A sample set consisted of 10 vials including 8 samples (plasma, urine, feces, or tissue), 1 control matrix (blank tissue), and 1 recovery matrix (spiked at 0.3 μg/mL PFOS for plasma and urine and 0.1 μg/g PFOS for tissues or feces). Control and recovery matrices were used for quality assurance and control purposes. The control matrix allowed for detection of any laboratory or residual contamination, and the recovery matrix assured the extraction was working properly. The control and recovery matrices for plasma, urine, and feces were from the steers used in this study but were collected prior to dosing. The control and recovery matrices for tissues were from beef liver, swine muscle, and swine fat from previous, nonrelated studies conducted in our lab, as well as the control animal. Extraction recoveries for PFOS in plasma, urine, feces, liver, muscle, and fat were 86.7 ± 14% (n = 8), 95.5 ± 10% (n = 8), 64.8 ± 7% (n = 6), 96.9 ± 20% (n = 4), 101.9 ± 0.7% (n = 3), and 101.3 ± 23% (n = 4), respectively. Extraction recoveries and reproducibility in different matrices were within acceptable standards for LC−MS/MS analysis established by previous work from our lab.[25]

PFOS in sample extracts (10 μL) was quantified by LC−MS/MS on an Alliance HPLC (Waters, Milford, MA) coupled to a quadrupole time of flight mass analyzer (QTOF, Waters). A Waters C-18 Symmetry column (2.1 mm × 100 mm, 3.5 μm particle size) and

mobile phase (0.3 mL/min) consisting of 95/5 water/MeOH with 2 mM ammonium acetate (mobile phase A) and 100% MeOH with 2 mM ammonium acetate (mobile phase B) were used to separate PFOS from matrix interferences. The mobile phase was initially 70/30 A/B (held for 0.2 min), which was then linearly changed to 15/85 A/B during the next 21 min; the mobile phase composition was then constant for 5 min and then returned to starting conditions. Using these chromatographic conditions, PFOS eluted at 17.9 min. Ionization of the analyte was achieved by electrospray ionization in negative ion mode. The desolvation temperature was 350 °C, and source temperature was 120 °C. The desolvation gas flow was 500 L/h, the cone gas flow was 20 L/h, and the capillary, cone, and collision voltages were 3.4 kV, 20 V, and 5 V, respectively. Precursor and fragment ions of m/z 498.9, 229.9, 98.9, and 79.9 were monitored in MS/MS scan mode for PFOS. Every sample extract injection was scanned also in MS scan mode to monitor for metabolite formation.

An 8-point external standard curve ranging from 0.007 to 1 μg/mL was made fresh in MeOH on the day of analysis from a stock solution (10 μg/mL PFOS) in acetonitrile. The linear portion of the standard curve was used to quantify PFOS in the extracts; if PFOS concentrations were above the linear portion, extracts were diluted and reanalyzed. A blank injection was performed after 4 sample injections to ensure that there was no carry-over. A check standard injection was performed after 20 injections to confirm instrument performance. Check standards were required to be within ±20% of actual concentration over the entire course of a sample set to guarantee accuracy of the calculated PFOS concentrations in the extracts. A method limit of detection (LOD) and limit of quantitation (LOQ) were determined in plasma to be 0.014 μg/mL and 0.048 μg/mL, respectively. Concentrations of PFOS in other tissues such as muscle, kidney, and liver were well above the standard curve and needed dilution, therefore a method LOD and LOQ were not determined.

Kinetic Parameter Estimates. Parameters (A, E, α, and β) describing PFOS absorption and distribution were estimated on the mean concentrations from plasma vs time data (0−17 days) using noncompartmental methods (PK-Solutions software; Summit Research Services; Montrose, CO); the calculated concentration maximum (C_{max}) and time maximum (T_{max}) are reported for plasma. To describe the initial absorption and distribution phases, only data from 0 to 17 days was used. For predictive purposes, plasma concentrations at each time point were averaged across all animals and least-squares parameter estimates were calculated after curve-stripping. Predicted plasma PFOS concentrations (C) were calculated using

$$C = A\ e^{-\alpha t} + E\ e^{-\beta t}$$

where t is time (h); and A and E are Y intercepts of lines having slopes of α and β, respectively.

RESULTS

PFOS Concentrations in Plasma. Average concentrations of PFOS in steer plasma ranged from 0.016 ± 0.008 μg/mL to 52.6 ± 3.4 μg/mL over 28 days following a single oral dose of 8 mg/kg bw (Figure 1). The corresponding mean (±SD) plasma concentrations are presented in the Supporting Information for each time point (Table S1). A plasma elimination half-life was not calculated because PFOS concentrations increased during the last week of the 28-day study. However, using the data in Figure 1 from 0 to 17 days, a C_{max} of 36.3 μg/mL and T_{max} of 4.7 days were calculated. After an apparent plasma peak and depletion, PFOS levels increased to a mean concentration of 52.6 ± 3.4 μg/mL at day 28, which was approximately 35.8 ± 4.3% of the PFOS dose (Table 1).

PFOS Concentrations and Excretion in Urine and Feces. Urine concentrations increased during the first 6 days, after which concentrations stayed nearly steady (0.12−0.16 μg/mL) until day 25, when levels began to drop below 0.1 μg/mL

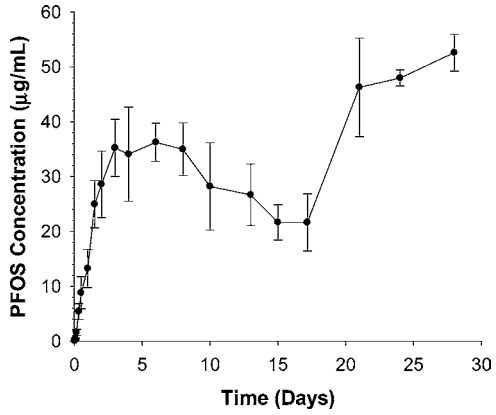

Figure 1. Mean plasma PFOS concentrations (μg/mL) and time data through 28 days after a single oral dose given to steers. Points represent mean concentrations of three animals from LC−MS/MS analysis ± one standard deviation.

Table 1. Mass Balance Mean (n = 3) Amounts and Percentages for PFOS in Steer Body Compartments at 28 Days Following Dosing

tissue	total amount[a] (mg)	% of dose
plasma	946.7 ± 113.2#	35.8 ± 4.3
feces (0−28 days)	291.1 ± 34.0*	11.0 ± 1.3
carcass remainder	149.6 ± 41.8#	5.7 ± 1.6
muscle	113.8 ± 15.9#	4.3 ± 0.6

lung	12.8 ± 11.8#	0.5 ± 0.4
kidney	3.1 ± 0.9#	0.1 ± 0.03
spleen	1.4 ± 0.3#	0.05 ± 0.01

[a](*) Total sum for all days of study. (#) Total from slaughter.

(Figure 2a). Cumulatively, PFOS excretion in urine was linear over 28 days but is presented on a log scale because of the range of values. Overall only 0.5 ± 0.07% of the dose was excreted in urine over the course of the 28-day study (Table 1).

Fecal concentrations increased over the first 6 days of the study to an apparent maximum of 6.4 ± 4.4 μg/g dw (Figure 3a). Thereafter, mean concentrations in feces ranged between 1.6 and 5.1 μg/g dw with a general decline (Figure 3a). Cumulative fecal excretion of PFOS was linear over the 28 days but was presented on a log scale due to the range of values (Figure 3b). Feces was the major route of elimination of PFOS, and cumulatively 11.0 ± 1.3% of the PFOS dose was excreted in the feces over the 28-day study. Urine and fecal mean (±SD) PFOS concentrations for each day are presented in the Supporting Information (Table S2).

PFOS Concentrations in Tissues and Body Burden. Figure 4 presents the mean concentrations of PFOS in plasma, urine, feces, liver, bile, muscle, kidney, lung, spleen, back fat, IP fat, and carcass remainder at the termination of the study. The muscle, liver, and bile mean PFOS concentrations were 1.1 ± 0.1 μg/g wet weight (ww), 17.9 ± 2.3 μg/g ww, and 36.9 ± 13.2 μg/mL, respectively. Kidney, lung, and spleen mean PFOS concentrations were 3.7 ± 0.5, 2.9 ± 0.6, and 2.3 ± 0.4 μg/g ww, respectively. Carcass remainder, back fat, and IP fat mean PFOS concentrations were 3.8 ± 0.5 μg/g ww, 5.7 ± 2.1 μg/g ww, and 3.5 ± 0.5 μg/g ww, respectively. The overall percents of dose for tissues are presented in Table 1. After plasma, the

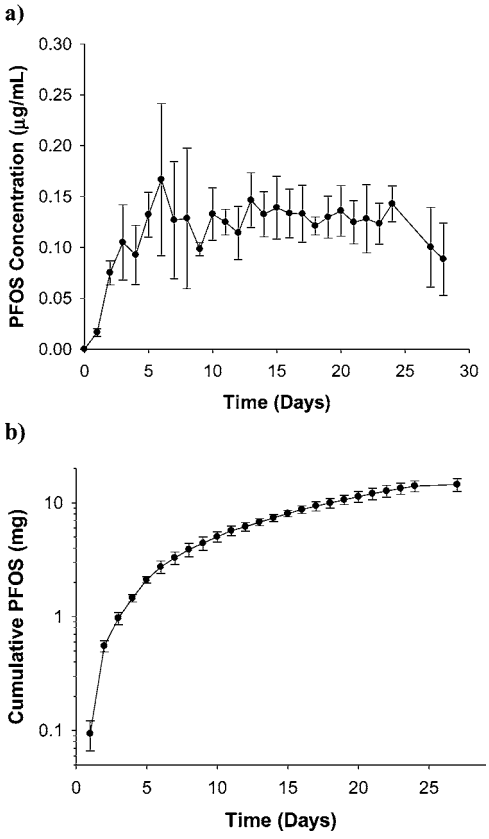

Figure 2. Mean urine PFOS concentrations (μg/mL) and time data through 28 days after a single oral dose given to steers (a). Cumulative urine PFOS amounts (mg) on a log scale excreted over time through 28 days after a single oral dose given to steers (b). Points represent mean concentrations (a) or cumulative PFOS amounts (b) of three animals from LC−MS/MS analysis ± one standard deviation.

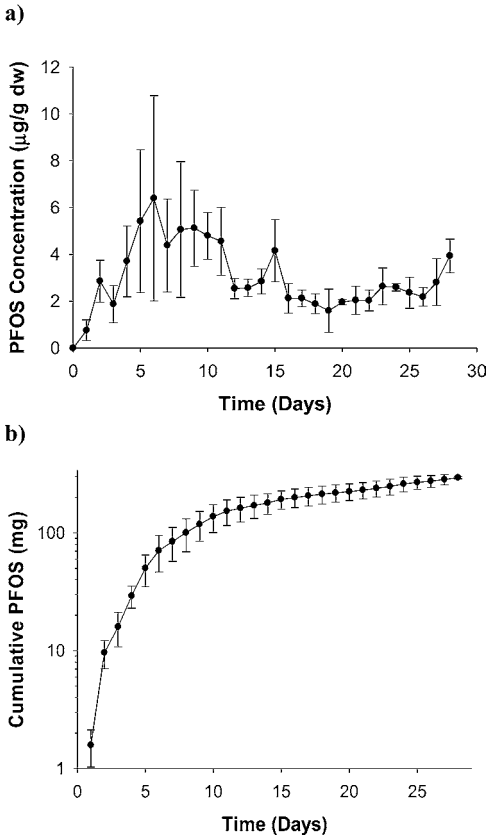

Figure 3. Mean fecal PFOS concentrations (μg/g dry weight) and time data through 28 days after a single oral dose given to steers (a). Cumulative fecal PFOS amounts (mg) on a log scale excreted over time through 28 days after a single oral dose given to steers (b). Points represent mean concentrations (a) or cumulative PFOS amounts (b) of three animals from LC−MS/MS analysis ± one standard deviation.

highest dose percents were in the carcass remainder at 5.7 ± 1.6% of administered dose, muscle at 4.3 ± 0.6%, and liver at 2.2 ± 0.2%. All other tissues were under 1% of the dose.

The mean overall body burden depletion from steers is linear with time (Figure 5). Each day of urine and feces PFOS amounts was cumulatively subtracted from the total dose. Using linear regression a body burden half-life can be calculated ($y = -11.532x + 2639.5$ and $r^2 = 0.9759$) to be 114.2 days.

DISCUSSION

This study was conducted to determine the tissue distribution and excretion of a single oral dose (~8 mg/kg bw) of PFOS in beef cattle. To date the only studies published on the fate of PFOS in ruminants are for sheep and dairy cattle.[12,20] Additional nonruminant models have been studied, including monkeys, rats, chickens, and mice.[6,21,31−36] In the U.S., the high rate of beef cattle production and the utilization of diverse feed sources including pasture, hay, and grain make them a logical and important food animal for investigations of persistent organic chemicals.[14,37,38] The major beef breed in production in the U.S. is Angus (full and crossbred);[39−41] therefore, Lowline Angus steers, an Angus breed of small stature, were used in this study to make dosing and handling easier.[42]

Plasma concentrations of PFOS were at or above the LOD (0.014 μg/mL) and LOQ (0.048 μg/mL) at all time points after 1 h. The calculated C_{max} and T_{max} were 36.3 μg/mL and 4.7 days, respectively, indicating the absorption of PFOS is

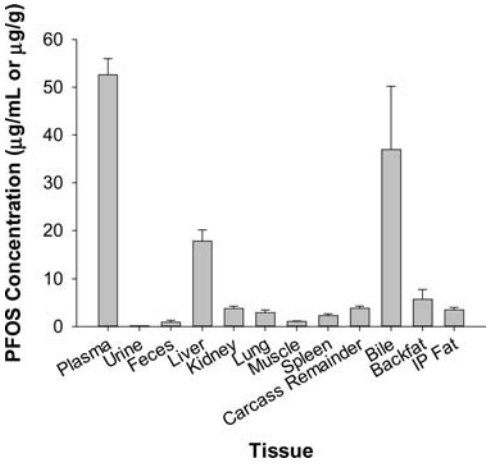

Figure 4. Mean tissue PFOS concentrations (μg/mL or μg/g) after 28 days following a single oral dose given to steers. Columns represent mean concentrations of three animals from LC−MS/MS analysis ± one standard deviation. Day 28 plasma, urine, and fecal concentrations are shown for comparison.

slower than that of PFOA, which had a T_{max} of 24 h.[25] Plasma concentrations increased until 6 days into the study (36.3 ± 3.5 μg/mL), when a distribution phase started. During the distribution phase, plasma concentrations slowly declined to 21.6 ± 5.2 μg/mL from days 6 to 17, but there were only small

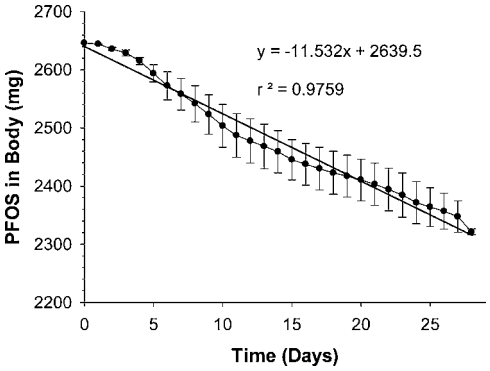

Figure 5. Mean PFOS remaining in the steer body (mg) with time through the 28 days after a single oral dose. Points represent mean amounts (mg) of PFOS remaining of three animals ± one standard deviation. Linear regression analysis provided a line equation of $y = -11.532x + 2639.5$ and an r^2 coefficient of 0.9759.

amounts of PFOS elimination in feces and urine, indicating PFOS was distributed to other parts of the steer. After day 17, plasma concentrations gradually increased to 52.6 ± 3.4 μg/mL at day 28, the last day of the study. A similar increase in PFOS concentration subsequent to an initial absorption and distribution phase has also been observed in an additional, longer duration study (Lupton et al., unpublished) in cattle. The secondary increase of PFOS plasma concentrations was possibly due to redistribution of PFOS from tissue. The continual high concentrations of PFOS in plasma could be the result of protein binding for transportation purposes throughout the body for distribution. At day 28 a large percentage of the dosed PFOS (~35%) was still circulating in the blood. A terminal plasma elimination half-life was not calculated due to the lack of an observable PFOS depletion phase. Extremely slow PFOS elimination contrasts with that of PFOA, which has a plasma elimination half-life of 19 h and is nearly quantitatively eliminated via the urine within two weeks of dosing.[25] PFOS serum depletion half-life estimates for monkeys and humans are on the order of hundreds of days to years.[43] Due to the approved study design, it was not feasible to continue this study for the period of time needed to determine the PFOS plasma half-life in steers. Even though we were not able to calculate a plasma elimination half-life, it was possible to calculate a body burden half-life of 114.2 days from the PFOS amounts remaining in the steers over time using the linear regression equation.

No metabolites of PFOS were observed in any of the compartments analyzed. The stability and chemical properties of PFOS would not likely allow for metabolite formation through defluorination or conjugation, and neither of these metabolic events were observed in other studies.[6,33,44] Since PFOS was not metabolized in steers, it must be excreted intact to reduce the body burden. In this study, the major route of excretion was through feces (11% of the PFOS dose); and elevated levels of PFOS were still being excreted in the feces at 28 days. The small amount of PFOS found in feces during the first few days of the study suggests that a majority of the PFOS was absorbed into the body and not excreted directly into feces. Higher amounts of PFOS excreted in the feces during later days of the study are most likely through contributions from the biliary elimination in feces.[6,12,44] At slaughter, biliary PFOS concentrations were second only to plasma at 36.9 μg/mL, which equates to approximately 0.9% of the dose in the bile volume collected at slaughter. There was minimal excretion of PFOS in the urine (0.5% of the PFOS dose), indicating urine was not a major route for PFOS clearance from steers. Similarly, urinary PFOS excretion was a minor route of elimination in rats, sheep, and dairy cows.[12,20,35] Considering that the small volume of bile (15−40 mL depending on steer) taken at slaughter contained almost double the amount of PFOS excreted in urine over the entire study (0.9% vs 0.5%), it is likely that the longer plasma half-life could be attributed to enterohepatic circulation, which is explained below. When the high rate of PFOS absorption, the rate of digesta passage, and the relatively low amount of PFOS elimination in urine and feces early in the study are collectively considered, probable involvement of enterohepatic circulation in PFOS distribution and elimination is logical.[27]

Taking into account the high concentrations of PFOS in the blood but minimal elimination through urine, it is likely that PFOS reaches the kidney through the blood but is either protein bound and unable to pass through the glomerulus or that PFOS circulates unbound and is filtered, but reabsorbed rather than excreted.[27] Obviously, the presence of PFOS in urine, even in small amounts, indicates that some unbound PFOS is filtered at the glomerulus and is moved through the tubules for urine excretion. Organic anion transporting polypeptides in the kidney can also bind to PFOS and prevent urinary excretion but allow passage to the liver and eventual secretion into bile and feces.[34,45] PFOS elimination differs markedly from the excretion of PFOA, which is quantitatively eliminated through the urine by steers, but reasons remain unclear as to why.[25] There are structural and chemical differences of PFOA and PFOS that could result in the differential elimination. For example, carboxylic vs sulfonic acid functional groups, water solubilities at 25 °C (9.5 g/L vs 680 mg/L, respectively), and pK_a (2.5 vs −3.3, respectively) differences.[6] Specifically, the pK_a can have an effect on protein binding. Once PFOS is in the liver, it is either transported to the bile and reabsorbed by the intestinal tract or eliminated in feces.

