A plausible mechanism for the synthesis of methyl D-glucofuranoside is shown in Figure 1. First, the reaction of DMSO with TCT leads to **I**, which is attacked by the C-1 hydroxyl group of D-glucofuranose to form **II**. Because DMSO is a good leaving group, the DMSO group may then be replaced by MeOH to form methyl D-glucofuranoside via an S_N2 mechanism. Another possibility is the formation of carbocation **III** from **II** and the attack of MeOH on the C-1 leading to methyl D-glucofuranoside via an S_N1 mechanism. Because only the C-1 carbon has a methoxy substituent, carbocation **III** pathway is more likely. A similar mechanism is applicable to the formation of methyl D-glucopyranose.

The reaction conditions developed here were then applied to other carbohydrates, and the results are shown in Table 4. When D-fructose was treated with TCT (2.0 equiv) in 8.5 equiv/mL of DMSO in MeOH, no products formed after 6 h (Table 4, entry 1). Reducing the amount of DMSO to 0.1 equiv/mL (Table 4, entry 2) yielded a mixture of methyl D-fructopyranoside **6a** and methyl D-fructofuranoside **6b** (**6a**:**6b** = 73:27, Table 4, entry 2) in 82% yield. Increasing the reaction time from 6 to 24 h gave a higher yield (96%) and a similar product mixture (**6a**:**6b** = 68:32, Table 4, entry 3). When the concentration of DMSO was reduced to 0.07 equiv/mL, furanoside **6b** became the major product (Table 4, entry 4). In these experiments, neither furanoside nor pyranoside could be produced as the sole product, but each could be produced as the major product by adjusting the concentration of DMSO in MeOH. The literature reports three methods for the preparation of methyl D-fructosides: an I_2/MeOH method (unspecified ratio of furanoside and pyranoside, 3 h, 61.5% yield),[12] a TsOH/MeOH method (furanoside, 12 h, 80% yield),[33] and an AcCl/MeOH method (furanoside:pyranoside = 3:1, 16 h, 92% yield).[34] Our results compare favorably with these results in terms of yields and furanoside and pyranoside selectivities.

D-Mannose could not be transformed into the furanoside even by changing the concentration of DMSO from 4.3 to 0.07 equiv/mL (Table 4, entries 5−7). This is probably because it has a C-2 axial OH and the MeOH/DMSO system cannot stabilize the D-mannofuranose. Methyl α-D-mannopyranoside was the major product in 91% yield with 0.1 equiv/mL of DMSO in MeOH and TCT (2.0 equiv) (Table 4, entry 7). This result is better than previously reported methods: HCl/MeOH (pyranoside, 2 h, 70% yield)[35] and Amberlite IRA-120/MeOH (pyranoside, 10 min, 74% yield).[36]

Treating D-arabinose with TCT (2.0 equiv) and 8.5 equiv/mL of DMSO led to only a 40% yield of pyranoside and furanoside (**8a**:**8b** = 90:10, Table 4, entry 8). When the reactions of D-arabinose with 0.1 or 0.07 equiv/mL of DMSO in MeOH were quenched after 1 h, furanoside was the major product in 73 and 97% yields, respectively (Table 4, entries 9 and 11). The pyranoside was the major product (80:20) when the reaction time was increased from 1 to 24 h (Table 4, entry 10). This method is better than the current methods in terms of yield and reaction rates. These current methods are 1% HCl/MeOH/Ag_2CO_3 (pyranoside, 24 h, no yield reported),[37] Amberlite IRA-120/MeOH (pyranoside, 12 h, 37% yield),[38] and 0.18N HCl/MeOH (furanoside, 5.5 h, 79% yield).[39]

Treating D-xylose with different concentrations of DMSO in MeOH and TCT (2.0 equiv) led to a selective synthesis of methyl D-xylofuranoside (Table 4, entries 12−15). With 8.5 equiv/mL of DMSO in MeOH, the yield was poor (Table 4, entry 12). Lowering the concentration of DMSO (0.07 equiv, Table 4, entry 13) and increasing the reaction time (24 h,

[a]D-Glucose (300 mg), TCT (2.0 equiv), DMSO (8.5, 17, or 25.5 equiv), MeOH (3, 4, or 5 mL), 6 h, 25 °C. [b]Isolated yield. [c]Determined by ^{13}C NMR analysis.

Table 4, entry 14) improved the yield to >80%. The optimized conditions were 0.1 equiv of DMSO in MeOH, 2.0 equiv of TCT in 1 h, and the furanoside was selectively synthesized in 93% total yield (pyranoside/furanoside = 7:93, Table 4, entry 15). The reaction rate of this reaction is higher than that of the known methods. The known methods are MeOH/HCl/$CaCO_3$ (furanoside, 12 h, quantitative),[40] Amberlite IRA-120/MeOH (pyranoside, 12 h, 53% yield),[38] and montmorillonite K-10 (pyranoside, 10 min, 87% yield).[41]

Methyl D-galactofuranoside could be obtained in 85% yield and methyl D-galactopyranoside in 80% yield by reacting D-galactose with TCT (2.0 equiv) and 0.1 or 8.5 equiv/mL of DMSO in MeOH (Table 4, entries 16 and 17). It is clear that the ratio of pyranoside to furanoside is controlled by the solvent polarities as in the case of methyl D-glucoside synthesis. In the above selective synthesis of methyl D-galactofuranoside, the ratio of furanoside to pyranoside was 93:7 in the crude product. The reported yields of methyl D-galactopyranoside synthesized using microwave irradiation are 100%[42] and 84%.[41] Two methods for the synthesis of methyl D-galactofuranoside as a major product catalyzed by $FeCl_3$ (furanoside:pyranoside = 75:20)[20] and in 75% yield are known.[12] Our method has better selectivity for furanoside.

In summary, a highly selective method to synthesize methyl D-glucofuranoside or pyranoside as the sole product via tuning the polarity of the solvent has been developed. The effect of the solvent polarity on the isomerization of D-glucose is supported by ^{13}C NMR analysis. Most of the reaction yields and rates for the production of methyl glycosides from D-mannose, D-fructose, D-arabinose, D-xylose, and D-galactose using the DMSO/MeOH/TCT

less sensitive to conformational changes; thus, enzyme activity under drastic conditions may become higher than that of the free enzyme.[10,11] With these improvements, the immobilized form of *Thermomyces lanuginosus* (TL IM) was more popular in modification of fats and oils. Palm stearin (PS) is an excellent alternative for the production of plastic fats with addition of other vegetable oils because of its solid fat content (SFC) and ability to promote β' crystallization. [12]

The main objective of this paper is modification ASO and PS catalyzed by TL IM to produce desirable low-*trans* plastic fats as an alternative for plastic fats. After interesterification, the properties of produced fats [fatty acid profile, slip melting point (SMP), solid fat content (SFC), polymorphic form, and microstructure et al.] were characterized by gas chromatography (GC), differential scanning calorimetry (DSC), X-ray diffractometry (XRD), and confocal laser scanning microscopy. Also, the *sn*-2 positional fatty acid compositions were determined to check the occurrence of acyl migration side reaction.

EXPERIMENTAL PROCEDURES

Reagents and Materials. PS (SMP, 53.0 °C) was purchased from Fengyi Biotechnology Co., Ltd. (Shanghai, China). ASO were supplied by Jiujiang Regression Biotechnology Development Co., Ltd. (Jiangxi, Jiujiang, China). TL IM from *Thermomyces lanuginosus* was purchased from Novozymes A/S (Bagsvaerd, Denmark) and stored at −18 °C until use according the recommendation. The specific activity of Lipozyme TL IM, which is immobilized on silica gel, was 181 IU/g, having 0.54 g/mL bulk density, and 0.3 to 1.0 mm particle diameter. Standards of fatty acid methyl esters (FAME) (GLC-463) were purchased from Nu-Chek Prep Inc. (Elysian, MN, U.S.A.). All other chemicals used were of either HPLC or analytical reagent grade.

Interesterification. In the preliminary experiment, the interesterification conditions of PS and ASO for producing plastic fats have been screened out. Finally, PS and ASO at ratios of 70:30, 65:35, and 60:40 were successfully achieved to produce plastic fats at 60 °C for 6 h using 10% (wt) of Lipozyme TL IM as a catalyst. The react conditions of Lipozyme TL IM catalyzed interesterification were consistent to our previous reports.[13,14] In order to determine the qualities of produced plastic fats, scale-up experiments were conducted. A total of 50 g of substrate PS and ASO at ratios of 70:30, 65:35, and 60:40 were placed in 250 mL Erlenmeyer flasks with a screw cap. The melted blends were reacted with Lipozyme TL IM (10 wt % of total substrates) in a shaking water bath at 60 °C; the mixing speed was set at 220 rpm. After the reaction, TL IM was separated from the mixtures by filtering. To remove free fatty acids, the same volume of hexane and five drops of phenolphthalein solution were added to the interesterified products (IPs). The mixture was titrated with 0.5 mol/L KOH solution in 95% ethanol until a pink color appeared. IPs were washed with warm water until the pink color disappeared. The upper layer was passed through an anhydrous sodium sulfate column to remove moisture, and the solvent was completely evaporated under nitrogen with moderate heat.

Fatty Acid Composition Analysis. Samples were methylated according to the procedures described by Zhu et al.[15] with slight modification. The fats were placed in a 20 mL tube with a screw cap, saponified by 0.5 mol/L methanolic NaOH, and then methylated by boron trifluoride in methanol (14%). FAMEs were analyzed by GC using an Agilent 6890N gas chromatograph (Santa Clara, CA, U.S.A.) equipped with a flame ionization detector, an autoinjector, and a fused silica capillary column (CP-Sil 88, 100 m × 0.25 mm × 0.2 μm i.d.). The oven was heated to 45 °C and then held at this temperature for 3 min. The temperature was then increased to 175 °C at a rate of 13 °C/min and was held for 27 min. This temperature was finally increased to 215 °C at a rate of 4 °C/min and then held for 35 min. The temperature of the injector and detector were set to 250 and 260 °C, respectively. Nitrogen was used as a carrier gas at a flow rate of 52 mL/min in split mode (50:1). Fatty acid compositions were identified by comparison with the retention times of standard mixtures. Analyses were performed in triplicate.

Fatty Acid Composition at *Sn*-2 Position. *Sn*-2 positional distribution was determined by partial hydrolysis using pancreatic lipase.[15] Ten milligrams of IPs or physical blends (PBs) was dissolved in 10 mL of Tris−HCl buffer (1 mol/L, pH = 7.6), 2.5 mL of 0.05% bile salt, and 1 mL of 2.2% calcium chloride solution; 10 mg of pancreatic lipase was subsequently added to this mixture. The mixture was vortexed for at least 1 min and then placed in a water bath at 37 °C for 3 min; vortexing for 30 s followed. Four milliliters of diethyl ether was added to the mixture to extract the hydrolytic product. The upper layer was dried using a sodium sulfate column. After blowing up by nitrogen gas, applied to a thin-layer chromatography (TLC) plate (Merck KGaA, Darmstsdt, Germany) coated with silica gel G and developed with a solvent mixture comprising diethyl ether/hexane/acetic acid (50:50:1, V/V/V). The plate was air-dried for 30 min and then visualized by spraying with iodine vapor. The band corresponding to the monoacylglycerol was scrapped off, methylated, and analyzed by GC as described above. Analyses were performed in triplicate.

Analysis of TAG by RP-HPLC. The Agilent 1100 HPLC system consisted of quadruples pump with an evaporative light-scattering detector (All-tech 2000ES, U.S.A.) operating at 55 °C and a nitrogen pressure of 1.7 bar. Each sample was dissolved in hexane and 10 μL of the dissolved sample were injected and separated by the Novo-Pak C18 colomn (150 × 3.9 mm, waters, Milford, MA, U.S.A.). Elution solvent consisted of (A) acetonnitrile and B isopropanol:hexane (1:1, v/v) at the flow rate of 1.8 mL/min. [15]

Determination of SMP. The SMP of the mixture was determined according to American Oil Chemists' Society Official Method No. *Cc* 3-25 (2009)[16] using the open tube melting point method. Capillary tubes filled with a 1-cm-high column of fat were stored in a refrigerator at 10 ± 1 °C for 16 h prior to measurement in a beaker of cold water. The water was stirred and heated gradually. The temperature at which the fat in the tube began to rise because of hydrostatic pressure was recorded. This temperature was considered the SMP and determined in triplicate.

X-ray Diffraction Spectroscopy. The polymorphic forms of fat crystals in the blends were determined by Empyrean XRD (PANalytical B.V., Almelo, Netherlands) using Cu Kα radiation (voltage of 40 kV; current of 35 mA; divergence, antiscatter, and receiving slits, fixed at 0.5°, 1°, and 8 mm, respectively). The samples were melted at 70 °C, poured into a rectangular plastic mold, and tempered at 24 °C for 16 h. The short spacing was scanned at 2θ ranging from 16° to 32° at a rate of 0.01°/80 s.[15] The α polymorph was identified by a short spacing of 4.15 Å. β' forms were mainly identified by short spacings of 3.8 and

4.2 Å or three minor short spacings at 3.17, 3.97, and 4.27 Å. β forms were observed by a short spacing of 4.6 Å.[17]

Differential Scanning Calorimetry. Melting and crystallization thermograms were determined using DSC (Model No. DSC-204 F1, NETZCH Corporation, Germany) equipped with a thermal analysis data station. Nitrogen (99.99% purity) as the purge gas was used at a flow rate of 20 mL/min. An empty aluminum pan was used as a reference, and the samples were precisely weighed (7 ± 0.5 mg) for DSC analysis. The samples were heated to 80 °C and held at this temperature for 10 min. The temperature was subsequently decreased at a rate of 10 °C/min to −60 °C. After holding for 10 min at −60 °C, the temperature was returned to 80 °C at a rate of 5 °C/min and maintained for 5 min. The solid fat content (SFC, %) was determined from the melting thermograms obtained by the thermal analyzer. For calculating solid fat content SFC, each DSC thermogram was divided into 5 °C increments (0, 5, 10, 15, 20, 25, 30, 35, 40, 45, 50, and 55 °C), and the total melting energy (J/g) was converted into a percentage to determine the SFC at each temperature increment.[18]

Microstructural Analysis. The samples were melted at 70 °C in a water bath and kept at this temperature for 30 min to destroy crystal memory. About 10 mg of melted fat was placed on a preheated microscope slide and covered with a preheated coverslip with the aid of a capillary tube. The samples were cooled to 25 °C and maintained at this temperature for 20 h. The crystal morphology of the fat samples was studied under isothermal conditions (25 °C).[13] The coverslips were fixed on the stage of a Zeiss inverted microscope and observed under a Carl Zeiss 710 confocal laser scanning microscope (Carl Zeiss Inc., Oberkochen, Germany) connected to a digital video camera. All photomicrographs were obtained with a 40 × 0.75 Zeiss Plan Neofluar objective.

Induction Time of Oxidation. The induction times of produced IPs (PS:ASO 70:30) and IPs with different dosages of α-tocopherol (50, 100, and 200 ppm) were determined using a Metrohm 679 Rancimat (Brinkaman Instruments Co., Des Plains, IL, U.S.A.). For Rancimat analysis, 3.0 g of the sample was placed in a Rancimat reaction vessel kept at a constant temperature of 110 °C. A stream of air was passed through the vessel at a rate of 10 L/h. The vapors released during oxidation together with the air were passed into a flask containing 50 mL of demineralized water and an electrode for measuring conductivity.[19] Analyses were performed in triplicate.

[a]Abbreviations: La = lauric acid; P = palmitic acid; S = stearic acid; O = oleic acid; L = linoleic acid. [b]Equivalent carbon number (ECN) = CN-2DB, where CN is carbon number of TAG and DB is total number of double bonds in TAG. [c]ND = not detected.

Texture Profile Analysis. Textural properties (i.e., hardness, adhesiveness, and cohesiveness) of PBs and IPs were determined at 4 and 23 °C using a TA-X2 texture analyzer (Stable Micro Systems, London, U.K.). A 45° conical probe attached to a 5 kg compression load cell was inserted into the sample at 1.0 mm/s to a depth of 10 mm from the sample surface; withdrawal was performed at the same speed. Hardness and adhesiveness were respectively defined as the maximum force (g) and negative force area (g·s) of the first compression. Cohesiveness (unitless) was determined as the ratio of the positive force area during the second compression to that during the first compression. Completely melted samples were placed into 50 mL beakers and tempered at 25 °C for 24 h.[20] Specimens were prepared in triplicate for each analysis.

Statistical Analysis. Statistical analysis was performed using the SAS software package (SAS Institute, Cary, NC, U.S.A.). Duncan's multiple range test was performed to determine significant difference ($P \leq 0.05$).

RESULTS AND DISCUSSION

Total and Positional Fatty Acid Composition and SMP. The *trans* fatty acids (*TFAs*) was not detected in all samples (Table 1). ASO contained palmitic (21.70%), oleic (42.40%), and linoleic (30.54%) acids. The fatty acid profile of ASO was very similar to that of rice bran oil, in which the major fatty acids were palmitic (19.4%), oleic (45.9%), and linoleic (32.1%) acids.[21] The palmitic acid content (21.70%) in ASO was higher than that in other vegetable oils, such as soybean oil, sunflower oil, sesame seed oil, rapeseed oil, and olive oil.[17,22−25] The high palmitic and oleic acid contents of ASO imply its high oxidative stability. The *sn*-2 positional fatty acid compostion in Table 2 showed ASO contained 89.02% unsaturated fatty acids (USFAs), of which oleic acid (52.11%) and linoleic acid (35.63%) were the major fatty acids. These results demonstrated that USFAs in ASO were preferentially located at *sn*-2 position. In the case of PS, more saturated fatty acids (SFAs) were detected where palmitic acid take up to 59.49 and 34.86% of total (Table 1) and *sn*-2 positional fatty acid (Table 2). The high amount of SFAs contributed to higher SMP (53.03 °C) (Table 1).

The total fatty acid compositions PBs and IPs were altered based on the mixing ratios of PS:ASO. With increasing the weight ratio of ASO in PBs and IPs, the ΣUSFA content of PBs and IPs increased while SMP decreased. In the case of positional fatty acids, the obviously different data between PBs and IPs were detected. ΣSFA of IPs (57.98−61.11%) were significantly higher than that of PBs (29.77−35.91%). In some sense, the alteration of positional fatty acid proved the interesterification reaction occurred. Although this data also implied that the interesterification increased the saturation at the *sn*-2 position, which can be attributed to the random replacement of acyl groups in the products via a process called acyl migration. Similar phenomena have been reported previously.[24] Acyl migration is an undesirable side reaction that cannot be avoided during esterification without adopting auxiliary measures. This phenomenon can explain the changes in fatty acid composition at *sn*-2 position after interesterification.

SMP of PBs and IPs are also listed in Table 1. Both in PBs and IPs, reducing ratio of PS caused decrease of SMP. After interesterification, IPs possessed a lower SMP compared to the corresponding PBs. The differences of SMP between PBs and IPs also demonstrated the interesterification occurred. A SMP of 33.2−37.6 °C was ideal for spread fat because it is solid at room temperature and can be melted at body temperature.[6]

TAG Analysis. Table 3 showed the TAG composition of ASO, PS, PB, and IPs of PS:ASO 70:30 with different catalyzed time. The major TAG species in ASO were LLO (10.19%), LOO (21.56%), PLO (17.69), and POO (15.34), whereas POO (10.78%), POP (48.45%), and PPP (28.75%) were the dominant TAG types in PS. Therefore, the TAG species were originated from ASO and PS according to their ratio. After interesterification, however, changes of the TAG species in IP (PS:ASO 70:30) were observed compared to its PB. IP showed a reduced amount on LLO (0.52%), LOO (3.9%), PPP (10.11%), and POP (25.85%), but an increase of PLO (12.54−13.49%) and PLP (7.43−8.27%). The changes of TAG composition suggested that the fatty acid rearranged within and between TAG backbones by Lipozyme TL IM, which may alter physical properties.

SFC Value. SFC is an important determinant of the texture of bakery fats. The SFC is responsible for the various functional characteristics of bakery fat, including organoleptic properties (flavor release and thickness), physical appearance, spread-

ability, and oil exudation.[26] Figure 1 shows the SFC profiles of PS, PBs (PS:ASO 70:30; 65:35; 60:40), and IPs (PS:ASO

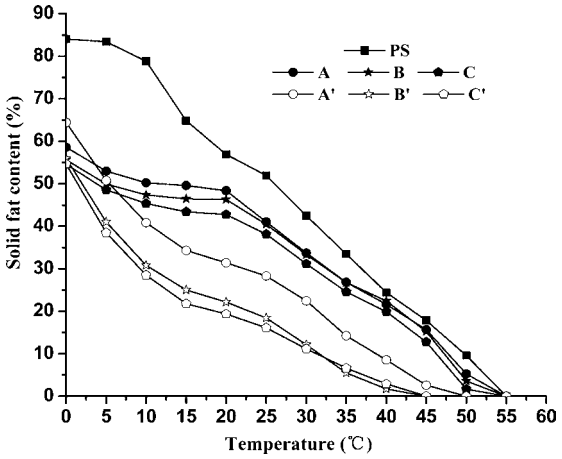

Figure 1. Solid fat content (SFC) of palm stearin (PS), the physical blends (PBs PS:ASO (wt/wt); A 70:30, B 65:35, C 60:40), and the interesterified products (IPs PS:ASO (wt/wt); A′ 70:30, B′ 65:35, C′ 60:40).

70:30; 65:35; 60:40) as a function of temperature. PS is a comparatively high melting fat that features an SFC of 24.41% even at 40 °C. Residual SFC values of 22.39%, 21.62%, and 19.88% were observed in PBs with PS:ASO ratios of 70:30, 65:35, and 60:40, respectively, at 40 °C. The sharpest decline in SFC appeared at the 25−30 °C range in PBs. In IPs, the fastest decline in SFC occurred at 0−5 °C. This shift is caused by the larger ratio of TAGs in IPs that liquefy at this temperature range. Shifts to lower temperature ranges may also explain the lower SMPs obtained in IPs compared with PBs. However, increasing the proportion of ASO decreased the prominence of the sharp drop in the 5 °C range in IPs. A similar study reported by Ming et al. shows a less pronounced drop in SFC upon decreasing the proportion of sunflower oil in enzymatic interesterified palm stearin−sunflower oil blends.[27]

SFC of IP PS:ASO 70:30 at 0−5 °C was slightly higher than that of PBs, similar to the results obtained by Kim et al. for the enzymatic interesterification of fully hydrogenated canola fat with olive oil.[28] This phenomenon may be attributed to the exchange of fatty acid residues in the two substrates to produce new TAG species after interesterification. The new species synthesized during interesterification could affect SFC profile of product at both high and low temperatures. Overall, IPs showed lower SFC contents than PBs at each temperature interval. For example, at 25 °C, IPs showed 16.11%−28.23% SFC, whereas PBs showed 38.16%−41.06% SFC. An SFC of 15%−35% at this temperature promotes the spreadability of margarine fats.[29] PBs with a higher SFC of 19.88%−21.62% at 40 °C may be used for cake manufacture.[30]

Crystallization and Melting Thermograms. The crystallization and melting properties of PS, PBs, and IPs were evaluated by DSC (Figure 2). The crystallization thermogram of PS (Figure 2A) exhibit two crystallization peaks at 2.4 and 26.4 °C, which correspond to the TAG fractions of high melting temperature and low melting temperature, respectively.[30] Figure 2A also shows the crystallization thermograms of the PS:ASO blends with different weight ratios before and after transesterification with LipozymeTL IM. Two exothermic peaks may be observed in PBs: the first occurred from 22.4 to

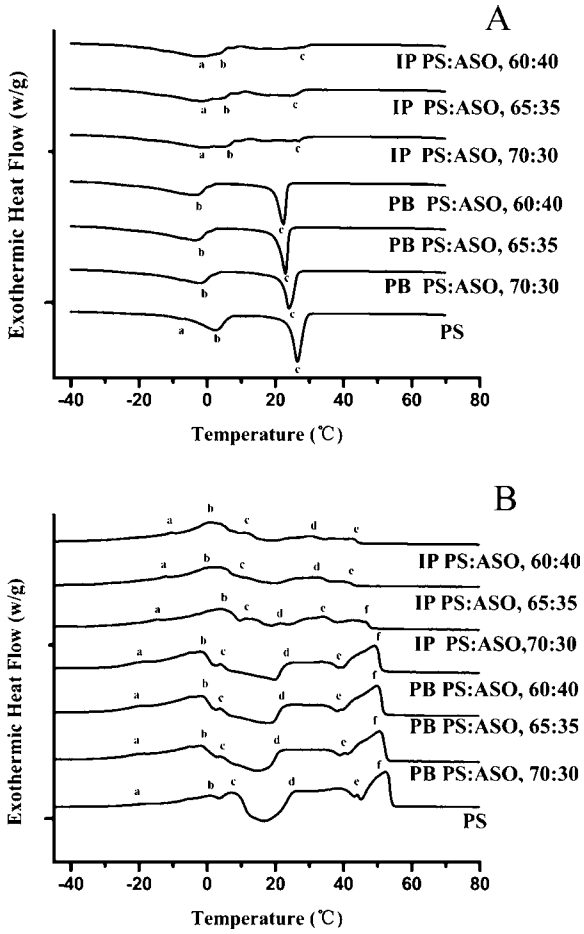

Figure 2. Differential scanning calorimetry (DSC) crystallization (A) and melting (B) thermograms of palm stearin (PS), the physical blends (PBs), and the interesterified products (IPs) of PS:ASO 70:30, 65:35, 60:40.

24 °C and the second occurred from −3.8 °C to −2.2 °C. Increasing the percentage of PS increased the representative peaks of higher-melting TAG (peak b) in terms of heights and areas and shifted them toward higher temperatures. IPs exhibited obviously broader and smaller exothermic peaks than PBs. Peak b was smaller than peak a, which indicated the formation of softer fats.

Figure 2B shows the endothermal profiles of PS and the PS:ASO blends of various ratios before and after interesterification. Five distinct melting peaks (peaks a to e) were observed in PS; peak e (at 52.4 °C) showed the largest and sharpest peak, which indicated that PS contained high-melting temperature TAGs.[23] The endothermic profiles of PBs were similar to that of PS but not to those of IPs. Five melting peaks of PBs ranging from −18.8 to 50.4 °C were observed; here, peak e, which occurred at high temperatures, showed the largest and sharpest peak. After interesterification, endothermic peaks b and c became broader and showed the largest size, whereas peaks d and e became narrower, smaller, and nearly disappeared. All of these changes indicated that most high-melting temperature TAGs are replaced by medium- and low-melting-temperature TAGs through rearrangement of fatty acids between TAGs during interesterification. The melting temperature of bakery fats normally ranges from 39 to 45 °C; IPs have this same melting point range.[22]

XRD Spectroscopy. Polymorphic forms of fat crystals are important criteria for determining the functional properties of bakery fats. The major polymorphs of fat crystals include the α (hexagonal), β' (orthorhombic), and β (triclinic) forms. Each polymorphic state has different properties. The α crystal form is characterized as the most unstable form and, therefore, features the lowest melting point. The β' form is a metastable and intermediate-melting polymorph. The β form is the most stable form and consequently has the highest melting point.[32] Table 4 lists the polymorphic forms of PBs and IPs analyzed by XRD.

PS was crystallized by the predominant β' (3.83, 3.90, and 4.20 Å) and β (4.60 Å) forms. PBs showed weak β crystal forms with short a spacing of 4.62 Å, strong β' forms with short spacings of 3.82, 3.90, 4.22, and 4.30 Å, and a very weak α crystal forms with a short spacing of 4.14 Å. IPs showed no α crystal forms, yielding β' forms with strong intensities (3.74, 3.89, and 4.30 Å) and β forms with weak intensity (4.61 Å) instead. We observed that the β' form increased whereas the β form decreased with increasing PS amount, which is attributed to the higher SFC and larger amount of fat crystals in samples with higher PS amounts. Similar results have previously been reported.[24] The β' form is desired for favorable molecular packing of the fatty acid chains of solid fats used to produce margarine or shortening because the small crystal size of this form stabilizes air and imparts better mouthfeel and spreadability; on the other hand, the β form comprises large crystals that give hardness as well as rough and sandy textures.[33]

Microstructural Analysis. The crystal microstructure of PBs (PS: ASO 70:30) and IPs (PS: ASO 70:30) were observed by confocal laser scanning microscopy. Figure 3 shows the distinct crystal morphologies of PBs and IPs. PBs presented very coarse, branched, and leaf-like crystals with crystal sizes of about 50−100 μm in diameter and compact packing. By contrast, IPs (PS: ASO 70:30) formed condensed, uniform, ball-like crystals with diameters of 20−30 μm. These findings agree with the XRD results, which indicated that IPs contain more β' polymorphs and less β polymorphs than PBs. Hartel reported that β' polymorphs have a spherulite-like shapes, whereas β polymorphs feature plate-shaped crystals.[34] Small, compact crystals are ideal for margarine fats and shortenings because these crystals can surround and stabilize air bubbles to impart better textural properties to a food product.

Texture Profile Analysis. Texture profile analysis was performed to evaluate the textural properties (hardness, adhesiveness, and cohesiveness) of PBs and IPs (PS:ASO 70:30) stored at room temperature (25 °C) (Figure 4). Significant changes in all textural attributes except cohesiveness were observed. PBs (3318.19 ± 86.67 g) were markedly harder than IPs (557.02 ± 12.75 g), which agrees with the SFC results, that is, the SFCs of PBs and IPs were 41.06% and 28.29%, respectively, at 25 °C. Hardness is positively related to the amount of solid fat. IPs were softer than PBs, which indicated the higher spreadablility of the former compared with the latter. PBs (PS:ASO 70:30) also showed more significant adhesive-

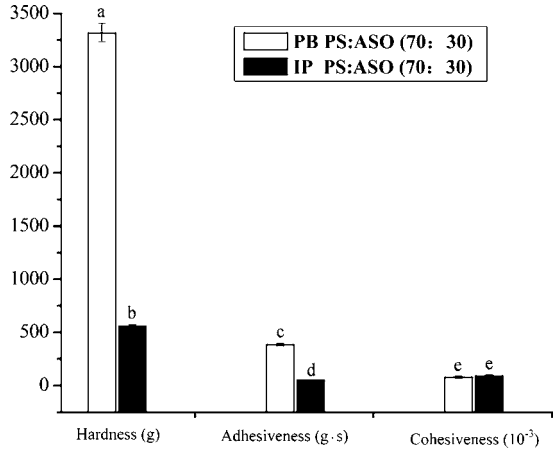

Figure 4. Hardness, adhesiveness, and cohesiveness of the physical blend (PB) and the interesterified product (IP) of PS:ASO 70:30 at 25 °C. Results are expressed as mean ± standard deviation (n = 3).

ness than IPs (PS:ASO 70:30). Adhesiveness reflects the stickiness or tackiness of plastic fats as well as the force required to remove fatty residues in the mouth, which is associated with the waxy taste of some fats. Thus, lower values of adhesiveness are preferred in edible oils.[35] IPs are potentially easier to spread and less persistent because of their lower adhesiveness. IPs possessed higher cohesiveness than PBs at 25 °C but differences between groups were not significant. Cohesiveness is related to the strength of internal bonds that make up the body of a product and describes how crumbly or brittle a food product is. IPs have stronger internal bonds and are therefore more brittle than PBs.

Induction Time of Oxidation. To develop a new lipid product, consideration of the nutritional and physical properties of the products as well as their oxidative stability is important. The oxidative stability of IPs (PS:ASO 70:30) was analyzed by measuring its induction time; longer induction times imply higher oxidative stability. Figure 5 shows that the induction time of IPs with PS:ASO 70:30 was 57 min. This induction time could be prolonged by addition of antioxidants such as α-tocopherol. In this study, the induction times of IPs fortified with 50, 100, and 200 ppm α-tocopherol significantly increased to 75, 91, and 108 min, respectively. α-Tocopherol appears to exert dose-dependent antioxidative effects from 50 to 200 ppm in ASO- and PS-based IPs.

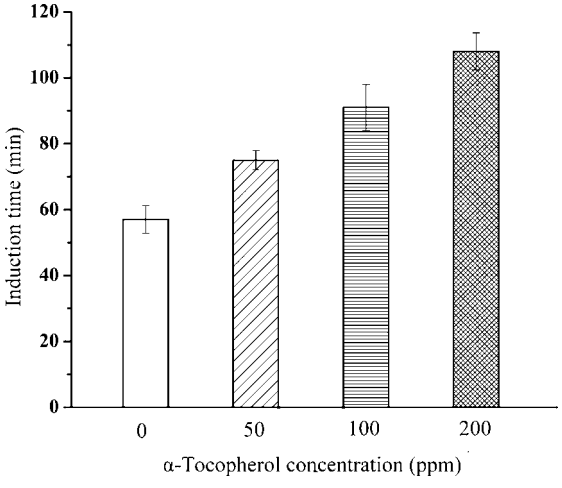

Figure 5. Induction time of the interesterified products (IPs, PS:ASO 70:30) with various antioxidant α-tocopherol concentrations.

In conclusion, the present study demonstrated the characteristics and feasibility of IPs from ASO and PS at different ratios of 70:30, 65:35, and 60:40 as plastic fats. Through analyses of fatty acid composition and physical prosperities, IPs were characterized as low TFAs, relative high content of USFAs (46.08%−50.12%), desirable physical properties (e.g., SFCs, SMPs), suitable crystal forms (β′ polymorph), and tender texture; these properties indicated IPs might be used in spreadable margarine, whereas PBs were used as shortening according to their wide SFC range. ASO can be considered as another potential resource for producing plastic fats to meet the increasing demands in the edible oil market. To make a successful application of lipase-catalyzed interesterification to produce plastic fats from ASO, we still need do further research such as how to tackle with the lipase inactivation after several recycling use.

estimated by inserting a preheated thermometer. When the thermometer was preheated to 65 and 78 °C, the temperature remained steady in the respective samples (165 and 198 kJ energy), the two lowest levels (settings) on the microwave oven. The amount of energy required to produce the corresponding temperature rise in the samples from room temperature (20 °C) is accounted for by an approximate 0.024% absorption of the total input energy, assuming the specific heat of the sample to be equal to that of water.

Cell Culture. Vero cells and Human Embryonic Kidney 293 cells (HEK293) were maintained in DMEM containing 10% fetal bovine serum (FBS) and 100 units/mL of both penicillin and streptomycin. Cells were trypsinized when ready to harvest.

Generation of Adenoviral Vectors That Express the GFP Gene. To visualize the effect of Shiga toxin on living cells, we measured changes in green fluorescent protein (GFP) expression levels. GFP gene was isolated from the Green Lantern vector (BRL) by digestion with the *Not I* restriction enzyme. The 750-bp fragment was purified from the gel using a Qiagen kit and was subcloned into the *Not I* site of the adenoviral shuttle plasmid between the Cytomegalovirus immediate-early promoter (CMV) and the polyadenylation signal from bovine growth hormone. The plasmid pJM17 containing the full length of the adenovirus genome including a 4.4-kb sequence of antibiotics resistance gene were cotransfected in HEK293 cells with the shuttle plasmid containing the GFP gene flanked by the adenovirus E1 sequences. After 10 days, the cytopathic effect appeared, and the transfected cells became round and detached from the plate. The cells were then analyzed by fluorescence microscopy to detect GFP gene expression. Individual plaques of Ad-GFP were amplified.[1,2]

Plaque Assays for Purification and Titration of the Adenovirus. Plaque assays depend on the ability of the adenovirus to propagate in HEK293 cells. Six 35-mm tissue culture plates were seeded with HEK293 cells. The cells were incubated at 37 °C in a 5% CO2 incubator until they were 90% confluent. Serial dilutions were made in the DMEM supplemented with 2% FBS. The diluted virus was added to the cells. After 2 h, the medium was removed and replaced with the Modified Eagle's medium (MEM) and 1% seaplaque agarose (FMC). The agar overlay was added to keep the virus localized after the cells had lysed. After 5 days, plaques were visible, and after 7 days, they were counted for titer determination.

Quantifying Stx2 Activity. Vero cells were plated on black 96-well plates (Greiner 655090 obtained from Sigma) at 1×10^4 cells in 100 μL of medium per well. Cells were incubated overnight to allow time for cells to attach to the plate. Spiked samples were added to each well, and the plates were then incubated for 48 h at 37 °C in a 5% CO2 incubator. The cells were then transduced with Ad-GFP at a multiplicity of infection (MOI) of 100 for 48 h. The medium was removed, and the cells were washed three times with pH 7.4 phosphate-buffered saline (PBS). Quantification of fluorescence emission by the cells expressing GFP was measured using a 528/20 nm emission filter and 485/20 nm excitation filter in a Synergy HT Multi-Detection Microplate Reader (BioTek, Winooki, VT, USA).

Visualized Stx2 by Gel Electrophoresis after Exposure to Microwaves. The electrophoresis equipment, buffers, gels, and SeeBlue Plus2 Protein Standard were purchased from Invitrogen (Carlsbad, CA, USA). Samples of Stx2 in phosphate-buffered saline (PBS, pH 7.4) were exposed to 165 and 198 kJ microwave treatments. The cooled Stx2 samples (2 μg) were then separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) using 4−12% NuPAGE Novex Bis-Tris mini gels following the manufacturer's protocol. To visualize proteins directly after gel electrophoresis, the gels were stained with Coomassie Blue G-250 (Bio-Rad, Hercules, CA, USA).

Statistical Analysis. Statistical analysis was performed with SigmaStat 3.5 for Windows (Systat Software, San Jose, CA, USA). Multiple comparisons among transduced treated cells were made. One-way analysis of variance (ANOVA) was used to compare transduced treated cells (containing increasing concentrations of toxin or milk) to transduced untreated cells. The experiments were repeated at least three times, and results with $P < 0.05$ were considered statistically significant.

RESULTS

Low Level of Microwave Energy Does Not Inactivate the Stx2 Toxin in Milk. To test whether microwave heating inactivates the Stx2 toxin produced by toxigenic *E. coli*, we generated adenoviral vectors that encode and express the green fluorescent protein (GFP) gene (Ad-GFP) and used the GFP fluorescent intensity in transduced Vero cells for quantitative measurement of biological effects and cell viability. Reduced fluorescent intensity of the cells is the result of inhibition of protein synthesis by the toxin and is compared with cells starved in phosphate-buffered saline (PBS, pH 7.4) that lacks essential nutrients. Samples of milk spiked with Stx2 were tested for Stx2 activity after exposure to 165 or 198 kJ microwave treatments. Figure 1 shows that the toxin was

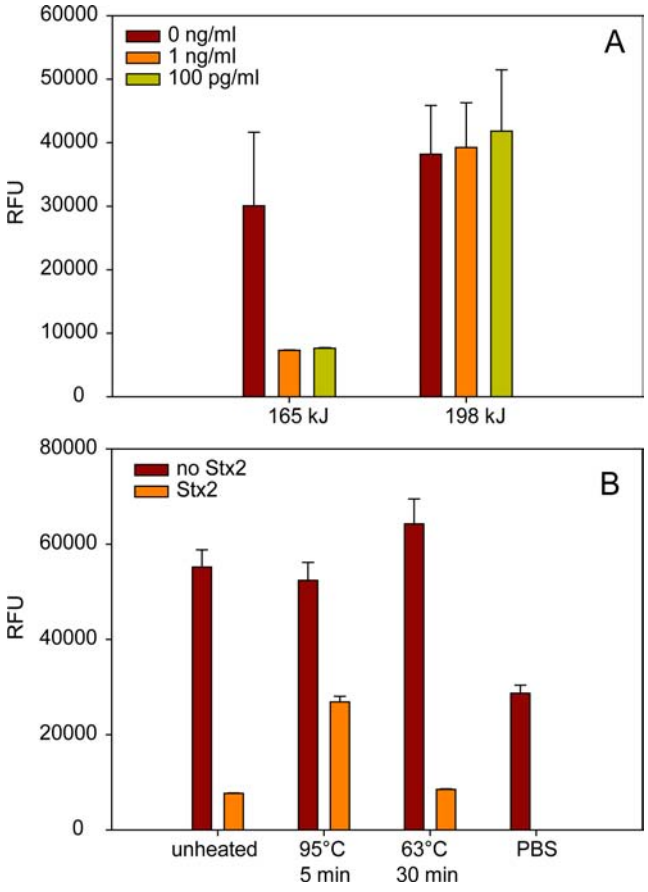

Figure 1. Microwave heating at 165 kJ does not reduce Shiga toxin inhibition of GFP expression. (A) Milk was spiked with 1 ng/mL or 100 pg/mL of Shiga toxin and treated with a microwave energy of 165 or 198 kJ. (B) Unheated milk containing Stx2 (1 ng/mL) was thermally treated at 95 °C for 5 min or pasteurized at 63 °C for 30 min. PBS buffer was used as a control, representing medium devoid of essential nutrients. Five microliters of spiked milk with 95 μL of medium was added to Vero cells. GFP expression was quantified fluorometrically after 48 h of incubation with the treated samples. Error bars represent standard errors.

inactivated neither by the low microwave radiation heating at 165 kJ nor by heat pasteurization. However, thermal heating at 95 °C for 5 min and the higher level of microwave radiation did reduce the activity of the toxin.

Degradation of Stx2 after Exposure to Microwave Treatment. Our results showed that heating of Stx2 with microwaves at 165 kJ did not inactivate the toxin. However,

exposure to the higher energy level of 198 kJ did inactivate the toxin. We then used SDS-PAGE to analyze the effect of exposure to the microwave treatment on Stx2 A and B subunits. As shown in Figure 2, microwave heating at 165 kJ did not

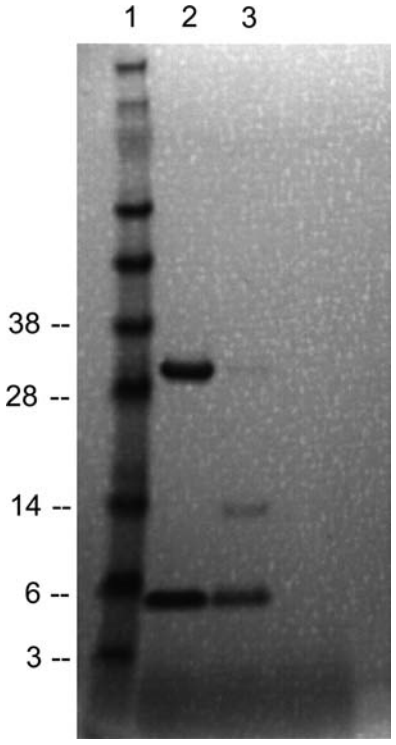

Figure 2. SDS-PAGE gel comparison of Stx2 samples (2 μg) treated at three microwave energy levels. The gel (NuPAGE Novex Bis Tris 4–12%) was stained with coomassie. Lane 1 shows the protein standard; lane 2, Stx2 treated at 165 kJ; lane 3, Stx2 treated at 198 kJ.

degrade the toxin. However, the microwave energy level of 198 kJ did degrade Stx2 and cut the A subunit into smaller sizes, with one fragment equal to a molecular weight of about 14 kD.

Microwave Heating at 198 kJ Destroys the Nutritional Value of Vero Cell Culture Medium. Our results showed that, under the tested conditions, Stx2 is inactivated by microwave heating at 198 kJ. To test whether microwave heating has the potential to reduce or destroy nutrients in culture medium used to grow the Vero cells, we quantitatively measured the biological effects of microwave energy on the cell culture medium. As shown in Figure 3, heating of the cell culture medium with a microwave energy of 165 kJ increased the cellular GFP fluorescent intensity comparable to that of the control untreated culture medium. Exposure to the higher energy level of 198 kJ resulted in decreased GFP fluorescent intensity. The intensity was reduced to the same level as exhibited by the PBS medium devoid of essential nutrients or the medium treated overnight at 100 °C. These results suggest that microwave heating at an energy level of >165 kJ caused a loss of the nutritional value of the growth medium, as indicated by its inability to support the growth of Vero cells.

These results were further confirmed by quantifying the fluorescent product of the cleaved substrate (glycyl-phenyl-alanyl-amino fluorocoumarin, GF-AFC) (Figure 4). This fluorogenic substrate enters cells and is cleaved by the protease activity of live cells, releasing AFC and generating a fluorescent signal proportional to the number of living cells. By contrast,

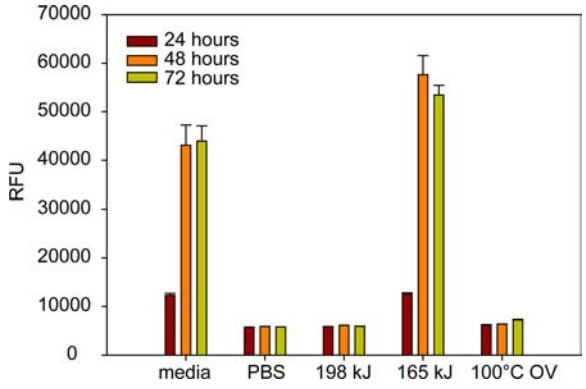

Figure 3. Microwave heating reduces the nutritional value of the cell culture medium as measured by reduced GFP expression in Vero cells. Samples of cell culture medium were treated with microwave energy at 198 or 165 kJ or by overnight heating at 100 °C. Untreated or treated medium or PBS was added to Vero cells. After incubation of treated culture medium for 24, 48, or 72 h with transduced Vero cells, GFP expression was quantified fluorometrically. Error bars represent standard errors. Note that the cell culture medium was microwaved in these experiments.

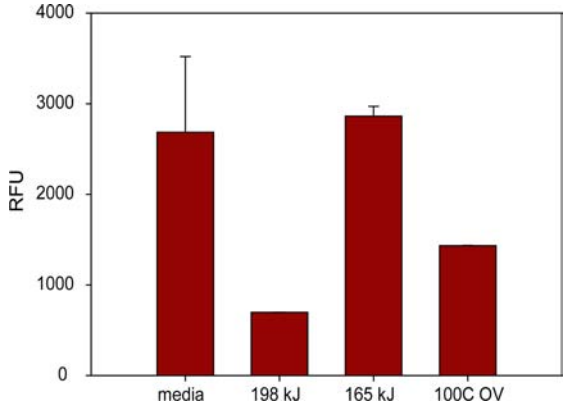

Figure 4. Microwave heating at energies of 198 kJ or higher lowers the nutrient value of the cell culture medium. Samples of cell culture medium were treated with microwave energy at 198 or 165 kJ or by overnight heating at 100 °C and then incubated for 72 h with Vero cells, followed by cleavage of the peptide GF-AFC by the live cell protease, releasing AFC and generating a fluorescent signal. The resultant fluorescence was measured by a fluorescence plate reader (excitation at 355 nm and emission at 523 nm). Error bars represent standard errors.

cells with compromised or disrupted cell membranes (i.e., dead cells) lose their protease activity and are unable to cleave the GF-AFC substrate. The absence of a fluorescent product usually formed in normal growing cells suggests that the cells have lost their viability. Figure 3 confirms by a second independent assay that medium treated at the higher levels of microwave energy or by overnight heating at 100 °C had a reduced ability to maintain the viability of the cells

DISCUSSION

Kindle et al.[5] found that microwave heating reduced the activities of *Pseudomonas aeruginosa*, *E. coli*, *Enterobacter sakazakii*, *Klebsiella pneumoniae*, *Staphylococcus aureus*, *Candida albicans*, *Mycobacterium terrae*, and bacteria in poliomyelitis vaccine suspended in five milk-type infant formulas. In another study, Santos Ferreira et al.[6] found that microwave heating of

dx.doi.org/10.1021/jf500278a | J. Agric. Food Chem. 2014, 62, 3301–3305

contaminated human milk prevented transmission of Chagas disease in mice caused by the protozoan *Trypanosoma cruzi* trypomastigotes.

The cited results indicate that pasteurization and microwave heating can be used to eliminate pathogenic bacteria such as *E. coli* from contaminated milk and milk-based products. There seem to be no reported studies on the effect of microwave heating on the biological activity of Stx2 or any other toxin in milk. Because high levels (306 ng/mL in milk and 452 ng/mL in meat)[7−9] of Shiga toxin have been observed in foods inoculated with *E. coli*, there is a need for such studies.

It has been reported that a malfunction at a milk production plant, prior to pasteurization, contributed to an outbreak of hemolytic uremic syndrome that was linked to drinking the subsequently pasteurized milk in which no live bacteria were found.[10] This finding suggests that the toxin produced and secreted by the bacteria was not inactivated by pasteurization and might be responsible for the illness

We previously reported that oral ingestion of Stx2 toxin alone without *E. coli* bacteria that produce the toxin causes histopathological changes in kidney, spleen, and thymus tissues and mortality in mice.[1] This finding demonstrated the need for new approaches to inactivate both the bacteria and the toxin produced by the bacteria. None of the cited studies examined the use of microwave radiation to inactivate Stx2 and other toxins produced by bacteria, although they do report effects beyond the mere elimination of the microbial pathogen.

In principle, microwave-induced inactivation of the toxin can occur by at least two pathways: (1) changes in the native integrity to a denatured form might inactivate the protein toxin by preventing molecular interaction with cell-membrane receptor sites of their host Vero cells and (b) the protein toxin with an AB5 structure in which five subunits are attached to a straight chain can undergo degradation (cleavage) to smaller fragments.

Figure 2 shows that the toxin seems to undergo degradation into smaller fragments and that the extent of degradation increases with the energy of the microwaves from 165 to 198 kJ. These results imply that the high-energy microwave radiation has the potential to protect consumers against adverse effects of Stx2 and possibly other toxins in contaminated water, milk, and possibly other foods. In the present study, we demonstrated that exposure of the milk solution to a higher level of microwave heating or to 95 °C for 5 min reduced Stx2 activity. In additional experiments, we found that heating reconstituted fat-free milk internally by higher microwave energy also inactivates Stx2 in milk. The use of microwave heating to inactivate the Shiga toxin complements published studies on the inhibition of the toxin's biological activity by naturally occurring compounds, reviewed in Friedman and Rasooly.[11] Exposure of food to microwave cooking is a much simpler process than the use of wet chemistry to inhibit the biological activity of Shiga and possibly other microbial and plant toxins that contaminate food.[12]

We also observed that the microwave heating destroyed the nutritional value of the culture medium used to grow the Vero cells. Our findings with the Shiga toxin and culture medium suggest the need to determine in detail the impact of microwave cooking on susceptible essential nutrients.

Finally, allthugh it is difficult to translate our results in culture medium and in milk to other food categories exposed to microwave radiation, the reported high susceptibility of vitamin C (ascorbic acid)[4,12,13] and vitamin B_1 (thiamin)[14,15] in different foods to microwave-cooking-induced destruction suggests that microwave destruction of these vitamins is a likely cause of the observed loss of nutritional value in the culture medium used to grow the Vero cells.

stages. Special emphasis was placed on the nutritional quality of sprouts, including protein and starch contents, and their potential bioavailability.

MATERIAL AND METHODS

Chemicals. Ferrozine (3-(2-pyridyl)-5,6-bis(4-phenylsulfonic acid)-1,2,4-triazine), ABTS (2,2-diphenyl-1-picrylhydrazyl), α-amylase, pancreatin, pepsin, bile extract, Folin−Ciocalteau reagent, linoleic acid, ammonium thiocyanate, pepsin, chymotrypsin, and phenolic standards linoleic acid were purchased from Sigma-Aldrich Co. (Poznan, Poland). All other chemicals were of analytical grade.

Materials. Lentil (*Lens culinaris* Medik.) seeds var. Tina were purchased from the Horticulture and Seed Enterprises PNOS S.A. in Ozarów Mazowiecki, Poland.

Germination. Seeds were sterilized in 1% (v/v) sodium hypochloride for 10 min, then drained, and washed with distilled water until they reached neutral pH. They were placed in distilled water and soaked for 6 h at 25 °C. Seeds were dark germinated 6 days, at 25 °C, in a growth chamber on Petri dishes (φ 125 mm) lined with absorbent paper (approximately 150 seeds per dish). Seedlings were watered with 5 mL of Milli-Q water daily.

Elicitation. For the experiments, 2-day-old sprouts were incubated for 1 h at 4 and 40 °C (TC and TH, respectively). Temperatures for treatments were selected according to previous screening studies (sprouts vigor, phenolics content, and antiradical potential). Plates were transferred to the climatic chamber, discovered, and incubated for 1 h at appropriate temperature. After that, sprouts were cultivated under standard conditions (see the section Germination). Sprout samples were gently collected, weighed (fresh mass), rapidly frozen, and kept in polyethylene bags at −20 °C. For each treatment, three replicates were taken for analysis.

Flour Preparation. Sprouts were dried in a forced-air oven at 50 °C for 12 h to moisture content < 10%.[8] After that, sprouts were ground in a labor mill and sieved (60 mesh). Sprout flours were stored at 4 °C.

Growth Analysis. In order to determine the influence of elicitation on the vigor of the sprouts, the growth factor was proposed. The growth factor was defined as an amount of fresh weight (in grams) obtained on the second, third, fourth, and sixth days of germination from 1 g of dormant seeds.

Phenolic Content and Antioxidant Activities. *Extract Preparation.* Lentil flours (0.2 g) were extracted three times with 4 mL of acetone/water/hydrochloric acid (70:29:1, v/v/v). After centrifugation (10 min, 6800 relative centrifugal force (rcf)) fractions were collected, combined, and used for further analysis.

Phenolic Analysis. *Determination of Total Phenolic Compounds.* The amount of total phenolics (TPC) was determined using Folin−Ciocalteau reagent. [16] The amount of total phenolics was calculated as a gallic acid equivalent (GAE) in milligrams per gram of dry mass (DW).

Determination of Flavonoid Content. Total flavonoid content (TFC) was determined according to the method described by Lamaison and Carnat.[17] Total flavonoid content was calculated as a quercetin equivalent (QE) in milligrams per gram of DW.

Determination of Condensed Tannins Content. Condensed tannin content (CTC) was determined according to the method described by Sun et al.[18] CTC was calculated as a (+)-catechin equivalent (CE) in milligrams per gram of DW.

Quantitative−Qualitative Analysis of Phenolic. Samples were analyzed with a Varian ProStar high-performance liquid chromatrography (HPLC) system separation module (Varian, Palo Alto, CA, USA) equipped with Varian ChromSpher C18 reverse phase column (250 mm × 4.6 mm) and ProStar DAD detector. The column thermostat was set at 40 °C. The mobile phase consisted of 4.5% acetic acid (solvent A) and 50% acetonitrile (solvent B), and a flow rate of 0.8 mL min^{-1} was used. At the end of the gradient, the column was washed with 50% acetonitrile and equilibrated to the initial condition for 10 min. The gradient elution was used as follows: 0 min, 92% A; 30 min, 70% A; 45 min, 60% A; 80 min, 60% A; 82 min, 0% A; 85 min, 0% A; 86 min, 92% A; and 90 min, 92% A. Detection was carried out at 270 and 370 nm. Spectrum analysis and a comparison of their retention times with those of the standard compounds identified the phenolics in a sample. Quantitative determinations were carried out with the external standard calculation, using calibration curves of the standards. Detailed information concerning method validation is presented in Table 1. Phenolics were expressed in micrograms per gram of DM. [3]

Antioxidant Aactivities. *Antiradical Activity (ABTS).* The experiments were carried out using an improved ABTS decolorization assay.[19] Free radical scavenging ability was expressed as Trolox equivalent (TE) in millimoles per gram of DW.

Reducing Power. Reducing power (RP) was determined by the method of Oyaizu.[20] RP was expressed as Trolox equivalent in millimoles per gram of DW.

Metal Chelating Activity. Chelating power (CHP) was determined by the method of Guo and co-workers.[21] CHP was expressed as ethylenediaminetetraacetic acid (EDTA) equivalent in milligrams per gram of DW.

Inhibition of Linoleic Acid Peroxidation. The inhibition of the hemoglobin-catalyzed peroxidation of linoleic acid (LPI) was determined.[22] The activity was expressed as quercetin equivalent (Q) in milligrams per gram of DW.

Total Antioxidant Capacity Index. Four complementary antioxidant methods were intergraded to obtain the total antioxidant

dx.doi.org/10.1021/jf403923x | J. Agric. Food Chem. 2014, 62, 3306−3313

capacity index (AI). [10] The index may be useful for evaluation the total antioxidant potential of sprouts from different germination conditions with respect to control. The AI was calculated as the sum of relative activities (RA) for each antioxidant chemical method divided by the number of methods (n).

$$AI = \Sigma RA_{(n)}/n$$

RA was calculated as follows:

$$RA = Ax/Ac$$

where Ax = activity of modified sprouts for the method and Ac = activity of control sprouts determined for the method.

Soluble Protein Content. A 500 mg sample was twice extracted with 5 mL of 0.5 M NaCl solution in 0.05 M Tris-Hcl buffer, pH 7.0, at 4 °C for 2 h. After centrifugation (10 min, 6800 rcf) fractions were collected, combined, and used for further analysis. Total protein contents were determined with the Lowry method,[23] using bovine serum albumin as the standard protein.

Nonprotein Nitrogen Content. A 100 mg sample was twice extracted with 5 mL of 10% ethanol (v\v) at 4 °C for 2 h. After centrifugation (10 min, 6800 rcf) fractions were collected, combined, and used for further analysis. Nonprotein nitrogen was determined with 2,4,6-trinitrobenzene sulfonic acid (TNBS) according to the methods described by Habeeb,[24] using L-leucine as the standard.

Total Starch Content. The total starch (TS) content was determined after dispersion of the starch.[25] The glucose content was determined by using the standard dinitrosalicylic acid (DNSA) method.[26] Total starch was calculated as glucose × 0.9. The free reducing sugar content of the samples was determined in order to correct the obtained total starch values. The sucrose content of the samples was also determined in order to correct the obtained total starch values. The samples dispersed in sodium acetate buffer, pH 5.0, were treated with 200 μL of (10 mg in 1 mL of 0.4 M sodium acetate buffer, pH 5.0) invertase (EC 3.2.1.26; 300 U mg^{-1}) for 30 min at 37 °C. After centrifugation, reducing sugars were analyzed in the supernatants using the DNS reagent.

Digestion in Vitro. Simulated mastication and gastrointestinal digestion was performed according to Świeca and co-workers.[27]

In Vitro Protein digestibility. The *in vitro* protein digestibility was evaluated on the basis of the total soluble protein content and the content of protein determined after digestion *in vitro*.[10]

$$PD/\% = 100 - [(Pr/Pt \times 100]$$

where PD = *in vitro* digestibility of the protein, Pt = total protein content, and Pr = content of proteins after *in vitro* digestion.

In Vitro Starch Digestibility. The *in vitro* digestibility of starch was evaluated on the basis of total starch content (TS) and resistant starch (RS) determined after digestion *in vitro*.

Resistant and Potentially Bioavailable Starch Content. The resistant (RS) and potentially bioavailable starch (AS) content was analyzed on the basis of results obtained after simulated gastrointestinal digestion. After centrifugation (3000g, 15 min) and removal of supernatant, the pellet was dispersed with 2 M KOH, hydrolyzed with amyloglucosidase, and then liberated glucose was quantified, as described above, for total starch (TS, 2.8). RS was calculated as glucose × 0.9. AS content was calculated as the difference between TS and RS.

In Vitro Starch Digestion Rate and Expected Glycemic Index. The digestion kinetics and expected glycemic index (eGI) of the lentil sprouts were calculated in accordance with the procedure established by Goni and co-workers.[25] eGI was calculated using the equation proposed by Granfeldt and co-workers:[28] eGI = 8.198 + 0.862HI. The hydrolysis index (HI) was calculated on the basis of the starch hydrolysis curve (0−180 min) as the percentage of total glucose released over 180 min in comparison to that released from white bread over the same duration.

Hydrolase Inhibitors Activity. *Trypsin Inhibitors Activity.* A 100 mg sample was extracted with 4 mL of 0.05 M phosphate buffer, pH 7.6, at 4 °C for 2 h. The trypsin inhibitor activity (TIA) was determined using α-*N*-benzoyl-DL-arginine-*p*-nitroanilidehydrochloride (BAPNA) as the substrate.[29] TIA was expressed as trypsin inhibitor units per milligram of DW sample. One trypsin unit was defined as the increase by 0.01 absorbance units at 410 nm of the reaction mixture.

Chymotrypsin Inhibitors Activity. A 100 mg sample was extracted with 4 mL of 0.05 M phosphate buffer pH 7.6 at 4 °C for 2 h. Chymotrypsin inhibitor activity (CIA) was determined using sodium beznzylo-DL-tyrosine-*p*-nitroanilide (BTpNA) as the substrate.[30] CIA was expressed as chymotrypsin inhibitor units per milligram of DW sample. One chymotrypsin unit was defined as the increase by 0.01 absorbance units at 410 nm of the reaction mixture.

α-Amylase Inhibitors Activity. For extraction, 100 mg (DW) of lentil sprouts was suspended in 4 mL of 50 mM phosphate buffer, pH 7.6, then stirred for 2 h at 4 °C, and centrifuged at 3000g for 60 min. α-Amylase inhibitor (αAI) activity was measured according to the method described by Alonso and co-workers. [6] One inhibitory unit was defined as the amount of αAI that completely inhibited one enzyme unit (the amount of α-amylase which realized 1 μmol of reducing groups/(1 min at 40 °C) in the reaction conditions).

Statistic Analysis. All experimental results were mean ± standard deviation (SD) of three parallel experiments. Two-way analysis of variance (ANOVA and Tukeỳs posthoc test) was used to compare groups within different elicitors. α values < 0.05 were regarded as significant.

RESULTS

Diverse biological effects of legumes food are commonly considered in terms of phenolic content. In the light of this, increasing of the antioxidant potential by phenolics overproduction in lentil sprouts was performed using natural plant stress response pathways. Sprouts metabolism was induced by incubation of 2-day-old sprouts at low (4 °C, TC and high 40 °C, TH) temperature. Since the aim of the study was to determine the influence of temperature treatments, the results obtained for elicited sprouts were always compared to those obtained for control sprouts from the corresponding day of germination.

One of the most important factors during trials aimed to overproduce secondary metabolites by elicitation is a negative influence of stressed factors on plant growth and yield. Generally, in our studies growth conditions did not influence negatively on fresh mass yield (Table 2). Extracts obtained from sprouts at different stages of germination (control and elicited) were preliminarily studied for their phenolics content (Table 2). Sprouts obtained by elicitation were characterized by elevated content of condensed tannins, flavonoids, and total phenolics. A small reduction of flavonoids content (about 6% in comparison to control) was only found for 6-day-old sprouts induced at 4 °C. Induction at 40 °C most effectively increased the flavonoids content in the sprouts; in comparison to the control condition, their amounts were higher by about 28%, 43%, and 49% for 3-, 4-, and 6-day-old sprouts, respectively. We have previously demonstrated that growth conditions affected significantly the qualitative and quantitative changes in polyphenols profiles of sprouts;[3,4,7,14] thus, a further, precise analysis was performed. An exemplary profile of lentil sprouts phenolics is presented in Figure 1. In comparison to control, during growth of elicited sprouts an increase of salicylic and chlorogenic acids content was observed. Both treatments reduced also the content of syringic acid in sprouts; its level was lower by about 88%, 84%, and 52% in the third, fourth, and sixth 230 days of cultivation, respectively. Additionally, in 3-, 4-, and 6-day-old sprouts determined amounts of caffeic and *p*-coumaric acids (except *p*-coumaric acid content in 6-day-old TH sprouts) were significantly lower than those found for control sprouts. Both treatments caused significant changes of flavonoids fractions. Surprisingly, the

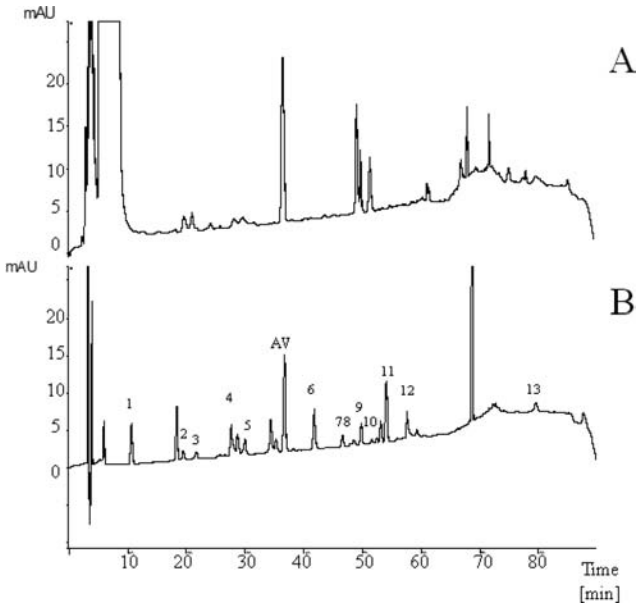

Figure 1. HPLC–DAD elution profile (270 nm) of standard and lentil samples ((A) 2-day-old sprouts; (B) standard): (1) hydroxybenzoic acid, (2) (+)-catechin, (3) vanillic acid, (4) chlorogenic acid, (5) syringic acid, (6) *p*-coumaric, (7) salicylic acid, (8) ferulic acid, (9) sinapinic acid, (10) *o*-coumaric acid, (11) daidzein, (12) quercetin, (13) naringenin, and (AV) internal standard. For details, see Materials and Methods.

levels of daidzein in elicited sprouts were lower than those determined for the control. It should be also noted that treated sprouts were characterized by significantly higher levels of (+)-catechin (Table 3). Phenolic compounds were determined by both spectrophotometric and HPLC techniques. Spectrophotometric methods are less precise (with respect to HPLC); however, they allow for better visualization of the effect of elicitation (changes are more visible). On the other hand, more accurate qualitative and quantitative data provided by HPLC technique coupled with diode array detection (DAD) technique allow to speculate about biological process taking place in the stressed plants, e.g., synthesis of the lignin precursors and changes in the phenylpropanoid metabolism such as synthesis of different classes of flavonoids.

In order to analyze the effect of elicitation and subsequent changes in the sprouts phenolics profile on the antioxidant capacities, four methods based on different modes of antioxidant action were used. The general trend of free radical scavenging, lipid preventing, and reducing properties in elicited lentil sprouts showed that induction significantly improved these activities (except the radical scavenging ability of 3-day-old sprouts). It is shown in Table 4 that temperature treatments caused a significant increase of radical scavenging ability of 4- and 6-day-old sprouts. Between elicited sprouts, the highest reducing power was determined on day 6 for sprouts induced at 40 °C (0.43 mmol of TE/(g of DW)), while the lowest, in those obtained on day 3 in those elicited at 4 °C (0.35 mmol of TE/(g of DW)). These parameters were higher than those determined for the respective control sprouts by 19% and 34%, respectively. It should be noted that, in comparison with samples cultivated under control conditions, sprouts obtained by induction at 40 °C (effect was not observed in the case of induction at 4 °C) were characterized by high chelating power; for 3-, 4-, and 6-day-old sprouts its activity was about 2-fold higher. Both studied modifications of sprouting (TH, TC) effectively elevated the ability to prevent lipids against oxidation. The best results were obtained on day 3, a 3.3- and 4-fold increase for TH and TC, respectively. Complementary antioxidant methods were intergraded to obtain the total antioxidant capacity index. All of the studied conditions significantly improved the nutraceutical value of sprouts. The highest antioxidant potentials were obtained for 6-day-old sprouts (2.25 and 3.11 for TC and TH, respectively) (Table 4).

Nowadays, one of the main areas of research is the search for new food products that in spite of nutritional quality also possess natural ingredients with biological activity. [1] Here it is presented that the induction of sprouts at 4 and 40 °C has allowed us to obtain a low-processed food with significantly enhanced antioxidant potential. Since elicitation may in some cases negatively influence nutrients content, we also placed a special emphasis on the nutritional quality of the sprouts.

On germination in control conditions, only a slight reduction in protein content was observed (Table 5). Elicitation by both

temperature stresses of 2-day-old sprouts caused a significant decrease in protein content only in 4- and 6-day-old sprouts: however, it did not affect protein digestibility. The processes of elicitation were associated with significant changes in the nonprotein nitrogen content. The highest levels of free amino acids and peptides were determined for 6-day-old sprouts elicited at 40 °C—95.1 mg/(g of DW) (increase by 25% in comparison to control sprouts). It should be noted that the used modification of sprouting caused a significant elevation of activity of trypsin and chymotrypsin inhibitors but, as was mentioned before, treatments had no significant effects on protein digestibility (Table 5).

Elicitation of sprouts influenced also starch degradation during sprouting (Table 6). In comparison to control (sprouts from corresponding days of germination), levels of total starch in 3-day-old sprouts elicited at 40 °C and 4-day-old sprouts elicited at 4 °C were significantly lower. Treatment at 4 °C caused a significant increase of potentially bioavailable starch and eGI value in 3-day-old sprouts. On the other hand treatment at 40 °C caused a significant decrease of resistant starch content in sprouts; with respect to control sprouts from corresponding days of germination its content was lower by about 15% and 18% for 3- and 4-day-old sprouts, respectively. Between elicited sprouts, the highest eGI was determined for 3-day-old sprouts induced at 4 °C (76.7; elevation by 13% in comparison to control 3-day-old sprouts), whereas the lowest was for 4-day-old sprouts induced at 40 °C (59.8; reduction by

about 16% in comparison to control 4-day-old sprouts). It should be mentioned that both treatments (except 3-day-old TC sprouts) caused an increase of α-amylase inhibitors activity in sprouts; however only in cases of 4-day-old TC and 6-day-old TH sprouts may this fact be linked with reduction of starch digestibility. In the others cases there was no simple relationship between eGI values, α-amylase inhibitor activity, starch digestibility, and resistant starch content (Table 6).

DISCUSSION

Modern communities are strictly focused on consumption of functional and direct food with desired properties; thus, there is need for search new tools that may be useful in designing such products. In recent years, food legumes have attracted a great deal of attention due to their functional components and health-promoting effects in relation to the prevention of chronic diseases including cardiovascular diseases, obesity, diabetes, inflammation, and cancer. [1] The role of germination as a method affecting the quality of food is well-documented.[3,4,8,27,31] The gradual reduction in phenolic content and the antioxidant potential of lentil sprouts during germination confirmed by previous studies fully justifies the use of elicitation in order to improve the nutraceutical properties of sprouts.[3,4,7,8,31] A significant statistical reduction was also observed in the total phenolic, tannin, and flavonoids contents of black soybeans;[2] soybeans, lentil, and alfalfa;[9] and cowpea, lentil, chickpea, and green gram[8] due to the effect of germination. Losses may result from leaching into the soak water and binding of polyphenols with other organic substances such as carbohydrate or protein. [32] On germination, protein, carbohydrates, and minerals become more bioavailable and bioaccessible.[3,9,10,27] In this study the gradual reduction of protein content and digestibility was also determined. On the third and fourth days of germination a significant decrease of total starch content and digestibility was observed. These data agree with the findings of Ghavidel and Prakash for the germinated green gram, cowpea, lentil, and chickpea.[8] Similar results were also obtained by Urbano and co-workers during germination of lentil.[33]

Changes of nutritional and nutraceutical potential occurring during sprouting depend on process conditions.[3,5,14] Additionally, sprouting conditions can have important effects on the composition of secondary metabolites with potential prohealth properties.[5] Although we did not investigate the mechanism of phenolic compound stimulation by temperature stress, previous studies have shown that most phenolic compounds are generated by the phenylpropanoid pathway, which is stimulated by biotic and abiotic stress.[5,12,34] In response to stress, plants induce endogenous plant hormones, which, in turn, induce enzymes involved in the phenylpropanoid pathway, including phenylalanine ammonia lyase (PAL), thereby resulting in the accumulation of phenolic compounds.[11,34,36] In comparison to control, during growth of elicited sprouts an increase of chlorogenic acid and (+)-catechin content was observed. However, chlorogenic acid was probably synthesized *de novo*; in the case of (+)-catechin some additional factors, such as the

dx.doi.org/10.1021/jf403923x | J. Agric. Food Chem. 2014, 62, 3306−3313

rate of condensed tanins degradation and/or the activation of endogenous enzymes (e.g., hydroxylases and polyphenoloxydases), played an important role.[3,8] Additionally, higher levels of *p*-coumaric acid in treated sprouts might be involved in overproduction of coumaryl-CoA, a key compound in flavonoids biosynthesis.[5,37] This statement may be also supported by the fact that elicited sprouts contained higher amounts of quercetin. An increase of cell barrier precursors such as *p*-coumaric, ferulic, and syringic acids was also observed that may be linked with cross-talk response on stress conditions.[36] Finally, an increased level of salicylic acid content in sprouts induced by heat and cold shocks may confirm the appearance of stress and the role of this compound in the signal transduction pathway.[34,38] Induction of sprouts metabolism by low and high temperature and subsequent elevation of phenolics was translated into an increase of antioxidant potential. Up to now, there are some reports concerning improvement of the nutraceutical potential of sprouts by elicitation. An increase in the free radical scavenging properties of dark germinated mung bean sprouts using natural elicitors, such as fish protein hydrolysates, lactoferrin, and oregano extract, is reported.[13] Also, Feng and co-workers [39] obtained a significant elevation in the antioxidant potential of black soybean sprouts by treatment with components of fungal cell walls. In studies of Oh and Rajashekar [40] chilling and high light intensity during growth of radish and alfalfa sprouts caused qualitative and quantitative changes in phenolic profiles and antioxidant activities. The effect of salinity stress on the nutritional quality of buckwheat sprouts was also studied.[41] A cited researcher observed an increase in phenolic compounds, carotenoids, and antioxidant capacity in the sprouts compared with the control. In the light of our results and cited studies, it may be stated that elicitation has been demonstrated to be a useful method for improving the antioxidant potential of low-processed foods.

Because modification of the growth (elicitation with abiotic and biotic factors) often has a negative impact on the sprouts growth and nutritional quality of food (content and bioaccessibility of nutrition and increased activity of hydrolases inhibitors), an evaluation of the influence of treatments was performed. In recent literature there are only a few reports concerning the influence of elicitation on the nutritional quality of sprouts.[10,27] A decrease in the protein content and subsequent elevation of the nonprotein nitrogen fraction may be explained by induction of proteolytic systems in response to stress conditions.[8,11,35] As had been reported by previous studies (cross-talk stress response theory), [36] a slight elevation of protease inhibitors activity was observed; however there was not any strong influence. Changes in total starch content in elicited sprouts may be due to modification of seedling metabolism in response to stress conditions, especially with the increased demand for energy needed to produce secondary metabolites. [11] Generally, growth conditions used to modify sprouts metabolism allow one to obtain product with a significantly enhanced phenolics content and antioxidant capacity. What is important is that modification did not affect negatively the growth and nutritional quality of the sprouts. In the light of epidemiological studies these kinds of sprouts (with enhanced antioxidant potential and lowered glycemic index) may be a predisposed product for specific consumers and consist of a useful tool for creating healthy eating habits.

the study. VOO was kindly furnished by Manuel Heredia Halcón (Cortijo de la Suerte Alta, Albendin-Baena-Cordoba). The tomato sauces were prepared following a regular home cooking process at the Torribera Campus, University of Barcelona (Barcelona, Spain). Tomatoes were washed, chopped in a breaker unit, weighed, and crushed with a Thermomix. Two variables were evaluated: VOO addition at two different concentrations and thermal treatment time. The VOO (5 and 10% of oil, w/w) was added to the chopped tomatoes, and the mixture was cooked at 95−96 °C for 15, 30, 45, or 60 min. The tomato sauces were aliquoted and stored in vacuum bags at −20 °C until the day of the analysis. A 4 × 2 mixed-level factorial design was performed, involving a total of 8 randomized runs. For the reproducibility, each process was evaluated three times (Figure 1). The phenolic profile of tomato sauce control without addition of VOO and the content of polyphenols in VOO are reported in Tables 1 and 2.

Extraction and Analysis of Polyphenols. *Extraction of Polyphenols from Tomato Sauces.* Extraction and analysis of each replicate of the treatment was carried out in triplicate in a darkened room with a red safety light to prevent analyte oxidation, following the procedure of Vallverdu-Queralt et al.[13] with some modifications.

Tomato sauces (0.5 g) were weighed and homogenized with 80% ethanol in Milli-Q water (4 mL); the homogenate was sonicated for 5 min and centrifuged (4000 rpm at 4 °C) for 15 min. The supernatant was transferred into a flask and extraction was repeated. Both supernatants were combined and evaporated under nitrogen flow; finally, the residue was reconstituted up to 2 mL with Milli-Q water containing 0.1% of formic acid and filtered through a 0.45-μm polytetrafluoroethylene (PTFE) filter from Waters (Milford, USA) into an insert-amber vial.

Solid phase extraction (SPE) was carried out to eliminate interferences such as ascorbic acid, amino acids, and reducing sugars. For this purpose, Oasis MAX cartridges with 30 mg of mixed-mode anion-exchange and reversed-phase sorbent from Waters (Milford, USA) were used following the procedure of Vallverdu-Queralt et al.[14] The eluted fractions were evaporated under nitrogen flow and the residue was reconstituted up to 500 μL with Milli-Q water containing 0.1% formic acid and filtered through a 0.45-μm PTFE filter into an insert-amber vial for HPLC analysis.

Extraction of Polyphenols from VOO. The extraction of phenolic compounds from VOO was performed following the procedure previously described by García-Villalba et al.[15] Briefly, diol cartridges Supelclean LC-Diol (500 mg, 3 mL) from Sigma (Madrid, Spain) were placed in a SPE vacuum manifold and conditioned passing 5 mL of methanol and subsequently 5 mL of *n*-hexane without vacuum. About 3 g of VOO was accurately weighted and then thoroughly mixed with 3 mL of *n*-hexane and loaded onto the SPE cartridge under vacuum. The cartridge was then washed with 5 mL of *n*-hexane to remove the nonpolar fraction of the oil and then dried with nitrogen to remove the *n*-hexane. Finally, the phenolic compounds were eluted with 10 mL methanol under vacuum and the eluate was evaporated to dryness. The dried residue was then reconstituted in 1 mL of methanol/water (7:3, v/v) and filtered through a 0.45-μm PTFE filter for HPLC analysis.

Analysis of Polyphenols. Liquid chromatography coupled to electrospray ionization tandem mass spectrometry (HPLC−ESI-MS/

dx.doi.org/10.1021/jf500416n | J. Agric. Food Chem. 2014, 62, 3314−3320

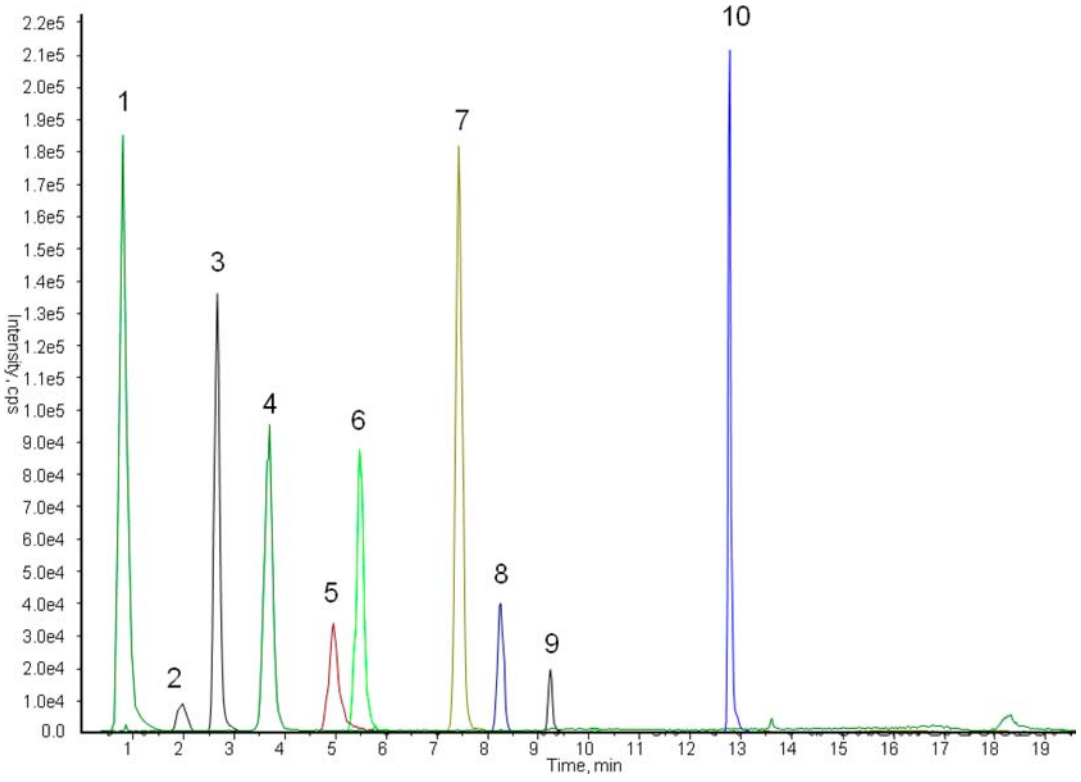

Figure 2. HPLC Chromatogram of tomato sauce treated during 15 min at 5% of VOO. 1. Hydroxytyrosol; 2. tyrosol; 3. protocatechuic acid; 4. chlorogenic acid; 5. caffeic acid; 6. *p*-coumaric acid; 7. rutin; 8. ferulic acid; 9. quercetin; 10. naringenin.

MS) was used to evaluate the content of flavonols, flavanones, and hydroxycinnamic acids in VOO and tomato sauces following the procedure of Vallverdu-Queralt et al.[13]

Liquid chromatography was performed with an Agilent series 1100 HPLC instrument (Agilent, Waldbronn, Germany) equipped with a quaternary pump, an autosampler, and a column oven set to 30 °C. A Luna C_{18} column 50 × 2.0 mm i.d., 5 μm (Phenomenex, Torrance, CA, USA) was used. The injection volume was 20 μL and the flow rate was 0.4 mL/min. Mobile phase consisted of Milli-Q water containing 0.5% acetic acid (A) and acetonitrile (B). Separation was carried out in 15 min under the following conditions: 0 min, 5% B; 10 min, 18% B; 13 min, 100% B; 14 min, 100% B; 15 min, 5% B. The column was equilibrated for 5 min prior to each analysis.

An API 3000 (PE Sciex, Concord, ON, Canada) triple quadrupole mass spectrometer equipped with a Turbo Ionspray source in negative-ion mode was used to obtain MS/MS data. Turbo Ionspray source settings were as follows: capillary voltage, −3500 V; nebulizer gas (N_2), 10 au (arbitrary units); curtain gas (N_2), 12 au; collision gas (N_2), 4 au; focusing potential, −200 V; entrance potential, −10 V; drying gas (N_2), heated to 400 °C and introduced to a flow rate of 6000 cm^3/min. The declustering potential and collision energy were optimized for each compound by infusion experiments: individual standard solutions (10 μg/mL) dissolved in 50:50 (v/v) mobile phase were infused at a constant flow rate of 5 μL/min using a model syringe pump (Harvard Apparatus, Holliston, MA, USA). Full-scan data acquisition was performed scanning from m/z 100 to 800 in profile mode and using a cycle time of 2 s with a step size of 0.1 u and a pause between each scan of 2 ms. For quantification purposes, data were collected in the multiple reaction monitoring (MRM) mode, tracking the transition of parent and product ions specific for each compound.

Quantification of polyphenols was performed by the internal standard method. Polyphenols were quantified related to their corresponding standard and results were expressed as μg/g fresh weight (FW).

Antioxidant Capacity. The antioxidant capacity of tomato sauces was measured using $ABTS^+$ and DPPH assays.[12]

$ABTS^+$ assay. One mM Trolox (antioxidant standard) was prepared in methanol once a week. Working standards were prepared daily by diluting 1 mM Trolox with methanol.

An $ABTS^+$ radical cation was prepared by passing a 5 mM aqueous stock solution of ABTS (in methanol) through manganese dioxide powder. Excess manganese dioxide was filtered through a 0.45-μm filter PTFE (Waters). Before analysis, the solution was diluted in methanol pH 7.4 to give an absorbance at 734 nm of 1.0 ± 0.1, and preincubated in ice. Then, 245 μL of $ABTS^+$ solution was added to 5 μL of Trolox or to tomato extracts and the solutions were stirred for 30 s. The absorbance was recorded continuously every 30 s with a UV/vis Multiskan Spectrum spectrophotometer from Thermo Fisher Scientific (San Jose, CA, USA) for 1 h and methanol blanks were run in each assay.

The working range for Trolox (final concentration 0−750 μM) was based on triplicate determinations and consisted of plotting the absorbance as a percentage of the absorbance of the uninhibited radical cation (blank). The activities of the tomato extracts were assessed at four different concentrations within the range of the dose−response curve. Each sample was analyzed in triplicate at each concentration. Results were expressed as mmol Trolox equivalent (TE)/100 g FW.

DPPH Assay. Antioxidant capacity was also studied by evaluating the free radical-scavenging effect on the DPPH radical. Solutions of known Trolox concentrations were used for calibration. Five μL of tomato extracts or Trolox was mixed with 250 μL of methanolic DPPH (0.025 g/L). The homogenate was shaken vigorously and kept in darkness for 30 min. Absorption of the samples was measured on a UV/vis Thermo Multiskan Spectrum spectrophotometer at 515 nm. The percentage of inhibition of the DPPH was calculated and plotted as a function of the concentration of Trolox for the standard reference data. The final DPPH values were calculated using a regression equation between the Trolox concentration and the percentage of DPPH inhibition and results were expressed as mmol TE/100 g FW.

Statistical Treatments. Treatments of tomato sauces were carried out in triplicate and each replicate was analyzed three times. Significance of the results and statistical differences were analyzed

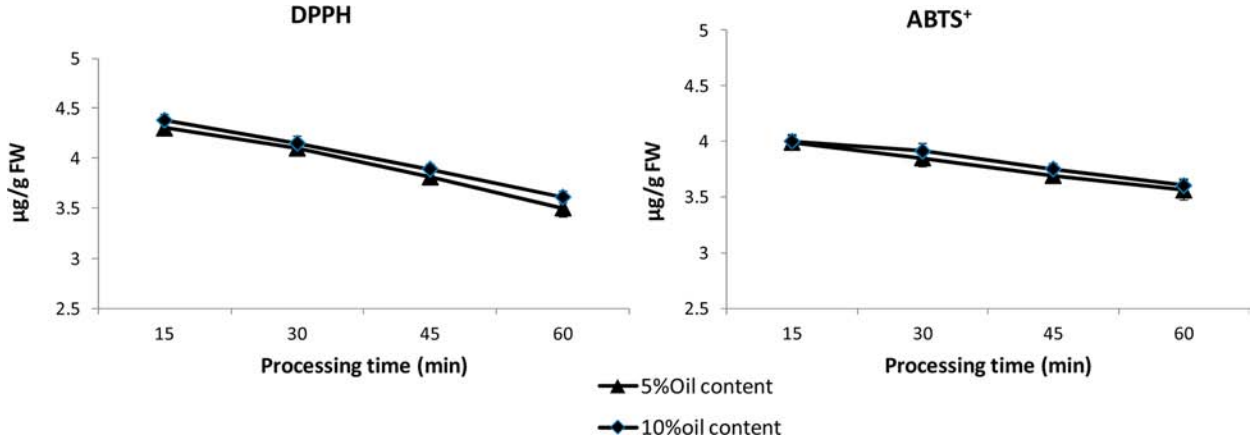

Figure 3. Changes in antioxidant capacity during processing time.

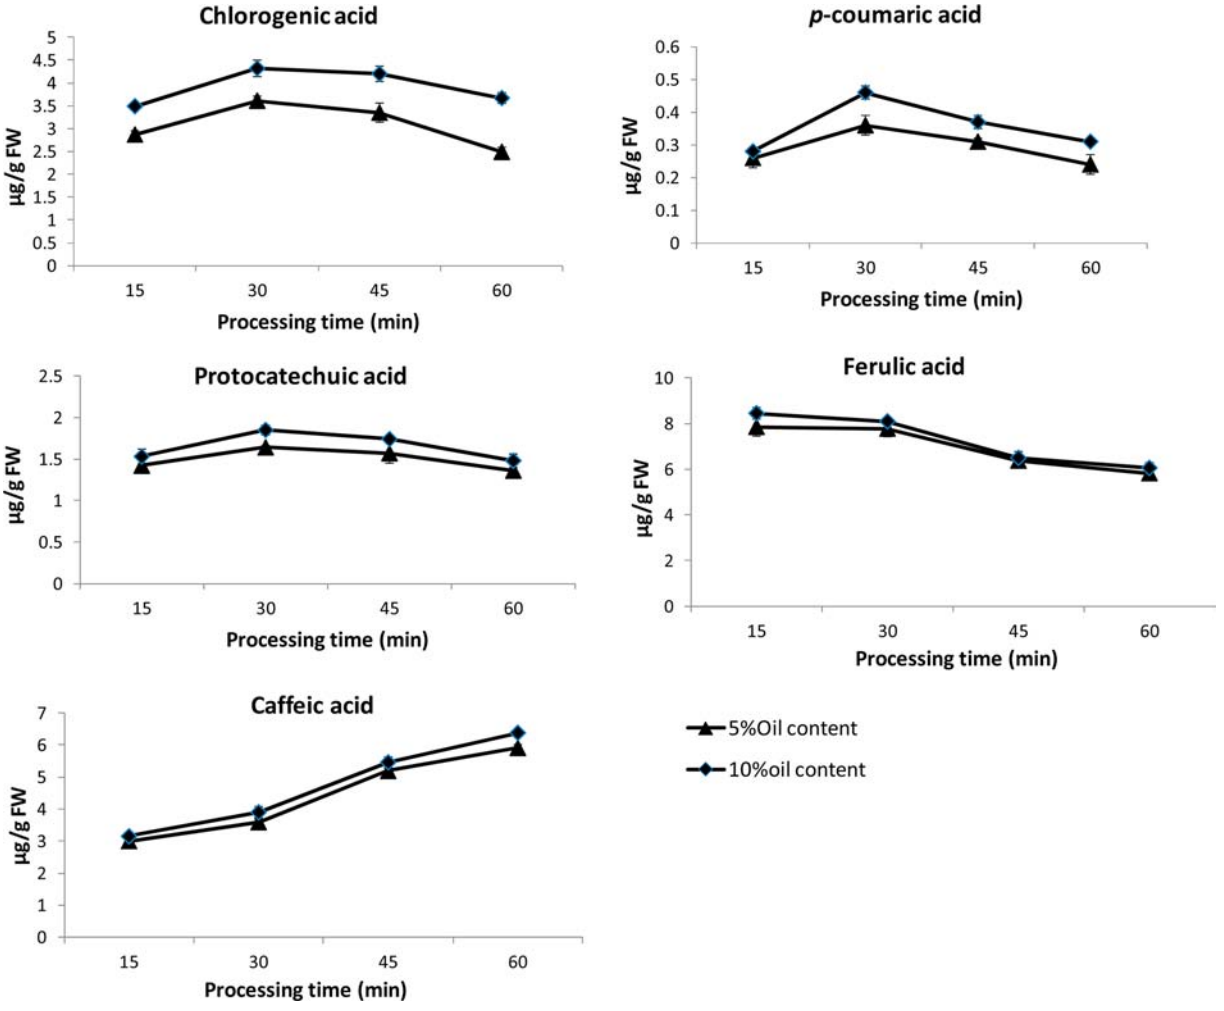

Figure 4. Changes in hydroxycinnamic and phenolic acids during processing time.

using Statgraphics plus v. 5.1 software (Manugistics, Inc., Rockville, MA, USA). Data were analyzed by multifactor analysis of variance and a Duncan multiple range test was applied to determine differences among means, with a significance level of $P = 0.05$.

RESULTS AND DISCUSSION

Changes in Antioxidant Capacity during Processing Time. It has been reported that some labile antioxidants are degraded during food processing, but other studies have shown that industrial-scale processing of tomatoes involving heat treatments may increase the levels of some bound antioxidants.[16,17] Figure 2 shows a chromatogram of tomato sauce treated during 15 min at 5% of VOO. Our analysis of antioxidant capacity showed that from 15 to 60 min of cooking, the level of antioxidants measured by the DPPH assay decreased from 4.3 to 3.5 μg/g FW in sauces containing 5% VOO and from 4.4 to 3.6 μg/g FW in sauces containing 10% extra VOO (Figure 3). The same pattern was observed in the

dx.doi.org/10.1021/jf500416n | J. Agric. Food Chem. 2014, 62, 3314−3320

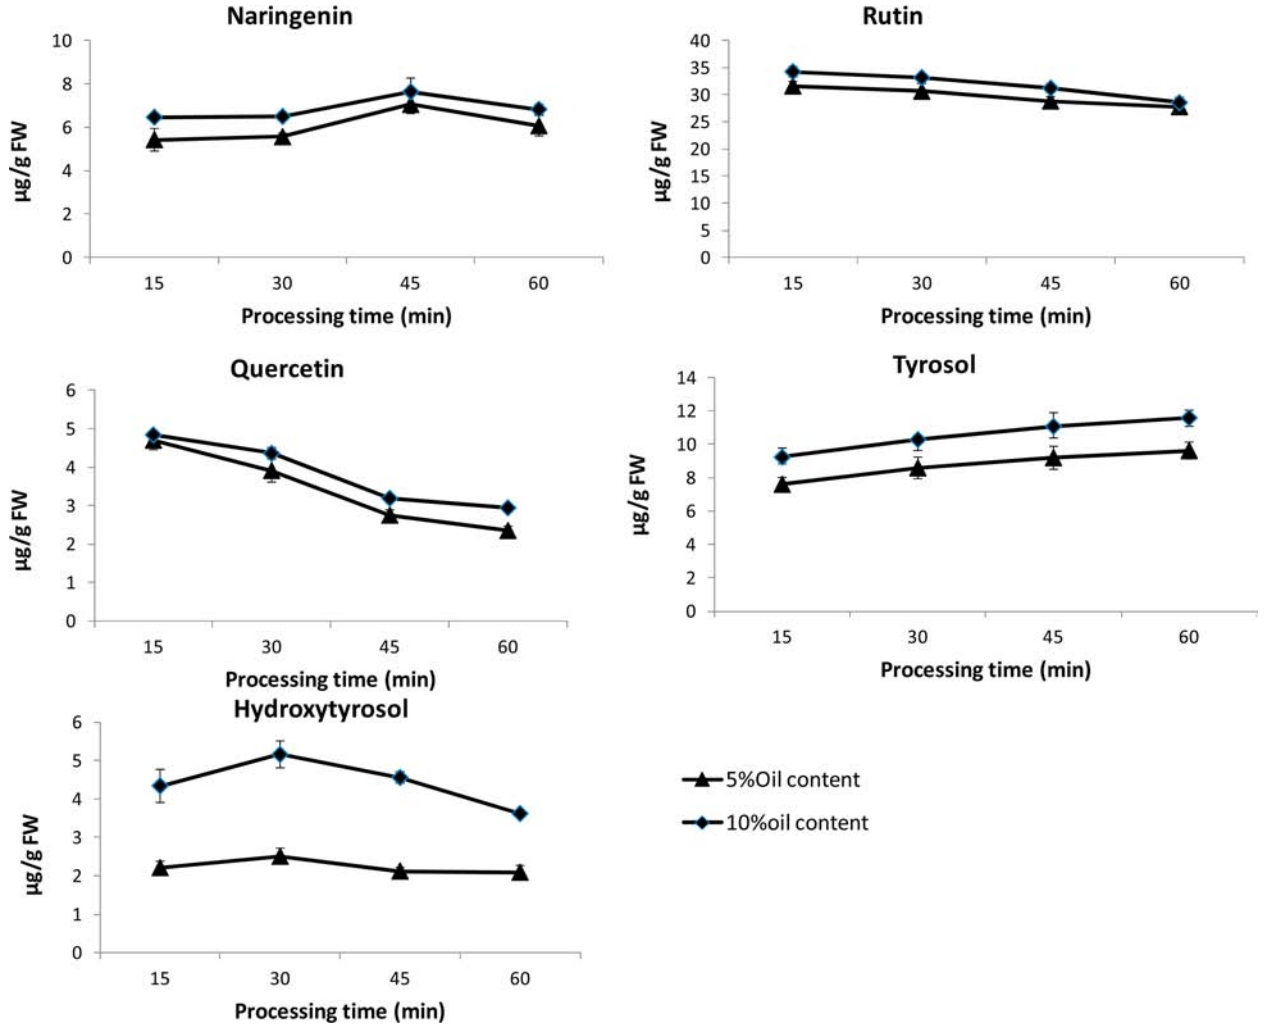

Figure 5. Changes in flavonols, flavanones, and other phenols.

ABTS$^+$ assay. Thermal processing of sauces might be expected to have an effect on heat-labile and oxidizable compounds. However, Dewanto et al.[18] reported that total polyphenols did not change during tomato processing.

The phenolic profile of tomato sauce control without addition of VOO and the content of polyphenols in VOO are reported in Tables 1 and 2. For all polyphenols, levels in tomato sauce control are lower than in samples containing 5% or 10% VOO (Figures 4 and 5). Probably, VOO enhances the extractability of phenolic compounds.[5] Moreover, tomato sauces with 5 and 10% VOO contain tyrosol and hydroxytyrosol due to the addition of VOO. It has previously been reported that the addition of olive oil to tomato sauces enriches meals with other polyphenols not present in tomatoes such as tyrosol and hydroxytyrosol.[3,6,7]

Changes in Hydroxycinnamic and Phenolic Acids during Processing Time. In our study, hydroxycinnamic and phenolic acids were also analyzed (Figure 4). *p*-Coumaric, protocatechuic, and chlorogenic acids achieved their maximum levels (0.3−4 μg/g FW) at 30 min of cooking, regardless of the amount of VOO added (5 or 10%) and then decreased slightly (at 45 and 60 min) (Figure 4). Higher levels of these compounds were found when sauces were supplemented with 10% rather than 5% of VOO. For example, at 30 min of cooking, sauces with 10% of VOO contained 4 μg/g FW of chlorogenic acid, whereas in those containing 5% of VOO, levels of chlorogenic acid were 3 μg/g FW (Figure 4). The same behavior was exhibited by protocatechuic and *p*-coumaric acids. The food matrix containing phenolic compounds plays a crucial role in determining their accessibility and bioavailability from food.[5] Thus, higher amounts of VOO could promote the extraction of phenolic compounds from tomato, leading to a higher phenolic content in the sauce.

Through the catalytic oxidation process, hydroxycinnamic acids can undergo oxidation to reactive *O*-quinones, which can interact with NH_2 and SH groups of amino acids.[19] However, in this work caffeic acid increased from 3 to 6 μg/g FW at 15−60 min of thermal treatment, irrespective of the amount of VOO added (5 or 10%) (Figure 4). It has been reported that air-drying tomatoes at 80 °C increases the number of free hydroxyl phenol groups owing to the hydrolysis of flavonoid glycosides and/or the release of cell wall polyphenols.[20] The 2-fold increase in caffeic acid we observed is in accordance with the results of Re et al.,[21] who reported a similar effect of heat treatment. In contrast, it should be noted that we observed the maximum concentration of ferulic acid at 15 min, after which it decreased slightly (at 30, 45, and 60 min). Values for ferulic acid at 15 min were 7.8 μg/g FW and 8.4 μg/g FW in sauces containing 5% and 10% of VOO, respectively (Figure 4). The addition of 10% of VOO slightly increased the amount of all

studied polyphenols, supporting the likelihood that olive oil added in the culinary process is an important factor increasing phenolic extractability.[5]

Changes in Flavonols, Flavanones, and Other Phenols. On the basis of average yearly consumption, red tomatoes contain 15 μg/g FW of flavonoids, determined as aglycones, according to the USDA flavonoid database. Naringenin (45%) is reported to be the main flavonoid in tomatoes, followed by quercetin (39%), myricetin (10%), and kaempferol (5%).[22] Other studies report rutin as the main flavonoid in several tomato cultivars.[14,22] In our work, rutin was the dominant flavonol in all the treatments, followed by naringenin. Naringenin contents increased slightly from 5.4 μg/g FW at 15 min of cooking to 6 μg/g FW at 45 min when sauces contained 5% of VOO. The same pattern was observed in sauces containing 10% olive oil. Longer cooking periods of up to 60 min resulted in a decrease in naringenin, irrespective of the content of added VOO (5 or 10%) (Figure 5). Our results are in accordance with Re et al.,[21] who analyzed the effects of three different methods for processing tomato sauces. The effect of processing on naringenin could be attributed to the formation of reactive quinones and the extensive oxidation process created during thermal processing.[23]

Similarly, rutin decreased from 35 μg/g FW in sauces cooked for 15 min with 5% of VOO to 28.5 μg/g FW after 60 min of cooking. The same pattern was observed in sauces containing 10% of VOO, with rutin decreasing from 30 to 27 μg/g FW during the thermal treatment (Figure 5). Capanoglu et al.[24] found that rutin decreased after heat treatments of up to 80 °C. These results are in agreement with those described previously.[25]

Quercetin decreased more abruptly during the cooking process than rutin, being reduced from 5 to 3 μg/g FW in sauces containing 5% VOO and from 4.7 to 2.30 μg/g FW in sauces containing 10% VOO (Figure 5). The acceleration of quercetin and rutin degradation may be caused by reactive oxygen species that are captured by flavonols. During thermal processing the flavonols are able to transfer one or two hydrogen atoms, forming quinonoid structures, which leads to the formation of quinones.[26] In the case of rutin, the 3-hydroxy-function at the *C*-ring is blocked by a sugar moiety, whereas in quercetin it remains unoccupied, thus explaining the higher stability of rutin toward oxidation.[27] Naringenin and rutin levels were slightly increased by the addition of 10% of VOO, once again suggesting that oil added in the culinary process may enhance the extractability of phenolic compounds from food.[5]

Finally, tyrosol and hydroxytyrosol from tomato sauces were also evaluated. Hydroxytyrosol increased during the cooking process from 15 to 30 min, decreasing thereafter (at 45 and 60 min), whereas tyrosol continued to increase slightly throughout (at 15, 30, 45, and 60 min) (Figure 5). These results are in line with those of Cheikhousman et al.,[28] who reported that during thermal oxidation hydroxytyrosol derivatives are the first antioxidants to be lost, which means they are the first compounds to be oxidized, while tyrosol derivatives seem to be the most stable compounds. This observed pattern is also in agreement with the high antioxidant activity of hydroxytyrosol and its secoiridoid derivatives in VOO compared with tyrosol derivatives.[29] Polyphenols from VOO are effective stabilizers of alpha-tocopherol during heating, thus contributing to the nutritional value of cooked foods.[30] The addition of VOO (5 or 10%) clearly enhanced the levels of both tyrosol and hydroxytyrosol, since both compounds are the main phenolic acids in VOO.[31]

In summary, in this work the effects of cooking time (15, 30, 45, and 60 min) and the amount of added VOO (5 and 10%) on the phenolic profile of tomato sauces were evaluated using HPLC−MS/MS. As a general pattern, the longer the cooking process, the greater the decrease in levels of polyphenols and antioxidants, with the exception of caffeic acid and tyrosol. However, during thermal treatments, free hydroxyl phenol groups may increase due to the hydrolysis of flavonoid glycosides and/or the release of cell wall polyphenols. Tomato sauces prepared with a higher percentage of VOO contained higher levels of polyphenols. Thus, the use of VOO in the culinary process may increase the range of phenolic compounds in the meal, and can also enhance phenolic bioavailability. There is not an increase in the antioxidant capacity with the oil addition, however, this does not mean that the functional capacity or the nutritional properties of these sauces with virgin olive oil have not increased; since a previous human intervention study from our group (data not yet published) demonstrated that the addition of refined oil in tomato sauce increased the antinflammatory properties of the sauce.

Table 1. Structures of the Major Dietary Groups of Flavonoids and a Few Examples

Group	Structure	Example (frequently found)
Flavones		Apigenin (R1=H); Luteolin (R1=OH)
Flavonols		Quercetin (R1=OH, R2= H); Kaempferol (R1=H, R2= H); Myricetin (R1=OH, R2= OH); Isorhamnetin (R1=OMe, R2= H).
Flavanones		Hesperetin (R1=OH, R2= OMe), Naringenin (R1=H, R2= OH),
Isoflavones		Genistein (R1=OH, R2= OH), Daidzein (R1=OH, R2= H), Glycitein (R1=OH, R2= H)
Flavan-3-ols		Catechin (R1= OH)
Anthocyanidins		Cyanidin (R1= OH, R2= H); Delphinidin (R1= OH, R2= OH); Malvidin (R1= OMe, R2= OMe); Petunidin (R1= OMe, R2= OH)

formation flavonoid metabolites that may or may not have similar effects in vivo as their precursors. Hence, it makes sense to investigate related compounds (with different substituent patterns) in vitro to shed light on the influence of structural changes introduced during metabolism.[21]

Antioxidants are also used as additives to different compounds to prolong their life span.[22,23] Sectors of industry with interest in antioxidants include the food industry, but also plastics and rubber, gas and fuel, lubricants, adhesives, and cosmetics. Increased interest in obtaining products from renewable resources in these sectors (e.g., oils that are more oxidation prone when derived from renewables) has led to a growing market.[24] For industrial use it is important that the antioxidant can be dissolved together with the target compound and also that its action will proceed over a significant time span, keeping sufficient stability.

The antioxidizing power of flavonoids is along with other physicochemical characteristics (i.e., stability and solubility) important for function and depends on the substituents that decorate the flavonoid backbone. The focus of this paper is to review the influence of some major substituents occurring naturally, or as a consequence of in vitro modifications, in different subclasses of flavonoids (especially focusing on hydroxyl groups and their modification by glycosylation and acylation). This is followed by a discussion of current knowledge of the influence of these substituent groups in relation to their application, including methodologies to measure antioxidizing properties, solubility, and stability. Finally, current attempts to modify substituent patterns in vitro by biotechnological methods are reviewed.

OVERVIEW OF NATURAL FLAVONOIDS AND THEIR SUBSTITUENTS

Flavonoids are classified according to chemical structure, and their functionality depends on this structure including the relative orientation of different substituent groups on the molecule.[25] As flavonoids have attracted the attention of researchers in various areas (ranging from chemistry to biology, pharmaceutical sciences, and medicine), they have been named by diverse criteria. The numbers of subclasses vary, depending on the classification system used. On the basis of the backbone structure the IUPAC nomenclature recommends classification of the flavonoids into flavones, isoflavan, and neoflavone (Figure 1).[26] However, in the literature flavonoids have been divided into many groups, which are not all correct; thus, to avoid the confusion about nomenclature IUPAC is running a project called "Recommendations on Nomenclature of Flavonoids" (www.iupac.org). The classification that we find most sensible is the one shown in Table 1, which is built on the major dietary components, named as flavones, flavonols, flavanones, isoflavones, flavan-3-ols, and anthocyanidins. Other minor groups of flavonoids include chalcones,

Table 2. Overview of Generally Occurring Flavonoid Glycosides and Acyls in Nature

subclass of flavonoids	position	monosaccharide	disaccharide	acyl group
flavones	5, 6, 7, 2′, 4′	glucose, galactose, xylose, rhamnose, arabinose, mannose	gentiobiose, rutinose, cellobiose, diglucose, dirhamnose	2-methylbutyric acid, 3-hydroxy-3-methylglutaric acid, acylated sugar
flavonols	3, 7, 5, 4′	glucose, rhamnose, xylose	rutinose,	isovaleric, vinylpropionic acid, acylated sugar
flavanones	5, 6, 7, 4′	glucose, rhamnose, galactose, fucose, arabinose	rhamnose-glucose	acylated sugar, *p*-coumaroyl
flavanonols	3, 7	glucose, rhamnose, arabinose	rhamnose-galactose	acylated sugar, isobutyric acid
isoflavons	7	glucose	not reported	malonic acid
flavan-3-ols (catechin)	7	glucose	not reported	
anthocyanidins	2, 3, 4, 5, 6, 7, 3′, 5′	glucose, galactose, rhamnose, xylose	sophorose, rutinose, sambubiose, robinobiose, gentiobiose	*p*-coumaric acid, caffeic acid, malonic acid, ferulic acid, sinapic acid

dihydrochalcones, dihydroflavonols, flavan-3,4-diols, coumarins, and aurones.[27]

The exact structure of flavonoids varies broadly within the different classes as a result of substitutions, and in plants the various substituent groups include, for example, OH groups, O- and C-methyl groups; methylenedioxy groups; O- and C-prenylation; furano, pyrano, and aromatic substitution; esterification, sulfation, and chlorination.[28−30] There are also many flavonoids available in nature in oligomeric forms, and one example is the tannins widely found in tea.[31]

Glycosyl groups (furanose and pyranose groups) are common in flavonoids and are connected via either O- or C-glycosylation. In the *C*-glycosides (found, e.g., in rice and cereals) the glycosyl group is linked to an aglycone carbon, usually at the C6- or C8-position.[32] More commonly, substitutions in flavonoids occur via reactions with the hydroxyl groups of the aglycone backbone, and *O*-glycosides are examples of this. The wide structural variation among flavonoid glycosides is thus influenced by several factors including linkage, number and nature of the sugars, and the hydroxylation pattern of the aglycone, which in turn determines the position of O-glycosylation. In nature, C-linked glycosylation is mostly found in the flavone group. In general, dicots or higher families have a tendency to accumulate flavone *O*-glycosides, whereas phylogenetically more primitive families such as ferns or gymnosperms produce more flavonol *O*-glycosides.[30,33] The O-glycosylated flavonoids are due to bioavailability frequently selected for analysis of potential effects on antioxidizing capacity, involving, for example, enzymatic modification trials in vitro (discussed below). A list stating the type and position of the O-linked glycosides and acyl groups of various types of flavonoids is given in Table 2. The substituents are affecting not only the antioxidizing properties but also the stability and solubility of the compounds. In the coming section we start by focusing attention on the antioxidizing capacity, including methods to obtain this on naturally occurring and differently substituted flavonoids.

MEASURING THE ANTIOXIDIZING PROPERTIES

The capacity of an antioxidant has, according to Biedrzycka and Amarowics,[34] been defined by Rice-Evans et al.[9] and is determined by (i) its reactivity as a hydrogen- or electron-donating agent (depending on its reduction potential), (ii) the fate of the resulting radical (controlled by the capacity to stabilize and delocalize the unpaired electron), (iii) the reactivity with other antioxidants, and (iv) the transition metal-chelating potential.

Antioxidizing (or reducing) properties can be displayed as either antioxidant activity or capacity. Antioxidant activity is molecule specific and can be described as a "rate constant of a reaction between a specific antioxidant and a specific oxidant", whereas antioxidant capacity measures "the amount (in moles) of a given free radical scavenged by a defined sample".[35] Measurements of antioxidant capacity can hence, depending on sample composition, yield scavenging ability either of an individual antioxidant or of the combined action of a mixture of antioxidants.

Flavonoids are known to be efficient scavengers of free radicals, such as $OH^{\bullet}$, $O_2^{\bullet}$, and $LOO^{\bullet}$ (lipid peroxide radicals).[9] Their potential as antioxidants is predicted by their reducing properties as hydrogen- or electron-donating agents, and evaluation is made using a variety of antioxidant assays, with different strengths and limitations. It is also difficult to compare data from investigations that use different methods, and thus it is recommendable to use a combination of assays. For this purpose, it is advisable to pick methods that are validated, standardized, and widely reported. A number of such methods are summarized in Table 3, along with a brief description of the analysis principle for the respective method. These methods, for example, include oxygen radical absorbance capacity (ORAC), Trolox equivalent antioxidant capacity (TEAC), 2,2-diphenyl-1-picrylhydrazyl (DPPH), ferric reducing antioxidant power (FRAP), cyclic voltammetry total reducing capacity (CV), Folin−Ciocalteu reducing capacity (FC), cupric reducing antioxidant capacity (CUPRAC), and total radical-trapping antioxidant parameter (TRAP).

Antioxidant assays can mainly be divided into one of the two groups: hydrogen atom transfer (HAT)-based assays[52] or electron transfer (ET)-based assays (see Table 3). HAT-based assays measure the capacity of an antioxidant to quench free radicals by hydrogen atom donation, and the majority involve a competitive reaction scheme. In these assays, thermal decomposition of azo-compounds generates peroxyl radicals, resulting in competition between the antioxidant and the substrate.[40] ET-based assays measure the ability of a potential antioxidant to transfer one electron to reduce any compound (which could be metals, carbonyls, and radicals). In principle, ET-based assays measure the capacity of an antioxidant to reduce an oxidant probe that changes color upon reduction[40] according to the following scheme:

$$\text{probe (oxidant)} + \text{antioxidant} \rightarrow \text{reduced probe} + \text{oxidized antioxidant}$$

Table 3. In Vitro Antioxidant Capacity Assays

	assays by hydrogen atom transfer reactions		assays by electron-transfer reaction

After completion (no more change in color), the degree of color change is proportional to the concentration of antioxidant.[40]

ANTIOXIDANT CAPACITIES OF DIFFERENTLY SUBSTITUTED FLAVONOIDS

Structures of A-, B-, and C-Rings and Their Hydroxylation. The phenolic groups of flavonoids (B-ring, Figures 1 and 2) supply readily available H-atoms ensuring that the

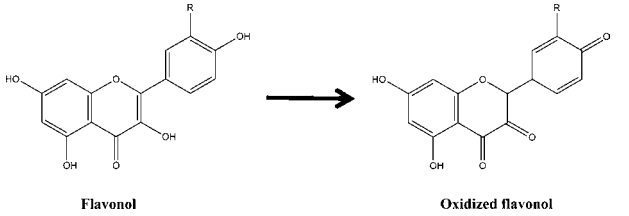

Figure 2. Structures of flavonols and their oxidized forms. R = OH, quercetin; R = H, kaempferol.

radicals produced can be delocalized over the flavonoid structure.[53] During the radical scavenging reaction, the flavonoid molecule donates a hydrogen atom to the reacting radical,[54] as shown in Figure 2. The flavonoid free radical formed in the reaction is more stable than the ROS that donates the electron due to the delocalization of the electron in the benzene ring (A-ring, Figures 1 and 2).

In vitro experiments have shown that substituents on the molecule affect the scavenging capability. Important for high antioxidizing capacity are the number and arrangement of hydroxyl groups on the aromatic backbone (A-, B-, and C-rings)[55−57] (Figure 3). Hydroxyls on the B-ring are important for the hydrogen-donating capacity. An *o*-dihydroxy group (catechol group) gives higher stability to the radical structure and takes part in electron delocalization[58] (Figure 3A). A

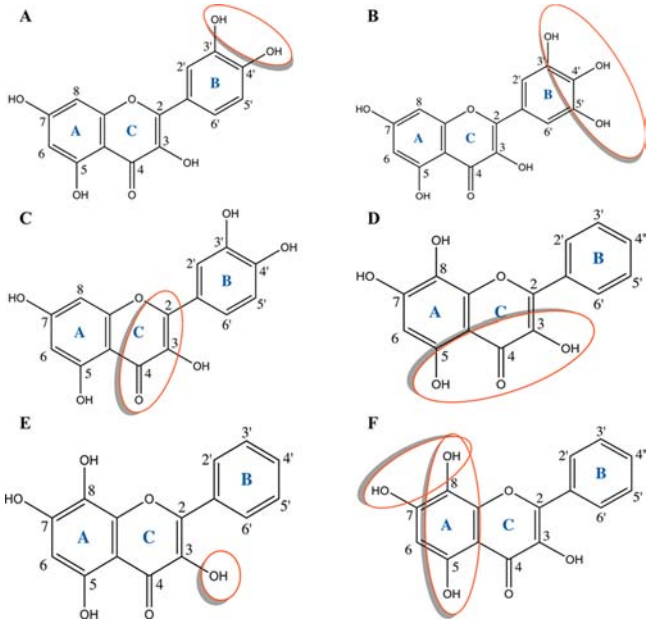

Figure 3. Basic structural features that characterize antioxidant functionality in polyphenols. Areas circled in red show features that are critical for efficient antioxidant function. Letters A, B, and C denote the ring structures of the flavonoid moiety.

pyrogallol group (hydroxyl groups at the 3′-, 4′-, and 5′-positions on the B-ring) enhances antioxidant capacity compared to flavonoids with single hydroxyl groups in ring B[59] (Figure 3B). Electron delocalization from ring B is promoted by a C-2, C-3 double bond combined with the 4-oxo function in the pyran ring (C-ring),[58] which also contributes to the antioxidant capacity (Figure 3C). In line with this, measurements using the TEAC assay (Table 3) show that quercetin presents enhanced antioxidant capacity compared to catechin[60] (see Table 1 for structures). The 3- and 5-OH groups (in the A- and C-rings, respectively) neighboring the 4-oxo function of the C-ring (Figure 3D) also promote high antioxidant capacity.[61] The presence of a free 3-OH group (Figure 3E) seems important as further modification (e.g., 3-glycosylation) leads to reduction of antioxidizing capacity.[55,62] In the A-ring, pairwise hydroxyl substitutions involving position 5 or 8 promote high antioxidant capacity. This is true for both 5,8- and 7,8-hydroxylation (Figure 3F), whereas corresponding groups at the 5,7-positions had little influence. A single 7-hydroxyl also had little effect, whereas a single 5-hydroxyl group (next to the 4-oxo function) increased antioxidant capacity.[63,64]

Following these criteria, a structure−antioxidant capacity relationship of flavonoids (quercetin > quercetin-3-*O*-rutinoside > kaempferol > luteolin) was proposed by Brown et al.[65] Quercetin (Table 1) has all requirements to exercise effective antioxidant function, mainly due to the presence of both a catechol group in the B-ring and a 3-hydroxyl group in the C-ring. Several studies[66,67] have also reported that flavanones with hydrogenated C-2 and C-3 (Table 1) are in principle inactive, indicating the importance of the double bond between C-2 and C-3 (Figure 3C), whereas luteolin (with the C-2, C-3 double bond and a 3′,4′-dihydroxyl group) has relatively high capacity.[66] The antioxidizing capacity of the anthocyanin molecule (with a structurally different C-ring, Table 1) is, however, high and in the same range as that of quercetin. The high capacity of the anthocyanin molecule has been attributed to its electron delocalization ability combined with its ability to form resonance structures upon changes in pH. The completely conjugated structure of anthocyanin allows electron delocalization, resulting in very stable radicals, which from this perspective is favorable.[59,68] Moreover, the positively charged oxygen atom in the C-ring makes it a better hydrogen-donating antioxidant compared to oligomeric proanthocyanidins and other flavonoids.[69]

Clearly, the antioxidant capacity of flavonoids is related to a combination of these chemical and structural elements. Generally, the higher degree of hydroxyl groups present in the flavonoid ring, the stronger the free radical scavenging will be. It is also apparent that hydroxyl groups of flavonoids are frequently sites of further modification, modulating antioxidant capacity by glycosylation, methylation, or, more rarely, acylation or sulfation.

Glycosylation Decreases Antioxidant Capacity. Most flavonoids are glycosylated in nature, and the position and nature of the sugar substituents are species specific.[70] Glycosylated flavonoids generally show decreased antioxidant capacity compared to the corresponding aglycones,[71] but glycosylation also modulates parameters, for example, solubility and stability, as discussed below. Zielinska et al.[72] determined antioxidant properties of quercetin and its glucosides from onion by the CV assay (Table 3) and showed that highest antioxidant capacity was obtained using the aglycone. The order of the antioxidant capacity was quercetin > quercetin-3-

dx.doi.org/10.1021/jf405570u | J. Agric. Food Chem. 2014, 62, 3321−3333

O-glucoside > quercetin-4′-*O*-glucoside > quercetin-3,4′-*O*-diglucoside. These results are in agreement with a report by Rice-Evans et al.[55] indicating that the antioxidant properties of quercetin glucosides were most affected by glycosylation of the hydroxyl group in the catechol group of the B-ring.

Plumb et al.[73] have also reported that antioxidant capacities of flavonol glycosides from tea decreased as the number of glycosidic moieties increased. Besides the total number of glycosidic moieties, the type of glycosylation (O- or C-) and the position and structure of the sugar play important roles. C-Glycosylation in the A-ring was in this case shown to decrease antioxidant capacity,[74] and this effect may be caused by the properties of the sugar molecule. Flavonoid glycosidic moieties occur most frequently as *O*-glycosides at the 3- or 7-position. The 7-glycoside (in ring A) resulted in a more pronounced decrease of capacity than 3-glycosylation in the C-ring.[75] Obviously, the presence of substituents also affects the bioavailability (uptake) of flavonoids by changing the solubility in hydrophilic solvents.

Acylation Is Mostly Investigated after in Vitro Modification. A way to improve the hydrophobic nature of flavonoids is, for example, to connect fatty acids to the hydroxyls by esterification. Acylated flavonoids may occur in natural sources (Table 2), but these modifications are not as common as glycosylation and do normally not encompass long hydrophobic molecules. In this field, in vitro acylation of flavonoids by fatty acids has been made and the effect of these substitutions on antioxidant capacity monitored (see also enzymatic modification, below). Hydroxyl groups on the sugar of a flavonoid glycoside (and not the backbone) are common targets for acylation and generally lead to reduced antioxidant capacity, although the results appear to be dependent on the model assay chosen to measure the resulting antioxidizing capacity. Acylation of quercetin-3-rutinoside via glucose with lauric acid (*n*-dodecanoic acid), more so than palmitic acid (hexadecanoic acid), negatively influenced overall metal chelation when compared to unesterified quercetin-3-*O*-rutinoside.[76] Acylation of the glucoside in quercetin-3-*O*-glucoside with fatty acids esters by Salem et al.,[77] on the other hand, resulted in the enhanced scavenging capacity of the quercetin-3-*O*-glucoside-ester against ABTS radicals but decreased it against DPPH and the superoxide radical. Furthermore, quercetin-3-*O*-glucoside esters exhibited an antioxidant capacity that depended on the acyl chain length, where the antioxidant capacity decreased with increasing acyl chain length.

Other Substituents. Methylation and sulfation of the free hydroxyl groups are examples of other substitutions, and these follow the trends seen for glycosylation and acylation in generally reducing antioxidant capacity. Rimbach et al.[78] studied the effect of sulfation and found that genistein-4′-sulfate was a less efficient antioxidant than genistein and genistein-4′,7-disulfate even less efficient. This indicates that sulfation masks important hydroxyl groups of the isoflavone molecule and decreases the antioxidant capacity of the resulting compound.

O-Methylated quercetin is also an example of a less potent peroxyl radical scavenger than unsubstituted quercetin, and several studies have reported that steric effects perturb the planarity of O-methylation, which may induce the suppression of antioxidant capacity.[75,79] Investigations, mainly using assays based on DPPH or ABTS (Table 3), have shown that the B-ring is especially sensitive to the position of methoxyl groups. Reduction of the antioxidant capacity was seen for 2′-*O*-methyl/4′,6′-hydroxy substitution in the B ring, whereas 2′,6′-hydroxy/4′-*O*-methyl substitution resulted in a lower effect.[80] Zima et al.[81] also showed that *O*-dihydroxy substitution of the flavanone B ring resulted in higher capacity than methoxylated compounds or compounds with para-located hydroxyl groups. Accordingly, reduction of antioxidant capacity by methylation depends on a combination of free hydroxyl groups and the position of methoxyl groups in the flavonoid.

Antioxidizing Effects Also Depend on the Chosen Model System. It is apparent that the antioxidant capacity of flavonoids has been studied in many different model systems to gain insights on structure−antioxidant capacity relationships and that the choice of assay system (depending on its mechanism) may affect the result obtained. In a recent study performed by Ishimoto et al.,[52] antioxidative properties of five typical flavonoids were assessed (kaempferol, quercetin, myricetin, isorhamnetin, and quercetin-3-glucuronide, Table 1) by the ORAC assay (Table 3). Despite previous findings that an increase in the number of hydroxyl groups in the B ring of a flavonol is generally correlated with an increase in antioxidative capacity, it was found that the ORAC level for kaempferol (with one hydroxyl group in the B-ring) was 1.5-fold higher than that of quercetin and myricetin (with two and three hydroxyl groups in their respective B-rings). It was also shown that the ORAC score of quercetin was comparable to the scores of both its methylated metabolite (isorhamnetin) and its 3-*O*-glucuronide.[52] In the same study, the ORAC score of (−)-epigallocatechin gallate was 1.5 times lower than that of its methylated metabolite, (−)-epigallocatechin 3-*O*-(3″-O-methyl)-gallate. On the other hand, (+)-catechin and (−)-epicatechin both showed remarkable antioxidative capacity (ORAC levels of 9.0 and 10.0 mol Trolox equiv/mol) compared to all 3′- and 4′-*O*-methyl-(+)-catechins and 3′- and 4′-*O*-methyl-(−)-epicatechins (ORAC values in the range of 5.7−6.5 mol Trolox equiv/mol). This shows that the scavenging ability depends not only on the structure of the antioxidant (discussed above) but also on the target molecule chosen to monitor oxidation.

In conclusion, antioxidant capacities are dependent on many specific structural features, of which one is the number and/or position of free hydroxyl groups of flavonoids. It is, however, also important to note that the choice of model system for measuring antioxidant capacity influences the results. Antioxidant assays differ from each other in terms of reaction mechanisms, oxidant and target/probed species, reaction conditions, and the form in which results are expressed.[36] Therefore, it is prudent to use more than one type of antioxidant assay and also consider the relevance of the assay in relation to putative use of the assayed molecule.

STABILITY AND SOLUBILITY ARE OTHER IMPORTANT PROPERTIES MODIFIED BY FLAVONOID SUBSTITUENTS

Most studies involving flavonoids have focused on the antioxidizing capacity. There are, however, other properties of importance, especially for use and selection of antioxidants for applied purposes. Such properties include the stability and solubility of the molecules. With increased industrial interest for use of antioxidants, the choice of antioxidant for a certain application will be dependent on both the possibility to dissolve the antioxidant and the possibility to prolong the shelf life of the antioxidant or of product compounds to which the antioxidant is added.

Substituents (such as the *O*-glycosyl groups connected to the hydroxyl groups in the flavonoids) not only regulate the antioxidizing capacity but also influence both the stability and solubility of the molecules. Although less attention has been given to these factors, they are important for successful use. Glycosylation frequently occurs in natural flavonoids and, in addition, both glycosylation and acylation have been done in vitro, to tune naturally occurring antioxidants to more desired properties for applied use. The effect of glycosylation and acylation on both stability and solubility is thus reviewed according to our current knowledge in the field.

Effect of Glycosylation on Stability. Relatively little information is available on the effect of glycosylation on the stability of flavonoid molecules. A few examples are however found where glycosylation has been shown to contribute to stability. For example, Buchner et al. measured the changes in concentration of rutin (also called quercetin-3-*O*-rutinoside or sophorin) and quercetin, in aqueous solution at 100 °C with air perfusion, and the results showed that rutin had higher stability compared to quercetin.[82] In another study of metal-catalyzed oxidative degradation, rutin and quercetin were dissolved in phosphate buffer containing Fe^{2+} and Cu^{2+}. It was also found that rutin had a slower degradation rate by monitoring the concentration changes during the degradation process.[83] Other oxidation studies (e.g., oxidation by peroxidase) of rutin and quercetin also reached the same conclusion.[84] In the study by Buchner et al.,[82] both quercetin and rutin were degraded in aqueous solutions at pH 5 and 8. Again, and at both conditions, the degradation of quercetin seemed to be much faster compared to that of rutin.

Rutin is glycosylated at a single point involving a disaccharide linked to the 3-OH on the quercetin C-ring. The stability of flavonoids is, however, also influenced by the number of glycosylated hydroxyl groups. As an example, studies have shown that boiling in water at 100 °C caused a greater decrease in quercetin-4′-glucoside content than in the content of quercetin-3,4′-diglucoside,[85,86] making the diglucoside more stable than the monoglucoside. The degradation was successive, and, for example, quercetin diglucosides almost completely broke down to aglycone via the monoglucose derivative by hydrolytic enzymes.[87−89]

Acylation Can Further Promote Stability. Although the mechanism is not known, the introduction of acyl groups has also been shown to enhance the thermostability of flavonoids. In Ishihara and Nakajima's study, in vitro monoacylation of quercetin-3-glucoside via a glucoside hydroxyl with nine different aromatic carboxylic acids all improved the thermostability and light-resistivity of the resulting flavonoids.[90] It was suggested that the reason for the improved stability by acylation might be that the intra- and intermolecular interactions, between the flavonoid skeleton and the aromatic ring in the acyl moiety, would prevent the degradation of the molecule.[90] A similar observation was reported by Fossen et al.[91] that complex anthocyanins such as petanin, which contains one aromatic acyl group, showed higher color intensity and stability than cyanidin-3-glucoside at pH 4.0−8.1.

In conclusion, the addition of the above substituents increased the stability of flavonoids. The additional sugar or acyl moiety could protect the aglycone from degradation to some extent, although so far there are no studies available to confirm the mechanism behind this.

Effect of Glycosylation on Solubility. Solubility is another important parameter that will determine whether it is possible to utilize an antioxidant as an additive. Solubility in oils can be desired to prevent oxidation,[92] and in addition solubility in water has previously been shown to improve the uptake of flavonoids supplied in the diet.[93] There is, however, very limited data on direct measurement of solubility of differently substituted flavonoids, like, for example, comparisons of glycosylated and nonglycosylated compounds. Moreover, some solubility data were obtained by comparing extraction[94] or chromatography data,[95] which makes it difficult to compare the solubility between different studies. Octanol−water distribution constant (log K_{ow}) values are related to water solubility, and such values can be used as index values for comparing the hydrophilicity of the flavonoids.[96,97] Frequently, available comparisons, however, report water solubility at a given temperature for different flavonoid compounds.

The presence of a sugar moiety usually increases the solubility of the flavonoids in water solutions. For example, quercetin has a low solubility in water at 25 °C (about 0.92 g/L).[98] Glycosylated quercetin[99] as well as other glycosylated flavonols[94] was reported to have considerably enhanced water solubility compared to the corresponding aglycone, although it is difficult to find exact numbers on the improvement from the literature. In the study of Chen et al.[94] it is reported that the higher solubility in water of glycosylated flavonols led to improved extraction yields. There was, however, no quantitative measurement of the solubility of the flavonols in the above studies. The position of the sugar moiety and the number of the bound sugars also play important roles. For example, the solubility of quercetin-3,4′-diglucoside, quercetin-3-glucoside, and quercetin-4′-glucoside in water solution decreases in the same order.[96,97] On the other hand, glycosylation will decrease the lipophilicity of the flavonoid aglycones. The review by Chebil et al., for example, shows that the solubility of rutin (quercetin-3-rutinoside) and isoquercitrin (quercetin-3-glucoside) was decreased in acetone and acetonitrile as compared to the solubility of the aglycone quercetin.[100]

Effect of Acylation on Solubility. If an increased lipophilicity is desired, acylation, particularly with long-chain fatty acids or vinyl esters from C4 to C18 in length, increases the solubility of flavonoids in organic solvent, that is, reflecting the lipophilicity of the flavonoids.[76,101] Such reactions have been done in vitro predominantly as enzymatic biotranformations. Another example is the use of aromatic acids such as hydroxycinnamic acids in acylation reactions, which have been shown to decrease the solubility of anthocyanins in cell cultures, which are hydrophilic environments.[95] However, acylation with small inorganic acids such as sulfuric acid instead increases the solubility of quercetin in water solution.[95] Therefore, it is reasonable to assume that acylation with hydrophilic acids will increase the hydrophilicity of the targeted flavonoids and vice versa.

All in all, although there are not so many studies comparing the absolute solubility data, this is very important in future flavonoid research. Existing literature data support the conclusion that the solubility of flavonoids is affected by the hydrophilicity of the additional moiety either through glycosylation or acylation. Adding hydrophilic groups will increase the hydrophilicity of the flavonoid; for example, glycosylation will increase the solubility of flavonoids in aqueous solution, whereas acylation will increase or decrease the solubility of flavonoids in aqueous solution by adding hydrophilic or hydrophobic acyl groups. Therefore, by choosing an appropriate method, it is possible to modify the solubility of

Table 4. Enzymatic Glycosylation of Flavonoids Using Glycoside Hydrolases

source	enzyme	donor	acceptor	product	reference
Aspergillus niger	cellulase	4NP-Fuc	catechin	catechin 4-β-D-fucopyranoside	112
Bacillus stearothermophilus	α-D-glucosidase	maltose	catechin	catechin 7-α-D-glucopyranoside catechin 5-α-D-glucopyranoside	112
Bacillus sp.	α-amylase	dextrin	catechin	catechin 7-α-D-maltoside catechin 5-α-D-maltoside	112
Leuconostoc mesenteroides	glucansucrase	sucrose	luteolin	luteolin-3′-α-D-glucopyranoside luteolin-4′-α-D-glucopyranoside	123
Leuconostoc mesenteroides	glucansucrase	sucrose	quercetin	quercetin-3′-α-D-glucopyranosides quercetin-4′α-D-glucopyranosides	123
Leuconostoc mesenteroides	glucansucrase	sucrose	myricetin	myricetin-3′-α-D-glucopyranoside myricetin-4′-α- D-glucopyranoside	123
Pencillium decumbens	cellulase	maltose	quercetin	quercetin-3-rutinoside	94
Humicola insolens	synthase Cel7B_E197S	α-glycosyl fluoride	luteolin	luteolin-5-α-D-glycosyl	119

flavonoid in vitro according to the need of the study, which of course, as described above, will also affect the antioxidant properties of the compounds. Enzymes are typically used to make selective modifications on flavonoids, and below some efforts in this field will be shown.

ENZYMATIC METHODS FOR IN VITRO MODIFICATION OF FLAVONOIDS

The use of enzymes and microorganisms has by the European Commission been identified as a key enabling technology in replacing nonrenewable chemicals and materials with renewable alternatives,[102−104] and for the purpose of flavonoid modification, enzymes classified as hydrolases (EC 3.*x*.*x*.*x*) are biocatalysts of special interest. Hydrolases can, depending on the reaction conditions, catalyze both hydrolysis and synthesis reactions and thus modify the content of glycosyl groups (using glycoside hydrolases (EC 3.2.1.*x*)[105]) or acyl groups (using lipases or carboxyl esterases (EC 3.1.1.*x*)[100]) in flavonoids in biotransformation reactions. These biotransformations may affect both the antioxidative power and the physicochemical properties of the target molecule, and the benefits of in vitro modification of flavonoid structures using enzymes include production possibilities in amounts that make bioavailability trials as well as proper investigations of physicochemical properties of designed molecules possible. In addition, novel compounds can be created, thus increasing the natural flavonoid diversity in the laboratory.[92,106−108] When it comes to practical use of flavonoids in pharmaceuticals, cosmetics, food, or other industrial applications, the relatively low solubility and stability in lipids or water (dependent on the molecule chosen), can also be improved by designed modifications,[109,110] avoiding current limitations.

Enzymatic Acylation Frequently Requires Glycosylated Acceptor Flavonoids. The enzymes most commonly used for in vitro modification to date are lipases, which have successfully been used to acylate flavonoids, using different esters (transesterification) and organic acids (direct esterification) as acyl donors, that, depending on the selected donor, can favor solubility of the product in lipids. Most lipases, however, require glycosylated flavonoid acceptor molecules for function, and they selectively acylate hydroxyl groups on glycosides and do not modify free hydroxyls on the flavonoid aglycone. Efforts in this field using lipases and carboxyl esterases (also including the protease subtilisin) have been carefully reviewed by Chebil and co-workers,[97] and it was shown that among the enzymes thus far used, it was only lipase PS from *Pseudomonas cepacia* (now renamed *Burkholderia cepacia*)[90,100] and carboxyl esterases from *Streptomyces rochei* and *Aspergillus niger*[100,111] that successfully acylated hydroxyls on a nonglycosylated phenolic antioxidant acceptor, which in both reported cases was catechin. A limited number of donor molecules were tried for these enzymes and were for lipase PS restricted to vinyl acetate (an ester of fossil origin), whereas for the carboxyl esterases a short series of esters were used, including ethyl acetate, ethyl propionate, phenyl propionate, and phenyl butyrate.[90,100,111]

Most commonly, free or immobilized forms of lipase B from *Candida antarctica* (CalB) have been used in various synthetic approaches for acylation of glycosylated flavonoids, using a range of donor molecules via both direct esterification and transesterification. The reaction conditions are largely influencing the yield, and immobilized CalB clearly showed the best conversion at water activities close to zero. The observed conversion yields vary largely between different studies, using different acyl donors. Different vinyl esters are relatively commonly used for this purpose[100] and, for example, the synthetic reaction in the production of 6-*O*-((+) catechin 7-*O*-α-D-glucopyranoside) cinnamate from vinylcinnamate reached a yield of 70%.[112] Among acyl donors tested in reactions involving CAL-B to obtain products with increased solubility in lipids, high conversion yields have in some cases been reported using fatty acid donors with carbon chains up to C18. For example, 71% yield has been noted in rutin palmitate synthesis using palmitic acid (C16:0) as donor in reactions using the immobilized form of CAL-B (Novozym435).[113]

From the available literature it can also be seen that the enzymes are to a certain extent regioselective. For example, CAL-B has by different authors been reported to prefer either the primary alcohol (C6-OH)[114] or the secondary alcohol at C4-OH[115] of the sugar for the acylation reaction. Most papers indicate monoacylation, but for isoquercitrin (quercetin-3-glucoside) diacylation on C6-OH and C3-OH has also been shown.[100]

Glycosides Can Be both Removed and Added by Glycoside Hydrolases. The hydrophilicity of flavonoids can also be varied by changes in the glycosidic group content. Glycoside hydrolases (GH) either catalyze hydrolysis or transglycosylation of glycosidic groups, and are in nature taking part in processes such as (i) degradation and assimilation of exogenous glycosides, (ii) recycling/remodeling of cellular components, or (iii) modification of biological activity of free glycosides.[104,116] These activities can of course also be utilized in vitro to deglycosylate flavonoids, for example, using thermostable β-glucosidase,[117] as well as to selectively glycosylate flavonoid molecules. The relationship between hydrolytic or transglycosylation activity varies between different enzymes and different GH families and can be modulated if the right conditions are found in the reaction, such as high sugar concentration and controlled water activity. Compared to the use of lipases, rather limited attempts have thus far been made in this field, but interest is increasing, and in addition to the use of natural enzymes, some nucleophile-mutated variants for improved performance have also been constructed and analyzed.[118,119] A problem encountered is that glycoside hydrolases require higher water activity (generally $a_w > 0.6$) than lipases,[120,121] whereas many flavonoid aglycones have low solubility in water.

Successful trials are summarized in Table 4 and include the use of a cellulase from *Aspergillus niger* and an α-amylase from a *Bacillus* sp., in reactions with 4-nitrophenyl-α-L-fucoside (4NP-Fuc) as sugar donor molecules and catechin aglycone as acceptor molecule. Although successful, the yields achieved under the conditions used were not so high, up to 26%.[112]

Attempts have also been made to optimize the conditions for glycosylation of the flavonoids. Quercetin glycosylation trials at various temperatures, pH values, solvents, and substrates using a *Penicillium decumbens* cellulase (40−60 °C, pH 6−7, 30−60% ethanol/water v/v) were made with glucose or maltose as the glycosyl donor. In this case, conversions up to 30% were reached.[122] Later, the same cellulase was used to assist in extractions of flavonoid compounds in mild solvents such as ethanol/water followed by transglycosylation of flavonoids, converting them into more polar molecules, but the highest transglycosylation yield was only 27% and was achieved using maltose and isorhamnetin.[94]

To overcome low glycosylation yields, an enzyme with higher natural transglycosylation activity, a glucansucrase from *Leuconostoc mesenteroides*, was used for glucosylation carried out in aqueous/organic solvents to improve flavonoid solubility. Conversion yields did, however, not improve so much, but varied depending on the flavonoid used, resulting in a conversion to glycosylated forms (Table 4) of luteolin (8%), quercetin (4%), and significantly higher for myricetin (49%).[123] In addition, using this enzyme, an α-linked glucoside (quercetin-α-D-glucopyranoside) not occurring in natural isolates was obtained.[124]

A new approach to glycosylate flavonoids is to use GHs, mutated in the catalytic nucleophile, so-called glycosynthases, to switch the enzyme mechanism to synthesis only. This methodology is established for oligosaccharide synthesis but has seldom been used for the modification of flavonoids. As the nucleophile of the enzyme is replaced, this approach requires that either fluorinated sugars or external nucleophiles are available in the reaction mixture.[125,126] In Yang et al.,[119] a high-throughput mass spectrometry-based method was used to assay biocatalysts and substrates for glycosynthesis, demonstrating that finding the right donor and acceptor is crucial for the glycosynthesis reactions. The glycosynthase Cel7B_E197S from *Humicola insolens* was found to catalyze the reaction, transferring an α-glycosyl fluoride (LacF) into the flavonoid, forming a glycosidic bond with a specificity for position 4′ and 6-linked OH groups on the flavonoid, with a rather high glycosylation yield (75−95%) compared to previous attempts using glycosidases and glycosyltransferases.[127] In addition, fair yields (up to 40%) were obtained using a glycosynthase of *Thermotoga neapolitana* β-glucosidase 3B, using a monoglucosylated quercetin as substrate in reactions obtaining the diglucoside, but required a second mutation in the active site for function.[128]

In summary, flavonoids are natural antioxidants, and they are getting more attention being molecules from renewable resources that can be utilized as additives in many types of products, ranging from food and pharmaceuticals to cosmetics and eventually larger scale industrial products. To efficiently use and select the antioxidants, a detailed understanding of the interplay between their activity, stability, and solubility is greatly aiding selection of suitable candidates. Substituents connected to their hydroxyl groups definitely have a role in the determination of these properties, and enzymatic routes to modify such substituents and properties are likely to play a role in future modification of natural flavonoids for more selective applications.

PFAAs, whereas foliage/root concentration factors were lowest, and it was concluded that sorption to root surface tissue was the major uptake mechanism for the long-chain PFAAs. Recently some more mechanistic uptake studies have been published, investigating the influence of abiotic parameters, such as pH values or temperature,[36,37] and investigating the influence of metabolic inhibitors on the uptake.[38] These studies have been conducted with maize and wheat plants. Although these studies provide some initial insights into plant uptake of PFAAs from soil, there is still limited mechanistic understanding of the uptake, how it is influenced by the properties of the PFAAs and the characteristics of the plants, and how the PFAAs are distributed between different plant tissues.

The goal of the present study was to investigate the uptake of PFAAs and their distribution in different plant parts. To that end three crops were grown hydroponically in a greenhouse. A hydroponic system was used so that the water uptake could be readily monitored and the bioavailable concentrations of the PFAAs in the root zone could be directly measured. Further advantages are the controlled supply of nutrients, which together with the controlled light conditions ensures an optimal growth. A limitation of hydroponic studies is that they do not include the effect of soil on modulating chemical availability. A further drawback is that the nutrient solution has to be renewed regularly, which can lead to variability in exposure concentration for surface active chemicals such as PFAAs.

The crops were chosen to represent a variety of physiology. Tomato is a fruit-bearing crop of economic importance. Zucchini is another fruit-bearing crop belonging to the family of Cucurbitaceae, which has been shown to have a unique capability to transfer some hydrophobic organic contaminants from roots to shoots.[39,40] Cabbage is an important crop of which part of the leaves (the cabbage head) is eaten, and leaves were hypothesized to be a plant tissue that would amass high concentrations of short-chain PFAAs. A set of 11 perfluorinated carboxylic acids (PFCAs; carbon chain length from C4 to C14) and 3 perfluorinated alkyl sulfonates (PFSAs; C4, C6, and C8) was selected to provide a broad foundation for assessing the influence of chemical properties on PFAA uptake and distribution. When harvested, the plants were divided into roots, stems, leaves, and edible parts (tomatoes, zucchinis, and cabbage heads) to explore PFAA distribution within the plant. In tomato and zucchini, the stem tissue was further divided into the main stem (called "stem") and the tissue connecting the main stem to the leaves ("twigs") to provide more spatial resolution in the study to the transport of the PFAAs from the roots to the above-ground plant parts.

MATERIALS AND METHODS

Chemical Reagents and Laboratory Materials. All chemicals used in this study were of the highest quality and purity available. The abbreviations, suppliers, and purities of the chemicals can be found in Table S1 of the Supporting Information (SI).

Materials used for extraction and cleanup of the samples included Florisil SPE cartridges (1000 mg, 6 mL) from Applied Separations (Allentown, PA, USA), Oasis WAX 3 cm^3 SPE cartridges (60 mg) from Waters (Wexford, Ireland), and Supelclean ENVI-Carb 120/140 from Supelco (Bellefonte, PA, USA). Polypropylene (PP) tubes (50 and 15 mL) with screw caps were purchased from Sarstedt (Nümbrecht, Germany); PP vials (2.0 and 0.3 mL) were purchased from VWR International (Amsterdam, The Netherlands). Acrodisc LC13 GHP Pall 0.2 μm filters were obtained from Pall Corp. (Port Washington, NY, USA). The 10 L PP buckets were acquired from Harcotom (Purmerend, The Netherlands).

Plant Culture and Exposure Experiments. The uptake study was performed in a greenhouse (14 h of light). The plants were pregrown in soil until the seed leaves (cotyledons) were fully developed (BBCH stage 10). The soil was carefully washed off before the plants were transferred to the hydroponic system, where only the roots of the plants were exposed to the nutrient solution. The system is described in more detail in our previous study.[35] Tomato (*Solanum lycopersicum* var. Moneymaker) plants were grown in hydroponic solutions with nominal concentrations of 10, 100, 1000 and 10000 ng/L for each PFAA. Because the highest spiked concentration for tomatoes resulted in very high concentrations in plant parts, the zucchini (*Cucurbita pepo* var. Black Beauty) and cabbage (*Brassica oleracea* convar. *capitata* var. *alba*) plants were exposed to 10, 100, 500, and 1000 ng/L. For each plant a 10 L bucket was filled with 8 L of Hoaglands nutrient solution (see Table S2 in the SI for composition) and spiked with 100 μL/L of the respective PFAA stock solution. Six replicates per concentration were used for cabbage and tomato, whereas only four replicates could be used for zucchini due to their size. Two plants of each species were grown in unspiked nutrient solution as blank controls, and two pots without plants were used for evaporation measurements.

The plants were randomly distributed in the greenhouse room, and plant growth and water uptake were determined by weighing. The zucchini and tomato plants eventually grew too big to be moved, so no new randomization of the plant distribution was possible from then on. Furthermore, the tomato plants grew too big to be supported by the available equipment and had to be cut back from time to time. Secondary shoots were continuously removed as well. Thus, for tomato only the lower plant parts were analyzed. Pruning of tomato side shoots is a common practice and was done as soon as the secondary shoots were noticeable. The trimming of the top part of the plants was necessary and done for all plants at the same height, so that individual differences between plants were minimized. In total, the cutoff biomass for each plant was much less than the total biomass of the plants at the end of the experiment. We do not expect that the pruning and trimming had an influence on the uptake of PFAAs.

During the experiment the nutrient solution needed to be renewed several times due to the water uptake of the plants. This was done by replacing the buckets with new buckets containing freshly prepared spiked nutrient solution. Differences between the uptake of water and the uptake of PFAAs meant that the PFAA concentrations changed somewhat during the experiment. With decreasing water levels in the buckets, the PFAA concentrations in the solutions can significantly increase. We describe below how we dealt with these complications. On average, the tomato plants took up 46.7 L of the nutrient solution, the cabbage plants 24.6 L, and the zucchini plants 41.4 L.

Tomato and zucchini fruits were harvested when they were ripe. Other plant parts were collected for analysis only after the experiment was stopped. Cabbage plants were divided into roots, stem, leaves, and head. Tomato and zucchini plants were divided into roots, stem, twigs, leaves, and fruits. Table S3 in the SI lists start and end dates of the growth experiment as well as dates of renewal of the nutrient solution and harvest dates of tomato and zucchini fruits. Samples were stored at −20 °C until extraction. No differences in plant growth were observed between the different spiking levels, and there were no visible effects of the compounds on the plant health (discoloring, spots). Not all of the cabbages survived until the end of the experiment, but at least three plants of each concentration survived. In total, 7 of 26 cabbage plants were lost. Cabbage survival was independent of the spiked concentration, and fatalities were most likely caused by the temperature in the greenhouse. The optimal temperature range for cabbage is between 15 and 20 °C. Temperatures above 25 °C, which were experienced for several days during the cabbage growth phase, can lead to inhibited growth and dropping of the outer leaves, which was observed for all cabbage plants in the experiment.

Extraction. After the plant samples had been washed with demineralized water, the material was dried superficially and homogenized with a household blender (Braun Multiquick MX

2050). The extraction method used is based on the method of Vestergren et al.,[41] which is a modification of the method published by Hansen et al.[42] Briefly, 10 g of the homogenate was weighed in a 50 mL PP tube and spiked with mass-labeled surrogate standards. After 5 mL of 0.4 M NaOH solution was added and vortex-mixed, the samples were left in the refrigerator overnight to allow the internal standards to distribute in the plant matrix. Next, 4 mL of 0.5 M TBA solution and 5 mL of a carbonate buffer (0.25 M Na_2CO_3/$NaHCO_3$) were added to the samples and thoroughly mixed. After the addition of 10 mL of MTBE and vortex-mixing for 1 min, the samples were sonicated for 10 min. Phase separation was achieved by centrifuging for 10 min at 3000 rpm. The MTBE phase was transferred to a new 50 mL PP tube and the extraction repeated two times. The extracts were combined and concentrated to approximately 2 mL using a Rapidvap (Labconco Corp., Kansas City, MO, USA). Florisil SPE-cartridges were prepared with 1 g sodium sulfate on top and conditioned with 10 mL MeOH and 10 mL MTBE before they were loaded with the extract. The elution of the nonpolar matrix was done with 10 mL of MTBE before the target compounds were washed off the cartridge with 10 mL of MeOH/MTBE (30:70, v/v). This extract was again evaporated with the Rapidvap to 1 mL final volume. An additional cleanup step following the Powley method with ENVI-Carb was added when the final extract was still strongly colored.[43]

Nutrient solution samples were extracted with Oasis WAX-SPE cartridges, except the samples from the 10 μg/L variant for tomato, which were directly injected. Between 20 and 150 mL of sample, depending on the nominal concentration, were spiked with internal standards and passed through the cartridges, which had been conditioned with 2 mL of 0.1% NH_4OH in MeOH (v/v) and 3 mL of H_2O. The loading speed was set to not exceed 2 drops per second. After the loaded cartridges had been washed with MeOH/H_2O (40:60, v/v), they were dried under vacuum before the PFAAs were eluted two times with 500 μL of 2% NH_4OH in MeOH (v/v).

All final extracts were passed through an Acrodisc LC 13 GHP Pall nylon filter into 2 mL PP vials and stored at 4 °C until analysis.

Analysis. The analysis was performed on an HPLC system (LC-20AD XR pump, SIL-20A autosampler, and SCL-10A VP system controller, Shimadzu, Kyoto, Japan) coupled with a tandem mass spectrometer (4000 QTrap, Applied Biosystems, Toronto, Canada). The HPLC was equipped with a precolumn (Pathfinder 300 PS-C_{18} column; i.d., 4.6 mm; length, 50 mm; particle diameter, 3 μm; Shimadzu, Duisburg, Germany) prior to the injection valve to remove potential background contamination. An ACE 3 C18-300 column (i.d., 2.1 mm; length, 150 mm; particle diameter, 3 μm; Advanced Chromatography Technologies, Aberdeen, Scotland) was used for separation and maintained at 30 °C. The mass spectrometer was equipped with an electrospray ionization interface, operating in the negative ionization mode, and was run in the scheduled MRM mode.

The purified extracts were diluted 1:1 with H_2O prior to analysis to match the initial composition of the mobile phase of the HPLC. A volume of 20 μL was injected. The mobile phase consisted of two eluents, A (40:60 MeOH/H_2O, v/v) and B (95:5 MeOH/H_2O; v/v; both with 2 mM ammonium acetate). The gradient used for separation and the mass transitions as well as other mass spectrometer settings can be found in the Supporting Information. Raw data were processed with Analyst software 1.5 (Applied Biosystems).

Quality Assurance and Control. Repeated extraction of a sample showed that the standard deviation of the concentrations between extractions was <10% for all analytes (n = 5, see Table S5 in the SI). Consequently, the samples were extracted once and injected in duplicate.

The concentrations were quantified using a 12-point calibration with fitted correlation lines that had an R^2 value of >0.99 for all analytes (no weighting was applied).

Our laboratory also participated successfully in various interlaboratory studies (see, e.g., ref 44). For further information on quality assurance and quality control measures, see also our previous study.[35]

In this study the average recovery of the internal standards was between 48% (PFBA) and 97% (PFDoA). Recoveries were determined by comparison with matrix extracts spiked with mass-labeled standards prior to injection. Interestingly, some matrices affected the signal of the compounds quite intensively. Cabbage head and zucchini roots, for example, reduced the PFBA signal by up to 80%. Signal enhancement on the other hand was at most 12%. See Tables S6 and S7 in the Supporting Information for detailed information on recoveries and matrix effects for all compounds and all matrices.

Limits of quantification (LoQs) (Table S8 in the SI) were calculated on the basis of the lowest validated calibration standard (signal to noise ratio ≥ 10). The LoQ was derived from the analyte mass injected scaled up to an extract volume of 1 mL and divided by the average extracted sample quantity for the matrix. Method blanks were prepared repeatedly with the same extraction procedure as the samples, but showed no quantifiable contamination. Solvent blanks were injected every 10 injections to check for contamination from the LC system and for memory effects, but no contamination or memory effects were observed.

Background concentrations were taken from plants growing in nonspiked nutrient solution (n = 2) and used to correct the PFAA concentrations found in spiked experiments by subtraction. Any resulting concentrations below the LoQ were neglected.

The nonbranched (further referred to as "linear PFOS (L-PFOS)") and branched isomers of PFOS were quantified separately, assuming equal response factors for branched and nonbranched isomers. Branched isomers for other PFAAs were also observed but were not quantified.

Data Analysis. Uptake factors calculated from the data were evaluated for outliers using box plots with SigmaPlot (Systat Software, Inc., Chicago, IL. USA). Outliers and values below the LoQ were not included in data interpretation. Statistical analysis of the data was performed using IBM SPSS 21 (IBM, Armonk, NY, USA). One-way analysis of variance (ANOVA) in combination with the Tukey test was conducted to assess the significance of differences between spiking levels and plant species. t tests were performed to evaluate the differences between compounds. All statements regarding differences in this study are based on a significance level of $p < 0.05$.

RESULTS AND DISCUSSION

Because there is no evidence for microbial, physical, or any other degradation of PFAAs, we consider the breakdown of the PFAAs to have been negligible in all matrices analyzed.

PFAA Concentrations in Nutrient Solution. With increasing water uptake the nutrient solution in the hydroponic system was depleted. When there was only a small volume left, high PFAA concentrations were measured that frequently exceeded the nominal spiked concentrations. There are two possible explanations. (I) As described in our previous study[35] and also shown by Reth et al.,[45] PFAAs accumulate at the air−water interface. This has been observed to be particularly pronounced for long-chain PFAAs. When only a small volume of water was left in the bucket, it was not possible to avoid sampling some surface water. This would have led to sampling of PFAAs that had accumulated at the water−air interface, which may have resulted in elevated concentrations in the sample. (II) The plants may take up water more efficiently than they take up PFAAs. This would have resulted in an enrichment of the compounds in the water and thus higher concentrations with time.

For the tomato, zucchini, and cabbage plants, the nutrient solution volumes at the time of sampling went down to a minimum of 113 mL. To calculate uptake factors, we determined average PFAA concentrations in the bulk solution that the plants had been exposed to during the entire period of exposure. To interpolate the concentrations in time and between pots, the following equations were used to calculate the nominal and bulk PFAA concentrations for each day:

$$C_{\mathrm{nom}(t)} = \frac{(C_{\mathrm{nom}(t-1)} \times V_{(t-1)}) - ((V_{(t-1)} - V_{(t)} - V_{\mathrm{evap}}) \times f \times C_{\mathrm{bulk}(t-1)}}{V_{(t)}} \quad (1)$$

$$C_{\mathrm{bulk}(t)} = \frac{C_{\mathrm{nom}(t)} \times V_{(t)}}{V_{(t)} + K \times A \times 1000000} \quad (2)$$

f is the effectiveness of the plant's uptake of the PFAA with the nutrient solution, K is the interface to bulk solution partition coefficient (m), V is the volume of nutrient solution (m^3), and A is the area of the air/nutrient solution interface in the bucket (m^2). The average bulk concentrations in the spike control pots were used as the initial values of C_{bulk} and (together with the nominal concentrations and A) to calculate K. For each PFAA and plant species, f was then fitted against the amount of PFAA taken up by the plant (i.e., f was chosen such that the median quotient of the predicted and measured mass of the PFAA in the plant was equal to 1). For tomato, where the total amount of PFAA taken up was not measured, we estimated the total amount by using the concentrations for the lower plant parts also for the mid and top plant parts. The resulting values for f for tomato were similar to the ones for cabbage and zucchini. The water concentrations calculated for the sampling days were quite close to the measured water concentrations. The daily concentrations estimated in this manner were used to calculate average bulk concentrations weighted with the water volume transpired by the plants. These bulk concentrations were employed to calculate plant tissue concentration factors (see below).

Roots. The PFAA uptake in the roots was assessed using the root concentration factor (RCF). The RCF was defined as the ratio between the concentration of a compound in roots and its bulk concentration in the nutrient solution to which the roots were exposed:[46]

$$\mathrm{RCF} = \frac{\text{concn in root (ng/g FW)}}{\text{concn in nutrient solution (ng/mL)}} \quad (3)$$

Over a broad concentration range, a linear relationship between exposure concentration and uptake of PFAAs was observed by Stahl et al.[30] and in our previous study.[35] We therefore averaged the RCFs from the different exposure concentrations. If the ANOVA–Tukey test showed that the RCF from a given exposure concentration was significantly different from all other exposure concentrations, then this value was excluded from the calculation of the mean RCF. For tomato, PFDoA, PFTrA, and PFTeA had significantly lower RCFs at the highest spiking level tested (10000 ng/L). This was not observed for cabbage and zucchini, which may be due to the lower maximum spiking level tested (1000 ng/L). We also observed lower RCF values for long-chain PFCAs (especially PFDoA, PFTrA, and PFTeA) in the 10000 ng/L spiking level in our lettuce study, where we concluded that the nonlinear uptake was caused by the nonlinear adsorption of the compounds to the root surface.[35] For cabbage the lowest spiking concentration resulted in significantly higher RCFs for PFOA, PFNA, PFDA, and Br-PFOS than for the other spiking concentrations. For zucchini the RCF for PFDA was significantly higher for the lowest spiking level than for other spiking levels. We have no explanation for these observations.

The RCFs for the PFCAs generally increased markedly with increasing chain length between PFBA and PFUnA and were quite similar for PFUnA through PFTeA (Figure 1). The RCFs for the PFSAs generally increased with increasing chain length

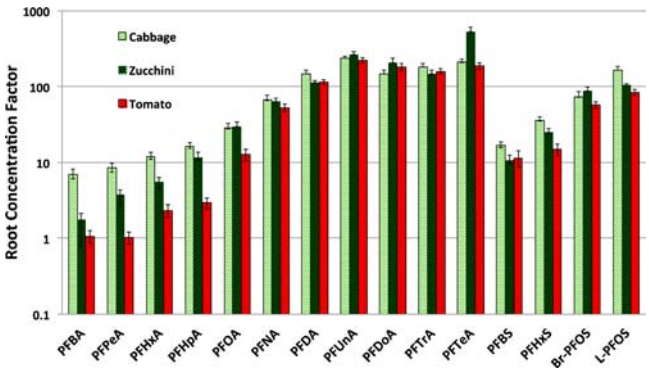

Figure 1. Root concentration factors (RCFs) for cabbage, zucchini, and tomato [(ng g^{-1})/(ng mL^{-1})]. The mean RCFs from each spiking level were averaged, whereby outliers were excluded (see text). Note the logarithmic scale. The error bars denote the standard error.

for all species. Different measures of hydrophobicity also increase with increasing chain length (SI Table S14), suggesting that the magnitude of root uptake may be determined by the hydrophobicity of the PFAA. However, for PFCAs with C > 11 the RCFs do not increase further, and hydrophobicity factors are not available for PFTrA and PFTeA, so it cannot be said with certainty that the root uptake is related to the hydrophobicity alone. The relationship between RCF and PFAA chain length is very similar to the relationship observed for lettuce in our previous study. The most pronounced difference is that lettuce showed a minimum RCF for PFHxA, whereas the three species studied here did not.

For the lettuce study we discussed two mechanisms for root uptake: sorption to the tissue between the root surface and the Casparian strip and uptake across the Casparian strip into vascular root tissue. We concluded that for lettuce sorption to root surface tissue is the dominant process for root uptake of the long-chain PFCAs, whereas for the short-chain PFCAs and PFSAs uptake across the Casparian strip into the vascular root tissue might be equally or more relevant.[35] Further support for this explanation can be found in the results presented below, which show that the stem concentration factors (SCFs) of PFDA are more than an order of magnitude less than the RCFs, even though PFDA has leaf concentration factors that are comparable to the short-chain PFCAs. Should uptake across the Casparian strip into vascular root tissue be the primary root uptake mechanism, one would expect the RCF and SCF to be similar if the vascular tissue in the roots and stem had similar sorption capacities for PFDA. The fact that the SCF is much smaller suggests that the sorption capacity of the root vascular tissue must be much greater than the sorption capacity of the stem vascular tissue or that sorption to the tissue between the root surface and the Casparian strip is an important root uptake mechanism for PFDA.

Above-ground Plant Parts. The distribution of PFAAs in the plant was assessed using various concentration factors. Concentration factors for each plant part (stem, leaves, twigs for tomato and zucchini, and edible parts) relative to the nutrient solution were calculated in the same way as the RCF and named analogously stem concentration factor (SCF), leaf concentration factor (LCF), twig concentration factor (TCF), and edible part concentration factor (ECF). Additionally,

concentration factors between plant parts (e.g., edible part/stem) were calculated to obtain insight into the translocation of the compounds within the plants.

Stem. All species had SCFs >1 for most of the compounds with the exceptions of PFBA, PFTrA, and PFTeA for zucchini and PFHpA, PFTrA, and PFBS for cabbage. The SCF for PFTeA for cabbage could not be calculated because the concentrations in the stem were below the LoQ (Figure 2). SCF values >1 denote an accumulation in the stem. The SCF values were in general much lower than the RCF values.

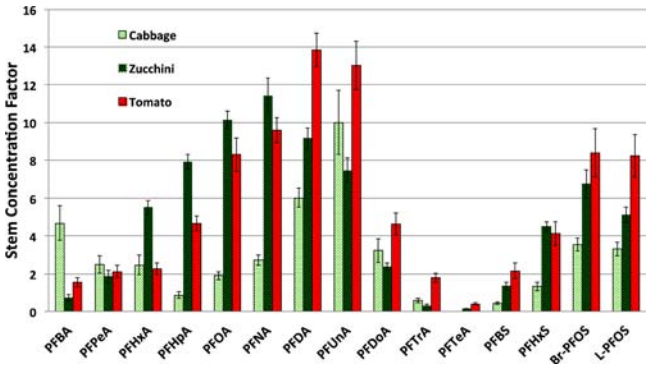

Figure 2. Stem concentration factors (SCFs) for cabbage, zucchini, and tomato [[(ng g^{-1})/(ng mL^{-1})]. The mean SCFs from each spiking level were averaged. The error bars denote the standard error.

The magnitude of the SCF is expected to depend largely on (I) the amount of PFAA being delivered by the transpiration stream from the roots and (II) the balance between retention of the PFAA in stem tissue versus further translocation with the transpiration stream to twigs and leaves. Lower SCFs were observed for the short-chain PFAAs (Figure 2). An explanation could be that the short-chain PFAAs do not partition as strongly into the stem tissue as their longer chain analogues. This could result in them not being retained in the stem tissue to the same extent, but rather being translocated further into other plant tissues. The higher SCF values of the C8−C11 PFAAs on the other hand can likely be explained by comparatively stronger sorption of the compounds on the stem tissue, resulting in stronger retention in the stem tissue and less translocation to twigs and leaves. An increase in organic matter/water partition coefficients with increasing PFAA chain length has been reported, for example, for sediment.[47] Also, experimentally determined hydrophobicity factors as well as modeled K_{OW} values have been observed to increase with increasing chain length[48,49] (SI Table S14). Therefore, it is not surprising that longer chain compounds are more retained in the stem tissue than short-chain compounds.

All three plant species showed a sharp decrease of the SCF for PFCAs with a chain length longer than C11. This is an indication that the translocation of these chemicals through the roots is considerably less efficient. One explanation could be restrictions on the ability of long-chain PFCAs to cross the Casparian strip. Another could be stronger partitioning of the long-chain PFCAs out of the xylem into the vascular tissue of the roots (see discussion under Roots above).

The low SCFs for the long-chain PFCAs also strengthen the argument for sorption to surface tissue being the dominant root uptake mechanism for these substances. Whereas the long-chain PFCAs had very low SCFs, they had the highest RCFs. Consequently, only a very small portion of the long-chain PFCAs in the roots was translocated to the stem.

Twigs. Twigs are present only in tomato and zucchini, because the leaves of cabbage grow directly on the stem. The twigs of zucchini are actually elongated leaf stalks (petioles), but because of their size they were analyzed separately from the leaf. The relationship between TCF and PFAA chain length was quite similar to the pattern observed for SCF, with the exception of PFBA and PFBS for tomato, where TCFs were much higher than SCFs (SI Figure S2). Furthermore, the twig/stem concentration factors (SI Figure S3) were close to 1 for most of the PFAAs with the notable exceptions of PFBA (3.3 in zucchini and 4.0 in tomato) and PFBS (4.0 in tomato). The explanations given for the SCFs can also be applied here.

Leaves. The LCFs were >1 in all plant species for all PFAAs except the long-chain PFCAs (Figure 3). This shows that all

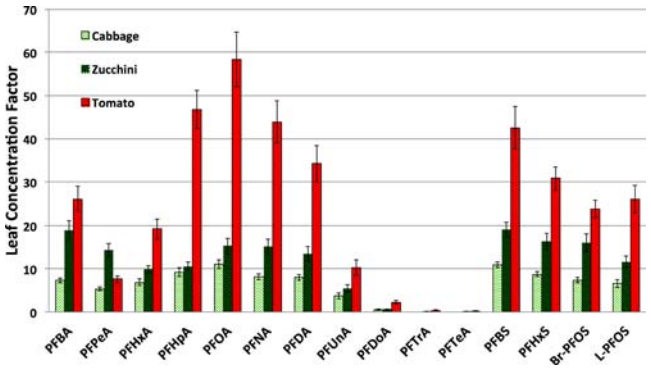

Figure 3. Leaf concentration factors (LCFs) for cabbage, zucchini, and tomato [[(ng g^{-1})/(ng mL^{-1})]. The mean LCFs from each spiking level were averaged. The error bars denote the standard error.

three plant species translocate all PFAAs except the long-chain PFCAs to the leaves and accumulate them there. One remarkable feature of these results is the similarity in the LCF values in a given plant for all compounds except the PFCAs >C10. The LCF values vary by a factor of <2 in both cabbage and zucchini. This indicates that the efficiency of these two plants at transferring the chemicals from nutrient solution to the leaves is relatively independent of the physical chemical properties within the property range bracketed by PFBA and PFDA/PFOS. Tomato shows a slightly different pattern with a maximum for PFOA and a pronounced minimum for PFPeA. The much lower LCF values for the PFCAs >C10 for all plants, despite their high RCF values (Figure 1), suggest that these substances are not transported effectively from the roots to the leaves. This was already indicated by the SCF and TCF results.

There were systematic differences in the LCFs between the plants; for zucchini and tomato they were on average 4.02 and 1.78 times higher, respectively, than for cabbage (with the exception of PFPeA in tomato). Factors that could influence the LCF include the amount of water transpired (higher transpiration would be expected to increase LCF) and leaf biomass (a high leaf biomass would tend to decrease LCF). However, no correlation could be found between LCFs and transpiration volumes, leaf biomass, or the quotient of these two parameters. The LCF is the result of more complex interactions among different plant tissues. More mechanistic insight into this is provided later.

Compared with the concentration factors of the other above-ground parts of the plants, the leaves show the highest

concentration factors for most of the compounds. The mass distributions of the chemicals between the different plant tissues show that of the above-ground tissues, the leaves also store the largest mass of all of the PFAAs (with the exception of PFPeA in tomato, Table 1 and Tables S9/S10 in the SI). This

Table 1. Mass Distribution of PFAAs in Different Tissues of Tomato Plants, Expressed as Percent of the Total Amount of PFAA Taken up by the Plant[a]

	Roots	Stem	Twig	Leaf	Fruit
PFBA	3%	4%	10%	43%	40%
PFPeA	5%	8%	7%	20%	60%
PFHxA	12%	8%	9%	42%	30%
PFHpA	12%	8%	9%	67%	4%
PFOA	29%	7%	9%	53%	1%

PFDA	72%	5%	5%	17%	0%
PFUnA	88%	4%	4%	5%	0%
PFDoA	90%	5%	3%	2%	0%
PFTrA	96%	2%	1%	1%	0%
PFTeA	98%	1%	0%	1%	0%
PFBS	21%	4%	9%	65%	1%
PFHxS	38%	5%	7%	49%	0%
Br-PFOS	68%	6%	5%	21%	0%
L-PFOS	71%	5%	4%	19%	0%

[a]Values shown are averages from all plants.

can be explained by the transpiration occurring in the leaves. The PFAAs are translocated to the leaves in the transpiration stream; there the water transpires and the PFAAs remain as residues in the leaves, where they accumulate.

Edible Part. In the edible part (i.e., cabbage head and tomato and zucchini fruits), no concentrations were detected above the LOQ for the long-chain PFCAs (C12−C14), not even at the highest tested exposure concentration (Table S11 in the SI). Consequently, no uptake factors could be calculated for these compounds.

The ECFs (Figure 4) were highest for the short-chain PFCAs and decrease with increasing chain length. Zucchini fruits were

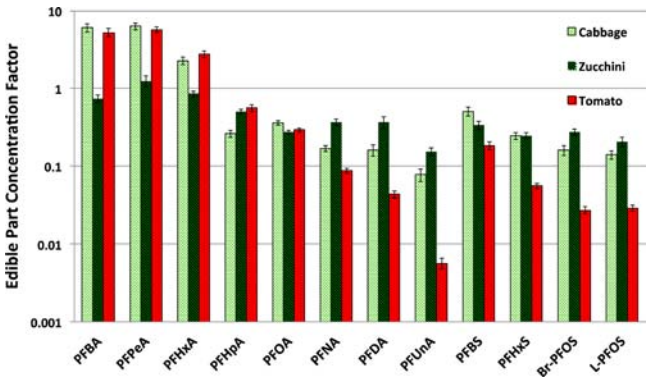

Figure 4. Edible part concentration factors (ECFs) for cabbage, zucchini, and tomato [[(ng g^{-1})/(ng mL^{-1})]. The mean ECFs from each spiking level were averaged. The error bars denote the standard error. Note the logarithmic scale.

far less contaminated than tomato fruits or cabbage heads. Thus, the exceptional ability of zucchini to accumulate some organic compounds such as polychlorinated dibenzo-*p*-dioxins (PCDDs) from soil[39] or water[40,50] was not observed for PFAAs.

The edible part/leaf transfer factors provide insight into the processes governing PFAA accumulation in the edible parts. Transpiration is low in fruits and in the cabbage head (which is tightly packed in leaves). The material for their development is provided by the phloem sap, which is produced in the leaves. It is thus to be expected that PFAAs will reach the fruits primarily via phloem sap. The efficiency of the leaf to fruit transfer of PFAAs can be assessed using the edible part/leaf transfer factor. All values were <1 in all cases (SI Figure S5), with values close to 1 for PFBA and PFPeA for cabbage and tomato. Because these two compounds sorb very little and transpiration is low from the edible parts, values close to 1 can be expected. The edible part/leaf transfer factor was similar for most compounds in zucchini and cabbage. For tomato it decreased exponentially with increasing chain length, and the difference between PFBA and PFUnA amounted to >3 orders of magnitude. A possible explanation for the different transport in the phloem sap is differences in the phloem sap composition, for example, different proteins.

Transpiration Stream Concentration Factor. The transpiration stream concentration factor (TSCF) describes the translocation potential of compounds from roots to aerial plant parts. Normally the TSCF is the concentration of the chemical in the transpiration stream divided by concentration in soil pore water.[46,51] Because direct measurement of the concentration in the transpiration stream was not possible, we estimated the TSCF by dividing the mass of the PFAAs in the aerial plant parts by the PFAA concentration in the nutrient solution multiplied by the volume of water transpired by the plant:

$$\text{TSCF} = [\text{concn in foliage (ng/g)} \times \text{foliage wt (g)}]/[\text{concn in nutrient solution (ng/mL)} \times \text{water transpired (mL)}] \quad (4)$$

Estimating the TSCF in this manner requires the assumptions that the compounds are not degraded in the plant, no chemical elimination from the plant occurs (e.g., loss of the compounds from the leaves to the atmosphere or back to the roots), and there is no other uptake pathway than through the roots (i.e., no atmospheric deposition). Due to the high persistence of the PFAAs and the low concentrations of the PFAAs in the above-ground parts of the control plants (no spiking with PFAAs of the nutrient solution), these assumptions are reasonable.

The TSCF values for cabbage, zucchini, and tomato thus calculated ranged between 0.05 and 0.23, with much lower values for the C12−C14 PFCAs (Figure 5). The TSCF values are relatively similar between compounds (generally a factor of <2) and between plant species (generally a factor of <2.5). There is, nevertheless, a consistent pattern in the TSCF values between the plants, with zucchini having significantly lower TSCF values than the other two tested species for all compounds except PFDoA. Because the TSCF was always <1, the transfer from the nutrient solution to the vegetative parts of the plants was inhibited. The pattern over chain length is similar for all three plant species and shows a minimum for PFHxA and a maximum for PFOA. This is also comparable to the pattern for lettuce from our previous study, with the difference that markedly higher values were measured for PFBA and the long-chain PFCAs (C > 10) in lettuce.

There is no consistent trend with the carbon chain length of the compounds, and there is no correlation between TSCF and

dx.doi.org/10.1021/jf500674j | J. Agric. Food Chem. 2014, 62, 3334−3342

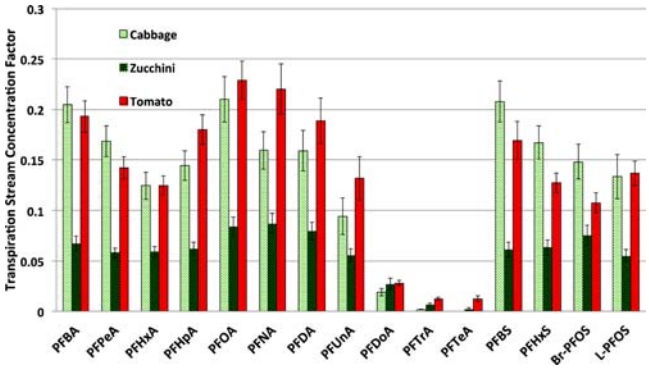

Figure 5. Transpiration stream concentration factors (TSCFs) for cabbage, zucchini, and tomato. The mean RCFs from each spiking level were averaged. The error bars denote the standard error.

measures of hydrophobicity such as log K_{OW} or log D_{OW} (SI Table S14). Briggs et al. reported that the TSCFs of nonionized chemicals depend on their log K_{OW} values and found the highest TSCF for compounds with a log K_{OW} of around 2.[51] As we discussed in our previous study,[35] PFAAs do not fit this model, as the PFAAs with a log K_{OW} around 2 show the lowest TSCF values, with the exception of the long-chain PFCAs.

Recently, Krippner et al.[37] reported a small influence of pH on the uptake of PFDA in maize roots, but found no influence of pH for C4−C9 PFCAs, PFBS, PFHxS, or PFOS. Due to very low pK_a values of PFAAs,[52] the compounds are in their ionic form at environmentally relevant pH levels. All plants in this study were grown in nutrient solutions with the same pH, so that interspecies differences cannot be explained by the influence of the pH.

Differences between Functional Groups and Isomers. To assess the influence of the PFAA functional group on PFAA uptake from soil and distribution in plants, PFBS was compared to PFPeA, PFHxS to PFHpA, and L-PFOS to PFNA, because these are pairs of compounds with the same length of perfluorinated carbon chain. Furthermore, branched and linear PFOS were compared to provide insight into the uptake of different isomers.

All PFSAs had significantly higher RCFs than the PFCAs with the same number of fluorinated carbon atoms by a factor of about 2−3. This shows that the uptake or adsorption is not only governed by the length of the fluorinated C chain, but rather by a combination of chain length and functional group. Higgins et al. came to similar conclusions when investigating the sorption of PFAAs to soils.[47] They found that the sorption of sulfonates was stronger than that of the carboxylic analogues. The higher RCFs for PFSAs correspond to higher values of several measures of hydrophobicity. The modeled log K_{OW}, as well as the experimentally determined log k_0 and log $P^{0'}$ (see Table S14 in the SI) are generally higher for the PFSAs than for their carboxylic analogues. However, this does not apply for the log D_{OW} values of the compounds.

In contrast, there were few significant differences in the TSCF between the PFSAs and the corresponding PFCAs. This suggests that the functional group had a minor influence on the uptake of the chemical into the root vascular tissue. Consequently, the stronger contribution of the sulfonate functional group to the RCF noted above is likely due to its contribution to a higher sorption to root surface tissue.

The transfer from leaves to the edible part was significantly higher for PFPeA and PFHpA than for the corresponding PFSAs. No difference was found between PFNA and L-PFOS.

A preference for the root uptake of the linear PFOS over the branched PFOS was also found for all species, but the difference was significant for only cabbage and tomato (Figure 1). This might be attributable to the smaller molecular volume of Br-PFOS resulting in lower root surface tissue/water sorption coefficients. However, no significant difference between branched and linear PFOS was found for the TSCF or the edible part/leaf concentration factor.

Clearly, some elements of the root uptake of PFAAs and their distribution in plants are influenced by the PFAA's functional group as well as its chain length.

Implications for Human Exposure. PFAA concentrations in the edible part were relatively low. The European Food Safety Authority (EFSA) has defined tolerable daily intake values (TDIs) for PFOA and PFOS of 1500 and 150 ng/kg body weight, respectively.[53] PFOA and PFOS concentrations in the edible parts of plants grown in the 1 μg/L exposure concentration did not exceed 0.5 and 0.2 ng/g fresh weight, respectively. Thus, to exceed the TDI for PFOA and PFOS, a person weighing 70 kg would need to eat around 210 and 50 kg, respectively, of these contaminated crops daily, which is of course impossible. The concentrations of the short-chain PFCAs were higher than the PFOA concentrations by up to a factor of ∼23 in cabbage and tomato and a factor of ∼5 in zucchini. Although no TDIs for these compounds exist, their toxicity is reported to be lower than for PFOA.[54] Because the concentrations of the most abundant PFAAs in tap and surface water are usually in the lower nanogram per liter range,[18] hydroponically grown crops generally should not be a danger to human health. However, should plants be exposed to much higher concentrations in soil or nutrient solution due to severe contamination, it is conceivable that TDI values could be exceeded and a risk for human health could occur.

All edible part/leaf transfer factors were <1 in all cases (see above and Figure S5 in the SI), which indicates that leafy crops with open leaves, such as spinach or some lettuce varieties, accumulate higher amounts in the edible part than fruit-bearing crops. Thus, leafy crops pose a higher risk for human exposure.

Mechanistic Description. The results of the present study can be summarized in the following simple mechanistic description of plant uptake of PFAAs from soil or nutrient solution and their distribution in plant tissue. PFAAs are taken up by the roots via the transpiration stream. With the exception of long-chain PFCAs (C > 10), their concentration in the transpiration stream entering the stem is ∼15% of the concentration in the nutrient solution. The majority of the PFAAs that enter the stem are carried with the transpiration stream to the leaves, where the transpiration of the water results in local accumulation of PFAAs. From the leaves, all PFAAs with the exception of long-chain PFCAs (C > 11) are transported via the phloem sap to the fruit and storage organs. Less PFAA accumulates in the fruit than in the leaves, which can in part be explained by the lower transpiration rate from fruits. There are species-specific differences in the effectiveness of this transfer: In cabbage and zucchini the effectiveness is similar both across chemicals and between species, whereas in tomato there is a pronounced decrease in transfer effectiveness with increasing chain length of the PFAAs. For the roots, there is a second accumulation mechanism in addition to the uptake with the transpiration stream, namely, sorption to root surface

tissue, which is especially important for the long-chain PFAAs. There was great consistency in this picture of PFAA uptake and distribution among the three plants studied here as well as the lettuce from the earlier study, the most notable difference being that lettuce also translocated long-chain PFCAs (C11−C14) to the above-ground plant parts.

This mechanistic description is plausible on the basis of the current understanding of contaminant behavior in plants and PFAA properties. However, it is based on controlled laboratory experiments in hydroponic solutions. Its applicability to plants growing in soil under field conditions needs to be demonstrated. The soil-related studies found in the literature do not provide enough information to calculate pore-water concentrations. Consequently, we believe that further experimental work is required to further develop our understanding of soil to plant transfer of PFAAs.

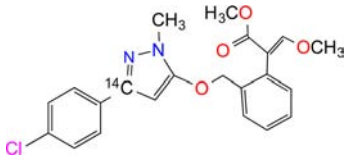

Figure 1. Chemical structure of SYP-3343.

performance liquid chromatography−liquid scintillation counting (HPLC−LSC) and thin-layer chromatography−isotope imaging (TLC−IIA) data indicated that both the radiochemical and chemical purities of the fungicide were over 98% and its specific activity was 5.042 ± 0.076 mCi/mmol.[17,18] 2,5-Diphenyloxazole (PPO) and 1,4-dis-[2′-(5′-phenyloxazolyl)]-benzene (POPOP) were of scintillation grade, purchased from Acros Organics (Geel, Belgium), and were used to prepare the scintillation cocktails as below: scintillation cocktail I, PPO (7.0 g) and POPOP (0.5 g) dissolved in a mixture of dimethyl benzene (650 mL) and glycol ether (350 mL); scintillation cocktail II, PPO (7.0 g) and POPOP (0.5 g) dissolved in a mixture of dimethyl benzene (600 mL), glycolether (225 mL), and ethanolamine (175 mL). The other chemical solvents were all analytical-grade.

Soil Preparation. Three representative soils were collected from the surface layers (0−20 cm) of agricultural regions in different areas of China, none of which had been previously applied with SYP-3343. The physical and chemical properties of these soils were shown in Table 1. The soil samples were air-dried, mixed, and sieved through a 1 mm sieve. The basic properties were determined using the standard methods.[19]

To examine the influence of soil microbes on ER, BR, and mineralization of SYP-3343, a subsample of loamy soil was sterilized through irradiation by Cobalt-60 at an absorbed dose of 6 kGy/100 g of soil.

Incubation and Treatments. The ^{14}C-labeled SYP-3343 was employed to determine the dynamic characteristics of SYP-3343 in soils. The incubation procedures were based on OECD guideline 307.[20] Briefly, after 300 g of soil sample (dry weight) was adjusted to a water holding capacity (WHC) of approximately 40% by adding distilled water, samples were pre-incubated in a dark cultivation cabinet at 25 ± 1 °C for 14 days to help the microbes adapt to the environmental change. An appropriate volume of the prepared ^{14}C-SYP-3343 in methanol solution (~7.4 × 10^5 Bq/sample) was added to each sample slowly. The treated samples were thoroughly mixed and placed in a fume hood to completely remove the methanol. Distilled water was added to readjust the soil moisture to about 60% WHC. The samples were incubated independently in the dark at 25 ± 1 °C under a continuous airflow. During the course of cultivation, moisture was maintained at 60% WHC using the weighing method. Each incubated flask was connected to a series of small flasks (see Figure S1 of the Supporting Information). First, two flasks (30 mL, 5.0 M NaOH) were set for scrubbing the inlet CO_2, while the following distilled water flask was used for maintaining constant soil moisture. Besides, the 1.0 M H_2SO_4 and glycol traps were used for absorbing volatile agents, and last two 5.0 M NaOH traps were set for trapping the released $^{14}CO_2$. At different time intervals (0, 5, 10, 20, 30, 45, 60, 75, and 100 days after treatment), the treated soils (10 g, dry weight) were sampled (three replicates) to subject the following extractions. The sterilized soil sample was analyzed under the same protocol, but all procedures were performed in a sterile environment.

^{14}C ER Analysis. The soil samples were extracted using four solvents (50 mL) in sequence, 0.01 M $CaCl_2$, acetonitrile/water (9:1, v/v), methanol, and dichloromethane, by shaking for 24 h and followed by centrifugation at 4000 rpm for 10 min, corresponding to the similar method reported by Mordaunt et al.[21] Subsequently, additional one or two extracting processes were conducted using methanol until no radioactivity could be detected in the extracts. After these exhaustive solvent extractions, the radioactivity of each supernatant was measured by a liquid scintillation counter (LSC, Wallac-1414, Wallac Co., Turku, Finland) using scintillation cocktail I.

Dissipation of Parent Compound Analysis. ER extracts were combined and concentrated on the vacuumed rotary evaporator (Eyela SB-1000, Eyela, Tokyo, Japan) at 37 °C, then recovered in 10 mL of methanol (chromatographic grade), and further condensed to 1.0 mL. The final extracts were passed through a 0.22 μm filter for HPLC analysis. A 20 μL aliquot of the final sample was injected into a Waters 2695 system (Waters 2998 photodiode array detector, Waters, Milford, MA) with a Diamonsil C_{18} column (5 μm, 250 × 4.6 mm, Dikama Technologies, Lake Forrest, CA). The column temperature was 28 ± 1 °C. The mobile phase was composed of A (methanol + 0.1% ethylic acid) and B (H_2O + 0.1% ethylic acid). The elution process was carried out under a gradient elution [A/B (%): 20:80 for 0 min, 75:25 for 20 min, 75:25 for 60 min, 100:0 for 65 min, 100:0 for 70 min, 0:100 for 75 min, 20:80 for 80 min] at a flow rate of 1.0 mL/min. A standard sample was used to confirm the retention time of the parent SYP-3343. Aliquots of the eluent were collected in a 20 mL glass scintillation vial at 1 min intervals. A total of 10 mL of scintillation cocktail I was added to each collected eluent for the radioactivity measurement by LSC.

^{14}C-BR Analysis. After 4−6 shaking extraction steps, the remaining soil pellets were placed in tubes and put inside the fume hood overnight to remove the residual solvent. The samples were then thoroughly mixed, and 0.5 g of soil was used for combustion with a biological oxidizer (OX-600, R.J. Harvey Instrument Corp., Hilldale, NJ). The oxidation procedure was held on for 4 min at 900 °C for combustion and 680 °C for catalysis, using scintillation cocktail II to absorb $^{14}CO_2$. The recovery efficiency of this procedure was more than 91.3%, measured by comparing the combustion of ^{14}C-SYP-3343 with a known radioactivity.

Mineralization Analysis. The measurement of mineralization was conducted by forcing air through the sample for 1.5 h/day to remove CO_2, which could be absorbed by two flasks of NaOH solution during the whole experimental period. This solution was changed every 5 days and stored in a refrigerator (4 °C) for further use of the radioactivity measurement. The two traps were combined and adjusted to a defined volume with distilled water. Then, a 1.0 mL aliquot was drawn, and its radioactivity was measured with 10 mL of scintillation cocktail I.

Statistical Analysis. The dissipation of parent ^{14}C-SYP-3343 was analyzed using the first-order regression model $C_t = C_0 \exp(-kt)$, where C_0 is the initial quantity, C_t is the quantity at time t, and k is the degradation constant. The half-life ($t_{1/2}$) value was calculated as ln 2/k.

All of the experiments were conducted in triplicate, and the standard deviations (mean ± standard deviation) presented in the text were calculated from the repeated measurements. Statistical analysis by one-way analysis of variance (ANOVA) was performed with SPSS 20.0 (IBM Corporation, Armonk, NY).

RESULTS AND DISCUSSION

Total ^{14}C Material Mass Balance. The total recovered ^{14}C was calculated as the sum of ^{14}C in continuous extraction steps,

Table 1. Basic Physical and Physicochemical Properties of the Selected Soils

number	soil type	pH	OM[a] (%)	CEC[b] (mequiv 100 g^{-1})	silt (%)	sand (%)	clay (%)
S1	coastal soil	8.23	1.23	11.77	31.32	26.32	42.36
S2	loamy soil	6.95	2.11	10.65	36.32	20.98	42.70
S3	red soil	5.53	2.65	8.93	33.25	21.01	45.75

[a]OM = organic matter. [b]CEC = cation-exchange capacity.

dx.doi.org/10.1021/jf500392d | J. Agric. Food Chem. 2014, 62, 3343−3347

BR, and CO_2 in mineralization after treatment. The total ^{14}C material mass balance was calculated by the total recovered ^{14}C to the initial added ^{14}C, ranging from 95.8 ± 2.9 to 103.5 ± 3.7% (n = 3) in the four tested soils. The high ^{14}C recoveries indicated that the procedure used for measuring the different residues was feasible.

Formation of the ER and Degradation of the Parent Compound. The decrease of ER over the incubation period was shown in Figure 2. In the initial 10 days of incubation, ER

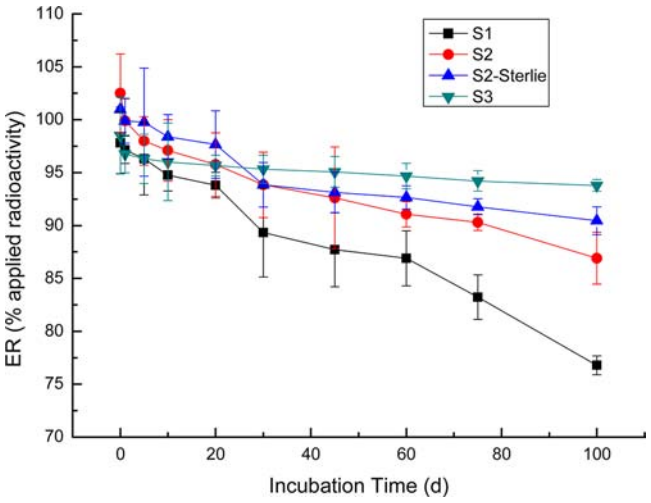

Figure 2. ER of SYP-3343 in aerobic soils (bars represent ±standard error of the mean).

was detected up to about 95% after the four extraction steps. A significant decrease of ER was observed in the coastal soil (S1); after incubation for 100 days, the ER ratio was determined to be 76.79 ± 1.89%. However, the ER level was almost constant in the red soil (S3), showing no significant decrease within the incubation time (p > 0.05), approximately 93.79 ± 3.55%, at the end of the incubation. In addition, ER in the sterilized loamy soil S2 (S2-sterile) was 90.45 ± 1.32%, which was slightly higher than ER in non-sterilized S2 (86.91 ± 2.45%), indicating that soil microbes may promote the dissipation of ER. However, only an inconspicuous decrease of ER in S3, from 98.5 ± 3.63 to 93.79 ± 3.55%, was observed over the incubation period. The ER levels in three tested soils were S1 < S2 < S2-sterile < S3. Possibly, the time dependence of the ER decrease can be attributed to the transformation into BR and mineralization to CO_2. Because of the high extraction rate, it may have potential harm to the downstream farm or water through irrigation. The above findings implied the specific type of soil needed to be considered for the use of fungicide in the context of environmentally friendly usage.

