saturation of cell wall binding sites would be reduced in riper skins, concomitant with increased total tannin concentration.

Nevertheless, it is evident that the effect of ripening on tannin extraction is more complex. The ongoing binding of intermediate molecular mass tannins even at higher applied concentrations, together with the high estimated saturation constant, could indicate that secondary interactions occur between surface-bound tannin and tannin in solution. This effect has been demonstrated in studies on tannin−cell wall interactions in apple[22,27,28] with the strong emphasis made that the formation of tannin "multilayers" through noncovalent interactions is likely to account for high saturation constants in the binding reaction. In particular, it was noted that this effect may favor multilayer formation by tannins of intermediate molecular mass[27] (±2900 g/mol) due to their increased propensity to form aggregates, a phenomenon observed to be lower for high molecular mass tannin (±20000 g/mol). This observation may further explain the reduction in adsorption of high molecular mass tannin at higher applied tannin concentrations, whereas the adsorption of intermediate molecular mass tannins remained constant (Figure 5B,D).

From a reinterpretation of the tannin extraction data obtained using aqueous ethanol concentrations, it is evident from the GPC cumulative molecular mass distribution that the highest molecular mass tannins were poorly extracted in aqueous ethanol, even at 50% v/v (Figure 2A−C). Rather, they were extractable only in 70% acetone, as shown by the shift in the cumulative molecular mass distribution of the extract (Figure 2D), which approached a molecular mass of 30000 g/mol at 100% elution. Therefore, quantitatively, the greatest effect of increasing ethanol in the extraction solvent was found for tannins within the intermediate molecular mass range (Figure 2A−C). This suggests that ethanol may selectively extract tannins of intermediate molecular mass, which are potentially associated as multilayers with cell wall constituents. Our previous work using model experiments in grape[24] highlighted this effect, such that small changes in ethanol concentration (12−20% v/v) reduce the interaction of tannins

dx.doi.org/10.1021/jf4050606 | J. Agric. Food Chem. 2014, 62, 1130−1141

of intermediate molecular mass with cell wall material, whereas a negligible effect of ethanol is exerted on the adsorption of high molecular mass tannin. Quantitative data from this experiment is shown in the Supporting Information (Figure S2). The selective effect of ethanol in driving the tannin−cell wall interaction response may also indicate the contribution of hydrophobic interactions, as indicated by Le Bourvellec and co-workers.[28]

Interaction of Cell Walls with Tannin and Anthocyanin. It was noteworthy from the extraction experiments that anthocyanin extraction was limited by ethanol concentration in a similar manner to tannin (Table 1). It is known that anthocyanin can associate with plant cell walls,[40] although the interaction of monomeric flavan-3-ols is thought to be negligible.[22] We have shown previously, using a wine system containing both tannin and monomeric anthocyanin, that grape cell wall material can remove anthocyanin in the presence of tannin.[41] What was unknown at the outset of the study is whether the interaction of tannin and anthocyanin influences binding events with the cell wall. In a model experiment, the adsorption of anthocyanin by cell walls was significant (29% removed from a 1 g/L solution) and enhanced by the presence of tannin (45% removed from a 1 g/L solution). The binding isotherms for this experiment across a range of anthocyanin concentrations are shown in Figure 6A. As anthocyanin concentration increased, tannin adsorption by cell wall material was not affected (Figure 6B). The estimated saturation constant for anthocyanin using the Langmuir equation was lower in the presence of tannin, but at the concentration range present in grapes, the system would be well below saturation. It therefore appears that for the conditions of the current study, anthocyanin did not influence tannin adsorption by cell walls. At the same time, skin tannin present in grapes might limit the extraction of anthocyanin.

In general, 50% v/v ethanol is considered a good solvent for anthocyanin, correlating well with accepted methods for anthocyanin analysis, and is useful in the prediction of anthocyanin extractability during grape ripening.[42] Conversely, some degradation of anthocyanin was found in acetone extracts (data not shown). From the results of the extraction experiment, it would therefore be expected that the 50% v/v ethanol extraction reflects true differences in anthocyanin concentration between grape samples, although this is not the case for tannin. Furthermore, the results indicated that anthocyanin content increased in riper samples, but that these differences were not reflected in dilute ethanol extracts except for the least ripe (22 °Brix) sample, which had the lowest extractable anthocyanin (Table 1). On the basis of the data from the model binding experiment with anthocyanin and grape cell walls, we propose that the poor extraction of anthocyanin at low ethanol concentration may be due, in part, to a significant interaction with cell walls. Increased anthocyanin extraction at higher ethanol concentrations may be due to a loss of hydrophobic interactions between anthocyanin and cell walls or between anthocyanin and cell wall-bound tannin, but does not exclude the contribution of ionic interactions.[40] This result showed that in a like manner for skin tannin, anthocyanin extraction could potentially be restricted by multiple noncovalent interactions. Further to this, an important observation toward interpreting the tannin extraction data was that anthocyanin is unlikely to affect the adsorption of tannin by cell walls within the concentration range occurring in grapes.

As discussed, the effect of either ripeness stage or increasing ethanol in the solvent on tannin extraction was mirrored by changes in anthocyanin extraction. Therefore, a pertinent question was whether complexing between anthocyanin and tannin could enhance the 280 nm absorbance, leading to erroneous conclusions regarding changes in tannin concentration using the methyl cellulose precipitable tannin assay. We have noted in previous research using tannins purified from the same grape sample set presented in the current study that anthocyanin incorporation into the tannin polymer caused minor increases in tannin color in immature grapes,[16] but from 22 °Brix onward there was no further color change observed. In comparing the methyl cellulose precipitation results from the same purified tannins[16] at different ripeness stages (Supporting Information Figure S3), it was found that no change in the methyl cellulose precipitation result was detected for a fixed concentration of tannin. On the basis of these results, and our observations that the presence of tannin in combination with grape cell walls potentially restricts anthocyanin extraction, we conclude that the similarity in anthocyanin and tannin extraction data between the different grape samples was a true effect.

Potential Mechanisms That May Increase Skin Tannin Concentration and Facilitate Sequestering to Cell Walls. In grapes, research has shown that the biosynthetic pathway for the synthesis of flavan-3-ols (precursors to tannin) is active up until the onset of ripening (veraison), and thereafter gene expression is down-regulated by the hormone abscisic acid (ABA), which signals the onset of veraison.[43] Whereas the cessation of gene expression for flavan-3-ol biosynthetic enzymes prior to veraison may indicate that tannin should decline during ripening, a concurrent decrease in monomeric flavan-3-ols is also observed. The reason for this phenomenon has not been addressed in the literature and, speculatively, flavan-3-ols could become polymerized to tannin during the ripening period if they remain intact within a subcellular compartment. A recent paper has suggested that the site of tannin polymerization in the grape cell is within a chloroplast-derived structure, the "tannosome".[44] These organelles originate from thylakoids within the chloroplast and are transported within membrane-bound vesicles, which become incorporated to the vacuole by invagination of the tonoplast membrane. According to the preliminary work by Brillouet and co-workers,[44] polymerization could occur within these organelles at any point following formation of the tannosome because these remain separated from cytoplasmic or vacuolar contents by a membrane. An important consideration based on this work[44] is that tannin may remain sequestered by a membrane at all ripeness stages, meaning that interaction between tannin and cell walls in situ would be improbable and potentially occur only once grape cell compartments are disrupted during crushing and fermentation. Nevertheless, in other studies on grape, the partitioning of tannin has been observed between vacuolar and cell wall fractions in both grape skins and seeds, with higher levels of polymerization occurring in cell wall-associated fractions.[18,19] Some studies have demonstrated that a fraction of high molecular mass tannin is nonextractable in acetone (<5% of acetone-extractable tannin), and this may possibly be covalently bound to the cell wall.[24,25] Furthermore, ultrastructural studies of grape skin cells show aggregations of phenolic-rich inclusions in immature grape cell walls, which are no longer evident in late-stage ripening, concomitant with increased invagination of the cell wall.[39] If a

pathway for tannin transport to the cell wall exists, the mechanism is currently unknown. However, a recent review on tannin biosynthesis, drawn from work on various plant species, has suggested that sequestering of tannin at the cell wall could be mediated by vesicle trafficking, where following deposition at the cell wall, tannin may be further oxidized and potentially polymerized by apoplastic polyphenol oxidase.[45] Irrespective of whether cell wall−tannin interactions occur in situ in the grape berry or only following grape crushing as the result of cell disruption, it appears that this phenomenon plays a significant role in limiting tannin extraction.

Implications for Winemaking Practice. In commercial winemaking, a correlation has been observed between enhanced skin tannin concentration, tannin molecular mass, and allocation grading.[46] Furthermore, in a wine sensory "quality" study, grapes with enhanced skin tannin and anthocyanin were associated with increased wine tannin and color, resulting in an improvement in rating by wine judges.[47] On the basis of the current data set, it is evident that despite increases in grape tannin and anthocyanin content with the progression of ripening, delaying grape harvest may not necessarily facilitate a higher skin tannin extraction. This would appear to be due to the significant limitation in extractability exerted by the interaction of skin tannin and anthocyanin with cell walls and, secondarily, the possibility that further tannin increases were sequestered within cell wall pores and therefore not extractable. The hypothesis that ripening could facilitate an enhancement of tannin extractability under the conditions of ferment (similar to our experiments with dilute alcohol) was not strongly supported by our results. Nevertheless, the molecular mass of tannin extracted from riper grapes increased, even when the extractable tannin content was not significantly affected. Although an increased wine tannin molecular mass may be associated with higher wine quality,[46] this may also cause excessive astringency in the wine, introducing the requirement for fining.

In conclusion, the current study has shown that the factors which underpin skin tannin extractability are complex:

(a) Increases in total skin tannin content with the progression of ripening were not consistently reflected by increases in ethanol-extractable skin tannin.
(b) The observed increase in cell wall porosity with ripening may partly explain this, because the proportion of skin tannin bound by noncovalent interactions within cell wall pores appears to increase in a corresponding manner, rendering a fraction of tannin nonextractable.
(c) The molecular mass of the ethanol-extractable skin tannin fraction shifted to a higher molecular mass average as total skin tannin content increased. This may be due to a change in the selectivity of tannin adsorption by cell walls at higher tannin concentrations. This could occur without a change in extractable tannin content because the total amount of tannin adsorbed by cell walls increases with ripening.[25]
(d) A relatively high affinity of anthocyanin adsorption by skin cell walls was observed, meaning that the extraction of anthocyanin in dilute ethanol (10 and 20% v/v ethanol) may also be limited by the interaction with cell walls. However, at wine-like concentration (2 g/L), anthocyanin did not reduce the adsorption of tannin by cell walls.

These observations highlight that skin cell walls may play a significant role in introducing noncovalent interactions with tannin, which in turn limits its extractability. Further research is required to move away from a simplistic model of tannin extraction, as directly dependent upon tannin concentration, to one that builds upon the multiple levels at which noncovalent interactions between tannin and macromolecules can occur. Ongoing research is needed to better understand how tannin forms colloid complexes with insoluble cell walls, as well as soluble polysaccharide and protein, and how these might affect tannin extractability.

physical stability.[21−23] However, apart from the studies of Horn et al.,[24,25] which evaluated protein-based emulsifiers (whey protein isolate and sodium caseinate) with phospholipid-based emulsifiers (with either 20 or 75% phospholipids), no previous studies have been reported on the physical and oxidative stabilization of fish oil-in-water emulsions with casein−phospholipid combinations. The results obtained by Horn et al.[24,25] demonstrated some advantages of using a combination of milk proteins and milk phospholipids, but it was not possible to assess the precise role of individual milk proteins or milk phospholipids on lipid oxidation.

Therefore, the objectives of this work were (i) to evaluate the antioxidant properties of three common phospholipids (soy lecithin, phosphatidylcholine, and phosphatidylethanolamine) to obtain a more comprehensive understanding of the antioxidant mechanisms of phospholipids and (ii) to investigate the additive effects of each of these three phospholipids and casein as emulsifiers on the physical and oxidative stabilities of fish oil-in-water emulsions at pH 7.

MATERIALS AND METHODS

Materials. Commercial cod liver oil was provided by Maritex A/S, a subsidiary of TINE, BA (Sortland, Norway), and stored at −40 °C until use. Sodium caseinate, CAS (Miprodan 30), was kindly donated by Arla Foods Ingredients amba (Viby J, Denmark). Arla reported a protein content of 93.5% in sodium caseinate for Miprodan 30. Fat-free soybean lecithin, LC (LIPOID P 20); phosphatidylcholine from soybean, PC (LIPOID S 100), and soy phosphatidylethanolamine, PE (LIPOID S PE), were kindly donated by Lipoid (Steinhausen, Switzerland). Data sheets from Lipoid reported the following compositions: for LIPOID P 20, 25% (w/w) phosphatidylcholine, 20% (w/w) phosphatidylethanolamine, 10% (w/w) phosphatidylinositol, 5% (w/w) phosphatidic acid and 40% (w/w) others (mostly glycolipids); a content of 97.3% (w/w) phosphatidylcholine for LIPOID S 100 and a concentration of 99.6% (w/w) phosphatidylethanolamine for LIPOID S PE. All other chemicals and solvents used were of analytical grade.

Characterization of the Fish Oil and the Phospholipids. Fatty acid compositions of the fish oil and the three phospholipids were determined by fatty acid methylation,[26] followed by separation through GC.[27] The quality of the three PL-based emulsifiers and the fish oil was determined by their peroxide value (PV), employing the colorimetric ferric−thiocyanate method at 500 nm as described by Shantha and Decker.[28] Furthermore, their content of tocopherol was also determined.[29]

Antioxidant Activity Assays. The methods for antioxidant activity assays were modified slightly from the original to adapt for microplate readings using a Synergy 2 Multi-Mode (BioTek Instruments, Inc., Winooski, VT, USA) microplate reader.