The highest concentrations of PFOS in the tissues, besides plasma and bile, were in liver (17.9 ± 2.3 μg/g). The high PFOS concentrations in liver and bile, and the prolonged presence of PFOS in plasma, collectively indicate the important role that enterohepatic circulation plays in PFOS fate and distribution. For steers, tissues ordered from highest concentration to lowest concentration were liver > back fat > kidney > intraperitoneal fat > lung > spleen > muscle. Fat samples were analyzed in this study to determine if any PFOS is distributed to those tissues. The fat samples (back fat and IP fat) have consistently higher concentrations than muscle samples, averaging 5.7 and 3.5 μg/g, respectively, vs 1.1 μg/g in muscle. These results are not typical where some studies observe low accumulation of PFOS in fat tissues,[31,34] however PFOS concentrations in fat samples from this study are lower than those concentrations observed in the liver and plasma, indicating that these tissues are still the primary accumulators of PFOS. Even though the muscle concentrations and carcass remainder (which consists of the remaining fat and tissues not collected separately) concentrations are lower than liver concentrations, muscle and carcass remainder still have the largest body burdens due to size of the tissue compartments compared to liver. For muscle (average mass 101 kg) and carcass remainder (average mass 46.4 kg), 4.3 ± 0.6% and 5.7 ± 1.6%, respectively, of the PFOS dose remained in these

compartments, compared to 2.2 ± 0.2% in the liver (average mass 3.8 kg). Higher liver and kidney concentrations of PFOS compared to muscle were also observed in sheep and dairy cows.[12,20] Unlike the observation of the high elimination of PFOA in steer urine,[25] PFOS circulated and was redistributed in the steer for a long period of time; this was confirmed by the large portion of the dose circulating in the bloodstream (~35%) at slaughter and the gradual decline then incline of PFOS concentrations in the plasma over the 28-day study. Approximately 39% of the dose was not accounted for in the mass balance, therefore, large compartments such as skin and bone, which were not in the carcass remainder, could be pools where PFOS is distributed in the steer. One other study that analyzed skin and bone observed concentrations similar to those observed in blood, indicating that distribution to these tissues is a likely source of the unaccounted PFOS.[34]

In this study an acute dose of PFOS was administered to steers. The elimination of PFOS was slow, and the study time of 28 days was not sufficient to allow us to calculate a plasma elimination half-life; however, a body burden half-life was calculated to be 114.2 days. An additional longer study is being conducted to determine the plasma elimination half-life in steers. To fully assess accumulation of PFOS in cattle and the possible human exposure to PFOS through beef consumption, studying the effects of chronic exposure would be necessary. Chronic exposure is an important aspect to consider because it will occur with beef cattle due to the continual application of biosolids to pastures.[8−10,24]

toxin.[13,14] Because deoxynivalenol-3-*O*-*β*-D-glucopyranoside inhibited protein synthesis of wheat ribosomes in vitro much more weakly than deoxynivalenol, it appeared that glycosylation of deoxynivalenol is a detoxification process in plants.[15]

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 2010 evaluated the health risks of 3-acetyldeoxynivalenol, 15-acetyldeoxynivalenol, and deoxynivalenol-3-*O*-*β*-D-glucopyranoside as well as deoxynivalenol. The Committee decided to set a group provisional maximum tolerable daily intake (PMTDI) at 1.0 mg/kg of body weight per day for deoxynivalenol, 3-acetyldeoxynivalenol, and 15-acetyldeoxynivalenol, but deoxynivalenol-3-*O*-*β*-D-glucopyranoside was not included in the group because data on the toxicity and occurrence were insufficient at that time.[16] However, recently, the occurrence of deoxynivalenol-3-*O*-*β*-D-glucopyranoside in various foods has been reported since its analytical standard became commercially available.[17−19] In addition, deoxynivalenol can be released from deoxynivalenol-3-*O*-*β*-D-glucopyranoside by some human intestinal bacteria.[20,21] On the basis of these backgrounds, not only deoxynivalenol acetates but also deoxynivalenol-3-*O*-*β*-D-glucopyranoside are considered to pose potential risks to humans.

In addition to deoxynivalenol-3-*O*-*β*-D-glucopyranoside, some masked trichothecene mycotoxins, such as glucosides of nivalenol, T-2 toxin, and HT-2 toxin, were detected in artificially contaminated cereals by MS analysis.[22−24] Because there is a possibility that these compounds exert their toxic effects after the release of aglycone during digestion, information about the occurrence of the glucosides in food products is important for conducting risk assessment of the parent mycotoxins. However, the lack of commercially available standards prevents the quantitative analysis of the glucosides.

The aims of this study were two-fold. The first was to isolate a glucoside of nivalenol from naturally contaminated wheat and to determine the chemical structure by NMR analysis. Information about a glucoside of nivalenol is as important as that for deoxynivalenol-3-*O*-*β*-D-glucopyranoside because nivalenol is frequently detected in various cereals. Second, methods for the simultaneous determination of nivalenol, deoxynivalenol, and their glucosides in wheat were developed to verify their occurrence.

MATERIALS AND METHODS

Chemicals. Solid crystals of deoxynivalenol and nivalenol and a standard solution of deoxynivalenol-3-*O*-*β*-D-glucopyranoside (50 ng/mL in acetonitrile) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Liquid chromatography grade acetonitrile and water and other chemicals were purchased from Wako Pure Chemicals (Osaka, Japan).

Q-TOF LC-MS Conditions. The LC system consisted of an Agilent 1200 series (Agilent Technologies, Palo Alto, CA, USA). The LC conditions were as follows: mobile phase, 10 mM ammonium acetate/acetonitrile; hold at 5% acetonitrile for 3 min, linear gradient of 5−90% acetonitrile for 10 min, hold at 90% acetonitrile for 6 min, linear gradient of 90−5% acetonitrile for 1 min, followed by equilibration at 5% acetonitrile for 20 min before the next injection. The flow rate was 0.2 mL/min, and the column used was a 150 mm × 2.1 mm i.d., 3 μm, InertSustain C18 (GL Sciences Inc., Tokyo, Japan). The column oven was held at 40 °C, and the autosampler tray was maintained at 4 °C. The HPLC system was connected to an Agilent 6530 Q-TOF mass spectrometer. An electrospray ionization (ESI) interface with Agilent Jet Stream Technology in the negative mode was used. The instrument was calibrated in the high-resolution mode (4 GHz) with a standard mass range (m/z < 3200). Reference masses at m/z 119.0363 and 980.0164 were continually introduced along with the LC stream for accurate mass calibration. The drying gas (nitrogen) temperature was set at 325 °C, drying gas flow at 10 L/min, nebulizer pressure at 30 psi, and capillary voltage (Vcap) at 3500 V. A centroid datum within the mass range m/z 100−1000 was acquired at a 1 spectrum/s rate with a MassHunter workstation (Agilent). Peak identification was performed using Qualitative Analysis software version B.04.00 (Agilent).

Purification of Nivalenol-3-*O*-*β*-D-glucopyranoside from Naturally Contaminated Wheat. Naturally contaminated ground wheat (12 kg) was extracted with 48 L of acetonitrile/water (85:15, v/v). Extraction was performed on a horizontal shaker for 120 min at 100 rpm. The filtrate was collected by vacuum filtration using an A-3S aspirator (Tokyo Rikakikai Co., Tokyo, Japan), 1.2 kg of silica gel 60 (63−200 mm particle size) (Merck KGaA, Darmstadt, Germany) was added to the filtrate, and the mixture was dried by removing the solvent on a rotary evaporator. Fifty grams of the dried silica gel was packed in a column (50 cm × 3 cm i.d.) and eluted with *n*-hexane (400 mL), ethyl acetate (400 mL), and ethyl acetate/methanol (80:20, v/v, 600 mL), successively. This process was repeated until all of the dried silica gel had been treated. The ethyl acetate/methanol fraction containing nivalenol-3-*O*-*β*-D-glucopyranoside was evaporated to dryness, and the residue was suspended in water. The suspension was extracted twice with ethyl acetate. The remaining water layer was evaporated to dryness, and the residue (40 g yield) was suspended in 400 mL of water. After centrifugation (3000*g*, 10 min), 2 mL of the supernatant was subjected to an HF Mega BE-C18 (5 mg) cartridge (Agilent), which was preequilibrated with 20 mL of water containing 10 mM ammonium acetate. The column was washed with 20 mL of water containing 10 mM ammonium acetate, and nivalenol-3-*O*-*β*-D-glucopyranoside was eluted from the cartridge with 20 mL of 10% acetonitrile in water containing 10 mM ammonium acetate. This process was repeated until all of the supernatant had been treated. The eluate was evaporated to dryness, and the residue (3.6 g yield) was subjected to an LC-20A series HPLC system (Shimadzu Corp., Kyoto, Japan). The column used was a 250 mm × 10 mm i.d., 5 μm, Inertsil ODS-3 (GL Sciences). Isocratic elution with 5% acetonitrile in water at a flow rate of 4.0 mL/min with detection at 220 nm was used to obtain fraction A (18.5−21 min retention time, 100 mg yield). Fraction A was purified by reverse-phase HPLC equipped with the same column. Isocratic elution with water containing 0.1% trifluoroacetic acid from 0 to 5 min and then gradient elution of 0−5% acetonitrile in 0.1% trifluoroacetic acid from 5 to 50 min at a flow rate of 4.0 mL/min with detection at 220 nm was used to obtain fraction B (45 min retention time, 16.9 mg yield). Fraction B was purified by reverse-phase HPLC equipped with the same column. Isocratic elution with water from 0 to 2 min and then gradient elution of 0−4% acetonitrile in water from 2 to 74 min at a flow rate of 4.0 mL/min with detection at 220 nm was used to obtain nivalenol-3-*O*-*β*-D-glucopyranoside (65 min retention time, 9.2 mg (19%) yield): $[\alpha]_D^{20}$ −5.5 (*c* 0.25, H_2O); HRESI-TOF/MS m/z 474.1743 (calcd for $C_{21}H_{30}O_{12}$, 474.1737); ^1H and ^{13}C NMR, see Table 1.

D-Glucose Oxidase Digestion. Five hundred micrograms of nivalenol-3-*O*-*β*-D-glucopyranoside was mixed with 4 M HCl (1 mL) and then hydrolyzed in a sealed test tube at 100 °C for 4 h. The reaction solution was dried on a rotary evaporator and lyophilized for 12 h. The resulting residue was dissolved in 400 μL of water and mixed with 50 μL of a 0.5 M potassium phosphate buffer (pH 6.0) and 100 U of D-glucose oxidase (Sigma-Aldrich) in 50 μL of water. The reaction solution was incubated at 35 °C for 1 h, and the solution was directly infused into the LC-MS. D-Glucose oxidase digestion resulted in the disappearance of the signal corresponding to glucose (m/z 179 $[M - H]^-$), which originated from nivalenol-3-*O*-*β*-D-glucopyranoside, and the appearance of a new signal corresponding to gluconolactone (m/z 177 $[M - H]^-$).

Analytical Method with the Multifunctional Column. Twenty-five grams of the wheat sample was extracted with 200 mL of acetonitrile/water (85:15, v/v). The extraction was performed on a horizontal shaker for 30 min at 180 rpm, and then the extract was filtered through a filter paper (Toyo Roshi Kaisha, Tokyo, Japan). A portion (10 mL) of the filtered extract was transferred into an InertSep VRA-3 multifunctional column (GL Sciences). The first 4 mL of eluate

[a]150 MHz (δ_C) and 500 MHz (δ_H) in D_2O. Dioxane δ_C 67.5 and DSS δ_H 0.00 were used as external standards. [b]From protons stated to the indicated carbon.

was discarded, and the next 4 mL of eluate was collected and evaporated to dryness. The residue was dissolved in 1 mL of 10% acetonitrile in water.

Analytical Method with the Immunoaffinity Column. Twenty-five grams of the wheat sample was extracted with 100 mL of distilled water and then shaken for 30 min. The extract was transferred to a 50 mL centrifuge tube and centrifuged at 1410*g* for 10 min. Aliquots of 10 mL of the supernatant were diluted with 50 mL of phosphate-buffered saline (PBS). After the diluted extract was filtered through a glass fiber filter GA-55 (Toyo Roshi Kaisha), 6 mL of the filtrate (equivalent to 0.25 g sample matrix) was applied to a DON-NIV WB immunoaffinity column (VICAM, Milford, MA, USA). The immunoaffinity column had a capacity of approximately 1 μg of nivalenol, deoxynivalenol, and their glucosides, respectively. When the toxins in the highly contaminated wheat samples (no. 1, 3, 4, and 5 in Table 3) were analyzed, the amount of the filtrate applied to the column was decreased to 1 mL (equivalent to 0.042 g of sample matrix). The column was washed with 10 mL of PBS followed by a wash with 10 mL of distilled water. Toxins were eluted using 0.5 mL of methanol followed by 1.5 mL of acetonitrile. The eluate was dried under nitrogen at 40 °C. The residue was dissolved in 0.25 mL of 10% acetonitrile in water.

LC-MS/MS Conditions. LC-MS/MS analyses were performed with a 3200 Q TRAP LC-MS/MS system (AB Sciex, Foster City, CA, USA) equipped with an ESI source and an LC-20A series high-performance LC system (Shimadzu Corp.). The column used was a 150 mm × 2.1 mm i.d., 3 μm, Inertsil ODS-3 (GL Sciences). Chromatographic separation was achieved at 40 °C, using a gradient elution of 5−73% acetonitrile in water from 0 to 8 min and then isocratic elution of 90% acetonitrile in water from 8 to 10 min at a flow rate of 0.2 mL/min. The sample was centrifuged at 10000*g* for 5 min before analysis. The injection volume was 10 μL. The ESI source was operated at 400 °C in the negative ionization mode. Other MS parameters were as follows: curtain gas at 10 psi, nebulizer gas (GS1) at 50 psi, turbo heater gas (GS2) at 50 psi, collision-activated dissociation gas at 5 (arbitrary units), multiple reaction monitoring, dwell time of 250 ms, and a 5 ms pause between mass ranges. The following multiple reaction monitoring transitions were used: nivalenol, 371 $[M + CH_3COO]^-$ to 281 (collision energy, −18 eV); nivalenol-3-*O*-*β*-D-glucopyranoside, 533 $[M + CH_3COO]^-$ to 263 (collision energy, −28 eV); deoxynivalenol, 295 $[M - H]^-$ to 265 (collision energy, −12 eV); deoxynivalenol-3-*O*-*β*-D-glucopyranoside, 517 $[M + CH_3COO]^-$ to 427 (collision energy, −24 eV).

Method Validation. The method was validated with deoxynivalenol-negative wheat (Trilogy Analytical Laboratory Inc., Washington, MO, USA) spiked at four concentrations, 10, 50, 250, and 1000 μg/kg, with six replicates for each analyte. When using the DON-NIV WB immunoaffinity column, the amount of the filtrate applied to the column was 6 mL for the samples spiked at 10, 50, and 250 μg/kg and 1 mL for the sample spiked at 1000 μg/kg. Detected concentrations were calculated on a peak area basis using Analyst version 1.5.1 software (AB Sciex). Limits of detection (LODs) and limits of quantification (LOQs) were calculated on the basis of signal-to-noise ratios of 3:1 and 10:1, respectively.

RESULTS AND DISCUSSION

Detection of a Nivalenol Glycoside in Naturally Contaminated Wheat. Naturally contaminated wheat was

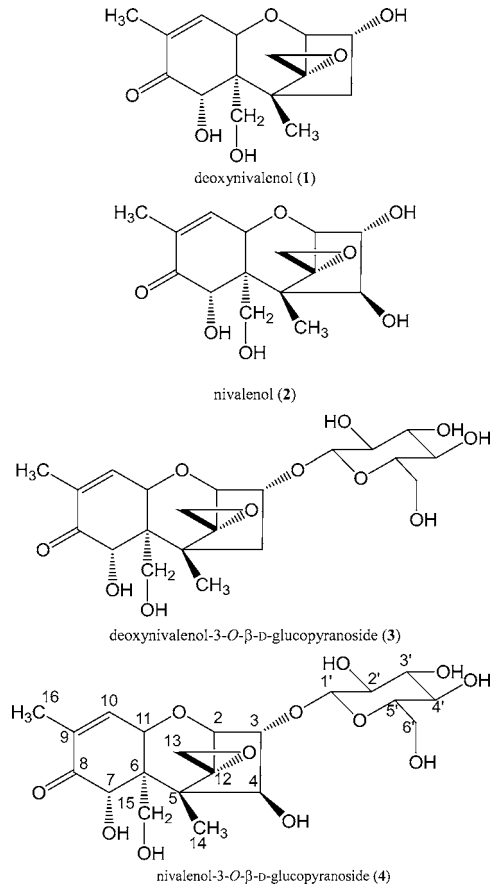

Figure 1. Structures of deoxynivalenol, nivalenol, and their glucosides.