Radioactivity analysis after HPLC fractionation showed that the degradation of SYP-3343 was in accordance with the bi-exponential equation (r^2 > 0.90; see Table S1 of the Supporting Information). The remaining parent compound was 17.8 ± 1.62, 39.2 ± 1.19, 65.5 ± 4.52, and 56.6 ± 1.58% of the applied amount in S1, S2, S2-sterile, and S3 at the end of incubation, respectively (Figure 3), which suggested that the degradation of SYP-3343 in S1 was fastest compared to S2, S2-sterile, and S3. A previous study found that the half-life of SYP-3343 in soil under field conditions was only 2.6−2.7 days.[22] However, the half-lives in the four-treated soils ranged from 43.8 to 169.0 days under lab conditions (see Table S1 of the Supporting

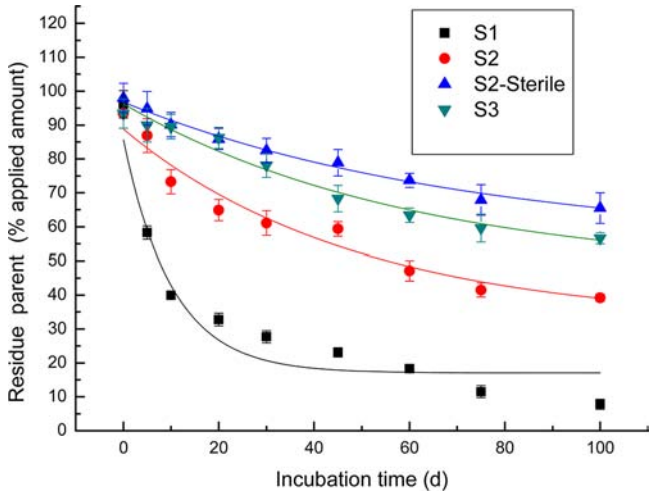

Figure 3. Dissipation of parent SYP-3343 in aerobic soils (bars represent ±standard error of the mean).

Information), which indicated that the degradation rates of SYP-3343 might be attributed to both the soil properties and its surroundings, such as pH, organic matter (OM), cation-exchange capacity (CEC), soil particles, temperature, and soil moisture. It is noteworthy that the half-life of the sterile S2 was about 2 times longer than the non-sterile S2 (169.0 versus 80.6 days), suggesting that microbes played an important role in its degradation. In S3, it has a calculated half-life of 123.7 days that exceeded the total incubation time. In general, degradation of parent SYP-3343 followed the order of S1 > S2 > S3 > S2-sterile. Previous studies showed that many chemicals (e.g., naproxen and carbamazepine) under different soil conditions had different rates of degradation.[23] Thus, it was likely to infer that soil enzymes, microbes, and sediments could selectively influence the performance of chemicals in soil.[24] The long-term dissipation may cause a potential hazard because of the accumulation in the future.

Formation of BRs. In the risk assessment of pesticides, BR is always used in the description of dissipation kinetics.[25] The BR fraction after 30 days of treatment treated with SYP-3343 increased rapidly in S1 and S2, but in the S2-sterile soil, no significant increase of BR was observed (p > 0.05). Furthermore, the BR in S3 was found to increase slightly until 1.73% at the end of incubation, which was much lower than those in S1 and S2. The formation of BR of many pesticides has been reported to be mediated by pH and CEC.[11] S3 has a low pH and CEC that may contribute to its low binding affinity. After 45 days of incubation, a significant difference between S2 and S2-sterile was observed (p < 0.01), indicating that soil microbes could affect the formation of BR. As shown in Figure 4, after incubation of 100 days, the BR followed the order of S1 (alkaline soil, 12.4%) > S2 (neutral soil, 9.9%) > S2-sterile (6.0%) > S3 (acid soil, 1.7%). These results demonstrated that SYP-3343 could be absorbed in the soil and increase with time. Therefore, the BR level reported here, which is much lower than 70%, satisfied the non-accumulation uniform principles demonstrated in laboratory tests.[13] The formation of BR was accompanied by degradation, which was also found in other chemicals, such as nonylphenol.[26]

Mineralization. It could be seen from Figure 5 that the mineralization of SYP-3343 increased gradually with time in the tested soils, indicating that the pyrazole ring could be gradually

dx.doi.org/10.1021/jf500392d | J. Agric. Food Chem. 2014, 62, 3343−3347

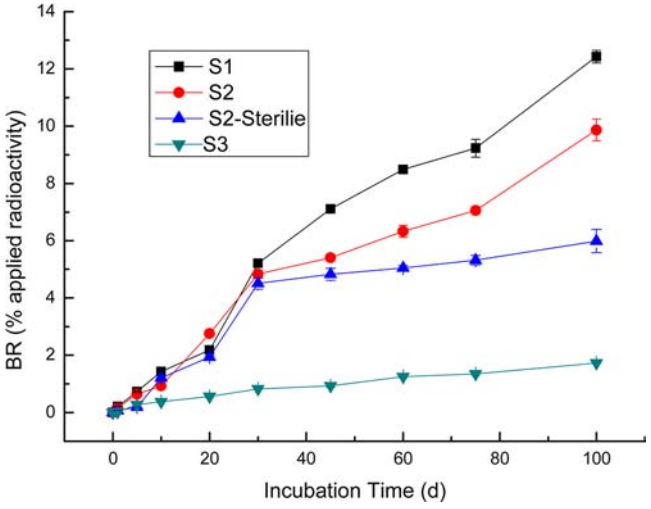

Figure 4. BR of SYP-3343 in aerobic soils (bars represent ±standard error of the mean).

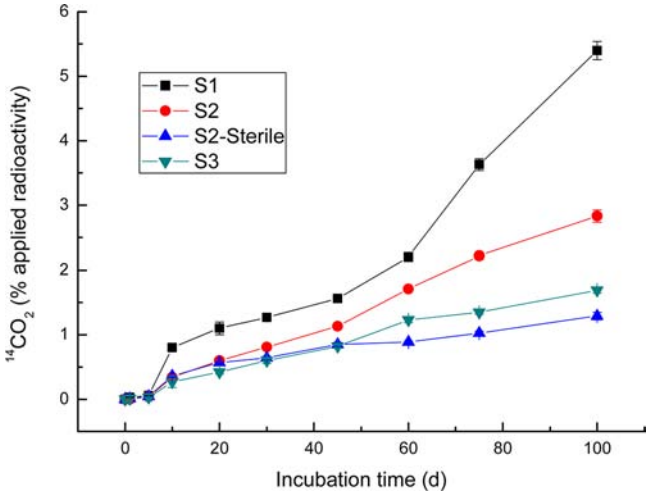

Figure 5. Mineralization of SYP-3343 in aerobic soils (Bars represent ±standard error of the mean).

opened under the present experimental conditions. The ratio of SYP-3343 mineralized to $^{14}CO_2$ was only 0.03−0.06% after 5 days of incubation. Despite the differences in soil properties, the mineralization ratio was lower than 5.4% in all treatments, suggesting that the cleavage of the pyrazole ring was difficult, so that the parent compound or metabolites of SYP-3343 might remain in aerobic soils for a prolonged period. After 100 days of incubation, the mineralization followed the pattern: S1 > S2 > S3 > S2-sterile.

A mineralization ratio of 2.83% was obtained in S2, which was about 2.5 times larger than that in S2-sterile (Figure 5). These findings indicated that soil microbes played an important role in SYP-3343 mineralization. Generally, the degree of mineralization can be affected by microbes and soil properties. A similar phenomenon was observed in the pesticide ZJ0273.[27] Because mineralization is regarded as one of the detoxification pathways, the above results indicated that SYP-3343 was not prone to degrade completely and might remain in soil as either the parent compound or a mixture of the parent compound and metabolites. Although it fits the non-accumulative principle stated by the Commission of the European Communities, it is not recommended to use in red soil. The potential toxicity of itself or its metabolites should deserve more attention. Therefore, more effective data should be acquired in the future for its environmentally friendly use.

■ NOTE ADDED AFTER ASAP PUBLICATION

There was a mistake in the chemical name for SYP-3343 ((*E*)-2-(2-((3-(4-chlorophenyl)-1-methyl-1*H*-pyrazole-5-yloxy)methyl)phenyl)-3-methoxyacrylate) in the first sentence of the formula in the abstract, and incorrect reference citations in the first and second paragraph of the Materials and Methods section of the version of this article published April 2, 2014. The correct version published April 16, 2014.

Mesoporous molecular sieves have attracted significant attention especially in their application in catalysis. Among the mesoporous silica materials, SBA-15 silica is emerged as a promising catalyst support in heterogeneous catalysis owing to its well-ordered structure, nanosized channel, large surface area, and sufficient silanol group for surface modification.[20] The immobilization of organic base groups on the surface of the mesoporous material by grafting or co-condensation can be recognized as a promising approach to create efficient solid base catalysts with improved catalytic properties as compared to conventional homogeneous catalysts.[20−22] This approach can allow the catalyst to be separated easily from the reaction mixture with no wastewater originating from the catalyst neutralization step.

TBD (1,5,7-triazabicyclo[4.4.0]dec-5-ene) is a strong bicyclic guanidine base (pK_b = 25) widely utilized as a homogeneous base catalyst for various chemical reactions.[23] Mesoporous silica materials could be organically functionalized through grafting reactions in which the organic base is anchored onto the surface of the pores with the preservation of a pore host structure. Kalita et al. covalently grafted TBD onto MCM-41 nanoparticles and proved that the TBD-functionalized MCM-41 material is efficient for Michael-addition reactions under solvent-free conditions.[24] However, this kind of heterogeneous base catalysts is seldom used for the CIE reaction.[19] Due to the increased interest and demand for practical application, the environmentally friendly benign and easy-separable solid base catalysts are highly desirable. In the present contribution, for the purpose of providing a highly efficient and green procedure for the interesterification reaction, the guanidine base TBD was covalently bound onto the surface of the mesoporous SBA-15 silica to form the heterogeneous catalyst SBA-15-pr-TBD. Thereafter, this hybrid organic−inorganic material was tested for the interesterification of tributyrin and methyl stearate in solvent-free system for the production of LCSL. For this purpose, the TBD base was previously linked to 1,3-glycidyloxypropyl-trimethoxysilane by nucleophilic addition to the epoxide moiety. The resulting TBD-organosilane compound was then anchored to the mesoporous SBA-15 silica by reaction of the trimethoxysilyl group with the surface silanol. The as-prepared solid base catalyst was characterized by using small-angle X-ray scattering (SAXS), Fourier transform infrared (FT-IR) spectra, thermo gravimetric analysis (TG-DTA), scanning electron microscopy (SEM), transmission electron microscopy (TEM), nitrogen adsorption−desorption and elemental analysis techniques. By using this solid base catalyst, the LCSL was produced in a solvent-free system by interesterification of tributyrin and methyl stearate in a batch reactor. The TAG compositions of the interesterified products were determined by high-performance liquid chromatography (HPLC). Moreover, the interesterification parameters, including the molar ratio of substrate, reaction temperature, reaction time, and reusability of the solid catalyst were investigated systematically in the present investigation.

MATERIALS AND METHODS

Materials. Tributyrin (≥98%) and methyl stearate (≥98%) were obtained from Sinopharm Chemical Reagent Corporation (Sanghai, China). Pluronic copolymer P123 ($EO_{20}PO_{70}EO_{20}$, average molecular weight was 5800), 1,3-glycidyloxypropyl-trimethoxysilane (≥99.8%), 1,5,7-Triazabicyclo[4.4.0]dec-5-ene (TBD, ≥98%) and tetraethylorthosilicate (TEOS, ≥98%) were purchased from Sigma-Aldrich. All the other materials used were of either analytical or chromatographical grades.

Catalyst Preparation. Mesoporous silica SBA-15 was prepared according to a hydrothermal approach using Pluronic P123 triblock copolymer as a template under acidic conditions.[20] In a typical synthesis, 10 g of Pluronic copolymer P123 was first dissolved in 75 mL of double distilled water and 300 mL of 2 mol/L HCl solution at room temperature, and then stirred at 313 K until a homogeneous solution was obtained. Thereafter, 21 g of tetraethylorthosilicate (TEOS) was added under stirring to the P123 solution, and the stirring was continued for 24 h at 40 °C. Subsequently, the solution was taken in a Teflon-lined autoclave and heated at 100 °C for 48 h. After cooling to room temperature, the solid product was filtered, then washed thoroughly with deionized water, and finally dried in air at room temperature. The SBA-15 powder was obtained by calcining the material in air at 550 °C for 6 h to remove the template. The mesoporous SBA-15 silica was used as a support material for preparation of the solid catalyst.

The organic base TBD can be allowed to immobilize onto the surface of SBA-15 silica through the condensation reactions of TBD-organosilane with the surface silanol group. Initially, the TBD-organosilane was prepared by the reaction of 1,3-glycidyloxypropyl-trimethoxysilane with TBD base. Typically, 0.6 g of TBD was added to a solution of 1,3-glycidyloxypropyl-trimethoxysilane (4 mL) in dry DMF (10 mL), and after this the resulting mixture was continued to stir for 48 h at room temperature under nitrogen atmosphere. Thereafter, the solution was poured into a flask containing dry toluene (15 mL) and SBA-15 (1.2 g, previously heated at 350 °C for 10 h), after which the mixture was refluxed for 48 h under nitrogen atmosphere. The solid base catalyst thus obtained was filtered under vacuum, washed carefully with toluene and methanol, and extracted with a Soxhlet apparatus for 24 h using a 1/1 diethyl ether/methylene chloride mixture. Finally the solid catalyst was dried at 60 °C for 12 h under vacuum prior to use.

Catalyst Characterization. Small-angle X-ray scattering (SAXS) measurements were performed on a Bruker AXS Nanostar instrument with the Cu Kα radiation using an acceleration voltage of 40 kV and a current of 30 mA. Fourier transform infrared spectroscopy (FT-IR) was recorded for functional group detection in the 400−4000 cm^{-1} range on a Shimadzu IR-Prestige-21 spectrometer using the usual KBr pellet method.

Thermogravimetric measurements (TG-DTA) were conducted on a TA Instrument TG 2050 thermogravimetric analyzer with a heating speed of 20 °C/min under air atmosphere with a flow rate of 100 mL/min. Scanning electron microscope (SEM) measurements were carried out with a field-emission microscope (JEOL, JSM-6390LV) using an accelerating voltage of 15 kV. Transmission electronic microscopy (TEM) images were taken using a JSM-6390LV transmission electronic microscopy at an accelerating voltage of 200 kV.

The elemental analysis for carbon, hydrogen and nitrogen contents of the samples to measure the TBD loading in the solid catalyst were carried out on a Carlo-Erba 1106 elemental analyzer.

The textural properties of the solid catalysts were measured by nitrogen adsorption−desorption isotherm method at liquid nitrogen temperature (−196 °C) using a Quantachrome NOVA 1000e instrument. The specific surface area was calculated by using the Brunauer−Emmett−Teller (BET) method. The total pore volume and the pore size distribution were assessed according to the Barrett−Joyner−Halenda (BJH) method based on the adsorption isotherm.

Interesterification Procedures. A certain amount of tributyrin and methyl stearate mixture was charged into a 50 mL round-bottom flask. After raw materials were melted absolutely and dried under reduced pressure at 80 °C, the CIE reaction was carried out in solvent-free system by the addition of 1.5 wt % of TBD-functionalized SBA-15 silica as a catalyst. The interesterification of tributyrin with methyl stearate was allowed to proceed under reduced pressure at 80 °C in a water bath with magnetic stirring (~750 rpm). After completion of the reaction, the interesterified product was filtered, and then employed for subsequent analysis.

Analyses of TAG Composition. Reversed-phase high-performance liquid chromatography (HPLC) was used to determine the TAG composition of the interesterified product. A commercially packed Genesis C18 HPLC column (15 cm length × 4.6 mm) was used to separate the TAGs. The protocol employed for the mobile phase involved linear elution gradients for a dichloromethane/acetonitrile (HPLC grade) system from 35% acetonitrile increasing to 55% dichloromethane in 45 min. The mobile phase flow rate was 1.2 mL/min. The column temperature was held at 40 °C. The TAG species were detected by an Alltech 500eVaporative light scattering detector. Individual peaks were identified tentatively according to Han et al.[5] HPLC analysis was run in duplicate for each sample of the interesterified product.

RESULTS AND DISCUSSION

Catalyst Characterization. Surface functionalization has been employed to prepare TBD-functionalized mesoporous SBA-15 material. The TBD base can be covalently tethered onto the framework surface of the mesoporous SBA-15 silica due to the presence of silanol groups, which can form strong chemical bonds with TBD-containing organosilane precursors.[22] In the present study, the solid base catalyst was prepared by two steps. The TBD base was first reacted with 3-trimethoxysilylpropoxymethyloxirane in anhydrous DMF to afford a TBD-containing organosilane by nucleophilic addition of TBD to the epoxide moiety. Then, in the second step, the resulting solution was allowed to react with the SBA-15 silica forming the solid base catalyst. The obtained solid catalyst was identified by FT-IR spectroscopy, SAXS, TG-DTA analysis, nitrogen adsorption−desorption, and elemental analysis techniques.

Figure 1 shows the SAXS patterns of SBA-15 silica and functionalized SBA-15 silica. The SAXS pattern of siliceous

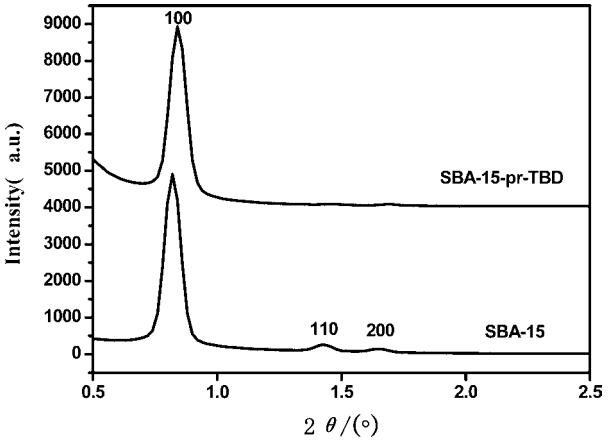

Figure 1. Small angle X-ray photoelectron spectroscopy patterns for samples: (a) SBA-15 and (b) SBA-15-pr-TBD.

SBA-15 exhibited an intense peak at 0.91° corresponding to the (100) reflection, and two low-intensity peaks at 1.56° and 1.76° that could be indexed as (110) and (200) reflections.[19,25] The (100) reflection was characteristic for p6mn symmetry, evidencing the formation of a well formed uniform hexagonal lattice.[24] For the functionalized SBA-15 material, the (100) peak was also observed in the SAXS pattern, however the (110) and (200) peaks were not clearly registered as evident from Figure 1. This observation suggested that the long-range ordering of the mesoporous structure remained unaltered even after incorporation of TBD into the SBA-15 silica. No obvious peak for (110) and (200) reflection was detected mostly likely owing to the decrease in the scattering contrast between the SBA-15 support walls and the filled pores with the organic moieties, which showed that the organic component was embedded into the channel of the support.[24−26] Moreover, the (100) peak of the functionalized SBA-15 silica was shown to shift to higher 2-theta value, revealing the reduction of pore size because of the incorporation of organic components into the pore channel of the support.[27] By drawing on the results, the ordered meso-structure of the siliceous SBA-15 is preserved after the incorporation of organic groups.

Figure 2 represents the FT-IR spectra of SBA-15 silica and SBA-15-pr-TBD sample. In the case of nonfunctionalized SBA-

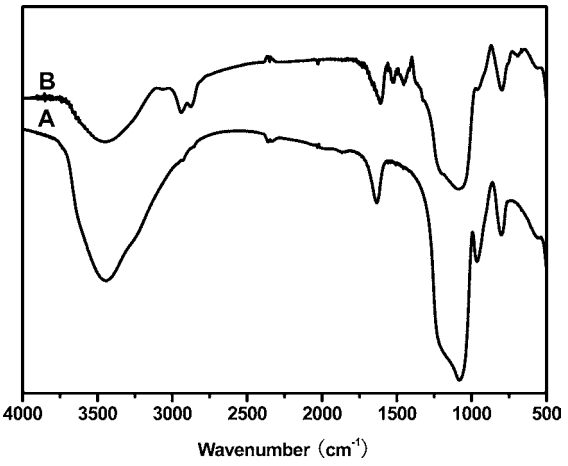

Figure 2. Fourier transform infrared spectra for samples. (a) SBA-15 and (b) SBA-15-pr-TBD.

15 silica, there was a broad IR absorption band centered at 3460 cm^{-1} mostly ascribed to the stretching vibration of framework hydroxyl groups and adsorbed water molecules, and the peak located at 1635 cm^{-1} was principally attributable to the bending mode of adsorbed water present in the SBA-15 material.[25] Moreover, a weak band in the mid-infrared region at 950 cm^{-1} for the SBA-15 support could be mainly responsible for Si−OH groups in SBA-15 silica.[27] Besides, three characteristic absorption bands around 1080 cm^{-1}, 780 cm^{-1}, and 470 cm^{-1} were the typical vibration modes of mesoporous framework Si−O−Si attributed to the condensed silica net in the samples.[27,28] By comparing the IR spectrum of the TBD-functionalized SBA-15 material, the IR characteristic peaks of surface hydroxyl groups at 3460 and 950 cm^{-1} were observed to decrease significantly in intensity after the organofunctionalization, thereby suggesting that the surface hydroxyl groups reacted with the anchored functional groups to form the functionalized SBA-15 material. In comparison with the SBA-15 support, new IR absorption bands at 2942 and 2876 cm^{-1} due to the CH_2 asymmetric and symmetric vibration respectively were appeared for the SBA-15-pr-TBD sample.[24,25] Additionally, the characteristic peaks at 1587 and 675 cm^{-1} for the TBD-functionalized SBA-15 material could be ascribed to the C═N stretching vibration and N−H bending vibration of TBD,[18,24] and these IR peaks were not found in the IR spectrum of the nonfunctionalized SBA-15 silica. On the basis of the results, the TBD has been successfully anchored on the surface of the SBA-15 material.

The thermal behavior of SBA-15-pr-TBD is illustrated in Figure 3. As indicated in this figure, the small amount of mass

dx.doi.org/10.1021/jf405434a | J. Agric. Food Chem. 2014, 62, 3348−3355

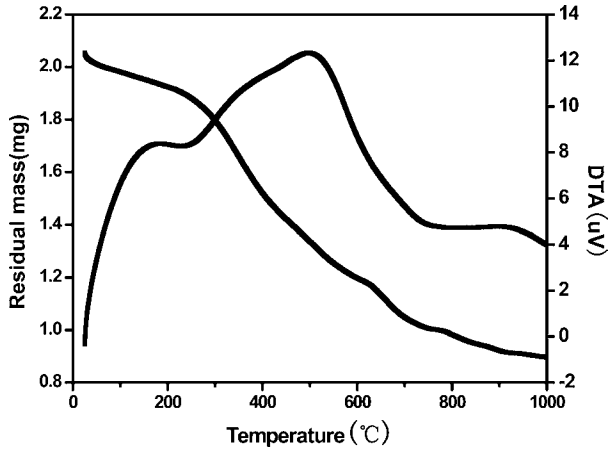

Figure 3. Thermo gravimetric curves of SBA-15-pr-TBD catalyst.

loss (about 8.7%) below 200 °C could be apparently originated from the removal of physically adsorbed water. Meanwhile, an endothermic event between 0 and 200 °C was also observed in the DTA curve. With further increasing the temperature, as shown in Figure 3, a significant mass loss in the temperature range of 200−750 °C (about 54.2%) and a strong endothermic event at about 500 °C were appeared. This main mass loss could be principally ascribed to the thermal decomposition of the organic moieties in the solid base catalyst. On the basis of the mass loss (200−750 °C), the amount of functional groups bound on the SBA-15 material could be estimated to be 2.23 mmol/g. Beyond a temperature of 750 °C, almost no obvious mass loss in the TG curve could be observed, revealing that the tethered organic moiety was decomposed totally at this temperature.

SEM techniques can be employed to study the morphology feature of the SBA-15-pr-TBD catalyst. The typical SEM micrograph of SBA-15-pr-TBD sample is shown in Figure 4. As can be seen, the SBA-15 silica displayed curved faceted and smooth rods based on elongated wheat-like macrostructures in SEM images.[19,24] The TBD-functionalized SBA-15 silica exhibited a similar wheat-like morphology to the non-functionalized SBA-15 silica. No significant variation in the surface morphology occurred after the modification of SBA-15 silica except that the domains were more densely packed.

The morphology property of the solid base catalyst was also characterized by TEM techniques. The TEM images of SBA-15 silica and TBD-functionalized SBA-15 silica are shown in Figure 5. The TEM images confirmed the presence of a honeycomb-like hexagonal array through the material for SBA-15 silica and TBD-functionalized SBA-15 silica.[25] The slight change in TEM image was observed after the functionalization of SBA-15 silica, thus implying that the incorporation of TBD into the SBA-15 silica does not destroy the mesopore structure of SBA-15 silica. This result is in good agreement with the other characterization technique results.

The C, H and N elemental analysis results for the solid base catalyst are summarized in Table 1. According to the results, the loading amount of TBD on the SBA-15 silica was calculated to be 2.35 mmol/g, which is in line with the result obtained from TG-DTA measurements.

The nitrogen adsorption−desorption isotherms of SBA-15 silica and SBA-15-pr-TBD catalyst are presented in Figure 6. For the two samples, the adsorption isotherm could be classed as type IV isotherm with H1-type hysteresis loop according to IUPAC classification, which was the typical behaviors of highly ordered mesoporous molecular sieves with narrow pore size distributions.[25,27] Moreover, the adsorption branch of isotherm displayed a sharp inflection at a relative pressure of about 0.65. This is characteristic of capillary condensation with uniform pore dimensions and high-ordering of the material. This phenomenon suggested that after the functionalization with the organic base the SBA-15 material could still maintain its mesoporous structure.

The textural properties of the samples are listed in Table 2. BET surface area and pore-size distribution were calculated using nitrogen adsorption at −196 °C. For pure SBA-15 silica, the mean pore size calculated from the N_2 adsorption−desorption isotherm was 6.65 nm, and the measured surface area and pore volume were determined to be 807 m^2/g and 1.25 cm^3/g, respectively, which are in accordance with the value reported in the literature.[19,24] As indicated in Table 2, for the SBA-15-pr-TBD catalyst, a surface area of 312 m^2/g and a pore volume of 0.43 cm^3/g were determined, and the pore size distribution was narrow with a mean pore diameter of 4.45 nm. Obviously, the SBA-15-pr-TBD catalyst showed some loss of surface area and a pronounced reduction in pore volume and pore diameter after the organofunctionalization, implying that the organic base was incorporated into the SBA-15 support. The decrease of these parameters upon the functionalization of SBA-15 silica could be expected since the partial filling of functionalized TBD base inside the mesopores would increase the average wall thickness, thus decreasing the pore diameter and BET surface area. Although such a change in the textural

properties, the functionalized SBA-15 silica still remained the typical mesoporous structure after the organofunctionalization reaction.

Influence of Interesterification Parameters. In the present study, the interesterification can substantially alter the TAG profiles of the starting oil blend, and the LCSL is produced by the interesterification of tributyrin and methyl stearate. The interesterified product was characterized by the combination of short-chain and long-chain acyl residues into a triacylglycerol structure. As shown in Figure 7, two new types of TAGs (SSL and SLL) were produced, representing the incorporation of stearoyl groups into the new type of TAGs. By varying the fatty acid composition and the ratio of SSL/SLL, the properties of the LCSL product can be improved accordingly.

As expected, there was no catalytic activity for the interesterification reaction to be observed for the SBA-15 support. However, after incorporation of TBD into the support, the SBA-15-pr-TBD catalyst displayed comparable activities toward the reaction. Figure 8 shows the TAG compositions on the solid base catalyst as a function of reaction time. At a reaction time of 0.5 h, the interesterified product contained 46.5% of SSL, 37.8% of SLL, and 3.4% of LLL (triacylglycerol that contains three long-chain acyl residues), suggesting that the interesterification proceeded smoothly by using the solid base catalyst. As indicated in Figure 7, the content of SLL was increased obviously with the reaction time in the first 1 h, and the increase became very slow beyond 1 h. However, upon prolonging the reaction time to 5 h, the content of SSL was gradually decreased and then remained almost constant beyond the reaction duration of 5 h. As observed, the LCSL content was shown to increase with increasing the reaction time from 0.5 to 1 h, and no remarkable alteration was found between 1 and 3 h. However, there was a decrease trend in the LCSL content beyond 3 h. In light of the results, it can be concluded that the suitable reaction time required for obtaining a good LCSL yield is 1 h.

Reaction temperature is another variable that can affect the interesterification reaction. The effect of reaction temperature on the interesterification reaction was investigated, and the results are illustrated in Figure 9. In absence of any solvent, the reaction temperature needs to be above the melting point of methyl stearate (38 °C), so that the interesterification reaction can be conducted by using the solid catalyst. As seen in Figure 8, when the reaction temperature was increased from 50 to 80 °C, the SLL content also increased from 33.7 to 47.3%. However, with subsequent increase in reaction temperature, the SLL content was dropped slightly. Besides, the SSL content was shown to decrease as the reaction temperature was increased from 50 to 80 °C, but no further variation in SSL content was observed beyond 80 °C. Moreover, the LCSL content of the interesterified product was gradually increased to 91.5% with

increasing the reaction temperature to 80 °C, and thereafter was diminished slightly at a temperature of 90 °C. Accordingly, in the present investigation, the proper temperature for the interesterification reaction is 80 °C.

The interesterification reaction is generally employed to produce structured lipids that have the improved functionality by rearranging the fatty acids on the glycerol backbone. For different mixtures of substrates, the interesterification was carried out by using the solid catalyst at a temperature of 80 °C. As shown in Figure 10, for all the experimental trials involving a variety of molar ratios of methyl stearate to tributyrin, the rapid depletion of tributyrin species occurred affording new SSL and SLL of TAGs simultaneously. With increasing methyl stearate/tributyrin molar ratio to 2:1, the content of SLL triacylglycerol in the interesterified product increased, while the SSL content

diminished. In this case, with higher methyl stearate/tributyrin molar ratio than 2:1, the SLL content was declined slightly and the SSL content remained nearly constant. In all of these trials, the LLL triacylglycerol was observed to increase on increasing the methyl stearate/tributyrin molar ratio. From Figure 9, it was observed that the content of LCSL was initially ascended from 84.7 to 91.5% with the increase in methyl stearate/tributyrin molar ratio from 0.5:1 to 2:1. However, beyond the molar ratio of 2:1, the lower content of LCSL was observed. Given the present results, the appropriate molar ratio of methyl stearate to tributyrin is found to be 2:1, with the LCSL content of 91.5%.

Reusability of the Catalyst. The reusability is an important aspect to evaluate the feasibility of a heterogeneous catalyst for its application in industrial processes, which makes it economic and preferable over homogeneous one. In order to study the catalyst reusability, consecutive reaction runs were carried out using the SBA-15-pr-TBD catalyst. At the end of the interesterification, the catalyst was recovered by filtration, washed with cyclohexane and ethanol, and dried at 120 °C overnight in a vacuum oven. The recovered catalyst was used for the next cycle, and this process was repeated for several times under the optimized reaction conditions as described above. The experimental results are illustrated in Figure 11. It was indicated that the LCSL yield was almost kept stable without significant loss of its catalytic activity (91.5% in the first cycle versus 85.8% in the fifth cycle) for up to five times of use, thus indicating the good stability of the catalyst. However, the catalytic activity was obviously decreased as the catalyst was used more than five times, mostly owing to the accumulation of impurities on the catalyst surface.

In light of the aforementioned results, a heterogeneous catalyst, SBA-15-pr-TBD, was prepared by reactions of TBD-organosilane with the mesoporous SBA-15 material. By using this solid base catalyst, the interesterification between tributyrin and methyl stearate in a solvent-free system was performed for the production of LCSL. All the characterization results indicated the successful anchoring of organic base TBD on the framework channel of mesoporous SBA-15 materials. After the functionalization of SBA-15 silica, the ordered mesoporous structure remained almost unchanged, which was favorable for improving the contact between the catalytically active component and reactants. Further, the solid catalyst is applicable to the interesterification reaction as a stable and highly active catalyst. Over this catalyst, the LCSL, composed of stearic acid and butyric acid, was successfully prepared in a heterogeneous manner. In the previous work, Han et al. reported that the interesterification of tributyrin and methyl stearate was conducted using a commercially immobilized lipase, Lipozyme RM IM.[5] Compared to the immobilized lipase, the SBA-15-pr-TBD catalyst shows higher activities for the interesterification reaction owing to the shorter reaction time employed and lower catalyst loading.

days before heading and up to 12 times after heading in each year. Sampling involved harvesting the whole plant about 15 cm above the soil, and the harvested biomass was separated into two parts: stems and leaves, and the heads. Only the heads were sampled in 2012, because the concentration in the stem plus leaf component was quite low in 2011 (see the Results). Sampling was done in triplicate. These samples were used to determine the FUM concentration. Details of the analysis are provided in the section Quantitative Analysis of FUMs.

Field Experiment 2: Differences in the FUM Concentration among Sites . We used the rice cultivar Yumeaoba in this experiment. Yumeaoba was cultivated at three sites in 2011 and 2012: the same experimental paddy field at NILGS that we used in field experiment 1, a farmer's paddy field in Ohtawara, Tochigi Prefecture, and a farmer's paddy field in Kumagaya, Saitama Prefecture. The sampling method was the same as in field experiment 1, but we did not use true replication at Ohtawara and Kumagaya; sampling was done in triplicate within the same field.

Isolation of FUM-Producing Fungi. Isolation of FUM-producing fungi was carried out in 2011. To isolate the fungi, we placed 3 to 5 cm samples of the leaf and stem or head tissues on plates of potato dextrose agar medium (PDA, Nissui Pharmaceutical Co. Ltd., Tokyo, Japan) containing 500 mg/L of streptomycin sulfate (Wako Pure Chemical Industries Co. Ltd., Osaka, Japan) and 500 mg/L of pentachloronitrobenzene (Tokyo Chemical Industry Co., Ltd., Tokyo, Japan). The plates were incubated at 25 °C in the dark for 5 to 7 days, and the fungi present in the cultures were picked up and transferred into water agar medium. A single isolate was obtained from each sample, except for one sample that contained two or more *Fusarium* species. We then isolated individual fungal spores and incubated them on PDA for 5 to 7 days in the dark at 25 °C. The colonies on PDA were used in subsequent FUM-production experiments and for identification to the species level.

FUM-Production Experiment Using the Isolated Fungi. We incubated the isolates in the dark on 1 g of corn grits in 1 mL of sterilized water at 25 °C for 7 days. We used noninoculated corn grits as a control. We then added 10 mL of methanol/water solution (3:1 v/v) to the incubated corn grits, homogenized the sample by stirring using a glass rod, and then set it aside overnight. We used 5 mL of the supernatant for our quantitative analysis of the FUM concentration. If the FUM concentration was greater than 1 mg/kg of the corn grits, we defined the isolate as a FUM-producing fungus.

Identification of *Fusarium* Species. We extracted total genomic DNA from the *Fusarium* isolates, as described previously.[14] We amplified part of the gene for translation elongation factor 1-α (EF-1α) by means of the polymerase chain reaction (PCR) using the primer pair EF-1H/EF-2T, following the method of O'Donnell.[15] We chose this gene because previous research[15] showed that it was capable of distinguishing among *Fusarium* species and between these species and other organisms. Purified PCR products were sequenced with an ABI Prism 3100 automated sequencer (Applied Biosystems, Foster City, CA) according to the manufacturer's instructions. The sequence data were compared with data in the DNA Data Bank of Japan (http://www.ddbj.nig.ac.jp/) by using the BLAST program.

Greenhouse Experiment: Inoculation with FUM-Producing Fungi. We used the cultivars Natsuaoba and Yumeaoba in this experiment. The greenhouse was kept at 25 °C under natural illumination. Seeds were germinated and then transplanted at a density of one plant per container into plastic containers (L 374 mm, W 254 mm, H 232 mm) filled with soil (Suitou-baido, Kantou-nousan Co. Ltd., Nasushiobara, Tochigi, Japan). We then added 3.5 g of inorganic fertilizer (14−14−14) to each container. We grew the seedlings for 40 days and then added an additional 2.5 g of the same fertilizer to each container as a top dressing.

We created a total of three treatments per cultivar in this experiment: control plants maintained in a separate greenhouse, noninoculated plants grown beside inoculated plants (hereafter, NBI plants), and inoculated plants. Triplicate measurements were collected from each treatment.

The inoculated plants were treated as follows: At 3 and 10 days after heading, we sprayed 50 mL of the spore solution from a height of about 50 cm above the rice plants to inoculate the head. After spraying, we covered the rice seedlings with a plastic bag for 12 h. The spore solution was prepared as follows: Isolates of *Fusarium fujikuroi* MO409[14] were grown on plates containing V-8 juice agar: 200 mL of V8 juice (Campbell Soup Company, Camden, NJ), 3 g of $CaCO_3$, and 15 g of agar/L. The plates were illuminated for 12 h with ultraviolet and violet light (FL15BLB lamps; Toshiba, Japan) and then left for 12 h in the dark, with both treatments at 25 °C. We incubated the solution in this manner for 14 days and then added 2 mL of sterile purified water to the plates. We then mixed the agar into the water and transferred the mixture into sterile purified water. After observing the spore density under a microscope, we adjusted the spore density to 1.0×10^5 cells/mL to produce the spore solution.

At 30 days after heading (the yellow-ripe stage) and 55 days after heading (the full-ripe stage), we harvested the plants at a height of 15 cm above the ground and divided them into two parts (stems plus leaves versus the heads).

Quantitative Analysis of FUMs. FUMs in the rice plants were quantitatively analyzed using the method described in our previous report[14,16] The fresh plant samples were dried in a forced-air oven at 65 °C for 48 h so that all concentrations could be expressed per unit dry weight. The dried samples were ground in a cutting mill (ZM200; Retsch GmbH, Haan, Germany) to pass through a 1 mm screen. We then added 30 mL of a methanol and water solution (3:1 v/v) to 2 g of each dried, ground sample.

We preconditioned an anion-exchange column (Bond Elut SAX; Varian Technologies, Palo Alto, CA) by washing it with 10 mL of a water and methanol solution (1:3 v/v); we then loaded the column with 10 mL of the supernatant from the sample solution and eluted the sample with 14 mL of methanol containing 10 mL/L acetic acid. The eluate was concentrated to 1 mL in vacuo and injected into a liquid chromatography−tandem mass spectrometry (LC/MS/MS) system (ACQUITY TQD UPLC; Waters, Milford, MA). The LC/MS/MS conditions were as follows: column, ACQUITY UPLC BEH C18 (2.1 mm ×50 mm, 1.7 μm; Waters); oven temperature, 40 °C; solvents, 1 mL/L aqueous formic acid/acetonitrile; running conditions, 0 to 3 min at 3/1 (v/v), a linear gradient for 3 to 4 min from 3/1 to 9/11; retention times of 2.8 min for $FUMB_1$ and 3.6 min for $FUMB_2$; monitored ions (ESI Positive), m/z 722.5 > 334.5 for $FUMB_1$, m/z 706.6 > 336.5 for $FUMB_2$; and confirmed ions, m/z 722.5 > 352.5 for $FUMB_1$, m/z 706.6 > 318.4 for $FUMB_2$.

The efficiency of FUM recovery from rice flour with a known FUM concentration (100 ng/g) was 108.2% ($FUMB_1$) and

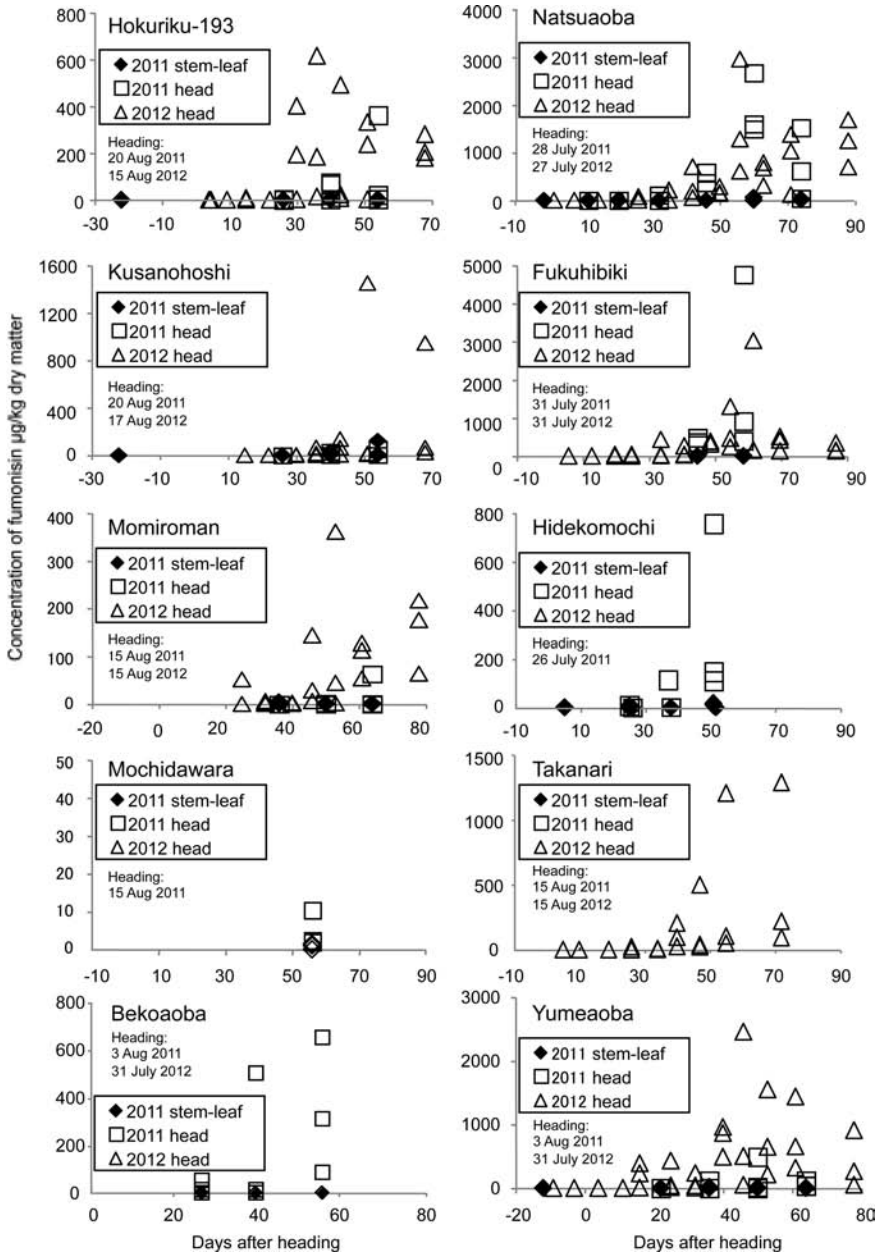

Figure 1. Changes in the fumonisin (FUM) concentration in the 10 cultivars during cultivation in field experiment 1 at the NILGS site. FUM concentrations represent the total ($FUMB_1$ + $FUMB_2$) content. Note that the *y*-axis scale differs among the graphs.

91.5% ($FUMB_2$), with a relative standard deviation (n = 3) of 2.6% ($FUMB_1$) and 4.5% ($FUMB_2$). The calibration curve had good linearity (>0.999) in the range of 0 to 5000 ng/mL for $FUMB_1$ and $FUMB_2$. The limit of quantification (LOQ) was 1 μg/kg DM ($FUMB_1$, $FUMB_2$). Values below the LOQ were treated as not detected. The total FUM concentration was defined as the sum of the concentrations of $FUMB_1$ and $FUMB_2$.

Statistical Analysis. To enhance the homoscedasticity that is required for performing ANOVA, we log-transformed the average FUM concentrations as ln(average +0.5w), where w is the maximum discrete width of the average. [17] To compare the cultivars, we analyzed the transformed averages using an unbalanced ANOVA in which the year (2011 and 2012) and the experimental plots (1, 2, and 3) were treated as blocks. When the ANOVA produced a significant result, we tested for differences among the cultivars in the FUM concentration using Tukey's HSD test.

To compare cultivation sites, we analyzed the log-transformed averages using an unbalanced one-way ANOVA in which the numbers of replicates were 3, 1, and 1 for the NILGS, Ohtawara, and Kumagaya sites, respectively. When the ANOVA produced a significant result, we tested for differences among the sites using Tukey's HSD test.

To compare the FUM concentrations among the inoculation treatments, we tested for treatment × cultivar interactions using Tukey's HSD test, because we suspected the existence of interactions.

To compare the FUM concentrations among the inoculation treatments, we tested the mean for treatment × cultivar combinations using Tukey's HSD test, because we suspected the existence of interactions. We calculated the mean using the log-transformed values of $FUMB_1$ + $FUMB_2$.

RESULTS

Changes in the FUM Concentration during Cultivation and Differences among the Cultivars. Figure 1 summarizes the changes during the growing season in the FUM concentrations in the rice plants of the cultivars grown at NILGS in 2011 and 2012. Table 1 summarizes the mean FUM concentration in the heads of each cultivar. Fukuhibiki had a significantly higher FUM concentration than Kusanohoshi, Momiroman, and Mochidawara. Bekoaoba and Natsuaoba had a significantly higher FUM concentration than Momiroman and Mochidawara. The other cultivars did not differ significantly.

Table 1. Mean Fumonisin (FUM) Concentrations in the 10 Cultivars Cultivated in Experiment 1[a]

cultivar	mean (±SE)[b]		
Fukuhibiki	6.150	(±0.529)	a
Bekoaoba	5.922	(±0.778)	ab
Natsuaoba	5.873	(±0.529)	ab
Hidekomochi	5.201	(±0.778)	abc
Yumeaoba	4.920	(±0.529)	abc
Hokuriku-193	4.102	(±0.529)	abc
Takanari	4.014	(±0.778)	abc
Kusanohoshi	3.480	(±0.529)	bc
Momiroman	2.741	(±0.529)	c
Mochidawara	1.976	(±0.778)	c

[a]Means represent log-transformed values, as described in the text. [b]Means followed by different letters differ significantly ($P < 0.05$, Tukey's HSD test).

The FUM concentrations in the stems and leaves of Hokuriku-193, Kusanohoshi, Fukuhibiki, and Momiroman were less than 10 μg/kg DM. The FUM concentration in stems and leaves of Hidekomochi at 40 days after heading were around 15 μg/kg DM (Figure 1). The FUM concentrations in stems and leaves of Natsuaoba were slightly higher than those in the other cultivars, reaching a maximum of 60 μg/kg DM.

In the heads, the FUM concentrations in all cultivars 30 days after heading were less than 10 μg/kg DM. However, by 40 days after heading, the FUM concentration in Natsuaoba, Fukuhibiki, Bekoaoba, and Hidekomochi began to increase. The FUM concentration reached its maximum around 50 to 70 days after heading, except for an earlier range of dates for Hokuriku-193 (40 to 60 days). Although the maximum concentration differed among the cultivars, the trend did not differ. The FUM concentration was greater than 100 μg/kg in Fukuhibiki, Bekoaoba, Natsuaoba, and Yumeaoba, although there was high variation among the replicates. For example, the FUM concentration in Natsuaoba at 56 days after heading ranged from less than 1000 μg/kg DM to more than 3000 μg/kg DM in 2012. Similarly, the FUM concentrations in Yumeaoba heads at this time ranged from less than 500 μg/kg DM to more than 2000 μg/kg DM.

Differences among the Sites in FUM Concentration. Figure 2 summarizes the FUM concentrations in Yumeaoba in the two paddy fields in Ohtawara and Kumagaya in 2011 and 2012. The result at NILGS is shown in the graph for Yumeaoba in Figure 1. Table 2 summarizes the statistical results. As in experiment 1, the maximum concentration was reached between 50 and 70 days after heading in both years and at both sites. In addition, the concentrations differed by more than 100% among the sites, and the NILGS site had a significantly higher mean concentration than the Kumagaya site. At the Ohtawara site, the maximum FUM concentration was 193 μg/kg DM. At the Kumagaya site, the maximum concentration was 113 μg/kg DM. The FUM concentration at Kumagaya was particularly low (<10 μg/kg) in 2012 until 90 days after heading, and in no sample was the concentration larger than 20 μg/kg DM.

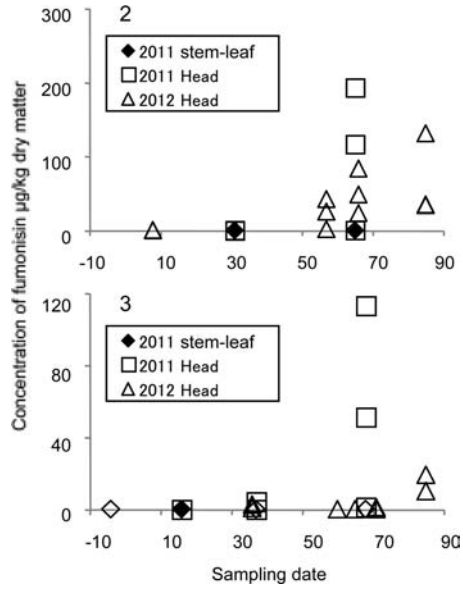

Figure 2. Differences in the FUM concentration between the two farm rice paddy sites. Values are the total FUM concentration ($FUMB_1$ + $FUMB_2$); the sampling date represents the number of days after heading. Upper (2): Ohtawara. Bottom (3): Kumagaya. Results for NILGS are shown in the graph for Yumeaoba in Figure 1. Note that the *y*-axis scale differs between the graphs.

Table 2. Differences in the Mean FUM Concentrations in Yumeaoba among the Three Field Sites[a]

location	mean (±SE)[b]		
NILGS	5.928	(±0.258)	a
Ohtawara	3.709	(±0.447)	ab
Kumagaya	2.272	(±0.447)	b

[a]Values are the log-transformed means (see the text for details). [b]Means followed by different letters differ significantly ($P < 0.05$, Tukey's HSD test).

Isolation and Identification of the FUM-Producing Fungi. We obtained 49 *Fusarium* isolates that were confirmed to produce FUM in the FUM production experiment. For these isolates, we obtained almost the full length of the EF-1α gene. We compared the sequences with those in the FUSARIUM-ID database (http://isolate.fusariumdb.org)[18,19] and calculated their similarities with two standard accessions (DQ790494 for *F. fujikuroi* and AF160280 for *F. proliferatum*). Of the 49 isolates, 48 had lengths of 638 to 640 bp and similarities of 99.2 to 99.7% with *F. fujikuroi*, whereas one had a length of 646 bp and 98.9% similarity with *F. proliferatum*. On the basis of these results, we identified the former isolates as *F. fujikuroi* and the latter as *F. proliferatum*.

We obtained the following numbers of isolates for the cultivars: 14 for Yumeaoba, 8 for Momiroman, 7 for Natsuaoba, 5 for Fukuhibiki, 5 for Hidekomochi, 4 for Hokuriku-193, 4 for Kusanohoshi, 1 for Bekoaoba, and 1 for Mochidawara. We obtained 31 isolates from the heads and 18 from the leaves and stems. The number of isolates also varied as a function of the

dx.doi.org/10.1021/jf405358h | J. Agric. Food Chem. 2014, 62, 3356−3362

number of days after heading: 1 at 0−10 days, 6 at 11 to 30 days, 20 at 31 to 51 days, and 22 at 51−74 days. The number of isolates also differed among the cultivation sites: 45 at NILGS, 3 at Ohtawara, and 1 at Kumagaya. We obtained FUM-producing *Fusarium* isolates from 9 of the 10 cultivars, excluding Takanari, and we isolated these fungi both from the stems and from the leaves and heads. The fungi were present from shortly after heading (7 days) to the end of the study period (74 days after heading), but the isolation frequency was greatest at 51 days after heading, with no distinction between the plant parts.

FUM-Producing Fungi in the Greenhouse. Figure 3 shows the results of the greenhouse inoculation experiment. At the yellow-ripe and full-ripe stages, the FUM concentrations in the stems and leaves of Natsuaoba and Yumeaoba ranged from undetectable to 5 μg/kg DM. The stem and leaf values were generally lower than the corresponding head values in both cultivars and were always lower in the inoculated plants. At the yellow-ripe stage, the FUM concentrations in the heads of the control and NBI plants were undetectable, whereas the inoculated heads of Natsuaoba and Yumeaoba had concentrations of 18 and 19 μg/kg DM, respectively. The inoculated plants had significantly higher concentrations than those in the other treatments in both cultivars. At the full-ripe stage, the FUM concentrations in the heads of the control and NBI plants were undetectable or very low, whereas the heads of the inoculated Natsuaoba and Yumeaoba plants had concentrations of 660 and 240 μg/kg DM, respectively, which were significantly higher than those in the other treatments.

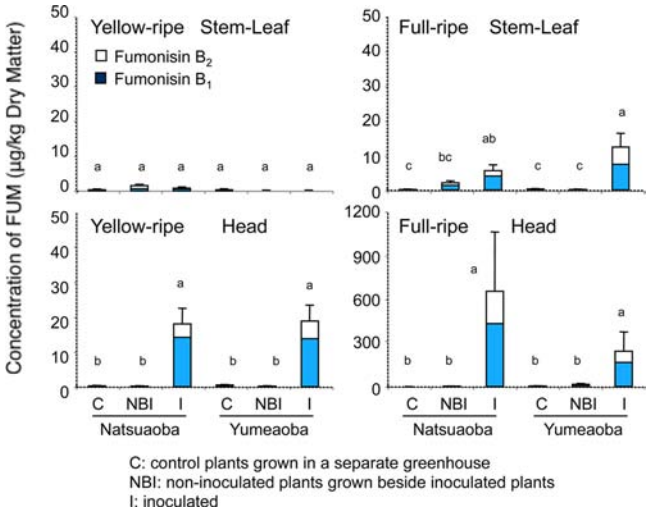

Figure 3. FUM concentrations in the greenhouse inoculation experiment; values are the total concentration of FUM ($FUMB_1$ + $FUMB_2$). Sample times were 30 days after heading for the yellow-ripe stage and 55 days after heading for the full-ripe stage. Values in each panel labeled with different letters differ significantly (Tukey's HSD test, $P < 0.05$). Values are means ± SE ($n = 3$) and were calculated using the log-transformed values of $FUMB_1$ + $FUMB_2$, as described in the text. Treatments: C, control plants grown in a separate greenhouse; NBI, noninoculated plants grown beside inoculated plants; I, inoculated plants. Note that the *y*-axis scale differs among the graphs.

DISCUSSION

In field experiment 1, the FUM concentrations in the heads of almost all cultivars started to increase by around 30 days after heading (the yellow-ripe stage) and became much higher than those in the stems and leaves by around 50 days after heading, which is near the full-ripe stage (Figure 1). This trend was similar for all cultivars, although the magnitudes of the increase differed among the cultivars. The reason for this pattern is currently unclear. Feng et al.[20] reported that deoxynivalenol production by *F. graminearum* increased greatly when sucrose, 1-kestose, and nystose were used as a carbon source in vitro. The increased FUM concentration in rice heads may similarly be a response to changes in some nutritional component in these tissues. Several cultivars differed significantly in their FUM concentration (Table 1). The FUM concentration tended to be higher in early maturing cultivars and low in late-maturing cultivars. The reason for this may relate to the cultivation time, a difference in the nutritional composition of the plants, or some other unknown cause. In corn, a similar difference in the mycotoxin concentration was observed among cultivars. [21] In future research, it will be necessary to determine the reasons for these differences, because they may support efforts to control the FUM concentration by means of appropriate cultivar selection.

In field experiment 2, we found that the FUM concentration was higher in the heads than in the stems and leaves for all cultivars at all sites. The FUM concentration in the heads increased greatly by 40 to 60 days after heading at all sites (Figure 1 and 2). This confirms the results in field experiment 1 (Figure 1). The FUM concentration in the heads grown at NILGS was significantly higher than that in the heads grown at Kumagaya (Table 2). This suggests that the FUM concentration was influenced by the cultivation environment. However, we did not obtain sufficient data on the cultivation methods and conditions at the three field sites to hypothesize about which cultivation-related factors might be responsible for these differences.

The isolated FUM-producing fungi were almost all *F. fujikuroi* (48 of 49 isolates). At NILGS, many *F. fujikuroi* isolates were obtained 31 days after heading. In contrast, at Kumagaya, we found few FUM-producing fungi, and the FUM concentration was significantly lower than at NILGS (Table 2). This may reflect differences among the sites in the inoculum levels. FUM-producing fungi were isolated from almost all cultivars, and the FUM concentrations differed among the cultivars. These fungi were also isolated from the stems and leaves, although the FUM concentrations were quite low compared with those in the heads. As we noted earlier, these differences may have resulted from differences in the nutrient compositions of the parts of the host plants, but this hypothesis must be confirmed in future research.

In the greenhouse inoculation experiment, the FUM concentration was substantially higher in the heads of inoculated plants than in the stems and leaves (Figure 3), especially at the full-ripe stage. This confirms the results of the two field experiments (Figures 1 and 2). The FUM concentration in the control and NBI heads did not increase until the full-ripe stage, even in NBI plants grown beside inoculated plants. On the other hand, the FUM concentration in the heads of inoculated plants increased rapidly after the yellow-ripe stage. These results suggest that inoculation of the plants 3 to 10 days after heading caused infection and greatly increased the FUM concentration in the rice heads between the yellow-ripe and full-ripe stages. In the field experiments, the isolation frequency was lower before the yellow-ripe stage than at the full-ripe stage. However, in the greenhouse experiment,

the presence of FUM-producing fungi just after the heading stage appears to be important for the increased FUM concentration. Yoshida et al. [22] reported that the most effective fungicide application for barley was at the anther-extrusion stage. Although crops likely differ in the optimal infection stage, it seems likely that the mycotoxin concentration in the *Poaceae* is strongly related to the time of infection. In other words, to control FUM concentrations in rice plants, it will be necessary to control infection by FUM-producing fungi just after the heading stage.

In summary, our results show that the FUM concentration in the heads of rice plants was substantially higher than that in the stems and leaves. In general, by around 30 to 40 days after heading (the yellow-ripe stage or late yellow-ripe stage), the FUM concentration began to increase and reached its maximum 50 to 70 days after heading (the full-ripe stage). The FUM concentration differed among the cultivars. Even within a cultivar, the FUM concentration varied widely among the three sites. Infection by FUM-producing fungi just after heading increased the FUM concentration in rice heads starting at the yellow-ripe stage.

These results suggest that control of FUM levels in forage rice can potentially be achieved by selecting cultivars in which infection produces a low FUM concentration by controlling FUM-producing fungi just after the heading stage by the application of appropriate fungicides and by obtaining a better understanding of the cultural factors that affect infection by the fungi and its subsequent growth.

fermentation broth of the biocontrol fungal strain *S. lamellicola* BCP. In addition, the in vitro and in vivo activities of the ethyl acetate layer and pure compounds were evaluated against phytopathogenic bacteria.

MATERIALS AND METHODS

Organisms and Culture Conditions. The following seven phytopathogenic bacterial strains were used for the antibacterial bioassay: *Acidovorax konjaci*, the causal agent of bacterial blight of konjac; *Agrobacterium tumefaciens*, the causal agent of crown gall disease; *Burkholderia glumae*, the causal agent of bacterial grain rot of rice; *Pectobacterium carotovorum* subsp. *carotovorum*, the causal agent of bacterial soft rot of potato; *Pseudomonas syringae* pv *lachrymans*, the causal agent of cucumber angular leaf spot; *R. solanacearum*, the causal agent of tomato bacterial wilt; and *Xanthomonas euvesicatoria*, the causal agent of pepper bacterial spot. All strains were grown on nutrient agar (NA) (Becton, Dickinson and Co., Sparks, MD, USA) and nutrient broth (NB), except *R. solanacearum*, which was grown in tryptone soy agar (TSA) (Becton, Dickinson and Co.) and tryptone soy broth (TSB) (Becton, Dickinson and Co.). *X. euvesicatoria* was cultured aerobically at 25 °C for 18−36 h, and the remaining strains were cultured aerobically at 30 °C for 18−36 h.

Isolation of Antibacterial Substances. Strain BCP was cultured on potato dextrose broth (PDB) medium (Becton, Dickinson and Co.) on a rotary shaker at 150 rpm and at 25 °C for 10 days as described previously by Kim et al.[4] The broth culture (10 L) was centrifuged at 10000*g* for 10 min. The obtained supernatant was mixed with an equal volume of acetone and incubated in a fume hood for 24 h. The precipitates were filtered out using filter paper, and the filtrate was concentrated under a vacuum to remove the acetone. The aqueous layer was then partitioned twice with equal volumes of ethyl acetate (EtOAc). The EtOAc layers were pooled and concentrated in a rotary evaporator at 40 °C to remove the organic solvent. The EtOAc concentrate (2.5 g) showed strong activity against *R. solanacearum* as determined by a disk diffusion assay.[4] The EtOAc concentrate was subjected to chromatography on a silica gel column [100 g of Kiesel gel 60 (230−400 mesh; E. Merck, Darmstadt, Germany), 3.4 cm × 40 cm, packed with EtOAc/methanol (MeOH) (9:1, v/v)] with successive elution with mixtures of EtOAc/MeOH/water (W) (80:10:2, v/v/v, 200 mL), EtOAc/MeOH/W (80:10:5, v/v/v, 200 mL), EtOAc/MeOH/W/acetic acid (80/10/8/1, v/v/v/v, 500 mL), and dichloromethane (DCM/MeOH/W (60:40:10, v/v/v, 500 mL), yielding 15 fractions, ABE 1−15. The fractions were monitored using thin-layer chromatography (TLC) (Kiesel gel 60GF 254, 0.25-mm layer thickness; E. Merck) with the developing solvent EtOAc/MeOH/W/acetic acid (80:10:8:1, v/v/v/v). The fractions were also assayed in vitro for growth inhibition of *R. solanacearum*. The active fractions ABE 5−8 displayed a similar pattern of primary components based on the TLC analysis and were pooled and further purified repeatedly using preparative HPLC (SCL-10A VP; Shimadzu Co., Kyoto, Japan) with a Capcell Pak C18 UG120 Å (5 μm, 20 mm × 250 mm; Shiseido Co., Tokyo, Japan). The combined fraction (460 mg) was eluted with a linear gradient from 45% MeOH to 100% MeOH for 30 min and then maintained at 100% MeOH for 10 min. The eluent (6.5 mL/min) was monitored at 204, 215, and 254 nm. Two compounds, **1** (85 mg) and **2** (23 mg), were isolated to purity by repeated preparative HPLC. Compound **3** (12 mg) was purified from fraction ABE 13 by preparative TLC (Kiesel gel 60GF 254, 0.5 mm layer thickness; E. Merck) with the developing solvent EtOAc/MeOH/W/acetic acid (80:10:8:1, v/v/v/v).

Degradative products of **1** were prepared by directed lactonization of fatty acids in the structure of **1** (12 mg), with the catalysis of 0.1 N HCl in CH_3CN (2 mL of a mixture of 1 mL of 0.1 HCl aq + 1 mL of CH_3CN). The reaction was performed at 80 °C for 2 h. The product was monitored by TLC with hexane/EtOAc (1:3, v/v) as the developing solvent. After working up the reaction, the nonpolar product was extracted twice with 1 mL of a mixture of EtOAc and hexane (3:1, v/v). The organic layers were pooled and concentrated under an N_2 stream at 40 °C until dryness. The residue was separated by preparative TLC using a mixture of hexane/EtOAc (1:3, v/v) to yield 4.2 mg of compound **4** and 5 mg of compound **5**.

The aqueous layer was concentrated to dryness and redissolved in 0.2 mL of 2 N HCl in a 7 mL screw-top vial. The vial was heated to 100 °C for 4 h to hydrolyze the sugar moiety. After hydrolysis, the mixture of products was divided into two parts. One portion was partitioned with DCM to remove the nonpolar impurities, and the aqueous layer was evaporated off under an N_2 stream. The residue was dissolved in MeOH and analyzed by TLC using DCM/MeOH/W (6:4:1, v/v/v) and was compared with authentic monosaccharides. The second portion was neutralized with $NaHCO_3$ and dried under an N_2 stream. The residue was acetylated with 0.2 mL of acetic anhydride/pyridine (1:1, v/v) at 100 °C for 45 min. After the acetylation reaction, the mixture of acetic anhydride/pyridine was removed under an N_2 stream. The residue containing the acetylated monosaccharide was dissolved into 0.2 mL of 2% $CuSO_4$ in water and partitioned twice with 0.5 mL of EtOAc. The EtOAc layers were pooled and dried under a nitrogen stream. The residue obtained after drying was dissolved in 50 μL of chloroform for GC-MS analysis. Authentic samples of glucose, rhamnose, mannose, galactose, and sorbitol (0.5 mg each) were also acetylated. The acetylated monosaccharides were analyzed by GC-MS on an SP2330 column (30 m × 0.32 mm i.d.; 0.25 μm film thickness; Supelco, Inc., Bellefonte, PA, USA) using He as the carrier gas with a temperature program of 120 °C (2 min) to 230 °C (5 °C min^{-1}) maintained for 12 min.

Structure Determination of Antibacterial Substances. The optical rotations of the purified compounds in MeOH were recorded on a JASCO J-20 automatic recording spectropolarimeter using a 1 cm path-length cell. The chemical structures were determined by mass and nuclear magnetic resonance (NMR) spectroscopy. Fast atom bombardment (FAB) analysis was performed with a glycerol matrix and Ar as the bombarding gas using a high-resolution mass spectrometer (JMS-AX505; JEOL Ltd., Tokyo, Japan). The electrospray ionization mass spectra (ESI-MS) of the purified compounds were recorded on an MSD1100 single-quadrupole mass spectrometer equipped with an ESI (Hewlett-Packard Co., Palo Alto, CA, USA). ^1H and ^{13}C NMR, COSY, HMQC, and HMBC spectra were recorded in CD_3OD (E. Merck) with a Bruker AMX-500 spectrometer (Bruker Analytische Messtechnik Gmbh, Rheinstetten, Germany).[7] The spectra were referenced to either tetramethylsilane (TMS) (^1H) or solvent signals (^{13}C). The coupling constants are reported in hertz. The chemical structures of the purified substances were analyzed on the basis of the MS and NMR spectral data and comparisons to reported values in the literature.

In Vitro Antibacterial Assay against Phytopathogenic Bacteria. An in vitro antibacterial assay was performed in 96-well microtiter plates based on a modification of the broth microdilution method.[8,9] The *R. solanacearum* strain was incubated in TSB medium, and the other bacteria were incubated in NB medium. The stock solutions of pure compounds dissolved in MeOH were diluted 100-fold with the proper growth medium for each strain and tested at final concentrations ranging from 0.39 to 100 μg/mL. Bacterial suspensions (50 μL) of each strain with an inoculum of 2 × 10^6 cells/mL were added to the wells containing 50 μL of 2-fold serially diluted pure compounds in the proper growth medium for a final volume of 100 μL in each well. The negative controls were treated with 1% MeOH, which corresponds to the highest concentration. The blank wells were prepared with culture medium containing pure compounds at the same test concentrations. The dilutions were prepared with three replicates, and the experiments were performed a minimum of three times. The inoculated plates were incubated at 30 °C, except for *X. euvesicatoria* at 25 °C, for 18−48 h after shaking at 300 rpm for 20 min on a microplate shaker. The optical density (OD) of each well was measured using a microplate reader (Bio-Rad, Benchmark Plus, USA) at 600 nm. The growth inhibition of each dilution was determined using the formula[9]

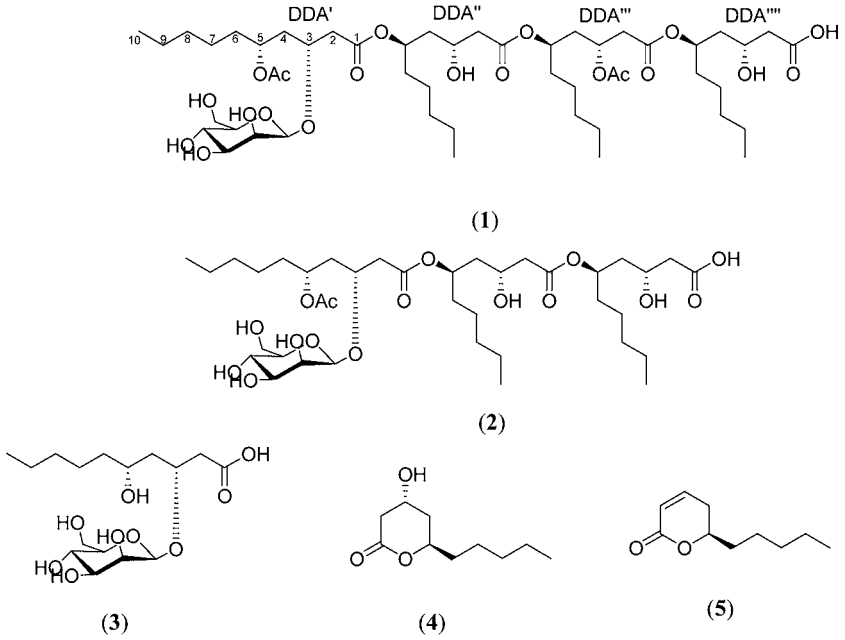

Figure 1. Chemical structures of the compounds isolated from the ethyl acetate layer of the *Simplicillium lamellicola* BCP broth. **1**, halymecin F; **2**, halymecin G; **3**, (3*R*,5*R*)-3-*O*-*β*-D-mannosyl-3,5-dihydroxydecanoic acid; **4**, (+)-(3*R*,5*R*)-3-hydroxydecan-5-olide; **5**, (−)-massoia lactone; DDA, 3, 5-dihydroxydecanoic acid.

$$\%\ \text{inhibition} = 100 \times [1 - \text{OD of treated well} / \text{OD of negative control well}]$$

where OD values of the negative control well and the OD of the treated well were corrected with the OD of the blank wells corresponding to each concentration. The IC_{50} values were derived from Probit analysis of the concentration−response data, with serially diluted concentrations of the pure compounds.

Disease Control Efficacy of the Ethyl Acetate Layer of *S. lamellicola* BCP against Tomato Bacterial Wilt. To evaluate the disease control efficacy of the EtOAc extract of *S. lamellicola* BCP culture broth against tomato bacterial wilt caused by *R. solanacearum* SL1944 (race 1, biovar 4),[10,11] 3-week-old tomato plants at the 4−5-true-leaf stage of 'Seokwang' were used. The plants were grown in vinyl pots with a volume of 170 mL in a greenhouse and were then transplanted into vinyl pots with a diameter of 7 cm (one plant per pot). Three different amounts of the EtOAc layer, 50, 100, and 200 mg, were dissolved in 2 mL of MeOH and then poured into 98 mL of distilled water containing 250 μg/mL Tween-20 to obtain test concentrations of 500, 1000, and 2000 μg/mL. *R. solanacearum* was cultured on TSA Petri dishes at 30 °C for 48 h and were subsequently washed twice from the dishes with sterile distilled water. The inoculum suspension was adjusted to an optical density OD_{600} of 0.1 (approximately 1.5×10^8 cells/mL) using sterile distilled water. The 20 mL aliquots of three EtOAc extract solutions were evenly applied to the soil of each pot. After 3 h, *R. solanacearum* was inoculated by applying 20 mL of the inoculum suspensions into the soil. The second treatment with the EtOAc layer was performed 5 days after the first treatment. Streptomycin sulfate (SM), a bactericidal antibiotic with a broad activity against both Gram-negative and Gram-positive bacteria, was used as a positive control at a concentration of 200 μg/mL. Pots treated with water containing Tween-20 (250 μg/mL) and MeOH (2%) served as the negative controls (CK). The plants were maintained in a controlled climate at 30 °C with a relative humidity of 70−80%. The disease severity was recorded on a scale of 0−5 as described by Winstead and Kelman.[12] The following scales were used: 0 = no symptoms, 1 = one leaf partially wilted, 2 = one to two leaves wilted, 3 = two to three leaves wilted, 4 = four or more leaves wilted, and 5 = death of the entire plant. The pots were arranged as a randomized complete block with five replicates per treatment. The experiment was repeated three times. The control value was calculated using the following formula: control value (%) = 100 × (disease severity of control − disease severity of treatment)/disease severity of control.

Statistical Analysis. The data obtained in this study were evaluated by one-way ANOVA, and the significance of the treatments was determined by Tukey's HSD for multiple comparisons ($P \leq 0.05$). The IC_{50} values were calculated on the basis of Probit analysis using WINPEPI software version 11.4.[13]

RESULTS AND DISCUSSION

This study focused on the identification of antibacterial metabolites produced by the biocontrol agent *S. lamellicola* BCP and the in vitro and in vivo activities of these compounds against phytopathogenic bacteria to identify either alternatives to currently used crop protection agents or lead compounds to synthesize derivatives with enhanced activities or environmental friendliness. The *S. lamellicola* BCP strain, previously identified as *A. strictum* BCP on the basis of morphological characteristics, was developed as a microbial fungicide for the control of various plant diseases, such as tomato gray mold and rice blast.[5,6] However, in the present study, we identified the strain as *S. lamellicola* BCP on the basis of sequence analysis of the 28S rRNA gene and ITS regions (Figures S1 and S2 in the Supporting Information). In addition, we found that the microbial fungicide also effectively suppressed the development of tomato bacterial wilt in fields. We previously reported that the antagonistic fungus produces verlamelin as an antifungal metabolite.[4] However, the metabolite did not show any antibacterial activity. Therefore, in this study, we characterized the antibacterial metabolites produced by *S. lamellicola* BCP.

Characterization of Substances from the Culture Broth of *S. lamellicola* BCP. When investigating the bioactivities of the EtOAc extract from the *S. lamellicola* BCP culture broth, we found that the EtOAc layer significantly inhibited the growth of *R. solanacearum* and also contained trimers and tetramers of (3*R*,5*R*)-3,5-dihydroxydecanoic acids (DDA) as the primary metabolites. Using bioassay-guided

dx.doi.org/10.1021/jf500361e | J. Agric. Food Chem. 2014, 62, 3363−3370

fractionation, the antibacterial metabolites were isolated from the EtOAc layer by various chromatographic methods.

Compound **1**, a main component (Figure 1) ($[\alpha]^{20}_{D}$ −11.9°; *c* 0.27, MeOH), was obtained as a colorless oil, and its molecular formula is $C_{50}H_{88}O_{20}$ as determined by FAB-MS ($[M + Na]^+$ 1032) and ESI-MS ($[M + Na]^+$ 1031.6) data. The FAB-MS and positive ESI-MS data (Figure 2) of **1** exhibited

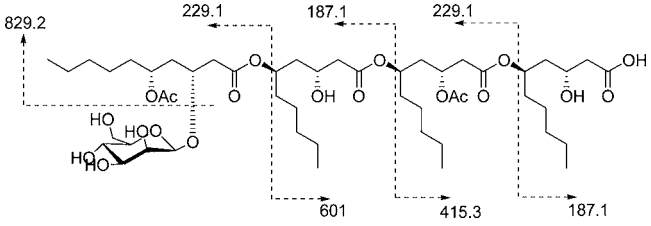

Figure 2. Fragmentation of halymecin F (**1**) ($C_{50}H_{88}O_{20}$, quasi-molecular ion peak *m/z* 1031.6 $[M + Na]^+$) generated by ESI-MS.

significant fragment peaks at *m/z* 829.2 $[M + H - 180]^+$, *m/z* 601 $[M + H - 180 - C_{12}H_{20}O_4]^+$, *m/z* 583 $[601 - H_2O]^+$, *m/z* 523 $[583 - 60]^+$, *m/z* 415.3 $[C_{22}H_{39}O_7]^+$, *m/z* 355.3 $[C_{22}H_{39}O_7 - 60]^+$, *m/z* 229.1 $[C_{12}H_{21}O_4]^+$, and *m/z* 187.1 $[C_{10}H_{19}O_3]^+$. Hydrolysis of **1** after lactonization yielded a hydrolysate containing a monosaccharide moiety. TLC analysis revealed that the sugar moiety is D-mannose on the basis of comparison to the authentic compound. GC-MS analysis of the acetylated product of the hydrolysate also confirmed the presence of pentaacetyl-β-D-mannose. These data suggest that **1** contains β-D-mannose, two acetyl groups (two losses of 60 in the MS spectrum), and $C_{10}H_{19}O_3$ units. The ^{1}H NMR spectrum of **1** (Table 1) displayed signals corresponding to four terminal methyl groups at δ 0.89 (12H, t, *J* = 7.01), two acetyl groups at δ 2.01 (3H, s) and 2.02 (3H, s), an anomeric proton at δ 4.61 (1H, brs), and a region of protons of oxygenated carbons. The ^{13}C NMR spectrum of **1** revealed the presence of 1 anomeric carbon at δ 101.18, 13 oxygenated carbons from δ 62.97 to δ 78.28, 6 carbonyl groups in the range of δ 172.47−173.63, and the methyl carbons of 2 acetyl groups at δ 21.24 (Table 1). On the basis of analysis of the COSY and HMQC spectra, assignment of the β-D-mannose moiety was verified. The proton spin system of the H1−H6 of each fatty acid was determined by COSY, and the position of the carbonyl group was determined by a cross peak between the methylene protons of the C-2 and the carbon of the carbonyl group. The long-range correlations of H-3 (δ 4.21, DDA′) with an anomeric carbon (101.18) on the HMBC spectrum demonstrated that the β-D-mannose moiety was situated at the C-3 of DDA′. The linkage of the C-5 with an acetyl group was deduced from cross peaks between the protons of the acetyl group and the C-4 (δ 39.84), C-5 (δ 72.78), and C-6 (δ 35.41) in the HMBC spectrum and the fragment peak at *m/z* 602 on the FAB-MS spectrum. The ester linkages between the carbonyl carbons with the C-5 in the remaining fatty acid chains were also deduced from the HMBC data. Furthermore, the HMBC data led to the assignment of the other acetyl group at the C-3 of DDA‴. The lactonization of **1** produced a known δ-lactone (**4**), which was identified as 3-hydroxydecan-5-olide. Its carbon chiral centers were determined as (3*R*, 5*R*) on the basis of the ^{1}H and ^{13}C NMR spectra and optical rotary power. A review of the literature and a comparison of the spectral data of **1** with mannosyl lipids suggested that the structure of **1** was a tetramer of 3,5-dihydrodecanoyl and that its structure was similar to that of halymecin B,[14] except for an additional acetyl group attached to the C-5 of DDA′. Compound **1** was named halymecin F, and its chemical structure is presented in Figure 1.

Compound **2** ($[\alpha]^{20}_{D}$ −8.99°; *c* 0.2, MeOH) was named halymecin G. Its molecular formula is $C_{38}H_{68}O_{16}$ as determined from the quasi-molecular ion peaks at *m/z* $[M + Na]^+$ 803.2 and *m/z* $[M - H]^-$ 779.7 in positive and negative ESI-MS spectra, respectively. These data suggest that **2** lacks one acetyl group and a DDA compared to **1**. The positive-FAB-MS spectrum of **2** showed significant fragment peaks at *m/z* 601 $[M + H - 180]^+$, *m/z* 373 $[C_{20}H_{37}O_6]^+$, and *m/z* 187.1 $[C_{10}H_{19}O_3]^+$. The fragmentation of 373 indicated a dimer of two DDA units without an acetyl group, and these data suggest that compound **2** is a partial structure of **1** and has an acetyl group located at DDA′. The ^{1}H and ^{13}C NMR spectra of **2** showed the presence of one acetyl group, one mannosyl moiety, four carbonyl carbons, and three terminal methyl groups. The location of the mannose moiety is at the C-3 of DDA′ via glycosidic linkage as determined by the HMBC correlation peaks at H-1 (4.61, mannose) with a carbon signal at 74.94. The stereochemical analysis for the DDAs of **2** was also performed as described for **1**, and the chemically degraded product was determined to be (3*R*,5*R*)-3-hydroxydecan-5-olide. Analysis of the 1D-NMR spectroscopic data and interpretation of the HMBC and HSQC allowed us to assign all signals of **2** and identified the compound as a monoacetate trimer of DDA units (Table 1 and Figure 1). Compound **2** was named halymecin G.

Compound **3** ($[\alpha]^{20}_{D}$ −2.9°; *c* 0.176, MeOH) has the molecular formula $C_{16}H_{30}O_9$ as determined by ESI-MS ($[M + Na]^+$ 389.2 and $[M - H]^-$ 365.4). The negative-ESI-MS spectrum of **3** showed a fragment peak at *m/z* 179.2 $[C_{10}H_{19}O_3 - H_2O]^+$, indicating a dehydrated DDA. The ^{1}H NMR spectrum of **3** exhibited a singlet of the anomeric proton H-1 (mannose) at δ 4.66 and a terminal methyl group at δ 0.91. The ^{13}C NMR spectrum had 16 carbon signals, including 6 carbons belonging to a β-D-mannose moiety and 10 carbons for one DDA. The position of the glycosidic linkage of the mannosyl and DDA was also determined by the HMBC analysis. Finally, compound **3** was identified as (3*R*,5*R*)-3-*O*-β-D-mannosyl-3,5-dihydroxydecanoic acid, and its NMR data and structure are presented in Table 1 and Figure 1.

δ-Lactones **4** and **5** were identified as (+)-(3*R*,5*R*)-3-hydroxy-decan-5-olide (EI-MS *m/z* 168 $[M - H_2O]^+$, $C_{10}H_{18}O_3$; $[\alpha]^{20}_{D}$ +39.9°; *c* 0.05, CH_2Cl_2), and (−)-massoia lactone (EI-MS *m/z* 168 $[M]^+$, $C_{10}H_{16}O_2$; $[\alpha]^{20}_{D}$ −65.9°; *c* 0.2, CH_2Cl_2),[15,16] respectively, on the basis of the analysis of the EI-MS, GC-MS, and 1D-NMR data (Figure 1; Table S1 and Figure S3 in the Supporting Information). In a previous study, compounds **4** and **5** were found as biologically active δ-lactones and were chemically synthesized from streptenol A. Optical rotary powers (**4**, $[\alpha]^{20}_{D}$ +36.9°; *c* 0.92, CH_2Cl_2; **5**, $[\alpha]^{20}_{D}$ −112.5°; *c* 1 $CHCl_3$) and MS and 1D-NMR data of these synthesized compounds were reported by Romeyke et al.[15] Although compounds **4** and **5** are chemically degraded products of compounds **1**−**3**, their presence in the EtOAc layer of the *S. lamellicola* BCP culture broth was also confirmed with TLC and GC-MS.

Halymecins were previously reported to be tetramers and trimers of (3*R*,5*R*)-3,5-dihydroxydecanoic acid isolated from *Fusarium* spp. and *Exophiala pisciphila*. All of the microorganism resources were collected from marine algae and sponges,[14,17] whereas *S. lamellicola* BCP was isolated as a

Table 2. Antibacterial Activity of the Isolated Compounds against the Growth of Seven Phytopathogenic Bacteria

name	IC_{50} (95% CI)[a]		
	1	2	3
A. konjaci	22.5(8.5−59.9)	>100	>100
A. tumefaciens	1.58 (0.91−2.74)	1.49 (0.18−2.95)	24.8 (16.9−36.4)
B. glumae	33.2 (18.9−58.4)	>100	NI[b]
P. carotovora subsp. *carotovora*	>100	>100	NI
P. syringae pv *lachrymans*	>100	>100	>100
R. solanacearum	73.8 (41.4−106.1)	75.8 (44.3−107.4)	>100
X. euvesicatoria	72.1 (40.6−103.6)	>100	>100

[a]The antibacterial activity is expressed as the IC_{50} (concentration causing 50% growth inhibition) as determined by the broth microdilution method. Growth inhibition was observed 2 days after treatment. 95% CI, 95% confidence interval. [b]No inhibition.

mycoparasite of *B. cinerea*. The present study identifies compounds **1**−**3** for the first time.

Antibacterial Activity. The in vitro antibacterial activity of compounds **1**−**3** was tested in 96-well microtiter plates, and the results are presented in Table 2. Compound **1** displayed a broad spectrum and strong antibacterial activity compared to compounds **2** and **3**. Compound **1** caused growth inhibition of all seven phytopathogenic bacteria and was highly active against *A. konjaci*, *A. tumefaciens*, and *B. glumae*, with IC_{50} values of 25.5, 1.58, and 33.2 μg/mL, respectively. *R. solanacearum* (IC_{50} 73.8 μg/mL) and *X. euvesicatoria* (IC_{50} 72.1 μg/mL) were moderately sensitive to compound **1**. However, *P. carotovora* subsp. *carotovora* and *P. syringae* pv *lachrymans* were highly tolerant to this compound. Compound **2** also affected the cell growth of all bacteria tested. It effectively inhibited the growth of *A. tumefaciens* with an IC_{50} value of 1.49 μg/mL. *R. solanacearum* growth was inhibited by compound **2**, with an IC_{50} value of 75.8 μg/mL. Compound **3** caused good growth inhibition of *A. tumefaciens*, but had no effect against *B. glumae* and *P. carotovora* subsp. *carotovora*. Of the three compounds, compound **1** showed the strongest antibacterial activity against the phytopathogenic bacteria tested.

The EtOAc extract from the *S. lamellicola* BCP broth was evaluated for in vivo antibacterial activity against *R. solanacearum* on 3-week-old tomato seedlings (Figure 3). The extract suppressed the development of bacterial wilt in a dose-dependent manner. *R. solanacearum* caused severe wilting damage on seedlings treated with distilled water and 500 μg/mL EtOAc extract 9 days after inoculation (Figure 3B). However, the EtOAc extract at concentrations of 1000 and 2000 μg/mL displayed strong control efficacies of 85 and 100%, respectively, against *R. solanacearum* 9 days after inoculation. These disease control efficacies were higher than that of streptomycin sulfate (200 μg/mL). These results suggest that the EtOAc extract and the fermentation broth of *S. lamellicola* BCP may be used as a natural bactericide to control tomato bacterial wilt.

Biocontrol provides an alternative to the use of synthetic agrochemicals and is used as part of an overall integrated plant disease management program. Several filamentous fungal species are known mycoparasites against various phytopathogenic fungi.[18−20] The biocontrol mechanism is most likely due to the action of cell wall degradative enzymes and secondary metabolites.[21−23] In addition, the microorganisms that produce microbial polyesters (polyhydroxyalkanoates) have long been considered important in various sectors, such as the food, pharmaceutical, cosmetic, fragrance, flavor, and biofuel industries.[17]

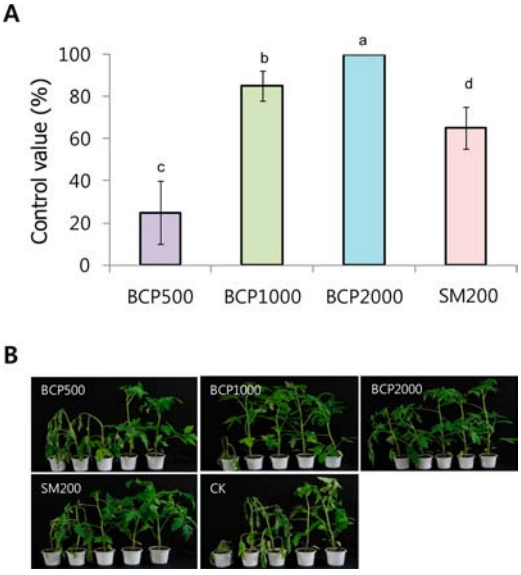

Figure 3. Control efficacy of the ethyl acetate layer of the *Simplicillium lamellicola* BCP culture broth in reducing wilting disease severity caused by *Ralstonia solanacearum* on tomato seedlings (A) and the treated plants 9 days after inoculation (B). BCP500, 500 μg/mL; BCP1000, 1000 μg/mL; and BCP2000, 2000 μg/mL, ethyl acetate extracts from the *S. lamellicola* BCP culture broth; ST200, 200 μg/mL of streptomycin sulfate; CK, untreated control. Each value represents the mean ± standard deviation of three experiments with five replicates each. Means (±SD) followed by the same letters above the bars are not significantly different (P = 0.05) in a Tukey's HSD test.

S. lamellicola BCP was reported to be a biocontrol fungus with good efficacy against *B. cinerea* and *M. grisea*.[5,6] *S. lamellicola* was previously known as *Cephalosporium lamellicola* and *Verticillium lamellicola*, which exhibited mycoparasitic interactions with phytopathogenic fungi causing rust diseases.[20,24] The strain BCP was also reported to produce verlamelin that significantly suppressed tomato late blight caused by *P. infestans*, wheat leaf rust caused by *P. recondita*, and barley powdery mildew caused by *B. graminis* f. sp. *hordei*.[4,25] In the present study, we demonstrated that *S. lamellicola* BCP produces different antimicrobial metabolites and may be considered a producer of polyesters of (3*R*,5*R*)-3,5-dihydroxydecanoic acid.

For the antimicrobial activities of substances containing (3*R*,5*R*)-3,5-dihydroxydecanoic acid, verbalactone isolated from the plant roots of *Verbascum undulatum* exhibited moderate antibacterial activity against *Salmonella enteritidis*, *Staphylococcus aureus*, and *S. epidermidis*.[26] Only a few tetramers and trimers of (3*R*,5*R*)-3,5-dihydroxydecanoic acid from three fungal strains

have previously been reported. Halymecins A, B, and C were isolated from *Fusarium* spp. FE-71-1, and halymecins D and E were isolated from *Acremonium* spp. FK-N30. Of these compounds, halymecin A is a tetramer of DDA and causes growth inhibition of bacteria, such as *Enterococcus faecium*, *Klebsiella pneumoniae*, and *Proteus vulgaris*. Halymecin A also showed strong antimicroalgal and cytotoxic activities.[14] Exophilin A was reported to be a trimer of (3*R*,5*R*)-3,5-dihydroxydecanoic acid isolated from *Exophiala pisciphila* NI10102. The trimer displayed antimicrobial activity against some Gram-positive bacterial strains, such as *Enterococcus faecium* and *Staphylococcus aureus*.[17] In our study, the mannosyl lipids halymecin F (**1**), halymecin G (**2**), and (3*R*,5*R*)-3-*O*-*β*-D-mannosyl-3,5-dihydroxydecanoic acid (**3**) were novel mannosyl lipids isolated from *S. lamellicola* BCP with antibacterial activities against phytopathogenic bacteria.

In addition, we successfully isolated and confirmed the presence of massoia lactone (**5**), an active metabolite member of the *Trichoderma* family,[23] in the culture broth of *S. lamellicola* BCP. Massoia lactone represents a minor component of the crude extracts of various *Trichoderma* spp., including *Trichoderma viride*. This compound was patented because it controls *B. cinerea* and *Phytopthora* species.[22] The role of *Trichoderma* antimicrobial metabolites in biocontrol remains unclear. Some of these compounds may be the major contributor to biocontrol activity for a certain strain but not for other strains.[21] The presence of massoia lactone (**5**) in *S. lamellicola* BCP suggests a relationship between the biocontrol mechanism of the strain and *Trichoderma* species. Our findings confirmed the production of mannosyl lipids **1**−**3** and massoia lactone from *S. lamellicola* BCP and the antibacterial activities of the novel mannosyl lipids against phytopathogenic bacteria. This strain may be considered a producer of polyesters of (3*R*,5*R*)-3,5-dihydroxydecanoic acid. The presence of the three novel mannosyl lipids in the fermentation broth cultures of *S. lamellicola* BCP was demonstrated in this study. Furthermore, the in vivo activities of the EtOAc extract against tomato bacterial wilt in a climate-controlled room and disease control of the microbial biopesticide Acre against tomato bacterial wilt in fields were also elucidated. These results suggest that *S. lamellicola* BCP and its mannosyl lipids could be used to control plant diseases caused by phytopathogenic bacteria.

extraction of different components from various sources.[16−19] Sonication involves the generation of sound waves that trigger extremely high alterations in pressure, leading to the formation of cavitation bubbles that damage the plant matrix and release extractive compounds.[16,20] The use of sonication in the release of nonextractable phenolics has not been widely investigated, more so the combination of sonication and alkaline hydrolysis.

Therefore, the aim of this study was to investigate the use of sonication and the combination of sonication and alkaline hydrolysis in the release of nonextractable phenolics from cauliflower waste. The yield of total nonextractable phenolics compared to the extractable fraction was also investigated. Different factors, such as sonication time, NaOH concentration, and temperature, were optimized to yield the highest total nonextractable phenolic content. Thereafter, the phenolic composition of the nonextractable fraction was characterized and quantified using advanced LC-MS techniques. Furthermore, the nonextractable phenolic compositions of the blade and petiole parts were also individually evaluated.

MATERIALS AND METHODS

Reagents. Kaempferol, quercetin, and ferulic, *p*-coumaric, gallic, and sinapic acids were purchased from Sigma (St. Louis, MO, USA). U(H)PLC-MS grade methanol and formic acid were acquired from Biosolve (Valkenswaard, The Netherlands). Analytical grade methanol used for extraction, HCl, and NaOH were purchased from VWR International (Leuven, Belgium).

Conventional Extraction of EP and Collection of Residues Containing NEP. Cauliflower (*Brassica oleracea* L. var. *botrytis*) wastes were obtained in a field in Ieper (Belgium) during harvest (July 2012), stored at −20 °C, and lyophilized. Dried leaves were ground and homogenized using a stirrer. Extraction was based on the method of Gonzales et al.[11] Briefly, approximately 2 g of leaves was placed in 50 mL tubes and homogenized with 15 mL of methanol at 10000 rpm using an ultraturrax for 45 s. The tubes were then placed on ice for 15 s. The mixture was centrifuged at 13000*g* for 10 min at 4 °C. The residue was re-extracted with 80% MeOH using the same procedure. After removal of the supernatant, the residue was dried under vacuum and stored at −20 °C until further analysis. Concurrently, blade and petiole parts were also manually separated and extracted separately. Extractions and analyses were done in triplicate.

Measurement of Total Phenolic Content (TPC). TPC was analyzed using the Folin−Ciocalteu method[21] with slight modifications and expressed as milligrams of gallic acid equivalents (GAE). Briefly, 50 μL of sample, 100 μL of Folin−Ciocalteu reagent, and 1.2 mL of distilled water were mixed in a 2 mL cuvette. After 5 min, 150 μL of 20% sodium carbonate was added and the mixture was incubated for 2 h in the dark. TPC was then measured at 760 nm. Calibration curves were drawn using gallic acid with R^2 values of >0.98. All analyses were performed in triplicates.

Alkaline Hydrolysis and Choice of Solvent on the Total Phenolic Content of Residues. Prior to optimization of the alkaline hydrolysis conditions, the choice of a suitable solvent and the effect of sonication were investigated. For this, a method previously used for the release of bound procyanidin from cranberry pomace by alkaline hydrolysis was employed.[7] Briefly, 0.1 g of residue was hydrolyzed using 2 mL of 2 M NaOH for 15 min at 60 °C in a screw-capped test tube previously flushed with nitrogen. The samples were then neutralized using 2 M HCl and extracted twice with different solvents for 2 min under vortex. Extraction solvents used were 4 mL of either methanol, acetone, or ethyl acetate (all containing 0.1% formic acid). The tubes were centrifuged for 10 min at 10000*g* and 4 °C. Extraction was done twice, and the supernatants were pooled and standardized to 20 mL using the corresponding solvents. Because methanol extracted significantly more phenolics, based on TPC, than ethyl acetate and acetone (results not shown), methanol was used as the extraction solvent for all other subsequent analyses.

Effect of Sonication and Combination with Alkaline Hydrolysis (Sonicated Alkaline Hydrolysis). The effect of sonication on the release of nonextractable phenolics was tested by mixing 0.1 g of residue with 20 mL of methanol in a sonicated bath for 15 min at 60 °C previously flushed with nitrogen. The ultrasonic extraction procedure was performed in an Elmasonic S60H unit with a frequency of 37 kHz and a nominal power of 180 W. The dimensions of the bath were 300 mm (W)/150 mm (D)/150 mm (H), and it was filled with 2 L of water. The suspension was centrifuged at 10000*g* at 4 °C for 10 min. The supernatant was kept for analysis.

Subsequently, the effect of combining alkaline hydrolysis and sonication was tested by sonicating a mixture of 0.1 g of residue with 2 mL of 2 M NaOH at 60 °C for 15 min. The phenolic content was extracted with methanol, as described above. Therefore, three setups were made: (1) alkaline hydrolysis, (2) ultrasound-assisted extraction, and (3) combined alkaline hydrolysis and sonicated extraction. Because sonicated alkaline hydrolysis significantly increased the TPC, optimization of this treatment was performed.

Optimization of the Sonicated Alkaline Treatment of the Residue. The conditions for sonicated alkaline hydrolysis were optimized to increase the TPC of the extract. Hydrolysis experiments were performed using a 3^3 factorial design comprising three different temperatures (40, 60, 80 °C), NaOH concentrations (1, 2, 4 M), and sonication time (15, 30, 45 min). Each treatment consisted of one temperature, one NaOH concentration, and one sonication time, thus 27 treatments in total. The analysis was performed in triplicates. Therefore, 0.1 g of residue was placed in each of 81 screw-capped test tubes, and these were hydrolyzed under various conditions as described in Table 1 and extracted as earlier described. Extracts are henceforth referred to as NEP solution.

Table 1. Treatment Conditions for Sonicated Alkaline Hydrolysis Treatment Optimization

temp (°C)	NaOH concn (M)	sonication time (min)
40	1	15
60	2	30
80	4	45

Solid Phase Extraction (SPE). A 1 mL aliquot of the NEP solution was diluted in 20 mL of 0.1% (v/v) formic acid (in ultrapure water) and loaded into a preconditioned C18 SPE cartridge (500 mg/4 mL) (Davison Discover Science, Deerfield, IL, USA). Preconditioning was done by loading the column with 2 × 3 mL of methanol and 2 × 3 mL of water, which was allowed to stand for at least 2 min for every solvent, prior to use. After sample loading, the cartridge was washed with 5 mL of 0.1% (v/v) formic acid and the phenolic compounds were recovered using 3 mL of methanol containing 0.1% (v/v) formic acid. The samples were then dried using nitrogen and redissolved in 1 mL of 10% methanol (0.1% v/v formic acid) prior to LC-MS analysis.

Identification of Compounds Using U(H)PLC-ESI-MS and Quantification by U(H)PLC-DAD. LC-MS analysis was performed with a Waters Acquity UPLC system (Waters Corp., Milford, MA, USA) connected to a Synapt HDMS TOF mass spectrometer (Waters Corp.). Chromatographic separation was done on a Waters Acquity BEHC18 column (2.1 mm × 150 mm, 1.7 μm particle size) attached to a Waters VanGuard precolumn (2.1 mm × 5 mm) using gradient elution. The mobile phase was composed of (A) water containing 0.1% (v/v) formic acid and (B) methanol containing 0.1% (v/v) formic acid. The column temperature was maintained at 40 °C, whereas the temperature of the autosampler was held at 10 °C. Five microliters of sample was injected, and a flow rate of 250 μL/min was applied during the gradient elution. The elution program was as follows: 0 min, 10% B; 0−6 min, 0−20% B linear; 6−12 min, 20% B isocratic; 12−13 min, 20−30% B linear; 13−23 min, 30−50% B linear; 23−30 min, 50−90% B linear; 30−35 min, 90% isocratic; 35−40 min, 90−10% B linear; and 40−45 min, 10% B isocratic. The eluent was then directed to the mass spectrometer equipped with an electrospray

dx.doi.org/10.1021/jf500835q | J. Agric. Food Chem. 2014, 62, 3371−3376

ionization (ESI) source. Data were acquired in continuum negative ionization in V-mode. Source parameters for the MS were set as follows: capillary voltage, 2 kV; sampling cone voltage, 40 V; extraction cone voltage, 4 V; source temperature, 150 °C; desolvation temperature, 350 °C; cone gas flow rate, 50 L/h; desolvation gas flow rate, 550 L/h. Collision energies were set at 6 V for low energy and 45 V for high energy. Mass range was set at 100−1500 Da with a scan speed of 0.2 s per scan using MassLynx software 4.1 (Waters Corp.). Structural characterization of the phenolic compounds, especially flavonoids, was based on an earlier published method.[11]

Quantification was done using a Thermo Dionex Ultimate 3000 U(H)PLC (ThermoScientific, Landsmeer, The Netherlands) equipped with a diode array detector at 280 and 330 nm using authentic standards. Column specifications as well as gradient elution are the same as described above. The content of flavonoid glycosides was quantified using their aglycone equivalents, kaempferol for kaempferol glycosides and quercetin for quercetin glycosides, whereas phenolic acids were quantified using authentic standards. Table 2 shows the R^2 values, limits of detection (LOD), and limits of quantification (LOQ) of the standards used. LOD and LOD were calculated using the equations

Table 2. Standards Used for the Quantification of Phenolics

	slope	intercept	R^2	LOD (ppm)	LOQ (ppm)
kaempferol	0.91	0.85	0.98	3.83	12.77
quercetin	0.96	−0.24	0.99	1.51	5.03
caffeic acid	2.20	0.76	0.99	0.85	2.82
coumaric acid	4.50	1.12	0.99	0.57	1.91
ferulic acid	2.36	0.35	0.99	0.33	1.09
synapic acid	0.65	0.28	0.99	0.83	2.77

$$\text{LOD} = 3\left(\frac{Sbl}{S}\right) \text{ and } \text{LOQ} = 10\left(\frac{Sbl}{S}\right) \quad (1)$$

where Sbl is the standard error of the intercept and S is the slope of the respective calibration curves as calculated using the LINEST function.

Statistical Analysis. Data were analyzed using one-way ANOVA using SPSS v.21 (IBM, Chicago, IL, USA). Differences were considered significant when $p < 0.05$. Differences between means (posthoc) were determined using the Tukey test.

RESULTS AND DISCUSSION

Figure 1 shows the TPC of the cauliflower waste after conventional extraction (EP), the residue following alkaline hydrolysis (60 °C, 2 M NaOH for 30 min), sonicated extraction, and sonicated alkaline hydrolysis. The TPC of the EP fraction was 6.1 ± 0.05 mg GAE/g dry waste. However, as shown, the residue left after conventional solvent extraction of the cauliflower waste contained a considerable amount of phenolics, which the current literature may have missed, regardless of the method employed. Sonication alone of the residue yielded the lowest TPC (1.5 ± 0.12 mg GAE/g dry waste). Alkaline hydrolysis, on the other hand, released significantly higher amounts of phenolics from the plant matrix (6.5 ± 0.27 mg GAE/g dry waste). However, this content is ever more significantly ($p < 0.05$) increased by the combination of sonication and alkaline hydrolysis (7.3 ± 0.17 mg GAE/g dry waste). The amount of NEP therefore comprises more than half of the total phenolic content, meaning that NEP is actually more than EP in terms of content.

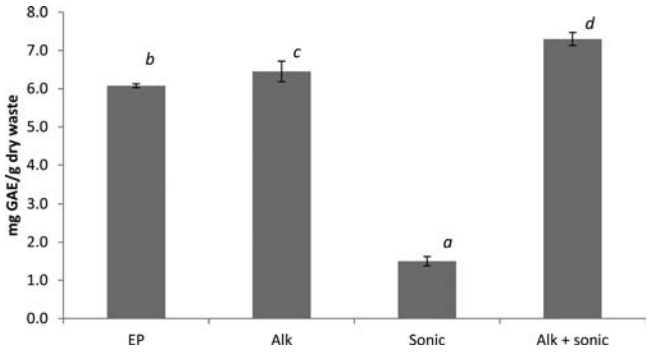

Figure 1. Total phenolic content of cauliflower waste (mg GAE/g dry waste) following conventional solvent extraction (EP), alkaline hydrolysis (Alk), sonicated extraction (Sonic), and sonicated alkaline hydrolysis (Alk+sonic). Different letters above bars indicate statistical difference ($p < 0.05$).

The results reveal that alkaline hydrolysis may not necessarily liberate all bound phenolic compounds in a short time span. Increasing the incubation time, however, may induce oxidation and loss of target compounds. Therefore, other techniques to increase yield without increasing temperature and incubation time are necessary.[7] In this study, it was shown that using ultrasonication along with alkaline hydrolysis serves as an effective method in increasing the yield of nonextractable phenolics. Ultrasonication, as earlier mentioned, damages the plant matrix, which increases the surface area of the sample. This probably allows the sodium hydroxide to react more efficiently in the matrix to break ester linkages and release the phenolic compounds. Although the use of sonication has been described as an effective method of extracting cellular content to liberate phenolics from various plant matrices,[17−19] its ability to break linkages that attach phenolics from other macromolecules has not been well described in the literature. Therefore, combining sonication and alkaline hydrolysis seems to be a logical method. It must be considered that ultrasonication causes an increase in temperature due to the shear forces generated. Therefore, the sonication was performed in a temperature-controlled sonic bath, and the temperature was manually adjusted whenever necessary. Because sonicated alkaline hydrolysis yielded higher TPC, the effects of temperature, NaOH concentration, and sonication time were investigated.

Figure 2 shows the 3D plot of the TPC as affected by time, NaOH concentration, and temperature. The ANOVA statistics are shown in Table 3. Accordingly, there are significant differences among treatments and also significant interactions among the different parameters, except for the interaction between NaOH concentration and sonication time. A significant interaction is noted when temperature is considered, which denotes the importance of this parameter. Looking at the

temp × M × min	8	2.391	0.028

effect of temperature alone, it was observed that TPCs at 60 and 80 °C are not significantly different from each other, but are both significantly higher than at 40 °C. With regard to process efficiency, 60 °C is preferred over 80 °C. Also, it was observed that at 60 °C, TPCs of 30 and 45 min of sonication were similar and are significantly higher than at 15 min. Finally, TPCs of 2 and 4 M were similar and are both significantly higher than at 1 M NaOH concentration. Therefore, the optimal conditions for the release of NEP from cauliflower waste were 60 °C and 2 M NaOH for 30 min under sonication. In the end, the TPC of the NEP solution was found to be 9.82 ± 0.82 mg GAE/g dry residue or around 7.3 mg GAE/g dry waste sample. With TPC of the EP fraction added, the waste material therefore contained 13.4 mg GAE/g dry waste, of which around 45% is extractable and 55% is nonextractable.

To gain a better understanding on the nonextractable phenolics from cauliflower waste, the extract after sonicated alkaline hydrolysis was passed through a C18 SPE column to remove the salts and prepare it for U(H)PLC analysis and phenolic content identification using a mass spectrometer. Figure 3 shows the U(H)PLC-DAD of the cauliflower waste

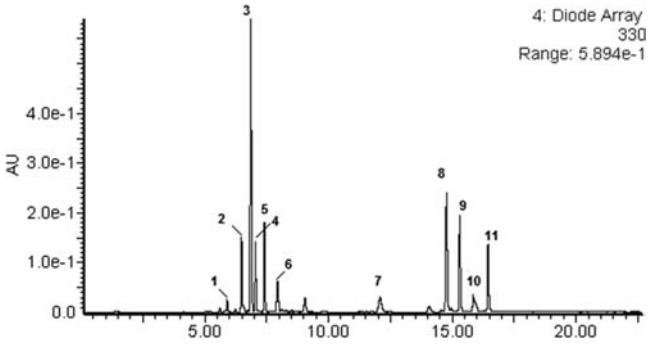

Figure 3. U(H)PLC-DAD chromatogram of cauliflower waste nonextractable phenolics (see Table 4 for peak identities).

NEP solution. Structural characterization and MS characteristics of flavonoid glycosides were described in a previous experiment on the EP fraction.[11] The occurrence of similar compounds in the NEP solution was detected by comparing their masses and retention times after LC-ESI and LC-DAD analysis. Table 4 shows the list of phenolics identified in the NEP solution as well as their content.

As shown, NEP is composed dominantly by flavonoid glycosides that are also found in the EP fraction. Kaempferol-3-*O*-diglucoside-7-*O*-glucoside is the most abundant flavonoid present in the NEP fraction (2.4 ± 0.1 mg/g dry waste), whereas sinapic acid (1.1 ± 0.0 mg/g dry waste) was the most abundant phenolic acid. It should be noted, however, that because the process involved alkaline hydrolysis, the analysis is limited to the fact that acylated flavonoid glycosides may also be present in the NEP fraction but cannot be determined. This is because alkaline hydrolysis also cleaves the ester linkage between the phenolic acid and the flavonoid glycoside.[12] Also, because phenolic acid glucosides are linked via an ester linkage, which is also degraded in alkaline conditions,[22] the occurrence of glucosidic forms of phenolic acids cannot be seen. Therefore, although phenolic acids and flavonoid glycosides may be isolated from the NEP fraction, the fact that they may actually come from the same parent molecule, for example, kaempferol-feruloyl-glycoside, or the occurrence of phenolic acid glucosides, such as feruloyl-glucoside, cannot be determined with this current method.

The high amounts of phenolic acids found in the NEP fraction are in agreement with previously reported data on the edible parts of *Brassica* species, wherein a marked increase in yield of phenolic acids was found after alkaline hydrolysis of residue left after conventional solvent extraction.[14,15,23,24] Indeed, phenolic acids are able to bind to macromolecules, such as fibers and other oligosaccharides, which hamper their extractability using conventional solvent extraction methods.

To investigate the distribution of these phenolic compounds within the waste stream, the waste was divided into blade, which constitutes the green leafy part, and petiole, which constitutes the major vein of the leaf. As shown in Table 5, the blades contain significantly higher amounts of phenolics than the petioles. Furthermore, the phenolic compositions of blades and petioles are found to be somewhat different. Greater variety and higher amounts of flavonoid glucosides and phenolic acids were extracted from the blade part than from the petiole. However, there seems to be a higher ratio of nonextractable phenolic acids in the petioles (relative to phenolic content) than in the blades. The most abundant phenolic compound from the blade is kaempferol-3-*O*-diglucoside-7-*O*-glucoside (4.51 ± 0.0 mg/g dry blade powder), whereas sinapic acid (0.29 ± 0.0 mg/g dry petiole powder) dominated the nonextractable phenolic content of the petioles. In total, 74% of the phenolic composition of the blades is composed of flavonoid glucosides. Conversely, most of the nonextractable phenolics in the petioles are phenolic acids, especially sinapic and ferulic acids, which comprised 57% of the phenolic content. This distribution could be due to the fact that phenolic acids are generally found to be bound to fibers and cell walls,[14] which are higher in the petioles than in the leaves. Whereas the linkage of phenolic acids in cell wall components has been largely observed, especially in *Brassica* species,[14,23,24] little is known about nonextractable flavonoids. Bound flavonoids have been characterized from pepper,[25] *Euphorbia*,[26] and other plants. An in-depth study on the tissue distribution of flavonoids in *Ligustrum vulgare* revealed that flavonoids, such as kaempferol and quercetin glucosides, are attached to lipid bilayers or noncovalently bound to proteins in the leaves.[27] Therefore, considering that studies of bound phenolics from *Brassica* have been done by first isolating the cell walls, information regarding flavonoids bound to membrane and membrane proteins may have been missed.

In conclusion, although no new compounds were found compared to the extractable fraction, the study showed that there are higher amounts of valuable health-promoting compounds from cauliflower waste than what is currently described in the literature. Results of this study may help food engineers and agriculturists devise methods for the scale-up extraction of these compounds for use in the agri-food industry.

Table 4. Phenolic Profile of Nonextractable Phenolics from Cauliflower Waste

peak	identity	rt (min)	m/z values MS	m/z values MS^E	λ_{max} (nm)	content[a] (μg/g dry waste)

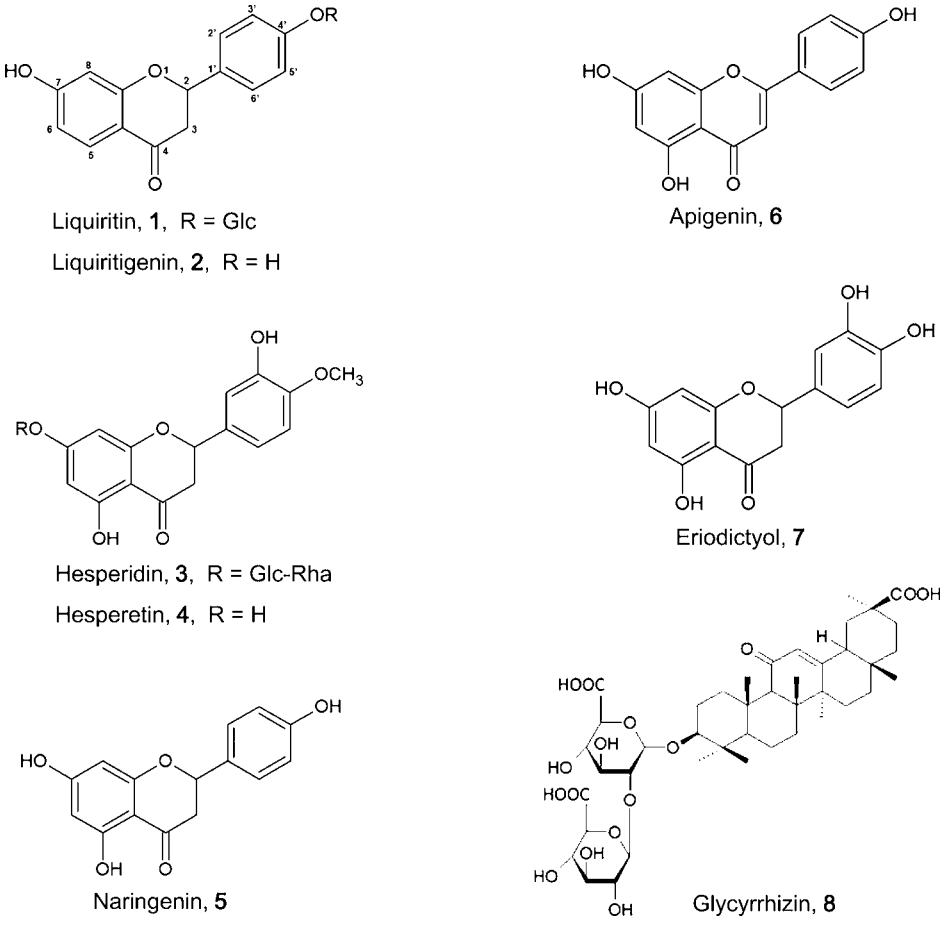

Figure 1. Structures of liquiritin, glycyrrhizin, and structurally related compounds.

supplements were purchased from a commercial market in Japan. Freund's complete and incomplete adjuvants, polyethylene glycol (PEG), and horseradish peroxidase (HRP)-labeled anti-mouse IgG (Fc specific) were obtained from Sigma (Steinheim, Germany). All other chemicals were standard commercial products of analytical grade.

Preparation of the Sample and Standard Solutions. Dried licorice root powder (100 mg) was extracted six times with 1.2 mL of methanol (MeOH) containing 0.1% NH_4OH with sonication for 20 min and centrifugation at 9000*g* for 2 min. The combined supernatant was evaporated with N_2 gas, and the residue was dissolved in 1.0 mL of MeOH containing 0.1% NH_4OH. The prepared extract solution was filtered using a 0.45 μm Cosmonice W filter unit (Nacalai Tesque, Kyoto, Japan) and was used as the sample solution. Solid licorice products such as candies and food supplements were dissolved in 10 mL of H_2O and then lyophilized. Freeze-dried licorice powder (200 mg) was extracted six times with 2.0 mL of MeOH containing 0.1% NH_4OH. The rest of the freeze-dried licorice powder procedure was the same as that followed for the dried licorice root powder. ELISA was used to analyze liquid samples such as beverages, beer, and soy sauce without any pretreatments.

Liquiritin was accurately weighed and dissolved in MeOH to prepare a 5 mg/mL stock solution. Several concentrations of liquiritin standard solutions were prepared by the serial dilution method (0.10, 0.20, 0.39, 0.78, 1.56, 3.13, 6.25, 12.5, 25, 50, and 100 μg/mL as liquiritin standard) using 20% MeOH. These samples and standard solutions were used for ELISA analysis.

Synthesis of Antigen–Carrier Protein Conjugates. Liquiritin–carrier protein conjugates were synthesized using a model based on the periodate oxidation method.[21] Liquiritin (5.0 mg) was dissolved in 0.4 mL of MeOH, and the solution was added dropwise to a sodium periodate (5.0 mg)/H_2O (0.4 mL) solution. Next, the mixture was stirred at room temperature for 30 min. After the oxidative reaction, KLH (5.0 mg) was added to 50 mM carbonate buffer (0.8 mL; pH 9.6) and was stirred at room temperature for 6 h. The oxidation reaction mixture was dialyzed against H_2O at 4 °C for 2 days and then lyophilized. Mice were then immunized with the liquiritin–KLH conjugate (3.6 mg), whereas the liquiritin–HSA conjugate (7.5 mg), which was prepared using the same method as for the liquiritin–KLH conjugate, was used for ELISA.

Analysis of the Liquiritin–Carrier Protein Conjugate by Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF MS). A previous study described how the hapten liquiritin–HSA conjugate was determined by MALDI-TOF.[26] Liquiritin–HSA conjugate (1–10 pmol) was mixed with a 10^3-fold molar excess of sinapinic acid in an aqueous solution containing 0.15% (v/v) trifluoroacetic acid. The mixture was subjected to a JEOL mass spectrometer (JMS) time-of-flight (TOF) mass monitor and irradiated with an N_2 laser (337 nm, 150 ns plus). The ion formed by each pulse was accelerated by a 20 kV potential into a 2.0 m evacuated tube.

Immunization, Hybridization, and Purification of mAb. All procedures and animal care were approved (approval no. 50) by the Committee on Ethics of Animal Experiments, Faculty of Pharmaceutical Sciences, Nagasaki International University; the procedures were conducted according to the Guidelines for Animal Experiments of the Faculty of Pharmaceutical Sciences, Nagasaki International University.

BALB/c male mice (6 weeks old) were intraperitoneally injected with the liquiritin–KLH solution four times. The first immunization was a 1:1 emulsion in Freund's complete adjuvant (0.5 mL, 50 μg of liquiritin–KLH). Two weeks later, a second immunization was repeated with the same amount of antigen, but the liquiritin–KLH solution was emulsified in Freund's incomplete adjuvant. After 2 weeks, a third immunization was administered, which consisted of

liquiritin–KLH (100 μg) dissolved in 0.5 mL of phosphate-buffered saline (PBS). The fourth and final immunization was repeated according to the method of the third immunization. Three days after the fourth immunization, immune splenocytes were exenterated and fused to a hypoxanthine–aminopterin–thymidine (HAT)-sensitive mouse myeloma cell line (SP2/0) using the PEG method. After HAT selection, the 2F8 hybridoma cell line secreting anti-liquiritin mAbs was cloned using a limited dilution method. The 2F8 hybridoma cell line was cultured at 37 °C under 5% CO_2 atmosphere in enriched RPMI1640–Dulbecco's–Ham's F12 medium containing 10% fetal bovine serum.

The mAbs that were prepared from the 2F8 hybridoma cell line were purified using a Protein G FF column (GE Healthcare UK Ltd., Amersham, UK). The cultured medium containing IgG (400 mL) was loaded into the column and was eluted with 100 mM citrate buffer (pH 2.7). The eluted IgG solution was adjusted to pH 7.0 with 1 M Tris-HCl buffer (pH 9.0) and then dialyzed against H_2O at 4 °C for 2 days. After lyophilization, anti-liquiritin mAb (7.52 mg) was obtained.

Direct ELISA. Liquiritin–HSA conjugate and other proteins (100 μL, 1 μg/mL) were dissolved in a 50 mM carbonate buffer (pH 9.6), loaded into a 96-well immunoplate, and incubated for 1 h. The plate was washed three times with PBS containing 0.05% Tween 20 (PBST). The plate was treated with 300 μL of PBS containing 5% skimmed milk (SPBS) for 1 h to reduce nonspecific reactions. After blocking, the plate was washed with PBST three times, and it was then reacted with 100 μL of anti-liquiritin mAb for 1 h. The plate was washed with PBST three times and incubated with 100 μL of a 1000-fold diluted HRP-labeled anti-mouse IgG solution for 1 h. After three washings of the plate with PBST, 100 μL of substrate solution of 0.1 M citrate buffer (pH 4.0) containing 0.003% (v/v) H_2O_2 and 0.3 mg/mL ABTS was added to each well and incubated for 20 min. The absorbance was measured with an Immuno Mini NJ-2300 microplate reader (Nalge Nunc, Roskilde, Denmark) at 405 nm. All reactions were conducted at 37 °C.

Competitive ELISA. Liquiritin–HSA (100 μL, 1 μg/mL) was dissolved in a 50 mM carbonate buffer (pH 9.6) and was loaded onto the 96-well immunoplate, which was then treated with 300 μL of SPBS to reduce nonspecific reactions. Fifty microliters of various liquiritin concentrations or samples dissolved in 20% MeOH solution were incubated with 50 μL of anti-liquiritin mAb solution (105.5 ng/mL) for 1 h. After three washings with PBST, the plate was then reacted with 100 μL of HRP-labeled anti-mouse IgG solution for 1 h. The plate was washed three times with PBST, and 100 μL of ABTS solution was added to each well and incubated for 20 min. Absorbance was recorded at 405 nm by a microplate reader. The glycyrrhizin contents in various foods containing licorice were determined by following a previously described method.[22]

Recovery Experiments. Various amounts of liquiritin standards (25, 50, and 100 μg) were spiked into dried licorice root powder (10 mg). Spiked samples were extracted six times with MeOH containing 0.1% NH_4OH under sonication, and the combined supernatant was evaporated with N_2 gas. The residue was dissolved in 1.0 mL of MeOH containing 0.1% NH_4OH and was filtered using a Cosmonice Filter W. The recovery experiment was performed by using a competitive ELISA.

The recovery of spiked liquiritin was calculated as follows:

$$\text{recovery (\%)} = \frac{\text{measured amount of liquiritin} - 298.07}{\text{spiked amount}} \times 100$$

The amount of liquiritin in the unspiked sample was determined to be 298.07 (μg) in dried licorice root powder (10 mg) by HPLC. For each level, three samples were analyzed.

Determination of Liquiritin Concentration by HPLC. Analytical HPLC was performed using the LC-8020 model III (Tosoh Co. Ltd., Tokyo, Japan). The column used was a 150 mm × 4.6 mm i.d., 3 μm, TSK gel ODS-100Z (Tosoh Co. Ltd.) at room temperature. The mobile phase was water/acetonitrile/acetic acid (82:18:1, by volume), and the flow rate was 0.7 mL/min. UV absorbance detection at 280 nm was used; in this case, the retention time of liquiritin was 14.6 min.

RESULTS AND DISCUSSION

Direct Determination of the Hapten–Carrier Protein Conjugate by MALDI-TOF MS Analysis. We evaluated the hapten number of liquiritin–HSA conjugate by MALDI-TOF MS analysis. A broad peak coinciding with the liquiritin–HSA conjugate was detected around m/z 68500 (data not shown). This result and the molecular weight of approximately 66400 for HSA revealed that the calculated value of the liquiritin component (MW = 418.4) was 4.83, indicating that at least four molecules of liquiritin were coupled with one molecule of HSA. Thus, the prepared liquiritin–HSA conjugate was suitable for use in ELISA by comparing these results to those of a previous study.[27]

The mAb was tested against liquiritin using a liquiritin–bovine serum albumin (BSA) conjugate as an immunogen. However, a suitable and specific mAb for liquiritin could not be obtained. Because the maximum molecular weight that can be detected by MALDI-TOF MS analysis is 260,000, determining the hapten liquiritin–KLH conjugate number using the MALDI-TOF MS system was impossible because the molecular weight of KLH is about 800,000. Thus, the liquiritin–KLH conjugate was prepared using the same procedure as for the liquiritin–HSA conjugate and was used as an immunogen for the anti-liquiritin mAb production without determination of the hapten liquiritin–KLH conjugate number.

Production and Characterization of Anti-liquiritin mAb. The immune splenocytes were fused with SP2/0 myeloma cells by using an established procedure in this laboratory. The 2F8 hybridoma cell line that produced mAb reactive to liquiritin was obtained and classified as IgG2a, which has a κ light chain.

The reactivity of anti-liquiritin mAbs was tested against the liquiritin–HSA conjugate and various proteins such as HSA, BSA, ovalbumin (OVA), and KLH with various anti-liquiritin mAb concentrations (Figure 2). Anti-liquiritin mAb did not recognize the HSA, BSA, OVA, and KLH carrier proteins; however, it specifically recognized the liquiritin portions in the liquiritin–HSA conjugate molecule. Furthermore, the absorbance, which was approximately 1.0, was obtained under the

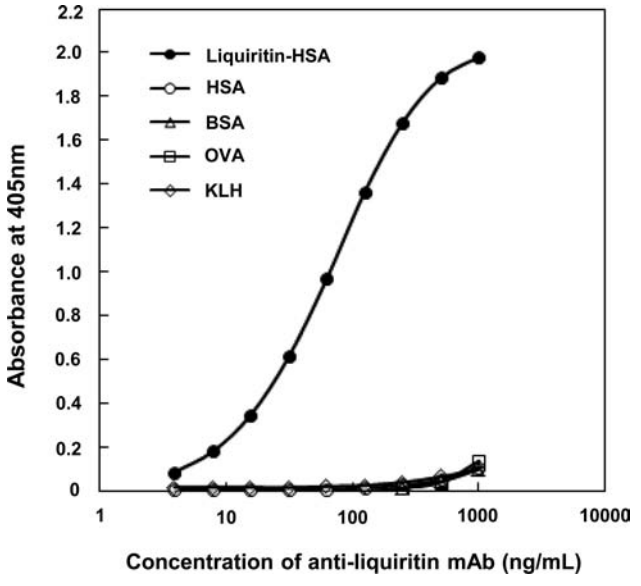

Figure 2. Reactivity of anti-liquiritin mAb against liquiritin–HSA conjugate and various proteins.

dx.doi.org/10.1021/jf404731z | J. Agric. Food Chem. 2014, 62, 3377–3383

antibody concentration (105.5 ng/mL) selected for competitive ELISA.

Assay Sensitivity and Specificity. The assay sensitivity was validated by using anti-liquiritin mAb with competitive ELISA. After incubation of anti-liquiritin mAb with competing liquiritin antigens, any mAb binding free liquiritin was washed out from the ELISA plate. The mAb binding to the liquiritin−HSA conjugate was bound to an enzyme-labeled secondary antibody and reacted to the substrate solution. Under these conditions, the full measuring range of the assay extended from 0.39 to 25 μg/mL (0.93−59.75 μM), as indicated in Figure 3.

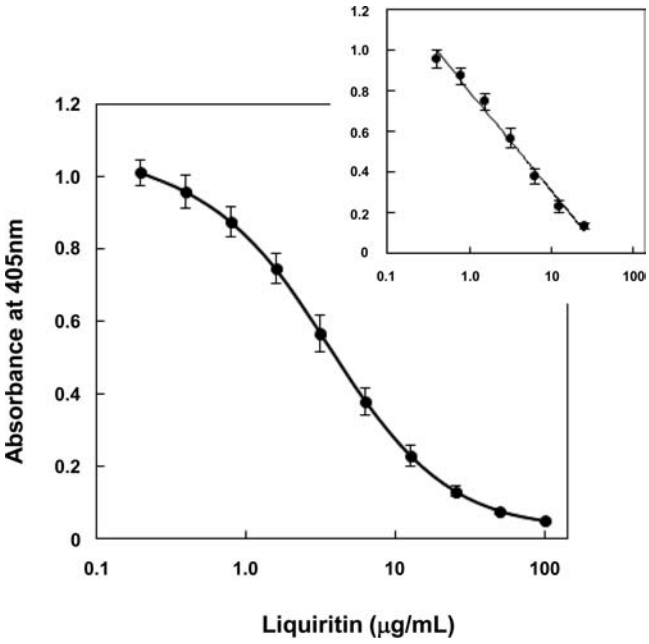

Figure 3. Calibration curve of liquiritin using anti-liquiritin mAb by competitive ELISA.

The cross-reactivities (CRs) of the anti-liquiritin mAb against the structurally related compounds were checked for the evaluation of assay specificity using competitive ELISA. The CRs were calculated and indicated as IC_{50} (μM).

$$IC_{50}\ (\mu M) = \text{concn}\ (\mu M)\ \text{of liquiritin or various structurally related compds yielding}\ A/A_0 = 50\%$$

A is the absorbance in the presence of the test compound, and A_0 is the absorbance in the absence of the test compound.

As indicated in Table 1, the mAb showed that the CRs against hesperetin (IC_{50} = 17.83 μM), liquiritigenin (IC_{50} = 33.09 μM), and naringenin (IC_{50} = 79.41 μM) have a flavanone molecular skeleton (Figure 1). On the other hand, flavones such as flavonols, flavanone, flavanols, isoflavonoids, flavonoid glycosides, and other tested compounds were not recognized by the anti-liquiritin mAb (Table 1). Thus, the hypothesis that the mAb simultaneously recognized the hydroxyl group at the C7 position and the hydrogen at C2 position as essential functions (Figure 1) was formulated.

The anti-liquiritin mAb that was obtained was comparatively recognized by liquiritigenin, and the ELISA that used the anti-liquiritin mAb performed in a linear range from 1.56 to 50 μg/mL (6.09−195.12 μM) for liquiritigenin (date not shown). Thus, the CR against liquiritigenin may have been an unexpected advantage from this experiment because an ELISA can now be developed for aglycone liquiritigenin using the anti-liquiritin mAb. A previous study developed an ELISA system for the aglycone of baicalin, baicalein, using anti-baicalin mAb, which had lower CRs against baicalein.[28]

Table 1. Cross-Reactivities of Anti-liquiritin mAb against Various Compounds

compound	classification	IC_{50} (μM)
liquiritin	flavanone glycoside	8.60
liquiritigenin	flavanone	33.09
hesperetin	flavonoid glycoside	17.83
hesperidin	flavanone	>100
(±)-naringenin	flavanone	79.41
(±)-eriodictyol	flavanone	>100
apigenin	flavone	>100
luteolin	flavone	>100
myricetin	flavonol	>100
quercetin	flavonol	>100
fisetin	flavonol	>100
kaempferol	flavonol	>100
isorhamnetin	flavonol	>100
(−)-epigallocatechin	flavanol	>100
(−)-epicatechin	flavanol	>100
daidzein	isoflavonoid	>100
rutin	flavonoid glycoside	>100
glycyrrhizin	triterpenoid	>100
3-monoglucuronyl-glycyrrhetic acid	triterpenoid	>100
glycyrrhetic acid	triterpenoid	>100
saikosaponin a	triterpenoid	>100
ginsenoside Rb1	triterpenoid	>100
peaoniflorin	monoterpenoid	>100

Assay Variation. The intra-assay (well-to-well) and inter-assay (plate-to-plate) variations were measured with a competitive ELISA because reproducibility and precision are important criteria for an immunoassay. The maximum relative standard deviations (RSDs) of intra-assay and interassay were 4.08 and 5.46%, respectively (Table 2). These results showed that competitive ELISA was accurate and precise for liquiritin.

Table 2. Validations among ELISA Runs for the Analysis of Liquiritin

	CV[a] (%)	
liquiritin (μg/mL)	intra-assay	interassay
0	0.60	3.49
0.39	1.81	1.25
0.78	4.08	1.23
1.56	2.71	3.29
3.13	1.73	4.29
6.25	0.95	3.20
12.50	1.12	5.22
25.00	0.62	5.46

[a]Data are mean ± SD for three replicate wells and three plates for each concentration within one plate from three consecutive days.

Recovery of Liquiritin by Competitive ELISA in Spiked Samples. The recovery experiment confirmed the accuracy of this assay system. Various amounts of liquiritin (25−100 μg) were added to the dried powder licorice root, and the amount of liquiritin was measured by competitive ELISA. The recovery was calculated, and the rates were between 100.9 and 103.7% with low RSD values (0.10−4.02%) as indicated in Table 3.

These results show that an ELISA using the anti-liquiritin mAb can be routinely used for phytochemical investigations involving crude plant extracts.

Table 3. Recovery of Liquiritin Determined by ELISA in Spiked Samples

spiked level (μg)	measured amount[a] (μg)	RSD[b] (%)	recovery[c] (%)
25	323.71 ± 0.31	0.10	102.6
50	348.50 ± 14.00	4.02	100.9
100	401.75 ± 14.12	3.51	103.7

[a]Data are mean ± SD from triplicate analyses for each sample. [b]Relative standard deviation. [c]Recovery (%) = (measured amount − 298.07)/spiked amount × 100.

Correlation of Liquiritin Contents in Licorice Roots Determined by ELISA and HPLC. To confirm the correlation results of liquiritin determination between ELISA and HPLC, the contents of liquiritin in various licorice roots using ELISA and HPLC were also analyzed. The concentrations of liquiritin, as determined by ELISA, were 0.95 ± 0.03, 3.11 ± 0.08, 1.34 ± 0.01, 0.17 ± 0.01, 0.78 ± 0.04, and 2.12 ± 0.08 g/kg dry weight root for samples 1, 2, 3, 4, 5, and 6, respectively. These values and HPLC liquiritin concentrations (concentrations were 0.92 ± 0.01, 3.02 ± 0.10, 1.39 ± 0.06, 0.20 ± 0.01, 0.94 ± 0.02, and 2.73 ± 0.01 g/kg dry weight root for samples 1, 2, 3, 4, 5, and 6, respectively) were similar. The correlation coefficient (R^2) between the analytical value of liquiritin from the ELISA and that from HPLC was 0.948 (Figure 4). This high correlation

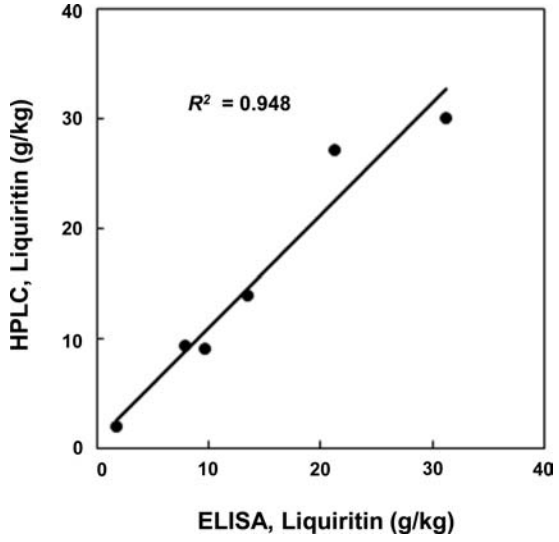

Figure 4. Correlative relationship of liquiritin contents in various licorice roots between the ELISA and HPLC.

indicates that the developed ELISA system could be useful in determining liquiritin in licorice crude extracts without any complicated pretreatments and without the influence of liquiritigenin on this assay system. Furthermore, competitive ELISA was at least 20 times more sensitive for liquiritin than compared with HPLC under the study conditions.

Determination of Liquiritin and Glycyrrhizin in Various Licorice Products for Quality Control Demonstrated by ELISA. Table 4 shows the quantitative analysis results of ELISA for liquiritin and glycyrrhizin in licorice root (Japanese Pharmacopoeia grade) and various foods and drinks

Table 4. Liquiritin and Glycyrrhizin Contents in Various Licorice Products Determined by ELISA[a]

	contents (g/kg)

including licorice. In a previous study, HPLC was most frequently used for liquiritin and/or glycyrrhizin analysis in numerous licorice roots that were used in traditional Chinese/Korean medicine.[14−17,29] Previously, glycyrrhizin and flavonoid concentrations including liquiritin in *Glycyrrhiza* species were determined by HPLC,[30] and licorice roots were applied to the glycyrrhizin ELISA system for quality control.[22] The quality control using both liquiritin and glycyrrhizin ELISA systems was not reported; thus, in this study the quality control of the licorice products was demonstrated by ELISA systems using the anti-liquiritin mAb and anti-glycyrrhizin mAb, respectively.

The calculated glycyrrhizin/liquiritin rate varied from 0.01 to 29.27 in all licorice products except for candies, beverages, and beer, as indicated in Table 4. Japanese Pharmacopoeia (JP) grade licorice root had a glycyrrhizin/liquiritin value of 1.70 that was obtained by ELISA. The difference of the glycyrrhizin/liquiritin value may be caused by the quality of the licorice plants because the liquiritin and glycyrrhizin components fluctuated with collection year and cultivation environment.[31] Furthermore, different licorice processing techniques and various preparation methods of licorice products could have affected the amount of glycyrrhizin/liquiritin in the licorice. Therefore, determining the amount of liquiritin in the licorice plants and products was necessary for quality control just as glycyrrhizin analysis of the Japanese Pharmacopoeia was regulated and reported by previous studies.[19,23−25,32]

Because licorice is used worldwide as a natural sweetener for food, it is an important herbal plant.[1] Liquiritin is one of the major flavonoid glycosides in licorice and is employed as a quality control marker for licorice in foods and phytochemical products because it has a variety of pharmacological activities.[2−8] Various analytical methods that have used chromatography have been reported;[14−17,29] however, an antibody-based immunochemical assay system has not been established for liquiritin in licorice plants and products.

In this study, an established 2F8 hybridoma cell line secreted mAb reactive to liquiritin, and an ELISA system using anti-liquiritin mAb was developed. Validation of ELISA confirmed its sensitivity, reproducibility, and accuracy from various validation experiments, and a correlation coefficient (R^2) of 0.948 was obtained between the ELISA and HPLC methods. The newly established immunochemical approach compared with instrumental analysis such as HPLC uses less organic solvent and is a cleaner analytical system; thus, the new immunochemical approach is better for the environment. Furthermore, an advantage of the developed ELISA system is that it can be directly applied to impure samples such as crude extracts and licorice products because complicated pretreatments are not necessary for the new system. These results show that ELISA can be a simple, fast, and convenient high-throughput analysis for numerous licorice samples and may apply to a small amount of analytical target samples.

In conclusion, the ELISA that was established in this study is a very useful technique for samples with many impurities such as crude extracts from the licorice root and its final products including functional foods that contain several hundred components. Moreover, the ELISA system can be useful for analyzing liquiritin in the manner that glycyrrhizin was analyzed in phytochemical products and medicine. There have been no previous papers indicating an immunoassay system for liquiritin; thus, this is the first time that an immunoassay system for liquiritin has been developed.

adapted to a microplate method[20] for the determination of proline in biological fluids. More recently, an isatin method for the determination of proline in grape juice was reported.[21] This method was robust for the analysis of end of fermentation samples and table wines and was linear over the concentration range 0−200 mg/L. However, the method involves an evaporation step and, as a result, interference from sugar concentrations >60 g/L was such that proline concentrations were considerably underestimated in grape juice.

The purpose of this study, therefore, was to revisit both methods to devise a simpler spectrophotometric method without the need for evaporation, as in the isatin method cited above, or the extraction step required with traditional ninhydrin methods. The final method developed is based on the ninhydrin reaction in strongly acidic conditions under which other amino acids do not interfere. Furthermore, relative volumes and the solvents were selected such that the need to extract the derived reaction product is obviated. The method was validated statistically, and results for 13 grape juice samples were compared with the HPLC−ninhydrin method for amino acid analysis. It was then applied to the determination of proline accumulation in microvine berries at all stages of development from fruit set to maturity.

MATERIALS AND METHODS

Reagents and Chemicals. All chemicals were of analytical grade or better, and freshly distilled water stored in a glass container was used for all experiments. Methanol, ethanol, dimethyl sulfoxide, glucose, and acetic, tartaric, malic, and formic acids were obtained from Carlo Erba, Val de Reuil, France. Individual amino acids (Ala, Asn, Arg, Asp, GABA, Glu, Glm, Ile, Leu, Lys, Met, Pro, Ser, Thr, Val) were obtained from Sigma-Aldrich (St Quentin-Fallavier, France). Isatin and ninhydrin were obtained from Fluka, France. Malvidin-3-glucoside was obtained from ExtraSynthèse, France.

Solutions. A synthetic grape juice was prepared containing 200 g/L glucose, 6 g/L malic acid, 8 g/L tartaric acid, and, for studies for the potential interference by anthocyanins, 250 mg/L malvidin 3-glucoside.

Stock solutions of 1 g/L of each of the amino acids were prepared in 0.1 M HCl and stored at −20 °C when not in use. Standard solutions of proline were prepared by serial dilution of the stock solution. A working mixture was prepared in water or synthetic grape solution containing typical concentrations of the principal grape amino acids: Ala, Asn, Glm, Ser, GABA, 100 mg/L; Arg, 500 mg/L; Asp and Glu, 150 mg/L; and 10 mg/L of the other amino acids.

Plant Material. The ML1 microvine that was used in this study shows a dwarf stature and produces inflorescences all along the main axes in the place of tendrils. This phenotype has been proposed as a new model for research in grapevine genetics and ecophysiology.[22−24] To study the proline accumulation pattern in berries of these plants, 10 plants were grown under controlled conditions in climate chambers under constant day/night temperatures (30/22 °C) for 3 months. All reproductive organs along the main axes from berry set to maturity were successively sampled within 2 h and immediately frozen in liquid nitrogen.

Determination of Proline by the Ninhydrin Method. Ground sample powder was diluted 5-fold with deionized water and frozen at −20 °C until analysis. Reconstituted samples were thawed and centrifuged at 3000*g* at 4 °C for 10 min. The supernatant was further diluted (5−20 times depending on the stage of development); 750 μL of the diluted sample was added to the same volume of formic acid and vortex-mixed for 2 min. A 750 μL aliquot of ninhydrin 3% in dimethyl sulfoxide (freshly prepared daily) was then added, and following vortex mixing, the reaction mixture was heated at 100 °C in a heating block for 15 min. The absorbance at 520 nm of the resultant salmon pink reaction product was then read on a Biochrom (UK) Libra S12 spectrophotometer. Concentrations were calculated by interpolation on a linear regression curve in the concentration range of 2.5−15 mg/L.

Validation. Calibration standards at five concentration points (2.5, 5, 7.5, 10, and 15 mg/L) were prepared in diluted (1 in 5) synthetic grape juice spiked with the analyte mixture. Standard calibration curves were obtained from unweighted least-squares linear regression analysis of the data. The slope and intercept of the calibration graphs were determined through linear regression of the absorbance versus concentration plot. Individual absorbances were then interpolated on the calibration graphs to determine the found (back-calculated) concentrations. The quality of fit was determined using back-calculated-to-nominal concentrations, and the "lack of fit" test was used to confirm the linearity of the method. Within-day and between-day precision and accuracy of the method were determined by carrying out replicate analyses of the calibration standards. Repeatability was determined by preparing and analyzing each calibration standard four times within a single day (i.e., 20 standards in total) under the same operating conditions. The intermediate precision was determined by carrying out the same operations over 4 days under different operating conditions (different reagents and materials). The precision was given by mean relative standard deviation of the absorbance values, and the accuracy of the method was evaluated as 100 × [mean found concentration/nominal concentration]. The method was cross-validated by comparing the results obtained by this method with those obtained for the same samples by the classic HPLC post-column derivatization with ninhydrin method.

Sugar and Organic Acid Analysis. Hexoses (glucose and fructose) and organic acids (malic, tartaric, citric, and shikimic acid) were determined in a single HPLC injection. The same (5-fold diluted) samples as were used for proline were further diluted 20-fold with 4.375 μM acetate as internal standard. To avoid potassium bitartrate precipitation, 1 mL of diluted sample was mixed with 0.18 g of Sigma Amberlite IR-120 Plus and agitated in a rotary shaker for at least 10 h before centrifugation (13000 rpm for 10 min). The supernatant was transferred into HPLC vials before injection on an Aminex HPX87H column eluted in isocratic conditions (0.05 mL min^{-1}, 60 °C, H_2SO_4).[25] Organic acids were detected at 210 nm with a Waters 2487 dual absorbance detector (Waters Corp., Milford, MA, USA). A refractive index detector Kontron 475 (Kontron Instruments, Rossdorf, Germany) was used to determine fructose and glucose concentrations. Concentrations were calculated according to a previously described method.[26]

RESULTS AND DISCUSSION

Method Development. Boctor[27] demonstrated that the reaction between isatin and proline is suitable to quantitatively determine proline in a protein hydrolysate and biological fluids. It is a highly specific color reagent for proline, forming a blue derivative, pyrrole blue. The technique adopted in this study was as previously described.[21] A 50 mg/L standard (100 μL) was diluted with citrate buffer (0.5 M, pH 4.1, 100 μL). Then 250 μL of a 0.075% (w/v) solution of isatin in acetone (250 μL) and ethanol (500 μL) was added. The tubes were evaporated to dryness in a heating block at 100 °C. The blue proline−isatin residue obtained was dissolved in aqueous 3 mL of acetone/water (2:1, v/v) and the absorbance of the resulting solution measured at 595 nm. This resulted in an absorbance reading of 0.37. Different permutations on the relative volumes and concentration of isatin (increasing to 0.3%) were investigated to obtain an increase in absorbance. However, the results proved inconclusive; it appeared that different absorbance values were obtained depending on the length of time it took the solvents to evaporate in the heating block, and it was difficult to obtain repeatable readings. Furthermore, when applied to real grape juice samples, absorbance reading were <0.1, and so it was concluded that the method would not be sufficiently sensitive for the intended purpose.

The reaction of ninhydrin with primary amino groups to form the purple dye known as Ruhemann's purple was discovered by Siegfried Ruhemann in 1910[28] and has been extensively used in amino acid analysis in a multitude of areas. Upon heating in an alkaline medium with substances containing primary amino groups ($-NH_2$), ninhydrin yields a product with a stable deep blue-violet color, with maximum absorption at about 570 nm. Under the same conditions, proline and hydroxyproline yield a yellow color. In 1952, Chinard[29] reported that at acidic pH, ninhydrin forms a red product with proline. A similar assay was described by Bates,[30] and it became the standard method for many laboratories to determine proline. In this context, the determination is performed according to the modification of the Bates method in which the formed derivative is extracted from the acid aqueous solution with toluene and measured at 520 nm. Wallrauch[31] found that the use of ethyl acetate to extract the color produced by the acidic ninhydrin reaction was necessary for highly colored juices with low proline content. Ough[32] proposed an improved procedure to analyze proline in grape juice and wine in which the extraction step was replaced by a dilution during cooling with water/isopropanol. No significant interferences from other amino acids were found in amounts normally present in these matrices. A further variation on that method was applied to the determination of proline in orange juice,[33] and a similar approach was adopted in the present study, in which dimethyl sulfoxide was used as a solvent for ninhydrin. The challenge that remained was to ensure that the highly water-insoluble reaction product remained in solution to obviate the need for extraction or further dilution. Therefore, the relative volumes of sample, formic acid, and 3% ninhydrin reagent in dimethyl sulfoxide, in addition to the concentration range, were optimized for this purpose. The final operating conditions are given under Materials and Methods. Initial experiments with proline in the concentration range of 50−100 mg/L resulted in a pink precipitate in a solution of the same color. The concentration range was reduced to the low milligrams per liter (2.5−15 mg/L) range, which provided a linear absorbance response as a function of concentration. The developed method, which requires neither extraction nor

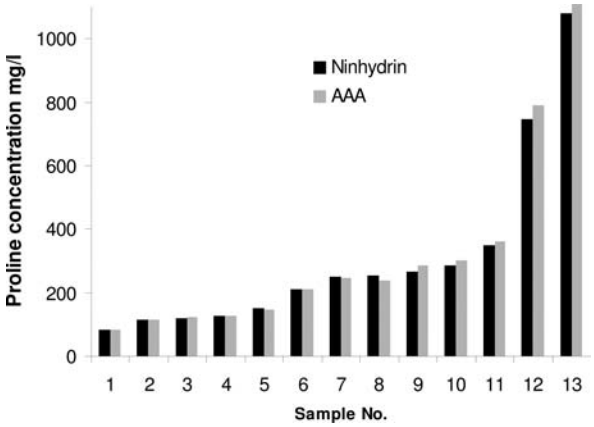

Figure 2. Histogram of proline concentrations obtained by using the proposed method and by using amino acid analysis.

dilution of the reaction product, was fully validated and a systematic study of matrix interferences is reported.

Interference Study. Different authors have reported various sources of interferences with the proline−ninhydrin assay, including high concentrations of sugars[34] and diverse amino acids.

Potential Interference from Sugars and Other Grape Juice Components. The sensitivity of the present method is such that the grape juice samples are diluted from 5- to 20-fold, resulting in final sugar concentrations of 10−40 g/L, concentrations that have not been reported to interfere with the assay. However, to verify this, a stock solution of 300 mg/L proline was prepared in synthetic grape juice (composition given under Materials and Methods). This solution was diluted 1 in 20, analyzed according to the developed method, and compared with an aqueous proline solution at 15 mg/L. Measured against blanks of synthetic grape juice or water, respectively, and subjected to the same reaction, the absorbances (n = 5) were not significantly different between the two groups. In all cases the blank (Supporting Information Supplemental Figure 1) is a pale yellow color with an absorbance of approximately 0.03.

Potential Interference from Other Amino Acids. Certain basic amino acids, such as ornithine, were reported by Chinard[29] to give colored products when heated with ninhydrin at low pH. With the exception of proline, the other commonly naturally occurring amino acids did not react significantly under these conditions. Given that in the grapevine, levels of these amino acids are substantially lower than those of proline, interference by these amino acids is likely to be negligible. Nonetheless, a mixture of amino acids at concentrations typical of grape juice was prepared in synthetic grape juice, diluted 20-fold with distilled water, and subjected to the assay. The result (Supporting Information Supplemental Figure 2) is a pale yellow solution, which gave an absorbance comparable to that of blank synthetic grape juice at approximately 0.03. It may thus be concluded that the other amino acids at typical grape juice concentrations do not interfere with proline determination by this assay.

Potential Interference by Anthocyanins. A potentially serious interference in this assay arises from anthocyanins (which strongly absorb at 520 nm) in red grape juice, an issue that as not been addressed in previous papers. Even diluted 20-fold, once formic acid is added to the grape juice sample, the intensely colored cation flavinium form of the anthocyanins is generated, thus increasing the intensity of the red color of the sample. Initially, carbon black was used with considerable success to remove the coloring matter, but it was found also to remove an unacceptably high amount (>10%) of proline. This observation is borne out in the literature.[35] Other adsorbents such as PVPP were found to be less effective in removing the coloring matter or also removed some proline, although to a lesser extent than carbon black. Another approach adopted was to evaluate the extent of interference by anthocyanins in the assay as it had been observed that the pink-purple color of the sample before the addition of the ninhydrin and heating transformed into the characteristic salmon pink of the proline−ninhydrin adduct after heating (Supporting Information Supplemental Figure 1).

Therefore, malvidin-3-glucoside was added to blank synthetic grape juice at a concentration of 250 mg/L; following 20-fold dilution and addition of formic acid, one sample was heated with ninhydrin in dimethyl sulfoxide and another with dimethyl sulfoxide only. The latter sample retained its color, whereas the color of the former was transformed to a pale yellow, the same color as is obtained with the blank (Figure 1). It therefore appears that ninhydrin reacts with anthocyanins in such a manner as to render them colorless. This reaction has not previously been reported in the literature and is currently under further investigation.

Validation. Calibration standards at five concentration points (2.5, 5, 7.5, 10, and 15 mg/L) were prepared in diluted

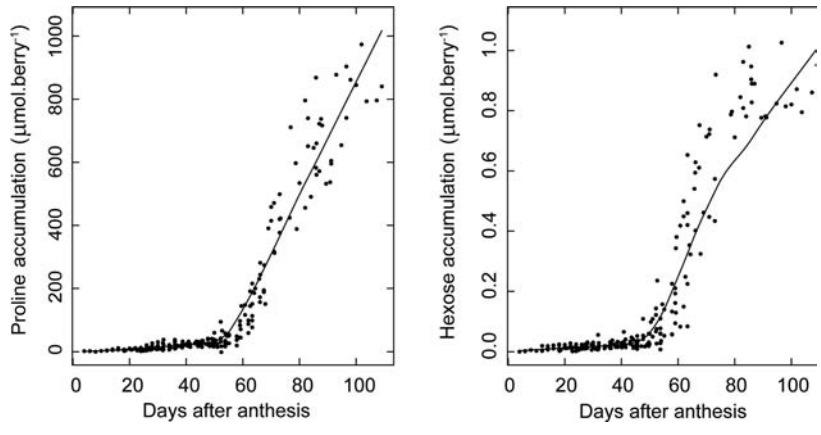

Figure 3. Proline and sugar accumulation in microvine berries. Lines are LOESS fits.

dx.doi.org/10.1021/jf404627n | J. Agric. Food Chem. 2014, 62, 3384−3389

(1 in 20) synthetic grape juice spiked with the analyte mixture. The repeatability or intraday precision is presented in Table 1. As may be seen, the intraday precision varies from <2% RSD to a maximum of 5.9%. The "lack of fit" test showed no significant deviation from linearity; the bias, calculated as the sum of the residuals (nominal − back-calculated concentration) was nonsignificant (t test P = 20.23%). Linear regression of the back-calculated-to-nominal concentrations provided a slope of 1.0013 and an intercept of −0.049. The accuracy of the method was evaluated as 100 × (mean found concentration/nominal concentration) as may be seen from Table 1, and percent difference between the nominal and back-calculated concentrations was in general <5%. The intermediate (interday) precision is presented in Table 2, and RSD values range from 2.03 to 3.59%. Although the limit of detection was not determined, it may be estimated at 1 mg/L given that 2.5 mg/L gives an absorbance of >0.2 and the blank (sample replaced by water) absorbance is 0.03.

Results obtained by this method for 13 grape juice samples were compared with those obtained for the same samples on a dedicated amino acid analyzer. Figure 2 shows a histogram of the values obtained by the two methods; the agreement is close (r = 0.99), thus adding further evidence of the utility of this new high-throughput method for the determination of proline in grapevine samples.

Application. As part of a cross-disciplinary project[36] to characterize the transcriptome and to map physiological and biochemical characteristics of the microvine berry, this method was applied to study the accumulation pattern of proline and compare it to those encountered in field-grown perennial macrovines.

The DRCF (dwarf, rapid cycling, and continuous flowering) microvine phenotype, discovered by Franks et al. in 2002,[37] shows dwarf stature and produces inflorescenes all along the main axes in place of tendrils. It has been demonstrated that this new material is suitable for genetic research[38] and can be grown under confined conditions in climate chambers.[23] The sugar content of DRCF berries was determined as described under Material and Methods.

As may be seen in Figure 3, both the proline and sugar accumulation patterns are similar to those encountered for classical field-grown vines. In fact, proline concentrations at close to maturity (approximately 1 mmol hexoses (g FW)$^{-1}$) were of the same order of magnitude as commonly found in other *Vitis vinifera* varieties (0.688 μmol (g FW)$^{-1}$ for Riesling up to 1794 μmol (g FW)$^{-1}$ for Cabernet Sauvigon).[39] Furthermore, this parallel between the accumulation of sugars and proline was also reported in the above reference, and the authors even suggested that the accumulation of proline may be a result of increased osmotic pressure arising from increased sugar concentration on the basis of the fact that proline is known to exercise an osmoprotective effect.

Given the reliability, precision, and ease of operation of this method, it could be envisaged for use in high-throughput analysis, such as in studies into the response of the grapevines (or indeed other fruiting plants and trees) to climate change, irrigation, N fertilization, etc. It could also be useful in screening fruit populations for adaptation to abiotic stress and, with appropriate extraction methods, in the analysis of proline accumulation in other plant parts.

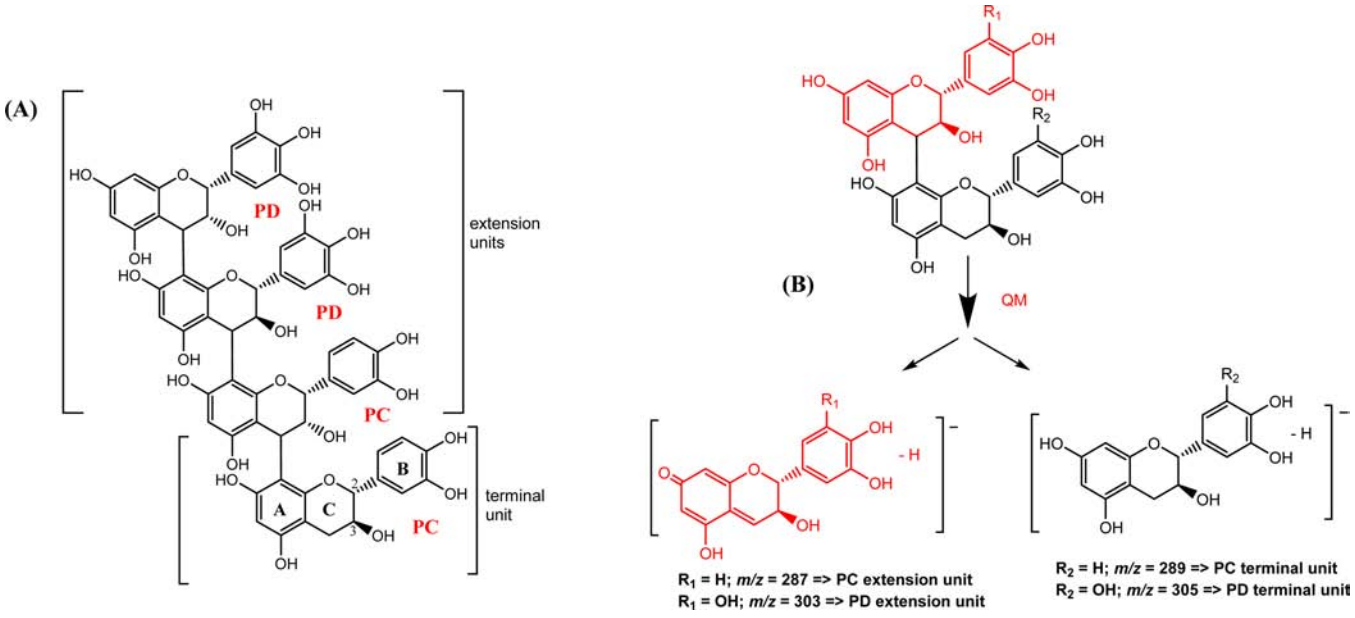

Figure 1. Model structure of a proanthocyanidin tetramer containing two prodelphinidin (PD) and two procyanidin (PC) units (A) and quinone methide fragmentation of proanthocyanidin dimer in negative ion mode ESI-MS (B).

relatively large amounts of plant tissue, in the range of hundreds of milligrams, for analysis.[17−19]

The development in LC-MS/MS instruments has been vast in recent years,[20−22] and the use of ultraperformance liquid chromatography combined with a mass spectrometer (UPLC-MS/MS) is becoming common also in proanthocyanidin studies.[23] UPLC enables rapid chromatography of different kinds of proanthocyanidin oligomers, whereas MS/MS fragments compounds into proanthocyanidin-specific precursor and product ions for detection with multiple reaction monitoring (MRM) methods. Specific fragmentations, that is, compound-specific methods, have been widely used for the identification and quantitation of relatively small proanthocyanidin oligomers.[23−25] However, no compound-specific methods have been reported for larger oligomers or proanthocyanidin polymers as the limit has been with tetramers.[23−26] Furthermore, to our knowledge, no group-specific method for the qualitative and quantitative determination of all proanthocyanidin sizes in plant samples has been reported. The present study explored the potential of UPLC combined with a triple-quadrupole mass spectrometer (TQ-MS) for the rapid qualitative and quantitative analyses of proanthocyanidins. Our main interest was in establishing a fast, sensitive, and selective method for the analysis of the two most common proanthocyanidin types: procyanidins and prodelphinidins.

MATERIALS AND METHODS

Chemicals and Reagents. LC-MS grade acetonitrile used in the UPLC analyses was from Sigma-Aldrich (Steinheim, Germany). Formic acid was from VWR (Helsinki, Finland). Water was purified with a Millipore Synergy water purification system (Merck KGaA, Darmstadt, Germany). Catechin was from Sigma (Sigma Chemical Co., St. Louis, MO, USA) and epigallocatechin from ExtraSynthese (Genay, France).

Materials. Pure compounds gallocatechin gallate, proanthocyanidin dimers and trimers, mixture of oligomers, and mixture of polymers (not fractions 1-F−13-F) used in optimization of cone voltages and collision energies were produced as described in Karonen et al.[17] Proanthocyanidin fractions 1-F−13-F were extracted from different plant materials with 70% aqueous acetone and subjected to Sephadex LH-20 column chromatography. F1 fractions were eluted with acetone/water (30:70, v/v) and F2 fractions with acetone/water (50:50, v/v). The procyanidin proportions of the fractions varied from 1 to 95% and the mDP from 2 to 14 (by thiolysis). The plant materials, fractions, and results from thiolysis are listed in Table 1.

Thiolysis. Thiolysis was carried out as described in Gea et al.[18]

HCl-Butanol Assay. A 0.1 mL aqueous solution of fractions 5F−13F (0.5 mg/mL) was added to 0.5 mL of a freshly prepared mixture of 1-butanol/hydrochloric acid (95:5 v/v) in 1.5 mL Eppendorf tubes. Tubes were locked with Eppendorf tube locks and vigorously mixed by hand. After mixing, tubes were placed in an oven at 95 °C for 2.5 h. Tubes were then cooled to room temperature, and the absorbance at 550 nm was measured using a Multiskan Ascent microplate photometer (Thermo Fisher Scientific, Shanghai, China). Standard curves were constructed using known concentrations of procyanidin-rich sample 1-F2 and prodelphinidin-rich sample 9-F2 in H_2O. Dilution range was from 5.0 to 0.1 mg/mL. Five replicates of each sample were run. Because the HCl-butanol assay measures only total proanthocyanidins and cannot separate procyanidins from prodelphinidins, the results were calculated by using the average calibration curve obtained from procyanidin and prodelphinidin standards separately.

UPLC-MS/MS Analysis. Sample analysis was carried out with an Acquity UPLC system (Waters Corp., Milford, MA, USA) coupled with a Xevo TQ triple-quadrupole mass spectrometer (Waters Corp., Milford, MA, USA). The UPLC system consisted of a sample manager, a binary solvent manager, a column, and a diode array detector. The column used was a 100 mm × 2.1 mm i.d., 1.7 μm, Acquity UPLC BEH Phenyl column (Waters Corp., Wexford, Ireland). The flow rate of the eluent was 0.5 mL/min. The elution profile used two solvents, acetonitrile (A) and 0.1% aqueous formic acid (B): 0−0.5 min, 0.1% A in B; 0.5−5.0 min, 0.1−30% A in B (linear gradient); 5.0−6.0 min, 30−35% A in B (linear gradient); 6.0−9.5 min, column wash and stabilization. UV and MS data were collected from 0 to 6 min. Negative ionization mode was used for MS analyses. ESI conditions were as follows: capillary voltage, 2.4 kV; desolvation temperature, 650 °C; source temperature, 150 °C; desolvation and cone gas (N_2), 1000 and 100 L/h, respectively; and collision gas, argon. Catechin (1 μg/mL) was used to monitor the stability of the ionization efficiency of the mass spectrometer.

Optimization of Cone Voltages and Collision Energies. When optimizing the cone voltages and the collision energies for the selected compounds and fractions, aqueous solutions of different proantho-

[a]F1 fractions were eluted with acetone/water (30:70; v/v) and F2 fractions with acetone/water (50:50; v/v); sample 3-F1 was passed through the Sephadex column twice; F1b after the second Sephadex purification. % PC, procyanidin concentration from total proanthocyanidin concentration as percent by thiolysis; mDP, mean degree of polymerization by thiolysis.

cyanidins were directly infused into the ESI source with a syringe pump at a flow rate of 5−40 μL/min. The concentrations of the aqueous proanthocyanidin solutions were 40 μg/mL for pure compounds and 2 mg/mL for proanthocyanidin-rich fractions. The ranges of cone voltage and collision energy varied between 10 and 170 V and between 5 and 50 eV, respectively.

Calibration Curves for Procyanidin and Prodelphinidin Contents. Solutions for calibration curves were produced from stock solutions (1.0 mg/mL) of procyanidin-rich sample 5-F2 (procyanidin content = 95%, determined by thiolysis) and prodelphinidin-rich sample 13-F2 (prodelphinidin content = 98%, determined by thiolysis) by dilution with acetonitrile/water (20:80, v/v). The dilution range was from 1.0 to 0.01 mg/mL.

Limit of Detection, Limit of Quantitation, and Linearity. Procyanidin and prodelphinidin dimers were used for determination of the limit of detection (LOD) and limit of quantitation (LOQ) for the presented MRM method at signal-to-noise ratios (S/N) >3 and >10, respectively. Dilution series were prepared from stock solutions of 40 μg/mL and diluted with H_2O. The dilution range was from 40 μg/mL to 0.019 ng/mL. Three replicates of each sample were run.

RESULTS AND DISCUSSION

Optimization of the MRM Methods. On the basis of the quinone methide cleavage theory (Figure 1B), both terminal and extension units of procyanidins and prodelphinidins yield different fragments,[4,27,28] and it was hypothesized that it would be possible to develop separate MRM methods for the specific detection of these fragments. To optimize MRM methods for the qualitative and quantitative analyses of procyanidin and prodelphinidin units of proanthocyanidins, direct flow injection experiments of the reference compounds were performed in both positive-ion and negative-ion modes. The reference compounds consisted of different proanthocyanidin monomers and oligomers, as well as semipurified mixtures of proanthocyanidin oligomers and polymers (fractions 1-F1−4-F2) (Table 1). Negative mode was superior to positive mode in terms of sensitivity, particularly for the terminal units (Figure 2) and, thus, negative-ion mode was selected to be used in the MRM methods.

As previously reported,[4,27,29,30] both procyanidin and prodelphinidin units of proanthocyanidins yielded two different types of ions in the collision-induced MS analysis depending on whether they represented the extension or terminal units of the

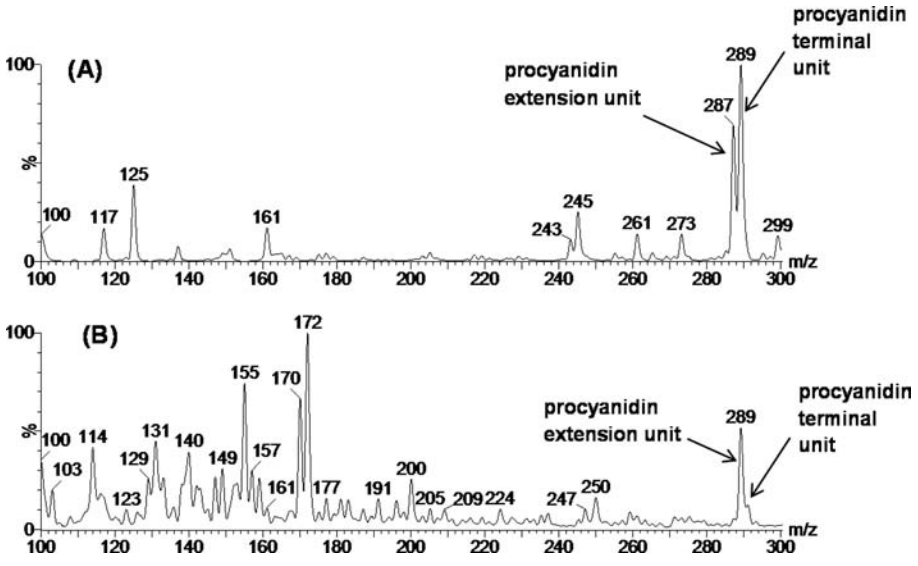

Figure 2. Detection of extension and terminal units of procyanidin trimer with negative-ion mode (A) and positive-ion mode (B).

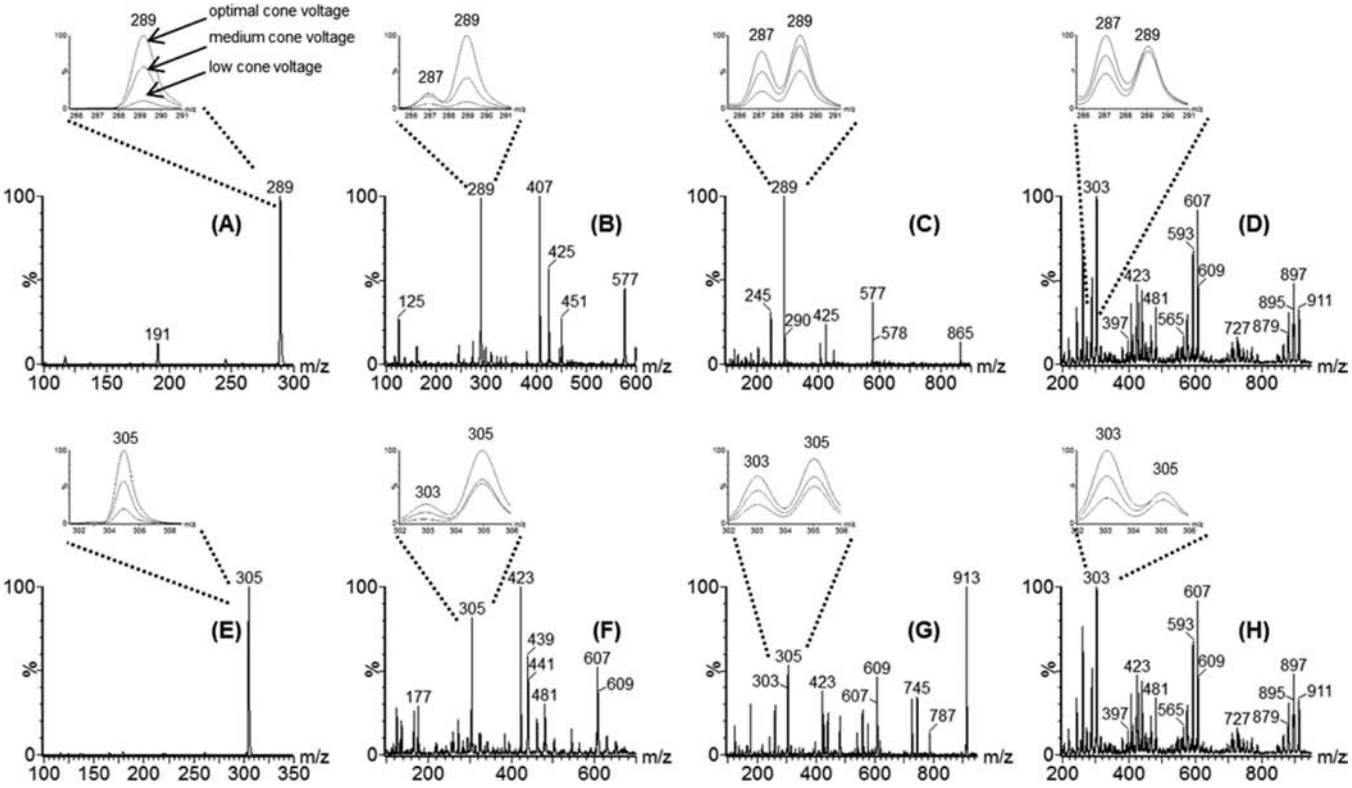

Figure 3. Mass spectra of proanthocyanidin monomers, dimers, trimers, and polymers obtained by in-source fragmentation: (A) catechin; (B) procyanidin dimer; (C) procyanidin trimer; (D) sample 1-F2; (E) epigallocatechin; (F) prodelphinidin dimer; (G) prodelphinidin trimer; (H) sample 1-F2. The insets show how the intensities of the extension units (m/z 287 and 303) and terminal units (m/z 289 and 305) change due to shifts in cone voltage. See Table 1 for fraction identities.

corresponding proanthocyanidin molecule (Figure 1B). For procyanidins the characteristic ions formed via quinone methide cleavage were m/z 287 and 289 and for prodelphinidins m/z 303 and 305, respectively. Also, ions formed by retro-Diels–Alder and heterocyclic ring fission mechanisms were detected at low intensity, but because these do not give specific information of proanthocyanidin extension and terminal units, they were not included in the MRM development section.

Figure 3 shows a comparison of the mass spectra of monomeric, dimeric, and trimeric procyanidins and prodelphinidins and oligomeric procyanidin/prodelphinidin mixture (sample 1-F2) with direct flow infusion into the MS. The zoomed m/z areas present results obtained with low, medium, and optimal cone voltages. In all cases the optimal cone voltage resulted in highest response and, correspondingly, the low cone voltage in lowest response. Catechin and epigallocatechin monomers yielded only ions at m/z 289 and 305, respectively. The other proanthocyanidin samples yielded ions at both m/z 287 and 289 for procyanidins and m/z 303 and 305 for prodelphinidins. The intensity of ions at m/z 287 and 303 increased as the degree of polymerization of the proanthocyanidin molecule increased, suggesting that the intensity of these ions in MS analysis was related to the number of extension units present in the original proanthocyanidin structure.

The cone voltage optimization experiments revealed that the larger the proanthocyanidin, the higher the cone voltage required to produce maximal ion intensities for the proanthocyanidin fragments. For monomers the optimal cone voltage was 30 V for ions at m/z 289 and 305. For dimers the optimal cone voltages were 50, 60, 60, and 55 V for ions m/z 287, 289, 303, and 305, respectively. Similar cone voltages have been also previously proposed for these fragmentations of the proanthocyanidin dimers and trimers.[31] For the proanthocyanidin fractions containing both oligomers and polymers, the optimal cone voltages ranged from 100 to 150 V. In general, the optimal cone voltage required for prodelphinidins was higher than that for procyanidins and higher for extension units (ions at m/z 287 and 303) than for terminal units (ions at m/z 289 and 305). These results indicate differences in the collision-induced dissociation of different types of proanthocyanidin molecules and that high energy is required to fragment as many extension units as possible.

The results from these experiments suggested that a single cone voltage cannot be used for the optimal detection of all types of proanthocyanidins. Therefore, the choice of an optimal cone voltage is not straightforward; the ideal cone voltage is highly dependent upon the size, composition, and structure of the analytes of interest. For example, when only small proanthocyanidins are studied, increasing the cone voltages beyond the optimum induces fragmentation before the ions enter the mass filter, resulting in a decrease in sensitivity. In contrast, when proanthocyanidin oligomers and polymers are studied, use of a too low cone voltage would lead to poor fragmentation of the original molecule and thus low sensitivity for the detection of the terminal and especially extension units. This in turn would cause underestimation of the concentrations of the oligomers and polymers.

Enhanced selectivity and sensitivity of the method is achieved by collision energies separately optimized for product ions of the specific procyanidin and prodelphinidin units. Such an approach allows the accurate qualitative and quantitative

Table 2. Cone Voltages and Collision Energies in the New MRM Method for the Detection of Procyanidin (PC) and Prodelphinidin (PD) Terminal and Extension Units

[a]CV, cone voltage.

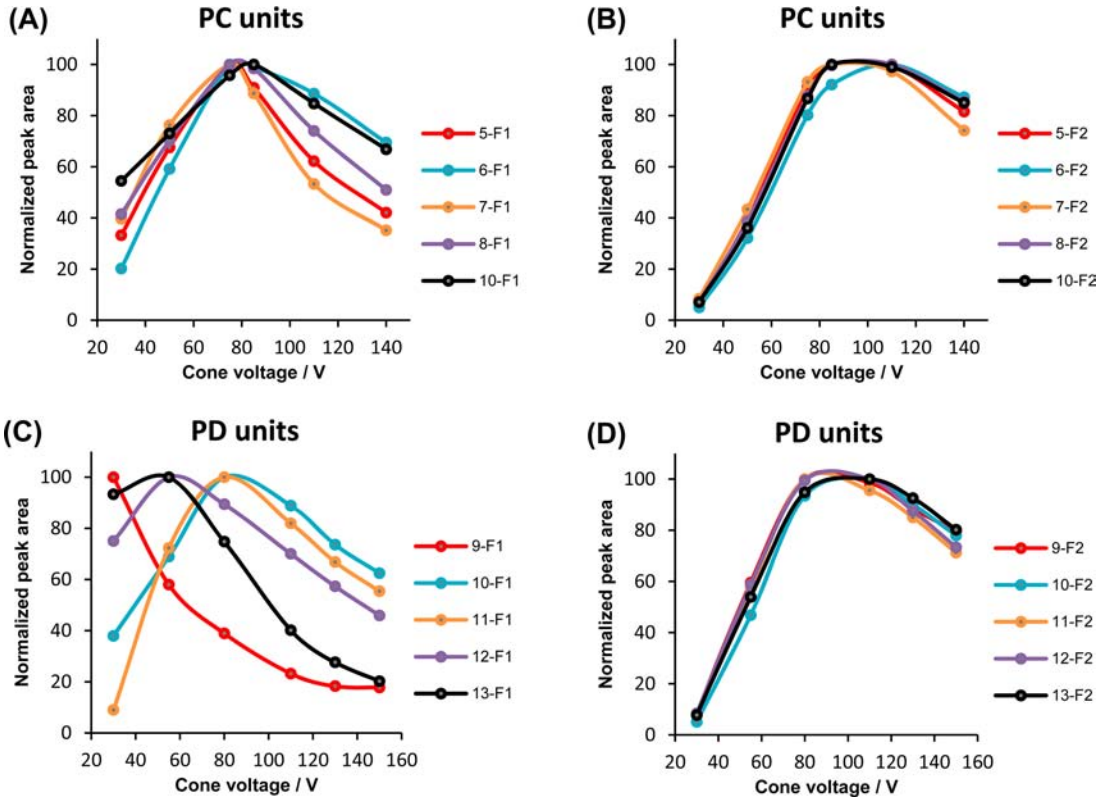

Figure 4. Normalized peak areas from the MRM chromatograms of procyanidin (PC) units (sum of procyanidin terminal and extension units) and prodelphinidin (PD) units (sum of prodelphinidin terminal and extension units) obtained with F1 fractions containing smaller proanthocyanidins (A, C) and F2 fractions containing larger proanthocyanidins (B, D). See Table 1 for fraction identities.

analyses of complex proanthocyanidins directly from plant crude extracts. In contrast to identifying optimal cone voltages, the choice of optimal collision energy was straightforward. The product ions produced from the ions derived from terminal and extension units always had the same optimal collision energy. The optimal collision energy for both transitions m/z 287 → 125 and 289 → 245 was 15 eV. For both transitions of m/z 303 → 125 and 305 → 125 the optimal collision energy was 20 eV. On the basis of the results from cone voltage and collision energy optimizations, one MRM method containing six different cone voltages for each terminal and extension unit ion and one optimal collision energy for the accumulation of the unit-specific product ions was developed (Table 2).

In previous studies, cone voltages and collision energies have been used for the optimization of separate MRM methods for small proanthocyanidin oligomers[32,32−36] and for studying the fragmentation patterns of proanthocyanidins.[22,37,38] No compound-specific MRM methods have been reported for larger proanthocyanidin oligomers or polymers as the limit has been with tetramers.[23−25,31] This highlights the novelty of our approach: to our knowledge, no previous study has used UPLC-MS/MS with a range of cone voltages and optimized collision energies for the detection of extension and terminal units and thus for the detection of total oligomeric and polymeric proanthocyanidins.

Effect of Optimized Cone Voltages and Sample Composition on Peak Areas. After optimization of MRMs, the new method was rigorously tested with an independent set of 18 structurally diverse proanthocyanidin fractions (5-F1−13-F2) prepared from nine plant species; the proportion of procyanidin units in these fractions ranged from 1 to 95% and mDP ranged from 2 to 10 (Table 1). Figure 4 shows the normalized peak areas for all 18 proanthocyanidin fractions plotted as a function of cone voltage. For better visual clarity, peak areas (a sum of terminal and extension units) for procyanidin-derived ions are shown for only the five procyanidin-richest fractions in Figure 4A,B. Similarly, peak areas (a sum of terminal and extension units) for prodelphinidin-derived ions are shown for the five prodelphinidin-richest fractions in Figure 4C,D.

For every F1 fraction, the largest procyanidin peak areas were detected with 75−80 V (Figure 4A). However, the profiles of

dx.doi.org/10.1021/jf500745y | J. Agric. Food Chem. 2014, 62, 3390−3399

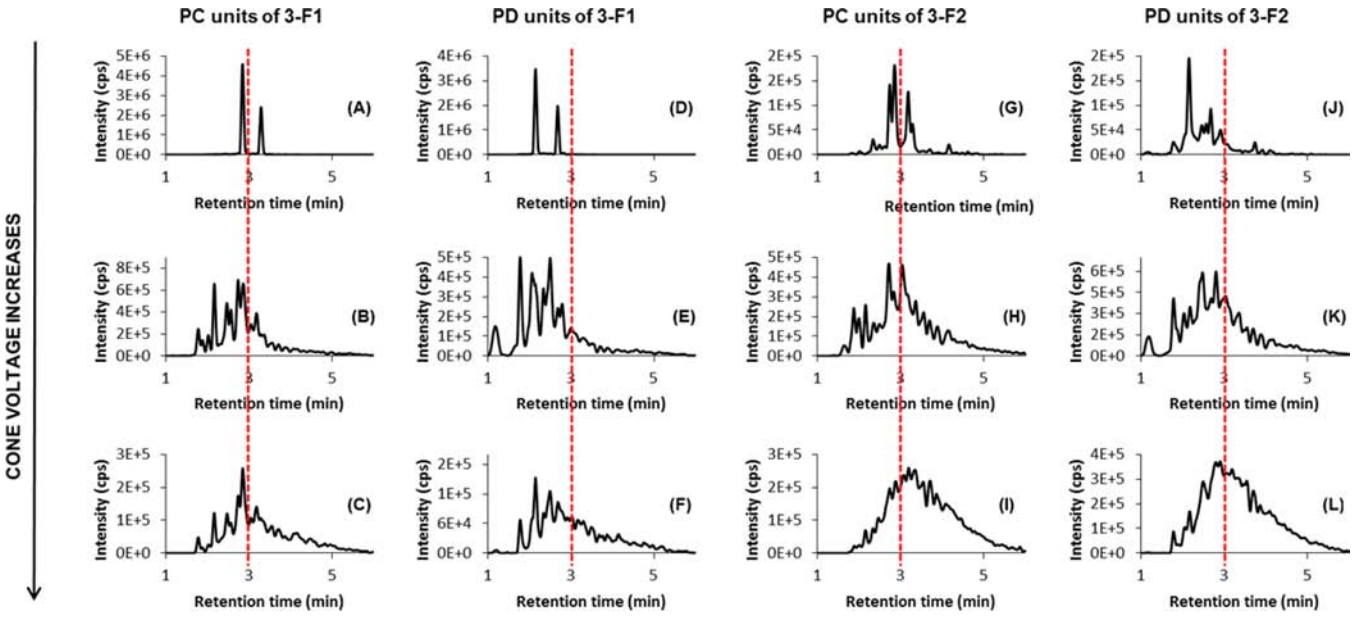

Figure 5. MRM chromatograms of procyanidin (PC) and prodelphinidin (PD) units for samples 3-F1 and 3-F2 (see Table 1) obtained with cone voltages of 30 V (A, D, G, J), 80 V (B, E, H, K), and 140 V (C, F, I, L).

the plots differed a little. In general, when the cone voltage increased beyond the optimal, the peak areas decreased more rapidly with samples having low mDP. This is in agreement with the earlier findings showing that smaller proanthocyanidins require lower cone voltages for their optimal detection.[31] In contrast, the procyanidin response of the larger proanthocyanidins of the F2 fractions did not significantly decrease even though the cone voltage was increased from 80 to 140 V (Figure 4B). This again confirmed the presence of larger proanthocyanidins in these samples.

The plots for prodelphinidin-richest F1 fractions were the most diverse compared to all other fractions (Figure 4C). The mDP values from thiolysis ranged from two to five and a qualitative comparison of the chromatograms revealed differences in the prodelphinidin composition of these fractions (data not shown). For example, fractions 9-F1 and 10-F1 both had an mDP of 3, but the prodelphinidin profiles differed. Detection with low cone voltage suggested that the 9-F1 sample contained a lot of monomers, which caused the sharp decrease in peak area with increasing cone voltage. The 10-F1 sample had a lot of oligomers in addition to monomers, and this explained the increasing peak area with increasing cone voltage. Similarly to the procyanidin detection (Figure 4B), the prodelphinidin-richest F2 fractions showed largest peak areas with cone voltages of 80−100 V. Also, the profiles of the two plots were similar (Figure 4B,D). The similarity among the F2 fractions was due to the absence of smaller proanthocyanidins, as these eluted generally in F1 fractions. Again, these results suggested that the developed MRM method is able to reveal whether the analyzed sample contains mainly small or large proanthocyanidins.

Qualitative Comparison of the MRM Chromatograms. The number of proanthocyanidin isomers increases with increasing degree of polymerization.[39] As a result, proanthocyanidin samples with high mDP generate a large unresolved hump in RP-LC.[40−43] However, a qualitative comparison of the chromatograms showed that higher cone voltages caused a shift in the detected proanthocyanidin hump to the right, that is, to later retention times and larger proanthocyanidins. When the chromatograms obtained with cone voltages of 30, 80, and 140 V are compared, a clear shift in the detected hump can be seen for both procyanidins (Figure 5A−C,G−I) and prodelphinidins (Figure 5D−F,J−L). A vertical line is shown that crosses the *x*-axis at 3 min to highlight these shifts. The lowest cone voltage detected mainly monomers and some smaller oligomers that are witnessed as sharp chromatographic peaks. Higher cone voltages also detected the proanthocyanidin hump characteristic for larger oligomers and polymers. In general, prodelphinidins eluted at earlier retention times than corresponding procyanidins. This can be seen when the chromatogram pairs A and D, B and E, C and F, G and J, H and K, and I and L in Figure 5 are compared. The elution time of compounds from reverse phase columns tends to be inversely related to their polarity; thus, shorter retention times of prodelphinidins would be expected because of their greater polarity associated with more extensive hydroxylation of the B-ring.[44]

In addition to the distribution of procyanidins and prodelphinidins along the chromatographic hump, the distribution of procyanidin and prodelphinidin extension and terminal units can be investigated by examining their MRM chromatograms. For example, the MRM chromatograms of extension units and terminal units of samples 1-F2 and 2-F2 are presented in Figure 6. To focus mainly on larger oligomers and polymers, MRM chromatograms with a cone voltage of 140 V were compared. In the 1-F2 sample, the MRM chromatographic hump of procyanidin extension units eluted later than prodelphinidin extension units and procyanidin and prodelphinidin terminal units (Figure 6A). This suggests that procyanidin extension units were most abundant in late-eluting proanthocyanidin molecules. It could also be seen that the chromatographic hump of terminal prodelphinidin units eluted earlier than terminal procyanidin units. This indicates that prodelphinidin terminal units were most abundant in earlier eluting proanthocyanidin molecules. In contrast, the shape of the chromatographic hump of procyanidin terminal units suggests that they were distributed fairly evenly among the proanthocyanidins. In contrast to the 1-F2 sample, the 2-F2

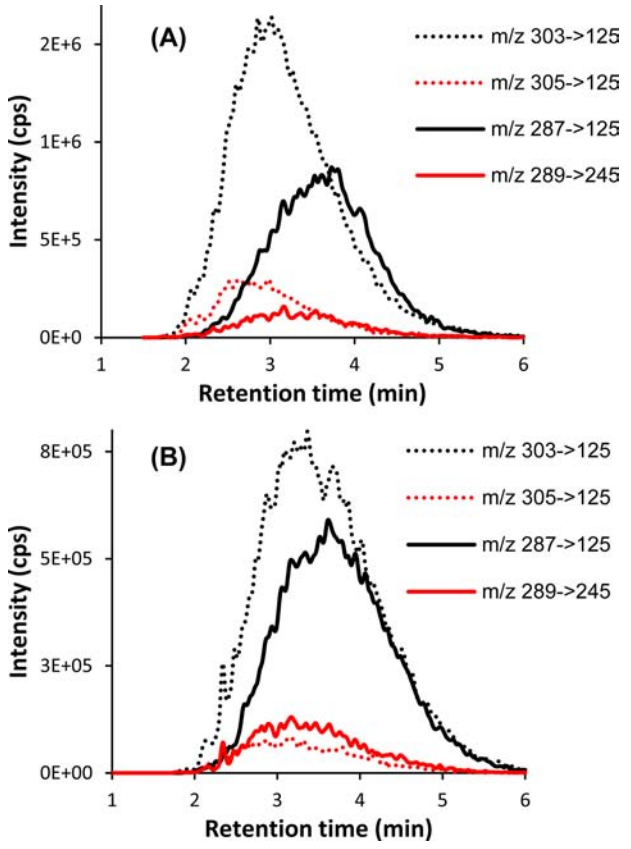

Figure 6. MRM chromatograms of procyanidin extension units (m/z 287 → 125), procyanidin terminal units (m/z 289 → 245), prodelphinidin extension units (m/z 303 → 125), and prodelphinidin terminal units (m/z 305→ 125) for samples 1-F2 (A) and 2-F2 (B). See Table 1 for fraction identities.

sample (Figure 6B) had a more uniform distribution of all procyanidin and prodelphinidin terminal and extension units, which would indicate a relatively homogeneous distribution of these units in the proanthocyanidins of this particular sample. The same kind of comparisons can be made at lower cone voltages to provide information on how the extension and terminal units of procyanidin and prodelphinidin are distributed across smaller oligomeric proanthocyanidins.

Determination of Proanthocyanidin Contents and Procyanidin/Prodelphinidin Ratios. To determine the total content of proanthocyanidins and procyanidin/prodelphinidin ratios, calibration curves were produced for the developed MRM method with pure procyanidins (fraction 5-F2) and pure prodelphinidins (fraction 13-F2). The five highest cone voltages were used for detection, and resulting peak areas were summed. The lowest cone voltage was not used to avoid monomer detection, because they are not classified as proanthocyanidins. These calibration curves were then used for estimation of procyanidin and prodelphinidin concentrations in all 18 proanthocyanidin fractions (5-F1−13-F2). The resulting proanthocyanidin contents were compared to proanthocyanidin contents estimated by thiolysis and HCl-butanol assay. Procyanidin/prodelphinidin ratios were then compared to procyanidin/prodelphinidin ratios estimated by thiolysis. A good correlation for proanthocyanidin contents with both thiolysis (R^2 = 0.82) and HCl-butanol assay (R^2 = 0.86) was achieved as was an excellent agreement for procyanidin/prodelphinidin ratios between the thiolysis and MRM results (R^2 = 0.98). These results suggest that our MRM approach allows both qualitative and quantitative analyses of complex proanthocyanidins directly from plant extracts.

Estimating the Mean Degree of Polymerization. On the basis of the quinone methide cleavage theory[4,27] (Figure 1B), it was hypothesized that an equation could be empirically developed to calculate the mDP of proanthocyanidins from total peak areas obtained for procyanidin and prodelphinidin extension and terminal units. A preliminary equation using estimated coefficients for each MRM transition was developed by comparing the thiolysis and MRM results from the 18 procyanidin- and prodelphinidin-rich fractions (5-F1−13-F2). Initially equations were developed individually for each cone voltage, but finally only one equation was developed by using the total peak area from the five highest cone voltages: 50, 75, 85, 110, and 140 V for procyanidins and 55, 80, 110, 130, and 150 V for prodelphinidins. The lowest cone voltage (30 V) was not used to avoid detection of monomers because monomers cause underestimation of the mDP. The resulting equation is as follows:

$$\mathrm{mDP} = \frac{0.37A_{287} + 0.42A_{289} + 2.15A_{303} + 0.68A_{305}}{0.42A_{289} + 0.68A_{305}}$$

A_{287}, A_{289}, A_{303}, and A_{305} are the sums of peak areas determined from MRM chromatograms of procyanidin extension units (m/z 287 → 125), procyanidin terminal units (m/z 289 → 245), prodelphinidin extension units (m/z 303 → 125), and prodelphinidin terminal units (m/z 305→ 125), respectively, with the five highest cone voltages (Table 2). The coefficients of the four ions differ due to the differing propensities of procyanidin/prodelphinidin extension and terminal units to undergo ionization. It should be noted that ionization coefficients could differ among UPLC-MS/MS instruments. Therefore, the correct ionization coefficients should be individually checked for each instrument. When this is done, the samples used should cover a wide range of proanthocyanidin types with various features (procyanidin/prodelphinidin ratio, mDP). In this study, 18 was a sufficient number of varying proanthocyanidin samples for adjusting these coefficients.

For the 18 samples used in the calibration, the mDPs estimated by the equation were naturally related (R^2 = 0.94) to results obtained by thiolysis. The equation was then independently tested with nine additional proanthocyanidin-rich fractions (1-F1−4-F2) to prove that it functions well also with other independent samples (R^2 = 0.90). Together these 27 fractions represented a diverse set of proanthocyanidins, with mDP values ranging from 2 to 15 and compositions varying from 95% procyanidin to 99% prodelphinidin. Therefore, these results indicated that the developed MRM method accompanied by this equation can reliably estimate the mDP of a wide variety of proanthocyanidins.