1,1-Diphenyl-2-picrylhydrazyl (DPPH) Radical Scavenging Activity. The scavenging effect on DPPH free radical was measured according to the method of Shimada et al.[30] with some modifications. One percent (w/w) solutions of the three phospholipids in ethanol were prepared and then diluted according to different dilution factors. In brief, 150 μL of each phospholipid solution was mixed with 150 μL of 0.1 mM ethanolic solution of DPPH. The mixture was then kept at room temperature in the dark for 30 min, and the absorbance was measured at 515 nm. For the blank, 150 μL of ethanol was used instead of the sample, and sample control was also made for each fraction by mixing 150 μL of sample with 150 μL of 95% ethanol. Triplicate measurements were performed. A BHT solution, 0.02% (w/w), was employed as positive control. Radical scavenging capacity was calculated as follows:

$$\text{DPPH inhibition (\%)} = \left(1 - \frac{(A_{\text{sample}} - A_{\text{sample.control}})}{A_{\text{blank}}}\right) \times 100 \quad (1)$$

Iron (Fe^{2+}) Chelating Activity. The iron chelating activity of the extracts was estimated according to the modified method of Dinis et al.[31] Phospholipids were dissolved in ethanol obtaining different solutions, 10% (w/w) for LC, 1% (w/w) for PC, and 5% (w/w) for PE, which were then diluted according to several dilution factors. First, 270 μL of distilled water was added to 200 μL of each phospholipid solution. Then, 10 μL of 2 mM ferrous chloride was added, and after 3 min, the reaction was inhibited by the addition of 20 μL of 5 mM ferrozine solution. The mixture was shaken vigorously and left at room temperature for 10 min; thereafter, the absorbance was measured at 562 nm. A blank was run in the same way by using ethanol instead of sample. Sample control was made for each sample without the addition of ferrozine. Triplicate measurements were carried out. An EDTA solution, 0.006% (w/w), was employed as positive control. The chelating capacity was calculated as follows:

$$\text{Fe}^{2+}\text{ chelating activity (\%)} = \left(1 - \frac{(A_{\text{sample}} - A_{\text{sample.control}})}{A_{\text{blank}}}\right) \times 100 \quad (2)$$

Reducing Power. The reducing power was measured according to the method of Oyaizu[32] with some modifications. Phospholipids were dissolved in ethanol, obtaining different solutions 1% (w/w), which were then diluted according to several dilution factors. To 200 μL of each phospholipid solution was added 200 μL of 0.2 M phosphate buffer (pH 6.6) and 200 μL of 1% (w/w) potassium ferricyanide. The mixture was incubated for 20 min at 50 °C. Then, 200 μL of 10% (w/w) trichloroacetic acid solution was added, and the mixture was shaken vigorously. Finally, 144 μL of this solution was mixed with 342 μL of distilled water and 46 μL of 0.1% (w/w) $FeCl_3$. After 10 min at room temperature, the absorbance was measured at 700 nm. Increased absorbance (A_{700}) of the reaction mixture indicated increased reducing power. Triplicate measurements were performed. An ascorbic acid solution, 0.009% (w/w), was employed as positive control.

Preparation of Emulsions and Sampling. Four emulsions were prepared with 10% (w/w) fish oil and emulsifier concentrations as follows: (i) emulsion 0.3CAS stabilized with 0.3% (w/w) of CAS, (ii) emulsion 0.3CAS+0.5LC stabilized with 0.3% (w/w) of CAS and 0.5% (w/w) of LC, (iii) emulsion 0.3CAS+0.5PC stabilized with 0.3% (w/w) of CAS and 0.5% (w/w) of PC, and (iv) emulsion 0.3CAS+0.5PE stabilized with 0.3% (w/w) of CAS and 0.5% (w/w) of PE. The buffer used was a 10 mM sodium acetate imidazole buffer (pH 7.0). CAS, LC, PC, and PE were dispersed in the buffer overnight at approximately 5 °C. Primary homogenization was done by adding the fish oil slowly to the buffer during mixing at 16000 rpm (Ystral mixer, Ballrechten-Dottingen, Germany). The fish oil was added during the first minute of mixing, and the total mixing time was 3 min. Secondary homogenization was done on a microfluidizer (M110L Microfluidics, Newton, MA, USA) equipped with a ceramic interaction chamber (CIXC, F20Y, internal dimension = 75 μm). Emulsions were homogenized at a pressure of 9000 psi, running three passes. To the emulsions were added 100 μM $FeSO_4$ to accelerate lipid oxidation and 0.05% (w/w) sodium azide to prevent microbial growth. Emulsions were stored in 100 mL closed bluecap bottles at room temperature (19−20 °C) in the dark for 14 days. Each bottle contained approximately 50 mL. Samples were taken at days 0, 4, 9, and 14 for lipid oxidation measurements. Measurements of pH, viscosity, and droplet size distributions were carried out at days 1 and 14, whereas zeta potential was determined at day 2. Samples for protein content in the aqueous phase were taken at day 3. A similar set of emulsions were also prepared at pH 3.5. However, as some of these emulsions were not physically stable, only data obtained at pH 7 will be shown and discussed in detail, but, when appropriate, reference to results obtained at pH 3.5 will be made.

Characterization of the Emulsions. *pH and Zeta Potential.* The pH values of emulsions were measured at room temperature directly in the sample during stirring (pH meter, 827 pH Lab, Methrom Nordic ApS, Glostrup, Denmark). Measurements were done in duplicate.

[a]LC, lecithin; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PV, peroxide value; nd, not detected. [b]As reported on the data sheet provided by the manufacturers. [c]Data are means of triplicate determinations. SD < 2%.

The zeta potential was measured in a Zetasizer (Zetasizer Nano ZS, Malvern Instruments Ltd., Worcestershire, UK) with a DTS-1060C cell at 25 °C. Before analysis, the emulsions were diluted 2:1000 in 10 mM sodium acetate imidazole buffer (pH 7). The zeta potential range was set to −100 to +50 mV, and the samples were analyzed with 100 runs. Measurements were done in triplicate.

Droplet Size. Droplet sizes were measured by laser diffraction using two different pieces of equipment: (i) With the Mastersizer 2000 (Malvern Instruments, Ltd.), emulsion was diluted in recirculating water (3000 rpm) until it reached an obscuration of 12−15%. Results are given in surface area mean diameter: $D_{3,2} = \sum d^3/\sum d^2$. Measurements were made in duplicate. (ii) A Zetasizer (Zetasizer Nano ZS, Malvern Instruments Ltd.) with a DTS-1060C cell was used at 25 °C. The samples were prepared as described for the zeta potential measurement. The results are given as *Z*-average diameter. For both types of equipment the refractive indices of sunflower oil (1.469) and water (1.330) were used as particle and dispersant, respectively. Measurements were made in duplicate.

Protein Concentration in the Aqueous Phase. Protein concentration in the aqueous phase was determined as previously described by Horn et al.[33] Samples (approximately 35 g) were centrifuged at 45000*g* for 50 min at 10 °C (Sorvall RC-6 PLUS, Thermo Fisher Scientific, Osterode, Germany). The lower aqueous phase was extracted with a syringe and needle and centrifuged once more at 70000*g* for 60 min at 15 °C (Beckman ultracentrifuge L8-60M, Fullerton, CA, USA). Once more, the lower aqueous phase was extracted and then filtered (Minisart NML 0.20 μm filter, Sartorius, Hannover, Germany). The protein content in the aqueous phase was determined with a BCA Protein Assay Reagent Kit (Pierce, Thermo Scientific, Rockford, IL, USA). Prior to analysis, samples were diluted 1:9 in 10 mM sodium acetate imidazole buffer (pH 7). Measurements were performed in duplicate.

Viscosity. Viscosities of the emulsions (15 mL) were measured using a stress-controlled rheometer (Stresstech, Reologica Instruments AB, Lund, Sweden) equipped with a CC25 standard bob cup system in a temperature vessel. Measurements were done at 20 °C over a shear stress range from 0.0125 to 1.64 Pa. Viscosities are given as the average viscosity of the linear part of the plot of shear stress versus viscosity expressed in centipoise (cP). Viscosities were measured twice on each emulsion.

Measurements of Lipid Oxidation. *Determination of Peroxide Value and Tocopherol Content.* Lipids were extracted from the dispersions according to the Bligh and Dyer method using a reduced amount of the chloroform/methanol (1:1 w/w) solvent.[34] Two extractions were made from each sample, and PV measurement was performed in duplicate. PV was measured according to the method described earlier.[28] For tocopherol determination, lipid extracts (1−2 g) were weighed off and evaporated under nitrogen and redissolved in hexane prior to analysis by using the same method as described previously.[29]

Secondary Oxidation Products, SPME GC-MS. Approximately 4 g of emulsion, 30 mg of internal standard (4-methyl-1-pentanol, 30 μg/g water), and 1 mL of antifoam (Synperonic 800 μL/L water) were weighed out in a 100 mL purge bottle. The bottle was heated in a water bath at 45 °C while purging with nitrogen (flow = 150 mL/min, 30 min). Volatile secondary oxidation products were trapped on Tenax GR tubes. The volatiles were desorbed again by heat (200 °C) in an Automatic Thermal Desorber (ATD-400, Perkin-Elmer, Norwalk, CT, USA), cryofocused on a cold trap (−30 °C), released again (220 °C), and led to a gas chromatograph (HP 5890IIA, Hewlett-Packard, Palo Alto, CA, USA; column, DB-1701, 30 m × 0.25 mm × 1.0 μm; J&W Scientific, Folsom, CA, USA). The oven program had an initial temperature of 45 °C for 5 min, increasing at 1.5 °C/min until 55 °C, at 2.5 °C/min until 90 °C, and at 12.0 °C/min until 220 °C, where the temperature was kept for 4 min. The individual compounds were analyzed by mass spectrometry (HP 5972 mass-selective detector, Agilent Technologies, USA; electron ionization mode, 70 eV; mass to charge ratio scan between 30 and 250). The individual compounds were identified both by MS library searches (Wiley 138 K, John Wiley and Sons, Hewlett-Packard) and by authentic external standards. The external standards employed were 1-penten-3-one, pentanal, 1-penten-3-ol, (*E*)-2-pentenal, 1-pentanol, hexanal, (*E*)-2-pentenol, (*E*)-2-hexenal, heptanal, (*E*)-4-heptenal, (*E*,*E*)-2,4-heptadienal, nonanal, (*E*,*Z*)-2,6-nonadienal, 2-ethylfuran, and 2-pentylfuran. These compounds were dissolved in 96% ethanol and diluted to concentrations of approximately 0.5, 1, 5, 10, 25, and 50 μg/g. Two calibration curves were made by injecting these solutions (30 mg) on 4 g of emulsion (0.3CAS and 0.3CAS+0.5LC emulsions). Measurements were made in triplicate in each sample.

Statistical Analysis. Statgraphics software (version 5.1) was used to carry out one-way analysis of variance (ANOVA) on the data.

Tukey's test was employed for that purpose, and differences between means were considered significant at $p \leq 0.05$. Furthermore, oxidation data were subjected to multivariate data analysis (The Unscrambler X, version 10.2, CAMO Software AS, Oslo, Norway). A principal component analysis (PCA) was carried out with the four different emulsions as objects and peroxide values and volatiles data as variables, with one variable representing the average of a given peroxide value or volatile at a specific sampling time point. Data were autoscaled to make the variables contribute equally to the model, and the PCA model was validated systematically segmented, according to replicates of the emulsions.

RESULTS AND DISCUSSION

Composition of Fish Oil and Phospholipids. The quality of the raw materials can have a great influence on the physical and oxidative stabilities of the final emulsions. For this reason, the fish oil and the three soybean phospholipids employed as emulsifiers were characterized in terms of peroxide value, fatty acid composition, and tocopherol content (Table 1). It was observed that the commercial cod liver oil utilized presented a very low PV (0.28 mequiv O_2/kg), a considerable content of monounsaturated fatty acids (16.3% of C18:1n-9 and 12.6% of C21:1n-9), and a percentage of omega-3 PUFA >20% (mainly EPA, C20:5n-3, and DHA, C22:6n-3). With regard to the tocopherol composition, it contained mainly α-tocopherol (200 μg/g) and γ-tocopherol (96 μg/g).

The three phospholipids had considerably higher PV than the fish oil, ranging from 1.48 for PC to 4.01 for PE. In terms of fatty acid composition, PC and PE presented almost the same content for each fatty acid, mainly C16:0 (~13%), C18:1n-9 (~9%), C18:2n-6 (~65%), and C18:3n-3 (~6%). This finding is explained by the fact that, according to the manufacturer, PE was produced from purified PC by conversion of the headgroup. Likewise, LC was composed by the same major fatty acids as PC and PE. However, it presented a higher content of saturated (21.5% of C16:0) and monounsaturated fatty acids (13.6% of C18:1n-9) and a lower percentage of polyunsaturated fatty acids (53.3% of C18:2n-6 and 4.7% of C18:3n-3) than the two other phospholipids. As far as their tocopherol composition is concerned (Table 1), PC contained almost twice as much α-tocopherol as PE, whereas α-tocopherol was not detected in LC. This may be due to the addition of α-tocopherol as antioxidant in the pr,oduction process of PC and PE. No other homologues of tocopherol were found in PE, and low percentages of γ- and δ-tocopherol were obtained for LC and PC.

Antioxidant Activity of Phospholipids. Phospholipids may act as antioxidants by different mechanisms. As a consequence, their antioxidant properties were evaluated by different methods such as DPPH, Fe^{2+} chelating and reducing power. To the best of the authors' knowledge, such a systematic study on the antioxidant properties of phospholipids has not previously been reported.