extracted with 85% acetonitrile in water, and the extract was analyzed by Q-TOF LC-MS. Compounds having estimated molecular formulas of $C_{15}H_{20}O_7$ and $C_{21}H_{30}O_{12}$ (compound **4**) were observed at retention times of 7.5 and 8.0 min, respectively. The former compound was identified as nivalenol. The molecular formula of **4** was larger than that of nivalenol by $C_6H_{10}O_5$. As a result of MS/MS fragmentation analysis, common fragment ions (*m*/*z* 191, 217, 233, 281) were found

dx.doi.org/10.1021/jf4048644 | J. Agric. Food Chem. 2014, 62, 1174−1180

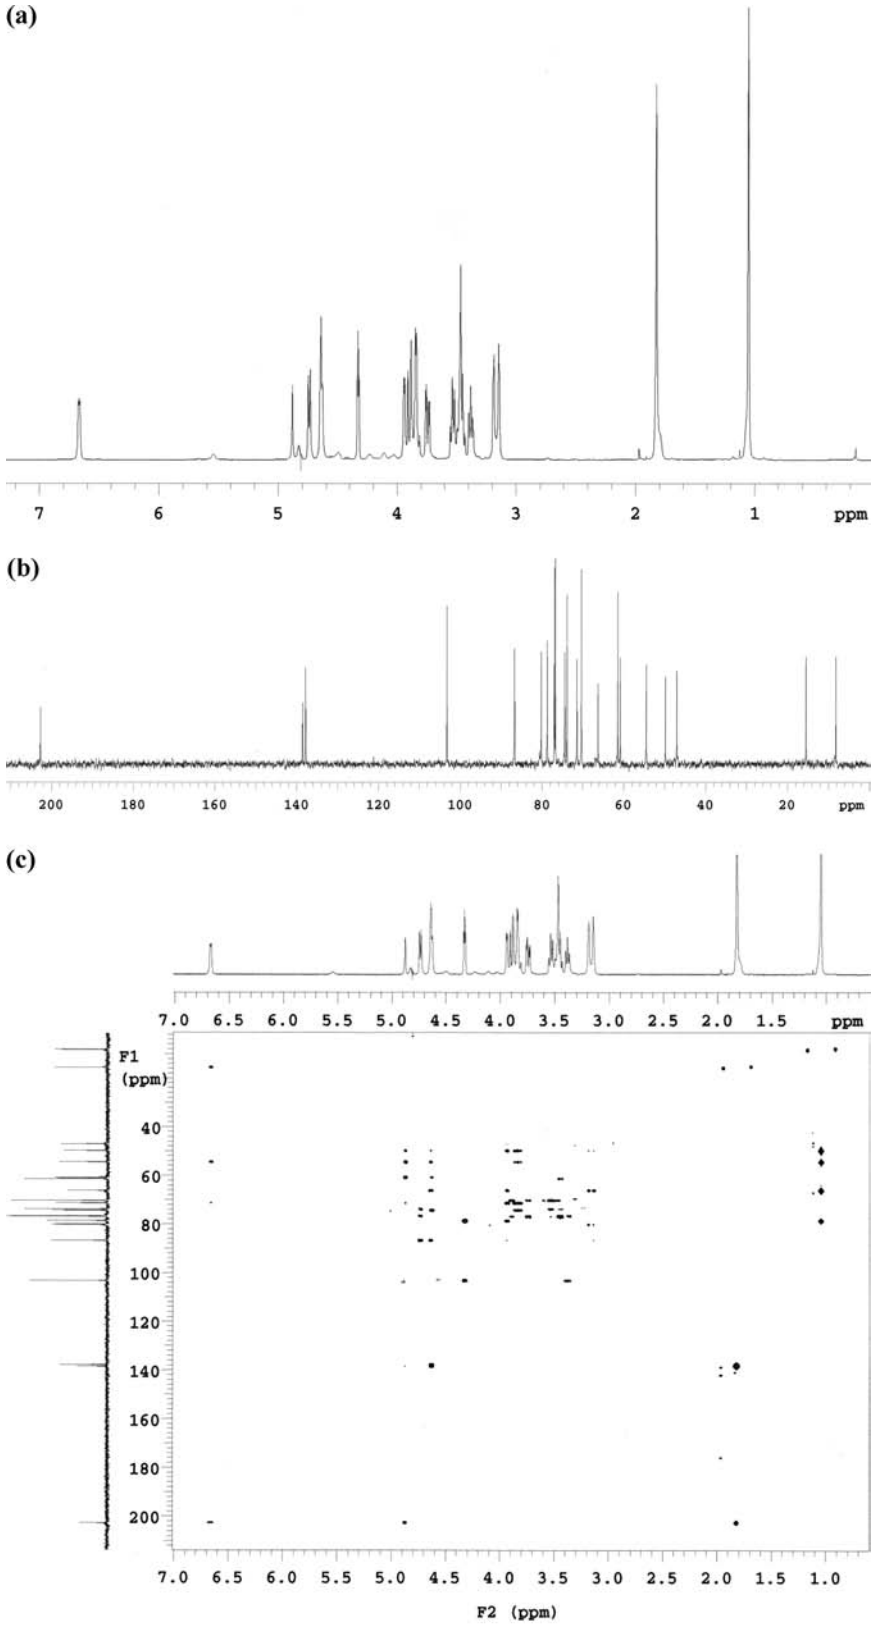

Figure 2. ^{1}H NMR spectrum (a), ^{13}C NMR spectrum (b), and HMBC spectrum (c) of nivalenol-3-*O*-*β*-D-glucopyranoside.

in nivalenol and **4** product ion spectra. From these results, **4** was suspected to be a nivalenol monoglycoside.

Isolation and Structure Determination of a Nivalenol Glycoside. Compound **4** was extracted from acetonitrile/water (85:15, v/v) from wheat. The extracts were fractionated by silica gel column chromatography, followed by liquid−liquid extraction. Further purification by C18 cartridges and reverse-phase HPLC afforded **4** in a yield of 9.2 mg from 12 kg of wheat. The ^{1}H and ^{13}C NMR spectra of **4** confirmed that it is a monoglycoside of nivalenol (Figure 2a,b). The sugar present in

dx.doi.org/10.1021/jf4048644 | J. Agric. Food Chem. 2014, 62, 1174−1180

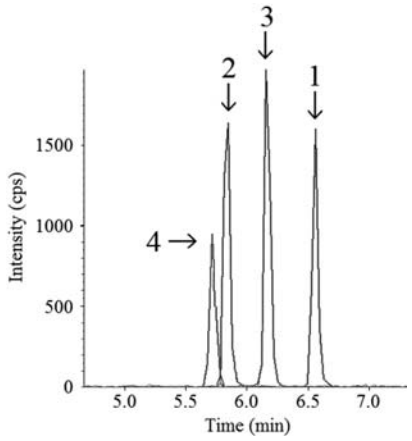

Figure 3. LC-MS/MS chromatogram of a standard solution (30 ng/mL concentrations of each analyte). Peaks: deoxynivalenol (**1**) (m/z 295 → 265); nivalenol (**2**) (m/z 371 → 281); deoxynivalenol-3-*O*-*β*-D-glucopyranoside (**3**) (m/z 517 → 427); nivalenol-3-*O*-*β*-D-glucopyranoside (**4**) (m/z 533 → 263).

4 was identified as glucose from NMR data, which are summarized in Table 1. A long-range coupling between C-3 of the nivalenol moiety and C-1′ of glucose observed in the HMBC spectrum of **4** showed that **4** was a nivalenol-3-*O*-glucopyranoside (Figure 2c). The $J_{H\text{-}1',H\text{-}2'}$ value (7.8 Hz) indicated a *β*-glycosidic linkage. Treating the acid hydrolysate of **4** with D-glucose oxidase showed the D configuration of the glucose residue of **4**. The structure of **4** was thus assigned as nivalenol-3-*O*-*β*-D-glucopyranoside (Figure 1).

Analytical Methods for Determination of Nivalenol, Deoxynivalenol, and Their Glucosides. Two purification methods were examined for the simultaneous determination of nivalenol, nivalenol-3-*O*-*β*-D-glucopyranoside, deoxynivalenol, and deoxynivalenol-3-*O*-*β*-D-glucopyranoside. The first is a method using a multifunctional column, InertSep VRA-3. The column, which contains ion exchange and reverse phase resins, is designed for purifying mycotoxins and agricultural chemicals from cereals. Previously, our group has reported a purification method using InertSep VRA-3 for the identification of deoxynivalenol, 3-acetyldeoxynivalenol, 15-acetyldeoxynivalenol, and deoxynivalenol-3-*O*-*β*-D-glucopyranoside in corn-based products.[25] The reported method was slightly modified to obtain good recoveries for nivalenol and nivalenol-3-*O*-*β*-D-glucopyranoside. The second is a method using a commercial immunoaffinity column. Some immunoaffinity columns that are designed for simultaneous purification of deoxynivalenol and nivalenol have recently been developed. In a preliminary study, deoxynivalenol, nivalenol, and their glucosides could be recovered from an immunoaffinity column, DON-NIV WB. Quantitation of the mycotoxins was performed by LC-MS/MS. A typical chromatogram is shown in Figure 3. To validate the two methods, they were applied to the analysis of spiked wheat samples containing nivalenol, nivalenol-3-*O*-*β*-D-glucopyranoside, deoxynivalenol, and deoxynivalenol-3-*O*-*β*-D-glucopyranoside at four levels in six replicates. Recoveries in the InertSep VRA-3 method were 81.5−91.3% for nivalenol, 69.8−75.3% for nivalenol-3-*O*-*β*-D-glucopyranoside, 65.8−71.7% for deoxynivalenol, and 68.3−85.3% for deoxynivalenol-3-*O*-*β*-D-glucopyranoside, whereas recoveries in the DON-NIV WB method were 87.1−93.3% for nivalenol, 94.1−103.5% for nivalenol-3-*O*-*β*-D-glucopyranoside, 86.4−96.5% for deoxynivalenol, and 95.0−100.1% for deoxynivalenol-3-*O*-*β*-D-glucopyranoside (Table 2). The LOQs for all analytes were within the range of 1−3 μg/kg. This result showed that both methods could be used to determine the four mycotoxins and that the recoveries obtained by the immunoaffinity column method were better than those obtained by the multifunctional column method.

The concentrations of nivalenol, nivalenol-3-*O*-*β*-D-glucopyranoside, deoxynivalenol, and deoxynivalenol-3-*O*-*β*-D-glucopyranoside in wheat samples were quantitated by the analytical method using an immunoaffinity column (Table 3). Nivalenol

and nivalenol-3-*O*-*β*-D-glucopyranoside were detected in all samples, and the percentages of nivalenol-3-*O*-*β*-D-glucopyranoside to nivalenol ranged from 12 to 27%. Deoxynivalenol and deoxynivalenol-3-*O*-*β*-D-glucopyranoside were also found in the samples, and the percentage of deoxynivalenol-3-*O*-*β*-D-glucopyranoside to deoxynivalenol was within the range of 5−14%.

In this study, a new derivative of nivalenol was isolated from nivalenol-contaminated wheat and was identified as nivalenol-3-*O*-*β*-D-glucopyranoside. Methods for the simultaneous determination of nivalenol, deoxynivalenol, and their glucosides in wheat were successfully developed and validated. Co-contamination of nivalenol-3-*O*-*β*-D-glucopyranoside with nivalenol, deoxynivalenol, and deoxynivalenol-3-*O*-*β*-D-glucopyranoside was observed in wheat, and the ratio of nivalenol-3-*O*-*β*-D-glucopyranoside to nivalenol was equivalent to that of deoxynivalenol-3-*O*-*β*-D-glucopyranoside to deoxynivalenol reported previously.[17] Because glycosylation is considered to be a detoxification process, it seems likely that nivalenol-3-*O*-*β*-D-glucopyranoside shows lower toxicity than nivalenol. However, as with deoxynivalenol-3-*O*-*β*-D-glucopyranoside, nivalenol-3-*O*-*β*-D-glucopyranoside may be hydrolyzed by intestinal bacteria and toxic nivalenol may be produced in the body. Therefore, nivalenol-3-*O*-*β*-D-glucopyranoside can be an important contributor to dietary exposure to trichothecene mycotoxins and should be monitored together with nivalenol, deoxynivalenol, and deoxynivalenol-3-*O*-*β*-D-glucopyranoside in foodstuffs.

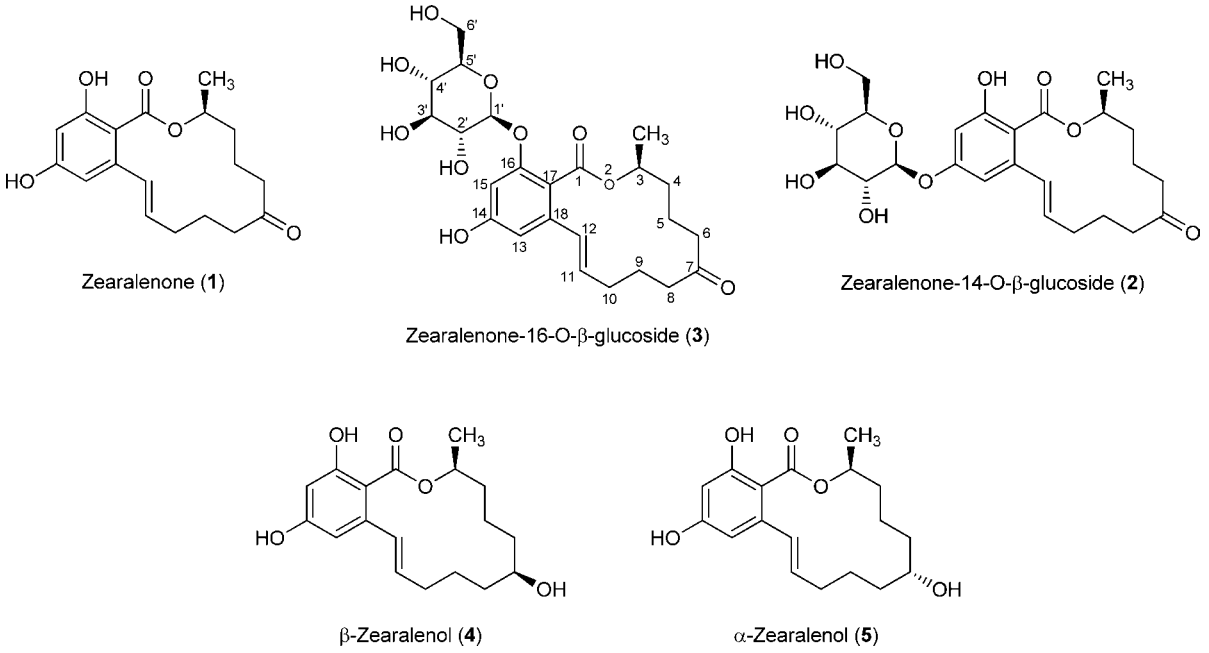

Figure 1. Chemical structures of zearalenone metabolites and numbering of atoms in zearalenone: zearalenone (**1**); zearalenone-14-*O*-*β*-glucoside (**2**); zearalenone-16-*O*-*β*-glucoside (**3**); *β*-zearalenol (**4**); *α*-zearalenol (**5**).

glucosides.[14] Analysis of the metabolization of zearalenone by *Arabidopsis* seedlings revealed that they very rapidly convert zearalenone to zearalenone-14-*O*-*β*-glucoside.[15] However, the accumulation is transient, and mass spectrometric analysis revealed that further derivatives were formed, such as zearalenone-malonyl-glucoside, zearalenone-dihexoside, and a zearalenone-pentosylhexoside. Also, the glucosides of the phase I metabolites (*β*-zearalenol (**4**) and *α*-zearalenol (**5**)) were observed.[15] The natural occurrence of a zearalenol-glucoside in maize was recently reported.[16] Zearalenone-14-*O*-*β*-glucoside does not interact with the human estrogen receptor in vitro,[13] but when fed to pigs it is rapidly converted back to zearalenone.[17] Thus, on a molar basis the estrogenicity of zearalenone-14-*O*-*β*-glucoside may be nearly equal to that of zearalenone in mammals (and humans), but no solid data are available.

Zearalenone co-occurs with other *Fusarium* toxins such as deoxynivalenol, but is typically formed rather late during the infection.[1,7] Previously, we reported several UDP-glucosyltransferases of barley, which were transcriptionally induced specifically by a deoxynivalenol-producing strain of *Fusarium graminearum*[18] and by deoxynivalenol application,[19] and characterized these genes by heterologous expression in yeast.[20] Because most of these genes did not confer increased resistance to deoxynivalenol, we tested for activity with zearalenone.

MATERIALS AND METHODS

Incubation of Toxin-Sensitive Yeast Expressing HvUGT14077 with Zearalenone. Three independent transformants of the toxin-sensitive *Saccharomyces cerevisiae* strain YZGA515 expressing the UDP-glucosyltransferase HvUGT14077 (GU170356.1),[20] or containing the empty vector, were propagated in liquid selective medium lacking leucine (SC-LEU) to an OD_{600} of 0.7 at 30 °C and 180 rpm. Fifty milliliters of the yeast suspensions was harvested by centrifugation, and the pellets were resuspended in 5 mL of SC-LEU, which contained 5 mg/L (=15.7 *μ*M) of zearalenone and was buffered with 50 mM sodium phosphate to pH 7.0. The zearalenone stock solution (5 mg/mL) was prepared in acetone. Zearalenone and zearalenone-14-*O*-*β*-glucoside were purified at the IFA-Tulln. Other chemicals, unless stated otherwise, were obtained from Sigma-Aldrich (Vienna, Austria). Cultures were incubated at 30 °C and 180 rpm, and samples were collected for HPLC-MS/MS analysis after 4, 8, 18, and 24 h.

HPLC-MS/MS Analysis. Zearalenone and its glucosylated derivatives were analyzed as described previously,[15] with slight modifications. Briefly, an 1100 HPLC system (Agilent Technologies, Waldbronn, Germany) was coupled to a QTrap LC-MS/MS system (AB Sciex, Foster City, CA, USA). Ionization was performed with an electrospray interface in negative ionization mode. Deviating from the original method, the column used was a 150 mm × 4.6 mm i.d., 5 *μ*m, Zorbax Eclipse C-8 (Agilent Technologies) for separation of the analytes by applying the same solvent gradient system (5 mM aqueous ammonium acetate/methanol). For zearalenone, the deprotonated precursor (m/z 317.1, declustering potential (DP) −51 V) was fragmented to m/z 130.9 (collision energy (CE) −38 V). The same selected reaction monitoring transition (m/z 479.1 → m/z 317.1, DP 31 V, CE 22 eV) was used for the detection and quantification of both zearalenone-14-*O*-*β*-glucoside and zearalenone-16-*O*-*β*-glucoside. To verify the apparent recovery of the method using complex fermentation media (with fecal bacteria), blanks were spiked at three concentration levels in triplicates.

LC-HR-MS spectra of the purified zearalenone-16-*O*-*β*-glucoside were acquired on a 6550 iFunnel QTOF coupled to a 1290 Infinity UHPLC system (Agilent Technologies). One microliter of a 1 mg/L solution of zearalenone-16-*O*-*β*-glucoside in MeOH/H_2O (30:70, v/v) was injected on a 150 mm × 2.1 mm i.d., 1.8 *μ*m, Zorbax SB-C18 rapid-resolution high-definition column (Agilent Technologies). A linear water/methanol gradient (both with 0.1% HCOOH) was applied. Full scan spectra over a range of m/z 50−1000 were acquired after positive and negative electrospray ionization. MassHunter B.05.01 was used for data acquisition, whereas MassHunter Qualitative Analysis B.06.00 was used for data evaluation.

Biocatalytical Production and Purification of Zearalenone-16-*O*-*β*-glucoside. Yeast strain YZGA515 expressing HvUGT14077 was cultivated in a 20 L single-wall glass autoclavable bioreactor (Applikon, Schiedeam, Netherlands) at 30 °C and 100 rpm. An overnight culture was added to 10 L of selective medium buffered with 50 mM sodium phosphate, resulting in an OD_{600} of 0.05. The cells were incubated overnight at 30 °C and 100 rpm, and the pH was kept

dx.doi.org/10.1021/jf405627d | J. Agric. Food Chem. 2014, 62, 1181−1189

constant during the fermentation at 7.0 by addition of 10 N NaOH. The zearalenone stock was added to reach 5 mg/L. After 4, 8, and 22 h, additional zearalenone was administered corresponding to further steps of 5 mg/L. After 24 h of incubation, the yeast supernatant was collected in 500 mL portions by centrifugation and 800 mL of methanol was added to the 8 L of supernatant. Zearalenone-14-*O*-*β*-glucoside and zearalenone-16-*O*-*β*-glucoside were purified from the supernatant as previously described.[14]

Structure Characterization by NMR. NMR spectra were measured in CD_3OD solution on an Avance DRX-400 FT-NMR spectrometer (Bruker BioSpin, Rheinstetten, Germany), operating at 400.13 MHz for ^1H and at 100.62 MHz for ^{13}C, at 300 K using a 5 mm inverse broadband Z-gradient probe head. Data were recorded and evaluated using TOPSPIN 1.3 (Bruker Biospin). All pulse programs were taken from the Bruker software library. Chemical shifts (established on the basis of the residual solvent resonances) are given in parts per million (ppm) relative to tetramethylsilane and coupling constants are in hertz (Hz).