Previously, thiolysis and phloroglucinolysis have been the most commonly used tools for achieving information of proanthocyanidin content, procyanidin/prodelphinidin distribution, and mDP from plant extracts.[2,13−17] However, in these methods, proanthocyanidins are cleaved into monomer units before analysis, and all information of the individual oligomers and polymers is lost. Therefore, these methods lack the possibility to characterize the original oligomer and polymer fingerprint. In the presented UPLC-MS/MS method, the proanthocyanidin fragmentation takes place after the chromato-

graphic step, and therefore it is possible to estimate how the different proanthocyanidins, in terms of their procyanidin and prodelphinidin composition and mDP, are distributed along the chromatographic hump typically produced by large proanthocyanidin oligomers and polymers. Another advantage of the presented UPLC-MS/MS method is its sensitivity. It can be used to analyze samples produced from as little as 1 mg of plant powder, whereas thiolysis and phloroglucinolysis typically require relatively large amounts of plant tissue, in the range of hundreds of milligrams, for analysis.[17−19]

Repeatability of the UPLC-MS/MS Mthod. The repeatability of the method was determined using Student's *t* test at the 95% confidence interval. Five replicates of nine different proanthocyanidin fractions (1-F1−4-F2) were analyzed with the MRM method containing six different cone voltages and one optimal collision energy for each terminal and extension unit (Table 2). Results were presented as confidence intervals of the sums of peak areas obtained with different cone voltages and concentrations for procyanidins and prodelphinidins, procyanidin/prodelphinidin ratios, and mDP values. The procyanidin and prodelphinidin concentrations were calculated as milligrams per gram in fractions and procyanidin/prodelphinidin ratios as percent procyanidin. The relative standard deviation (RSD) for all nine samples with five replicates was determined from these results. The results showed that the quantitative determination of procyanidins is generally slightly less accurate than that for prodelphinidins (RSD = 3.5 and 2.1%, respectively). The RSDs for procyanidin/prodelphinidin ratio and mDP were small (0.6 and 1.4%, respectively), which demonstrates the pronounced reliability of this method for these qualitative measurements.

Limit of Detection, Limit of Quantitation, and Linearity. LOD, LOQ, and linearity were determined with the presented method for procyanidin and prodelphinidin dimers. LOD for procyanidin dimer was 16 ng/mL, whereas LOQ was 23 ng/mL. For prodelphinidin dimer, the corresponding values were 170 and 190 ng/mL, respectively. There was a difference in the efficiency of detection of procyanidin terminal and extension units; procyanidin terminal units were detected at 8 times lower concentration than the extension units. For prodelphinidins the difference was smaller; prodelphinidin terminal units were detected at 2 times lower concentration than prodelphinidin extension units. The linear areas were 0.04−2.5 μg/mL for procyanidins and 0.5−10 μg/mL for prodelphinidins. However, because the methodology presented is group-specific, that is, it is used for the analysis of the total amount of proanthocyanidins, values determined with pure dimers do not truly illustrate the limits of the method. Depending on the analyzed samples, different types of proanthocyanidins are detected from very small concentrations, whereas other proanthocyanidins can be detected only from more concentrated samples. In this study, it was not possible to determine the limits of detection of all possible individual proanthocyanidin compounds, and this will have to wait until pure oligomers and polymers of procyanidin and prodelphinidin compounds become available.

Use of the Method for Proanthocyanidin Characterization. Plants produce complex and often heterogeneous mixtures of procyanidins and prodelphinidins and, apart from small oligomers, it is practically impossible to purify large procyanidin and prodelphinidin oligomers or polymers individually.[6,14,45] For this reason the current research utilized a mixture of oligo- and polymeric quantitation standards that were chosen on the basis of their procyanidin and prodelphinidin purities. Naturally, the best quantitation results are expected with proanthocyanidin standards that are isolated from the very same species that is investigated for its proanthocyanidin content. This approach lowers the risk of utilization of wrong types of quantitation standards, but is too laborious with investigations that include hundreds of species, for example. In such cases, our MRM method offers a practical solution to significantly narrow the need for hundreds of standards.

We have used the method for the analysis of crude extracts of over 1000 plant species and found that the MRM chromatographic proanthocyanidin profiles (chromatographic fingerprint of the procyanidin and prodelphinidin extension and terminal units) (Figure 6) are not different with all of the species. Instead, it is possible to find several species clusters that share similar proanthocyanidin profiles (Salminen, unpublished observations). Thus, it would be sufficient to isolate one well-characterized proanthocyanidin standard per a given species cluster as proanthocyanidin fingerprints do not differ significantly within the cluster. Such an approach would allow the production of a library of proanthocyanidin standards, and each time the most correct standard could be chosen for any new plant species that was analyzed for its proanthocyanidin fingerprint during the 10 min analysis with the developed MRM method.

The present method can be used for both qualitative and quantitative analyses of complex proanthocyanidins directly from plant crude extracts. Instead of time-consuming degradation required by thiolysis or phloroglucinolysis, the present method describes in-source fragmentation of the UPLC-separated proanthocyanidin molecules by cone voltages optimized for terminal and extension units of procyanidins and prodelphinidins. UPLC enables rapid chromatography of different kinds of proanthocyanidins, whereas TQ-MS fragments compounds into proanthocyanidin-specific precursor and product ions for detection with MRM methods. The selective nature of the method enables the estimation of both the procyanidin/prodelphinidin ratio and mDP for the proanthocyanidins during the 10 min MS/MS analysis. Furthermore, because the proanthocyanidin fragmentation takes place after the chromatographic step, it is possible to estimate how the different proanthocyanidins in terms of their procyanidin and prodelphinidin composition and mDP are distributed along the chromatographic hump typically produced by large proanthocyanidin polymers. The UPLC-MS/MS method is able to handle 140 extracts, produced from as little as 1 mg of plant powder, in a day, and it offers a user-friendly, robust, and fast addition to the chemistry tools currently used for the qualitative and quantitative screening of large numbers of proanthocyanidin-containing plants for their bioactive proanthocyanidin types and content.

method[20] avoided the introduction of EOF reverse additives (such as cetyltrimethylammonium chloride and cetyltrimethylammonium bromide) in the background electrolyte (BGE), which made the BGE simple and the baseline steady and smooth and further improved the repeatability and detection. In our lab, we also prepared a trimethylamine amination polychloromethyl styrene nanolatex (TMAPL) and TMAPL-coated capillary column (ccc-TMAPL; Figure 1), and it has

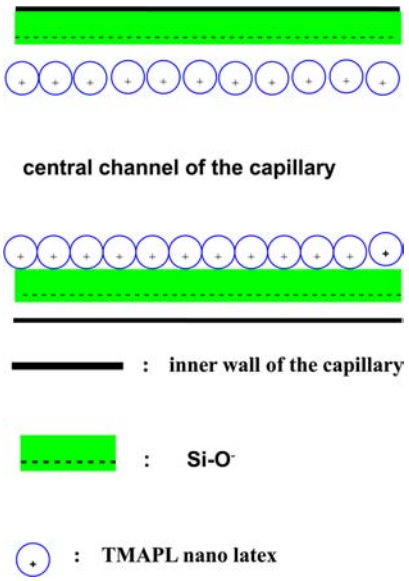

Figure 1. Schematic representation of the coating of the ccc-TMAPL.

been successfully applied for bromate analysis by OT-CEC.[36] Built on this success, we have in the present work crafted two major aims as follows: (i) to validate the practicability of the ccc-TMAPL and (ii) to develop an OT-CEC method for the analysis of nitrites and nitrates in hams and sausages.

MATERIALS AND METHODS

Reagents and Apparatus. Unless specified otherwise, all chemicals were of analytical reagent grade and obtained from Beijing Chemical Factory (Beijing, China). Thiourea was used as a neutral marker to measure the EOF and purchased from the Tianjin Dingshengxin Chemical Industry Limited Company (Tianjin, China). Water was purified using a Milli-Q water purification system (Millipore Corporation, Bedford, MA). The ham and sausage samples (made in different food factories in China) were purchased from the local supermarket. Their production dates were between May 2013 and June 2013, and they were kept in a refrigerating cabinet at 4 °C in the supermarket. All of solutions were degassed prior to use and filtered through a 0.22 μm membrane filter. Stock solutions (1 mg/mL) of $NaNO_3$ and $NaNO_2$ were prepared in deionized water. Quantification of samples was made using calibration curves of both nitrate and nitrite at the final concentrations of 10, 25, 50, 100, and 200 μg mL^{-1}. Each determination was performed in triplicate.

All experiments were performed on an Agilent CE system fitted with a diode-array detector and ChemStation software (Agilent Technologies, Waldbronn, Germany). The apparent pH was measured using a pH meter (Shanghai Weiye Factory, Shanghai, China). The dimensions of the bare fused-silica capillaries (Yongnian Optical Fiber Corporation, Hebei, China) were an inner diameter of 50 μm and a length of 50 cm (41.5 cm to the detection window). The ccc-TMAPL (Figure 1) is of 50 μm inner diameter and 50 cm length (41.5 cm to the detection window) coated with flushing TMAPL nanolatex through the bare fused-silica capillary. The preparation procedures of the ccc-TMAPL are the same as mentioned in our previous work[36] by introducing TMAPL nanoparticles into a treated bare fused-silica capillary 3 times, respectively. The nanoparticles will be coated onto the inner wall surface of the capillary by the electrostatic absorption interaction. The ccc-TMAPL has been characterized by infrared spectrum and EOF values. The absorptions at 1400 and 1637 cm^{-1} are observed and associated with the C−N and benzene ring stretching vibrations, respectively. Its EOF values are reversed and steady at ca. $-16.81 \pm 0.83 \times 10^{-5}$ cm^2 V^{-1} s^{-1} with pH 7.30−8.03. These results indicate that TMAPL has been successfully coated onto the inner wall of the capillary.

Electrophoretic Procedures. Before the electrophoretic procedure, the ccc-TMAPL was flushed with water for 30 min. After each separation run, the ccc-TMAPL was flushed with water for 3 min and running buffer solution for another 3 min to re-equilibrate the ccc-TMAPL. It is noteworthy that, to ensure reproducibility and accuracy of the determination, the buffer solution was changed after every 7−8 runs. All separation runs were undertaken at 25 °C. The separation voltage was −20 kV, and injections were performed hydrostatically using an applied pressure of 50 mbar for 3 s. Under the detection at 235 nm, the EOF (thiourea as marker) was determined when the buffer solution was 20 mM Tris and 12 mM $HClO_4$ with pH 8.03.

Sample Pretreatment. For sample preparation, similar procedures,[6] with a slight modification, were applied to extract nitrites and nitrates and deproteinized. A total of 100 g of the minced ham and/or sausage was mixed with deionized water (8 mL) and 1 g of activated charcoal in a 10 mL volumetric flask. Nitrites and nitrates were ultrasonically extracted for 30 min, and the volumetric flask was shaken 1 time per 5 min. Then, the volumetric flask was incubated in a warm water bath at 75 °C for 5 min, and then the liquid was tranferred to a 25 mL volumetric flask. the aforementioned extraction was repeated twice. About 20 mL of collected liquid was diluted 3 times to 25 mL with 5 mL of acetonitrile, and a portion (10 mL) was centrifuged for 15 min at 1000 revolutions/min. Then, 5 mL of supernatant was taken out and filtered through a 0.22 μm membrane filter before use.

RESULTS AND DISCUSSION

Condition Choice for Separation of Nitrite and Nitrate by OT-CEC. As reported in our previous work,[36] the ccc-

−25	1.65	25076	42777

TMAPL possesses good separation selectivity for nitrites and nitrates because of the additional chromatographic interaction between the TMAPL coating and target analytes, which is similar to that observed in the published literature.[22] Using the usual Tris−$HClO_4$ buffer system[22,37] (ClO_4^- with high

[a]The IC method[40] was used with an IonPac AS9-HC anion-exchange column (250 × 4 mm inner diameter, 13 μm).

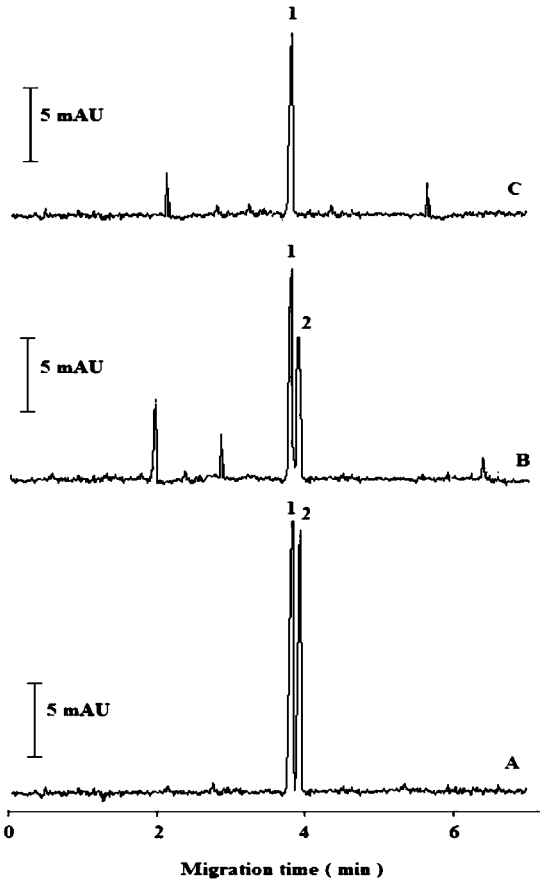

Figure 2. Typical electrochromatograms of (A) standard of nitrite and nitrate, (B) number 6 ham and (C) number 2 sausage samples. Conditions: column, 50 μm × 50 cm (effective length of 41.5 cm) ccc-TMAP; BGE, 20 mmol L^{-1} Tris + 13.5 mmol L^{-1} $HClO_4$ (pH 7.87); separation voltage, −20 kV; sample injection, 50 mbar × 3 s; detected wavelength, 214 nm; and temperature, 25 °C. Peaks: 1, nitrite; 2, nitrate.

eluotropic strength as a competing anion to elute nitrites and nitrates), the separations of nitrite and nitrate with different $HClO_4$ concentrations (13.0, 13.5, 14 0.0, 14.5, and 15.5 mmol L^{-1}) in BGE were carried out. The resolutions (Rs) and theoretical plates for both nitrites and nitrates were calculated and listed in Table 1. From Table 1, the larger Rs and higher theoretical plates could be obtained using 20 mmol L^{-1} Tris + 13.5 mmol L^{-1} $HClO_4$ (pH 7.87) as BGE of OT-CEC. It is noteworthy that the weakly acidic and basic buffers (pH < 8) are preferential for avoiding the TMAPL coating destroyed, which ensured the stability of EOF. The EOF values of about $-16.81 \pm 0.83 \times 10^{-5}$ cm^2 V^{-1} s^{-1} with pH 7.30−8.03[34] and about $-15.02 \pm 0.71 \times 10^{-5}$ cm^2 V^{-1} s^{-1} with pH 4.70−6.85 were obtained, which showed the reversal and steady EOFs. At the same time, the baselines with coated columns[14,20] are smoother than those by the CZE method without coated columns.[17,38] At the same time, the coating was removed by flushing 0.1 mmol L^{-1} NaOH solution and EOF will change to

dx.doi.org/10.1021/jf500020w | J. Agric. Food Chem. 2014, 62, 3400−3404

the normal positive value. This result implies that TMAPL is coated on the capillary based on the electrostatic absorption.

In the CE method, separation voltage can greatly affect migration time, Joule heat, Rs, and column efficiency. The separations, theoretical plates, and Rs (Table 2) for nitrites and nitrates were obtained under different separation voltages at −15, −20, and −25 kV. Using separation voltage at −20 kV, both nitrite and nitrate were baseline-resolved, and their theoretical plates and Rs were better than those at −15 and −25 kV.

Taking the migration time, Rs, and column efficiency into consideration, −20 kV of separation voltage and 20 mmol L^{-1} Tris + 13.5 mmol L^{-1} $HClO_4$ (pH 7.87) BGE were optimized for the separation of nitrites and nitrates.

Methodology. Under the optimized conditions, the standard solutions of both nitrites and nitrates (10, 25, 50, 100, and 200 μg mL^{-1} for each) were injected and performed by OT-CEC. Their regression equations (peak area y against concentration x) were obtained as follows:

for nitrate

$$y = 0.6756x - 0.1778 \quad (n = 5;\ R^2 = 0.9915)$$

for nitrite

$$y = 0.6585x - 0.1667 \quad (n = 5;\ R^2 = 0.9967)$$

The limits of detection (LODs) for nitrate and nitrite were found to be 3.5 and 4.2 μg mL^{-1} by calculating a sinal-to-noise ratio of 3. These LODs allow for nitrates and nitrites in hams and sausages to be detected out at their limits of quantitation (LOQs) of ca. 0.89 and 1.05 μg g^{-1}, respectively. These LOQs were similar to those by the reported CE method.[17]

To evaluate the accuracy of the method, the recoveries (Table 3) for both nitrites and nitrates were investigated by adding standard nitrites and nitrates to the number 1 ham sample (100 g) to prepare the test samples. It can be seen from Table 3 that the relative standard deviations (RSDs) of the migration times and peak area were less than 2.0 and 3.5%, respectively. The recoveries were between 94 and 103%. It implies that the developed OT-CEC was accurate and reproducible.

Application. Using the above method, the contents of nitrites and nitrates in ham and sausage samples were carried out. The determination results were listed in Table 4, and the typical electrochromatograms of the ham and sausage samples were represented in Figure 2. From Table 4, nitrites and/or nitrates were found ranging from 10 to 40 mg kg^{-1} in most samples. They are safe for the consumers. However, the contents of nitrites in number 5 sausage and nitrates in number 2 ham were exceeded by their maximum residue limit (MRL) of 50 μg g^{-1} in meat products.[39] Both of them should be prohibited on sale. It is noteworthy that the determination results of nitrites and nitrates in the real samples were coincident by the developed OT-CEC and the referenced ion chromatographic (IC) method.[40] It displays that the proposed OT-CEC is an accurate and practical method for the determination of nitrites and nitrates in foodstuffs.

In conclusion, a new and practical method for the separation and determination of nitrites and nitrates in hams and sausages was developed by OT-CEC using ccc-TMAPL as the column. The method was simple as a result of avoiding the introduction of an EOF reverse additive (such as CTAC and CTAB) in BGE while featuring good repeatability and accuracy. The results demonstrated that the ccc-TMAPL was of stability, and the developed method was suitable for the analysis of trace hazardous anions, nitrites, and nitrates. It would promise to be a practical application in the field of food safety analysis.

(Inset) Photograph of **1** solution (10 μM) upon irradiation under UV light (365 nm) in the absence or presence of HSO_3^- (10 μM). λ_{ex} = 400 nm. Slits: 5 nm/5 nm. (B) Absorption spectra of **1** (20 μM) in PBS buffer (pH 7.4, 10 mM) obtained upon titration with HSO_3^-. (Inset) Photograph of **1** solution (20 μM) in the absence or presence of HSO_3^- (10 μM). The equivalents of HSO_3^- were varied in the following order: 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.5, 2.0, 3.0, and 5.0.

addition reaction on the basis of our previous study,[20] and the interrupted π-conjugation led to the emission of 2-methylene benzo[*e*]indoline recovery at 465 nm. Thus, two well-separated emission peaks before and after the HSO_3^- addition could be obtained ($\Delta\lambda$ = 106 nm). Treatment with HSO_3^- resulted in an obvious color change in the test papers stained by probe **1**. Moreover, probe **1** could determine the HSO_3^- level in real sugar samples with good recovery.

MATERIALS AND METHODS

General Methods. All reagents and solvent were purchased from commercial sources and used without further purification, if not otherwise stated. All reactions were carried out on the magnetic stirrers, and their reaction process was monitored by thin layer chromatography (TLC). Absorption and fluorescence spectra were taken on a Shimadzu UV-1800 spectrophotometer and a Hitachi F-2700 fluorescence spectrometer, respectively. ^{1}H NMR and ^{13}C NMR measurements were recorded at 600 and 150 MHz on a Bruker Avance 600 MHz spectrometer. Dimethyl sulfoxide (DMSO-d_6) was solvent, and tetramethylsilane (TMS) was used as internal standard. ESIMS were taken on a Fourier transform ion cyclotron resonance mass spectroscopy (Varian 7.0T).

Preparation of Probe 1. Probe **1** were prepared according to the method we reported previously by a simple one-step reaction of 4-trifluoromethylbenzaldehyde in ethanol solution.[26] 1,2,3,3-Tetramethylbenz[*e*]indolium iodide (1.05 g, 3 mmol) was dissolved in ethanol (5 mL), then 4-trifluoromethylbenzaldehyde (0.52 g, 3 mmol) was added, and the reaction mixture was heated at reflux for 12 h. Then the reaction mixture was cooled to room temperature, and the precipitate was collected by filtration, washed with cold ethanol, and dried in vacuo. Probe **1** was obtained as an orange solid in 80% yield (1.2 g). ^{1}H NMR (600 MHz, DMSO-d_6): δ 8.50 (d, J = 16.6, 2H), 8.44 (d, J = 8.4, 2H), 8.38 (d, J = 8.1, 1H), 8.32 (d, J = 8.9, 1H), 8.25 (d, J = 8.1, 1H), 7.96 (d, J = 7.9, 2H), 7.84 (m, 2H), 7.77 (m, 1H), 4.32 (s, 3H), 2.03 (s, 6H). ^{13}C NMR (150 MHz, DMSO-d_6): δ 186.0, 152.5, 142.8, 142.1, 141.7, 136.8, 134.4, 134.0, 133.4, 131.9, 130.8, 130.0, 129.3, 126.7, 118.9, 116.9, 57.6, 39.2, 28.1. HRMS (ESI): calcd for $[M]^+$ 380.1621, found 380.1627.

RESULTS AND DISCUSSION

Probe **1** was easily synthesized in a one-step reaction by using 1,2,3,3-tetramethylbenz[*e*]indolium iodide and 4-trifluoromethylbenzaldehyde in ethanol. The synthetic route and the purification were simple. The total yield was 68%. The structure

dx.doi.org/10.1021/jf5004539 | J. Agric. Food Chem. 2014, 62, 3405−3409

of probe **1** was characterized via ^{1}H, ^{13}C NMR, and ESIMS (Figures S1−S3 in the Supporting Information).

As expected, probe **1** possessed good water solubility. The reaction media, pH value, and response time were investigated to optimize the sensing conditions. The fluorescent spectral response of **1** (10 μM) in the absence and presence of HSO_3^- (10 μM) at different pH values was evaluated as shown in Figure 1. The probe was stable in a pH range of 1−8 and displayed the best response for HSO_3^- in the physiological pH region. Thus, the PBS buffer solution (pH 7.4, 10 mM) was selected for the spectral studies. Time-dependent modulations in the fluorescence of the probe (10 μM) in the presence of HSO_3^- (1, 5, and 10 μM) suggested that the reaction could be completed within 90 s in the experimental conditions (Figure S4 in the Supporting Information). Thus, the detection was delayed for 90 s to ensure the reaction between **1** and HSO_3^- accomplished completely.

The fluorescence spectra of probe **1** (10 μM) after addition of various amounts of HSO_3^- (0−50 μM) are shown in Figure 2A. Probe **1** exhibits an emission at 571 nm, which was attributed to the large π-conjugation. The addition of HSO_3^- resulted in a gradual decrease in emission at 571 nm and an increase in emission at 465 nm, which corresponds to the 2-methylenebenzo[*e*]indoline moiety. A well-defined isoemissive point at 550 nm was also observed. The ratiometric change in fluorescence intensity indicated that the addition reaction between **1** and HSO_3^- interrupted the π-conjugation, and the fluorescence of 2-methylenebenzo[*e*]indoline was recovered. Accordingly, the fluorescence color changed from orange to cyan. The ratio of the emission intensities at 465 and 571 nm (I_{465}/I_{571}) was enhanced with the addition of HSO_3^- and became constant when the amount of HSO_3^- added reached 1 equiv (10 μM), which suggests a 1:1 binding stoichiometry between **1** and HSO_3^- (Figure S5 in the Supporting Information). The ratio value increased by >120-fold (from 0.12 to 15.4). To our knowledge, the notable fluorescent spectral change caused by 0.1 equiv of HSO_3^- (1 μM) and obtaining the maximal spectral signal with 1 equiv of HSO_3^- (10 μM) were impressive and unprecedented compared with those of many reported HSO_3^- probes. In similar conditions, the ratio changes produced an excellent linear function with HSO_3^- concentration between 0 and 10 μM (Figure S6 in the Supporting Information), and the detection limit for HSO_3^- was 5.6×10^{-9} M (R^2 = 0.9935). The absorption spectrum of probe **1** (20 μM) showed two strong bands at 310 and 360 nm (Figure 2B). The decrease in band intensity upon the addition of HSO_3^- also suggests that the π-conjugation was broken. This phenomenon leads to a solution color change from yellow to colorless. The noticeable color change indicates that HSO_3^- can be detected with the naked eye by using probe **1**.

The ratiometric sensing selectivity of probe **1** for HSO_3^- was further examined in PBS buffer (pH 7.4, 10 mM) as shown in Figure 3. Among the added representative anions, including HS^-, CN^-, F^-, Cl^-, Br^-, I^-, AcO^-, ClO_4^-, NO_3^-, N_3^-, SO_4^{2-}, HSO_4^{2-}, SCN^-, PO_4^{3-}, $H_2PO_4^-$, and HPO_4^{2-} (100 equiv, respectively), only HS^- caused an intensity change because of the 1,2-addition reaction with a fluorescent color change from orange to colorless. The other anions did not induce any significant fluorescence change, and the I_{465}/I_{571} values varied in a limited range between 0.15 and 1.2. By contrast, treatment of **1** with HSO_3^- resulted in an obvious ratiometric fluorescent response. Probe **1** was originally synthesized to detect CN^- in water, and the pH value of the solution changed from 7.2 to 9.4

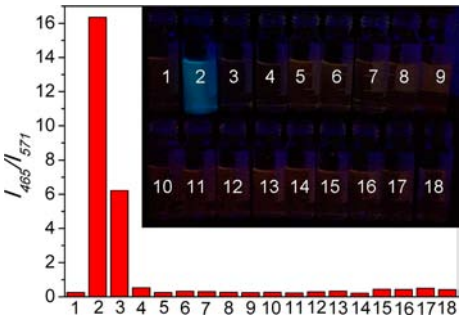

Figure 3. Emission ratio I_{465}/I_{571} of **1** (10 μM) in PBS buffer (pH 7.4, 10 mM) in the presence of various species. λ_{ex} = 400 nm. Slits: 5 nm/5 nm. (Inset) Corresponding fluorescent color changes under a handle UV lamp (365 nm): 1, probe alone; 2, HSO_3^- (10 μM); 3, HS^-; 4, CN^-; 5, F^-; 6, Cl^-; 7, Br^-; 8, I^-; 9, AcO^-; 10, ClO_4^-; 11, NO_3^-; 12, N_3^-; 13, SO_4^{2-}; 14, HSO_4^-; 15, SCN^-; 16, PO_4^{3-}; 17, HPO_4^{3-}; 18, $H_2PO_4^{3-}$ (3−27, 1000 μM).

with the addition of CN^-. However, the constant neutral pH condition suppressed the necleophilic addition of CN^- to **1** as the protonation of CN^- [p*K*a (HCN) = 9.2].[30,31] Competition experiments of probe **1** were also ascertained by various species mentioned previously in the same environment. The signaling of **1** toward HSO_3^- (1 equiv) was not affected by the presence of 100 equiv of coexisting species (Figure S7 in the Supporting Information). The phenomenon suggests that probe **1** could be used as an efficient signaling probe for HSO_3^- in aqueous media.

There was no spectral change when HSO_3^- was added to the solution of 1,2,3,3-tetramethylbenz[*e*]indolium iodide because of the steric effect. Hence, we proposed a 1,4-addition reaction occurred between **1** and HSO_3^- rather than a 1,2-addition reaction, and ^{1}H NMR analysis was carried out to demonstrate the proposed addition mechanism (Figure 4). After HSO_3^- was

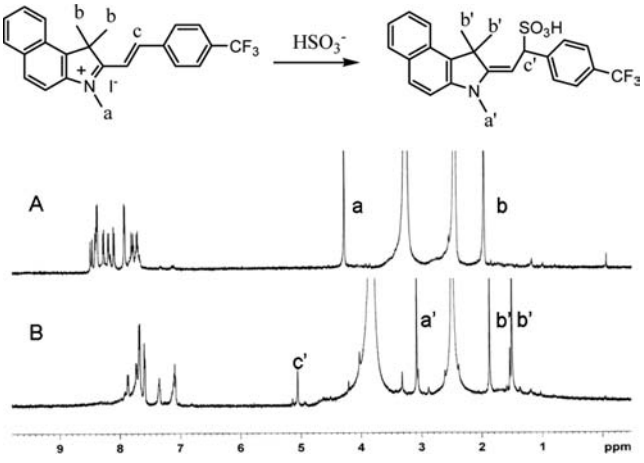

Figure 4. ^{1}H NMR spectral change of **1** (3×10^{-3} M) in the absence (A) and presence of 1 equiv of $NaHSO_3$ (B) in DMSO-d_6/D_2O = 9:1 (v/v).

added into the solution of **1**, all of the ^{1}H NMR signals shifted upfield because the nucleophilic attack of HSO_3^- toward C-4 disturbed the π-conjugation and weakened its electron-withdrawing characteristic. The proton signal (H^a, at δ 4.34) of the methyl group connected with N^+ was significantly shifted upfield to δ 3.05. The proton signal (H^b, at δ 2.03) of the two methyl groups was also shifted upfield and divided into two

dx.doi.org/10.1021/jf5004539 | J. Agric. Food Chem. 2014, 62, 3405−3409

single signals ($H^{b'}$, at δ 1.87 and 1.48), which become nonequivalent after the formation of **1**−SO_3H. Moreover, the proton signal (H^c, at δ 7.7−8.5) appeared at δ 5.05 after the HSO_3^- addition. Furthermore, the formation of **1**−SO_3H was further confirmed via mass spectrometry analysis, where the peak at m/z 460.1193 (calcd 460.1200) corresponding to $[M + SO_3]^-$ was clearly observed (Figure S8 in the Supporting Information).

To demonstrate the practical application of probe **1** for the detection of HSO_3^-, a preliminary paper test strip system was developed, as shown in Figure 5. After the neutral filter papers had been dipped into the solution of probe **1** (10 μM) and dried, yellow emission test papers were obtained under UV light (365 nm). When the various anion solutions (0.1 M) were dripped onto the test paper, only HSO_3^- induced a fluorescent color change from yellow to cyan. Although HS^- and CN^- also caused color changes from yellow to blue, they could be easily distinguished by the naked eye.

Figure 5. Photographs of the test paper exposure to various species under UV light (365 nm): 1, probe alone; 2, HSO_3^- (10 μM); 3, HS^-; 4, CN^-; 5, F^-; 6, Cl^-; 7, Br^-; 8, I^-; 9, AcO^-; 10, ClO_4^-; 11, NO_3^-; 12, N_3^-; 13, SO_4^{2-}; 14, HSO_4^-; 15, SCN^-; 16, PO_4^{3-}; 17, HPO_4^{3-}; 18, $H_2PO_4^{3-}$.

Finally, probe **1** was used to detect HSO_3^- in real samples. Granulated sugar, soft sugar, and crystal sugar purchased from a supermarket were used in the sample analysis. Sample solution was prepared by dissolving 5.0 g of sugar in deionized water and diluting to 10 mL. Aliquots of the sugar solution were added directly to the PBS buffer (pH 7.4, 10 mM) containing **1** (10 μM), and the emission intensities at 465 and 571 nm were recorded. Table 1 shows that probe **1** was able to determine HSO_3^- concentration in sugar with good recovery. The HSO_3^- levels in these samples were calculated to be 17.21, 10.70, and 14.58 mg/kg, respectively. To validate the accuracy of the method, we detected these sugar samples by a titration method,[32] and equivalent results were obtained as shown in Table 2.

Table 1. Results for the Determination of HSO_3^- in Various Samples

sample	HSO_3^- level (μmol/L)	added (μmol/L)	found (μmol/L)	recovery (%)
granulated sugar	4.13	3	7.26	101.8
		5	9.21	100.8
soft sugar	2.57	3	5.49	98.6
		5	7.48	98.8
crystal sugar	3.50	3	6.32	97.2
		5	8.24	97.0

Table 2. Results of This Method Compared with a Titration Method for HSO_3^- from Sugar Samples

sample	titration method (mg/kg)	this method (mg/kg)
granulated sugar	17.5	17.21
soft sugar	10.1	10.70
crystal sugar	14.3	14.58

In summary, a ratiometric fluorescent probe for HSO_3^- was introduced. The probe showed high selectivity and sensitivity to HSO_3^- in aqueous media with a short response time. The sensing mechanism was based on the 1,4-addition, which was confirmed via ^1H NMR titration and HRMS studies. Moreover, a simple test paper prepared using probe **1** for the rapid monitoring of HSO_3^- was developed, which could be used as a convenient signaling tool for HSO_3^- determination in chemical analyses. The aqueous solution of probe **1** could also be used to determine HSO_3^- levels in sugar samples.

Apoptosis is a highly regulated programmed cell death process that eliminates dysfunctional cells from the body by self-degradation.[6] Apoptosis can be triggered in a cell through either the extrinsic pathway or the intrinsic pathway. The extrinsic pathway is initiated through the stimulation of transmembrane death receptors such as Fas receptors, located on the cell membrane.[7] In contrast, the intrinsic pathway of apoptosis is driven by a mitochondria- mediated death signaling cascade through the release of death signal factors, and these two apoptotic pathways are executed mainly by a class of cysteine proteases known as caspases.[8]

During apoptosis, engagement of the mitochondrial pathway involves mitochondrial membrane permeabilization (MMP), which depends on activation, translocation, and oligomerization of multidomain Bcl-2 family proteins such as Bax or Bak. MMP triggers the release of cytochrome *c* and other apoptogenic proteins into the cytosol followed by the activation of caspase cascades, which eventually results in poly(ADP-ribose) polymerase (PARP) cleavage and apoptosis.[9] Besides, MMP induces apoptosis through altering the levels of expression of Bcl-2 family proteins.[10] PARP are critical to DNA repair and apoptosis signaling, and play an important role in various mechanisms of cellular stress.[7,8]

Apoptosis can also occur via the caspase-independent apoptotic pathway in which apoptosis-inducing factor (APIF) plays a key role.[11,12] APIF protein is normally confined to mitochondria and is released by cleavage of calpains upon apoptotic stimulation.[13,14] The truncated form of APIF protein acts as a pro-apoptotic mediator, which translocates first from mitochondria into the cytosol followed by entry into the nucleus, where it promotes chromatin condensation and DNA degradation.[15,16]

Codium decorticatum is a dark green alga belonging to the family Codiales, and it is commonly found in the Gulf of Mannar region, India. Thus far, there has been no report on the biological properties of glycoprotein (GLP) from seaweeds. Hence, in the present study, GLP from *C. decorticatum* was extracted, purified, and investigated for its cytotoxicity potential on human breast cancer (MDA-MB-231) cells against normal (HBL-100) breast epithelial cells that served as control. Also, the apoptotic effect of GLP through activation of intrinsic signaling cascade pathway in MDA-MB-231 breast cancer cells was evaluated with respect to the expression of mitochondrial membrane proteins, ROS generation and cleavage of PARP, and up- and downstream events of bcl-2 family genes.

MATERIALS AND METHODS

Materials and Chemicals. Toluidine Blue O and ammonium sulfate were purchased from SRL Chemicals, Mumbai, India. Q-Sepharose anionic exchanger, Dulbecco's minimal essential medium (DMEM), penicillin, streptomycin, 2′,7′-dichlorofluorescein-diacetate (DCFH-DA), DAPI stain, Acridine orange (AO), ethidium bromide (EtBr), and propidium iodide (PI) were purchased from Sigma Aldrich, USA. Dialysis membrane (MWCO 12−14 kDa) and methyl thiazol tetrazolium salt were purchased from HiMedia, India. Coomassie Brilliant Blue (CBB) stain, periodic acid−Schiff (PAS) stainm and medium-range protein marker (14.3−97.4 kDa) for SDS-PAGE were purchased from Genei, India. Fetal bovine serum was purchased from Gibco, Inc., USA. LDH assay kit was procured from Cayman Chemicals, USA. cDNA synthesis kit (SuPrimeScript RT Master Mix, catalog no. SR2000) was purchased from GeNetBio. Primary antibodies against cytochrome *c* and caspase 3 were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). Anti-PARP antibody was procured from Pharmingen, San Diego, CA, USA. Antibody against β-actin was purchased from Bio-World (St. Louis Park, MN, USA). Horseradish peroxidase-conjugated secondary antibodies were purchased from Jackson Immuno Research (West Grove, PA, USA). All other reagents and chemicals were of the highest purity grade.

Extraction and Purification of GLP from *C. decorticatum*. The collection of fresh and healthy *C. decorticatum* specimens was made between December 2011 and January 2012 during low tide at the depth of 1−3 m along the coast of Kilakarai, Gulf of Mannar, Tamil Nadu, India. The collected algae were washed with seawater and distilled water. The fresh thallus of the alga was powdered with liquid nitrogen and stored at −80 °C until used. One hundred and fifty grams of powder was added to 1 L of 0.05 mM phosphate buffer (pH 7.2) and dispersed for 6 h with constant stirring at 4 °C followed by filtration using cheesecloth to remove insoluble debris. Furthermore, the sample was centrifuged at 12500 rpm for 20 min to remove insoluble matter. The supernatant was saturated with 20% followed by 70% ammonium sulfate and centrifuged at 12000 rpm for 20 min to obtain pellets, which were dissolved and dialyzed against 0.05 M phosphate buffer at pH 7.2. The dialyzed sample was loaded onto Q-Sepharose anionic exchange column (30 cm × 2.5 cm) and washed with 0.05 M phosphate buffer at pH 7.2. The sample was eluted serially with 50 mL of 50, 100, 150, 200, 300, 400, 500, and 700 mM NaCl in the same buffer with a flow rate of 2.0 mL/min. Fractions of 5 mL volume were collected and read at 280 and 490 nm using a UV−vis spectrophotometer (DU-40 spectrophotometer, Beckman, USA) for identification of protein- and carbohydrate-rich fractions, respectively. Furthermore, GLP-rich fractions showing the presence of GLP band by CBB and PAS staining methods on sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) were collected, pooled, dialyzed against the same buffer, lyophilized (Vir Tis FTS systems, Warminster, PA, USA), and stored in vials at 4 °C for further use (Scheme 1). The purity of the GLP fraction from anion

exchange chromatography was analyzed by the presence of a single band detected with CBB staining (for protein) and PAS staining (for polysaccharides) on SDS-PAGE. Besides, Toluidine Blue O staining was employed for the detection of polysaccharides resolved in agarose gel by electrophoresis.

Cell Culture and Maintenance. The selected cell lines of human MDA-MB-231 and HBL-100 cells were obtained from National Centre for Cells Science (NCCS), Pune, India. Detailed culture conditions are provided in the Supporting Information.

Cell Proliferation Assay. Cell proliferation was analyzed by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) assay, as described by Mosmann.[17] Briefly, exponentially growing MDA-MB-231 and HBL-100 cells (1×10^4 cells/mL) were seeded in 96-well plates in a final volume of 100 μL/well and were treated with 10 μL of test sample (GLP) in FCS-free complete medium at various concentrations (5−100 μg/mL) for 48 h. One hundred microliters of MTT (5 mg/mL) was added to treated cells, and the plates were incubated at 37 °C for 4 h. The supernatant was aspirated, and 100 μL of dimethyl sulfoxide (DMSO) was added to each well to dissolve the Formosan crystals. Absorbance was measured at 620 nm using a 96-well microplate reader (THERMO Multiskan, USA), and the inhibitory concentrations (IC_{25}, IC_{50}, and IC_{75}) were determined for GLP causing reduction in cell viability. The percentage of cell survival was calculated using the following formula:

$$\text{cytotoxicity (\%)} = (\text{mean exptl absorbance} / \text{mean control absorbance}) \times 100$$

The control wells were not treated with GLP.

Lactate Dehydrogenase (LDH) Assay. The LDH assay was performed with an LDH colorimetric assay kit using an ELISA reader according to the manufacturer's protocol. Detailed experimental conditions are provided in the Supporting Information.

Determination of Apoptosis Induction and Cell Death. The induction of apoptosis by GLP-treated cells was analyzed by AO/EtBr staining. Detailed conditions for this method are provided in the Supporting Information.

Fluorescent Microscopic Studies on Chromatin Condensation. The condensation of chromatin and nuclear fragmentation in GLP-treated cells were analyzed by DAPI staining. Detailed conditions are provided in the Supporting Information.

Measurement of ROS Generation. 2′,7′-Dichlorofluorescein-diacetate (DCFH-DA) can be deacetylated by intracellular esterase to nonfluorescent DCFH, which can be oxidized by ROS, resulting in the formation of fluorescent compound 2′,7′-dichloroflorescein (DCF). The fluorescence intensity of DCF is proportional to the amount of ROS produced by the cells. After seeding of 5×10^5 cells/well to a 6-well plate, the cells were treated with GLP for 24 h in dose-dependent concentrations. Subsequently, cells were washed once with ice-cold PBS and incubated with DCFH-DA (50 μM final concentration) at 37 °C for 30 min in the dark. Then, the cells were washed twice and maintained in 1 mL of PBS. ROS generation was assessed using a fluorescence microscope (Nikon Eclipse, Inc., Japan) at excitation and emission wavelengths of 488 and 530 nm, respectively, and the mean fluorescence intensity of DCF was evaluated.

Determination of $\Delta\Psi_m$ by Flow Cytometry. MDA-MB-231 cells (1×10^5/mL) were seeded in a 6-well plate containing complete medium and allowed to attach for 24 h. The cells were treated with GLP for 24 h in dose-dependent concentrations and harvested. The medium was removed, and the adherent cells were trypsinized. The cells were pelleted by centrifugation at 2000 rpm for 10 min followed by resuspension with 1 mL of Rhodamine 123 (Rh 123; 5 μg/mL in methanol) for 30 min at 37 °C in dark, washed with PBS twice, and resuspended in PBS. Then, Rh 123-stained cells were fixed with 4% paraformaldehyde for 10 min. Finally, the cells were washed with methanol and analyzed for change in $\Delta\Psi_m$ using BD FACS caliber (FL-1 detector with 530 nm band-pass filter). Data were analyzed using Cell Quest Pro 6.0 software (BD Biosciences, San Jose, CA, USA).

Cell Cycle Analysis. Measurement of cellular DNA content and distribution of cells for cell cycle analysis were carried out by flow cytometry. Detailed experimental conditions are provided in the Supporting Information.

Semiquantitative Reverse Transcription PCR (RT-PCR) for Mitochondrial Gene Expression. RT-PCR was performed to determine changes in the expression of bax, bcl-2, and internal control β-actin genes. TriZol reagent was used to isolate total RNA and reverse transcribed. Briefly, the cDNA was synthesized using a cDNA synthesis kit and amplified according to the manufacturer's protocol in a 25 μL reaction mixture containing random primer pairs (1.0 μL): 10× buffer (5.0 μL), cDNA (2.0 μg), 25 mM/L MgCl (3.0 μL), 10 mM/L dNTPs (1.0 μL), and Taq polymerase (2.5 units). Amplification cycles consisted of denaturation at 94 °C for 1 min, primer annealing at 57 °C for 45 s, and extension at 72 °C for 45 s, for a total of 30 cycles followed by a final extension at 72 °C for 10 min. The following primer sequences were used for amplification: (a) bax gene, forward 5′-TTTGCTTCAGGGTTTCATCC-3′ and reverse 5′-CAGTTGAAGTTGCCGTCAGA-3′; (b) bcl-2 gene, forward 5′-CATCCATTATAAGCTGTCGCA-3′ and reverse 5′-TGCCGG-TTCAGGTACTCAGT-3′; and (c) β-actin, forward 5′-GTTGCT-ATCCAGGCTGTGC-3′ and reverse 5′-GCATCCTGTCGGCAA-TGC-3′. The PCR products were electrophoresed and visualized by transillumination system (Alpha Innotech Image viewer 6.0.0, Japan).

Analysis of Expression of Mitochondrial Membrane Proteins by Western Blot. Cells (1×10^6 cells/well) were transferred to a culture dish (100 mm × 20 mm) for 24 h; the cells were treated for 24 h with GLP in dose-dependent concentration, harvested, and washed twice with ice-cold PBS. Subsequently, a 1.5 mL microfuge tube containing cell extract was centrifuged at 2500 rpm for 5 min to discard the supernatant. Treated cells were washed in PBS and lysed in 100 μL of buffer containing 50 mM Tris-HCl (pH 8.0), 150 mM NaCl, 1% Triton X-100, 1 mM phenylmethanesulfonyl fluoride, 10 μg/mL pepstatin, and 10 μg/mL leupeptin. After 20 min, extracts were centrifuged at 12000 rpm for 10 min at 4 °C, and the supernatants were stored at −80 °C until further use. Proteins (30 μg/lane) were separated using 10% SDS-PAGE and transferred to PVDF membranes. The membranes were blocked in TBST solution containing 5% (w/v) nonfat milk for 2 h, followed by overnight incubation at 4 °C with primary antibodies such as cytochrome *c*, caspase 9, caspase 3, and β-actin. After being washed with TBST buffer, the membranes were incubated for 1 h with the secondary antibody, horseradish peroxidase-conjugated goat anti-rabbit IgG. Antibody-bound proteins were detected using enhanced chemiluminescence reagents. Blots were washed with washing buffer and incubated with secondary antibodies conjugated with horseradish peroxidase for 1 h at room temperature.

Poly(ADP-ribose) Polymerase (PARP) Cleavage Analysis. Protein samples (50 μg) in nuclear fractions were resolved on 7.5% SDS-PAGE gels and transferred to nitrocellulose membranes. The membranes were blocked overnight with BSA solution (5% bovine serum albumin in PBS) and 0.1% Tween 20 at 4 °C and thereafter incubated with anti-PARP antibody (1:2000). The immune complexes were visualized as described for immune-blot analysis.

Statistical Analysis. All of the experiments were done in triplicates, and the experiments were repeated at least three times. The statistical software SPSS version 17.0 (SPSS Inc., Chicago, IL, USA) was used for analysis. *p* values were determined using Student's *t* test; (*) $p \leq 0.05$ and (**) $p \leq 0.01$ were considered statistically significant.

RESULTS

Extraction and Purification of GLP from *C. decorticatum*. The crude extract from *C. decorticatum* was precipitated with 20 and 70% ammonium sulfate fractionation, and the precipitate of the 70% ammonium sulfate saturated fraction was subjected to dialysis. The dialyzed sample was loaded onto the Q-Sepharose anion exchange column chromatograph and fractions were collected. A total of 80 fractions were collected and the content of protein and carbohydrate was determined

for each fraction. Eight GLP-rich fractions (Figure 1A), eluted with 500 mM NaCl solution, were identified, and each fraction

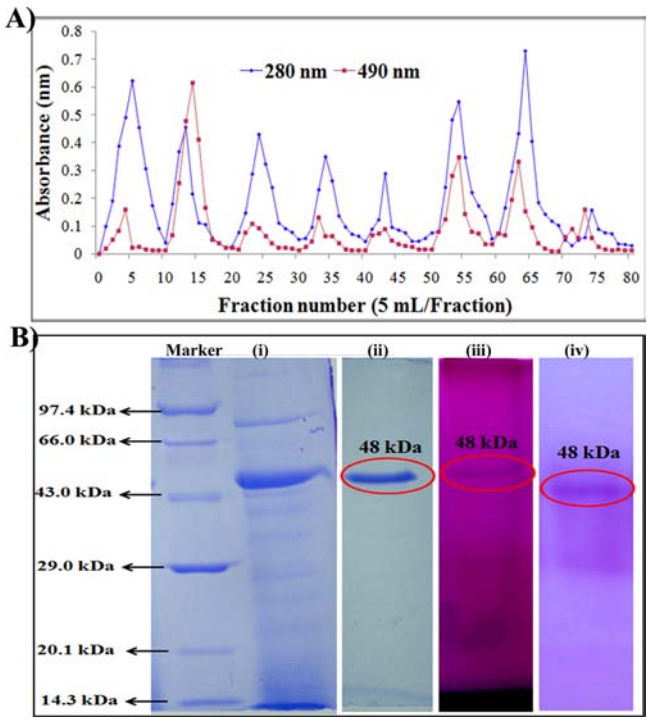

Figure 1. (A) Elution profile of crude GLP-rich extract on Q-Sepharose Fast Flow chromatography. (B) Electrophoretic analysis of GLP from *C. decorticatum*. CBB staining reveals (i) GLP-rich crude fraction and (ii) purified GLP by SDS-PAGE; PAS staining shows (iii) purified GLP by SDS-PAGE; Toluidine Blue staining shows (iv) purified GLP by agarose gel electrophoresis.

was again checked for purity by SDS-PAGE stained with CBB and PAS for protein and GLP, respectively. Among the 8eight fractions, six were homogeneous and were pooled, dialyzed, and lyophilized. We confirmed the presence of a GLP band having the molecular mass of ~48 kDa (Figure 1B). The yield of the purified GLP was found to be 195 mg (0.13%) from 150 g of dried extract of *C. decorticatum*, and the contents of carbohydrate and protein in GLP were found to be 36.24 and 63.76%, respectively. The detailed process of extraction and purification of GLP is depicted in Scheme 1.

GLP Reduces Cell Viability and Causes Membrane Damage. To investigate the effects of apoptotic cell death induced by GLP, MDA-MB-231 and HBL-100 cells were treated with GLP at different dose levels for 24 h and subjected to MTT assay. Results showed that MDA-MB-231 cells exhibited strong growth inhibitory effects when compared to HBL-100 cells (Supporting Information Figure S2). We evaluated the effect of GLP upon cell viability and plasma membrane damage of normal cell lines against untreated controls (Supporting Information Figure S2; Figure 2A,B). The cytotoxicities of GLP in dose-dependent concentration for MDA-MB-231 and HBL-100 cells were found to be 75 ± 0.23 μg/mL (IC_{25}), 55 ± 0.32 μg/mL (IC_{50}), and 30 ± 0.43 μg/mL (IC_{75}) and 90 ± 0.57 μg/mL (IC_{25}), 80 ± 0.48 μg/mL (IC_{50}), and 60 ± 0.26 μg/mL (IC_{75}), respectively (Figure 2A).

The extent of cell membrane damage of GLP-treated MDA-MB-231 cells at dose-dependent concentrations in 24 h was measured by LDH release assay (Figure 2B). The percentage of added LDH protein either absorbed or inactivated by dose-dependent concentrations in 24 h is shown in Figure 2B. The figure shows that the release of LDH was greater when the cells were treated with increasing concentrations of GLP.

In addition, direct observation using an inverted microscope revealed numerous morphological changes in MDA-MB-231 cells treated with GLP (data not shown). There are no significant cytotoxic effects of GLP in normal HBL-100 cells; hence, additional apoptotic parameters were performed only for cancer cells. In MDA-MB-231 cells, chromatin condensation, loss of nuclear construction, and formation of apoptosis bodies appeared in a dose-dependent manner after GLP treatment. To examine whether GLP inhibits the proliferation of MDA-MB-231 cells by inducing apoptosis, cells were investigated by nuclear DAPI staining (Figure 2C). The GLP-treated cells exhibited typical morphological features of apoptosis with nuclear fragmentation, whereas control (untreated) cells did not show these features.

Detection of Apoptosis Induction and Cell Death by AO/EtBr and DAPI Staining. Using fluorescence microscopy, necrotic and apoptotic cells were distinguished on the basis of overall cell morphology and cell membrane integrity. Upon staining with AO/EtBr, apoptotic cells containing apoptotic bodies and necrotic cells were observed as orange and red, respectively, whereas untreated MDA-MB-231 cells were found to exhibit green fluorescence with the absence of morphological changes (Figure 3). However, morphological changes as well as the induction of apoptosis in these cells were detected after treatment with GLP at dose-dependent concentrations for a period of 24 h, and the percentage of apoptotic induction is depicted in Figure 3.

DAPI is also known to form fluorescent complexes with double-stranded DNA and is useful in finding the apoptotic condensed nuclei. The 80−90% confluent MDA-MB-231 cells were seeded in 24-well plates and exposed to GLP for 24 h. The morphology and the condensed nuclei chromatins were observed in the cells using a fluorescence microscope after cell fixation. Apoptotic nuclei were identified by the reduced nuclear size and gathering of condensed chromatin at the periphery of the nuclear membrane besides the fragmented morphology of nuclear bodies (Figure 2C).

GLP Increases Intracellular ROS Level in MDA-MB-231 Cells. ROS play a central role in the regulation of cellular apoptosis. We examined the effect of GLP in intracellular ROS generation due to increase in $\Delta\Psi_m$ loss that could mediate intrinsic apoptotic signaling pathways (Figure 4). ROS scavenger DCFH-DA was used to confirm the role of ROS in GLP-induced apoptosis. The results showed that there was a reduction of $DCFH_2$ into DCF through esterase activity due to the release of peroxidase cytochrome *c* in the cytosol leading to increased production of ROS in GLP-treated MDA-MB-231 cells (Figure 4A,B) when compared to untreated cells (data not shown). After exposure of MDA-MB-231 cells to 75 ± 0.23 μg/mL (IC_{25}), 55 ± 0.32 μg/mL (IC_{50}), and 30 ± 0.43 μg/mL (IC_{75}) GLP for 24 h in a dose-dependent manner with untreated control cells, the ROS levels in these cells were measured as 21 ± 4.76, 43 ± 6.60, 62 ± 4.30, and 76.04 ± 5.34%, respectively (Figure 4B). The production of ROS is increased in a dose-dependent manner in GLP-treated MDA-MB-231 cells (Figure 4A,C). These data suggested that ROS generation is required for $\Delta\Psi_m$ loss and subsequent induction of intrinsic apoptotic signaling pathways in GLP-treated MDA-MB-231 cells.

GLP Triggers Mitochondria-Dependent Apoptosis. To investigate the molecular mechanism of GLP-induced apoptosis, we examined the effect of GLP on mitochondrial function in MDA-MB-231 cells using Rh 123 fluorescence staining. Treatment with increasing concentrations of GLP induced a dose-dependent loss of $\Delta\Psi_m$ (Figure 5A). In addition, we found the dose-dependent release of cytochrome *c* from mitochondria into the cytosol, which was associated with changes in the ratio of expression of bcl-2/bax. These data reveal that GLP could cause mitochondrial dysfunction in MDA-MB-231 cells. The role of GLP in intracellular $\Delta\Psi_m$ dysfunction and the subsequent induction of mitochondria-mediated intrinsic apoptotic signaling pathways in MDA-MB-231 cells were evaluated by FACS analysis. The results showed that the loss of $\Delta\Psi_m$ increased in a dose-dependent manner in cells treated with GLP for 24 h, and this resulted in induction of intrinsic apoptotic signaling pathway in the cells (Figure 5B,C).

GLP Promotes G_2/M Arrest in MBA-MB-231 Cells. To understand the cell death mechanism, GLP was evaluated for its effect on cell cycle and induction of apoptosis in cancer cells by flow cytometry. The results on cell cycle analysis for untreated control cells and GLP-treated cells with dose-dependent concentrations are depicted in Figure 6A. From the figure, it was observed that there was a significant increase in cells at sub-G_0 as well as G_2/M phases (∗∗, $p \leq 0.01$). The cells at G_0/G_1 phase decreased significantly (∗, $p \leq 0.05$), whereas those at S phase did not change significantly (Figure 6B). The study findings revealed the effect of GLP on the accumulation of cells in G_2/M phase accompanied by cell cycle arrest (Figure 6). It was shown that GLP arrested the growth of cancer MDA-MB-231 cells in G_2/M phase. This suggested that GLP might act as a G_0/G_1 checkpoint that controlled the progression of cells from G_1 to S phase and thereby prevented the replication of DNA. These results suggested that the GLP delayed cell cycle progression by arresting cells in the G_2/M phase of cell cycle, resulting in apoptosis.

Expression of bcl-2 Family Genes, Attenuation of MMP, Loss of $\Delta\Psi_m$, and Induction of Apoptosis. As

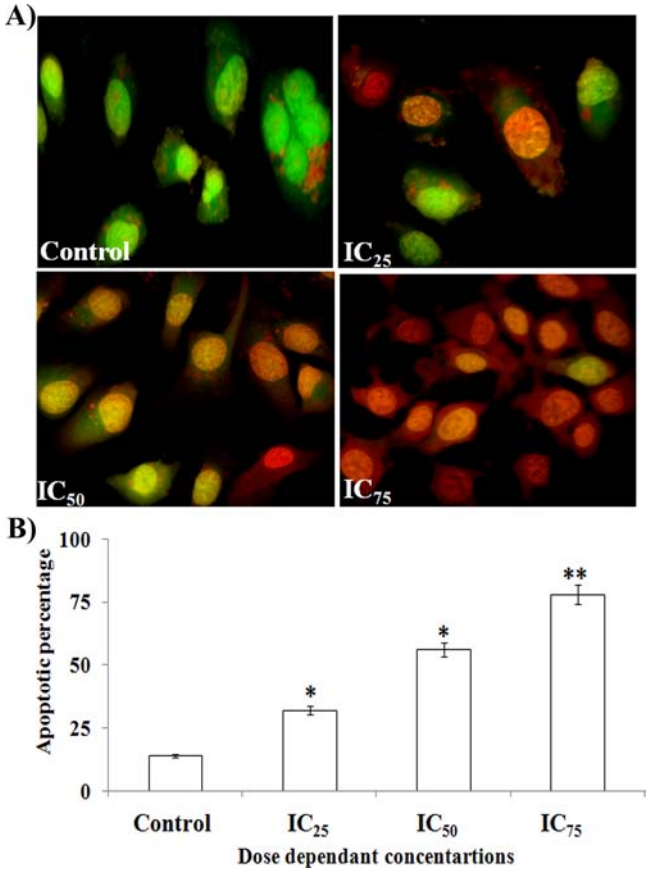

Figure 3. (A) Images of fluorescent microscopic analysis of GLP-induced apoptosis in MDA-MB-231 cells stained with AO/EtBr. Viable cells are shown in green, necrotic cells in red, and apoptotic cells in orange. (B) Graph shows apoptotic cells (%) after treating MDA-MB-231 cells with GLP. (*) $p \leq 0.05$ and (**) $p \leq 0.01$, compared with untreated cells (control groups).

shown in Figure 7A, an additional experiment was carried out to elucidate whether GLP-induced apoptosis is associated with the expression of bcl-2 family member genes such as bax and bcl-2. Cells were exposed to dose-dependent concentrations of GLP for 24 h with untreated control cells, and the expression profile of pro-apoptotic bax and anti-apoptotic bcl-2 family genes in response to dose-dependent manner was elucidated (Figure 7A). The gene expression profiles in GLP-induced apoptosis of MDA-MB-231 cells were further confirmed by investigating with densitometry calculations (Figure 7B). As shown in Figure 7B, exposure of cells to dose-dependent concentrations led to change in the expression of mitochondrial pro-apoptotic and anti-apoptotic genes. Furthermore, we investigated the role of mitochondria in GLP-induced apoptosis of MDA-MB-231 cells by measuring Rh 123 dye retention. As shown in Figure 7B, MDA-MB-231 cells treated with GLP exhibited a significant reduction in mitochondria dysfunction in a dose-dependent manner.

GLP Induces Apoptosis through a Caspase 3-Dependent Pathway. The mitochondrial pathway is one of the major apoptotic pathways, which is often related to the loss of $\Delta\Psi_m$. The release of cytochrome *c* from mitochondria to cytosol is the limiting factor in the mitochondrial pathway, and the loss of $\Delta\Psi_m$ has been suggested to cause the release of cytochrome *c*. Here, we investigated the activation of caspases and the subsequent proteolytic cleavage of PARP proteins in MDA-MB-231 cells by Western blotting. Western blot analysis suggested that GLP treatment with dose-dependent concentrations led to a significant increase in caspase 3, caspase 9, and PARP proteins (Figure 8A and B). The release of cytochrome *c* (14 kDa) could initiate apoptosis via the mitochondrial pathway by activation of caspase 9 and caspase 3, and cleavage of PARP. 37/35 kDa caspase 9, upon cleavage, was converted to active caspase 9 having the molecular weight of 17 kDa. The molecular weight of PARP before and after cleavage was 116 and 89 kDa, respectively (Figure. 8). After MDA-MB-231 cells were treated with GLP in dose dependent concentration for 24 h, the release of cytochrome *c* increased in a concentration-corresponding manner (Figure 8). The ratios for densitometric values of expression of cytochrome *c*/*β*-actin, caspase 9/*β*-actin, caspase 3/*β*-actin, and PARP/*β*-actin for control and cancer cells were also calculated (Figure 8B). These results suggested that GLP induced caspase 3-dependent apoptosis in MDA-MB-231 cells.

DISCUSSION

Cancer is one of the most common diseases that threaten human life. Unfortunately, the drugs used for cancer therapy are toxic and affect not only cancer cells but also normal cells. Thus, finding novel, effective, and nontoxic compounds from natural sources is important now more than ever before. Induction of apoptosis has been the target mechanism for cancer treatments, and DNA fragmentation is a marker of cell death. There have been limited studies on cytotoxic effects and apoptotic induction activities of GLP specifically against cancer cells;[18] however, there are no reports of GLP from green seaweeds having antiproliferative activities toward cancer cells.[19] Studies report that oral consumption of seaweeds significantly decreases the incidence of carcinogenesis in vivo.[5] Hence, we attempted to isolate and purify GLP from green seaweed *C. decorticatum* and evaluated its cytotoxic activities and antiproliferative mechanisms by induction of apoptosis using an in vitro cancer cell line model.

In Figure 1, purified GLP from *C. decorticatum* was shown as a single band on SDS-PAGE with a molecular mass of about 48 kDa consisting carbohydrate (36.24%) and protein (63.76%) moieties. The gels stained with Schiff's reagent and CBB reagent confirmed it as glycoprotein (GLP).

To elucidate clearly the specificity of GLP toward cancer cells, the cytotoxic effect of GLP on MDA-MB-231 cells was compared with normal breast HBL-100 cells. GLP of the study, with its inhibitory concentrations on cancer cells, produced no toxicity or variations in proliferative effects in HBL-100 cells as evidenced by MTT assay. Our data regarding MTT assay, LDH assay, and nuclear fragmentation were consistent, and these results suggested that GLP could penetrate test cancer cells (MDA-MB-231) and destroy plasma membrane integrity, which consequently caused apoptosis in the cells and LDH leakage (Figure 2B). The LDH assay was found to be susceptible to interference from particle adsorption or protein inactivation. The exact mechanism could not be determined by our experiments because both could cause a decrease in the measurable LDH protein, resulting in a false indication of a nontoxic response. There was a reduction in the measurable LDH content with increasing dose-dependent concentrations of GLP until a seemingly steady state condition was observed. The amount of LDH reduction was also affected by the concentration of GLP in 24 h. Han et al.[14] found indications of LDH binding to titanium dioxide nanoparticles during cell

exposure but did not confirm with cell-free measurements of LDH absorption. The differences between our results and those of other groups may be due to the presence of other proteins or biological compounds that affect LDH absorption to particles.[14] Our measurements were performed with pure GLP in PBS with adherent cells, whereas other studies used different media or had the additional presence of intracellular proteins and cell debris generated during cell exposure.

The present study showed that after exposure to the GLP, MDA-MB-231 cells displayed typical apoptotic appearances such as nuclei condensation, cell shrinkage, and apoptotic bodies along with accumulation of a sub-G_1 cell cycle population, substantiating the activation of an intrinsic apoptotic pathway in cancer cells.[18−22] Although the caspase activation occurred in MDA-MB-231 cells, an increase in the expression of pro-apoptotic bcl-2 member genes resulted in nuclear translocation of APIF, which could be due to loss of $\Delta\Psi_m$.[23]

GLP induced apoptosis and cell death via cell cycle arrest in human breast cancer cell lines and not in normal cells. Results from Figure 2A clearly show that GLP induced cytotoxicity and reduced cell viability in breast cancer cell lines through induction of G_2/M phase arrest. It was reported that cell cycle control represents a major regulatory mechanism for cell growth,[24] wherein anticancer agents can play a role in blocking the progression of cell cycle, and development of new cancer therapeutics can be promising with this approach.[25,26] Cell cycle progression is partly controlled by a family of protein

dx.doi.org/10.1021/jf405329e | J. Agric. Food Chem. 2014, 62, 3410−3421

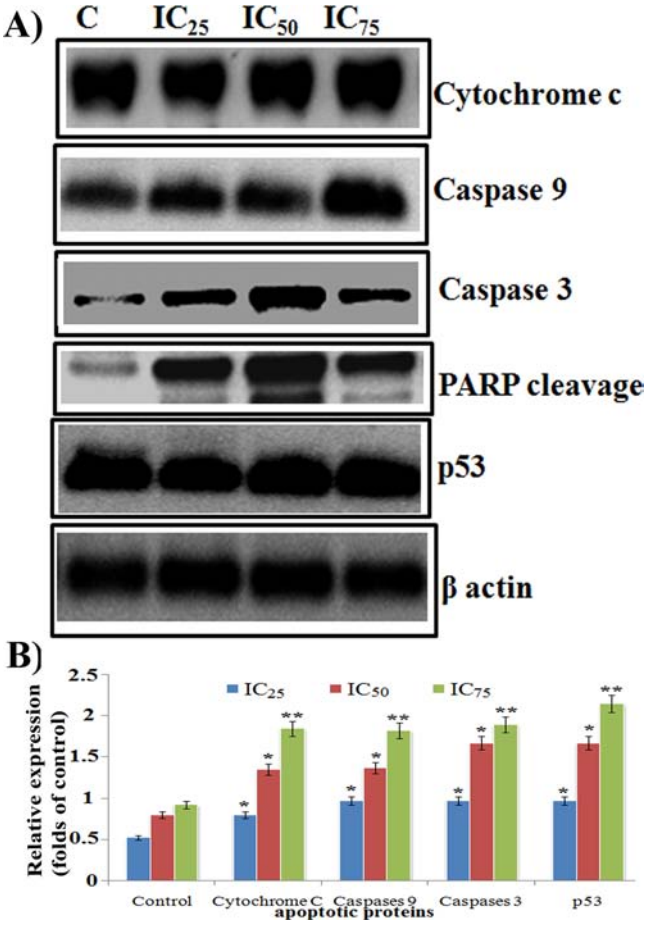

Figure 8. (A) Effect of GLP on activation of caspases, cleavage of PARP, release of cytochrome *c*, and $\Delta\Psi_m$ loss was evaluated by Western blotting and densitometry. Activities of caspases are indicated in percentage against unstimulated cells. Percentage of apoptotic population is represented on the basis of densitometry profile compared with its internal control *β*-actin. (B) Densitometry analysis of intrinsic apoptotic related protein expression of MDA-MB-231 cells treated with GLP. (∗) $p \leq 0.05$ and (∗∗) $p \leq 0.01$, compared with untreated cells (control groups).

kinase complexes in eukaryotic cells including cyclin-dependent kinases (CDKs) and their activating partners, the cyclins.[27] Together, these results suggested that GLP delayed cell cycle progression by arresting cells in the G_2/M phase of the cell cycle, resulting in significant induction of apoptosis.

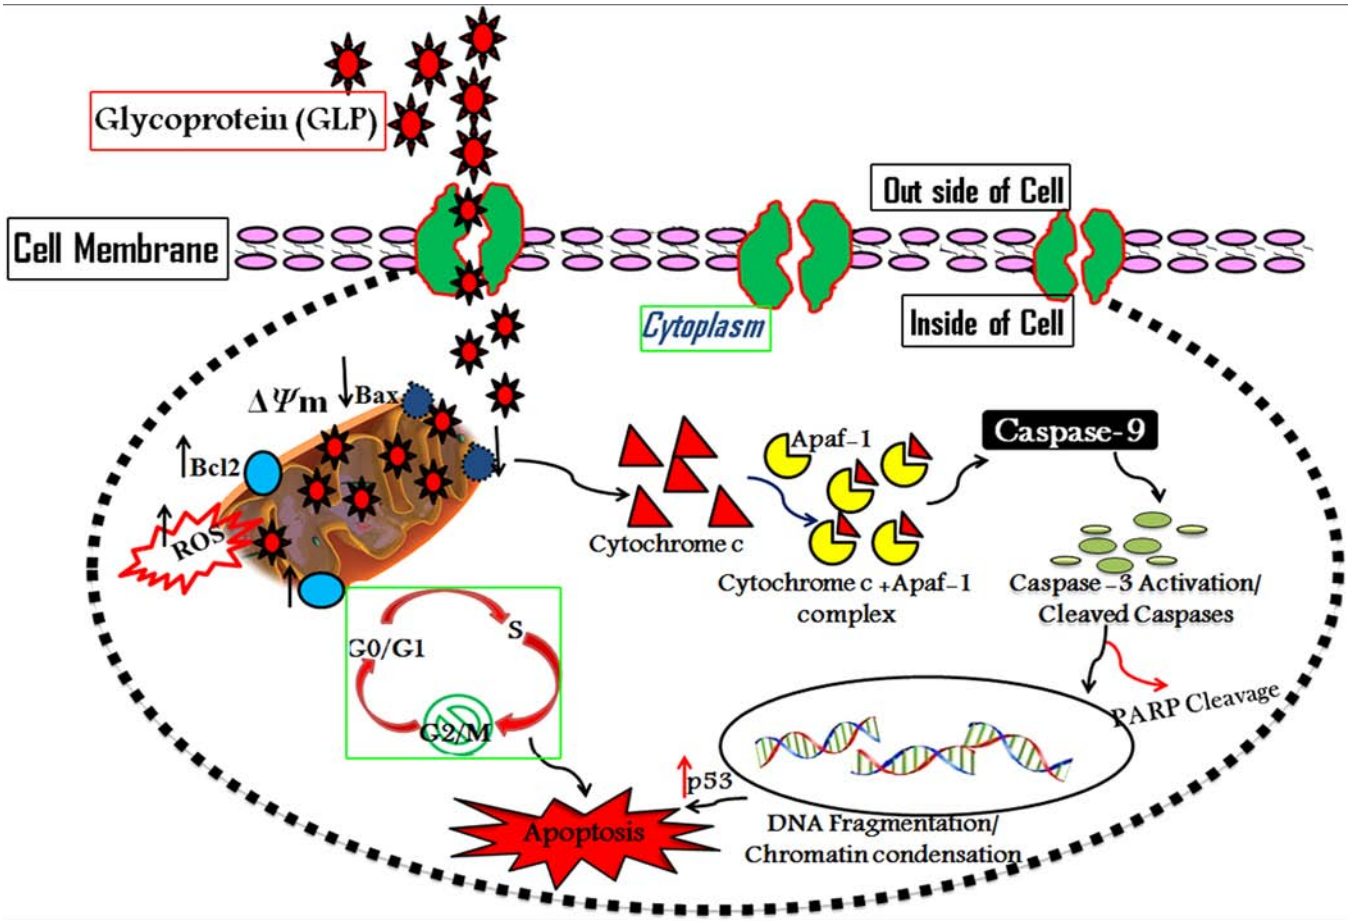
Mitochondrial characteristics, such as mitochondrial mass, mitochondrial DNA, MMP, oxygen/glucose consumption, ROS, and ATP,[28,29] can aid in understanding the differences between sensitive and resistant cancer cells. An increasing number of studies have suggested that the function and integrity of mitochondria may affect the viability, proliferation/division, cytotoxic resistance, and hypoxic tolerance of cells. Hence, properties of mitochondria of cancer cells might become the basis of designing chemotherapeutic agents for effective cancer treatment. Mitochondrial targets such as (i) mitochondrial permeability transition, (ii) outer membrane permeabilization, and (iii) mitochondrial metabolism and metabolic reprogramming[30,31] have been recognized for developing potential strategies to overcome chemotherapeutic resistance. It is well-known that an increase in intracellular ROS can lead to apoptosis. On the other hand, a decrease of ROS can also ruin the stability of mitochondria, which is followed by a loss of $\Delta\Psi_m$, release of cytochrome *c* into cytosol, and activation of the caspase cascade.[32,33] To support this standpoint, GLP could be employed to circumvent cancer resistance due to its ability to target the hyperpolarized mitochondria.

Mitochondrial membrane dysfunction and the release of pro-apoptotic factors from the intermembrane space are controlled by Bcl-2 members.[34] The intrinsic mitochondrial-dependent pathway involves the disruption of outer mitochondrial membrane integrity that was followed by the reduction in MMP and the release of cytochrome *c* and other pro-apoptotic molecules from the mitochondria to the cytosol.[35] Additionally, the bcl-2 family genes and proteins are the essential regulators of apoptosis through controlling mitochondrial permeability.[36] A low concentration of ROS is important in redox balance and cell proliferation.[37] However, excessive ROS accumulation induces protein oxidation, lipid peroxidation, and DNA damage in cells, followed by cell death or apoptosis. It was reported that phenolic acids provoked ROS generation in HepG2 cells and IMR-32 cells.[38,39] Our results also showed that GLP could induce ROS generation in MDA-MB-231 cells. Furthermore, pretreatment of ROS significantly blocked GLP-induced cell death, confirming the involvement of ROS in this process. It has been demonstrated that ROS-mediated apoptosis is modulated by Akt and MAPK signaling pathways in HepG2 cells and U-937 cells, respectively.[38,39] Therefore we hypothesized that ROS might play a key role in regulating intrinsic apoptotic signaling pathways in GLP-induced apoptosis, which was substantiated in the present study by Western blotting and semiquantitative RT-PCR analysis of expression of apoptotic proteins and bcl-2 family genes, respectively (Figures 4−8).

The caspase cascade is a key pathway in the apoptotic signal transduction. Caspases include two types of subfamilies: upstream initiator caspases such as caspase 9, which are involved in regulatory events, and downstream effector caspase such as caspases 3 and 6, which correspond to the change in cell morphological events and to the cleavage on nuclear protein, PARP.[28,40] Thus, the increased activity of caspases in cells may enhance the risk of apoptosis. The present study showed that the treatment of cancer cells by GLP markedly elevated the activity of cytochrome *c*, caspase 9, and caspase 3, suggesting the activation of both upstream and downstream caspase cascades in these cells. Following caspase activation, an increasing number of proteins including PARP are degraded or cleaved,[36,37,41−46] which consequently promotes nuclear condensation and cell shrinkage, resulting in cell death. The results of our present study revealed that GLP activated caspase cascades and promoted the release of apoptotic factors to facilitate apoptosis in the cancer cells (Figure 8). The involvement of PARP in DNA repair is based on an earlier observation that the activity of this enzyme is increased several hundred-fold following DNA damage.[41,47] Many insights into possible functions of PARP in different biological processes were obtained from in vitro experiments employing NAD^+ analogues as inhibitors of poly(ADP-ribosylation) (e.g., nicotinamide, benzamide, and their derivatives).[47] These findings were further supported by PARP inhibition in intact MDA-MB-231 cells (Figure 8). Inhibition of PARP activity has been shown to protect cells from undergoing apoptosis.[42−46]

In summary, this study focused on the potential of a purified glycoprotein (GLP) from *C. decorticatum* for inducing apoptosis in human breast cancer MDA-MB-231 cells. GLP inhibited the growth of cancer cells when they were treated

Scheme 2. Proposed Schematic Diagram of GLP-Mediated Apoptosis in MDA-MB-231 Cells[a]



[a]GLP induces ROS generation, which promotes $\Delta\Psi_m$ loss and intrinsic apoptotic signaling pathways resulting in changes in the expression levels of bax/bcl-2. This leads to mitochondrial dysfunction and caspase 3 activation. Finally, GLP induces PARP cleavage and apoptosis in MDA-MB-231 cells via G_2/M cell cycle arrest, which mediates the nuclear damage of the cells.

with dose-dependent concentrations of GLP for 24 h. Observation of morphological changes in GLP-treated cancer cells suggested that apoptosis was induced in these cells, which was further confirmed by PARP cleavage (Figure 8). We also showed that mitochondria played a central role in the apoptotic induction process, and the mitochondria destabilization involves formation of ROS, release of cytochrome *c*, and activation of multiple caspases in MDA-MB-231 cells treated with GLP. GLP regulated mitochondrial membrane protein expression for the induction of intrinsic apoptotic pathway by causing G_2/M phase cell cycle arrest and halting cell cycle progression. Besides, it induced apoptosis through ROS generation from mitochondrial membranes of cancer cells and caused $\Delta\Psi_m$ stress, resulting in mitochondrial dysfunction. A schematic model depicting the actions of GLP is presented in Scheme 2. Our results supported the emerging picture of GLP from biological sources, especially from *C. decorticatum*, with respect to their therapeutic potential to treat breast cancers.

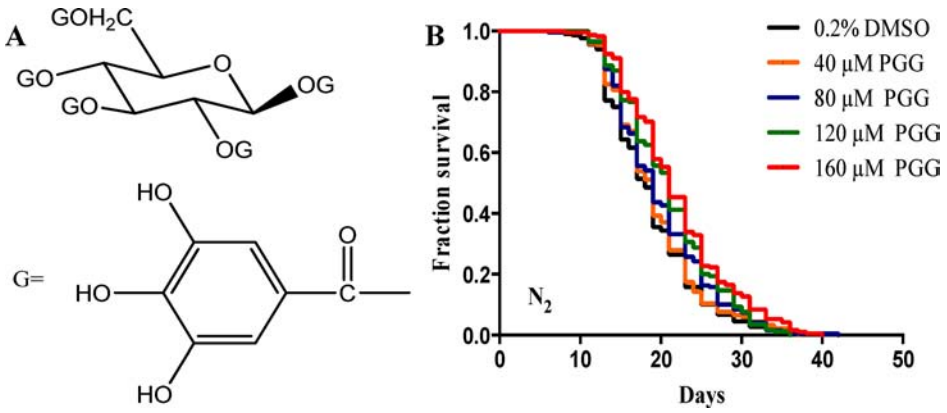

Figure 1. Effect of PGG treatment on the median lifespan of *C. elegans*. (A) Chemical structure of PGG. (B) Survival curves of wild-type (N_2) worms raised at 20 °C on the plates containing either 0.2% DMSO (control) or final concentrations of PGG (40, 80, 120, or 160 μM). The survival curves treated with 120 or 160 μM PGG were significantly different by the Log-rank test ($P < 0.05$). Four independent trials were performed.

(ad1116), *sir-2.1(ok434)*, *mev-1(kn1)*, *isp-1(qm150)*, and *clk-1(qm30)*. (The properties of the mutants are provided in Supporting Information.) All nematodes used in the study were supplied by the Caenorhabditis Genetics Center (CGC, University of Minnesota, Minneapolis, MN, USA).

Preparation of Treatment Plates. PGG (the chemical structure was presented in Figure 1A) was isolated from Eucalyptus leaves in our lab and was identified by comparing its nuclear magnetic resonance (^{1}H NMR and ^{13}C NMR) data with the reported literature.[12] PGG stock solution (80 mM in 100% DMSO) was diluted to the proper concentration. Then 5 μL of solution was added to 95 μL of *Escherischia coli* OP50, and the mixture was seeded onto the NGM plate (35 × 10 mm) and remained dry. To avoid autoxidation and polymerization of PGG, we analyzed the extraction of mixture with HPLC after it was seeded and found that there was a peak in the extraction that was identical with that of PGG. So PGG did not change before the treatment (the HPLC and MS of the PGG are provided in Supporting Information, Figures S1 and S2). The treatment plates contained different doses (final concentrations: 40, 80, 120, and 160 μM in 0.2% DMSO, respectively) of PGG or control solvent (0.2% DMSO).

Lifespan Assay. Lifespan analysis was performed by the same assay for all strains. If not stated otherwise, eggs isolated with hypochlorite (bleached with 5% sodium hypochlorite and 2.5 M sodium hydroxide) were transferred to the treatment plates and maintained at 20 °C in a temperature-controlled incubator. Synchronization was performed at L_4 larvae stage, and age synchronized young L_4 larvae (20 worms per plate and total of 3 plates per treatment) were then transferred to fresh treatment plates. During the reproductive period, these worms were transferred daily to new treatment plates and thereafter about every other day.

Live and dead *C. elegans* were counted daily (starting from the first day of hatching) until all individuals were dead. Nematodes that failed to respond to a gentle touch were scored as dead. Nematodes suffering from hatching of embryos within the adult hermaphrodite prior to eggs being laid (a so-called 'internal hatch') and those who escaped from the NGM agar were censored. Experiments were always performed in parallel with a control group. In the experiments assessing life span, reproduction, and pharyngeal pumping, treatments started from hatching unless otherwise stated.

Reproduction Assay. This assay was performed according to the previously reported method.[13] Wild-type *C. elegans* (10 individuals, 2 worms per plate) were shifted to fresh plates every day during the reproduction day, and the plates with eggs were left at 20 °C for 24 h to allow eggs to hatch. The number of progeny of each worm was counted at the L_4 stage to verify that eggs were hatched. Assay for each experiment was performed triplicates.

Pharynx Pumping Rate. Pharyngeal pumping was recorded on days 5, 10, and 15. Nematodes (10 individuals) were randomly selected, and the pumping assay was performed on NGM agar plate at room temperature. The number of their pharyngeal contractions was counted for 30 s.[13] All pumping rates were measured on a lawn of OP50 bacteria. The assay was repeated thrice with 10 worms per assay.

Age Pigments Fluorescence Spectroscopy. Fluorescence intensities of age pigments were measured as described.[13] Wild-type worms were raised from eggs on plates as in the lifespan assays. On days 5, 10, and 15 of life, 50 *C. elegans* were transferred to 50 μL of 10 mM NaN_3 solution in a single well of a 96-well white FluoroNunc plate. The 96-well plate was scanned in a spectrofluorimeter (Fluorolog-3, JobinYvon Inc., Edison NJ, USA). The fluorescence peak intensities of age pigments were obtained by scanning through the range of excitation wavelengths from 280 to 410 nm and an emission wavelength of 430 nm.

Locomotion Assay. *C. elegans* were raised from eggs similar to the lifespan assays. On days 5, 10, and 15, a total of 40 worms with or without PGG treatment were measured for body bend rate in liquid. Briefly, each time 4 worms were placed in 20 μL of M9 buffer on a glass slide. The locomotion of the worms was recorded by video for 30 s using a Qimaging Rotera-XR digital camera attached to a dissecting microscope and streamplx imaging software (ver. 3. 17. 2, NorPix Inc., Montreal, Quebec, Canada). Body bends in each frame of the 30 s film were analyzed by CeleST software. The assay was repeated three times with 40 worms per assay.[13]

Thermotolerance Assay. The thermotolerance assay was performed with hermaphrodites at 20 °C as for the aging assay. The adult worms with and without PGG treatment were shifted from 20 to 35 °C on day 4. Survivals were scored every hour after the temperature shift. Worms that died from desiccation on the sides of the plate were excluded.[3]

Accumulation of Reactive Oxygen Species (ROS). Accumulation of ROS was determined according to a modified protocol.[14] H_2DCF-DA (2,7-dichlorodihydrofluorescein diacetate) is a membrane-permeable compound and is converted to H_2-DCF when entering the cells of the worm. This nonfluorescent probe would be oxidized by ROS to yield the fluorescent dye DCF. Briefly, the worms were maintained and treated as in the lifespan method. After treatment with PGG or control for 96 h, worms were placed on a NGM plate to remove the bacteria three times. Then 80 worms were transferred to 50 μL of M9 buffer in a 96-well plate. In the meantime, 50 μL of fresh 100 μM H_2-DCF-DA solution in M9 buffer (100 mM stock solution in DMSO) was pipetted to the well (final concentration was 50 μM). On each plate, a control well containing H_2-DCF-DA without worms was included. Emission fluorescence intensity at 528 nm with excitation at 485 was recorded every 15 min for 12 h at 25 °C using a Synergy HT multimode microplate reader (Bio Tek Instruments Inc., Winooski City, VT, USA). The results are presented as means ± SD of relative fluorescence units (RFU) of three independent experiments with 240 individual worms in total.

Quantification of GFP-Labeled SOD-3 Expression. The GFP of the transgenic strain CF1553 {muIs84 [pAD76 (*sod-3*::gfp)]} can

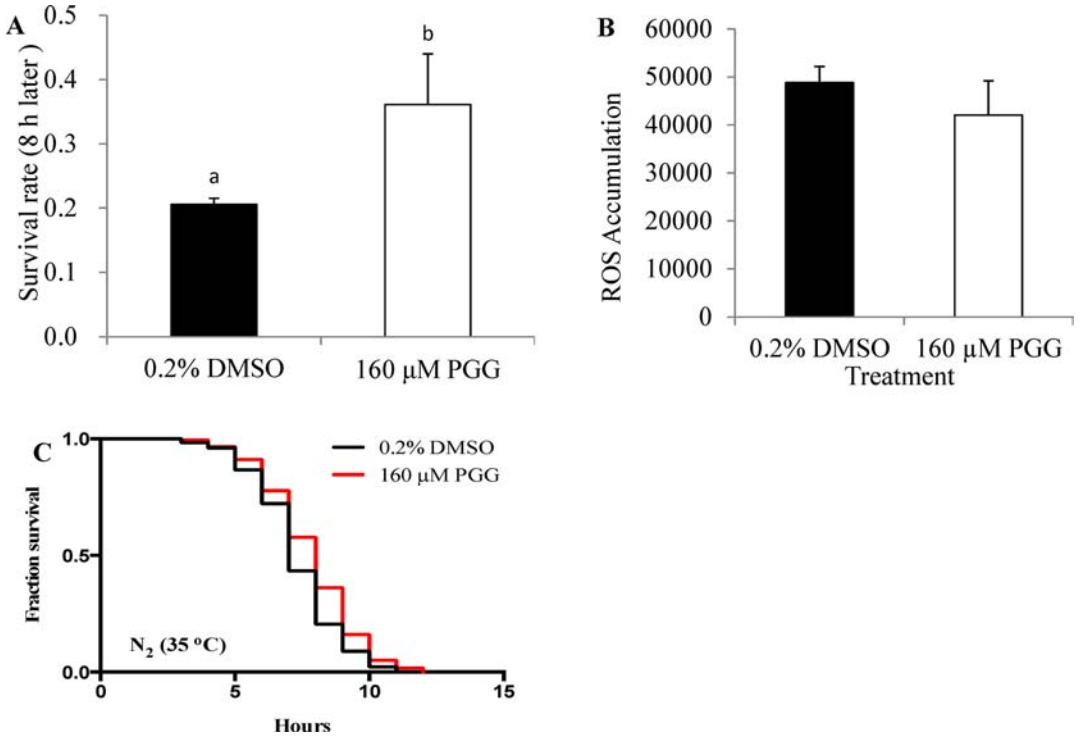

Figure 3. Effect of PGG treatment on thermal resistance and ROS accumulation. (A) Survival rates after being treated for 8 h after the worms were shifted from 20 to 35 °C on day 4. The different letters in the column denoted values that were significantly different ($p < 0.05$). (B) After treatment with PGG or control for 96 h, worms were placed on a NGM plate to remove the bacteria three times. Then 80 worms were transferred to 50 μL of M9 buffer in a 96-well plate and mixed with 50 μL of fresh 100 μM H_2-DCF-DA (final concentration, 50 μM). Emission fluorescence intensity at 528 nm with excitation at 485 was recorded every 15 min for 12 h at 25 °C. (C) Survival curve of worms after the worms were shifted from 20 to 35 °C on day 4.

spectrofluorometer (Fluorolog-3, Jobin Yvon Inc., Edison, NJ, USA). The results are the average fluorescence intensity levels of three independent trials.

Statistical Analysis. All results were presented as mean ± SD (n = 3). Assays for each experiment were performed three or four times. Log-rank (Mantel-Cox) tests were performed to analyze the survival curve using Graph Pad Prism version 5.00 for Windows (GraphPad Software, Inc., San Diega, CA, USA). One-way analysis of Variance (ANOVA) was performed using SPSS software (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Effect of PGG Treatment on the Median Lifespan of *C. elegans*. To address the concern about the stability of the *C. elegans* system used, first, the anti-aging effect of resveratrol (100 μM) (National Institutes for Food and Drug Control, Beijing, China) was investigated because of its widely anti-aging effect across diverse species including *C. elegans* and well-known mechanism of action.[8,16] We found that worms raised on 100 μM resveratrol not only manifested a significant survival curve ($P < 0.0001$ by the Log-rank test) but also showed a 13.2% increase in median lifespan (20.0 ± 1.0 days with resveratrol treatment vs 17.7 ± 0.6 days with control) ($p < 0.05$, ANOVA) (The survival curve for resveratrol is provided in Supporting Information, Figure S3), which was consistent with the results (approximately14%) obtained from the literature.[8] These results indicated the determination of lifespan in *C. elegans* in our lab was stable and comparable. So we continued to analyze the anti-aging effect of PGG with high cellular antioxidant activity in *C. elegans*.[12] To understand comprehensively the anti-aging effect, four different concentrations of PGG ranging from 40 to 160 μM were tested. The treatment of the wide-type worm started from embryo till death. We found that different concentrations of PGG had different performances. Of the four concentrations, worms raised on 160 μM PGG not only manifested a significant survival curve (Figure 1B) ($P < 0.0001$ by the Log-rank test) but also had a median lifespan of 21.5 ± 2.4 days with maximum lifespan of 40 days and increased by 18% ($p < 0.05$, ANOVA) in median lifespan. Worms treated with 40, 80, and 120 μM PGG did not show a significant increase in median lifespan, but their treatment showed a slightly increasing trend in median lifespan (4%, 3%, and 11% increase for 40, 80, and 120 μM PGG, respectively). Furthermore, worms cultured on 120 μM PGG displayed a significant different right-shifted survival curve ($P = 0.0010$ by the Log-rank test) when compared with the control, and the survival curve of 120 μM PGG was continuously above that of control (Figure 1B). Although worms treated with 120 μM PGG did not show significant increase in median lifespan, it was more effective than control in the survival curve.

Taken together, these findings indicated that PGG supplementation could prolong median lifespan in *C. elegans*, and the optimal concentration was observed at 160 μM PGG (increased by 18% in median lifespan) during the tested concentrations. Therefore, 160 μM PGG was chosen for further study.

Effect of PGG Treatment on Physiological Functions of *C. elegans*. The decline of physiological functions such as self-fertile reproduction, pharyngeal pumping, age pigments, and locomotion happened in the aging process. To determine whether PGG caused side effects on the physiological functions at the optimal concentration, we analyzed those physiological function changes under PGG treatment. First, it is critical to

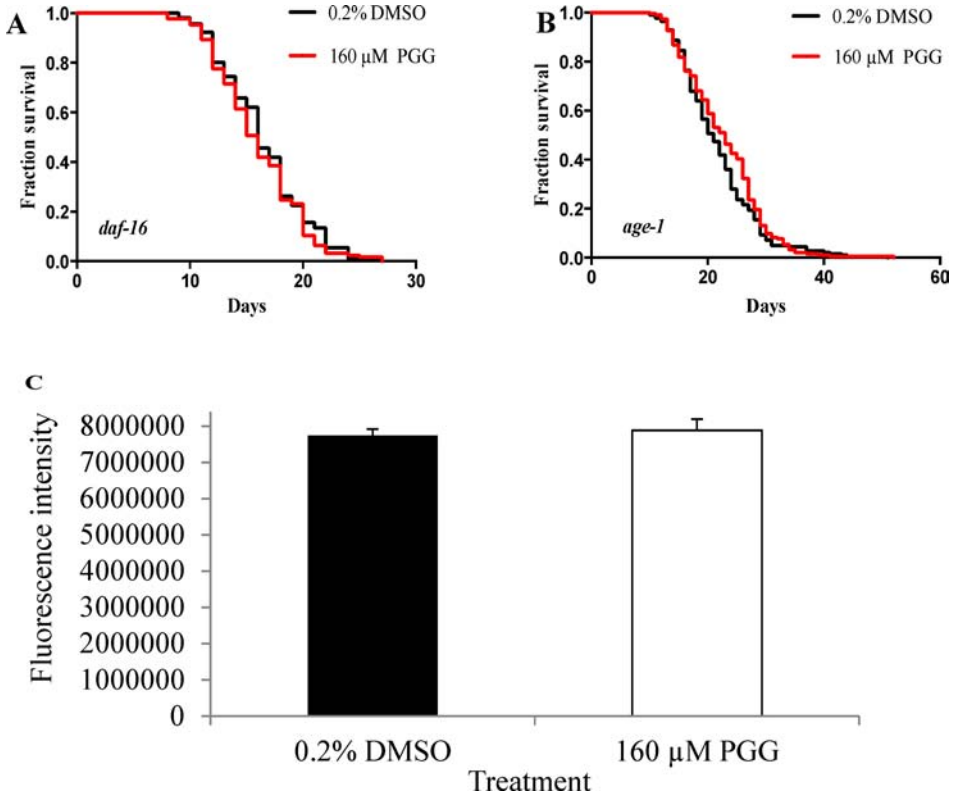

Figure 4. Effect of IIS pathway on the longevity extension induced by PGG. (A) Survival curves of *daf-16(mgDf50)* (Log-rank test, $P = 0.2774$). (B) Survival curves of *age-1(hx546)* (Log-rank test, $P = 0.0003$). (C) Worms of transgenic strain CF1553 [muIs84 [pAD76 (sod-3::gfp)]] were raised from eggs on plates as in the lifespan assays until day 5 of life. The level of expression of GFP in the transgenic strain was measured using an in vivo spectrofluorometer. The results are the average fluorescence intensity levels of three independent trials.

investigate progeny production because a few mechanisms that extend the longevity have an impact on it.[17] We recorded the effect of PGG treatment on the progeny production daily to investigate whether PGG suppressed or delayed it. Worms cultured on medium containing 160 μM PGG showed neither slowed reproduction nor reduced total progeny production. These results demonstrated that median lifespan extension induced by PGG treatment was not obtained by suppressing or delaying progeny production (Figure 2A).

One well-conserved feature of aging is the decline of pharyngeal pumping, which is rhythmic contraction in the neuromuscular organ.[18] We investigated whether PGG had an effect on pharyngeal pumping rate on days 5, 10, and 15. We found that pharyngeal pumping decreased with age, but PGG treatment did not affect the pharyngeal pumping rate in the three stages (Figure 2B). So the possibility that PGG extended lifespan by reducing food intake that results into dietary restriction could be ruled out.

Age pigments contain both intracellular and extracellular age-related, fluorescent material and include advanced glycation end-products and lipofuscin, a heterogeneous mix of oxidized and cross-linked molecules (proteins, lipids, and carbohydrates) that accumulate in intestinal lysosomes.[19] We measured the accumulation of age pigments in worms with PGG treatment in order to see the effect of PGG on the aging process. As shown in Figure 2C, age pigment fluorescence levels did not significantly lower or increase when the worms were cultured on 160 μM PGG at three stages. Therefore, PGG-induced lifespan extension was not associated with any significant change in the accumulation of age pigments .

Locomotion ability declines on solid and liquid media with increasing age, which is correlated with the level of muscle deterioration.[18] To determine whether PGG can enhance lifespan by extending locomotory ability, we tested the effect of the PGG treatment on the swimming vigor, defined as head thrash per unit time in a liquid environment, at early, middle, and late life stages (on days 5, 10, and 15, respectively). We found that head thrash of the worms declined with the increasing day and PGG treatment did not significantly change the swimming rates at the three stages (Figure 2D). These findings indicated PGG neither caused detrimental effects in locomotory ability nor increased swimming in a liquid environment.

To summarize, PGG treatment prolonged the median lifespan without causing obvious defect in physiological functions including fertility, pharyngeal pumping rate, age pigments, and locomotion ability. So we continued to gain insight into the related mechanisms.

Effect of PGG Treatment on Thermal Resistance and ROS Accumulation. Longevity extension is generally related with elevated survival under the conditions of stress.[20] To exploit whether PGG enhanced heat stress resistance, worms treated with or without compound were shifted from 20 to 35 °C on day 4. The survival rates after 8 h at 35 °C were increased significantly by PGG treatment (increasd from 21% to 36%) (Figure 3A). Compared with the control, the group with PGG treatment showed a significantly different survival curve ($P = 0.016$ by the Log-rank test) (Figure 3C). The findings suggested that PGG supplementation could act

dx.doi.org/10.1021/jf500210p | J. Agric. Food Chem. 2014, 62, 3422−3431

protectively under the thermal stress and enhance resistance to heat shock in *C. elegans*.

According to the free-radical theory of aging, an excess of reactive oxygen species (ROS) is responsible for the process of aging and the lifespan extension is associated with damage caused by ROS.[21] Therefore, we measured the effect of PGG on the intracellular amount of ROS. The accumulation of ROS was measured using H2DCF-DA, which is converted to the fluorescent dye DCF intracellularly. In states of exposure to PGG for 96 h, the reduction of ROS accumulation induced by PGG was not significantly different (Figure 3B). Strikingly, PGG showed high antioxidant activity in both chemical-based and cell-based assays[12] but did not exhibit the ROS scavenging activity in *C. elegans*. In fact, many factors and processes such as uptake, metabolism, and interaction need to be considered if the antioxidant activity needs to take effect in the whole organism. The reason for the failure in ROS scavenging ability could be that the antioxidant property of PGG was not sufficient to reduce the accumulation of ROS in *C. elegans* or the bioavailability of PGG was low in *C. elegans*.

Effect of PGG on Median Lifespan of Mutants Involved with the IIS Pathway. The insulin/IGF signaling (IIS) pathway is well-known to be a central controller of longevity in *C. elegans* regulated via the phosphorylation situation of the transcription factor DAF-16.[22] PGG could interact with DAF-2 (the proteins encoded by *daf-2*),[11] the only homologue of insulin receptor in the *C. elegans*, which could reduce their activity and result in lifespan extension through triggering the IIS pathway. To clarify this possibility, we tested a *daf-16(mgDf50)* null mutant strain cultured on 160 μM PGG and found that PGG did not increase the median lifespan of the *daf-16* mutant [16.7 days for the *daf-16(mgDf50)*] null mutant vs 17.3 days with PGG treatment (Figure 4A and Table 1). This finding suggested that PGG could extend median lifespan by acting through a mechanism that is dependent on DAF-16/FOXO. Next, to further understand the genetic requirement for the IIS pathway in the action, we tested the effect of long-lived *age-1(hx546)* mutants treated with PGG. Interestingly, worms cultured on 160 μM PGG displayed a significantly different survival curve compared with *daf-16(mgDf50)* mutant (the control), but PGG did not extend the median lifespan of *age-1(hx546)* (Figure 4B and Table 1). These findings suggested that PGG could be dependent on *daf-16(mgDf50)* and *age-1(hx546)* to increase median lifespan.

Considering that DAF-16 nuclear localization affects lifespan in the IIS pathway and *sod-3* is one of the DAF-16 direct target genes and encodes a Fe/Mn superoxide dismutase, we tested the effect of PGG on the fluorescence intensity in worms of the transgenic strain CF1553, which is SOD-3::GFP reporter gene expression.[15] However, the PGG-treated group did not demonstrate significant change in fluorescence intensity of the transgenic CF1553 on day 5 (Figure 4C). These results suggested that although *age-1* and *daf-16* were necessary for PGG-mediated median lifespan extension, the whole IIS pathway could not be a direct target of PGG. The possibility of this phenomenon was that PGG could act on another pathway that involved with *daf-16* and *age-1*. It has been proven that multiple interaction partners are necessary for proper DAF-16 activity.[23]

Effect of PGG on Median Lifespan of Mutants Involved with Dietary Restriction and the Sir-2.1 Pathway. The other well-known mechanism considered could be dietary restriction.[5] PGG also has the tannins' common characteristics of binding proteins by forming hydrogen and ionic bonds,[11] which would inhibit digestive enzymes and cause effects that are similar to a dietary restriction. Therefore, to test whether PGG extended the lifespan by acting through dietary restriction, the effect of PGG on the lifespan of the *eat-2(ad1116)* mutant was investigated, which is a long-lived mutant and a genetic model for dietary restriction due to decreased pharyngeal pumping in *C. elegans*.[5] PGG did not increase the median lifespan of the *eat-2(ad1116)* mutant (Figure 5A and Table 1). This indicated that PGG was depend on *eat-2(ad1116)*, which could be consistent with the model that PGG acts by stimulating the DR pathway. However, one feature of dietary restriction in *C. elegans* is a reduction of total number of progeny or an extended period of progeny production.[17] We found that PGG did not change the progeny production. To summarize, the results suggested that PGG did not act exactly through DR to increase median lifespan.

Given the genetic indication that dietary restriction (DR) was involved with the mechanism and the botanical polyphenol antioxidant resveratrol, a DR mimetic, extends the lifespan by stimulating the activity of *sir-2.1*, which encodes a histone deacetylase-like protein that integrates metabolic situation with lifespan,[24] we accordingly hypothesized that *sir-2.1* might be also involved into the mechanism of action of PGG-mediated longevity because of the common properties of polyphenol and antioxidant. Given that possibility, we tested PGG effects on the *sir-2.1(ok434)* mutant. We found PGG did not extend the lifespan of a *sir-2.1* null mutant (Figure 5B and Table 1).

Table 1. Genetic Requirement for Lifespan Extension Induced by PGG

genotype	treatment	median lifespan[a] (mean ± SD) (days)	maximum lifespan[a] (mean ± SD) (days)	genetic requirement
daf-16	0.2% DMSO	16.7 ± 1.2	24.0 ± 0.0	yes
	160 μM PGG	17.3 ± 1.2	23.3 ± 1.2	
age-1	0.2% DMSO	21.0 ± 1.8	44.8 ± 4.3	yes
	160 μM PGG	23.0 ± 3.2	37.8 ± 9.6	
eat-2	0.2% DMSO	21.3 ± 1.5	36.7 ± 5.5	yes
	160 μM PGG	22.7 ± 2.5	36.0 ± 2.0	
sir-2.1	0.2% DMSO	20.0 ± 0.0	29.3 ± 3.8	yes
	160 μM PGG	20.0 ± 0.0	31.7 ± 5.0	
isp-1	0.2% DMSO	23.0 ± 0.0	38.0 ± 3.5	yes
	160 μM PGG	21.0 ± 2.0	39.3 ± 1.2	
mev-1	0.2% DMSO	12.7 ± 1.0	18.5 ± 2.9	no
	160 μM PGG	**14.3 ± 1.2***	19.7 ± 0.8	
clk-1	0.2% DMSO	17.7 ± 1.5	36.0 ± 4.6	no
	160 μM PGG	**23.0 ± 2.6***	37.3 ± 3.2	

[a]The median lifespan is the time at which fraction survival equals 50%. The maximum lifespan is the time at which fraction survival equals 0%. The data was analyzed by One way-ANOVA analysis (SPSS 13), and and asterisk (*) designates significantly different values ($p < 0.05$).

dx.doi.org/10.1021/jf500210p | J. Agric. Food Chem. 2014, 62, 3422−3431

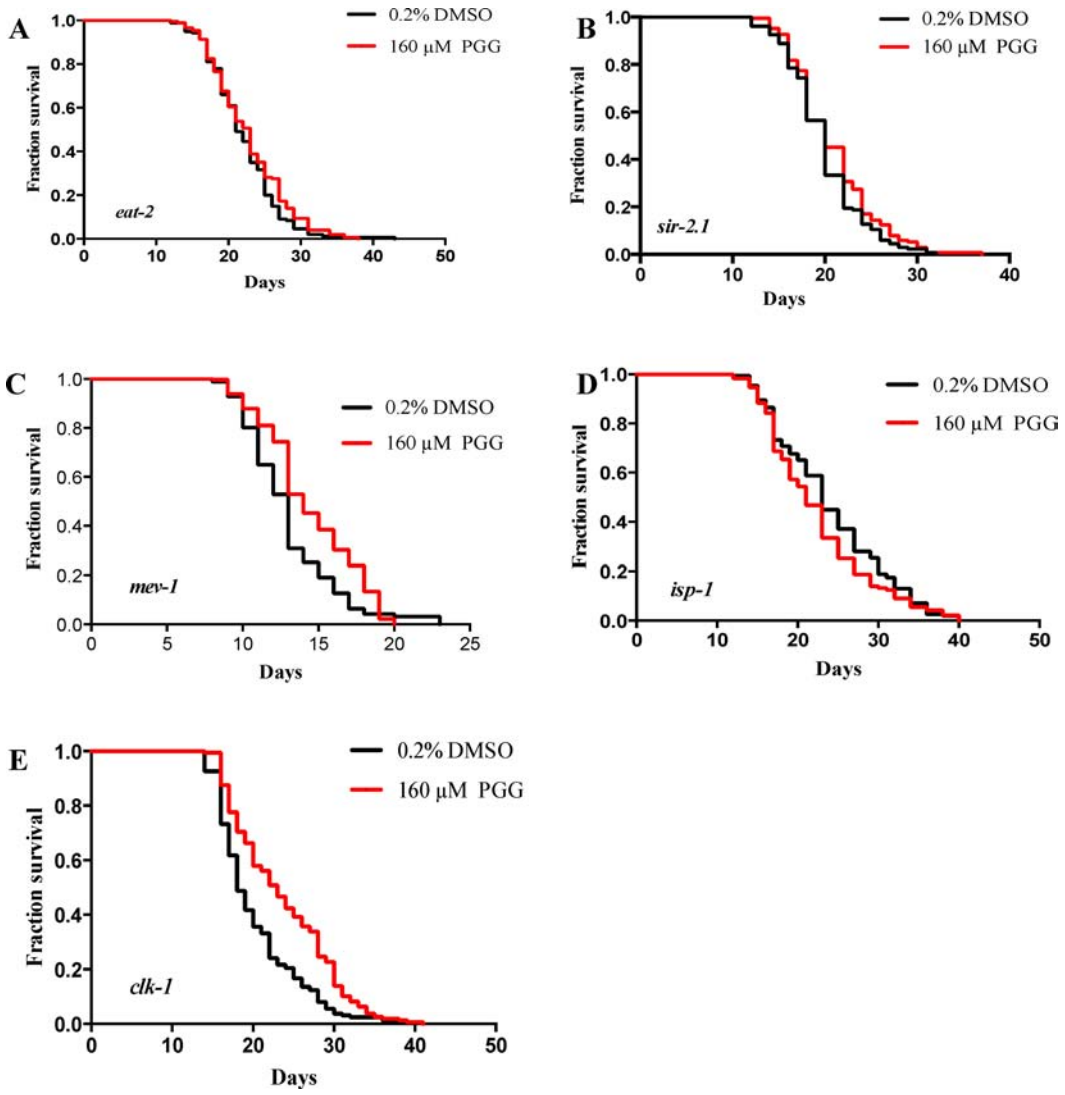

Figure 5. Survival curves of mutants raised at 20 °C on plates containing 0.2% DMSO (control) or 160 μM PGG. (A) The *P*-value for *eat-2(ad1116)* was 0.1010 (Log-rank test). (B) The *P*-value for *sir-2.1(ok434)* was 0.0702 (Log-rank test). (C) The *P*-value for *mev-1(kn1)* was <0.0001 (Log-rank test). (D) The *P*-value for *isp-1(qm150)* was 0.0730 (Log-rank test). (E) The *P*-value for *clk-1(qm30)* was <0.0001 (Log-rank test).

However, lifespan extension by resveratrol is mediated by *sir-2.1* and is independent on the insulin/IGF pathway.[25] The finding indicated that PGG acted differently from resveratrol, but Sir-2.1 signaling was part of the mechanism that increased the longevity induced by PGG.

Effect of PGG on Median Lifespan of Mutants Involved with Mitochondrial Electron Transport Chain Pathway. Oxidative stress is a factor of aging,[21] and ROS is mainly generated from mitochondrial metabolism.[26] Gene-encoded components in mitochondrial transport chains are identified to alter levels of oxidative stress in *C. elegans*.[26] So we wanted to elucidate whether mitochondrial function was the underlying mechanism of the lifespan extension. First, we observed the lifespan of the *mev-1(kn1)* mutant, which strain has a defect in the succinate dehydrogenase cytochrome *b* large subunit in the complex II of the mitochondrial electron transport chain. We found that PGG increased significantly the lifespan of the *mev-1(kn1)* mutant (Figure 5C and Table 1). Strikingly, PGG did not reduce internal reactive oxygen species (ROS) but prolonged the lifespan of mutant *mev-1*, which is hypersensitive to oxidative stress. The results indicated that PGG might act independently of MEV-1, but the lifespan extension for *mev-1(kn1)* might not be attributed to a direct antioxidative property of PGG. According to report, supernumerary apoptosis also contributed to the shortened lifespan of *mev-1*.[27] Like the coenzyme Q_{10}, PGG may prolong the longevity of *mev-1* mutant by lowering apoptosis.[10]

The mutation in iron sulfur protein (*isp-1*) resulted in low oxygen consumption, insensitivity to ROS, and long longevity. The *isp-1* gene encodes a component of mitochondrial complex III, which accepts electrons and protons from mitochondrial complexes I and II.[26] We found that *isp-1(qm150)* mutant with PGG treatment did not exhibit median lifespan extension (Figure 5D and Table 1), which indicated PGG might act dependently on ISP-1.

The gene *clk-1* encodes a demethoxyubiquinone hydroxylase that is necessary for the biosynthesis of ubiquinone (coenzyme Q_{10}). The long-lived *clk-1(qm30)* mutant is deficient in the endogenous form of coenzyme Q_{10}, which is responsible for the carrying of electron and protons from mitochondrial complexes I and II to complex III.[28] To test whether other mitochondrial function mutants were important for the extension benefit, we

dx.doi.org/10.1021/jf500210p | J. Agric. Food Chem. 2014, 62, 3422−3431

measured the lifespan effect on *clk-1*. We found that the median lifespan in *clk-1* mutant treated with PGG increased by 30% compared to the control (Figure 5E and Table 1)m which suggested that PGG might act independently of CLK-1.

Taken together, PGG treatment acted independently on MEV-1 and CLK-1 but acted dependently on ISP-1. The mitochondrial electron transport chain was partially involved with the PGG-mediated longevity extension.

Model of Action for the Longevity Extension Mechanism Mediated by PGG. A variety of genetic, environmental, and pharmacological treatments affect the lifespan. We will discuss how the PGG treatment extended the lifespan of *C. elegans*. First, there is a hormesis hypothesis that exposure to low-level toxic stress would result in a protective stress reaction and lifespan extension, which indicates that hormesis can slow down aging.[29] The mechanism of action for lifespan extension induced by tannin acid, one of the hydrolyzable tannins, was involved with a hormesis effect.[30] However, there was little possibility that the mechanism of action for PGG was consistent with the hormesis effect because even the low concentration treatments (40, 80, and 120 μM) did not show significant increase in median lifespan, the different concentration of PGG treatments also showed increase trend in lifespan, and 120 μM PGG displayed a significant different survival curve. What is more, 160 μM PGG did not show an obvious defect in physiological function. Further experiments at higher concentrations are needed to totally rule out this possibility. Second, there are physiological processes that promote a short lifespan, and inhibiting these processes can result in a longevity extension. Age pigments and ROS promoting aging were generated during the aging process.[19] Since PGG treatment did not reduce the accumulation of age pigments and ROS, we can rule out this possibility that PGG treatment extends the lifespan by lowering the accumulation of age pigments and ROS, but there is a possibility that PGG treatment directly or indirectly binds and decreases the activity of specific protein that inhibits longevity. Third, there is trade-off between reproduction and longevity. According to Kirkwood's "disposable soma theory", the energy for required lifespan extension is diverted from reproduction.[31] This explanation is unlikely to be considered for PGG treatment because PGG did not reduce reproduction. Fourth, longevity extension is generally related with elevated survival under the conditions of stress.[20] We found that PGG supplementation can enhance resistance to heat stress in *C. elegans*, So the longevity extension of PGG could be attributed to its protective effect under heat stress.

Finally, except for those factors, many genetic manipulations and pathways are known to influence aging, including insulin/IGF-1 signaling, caloric restriction signaling, and mitochondrial respiration. First, our results showed PGG increased neither the median lifespan of the *daf-16* or *age-1* mutants nor the fluorescence intensity of SOD-3. Those results indicated that although *age-1* and *daf-16* were necessary for PGG-mediated median lifespan extension, the IIS pathway might not be a direct target of PGG. Here, we came up with two explanations for that. The first explanation is that PGG or its metabolite directly binds one of the targets that function downstream of DAF-16. The second explanation is that the effect of PGG on the median lifespan of *age-1* and *daf-16* mutants reflects the toxicity of combining the mutation and the drug treatment. So the IIS pathway seemed not sufficient to explain PGG-mediated longevity. It has been proven that multiple interaction partners are necessary for proper DAF-16 activity.[23] Second, according to our current results, EAT-2 and Sir-2.1 in the DR mimetic pathway were also involved in the mechanism of action of lifespan extension induced by PGG but did not affect fecundity or pharyngeal pumping rate. According to report,[32] SIR-2.1 acts in parallel to the insulin-like pathway to regulate DAF-16 in a manner dependent on 14-3-3 proteins during stress and extended lifespan. So *sir-2.1* might act through DAF-16 in PGG-mediated longevity extension. We also found that the mitochondrial electron transport chain became partly involved in the PGG-mediated longevity extension. PGG treatment acted independently of MEV-1 and CLK-1 but acted dependently of ISP-1.

In summary, the insulin/IGF-1 signaling pathway, caloric restriction, mitochondrial metabolism, and Sir-2.1 signaling pathways could partly be involved with the specific mechanisms of action for PGG in lifespan. This finding is in agreement with the report that PGG shows a variety of biological activities through multiple mechanisms.[11] So we propose that the general model of action for PGG in longevity extension is that PGG or its metabolite likely binds one or more targets that function downstream of DAF-16 and EAT-2. The targets likely act through the ISP-1 pathway and trigger a series of events that elevate stress resistance and extend longevity (Figure 6).

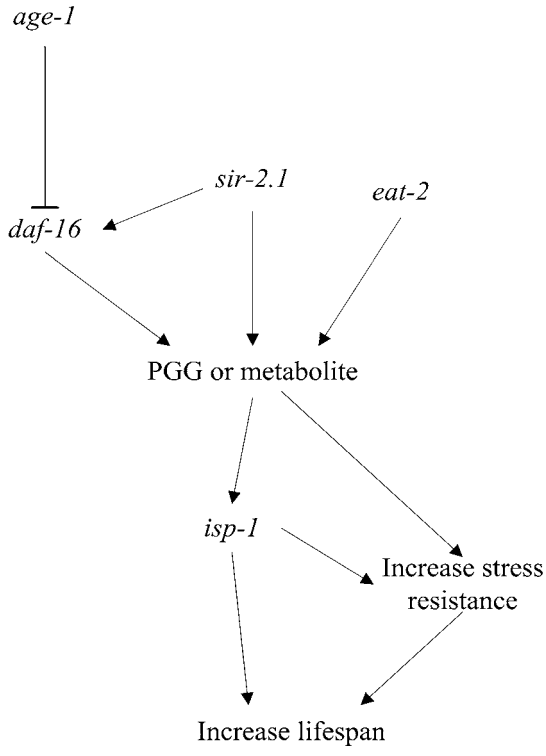

Figure 6. Model of action of the longevity extension mediated by PGG. PGG likely bound one or more targets that function downstream of DAF-16 and EAT-2. The targets likely acted through the ISP-1 pathway and triggered a series of events that elevated stress resistance and extended longevity.

Compared with the single-target therapeutics, multitarget therapeutics regulate multiple nodes of the disease network simultaneously and shows a synergistic effect and are unlikely to induce resistance, providing optimal clinical use.[33] Thus, there is a general agreement that molecules interfering simultaneously with multiple targets might be more effective

than single-target agents, and scientists have recently proposed that a new generation of drugs, able to inhibit more than one pathway, would probably play a major role.[34] So our results provide the first insights into the mechanism of longevity extension mediated by PGG in *C. elegans*, which might be developed into a novel multitarget drug for promoting healthy aging.

In conclusion, the lifespan and resistance under acute heat stress for *C. elegans* were improved without causing obviously adverse effects on physiological functions including reproduction, pharyngeal pumping rate, age pigments accumulation, and swimming ability. These significant findings indicated that the IIS pathway, dietary restriction, Sir-2.1 signaling, and mitochondrial electron transport chain could partly be involved with lifespan extension mediated by PGG and PGG could target multiple longevity mechanisms to extend lifespan. One possible mode of action drawn from our findings was that PGG or its metabolite likely bound one or more targets that functioned downstream of DAF-16 and EAT-2, and the targets likely acted through the ISP-1 pathway and triggered a series of events that elevated stress resistance and extended longevity. Our results provided the first insights into the mechanism of longevity extension mediated by PGG in *C. elegans*, which may be exploited in novel multitarget therapeutics for prolonging lifespan.

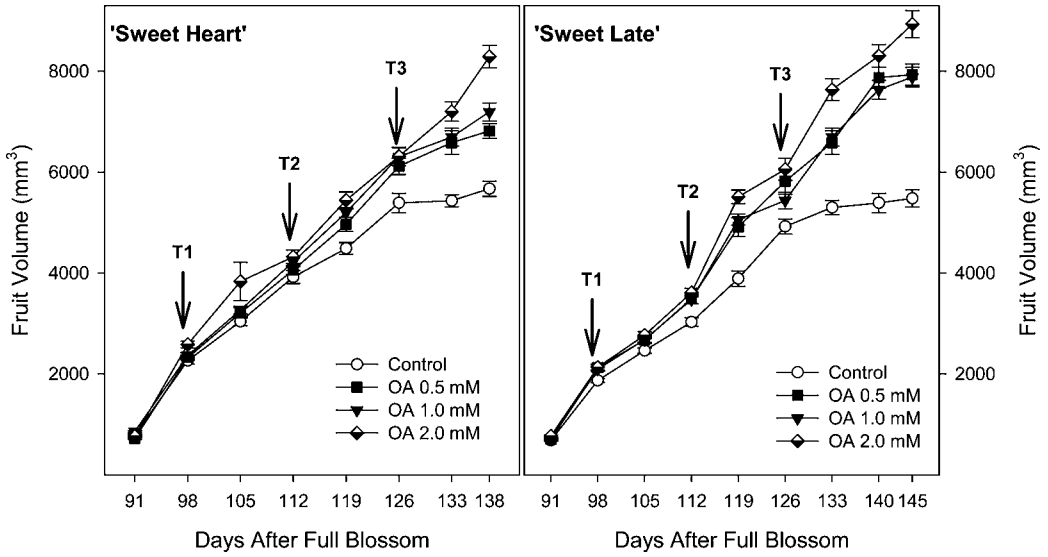

Figure 1. Fruit volume (mm^3) during on-tree fruit development of 'Sweet Heart' and 'Sweet Late' sweet cherry cultivars treated with oxalic acid (OA, 0.5, 1.0, or 2.0 mM) at 98, 112, and 126 days after full blossom (T1, T2, and T3). Data are the mean ± SE.

Spain). Freshly prepared solutions (containing 0.5% Tween 20) were foliar sprayed with a mechanical mist sprayer and repeated at three dates of the growth cycle: T1 (at pit hardening, 98 days after full blossom, DAFB), T2 (initial color changes, 112 DAFB), and T3 (onset of ripening, 126 DAFB). These dates corresponded to key events in the fruit developmental process, according to previous experiments.[3] Before T1 treatment, 20 fruits were labeled around the equatorial perimeter of each tree, in which fruit growth was followed by measuring polar, suture, and cheek diameters, and then fruit volume was calculated as previously reported.[3] On a weekly basis, from 1 week before the T1 treatment to commercial harvesting, 20 fruits (similar to those labeled) for each tree (or replicate) were picked for further analytical determinations: fruit firmness, color, total soluble solids (TSS), and total acidity (TA). In addition, the content of bioactive compounds (total phenolics and total anthocyanins) and total antioxidant activity were determined in fruits from control and 2.0 mM OA treated trees. In these fruits, the individual contents of anthocyanins, flavonols, and chlorogenic acid derivatives were measured at the last sampling date (commercial harvest). At the time of harvesting, 100 cherries from each tree, cultivar, and treatment were randomly picked for determining the fruit weight.

Ripening Parameters. Color was determined in each cheek of 20 fruits from each replicate by using a Minolta colorimeter (CRC200, Minolta Camera Co., Japan), using the CIELab coordinates and expressed as a^*/b^* index. Fruit firmness was determined independently in 20 fruits of each replicate using a TX-XT2i texture analyzer (Stable Microsystems, Godalming, UK) interfaced to a personal computer, with a flat steel plate mounted on the machine. For each fruit, the cheek diameter was measured, and then a force that achieved a 3% deformation of the fruit diameter was applied. Results were expressed as the force−deformation ratio (N mm^{-1}) and were the mean ± SE. After that, the 20 fruits of each sample were cut in small pieces to obtain a homogeneous sample for each replicate. TSS were determined in duplicate in the juice obtained from 5 g of each sample with a digital refractometer Atago PR-101 (Atago Co. Ltd., Tokyo, Japan) at 20 °C and expressed as grams per 100 g (mean ± SE). Total acidity (TA) was determined in duplicate in the same juice by automatic titration (785 DMP Titrino, Metrohm) with 0.1 N NaOH up to pH 8.1, using 1 mL of diluted juice in 25 mL of distilled H_2O, and results (mean ± SE) were expressed as grams of malic acid equivalent per 100 g of fresh weight.

Total Antioxidant Activity (TAA) Determination. TAA was quantified in duplicate in each sample as previously described.[10] Briefly, 5 g was homogenized in 5 mL of 50 mM sodium phosphate buffer, pH 7.8, and 3 mL of ethyl acetate and then centrifuged at 10000*g* for 15 min at 4 °C. The upper fraction was used for total antioxidant activity due to lipophilic compounds (L-TAA) and the lower fraction for total antioxidant activity due to hydrophilic compounds (H-TAA). In both cases, TAA was determined using the enzymatic system composed of the chromophore 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), the horseradish peroxidase enzyme (HRP), and its oxidant substrate (hydrogen peroxide, H_2O_2), in which $ABTS^{\bullet+}$ radicals are generated and monitored at 730 nm. The reaction mixture contained 2 mM ABTS, 15 μM H_2O_2, and 25 μM HRP in 50 mM sodium phosphate buffer (pH 7.8) in a total volume of 1 mL. The decrease in absorbance after adding the extract was proportional to the TAA of the sample. A calibration curve was performed with Trolox ((*R*)-(+)-6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) (0−20 nmol) from Sigma (Madrid, Spain), and results are expressed as milligrams of Trolox equivalent per 100 g of fresh weight.

Bioactive Compound Determination. Total phenolics were extracted according to the Tomás-Barberán et al. protocol[20] using water/methanol (2:8) containing 2 mM NaF (to inactivate polyphenol oxidase activity and prevent phenolic degradation) and quantified in duplicate using the Folin−Ciocalteu reagent, and results (mean ± SE) were expressed as milligrams of gallic acid equivalent per 100 g of fresh weight. Total anthocyanins were determined according to the method of García-Viguera et al.[21] adapted as previously reported[10] and calculated as cyanidin 3-glucoside equivalent (molar absorption coefficient of 23900 L cm^{-1} mol^{-1} and molecular weight of 449.2 g mol^{-1}), and results were expressed as milligrams per 100 g of fresh weight and were the mean ± SE. For individual phenolic compounds, the protocol described by Gironés-Vilaplana et al. was followed.[22] Briefly, lyophilized samples (100 mg) were mixed with 1 mL of methanol/formic acid/water (25:1:24, v/v/v), vortexed, sonicated in an ultrasonic bath for 60 min, and centrifuged at 10500*g* for 5 min. The supernatant was filtered through a 0.45 μm PVDF filter (Millex HV13, Millipore, Bedford, MA, USA) and used for HPLC analysis. The HPLC system was equipped with a Luna C18 column (25 cm × 0.46 cm i.d., 5 μm particle size; Phenomenex, Macclesfield, UK) with a C18 security guard (4.0 × 3.0 mm) cartridge system (Phenomenex). Water/formic acid (99:5, v/v) and acetonitrile were used as mobile phases A and B, respectively, with a flow rate of 1 mL/min. The linear gradient started with 8% of solvent B, reaching 15% of solvent B at 25 min, 22% at 55, and 40% at 60 min, which was maintained up to 70 min. The injection volume was 20 μL. Chromatograms were recorded at 280, 320, 360, and 520 nm. Different phenolics were characterized by chromatographic comparison with analytical standards as well as quantified by the absorbance of their corresponding peaks.

[a]Data are the mean ± SE. Different letters within a row show significant differences at $p < 0.05$.

Hydroxycinnamic derivatives, *p*-coumaroylquinic acid, and hydroxybenzoic acid were characterized by chromatographic comparison according to previous reports based on retention time and UV−vis spectra.[20] Anthocyanin standards (cyanidin 3-glucoside, cyanidin 3-rutinoside, and pelargonidin 3-rutinoside) were purchased from Polyphenols SA (Sandnes, Norway). Anthocyanins were quantified as cyanidin 3-*O*-glucoside at 520 nm, cinnamic acids as 5-*O*-caffeoylquinic acid at 320 nm, and flavonols as quercetin 3-*O*-rutinoside at 360 nm and expressed as milligrams per 100 g of fresh weight (mean ± SE).

Statistical Analysis. Data for the analytical determinations were subjected to analysis of variance (ANOVA). Sources of variation were days after full blossom and treatment or just treatment for individual anthocyanins, flavonols, and chlorogenic acid derivatives. Mean comparisons were performed using Tukey's HSD test to examine if differences were significant at $P < 0.05$. Linear regressions were performed between phenolic and anthocyanin concentrations, as well as among total phenolics and H-TAA, taking into account data from cultivars, treatments, and all sampling dates. All analyses were performed with SPSS software package v. 12.0 for Windows.

RESULTS AND DISCUSSION

Sweet Cherry Growth and Ripening Parameters. Fruit growth (measured as fruit volume) increased sharply from 91 DAFB until 126 and 133 DAFB in control fruit from 'Sweet Heart' and 'Sweet Late' cultivars, respectively, the increase being lower from this time to commercial maturity stage (Figure 1). However, in cherries from OA-treated trees the increase in fruit volume continued until the last sampling date, the highest fruit volume being reached with OA treatment at 2.0 mM in both sweet cherry cultivars. The effect of OA treatments on increasing fruit growth was also evident in the final fruit weight at the last sampling date, with values of 6.77 ± 0.13 and 6.62 ± 0.14 g for control fruits of 'Sweet Heart' and 'Sweet Late' cultivars, respectively, and significantly higher in cherries from OA-treated trees, ca. 8 and 8.5 g with 2.0 mM OA for 'Sweet Heart' and 'Sweet Late', respectively (Table 1).

Texture is one of the most important attributes in sweet cherry, and it is often used for quality assessment, although there are considerable genotypic differences.[3] Fruit firmness decreased sharply as fruit weight increased (data not shown), which simply reflects cell enlargement during fruit growth, whereas softening in the last days of on-tree fruit ripening has been attributed to cell wall modification, mainly due to increases in β-galactosidase activity.[3,23] However, fruit firmness at commercial ripening stage was significantly higher in cherries from OA-treated trees than in controls, especially with the 2.0 mM dose (Table 1). In plum and sweet cherry, postharvest treatments with OA decreased softening during storage as compared to control fruits, due to reduced activities of polygalacturonase and pectin methylesterase enzymes, leading to less pectin degradation and in turn to maintenance of fruit firmness,[13,19] which could be also reduced by preharvest OA treatments. In addition, the formation of oxalate-insoluble pectin could occur as a result of OA treatment, leading to a slowing of the softening process during on-tree ripening. In previous papers, it has been shown that the color parameter ratio a^*/b^* is a good index to describe the ripening process in sweet cherry, because it showed both a continuous increase until the last sampling date and important differences among cultivars.[3] Values at harvest of a^*/b^* index in 'Sweet Heart' and 'Sweet Late' cultivars were significantly higher in fruits from OA-treated trees than from controls, independent of the applied OA dose, showing a deeper red color in treated fruits than in controls (Table 1). In addition, TA and TSS were also increased in cherry fruits as a consequence of OA treatments, which could be attributed to an increase of net photosynthesis in OA-treated trees, this effect being also responsible for the higher fruit size and weight of cherries from treated trees as compared with those from control ones. In this sense, it has been reported that postharvest OA treatment of jujube fruit increased the abundance of three photosynthesis-related proteins, RuBisCO activase, RuBisCO large subunit-binding protein subunit β, and PSII oxygen-evolving complex protein.[15]

Postharvest OA treatment delayed the ripening process in climacteric fruits, such as mango,[12] plum,[13] banana,[24] and jujube fruit,[15] through inhibition of ethylene production. Although sweet cherry is a nonclimacteric fruit, postharvest OA treatments have been also effective in delaying the ripening process and maintaining fruit quality during storage, as well as in pomegranate, another nonclimacteric fruit.[16] However, in this experiment no effect of preharvest OA treatments was observed on the ripening process of sweet cherry, and fruits from control and treated trees were harvested on the same date.

Bioactive Compounds and Total Antioxidant Activity. Because the main effect of OA treatments on improving fruit quality parameters was obtained with the 2 mM dose, the content of bioactive compounds and antioxidant activity were

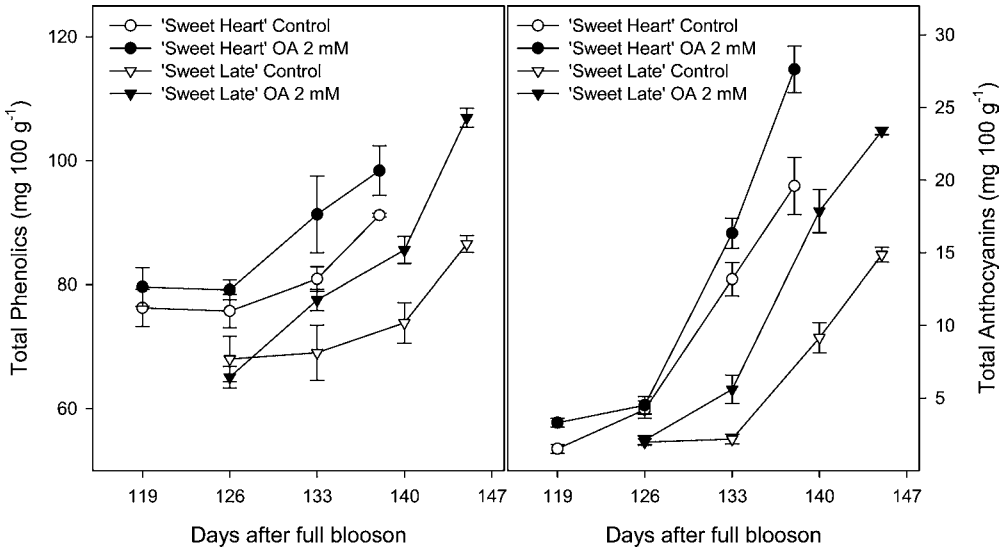

Figure 2. Total phenolics and total anthocyanins during on-tree fruit development in 'Sweet Heart' and 'Sweet Late' sweet cherry cultivars treated with oxalic acid (OA) at 2.0 mM, at 98, 112, and 126 days after full blossom. Data are the mean ± SE.

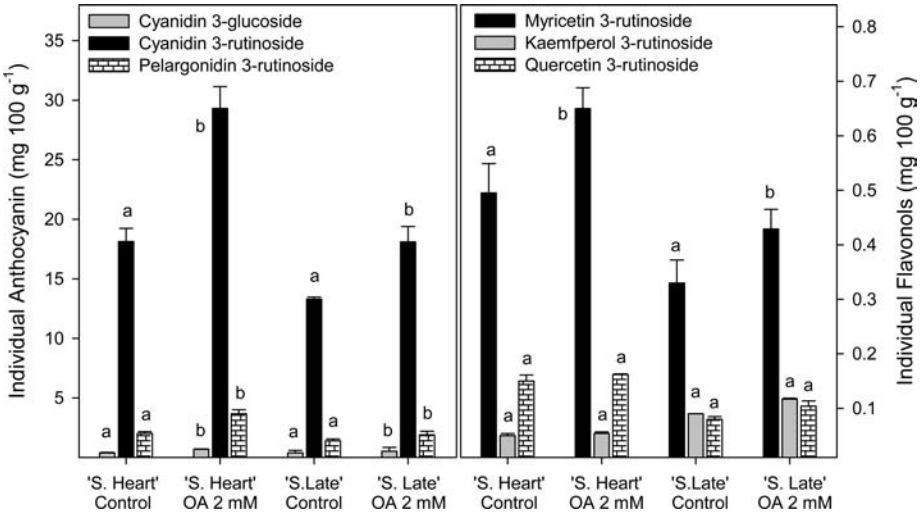

Figure 3. Individual anthocyanins and flavonols at commercial harvest in 'Sweet Heart' and 'Sweet Late' sweet cherry cultivars treated with oxalic acid (OA, 2.0 mM) at 98, 112, and 126 days after full blossom. Data are the mean ± SE. Bars with different letters show significant differences between control and treated fruits for each cultivar and individual compounds.

analyzed in cherries from control and 2 mM OA-treated trees. Total phenolics and anthocyanin concentrations increased sharply during the last 2 weeks of fruit ripening on-tree, although these values were higher in sweet cherries from OA-treated trees than in those from controls, for both cultivars (Figure 2). Accordingly, a significant increase in total phenolics as a consequence of postharvest OA treatment was also found during cold storage in sweet cherry,[19] as well as during storage at room temperature in the peel of banana[25] and mango[26] fruits, which was related to induced resistance against pathogenic attack. However, the mechanism behind how the OA treatment affects the phenolic content at molecular levels is still not completely known and deserves further research. On the contrary, in 'Damili' plum, postharvest OA treatment delayed the increase of anthocyanin content that occurred in control fruits during storage, attributed to a lower activity of phenylalanine ammonia-lyase (PAL), the key enzyme involved in the biosynthesis of anthocyanins.[13] However, in this fruit, the flesh reddening is associated with senescence and chilling injury symptoms, whereas in sweet cherry the accumulation of anthocyanins during development on-tree is a normal process of fruit ripening.[3] In addition, a close relationship was found between total phenolic and total anthocyanin concentrations ($y = 0.68x - 45.3$; $r^2 = 0.812$), taking into account data for both cultivars, treatments, and sampling dates, showing that in these sweet cherry cultivars anthocyanins are the main phenolic compounds, according to previous studies in other cherry cultivars.[10,27]

The predominant anthocyanin in both cherry cultivars was cyanidin 3-rutinoside followed by pelargonidin 3-rutinoside and cyanidin 3-glucoside, according to previous studies in other cherry cultivars,[8,10,27,28] and all of them were significantly higher in OA-treated than in control cherries at the last harvest sampling date (Figure 3). The individual flavonols were found at low concentrations, the main of them being myricetin 3-rutinoside in both sweet cherry cultivars, followed by quercetin 3-rutinoside and kaempferol 3-rutinoside, and all of them were significantly increased by OA treatment (Figure 3). Accord-

ingly, the main chlorogenic acid derivatives, neochlorogenic acid and chlorogenic acid, were also increased by OA treatment, whereas hydroxycinnamic derivative, *p*-coumaroylquinic acid, hydroxybenzoic acid, caffeic acid, and ferulic acid were found at low concentrations, without significant differences between cherries from control and treated trees (Figure 4). The

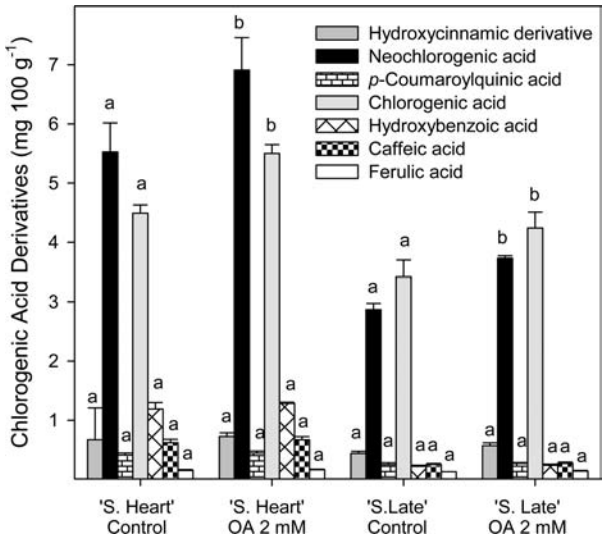

Figure 4. Individual phenolic acid derivatives at commercial harvest in 'Sweet Heart' and 'Sweet Late' sweet cherry cultivars treated with oxalic acid (OA, 2.0 mM) at 98, 112, and 126 days after full blossom. Data are the mean ± SE. Bars with different letters show significant differences between control and treated fruits for each cultivar and individual compounds.

flavonols and phenolic acid profile found in these cherry cultivars differed from previous results for other ones. Thus, for instance, in 'Lapins', 'Burlat', and 'Sylvia' cultivars *p*-coumaric acid derivatives were the main phenolic acids, together with chlorogenic and neochlorogenic acids,[2] and quercetin 3-rutinoside was the main flavonol in the 'Lapins' cultivar, which also varied depending on the cherry rootstock.[29]

TAA was measured in hydrophilic (H-TAA) and lipophilic (L-TAA) fractions separately, because early reports demonstrated that the contribution of L-TAA was about 20−30% of the TAA in a wide range of sweet cherry cultivars.[3] In 'Sweet Heart' and 'Sweet Late' cultivars H-TAA and L-TAA increased during fruit ripening on-tree, although the levels were significantly higher in fruits from OA-treated trees than in controls, especially for H-TAA (Figure 5). High correlation was found between total phenolic and H-TAA ($y = 2.16x - 95.9$; $r^2 = 0.687$), which is in agreement with previous papers reporting that phenolic compounds are the main hydrophilic compounds responsible for the antioxidant capacity of sweet cherry[2,3,10] and its health beneficial effects, such as the inhibition of human cancer cell proliferation.[31] Nevertheless, ascorbic acid is another hydrophilic compound that can also contribute to this antioxidant activity.[7] Accordingly, antioxidant activity due to phenolic compounds increased in banana peel as a consequence of postharvest OA treatment.[25] In addition, postharvest OA treatment of peach[14] and mango[18] fruits increased activities of the antioxidant enzymes superoxide dismutase, catalase, peroxidase, ascorbate peroxidase, and polyphenol oxidase. These antioxidant enzymes, together with the antioxidant compounds (phenolics, carotenoids, and ascorbic acid), are involved in scavenging free radicals and reactive oxygen species, which are generated during ripening and senescence.[30] Thus, preharvest OA treatment could also increase the antioxidant ability against oxidative damage and account for the beneficial effect of reducing cherry quality deterioration during postharvest storage.

In summary, results show for the first time that the application of the natural compound OA as preharvest treatment increased fruit size and other parameters related to sweet cherry fruit quality, such as firmness and color, but did not affect the normal ripening process on-tree. In addition, at harvest the content of bioactive phenolics, including anthocyanins, flavonols, and chlorogenic acid derivatives, and H-TAA and L-TAA were significantly higher in fruits from treated trees than in control fruits. Thus, OA preharvest treatment could be a natural and useful tool to improve the

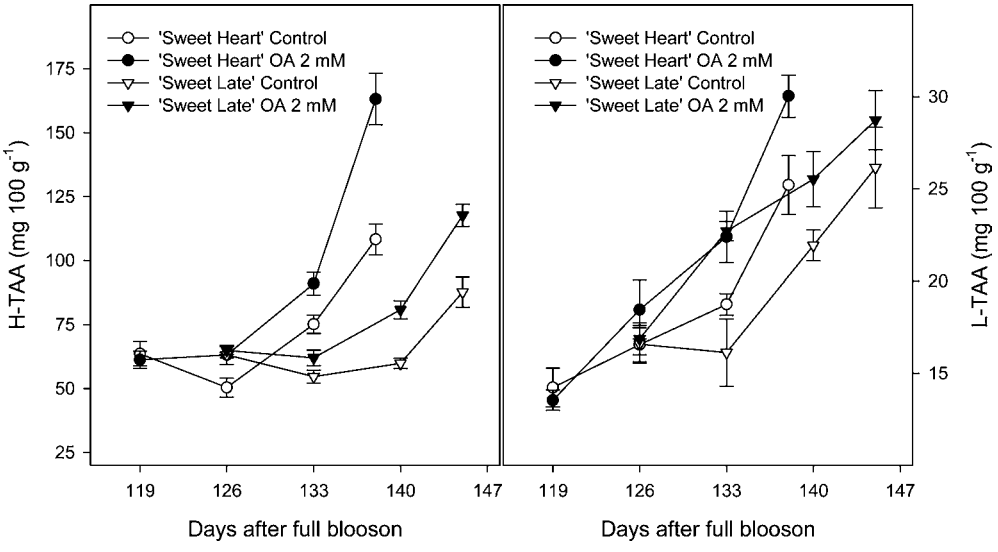

Figure 5. Changes in hydrophilic (H-TAA) and lipophilic total antioxidant activity (L-TAA) during on-tree fruit development in sweet cherry 'Sweet Heart' and 'Sweet Late' sweet cherry cultivars treated with oxalic acid (OA, 2.0 mM) at 98, 112, and 126 days after full blossom. Data are the mean ± SE.

through oxidiation of lactose with bromine under mild conditions. Since then, many chemical, electrocatalytic,[30−32] and microbial or enzymatic processes[33,34] for the production of lactobionic acid have been investigated. The major application of lactobionic acid is its use as a constituent in solutions that stabilize organs before transplantation. This is based on the excellent metal-chelating properties of the acid which reduce the oxidative damages, caused by certain metal ions, to tissues during the storage and preservation of organs.[35] Additionally, the acid is also used for the stabilization of interferon preparations or for the improvement of solubility of macrolide antibiotics such as erythromycin.[36] Furthermore, lactobionic acid can have its utility as a biodegradable cobuilder in washing powder, which can contain up to 40% lactobionic acid.[37] The fatty acid derivatives of lactobionic acid can be used as biosurfactants. Lactobionic acid could have several possible applications in food technology. These include improvement in the taste perception of sour, elimination of bitterness, flavor enhancement, preservation of aroma freshness, and reduction of souring and ripening time of cheese and yogurt products.[38] Moreover, its mineral salt complexes are used for the fortification of functional drinks with essential minerals,[39] and its addition to functional food might be useful for its presumed prebiotic effect.[40]

T. clypeatus produces large quantities of endo-1,4-β-glucanase, β-glucosidase, and CDH in cellulose-containing medium.[41,42] The fungus was reported to be the highest producer of CDH.[42] In the present investigation, several agro-industrial byproducts were tested as substrates for CDH production by *T. clypeatus* (CDHtc) during shake-flask fermentations and the suitability of TKP was evaluated to stimulate CDH production in a 5 L stirred-tank fermenter.

MATERIALS AND METHODS

Microorganism. The stock cultures of *T. clypeatus* were maintained in PDA slants (20% potato extract, 2% dextrose, and 1.5% agar, pH 7.0) at 4 °C. Mycelia were transferred to fresh PDA slants for growth at 30 °C for 5 days. These slants were then stored at 4 °C for use in inoculum preparation.

Agro-residues. Corncob, coconut coir, rice husk, wheat bran, ground nut shell, sugar cane bagasse, sawdust (from *Tectona grandis*), and TKP were collected from the local markets of Kolkata, India. Various media constituents including malt extract, yeast extract, peptone, and other salts including buffer components were purchased from Hi-Media, Bombay, India. Fine chemicals including 2,6-dichlorophenol indophenol (DCIP), cellobiose, and other analytical reagents were obtained from Sigma-Aldrich, USA.

Substrate Preparation. The substrates were washed thoroughly in distilled water and dried at 50 °C until use. Corncob, coconut coir, ground nut shell, and bagasse were crushed to a fine powder in a grinder and sieved (mesh size BSS 30) to get a homogeneous powder (diameter of particles <5 mm). The powdered agro-residue samples were used as the starting material for further experiments. The moisture content of the dried biomasses was around 2%.

Preparation of Inoculums. Five-day-old mycelia of *T. clypeatus* from PDA slants were transferred to 100 mL of MYG liquid medium (1% malt extract, 0.4% yeast extract, and 1% glucose) in 500 mL polypropylene flasks with two 1 cm diameter glass beads and incubated at 30 °C for 5 days under constant shaking of 150 rpm. The fragmented mycelial culture (1% v/v ∼ 0.018% w/v unless or otherwise specified) was used as the inoculum for CDHtc production.

Cultural Conditions for CDH Production. The basic media for CDHtc contained 1.0% cellulose or agro-residues as and where specified, 0.15% KH_2PO_4, 0.037% $CaCl_2{\cdot}2H_2O$, 0.03% $ZnSO_4$, 0.05% $MgSO_4$, 0.05% H_3BO_3, 0.0036% $MnCl_2$, 0.0032% Na_2MoO_4, and 2.2% $NH_4H_2PO_4$. The pH values of the media were adjusted to 7.0 before autoclaving. Yeast extract (0.2%) and peptone (0.2%) were added in the medium as and where mentioned. The fungus was cultured for up to 17 days at 30 °C under constant shaking of 150 rpm. Aliquots of the culture filtrate were collected at 1 day intervals and clarified by centrifugation at 21000*g* for 30 min to determine the enzyme activities. The culture medium was adjusted to its original volume with fresh medium after each collection.

Enzyme Production in 5 L Stirred-Tank Bioreactor. Large-scale enzyme production was carried out in a 5 L benchtop stirred-tank bioreactor (BioFlo 3000, New Brunswick Scientific Co., Inc., New Brunswick, NJ, USA). The fermenter was equipped with an automatic computerized control system (Bio Command Software, New Brunswick Scientific Co.) for temperature, aeration, agitation, and pH. The temperature was maintained at 30 °C. Air was supplied at a continuous rate of 1.0 vvm. Agitation was limited to 150 rpm. The initial pH of the medium was adjusted to 7.0 before sterilization, and no pH control was imposed during growth. Dow Corning silicon antifoam (0.2% v/v) was used to check the frothing during the fermentation. Samples were withdrawn after every 24 h during 12 days of fermentation and centrifuged at 21000*g* for 30 min. The supernatants thus obtained were used as enzyme solutions for the assays.

Enzyme Activity Assay. CDHtc activity was measured by following the decrease in absorbance of DCIP for 5 min at 520 nm, pH 5.0, and 25 °C with a Shimadzu UV−vis spectrophotometer (model 1700).[43] The reaction mixture (1 mL) contained 20 mM cellobiose, 0.3 mM DCIP, 100 mM sodium acetate buffer (pH 5.0), and enzyme solution. One unit (U) of enzyme activity was defined as the amount of enzyme that reduced 1 μmol of DCIP per minute under the experimental conditions. All results presented are the mean of five replicates. The error bars in the figures indicate standard deviations.

Measurement of Mycelial Growth. Mycelial growth was measured by determining the glucosamine concentration after acid hydrolysis of mycelia following the method of Desgranges et al.[44] Mycelia after growth were collected through centrifugation at 21000*g* for 30 min and washed repeatedly to remove the media remaining with the mycelial pellets. Subsequently, the samples were freeze-dried and treated with 10 mL of 10 M HCl for 16 h at 20 °C. Hydrolysis was completed by autoclaving the acid-hydrolyzed mycelia at 121 °C for 2 h after the total volume of the incubation mixture had been adjusted to 50 mL with the addition of distilled water. The concentration of glucosamine−HCl released after hydrolysis of the mycelia was measured colorimetrically according to the method of Nilsson and Bjurman.[45]

Measurement of Crystallinity. The crystallinity of the agro-residue samples was determined by using a wide-angle X-ray diffractometer. The samples were transferred to the glass sample holder and analyzed under plateau conditions. The radiation was generated at a voltage of 40 kV and a current of 40 mA. The scan scope was set between 7° and 40° with a step size of 0.02°. Holding time was 1 s. The crystallinity index along with the intensity of the main crystalline plane (002) and the amorphous fraction was calculated using the intensity at ∼18°of 2θ for amorphous fraction and maximum intensity of (002) plane at ∼22.5° of 2θ for crystalline fraction as described by Segal et al.[46] and Sasmal et al.[47]

$$\mathrm{CRI} = \frac{(I_{002} - I_{\mathrm{amor}})}{I_{002}} \times 100 \quad (1)$$

CRI = crystallinity index, I_{002} = intensity at 22.5°, and I_{amor} = intensity at 18°.

Fourier Transform Infrared Spectroscopy (FTIR) Study. FTIR is accomplished to provide accurate predictions of the chemical composition of lignocellulosic biomass as minimal sample preparation is required and very small quantities of agro-residue sample (2 mg) can be analyzed when compared to conventional gravimetric techniques, for which several grams are required.[48] An FTIR spectrum contains information on the fundamental vibrations and has more separation between similar signals, for example, hydroxyls for carbohydrate isomers.[49]

Table 1. Crystallinity Index and Structural Components of Biomasses

biomass	crystallinity (%)	cellulose (%)	hemicellulose (%)	lignin (%)	ash (%)
coconut coir	47.42 ± 0.8	43 ± 0.5	12 ± 0.6	32.5 ± 0.2	1.5 ± 0.4
corncob	27.79 ± 0.2	38.2 ± 0.2	24.6 ± 0.8	28.6 ± 0.5	3.9 ± 0.2
ground nut shell	50.04 ± 0.6	34.2 ± 0.2	17.4 ± 0.5	31.4 ± 0.4	4.5 ± 0.1

TKP	18.37 ± 0.8	22.87 ± 0.8	20.12 ± 0.8	41.6 ± 0.2	0.39 ± 0.3
cellulose	84.28 ± 0.1				

FTIR study of the subjected agro-residue samples was carried out by dispersing the dried (50 °C for 24 h) powdered samples (2 mg) of the fibers of biomass on IR grade potassium bromide (200 mg). Diffuse reflection method of FTIR analyses was performed using a Shimazdu spectrophotometer (IR Affinity-1). All of the spectra were obtained using the Happ-Genzel apodization function, a resolution of 4 cm^{-1}, and an interval of 1 cm^{-1}, and 64 scans were performed for each background and sample spectra, respectively. The reproducibility of the spectra of all the samples was verified on three sample preparations, from 64 scans with a resolution of 4 cm^{-1}. FTIR spectra were interpreted following the characteristic bands for all functional groups as reported in the literature. The assignments of bands to structural components (as determined by other researchers) are provided in the results.

RESULTS AND DISCUSSION

XRD and FTIR Analyses of the Agro-residues. The degree of crystallinity depends on the molecular arrangement of

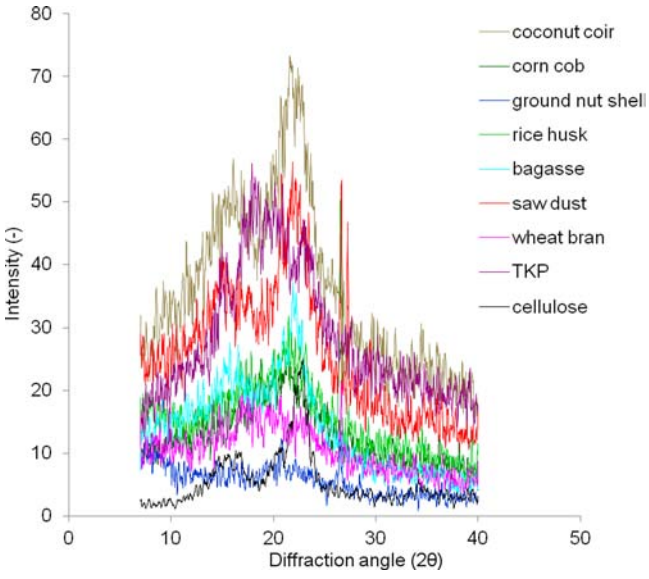

Figure 1. X-ray diffraction analysis of agro-residues.

lignin, cellulose, and hemicellulose content. The maximum crystallinity was observed in sugar cane (56.83%) and least in TKP (18.37%) as shown in Table 1, obtained from the XRD graph (Figure 1). The least crystallinity index of TKP manifests the highly amorphous nature of this substrate comparative to other agro-residues, which favors the growth of micro-organisms.[50]

The fingerprints of FTIR are illustrated in Figure 2. FTIR spectroscopy has been widely used for both quantitative and qualitative determinations of wood density,[51] chemical

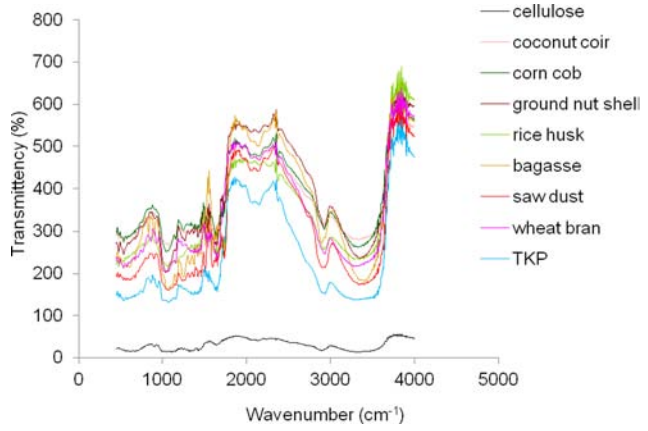

Figure 2. FTIR analysis of all tested agro-residue samples.

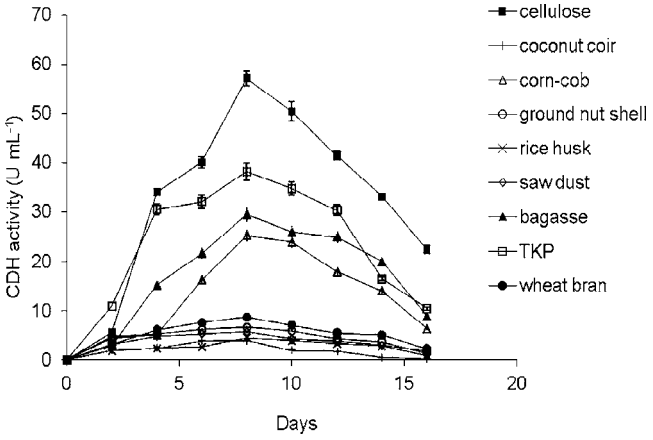

Figure 3. CDHtc production with 1% of different agro-residues in the media: (■) cellulose; (+) coconut coir; (Δ) corncob; (○) ground nut shell; (×) rice husk; (◇) sawdust; (□) TKP; (●) wheat bran; (▲) bagasse. (Reaction conditions: biomass load = 1%, pH 7.0, temperature = 30 °C, RPM = 150.)

constituents,[49] and lignin distribution.[52] As the major component of all the agro-residues are cellulose based, the observed FTIR spectra can be ascribed mainly to these components, that is, cellulose, hemicellulose, and lignin. Lignin is a complex polymer of aromatic coniferyl, coumaryl, and sinapyl alcohols, which can be described by the fingerprints near 1700 cm^{-1} for unconjugated and 1650 cm^{-1} for conjugated carbonyl compounds.[53,54] The maximum intensity in this region signifies the presence of lignin.[55] The present study shows that TKP has less intensity in all of the regions mentioned above, which signifies that it contains lesser amounts of lignin and other chemical constituents. Results

also reveal the amorphous nature of TKP through crystallography and FTIR profile, which demonstrate the fitness of its candidacy as a lignocellulosic feedstock for fermentation process.

CDHtc Production in Shake-Flasks Using the Agro-residues. *T. clypeatus* produces 55.88 U mL^{-1} CDH, which is estimated to be highest among all reported species.[41] Initially, we investigated the effect of different agro-residues on CDHtc production in shake-flask fermentations by replacing cellulose with these cheap substrates. Agro-residues (1% each) such as corncob (25.29 U mL^{-1}) and bagasse (29.5 U mL^{-1}) were found to be good substrates of CDHtc. However, among all of the tested agro-residues, TKP gave maximum enzyme yield. However, the yield was ∼67% of that obtained in the cellulose-containing medium (Figure 3). TKP is one of the cheapest gums available in India. The chemical constituents of TKP include (% w/w) carbohydrate (73.68), protein (14.38), ash (3.28), and moisture (8.67).[56] The carbohydrate part is composed of a (1→4)-β-D-glucan backbone substituted with α-D-xylopyranoside and β-D-galactopyranosyl (1→2)-α-D-xylopyranose linked (1→6) to glucose residues in the side chain.[57] The rich carbohydrate content of TKP also proves to be a good supplement to cellulose for CDHtc production under submerged conditions.

It was observed that carbon sources, such as yeast extract, casein hydrolysate, or other gluconeogenic amino acids, directly related to the citric acid cycle allowed secretion of endo-1,4-β-glucanase by *T. clypeatus* in cellulose medium.[41] The authors suggested that in *T. clypeatus* a negative regulation was mediated by the carbon catabolic product(s) that regulated growth as well as secretion of endo-1,4-β-glucanase. Similar results were observed for obtaining CDHtc in cellulose medium, where addition of yeast extract or peptone was found to be essential for growth and CDHtc production in the extracellular medium (Figure 4). The combined effect of yeast extract and peptone is more impressive than their individual effects. The mycelial growth was increased by 2−2.3 times (Figure 4a), whereas production of CDH was almost 2.4−2.5 times more when both yeast extract and peptone were added in cellulose medium, respectively (Figure 4b). The need for both yeast extract and peptone is unavoidable in cellulose medium; however, it was observed that when TKP was used as a substrate, the need for both of these costly ingredients can be avoided for CDHtc production. The yield of CDH was improved ∼2.6 times only after the addition of yeast extract and peptone along with TKP. Therefore, the presence of yeast extract or peptone was not necessary to induce CDHtc secretion in TKP-containing medium (Figure 5). The result indicated the possible presence of some compound(s) in the substrate that restricted the carbon catabolic rates similar to the

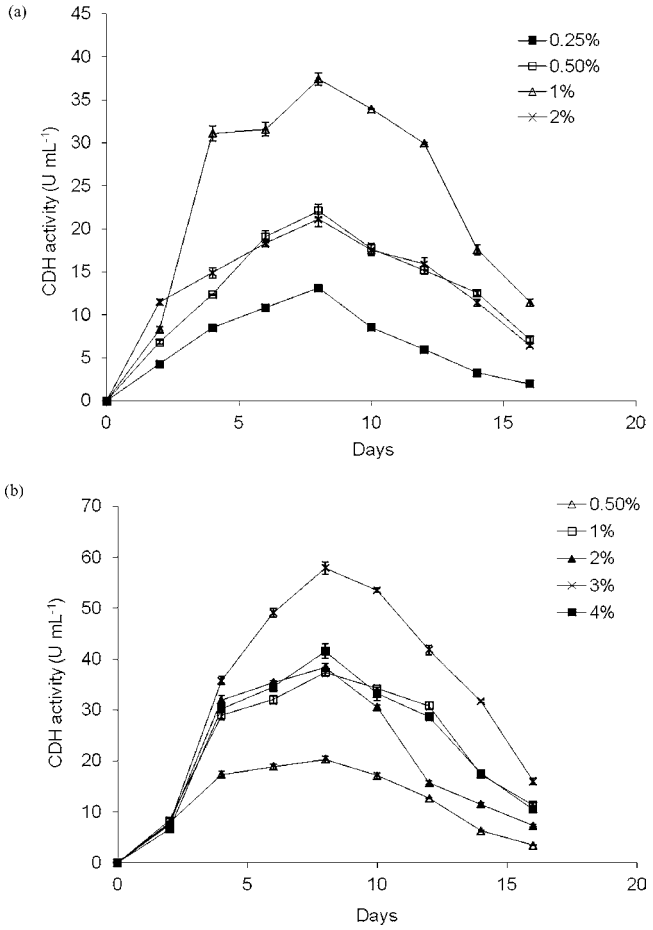

Figure 6. CDHtc production in TKP medium: (a) enzyme production in 1% TKP with variation of inoculum concentration ((■) 0.25%, (□) 0.50%, (△) 1.0%, (×) 2.0%); (b) enzyme production with 1% inoculum using different concentrations of TKP ((△) 0.50%, (□) 1%, (▲) 2%, (×) 3%, (■) 4%).

Table 2. Specific Growth and Biomass Production of *T. clypeatus* at Different TKP Concentrations

	TKP concentration				
	0.5%	1%	2%	3%	4%
r (h^{-1})	0.0242	0.0249	0.0251	0.0257	0.0279
K (mg mL^{-1})	6.2	6.58	7.17	7.13	6.2

findings of Mukherjee et al.[41] The higher yield of CDHtc in the presence of yeast extract or peptone with TKP might be due to the high rate of mycelial growth (Figure 5b) as observed earlier by Saha et al.[42]

In shake-flask cultures, the yield of CDHtc increased with the increase in inoculum concentration, and maximum enzyme activity (37.42 U mL^{-1}) was observed in the presence of 0.018% inoculum (w/v) in 1% TKP-containing medium (Figure 6a). However, with further increase in inoculum concentration, the enzyme production decreased possibly due to the depletion of media nutrients, which might result in lower metabolic rates.

CDHtc production increased with higher concentrations of TKP in shake-flask cultures with 1% (v/v) inoculum. The yield of enzyme was not improved further with the increase in inoculum concentration (Figure 6a). Maximum enzyme production (57.9 U mL^{-1}) occurred on the eighth day of

total	12	3136.547	261.379		

fermentation in 3% TKP medium (Figure 6b). However, on the same day, with 4% TKP concentration, the enzyme yield was lower (41.53 U mL^{-1}) compared to that obtained using 3% TKP, with 1% (v/v) inoculum, possibly due to the enhanced viscosity (apparent viscosity was reached 0.8−14 cP at a shear rate range of 10−400 s^{-1}) of the media that led to poor aeration during fermentation (the DO level reached 4.5%). The agro-residue at 5% concentration could not be used in shake-flask cultures because the medium density was too high to carry out submerged fermentations.

It has been observed that there is a definite relationship between fungal growth and CDH production by *T. clypeatus* in

dx.doi.org/10.1021/jf405278y | J. Agric. Food Chem. 2014, 62, 3438−3445

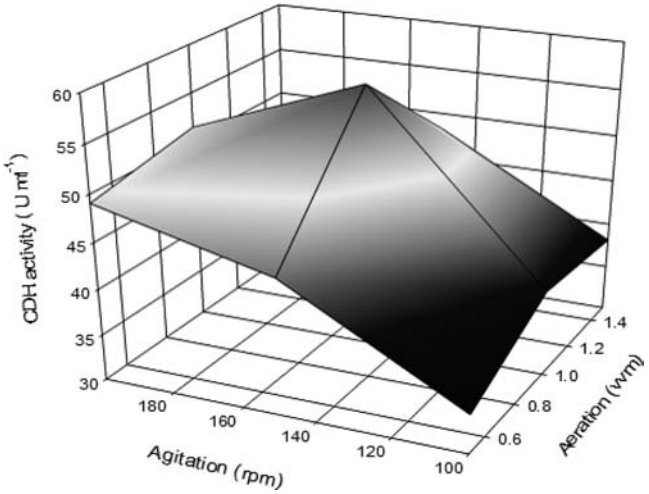

Figure 9. Surface plot for the enzyme activity (CDH U mL^{-1}) as a function of aeration (vvm) and agitation (rpm) after fermentation.

both cellulose and TKP media, where the enzyme production was directly proportional to the growth of the organism (Figures 4 and 5).

Modeling of Biomass Production. The modeling of biomass production at variable concentrations of principle carbon source (TKP) was studied. The logistic equation was used to describe the rate of biomass changes, that is, production of biomass as a function of biomass alone. The logistic model used in this study is described in eq 1

$$X = \frac{K}{1 + C\exp(-rt)} \quad (1)$$

where C = constant.

The equation described in this study is already proven for the microbial growth prediction[58] and has been widely used for describing the growth of microorganisms, too.[59,60] The phase of death is not considered in the logistic model.

By differentiating eq 1 we get eq 2

$$\frac{dX}{dt} = rX\left(1 - \frac{X}{K}\right) \quad (2)$$

where X = amount of mycelia (mg mL^{-1}), r = specific growth rate, K = carrying capacity, and t = time. The values of r and K were determined at different TKP concentrations that are shown in Table 2.

CDHtc Production in a 5 L Bioreactor. Large-scale production of CDH has been restricted to only a few organisms. Schmidhalter and Canevascini[61] cultured the brown-rot fungus *Coniophora puteana* in bioreactors with working volumes of 1.8 and 6 L. The authors found that maximum production of CDH occurred when the fungus was grown with amorphous cellulose. Baminger et al.[62] carried out laboratory fermentation of *Sclerotium rolfsii* in a 20 L stirred-tank bioreactor with a working volume of 15 L with cellulose as the carbon source, which yielded 7400 U mL^{-1} of cytochrome *c* reducing activity and 7500 U mL^{-1} of DCIP reducing activity in the extracellular medium after 130 h of cultivation. Raices et al.[63] investigated the induction of CDH and cellobiose quinone oxidoreductase (CBQ) in *Phanerochaete chrysosporium*. The fungus was grown in a 10 L automatic bioreactor with cellobiose as carbon source. Ludwig et al.[64] studied the production of CDH from *Trametes pubescens* and *Trametes villosa* in a 20 L laboratory bioreactor with 15 L of medium containing cellulose and yeast extract. The maximum enzyme activities for DCIP reduction (1450 U L^{-1}) and cytochrome *c* reduction (1600 U L^{-1}) were reached after 150 h of cultivation of *T. pubescens*. The cultivation of *T. villosa* yielded DCIP reducing activity of 830 U L^{-1} and cytochrome *c* activity of 680 U L^{-1} in the extracellular medium after 173 h of cultivation. Zamocky et al.[65] studied the production of the heterologous protein CDH from *Myriococcum thermophilum* in the methylotrophic yeast *Pichia pastoris* in a bioreactor. After optimization of the various process parameters, CDHtc production was monitored in a 5 L fermenter with 4 L of medium containing 3% TKP and 1% inoculum (v/v). Yield of the enzyme (57.4 U mL^{-1}) in the bioreactor (Figure 7) was almost similar to that observed in shake-flask fermentation (57.05 U mL^{-1}). However, the optimum day for the enzyme production in the bioreactor shifted to the sixth day compared to the shake-flask fermentations (Figure 7). The calculated correlation coefficients between CDHtc yield and biomass production in the fermenter showed that these two parameters correlated well. The value of the coefficient was ~0.94. The novelty of the paper relies on the report of highest large-scale CDH production of 57400 U L^{-1} using the cheap agro-residue TKP. These findings suggest that a laborious and expensive technique such as heterologous protein expression would not be needed to achieve CDH production on an industrial scale. Furthermore, we found that by total replacement of cellulose, yeast extract, and peptone, *T. clypeatus* in the presence of TKP produces ~2.6 times less CDH, which is appreciable when compared to the reduced production cost by ~2 times.

The viscosity and dissolved oxygen profile in the 5 L bioreactor were also examined thoroughly. The apparent viscosity reached 0.8−28 cP at a shear rate range of 10−400 s^{-1}. The proper aeration in the bioreactor led to improved enzyme production as well as the viscosity of the broth, which was quite difficult to obtain in the shake flask. The time profile of enzyme production is depicted in Figure 8. The three-dimensional graph shows a nonlinear pattern with respect to growth of biomass and time. It was observed that the enzyme production reached maximum at the exponential phase of biomass growth. The production of enzyme declined after the 12th day of the fermentation process possibly due to the lack of nutrients in the medium. Therefore, the modeling study considered the data up to 12 days only. This phenomenon can be explained mathematically by eq 3

$$z = \frac{a}{\left[1 + \left(\frac{x - x_0}{b}\right)^2\right]\left[1 + \left(\frac{y - y_0}{c}\right)^2\right]} \quad (3)$$

where z= CDH activity (U mL^{-1}), x = mycelial growth (mg mL^{-1}), y = fermentation time (days), and a, b, and c = constants.

The values of the constants were determined as a = 72.027, b = 2.696, and c = 4.742 (Table 3). An analysis of variance (ANOVA) was carried out to investigate the robustness of the model (Table 4). The Fisher ratio (F value; Table 4) was found to be quite higher (p value <0.0001) than the corresponding calculated value, which shows that the model was statistically significant.

Effects of aeration and agitation on enzyme production were also studied. Agitation speed was varied from 100 to 200 rpm and aeration rate from 0.5 to 1.5 vvm (volume of air sparged per volume of broth per minute). According to the results from

dx.doi.org/10.1021/jf405278y | J. Agric. Food Chem. 2014, 62, 3438−3445

the experimental design, as depicted from Figure 9, the enzyme production was influenced by both aeration and agitation. Merely increasing both parameters such as agitation speed beyond 150 rpm and aeration >1 vvm does not improve the production much.

MATERIALS AND METHODS

Materials. α-Cellulose (DP 900), DMSO, IPA, and DBU were purchased from Sigma-Aldrich Co. (Guangzhou, China), and CTA was purchased from Acros Organics (Morris Town, NJ, USA). Other chemicals were supplied by Guangzhou Chemical Reagent Factory (Guangzhou, China). All chemicals were of analytical reagent grade and directly used as received without further purification.

Cellulose Acetylation. The acetylation of cellulose was carried out under mild conditions in DMSO by using IPA as acetylation reagent and DBU as catalyst. α-Cellulose (0.5 g) was suspended in DMSO (10 mL) in a 50 mL vial. The mixture was agitated for 15 min at room temperature for cellulose dispersing and swelling. Then, 5 mL of IPA and 1.5 mL of DBU were added into the cellulose suspension, and the obtained yellow mixture was put in an oil bath at 70−130 °C for cellulose acetylation with magnetic agitation for 3−12 h. After the required time, the resulting dark brown mixture was poured into 750 mL of a mixture of distilled water and ethanol (2:1, v/v). The precipitates formed were filtered out and thoroughly washed with 750 mL of ethanol (three times). The residues were dried overnight under vacuum at 60 °C.

DS Determination by Titration. The DS of CA was determined by titration according to the published procedure[22,23] with some modifications. Dried and well-pulverized sample (0.5 ± 0.0001 g) was added into 75% ethanol (20 mL) in a flask and stirred at 60 °C for 30 min. Then, 20 mL of standard 0.5 M NaOH solution was added into the mixture and stirred at 60 °C for another 30 min. To guarantee the saponification of acetates, the mixture was stirred at room temperature for 72 h. The blank was run under the same conditions without the addition of CA. After the required time, the excess alkali was titrated with standard 0.5 M HCl with phenolphthalein as an indicator. Then, another 1 mL of standard HCl (0.5 M) was added and stirred overnight. The excess acid was back-titrated with standard 0.5 M NaOH solution to the phenolphthalein end-point. The DS was calculated according to the equations

$$m = [(A - B)N_b - (C - D)N_a] \times 43/W \quad (1)$$

$$DS = (162 \times m)/(43 - 42 \times m) \quad (2)$$

where m (g) is the content of acetyl group, DS is the average number of acetyl groups attached to an anhydroglucose unit (AGU) in cellulose, A (mL) is the total volume of standard NaOH solution added into the samples, B (mL) is the total volume of standard NaOH solution added into the blank, N_b (mol/mL) is the molarity of the standard NaOH solution, C (mL) is the total volume of standard HCl added into the samples, D (mL) is the total volume of standard HCl added into the blank, N_a (mol/mL) is the molarity of the standard HCl, W (g) is the weight of sample analyzed, 43 (g/mol) is the molar mass of an acetyl group, 162 (g/mol) is the molar mass of an AGU, and 42 (g/mol) is the net increase of the mass of an AGU for each acetyl substituted.

FT-IR. FT-IR spectra of unmodified cellulose and CA were recorded on a spectrophotometer (Tensor 27, Bruker, Germany) using a KBr disk containing 1% sample in the range of 4000−400 cm^{-1} at a resolution of 2 cm^{-1}. To remove the present moisture, the following modified procedure was adopted according to the earlier studies.[24−26] A small amount of sample, previously dried at 105 °C for >10 h, was ground for 2−10 min in a grinder (Mikro-Dismembrator S, Sartorius, Germany). KBr, previously dried at 105 °C for >10 h, was mixed with the ground sample with a ratio of sample to KBr of 1:100 (w/w). The mixture was ground for 2 min and further dried overnight in an oven at 105 °C. The dried mixtures were cooled in desiccators and measured on the FT-IR spectrophotometer as soon as possible after removal from the desiccators. The blank experiment without sample was done from KBr pellet as a reference.

^{1}H NMR and ^{13}C NMR. The ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker AVIII HD 600 spectrometer (Germany). The ^{1}H NMR spectra were recorded at 298.0 K from the dried samples (10−15 mg) dissolved in 0.5 mL of DMSO-d_6 and a drop of trifluoroacetic acid-d. The detailed collecting and processing parameters for the ^{1}H NMR analysis were as follows: number of scans, 16; receiver gain, 69; acquisition time, 2.7263 s; relaxation delay, 1.0 s; pulse width, 11.0 s; spectrometer frequency, 600.17 MHz; and spectral width, 12019.2 Hz. For ^{13}C NMR analysis, dried samples (25−40 mg) were dissolved in 0.7 mL of DMSO-d_6, and the spectra were recorded at 353.1 K to obtain improved spectral resolution and an acceptable signal-to-noise ratio. The detailed collecting and processing parameters were as follows: number of scans, 10000; receiver gain, 187; acquisition time, 0.9088 s; relaxation delay, 2.0 s; pulse width, 12.0 s; spectrometer frequency, 150.91 MHz; and spectral width, 36057.7 Hz.

The DS values of CA were also calculated on the basis of the ^{1}H NMR analysis according to eq 3[27−29]

$$DS = 7 \times I_{(CH_3,H)}/[3 \times I_{(AGU,H)}] \quad (3)$$

where $I_{(CH_3, H)}$ is the integration of the resonances assigned to methyl protons of acetyl group ($\delta \sim 1.70$−2.20), 7 and 3 are the amounts of protons in the glucose ring and acetyl group, respectively, and $I_{(AGU, H)}$ is the integration of the resonances assigned to protons of the glucose ring ($\delta \sim 2.8$−5.5).

Intrinsic Viscosity. For each acetylated sample, a solution in DMSO at the concentration of 2 g/L was prepared. Experimental determination of intrinsic viscosity was carried out by counting the efflux time of the solvent and sample solution in an Ubbelohde viscometer (0.01203 mm capillary). Before each measurement, the viscometer was immersed in a thermostatic bath (PTI-TV 2000/AKV, Germany) at 25 ± 0.01 °C for 20 min to stabilize the temperature.

RESULTS AND DISCUSSION

Cellulose Acetylation. DS of CA determined by titration is shown in Table 1. As shown in Table 1, cellulose acetylation was successfully performed in DMSO with DBU as a catalyst and IPA as an acetylation reagent. The schematic DBU-mediated acetylation of cellulose is shown in Figure 1, and the proposed catalytic mechanism of DBU for cellulose acetylation is illustrated in Figure 2. In the cellulose acetylation, DBU acts as an acyl transfer agent. The nucleophilic nitrogen in the DBU molecule attacks the electron-deficient carbon of the acetyl group in IPA and gives rise to cleavage of the C−O bond and the formation of N-acetylated intermediate **2**. This intermediate can react with the hydroxyl group of cellulose **1**, resulting in the

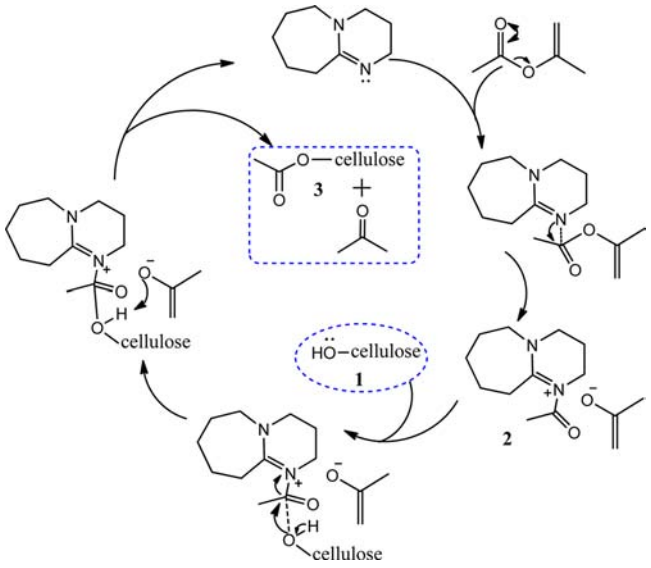

Figure 2. Proposed catalytic mechanism of DBU for cellulose acetylation.

formation of the desired CA **3** and byproduct acetone after deprotonation and isomerization. DBU enters into the next cycle of catalyzed reaction to perform the cellulose acetylation. As shown in Table 1, the DBU-catalyzed acetylation was very efficient. CA with DS > 2.0 was easily obtained under the selected conditions, which was probably due to the high catalytic activity of DBU. Per-O-acetylation was achieved within 3 h at 130 °C, within 6 h at 110 °C, and in 9 h at 90 °C, indicating increased acetylation with higher reaction temperature. In addition, reaction time had a positive effect on acetylation. At 70 °C, DS of CA reached 1.81 within 3 h, 2.14 within 6 h, 2.17 with 9 h, and 2.20 in 12 h; similarly, at 90 °C, DS was 2.10, 2.39, 2.74, and 2.93 at 3, 6, 9, and 12 h, respectively. Clearly, the influence of reaction time on DS at 70 °C was less than that at 90 °C, which was probably due to the low activity of DBU-catalyzed transesterification of cellulose in DMSO at low temperature. At higher temperature, cellulose per-O-acetylation was readily achieved to produce CTA with DS 2.90−2.99. Compared with the traditional methods to produce CTA, this procedure exhibits noticeable advantages. DMSO and unreacted IPA can be recycled and reused after the removal of water, ethanol, and byproduct acetone, which is easily achieved by simple evaporation under reduced pressure. Ethanol used in the procedure could also be recycled. More importantly, the modification conditions in this procedure are very mild, without any acidic reagents, avoiding the degradation of cellulose macromolecules and equipment corrosion. This very mild procedure is promising for the production of cellulose-based biocomposites in many fields.

The solubility of the prepared CA was also studied in common organic solvents including DMSO, chloroform, methylene chloride, acetone, THF, and DMF, and the results are shown in Table 2. As expected, CA prepared in DMSO followed by precipitation in ethanol is still soluble in DMSO.

[a]DS_1, calculated by titration. [b]++, soluble. [c]+, swelling. [d]−, insoluble.

Meanwhile, the solubility of CA samples in chloroform, methylene chloride, and DMF is similar to the results reported in previous studies.[12,30] CA with DS ranging from 2.0 to 2.7 was reported to be soluble in acetone.[13] However, in the present study, CA with DS ranging from 1.81 to 2.99 was insoluble in acetone, which was probably due to the high DP of cellulose in this study. The similarly different solubility of CA with increased molecular weight was also reported, and the results showed that the dissolution of CA in acetone was achieved with a molecular weight of $<10^5$, whereas it failed when this value was exceeded.[31] THF could dissolve CA with DS 1.5−2.77.[12] However, in the present study CA samples were insoluble in THF, similar to acetone, due to the relatively high DP of the original cellulose.

FT-IR. Figure 3 illustrates the FT-IR spectra of unmodified α-cellulose, the prepared CA samples 1, 6, and 12 in Table 1, and the commercial CTA. In comparison with that in α-cellulose, the intensity of the band at 3440 cm^{-1} for O−H stretching significantly decreased in the prepared CA samples and the commercial CTA, which was obviously due to acetylation of hydroxyl groups in cellulose. Moreover, the bands at 1750 cm^{-1} for C═O stretching, 1380 cm^{-1} for C—H bending, and 1235 cm^{-1} for the symmetric stretching of C—O in ester noticeably increased after acetylation, indicating the attachment of an acetyl group onto cellulose macromolecules. The intensities of these three important bands increased from sample 1 to sample 6 and to sample 12, corresponding to the increased DS in Table 1. Compared with the commercial CTA, sample 12 exhibited a similar FT-IR spectrum with the same

dx.doi.org/10.1021/jf5002233 | J. Agric. Food Chem. 2014, 62, 3446−3452

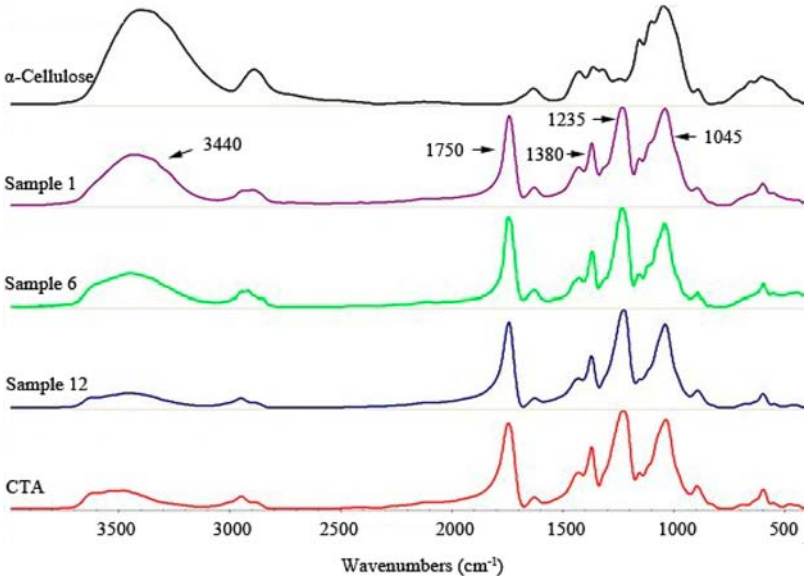

Figure 3. FT-IR spectra of α-cellulose, the prepared CA samples 1 (DS 1.81), 6 (DS 2.39), and 12 (DS 2.99), and the commercial CTA.

characteristic bands and similar intensities, suggesting the achievement of per-O-acetylation of sample 12.

FT-IR analysis also provides a method to comparatively evaluate the DS of CA on the basis of the ratio of the height of the peak at 3440 cm^{-1} for hydroxyl stretching to the integrated area of the absorbance at 1750 cm^{-1} assigned to carbonyl stretching.[32] As shown in Table 3, the ratio significantly decreased from acetylated cellulose sample 1 to sample 6 and to sample 12, which was consistent with the increased DS in Table 1. In addition, sample 12 had a similar ratio to commercial CTA, indicating the successful preparation of the per-O-acetylated cellulose under the selected conditions.

^{1}H NMR and ^{13}C NMR. ^{1}H NMR is a common method to determine the DS of modified cellulose. In the present study, DS of CA samples was also determined by ^{1}H NMR, and the results are listed in Table 1. The DS values from ^{1}H NMR without any pretreatment (perdeuteroacetylation or perpropionylation) are reliable and time-saving compared with those determined by titration. However, the absorbed water in DMSO exhibits the signals in the range of the protons from AGU units, resulting in the interference of DS determination by ^{1}H NMR, even far different from those by titration. In this paper, a drop of trifluoroacetic acid-*d* was added to remove the interference from water.[27,28] According to Table 1, the DS values from ^{1}H NMR were very close to those determined by titration, confirming the achievement of CA with high DS under the transesterification procedure.

Figure 4 illustrates the ^{13}C NMR spectra of partially acetylated (sample 5) and per-O-acetylated cellulose (sample 11). The carbon signals at 103.2, 99.4, 80.3, 75.8, 70.3−73.4, and 62.3 ppm are attributed to C-1, C-1_s (hydroxyl group of C-2 is substituted), C-4, C-4_s (hydroxyl group of C-3 is substituted), the combined C-2, C-3, and C-5, and C-6_s (hydroxyl group of C-6 is substituted) of AGU, respectively. Comparatively, the carbon signals for C-1 and C-4 in partially acetylated cellulose sample 5 disappeared in per-O-acetylated cellulose sample 11, indicating the complete substitution of hydroxyl groups at C-2, C-3, and C-6 positions. In addition, the strong signals at about 20 and 170 ppm are assigned to the carbons from methyl (C-7) and carbonyl (C-8) in the acetyl group attached onto cellulose, indicating the occurrence of DBU-catalyzed transesterification in DMSO. Detailed information on signals at about 170 ppm provided more support to acetylation, as shown in the upper left corner inset in Figure 4. Theoretically, each kind of AGU unit with hydroxyl groups substituted at different positions is present in the partially acetylated cellulose, and the marginally different signals assigned to the attached carbonyl carbons give the complicated spectrum of partially acetylated cellulose.[33−35] As shown in the upper left corner inset in Figure 4, sample 5 exhibited a more complicated spectrum than sample 11, which provided clearly resolved peaks of carbonyl carbons due to high DS. Clearly, the well-resolved carbonyl carbon signals confirmed the per-O-acetylation of sample 11. On the basis of the NMR analyses, the acetylation reaction occurs under the selected conditions and per-O-acetylation is confirmed.

Intrinsic Viscosity. Intrinsic viscosity of polymers measured in solution provides insight into molecular structure. According to the single-point method,[36] the intrinsic viscosity is calculated using the relationships

$$[\eta] = \sqrt{2(\eta_{sp} - \ln(\eta_r))}/c \quad (4)$$

$$\eta_{sp} = \eta_r - 1 \quad (5)$$

$$\eta_r = t/t_0 \quad (6)$$

dx.doi.org/10.1021/jf5002233 | J. Agric. Food Chem. 2014, 62, 3446−3452

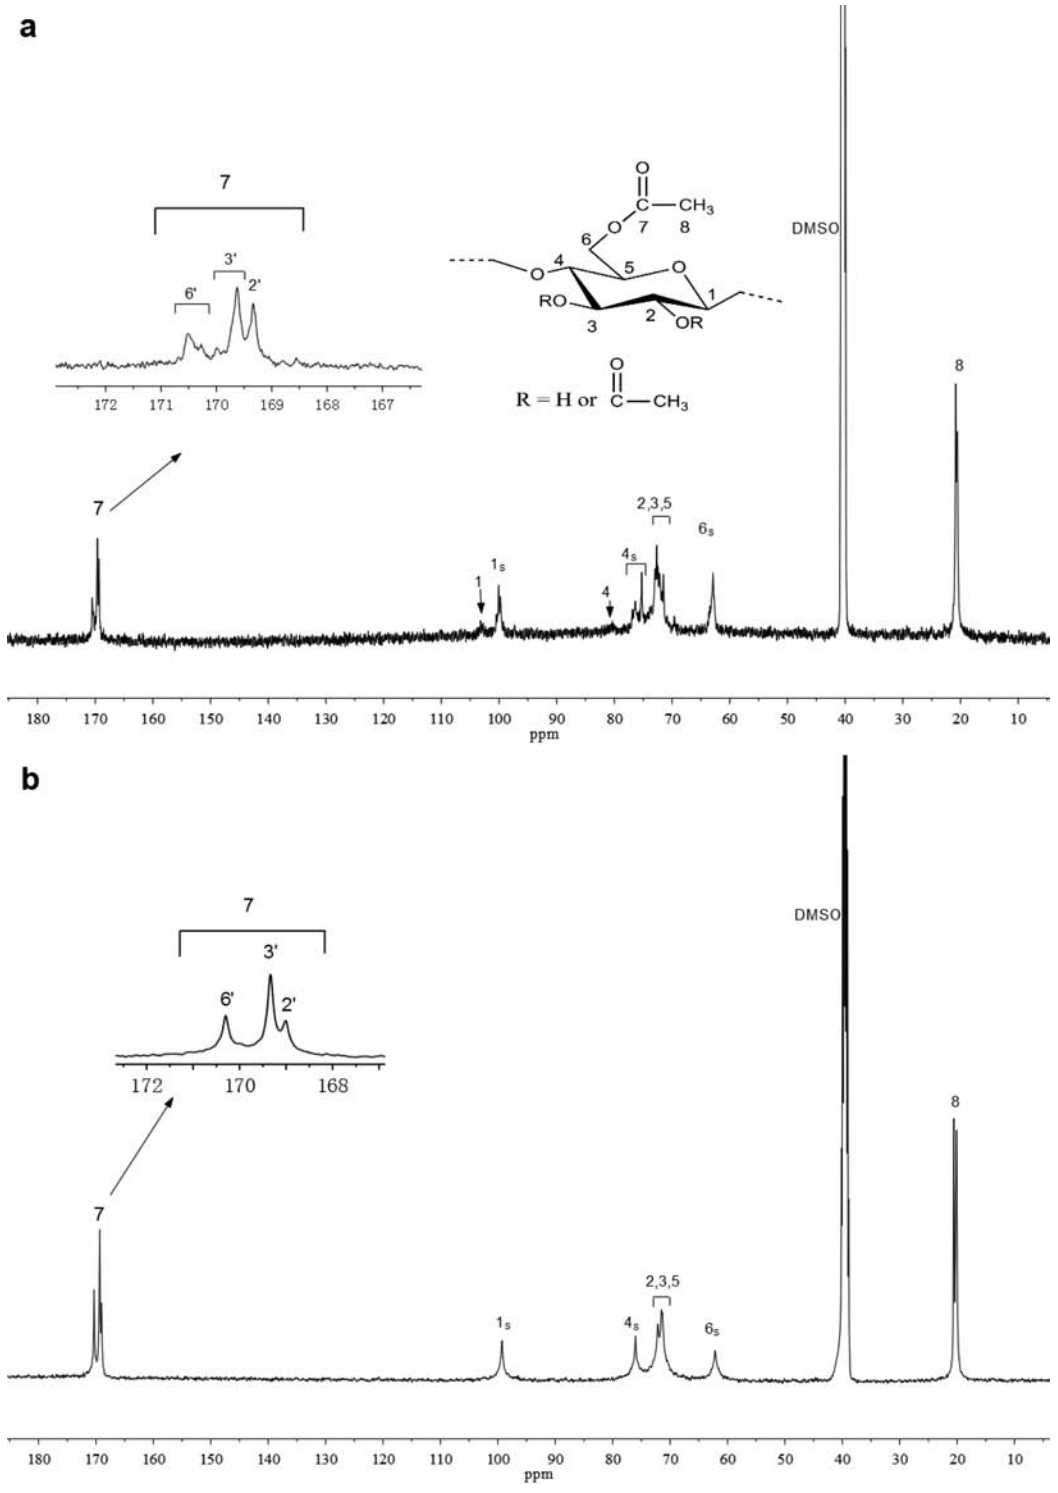

Figure 4. ^{13}C NMR spectra of sample 5 (a, DS 2.14) and sample 11 (b, DS 2.96).

where $[\eta]$ is the intrinsic viscosity, η_r is the relative viscosity, η_{sp} is the specific viscosity, c is the concentration of the solution, and t and t_0 are the solution and solvent efflux times, respectively.

On the basis of these equations, the intrinsic viscosity of a polymer in solution at a certain concentration could be determined from the efflux time of the solution and the solvent. According to the Mark−Houwink−Sakurada equation, the relationship between the intrinsic viscosity of a polymer solution and the molecular weight of the polymer is provided as

$$[\eta] = K(\overline{M}_v)^a \quad (7)$$

where K and a are constants relative to the type of polymer and solvent at a given temperature.