DPPH Radical Scavenging Activity. Figure 1a shows the DPPH radical scavenging activity of the three phospholipids assayed (LC, PC, and PE). Although they presented different α-tocopherol contents (Table 1), they exhibited similar DPPH inhibition, approximately 95% at a concentration of 1% (w/w). It was also observed that for LC, PC, and PE, the DPPH radical scavenging activity decreased with decreasing concentration until being practically constant at concentrations below 0.11% (w/w), equating to a dilution factor of 9. This radical scavenging activity may be related, similarly to the regeneration of α-tocopherol by phospholipids, to the proton-donating

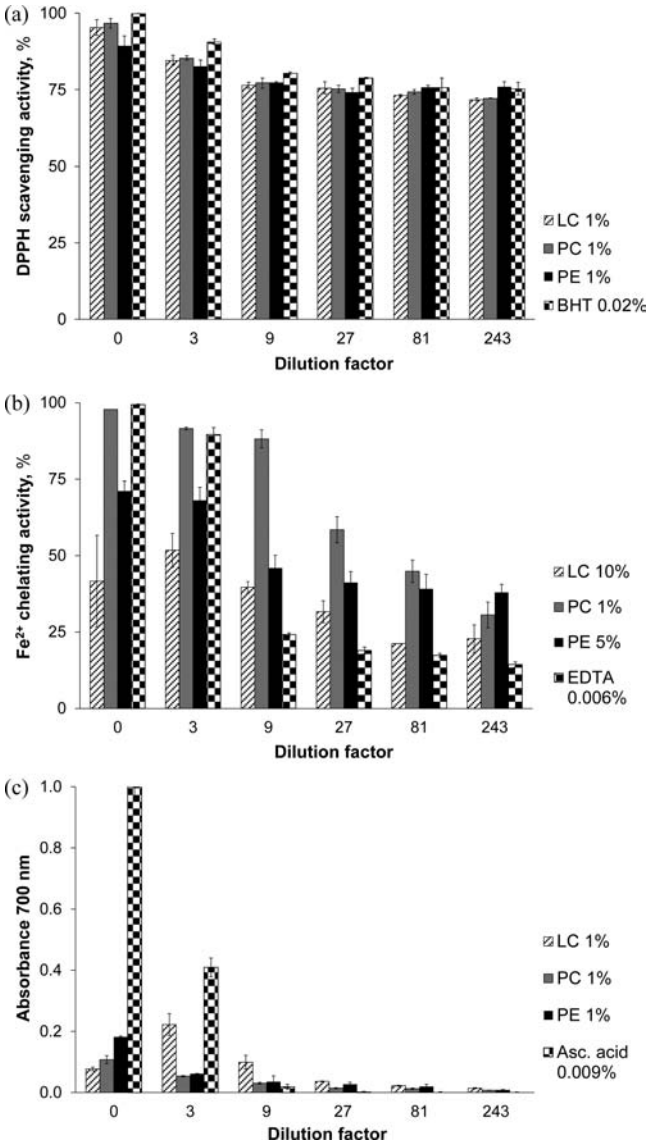

Figure 1. Antioxidant capacity of the phospholipids: (a) DPPH radical scavenging activity; (b) Fe^{2+} chelating activity; (c) reducing power. Results are the average of triplicate determinations ± standard deviation. Legends indicate the concentration of the raw solutions (dilution factor of 0). LC, lecithin; PC, phosphatidylcholine; PE, phosphatidylethanolamine; Asc. acid, ascorbic acid.

capacity of the amino group of phosphatidylcholine and phosphatidylethanolamine.[18] Nevertheless, it should be mentioned that the three phospholipids tested were found to be less effective DPPH scavengers than BHT. Espín et al.[35] reported DPPH radical scavenging activity for phospholipids presented in the lipid fraction of several vegetable oils, but it was considerably lower when compared with DPPH inhibition of α-tocopherol. On the other hand, Reiss et al.[36] reported a marked free radical scavenging activity for plasmalogen phospholipids (plasmenylethalomine and plasmenylcholine). The authors mainly attributed this fact to interactions of enol ether double bond with initiating peroxyl radical, which result in products of enol ether oxidation that apparently do not propagate the oxidation of polyunsaturated fatty acids. Furthermore, peroxyl radicals can also react with phosphatidylcholine to yield stable molecules such as trimethylammonium oxides.[37]

dx.doi.org/10.1021/jf405073x | J. Agric. Food Chem. 2014, 62, 1142−1152

Additionally, phospholipids have been proven to considerably enhance the antioxidant activity of chain-breaking antioxidants such as α-tocopherol, both in bulk oils[18,19] and in oil-in-water emulsions.[20] A synergistic effect of phospholipids with trolox, another phenolic antioxidant, was also described by Chen et al.[38]

Iron (Fe^{2+}) Chelating Activity. Transition metal ions, mainly Fe^{2+} and Cu^{2+}, highly contribute to lipid autoxidation in real food emulsions. Thus, antioxidants that behave as metal chelators are considered to play an important role in the improvement of the oxidative stability of emulsions.[39] Phospholipids have been reported to exhibit chelating activity, but contradictory results were described in the literature. Pokorný et al.[17] stated that phosphatidylinositol and other acidic phospholipids form inactive complexes with metal ions, whereas phosphatidylcholine and phosphatidylethanolamine do not possess such metal chelating properties. On the contrary, Yoon and Min[40] found that phospholipids, including phosphatidylcholine, improved the oxidative stability of purified soybean oil when iron was added. Zambiazi et al.[41] attributed the metal chelating properties to the amino group of phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine and to the sugar moiety of phosphatidylinositol.

In the present study, except for dilution factor 243, it was observed that PC presented the highest capacity to bind metal ions followed by PE, whereas LC exhibited the lowest metal chelating activity (Figure 1b). For all three phospholipids, Fe^{2+} chelating activity was concentration dependent, increasing with concentration. Although all of the phospholipids were considerably less effective than EDTA in binding metal ions, they may represent a unique type of chelator in case they can act in the lipid phase.[37] However, more studies are necessary to explain why PC had better metal chelating activity than PE and LC.

The superior Fe^{2+} chelating activity of PC may explain the results obtained by Cardenia et al.[37] These authors found that phosphatidylcholine with either oleic or palmitic acid aliphatic side chain was more effective than 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine at inhibiting lipid oxidation in 1% (w/w) stripped soybean oil-in-water emulsions at pH 7. Bandarra et al.[18] also described that the addition of phosphatidylcholine to refined sardine oil resulted in a higher protection against lipid oxidation when compared to the addition of phosphoethanolamine, cardiolipin, and α-tocopherol.

Reducing Power. The reducing power of phospholipids was evaluated to determine their capacity to donate electrons. In that way, they may convert free radicals to more stable products and terminate the radical chain reactions.[42] However, compounds exhibiting reducing power may also have a prooxidative effect, especially when Fe^{3+} is reduced to Fe^{2+} in the presence of already existing hydroperoxides.[43]

Figure 1c shows the reducing power for LC, PC, and PE. It was observed that they exhibited an insignificant reducing power when compared with ascorbic acid. For the three cases, absorbances at 700 nm lower than 0.2 were obtained for 1% (w/w) solutions. The higher reducing power exhibited by PE at a dilution factor of 0 may be explained by the fact that ascorbyl palmitate was added during the manufacturing process for its stabilization. Ascorbyl palmitate was reported in previous studies to exhibit reducing power.[43,44]

Characterization of the Emulsions. *pH and Zeta Potential.* Table 2 shows that the actual pH of the emulsions was exactly the pH aimed at (pH 7). With regard to the surface

Table 2. Values of pH, Zeta Potential, Droplet Size, Concentration of Protein in the Aqueous Phase, and Viscosity of the Emulsions

dx.doi.org/10.1021/jf405073x | J. Agric. Food Chem. 2014, 62, 1142−1152

charge of the droplets, negative zeta potentials, ranging from −22.8 to −32.9 mV, were obtained for all of the emulsions (Table 2). This finding can be explained by the fact that casein is negatively charged at pH values above its isoelectric point (around pH 4.6).[45] In addition, phosphatidylcholine and phosphatidylethanolamine, which are zwitterionic ions, do not carry net charge at neutral conditions. Likewise, in the case of lecithin, which is a mixture of phospholipids, phosphatidylinositol (anionic ion) is also negatively charged at pH 7,[46] and this explains why the use of a combination of casein and LC made the zeta potential slightly more negative compared to the use of casein alone, whereas less negative zeta potential values were obtained for the combinations of casein with PC and PE.

On the contrary, emulsions (0.3CAS and 0.3CAS+0.5PC) prepared at similar conditions but at a lower pH (3.5) showed positive values of zeta potential, 22.4 and 20.5 mV, respectively (data not shown). As for the emulsions at high pH, these results also revealed that the addition of PC did not improve the zeta potential of the emulsion. Indeed, the difference between both values (22.4 ± 2.4 and 20.5 ± 1.8 mV) was not statistically significant.

Particle Size Distribution (PSD), Droplet Size, Casein Content in the Aqueous Phase, and Viscosity. As far as the PSD of the emulsions is concerned, the results obtained from the analysis with the Mastersizer 2000 revealed that the emulsion stabilized only with casein had a monomodal PSD with a peak at 450 nm (data not shown). In contrast, the three emulsions in which combinations of casein and phospholipids were employed presented bimodal distributions, with a larger population of smaller droplets (mean diameter at peak = 200−400 nm) and a smaller population of larger droplets (mean diameter at peak = 1000−1200 nm). Although large unilamellar vesicles could present diameters >100 nm,[47] the peak found between 200 and 400 nm may be more likely due to the existence of small droplets covered by a phospholipid monolayer, protein−phospholipid, or protein alone. Similar bimodal distributions were reported by Fang and Dagleish[48] for 20% soybean oil-in-water emulsion stabilized with 0.7% casein and 0.5% dioleoylphosphatidylcholine and by Lu et al.[47] for 9.5% fish oil-in-water emulsions stabilized with 0.5% lecithin obtained from fish byproducts.

Likewise, the Zetasizer analysis gave similar monomodal and biomodal PSD values for the emulsions stabilized with casein alone and with combinations of casein and phospholipids, respectively (data not shown). Due to the fact that the PSD of the emulsions with casein and phospholipids did not present any peak around 4 nm, it was assumed that micelles were not formed from monolayers of phospholipid molecules.[49]

With regard to the mean droplet sizes of the emulsions, the results given as surface are mean diameter ($D_{3,2}$) and as *Z*-average diameter followed the same rank order for the four emulsions evaluated (Table 2). At day 1, the mean droplet sizes of the four emulsions increased in the order 0.3CAS+0.5LC ≈ 0.3CAS+0.5PC < 0.3CAS < 0.3CAS+0.5PE. Smaller droplet sizes are preferred to increase the physical stability of the emulsions.[47] Fang and Dalgleish[48] also reported a reduction on the initial droplet size when incorporating dioleoylphosphatidylcholine to emulsions stabilized with casein. Table 2 also shows that the addition of phospholipids increased the protein concentration in the aqueous phase for the emulsions with LC, PC, and PE. This finding suggested that part of the casein at the interface was substituted by phospholipids. This was in agreement with the suggestion by Fang and Dalgleish.[21] Nevertheless, as the protein concentration in the aqueous phase is also dependent on the temperature employed for the separation,[50] it should be noted that the values shown in Table 2 were obtained at 10 °C.

Although emulsions with LC and PC exhibited good physical stability, emulsions with only casein and casein plus PE increased their mean droplet sizes, and their size distributions moved to larger sizes after 14 days of storage. This denotes that only 0.3% of casein was not a sufficient amount of emulsifier to stabilize 10% fish oil-in-water emulsions during 14 days. In the case of the emulsion 0.3CAS+0.5PE, the physical instability could be due to the lower hydrophilic−lipophilic balance (HLB) of PE at neutral pH, which makes it less appropriate to stabilize oil-in-water emulsions.[51] Despite the increase in droplet sizes observed for 0.3 CAS and 0.3 CAS+PE during storage, no creaming occurred in any of the emulsions during the 14 days. Considering the emulsions prepared at pH 3.5 (0.3CAS and 0.3CAS+0.5PC), larger mean droplet sizes at day 0 and more physically unstable emulsions were obtained (results not shown). Creaming was also observed during storage, particularly for the emulsion with PC. This behavior could perhaps be related to the swelling of PC, which becomes more hydratable at acidic pH, diminishing its capacity as emulsifier.[52]

The rheology of the emulsion can determine the diffusion of prooxidants in the system.[53] The viscosities at day 1 of the four emulsions ranged from 1.37 to 1.61 cP (Table 2). It was observed that the addition of phospholipids as secondary emulsifiers produced a significant and almost identical reduction in the viscosity of 0.3CAS+0.5LC, 0.3CAS+0.5PC, and 0.3CAS+0.5PE emulsions compared to the value obtained for the 0.3CAS emulsion. This decrease in viscosity is not explained by a reduction in the mean droplet size. Therefore, it may be related to other properties of the emulsions such as the composition of the interfacial layer and the concentration of protein in the aqueous phase.[54] As shown in Table 2, the viscosities of the four emulsions increased significantly after 14 days of storage. This may suggest that molecular interactions between casein and phospholipids took place, but this needs further investigation.

Tocopherol Concentration. The amount of α-tocopherol in the emulsions significantly decreased during storage (Table 3), whereas this was not the case for β-, γ-, and δ-tocopherol, which were maintained practically constant for all of the emulsions at 4, 90, and 37 μg/g lipid, respectively. The highest content of α-

Table 3. Tocopherol Content for the Emulsions

	α-tocopherol (μg/g lipid)	
emulsion[a]	day 0[b,c]	day 14[b,c]
0.3CAS	181.7 ± 6.1w,*	157.1 ± 2.4w,*
0.3CAS+0.5LC	195.1 ± 2.1x,*	158.8 ± 1.1w,*
0.3CAS+0.5PC	253.9 ± 9.6y,*	231.9 ± 0.9x,*
0.3CAS+0.5PE	226.5 ± 4.7z,*	197.8 ± 5.2y,*

[a]0.3CAS, 0.3% (w/w) of casein; 0.3CAS+0.5LC, 0.3% (w/w) of casein and 0.5% (w/w) of lecithin; 0.3CAS+0.5PC, 0.3% (w/w) of casein and 0.5% (w/w) of phosphatidylcholine; 0.3CAS+0.5PE, 0.3% (w/w) of casein and 0.5% (w/w) of phosphatidylethanolamine. [b]For each column letters w−z indicate significant differences between samples ($p < 0.05$). [c]Significant differences between days 0 and 14 are indicated by either *, significantly different, $p < 0.05$, or ns, not significantly different.

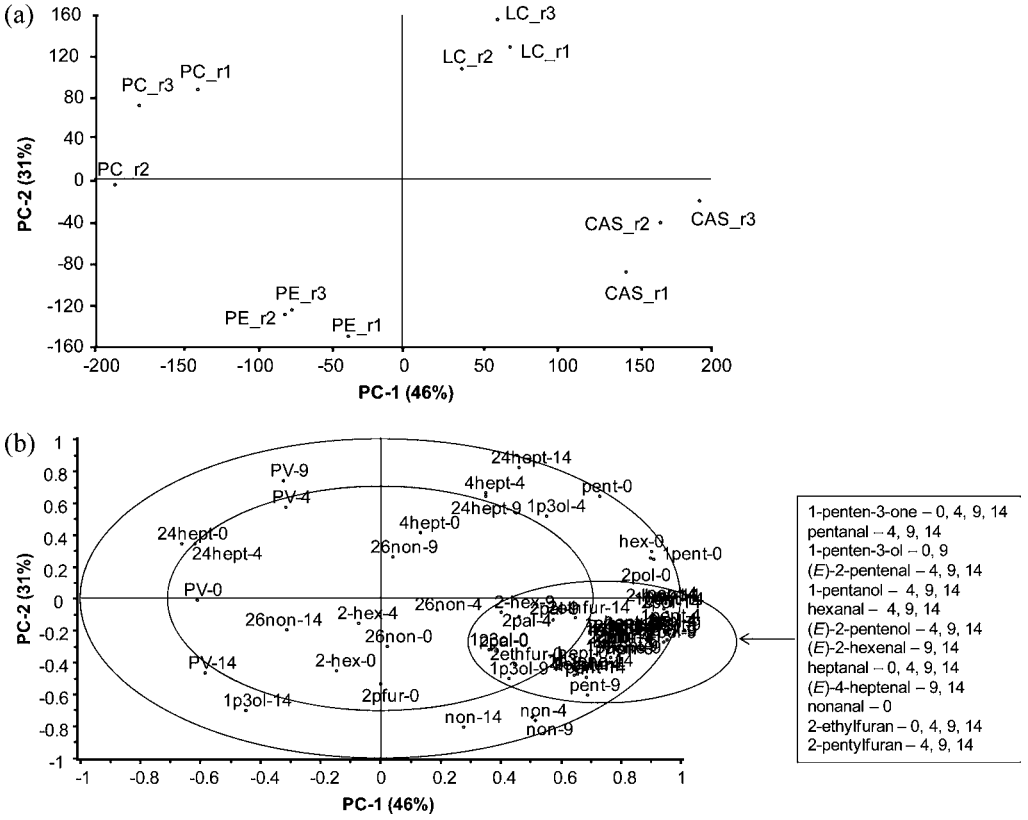

Figure 2. Principal component analysis (PCA) plots of lipid oxidation data: (a) scores plot with all sample replicates (r1, r2, and r3); (b) loadings plot (0–14 indicate sampling days 0–14). PV, peroxide value; LC, lecithin; PC, phosphatidylcholine; PE, phosphatidylethanolamine.