Incubation of Barley, Wheat, and *Brachypodium distachyon* with Zearalenone. Barley seeds of the varieties 'Morex' (six-rowed spring malting, University of Minnesota) and 'Signora' (a two-rowed spring barley brewing variety dominant in Austria) were surface-sterilized by incubation with a solution containing 5% (v/v) sodium hypochlorite (14% active chlorine) and 0.1% (v/v) Triton X-100 for 7 min. The sterilization solution was removed completely, and seeds were incubated with 70% (v/v) ethanol for 1 min and washed three times with sterile distilled water. The seeds were placed on Murashige and Skoog basal medium containing 0.5% (w/v) sucrose and 2% (w/v) agar in magenta plant culture boxes with a cycle of 15 h of light at 20 °C and 9 h of darkness at 10 °C for 1 week.

Seedlings were transferred to liquid macronutrient salt medium (1650 mg/L ammonium nitrate, 1900 mg/L potassium nitrate, 370 mg/L ammonium sulfate, 50 mM phosphoric acid, buffered to pH 7.0 with 10 N NaOH) without sugar containing 5 mg/L zearalenone and 1 mg/L deoxynivalenol. The 5 mg/mL zearalenone stock was prepared in acetone, and the 1 mg/mL deoxynivalenol stock was prepared in water. Plants were incubated at 21 °C with constant light at 100 rpm. Metabolites were extracted from roots and leaves separately after 24 h of incubation by adding 1 mL of ethanol to 200 mg of plant material and wet grinding of the tissue with a Retsch Mixer Mill (Retsch, Haan, Germany) for 1 min at high speed.

The *Triticum aestivum* suspension culture (derived from wheat cultivar Heines Koga II, DSMZ PC-998) was obtained from the Plant Cell Culture Collection of the Leibniz Institute, DSMZ, German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany) and weekly subcultured in Gamborg B5 medium (Duchefa Biochemie, Netherlands) in constant light at 21 °C and 100 rpm. The *B. distachyon* cell culture[21] derived from line Bd21 was kindly provided by Dr. Carl Ng (University College, Dublin, Ireland) and cultivated in SCM medium containing 4.4 g/L Linsmaier and Skoog medium basal salt mix including vitamins (Duchefa Biochemie, The Netherlands), 3% (w/v) maltose (Roth, Germany), 7.5 mg/L 2,4-dichlorophenoxyacetic acid (2,4-D), and 0.75 mg/L kinetin with pH set to 5.8 with 1 M KOH. Bd21 cells were propagated at 21 °C in darkness and also subcultured weekly by combining 50 mL of culture with 50 mL of fresh medium. About 200 mg of each cell culture was harvested by centrifugation and resuspended in 1 mL of the respective medium containing 2 mg/L of zearalenone and 1 mg/L deoxynivalenol. Samples were incubated at 21 °C and shaken for 4, 18, and 24 h. The cells were centrifuged, and the metabolites were extracted from the cell pellet as described for barley roots and leaves. All supernatants were analyzed by HPLC-MS/MS.

Incubation of Intestinal Bacteria with Zearalenone-16-*O*-*β*-glucoside. The in vitro fecal hydrolysis assay was conducted using samples collected from six healthy donors (four women and two men, ages 28−38 years) who had signed informed consent forms. Two incubation media were tested: (a) distilled water and (b) the complex fermentation medium as previously described by Dall'Erta et al.[22] For the fecal slurry, 4 mL of water was added to 1 g of fecal material and homogenized. Five hundred microliters of a 2 mg/L zearalenone-16-*O*-*β*-glucoside solution in the respective medium was added to 500 μL of fecal slurry, and samples were flushed with nitrogen for 10 s. Tubes were incubated at 37 °C, and the reaction was stopped after 0.5 and 2 h of incubation by adding 1 mL of ethanol. As a negative control, 500 μL of water was added to 500 μL of fecal slurry, and as a positive control 500 μL of water was added to the incubation medium containing 2 mg/L of zearalenone-16-*O*-*β*-glucoside. Supernatants were sterilized using Ultrafree-CL sterile filters with a pore size of 0.2 μm (Millipore, Schwalbach, Germany) prior to analysis by HPLC-MS/MS.

RESULTS

HvUGT14077 Expression in Yeast Interferes with Estrogen Receptor Activation. In a previous study, we reported the functional analysis of four barley UDP-glucosyltransferase genes,[20] which were highly induced by the application of the *Fusarium* mycotoxin deoxynivalenol.[19] Although recombinant HvUGT14077 protein was clearly detected in yeast, no deoxynivalenol resistance was observed. To test for activity with zearalenone, we transformed the expression vectors into the previously described yeast estrogen reporter strain YZCP908[13] and observed diminished activation.

Production of a New Glucoside by HvUGT14077 Expression in Yeast Transformants Treated with Zearalenone. To determine the mechanism in which HvUGT14077 metabolizes zearalenone and hence interferes with estrogen receptor activation, we incubated YZGA515 expressing HvUGT14077 and the empty vector control with 5 mg/L (15.7 μM) zearalenone. Analysis of the supernatant by LC-MS/MS revealed the production of zearalenone-14-*O*-*β*-glucoside[13] and a second compound with the same mass, however, with a different retention time (Figure 2). As shown later, the hypothesis that this new metabolite might be zearalenone-16-*O*-*β*-glucoside (**3**) was confirmed. In a small-scale experiment (50 mL shake culture), the transformed yeast strain was able to metabolize the administered zearalenone rapidly, most of it within 4 h (Figure 3). At time point 0 only about 50% of the input was detected in the supernatant. After

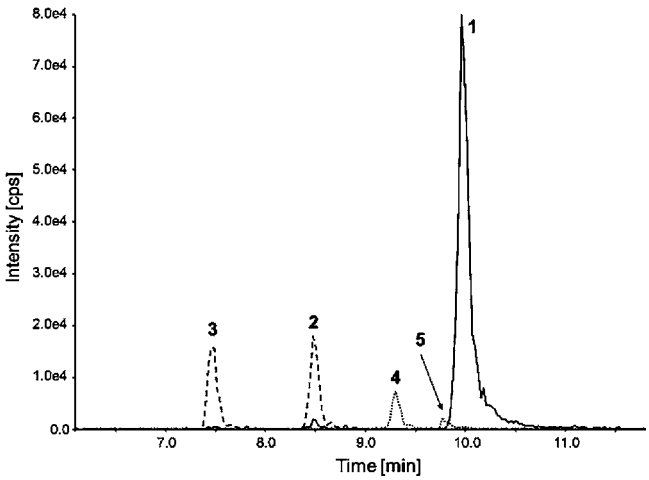

Figure 2. Chromatogram of metabolites produced by zearalenone-treated yeast strain YZGA515 expressing HvUGT14077. Each mass transition is displayed as a separate line. Zearalenone (**1**) has a retention time of 9.9 min; *α*-zearalenol (**5**), 9.8 min; *β*-zearalenol (**4**), 9.5 min; and zearalenone-14-*O*-*β*-glucoside (**2**), 8.5 min. The new compound, zearalenone-16-*O*-*β*-glucoside (**3**), with a retention time of 7.5 min, has the same mass-to-charge-ratio as compound **2**.

dx.doi.org/10.1021/jf405627d | J. Agric. Food Chem. 2014, 62, 1181−1189

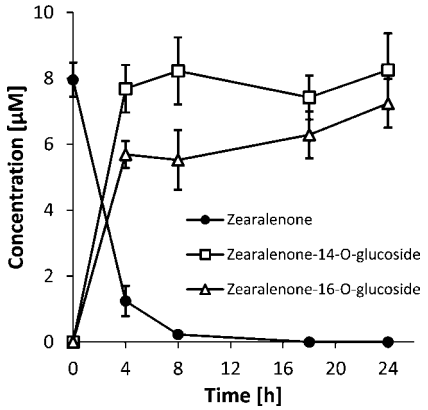

Figure 3. Time course of metabolization of zearalenone in a small-scale experiment.

24 h, a nearly complete conversion of the zearalenone input, to a mixture of both glucosides with roughly 1:1 ratio, was observed (about 44% zearalenone-16-*O*-*β*-glucoside, Figure 3).

Biocatalytic Production and Purification of the New Glucoside. To obtain enough of the new zearalenone-glucoside for structure elucidation, the strain YZGA515 expressing HvUGT14077 was cultivated in 10 L of medium at pH 7.0 in a 20 L bioreactor. Due to its limited solubility in aqueous medium and its toxicity for the yeast strain at higher concentrations, 5 mg/L zearalenone was added consecutively at the beginning and again after 4, 8, and 22 h of incubation. The pH levels remained stable between 6.7 and 7.0, and the yeast showed normal growth starting at an OD_{600} of 5.3 and reaching 10.7 after 24 h. In the fermentation supernatant with a zearalenone input of 200 mg after 24 h, 39 mg of zearalenone-14-*O*-*β*-glucoside and 38 mg of zearalenone-16-*O*-*β*-glucoside were obtained. As a first purification step, 500 mL portions of the fermentation supernatant containing 10% (v/v) methanol were loaded to equilibrated C18 solid phase extraction columns. None of the zearalenone metabolites were detected in the flow-through. Washing the column with 10 mL of 30% methanol resulted in some losses (1.9 mg of zearalenone-14-*O*-*β*-glucoside and 9.5 mg of zearalenone-16-*O*-*β*-glucoside). The glucosides were eluted from the columns with 60% (v/v) methanol, which resulted in a recovery of 34.4 mg of zearalenone-14-*O*-*β*-glucoside and 27.8 mg of zearalenone-16-*O*-*β*-glucoside. A second purification step was conducted using preparative HPLC. The retention time for zearalenone-14-*O*-*β*-glucoside was 5.0 and that for zearalenone-16-*O*-*β*-glucoside was 3.7 min. After evaporation of the solvent, totals of 24.3 mg of zearalenone-14-*O*-*β*-glucoside and 21.4 mg of zearalenone-16-*O*-*β*-glucoside were obtained.

Structural Characterization by HR-MS and NMR. HR-MS verified the isolated substance to be a $C_{24}H_{32}O_{10}$ compound, consistent with the hypothesis of a zearalenone-glucoside. In positive ion mode the $[M + H]^+$ ion showed an m/z value of 481.2064 (Δm = −0.81 ppm), whereas the $[M + Na]^+$ ion was measured at m/z 503.1887 (Δm = −0.23 ppm). After negative electrospray ionization, the $[M - H]^-$ ion showed an m/z value of 479.1929 (Δm = 1.37 ppm) and the $[M + HCOO]^-$ ion, m/z 525.1969 (Δm = −1.62 ppm). MS/MS spectra showed the cleavage of the glucose moiety. Further fragments from zearalenone could not be used to differentiate between zearalenone-16-*O*-*β*-glucoside and zearalenone-14-*O*-*β*-glucoside.

The ^1H and ^{13}C NMR data for zearalenone-16-*O*-*β*-glucoside are shown in Figure 4 and summarized in Table 1. For structure elucidation, HH-COSY, HC-HSQC, and HC-HMBC spectra were recorded. Using these two-dimensional methods, the structure of zearalenone-16-*O*-*β*-glucoside was confirmed, and complete signal assignments were established. In particular, the carbon signals of the benzene ring were assigned on the basis of direct and long-range correlations of the aromatic (H13, H15) and olefinic (H11, H12) protons. Then, the attachment position of the glucose moiety at the zearalenone skeleton could be determined by long-range coupling of the glucosyl-H1 to the C16 carbon.

Formation of Zearalenone-16-*O*-*β*-glucoside in Zearalenone-Treated Barley. To test whether zearalenone-16-*O*-*β*-glucoside is also formed in planta, we treated barley seedlings with an initial root length of about 1.5 cm with 5 mg/L zearalenone in liquid cultures. The average values of two biological replicates each containing pools of three seedlings are shown in Figure 5. In the control medium without added zearalenone, none was detected, whereas in the spiked control medium with a theoretical input of 78.5 nmol only 61.9 nmol was determined after 24 h. Zearalenone was not detected in the supernatants or in the roots of 'Morex' and 'Signora' seedlings incubated in medium lacking zearalenone. Approximately 1−7% of the added zearalenone was still present in the supernatants of both varieties, and only a small portion of the input (0.5−1%) was recovered as zearalenone-14-*O*-*β*-glucoside and zearalenone-16-*O*-*β*-glucoside in the supernatant. Although a significant amount of the added zearalenone was recovered in the root extracts, 66 and 87% of the input were converted to zearalenone-16-*O*-*β*-glucoside by 'Morex' and 'Signora' seedlings, respectively. The cotyledons were upright above the zearalenone-containing medium, without direct contact. They contained only minimal amounts of zearalenone and zearalenone metabolites. Only 3−5% of the administered zearalenone was metabolized to the previously described masked mycotoxin zearalenone-14-*O*-*β*-glucoside in barley; about 16−18-fold more zearalenone-16-*O*-*β*-glucoside than zearalenone-14-*O*-*β*-glucoside was detected in the barley root samples.

Zearalenone Glycosylation by Wheat and *Brachypodium* Suspension Cultures. Due to a higher sensitivity of suspension cultures, only 2 mg/L of zearalenone was added to the media instead of the 5 mg/L used in the barley seedling test. Panels a and b of Figure 6 show the results of a time course of treatment of the *Brachypodium* suspension culture with zearalenone as an average of three biological replicates. The input of 6.2 *μ*mol of zearalenone was metabolized by the approximately 200 mg of wet weight of cells, and within 18 h only 21% remained in the medium. A significant portion of zearalenone (50% after 4 h and 14% after 24 h) was found to be present in the extracted cell pellet. About 46% of the input was converted to zearalenone-16-*O*-*β*-glucoside within 4 h, which further increased to 76% after 18 h.

A very different situation was observed with a wheat suspension culture (Figure 6c,d). Again, zearalenone added to the medium rapidly became undetectable, but compared to *Brachypodium* the intracellular concentrations of zearalenone, zearalenone-14-*O*-*β*-glucoside, and zearalenone-16-*O*-*β*-glucoside remained low. After 24 h, only 13% of the input was converted to zearalenone-14-*O*-*β*-glucoside and zearalenone-16-*O*-*β*-glucoside, respectively, and detected in the cell extracts. Compared to *Brachypodium*, a larger portion of zearalenone-14-

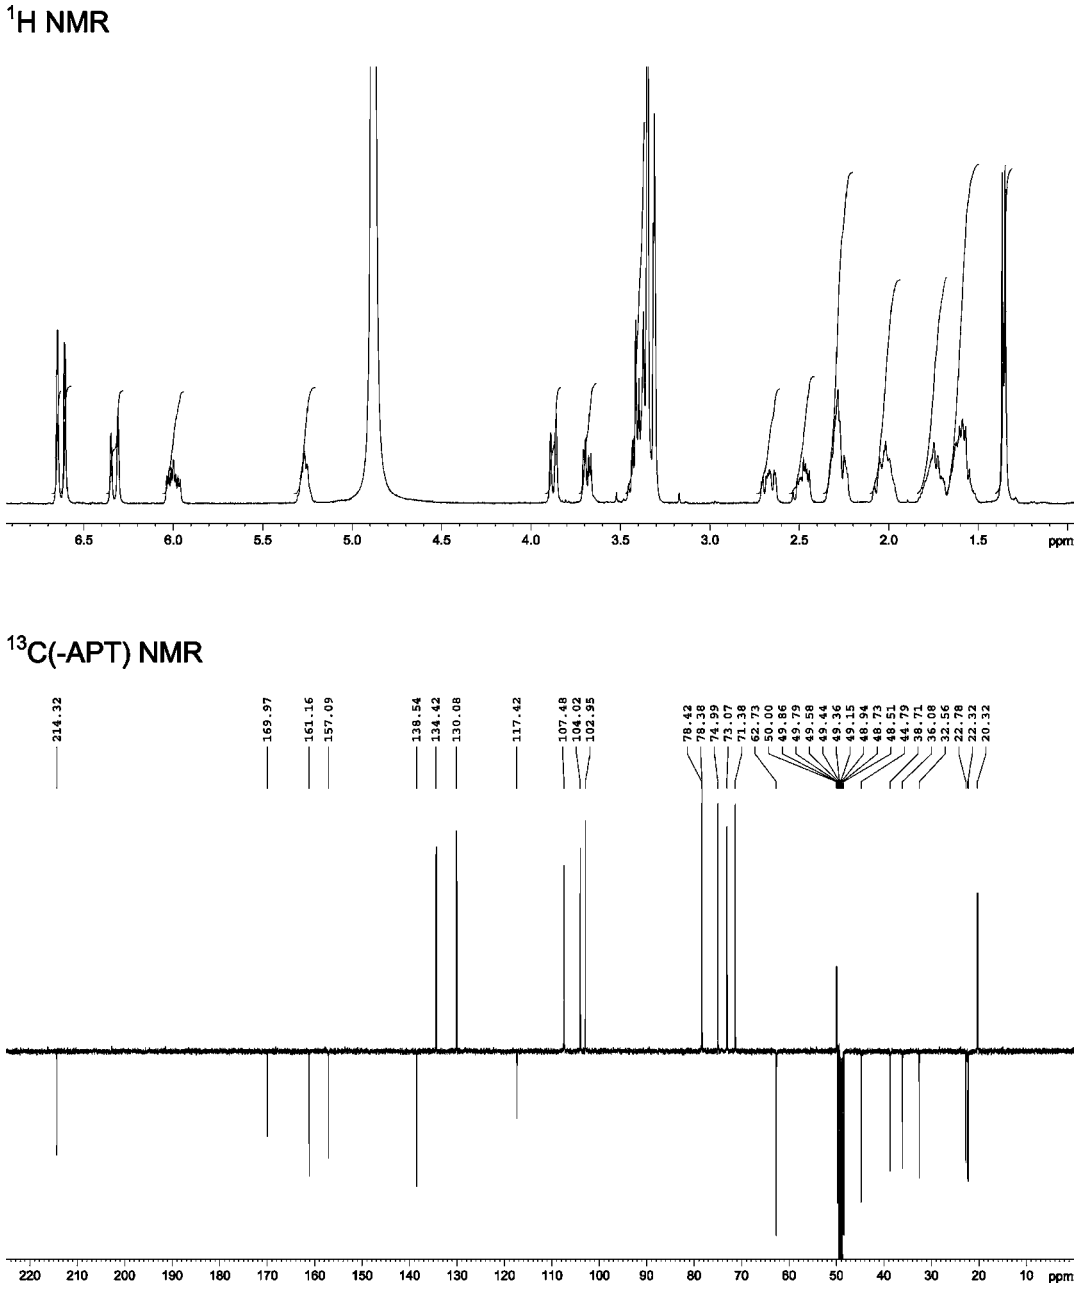

Figure 4. ^{1}H and ^{13}C(-APT) NMR spectra of zearalenone-16-*O*-*β*-glucoside.

O-*β*-glucoside also appeared in the supernatant of wheat cells, but practically no zearalenone-16-*O*-*β*-glucoside was detected. Zearalenone, zearalenols, and zearalenone-glucosides add up to only about 40%; a significant portion of the administered zearalenone is unaccounted for. A search for masses of other possible zearalenone metabolites revealed that a large portion of the input might be present in the cells as zearalenone-malonyl-glucoside, for which a reference substance is not yet available. The crude assumption that zearalenone-malonyl-glucoside shows the same response during ionization in the mass spectrometer leads to the estimate that potentially 30% of the added zearalenone may be converted to zearalenone-malonyl-glucoside in the wheat suspension culture.