It is suggested from eq 7 that the changes of the molecular weight of polymers can be inferred from the varied intrinsic viscosity of polymer solution. The intrinsic viscosity of the dilute solution of cellulose and cellulose derivatives depends primarily upon the molecular weight of the cellulose materials.[37] Therefore, although the constants K and a are

dx.doi.org/10.1021/jf5002233 | J. Agric. Food Chem. 2014, 62, 3446−3452

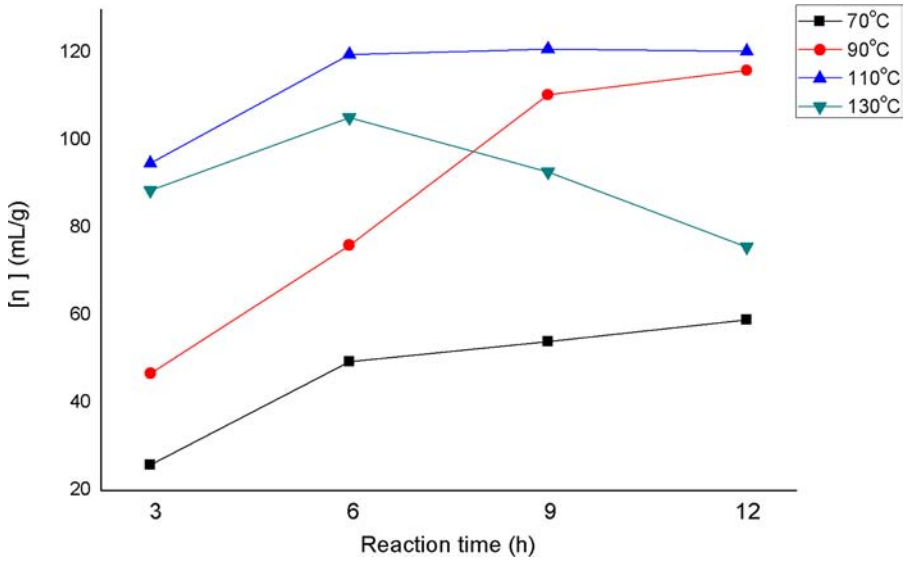

Figure 5. Intrinsic viscosity of CA solution in DMSO.

not proposed for CA in DMSO, the changes of the molecular weight of acetylated cellulose are still implied from the varied intrinsic viscosity of the dilute CA solution in DMSO. As shown in Figure 5, an increase of the intrinsic viscosity was clearly observed with the increased reaction time from 3 to 12 h at 70−90 °C and from 3 to 6 h at 110−130 °C, corresponding to the increased DS in Table 1. Similarly, the intrinsic viscosity of CA solution in DMSO was almost stable at 110 °C from 6 to 12 h, in agreement with the stable and highest DS of per-O-acetylated cellulose, confirming the degradation of cellulose does not occur during the mild transesterification of cellulose in DMSO below 110 °C with IPA as acetylating reagent and DBU as catalyst. However, at higher temperature (130 °C) and long reaction time (6−12 h), the intrinsic viscosity unexpectedly decreased. Considering the almost stable DS in Table 1, this decrease was attributed to the degradation of cellulose macromolecule at relatively mild condition (130 °C for 6−12 h). On the basis of these findings, it was suggested that the degradation of cellulose during acetylation under the selected conditions did not occur at low temperature (70−110 °C) and did occur at high temperature (130 °C) over a long reaction time (6−12 h).

In conclusion, the per-O-acetylation of cellulose was achieved in DMSO with IPA as acetylating reagent and DBU as catalyst. Titration, FT-IR, ^{1}H NMR, and ^{13}C NMR analyses provided evidence of cellulose per-O-acetylation. The degradation of cellulose did not occur at low temperature (70−110 °C) due to the mild conditions of the transesterification reaction. However, the degradation did occur at higher temperature (130 °C) over a long time (6−12 h).

water deficit,[16,17] and crop management practices such as seeding rate, row spacing, and planting date.[8]

Syngenta has genetically modified soybean (*Glycine max* (L.) Merr.) to express an *hppd* gene derived from oat (*Avena sativa* L.). This gene, designated *avhppd-03,* encodes a *p*-hydroxyphenylpyruvate dioxygenase isozyme (AvHPPD-03) that has >99.7% sequence identity with the HPPD isozyme from *A. sativa*. In comparison with the endogenous soybean HPPD, the AvHPPD-03 isozyme from oat has reduced binding affinity for mesotrione, a herbicide that inhibits HPPD. The *avhppd-03* gene is linked to a constitutive promoter that expresses AvHPPD-03 at a higher level than the wildtype soybean *hppd*. Expression of *avhppd-03* in soybean plants confers a mesotrione tolerance phenotype. Syngenta has produced three mesotrione-tolerant soybean events (SYHT04R, SYHT06W, and SYHT0H2) and has evaluated the effect of expression of *avhppd-03* on tocochromanol levels in seeds from these events grown under field conditions in two consecutive years.

MATERIALS AND METHODS

Production of Seed Samples. During 2009 and 2010, three soybean events expressing *avhppd-03* and the corresponding non-transgenic, near-isogenic control variety 'Jack'[18] (maturity group 2.9) were grown according to local agronomic practices in the United States. The field trials were conducted at six locations (in Nebraska, Ohio, Michigan, Arkansas, Missouri, and Iowa) in 2009 and at eight locations [in Nebraska, Missouri, Iowa, Illinois (2), North Carolina, Pennsylvania, and Indiana] in 2010. One event (SYHT04R) was grown in both years, and the other two events (SYHT06W, SYHT0H2) were each grown in one year (2009 or 2010, respectively). To establish a range of natural variability, six nontransgenic precommercial Syngenta soybean reference varieties (maturity groups 2.3−3.5) were also grown at the same locations in the same years.

At each location, two entries of each transgenic soybean event, the corresponding control soybean, and the reference varieties were grown in a randomized complete block design with four replicate plots for each entry. In each trial, one entry of each transgenic soybean event was treated with mesotrione herbicide (0.1 kg active ingredient per hectare) at the V3−V5 growth stage.[19] The other transgenic entry was not treated with mesotrione. All entries within a trial were treated with maintenance chemicals as needed for optimum plant health.

Seed samples were obtained from 30 randomly selected plants from each plot after plants reached full maturity (R8 stage).[19] Representative subsamples were finely ground on dry ice and maintained at approximately −20 °C until they were analyzed.

Quantitation of Tocopherol and Tocotrienol Levels in Soybean Seed. The levels of tocopherols and tocotrienols in the seed were determined by Covance Laboratories, Inc. (Madison, WI, USA) using validated methods based on literature references. Representative aliquots from the homogeneous samples were analyzed in a random order. Following quantitation of the tocochromanols, all results were converted to equivalent units of dry weight based on the moisture content of the seed samples.

Tocopherols. To release vitamin E, the aliquots (approximately 6 g) were saponified to break down any fat. The saponified mixture was extracted with diethyl ether, evaporated to near dryness, and diluted to a volume of 2 mL in hexane. The levels of *α*-, *β*-, *γ*-, and *δ*-tocopherols were quantitated by high-performance liquid chromatography (HPLC) using fluorescence detection (excitation, 292 nm; emission, 325 nm). HPLC was performed with the following parameters: a silica column (ES Ind. Chromegabond Diol 3 μm 60 Å, 15 cm × 4.0 mm), guard column (Diol, 12.5 mm × 4.6 mm, 4 μm packing), flow rate of 1.0 mL/min, run time of 20 min, and injection volume of 15 μL, with mobile phase A [3% tetrahydrofuran (THF), 0.05% glacial acetic acid (HOAc) in iso-octane] and mobile phase B (30% THF, 0.05% HOAc in iso-octane).[20−22]

Tocotrienols. Aliquots (approximately 2 g) were treated with sodium bicarbonate and sodium ascorbate to buffer the solution. Pyrogallol (4 mL) was added as an antioxidant. The samples were extracted with 8 mL of 2,2,4-trimethylpentane (iso-octane), and dimethyl sulfoxide (4 mL) was added to increase extraction efficiency. Methanolic sulfuric acid solution (3.33 N) was added to further break down the sample matrix. Additional iso-octane (8 mL) was added to aid in phase separation. The samples were centrifuged, and the *α*-, *β*-, *γ*-, and *δ*-tocotrienols in the supernatant were quantitated by HPLC and fluorescence detection (excitation, 292 nm; emission, 325 nm). The HPLC was performed with

[a]Tocopherol levels given as micrograms per gram seed dry weight. [b]When some values were <LOQ means could not be calculated (shown as –). [c]Bold values and asterisks indicate significant differences between the transgenic soybean and the control soybean ($p < 0.05$). [d]The limit of quantitation (LOQ) for all tocopherols was 5.3–7.3 μg/g DW, varying with the moisture content of the sample. [e]Crop treated with mesotrione herbicide indicated with +.

the following parameters: a silica column (ES Ind. Chromegabond Diol 3 μm 60 Å, 15 cm × 4.0 mm), flow rate of 1.0 mL/min, run time of 30 min, and injection volume of 60 μL, with mobile phase A (3% THF, 0.05% HOAc in iso-octane) and mobile phase B (30% THF, 0.05% HOAc in iso-octane).[21,23−25]

Statistical Comparisons. The data for the quantifiable tocopherols were subjected to analysis of variance (ANOVA) using the following mixed model:

$$Y_{ijk} = U + T_i + L_j + B(L)_{jk} + LT_{ij} + e_{ijk}$$

In this model, Y_{ijk} is the observed response for entry i at location j block k, U is the overall mean, T_i is the entry effect, L_j is the location effect, $B(L)_{jk}$ is the effect of block within location, LT_{ij} is the location-by-entry interaction effect, and e_{ijk} is the residual error. Entry was regarded as a fixed effect, whereas the effects of location, block within location, and location-by-entry interaction were regarded as random.

The statistical significance of the differences in levels of α-, γ-, and δ-tocopherols were assessed using t tests for comparisons between the control soybean and each of the transgenic soybean lines and between the control soybean and each of the transgenic soybean lines treated with mesotrione. Significance was based on an α level of 0.05. No statistical comparisons were performed for β-tocopherol or any tocotrienols because the levels were below the limit of quantitation in most or all samples.

RESULTS AND DISCUSSION

Levels of α-tocopherol, the isoform with the highest vitamin E activity in humans,[26] were variable across the three events, and most differences observed in the comparisons of the transgenic soybean and the control soybean were small and not statistically significant. The only statistically significant change in the level of α-tocopherol observed was a 12% decrease in the 2010-grown SYHT0H2 soybean that was not treated with mesotrione [22.8 μg per gram seed dry weight (μg/g DW)] when compared with the control soybean (25.8 μg/g seed DW). The levels of β-tocopherol, and all tocotrienols (data not shown), were either below, or only slightly above, the limit of quantitation.

Increased seed γ-tocopherol and δ-tocopherol levels were consistently observed in *avhppd*-03-expressing soybean events. In seed produced from field trials in both years, levels of these two vitamin E isoforms were statistically higher in all three *avhppd*-03-expressing soybean events compared with levels in the near-isogenic, nontransgenic control soybean (Table 1). Mean levels of γ-tocopherol increased by as much as 21% (1.2-fold) in the SYHT06W soybean treated with mesotrione herbicide (206 μg/g seed DW) when compared with the control soybean (171 μg/g seed DW). Mean levels of δ-tocopherol increased by as much as 72% (1.7-fold) in the SYHT04R soybean (105 μg/g seed DW) when compared with the control soybean (61.1 μg/g seed DW) (Table 2).

These findings were expected because they are consistent with reports that overexpression of HPPD in plants resulted in increased tocochromanol content.[6,27,28] The observed increases in the levels of the γ and δ isoforms, without corresponding increases in the α and β isoforms, are consistent with previous

Table 2. Increases in γ- and δ-Tocopherol Levels in Three *avhppd-03*-Expressing Soybean Events

	γ-tocopherol		δ-tocopherol	
line	Δ%[a]	Δ-fold[b]	Δ%	Δ-fold
2009 Trials				
SYHT04R	9	1.1	52	1.5
SYHT04R+[c]	14	1.1	58	1.6
SYHT06W	18	1.2	58	1.6
SYHT06W+	21	1.2	62	1.6
2010 Trials				
SYHT04R	14	1.1	72	1.7
SYHT04R+	16	1.2	67	1.7
SYHT0H2	12	1.1	30	1.3
SYHT0H2+	7	1.1	25	1.3

[a]Δ% = percent increase when compared to control, calculated as (transgenic − control)/control × 100). [b]Δ-fold difference based on comparison of means (transgenic mean/control mean). [c]Crop treated with mesotrione herbicide indicated with +.

hypotheses that tocopherol methyltransferase (TMT) is a rate-limiting enzyme in the tocopherol biosynthetic pathway.[29,30]

When comparisons between transgenic soybean and the corresponding nontransgenic comparators are considered, the inherent natural variability of tocochromanols in soybean is pertinent. Within a single crop season, levels of γ-tocopherol in the control soybean grown in this study varied by almost 10-fold. The tocopherol contents of the six soybean reference varieties were also quite variable, with levels of γ-tocopherol varying by almost 18-fold and levels of δ-tocopherol varying by nearly 7-fold within a single year. Because the six varieties represented a very limited range of maturity groups (from 2.3 to 3.5), it would be expected that the wider range of 13 soybean maturity groups grown globally across latitudes and under significantly variable cultivation practices, would exhibit a greater range in tocochromanol levels.

Although statistically significant increases in γ- and δ-tocopherol were observed in the three *avhppd-03*-expressing soybean events, these absolute differences (<2-fold, Table 2) in concentration were quite small when viewed in the context of the existing natural variability of soybean tocopherol levels. For α-tocopherol, the most biologically active tocopherol for humans, the International Life Sciences Institute crop composition database[31] reports a 32-fold range of variability in conventional soybean seed. Under high-temperature conditions at different developmental stages of two soybean cultivars, Chennupati et al. reported α-tocopherol concentrations increased by as much as 7-fold (752%), γ-tocopherol decreased by an average of 34%, and δ-tocopherol decreased by 74%.[15] In 89 Brazilian soybean cultivars grown across multiple locations, Carrao-Panizzi and Erhan reported a 16-fold difference in α-tocopherol levels, an 11-fold difference in β-tocopherol levels, a 4-fold difference in γ-tocopherol levels, and a 3-fold difference in δ-tocopherol levels among the cultivars, and within a single cultivar grown at 15 locations, variability of nearly 8-fold was observed.[17]

HPPD activity also appears to be one of the key factors influencing the production of tocopherols, as evidenced by reports of increased tocopherol levels in *Arabidopsis* (*Arabidopsis thaliana*),[6,27,28] tobacco (*Nicotiana tabacum*),[32,33] canola (*Brassica napus* L.),[6] and soybean (*Glycine max* L.)[6] engineered with additional *hppd* genes.

The high degree of natural variability for soybean tocopherol levels is well documented and corresponds with global food standards. Variability of up to 39-fold is observed in the Codex Alimentarius standard for soybean oil (Table 3).[34]

Table 3. Codex Alimentarius Standard Ranges for Tocopherol Levels in Soybean Oil (Codex Alimentarius Commission 2001)

tocopherol	standard range (mg/kg)	fold range
α-tocopherol	9−352	39-fold
β-tocopherol	undetectable (<1)−36	∼36-fold
γ-tocopherol	89−2307	26-fold
δ-tocopherol	154−932	6-fold

As noted by the Institute of Medicine Food and Nutrition Board, no adverse consequences in humans or laboratory animals have been documented from eating high dietary vitamin E obtained from food.[26] The only reports of adverse consequences in humans have been in studies in which vitamin E as α-tocopherol was given as supplements.[35] However, a greater public health problem for most Americans is the inadequate intake of vitamin E relative to recommendations.[36,37] Food sources of vitamin E are largely from vegetable oils, and soybean oil is particularly rich in γ-tocopherol.[38] However, the processing of soybeans to generate vegetable oil involves cooking and a distillation process that removes much of the vitamin E.[39] Commercially, the vitamin E is added back to protect the soybean oil or is used to make vitamin E supplements. It should be noted that there are beneficial effects of dietary non-α-tocopherols, specifically γ-tocopherol,[40] especially with regard to cancer.[41] Thus, the slight increases in some forms of tocopherol in these transgenic soybean events expressing an oat *hppd* gene may have a slight benefit but, given the processing of soybeans, are unlikely to have a material impact on human nutrition with regard to soybean oil and its vitamin E concentrations.

flavonoids including apigenin, catechin, daidzein, diosmin, epicatechin, eriodictyol, genistein, hesperetin, hesperidin, isorhamnetin, kamempferol, luteolin, morin, myricetin, naringenin, naringin, neohesperidin, quercetin, quercitrin, and rutin used for phenolic composition analysis were purchased from Sigma Co. (St. Louis, MO, USA). Proanthocyanidin A2 was prepared as reported previously.[11] LPS, glutamine, Griess reagent [1% sulfanilamide, 0.1% *N*-(1-naphthyl)-ethylenediamine dihydrochloride, and 2.5% phosphoric acid), ethylenediaminetetraacetic acid (EDTA), phenylmethanesulfonyl fluoride (PMSF), phosphate-buffered saline (PBS), sodium chloride (NaCl), sodium nitrite ($NaNO_2$), Triton X-100, and Tris were obtained from Sigma Co. (St. Louis, MO, USA). RPMI-1640 medium, fetal bovine serum (FBS), and penicillin-streptomycin-amphotericin (PSA) were purchased from Gibco/Invitrogen Co. (Carlsbad, CA, USA). Enzyme immunoassay (EIA) kits for determination of TNF-α, IL-1β, and IL-6 were purchased from Invitrogen Co. (Carlsbad, CA, USA). An EIA kit for PGE2 assay was purchased from Cayman Chemical (Ann Arbor, MI, USA). A lactic dehydrogenase (LDH) assay kit was purchased from Bioassay Systems (Hayward, CA, USA). A Cell Counting Kit-8 (CCK-8) was purchased from Enzo Life Sciences Inc. (Farmingdale, NY, USA). The specific antibodies for iNOS, COX-2, phosphorylated IκBα (P-IκBα), IκBα, p50, p38, JAK2, phosphorylated JAK2 (P-JAK1/2), STAT1, phosphorylated STAT1 (P-STAT1), STAT3, phosphorylated STAT3 (P-STAT3), poly-(ADP ribose) polymerase (PARP), and β-actin were purchased from GeneTex Inc. (Irvine, CA, USA). IκB kinase (IKK) α/β, phosphorylated IKKα (Ser180)/IKKβ (Ser181) (P-IKKα/β), c-Jun NH_2-terminal protein kinase 1/2 (JNK1/2), phosphorylated JNK1/2 (P-JNK1/2), phosphorylated ERK1/2 (P-ERK1/2), and phosphorylated p38 (P-p38) were purchased from Santa Cruz Biotechnology Inc. (Santa Cruz, CA, USA). p65 and ERK1/2 were purchased from Spring Bioscience, Inc. (Danvers, MA, USA). Horseradish peroxidase-conjugated antigoat or antirabbit IgG was purchased from Bio-Rad Laboratories, Inc. (Hercules, CA, USA). A nuclear extraction kit (AY2002) was purchased from Panomics, Inc. (Redwood City, CA, USA).

Preparation of LFEE. Fresh litchi flowers gathered from a farm in Taichung, Taiwan (March 2012) were lyophilized with a freeze-dryer (Vastech Scientific Co., Ltd., Taipei, Taiwan). The samples were extracted with ethanol (1/20, g/mL) for 24 h in the dark. After the mixture had been filtered, the solvent was evaporated to dryness on a rotary evaporator (Panchun Scientific Co., Kaohsiung, Taiwan). The extract was then stored at −80 °C in an airtight bottle before use in experiments.

Determination of Phytochemicals in LFEE. The extract (5 mg) was dissolved in MeOH (20 mL) for high-performance liquid chromatography (HPLC) analysis. The determination of flavonoid and phenolic acid was performed based on the report of Chen et al.:[4] stationary phase, Hypersil GOLD C_{18} column (250 × 4.6 mm, 5 μm; Thermo Fisher Scientific Inc., Fairlawn, NJ, USA); mobile phase, MeOH (solvent A) and 9% CH_3COOH prepared with dd H_2O (solvent B) (conditions: 0−5 min, increase from 5% to 17% A; 5−25 min, maintain at 17% A; 25−40 min, increase from 17% to 31% A; 40−76 min, maintain at 31% A; 76−80 min, increase from 31% to 40% A; 80−120 min, maintain at 40% A); flow rate, 0.8 mL/min; detection, 210−650 nm. Proanthocyanidins were determined according to the method of Hwang et al.:[6] stationary phase, Hypersil GOLD C_{18} column (250 mm × 4.6 mm i.d., 5 μm); mobile phase, ACN (solvent A) and 2% CH_3COOH prepared with dd H_2O (solvent B) (conditions: 0−5 min, increase from 10% to 20% A; 10−13 min, increase from 20% to 30% A; 13−15 min, increase from 30% to 100% A; 15−20 min, maintain at 100% A); flow rate, 1 mL/min. The analytical equipment included a PrimeLine Gradient model 500G HPLC pump system (Analytical Scientific Instruments, Inc., El Sobrante, CA, USA), an S-3210 photodiode-array (PDA) detector (Schambeck SFD GmbH, Bad Honnef, Germany), and a Thermo Finnigan LCQ classic quadrupole ion trap HPLC−mass spectrometry (MS) system (Gentech, Arcade, NY, USA) equipped with an electrospray ionization (ESI) source (positive-ion mode). The HPLC−MS instrument was used to determine mass spectra recorded from m/z 50 to 1000 with the following conditions: nebulizer pressure, 70 psi; capillary temperature, 200 °C; dry gas flow, 11 L/min; electrospray voltage of the ion source, 3000 V; capillary exit, −159 V; skimmer, 40 V.

Cell Line. Murine macrophage RAW264.7 cells obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA) were cultured in RPMI-1640 medium supplemented with 10% heat-inactivated FBS and 1% PSA. The cells were incubated in a Thermo Scientific Forma Direct-Heat CO_2 Incubator (Thermo Fisher Scientific Inc., Mississauga, ON, USA) (37 °C, 5% CO_2).

Cell Viability Assay. CCK-8 was used for the cell viability assay. The kit contained WST-8 [2-(2-methoxy-4-nitrophenyl)-3-(4-nitrophenyl)-5-(2,4-disulfophenyl)-2H-tetrazolium, monosodium salt], which can be reduced by dehydrogenase in the cell and produces an orange-colored formazan that is soluble in tissue culture medium. The level of the formazan dye is proportional to the number of living cells.[12] RAW264.7 cells were plated at a density of 1×10^6 cells/well into 24-well plates, preincubated for 1 h with various concentrations (0, 0.1, 0.2, 0.3, 0.4, and 0.5 mg/mL) of LFEE (dissolved in EtOH), and stimulated with or without 1 μg/mL of LPS for 24 h at 37 °C in the CO_2 incubator. The EtOH concentration in each well was 0.0475% (v/v), which was the final concentration after the LFEE/ethanol solution had been diluted with PBS. After treatment, the CCK-8 solution (10 μL) was added to each well, and the mixture was incubated for 2 h at 37 °C. The absorbance at 450/595 nm was read using a microplate reader (Multiskan Spectrum, Thermo Scientific Co., Vantaa, Finland). The absorption from the control cells was set as 100% cell viability.

LDH Assay. LDH released from damaged cells was determined according to the method of Haslam et al.[13] RAW264.7 cells were plated at a density of 1×10^6 cells/well into 24-well plates, preincubated for 1 h with various concentrations (0, 0.1, 0.2, 0.3, 0.4, and 0.5 mg/mL) of LFEE (dissolved in EtOH), and stimulated with or without 1 μg/mL of LPS for 24 h at 37 °C in the CO_2 incubator. The EtOH concentration in each well was 0.0475% (v/v). After treatment, the 24-well culture plates were centrifuged at 300g for 5 min, and 50 μL of supernatant was transferred from each well to clear flat-bottom 96-well plates. LDH assay reagent (100 μL) was then added to each well of the 96-well plates and incubated for 30 min in the dark. After the addition of 15 μL of 1 N HCl, the absorbance at 450/595 nm was read using a microplate reader (Multiskan Spectrum, Thermo Scientific Co., Vantaa, Finland). Culture medium wells (no cells, blank) and control well cells treated with Triton X-100 (total lysis) were also assayed. Results are expressed as percentages of the maximum LDH release in the total lysis and sample wells.

Determination of Nitrite, PGE2, and Pro-Inflammatory Cytokines. RAW264.7 cells were plated at a density of 1×10^6 cells/well in 24-well plates, pretreated with various concentrations (0, 0.1, 0.2, and 0.3 mg/mL) of LFEE (dissolved in EtOH), and stimulated with or without 1 μg/mL of LPS for 24 h at 37 °C in the CO_2 incubator. The EtOH concentration in each well was 0.0475% (v/v). NO levels in the cultured medium were determined as nitrite using Griess reagent.[14] Each cultured medium (supernatant, 100 μL) was mixed with Griess reagent (100 μL) and incubated for 10 min. The absorbance of the mixture was read at 540 nm using a microplate reader. The nitrite levels were calculated with a standard curve developed using $NaNO_2$. The levels of $PGE2_2$ and pro-inflammatory cytokines (TNF-α, IL-1β, and IL-6) in the cultured medium (supernatant) were determined with an enzyme-linked immunosorbent assay (ELISA) in accordance with the manufacturer's protocols. The absorbances of $PGE2_2$ and the cytokines were measured at 412 and 450/650 nm, respectively, with a microplate reader.

Preparation of Nuclear Extracts. Nuclear−cytoplasmic fractionation was conducted using NE-PER Nuclear and Cytoplasmic Extraction Reagent kits (Thermo Fisher Scientific Inc., Rockford, IL, USA) according to the manufacturer's protocol. The samples were incubated with rocking at 4 °C for 15 min and centrifuged for 5 min at 12000*g*. The protein concentration of the supernatant was determined with a Bicinchoninic Acid protein assay kit (Thermo Fisher Scientific Inc., Rockford, IL, USA).

Western Blotting Analysis. Western blotting analysis was performed based on the report of Jung et al.[15] RAW264.7 cells were plated at a density of 1×10^6 cells/well in 24-well plates, pretreated with various concentrations (0, 0.1, 0.2, and 0.3 mg/mL) of LFEE (dissolved in EtOH), and stimulated with or without 1 μg/mL of LPS for 24 h at 37 °C in the CO_2 incubator. The EtOH concentration in each well was 0.0475% (v/v). Subsequently, the cells were washed with PBS, collected, suspended in the lysis buffer [150 mM NaCl, 10 mM Tris (pH 7.5), 5 mM EDTA, 1% Triton X-100] with protease inhibitors (1 μg/mL leupeptin and 100 μg/mL PMSF), and centrifuged at 12000*g* for 20 min at 4 °C to yield cell lysates. The protein levels were measured with a protein assay kit (Bio-Rad Laboratories, Inc., Hercules, CA, USA). The proteins (RAW264.7 lysates) were separated with 10% sodium dodecyl sulfate (SDS) polyacrylamide gels and transferred to poly(vinylidene difluoride) (PVDF) membranes (New Life Science Products, Inc., Boston, MA, USA). The membranes were then blocked in Tris-buffered saline (TBS)/Tween 20 solution with 5% nonfat dry milk and incubated sequentially with primary antibody and horseradish peroxidase-conjugated antigoat or antirabbit IgG (Bio-Rad Laboratories, Inc., Hercules, CA, USA). The protein bands were visualized with an enhanced chemiluminescence (ECL) system (Amersham Biosciences, Piscataway, NJ, USA), and their densities were quantified using Alpha Imager 2200 software (Alpha Innotech Co., San Leandro, CA, USA).

Statistical Analysis. All assays were performed in triplicate, and the mean values were calculated. The data were subjected to analysis of variance (ANOVA), and Duncan's multiple range tests were used to assess differences between means. Significant differences were concluded at a level of $p < 0.05$.

RESULTS

Flavonoids, Phenolic Acids, and Proanthocyanidin A2 in LFEE. Five flavanoids [total amount, 102.73 ± 5.50 mg/g of dried extract (mg/gDE)], including epicatechin (78.77 ± 4.21 mg/gDE), rutin (19.05 ± 1.02 mg/gDE), naringin (0.39 ± 0.01 mg/gDE), quercitrin (2.22 ± 0.12 mg/gDE), and neohesperidin (2.30 ± 0.14 mg/gDE), and nine phenolic acids (total amount, 60.31 ± 4.52 mg/gDE), including gallic acid (0.25 ± 0.01 mg/gDE), gentisic acid (32.14 ± 2.72 mg/gDE), chlorogenic acid (2.32 ± 0.08 mg/gDE), vanillic acid (0.60 ± 0.04 mg/gDE), *p*-coumaric acid (0.17 ± 0.01 mg/gDE), ferulic acid (18.25 ± 1.37 mg/gDE), sinapic acid (4.64 ± 0.20 mg/gDE), syringic acid (0.88 ± 0.04 mg/gDE), and *p*-anisic acid (1.06 ± 0.05 mg/gDE), were identified in LFEE. In addition, proanthocyanidin A2 (the major proanthocyanidin) was present in the extract at a level of 79.31 ± 2.95 mg/gDE. LFEE was then dissolved in EtOH to estimate its anti-inflammatory activity with LPS-stimulated RAW264.7 cells.

Viability and LDH Release of RAW264.7 Cells Treated with LFEE. The EtOH concentration in the medium of RAW264.7 cells (47.5 μL of EtOH in 100 mL of medium) provided good dissolution ability for LFEE. Also, it did not influence the assay of the anti-inflammatory activity of LFEE. The CCK-8 assay showed that an LPS concentration of 1 μg/mL and/or an LFEE concentration of less than 0.4 mg/mL did not significantly change RAW264.7 cell proliferation. Similar results were seen in the LDH assay; an LPS concentration of 1 μg/mL and/or an LFEE concentration of less than 0.4 mg/mL did not significantly impair RAW264.7 cells (data not shown). Therefore, LFEE concentrations of 0, 0.1, 0.2, and 0.3 mg/mL were used in this investigation.

Effects of LFEE on LPS-Stimulated Productions of Nitrite, PGE2, and Pro-Inflammatory Cytokines and Protein Expressions of iNOS and COX-2 in RAW264.7 Cells. Figure 1 shows that LPS stimulation substantially increased the productions of nitrite, $PGE2_2$, and pro-inflammatory cytokines (IL-1β, IL-6, and TNF-α) in RAW264.7 cells. When the cells were pretreated with LFEE, the levels of LPS-induced nitrite, $PGE2_2$, IL-1β, IL-6, and TNF-α were lowered significantly, especially for the cells pretreated with 0.3 mg/mL LFEE.

For the Western blot analysis, Figure 2 shows that LPS highly induced the expressions of iNOS and COX-2 in RAW264.7 cells; nevertheless, their expressions were decreased significantly when the cells were pretreated with LFEE. The higher the LFEE concentration, the greater the suppressive effect. The reduction of the expressions of iNOS and COX-2 responded to the downregulation of the productions of NO and $PGE2_2$.

Effects of LFEE on LPS-Induced IKKα/β Phosphorylation and Translocation of NF-κB p50/p65 Subunits in RAW264.7 Cells. Figure 3 shows that LPS treatment caused the translocation of cytoplasmic p50 and p65 to the nucleus. Following LFEE pretreatment, the levels of translocated p50 and p65 were decreased significantly. The results demonstrated that LFEE-mediated suppression of the production of pro-inflammatory mediators is regulated by the NF-κB pathway in LPS-stimulated RAW264.7 cells.

Upon LPS stimulation, IKK α/β phosphorylation was greatly increased in RAW264.7 cells. However, this increase was lowered significantly when the cells were pretreated with LFEE.

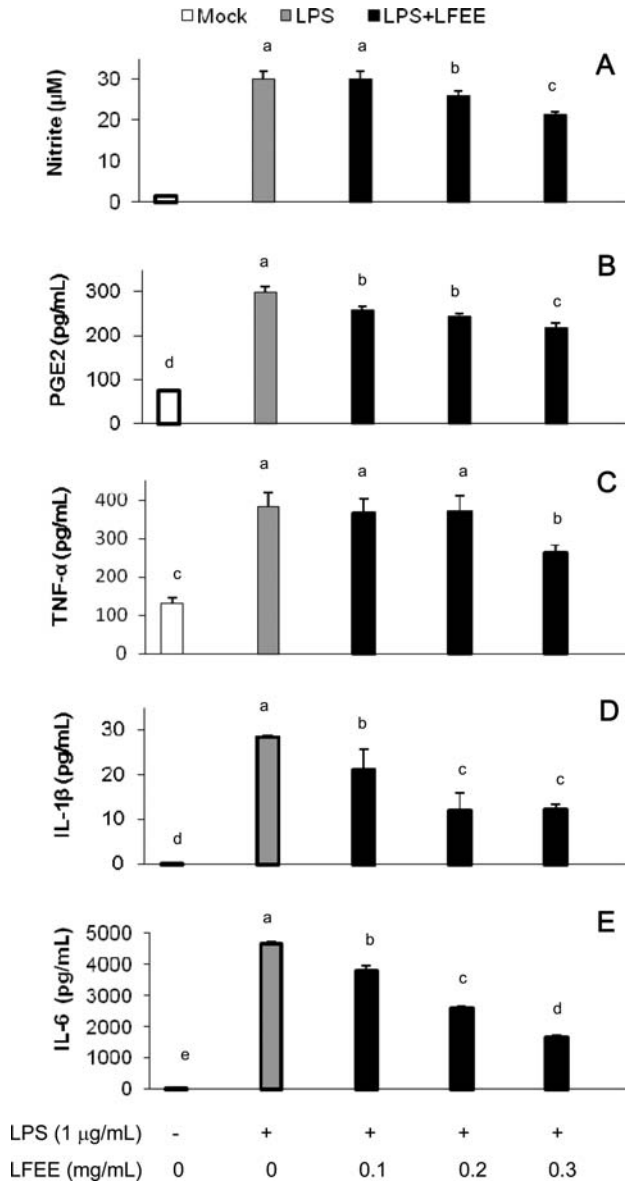

Figure 1. Effects of LFEE on LPS-stimulated productions of NO, PGE2, IL-1β, IL-6, and TNF-α in RAW264.7 cells. The cells plated in 24-well plates (1×10^6 cells/well) were pretreated with various concentrations (0−0.3 mg/mL) of LFEE for 1 h and then stimulated with or without (mock) LPS (1 μg/mL) for 24 h. The cultured media were used for assays. The level of (A) nitrite was determined through Griess reagent to evaluate NO production. The levels of (B) PGE2, (C) TNF-α, (D) IL-1β, and (E) IL-6 were measured by ELISA. Each value is expressed as mean ± SD (n = 3). Means with different letters are significantly different at the level of $p < 0.05$.

Therefore, LFEE suppression of NF-κB activation was caused by reducing the phosphorylation of the IKK complex.

Effects of LFEE on LPS-Induced Phosphorylation of Mitogen-Activated Protein Kinases (MAPKs) in RAW264.7 Cells. Figure 4 shows that MAPKs including JNK, p38, and ERK were markedly activated by LPS in RAW264.7 cells. LFEE pretreatment significantly lowered ERK phosphorylation in a dose-dependent manner; nevertheless, phosphorylated JNK and p38 did not show a significant decrease. Therefore, ERK inactivation is responsible for the LFEE-mediated suppression of the productions of pro-inflammatory mediators in LPS-stimulated RAW264.7 cells.

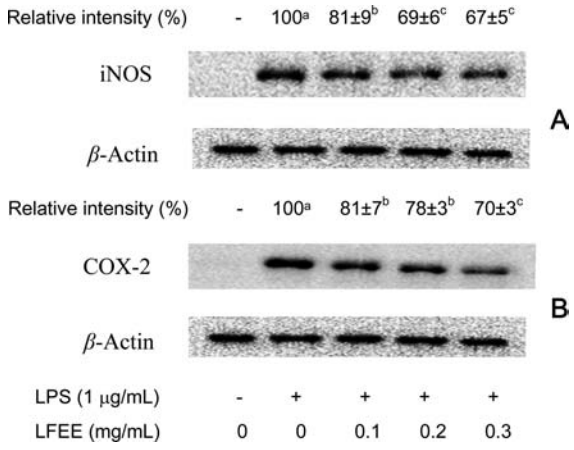

Figure 2. Effects of LFEE on LPS-stimulated protein expressions of iNOS and COX-2 in RAW264.7 cells. The cells were pretreated with various concentrations (0−0.3 mg/mL) of LFEE for 1 h and then stimulated with or without LPS (1 μg/mL) for 24 h. Protein levels of (A) iNOS and (B) COX-2 were measured by Western blot; the signals of iNOS and COX-2 were normalized to the β-actin signal. Each data point represents the mean ± SD of three independent experiments and is expressed as the percentage of the culture treated with LPS alone. Means with different letters are significantly different at the level of $p < 0.05$.

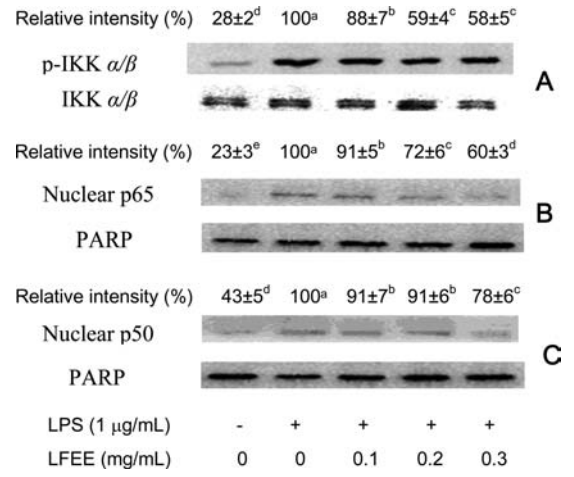

Figure 3. Effects of LFEE on LPS-induced phosphorylation of IκB IKKα/β and NF-κB p50 and p65 subunits in RAW264.7 cells. The cells were pretreated with various concentrations (0−0.3 mg/mL) of LFEE for 1 h and then stimulated with or without LPS (1 μg/mL) for 24 h. The levels of (A) phosphorylation of IKKα/β and IKKα/β were measured with Western blot; the ratios of immunointensity between phosphorylated IKKα/β and IKKα/β are shown. The levels of (B,C) nuclear translocation of NF-κB (B) p50 and (C) p65 subunits were measured with Western blot; each of their signals was normalized to the β-actin signal. Each data point represents the mean ± SD of three independent experiments and is expressed as the percentage of the culture treated with LPS alone. Means with different letters are significantly different at the level of $p < 0.05$.

Effects of LFEE on LPS-Induced Phosphorylation of JAK2, STAT1, and STAT3 in RAW264.7 Cells. Figure 5 shows that the expressions of phosphorylation of STAT1 and STAT3 could be significantly increased in RAW264.7 cells through LPS stimulation. When the cells were pretreated with a higher concentration of LFEE, a greater reduction of STAT3 activation, but not STAT1 activation, could be observed.

dx.doi.org/10.1021/jf5003705 | J. Agric. Food Chem. 2014, 62, 3458−3465

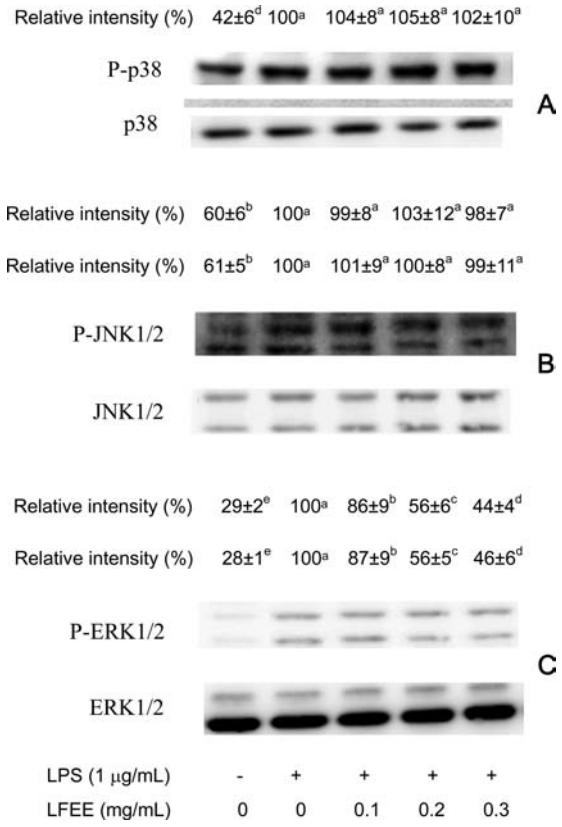

Figure 4. Effects of LFEE on LPS-activated MAPKs in RAW264.7 cells. The cells were pretreated with various concentrations (0−0.3 mg/mL) of LFEE for 1 h and then stimulated with or without LPS (1 μg/mL) for 24 h. The levels of total or phosphorylated (A) p38, (B) JNK1/2, and (C) ERK1/2 were measured with Western blot; the ratios of immunointensity between the MAPKs and the phosphorylated MAPKs are shown. Each data point represents the mean ± SD of three independent experiments and is expressed as the percentage of the culture treated with LPS alone. Means with different letters are significantly different at the level of $p < 0.05$.

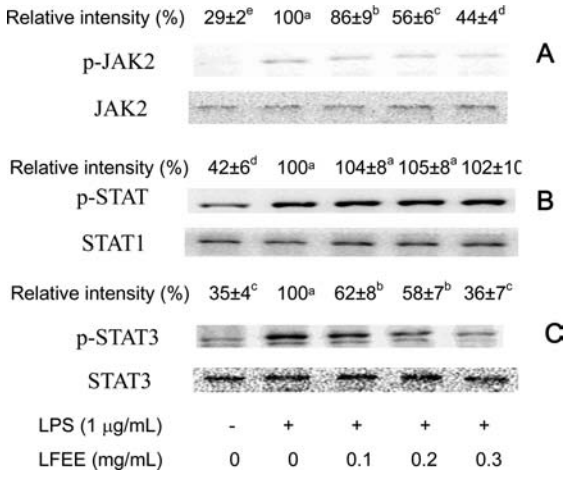

Figure 5. Effects of LFEE on LPS-activated JAK2 and STATs in RAW264.7 cells. The cells were pretreated with various concentrations (0−0.3 mg/mL) of LFEE for 1 h and then stimulated with or without LPS (1 μg/mL) for 24 h. The levels of total or phosphorylated (A) JAK2, (B) STAT1, and (C) STAT3 were measured with Western blot; the ratios of immunointensity between JAK2 and phosphorylated JAK2 and between the STATs and the phosphorylated STATs are shown. Each data point represents the mean ± SD of three independent experiments and expressed as the percentage of the culture treated with LPS alone. Means with different letters are significantly different at the level of $p < 0.05$.

Therefore, STAT3 inactivation should be associated with the anti-inflammatory effect of LFEE.

Similarly, LPS stimulation significantly increased JAK2 phosphorylation in RAW264.7 cells. LFEE addition caused a dose-dependent decrease of JAK2 activation. Therefore, LFEE cessation of STAT3 activation is caused by attenuating JAK2 activation.

DISCUSSION

During inflammation, excess levels of NO, $PGE2_2$, and cytokines (IL-1β, IL-6, and TNF-α) are induced by activated inflammatory cells (e.g., eosinophils, macrophages, mononuclear phagocytes, neutrophils). This leads to the damaging of cells and tissues and the activation of macrophages in inflammation-associated diseases (e.g., rheumatoid arthritis, chronic hepatitis).[14] Macrophages play an important role in regulating several immunopathological conditions and inducing overexpression of the pro-inflammatory mediators of the inflammatory process.[14]

Throughout the inflammatory processes, iNOS and COX-2 expressions are notably increased and promote the generations of NO and $PGE2_2$, respectively. Thus, inhibition of NO and $PGE2_2$ production could be an important marker for anti-inflammatory effects.[16] NF-κB plays a principle role in regulating the expressions of COX-2 and iNOS by the transcription factor. It exists in the cytoplasm as inactive heterodimers composed of the p50 and p65 subunits that are bound to the inhibitor of κB (IκB). Upon inflammatory stimulation including LPS, IκB kinase (IKK) is activated, after which IκB ubiquitination and degradation is induced. NF-κB is then free to translocate from the cytosol to the nucleus, where it promotes transcription of target genes and further induces the transcription of pro-inflammatory mediators, such as iNOS, COX-2, TNF-α, and cytokines.[17−20] Kim et al.[18] indicated that many anti-inflammatory agents exhibit their potencies by suppressing NF-κB signaling.

Ho et al.[8] found that logan aqueous and ethanolic extracts contain abundant levels of phenolic compounds that can suppress LPS-induced iNOS expression as well as NO production in RAW264.7 cells. These extracts can also inhibit $PGE2_2$ generation. Hu and Kitts[21] reported that ethanolic extracts of dandelion (*Taraxacum officinale*) flower with caffeic acid, chlorogenic acid, luteolin, and luteolin-7-O-glucoside suppress the expressions of iNOS and COX-2 and the productions of NO and $PGE2_2$ in LPS-activated RAW264.7 cells. Choi et al.[22] demonstrated that ethanolic extract of *Inula japonica* (Inulae Flos) flower inhibits LPS-stimulated iNOS expression, NO production, and release of pro-inflammatory cytokines (TNF-α and IL-6) through the downregulation of NF-κB activation in RAW264.7 cells. Jung et al.[17] found that methanolic extracts of *Panax notoginseng* flower significantly inhibit the expressions of iNOS and COX-2 as well as the productions of NO and $PGE2_2$ in LPS-stimulated RAW264.7 cells. The extract also significantly inhibits the production of TNF-α and IL-1β. The molecular mechanism of the extract-mediated attenuation in RAW264.7 cells has a close relationship to the suppression of the translocation of NF-κB p65 subunit into the nucleus.

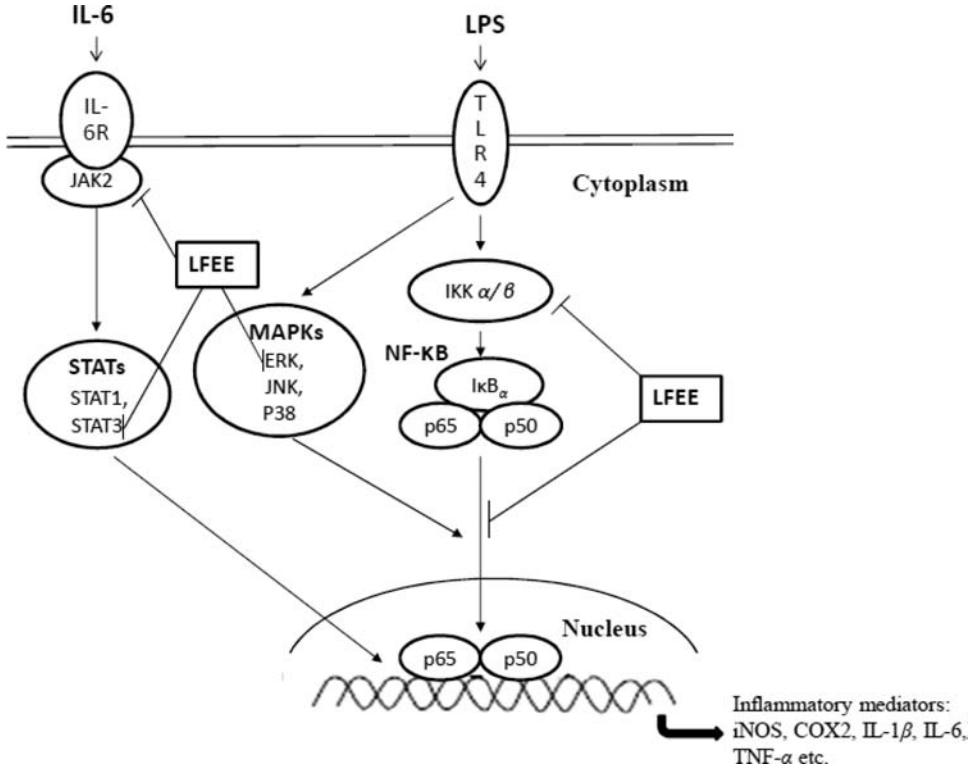

Figure 6. Possible role of LFEE in the production of LPS-stimulated pro-inflammatory mediators in RAW264.7 cells.

Our study showed that LFEE downregulates the expressions of iNOS and COX-2 as well as the productions of NO and $PGE2_2$ in LPS-stimulated RAW264.7 cells (Figures 1 and 2). In addition, LFEE could also lower the secretions of pro-inflammatory cytokines, TNF-α, IL-1β, and IL-6 (Figure 1). The molecular mechanism of LFEE-mediated attenuation in the RAW264.7 cells was closely related to suppression of IκB kinase activation followed by inhibition of the translocation of NF-κB p50/p65 subunits into the nucleus (Figure 3). These results suggest that LFEE suppresses the expression of pro-inflammatory mediators by downregulating the NF-κB pathway in stimulated macrophages.

MAPKs including ERK, JNK, and p38 are a group of signaling molecules. They also appear to play a crucial role in inflammatory processes.[23] Kaminska[24] indicated that LPS could stimulate MAPK cascades and the pathways leading to activation of NF-κB. Upon MAPK activation, transcription factors present in the cytoplasm or nucleus are phosphorylated, leading to target gene expression resulting in a biological response. Reports[25−27] have indicated that MAPK pathways are involved in LPS-induced iNOS and COX-2 expression in macrophages.

Choi et al.[22] reported that LPS-stimulated RAW264.7 cells cause phosphorylation of ERK, JNK, and p38; nevertheless, ERK and p38 phosphorylation could be significantly inhibited through treatment with the ethanolic extract of the *Inula japonica* (Inulae Flos) flower. Jung et al.[17] reported that the methanolic extract of *Panax notoginseng* flower suppresses the phosphorylation of ERK1/2 and JNK and slightly decreases the phosphorylation of p38 in LPS-stimulated RAW264.7 cells.

In agreement with previous investigations, ERK, JNK, and p38 could be phosphorylated remarkably as the RAW264.7 cells were stimulated with LPS. Treatment with LFEE was observed to significantly lower ERK phosphorylation in the LPS-stimulated RAW264.7 cells (Figure 4). The results suggest that blocking of the ERK pathway is involved in the suppression of LPS-stimulated NF-κB bound by LFEE in RAW264.7 cells.

IL-6 provokes a broad range of cellular and physiological responses, including immune response and inflammation. IL-6 could use the JAK/STAT signaling pathway for signal transduction.[28] IL-6 signaling is initiated by binding to its receptor subunit IL-6R (IL-6-binding α-subunit receptor), which subsequently transduces a signal that activates intracytoplasmic JAKs. The activated JAKs could transduce the intracellular signal by further phosphorylating and activating STATs. The activated STATs could translocate to the nucleus, where they activate NF-κB.[29] Ichikawa et al.[30] demonstrated that LPS could induce the activation of the STAT pathway, leading to a significant production of pro-inflammatory mediators in RAW264.7 cells.

To the best of our knowledge, no reports regarding the suppression of pro-inflammatory responses in macrophages by flower extract with a focus on STAT signaling have been published. In this study, we found that LFEE could decrease IL-6 secretion, which might lead to further lowering of the activation of JAK2 and STAT3 but not STAT1 in LPS-induced 264.7 cells. The results illustrate that blocking the STAT cascade is another important mechanism contributing to the anti-inflammatory activity of LFEE in macrophages.

Our investigation found that the molecular mechanism for LFEE-mediated attenuation of LPS-induced inflammatory responses in RAW264.7 cells correlates with downregulation of IKK α/β phosphorylation, thus inhibiting p50 and p65 subunits translocation into the nucleus. Furthermore, LFEE inhibits the LPS-induced activation of ERK as well as JAK2/STAT3. The results are summarized in Figure 6.

dx.doi.org/10.1021/jf5003705 | J. Agric. Food Chem. 2014, 62, 3458−3465

LFEE was found to contain abundant phenolic components including five flavanoids (epicatechin, rutin, naringin, quercitrin, and neohesperidin), nine phenolic acids (gallic acid, gentisic acid, chlorogenic acid, vanillic acid, *p*-coumaric acid, ferulic acid, sinapic acid, syringic acid, and *p*-anisic acid), and proanthocyanidin A2. Our previous results[11] also showed that proanthocyanidin A2 and epicatechin are the two major compounds responsible for the antioxidation activity of LFEE. Ho et al.[8] indicated that proanthocyanidin A2 is the key anti-inflammatory component in the longan flower extract. Bellik et al.[31] reported that gallic acid, ferulic acid, coumaric acid, and rutin have anti-inflammatory effects. They are also found in the LFEE. Therefore, these compounds should contribute to the anti-inflammatory activity of LFEE. Through evaluation of the LFEE anti-inflammatory effect with LPS-mediated RAW264.7 macrophages, remarkable suppression of the protein expressions of iNOS and COX-2; the productions of NO and PGE2; and the secretions of IL-1β, IL-6, and TNF-α was found. The results demonstrated that LFEE modulates inflammatory processes through the inactivation of NF-κB, ERK, and JAK2/STAT3. Litchi flower should have the potential to be exploited as a functional food for anti-inflammation activity.

between the intake of wine and death resulting from coronary heart disease.[16] Since then, a lot of different targets have been found to be influenced by resveratrol treatment.[17,18] Previous studies showed that red wine polyphenols contribute to improvements in endothelial dysfunction and ultimately reduce the blood pressure and associated cardiac and vascular diseases.[19,20] Our previous studies have shown that resveratrol can protect cerebrovascular endothelial cells from oxLDL-induced apoptotic insults through Lox-1 receptor-mediated signal-transducing events.[21,22] But to date, much less is known about the effects of the consumption of red wine on high-fat diet-influenced BBB damage and subsequent neuronal damage. Therefore, in this study, we attempted to evaluate the effects of resveratrol on high-fat diet-induced disruption of the BBB and its possible mechanisms.

MATERIALS AND METHODS

Chemicals. Resveratrol, Evans blue dye, sodium pentobarbital, methanol, and Triton-X were purchased from Sigma (St. Louis, MO, USA). The purity of resveratrol used in this study was 99%. Acetone and ethanol were bought from Mallinckrodt Baker (Paris, KY, USA). Phosphate-buffered saline buffer (PBS) was prepared by mixing 0.14 M sodium chloride, 2.6 mM potassium chloride, 8 mM sodium phosphate, and 1.5 mM potassium phosphate. Sodium chloride, potassium chloride, sodium phosphate, and potassium phosphate were purchased from Sigma.

Animals. All procedures were performed according to the National Institutes of Health Guidelines for the Use of Laboratory Animals and approved by the Institutional Animal Care and Use Committee of Taipei Medical University, Taipei, Taiwan. Male ICR mice weighing 20−25 g were purchased from the Animal Center of the College of Medicine, National Taiwan University, Taipei, Taiwan. Before the experiments began, mice were allowed to acclimatize for 1 week in their animal quarters with air conditioning and an automatically controlled photoperiod of 12 h of light daily. Animals were allowed free access to rodent laboratory chow (Purina Mills, St. Louis, MO, USA).

Experimental Design. Animals were randomly divided into (1) normal diet-, (2) normal diet + resveratrol-, (3) high-fat diet-, and (4) high-fat diet + resveratrol-treated groups. The normal standard diet contained 5.1% fat (unsaturated fatty acids), 23.5% protein, and 50.3% complex carbohydrates. The composition of the high-fat diet included 20.1% fat (saturated fatty acids), 18.3% protein, and 51.2% carbohydrates. Our previous studies have shown that resveratrol at 10 μM can protect cerebrovascular endothelial cells from oxLDL-induced apoptotic insults.[21,22] Provinciali et al. reported that when a mouse drank 1 mg/L resveratrol daily, the serum concentrations of resveratrol were about 4 μM.[23] Thus, in the present study, resveratrol was dissolved in methanol and diluted with tap water to a concentration of 2.5 mg/L. The respective dose of resveratrol daily exposed to a mouse was 0.4 mg/kg body weight. Mice were administered a high-fat diet and resveratrol for 8 weeks. Control animals received 0.02% ethanol. The tap water with resveratrol was refreshed every day. The amounts of water and food consumed and the body weights were measured. At the end of the experiments, animals were sacrificed. Blood samples were collected and centrifuged to obtain serum. The brains were removed, weighed, and collected.

Analysis of Serum Cholesterol and LDL. After drug treatment, ICR mice were sacrificed and the blood was collected. Serum fractions were prepared by centrifugation of blood samples. Levels of serum total cholesterol, triglycerides, and high-density lipoprotein (HDL) were measured according to commercial kits provided by Randox Laboratories (Crumlin, Ireland, UK). Amounts of LDL were calculated by the formula LDL = total cholesterol − triglycerides/5 − HDL.

Assays of the BBB Integrity. Integrity of the BBB was analyzed by assessing extravasation of Evans blue dye according to a previously described method.[24] Briefly, after drug treatment, 0.1 mL of Evans blue dye (2%) was intravenously injected and allowed to circulate for 1 h. Subsequently, mice were intraperitoneally anesthetized with 80 mg sodium pentobarbital per kg body weight and perfused with PBS until a colorless perfusion fluid was obtained from the right atrium. Then, the brains were removed, weighed, and photographed for colorimetric blue signals.

Confocal Microscopic Analysis of Evans Blue Dye. To further determine the effects of resveratrol and a high-fat diet on the BBB integrity, a confocal microscopic analysis of Evans blue was carried out as described previously.[25] Briefly, after drug treatment, Evans blue dye was intravenously injected into mice. Following perfusion, the brain tissues were removed and sliced for the analysis of fluorescent signals excited by Evans blue in the brains using a confocal laser scanning microscope (model FV500, Olympus, Tokyo, Japan). Images were acquired and quantified using FLUOVIEW 4.0 software (Olympus).

Confocal Microscopic Analyses of Occludin and ZO-1 Polymerization, Factor VIII, and Activated Caspase-3. Polymerization of occludin and ZO-1 in brain tissues was recognized by specific antibodies, and these were visualized using confocal microscopy following a previously described method.[12] Briefly, after drug administration, brain tissues were removed, collected, and sliced. Tissues were fixed with a fixing reagent (acetone/methanol, 1:1) at −20 °C for 10 min. Following rehydration, the brains were incubated with 0.2% Triton X-100 at room temperature for 15 min. Rabbit polyclonal antibodies used in this study were respectively generated against human occludin and ZO-1 proteins (Invitrogen, Carlsbad, CA, USA). Immunodetection of occludin and ZO-1 in mouse brain tissues was carried out at 4 °C overnight. After washing, slices were sequentially reacted with the second antibodies and biotin-SP-conjugated AffiniPure goat antirabbit immunoglobulin G (IgG) (Jackson ImmunoResearch, West Grove, PA, USA) at room temperature for 1 h. After washing, the third antibody with Cy3-conjugated streptavidin (Jackson ImmunoResearch) was added to the brain slices and reacted at room temperature for 30 min. Localization of the BBB in brain tissues was recognized using an antibody against factor VIII protein (BioGenex, San Francisco, CA, USA). Activated caspase-3 was immunodetected using a polyclonal antibody against human cleaved caspase-3 (Cell Signaling Technology, Danvers, MA, USA). A confocal laser scanning microscope (Olympus) was utilized for sample observation. The excitation wavelength was set to 568 nm, while a 585-nm long-pass filter was used to collect the emitted light. Images were acquired and quantified using FLUOVIEW software (Olympus).

Immunodetection of Occludin and ZO-1. After drug treatment, the brains were removed and homogenized with lysis buffer (50 mM Tris-HCl (pH 7.4), 150 mM NaCl, 1 mM EGTA, 1% NP-40 supplemented with 1 mM PMSF, 1 μM aprotinin, 1 μM leupeptin, 1 mM Na_2VO_4, and 1 mM NaF). Protein concentrations were quantified using a bicinchonic acid protein assay kit (Pierce, Rockford, IL, USA). Proteins

(50 μg/well) were subjected to sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), and transferred to nitrocellulose membranes as described previously.[21] Membranes were blocked with 5% nonfat milk at 37 °C for 1 h. Occludin and ZO-1 proteins were immunodetected using polyclonal antibodies (Invitrogen). β-Actin was immunodetected using a mouse monoclonal antibody against mouse β-actin (Sigma) as an internal control. Intensities of the immunoreactive protein bands were determined using an UVIDOCMW vers. 99.03 digital imaging system (UVtec, Cambridge, UK).

Terminal Deoxynucleotidyl Transferase dUTP Nick End Labeling (TUNEL) Assay. A TUNEL assay was performed using the In Situ Cell Death Detection Kit (Roche Diagnostics, Mannheim, Germany), following the manufacturer's instructions. In brief, brain sections were fixed in 4% paraformaldehyde for 20 min and incubated with 0.1% Triton X-100 for 10 min. A TUNEL labeling reaction with fluorescein-conjugated dUTP was carried out at 37 °C for 60 min. These samples were then double-stained with a monoclonal antibody that specifically recognizes a vertebrate nervous system- and neuron-specific nuclear protein (NeuN; Millipore, Billerica, MA, USA) and endothelium-specific factor VIII, and observed under a confocal microscope (Olympus) as described previously.[22]

Statistical Analyses. The statistical significance of differences between the control and drug-treated groups was evaluated using Student's *t*-test, and differences were considered statistically significant at p values of <0.05. Differences between resveratrol- and high-fat diet-treated animals were considered significant when the p value of Duncan's multiple-range test was <0.05. Statistical analysis between groups over time was carried out by a two-way analysis of variance (ANOVA).

RESULTS

Resveratrol Alleviates High-Fat Diet-Induced Alterations Of Body Weights and Amounts of Total Cholesterol and LDL. After consuming a high-fat diet for more than 3 weeks, the body weight of ICR mice significantly increased (Table 1). Resveratrol did not change the body weights of control or high-fat diet-treated animals. Administration of both resveratrol and a high-fat diet did not affect the ratio of brain weight to body weight (data not shown). Administration of a high-fat diet to mice for 8 weeks caused a significant 54% increase in the level of serum total cholesterol (Figure 1A). Resveratrol alone decreased serum cholesterol levels by 16%. Simultaneously, the high-fat diet-augmented serum total cholesterol was reduced by 18% after resveratrol administration (Figure 1A). The high-fat diet caused a 2.2-fold increase in the amount of serum LDL (Figure 1B). Resveratrol did not affect the basal level of LDL but significantly decreased the high-fat diet-caused enhancement of serum LDL by 33%.

Resveratrol Protects Against High-Fat Diet-Induced Breakage of the BBB. An assay of the BBB integrity showed that Evans blue dye did not pass through the BBB in control mice (Figure 2A, top-left panel). After exposure to a high-fat diet for 8 weeks, the integrity of the BBB was disrupted, such that Evans blue dye passed the barrier and appeared in brain tissues (bottom-left panel). Resveratrol did not affect the permeability of the BBB (top-right panel), but obviously protected against high-fat diet-induced breakage of the BBB (bottom-right panel).

The resveratrol-involved protection against high-fat diet-induced insults to the BBB was further confirmed by confocal microscopy (Figure 2B). Evans blue dye was not detected in control brain slices. Meanwhile, when exposed to a high-fat diet for 8 weeks, Evans blue dye penetrated the BBB and then was observed in cerebral cortex. Resveratrol did not affect the permeability of the BBB, but prevented high-fat diet-caused damage (Figure 2B). The intensities of fluorescent signals were quantified and analyzed (Figure 2C). Treatment of ICR mice with a high-fat diet increased the signals of Evans blue dye in brain slices by 22-fold. However, exposure to resveratrol caused a significant 88% decrease in high-fat diet-induced BBB breakage (Figure 2C).

High-Fat Diet and Resveratrol Did Not Cause Death of Cerebrovascular Endothelial Cells. The localization and structure of the BBB were recognized by immunodetecting endothelium-specific factor VIII as analyzed by confocal microscopy (Figure 3). In control brain slices, factor VIII-recognizing cerebrovascular endothelial cells were observed. However, administration of neither a high-fat diet, resveratrol, nor a combination of resveratrol and the high-fat diet caused the death of cerebrovascular endothelial cells (Figure 3).

Resveratrol Attenuates High-Fat Diet-Induced Interruption of the Tight Junction Proteins, Occludi, and ZO-1 but Does Not Affect Their Protein Syntheses. Mechanisms of resveratrol-involved protection against high-fat diet-induced breakage of the BBB were determined by immunodetection of occludin and ZO-1, two typical tight junction proteins (Figure 4). In control mice, continuous occludin polymers were observed (Figure 4A). However, after administration of a

[a]Male ICR mice were treated with the control normal diet, resveratrol (Res), the HFD, and a combination of Res and the HFD for 8 weeks. Body weights were measured and statistically analyzed. Each value represents the mean ± SEM for $n = 6$. The asterisk symbol, *, indicates that the values significantly ($p < 0.05$) differ from the respective control group.

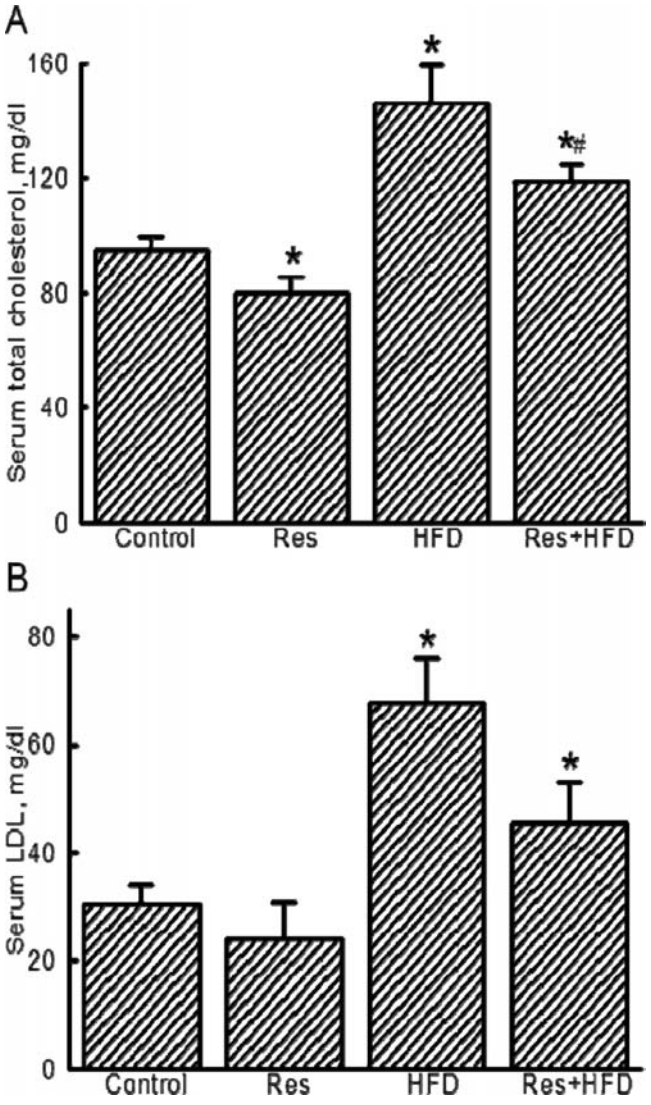

Figure 1. Effects of resveratrol (Res) on high-fat diet (HFD)-induced enhancement of serum total cholesterol and LDL. Male ICR mice were fed the control normal diet, Res, an HFD, and a combination of Res and the HFD for 8 weeks. After drug treatment, animals were sacrificed, and the blood was collected for analyses of total cholesterol (A) and LDL (B). Each value represents the mean ± SEM for $n = 6$. The asterisk and number symbols, * and #, indicate that values significantly ($p < 0.05$) differ from the respective control and HFD-treated groups.

high-fat diet, the occludin-formed polymers were disrupted into discontinuous spots. Resveratrol did not affect occludin polymerization, but lessened high-fat diet-caused disruption of the tight junction structure (Figure 4A). Similarly, continuous and uniform ZO-1 polymers were observed in control mouse brains (Figure 4B). After exposure to a high-fat diet for 8 weeks, the structure of ZO-1 polymerization was interrupted. Resveratrol did not change the ZO-1 tight junctions, but alleviated high-fat diet-caused breakage of ZO-1 polymerization (Figure 4B).

The intensities of the fluorescent signals presented in Figure 4A, B were quantified and statistically analyzed, and are presented in Table 2. Our data reveal that administration of a high-fat diet to mice for 8 weeks decreased polymerization of occludin and ZO-1 by 48% and 45%, respectively. Resveratrol did not alter the tight junctions constructed by occludin and ZO-1. However, cotreatment with resveratrol and a high-fat diet completely lowered the diet-induced breakage of occludin and ZO-1 tight junctions (Table 2).

To further determine the possible mechanisms of resveratrol-engaged preclusion of high-fat diet-caused rupture of occludin and ZO-1 tight junctions, immunoblot analyses were carried out (Figure 4C, D). Occludin and ZO-1 were immunodetected in control mouse brains (Figure 4C, top-two panels, lane 1). Resveratrol did not affect the contents of these two junction proteins in brain tissues (lane 2). After treatment with a high-fat diet and a combination of resveratrol and the high-fat diet for 8 weeks, the amounts of occludin and ZO-1 were not affected (lanes 3 and 4). Levels of β-actin were immunodetected as the internal controls (Figure 4C, bottom panel). These immunoreactive protein bands were quantified and analyzed (Figure 4D). Administration of neither resveratrol, a high-fat diet, nor a combination of resveratrol and the high-fat diet affected the contents of occludin or ZO-1 in brain tissues.

Resveratrol Defends Against High-Fat Diet-Induced Caspase-3 Activation and DNA Fragmentation of Brain Neurons. The protection by resveratrol against high-fat diet-induced insults to brain neurons was evaluated by analyzing activated caspase-3 and damage to genomic DNA (Figure 5). Brain neurons are specifically recognized by NeuN. Exposure of mice to a high-fat diet for 8 weeks increased the levels of cleaved caspase-3 in brain tissues (Figure 5A). Resveratrol did not affect caspase-3 activation. However, following cotreatment with resveratrol, the high-fat diet-caused caspase-3 activation obviously decreased (Figure 5A). Data from the TUNEL assay revealed high-fat diet-induced DNA fragmentation of brain neurons (Figure 5B). Resveratrol did not lead to DNA damage but obviously lowered high-fat diet-caused fragmentation of genomic DNA in brain neurons.

■ DISCUSSION

The cardioprotective effects of resveratrol, a constituent of red wine, are widely accepted, but its roles in the cerebral BBB are not well understood. This study showed that exposure of ICR mice to a high-fat diet for 8 weeks elevated the levels of serum total cholesterol and LDL, and body weight, but resveratrol significantly lowered such augmentations. At the same time, resveratrol protected the BBB from high-fat diet-induced interruption. The BBB is an important barricade situated in cerebral capillaries to maintain the homeostasis of the cerebral microenvironment.[9] Dysfunction of the BBB leads to profound and irreversible injuries to brain neurons.[25] In parallel with injuries to the BBB, this study showed that a high-fat diet induced insults to brain neurons. However, resveratrol decreased such damage. Therefore, the data presented in this study show that resveratrol can protect against high-fat diet-induced breakage of the BBB and consequently attenuate damage to brain neurons caused by this diet.

After exposure to resveratrol for 8 weeks, the high-fat diet-caused increase in body weight significantly decreased. Resveratrol can disturb the adipocyte life cycle via inhibiting adipogenesis or inducing apoptosis.[26] Accordingly, resveratrol possibly decreases the body weight through interfering with the adipocyte life cycle. Simultaneously, this study demonstrated that the high-fat diet-caused enhancements of serum total cholesterol and LDL were significantly reduced by resveratrol. As critical indicators of obesity, the augmentation of total cholesterol and LDL indicates the potential induction of tissue/cell damage.[27] In obese rats, long-term administration of resveratrol was reported to reduce the blood pressure through

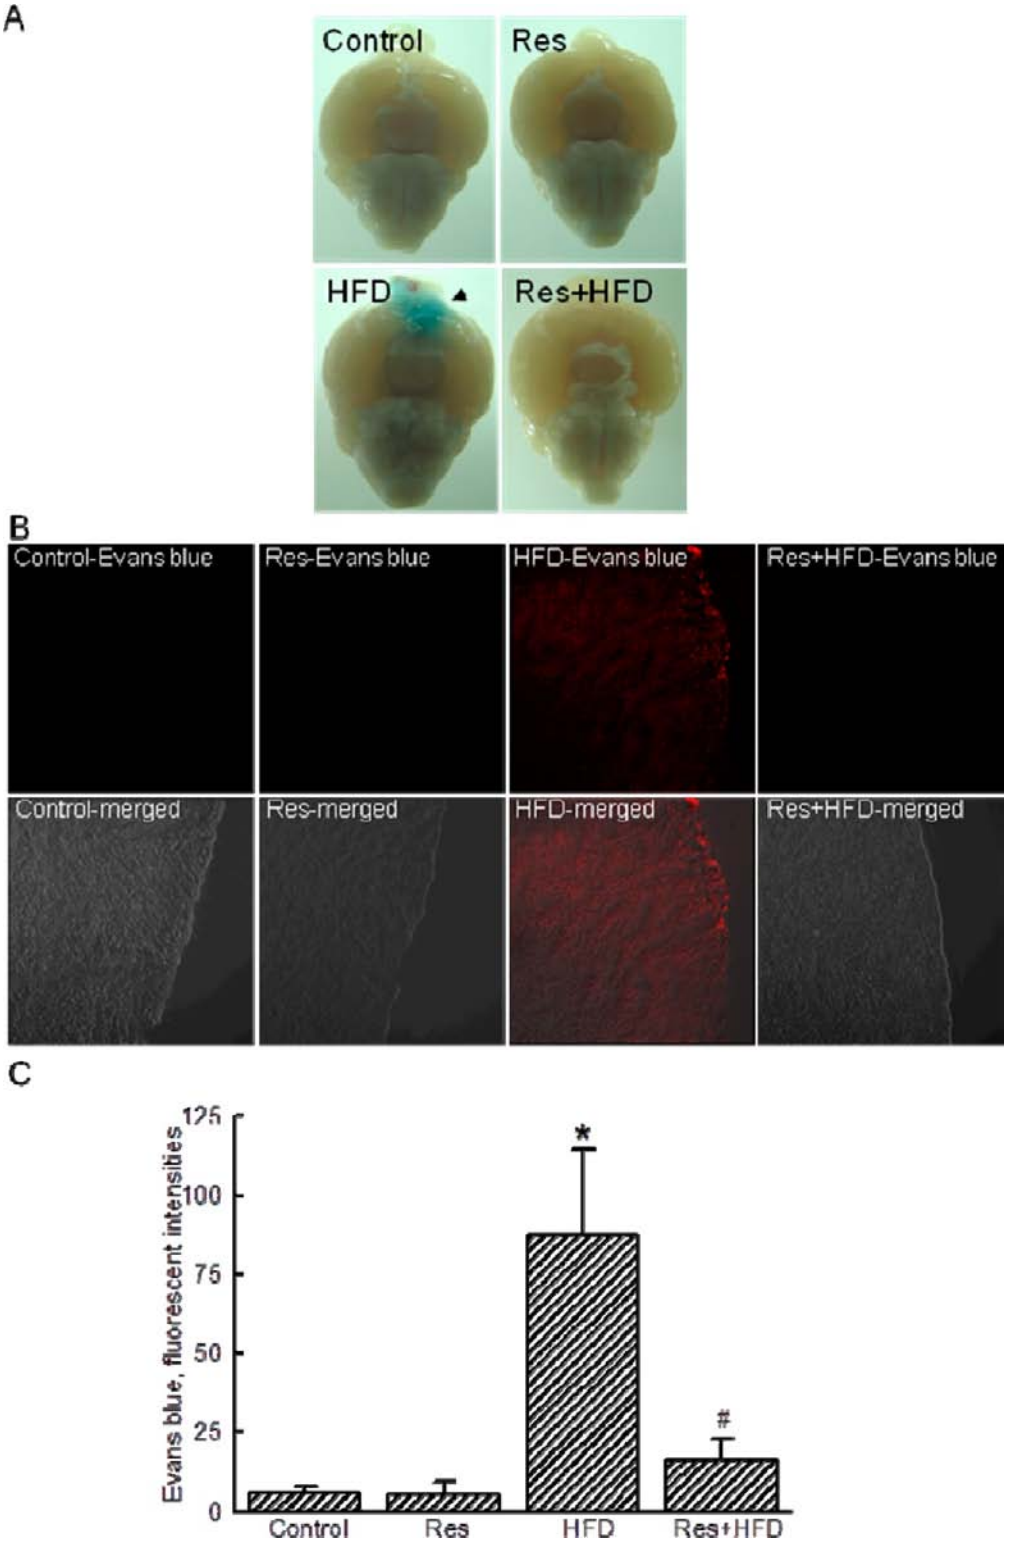

Figure 2. Effects of resveratrol (Res) on high-fat diet (HFD)-induced extravasation of Evans blue dye through the blood-brain barrier. Mice were fed the normal diet, Res, HFD, and a combination of Res and HFD for 8 weeks. After drug treatment, Evans blue dye was intravenously injected into animals and allowed to circulate for 1 h. Following reperfusion to wash out the dye in the vessels, mice were sacrificed and the brains were collected and photographed (A). Evans blue dye in brain slices was analyzed using confocal microscopy (B). Intensities of the fluorescent signals were quantified and statistically analyzed (C). Each value represents the mean ± SEM for $n = 6$. The asterisk and number symbols, * and #, indicate that values significantly ($p < 0.05$) differed from the respective control and HFD-treated groups. Magnification of confocal images: 600×.

decreasing total cholesterol levels.[28] LDL and its oxidized derivative, oxLDL, can induce pathophysiological conditions in various tissues and cells.[29] Reductions in the levels of total cholesterol and LDL can partially explain the potential of resveratrol to improve the health and survival of animals on a high-calorie diet.

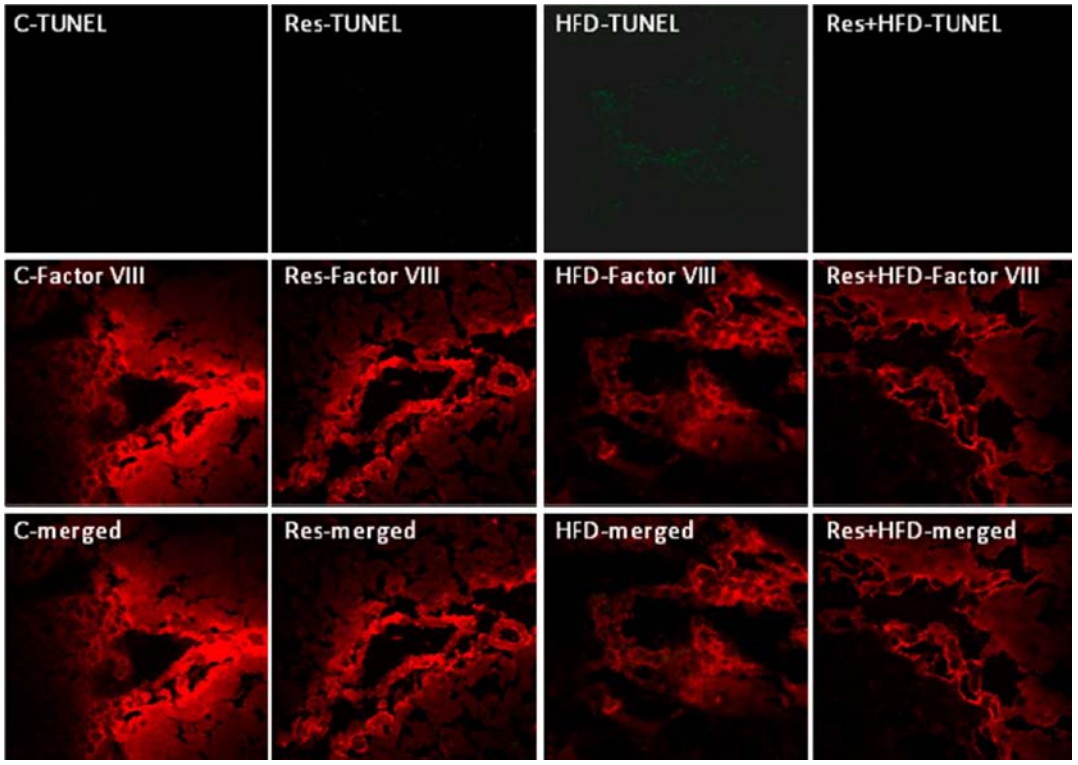

Figure 3. Effects of resveratrol (Res) and a high-fat diet (HFD) on distribution of cerebrovascular endothelial cells. Mice were fed the normal diet (C), Res, HFD, and a combination of Res and HFD for 8 weeks. After drug treatment, the brain tissues were frozen and sliced. TUNEL assays were performed and analyzed by confocal microscopy (top panels). Levels of factor VIII, an endothelium-specific protein, were immunodetected and analyzed by confocal microscopy (middle panels). The merged signals are also presented (bottom panels). Magnification of confocal images: 600×.

Many epidemiologic studies showed that elevated total cholesterol and LDL are possible risk factors for ischemic stroke.[30] In a hamster model, red wine, dealcoholized red wine, and especially grape juice inhibited atherosclerosis.[31] A previous study also reported that treatment with red wine can protect against oxidative stress and enhanced antioxidant enzyme activities in the brain and kidneys of rats fed a hyperlipidemic diet.[32] This study showed that mice fed a high-fat diet for 8 weeks exhibited hypercholesterolemia and increased circulating LDL levels, but oral intake of resveratrol simultaneously improved such elevation. High-fat diet-induced hypercholesterolemia is associated with endothelial dysfunction in cerebral arterioles which subsequently promotes the development of atherosclerosis and pathological changes in the CNS.[7,8] Therefore, resveratrol may lessen high-fat diet-induced cerebral diseases such as ischemic stroke.

The BBB is a complex structure acting essentially as a selective barrier for maintaining the cerebral microenvironment, and the main components responsible for the barrier properties are the tight junctions.[9,10] Disruption of tight junctions by drugs or disease is a destructive change that leads to impaired integrity of the BBB, thus compromising brain functions.[10,11] Ghribi et al. reported that hypercholesterolemia compromises the BBB in rabbits fed a cholesterol-enriched diet for 7 months.[33] Our present study further showed that exposure of ICR mice to a high-fat diet for 8 weeks induced hypercholesterolemia and simultaneously increased the extravasation of Evans blue dye. The appearance of Evans blue dye in brain tissues after intravenous perfusion and reperfusion indicates breakage of the BBB.[34] Our data suggest that a high-fat diet might contribute to the pathogenesis of brain-related diseases such as ischemia or Alzheimer's disease by virtue of its ability to disrupt the BBB integrity. However, resveratrol administration can alleviate the high-fat diet-caused damage to the BBB and brain neurons.

Table 2. Quantification of the Fluorescent Intensities Presented in Figure 4A, B[a]

	occludin (fluorescent intensity)	ZO-1 (fluorescent intensity)
control	398 ± 11	323 ± 14
Res	428 ± 163	313 ± 40
HFD	207 ± 10*	179 ± 20*
Res+HFD	303 ± 101	283 ± 28#

[a]Male ICR mice were treated with resveratrol (Res), a high-fat diet (HFD), and a combination of Res and the HFD for 8 weeks. Tight junction proteins were immunodetected and analyzed by confocal microscopy. Intensities of immunoreacted fluorescent signals were quantified and analyzed. Each value represents the mean ± SEM for $n = 6$. The asterisk and number symbols, * and #, indicate that the values significantly ($p < 0.05$) differ from the respective control and HFD-treated groups.

Cerebrovascular endothelial cells are major components of the BBB.[9] Our previous study demonstrated that oxLDL induces apoptotic insults to cerebrovascular endothelial cells,[12] and such insults are attenuated by resveratrol (data not shown). The data presented in this study further reveal that resveratrol can lower high-fat diet-augmented LDL levels. LDL is easily oxidized into oxLDL at the moieties of apolipoprotein B and lipids.[29] Thus, resveratrol may decrease high-fat diet-induced apoptotic insults to cerebrovascular endothelial cells and then protect against BBB damage. In addition, astrocytes and pericytes are two cell components of the BBB.[9] Our preliminary results showed that oxLDL could induce apoptosis of astrocytes.

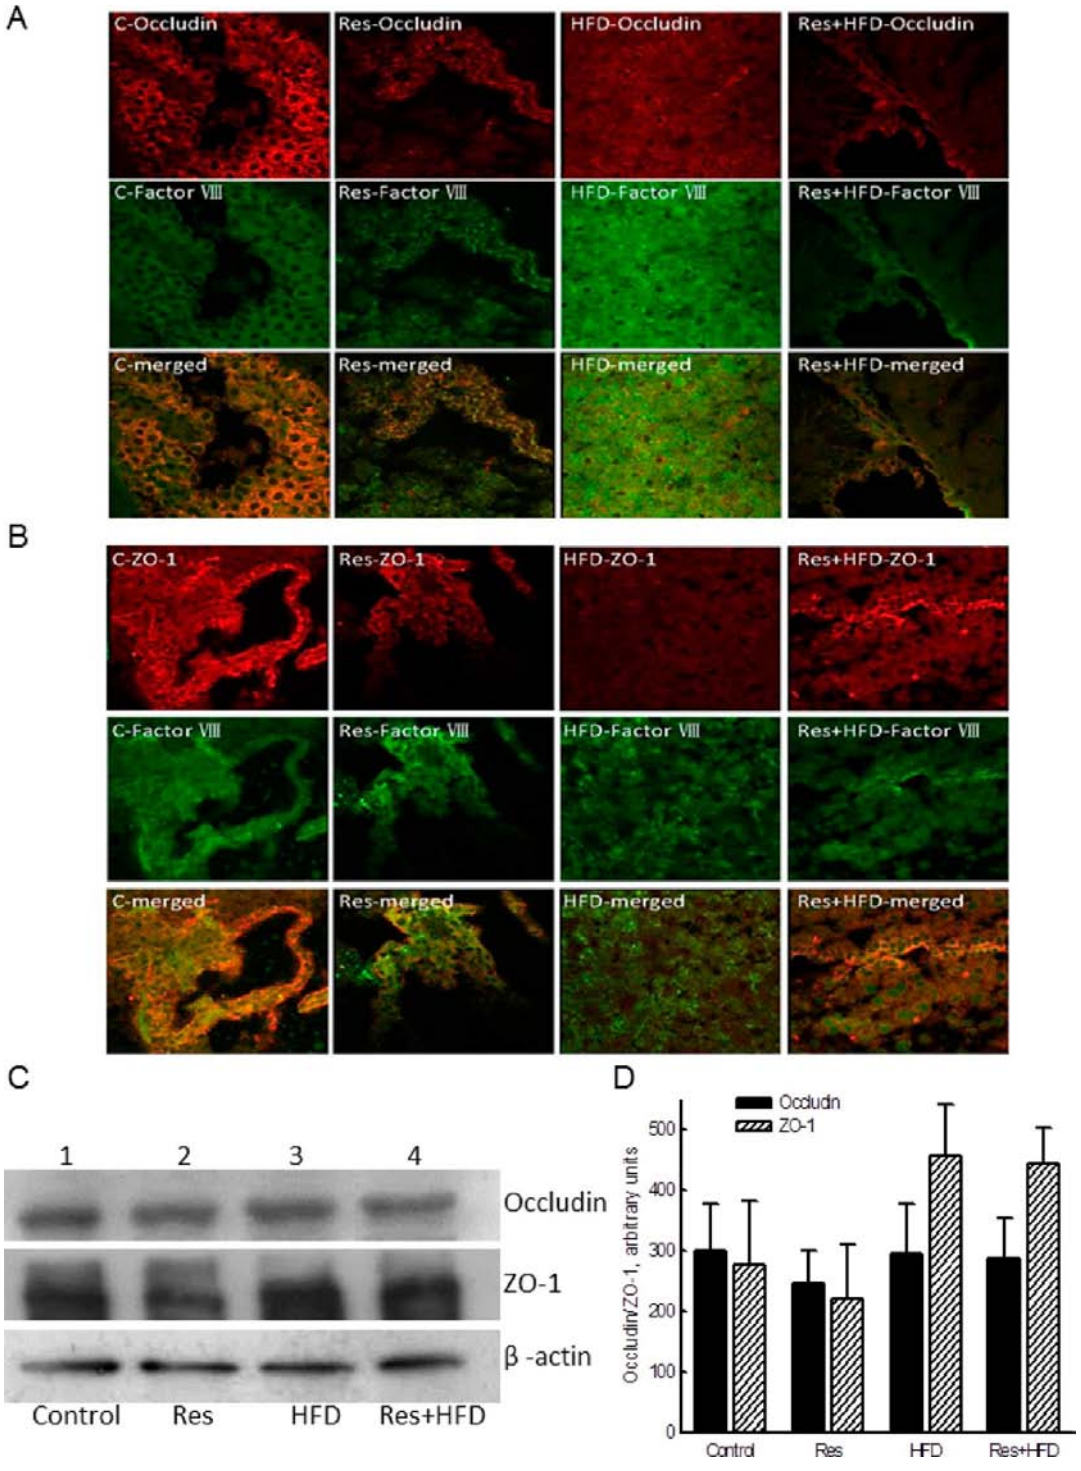

Figure 4. Effects of resveratrol (Res) on high-fat diet (HFD)-induced disruption of occludin and ZO-1 tight junctions and their protein levels. Mice were fed the normal diet, Res, HFD, and a combination of Res and HFD for 8 weeks. After drug treatment, the brain tissues were frozen and sliced. Occludin- and ZO-1-formed tight junctions were immunodetected and analyzed by confocal microscopy (A, B). Intensities of the fluorescent signals were quantified and statistically analyzed, and are presented in Table 2. Total proteins from animals were prepared for immunodetection of occludin and ZO-1 (C, top two panels). Levels of β-actin were detected as the internal standard (bottom panel). These protein bands were quantified and analyzed (D). Each value represents the mean ± SEM for $n = 6$. C, control. Magnification of confocal images: 600×.

Nevertheless, treatment of astrocytes with resveratrol lowered oxLDL-induced damage. A previous study reported that exposure of diabetic rats to a high-fat diet decreased number of retinal pericytes.[35] Interestingly, Kim et al. demonstrated the protective effects of resveratrol against diabetes-induced pericyte loss in mouse retinas.[36] Hence, astrocytes and pericytes may also contribute to resveratrol-involved protection of the BBB against high-fat diet-induced injuries. However, studies about interaction of resveratrol with cerebrovascular pericytes are limited. In our lab, the effects of resveratrol and high-fat diet on astrocytes and pericytes will be further examined.

dx.doi.org/10.1021/jf403286w | J. Agric. Food Chem. 2014, 62, 3466−3475

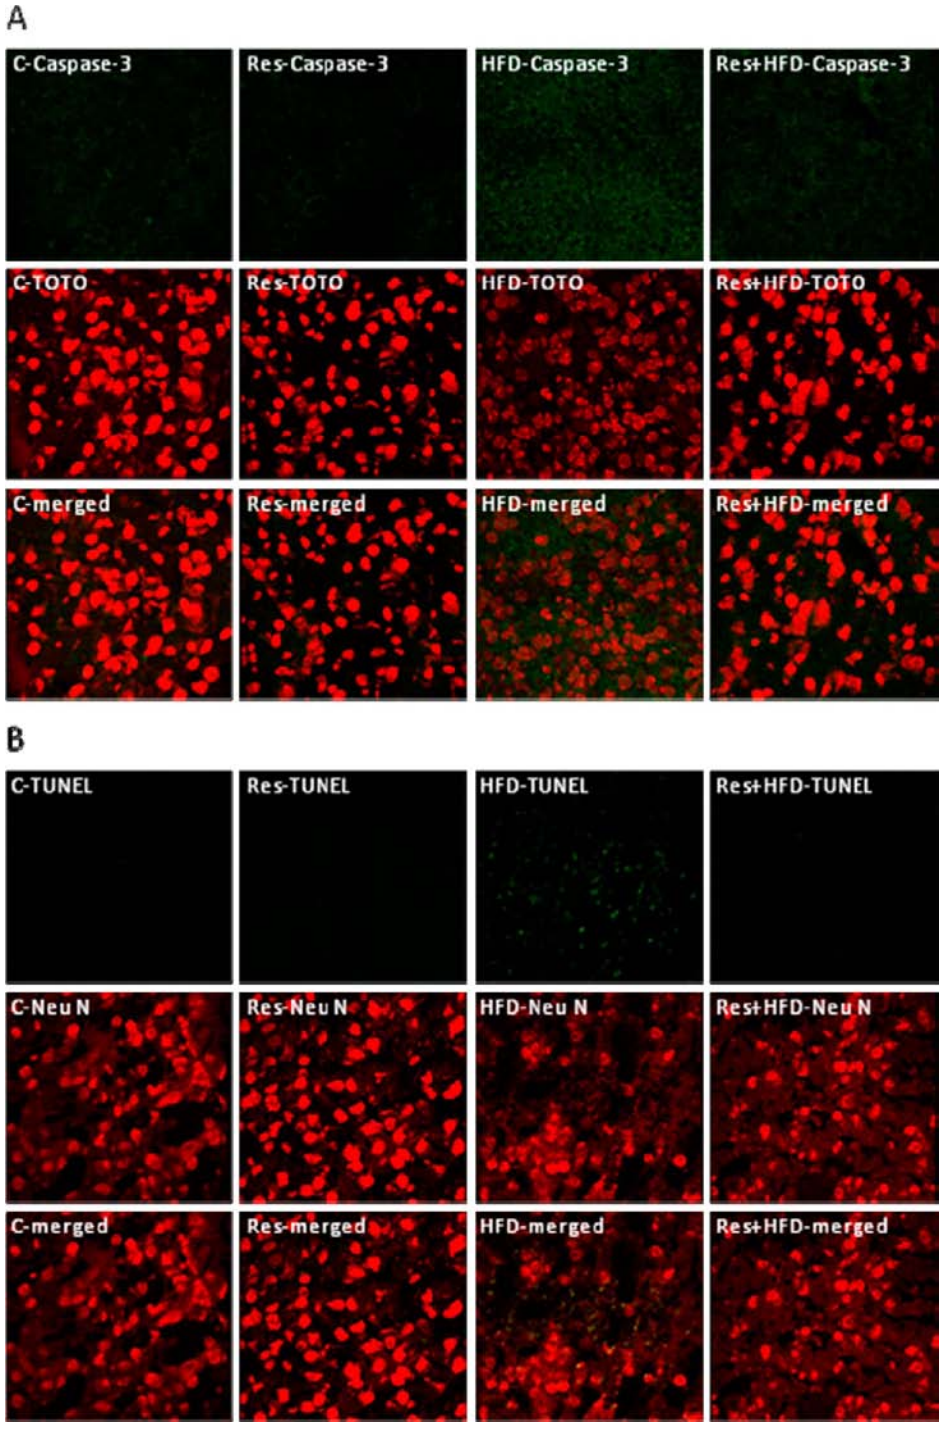

Figure 5. Effects of resveratrol (Res) on high-fat diet (HFD)-induced damage to brain neurons. Mice were fed the normal diet, Res, HFD, and a combination of Res and HFD for 8 weeks. After drug treatment, the brain tissues were frozen and sliced. Levels of activated caspase-3 were immunodetected and analyzed by confocal microscopy (A). TUNEL assays were executed and analyzed by confocal microscopy (B). Brain neurons are specifically recognized by NeuN. Magnification of confocal images: 600×.

Occludin and ZO-1 are two typical tight junction proteins which comprise the BBB.[9,21] Our results reveal that resveratrol could ease the high-fat diet-caused interruption of occludin and ZO-1 tight junctions. However, immunoblotting analyses showed no effect of resveratrol and a high-fat diet on the contents of occludin and ZO-1 in mouse brains. Cytoskeleton and cellular adenosine triphosphate (ATP) have been reported to participate in construction of the tight junction barrier.[37,38] Our previous study showed that oxLDL induced disruption of cytoskeleton polymerization and ATP synthesis in cerebrovascular endothelial cells, but treatment with resveratrol lessened such injuries.[21] As a result, one possible reason that resveratrol could ameliorate high-fat diet-induced disturbance of occludin and ZO-1 tight junctions may occur through promoting cytoskeleton construction and energy production. Taken together, resveratrol possibly protects the BBB against high-fat diet-induced breakage through suppression of damage to cerebrovascular endothelial cells and polymerization of occludin and ZO-1.

dx.doi.org/10.1021/jf403286w | J. Agric. Food Chem. 2014, 62, 3466−3475

Latour et al. reported that early BBB breakdown precedes neuronal damage in human focal brain ischemia.[39] After exposure to resveratrol for 8 weeks, the high-fat diet-caused caspase-3 activation and DNA fragmentation simultaneously decreased. Caspase-3 activation and DNA fragmentation are two important characteristics of cells undergoing apoptosis.[12,22] Thus, resveratrol protects brain neurons against high-fat diet-induced neuronal damage via an antiapoptotic mechanism. Studzinski et al. showed that consumption of a Western diet for 4 weeks significantly elevated cerebral oxidative stress and induced brain damage.[40] Resveratrol has efficient antioxidant activity to scavenge lipid hydroperoxyl free radicals.[18,21] Such antioxidant properties, at least in part, protect neuronal cells from high-fat diet-induced damage. Dysfunction of the BBB is recognized as a critical cause of brain neuron injuries.[22,24] Therefore, resveratrol can defend against high-fat diet-induced injuries of brain neurons through lessening the breakage of the BBB.

In conclusion, this study showed that a high-fat diet increased the body weight and serum levels of total cholesterol and LDL, but resveratrol significantly decreased such augmentations. The high-fat diet-induced interruption of the BBB integrity decreased after resveratrol administration. Resveratrol attenuated high-fat diet-caused breakage of the BBB through improving polymerization of occludin and ZO-1. Consequently, the high-fat diet-induced caspase-3 activation and DNA fragmentation were alleviated by resveratrol. Therefore, we suggest that long-term administration of resveratrol can protect against high-fat diet-caused disruption of the BBB through activating polymerization of occludin and ZO-1, and attenuates apoptotic injuries to brain neurons by dietary fat.

and elucidate the processes involved. Recent studies by Upreti et al. have characterized some of the photoinduced degradation products of monatin,[27] but more rigorous investigation of the mechanisms is required to fully understand the degradation pathways of monatin and the conditions under which this occurs. We postulated that monatin may undergo photodegradation pathways similar to those recently elucidated for the structurally related amino acid tryptophan and its derivatives.[29−31] We report here on studies carried out to examine the mechanisms of monatin degradation and the factors that influence these processes.

MATERIALS AND METHODS

(2*R*,4*R*)-Monatin salt (Na) was supplied by Cargill Ltd. (Wayzata, MN, USA). Hydrogen peroxide, 30% solution, iron(II) sulfate heptahydrate were supplied by Merck (Darmstadt, Germany). Catalase (bovine liver), citric acid, deuterium oxide (97%), xylenol orange tetrasodium salt, Rose Bengal, trisodium citrate dehydrate were supplied by Sigma-Aldrich (Castle Hill, NSW, Australia). All water (H_2O) was filtered to Nanopure quality using a four-stage Milli-Q system (Millipore, North Ryde, Australia)). Sulfuric acid, 95−98% (~18 M), was from Ajax Finechem (Sydney, NSW, Australia). Syringe filters (0.45 μm, 33 mm diameter) were from Sartorius (Dandenong South, VIC, Australia). Disposable plastic cuvettes (0.5−2.0 mL, 1 cm path length) were from Interpath (West Heidelberg, VIC, Australia).

Composition of Mock Beverage Solutions. Standard beverage solutions consisted of monatin (0.005%, 170 μM), sodium benzoate (0.015%, 1 mM), citric acid (0.16%, 8.3 mM), and trisodium citrate (0.02%, 680 μM) in Nanopure water or deuterium oxide (D_2O) with the pH/pD adjusted to 3.0. Variations are discussed as appropriate in the text.

Photooxidation Apparatus. Beverage samples were illuminated using a light box (Medlite, Sydney, Australia) fitted with a circular 32 W daylight fluorescence tube (FCL32D; 1890 lm; NEC, Tokyo, Japan) and opaque diffuser. The samples were placed a fixed distance from the illumination source to receive a standardized light exposure of 7.5 W m^{-2} (equivalent to 3000 Lux; for lamp profile see Supporting Information Figure 1A). Light doses were calibrated using a Stellarnet spectrometer (Comet-SL-3C-50, Warsash Scientific, Redfern, NSW, Australia).

Oxidation of Monatin with Singlet Oxygen. Singlet oxygen-mediated photooxidation of monatin beverage solutions was achieved using a modification of a previous method.[32,33] Briefly, Rose Bengal (10 μM) was added to the standard monatin beverage solutions (as above). The samples were kept at 21 °C and bubbled with compressed air during illumination for up to 15 min with visible light (820 W m^{-2} equivalent to 250 000 Lux; for lamp profile see Supporting Information Figure 1B) from an AV2050 slide projector (Kodak, Box Hill, VIC, Australia).

Columns and Mobile Phases Used for Liquid Chromatography. Chromatographic separations were carried out on an Acquity HSS T3 UHPLC column (2.1 × 100 mm; 1.8 μm pore size; Waters, Rydalmere, NSW, Australia) using gradients (as specified below) of solvent A (10 mM ammonium formate, with 0.1% formic acid in water) and solvent B (10% acetonitrile in methanol).

Quantification of Monatin Oxidation Products by UHPLC with UV or Accurate Mass QTOF Detection. UHPLC of monatin and its reaction products was carried out with a column temperature of 45 °C and a mobile phase (0.6 mL min^{-1}) consisting of a gradient (see above for buffer compositions) as follows: 5% solvent B and 95% solvent A for 1.5 min with a linear increase to 12% solvent B over the next 2 min and a further increase to 35% solvent B over the next 5.5 min. The column was then washed by increasing to 95% solvent B over 2 min, holding at 95% B for 1 min, before decreasing to 5% B over 0.1 min, with 1.9 min reequilibration prior to the next injection. Samples were filtered with centrifugal filters (MF 0.2 μm; Pall Nanosep, Somersby, NSW, Australia) to remove particulate matter prior to analysis and placed in glass HPLC vials. Quantification of monatin and its products was carried out (at 280 nm) using a Shimadzu Nexera UHPLC system (Shimadzu, South Rydalmere, NSW, Australia) following 2 μL injections. Monatin eluted at 5.07 min, and the corresponding monatin lactone (lactone) at 4.33 min. Peak areas were determined using Lab Solutions 5.32 SP1 (Shimadzu).

Accurate mass and MS/MS analyses of monatin products (20 μL sample injections) were carried out using an Agilent 1290 UHPLC system (Agilent Technologies, Santa Clara, CA, USA) coupled to an Agilent 6530 QTOF instrument (Agilent Technologies) operating in both positive and negative ionization modes with an Agilent Jet Stream electrospray source. The QTOF spectrometer was operated under the following conditions: source gas temperature of 350 °C, drying gas flow of 10 L/min, nebulizer gas pressure of 20 psig, sheath gas temperature of 385 °C, sheath gas flow of 12 L/min, VCap of 3000 V, and a fragmentor voltage of 125 V. Ultrahigh purity nitrogen was used as the collision gas for MS/MS experiments.

Analysis of Monatin Oxidation Products by LC−MS/MS. A Thermo LCQ Deca XP MAX Plus (Thermo Fisher, North Ryde, NSW, Australia) ion-trap instrument coupled to a Finnigan Surveyor HPLC (Thermo Fisher) system was used with electrospray ionization in positive ion mode. Samples were held at 10 °C prior to injection (20 μL), before separation at 40 °C at a flow rate of 100 μL min^{-1}. Compounds were eluted using the following gradient: 100% solvent A for 10 min, then a linear increase to 40% B over 20 min, followed by a rapid increase to 100% B over 5 min, a 5 min wash with 100% B, before returning to 100% A over 2 min and reequilibration with solvent A for 18 min, to give a total run time of 70 min. The electrospray needle was held at 4.5 kV. Helium was used as the collision gas, and nitrogen was used as the sheath and sweep gas set to 70 and 30 arbitrary units, respectively. The temperature of the heated capillary was 250 °C. Selective ion monitoring (SIM) detection was carried out with an isolation width of ±1 mass unit from the specified m/z values as required, with collision energies of 28 or 35%.

Quantification of Peroxides by the FOX Assay. Peroxides were quantified using a modified FOX assay, with data reported as H_2O_2 equivalents as the reaction stoichiometry for monatin-derived peroxides with the FOX reagent is unknown.[34] The FOX reagent was prepared from xylenol orange (3,3-bis[*N*,*N*-bis(carboxylmethyl)amino-methyl]-*o*-cresolsulfonephthalein, Na^+ salt), sulfuric acid, and iron(II) sulfate (5 mM, 0.5 M, and 5 mM, respectively). Organic peroxide levels were determined after treatment (15 min) of samples with catalase (50 μL of a 1 mg mL^{-1} solution) to remove H_2O_2 before addition of the FOX reagent. Previous studies have verified that organic peroxides are not affected by catalase.[33,35]

Sample Concentration for UHPLC and LC−MS/MS Analysis. Photolyzed monatin standard beverage samples were concentrated as necessary using the following procedure. Ten milliliters of solution was treated overnight with washed Chelex 100 resin (BioRad, Gladesville, NSW, Australia) to remove trace metal ions. The supernatant was removed, and 1 mL aliquots were dried by vacuum centrifugation (18 h). Dried samples were reconstituted in 100 μL of Nanopure water (giving a 10-fold concentration of the sample) before filtering using 0.2 μm centrifugal filters. Samples were kept at <10 °C prior to analysis.

Statistical Analyses. Data are reported as mean ± standard error of the mean (SEM) from three or more independent experiments. Statistical analyses were performed using GraphPad Prism 5 (GraphPad Software, San Diego, CA; http://www.graphpad.com) using two-way ANOVA with Bonferroni's post hoc test. Significance was taken as $p < 0.05$.

RESULTS

Time Course and Treatment Studies. *Monatin Degradation in the Presence of Light.* Because previous studies have provided evidence of monatin degradation on exposure to UV/visible light,[25,27] initial experiments quantified monatin photodegradation under a variety of conditions. Mock beverage solutions of monatin [0.005% (170 μM); pH 3 in citrate buffer; see Materials and Methods] were illuminated by fluorescent light (7.5 W m^{-2}) in colorless, transparent PET bottles using a light

box. Samples were removed at regular time points, stored at −20 °C, and analyzed by UHPLC (see Supporting Information Figure 2 for example traces). The parent monatin peak decreased in intensity with increasing photolysis time (Figure 1A), with ∼27% loss observed after 14 days and ∼76% by 50 days.

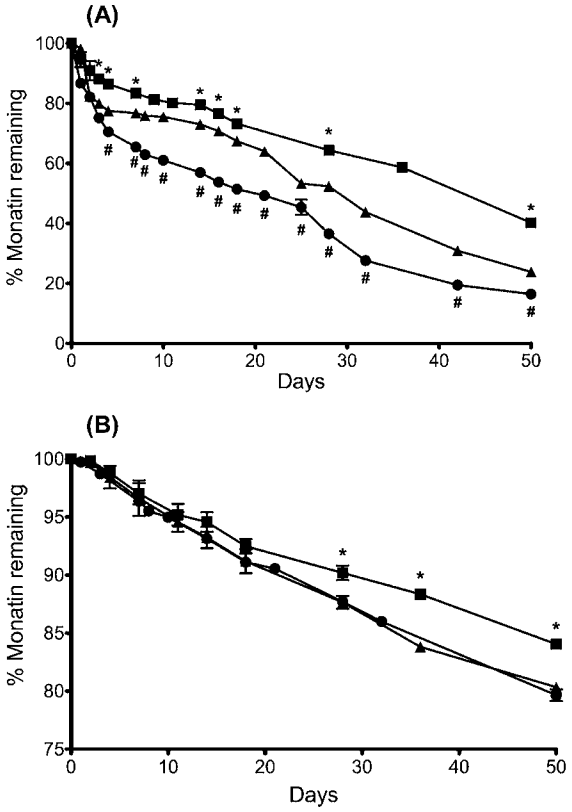

Figure 1. Monatin loss over time: (A) following illumination with a fluorescent light source (7.5 W m^{-2}) and (B) following incubation in the dark (note difference in vertical axis scale between A and B). The mock beverage samples (170 μM monatin) were prepared in H_2O control (▲), D_2O (●) or Chelex-treated (■) citrate buffers (pH 3). Values are shown as mean ± SEM (N = 3 replicates). # Statistically significant from control (P < 0.05). * Chelex treatment significantly different from D_2O and control (P < 0.05).

To investigate whether $^1O_2$ plays a role in monatin photodegradation, beverage solutions were prepared with D_2O in place of H_2O, as the decay rate of $^1O_2$ is slowed in D_2O,[36,37] thereby promoting $^1O_2$-mediated processes. Photolysis of monatin solutions in D_2O enhanced monatin loss, with ∼43% of the parent lost after 14 days, and ∼84% by 50 days (Figure 1A).

The involvement of metal ions (via possible interaction with dissolved O_2 or peroxides; see eqs 1−4[38]) was probed by treating either the citrate buffer prior to preparation of the monatin solutions, or the monatin solutions once generated, with Chelex 100 resin to remove adventitious metal ions. Photolysis of these Chelex-treated samples resulted in significantly less parent monatin loss compared with those prepared in untreated buffer. The data obtained with both Chelex treatments were identical, with ∼20% monatin lost after 14 days, and ∼60% after 50 days (Figure 1A; data for Chelex-treated preformed monatin solutions not shown).

$$[\text{monatin}] + Fe^{3+} \rightarrow Fe^{2+} + [\text{monatin}]^{+\bullet} \quad (1)$$

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^{-\bullet} \quad (2)$$

$$2O_2^{-\bullet} \rightarrow O_2 + H_2O_2 \quad (3)$$

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + HO^- + HO^{\bullet} \quad (4)$$

Degradation of Monatin in the Absence of Light. Identical mock beverage solutions to those described above were kept in the dark for 50 days. Monatin degradation was much slower in the absence of light than in its presence, with samples prepared in control (H_2O) or D_2O buffers losing ∼7% of parent monatin after 14 days (and ∼20% after 50 days), whereas in Chelex-treated samples, ∼6% and ∼16% of monatin was lost after 14 and 50 days, respectively (Figure 1B).

Effect of Chelating Agents and Added Transition Metal Ions. The protective effect of Chelex pretreatment is consistent with a role for metal ions in monatin degradation, irrespective of the presence of light. Thus, experiments were repeated with either added metal ion chelators or added metal ions to identify species that might be involved. EDTA (a nonspecific metal chelator, 50 μM) or desferrioxamine (a specific iron chelator, 50 μM) was added to standard mixtures and illuminated for 14 days. Controls were prepared with untreated or Chelex-treated citrate buffer (control). After 14 days, the control samples had lost ∼31% monatin, compared with ∼24%, ∼21%, and ∼20% for the samples prepared with EDTA, desferrioxamine, and Chelex-treated buffer, respectively (Figure 2A). The similar levels of monatin loss observed with each of these treatments are consistent with trace metal ions, particularly iron ions, playing a role in monatin degradation.

For experiments with added metal ions, Fe_2SO_4 (100 nM or 50 μM) or $CuCl_2$ (50 μM) were added to Chelex-treated mock beverage solutions. The samples were illuminated (or kept in the dark) for 14 days together with control samples without any metal ion additions. After 14 days, Chelex-treated samples had lost ∼20% monatin, whereas with Fe_2SO_4, a greater loss that was dose-dependent (∼28% with 100 nM and ∼89% with 50 μM Fe_2SO_4; Figure 2B) was observed. Samples supplemented with $CuCl_2$ (50 μM) lost only ∼14% of monatin, less than that observed in the controls. The loss of monatin in nonilluminated samples was much less than in the photodegraded samples, but the pattern of monatin loss followed that in the illuminated samples [8% (control), 6% ($CuCl_2$), 9% (100 nM Fe_2SO_4), and 16% (50 μM Fe_2SO_4)].

Characterization of Intermediates. In addition to monatin loss during light exposure, UHPLC analysis demonstrated growth of a peak at 4.33 min. This peak reached maximal intensity after a few days before declining at longer times. This peak is assigned to monatin lactone [**3**], which is in equilibrium with parent monatin (Scheme 2).[10,23,24] The extent of lactonization versus oxidation was assessed by comparing peak areas. The rapid loss of monatin during the initial photolysis period (Figure 2) was mirrored by an increase in lactone. From comparison of the peak areas, it is estimated that ∼60% of the initial monatin loss (corresponding to ∼15% of the total monatin present) arises from lactone formation. From here on, "total indole" is used to refer to the total of monatin and lactone (calculated assuming an identical extinction coefficient for both compounds; data not shown).

Photooxidation of Trp [**2**] gives Trp peroxides as major initial products; these undergo photodegradation on extended illumination.[29] Thus, the ferrous xylenol orange (FOX) assay [34] was used to measure the formation of H_2O_2 or monatin

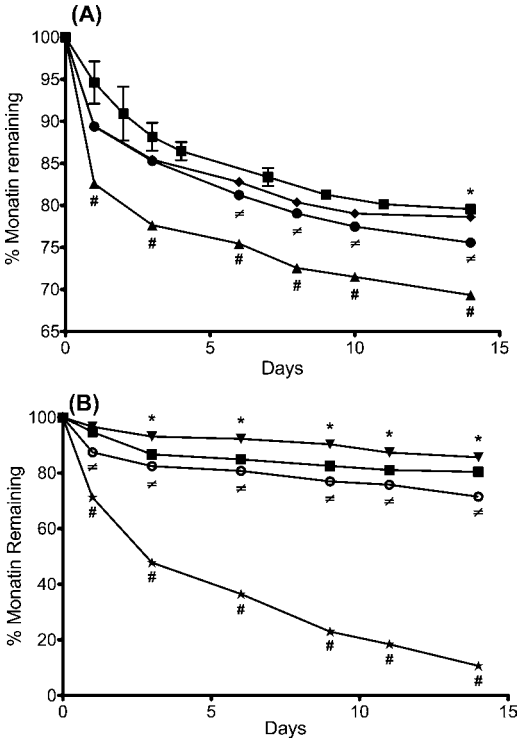

Figure 2. The effect of metal ion chelators on monatin loss in illuminated mock beverage solutions (7.5 W m^{-2}). (A) Mock beverage solutions were treated with different metal chelators (untreated buffer control (▲), desferrioxamine (50 μM; ♦), EDTA (50 μM; ●), and Chelex-treated buffer (■). # Statistically significant to control (P < 0.05). * Chelex and desferrioxamine treatments significantly different from EDTA and control (P < 0.05). ≠ EDTA treatment significantly different from other treatments (B) Mock beverage samples prepared with Chelex-treated buffer (■) were spiked with $CuCl_2$ (50 μM;▼), Fe_2SO_4 [100 nM (○), or 50 μM (★)]. # Treatments statistically significant to spiked Fe_2SO_4 [50 μM] (P < 0.05). ≠ Samples with added Fe_2SO_4 [100 nM] significantly different from other treatments. * Samples with added $CuCl_2$ [50 μM] significantly different from all other treatments (P < 0.05). All values are shown as mean ± SEM (N = 3 replicates). Note the difference in the y-axis scale between A and B.

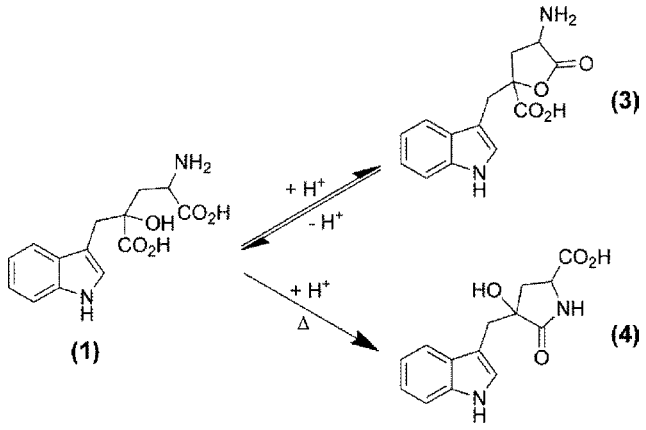
Scheme 2. Intramolecular Rearrangement Reactions of Monatin [1] To Form the Monatin Lactone [3] and Lactam [4]



peroxides in light-exposed standard beverage solutions of monatin prepared with H_2O-, D_2O-, or Chelex-treated citrate buffers. Pretreatment of the samples with catalase prior to the assay allowed the proportion of H_2O_2 versus monatin-derived peroxides to be assessed (as catalase does not remove organic peroxides[33,35]).

An increase in total peroxide levels over ~30 days of illumination was observed in all cases, after which peroxide levels started to decrease (Figure 3). Catalase pretreatment

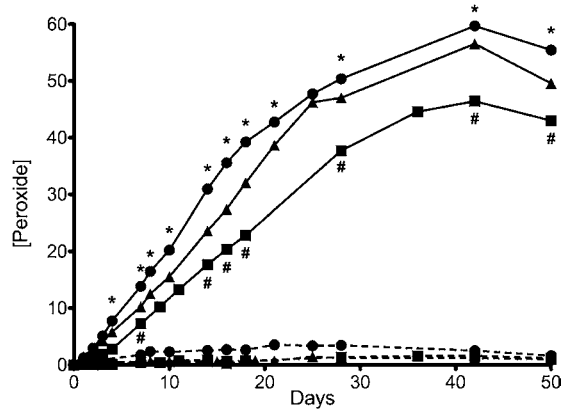


Figure 3. Concentration (μM) of all peroxides (solid lines) or organic peroxides (dashed lines) generated following illumination (7.5 W m^{-2}) of monatin beverage solutions prepared with H_2O control (▲), D_2O (●), or Chelex-treated (■) buffers. Values are shown as mean ± SEM (N = 3 replicates). # Statistically significant to Chelex-treated buffers (P < 0.05). * D_2O significantly different from H_2O control and Chelex-treated (P < 0.05). Organic peroxide concentrations were statistically different when compared with the total peroxide concentrations at all illumination times (P < 0.05).

showed that the majority of the detected peroxide(s) was H_2O_2 (>40 μM), with lower, but significant, levels (≤4 μM) of monatin peroxides. The peroxide levels achieved in D_2O buffer were higher (up to 60 μM) than in samples made up using H_2O or Chelex-treated buffer (57 and 46 μM, respectively) after 42 days of illumination (Figure 3). The corresponding peroxide levels in samples kept in the dark were significantly lower (<5 μM total and <1 μM monatin peroxides), indicating that photochemical processes account for much of their production. In the absence of light, the proportion of organic peroxides generated (~20%) was much higher, and Chelex treatment of the buffer had a much smaller, but still significant, protective effect (data not shown).

Peroxide concentrations in metal ion spiked solutions of monatin (see above) were also assessed. Illuminated samples containing Fe_2SO_4 (50 μM) exhibited a significant increase in peroxide levels (total, 12 μM; organic, 8 μM) after 1 day of incubation, but no further increase at longer time points. In contrast, nonspiked samples showed a linear increase over 14 days that reached 11 μM total peroxides and <1 μM organic peroxide. Samples spiked with 50 μM $CuCl_2$ generated lower levels of peroxides (3 μM total, 1 μM organic). In the absence of light, the corresponding Chelex-treated and $CuCl_2$-spiked samples accumulated <2 μM total peroxides over 14 days, whereas in the 50 μM Fe_2SO_4-spiked samples, significant accumulation of predominantly organic peroxides (9 μM) occurred. The effect of EDTA and desferroxamine on peroxide formation could not be assessed because these compounds interfere with the FOX assay.

Peroxide Formation in Monatin Solutions Exposed to a Singlet Oxygen-Generating System. The experiments with D_2O buffers suggest a role for $^1O_2$ in monatin photodegradation, consistent with the peroxide formation observed on Trp [2]

dx.doi.org/10.1021/jf404198w | J. Agric. Food Chem. 2014, 62, 3476−3487

exposed to $^1O_2$.[29] The role of $^1O_2$ in monatin-derived peroxide formation was examined by adding Rose Bengal (RB; 10 μM) to mock beverage samples of monatin prepared in H_2O or D_2O citrate buffer (pH 3) and subsequently exposing these materials to light. The samples (together with controls without RB) were bubbled with air and photolyzed with a slide projector (820 W m^{-2}). The peroxide levels in the samples containing RB increased significantly over 15 min of photolysis (Figure 4A), with >70% of the peroxides attributed to organic (presumed to be monatin-derived) species. In the absence of RB, insignificant levels of peroxide were detected. In identical experiments in D_2O citrate buffer, elevated peroxide levels were detected (Figure 4A), consistent with $^1O_2$ being the primary oxidant in this system.

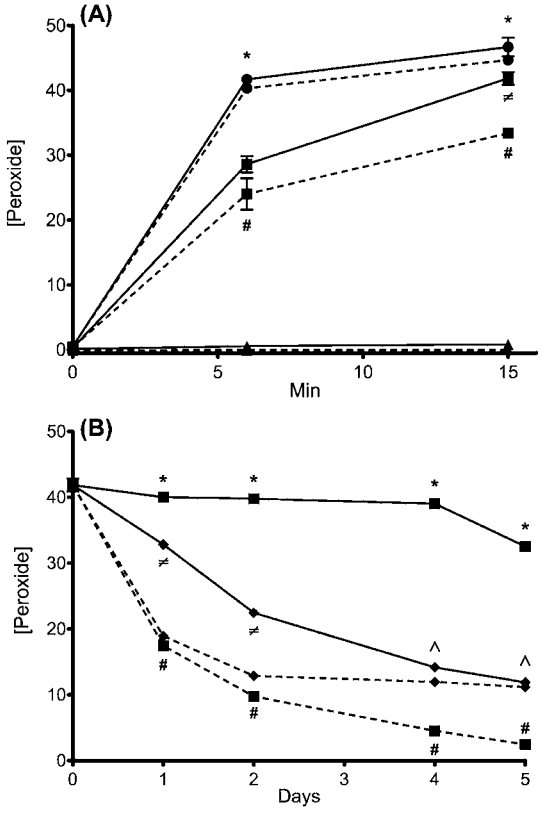

Figure 4. (A) Concentration (μM) of total peroxide (solid lines) or organic peroxide (dashed lines) formed in Rose Bengal photosensitized beverage solutions of monatin on photolysis with a slide projector (820 W m^{-2}) for 15 min. Control H_2O (▲), Rose Bengal in D_2O buffers (●), Rose Bengal in H_2O buffers (■). # Statistically significant to Rose Bengal in H_2O buffer ($P < 0.05$). ≠ Total peroxides for Rose Bengal in H_2O buffers significantly different from other treatments. * Both total and organic peroxides for Rose Bengal in D_2O buffer significantly different from all other treatments ($P < 0.05$). Control samples were statistically significant throughout ($P < 0.05$). (B) Stability of organic peroxides generated by Rose Bengal/light/O_2/monatin photolysis to thermal- (■) or Fe_2SO_4 (40 μM; ♦)-stimulated decay in the dark over a period of 5 days (total peroxide, solid lines; organic peroxide, dashed lines). # Statistically significant to thermal decomposition of organic peroxides ($P < 0.05$). ≠ Total peroxide decomposition with added Fe_2SO_4 [40 μM] significantly different from other treatments.^ Levels of organic and total peroxides exposed to Fe_2SO_4 [40 μM] significantly different from other treatments. * Total peroxides in thermally exposed samples significantly different from all other treatments ($P < 0.05$). Values are shown as mean ± SEM ($N = 3$ replicates, with error bars being smaller than the symbol in some cases).

The thermal stability (in the dark) of the (monatin-derived) organic peroxides was monitored for 5 days following photolysis. Parallel experiments with Fe_2SO_4 (40 μM) added to stimulate peroxide decay were also carried out, as with Trp-derived peroxides in which concomitant radical formation occurred.[29] For the untreated (no added Fe_2SO_4) samples, the total peroxide levels remained relatively constant over 5 days (Figure 4B), but the organic peroxide levels dropped to ∼33% of the initial concentration (44 μM) (Figure 4B). Addition of Fe^{2+} promoted both total and organic peroxide decay (Figure 4B), with the rate of peroxide decay less in samples in D_2O compared with samples in H_2O (data not shown).

LC−MS Analysis of Parent Monatin and Monatin Lactone. LC−MS analysis of control, nonilluminated samples of monatin exhibited a strong peak at ∼35.8 min in the UV (280 nm) detection channel. The full mass spectrum of this peak had an intense ion with m/z 293.3, consistent with (protonated) parent monatin ([**1**]; $[monatin+H]^+$). The identity of this peak was confirmed by selective ion monitoring (SIM) of the m/z 293.3 ion (Figure 5A), with the fragmentation spectrum (Table 1) consistent with that for monatin.[27] The chromatograms of nonilluminated monatin also contained a weaker peak (∼ 3% of the monatin peak detected at 280 nm) at ∼33.5 min. This peak had m/z 275.3 and fragmented (Figure 5B, Table 1) in a manner consistent with monatin lactone [**3**] as described previously.[27]

Photolysis of monatin solutions in the presence or absence of metal ions resulted in a time-dependent loss of the monatin and lactone peaks, with numerous new peaks detected using UV detection at 280 nm. In previous studies examining photooxidation of Trp [**2**], multiple products containing one or two incorporated oxygen atoms were detected (Scheme 3, refs 29−31), and Upreti et al. have reported the incorporation of a single oxygen atom to generate a 2-hydroxyindole derivative ([**12**], Scheme 4) after short-wavelength UV photolysis.[27] The identity of these oxygenated products was examined by LC−MS/MS analysis.

LC−MS/MS Analysis of $[M + 16 + H]^+$ Monatin Photoproducts. Selective ion monitoring of m/z 309.3 (corresponding to the mass of monooxygenated monatin) revealed three new peaks whose intensities increased with photolysis time. Two of these peaks eluted at early times (∼8.1 and ∼11.2 min; Figure 5C,D) with fragmentation patterns (Figure 6A,B, Table 1) similar to those reported by Upreti et al. for 2-hydroxymonatin [**12**].[27] Interestingly, although the fragment ion masses were the same for the $[monatin + 16 + H]^+$ species at ∼8.1 and ∼11.2 min, the intensity of the fragment ion with m/z 272.9 (corresponding to loss of two H_2O, Table 1) was greater for the peak eluting at ∼11.2 min. This was also observed previously for Trp photooxidation products (Scheme 3; cis and trans isomers of [**7**]); thus, the two monooxygenated monatin-derived species detected at early elution times have been assigned to the cis and trans isomers of the 3α-hydroxypyrolloindole derivatives [**13**] of monatin that arise through cyclization of the α-amino group onto the oxidized indole ring (see Scheme 4).[29−31] In monatin, ring closure could potentially occur via a γ-carbon OH group, so experiments were carried out with indole-3-lactic acid instead of Trp [**2**] (in which a hydroxyl replaces the α-amino group). These studies indicate that ring closure via the OH group occurs less readily than with the α-amino group of Trp [**2**] (data not shown). The fragmentation spectra for the $[monatin + 16 + H]^+$ species at ∼8.1 and ∼11.2 min support predominant ring closure via the α-amino group because fragment ions consistent with the loss of H_2O (m/z 291.1) and $2H_2O$ (m/z 272.9), but not NH_3

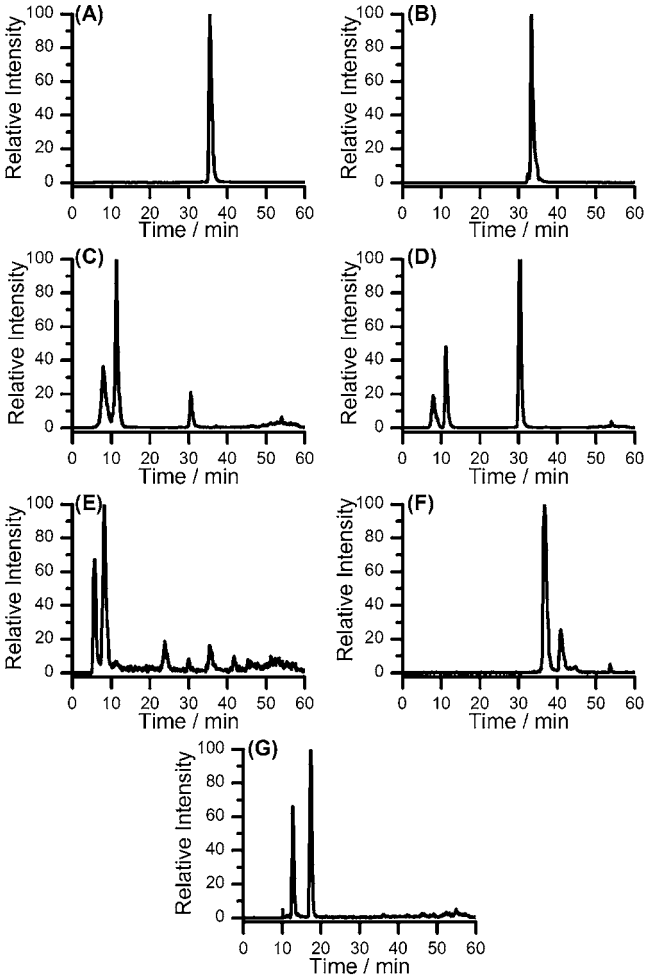

Figure 5. Selected ion chromatograms obtained from samples (concentrated 10-fold) photo-oxidized (7.5 W m^{-2}) for 14 days (unless otherwise stated) for (A) monatin (m/z 293.3 → full scan), (B) monatin lactone (m/z 275.3 → 158.1), (C) monatin alcohols (m/z 309.3 → full scan) in the absence of added Fe^{2+}, (D) monatin alcohols (m/z 309.3 → full scan) in the presence of 100 nM Fe^{2+}, (E) cyclized monatin diols (m/z 325.3 → 306.9; retention times, 5.7 and 8.1 min) in the absence of added Fe^{2+}, (F) *N*-formylkynurenine derivative of monatin (m/z 325.3 → 297.1; retention time, 36.6 min) in the presence of 100 nM Fe^{2+} and (G) cyclized monatin peroxides (m/z 325.3 → full scan; retention times, 12.7 and 17.3 min) formed by 10 μM Rose Bengal photosensitization.

(m/z 292.1) or NH_3 + H_2O (m/z 274.1), are detected, suggesting that the α-amino group is no longer free but contained in the heterocycle.

The third peak with m/z 309.3 eluted at ∼31.2 min (Figure 5C) and was more abundant when the samples were spiked with 100 nM Fe^{2+} (Figure 5, D vs C). This species yielded an intense fragment ion with m/z 291.0 (consistent with loss of H_2O), with only one other weak fragment ion (intensity <2% of the m/z 291.0 fragment; Table 1). This peak appears to correspond to the keto/enol equilibrium mixture of 2-hydroxymonatin (Scheme 4, [**12**]) reported previously,[27] although using different elution methods makes direct comparison impossible. This assignment is also consistent with a late eluting $[M + 16 + H]^+$ peak observed from photooxidized Trp, which was assigned to 3-hydroxy-Trp ([**5**], Scheme 3).[29]

LC−MS/MS Analysis of [M + 32 + H]$^+$ Monatin Photoproducts. The formation of dioxygenated monatin products was investigated by SIM of m/z 325.3 ions. Two peaks were detected at ∼5.7 and ∼8.1 min (Figure 5E) in samples with or without Fe^{2+} present, although their presence was favored by the absence of metal ions. In more heavily oxidized samples, a later-eluting peak of the same mass was detected at ∼36.6 min (Figure 5F). Low-intensity peaks were also detected at ∼23.4, ∼27.0, and ∼41.8 min, but their low abundance precluded further analysis.

The fragmentation spectra for the two early-eluting peaks are very similar, with only small differences in the relative intensities of the fragment ions (Table 1, Figure 6C,D). The two main fragment ions (Table 1) are consistent with consecutive loss of two H_2O molecules from the dioxygenated monatin. The other major fragment ion (m/z 146.1) has been reported previously for 2-hydroxymonatin and assigned to a fragment consisting of a monooxygenated indole ring.[27] This common indole-derived fragment was also detected for dioxygenated Trp products assigned to dioxindolylalanine [**8**], cyclized 3α-dihydroxypyrolloindoles [**9**], and cyclized 3α-hydroperoxypyrolloindoles [**10**] formed on $^1O_2$-mediated oxidation of Trp (Scheme 3).[29−31,39] Weak fragment ions were also detected for the peaks eluting at ∼5.7 and ∼8.1 min (Table 1), but as with the monooxygenated monatin products and dioxygenated Trp products ([**8**, **9**], Scheme 3), the relative fragment ion intensities varied.[29−31,39] These dioxygenated monatin peaks were thermally stable and have been assigned to the monatin derivatives ([**15**, **16**], Scheme 4) of the dioxyindolylalanine [**8**] and cyclized diol [**9**] species characterized previously with Trp (Scheme 3) rather than peroxides (which would be thermally unstable). The predominant form of these ring tautomers in acidic solutions is likely to be the dioxyindolyl species [**15**] (cf. data in ref 39), rather than the cyclized diol [**16**], which is favored at alkaline pH.[40]

The dioxygenated peak detected at ∼36.6 min has a markedly different fragmentation pattern (Figure 6G, Table 1) from the earlier eluting peaks. It is suggested, by comparison with free Trp,[29−31] that this product is the monatin equivalent ([**17**], Scheme 4) of *N*-formylkynurenine ([**11**], Scheme 3) in which addition of two oxygen atoms results in pyrrole ring cleavage.

LC−MS/MS Analysis of Oxygenated Monatin Products Formed by Rose Bengal-Mediated Photooxidation. Because many of the monatin products appear to be similar to those detected from $^1O_2$-mediated oxidation of Trp, oxidation of monatin with RB and light was examined. LC−MS/MS of these samples revealed many of the mono- and dioxygenated species that were observed in the direct photodegradation studies, but over different time frames and concentrations.

Analysis of samples by SIM immediately after photolysis (or following prolonged storage at −20 °C) showed two dioxygenated monatin products (m/z 325.3) (Figure 5G) that were not observed in the direct photolysis studies (Figure 5E). These species eluted at ∼12.7 and ∼17.3 min but were absent (or detected at much lower levels) in samples stored at 22 °C for up to 5 days or after addition of 40 μM Fe^{2+}. This thermal instability suggests that these are the cis and trans isomers of the monatin analogues ([**18**], Scheme 4) of the cyclized 3α-hydroperoxypyrolloindole species ([**10**], Scheme 3) detected with Trp (i.e., monatin peroxides). The fragmentation spectra (Figure 6E,F, Table 1) support these assignments, with each exhibiting a fragment ion at m/z 291.0 corresponding to loss of H_2O_2 (34 mass units). Numerous other fragment ions were detected (Figure 6E,F, Table 1), but as with the corresponding alcohols, variations in the fragment ion intensities between the two species are consistent with an assignment to the cis and trans isomers of the cyclized peroxides [**18**]. Decomposition of these peroxides resulted in an increased concentration of the pair of

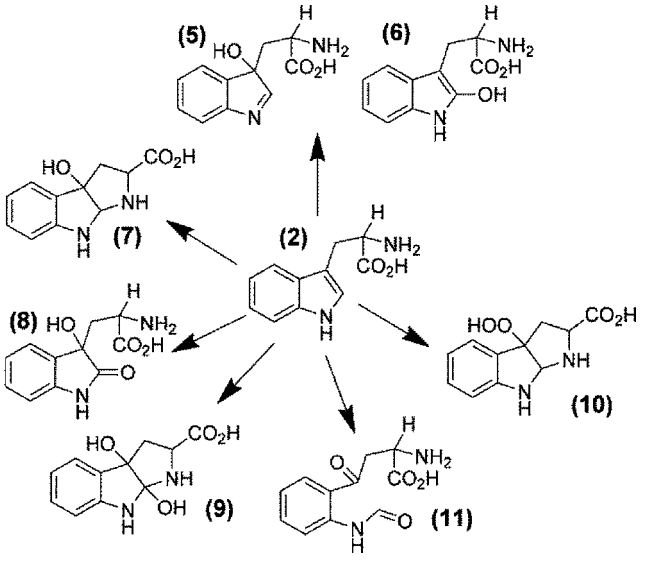
263.2[f]	40.3	no fragment ions detected	indigo [**21**]

[a]Fragment ions are listed in order of decreasing intensity, with assignments or mass differences of neutral losses in parentheses. High accuracy QTOF and UHPLC−MS/MS analysis of some photoproducts was also carried out, and the data are summarized in the following footnotes. [b]$[M + H]^+$ = 227.0821, $[M- H]^-$ = 225.0675, predicted chemical formula $C_{13}H_{10}N_2O_2$, fragment ions (+ve ion), m/z 183.0914 ($-CO_2$), 209.0710 ($-H_2O$), 156.0808 ($-C_2HNO_2$). [c]$[M + H]^+$ = 241.0618, $[M- H]^-$ = 239.0475, predicted chemical formula $C_{13}H_8N_2O_3$, peak was of insufficient intensity for accurate mass MS/MS. [d]$[M + H]^+$ = 243.0773, $[M- H]^-$ = 241.0631, predicted chemical formula $C_{13}H_{10}N_2O_3$, fragment ions (+ve ion), m/z 215.0819 (−CO). [e]$[M + H]^+$ = 263.1036, $[M- H]^-$ = 261.0889, predicted chemical formula $C_{13}H_{14}N_2O_4$, fragment ions (+ve ion), m/z 200.0703 ($-CH_5NO_2$), 132.0440 ($-C_8H_5NO$). [f]$[M + H]^+$ = 263.0823, predicted chemical formula $C_{16}H_{10}N_2O_2$.

Scheme 3. Summary of the Photooxidized Products Previously Identified for Trp [2].[29−31,39]

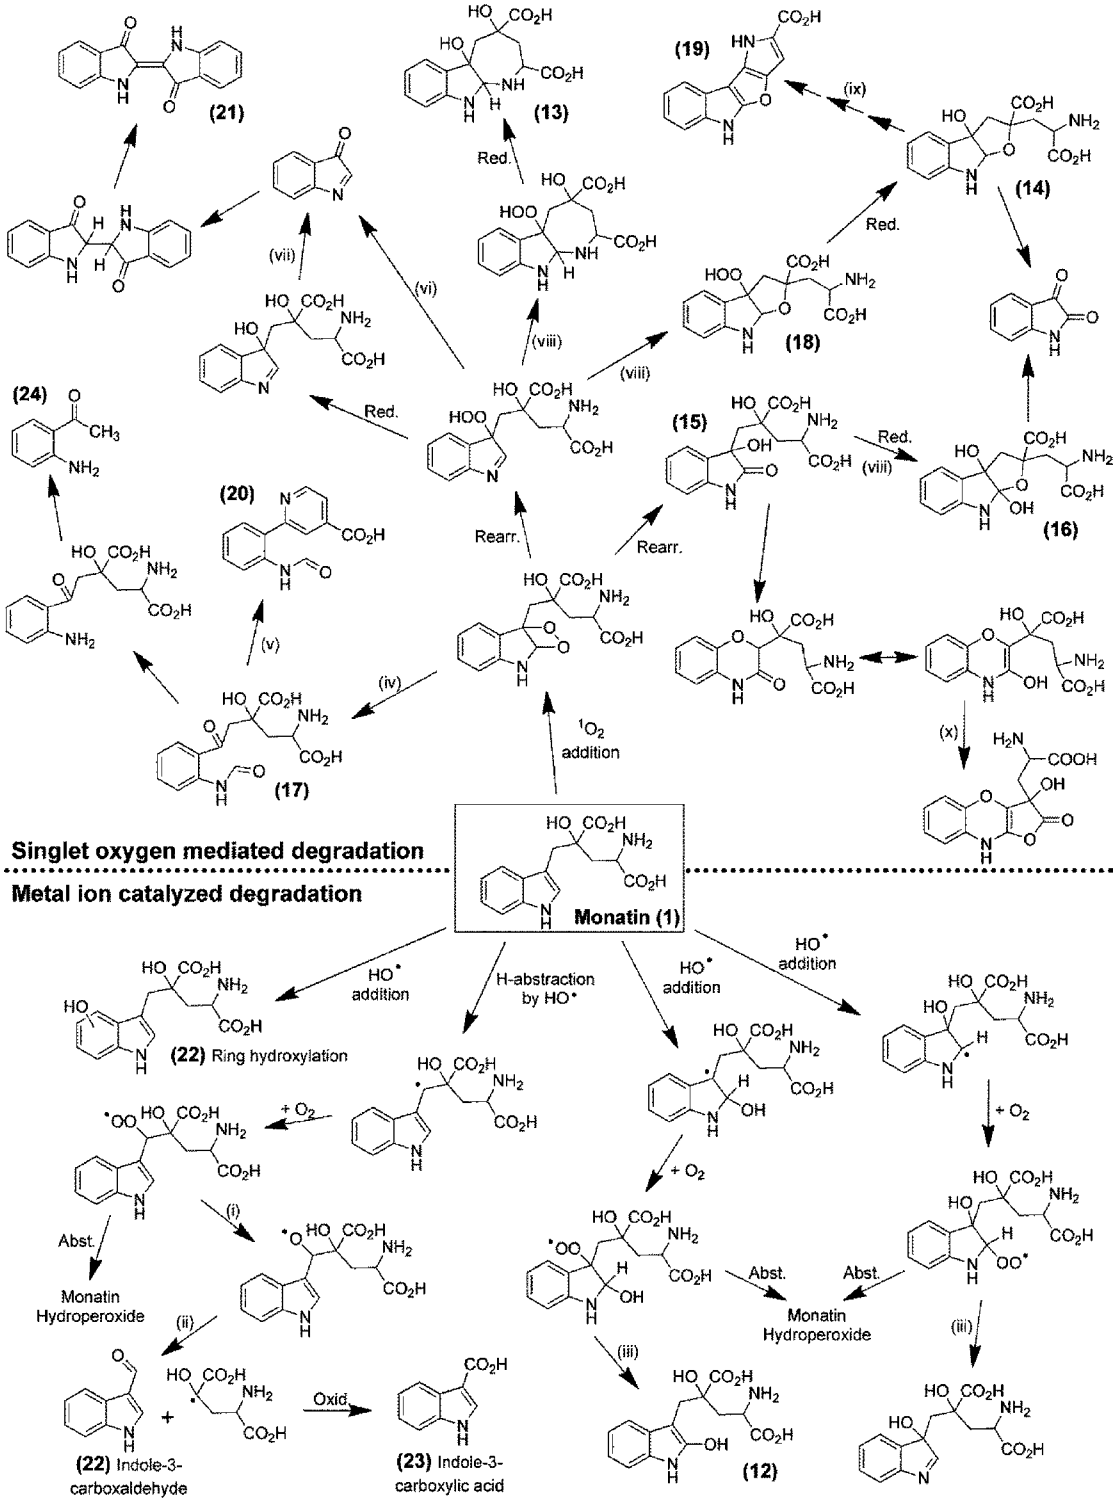


monooxygenated monatin species (m/z 309.3) at ∼8.1 and ∼11.2 min, consistent with peroxide decomposition to the corresponding alcohols [**14**]. The m/z 309.3 peak observed at ∼31.2 min in the direct photolysis experiments (i.e., 7.5 W m^{-2}, no RB) was much less intense with RB oxidation (data not shown). This suggests different mechanism(s) of formation of the three mono-oxygenated monatin species (m/z 309.3), with the early eluting, ring-closed species (8.1 and 11.2 min, [**14**]) generated primarily by $^1O_2$ reactions, whereas the 2-hydroxyindole product [**12**] eluting at ∼31.2 min may be generated primarily by radical pathways.

LC−MS/MS Analysis of Other Monatin Photoproducts. In addition to the above mono- and dioxygenated monatin products, LC−MS/MS studies identified multiple other product peaks with m/z 227.1, 241.1, 243.1, and 263.1 (Table 1) on photolysis of monatin; SIM studies of these masses are discussed in order of increasing m/z below.

A new peak (m/z 227.1) eluted at ∼32.6 min (Supporting Information Figure 3A, Table 1) whose intensity increased after 14 days of photolysis and was further enhanced when samples were spiked with 10 μM Fe^{2+}. A much weaker intensity peak (m/z 227.1) was also detected at 11.8 min (Supporting Information Figure 3A, Table 1), but this was detected only upon photolysis of Fe^{2+}-spiked samples. The identities of these products have not been determined unequivocally, but accurate mass (QTOF) measurements (Table 1 footnote) for the ∼32.6 min peak are consistent with a formula of $C_{13}H_{10}N_2O_2$ (cf. $C_{14}H_{16}N_2O_5$ for monatin). The low carbon−hydrogen ratio for this species is

Scheme 4. Proposed Degradation Mechanisms of Monatin [1][a]



[a]Key to abbreviations: Abst., hydrogen atom abstraction; Red., reduction; Oxid., oxidation; Rearr., rearrangement. (i) Via dimerization to unstable tetroxide with O_2 elimination or hydroperoxide formation followed by one electron reduction. (ii) β-Scission. (iii) Elimination of $HO_2^\bullet$ to generate H_2O_2. (iv) Oxidative ring-opening. (v) Cyclization, H_2O elimination, and aromatization. (vi) Via alkoxyl radical and β-scission. (vii) Side chain cleavage. (viii) Ring closure. consistent with a cyclized, aromatized structure. Although accurate mass UHPLC–MS/MS (Table 1 footnote) data was obtained, no structural assignment is possible. The other peak with m/z 227.2 that eluted at ~11.8 min was too weak for accurate mass and MS/MS analysis.

A product peak with m/z 241.1 eluted at 29.9 min (Supporting Information Figure 3B, Table 1), which increased in intensity on

dx.doi.org/10.1021/jf404198w | J. Agric. Food Chem. 2014, 62, 3476–3487

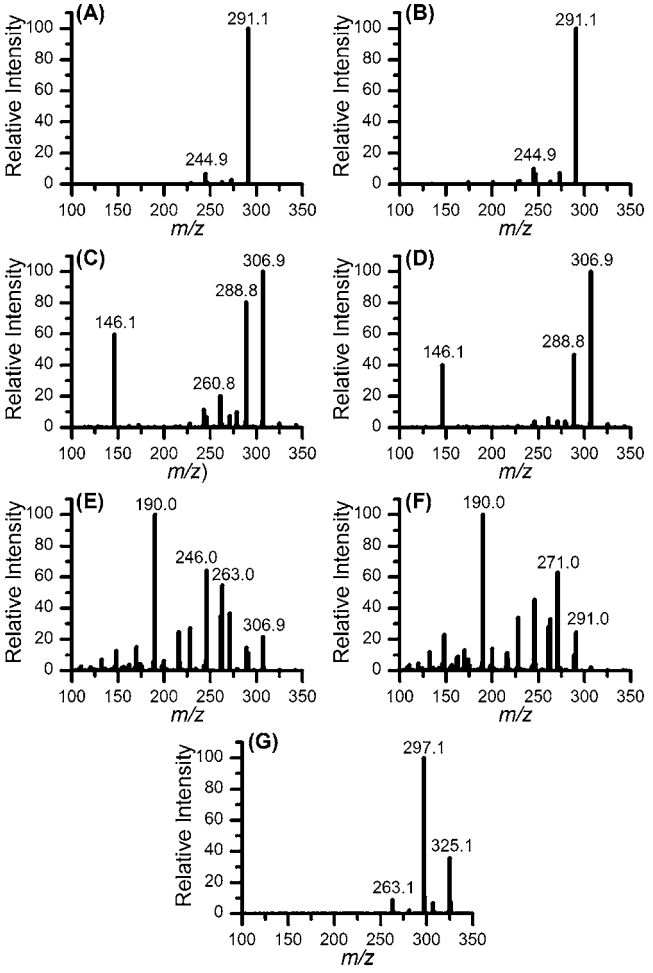

Figure 6. MS/MS spectra for mono- and dioxygenated products of monatin obtained from samples exposed to illumination (7.5 W m^{-2}) for 14 days in Chelex-treated buffer and subsequently concentrated 10-fold (except where otherwise stated). (A, B) cyclized monatin alcohols (m/z 309.3) eluting at 8.1 and 11.2 min, (C, D) cyclized monatin diols (m/z 325.3) eluting at 5.7 and 8.1 min, (E, F) cyclized monatin peroxides (m/z 325.3) eluting at 12.7 and 17.3 min (formed by photosensitization with Rose Bengal), and (G) *N*-formylkynurenine derivative of monatin (m/z 325.3) eluting at 36.6 min detected in samples with 100 nM Fe^{2+} added to sample.

exposure to light and spiking with Fe^{2+}. LC−MS/MS data (Table 1) show facile loss of H_2O and CO, and accurate mass QTOF analysis (Table 1 footnote) gave a chemical composition of $C_{13}H_8N_2O_3$. These data are consistent with an assignment to an extensively cyclized, unsaturated structure ([**19**], Scheme 4), which may arise via the cyclized peroxide structures ([**18**], Scheme 4).

Several low-intensity peaks with m/z 243.2 were detected from 25 to 40 min, but they were too weak to characterize. In addition, a relatively intense peak (m/z 243.2, ∼46.0 min; Supporting Information Figure 3C, Table 1) eluted ∼10 min after parent monatin. The peak intensity was dependent on photolysis time and the presence of Fe^{2+}. QTOF analysis (Table 1 footnote) gives a formula of $C_{13}H_{10}N_2O_3$ for the uncharged molecule, and accurate mass UHPLC−MS/MS suggested facile loss of CO (Table 1 footnote). LC−MS^3 experiments demonstrated sequential loss of H_2O and CO from the m/z 215.2 fragment ion (Table 1). This peak was assigned to 2-(2-formamidophenyl)isonicotinic acid (2-2-FAPINA; [**20**], Scheme 4) as previously;[27] this species is proposed to form via the ring-opened, oxidized monatin derivative [**17**], equivalent to *N*-formylkynurenine [**11**] in Trp oxidation (Scheme 3).

Two peaks with m/z 263.2 eluted at ∼31.7 and ∼40.3 min (Supporting Information Figure 3D, Table 1). The ∼31.7 min peak intensity increased with photolysis and/or spiking with Fe^{2+} (10 μM); the weaker peak at 40.3 min was observed only on illumination of Fe^{2+} spiked samples. QTOF analysis (Table 1 footnote) indicated formulae of $C_{13}H_{14}N_2O_4$ and $C_{16}H_{10}N_2O_2$ respectively. Accurate mass UHPLC−MS/MS (Table 1 footnote) data suggest, but do not prove, that the latter species is a dimeric indigo-like species (e.g., [**21**], Scheme 4). The earlier eluting species could not be characterized.

Authentic samples of previously reported monatin degradation products[25,27] or other feasible products (see Scheme 4), including indole-3-carboxaldehyde (m/z 146.2; [**22**]), 3-indole acetic acid (m/z 176.2), indole-3-carboxylic acid (m/z 162.2; [**23**]), 3-methyl-indole (skatole; m/z 132.2), and 2-amino-acetophenone (m/z 136.2; [**24**]) were monitored by SIM. All of these materials were readily detected, except indole-3-carboxylic acid and skatole that ionize poorly. None of these materials were detected in the photolyzed samples, either with or without 10 μM Fe^{2+}. However, upon 10-fold concentration of photo-oxidized samples, indole-3-carboxaldehyde (also known as 3-formylindole) was detected by selective reaction monitoring of the m/z 146.2 → m/z 118.2 fragmentation (due to loss of CO), consistent with a previous report.[27]

The formation of low yield products was investigated by exposing monatin samples to light (7.5 W m^{-2}) for up to 3 months. When these samples were concentrated ∼10-fold by vacuum centrifugation, several new peaks (m/z 225.2 (28.7 min), 291.1 (11.2, 28.1, 30.7, 32.4, 34.1, 37.4 min), 343.0 (27.6 min), and 363.0 (25.6 min)) were observed by full-scan LC−MS. These peaks were verified by LC−MS/MS and most readily lost H_2O (−18 m/z), CO (−28 m/z), or both H_2O and CO (−46 m/z); however, these species could not be characterized by accurate mass (QTOF or UHPLC−MS/MS) measurements because of their low abundance even in heavily oxidized, concentrated samples.

DISCUSSION

The data described above and those from previous studies,[25,27,28] including one using high-intensity simulated sunlight,[27] demonstrate that monatin degrades in mock beverage solutions over extended illumination periods. The results obtained in the current study show that the rate and extent of monatin consumption varies significantly, depending on the conditions employed, and that multiple mechanisms and intermediates are involved. A considerable proportion (76%) of monatin was lost in samples prepared in a standard citrate (mock beverage) buffer that was exposed to standard fluorescent light illumination (7.5 W m^{-2}) for 50 days. In the current studies, a (relatively low level) fluorescent light source was used to provide a model relevant to commercial storage and vending situations. A previous study employed a sun-test chamber that was equivalent to 4 days of direct sun exposure in the Arizona desert.[27] With our milder conditions, much of the monatin lost over the initial few days arises from intramolecular rearrangement to the corresponding lactone ([**3**], Scheme 2), with ∼15% of the initial monatin converted to the lactone over the first 14 days of photolysis and ∼10% converted to oxidation products. This lactonization is associated with a loss in sweetness,[41] but it does not appear to lead to unpleasant flavors or aromas. This suggests that the major

loss of sweetness and the development of negative taste and sensory effects in mock monatin beverage solutions arise from alternative oxidative processes.

In parallel experiments with citrate buffer prepared using D_2O in place of H_2O, an enhanced rate of photodecomposition was observed with up to 84% of monatin consumed by day 50. This suggests a major role for $^1O_2$ in the photodegradation because D_2O enhances the lifetime of $^1O_2$ and thereby enhances damage.[31,32] A key role for species generated by light is confirmed by studies using samples kept in the dark, in which the rate of monatin loss was markedly reduced, but not entirely eliminated. The loss of monatin in the dark demonstrates that non-light-induced reactions also lead to monatin degradation, but at a slower rate. Significantly, there was no difference in monatin degradation between samples prepared in D_2O or H_2O citrate buffer in the dark; thus, $^1O_2$ plays a major role only in light-exposed samples. It is proposed that in the initial stages of the reaction, $^1O_2$ arises from (inefficient) photosensitization reactions mediated by the indole ring; however, once indole ring degradation has commenced, either via the mediation of $^1O_2$ or radicals, more efficient photosensitizers are formed, such as *N*-formylkynurenine, kynurenine, and indigo derivatives (Scheme 4), that are more efficient photosensitizers of $^1O_2$ and drive further oxidation.[42,43]

Given the data implicating $^1O_2$ in light-induced monatin degradation, photooxidation induced by a RB/light/O_2 system was examined because this gives high levels of $^1O_2$. High yields of monatin peroxides were formed as well as multiple downstream products, with the peroxide yields further increased when the experiments were carried out in D_2O (cf. refs 31, 32). The monatin peroxides were long-lived in the absence of light and metal ions, but their decay was enhanced by the deliberate addition of Fe^{2+}. By analogy with $^1O_2$-generated Trp, His, and Tyr peroxides,[29,32,33] it is likely that Fe^{2+}-mediated reduction of monatin peroxides results in the formation of monatin radicals that contribute to photoinduced monatin degradation.

Significant levels of H_2O_2 and organic peroxides were detected in the mock beverage samples illuminated with a fluorescent light source (7.5 W m^{-2}) in the absence of RB, suggesting that peroxides are key intermediates, because the levels of these materials and the rate of monatin loss were enhanced by D_2O. At least some of the H_2O_2 formation appears to arise via $^1O_2$-mediated reactions, with this postulated to occur via elimination from endo- or hydroperoxide intermediates. The peroxide levels detected in the illuminated samples were significantly higher than those present in the dark controls, consistent with the greater rate of degradation upon light exposure and the mediation of these species.

The removal of trace transition metal ions (by pretreating buffers with Chelex 100-resin) significantly attenuated monatin degradation. Furthermore, the peroxide levels detected in Chelex-treated buffer samples were much lower than in nontreated buffers. These data suggest that transition metal ions also play a key role in monatin degradation, both in illuminated and nonilluminated samples. This hypothesis is supported by addition of the metal ion chelators EDTA and desferrioxamine, which had an effect on monatin stability that was similar to treatment with Chelex resin. Conversely, spiking of Chelex-treated mock beverage samples with Fe^{2+} led to enhanced rates of monatin loss, with this dependent on the added Fe^{2+} concentration. These data implicate Fe^{2+} in monatin degradation under mock beverage conditions in both nonilluminated and illuminated samples, particularly because equivalent samples spiked with Cu^{2+} (instead of Fe^{2+}) exhibited *less* monatin degradation than nonspiked controls. This effect may be due to light absorption by the Cu^{2+} ions. A role for Fe^{2+} in monatin degradation is further supported by the enhanced initial rate of total and organic peroxide formation in the spiked samples. This effect was lost over longer times, probably because of Fe^{2+}-catalyzed degradation of the peroxides (eqs 1−4), with these secondary reactions contributing to the overall extent of monatin degradation.

The mechanistic insight into monatin degradation provided by the data obtained, together with the product analyses outlined here and elsewhere,[25−28] has allowed a scheme to be proposed that accounts for the observed products and processes known to affect monatin degradation (Scheme 4). This scheme also indicates a pathway through which direct UV photolysis can initiate (or enhance) monatin photodegradation, because it is well established that direct (short-wavelength) UV absorption by Trp can result in photoionization to yield a radical cation that can deprotonate to give a neutral indolyl radical or a radical at the β-carbon (i.e., at the methylene $-CH_2-$ linking the indole ring to the amino acid backbone).[42,43] Analogous reactions with monatin would provide pathways to δ-carbon and indolyl radicals proposed as intermediates on the pathway to indole-3-carboxaldehyde [**22**] and indole-3-carboxylic acid [**23**] formation. Because these direct photoionization reactions occur primarily with short-wavelength UV light, this proposed mechanism would account for the lower levels of indole-3-carboxaldehyde [**22**] and indole-3-carboxylic acid [**23**] (and associated off-flavors and aromas) detected in the current study compared with those reported previously[25,27] in which light sources with greater output at shorter wavelengths were employed. These observations indicate a potential route through which the formation of undesired materials might be mitigated.

In summary, the current studies have provided a detailed mechanistic analysis and rationale for the photodegradation of the high-potency sweetener monatin under simulated acidic beverage conditions (mock lemon/lime systems). These studies demonstrate that both photooxidation reactions and metal ions contribute to monatin degradation, with these two pathways being synergistic. The product profiles determined by UHPLC and LC−MS/MS are consistent with a role for both $^1O_2$- and radical-mediated pathways in the presence of light, and primarily metal-ion catalyzed, radical-mediated pathways in the absence of light. In both cases, peroxides (either H_2O_2 or monatin-derived) are likely to be key intermediates. The conditions used here represent typical storage and vending conditions for beverages, providing a mechanism-based approach to optimize monatin-containing beverage compositions with prolonged shelf lives. Strategies to minimize these degradation pathways have also been investigated (Storkey et al., unpublished results).

Table 1. Maturity and Quality Attributes of 'October Sun' and 'Jesca' Peaches at Harvest and after 5 Days at 20 °C[a]

parameter	'October Sun'				'Jesca'			
	harvest		harvest + 5 days		harvest		harvest + 5 days	
wt (g)	209.1	a	197.3	b	210.9	a	202.6	ab
diameter (cm)	7.82	a	7.60	a	7.89	a	7.75	a
fruit surface[b] (cm^2)	192.1	a	181.5	a	195.6	a	188.7	a
ethylene production ($\mu L\ kg^{-1}\ h^{-1}$)	0.38	c	0.77	c	4.71	b	6.72	a
respiration rate (mL $CO_2\ kg^{-1}\ h^{-1}$)	229.3	b	164.6	c	251.9	ab	283.6	a
firmness (N)	49.0	a	5.5	c	37.1	b	8.7	c
wt loss (%)			5.6	a			3.9	a
SSC (°Brix)	12.8	ab	13.2	a	12.3	b	13.1	a
TA ($g\ L^{-1}$)	8.1	a	7.1	a	5.4	b	5.3	b
SSC/TA ratio	1.6	b	1.9	b	2.3	a	2.5	a
hue (deg)	49.2	c	50.5	c	87.0	a	81.6	b
lightness (L^*)	47.8	d	50.2	c	70.2	a	67.8	b

[a]Values represent means of 15 or 3 (ethylene and CO_2 production) replicates. Mean values followed by a different letter within the same row are significantly different at $P \leq 0.05$ (LSD test). [b]Total surface was estimated from the average diameter of each fruit assuming a spherical shape.

(September 7 and October 7, respectively) from a commercial orchard located in Alguaire, in the area of Lleida (northeastern Spain), at marketable maturity according to the usual indices in the producing area. Uniform, defect-free samples were selected and transported directly to the laboratory, where they were kept at 20 °C for 5 days to simulate commercial shelf life.

Standard quality parameters were determined on 15 fruits per each cultivar and analysis date. Fruit firmness (N) was measured on opposite sides of each fruit using a hand-held Effegi penetrometer (model FT 327; Milan, Italy) equipped with an 8 mm diameter tip. The weight of 15 fruits was assessed at harvest and 5 days thereafter to determine weight loss (%). Soluble solids content (SSC) and titratable acidity (TA) were assessed in juice pressed from the whole fruit. SSC was determined with a digital hand-held refractometer (Atago, Tokyo, Japan), and results were expressed as °Brix. For TA determination, 10 mL of juice was diluted in 10 mL of distilled water and titrated with 0.1 M NaOH to pH 8.1; results are given as grams of malic acid per liter. Skin color was determined at two opposite equatorial points of 15 fruits using a portable tristimulus colorimeter (Chroma Meter CR-200, Minolta Corp., Osaka, Japan), with CIE D_{65} illuminant and 8 mm aperture diameter. Lightness (L^*) values were recorded, and hue angle was calculated from a^* and b^* parameters as arctg b^*/a^*.

For the assessment of ethylene production and respiration rates, three fruits per each cultivar were kept individually in 3 L glass jars, continuously aerated with humidified air at a rate of 1.5 L h^{-1}. Gas samples (1 mL) of the effluent air were taken with a syringe and injected into a gas chromatograph (model 6890N; Agilent Technologies, Madrid, Spain) equipped with a flame ionization detector and an alumina column (1.5 m × 3 mm). Analyses were conducted isothermally at 100 °C, with N_2 as the carrier gas, in the presence of air and H_2 (45, 400, and 45 mL min^{-1}, respectively). The injector and detector were held at 120 and 180 °C, correspondingly, and results are expressed as microliters per kilogram per hour. Respiration was determined as CO_2 production by directly connecting the effluent air from each jar to an infrared gas analyzer (Sensotran S.L., El Prat de Llobregat, Spain). Results are given as milligrams of CO_2 per kilogram per hour).

Chemical Standards and Reagents. The reagents and standards used for the analysis of cuticular components were supplied by Sigma-Aldrich (Steinheim, Germany). All standards used were of analytical grade.

Cuticle Isolation. Skin samples were taken at harvest and 5 days thereafter, and cuticles were isolated and analyzed as described below. Exocarp segments were excised from the cheek region of five fruits using a cork borer (13 mm i.d.). Twelve skin disks were so obtained from each individual fruit. Cuticular membranes (CM) were isolated enzymatically by incubation at 37 °C in 0.2% (w/v) cellulase and 100 U mL^{-1} pectinase in 50 mM citrate buffer (pH 4.0) until no more material was released, in the presence of 1 mM NaN_3 to prevent microbial growth. After isolation, CM were washed in citrate buffer (50 mM, pH 4.0) at 37 °C once or twice every day until no material was left in suspension, thoroughly rinsed in distilled water,[11] dried at 40 °C, and kept in hermetically capped vials until used. The mass of CM was determined gravimetrically and expressed per unit of fruit surface ($\mu g\ cm^{-2}$) as well as on a total surface basis (mg per fruit).

Extraction and Analysis of Cuticular Wax Compounds. Waxes were recovered from the 60 dry CM disks (79.64 cm^2/sample) obtained in each case. CM samples were dewaxed by shaking in $CHCl_3$ (1 mg of sample mL^{-1}) for 24 h at 25 °C, followed by incubation (15 min) in an ultrasonic bath. This dewaxing procedure was repeated three times. After filtration, the chloroform extracts were pooled and concentrated using a rotary evaporator at 50 °C and the waxes transferred to a preweighed vial, dried under N_2 until complete dryness, and weighed in a microbalance for calculation of total wax yield ($\mu g\ cm^{-2}$). Free hydroxyl and carboxyl groups were converted respectively into their trimethylsilyl (TMSi) ethers and esters by derivatizing with *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) in pyridine (2:1, v/v) for 15 min at 100 °C.

After derivatization, eicosane (C_{20}) and dotriacontane (C_{32}) were added to wax samples as internal standards, and the mixtures were injected (1 μL) in on-column mode into a gas chromatography−mass spectrometry (GC-MS) system for compound identification. GC equipment (Agilent 6890N) coupled with a quadrupole mass selective detector (Agilent 5973N) was used for these analyses, equipped with a capillary column (BPX5, 30 m × 0.25 mm, 0.25 μm; SGE Europe Ltd., Milton Keynes, UK). Wax compounds were identified by comparing their retention indices with those of standards and their identities then confirmed by matching their electron ionization mass spectra (EI-MS) (70 eV, m/z 50−700) with those from the NIST 08 MS library. The oven was set at 50 °C (2 min), and the temperature was raised initially at 40 °C min^{-1} to 200 °C, kept at 200 °C for 2 min, raised again at 3 °C min^{-1} to 310 °C, and then kept constant at 310 °C for 30 min. Helium was used as the carrier gas (2 mL min^{-1}). Quantitative determination of wax compounds was carried out under the same chromatographic conditions using a GC system equipped with a flame ionization detector (FID).

Extraction and Analysis of Cutin Monomers. Samples (10 mg) of dewaxed cuticular membranes (DCM) were hydrolyzed in 3 mL of 1 M HCl in 100% MeOH and esterified in the same solvent for 2 h at 80 °C. After cooling, 2 mL of saturated NaCl was added to the methanolysate. The cutin monomers were extracted three times in 2 mL of hexane for 10 min, followed by thorough mixing and centrifugation at 20 °C. The monomer extracts were combined and evaporated to dryness in a N_2 steam. Cutin yields were determined gravimetrically as micrograms per square centimeter. Dry cutin samples were derivatized with BSTFA for 15 min at 100 °C, and then heptadecanoate (C_{17}) and tricosanoate (C_{23}) were added as

cutin yield (mg/fruit)	31.5	ab	34.2	a	21.8	b	35.4	a
cutan yield[c] (μg cm^{-2})	824.2	bc	859.9	a	822.7	c	857.3	ab
cutan yield[c] (mg/fruit)	158.3	a	156.1	a	160.9	a	161.8	a
wax (%)	34.4	ab	34.4	ab	31.3	b	39.3	a
cutin (%)	10.9	a	11.8	a	8.2	b	10.9	a
cutan[c] (%)	54.7	ab	53.8	ab	60.5	a	49.8	b

[a]Yields represent means of three replicates. Mean values followed by a different letter within the same row are significantly different at $P \leq 0.05$ (LSD test). [b]Recovered from 60 skin disks (12 disks × 5 fruit), corresponding in total to 79.64 cm^2. [c]Cutan yields were taken as the nonhydrolyzable residue remaining after cutin extraction.

internal standards, and the mixtures were injected (1 μL) to GC-FID for quantitative determination.

Cutin compounds were identified from their EI-MS spectra (70 eV, m/z 50−700) after GC-MS analysis using the same GC-MS system as described in the previous section. The oven was set and held at 50 °C for 2 min, and then the temperature was raised to 250 °C at 10 °C min^{-1}, kept at 250 °C for 1 min, raised again at 3 °C min^{-1} to 310 °C, and kept at that temperature for 20 min. The same chromatographic conditions were used for quantitative determination of cutin compounds by GC-FID.

Statistical Analysis. A multifactorial design with cultivar and days after harvest as factors was used to statistically analyze the results. All data were tested by analysis of variance (ANOVA) with the Minitab 16 program package, and means were separated by Fisher's LSD test at $P \leq 0.05$.

RESULTS AND DISCUSSION

The standard indicators of physiological and commercial maturity were determined at harvest. The values for these parameters (Table 1) were generally within the recommended ranges for this species in the producing area, showing that fruits were picked at a suitable maturity stage. Fruit size and firmness at harvest were above the minimum requirements for commercialization (≥70 mm and >30 N, respectively), and SSC values were around 12−13%, which in peach are associated with high consumer acceptance scores.[12] In both cultivars, fruit firmness decreased sharply 5 days after harvest, this loss being somewhat less dramatic for 'Jesca' samples. Although TA levels in 'October Sun' peaches were a bit higher than recommended for these fruits (4−7 g L^{-1}), acidity declined after the fruit had been kept at 20 °C for 5 days. Differences in hue and lightness of fruit surface reflect the different typologies of the two genotypes selected for this study, 'October Sun' and 'Jesca' being, respectively, a yellow-fleshed cultivar displaying 100% red skin and a yellow-skinned variety. Ethylene production rates by 'Jesca' fruit were approximately 10-fold those by 'October Sun' samples, but respiration rates were similar in both cases.

Fruit lost some weight after the simulated commercial period at 20 °C, although this loss was significant only in 'October Sun' samples (Table 1). Despite weight loss, fruit diameter and total surface did not show significant differences in comparison with those at harvest. These data were used to express cuticle amounts obtained from fruit skin on a whole fruit basis. The absolute amount of cuticle recovered from the 60 skin disks (roughly 80 cm^2 in total) was higher in 'October Sun' than in 'Jesca' (120 vs 108 mg, respectively) (Table 2). When these amounts were expressed per unit surface area (μg cm^{-2}) and per total fruit surface (mg fruit^{-1}), differences were not significant. However, whereas cuticle yields remained unchanged in 'October Sun' fruit after being kept for 5 days at 20 °C, a significant increase was found in 'Jesca' samples (Table 2), which suggests cuticle thickening in these fruit after harvest. The same trend was observed for total wax and cutin, yields after 5 days at 20 °C remaining at similar levels in 'October Sun' but increasing in 'Jesca' in comparison with those at commercial harvest, in both absolute (mass per surface unit and mass per total surface) and relative (%) terms. Because total fruit surface did not change significantly after the shelf-life period (Table 1), this observation possibly reflects active cuticle deposition taking place during that time.

Wax percentages in cuticles of 'October Sun' and 'Jesca' fruit at harvest were similar and represented around 34 and 31% of total cuticle recovered, respectively (Table 2). In contrast, cutin percentage at harvest was significantly higher in 'October Sun' than in 'Jesca' cuticles (11 vs 8%). We are aware of only one previously published study on peach fruit cuticle, in which cuticles of the 'Calrico' cultivar were found to be composed of 27% waxes and 23% cutin.[2] Trichomes were removed and analyzed separately, and found to contain lower percentages of wax (15%) and cutin (19%). However, the detailed composition of these cuticular fractions was not reported. Therefore, in this work we extracted and analyzed waxes and cutin monomers from cuticles isolated from peach fruit.

Wax Composition of Peach Fruit Cuticles. Compositional analysis of cuticular waxes of 'October Sun' and 'Jesca' fruit revealed that, despite being composed of similar chemical families, cultivar-related differences exist in the abundance of particular compounds. The main wax type in quantitative terms was triterpenoid acids, which agrees with observations for sweet cherry fruit (Belge et al., unpublished data),[13,14] the only stone fruit species for which detailed information on cuticle waxes is available. Significant differences in the total content of triterpenoid acids in cuticular waxes of fruit at harvest were found between both cultivars, levels being higher in 'October

Sun' (52%) than in 'Jesca' (44%). Substantial amounts of ursolic and oleanoic acids were detected in both cases (Table 3). However, although ursolic acid has been consistently found to be largely dominant among the triterpenoid components of sweet cherry waxes (ranging from 47 to 60% of total waxes depending on the cultivar considered) (Belge et al., unpublished data),[13,14] amount differences with oleanoic acid, the second triterpene in quantitative terms, were moderate in both peach genotypes studied herein, particularly in 'October Sun' samples (Table 3). Ursolic acid percentages over total cuticular waxes in 'October Sun' and 'Jesca' were approximately 29 and 27% at harvest, whereas those of oleanoic acid were around 23 and 17%, correspondingly. The amount of total triterpenes was maintained in 'October Sun' samples along the simulated commercial life subsequent to harvest, both in relative (Table 3) and absolute (Figure 1) terms. In contrast, the absolute amount of total triterpenes (μg cm^{-2}) increased significantly in 'Jesca' fruit after harvest (Figure 1), which indicates that triterpenes must have been actively synthesized during the shelf-life period. However, triterpene synthesis was apparently not intense enough to keep pace with higher cuticle

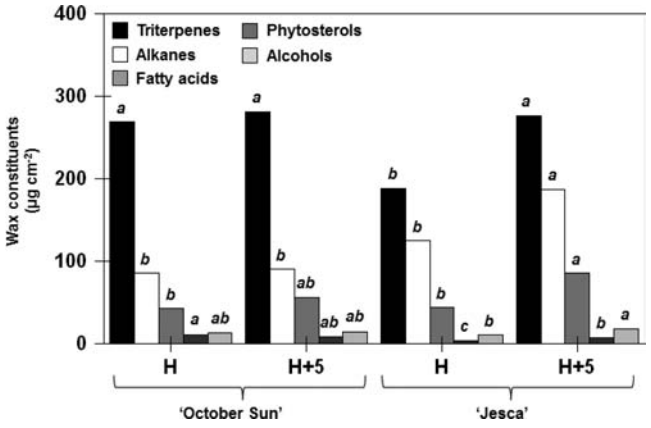

Figure 1. Amount (μg cm^{-2}) of the main families of wax constituents identified in cuticles of 'October Sun' and 'Jesca' peaches at harvest (H) and after 5 days at 20 °C (H+5). For each type of wax constituent, values bearing different letters are significantly different at $P \leq 0.05$ (LSD test).

yields (Table 2), resulting in a significantly decreased percentage of total triterpenes over total waxes (Table 3).

Alkanes were the second most important type of wax components in quantitative terms, also in accordance with observations for sweet cherry (Belge et al., unpublished data).[13,14] Yet, cuticular waxes of the nonmelting 'Calrico' peach were reported recently to contain as much as 76% of *n*-alkanes,[2] thus standing for the main group of wax components. Although the percentage of total alkanes detected herein was much lower, 'Jesca' cuticles were remarkably richer in this type of wax compound than those obtained from 'October Sun' fruit (roughly 29 vs 16% at harvest, correspondingly), which shows substantial cultivar-to-cultivar variability. In most published studies on composition of fruit cuticles, *n*-nonacosane (C_{29}) and/or *n*-hentriacontane (C_{31}) have been reported to be the main alkanes in cuticular waxes.[1] This is in contrast with data shown herein for peach fruit. Although important amounts of *n*-nonacosane (3−4%) were indeed detected in cuticular waxes of both cultivars, the predominant alkanes were *n*-tricosane (C_{23}), *n*-pentacosane (C_{25}), and *n*-heptacosane (C_{27}), which in 'Jesca' accounted together for almost 24% of total waxes at harvest, even though levels in 'October Sun' were lower (roughly 11%) (Table 3). Cultivar-related differences were also observed in relation to the evolution of total alkanes after harvest, which remained unchanged in 'October Sun' in both absolute (Figure 1) and relative (Table 3) terms. In contrast, a significant decline in alkane percentage over total waxes was observed for 'Jesca' after 5 days at 20 °C. However, alkane biosynthesis must have taken place after harvest, because the amount per surface area unit (μg cm^{-2}) increased significantly (Figure 1), hence contributing to the observed increment in cuticle yields (Table 2).

Cuticular wax constituents of both peach cultivars also included substantial amounts of fatty acids, particularly of those of the C_{18} type (Table 3). Linoleic acid was prominent among this type of wax components, followed by oleic and stearic acids. Cuticular waxes of fruit assessed were also rich in the C_{16}-type palmitic acid. Generally speaking, the percentage of fatty acids in cuticular waxes, as well as their total amount per unit of surface area (Figure 1), showed an increasing trend during the shelf-life period at 20 °C, although some variability was found for particular compounds (Table 3).

Cuticles of 'October Sun' fruit were richer in phytosterols than those of 'Jesca', both in relative (Table 3) and absolute (Figure 1) terms. This difference was due to a higher content of campesterol, because the percentages of β-sitosterol were similar in both cases. With regard to alcohols, the percentage over total waxes and the amount per surface unit at harvest were similar in both cultivars. However, cultivar-related differences were observed in the specific composition of this type of wax constituents: whereas 'Jesca' was richer in tricosanol (C_{23}) and tetracosanol (C_{24}), cuticles of 'October Sun' contained higher percentages of hexacosanol (C_{26}) and triacontanol (C_{30}).

The data thus indicate the existence of significant differences in the percentage of particular families of wax constituents in the fruit cuticles of both peach cultivars considered in this study. Whereas 'October Sun' fruits were richer in triterpenoid acids and phytosterols, 'Jesca' cuticles contained a higher percentage of alkanes (Table 3). The possible relationship of these differences with the postharvest performance of each particular genotype deserves further attention. For instance, it has been suggested that the waterproofing properties of fruit cuticles are defined primarily by the *n*-alkane components,[15] because the presence of amorphous waxes such as triterpenoids would impair the transpiration barrier function of cuticles.[16] Accordingly, dehydration rates in pepper fruit correlated inversely with the ratio of alkanes to triterpenoids plus sterols.[17] The composition data obtained herein indicate that this ratio was 0.31 in 'October Sun' and 0.65 in 'Jesca' at commercial harvest, which agrees with lower weight loss in the latter after 5 days at 20 °C (5.6 vs 3.9%, respectively) (Table 1).

The data also indicate that postharvest modifications in the composition of cuticular waxes were more intense in 'Jesca' than in 'October Sun' fruits. For 'October Sun', no significant changes were found after the simulated shelf-life period in the total amount of the main families of wax constituents in terms of mass per surface unit (Figure 1) and, for the quantitatively main types of compounds (triterpenes, alkanes, and acids), also not in relative terms (Table 3). In contrast, the percentage of fatty acids over total waxes increased significantly in 'Jesca' fruit after the same period, whereas that of triterpenes and alkanes decreased (Table 3). However, the absolute amount of all types of wax compounds identified herein increased significantly (Figure 1), indicating active biosynthesis in this cultivar after harvest, which must have accounted for augmented cuticle yields in these fruits (Table 2).

Cutin Composition of Peach Fruit Cuticles. Although significant differences were found at harvest between both cultivars in the relative (%) amount of cutin recovered from fruit cuticles, the total amounts of cutin were similar when expressed in terms of mass per surface unit and per total surface (Table 2). Detailed analysis of cutin monomer composition revealed that the cutin fraction of 'October Sun' and 'Jesca' peach fruit at harvest maturity was composed mainly of C_{18} monomers (54.7 and 57.1%, respectively), comprising mono-carboxylic, α,ω-dicarboxylic, and ω-hydroxylated acids (Table 4). The most abundant of these C_{18} constituents were 18-hydroxyoleic acid, oleic acid, linoleic acid, 1,18-oleic diacid, and 18-hydroxylinoleic acid. In turn, palmitoleic acid predominated among the C_{16}-type monomers. This contrasts with findings on sweet cherry fruit, another *Prunus* species, in which, conversely, undetectable or very low levels of palmitoleic acid could be found in cutin, hexadecane-1,16-dioic acid (Belge et al., unpublished data) or 9,16-dihydroxypalmitic acid[14] being the

predominant C_{16}-type monomers, depending on the cultivar considered. Although currently available information on the specific composition of fruit cuticles is limited, published studies indicate that substantial variability exists among species or even cultivars,[1] meaning that there is ample opportunity for further research.

Only minor quantitative differences in cutin composition were found at harvest between both cultivars considered, whereas the main types of constituent compounds were the same. Cutin of 'October Sun' fruit was richer in dicarboxylic and hydroxylated acids, whereas that of 'Jesca' peaches displayed higher percentages of monocarboxylic acids, alkanes, and alcohols (Table 4). Dicarboxylic and ω-hydroxyacids have been suggested to be important for the formation and cross-linking of the cutin polymers,[18,19] which might account partially for lower total amounts of cutin in cuticles isolated from 'Jesca' fruit (Table 2).

However, results revealed a different evolution of particular compounds after harvest for each of the peach genotypes assessed. The percentages of particular cutin monomer types in 'October Sun' cuticles showed limited changes after shelf life at 20 °C, the only significant variation observed being restricted to an increase in total alkanes, expressed both as the percentage over total cutin (Table 4) and as micrograms per square centimeter of surface area (Figure 2), even though unchanged or even declining levels could also be found for individual compounds. Contrarily, the amount of all of the identified types of cutin monomers increased significantly after harvest when expressed per unit of surface area (Figure 2), which indicates that the involved biochemical pathways were up-regulated during that period. Yet, owing to augmented cuticle yields (Table 2), the amounts of some of these families of cutin compounds were lower than at harvest when expressed as a percentage (Table 4), suggesting that not all of the related processes were enhanced to the same extent.

In conclusion, the composition of cuticular waxes and cutin monomers in cuticles isolated from peach fruit was characterized for the first time in both a melting and a

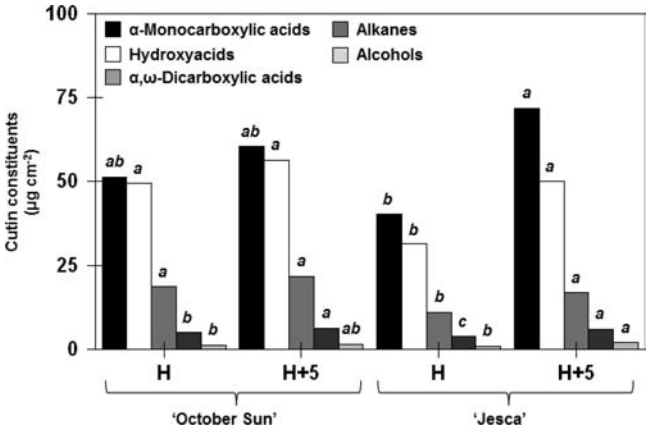

Figure 2. Amount (μg cm^{-2}) of the main types of cutin monomers identified in cuticles of 'October Sun' and 'Jesca' peaches at harvest (H) and after 5 days at 20 °C (H+5). For each type of cutin monomer, values bearing different letters are significantly different at $P \leq 0.05$ (LSD test).

nonmelting cultivar. The triterpenoid ursolic and oleanoic acids and the alkanes *n*-tricosane and *n*-pentacosane were quantitatively prominent among the wax compounds identified, whereas cutin composition was dominated by the C_{18} monomer type. Some quantitative differences in the abundance of particular components were observed between the cuticles isolated from 'October Sun' and 'Jesca' peaches at harvest, but postharvest modifications in cuticle composition were more intense in 'Jesca'. The question arises whether this aspect may relate to the different ethylene production rates observed in each case (Table 1). A few published studies have provided evidence that the composition of cuticular waxes may be an ethylene-associated attribute in some fruit species. For example, 1-MCP treatment of 'Red Fuji', 'Autumn Gold', and 'Royal Gala' apples largely attenuated the quantitative changes observed after long-term cold storage in the contents of particular wax constituents required for the formation of cuticular wax crystals.[20,21] Accordingly, ethylene treatment of 'Navelate' orange fruit increased the content of epicuticular waxes and caused surface structural changes during shelf life at 22 °C.[22] To the best of our knowledge, this is the first study characterizing the composition of the cuticle of peach fruit and describing the changes therein after harvest. Further work focusing on these modifications in response to different factors will be required for a deeper understanding of the physiological consequences of these compositional changes and of their influence on quality attributes of peach fruit.

spectroscopy in conjunction with high-throughput data analysis. Our aims are to understand (1) the metabolic phenotype modulation in crabs responding to low-salinity exposure and (2) the physiological advantages caused by low-salinity training.

MATERIALS AND METHODS

Chemicals and Reagents. Methanol, sodium chloride, $K_2HPO_4\cdot 3H_2O$, and $NaH_2PO_4\cdot 2H_2O$ (all of analytical grade) were purchased from Sinopharm Chemical Co., Ltd. (Shanghai, China), and sodium azide was bought from Fuchen Chemical Reagent Co. (Tianjin, China). Sodium 3-trimethylsilyl [2,2,3,3-$^2D_4$]propionate (TSP-d_4) and deuterated water (D_2O, 99.9% D) were obtained from Cambridge Isotope Laboratories, Inc. (Tewksbury, MA, USA).

Animals and Sample Treatment. Larvae of *P. trituberculatus* (about 3.0 g) from a commercial farm in Xiangshan, China, were put into a salinity of 4‰ for 72 h for natural selection. The surviving individuals were collected and named the screened group (SG). The larvae crabs having no experience in low salinity were named the wild group (WG). All of the crabs were fed frozen fish once daily at 5:00–6:00 p.m. For the low-salinity tolerance study, 30 SG crabs and 30 WG crabs with average weight of 65.3 ± 5.2 g per individual were exposed to 4‰ salinity stress. Six crabs of each group were sacrificed following the sample collection at time points of 0, 12, 24, 48, and 72 h, respectively. The muscle tissue of each crab was immediately collected, homogenized, and snap-frozen in liquid nitrogen and stored at −80 °C until metabonomic analysis.

Metabolite Extraction of Crab Muscle. Each of the muscle samples (200 mg) was homogenized in 1 mL of ice-cold H_2O/methanol (1:2 v/v) extraction solution followed by sonification on wet ice for 150 cycles with each cycle consisting of a 2 s sonication and a 2 s break. Supernatant for each sample was collected respectively after 10 min of centrifugation (12000 rpm, 4 °C). The remaining solid residues of each sample were further extracted once using the above extraction procedure. After centrifugation for 10 min (12000 rpm and 4 °C), the resultant two supernatants were combined and lyophilized following removal of methanol in vacuo. The extracts were then reconstituted into 600 μL of phosphate buffer (0.1 M K_2HPO_4/NaH_2PO_4, 0.1% NaN_3, 0.005% TSP, 100% D_2O, pH 7.4). Following centrifugation, 550 μL of the supernatant from each extract was transferred into a 5 mm NMR tube for NMR analysis.

NMR Spectroscopic Analysis. All of ^{1}H NMR spectra of muscle extracts were acquired at 298 K on a Bruker Avance III 600 MHz spectrometer, operating at 600.13 MHz for ^{1}H equipped with an inverse cryogenic probe (Bruker Biospin, Germany). For all of the extracts, a standard water-suppressed ^{1}H NMR spectrum named NOESYGPPR1D pulse sequence (recycle delay−G_1−90°−t_1−90°−t_m−G_2−90°−acquisition) was recorded with recycle delay of 2 s, t_1 of 3 ms and t_m of 100 ms. Meanwhile, the 90° pulse length was adjusted to approximately 10 μs, and 64 transients were collected into 32 K data points for each spectrum with a spectral width of 20 ppm.

For NMR signal assignment purposes, a series of two-dimensional NMR spectra were acquired for selected samples and processed according to a previously reported method, including ^{1}H−^{1}H correlation spectroscopy (COSY), ^{1}H−^{1}H total correlation spectroscopy (TOCSY), ^{1}H−^{13}C heteronuclear single-quantum correlation (HSQC), and ^{1}H−^{13}C heteronuclear multiple-bond correlation spectra (HMBC).[26,27]

NMR Data Processing and Multivariate Data Analysis. All free induction decays were multiplied by an exponential function with a line-broadening factor of 1 Hz and zero-filled to 128 K prior to Fourier transformation. After manual phase- and baseline correction with the chemical shift referenced to TSP as δ 0.00, all ^{1}H NMR spectra (δ 0.7–9.5) without residual water signals δ 4.70–5.15 were integrated into regions with equal widths of 0.004 ppm (2.4 Hz). All of the integral regions were normalized to wet weight of muscle for each spectrum to compensate for the overall concentration differences prior to the multivariate data analysis.

Multivariate data analysis was performed with the software package SIMCA-P$^+$ (12.0, Umetrics, Umea, Sweden). Principal component analysis (PCA) was carried out using the mean-centered NMR data to obtain an overview of group clustering and search for possible outliers. Subsequently, orthogonal projection to latent structure discriminant analysis (OPLS-DA) was conducted with six-fold cross-validation using the unit-variance scaled NMR data as *X*-matrix and the group information as *Y*-matrix. All OPLS-DA models were validated by CV-ANOVA approach with $p < 0.05$ as the significant level.[28] The coefficient plots of OPLS-DA models were displayed to show changed metabolites at different post-treatment time points in both WG and SG crabs against their levels at 0 h. A cutoff value of 0.755 was used in the present study, and the metabolites with $r > 0.755$ or $r < -0.755$ were considered to be statistically significant ($p < 0.05$).

Univariate Data Analysis. The selected metabolites with significant difference at different time points of post-treatment obtained from multivariate data analysis were further analyzed with Student's *t* test (if criteria met) or nonparametric tests. The concentration of these metabolites was calculated by the integral of least-overlapping NMR signals for those metabolites as described previously,[29] using SPSS 13.0 software (SPSS, Chicago, IL, USA). To illustrate the dynamic metabolite changes induced by low-salinity

dx.doi.org/10.1021/jf405668a | J. Agric. Food Chem. 2014, 62, 3496−3503

challenge, the ratio for metabolite concentrations in both WG and SG crabs at different time points of post-treatment were also calculated as previously described[20,30] in the form of $(C_T - C_0)/C_0$, where C_T denotes the concentration of metabolite at the time point of post-treatment and C_0 denotes the concentration of metabolite at 0 h.

RESULTS

Metabolites in the Crab Muscle Extracts. Figure 1 shows representative 600 MHz ^{1}H NMR spectra of muscle extracts obtained from WG and SG crabs. Both ^{1}H and ^{13}C NMR resonances for detectable metabolites were assigned according to the published results[25] and further confirmed by a series of 2D NMR spectra including COSY, TOCSY, HSQC, and HMBC. The detectable metabolites of muscle extracts include a range of amino acids, sugars, carboxylic acids, trimethylamine-*N*-oxide (TMAO), betaine, and nucleotides (Supporting Information Table S1). To obtain more details on the metabolite alterations induced by low-salinity stress, multivariate data analysis and univariate data analysis were conducted on these NMR data.

Metabolite Alterations Induced by Low-Salinity Exposure. To summarize the similarities and differences between low-salinity-induced metabolic phenotypes in WG and SG crabs, the mean PCA metabolic trajectories for each crab group were plotted in the first two principal components (Figure 2). Clearly, both WG and SG crabs presented a similar

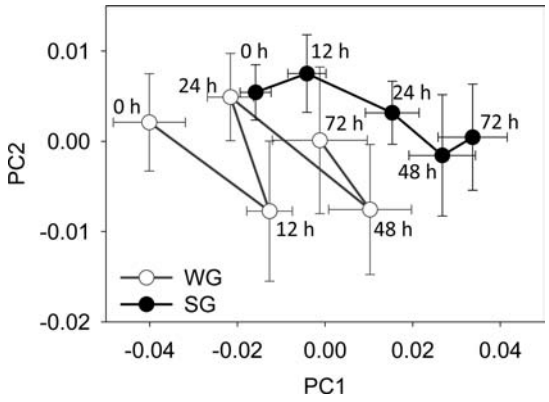

Figure 2. PCA trajectories generated from muscle extract profiles obtained from WG and SG as a function of low-salinity exposure.

tendency of metabolic alteration in response to low-salinity stress. However, the metabolic responses of SG crabs to low-salinity stress exhibited a more direct shift of metabolic profiles than WG crabs during the 72 h treatment.

The PCA scores plots of the ^{1}H NMR spectral data also revealed a clear difference of metabonome at each time point of post-treatment compared to 0 h in both WG and SG crabs (Supporting Information Figure S1). The metabolite alterations in WG and SG induced by low salinity were extracted using OPLS-DA models with R^2X and Q^2, which indicate the quality of these models. The validity of each OPLS-DA model was further evaluated with the CV-ANOVA approach ($p < 0.05$). OPLS-DA loadings plots were obtained to show the metabolites in muscle extracts from WG and SG crabs exposed to low salinity at different time points of 12, 24, 48, and 72 h against their levels of 0 h, respectively. Although the Q^2 of each OPLS-DA model in our present study was >0.5, only two of the models for SG passed the rigorous test of CV-ANOVA. These two models and their corresponding OPLS-DA coefficient plots are illustrated in Figure 3. The dynamic changes of representative metabolites in two *P. trituberculatus* strains exposed to low salinity at different time points of post-treatment are shown in Figure 4. Their corresponding correlation coefficients, which are above the cutoff value, 0.755, are listed in Table S2 in the Supporting Information.