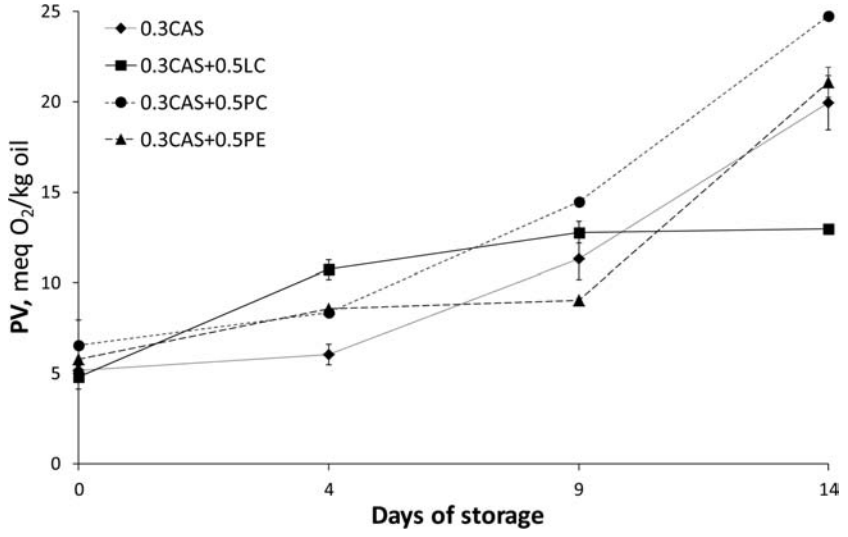

Figure 3. Peroxide value of the emulsions during storage at room temperature. Results are the average of duplicate determination ± standard deviation. 0.3CAS, 0.3% (w/w) of casein; 0.3CAS+0.5LC, 0.3% (w/w) of casein and 0.5% (w/w) of lecithin; 0.3CAS+0.5PC, 0.3% (w/w) of casein and 0.5% (w/w) of phosphatidylcholine; 0.3CAS+0.5PE, 0.3% (w/w) of casein and 0.5% (w/w) of phosphatidylethanolamine.

tocopherol was presented for the 0.3CAS+0.5PC emulsion followed by the 0.3CAS+0.5PE emulsion due to the higher α-tocopherol content of these two phospholipids. It was also observed that the consumption of α-tocopherol, calculated as α-tocopherol concentration at day 0 minus α-tocopherol concentration at day 14, followed the order 0.3CAS+0.5LC > 0.3CAS+0.5PE > 0.3CAS > 0.3CAS+0.5PC.

Lipid Oxidation in Emulsions. A PCA model was calculated to get a visual overview of all variables and to interpret correlations between the variables. In the PCA, the first principal component (PC1) explained 46% of the variance and the second principal component (PC2) explained 31% (Figure 2a). The scores plot showed that replicates for each type of emulsion were located together in the plot. Furthermore, the plot showed that the LC emulsion was located in the first quadrant, the PC emulsion in the second quadrant, the PE emulsion in the third quadrant, and the CAS emulsion in the fourth quadrant. Hence, the different emulsions

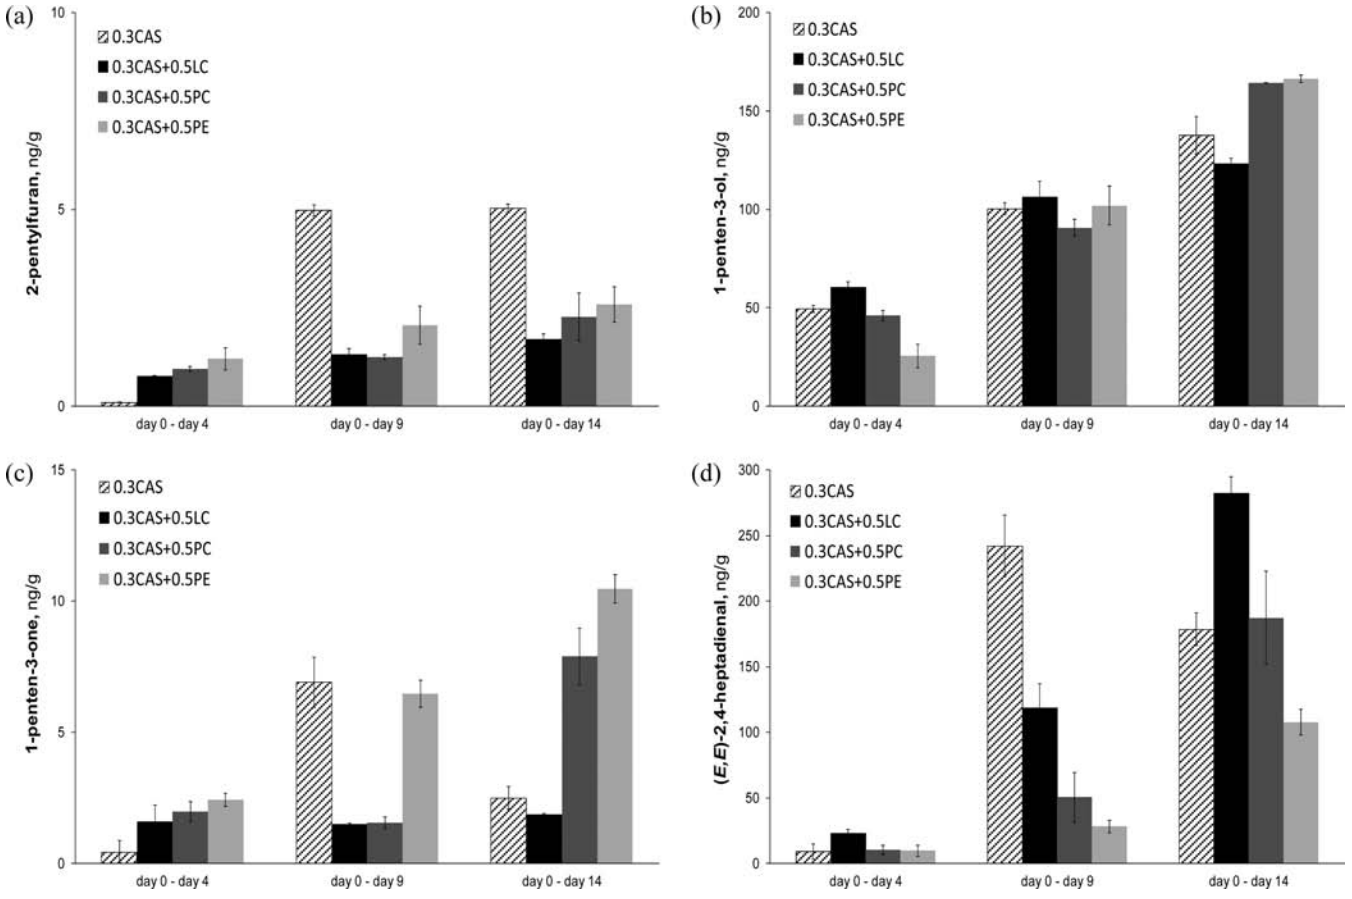

Figure 4. Increase of the concentration of secondary oxidation products in the emulsions (a) 2-pentylfuran, (b) 1-penten-3-ol, (c) 1-penten-3-one, and (d) (*E*,*E*)-2,4-heptadienal during storage at room temperature. Results are the average of triplicate determinations ± standard deviation. 0.3CAS, 0.3% (w/w) of casein; 0.3CAS+0.5LC, 0.3% (w/w) of casein and 0.5% (w/w) of lecithin; 0.3CAS+0.5PC, 0.3% (w/w) of casein and 0.5% (w/w) of phosphatidylcholine; and 0.3CAS+0.5PE: 0.3% (w/w) of casein and 0.5% (w/w) of phosphatidylethanolamine.

had different values on both the PC1 and PC2 axes, indicating that they behaved differently with respect to the parameters measured.

Peroxide Value. The PCA loadings plot showed that peroxide values were located to the left in the plot, in the second and third quadrants, indicating that PE and especially PC emulsions had higher PVs than the other two emulsions (Figure 2b). PV at initial time (PV-0) has a value of approximately 0 in PC2, indicating less contribution from this variable than the other PV variables. The raw data confirmed this interpretation of the model, as it was observed that all of the emulsions had a similar initial PV (~6 mequiv O_2/kg oil) and all of them suffered an increase in PV over time of storage. The emulsion with PC had the highest concentration of hydroperoxides after 14 days (24.7 mequiv O_2/kg oil), followed by the emulsion with PE (21.1 mequiv O_2/kg oil) and then the emulsion stabilized with only casein (19.9 mequiv O_2/kg oil) (Figure 3). Although PV increased rapidly between days 0 and 4 for the emulsion with LC, the scores for this emulsion correlated negatively with PV-14 in the PCA, and the raw data also indicated that it had the lowest PV at day 14 (12.9 mequiv O_2/kg oil).

Secondary Volatile Oxidation Products. The PCA loadings plot showed that the most volatiles were located in the fourth quadrant, indicating a higher concentration of volatiles in the CAS emulsion than the other emulsions (Figure 2b). This was confirmed by the raw data because CAS emulsion suffered a higher increase from day 0 to day 14 in the concentration of the following volatiles: 2-pentylfuran (Figure 4a), 2-ethylfuran, (*E*)-4-heptenal, heptanal, and (*E*)-2-hexenal (data not shown). This may be due to the physical instability, the second most negative zeta potential, and the lowest protein content in the aqueous phase shown by the emulsion stabilized with only 0.3% (w/w) of CAS (Table 2).

Figure 2b also suggests that the emulsion with PE presented the highest content of 1-penten-3-ol at day 14. It was confirmed by the raw data shown in Figure 4b, although a similar level of 1-penten-3-ol was found for the emulsion with PC. In addition, the emulsion with PE also had the largest increase in concentrations of other volatiles, namely, 1-pentanol, pentanal, hexanal, (*E*)-2-pentenol, and nonanal (data not shown). The emulsion with PC was the third most oxidized with high increases in the content of 1-penten-3-ol (Figure 4b), 1-penten-3-one (Figure 4c), (*E*,*E*)-2,4-heptadienal (Figure 4d), and (*E*,*Z*)-2,6-nonadienal (data not shown). This emulsion may present a lower concentration of volatiles than the emulsion with PE due to (i) the superior chelating properties shown by PC (Figure 1b) and (ii) its improved physical stability when compared with the emulsion stabilized with PE (Table 2).

The emulsion with LC presented the highest content of (*E*,*E*)-2,4-heptadienal at day 14 (Figure 4d), as was also indicated by the PCA. However, this emulsion showed the lowest increase from day 0 to day 14 for the following volatiles: 2-pentylfuran, 1.7 ng/g (Figure 4a); 1-penten-3-ol, 123.0 ng/g

dx.doi.org/10.1021/jf405073x | *J. Agric. Food Chem.* 2014, 62, 1142−1152

(Figure 4b); and 1-penten-3-one, 1.8 ng/g (Figure 4c). These findings, together with the lowest PV determined at day 14 (12.9 mequiv O_2/kg oil) and the maximum consumption of α-tocopherol during storage observed for this emulsion when compared with the others, indicated that the emulsion stabilized with the combination of casein and LC was the most oxidatively stable.

Nevertheless, this finding cannot be explained by the physical data obtained for this emulsion (Table 2). The emulsion with LC had the most negative zeta potential (−32.9 mV), which would increase the attraction of transition metal ions to the interface, and the lowest droplet size ($D_{3,2}$ = 210 nm), which implies larger surface for the contact between metal ions and hydroperoxides. Both facts could lead to less oxidatively stable emulsions[55,56] because metal ions catalyze the initiation of free radicals as well as the decomposition of hydroperoxides to secondary oxidation products. In addition, the protein content in the aqueous phase of this emulsion was practically identical to that of the other emulsions with phospholipids (Table 2), and LC also did not show better metal chelating activity than the other phospholipids (Figure 1b). Moreover, the DPPH scavenging activity of LC was not higher than the rest of phospholipids (Figure 1a), but it resulted in similar percentages of inhibition despite a lower α-tocopherol content than the other phospholipids (Table 1).

Therefore, these results suggested that the improved oxidative stability of the LC emulsion may be related to other factors such as the characteristics of the interface. In this regard, previous studies stated that a change in the thickness and structure of the interfacial layer was obtained when lecithin was added to emulsions stabilized with a low concentration of casein (0.3% w/w).[21,48] According to these authors, the surface concentration of casein is not the only important factor influencing the adsorbed casein layer thickness. They concluded that a thicker interfacial layer is produced due to the fact that the added phospholipids take up space at the interface, leading casein to adopt a conformation that projects farther into the aqueous phase. In this study, incorporation of phospholipids at the interface may have occurred as suggested by the increase of protein concentration in the aqueous phase for the emulsions with phospholipids when compared with the CAS emulsion (Table 2). Thus, it could lead to the previously commented modification of the interface. In the case of LC, its content in charged phospholipids such as phosphatidylinositol and phosphatidic acid, which are more soluble in water and are then more easily adsorbed at the oil−water interface,[57] may cause the suggested differences in the physical structure and thickness of the LC emulsion. However, this requires further research to be confirmed.