Hydrolysis of Zearalenone-16-*O*-*β*-glucoside by Intestinal Bacteria. Dall'Erta et al.[22] showed a high conversion of zearalenone-14-*O*-*β*-glucoside by intestinal bacteria incubated in a complex medium containing starch, peptone, tryptone, yeast extract, pectin, mucin, casein, arabinogalactan, etc., in grams per liter amounts. In pilot experiments using 1 mg/L zearalenone-16-*O*-*β*-glucoside also an almost complete conversion to zearalenone was observed by intestinal bacteria incubated in water (data not shown). To test the differences between incubating fecal samples in the complex medium of Dall'Erta[22] and water, a concentration of 1 mg/L zearalenone-16-*O*-*β*-glucoside was selected. The fecal samples are a complex analytical matrix causing high variability. The recovery of zearalenone in the feces resuspended in the Dall'Erta fermentation mix was only 35%, with large variability (22% relative standard deviation), whereas the water-resuspended samples were rather unproblematic (on average 81% recovery with 11% relative standard deviation). Overall, due to the high relative standard deviation, the results are to be regarded as

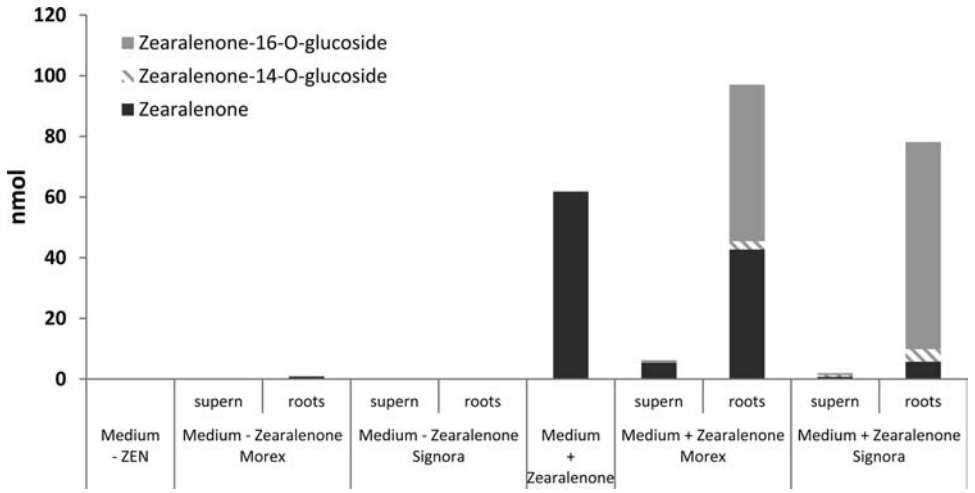

Figure 5. Distribution of zearalenone and its metabolites 24 h after incubation with 15.7 μM zearalenone with axenic cultures of seedlings of the barley cultivars 'Morex' and 'Signora'. Shown are zearalenone and detected metabolites remaining in the medium (supernatant, abbreviated supern.) and extracted from the roots.

semiquantitative. In both cases very rapid hydrolysis of zearalenone-16-*O*-*β*-glucoside was observed and nearly all of the input was recovered as zearalenone within 30 min of incubation, regardless of the suspension medium (Table 2). No remaining zearalenone-16-*O*-*β*-glucoside was found in the spiked fecal slurry of any of the volunteers after 2 h.

DISCUSSION

We elucidated that the UDP-glucosyltransferase HvUGT14077 can produce a mixture of the known masked mycotoxin zearalenone-14-*O*-*β*-glucoside (**2**) and the new zearalenone-16-*O*-*β*-glucoside (**3**) in roughly equimolar amounts. The diminished response to zearalenone in the engineered yeast strain YZCP908 expressing this gene is a first indication that zearalenone-16-*O*-*β*-glucoside, like zearalenone-14-*O*-*β*-glucoside,[13] no longer interacts with the estrogen receptor. This hypothesis will be tested with the new metabolite at hand in future in vitro interaction studies. Yeast expressing the *HvUGT14077* gene allowed straightforward production of zearalenone-16-*O*-*β*-glucoside. The use of an ABC transporter-deficient strain increases the uptake of zearalenone[23] but has the disadvantage of increasing sensitivity. Concentrations higher than 5 mg/L are toxic for the strain YZGA515. The conditions used for fermentation can still be optimized to increase the yield of glucosides, for example, by more sophisticated zearalenone administration regimes. The cleanup from large volumes of rather dilute fermentation broth is clearly a viable alternative to chemical synthesis. So far, we are only aware of one publication describing the chemical synthesis of zearalenone-16-*O*-*β*-glucoside, as a byproduct of synthesis of zearalenone-14-*O*-*β*-glucoside.[24] Presumably, only small amounts were obtained, which were insufficient for structural

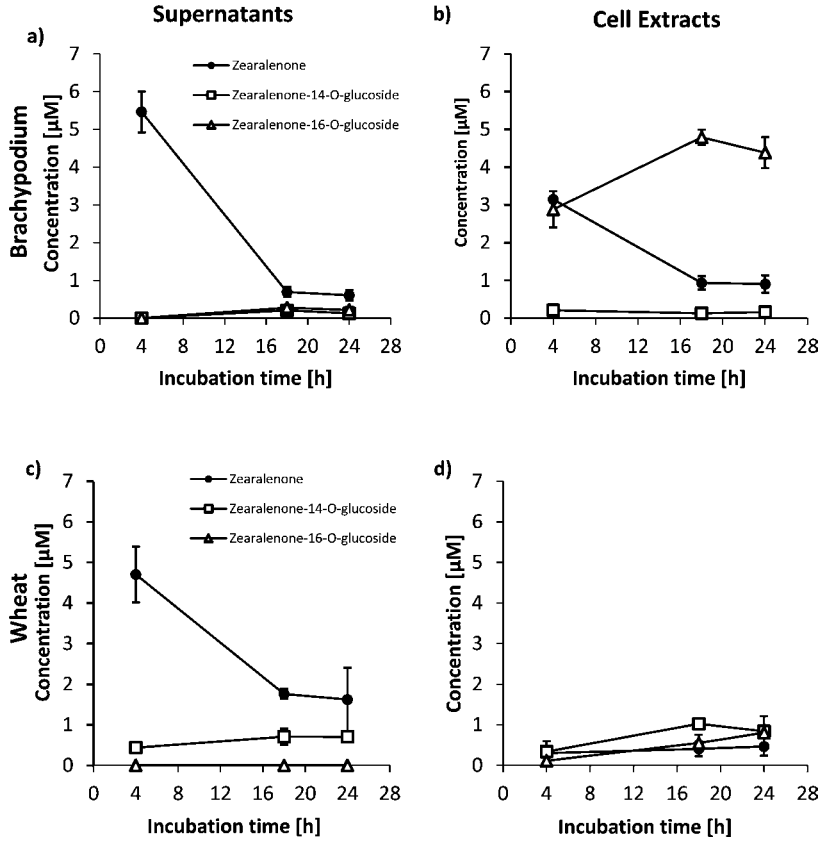

Figure 6. Time course of zearalenone metabolization by suspension cultures *Brachypodium distachyon* Bd21 (a, b) and wheat (PC-998) (c, d). Initial concentration was 6.2 μM zearalenone.

[a]The input of 2.08 nmol of **3** was used as 100% to calculate conversion. Samples A–F represent the six feces donors. Values shown have a relative standard deviation of 11% for samples in water and 22% for the Dall'Erta fermentation mix,[22] respectively.

characterization. However, the authors did test three commercially available zearalenone immuno-affinity columns with the compound "tentatively identified as zearalenone-16-*O*-β-glucoside" and reported recoveries below 1%.[23] It is therefore highly likely that zearalenone-16-*O*-β-glucoside escapes widely used antibody-based detection methods, one of the criteria for a "masked" mycotoxin. The yeast biocatalytical production and cleanup described in this work are straightforward, and with this approach it should be possible to produce the worldwide need of an analytical reference substance. It would also be possible to produce larger amounts for future toxicological studies.

Using the yeast-produced reference substance, we investigated zearalenone metabolization in two barley cultivars ('Morex' and 'Signora') and found that both preferentially convert zearalenone into the new glucoside (16–18 times more zearalenone-16-*O*-β-glucoside than zearalenone-14-*O*-β-glucoside was observed in roots). Because HvUGT14077 produces a near 1:1 mixture, the preferential accumulation of zearalenone-16-*O*-β-glucoside in barley suggests that other UGTs exist in

the barley genome that can nearly exclusively generate zearalenone-16-*O*-*β*-glucoside. UDP-glycosyltransferases, most of which are expected to be glucosyltransferases, are encoded in plant genomes by an extremely large family. The model plants *A. thaliana* and *B. distachyon*[25,26] contain approximately 120 and 178 predicted UGTs, respectively.[27,28] An alternative hypothesis is that the zearalenone-glucosides transiently observed are the result of a dynamic equilibrium, as the glucosides are rapidly metabolized into further compounds such as malonyl-gucoside and diglucoside and other unknown forms. Potentially, the speed of downstream reactions could be largely different for the two zearalenone-glucosides and different in various plant species. In zearalenone-treated *Arabidopsis*, zearalenone-14-*O*-*β*-glucoside was found inside the plant transiently in high levels, but after 24 h, intracellular zearalenone-14-*O*-*β*-glucoside was decreased and much of the input was converted to unknown compounds.[15] Zill et al.[29] showed that in maize suspension cells treated with radiolabeled zearalenone 50% of the input was found in the nonextractable "insoluble residue".

In zearalenone-treated transgenic yeast, nearly all of the zearalenone-glucosides that are produced are efficiently transported across the plasma membrane by unknown transporters and released into the medium. In contrast, in the plant cell experiments only a small percentage of the zearalenone-glucosides was found in the medium; most of it is presumably stored in vacuoles. The soluble derivative is a "masked" mycotoxin if it is hydrolyzed by intestinal hydrolytic enzymes of the intestinal flora. In principle, two different types of hydrolytic enzymes could be relevant for reactivation of masked mycotoxins. Some bacteria contain either periplasmatic *β*-glucosidases (e.g., *Sphingomonas*[30]) or presumably cytosolic glycoside hydrolase family 1 members (e.g., the lactic acid bacterium *Oenococcus*[31]). Such enzymes can be easily expressed in *Escherichia coli* and are not sensitive to aerobic conditions or require cell integrity. The complex nutrient-rich incubation buffer used by Dall'Erta et al.[22] to generate the fecal slurry should be unnecessary, or in the worst case some ingredients may even be inhibitory (e.g., glucose released from starch due to end product inhibition). Alternatively bacteria have phosphoenolpyruvate-dependent phosphotransferase systems, where uptake of *β*-glucosides is coupled with phosphorylation of the incoming glucose. After translocation, intracellular 6-phospho-*β*-glucosidases[32] cleave the *β*-glycosidic bond, releasing 6-P-*β*-glucose, which is utilized by the bacteria. Avoiding oxidative damage of cells by maintaining strictly anaerobic conditions during resuspension and the incubation[22] may be relevant in this case to allow efficient uptake. Yet phosphoenolpyruvate-dependent phosphotransferase systems for *β*-glucosides are generally transcriptionally repressed by the presence of preferred nutrients (as present in the Dall'Erta mix), but this process is expected to become evident only after longer incubation. We have not found evidence that resuspending fecal samples in water instead of the complex mixture described by Dall'Erta reduces the ability of fecal bacteria to hydrolyze zearalenone-glucosides. An advantage of resuspending the samples in water is that matrix effects are lower and the recovery rates much higher. In pilot experiments, we furthermore found that fecal samples stored for 24 h under aerobic conditions at 4 °C have essentially unchanged ability to hydrolyze zearalenone-14-*O*-*β*-glucoside (data not shown). Maintaining strict anaerobic conditions does not seem to be critical. In conclusion, one can assume that ingested zearalenone-16-*O*-*β*-glucoside is cleaved in the intestines and therefore available for absorption. Zearalenone-16-*O*-*β*-glucoside fulfills the criteria of a masked mycotoxin. Studies on the natural occurrence and toxicological relevance are therefore warranted.

^{13}C labeled (U-^{13}C) glucose, and the chemical shift reference compound [3-(trimethylsilyl)propionic-d_4 acid] sodium salt (TSP, δ = 0 ppm) were purchased from Cortecnet (Voisins-Le-Bretonneux, France). $CDCl_3$ (99.8% D) containing 0.03% TMS was purchased from Euriso-Top (Saint-Aubin, France). CD_3OD (99.8% D), 1,12-dibromododecane 98%, triethylamine, brucine sulfate salt hydrate, and benzoic acid were purchased from Sigma-Aldrich (Tres Cantos, Spain). Sulfo(4)calixarene was prepared as described previously.[32] Surfactant 1,12-bis(triethylammonium bromide) was prepared from 1,12-dibromododecane and ethanol using the method described by Lago et al.[33] The sample of [U-^{13}C]colanic acid was obtained by expression in *Escherichia coli* K92 using the protocol described by Gonzalez-Clemente et al.[34] and using U-^{13}C-labeled glucose as the source of carbon.

Sample Preparation. Samples were prepared in 5 mm NMR standard tubes. The sample of benzoic acid was prepared as 20 mM in 0.6 mL of D_2O/CD_3OD 1:1 v/v with 0.03% of TSP. The sample of wine was prepared by mixing 0.4 mL of wine of type Anciño-Ribeiro with 0.1 mL of a buffer of 1 M deuterated sodium acetate (pH 4.5) containing 0.5 mM TSP. The olive oil sample was prepared by mixing 0.5 mL of olive oil from Andalucía (Spain) in 0.1 mL of $CDCl_3$. A sample of brucine was prepared as 30 mM in 0.6 mL of $CDCl_3$. A sample of 10 mM sulfo(4)calixarene and 10 mM dodecane 1,12-bis(triethylammonium bromide) surfactant was prepared in 0.6 mL of a 1:1 v/v mixture of solvents D_2O/CD_3OD. A sample of the isolated U-^{13}C-labeled polysaccharide colanic acid was prepared by dissolving 15 mg of the dry polysaccharide in 0.6 mL of D_2O.

Nuclear Magnetic Resonance Measurements. The NMR spectra were acquired at 25 °C in an Agilent (Varian) Inova 17.6 T spectrometer (750 MHz proton resonance) equipped with an inverse detection triple resonance probe ^{1}H /^{13}C /^{31}P and triple axis shielded PFG gradients for use with conventional 5 mm NMR tubes. NMR data processing and analysis were performed with Mestrenova software (Mestrelab Research Inc.)

Theoretical Background. *Theory of 1D s-Filter Experiment.* The s-filter pulse sequence proposed for the editing of ^{1}H singlet peaks is shown in Figure 1a. The sequence incorporates two basic elements after the first excitation pulse: one is a spin−echo ($^{\Delta}/_2$−180°−$^{\Delta}/_2$) period for the evolution of single quantum coherences (SQC), and the second element is a zero-quantum coherence (ZQC) filter scheme [90°−(180°$_{SL}$ + G_{SL})−90°] originally proposed by Thrippleton and Keeler.[35] For a signal with a nominal value J of the proton−proton scalar coupling, the application of the s-filter sequence of Figure 1a with just one cycle (n = 1) generates the product operators at the selected points as shown in Scheme 1.

During the spin−echo element, a coupled signal evolves into a sum of SQC in-phase and antiphase terms. The SQC in-phase term generated at point 2 is stored as z-magnetization during the subsequent MQC/ZQC filter and is the only term that is finally detected in the experiment. The SQC antiphase term generated at point 2 is converted during the MQC/ZQC filter into a mixture of DQC/ZQC terms that are purged (dephased) at point 4 by the spatial encoding PFG gradient G_{SL} applied simultaneously with the π adiabatic inversion pulse.[35] Strong coupled multiplets (i.e., $|^nJ_{HaHb}| \leq |\nu_a - \nu_b|$) are also eliminated at point 4 when the second $^{\pi}/_2$ pulse is applied with phase $\phi_3 = x$ or $-x$, as they are efficiently transformed into a mixture of coherences of even order MQC and ZQC terms.[24] Neglecting relaxation effects, in one cycle of the s-filter experiment of Figure 1a the intensity of a signal, S, is given by eq 1

$$S \propto S_0 \cos(\pi J \Delta) \quad (1)$$

where S_0 is the original intensity of the signal and Δ the delay used in the spin−echo.

For our goal to eliminate coupled signals, the generation of SQC antiphase terms must be maximized at point 2, which occurs when the suppression condition $\Delta = 1/(2J)$ is matched. Nevertheless, for the general case of a NMR spectrum containing signals with different couplings, some of them will necessarily mismatch the suppression condition. Thus, the s-filter experiment of Figure 1a used with just a single cycle (n = 1) can only provide strong suppression in a small range of coupling constants that match the aforementioned condition. To better sculpt the suppression profile for an arbitrary set of coupling constants in the ^{1}H spectrum, the s-filter is cycled for a number of steps n that explore several values of the delay Δ (Figure 1a). For a generic signal, S, its intensity after n cycles of s-filter is given by eq 2. The incorporation of the relaxation effects during the s-filter experiment gives eq 3.