To ensure the reliability of the obtained results, the selected metabolites were further studied using univariate data analysis. Our results showed that most alterations in the metabolite levels were in agreement with those from multivariate data analysis. Interestingly, the alterations of some metabolites previously shown to be nonsignificant in multivariate data analysis presented a significant difference at the level of $p < 0.05$. As an example, an increase in the ATP levels of WG crabs was significant from 2.05 ± 0.54 mg/g crab muscle at 0 h to 4.97 ± 1.47 mg/g crab muscle at 12 h ($p = 0.003$), 5.67 ± 1.37 mg/g crab muscle at 48 h ($p = 0.001$), and 3.76 ± 0.79 mg/g crab muscle at 72 h ($p = 0.001$) (Table 1 and Table S3 in the Supporting Information). Moreover, a significant elevation in the ATP levels of SG crabs was also observed from 2.49 ± 0.17 mg/g crab muscle at 0 h to 4.75 ± 1.17 mg/g crab muscle at 12 h ($p = 0.001$) and 3.42 ± 0.43 mg/g crab muscle at 24 h ($p = 0.001$) based on the univariate data analysis.

For WG crabs, 12 h of low-salinity exposure resulted in significantly reduced levels of inosine and a range of amino acids, including valine, isoleucine, leucine, alanine, histidine, and glutamine, accompanied by drastically elevated levels of trigonelline and ATP. The 24 h low-salinity challenge merely led to significantly decreased levels of succinate and inosine, as well as more amino acids including valine, isoleucine, leucine, alanine, methionine, glutamate, glutamine, lysine, histidine, tyrosine, and phenylalanine. When WG crabs were exposed to low salinity for 48 h, the levels of trigonelline, TMAO, and ATP were markedly increased, whereas the levels of valine, isoleucine, leucine, alanine, glutamine, histidine, and inosine were greatly decreased. At 72 h, crabs presented dramatically elevated metabolites including inosine, 2-pyridinemethanol (2-PM), trigonelline, TMAO, and ATP along with significantly reduced metabolites including valine, leucine, alanine, methionine, and glutamine at all time points of low-salinity treatment. Conversely, low salinity caused more extensive alterations of metabolites in SG crabs relative to WG crabs. At 12 h, the levels of alanine, histidine, and inosine were significantly decreased, whereas the levels of 2-PM, trigonelline, and ATP were remarkably increased in the low-salinity-exposed SG crabs. At 24 h, SG crabs exhibited a significant decrease in the levels of inosine and a range of amino acids including valine, isoleucine, leucine, alanine, methionine, glutamate, glutamine, succinate, lysine, histidine, tyrosine, and phenylalanine accompanied with a dramatic increase in the levels of 2-PM and ATP. Similar changes of metabolites occurred at 48 h, but trigonelline and TMAO were significantly elevated instead of glutamate, lysine, and succinate, for which significant alterations were detected in 24 h low-salinity-exposed SG crabs. At 72 h, a significant elevation in the levels of 2-PM, trigonelline, and TMAO was observed in low-salinity-exposed SG crabs, together with a remarkable decline in the levels of a range of amino acids, including valine, isoleucine, leucine, alanine, methionine, glutamate, glutamine, histidine, tyrosine, and phenylalanine.

The dynamic metabolite changes due to low-salinity exposure by calculating the concentration changes for those metabolites with significant differences (Table 1) are illustrated in Figure 5. A range of amino acids responded vigorously after

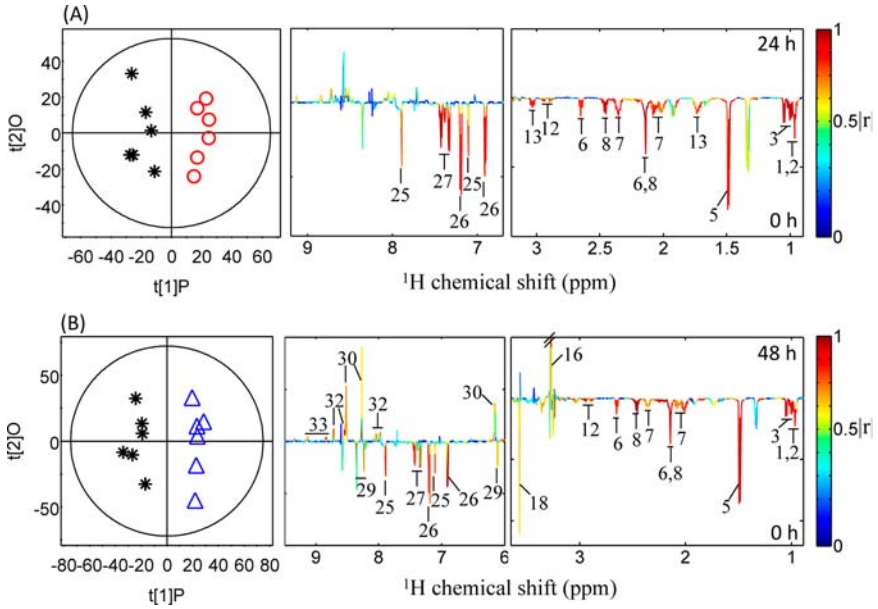

Figure 3. OPLS-DA scores plots (left) and corresponding color-coded correlation coefficient loadings plots (right) generated by comparisons between muscle extract spectra of SG at 0 h (black star) and those from SG exposed to low salinity at the time points of 24 h (red circle) and 48 h (blue open triangle), respectively. These models are cross-validated with CV-ANOVA, $p = 1.60 \times 10^{-2}$ and $p = 6.59 \times 10^{-3}$, respectively. Metabolite keys to the numbers are shown in Figure 1 and the Supporting Information Table S1.

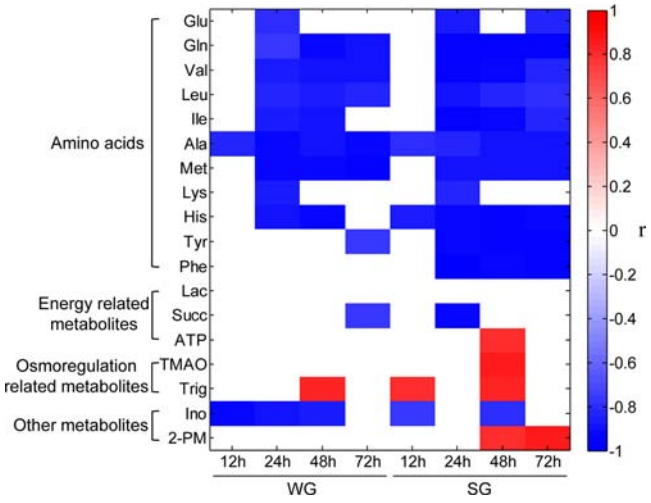

Figure 4. Dynamic alterations of key muscle extract metabolites in response to low-salinity exposure to WG (left) and SG (right). The color indicates a correction coefficient as scaled on the right-hand side. The warm colors (e.g., red) denote an increase in the level of metabolites at the time points of 12, 24, 48, and 72 h against the level of 0 h exposed to low salinity, respectively, and the cool colors (e.g., blue) indicate a decrease. Glu, glutamate; Gln, glutamine; Val, valine; Leu, leucine; Ile, isoleucine; Ala, alanine; Met, methionine; Lys; lysine; His, histidine; Tyr, tyrosine; Phe, phenylalanine; Lac, lactate; Succ, succinate; ATP, adenosine triphosphate; TMAO, trimethylamine-*N*-oxide; Trig, trigonelline; Ino, inosine; 2-PM, 2-pyridinemethanol.

low-salinity exposure. For example, the levels of valine, leucine, alanine, and glutamine declined throughout the post-treatment in WG crabs. Different from these amino acids, the inosine level fluctuated with a 47% decrease before the first 48 h of low-salinity challenge and a 35% increase at 72 h for both WG and SG crabs. In addition, the level of ATP dramatically increased about 180% at 48 h against the level of 0 h in both WG and SG crabs. Interestingly, we noted that the concentration ratio of 2-PM changed significantly in SG crabs throughout low-salinity exposure with the highest increase up to 170% at 48 h of low-salinity exposure against the level of 0 h, whereas it changed dramatically at 72 h in WG crabs. It is also worthwhile noting that the level of trigonelline increased for 35−67% in SG crabs but only 4−37% in WG crabs after low-salinity exposure.

DISCUSSION

This study showed the dynamic metabolic responses of two *P. trituberculatus* strains to low-salinity stress. We found that low-salinity exposure resulted in essential metabolic changes involving many pathways including osmoregulation, gluconeogenesis, and energy production (Figure 6). The SG crabs presented a quicker metabolic modulation in response to low-salinity exposure compared to WG crabs. Such differential characterization might result from low-salinity training, which determines their different abilities to adapt and acclimate to low salinity.

Osmotic Rebalancing. In this study, we observed a significant elevation in the level of TMAO in both WG and SG crabs after 48 h of low-salinity stress (Figure 3; Table 1). It has been well documented that TMAO functions as a ubiquitous compatible osmolyte in marine crustraceans.[31] Our observations suggest that low-salinity stress can cause a disturbance in the osmotic homeostasis in two crab groups. TMAO accumulation may contribute to the rebalance of the osmotic equilibrium. Moreover, a significant elevation in the trigonelline (nicotinic acid betaine) level compared to controls was also observed in muscle tissue extracts of WG and SG crabs exposed to low salinity (Figure 3; Table 1). This quaternary ammonium compound is a methylated product of nicotinic acid (vitamin B_3)[32] and has been reported to function as a compatible osmolyte or an osmoprotectant on enzymes when animals and plants are subjected to salinity and water deficit stress.[33−38] Interestingly, the increased trigonelline accumulation has been found in muscle tissue extracts of green shore crab *Carcinus maenas* exposed to the two highest seawater CO_2

[a]Average concentration and standard deviation (mean ± SD, mg/g crab muscle) were obtained from six parallel samples. Significance when compared with 0 h: *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$. [b]ATP, adenosine triphosphate; TMAO, trimethylamine-*N*-oxide; 2-PM, 2-pyridinemethanol.

levels.[39] Taken together, trigonelline may play a role in rebalancing the osmotic pressures for low-salinity adaptation and acclimation of *P. trituberculatus*. This osmotic rebalance is also supported by a previous study in which membrane fluidity, lipid composition, fatty acid concentration, and intra/extracellular ion concentration were significantly changed in estuarine mud crabs in response to salinity stress.[40] It is further supported by another previous investigation on increased level of total phospholipids of posterior gills when crab *Eriocheir sinensis* was acclimated in a low-salinity challenge.[41]

In addition, we note that low-salinity-trained SG crabs contain a higher concentration of TMAO than WG crabs, especially highlighted at 24 h with an approximate 45% higher than that in SG crabs (Table 1). Such difference in the TMAO concentration between two crab groups might result from the low-salinity training. It is possible that SG crabs can obtain far-reaching metabolic alterations and gain swifter response to low salinity than WG crabs. In fact, a PCA trajectory plot (Figure 2) clearly indicates the distinctive feature of metabolite alterations in SG crabs. It also implies a trend of metabolic changes in WG crabs toward SG crabs. Our observations are in broad agreement with previous findings in which heat hardening accelerates the reestablishment of metabolite homeostasis in *Drosophila melanogaster*.[42]

Gluconeogenesis from Amino Acids and Energy Accumulation. Another prominent finding is a rise in the ATP level in the crab muscle after low-salinity stress (Figure 3; Table 1). Consistently, an increase in energy production for ion transportation has been observed in *Callinectes sapidus* and *Callinectes similis* exposed to low salinity.[43] ATP can be produced by three main pathways including glycolysis, respiration, and β-oxidation. In glycolysis, glucose is metabo-

dx.doi.org/10.1021/jf405668a | J. Agric. Food Chem. 2014, 62, 3496−3503

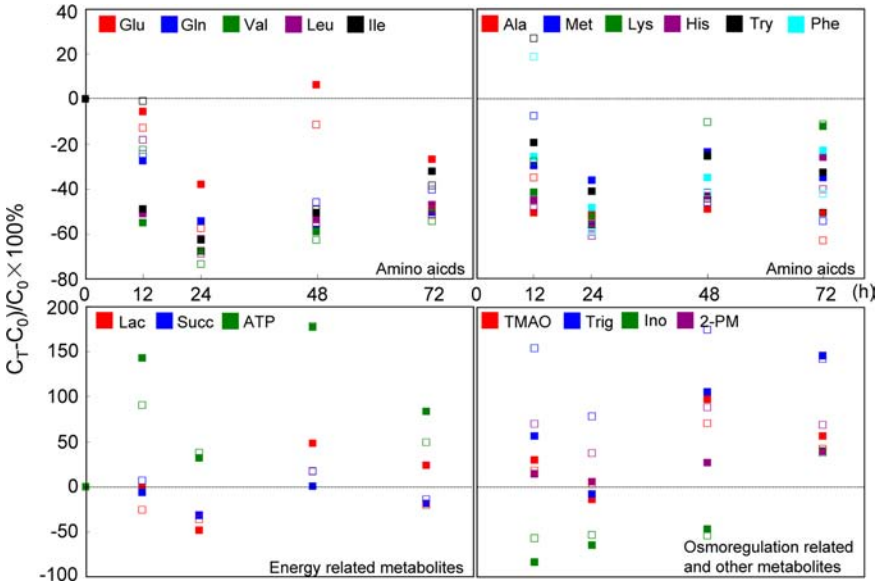

Figure 5. Dynamic changes of muscle metabolites as a function of low-salinity stress. The empty symbols represent SG crabs, whereas the solid ones represent WG crabs.

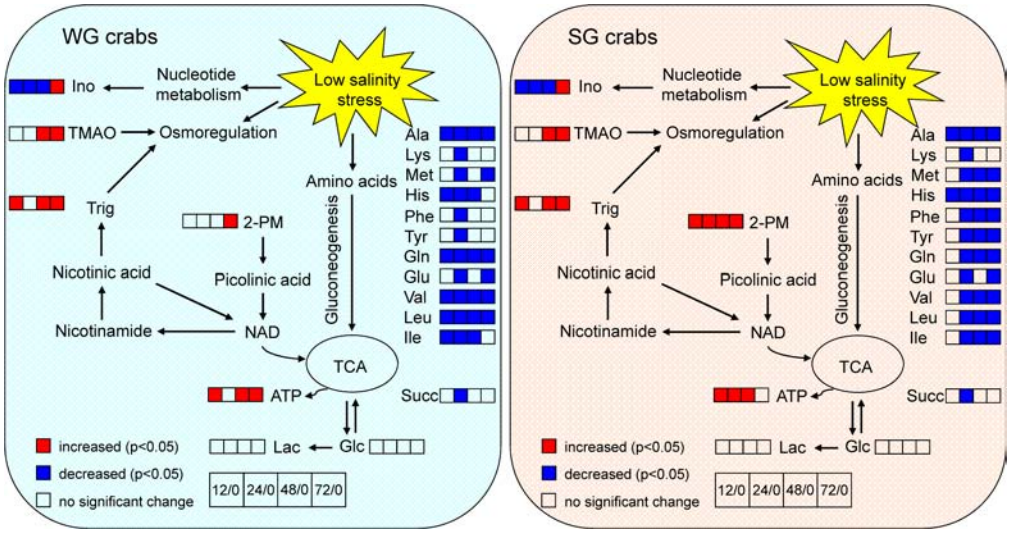

Figure 6. Summary of dynamic metabolic responses of WG and SG crabs to low-salinity exposure. Metabolites with red or blue boxes represent significant increases or decreases in levels, respectively, at the significance level of $p < 0.05$ at this time point against the level at 0 h. NAD, nicotinamide adenine dinucleotide; TCA, tricarboxylic acid.

lized to pyruvate and the latter is a substrate for the tricarboxylic acid (TCA) cycle and anaerobic respiration. Intriguingly, no significant alteration in the levels of glucose was caused by low salinity in crabs in this study. However, we noted a pronounced depletion of the amino acid pool in low-salinity-exposed crabs, which has also been observed in crab muscle and hepatopancreas responding to low-salinity challenge.[15] It is known that most amino acids are glucogenic amino acids, which can be converted into glucose through gluconeogenesis, thus likely replenishing the consumption of glucose in the ATP production in our study. This notion is consistent with previous findings of enhanced production of glucose by gluconeogenesis in the hepatopancreas of crab *Chasmagnathus granulata* in response to low-salinity challenge.[44] Moreover, gluconeogenesis promotion is concomitant with the decreased level of succinate (Table 1),[23] which is also in agreement with our observation in low-salinity-stressed crabs. However, we cannot exclude the responsibility of β-oxidation of fatty acid for the elevated level of ATP due to low salinity because lipids seem to be the major source of energy in crustaceans[45] and have previously been found significantly lower in gill and muscle of crabs subjected to hypo-osmotic stress.[16,45]

Similarly to the TMAO alteration, the more significantly accumulated ATP and depleted amino acid pool in SG crabs relative to WG crabs indicate low-salinity training enabled crabs to develop an ability for more extensive metabolic modulation (Table 1).

Other Metabolic Changes. The inosine was noted to be markedly decreased in both WG and SG crabs during the first 48 h of low-salinity challenge but remarkably increased at 72 h. This nucleotide is involved in the nucleotide metabolism. The significant fluctuation in the inosine levels may result from the altered NAD cycle activity induced by low salinity.

dx.doi.org/10.1021/jf405668a | J. Agric. Food Chem. 2014, 62, 3496−3503

In addition, we observed a significant 2-PM accumulation in crabs during the low-salinity exposure. Importantly, a faster rise occurred in SG crabs than in WG crabs (Table 1; Figure 5), implying a role during the response of crabs to low salinity. 2-PM is a picolinic acid-related compound that has a growth-simulating effect in rats.[46] It has also been shown to improve the immune system and induce apoptosis in HL-60 cells.[47,48] However, little information exists on the physiological function of 2-PM in marine crustraceans. Future studies should determine the positive role of 2-PM in crabs responding to low salinity.

In this study, we found that the dominant metabolites in crab muscle comprise amino acids, sugars, carboxylic acids, betaine, TMAO, trigonelline, and nucleotides. The strategy of metabolic modulation of *P. trituberculatus* in response to low salinity includes osmotic rebalancing, enhanced gluconeogenesis from amino acids, and energy accumulation. These metabolic adaptions were manifested in the accumulation of TMAO, ATP, 2-PM, and trigonelline and in the depletion of the amino acid pool as well as in the fluctuation of inosine levels. This lends to support to the fact that low-salinity training accelerates the response of crabs to low-salinity stress. These findings provide a comprehensive insight into the mechanisms of metabolic modulation in *P. trituberculatus* in response to low salinity. Our work also highlights the approach of NMR-based metabonomics in conjunction with multivariate data analysis and univariate data analysis in understanding the strategy of metabolic phenotype modulation against stressors.

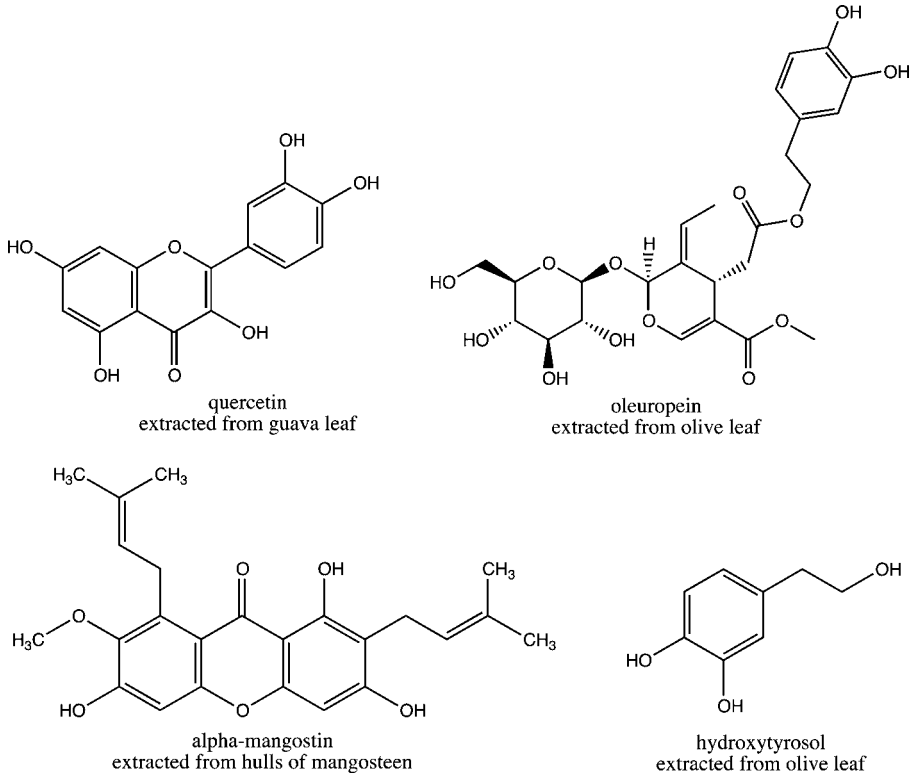

Figure 1. Chemical structures of polyphenols that have been extracted and isolated and found to effectively inhibit adipogenesis via in vitro test on 3T3-L1 preadipocyte cells.

icals that exhibit antioxidant and anti-inflammatory capabilities are also present in the less studied components of the fruits, which includes the rinds, seeds, peels, flowers, and leaves of the fruit. In this paper, the role of these aforementioned components in altering the obesity pathophysiology will be reviewed. Following this, the need for the development of effective fruit waste processing/recycling techniques to effectively tap the maximum potential of tropical fruit waste components as future potential therapeutics will be addressed.

POTENTIAL OF TROPICAL FRUIT WASTE COMPONENTS AS ANTIOBESITY SUPPLEMENTARY TREATMENT

Multiple studies have shown that phytochemical compounds present in tropical fruits possess the ability to inhibit adipogenesis and essentially may offer a suitable therapy against obesity.[7,16,17] These phytochemicals could work as fatty acid synthase (FAS) inhibitors, preventing the formation of fatty acids and their accumulation in the body.[18] Alternatively, they may inhibit the differentiation of preadipocytes to adipocytes (adipogenesis).[10,19,20] Tropical fruits are rich in a diverse array of bioactive phytochemicals that can do so.[21,22] Among the bioactive phytochemical compounds in tropical fruits, quercetin[20] and hydroxytyrosol and oleuropein[16] (Figure 1) are some of the well-known polyphenols that have been identified and found to effectively inhibit adipogenesis in vitro, via the different mechanistic pathways mentioned. Interestingly, these bioactive phytochemicals have recently been discovered to be present in the inedible or waste components of the tropical fruit parts.[17,23,24] In addition, a series of comparative studies have found that the extracts of these "fruit waste components" have higher polyphenol content than the main flesh, thereby making them a potentially more prospective therapeutic source for further studies.[19,25,26]

Ideally, with enough studies to support their antiobesity capabilities, the idea of utilizing these waste components as potential therapeutics will not only help to supplement more alternatives for antiobesity treatment but also potentially reduce environmental concern as this simultaneously offers a solution to reduce landfill waste problems as well.

TROPICAL FRUIT WASTE COMPONENTS AND THEIR BIODEFENSIVE POTENTIAL AS ANTIOBESITY THERAPEUTICS

Different components of tropical fruit wastes, mainly the seeds, flowers, and leaves as well as rinds, have been found to successfully regulate lipid accumulation. This section introduces these previous discoveries brought by the scientific community in the pursuit of novel phytochemical-based antiobesity therapeutics. Various methods have been developed to identify and analyze the qualitative and quantitative occurrence of bioactive compounds in the fruit waste extracts (Table 1) such as normal phase silica gel column chromatography, reversed phase high-performance liquid chromatography (HPLC), liquid chromatography–mass spectrometry (LC-MS), HPLC-linked with photodiode array detector (HPLC-PDA), and the sophisticated methods involving electrospray ionization tandem mass spectrometry (ESI-MS).

Seeds. Although some seeds may be edible such as those of corn and nuts, the majority of the tropical fruit seeds are inedible and are often discarded after consumption of the fruit. Phytochemicals present within these seeds have been found to exhibit properties that are capable of preventing oxidative stress, a process linked to being overweight and to the onset of diseases including diabetes.[17]

Avocado Seeds (Persea americana Mill). Avocado seeds (*P. americana* Mill) have been found to contain elevated levels of phenolic compounds and exhibit antioxidant properties.[17,27] The seed, which is inedible, represents the majority bulk of the fruit that is often discarded. In an experimental study conducted by Gu et al. on a variety of avocado cultivars, it was found that seeds contained the highest antioxidant capacities, phenolic content, and procyanidins, whereas the pulp had the lowest. A series of compounds were identified in peels and seeds using a normal-phase HPLC-ESI-MS analytical technique including catechin, epicatechin, A- and B-type dimers, trimers, tetramers, pentamers, and hexamers. On the basis of the close correlations and further in vitro analysis between the total phenolic content in the avocado and the antioxidant capacities, the study concluded that procyanidins were the major phenolic compounds that contributed to this effect.[27]

In a separate in vivo experimental model reported by Pahua-Ramos et al. using a hypercholesterolemia mouse, treatment with avocado seed flour (ASF) was reported to drastically reduce the levels of total cholesterol, low-density lipoprotein cholesterol (LDL-C), and atherogenic index. This effect could be attributed to the phenolic content, antioxidant activity, and/or dietary and crude fiber content of the seed. Further analysis of the chemical composition of the ASF using HPLC-PDA found that protocatechuic acid was the major phenolic compound identified in ASF to contribute to the overall hypolipidemic effect on the in vivo model.[17] Such differences in the major phenolic compounds contributing to the different bioactive effects on experimental models as reported by the above studies highlight the wide array of potential therapeutic capabilities that avocado seeds may possess.

The various chemical compositions of phytochemical compounds identified in avocado seeds as reported by Rodriguez-Carpena et al. that include catechins (sum of catechin and epicatechin), hydroxycinnamic acids (*p*-hydroxybenzoic, protocatechuic, vanillic, syringic, and gallic), and procyanidins[28] implied that therapeutic effects exhibited by avocado seed extracts in both in vivo and in vitro experimental model could be due to a collective effect of several phenolic compounds acting together. This further suggests that a study involving the isolation of such compounds from these seed extracts, and testing its individual effects on various biological activities would therefore be useful to understand this phenomenon. The overall in vitro and in vivo experimental models have indicated how avocado seeds, typically regarded as industrial wastes during avocado processing, do have therapeutic properties that can potentially be exploited as a future source of alternative remedy. Phenolic compounds present within the seed have been hypothesized to be responsible for the antioxidant capacities and hypolipidemic effect observed. However, studies involving the isolation of the individual bioactive compounds on the overall lipid regulation effect are still understudied.

Hunteria umbellata (HU) Seeds. Traditionally, *HU* seeds have been widely used for the local management of obesity, diabetes, and hyperlipidemia among the Nigerian folk medicine community.[29,30] Understanding the dearth of scientific reports on the therapeutic potential of this plant, particularly in the management of obesity and hyperlipidemia, Adeneye et al. investigated its respective effects via in vivo experimental models (i.e., rats). These rats included normal, olive-induced hyperlipidemic, and Triton-induced hyperlipidemic rats. In their study, they found that with dose-dependent dosage of

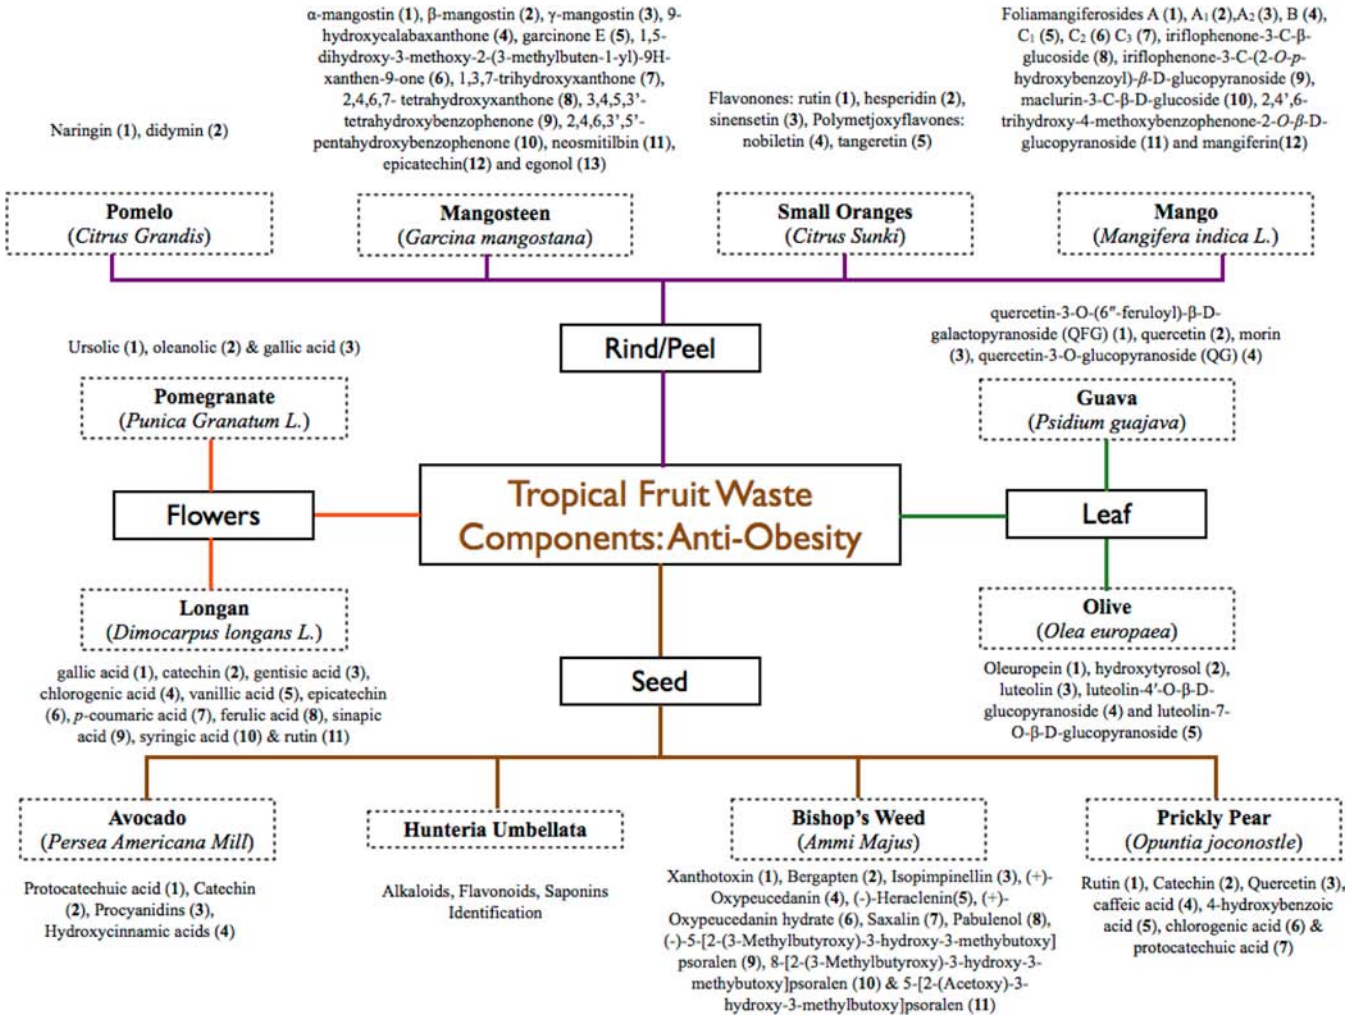

Figure 2. Summary of some examples of tropical fruit waste components that have been experimentally found to possess special properties in their extract that may potentially be used to treat obesity and its associated diseases through its ability to regulate lipid accumulation in living cells.

aqueous seed extract *HU*, reductions of weight gain pattern and levels of serum lipids, adiposity (measured using Lee's index), and coronary artery risk index (represents the ratio of LDL-c to HDL-c and antherogenic indices (AI), ratio of total cholesterol to HDL-c) were observed. Their assessment of the histopathological effect of hepatic fatty degeneration on the test rat's liver further revealed the biochemical evidence of the antihypertriglyceridemic and hypocholesterolemic activities of *HU*.[31] With prior identification of primary phytochemical compounds present in the extract that mainly consist of alkaloids, flavonoids, and saponins,[29,32] the author concluded that the antiobesity and antihyperlipidemic effects observed were likely mediated via inhibition of intestinal lipid absorption and de novo triglyceride and cholesterol biosynthesis. This conclusion was collectively made in close reference to several other studies done by Schoenfelder et al. as well as Han et al. that highlight phytocomponents', such as saponins', capacity to increase intestinal absorption of dietary lipid bioactivity, respectively.[33,34] The isolation of bioactive compounds from this crude seed extract, however, has yet to be done.

Bishop's Weed (Ammi majus) Seeds. Among some of the lesser known species would be *A. majus* that is typically grown in Egypt. The initial study of this species of seed was inspired from its common use in folk medicine to treat various ailments such as vitiligo.[35] Koriem et al. used an in vivo experimental model, particularly on albino rats, to evaluate the antihyperlipidemic, anti-inflammatory, and analgesic as well as antipyretic activities of the extract. In their study, they discovered that the administration of alcoholic *A. majus* seed extract resulted in a significant decrease in concentrations of cholesterol, triglycerides, and LDL as well as an increase in HDL in a dose-dependent manner. The aforementioned results therefore suggested positive antihyperlipidemic, anti-inflammatory, analgesic, and antipyretic effects of the seed extract.[36] Although the study did not isolate the chemical compounds responsible for the respective effects mentioned, 12 furocoumarins that may be responsible for the aforementioned effects were identified. The identification of these 12 furocoumarins (Figure 2) was in line with several other studies previously done on the same species.[37,38] Further studies involving the isolation of the furocoumarins along with other compounds is required to further investigate the mechanistic angle of the respective effects addressed.

Prickly Pear Seeds (Opuntia joconostle). The prickly pear (*O. joconostle*) is a species in the cactus family, Cactaceae, that grows widely in North American deserts, mainly in the southwestern part of the United States, Mexico, and Canada. High antioxidant activities of different parts of prickly pear have been reported (62.96% in pericarp, 42.27% in mesocarp, and 51.70% in endocarp) and are related to phenolic and flavonoid

composition.[7] This content was found to be especially higher in seeds than in peel (23-fold), mesocarp (34-fold), and endocarp (47-fold).[39] Clinical studies have reported that consumption of the *O. joconostle* pericarp may reduce glucose and cholesterol levels and modify LDL-C levels in patients with both type 1 and 2 diabetes.[7] In addition to these papers, a study reporting the influence of the *O. jocostle* seed methanolic extract on the plasma lipid profile in mouse models showed that the seed extract was also able to prevent an increase in total cholesterol, LDL-C, triglyceride level, and atherogenic index. Of the seven polyphenol compounds identified in the fruit component via the HPLC-PDA analytical system (Figure 2), the study concluded that the observable effects were believed to be caused by the flavonoids present in the seed, specifically quercetin, rutin, and catechin. It possibly occurs through the up-regulation of LDL receptor expression and inhibition of hepatic lipid synthesis and lipoprotein secretion, thereby enhancing cholesterol elimination through bile acids.[40]

Overall, the ability of the methanolic extract of prickly pear seeds to exhibit hypolipidemic activity with no apparent toxic manifestations suggests that this could be an ideal supplement to short-term hypercholesterolemia treatment. Such seed extracts from *P. americana*, *H. umbellata*, *A. majus*, and *O. joconostle* could potentially be used as future antiobesity therapeutics in the long run with the development of a proper processing and extraction technique for these seed components.

Flowers. The flower is a structure specialized for sexual reproduction. Many flowers have evolved traits such as brightly colored petals and attractive chemical scents to attract pollinators. In addition to facilitating the reproduction of flowering plants, the polyphenols, flavonoids, and anthocyanin present in flowers have recently been discovered to potentially exhibit medicinal properties.[41,42] We could gain much from exploring and tapping the antiobesity potential of the phytochemicals that flowers contain as some studies have shown.

Pomegranate Flower (Punica granatum L.). The pomegranate (*P. granatum* L.) is considered to be one of the oldest known edible fruits and is the symbol of abundance and prosperity in some cultures. The pomegranate has been known to be a fruit of multiple health purposes for many centuries. Recently, there has been scientific evidence suggesting the therapeutic activity observed in pomegranate such as antiatherogenic, antioxidant, anticarcinogenic, and anti-inflammatory effects.[41,43,44] These beneficial effects were attributed to the antioxidative properties of pomegranate phenolic compounds, such as tannins and anthocyanin, present in its fruit components.[44]

A series of in vivo and in vitro experimental models using pomegranate flower (PGF) extract have been found to result in hypoglycemic, hypolipidemic, and anti-inflammatory effects in type 2 diabetes, obesity, and related cardiovascular diseases based on its modulation of PPARα- and/or PPARγ-mediated gene transcription. It is hypothesized in a review by Li et al. that the components present in PGF extract were able to promote a dual function activating both PPARα and PPARγ that accounts for the desired bioactivity required for treatment of diseases such as type 2 diabetes and obesity.[45] The biologically active components that have been identified in PGF extract via HPLC methods[46] include gallic, ursolic, and oleanolic acids. In a study done by Jang et al., commercially obtained gallic acid was seen to effectively an exhibit hypolipidemic effect on high fat diet-induced hyperlipidemia mice.[47] Ursolic and oleanolic acids are two triterpenoids that have long been recognized to have significant medicinal properties to the extent that these compounds have been isolated, treated, and marketed in countries such as China as an oral drug for human liver disorders as early as the 1980s.[48] The possible mechanisms for the pharmacological effects and the prospects for these two compounds exhibiting antihyperlipidemia, antitumor activity, and anti-inflammation have also been discussed by Liu et al., suggesting that the presence of these two compounds identified in PGF makes it a potentially useful source not just for antiobesity but other associated diseases as well.[49]

In close relation to this, an in vivo experimental model study of Zucker diabetic fatty (ZDF) rats conducted by Li et al. showed that the administration of PGF extracts was able to exert a protective effect, preventing the increase in blood glucose level, total cholesterol, triglycerides, LDL-C, and lipid peroxidation levels of infected mice.[41,42] This phenomenon could be explained by the ability of the bioactive components present within PFG extract to enhance the expression of PPARα and acyl-CoA oxidase (ACO) mRNAs as observed in the liver-derived HepG2 cell line.[41] These series of studies thereby highlighted the ability of PGF to ameliorate obesity via a varied series of mechanistic pathways that essentially leads to the decrease of lipid accumulation in liver.

Longan Flower (Dimocarpus longans Lour.). Longan (*D. longans* Lour.) is a tropical tree that produces edible fruit which is widely grown in Myanmar through southern China and Southeast Asia. Unpollinated longan flowers are generally regarded as disposable byproducts. Yang et al. have identified several phenolic acids and flavonoids present in longan flower water extract (LFWE) via HPLC methods running against several commercially available phenolic acid and flavonoid standards, of which gentisic acid, epicatechin, and ferulic acid were among the major compounds identified. The study went on to investigate the effects of administration of LFWE on 9-week-old Sprague−Dawley hypercaloric rats. It was found that LFWE was able to lower the liver cholesterol and triglyceride levels as well as inhibit pancreatic lipase activities by up-regulation of LDL-receptor and PPARα mRNA expression. It was also found to have lowered the rate of lipid biosynthesis via the down-regulation of sterol regulatory element binding protein-1c (SREBP-1c), a critical transcription factor that stimulates several lipogenic enzymes involved in fatty acid biosynthesis, as well as fatty acid synthase (FAS) gene expression.[23]

This observation is further supported by a series of other studies highlighting the similar ability of naturally occurring polyphenols contributing to similar effects.[50,51] Overall, Yang et al. have shown the ability of LFWE to result in antiobesity and hypolipidemic effects via a combined effect of decreased exogenous lipid absorption, normalization of hepatic PPARα gene expression, suppression of pancreatic activity and SREBP-1c and FAS gene expression, and higher fecal triglyceride. Hsieh and colleagues have also demonstrated the role of epicatechin as the major component in longan flowers that promotes antioxidant effects on cells.[52] These series of studies have shown a collectible amount of findings, which significantly indicated the ability of longan flowers to be used as future therapeutics against not just obesity but also a series of other associated diseases.

Leaves. Leaves are organs of the plants where photosynthesis takes place by which captured solar energy is converted into useful chemical energy, which liberates oxygen required for

respiration by living organisms. Besides the photosynthetic roles, leaves also serve as a chemical energy storage point for plants. Tapping this knowledge, several studies have been done to investigate the efficacy of phytochemical compounds present in leaves as potential therapeutics for obesity.

Mango Leaves (Mangifera indica L.). Mango leaves (*M. indica* L.) have proven to be beneficial in alleviating diabetes and inhibiting triglyceride accumulation in 3T3-L1 cells. It is thus a prospective candidate for such tropical fruit waste component to be recycled and used as potential therapeutics for related diseases, namely, diabetes and obesity. In a study conducted by Kumar et al., mangiferin, a bioactive phytochemical component, was extracted and isolated from stem bark of *M. indica* and subjected to a glucose utilization test with 3T3-L1 cells. The results showed that treatment of the 3T3-L1 cells with mangiferin increased the glucose utilization in a dose-dependent manner.[53] Zhang et al. isolated 12 active fractions, as highlighted in Figure 2, via ordinary and reversed phase silica gel column chromatography as well as HPLC from *M. indica* L. leaf extracts and tested each compound against 3T3-L1 cells to monitor their respective effects on gene expression. The study indicated that of the 12 compounds (summarized in Figure 2), foliamangiferoside A, iriflophenone-3-*C*-β-glucoside, iriflophenone-3-*C*-(2-*O*-*p*-hydroxybenzoyl)-β-D-glucopyranoside, maclurin-3-*C*-β-D-glucoside, and mangiferin were able to significantly suppress the accumulation of triglyceride in mature 3T3-L1 cells and inhibit the expression of genes including SREBP1c, FAS, and hormone-sensitive lipase (HSL), all associated with triglyceride biosynthesis.[54]

Olive Leaves (Olea europaea). Several studies have suggested that oleuropein and hydroxytyrosol present in *O. europaea* leaves are the key antioxidants responsible for preventing LDL oxidation and protecting cells against numerous diseases.[55−57] Oleuropein is a principal phenolic compound in olive leaves, which can produce other bioactive substances such as hydroxytyrosol upon hydrolysis. Drira et al. obtained these bioactive compounds commercially to study their respective in vitro inhibition activity on adipocyte differentiation using 3T3-L1 preadipocyte cells. The results showed that oleuropein and hydroxytyrosol dose-dependently suppressed intracellular triglyceride accumulation during adipocyte differentiation without effect on cell viability. PPARγ, C/EBPα, and SREBP-1c transcription factors and their downstream targets (GLUT4, CD36, and FASN), all of which are adipogenesis-related genes, were down-regulated after treatment by oleuropein and hydroxytyrosol. In addition, a flow cytometry study also revealed that both polyphenols were able to inhibit the division of 3T3-L1 preadipocytes during mitotic clonal expansion and cause cell cycle delay. This combinative effect of the bioactive compounds extracted and isolated from olive leaves was observed to collectively result in an overall reduction of lipid accumulation in 3T3-L1 cells and thus regulate the size of fat cells, giving them potential as useful obesity-preventive additives to foods and drinks.[16]

In addition, besides oleuropein and hydroxytyrosol, among other phenolic compounds that were identified in the most recent study conducted by Kontogianni et al. via liquid chromatography−ultraviolet−visible (UV−vis) diode array coupled to electrospray ionization multistage mass spectrometry (LC/DAD/ESI-MS) were luteolin, luteolin-4′-*O*-β-D-glucopyranoside, and luteolin-7-*O*-β-D-glucopyranoside. These compounds were assigned as potent advanced glycation end product (AGE) inhibitors, which may potentially be useful for treatments for associated diseases that include diabetes.[58,59]

Guava Leaves (Psidium guajava). Guava (*P. guajava*) leaves have been used as traditional medicine for various kinds of diseases over centuries.[60] The rich content of antioxidants, antibacterial agents, anti-inflammatory agents, and tannins present in *P. guajava* leaves makes it a medicinally useful tool for traditional remedy. In a recent study, Yang et al. reported that quercetin-3-*O*-(6″-feruloyl)-β-D-galactopyranoside (QFG), an active compound isolated and extracted from *P. guajava* via octadecylsilyl silica gel (ODS) HPLC, has suppressive effects on adipogenesis in 3T3-L1 preadipocytes through down-regulation of PPARγ and C/EBPα expression.[20]

Quercetin is a typical flavonoid proven to play a pivotal role in the prevention of obesity[61,62] and is abundant in guava leaves. It was extracted and its suppressive effects on adipogenesis were compared with QFG. The efficacy of the two respective compounds was analyzed via Oil Red O staining[63] and triglyceride assay. It was found that QFG inhibited adipogenesis in a dose- and time-dependent manner and exerted a stronger suppressive effect than quercetin in all setups. Both mRNA and protein expressions of the key adipogenic transcriptional factors, PPARγ and C/EBPα, were inhibited by QFG. These series of results suggest that both QFG and quercetin present in *P. guajava* leaves were able to effectively suppress adipogenesis.[20] In a separate study, it was also found that quercetin was able to inhibit adipogenesis in 3T3-L1 preadipocytes by adenosine monophosphate kinase (AMPK) and mitogen-activated protein kinase (MAPK) pathways and that the combination of quercetin and resveratrol enhanced the inhibition.[62,64]

Essentially, these series of studies showing the therapeutic capabilities of the major bioactive components identified in guava leaves have certainly shown the potential of such fruit waste components to be used as alternative sources of remedy.

Potential Antidiabetic Properties of Tropical Fruit Leaves. Although this review mainly highlights the key tropical fruits that have been discovered to exhibit antiobesity potential, a series of related diseases that often can be associated with obesity cannot be neglected. A commonly related disease that can be linked with obesity is type 2 diabetes. A review by Kahn et al. discussed how obesity subsequently leads to an increased risk of developing insulin resistance and, consequently, type 2 diabetes. As mentioned, "in obese individuals, adipose tissue releases increased amounts of non-esterified fatty acids, glycerol, hormones, pro-inflammatory cytokines and other factors that are involved in the development of insulin resistance. When insulin resistance is accompanied by dysfunction of pancreatic islet β-cells, failure to control blood glucose levels results. Abnormalities in β-cell function are therefore critical in defining the risk and development of type 2 diabetes."[65]

Understanding how obesity can lead to diabetes via several underlying mechanisms, we will then discuss some examples of tropical fruit leaf components that have been found to exhibit antidiabetic activity. To name some examples, the amla and papaya leaves will be discussed in the following section. There have yet to be studies done on the same component exhibiting antiobesity effects.

Papaya Leaves (Carica papaya). Traditionally, papaya leaves have been widely used in Mexican folk medicine to treat diabetes and inflammation as well as diarrhea.[66,67] In a study done by Juárez-Rojop et al. the hypoglycemic effect of the

aqueous extract of *C. papaya* leaves in streptozotocin-induced diabetic rats was evaluated. It was found that the administration of this extract was able to significantly reduce the blood glucose level in diabetic rats and decrease cholesterol and triacylglycerol as well as amino-transferase blood levels. Additionally, the cell size preservation observed under histological reference of the diabetic rat's pancreas further suggested the ability of *C. papaya* aqueous extract to help in islet regeneration. In the liver histopathological examination, it was further revealed that the aqueous extract was able to prevent hepatocyte disruption, as well as accumulation of glycogen and lipids. On the basis of the collective data gathered from their study, the author confirmed the hypoglycemic effect of *C. papaya* leaves and their ability to prevent further disruption produced by diabetes.[68] However, admittedly, the lack of studies investigating the implicated phytochemical constituents and the exact mechanism of action responsible for the overall positive activity mentioned has yet to be addressed.

Amla Leaves (Emblica officinalis). In traditional Indian medicine, all parts of *E. officinalis* Gaertn. plant including the fruit, seed, leaves, root, bark. and flowers are used in various herbal preparations for the treatment of diabetes mellitus and chronic diarrhea and as an anti-inflammatory and antipyretic. In a study conducted by Nain et al. using in vivo streptozotocin-induced diabetic rats as an experimental model, they discovered that the extract of leaves of *E. officinalis* Gaertn. (HMELEO) was able to effectively normalize the impaired antioxidant status in streptozotocin-induced diabetic rats in a dose-dependent manner. In addition to this, its ability to exert rapid protective effects against lipid peroxidation by scavenging free radicals thereby contributes to the overall reduction in the risk of diabetic complications.[69] Although the study did not isolate or identify the phytochemicals that were responsible for the observed bioactivity, the author cross-linked with a series of previous studies of the same species suggesting that ellagic acid, gallic acid, ascorbic acid, tannins emblicannin A and B, and tannoids kaempferol, kaempferol-3-*O*-glucoside, and rutin may be the bioactive compounds.[70,71]

Rind/Peel. The outer covering of a fruit is known as the peel or rind. However, there is a subtle difference between the rind and the peel. The rind generally is harder and thicker, whereas the peel/skin is generally thin and soft. Rinds, peels, and skins of fruits contain several phytochemicals that can help maintain good health, which is evident in several studies.[18,19,24,72]

Mangosteen Rind (Garcina mangostana). A potentially useful tropical fruit rind that has shown to exhibit antiobesity potentials would be that of the *G. mangostana* fruit. The fruit hulls of *G. mangostana*, just like *P. guajava* leaves, have long been used throughout Southeast Asia as a medical plant for a wide variety of treatments.[73] Modern research has identified and isolated 13 phenolic compounds from the hulls of *G. mangostana* by column chromatography, which are α-mangostin, β-mangostin, γ-mangostin, 9-hydroxycalabaxanthone, garcinone E, 1,5-dihydroxy-3-methoxy-2-(3-methylbut-en-1-yl)-9*H*-xanthen-9-one, 1,3,7-trihydroxyxanthone, 2,4,6,7-tetrahydroxyxanthone, 3,4,5,3′-tetrahydroxybenzophenone, 2,4,6,3′,5′-pentahydroxybenzophenone, neosmitilbin, epicatechin, and egonol.[74]

In an experiment done by Quan et al., it was discovered that among the 13 phenolic compounds isolated,[74] α-mangostin induced apoptosis and suppressed differentiation of 3T3-L1 cells through inhibition of fatty acid synthase (FAS). Further Oil Red O staining tests showed that it was able to prevent the intracellular lipid accumulation of the differentiating adipocytes and that it stimulated fat cell breakdown in the mature adipocytes.[18] Loftus et al. highlighted how central inhibition of FAS suppressed food intake and led to dramatic weight loss in mice.[75] It is believed that natural sources of nutraceuticals that are capable of reducing FAS activity or expression levels may be useful for the supplementary treatment of obesity. Among the 13 phenolic compounds present in the hulls of *G. mangostana* (Figure 2), it was found that phenolic constituents containing the conjugated system of phenyl and carbonyl, especially xanthones and benzophenones, particularly α-mangostin, γ-mangostin, garcinone E, and 2,4,6,3′,5′-pentahydroxybenzophenone, exhibited the strongest inhibitory activity of FAS.[74]

These series of findings suggesting the ability of isolated components extracted from the hulls of mangosteen fruit, namely, α-mangostin, to induce apoptosis of 3T3-L1 preadipocytes that consequently suppressed lipid accumulation as well as α-mangostin, γ-mangostin, garcinone E, and 2,4,6,3′,5′-pentahydroxybenzophenone exhibiting strong inhibitory activity of FAS, certainly highlights the great potential of this fruit component to be exploited and used to treat obesity.

Citrus Genus Peel (C. sunki, C. reticulata, C. grandis, C. aurantifolia). Over the past years, a series of studies have been done on the *Citrus* family. Whereas the flesh itself has been widely known to contain antioxidants and weight -loss properties,[76] the peels of a few species were recently discovered to exhibit a wide range of biological activities, including antioxidative, antihypertension, antihyperglycemia, and anti-obesity effects.[77−79] Among the species identified include the peels of *C. sunki*, *C. ichangenesis*, and *C. grandis*. These potentially health-promoting effects observed from the citrus components have been ascribed to the bioactive compounds present such as flavanoids, coumarins, polyphenols, limonoids, and alkaloids.

The immature *C. sunki* peel extract as recently discussed by Kang et al. was found to exhibit antiobesity effects by β-oxidation and lipolysis in adipose tissue.[77] The study was based on an in vivo experimental model of which controlled dosage of *C. sunki* extract was administered to high fat diet-induced obese mice, and their respective liver, epididymal tissue, and perirenal adipose tissue were regularly monitored. Protein expressions of the related pathways were then investigated by obtaining the total RNA from the respective adipose tissue of mice and in vitro 3T3-L1 adipocyte cells, via reverse transcription polymerase chain reaction (RT-PCR). The collective data were sufficient for the author to conclude that the peel of *C. sunki* had an antiobesity effect. However, although no phytochemicals were isolated in the study, polymethoxyflavonones (PMFs), namely, tangeretin and nobiletin, were identified in the extract and deduced to be the possible bioactive compounds that mediate the antiobesity effect.[77,80]

In a research study done by Ding et al., they made a similar observation in *C. grandis*, more commonly known as the pomelo, peels. Using an in vivo experimental model of obese C57BL/6 mice induced with a high-fat diet (HFD), they found that the peel crude extract was able to block the body weight gain and lower the blood glucose level, serum total cholesterol, liver lipid levels, and serum insulin levels as well as improve glucose tolerance and insulin resistance. Further effects of the extract on various gene expressions were also investigated using quantitative RT-PCR via extraction of total RNA from mouse tissues. Interestingly, despite the lack of identification of

bioactive compounds[81] presented in their study, Ding et al. brought up several differences in bioactivity of *C. grandis* originating from different cultivars.[82] This observation, therefore, illustrated an important fact as to how agronomic factors, such as environmental factors and varied conditions, may affect the overall bioactivity and antioxidant capacity of the fruit.

Mango Peel (Mangifera indica L.). *M. indica* L. is a tropical fruit that is rich in a diverse array of bioactive phytochemicals. There is a growing body of evidence that links phytochemicals with the inhibition of adipogenesis and protection against obesity. In particular, Taing et al. carried out an experiment demonstrating not only the effect of the mango peel extract on adipogenesis in 3T3-L1 cells but also how the differences in phytochemical quantity and composition between species of the same fruit can exhibit different adipogenesis inhibition efficiencies.[19]

Methanol extracts of peel and flesh from three archetypal mango cultivars, Irwin, Nam Doc Mai, and Kensington Pride, were assessed for their effects on the 3T3-L1 preadipocyte cell line model of adipogenesis, respectively. Whereas the flesh from all three cultivars was ineffective, two of the peel extracts, namely, Irwin and Nam Doc Mai, inhibited adipogenesis. This observation was further analyzed, and it was concluded that differences in phytochemical composition between mango cultivars may influence their effectiveness in inhibiting adipogenesis and that specific components within the phenolic content make a major contribution to its overall antiadipogenic effects. The studies further showed that the inhibition of adipogenesis occurred possibly through the inhibition of mitotic clonal expansion, mediated by pathways similar to those of the red grape component resveratrol.[83] Essentially, regardless of the different efficiencies, the ability of *M. indica* L. to promote positive inhibition effects toward adipogenesis puts forth another fruit waste component as a potential tropical fruit source to treat obesity.

In general, several studies of various tropical fruit components and their respective observed biological activities have certainly highlighted the potential benefits that may result when they are used as supplements for the treatment of obesity, along with its related diseases such as diabetes. The study of mango peels originating from various cultivars, as discussed by Taing et al., exhibiting varied effects on the overall biological activity suggests that the chemical composition present in fruits may differ, even if they are from the same species. The environmental factor, weather conditions, amount of nutrition, and the overall agricultural technique used to grow these fruits will essentially determine the primary composition of the fruit components. Ideally, then, before the agronomic approaches can be developed to alter the agricultural conditions leading to an effective yield of fruit components consisting of highly bioactive phytochemicals, the actual bioactive phytochemicals have to first be determined. This would therefore require further isolation and elucidation of the active compounds responsible for the overall respective antihyperlipidemic, anti-inflammatory, hypoglycemic, and antiobesity effects as addressed previously.

Although the isolation and effective separation process of various chemicals from the fruit waste components may be time-consuming, it is absolutely necessary for the effective development of this field. The presence of more advanced analytical devices such as the prep-HPLC, supercritical fluid extraction technique, and LC-MS, for instance, will definitely help to facilitate this research. The subsequent steps would therefore require further elucidation of chemical structure for the novel bioactive phytochemicals. As for the existing/current bioactive chemicals identified, further investigation is required so that absolute confirmation of its respective bioactive capacity proposed can be done.

PHYTOCHEMICALS RESPONSIBLE FOR THE RESPECTIVE BIOACTIVITY

Polyphenols are often associated as the component responsible for antioxidant effects commonly observed in natural products.[84,85] Therefore, this would also suggest that if a fruit component exhibits high antioxidant capacity, it effectively means that there is a high presence of polyphenols in the fruit component. In addition to this, polyphenols have also been found in several studies to be responsible for the positive antiobesity effect as established by Wang et al.[86] In relation to the commonly suggested "high antioxidant capacity in natural components reflecting higher potential to treat disease" phenomenon, a comparative study recently published by Al-Mansoub et al. on antihyperlipidemic and antioxidant effects of *Garcinia atroviridis* showed an interesting observation that suggests otherwise. In their study, they revealed that the aqueous extract was observed to contain fewer polyphenols than the methanolic extract but reflected a stronger bioactivity (antihyperlipidemic effect). This finding further suggested that there were other compounds besides polyphenols that were involved, leading to the overall efficacy of the bioactivity observed.[87]

From the collection of major compounds identified in the series of studies as summarized in Table 1, we have found that the bioactive phytochemicals recommended were not necessarily polyphenols. In promegranate flowers, for instance, the major compounds identified were oleanolic acid and ursolic acid,[41] whereas in the bishop's weed, the main components identified as exhibiting antiobesity activities were the furocoumarins. Among some of the other nonpolyphenols were the polymethoxyflavonones (PMFs) found in *C. sunki* and flavonoids in *C. grandis* and *H. umbellata*.[31,77,82] Therefore, the independent role of polyphenols in inducing positive antiobesity effects was questioned. How these phytochemicals were proposed in the studies to effectively result in the reduction of lipid accumulation at the adipocytes, a characteristic of antiobesity properties, differed from one component to another. Could it be a combinatorial effect with other compounds mentioned? Do they share a similar lipid accumulation inhibition mechanism as polyphenols?

Although the exact role of the bioactive compounds in the overall inhibition of lipid accumulation has yet to be determined, various studies have shown the different possible mechanisms that these compounds may play. On the basis of the mechanistic analysis of how the respective major bioactive compounds identified play a role in the overall positive antiobesity effect, it was observed that each compound reacts differently from one another, regardless of its class (i.e., polyphenols or flavonoids or PMFs). Typically, this boils down to the different set of genetic expressions that these compounds affect, which gradually leads to the overall antiobesity effect observed in the end. Between the polyphenols identified in olive leaves and mango leaves, for instance, the oleuropein and hydroxtyrosol in olives were found to prevent 3T3-L1 adipocyte differentiation via the inhibition of the mitotic clonal expansion and down-regulation of the adipogenesis-related genes, namely, PPARγ, C/EBPα, and SREBP-1c,[16] whereas the

foliamangiferoside A, iriflophenone-3-*C*-β-glucoside, and mangiferin found in mango leaves were found to result in the same effect but via the down-regulation or inhibition of the FAS and hormone-sensitive lipase (HSL) gene expression.[54] In *C. sunki* peel extract, where the major compounds identified were mainly flavonoids, it was found that the observed antiobesity effect proceeded via elevated β-oxidation and lipolysis in adipose tissue. This was deduced from a series of results that included the crude extract's ability to increase AMPK and ACC phosphorylation in mature 3T3-L1 adipocytes.[77]

We therefore conclude that there is indeed no one mechanism that is used to find the cure to obesity. Many scientists used different models in identifying antiobesity capacity, some of which use the in vivo experimental model, whereas others use the in vitro assay, typically 3T3-L1 adipocyte cells. There is, however, no specific right or wrong answer to this phenomenon. The mechanisms by which these bioactive compounds proceed to sequentially result in an overall positive antiobesity effect vary from one fruit component to another. The roles of the specific bioactive phytochemicals, mainly the polyphenols, flavonoids, and furocoumarins, in the overall mechanism have yet to be established. More research, particularly in the area of isolation, identification, and elucidation of bioactive compounds, has to be done. Subsequently, crystallization of these compounds can then proceed, in order for computational modeling to be generated to further investigate how these respective bioactive compounds play an essential role in the overall mechanism (such as adipogenesis), that leads to the positive antiobesity effect, initially observed in vivo.

Following this, only then can the in vivo as well as clinical studies, using the isolated bioactive phytochemicals, be facilitated to support the therapeutic roles of fruit waste components in the overall effect of obesity treatment. Such results may then push for further development of new agronomic approaches, implementing new technological innovation to cultivate tropical fruit parts enriched in a specifically desired composition of phytochemicals and, at the same time, an effective large-scale processing technique of specific tropical fruit wastes can be strategized.

DEVELOPMENT OF EFFECTIVE FRUIT WASTE PROCESSING/RECYCLING TECHNIQUES AND AGRONOMIC ADVANCES

In the pursuit of finding an alternative means to combat obesity using natural sources, studies of fruit waste components have been done, and they have appeared to be prospective sources of remedy due to their high bioactivity and lesser tendency of inducing detrimental side effects. Although more elaborate studies have to be done specifically on the isolation and elucidation of compounds responsible for their respective bioactivity, as addressed earlier in the review, there are a few other challenges that have to be dealt with. To effectively tap the maximum potential of tropical fruit waste components as future therapeutics, an effective large-scale processing technique for these waste components has to be designed. Other relevant factors include finding the right places and equipment to store these components to prevent them from decaying, intricate engineering of large-scale extraction techniques to take up only the desired materials, and implementing necessary agronomic advances to utilize and develop new technological innovations to cultivate crops containing high useful phytochemical compositions.

FUTURE OF TROPICAL FRUIT WASTE COMPONENTS

Tropical fruit waste components, as discussed in this review, have various bioactive components with health benefits. The combination of these effects rendered by the reported tropical fruit "waste components" is crucial to prevent the development of complex pathophysiology of obesity and diabetes. The extraction of these components and in-depth study of their effects on the various genetic expression using in vitro and in vivo test models, as addressed in this paper, have shown clear evidence of the positive effects that these bioactive phytochemicals possess. This essentially suggests the potential use of such components as future therapies to further supplement antiobesity treatments. In addition, as these components originate from natural sources, the likelihood of these extracts being toxic and detrimental is decreased.[9]

Further studies involving the isolation of bioactive compounds from tropical fruit waste components and the elaboration of a mechanistic approach toward the overall lipid regulation in cells is, however, still necessary for further advances in the development of these waste components. The exact structural roles of the bioactive phytochemicals in the overall antiobesity mechanism have to be further looked into, of which some of the studies may encompass the need for chemical crystallization and computer modeling. In addition, further large-scale defined basic and clinical studies are critical to determine optimal dietary regimens to achieve the desired beneficial health effects. Ultimately, only with enough positive and reliable relevant data can the commercial use of these tropical fruit waste components as future therapeutics be advocated.

defense was postulated.[15] Consistent with a role in defense, eSBU and jack bean seed urease display insecticidal effects, in part due to the action of a subpeptide released by cathepsin-type proteases in the gut of susceptible insects.[7,8]

Soybean expresses a second urease, the tissue-ubiquitous urease (uSBU), essential for assimilation of urea, either endogenously generated or environmentally available. uSBU is encoded by *Eu4* (Glyma11g37250), which is expressed in all tissues examined, including callus and the developing embryo.[11,16] Loss of uSBU activity leads to accumulation of urea in seeds and in leaves to the extent that leaf tips become necrotic,[14] a trait also observed in soybean plants deprived of nickel,[17] a component of the urease active site. Endogenous urea is produced by arginase action, for example, during mobilization of seed protein reserves.[18] Consistent with a general role of ureases in defense, uSBU-suppressed soybean plants showed increased susceptibility to fungal infection.[19]

Few, if any, studies have addressed the involvement of urease in the symbiosis of nitrogen-fixing bacteria and their host plants. In light of the now recognized multifunctionality of ureases,[7,20] the main objective of this study was to test the hypothesis that both plant and bacterial enzymes are involved in communication between the soybean plant and its symbiont *B. japonicum*.

MATERIALS AND METHODS

Plant Material. Seeds of *Glycine max* (L.) Merr cv. Williams 82 were commercially available (Missouri Seed Foundation). Soybean double mutant *eu1-a,eu4* (in the Williams 82 background) has a lesion in the *eu1* gene and is null for synthesis of eSBU protein[12,21] and transcript.[11] The *eu-1* allele was orignally termed *eu1-sun* (seed urease-null[11]) and is here termed *eu1-a*, consistent with designation of alleles of other soybean urease loci.[13] The second lesion is a missense alteration in the *eu4* gene, resulting in inactive ubiquitous urease.[16,22] Two homozygous double mutant strains were employed—both contained the same *eu1-a* null allele[11] but differed in the *eu4* allele (*aj3* vs *aj6*), each containing a unique single base missense mutation inactivating the ubiquitous urease.[16]

Bacterial Strains and Culture Conditions. *B. japonicum* strain USDA110 was routinely maintained on HM salts medium[23] supplemented with 0.5% yeast extract at 28 °C with shaking (200 rpm). When necessary, antibiotics were supplied at 150 $\mu g \cdot mL^{-1}$ (kanamycin) and 30 $\mu g \cdot mL^{-1}$ (chloramphenicol). *Escherichia coli* strains were cultured on Luria−Bertani medium at 37 °C.

Construction of B. japonicum Urease Mutants. Primers used in this work are described in Table 1. To generate mutants, the genes of interest were amplified with primers ureABC-F and ureABC-R or ureG-F and ureG-R. Polymerase chain reaction (PCR) products contained the full sequence of the genes of interest in addition to about 400 bp 5′ and 3′ flanking sequence. The PCR products were inserted into the suicide vector pKnockout,[24] generating PKO Ω−URE. A kanamycin cassette from pHP45 Ω−Km[25] was amplified with primers PS1 and PS2, and then, this product was used as the template for another PCR with primers Delta ureABC-F/R and Delta ureG-F/R, generating pKO Ω−URE−Km. These primers added to the kanamycin gene 40 base pairs identical to regions flanking the genes of interest. This construct was transferred from *E. coli* DH5α to *B. japonicum* USDA110 by triparental conjugation with the helper plasmid pRK2073.[26] Deletion mutant recombinants were selected by kanamycin resistance and confirmed as described in the Results section.

Canavalia ensiformis Urease (JBU). Urease type C-III from jack bean (Sigma−Aldrich) was used in all experiments. The protein (hexameric form, M_r = 540 kDa) was solubilized in 20 mM sodium phosphate buffer, pH 7.0.

Soybean Embryo-Specific Urease. eSBU was purified as described[27] from soybean flour (Sigma−Aldrich) and dialyzed against 20 mM phosphate buffer, pH 7.0 prior to use.

Soybean Ubiquitous Urease. Cells of *E. coli* BL21-RIL:pGEX-4T-2 containing the full length cDNA encoding the uSBU[28] were grown in 2xYT medium (16 $g \cdot L^{-1}$ tryptone, 10 $g \cdot L^{-1}$ yeast extract, 5 $g \cdot L^{-1}$ sodium chloride, pH 7.0) containing ampicillin (150 $\mu g \cdot mL^{-1}$) and chloramphenicol (40 $\mu g \cdot mL^{-1}$) and maintained at 37 °C with shaking (200 rpm). When the culture reached 0.7 OD_{600}, the expression of uSBU fused to glutathione S-transferase at its N terminus (GST-uSBU) was induced by adding 0.55 mM IPTG, keeping the culture at 24 °C with shaking (200 rpm) for 15 h. Bacteria were collected by centrifugation, suspended in phosphate-buffered saline (PBS, 140 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 1.8 mM KH_2PO_4, pH 7.3), and subjected to lysis by ultrasound. After centrifugation at 60 000*g* for 25 min, the supernatant was passed through a 0.45 μm membrane, and the filtrate was applied onto a Glutathione Sepharose 4B (GE Healthcare) column. Retained GST-uSBU was eluted with 10 mM reduced glutathione in 50 mM Tris−HCl, pH 8.0. The GST protein (not fused to uSBU) was used as a control and was obtained from *E. coli* BL21:pGEX-4T-2 grown in 2xYT medium supplemented with 150 $\mu g \cdot mL^{-1}$ ampicillin and maintained at 37 °C with shaking (200 rpm). When the culture reached 0.7 OD_{600}, expression of GST was induced by adding 1 mM IPTG, and the culture was maintained at 37 °C for 3 h with shaking (200 rpm). Purification of GST was performed by affinity chromatography as described above.

Urease Activity. The phenol-nitroprusside colorimetric determination of ammonia[29] was used to determine urease activity in soybean tissues and nodules. One unit of urease activity was defined as the amount of enzyme that produces 1 μmol of ammonia per minute at 37 °C. Alternatively, urease activity in whole cells or tissue samples was semiquantitatively evaluated in a weakly buffered urea solution containing a pH indicator. Samples were incubated in 1 mL of 100 mM urea, 1 mM EDTA, 10 mM KPO_4, pH 7.0, and 5 $mg \cdot L^{-1}$ cresol red and kept at room temperature. Urease-positive samples turned the solution sequentially from yellow to pink to vermillion[30] in a time frame dependent on urease level.

Urease Inactivation. JBU and eSBU were inactivated by treatment with *p*-hydroxy-mercurybenzoate (Sigma−Aldrich), as previously described.[27] Excess inhibitor was removed by extensive dialysis against

20 mM phosphate buffer, pH 7.0. In one set of experiments, urease-inhibited soybean plants were obtained by adding 100 μM phenylphosphorodiamidate (PPD) (Sigma–Aldrich) to the plant nutrient solution.[31] PPD is an analogue of urea that binds to the urease active site.[32]

Chemotaxis Assays. *B. japonicum* chemotaxis was assayed as described[33] with minor modifications, using a 48-well Boyden chamber (Neuroprobe Microchemotaxis System, Gaithersburg, MD) with 2 μm PVP-free polycarbonate filters. Chemotactic stimulation was tested in 50 μL containing 9 μM of one of the following: GST-uSBU, eSBU, JBU, soybean genistein (Sigma–Aldrich), lectins (Sigma–Aldrich) from *Phaseolus vulgaris*, *G. max*, and *C. ensiformis*, or bovine serum albumin (BSA). Individual putative attractants, diluted with 20 mM phosphate buffer, pH 7.0, were added to the top wells of the Boyden chamber. *B. japonicum* cells suspended in saline solution (10^6 cells·mL^{-1}) were added (28 μL) to the bottom chamber wells and incubated 60 min at room temperature, after which bacterial cells in the top wells were collected and plated counting of colony-forming units (CFUs).

Plant Growth and Inoculation. Soybean seeds were surface sterilized and germinated as described.[34] After 48 h, seedlings were inoculated with isogenic *B. japonicum* USDA110 urease-positive or urease-negative mutants for 30 min and then planted in autoclaved Leonard jars[35] containing a 1:1:1 mixture of vermiculite/perlite/sand supplied with a nitrogen-free plant nutrient solution.[36] During growth, sterile nutrient solution was added to the lower reservoir as needed. Plants were maintained in growth chambers at 28 °C and 16 h light. Nodules were harvested from the roots 16–42 d after planting and kept frozen at −80 °C until use.

Leghemoglobin Content. Nodules were transferred to 2 mL tubes containing a 5 mm steel ball. PBS was added, and nodules were macerated and homogenized in a TissueLyser system (Qiagen) with pulses of 3 min at a frequency of 30 Hz. Samples were subjected to two cycles of centrifugation, first at 3000*g* for 10 min and the second at 18 000*g* for 20 min. Leghemoglobin content (mg·mg^{-1} protein) in the second supernatant was estimated by absorbance at 410 nm and an extinction coefficient[37] of 33.9 × 10^3 L·mol^{-1}·cm^{-1}.

Protein Determination. The protein content of samples was determined by their absorbance at 280 nm or alternatively by the Coomassie dye method[38] using BSA as the standard.

Electron Microscopy. Nodule samples were fixed in 25% glutaraldehyde in 0.1 M phosphate buffer (pH 7.0) for 1 h at room temperature and then kept at 4 °C for 16 h. Samples were then washed with three changes of 0.1 M phosphate buffer and postfixed in 2.0% osmium tetroxide for 1 h. Samples were again washed with buffer as above before being dehydrated through 30%, 50%, 70%, 95%, and 100% acetone. The tissues were then embedded stepwise in Epon resin. For polymerization, the material was kept at 60 °C for 72 h. The resulting blocks of embedded biofilm were sectioned in an ultramicrotome (Leica Ultracut UCT) with a diamond knife at a thickness of 800 nm and stained with aqueous toluidine blue and 1% basic fuchsin. Ultrathin sections (100 nm thick) were prepared using the same ultramicrotome and post contrasted with uranyl acetate and lead citrate. Samples were visualized under a transmission electron microscope (Philips model EM208S, Center of Electron Microscopy and Microanalysis, Universidade Luterana do Brasil, Canoas, RS).

Statistical Analysis. Data were evaluated using "one-way" ANOVA followed by the *t* test of Bonferroni or Tukey. A *p* value less than 0.05 was considered statistically significant. All analyzes were performed using GraphPad Prism software (version 5.0 for Windows).

RESULTS

Construction of *B. japonicum* Mutants. To examine the role of ureases in the interaction between soybean and *B. japonicum*, two mutants of *B. japonicum* were constructed. The mutant strain Δ*ureABC* is deleted in the three urease structural genes thus lacking urease protein. The mutant strain Δ*ureG* has a deletion of the gene encoding the accessory protein UreG, which participates in the assembly of the protein metallocenter, thus producing an enzymatically inactive apoenzyme, with no Ni^{2+} in its active site.[39] The approach used for construction of the mutants consists of inserting the gene that confers resistance to kanamycin via homologous recombination in regions flanking the target genes into the genome of *B. japonicum*. Mutants were confirmed by PCR (Figure 1) employing genomic primers

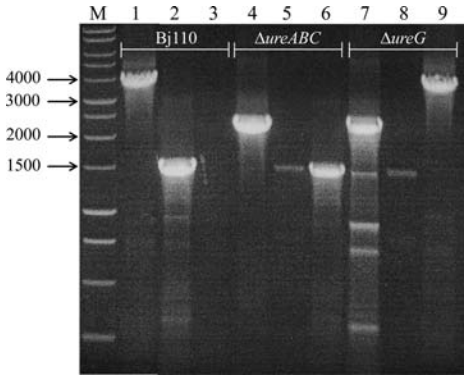

Figure 1. Validation of mutants by PCR. Genomic DNA from wild-type *B. japonicum* USDA110 (Bj110) and deletion mutants (Δ*ureABC* and Δ*ureG*) was subjected to PCR with specific primers. (1) Intact ureABC, (2) intact *ureG*, (3) Can^r, (4) interruption of *ureABC* by Can^r, (5) Can^r, (6) intact *ureG*, (7) interruption of *ureG* by Can^r, (8) Can^r, (9) intact *ureABC*.

flanking the putative insert and by the absence of ureolytic activity. In the PCR amplifications, the sizes of *ureABC* and *ureG* fragments in Bj110 are 3814 and 1491 bp, respectively. Homologous recombination in the regions flanking the genes of interest promotes the insertion of the kanamycin resistance gene (Can^r). Thus, in the genomic PCR amplifications, Δ*ureABC* generates a fragment of 2212 bp, while no change is seen in *ureG*. In turn, from the DNA of mutant Δ*ureG*, a fragment of 2287 bp is amplified without change in *ureABC*.

To verify the ureolytic activity, 1 mL of stationary-phase bacterial cells were collected by centrifugation and suspended in a solution containing weakly buffered 100 mM urea and pH indicator cresol red (Materials and Methods). Alkalinization of the medium by urea hydrolysis induced a color change of the pH indicator after 2 h at room temperature by wild-type bacterium Bj110. Mutants Δ*ureG* and Δ*ureABC* showed no ureolytic activity, since after incubation the medium kept the original yellow color for at least 16 h (Figure S1, Supporting Information). Lack of urease was further confirmed by the lack of growth of the mutant bacteria on minimal medium containing urea as the sole nitrogen source (data not shown).

Chemotaxis toward Plant Ureases. Plant ureases were found to be strongly chemotactic to *B. japonicum*. JBU, eSBU, and recombinant GST-uSBU induced chemotaxis of *B. japonicum* in the 0.1–9 μM concentration range. Figure 2 shows that increasing concentrations of JBU and GST-uSBU were accompanied by an increase in the CFUs of *B. japonicum* recovered in the upper compartment of the Boyden chamber. While recombinant GST-uSBU is fused to GST, recombinant GST alone induced a much weaker chemotaxis. The GST response peaked at 0.5 μM, whereas chemotaxis increased steadily up to 9 μM GST-uSBU.

It was shown previously that GST-uSBU is not active enzymatically,[28] most likely due to lack of incorporation of Ni into the urease active site by the *E. coli* host, lacking urease accessory proteins. The contribution of the ureolytic activity to chemotaxis was evaluated by testing enzymatically active plant

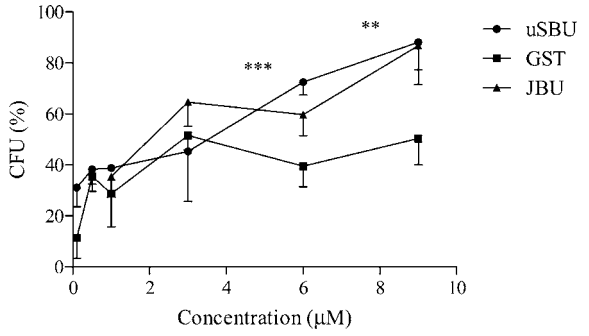

Figure 2. Response curve of *B. japonicum* to various concentrations of soybean ubiquitous urease (uSBU), jack bean urease (JBU), and glutathione-S-transferase (GST). The experiment was performed in a Boyden chamber containing 10^6 cells·mL^{-1} of Bj110 in the lower wells and different concentrations of uSBU or GST (control) in the upper wells. After 1 h at room temperature, the cells that migrated to the upper wells of the chamber were collected and plated for CFU counts. The points represent the mean ± SD of triplicates. Points marked with ** ($p < 0.01$) or *** ($p < 0.001$) were significantly different compared to control at the same dose by the Bonferroni test.

ureases eSBU and JBU before and after treatment with *p*-hydroxymercuribenzoate (*p*-HMB), an irreversible inhibitor of urease catalytic activity.[27] Ureases (3 μM) were added to the upper compartment of the Boyden chamber, and no significant differences were observed in their chemotactic effect, regardless of their ureolytic activities (Figure 3). Chemotaxis assays with

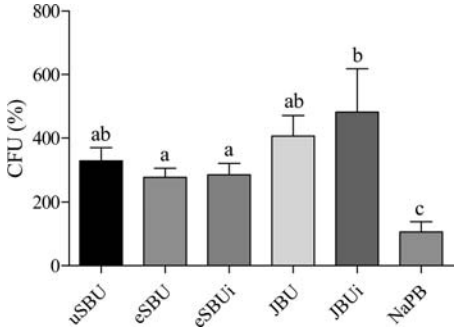

Figure 3. Effect of ureolytic activity in the chemotaxis of *B. japonicum* to plant ureases. Ureases were incubated at 4 °C for 16 h with 50 mM *p*-hydroxymercuribenzoate (*p*-HMB). Excess inhibitor was removed by dialysis prior to testing. All proteins were tested at a concentration of 3 μM. After 1 h at room temperature, the cells that migrated to the upper compartment of the chamber were collected and plated for CFU counts. (eSBU) soybean embryo-specific urease, (eSBUi) inactivated eSBU, (JBU) *C. ensiformis* urease, (JBUi) inactivated JBU, (uSBU) soybean recombinant ubiquitous urease. Bars represent the mean ± SD of triplicates.

mutants of *B. japonicum* indicated that the absence of the urease protein (Δ*ureABC*) or of its ureolytic activity (Δ*ureG*) in the bacteria did not alter their attraction to uSBU, as illustrated in Figure 4.

Finally, we compared the response of *B. japonicum* cells to the chemotactic effect of nonurease proteins (BSA, GST, and the lectins PHA-L from *P. vulgaris*, soybean agglutinin SBA, and jack bean concanavalin A) and the soybean flavonoid genistein. It can be observed in Figure 5 that soybean or jack bean ureases were the most potent chemotactic stimuli compared to the other tested compounds, followed by plant lectins. GST and BSA also

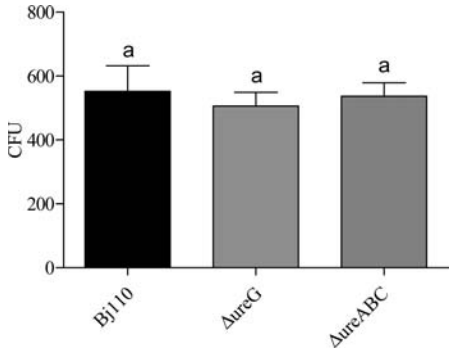

Figure 4. Chemotactic response of wild-type and urease deficient *B. japonicum* to uSBU. The experiment was performed in a Boyden chamber containing 10^6 cells·mL^{-1} of bacteria in the lower wells and 9 μM uSBU in the upper wells. After 1 h at room temperature, the cells that migrated to the upper wells of the Boyden chamber were recovered and plated for CFU counts. Bars represent the mean ± SD of six replicates.

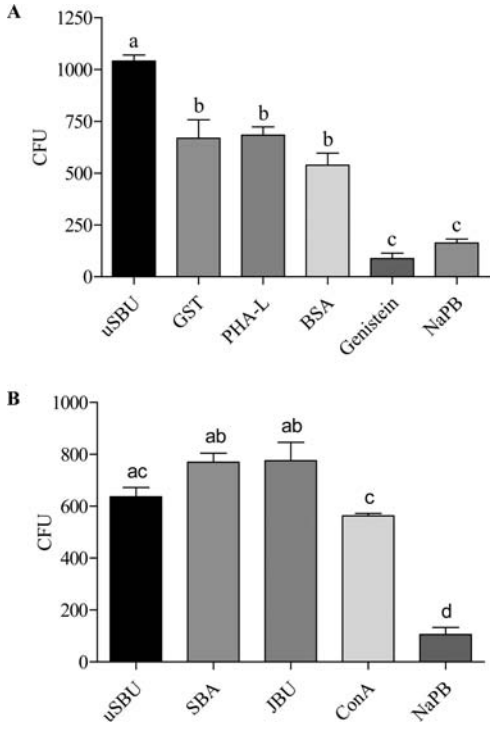

Figure 5. (A) Chemotactic response of *B. japonicum* USDA110 induced by 9 μM of the following: ubiquitous recombinant urease soybean (uSBU), the GST fusion protein, a lectin from *P. vulgaris* (PHA-L), bovine serum albumin (BSA), and genistein from soybean. (B) Chemotactic response of *B. japonicum* USDA110 induced by 9 μM ubiquitous recombinant urease soybean (uSBU), soybean lectin (SBA), *C. ensiformis* urease (JBU), and *C. ensiformis* lectin (ConA). Sodium phosphate buffer (NaPB, 20 mM) was used as a control. After 1 h at room temperature, the cells that migrated to the upper compartment of the Boyden chamber were recovered and plated for CFU counts. Columns with the same letter do not differ by the Tukey test ($p > 0.05$).

induced migration of *B. japonicum* but were significantly less chemotactic than ureases. Genistein was a very poor attractant.

Assays of Nodule Properties. To evaluate the role of plant and bacterial ureases in nodulation and nitrogen fixation, wild-type and urease-negative soybean were inoculated with wild-type and urease-negative *B. japonicum* mutants in all possible

dx.doi.org/10.1021/jf5000612 | J. Agric. Food Chem. 2014, 62, 3517−3524

combinations. The number and fresh weight of nodules were determined 21 d after inoculation.

Wild-type plants showed a higher number of nodules when compared to mutant plants, regardless of the inoculated bacterial strain (Figure 6A). However, there was a marked increase in the size of nodules in mutant plants *eu1-a,eu4*, again regardless of the inoculated strain. No differences were seen in the total fresh mass of nodules per plant (Figure 6B).

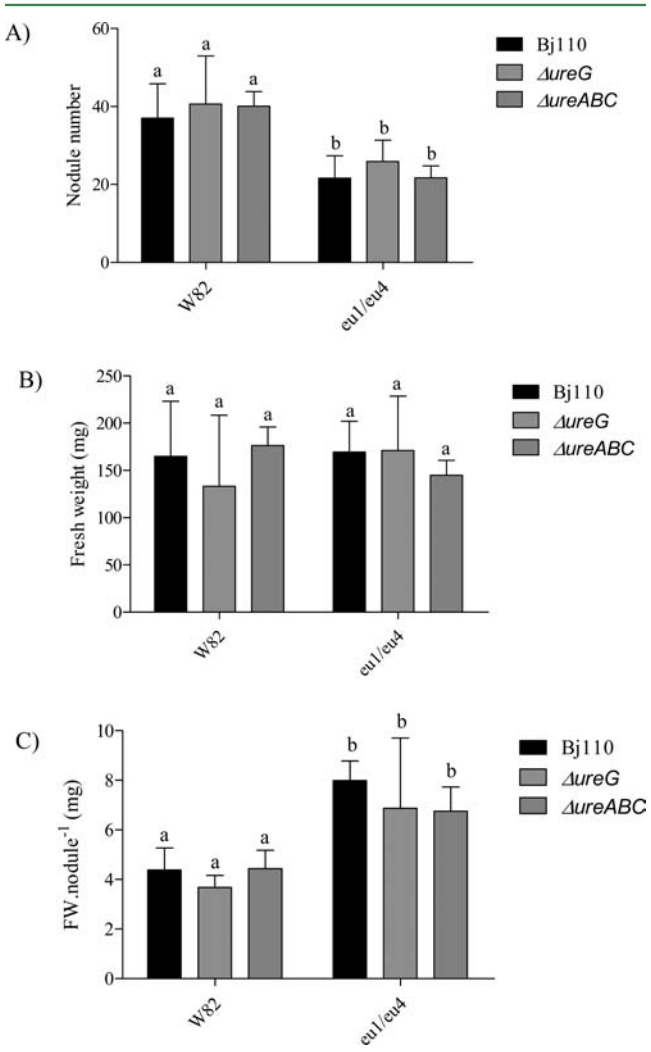

Figure 6. Wild-type soybean plants (W82) and a mutant deficient in embryo-specific and ubiquitous ureases (eu1/eu4) were inoculated with *B. japonicum* wild-type (Bj110), with a mutant strain that produces an apourease (Δ*ureG*), or a mutant strain that does not produce urease (Δ*ureABC*). Nodule number and weight were assessed 21 d after inoculation. (A) Number of nodules per plant. (B) Total fresh weight of nodules per plant. (C) Ratio between the total fresh weight of nodules and the number of nodules. Bars represent the mean of five Leonard pots, each containing 2−3 plants. Bars with the same letter do not differ by the Tukey test ($p > 0.05$).

To evaluate the importance of urease enzyme activity during soybean nodulation by *B. japonicum*, we used the urease inhibitor PPD, an analogue of urea that binds to the active site of the enzyme.[32] Wild-type soybean seedlings were inoculated with wild-type *B. japonicum* as described in Materials and Methods, and 100 μM PPD was added to the nutrient solution in the Leonard jars. Inhibition was maintained throughout the experimental period. Plants were analyzed 21 d after inoculation by counting and weighing the nodules formed. At the end of the experiment, urease activity was measured in extracts of leaves and nodules, confirming the inhibition of the enzyme by PPD (data not shown). Still, no differences were observed either in the number or fresh weight of nodules of PPD-treated urease-inhibited plants (data not shown).

Nodule Analysis by Optical and Transmission Electron Microscopies. Nodules of wild-type and *eu1-a,eu4* plants collected 35 d after inoculation with the *B. japonicum* wild-type strain were analyzed by optical and transmission electron microscopies. No alterations in architecture and histological organization of the nodules in the urease-deficient plants were observed (Figure S2, Supporting Information).

Leghemoglobin (LegHb) Content. The amount of LegHb in the supernatant of nodule macerates was estimated at times from 16 to 42 d after inoculation. As can be observed in Figure 7 (and Table S1, Supporting Information), the accumulation of LegHb from wild-type and mutant plants followed the same trend, regardless of the inoculant bacterial strain. Wild-type plants had lower nodule LegHb content at day 16, and it rose rapidly, peaking at 21 d after inoculation. On the other hand, nodules from mutant plants had a higher level of LegHb at 16 d after inoculation compared to wild-type but were slower to reach the maximal LegHb content, observed only at 35 d after inoculation (Figure 7). The altered pattern of accumulation of LegHb in *eu1-a,eu4* plants suggests that lesions in the structural genes of both soybean ureases, resulting in the absence of eSBU and in an inactivated uSBU, somehow compromised the symbiosis between the plant and the bacterium, delaying the LegHb peak from 21 d in the wild plant to about 35 d after inoculation.

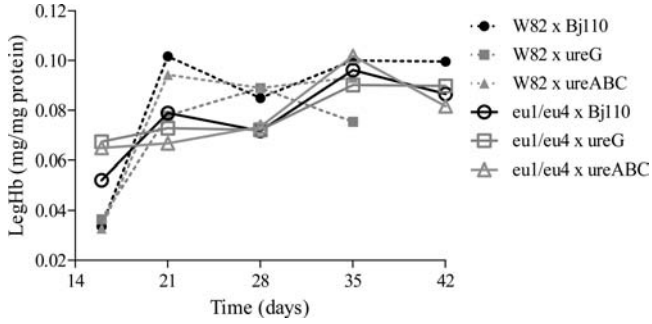

Figure 7. Leghemoglobin (LegHb) content of nodules versus time postinoculation. Wild-type (W82) and mutant (eu1/eu4) soybean plants were inoculated with wild-type *B. japonicum* (Bj110), with a mutant strain that produces an apourease (Δ*ureG*) or with a mutant strain that does not produce urease (Δ*ureABC*). LegHb content was measured by absorbance at 410 nm in extracts of nodules collected from 16 up to 42 d after inoculation. Each point is the average of three to six replicates.

DISCUSSION

Ureases have highly conserved structures and very similar catalytic mechanisms, reflective of their conservation throughout evolution.[40] In microorganisms, urease activity is involved in the assimilation of urea nitrogen, in pathogenicity in animals and humans, and in the metabolism of ruminants.[7] On the other hand, the physiological role(s) of this enzyme in plants is(are) still a matter of debate.[1,7] Addressing this question with in vivo studies using urease-deficient organisms may help to advance our understanding of the biological properties of this enzyme.

dx.doi.org/10.1021/jf5000612 | J. Agric. Food Chem. 2014, 62, 3517−3524

Here, we investigated the hypothesis that ureases from soybean and/or *B. japonicum* could be involved in the signaling between plant and bacterium—a concept originally suggested by the common platelet aggregation properties of plant ureases and the urease of the soil bacterium, *Bacillus pasteurii*.[41] Previous results from our group with canatoxin,[42] an isoform of jack bean urease, and *Helicobacter pylori* urease[33] have shown that these proteins are chemotactic to neutrophils and other proinflammatory cells. Considering these data, we evaluated a possible chemotactic activity of SBU toward *B. japonicum*. Our results showed that *B. japonicum* cells are attracted to SBU isoforms and to JBU and that this response is independent of urease enzymatic activity or the urease status of the bacteria. Thus, plant ureases exert chemotaxis in bacteria, as well as in eukaryotic cells such as neutrophils and monocytes.

High molecular-weight components in root exudates, which include lectins,[43] can affect symbiosis between plants and nodule bacteria. Plant lectins are known to act as chemoattractants and to promote adhesion of rhizobia to root hairs, enhancing the symbiotic properties of root nodule bacteria. Not all steps of lectin−rhizobia interaction are species-specific.[44] Accordingly, here, *B. japonicum* migrated toward different legume lectins. As reported previously,[45] genistein behaved as a weak attractant to *B. japonicum*.

Chemotaxis induced by ureases is also not species-specific, as jack bean urease also attracted *B. japonicum*, and in the same micromolar concentration range observed for lectins. It is not known if ureases are present in root exudates. However, it is plausible to think of a gradient of urease originating from death/shedding of root (or root cap) cells, with concentrations decreasing with distance from roots. Chemotaxis of *B. japonicum* toward soybean urease may be indirectly implicated in the nodulation process, directing the bacteria toward the roots. On the other hand, GST and BSA stimulated chemotaxis of *B. japonicum* similarly to soybean lectin. Previously, Sytnikov et al.[46] reported that incubating *B. japonicum* with the nonplant protein human serum albumin (at 0.4 μM), resulted in soybean plants with increased nodule nitrogen-fixing activity.

The Boyden chamber allowed easy assay of migration after 1 h of simultaneous exposure to multiple attractants, within the same time frame as the Pfeffer's capillary tube method.[47] Both methods are much faster than the swarm plate assay,[48] for which migration is measured after 48 h. Only the bacteria that crossed the 0.2 μm filter and were recovered in the liquid medium in the opposite chamber were plated for CFU analysis.

To the best of our knowledge, there are very few published studies that evaluated the role of ureases in the symbiosis between plants and microorganisms. Toffanin and co-workers[49] used a *Rhizobium leguminosarum* strain mutated in the *ureE* gene to show that urease activity is not important for biological nitrogen fixation in pea. This mutation prevents the proper formation of the urease active site, since in the absence of accessory protein UreE, there is no incorporation of Ni^{2+} into the apoenzyme.[39] However, this mutation does not affect the synthesis of apoenzyme(s), which could be contributing to the process of nodulation independently of ureolytic activity.

In our study, we used urease-deficient mutants of soybean as well as *B. japonicum*. In agreement with the study by Toffanin and co-workers,[49] who concluded that the urease of *R. leguminosarum* was not implicated in nodulation, our data showed that neither *B. japonicum* apo-urease (in Δ*ureG*) nor active *B. japonicum* urease affected nodulation in soybean.

In contrast, we showed that in *eu1-a,eu4* soybean plants, nodulation by *B. japonicum* is compromised, yielding higher mass nodules in a reduced number with no gross alteration in morphology. This double mutant does not synthetize eSBU (*eu1* null allele[11]) and produces an enzymatically inactive uSBU.[16] Two missense point mutations *eu4* alleles have been described (G468E in the *aj3*/*aj3* allele and R201C in the *aj6*/*aj6* allele, now termed *eu4-a* and *eu4-b*, respectively[16]). Both changes are radical as all bacterial, fungal, and plant urease sequences showing significant alignments with uSBU have the wild-type Arg201 and Gly468 residues at these positions. Modeling of either mutated uSBU showed that the affected amino acids occur at different points of the surface of the protein likely contributing contacts at the interfaces of the urease trimer. Thus, both amino acids are probably important for maintaining urease structure and/or function.[16] It has been shown that leaves of *eu4*(*aj3*) plants produce 40% the wild-type urease antigen,[22] consistent with instability of the mutant uSBU in *eu4*(*aj3*).

It can be argued that mutagenesis to derive the *eu4* mutation resulted in an altered genetic background, influencing nodule size and number. Arguing against a "background" effect on nodule size/number, we employed two different *eu1-a,eu4* double mutants, each with a different *eu4* mutant allele and hence each derived from a separate mutagenic event.

Torisky and Polacco reported that the eSBU is abundant in roots of 4 d old soybean plantlets, both in the wild-type Williams 82 or in the *eu4*(*aj3*) mutant plant, with specific activities at the root/shoot junction region of about 1500 and 3000 units per milligram of protein, respectively.[10] In roots of 4 d old *eu1-a*/*eu1-a* plants, which produce only uSBU, the specific urease activity reached 20 units per milligram of protein. The eSBU found in the young radicles is derived from the cotyledons, and its levels in the roots decline as the plant grows, but 5% of the 4 d value still remains after the third week of development.[10] In our work, *B. japonicum* was inoculated in soybean seedlings 48 h after germination. Thus, the deleterious effects we observed in the double mutant *eu1-a,eu4* plants could be due to the absence of the eSBU in the initial phase of root development, or reflect the presence of a mutated uSBU, or be a sum of both traits. We did not measure the content of urease protein in the roots of the double mutants *eu1-a,eu4* plants.

We assessed the ability of nodules to fix nitrogen by quantifying LegHb. The presence of this protein in the nodules is connected to nitrogenase activity, which is extremely sensitive to O_2; a function of LegHb is to maintain a low O_2 environment inside the nodules.[50] Hence, the LegHb content is an indirect measure of nitrogenase activity and hence total biological nitrogen fixation at a given developmental stage.

The time course of LegHb accumulation was altered in nodules of soybean *eu1-a,eu4* plants. Mutation in both plant urease genes delayed the LegHb peak from 21 d in the wild plant to 35 d in mutant plants, independent of the bacterial strain, implicating a role of the plant ureases in the soybean−*B. japonicum* symbiosis.

In previous studies[31], we observed no changes in total protein content or ureides in inoculated soybean plants, treated or not treated with PPD. Accordingly, we reported here that the nodulation process was also not affected in inoculated wild-type soybean plants grown in the presence of PPD. These results indicate that any possible role of urease on nodulation would be independent of ureolytic activity, either from the plant or from the bacterial enzymes.

Taken together, our results show that a deficiency (quantitative and/or qualitative) of soybean ureases alters the physiology of the nodules with consequent changes in nitrogen fixation. In addition, altered urease levels/structure may potentially interfere with chemotactic signals triggered by soybean plants in the rhizosphere. None of these processes apparently involves the bacterial urease.

The data shown here represent a new approach in studies of ureases. The multifunctionality of this protein and the lack of consensus about its physiological function(s) make it important to develop studies that go beyond considering urease as solely a ureolytic enzyme, expanding information to understand the conservation of this macromolecule during evolution and its presence in the most diverse organisms.

[a]Culture collection of H. J. Schroers, Agricultural Institute of Slovenia. [b]Values are given as minimal inhibitory concentration (MIC) of the crude extract.

Dickinson, Difco, USA), 5 g of yeast extract (Biolife, Italy), 15 g of technical agar (Biolife, Italy)]. Colony plugs of SBFS fungi were placed at a distance of 15 mm from the edge of a 90 mm diameter plastic Petri dish. Following incubation for 4 days in darkness at 23 °C, aqueous conidial suspensions of *C. fioriniae* were placed in the colony center by needle point inoculation. Negative control plates consisted of needle point inoculated *C. fioriniae* colonies. The dual culture plates were incubated at 23 °C in the dark. The inhibitory effect of *M. tardicrescens* was measured and described after 7, 8, 10, 12, and 14 days of incubation. The assay was replicated three times per SBFS strain. The percentage inhibition of mycelial growth (PIMG) was determined according to the method of Lahlali and Hijri:[11] PIMG = $100 \times (R_1 - R_2)/R_1$, where R_1 was the radial colony growth of *C. fioriniae* in control plates and R_2 the inhibited radial colony growth of *C. fioriniae* in dual culture plates toward the colony of *M. tardicrescens* (mm). Mean values were then calculated from three replicates.

Bioactivity-Guided Fractionation. The effect of methanolic SBFS fungal extracts (prepared by extraction of the agar plates with 20 mL of methanol for 20 min and subsequent filtration of the methanol and its evaporation in vacuo) was tested on the growth of *C. fioriniae* and *Mucor hiemalis* in agar diffusion assays using 10 mL of MYC medium [10 g/L phytone peptone; 10 g of glucose; 11.9 g of Hepes (Carl Roth, Germany), 18 g/L agar (BD) (Bacto, USA)] poured into 90 mm Petri dishes as the base layer. After solidification, 5 mL of MYC medium prepared with 9 g/L agar (BD) (Bacto, USA) together with 5 mL of conidial suspension from *C. fioriniae* and *M. hiemalis* (1×10^6 conidia/mL) was poured onto the base layer. Test substances were applied as methanolic solutions (50 μL, 1 mg/mL) on sterile filter disks of 10 mm diameter (Schleicher & Schuell), allowed to dry, and placed onto the surface of the agar plates. After incubation (25 °C for 48 h), the zone diameter (mm) of the growth inhibition was determined.

Cultivation of *Microcyclospora tardicrescens* Strain 1936 and Preparation of Crude Extracts for Preparative HPLC. Six colony plugs of *M. tardicrescens* strain 1936 were excised from 10-day-old PDA incubated at 23 °C, transferred to 100 mL of YMG medium[7] in 250 mL Erlenmeyer flasks, and incubated at 23 °C on a rotary shaker with 140 rpm for 10 days. Fungal mycelium and culture fluid were then transferred to CYA plates (30 replicates, ca. 3 mL of fungal culture per plate) and incubated for 10 days at 23 °C in darkness. The fungal biomass was lyophilized with the entire agar plates and extracted two times with 1300 mL of methanol for 30 min in an ultrasonic bath at 40 °C. The liquid extracts were filtered through a paper, combined, and evaporated to dryness. The crude extract was then partitioned between 300 mL of water and 300 mL of ethyl acetate (J. T. Baker, Germany). Whereas the aqueous phase was discarded because of lack of bioactivity, the bioactive organic phase was analyzed by ESIMS before fractionation by preparative HPLC.

Isolation of 1 and 2. The crude extract was fractionated by preparative RP HPLC. A 250 × 21 mm i.d., 5 μm, VP Nucleodur C18 Gravity (Macherey-Nagel, Düren, Germany) column was utilized, and an acetonitrile−water gradient with 0.5% HCOOH, 20−100% MeCN in 30 min, and flow = 20 mL/min provided 4.2 mg of **1**, 1.1 mg of **2**, and 2.4 mg of a mixture of **1** and **2**, all with strong antifungal activity. **1** eluted at 16.8−17.8 min, and **2** eluted at 16.4−17.2 min. Silica gel HPLC with a 250 × 20 mm, 7 μm, Nucleosil 100 Å column (Knauer, Berlin, Germany) and isocratic conditions (97% dichloromethane, 3% methanol, flow = 20 mL/min) yielded 5.5 mg of **1** and 3.2 mg of **2**. **1** eluted at 3.8−5.8 min, and **2** eluted at 7.7−10.2 min.

Trichothecolone Acetate (1). ^{1}H (700 MHz, chloroform-*d*) and ^{13}C (175 MHz, chloroform-*d*) NMR spectroscopic data are shown in Table 3; ESI-MS, *m*/*z* 307.1 [M + H$^+$]; HRESIMS (*m*/*z*) found 307.1536 [M + H$^+$], calcd for $C_{17}H_{23}O_5$ 307.1540. Spectroscopic and spectrometric data are in good agreement with the literature.[12,13]

7-Hydroxytrichothecolone Acetate (2). **2** was obtained as a white amorphous powder; $[\alpha]^D_{25}$ = +34 (*c* 0.2, MeOH); UV (MeOH) λ_{max} (log ε) 226 (3.82); IR (KBr) ν_{max} 3450, 2963, 2926, 1737, 1685, 1261, 1243, 1081, 1034, 968, 802 cm^{-1}; ^{1}H (700 MHz, chloroform-*d*) and ^{13}C (175 MHz, chloroform-*d*) NMR spectroscopic data are shown in Table 3; ESIMS *m*/*z* 323.1 [M + H$^+$]; HRESIMS *m*/*z* 323.1481 [M + H$^+$] (calcd for $C_{17}H_{23}O_6$, 323.1489).

Biological Assays for Evaluation of Antimicrobial and Cytotoxic Activities. Biological assays were performed as previously described.[14] The compounds were tested against the bacteria *Bacillus subtilis* DSM 10, *Escherichia coli* DSM 1116, and *Staphylococcus aureus* DSM 346 and the fungi *Colletotrichum fioriniae* HJS 2018, *Pichia anomala* DSM 6766, *Candida albicans* DSM 1665, and *Saccharomyces cerevisiae* DSM 1333. The concentration of the purified compounds was tested at 100, 50, 25, 12.5, 6.25, 3.13, 1.56, and 0.78 μg/mL. The criterion of the minimal inhibitory concentration (MIC) was defined as the lowest concentration showing no visible bacterial or fungal growth after 24 h of incubation.

RESULTS AND DISCUSSION

Isolation of Strains and Co-Cultivation. Eleven strains (Table 1) were significantly antagonistic to fungal growth in dual culture and were chosen for further studies. Extracts of liquid cultures of all of these strains showed antifungal activity against *Colletotrichum fioriniae* with MIC values between 6.3 and 50 μg/mL (Table 1). Some of them were also active against *P. anomala* and *B. subtilis*. *Microcyclospora tardicrescens*

strain 1936 inhibited the colony growth of *C. fioriniae* by 46% after 7 days of incubation and by 55% after 14 days (Table 2; Figure 1) and was selected for scale-up and preparative chromatography. An extract from cultivation of strain 1936 on 30 agar plates was processed by a bioassay-guided fractionation strategy using *C. fioriniae* as indicator organism. Fractionation of the crude extract by reverse phase HPLC resulted in an active fraction that consisted of a mixture of two bioactive metabolites according to HPLC-MS analyses. Subsequent silica gel HPLC resulted in the isolation of both metabolites (**1** and **2**) as white powders.

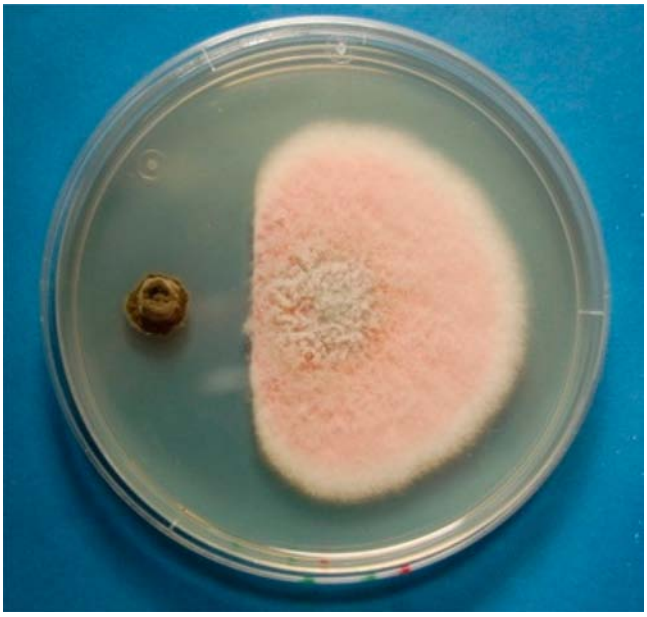

Figure 1. *Microcyclospora tardicrescens* strain 1936 (left) inhibiting the colony growth of *Colletotrichum fioriniae* (right) after 10 days of dual culture incubation on Czapek yeast agar at 23 °C.

HRESIMS revealed the molecular formula of $C_{17}H_{22}O_5$ for compound **1**. The ^{1}H and ^{13}C NMR spectra (Table 3) indicated the presence of four methyl groups, one sp^2 olefinic carbon, one quaternary sp^2 carbon, three sp^3 quaternary carbons, one of which connected to oxygen, three oxygen-bearing methines, three methylenes, and two carbonyls. COSY and HMBC NMR data provided the characteristic structure of 12,13-epoxytrichothec-9-en-8-ones and identified the metabolite as the known trichothecolone acetate (Figure 2).[12,13]

[a]Assignments confirmed by 2D COSY, HSQC, and HMBC experiments.

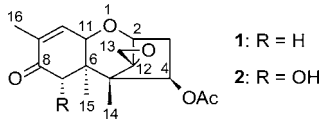

Figure 2. Chemical structures of **1** and **2** isolated from *M. tardicrescens* strain 1936.

For compound **2**, HRESIMS gave the molecular formula $C_{17}H_{22}O_6$. The molecular formula, together with an absorption at 3450 cm^{-1} in the IR spectrum, indicated that **2** is a hydroxylated derivative of **1**. Furthermore, the ^{1}H and ^{13}C NMR spectra of **2** (Table 3) resembled those of **1** with the exception of the absence of a methylene signal for 7-H_2 (δ_C 42.1; δ_H 2.88 and 2.30). Instead of the aforementioned methylene signal, an oxygenated methine (δ_C 74.4, δ_H 4.81) was observed together with a broad singlet at 3.72 ppm; the absence of an HSQC connection of this signal revealed it to be connected to an oxygen atom. The methine gave HMBC correlations (Figure 3) to C-5, C-6, C-8, C-9, C-11, and C-15 and the hydroxyl group to C-6, C-7 and C-8. Thus, the more polar metabolite **2** was identified as 7-hydroxytrichothecolone acetate. The stereochemistry (Figure 4) of the additional chiral center of **2** was assigned by interpretation of the ROESY spectrum in conjunction with the known stereochemistry of trichothecolone acetate (**1**).[15] In the ROESY spectrum 7-OH correlated with 13-H_2, whereas 7-H showed correlations to 14-H_3 and 15-H_3. These observations were confirmed by a 1D NOESY experiment irradiating at the shifts of 7-H and 7-OH. Thus, an *S*-configuration can be deduced for C-7.

Trichothecenes are a family of over 200 toxins with a common tricyclic 12,13-epoxytrichothec-9-ene core structure.[16,17] The trichothecenes are agriculturally important mycotoxins that present a potential threat to animal and

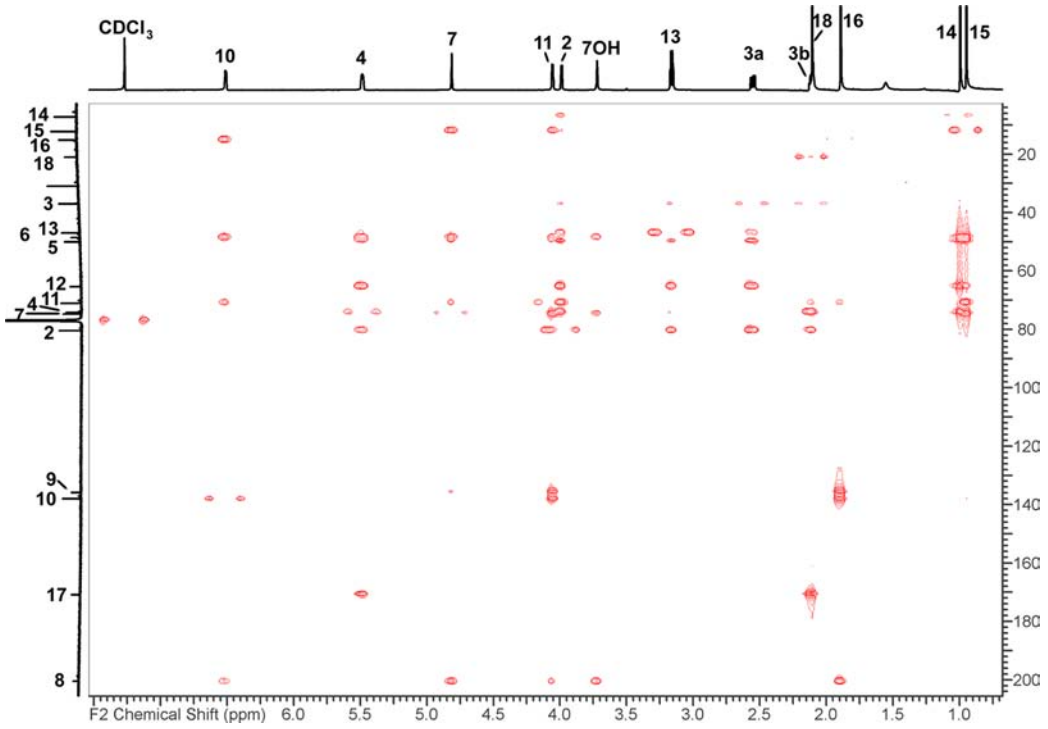

Figure 3. HMBC NMR (700 MHz, $CDCl_3$) spectrum of (*S*)-7-hydroxytrichothecolone acetate (**2**).

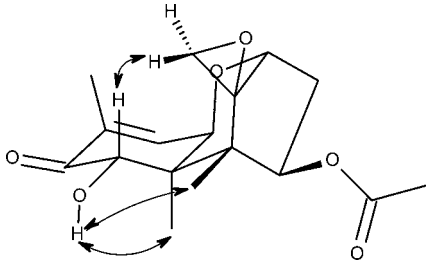

Figure 4. Selected NOE correlations indicating the configuration of **2**.

human health throughout the world.[17] This large family of toxins is produced by fungi in genera, such as *Fusarium*, *Myrothecium*, *Trichoderma*, *Trichothecium*, and *Stachybotrys* (and the compounds we have isolated are actually most similar to some metabolites from *Trichothecium*).[18] Those genera all belong to the order Hypocreales, whereas the SBFS fungi studied belong to the Capnodiales. It should be interesting to compare the biosynthesis gene clusters for trichothecenes in *M. tardicrescens* with those of the above-mentioned fungi. However, this was beyond the scope of the present study and would afford extensive work using methods of molecular biology. The only capnodialean fungus previously reported to produce trichothecenes is *Peltaster fructicola*. Among other compounds, this species produced trichothecolone acetate (**1**), which showed antifungal properties in vitro against *Botryosphaeria* causing bitter rot.[5] The here-reported rediscovery of **1** from *M. tardicrescens* strain 1936 indicates that trichothecenes might occur more widely in the Capnodiales or other related SBFS fungi. However, retrospective analysis of the extracts of strain 1935, another representative of *M. tardicrescens*, and of the other 70 isolated strains by HPLC-MS using pure compounds of **1** and **2** as internal standards did not yet result in the discovery of another trichothecene producer.

The bioactivity of **1** and **2** was evaluated by determining their MIC against a broad test panel of bacteria and fungi (Table 4).

Table 4. Antifungal Activity of Compounds 1 and 2 from *M. tardicrescens* Strain 1936 against Selected Fungal and Bacterial Strains (as Minimum Inhibitory Concentration, MIC, in μg/mL after 24 h)[a]

	strain			
compound	*Colletotrichum fioriniae*	*Pichia anomala*	*Candida albicans*	*Saccharomyces cerevisiae*
trichothecolone acetate (**1**)	6.25	50	50	6.25
7-hydroxy-trichothecolone acetate (**2**)	12.5	50	100	12.5

[a]The bacteria *Bacillus subtilis*, *Escherichia coli*, and *Staphylococcus aureus* were also tested but proved insensitive up to 100 μg/mL.

Compounds **1** and **2** showed no activity against the bacteria *Bacillus subtilis*, *Escherichia coli*, and *Staphylococcus aureus* but moderate activity against *Colletotrichum fioriniae* and *Saccharomyces cerevisiae* besides weak activity against *Pichia anomala* and *Candida albicans*. In a proliferation assay against the mouse fibroblast cell line L-929, strong cytotoxic effects were determined for both **1** (IC_{50} = 0.08 μg/mL) and **2** (IC_{50} = 0.17 μg/mL). All of these effects can be explained by the well-known inhibitory activity of eukaryotic protein synthesis.[16,17] However, the biological role of the observed trichothecenes for SBFS fungi in nature remains elusive. They could inhibit competitor SBFS fungi occupying the same ecological niche or plant pathogenic microorganisms that colonize the exocarps before fruit invasion. However, trichothecenes are known to act also as phytotoxins and may present plant pathogen virulence factors in the SBFS/fruit system.

To demonstrate a possible role of **1** and **2** in vivo, we cultivated *M. tardicrescens* 1936 on apple skin. Unfortunately, we could not detect either **1** or **2** due to strong contamination by wax in the extracts, which precluded their straightforward detection by analytical HPLC. A scale-up procedure and semipreparative HPLC separation prior to detection seems necessary to obtain more conclusive results. Therefore, we cannot assess the extension of a potential hazard resulting from trichothecene mycotoxins produced by SBFS fungi. However, the fact that juxtaposing colonies of different SBFS fungi are frequently separated from each other indicates that bioactive metabolites may be released on or into the fruit exocarp. SBFS are obviously well-adapted to epiphytically colonize fruit exocarps, whereas they are not known as fruit-destroying disease agents. Plants may profit mutualistically from the release of small amounts of toxic components, tolerated by the plant but inhibiting the development of other pathogenic agents.

Our results indicate that SBFS fungi are able to produce secondary metabolites with a wide spectrum of antibacterial and antifungal activities. The exploration of these substances might be suited as pharmaceuticals or in agriculture. Certainly, they will help us to understand the complex relationship between the different SBFS fungi and their plant hosts. Evaluation of the other strains listed in Table 1 is presently ongoing, and we expect to isolate further non-trichothecene bioactive compounds that may have some practical utility.

intervals, the samples were analyzed directly by liquid scintillation counting (LSC) to determine the total test substance related amounts in each sample to account for mass balance. Applied test substance recovery was quantitative in all reaction samples.

For high-temperature reactions, each test vessel was filled, leaving a small headspace to allow for expansion during heat treatment, with ca. 12 mL of sterile buffer containing the test substance. The test vessels were capped and heat-treated at either 90, 100, or 120 °C for short durations (<1 h) as is customary for such regulatory studies. Samples incubated at 90 °C were placed in a water bath. Samples incubated at 100 and 120 °C were placed in an oven maintained at constant temperature.

Sample Analysis. Test solutions were subjected to HPLC analysis to investigate the nature of the products formed, and identities of the products were established by a comparison of the HPLC retention times as well as by mass spectroscopy. The following equipment was used for these experiments: a Waters/Micromass Q-TOF micromass spectrometer operating MassLynx software (version 4.0, S.P. 2), an Agilent UV detector, and an Agilent 1100 liquid chromatograph. Radiodetection was performed by means of a Packard 505TR radioactivity flow detector and Flo-One software. The column employed was a Luna C_{18}, 150 mm × 4.6 mm, 5 μm (Phenomenex) with a guard column: Securiguard C_{18}, 3.0 × 4.0 mm (Phenomenex). HPLC analysis was conducted at ambient temperature. Mobile phases A (0.1% formic acid in Milli-Q water) and B (0.1% formic acid in acetonitrile) were used for a gradient, which started at 60% A and gradually decreased to 0% A, with balance as solvent B over 20 min. Solvent flow rate was 1 mL/min, and injection volumes for the analysis solutions were in the 10−200 μL range. The UV detector used in tandem was set for detection at 254 nm. Mass spectral analysis conducted for confirmation of various components was in positive ion mode with electrospray ionization. Various settings for the mass spectrometer were as follows: capillary voltage, 3500 V; sample cone, 25 V; extraction cone, 0.8 V; source temperature, 80 °C; and desolvation temperature, 150 °C.

Product Identification. The hydrolysis reaction components were easily identified initially on the basis of the HPLC retention times. A few chromatograms included in Figure 4 illustrate the main hydrolysis

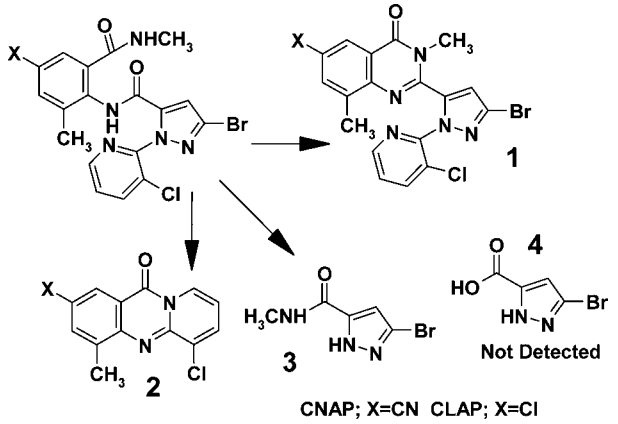

Figure 2. Degradation reactions of chlorantraniliprole and cyantraniliprole under hydrolysis conditions.

components. Analysis of typical CNAP hydrolysis samples showed two radiocarbon-containing peaks at 8.1 and 16.3 min. These peaks were coincident with peaks at 7.8 and 16 min in the UV chromatogram and at 8 and 16.1 min in the TIC from mass spectrometer detection. Unchanged CNAP in the hydrolysis samples was identified by comparing the retention time of the radioactive peak near 8 min with that of an authentic standard. LC-MS analysis was performed on selected samples to confirm the product identity as CNAP. The background-subtracted full-scan spectrum of the peak at 8 min in the TIC matched that of the CNAP reference standard with a major ion cluster at m/z 473, 475, and 477 and a small fragment at m/z 284, 286,

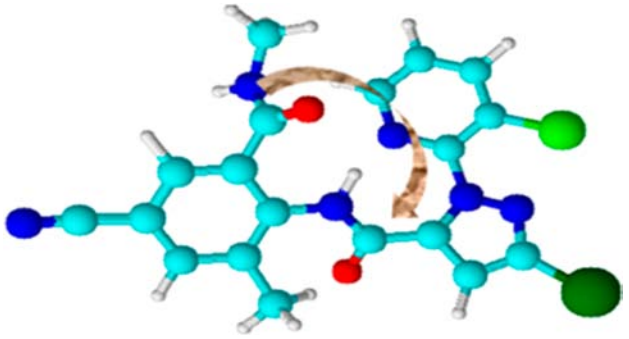

Figure 3. Intramolecular juxtaposition of amide functionality.

and 288. The three-ion clusters reflected the isotopes due to one Br and one Cl atom present in the molecule. HPLC cochromatography with authentic standards and mass spectral analysis confirmed this component as CNAP.

Degradate **1** from CNAP was identified using HPLC by comparing the retention time of the radioactive peak with that of an authentic standard. The background-subtracted full-scan spectrum of the peak at 16.1 min in the TIC was in good agreement with that of degradate **1** reference standard, and a molecular ion cluster at m/z 455, 457, and 459 further verified its identity.

High-temperature hydrolysis showed two additional components in small amounts. A component detected only in the PC-labeled samples accounted for 5−8% of the applied radioactivity (AR) in high-temperature hydrolysis samples. LC-MS analysis showed ions at m/z 204 and 206 in the background-subtracted full-scan spectrum of the TIC at 13.7 min. This spectrum was in good agreement with the reference standard of degradate **3**. Another component was a minor product in CN-labeled CNAP samples, which accounted for about 5% of product mixture. LC-MS confirmed that the molecular ion cluster present at m/z 270 and 272 was in good agreement with the reference standard of degradate **2**, as was the HPLC retention time.

Degradation products were identified for CLAP in a manner similar to those described above for CNAP. Identification of CLAP degradates **1**−**3** was also confirmed via HPLC and mass spectral methods. Chromatographic as well as mass spectrum information on CLAP has been reported previously[6] in connection with another study and does not need repetition here.

Determination of Rate Constants. Optimization of kinetics and rate constant calculations was conducted by setting up a first-order kinetics model in ModelMaker (software purchased from apbenson.com). The model, which is represented in the graphic below, illustrates CNAP degrading to degradate **1** and to all other products (denoted as sink). The rate constants for each transformation were iteratively optimized on the basis of the observed percent of each component at various sampling intervals. Because degradation to **1** was the main product in most of the experiments, the rate constant associated with process F2 was found to be a very small number or manually set to a very small value to mimic essentially no transformation. Whenever possible, it too was allowed to optimize in the cases when minor products accounted for a meaningful portion (approximately 5%) of degradation. Rate constants generated using this software program are summarized in Table 1, and the optimized decline/formation curves are illustrated in Figure 5. (Dots in Figure 5 represent the observed data; all observed amounts are expressed as percent of applied radioactivity, abbreviated %AR.)

CNAP	7	25	30	0.0229	298	24.9
CNAP	7	35	8	0.0923	308	
CNAP	9	15	3.10	0.2234	288	
CNAP	9	25	0.85	0.8152	298	14.9
CNAP	9	35	0.58	1.203	308	
CLAP	9	15	50	0.0138	288	
CLAP	9	25	10	0.069	298	26.9
CLAP	9	50	0.3	2.264	323	

In some cases, particularly at pH 9, it was apparent that some hydrolytic conversion of the test compound had taken place at time 0 during the short interval between dosing and analysis. To more accurately treat these data for kinetics analysis, the amount of degradate **1** observed at time 0 was added back to the observed amount of parent compound, and the amount of this degradate was treated as 0%.

For calculation of thermodynamic parameters, the linear form of the Arrhenius equation (eq 1) was fitted to the data (plots of ln k vs $1/T$, shown in Figure 6), using the trend line feature in Microsoft Excel. The slope of the line was used to calculate the activation energy using (eq 2).

$$\ln k = [(-E_a/R) \times (1/T)] + \ln A \quad (1)$$

k = degradation rate constant (day^{-1}), E_a = activation energy (cal/mol), R = gas constant (1.987 cal/mol·K), T = temperature (K), and A = constant.

$$\text{slope} = -E_a/R \text{ or } E_a = \text{slope} \times R \quad (2)$$

RESULTS AND DISCUSSION

The material balance of radioactivity for all test samples was within the range of 96−103.5% of the total applied quantity, which demonstrated that the observed products accounted for

dx.doi.org/10.1021/jf500671w | J. Agric. Food Chem. 2014, 62, 3531−3536

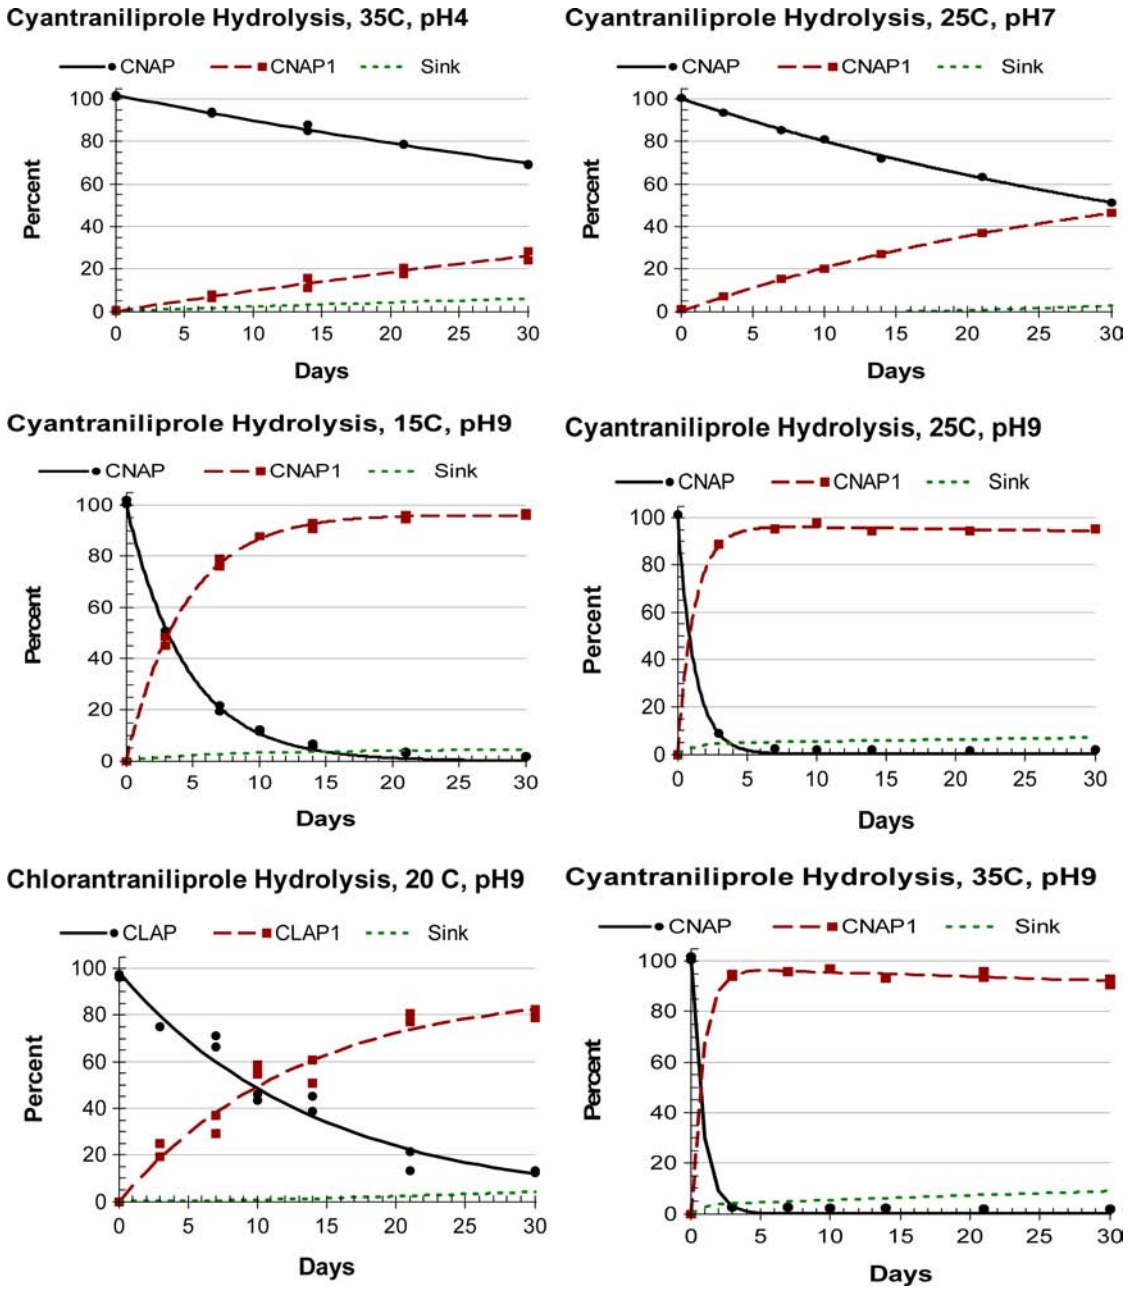

Figure 5. Cyantraniliprole and chlorantraniliprole hydrolysis in various pH buffers.

the entire applied material. The products observed were analogous for both compounds, as they are outlined in Figure 2, and were the only products observed in these experiments.

For both CLAP and CNAP hydrolysis experiments at all pH values, the main hydrolysis product, which accounted for the largest amount in the reaction mixtures, was a result of cyclodehydration, identified as degradate **1**. For CNAP, the hydrolysis was slow at pH 4 with minimal amounts of degradate **1**, especially at lower temperatures. Only 1.4−2.7% of degradate **1** was observed at 15 °C after 30 days, and its percentage increased to 8% at 25 °C and up to 28% at 35 °C. Transformation of CNAP at 35 °C and pH 4 is illustrated in Figure 5. Once the solution pH was increased to pH 7, the formation of degradate **1** from CNAP further increased at each temperature, as compared to pH 4 results, and the maximum amounts observed after 30 days were 16, 49, and 88% at 15, 25, and 35 °C, respectively. At pH 9, the reaction was quite rapid and transformation of CNAP to **1** was nearly quantitative, even at 15 °C. Degradate **1** accounted for 96−98% within the 30 day period at all three temperatures and pH 9. The transformation, as expected, proceeded at the fastest rate at the higher temperatures of 35 °C, and the parent compound disappeared entirely by day 5. Products **2** and **3** were not encountered in a meaningful proportion. Only at the higher temperature were ∼1−3% of additional products noted, and they were identified as degradates **2** and **3**, on the basis of the similarity of the HPLC retention times.

In short-exposure−high-temperature experiments for CNAP, conducted at 90−120 °C, the primary product observed was again identified as the cyclization product degradate **1** (maximum 14% AR); however, the additional pathway that leads to products **2** and **3** started to become competitive. Hydrolysis was most pronounced at pH 5 (100 °C), due to the

dx.doi.org/10.1021/jf500671w | J. Agric. Food Chem. 2014, 62, 3531−3536

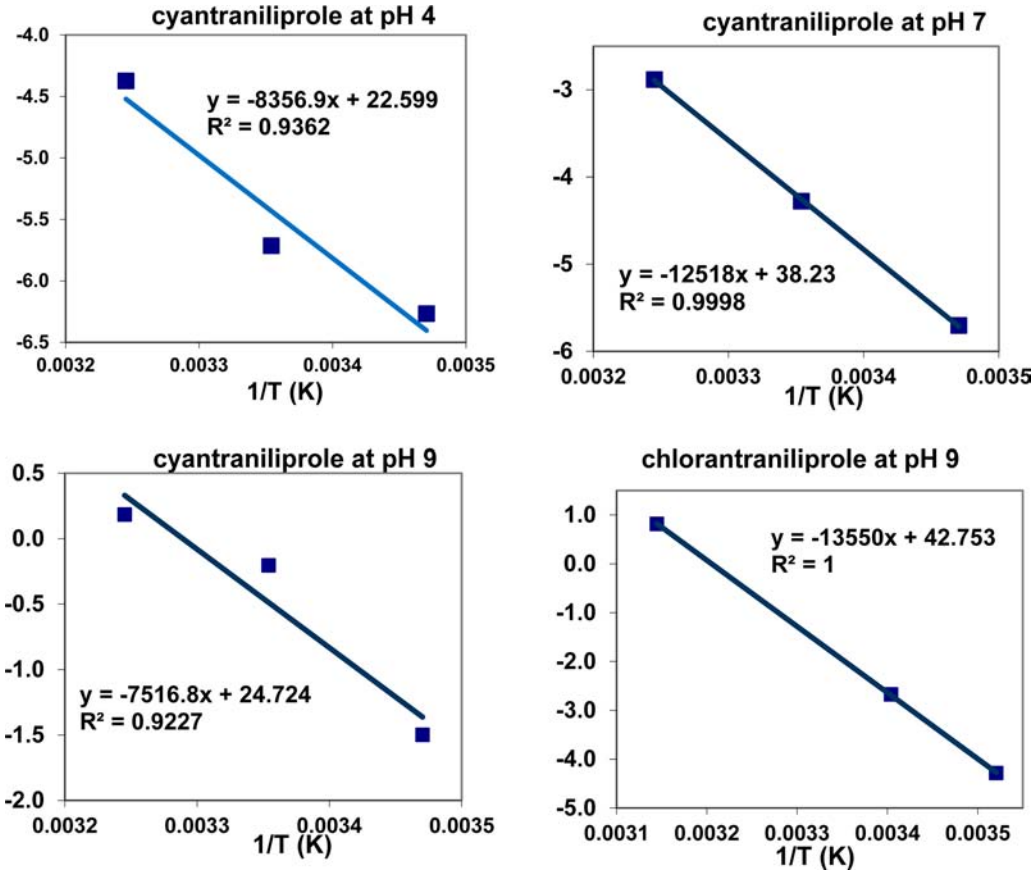

Figure 6. Arrhenius plots (ln k vs $1/T$).

longer incubation time (60 min), and in addition to degradate **1**, two additional components observed were identified as degradate **3** (maximum 5.8% AR) in PC-labeled samples and degradate **2** (maximum 9.7% AR) in CN-labeled samples.

In comparison with CNAP, CLAP was considerably slower in all hydrolytic transformations, including its conversion to degradate **1**. Virtually no degradation was noted at pH 4 and 7 for CLAP. Only at pH 9 did conversion to degradate **1** warrant further scrutiny, and increasing degradate amounts were found with rising reaction temperatures. Slower degradation of CLAP as compared with CNAP is obvious from the illustration in Figure 5. Similarly high temperature transformations, leading to additional degradates **2** and **3**, were also noted for CLAP at 90−120 °C, but with lower conversion into each of these degradates. Compounds **2** and **3** were observed only in the BC and PC-labeled experiments, respectively. In all of these experiments, any free carboxylic acids resulting from hydrolysis of any of the amides were notably absent.

Transformation data under various conditions of temperature and pH, for both CNAP and CLAP, to degradate **1** were used to model the kinetics of this transformation and to obtain the rate constants for this reaction. The rate data are summarized in Table 1 and also illustrated in the kinetics plots for selected experiments in Figure 5. Formation of degradates **2** and **3** was captured by the sink term used in kinetics modeling. A comparison of rate constants at pH 9 for CLAP and CNAP indicated that conversion to degradate **1** was nearly 15-fold faster for the latter compound. Arrhenius plots for both compounds and for each pH are illustrated in Figure 6. The activation energy, E_a, for CNAP was calculated as 16.6, 24.9, and 14.9 kcal/mol for pH 4, 7, and 9, respectively.

In all cases, the main product observed (degradate **1**) was clearly a result of cyclization with concomitant loss of water. A reaction carried out in water and leading to loss of water was somewhat counterintuitive, but not unprecedented. Weddige[8] had reported that attempted recrystallization of similar diamides in alkaline ethanol led to the isolation of the cyclized molecules instead of the diamides. Errede[9] postulated that hydrogen bonding with the solvents used in this reaction had a strong influence on the course of cyclization reaction. Errede further reported that the presence of water, and not anhydrous solvents, facilitated cyclodehydration. Therefore, observation of predominantly cyclodehydration in aqueous buffers was not a unique phenomenon in our experiments. An examination of the structure, as depicted in Figure 3, underscores that the benzamide nitrogen is well-positioned for initial cyclization via a nucleophilic attack onto the pyrazole carbonyl; this reversible reaction can easily happen in any media. In our view, it is the elimination of water, which leads to a stable quinazolinone ring, that has a strong pH dependence. This is also the reaction that is amenable to a significant substituent (X) effect. The initial cyclization leading to intermediate **1A** could, in principle, be catalyzed by an acid or base, which explains decreased E_{act} under both acidic and neutral conditions. Once this intermediate is generated, dehydration by protonating the "OH" reaction receives more pronounced acceleration via proton abstraction in intermediate **1A** (Figure 7), followed by expulsion of OH. This proton abstraction on "NH" located in the para position to substituent X explains the pH effect on the reaction rate. The proton abstraction from NH, which is strongly influenced by the nature of substituent X, explains a 15-fold faster reaction of CNAP versus CLAP. The

dx.doi.org/10.1021/jf500671w | J. Agric. Food Chem. 2014, 62, 3531−3536

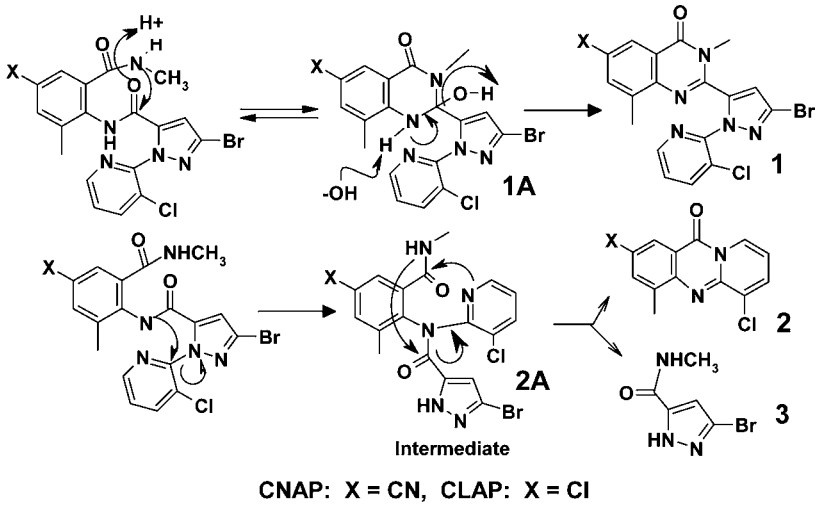

Figure 7. Mechanism of formation of degradates **1**, **2**, and **3**.

inductive effect of CN versus Cl (0.56 for CN vs 0.46 for Cl[11]) partly explains the ease of proton abstraction in CNAP. Resonance effect contribution from CN substituent undoubtedly assists this process further. The energy of activation (E_{act}) for this reaction is significantly lower (14.9 kcal/m) at pH 9 for CNAP and much lower than E_{act} for CLAP (26.9 kcal/m). The pK_a for CNAP, 8.8, versus 10.8 for CLAP, is also possibly due to the ease of amide deprotonation in CNAP.

Equally interesting was the formation of minor products (**2** and **3**) at high temperatures, which are formed via an entirely different intramolecular rearrangement. A pseudo Smiles rearrangement involving migration of nitrogen accounts for initial transformation into intermediate **2A**. E_{act} associated with such a reaction is considerably higher[10] than the values we calculated for transformation into degradate **1**, which is the reason this reaction makes a significant contribution only at high temperatures. Formation of the intermediate **2A** also requires ionization of the same amide N−H bond, which explains why even this reaction was more prominent for CNAP as compared to CLAP. Intermediate **2A** (Figure 7) has been not only observed but also isolated as a stable entity in some structurally related compounds. Subsequently, formation of degradates **2** and **3** occurs via intramolecular reorganization of the structure in which the transfer of CH_3NH occurs in concert with a nucleophilic attack by pyridine−nitrogen onto the amide−carbonyl, leading to molecular fission into the two degradates. A transition state associated with this reaction has been previously illustrated[6] in the papers from our laboratories. In conclusion, hydrolytic degradation of CLAP and CNAP led to some unusual products, all due to intramolecular reactions rather than typical hydrolytic degradation of the amides. The ease of conversion of these compounds to degradate **1** in aqueous media also makes it a prominent metabolite in environmental as well as plant and animal studies.

reliable differentiation of bitter and sweet fennel is beneficial for pharmaceutical quality control, because both fennel types are included in the European Pharmacopoeia and possess different applications in the food and pharmaceutical industries.[17−19] Therefore, the aim of this work was to develop new rapid and easy to perform analytical methods based on vibrational spectroscopy techniques (IR, NIR, and Raman) allowing a reliable discrimination of different wild fennel chemotypes occurring in nature. Furthermore, it was aimed to determine simultaneously the individual content of valuable substances in fennel fruits without the necessity of performing any sample preparation.

In this context a new chemotype of fennel, the essential oil of which is dominated by the phenylpropanoid γ-asarone, was discovered for the first time and characterized by GC-MS, nuclear magnetic resonance (NMR), and IR spectroscopy.

MATERIALS AND METHODS

Chemicals. Pure standard substances (*trans*-anethole, α-pinene, *p*-cymene, limonene, fenchone, estragole, anisaldehyde, α-asarone, and β-asarone, all >98%; myrcene, 95%; γ-terpinene, 97%) were purchased as analytical standards for terpene analysis or GC reference from Roth (Karlsruhe, Germany) and Sigma-Aldrich (Taufkirchen, Germany), respectively. All other reagents were of analytical grade and used without further purification.

Plant Material. Fruits of different fennel accessions were provided by the Institute of Plant Genetics and Crop Plant Research in Gatersleben (IPK) and of the Federal Plant Variety Office in Dachwig (Germany). For further botanical description (as far as obtainable) see Table 1.

Reference GC-FID and GC-MS Analyses. Approximately 200 mg of air-dried fennel fruits was homogenized in 10 mL of CCl_4 with an Ultra Turrax T25 blender for 1 min. Each accession was extracted twice, and the individual extracts were subsequently analyzed after centrifugation (4 min at 2415 *g*) by gas chromatography−flame ionization detection (GC-FID) using an Agilent gas chromatograph 6890N, fitted with an HP-5 column (50 m ×x 0.32 mm i.d., film thickness = 0.52 μm). This GC instrument is routinely used for essential oil analysis and continuously validated with external standards. Hence, no repeat determination was performed and each sample was investigated once. Detector and injector temperatures were set at 280 and 250 °C, respectively. The following oven temperature program was used: heating from 80 to 220 °C at a rate of 8 °C/min. This final temperature was held for 10 min. Carrier gas was hydrogen with a constant flow rate of 1 mL/min (split = 1:20). GC-MS analyses of the fennel extracts were performed using an Agilent MSD 5972/HP 5890 series II, equipped with a 30 m × 0.25 mm i.d., 0.5 μm, HP-5MS column. Column temperature was programmed from 60 to 120 °C at a rate of 3 °C/min, increased to 220 °C at 8 °C/min, and held for 10 min. Carrier gas was helium with a constant flow rate of 1.1 mL/min and a split of 1:10. Injector and detector temperatures were set at 250 and 280 °C, respectively. The ionization energy was set at 70 eV. Identification of the detected compounds was based on their relative retention times and their mass spectra in comparison with those observed for the above-mentioned pure standard substances. The other compounds were tentatively identified by using the NBS75K and Wiley 138 library databases of the GC-MS system. The percentage composition of the volatile fraction was computed from the GC peak areas according to the 100% method without using any correction factors. Identification and structural determination of γ-asarone were performed on the basis of the MS fragmentation patterns compared to authenticated standards (α- and β-asarone).

For further analysis, the essential oil of FOE 87 was obtained by hydrodistillation of approximately 2 g of fennel fruits.

Vibrational Spectroscopic Measurements. Besides the above-mentioned terpenoid standards and the intact fennel fruits, also solvent extracts of fennel fruits were investigated by Raman and ATR-FTIR spectroscopy. These extracts were produced following the protocol described under Reference GC-FID and GC-MS Analyses.

ATR-FTIR Spectroscopy. MIR spectra of intact fennel fruits, CCl_4 solvent extracts, and pure standards were recorded in the wavenumber range from 4000 to 375 cm^{-1} with a portable ATR diamond crystal infrared spectrometer (Alpha, Bruker Optics GmbH, Ettlingen, Germany). Approximately 5−10 mg of the standards was placed on the surface of the diamond crystal and directly measured. One hundred microliters of the solvent extracts was applied dropwise on the diamond crystal, and the spectra were recorded after evaporation of the solvent (observation of the disappearing CCl_4 absorption bands). Intact fennel fruits were measured under gently pressure with the interior side directed to the crystal, keeping the pressure constant for all measurements and avoiding damage to the fruits. All spectra were composed of 32 scans with a spectral resolution of 4 cm^{-1}. Each sample was measured triply, and the resulting triplicates were finally averaged and used for later chemometric calculations.

Figure 2. Mass spectra of α-asarone (top) and β-asarone (middle) standards and of the main component in the volatile fraction of FOE 87 identified as γ-asarone (bottom).

Identification and structural determination of γ-asarone were performed by comparing the ATR-FTIR spectrum of purified γ-asarone with the α- and β-asarone standard. Pure γ-asarone was obtained by thin layer chromatography (TLC) of the extract of accession FOE 87 prepared for GC-MS. TLC was performed at TLC-aluminum sheets coated with silica gel 60 F254 (layer thickness of 0.2 mm) obtained from Merck KGaA, Darmstadt, Germany. As mobile phase a solvent mixture of chloroform and hexane at the volume ratio of 3:1 was used. The relatively low amount of purified γ-asarone was completely used for ATR-FTIR analyses.

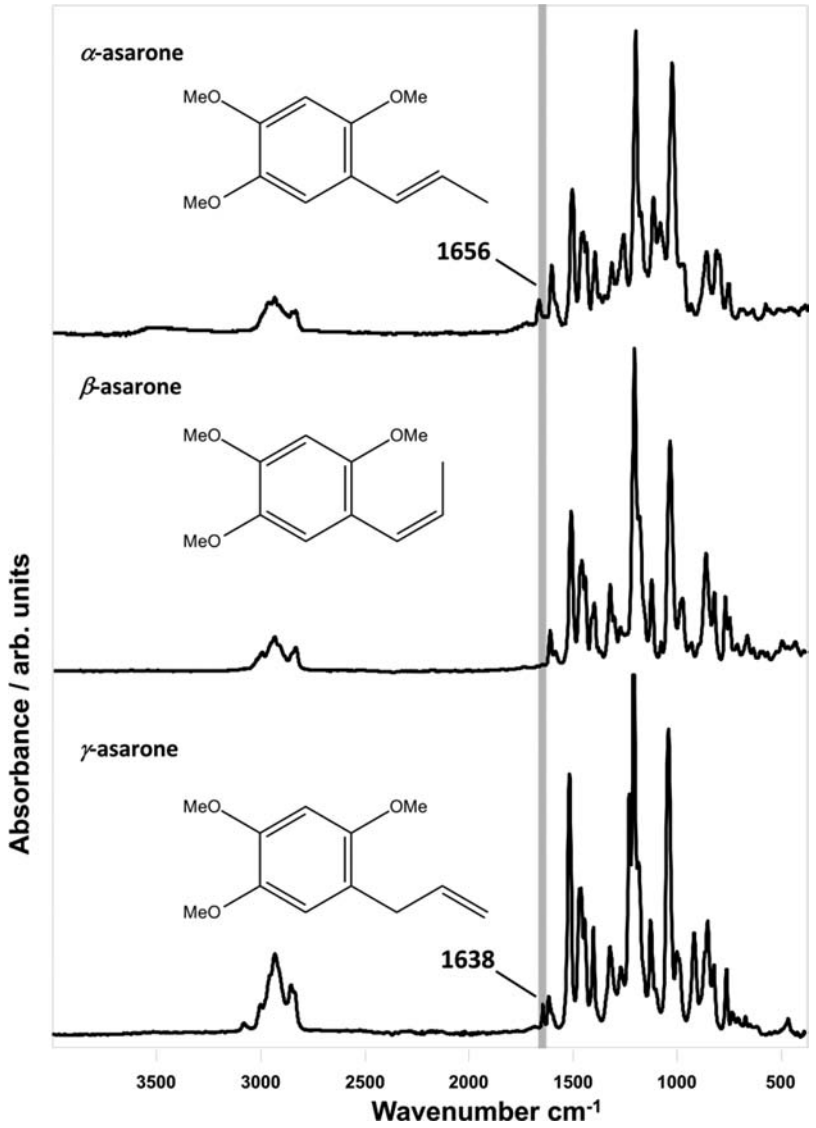

Figure 3. ATR-FTIR spectra of α-asarone (top) and β-asarone (middle) standards and of the main component in the volatile fraction of FOE 87 identified as γ-asarone (bottom).

NIR Spectroscopy. NIR analyses were performed in the range from 12500 to 3600 cm^{-1} with a spectral resolution of 8 cm^{-1} on an FT-NIR spectrometer (Multi Purpose Analyzer, Bruker Optics). Approximately 0.5 g of fennel fruits was loosely packed in glass cuvettes, and the resulting spectra were collected during 32 scans; the raw spectra were corrected for the effects resulting from scatter and baseline drift using the weighted multiplicative scatter correction algorithm (WMSC) of the OPUS 6.5 software (Bruker GmbH, Germany). Each sample was analyzed with three-fold repetition followed by averaging of the triplicates. Averaged spectra were exclusively used for the subsequent chemometric evaluation.

FT-Raman Spectroscopy. Raman spectra were recorded on a Bruker RFS 100S with a diode-pumped Nd:YAG laser, emitting at 1064 nm, and a germanium detector cooled with liquid nitrogen. All spectra were measured with a resolution of 4 cm^{-1} in the range from 4000 to 100 cm^{-1} with a laser power of 500 mW supplied by a focused laser spot size of 100 μm in diameter. The fennel extracts were directly measured in solution in glass vials and the spectra were accumulated from 64 scans. As far as the samples were measured in liquid solution, no measurement replications were performed, and each sample was analyzed only once.

Because of high fluorescence appearance at lower laser energy and burning of the sample by increasing energy, it was unfortunately not possible to obtain meaningful Raman spectra of the fennel fruits. Hence, only the extracts were analyzed by Raman spectroscopy.

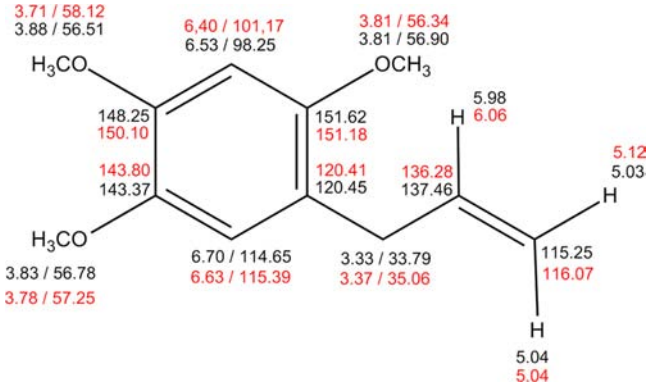

Figure 4. Chemical shifts of the ^{1}H and ^{13}C NMR spectra from the postulated γ-asarone structure and the calculated theoretical shifts (red) obtained from ACD software (Advanced Chemistry Development Inc., Toronto, Canada).

^{1}H and ^{13}C NMR Spectroscopy. Because of the relatively high concentration of the unknown phenylpropanoid structure in the essential oil of FOE 86 and FOE 87, the crude essential oil of FOE 87, obtained by hydrodistillation, was redissolved in deuterated chloroform

dx.doi.org/10.1021/jf405752x | J. Agric. Food Chem. 2014, 62, 3537−3547

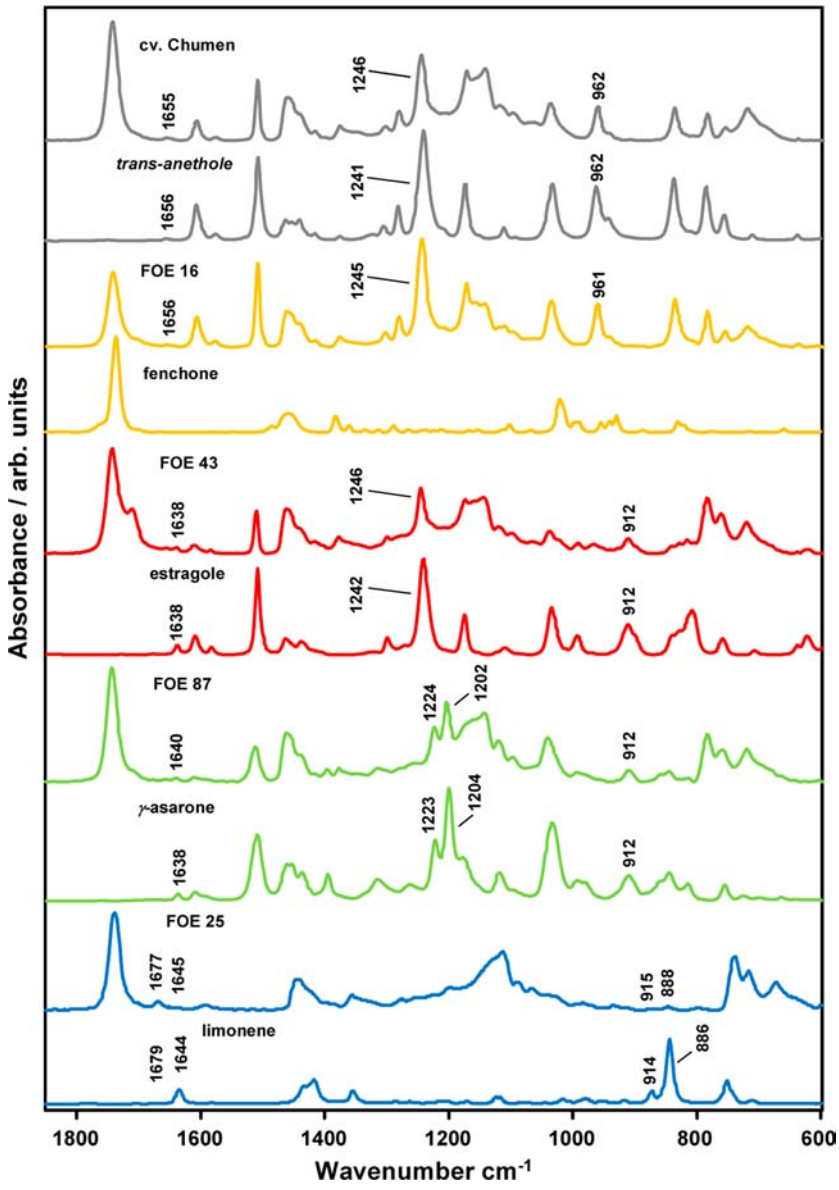

Figure 5. ATR-FTIR spectra obtained from CCl_4 extracts of different fennel genotypes and the corresponding standards for the most valuable components in the volatile fraction.

($CDCl_3$, Deutero GmbH, Germany) and investigated by ^1H and ^{13}C NMR without previous purification.

The ^1H NMR (200 MHz) and the ^{13}C spectrum (50 MHz) were recorded on a Varian Gemini 2000), both at 298 K. The chemical shifts, δ, are given in parts per million. The solvent signals of $CDCl_3$ were used for internal calibration and appeared at δ 7.26 (^1H) and δ 77.16 (^{13}C), respectively.

Additionally, the ^{13}C spectrum of γ-asarone was calculated using ADS software (Advanced Chemistry Development Inc., Toronto, ON, Canada), and the theoretical signals were compared to the experimentally determined results.

Chemometrics. For estimating the variability of the samples, hierarchical cluster analysis (Ward's algorithm) was applied under usage of the instrument software OPUS 6.5 (Bruker, Germany).

Relevant spectral ranges were determined by comparison of sample spectra with those of appropriate standards and by principal component analysis (PCA).

RESULTS AND DISCUSSION

The molecular structures of the most important volatile substances occurring in the analyzed fennel fruits are presented in Figure 1, whereas Table 2 shows the mean values for the most important volatile components as determined by GC-FID.

As can be seen in Table 2, each genotype shows an individual metabolic profile in the volatile fraction and can be classified into different groups according to its main component(s).

Except accession FOE 25, all considered fennel fruits contained fenchone in the concentration range between 6.29 and 35.08% in the solvent extracts and are dominated by at least one phenylpropanoid species as the main component, either *trans*-anethole or estragole.

In contrast, the CCl_4 extract of FOE 25 is dominated by nearly 47% of limonene and 29% of piperitenone oxide. The identification of piperitenone oxide has already been performed earlier by Badoc et al. on the basis of GC–high resolution MS data using the same fennel subspecies (*F. vulgare* sp. *piperitum*, Table 1).[3] Accordingly, this accession is assigned to the piperitenone/piperitenone oxide chemotype.[3,5]

Identification of a New Fennel Chemotype and Structural Evaluation of γ-Asarone. Two other accessions,

dx.doi.org/10.1021/jf405752x | J. Agric. Food Chem. 2014, 62, 3537−3547

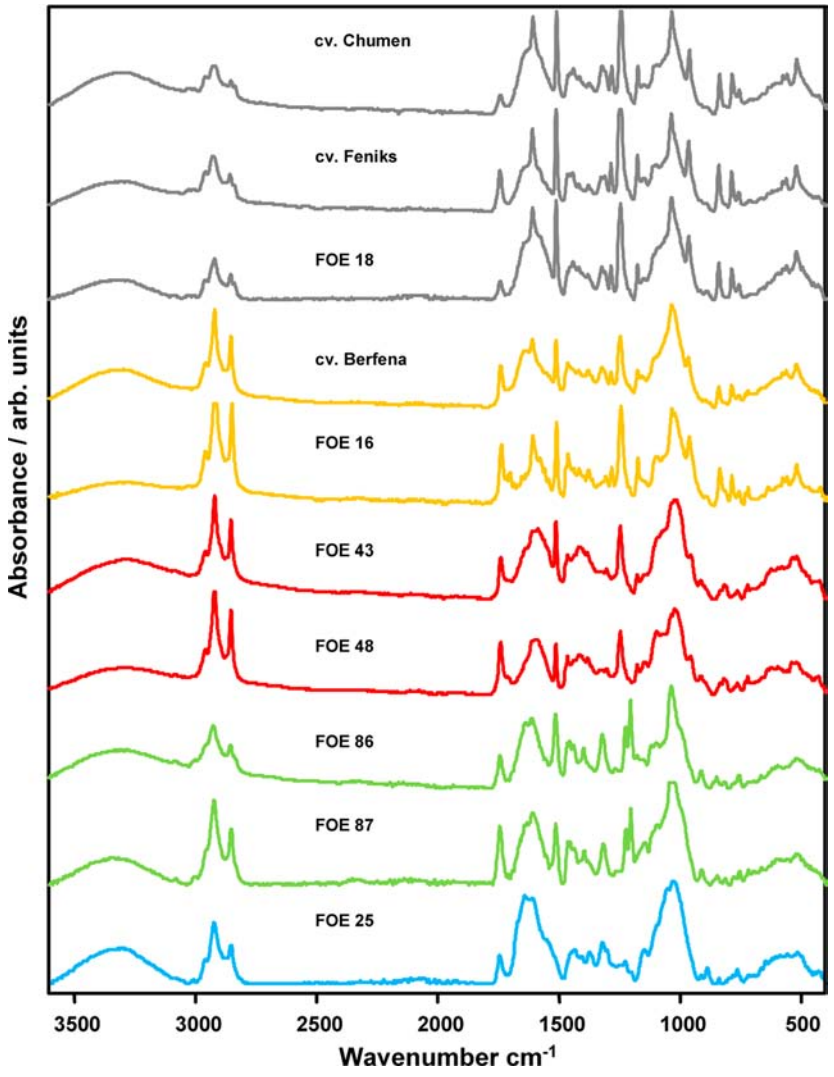

Figure 6. ATR-FTIR spectra obtained from the fruits of different fennel genotypes.

FOE 86 and FOE 87, also contain high amounts of a phenylpropanoid substance, but neither estragole nor *trans*-anethole could be detected in these samples by GC-MS or vibrational spectroscopy. Nevertheless, the MS data clearly showed a structural relationship to estragole and *trans*-anethole, but indicates a higher substitution of the aromatic ring system with three methoxy groups (Figure 2).

The molecular ion M^+ with m/z 208 indicates three methoxy groups as substituents at the aromatic ring. Comparison of the mass spectra of α- and β-asarone standards with those of the unknown component in FOE 86 and FOE 87 shows a higher fragment at m/z 177 $(M - 31)^+$ for the extract (Figure 2, bottom). This is caused by the higher fragmentation tendency of the ring system at the methoxy groups (-31 m/z) in the extract compared to α- and β-asarone. With the conjugated side chain in α- and β-asarone, fragmentation appears more at the C3 substituent as shown in the relatively low intensity of fragment m/z 177 (Figure 2, top and middle).

The corresponding ATR-FTIR spectrum additionally showed an allylic character of the aliphatic C═C double bond similar to that of estragole (Figure 3).

Hence, under usage of GC-MS and ATR-FTIR and in comparison to α- and β-asarone as commercially available standards, the structure of the unknown compound was proposed as γ-asarone (Figure 1), which is already known to be present in the essential oil of various plant species and for its fungitoxic and antibacterial activity.[20−22]

The *cis*−*trans* isomers α-asarone and β-asarone themselves could be excluded as the unknown phenylpropanoid, as the results from ATR-FTIR clearly manifest the allyl substituent at the aromatic ring.

To prove the suggestion of the γ-asarone structure, ^{1}H and ^{13}C NMR experiments of the pure essential oil of FOE 87 were performed. Because of the relatively high concentration of this compound of about 70% in the essential oil fraction, no prior purification step was performed.

Figure 4 presents the results from ^{1}H and ^{13}C NMR as well as from the theoretical calculation of the ^{13}C NMR spectrum. Besides the very good correlation of theoretical and experimental data, the signal assignment is in good accordance with NMR data for γ-asarone described in the literature.[23]

The occurrence of γ-asarone in *F. vulgare*, representing nearly 70% of the essential oil of accessions FOE 86 and FOE 87, is described here for the first time. This is why we introduce the name "γ-asarone type" for this new fennel chemotype.

Spectroscopic Analysis. Generally, all vibrational spectroscopy methods applied in this study are useful for rapid and reliable discrimination of the described fennel chemotypes.

dx.doi.org/10.1021/jf405752x | J. Agric. Food Chem. 2014, 62, 3537−3547

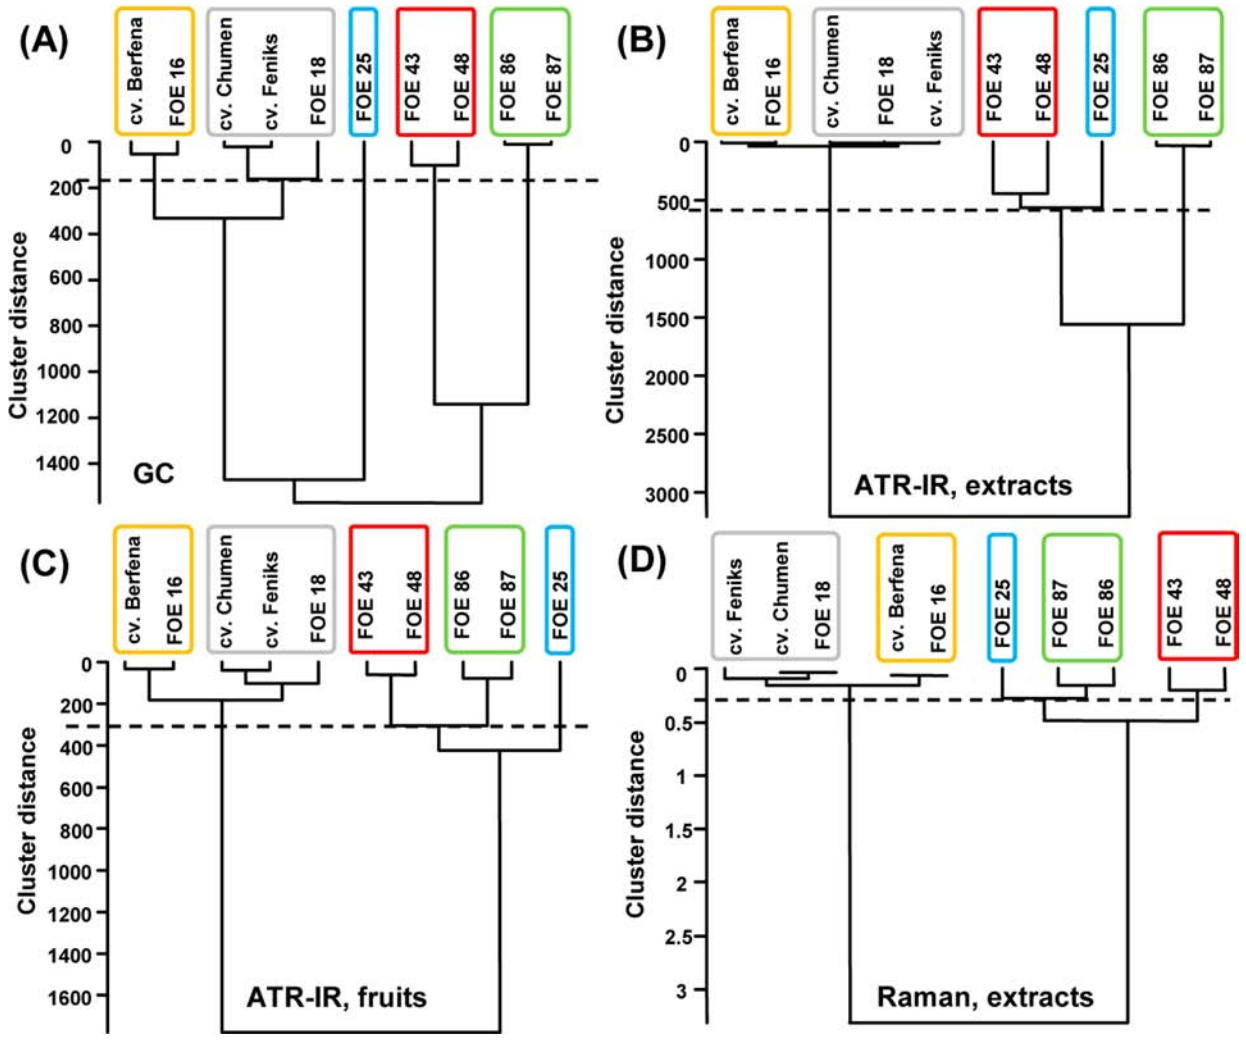

Figure 7. Hierarchical cluster analysis of 10 different fennel accessions based on the GC-FID data (A), the ATR-FTIR spectra of the CCl_4 extracts (B), the ATR-FTIR spectra of the intact fruits (C), and the Raman spectra of the CCl_4 extracts (D). The dashed line marks the lowest level of complete discrimination of the individual clusters.

For NIR, only intact fruits were analyzed because of the small available amounts of solvent extracts. For ATR-FTIR the extracts as well as the intact fruits were evaluated, whereas for Raman only the extracts were analyzed (see FT-Raman Spectroscopy). High fluorescence appearance in the spectra along with burning of the sample under the applied laser energy made it impossible to obtain meaningful Raman spectra with the used spectrometer.

ATR-FTIR Spectroscopy. As presented in Table 2, all fennel accessions contain higher amounts of a ketone (fenchone or piperitenone oxide) and an unsaturated phenylpropanoid substance. The high IR activity of the C═O bond resulting in strong signals in the ATR spectra of the extracts as well as the fennel fruits made it nearly impossible to distinguish the different fennel chemotypes on the basis of their fenchone/piperitenone oxide content. Figure 5 shows the ATR spectra of the individual fennel extracts in the fingerprint region from 1850 to 600 cm^{-1} and the corresponding reference compounds for the main volatile components.

In nearly all fennel accessions the strong $\nu_{C=O}$ absorption band around 1742 cm^{-1} dominates the spectrum in the fingerprint region even if the concentration of the corresponding carbonyls (fenchone/piperitenone oxide) in sum averages only 7.75% (cv. Chumen). As a consequence, the strong IR activity of this polar bond with its high dipole moment makes it impossible to distinguish the different genotypes on the level of their fenchone/piperitenon oxide concentration.

Besides the ketone function, the phenylpropanoids as well as the terpenoids differ only in their carbon structure and the presence and number of methoxy groups.

As can be easily seen when the MIR spectra of the extracts are compared with those of the pure standards, *trans*-anethole and estragole can be distinguished only by the signals resulting from the nonaromatic C═C double bond. Because of the resonance effect in *trans*-anethole, the signals for $\nu_{C=C}$ (1656 cm^{-1}) and γ_{CH} (962 cm^{-1}) are shifted hypsochromically to higher wavenumbers, compared to estragole ($\nu_{C=C}$ at 1638 cm^{-1} and γ_{CH} at 912 cm^{-1}) and γ-asarone ($\nu_{C=C}$ at 1640 cm^{-1} and γ_{CH} at 912 cm^{-1}).

For the two isolated double bonds in limonene the corresponding signals are $\nu_{C=C}$ at 1679 and 1644 cm^{-1} as well as γ_{CH} at 914 and 886 cm^{-1}.

For the differentiation of estragole and γ-asarone the wavenumber range from 1200 to 1130 cm^{-1}, showing the asymmetric and symmetric valence vibrations ν_{C-O-C} from the different methoxy groups, proved to be suitable.

dx.doi.org/10.1021/jf405752x | J. Agric. Food Chem. 2014, 62, 3537−3547

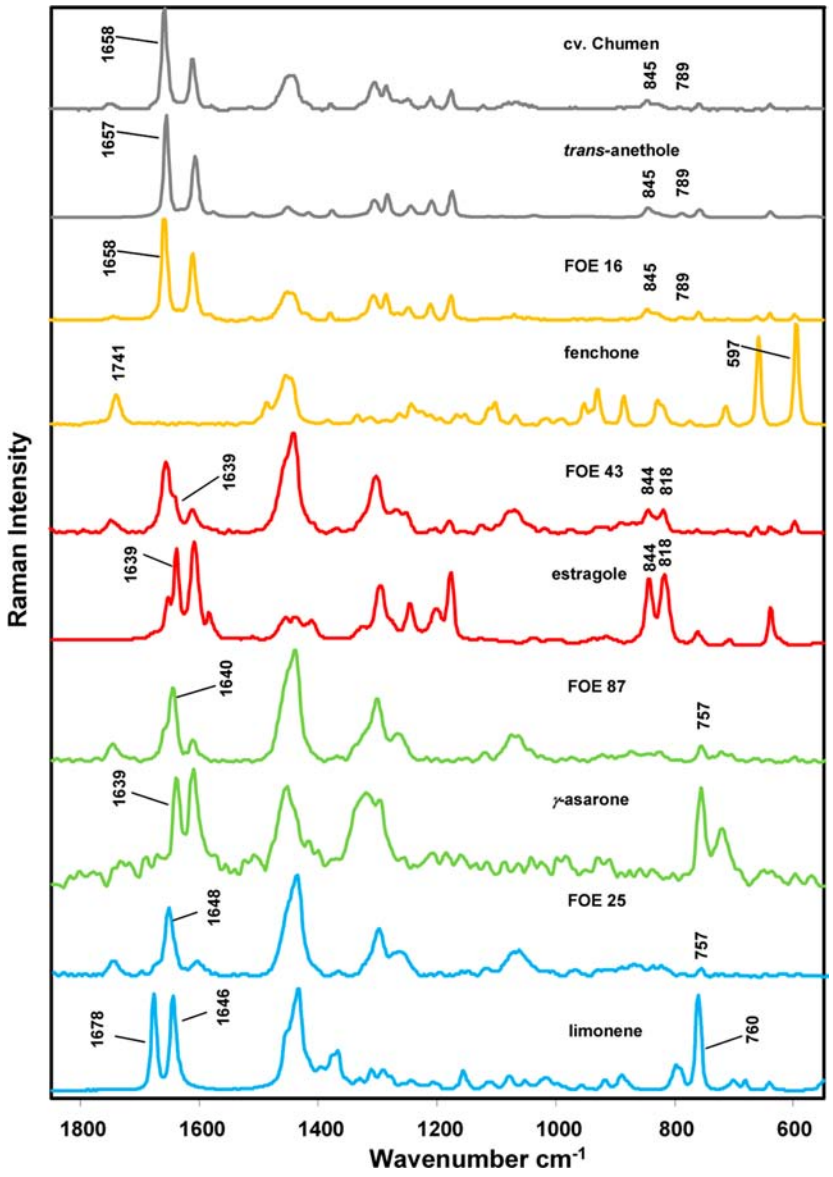

Figure 8. Raman spectra of CCl_4 extracts from different fennel genotypes and the corresponding standards for the most valuable components in the volatile fraction.

Despite the relatively weak IR activity of the C═C double bonds, cluster analysis on the basis of the above-mentioned spectral ranges results in a successful differentiation and classification of the four considered fennel chemotypes, even for the intact fennel fruits, the spectra of which are dominated by matrix signals from starch, lipids, and water (Figure 6).

Figure 7 shows the hierarchical cluster analysis of all fennel accessions investigated in this study according to the GC-FID data (A), compared to the ATR-FTIR spectra of the fennel extracts (B) and the intact fruits (C), as well as the Raman spectra of the extracts (D, discussed later).

According to the qualitative and quantitative composition of their volatile fraction, the 10 considered fennel genotypes can be classified into 4 chemotypes: the *trans*-anethole type with accessions cv. Berfena, FOE 16, FOE 18, cv. Chumen, and cv. Feniks; the estragole type with FOE 43 and FOE 48; the γ-asarone type with FOE 86 and FOE 87; and the piperitenone oxide type FOE 25, shown in Figure 7A.

The same classification is obtained by ATR-FTIR for both the fruits and the extract (Figure 7B,C). The only difference is the subgrouping of FOE 25, which is pooled together with the estragole type and the γ-asarone type in a larger cluster for ATR-FTIR and with the *trans*-anethole type for GC. This might be easily explained by the absence or very low concentration of *trans*-anethole in FOE 25, the estragole type, and the γ-asarone type.

Additionally, for the fruits and the extracts, a strict separation of sweet and bitter fennel, as demanded by the European Pharmacopoeia, can be observed between the cluster of the *trans*-anethole chemotype. The two accessions, cv. Berfena and FOE 16, contain much more than 15% of fenchone and simultaneously a content of *trans*-anethole of about 60%. In contrast, cv. Chumen, cv. Feniks, and FOE 18 show a fenchone content between 6 and 10% going along with concentrations of *trans*-anethole of 73% and higher. The slightly lower values for *trans*-anethole, as demanded by the European Pharmacopoeia, is a consequence of the solvent extraction used in this work instead of water steam distillation.

dx.doi.org/10.1021/jf405752x | J. Agric. Food Chem. 2014, 62, 3537−3547

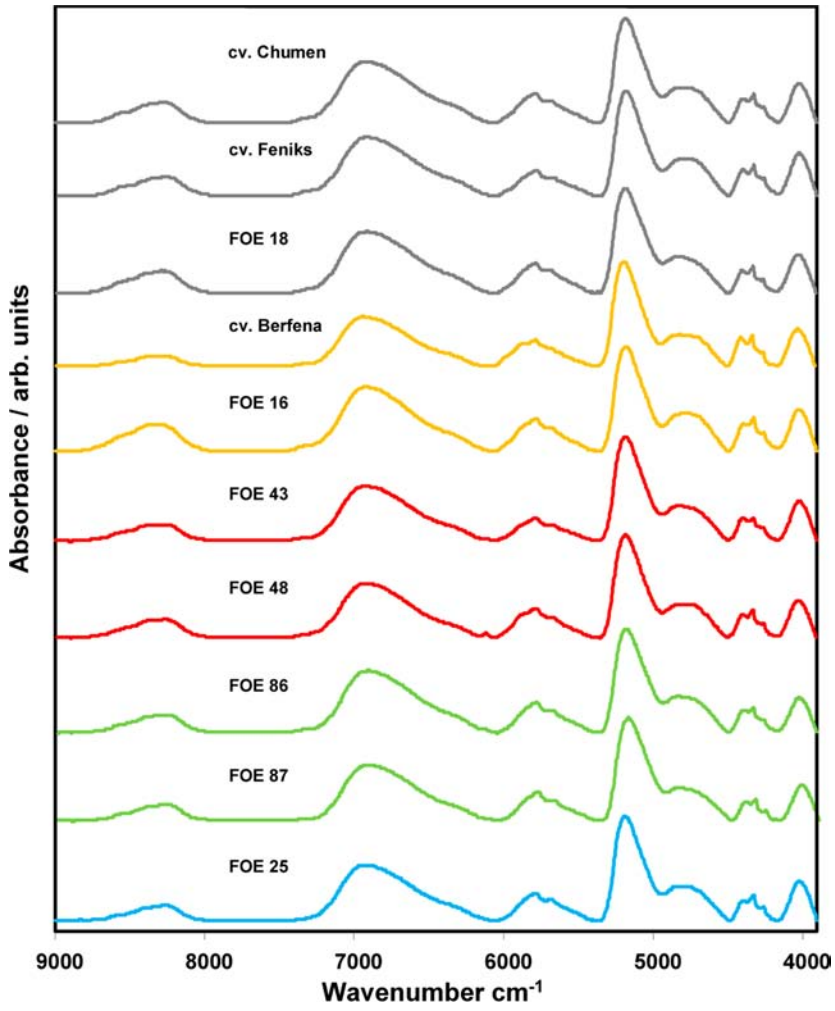

Figure 9. NIR spectra of intact fennel fruits from different fennel genotypes.

Hence, the ATR-FTIR technique offers for both the extracts and the intact fruits a fast tool for the discrimination of different fennel chemotypes according to the chemical profile of their volatile fraction and additionally allows a fast differentiation of sweet and bitter fennel within one chemotype, the *trans*-anethole type.

Raman Spectroscopy. The principle of Raman spectroscopy is the changing polarizability of a bond through the absorption of light. Therefore, structures with unsaturated carbon bonds, especially when conjugated, are highly Raman active.

Because the most significant differences in the structure of the essential oil components are the number and connectivity of C═C double bonds, one can expect an unambiguous classification of the fennel accessions by Raman spectroscopy. Figure 8 presents the Raman spectra of fennel extracts from five representative genotypes in the fingerprint region from 1800 to 550 cm^{-1} compared to the corresponding standards of the main components in the volatile fraction.

As already mentioned for ATR-FTIR, the main differences in the spectra are due to the vibrations of the C═C double bond in the side chain. The conjugation of this bond with the aromatic ring system in *trans*-anethole results in a hypsochromic shift of $\nu_{C=C}$ to 1658 cm^{-1} compared to estragole with its isolated C═C and $\nu_{C=C}$ at 1638 cm^{-1}. Limonene is determined by its γ_{CH} at 760 cm^{-1}. According to previous work, the vibration at 597 cm^{-1} was set as a marker band for fenchone because no other main component shows any significant signal at this spectral range.[10]

On the basis of these marker bands hierarchical cluster analysis was performed resulting in a classification of the fennel extracts according to their chemotype as shown in Figure 7D.

According to the results from ATR-FTIR, the same grouping of the fennel genotypes according to their main components in the volatile fraction is obtained. The first criterion for the clustering (cluster distance around 3.5) is the nature of the C═C double bond in the side chain resulting in one cluster containing the *trans*-anethole type (conjugated C═C, $\nu_{C=C}$ to 1658 cm^{-1}) and one containing the estragole type, γ-asarone type, and piperitenone oxide type (isolated C═C in estragole, γ-asarone, and limonene).

The next classification at a cluster distance of 0.5 separates the estragole type from the γ-asarone type and the piperitenone oxide type due to the contents of fenchone (597 cm^{-1}). The same attribute separates the "sweet" fennel from the "bitter" fennel in the cluster of the *trans*-anethole- type (cluster distance around 0.2). Finally, discrimination between FOE 25 and FOE 86/FOE 87, the piperitenone oxide type, and γ-asarone type results on the basis of the limonene content and its marker band γ_{CH} at 760 cm^{-1}.

In conclusion, the results obtained in this study show that Raman spectroscopy allows a fast and precise discrimination of different fennel chemotypes according to their chemical

dx.doi.org/10.1021/jf405752x | J. Agric. Food Chem. 2014, 62, 3537−3547

composition even on the level of a single spectrum. As already presented for ATR-FTIR, Raman spectroscopy is also a suitable tool to distinguish between sweet and bitter fennel without application of time-consuming chromatography.

NIR Spectroscopy. NIRS has been established for years as a fast and nondestructive method for qualitative and quantitative evaluation of numerous primary and secondary metabolites directly in plant material.[12,24−26]

A few years ago our group already developed a reliable quantification protocol for the determination of valuable essential oil components directly in intact fennel fruits, presenting NIRS as a promising tool for the chemotaxonomical characterization of the considered fennel chemotypes.[16] According to former studies performed on basil, oregano, and thyme, the NIR spectra of the analyzed fennel fruits are dominated by overtones or different combinations of C−H stretching and bending vibrations occurring between 4000 and 9000 cm^{-1}. As shown in Figure 9, the NIR spectra of the fruits obviously show no significant differences.

As the essential oil composition structurally differs only in comparatively narrow ranges, the similarity of the NIR spectra is evident. Nevertheless, even those small variations can be sufficient for a successful interpretation by applying chemometric algorithms.

Figure 10 presents a cluster analysis based on NIR spectral data resulting in a strict separation of all four fennel chemotypes

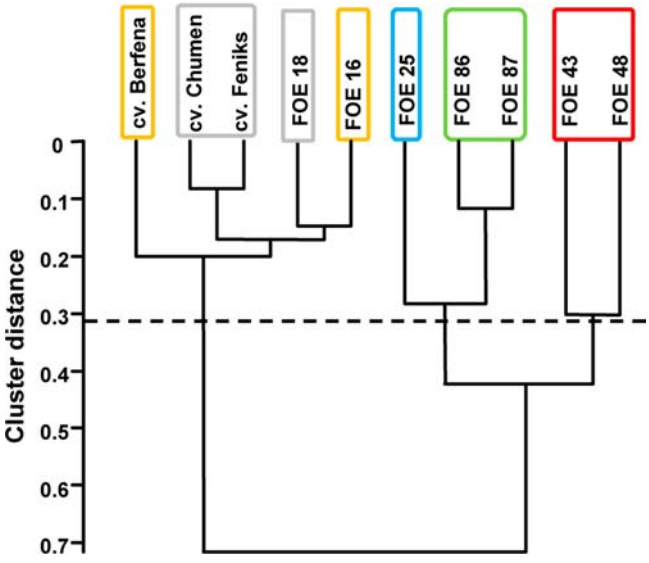

Figure 10. Hierarchical cluster analysis of 10 different fennel accessions based on the NIR spectra of the intact fruits.

in the same manner as described for Raman and ATR-FTIR spectroscopy. The considered spectral ranges are restricted to combination vibrations and the first and second overtones of C−H and C−C (4100−4650, 6000−6250, and 8200−9000 cm^{-1}). Only the discrimination of sweet and bitter fennel is not sufficiently obtained when this NIRS method is applied.

Nevertheless, NIRS offers a fast and easy way to distinguish different fennel chemotypes on the base of their main essential oil components directly in intact fruits. An indirect discrimination of sweet and bitter fennel can be obtained by the verified prediction of the *trans*-anethole and fenchone contents by NIRS, published by Steuer and Schulz.[16] Furthermore, the special advantage of NIRS measurements over mid-IR or Raman spectroscopy is that analyzed samples are more representative with regard to their sample presentation technique and sample quantity (approximately 0.5 g of the fennel fruits is put into glass cuvettes, resulting in a "sample layer" of about 15 mm thickness with a penetration depth of the NIR beam of several millimeters). This guarantees improved sample homogeneity compared to the two other vibrational spectroscopy techniques.

the lipid bilayer significantly and that insertion of each terpene in the bilayer is driven by a different balance of entropy and enthalpy, determined by the functional groups present on the terpene.[19]

One of the common antimicrobial monoterpenes found in several EOs is α-pinene. The strained four-membered ring of α-pinene is very reactive and makes it prone to opening and skeletal rearrangements.[20,21] In addition to research about the antimicrobial activity of monoterpenes/monoterpenoids, there has been some recent work by Wilderman and colleagues that has shown that (+)-α-pinene (**1a**) is a potent P_{450} 2B inhibitor.[22] With microbes becoming increasingly resistant to known antibiotics, it is imperative to develop drugs that are active against the next generation of microbes. Both enantiomers of α-pinene are readily available, and hence it is an excellent starting material for synthesizing a variety of functionally and skeletally altered α-pinene derivatives. In this study, we investigate the structure−antimicrobial activity relationship for both (+)- and (−)-α-pinene and the corresponding derivatives. Antimicrobial activity was assessed on four test microorganisms (*Staphylococcus aureus*, *Micrococcus luteus*, *Escherichia coli*, and *Candida albicans*) using a bioautographic assay.[23,24] This bioassay gave good reproducibility. Lastly, membrane fatty acid composition of the test microorganisms was determined by fatty acid methyl ester (FAME) analysis.

MATERIALS AND METHODS

Chemicals. Silica gel 60 Å 70−230 or 230−400 mesh ASTM from Sigma-Aldrich was used for gravity column chromatography. TLC plates containing silica on aluminum/glass with a fluorescent indicator (254 nm), starting materials (+)-α-pinene 98% and (−)-α-pinene 98%, lithium aluminum hydride (LAH) powder, and all ACS grade solvents were purchased from Sigma-Aldrich and used as such. Chlorosulfonylisocyanate (CSI) 98+% was purchased from Acros Organics. IR spectra were recorded on a Perkin-Elmer FTIR 1600 series in CH_2Cl_2 solution, and ^1H and ^{13}C NMR spectra were recorded on a JEOL Eclipse 300 MHz NMR spectrometer in $CDCl_3$. Synthesized compounds were >95% pure as verified by ^1H NMR and were purified by chromatography, recrystallization, or trituration. Modified experimental procedures[25] for **9a**, **10a**, **11a**, **12a**, **13a**, and **14a** are provided in the Supporting Information along with the ^1H NMR and ^{13}C NMR spectra of the synthesized compounds.

Microorganisms and Culture Media. Three of the microorganisms used in this study (*M. luteus*, *E. coli*, and *S. aureus*) were clinical isolates and were received as a gift from Katherine Greiner, Associate Professor of the Medical Technology Program at Marist College; *C. albicans* (ATCC 90294) was purchased from Sigma. The bacterial cultures were subcultured in Luria−Bertani (LB) medium, and the yeast was subcultured in Sabaraud (SAB) at 37 °C for 12−14 h (*M. luteus* was grown at 25 °C for 60−72 h) at 135 rpm. The optical density of the culture was measured with a UV−vis Beckman 650 spectrophotometer at 600 nm (OD_{600} = 1 corresponds to approximately 10^9 cells/mL).[26] Culture media were autoclaved at 120 °C for 20 min.

Bioautographic Assay. The antimicrobial activity of the nine compounds synthesized was evaluated against four test microorganisms (Gram-positive bacteria *S. aureus* and *M. luteus*, Gram-negative bacterium *E. coli*, and unicellular fungus *C. albicans*) by bioautographic assay using a modified published procedure.[23,27] Each TLC glass plate was divided into 20 equal squares. Stock solution of each of the compound was made (1 mg/10 μL of dichloromethane), and 25 μL of this solution was spotted (2.5 mg of the compound), making sure that all of the spots were close to 3 mm in diameter. The positive control used was Sigma A5955 (antibiotic−antimycotic solution comprising penicillin G (100,000 units/mL), streptomycin sulfate (10 mg/mL), and amphotericin B (25 μg/mL)), and the negative control used was dichloromethane. The log phase microbes were sprayed on the TLC plates (∼7−10 mL) ensuring that the plates were evenly wet, followed by a spray of (∼7−10 mL) half-strength LB agar (maintained in a water bath at ∼55 °C). Each plate was placed on cork supports in a humid chamber (made by placing wet paper towels in plastic containers) in an incubator at 37 °C (25 °C for *M. luteus*) for 12−18 h to allow the bacteria to grow.[23] A freshly prepared aqueous solution (5 mg/mL) of (3-(4,5-dimethylthiazol-2yl)-2,5-diphenyltetrazolium bromide) (MTT) was sprayed (1−2 mL) on the plate covered with bacteria, and the plate was put back in a humid chamber at the appropriate temperature for 4−5 h or until the purple color appeared. Actively growing microbes convert MTT (yellow) to formazan (purple). Zones of inhibition appear white against a purple background.

Microbial Growth Inhibition Measurements. The inhibition diameter was taken as an average of four measurements per TLC plate. The diameter of each inhibition zone was further determined in four different directions (0°, 45°, 90°, and 135°) as described in the literature.[27,28] The bioassay for each compound was done in triplicate.

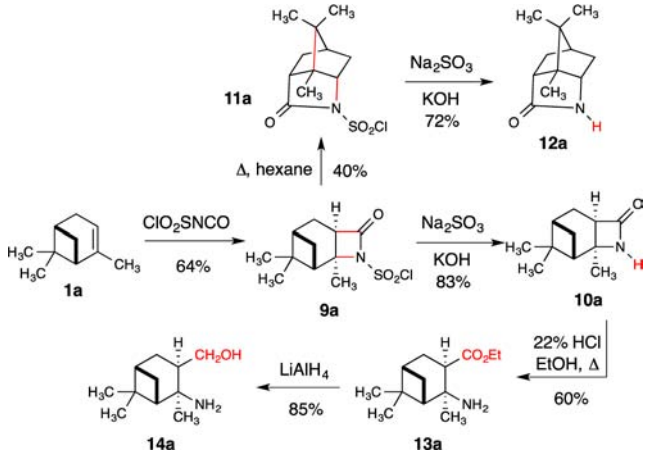
Statistical Analysis. Data were statistically evaluated using one-way ANOVA, followed by a post hoc Newman−Keuls multiple-comparison test. The values were expressed as the mean ± SD and considered significant at $p \leq 0.05$.

FAME Analysis. Bacterial and yeast cultures were grown, and fatty acids were extracted using the methods described by Sasser.[29] Extracts were analyzed using an Agilent 6890N gas chromatograph with an Agilent Ultra 2 column. Sherlock Microbial ID system version 4.5 was used to analyze the data.

RESULTS AND DISCUSSION

Investigation of this approach began with the synthesis of α-pinene derivatives using modified literature procedures.[20,25] Treatment of (+)-α-pinene (**1a**) with chlorosulfonylisocyanate furnished the β-lactam *N*-sulfonyl chloride **9a** in 64% yield as a single stereoisomer (Scheme 1). The N−S bond was

Scheme 1. Synthetic Modifications of α-Pinene



subsequently cleaved using sodium sulfite to give H-β-lactam **10a** in an 83% yield. Alternatively, rearrangement of the α-pinene skeleton by refluxing lactam **9a** in hexanes provided the γ-lactam *N*-sulfonyl chloride **11a** in modest yield (40%). The sulfonyl group of γ-lactam **11a** was cleaved as above to yield H-γ-lactam **12a** in 72% yield. Finally, opening of the β-lactam with ethanol under acidic conditions provided ethyl ester **13a** in 60% yield. Ester **13a** was reduced with lithium aluminum hydride to provide amino alcohol **14a** in 85% yield.

dx.doi.org/10.1021/jf403586t | J. Agric. Food Chem. 2014, 62, 3548−3552

Additionally, the corresponding enantiomers of the β-lactam **10a**, amino ester **13a**, and amino alcohol **14a** were synthesized using the same route except beginning with (−)-α-pinene (**1b**).