By comparison of the emulsions at pH 3.5 and 7, it was observed that emulsions at pH 3.5 presented a lower content of hydroperoxides but their volatiles content was considerably higher. Although the positive zeta potential of these emulsions may result in a repulsion of metal ions, causing a decrease of lipid oxidation, at low pH the solubility of iron increases, accelerating the decomposition of hydroperoxides to volatiles.[25]

In conclusion, it may be stated that employing a combination of soybean lecithin, 0.5% (w/w), and casein, 0.3% (w/w), as emulsifier improved the physical and oxidative stabilities of fish oil-in-water emulsions at pH 7, when compared to an emulsion stabilized only with casein, 0.3% (w/w). Soy LC is preferred instead of pure soy PC or PE due to its superior emulsifying properties as a consequence of the different phospholipids (phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidic acid) present in its composition. Moreover, the addition of LC could result in a favorable structure and thickness of the interfacial layer, which may reduce lipid oxidation. Additionally, LC is a cheaper product and, thus, its application to food processing is more economically viable when compared to pure phospholipids.

from Luzchem (Ottawa, Canada) using the third harmonic (355 nm) of a pulsed Q-switched Nd:YAG laser (Brilliant B, Les Ulis, France) attenuated to 14 mJ·cm^{-2} as the excitation source with 8 ns of pulse duration. Appropriate UV cutoff filters were used to minimize the sample degradation by the monitoring light. The samples were excited in 1.0 cm ×1.0 cm fluorescence cuvettes from Hellma (Mulheim, Germany). The signal from the monochromator/photomultiplier detection system was captured by a Tektronix TDS 2012 digitizer (Beaverton, OR). The laser system and the digitizer were connected to a personal computer via General Purpose Instrumentation Bus (GPIB) and serial interfaces controlling all the experimental parameters and providing suitable processing and data storage capabilities. Each kinetic trace was averaged 16 times, and observed rate constants were determined by fitting the data with MatLab R2008 to exponential decay functions (Mathworks Inc., Natick, MA). All measurements were made with fresh solutions thermostatted at 25.0 ± 0.1 °C and purged with high-purity N_2 (White-Martins, Sertãozinho-SP, Brazil) for 60 min before the experiment.

Fluorescence Measurements. Fluorescence measurements were carried out using a Hitachi F-7000 fluorescence spectrometer (Hitachi High-Tech, Tokyo, Japan) at 25 °C using a thermostated cell holder. Samples were excited in 1.0 cm ×1.0 cm fluorescence cuvettes from Hellma (Mulheim, Germany), and the emission spectra were recorded for excitation at 445 nm. Fluorescence lifetime measurements were performed with an Optical Building Blocks Corp. Fluorometer (Birmingham, United Kingdom), using the time-resolved mode. The excitation and emission wavelengths were λ = 460 and 530 nm, respectively. Fluorescence decay times were fitted using a mono-exponential decay function, and the best fit was obtained by optimized Chi-square residuals and standard deviation parameters. All solutions were deaerated by purging the cuvette with high-purity N_2 (White-Martins, Sertãozinho-SP, Brazil).

Time Resolved Fluorescence Spectroscopy. Time-resolved fluorescence of the sample was measured by time-correlated single-photon counting using a picosecond spectrometer equipped with Glan-Laser polarizers (Newport, Irvine, CA), a Peltier-cooled PMTMCP from Hamamatsu model R3809U-50 (Hamamatsu, Japan) as the photon detector, and Tennelec-Oxford (Oxford, Abingdon, U.K.) counting electronics. The light pulse was provided by frequency doubling the 200 fs laser pulse of a Mira 900 Ti-sapphire laser pumped by a Verdi 5 W coherent laser (Santa Clara, CA), and the pulse frequency was reduced to 800 kHz using a pulse picker (Conoptics, Danbury, CT). The fluorescence decays were taken in magic angle (λ_{exc} = 400 nm) and analyzed by a reconvolution procedure with instrument response function (irf) with exponential decay models, and the goodness of the fit was evaluated by the Chi-square statistical parameters. Steady-state fluorescence was measured on a Hitachi F-7000 spectrofluorometer (Hitachi Hi-Tech, Mito, Japan) at 25 ± 0.1 °C. All solutions were deaerated by purging the cuvette with high-purity N_2 (White-Martins, Sertãozinho-SP, Brazil).

Steady State Photolysis. An aqueous solution (pH = 7.4, ionic strength 0.2 mol·L^{-1}, 25 ± 0.5 °C) with 40 × 10^{-6} mol·L^{-1} riboflavin and 8 × 10^{-6} mol·L^{-1} myoglobin was exposed to 436 nm monochromatic light generated by a mercury lamp (HBO 200 w/4 short arc, Osram, Augsburg, Germany) accommodated with a focusing quartz lens, a water-filled heat filter and an Oriel narrow-band interference filter (center wavelength, 436 nm; Oriel Corp., Irvine, CA). The intensity of light, I_o, was measured by ferrioxalate actinometry[19] and had the average value of 2 × 10^{-6} einstein·s^{-1}·cm^{-2}. The absorbance measurements were carried out employing a Hitachi U-3501 (Hitachi-Hitech, Japan) spectrophotometer. All solutions were deaerated by purging the cuvette with high-purity N_2 (White-Martins, Sertãozinho-SP, Brazil).

SDS–PAGE Electrophoresis. Protein containing samples were collected and diluted in SDS sample buffer to a protein concentration of 1 mg·mL^{-1} (106 mM Tris·HCl, 141 mM Tris·Base, 2% SDS, 10% glycerol, 0.51 mM EDTA, 0.22 mM SERVA Blue G250, 0.175 mM Phenol Red; pH 7.4) and boiled for 5 min. 15 μL was loaded onto Tris-acetate gels (10% polyacrylamide, Invitrogen, Carlsbad, CA) and run at 125 V for 45 min. Gels were stained with 0.1% Coomassie brilliant blue R-250 colorant. Following destaining, proteins were identified by comparing relative motilities to molecular weight standards (Precision Plus Protein ALL Blue Standards; Bio-Rad, Berkley, CA) run under the same experimental conditions.

Western Blotting. 25 μL of protein (1.0 mg·mL^{-1}) from samples added to 25 μL in 4× LDS sample buffer with 50 mM DTT was electrophoresed on 8–12% SDS–polyacrylamide gel under reducing conditions and transferred to polyvinylidene difluoride membranes (0.20 μm pore size; Invitrogen, Carlsbad, CA) using a Nu-PAGE Transfer Buffer (Invitrogen, Carlsbad, CA) with 10% methanol. The membranes were blocked in 5% nonfat dried milk in Tris-buffered saline/Tween-20 (TBS-T; 20 mM Tris, pH 7.5, 150 mM NaCl, 0.3% Tween-20) for 1 h at room temperature. Immunoblotting was performed using a mouse monoclonal affinity-purified antibody (1:1000) to myoglobin, for 24 h at 4 °C in 1% nonfat dried milk in TBS-T. The membrane was then washed three times in TBS-T and incubated with a 1:2000 horseradish peroxidase-conjugated mouse affinity-purified antibody to mouse IgG, (GE Healthcare, Litle Chalfont, U.K.), in TBS-T for 2 h at room temperature. After three washes in TBS-T, proteins were visualized using the enhanced chemiluminescent system model ECL-plus.

RESULTS AND DISCUSSION

Oxidation of meat and meat products involves lipids, proteins, and heme-pigments and leads to rancidity, loss of tenderness, and discoloration.[16,17] Oxidation processes in meat are initiated by exposure to light, by iron catalysis, and by enzymatic processes including pseudoperoxidase activity of heme-pigments.[20,21] Notably, oxidation of lipids, proteins, and pigments is coupled, and the relative importance of the various initiators under specific conditions still remains an open question.

Riboflavin shows strong absorption in the spectral region for which fluorescent light used for retail display has high intensity, see Figure 1. Oxymyoglobin, MbFe(II)O_2, and metmyoglobin,

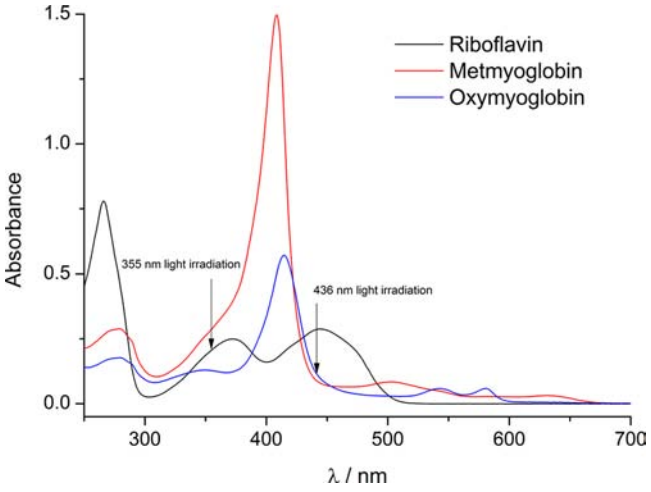

Figure 1. UV–vis absorption spectra for aqueous phosphate buffer pH 7.4 of riboflavin, 27 × 10^{-6} mol·L^{-1}, metmyoglobin, 8 × 10^{-6} mol·L^{-1}, and oxymyoglobin, 4.610^{-6} mol·L^{-1}. Arrows indicate the excitation wavelength for the steady-state photolysis (436 nm) and laser flash photolysis (355 nm).

MbFe(III), both absorb light in the visible region, but since the quantum yield for oxidation of MbFe(II)O_2 is very small for visible light and MbFe(III) is not photoreactive, direct photooxidation is of little importance.[22] None-heme meat proteins does not absorb visible light, and as for MbFe(II)O_2, riboflavin photosensitized processes should rather be considered.[2]

Riboflavin is highly fluorescent as may be seen from the emission spectra shown in Figure 2A for aqueous solutions of

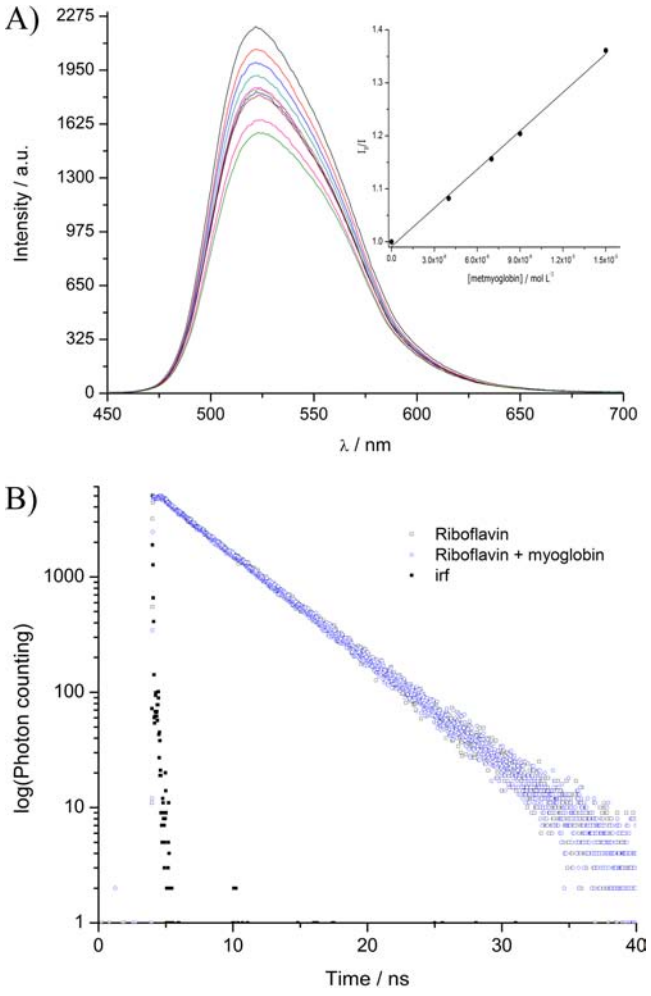

Figure 2. (A) Fluorescence emission spectra of riboflavin, 10×10^{-6} mol·L^{-1}, in aqueous solution pH 7.4 for increasing concentration of metmyoglobin ranging from 1 to 20×10^{-6} mol·L^{-1}. Inset: Stern–Volmer plot, see eq 1. (B) Fluorescence lifetime measurements by time-resolved single photon counting for riboflavin, 18×10^{-6} mol·L^{-1}, in the absence or presence of 7×10^{-6} mol·L^{-1} metmyoglobin in anaerobic aqueous phosphate buffer pH 7.4, irf = instrument response function.

riboflavin with increasing concentration of MbFe(III). Excitation at 436 nm was used in order to reduce inner-filter effects, compare with Figure 1, and the reduction in fluorescence intensity by the presence of MbFe(III) can rather be assigned to quenching by myoglobin. The fluorescent lifetime was found to have the value of $\tau = 4.8$ ns at 25 °C independent of the presence of MbFe(III) as seen from Figure 2B, in agreement with static rather than dynamic quenching of ^{1}Rib by MbFe(III). The fluorescence intensity was analyzed according to the Stern–Volmer equation,

$$\frac{I_o}{I} = 1 + k_q \times t \times [\text{MbFe(III)}] \quad (1)$$

in which I_o is the fluorescence intensity at 525 nm in the absence of MbFe(III), and I is the intensity for increasing concentration of MbFe(III), see inset in Figure 2A. The observed linearity of the Stern–Volmer plot provided an apparent value for k_q of 4.84×10^{12} L·mol^{-1}·s^{-1} and similar value for MbFe(II)O_2, see Table 1, which both are above the

Table 1. Second-Order Rate Constant of Singlet-Excited State Riboflavin Quenching, ^1k_q, and of Triplet-Excited State Riboflavin Reductive Quenching, k_2, by Myoglobins in Aqueous Phosphate Buffer pH 7.4 (0.2 mol L^{-1} NaCl) at 25 °C

species	^1k_q (L·mol^{-1}·s^{-1})[a]	k_2 (L·mol^{-1}·s^{-1})
metmyoglobin	6.4×10^{12}	$3.1 \pm 0.4 \times 10^9$
oxymyoglobin	4.8×10^{12}	$3.0 \pm 0.5 \times 10^9$

[a] from the Stern–Volmer treatment of the steady-state fluorescence data for dynamic quenching.

diffusion limit for a second-order process, further confirming that the quenching of ^{1}Rib is static rather than dynamic. The quenching was accordingly rather analyzed accordingly to[23]

$$\frac{\log I_o + I}{I} = \log K_a + n \times \log[\text{MbFe(III)}] \quad (2)$$

in which K_a is the equilibrium constant for

$$\text{Rib} + n\text{MbFe(III)} \leftrightharpoons \text{Rib(MbFe(III))}_n \quad (3)$$

and n is the number of quenchers binding to the emitting compound in the ground state. The values determined for K_a and n for the three temperatures, see Figure 3, is collected in Table 2 and provides the thermodynamic parameters $\Delta H° = -112 \pm 22$ kJ·mol^{-1} and $\Delta S° = -296 \pm 75$ J·mol^{-1}·K^{-1} for the reaction of eq 3 using the Van't Hoff equation. The binding of MbFe(III) to Rib is an exothermic process with a 1:1 stoichiometry, and the static quenching is highest at low temperatures as usually observed for hydrophobic interaction.