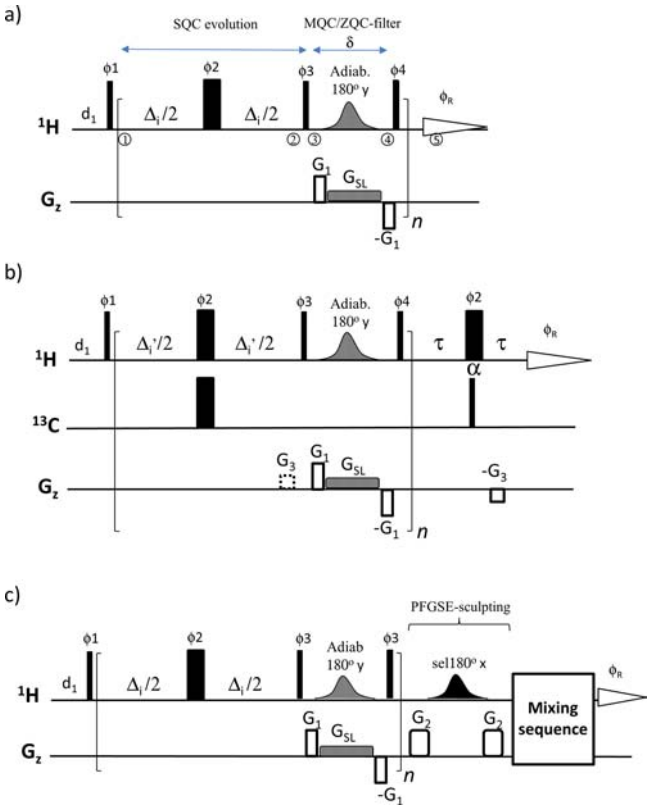

Figure 1. (a) Pulse sequence of 1D ^{1}H s-filter experiment. (b) Pulse sequence 1D ^{1}H s-filter experiment with suppression of proton signals attached to ^{13}C (e.g., ^{13}C satellites). (c) Generic scheme of 1D ^{1}H-selective s-filter experiments by combination of the s-filter and PFGSE-sculpting method. A mixing sequence such as ROESY, NOESY, DOSY, T_1, or T_2 is optionally introduced at the end of the experiment before the acquisition. In these experiments, narrow and wide lines correspond to hard pulses of 90° and 180°, respectively. The delays Δ_i are taken from Table 1 for the suppression of coupled protons. The delays Δ_i' are calculated as the closest value to the corresponding Δ_i of Table 1 that match the condition $\Delta_i' = k \times 1/(2J_{CH})$, where k is an integer number and J_{CH} is the one bond ^{1}H−^{13}C coupling constant. The shaped pulse (striped pulse) is an adiabatic inversion CHIRP pulse of 4 ms duration and 20 kHz bandwidth which is applied simultaneously with a slice-selection gradient G_{SL} with a nominal power ~3.38 G/cm. The power of G_{SL} is steadily increased between 5 and 10% for consecutive cycles to prevent accidental refocusing of coherences. G_1 is an optional purge gradient of power 15 G/cm and G_2 is 23 G/cm. G_3 and $-G_3$ are small gradients of 1 ms used for coherence selection with a power of 3.8 and −3.8 G/cm, respectively. G_3 is only applied during the first cycle of the series (n = 1). In sequence b, the ^{13}C pulse labeled with α is a hard pulse with a nominal flip angle of 90° or 270°, and the delay τ is set to $1/(2J_{CH})$. The phase cycling is $\phi_1 = \phi_R$ = 0, 0, 2, 2, 2, 2, 0, 0; ϕ_2 = 1, 1, 3, 3, 3, 3, 1, 1; and ϕ_3 = 0. Other phases are indicated. Compensation of T_1 relaxation occurring during the n cycles of MQC/ZQC filter can be obtained by setting ϕ_3 = 0 and the slice-selective gradient positive (+1 × G_{SL}) for cycles with odd number and by setting ϕ_3 = 2 and the slice-selective gradient negative (−1 × G_{SL}) for cycles with even number.

$$S = S_0 \prod_{i=1}^{n} \cos(\pi J_i \Delta_i) \exp\left(-\frac{n\Delta_i}{T_2}\right)\left[1 - 2\exp\left(-\frac{n\delta}{T_1}\right)\right] \tag{3}$$

where n is the number of cycles, Δ_i the SQC evolution periods, δ the (constant) duration of the MQC/ZQC filter during each cycle, and T_2 and T_1 are the transversal and longitudinal relaxation times.

Neglecting relaxation effects, numerical analysis of eq 2 provided optimum values of the delays Δ_i for a given number of cycles n of the s-filter experiment (Figure 1a). These results are given in Table 1 and correspond to the best possible performance for the editing of singlets and small coupled signals in a convenient range that was fixed to ${}^nJ_{HH} \leq 3$ Hz. In Figure 2 are represented the signal intensity profiles using the optimized parameters of Table 1 for a number of cycles between 2 and 5. It can be seen in Figure 2a (or Figure 2b) that when the 1D s-filter experiment is used with a limited number of cycles, $n = 2$ (or $n = 3$), the experiment does not provide sufficiently strong attenuation (over 90%) for all possible couplings above 3 Hz. On the contrary, by using the optimized parameters for a number of cycles $n > 3$, strong attenuation over 90% is attained for signals with couplings above 3 Hz, while those signals with smaller couplings, and in particular singlets, have substantially stronger intensity, as can be seen in the profiles of Figure 2c,d.

It can be noticed in Table 1 that as the number of cycles n is increased, so is the required mixing time of the s-filter experiment, which introduces a certain penalty in the sensitivity of the detected signals due to relaxation effects (eq 3). In general, samples of small metabolites in solution often have sufficiently long relaxation times to accommodate the mixing times of Table 1 without compromising their sensitivity; otherwise, a compromise must be found to limit the number of cycles n.

The s-filter spectrum has a semiquantitative character. In principle, the integrals measured for a certain metabolite in samples of the same type could be directly analyzed with multivariate statistical analysis methods for metabolite profiling.[1−4] The expected differences of T_1's and T_2 among metabolites, in general, advise against the direct analysis of the integrals in the s-filter spectrum to determine relative or absolute concentrations of metabolites. However, the mentioned quantitative analysis could be feasible if signal correction factors are determined using the reference integrals of the ^{1}H spectrum.[36] In this way, the corrected quantitative integrals could be introduced into the statistical treatment of the integrals used for metabolomics studies.[1−4]

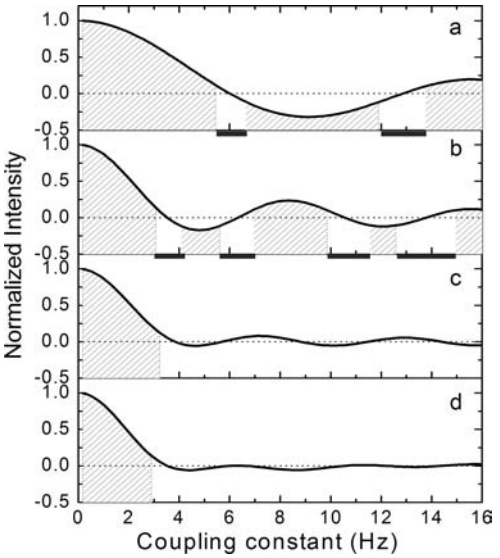

Figure 2. Signal intensity profile vs nominal value of the coupling constant in the 1D s-filter experiment. The curves are obtained by application of eq 2 to the optimized parameters of Table 1. (a) 1D s-filter[2] with two cycles ($n = 2$), (b) 1D s-filter[3] with three cycles, (c) 1D s-filter[4] with four cycles, and (d) 1D s-filter[5] with five cycles. The shaded areas under the curve represent signals with normalized absolute intensity above 10%.

A final point that was considered refers to the duration of the ZQC/MQC block in Figure 1a. The duration of this block introduces T_1 relaxation losses during the n cycles of the s-filtering sequence (eq 3). As deduced theoretically by Thrippleton and Keeler,[35] ZQC cancelation critically depends on the duration of the 180° adiabatic pulse. The attenuation can be approximated to $1/(\Omega_{ZQ}\tau_f)$, where Ω_{ZQ} is the difference of frequency (in rad s^{-1}) of two coupled signals, and τ_f is the duration of the adiabatic pulse.[35] As the s-filter experiment is normally employed with several cycles, a compromise was made here to set τ_f conveniently short. In the examples presented in this work a Chirp adiabatic inversion pulse of duration $\tau_f = 4$ ms and 40 kHz bandwidth were employed. Theoretically, under such conditions the intensity of ZQC terms of two coupled signals with Ω_{ZQ} of 500 Hz would be attenuated to 8% of its original size.

Theory of 1D s-Filter Experiment with Suppression of Protons Bound to ^{13}C. The removal of the ^{13}C satellites of all the proton signals is of interest for the identification of small signals of metabolites that could be hidden on the ^{13}C satellite peaks. On the basis of the same principles described above for the ^{1}H s-filter sequence of Figure 1a, the modified sequence of Figure 1b is proposed to obtain a ^{1}H s-filter experiment with suppression of the signals of protons directly attached to ^{13}C (e.g., ^{13}C satellites), either for singlet or multiplet peaks. The sequence incorporates one 180° ^{13}C pulse at the middle of each spin−echo. The delay Δ_i' of each cycle n has to be slightly

Table 1. Optimized Values of the Delays Δ_i in the 1D s-Filter Experiment for a Given Number of Cycles n[a]

selected couplings (Hz)	s-filter^n cycles, n	Δ_1 (ms)	Δ_2 (ms)	Δ_3 (ms)	Δ_4 (ms)	Δ_5 (ms)	Δ_6 (ms)	mixing time (ms)[b]	Q_f[c]
0.1, 3	2	39	83					139	0.747
0.1, 3	3	36	79	142				269	1.179
0.1, 3	4	35	57	88	131			327	2.847
0.1, 3	5	35	41	75	83	142		396	5.330
0.1, 3	6	33	38	55	75	88	131	444	13.31

[a]These parameters are the more favorable for the editing of singlets and signals with small couplings (${}^nJ_{HH} \leq 3$ Hz). [b]The calculated mixing time includes a period $\delta = 4$ ms for each cycle of the ZQC/MQC filter. [c]The quality factor (Q_f) is calculated as the signal intensity in the selected range of couplings divided by the signal intensity outside the selected range of couplings. The full range of couplings explored covers from 0.1 to 20 Hz.

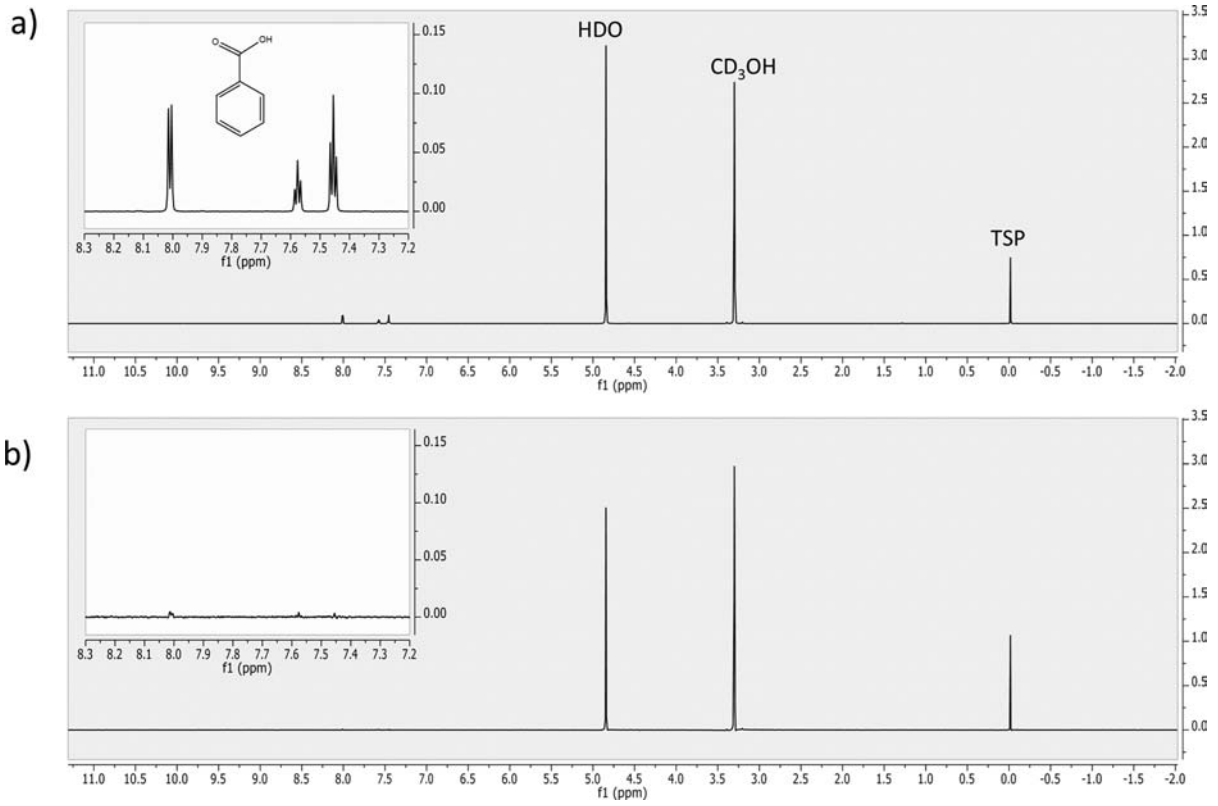

Figure 3. Spectra of a sample of benzoic acid in D_2O/CH_3OD and TSP. (a) 1D ^1H spectrum and (b) 1D ^1H s-filter[3] spectrum obtained with the experimental parameters simulated in Table 1 for three cycles (n = 3). The two spectra are normalized and represented at the same vertical scale. The inset shows the signals of benzoic acid.

modified from the correspondingly value Δ_i in Table 1 (as described in the caption of Figure 1b). The objective is to synchronize the total duration of each spin−echo so as to maximize the generation of $^1H-^{13}C$ terms of the form $2 \times H_xC_z$ exactly at the end of the spin−echo. This term is then converted into a ZQC term of the form $2 \times H_zC_z$ by effect of the second 90° proton pulse, and it is filtered out during the subsequent MQC/ZQC filter block. Thus, through the several cycles n of the sequence, the signals of all the protons bound to ^{13}C are efficiently suppressed.

Theory of 1D s-Filter Reverse Experiment (s-Filter^{rev}) for the Editing of Multiplets. The s-filter experiment in combination with difference spectroscopy is a straightforward possibility to obtain a 1D reverse s-filter spectrum (s-filter^{rev}), that is, a spectrum that shows only the signals of the multiplets but not the singlets (or small couplings).

For optimum results, the 1D s-filter^{rev} spectrum is obtained by subtraction in alternate scans of the FIDs of two subspectra: one is the T_1-filter spectrum based in the well-known inversion−recovery sequence (180°−τ_{rec}−90°−acq), and the other is the s-filter[1] experiment of Figure 1a (number of cycles n = 1). The total scan duration and other relevant parameters are made the same for the two subspectra, so as to minimize potential subtraction errors due to the relaxation effects during the two scans. In particular, the same mixing time is used in both subspectra by setting the delay τ_{rec} of the inversion−recovery spectrum equal to the duration $\Delta + \delta$ of the s-filter[1] experiment.

RESULTS AND DISCUSSION

As mentioned in the Introduction, discerning singlet peaks in areas of the NMR spectrum with overlapping metabolites is not always feasible with 1D or 2D proton homonuclear NMR spectra. The 1D s-filter experiment is proposed for the specific editing/filtering of singlets peaks and signals with small couplings.

As a proof of concept of the application of the 1D s-filter experiment to the selection of singlets, the experiment of Figure 1a was tested with a sample of benzoic acid dissolved in D_2O/CD_3OD and TSP. Figure 3 shows the excellent suppression of the aromatic multiplets in this sample while the signals of the singlets corresponding to HDO, CD_3OH, and TSP are cleanly edited in the s-filtered spectrum.

The excellent performance of the s-filter obtained in the previous example encouraged us to test the methodology with real cases of complex mixtures of foodstuffs that are of interest in the food industry. The first type of sample chosen for study is a wine sample. The spectra of parts a and b of Figure 4correspond to the 1D ^1H and the 1D s-filter spectra of the wine sample, respectively. Clearly, the 1D s-filter spectrum offers a remarkable simplification of the proton spectrum; singlets peaks of acetyl groups and other singlets or peaks with small couplings ($^nJ_{HH} \leq 3$ Hz) are clearly edited in the s-filter spectrum of Figure 4b, while the remaining signals (multiplets) are completely or significantly attenuated. The reverse s-filter experiment (1D s-filter^{rev}) obtained for this wine sample is shown in Figure 4c. It provided a clean editing of the multiplets with good phase properties and semiquantitative character. For this wine sample, the combination of s-filter and s-filter^{rev} spectra of Figure 4b,c improved the possibilities for signal assignment and quantification in those regions in which singlets and multiplets strongly overlap.

A second type of food sample tested with the s-filter methodology is olive oil. The typical proton spectrum of olive oil contains a number of strong signals of fatty acids that overlap with the signals of other less abundant metabolites. In addition, the ^{13}C satellites of such strong signals also have a

dx.doi.org/10.1021/jf4044869 | J. Agric. Food Chem. 2014, 62, 1190−1197

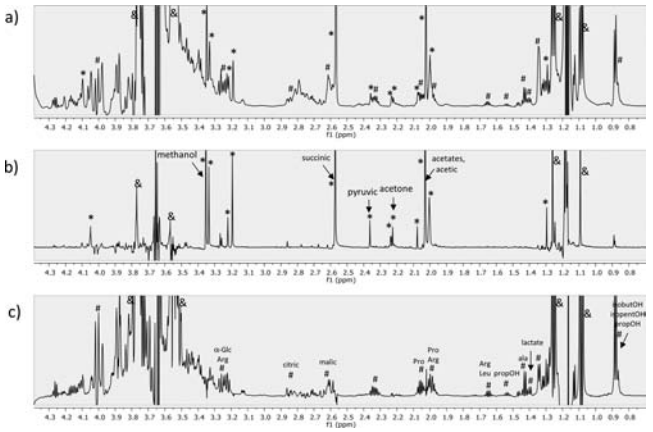

Figure 4. Region of the ^{1}H NMR spectra of a sample of wine. (a) 1D ^{1}H watergate spectrum, (b) 1D s-filter[4] watergate spectrum based on the sequence of Figure 1a. The delays were adjusted to the values reported in Table 1 for a number of cycles $n = 4$. (c) 1D ^{1}H s-filter^{rev} watergate spectrum based on the subtraction of the FIDs of a T_1-filter and s-filter (sequence of Figure 1a) in alternate scans with a mixing time of 75 ms (i.e., duration of the inversion−recovery and Δ delay is 75 ms). In the three spectra the strong water peak at 4.7 ppm was suppressed by watergate and the strong signals of ethanol at 1.17 and 3.65 ppm were partially suppressed by presaturation. Singlets and multiplets having very small couplings are labeled with asterisks. Multiplets with larger couplings are labeled with the hash symbol. The ^{13}C satellites signals of ethanol are labeled with the ampersand symbol.

relevant intensity, and unless the spectrum is obtained with ^{13}C decoupling, they contribute to the spectral overlapping. The application of the s-filter experiments to the olive oil sample is shown in Figure 5, where parts a and b compare the ^{1}H spectrum and the ^{1}H s-filter[4] spectrum with ^{13}C satellite suppression. There are a number of signals that can be identified as singlets in the second spectrum that are not evident in the former spectrum, in particular, the singlets in the region between 0.4 and 1.1 ppm. The s-filter^{rev} spectrum of this sample is given in Figure 5c and shows that all the singlet peaks are cleanly suppressed while the intensities of the multiplets are relatively well preserved, as compared with the proton spectrum of Figure 5a. Again, the combination of s-filter and s-filter^{rev} spectra of Figure 5b,c eased the task of signal assignment and quantification in those regions in which singlets and multiplets strongly overlap.

A different type of application of the ^{1}H s-filter^{rev} experiment is for the suppression of residual signals of certain solvent/s that generate singlets in the proton spectrum. Some typical cases are solvents such as D_2O or CD_3OD when they are not completely deuterated. An important advantage of the method is that, as the s-filter^{rev} experiment does not rely in selective pulses to accomplish the suppression, it potentially allows the observation of multiplet signals that could be hidden under a relative intense singlet solvent peak. An example of the use of the s-filter^{rev} for multiple solvent suppression is provided in Figure S1 (Supporting Information).

s-Filter Hybrid Experiments. The s-filter sequence of Figure 1a can be implemented as a building block for excitation in other types of NMR experiments. Thus, the resulting 1D or *n*D s-filter hybrid experiment should provide the editing of the responses of the signals of singlets and small couplings in the type of spectrum selected.