Most common antimicrobial agents in use are those containing the β-lactam ring.[30] Such antibiotics are known to work on bacteria via two mechanisms that target the cell wall synthesis.[31] A Cambridge database-based study correlates biological activity in β-lactams with Woodward and Cohen structural parameters.[32] It should be noted that well-known antibiotic β-lactams have a tertiary nitrogen in the β-lactam ring, whereas the α-pinene-based β-lactams **10a** and **10b** have a secondary nitrogen. Because lactams **10a** and **10b** are derived from α-pinene, we assume that they will also interact in the membrane like other pinene derivatives, although the antimicrobial activity of these compounds via inhibition of cell wall synthesis cannot be ruled out. The antimicrobial results are shown in Figures 1 and 2. β-Lactam **10b** is more

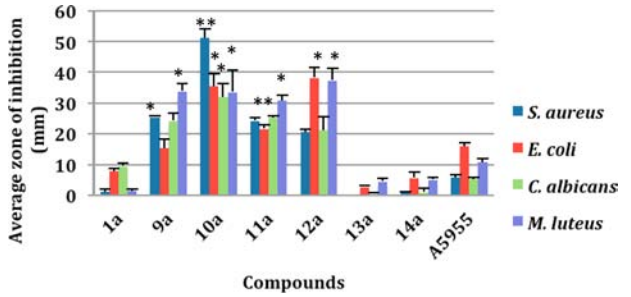


Figure 1. Antimicrobial activity of (*R*)-(+)-α-pinene (**1a**) and its derivatives: β-lactam **10a**, β-lactam *N*-sulfonyl chloride **9a**, γ-lactam **12a**, γ-lactam *N*-sulfonyl chloride **11a**, amino ester **13a**, and amino alcohol **14a**. (∗) $P < 0.05$ and (∗∗) $P < 0.01$, compared to **1a** at the corresponding time. The antimicrobial potential of **13a** and **14a** was found to be not significant compared to **1a** at the corresponding time.

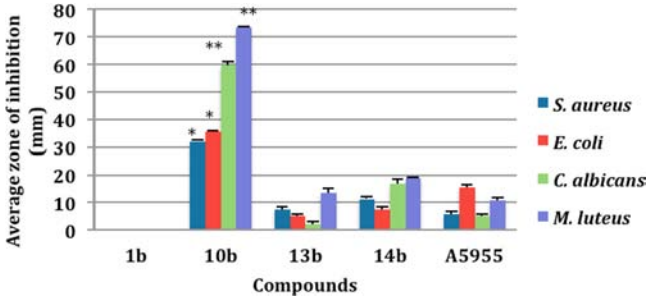

Figure 2. Antimicrobial activity of (*S*)-(−)-α-pinene (**1b**) and its derivatives, β-lactam**10b**, amino ester**13b**, and amino alcohol**14b**. (∗)$P < 0.05$ and (∗∗) $P < 0.01$, compared to **1b** at the corresponding time.

antimicrobial than **10a** toward *M. luteus* and *C. albicans*, whereas lactam **10a** shows greater antimicrobial activity toward *S. aureus*. Lastly, N−H lactams **10a** and **10b** show similar zones of inhibition toward *E. coli*. It should be noted that both β-lactams have greatly enhanced antimicrobial activity toward all four test microorganisms in comparison to the starting materials, (+)- and (−)-α-pinene, respectively. β-Lactam **10a** (as compared to its starting material (+)-α-pinene **1a**) showed an approximately 43-fold increase in antimicrobial activity toward *S. aureus*, a 22-fold increase toward *M. luteus*, a 4.5-fold increase toward *E. coli*, and a nearly 3.5-fold increase toward *C. albicans*. Similarly, β-lactam **10b** (as compared to its starting material (−)-α-pinene **1b**) showed an approximately 32-fold increase in antimicrobial activity toward *S. aureus*, a 73-fold increase toward *M. luteus*, a 35-fold increase toward *E. coli*, and a 60-fold increase toward *C. albicans*.

We next examined the differences in antimicrobial potential between β-lactam (**10a**) and γ-lactam (**12a**) derived from (+)-α-pinene (**1a**) (Figure 1). Overall, β-lactam **10a** showed a stronger antimicrobial activity than γ-lactam **12a**. Although *M. luteus* and *S. aureus* are both Gram-positive bacteria, there is a statistically significant difference in antimicrobial activity of **10a** and **12a** toward *S. aureus*. Compound **10a** shows more than twice the area of inhibition with *S. aureus* compared to **12a** but similar antimicrobial activity toward *M. luteus*. Lactam **12a** showed the largest zones of inhibition for *E. coli* (Gram-negative) and *M. luteus* (Gram-positive). Compound **12a** is half as effective toward *C. albicans* and *S. aureus* as compared to *M. luteus* and *E. coli*. β-Lactam-containing antibiotics, such as penicillin G, are effective against Gram-positive bacteria, but not as effective against Gram-negative bacteria, whereas ampicillin and amoxicillin are effective against both Gram-positive and Gram-negative bacteria.[33] γ-Lactam **12a** is effective against both Gram-positive and Gram-negative bacteria, but its activity is found to be less than that of β-lactam **10a**. Lower antimicrobial activity of γ-lactam in comparison to β-lactam can partly be attributed to the ring strain found in the latter. γ-Lactam contains a five-membered ring, which is more stable than the four-membered ring found in a β-lactam. Due to the ring strain present in β-lactam, it is prone to opening by nucleophilic addition.[21] Stronger intramolecular hydrogen bonding is known to exist in γ-lactams, which may also contribute to its lower antimicrobial activity.[34] The bioassay shows that the two *N*-sulfonyl chlorides of β-lactam and γ-lactam (**9a** and **11a**, respectively) have similar antimicrobial activity.

Earlier studies have shown that introducing a single alcoholic (or amino functional group) in the α-pinene nucleus increases the antimicrobial activity, compared to the antimicrobial activity of (+)-α-pinene derivatives having other functional groups.[27] It is speculated that the presence of the alcoholic or amino functional group makes the compound more water-soluble and thereby helps it transverse the polar cell wall.[35−37] This allows the compound to reach the site of action, the microbial membrane, in greater concentration and hence permeate it more efficiently.[35−37] Therefore, we chose to synthesize amino ester **13a** and amino alcohol **14a** to determine if adding both the alcoholic and amino functions to the α-pinene nucleus will make the compound more antimicrobial than when only one of the two functional groups is present. Consequently, we synthesized two pairs of enantiomeric compounds (**13a** and **13b**; **14a** and **14b**). Overall, amino alcohol **14a** was found to be less antimicrobial than the starting material (**1a**) (Figure 1). Amino alcohol **14b** shows antimicrobial activity toward all four microorganisms used in the study (Figure 2) and by comparison is more antimicrobial than the starting material (**1b**), which under the test conditions did not exhibit any antimicrobial activity. However, the differences in antimicrobial activity of the two amino alcohols **14a** and **14b** were found to be statistically not significant. Both **14a** and **14b** were less antimicrobial than the previously evaluated (1*R*,2*R*,3*R*,5*S*)-(−)-iso-pinocampheol or (1*R*,2*R*,3*R*,5*S*)-(−)-iso-pinocampheylamine.[27] Lastly, ester **13b** was found to be more antimicrobial than the starting material (**1b**) (Figure 2). Conversely, ester **13a** displayed less antimicrobial activity

[a]Percentage composition reported as an average of two runs.

toward the four microorganisms in comparison to (**1a**); however, statistically the difference is not significant.

The antimicrobial potential of the enantiomeric starting materials (**1a** and **1b**) and β-lactams (**10a** and **10b**) is significantly different from each other not only toward various microorganisms used in this study but also in their extent of antimicrobial activity, whereas the antimicrobial potential of the amino esters (**13a** and **13b**) and amino alcohols (**14a** and **14b**) derived from the corresponding α-pinenes is found to be not significant as compared to their respective starting materials. Because the amino alcohols (**14a** and **14b**) have both hydroxyl as well as the amino functional groups, it is expected that these enantiomers will have much greater antimicrobial activity than α-pinene derivatives containing either of the two functional groups. This, however, was not the case. A possible explanation for this could be that amino alcohols and amino esters are known to form strong intramolecular hydrogen bonds due to the formation of a six-membered ring.[38,39] It is known that intramolecular hydrogen bonding affects the physical properties such as solubility of molecules.[40] Therefore, H-bonding capacity (inter versus intra) directly would affect the water solubility of a compound. The strong intramolecular hydrogen bonding in the amino alcohols (**14a** and **14b**) as well as the amino esters (**13a** and **13b**) would lower the water solubility of these compounds and hence might prevent these compounds from crossing the polar cell wall to reach the site of action, the cell membrane.[35−37] Structural features (carbon skeleton and functional groups) being the same, additional factors such as chirality and the capacity to hydrogen bond (intramolecular H-bonding seems to lower it, and intermolecular H-bonding seems to increase it) play an important role in determining the antimicrobial activity of this class of compounds.

Skeletally modified α-pinene derivatives studied were **9a**, **10a**, **10b**, **11a**, **11b**, and **12a**. All of these skeletally modified derivatives were much more antimicrobial than their corresponding starting material (+)-α-pinene **1a** and (−)-α-pinene **1b**, indicating that the carbon skeleton affects the antimicrobial activity. Functional groups present also affect antimicrobial activity. The starting materials (+)-α-pinene **1a** and (−)-α-pinene **1b** have alkene functionality that was converted to amino ester (**13a**, **13b**) amino alcohol (**14a**, **14b**), lactams (**10a**, **10b**, **12a**,) and lactam *N*-sulfonyl chloride (**9a**, **11a**,**11b**). Of the various functional groups evaluated, lactams proved to be the most antimicrobial followed by lactam *N*-sulfonyl chlorides. It also matters which enantiomer was used to synthesize a particular derivative (derived from (+)-α-pinene versus (−)-α-pinene). Of the two starting materials, (+)- and (−)-α-pinene, only (+)-α-pinene was found to be antimicrobial against all four test microorganisms at the reported concentration. However, derivatives obtained from (−)-α-pinene proved to be more antimicrobial than their mirror images obtained from the (+)-enantiomer. Although additional derivatives would have to be synthesized and evaluated to make a conclusive inference, our results suggest that derivatives of the most antimicrobial compound may not necessarily be more antimicrobial.

FAME results of the membrane composition of the test microbes (Table 1) show that the membrane composition of the four test microorganisms is very different and no linear relationship can be seen between a particular lipid and antimicrobial activity of the compounds evaluated in this study. Despite that, there is one interesting result from the FAME analysis. For all of the pinene derivatives (**10b**, **13b**, and **14b**) obtained from (−) α-pinene, *M. luteus* seemed to be the most susceptible microorganism. For the pinene derivatives obtained from the (+)-α-pinene, *M. luteus* seems to be the most susceptible microorganism for the two *N*-sulfonyl chlorides of β-lactam and γ-lactam. The membrane composition of *M. luteus* (Table 1) is unique and is mainly composed of 15:0 ANTEISO fatty acid (∼84%). The other three microorganisms have a spread of different membrane fatty acids.

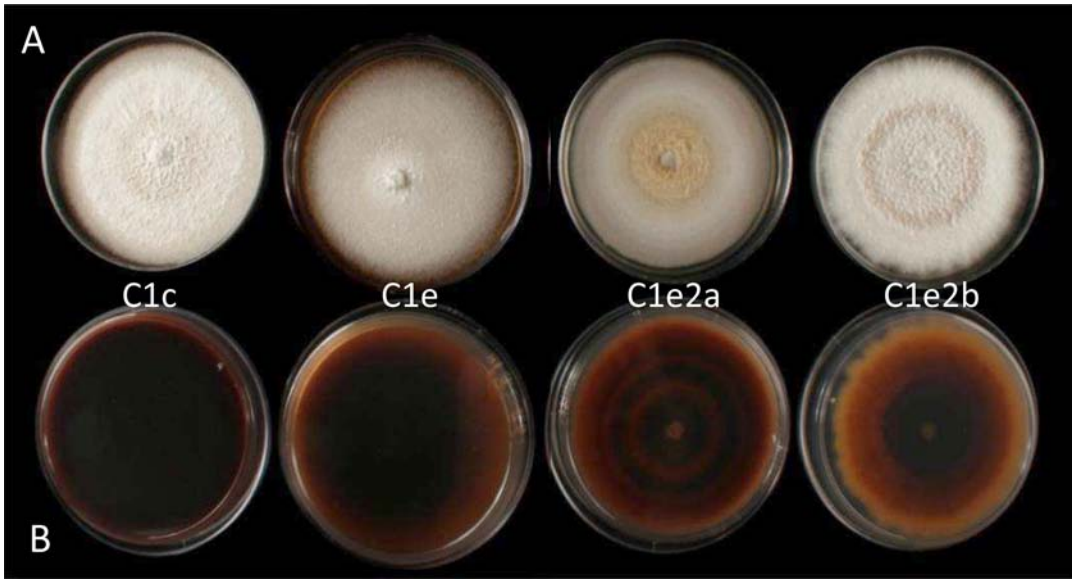

Figure 1. Morphological variants of *Edenia gomezpompae*: (A) colony appearance on potato dextrose agar (PDA) after 14 days at 25 °C; (B) reverse of culture showing typical reddish-brown pigmentation.

Fermentations of Morphological Variants of *E. gomezpompae*. Each morphological variant of *E. gomezpompae* (C1c, C1e, C1e2a, and C1e2b) was cultured in Fernbach flasks (2800 mL), each containing 1200 mL of potato dextrose broth (PDB). Each flask was inoculated with three 1 cm^2 agar plugs taken from a stock culture of *E. gomezpompae* on PDA maintained at 28 °C. Flask cultures were incubated under static conditions at 28 °C and a 12:12 h light−dark photoperiod with a T12 30 W fluorescent light (Phillips, Chihuahua, Mexico) for 90 days.

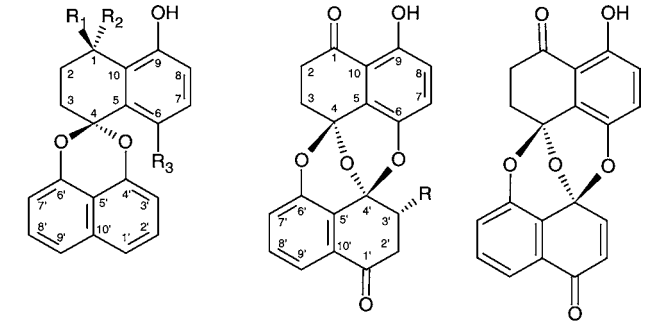
Extraction of Phytotoxins Produced by *E. gomezpompae*. At the end of fermentation, whole broth was filtered through cheesecloth to separate the culture medium from the mycelium. The culture medium (Med) was subsequently extracted with CH_2Cl_2 (equal volume × 5) and EtOAc (equal volume × 5). Both organic phases were combined and filtered over anhydrous Na_2SO_4 and concentrated in vacuo to yield 169 mg (C1c Med), 242 mg (C1e Med), 342 mg (C1e2a Med), and 149 mg (C1e2b Med) of a reddish solid. The mycelium (Myc) was macerated with 2 L of CH_2Cl_2 (× 5) and 2 L of EtOAc (× 5). The combined organic phases were filtered over anhydrous Na_2SO_4 and concentrated in vacuo to yield 821 mg (C1c Myc), 979 mg (C1e Myc), 2086 mg (C1e2a Myc), and 1901 mg (C1e2b Myc) of a reddish solid.

Isolation of Phytotoxic Compounds from *E. gomezpompae*. The combined phytotoxic extracts of morphological variants from *E. gomezpompae* (~5 g) were subjected to column chromatography on silica gel (630 g) eluting with a gradient of *n*-hexane/CH_2Cl_2 (100:0 to 0:100) and CH_2Cl_2/MeOH (99.9:0.1 to 50:50). From this chromatography, 241 fractions (200 mL each) were obtained. Fifteen fractions, F-I−F-XV, were pooled according to TLC analysis.

Bioactivity in a Petri dish bioassay showed 10 active pools (FIII−FXII). From primary fractions V (313 mg) and VII (188 mg) eluted with low-polarity *n*-hexane/CH_2Cl_2 (6:4), the known palmarumycins CP_2 (**6**) and CP_{17} (**3**) were isolated, respectively; then, they were purified by successive recrystallizations from CH_2Cl_2. The yields from this process included 128 mg of **6** and 31 mg of **3**. From fraction VIII (365.5 mg) eluted with *n*-hexane/CH_2Cl_2 (2:8) was isolated preussomerin EG_1 (**7**). After exhaustive washing with an *n*-hexane/dichloromethane mixture (1:1), as well as recrystallization from CH_2Cl_2/MeOH (99:1), 75 mg of compound **7** was obtained. Active fraction IX (111.7 mg) eluted with 100% CH_2Cl_2 was purified by successive preparative TLC (CH_2Cl_2 × 2) to yield preussomerin EG_4 (**4**) (25.9 mg) and an additional 26 mg of **7**. Fraction X (467 mg), eluted with CH_2Cl_2/MeOH (99:1), was chromatographed on a silica gel (135 g) column, eluting with a gradient of *n*-hexane/CH_2Cl_2 (50:50 to 0:100) and CH_2Cl_2/MeOH (99.9:0.1 to 50:50). Thirteen secondary fractions were obtained (F-X1−F-X13). Fraction X-9 (140 mg), eluted with CH_2Cl_2/MeOH (99:1), was further resolved by extensive preparative TLC (*n*-hexane/acetone 80:20) to yield 6.8 mg of ergosta-4,6,8(14),22-tetraen-3-one (**5**), 24 mg of preussomerin EG_3 (**9**), 6 mg of palmarumycin EG_1 (**1**), and 16.6 mg of palmarumycin CP_{19} (**2**). Primary fraction XI (870 mg), eluted with CH_2Cl_2/MeOH (98:2), was rechromatographed on a silica gel (149 g) column, eluting with a gradient of CH_2Cl_2/MeOH mixtures (99.9:0.1 to 50:50). Twelve secondary fractions were obtained (F-XI1−F-XI12). From secondary fraction XI-5 (186 mg), eluted with CH_2Cl_2/MeOH (98:2), preussomerin EG_2 (**8**) (12.1 mg) spontaneously crystallized, and after successive recrystallizations from CH_2Cl_2/MeOH (9:1), 9.5 mg of preussomerin EG_2 (**8**) was obtained. Finally, extensive TLC (*n*-hexane/acetone 80:20 × 2) of fraction XI-2 (8.5 mg) yielded an additional 3.0 mg of palmarumycin CP_{19} (**2**) (Figure 2).

Phytogrowth-Inhibitory Bioassays. The phytogrowth inhibitory activity of organic extracts from four morphological variants of *E. gomezpompae* and pure compounds was evaluated on seed germination, root elongation, and seedling respiration of two dicotyledonous species, *Amaranthus hypochondriacus* Amaranthaceae (amaranth) and *Solanum lycopersicum* var. *lycopersicum* (Solanaceae) (Italian tomato; pomodoro), and one monocotyledonous plant, *Echinochloa crus-galli*; Poaceae (barnyardgrass). Amaranth seeds were purchased at a local market in Tulyehualco in Mexico Federal District, and the tomato seeds were purchased at Semillas Berentsen, S.A. de C.V. in Celaya, Guanajuato State, whereas barnyardgrass seeds were collected from plants grown at the Instituto de Ecología (UNAM) greenhouse.

Bioassays to test the phytotoxic effects of the organic extracts of culture media and mycelia from morphological variants of *E. gomezpompae* on seedling growth were evaluated using a Petri dish bioassay.[3,4] The pure compound and organic extracts were evaluated at 50, 100, and 200 μg/mL by dilution in agar (1%). Each treatment was added to sterile agar in 6 cm Petri dishes prior to its solidification (~40 °C). Pure agar (1%) was used as negative control and agar with Rival [glyphosate: *N*-(phosphonomethyl)glycine] (Monsanto, Sao Paulo, Brazil) at 50, 100, and 200 μg/mL as positive control. Thirty seeds of each test plant were sown directly onto the agar of each Petri dish following a complete randomized design with four replications per treatment. The number of seeds used for each experiment was selected so that appreciable change in O_2 uptake could be detected. Petri dishes were wrapped in Parafilm foil and randomly placed in a germination cabinet under conditions of darkness at 27 °C. Seed germination, root



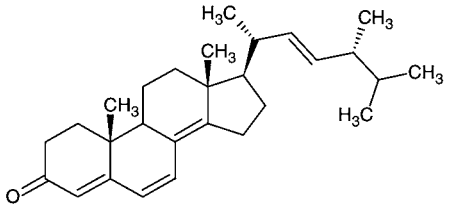


Figure 2. Structures of phytotoxic compounds isolated from the endophytic fungus *Edenia gomezpompae*.

elongation, and seedling respiration were measured 24 h after treatment for *A. hypochondriacus*, 48 h after treatment for *E. crus-galli*, and 72 h after treatment for *S. lycopersicum*.[3]

Seed respiration was measured polarographically as oxygen uptake during the germination process with a Clark-type electrode connected to a YSI 5300A biological oxygen monitor. The seedlings were transferred into a glass chamber containing 4 mL of air-saturated deionized water at 27 °C. Oxygen uptake, in the presence of different concentrations of organic extracts and pure compounds, was measured during 3 min. The requirement for oxygen was plotted as a percentage of the control at 100%.[4]

Isolation of Intact Mitochondria. Mitochondria were obtained by employing a modification of the proposed protocol by Rödinger et al.[5] One hundred and twenty grams of fresh green and turgid spinach leaves were washed with distilled water; then the central rib and the apex were removed. Afterward, they were fragmented into pieces and soaked in 200 mL of an extraction buffer (0.45 M sucrose, 15 mM MOPS, 1.5 mM EGTA, adjusting the pH to 7.4 with KOH and adding 0.6% PVP immediately prior to its use, 0.2% BSA, 10 mM DTT, and 0.2 mM PMSF). All of these were blended in a blender in five 5 s periods for each at maximal speed. Then, the homogenate was filtered through a six-layer cloth filter and centrifuged at 9000 rpm for 5 min. The pellet was discarded and the supernatant centrifuged at 16000 rpm for 10 min. The supernatant was again discarded, and the pellet that contained mitochondria was resuspended with a fine brush in 2 mL of washing buffer (0.3 M sucrose, 10 mM MOPS, 1 mM EGTA, adjusting the pH 7.2 with KOH and adding 0.2 M PMSF immediately prior to its use). Later, this suspension was placed in tubes containing Percoll concentration gradients. The gradient was previously prepared with 6 mL of 45, 25, and 5% of Percoll and 0.3 M sucrose buffer, 10 mM MOPS, pH 7.2, with KOH. The suspension was centrifuged for 45 min at 12800 rpm. Then, the intact mitochondria formed a plug, which was recovered on the 45% fraction of Percoll. This plug was added to 15 mL of resuspension buffer (0.3 M mannitol, 10 mM MOPS, 1 mM EDTA). The matrix was pH adjusted to 7.4 with KOH by adding 0.1% BSA immediately prior to its use and centrifuged during 15 min at 12800 rpm; finally, the pellet was resuspended in the buffer, and resuspension buffer was added in sufficient quantity to obtain 10 μg protein/μL (about 6 mL). The entire isolation process was carried out at 4 °C. Protein concentration was determined according to the method of Bradford.[6]

Once the mitochondria were isolated from the intact mitochondria suspension, 500 μL was transferred into a glass chamber. Oxygen consumption for the mitochondria at 27 °C was measured every 5 s for 3 min using a Clark-type electrode connected to a YSI 5300A biological oxygen monitor. The extracts were evaluated at 100 and 200 μg/mL, and the pure compounds were tested at 200 μg/mL. Only 2,4-dinitrophenol, used as positive control, was tested within the 10−800 μM concentration range. Linear regression analysis of the decreasing oxygen concentration in each extract or pure compound quantitatively determined oxygen consumption for the sample.

HPLC Analysis for Monitoring Secondary Metabolites Profile of the Extracts of Morphological Variants. HPLC analyses were performed on an Alliance 2695 system equipped with a model 2996 photodiode array detector (Waters, Milford, MA, USA). Analytical HPLC was performed using a reversed phase column (Atlantis C_{18}, 5 μm × 150 mm × 4.6 mm i.d.), at room temperature with a flow rate of 0.6−1 mL/min. The samples were filtered through a 0.4 μm nylon filter before HPLC analysis. Control of the equipment, data acquisition, and processing and management of chromatographic information were performed by the Empower 2.0 software program (Waters). The chromatograms were overlapped and colors added by using Gimp ver. 2.8.8 software, but no modifications were made in scale proportions.

Five milligrams of organic extracts from culture medium and mycelium of each morphological variant was taken and dissolved in 1 mL of acetonitrile. After filtering, they were analyzed by reversed phase HPLC using a gradient system starting with MeCN/H_2O, 80:20, to 100% MeCN for 0−30 min with a flow rate of 0.6 mL/min and maintaining this up to 40 min, with a flow rate of 1 mL/min. A known amount of an authentic pure sample of each compound was analyzed, and its retention time and peak size were determined. Retention times (t_R) of preussomerin and palmarumycin peaks were detected at wavelengths of 225 nm: **8** (t_R 13.9 min), **1** (t_R 17.4 min), **9** (t_R 18.0 min), **4** (t_R 18.6 min), **7** (t_R 19.5 min), **2**, **3** (t_R 20.1 min), and **6** (t_R 23.3 min).

Statistical Analysis. Experimental results concerning the effect of culture media and the mycelia extracts from morphological variants of *E. gomezpompae* and pure compounds on phytogrowth inhibitory activity and intact mitochondrial oxygen consumption were analyzed by analysis of variance (ANOVA) and Tukey statistical tests[7] utilizing GraphPad Prism ver. 5.01 statistical computer software (GraphPad software, La Jolla, CA, USA). The IC_{50} value (50% inhibitory concentration) for each activity was calculated by Probit analysis[8] based on the average percentage of inhibition obtained at each concentration of the different treatments. Data are represented as mean ± standard deviation (SD). A P value of ≤0.05 (*) was employed to indicate statistical significance.

Palmarumycin EG_1 (1). Colorless solid powder, mp 230 °C (decomp); $[\alpha]^{25}_D$ = −14 (c 0.1, $CHCl_3$); UV λ_{max} (log ε) 328.5 (3.3), 325.5 (3.13), 314.5 (3.46), 310.6 (3.42), 300.5 (3.58), 296 (3.54), 288 (3.58), 255 (2.82), 226.5 (4.38), 212.6 (4.16); IR t_{max} (KBr) 3453, 3063, 1608, 1468, 1409, 1376, 1264, 1053 cm^{-1}; ^1H and ^{13}C NMR, see Table 2; EIMS m/z 350 [M^+ (19)], 318 (100), 301 (7), 300 (7), 273 (7), 175 (7), 160 (24), 144 (7), 131 (8), 115 (5); HRMS m/z 350.11540 (calcd for $C_{21}H_{18}O_5$ 350.11542).

Preussomerin EG_4 (4). Yellowish amorphous solid, mp 242.1−246.0 °C; UV λ_{max} (log ε) 360 (3.65), 332 (3.47), 315 (3.56), 281 (3.12), 258 (4.17), 243.5 (4.01), 220 (4.48) nm; IR t_{max} (KBr) 3434, 3085, 1690, 1642, 1593, 1473, 1365, 1331, 1291, 1230 cm^{-1}; ^1H and ^{13}C NMR, see Table 3; ESIMS m/z 350 [M^+ (100)], 332 (7), 305 (4), 192 (9), 176 (82), 174 (34), 175 (19), 147 (8), 120 (4), 91 (4), 77 (4), 55 (5); HRMS m/z 350.0788 (calcd for $C_{20}H_{14}O_6$, 350.0790).

X-ray Crystallographic Analysis of Palmarumicyns CP_{19} (2) and CP_{17} (3). Colorless crystals of dimension 0.36 × 0.18 × 0.2 mm and yellow prisms of dimension 0.30 × 0.20 × 0.20 mm were obtained from slow evaporation of CH_2Cl_2 solution, for CP_{19} (**2**) and CP_{17} (**3**), with empirical formulas $C_{21}H_{18}O_4$ and $C_{20}H_{14}O_5$ and M_r = 334.35 and M_r = 334.31, respectively. CP_{19} (**2**) crystallized in monoclinic $P2_1$ (no.

dx.doi.org/10.1021/jf500965k | J. Agric. Food Chem. 2014, 62, 3553−3562

4) and CP_{17} (**3**) crystallized in triclinic system, P-1 (no. 2). The cell dimensions for CP_{19} (**2**) were a = 12.927(3) Å, b = 7.925(2) Å, c = 17.046(4) Å, α = 90°, β = 109.883(3)°, γ = 90°, V = 1642.2(7) Å^3, Z = 4, D_{calcd} = 1.352 Mg/m^3, mμ 0.093 mm^{-1}, and F(000) = 704, and those for CP_{17} (**3**) were a = 8.5101(6) Å, b = 12.8482(9) Å, c = 15.1746(10) Å, α = 66.0760(10)°, β = 83.5180(10)°, γ = 89.6990(10)°, V = 1505.44(18) Å^3, Z = 4, D_{calcd} = 1.475 Mg/m^3, mμ 0.107 mm^{-1}, and F(000) = 696. Temperature = 298(2) K. Both compounds were irradiated with Mo Kα radiation (λ = 0.71073 Å) on the Bruker Smart APEX diffractometer with AXS CCD area detector using a SMART program.[17] The data reduction was performed with the SAINT program.[9] Totals of 12965 and 12393 reflections were collected, of which 6016 (R_{int} = 0.0644) and 5289 (R_{int} = 0.0324) were independent, respectively. The structures were solved by direct methods and refined using full-matrix least-squares on F^2 using the programs SHELXS[10] and SHELXL,[10] respectively. The ORTEP-3[11] program was used to prepare the figures. Two crystallographic independent molecules were found in the unit cell in both compounds. The final values S = 0.846, R1 = 0.545 and wR2 = 0.0884 were based on 3304 reflections observed, 459 parameters for CP_{19} (**2**), and S = 0.865, R1 = 0.0362, and wR2 = 0.0728 were based on 5289 reflections observed, 463 parameters for CP_{17} (**3**). The largest different peak and hole were 0.400 and −0.148 e Å^{-3} and 0.147 and −0.162 e Å^{-3}, respectively.

RESULTS AND DISCUSSION

Morphological Variants of *E. gomezpompae*. The endophytic fungus *E. gomezpompae* was obtained from the leaves of *C. acuminata* collected at the Ecological Reserve "Eden"; four isolates of this species corresponding to strains C1c, C1e, C1e2a, and C1e2b were obtained. The differences in macroscopic characteristics exhibited by these strains were significant (Figure 1). However, microscopic characteristics and molecular studies revealed they were from the same species;[1] therefore, they were morphological variants of *E. gomezpompae* (isolate C1c). The morphological characteristics of microorganisms can be affected during antagonistic interspecific interactions due to their phenotypic plasticity, that is, the ability of a single genotype to produce more than one alternative form of morphology, physiological state, and/or behavior in response to environmental conditions.[12] Therefore, it is important to study whether the biological activity is modified by the morphological variants of the fungus, particularly because many secondary metabolites of fungal origin are of economic value due to their many and diverse biological activities.

In this context, we investigated the phytotoxic properties of the culture media and mycelia organic extracts of four morphological variants of *E. gomezpompae* as well as those of their pure compounds. The strains were grown under static conditions on PDB. In these conditions the mycelia of the fungi were developed better. The culture media and the mycelia were extracted with CH_2Cl_2 and EtOAc. The initial phytotoxic activity of the resulting extracts was evaluated on seed germination, root elongation, and seedling respiration of *A. hypochondriacus*, *S. lycopersicum*, and *E. crus-galli* using a Petri dish bioassay. According to the results summarized in Table 1, all extracts inhibited seed germination, root elongation, and seedling respiration of the three target species in a concentration-dependent manner (data not shown). The extracts from culture media were more phytotoxic than the mycelia extracts, showing IC_{50} values of <200 μg/mL. The extracts of morphological variant C1c showed the highest phytotoxic potential.

Isolation of Phytotoxic Compounds Produced by *E. gomezpompae*. TLC and HPLC chromatograms of the morphological variant extracts exhibited similar profiles. Therefore, the extracts were combined and fractionated by column chromatography for chemical analysis. This process led to the isolation of compounds **1**−**9**, including two new naphthoquinone spiroketals, namely, palmarumycin EG_1 (**1**) and a preussomerin EG_4 (**4**), which were characterized by extensive spectroscopic methods. In addition, known preussomerins EG_1−EG_3 (**7**−**9**) and palmarumycins CP_{19} (**2**), CP_{17} (**3**), and CP_2 (**6**) and the ergosta-4,6,8(14),22-tetraen-3-one (**5**) were obtained (Figure 2). Compounds **2**, **3**, and **5** are new to this species. Compounds **6**−**9** were identified by comparison with authentic samples;[2] compounds **2**,[2] **3**,[13,14] and **5**[15,16] were identified from their IR and ^{1}H NMR spectroscopic data. These were identical to those previously described in the literature.

Structural Elucidation of Compounds 1 and 4. *Palmarumycin EG_1 (**1**).* The molecular formula was established

Table 1. Phytogrowth-Inhibitory Activity of the Organic Extract from Morphological Variants of *Edenia gomezpompae* on the Germination, Root Elongation, and Seedling Respiration of *Amaranthus hypochondriacus*, *Solanum lycopersicum*, and *Echinochloa crus-galli*

as $C_{21}H_{18}O_5$ (13 unsaturations) by HRMS. The IR spectrum displayed the absorption bands indicative of the presence of hydroxyl (3453 cm^{-1}) and aromatic groups (1608 cm^{-1}). ^1H and ^{13}C NMR spectra suggested that the molecule was a deoxypreussomerin type of compound related to palmarumycin CP_{19} (2). The 1,8-dihydroxynaphthalene ring system and the substitution pattern in the nonaromatic ring in both molecules were identical, but the third aromatic ring was different. Thus, the two exchangeable singlets D_2O at δ 7.57 (OH-6) and 7.03 (OH-9), plus the AB-spin system at δ 6.94 (d, J = 9.0 Hz; H-7) and 6.96 (d, J = 9.0 Hz; H-8) in the ^1H NMR spectrum indicated the presence of a *p*-hydroquinone fragment in the

molecule. Signals at δ 149.5 and 149.4 in the ^{13}C NMR confirmed this assignment. Furthermore, the correlations observed in the NOESY and HMBC spectra supported the presence of the hydroxyl groups at C-6 and C-9 of the palmarumycin skeleton (Table 2). The signals and coupling pattern in the ^1H NMR spectrum for the oxymethine (δ 4.85, H-1, pseudo-t dd, J = 6.0, 7.5 Hz) and methoxy groups (s, δ_H 3.48) were similar to those of palmarumycin CP_{19} (**2**), suggesting that **1** was its 6-hydroxy analogue; the HMBC and $^1H-^1H$ NOESY data (Table 2), as well as the mass fragments at m/z 318 and 160 were assignable to hydrobenzoquinone and 1,8-dihydroxynaphthalene subunits, respectively, were consistent with this structural proposal. Finally the negative value of

dx.doi.org/10.1021/jf500965k | J. Agric. Food Chem. 2014, 62, 3553−3562

the specific optical rotation led us to propose the same *S* absolute configuration at C-1 as for **2**.[14,17,18]

Palmarumycins CP_{19} (**2**) and CP_{17} (**3**) were previously described by Martínez-Luis et al. as new metabolites from *Edenia* sp. obtained from the leaves of *Petrea volubilis* L.[14] The spectroscopic and spectrometric properties of both compounds were identical to those reported. In the present study, however, we confirmed the structural assignments of **2** and **3** by single-crystal diffraction X-ray analysis (Figures 3 and 4).

Preussomerin EG_4 (4). Mass spectrometric analysis of preussomerin EG_4 (**4**) gave a molecular ion at *m/z* 350 ($C_{20}H_{14}O_6$, 14 unsaturations), thus differing from preussomerin EG_1 (**7**) by 2 mass units. The infrared spectrum of **4** showed absorption bands for a conjugated carbonyl at 1642 cm^{-1}. As with compound **7**, the NMR spectrum contained resonances for 1,2,3-trisubstituted and 1,2,3,4-tetrasubstituted aromatic rings. The most obvious differences in the spectra (Table 3) were the absence of the two vinyl signals (δ_C/δ_H 133.27/6.56 and 141.24/7.17) for the *cis*-olefinic nuclei of preussomerin EG_1 (**7**).[2] Instead, the ^1H NMR spectrum of **4** displayed four self-coupled aliphatic protons in the upfield region of the spectrum between δ 2.50 (H-2′) and 3.36 (H-3′), which were correlated with the signals at δ 33.8 and 32.8, respectively, in the HSQC experiment. Two conjugated carbonyls appearing at δ_C 195.8 and 202.2 were also detected in the ^{13}C NMR spectrum, which were assigned to C-1′ and C-1, respectively, on the basis of the observed HMBC correlations (Table 3). The other HMBC and NOESY correlations summarized in Table 3, as well as the mass fragments at *m/z* 174, 175, and 176 observed in the MS spectrum, were in agreement with structure **4** for the new natural product,[19] which was given the common name of preussomerin EG_4.

Phytogrowth-Inhibitory Activity of the Natural Compounds. Natural products **2**–**9** were evaluated for their ability to inhibit the seed germination, root elongation, and seedling respiration of *A. hypochondriacus*, *S. lycopersicum*, and *E. crus-galli*. Figure 5 depicts the phytotoxic effect of the isolate compounds at 100 μg/mL. The results are expressed as inhibition percentages. In general, the compounds tested exhibited a significant phytotoxic effect and were more potent as germination and root elongation inhibitors than as seedling respiration inhibitors (Figure 5). All eight compounds reduced the germination of the three target species. Compounds **4** and **7**–**9** at 100 μg/mL inhibited germination by >50%, being more potent than the positive control Rival (glyphosate) (Figure 5A). Compounds **2**, **8**, and **9** were more active as root elongation inhibitors (>50%) of *A. hypochondriacus* and *E. crus-galli*. Only compound **8** significantly inhibited (>50%) the root elongation of three species (Figure 5B). On the other hand, the compounds tested also significantly inhibited the seedling respiration of *S. lycopersicum*. The phytotoxic activity was comparable to that of the positive control. Only compound **2** significantly inhibited the oxygen consumption of three seedlings, and compounds **4** and **7** also significantly inhibited the seedling respiration of *S. lycopersicum* and *E. crus-galli* (Figure 5C). In summary, all compounds inhibited seed germination, root elongation, and seedling respiration of the three target species in a concentration-dependent manner. Table 4 summarizes the phytotoxic effect of the isolate compounds expressed as IC_{50} values. The IC_{50} values confirm that, in general, compounds **2**–**9** were more potent as germination and root elongation inhibitors than as seedling respiration inhibitors.

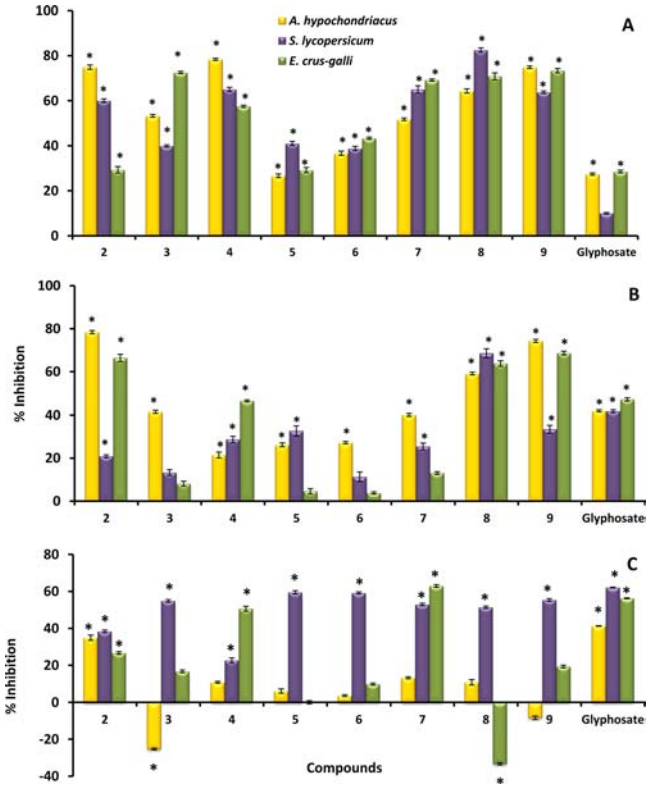

Figure 5. Phytotoxic effect of bioactive compounds (100 μg/mL) isolated from endophytic fungus *Edenia gomezpompae* on (A) seed germination, (B) root elongation, and (C) seedling respiration of *Amaranthus hypochondriacus*, *Solanum lycopersicum*, and *Echinochloa crus- galli*. Palmarumycins CP_{19} (**2**) and CP_{17} (**3**), preussomerin EG_4 (**4**), ergosta-4,6,8(14),22-tetraen-3-one (**5**), palmarumycin CP_2 (**6**), and preussomerins EG_1 (**7**), EG (**8**), and EG_3 (**9**). A positive value represents inhibition; a negative value represents stimulation. Vertical bars represent SD, $n = 4$; (∗)$P < 0.05$.

Mitochondrial Oxygen Consumption. In an attempt to discover potential herbicidal agents with an effect on respiration, the phytotoxic extracts from morphological variants of *E. gomezpompae* and pure compounds were further evaluated for their capacity to inhibit mitochondrial respiration in intact mitochondria isolated from spinach. In general, the extracts demonstrated significant inhibition in the mitochondrial respiratory chain at the highest test concentration of 200 μg/mL (Figure 6). However, the inhibitory effect was low. Both organic extracts of morphological variant C1e2a and the mycelium extracts of morphological variants C1e were most active on mitochondrial respiration, inhibiting its activity by approximately 40%. It is noteworthy that extracts of morphological variant C1e2a were the least phytotoxic on the three plants tested (IC_{50} values of >200 μg/mL); however, these were the extracts with the greatest effect on mitochondrial oxygen consumption, indicating the presence of the phytotoxic compounds.

Furthermore, oxygen consumption in intact mitochondria was significantly inhibited by compounds **2**–**9**; however the effect was lower than that of the positive control. In general, preussomerins were more active than palmarumycins. Preussomerins EG_4 (**4**) and EG_1 (**7**) and palmarumycins CP_{17} (**3**) and CP_2 (**6**) were more active, inhibiting 34, 26, 17, and 26%, respectively (Figure 6).

Table 4. Phytogrowth-Inhibitory Activity of Isolated Compounds from *Edenia gomezpompae* on the Germination, Root Elongation, and Seedling Respiration of *Amaranthus hypochondriacus*, *Solanum lycopersicum*, and *Echinochloa crus-galli*

[a]Rival = glyphosate, *N*-(phosphonomethyl) glycine (positive control).

HPLC Analysis of Secondary Metabolites Production from Extracts of Morphological Variants. Preussomerin and palmarumycin contents in morphological variants of *E. gomezpompae* were analyzed by HPLC (Figure 7). The chromatographic profiles showed that the four variants showed differences in the concentration of the major components (Table 5). These results could be due to the phenotypic plasticity of *E. gomezpompae*; accordingly, each phenotype, with different morphology and different biological activity, exhibited also important differences in chemical compound production.

The highest activity on mitochondrial respiration of culture broth extracts of morphological variants C1e and C1e2a could be associated with the presence of many peaks in the chromatographic region from 0 to 7 min, which should be further investigated. On the other hand, the highest activity against seed germination, root elongation, and seedling respiration of C1c, C1e, and C1e2b culture media extracts

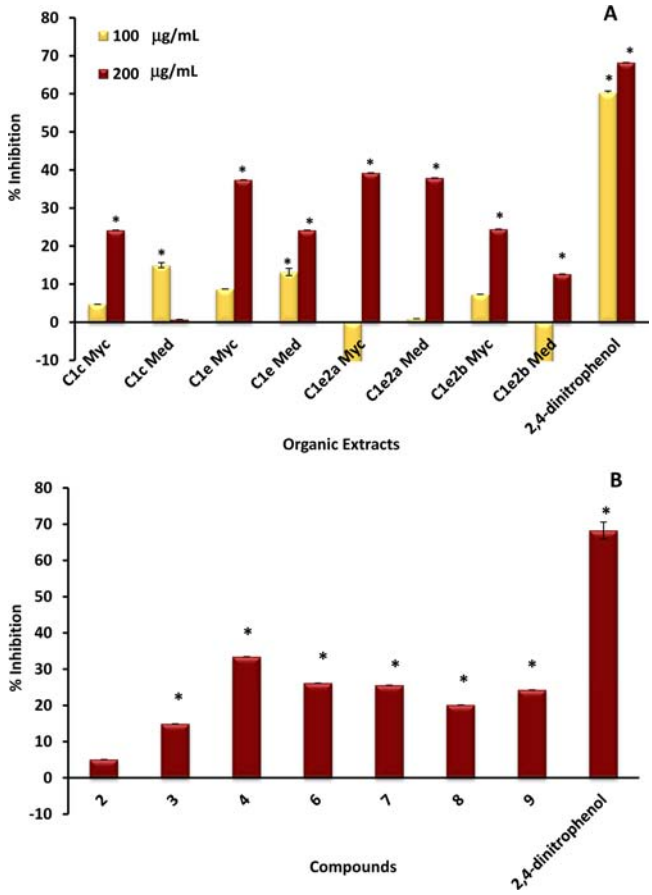

Figure 6. Inhibitory activity of the organic extract (100 and 200 μg/mL) from (A) morphological variants of *Edenia gomezpompae* and (B) phytotoxic compounds (200 μg/mL) on mitochondrial oxygen consumption on intact mitochondria isolated from spinach. Palmarumycins CP_{19} (**2**) and CP_{17} (**3**), preussomerin EG_4 (**4**), palmarumycin CP_2 (**6**), and preussomerins EG_1 (**7**), EG (**8**), and EG_3 (**9**). A positive value represents inhibition; a negative value represents stimulation. Vertical bars represent SD, $n = 4$; (*) $P < 0.05$.

can be associated with the presence in high amounts of preussomerin EG_3 (**8**), and the highest inhibitory activity of C1c of mycelium extracts was associated with the highest abundance of palmarumycin CP_2 (**6**)

Because all components detected in each variant were active, they are of possible benefit for the plant species hosting the fungus in its natural habit. The endophytic fungi generally exist harmlessly within their host, but under different conditions they could be facultative pathogens.[20] On the other hand, the secondary metabolites produced by endophytic fungi play a role in vivo and are important for numerous metabolic interactions between fungi and their plant hosts, such as signaling and regulation of the symbiosis.[21,22] Some may also serve in the overall biology of the plant, especially as it relates to insects and disease, as well as other environmental stresses including drought tolerance.[23−25] One of the important roles of endophytic fungi is to initiate the biological degradation of dead or dying plant hosts, which is necessary for nutrient recycling.[26] As a result, it is possible that the phytotoxins produced by *E. gomezpompae* are involved in the role in plant host defense and/or in the biological degradation of dead or dying plant hosts.

In summary, naphthoquinone spiroketals **2**–**8** biosynthesized by four morphological variants of *E. gomezpompae* possess phytotoxic properties against seed germination, root elongation, and seedling respiration of two dicotyledon species, *A. hypochondriacus* and *S. lycopersicum*, and one monocotyledon plant, *E. crus-galli*, and a slight effect on the respiration of intact mitochondria. According to these results, further studies will be carried out to better understand the mechanism of action associated with the phytotoxic effects of the organic extracts and selected phytotoxins produced by *E. gomezpompae*. In particular, preussomerins EG_4 (**4**) and EG_1 (**7**) and palmarumycins CP_{17} (**3**) and CP_2 (**6**) will be considered for exploration in the immediate future on the basis of their inhibitory effect on oxygen consumption in intact mitochondria.

[a]Mineral mixture, AIN-93 M (Oriental Yeast Corp., Tokyo, Japan). [b]Vitamin mixture, AIN-93 (Oriental Yeast Corp., Tokyo, Japan).

control (n = 8) and (4) SAMR1 SP (n = 8). The control group was fed a normal AIN-93 M diet (Oriental Yeast, Tokyo, Japan) and the SP group was fed a SP diet containing 7% (w/w) SP (Table 1). The mice were allowed free access to the diet and tap water. Food intake and body weight were measured once a week. After 26 weeks, all mice were tested in the Morris water maze and then sacrificed. The brain was rapidly excised and quickly put on ice. These tissues were soaked in RNA later (Sigma-Aldrich, St. Louis, MO) and RIPA lysis buffer (Santa Cruz Biotechnology, Santa Cruz, CA) for RNA isolation and Western blot, respectively, and then stored at −80 °C until use.

Morris Water Maze for Cognitive Testing. Spatial learning and memory of animals were tested in a Morris water maze.[17] A circular plastic pool (diameter, 120 cm; height, 50 cm) was filled with water kept at 25 ± 1 °C. An escape platform (diameter, 11 cm) was hidden 1 cm below the surface of water on a fixed location in the pool. On training trials, the mice were given four trials per session for 7 subsequent days in the presence of the platform, each trial having a ceiling time of 60 s and a trial interval of approximately 20 s. When mice found the platform, they were allowed to stay on it for 20 s. The mice that did not find the platform within 60 s were placed on the platform for 20 s at the end of trial. One day after the last training trial sessions, mice were subjected to a probe trial session in which the platform was removed from the pool. The mice were allowed to swim for 120 s to search for it. Escape latency time (the first time that the mice crossed the former platform) and time in target quadrant (time searching the pool quadrant where the platform had been) were recorded and analyzed by an overhead camera and ANY-maze video tracking system software (Stoelting Co., Wood Dale, IL).

RNA Isolation. Total RNA was isolated from the tissues of each mouse using RNAiso Plus (TaKaRa Bio, Shiga, Japan) according to the manufacturer's instructions. Briefly, brain tissues were homogenized in RNAiso Plus. Total RNA was extracted with the phenol-chloroform method, followed by isopropyl alcohol precipitation and ethanol washing. cDNA was synthesized using a Rever Tra Ace qPCR RT kit (Toyobo, Osaka, Japan) according to the manufacturer's instructions.

Real-Time PCR Quantification. Quantification of relative gene expression was performed by real-time quantitative PCR, using a StepOne Real-time PCR System (Applied BioSystems, Foster City, CA). Real-time PCR was carried out using the Kapa SYBR Fast qPCR kit (Kapa Biosystems, Woburn, MA). Quantitative PCR was carried out using the thermal cycling program, which consisted of one cycle at 95 °C for 3 min, 40 three-segment cycles (95 °C for 3 s and 60 °C for 20 s), and a final dissociation cycle (95 °C for 15 s and stepwise increase from 60 to 95 °C). To normalize the amount of total RNA present in each reaction, β-actin was used as an internal standard, and the expression in the experimental group was expressed as folds of SAMP8 controls using the comparative Ct method. The primer sequences were as follows: NGF: 5′-CAAGCGTTGACAACAGATGA-3′ (forward) and 5′-CAGCCTCTTCTTGTAGCCTTCC-3′ (reverse), BDNF: 5′-GCGGCAGATAAAAAGACTGC-3′ (forward) and 5′-CTTATGAATCGCCAGCCAAT-3′ (reverse), NT-3: 5′-TTTCTCGCTTATCTCCGTGGCATCC-3′ (forward) and 5′-GGCAGGGTGCTCTGGTAATTTTCCT-3′ (reverse), SIRT1: 5′-TGACCGATGGACTCCTCACT-3′ (forward) and 5′-ACAATCTGCCACAGCGTCAT-3′ (reverse), and β-actin: 5′-GCGGCAAAGACAAGAAAAAG-3′ (forward) and 5′-GAAGTGGTCCTCCCAGTCAT-3′ (reverse).

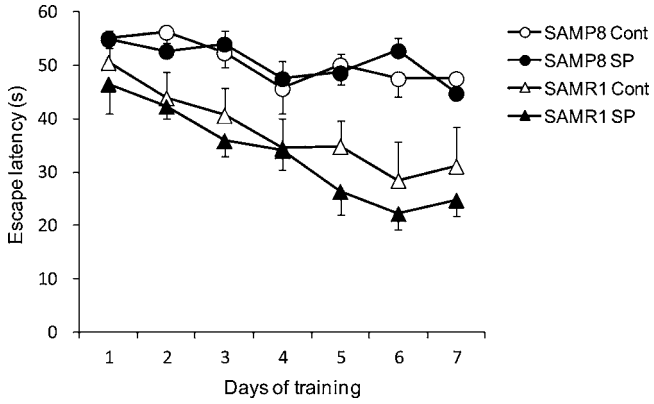

Figure 1. Effect of soy peptides (SP) oral administration for 26 weeks on spatial learning and memory ability during the training trial sessions of the Morris water maze performance in SAMP8 and SAMR1 mice. Escape latency was used as a measure of spatial leaning in the platform task. Data are expressed as means ± SEM.

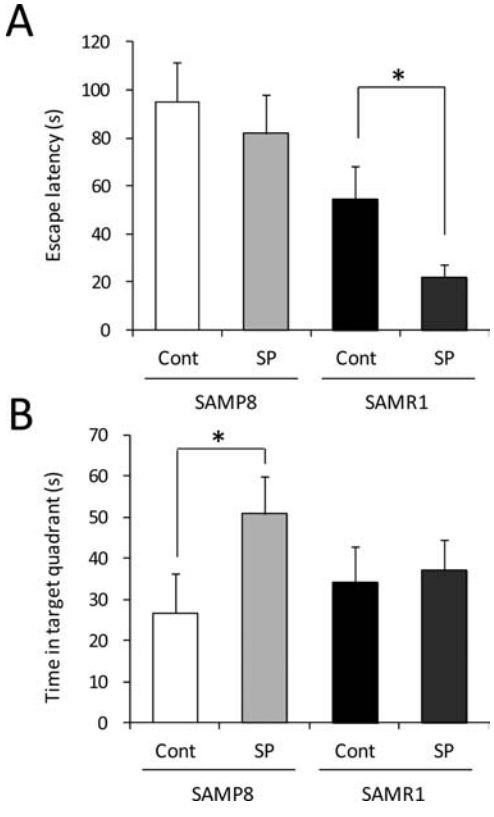

Figure 2. Effect of SP oral administration for 26 weeks on spatial learning and memory ability during the probe trial session of the Morris water maze performance in SAMP8 and SAMR1 mice. (A) Escape latency and (B) time in target quadrant were used as a measure of spatial leaning in the hidden platform task. Data are expressed as means ± SEM *p < 0.05: significantly different from control.

Western Blotting Analysis. The brain tissues were homogenized in RIPA lysis buffer according to standard procedures and centrifuged

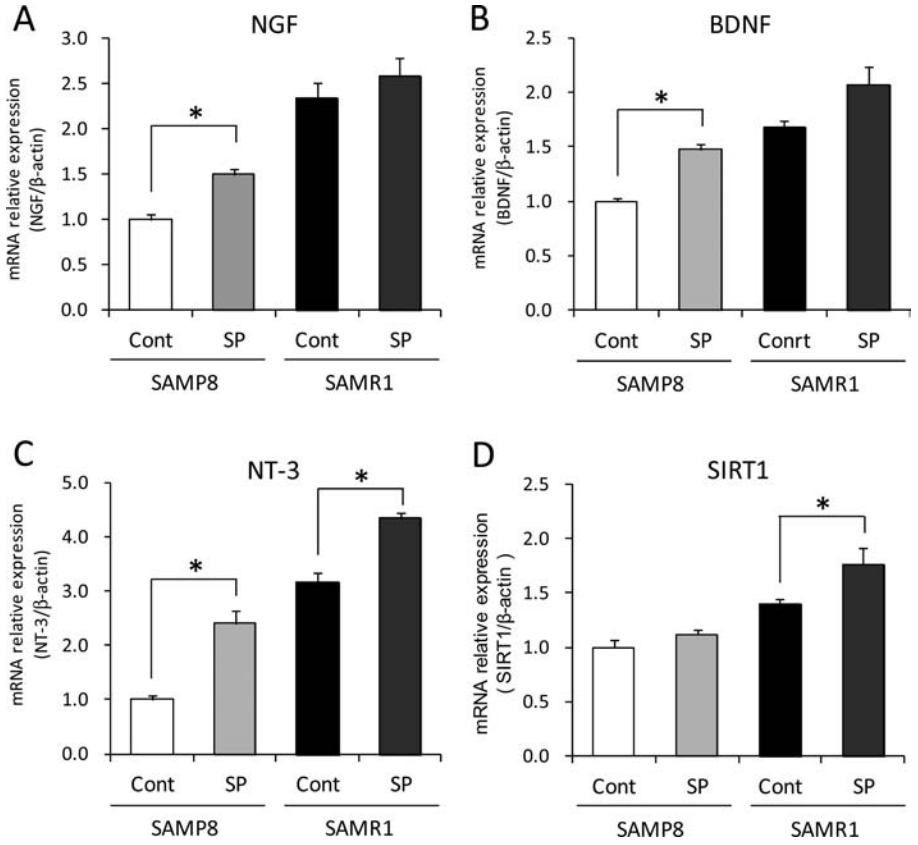

Figure 3. Effect of SP oral administration on mRNA expressions of (A) NGF, (B) BDNF, (C) NT-3, and (D) SIRT1 in the brain from SAMP8 and SAMR1 mice. Data are expressed as means ± SEM *$p < 0.05$: significantly different from control.

at 12 000 rpm for 10 min at 4 °C. The supernatants were collected and protein concentration was determined using the BCA protein assay with bovine serum albumin as standard. Levels of NGF, BDNF, NT-3, CREB, and Ser-133 phosphorylated CREB, extracellular-regulated kinase1/2 (ERK1/2), and Thr-185/Tyr-187 phosphorylated ERK1/2 were analyzed by Western Blot. Briefly, protein samples (12.5 μg) were electrophoresed on 15% polyacrylamide gels and blotted onto polyvinylidene fluoride membranes (Clear Blot Membrane-P; ATTO, Tokyo, Japan). Blots were incubated with antibodies against NGF (1:500, Abcam, Cambridge, MA), BDNF (1:1000, Sigma-Aldrich), NT-3 (1:250, Abcam), CREB (1:750, Abcam), Ser-133 phosphorylated CREB (1:500, Abcam), ERK1/2 (1:500, Enzo Life Sciences, Farmingdale, NY), phosphorylated ERK1/2 (1:1000, Enzo), and β-actin (1:5000, Sigma-Aldrich), followed by antirabbit IgG horseradish peroxidase-conjugate (1:5000, Anaspec, San Jose, CA). Chemiluminescence detection was performed using Pierce Western blotting substrate (Thermo Scientific, Rockford, IL) and AE-9300 Ez-Capture (ATTO). β-Actin was used as an internal control for Western Blot.

Immunostaining. The harvested brains were washed once in cold PBS to remove blood and fixed with 30% paraformaldehyde. The tissues were embedded in paraffin and sectioned at a thickness of 6 μm. Following blocking with 10% goat serum in PBS containing 0.1% Tween 20, the sections were incubated with antibody against NT-3 (1:750, Abcam, Cambridge, MA). After rinsing six times with 0.1% BSA in PBS, samples were further incubated the secondary antibody, Alexa Fluor 488 goat antirabbit IgG (H&L) (1:1000, Abcam). After rinsing six times with 0.1% BSA in PBS, the sections were mounted with immunoselect antifading mounting medium DAPI (Dianova, Hamburg, Germany). We acquired images with an EVOS fluorescence microscope (EVOS fl; Advanced Microscopy Group, Bothell, WA).

Statistical Analysis. Data are presented as mean ± SEM the training session data in Morris water maze were analyzed by two-way ANOVA and the other data were analyzed with Student *t* test. A level of $p < 0.05$ was considered significant.

RESULTS

SAMP8 and SAMR1 were fed control or SP for 26 weeks from 16 weeks of age. Dietary food intake and weight gain did not differ among groups throughout the experiments (data not shown). The Morris water maze test was performed to investigate the effects of a prolonged consumption of SP on the decline in spatial memory and learning abilities of SAMP8 and SAMR1. The probe trial was performed the day after completing the 7-day training trial. In the Morris water-maze training session, SAMR1 rapidly learned the location of the platform, whereas SAMP8 had longer escape latency on every test days compared to SAMR1 (Figure 1). No significant decrease in escape latency was observed between control and SP-fed groups of SAMP8. In contrast, the escape latency of SP-fed SAMR1 mice was shortened compared to that of control mice; however, there was no statistical difference. In the probe trial, the escape latency of SP-fed SAMP8 and SAMR1 mice was faster than that of their controls (Figure 2A). Statistically significant decrease in escape latency was observed in the SP-fed SAMR1 groups. On the other hand, SP-fed SAMP8 mice spent significantly more time in the target quadrant as compared to control mice (Figure 2B).

We next examined whether SP feeding can modulate the expression of neurotrophic and longevity factors in the brain (Figure 3). The mRNA expression of NGF, BDNF, and NT-3 in SAMP8 and SAMR1 mice was up-regulated by SP feeding. Among them, a statistical significant increase of NT-3 expression was found in both SP-fed groups of SAMP8 and SAMR1. On the other hand, an increase in the mRNA expression of SIRT1 was observed in the SP-fed SAMR1, but not SP-fed SAMP8.

dx.doi.org/10.1021/jf405416s | J. Agric. Food Chem. 2014, 62, 3563−3569

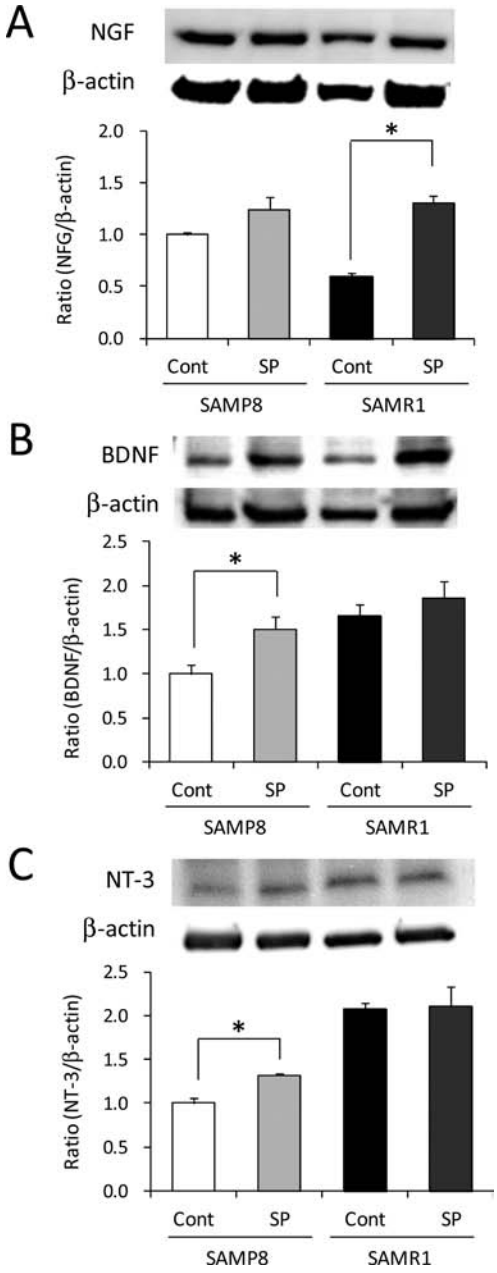

Figure 4. Effect of SP oral administration on protein level of NGF, BDNF, and NT-3 in the brain of SAMP8 and SAMR1 mice. (A) Representative images of Western blotting. (B) Densitometric quantification of band intensities. Data are expressed as means ± SEM $*p < 0.05$: significantly different from control.

The protein levels of NGF, BDNF, and NT-3 in the brain was analyzed using Western blotting (Figure 4). There was a significant increase in BDNF and NT-3 protein levels of SP-fed SAMP8 group compared to control group, whereas no increase was observed in SP-fed SAMR1 group. In contrast, a significant increase in the NGF protein level was observed in SP-fed SAMR1, but not SP-fed SAMP8. Since the hippocampus is important for many aspects of learning and memory, the localization of NT-3 in the hippocampus was examined using immunostaining followed by fluorescence microscopy (Figure 5). NT-3 protein expression was confirmed in the hippocampus of SAMP8 mice. Further, the phosphorylated level of transcription factor CREB in brain was examined to demonstrate whether

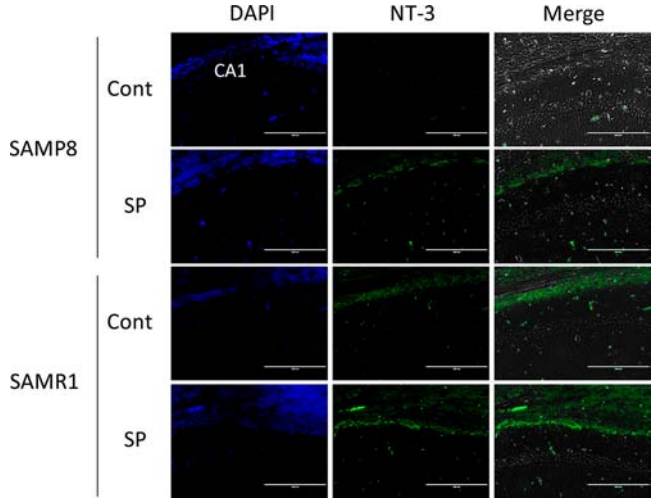

Figure 5. Localization of NT-3 in the hippocampus containing the CA1 layer was examined using immunostaining. Scale bar: 100 μm.

CREB activation occurs (Figure 6). A significant increase in the phosphorylated CREB was observed in the brain of SP-fed SAMP8 group compared with the control group. The phosphorylated ERK1/2 of SP-fed SAMP8 group was increased compared with that of the control group, although this was not statistically significant.

DISCUSSION

Recently, much attention has been focused on a potential neuromodulatory functions and brain protective properties of naturally occurring compounds. Our study demonstrated that the SP-fed mice improved spatial learning and memory when compared with the control mice. The interesting finding of the present study is the significant up-regulation of neurotrophic factors such as NGF, BDNF, and NT-3, which promote neurogenesis, neurodifferentiation, neuroprotection, and neuroplasticity.[18] NT-3 is widely distributed throughout both the peripheral and central nervous system[19] and plays a crucial role in the promotion of neuronal survival and nerve fiber outgrowth and in the enhancement of regeneration of damaged nerve.[20] Thus, the NT-3 enhancement in the brain is a potential therapeutic strategy for preventing age-related cognitive decline. Generally, BDNF exerts multiple cellular functions, including the protective effects on crucial neuronal circuitry involved in Alzheimer's disease (AD).[21] Previous studies have been demonstrated that Ginkgolide B inhibits Aβ (25−35)-induced apoptosis in hippoicampal neurons via up-regulation of BDNF expression.[22] Further, resveratrol treatment enhanced the generation of newborn neurons in dentate gyrus and restored the decreased hippocampal BDNF level significantly in prenatally stressed rat brain.[23] The present study suggests that it is possible to use SPs to prevent degenerative neurological disorders of aging because SPs have minor side effects. It is well-known that the dysregulation of adult neurogenesis progresses in AD patients and in various AD model mice.[24,25] Thus, neurotrophic agents may have therapeutic potential for prevention and treatment of AD.

This study showed that SP administration resulted in an increased SIRT1 expression level of SAMR1 mice. Sirtuin activity has been shown to play a significant role in promoting longevity, preventing disease and increasing cell survival.[26] Thus, the up-regulation of SIRT1 might contribute to the protective effect on cognitive decline in SP-fed SAMR1.

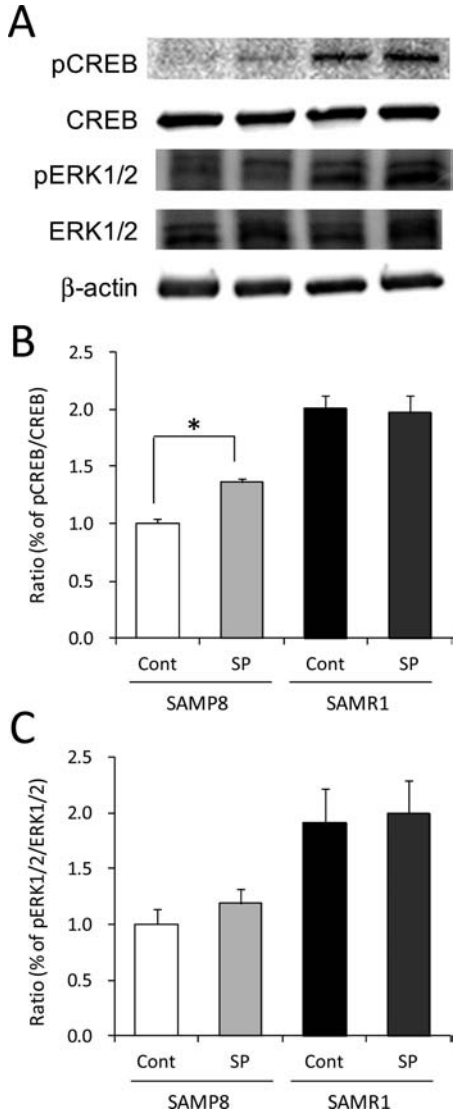

Figure 6. Effect of SP oral administration on protein level of phosphorylated CREB and ERK1/2 in the brain from SAMP8 and SAMR1 mice. Data are expressed as means ± SEM $*p < 0.05$: significantly different from control.

Porquet et al.[9] have demonstrated that SIRT1 activation by long-term dietary resveratrol not only reduces cognitive impairment but also increases mean life expectancy and maximal life span in SAMP8 and SAMR1. During our experiment, there were no deaths in SAMR1 mice; however, the up-regulation of SIRT1 expression by dietary SP may affect the longevity of SAMR1 mice.

Neurotrophic factors termed neurotrophins (NGF, BDNF, NT-3, and NT-4/5) play an important role in the growth and survival of neurons. CREB is a transcription factor implicated in the control of adaptive neuronal responses and the regulation of neurotrophic genes.[27,28] This study suggests that increased gene expression of NGF, BDNF, and NT-3 observed in SP-fed SAMP8 group was accompanied by activation of CREB-dependent pathways. The induction of neurotrophic factors by SP feeding could contribute to a protective effect on cognitive decline in SAMP8. Recent work suggests that the trans-activation of CREB was mainly caused by the mitogen-activated protein kinase/extracellular-regulated kinase (MAPK/ERK), which plays an important role in long-term synaptic plasticity and memory formation.[29,30] However, no significant increase in phosphorylated ERK protein levels was observed in this study. A number of kinases, including protein kinase A protein kinase C, and AKT, are also known to be phosphorylate and activate CREB.[31] Therefore, it seems that another signaling pathway exists in the activation of CREB by SP feeding. Further investigation is needed to explore the signal transduction cascade to induce the neurotrophic factors in the SP-fed SAMP8 group.

In the experiment of water maze task, no significant difference in escape latency was observed between control and SP-fed groups in the training session in both SAMP8 and SAMR1. However, a significant difference was observed in the probe trials in escape latency of SAMR1 and in time in target quadrant of SAMP8. This discrepancy is caused by a difference of the time-limit between training session and probe trials, which were 60 and 120 s, respectively. In particular, since SAMP8 at 42 weeks were not quick in movement, they needed more time compared to SAMR1. Therefore, it is considered that the measurement of time in the target quadrant is suitable to evaluate the spatial learning and memory ability of SAMP8. Taking these results into consideration, our data support that the SP feeding could affect the memory function of both SAMP8 and SAMR1.

In the present study, we used SAMP8 mice as a model of age-related cognition disorder and SAMR1 mice as normal aging control mice. Indeed, SAMP8 showed not only greater decline in performance in the Morris water maze but also decreased expression levels of neurotrophic factors. A significant increase of SIRT1 mRNA was found in only SP-fed SAMR1, while a significant increase of pCREB was found in only SP-fed SAMP8. These results suggest that the working point of SP feeding in SAMP8 is different from that of SAMR1. It is reasonable to assume that this difference was caused by different gene expression profiles of receptors and coregulators.

The SP used in this study was composed mainly di- and tripeptides, and this peptide mixture have been reported to increase the serum levels of amino acids more rapidly than the original soy proteins or an amino acid mixture of equivalent composition.[32] It was also shown that short-term oral intake of SP increases neuroactive amino acids such as the neurotransmitter L-glutamate, its precursor L-glutamine, the neuromodulator D-asparatate, and branched-chain amino acids such as L-valine, L-leucine, and L-isoleucine.[33] Generally, dipeptides and tripeptides are absorbed by small intestinal cells in peptide form using the PepT1 peptide transporter and hydrolyzed by cellular enzymes and the resultant amino acids are transported across the serosal membrane. Taking these results into consideration, it appears possible that neuroactive amino acids produced from the SP exhibit an effective nutraceutical for promoting brain function. The mechanism for oligopeptide transport in the intestinal tract is not fully understood; however, Shimizu et al. demonstrated that antihypertensive tripeptide VPP transpiorted across human intestinal epithelial cells monolayers via the paracellular route, which is a nondegradation pathway.[34] It is possible that the intact dipeptides directly contribute to the induction of neurotrophic factors. Further studies are needed to determine the mechanism of action and identify the active sequence of peptides.

In conclusion, the present study has demonstrated that SPs have the potential for the prevention of cognitive impairment via the neurotrophic effects in SAMP8 mice. These results indicated that SP may play an important role for the prevention of age-related cognitive decline and neurodegenerative diseases such as AD.

feeding species-rich herbage on BH of the major FAs.[8,14] Only one study emanates the effect that single plant species have on BH of major FAs[13] but to the authors' knowledge, studies on the importance of feeding regimen for BH of major FAs in single plant species to minimize BH rate of beneficial PUFAs are missing.

The aim of the present study was to elucidate the effect of (i) feeding either TMR, pure grass, or species-rich silage on BH rate of ALA and LA, (ii) study differences in BH rate of ALA and LA in single plant species, and (iii) whether BH rates of ALA and LA in single plant species depend on the feeding regimen of the donor cow.

MATERIALS AND METHODS

Treatment of the Donor Cows. Three lactating Holstein cows (weight, 573 ± 43 kg; daily milk yield, 30 ± 4 kg), fitted with ruminal cannulas, were housed in tie stalls. The experiment was carried out at Aarhus University, Department of Animal Sciences, Denmark, and was carried out in accordance with the Danish Ministry of Justice Law No. 1306 (November 23, 2007) on animal experiments and care of experimental animals. The cows were subject to three different diets. Each dietary treatment lasted three coherent weeks with one daily feeding at 3:45 p.m. The normal diet of the cows in the research facility was a traditional total mixed ration (19.0% starch, 18.1% crude protein, and 4.1% crude fat on DM basis) composed of (% of DM) 35 corn silage, 31 grass clover silage, 14 barley, 9 rapeseed, 9 soybean meal, and 2 vitamin and mineral mixture. The TMR was chosen to represent BH in a traditional conventional feeding regimen. After 21 days, the diet was changed to herb silage acquired from a local farmer (HERB) (0.19% starch, 14.1% crude protein, and 3.9% crude fat on DM basis). The silage was composed of 10 different species with the following botanical composition (% of kg sown mixture): 24 salad burnet (*Poterium sangusisorba*), 12 chicory (*Cihorium intybus*), 12 caraway (*Carum carvi*), 12 birdsfoot trefoil (*Lotus corniculatus*), 12 English plantain (*Plantago lanceolata*), 11 alfalfa (*Meticago sativa*), 8 white meliot (*Melilotus officinalis*), 5 borago (*Borago officinalis*), 2 yarrow (*Achillea millefolium*), and 2 red clover (*Trifolium pratense*). Finally, the cows were switched to a diet composed of pure perennial ryegrass (*Lolium perenne*) silage grown on the research facility (GRASS) (0.93% starch, 15.5% crude protein, and 3.5% crude fat on DM basis). To maximize diet effects, concentrate was not added to the HERB or to the GRASS diet. One cow had to be taken out of the experiment in the second week on the pure ryegrass feeding due to disease, resulting in only two replicas in the GRASS feeding period.

Design of the in Vitro Experiment. Five single plant species in three replicas (alfalfa (*M. sativa*), birdsfoot trefoil (*L. corniculatus*), chicory (*C. intybus*), English plantain (*P. lanceolata*), salad burnet (*P. sangusisorba*)) and a clover grass mixture (% of DM) (80 white clover (*Trifolium repens*) and 20 perennial ryegrass (*Lolium perenne*)) were investigated. Cultivation, handling, and chemical composition of the herbs and the clover mixture are described elsewhere.[19,20] The five plant species were chosen because they already are commonly used in seed mixture for pasture on Danish organic farms and have shown persistence in regrowth after cutting.

Rumen fluids were collected at day 21 in each of the three feeding periods at 7 a.m. Rumen fluids were filtered through double-layered cheesecloth and then immediately transferred separately under anaerobe conditions to the laboratory in sealed and preheated vacuum flasks. Twenty-two milliliters of the strained rumen fluid was transferred to 60 mL tubes. Prior to the transfer of the rumen fluid, 1 g of freeze-dried plant species and 22 mL of buffer solution were added to the tubes. The buffer was prepared according to the method of McDougall.[18] The lid of the tube was punctured with an injection needle and then equipped with a syringe to allow gas escape from the tubes without compromising the anaerobic environment. Incubations were stopped at 0, 2, 4, 6, 12, 24, and 30 h by placing test tubes containing buffered rumen fluid and plant materials in an ice slurry. The complete samples were freeze-dried and stored at −20 °C until further analysis.

Throughout the experiment, the pH value was followed in samples of the buffered rumen fluid with the added material of alfalfa and birdsfoot trefoil. Over the experimental period the pH value decreased on an average by 1.0 unit. The lowest pH value after 30 h was observed in TMR fluids (0 and 30 h; pH 6.7 and 5.9, respectively). The pH values after 0 and 30 h in HERB samples were 7.9 and 6.2, respectively, and in GRASS samples, 7.1 and 6.2, respectively.

Fatty Acid Analysis. Lipids were extracted in a mixture of chloroform and methanol according to the method of Bligh and Dyer[21] after acidification by boiling in 3 mol/L of HCl for 1 h, and FA were converted into methyl esters (FAME) as described by Jensen.[22] Lipids were quantified as FA methyl ester according to Jensen and Nielsen[23] with small adjustments to the temperature program. Briefly, 250 mg of the freeze-dried samples was weighed in culture tubes and extracted with 4 mL of chloroform containing C17:0 (heptadecanoic acid, Sigma-Alrich, St. Louis, MO, USA) as internal standard, 3 mL of methanol, and 1.5 mL of distilled water. The extracts were centrifuged for 10 min at 3000*g*. After extraction, 1 mL of the extracts was transferred to new culture tubes, evaporated to exact dryness under a stream of N_2, and then methylated. Fatty acids were methylated with 0.8 mL of NaOH in methanol (0.5 M), sealed with Ar, and placed at 100 °C for 15 min. After cooling, 1 mL of boron trifluoride was added, and tubes were sealed with Ar and placed at 100 °C for 45 min. FA methyl esters were then extracted with 1 mL of heptane and analyzed with a gas chromatograph (Hewlett-Packard 6890 series, Agilent Technologies, Palo Alto, CA, USA) equipped with an automatic column injector (Hewlet Packard 7673), a capillary column of 30 m × 0.32 mm i.d., 0.25 μm thickness (Omegawax 320; Supelco, Sigma-Aldrich), and a flame ionization detector. The initial temperature was set at 170 °C, and then the temperature was raised to 200 °C at the rate of 2 °C/min. The 200 °C was held for 5 min and finally raised to 220 °C at the rate 5 °C/min. Fatty acids were identified by comparison of retention times with external standards (GLC-68C, Nu-Prep-Check, Elysian, MN, USA). Four to five peaks eluted between the peaks of C18:1n-9 and C18:2n-6 contributing to approximately 5% of total FA composition. These peaks were most likely different C18:1 isomers, but we were not able to identify these peaks.

Twenty-two samples (representing the whole incubation time from 0 to 30 h) were processed without internal standard to secure the applicability of C17:0 as internal standard. Chromatograms of samples processed without addition of internal standard showed that naturally occurring C17:0 contributed with an area of <0.5% of the area from the added 5 mg of C17:0. The contribution of naturally occurring C17:0 therefore could be neglected.

Kinetic Calculations. According to the Michaelis−Menten equation

$$V = V_{max} \times \frac{[s]}{k_M + [s]}$$

a Hanes plot is a straight line. The results determined in the in vitro BH experiment were analyzed by linear regression according to the Hanes plot as the time ($[s]$, hours) against the time divided by the amount of ALA or LA disappeared or C18:0 formed (hour/g/kg DM).

V_{max} (g FA/kg DM) was calculated as the reciprocal slope, and K_M (hour) was calculated as the intercept multiplied by V_{max} and is the time for 50% reduction in ALA and LA concentration or 50% increase in C18:0 formation. For ALA and LA their initial concentrations were subtracted from the concentration at the time when incubation was stopped (e.g., time = 0 h subtracted from time = 2, 4, 6, 12, 24, and 30 h), giving the total sum of products from the BH at the given time. Rumen BH is a complex system, where formation of the different intermediates can originate from isomerization, desaturation, or hydrolysation along the different BH pathways,[24] and therefore modeling of intermediates is difficult. In the current study modeling of the intermediate C18:1*t*11 was attempted under the assumption that the concentration would increase over time as a result of BH. The

results are to be considered as the apparent appearance of C18:1*t*11 for the reasons stated above.

Statistics. Statistical analysis was carried out using the PROC MIXED procedures in the SAS package, ver. 9.2, with diet, single species, and the interactions between diet and single species as fixed effects. The effect of cow was tested, but no significance was found, and so cow was included as a random effect in the final model. Differences in mean treatment effects were tested using the PDIFF command. The general model used was

$$Y_{ij} = \mu + D_i + S_j + (D \times S)_{ij} + C_{ijk} + e_{ijk}$$

where μ is the overall mean, D_i and S_j are the fixed effects of diet$_i$ and single species$_j$, $(D \times S)_{ij}$ is the interaction between diet$_i$ and single species$_j$, C_{ijk} is the random effect of cow, and e_{ijk} is the residual error. Random effects were assumed to be normally distributed with a mean value of 0 and constant variance, $C_{ijk} \sim N(0, \sigma_C^2)$ and $e_{ijk} \sim N(0, \sigma^2)$. Significance was accepted at $P \leq 0.05$.

RESULTS

Fatty Acid Content in Single Species. Total FA content in the herb species varied from 12.4 g/kg DM in alfalfa to 22.8 g/kg DM in birdsfoot trefoil (Table 1). ALA was the dominating FA in all species with LA or C16:0 as the second dominating FA. Following the content of total FA, the lowest contents of ALA and LA were seen in alfalfa (4.49 and 2.60 g/kg DM, respectively), and the highest contents were seen in birdsfoot trefoil (12.3 and 4.00 g/kg DM, respectively).

Fatty Acid Composition of Rumen Fluid. The initial FA profile differed between the diets (Table 2). The sum of ALA and LA was highest in the HERB and GRASS diets, although the LA content was highest in the TMR diet. The accumulation of intermediates of BH, represented by C18:1*t*11, was highest in the rumen fluid from the TMR diet, whereas no differences were seen between the HERB and GRASS diets. CLA was detected in only trace amounts and could not be used to highlight further differences in intermediates of BH. The end product of rumen BH C18:0 was found to be similar in rumen fluid from the TMR and GRASS diets, whereas it was significantly lower in rumen fluid from the HERB diet.

Effect of the Donor Cows' Diet on Biohydrogenation Rate. Biohydrogenation of ALA and LA occurred at a faster rate in rumen fluid from cows fed TMR diet compared to

[a]Means within a column with different letters indicate significant differences ($P \leq 0.05$). [b]To be considered as apparent appearance due to the complexity of formation of BH intermediates.

HERB or GRASS diets, indicated by low K_M and high V_{max} values in the TMR group ($P < 0.001$) (Table 3). In accordance with the BH pattern for ALA and LA, the TMR diet also showed the fastest formation of C18:0 shown by a low K_M value and a high V_{max} value ($P < 0.001$). The apparent appearance of C18:1*t*11 was fastest in the TMR diet compared to both GRASS and HERB diets as shown by the lower K_M values ($P < 0.001$), but V_{max} was numerically highest in the HERB diet.

Effect of Species on Biohydrogenation Rate. Salad burnet and alfalfa differentiated from the other species, as they showed the lowest BH rate of ALA and LA, indicated by the lowest V_{max} values ($P < 0.001$ and $P = 0.019$, respectively) and also the lowest K_M values for the formation of C18:0 ($P < 0.001$) (Table 4). Birdsfoot trefoil showed the highest BH rate of both ALA and LA. Plantain had numerically lower V_{max} values for ALA and LA than alfalfa, but the formation of C18:0 was significantly higher ($P < 0.05$). Apparent formation of C18:1*t*11 revealed differences when compared to BH patterns for formation of C18:0 in the single plant species, as salad burnet and chicory seemed to have the lowest apparent formation rate of C18:1*t*11. The highest apparent formation rate seemed to occur in plantain, which was one of the species with the lowest BH rate of ALA and LA (Figure 1), although the K_M value for C18:1*t*11 was highest in the clover grass mixture ($P < 0.001$).

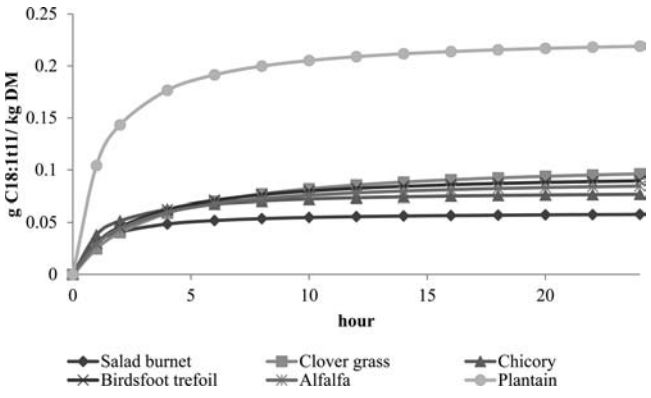

Figure 1. Apparent appearance of C18:1*t*11 in single species. Although only K_M was found significantly different between species, data modeled according to Michaelis–Menten kinetics highlight these differences between plant species.

Effect of Diet and Species Interaction on Biohydrogenation Rate of ALA. A significant interaction between diet and species was seen for K_M for ALA ($P = 0.005$). Only alfalfa seemed to react differently when compared to the general effect of diets, as the highest K_M value for alfalfa was seen in the GRASS diet compared to both TMR and HERB diets (6.36, 0.72, and 2.41, respectively, $P = 0.005$); this implies a lower BH of ALA in the GRASS diet (Figure 2) . No significant effect of

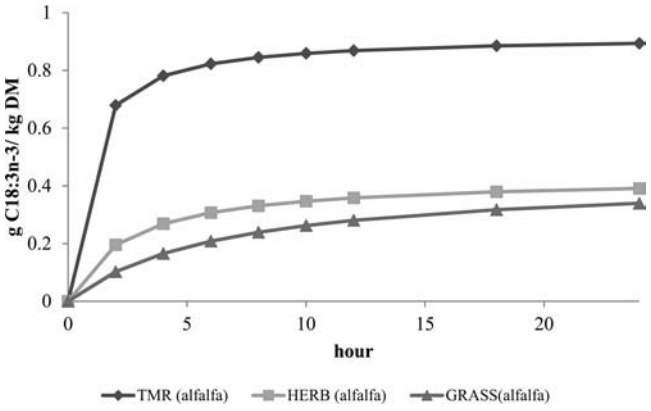

Figure 2. Effect of interaction between diet and plant species for disappearance of C18:3n-3 in alfalfa in rumen fluid from TMR, GRASS, and HERB fed donor cows modeled according to Michaelis–Menten kinetics. The effect of interaction between diet and plant species was seen only for K_M values of C18:3n-3 ($P = 0.005$), and only alfalfa behaved differently compared to the general effect seen for diet.

interaction between diet and species was seen for LA, C18:0, or C18:1*t*11 for either K_M ($P = 0.66$, $P = 0.08$, and $P = 0.33$, respectively) or V_{max} ($P = 0.24$, $P = 0.77$, and $P = 0.81$, respectively).

Michaelis–Menten Kinetics. Application of Michaelis–Menten kinetics to model rumen BH of C18 FAs showed high regression values (R^2) for the fitted Hanes plots and were on average 0.972, 0.933, 0.965, and 0.968 and for ALA, LA, C18:0, and C18:1*t*11, respectively (data not shown). The R^2 for ALA ranged from 0.734 (data for alfalfa in rumen fluid from GRASS-fed donor cows) to 0.997 for LA from 0.649 (data for salad burnet in rumen fluid from HERB-fed donor cows) to 0.997. For C18:0, R^2 ranged from 0.840 (data for birdsfoot trefoil in rumen fluid from GRASS-fed donor cows) to 0.998.

DISCUSSION

Effect of Diet on Rumen Fluid FA Profile and Biohydrogenation. One of the hypotheses for the higher content of ALA and LA in milk from cows grazing alpine pasture or fed species-rich silages is that the feeding regimens would lead to reduced BH of PUFAs. Thus, accumulation of ALA and LA in the rumen fluid should occur compared to feeding pure ryegrass.[14] As seen in other studies, when ryegrass and species-rich herbage were compared,[2,14] no differences in ALA and LA rumen content between the HERB or GRASS diets were seen. Thus, this indicates that accumulation of PUFAs in the rumen cannot solely explain differences in milk ALA and LA contents when species-rich herbages and clover or ryegrass grass herbages[2,9] are compared.

It has been speculated that species-rich herbages could contain secondary plant metabolites that would inhibit normal BH pattern and thus lead to accumulation of BH intermediates such as C18:1*t*11.[24] As a consequence, this would reduce the production of C18:0 in the rumen. Although the content of C18:0 was higher in the GRASS rumen fluid compared to the HERB fluid, the contents of C18:1*t*11 were not different between the HERB and GRASS diets. One of the major BH intermediates of LA, c9*t*12 CLA, was detected in only trace amounts in a few samples and could not be used to detect differences in rumen BH. Nevertheless, the significantly lower content of C18:0 in HERB rumen fluid suggests some alterations in rumen BH in HERB diet compared to both GRASS and TMR diets. Further identification of unidentified peaks that occurred in the present study would probably have helped to emphasize these alterations.

In the present study, rumen fluid from cows on the TMR diet had a significantly higher content of LA than rumen fluid from cows fed the HERB and GRASS diets. A high content of LA is shown to be more toxic than C18:1 isomers to bacteria cells responsible for conversion of LA to C18:1*t*11.[25] The slow and low apparent appearance of C18:1*t*11 and fast formation of C18:0 from the TMR diet in the in vitro batches indicates such possible effects of the TMR diet on the rumen bacterial cultures compared to both HERB and GRASS diets, as the apparent appearance of C18:1*t*11 was similar in the HERB and GRASS diets. The supplies of energy and fermentable carbohydrates for the microbes are also higher on the TMR diet than on the HERB and GRASS diets and possibly provide better bacteria growth. Combined with a numerically lower pH value and thus more hydrogen available for BH, this could contribute to optimized conditions for BH in the rumen and could be one explanatory factor for a higher BH rate in the TMR diet.

Effect of Species on Biohydrogenation. The single plant species differ in chemical composition,[20] and these factors could therefore influence the BH rate. Optimal conditions for BH would among others include supply of energy and protein as well as content of secondary metabolites in single plant species to the bacterial cultures responsible for BH.

Clear differences in BH were seen between the investigated species. Although the K_M values were significantly different only for the end BH product, C18:0, alfalfa and salad burnet continuously showed the lowest BH of ALA and LA, whereas the fastest BH occurred in birdsfoot trefoil. An interesting factor is that alfalfa had the lowest and birdsfoot trefoil the highest content of both ALA and LA, and if only the disappearance of PUFA were investigated, the initial content of single FAs could possibly interfere with the results; however, as these differences are taken into consideration when using the model, the initial FA content cannot explain the differences in BH in these two species from the Fabacea family. Apparent recovery of ALA from feed to milk is also reported to improve when feeding alfalfa compared to feeding grass and a grass clover mixture,[26] which supports our findings with a slow and low BH of ALA in alfalfa when added as single species to in vitro cultures. To the authors' knowledge only one study has looked into the effect of single species on rumen BH, and the differences seen in BH could not be based on simple family classification as well.[13] Therefore, it seems family classification cannot explain the differences seen in the present study.

In recent years evidence for the inhibitory effects of tannins on rumen BH has been shown,[12,27] which has been linked to possible changes in the microbial and protozoa communities.[28] Birdsfoot trefoil is known to contain tannins[29] and in theory should have shown reduced BH of ALA and LA, but was in fact the species with the highest BH of both ALA and LA. On the other hand, alfalfa does not contain considerable amounts of tannins[30] and was one of the single species with the slowest BH of both ALA and LA. The other species with one of the slowest BH of ALA and LA was salad burnet, which is also known to contain tannins.[31] Although different tannins in single plant species could affect rumen BH differently, the content of tannins does not seem to be the only explanatory factor for reduced rumen BH caused by single plant species.

Chemical composition and digestibility of the plants species used in the present in vitro study differed considerably.[20] However, it seems that these differences do not explain the effect on rumen BH of salad burnet, plantain, and alfalfa, but instead further emphasize the complexity of rumen BH as species.

Although BH of ALA and LA was reduced in alfalfa and salad burnet, C18:0 was formed rapdily in the two plant species, too, especially in alfalfa. This could mean that the reaction responsible for the formation of C18:0 saturates faster in alfalfa and salad burnet than in the other species, reducing the conversion of ALA and LA to their respective BH intermediates, as indicated by the high K_M and low V_{max} values. The fact that different species seems to affect the rumen BH pathway differently[4,13] is supported by different apparent formation rates of C18:1*t*11 in the present study; birdsfoot trefoil was not different from alfalfa, although V_{max} values for ALA were significantly different between the two plant species. Plantain, on the other hand, seemed to accelerate the apparent appearance of C18:1*t*11, although it was one of the species showing the slowest BH of both ALA and LA. Plantain is a species with high values of phenolic acids[32] as is salad burnet,[31] and they had the highest and lowest apparent appearance of C18:1*t*11, respectively. This again highlights the complexity in the mechanism affecting rumen BH.

To a certain extent the clover−grass mixture follows the pattern seen for salad burnet. No single cultures of the white clover and ryegrass were sown, and as season and harvest can affect the growth and nutritional composition of plants,[7,33] the clover−grass mixture cultivated under the same conditions as the other species was used. It has been shown that white clover increases milk content of ALA compared to grass[26] through increased passage rate or high content of ALA.[10,11] This could explain the similar BH rate of the clover−grass mixture and salad burnet. As white clover and ryegrass are very different, both physically and chemically,[26,34] it would have been interesting to investigate the effect of the single species on

rumen BH, but for reasons stated above this was not possible in the study presented here. The mixture, although predominately containing white clover, could possibly interact with the rumen microflora different from a single species. In the present study no clear correlation between single species trait and BH of ALA and LA was seen, and further studies are required to elucidate the differences in BH of ALA and LA observed between species.

The interaction between diet and species on BH of ALA offers another interesting aspect, especially as alfalfa was the only species behaving differently when the HERB and GRASS diets were compared. It has repeatedly been shown that a diet containing alfalfa has a positive effect on milk content of ALA.[10] Although alfalfa does not contain noticeable amounts of tannin, it has been shown to contain flavonoids,[35] which could have a specific impact on rumen BH. It has been shown that flavonoids alter rumen fermentation patterns,[36] but the cause of the surprising effect of alfalfa in the GRASS diet is not clear yet and warrants further studies.

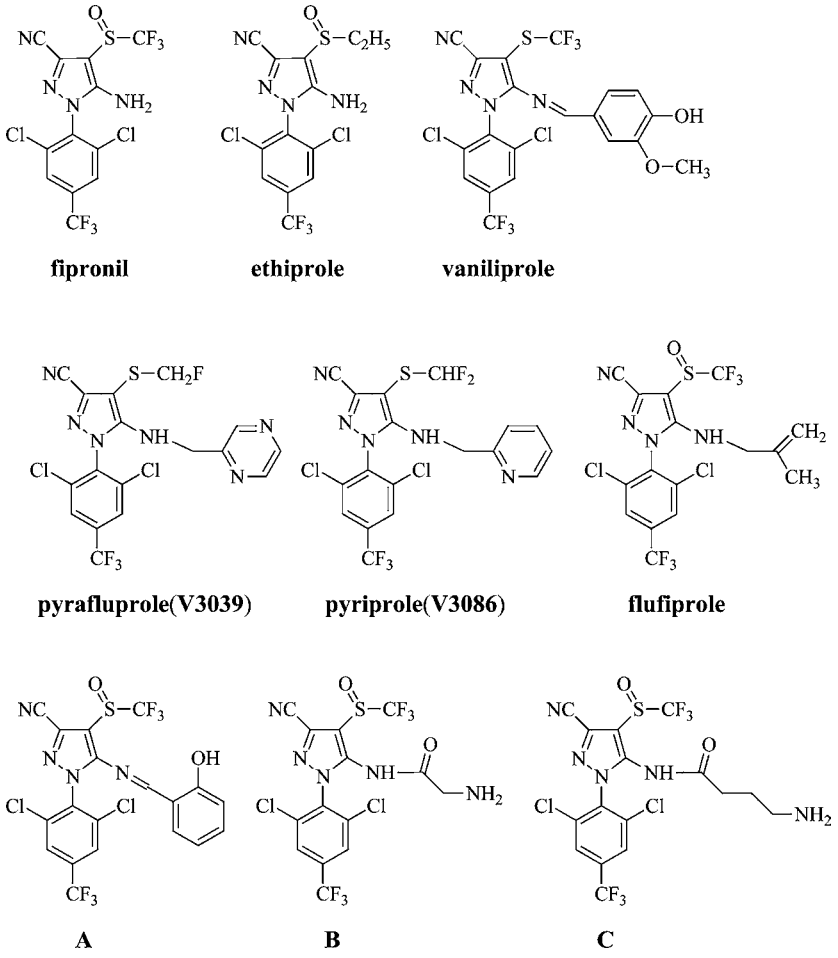

Figure 1. Structures of fipronil derivatives.

side effects due to the reduced ability to penetrate the blood–brain barrier.

To develop dual-target insecticides that act on $GABA_AR$ and nAChRs, we herein report the synthesis and structure–activity relationships (SARs) of phenyl pyrazole inner salts of fipronil derivatives (**1a–1g**) and phenyl pyrazole amido (hydantoin) derivatives (**2a–2d**). **1a–1g** compounds, containing the phenyl pyrazole structure of fipronil and quaternary ammonium structure, would probably act on the two targets $GABA_AR$ and nAChRs.[23−29]

MATERIALS AND METHODS

General. All melting points were obtained with a RY-1G melting point apparatus (Tianjin Tianguang Optical Instruments Co. Ltd., China) and are uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker AVANCE 600 (600 MHz) or Bruker AC-P400Q instrument. ESI-MS was recorded on AccuTOF CS JMS-T100CS (JEOL), and EI-MS was recorded on DSQ (Thermo). EI-HRMS was recorded on MAT95XP (Thermo). ESI-HRMS was recorded on LTQ Orbitrap Elite (Thermo Fisher) or ESI-Q-TOF (Bruker Daltonics).

General Procedure for the Synthesis of Intermediate 2-Bromo-*N*-(3-cyano-1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-4-(trifluoromethylsulfinyl)-1*H*-pyrazol-5-yl) Acetamide (Compound 1). Almost 98% fipronil (4.4 g, 0.01 mol) was dissolved in anhydrous tetrahydrofuran (40 mL), to which sodium hydride (0.8 g of 36% oil dispersion) was added three times below 0 °C under nitrogen and stirred below 10 °C. After 3 h, bromoacetyl bromide (7 mL) was added and stirred at room temperature for another 3 h. The reaction mixture was filtered and the filtrate evaporated in vacuo. The solid residue was purified by chromatography and eluted with petroleum ether/ethyl acetate (3:1, v/v) to give clear colorless crystals (mp 105–107 °C, yield = 72%). ^{1}H NMR ($CDCl_3$, 600 MHz) δ 9.22 (s, 1H, NH), 7.77 (s, 2H, ArH), 4.12 (s, 2H, CH_2); ^{13}C NMR (150 MHz, $CDCl_3$) δ 171.37, 164.07, 141.38, 136.03, 135.58, 134.80, 134.57, 134.36, 126.59, 126.57, 126.18, 109.64, 107.90, 26.63; ESI-MS, m/z (%) 559 $[M + H]^+$ (40), 581 $[M + Na]^+$ (100), 597 $[M + K]^+$ (28).

General Procedure for the Synthesis of Compounds 1a–1g. Compound **1** (3.00 g, 0.0054 mol) was dissolved in 15 mL of THF in a 150 mL round-bottom flask equipped with a magnetic stirrer and a calcium tube. Then 0.01 mol of tertiary amine or nitrogen heterocycles in 10 mL of THF was dropped into the solution and stirred for 2–4 h at room temperature. The reaction mixture was evaporated in vacuo. The residue was purified by chromatography eluting using ethyl acetate/methanol and afforded the desired products **1a–1g**.

*(3-Cyano-1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-4-((trifluoromethyl)sulfinyl)-1H-pyrazol-5-yl) (2-(Trimethylammonio) acetyl)amide (**1a**).* Column chromatography (ethyl acetate/methanol = 7:1 → 6:1, v/v) afforded compound **1a** as a clear colorless crystal: mp 199–201 °C; yield = 89%. ^{1}H NMR (600 MHz, $(CD_3)_2CO$) δ 8.05 (s, 2H, ArH), 3.95 (d, 1H, J = 15.6 Hz, CH_2-1), 3.90 (d, 1H, J = 15.6 Hz, CH_2-2), 3.35 (s, 9H, 3 × CH_3); ^{13}C NMR (150 MHz, $(CD_3)_2CO$) δ 167.1, 152.6, 139.3, 136.8, 134.0, 133.8, 133.5, 128.8, 126.8, 126.6, 126.1, 124.3, 122.5, 113.6, 104.2, 68.8, 53.9; EI-MS, m/z (%) 535 $[M]^+$ (80); EI-HRMS for $C_{17}H_{13}Cl_2F_6N_5O_2S$ $[M]^+$, calcd 535.0066, found 535.0061.

*(3-Cyano-1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-4-((trifluoromethyl)sulfinyl)-1H-pyrazol-5-yl) (2-(Triethylammonio)-acetyl)amide (**1b**).* Column chromatography (ethyl acetate/methanol = 8:1 → 6:1, v/v) afforded compound **1b** as a clear colorless crystal: mp 180–182 °C; yield = 75%. ^{1}H NMR (600 MHz, MeOD) δ 8.03 (s,

dx.doi.org/10.1021/jf405512e | J. Agric. Food Chem. 2014, 62, 3577–3583

2H, ArH), 4.82 (s, 2H, CH_2), 3.63−3.72 (m, 2H, CH_2), 3.37−3.41 (m, 4H, $2CH_2$), 1.14−1.17 (m, 9H, 3 × CH_3); ^{13}C NMR (150 MHz, $CDCl_3$) δ 167.5, 152.9, 139.3, 137.5, 137.4, 135.3, 135.1, 134.8, 134.6, 127.1, 127.1, 126.4, 124.6, 124.3, 122.8, 113.4, 104.9, 61.0, 54.7, 7.8; EI-MS, *m/z* (%) 577 $[M]^+$ (30); EI-HRMS for $C_{20}H_{19}O_2N_5Cl_2F_6S$ $[M]^+$, calcd 577.0535, found 577.0534. (The single crystal data are available from Cambridge Crystallographic Data Centre (CCDC 975075).)

General Procedure for the Synthesis of Compounds 2a−2d. *N-(3-Cyano-1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-4-((trifluoromethyl)sulfinyl)-1H-pyrazol-5-yl)-2-(2,4-dichlorophenoxy) Acetamide (**2a**).* 2,4-Dichlorophenoxyacetyl chloride was synthesized according to a method from the literature.[30] Almost 98% fipronil (4.4 g, 0.01 mol), triethylamine (0.013 mol), and *N*,*N*-dimethylaminopyridine (DMAP) (0.001 mol) dissolved in chloroform (15 mL) were added to 2,4-dichlorophenoxyacetic chloride (2.14 g, 0.009 mol). The reaction mixture was stirred at reflux temperature for about 3 h and monitored by TLC. After cooling to room temperature, the reaction mixture was filtered, and dichloromethane (20 mL) was added and washed with 1 M HCl (10 mL) and water (2 × 20 mL). The organic extracts were dried with anhydrous sodium sulfate and then evaporated in vacuo. The solid residue was purified by column chromatography by petroleum ether and ethyl acetate to give clear colorless crystals (yield = 46%): mp 161−163 °C. ^{1}H NMR (400 MHz, DMSO-d_6) δ 8.35, 8.31 (2H, s, $CF_3C_6H_2Cl_2$), 7.57 (1H, d, *J* = 2.0 Hz, 3-$C_6H_3Cl_2$), 7.34 (1H, dd, *J* = 2.0, 8.0 Hz, 5-$C_6H_3Cl_2$), 6.91 (1H, d, *J* = 8.0 Hz, 6-$C_6H_3Cl_2$), 4.90, 4.85 (2H, d, *J* = 16.0 Hz, CH_2); ESI-MS, *m/z* (%) 638 (100) $[M + H]^+$, 641 $[M + H + 2]^+$, 643 $[M + H + 4]^+$.

*N-(3-Cyano-1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-4-((trifluoromethyl)sulfinyl)-1H-pyrazol-5-yl)-2-(2,4,5-trichlorophenoxy) Acetamide (**2b**).* Compound **2b** was synthesized according to the same method as used for **2a**. Compound **2b** was colorless crystals (yield = 34%): mp 147−149 °C. ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.63 (1H, s, NH), 8.40, 8.36 (2H, s, $CF_3C_6H_2Cl_2$), 7.84, 7.25 (2H, s, 6,3-$C_6H_2Cl_3$), 4.98 (2H, s, CH_2); ESI-MS, *m/z* (%) 672 (100) $[M + H]^+$, 675 $[M + H + 2]^+$.

*N-((3-Cyano-1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-4-((trifluoromethyl)sulfinyl)-1H-pyrazol-5-yl)carbamoyl)-2-(2,4-dichlorophenoxy) Acetamide (**2c**).* 2-(2,4-Dichlorophenoxy) acetamide and 2-(2,4-dichlorophenoxy) acetyl isocyanate was synthesized according to a method from the literature.[30] 2-(2,4-Dichlorophenoxy) acetyl isocyanate (2.5 g, 0.01 mol) was dissolved in anhydrous diethyl ether (50 mL), to which fipronil (4.4 g, 0.01 mol) dissolved in anhydrous diethyl ether (20 mL) was added below 0 °C, stirred at room temperature, and monitored by TLC. The reaction mixture was filtered and the filtrate evaporated in vacuo. The solid residue was purified by chromatography and eluted with petroleum ether/ethyl acetate to give colorless crystals (yield = 57%): mp 142−144 °C. 1H NMR (400 MHz, $CDCl_3$) δ 10.96, 8.94 (2H, s, 2NH), 7.86−7.83 (2H, s, $CF_3C_6H_2Cl_2$), 7.46 (1H, d, *J* = 2.2 Hz, 3-$C_6H_3Cl_2$), 7.27 (1H, dd, *J* = 2.2, 8.0 Hz, 5-$C_6H_3Cl_2$), 6.85 (1H, d, *J* = 8.0 Hz, 6-$C_6H_3Cl_2$), 4.64 (2H, s, CH_2); ESI-MS, *m/z* (%) 685 $[M + H + 4]^+$ (50), 684 $[M + H + 2]^+$ (100), 681 $[M + H]^+$ (80).

*N-((3-Cyano-1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-4-((trifluoromethyl)sulfinyl)-1H-pyrazol-5-yl)carbamoyl)-2-(2,4,5- trichlorophenoxy) Acetamide (**2d**).* Compound **2d** was synthesized according to the same method as used for **2c**. Compound **2d** was colorless crystals (yield = 37%): mp 101−103 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ 10.87, 8.85 (2H, s, 2NH), 7.81, 7.78 (2H, s, $CF_3C_6H_2Cl_2$), 7.51 (1H, s, 6-$C_6H_2Cl_3$), 6.97 (1H, s, 3-$C_6H_2Cl_3$), 4.60 (2H, s, CH_2); ESI-MS, *m/z* (%) 717 $[M + H + 2]^+$ (100), 715 $[M + H]^+$ (60).

Bioactivity Assay against *Plutella xylostella*. *Rearing Methods for P. xylostella.* Healthy larvae of *P. xylostella* were collected from the experimental farm of Dongguan Agricultural Science Research Center, Guangdong, China, and were reared on Chinese cabbage (*Brassica rapa*) under cage conditions of 24−29 °C, 70−80% relative humidity, and photoperiod 16:8 h light/dark for the third-instar larvae.

Assessment of Bioactivity on P. xylostella. The bioactivities of phenyl pyrazole derivatives and fipronil against the third-instar larvae of *P. xylostella* were determined by the leaf disk-dipping assay. Leaves of Chinese cabbage grown in the greenhouse were collected, and disks (5.5 cm diameter) were punched from each leaf. The compounds were dissolved in acetone and suspended in distilled water containing Triton X-100. Leaf disks were dipped in each test solution for 30 s and allowed to dry for 2 h. The treated leaf disks were placed into Petri

[a]Reagents and conditions: (a) $SOCl_2$; (b) fipronil, triethylamine, DMAP, $CHCl_3$; (c) $NH_3{\cdot}H_2O$; (d) $(COCl)_2$, 1,2-dichloroethane; (e) fipronil, anhydrous diethyl ether.

dishes (9 cm diameter). Then, 10 *P. xylostella* larvae were introduced into each dish. Distilled water containing an acetone−Triton X-100 solution but not the test compound was used as the control. Petri dishes were kept in an incubator at 26 °C and 85% relative humidity under a photoperiod of 16:8 h light/dark. All treatments were replicated five times. Mortalities were determined 24 h after treatment. The death rate of each treatment group was confirmed. The LC_{50} value was calculated by the SPSS software.

Docking Study. The *Musca domestica* GABA receptor subunit sequence was obtained from the NCBI database (GenBank AAC23602.1). The sequence and structure of the nicotinic acetylcholine receptor (nAChR) were obtained from the RSCB protein data bank at 4 Å resolutions (PDB ID 2BG9). The amino acid sequence of the subunit was edited to remove the extracellular region and residues in the loop between transmembrane (TM) domains 3 and 4 (TM3−TM4 loop). Using the sequence analysis program above, sequence alignment was carried out. The sequence and structure of the nicotinic

dx.doi.org/10.1021/jf405512e | J. Agric. Food Chem. 2014, 62, 3577−3583

acetylcholine receptor (nAChR) were obtained from the RSCB protein data bank at 4 Å resolutions (PDB ID 3C79). The models of the transmembrane region of the GABA receptor subunit were built by homology modeling using the MODELER program with the default parameters. In the model building, we employed an optimization method involving conjugate gradients and molecular dynamics to minimize violations of the spatial restraints. All molecule modeling was done using Discovery Studio 2.5 on SGI workstation. The initial structures of these compounds were built and energetically minimized. To investigate how the insecticide anchored at the putative binding cavity, fipronil and phenyl pyrazole inner salts were docked into the ion channel pore formed by the second transmembrane segments of the homooligomeric receptor. Binding site interactions of compounds and AChBP are simulated with *Aplysia californica* AChBP on the basis of its structure cocrystallized with bound IMI (Protein Data Bank code 3C79). The A−E subunit interface of the AChBP−IMI complex is arbitrarily used for modeling because the homomeric AChBP pentamer has five identical binding pockets localized at subunit interfacial regions. The compound is docked into the ligand-binding pocket of IMI. All molecule dockings were done using the CDOCK program with the default parameters. The docking complexes were solvated in the water layer in a truncated octahedral periodic box. Then, the complexes were minimized using the molecular dynamics simulation.

RESULTS AND DISCUSSION

Synthesis. The synthesis of compounds **1a−1g** and **2a−2d** was outlined in Schemes 1 and 2. Fipronil was reacted with bromoacetyl bromide in the presence of sodium hydride to afford the key intermediate **1**. Compounds **1a−1g** were obtained via the reaction of intermediate **1** and tertiary amine or nitrogen heterocyclic compounds in the presence of tetrahydrofuran. Compounds **2a−2d** were obtained by using the classical methodology.

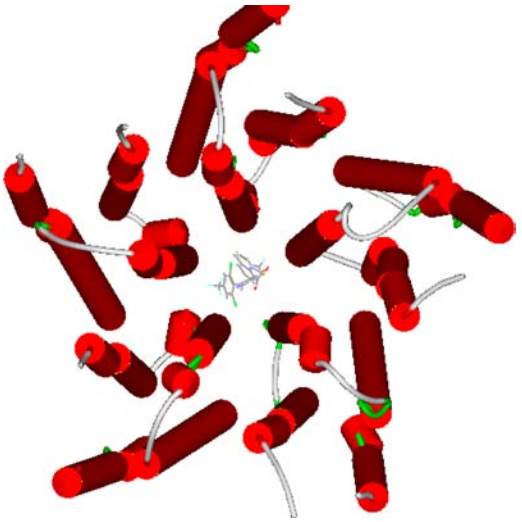

Figure 2. Model of compound **1d** in the $GABA_A$ receptor $\beta 3$ homopentamer binding site. It shows a model of the ion channel with five helices and compounds docked into the putative binding site, which it clearly fills to block the pore. Compounds interact with resides of TM2 and contact A2, T6, and L9 coinciding with mutation experiments.

Figure 3. Simulated binding site interactions of compound **1d** with the *Aplysia californica* AChBP structural surrogate of the extracellular domain of the nAChR. The structure of *Aplysia californica* AChBP cocrystallized with bound IMI (Protein Data Bank code 3C79) shows the binding site of IMI was located in the interface of the AChBP subunit. Simulated docking shows docking compounds in the same site formed $\pi-\pi$ stacking interactions and hydrogen bonding.

SAR. The preliminary insecticidal activities of compounds **1a−1g** and **2a−2d** were assessed by the leaf disk-dipping assay, and the results are listed in Table 1. Due to the low insecticidal activities of **2a−2d**, the SAR study does not include the compounds **2a−2d**.

For the alkyl quaternary ammonium **1a−1c**, the activities decreased from 15.10 $\mu g\ mL^{-1}$ (LC_{50} value, 24 h) to 24.69 $\mu g\ mL^{-1}$ (LC_{50} value, 24 h) against *P. xylostella*, respectively, whereas the bulk of R^1, R^2, and R^3 increased. The activity of compound **1a**, 15.10 $\mu g\ mL^{-1}$ (24 h LC_{50} value), was better than that of fipronil, 24.93 $\mu g\ mL^{-1}$ (24 h LC_{50} value), against *P. xylostella*, indicating that the steric hindrance of $NR^1R^2R^3$ is unfavorable for the insecticidal activity of the phenyl pyrazole inner salts.

dx.doi.org/10.1021/jf405512e | J. Agric. Food Chem. 2014, 62, 3577−3583

Compounds **1d**−**1g** are heterocyclic quaternary ammoniums. It is clear that the insecticidal activity obviously increased when the ring of $NR^1R^2R^3$ was enlarged. For instance, compounds **1d** (10-member bicyclic aromatic ring, 8.31 μg mL^{-1}, 24 h LC_{50} value) and **1e** (6-member ring, 12.85 μg mL^{-1}, 24 h LC_{50} value) have better activity than fipronil (24.93 μg mL^{-1}, 24 h LC_{50} value) against *P. xylostella*. This result is opposite to traditional agonists, as the increase of the bulk of R^1, R^2, and R^3 weakens the activity significantly.[31] This may confirm the effect of the unique heterocyclic quaternary ammonium conformation, possibly due to the influence of the size of cycle on the conformation. Therefore, an appropriate conformation is critical for the interaction between cationic nitrogen and receptor.

With the pyridine group considered to be the key pharmacophore in **1e**, compounds **1f** and **1g** were synthesized. The bioassay data on compounds **1e**, **1f**, and **1g** revealed that a large substituent at the 4-position of the 6-member $NR^1R^2R^3$ ring is not preferred. A substitution at the 4-position of the 6-member $NR^1R^2R^3$ ring is unfavorable for the insecticidal activity, and steric hindrance may weaken the activity. The bioactivity of compound **1f** ($NR^1R^2R^3$ = *N*,*N*-dimethylpyridin-4-amine) was similar to that of fipronil, but **1g** ($NR^1R^2R^3$ = 4-methylpyridine) was more active than fipronil with an insecticidal activity of 18.55 μg mL^{-1} (24 h LC_{50} value). These results suggested that the substituent at the 4-position of the 6-member $NR^1R^2R^3$ ring might bind to the receptor as an H-bond acceptor.

Furthermore, the influence of the substituted groups of the 4-pyridine ring on insecticidal activity was explored. As compared to compound **1e** (12.85 μg mL^{-1}, 24 h LC_{50} value) without any substituted group, the electron-donating group (**1f**, 4-$N(CH_3)_2$, 24.71 μg mL^{-1}, 24 h LC_{50} value, and **1g**, 4-CH_3, 18.55 μg mL^{-1}, 24 h LC_{50} value) at the 4-position was unfavorable for insecticidal activity.

Because of the special conformation of the heterocyclic quaternary ammonium structure, substitution at the 4-position of the pyridine ring was unfavorable for cooperative $\pi-\pi$ interaction.[32] This may confirm the effect of the special heterocyclic quaternary ammonium conformation.

On the contrary, **1e** with pyridine for $NR^1R^2R^3$ exhibited excellent insecticidal activity (12.85 μg mL^{-1}, 24 h LC_{50} value) and may have a special conformation to bind to receptors. Inspired by this result, we introduced quinoline to the fipronil molecule and obtained **1d** with a rather good insecticidal activity (**1d**, 8.31 μg mL^{-1}, 24 h LC_{50} value). The insecticidal potency of **1d** and **1e** indicated that a quinoline or pyridine ring at a proper position of $NR^1R^2R^3$ was preferred, which might contribute to affinity with a suitable conformation and/or hydrogen bonding and cooperative $\pi-\pi$ interaction.[33]

Docking Study. To clarify the binding mode of our synthesized phenyl pyrazole inner salts, compounds were docked in the active site of the $GABA_A$ receptor recombinant β3 homopentamer and the crystal structures of the acetylcholine binding protein (AChBP) (Figure 2).[34] The fipronil-related phenyl heterocyclic compounds were effective as noncompetitive antagonists to the housefly GABA receptor. Several observations suggest that the noncompetitive antagonists interact with the same position of the M2 transmembrane segment region on the cytoplasmic side [A]. As a channel blocker, the fipronil-related noncompetitive antagonists interact with the ion channel associated with the β3-homopentamer.

The structure of *A. californica* AChBP cocrystallized with bound IMI (Protein Data Bank code 3C79) shows the binding site of IMI was located in the interface of the AChBP subunit. Simulated docking shows docking compounds into the same site formed $\pi-\pi$ stacking interactions and hydrogen bonding (Figure 3).[35] The interaction was not the same with IMI.

In summary, by selecting phenyl pyrazole inner salts of fipronil derivatives as the lead compounds, a series of phenyl pyrazole inner salts were designed and synthesized to search for a new dual-target insecticide with low side effects. Extensive SAR studies revealed that a suitable $NR^1R^2R^3$ was critical for the insecticidal activity, which might be beneficial to expose the cationic nitrogen to bind to the receptor and possibly interact with the receptor via hydrogen bonding and cooperative $\pi-\pi$ interaction. More importantly, compound **1d**, a new type of quinoline quaternary ammonium salt, showed potent insecticidal activity, which would be very valuable for the further development of dual-target insecticides. The action mechanism of dual-target phenyl pyrazole inner salts deserves further study.

Fungal Material. The endophytic fungal strain KJ-1 was isolated from the symptomless tissue of stem bark of *M. azedarach* L., which was collected at Yangling, Shaanxi province, China, in August 2011. The species was identified on the basis of the phylogenetic taxonomy with sequence alignment of ITS and had a genetic closeness of 100% to the *B. dothidea* strain. This strain was defined as *B. dothidea* KJ-1 and was deposited at the College of Science, Northwest A&F University, China.

Fermentation and Cultivation. The producing strain was cultured on a plate of potato dextrose agar (PDA) medium at 28 ± 0.5 °C for 5 days. Then one piece (approximately 7 mm^2) of mycelium was inoculated aseptically to 50 mL Erlenmeyer flasks each containing 20 mL of PD liquid medium, and the seed liquids were incubated at 28 ± 0.5 °C for 3 days on a rotary shaker at 120 rpm. A suspension (100 μL) of the seed liquid was inoculated aseptically to 500 mL Erlenmeyer flasks each containing 60 g of rice and 90 mL of distilled water. There were 300 flasks in total, and the flask cultures were incubated at 28 ± 0.5 °C for 4 weeks.

Extraction and Isolation. Strain cultures were ultrasonically extracted three times with methanol (MeOH). The solvent was removed and dried under vacuum to yield a crude extract. The extract was dissolved in 90% MeOH/H_2O (4 L) and further extracted three times with petroleum ether, and the remaining layer was adjusted to 50% aqueous methanol and extracted by chloroform. The chloroform extract (60 g) was separated by silica gel CC with $CHCl_3$/MeOH (100:0 to 0:100) to provide four fractions.

Fraction 1 ($CHCl_3$) was separated by PTLC and repeated CC on silica gel, Sephadex LH-20, to yield compounds **4** (25 mg), **14** (6.5 mg), and **18** (85 mg). Fraction 2 ($CHCl_3$/MeOH = 50:1) was separated by repeated CC on silica gel, Sephadex LH-20, followed by purification with PTLC to yield compounds **5** (13 mg), **6** (12 mg), **10** (8.5 mg), **11** (9.5 mg), and **16** (2.5 mg). Fraction 3 ($CHCl_3$/MeOH = 20:1) was chromatographed over repeated CC on MCI gel, silica gel, Sephadex LH-20, and RP-C_{18} to yield compounds **1** (8 mg), **2** (9 mg), **3** (9 mg), **12** (90 mg), **13** (2.5 mg), and **17** (5 mg). Fraction 4 ($CHCl_3$/MeOH = 5:1) was separated by repeated CC on silica gel, Sephadex LH-20, and RP-C_{18} to yield compounds **7** (13 mg), **8** (13 mg), **9** (38 mg), and **15** (40 mg).

3-Hydroxy-2-methoxy-5-methylpyridin-2(1*H*)-one (1). Light orange crystal (MeOH); mp 272.5−273.1 °C; UV (MeOH) λ_{max} (log ε) = 207 (2.30), 285 nm (0.60); IR (KBr) ν_{max} = 3442, 3017, 2927, 1630, 1571, 1461, 1221 cm^{-1}; ^1H and ^{13}C NMR data are shown in Table 1; ESI-MS *m/z* 156.0 $[M + H]^+$; HR-ESI-MS *m/z* 156.0647 ($[M + H]^+$, $C_7H_{10}NO_3^+$; calcd 156.0655).

3-Hydroxy-*N*-(1-hydroxy-3-methylpentan-2-yl)-5-oxohexanamide (2). Colorless solid; $[\alpha]_D^{23}$ −6.33 (*c* 0.14, $CHCl_3$); IR (KBr) ν_{max} = 3373, 3315, 1695, 1651, 1558, 1360, 1281 cm^{-1}; ^1H and ^{13}C NMR data, see Table 1; ESI-MS *m/z* 245.81 $[M + H]^+$; HR-ESI-MS *m/z* 268.1507 ($[M + Na]^+$, $C_{12}H_{23}NaNO_4^+$; calcd 268.1519).

3-Hydroxy-*N*-(1-hydroxy-4-methylpentan-2-yl)-5-oxohexanamide (3). Colorless solid; $[\alpha]_D^{23}$ −4.51 (*c* 0.12, $CHCl_3$); IR (KBr) ν_{max} = 3325, 3278, 1707, 1657, 1575 cm^{-1}; ^1H and ^{13}C NMR data, see Table 1; ESI-MS *m/z* 267.98 $[M + Na]^+$; HR-ESI-MS *m/z* 268.1506 ($[M + Na]^+$, $C_{12}H_{23}NaNO_4^+$; calcd 268.1519).

Antifungal Bioassay. Metabolites were tested in vitro for the antifungal activity against four different phytopathogenic fungi: *Colletotrichum gloeosporiodes*, *Gibberella saubinetti*, *Botrytis cinerea*, and *Alternaria solani*. All of these phytopathogenic fungi tested were provided by the College of Plant Protection, Northwest A&F University, and were deposited at the College of Science, Northwest A&F University, China.

Antifungal activity was assessed by the microbroth dilution method in 96-well flat-microtiter plates using a potato dextrose (PD) medium.[12] Compounds were made up to 4 mM in DMSO. Two commercial fungicides, carbendazim and hymexazol (Aladdin Chemistry Co. Ltd.), together with toosendanin, the efficient pesticide from *M. azedarach* L., were used as positive controls. The solution of equal concentration of DMSO was used as a negative control. The fungi were incubated in the PD medium for 18−36 h at 28 ± 0.5 °C at 150 rpm, and spore concentrations of different microorganism were diluted to approximately 1 × 10^6 colony-forming units/mL (CFU/mL) with PD medium. In flat microtiter plates, tested compounds, fungal suspension, and sterile water were added to make up final concentrations of the compounds in the range of 1.57−200 μM. Each measurement consisted of three replicates. Cultures then grew in the dark at 28 ± 0.5 °C for 48 h. Minimum inhibitory concentrations (MICs) were inspected as the lowest concentrations in which no fungal growth could be observed.

Antibacterial Bioassay. Metabolites were tested in vitro for the antibacterial activity against four pathogenetic bacteria: *Escherichia coli*, *Bacillus subtilis*, *Staphyloccocus aureus*, and *Bacillus cereus*. All of these tested pathogenetic bacteria were deposited at the College of Science, Northwest A&F University, China.

Antibacterial activity was assessed by the microbroth dilution method in 96-well flat microtiter plates using a beef protein liquid (BP) medium.[12] Antibacterial activity was assessed according to the same procedure as antifungal bioassay. Streptomycin sulfate, ampicillin, and toosendanin were used as positive controls, and the solution of equal concentration of DMSO was used as a negative control. Cultures were grown for 24 h at 37 ± 0.5 °C in the dark without shaking, in a moist chamber.

1,1-Diphenyl-2-picrylhydrazyl (DPPH) Radical Scavenging Assay. A previously described method[13] was used to evaluate the radical scavenging capability of metabolites using DPPH. The reaction mixture (total volume = 4 mL), consisting of 1 mL of 0.2 mM DPPH in methanol and 3 mL of sample solution in methanol, was shaken vigorously and left to stand for 30 min in the dark; each measurement consisted of three replicates, and the absorbance was then measured at 517 nm. Tertiary butylhydroquinone (TBHQ) and vitamin C (V_C) were used as positive controls. Lower absorbance of the reaction mixture indicated higher free radical scavenging activity. The DPPH radical concentration was calculated using the equation

$$\text{DPPH scavenging effect (\%)} = (1 - A_1/A_0) \times 100\%$$

where A_0 and A_1 are the 517 nm absorption of the control and the absorption of the sample reaction mixture, respectively.

Brine Shrimp Bioassay. Metabolites were tested in vitro for the brine shrimp (*Artemia salina*) bioassay, processed according to the previously identified method.[12] The final concentrations of the tested compounds were 10, 50, and 100 μM. Toosendanin was used as the positive control, and DMSO as the negative control. The lethality of each concentration was recorded.

Cytotoxic Assay. In vitro cytotoxicity was assessed by using the SRB colorimetric assay.[14] Briefly, 100 μL of HCT116 cells containing 2.5 × 10^4 cells/mL was added to each well of the 96-well flat microtiter plates and allowed to attach for 24 h. Then the medium was replaced by fresh medium, and cells were incubated with various amounts of the test compounds. After incubation for an additional 72 h at 37 °C, sulforhodamine B solution 0.4% (w/v) in 1% acetic solution was added to each well, and then bound sulforhodamine B was subsequently solubilized with 10 mM Tris base (pH 10.0), and the absorbance was read at 560 nm using an Epoch microplate reader. Each measurement consisted of three replicates. The percentage of cell viability was calculated relative to control wells designated as 100% viable cells. The IC_{50} values were measured by sigmoidal fit using Origin 7.5 software.

X-ray Single-Crystal Diffraction. Crystals of compound **1** were grown in methanol at room temperature. Crystallographic data for **1** were collected on a SuperNova Eos diffractometer with graphite monochromatic Cu Kα radiation at 298(2) K. All calculations were performed using the SHELXL-97 program.[15] Crystallographic data and experimental details for structure are listed in Table S1 in the Supporting Information. Parameters in CIF format are available as Electronic Supplementary Publication from Cambridge Crystallographic Data Centre (CCDC978829). These data can be obtained from http://www.ccdc.cam.ac.uk/conts/retrieving.html.

RESULTS AND DISCUSSION

Structure Elucidation. Compound **1** was obtained as a light orange crystal, and its molecular formula was assigned as $C_7H_9NO_3$ on the basis of the pseudomolecular ion at *m/z* 156.0647 $[M + H]^+$ in HR-ESI-MS, requiring four degrees of unsaturation. The IR spectrum showed absorption for hydroxyl group and/or amide proton (3442 cm^{-1}) and a conjugated amide carbonyl group (1630 cm^{-1}). A strong UV absorption appeared at 285 nm, indicating that **1** contained a chromophoric moiety. The ^1H NMR spectra of **1** (Table 1) displayed the presence of one methyl (δ 2.21, s), one methoxyl (δ 4.02, s), and one double-bond proton (δ 6.05, s). The ^{13}C NMR and DEPT spectra of **1** (Table 1) revealed seven carbon signals, including one methyl (δ 19.0 q), one methoxyl (δ 59.7 q), one olefinic methine (δ 100.5 d), and four sp^2 quaternary carbons (including one oxygenated olefin at δ 159.2 and 132.0 (two oxygenated olefinic carbons), a trisubstituted olefin carbon (δ 141.0 s), and an amide carbonyl (δ 162.7 s)). The assignment of all ^1H and ^{13}C NMR signals for **1** was achieved by analysis of HSQC and HMBC spectral data. In the HMBC spectrum of **1**, correlations of H-4 (δ 6.05) with C-2, C-3, C-5, and C-6, H_3-6 with C-4, C-5, and H_3-7 to C-2 indicated locations of the methyl at C-5 (δ 141.0) and the methoxy group at C-2 (δ 132.0) in the molecule. This evidence suggests the existence of one 2-methoxy-3-hydroxypenta-2,4-diene moiety. Considering the molecular formula of **1**, the remaining carbonyl and secondary amino NH groups should form an amide −CONH− unit that was attached to C-2 and C-5, respectively. However, no correlations from NH to C-1, C-2, C-5, and C-6 in the HMBC spectrum were observed. From the above-mentioned data, the planar structure of **1** was deduced as shown in Figure 2a. X-ray single-crystal diffraction of **1** with Cu

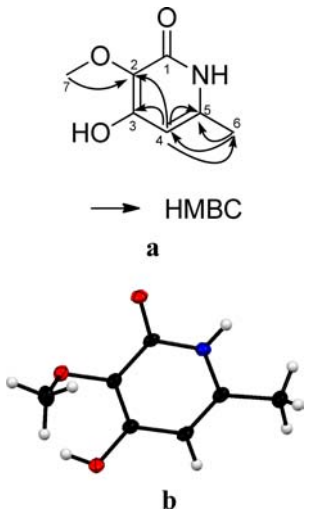

Figure 2. Key HMBC (**2a**) and ORTEP diagram (**2b**) of **1**.

Kα radiation confirmed the proposed structure (Figure 2b; for further details see Table S1 in the Supporting Information). Thus, the structure of **1** was elucidated as 3-hydroxy-2-methoxy-5-methylpyridin-2(1*H*)-one.

Compound **2** was obtained as a colorless solid and analyzed for the molecular formula $C_{12}H_{23}NO_4$ by HR-ESI-MS (*m/z* 268.1507 $[M + Na]^+$), requiring two degrees of unsaturation. The ^1H NMR and ^{13}C NMR spectra of **2** (Table 1) showed two aliphatic methyl doublets [δ_H 0.88 (3H, d, *J* = 7.4 Hz), 0.91 (3H, d, *J* = 6.9 Hz); δ_C 11.3 (q), 15.5 (q)], one methyl singlet [δ_H 2.19 (3H, s); δ_C 30.8 (q)], four aliphatic methylenes [δ_H 1.13 (1H, m, H-4′b), 1.48 (1H, m, H-4′a), 2.36 (1H, dd, *J* = 14.9, 7.7 Hz, H-2b), 2.45 (1H, dd, *J* = 14.9, 3.7, H-2a), 2.67 (1H, dd, *J* = 17.5, 4.3 Hz, H-4b), 2.73 (1H, dd, *J* = 17.5, 8.1 Hz, H-4a), 3.59 (1H, dd, *J* = 11.2, 6.8 Hz, H-1′b), 3.71 (1H, dd, *J* = 11.1, 3.3 Hz, H-1′a); δ_C 25.5 (t), 42.3 (t), 49.1 (t), 63.5 (t)], three aliphatic methines [δ_H 1.60 (1H, m), 3.81 (1H, m), 4.39 (1H, m); δ_C 35.7 (d), 56.0 (d), 65.0 (d)], two hydroxyls [δ_H 3.20, 4.25 (1H each, s)], one amide proton [δ_H 6.52 (1H, d, *J* = 8.5 Hz)], and two carbonyl carbons including an amide carbonyl one (δ_C 172.1) and a ketone carbonyl carbon (δ_C 209.3). The above evidence suggests that this compound is a short-chain fatty amide derivative. The correlations observed in the $^1H-^1H$ COSY and HSQC spectra of **2** indicate the presence of the following distinct spin systems: $HOCH_2-CH(NH)-CH(CH_3)-CH_2CH_3$ (C-1′ to C-5′), and $-CH_2CH(OH)CH_2-$ (C-4 to C-2). These data and HMBC correlations of NH/C-1, -2′, -3′, H-1′a/C-2′, -3′, H-2′/C-1, -1′, -3′, -4′, -6′, H-3′/C-4′, H-4′b/C-2′, -3′, -5′, -6′, H-6′/C-2′, -3′, -4′, H-2/C-1, -3, -4, H-4/C-2, -3, -5, and H-6/C-4 revealed a fatty amide of an isoleucinol and locations of a hydroxyl at C-3 and one ketone carbonyl group at C-5, as shown in Figure 3.

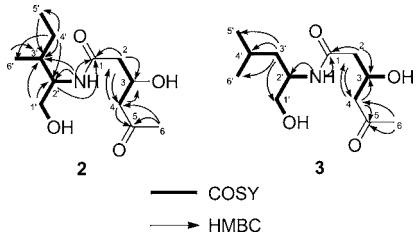

Figure 3. Key HMBC and $^1H-^1H$ COSY correlations of **2** and **3**.

These findings also confirmed the presence of an acyl residue, namely, 3-hydroxy-5-oxohexanoyl group ($CH_3COCH_2CH(OH)CH_2CO-$). Thus, the structure of **2** was determined to be 3-hydroxy-*N*-(1-hydroxy-3-methylpentan-2-yl)-5-oxohexanamide.

Compound **3** was obtained as a colorless solid. Its molecular formula was assigned as $C_{12}H_{23}NO_4$ on the basis of the molecular ion at *m/z* 268.1506 $[M + Na]^+$ in the HR-ESI-MS. Comparison of its ^1H and ^{13}C NMR spectra (Table 1) with those of **2** suggests that compound **3** had the same framework as **2**. A significant difference was that the aliphatic C-6′ methyl should be placed at C-4′ (δ_C 24.9 d) in **3** rather than at C-3′ (δ_C 35.7 d) as in **2**. The structure of **3** was further confirmed by analysis of $^1H-^1H$ COSY correlations of NH/H-2′, H-2′/H-1′, -3′, H-1′/1′-OH, H-4′/H-3′, -5′, -6′, H-3/H-2, 3-OH, -4, and the HMBC correlations of NH/C-1, -2′, H-3′/C-2′, -4′, -5′, -6′, H-4′/C-3′, -5′, -6′, H-2/C-1, -3, -4, H-4/C-2, -3, -5, H-6/C-4, -5 (Figure 3). Thus, the structure of **3** was elucidated as 3-hydroxy-*N*-(1-hydroxy-4-methylpentan-2-yl)-5-oxohexanamide, which possesses a leucinol unit. Although it can be searched in SciFinder, it is a new natural product, and this is the first report of its spectral data. Compounds **2** and **3** belong to a group of ceramides. Absolute stereochemistries of **2** and **3** remain undetermined due to limited amounts.

The structures of 15 known compounds were identified as pycnophorin (**4**),[16] stemphyperylenol (**5**),[17] altenuene (**6**),[18] chaetoglobosin C (**7**),[19,20] chaetoglobosin F (**8**),[20] altenusin (**9**),[21] djalonensone (**10**),[22] alternariol (**11**),[23,24] 5′-methoxy-6-methylbiphenyl-3,4,3′-triol (**12**),[14] 7-hydroxy-1-isochromanone

(**13**),[25] ergosterol peroxide (**14**),[26] β-sitosterol glucoside (**15**),[27] 5-(hydroxymethyl)-1*H*-pyrrole-2-carbaldehyde (**16**),[28] 5-hydroxymethylfurfural (**17**),[29] and cerebroside C (**18**)[30] by comparison of their spectroscopic data with those reported in the literature, including UV, IR, NMR, and MS data. To our knowledge, this is the first report of the isolation of these compounds from *B. dothidea* as endophytic fungus.

Interestingly, perylenequinone derivatives, for example, stemphyperylenol (**5**), have been previously reported from the genera *Alternaria*, *Stemphylium*, and *Talaromyces*.[31−34] Altenuene derivatives, for example, altenuene (**6**), have been reported from the genera *Alternaria*,[35−37] *Ulocladium*,[14] *Nigrospora*, and *Phialophora*.[38] In addition, alternariol analogues (**10** and **11**) have been previously reported from several genera of microorganisms,[36−43] especially from the common fungal genus *Alternaria*.[35] Chaetoglobosins (**7** and **8**) are a family of cytochalasans with a wide range of biological activities targeting cytoskeletal processes, which have been produced by several genera of microorganisms, especially by the common fungal genus *Chaetomium*.[44,45] According to previous investigations, alternariol and alternariol monomethyl ether were reported to have antimicrobial, cytotoxic, and antitumor activities,[35,36] and alternariol (**11**) showed antiviral effects against herpes simplex virus in vitro.[38] Some perylenequinone derivatives are phytotoxins and mutagenic.[46,47]

Antimicrobial Assays. Metabolites **1**−**18** were tested in vitro for antifungal activity against four phytopathogenic fungi: *Colletotrichum gloeosporiodes*, *Gibberella saubinetti*, *Botrytis cinerea*, and *Alternaria solani*. None of the tested compounds displayed any obvious antifungal activities against *C. gloeosporiodes* and *G. saubinetti* (Supporting Information Table S2). Compounds **4**, **5**, **7**, **10**, **11**, **15**, and **17** showed strong to moderate antifungal activities against *A. solani* (MICs of 1.57−25 μM) and did not have effects against *B. cinerea* (Table 2).

Table 2. Inhibitory Effects of Compounds 1−18 on Phytopathogenic Fungi[a]

	phytopathogenic fungi[a] (MIC, μM)	
compd	*B. cinerea*	*A. solani*
4	100	6.25
5	100	1.57
7	200	12.5
10	25	25
11	NA	12.5
12	NA	50
15	100	6.25
16	100	50
17	50	6.25
carbendazim	12.5	1.57
hymexazol	200	6.25
toosendanin	200	6.25

[a]NA, inactive. Compounds with no antifungal activity are not shown in the table.

Methylation of 5-OH in alternariol (**11**) resulted in diminished activity (MIC of 25 μM for djalonensone (**10**) vs MIC of 12.5 μM for **11**) to *A. solani*. Of these compounds, stemphyperylenol (**5**), with the lowest MIC value of 1.57 μM, had the best inhibition, which is comparable to that of the positive control, carbendazim (MIC of 1.57 μM), or better than those of hymexazol and toosendanin (MICs of 6.25 μM), indicating that it could be used as a fungicide or as a lead compound of new fungicides to *A. solani*. Compound **10** also displayed moderate antifungal activities against *B. cinerea* (MIC of 25 μM).

Compounds **1**−**18** were tested in vitro for their antibacterial activity against pathogenetic bacteria *Escherichia coli*, *Bacillus subtilis*, *Staphyloccocus aureus*, and *Bacillus cereus*, and the results are listed in Table S3 in the Supporting Information. The results showed that compound **4** mildly inhibited the growth of *B. subtilis* and *S. aureus* with both having MICs of 25 μM; the effects are much weaker than those of two positive controls, ampicillin and streptomycin sulfate, whereas the other compounds had weak activity (MICs of >50 μM).

DPPH Radical Scavenging Assay. Both compounds **9** and **12** showed marked DPPH radical scavenging activities with IC_{50} values of 17.6 ± 0.23 and 18.7 ± 0.18 μM, respectively, which are weaker than those of the positive controls TBHQ and Vc (IC_{50} of 10 μM). These results are in agreement with those reported by Wang et al.[14] Compounds **1** and **4** were found to be weak DPPH scavengers at concentrations of 50 μM, with scavenging rates of 22.5 and 30.9%, respectively, and the remaining metabolites showed no activity. From a comparison of the structures of compounds **6**, **10**, and **11** to compounds **9** and **12**, it can be found that opening of the middle ring can result in enhanced DPPH scavenging capacity.

Brine Shrimp Bioassay. Brine shrimp can be used as a convenient bioassay model for insecticidal activity.[48] Compounds **1**−**18** were evaluated for insecticidal activity, and brine shrimp lethality is shown in Table S4 in the Supporting Information. Among the compounds tested, compound **4** was found to show the best activity with lethality of 43.8% at a concentration of 100 μM, whereas the other compounds were inactive.

Cytotoxicity Bioassay. Compounds **1**−**18** were also evaluated in vitro against cancer cell line HCT116 by the sulforhodamine B (SRB) colorimetric assay, and the results are summarized in Table 3. Among them, compounds **5** and **6** exhibited the strongest cytotoxicity against HCT116 with an IC_{50} value of 3.13 μM, which is comparable to that of the positive control etoposide (IC_{50} of 2.13 μM), whereas compounds **4**, **8**, **9**, and **11** exhibited moderate activity (IC_{50} of 10−40 μM), and the remaining compounds were inactive (IC_{50} of >40 μM). These results indicate that compounds **5** and **6** could be promising lead compounds for the development of new antitumor drugs and need to be studied for their mechanisms of action.

Table 3. Cytotoxicity of Compounds 1−18 against Human Colorectal HCT 116 Cell Line[a]

compd	IC_{50}[a] (μM)	compd	IC_{50}[a] (μM)
1	>100	**11**	33.9
2	>100	**12**	73.4
3	>100	**13**	NA
4	21.4	**14**	72.3
5	3.13	**15**	NA
6	3.13	**16**	>100
7	>100	**17**	NA
8	26.5	**18**	NA
9	28.9		
10	NA	etoposide	2.13

[a]NA, inactive.

In recent years, many metabolites having plant protection have been identified from plant endophytes, such as ambuic

acid and phenazine-1-carboxylic acid.[49,50] In the present study, the secondary metabolites produced by the endophyte *B. dothidea* were found to have some antimicrobial and antioxidant activities. Stemphyperylenol (**5**) was found to display significant antifungal activity against *A. solani*. Altenusin (**9**) and 5′-methoxy-6-methylbiphenyl-3,4,3′-triol (**12**) showed marked DPPH radical scavenging activities. These bioactive metabolites in *B. dothidea* could protect the host plant against pathogenic attacks and oxidation stress in nature, which may play a defensive role.

of their conjugates were investigated in relation to their protein structures. Because heat treatment and gastric digestion can affect the allergenic character, the immunoreactivity of PTT conjugates was assessed after these two treatments.

MATERIALS AND METHODS

Materials. Potato protein Solanic 206P (PTT ≈ 75%, PIs ≈ 25%) was kindly provided by Solanic (Foxhol, Ne). Potato galactan and endo-1−4-β-D-galactanase from *Aspergillus niger* were purchased from Megazyme (Wicklow, Ir). Furosine standard was purchased from Neosystem Laboratories (Strasbourg, Fr). Biogel P2 extra fine, Bradford reagent, and broad range SDS−PAGE standards were purchased from Bio-Rad (Philadelphia, PA). Four potato-sensitive human sera (Table SI-1, Supporting Information) were acquired from PlasmaLab (Everett, WA) (8.75−22.40 kU_A/1 potato specific IgE, ImmunoCAP; Pharmacia, Uppsala). Sera from nonallergic (no specific IgE) and dust-mite allergic (>100.00 kU_A/1 dust-mite specific IgE) individuals as controls were also obtained from PlasmaLab. All other chemicals were purchased from Sigma Chemical Co. (St. Louis, MO).

Preparation of Conjugates. PTT and PIs present in Solanic 206P were separated by ultrafiltration using a stirred ultrafiltration unit (Amicon system, Millipore, Billerica, MA) fitted with a 30 kDa molecular mass cut-off membrane. The SDS−PAGE gels (Figure SI-2, Supporting Information) of the purified PTT and PIs were analyzed using AlphaView Software (Cell Biosciences, Santa Clara, CA). The retentate recovered upon ultrafiltration was composed of 90% PTT, while the filtrate consisted of 95% protease inhibitors. The retentate and the filtrate containing PTT and PI-enriched extracts were freeze-dried separately. GOS (MW of 1,990.9 g/mol) were prepared from potato galactan using endo-(1−4)-β-D-galactanase from *A. niger* as described previously.[25] PTT or PIs and each of the galactose or GOS or galactan at the molar ratio of 1:9 were dissolved in 0.1% (w/v) of 0.05 M sodium phosphate buffer (pH 7.0). Protein−carbohydrate mixtures were lyophilized and incubated in sealed glass desiccators at 48 °C for 1 to 3 days under a controlled a_w value of 0.65 equilibrated with a saturated solution of potassium iodide. Control experiments (control PTT and PIs) were performed with selected proteins incubated under the same conditions in the absence of carbohydrates.

Determination of Glycation Extent of Potato Proteins with Selected Carbohydrates. To determine the extent of glycation of PTT and PIs, the percent blocked lysine was estimated from the total free amino content and the acid-generated furosine content, according to a modified method of Seo et al.[25] The free amino groups of native PTT and PIs were determined using a trinitrobenzene sulfonic acid (TNBS) assay. Then, 0.25 mL of 0.01% (v/v) TNBS was added to 0.5 mL of native protein solutions (10 mg/mL) in 0.1 M sodium bicarbonate buffer (pH 8.5). After 2 h of incubation at 37 °C, 0.25 mL of 10% (w/v) sodium dodecyl sulfate (SDS) and 0.125 mL of 1 M HCl were added to the mixtures to solubilize the protein and to avoid their precipitation. The assays were run in triplicate, and the standard curve was constructed using L-leucine. To estimate the ϵ-*N*-2-(furoylmethyl)-L-lysine (furosine), 500 μL of the 20 mg/mL of protein sample in water was hydrolyzed with 200 μL of 8 M HCl for 23 h at 110 °C capped under nitrogen. The hydrolyzed sample was cooled to room temperature and centrifuged at 13,000*g* for 15 min. The supernatant (500 μL) was applied to a previously activated Sep-Pak C18 cartridge (Waters Corp, Milford, MA). Furosine was eluted with 3 M HCl and evaporated until dryness under nitrogen. The sample was resolubilized in 200 μL of a water/acetonitrile/formic acid mixture (95:4.5:0.5, v/v/v) and analyzed through high-pressure liquid chromatography (HPLC). A Waters Bioseparations module and a photodiode array detector equipped with Empower 2 software for data collection were used. A sample volume of 20 μL was separated using a Waters Symmetry Shield RP8 3.5 μm (4.6 × 50 mm) column using an isocratic elution of 5 mM octanesulfonic acid in water/acetonitrile/formic acid mixture (79.8:20:0.2, v/v/v) for 20 min at a flow rate of 0.3 mL/min. The detection of furosine was performed at 280 nm. The calibration curve was constructed using a furosine standard. All assays were run in triplicate and injected with and without the internal standard. No furosine was detected in the control samples, nonincubated mixtures of protein and carbohydrate. The final percentage of blocked lysine was indirectly estimated from the total free amino content and furosine content using the following equation, considering that the Amadori compound, tagatosyllysine, formed during the Maillard reaction, generates about 42% furosine upon 8 M HCl hydrolysis.[26]

$$\text{Percent blocked lysine} = (1/0.42 \times \text{furosine}) \times 100/\text{total lysine} \quad (1)$$

Purification of Patatin Conjugates. Native PTT, incubated control PTT, as well as PTT/galactose, PTT/GOS, and PTT/galactan conjugates were subjected to ultrafiltration using a stirred ultrafiltration unit (Amicon system, Millipore) fitted with a 30 kDa or 300 kDa molecular mass cutoff membrane to remove the smaller Maillard reaction species and the unreacted saccharides present in the mixture. The retentates were collected for further analyses.

Simulated Gastric Digestion. Native PTT, incubated control PTT, and PTT conjugates were subjected to simulated gastric digestion according to the modified method of Moreno et al.[27] Proteins and glycoproteins (1 mg/mL) were solubilized in simulated gastric fluid (0.75 M NaCl, pH 2.5). To initiate the enzymatic digestion, porcine pepsin (7 mg/mL, ≥ 2,500 units/mg protein) was then added at a ratio of 1:50 (v/v). After the digestion was performed at 37 °C for 2 h, the pH was raised to 7.5 with 0.125 M ammonium carbonate. To simulate the duodenal environment, the following solutions were added: (1) 10 μL of the following bile salt mixture (0.025 M sodium taurocholate, 0.025 M sodium glycodeoxycholic acid, 0.4 M $CaCl_2$, and 0.5 M Bis−Tris) and (2) 6 μL of porcine trypsin (3 mg/mL, ≥ 6,000 units/mg protein) and 10 μL of bovine α-chymotrypsin (4.77 mg/mL, ≥ 39 units/mg protein). The samples were then incubated at 37 °C for 1 h. The reaction was stopped by heating the samples in boiling water for 5 min. The control without the incubation steps was prepared as the unhydrolyzed control, and the native PTT was used as the hydrolyzed control. All assays were done in triplicate.

The quantification of the digested species was performed with a Beckman HPLC (Beckman Coulter, Fuellerton, CA) system equipped with a programmable solvent module (model 126), a photodiode array detector and 32 Karat software for data collection. The separation was performed on a Zorbax SB-C8 (4.6 × 150 mm, 5 μm, Agilent Technologies, Mississauga, ON, Canada). The digested sample (20 μL) was injected in triplicate. The absorbance was measured at 214 nm. A linear gradient at a flow of 0.5 mL/min was used using water/acetonitrile/formic acid (90:10:0.1, mL/mL/mL) as solvent A and water/acetonitrile/formic acid (10:90:0.07, mL/mL/mL) as solvent B. The elution gradient was as follows: 1−45 min, 50% B; 45−50 min, 100% B; 50−55 min, 58% B; 55−60 min, 0% B; and 60−80 min, 0% B. The unhydrolyzed control was used as a standard to quantify the unhydrolyzed PTT in the samples.

$$\text{Percent protein digestion} = 100 - ((\text{the peak area of unhydrolyzed PTT over the peak area of the PTT control}) \times 100) \quad (2)$$

The samples were kept at −20 °C before the assessment of their immunoreactivity.

Determination of IgE-Immunoreactivity. Native PTT or PIs were diluted with PBS buffer containing 0.1% (v/v) Tween 20 (PBS-T) to reach a final concentration of 5.4 μg/mL, coated onto flat-bottomed high binding polystyrene Costar 3590 microtiter plates with 96 wells (50 μL per well, Corning, Tewksbury, MA), and incubated overnight at 4 °C. The sera pool or control serum (diluted 1:3 with 1% w/v BSA in PBS-T) was mixed with conjugates as inhibitor (0.0012000 μg/mL in 1% w/v BSA in PBS-T) at a ratio of 1:1 (v/v) and incubated overnight at 4 °C. As a positive control, a BSA solution (0.001−2000 μg/mL in 1% w/v BSA in PBS-T) was incubated with the antipotato sera pool. The pool was composed of sera from 4 subjects with high levels of specific IgE antibody to potato proteins (PlasmaLab). Human serum with specific IgE antibody to dust mites but none to potato proteins was used as the control. The microtiter plate coated with native proteins was

washed 3 times with 300 μL of PBS-T using a Biotek ELx405 microplate washer (Winooski, VT) and was blocked using 5% (w/v) BSA in PBS-T for 2 h at 25 °C. After washing 3 times with PBS-T, 50 μL of PTT conjugates and serum pool mixtures were added onto the PTT-coated microtiter plate. The plate was incubated at 25 °C for 2 h and washed with PBS-T three times. After incubation with 50 μL of anti-human IgE conjugated with horseradish peroxidase (1:2000 dilution with 1% w/v BSA in PBS-T) for 1 h at 25 °C, the plate was washed 3 times and developed with 50 μL of substrate solution (3,3′,5,5′-tetramethylbenzidine, TMB, Bioshop, Burlington, ON, Canada) at 25 °C for 15 min. The reaction was stopped by adding 50 μL of 0.5 M sulfuric acid solution. The absorbance was measured at 450 nm. The loss of the specific IgE binding ability of the patients' sera resulting from the conjugation of PTT with galactose/GOS/galactan was expressed as follows:

$$\text{Percent inhibition} = 100 - ((\text{absorbance of the glycated samples preincubated with sera pool}/\text{absorbance of positive control}) \times 100) \quad (3)$$

The experimental values were fitted to a four-parameter logistic equation using the SigmaPlot software from SPSS Inc. (Chicago, IL) and were subjected to normality (Shapiro-Wilk) and to constant variance tests to validate assumptions of one-way analysis of variance (ANOVA). IC_{50} was defined as the concentration of inhibitor at the inflection of the fitted curve. All assays were done in triplicate. p values ≤ 0.05 were considered to be statistically significant. To assess the effect of heat treatment, PTT and its conjugates (20 mg/mL) were incubated at 80 °C for 15 min before assessing their immunoreactivity.

Protein Primary Sequence Analysis. The primary sequence of PTT and its conjugates were analyzed through protein mass mapping, which consists of the tryptic hydrolysis of proteins followed by mass spectrometric analysis of the released peptides.

Tryptic Digestion. The digestion of PTT and its conjugates were performed on a MassPrep liquid handling robot (Micromass, Manchester, U.K.) according to the protocol of Shevchenko et al.[28] with modifications of Havlis et al.[29] The native PTT, the incubated control PTT, and the PTT conjugates (10 μL each; 1 μg/mL) were resolved by electrophoresis (Mini-Protean Tetra system, Bio-Rad) on Mini-Protean TGX precast gels (Bio-Rad). Proteins bands taken from the SDS–PAGE gel were reduced with 10 mM dithiothreitol and alkylated with 55 mM iodoacetamide. Trypsin digestion was performed using 105 mM of modified porcine trypsin (sequencing grade, Promega, Madison, WI) at 58 °C for 1 h. Digestion products were extracted using a formic acid/acetonitrile/water mixture (1:2:97, v/v/v) followed by a formic acid/acetonitrile/water mixtire (1:50:49, v/v/v). Recovered extracts were pooled, dried by vacuum centrifugation, resuspended into 10 μL of 0.1% (v/v) formic acid, and analyzed by mass spectrometry.

Mass Spectrometry. Peptide samples were separated by online reversed-phase (RP) nanoscale capillary liquid chromatography (nanoLC) and analyzed by electrospray–mass spectrometry (ES-MS/MS). Analyses were performed with a Thermo Surveyor MS pump connected to an LCQ Deca XP mass spectrometer (Thermo Electron, San Jose, CA) supplied with a nanoelectrospray ion source (Thermo Electron, San Jose, CA). Peptides were bound on a cap trap (Michrom Bioresources, Auburn, CA) at 10 μL/min after which chromatographic separation took place using a PicoFrit column BioBasic C18 (10 cm ×0.075 mm) (New Objective, Woburn, MA) set with a linear gradient from 2 to 50% of solvent B (acetonitrile and 0.1% v/v formic acid) for 30 min, at 200 nL/min (obtained by flow-splitting). Mass spectra were acquired using a data-dependent acquisition mode using Xcalibur software, version 1.2. Each full scan mass spectrum (400–2000 m/z) was followed by collision-induced dissociation of the three most intense ions. The dynamic exclusion (30 s exclusion duration) function was enabled, and the relative collisional fragmentation energy was set to 35%.

Database Searching. All MS/MS samples were analyzed using Mascot (Matrix Science, London, UK; version 2.4.1) and X! Tandem (The GPM, thegpm.org; version CYCLONE (2010.12.01.1)). X! Tandem was set up to search the UR12_5_SolanumTub_20120718 database (2615 entries) also assuming trypsin. Mascot was set up to search the UR12_5_SolanumTub_20120718 database assuming the digestion enzyme trypsin. Mascot and X! Tandem were searched with a fragment ion mass tolerance of 0.100 Da and a parent ion tolerance of 0.100 Da. Carbamidomethyl of cysteine was specified in Mascot and X! Tandem as a fixed modification. Dehydrated of the N-terminus, Glu→pyro-Glu of the N-terminus, ammonia-loss of the N-terminus, Gln→pyro-Glu of the N-terminus, deamidated of asparagine and glutamine, oxidation of methionine, and hex of lysine and arginine were specified in X! Tandem as variable modifications. Glu→pyro-Glu of the N-terminus, Gln→pyro-Glu of the N-terminus, deamidated of asparagine and glutamine, oxidation of methionine, hex of lysine and arginine, galactosyl of lysine, and galactosyl (R) of arginine were specified in Mascot as variable modifications.

Criteria for Protein Identification. Scaffold (version 3.6.2, Proteome Software Inc., Portland, OR) was used to validate MS/MS based peptide and protein identifications. Peptide identifications were accepted if they could be established at greater than 95.0% probability as specified by the Peptide Prophet algorithm.[30] Protein identifications were accepted if they could be established at greater than 95.0% probability and contained at least 2 identified peptides. Protein probabilities were assigned by the Protein Prophet algorithm.[31] Proteins that contained similar peptides and could not be differentiated based on MS/MS analysis alone were grouped to satisfy the principles of parsimony.

Secondary Structure Analysis. The secondary structure analysis of PTT and it conjugates was analyzed by Fourier transform infrared spectroscopy (FTIR). The samples were dissolved in ^2H_2O to achieve a final concentration of 100 mg protein/mL. Infrared spectra were recorded using a 8210 Nicolet FTIR spectrometer (Thermo Electron Corporation, Madison, WI) equipped with a deuterated triglycine sulfate (DTGS) detector. The spectrometer was continuously purged with dry air from Balston dryer (Balston, Haverhill, MA). The samples (9 μL) were placed between two CaF_2 windows separated by a 25 μm Teflon film spacer (Harrick Scientific, Pleasantville, NY). Each spectrum was obtained by coadding 256 scans to minimize the signal-to-noise ratio. Fourier self-deconvolution (FSD) in the amide I′ region was performed using Omnic 6.0 software (Thermo Electron Corporation, Madison, WI) applying a bandwidth of 40 cm^{-1} and a resolution enhancement parameter of 3. The curve fitting was performed by using Origin 8 (OriginLab, Northampton, MA). The Gaussian function was chosen to fit the overlapped peaks. The amide I′ region of PTT solution in ^2H_2O revealed five components upon deconvolution and curve-fitting. The band at 1628 cm^{-1} had been assigned to strongly bonded β-strands indicative of an aggregated strands type structure.[32] The remaining structures were assigned as follows: bands at 1637 ± 3.0 and 1675 ± 5.0 cm^{-1} as β-sheets, band at 1645 ± 4.0 cm^{-1} as random coils, bands at 165 ± 4.0 cm^{-1} as α-helices, and bands at 1671 ± 3.0 and 1689 ± 2.0 cm^{-1} as β-turns.[33]

Three-Dimensional Mapping. The FASTA format of amino acid sequence of PTT (accession number Q2MY50, UniProtKB) was submitted to Swissmodel.[34] This server used the template of SeMet Patatin (Protein Data Bank ID: 1OXW) for the prediction. The predicted model had a Q-MEAN Z-score, a useful measure for the description of the absolute quality of theoretical models, of −1.12, which indicates acceptable quality. The predicted model was viewed by Jmol.[35]

RESULTS AND DISCUSSION

Glycation Extent of Potato Proteins. Table 1 shows the percent blocked lysine of conjugates of PTT and PIs. As compared to GOS and galactan, higher levels of glycation of PTT and PIs with galactose were obtained with percent blocked lysine of 33.3 and 25.2%, respectively. These results are in agreement with other studies[36] in which the higher reactivity of monosaccharides was attributed to their higher proportion in the open-ring form and/or to their high affinity to the glycation sites of PTT.[37] The difference in the number of glycated residues between PTT and PIs can be explained by the different accessibilities of Lys ε-amino groups.[38] Indeed, there are 24

Table 1. Extent of Glycation of PTT and PIs with Selected Carbohydrates

conjugates	incubation time (days)	blocked lysine (%)[a]
PTT/galactose	1	33.3 (±0.5)
PTT/galactose	3	77.0 (±1.7)
PTT/GOS	3	4.0 (±0.0)
PTT/galactan	3	9.1 (±0.0)
PIs/galactose	1	25.2 (±0.0)
PIs/GOS	3	10.3 (±0.0)

[a]Experimental results are averages of triplicates. and the standard deviations are given.

and 10−14 reactive amino groups on PTT and on major PIs, respectively (accession numbers Q2MY50, P58514, Q41448, and P16348, UniProtKB). The higher percent blocked lysine of PTT is attributed to the high number of its more exposed Lys residues as compared to the PIs. However, the lower level of conjugation of potato proteins with GOS can be attributed to the high rate of the glycoxidation reaction of GOS competing with the glycation rate through the progress of the Maillard reaction.[39,40] The results also show that the percent level of blocked lysine of PTT (4%) upon glycation with GOS was lower as compared to that of PIs (10.3%). These results reveal the higher susceptibility of PTT to form protein aggregates upon the generation of protein cross-linking dicarbonyls through the glycoxidation/autoxidation of GOS,[39] therefore leading to the lower accessibility of the glycation sites as compared to PIs.

Effect of Glycation on the Immunoreactivity of PTT and PI Conjugates. To determine the allergenic potential of native and conjugated potato proteins, IgE binding activity of the native protein was investigated by an inhibition ELISA assay using a serum pool of four subjects with specific IgE to potato proteins. The sera from different donors were first tested individually against native PTT and protease inhibitors to confirm the extent of their immunoreactivity (data not shown). The sera were then pooled to obtain a more general immunoreactivity profile. The IgE's in the serum pool showed immunoreactivity to the patatin band (Sol t 1 allergen, Figure SI-3, Supporting Information) but also to some protease inhibitors (Sol t 2−4 allergen, Figure SI-3, Supporting Information). An anti-dust mite serum sample was used as a negative control. Figure 1A demonstrates a typical inhibition curve for the native PTT and the PTT conjugates. Control experiments performed with incubated PTT without carbohydrates demonstrated a decrease in the concentration required for half-maximal inhibition of IgE binding (IC_{50} of 0.82 μg/mL, $p < 0.01$) as compared to the native PTT (IC_{50} of 1.19 μg/mL, $p < 0.01$). This increase in IgE binding affinity of PTT upon incubation is attributed to a change in PTT structure, leading to a higher exposure of its epitopes. The IC_{50} of PTT/galactose and PTT/GOS conjugates were estimated to be 0.70−0.90 μg/mL (1−3 days incubation; $p < 0.01$) and 0.38 μg/mL ($p < 0.01$), respectively. These experimental findings reveal an increase in the level of IgE binding extent upon the glycation of PTT with galactose and GOS as compared to the native PTT. These results are attributed to an increased exposure of the epitopes and/or the formation of novel IgE-binding sites upon covalent modifications of PTT during glycation with small carbohydrates.[41,42] As compared to PTT/galactose conjugates formed upon 1 day of incubation, the slightly lower immunoreactivity obtained with PTT/galactose conjugates obtained upon 3 days of incubation indicates further structural changes due to extensive glycation leading to lower exposure of

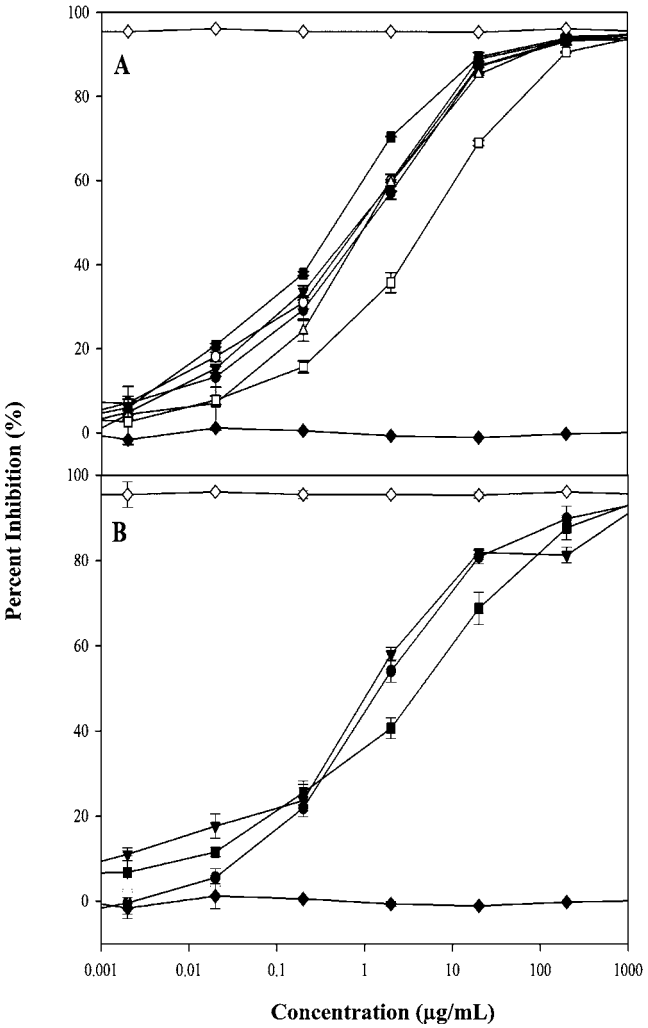

Figure 1. Effect of glycation on PTT and PI immunoreactivity obtained through inhibition ELISA: (A) PTT (●), incubated PTT (○), PTT/galactose conjugates (1-day) (▼), PTT/galactose conjugates (3-day) (Δ), PTT/GOS conjugates(■), PTT/galactan conjugates (□), positive control (♦), and negative control (◊). (B) PIs (●), PIs/galactose conjugates (▼), PIs/GOS conjugates (■), positive control (♦), and negative control (◊).

the epitopes. In contrast, lower immunoreactivity of ovalbumin after glycation with glucose was reported by Ma et al.[43] However, the results show that the glycation of PTT with galactan (IC_{50} of 5.49 μg/mL; $p < 0.01$) resulted in a significant decrease in the affinity for the specific IgE as compared to the native PTT (IC_{50} of 1.19 μg/mL, $p < 0.01$). Similarly, Aoki et al.[41] have reported a decrease in the IgE binding activity of a major allergen of Japanese cedar, Cry j 1, conjugated with galactomannan and attributed this decrease in immunoreactivity to the effectiveness of polysaccharide chains at masking the molecular surface epitopes of an allergen.

Control experiments performed with control incubated PIs without carbohydrates did not show any difference in IgE binding level compared to that of the native proteins (data not shown). Contrary to the results obtained with PTT (Figure 1A), the conjugation of PIs to carbohydrates resulted in lower immunoreactivity as compared to the native compound (IC_{50} of 1.11 μg/mL, $p < 0.01$), where the conjugation with GOS (IC_{50} of 5.17 μg/mL, $p < 0.01$) resulted in a higher decrease in immunoreactivity than that with galactose (IC_{50} of 1.21 μg/

dx.doi.org/10.1021/jf5003073 | J. Agric. Food Chem. 2014, 62, 3591−3598

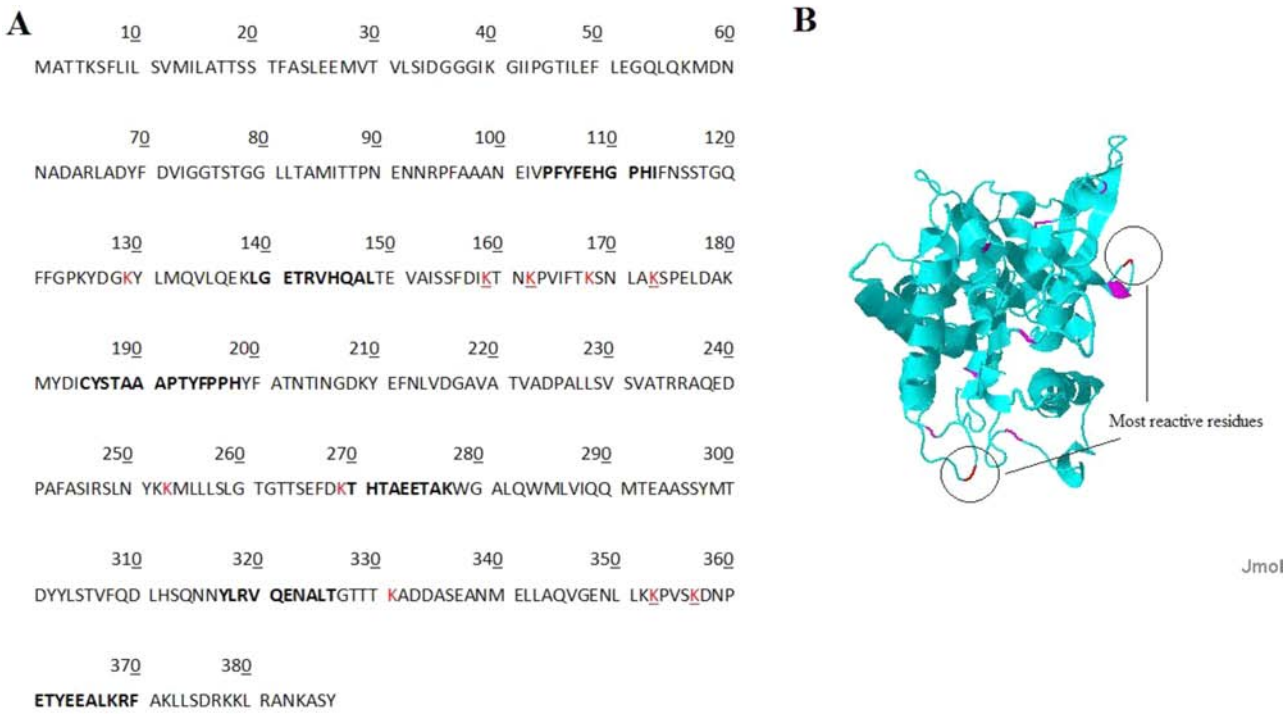

Figure 2. (A) Amino acid sequence of PTT glycated with galactose (red), glycated with GOS (red, underlined), and documented epitopes (bold). (B) Three-dimensional mapping of PTT with glycated residues (magenta) and the most reactive glycated residues (red).

mL, $p < 0.01$) (Figure 1B). It is likely that the conjugation of PIs to galactose or GOS resulted in epitope modification and/or to epitope shielding, thereby affecting the antigen−antibody recognition.[43] A decrease in the immunoreactivity of lysozyme was also obtained, in our previous study, upon its conjugation with galactose and GOS.[44]

The overall results emphasize that the immunoreactivity effect is allergen and carbohydrate dependent.[19] For further studies, PTT, being a heat-labile allergen, was selected to study the effects of the primary and secondary molecular modifications upon glycation and thermal treatment on immunoreactivity.

Location of Conjugated PTT Residues. To determine the conjugated residues on PTT, the skipped trypsin cleavage sites due to glycation of lysine residues and the increase in molecular weight of the digested peptides were identified by peptide mapping of conjugated PTT (Figure 2A). Table SI-4 in the Supporting Information summarizes the peptide masses identified through MS analysis. As expected, the highest number of glycated residues was found in PTT glycated with galactose, after one day of incubation, (Lys 129, 159, 162, 168, 173, 253, 269, 331, 353, and 357, in red) as compared to PTT glycated with GOS, after three days of incubation (Lys 159, 162, 173, 353, and 357, underlined in red) confirming the higher reactivity of the smaller carbohydrate compared to that of the larger one. The most reactive residues were Lys 159 and 357, which were found in the highest proportion in their conjugated state. The glycated residues did not overlap with the amino acid sequence of the epitopes previously identified in PTT (in bold),[45] which demonstrates that the direct blocking of these epitopes did not occur. This supports our inhibition ELISA findings where no decrease in the immunoreactivity of PTT was observed upon its conjugation with galactose (Figure 1A). On the contrary, the minor increase observed in the immunoreactivity might be explained by the conjugation of the carbohydrate to the residues that are found in close proximity to the documented epitopes, such as Lys 269 and 357, which could have resulted in an increased exposure of these epitopes. The three-dimensional mapping of the PTT (Figure 2B) demonstrated that the glycation sites (in magenta) were mostly found toward the termini of individual PTT secondary structures, such as the α-helix and β-sheet, which indicates a minimal change in the secondary structure due to glycation. The most reactive residues (in red) are very easily accessible according to the three-dimensional mapping of the native PTT.

Investigation of the Secondary Structure of PTT Conjugates. Table 2 shows the percent change in the secondary structure of the conjugates compared to that of the native PTT estimated through FTIR. The FTIR spectrum of native PTT shows the presence of 13.8% aggregated strands, 43.3% β-sheet, 9.2% β-turns, and 33.7% α-helix. The FTIR spectrum of the control incubated PTT showed negligible change (<1%) in the protein's secondary structure upon incubation at mild temperature of 48 °C. The results also show that the glycation with galactose had minimal effects on the secondary structure of PTT with 9.2, 43.1, 8.6, and 39.1% of aggregated strands, β-sheet, β-turn, and α-helix, respectively. These results confirm the high affinity of galactose to exposed glycation sites located at the

Table 2. Effect of Glycation on the Secondary Structures of PTT and Its Conjugates Obtained through FTIR[a]

PTT sample	α-helix (%)	β-sheets (%)	β-turns (%)	aggregated sheets (%)
PTT	33.75	43.27	9.16	13.82
incubated PTT	34.19	42.36	9.07	14.38
PTT/galactose	39.02	43.14	8.62	9.22
PTT/GOS	34.54	43.29	9.43	12.74
PTT/galactan	31.10	37.99	6.94	23.96

[a]Each spectrum was obtained by coadding 256 scans.

dx.doi.org/10.1021/jf5003073 | J. Agric. Food Chem. 2014, 62, 3591−3598

termini of PTT secondary structures (Figure 2B), leading to minimal secondary structural changes of PTT upon glycation. Similar low structural changes were exhibited by PTT/GOS conjugates with 12.7, 43.3, 9.4, and 34.6% of aggregated strands, β-sheet, β-turn, and α-helix, respectively. The most significant changes in the secondary structure of PTT were observed upon glycation with galactan with 24.0, 38.0, 6.9, and 31.1% of aggregated strands, β-sheet, β-turn, and α-helix, respectively; these results are due to the disruption of intermolecular noncovalent interactions that stabilize the secondary structure of PTT.[46] The significant structural changes observed in the PTT/galactan conjugates resulted in the burying of IgE specific epitopes between the protein molecules and to the subsequent decrease in IgE binding affinity.[47] Although relatively small, the changes in PTT secondary structure upon conjugation with the smaller carbohydrates induced an exposure of inner epitopes, leading to an increase in the immunoreactivity as observed in Figure 1A. Ma et al.[43] have reported that the increase in the immunoreactivity of the ovalbumin conjugated with glucose was due to the exposure of hydrophobic epitopes upon glycation.

Effect of Heat Treatment on the Immunoreactivity and the Secondary Structures of PTT Conjugates. The effect of heat treatment (80 °C for 15 min) on the immunoreactivity of native PTT and PTT conjugates was assessed (Table 3). The

Table 3. Effect of Heat Treatment on PTT Conjugates' Immunoreactivity Obtained through Competition ELISA[a]

		IC_{50} (μg/mL)[a]	
conjugates	incubation time (days)	nonheated	heated
PTT		1.19 (±0.11)	2.77 (±0.66)
incubated PTT	3	0.82 (±0.16)	2.64 (±0.28)
PTT/galactose	1	0.70 (±0.10)	0.98 (±0.65)
PTT/GOS	3	0.38 (±0.05)	0.03 (±0.01)
PTT/galactan	3	5.49 (±0.79)	0.81 (±0.05)

[a]IC_{50} is the concentration of PTT conjugates that produced 50% inhibition of antibody binding to the native PTT. All assays were done in triplicate. p values ≤0.05 were considered to be statistically significant.

heat treated native PTT demonstrated a significant decrease in the IgE binding affinity with an IC_{50} value of 2.77 μg/mL ($p < 0.01$) as compared to the nonheat treated PTT (IC_{50} value of 1.19 μg/mL ($p < 0.01$). Koppelman et al.[47] have obtained similar results to native PTT after heat treatment and attributed the decrease in the immunoreactivity to the hiding of the epitopes through their aggregation, caused by the exposure of hydrophobic regions of PTT during heat induced denaturation. However, the heat treatment did not affect the IgE binding affinity of PTT/galactose conjugates (IC_{50} of 0.98 μg/mL, $p < 0.01$). Contrary to PTT/galactose conjugates, an increase in the IgE binding affinity of PTT/GOS conjugates (IC_{50} of 0.03 μg/mL, $p < 0.01$) and of PTT/galactan conjugates (IC_{50} of 0.81 μg/mL, $p < 0.01$) were obtained after heat treatment. These results can be explained by an increase in the exposure of the epitopes after a partial protein unfolding and/or by the efficiency of longer carbohydrate chains (GOS, galactan) in preventing thermal protein aggregation upon glycation, leading to a better accessibility of the epitopes by IgE.[47] The increase in the immunoreactivity observed with the PTT conjugates are in direct contrast to the results obtained by Vissers et al.[48] where carbohydrate conjugated 2S albumins had lower IgE binding capacity after heat treatment.

To better understand the effect of the conformational changes on the immunoreactivity of PTT conjugates, the changes in secondary structures after heat treatment (Figure 3) were

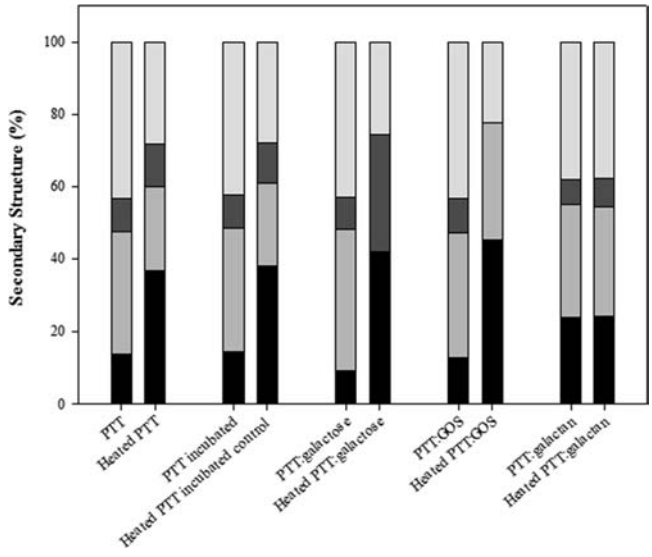

Figure 3. Effect of heat treatment on PTT and its conjugates' secondary structure obtained through FTIR: intermolecular β-sheet (black rectangle), α-helix (medium gray rectangle), β-turn (dark gray rectangle), and intramolecular β-sheet (light gray rectangle).

assessed. The results demonstrate that the partial unfolding of PTT and its conjugates upon heat treatment supports previous findings.[49] Indeed, an increase in the intermolecular β-sheets (>23.03%) after heat treatment was observed for PTT and its conjugates, except for PTT/galactan conjugates. These results confirm the strong tendency of native PTT and its conjugates with galactose and GOS to aggregate upon partial denaturation. Although the largest increase in the aggregated sheets was observed with PTT/galactose (32.67%) and PTT/GOS (32.45%) conjugates upon heat treatment, these changes did not lead to a decrease in the immunoreactivity of the conjugates, as observed with the native and the control PTT (Table 3). The major secondary structural changes observed with PTT/galactose and PTT/GOS conjugates were the complete loss of α-helices and β-turns, respectively; such structural modifications resulted in an increased exposure of the PTT epitopes, leading to an increase in the immunoreactivity of these conjugates even after aggregation (Table 3). On the contrary, galactan stabilizes PTT against heat denaturation with only 2.71% total change in the secondary structure. However, the relatively small change in the secondary structure resulted in an exposure of the hydrophobic epitopes. In addition, the lack of subsequent protein aggregation after exposure of the hydrophobic groups due to galactan conjugation resulted in a significant increase in immunoreactivity (Table 3).

Effect of Digestion on the Immunoreactivity of PTT Conjugates. The effect of in vitro simulated gastric digestion on the allergenic potential of native PTT and its conjugates was assessed by subjecting the samples to simulated gastric digestion before measuring their immunoreactivity by inhibition ELISA (Figure 4). The highest percent digestion was obtained with the native PTT (59.6%) as compared to PTT conjugates. The low percent digestion of PTT conjugates is explained by the fact that the cleavage site of one of the digestive enzymes, trypsin, is specific toward the Lys residues, which are involved in the

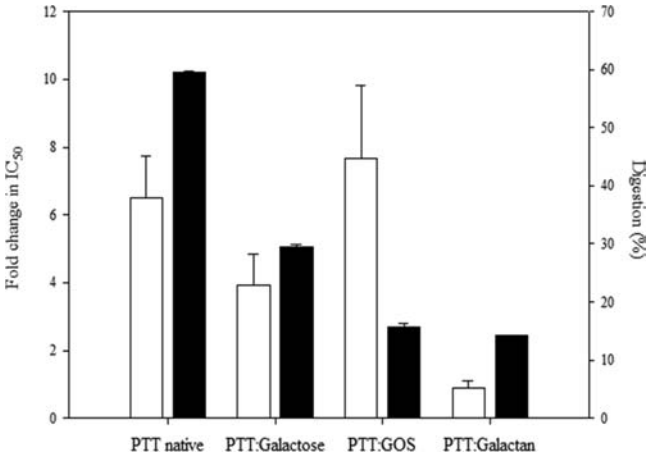

Figure 4. Effect of simulated gastric digestion on PTT conjugates' immunoreactivity: fold change in IC_{50} (white bar) and percent digestion (black bar).

conjugation reaction with carbohydrates. These results are in accordance with those reported by Jiménez-Saiz et al.[42] showing a decrease in ovalbumin conjugates' digestibility as a result of glycation. Nevertheless, as compared to PTT/galactose conjugates (29.5% degree of digestion), the higher resistance of PTT/GOS (15.7%) and PTT/galactan (14.2%) conjugates to digestion could be due to the large size of their carbohydrates moieties, shielding PTT proteolytic sites. The results (Figure 4) also show that the digestion resulted in a 6.51-fold decrease in the IgE binding affinity of native PTT as compared to the nondigested one; these experimental findings can be explained by the disruption of both conformational and sequential epitopes. Similarly, a decrease in the IgE binding affinity of PTT/galactose and PTT/GOS conjugates by 3.94- and 7.66-fold, respectively, was obtained upon digestion. In contrast, the IgE binding affinity of digested PTT/galactan conjugates remained unchanged compared to that of the undigested conjugates; this can be due to the large polysaccharide chains that have sterically blocked the disruption of the epitopes.[41] However, compared to the digested native PTT (IC_{50} of 7.75 μg/mL, $p < 0.01$), a higher retention in IgE binding was exhibited by digested PTT/galactose (IC_{50} of 2.76 μg/mL), PTT/GOS (IC_{50} of 2.91 μg/mL), and PTT/galactan conjugates (IC_{50} of 4.90 μg/mL). These high immunoreactivities of digested conjugates is due to their lower susceptibility to digestion, thereby preserving the integrity of IgE binding sites on conjugated PTT.

The present investigation attempts to develop an oral colon-targeted controlled-release system by an aqueous dispersion film coating process at low temperature. Starch was treated by a high-temperature−pressure reaction, enzymatic debranching, and retrogradation. The structural changes and the digestion resistibility were investigated. With the aqueous dispersion film coating technique, the formation of RS3 and the film coating could be achieved simultaneously. Thus, in this study, insulin-loaded microparticles coated with the in situ formed RS3 film were prepared, following optimization of the colon-targeting controlled-release property of the RS3 film-coated microparticles by in vitro experiments (i.e., under the conditions of simulated human GI tract). Furthermore, the in vivo effectiveness of the RS3 film-coated insulin-loaded microparticles was evaluated by tissue immunocytochemistry and in vivo insulin bioactivity studies in streptozotocin (STZ)-induced diabetic rats.

MATERIALS AND METHODS

Materials. High-amylose corn starch (Gelose 50, G50) was obtained from Penford (Australia). Pullulanase was of analytical grade and supplied by Yulibao Biology and Technology Co., Ltd. (Guangzhou, China). Termamyl α-amylase (120 KNU/g) from *Bacillus licheniformis* and Amyloglucosidase (300 AGU/g) from *Aspergillus niger* were purchased from Novo Nordisk Bioindustrials (Guangzhou, China). Microcrystalline cellulose was purchased from Anhui Shanhe Medicinal Accessary Material Co., Ltd. (Huainan, China). 5-Aminosalicylic acid (5-ASA) was supplied by Yuancheng Technology Development Co., Ltd. (Wuhan, China). Commercial long-acting insulin was purchased from Newprobe Bioscience and Technology Co., Ltd. (Beijing, China). Medicinal starch was supplied by Defeng Starch Sugar Co., Ltd. (Shunde District, Foshan, China). Pepsin, pancreatin, and STZ were purchased from Sigma-Aldrich Co. LLC (Santa Clara, CA, USA) and were of pharmaceutical grade. The rest of the chemical reagents were of analytical grade.

Preparation of RS. The preparation procedure used in this work was according to our earlier method of high-temperature−pressure and debranching treatment, which can increase the RS content of starch.[31] About 25 g of dry high-amylose corn starch was dispersed in 225 mL of water and cooked in a sealed pressure reactor (Parr 4545, Parr Instrument Co., USA) at 110 °C under the pressure of 12.4 MPa with stirring at 200 rpm for 30 min. Then, the gelatinized starch dispersion was cooled to 60 °C, and its pH value was adjusted to 5.0 using 10% (w/v) citric acid. Subsequently, different amounts of pullulanase were added to the reactor for debranching the starch molecules at 60 °C under atmospheric pressure with stirring at 20 rpm for 6 h. The debranched starch was cooked at 100 °C for 10 min to stop the enzymatic hydrolysis and then cooled and stored at 4 °C for 24 h (during which retrogradation happened). Then, parts of the retrograded starch pastes were spray-dried for the analysis of characteristics, and the other parts were diluted by purified water for the preparation of the RS3-based aqueous dispersions.

Digestion Resistibility and Structural Changes of the RS Samples. *Digestion Resistibility in the Upper GI Tract.* The RS content of the RS3 samples was determined by using method 991.43, total dietary fiber (TDF), of the Association of Official Analytical Chemists (AOAC) in in vitro model with Termamyl α-amylase and Amyloglucosidase.

Molecular Molar Mass (M_w) Analysis. The molecular molar mass (M_w) analysis was carried out by using a gel permeation chromatography (GPC) system coupled with a multiangle light scattering (MALS) detector and a refractive index (RI) detector. The GPC system consisted of a pump (1515, Waters, Milford, MA, USA), an autoinjector with a 0.1 mL loop (717, Waters), and a column (Sytyragel HMW7 GPC column, 7.8 × 300 mm, Waters). The MALS detector (632.8 nm, DAWN HELEOS, Wyatt Technology, Santa Barbara, CA, USA) and the RI detector (Optilab rex, Wyatt Technology) were connected to the column.

Fifty milligrams of starch was dispersed in 10 mL of dimethyl sulfoxide (DMSO) containing LiBr (50 mM) with heating in a boiling water bath for 1 h, followed by the shaking of the sample at 60 °C in the water bath for another 12 h. Before injection, the starch sample solutions were filtered using a membrane filter (5.0 μm LS, Millipore Corp., Bedford, MA, USA). The mobile phase used for GPC was DMSO (HPLC grade) containing LiBr (50 mM), which had been filtered through a 0.2 μm membrane filter (0.2 μm FG, Millipore Corp.) and degassed by ultrasound. The flow rate of the mobile phase was 0.7 mL/min; the column was maintained at 45 °C, and the detectors were maintained at 25 °C. The specific RI increment value (dn/dc) of starch in DMSO was found to be 0.074 mL/g.[32] The data were analyzed by the Astra 3.4 software program (Wyatt Technology).

X-ray Diffraction (XRD). Wide-angle X-ray powder diffraction analysis was performed using an X-ray diffractometer (X'Pert Prox, PANalytical, Eindhoven, The Netherlands) operating at 40 kV and 40 mA with Cu Kα radiation (λ = 0.1542 nm). The diffractograms of the RS3 samples were acquired at an angular range of 2θ from 4° to 40° with the step size of 0.033° and the counting time of 4 s for each step. The samples were sieved through 0.180 mm and equilibrated at 25 °C for 24 h prior to the analysis. The relative crystallinity of the samples was quantitatively estimated according to the method of Nara and Komiya.[33] A smooth curve connected with the constant peak baseline was computer-plotted on the diffraction. The ratio of the upper area (crystalline portion) to the total diffraction area (based on a linear baseline) was taken as the relative crystallinity with the software MDI Jade 6.0.

Small Angle X-ray Scatting (SAXS). SAXS measurements were performed on a SAXSess camera (Anton-Paar, Graz, Austria) using Cu Kα radiation (0.1542 nm wavelength) at 40 kV and 50 mA according to our previous studies.[31,34] The starch slurries with similar moisture content (60%, w/w) were prepared for this experiment and equilibrated at 26 °C for 24 h before the analysis. The samples were filled into a paste sample cell and fixed and placed in a TCS 120 temperature-controlled unit (Anton Paar) along the line-shaped X-ray beam in the evacuated camera housing. Each measurement was collected for 10 min. The 2D data were integrated into the 1D scattering function $I(q)$ as a function of the magnitude of the scattering vector q and normalized. The background and smeared intensity were removed using the SAXSquant 3.0 software program for further analysis.

If Bragg's law is applied, q is proportional to the inverse of the apparent periodic length d, as $d = 2\pi/q$. The surface/mass fractal structure can be obtained from the slope of the log−log SAXS graph according to the method of Suzuki, Chiba, and Yarno.[35] The scattering objects with a surface fractal dimension (D_s) are more compact than those with a mass fractal dimension (D_m).

Preparation of the RS3 Film-Coated Microparticles. Bioactive component-loaded microparticle cores (containing microcrystalline cellulose and starch in the ratio of 3:1 and the bioactive component in varied content) were obtained via extrusion−spheronization.[5] 5-ASA and insulin were chosen as model bioactive components, respectively. During the extrusion−spheronization, the temperature was kept at 5−10 °C to maintain the activity of the bioactive components.

Purified water was added into the retrograded starch pastes until starch-based aqueous dispersions (8%, w/w) were obtained. After homogenization by a high-pressure homogenizer (Panda Plus2000, Gea Niro Soavi, Italy), 1,2-propanediol was added into the dispersions, which were then stirred for 8 h by a magnetic stirrer. Thus, the RS3-based aqueous coating dispersions were obtained.

The bioactive component-loaded microparticle cores were coated using a bottom spray fluid bed coater (Mini-XYT; Xinyite Technology Co., Shenzhen, China) until the coated-film thickness of 5−30% (w/w) was achieved, which was representative of the dry weight gain of the microparticles.[5] The process parameters were as follows: inlet temperature at 45 ± 1 °C; temperature of the bioactive component-loaded microparticles at 30 ± 1 °C; spray rate of coating dispersion at 0.7−0.8 mL/min; atomization pressure at 0.15 MPa; and fluidization pressure at 0.15 MPa. After coating, the coated microparticles were further fluidized dried at 35 °C for different times.