The good linearity seen for the plot according to eq 2 for each of the three temperatures indicates that the quenching is dominating by the ground state binding of the MbFe(III) to Rib rather than by a dynamic process, as is also in agreement with the values of K_a around 10^4 mol·L^{-1}. The decrease in entropy for binding of MbFe(III) to Rib could indicate a strong hydrophobic interaction without significant solvent involvement. The isoalloxazine ring of riboflavin is hydrophobic and has the possibility of binding to a hydrophobic surface region of myoglobin.

The singlet excited state of riboflavin is too short-lived for bimolecular reactions in contrast to the triplet excited state, ^{3}Rib, with a lifetime of 15 μs in aqueous solution. The reaction of ^{3}Rib as generated by laser flash photolysis with 355 nm excitation, see Figure 1, with MbFe(II)O_2 and MbFe(III) was followed using transient absorption spectroscopy. The decay of ^{3}Rib, absorbing in the near-infrared region, was increased in rate by the presence of myoglobins as seen from Figure 4 for MbFe(II)O_2 and MbFe(III). The rate of decay of ^{3}Rib followed first-order kinetics, and the observed pseudo-first-order rate constant was found to depend on the myoglobin concentration according to

$$k_{obs} = k_o + k_2[\text{myoglobin}] \quad (4)$$

both for MbFe(II)O_2 and for MbFe(III), as seen from the insets in Figure 4. The second-order rate constant for reaction of ^{3}Rib with MbFe(III) had the value of $k_2 = (3.1 \pm 0.4) \times 10^9$ L·mol^{-1}·s^{-1} and with MbFe(II)O_2 the value of $k_2 = (3.0 \pm 0.5) \times 10^9$ L·mol^{-1}·s^{-1}. ^{3}Rib is a strong oxidant, and the reaction

(B) k_{obs} from exponential fitting of absorption decay versus oxymyoglobin concentration according to eq 4

with the myoglobins is an electron-transfer reaction from the protein backbone in myoglobin to ^{3}Rib in agreement with assignment of the reaction of ^{3}Rib with other water-soluble compounds as electron donors. Metmyoglobin was in agreement with this assignment found to be cross-linked using SDS−PAGE electrophoresis[24] and at the same time degrading into smaller protein units, see Figure 5. Western blotting confirmed the degradation of MbFe(III) by reaction with ^{3}Rib, see Figure 6. The involvement of radicals in the degradation of myoglobins upon reaction with ^{3}Rib is further confirmed by SDS−PAGE electrophoresis, as addition of DMPO, a nitrone spin-trap, yields significant protection of MbFe(III), indicating that quenching of ^{3}Rib by MbFe(III) involves electron transfer rather than energy transfer.

The rate of reaction between ^{3}Rib and each of the two myoglobins is faster by almost a factor of 10 when compared with other proteins like β-casein, β-lactoglobulin, and bovine serum albumin for which the same reaction with ^{3}Rib has been studied.[2] The facile reaction seems to be related to the hydrophobic interaction in the ground state between the two reactants as detected by fluorescence quenching of ^{1}Rib by

dx.doi.org/10.1021/jf405182f | J. Agric. Food Chem. 2014, 62, 1153−1158

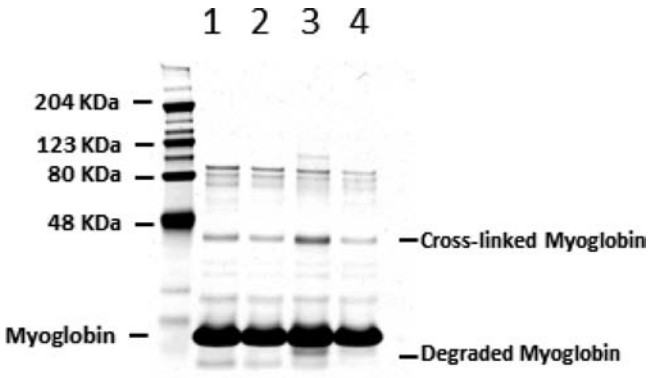

Figure 5. SDS–PAGE profile for aqueous phosphate buffer solution pH 7.4 containing (1) 8×10^{-6} mol·L^{-1} myoglobin and 30×10^{-6} mol·L^{-1} riboflavin kept in the dark; (2) 8×10^{-6} mol·L^{-1} metmyoglobin, 30×10^{-6} mol·L^{-1} riboflavin, and 30×10^{-3} mol·L^{-1} DMPO kept in the dark; (3) 8×10^{-6} mol·L^{-1} metmyoglobin and 30×10^{-6} mol·L^{-1} riboflavin exposed to 436 nm light for 1 h; (4) 8×10^{-6} mol·L^{-1} metmyoglobin, 30×10^{-6} mol·L^{-1} riboflavin, and 30×10^{-3} mol·L^{-1} DMPO exposed to 436 nm light for 1 h.

MbFe(III). The close interaction between ^{3}Rib and MbFe(III) or MbFe(II)O_2 will limit the diffusion distance or requirement of rearrangement prior to electron transfer resulting in the high effective rate approaching the diffusion limit. However, the observation of second-order kinetics for the electron transfer implies that the process is not intramolecular but rather a reaction between two molecules.

The heme iron was not affected by the reaction with ^{3}Rib in MbFe(III) or MbFe(II)O_2 as the visible spectrum of MbFe(II)O_2 did not change during reaction of MbFe(II)O_2 with ^{3}Rib. Neither was MbFe(III) oxidized to MbFe(IV)=O or reduced to MbFe(II) by ^{3}Rib (data not shown).

Oxymyoglobin is light sensitive, but only UV light is of importance for direct photooxidation to yield metmyoglobin, and UV absorbers in the food packing material protect meat color.[21] Riboflavin may, however, through photosensitized reactions, oxidize myoglobins, as shown by laser flash photolysis and transient absorption spectroscopy. The very efficient electron transfer between myoglobin and triplet-excited state riboflavin will, however, not affect the heme iron but only the myoglobin protein. For meat, riboflavin is accordingly concluded to be a photosensitizer for protein degradation but not for discoloration.

MATERIALS AND METHODS

Wines. We studied commercial sparkling wines that had been produced on an industrial scale at the Freixenet S.A. winery. The production process involved removing the lees and adding the appropriate amount of *liqueur d'expédition* that corresponded to the Brut category (sugar content < 12 g/L). The wines were produced from a blending of the grape varieties Macabeu, Xarel·lo, and Parellada. For over 2 years, six series of sparkling wine (coded A, B, C, D, E, and F) were kept under three temperatures: room (20 °C), cellar (16 °C), and fridge (4 °C). Production involved either the traditional (A, B, E, and F) or Charmat (C and D) methods. Wines E and F were Reserva category (>15 months of aging). Two bottles from each series of wine at each temperature were taken at 0, 4, 8, 12, and 20 months of storage for wines A–D and at 0, 4, 12, and 30 months for wines E and F. In total, we used 144 bottles of 75 cL from six series of commercial sparkling wines. Table 1 shows some of the enological parameters of each series at the initial sampling point (time zero). All bottles were opened in the dark, degassed, and stored at −20 °C until analysis.

Table 1. Commercial Sparkling Wine Characteristics at the Initial Sampling Point

sampling wine series	pH	free SO_2 (mg/L)	total SO_2 (mg/L)	total sugar content (g/L)	alcohol content (vol %)	CO_2 pressure (bar)
A	3.02	18	132	9.8	11.6	6.2
B	3.03	18	116	10.2	11.7	6.2
C	3.03	22	131	11	10.6	4.9
D	3.03	22	116	10.8	10.4	5.1
E	2.98	21	126	9.5	11.7	6.0
F	2.98	19	104	9.3	11.8	6.1

Chemicals. Deionized water was purified with a Milli-Q water system (Millipore, Bedford, MA). Acetonitrile [high-performance liquid chromatography (HPLC) grade] and acetic acid were purchased from Prolabo-VWR (Fontenays/Bois, France). Gallic acid (>98%), tyrosol (>98%), caftaric acid (>97%), caffeic acid (98%), catechin (>98%), *p*-coumaric acid (>98%), and 5-HMF (>99%) were supplied by Sigma-Aldrich (Saint Quentin Fallavier, France), while protocatechuic acid (>90%) and ferulic acid were acquired from Extrasynthese (Genay, France).

Enological Parameters. The total sugar content, alcohol content, pH, and free and total sulfur dioxide were measured using well-established standard methods[21] (Table 1).

Absorbance at 420 nm was considered as the browning index because it is a typical, fast, and easy parameter that is used by the producers of Spanish sparkling wines. It was measured using a 10 mm path length quartz cuvette. Values were multiplied 1000-fold and expressed as milli-absorbance units (mAU). A Shimadzu UV-3600 spectrophotometer (Duisburg, Germany) was used. All measurements were taken in duplicate.

Identification and Quantification of Phenolics. We used a Thermo Finnigan Surveyor HPLC system (Les Ulis, France) comprised of an autosampler (Surveyor Autosampler Plus), a quaternary pump (Surveyor LC Pump Plus), and an ultraviolet–visible (UV–vis) detector (Surveyor PDA Plus) hyphenated to a fluorescence detector (Finnigan FLD Plus) and a Thermo-Finnigan LCQ Advantage MS spectrometer equipped with an ion trap mass analyzer, all controlled by the Xcalibur data treatment system. Photodiode array (PDA) detection was configured to read from 200 to 600 nm, while for the fluorescence detection, λ_{ex} = 280 nm and λ_{em} = 320 nm [superhigh photomultiplier tube (PMT) voltage]. Electrospray ionization mass spectrometry was performed in negative and positive modes, reading m/z between 80.00 and 1200.00 with the following optimized parameters: capillary temperature, 300 °C; capillary voltage, −5 V; nebulizer gas flow, 1.75 L/min; desolvation gas flow, 1 L/min; and spray voltage, 5 kV.

The analyses were carried out in a Nucleosil 100-5 C_{18} column (250 × 4 mm, 5 μm, Agilent, France) at room temperature, and the samples were kept at 8 °C in the sample tray. The following eluents were used: solvent A, water/acetic acid (99:1, v/v); and solvent B, acetonitrile/acetic acid (99:1, v/v). The elution gradient was as follows: 0 min, 3% B; 24 min, 6% B; 30 min, 6% B; 38 min, 12% B; 46 min, 20% B; 50 min, 20%; 58 min, 60% B; 63 min, 80% B; and 68 min, 80% B. The system was re-equilibrated for 10 min before the next injection.

For identification proposes (Table 2), 5 mL of sparkling wine samples was evaporated under vacuum (below 30 °C) and the residue was redissolved in 500 μL of solvent A from the HPLC methodology (concentration of 10:1). The concentrated fraction was used for compound identification by high-performance liquid chromatography–photodiode array–fluorometric detection–mass spectrometry (HPLC–PDA–FLD–MS), by comparing the retention times to co-injected commercial standards (when available), UV spectra, and mass spectrometry (MS) spectra (in positive and negative modes).

Table 2. Identification and Quantification Parameters of the Phenolics in the Sparkling Wine Samples[a]

compound	Rt (min)	λ (nm)	std add	ESI–MS	% CV
gallic acid	6.6	272	+	(−) 169	5
protocatechuic acid	11.4	260	+	(−) 153	5
tyrosol	16.0	257	+	(+) 139	4
caftaric acid	18.1	328	+	(−) 311	5

Rt, retention time; λ, wavelength; std add, standard addition; ESI–MS, positive or negative and its m/z; nf, not found. [b]Excitation and emission.

For the quantification, recently filtered (0.45 μm) wine samples, with no prior treatment, were injected directly (20 μL) into the system. Each sample was injected in duplicate. Each compound was quantified using an external calibration curve obtained from the corresponding standard measured at the maximum wavelength, except for caftaric, grape reaction product or 2-*S*-glutathyonilcaftaric (GRP), *cis*-/*trans*-coutaric, and fertaric acids, in which the respective free non-esterified standards (caffeic, *p*-coumaric, and ferulic acids) were used. Quantification was performed by PDA detection at the maximum wavelength of each compound, except for catechin, for which fluorometric detection (FLD) was used.

5-HMF Quantification. The method described by Serra-Cayuela et al.[18] was used for the determination of this compound. Briefly, an ultra-high-performance liquid chromatography (UHPLC) Acquity chromatographic system (Waters, Milford, MA) with a binary pump, an autosampler, and a photodiode array detector (DAD, Waters 2996) was employed. The system was controlled by Empower Pro 2 (Waters, Milford, MA). Chromatographic separation was carried out using a BEH C_{18} column (50 × 1.0 mm inner diameter) with a particle size of 1.7 μm (Waters, Milford, MA), kept at 40 °C. The mobile phase consisted of eluent A as a solution of acetonitrile/water/formic acid (2:97:1, v/v/v) and eluent B as a solution of acetonitrile/water/formic acid (80:19:1, v/v/v). The mobile phase was passed through a 0.22 μm polytetrafluoroethylene (Acrodisc, CR PTFE, Waters, Milford, MA) filter. Sample vials in the injector were maintained at 10 °C, and the injected volume was 5 μL. The linear gradient conditions were as follows: 0 min, 0% B, 3 min, 20% B; 3.5 min, 100% B; 4 min, 0% B; and 5 min, 0% B, at a flow rate of 0.800 mL/min. Data were acquired

with the Empower Pro 2 software. Chromatograms were monitored at 284 nm. Sparkling wine samples and the 5-HMF standard were passed through a Waters (Waters, Milford, MA) 13 mm polypropylene (PP) of 0.22 μm pore size filter before injection. All samples were analyzed in duplicate using external calibration curves.

Statistical Analysis. The analytical replicates were averaged to produce the sample (bottle) value and then the variance within the two bottles; finally, the variances within the wines series (A–F) were used to calculate the overall variance and 95% confidence limits.

Principal component analysis (PCA) was employed to observe trends in the data. The first two principal components were used to plot the scores and loadings separately.

Analysis of variance (ANOVA) was applied for the parameters analyzed (general parameters, phenolics, A_{420}, and 5-HMF) to observe whether the factors time and temperature were significant as well as their interaction with the series factor. To show the compound behaviors along shelf life, the coefficients of variation (% CV) between initial and final concentrations were calculated as well as the means and the 95% confidence intervals of each series and time–temperature points. When there was not interaction time series, all of the series were joined, at each temperature, and the statistical differences between time points were carried out.