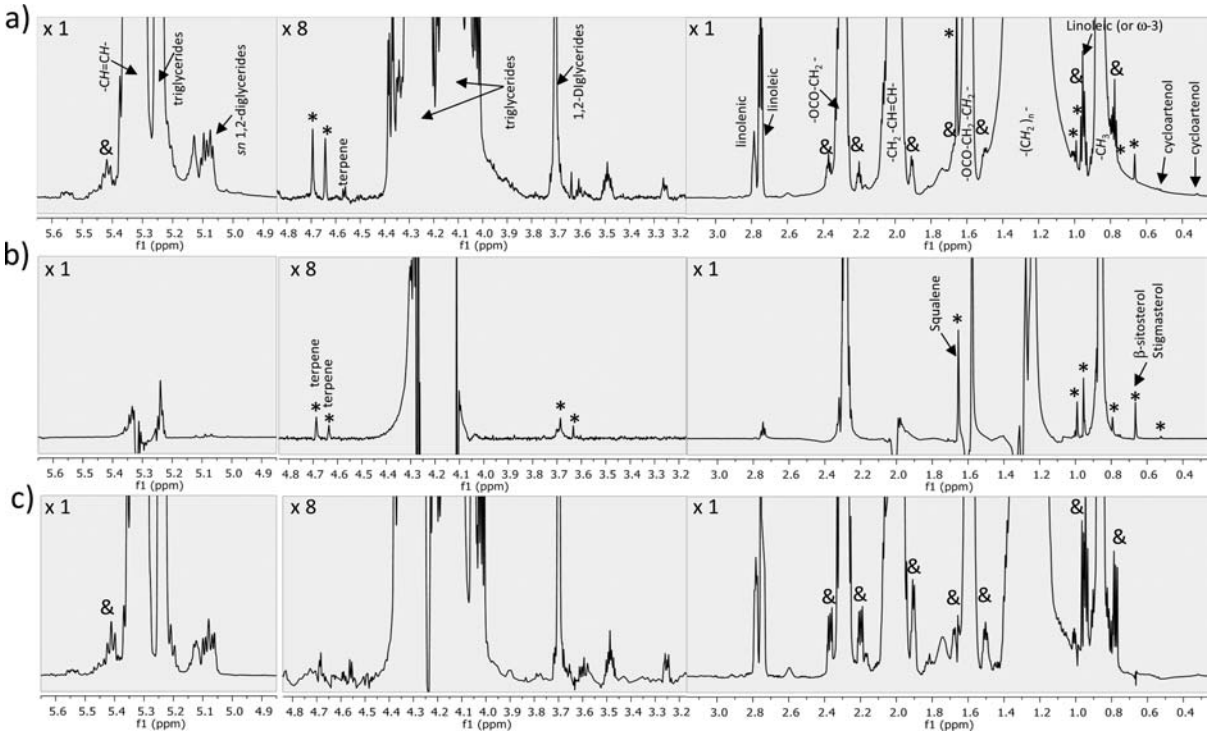

Figure 5. NMR spectra of a sample of olive oil dissolved in $CDCl_3$. (a) 1D ^{1}H spectrum, (b) 1D ^{1}H s-filter[4] spectrum with ^{13}C satellite suppression (sequence Figure 1b), and (c) 1D ^{1}H s-filter^{rev} spectrum based on the subtraction of the FIDs of a T_1-filter and s-filter (sequence Figure 1a) in alternate scans with a mixing time of 75 ms (i.e., duration of the inversion−recovery and Δ delay is 75 ms). The spectra show three regions represented at the relative vertical scale. Singlets peaks are indicated with an asterisk. In parts a and c, the ^{13}C satellites signals are labeled with the ampersand symbol. The assignment of signals is based on ref [12].

dx.doi.org/10.1021/jf4044869 | J. Agric. Food Chem. 2014, 62, 1190−1197

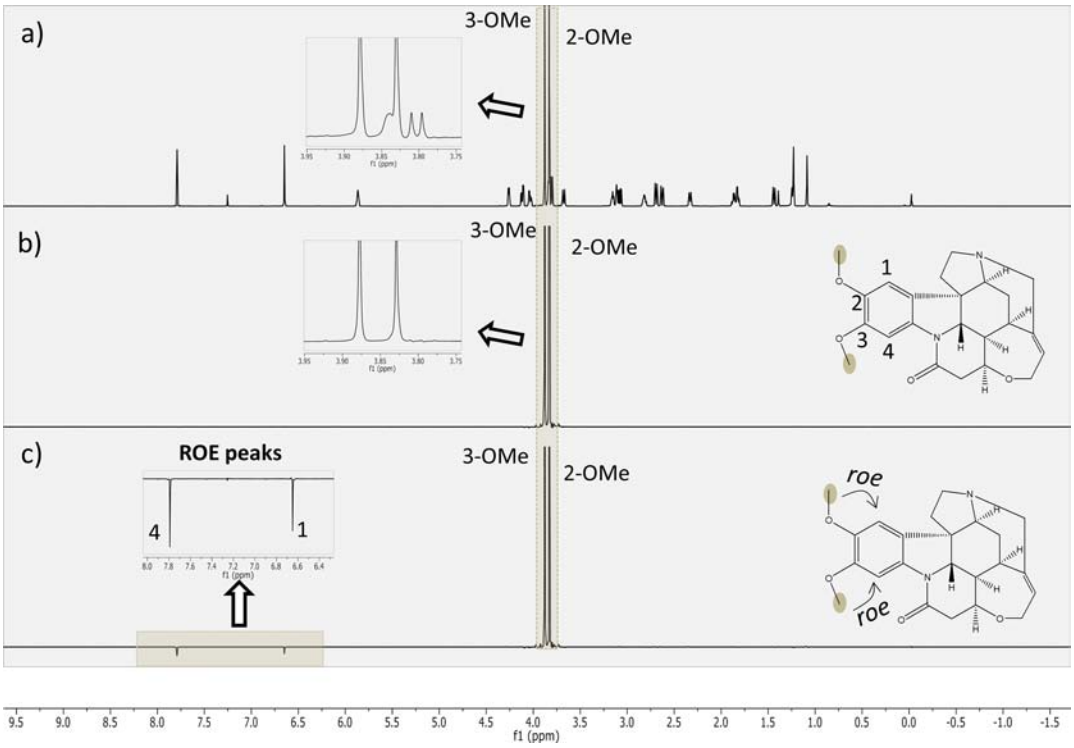

Figure 6. Spectra of a sample of brucine dissolved in $CDCl_3$. (a) ^1H spectrum, (b) selective 1D s-filter^3-PFGSE spectrum, and (c) selective 1D s-filter^3-PFGSE-ROESY spectrum with a ROESY mixing time of 400 ms. In spectra b and c the selective pulse was an r-snob pulse of 12 ms applied at 3.85 ppm and covering a bandwidth of 0.2 ppm.

One of the possibilities explored was the incorporation of s-filter into the well-known excitation sculpting scheme based on the sequence of PFGSE (pulse-field gradient spin−echo).[37] Such combination results in the 1D selective s-filter sequence (1D sel-s-filter) of Figure 1c. Additionally, a mixing sequence (e.g., ROESY, NOESY, DOSY, T_1, T_2, etc.) can be incorporated at the end of this sequence for the observation of a certain property of interest. The main advantage of the 1D sel-s-filter experiment proposed is that it permits one to isolate the response(s) of specific signal(s) of singlets that may overlap with multiplets in crowded spectra. As a proof of concept of the method, Figure 6 shows the results obtained for the molecule brucine. The 1D sel-sfilter spectrum of Figure 6b shows that the selective excitation of the two singlets of brucine at ∼3.85 ppm without the appearance of the signals of the multiplets that are in their proximities or partially overlap with them is possible. Figure 6c shows that a 1D sel-s-filter-ROESY spectrum permits the detection of the ROE responses exclusively from the two singlet peaks selected.

Other straightforward possibilities for hybrid experiments is the combination of s-filter with a conventional 2D NMR experiment such as HSQC, HMBC, ROESY, T_1, T_2, or DOSY. One example of a 2D s-filter HSQC hybrid spectrum is shown in Figure S2 (Supporting Information). The 2D s-filter-HSQC experiment can potentially be useful as a complement for assignment in combination with methyl-TROSY HSQC based NMR experiments,[38] as the former experiment will show exclusively the signals of isolated methyls. Methyl-TROSY experiments are usually performed with either fully or partially ^{13}C isotopically enriched samples, and there are situations in which the distinction between singlets protons bound to ^{13}C from singlets protons bound to other type of nuclei is relevant. For this reason, a version of the s-filter experiment is given in Figure S3 (Supporting Information), which edits the responses of the mentioned types of singlet protons with opposite phase. One example of the application of the s-filter experiments of Figures 1a,b and S3 (Supporting Information) for the editing or suppression of singlet protons bound to ^{13}C in a uniformly ^{13}C-labeled sample is provided in Figure S4 (Supporting Information).

Metabolomics Applications of s-Filter Experiments. The s-filtered experiments described above could find application to enable the detection, assignment, and/or quantification of target compounds in NMR-based chemometric applications of complex mixtures of metabolites. The type of sample that can be studied with this methodology includes those of agriculture origin, food, and biofluids. In this regard, the s-filter methodology permits the spectral editing of a number metabolites that generate singlet peaks, such as isolated methyls, methoxys, and acetyl groups that are present in metabolites such as glycine, creatine, *N*-acetyl aspartate, choline, and succinic acid. A list of compounds that can be edited with the s-filter experiment in wine and olive oil samples is provided in Tables S1 and S2 (Supporting Information), respectively. Software for automatic analysis and peak peaking algorithms could also benefit from the type of spectral simplification that the s-filter provides.

that can be further taken up by the host and thus appear in plasma and urine.[30]

Despite the metabolism of main GTE components being fairly well understood, the in vivo bioactivity of specific GTE catechins (free and/or conjugated) are largely unknown.[26] A number of in vitro studies have related specific catechins and various metabolic effects relating to inflammation,[31] nitric oxide production,[32] adipocyte proliferation,[33,34] lipogenic activity,[35] altered nutrient absorption,[36,37] and thermogenic properties.[38] It has also already been shown that certain catechins may be more potent at inducing metabolic effects in vitro, specifically those catechins that possess a gallate ester.[31,39] It is important to highlight that the concentrations of catechins are approximately 5−50 times lower in human plasma than concentrations usually used in vitro.[39−42] In addition, in vitro studies predominantly have used the parent compounds found in GTE and free catechins, despite catechins predominantly being in the conjugated form in vivo.[26]

Exploring the bioactivity of GTE catechins in vivo may be an alternative approach to in vitro testing. With this in mind, we have previously shown using a metabolomics approach that 7 days of GTE supplementation intake is capable of inducing changes in a number of endogenous metabolites including but not limited to fat metabolism, TCA cycle intermediates, lipolysis, and phospholipids and sphingolipid at rest and during exercise.[43] However, although our data show that 7 days (chronic) of GTE supplementation is capable of targeting an array of biological processes, the acute effects on endogenous metabolites upon consumption of a single bolus dose of GTE remain unclear. Determining these effects at peak catechin concentrations in blood may give insight into specific potential bioactive catechin candidates, their biological targets, and the mechanisms underlying the acute effects that have been observed on vascular function[7,44] and fat oxidation.[10]

The primary aim of this placebo-controlled intervention study was therefore to assess the concentrations of seven total (conjugated + free) and free GTE catechins and some catechin metabolites (henceforth called catechin/metabolites) in human plasma after a single dose (acute) of GTE or placebo (PLA) and following 1 day (GTE1), 7 days (GTE7) GTE (2 × 559 mg catechins/day, 120 mg caffeine/day), or PLA supplementation using a targeted LC-MRM-MS-based method. This analytic approach ensured comprehensive insights into the plasma concentrations of free catechins in comparison to total catechin concentrations. Second, the study also aimed to assess the acute effects on a large number of endogenous metabolites 2 h after the intake of the single bolus drink of GTE or PLA. This approach allowed for gaining a greater understanding of the metabolic effects that are induced when catechin concentrations peak in the circulation. The endogenous metabolites were measured in plasma using 4-phase metabolite profiling and catecholamine profiling as previously outlined.[43] In addition, the current study also explored correlations between the concentrations of free and total conjugated catechin/metabolites and the most affected endogenous metabolites in order to identify potential bioactive catechins. The current investigation adds to previous published work reporting results on whole body fat oxidation[24] and on the metabolome at baseline and during exercise following GTE7.[43]

MATERIAL AND METHODS

Study Design. The study was designed as a placebo-controlled, double-blind, randomized, parallel study (Figure 1) and has been

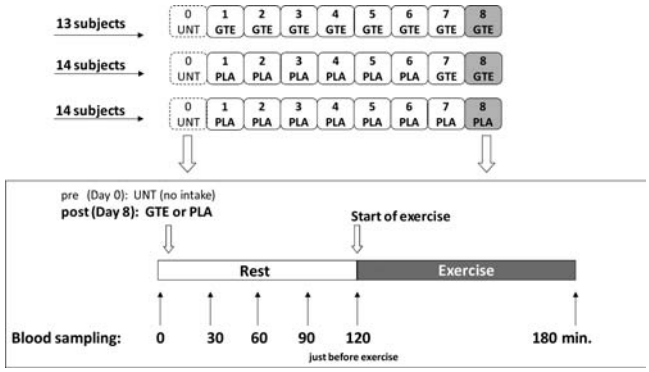

Figure 1. Study design.

described previously.[24,43] In brief, 39 healthy physically active male participants were recruited for the purposes of the study. Participants were randomly allocated into a group who received 7 days of GTE supplementation (GTE7) (n = 13, age 22 ± 5 y, weight 77.6 ± 12.0 kg, BMI 24.3 ± 3.0 kg/m^2), a group who received 6 days of PLA followed by 1 day GTE supplementation (GTE1) (n = 12, age 21 ± 2 y, weight 77.7 ± 9.6 kg, BMI 24.2 ± 1.9 kg/m^2), or a groups who received only PLA for 7 days (PLA) (n = 14, age 22 ± 8 y, weight 78.8 ± 10.2 kg, BMI 24.7 ± 2.7 kg/m^2). The study was approved by the University of Birmingham Ethics Committee. Subjects visited the Human Performance Lab on two separate occasions, namely, pre (Day 0, D0) and post (Day 8, D8) supplementation, following a 10 h overnight fast and having refrained from caffeine, alcohol, and physical activity for 24 h. Each participant received a controlled diet that was consumed 24 h prior to both visiting occasions. On D0 and D8, respectively, an initial 5-mL fasted blood sample was taken at t = 0 min (baseline). Participants then rested in a seated position for 2 h with a blood sample taken at t = 30, 60, 90, and 120 min. Following this, each participant performed a 1-h exercise session on a cycle ergometer at a moderate intensity (50% Wmax), with blood samples collected throughout (t = 140, 150, 160, 180 min). The D0 and D8 trials were identical apart from the ingestion of a single bolus of either GTE (559 mg catechins, 120 mg caffeine), for those who had received GTE7 or GTE1, or PLA following the fasted blood sample (t = 0 min) on D8. Subjects began consuming the supplements on the day following the D0 trial. The supplements were provided in the form of a 330-mL drink. Participants were instructed to consume two drinks per day, 1 h prior to breakfast and another 1 h prior to dinner. The GTE (Taiyo International, Japan) provided a total catechin concentration of 559 mg and 120 mg of caffeine per drink. A breakdown of the composition of GTE and PLA drinks is shown in Table 1.

The current investigation adds to previous published work reporting results on whole body fat oxidation[24] and on the metabolome.[24,43] It first assessed the concentrations of GTE catechin/metabolites across rest (t = 0−120 min) and exercise (t = 120−180 min) on D8 only, which was not established in our previous work.[43] Secondly, it assessed the acute effects of GTE on various metabolites at rest following the final single bolus of GTE or PLA on D8 (t = 0−120 min), as opposed to baseline (t = 0) and during exercise (t = 120−180 min) following GTE7 or PLA, as reported previously.[24,43]

Sample Collection. Each blood sample was collected in chilled EDTA-containing tubes (Becton Dickinson) and stored on ice. Subsequently, plasma was separated by centrifugation (1500g, 10 min, 4 °C), aliquoted in 1-mL samples, and stored at −80 °C for later analysis.

Plasma Analysis of Polyphenols. In the present study, the concentrations of catechin/metabolites collected through the 180-min experiment trial were measured with and without prior enzymatic deconjugation of glucuronides and suphates. This yielded the concentrations of total (free + glucuronides + sulphates) and free (polyphenols not conjugated to glucuronides and sulphates) catechin/metabolites. To determine the total concentrations of specific polyphenols, the polyphenols were deconjugated by β-D-glucuroni-

dase. For this, 200 μL of EDTA plasma, 20 μL of stabilizer solution (10% ascorbic acid containing 0.1% EDTA), 20 μL of 1.5 mol L^{-1} sodium acetate (NaOAc, pH 4.8), and 10 μL of β-glucuronidase (50,000 U L^{-1} in acetate buffer) were mixed and incubated at 37 °C for 45 min. To measure the concentrations of nondeconjugated (free) polyphenols, only 200 μL EDTA plasma, 20 μL of stabilizer solution (10% ascorbic acid containing 0.1% EDTA) and 20 μL of 1.5 mol L^{-1} sodium acetate (NaOAc, pH 4.8) were mixed.

Then 40 μL of internal standard ((±)-taxifolin, TXF, 250 ng L^{-1} in methanol/water, 1:1), 300 μL of water, 10 μL of 2 M HCl, and 1 mL of ethyl acetate (EtOAc) were added, vortexed for 30 s, and centrifuged at 3000*g* for 10 min. The EtOAc top layer was transferred to a clean screw-capped glass tube. The extraction with EtOAc was repeated twice. Ten microliters of 0.4% ascorbic acid was added to the combined EtOAc fractions and dried under N_2 at room temperature. The residue was dissolved in 100 μL of methanol, vortexed, and sonicated for 10 min. Then 100 μL of Milli-Q water was added. The samples were vortexed, sonicated, and centrifuged at 17000*g* for 10 min. From the supernatant, 5 μL was injected into the high-performance liquid chromatography multiple-reaction monitoring mass spectrometer (HPLC-MRM-MS) system (Agilent 6410 mass spectrometer equipped with an Agilent 1200SL HPLC (Agilent Technologies, Amstelveen, The Netherlands) and an HTC PAL autosampler (CTC Analytics, Zwingen, Switzerland). The phenolic compounds were separated on a XBridge Phenyl plus guard column [2.1 mm × 150 mm, 3.5 μm] (Waters, Milford, US) at a flow rate of 0.2 mL/min and at a column temperature of 55 °C using solvent A (0.1% (v/v) acetic acid in water) and solvent B (0.1% (v/v) acetic acid in acetonitrile) programmed in the following gradient: 0−3 min 2% B, until 3 min 2% B, until 4 min 10% B, until 14 min 20% B, until 29 min 100% B, until 34 min 100% B, until 35 min 2% B, until 45 min 2% B.

The HPLC system was coupled to a triple-quadrupole mass spectrometer (Agilent 6410). The separated phenolic compounds were detected in the API negative multiple-reaction monitoring mode. The capillary voltage was 4 kV, the gas temperature was kept at 350 °C, the gas flow was 12 L/min and the nebulizer pressure was 30 psi. The MS settings of the phenolic compounds are shown in Supporting Information (Supplementary Table S1).