Table 1. RS3 Samples and Their GPC-MALLS Parameters, Crystallinity, and SAXS Parameters

pullulanase activity (U/g)	RS content[a] (%)	M_w (g/mol)	R_g[a] (nm)	conformation	crystallinity (%)	α	D_s	D_m	A_q
0	10.4 ± 0.4^A	3.501×10^6 (2%[b])^A	85.0 (1%)^A	spherical	34.4	−3.82	2.18		0.1077
5	10.8 ± 0.7^A	1.463×10^6 (5%)^B	56.2 (1%)^B	spherical	37.2	−1.71		1.71	0.7190
10	15.6 ± 0.6^B	7.315×10^5 (2%)^C	47.5 (2%)^C	spherical	41.4	−1.81		1.87	0.7637
50	20.1 ± 0.7^C	3.271×10^5 (1%)^D	36.2 (3%)^D	spherical	45.6	−1.87		1.87	0.7681
100	34.3 ± 0.7^D	1.692×10^5 (3%)^E	33.8 (9%)^D	spherical	59.5	−2.06		2.06	0.8395
200	41.8 ± 0.8^E	3.067×10^4 (1%)^F	29.4 (5%)^E	spherical	62.7	−2.06		2.06	0.8420

[a]Values followed by the different upper case letters within a column differ significantly ($n = 3$, $P < 0.05$). [b]Precision of global fit.

In Vitro Release Testing and Related Morphological Observation. The bioactive component release tests were carried out using a dissolution rate test apparatus according to the USP23 dissolution method. The RS3 film coated microparticles were incubated in simulated gastric fluid (SGF) for the first 2 h, then in simulated intestinal fluid (SIF) for another 6 h, and afterward in simulated colonic fluid (SCF) for an additional 22 h, in sequence, all at 37 °C.[5,28,29] When the simulated digestive fluid was changed, the microparticles were filtered by filter paper under vacuum, washed with distilled water two times, and then put into the following simulated digestive fluid. At each of the predetermined time points, 5 mL of the tested sample was withdrawn and analyzed for the 5-ASA or insulin content by a UV spectrophotometer (Unico, UV-3802, Shanghai, China).

The morphological change of the RS3 film-coated microparticles during the release process in the simulated fluids was monitored by a scanning electronic microscope Hitachi S3700 (Tokyo, Japan).

In Vivo Release of Insulin from Microparticles after Oral Administration. The in vivo insulin bioactivity of the microparticles was evaluated using a STZ-induced diabetic animal model. STZ (40 mg/kg of rat) in 0.1 M citrate buffer (pH 4.5) was injected intraperitoneally into male Sprague−Dawley (SD) rats, each weighing 273 ± 12 g (Guangdong Animal Experimental Centre, Foshan, China). Two weeks after the STZ treatment, the fasting plasma glucose levels of the rats were monitored at 24 h after fasting. If two successive glucose levels of the rats were >7.8 mmol/L, the rats were diagnosed as having type II diabetes and were used for the in vivo insulin release studies.

Tissue Immunocytochemistry. The rats with type II diabetes were fasted with free access to water for 24 h before the study. The RS3 film-coated insulin-loaded microparticles were orally administered to the stomach via polyethylene tubing under light ether anesthesia. Insulin was dosed at 25 U/kg body weight. Dose selection was based on the expected pharmacodynamics of insulin. At certain times after their oral administration, the rats were sacrificed by cervical dislocation; the tissues of the stomach, small intestine, and colon were obtained, and the insulin distribution in the different parts of the rat GI tract were detected using the hematoxylin−eosin and immunohistochemical staining method. Formalin-fixed, paraffin-embedded tissue sections of the stomach, small intestine, and colon of the rats were used for immunohistochemical studies according to the protocol specified in the ImmunoCruz rat ABC staining kit (Santa Cruz Biotechnology, Inc.). The section slides were washed in xylene and hydrated in different concentrations of alcohol and then were pretreated with 3% H_2O_2 for 10 min and 5% nonimmune bovine serum albumin for 15 min to seal the compounds, which can result in nonspecific background brown color. The slides were incubated with the primary antibody against insulin at 4 °C for 12 h. A horseradish peroxidase-conjugated secondary antibody was applied to locate the primary antibody. The specimens were stained with diaminobenzidine chromogen and counterstained with hematoxylin. The presence of brown staining was considered to be a positive identification of insulin. An optical microscope was used to observe the images on the slides, and the images were analyzed by the Image-Pro Plus (IPP) software program.

Insulin Bioactivity. The type II diabetic rats were randomly divided into five groups (the average plasma glucose concentrations of the different groups differed by ≤2 mmol/L). Before the test, all of the rats were fasted for 12 h with free access to water. The insulin-loaded microparticles coated by RS3 film were orally administered to the stomach via polyethylene tubing under light ether anesthesia. Insulin was dosed at different dosages, that is, 15, 25, and 35 U/kg body weight, respectively. The group that was subcutaneously injected with 25 U/kg of commercial long-acting insulin was used as the positive control group and the diabetic group without insulin treatment was used as the negative control group. After insulin administration, the rats in all of the groups were allowed to eat freely. At predetermined time points, the plasma glucose concentrations of the rats were monitored by the glucose oxidase method. The relative pharmacodynamic bioactivity of insulin (F_{rel}%) was calculated using the equations

$$F_{rel} = \frac{\frac{[AUC_T]}{dose_T}}{\frac{[AUC_{iv}]}{dose_{iv}}} \times 100$$

$$AUC = \sum_{n=0}^{8} (t_{n+1} - t_n) \times \frac{(100 - P_n) + (100 - P_{n+1})}{2}$$

$$P_n\% = \frac{C_n}{C_0} \times 100$$

where C_n and t_n are the plasma glucose concentration (mmol/L) and monitored time (h) at the nth blood collection, respectively; P_n % is the relative plasma glucose level (% of initial plasma glucose concentration); AUC is the total area of all the trapeziums between every two neighboring points and the 100% horizontal line in the relative plasma glucose concentration−time profile; dose is the intake dosage of insulin; and the subscripts T and iv represent oral administration and subcutaneous injection, respectively.

For the analysis of plasma insulin concentrations, blood samples were centrifuged and subsequently determined by an enzyme immunoassay kit (BG Co., USA), and the relative insulin bioavailability (B_{rel}%) of the insulin-loaded microparticles coated with RS3 film after oral administration was calculated.[36]

Statistical Analysis. All data were subjected to statistical analysis using the SPASS 10.0 statistical package and were presented as mean ± standard deviation (±SD). Differences between groups were estimated by analysis of t test, and $P < 0.01$ was considered to indicate a statistically significant difference between two groups.

RESULTS AND DISCUSSION

Preparation and Characteristics of the RS3 Samples. *Preparation of the RS3 Samples.* As the delivery carrier for colon-specific controlled release system, the starch-based film coated to the surface of the microparticles loaded with bioactive components must have suitable digestion resistibility to realize the delivery of the microparticles targeting the colon. Thus, the digestion resistibility of the RS3 films with different molecular molar masses, formed by the aggregation of gelled starch molecules upon dehydration and drying during the aqueous dispersion coating process, was investigated. The gelled starch molecules with different molecular molar masses were obtained by the high-temperature−pressure and debranching treatment and the RS contents of the treated starch samples with different

dx.doi.org/10.1021/jf500472b | J. Agric. Food Chem. 2014, 62, 3599−3609

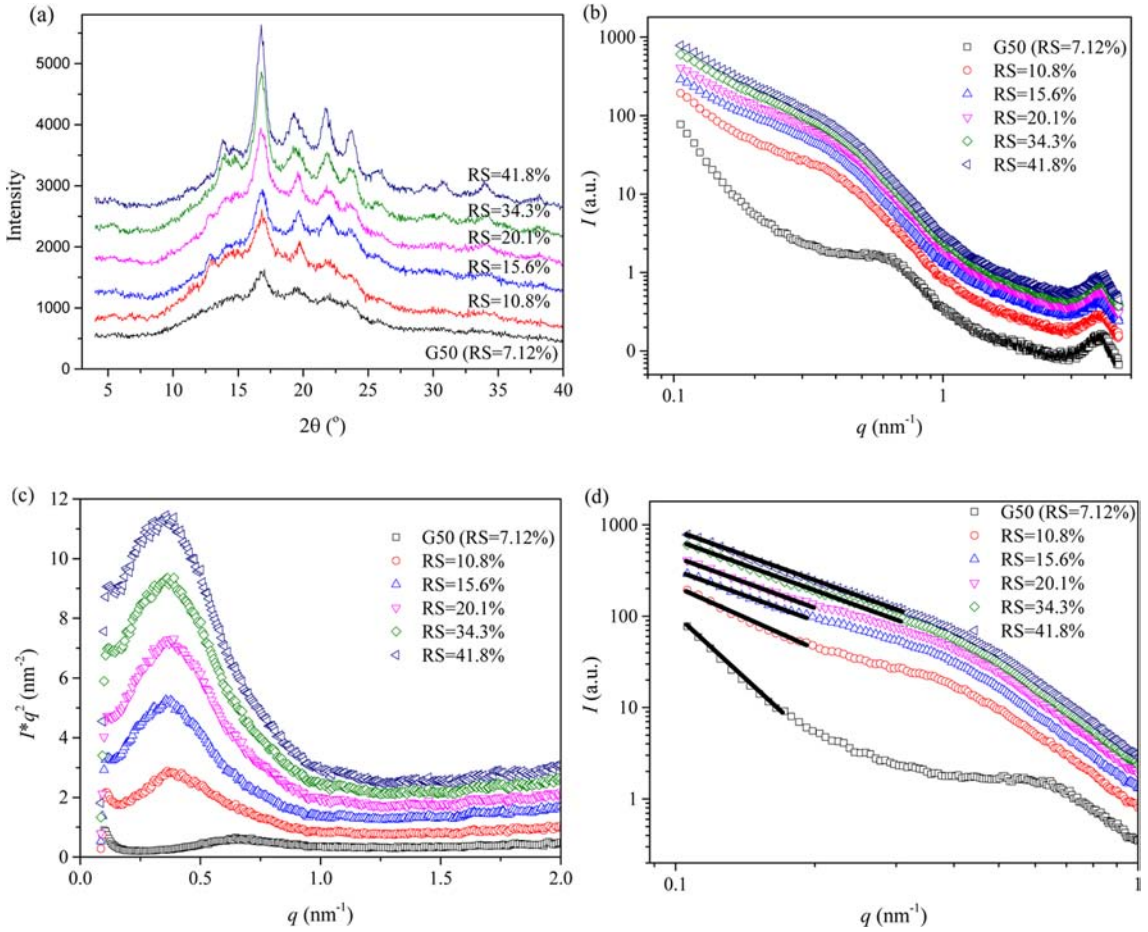

Figure 1. XRD patterns (a) and SAXS patterns of native G50 starch and the RS3 samples with different RS contents: (b) double-logarithmic SAXS patterns; (c) $I \times q^2 - q$ SAXS patterns; (d) double-logarithmic SAXS patterns in the range of $0.08 < q < 1$. The real lines show the relationship $I \sim q^{\alpha}$). All of the intensities are shifted along the ordinate to avoid overlapping of the symbols.

amounts of the debranching enzyme, pullulanase, are shown in Table 1.

A significant increase in the RS content, reaching a maximum value of 41.8%, was observed when the pullulanase content used in the treatment was increased to 200 U/g. Nevertheless, when the amount of pullulanase was increased to 300 U/g, the RS content was reduced to 33.7%, which indicated that a further increase in the amount of pullulanase reduced the RS content ($P < 0.05$). The high-temperature−pressure and debranching treatment with a suitable amount of pullulanase, followed by subsequent retrogradation and drying, could result in the degradation of starch molecules, and some of the degraded molecules of suitable molar mass could reassociate to form tightly packed ordered aggregations stabilized by hydrogen bonding, which were more difficult for starch enzymes to hydrolyze, leading to the formation of a higher amount of RS3. However, with a further increase in the amount of pullulanase, the starch molecules could be degraded further, and these molecules could not preferably form tightly packed ordered aggregations; thus, a decrease in the RS content was observed. The results here demonstrate that the digestion resistibility of starch could be improved by the high-temperature−pressure and debranching treatment and the following retrogradation and drying processes. Thus, the RS3 film with suitable digestion resistibility can be obtained through controlling the starch molecular molar mass during the preparation of starch-based aqueous coating dispersion and the subsequent aqueous dispersion coating process (where retrogradation and drying occur).

Weight-Average Molecular Molar Mass (M_w). After the high-temperature−pressure and debranching treatment, the M_w of native G50 starch was reduced from 3.501×10^6 to 1.463×10^6 g/mol when the RS content was 10.8% (Table 1). The M_w was further reduced to 3.271×10^5 g/mol when the RS content was 20.1% and to 3.067×10^4 g/mol when the RS content was 41.8%. This shows that the high-temperature−pressure and debranching treatment could result in a significant decrease in the M_w of starch ($P < 0.05$). The decrease in the R_g value with an increase in the RS content suggests that the starch molecular size became smaller after the high-temperature−pressure and debranching treatment, which is consistent with the results regarding the M_w. In addition, as seen from the results of the logM_w/log R_g, the conformation of molecules of the RS3 samples was spherical and was not changed with the varied RS content. Along with the RS contents of the samples after the treatment with pullulanase, it seems that the degraded starch molecules with $M_w = 3.067 \times 10^4$ g/mol should preferably form RS3 and the starch molecules with M_w below or above 3.067×10^4 g/mol could be easily digested by the enzyme.

Crystalline Structure. Figure 1a shows the wide-angle XRD spectra of native G50 starch and the RS3 samples with different RS contents, and the relative crystallinity values are shown in Table 1. It can be seen that the native G50 starch gives the strongest diffraction peak at around $2\theta = 17.0°$and a few small

dx.doi.org/10.1021/jf500472b | J. Agric. Food Chem. 2014, 62, 3599−3609

peaks at around 2θ values of 5.6°, 15.0°, 22.0°, 23.4°, and 26.0°, which are indicative of the B-type diffraction pattern, and one peak at 19.8°, which was related to the V-type diffraction pattern. Thus, native G50 starch presented a B+V-type diffraction pattern.[37,38] Comparaed with the XRD pattern of native G50 starch, RS3 samples with RS content between 10.8 and 20.1% showed a new diffraction peak at around 2θ = 13.0°, and this peak changed to about 14.0° as the RS content increased. These two peaks are also related to the B-type diffraction pattern. For the RS3 samples with RS content of 34.3 and 41.8% the peak at around 2θ = 26.0° became distinct as the RS content increased. Although the RS3 samples exhibit a similar B+V-type crystal form, most of the peak intensity was gradually strengthened with an increase in the RS content, which indicated that the starch molecules in RS3 samples can form better-crystallized B- and V-type crystals after the high-temperature−pressure and debranching treatment. The relative crystallinity sharply increased with an increase in the RS content. Particularly, when the RS content was 41.8%, the relative crystallinity reached 62.7%. Combined with the M_w data, it is concluded that the starch molecules with M_w = 3.067 × 10^4 g/mol tended to arrange and form the crystalline structure. These results indicate that the total amount of crystallinity should be one of the reasons for the enhanced starch resistibility against enzymatic digestion.

Lamellar Structure. Figure 1b shows the double-logarithmic SAXS patterns of native G50 starch and the RS3 samples. It can be seen from Figure 1b that native G50 starch had an apparent scattering peak at q = 0.65 nm^{-1}, which corresponds to a Bragg distance of about 9.7 nm and is considered due to the long-range periodicity occurring from the alternating crystalline and amorphous lamellar structure of the starch granule.[34,39−41] After the high-temperature−pressure and debranching treatment with the following retrogradation and drying processes, the peak at q = 0.65 nm^{-1} disappeared in the scattering patterns of the RS3 samples. Instead, there was a shoulder-like peak at q = 0.42 nm^{-1}, corresponding to a Bragg distance of about 14.9 nm, suggesting the formation of a new repeat aggregation structure with the repeat distance of about 14.9 nm.

The difference in the aggregation structure can cause a difference in the electron density, which influences the scattering intensity. The ordering of starch molecules can be quantified by calculating the area under the curve ($\int_0^\infty I(q)q^2 dq$) (Figure 1c). As the RS content increased, the integrated area (A_q) under the SAXS curve also increased (Table 1). During the high-temperature−pressure and debranching treatment with following retrogradation and drying processes, the starch molecules rearranged and aggregated. Thus, the molecular ordering in the aggregation structure of RS3 samples increased. These results indicate that the higher amount of starch molecular aggregation orders as a result of the newly formed repeat aggregation structure with the repeat thickness of about 14.9 nm contributed to the higher resistibility against enzymatic digestion of the RS3 starch samples.

Fractal Structure. As presented in the double-logarithmic SAXS patterns (Figure 1d), the solid lines show the relationship of $I \sim q^{-\alpha}$ and the fractal dimensions are shown in Table 1. It can be seen from Figure 1d and Table 1 that native G50 starch showed a surface fractal structure in the length scale of 36.5 < d < 59.3 nm and the D_s was close to 2.18. For the RS3 samples, a mass fractal structure in the length scale of 31.7 < d < 59.3 nm was shown, with the D_m increasing from 1.71 to 1.87 with an increase in the RS content from 10.8 to 20.1%. A further increase in the RS content from 34.3 to 41.8% would contribute to the formation of a mass fractal structure in the larger length scale of 20.3 < d < 59.3 nm with the D_m of 2.06. This suggests that the treatment contributed to an increase in the compactness of the scattering objects and the formation of the mass fractal structure in a larger scale range. On the basis of the fractal geometry, the D_m of the linear arrangement, the surface-like arrangement, and the regular arrangement (such as a cube or sphere) are 1, 2, and 3, respectively.[35] Thus, the arrangement of the scattering objects in these RS3 samples changed from the linear form to the surface-like form. Considering the RS contents, it is evident that the mass fractal structure in the larger length scale of 20.3 < d < 59.3 nm with a higher D_m value contributed to a higher RS content. The reason could be that some glucosidic bonds of the starch molecules were masked by the ordered aggregations of starch molecular chains in the scattering objects. Meanwhile, when the scattering objects became more compact with an increasing D_m value, it could be more difficult for the starch enzymes to attack the active sites of starch molecules of these scattering objects with a mass fractal structure.

In Vitro Insulin Release from the RS3 Film-Coated Microparticles. *In Vitro Release Behavior.* To optimize the colon-targeting release property of RS3 film, the RS3 film-coated microparticle delivery system was obtained using 5-ASA as the model bioactive compound and the effects of RS content, plasticizer content, film coating thickness, and heat treatment time after coating on the 5-ASA release behavior from the RS3 film-coated microparticles in the simulated human GI tract were investigated, and the results were presented in Figure 1S of the Supporting Information. On the basis of the optimization of the coating process for colon-targeting obtained from Figure 1S, the RS3 film-coated microparticles, in which insulin was loaded, were prepared using the RS3 film with the molecular molar mass of 3.067 × 10^4 g/mol (of which the RS content was 41.8%) as the coating material, with the 1,2-propanediol content being 10%, the coating thickness being 30%, and the time of heat treatment after coating being 8 h; the insulin release profiles are shown in Figure 2. It can be seen from the results that the RS3 film-coated microparticles showed a good colon targeting and release property. The cumulative release percentage of insulin was up to 25.31% within the first 8 h in the upper GI tract and then reached 80.66% at 30 h, suggesting that about 55% of insulin could be delivered to the SCF and

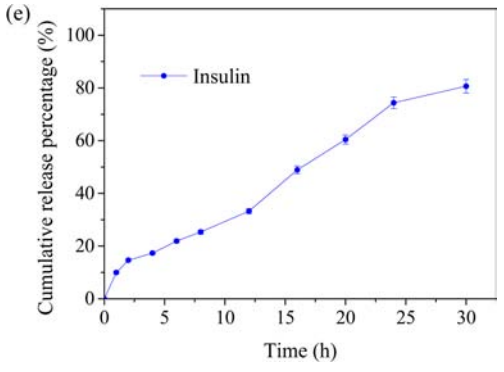

Figure 2. Insulin release from RS3 film-coated microparticles using the RS3 film with RS content of 41.8% as the coating material, with the 1,2-propanediol content being 10%, the coating thickness being 30%, and the time of heat treatment after coating being 8 h.

could be released sustainably from the RS3 film-coated microparticles in SCF.

Morphological Change of the RS3 Film-Coated Microparticles. To investigate the insulin release mechanism from RS3 film-coated microparticles in the simulated human GI tract, SEM was used to observe the coating film surface on the microparticles after incubation in SGF, SIF, and SCF for the specific periods. The insulin-loaded microparticles coated by the RS3 film under the optimization coating process were incubated in SGF, SIF, and SCF for the specific periods, and the results are shown in Figure 3. It is revealed that the surface morphology of the RS3 film-coated microparticles could be affected by the incubation time. From Figure 3a,b, it can be seen that the microparticles were rounded and the surface of the coated RS3 film showed no obvious change after 2 h in SGF (Figure 3c,d), suggesting that the film could resist the acid in SGF. Transferred to and immersed in SIF (pH 6.8) for another 6 h, the microparticles displayed a few small holes on their coated film. After 2 h in SGF and 6 h in SIF (Figure 3e,f), although a few small holes appeared, the film still kept its integrity, which showed the ability to resist the enzyme in SIF. The next immersion of the microparticles in SCF (pH 7.0) for another 16 h resulted in an increased amount of holes on the surface. After 24 h in these digestive fluids (2 h in SGF, 6 h in SIF, and 16 h in SCF, Figure 3g,h), more holes and cracks emerged and the integrity of the film was impaired. With the prolongation of soaking time (Figure 3i,j), the sizes of holes on the microparticle surfaces were even larger and cracks appeared, deepening toward the interior, suggesting that the coated RS3 film was almost disintegrated. It is shown that the RS3 film has good resistance to degradation by the acid and enzymes in the simulated upper GI tract. Therefore, the RS3 film exhibits a good colon-targeting property.

In Vivo Insulin Release from RS3-Film Coated Microparticles. *Distribution of Insulin in the GT Epithelial Tissues of Rats.* After testing the in vitro colon targeting behavior of the RS3-film coated microparticles, it was worthwhile to assess the in vivo behavior of formulation in terms of the residence time of formulation in different parts of the GI tract. By tissue slices and immunohistochemistry, the insulin release property of the RS3 film-coated microparticles in the type II diabetic model rats was studied. The images showing the insulin distribution in the GI epithelial tissues of rats after administration of the RS3 film-coated microparticles for different times are shown in Figure 4. Before administration, the immunohistochemical images displayed a blue background, indicating no positive insulin sign in the stomach, small intestine, and colon of the rats (Figure 4a–c). At 2 h after intragastric administration, there was a slight insulin positive sign (the brown part) in the stomach of rats (Figure 4d), which means a very small amount of insulin released in the stomach. Meanwhile an insulin positive sign was also observed in the small intestine (Figure 4e), which was due to the fact that part of the insulin released in the stomach had reached the small intestine and some of the insulin released from the microparticles reached the small intestine, although no positive sign was observed in the colon at this moment (Figure 4f). At 8 h after intragastric administration, although there was no insulin positive sign in the stomach, a strong insulin positive sign was shown in the small intestine (Figure 4g,h) and a slight insulin positive sign was reflected in the colon (Figure 4i). From 24 h after intragastric administration, the insulin positive sign concentrated in the colon, suggesting that the microparticles had reached the colon, where the insulin had been released from the microparticles (Figure 4l,o).

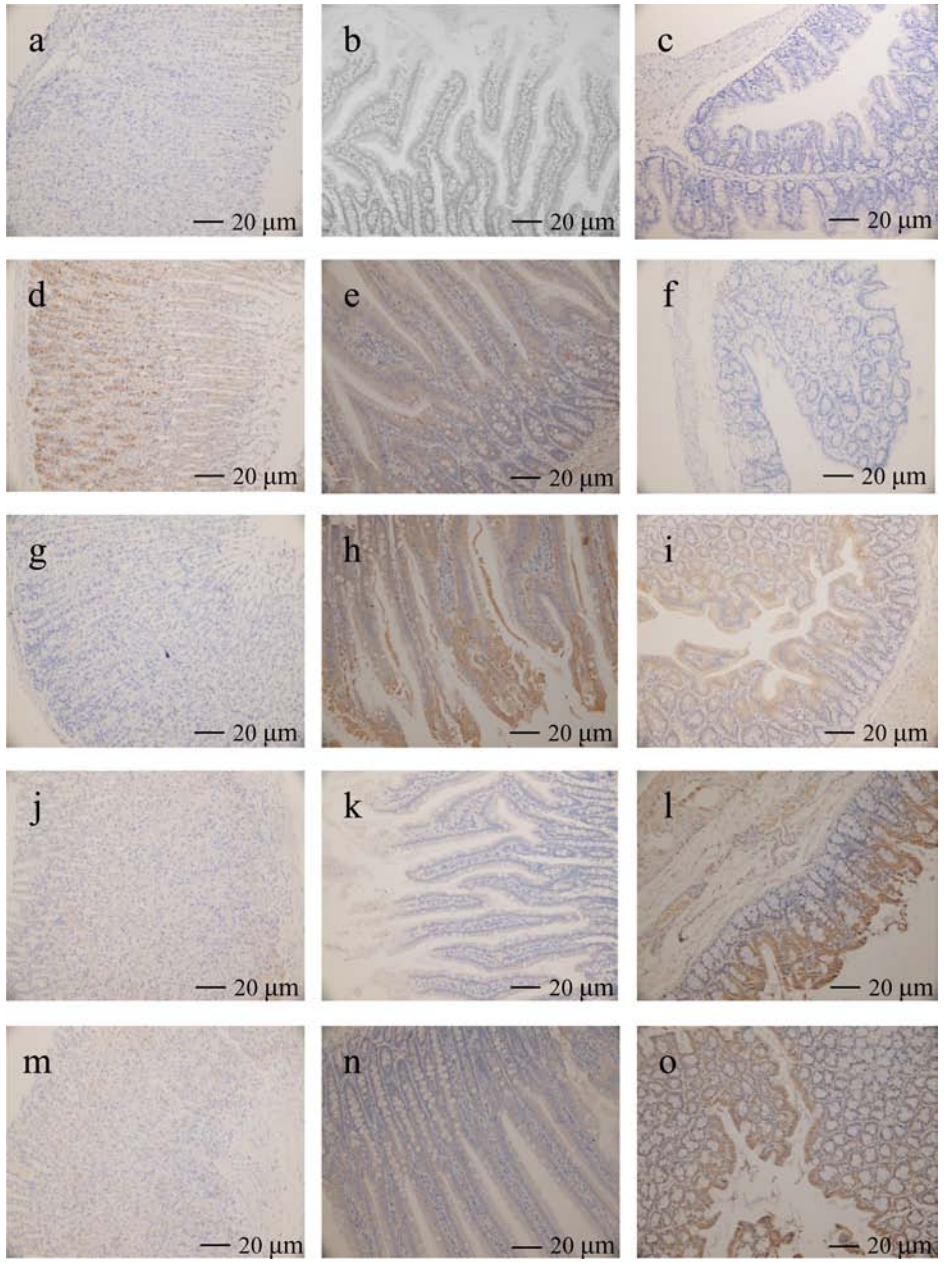

Figure 4. Insulin distribution in the gastrointestinal epithelial tissues of rats after administration of the RS3 film-coated microparticles for different times: (a) stomach, 0 h; (b) small intestine, 0 h; (c) colon, 0 h; (d) stomach, 2 h; (e) small intestine, 2 h; (f) colon, 2 h; (g) stomach, 8 h; (h) small intestine, 8 h; (i) colon, 8 h; (j) stomach, 24 h; (k) small intestine, 24 h; (l) colon, 24 h; (m) stomach, 30 h; (n) small intestine, 30 h; (o) colon, 30 h.

By the color image analytic system IPP, the optical density of insulin could be determined, and the result is shown in Table 2. Before administration, no insulin was determined in the stomach, small intestine, and colon of the rats. At 2 h after administration, a small amount of insulin was released in the stomach and small intestine. Then, the microparticles reached the small intestine and released insulin at 8 h, as shown by a high optical density of insulin determined in the small intestine and a slight optical density of insulin in the colon. At 24 h after administration, the optical density of insulin in the colon reached the highest value (0.57 ± 0.02). When the administration time reached 30 h, a low optical density of insulin was determined in the small intestine, but the optical density of insulin was maintained at a high level, indicating a

large amount of insulin released in the colon. These results showed that the RS3 film-coated microparticles could target insulin to the colon.

In Vivo Bioactivity of Insulin-Loaded RS3 Film-Coated Microparticles. In the treatment of diabetes mellitus, steadily decreasing the plasma glucose concentration is important to the patients. The fluctuation of plasma glucose concentration in the therapeutic process could make the patients suffer from glycopenia and glycemic excursion, which might lead to diabetic complications.[42] In this study, the plasma glucose concentration and corresponding plasma insulin concentration of the different type II diabetic rat groups with different treatments at different postadministration times were investigated, and the results are presented in Table 3.

It can be seen from Table 3 that the plasma glucose concentration of the type II diabetic rats (negative control group) without insulin treatment was higher (18.6−29.7 mmol/L) than those of the positive control group, subcutaneously injected with commercial long-acting insulin, and the test groups which were fed by the RS3 film-coated microparticles with the same insulin load through an oral route. Although theoretically endogenous insulin could still be produced in the type II diabetic rats, the plasma insulin concentration was too low to control the plasma glucose level. Therefore, the plasma glucose concentration of this group remained higher during the whole monitoring period (30 h).

For the insulin-injected (positive control) group, from 2 to 6 h after injection, there was a sharp increase (from 39.06 ± 4.32 to 493.25 ± 34.54 mU/L) in the plasma insulin concentration, accompanied by a sharp decrease (from 19.5 ± 1.5 to 6.2 ± 0.5 mmol/L) in the plasma glucose concentration. The percentage of decrease in the plasma glucose concentration was 74.2 ± 0.8% from the beginning (0 h) to 6 h (Figure 5a). Although a strong hypoglycemic effect was observed between 6 and 24 h after injection in the insulin-injected group rats (Figure 5a), a glycopenia (an abnormally low plasma glucose level of 3.4 ± 0.4 mmol/L) occurred at 12 h after injection when a maximum plasma insulin concentration of 667.79 ± 68.34 mU/L was reached. After that, the plasma glucose concentration experienced a rapid increase.

After the RS3 film-coated microparticles containing 25 U/kg insulin were orally administered, a high level of the plasma

insulin concentration could be maintained from 6 h after oral administration as well; furthermore, for a longer period of time (up to 30 h) compared with the trend shown by the insulin-injected (positive control) group. A moderate hypoglycemic effect was observed at 6 h after oral administration but the plasma glucose concentration was still higher than that of the insulin-injected group at the same time. There was a 47.8 ± 1.6% decrease in the plasma glucose concentration from 0 to 6 h when the plasma insulin concentration was increased to 196.80 ± 19.10 mU/L (Figure 5a), indicating that some insulin released from the RS3 film-coated microparticles had entered the colon. At 8 h after oral administration, the plasma glucose concentration was decreased to 7.2 ± 0.4 mmol/L, and there was a 68.3 ± 1.3% decrease from the beginning (0 h) (Figure 5a). A significant hypoglycemic effect was shown from 8 to 26 h after oral administration of the RS3 film-coated insulin-loaded microparticles (Figure 5a). Although the plasma glucose concentration increased to 15.7 ± 0.6 mmol/L at 30 h after oral administration, it was still much lower than that of the insulin-injected group rats (21.6 ± 0.6 mmol/L). Furthermore, no glycopenia was observed between 8 and 26 h (total 18h) after oral administration and the hypoglycemic effect was slowly but steadily maintained for a long time (Figure 5a), suggesting that insulin could be well protected by the RS3 film-coated microparticles from the degradation by the various proteolytic enzymes in the upper digestive tract and therefore the colon-targeting controlled release of insulin was achieved. The results here show that the RS3 film-coated microparticles could target insulin to the colon and could maintain a sustainable release of insulin, which would not lead to hypoglycemia and glycemic excursion. Compared with that of the insulin-injected group, the relative insulin bioavailability (B_{rel}%) of the RS3 film-coated microparticles containing the same insulin dosage after oral administration was 88.2 ± 1.2% (Table 3), and the relative pharmacodynamic bioavailability (F_{rel}%) was as high as 97.5 ± 1.6% (Table 4).

Experiments were further carried out to investigate the effect of dosage of oral administration of the RS3 film-coated microparticles received by the type II diabetic model rats on the change in the plasma glucose concentration, and the results are shown in Table 4. The hypoglycemic effect was further increased by an increase in the dosage of oral administration. It can be seen that the plasma glucose concentration declined to a lower range (<8 mmol/L) at 10 h after oral administration of the low-dose microparticles and was kept within the lower range for another 14 h (seen from Figure 5b). The medial-dose group experienced a steady decrease in the plasma glucose concentration from 8 h after oral administration, which was a little more rapid than that of the low-dose group. In contrast to those of these two groups, the plasma glucose concentration of the high-dose group decreased more rapidly within 2−10 h after oral administration (P < 0.01) and kept within the lower range from 8 to 30 h (for a total of 22 h) (seen from Figure 5b). The maximum percentages of decrease in the plasma glucose concentration of the low-dose microparticles group, medial-dose group, and high-dose group were 76.0 ± 1.1, 78.0 ± 2.0, and 82.8 ± 0.6%, respectively (Figure 5b). These results indicate that the insulin plasma concentration was related to the dosage of administration. An increase in the dosage of oral administration of insulin could lead to a remarkable decrease in the plasma glucose level. Compared with the insulin-injected group, the relative pharmacodynamic bioactivities (F_{rel}%) of insulin in the high-dose microparticles group, medial-dose microparticles group, and low-dose microparticles group were 115.1 ± 1.3, 97.5 ± 1.6, and 88.2 ± 4.0%, respectively (Table 4). In conclusion, the RS3 film-coated microparticles can protect the insulin from enzymatic degradation in the upper digestive tract, prolong the insulin release time, and enhance the hypoglycemic effect. The plasma glucose concentration of the diabetic model rats was decreased steadily by using the RS3 film-coated microparticles for the delivery of insulin. Thus, this study demonstrates the potential of the RS3 film-coated microparticles for the colon-targeting delivery of insulin and other polypeptide or protein ingredients.

and pest insects.[4] The breakdown products of glucosinolates include allyl isothiocyanate (AITC), allylcyanide, and 1-cyano-2-hydroxy-3-butene, which have also been proposed for fumigation of stored product pests because of the volatile nature of these compounds.[3] Oriental mustard, *B. juncea*, has been developed into a biopesticide that can control nematodes, a pest that leads to $78 billion U.S. in crop losses. AITC is the principal product formed from allylglucosinolate (sinigrin) that is found in *B. carinata*, *B. juncea*, and *B. napus*, with the highest concentrations found in the seeds of *B. juncea*. The seeds and bran or husk contain 5 and 2% sinigrin, respectively. Indian mustard, *B. juncea*, contains glucosinolates that were shown to reduce herbivore feeding and the associated damage to the plant.[14] The focus of the current project was to extract these known compounds for biopesticide use through an alternative process, thermochemical conversion.

Prior to this study, it was determined that many natural products, including glucosinolates, are stable at moderately high temperatures. Pyrolysis is the thermochemical process that can convert abundant agricultural biomass residues into gases, bio-oils, and char by heating under the absence of oxygen, and the products from pyrolysis are recognized as a CO_2-neutral alternative compared to fossil fuels.[15] The use of these end products includes fuels, chemicals, and fertilizers. Previous research by our group determined that pyrolysis products produced from a variety of crop residues are active as pesticides, and the chemical content was analyzed. Bio-oil from tobacco stalks and leaves,[15,16] tomato leaves and stalks,[17] coffee grounds,[18] and cellulose, hemicellulose, and lignin[19] had antimicrobial and insecticidal activity. The separation of the bio-oil components responsible for pesticidal activity has identified many small molecules, including phenols and their derivatives. However, these compounds may not be desirable for crop protection because of the broad toxic effects of phenol derivatives.[20]

For this reason, the current project focused on specific compounds and biomass with known pesticidal properties and applied pyrolysis as a unique method for separation and isolation. In the present study, dried straw from *B. napus*, *B. carinata*, and *B. juncea*, as a potential source of the known anti-herbivore compounds and as a source of other insecticide material, was converted by thermochemical means through the process of fast pyrolysis. The resulting bio-oils were evaluated as a source of material for pesticide use and then further fractionated to isolate the active compounds. The hypothesis of the project was that glucosinolates or isothiocyanates present in the Brassicaceae straw material would contribute to the insecticidal activity of extracts. In contrast, it was other compounds, including fatty acids, hexadecanoic and octadecanoic acids, that were isolated in the active fractions and determined to be potentially responsible for both acute toxicity and feeding deterrence.

MATERIALS AND METHODS

Biomass and Insects. The canola *B. napus* and mustard *B. juncea* and *B. carinata* straw were collected from Agriculture and Agri-Food Canada (AAFC), Saskatoon, Saskatchewan, Canada, research fields in October 2008 (batch 1). In 2010, *B. juncea* was collected from the same research fields to provide a second year of biomass for a comparison to the 2008 findings (batch 2). The field-dried straw was ground using a blender/mixing mill and sieved to a Sauter mean diameter of 60 μm for pyrolysis.

Colorado potato beetle (CPB), *Leptinotarsa decemlineata* Say (Coleoptera: Chrysomelidae), was maintained without exposure to insecticides for over 100 generations at the AAFC, London, Ontario, Canada, laboratory. The colony was reared at an average temperature of 25 °C, 50% relative humidity (RH), and a photoperiod of 16:8 light/dark on greenhouse grown potato plants (var. Kennebec).

Bioassay Method. A potato leaf disc bioassay was used to test the insecticidal activity of the original bio-oil, and extracts were prepared through aqueous and solvent separations or high-performance liquid chromatography (HPLC) fractionation. A 50 μL sample of bio-oil extract was spread on the top of a 4 cm diameter potato leaf disc, and a 100 μL sample of bio-oil extract was spread on the bottom of the leaf disc. All leaf discs were held in the fume hood for 20 min to ensure adequate drying before transferring the disc to a 4.25 cm Gelman Petri dish with a moistened (30 μL of water) filter paper to maintain humidity. Control leaf discs were treated with the same volume of reverse osmosis (RO) water or acetone as a check for the aqueous- or organic-phase bio-oil, respectively. Five first instar CPB larvae were placed on each leaf disc, and the Petri dishes were put into a holding chamber for 3 days (25 °C, 50% RH, and 16:8 light/dark). All trials were repeated 3 times. Mortality and leaf consumption was assessed at 24, 48, and 72 h. Fatty acid, octadecanoic and hexadecanoic acids, and methyl ester bioassays were conducted with similar volumes of each compound dissolved in acetone at 1 and 10 mg/mL concentrations and applied to potato leaf discs, as described above.

Pyrolysis and Bio-oil Preparation. The canola and mustard bio-oils were produced by pyrolysis at 300 and 500 °C. Bio-oil produced in the first batch was from all three *Brassica* species, while the second batch was only *B. juncea* bio-oil. Further purification of the aqueous fraction of the first batch mustard straw bio-oils focused on *B. juncea* bio-oil because of the greater quantities of dry *B. juncea* bio-oil available for testing. Pyrolysis was carried out using a fluidized-bed pilot plant with a 0.078 m diameter atmospheric fluidized-bed reactor, as described by Booker et al.[15] The dried, ground straw was injected into the reactor and produced vapors that exited at the top of the reactor and were collected in a bio-oil-condensing system consisting of a cyclonic condenser (aqueous and organic phases) immersed in chilled water and an electrostatic precipitator (ESP) that charged fine droplets escaping from the condenser and then used an electric field to collect them. The bio-oil collected from the condenser contains both polar and nonpolar compounds, while the ESP bio-oil is one-phase, which contains nonpolar compounds that dissolves in acetone. The condenser and ESP were weighed before and after each run to obtain an accurate liquid yield. The amount of bio-oil collected in the condenser and ESP was typically greater after 500 °C pyrolysis compared to 300 °C. The 500 °C pyrolysis of ground *B. juncea* straw, the condenser, and ESP yields were 24 and 14%, respectively, for a total yield of 38% (all reported yields are on a mass basis). Reducing the pyrolysis temperature to 300 °C decreased the condenser and ESP yields to 17 and 6%, respectively, for a total yield of 23%. The same reactor conditions yielded greater amounts of bio-oil when tobacco leaf and coffee grounds were pyrolyzed at 500 °C, a 43% yield,[15,18] and similar yields were obtained with tobacco leaf using a batch or slow pyrolysis.[21]

The bio-oil from the condenser was passed through a 9 cm diameter, qualitative filter paper (Whatman, U.K.) and then separated into aqueous and organic phases. Filtering removed solid material (char and other precipitates) that was not soluble in either water or organic solvent. All three phases (condenser aqueous and organic and ESP phases) were dried and then redissolved in either water (aqueous phase) or acetone (organic and ESP phases) to make a solution with a concentration of 30 or 50 mg/mL. The bioactivity was tested by the CPB–potato leaf dip bioassay.

Solvent Extraction. A selected bio-oil phase, 3 g, was separated by mixing equal parts water and dichloromethane (DCM) (the ratio of bio-oil/solvent was 1:50). A residue that did not dissolve in water, ethanol, methanol, or DCM was partially dissolved in acetone. When tested with the insect bioassay, no activity was observed with this layer. The original bio-oil phase, fraction A, was separated into the water phase, fraction B, and the DCM phase, fraction C (Figure 1). Fractions B and C were evaporated to dryness at 50 °C and redissolved with water (fraction B) and acetone (fraction C) to make a solution of 30

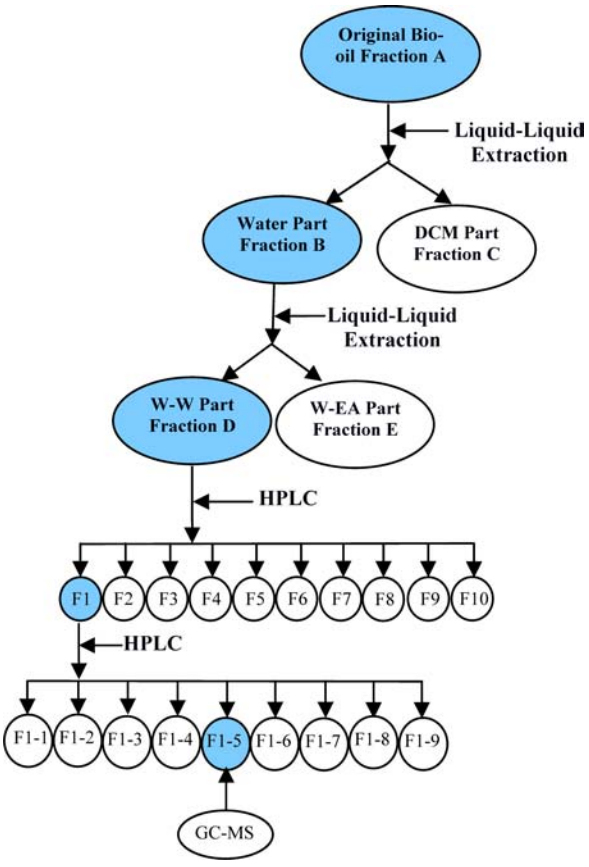

Figure 1. *Brassica* bio-oil purification diagram. All bio-oil phases and liquid−liquid separations colored blue indicate separations and fractions that caused high CPB larval mortality and/or feeding deterrence.

mg of dried B or C/mL, respectively, and the bioactivity was tested by the CPB−potato leaf disc bioassay.

The batch 1 bio-oil fraction B was further separated with water and ethyl acetate (EA) using equal parts of each (1:50 bio-oil/water−solvent) to create fraction D (water−water phase) and fraction E (water−EA phase). According to the bioassay results of these fractions, only fraction D was considered for further fractionation and purification. The second batch bio-oil fraction B was not separated by water−EA but freeze-dried at −80 °C overnight, and the final weight and concentration were calculated. Tests with the insect bioassay were performed with 30 and 50 mg/mL concentrations redissolved in water. The batch 2 aqueous fraction B for both the 300 and 500 °C bio-oils was measured in a preweighed vial and dried using a stream of nitrogen. The samples were redissolved in water to a concentration of 50 mg/mL and tested with the insect bioassay.

Gas Chromatography−Mass Spectrometry (GC−MS) Analysis. A HP 6890 Series gas chromatography system with a 5973 mass selective detector was used to analyze the various extracted bio-oil fractions. The experiments were performed on a HP-5MS, 30 m column, with an inner diameter of 0.25 mm and a film of 0.25 μm (Agilent Technologies). A 1 μL sample with a pulsed splitless injection at 25 psi until 0.5 min was followed by purge flow to split vent 40 mL/min at 1 m. The injector and auxiliary temperatures were maintained at 300 °C. The oven temperature began at 60 °C for 2 min, then was increased at 10 °C/min to 280 °C, and was held for 6 min. A mass/charge scan range of 50−300 at a rate of 2.98 scans/s was used.[16] The National Institute of Standards and Technology (NIST) 2008 library was used to identify the peaks found in the GC−MS chromatograms for the *Brassica* bio-oil liquid−liquid phases. A total of 10 standards were obtained to confirm the presence of the phenols previously found in bio-oil fractions.[16] These included phenol, 3-methylphenol, 4-methylphenol, 4-ethylphenol, 2-methylphenol, indole, D-limonene, 2,4-dimethylphenol, 3,4-dimethylphenol, and 2,3-dimethylphenol.

HPLC Fractionation and Isolation: Purification for Aqueous Fraction D. To further separate the chemical components in the batch 1 bio-oil fraction D, an Agilent 1200 Series HPLC was used with a Waters symmetry semi-preparative C18 column (7 μm, 7.8 × 300 mm). This HPLC instrument was equipped with a photodiode array detector and ChemStation software, which was used for the data acquisition and analysis. Injections (200 μL) were made using an Agilent 1200 autosampler. The binary mobile phase was composed of water and acetonitrile (AcN). The flow rate was kept constant at 3 mL/min for a total run time of 70 min. The system was run with the following gradient program: 100% water was run for 10 min, then linearly changed to 80% water/20% AcN over 10 min, then linearly changed to 50% water/50% AcN over 25 min, then linearly changed to 100% AcN over 5 min, where it was held for 10 min, and then brought back to 100% water in 1 min, where it was held for 9 min. The time-based trigger mode was used to collect 2 min fractions starting at 2 min. The concentration of fraction D was 30 mg/mL with 50 injections for a total of 10 mL of fraction D. The 34 fractions collected were combined into 10 subfractions based on chromatogram peak occurrences (Figure 1). All subfractions were evaporated to dryness, and then 10 mL of distilled water was added to redissolve samples for use in the leaf disc bioassay.

Purification of Aqueous Subfraction F1. According to the bioassay results, the most polar fraction, F1, was the most active. Further subfractionation was used to resolve the F1 compounds with the same semi-preparative column as above. Samples were run isocratically with 98% water/2% AcN for a total run time of 20 min. The injection volume was 100 μL, and 50 injections were run. Between 1 and 7 min, the flow rate was linearly decreased from 1 to 0.7 mL/min and held at 15 min. The trigger mode of the collector was peak-based (from 8.5 to 11 min) and time-based (from 11 to 15 min, with time slices of 1 min). The purification of F1 produced only five peaks, and nine fractions were collected (Figure 1). All fractions were evaporated to dryness, and 5 mL of water was added to redissolve for the bioassay. The insecticidal activity was found primarily in fraction 1-5 and partly in fraction 1-4.

Aqueous F1-5 Subfractionation. To isolate the individual peaks in fraction F1-5, a Water's amino semi-preparative column was used (Nova NH_2, 4 μm, 7.8 × 250 mm) to collect the F1-5 fractions. A 100 μL injection volume for a total of 40 injections was used, and the flow rate was 3 mL/min for a total run time of 26 min. The system was run with the following gradient program: 5% water/95% AcN isocratic for 3 min, then increased to 90% water/10% AcN at 15 min, and then brought back to 5% water/95% AcN in 1 min, where it was held for 10 min. The trigger mode of the fraction collector was peak-based (from 4 to 9 min, with the maximum peak duration of 1 min) and time-based (from 14 to 26 min, with time slices of 2 min). This purification of F1-5 with the same program produced four peaks collected over 10 fractions, which were dried and then redissolved into 4 mL of water.

GC−MS Analysis. The aqueous fractions collected from the amino semi-preparative column were analyzed using a 7890A GC system (5975C MSD, Agilent Technologies) with a HP-5MS, 30 m × 250 μm × 0.25 μm, column (Agilent). The oven temperature began at 70 °C for 5 min and then increased at 5 °C/min to 290 °C, where it was held for 10 min. A mass/charge scan range of 40−1050 was used at a rate of 1.49 scans/s. Samples were prepared by drying 20 μL of the 50 mg/mL bio-oils in GC vials and preparing a 1 mg/mL solution. The bio-oil solution was filtered using a 0.45 μm nylon CHROMSPEC filter, and 100 μL of the bio-oil solution was added to a GC vial, with 10 μL of 0.2 mg/mL ribitol being added. Solutions were dried with N_2 for 5 min and derivatized by adding 80 μL of methoxyamine hydrochloride (MOX, 20 mg/mL in pyridine, Sigma) to the vial and heating at 50 °C for 1.5 h in a heating block, after which 80 μL of *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA, Sigma) was added with heating at 50 °C for 0.5 h.

Fatty acid standards, hexadecanoic (palmitic) acid (Sigma) and octadecanoic (stearic) acid (Eastman Organic Chemicals), were dissolved in acetone at concentrations of 1, 5, 15, and 50 mg/L, and

100 μL of each standard solution was added to 1.5 mL amber GC vials. To each one of the vials containing the standard solutions, 10 μL of 0.2 mg/mL ribitol was added as an internal standard. Solutions were dried with N_2 for 5 min and derivatized as described above.

Statistical Analyses. Statistical analysis was undertaken using Graphpad Prism 5.01 software, and the log-transformed and arcsine-transformed data were subjected to the general linear model procedure to test the significant differences between individual fractions using two-way analysis of variation (ANOVA) and Bonferroni post-tests.

RESULTS AND DISCUSSION

Insecticide Bioassay-Guided Separation of *Brassica* Bio-oil. The CPB bioassay determined that the batch 1 mustard straw condenser bio-oil produced at 300 °C was more active than the oil produced at 500 °C, despite the higher yield at 500 °C (data not shown). To isolate and identify the more active components, the remaining tests focused only on the 300 °C bio-oil, where the condenser bio-oil was separated into aqueous and solvent phases and compared to the ESP solvent-soluble phase.

From the bioassay results, the aqueous bio-oil phases of all three *Brassica* species collected in the condenser were just as active as the ESP solvent phase because they all produced 100% CPB mortality after 72 h at the 30 mg/mL concentration. The condenser organic phase contained less active components because there was <20% mortality for the two mustard species bio-oils (Figure 2). On the basis of these results, further

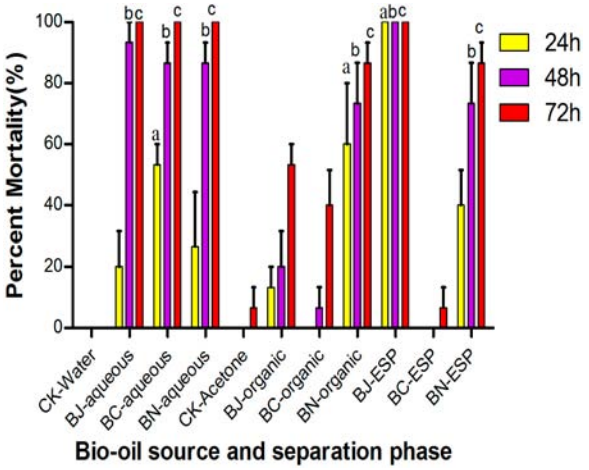

Figure 2. Percent mortality ± standard error for CPB larvae after 24, 48, and 72 h of exposure to condenser aqueous, organic, and ESP phases of *B. carinata* (BC), *B. juncea* (BJ), and *B. napus* (BN) bio-oil (30 mg/mL) produced with 300 °C pyrolysis in batch 1. Bars with a letter are significantly different ($p < 0.05$; a, b, and c for 24, 48, and 72 h, respectively) compared to control mortality at the same time.

examination focused on the aqueous *B. juncea* bio-oil phase (fraction A of Figure 1) produced in batches 1 and 2 because of its high availability. Fraction A was separated by liquid−liquid extraction with water and DCM and produced a water fraction (fraction B of Figure 1) and solvent fraction (fraction C of Figure 1). Both fractions B and C at 30 mg/mL produced significantly greater CPB mortality compared to controls after 48 h ($p < 0.05$) and reduced feeding at 24 h with relatively low mortality [degrees of freedom (df) = 14; $F = 34.1$; $p < 0.05$; Figure 3]. Fraction B was selected for further study because it produced 25% greater mortality at 30 mg/mL than fraction C (df = 14; $F = 5.1$; $p < 0.05$; Figure 3). Fraction B was further

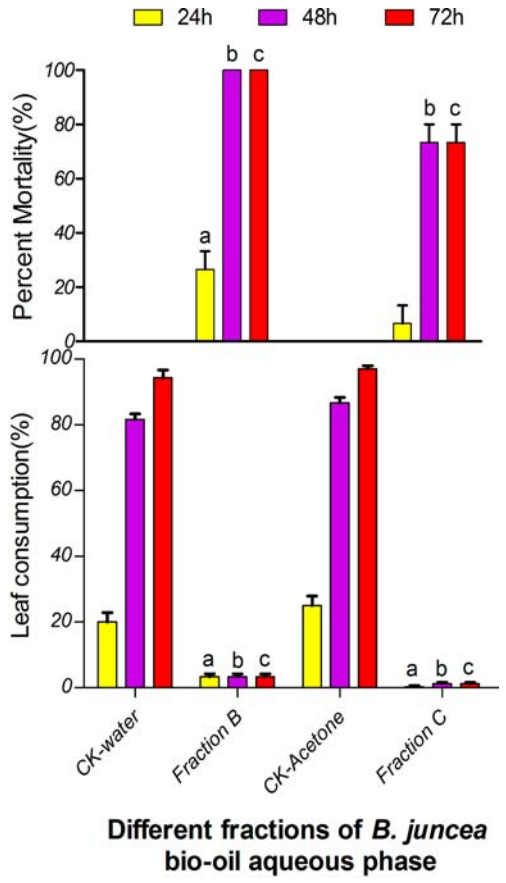

Figure 3. Percent mortality and percent leaf consumption ± standard error for CPB larvae after 24, 48, and 72 h of exposure to 3 and 30 mg/mL *B. juncea* aqueous (fraction B) and organic (fraction C) separations. Bars with a letter are significantly different ($p < 0.05$; a, b, and c for 24, 48, and 72 h, respectively) compared to control mortality and leaf consumption at the same time.

purified with water (fraction D dissolved in water) and EA (fraction E dissolved in acetone), and bioassays determined that fraction D produced 100% greater mortality at 30 mg/mL compared to fraction E (df = 16; $F = 7.3$; $p < 0.05$; Figure 4).

There was no significant difference in mortality for 30 mg/mL fraction E treatments compared to the solvent control ($p > 0.05$), but feeding was reduced at 48 h ($p < 0.001$; Figure 4). GC−MS analyses of the separated bio-oil phases for *B. juncea* batch 1 determined that fraction C contained phenols, such as 2-methoxyphenol and 2,6-dimethoxyphenol, while fraction E contained a large proportion of phenols, including catechin, *p*-dihydroxybenzene, and other benzene compounds (Table 1).

Hydroquinone, also present in fraction E, is one of several that may be considered genotoxic and mutagenic, and 1,2-benzenediol or catechol is a likely human and animal carcinogen.[20] In the redissolved condenser solid and the ESP bio-oil, phenol compounds were also predominant. All phenol derivatives are undesirable contaminants, and it would be best to avoid these types of compounds in a biopesticide because potential health and environmental problems could occur with the necessary concentrations required for insect control. Fraction D, the aqueous phase, did not contain phenol-related compounds but did contain 1,1-dimethylhydrazine, considered to be carcinogenic and a skin hazard.[20] However, this compound was not measured in the final aqueous fraction of batch 2 (Tables 2 and 3).

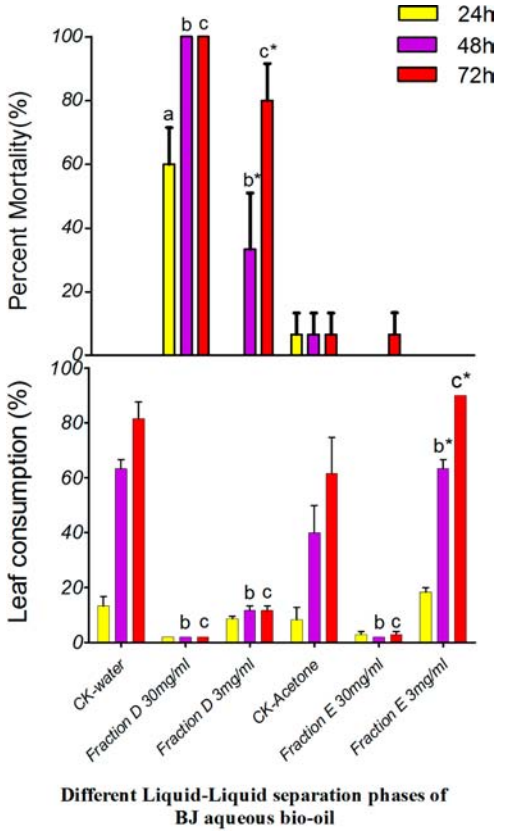

Figure 4. Percent mortality and percent leaf consumption ± standard error for CPB larvae after 24, 48, and 72 h of exposure to 3 and 30 mg/mL *B. juncea* aqueous–aqueous (fraction D) and aqueous–organic (fraction E) separations. Bars with a letter are significantly different ($p < 0.05$; a, b, and c for 24, 48, and 72 h, respectively) compared to control mortality and leaf consumption at the same time. Bars with an asterisk indicate a significant difference between treatments at the same time period within each separation phase (aqueous or solvent).

Table 1. GC–MS Analyses of Batch 1 Bio-oil Samples and Separated Fractions

sample (fraction)	compounds present in the highest concentration in samples from aqueous and solvent separated phases of the original bio-oil prepared from *B. juncea* straw
condensor liquid (fraction C)	2,6-dimethoxyphenol, 2-methoxyphenol, and 4-hydroxy-3,5-dimethoxybenzaldehyde
condensor liquid (fraction D)	1,1-dimethylhydrazine, 2-methylhexadecanal, and dimethyl sulfide
condensor liquid (fraction E)	1,2-benzenediol (catechol), hydroquinone, and 3-methoxy-1,2-benzenediol
condensor solid	2,6-dimethoxy-4-(2-propenyl)-phenol, 2,6-dimethoxyphenol, and 4-hydroxy-3,5-dimethoxybenzaldehyde
ESP	2,6-dimethoxyphenol (syringol), 2,6-dimethoxy-4-(2-propenyl)-phenol, and (*E*)-9-octadecenoic acid

In a previous work by our group,[16] much of the insecticidal and antimicrobial activities were associated with the solvent phase of the tobacco bio-oil, because of the presence of many phenol compounds, especially the dialkylated phenols. However, it was concluded that the observed pesticide activity of the bio-oil solvent fraction would require multiple combinations of the individual phenols or excessively high concentrations of individual compounds, and those phenols and their derivatives would be difficult to register because of their broad toxic effects.[20] In the present study, many similar compounds were found in the solvent phase of the *B. juncea* bio-oil collections, but fraction D did not contain these compounds, even though insecticidal activity was present. Therefore, the insecticidal activity associated with fraction D was pursued as a potential source of compounds other than phenols. Therefore, further research was conducted to isolate the active compounds and analyze for any known harmful chemicals within fraction D.

Insecticide Bioassay-Guided HPLC Fractionation of the *B. juncea* Aqueous Bio-oil Phase (Fraction D). To determine the active compounds in fraction D, further separation of the liquid–liquid phase of the *B. juncea* condenser bio-oil was accomplished by HPLC fractionation into 10 fractions. Subsequent bioassay results indicated that the most polar, fraction 1, collected between 2 and 4 min (Figure 5), produced the greatest mortality relative to the control and other nine fractions (df = 22; $F = 41.6$; $p < 0.05$; Figure 6).

Fraction 1 produced the same CPB mortality and reduced leaf consumption as the original aqueous phase (df = 22; $F = 25.5$; $p < 0.05$; Figure 6). The HPLC chromatogram for peak areas visible at 205 nm shows a number of partially resolved peaks within fraction 1 (Figure 5). To separate these peaks,

dx.doi.org/10.1021/jf500048t | J. Agric. Food Chem. 2014, 62, 3610–3618

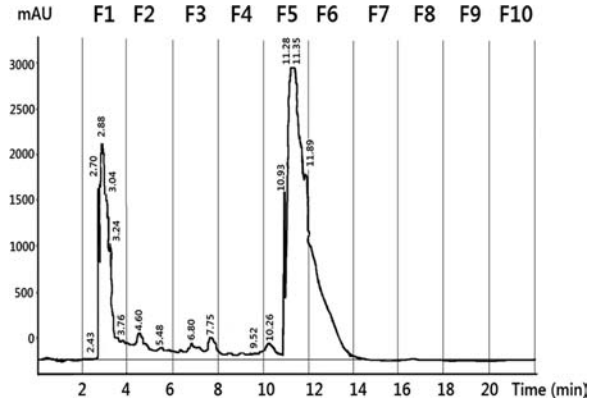

Figure 5. HPLC chromatogram showing *B. juncea* aqueous−aqueous (fraction D) subfractionation and active fraction 1.

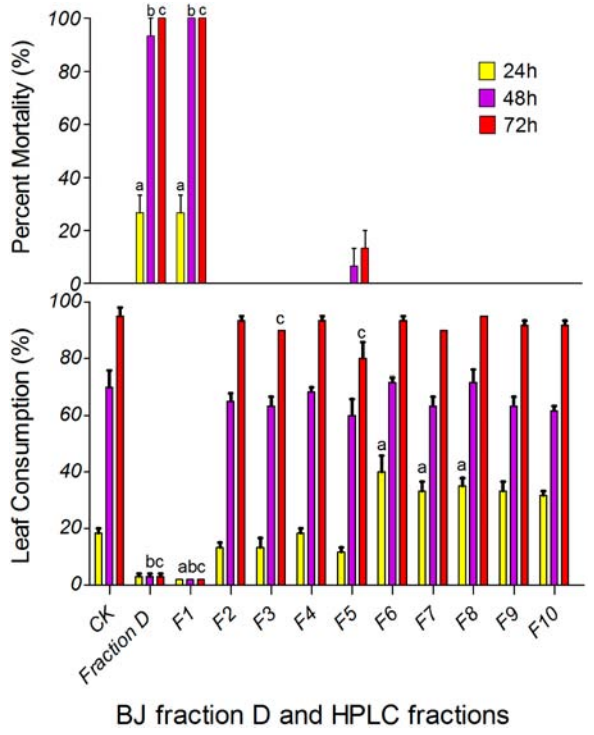

Figure 6. Percent mortality and percent leaf consumption ± standard error for CPB larvae after 24, 48, and 72 h of exposure to 10 HPLC fractions (F1−F10) of *B. juncea* aqueous−aqueous (fraction D) separation. Bars with a letter are significantly different ($p < 0.05$; a, b, and c for 24, 48, and 72 h, respectively) compared to control mortality and leaf consumption at the same time.

HPLC purification of fraction 1 (F1) was again used to isolate five peaks and nine subfractions were collected. Insecticidal activity was found primarily in subfraction 1-5 and partially in subfraction 1-4, where the 48 h CPB mortality was 53.33 and 20%, respectively (Figure 7). Again the subfraction activity was not significantly different from F1 after 72 h (df = 9 and 54; $F = 83.89$; $p > 0.05$).

Both subfractions 1-5 and 1-4 reduced leaf consumption to 5 and 13.3% after 48 h of treatment, respectively (Figure 7), an effect not significantly different to the activity demonstrated by F1 (df = 9 and 54; $F = 83.89$; $p > 0.05$). Further purification of F1-5 by HPLC using an amino column indicated the presence of four peaks, and a further 10 collections were made. The combined amino column fraction of F1-5 was analyzed using

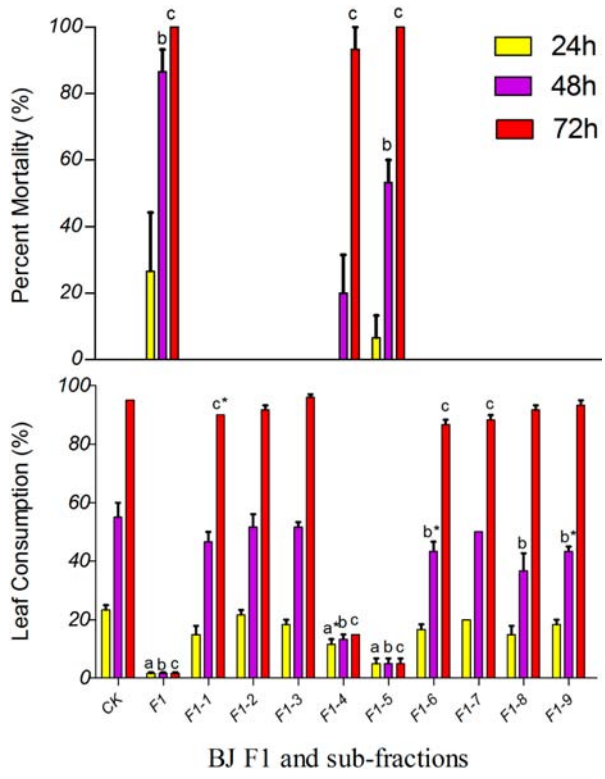

Figure 7. Percent mortality and percent leaf consumption ± standard error for CPB larvae after 24, 48, and 72 h of exposure to 10 HPLC subfractions of the *B. juncea* aqueous−aqueous (fraction D) F1 fraction. Bars with a letter are significantly different ($p < 0.05$; a, b, and c for 24, 48, and 72 h, respectively) compared to control mortality and leaf consumption at the same time. Bars with an asterisk indicate a significant difference between treatments at the same time period within each separation phase (aqueous or solvent).

the Agilent 7890A GC−MS, and three of the major peaks were identified as fatty acids, hexadecanoic and octadecanoic acids (palmitic and stearic acids, respectively), and monooctadecanoylglycerol based on the NIST 2008 (version 2.0.f) library match. Unfortunately, the concentration of each fatty acid could not be calculated; however, the batch 2 condenser aqueous samples prepared at 300 and 500 °C, as described in the Materials and Methods, were also determined to contain hexadecanoic and octadecanoic acids (panels A and B of Figure 8) among other compounds found in the 300 °C (Table 2) and 500 °C (Table 3) bio-oil aqueous fractions. These fractions were also found to have insecticidal activity at 50 mg/mL, significantly reducing leaf consumption relative to the controls (df = 3; $F = 110.6$; $p < 0.0001$; Figure 9). No difference in insecticidal activity was determined between the two temperature bio-oil fractions ($p > 0.05$), but the concentration of both fatty acids was 4−5-fold greater in the 500 °C aqueous bio-oil fraction relative to the 300 °C aqueous bio-oil fraction (254−309 versus 1023−1282 ppm). Similarly, there was no greater feeding repellency observed with the 500 °C aqueous fraction ($p > 0.05$; Figure 9). It was assumed that the fatty acids found in aqueous fractions from both 300 and 500 °C pyrolysis likely originated from the biomass and did not degrade during the pyrolysis process. However, because the concentration of both fatty acids was greater in the higher temperature bio-oil in batch 2, it is possible that these compounds are formed under pyrolysis conditions or released in greater amounts from the biomass. Unfortunately, this comparison could not be

dx.doi.org/10.1021/jf500048t | J. Agric. Food Chem. 2014, 62, 3610−3618

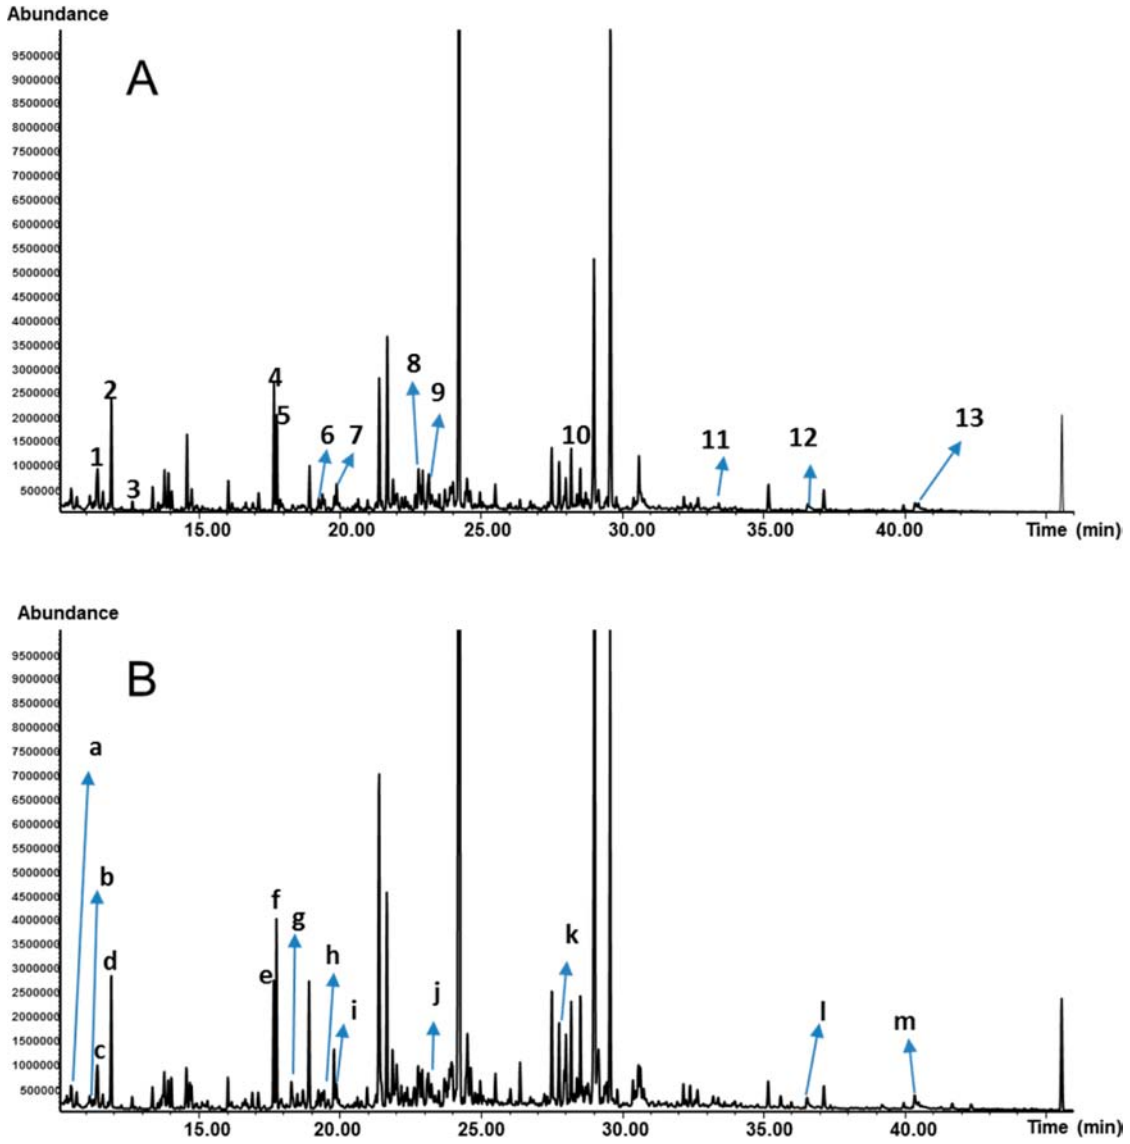

Figure 8. Total ion chromatogram (TIC) GC–MS, with 3× enhancement of the *B. Juncea* bio-oil aqueous phase: (A) fraction A produced at 300 °C pyrolysis and (B) fraction B produced at 500 °C pyrolysis (batch 2).

confirmed with the batch 1 bio-oil. Because there was no difference in the concentration between hexadecanoic or octadecanoic acids in the aqueous phase of the batch 2 condenser bio-oil at either pyrolysis temperature, this confirms that the relative amounts of each are similar under the same heating conditions. Shin et al.[22] found that octadecanoic acid was stable at 300 °C and up to 370 °C, but unsaturated fatty acids, such as oleic and linoleic acids, are less stable. This suggests that higher temperatures, such as 500 °C, would degrade fatty acids faster than 300 °C, but in this study, the short pyrolysis residence time in the bubbling-bed reactor may not be a sufficient exposure to degrade the compounds. Higher pyrolysis temperatures will create increasingly smaller compounds because the reaction breaks down large molecules present in the biomass to form gases and other compounds, such as phenols.

The presence of fatty acids in the aqueous fractions may explain the insecticidal activity, both toxicity and feeding deterrence. To confirm whether the fatty acids were active in the 1–10 mg/mL range, a bioassay with standards for both fatty acids and their respective methyl esters was used to measure the feeding deterrent effect. No significant effect on leaf consumption relative to controls was determined, even at the higher concentration ($p > 0.05$), except with the methyl ester of hexadecanoic acid at 10 mg/mL (df = 4; $F = 8.18$; $p < 0.005$; Figure 10).

Therefore, the two fatty acids are not solely responsible for the insecticidal activity observed with the batch 2 bio-oil but could have contributed to the activity observed with the aqueous bio-oil fractions generated in batch 1 (concentrations appeared higher but were not determined). Fatty acids have been documented to have insecticidal activity against a number of insect pests. As early as the 1850s, whale oil soap was found to be the cheapest and most effective insecticide for the rose chafer *Macrodactylus subspinosus*.[23] Since then, other fatty acids, such as oleic acid, lauric acid, etc., have been used to control a variety of insect pests over the years, as reviewed by Kabara.[23] More recent studies have documented that pure myristic acid at 50 $\mu g/\mu L$ produced 53% mortality with wheat weevil *Sotophilus granarius*, which were topically treated with 1 μL of solution per

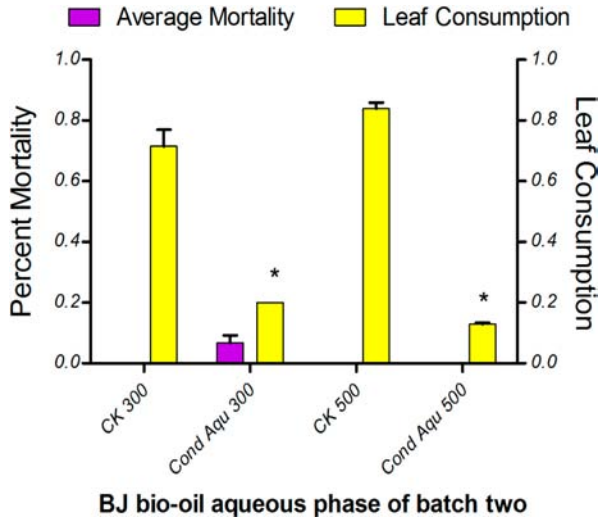

Figure 9. Percent mortality and percent leaf consumption ± standard error for CPB larvae after 72 h of exposure to 50 mg/mL *B. juncea* aqueous phase produced with 300 and 500 °C pyrolysis (batch 2). Bars with an asterisk are significantly different ($p < 0.001$) compared to respective control leaf consumption.

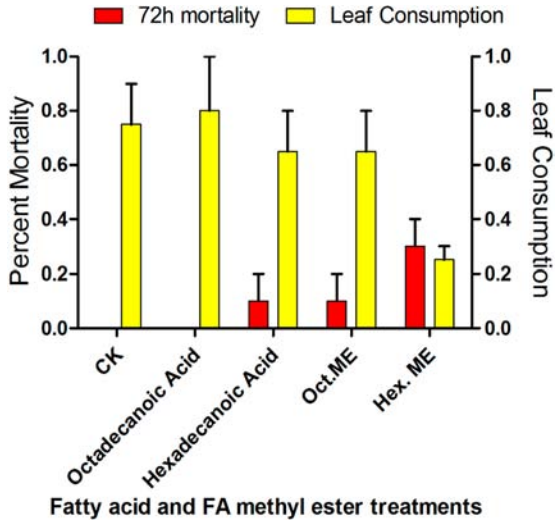

Figure 10. Percent mortality and percent leaf consumption ± standard error for CPB larvae after 72 h of exposure to 10 mg/mL hexadecanoic and octadecanoic acids and their methyl esters.

insect,[24] and that lauric acid achieved 100% mortality against cotton aphids *Aphis gossypii*, with a 0.5% (w/w) concentration.[25] In the latter case, the toxicity to the aphids was probably related to suffocation and/or desiccation through changes to the cuticle and cell permeability. Plant extracts that contain fatty acids with insecticidal activity include the Egyptian *Halocnemon strobilacium* (Chenopodiaceae).[26] The crude extract contained almost 70% fatty acids and their esters, with the largest proportion being oleic acid ester (38%) and octadecanoic acid (16%). Bioassays with individual fatty acids, linolenic and linoleic acids, were found to have similar larvicidal activity against the fall armyworm *Spodoptera frugiperda*.[27] Both linolenic and linoleic acids were found in the largest proportion in hexane extracts of *Ricinus communis* (Euphorbiaceae) leaves, 48 and 15%, respectively, while hexadecanoic and octadecanoic acids were lower (13 and 1.7%, respectively). However, as the work of Shin et al.[22] found, oleic and linoleic acids will not survive higher pyrolysis temperatures, perhaps suggesting that the hexadecanoic and octadecanoic acids would be the likely fatty acids to be found in the bio-oil. In the present study, hexadecanoic methyl ester was more active against the CPB than hexadecanoic acid or the octadecanoic methyl ester. The methyl esters of hexadecanoic acid were active against cabbage looper *Trichoplusia ni* as both toxins and repellents.[28] Herein, GC−MS analysis of the two aqueous fractions in both the 300 and 500 °C bio-oils identified many other compounds based on NIST 2008 library matches (Tables 2 and 3), a combination of which could synergize the activity of the fatty acids but was not tested. Sinigrin but not AITC was detected in most of the Soxhlet extracts of *B. carinata* seed, *B. juncea* straw, and the bio-oil aqueous phase for *B. juncea* (data not shown). However, sinigrin elutes later than fraction 1 with the HPLC method applied, and no insecticidal activity was associated with the fractions containing sinigrin; therefore, it is not responsible for the activity observed in fraction F1-5.

Conversion of the fatty acids isolated in the aqueous bio-oil fractions to methyl esters by esterification will provide a more valuable pesticide material. These interesting findings indicate that the polar phase (fraction D) of pyrolysis bio-oils is a promising use of agricultural residue biomass that can be converted by a thermochemical process. It has yet to be determined whether or not the fatty acid yield is affected by pyrolysis, because this would suggest whether the starting material is crucial to the final products. However, plant material that contains high levels of fatty acids to begin with affords a more promising source of biomass to extract these compounds for insecticidal application. Considering the possible toxic compounds produced during pyrolysis, any future pyrolysis bio-oil products should be tested for non-target and environmental toxicity prior to their recommendation for use in agriculture.

perspective, and according to our knowledge hydrotropic pretreatment is an emerging technology.

MATERIALS AND METHODS

Materials. Sugar cane bagasse was obtained from Centro de Tecnologia Canavieira, Brazil. For removal of sucrose, bagasse was washed with tap water until the washing liquor was colorless and thereafter stored in a freezer room. Sodium hydroxide (NaOH), 30% hydrogen peroxide (H_2O_2), and sodium xylene sulfonate (SXS) with 90% purity as hydrotropic solvent were purchased from Fluka. Commercial enzymes cellulase (Celluclast 1.5 L) and β-glycosidase (Novozyme 188) were kindly supplied by VTT Technical Research Centre of Finland. The activities of the cellulase and the β-glycosidase were 75 FPU/mL and 5900 nkat/mL, respectively. All chemicals and enzymes were used as received without further purification.

Pretreatment Methods. *Dilute Alkaline Pretreatment.* Bagasse was treated by 0.2 g/g (substrate) NaOH at 60 °C in a water bath for 2 h. The liquid/solid ratio (w/w) was 10:1. After pretreatment, the residue of bagasse was washed until the pH was neutral.[25]

Sodium Hydroxide–Hydrogen Peroxide Pretreatment. Bagasse was treated by same dosage of NaOH as alkaline treatment together with 0.25 g/g (substrate) H_2O_2 in a 500 mL flask. The flask was put on a magnetic stirrer at 150 rpm for 24 h. To avoid decomposition of H_2O_2, the reaction was carried out in a dark place at room temperature. The liquor/wood ratio (w/w) was 10:1. Upon completion, the substrate was washed until neutral and then stored in a freezer.[26]

Hydrotropic Pretreatment. Bagasse was pretreated by 30% (w/v) SXS and 0.17% (w/v) formic acid in a revolving digester under the controlled temperature of 160 °C for 40 min; the liquor/wood ratio (w/w) was 10:1, and the initial pH was 3.5 ± 0.05. After pretreatment, the substrates were disintegrated and washed with 5% (w/w) NaOH solution and then washed by tap water until the washing liquor was colorless.

After pretreatments, all treated samples were collected and weighed for further analysis and tests.

Enzymatic Hydrolysis of Pretreated Samples. The pretreated samples were hydrolyzed by cellulase at a dosage of 20 FPU/g substrate together with 300 nkat β-glycosidase/g substrate at 50 °C in pH 5.0. Consistency was 20 mg/mL (w/v). Acetic acid buffer was used to modify the pH. The reaction time interval was 2, 6, 24, 48, and 72 h, respectively. The enzyme hydrolysis was ended by boiling for 10 min. After cooling with cold water, the hydrolysate was centrifuged at 1730*g* (3000 rpm) for 20 min. The supernatant was collected for sugar analysis.

Chemical Composition Analysis. The reference sample and pretreated samples were first extracted with acetone for 5 h in a Soxhlet device. The extractive free samples were used for chemical composition analysis. Glucan, xylan, and lignin content of untreated and pretreated biomass were determined following the NREL procedure for the determination of structural carbohydrates and lignin in biomass.[27] The loading yield after pretreatments (Y_{solid}), the recovered ratio of glucan or xylan ($R_{glucan/xylan}$), and the delignification rate ($R_{delignification}$) were calculated by the following formulas:

$$Y_{solid}\ (\%) = \frac{\text{pretreated biomass (g)}}{\text{original biomass (g)}} \times 100 \quad (1)$$

$$R_{glucan/xylan}\ (\%) = \frac{Y_{solid} \times C_{glucan/xylan\ of\ pretreated\ biomass}}{C_{glucan/xylan\ of\ original\ biomass}} \quad (2)$$

$$R_{delignification}\ (\%) = 1 - \frac{Y_{solid} \times C_{lignin\ of\ pretreated\ biomass}}{C_{lignin\ of\ original\ biomass}} \quad (3)$$

Glucan and xylan of both enzyme and sulfuric acid hydrolyzed pretreated samples (45 μm syringe film filtered) were detected by using a HPLC system (model 1200, Agilent, USA) equipped with a Bio-Rad Aminex HPX-87H column (300 mm × 7.8 mm) and refractive index detector. The column was operated at 55 °C with 0.005 mol/L H_2SO_4 solution as the mobile phase at a flow rate of 0.5 mL/min. Sample injection volume was 20 μL. Quantitative analysis was performed using a calibration with external standards of known concentrations. For each experiment on the pretreatments and the enzymatic hydrolysis, at least three replicates were made, and the average of the results was reported. The glucan and xylan yield after enzymatic hydrolysis was calculated on the basis of the glucan and xylan contents of the initial raw material.

Topochemical Characterization. Untreated and treated biomasses were evaluated with field emission scanning electron microscope (FE-SEM) LEO 1530 Gemini equipment. Samples were previously coated with carbon using a coating system equipped with a rotating base. Images were obtained with 500× and 15000 × magnifications.

X-ray spectroscopy (XPS) spectra were obtained with a Physical Electronics PHI Quantum 2000 ESCA instrument equipped with a monochromatic Al Kα X-ray source. Low-resolution spectra were measured in 3.5 min with a pass energy of 187 eV and high-resolution spectra of C_{1s} peak in 9 min using a pass energy of 23 eV. At least four different spots were measured on each sample. The O/C ratios were calculated from the low-resolution XPS spectra. Both acetone-extracted samples (Soxhlet, acetone/water mixture 9:1 (v/v), overnight) and unextracted samples after freeze-drying were analyzed. The surface coverage by lignin (S_{lig}), carbohydrates (S_{carb}), and extractives (S_{ext}) were calculated according to the following equations using the average O/C ratio value:[17,19,24]

$$S_{ext} = (O/C_{extracted} - O/C_{before\ extraction}) / (O/C_{extracted} - O/C_{extractives}) \times 100 \quad (4)$$

$$S_{lig} = (O/C_{extracted} - O/C_{carbohydrate}) / (O/C_{lignin} - O/C_{carbohydrate}) \times 100 \quad (5)$$

$$S_{carb} = 100 - S_{lig}\% \quad (6)$$

$$O/C_{carbohydrate} = 0.83, \quad O/C_{lignin} = 0.33, \quad O/C_{extractives} = 0.09$$

ATR-FTIR was used to analyze the samples after pretreatment. Small amounts of freeze-dried samples after pretreatment were placed on the diamond probe of Nicolet IS 50 FTIR (software OMNIC 7.3, wavenumbers in cm^{-1}). Thirty-six scans were acquired for each sample, recorded from 4000 to 400 cm^{-1}.

Time-of-flight secondary ion mass spectrometry (ToF-SIMS) analysis was performed with a Physical Electronics ToF-SIMS TRIFT II spectrometer on the pretreated and enzymatically

dx.doi.org/10.1021/jf500582w | J. Agric. Food Chem. 2014, 62, 3619−3625

hydrolyzed samples. All of the samples were freeze-dried after the acetone extraction. The instrument was equipped with a primary ion beam of $^{69}Ga^{+}$ liquid metal ion source and an electron flood gun for charge compensation. Positive secondary ions were detected using 25 kV acceleration voltage in 8 min. At least three measurements were done on each sample.

RESULTS AND DISCUSSION

Chemical Composition of Bagasse after Pretreatments. The chemical compositions of bagasse after dilute alkaline, alkaline peroxide, and hydrotropic pretreatments are given in Table 1. With dilute alkaline, alkaline peroxide, and hydrotropic pretreatments, the total amount of lignin in bagasse was reduced from the original 17.7 to 6.4, 8.4, and 6.3%, respectively. The pretreatment technology was applied before enzymatic hydrolysis process to overcome the limits for enzyme access to the polysaccharides, where cell wall lignin is one of the main causes of recalcitrance.[16,17] Lignin was removed as expected by all three of the used pretreatment methods, typically by hydrotropic pretreatment. Another significant difference was detected between the methods with regard to their impact on the bagasse carbohydrates. As shown in Table 1, hemicelluloses were less degraded by diluted alkaline and alkaline peroxide pretreatment than by hydrotropic pretreatment. However, hydrotropic pretreatment could remove both lignin and hemicelluloses. For instance, arabinan was almost totally degraded, and xylan was efficiently removed, whereas only slightly lower glucan was recovered in the hydrotropic process compared with other methods used (Table 1). As reported, acid pretreatment and steam explosion could also remove hemicelluloses, but acid pretreatment may cause equipment corrosion,[6] whereas steam explosion may require high capital cost, particularly for large-scale production.[8] Although alkali-based pretreatment can remove lignin, high capital cost in the chemical recovery system or wastewater treatment may be needed. Therefore, hydrotropic pretreatment was appropriate for removing xylose and lignin from bagasse, and it was an efficient technology to remove mainly hemicellulose in comparison with acid pretreatment and steam explosion. Certainly, more extensive studies of hydrotropic pretreatment (e.g., the optimization of pretreatment conditions, economic evaluation for overall process) for different feedstocks should be performed in the future. Furthermore, the recovery of lignin and xylan from hydrotropic pretreatment process can be a promising biorefinery application for producing high-value-added chemicals and biomaterials.[14,15]

Surface Chemical Composition after Pretreatment Analyzed by XPS. The elemental composition of the sample surfaces was investigated by XPS. The main constituents were carbon and oxygen. In the reference sample (Bref), additionally small amounts of N, Al, and Si were detected in the XPS low-resolution spectra. These were probably originated from the native constituents in sugar cane. In Table 2, the O/C ratios before and after sample extraction are given. As can be seen, the removal of carbon-rich material from the bagasse surface during pretreatments and, on the other hand, during the acetone extraction, is demonstrated by the increase of the O/C ratio. Furthermore, the surface coverage by lignin, carbohydrates, and extractives of bagasse after different pretreatment methods was gained from the XPS results (Table 2). After the pretreatments applied, the surface of bagasse samples contained more carbohydrates and less lignin than the reference sample. The surface coverage by lignin value of BN and Bsxs were on the same level. However, during alkaline pretreatment, together with lignin removal a notable amount of extractives was reduced from the fiber surface as well.

Table 2. Surface Chemical Composition of Bagasse after Pretreatment As Detected by XPS

sample	O/C_{ext}	O/C	S_{exts} (%)	S_{lig} (%)	S_{carb} (%)
Bref	0.68 (0.11)[a]	0.45 (0.03)[a]	38.1	31.0	69.0
BN	0.77 (0.06)	0.69 (0.03)	12.6	11.8	89.2
BH	0.84 (0.11)	0.63 (0.03)	28.6	0	100
Bsxs	0.77 (0.04)	0.61 (0.02)	24.7	11.3	89.7

[a]The standard deviation is presented in parentheses.

Table 2 also shows that the O/C value of BH after extraction was close to that of pure cellulose. However, this high O/C ratio was probably caused by oxidation of surface lignin and insertion of oxygen atoms to form carbonyl and carboxyl groups. According to the results shown in Table 1, the residual total lignin of BH was 8.4%, which was higher than that of BN and Bsxs, but the surface coverage by lignin for BN and Bsxs was >11%, whereas the BH had 0%. This was a limitation of the XPS method to assess detailed chemical changes in surface lignin. ATR-FTIR and ToF-SIMS spectrometry methods were applied here to complement XPS data.

ATR-FTIR of Bagasse after Pretreatment. The samples after pretreatment were measured by ATR-FTIR. The analysis depth of ATR-FTIR was from <200 nm to >1 μm, which was deeper than XPS (5−10 nm). The spectra are shown in Figure 1, and the bonding vibrations are summarized in Table 3.[5,10,25−32] The broad band from 3340 cm^{-1} has been reported as the O−H bond that could be found in carbohydrates and lignin, and for agriculture materials, the signal also possibly arises from the aliphatic fraction of waxes.[5,10] With the different pretreatment methods, this group did not obviously change. In Figure 1, 2896 cm^{-1} is the C—H bond in polysaccharides.[30] It was stronger in the pretreated bagasse samples. The signal at 1733 cm^{-1} is attributed to the C═O of acetyl groups in hemicellulose that was obviously shown in the untreated bagasse but not detected in BN, BH, or Bsxs samples, because of the removal of acetyl groups during pretreatment.[30] The

Table 3. Chemical Bond Assignment of ATR-FTIR for Bagasse after Pretreatments

wavenumber (cm^{-1})	vibration	source
3340	O—H stretching	water/polysaccharides
2896	C—H (CH_2) stretching	polysaccharides
1730	C═O stretching	acetyl groups of hemicelluloses
1605	C—Ph aromatic ring	lignin
1510	C═C aromatic ring	lignin
1240	C—O	guaiacyl lignin
1036	C—O—C	polysaccharides
904	C—H deformation	lignin
835	C—H out of plane	*p*-coumaric ester groups

signals at 1605 and 1510 cm^{-1} were signs of lignin, and 1240 cm^{-1} was assigned to the aryl C−O bond from guaiacyl lignin, which existed only in untreated bagasse, indicating lignin dissolution during pretreatment.[28,31] The signal at 904 cm^{-1} was assigned as the β-glucosidic bond, which was stronger in the pretreated samples because of more carbohydrate on the fiber surface,[28] and this is in agreement with the results by XPS in Table 2. The signal at 835 cm^{-1} has been reported as the ester carbonyl signal of *p*-coumaric ester groups,[31] and it was detected only in the untreated sample.

Surface Morphology after Pretreatment. The surface morphology of bagasse samples after pretreatment was investigated by FE-SEM. In Figure 2a, the reference bagasse fiber was covered by some fragments, probably fibrils created by mechanical forces during the sugar cane squeeze stage in the sugar mill. The pits in the cell wall were shown in all samples at such high magnification, 15000×. Shrinkage trace was present on alkaline-treated fiber that proved the fiber swelling caused by alkaline pretreatment in Figure 2b. Alkaline treatment could swell wheat straw fiber, leading to the increase of the internal surface,[11] and the same action to sugar cane bagasse was found. After alkaline peroxide pretreatment, some substances formed spider web-like structures covering the fiber surface in Figure 2c. A similar phenomenon was found on softwood fiber surface after mechanical refining treatment because of xylan released from the fiber wall readsorbing on the surface.[16] It was probably due to the high surface carbohydrates covering bagasse fiber, as detected by XPS (Table 2). These substances were probably released from the collapsed inner fiber wall, which is shown in Figure 2d. After hydrotropic pretreatment, the fibrils could be seen in Figure 2e. It seems that the surface cell wall was ripped off. Fibers were expanded and more pores exposed. The performance of the fiber digestibility improved by pretreatment cannot be sufficiently explained by the change of chemical composition only. The fiber structure features and cell wall damage created by the pretreatment procedure could assist the enhancement of the fiber accessibility for enzyme as well.[32,33] The factors affecting the fiber accessibility are complementing each other.

Enzymatic Hydrolysis of Pretreated Bagasse. After dilute alkaline, alkaline peroxide, and hydrotropic pretreatments, the glucan and xylan yields of bagasse were studied (Figures 3 and 4). The maximum glucan yields of bagasse samples BN, BH, and Bsxs were 78.3, 73, and 83.9%, respectively. The glucan yield achieved from low-temperature alkaline pretreatment at 60 °C for 2 h was better than that from the sodium hydroxide peroxide pretreatment at room temperature for 24 h. This was because of the lesser contents of lignin

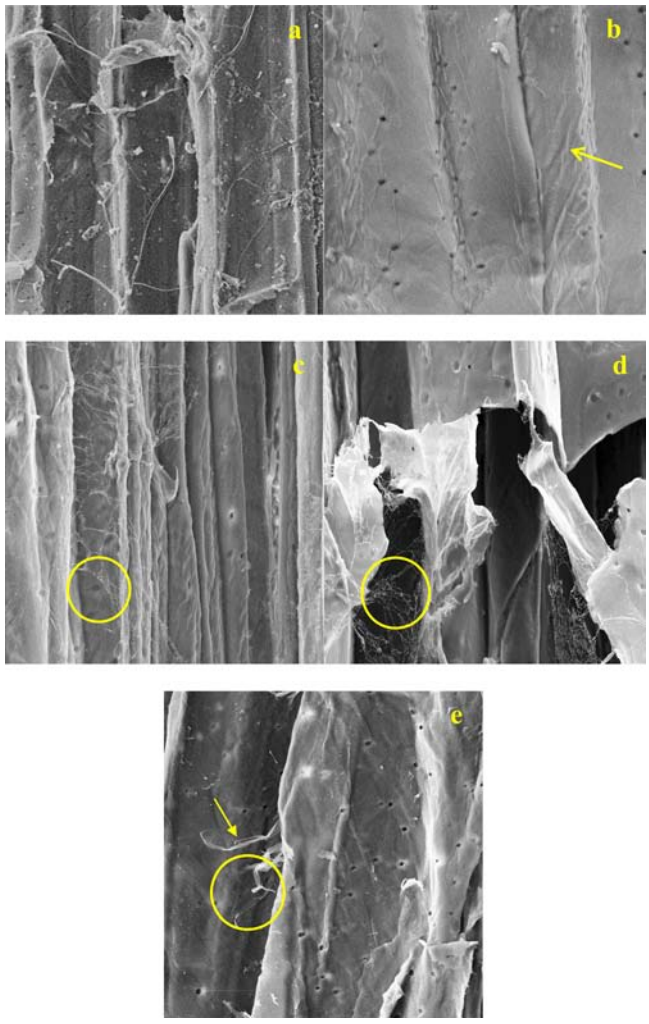

Figure 2. Morphology of bagasse after pretreatment (Bref (a), BN (b), BH(c, d), Bsxs (e)).

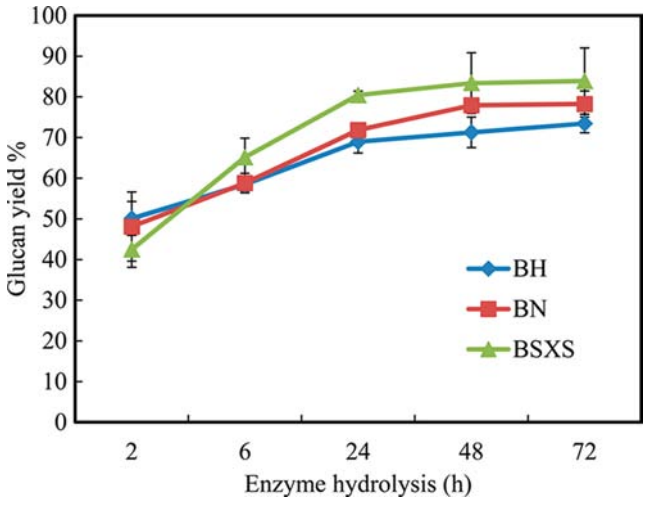

Figure 3. Glucan yield of bagasse after enzyme hydrolysis.

and hemicelluloses in BN (Table 1), as both lignin and hemicelluloses are key barriers for glucan conversion.[34] On the other hand, the surface distribution of lignin and xylan is also of critical importance for enzymatic hydrolysis.[17] According to the results in Figure 3, the highest glucan yield could be achieved

dx.doi.org/10.1021/jf500582w | J. Agric. Food Chem. 2014, 62, 3619−3625

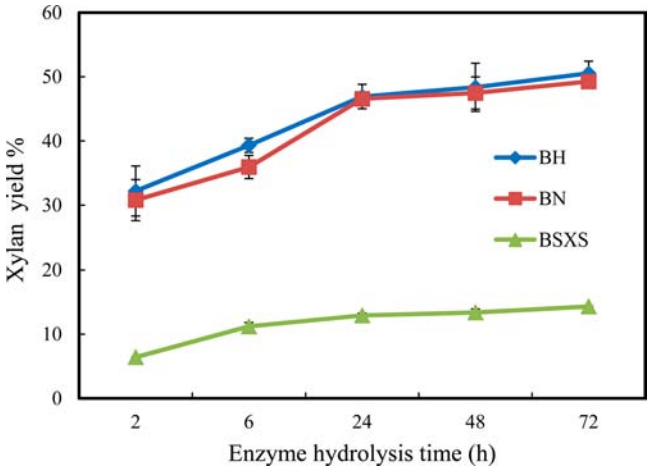

Figure 4. Xylan yield of bagasse after enzyme hydrolysis.

by hydrotropic pretreatment. This is due to the lower lignin and xylan content (Table 1) as well as the lesser surface coverage by lignin and xylan (Table 2) on bagasse fibers after hydrotropic pretreatment. Similar results were also reported for the pretreatment of common reed.[17] The low xylan yield for the case of hydrotropic pretreatment (Figure 4) was because of the low xylan recovery (Table 1). Therefore, on the basis of the results obtained, it could be concluded that among the studied pretreatment techniques, the hydrotropic method was the most efficient one to significantly improve the glucan conversion for bagasse.

Surface Chemical Characterization by ToF-SIMS. The surface chemical composition and the component distribution on the outermost surface of bagasse after alkaline, sodium hydrogen peroxide, and hydrotropic pretreatments were studied by TOF-SIMS. Samples after the following enzymatic hydrolysis were investigated also. The surface sensitivity and specificity of ToF-SIMS is 1−3 nm. Thus, ToF-SIMS can provide more detailed information on surface chemical compositions.[16,35] Sugar monomers from hexosans (cellulose, mannan, galactan) were identified by ToF-SIMS spectrum at m/z 127 and 145 and from pentosans at m/z 115 and 133. In ToF-SIMS, lignin gives the characteristic mass fragments m/z 107 and 121 from the *p*-hydroxyphenyl (H) unit, m/z 137 and 151 from the guaiacyl (G) unit, m/z 167 and 181 from the syringyl (S) unit,[36] and m/z 77 and 91 from the general aromatic ring.[21,37]

In Figure 5, the mass region m/z 100−200 of the alkaline hydrogen peroxide and hydrotropic pretreated samples is displayed as well as the same after enzymatic hydrolysis. In general, in the pretreated samples the sugar monomer fragments were clearly seen in the spectra. After the enzymatic hydrolysis again, the lignin peaks were visually more evident in

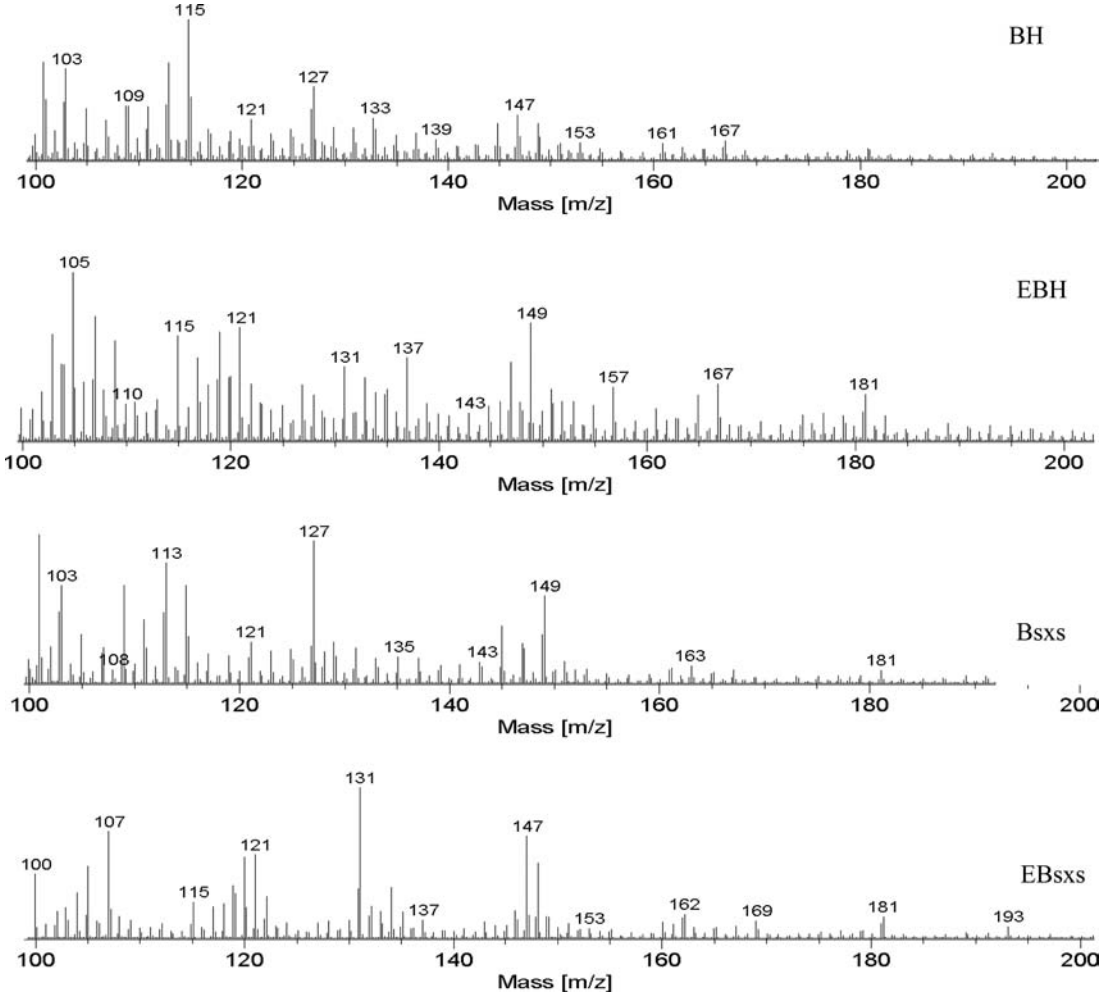

Figure 5. Positive ion ToF-SIMS spectra of BH, EBH, Bsxs, and EBsxs in the mass range m/z 100−200.

dx.doi.org/10.1021/jf500582w | J. Agric. Food Chem. 2014, 62, 3619−3625

the spectra. This was verified when the peak intensities were compared numerically.

The relative peak intensities of the characteristic mass peaks of carbohydrates and lignin were calculated (Table 4). The bagasse samples after both pretreatment and enzyme hydrolysis were studied in Table 4. The increasing ratio between carbohydrate and lignin peak intensities reflects lignin reduction on the fiber surface. After hydrotropic pretreatment, the ratio value between carbohydrates and lignin was increased about 3 times compared with the reference. This supports the finding that lignin on the surface was profusely removed by hydrotropic pretreatment (Table 2). The peak intensities of hexose monomer fragments and pentose monomer fragments in the ToF-SIMS spectra were also compared (Table 4). For that, the peak intensities were normalized individually by the total counts in the spectrum. After the hydrotropic pretreatment, the ratio value of hexose to total was raised to 4 times compared to the reference. Hexose of bagasse is mainly from cellulose that contains glucose according to the results shown in Table 1. Results from ToF-SIMS are in good agreement with XPS in Table 2. After enzymatic hydrolysis, the ratio value of carbohydrates to lignin was decreased following the hydrolyzation and removal of carbohydrates from the sample surfaces. This was not detected in the reference sample. It can be seen as a clear indication of the impact of the pretreatments on the hydrolysis efficiency by reducing the biomass recalcitrance. The value had no large difference between the different pretreatment methods. Hexose and pentose ratios follow the same trend. Especially for the hydrotropic pretreated bagasse, the hexose ratio was reduced from 4.8 to 0.8. Most of the glucose was hydrolyzed by hydrotropic pretreatment. In the case of BH and BN, xylan hydrolysis was also contributing to the decreasing ratio between carbohydrates and lignin. Thus, ToF-SIMS also demonstrated the high efficiency of hydrotropic pretreatment on delignification and enzyme saccharification.

Table 4. Ratio of the Peak Intensities of the Characteristic Mass Peaks of Carbohydrates and Lignin between Bagasse (B) Samples after Pretreatment and Enzymatic Hydrolysis (E) in ToF-SIMS

sample	carbohydrates/lignin	hexose/total × 10^3	pentose/total × 10^3
Bref	0.67 (0.07)[a]	1.1 (0.3)[a]	1.7 (0.6)[a]
BN	1.09 (0.51)	2.3 (1.4)	3.1 (1.8)
BH	1.27 (0.48)	2.6 (1.1)	3.1 (1.8)
Bsxs	1.82 (0.43)	4.8 (1.3)	3.7 (0.7)
EBref	1.02 (0.27)	3.1 (0.7)	2.7 (0.2)
EBN	0.36 (0.01)	0.7 (0.1)	1.2 (0.1)
EBH	0.47 (0.04)	0.6 (0.3)	1.0 (0.4)
EBsxs	0.48 (0.12)	0.8 (0.3)	2.2 (0.9)

[a]The standard deviation is presented in parentheses.

Overall, the bulk chemical composition, surface chemical distribution, and fiber morphology are correlated and should be considered together for comprehensive understanding of the mechanism of pretreatment to accelerate enzymatic hydrolysis. The glucan yield of sugar cane bagasse by enzymatic hydrolysis was advanced by mildly alkaline and alkaline hydroxide pretreatments at room temperature. A much better improvement was achieved with hydrotropic pretreatment through lignin removal and change in surface distribution. Typically for hydrotropic pretreatment, in addition to delignification, xylan was significantly removed. The surface morphology features after hydrotropic pretreatment also benefit enzyme access to fibers. A new biorefinery platform combining production of cellulosic ethanol and recovery of lignin and xylan can be developed on the basis of our results.

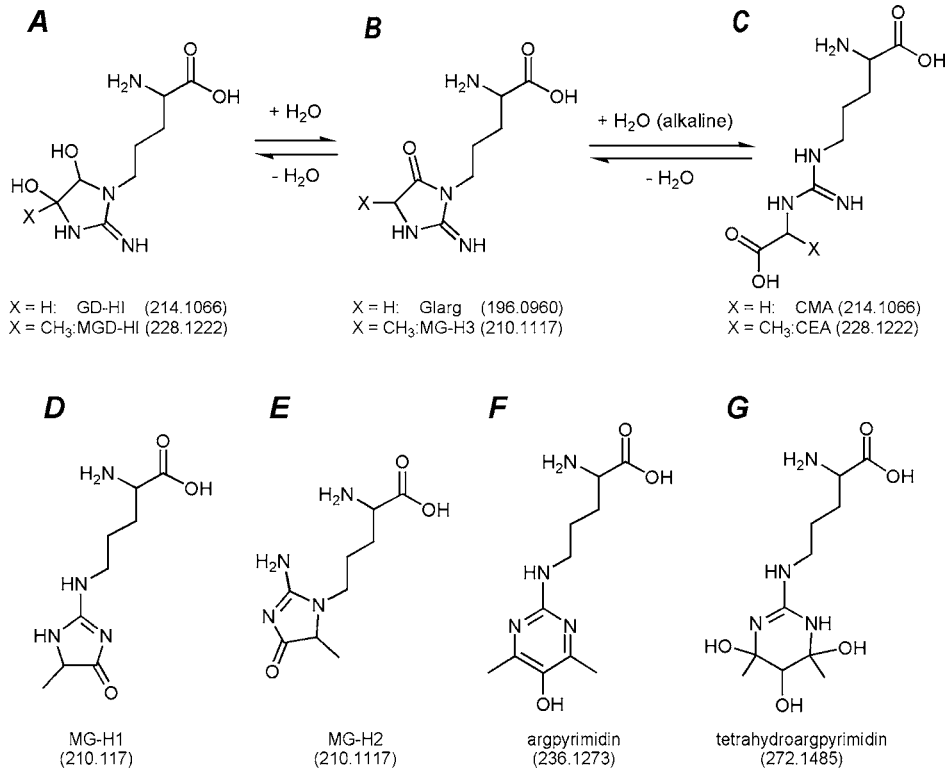

Figure 1. Structures and mass increments of glyoxal- (A, B) and methylglyoxal-derived (C−G) arginine-AGEs: Glarg (A), CMA (B), MG-H1 (C), MG-H2 (D), MG-H3 (E), CEA (F), and argpyrimidine (G).

their formation and degradation was studied for a period of 4 h. Additionally, the effects of reactive oxygen species (ROS) and nearby amino acid residues were evaluated.

MATERIALS AND METHODS

Chemicals. Suppliers and their products were as follows: Iris Biotech GmbH (Marktredwitz, Germany): 9-fluorenylmethoxycarbonyl (Fmoc-) rink amide AM resin and Fmoc-L-Arg(Pbf)−OH (peptide synthesis grade); ORPEGEN Pharma (Heidelberg, Germany): all other Fmoc-protected L-amino acids (peptide synthesis grade); Biosolve (Valkenswaard, Netherlands): *N,N′*-dimethylformamide (DMF, ≥99.8%), piperidine (≥99.5%), and dichloromethane (DCM, ≥99.9%); Carl Roth GmbH & Co KG (Karlsruhe, Germany): trifluoroacetic acid (TFA, 99.9%), α-D-glucose hydrate (≥99.5%), potassium hydrogen phosphate (≥99%), and potassium dihydrogen phosphate (≥99%); VWR International GmbH (Dresden, Germany): diethyl ether (100%) and acetonitrile (≥99.9%). All other chemicals were purchased from Sigma-Aldrich Chemie GmbH (Taufkirchen, Germany). Water was purified in-house (resistance 18 mΩ/cm) on a PureLab Ultra Analytic System (ELGA Lab Water, Celle, Germany).

Peptide Synthesis. Peptides Ac-ASGAGSARASGXASA-NH_2 with X = Ala (1), X = His (2), and X = Glu (3) were synthesized on a multiple peptide synthesizer Syro2000 (MultiSynTech GmbH, Witten, Germany) by Fmoc/*tert*-butyl-chemistry using eight equivalents (equiv) of Fmoc-amino acid derivatives (or acetic acid for N-terminal acetylation) activated with DIC/HOBt in DMF.[23] Peptides were cleaved with TFA at RT (2 h), precipitated with diethyl ether, and purified by RP-HPLC using formic acid or TFA (0.1% v/v) in water (eluent A) and 60% (v/v) aqueous acetonitrile (eluent B) using a gradient slope of 1% eluent B/min. The peptides were aliquoted (32 nmol) in 1.5-mL safe lock tubes (Eppendorf AG, Hamburg, Germany), dried under vacuum, and stored at −20 °C.

In vitro Glycation Reactions with Model Peptides. Peptide aliquots were reconstituted in potassium phosphate buffer (0.1 mol/L, pH 7.4, 0.1 mL) containing iron(II) sulfate (0, 18, or 590 μmol/L) and ascorbic acid (0, 60, or 1200 μmol/L), and incubated (95 °C, up to 4 h) under continuous shaking (450 rpm) in the absence or presence of D-glucose (25 mmol/L). Incubations were stopped by addition of aqueous EDTA (6 mmol/L, 10 μL) on ice and stored at −80 °C.

RP-HPLC-ESI-QqTOF-MS and MS/MS. Samples corresponding to an initial amount of 90 pmol peptide were separated on a Aqua C_{18}-column using a HPLC 1100 system (Agilent Technologies, Böblingen, Germany) consisting of a binary gradient pump (G1312A), online micro degasser (G1379A) and Marathon autosampler (10 μL full loop injection, Spark Holland B.V., Emmen, Netherlands). Eluents A and B were water and acetonitrile, respectively, containing formic acid (0.1%, v/v). Elution was achieved by isocratic conditions (3% eluent B, 5 min) followed by two consecutive linear gradients to 40% (3 min) and 95% eluent B (23 min) using a flow rate of 220 μL/min. LC-MS/MS relied on a shallower gradient (from 4% to 30% eluent B in 4 min and then to 37% eluent B in 14 min). The ESI-QqTOF-MS was equipped with a TurboIon Spray source (QSTAR Pulsar I; AB Sciex, Darmstadt, Germany) and operated in positive ion mode using the Analyst QS 1.0 software (AB Sciex, Darmstadt, Germany). Ion spray voltage and declustering potential were set to 5000 and 50 V, respectively. Curtain, nebulizing, and drying gases were set to 30 psig. The ion source was held at 450 °C. Spectra were acquired with automatically adjusted pulsing frequency and 1 s accumulation time. Collision-induced dissociation (CID) MS/MS experiments relied on low Q1 resolution, collision potentials of 40−70 V, and nitrogen as collision gas (5 psig). In MS mode the instrument was calibrated with a mixture of glycine, sucrose, and maltoheptaose (250 μmol/L each, 60%, v/v aq. acetonitrile) using the $[MH + Gly]^+$ ions of sucrose (m/z 418.1555) and maltoheptaose (m/z 1228.4196). Calibration of the tandem mass spectra relied on y_1- (m/z 175.195) and y_{11}-ions (m/z 1285.545) of the doubly protonated [Glu-1] fibrinogen peptide 1. Relative quantification was performed by integration of extracted ion chromatograms (XICs, ± 0.1 m/z-units) at specific retention times.

RESULTS

Identification of Arginine-Derived Glycation Products. When peptide **1** was incubated with D-glucose and $Fe(II)SO_4$ at 95 °C, a total of eight peptide products with lower or higher masses than the original peptide were detected by RP-HPLC-ESI-QqTOF-MS already after 15 min of exposure time (Table 1). Reaction products were numbered in their elution order and identified by their exact m/z values and tandem mass spectra (Table 1 and Figure 2). The tandem mass spectra typically displayed intense signals of the b-ion series indicating that the mass shift was located at Arg8, while in some cases it was deduced from the exact mass shift of a peptide fragment (Supporting Information (SI) Figure S-1). The increment masses revealed three glyoxal- (Glarg, GD-HI, and CMA) and two methylglyoxal-derived modifications (MG-H and MGD-HI) as well as ornithine (loss of urea). Furthermore, two signals with m/z-values corresponding to an argpyrimidine-modified peptide were detected at different retention times (Table 1). Neither cross-linked products (dimers) nor oxidized arginine residues, such as hydroxy-arginine or glutamate-5-semialdehyde, were observed.[24]

Some modified peptides displayed characteristic fragment ions that further supported the deduced structures. Glarg- (**1-2**) and MG-H-containing peptides (**1-7**, Figures 2B and SI S-1B) as well as the corresponding hydrated forms (**1-3** and **1-8**, respectively) displayed signals at m/z 152.1 and 166.1. Most likely, these signals were related to the arginine immonium ion (Im, m/z 129.1) and represented the corresponding Im-NH_3 fragment (m/z 112.1) containing Glarg and MG-H moieties (mass shifts of 40 and 54 m/z-units, respectively). If this assumption is correct, then the signals would represent hydroimidazolinone and dihydroxyimidazolidine and thus confirm **1-3** and **1-8** as glyoxal- and methylglyoxal-derived dihydroxy-imidazolidines (GD-HI and MGD-HI), respectively (Table 1, Figure 1). As the MG-H-modified peptide eluted in one peak in RPC using different eluent compositions (SI Figure S-2), it remains open, if it was a single MG-H-modified peptide or a mixture of different MG-H-versions. Based on the absence of the signal at m/z 152.1 in the tandem mass spectrum of peptide **1-5**, this analyte was annotated as CMA (Table 1).

Table 1. Retention Times, Precise Masses, and Arginine-Derived AGE-Modified Peptides Identified during the Incubation of Peptide 1 with D-Glucose (25 mmol/L) in the Presence of $Fe(II)SO_4$ (18 μmol/L)

no.	t_R (min)	m/z^a $[M + 2H]^{2+}$	Δm^b	residue in position 8	mass accuracy (ppm)
1	18.6	616.831 ± 0.006	+0.00	arginine	46.2
1-1	18.3	595.802 ± 0.002	−42.06	ornithine	17.4
1-2	18.5	636.805 ± 0.003	+39.95	Glarg	7.9

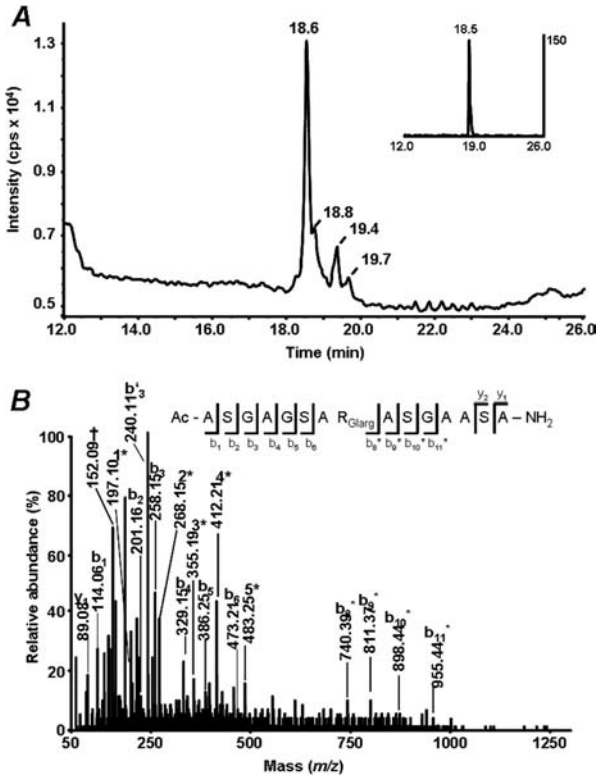

Figure 2. Total ion current chromatogram (A), extracted ion chromatogram (m/z 636.8 ± 0.1; small insert), and tandem mass spectrum of the precursor ion at m/z 636.8 (B) representing Glarg-containing peptide $ASGAGSAR_{Glarg}ASGAASA$.

CEA was neither detected here nor in any of the other incubation mixtures.

Kinetics of Arginine-Related AGEs. Unmodified peptide **1** was very stable when incubated with iron(II) sulfate (18 μmol/L, 95 °C). Basically no degradation products were detected by RPC-MS. The peak area, which was calculated from the XICs, decreased only to ∼86% after 4 h (t test: $p = 0.14$; Figure 3A). The degradation rate was significantly higher in the presence of D-glucose, with 46% of the initial peptide amount left after 1 h and only 5% after 4 h. Obviously, the peptide loss was related to glucose oxidation[25] yielding glyoxal- and methylglyoxal-derived AGEs or oxidative degradation of the peptide backbone.[26] As described above, the incubation yielded eight modified peptides in reasonable quantities (Table 1), which could be separated by RPC and MS and thus be quantified from their XICs. It should be noted that Arg-derived modifications with different gas phase basicity could influence the ionization properties of AGE-modified peptides significantly. Thus, only signal intensities of structurally related peptides can be used to estimate their relative quantities at different time points.

The detected amount of the GD-HI-modified peptide (**1-3**) increased for 45 min and decreased afterward almost to background level after 4 h (Figure 3B). The Glarg-peptide (**1-2**) quantity increased during the first hour and was basically stable within the error range afterward (Figure 3B). The same was true for the CMA-adduct (**1-5**). Considering the slow degradation of the unmodified peptide, it can be concluded that Glarg- or CMA-modified peptides were either not further produced after 1 h or they were immediately degraded upon formation.

dx.doi.org/10.1021/jf4050183 | J. Agric. Food Chem. 2014, 62, 3626−3635

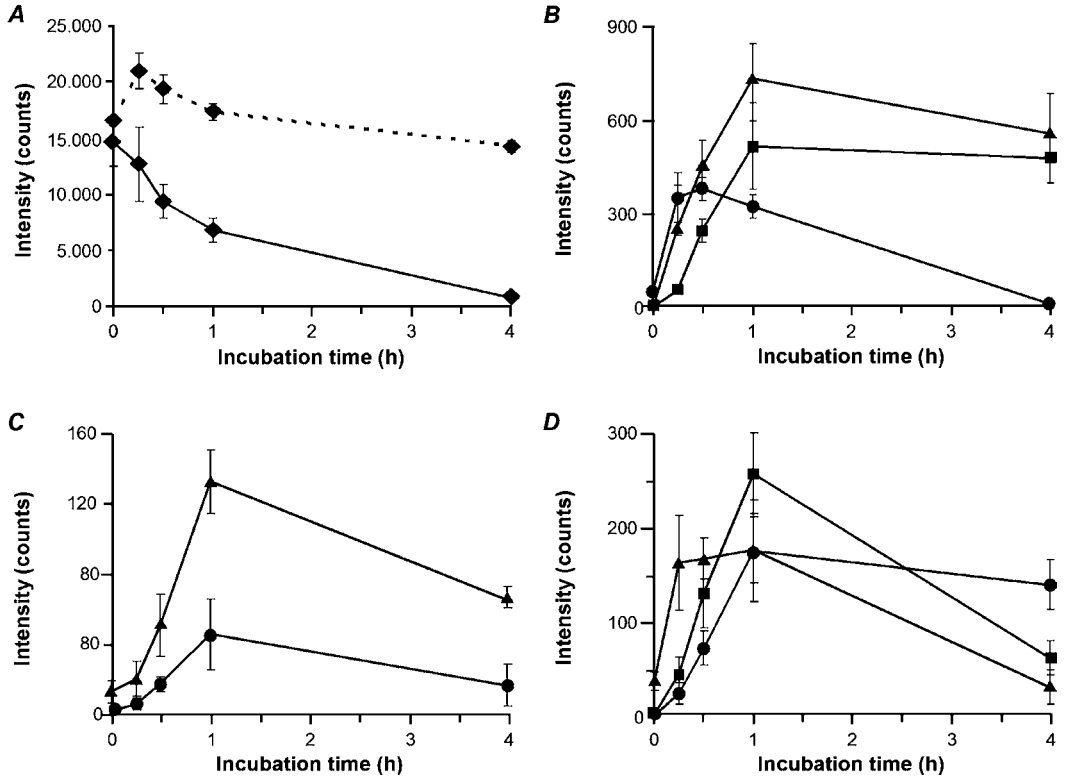

Figure 3. Degradation of peptide **1** (A, ♦) when incubated with (solid) and without (dotted) D-glucose (25 mmol/L) Fe(II)SO_4 (18 μmol/L) and formation of the detected AGE products (B–D). Aliquots were analyzed after 0, 15, 30, 60, and 240 min by RPC-ESI-QqTOF-MS in positive ion mode. Presented are the peak areas calculated by integrating the XICs of the doubly protonated quasimolecular ions ($\pm$0.10 m/z-units) containing a glyoxal-derived residue (B), i.e. Glarg (▲), GD-H1(●), and CMA (■), a methylglyoxal-derived residue (C), i.e. MG-H (▲) and MGD-H1 (●), or another reaction product (D), i.e. ornithine (■) and argpyrimidine (**1-4** ▲, **1-6** ●).

The two methylglyoxal-derived modifications, i.e. MG-H (**1-7**) and MGD-HI (**1-8**), showed similar kinetics as GD-HI with increasing amounts up to around 1 h and a decrease afterward (Figure 3B and C). The degradation rates from 1 to 4 h were slightly higher than that for the unmodified peptide (Figure 3), but lower than that for the GD-HI peptide. The signal intensities of the methylglyoxal-derived products were 10-fold lower than for the corresponding glyoxal-derived peptides.

The formation and degradation of the ornithine-containing peptide (**1-1**) resembled the kinetics for MG-H and to a lower extent that of Glarg (Figure 3D). Interestingly, the two products annotated as argpyrimidine (**1-4** and **1-6**) showed different kinetics with the earlier eluting compound being produced fast within the first 15 min, and then slightly increased up to 1 h before it slowly decreased. Peptide **1-6** increased continuously for 1 h and decreased 20% during the following 3 h period, which resembled the kinetics of GD-HI (Figure 3). Thus, the two products annotated as argpyrimidine must have different structures and should be formed and degraded by different reactions. Further studies are required to identify their stereochemical structures and origins.

Influence of Nearby Residues on Formation of Arg-Derived AGEs. Up to this point, only one inert peptide sequence was studied containing a single reactive arginine residue in position eight. Thus, we extended our study to two highly conserved peptides by substituting Ala-12 with His (peptide **2**) or Glu (peptide **3**). These peptides were incubated with glucose and iron sulfate in conditions identical to those described for the alanine-containing analogue. Peptide **3** was as stable as peptide **1** (~80%), whereas the content of peptide **2** decreased to 60% after 4 h incubation (SI Figure S-3). In the presence of glucose, all three peptides demonstrated very similar degradation kinetics and their amounts decreased to about 5% after 4 h.

Interestingly, the kinetics of all three glyoxal-derived products, i.e. Glarg (***i*-2**, *i* corresponds to the peptide number), GD-HI (***i*-3**), and CMA (***i*-5**) depended on the substitution in position 12 (Figure 4A–C). All three peptides showed very similar formation kinetics of Glarg and GD-HI during the first 30 min. The content of the Glarg-modified peptide **2** (Glu) decreased afterward and was near background levels at the end of the incubation period. The amounts of the corresponding Ala- and His-containing peptides increased further up to 60 min before they decreased slowly with the Glarg-modified peptide **3** being always present at high levels (Figure 4A). The GD-HI-modified products showed a similar profile, but here peptides **1** and **2** showed similar kinetics reaching the maximal amounts after 45 min, whereas the quantities of the GD-HI-modified peptide **3** increased further for the next 15 min and then decreased relatively fast afterward. Surprisingly, CMA-modified peptides showed a different behavior with peptide **3** forming very small amounts of the CMA-product, whereas peptide **2** was modified at higher levels than peptide **1** between 1 and 4 h (Figure 4C).

Unexpectedly, the substitutions had only minor effects on the kinetics of both methylglyoxal products (Figure 4D and E), although His might favor the formation of MG-H at the beginning. The only difference was seen for the MGD-HI-containing peptides in the last 3 h of the incubation period, when peptide **2** was degraded faster than peptide **3**. Thus, our

dx.doi.org/10.1021/jf4050183 | J. Agric. Food Chem. 2014, 62, 3626–3635

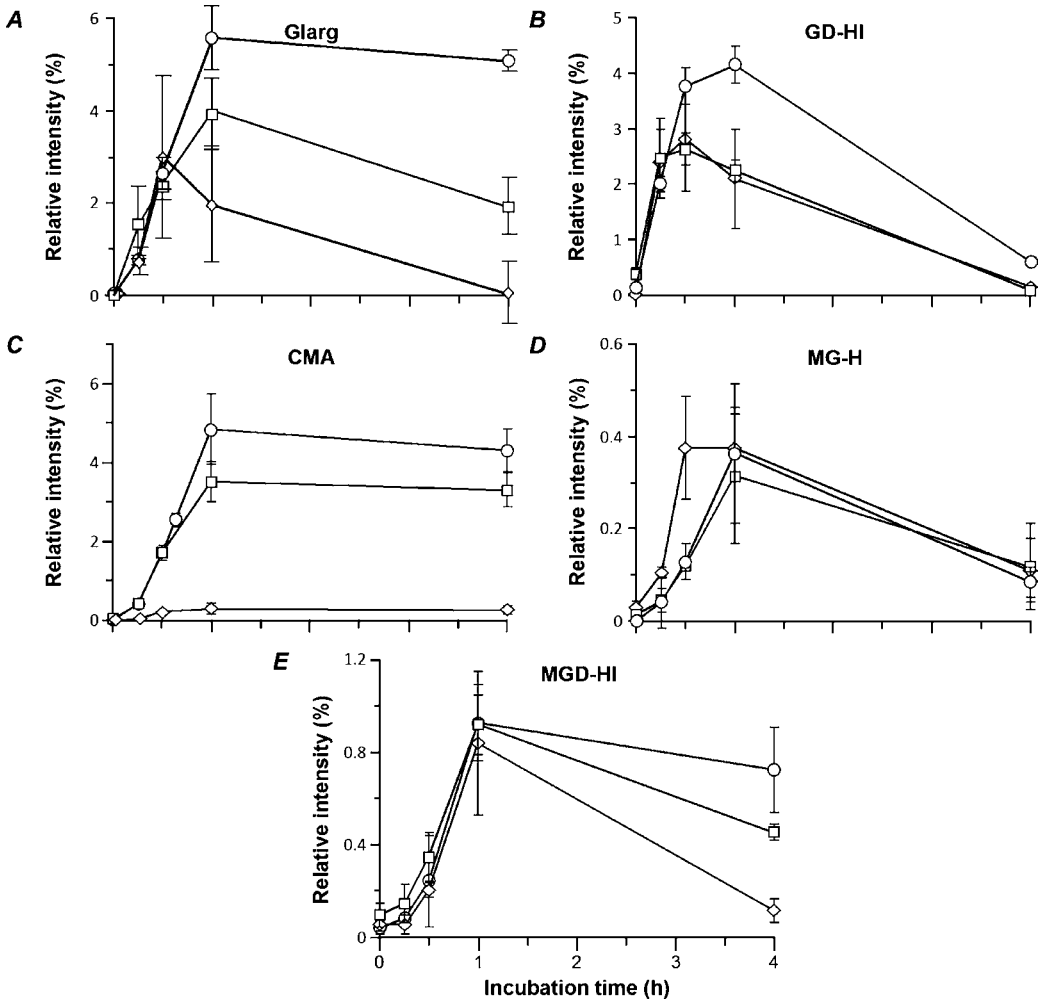

Figure 4. Formation and degradation curves of Glarg- (*i*-**2**, A; *i* denotes the peptide number), GD-HI- (*i*-**3**, B), CMA- (*i*-**6**, C), MG-H- (*i*-**8**, D), and MGD-HI-modified (*i*-**9**, E) peptides **1** (□), **2** (◊), and **3** (○). Peptides were incubated with D-glucose (25 mmol/L) and Fe(II)SO_4 (18 μmol/L) at 95 °C. Samples were analyzed by RPC-ESI-QqTOF-MS in positive ion mode after incubation periods of 0, 15, 30, 60, and 240 min. Intensities were calculated as peak areas by integrating the XICs (n = 3) of the doubly protonated quasimolecular ions (±0.10 m/z-units).

findings give support for stabilizing effect of His and a destabilizing effect of Glu on MGD-HI (Figure 4E).

Effect of ROS on the Formation and Degradation of Arginine-Derived AGEs. After analyzing the formation and degradation of AGEs under weak oxidation conditions (18 μmol/L Fe(II)SO_4), the influence of lower and higher iron(II)-concentrations as well as the presence of ascorbate at two different concentrations was tested for peptide **1**. Based on the above results the incubation period was reduced to 195 min, as the signals of all AGEs reached the highest intensities after about 1 h. Additionally, the incubation mixtures were analyzed at six time points within the first hour to describe the quantitative changes more precisely. In the absence of D-glucose, the unmodified peptide was degraded by approximately 50% within the first hour with only 5% left after 195 min of incubation. In the presence of D-glucose, the peptide was always degraded at very similar rates mostly independent of the Fe(II) and ascorbate concentrations. Higher Fe(II) concentrations appeared to favor the degradation slightly, whereas ascorbate accelerated it at low Fe(II) concentrations (3.3-fold molar access of ascorbate) and reduced it for high Fe(II) concentrations (2-fold molar access of ascorbate) (Figure 5A).

The Glarg-modified peptide (**1**-**2**) was obtained at around 20% lower quantities in the absence of iron(II) and approximately 70% higher quantities at high iron(II) concentrations relative to the original conditions. Addition of ascorbate significantly increased Glarg formation at low iron(II) concentration conditions, but decreased its formation at high iron(II) concentration (Figure 5B). The maximal amount of Glarg was detected in all samples after approximately 1 h. The GD-HI-modified peptide (**1**-**3**) showed basically a similar dependence on the iron(II) and ascorbate concentrations as the Glarg-containing peptide (Figure 5B and C) with the maximal product quantities obtained after 45 to 60 min. Afterward the peptide amounts decreased significantly and reached nearly identical levels at the end of the incubation period. Formation of the CMA-modified peptide (**1**-**5**) depended on the iron(II) and ascorbate concentrations as described above for Glarg and GD-HI. The highest levels were again obtained after 1 h. The degradation, however, depended on the presence of ascorbate. Without ascorbate the product amounts were stable from 60 to 195 min, whereas they decreased significantly in the presence of ascorbate (Figure 5D).

dx.doi.org/10.1021/jf4050183 | J. Agric. Food Chem. 2014, 62, 3626−3635

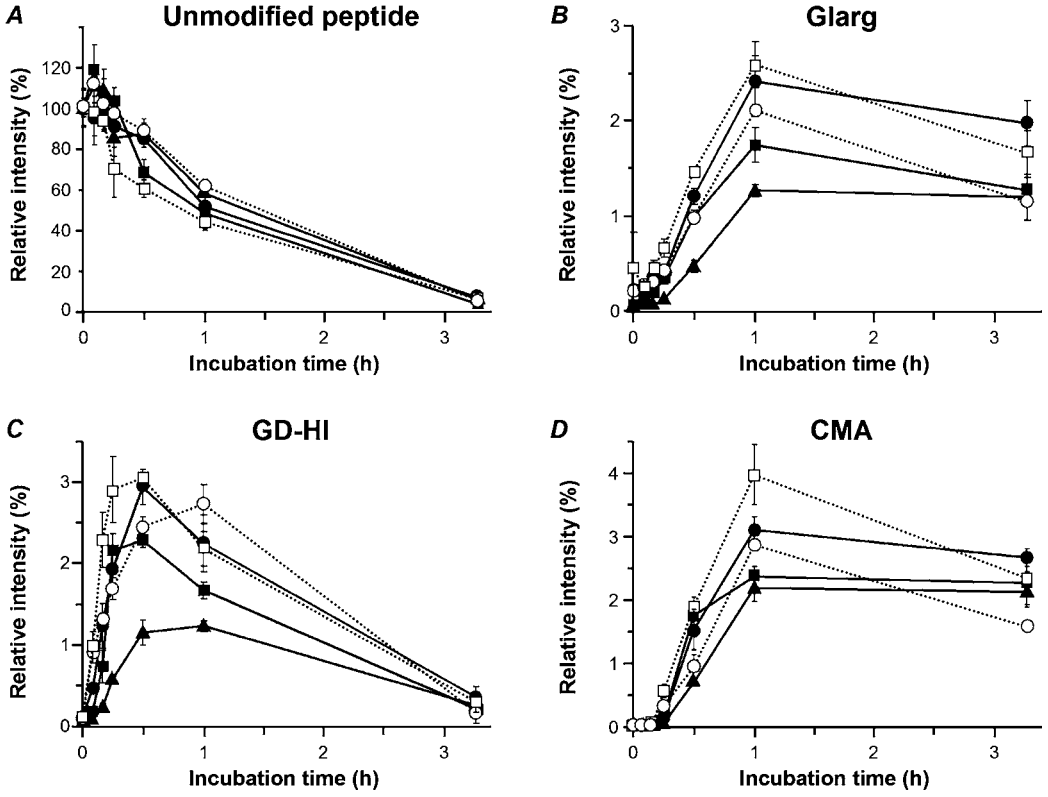

Figure 5. Time-course curves of unmodified (**1**, A), Glarg- (**1-2**, B), GD-HI- (**1-3**, C) and CMA-modified peptides (**1-5**, D) observed after incubation of peptide **1** with D-glucose and different concentrations of iron(II) and ascorbate. Peptide **1** was incubated at 95 °C with D-glucose (25 mmol/L) in phosphate buffer (▲) containing 18 μmol/L $Fe(II)SO_4$ (■), 590 μmol/L $Fe(II)SO_4$ (●), 18 μmol/L $Fe(II)SO_4$ and 60 μmol/L ascorbate (□), or 590 μmol/L $Fe(II)SO_4$ and 1.2 mmol/L ascorbate (○). Samples were analyzed by RPC-ESI-QqTOF-MS in a positive ion mode after incubation periods of 0, 5, 10, 15, 30, 60, and 195 min. Intensities were calculated as peak areas by integrating the XICs (n = 3) of the doubly protonated quasimolecular ions (±0.10 m/z-units).

DISCUSSION

Peptide Sequence and Incubation Conditions. To simplify the data analysis and to obtain mostly Arg-derived modifications at a single position, the peptide sequence consisted only of Ala, Gly, and Ser. These three amino acids are relatively inert against oxidation and do not react with intermediately formed aldehydes, such as glyoxal and methylglyoxal. At the same time they are relatively polar and thus guarantee a good solubility, even when the guanidino-group is transformed to a hydrophobic AGE. The only reactive groups would be the N-terminus, which could even be glycated, and the C-terminus. To avoid any degradation at the termini, these were blocked by acetylation and amidation, respectively. Additionally, Arg was flanked by two inert Ala-residues, which contain only a side-chain methyl-group that is unlikely to interfere sterically with reactions at the guanidino-group. Finally and very important for deducing AGE-modified peptides, the tandem mass spectra of model peptide Ac-ASGAGSARAS-GAASA-NH_2 (**1**) displayed an almost complete b-series at similar intensities all over the mass spectrum (SI Figure S-1A). Therefore, although proline would prevent ordered structures, it was excluded from the sequence, to avoid any influence on the fragmentation pattern and interference with modification-specific signals.[27]

The selected D-glucose concentration corresponded to the highest levels occurring in mammals,[28,29] which represent a good landmark for the maximal "natural" sugar load in protein-rich food. The iron(II) concentration was similar to the levels found in blood and tissue.[30]

Qualitative Analysis of Arg-Derived AGEs. The pattern of identified glyoxal-derived products (GD-HI, Glarg, and CMA) matched well to data reported previously for amino acids.[8] As we observed only one symmetrical chromatographic peak for MG-H (SI Figure S-4), it remains unclear if only one of the three reported MG-H-isomers was produced or several that were not resolved by RP-HPLC. At the amino acid level, this separation is achieved significantly easier than in a 15-residue-long peptide, where the relatively polar MG-H will only slightly contribute to the retention. Thus, further studies using shorter peptides are necessary to provide a better chromatographic separation.

Recently MGD-HI was proposed as an intermediate of MG formation using methylglyoxal and Boc-protected arginine.[22] This compound was indeed detected here and tentatively identified by its characteristic MS/MS fragmentation pattern. Most likely it is more stable within a peptide or protein sequence than at the amino acid level, which would indicate an influence of the α-carboxyl-group on the product stability.

In spite of ornithine not being considered as an AGE product, it is a well-known marker of Arg-related AGEs in proteins.[31] Here, we could show that Arg can lose urea at significant levels and that the obtained Orn is relatively quickly degraded afterward, most likely through glycation of its δ-amino group. Nevertheless, this possibility was not further investigated.

dx.doi.org/10.1021/jf4050183 | J. Agric. Food Chem. 2014, 62, 3626−3635

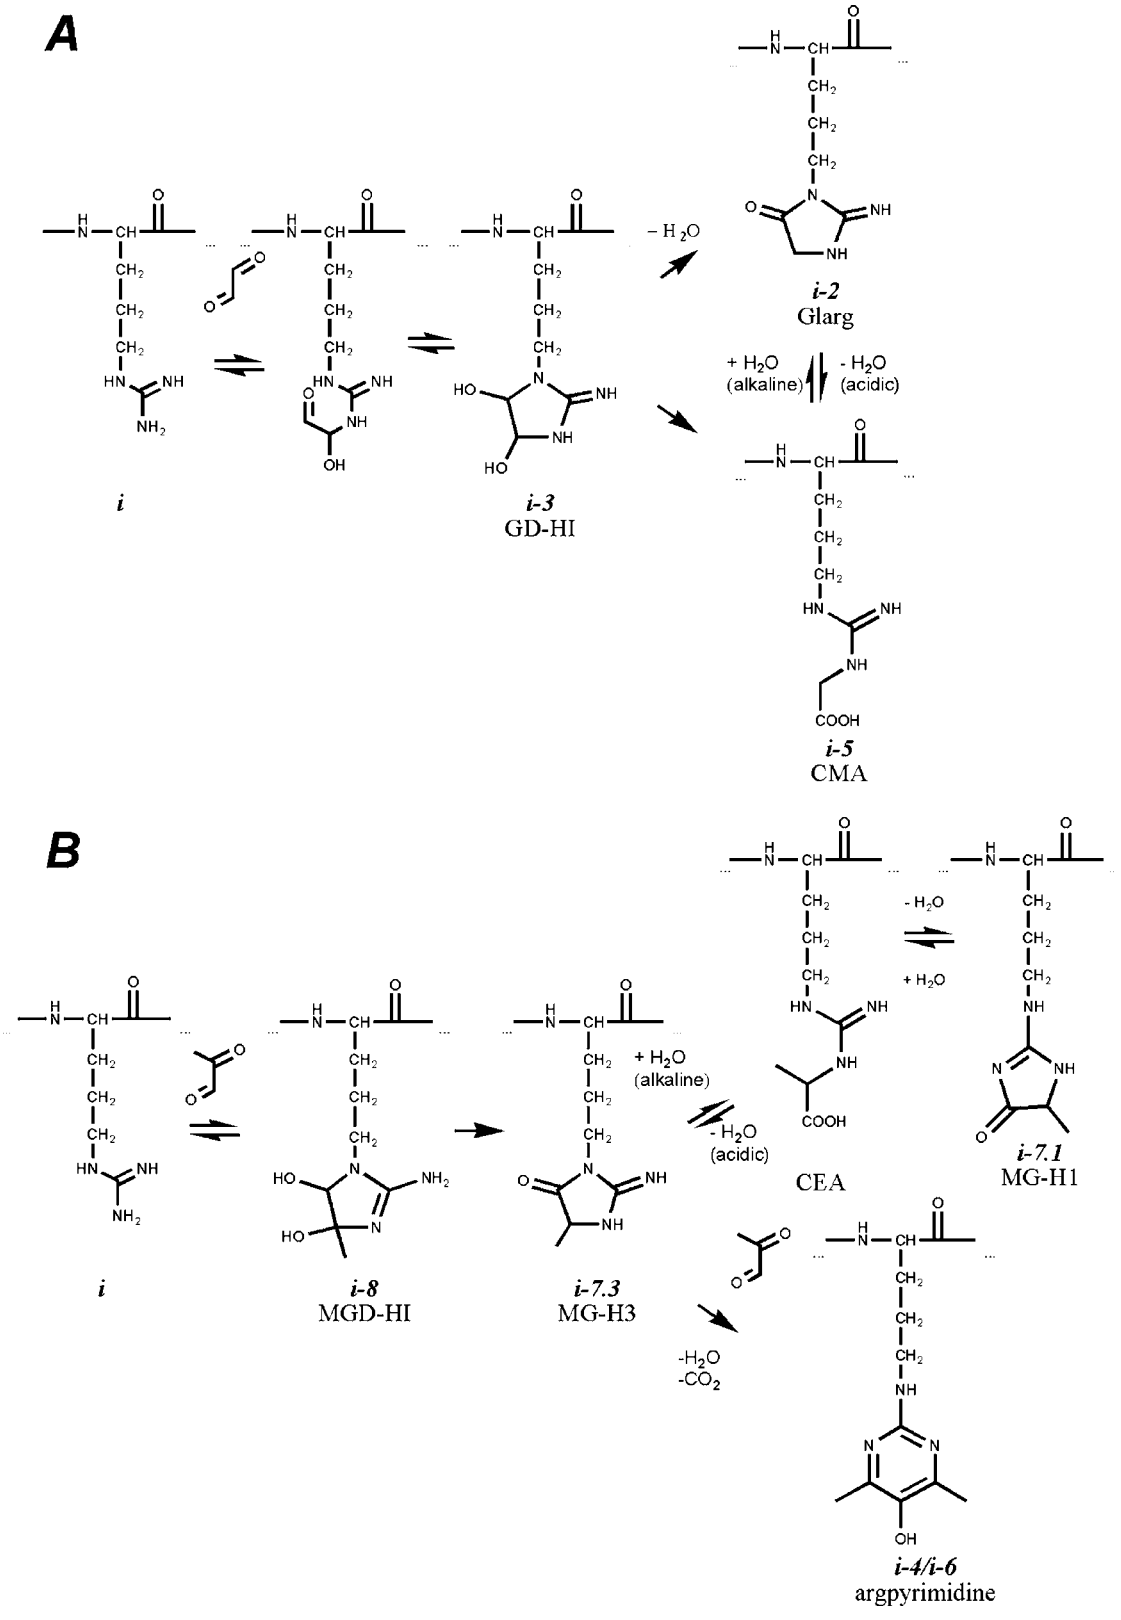

Figure 6. Proposed pathways of the formation of arginine-related peptide glyoxal- (A) and methylglyoxal- (B) derived glycation end-products.

The fragmentation patterns of AGE-containing peptides by CID displayed many internal fragment ions, which were not observed for the unmodified peptide and thus can be considered as characteristic for AGE-modified peptides containing hydroimidazolinone or dihydroxyimidazolidine groups (SI Figure S-1B–E and Table S-1). These signals likely originated from the nucleophilic attack of the imino nitrogen on a carbonyl C atom of the peptide backbone[32] These internal fragments and the immonium ions (Im-NH_3) distinguished isobaric dihydroxyimidazolidine from carboxymethylated or

dx.doi.org/10.1021/jf4050183 | J. Agric. Food Chem. 2014, 62, 3626–3635

carboxyethylated species. The patterns of these signals in the product ion mass spectra of GD-HI-modified peptide **1-3** (m/z 645.8) and the Glarg-modified peptide **1-2**, for example, were quite similar (SI Figures S-1C and S-2B, respectively). In contrast, the tandem mass spectrum of CMA-modified peptide **1-5** did not display any of these internal fragments (SI Table S-1). Thus, the increment mass of 214 m/z-units indicated CMA at position 8 (SI Figure S-1E).

The two weak signals at m/z 656.8 eluting at 18.5 and 18.8 min were annotated as argpyrimidine-containing peptides (**1-4** and **1-6**, Table 1), but the tandem mass spectra did not provide sufficiently intense signals to deduce their structures. Obviously, the low levels of methylglyoxal produced by oxidation of glucose reduced the probability that the guanidino group can react with two dicarbonyl molecules before the intermediate undergoes further modifications. This confirms earlier reports that the reaction of MG-H3 with a second methylglyoxal molecule requires high dicarbonyl concentrations and long incubation times at the amino acid level.[22] Our data collected under physiological conditions indicate, however, that these AGE-modifications will be produced at very low levels in vivo.

Mechanistic Considerations of AGE-Formation and Degradation. Although signal intensities in ESI-MS depend on many factors and are difficult to judge even for closely related sequences, several Arg-derived AGE modifications have closely related structures and properties, and thus show similar ionization properties in peptides. This was shown, for example, for the model peptide and its Glarg- and MG-H2-modified versions that were displayed in the mass spectra at very similar intensities (SI Figure S-5). Only the carboxyl groups of CMA and CEA should significantly weaken their ionization. For hydroimidazolone-related AGE-modifications, the relative signal intensities are expected to be closely dependent upon their concentrations (SI Figure S-4). Thus, it is possible to quantify not only the signal intensity of a given AGE-modification at different time points, but also the relative contents of chemically related products, i.e. Glarg, GD-HI, MG-H, MGD-HI, and argpyrimidine.

The Glarg-modified peptide **1-2** showed a degradation time curve identical to that of its dihydroxyimidazolidine precursor GD-HI (**1-3**), though at a higher intensity after 30 min (Figure 3B). The spectral intensities of the CMA-modified peptide **1-5** were just below those of **1-2**, but considering the suppressive effect of the negatively charged carboxyl-group of CMA, peptide **1-5** was probably present at significantly higher quantities than **1-2** (Glarg) and especially **1-3** (GD-HI). The delayed appearance of **1-5** (CMA) relative to **1-2** (Glarg) and the earlier degradation of **1-3** (GD-HI) might indicate that GD-HI is the precursor of Glarg, which is further processed to CMA. This assumption is in full agreement with a mechanism proposed by Glomb and Lang at the amino acid level.[8] The authors observed a 50% conversion of Glarg to CMA within 6 h at 37 °C. The higher temperatures applied here should accelerate the reaction around 60-fold considering that chemical reactions are typically accelerated 2-fold when increasing the reaction temperatures by 10 °C. Thus, hydrolytic cleavage of the hydroimidazolone ring of Glarg appears to be the dominant pathway of CMA formation, though the ring-opening reaction of GD-HI might represent a minor pathway (Figures 3B and 6A).

Methylglyoxal-derived products MG-H (peptide **1-7**) and MGD-HI (peptide **1-8**) showed the same time dependence as the above-discussed glyoxal-derived AGEs (Figure 3B and C), but their signal intensities and thus their quantities were around 5−10 times lower than those for Glarg and GD-HI, respectively. This difference can be explained by the higher glyoxal concentrations in comparison to methylglyoxal during glucose degradation.[33] Therefore, a lesser amount of MG-H was produced than Glarg during the first 15 min (Figure 2C). The degradation of Glarg and MG-H occurred at similar rates indicating that they are equally stable and their spectral decrease results mostly from peptide degradation. The same appears to be true for MGD-HI and GD-HI (Figure 3B and C).

The mechanisms of hydroimidazolinone formation and degradation were comprehensively evaluated by incubating Boc-Arg-OH with methylglyoxal.[22] The authors proposed the formation of MG-H3 through a dihydroxy-imidazolidine precursor, but could not detect it. This intermediate was, however, detected in tryptic digests of human plasma treated with methylglyoxal in vitro,[34] indicating, in line with our findings, that MGD-HI is more stable in peptides and proteins than in Boc-Arg-OH. At neutral pH MG-H3, its hydrolysis product CEA, and MG-H1 form an equilibrium.[22] As we detected only MG-H, the CEA-product was present at significantly lower levels (below the detection limit) indicating that the equilibrium was shifted to the most stable product MG-H1. This would also explain why we detected only a single MG-H peak, corresponding to MG-H1 whereas MG-H3 was below the detection limit. Alternatively, MG-H3 could be further processed, for example to argpyrimidine. In this case analogue **1-7** would also correspond to MG-H1. This could be clarified by NMR, but NMR spectroscopy requires considerably larger amounts of samples. This was not further investigated, as the functional effects of MG-H do not appear to depend upon the isomer.

The increasing amounts of the Orn-containing peptide confirm the proposed equilibrium between AGE formation and cleavage,[31] which may involve a ring-opening reaction with a subsequent nucleophilic attack of the guanidine nitrogen on the β-C atoms of CMA or CEA. Among the two products annotated as argpyrimidine, only **1-6** accumulated over time as reported previously for Boc-Arg-OH at 37 °C.[22] The intensities of argpyrimidine and MG-H pseudomolecular ions were quite similar, though glucose is slowly degraded to methylglyoxal under the applied conditions.[33] Assuming similar ionization efficiencies for both peptides, our findings indicate that argpyrimidine but not CEA was the main product of MG-H transformation. Thus, the detected hydroimidazolone was presumably MG-H3, which reacted more or less quantitatively with a second methylglyoxal molecule to yield argpyrimidine (peptide **1-6**). Based on the kinetics of **1-6** and **1-7** it can be concluded that either (i) MG-H is not the only precursor of argpyrimidine, or (ii) at least one relatively stable MG-H-derived intermediate of argpyrimidine formation exists though not detected here (Figure 6B).

Neighbor Group Effect. In vitro and in vivo data indicate that basic and acidic residues in the *i+4* position (nearest side chain in an α-helix) modulate both Schiff base formation and Amadori-rearrangement[35,36] whereas such neighbor group effects have not been investigated for Arg-derived AGE-modifications. Thus, we studied the influence of Glu- and His-substitutions at position 12 (*i+4* relative to Arg-8). As the basic or acidic residue altered the ionization efficiencies relative to the original peptide, the peak areas were normalized to the preincubation peak area of each peptide (SI Figure S-3).

dx.doi.org/10.1021/jf4050183 | J. Agric. Food Chem. 2014, 62, 3626−3635

His substitution yielded higher Glarg quantities, while the negatively charged Glu reduced them (Figure 4A). Both observations can be explained by the proton-catalyzed formation of Glarg.[8] The protonated His residue should favor this reaction whereas the deprotonated Glu residue would disfavor it. This His effect was also obtained for GD-HI-modified peptide 3 (Figure 4B). Considering additionally the kinetics of the Glarg-containing peptides (Figure 4A), Glu most likely suppressed the dehydration process of GD-HI accompanied by Glarg formation (Figure 6A). Remarkably, the basic and acidic residues did not affect the rate of GD-HI formation. Hence, the stabilizing effect that prevents degradation of Glarg- and CMA-containing peptides might be more important than the catalytic effect. Interestingly, this stabilization was also observed for MGD-HI, but not for its direct product MG-H (Figure 4E and D, respectively).

The presence of Glu drastically reduced the quantities of CMA (Figure 4C), most likely by forming an ion pair with Glarg. This would increase the electron density of the hydroimidazolone ring in position C-5 and thus reduce the strength of the nucleophilic addition of a hydroxide, the reaction of which initiates the bond cleavage between C_4 and C_5 to convert Glarg into CMA. Additionally, the negative charge of the carboxylate might also prevent the nucleophilic attack of the hydroxide.

Variation of Oxidation Conditions. As the initially chosen incubation conditions yielded dominantly glyoxal-derived AGEs (peptides **1**-**2**, **1**-**3**, and **1**-**5**), the oxidation conditions were varied assuming that ROS production levels might influence peptide degradation rates and AGE patterns. Thus, the H_2O_2-driven Fenton reaction[37] was studied for trace, low, and high iron(II) concentrations, and enhanced by ascorbate-mediated Fe(III) reduction.[38,39]

The higher peptide degradation rates observed for low additive concentrations (Figure 5A) may indicate a dual role of ascorbate with pro-oxidative effects at low concentrations and antioxidative properties at high concentrations.[38] Expectedly, the opposite effects were obtained for the AGE modifications (Figure 5B–D). Most probably, iron(II) had a pro-oxidative effect by accelerating metal-catalyzed autoxidation of glucose and thus favored the production of α-dicarbonyls (glyoxal and methylglyoxal),[25] whereas ascorbate had only a low influence. Remarkably, GD-HI (**1**-**3**) was produced much faster than Glarg (**1**-**2**) and CMA (**1**-**3**), which both showed similar formation rates. This correlates to the reportedly faster glucose oxidation caused by higher ROS quantities[25] and thus higher levels of glyoxal. Remarkably, both Glarg- and CMA-containing peptides were stable in the absence of iron(II) and only slowly degraded in the presence of iron(II). The addition of ascorbate increased the degradation of both peptides strongly, very similar to that of GD-HI that was very labile under all conditions.

Our observations clearly indicate that glycoxidation is a relatively fast process with many products already formed after short periods of elevated temperatures. Whereas the peptides were relatively stable in the absence of sugars when heated under air atmosphere, the addition of D-glucose drastically accelerated peptide degradation including the formation of seven different AGE products, a process that was even more pronounced in the presence of low iron(II) concentrations, a condition characteristic to commercial meat products. Hence, cooking of protein-rich food in the presence of sugars can produce presumably toxic compounds within a few minutes. It should be noted, however, that the content of these AGE-modified peptides decreased for longer heating periods, although it is unclear if only the peptide was further degraded leading to a heterogeneous mixture of small peptides and amino acids not detectable by RPC-ESI-MS or if the AGE modification itself was eliminated along with cleavage of the peptide chain. Since this issue remains to be answered to evaluate the potential toxicity of AGEs produced during cooking, further research is needed to characterize the formation and degradation of peptide- and protein-related AGEs using conditions more closely mimicking household food cooking protocols.

addition on the properties of starch seems to be very important. In this study, we aimed at determining the effect of alkali treatment on functionality and *in vitro* enzymic digestibility of bread wheat starch. The information obtained will be very useful in understanding the effect of NaOH addition on the quality and nutrition of starchy food products.

EXPERIMENTAL SECTION

Materials. Beijing 0045 is a leading hard wheat variety in the northern China plain region. Sound grains harvested in 2011−2012 season were provided by the Institute of Crop Science, Chinese Academy of Agricultural Science. Dried wheat grains were tempered and milled into flour using a Buhler Experimental Mill (Buhler Bros, Uzwil, Switzerland), with the flour yield of 75%. Starch was isolated from wheat flour using a dough ball method.[21]

Preparation of Alkali-Treated Starch. Alkali-treated starch was prepared according to Wang and Copeland,[22] with minor modifications. Three lots of wheat starch (10 g, dry weight) were each suspended in 100 mL of 0.025 and 0.0625 M NaOH solution. After incubation at 30 °C for 1, 2, and 3 weeks with intermittent shaking by hand to resuspend the starch granules, the slurry was filtered through Whatman No. 1 filter paper with suction. The starch cake was washed with distilled water until the pH value of the filtrate was 7 and then washed twice with water-free ethanol. The resulting alkali-treated starch was dried overnight at room temperature.

Protein and Lipid Contents. The nitrogen content of starch samples was determined by standard Kjeldahl methodology. The protein content (%) was then calculated from protein (%) = nitrogen (%) × 6.25. The lipid content of starches was determined gravimetrically after extraction with ether at 60−70 °C for 6−8 h.

Apparent Amylose Content. The apparent amylose content was determined by the iodine binding colorimetric method.[23]

Starch Crystallinity. Starch crystallinity was measured using a Panalytical X'Pert Pro X-ray diffractometer (PANalytical, Eindhoven, Netherlands) with a Co Kα source (λ = 0.1789 nm) operating at 45 kV and 35 mA. The detailed operating conditions and sample treatment before measurement were described elsewhere.[24] The relative crystallinity was quantitatively estimated as a ratio of the crystalline area to the total area between 4 and 40° (2θ) using the Origin software (version 7.5, Microcal, Inc., Northampton, MA).

Fourier Transform Infrared (FTIR) Spectroscopy. The infrared (IR) spectra were obtained with a Bruker Tensor 27 FTIR scanner (Bruker, Germany). The starch samples were mixed with KBr powder in a weight ratio of 1:150 and then ground finely. The resulting fine powders were pressed into the transparent round tablets and tested by the transmission method. The sample holder with KBr was used for the background spectra, and 64 co-added scans were taken for each sample from 4000 to 400 cm^{-1} at a resolution of 4 cm^{-1}. The samples were dried at 105 °C for 12 h before analysis to avoid interference by moisture. The ratio of absorbance at 1045 to that at 1022 cm^{-1} was calculated to represent the short-range ordered structure of starch.[25]

Granule Morphology. Native and alkali-treated starches were fixed onto the surface of double-sided, carbon-coated adhesive tape attached to an aluminum stub. The mounted starch samples were coated with gold prior to imaging in a scanning electron microscope (SU1510, Hitachi High-Technologies Corporation, Tokyo, Japan). The accelerating voltage was 10.0 kV.

Particle Size Distribution. The particle size distribution of native and alkali-treated starch granules was measured using laser light scattering (Mastersizer X, Malvern, U.K.). A polydisperse mode of analysis and a 300 mm lens were used. The starch was evenly dispersed in deionized water with magnetic agitation to attain an obscuration of 20−30%. The measurements were performed in duplicate. The median volume-based diameter was used to represent the average particle size.

Swelling Power and Starch Solubility. Swelling power (SP) and starch solubility (SS) of native and alkali-treated starches were determined in triplicate according to the method described elsewhere.[26]

Thermal Analysis. Thermal transition analysis of starch samples was made using a differential scanning calorimeter (DSC 200 F3, NETZSCH, Selb, Germany) equipped with a thermal analysis data station and data recording software. The operating conditions and definitions of thermal transition parameters were described elsewhere.[27]

Pasting Properties. The pasting profiles were analyzed using a Newport Scientific rapid visco analyzer 4 (RVA-4) (Newport Scientific, Warriewood, New South Wales, Australia). Starch slurries containing 8% (w/w) starch (dry weight) in a total weight of 28 g were held at 50 °C for 1 min before heating at a rate of 6 °C/min to 95 °C, holding at 95 °C for 5 min, then cooling at a rate of 6 °C/min to 50 °C, and held at 50 °C for 2 min. The speed of the mixing paddle was 960 rpm for the first 10 s and then 160 rpm for the remainder of the experiment. Peak viscosity (PV), viscosity at trough [also known as minimum viscosity (MV)], and final viscosity (FV) were recorded, and breakdown (BD, which is PV minus MV) and setback (SB, which is FV minus MV) were calculated using the Thermocline software provided with the instrument.

***In Vitro* Starch Digestibility.** *In vitro* starch digestibility was determined by a modified Englyst et al. procedure.[28] Amylase solution was prepared by suspending 1.3 g of porcine pancreatic α-amylase (28 units/mg, Sigma A3176) in 11.9 mL of water at 37 °C with magnetic stirring for 10 min. The mixture was centrifuged (1500*g* for 10 min) and 0.1 mL of amyloglucosidase (3260 units/mL, Megazyme) was added to 8 mL of the supernatant. Starch (100 mg) was dispersed in 4 mL of 0.1 M sodium acetate buffer (pH 5.2), and after adding 1 mL of the freshly prepared enzyme solution, the mixture was incubated at 37 °C with magnetic stirring (260 rpm). Aliquots (0.1 mL) were taken at intervals and mixed with 0.9 mL of 95% ethanol. The glucose released was measured by the glucose oxidase−peroxidase reagent (Megazyme). Starch classifications based on the rate of hydrolysis were rapidly digested starch (RDS, digested within 20 min), slowly digested starch (SDS, digested between 20 and 120 min), and resistant starch (RS, undigested starch after 120 min).

Statistical Analysis. All experiments were conducted at least twice, and the results were reported as the mean values and standard deviations (SDs). In the case of X-ray diffraction (XRD) and FTIR, only one measurement was performed. Analysis of variance (ANOVA) by Duncan's test ($p < 0.05$) was conducted using the SPSS 10.0 statistical software program (SPSS, Inc., Chicago, IL).

SEM photographs of native and alkali-treated wheat starch granules: (A1 and A2) native starch, (B1 and B2) 0.1% NaOH for 1 week, (C1 and C2) 0.1% NaOH for 2 weeks, (D1 and D2) 0.1% NaOH for 3 weeks, (E1 and E2) 0.25% NaOH for 1 week, (F1 and F2) 0.25% NaOH for 2 weeks, and (G1 and G2) 0.25% NaOH for 3 weeks.

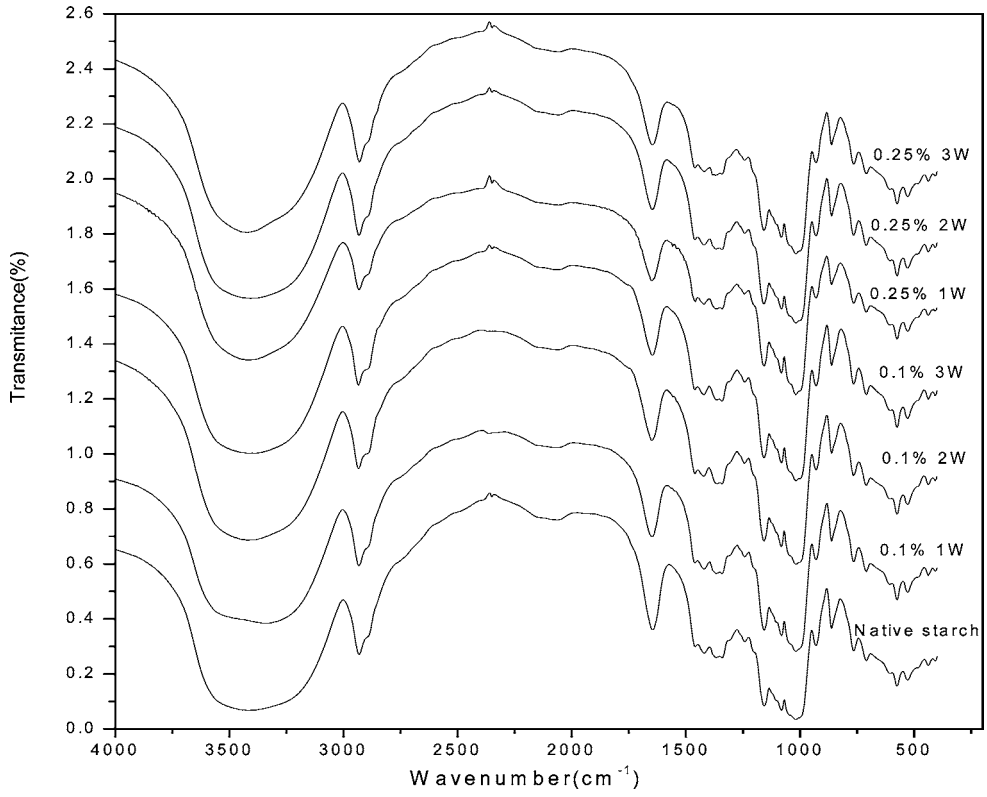

Figure 2. FTIR spectra of native and alkali-treated wheat starches.

RESULTS

Protein, Lipid, and Amylose Contents. Native wheat starch had a protein content of 0.46%, which was decreased significantly by alkali treatments (Table 1). After 0.1% NaOH treatment, the protein content decreased to 0.30−0.34%. The protein content decreased further when starch was treated with 0.25% NaOH. No significant differences were observed in the protein content of starches treated for different times. The lipid content decreased from 0.59% for native starch to 0.25% for starch treated with 0.25% NaOH for 3 weeks. Similarly, no significant differences were noted in the lipid content of starches treated for different times. The amylose content of native wheat starch was 27.1%, which remained essentially unchanged after alkali treatment.

Starch Granule Morphology and Particle Size Distribution. Native wheat starch was observed to be composed of

dx.doi.org/10.1021/jf500249w | J. Agric. Food Chem. 2014, 62, 3636−3643

two populations of granules, namely, large A-type granules and small B-type granules (Figure 1). The surface of granules was largely smooth, with some grooves or indentations. After 0.1% NaOH treatment, some starch granules were observed to be deformed or roughened on the surface (panel D1 of Figure 1). A very small proportion of granules was observed to be disrupted (panels C2 and D2 of Figure 1). These changes became more obvious after longer exposure to the alkali or after treatment with 0.25% NaOH. Some starch granules appeared to adhere to form some aggregates or agglomerates (panel G1 of Figure 1). In contrast, the large A-type granules were subjected to more severe damage than the small B-type granules. Native wheat starch had an average granule size of 21.1 μm. The 0.1% NaOH treatment did not cause significant changes in the average granule size. However, the average granule size increased significantly to about 25.0 μm after 0.25% NaOH treatment (Table 1).

FTIR of Native and Alkali-Treated Starches. The FTIR spectrum of native wheat starch is presented in Figure 2. The characteristic peaks at 3380 and 2930 cm^{-1} were attributed to the vibration of O−H stretching and the C−H deformation of the glucose unit, respectively. The absorbance at 1643 cm^{-1} was assigned to the vibration of O−H stretching of water absorbed in the amorphous regions of starch. There were three characteristic peaks occurring between 1019 and 1065 cm^{-1}, which were assigned to the vibration of C−O stretching. The peak at 1019 cm^{-1} was ascribed to the vibration of C−O−H deformation. Absorbances at 1080 and 1156 cm^{-1} were assigned to the coupling of C−O, C−C, and O−H bond stretching and bending and asymmetrical stretching of the C−O−C glycosidic bond.[25,29] Alkali treatment did not greatly alter the FTIR spectra of starch samples. However, there was a small decrease in the absorbance ratio at 1045 and 1022 cm^{-1} after alkali treatment (Table 1), from 0.658 for native starch to 0.647 for starch treated with 0.25% NaOH for 3 week.

XRD. Native wheat starch presented a characteristic XRD pattern of A-type polymorphs (Figure 3), with the diffraction

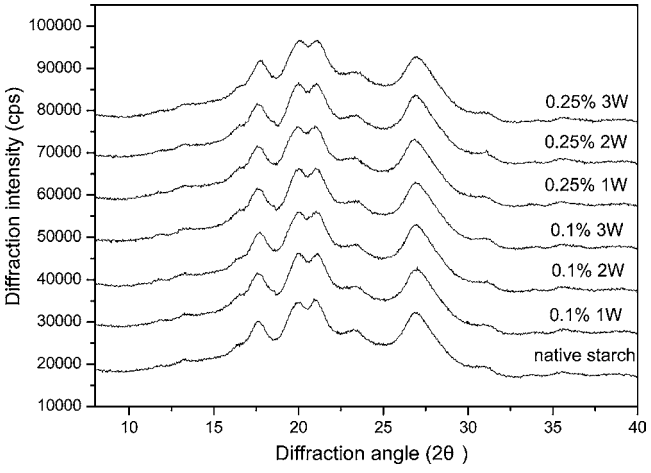

Figure 3. XRD patterns of native and alkali-treated wheat starches.

peaks occurring at 2θ 17.7°, 20.1°, 21.1°, and 26.9°. Alkali treatment did not change the polymorphic forms of wheat starch. The relative crystallinity of native wheat starch granules was about 32.7%, which slightly decreased to about 31.4−31.6% after alkali treatment (Table 1).

Swelling Power and Starch Solubility. Native wheat starch granules had a swelling power of 11.4 g/g, which increased significantly to 13.0−14.0 g/g after alkali treatment (Table 2). No significant differences were observed between alkali-treated starches. Likewise, alkali treatment resulted in the significant increase in starch solubility from 10.9% for native starch to 22.1% for starch treated with 0.25% NaOH for 3 weeks. The degree of increase varied with treatment time and NaOH concentration.

Thermal Transition. The thermal transition profiles of native and alkali-treated starches are presented in Figure 4, and the corresponding parameters are summarized in Table 2. The onset (T_o), peak (T_p), and conclusion (T_c) temperatures of wheat starch were 57.3, 61.7, and 66.1 °C, respectively. The enthalpy change (ΔH) was 9.3 J/g (Table 2). Alkali treatment resulted in the significant increase in T_o, T_p, and T_c of wheat starch. For example, T_o, T_p, and T_c increased to 61.7, 64.9, and 68.7 °C for starch treated with 0.25% NaOH for 3 weeks. Starch treated with 0.25% NaOH showed a greater increase in thermal transition temperatures than starch treated with 0.1% NaOH. For starch treated with 0.1% NaOH, longer treatment resulted in the greater increase in the thermal transition temperatures. However, no significant differences were observed between starches treated with 0.25% NaOH. The thermal transition temperature range ($T_c - T_o$) decreased from 8.8 °C for native starch to 7.0 °C for starch treated with 0.25% NaOH for 3 weeks, but the enthalpy change did not change significantly after alkali treatment.

Pasting Properties. The pasting profiles and parameters of wheat starch before and after alkali treatment are summarized in Figure 5 and Table 3, respectively. Alkali treatment increased breakdown viscosity and setback viscosity but decreased trough viscosity and pasting temperature. The 0.25% NaOH treatment decreased trough viscosity of wheat starch more greatly than the 0.1% NaOH treatment. However, the 0.1% NaOH treatment increased breakdown viscosity and setback viscosity of wheat starch more significantly than the 0.25% NaOH treatment. Alkali treatment significantly decreased the pasting temperature from 89.6 to 67.4 °C, with no significant differences being observed between alkali-treated starches. In contrast to the above pasting parameters, the peak and final viscosities were affected by alkali treatment in different ways. For example, the peak and final viscosities were increased after 0.1% NaOH treatment but decreased after 0.25% NaOH treatment.

***In Vitro* Enzymatic Digestibility.** The proportions of RDS, SDS, and RS in wheat starch were changed after alkali treatment (Table 4). Alkali treatment increased the RDS and SDS contents of starch granules significantly, with the latter being increased more greatly from 13.6% in native starch to 34.5% in starch treated with 0.25% NaOH for 2 weeks. Significant differences were noted in RDS and SDS contents between alkali-treated starches. In contrast to RDS and SDS, the RS content was decreased significantly from 69.9% in native starch to 45.2% in starch treated with 0.25% NaOH for 2 weeks. Likewise, significant differences were observed in the RS content between alkali-treated starches.

DISCUSSION

Effect of the Alkali Treatment on the Structure of Wheat Starch Granules. Alkali treatment decreased the protein and lipid contents of wheat starch significantly. Similar observations have also been reported with starches treated with alkali solution[13] and SDS buffer[7] or washed with alkali solution in starch extraction.[30−33] The decreased protein and lipid contents of alkali-treated starch could be attributed to the solubilization of surface starch granule-associated proteins and lipids as internal

proteins, and lipids are hardly extracted from the ungelatinized starch granules.[34] Alkali treatment did not change the amylose content of wheat starch significantly, indicating that leaching or degradation of amylose molecules did not occur during treatment. In previous studies, alkali treatment has been shown to decrease the amylose content of pea starch granules[22] or sago, corn, and potato starch granules.[13] The effect of alkali treatment on pea starch granules was regarded as being analogous to a limited form of gelatinization.[22] In this study, the alkali-induced gelatinization of wheat starch granules could be too limited to render the leaching or degradation of amylose molecules.

Alkali treatment resulted in the deformation, disruption, or coalescence of wheat starch granules, as was also noted for alkali-treated pea, sago, corn, and potato starches[13,22,35] or alkali-washed rice and pinhão starches.[30−32] The obvious morphological changes, such as disruption and coalescence, of starch granules after 0.25% NaOH treatment could result from the small swelling of wheat starch granules during alkali treatment, as evidenced by the small increase in the average particle size. The swelling of starch granules was proposed to mainly occur at amorphous growth rings and lamellae, with little effect on high-density crystalline lamellae.[32] As a result, the relative proportion of amorphous to crystalline regions increased, consistent with the observed small decrease in relative crystallinity and absorbance ratios from 1045 to 1022 cm^{-1} of alkali-treated starches. The

decreased crystallinity of alkali-treated starch was also observed with pea,[22] pinhão,[32] and rice[30] starches.

Effect of the Alkali Treatment on Starch Functionality. Swelling power and starch solubility of the wheat starch were increased greatly by the alkali treatment. The considerable increase in swelling power of alkali-treated wheat starch could be attributed to the partial removal of surface proteins and lipids, which were considered to inhibit the swelling of starch granules. Similar results were also reported by other researchers.[7,10,11] In other studies, the observed increase in swelling power of alkali-treated corn and potato starches was attributed to the reduction of restraining effects of amylose in the amorphous regions, allowing for the granules to swell more freely.[13,35] Upon heating in excess water, alkali-treated starch granules were visually observed to form a more transparent and softer paste, which was poured out in a small amount with supernatant during the swelling power test. The separated paste in the supernatant was taken as solubilized starch, hence resulting in the large increase in starch solubility.

Alkali treatment increased the thermal transition temperatures of wheat starch but decreased the temperature range. Higher DSC transition temperatures are thought to be associated with a higher degree of crystallinity or more ordered crystalline structure, which makes the granules more resistant to be gelatinized. Because there was a small decrease in relative crystallinity, the increased gelatinization temperature and decreased temperature range indicated that the stability and homogeneity of the crystal structure of alkali-treated starch was enhanced in comparison to that of native starch. In addition to the solubilization of surface proteins and lipids, the annealing of starch granules during alkali treatment may also occur, which leads to the increased stability and homogeneity of the crystal structure.[36] The enthalpy change was little changed by alkali treatment, consistent with the slight decrease in the relative crystallinity of starch granules. Previous studies have shown that the effect of alkali treatment on the starch thermal transition varies with the alkali concentration, treatment period, and starch sources.[13,22,35]

Alkali treatment with 0.1% NaOH significantly increased the peak viscosity, with 1 week treatment leading to the greatest increase. The increase in peak viscosity is consistent with the increased swelling power of alkali-treated starches. In contrast, 0.25% NaOH treatment resulted in the decreased peak viscosity of wheat starch, with three week treatment causing the greatest decrease. The decrease in peak viscosity of alkali-treated starches with 0.25% NaOH seemed to be inconsistent with the increased swelling power. After treatment with 0.25% NaOH, starch granules were assumed to be more fragile to destruction (or amylopectin molecules more vulnerable to degradation), especially when heated under the shear forces.[22] The decreased peak viscosity after 0.25% NaOH treatment was indicative of the degradation of amylopectin molecules during RVA heating under shear forces. The degradation of amylopectin molecules was further corroborated by the decreased trough viscosity and increased breakdown viscosity of alkali-treated starches. The setback viscosity is thought to result from the rearrangement of amylose molecules that have leached from swollen starch granules during cooling and is indicative of the retrogradation tendency of starch.[37] The increased setback viscosity of alkali-treated starch indicated the faster retrogradation of starch paste. Alkali treatment decreased the pasting temperature by about 12 °C, indicating that alkali-treated starch has a more rapid swelling tendency than native starch. Alkali treatment has been shown to influence the pasting properties of starches in different ways, depending upon the alkali concentration, treatment period, temperature, and starch sources.[11,13,22,35]

Effect of the Alkali Treatment on Starch *in Vitro* Digestibility. Alkali treatment greatly decreased the RS content and increased the RDS and SDS contents, indicating the increased digestibility of wheat starch after alkali treatment. The increased digestibility of alkali-treated starch could be attributed to factors such as the removal of some surface proteins, roughening on the granule surface, disruption of starch granules, or increased amorphous regions in starch granules. The digestion of native starch granules is a very complex process consisting of the diffusion of the enzymes into the substrate, adsorption of enzymes to the substrate, and hydrolytic event.[38−40] Of these processes, the diffusion of α-amylase into the substrate is considered as a key step of hydrolysis. The presence of some surface non-starchy substances, such as proteins and lipids, can limit the rate of enzymatic hydrolysis by reducing the diffusion of enzymes into the granules and blocking the adsorption site of the substrate.[9,19] Removal of surface proteins and lipids after alkali treatment could greatly accelerate the penetration of enzymes into the granules and absorption of enzymes to its substrate, therefore increasing the digestibility of alkali-treated starch. In addition, roughening on the granule surface or granule disruption could also enhance the accessibility of enzymes to starch, hence increase the enzymatic digestibility. With the easy penetration of enzymes into alkali-treated starch granules, the resistant part of starch is more accessible for amylase to digest than that of native starch granules, leading to the decreased RS content.

In summary, alkali treatment can remove the proteins and lipids (mostly from the surface) from starch granules without significantly affecting the internal crystalline structure of starch. In contrast, the functionality of starch granules was altered greatly by alkali treatment. The swelling power and starch solubility were increased greatly by alkali treatment. However, the alkali treatment effect on properties of thermal transition and pasting varied with the concentration of NaOH and treatment period. The *in vitro* digestibility of starch granules was increased significantly by alkali treatment, as evidenced by the increased RDS and SDS contents and decreased RS content. The alkali-induced changes in functionality and *in vitro* digestibility of wheat starch granules could be predominantly attributed to the removal of surface proteins and lipids, but the alterations to granular morphology and small swelling of amorphous regions may also be taken into account. Our results clearly indicated that alkali treatment can be taken to be an important modification method to modify the quality and nutritional properties of starchy food products.

with acetone, acetonitrile, or methanol. Stock solutions were diluted with proper solvent to make standard solutions in the range of 0.01−5 mg/L to prepare calibration curves. All of the solvents were of pesticide grade (TEDIA, USA) or analytical grade and purchased from Merck Co. (Darmstadt, Germany). Anhydrous Na_2SO_4 was purchased from Merck (Taipei, Taiwan). Commercial acetamiprid 20% SP, chlorpyrifos 22.5% EC, deltamethrin 2.4% SC, and methomyl 40% SP were purchased from Great Victory Chemical, Xinnong, Bayer, and Du Pont, respectively, Taiwan.

Extraction Procedures. A 20 g portion of vegetable sample was weighed in a glass jar of a blender and homogenized with 60 mL of acetone for 1 min. The macerate was then filtered under vacuum through a funnel using Advantec no. 2 filter paper (Toyo Roshi Kaisha, Japan). The volume of filtrate was adjusted to 100 mL with the same solution. For cabbage and Chinese cabbage before solid phase extraction (SPE), a 10 mL portion of filtrate solvent was transferred into a separatory funnel and partitioned twice with 50/30 mL of ethyl acetate. The organic phase was collected, filtered through 20 g of anhydrous Na_2SO_4, and evaporated to dryness under reduced pressure. For all vegetables, the residue was dissolved in 3.5 mL of a solution of *n*-hexane/acetone (90:10, v/v) and loaded to the Florisil (1000 mg/6 mL, JT Baker) cartridge (×2) for SPE. The combined cartridges were previously conditioned with 10 mL of *n*-hexane, followed by sample loading and collecting with 3.5 + 7 mL of *n*-hexane/acetone (90:10, v/v) and collecting with 8 mL of *n*-hexane/acetone (50:50, v/v) after washing with 10 mL of *n*-hexane/acetone (90:10, v/v). The combined eluents were evaporated to dryness under nitrogen and reconstituted to 2 mL of acetonitrile for GC/μ-ECD analysis to determine acetamiprid, chlorpyrifos, and deltamethrin. A 1 mL portion of acetonitrile was reconstituted to methanol for the HPLC-FLD (OPA post reaction) analysis to determine methomyl.

GC/μ-ECD. An Agilent 6890 (Taipei, Taiwan Ltd.) gas chromatograph equipped with a 63Ni μ-electron-capture detector (μ-ECD) and a fused silica capillary column DB-608 (30 m × 0.25 mm i.d., 0.25 μm film thickness) was used. The operating conditions were as follows: initial temperature, 200 °C (5 min), increased at 10 °C min^{-1} to 220 °C for 2 min and increased at 20 °C min^{-1} to 280 °C for 10 min; injector temperature, 270 °C; N_2 carrier gas; column average linear velocity (μ = 40 cm/s) operated in the splitless mode; injection volume, 1 μL; detector temperature, 300 °C; makeup gas, N_2. Identification of acetamiprid, chlorpyrifos, and deltamethrin was carried out by comparing their individual retention times on GC/μ-ECD. The amounts of standards in the test solution were calculated from the peak areas. If the amount corresponding to the peak areas was larger than that of the maximum amount from the calibration curve, the test solutions were diluted to an appropriate concentration.

HPLC with Postcolumn Derivatization and Fluorescence Detection (FLD). The system consisted of an Agilent model 1100 HPLC quaternary pump, a model G1313A autoinjector, and a model G1321A fluorescence detector. All runs were acquired and processed using the Agilent ChemStation software. Chromatographic separations were carried out on a Merck LiChroCart 250 × 4.0 mm i.d. cartridge column, packed with LiChrosphere 100 RP select B (5 μm), in conjunction with a 4.0 × 4.0 mm i.d. guard column, packed with LiChrosorb 100 RP-18. Isocratic analysis was performed with a methanol/water (60:40) mobile phase at a flow rate of 0.8 mL min^{-1}. The postcolumn reaction system consisted of a Pickering PCX 5000 postcolumn reaction module. The first pump added a 0.05 M NaOH solution through a vortex mixing chamber (1.2 μL volume) to the column eluent. Hydrolysis took place in a PTFE knitted tube (5.1 m × 0.25 mm i.d.; 1.0 mL volume), kept at a temperature of 100 °C. After the hydrolysis reaction coil, *o*-phthalaldehyde/thiofluor reagent (0.05 M) was added through the second mixing chamber. The flow rate of both reaction solutions was 0.3 mL min^{-1}. The excitation and emission wavelengths for fluorescence detection were 330 and 460 nm, respectively.

Recovery Test. The specificity of the analytical method was confirmed by analysis of blank vegetable samples in triplicate and by processing through the extraction procedures described above. No interference peak was observed on the chromatograms from the blank samples. The accuracy and precision of the analytical method were confirmed by the recovery test of acetamiprid, chlorpyrifos, deltamethrin, and methomyl.

Field Experiments. The field experiments on head lettuce (*Lactuca sativa* L. var. *capitata* L.), cabbage (*B. oleracea* Linn. var. *capitata* DC.), Chinese cabbage (*B. pekinensis* Skeels), and broccoli (*B. oleracea* var. *italica*) were conducted in a field in Changhua, Taiwan, from September 15, 2008, to January 14, 2009. The experimental design was a split-plot arrangement of a randomized complete block with three replicates. The tank mix of acetamiprid 20% SP, chlorpyrifos 22.5% EC, deltamethrin 2.4% SC, and methomyl 40% SP was applied at the recommended (label) dose (0.2, 1.5, 1.0, and 0.8

L/ha) and at 2 times the rates (0.4, 3.0, 2.0, and 1.6 L/ha), respectively. They were applied with a hand-driven knapsack sprayer. One application was conducted at 65 days (for Chinese cabbage and head lettuce), 80 days (for cabbage), and 98 days (for broccoli) after seeding of the respective vegetables.

Sampling and Storage. Sample (12 plants at least) collection was initiated 2−3 h after foliar application of a tank mix of four pesticides. The process of collection was repeated at 3, 6, 9, 12, 15, 18, and 21 days afterward to determine the residues of four pesticides in/on vegetable samples. Meteorological conditions were continuously recorded. During the period of pesticide application and sampling, daily total rainfall amounts ranged from 0 to 18.7 mm/day. The minimum and maximum temperatures were 10.1 and 31.1 °C, respectively. The stability of pesticides in vegetable samples during frozen storage was evaluated using 20 g aliquots of blank vegetable samples. The prepared blank samples in triplicate were spiked at levels of 0.25, 0.5, and 1 ppm (μg/g) of the four pesticides. The residues in blank samples were determined as described above.

RESULTS AND DISCUSSION

Recoveries of Pesticides. The recoveries of analytical methods were 72.3−109.0% (levels, 0.125−1.0 mg/kg; RSD, 0.3−9.6%; n = 3) for the residue determination of four insecticides on head lettuce, broccoli, cabbage, and Chinese cabbage. Limits of quantification (defined as a signal-to-noise ratio >10) were 0.01 mg/kg (Table 2).

Comparative Dissipation of Pesticides on Vegetables. Residues of four pesticides in/on four vegetable samples collected after pesticide application at double doses are shown in Figure 1−4. Whereas the initial deposits of all pesticides on head lettuce were higher than those of the other three crops at 0 days after application, the residues on all crops dissipated with time. On the four vegetables, acetamiprid residues declined to less than the tolerance (MRL), 2.0 mg/kg, at the recommended preharvest interval (PHI, 6−12 days, Figure 1). On head lettuce and broccoli, the concentrations of chlorpyrifos and deltamethrin were still higher than the tolerance at the PHI of 6−10 days (Figures 2 and 3). Only on the head lettuce were the residues of methomyl higher than 0.7 mg/kg at 6 days after application (Figure 4). Ripley et al. compared the residues of pesticides on different vegetables. The residues of five of the nine pesticides applied to cabbage, Chinese cabbage, and bok choi did not differ significantly from 3 to 14 days after application, but the

residues of cypermethrin and three fungicides were significantly higher on Chinese cabbage and bok choi.[8] Residues were generally significantly higher on bok choi than on the other cultivars.[8] Ripley et al. found that structure significantly affects

residue deposit and dissipation of pesticides on vegetables because of the higher exposed surface area-to-mass ratios; leafier crops had higher residue concentrations than head varieties.[8] Their results showed that different PHIs might be necessary to achieve established MRLs for the different cultivars.[8] Zhang et al. evaluated multiresidual dynamics of the pesticides in the spring (*B. oleracea* L. var. *capitata*) and autumn (*B. chinensis* L.) cabbages.[5,6] Their results showed that the pesticide residues were closely related with the times and dosages of application and the weather after spraying.[5,6] Raina and Raina studied the dissipation of chlorpyriphos on cauliflower following pesticide applications and recommend a safe preharvest interval of 6 days.[9]

Lots of variations of residue levels on different crops have been reported. Wang et al. studied pyrimorph residues in tomatoes and cucumbers and showed relatively similar dissipation rates, with half-lives of 5.8−7.7 days in tomatoes and 5.7−7.1 days in cucumbers.[10] Fujita et al. considered the difference in the relative distribution of acetamiprid and cypermethrin between cabbage and grapes might be due to the influence of various factors such as differences in crop species, plant cultivation methods, and physicochemical properties of the pesticides.[7] They found that the variability factors in the residue levels of both pesticides in cabbage were clearly higher than those in grapes.[7] Yu et al. reported that both the hermetic environment of a greenhouse and season affected dissipation rates of chlorpyrifos on pakchoi (leafy vegetable).[11] They found that chlorpyrifos declined more rapidly outside than inside the greenhouse.[11] Lozowicka et al. monitored the presence of pesticide residues in broccoli, Brussels sprouts, cauliflower, and head and Chinese cabbages produced in northeastern Poland (2006−2009), which could not be considered a serious public health problem.[12]

The global food classification and crop group was revised by Codex and the International Crop Grouping Consulting Committee (ICGCC). Head lettuce was grouped within the leafy vegetables but not a member of bulb or cole vegetables according to the classification of Codex or ICGCC. Our results indicated that head lettuce contains higher residues than other vegetables. The major production of vegetables is cabbage in Taiwan. Residues of eight of the nine pesticides on head lettuce were lower than on the other lettuces 1 day after the last application.[8] There are significantly different residue potentials and cultivated behaviors between head lettuce and the other leafy lettuces, so that head lettuce is not suitable for grouping within the leafy vegetables with small leaves.[8]

The present study demonstrated that the initial deposits of all pesticides in head lettuce were higher than in broccoli, cabbage, and Chinese cabbage. The concentrations of some pesticides were still higher than MRLs at the PHIs if treated with higher doses.

Storage Stability. All treated samples in this study were stored frozen for no longer than 336 days between sampling and analysis. Fortified and unfortified samples were analyzed to evaluate the storage stability of insecticides in vegetable samples during storage at −20 ± 5 °C for up to 336 days. The results indicated that these insecticides were stable in samples under frozen condition for up to 336 days.

International Forum, organized for the first time this year, brought interesting topics and comparisons between regulatory enforcement and monitoring approaches from different countries.