Linear regression was used to determinate the relationships between the compounds with time at each temperature and also to calculate the velocity constants (k). To check whether there were differences between the slopes (velocity constants), we performed the Tukey honest significant difference (HSD) multi-range test.[22] To check the goodness of fit of the models, the observed values were plotted against the predicted values.

A box-and-whisker plot was performed as an exploratory data analysis to show the distribution of 5-HMF values and to establish the interval covered by the middle 50%, interquartile range, of the data (box Q_{25}–Q_{75}). Whiskers are drawn from the edges of the box to the largest and smallest values, unless there are concentrations unusually far away from the box (outliers). The outliers are considered when their values are higher than 1.5-fold the interquartile range (box height) above or below the box, and they are represented by circles. Only the threshold of outliers above the interquartile range (Q_{75}–Q_{25}) was considered (upper inner fence). With the difference between this upper limit and the median, the maximum variation that a wine can undergo before it has overbrowned was calculated.

Statistical significances were set at $p < 0.05$. Version 2.15 of the R (Foundation for Statistical Computing, Vienna, Austria), with the FactoMineR and Hmisc packages, was used for all statistical and graphical analyses.

RESULTS AND DISCUSSION

Six series of commercial sparkling wines were stored at three temperatures (fridge, 4 °C; cellar, 16 °C; and room, 20 °C) for over 2 years. Table 1 shows the main enological parameters of the series at the initial sampling point (time zero). All parameters remained constant during storage, except for free SO_2. For all series, the concentration of free SO_2 fell below the limit of quantification (LOQ; 6 mg/L) within the first 4 months and until the end of sampling (data not shown). In model wines, it has been observed that this compound can react with aldehydes, such as 5-HMF, and flavonoids, such as catechin.[23,24] However, the lowest concentration of free SO_2 (which is the reactive form) seems to not have a relevant impact on the compounds studied in comparison to the effect of the temperature and time factors throughout the study. Further work would be required to specifically assess the impact of SO_2 and catechin on the kinetics of 5-HMF accumulation in sparkling wines.

PCA was used to observe the trends of the compounds during storage (Figure 1). Scores were affected by the factors time, temperature, and sparkling wine series (Figure 1a). The first component showed that the scores for the sparkling wine samples tended to change positively with time. 5-HMF, *trans*-coutaric acid, *p*-coumaric acid, caffeic acid, catechin, and the A_{420} parameter were the variables that contributed greatly to this first component (Figure 1b) and went in the same direction as time, except catechin, which went in the opposite direction. Thus, the more aged wines have higher amounts of 5-HMF, *trans*-coutaric acid, and *p*-coumaric acid, while they have less catechin ($p < 0.05$). In contrast, the scores for the second component were mainly distributed by sparkling wine series, determining the gallic acid, GRP, *cis*-coutaric acid, and caffeic acid amounts.

dx.doi.org/10.1021/jf403281y | J. Agric. Food Chem. 2014, 62, 1159−1166

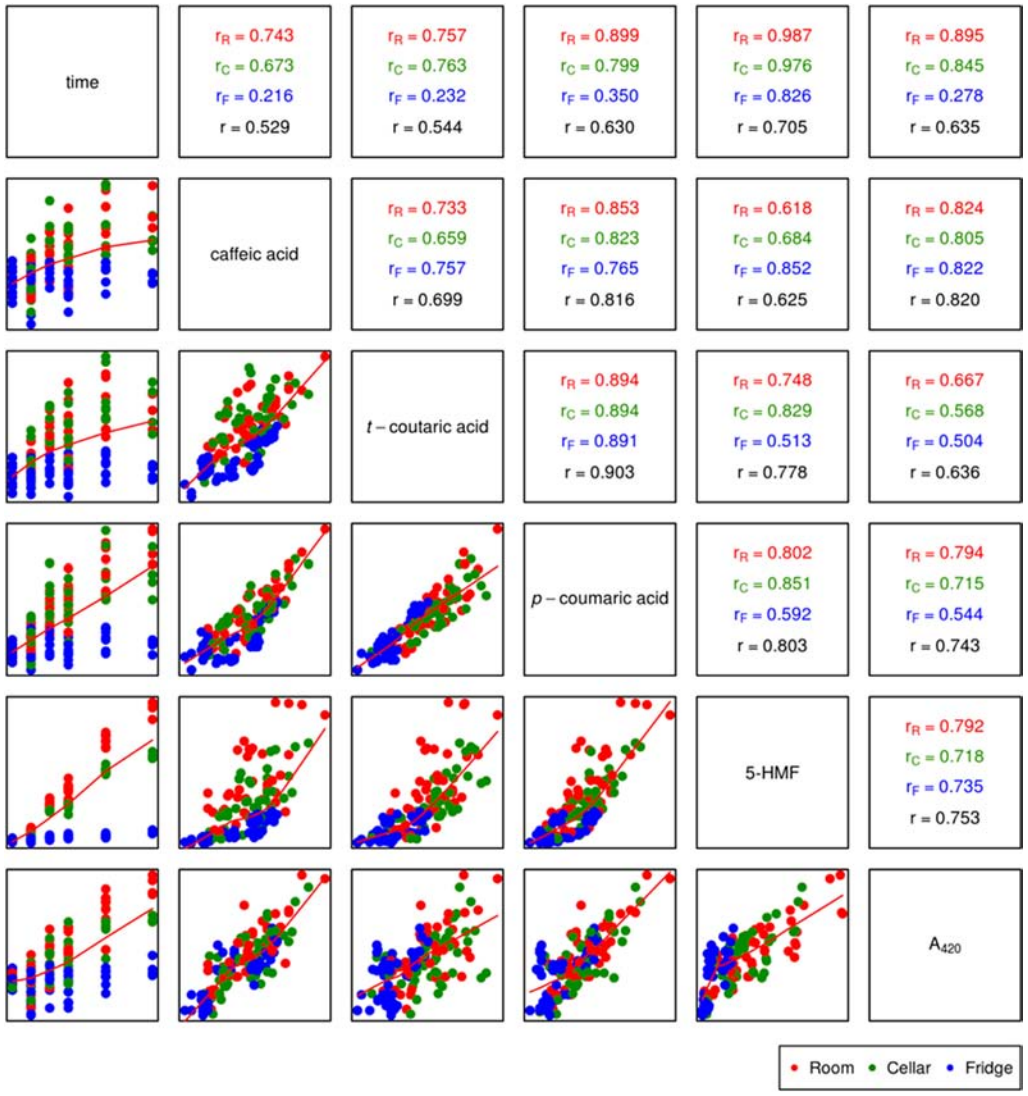

Figure 2. Pearson correlation between selected phenolics, 5-HMF, A_{420}, and time at each temperature and the overall value.

Table 3 shows the initial values of each compound and the A_{420} parameter. GRP, caftaric acid (both quantified as caffeic acid equivalent), tyrosol, and protocatechuic acid were the compounds with the highest concentration. In contrast, flavan-3-ol catechin and the hydroxycinnamic *p*-coumaric acid were the phenolics with the lowest content. Table 3 also shows the percentage of variation between the final and initial point for each wine series and each storage temperature. These percentages of variation are only shown when the difference was statistically significant by the ANOVA test. The compound 5-HMF had by far the greatest positive variation during shelf life. Thus, this compound underwent considerable changes during storage at the temperatures studied. To a lesser extent, caffeic acid, *trans*-coutaric acid, *p*-coumaric acid, and A_{420} also underwent positive variation during storage. A compound must meet a certain requirement to be used as a marker; it should behave in the same way in all series. Consequently, gallic acid, tyrosol, and fertaric acid were discarded as markers. These compounds, along with protocatechuic acid, were rejected because they increased or decreased depending upon the wine series. Finally, caftaric acid, GRP, *cis*-coutaric acid, and catechin were not further considered, because all of these compounds always decreased with time. A marker cannot disappear over the shelf life of a product, because this would make it difficult to determine the storage time.

Figure 2 shows the correlation of the compounds that had the highest coefficient of variation and always increased over time (5-HMF, caffeic acid, *trans*-coutaric acid, and *p*-coumaric acid), as well as the classic browning parameter (A_{420}). All compounds had a high correlation with A_{420}, with caffeic acid being the compound with highest correlation. The correlation with caffeic and *p*-coumaric acids could be due to the fact that both arise from the hydrolysis of their respective esters (caftatic and *cis*-coumaric acids). Caffeic, *trans*-coutaric, and *p*-coumaric acids did not change significantly at low temperatures (ANOVA test), and no difference was observed between 16 and 20 °C (Figure 2 and Table 3). Thus, only 5-HMF changed significantly ($p < 0.05$) at all temperatures and wine series. Therefore, this compound had the most suitable characteristics to be a time−temperature marker, which led us to study its kinetics. Moreover, 5-HMF was correlated ($p < 0.05$) with the A_{420} parameter, which is usually monitored in wineries by measuring browning[3,25] (Figures 1b and 2).

5-HMF and A_{420} Models. The kinetics of 5-HMF (Figure 3a) and A_{420} (Figure 3b) were studied and compared. To determinate the reaction order, the integrated kinetic equations

dx.doi.org/10.1021/jf403281y | J. Agric. Food Chem. 2014, 62, 1159−1166

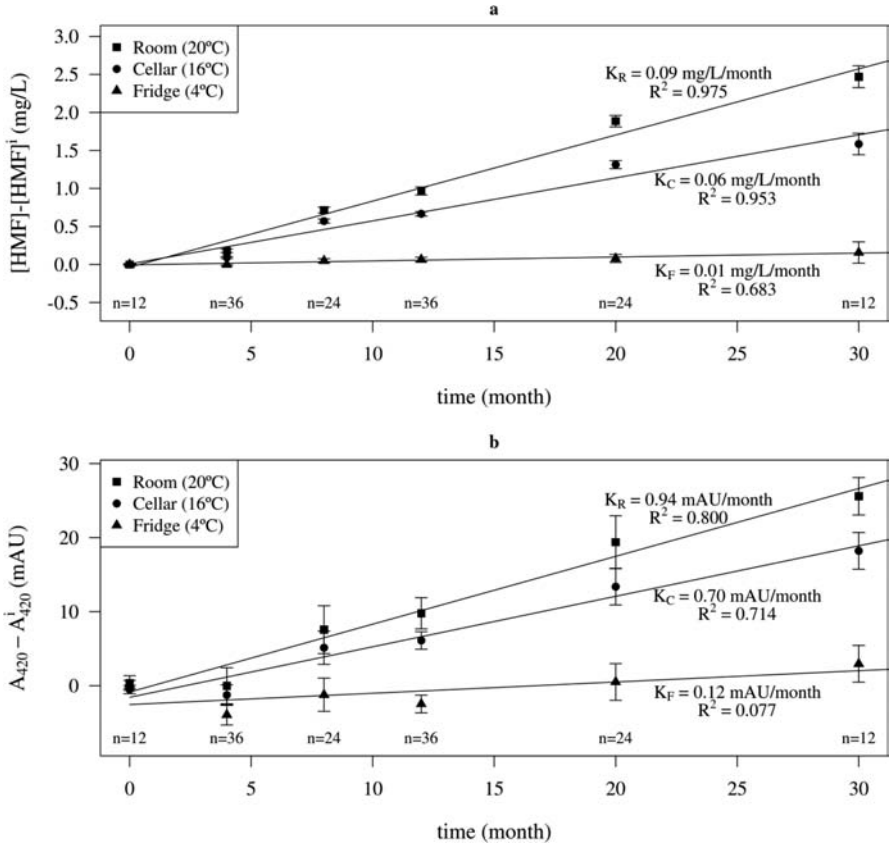

Figure 3. Kinetics of (a) 5-HMF and (b) A_{420} of commercial sparkling wines during storage at three temperatures (room, cellar, and fridge). The mean, the 95% confidence interval, and the number of samples (n) for the set of all series (A–F) at each time point are plotted. The velocity constant of formation (k) of the zero-order kinetics is also shown for each temperature.

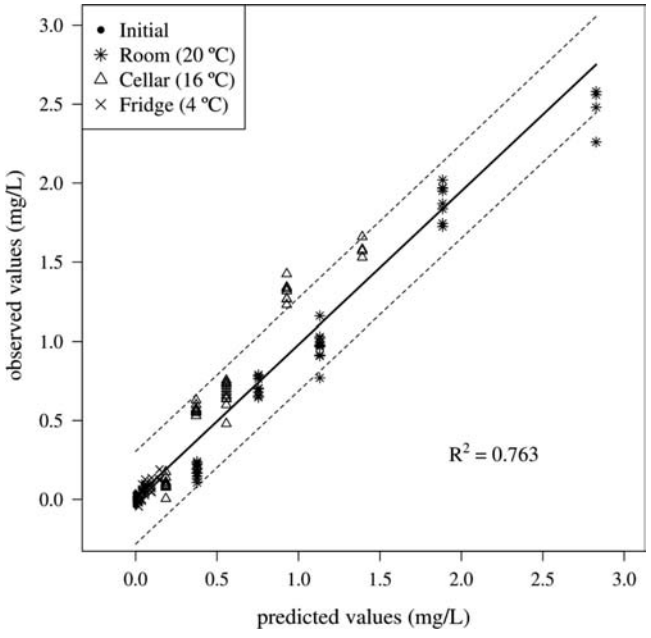

Figure 4. Correlation between observed versus predicted values to check the goodness of fit of the prediction model of 5-HMF, with dashed line representing the 95% prediction interval.

of zero, first, and second order were tested to find the reaction order that best fit the experimental data (data not shown). Both 5-HMF and A_{420} showed zero-order kinetics (eq 1), increasing linearly over time

$$Y = Y_i + kt \quad (1)$$

where Y is the 5-HMF content (mg/L) or absorbance at 420 nm (mAU), Y_i is the initial value of the 5-HMF content (mg/L) or initial absorbance (mAU), k is the velocity constant (expressed as mg L^{-1} $month^{-1}$ for 5-HMF or mAU/month for A_{420}), and t is time (in months).