The papers included in this special section of the *Journal of Agricultural and Food Chemistry* are a good representation of the topics discussed at the 2013 NACRW and should provide an invitation to the future meetings, including the next one, which will be held July 20−23, 2014, at the TradeWinds in St. Pete Beach, FL, USA. Please come to learn, discuss, and network with your colleagues and take advantage of the many opportunities that this friendly event has to offer!

compounds, which have been used extensively as fragrance fixatives in PCPs, are also recognized as common contaminants in the environment, especially in water.[10] Previous concern arising from the use and persistence of nitro musks has led to restrictions on their use, and in recent times these compounds have been replaced by polycyclic musks, in particular galaxolide and tonalide. These are reported to account for around 90% of polycyclic musk usage in Europe during the past decade,[15] but there is only limited information on their occurrence in the environment and their potential uptake into food.

MATERIALS AND METHODS

Prioritization. The scope of the prioritization undertaken was dependent on the food type and contaminant group of interest. Usage information was used to identify the most used HPs and VMs in the United Kingdom (UK), whereas appropriate usage data for PCPs could not be identified and, therefore, compound identification was based on expert opinion. Prioritizations were performed for nine different scenarios: HPs and PCPs in leaf crops, root crops, fish, and offal and VMs in leaf crops, root crops, fish, offal, and mushrooms. For example, the prioritization of HPs in leaf crops considered usage, adsorption to sewage sludge, sludge application to land, irrigation of contaminated surface waters, and subsequent uptake into root and translocation to leaves.[16,17] The prioritization of VMs in farmed fish considered the potential surface water concentrations resulting from the treatment of intensively reared and pasture animals[18] and the subsequent theoretical fish steady-state plasma concentration.[19] Once the individual prioritizations were complete, the list was then finalized, taking into account the availability of methods for the analysis of the top-ranked compounds. The list of compounds analyzed by liquid chromatography−tandem mass spectrometry (LC-MS/MS) is given in Table 1. Also, six musk compounds (cashmeran, celestolide, galaxolide, tonalide, musk-xylene, and musk-ketone) were included in the study and analyzed by gas chromatography (GC)−high resolution (HR) MS.

Reagents. HP, VM, and PCP standards were obtained from Qmx Laboratories (Thaxted, UK), Toronto Research (Toronto, Canada), Witega (Berlin, Germany), or Sigma-Aldrich (Gillingham, UK). Thirteen labeled analogues were used in this study: difloxacin-d_3, ciprofloxacin-d_8, enrofloxacin-d_5, flubendazole-d_3, and dinitrocarbanilide-d_8, purchased from Witega; ^{13}C-erythromycin-d_3, danofloxacin-d_3, lincomycin-d_3, sulfadiazine-d_4, and tetracycline-d_6, obtained from Toronto Research; diclofenac-d_4 and ^{13}C-PCB77 from Cambridge Isotope Laboratories (Tewksbury, MA, USA); and ^{13}C methyl paraben from Fluka (Gillingham, UK).

Oxalic acid, glacial acetic acid, anhydrous sodium sulfate, aluminum oxide, sodium chloride, potassium phosphate monobasic, heptafluorobutyric acid (HFBA), and BakerBond CBX (500 mg, 6 mL) cartridges were acquired from Fisher Scientific (Loughborough, UK). Ethylenediaminetetraacetic acid (EDTA) disodium salt and trichloroacetic acid were purchased from Alfa Aesar (Heysham, UK). UPLC grade methanol, acetonitrile, and formic acid were obtained from Biosolve (Greyhound Chromatography, UK). Chromasolv acetonitrile and methanol, and magnesium sulfate, were purchased from Sigma-Aldrich. Doubly distilled grade dichloromethane, *n*-hexane, and ethyl acetate were acquired from Rathburn Chemicals (Walkerburn, UK). Polytetrafluoroethylene (PTFE, 0.22 μm) filters were obtained from QMX Laboratories. Dispersive solid-phase extraction (SPE) sorbents (Bondesil C_{18}, NH_2, and PSA) were supplied by Agilent (Wokingham, UK). Ultrapure water (18.2 MΩ cm) was obtained using a Purelab ultrapure water system (ELGA Purelab, UK).

Sampling. Approximately 400 individual food/crop samples were collected for analysis. Sample preparation (including compositing and separation of component plant parts) produced around 200 samples for analysis. Samples were homogenized under cryogenic conditions using dry ice to minimize any loss of analytes. After cryogenic homogenization, the subsamples requiring screening for musk compounds were freeze-dried.

Fish and Shrimp. A total of 30 samples of fish were collected from fish farms downstream of large urban sewage treatment effluent release points or from catchments close to areas of intensive livestock production. In addition, 21 samples of fish and 32 samples of shrimp imported from countries in Southeast Asia were also analyzed because of frequent detection of residues and reports issued by the EU Rapid Alert System for Food and Feed (RASFF). Fish were filleted, and the muscle including the subcutaneous fat was retained for analysis; the head, tail, and gut contents were not analyzed.

Mushrooms. A total of 33 mushroom samples were collected from retail sources (sample origins labeled as UK, Ireland, or China) and growers in England. Mushroom samples (*Agaricus bisporus*) cultivated using compost from the two main commercial suppliers in the UK were obtained. The mushroom samples collected in the early stages of the study were brushed and rinsed (tap water) to remove compost adhering to the surface. A number of mushroom samples collected during the later stages in the study were peeled and destalked prior to extraction and these parts analyzed separately. In addition to mushrooms, associated compost material was also collected.

Bovine Offal. Samples of bovine liver and bovine kidney were collected from abattoirs located in areas where the uptake of VMs or HPs and PCPs was considered a possibility: either rural areas associated with intensive livestock production or locations near major conurbations in the UK, respectively. Slices of kidney (typically 100 g) from 105 individual animals and slices of liver (typically 100 g) from another 95 individual animals were collected. On receipt at the laboratory the tissues were combined (5 samples representing 5 different animals, collected on the same day from the same abattoir) to produce a total of 40 composited samples (21 kidney and 19 liver) for analysis. This approach was employed to increase the chance of detecting residues because a greater number of animals would ultimately be tested.

Root and Foliage Crops. A total of 22 samples of sugar beet, oilseed rape, and wheat were analyzed. Sugar beet leaves and roots were analyzed separately. Similarly, the stalks and heads of wheat were separated and treated as individual samples. For oilseed rape the oilseeds were separated from the foliage. These crops were collected from fields that had received applications of animal manures (pig slurry or cattle manure) or biosolids just before the sampled crop was sown.

Table 2. Overview of Commodities and Compounds Classes Tested

	multiresidue	aminoglycosides	parabens	coccidiostats	musks
imported fish	yes		yes		yes
imported shrimp	yes		yes		yes
trout	yes		yes		yes
mushrooms	yes	yes		yes	
offal	yes				yes
plant crops	yes				yes

Sample Preparation. *Multianalyte/Multiclass Method.* The extraction method was based on the acetonitrile water extraction method described elsewhere.[20] Briefly, cryogenically milled analytical portions (5 g) of the samples were spiked with 12 available deuterated/^{13}C-labeled analogues. Water (2−5 mL depending on the sample) was added and the extraction performed using 1% oxalic acid in acetonitrile (15 mL). Anhydrous sodium sulfate (5 g) was added to reduce the water content prior to a cleanup step using dispersive solid-phase extraction (dSPE) with C18 and primary−secondary amine (PSA) to reduce the matrix coextractives. Finally, an aliquot (3 mL) of the extract was evaporated and reconstituted with acetonitrile/water (1:1, 1 mL). The final solvent composition was selected as a compromise between sufficient analyte solubility and acceptable chromatographic peak shapes for early-eluting polar compounds. All extracts were filtered through 0.22 μm PTFE filters.

In the case of kidney and liver, 1% acetic acid in acetonitrile (instead of oxalic acid) was used because this modifier resulted in lower amounts of coextractives.

Parabens. Cryogenically comminuted samples (5 g) spiked with ^{13}C-labeled methyl paraben were extracted with acetonitrile (10 mL). Magnesium sulfate (2 g) was added to reduce the volume of water in the final extract. Resultant extracts were purified by means of dSPE using C_{18} and PSA. Finally, an aliquot (4 mL) of the extract was concentrated to give a final volume of 1 mL in a mixture acetonitrile/water (1:1). All extracts were filtered through 0.22 μm PTFE filters.

Coccidiostats. Cryogenically milled mushroom samples (5 g), spiked with dinitrocarbanilide-d_8, were extracted with 1% acetic acid in acetonitrile (15 mL). Anhydrous sodium sulfate (5 g) was added to reduce the volume of water, prior to dSPE cleanup with C_{18} and NH_2. Finally, an aliquot (3 mL) of the cleaned up extract was evaporated and reconstituted with acetonitrile/water (3:1). All extracts were filtered through 0.22 μm PTFE filters.

Aminoglycosides. Aminoglycoside residues were extracted from mushroom samples using a phosphate (20 mM KH_2PO_4) and EDTA (0.4 mM Na_2EDTA) buffer containing trichloroacetic acid (2%) to precipitate proteins. The extract was then neutralized and cleaned up using a weak cation exchange solid-phase extraction cartridge (BakerBond CBX, 500 mg), which was eluted with 10% acetic acid in methanol (3 mL). The methanolic eluate was evaporated and reconstituted in an aqueous solution of an ion-pair reagent (400 μL of 20 mM HFBA).

Musks. An aliquot (10 g) of the freeze-dried sample was homogenized with a mixture of dichloromethane/hexane (40:60, 30 mL) and placed in an ultrasonic bath for 30 min at 40 °C. The extract was cooled, filtered through anhydrous sodium sulfate, and then concentrated to ∼0.5 mL. The concentrated extract was purified on activated alumina (6 g) previously washed with hexane (100 mL) followed by ethyl acetate/hexane (1:10), before elution of musks with ethyl acetate/hexane (1:2) and ethyl acetate. The extracts were concentrated to ∼250 μL with the addition of ^{13}C-labeled PCB77 internal standard. For some matrices, in particular kidneys, the final extracts were allowed to stand refrigerated, overnight/ and were then centrifuged to remove any solid material (e.g., salts) that may have precipitated, prior to analysis.

Analytical Approach. Due to the diversity of samples analyzed and because individual samples, even of the same sample type, can exhibit different suppression effects, a sample "overspiking" approach (single-point standard addition) was employed to assess the validity of each individual LC-MS/MS commodity−analyte result. In this approach each sample was analyzed twice, once without addition of analyte and once following addition of a known amount of analyte (typically equivalent to 1−10 ng/g in the sample, see Table 1). This enabled the detection of the analyte at the spiked concentration to be verified for each individual sample.

Analyte concentrations were quantified against matrix-matched calibration standards. The calibration curve typically comprised five concentration levels prepared using a single sample known to be blank and of the type relevant to the sample batch. Blanks were subject to the same procedures as the samples and were spiked with the corresponding standards and internal standards at the end of the extraction and immediately before the evaporation step. Internal calibration was used for a selected number of compounds; others were quantified by external standardization (Table 1).

Analytical standard solutions of each of the six musks were serially diluted in *n*-nonane and used to produce calibration standards for the quantification. The linearity of measurement with target musk compounds normalized to ^{13}C-PCB77 was confirmed over a range corresponding to <0.2−50 ng/g. An in-house reference material (fortified pike tissue) was run with each batch of samples analyzed. Results for these were in agreement with fortified values.

Determination Conditions. The analytical methods developed in this study included a multianalyte/multiclass procedure for the determination of 36 different VM and HP compounds and separate chemical-class specific methods for the determination of 10 aminoglycosides, 7 coccidiostats, 7 parabens, and 6 musks. Table 2 gives an overview of the combination of commodities and compound classes tested. Table 1 summarizes the ionization modes (positive or negative), capillary voltages, collision energies, and the transitions included in the LC-MS/MS methods. The method for the analysis of aminoglycosides included only one MS/MS transition for most of the compounds to optimize the response of the primary transition for the purpose of screening. Any samples found to contain potential residues of aminoglycosides would require further analysis.

Multianalyte/Multiclass Analysis. As well as parabens and coccidiostats, determinations were performed by ultraperformance liquid chromatography−electrospray (UPLC-ESI)-MS/MS using an Acquity UPLC-Xevo TQ-S system (Waters, Manchester, UK). Instrument conditions were typically within the following values: capillary voltage between 1 and 2.5 kV (the ESI source was operated in the negative mode for parabens and in positive mode for all other compounds), desolvation temperature and gas flow were 500 °C and 1000 L/h, respectively. The cone gas flow was maintained at 150 L/h and the source temperature set at 150 °C.

Aminoglycosides. Analyses were performed by high-performance liquid chromatography (HPLC)-ESI-MS/MS (Alliance 2695-Quattro Ultima, Waters). Instrumental conditions were the following: capillary voltage, 3 kV (ESI source operated in positive mode); desolvation temperature and gas flow, 300 °C and 741 L/h, respectively. The cone gas flow was mantained at 108 L/h and the source temperature set at 120 °C.

Chromatographic Conditions. *Multianalyte/Multiclass Method.* Separation of analytes was achieved using a Phenomenex Kinetex XB-C18 (100 × 2.1 mm, 2.6 μm) column maintained at 40 °C and gradient elution using (A) 0.1% formic acid in water and (B) 0.1% formic acid in methanol/acetonitrile (1:1). The gradient program was as follows: 95% A (0−0.2 min), 5% A (3.0−6.6 min), 95% A (6.7−8.0 min). The flow rate during the separation was set at 0.4 mL/min, but increased to 0.5 mL/min between 3.6 and 7.5 min to minimize the

dx.doi.org/10.1021/jf4052418 | J. Agric. Food Chem. 2014, 62, 3651−3659

time required to clean the column after elution of the analytes. The injection volume was 3 μL.

Parabens. Target compounds were separated using a Phenomenex Kinetex XB-C18 (100 × 2.1 mm, 2.6 μm) column maintained at 40 °C using gradient elution with (A) 1 mM ammonium acetate in water and (B) 1 mM ammonium acetate in methanol. The gradient program was as follows: 60% A (0−0.2 min), 45% A (2.5−4.9 min), 5% A (5.1−6.1 min), 60% A (6.3−7.8 min). The mobile phase flow used was 0.4 mL/min, and the injection volume was 1 μL.

Coccidiostats. The chromatographic separation was achieved using a Waters Acquity CSH phenyl-hexyl column (100 × 2.1 mm, 1.7 μm) maintained at 40 °C and gradient elution using (A) 0.1% formic acid in water and (B) 0.1% formic acid in methanol/acetonitrile (1:1). The gradient program was as follows: 95% A (0−0.2 min), 60% A (1 min), 5% A (3.0−5.6 min), 95% A (5.7−7 min). The mobile phase flow was set at 0.4 mL/min (0.5−0.6 mL/min from 3.5 to 5.7 min), and the injection volume was 1 μL.

Aminoglycosides. Aminoglycosides were separated using a Phenomenex Gemini C_{18} (100 × 2 mm, 3 μm) column maintained at 30 °C using a ternary gradient with water (A), acetonitrile (B), and 100 mM HFBA aqueous solution (C). The gradient was the following: 75% A, 5% B, 20% C (0−0.5 min); 20% A, 60% B, 20% C (1 min); 10% A, 70% B, 20% C (12 min); 0% A, 80% B, 20% C (12.1−15.0 min); 75% A, 5% B, 20% C (15.1 min). The injection volume was 30 μL and the flow rate set at 0.25 mL/min.

Musks. Musk determinations were performed using a Micromass Autospec high-resolution mass spectrometer coupled to an Agilent 6890N gas chromatograph fitted with an Agilent J&W DB-5 MS fused silica capillary column (60 m × 0.25 mm i.d., 0.25 μm film thickness) and a programmable temperature vaporisation (PTV) injector operated in constant flow (∼1 mL/min helium) mode. The mass spectrometer was operated in electron ionization (EI) mode at a mass resolution of ∼10000 (at 10% peak height). Two ions were monitored in the selected ion monitoring (SIM) mode: *m/z* 206.1671, 191.1436 (cashmeran); *m/z* 244.1827, 229.1592 (celestolide); *m/z* 258.1984, 243.1749 (galaxolide); *m/z* 258.1984, 243.1749 (tonalide); *m/z* 282.0726, 297.0961 (musk-xylene); and *m/z* 279.0981, 294.1216 (musk-ketone). An acceleration voltage of 7 kV was used in conjunction with an electron energy of 32−37 eV and a trap current of 450 μA. The GC-MS interface was set to 280 °C.

Samples (5 μL) were injected into the PTV injector at 60 °C. The PTV injector program consisted of a 3 min isothermal period at 60 °C followed by heating at 12 °C/s to 320 °C, for 10 min, then at 12 °C/s to 340 °C to the end of the run. The chromatographic separation was achieved using the following temperature program: isothermal period at 60 °C (5 min), 24 °C/min to 160 °C for 2 min, 3 °C/min to 250 °C, and 5 °C/min to 300 °C for 3 min.

RESULTS AND DISCUSSION

Validation. Validation of the LC-MS/MS methods was based on an overspiking approach in an attempt to counter matrix effects from the complex samples analyzed. This approach, which we refer to as sample overspike validation, involved analysis of all samples without spiking and with overspiking at 1−5 ng/g (10 ng/g in the case of aminoglycosides).

This overspiking approach demonstrated whether or not the response obtained for each analyte in each sample was acceptable. Recoveries were calculated against matrix-matched calibration standards prepared from blank samples. With the exception of aminoglycosides, linearity was typically confirmed over a range corresponding from 0.2 to 5 ng/g for LC-MS/MS compounds spiked at 1 and 1.0−25 ng/g for compounds spiked at 5 ng/g (see Table 1). For aminoglycosides, the calibration curves were linear over the range 1−20 ng/g. As expected, the recoveries were more variable than those obtained with the usual approach to validation (spiking a single matrix in a single batch), but were considered to provide a more realistic assessment of method performance. In total, >6500 recovery determinations were carried out to support the validity of the methods used.

The assessment of the results from the multiresidue method for the samples of fish and shrimp overspiked at 1 ng/g (24 analytes) and 5 ng/g (12 analytes) demonstrated that the method was fit for the purpose. The majority of recoveries were in the range of 60−120%, and associated relative standard deviations (RSDs) were generally <20%. The method did not produce reliable results and/or the response was insufficient for cefalexin, chlorhexidine, florfenicol amine, sulfasalazine, and tramadol. For the analysis of both imported fish and shrimp, enrofloxacin, chlortetracycline, and flucloxacillin suffered from irreproducible calibration. The analyte responses in mushroom were generally not as good as in fish, but most of the recoveries were in the range of 53−107% with associated RSDs between 8 and 33%. Florfenicol amine and chlorhexidine gave no detectable response at any of the concentrations (up to 10 ng/g) tested, possibly because of suppression of the response by matrix coextractives. In the case of liver samples, the majority of recoveries were in the range of 57−104% with associated RSDs below 29%. For kidney composite samples recoveries were generally between 50 and 127% with associated RSDs below 23%. Oilseed rape proved to be the most challenging plant crop matrix. Ten compounds that were detected in other matrices (e.g., sugar beet) could not be reported in oilseed rape due to lack of sufficient selectivity or sensitivity. For sugar beet samples (roots and leaves) recoveries ranged from 52 to 135%, excluding salinomycin and quinine. Recoveries for wheat heads and stalks were quite similar and above 50% with the exception of salinomycin and with RSD <20% excluding chlortetracycline and robenidine.

The collated recovery results for parabens in fish and shrimp were in the range of 79−125% with associated RSDs in the range of 4−23%. In the case of coccidiostats in mushrooms, recoveries were in the 41−106% range with associated RSDs below 13% except for diclazuril, which was more variable.

During an initial validation using matrix-extracted calibration (spikes before extraction), 10 aminoglycosides were detected at 2−5 ng/g in mushroom samples with recoveries in the range of 98−127% with associated RSDs in the range of 7−20%. Unfortunately, the response of the LC-MS/MS could not be maintained during the analysis of sample batches, presumably because of differences in matrix effects, and thus the reporting limits had to be raised. This is one of the reasons why we opted for the overspiking approach to ensure the validity of the data generated in each batch. The collated recovery results for seven aminoglycosides from the overspiking of each individual mushroom samples at 10 ng/g were in the 58−85% range with associated RSDs in the range of 9−20% For neomycin B low and variable recoveries were observed, but the response was sufficient to screen samples, especially as the overspike was detected in all cases. Streptomycin and spectinomycin were not detected at the highest spiking concentration (10 ng/g), and hence no results were obtained for these two compounds.

The linearity of measurement with target musk compounds normalized to ^{13}C-PCB77 was confirmed over a range corresponding to <0.2−50 ng/g. The analytical recoveries were typically in the range of 50−100%, but musk-xylene, which is more labile, generally gave lower recoveries (typically 30−46%). Measurement precision determined using a fish

matrix was found to be in the range of 13–21% (RSD) except for cashmeran, which was higher at 30%.

The recoveries for analyte–sample combinations found to contain incurred residues are presented in Table 3. The reporting limits for analytes determined by LC-MS/MS across the different matrices are presented in Table 4. The reporting limits for musk compounds were found to be as low as 0.01–0.02 ng/g but typically higher, around 0.15 ng/g, for galaxolide and tonalide, reflecting their widespread environmental presence and much greater current use.

Table 4. Overview of LC-MS/MS Reporting Limits for the Several Compounds Tested across the Different Matrices

[a]S/N, signal-to-noise ratio.

Study Findings. A summary of the residues found in the different matrices analyzed are presented in Table 5. Results indicate that the uptake of target chemicals was limited, and the residues detected were mostly at low nanograms per gram concentrations. Some differences observed between samples were related to the country of origin and sampling location.

Fish and Shrimp. Samples of trout from the UK contained up to eight different contaminants, whereas fish and shrimp from Southeast Asia were found to contain up to five of the targeted analytes. Methyl paraben (MeP) was found in the concentration range of 0.6–2.8 ng/g in 23 samples (77%) of UK trout and propyl paraben (PrP) in 19 samples (63%) at concentrations in the range of 0.4–1.3 ng/g. By contrast, these compounds were detected at lower concentrations in fish and shrimp imported from Southeast Asia. Because parabens are approved for use as food preservatives,[14] the low concentrations detected in this study are not likely to give cause for concern to regulators. Initially, it was thought that the results could reflect the difference in usage of these compounds in Southeast Asia and the UK; however, Ramaswamy et al.[21] detected MeP, PrP,

Table 5. Overview of Residues Found in the Selected Commodities[a]

	residues (ng/g)

[a]Range of found concentrations, with the percentage of samples containing residues above reporting limit given in parentheses; i, indicative value (residue concentration outside calibration range or calibration issues). Number of samples analyzed for musk compounds were UK trout (29), imported fish (10), imported shrimp (10), liver (17), and kidney (18).

and ethyl paraben (EtP) compounds in >90% of the analyzed samples at concentrations up to 3600 ng/g (MeP) in different species from Manila Bay in The Philippines, which suggests that the occurrence of these chemicals in fish is scenario-related.

MeP and PrP (as well as EtP) are the most commonly found paraben species in the environment.[11−13] MeP and PrP occur in raw wastewater at concentrations up to 10 and 2.8 μg/L, respectively.[13] However, their elimination rates at wastewater treatment plants have been reported to be high, and thus very low levels are found in effluent samples.[21,22] This may explain why low concentrations of parabens were found in fish samples obtained from fish farms located downstream of wastewater treatment plants compared to other scenarios (Table 6).

Residues of enrofloxacin (0.3−5.1 ng/g), a fluoroquinolone antibiotic, were detected in 21 samples (100%) of fish and in 2 samples (6%) of shrimp (1.3 and 4.7 ng/g) from Southeast Asia. By contrast, no residues of enrofloxacin were detected in UK trout, but this is not surprising because enrofloxacin is not authorized for use on fish in the UK. One sample of shrimp from Bangladesh contained a residue of lincomycin at 1.10 ng/g.

The results obtained for enrofloxacin are in general agreement with reports in the literature. He et al.[23] reported the occurrence of selected fluoroquinolones (norfloxacin, ciprofloxacin, and enrofloxacin) in fish collected from two marine aquaculture regions of the Pearl River Delta in China. The presence of this fluoroquinolone in farmed shrimp from Vietnam has also been reported in recent years.[24]

Residues of musk compounds occurred at higher concentrations (up to 50 ng/g) and higher frequency (100%) in trout collected in the UK compared to imported fish from Southeast Asia, for which 70% of the samples contained residues of up to 0.3 ng/g. Shrimp imported from Southeast Asia showed considerably lower occurrence and were found to contain only musk-xylene at 0.04 and 0.06 ng/g in two samples and musk-ketone at 0.02 ng/g in one sample. The highest concentrations of galaxolide and tonalide occurred in fish collected from fish farms located downstream of large urban sewage treatment effluent release points in the UK (Table 6). As only one species of freshwater fish (trout) was investigated, species selective uptake cannot be ruled out. However, other studies on contaminants in freshwater fish indicate a greater dependence of contaminant occurrence on local pollution levels. The occurrence of the individual musk compounds in fish and shrimp confirms the potential for human dietary exposure and may also indicate the chronology and magnitude of usage. "Older" compounds such as musk-xylene and musk-ketone, which are no longer used, were either not detected or occurred at a much lower frequency than polycyclic musk compounds such as galaxolide and tonalide. The use of these is more recent, accounting for >90% of polycyclic musk usage.[15] Similarly, the lower occurrence of cashmeran and celestolide may reflect their decreasing usage.

Mushrooms. Residues of trimethoprim, which is used as a potentiator for sulfonamide antibiotics, were detected at approximately 0.07−0.73 ng/g in 18 (72%) mushroom samples both in mushroom caps and in peelings/stalks at similar concentrations, indicating that occurrence was not due to surface contamination. Identification of trimethoprim was based on the ratio of two transitions in the sample compared to the ratios in a matrix-matched standard. Selected samples were reanalyzed using a different column and including an

additional third transition in the method to provide more confidence on the identification of these very low level residues. Additional evidence of identification of trimethoprim for some samples was also provided by MS/MS with measurement of the fragment ions at 35000 resolution (Thermo Scientific Orbitrap technology). Although trimethoprim was not detected in the selected compost samples analyzed (possibly due to deficiencies of the extraction method for compost), the relatively consistent concentration of trimethoprim throughout the mushroom does suggest possible uptake. Further analysis of the compost using improved methodology is required to attempt to detect residues and thus provide further evidence for possible uptake.

No residues of aminoglycosides were detected in mushrooms at or above 5 ng/g. The method of analysis was particularly problematic for compost. Without reliable detection of aminoglycosides in mushroom litter, it is difficult to conclude that no uptake occurred.

Samples of mushroom compost prepared from chicken litter were screened for veterinary drugs by LC-ToFMS. The mushroom compost matrix proved to be difficult, binding analytes to give rise to low recovery or causing matrix suppression and chemical interference in LC-MS. No residues of the sulfonamides sought were detected in the compost, but this could have been as a result of poor extraction with the methods employed. Residues of coccidiostats were detected in selected composts at estimated concentrations up to 60 ng/g DNC, 54 ng/g monensin, and 1 ng/g narasin. At this point, it was decided to screen the mushroom samples for a number of coccidiostats not included in the priority list. Although a specific method for the analysis of coccidiostats was employed, the recovery of coccidiostats spiked into the compost matrix were variable and <40%, indicating that the extraction efficiency for incurred residues is likely to be poor. Hence, further investigation using a more appropriate method is required to be able to provide a more definitive conclusion. No residues of coccidiostats were detected in any of the mushroom samples analyzed. Strong binding to the compost could explain why there was no bioavailability of these compounds.

Bovine Offal. Composite liver and kidney samples contained up to five different residues. Residues of decoquinate (0.4 and 0.5 ng/g), diclofenac (0.2 and 0.2 ng/g), and tilmicosin (0.3 and around 7.9 ng/g) were found in composite samples of liver. Decoquinate at 0.5 ng/g was also found in one composite sample of kidney.

Diclofenac, decoquinate, and tilmicosin are all approved for use in cattle in the UK; therefore, it is impossible to differentiate whether the residues detected in the bovine liver and kidney samples were a result of normal medication or indirect exposure through the contamination of food and/or drinking water.

Musk residues found in offal samples were at much lower concentrations than those detected in fish samples. In liver samples, galaxolide showed the highest concentrations (0.8−2.3 ng/g in seven composite samples) followed by tonalide (0.4−1.2 ng/g in three composite samples). Residues of cashmeran, celestolide, and musk-xylene were not detected (LOD−0.3 ng/g) in any samples of liver. Musk-ketone was not detected in any of the composite samples. In the case of kidney, neither musk-xylene, musk-ketone, nor cashmeran was detected in composite samples. As for liver samples, the highest residue concentrations corresponded to galaxolide (0.9−~2.5 ng/g) followed by tonalide (0.2−0.4 ng/g) and celestolide (three samples contained 0.02 ng/g).

Root and Foliage Crops. The only residues detected in crops were musk compounds. Residues of all six musks were detected at or above respective reporting limits in wheat samples with concentrations up to 4.5 ng/g. Two of three samples of sugar beet leaves contained cashmeran at 0.2 ng/g. None of the three samples of sugar beet roots analyzed contained musk compounds at detectable concentrations. This may suggest contamination of foliage, either by aerial deposition or from surface contact with contaminated soil, but the reasoning can only be tentative given the low number of samples analyzed.

Hu et al.[25] systematically evaluated the occurrence and potential uptake of 10 veterinary antibiotics by crops (radish, rape, celery, and coriander) in fields amended with manure in northern China. Uptake in different crops was variable. Radish leaves were found to contain nine antibiotics at concentrations between 0.1 and 57 ng/g, whereas in roots three compounds were detected: oxytetracycline at 8.3 ng/g, sulfadoxine at 0.1−0.4 ng/g, and lincomycin at 1.5−3.9 ng/g. Across all of the crops in this study the highest concentrations were found in leaves followed by stems and roots. In our study only a limited number of plant crop samples were analyzed. Musk residues were detected in sugar beet leaves but not in the roots (data based only on three samples). Because sugar beet roots, compared to radish, are relatively large, any low-concentration residues may have been further diluted by growth of the root. Crop samples were collected from fields that had received biosolid or slurry/manure applications. No attempt was made to confirm whether these materials contained any of the analytes of interest; therefore, the lack of detection does not necessarily represent a lack of uptake, but could indicate the soil improvers did not include the contaminants in the first place.

Funding

We acknowledge the U.K. Food Standards Agency for funding the work (FS241004). M.G.L. acknowledges her funding through a postdoctoral contract by the Spanish Ministry of Education, Culture and Sport (National Programme for Human Resources Mobility R&D and Innovation 2008-2011).

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

We acknowledge the support from the farms, fish farms, mushroom growers, and abattoirs that allowed sample collection from their establishments. Moreover, we thank Jonathan Hulland (Centre for Environment, Fisheries and Aquaculture Science), Tim Burch (Anglian Water Ltd.), and Gemma Forrest (Food Standards Agency) for their assistance with site identification and sample collection. In addition, we thank the many analysts at Fera who also contributed to sample preparation and analysis, particularly Daniel Kneale, Melissa Bowen, Alyson Moore, Melanie Holland, Mike Hetmanski, Frankie Smith, James Jowett, and Lewis Hutchinson.

data that can be evaluated later to look for additional nontargeted compounds.

Another reason to collect exact mass data for a large number of compounds is that elemental compositions for product ions can be proposed using a combination of measured exact

dx.doi.org/10.1021/jf405321w | J. Agric. Food Chem. 2014, 62, 3660−3674

masses, isotope patterns, predictive fragmentation pathways, and published literature. The compiled data will be useful for the development of future veterinary drug residue methods regardless of the MS platform (e.g., Orbitrap or triple quadrupole) that is utilized. This paper describes the collection and evaluation of measured exact mass data for approximately 200 veterinary drugs obtained using a LC Q-TOF MS. In addition, determining how well the compounds of interest chromatograph and are extracted from a matrix with a given analytical method is important when implementing these procedures to analyze regulatory samples. The performance of many of these compounds through the milk screening extraction procedure described earlier[1] was evaluated, and these results are also reported.

MATERIALS AND METHODS

Reagents and Consumables. Solvents used to prepare standard stock solutions (methanol and dimethylformamide (DMF)) were HPLC grade purchased from EMD Chemicals (Billerica, MA). The water, acetonitrile, and formic acid used to prepare the LC mobile phase were LC-MS grade (Fisher Optima, Fair Lawn, NJ). Formic acid solution (0.1% v/v) was prepared by pipetting 1.0 mL of formic acid into a 1000 mL graduated cylinder and diluting to mark with water. Amicon Ultra centrifugal filters (0.5 mL, 3000 Da molecular weight cutoff, no. UFC500396) were purchased from Millipore Corp. (Bedford, MA). LC column was YMC ODS-AQ, 120 Å, 2 mm × 100 mm, 3 μm, no. 50−874−228 (Fisher Scientific, Houston, TX).

Standard Preparation. The majority of standards used in this study were purchased from Sigma Aldrich (St. Louis, MO). Several other compounds were already being used in our laboratory for regulatory residue methods, and these were primarily purchased from U.S. Pharmacopeia (Rockville, MD). A few of the less common compounds were purchased from alternative sources such as LKT (St. Paul, MN) and Waco (Richmond, VA). Individual stock solutions were prepared for all compounds at a concentration of approximately 100 μg/mL (ranging from ∼50 to 200 μg/mL) in methanol depending on solubility and amount of standard available. If not soluble in methanol, the standards were dissolved in water or DMF. Mixed working standards were made by diluting an appropriate volume (after correcting for purity and any counterion) of stock standards to 10 mL with either methanol or water to give a final concentration of 1000 ng/mL. Then serial dilutions were prepared with 0.1% formic acid at concentrations of 100, 10, and 1 ng/mL for LC Q-TOF MS analysis.

LC Q-TOF MS Parameters. The LC Q-TOF MS was operated using the conditions described earlier.[1] Briefly, the instrument was an Agilent (Santa Clara, CA) quadrupole time-of-flight (Q-TOF) 6530 mass spectrometer coupled to an Agilent 1290 liquid chromatograph. Electrospray ionization with Agilent Jet Stream Technology was utilized. The time-of-flight MS was calibrated daily. Typical resolution values obtained during calibration were 9000 (m/z 322) and 15000 (m/z 1522) full width half-maximum. A reference mass solution was continuously introduced along with the LC stream for accurate mass calibration at a flow rate of ∼0.005 mL/min using a stand-alone LC pump with a flow of 0.5 mL/min and a 100:1 splitter (Agilent no. G1607-60000). Reference masses at m/z 121.05087 (purine) and m/z 922.00980 (hexakis(1*H*,1*H*,3*H*-tetrafluoropropoxy) phosphazine) were used for positive ion; m/z 112.985587 (trifluoroacetate) and 966.000725 (formate adduct of hexakis(1*H*,1*H*,3*H*-tetrafluoropropoxy) phosphazine) were used for negative ion.

The following parameters were used for the MS source: fragmentor (150 V), nozzle (250 V), Vcap (4000 V), drying gas (11 L/min, N_2), sheath gas (11 L/min, N_2). The TOF (MS^1 only) data acquisition rate was 4 GHz (to m/z 1700) and the actual scan range was m/z 100−1200 at a rate of 1.08 spectra/s. Data were collected in both centroid and profile modes. In general, to minimize processing time only centroid data were evaluated, but profile data could be used to better distinguish coeluting isobaric compounds if needed. Compounds that ionized in the negative ion mode were analyzed separately using a different acquisition program. The MS source parameters were as above for negative ion except that the Vcap and nozzle voltages were 2000 and 200 V, respectively.

The LC program was also consistent with previous work[1] using an YMC ODS-AQ column with gradient of 0.1% formic acid and acetonitrile as follows: 5% acetonitrile for 2 min, ramp 5−50% acetonitrile over 10 min, hold at 50% acetonitrile for 1 min, ramp 50−100% acetonitrile over 3 min, hold at 100% acetonitrile for 2 min. The flow rate was 250 μL/min, and the column was maintained at room temperature (22 ± 1 °C). A postequilibration time of 3 min was used. Injections of 10 μL were made with a 3 s 50:50 methanol:water needle wash. For most analytes, the column was held at 100% acetonitrile for the 2 min described above for a total analysis time of 18 min. However, some compounds being investigated did not elute in that time frame, so an additional 4 min of 100% acetonitrile can be added to the chromatographic program to make an extended LC program that is 23 min long.

Once retention times and precursor ions (MH^+, $M - H^-$, or MNa^+) were established, MS/MS data were collected at three different collision energies (CEs) for each compound. The formula "[3 × (mass/100)] + 10" is suggested by Agilent to calculate a reasonable CE for compounds using their acquisition software and was used here; data were also collected at approximately 10 V higher and lower than that value. Medium isolation width (4 m/z) and 200 ms/spectrum were used to collect product ion spectra. These spectra, along with retention time information, were added to the in-house database using the Agilent *Personal Compound Database Library* software.

Solvent Standard Analysis. For the initial analysis, compounds were randomly mixed according to the order in which they were prepared (mixtures of 4−10 analytes). These mixed solvent standard solutions were prepared at concentrations of 100, 10, and 1 ng/mL and analyzed. Compounds that had been characterized and documented previously[1,11] were not reanalyzed, but those data are also shown in Table 1.

Milk Samples. Several brands of pasteurized whole milk were purchased from local retail stores. After testing to ensure that this milk did not contain any analytes, it was used for negative control and was fortified with target compounds. Incurred (raw) milk obtained from the Food and Drug Administration's Center for Veterinary Medicine was also used. Milk was aliquoted (1.0 mL) into 15 mL centrifuge tubes and frozen (−40 °C) until needed.

Extraction of Milk Samples. Analytes were fortified into milk and extracted using the method published earlier[1] and briefly described here. Acetonitrile (1.0 mL) was added to 1.0 mL of milk, and the sample was vortex mixed for 20 s and then centrifuged at 3250 rcf (× *g*) and 4 °C for 20 min. A 1.0 mL aliquot of the resulting supernatant was transferred to a 16 mm × 150 mm disposable glass tube containing 0.5 mL of 0.1% formic acid. Using a Turbo-vap set at 40 °C with nitrogen (10−15 psi), the solvent was evaporated until the volume was slightly less than 0.5 mL. The sample may be quite cloudy at this point. Sample cleanup was performed with 3000 Da molecular weight cutoff centrifuge filters that were first prewashed by adding 0.5 mL of 0.1% formic acid to the filters and centrifuging at 17000 rcf (× *g*) for 5 min. The extracts were added to the cutoff filters, and the volume was adjusted as needed to ∼0.5 mL with 0.1% formic acid. The samples were centrifuged at 17000 rcf (× *g*) for 15 min, and then the filtered extracts were transferred to LC vials (polypropylene with conical insert for low volume) for analysis.

Fortification and Validation Protocol. For the fortification experiments, analytes were generally grouped by class (e.g., sulfonamides, quinolones, macrolides) and mixed fortification standards were prepared at 1000 ng/mL using methanol or water. Milk was fortified at levels varying from 5 to 100 ng/mL by adding an appropriate volume of the mixed fortification standard. For example, to fortify 1 mL of milk at 10 ng/mL, 10 μL of the 1000 ng/mL mixed fortification standard was added. Samples for each level were prepared in triplicate and analyzed by using both TOF (MS^1) and MS/MS acquisition programs. For some compounds that performed poorly, a higher concentration fortification standard was made at 10000 ng/mL (10 μg/mL) and added to the milk, for a final fortification level of

dx.doi.org/10.1021/jf405321w | J. Agric. Food Chem. 2014, 62, 3660−3674

500−1000 ng/mL. For analytes that performed well in initial testing (~60 new compounds were detected at 10 ng/mL or lower), additional validation samples (n = 20) were prepared by fortifying milk at 10 ng/mL. Three different sources of milk (retail organic whole (n = 6), retail nonorganic whole (n = 6), and raw (n = 8)) were used for this part of the method validation. Nonfortified samples from each source of milk were also analyzed as negative controls. The number of false negatives and the precision of the analyte response (MS^1 only) at the 10 ng/mL fortification level were determined from this expanded sample set.

Data Analysis. The TOF data were evaluated against a database of compounds compiled in-house for their possible veterinary drug application (n = 267). Using Agilent's MassHunter *Find by Formula* algorithm, data files were compared to the database using search windows of 10 ppm and a 1 min retention time for ions corresponding to $[M + H]^+$, $[M - H]^-$, or $[M + Na]^+$. Mass accuracy errors were obtained by comparing experimental data to potential matching compounds in the database. The MS/MS data were processed by manually extracting narrow window (10 ppm) product ion scans. Product ion spectra from the resulting extracted ion chromatograms were evaluated by comparing mass assignments to theoretical values.

RESULTS AND DISCUSSION

Analysis of Solvent Standards. Our laboratory has an in-house database that contains formulas and exact mass data for 267 veterinary drugs. Approximately 200 of these analytes were included in this study and are listed in Tables 1 and 3. The remaining are minor components of mixtures (e.g., eprinomectin B1b) or drug metabolites for which no standards were available. Although this database may change over time when new compounds are added or more analytical standards become available, this paper describes the process and impact of adding additional data (retention time, product ions, and method performance information) to exact mass data when applying this technology to regulatory food analyses. With very few exceptions, all of the compounds analyzed by this LC QTOF MS method were detected. Many analytes could be detected at levels down to 1 ng/mL using the *Find by Formula* software program; others were found only at concentrations of 100 or 10 ng/mL. A list of the compounds analyzed, their formulas, neutral masses, and precursor ions are given in Table 1. Most were detected as the protonated molecules with a measured mass within 2 ppm of the theoretical values. Some compounds, including ionophores such as monensin, formed sodium adducts; others were detected only in negative ion mode. For a few analytes, degradation products were observed, in addition to or instead of, the expected parent compound. This has been documented previously for penicillin G and macrolides.[1,5,13,14] In another example, troleandomycin should have a formula of $C_{41}H_{67}NO_{15}$ with a protonated molecule at m/z 814.4583. Instead, only m/z 772.4478 was observed, indicating degradation by loss of an acetyl group to form desacetyl troleandomycin, a compound isobaric with desmycosin which is a degradation product of tylosin. Others[15] have observed this as well, listing the expected precursor ion of troleandomycin as m/z 772.5.

The observed retention times for these compounds are also listed in Table 1. The retention times remained fairly stable over time (well within the 1 min time window) regardless of whether analyzing solvent standards or milk extracts, with instrument maintenance, and with LC column replacement. Some nonpolar compounds, including the avermectins, required an extended chromatographic program to elute from the LC column. Although the retention times generated will be specific to this column and mobile phase gradient, the relative polarities of these compounds as measured by elution times on a reversed-phase LC column should still be useful to others.

Using Experimental Data to Rule out False Detects. Using the *Find by Formula* algorithm and only measured exact mass data (no retention time matching required) resulted in many false detects in milk samples, even when being compared to a relatively small (n = 267) database of compounds. This is in part due to the need to set the mass window relatively wide (10 ppm) for the initial screen. We have previously shown that when using instruments with medium (10−15K) resolution, interfering matrix components can cause shifts in mass accuracy.[1] Table 2 shows an increase in false negatives, especially at lower residue levels, when the mass window is narrowed to 5 ppm.

Table 2. Percent False Negatives for Milk Fortified with Sulfadimethoxine, Oxytetracycline, Penicillin G, and Erythromycin

fortification level[a] (ng/mL)	5 ppm window (%)	10 ppm window (%)
20	13	3
10	27	10

[a] N = 60 at each level (5 samples × 3 replicate injections × 4 residues).

The use of a relatively wide mass window can lead to the apparent detection of compounds that are not actually present (false detects that could lead to the reporting of false positives), especially when sample extracts are not very clean because rapid generic extraction procedures are used. In some cases using the *Find by Formula* program, the ^{13}C (M + 1) isotope ion of a matrix component will match the m/z of a compound in the database when screening with a wide m/z window. Others have also observed this phenomenon.[9,12] An example of this is shown in Figure 1, where moxidectin was "detected" even though the ion correlating with the protonated molecule of moxidectin (m/z 640.3844) is part of an isotope pattern for an ion at nominal m/z 639. Analysis of an actual standard of moxidectin shows a peak at a much later retention time, with MNa^+ as the primary ion. There can also be ubiquitous impurities, either from matrix or instrument background, that are isobaric with known analytes. Figure 2 shows a false detect for netilimicin in a milk extract. The mass accuracy (<5 ppm) and isotope pattern indicate a reasonable match for this compound. But because netilimicin is an aminoglycoside, it is not expected to elute in the middle of the gradient program with good chromatographic peak shape. However, until an actual standard of this compound could be obtained and was observed to elute with the solvent front as expected, it could not be completely ruled out. The product ion spectrum of netilimicin also does not match that obtained from the impurity (data not shown).

By adding retention time and product ion data for most compounds in the database, the analysis of samples becomes much more efficient as many false detects can be ruled out quickly based initially on retention time matching followed by product ion comparison if needed. Data files from milk sample extracts (N = 120; 40 samples injected in triplicate) were evaluated against the veterinary drug database with and without retention time matching. When retention time matching was included, significantly fewer compounds (average of 3) were detected as compared to when only accurate mass was used (average of 30 compounds "found" in each data file). Instrument companies are also aware of these issues, and in

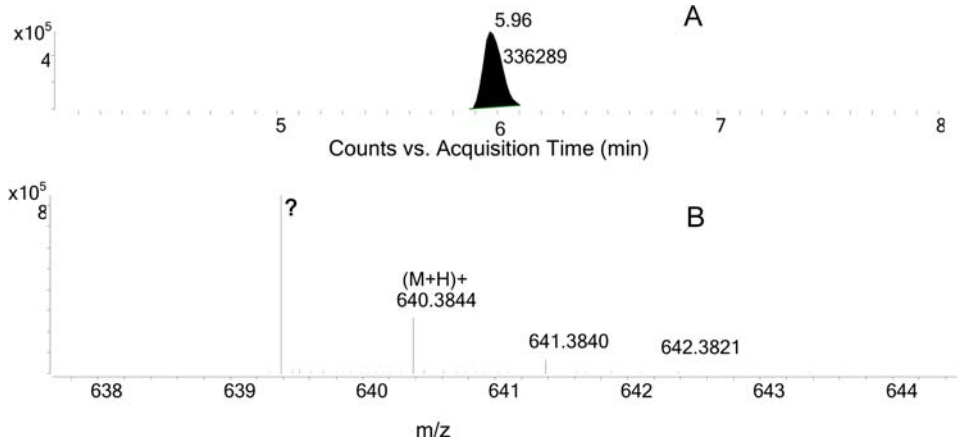

Figure 1. False detection of moxidectin. Extracted ion chromatogram in milk extract with 10 ppm window for MH^+ (m/z 640.3844) gives reasonable chromatographic peak (A), but inspection of the MH^+ spectral pattern (B) shows this ion is ^{13}C isotope peak of another (matrix) compound.

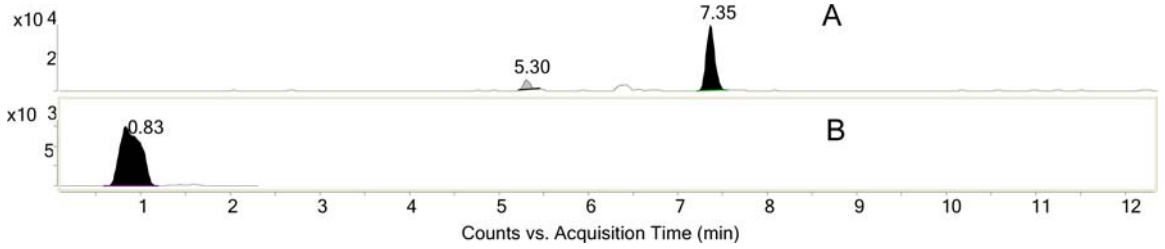

Figure 2. False detection of netilimicin. Extracted ion chromatogram in milk extract with 10 ppm window for MH^+ (m/z 476.3079) gives reasonable chromatographic peak (A), but analysis of a 100 ng/mL standard of netilimicin (B) indicates analyte has very different retention time.

addition to improving their software data mining capabilities, they are developing "turn-key kits" for residue analysis. For example, Waters Corp. is marketing the *UNIFI* package[16] for pesticide analysis which includes standard mixes, chromatographic columns, methods, and databases that include retention times and product ion spectra specific to their methodology. Agilent has recently developed a similar kit for residues including veterinary drugs, hormones, and many pesticides.[17]

Detection of Analytes in Milk Extracts. Ideally, the compounds that are detected with the LC Q-TOF MS instrumental method could also be reliably monitored in milk using this method. To determine the actual ability of this method to detect analytes of interest in this matrix, varying levels of these compounds were fortified into control milk samples that were then extracted. A majority (56%) of the analytes tested in milk extracts could be successfully detected using the *Find by Formula* program at levels of 10 ng/mL or lower (see Table 1 and Figure 3). At fortification levels of 100 ng/mL, over 70% of analytes could be detected. The estimated screening limit of detection is defined as the level at which an analyte was found in all three replicate injections. For a few analytes (noted in Table 1), the compound was found in only two of the replicates at the level of detection but was also found in at least one replicate at a lower level of fortification. Analytes that had been previously validated for the milk screening method were not reanalyzed. This initial set of 25 compounds had tolerance or safe levels in the United States. So although the majority of the data for these analytes were collected for samples fortified at that "1X" level, some experiments were performed to determine the limits of detection in milk. These results were published previously[1] but are also included in Table 1 for comparison.

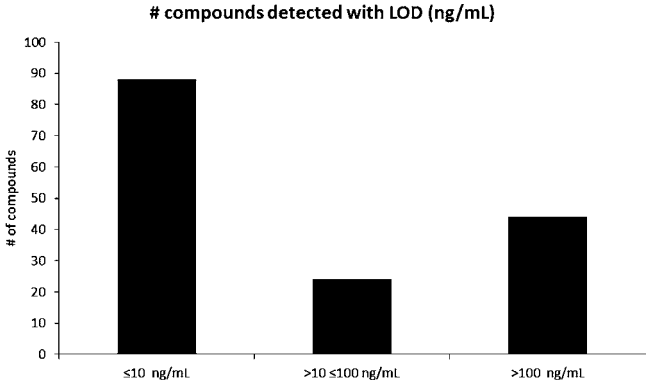

Figure 3. Screening LODs (ng/mL) for analytes in milk. LOD is defined as the fortification level at which an analyte is found. A total of 156 compounds were tested.

For most new analytes that could be detected at 5−10 ng/mL in the initial experiments, additional replicates (n = 20) using three different sources of milk fortified at 10 ng/mL were prepared and analyzed. The majority of analytes in this validation were detected in all 20 replicates (or >90%) using *Find by Formula* analysis of the MS^1 data. The few exceptions were acepromazine and sulfaguanidine, as well as two cephalosporins. In addition, the variance of the signal from analytes in milk fortified at 10 ng/mL is also documented in Table 1. In general, the relative standard deviation for the analytes tested at this level was 20−25%. Given the fact that the final extract volume was not meticulously controlled and internal standards were not used, this type of variance is reasonable and acceptable for this type of screening method. Some residues, especially those with a lower response and

[a]Product ions listed in order of abundance (will depend on collision energy used). [b]Experimental exact mass for ion differed from the theoretical value listed in this table by 5−20 ppm. [c]Experimental exact mass for ion differed from the theoretical value listed in this table by more than 20 ppm.

larger molecules such as macrolides, showed more variability. This was also observed in the original method.[1]

Because this is an evaluation of a screening procedure, not a quantitative method, the recoveries for these analytes were not calculated. Only the ability of the method to reliably detect analytes at specific fortification levels was tested. This parallels work published previously to evaluate residue screening methods[7] and is consistent with FDA guidelines,[18] indicating qualitative broad-band screening methods should determine the minimum detectable concentration. In general, compounds with medium polarity (eluting between 4 and 12 min with this chromatographic program) performed well. For example, fluoroquinolones/quinolones, macrolides and lincomycins, many sulfonamides, and some *β*-lactams could be reliably detected in milk samples that had been fortified at low (≤10 ng/mL) levels.

On the other hand, some analytes were only detected at very high fortification levels or not at all. There are several possible reasons for this. One is simply that the analytes do not respond (ionize) very well and their levels of detection, even for solvent standards, are quite high. Many of the cephalosporin compounds fall into this category. Compounds that were not detected at all include rifampin, clavulanate, and cefoxitin. Another reason why analytes may not be detected in fortified milk samples is that they are not extracted or recovered from the milk matrix with this procedure. For example, the aminoglycosides are detected in solvent standard, but they are very polar and elute with the solvent front. It has been shown that while acetonitrile solvent extraction is effective for many veterinary drug residues, these compounds need a more polar extraction procedure.[19,20] Aminoglycosides were detected in milk samples that were fortified postextraction (endspike) using this LC Q-TOF MS method. For other analytes, such as avermectins, compounds were not observed in either extracted milk or in postfortified samples. This indicates that matrix effects (ion suppression) are severe for these analytes. This is not surprising as the sample cleanup is minimal with no defatting and these compounds typically elute very late in the chromatogram with 100% acetonitrile. Some compounds in the database that are not a concern in milk (ionophores, dyes) were not tested through the extraction method, but the experimental data obtained from analyzing solvent standards of these compounds is still useful to rule out false detects in milk samples.

The challenge of finding the best extraction for a wide variety of veterinary drug residues has been evaluated by others.[6,21,22] In a recent review, Berendsen et al.[21] discussed the advantages and disadvantages of several types of extraction procedures including SPE, dispersive SPE (QuEChERS), and simple solvent extraction. Their conclusions were that simple solvent extractions were often best because they did not discriminate against analytes, but success was not universal and matrix effects could be problematic. Others[5] have found that QuEChERS extraction procedure for veterinary drug screens using HRMS has worked well for many compounds, but others (aminoglycosides, *β*-lactams, tetracyclines) were excluded for poor performance. Also, Nacher-Mestre et al.[7] used a generic extraction for residues in feed and fish with minimal sample cleanup and found that many compounds could only be detected at 100 ng/g or not at all. This is consistent with what has been observed in this work. The results presented here indicate that this procedure may not be applicable to all veterinary drug residues. Therefore, it is important to note that while high resolution instruments allow us to monitor for more analytes, they should still not be considered "universal".

Proposed Identification of Product Ions. Product ion spectra were also collected from solvent standard mixes and milk extracts. Elemental composition of the product ions were proposed using the experimental *m/z* and generating formulas (using Agilent *Mass Hunter Formula Calculator Tool*) restraining the number and type of atoms to those found in the precursor ion. These data are shown in Table 3. When possible, these postulated ions were evaluated for reasonableness by generating structures using Agilent's *Molecular Structure Correlator* program and *ChemDraw* as well as comparing to fragmentation patterns in the published literature.[4,23−25] The experimental mass accuracy for the product ions from the analysis of 100 ng/mL solvent standards was within ±5 ppm of the value of the proposed structures unless otherwise noted in Table 3. More specific literature references identifying product ions for specific classes of compounds are also listed in Table 3.

In the literature, there is general consensus that at least one product ion is required to confirm the identity of analytes even when using measured exact mass data.[4,7,8,25,26] In some cases,

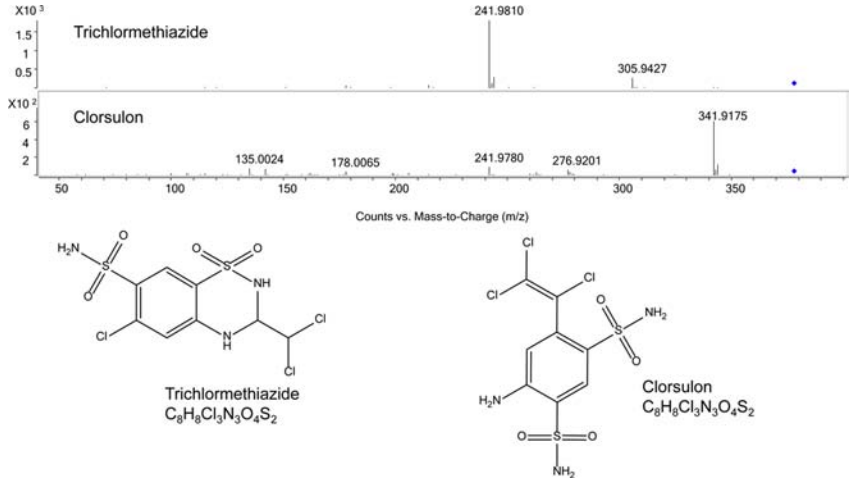

Figure 4. MS/MS spectra of isobaric compounds (m/z 377.8949). Solvent standard solutions (100 ng/mL) were analyzed using 20 V collision energy for both compounds.

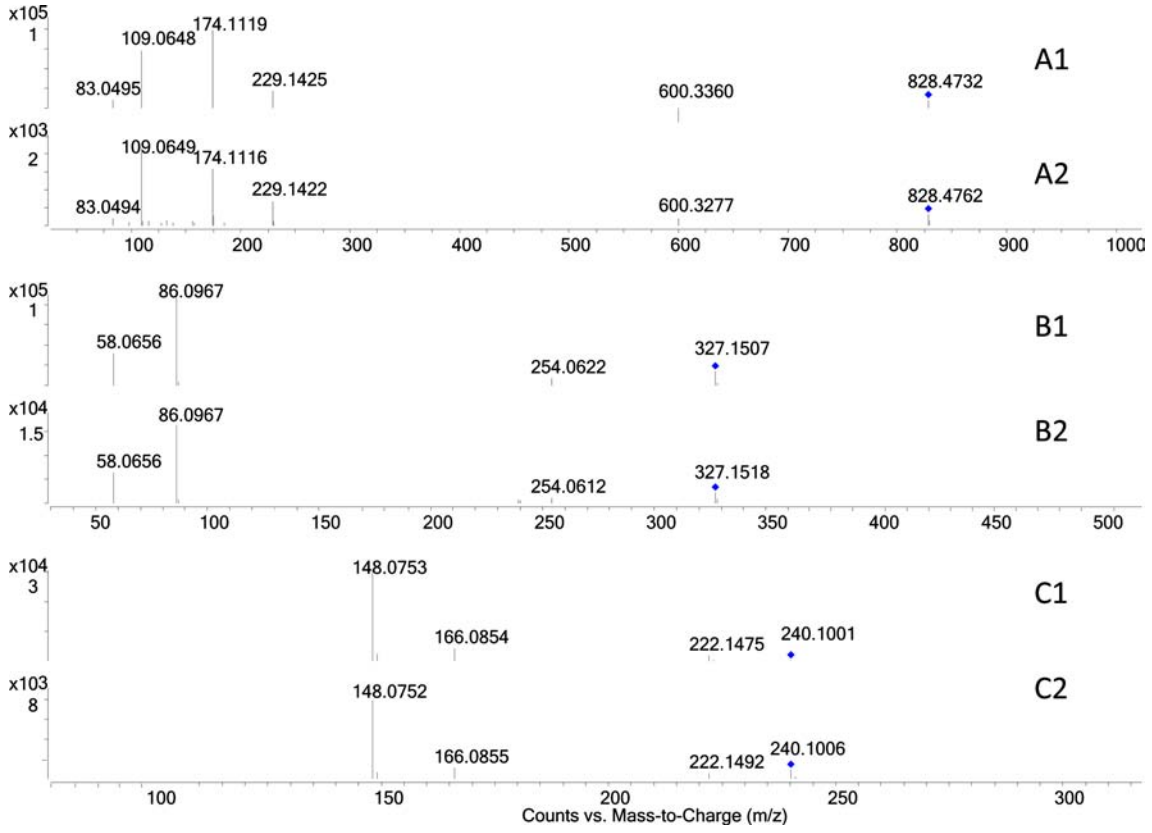

Figure 5. MS/MS spectra of josamycin (A), acepromazine (B), and salbutamol (C) in 100 ng/mL solvent solutions (1) and in extracts from milk fortified at 100 ng/mL (2).

unique MS/MS product ion spectra may be needed to distinguish between isomeric compounds. For example, clorsulon and trichlormethiazide are compounds that both have the formula $C_8H_8Cl_3N_3O_4S_2$, ionize in negative ion mode, and have very similar retention times. Figure 4 shows the structures and respective product ion spectra for these two compounds. For example, clorsulon has a large product ion at m/z 341.9175 corresponding to loss of HCl that is not present in the MS/MS spectrum of trichlormethiazide. We have previously shown[1] that product ion spectra were needed to identity desenrofloxacin, a metabolite of enrofloxacin, to distinguish it from another isomeric fluoroquinolone, pefloxacin.

Using the exact mass capability of this instrument to catalogue a database of potential fragment ions for a large number of analytes should prove very helpful for the development of veterinary drug residue MS methods in general, regardless of the specific platform. For example, a single-stage Orbitrap (Exactive) instrument does not have the ability to isolate a precursor ion prior to forming product ions. Using the information in Table 3 would give confidence that the product ions observed are directly related to the precursor

dx.doi.org/10.1021/jf405321w | J. Agric. Food Chem. 2014, 62, 3660−3674

ion of interest rather than produced from matrix components. In addition, it is also useful to identify product ion structures detected in a triple quadrupole multiple reaction monitoring experiment and this information is not always available in the literature.

Using the LC Q-TOF MS, it is also possible to evaluate the product ion spectra for analytes in milk samples. The development of criteria for the confirmation of identity using measured exact mass data is still in progress.[26] The data generated in this study indicate that the fortification level required to obtain an MS/MS spectrum with two or more product ions with mass accuracy within 5 ppm of the theoretical value is typically 2−5 times higher than the screening level of detection with this instrument. Examples of product ion spectra from solvent standards and milk extracts are shown in Figure 5. The fragment ions from compounds in the milk extracts have very similar measured exact mass (generally within 5 ppm) and relative intensity when compared to those from solvent standards.

In conclusion, the use of LC QTOF MS has the potential to greatly expand the scope of monitoring for contamination of food by veterinary drug residues. When searching accurate mass databases for low levels of residues in complex matrices, it is critical to overcome the challenge of not reporting false negatives while also avoiding an onerous number of false detects. This can be achieved by using adequately wide mass extraction windows combined with retention time matching to known standards. Using this method, data including retention times, as well as accurate mass measurements for precursor and product ions, have been collected for over 200 veterinary drugs for which standards are available. The screening limits of detection in milk for many of these compounds using a rapid extraction procedure have been determined. In addition to the 25 compounds that were initially included in this screening procedure, the method performance (number of false negatives, reproducibility) for approximately 60 additional compounds in milk fortified at the 10 ng/mL level was performed.

database[21] as well as on the basis of recent data concerning the usage and import of pesticides in Uruguay. This paper focuses on the validation of an analytical procedure for the determination of pesticide residues in beeswax, a peculiar matrix often containing high levels of incurred pesticides, as well as on the strategies applied to overcome the analytical difficulties found.

EXPERIMENTAL PROCEDURES

Chemicals and Standards. Acetonitrile and methanol of HPLC quality were from Merck (Darmstadt, Germany). Water was deionized in the laboratory using a Millipore (Billerica, MA, USA) Direct-Q 3 water purification system. Ammonium formate was purchased from Sigma-Aldrich (Steinheim, Germany). Magnesium sulfate anhydrous, reagent grade, was from Sigma-Aldrich (St. Louis, MO, USA), and formic acid p.a. (98−100%) was purchased from Merck. A solution of 5% formic acid (v/v) was prepared in acetonitrile. The bulk amino sorbent (Bondesil-PSA, 40 μm) was from Varian (Palo Alto, CA, USA). Analytical standards, ≥95% purity, were from Dr. Ehrenstorfer (Augsburg, Germany), Riedel-de Haen (Seelze, Germany), and LGC Promochem (Wesel, Germany). Stock standard solutions of 1 mg/mL were prepared, considering standard purity, by weighing individual analytical standards into flasks and dissolving and diluting them to accurate volume with acetonitrile using an automatic dispenser.

Working standard mixtures were prepared by appropriately diluting multiple stock solutions with acetonitrile using an automatic dispenser. The stock solutions of PCB 138 and chlorpyrifos D_{10}, which were employed as internal standards (ISTDs), were prepared in the same way as the pesticide stock standard solutions. An ISTD working mixture containing 20 μg/mL of each ISTD was also prepared in acetonitrile. The ISTD working mixture was mainly used for spiking the matrix prior to sample preparation in recovery experiments. An appropriate dilution of this ISTD solution to 2 μg/mL with acetonitrile was also prepared and was mainly used for the preparation of matrix-matched calibration standards. All solutions, except the ISTD working solution, were stored in the dark at 4 °C.

Apparatus. The automatic dispenser was an OPUS model (20 or 50 mL) from Hirschmann Laborgeräte (Eberstadt, Germany). A Repro high-precision sample divider from Bürkle (Bad Bellingen, Germany) was employed to portion the solids needed for dSPE.

GC×GC-TOF analysis was performed with a Pegasus 4D GC×GC/TOF-MS from Leco Corp. (St. Joseph, MI, USA). Sample injection volume was 3 μL with helium as carrier gas at a flow rate of 2 mL/min. The initial inlet temperature was set at 40 °C and increased after 0.6 min to 300 °C at a rate of 720 °C/min with a hold for 2 min and then decreased to 280 °C at the same rate with a hold for 5 min. The split valve remained open during the first 30 s following injection to allow

solvent evaporation at a flow rate of 20 mL/min and a pressure of 0.73 psi (solvent vent mode). After this 30 s period, the split valve was closed again (to transfer the analytes to the analytical column) and reopened at 2 min after injection. The first-dimension column was a DB-5MS (30.3 m, 0.25 mm i.d., 0.25 μm df). The temperature profile started at 80 °C, which was kept for 2 min and then ramped at 30 °C/min to 220 °C, then ramped again at 8 °C/min to 280 °C, and finally ramped at 20 °C/min to 300 °C with a hold for 10 min. The second-dimension column was a VF-17 ms (1.8 m, 0.1 mm i.d., 0.1 μm df), and the temperature profile was exactly the same as the first dimension only with a temperature offset of +30 °C. The second-dimension separation time was set to 4 s and controlled with an internal thermomodulator creating a hot/cold pulse. This instrument utilizes electron impact ionization (EI). The ion source temperature was set at 200 °C. The detector voltage was set at 1600 V and the filament bias at −70 V. The mass range collected was 70−550 amu with an acquisition rate of 200 spectra/s.

LC-MS/MS was performed with a Waters (Milford, MA, USA) Acquity UPLC system coupled to an API 4000 Qtrap MS/MS from Applied Biosystems (Foster City, CA, USA) run in the MS/MS mode. LC separation was performed on a Phenomenex (Torrance, CA, USA) Aqua 150 mm × 2 mm, 3 μm particle size, C18 column. The operation of the LC gradient involved the following two eluent components: (A) water/ammonium formate 5 mM; (B) methanol/ammonium formate 5 mM (%). It was run at 100 μL min^{-1} starting with 100% component A at injection time and gradually changing to 30% A (70% B) over 3 min, then to 15% A (85% B) over 3 min at 300 μL min^{-1}, followed by a shift to 10% A (90% B) over 3 min. This eluent composition was kept for 3 min and then shifted back to the starting conditions (100% component A) and kept there until 22 min after injection. The injection volume was 5 μL. MS/MS detection was performed in the multiple-reaction monitoring (MRM) mode using an ESI interface in the positive ion mode. The ionization voltage was 4500 V, the nebulizer gas was synthetic air at 70 psi, and the curtain gas was nitrogen at 30 psi. The solvent evaporation in the source was assisted by a drying gas (heated synthetic air at 425 °C/50 psi). Numerous experiments using solutions of the individual analytes were performed to determine the optimal MRM transitions, collision energies (CE), and declustering potentials (DP) for each individual compound. For this, the standard solutions were infused directly to the instrument by a syringe at constant flow. The MS/MS settings used in this study are listed in Table 1.

Methodology. Wax (2 ± 0.1 g) was weighed into a 50 mL centrifuge tube, 10 mL of acetonitrile was added, and the tube was closed and placed in a water bath at ∼80 °C. After the wax had melted, the tube was shaken vigorously for 10−15 s and placed back into the water bath to melt again. The procedure was repeated four times. Then, the tube was left to cool to room temperature and put into the freezer (−18 °C, for at least 2 h, e.g., overnight) for precipitation of the wax. An aliquot of the extract was transferred into a PP single-use centrifugation tube, which contained 25 mg of PSA primary−secondary amine (PSA) and 25 mg of C18 sorbent per milliliter of extract; the internal standard was added and the tube shaken vigorously for 30 s and centrifuged for 5 min at 3000 U/min. Finally, the cleaned extract was transferred into a screw-cap vial, and the pH was quickly lowered to ca. 5 by adding a 5% formic acid solution in acetonitrile (v/v) (10 μL/mL extract) and injected in LC-MS/MS and/or GC×GC-TOF.

Matrix-Matched Calibration and Recovery Calculations. Five-level matrix-matched calibration curves were constructed for matrix effects evaluation. Two-level calibrations within the dynamic range were performed for the evaluation of each recovery level: calibrant 1 at 60% and calibrant 2 at 120% of the aimed concentration of each level (0.01, 0.1, and 0.2 mg/kg). Calibration levels were prepared by adding the desired volume of appropriate dilution of working standard solutions to 1 mL of blank extract and equaling all of the final volumes within a batch (recoveries, blanks, and calibration vials) with acetonitrile. Recoveries were calculated as the percentage from the known added concentration of pesticides of the calculated concentration of the extract by interpolation.

RESULTS AND DISCUSSION

Impact of Sample Amount on Pesticide Residue Recoveries. The distribution of pesticides between the added acetonitrile and the liquefied beeswax phase depends on the volume ratio of the phases and the lipophilicity of the pesticides as reflected by their Log K_{OW} values. Increasing the beeswax phase volume will affect the partitioning equilibrium of the pesticides and consequently their recoveries, with lipophilic pesticides experiencing the highest losses. Influence of wax sample size was studied as follows: Different sample amounts of wax (0.5, 1, 1.5, 2, 3, 4, and 5 g) were spiked with 200 μL of a pesticide mixture containing 1 μg/mL of each pesticide dissolved in acetonitrile (0.2 μg of each pesticide) and immediately extracted according to the described procedure.

Figure 1 shows how the variation of the sample size affected the recoveries for some of the most lipophilic pesticides. As

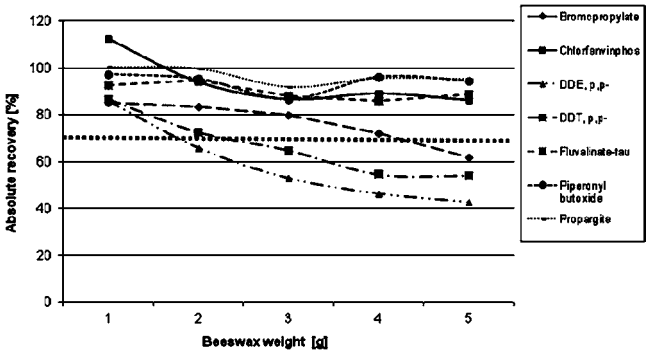

Figure 1. Influence of sample weight on pesticide recovery.

expected, pesticide recoveries decreased as the volume of the wax phase increased. The recovery drop was most pronounced for pesticides with strong lipophilic character such as DDT, DDE, and bromopropylate (Log K_{OW} values of 6.91, 6.36, and 5.4, respectively) that have a strong tendency to remain in the liquefied wax rather than to partition into the acetonitrile phase. On the basis of the results of this experiment, a ratio of 2 g of wax sample to 10 mL of acetonitrile was considered as a good compromise giving acceptable recoveries (70−120%) for almost all tested wax-relevant pesticides and a tolerable load of coextractives in the final extract of ca. 0.7 mg/mL, which corresponds to ca. 0.35% of the initial matrix weight employed for extraction (200 mg/mL). The same sample to acetonitrile ratio has been employed for the extraction of pesticide residues from vegetable oils.[20] The authors reported similar observations regarding the matrix load in the final extracts. It should be noted that when the ratio between wax and acetonitrile is kept constant, the recoveries achieved should be in principle highly reproducible, thus allowing for recovery-based result corrections with the help of suitable recovery factors derived from validation experiments.

Extractability of Incurred Residues Depending on Particle Size. The poor ability of acetonitrile to dissolve highly lipophilic compounds is, on the one hand, beneficial because it limits the amount of lipids (including waxes) dissolved in the raw and cleaned-up extract; on the other hand, it also considerably limits the accessibility of apolar pesticides incorporated in these lipids, which is the key to achieving good extraction yields and a broad scope method.

To demonstrate the importance of melting the wax to obtain optimal accessibility of residues enclosed in wax and to check

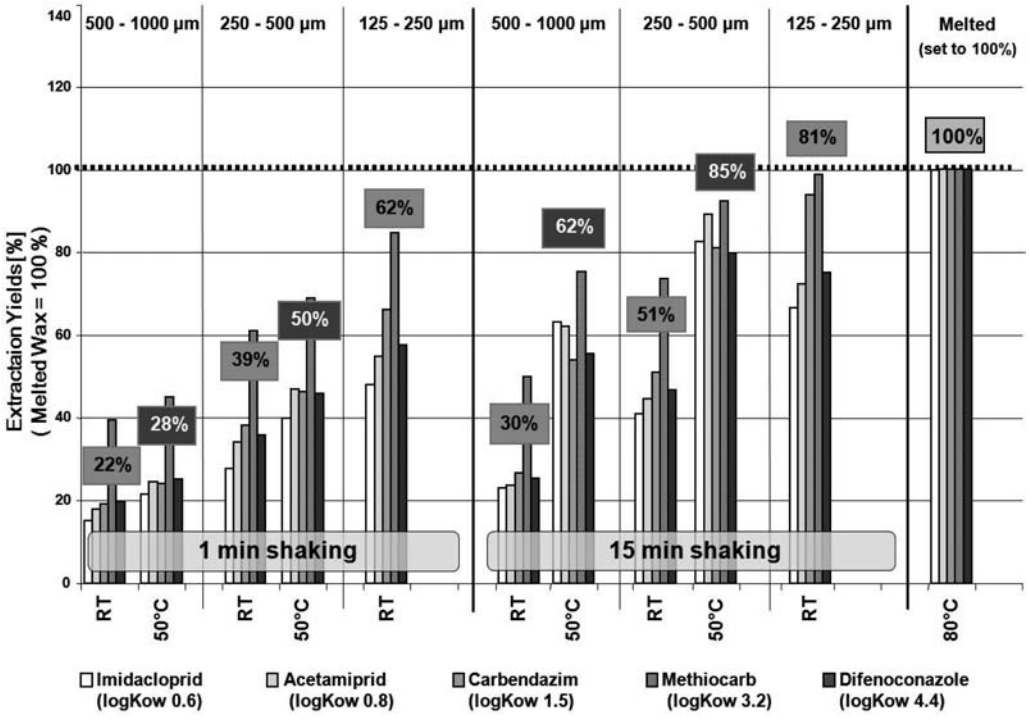

Figure 2. Impact of particle size (fractions 125−250, 250−500, and 500−1000 μm), temperature (room temperature, 50 and 80 °C), and shaking time (1 and 15 min) on the extraction yields of pesticides incorporated in beeswax. Results obtained when the wax was extracted at 80 °C (using the procedure described here) were set to 100%, n = 3, in each case. The percentage values in boxes indicate the average relative extraction yields of five wax-incorporated pesticides (imidacloprid, acetamiprid, carbendazim, methiocarb, and difenconazole).

how the comminution grade of wax affects extractability, a certain amount of beeswax was melted and spiked with a mixture of pesticides covering a broad polarity range at a level of ca. 0.1 mg/kg. By spiking the melted beeswax, a homogeneous residue distribution within it was ensured. Then, the spiked wax was deep frozen (−80 °C), intensively milled with a knife mill, adding some dry ice to keep it cold, and finally sieved into fractions (125−250, 250−500, and 500−1000 μm). Afterward, 2 g of each beeswax fraction was extracted for 1 or 15 min with acetonitrile without the addition of water. The extractions were conducted in triplicate at two different extraction temperatures: ambient (room temperature) and 50 °C. The results obtained for each pesticide as well as for all pesticides together were averaged. The results obtained when the wax was extracted at 80 °C (in melted condition as described under Methodology) were set to 100%. Figure 2 shows the results of this experiment, whic simultaneously demonstrates the positive effect of a good comminution grade (larger surface area) and of higher temperatures (better extraction kinetics and soaking of the wax) on the pesticide yields. Nevertheless, even for the finest wax fraction (125−250 μm) the average relative extraction yield at ambient temperature was only 81% compared to the yield at 80 °C, although the full volume of wax was available for potential partitioning losses at 80 °C as oposed to only the surface of the wax at ambient temperature. This experiment nicely demonstrates the difficulty of the extraction solvent to access residues incorporated in the wax and that decreasing particle size (i.e., increasing wax surface area) improves residue accessibility and thus extraction yields. Melting the wax ensured optimal accessibility to the residues via liquid−liquid partitioning.

Similar observations were made when a commercial beeswax containing incurred residues of τ-fluvalinate, piperonil butoxide, propargite, and coumaphos was extracted (results not shown here).

Comparison of Different Cleanup Possibilities. Beeswax is composed of a variety of highly lipophilic compounds such as esters of long-chain aliphatic alcohols with fatty acids or hydroxy-fatty acids, long-chain hydrocarbons, and trace levels of carotenoids. On the basis of their low solubility in acetonitrile, such highly lipophilic compounds are not expected to be present at remarkable levels in the final extracts. It is also expected that these compounds can be additionally removed to a large extent either by freezing-out (which further reduces their solubility, forcing them to precipitate) or via dispersive solid phase extraction (dSPE) using RP-C18 sorbents. Beeswax also contains a relatively more polar fraction of compounds that contains free long-chain fatty acids such as melissic and cerotic acid (that make ca. 12% of the beeswax), free hydroxy-fatty acids, and free aliphatic fatty alcohols. These compounds are still lipophilic enough to be removed to a certain degree via freeze-out or via dSPE using C18 sorbents but, in particular for the fatty acids, the cleanup approach of choice is dSPE with amino sorbents (such as PSA). Some of the polar pigments originated from the flowers visited by bees (e.g., anthocyanidines) can also be removed via dSPE.

Various experiments were conducted to study the extent to which beeswax coextractives can be removed via freeze-out and/or dSPE using C18 and/or PSA. The efficiency of cleanup was assessed on the basis of the remaining dry residue following extract evaporation but also by observing GC×GC-TOF chromatograms. Practical aspects, that is, the simplicity of the cleanup procedure, were also taken into account.

Following the first extraction step (2 g of wax + 10 mL of acetonitrile at 80 °C in a water bath), aliquots were taken from the initial extract and subjected to different cleanup procedures

Table 2. Extract Dry Residue Derived with Different Cleanup Procedures

	dry residue (mg) per mL of extract	compared to dry residue in raw extract (=100%)	compared to initial sample amount (200 mg/mL = 1000‰)
without cleanup (raw extract)	3.12	100	15.6
freeze-out 1 h	2.80	90	14.0
freeze-out 2 h	2.72	87	13.6
freeze-out 4 h	2.60	83	13.0
+3% H_2O freeze-out 1 h	2.75	88	13.7

PSA/C18 (25/25 mg/mL)	0.85	27	4.3
freeze-out/PSA (25 mg/mL)	0.77	25	3.8
freeze-out/PSA/C18 (25/25 mg/mL)	0.71	23	3.5

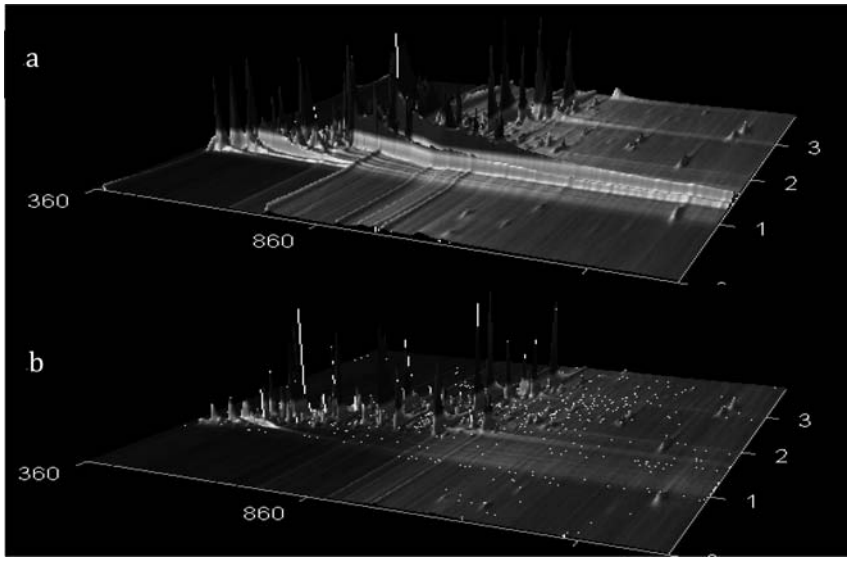

Figure 3. GC×GC-TOF plots of (a) raw extract (without cleanup) and (b) extract following dSPE with PSA.

as follows: (a) freeze-out (leave the aliquot for 1, 2, and 4 h in a freezer (−20 °C)); (b) dSPE with PSA (25 and 50 mg/mL); (c) dSPE with C18 (25 and 50 mg/mL); (d) freeze-out followed by dSPE with PSA (25 mg/mL); and (e) dSPE with PSA plus C18 (25 mg/mL each).

The influence of water addition to the raw extracts on the removal of coextractives during cleanup was also studied. A positive effect was expected in the removal of lipophilic compounds due to an increased polarity of the solvent and a negative effect regarding the efficiency of dSPE with PSA due to water interference with hydrogen bond formation between the amino groups of the sorbent and polar moieties of fatty acids or other coextracted matrix components. The following additional experiments involving water addition to the initial extract were conducted: (f) water addition (3, 6, and 10%) followed by freeze-out (1 and 2 h); (g) water addition (3, 6, and 10%) followed by dSPE with C18 (25 and 50 mg/mL); and (h) water addition (3 and 6%) followed by dSPE with PSA (25 mg/mL).

As can be seen in Table 2, dSPE using PSA removed the largest fraction of coextractives from the initial extracts (ca. 70−

[a]Pesticide present as incurred residue in the beeswax sample used for spiking.

75% of the dry residue was removed). PSA effectively removed fatty acids that give large tailing peaks in GC as shown in Figure 3. Dispersive SPE using C18 sorbent and freeze-out proved to act similarly, both removing ca. 15−20% of the dry residue when no water was added and between 25 and 30% when water was added. Nevertheless, GC-MS/MS chromatograms looked similar for both treatments. Freeze-out is more difficult to handle than dSPE with C18 sorbent as it requires a filtration step through cotton, during which part of the precipitated lipids redissolve due to temperature increase. However, as it was observed that when the extract was allowed to cool to room temperature on the bench, wax precipitation was slowed, an additional freeze-out step to speed precipitation and increase repeatability was included. This is followed by dSPE with PSA sorbent and C18 sorbent, the latter serving the further reduction of lipids in the extract but not being absolutely necessary. For simplicity the freeze-out step was conducted in the extraction tube with the aliquot employed for dSPE being directly withdrawn from the cold vessel without any need for a tedious filtration step.

Cleanup with a combination of PSA and C18 (or freeze-out) is highly recommended to reduce the matrix coextractives introduced into the GC and LC system. Introduction of non-cleaned-up extracts would require shorter maintenance intervals and reduce the overall productivity, especially for GC systems.

Water addition was slightly beneficial in all experiments, helping to remove additional lipids, but the benefits did not justify the additional workload introduced by water addition and its subsequent removal with $MgSO_4$. Within this context the conditions described under Experimental Procedures were preferred. Two grams of wax was melted at 80 °C in a water bath and extracted with acetonitrile. The extracting solution was left to cool to room temperature and frozen out for at least 2 h (e.g., overnight). From the cold solution, an aliquot was subjected to dSPE cleanup using C18 and PSA sorbents (25 mg/mL). Following acidification with 5% formic acid in acetonitrile (10 μL/mL) and ISTD addition, the extracts were analyzed by GC×GC-TOF and LC-MS/MS.

Method Validation. After the optimal sample amount, particle size, and the best cleanup approach had been chosen, five replicates of spiked blanks of beeswax at different levels (0.1 and 0.2 mg/kg for GC×GC-TOF analysis and 0.01, 0.1, and 0.2 mg/kg for LC-QTrap analysis) were analyzed to assess accuracy (% recovery) and repeatability (% RSD) of the procedure.

In agreement with the analytical quality control procedures document by DG-SANCO,[22] the limits of quantification (LOQs) were considered as the lowest successfully validated levels, that is, the levels at which acceptable recoveries (70−120%) and RSDs (<20%) were achieved. LOQs would have been surely different if other spiking levels were chosen. Of course, LOQs will also depend on other factors such as the type of instrumentation used and its condition.

For GC×GC-TOF matrix-matched calibration was used, whereas for LC-MS/MS calibration curves were constructed using both solvent-based and matrix-matched standards at five concentration levels (0.001, 0.002, 0.01, 0.02, and 0.05 μg/mL, corresponding to 0.005, 0.01, 0.05, 0.1, and 0.25 mg/kg beeswax). GC×GC-TOF analysis was conducted using an ISTD, whereas no ISTD was used in LC-MS/MS.

The matrix effects were calculated as the percentage difference in the best-fit slopes of the matrix-matched calibration curves versus the respective best-fit slopes of the solvent calibration curves. The peak areas rather than the relative peak areas against the ISTD were used to avoid matrix effects on the ISTD that potentially affect the calculation.[23]

In GC×GC-TOF large and positive matrix effects were observed (Table 3) except for propargite, which presented a negative effect.

In LC-MS/MS matrix effects were quite pronounced and variable from analyte to analyte as shown in Table 4. This is explained by the fact that matrix effects depend on whether a target analyte coelutes with coextracted matrix components, affecting the yield of free analyte ions generated within the ESI-ion source and thus the detection signals. A dSPE cleanup of the raw wax extracts with PSA contributed in reducing to some extent the matrix effects of certain compounds (boscalid from −10 to −1; imidacloprid from −50 to 3; tebuconazole from −33 to 9; dimethoate from 20 to −2; carbaryl from −20 to 3; thiacloprid from −25 to 1). Similar observations were also previously made using extracts of other "difficult" commodities such as oranges.[24] When matrix effects remain strong, the use of matrix-matched calibration standards (prepared from extracts of blank matrix so far available) or the method of standard

[a]Pesticides present as incurred residues in the beeswax sample used for spiking. [b]Recovery experiment at 0.01 in blank beeswax (Pharmacognosy collection).

additions is recommended to obtain reliable quantification.[22] Matrix coextractives in LC-MS/MS mainly cause signal suppression, whereas signal enhancement is typically observed in GC applications. This is due to the different mechanisms behind matrix effects in each case.[25,26] Matrix coextractives of beeswax behave as analyte protectants hampering pesticide degradation in the injector and along the chromatographic column, resulting in signal enhancement.

Recoveries of GC- and LC-amenable pesticides were in almost all cases between 70 and 120% with RSDs below 20% at least at one of the levels assayed (Tables 3 and 4). The exceptions were mainly due to the incurred residues found in the commercial beeswax that was used to conduct the recovery experiments. Some recovery experiments were repeated using as blank material all of the beeswax from the year 1932 that could be withdrawn from the Pharmacognosy collection of the Chemistry College of Universidad de la República, which did not contain pesticide residues. Recoveries could then be properly evaluated for carbaryl, hexythiazox, and methoxyfenozide at 0.01 mg/kg ranging from 87 to 116% and RSDs being below 18%, whereas chlorpyrifos could not be quantified at this low level. Coumaphos and τ-fluvalinate were studied at higher levels (0.2 and 0.1 mg/kg) because they are used directly inside the hive to protect bees from mites. Good results were obtained for τ-fluvalinate at the level of 0.2 mg/kg (102% recovery and 5% RSD) and for coumaphos at both levels (103 and 109%

dx.doi.org/10.1021/jf405771t | J. Agric. Food Chem. 2014, 62, 3675−3683

recoveries; 4 and 10% RSDs, respectively). With beeswax being a natural product, differences in composition between samples were expected. Table 5 shows validation data for a group of

selected pesticides spiked onto three different beeswax samples (samples purchased in Germany and Uruguay and the wax from the Pharmacognosy museum). These data further demonstrate the suitability and ruggedness of the method for this complex matrix. The use of different beeswax samples with different incurred residues for analytical validation purposes is a useful tool not only to cross check the obtained results but also to broaden the scope of compounds that can be successfully validated. In summary, a simple variation of the QuEChERS method, involving extraction of wax at high temperatures (~80 °C) to enable liquid–liquid partitioning between the liquefied wax phase and acetonitrile followed by a simple freeze-out plus a dSPE step, proved to be effective for the multiresidue analysis of 51 pesticides in beeswax. Several critical aspects (sample weight, particle size, and different cleanup options) were studied in the course of method development. A comprehensive cleanup involving freeze-out and dSPE using PSA and C18 was shown to remove ca. 75% of the coextractives from the raw extract and ca. 99.6% of the initial wax. Quantitative analysis was accomplished by LC-MS/MS and GC×GC-TOF. Fifty-one pesticides proved to be accurately determined with the developed methodology. The method can be easily expanded to other pesticides that, although not included in the present study, could be found in beeswax samples produced in other environments or agricultural systems. Beeswax is a long-term "pollution reservoir" due to its particular physicochemical properties; it stores the pesticide residues to which the hive is exposed. Therefore, the analysis of this complex matrix will give relevant data on the sustainability of specific agroecosystems.

[a]Recoveries <70% and >120% and SDs >20% are highlighted in bold.

Sep is a new commercially available sorbent based on zirconium oxide. Formic acid (88% purity) was obtained from Spectrum Quality Products Inc. (New Brunswick, NJ, USA). Standard Reference Materials (SRMs) 1974b (Organics in Mussel Tissue) and 1947 (Lake Michigan Fish Tissue) were purchased from the National Institute of Standards and Technology (NIST, Gaithersburg, MD, USA).

Approximately 1 kg filets of catfish muscle tissue were purchased from local food stores. Samples were homogenized with an Ultra-Turrax T25 homogenizer (Janke & Kunkel GmbH & Co., IKA Labortechnik, Wilmington, NC, USA) and stored in a −18 °C freezer. The average fat content of catfish muscle is 5.9% by weight,[2] and measured moisture content was 80%.

A standard mixture of pesticides at 20 μg/mL in 0.05% formic acid in MeCN was used as a spiking solution for 100 and 50 ng/g spiking levels, and a pesticide standard mixture at 500 ng/mL in 0.05% formic acid in MeCN was used for 5 and 1 ng/g spiking levels in the recovery experiments. A mixture of atrazine-d_5 and fenthion-d_6 at 10 μg/mL was prepared in 0.05% formic acid in MeCN.

Sample Preparation. The sample preparation was based on the unbuffered QuEChERS method with MeCN extraction and d-SPE with zirconium-based sorbent Z-Sep as previously described:[10] (1) weigh 10 g of homogenized sample into a 50 mL polypropylene centrifuge tube; (2) add 1000 ng of internal standards (ISTDs), yields 100 ng/mL; (3) add 10 mL of MeCN and vigorously shake by hand for 30 s; (4) pour the entire extract, including tissue, into another 50 mL centrifuge tube with 4 g of anh $MgSO_4$ and 1 g of NaCl; (5) shake vigorously for 1 min and centrifuge the tube for 2 min at 3250 rcf; (7) take 1 mL of the extract into a mini-cetrifuge 2 mL tube containing 50 mg of Z-Sep and 150 mg of anh $MgSO_4$; (8) shake the tube vigorously for 30 s and centrifuge for 2 min at 3250 rcf; (9) transfer 0.5 mL of the catfish extract into an autosampler vial for GC analysis. For a reagent blank sample, use 5 mL of DI water in place of a tissue. The equivalent tissue concentration per sample extract was 1 g/mL.

Low-Pressure Gas Chromatography/Tandem Mass Spectrometry (LP-GC/MS-MS). An Agilent (Little Falls, DE, USA) 7000B triple−quadrupole mass spectrometer (GC-MS/MS) with electron ionization (EI) high-sensitivity source was interfaced to an Agilent 7890A gas chromatograph operated in low-pressure vacuum outlet mode. The separation was achieved on a 15 m × 0.53 mm × 1 μm film thickness Rti-5 ms GC column connected to a 5 m × 0.18 mm noncoated guard column from Restek (Bellefonte, PA, USA). The calculated virtual column length used for the GC configuration was 5.5 m × 0.18 mm i.d. (vacuum outlet). Ultrahigh-purity helium (He) was used as a carrier gas at a 2 mL/min constant flow rate. At the transfer line the GC column was connected to a ∼17 cm × 0.53 mm i.d. phenyl-methyl deactivated guard column (Restek). Both connections were secured by Ultimate Union column connectors (Agilent). More details on the LP-GC-MS/MS can be found elsewhere.[11,12]

The GC oven temperature program was as follows: 70 °C held for 1.5 min, ramped at 80 °C/min to 180 °C, then ramped at 40 °C/min to 250 °C, followed by 70 °C/min to 290 °C, and held for 4.5 min. The total run time was 10 min. The MSD transfer line was at 250 °C, and the ion source was set at 320 °C. The QqQ collision gas was nitrogen at 1.5 mL/min, and quench gas was He at 2.25 mL/min. EI energy was −70 eV, quadrupole temperatures were set at 150 °C, and the solvent delay was at 2 min. An Agilent Multimode Inlet (MMI) was operated as a programmable temperature vaporizer with solvent vent mode of He flow at 50 mL/min with an injection volume of 5 μL. The MMI temperature program was 70 °C held for 0.31 min (at which point the vent was closed), then ramped to 420 °C at 320 °C/min, and held at 420 °C for the rest of the GC run.

Two multiple reaction monitoring (MRM) transitions and their ratios were used for identification as previously described.[13] The MRM method was divided into 13 time segments with a dwell time of 2.5 ms and the "wide" MS resolution.

Method Evaluation. Five replicates of fortified catfish samples were prepared for each spiking level (1, 5, 50, and 100 ng/g) as described under Sample Preparation. Each batch of samples included a reagent blank and a sample blank (the catfish sample spiked with internal standards only). Matrix-matched calibration standards at concentrations of 0.5, 1, 5, 10, 25, 50, 100, 250, and 400 ng/mL were used to calculate the recoveries of the pesticides. Fenthion-d_6 was used as an ISTD for pesticide quantification, and atrazine-d_5 was used as a back-up ISTD if needed. Method detection limits were determined as the pesticide's lowest calibrated levels (LCL). Visual inspection of

calibration curves and linear regression R^2 values ≥0.99 demonstrated linearity.

NIST standard reference materials (SRMs) 1974b (Organics in Mussel Tissue) and 1947 (Lake Michigan Fish Tissue) with certified/reference values for select pesticides were used to validate the method "trueness" (% accuracy vs the certified value). In the case of SRM 1974b, 10 g of material was extracted as described above. The equivalent tissue concentration per sample extract for SRM 1974b was 1 g/mL. In the case of SRM 1947, 5 g of material was used to prepare the extract, and the equivalent tissue concentration per sample extract was 0.5 g/mL. Five replicates of each SRM were analyzed in the experiment.

RESULTS AND DISCUSSION

In terms of sensitivity, the developed method provided relatively low detection limits −0.5−1 ng/g for all of the pesticides, except cypermethrin, α-endosulfan, iprodione, and resmethrin, for which the detection limits were 5 ng/g (see Table 1). Because the lowest tolerances for pesticides in food are established at 10 ng/g,[7] this method allows pesticide measurement even below tolerance levels and at environmentally relevant concentrations.

Four spiking levels were used to validate the method, and each level was tested in five replicates plus one reagent blank and one sample blank per batch. The calculated average recoveries and standard deviations for the five replicated catfish samples fortified at the four spiking levels are presented in Table 1. For the majority of pesticides, the recoveries were satisfactory, ranging from 70 to 120% for all spiking levels. Chlorothalonil showed highly variable recoveries, with 112% for the 1 ng/g spiking level, and 41, 12, and 19% for the 5, 50, and 100 ng/g spiking levels, respectively. For 21 pesticides, recoveries exceeded 120% (127−149%) at the spiking level close to their detection limit (Table 1, highlighted in bold). On the other hand, phosphamidon (64%) and dicrotophos (52%) recoveries were below 70% at the 1 ng/g spiking level. More uncertainties of quantification are observed at the lowest concentrations close to detection limits.

Method repeatability, expressed in standard deviation for five replicate samples, was satisfactory (<20%) for the majority of pesticides, with the exceptions of diazinon (25%), endosulfan sulfate (23%), and propiconazole (24%) for the 1 ng/g spiking level and simazine (21%) and trifluralin (22%) for the 50 and 100 ng/g spiking levels, respectively.

To show the accuracy of measurements of the developed method, the standard reference materials SRMs 1974b (Organics in Mussel Tissue) and 1947 (Lake Michigan Fish Tissue) with the certified/reference values for the selected pesticides were analyzed. Each SRM was prepared in five replicates as described under Sample Preparation. The measured values were in good agreement with certified values for both of the SRMs (see Tables 2 and 3). For SRM 1947, the average accuracy measured as a percent of the measured concentration versus the certified concentration was acceptable (71−118%) for all 15 pesticides except *trans*-chlordane (136%) and mirex (58%). Relative standard deviations (RSDs) were from 3 to 14%, indicating the method's acceptable repeatability.

For the SRM 1974b, the calculated accuracy for the 11 pesticides was 72−118% for all of the pestcides, except *o,p'*-DDT + *p,p*-DDD (45%) and heptachlor (133%). Heptachlor's certified concentration in SRM 1974B is 0.212 ng/g, which is below its detection limit (0.5 ng/g); however, heptachlor's amount was calculated at 0.282 ng/g in the SRM material. RSDs were acceptable for all pesticides: 4−12% in SRM 1974b.

Table 2. Determined Pesticide Concentrations (Wet Weight Basis) with the Method for SRM 1947, $n = 5$[a]

	certified/reference value (ng/g ± SD)	measured value (ng/g ± SD)	% accuracy (RSD, %)

[a]Recoveries outside the acceptable range (70−120%) are highlighted in bold.

SRM 1974b is a mussel sample with total extractable organics (TEO) of 6.3%, which is close to the TEO determined for the catfish samples in this study (5.9%). On the other hand, SRM 1947 is a fish tissue with 10.4% extractable fat. The accuracy of the measurements, achieved by this method, in SRM 1947 with higher TEO, makes it applicable to fish/seafood samples with variable fat content.

Analysis of Catfish Samples from the Market. To demonstrate the applicability of the developed method to real-world samples, it was applied for the analysis of 20 catfish samples from different countries: United States, China, Vietnam, and Cambodia, purchased at supermarkets. Catfish samples were homogenized and prepared as described above. A reagent blank, replicate samples, a matrix spike sample, and SRM samples were included in each batch of samples for quality assurance/control purposes. Residues of dimethoate (ND−8.3 ng/g), hexachlorobenzene (ND−3.7 ng/g), β-BHC and lindane (ND−5.2 ng/g), *cis*-nonachlor (ND−0.6 ng/g), *trans*-nonachlor (ND−2.3 ng/g), chlorpyrifos (ND−2.8 ng/g), trifluralin (ND−35.2 ng/g), *p,p*-DDE (ND−0.8 ng/g), *p,p*-DDD (ND−4.8 ng/g), *o,p*-DDD (ND−1.2 ng/g), *o,p*-DDT and *p,p*-DDD (ND−7.2 ng/g), *cis*-chlordane (ND−2.3 ng/g),

dx.doi.org/10.1021/jf404389e | J. Agric. Food Chem. 2014, 62, 3684−3689

trans-chlordane (ND−1.1 ng/g), and α-BHC (ND−4.1 ng/g) were measured in catfish samples.

Some of the pesticides measured in catfish samples, including DDT and its metabolites DDE and DDD, lindane, hexachlorobenzene, and chlordane, are persistent organochlorine pollutants identified by the Stockholm Convention.[14] These pesticides were banned many years ago, but due to their persistence (for example, DDT's estimated half-life is 20−30 years),[15] they are still being detected today. α-BHC and trifluralin were the most frequently detected pesticide residues measured in fish samples (38% frequency of detection) in concentrations ranging from 1.7 to 4.1 ng/g (α-BHC) and from 1.4 to 35.2 ng/g (trifluralin). Trifluralin had the highest measured concentration among all of the pesticides (35.2 ng/g). Because there are no tolerances established for these pesticides in fish/catfish, it is unclear if the amounts measured in catfish in this study may cause any human health effects for people consuming these fish. For most commodities, such as barley, corn, and wheat, trifluralin's lowest tolerance is 50 ng/g, and the amounts measured in catfish in our study were below this value. For most of the pesticides in fruits and vegetables, the tolerances are established at 10 ng/g, and all of the pesticides in this study, with the exception of trifluralin, were measured in concentrations below 10 ng/g. Chronic exposure to low levels of pesticides, most of which are lipophilic and therefore may accumulate in human fat,[16] is another under investigated area. Therefore, monitoring of trace amounts of pesticides in the imported/exported food supply is important for consumer protection.

In conclusion, a simple and fast analytical method for the simultaneous determination of multiple pesticides was developed and validated. A QuEChERS-based extraction with MeCN allowed for fast and efficient extraction without coextracting significant amounts of fat and lipids. Cleanup with Z-Sep in d-SPE provided significant removal of coextractive materials[10] and excellent recoveries and acceptable SDs for the majority of selected pesticides, even at a low spiking level (1 ng/g), making the method applicable for analysis at environmentally relevant concentrations. The method is simple and fast; a batch of 10 homogenized samples can be prepared within 1 h by a single analyst, and LP-GC/MS-MS provides fast separation of analytes within 9 min. The calculated sample preparation cost is ≈$2.5/sample using bulk materials, and small amounts of organic solvent used for extraction lead to reduced solvent waste and minimal environmental impact. With low detection limits achieved by this method, it can be easily applicable to the analysis of pesticide residues at environmentally relevant concentrations, and the generated data on their occurrence may aid in future risk assessment and regulations.

MATERIALS AND METHODS

Chemicals and Materials. Enrofloxacin (EFC), tilmicosin (TLS), trimethoprim (TMP), sulfaclozine (SCZ), sulfamethoxazole (SMX), and sulfaquinoxaline (SQX) standards were purchased from Sigma-Aldrich (St. Louis, MO, USA). Methanol and acetonitrile were purchased from J. T. Baker (Phillipsburgh, NJ, USA). NaCl was purchased from Fisher Scientific (Worcester, MA, USA). Nitrogen was purchased from Airgas (Malvern, PA, USA). All deionized water was prepared using a Barnstead Nanopure II (Dubuque, IA, USA). The large-capacity mixer was purchased from Glas-Col (Terre Haute, IN, USA). The 0.2 μm nylon filters were purchased from Whatman (Florham Park, NJ, USA). The TurboVap liquid concentrator was purchased from Biotage (Charlotte, NC, USA). The centrifuge was purchased from Thermo Scientific (Waltham, MA, USA). Disposable centrifuge tubes, monoject 3 mL luer lock syringes, autosampler vials, and Kuderna–Danish concentrator tubes were purchased from Krackeler Scientific (Albany, NY, USA).

Standard Preparation. All individual standard solutions were prepared by dissolving the appropriate amount of neat standard in methanol, and each stock standard was prepared to a 100 μg/mL solution. A 1 μg/mL mixed standard solution was prepared by mixing 1 mL of each of the six standards into 100 mL of methanol, which was further diluted to a 0.1 μg/mL solution. Five levels of matrix-matched working standards were prepared by diluting the 0.1 μg/mL mix solution with extracted matrix of antibiotic-free chicken jerky. A 15 ng/mL standard was prepared by adding 850 μL of matrix and 150 μL of 0.1 ug/mL mix solution. A 11.25 ng/mL standard was prepared by adding 100 μL of matrix and 300 μL of the 15 ng/mL standard. A 7.5 ng/mL standard was generated by adding 100 μL of matrix and 100 μL of 15 ng/mL standard. A 3.75 ng/mL standard was prepared by adding 300 μL of matrix and 100 μL of 15 ng/mL standard. A 1.5 ng/mL standard was prepared by adding 360 μL of matrix and 40 μL of 15 ng/mL standard.

Sample Preparation/Extraction. Each chicken jerky strip was designated a subsample of the container from which it was taken. The entire jerky treat strip was ground using a Retch grinding mill equipped with a 0.75 mm screen set at a speed of 12000 rpm. The ground sample

			253.9 → 92.2	35	30	0.1

[a]All compounds ESI+, MRM.

was then placed in a 50 mL polypropylene centrifuge tube. To extract all six of the antibiotics, two extractions were used.

Extraction 1 (for the extraction of sulfamethoxazole, enrofloxacin, trimethoprim and tilmicosin): weigh 1.0 g of ground sample into a disposable 50 mL polyprolylene centrifuge tube and record the weight to 0.001 g; add spikes; add 5.0 mL of deionized water and mix using a mixer at high speed for 5 min; add 10 mL of acetonitrile and mix well using a mixer at high speed for 20 min; add 2 g of NaCl and mix well using a mixer for 5 min; centrifuge at 3000 rpm for 10 min; transfer a 5.0 mL aliquot of supernatant into a 10 mL graduated concentrator tube; concentrate to between 0.2 and 0.1 mL under nitrogen using a turbovap liquid concentrator; add deionized water to the 1.0 mL level and mix well using a mixer at high speed; filter through a 0.2 μm luer lock disk filter using a disposable monoject lock syringe directly into a 2 mL autosampler vial; analyze by UPLC-MS/MS.

Extraction 2 (for the extraction of sulfaclozine and sulfaquinoxaline): weigh 1.0 g of ground sample into a disposable 50 mL polyprolylene centrifuge tube and record the weight to 0.001 g; add spikes; add 5.0 mL of deionized water and mix using a mixer at high speed for 5 min; add 10 mL of acetonitrile and mix well using a mixer at high speed for 20 min; add 2 g of NaCl and mix well using a mixer for 5 min; centrifuge at 3000 rpm for 10 min; transfer a 5.0 mL aliquot of supernatant into a 10 mL graduated concentrator tube; concentrate to 0.3 mL under nitrogen using a turbovap liquid concentrator; add deionized water to the 1.0 mL level and mix well using a mixer at high speed; filter through a 0.2 μm luer lock disk filter using a disposable monoject lock syringe directly into a 2 mL autosampler vial; analyze by UPLC-MS/MS.

Method Validation. The method was validated by determining limits of detection and limits of quantitation and evaluating the results of various levels of spikes. The LOD was determined by obtaining a chicken jerky sample that was free of any of the antibiotics and spiking it at 1.0 ng/g in duplicate. The resulting response of each parent daughter transition was determined to be at least 3 times that of the accompanying noise. Additionally, the ratio of the quantitation ion to the qualifier ion was calculated and compared to that of the standard. The measured ratios of the sample must agree with that of the standard within 15% for an identification to be made. Also, the retention time of an analyte in a sample must match that of the standard within 5%. The LOQ was determined to be 3 times the LOD or 3.0 ng/g. Antibiotic-free chicken jerky was spiked at LOQ (1.0 ng/G), 5 × LOQ (15 ng/g), and 10 × LOQ (30 ng/g). Each spike level was extracted and analyzed three times, and recoveries were calculated.

UPLC-MS/MS Conditions. Liquid chromatographic separation was performed using a Water Acquity UPLC binary pump, column heater, in-line degasser, and autosampler. The UPLC system was coupled to a Waters Quattro Premier XE triple-quadrupole mass spectrometer. Samples were held at 15 °C in the autosampler. The analytical column was an Acquity BEH C18, 1.0 × 100 mm, with 1.7 μm particle size. Mobile phase A consisted of 0.15% acetic acid in deionized water, and mobile phase B was 0.15% acetic acid in acetonitrile. For method 1 (sulfaclozine and sulfquinoxaline) the initial UPLC conditions were 90% A and 10% B and were held constant for 2.0 min. From 2.0 to 8.2 min, the gradient was changed from 90% A−10% B to 2% A−98% B. At this point the mobile phase was returned to the initial conditions and held for 3.8 min. For method 2 (sulfamethoxazole, enrofloxacin, trimethoprim, and tilmicosin) the initial UPLC conditions were 96% A and 4% B and were constant for 2.0 min. From 2.0 to 8.2 min, the gradient was changed from 96% A−4% B to 2% A−98% B. At this point the mobile phase was returned to the initial conditions and held for 3.8 min. For both methods the flow rate was held at 0.13 mL/min, the injection volume was 10 μL, and the column was held at 65 °C throughout the chromatographic run.

RESULTS AND DISCUSSION

UPLC-MS/MS Conditions. Infusion experiments of all analytes yielded strong protonated molecular ions [M + 1] in full scan ESI. In all cases this ion was used as the precursor, and fragmentation produced at least two products. For confirmational purposes two product ions were chosen to monitor in multiple reaction monitoring (MRM) mode. Most product ions have been previously reported with the exception of sulfaclozine, which has not been studied extensively.[14,16,17,21] ESI+ ionization of sulfaclozine produced strong signals at m/z 284.9 along with the corresponding A + 2 isotope (Figure 1). Fragmentation of m/z 284.9 yields several products including m/z 93.9 and 155.9 (b). Both of these products have been previously reported for other sulfonamides, indicating a fragmentation pattern common to this class.[14,22] Although most analytes in this study generated several abundant fragmentation products, many times the matrix being studied can influence the choice. In the case of sulfaclozine, although 284.9 → 155.9 and 284.9 → 93.9 were not the most abundant products observed during infusion, they were affected to the least extent by the matrix after extraction. In a similar way two transitions were determined for sulfaquinoxaline, sulfamethoxazole, enrofloxacin, trimethoprim, and tilmicosin (Table 1).

Various chromatographic conditions were evaluated to optimize peak shape and signal strength. All six analytes

Table 2. Recovery Efficiencies for All Six Antibiotics in Chicken Jerky Treats

	ave % recovery (n = 3)						
	LOQ	5 × LOQ	10 × LOQ	overall % recovery av	correl coeff	20 point SD	20 point av
enrofloxacin	49.7	67.7	60.7	59.4	0.99748	12.84	49.3
sulfaclozine	125.0	92.3	95.0	104.1	0.99949	27.91	76.0
sulfaquinoxaline	125.3	81.0	96.3	100.9	0.99987	29.54	70.2
trimethoprim	54.7	55.7	59.7	56.7	0.99997	12.73	61.4
tilmicosin	67.3	94.0	100.3	87.2	0.99702	23.07	68.2
sulfamethoxazole	68.7	60.0	63.0	63.9	0.99628	20.26	64.7

performed best using a mobile phase of A = 0.15% acetic acid and B = 0.15% acetic acid in acetonitrile. Unfortunately, due to differences in water solubility, trimethoprim and tilmicosin produced optimal peak shape with initial conditions of A = 96%, whereas sulfaclozine, sulfaquinoxaline, sulfamethoxazole, and enrofloxacin performed best with mobile phase A beginning at 90%. Because of this, two injections were made per sample.

Sample Preparation and Extraction. This investigation into the possibility of an unknown contaminant was unusual in that it appeared not every animal that consumed the chicken jerky became ill. If the suspect products were the cause of the illnesses, this would mean that either not every one of these products contained the contaminant or that not every animal was susceptible to becoming ill from the contaminant. To minimize the possibility that hot spots of contamination would be diluted to the point of not being detectable, each chicken jerky treat was homogenized separately as opposed to many treats being homogenized and combined as one sample.

The use of acetonitrile led to good recovery of the six analytes; however, there were slight differences in recovery depending on the final concentration procedure. Sulfaclozine and sulfaquinoxaline were found to recover better when the final concentration step was ended at 0.3 mL, whereas the remaining analytes were extracted more efficiently when concentrated to between 0.2 and 0.1 mL.

Matrix-induced signal suppression was corrected with the use of matrix-matched external standards. This was accomplished by extracting chicken jerky that was found to be free of analytes and diluting the standard mix in the extract. A five-point curve was generated for each analyte from 1.5 to 15 ng/mL, and samples found to contain analytes greater than the highest level were diluted and reanalyzed.

Method Validation. The LOD for all analytes was determined to be 1.0 ng/g through spiking experiments. This is lowest concentration at which an analyte produces well-resolved peaks at least 3 times the signal-to-noise for both transitions and can pass the confirmation criteria. The confirmation criteria include matching the retention time of that of a standard within 5% and matching the ion ratio of a standard within 15%. Results of LOQ, 5 × LOQ, and 10 × LOQ spikes are presented in Table 2. Recovery efficiencies for all compounds were between 50 and 100%, although enrofloxacin and trimethoprim were below 60%. Efforts were made to improve these recovery efficiencies including extending the time the sample is mixed in acetonitrile and sonication during this step without success. The 20-point average recovery and standard deviation in Table 2 refers to the QC results that accompanied the last 20 sample sets analyzed. These results show somewhat lower recoveries and several standard deviations above 20%. This may be due to the variation in sample type as more products were analyzed for these compounds. A five-point matrix-matched external calibration curve was used for the quantification of all analytes. Good linearity was seen for all compounds, and acceptability was measured by correlation coefficient being >0.995 (Figure 2).

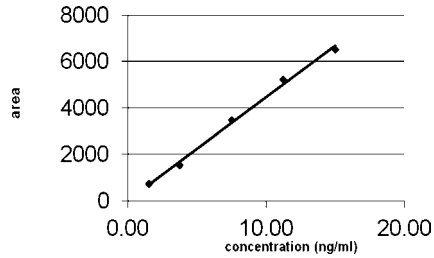

Figure 2. Sulfaclozine calibration curve.

Sample Results. Figure 3 shows typical chromatograms from each analyte found in a sample (a), a standard (b), and a blank chicken jerky (c). The selected transitions for all analytes provided well-resolved peaks and did not suffer from matrix interferences.

Chicken jerky dog treats are typically sold in bags containing from 10 to 60 individual treats. As previously described, each treat was individually ground using a Retch grinding mill and are given a sample number, which denotes it is one of a given number of treats from a given bag. In this way we can determine the homogeneity of antibiotic contamination and identify high and low concentrations of the analytes. A summary of the results is presented in Table 3. Over 800 samples of various types of dog treats have been analyzed using this method. The sample type with the most detections of antibiotics and the highest concentration of antibiotics is chicken jerky. Sulfaclozine was found the most frequently in this sample type (30% of samples) and was found at the highest concentration (2873 ng/g). Sulfaquinoxaline was the second most frequently detected antibiotic and is the only compound evaluated in this study with an FDA tolerance. The U.S. Code of Federal Regulations, Title 21 chapter I, section 556.685, indicates a 100 ng/g tolerance for sulfaquinoxaline in chicken. This tolerance was exceeded in several chicken jerky samples, with the highest concentration found at 828 ng/g. Sulfaclozine, sulfamethoxazole, enrofloxacin, trimethoprim, and tilmicosin are not allowed in chicken at any level. The chicken-based treats indicated in Table 3 refer to treats that contained ingredients other than chicken but seemed to have chicken as a main component. These treats had many fewer antibiotic detects as well as lower concentrations of analytes. Salmon- and duck-based treats had the lowest percentage of detects, with only sulfaquinoxaline detected in 3% of these samples.

Analyzing each jerky treat individually allowed for the observation of differences between each strip within one bag within each bag. Our analysis shows that some treats contain

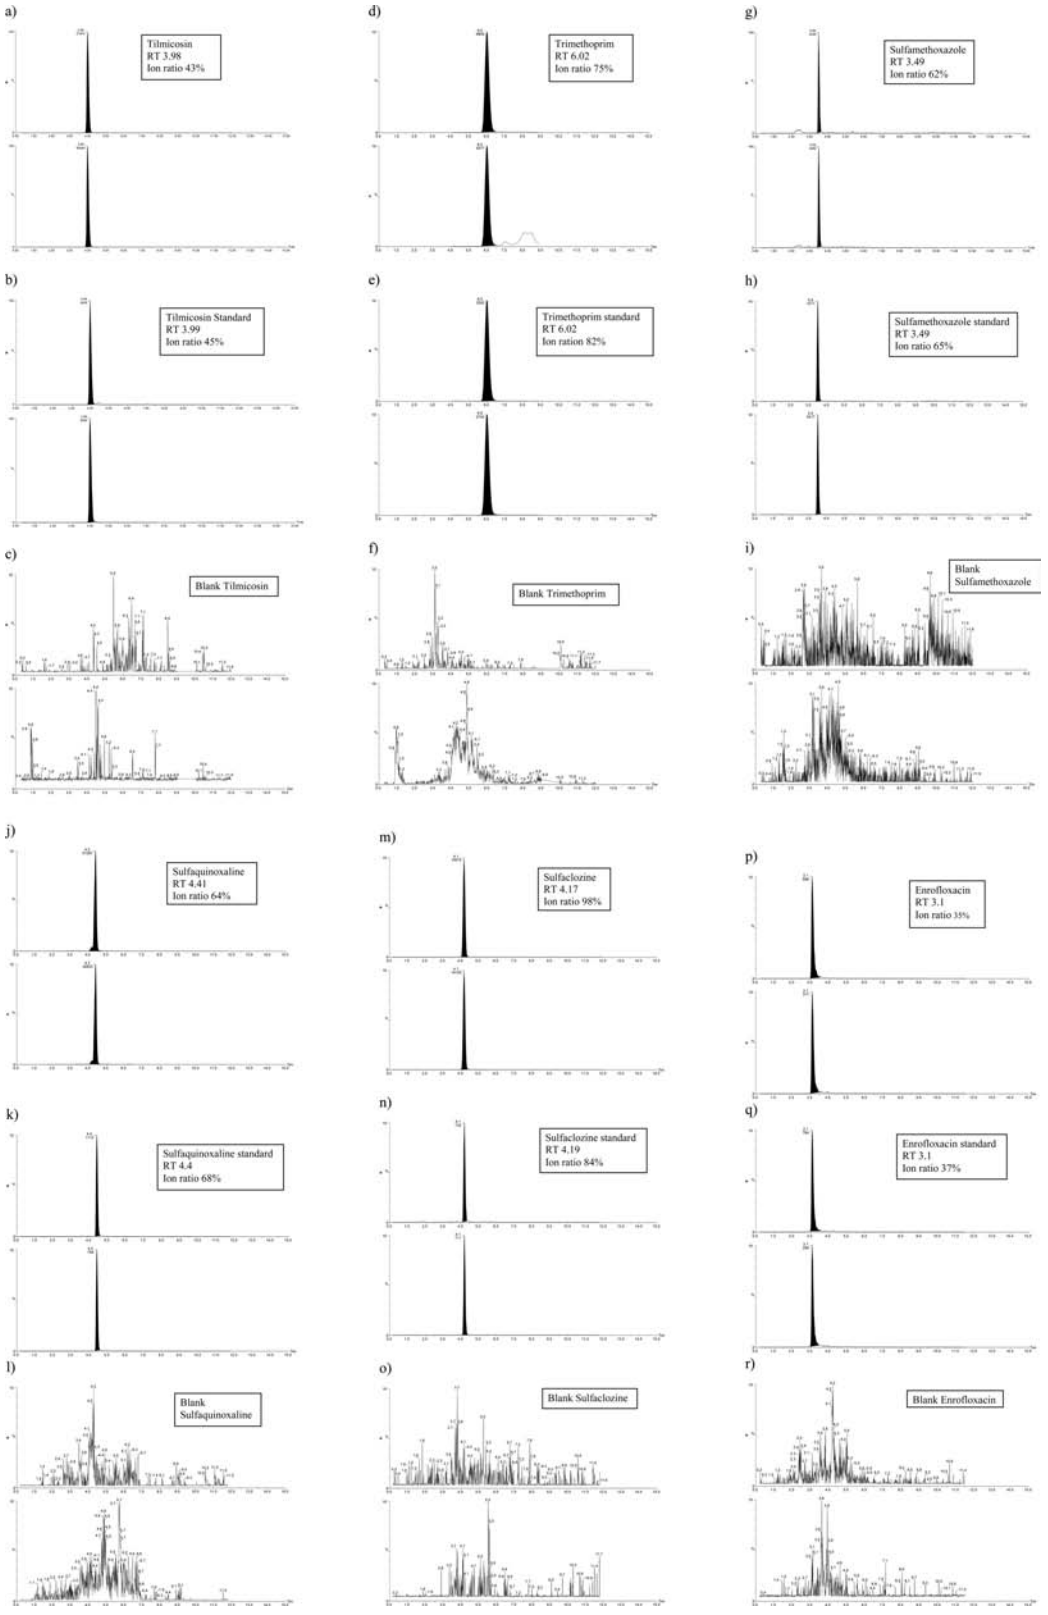

Figure 3. Chromatograms of incurred TLS (a), TLS standard (b), blank TLS (c), incurred TMP (d), TMP standard (e), blank TMP (f), incurred SMX (g), SMX standard (h), blank SMX (i), incurred SQX (j), SQX standard (k), blank SQX (l), incurred SCZ (m), SCZ standard (n), blank SCZ (o), incurred EFC (p), EFC standard (q), and blank EFC (r).

much higher levels of antibiotic residues than other treats from the same bag. Table 4 shows the results of two bags of chicken jerky treats where 10 treats were analyzed from bag 1 and 4 were analyzed from bag 2. Whereas tilmicosin was detected in all samples from this bag, the concentration found in treat 10 was >40 times higher than was found in the other 9 treats. Three antibiotics were detected in all four treats from bag 2; however, two of the four treats had 100 times as much sulfaclozine and

			4	sulfaclozine	12
				sulfaquinoxaline	12
				Enrofloxacin	<3

sulfaquinoxaline as the other two treats did. These differences indicate that there are hot spots of high concentrations of antibiotic residues within bags of treats. This illustrates the differences that can occur between individual pieces of a product of this type. Analyzing a small number of treats from a given bag or homogenizing all of the contents from a bag would not identify these differences or detect highly contaminated individual pieces.

A method for the detection of six antibiotics in chicken jerky treats was developed and applied to the analysis of retail samples. The analysis of >800 samples indicated that these antibiotics were consistently present in chicken jerky treats imported from China. In addition, the levels found were above the U.S. FDA tolerance. Whereas there is currently no evidence indicating the presence of these antibiotics is related to the illnesses and deaths of dogs, their presence in food or animal feed is not allowed in most countries including the United States, Canada, and the European Union.

extraction procedure detailed below. Calibration standards were prepared daily for each matrix type.

Samples. Apple samples from the 2013 growing season, which either had no wax coating or had a morpholine-free coating, were provided by local growers. Whole citrus samples from the 2012 and 2013 growing seasons were provided by the USDA-IR4 program and had no coatings. All samples at the Trace Analytical Laboratory (TAL, UC Davis, CA, USA) facility were homogenized in the presence of dry ice using a Blixer food processor (Robot-Coupe USA, Inc.). Each chopped sample was stored in a labeled jar (approximately 1 L), and a lined lid was loosely closed on top to allow the dry ice to sublime during storage at −20 °C. All samples at the Pacific Agricultural Laboratory (PAL, Portland, OR, USA) facility were homogenized fresh using a Blendtec high-speed blender.

Extraction. Fifteen grams of homogenized sample was weighed into a 50 mL polypropylene centrifuge tube, and water (1.4−2.4 mL) was added to yield 15 mL of total water based on moisture content of commodity.[11] The addition of water aids in the extraction of morpholine. Recovery samples were fortified at this point, and 15 mL of 1% acetic acid in methanol was added to the tube. A ceramic homogenizer was added to each tube and shaken vigorously for 1 min by hand or using a mechanical shaker at 1000 strokes/min (Geno/Grinder, model 2010, SPEX CertiPrep). Following extraction, the sample tubes were centrifuged at 4000 rpm for 5 min. The supernatant was poured off into clean culture tubes and stored at ∼5 °C prior to analysis. Typically, the extracts were stored for no more than 2 days. An aliquot of the extract was then diluted 1:5 with 20 mM ammonium formate in 60:40 water/MeCN (v/v, adjusted to pH 3.5 with formic acid) and filtered through a 0.2 μm PTFE syringe filter (VWR International) before it was submitted for LC-MS/MS analysis.

Sample Analysis. At the PAL facility, sample analysis was conducted using a Waters Acquity UHPLC system (binary) coupled to a Waters Xevo tandem mass spectrometer via electrospray ionization (ESI). The TAL facility utilized an Agilent 1200 series binary LC coupled to an Agilent 6430 tandem mass spectrometer equipped with ESI. See Table 1 for instrument-specific conditions.

Table 1. Mass Spectrometer Instrument Parameters

parameter	Waters Xevo	Agilent 6430
source temperature	150 °C	300 °C
desolvation temperature	450 °C	N/A
source gas flow (N_2)	800 L/h	11.5 L/min
cone/nebulizer gas flow (N_2)	5 L/h	50 psi
capillary voltage	1000 V	1000 V
collision gas	Ar (0.11 mL/min)	N_2 (8 mTorr)
morpholine primary transition	88.1 → 70.1[a]	88.1 → 70.1
morpholine secondary transition	88.1 → 42.1[b]	88.1 → 42.1
frag/collision energy (primary)	30/12	40/14
frag/collision energy (secondary)	30/12	40/22
ion ratio 42.1/70.1	20 ± 10%	40 ± 10%

[a]Proposed collision-induced dissociation: $[M + H]^+$ → loss of water (18). [b]Proposed collision-induced dissociation: $[M + H]^+$ → loss of $HOCH_2CH_3$ (46).

Chromatographic separation was accomplished with a SIELC Technologies hydrophilic interaction (HILIC) Primesep-A column (100 × 2.1 mm i.d., 5.0 μm particle size,). The PAL system utilized a column heater, which held the analytical column at 45 °C, whereas the TAL system was operated at ambient temperature (∼25 °C). The mobile phase was operated in isocratic mode with a composition of 20 mM ammonium formate in 60:40 water/MeCN (adjusted to pH 3.5 with formic acid) at 0.50 mL/min (TAL) and 0.55 mL/min (PAL). Following the completion of the analytical set, the column was flushed with 20 mM ammonium formate and then MeCN to remove accumulated matrix. Injection volume was 10 μL. Morpholine residues were quantified using a linear standard curve method with $1/x$ weighting. Typically, the primary transition was used for quantitation, and the secondary transition and ion ratio were used for compound confirmation.

Table 2. Morpholine Residue Recoveries (Percent) in Apples and Citrus

	fortification level[a]			
commodity	0.01 μg/g	0.04 μg/g	0.2 μg/g	calcd MDL[b] (μg/g)
TAL Testing Facility				
apple	104 ± 6	100 ± 2	107 ± 1	0.0018
orange	106 ± 5	101 ± 2	107 ± 3	0.0015
lemon	104 ± 3	102 ± 1	107 ± 1	0.0010
grapefruit	103 ± 3	102 ± 2	109 ± 2	0.0010
PAL Testing Facility				
apple	108 ± 13	104 ± 2	94 ± 4	0.0040
orange	92 ± 11	92 ± 2	92 ± 3	0.0034

[a]Replication for each fortification level, $n = 7$. [b]Calculated MDL: standard deviation at 0.01 μg/g fortification level × 3.143 (Student t_{99} $(n - 1)$).

RESULTS AND DISCUSSION

Method Development. During the initial phases of method development, one of the main goals was to have a very simple and rapid sample workup that could provide a target limit of quanititation (LOQ) of 0.01 μg/g. This target

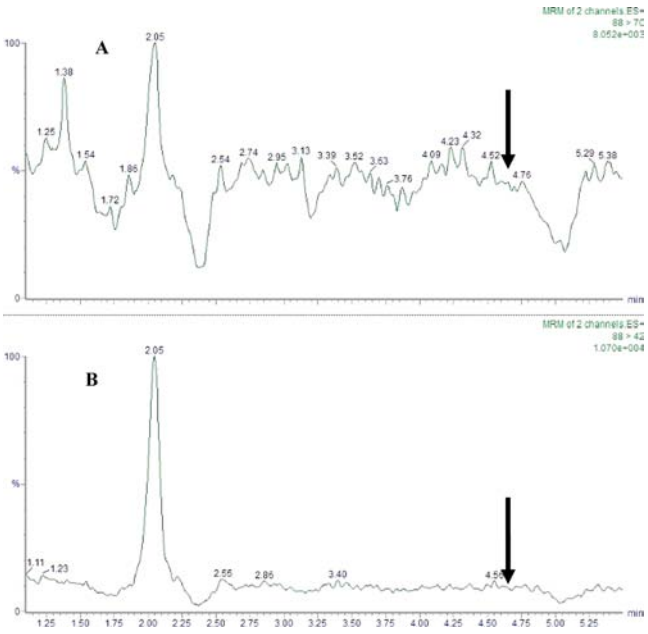

Figure 5. Extracted ion chromatograms of apple control sample from Waters Xevo: (A) MRM transition 88 → 70; (B) MRM transition 88 → 42.

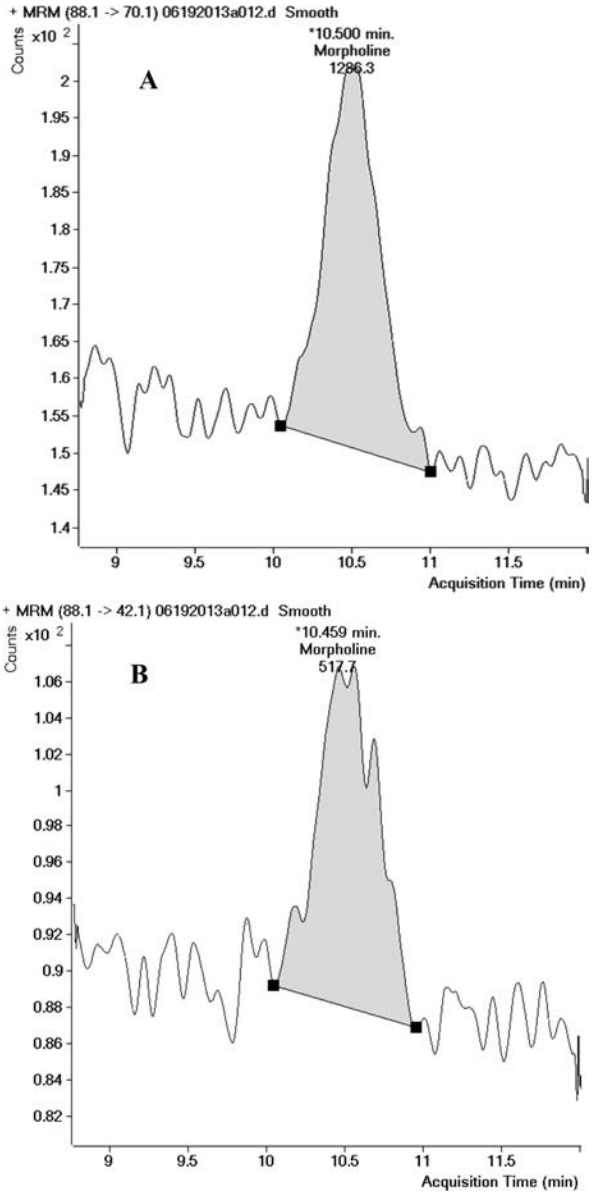

Figure 6. Extracted ion chromatograms of 1 pg/μL (equivalent to 0.01 μg/g) calibration standard from Agilent 6430: (A) MRM transition 88 → 70; (B) MRM transition 88 → 42.

was based on the default threshold which some governmental agencies, such as the EU, typically set at 0.01 μg/g on compounds that do not have established tolerances.[12] Another goal was to have a method that utilized a relatively small amount of solvent and did not require the use of expensive and often difficult to obtain labeled internal standards. Gros et al. reported an LC-MS/MS based method for the determination of morpholine on pineapples which was able to achieve an LOQ of 0.01 μg/g.[13] Although this method achieved the target LOQ, the procedure was not favorable as it required a dual solid phase extraction cartridge system, which adds additional time and cost to the analysis. An unpublished method by Anastassiades et al. described a procedure for very polar, non-QuEChERS-amenable compounds in foods that utilizes acidified methanol extraction and determination by LC-MS/MS.[14] This method met our needs in terms of simple and rapid sample workup but only showed recovery data on lime at 1.0 μg/g and extrapolated LOQs on apples and citrus at 0.01 μg/g.[14,15] We therefore adopted a similar extraction procedure utilizing acidified methanol as in the Anastassiades method as a starting point for our method development.

Initial attempts to run morpholine on a traditional reverse phase C_{18} column resulted in little to no retention and very poor peak shape under high-aqueous conditions. As morpholine has relatively high polarity, this observation was not unexpected. To improve retention and peak shape, a HILIC column was chosen. During early instrumental analysis fortified extracts were compared to external standards prepared in solvent to assess possible ion enhancement/suppression. It was

dx.doi.org/10.1021/jf500734b | J. Agric. Food Chem. 2014, 62, 3697−3701

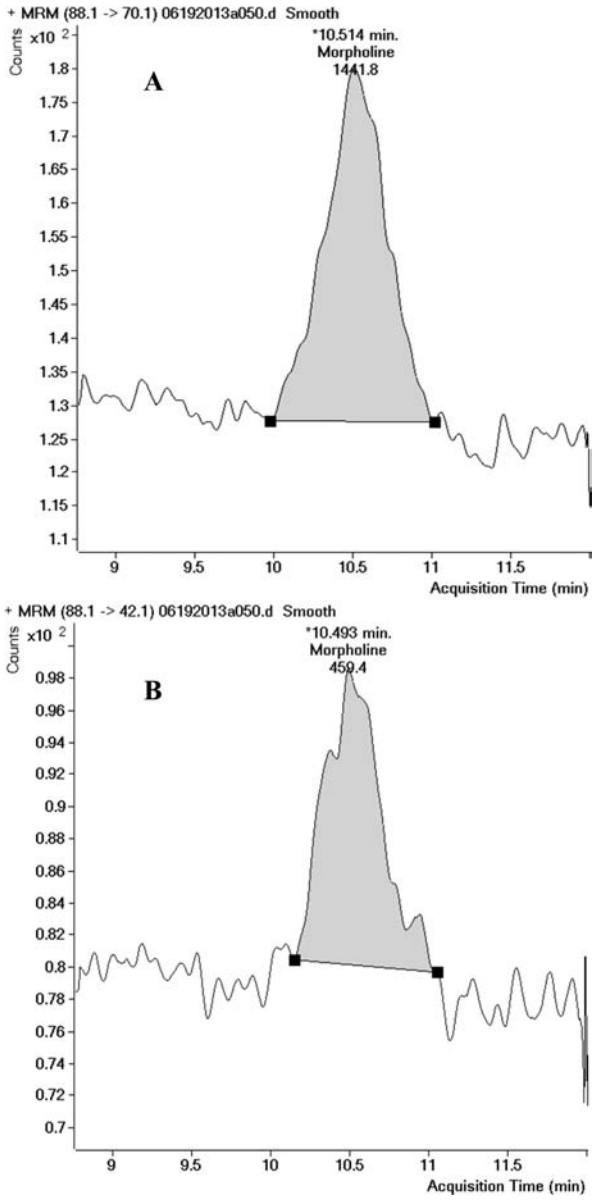

Figure 7. Extracted ion chromatograms of apple control sample fortified at 0.01 μg/g from Agilent 6430: (A) MRM transition 88 → 70; (B) MRM transition 88 → 42.

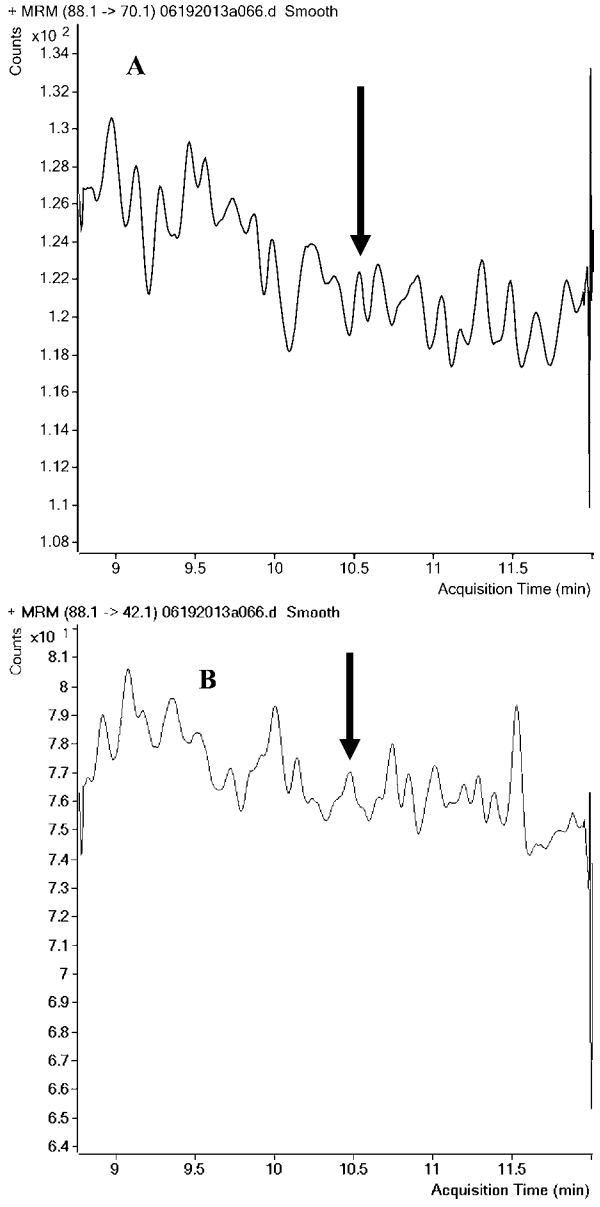

Figure 8. Extracted ion chromatograms of apple control sample from Agilent 6430: (A) MRM transition 88 → 70; (B) MRM transition 88 → 42.

observed that the response from the fortified extracts was suppressed >20% relative to the standard in solvent. As a result of these observations, the researchers chose to prepare matrix-matched standards for each crop type (apple and citrus) to correct the suppression effects.

Method Validation. In addition to the goals above, the method needed to be rugged and transferrable to other laboratories that may utilize instrumentation from different vendors (e.g., Agilent or Waters). Therefore, method validation was conducted at both the PAL and TAL facilities. All control samples used for the validation studies showed no significant morpholine residues for apple or citrus above the instrument limit of detection (LOD) of 0.3 pg/μL as defined by a S/N > 3. The LOQ was defined as 1 pg/μL (0.01 μg/g equivalent), which achieved a S/N > 10. Recovery data (Table 2) generated at the PAL facility for apples and oranges ranged from 84 to 120% over three levels of fortification (0.2, 0.04, and 0.01 μg/g) with all standard deviations ≤15% (n = 7 for each fortification level). The TAL facility produced recovery data for apples, oranges, lemons, and grapefruits that ranged from 97 to 112% over the same fortification levels listed above. As with the PAL data, good precision was observed at the TAL facility with all standard deviations ≤15% (n = 7 for each fortification level). Overall, the results from apple and orange method validation correlated very well between the two laboratories (Table 2). Lemons and grapefruits were also validated to assess the method on different types of citrus. As can been seen in Table 2, the results have excellent correlation to the results from the orange validation and suggest the method is suitable for citrus as a crop group. The coefficient of determination (R^2) for morpholine was ≥0.99 at both facilities. An example calibration curve can be seen in Figure 2. Typical chromatograms of standards and crop extracts can be seen in Figures 3−8 for both instruments. Retention time differences can be

dx.doi.org/10.1021/jf500734b | J. Agric. Food Chem. 2014, 62, 3697−3701

attributed to different flow rates, slight pH differences in the mobile phase preparation, and the usage of a column heater at the PAL facility.

As a result of the research conducted, a rapid, rugged, and selective method was developed for the screening of morpholine in apple and citrus fruits. With the method presented herein, 50 samples can be extracted in ∼4 h and analyzed by LC-MS/MS overnight.

and DCBC.[6] The metabolites, however, are not well recovered from the ginseng matrix using this method.

Zoxamide, the parent compound, is well recovered from ginseng root by a modification of the commonly used multiresidue method known as the QuEChERS-based (for quick, easy, cheap, effective, rugged, safe) approach,[7] which has gained international popularity for its extraction efficiency and ease of use. However, the small acid metabolites of zoxamide (DCHB molecular weight 221.04 and DCBC molecular weight 235.02) were not well recovered from ginseng root through the aforementioned QuEChERS multiresidue approach during the initial recovery trials in this work. Residue analytical methods are required by the EPA to determine the parent compound and metabolites of significance to enforce tolerances.[8] The residue analytical method presented here is a miniaturized extraction that effectively recovered the small acid metabolites DCHB and DCBC as well as the zoxamide parent molecule and uses liquid chromatography coupled with tandem quadrupole mass spectrometry (UPLC-MS/MS). This method rivals the QuEChERS-based approach for its ease of use and rapid sample preparation time.

MATERIALS AND METHODS

Materials and Standards Preparation. Zoxamide and the zoxamide metabolite DCHB analytical standards, of 99.1 and 99.82% purity, respectively, were provided by the U.S. EPA National Pesticide Standard Repository. The zoxamide metabolite DCBC, of 98.8% purity, was provided by the U.S. Department of Agriculture Inter-Regional Research Project No. 4 (IR-4 Project, also referred to as the Minor Crop Pest Management Program). American ginseng root samples, untreated with pesticides, dried for 2 weeks at 35 °C, and finely homogenized using a Wiley mill, were also provided by the IR-4 Project. HPLC grade acetonitrile, ethyl acetate, toluene, and sodium hydroxide solution 40% were purchased from Fisher Scientific (Pittsburgh, PA, USA). Hydrochloric acid 37% ACS Reagent, reagent plus grade ≥99 glycine, and ammonium hydroxide solution 28−30% were purchased from Sigma-Aldrich (St. Louis, MO, USA). Supelclean ENVI-Carb SPE tubes, 0.5 g, 6 mL, were purchased from Supelco Analytical (Bellefonte, PA, USA). pH indicator strips (pH 0−2.5 and 0−14) were purchased from colorpHast (Gibbstown, NJ, USA). Eppendorf variable-volume (10−100 μL, 100−1000 μL) pipets were from Eppendorf AG (Hamburg, Germany), calibrated and certified.

Separate stock solution standards of zoxamide and metabolite DCBC were prepared by dissolving approximately 25 mg in 25.0 mL of acetonitrile for approximately 1.0 mg/mL standard concentrations. Intermediate dilutions were prepared by transferring 1.0 mL of the stock solutions to separate 100 mL volumetric flasks and diluting to volume with acetonitrile for concentrations of 10.1 μg/mL zoxamide and 10.9 μg/mL DCBC. The metabolite DCHB standard was prepared by dissolving approximately 10 mg in 25.0 mL of acetonitrile for a stock standard concentration of approximately 0.4 mg/mL. An intermediate dilution was prepared by transferring 2.5 mL of DCHB stock standard to a separate 100 mL volumetric flask and diluting to volume with acetonitrile for a concentration of 10.6 μg/mL. A second intermediate dilution (1.01 μg/mL) of zoxamide standard was prepared by transferring 0.5 mL of the 10.1 μg/mL standard and diluting to a final volume of 5.0 mL in acetonitrile. A mixed solvent standard, used to prepare the matrix-matched standards for quantitation and for fortification of untreated control ginseng extracts, was prepared by transferring 0.1 mL of the metabolite intermediate standards (10 μg/mL) and diluting to a final volume of 2.0 mL in acetonitrile for final concentrations of 532 ng/mL DCHB and 545 ng/mL DCBC. A second mixed standard, also used for the matrix-matched standards for quantitation and for fortification of control ginseng extracts, was prepared by transferring 0.040 mL of the zoxamide intermediate standard (1.01 μg/mL) and 0.113 and 0.110 mL of the metabolite intermediate standards (10 μg/mL) and diluting to a final volume of 2.0 mL in acetonitrile for a final concentration 20 ng/mL zoxamide and 600 ng/mL DCHB and DCBC. A standard of zoxamide, used for the matrix-matched standards and for fortification of control ginseng extracts, was prepared by transferring 0.044 mL of the zoxamide intermediate standard (1.01 μg/mL) and diluting to a final volume of 2.0 mL in acetonitrile for a final concentration of 22 ng/mL.

A 4 M NaOH solution was prepared by adding 10 mL of 10 M solution to a 25 mL volumetric flask and diluting to volume with Millipore water. The 1 M glycine buffer solution at pH 10 was prepared by dissolving 7.5 g of glycine with 60 mL of Millipore water in a 100 mL graduated cylinder, adding 3.5 mL of 4 M NaOH, and then diluting to 100 mL volume[9−12] with Millipore water.

Sample Preparation. A schematic of the extraction and cleanup procedure is shown in Figure 2. Dried, finely ground ginseng root (0.2 g) was weighed into a screw-capped polypropylene 15 mL centrifuge tube. Glycine buffer (1 M), pH 10 (2 mL), was added and vigorously vortexed for 30 s. Millipore water (2 mL) was added and shaken vigorously by hand for 1 min. Both 1 N HCl (0.8 mL) and 12 N HCl (0.2 mL) were added to the aqueous extract and vigorously shaken for 1 min. Four milliliters of ethyl acetate was added and the centrifuge tube vigorously shaken for 1 min and centrifuged (Jouan Inc.,

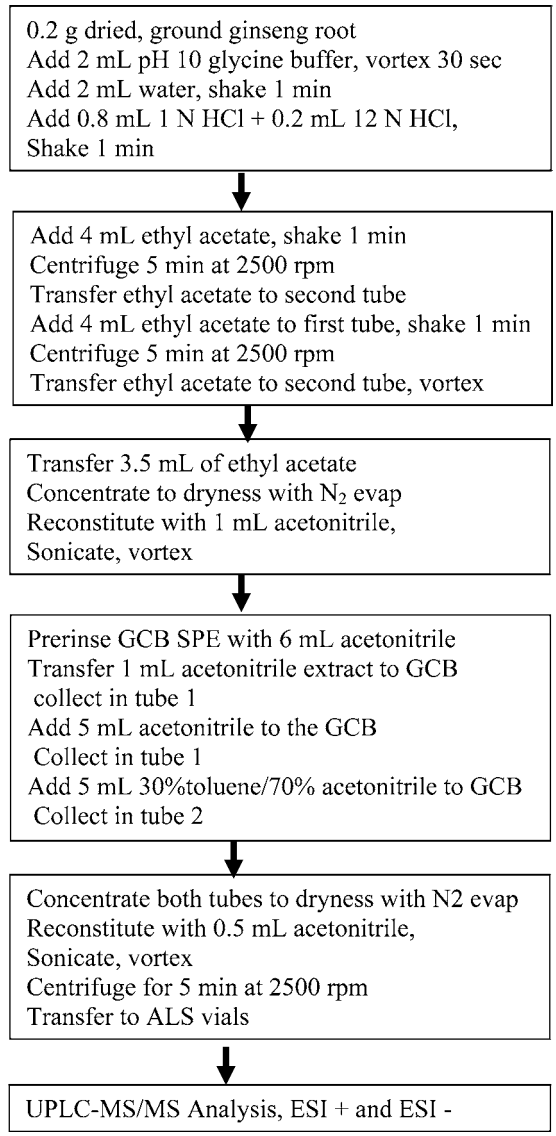

Figure 2. Flowchart of the method for the analysis of zoxamide and its metabolites (DCHB and DCBC) in dried ginseng powder.

Table 1. Analyte Name, Retention Time, Primary and Confirmatory Ion Transitions, and Molecular Formulas of Zoxamide and Its Metabolites

compd	mol formula	mol wt	retention time (min)	LOD (ng/g)	primary and confirmatory ion transitions (P/C ratio %)
zoxamide	$C_{14}H_{16}Cl_3NO_2$	336.64	5.45	6.7	**336**, 186.9, 158.8 (2.2)

Winchester, VA, USA) for 5 min at 2500 rpm at ambient temperature. The ethyl acetate layer (2 mL) was transferred to a second 15 mL centrifuge tube. Ethyl acetate (4 mL) was added to the first tube containing the ginseng and hand shaken again vigorously for 1 min and centrifuged for 5 min at 2500 rpm. The ethyl acetate layer (5−6 mL) was removed and added to the second tube (sum 7−7.5 mL) and vigorously vortexed for 10 s. A portion of the ethyl acetate extract (3.5 mL) was transferred to a third 15 mL tube and concentrated to dryness with nitrogen evaporation (N-EVAP, Organomation Associates, Inc., Berlin, MA, USA). Acetonitrile (1 mL) was added to the centrifuge tube, sonicated for 10 s, and vortexed for 10−15 s. A GCB SPE cartridge was prerinsed with acetonitrile to waste. The extract (1 mL) was transferred to the GCB and collected, without vacuum, in a 15 mL tube labeled fraction 1. Acetonitrile (5 mL) was added to the GCB and collected in the same tube. A solution of 30% toluene/70% acetonitrile (5 mL) was added to the GCB and collected in a second tube labeled fraction 2. Both tubes were concentrated to dryness using nitrogen evaporation. Acetonitrile (0.5 mL) was added to both tubes, vortexed for 15 s, sonicated for 15 s, and centrifuged for 5 min at 2500 rpm. The extracts were transferred to LC autosampler vials for UPLC-MS/MS analysis. Sample preparation time for a set of 6−10 samples is 45 min or less.

UPLC-MS/MS Analysis. A Waters Acquity ultraperformance liquid chromatograph (UPLC) was equipped with a Quattro Premier tandem quadrupole mass spectrometer and an Acquity HSS-T3 column (100 mm × 2.1 mm) of 1.8 μm particle size, all supplied by Waters (Milford, MA, USA), with a void volume of 0.24 mL[13] and a dwell volume of 0.090 mL. Reverse phase operating conditions were as follows: an injection volume of 5 μL at ambient column temperature; a flow rate of 0.3 mL/min using a mobile phase of acetonitrile, H_2O, and ammonium hydroxide prepared as two separate solutions: solvent A, 100% H_2O and 1 mM ammonium hydroxide (500 mL of H_2O + 34 μL of NH_4OH); solvent B, 100% ACN and 3.5 mM ammonium hydroxide (500 mL of H_2O + 120 μL of NH_4OH). The initial conditions were set at 100% solvent A for 2 min using a 0.3 mL/min flow rate; a linear gradient was programmed within 2 min to 10 + 90 (solvent A + solvent B), followed by a 2 min linear gradient to 30 + 70 (solvent A + solvent B) continuing at 0.3 mL/min, and a step back to 100% solvent A for a 3 min equilibration for a total analysis time of 10 min. The mass spectrometer was operated by switching between positive (ESI^+) and negative (ESI^-) electrospray ionization (interchannel delay of 0.020 s) in the multiple reagent monitoring (MRM) mode. The ion source temperature was 130 °C and the desolvation temperature 450 °C. The cone gas flow (high-purity compressed nitrogen) was 50 L/h, and the desolvation gas flow was 800 L/h of nitrogen gas. The collision cell gas was ultrahigh-purity argon with a flow of 0.3 mL/min. Two precursor/product ion transitions were monitored for each compound, and the sum of the areas of both the target ion and the confirmatory ion were used as the total response for quantitation. Analytes were further confirmed when MRM ion transition ratios were within ±20% (absolute) of the ratios in standards. The MRM ion transitions, cone voltages, and collision energies used were as follows: for zoxamide (ESI^+), 336.0 → 158.80 (30 V, 40 eV) and 336.0 → 186.9 (30 V, 20 eV); for DCHB (ESI^-), 218.8 → 144.6 (25 V, 14 eV) and 218.8 → 174.8 (25 V, 10 eV); for DCBC (ESI^-), 232.8 → 108.8 (10 V, 21 eV), 232.8 → 152.8 (10 V,14 eV), and 232.8 → 188.8 (10 V, 9 eV) (see Table 1). Because an external standard was used for quantitation, the retention times of the compound of interest in the standard and the same compound in the sample were ±0.1 min.

Fortification Studies. For all fortification studies, various amounts of spiking standards prepared in acetonitrile were added to 0.2 g test portions of dried control ginseng root in centrifuge tubes. The tubes containing fortified ginseng were vigorously vortexed to distribute the analytes through the ginseng test portions, and the tubes were uncapped to allow the acetonitrile solvent to evaporate prior to sample extraction. For quantification by external calibration, matrix-matched standards were used. Matrix-matched standards were prepared by extracting control ginseng samples (as described above under Sample Preparation including GCB cleanup) and then fortifying the dried extracts with the acetonitrile standards and adjusting the final volume to 0.5 mL with acetonitrile.

For LOD and LOQ fortification studies of DCHB and DCBC, appropriate amounts of a mixed spiking standard containing DCHB (532 μg/mL) and DCBC (545 μg/mL) were added to 0.2 g of ginseng for final concentrations of 0.071 and 0.216 μg/g for DCHB and 0.073 and 0.221 μg/g for DCBC. The matrix-matched standards were prepared at concentration levels of 14.4, 28.7, 86.2, and 172.5 ng/mL for DCHB and 14.7, 29.4, 88.3, and 176.5 ng/mL for DCBC.

For the LOD fortification study of zoxamide, an appropriate amount of a standard of zoxamide (22.4 ng/mL) was added to 0.2 g of ginseng to a final concentration of 0.007 μg/g. The matrix-matched standards were prepared at concentration levels of 0.605, 1.21, and 3.63 ng/mL for zoxamide.

For the fortification studies of the LOQ of zoxamide and 3× LOQ of DCHB and DCBC, a mixed spiking standard prepared in acetonitrile containing zoxamide (20 ng/mL), DCHB (600 ng/mL), and DCBC (600 ng/mL) was added to 0.2 g of ginseng to final concentrations of 0.020 μg/g (zoxamide) and 0.6 μg/g (DCHB and DCBC). The matrix-matched standards were prepared at concentration levels of 1.18, 3.53, 7.07, and 14.1 ng/mL for zoxamide and 35, 105, 210, and 420 ng/mL for DCHB and DCBC.

For the fortification studies of 10× LOQ of zoxamide and 30× LOQ of DCHB and DCBC, various amounts of the intermediate dilutions of 1.01 and 10 μg/mL were added directly to 0.2 g of ginseng to final concentrations of 0.2 μg/g (zoxamide) and 6.0 μg/g (DCHB and DCBC). The matrix-matched standards were prepared at concentration levels of 1.18, 3.53, 7.07, 14.1, 28.3, and 35.3 ng/mL for zoxamide and 35, 105, 210, 420, 830, and 1045 ng/mL for DCHB and DCBC.

Statistics and Calculations. Averages and standard deviations from fortification studies were determined using Microsoft Excel 2003. Linear regressions, correlation coefficients, and analyte concentrations from fortification studies for the UPLC-MS/MS were calculated with the Waters Target Lynx/Mass Lynx software version 4.1 using the sum of peak area responses of the primary ion transition and the confirmatory ion transition.

RESULTS AND DISCUSSION

Extraction Procedure. Recoveries of >90% have been reported for the parent molecule, zoxamide, from ginseng using an acetonitrile extraction of the QuEChERS approach,[2] but the acid metabolites are not well recovered from this matrix. Although a solution of 2% sodium bicarbonate in acetonitrile effectively extracts the metabolites from potato matrices,[6] this solution yielded recoveries of only 30−40% for the acid metabolites in ginseng during the initial recovery trials in this work. To effectively extract the metabolites of zoxamide from ginseng, several different aqueous solutions of various pH values, including glycine buffer solutions,[9−12] a sodium

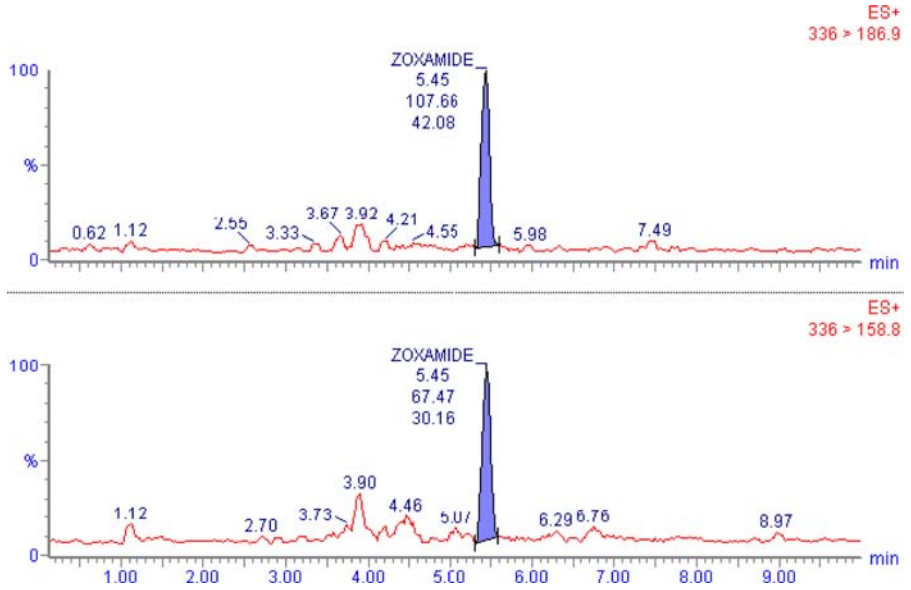

Figure 3. LC-MS/MS of ginseng root fortified with zoxamide at the LOQ of 0.020 ppm.

hydroxide solution, and a neutral acetonitrile/water solution, were evaluated. The results of these trials revealed that a glycine buffer solution (pH 10) effectively recovered both the parent molecule, zoxamide, and the metabolites DCBC and DCHB from the ginseng matrix with average recoveries >95 and >86%, respectively (Table 2).

The 2% sodium bicarbonate/acetonitrile method, which was developed for the extraction of the metabolites from potato,[6] yields poor recoveries of the metabolites from ginseng root and also required derivatization with diazomethane to methylate the metabolites to their methyl esters prior to GC determination. In the method presented here for ginseng root, derivatization with diazomethane is not required. The purified ginseng extract is directly injected into the LC-MS/MS without derivatization. Specifically, in this method, 0.2 g of ground, homogenized ginseng matrix is rendered alkaline with glycine buffer (pH 10) to extract the parent and metabolite molecules and then diluted with water. The solution is acidified with 1 N HCl to neutralize the acid metabolites and partitioned into ethyl acetate in preparation for LC analysis without the need for derivatization.

Initially during the development of the method, the aqueous ginseng extracts were centrifuged prior to partitioning with ethyl acetate. When the aqueous extracts were centrifuged and decanted from the ginseng solids and then partitioned with ethyl acetate, the recoveries of the metabolites DCHB and DCBC were acceptable, but the extraction efficiency of the parent molecule, zoxamide, resulted in low recoveries (30%). By partitioning the water/buffer−ginseng mixture with ethyl acetate in the presence of the ginseng solids, followed then by centrifugation, zoxamide recoveries were improved to >90% and the extraction efficiency of the metabolites remained the same.

A 3.5 mL aliquot of the 7.5 mL ethyl acetate extract is taken through cleanup for instrumental analysis. The remaining 3.5 mL portion of ethyl acetate extract is reserved for a potential second analysis if necessary. A simple solid phase extraction (SPE) cleanup method using graphitized carbon black (GCB) was used for the complete recovery of the analytes. Two fractions were collected through the GCB and injected separately. The first, 5 mL of acetonitrile, captures approximately 30% of the zoxamide analyte. The second fraction of 5 mL of toluene/acetonitrile, 30:70, captures the remaining 70% zoxamide and the metabolites DCHB and DCBC. Two fractions are used because the zoxamide response is affected by matrix coextractants and more coextractants are present in the second, toluene, fraction. To calculate zoxamide recovery, the levels of zoxamide found in the first and second fractions are summed. The advantages of the GCB cleanup are simplicity and speed. The final acetonitrile extract is centrifuged prior to instrumental analysis. Alternatively, filtration with syringe filters should be tested for suitability for the full recovery of the analytes.

Method Validation. Zoxamide and its metabolites, DCHB and DCBC, were analyzed using UPLC-MS/MS. Retention times, quantitation, confirmation, and regression coefficients of zoxamide were determined in the electrospray positive (ESI^+) mode and DCHB and DCBC were determined in the electrospray negative (ESI^-) mode. The extraction and

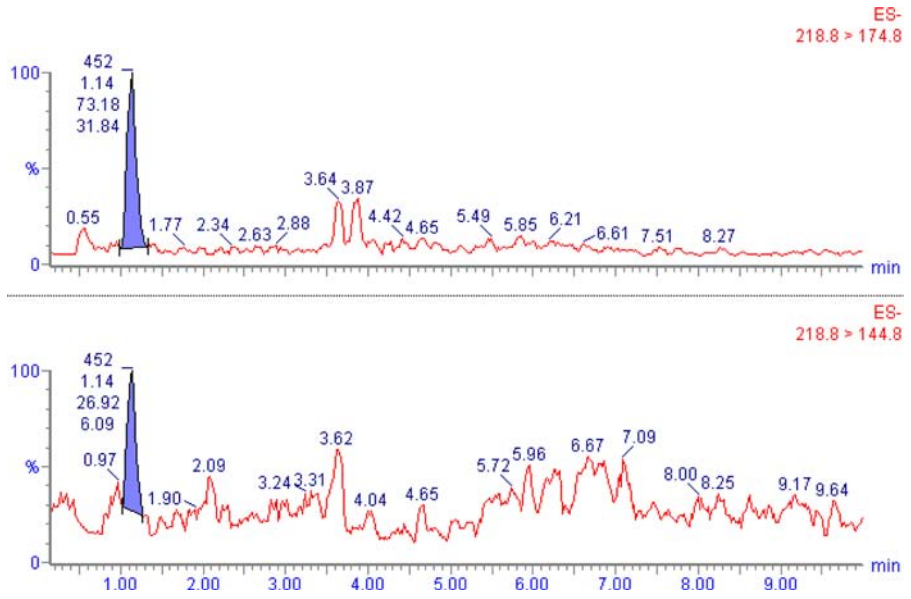

Figure 5. LC-MS/MS of ginseng root fortified with metabolite DCHB at the LOQ of 0.200 ppm.

instrumental analysis method was validated at three different fortification levels for zoxamide including replicates at the limit of detection (LOD), the limit of quantitation (LOQ), and 10× the LOQ. Four different levels were evaluated for the studied metabolites, DCBC and DCHB, including the limit of detection (LOD), the limit of quantitation (LOQ), and 3× and 10× the LOQ. The LOD was defined by the fortification level with a signal-to-noise of a minimum of 3:1, which was determined by the Mass Lynx software and is the standard deviation of the noise data in the monitored range, for both the primary and confirmatory ion transitions; the LOQ was defined by 3× the LOD. Table 2 lists the results of method validation. In general, the regression coefficients r^2 for the matrix-matched calibration curves of each analyte were as follows: zoxamide ranged from 0.986 to 0.998; DCHB, $r^2 > 0.995$; and DCBC, $r^2 > 0.988$. Figures 3, 5, and 7 show chromatograms of ginseng root extract fortified at the LOQ of 0.020 μg/g for zoxamide and 0.2 μg/g for DCHB and DCBC metabolites. The peak shapes are consistent and Gaussian with baseline separations. No significant background interfering peaks are observed in the control ginseng chromatograms shown in Figures 4, 6, and 8.

Instrumental Analysis. Weak acids, such as acetic acid and formic acid, are frequently used mobile phase modifiers that increase ionization of many analytes using positive ESI.[14] However, neither formic acid nor acetic acid improved the response of the acid metabolites, DCHB and DCBC, in the ESI^- mode. The neutral salts, ammonium formate and ammonium acetate, which are also commonly used modifiers in ESI^+ mode, also did not result in improved ionization of the zoxamide metabolites in ESI^- mode. The volatile base,

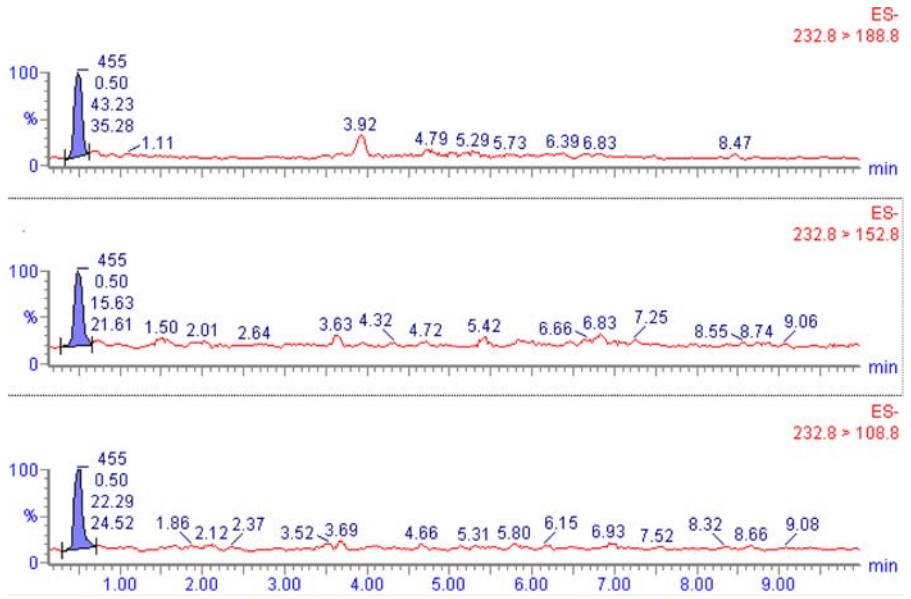

Figure 7. LC-MS/MS of ginseng root fortified with metabolite DCBC at the LOQ of 0.200 ppm.

ammonium hydroxide, resulted in the ionization of the small metabolite molecules DCBC and DCHB in the negative-ion mode ESI. A low concentration of 1 mM ammonium hydroxide in the aqueous mobile phase was sufficient for ionization in the ESI$^-$ mode, and higher molar concentrations did not improve ionization or detection limits.

Fortification Studies. The recoveries from fortification studies of zoxamide and the metabolites DCHB and DCBC, evaluated by UPLC-MS/MS and based on external calibration using ginseng root matched standards, are shown in Table 2. The dried, powdered ginseng was fortified with zoxamide to levels of 0.007, 0.020, and 0.202 μg/g; DCHB to levels of 0.071, 0.216, 0.600, and 6.0 μg/g; and DCBC to levels of 0.073, 0.221, 0.600, and 6.00 μg/g. The mean recovery ranges for zoxamide and the metabolites at the aforementioned levels were from 95 to 124% for zoxamide, from 86 to 106% for DCHB, and from 95 to 113% for DCBC.

Matrix Effects. The use of ginseng matrix-matched standards for quantitation instead of solvent standards was necessary because of pronounced matrix effects from ginseng extracts. Although there were no significant matrix interferences, the presence of the ginseng matrix reduced the signal by approximately 3× for DCHB, 4× for DCBC, and 6× for zoxamide. Although recoveries at the LOD of DCHB and DCBC were generally consistent using ginseng matrix standards, recoveries of zoxamide at the LOD of 0.007 μg/g were less consistent.

The challenge of the ginseng matrix was the efficient extraction of the metabolites of the parent molecule zoxamide. The miniaturized extraction presented here effectively recov-

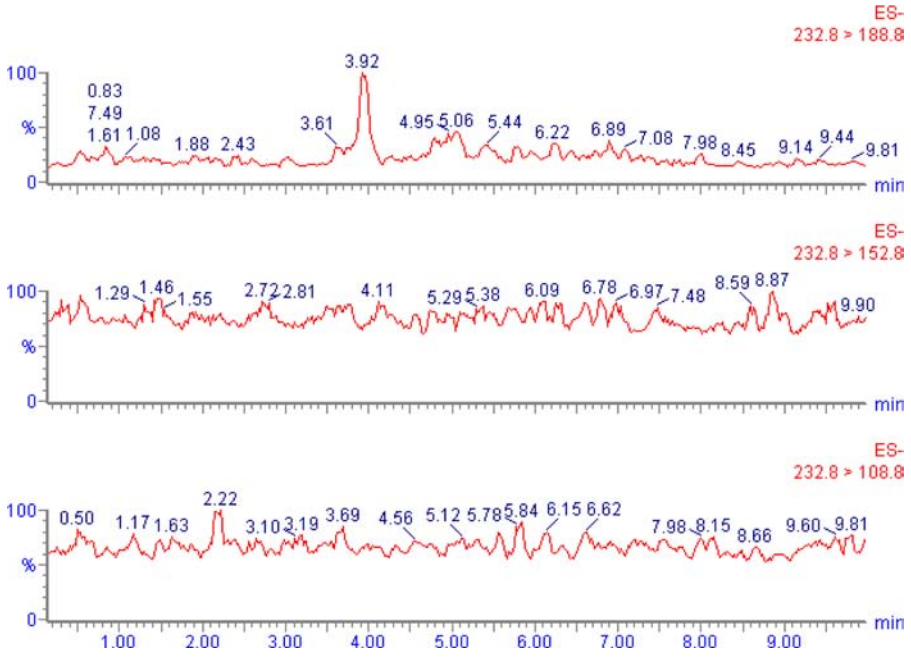

Figure 8. LC-MS/MS of ginseng root control in ES^- at the retention time and transitions of DCBC.

ered the acid metabolites 3,5-dichloro-4-hydroxymethyl benzoic acid and 3,5-dichloro-1,4-benzenedicarboxylic acid at a LOQ of 0.2 ppm as well as the parent, zoxamide, at a LOQ of 0.02 ppm from fortified ginseng root samples. The method uses a pH 10 1 M glycine buffer and also uses a simple graphitized carbon black cleanup and UPLC-MS/MS for quantitation. Unlike other single-analyte or specialized methods, this extraction method is simple and rapid. This analytical method is suitable for the EPA approved use of the fungicide zoxamide for ginseng root crops.

[a]Collision energy (eV) is given in parentheses.

introduced by Anastassiades and Lehotay et al. in 2003.[15,16] Its main advantage is comprehensiveness, being useful for the analysis of various pesticides. A great deal of literature suggests that better results are obtained by the QuEChERS method with efficient removal of matrix compounds and higher recoveries of pesticides with minimal solvent.[9,17−20] The first step of the QuEChERS method is to extract the analytes from samples with a small amount of acetonitrile, followed by liquid−liquid partition by salting-out with sodium chloride and magnesium sulfate. Then, a cleanup step is often carried out by mixing the acetonitrile extract with loose sorbents, which was based on reversed-dispersive solid phase extraction (r-DSPE) to absorb the interference substances in the matrices, rather than the analytes. In most cases, primary−secondary amine (PSA), graphitized carbon black (GCB), or C_{18} was used as r-DSPE sorbent to remove the interference substances in the matrix such as fatty acid compounds, pigments, sterols, and other nonpolar interfering substances.[21−23]

Carbon nanotubes (CNTs), first reported by Iijiama in 1991,[24] are interesting carbonaceous materials as new carbon-based nanomaterials. According to the carbon atom layers in the wall of the nanotubes, CNTs can be divided into single-walled carbon nanotubes (SWCNTs) and multiple-walled carbon nanotubes (MWCNTs). MWCNTs have been widely used as sorbent materials in inorganic elements, pollutants, and veterinary drugs.[25−27] In our previous study, MWCNTs were used as alternative reversed-dispersive solid phase extraction materials in pesticide multiresidue analysis with the QuEChERS method.[28,29] They were also mixed with other sorbents such as PSA and GCB for dispersive cleanup of acetonitrile extracts from tea samples.[30]

A more practical way to perform the r-DSPE method is to use cartridges (like most SPE cartridges) where the sample matrix compounds in the acetonitrile extraction interact with the sorbents.[31] In the work presented here, an r-DSPE cleanup method for tomato product extracts was developed using multiplug filtration cleanup (m-PFC) followed by gas chromatography−triple-quadruple tandem mass spectrometry (GC-MS/MS) analysis. The cartridges of m-PFC contained MWCNTs and anhydrous magnesium sulfate to efficiently clean up QuEChERS extracts prior to analysis. The proposed technique based on MWCNTs intends to adsorb the interfering substances in the matrices, rather than the analytes, and anhydrous magnesium sulfate could remove water from the extract. The m-PFC method is shown to be very rapid to perform without any solvent evaporation. It is expected to facilitate routine analyses of pesticides in fresh vegetable/fruit samples such as tomato and its processed products.

MATERIALS AND METHODS

Standards, Reagents, and Materials. Analytical standards of the pesticides in the study were provided by the Institute of the Control of Agrochemicals, Ministry of Agriculture, Peoples' Republic of China. The purities of the standard pesticides were from 95 to 99%. Stock solutions of 10 mg L^{-1} for pesticide mixtures were prepared in acetonitrile and stored at −20 °C. The working solutions were prepared daily. HPLC grade acetonitrile was obtained from Fisher Chemicals (Fair Lawn, NJ, USA). Analytical reagent grade anhydrous sodium chloride (NaCl) and magnesium sulfate ($MgSO_4$) were obtained from Sinopharm Chemical Reagent (Beijing, China). MWCNTs with average external diameters of 10−20 nm were provided by Tianjin Bonna-Agela Technologies Co., Ltd. (China). M-PFC tips were packed with 10 mg of MWCNTs and 150 mg of anhydrous magnesium sulfate with assistance from Tianjin Bonna-Agela Technologies.

GC-MS/MS Analytical Conditions. Determinations were performed using an Agilent 7000B triple-quadrupole mass spectrometer interfaced to an Agilent 7890A GC. An Agilent Technologies capillary column HP1701 MS analytical column (30 m × 250 μm × 0.25 μm film thickness) was used for GC separation, with helium (99.9999%) as carrier gas at a constant flow rate of 1.2 mL min^{-1}. The column temperature was initially at 80 °C (hold for 1 min), increased to 150 °C at a rate of 30 °C min^{-1} and then to 210 °C at a rate of 3 °C min^{-1}, and finally increased to 290 °C at a rate of 10 °C min^{-1}, holding for 12 min. The temperature of the injector port was 260 °C, and a volume of 1 μL was injected in splitless mode. The total running time was 43 min.

The mass spectrometer was operated in electron ionization mode (70 eV). Default instrument settings of collision gas flow of N_2 at 1.5 mL min^{-1} and He at 2.25 mL min^{-1} and quadrupole temperature of 150 °C were used in all MS/MS experiments. The detector voltage was automatically set by the instrument after automated MS/MS tuning, which was typically 1250 V. A full autotune of the mass spectrometer using the default parameters of the instrument was performed before each sequence. Agilent MassHunter was used for instrument control and data acquisition/processing. For the final multiple reaction monitoring (MRM) acquisition method, two ion transitions at the experimentally optimized collision energy (CE) were monitored for each analyte. Both pairs of the MRM transitions were used for confirmation analysis, which meets the EU Decision,[32] and the most sensitive transitions were selected for quantification analysis.

To obtain better separation efficiency, the 186 compounds were divided into two groups: groups A and B consisted of 92 and 94 compounds, respectively. Therefore, the 186 pesticides were detected by two GC-MS/MS analyses. Table 1 summarizes the optimized MS/MS conditions for the individual analytes and their typical retention times (RT) in groups A and B.

Sample Preparation. The tomato, tomato juice, and ketchup samples were obtained from a local supermarket, and tomato samples were homogenized with a blender for 1 min at room temperature. For recovery determination, the homogenized samples (10.0 ± 0.1 g) were spiked by the addition of the standard stock solutions at two concentration levels of 10 and 100 μg kg^{-1}. The spiked samples were set aside for 30 min before extraction.

An amount (10.0 ± 0.1 g) of ground tomato, tomato juice, or ketchup samples was weighed into a 50 mL centrifuge tube, and 10 mL of acetonitrile was added. The resulting solution was shaken by the vortex for 1 min. One gram of sodium chloride and 4 g of anhydrous magnesium sulfate were added for tomato and ketchup extracts, and 3 g of sodium chloride and 4 g of anhydrous magnesium sulfate were added for tomato juice extracts. The tube was cooled to room temperature in an ice−water bath immediately. The centrifuge tube was shaken vigorously for 1 min to prevent salt agglomeration before centrifugation at 3800 rpm for 5 min. The supernatant was used for further m-PFC.

M-PFC Procedures. A 1 mL aliquot of the initial extracts was used for extraction, which was introduced into a 2.0 mL microcentrifuge tube. The m-PFC procedure was carried out with a 2.0 mL syringe and an m-PFC tip. The sorbent in the tip was 10 mg of MWCNTs mixed with 150 mg of $MgSO_4$.

Schematic diagrams of an m-PFC tip and the procedures are shown in Figure 1. As shown in Figure 2, the syringe needle was kept under

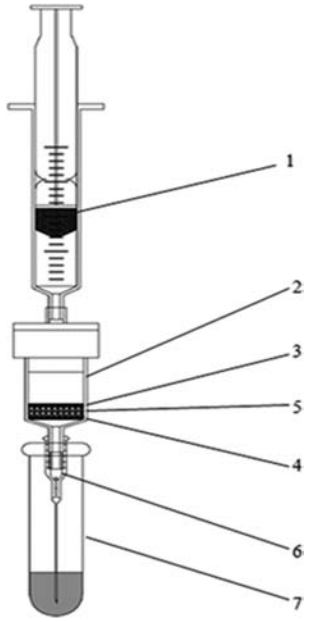

Figure 1. Schematic diagram of an m-PFC tip: 1, syringe; 2, column; 3, PE frits (upper); 4, PE frits (low); 5, MWCMNs (10 mg) and anhydrous magnesium sulfate (150 mg); 6, syringe needle; 7, 2.0 mL microcentrifuge tube.

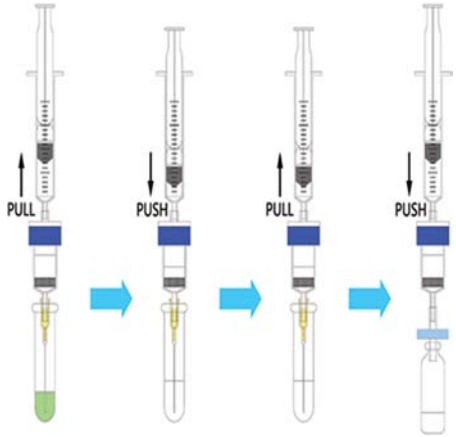

Figure 2. Schematic diagram of the rapid m-PFC method.

the surface of the extract, and then the syringe piston was pushed and pulled as follows: Step 1, pull the piston. All of the extracts were sucked into the m-PFC tip and filtered through the sorbent. Step 2, push the piston. All of the extracts were pressed into the microcentrifuge tube and filtered through the sorbent a second time. Step 3, repeat steps 1 and 2 twice. Step 4, remove the needle and press the extracts into an LC vial to carry out the chromatographic analysis. At the same time, the acetonitrile layer was filtered through a 0.22 μm filter membrane.

Method Performances. Three kinds of tomato products were selected for validation purposes: tomato, tomato juice, and ketchup. Validation data were obtained for each type of sample. The following parameters were determined during validation of the analytical method: linearity, limit of quantification (LOQ), limit of detection (LOD), accuracy, and precision. Linearity was studied using matrix-matched calibration by analyzing samples of tomato, tomato juice, and ketchup. The recovery and reproducibility experiments were carried out for each sample in five replicates at two fortification levels (10 and 100 μg kg^{-1}). The LODs were determined as the concentration of analyte giving a signal-to-noise ratio (S/N) of 3 for the target ion (the less intense transition); LOQs were determined as the concentration of analytes giving a S/N of 10 for the target ion (the less intense transition).

RESULTS AND DISCUSSION

Optimization of GC-MS/MS Conditions. Optimization of triple-quadrupole MS/MS was a rather demanding task because specific experimental conditions were required for each target compound to conduct analyses.[33] To find the retention times and the best resolution between the analyte peaks, preliminary experiments were carried out systematically in full scan mode using compound standard solutions.

A tandem mass detector has high selectivity and sensitivity and provides an effective solution. The relevant consideration included the choice of precursor ions, product ions, and optimization of collision energies for best response. The mass spectrometric parameters option was initially performed by full scan for the compounds. After that, the precursor ion for each analyte was selected, and then the collision energy voltages (potential on second quadrupole) were optimized to generate MS/MS product ions. The characteristic ion transition and collision energy for each compound during MRM acquisition are listed in Table 1. The collision energy was optimized for two selective ion transitions for every pesticide. Both pairs of MRM transitions were used for confirmation analysis, which meets the EU Decision,[32] and the most sensitive transitions were selected for quantification analysis.

Because of the large number of compounds to be detected, the 186 pesticides were divided into two groups and analyzed twice by GC-MS/MS. Groups A and B consisted of 92 and 94 compounds, respectively. The conditions of gas chromatography for the two groups were the same, but the MS/MS conditions were different due to the various pesticides. The developed method was highly selective with the monitoring of specific MRM of each analyte, which was essential to reduce the risk of false-positive results.

Extraction Procedure Optimization. In the original QuEChERS method, the amounts of acetonitrile and sodium chloride were 10 mL and 1 g per 10 g of sample, respectively. In our pre-experiments, the original QuEChERS extraction procedure with 1 g of sodium chloride and 10 mL of acetonitrile was used, and good recoveries (>70%) could be obtained for most pesticides in the matrices of tomato and ketchup. However, when it came to tomato juice, the recoveries for 82 pesticides (of the 186 pesticides) decreased below 60%, probably due to the high content of water in juice. To obtain better recoveries for tomato juice, different amounts of sodium

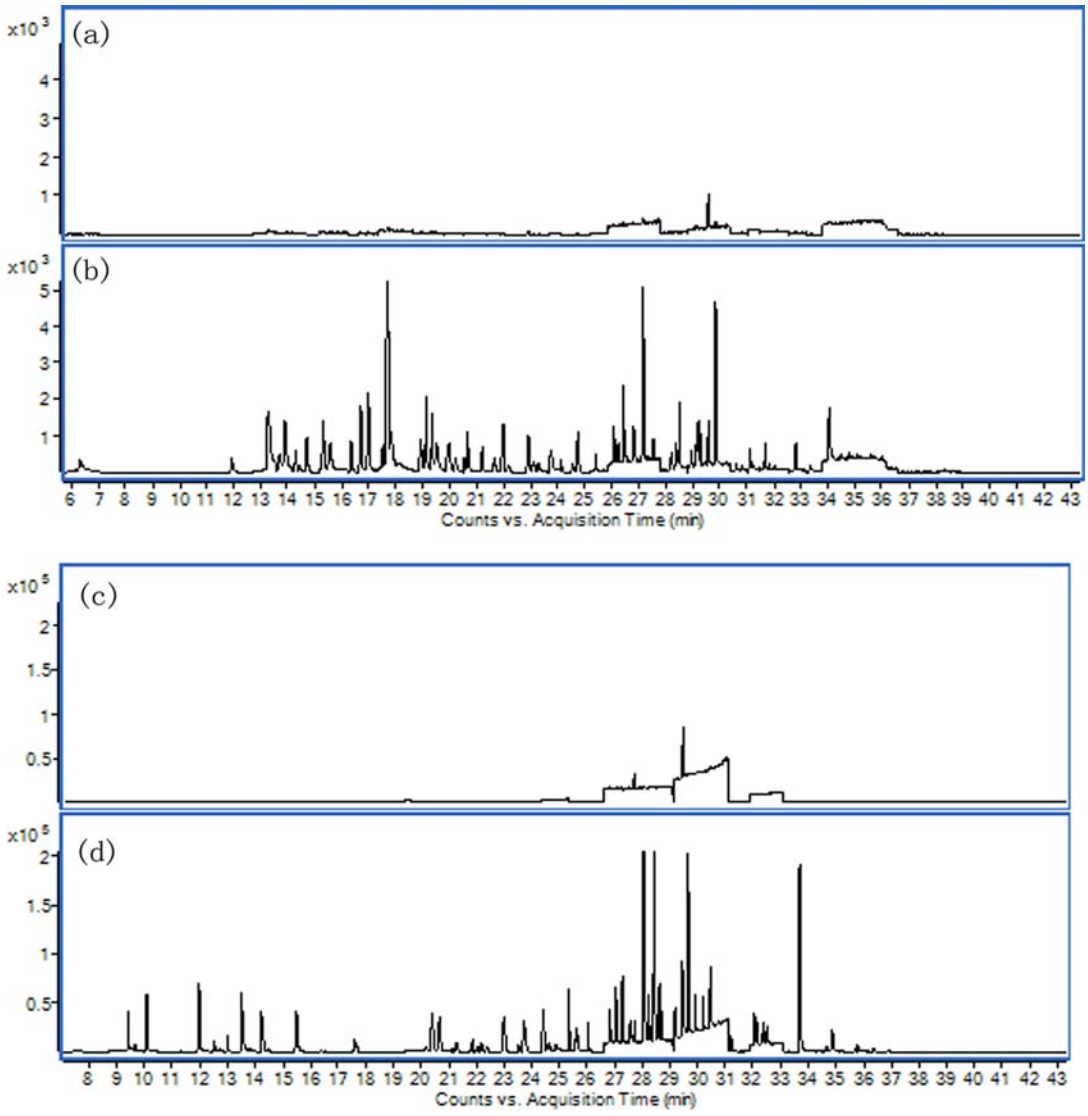

Figure 3. Chromatograms for tomato extracts after m-PFC: (a) total ion current (TIC) chromatogram for a typical blank sample of the target analytes in group A; (b) TIC chromatogram for a typical blank sample spiked at 10 μg kg^{-1} of the target analytes in group A; (c) TIC chromatogram for a typical blank sample of the target analytes in group B; (d) TIC chromatogram for a typical blank sample spiked at 10 μg kg^{-1} of the target analytes in group B.

chloride (1, 2, and 3 g) were employed and analyzed in triplicate at one calibration point (100 μg kg^{-1}). It was shown that the salting-out effect of 3 g of sodium chloride was notably higher in comparison with the other amounts, and the recoveries for most compounds were satisfactory and acceptable. Therefore, 3 g of sodium chloride was added for salting-out after acetonitrile extraction, which was employed as the optimum amount for the matrix of tomato juice in the study. The original QuEChERS extraction procedure (1 g of sodium chloride) was used for the other two matrices of tomato and ketchup.

M-PFC Process. The m-PFC process was performed to remove the sample matrix in the extract prior to chromatographic analysis. The removal of interference substances in the matrices is necessary to ensure reproducible peak intensities for quantitative analysis. The proposed cleanup method was based on the m-PFC procedure with the mixture of anhydrous magnesium sulfate and MWCNTs. Anhydrous magnesium sulfate was used to remove the water in the matrices, and MWCNTs were used to remove other interference substances such as fatty acids, pigments, and other matrix compounds.

In our previous study, we found that MWCNTs could be used as alternative r-DSPE materials in pesticide multiresidue analysis with the QuEChERS method.[28] The optimal amount of MWCNTs was 10 mg, which was suitable for cleanup. A smaller amount of MWCNTs (5 mg) could not obtain as good a cleanup performance as 10 mg of MWCNTs and 15 mg or more MWCNTs could lead to low recoveries (<70%) for most pesticides. In addition, the final samples processed by 10 mg of MWCNTs looked transparent in color. In this study, we used 10 mg of MWCNTs mixed with 150 mg of $MgSO_4$ as the sorbent, referred to the previous work. In most cases, the recoveries could meet the requirement of the pesticide residue analysis.

To obtain the best recovery and cleanup performance, the cycles of pulling and pushing during the m-PFC procedure were optimized. Better recoveries were achieved with one or two times of pulling and pushing, but the cleanup performance was not as good as three times, and there were more

chromatographic interferences when pulling and pushing one or two times. The recoveries for most compounds (expect eight compounds) were also acceptable when three times of pulling and pushing were used. In addition, four or more times were also tested, but there was no significant difference for the cleanup performance between three times and four times. As a result, three times of pulling and pushing was chosen as the optimized m-PFC procedure.

Figure 3 shows GC-MS/MS chromatograms of the blank tomato sample and the spiked sample after cleanup procedures using m-PFC, respectively. Little interference appeared in the chromatogram of samples. Finally, 10 mg of MWCNTs mixed with 150 mg of $MgSO_4$ (1 mL extract) was used for the m-PFC process in the further studies because acceptable recoveries and good cleanup performances were both obtained for most compounds.

Method Validation. The linearity of the method was tested using matrix-matched calibration solutions. As recommended in EU guidelines, in our study validation experiments were calculated using matrix-matched calibration standards for the more accurate results, excluding any influence produced by matrix effects. Calibration curves were constructed from calibration solutions in extracts of three kinds of matrices, tomato, tomato juice, and ketchup at five different concentrations in the range of 5−200 μg L^{-1} for all pesticides. The quantitative results of a detection method greatly depend on its calibration. As shown in Table 2, good linearity was found for most pesticides with coefficients of determination (R^2) better than 0.990.

As LODs and LOQs are matrix dependent, the proposed method was tested for extraction and determination of multiresidues in different kinds of matrices (tomato, tomato juice, and ketchup), which manifested various levels of LOD and LOQ. In this study, LODs and LOQs were calculated as the concentration giving signal-to-noise ratios of 3 (S/N = 3) and 10 (S/N = 10), respectively, which was analyzed by the MassHunter Workstation software qualitative analysis version B.03.01/build 3.1.346.0 and Microsoft Excel. As shown in Table 2, the LODs for these pesticides studied ranged from 0.2 to 3 μg kg^{-1} in the three matrices and the LOQs ranged from 1 to 10 μg kg^{-1}.

To study the accuracy and precision of the proposed method using GC-MS/MS analysis, three different sample matrices were spiked with standard pesticides at a low level (10 μg kg^{-1}) and a high level (100 μg kg^{-1}). The results of the average recoveries and relative standard deviations (RSDs) of pesticides spiked at the two levels are shown in Table 3. The recoveries of most pesticides were in the range from 70 to 137% (71−137% for tomato, 70−131% for tomato juice, and 70−130% for ketchup). RSDs were below 15% for most cases. However, low recoveries (<65%) were obtained for eight compounds (cyprodinil, diflufenican, prochloraz, pyrimidifen, quinoclamine, quinoxyfen, cyflufenamid, and pyrimethanil). The nature of these compounds is readily suggested by their chemical structures (Figure 4). It was found that all eight pesticides contained two rings at least or one benzoheterocycle. The recoveries for the eight compounds ranged from 20 to 65% and RSDs were>20% in some cases, which could not meet the requirements for the analysis of pesticides. By reducing the cycles of m-PFC procedure to one or two times of pulling and pushing, the recoveries of those compounds increased a little (by 5−15%) and RSDs were >15%, which still could not meet the requirements for the analysis of pesticides. As a result, the m-PFC based on the MWCNTs process might not be suitable for the analysis of those compounds containing many rings or benzoheterocycle. It is possible to incorporate an alternative sorbent to extract these compounds using m-PFC technology.

Real Samples Analysis. To evaluate the proposed method, it was applied to the analysis of real samples. It was used for the analysis of pesticide residues in 10 tomato, 5 tomato juice, and 5 ketchup samples, which were obtained from local markets and supermarkets in Beijing. All of the samples were extracted and analyzed as described under Materials and Methods. From the analytical results, chlorpyrifos (1.6−8.1 μg kg^{-1}), procymidone (17−51 μg kg^{-1}), flucythrinate (5.6−8.7 μg kg^{-1}), and metalaxyl (2.3−11.2 μg kg^{-1}) were detected in six tomato samples. Procymidone (2.5 μg kg^{-1}) was detected in one tomato juice sample. Chlorpyrifos residues were detected in one ketchup sample, with the concentration of 3.3 μg kg^{-1}.

A rapid and sensitive method for the analysis of multiresidues in tomato products has been developed using m-PFC technology combined with the QuEChERS method. The m-PFC process provided an effective method for cleanup of pesticide extracts from matrices. The cleanup procedure after extraction was focused on removing the interfering substances in the matrices, rather than extracting and isolating the analytes. In most cases, satisfactory recoveries of 70−130% were obtained with relative standard deviations of <15%. The sample cleanup process was achieved without any solvent evaporation or vortex or centrifugation procedure. The feasibility of rapid, high-throughput analysis of pesticides by performing the m-PFC process of acetonitrile extracts of tomato products in tens of seconds with no additional concentration and solvent exchange steps is demonstrated.

Table 3. Average Recoveries and Relative Standard Deviations (RSDs) at Two Spiked Levels in Tomato, Tomato Juice, and Ketchup

	average recovery (%) (RSD, %) (n = 5)					
	tomato		tomato juice		ketchup	
compound	10 μg kg^{-1}	100 μg kg^{-1}	10 μg kg^{-1}	100 μg kg^{-1}	10 μg kg^{-1}	100 μg kg^{-1}