The velocity constants (k) were calculated at each temperature (k_R, room; k_C, cellar; and k_F, fridge. 5-HMF (Figure 3a) showed higher differentiation than the A_{420} parameter between the velocity constants at various temperatures (Tukey HSD test) because 5-HMF has lower variability than A_{420} (Figure 3b). Moreover, the A_{420} parameter at the fridge temperature did not change significantly with time (Figure 3b and Table 3). According to the results indicated above, we will focus only on 5-HMF kinetics to construct a prediction model because this compound has less variability, is more sensitive, and can be used in a larger range of temperatures than the A_{420} parameter. We used the Arrhenius equation (eq 2) to predict k at any temperature

$$k = Ae^{\left(\frac{-E_a}{R(T+273.15)}\right)} \quad (2)$$

where k is the pseudo-zero-order rate constant (mg L^{-1} $month^{-1}$), A is the pre-exponential constant, T is the temperature (°C), E_a is the activation energy (kJ/mol), and R is the universal gas constant (8.314 J K^{-1} mol^{-1}). E_a and A are obtained from a representation of the natural logarithm of eq 2. The slope multiplied by R provided E_a, while A was obtained from the y intercept. For 5-HMF, the values were E_a =

dx.doi.org/10.1021/jf403281y | J. Agric. Food Chem. 2014, 62, 1159–1166

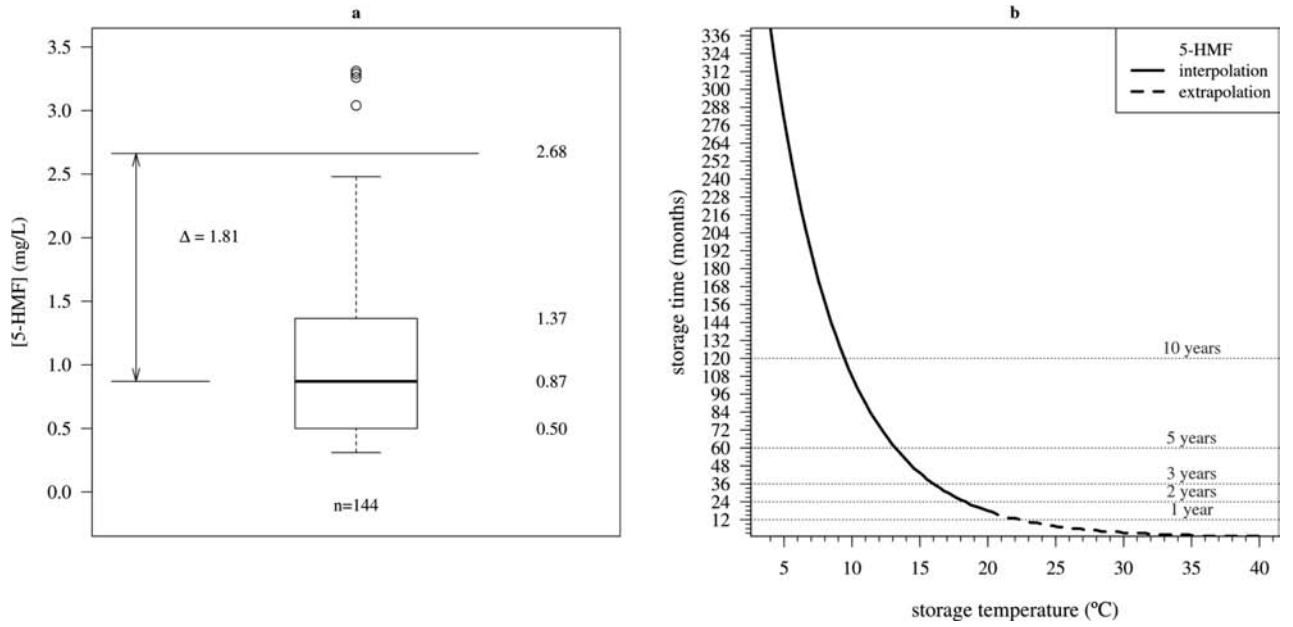

Figure 5. (a) Box-and-whisker plot of 5-HMF values for all of the series samples. The first, second, and third quartiles and the minimum and maximum values of each category are shown. The outlier limit, defined as 1.5-fold the interquartile difference, and its distance to the median are indicated. The outliers are represented by circles. (b) Time−temperature plot for predicting the shelf life of sparkling wines. The dashed lines indicate the extrapolation of the models.

125 kJ/mol and $A = 2 \times 10^{21}$ mg L^{-1} $month^{-1}$. These E_a and A values allowed us to establish eq 3, which was obtained by substituting eq 2 into eq 1. This equation can be used to predict the 5-HMF content, depending upon the length and temperature of storage

$$[\text{HMF}] = [\text{HMF}]_i + 1.7 \times 10^{21} e^{\left(\frac{-15014}{(T+273.15)}\right)} t \quad (3)$$

where [HMF] is the content of 5-HMF in mg/L, $[\text{HMF}]_i$ is the initial content (mg/L), T is the temperature (°C), and t is the time (months).

Sparkling Wine Shelf Life Prediction. Figure 4 shows the correlation between observed versus predicted values to show the goodness of the fitted model. The predicted model could be used to assess the length of storage depending upon the temperature conditions. At higher temperatures (outside the range studied) the behavior may be used by extrapolation. For instance, a sparkling wine stored at 25 °C for 15 months would increase its 5-HMF content by 4.05 mg/L.

The "best before" date of wine is regulatory not considered. However, it is of great interest for winemakers to know the shelf life of a wine. To determine whether a wine had anomalous data related to browning, we performed a box-and-whisker plot for 5-HMF (Figure 5a), which shows the median and upper inner fence for all of the samples. The latter parameter indicates the limit from which point the samples were considered overdeveloped (statistical outliers) and is defined as 1.5-fold the interquartile difference ($Q_{75}-Q_{25}$). Thus, the difference between the upper inner fence and median was considered the maximum variation that a wine can undergo before it has overdeveloped. This assessment is purely mathematical and does not take into account sensory aspects. The variation was 1.81 mg/L (Figure 5a); therefore, eq 4 is obtained substituting this value in eq 3. With this equation (eq 4), we can predict the maximum time of storage, depending upon the temperature

$$t = 9.9 \times 10^{-22} e^{\left(\frac{15014}{(T+273.15)}\right)} \quad (4)$$

where t is the time (months) and T is the temperature (°C).

Thus, this equation can be used to predict the maximum time before a wine overdevelops at a certain temperature or vice versa. Figure 5b graphically represents eq 4. The representation is also extrapolated outside the range of temperatures studied (dashed curve), thus showing the behavior in most common storage conditions. Thus, a sparkling wine stored at 20 °C would have overdeveloped after the first year and a half according to measurements of 5-HMF. At lower temperatures (4−16 °C), wines evolve slowly, with their life lengthening for many years. For instance, by extrapolation of the prediction model, at intermediate temperatures (16−24 °C), the shelf life of the sparkling wines would range from around 1 to several years. For storage at higher temperatures (above 27 °C), the prediction model indicates that sparkling wines should be consumed as soon as possible (within the first few months). Notwithstanding, because sparkling wines are produced from different grape varieties (blanc de blanc or blanc de noir) and blending, we believe that each winery could calculate the shelf life of their sparkling wine using their own initial value and the limit beyond which they consider the wine has overdeveloped. Once these values have been determined, the shelf life could be calculated by applying them to eq 3.

In summary, sparkling wines are stable at regular storage temperatures. Lower temperatures (fridge) can almost completely prevent browning and inhibit other reactions that involve phenolics. The hydroxycinnamic acids: caffeic, *trans*-coutaric, and *p*-coumaric, were the phenolics that have the highest correlation with browning and time, and their concentration increased over time. The compound 5-HMF proved to be a better time−temperature marker than A_{420} or any of the phenolics tested, because it increased linearly with time at all temperatures, was more sensitive, even at low temperatures, and more precise (with lower variability). The

dx.doi.org/10.1021/jf403281y | J. Agric. Food Chem. 2014, 62, 1159−1166

mathematical models allow us to determinate the concentration of 5-HMF, depending upon the length and temperature of storage. The model could be used by wineries to predict sparkling wine shelf life, that is, to determinate how long sparkling wines can be stored at a certain temperature before they overdevelop. Furthermore, in the case of complaint, the wineries can use 5-HMF as a reliable marker to reveal the conditions under which the sparkling wine had been stored.

PFOS distribution and elimination in food animals is critical for assessing dietary exposures and predicting associated risks. Exposures to cattle grazing on PFOS-contaminated pastures in both Europe and the United States have heightened concerns over human contact with PFOS in meat products.[23,24] Considering the very high bioaccumulation factor (BAF) and bioconcentration factor (BAC) for PFOS, limiting human exposures to PFOS is important.[1] To this end, a study was conducted to determine the accumulation and depletion of PFOS in plasma, and the tissue distribution of PFOS in cattle administered a single oral bolus dose of PFOS at 8 mg/kg.

MATERIALS AND METHODS

Safety. The toxicity of PFOS is believed to be minimal at the concentrations utilized for the study; however, all treated animals and corresponding samples produced from the study were considered radioactive due to the coadministered PFOA and were handled and disposed of by proper laboratory methods.

Chemicals and Materials. Perfluorooctane sulfonate (purity ≥98%), tetrabutylammonium hydrogen sulfate (TBAHS), and ammonium acetate were purchased from Sigma-Aldrich (St. Louis, MO). Other reagents included sodium carbonate (Fisher, Pittsburgh, PA), methyl *tert*-butyl ether (MTBE, BDH, Radnor, PA), HPLC grade methanol (MeOH, Honeywell Burdick and Jackson, Morristown, NJ), and 1,1,1,3,3,3-hexafluoroisopropanol (HFP, TCI, Portland, OR).

Study Design and Sample Collection. Four Lowline steers (#179−182, *Bos taurus*) were purchased from Effertz EZ Ranch (Bismarck, ND). The steers were raised in 3.1 × 3.4 m concrete-floored pens at the Biosciences Research Laboratory in Fargo, ND, for 8 months prior to the study. The Institutional Animal Care and Use Committee (IACUC) and the USDA Radiation Safety Committee approved the animal protocol. Twenty-four hours prior to dosing, the steers (329 ± 36 kg) were acclimated to stainless steel metabolism crates, during which time jugular catheters were surgically inserted for blood collection. The steers were provided feed and water ad libitum. To determine background levels of PFOS in the steers and to have control samples, blood, urine, and feces were collected 24 h prior to dosing. After the 24 h acclimation period, three of the steers were administered a single, oral dose of PFOS in a gelatin capsule at approximately 8 mg/kg body weight (bw). A relatively high dose of PFOS was utilized in this preliminary study to ensure that PFOS residues would be readily detectable in the tissues. Steers were housed in stainless steel metabolism crates for the duration of the 28-day study. Since PFOS and PFOA are commonly detected in the same samples, all of the steers (#179−182) were also given a simultaneous oral dose of [1-^{14}C]-perfluorooctanoic acid (PFOA, 1 mg/kg bw, 0.6 mCi per steer) to assess the pharmacokinetics of PFOA (previously published work).[25]

Blood was collected at 1, 2, 4, 8, 12, 24, 36, 48, 72, and 96 h, and at 6, 8, 10, 13, 15, 17, 21, 24, and 28 days after dosing. Jugular catheters were used to collect whole blood via a syringe which contained heparin to prevent clotting. When jugular catheters lost patency (most often due to the action of neck rubbing against the headgate), heparinized polypropylene Vacutainer tubes (BD, Franklin Lakes, NJ), were used to collect whole blood through 21 gauge needles. Collected whole blood was centrifuged at 1160*g* for 15 min at 5 °C to separate the plasma from the corresponding red blood cell fraction, which were put into separate vials and then frozen at −20 °C until analysis.

Urine and feces were collected quantitatively in 24 h increments for all 28 days. Urine was collected as described by Paulson and Cottrell.[26] Briefly, modified incontinent bags were attached to the steers with Tygon tubing (Saint-Gobain Performance Plastics, Akron, OH) running into polypropylene buckets. Urine was weighed daily and thoroughly mixed, and an aliquot was removed for later analysis. Feces were collected in stainless steel trays in the bottom of the large metabolism crates. All feces within each steer's daily 24 h collection period were thoroughly mixed in a stainless steel mixing bowl using a Hobart mixer, weighed, and subsampled. All urine aliquots and feces subsamples were stored frozen at −20 °C until analysis.

The steers were euthanized, eviscerated, and deboned on day 28 of the study. Liver, kidney, spleen, lung, brain, pancreas, diaphragm, muscle, bile, and carcass remainder (trimmings) were quantitatively collected for analysis. Representative samples of back fat and intraperitoneal (IP) fat were subsampled for analysis. All other tissues collected were whole organs/tissues that were ground and homogenized before a subsample was removed. The masses of the skin and bone were taken, but these compartments were not analyzed. Blood volumes were estimated from the relationship of animal body weight and blood volume to calculate PFOS percent dose in blood,[27] but the whole volume or weight of the blood was not recorded at time of slaughter. All plasma and tissue subsamples were frozen at −20 °C until analysis.

Extraction Procedure and LC−MS/MS Analysis. Extraction of PFOS from plasma and urine was accomplished by the modified ion-pairing method described by Hansen et al.[28] Briefly, 0.5 mL of plasma or urine was added to 1 mL of 0.5 M TBAHS (pH 10), 2 mL of 0.25 M sodium carbonate, and 5 mL of MTBE, shaken using a Magni Whirl shaker (Blue M, Blue Island, IL) for 15 min, and subsequently centrifuged at 1160*g* for 15 min. The MTBE layer was pipetted into a second tube, and the extraction was repeated two more times. Combined MTBE layers were evaporated to dryness under nitrogen, reconstituted with 0.5 mL of MeOH, and filtered through a 0.2 μm nylon syringe filter prior LC−MS/MS analysis.

One to two grams of tissue or feces was also extracted using the above ion-pairing liquid−liquid extraction method, but with two additional steps described by previously.[28,29] Tissue or feces samples were homogenized in TBAHS (1 mL) and sodium carbonate (8 mL) using an Ultra-Turrax Tissumizer (Tekmar Company, Cincinnati, OH). After homogenization, the sample was extracted with MTBE as described above and evaporated under nitrogen to 0.5 mL, 0.5 mL of HFP was added, and extracts were vortexed for 30 s to precipitate proteins. Extracts were then centrifuged at 3210*g* for 25 min, and the supernatants were filtered through a 0.45 μm nylon syringe filter. Filtered extracts were evaporated to dryness under nitrogen, reconstituted with 0.5 mL of MeOH, and filtered again through a 0.2 μm nylon syringe filter prior to LC−MS/MS analysis.

A MeOH extraction method previously described was utilized to extract adipose tissue and carcass remainder.[30] Briefly, 1−2 g of tissue was weighed and homogenized in MeOH (8 mL) for 30−60 s with a Tissumizer. Samples were shaken for 20 min on a Magni Whirl shaker and centrifuged at 2060*g* for 15 min, and the MeOH was decanted. The process was repeated two more times. MeOH extracts were combined and evaporated to dryness under nitrogen and then reconstituted with 0.5 mL of MeOH. Each sample was then filtered through a 0.2 μm nylon syringe filter prior to LC−MS/MS analysis.