Samples were analyzed batch-wise and controlled by two quality control samples (QCs) per sample batch. The QCs were prepared by spiking commercial human plasma with 11 phenolic standards until a final concentration of 100 μg L^{-1}. The standards included (−)-catechin (C), (−)-epicatechin (EC), (−)-gallocatechin (GC), (−)-epigallocatechin (EGC), (−)-epicatechin gallate (ECG), (−)-epigallocatechin gallate (EGCG), 3/4-*O*-methylgallic acid (3/4-OMGA), 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone (3,4-diOH-VL), and 5-(3′-methoxy-4′-hydroxyphenyl)-γ-valerolactone (3MeO-4-OH-VL). These phenolic compounds were quantified in plasma by means of 10-point calibration curves using external standards.

Under the currently described conditions, 3-*O*-methylgallic acid (3-OMGA) could not be fully separated from 4-*O*-methylgallic acid (4-OMGA). Therefore, combined values for 3/4-OMGA are reported. Similarly, combined ECG values are reported for ECG and CG. The peak areas of the internal standards as well as the target compounds were determined using Agilent's MassHunter Quantitative Analysis software (version B.03.02, Agilent Technologies, Santa Clara, CA).

Metabolite Profiling of Plasma. Four-phase metabolite profiling was performed at Metanomics Health GmbH, Berlin, Germany. Due to limited resources, only the plasma samples collected on Day 8 at t = 0 and 120 min from subjects following GTE7 and PLA supplementation were analyzed. This approach included the semi-quantitative broad metabolite profiling (GC−MS and LC−MS/MS) of the lipid and polar phases of plasma. In addition, 10 catecholamines and their related metabolites were measured by online SPE-LC−MS/MS. The methods have been published elsewhere.[43] In total, 238 mostly endogenous metabolites were detected including 163 known metabolites and 75 metabolites that were not chemically identified with sufficient certainty (i.e., thus excluded in the present study).

Data and Statistical Analysis. To assess the acute effect on the endogenous metabolites after a single bolus intake of GTE or PLA, the differences between the metabolite concentrations measured at t = 120 min and t = 0 min (Δ(T120−0)) on D8 were calculated for each of the 163 endogenous metabolites to exclude the baseline (chronic) effects due to 7-day GTE supplementation. Multivariate analysis including PCA [principal component analysis] and PLS-DA [partial least-squares/projection to latent structures-discriminant analysis] was performed using SIMCA P+ version 12 software (Umetrics, Umea, Sweden). Data were scaled to unit variance, which introduces a common scale for all metabolites independent of their absolute amount of variance. The unsupervised PCA was used to detect outliers, trends, patterns, and groupings among samples and variables. Two subjects were identified as outliers and thus excluded from further analysis. The supervised projection method PLS-DA was used to display the maximum covariance of data with a defined Y variable (class, categorical) in the data set. For this the data set was grouped in two classes (GTE and PLA). To ensure validation of the PLS-DA the cross-validated cumulative Q^2 value was used as a measure of the predictive value. A 7-fold cross-validation was performed by the leave-one-subject-out method to ensure that cross-validation was not inappropriately facilitated by the presence of related samples. A Q^2 value of 1 indicates maximum predictive power, whereas Q^2 values close to or below 0 indicate a lack of predictive power. In addition, 999 models with randomly permutated data were calculated to determine the significance of the model and to avoid overfitting. The significance was calculated by dividing the number of random models with Q^2 values larger than the actual model to the total number of random models. Metabolites that significantly contributed to the discrimination of the GTE and PLA groups were selected on the basis of their importance. Box plots and t tests of the most important metabolites were calculated for additional verification of the PLS-DA results.

To identify potential bioactive components of GTE catechins/metabolites, a correlation matrix (Pearson) was calculated correlating the $\Delta(t_{120} - t_0)$ values of the catechin/metabolties and those endogenous metabolites that were affected by GTE. To make sure that the dependency of the overall pattern was above noise level, the overall strength of the correlations was checked by permutation tests.

RESULTS

Catechin Kinetics in Plasma. The total (conjugated + free) and free concentrations of 7 catechins, 3/4-OMGA, and 2 valerolactones were measured in human plasma from subjects in the GTE7, GTE1, and PLA groups following ingestion of a single bolus drink of GTE or PLA on D8. Their average concentrations are plotted in Figure 2, and their maximum concentrations (c_{max}) as well as the area under the curve values

between t = 0 min and t = 180 min (AUC(t_0−t_{180})) are shown in Table 2.

Relative to the other catechins, EGCG was the most abundant catechin in the GTE supplement (37.1% of total catechins) and in plasma (35.0% of AUC(t_0−t_{180})$_{total}$ (GTE7), 36.1% (GTE1). In contrast, ECG (4.6%) and EC (8.4%) were low abundant in the GTE supplement but were present at relatively high concentrations in plasma, when compared to the other catechins (ECG/GC: 21.9% (GTE7) and 16.3% (GTE1); EC: 13.71% (GTE7) and 15.61% (GTE1)). In comparison, the concentration of C (2.1%) and GC (9.85%) were also at low concentrations in the GTE supplement, yet only 0.41% (GTE7) and 0.46% (GTE1) of C and 0.12% (GTE7) and 0.14 (GTE1) % of GC relative to total catechins were detected in plasma. Less pronounced differences between the relative concentrations in the GTE supplement and in plasma were found for GCG and EGC. The ratios of the concentrations in plasma to those in the GTE supplement relative to total catechins, respectively, followed the order ECG/CG > EC > GCG > EGCG > EGC > C > GC.

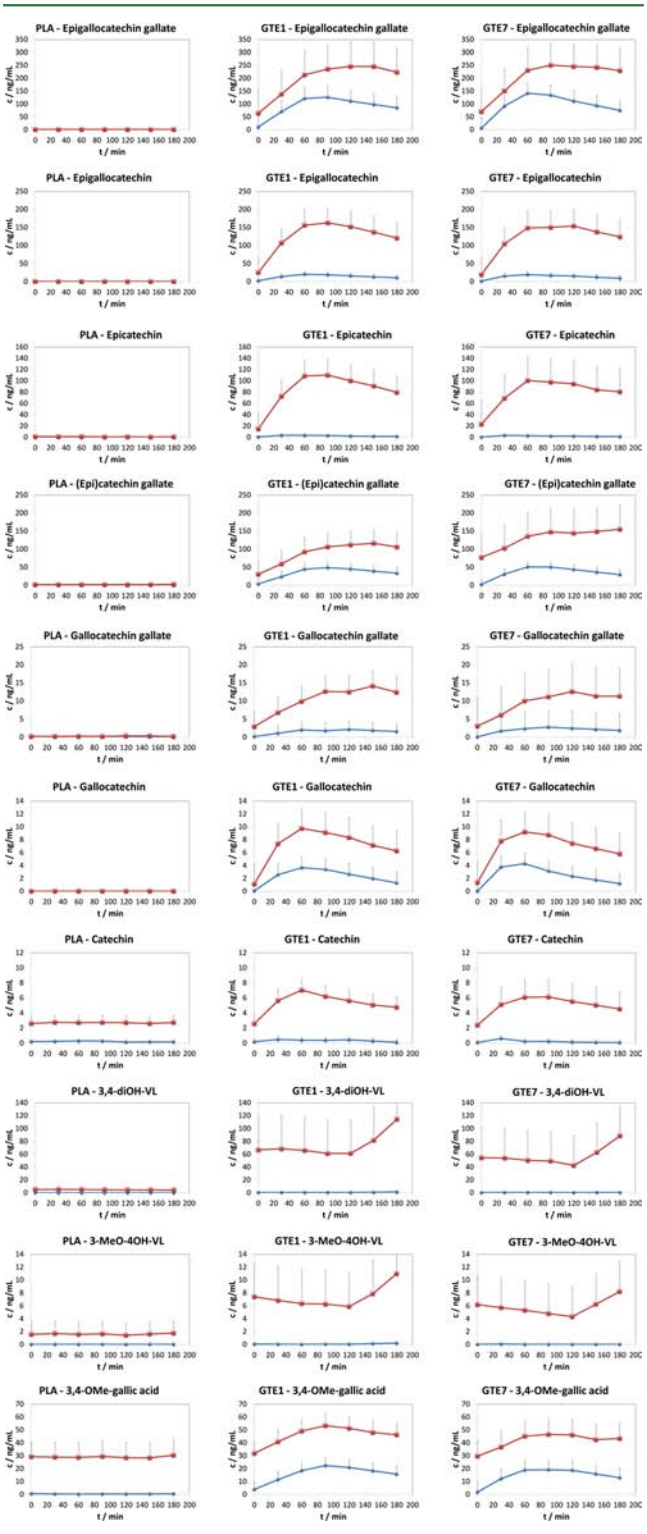

Figure 2. Individual catechin/metabolite concentrations and standard deviations in plasma at rest (0−120 min) and after exercise (180 min) following GTE7, GTE1, and PLA supplementation. The red and blue curves indicate the total (conjugated + free) and free concentrations, respectively.

In total 32% (GTE7) and 30% (GTE1) (based on c_{max}) of all catechins were present in the free form, meaning that the majority of catechins circulate in plasma as glucuronates and sulphates (Table 2, Figure 2). Free catechins were mostly found in those that possessed a gallic acid moiety, including EGCG, ECG/CG, as well as GC and GCG contributing 57%, 33%, 47%, and 22% to their total concentrations in GTE7, respectively. In comparison, EGC, EC, and C mainly appeared in the conjugated form contributing 88%, 97%, and 90% to their total concentrations in GTE7, respectively.

Although our data did not allow for determining the bioavailability because of incomplete kinetic curves (no return to baseline), we estimated the concentrations of total catechins with respect to their concentrations in the GTE. For this, we calculated the sum of the plasma concentrations of all catechins that were measured within 3 h excluding the baseline levels (t = 0 min). Assuming a total blood volume of 5 L for a typical male and no differences in catechin concentrations between plasma and blood, only 0.47 ± 0.2% (GTE7) and 0.49 ± 0.17% (GTE1) of the total amount of ingested catechins (559 mg) were on the average retrievable in plasma within 3 h after GTE consumption.

No significant differences in free or conjugated catechin concentrations were observed between GTE7 and GTE1 following the intake of the single bolus drink on D8. There was also no significant difference in baseline values between GTE7 and GTE1, except for the higher concentration of ECG after 7-day GTE consumption when compared to 1-day GTE consumption (GTE7: 77 ± 56 ng/mL; GTE1: 30 ± 19 ng/mL; p = 0.016) .

The average t_{max} for the catechins was 60−120 min following ingestion, which coincided with the beginning of the exercise bout (120 min). The exercise bout did not appear to alter the catechin kinetics in the plasma, as represented in the final 60 min of the trial (120−180 min) (Figure 2).

The two gut microbial-derived valerolactones, 3,4-diOH-VL and 3-MeO-4-OH-VL, were present at baseline and only increased after 120 min following GTE supplementation on D8. They were only present in the conjugated form. In general, higher concentrations were observed for 3,4-diOH-VL than for 3-MeO-4-OH-VL. We also observed a large increase in 3/4-OMGA over the course of the trial with t_{max} between 90 and 120 min. Those subjects who ingested PLA also had an elevated 3/4-OMGA concentration throughout the trial, despite the significantly lower total catechin concentrations (Figure 2). Marginally elevated concentrations of 3MeO-4-OH-VL, 3,4-diOH-VL, and C were also observed in those subjects receiving PLA. This may be explained by the consumption of

other polyphenol food sources during the 24 h prior to the trial.[45]

Effects on Endogenous Metabolites Following Acute GTE Intake. Using 4-phase metabolite profiling and targeted analysis of 10 catecholamines, the relative concentrations of a total of 163 known, mostly endogenous metabolites were measured in plasma at baseline (t = 0) and 2 h after the single bolus intake on Day 8 (t = 120 min) under resting conditions. Differences between the concentrations at t = 120 min and t = 0 ($\Delta(t_{120} - t_0)$) were calculated for each metabolite and for each subject in the GTE7 and PLA groups to assess the pure acute effects of the single bolus intake without taking into account any baseline (chronic) effects due to the 7 day GTE supplementation. The multivariate analysis (PLS-DA) identified a significant discrimination between metabolite changes induced by GTE7 and PLA (Q^2 = 0.492 with a significance of 2.2%) (Figure 3). On the basis of the PLS-DA, a total of 27 metabolites were found to be the most important in driving the significant discrimination between GTE7 and PLA (Figure 3, panel D). In addition, t tests were performed on each metabolite resulting in 16 significant ($p < 0.05$) metabolite changes between the GTE7 and PLA groups. They were also found using PLS-DA. The discrepancy in the number of significant metabolite changes between multivariate (27) and univariate (16) statistical analysis may be explained by combined effects only observed in multivariate analysis. The changes of the 16 altered metabolites are visualized using box plots (Figure 4). Significant reductions were observed for hippuric acid and cholesterylesters (C16:0, C18:1, C18:2), while the concentrations of caffeine, salicylic acid, taurine, 3,4-

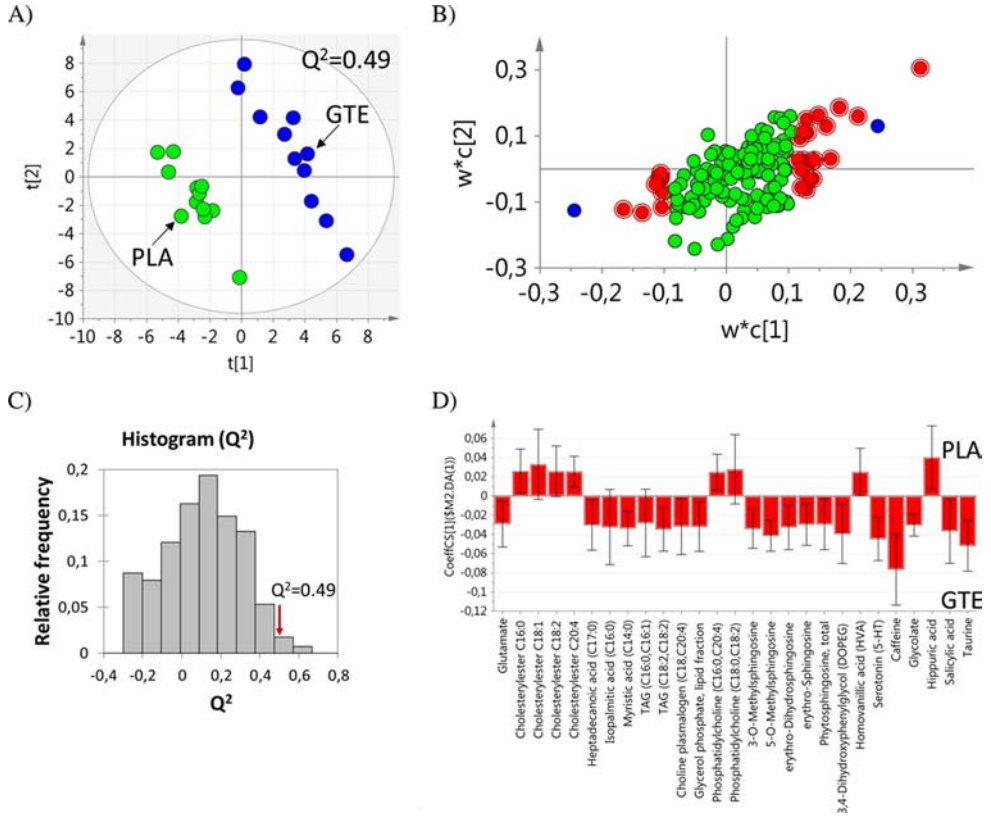

Figure 3. (A) PLS-DA score plot of PC-1PC-2 based on 163 metabolite concentrations and unit-variance scaling. The data represent differences between relative concentrations measured on D8 at time point t = 120 min and t = 0 min. The blue and green circles indicate the GTE7 and PLA treatment groups, respectively. R^2X = 0.184, R^2Y = 0.972, Q^2 = 0.492. (B) Loading plots (w*c) for PC1 and PC2; green/red and blue circles indicate the x- and y-loadings, respectively. (C) Histogram of Q^2-values of 999 models from randomly permuted data. (D) Coefficient plot of PC1 including only the most important variables as selected from loading plot (panel B, red circles).

dihydroxyphenylethylene glycol, serotonin, TAG (C16:0, C16:1), TAG (18:2, C18:2), sphingosines (3-*O*-methylsphingosine, 5-*O*-methylsphingosine, *erythro*-dihydrosphingosine), and fatty acids (C17:0, C14:0) were significantly increased 2 h after the single bolus intake of GTE when compared to PLA.

Correlation between Exogenous and Endogenous Metabolites. To investigate which catechin/metabolite potentially induced an effect on an endogenous metabolite, a Pearson correlation matrix was calculated based on the $\Delta(t_{120} - t_0)$ values of total, free, and conjugated (conj = total − free) catechin/metabolites and the endogenous metabolites that significantly changed after the single bolus GTE intake on D8. Several strong positive ($R > 0.72$, $p < 0.01$) and negative ($R < -0.72$, $p < 0.01$) correlations between the endogenous and exogenous metabolites were observed, which are shown in Figure 5.

DISCUSSION

In this study we found that the ratios of the maximum concentrations in plasma to the concentrations in the GTE supplement relative to the total catechins, respectively, followed the order: ECG/CG > EC > GCG > EGCG > EGC > C > GC. Another key outcome of the present analyses is that EGCG, CG/ECG, GC and GCG in their free form contributed 57%, 33%, 47% and 22% to their total plasma concentrations, respectively, while EGC, EC, and C mainly appeared in the conjugated form. We also observed significant effects on 16 mostly endogenous metabolites 2 h after the intake of a single bolus drink of GTE, when compared to PLA. These included reductions in hippuric acid and cholesterylesters (C16:0, C18:1, C18:2) and increases in caffeine, salicylic acid, taurine, 3,4-dihydroxyphenylethylene glycol, serotonin, TAG (C16:0, C16:1), TAG (18:2, C18:2) and sphingosines (3-*O*-methylsphingosine, 5-*O*-methylsphingosine, *erythro*-dihydrosphingosine) and fatty acids (C17:0, C14:0).

Catechin Kinetics in Plasma. Our results on the catechin/metabolite concentrations in plasma are in agreement with previous studies, while also extending the current literature on GTE bioavailability through the comprehensive investigation of seven catechins, 3/4-OMGA, and two gut microbial-derived metabolites. We showed that GTE7 and GTE1 resulted in similar transient increases in both total and free catechins when compared to PLA over the course of a 180-min trial (Figure 2). As previously shown,[15,25,46] t_{max} was observed between 60 and 120 min following a single bolus of GTE on the final day of supplementation (Day 8), which was similar for GTE7 and GTE1 (Figure 2). This illustrates that catechins in general did not accumulate in the circulation following GTE7, despite the longer supplementation duration. In agreement, Chow et al.[15] have shown that 4 weeks of 400 mg/day EGCG or polyphenol E did not alter the AUC for free or total EGCG, EGC, and EC. Also in this study, the ratio of free to conjugated catechins were virtually identical in the GTE1 and GTE7 groups, indicating that 7 days of supplementation did not affect the catechin metabolism by, for instance, inducing metabolizing enzymes that would result in a higher percentage of conjugated catechins with respect to free catechins. At baseline, only ECG was increased after 7-day GTE supplementation when compared to

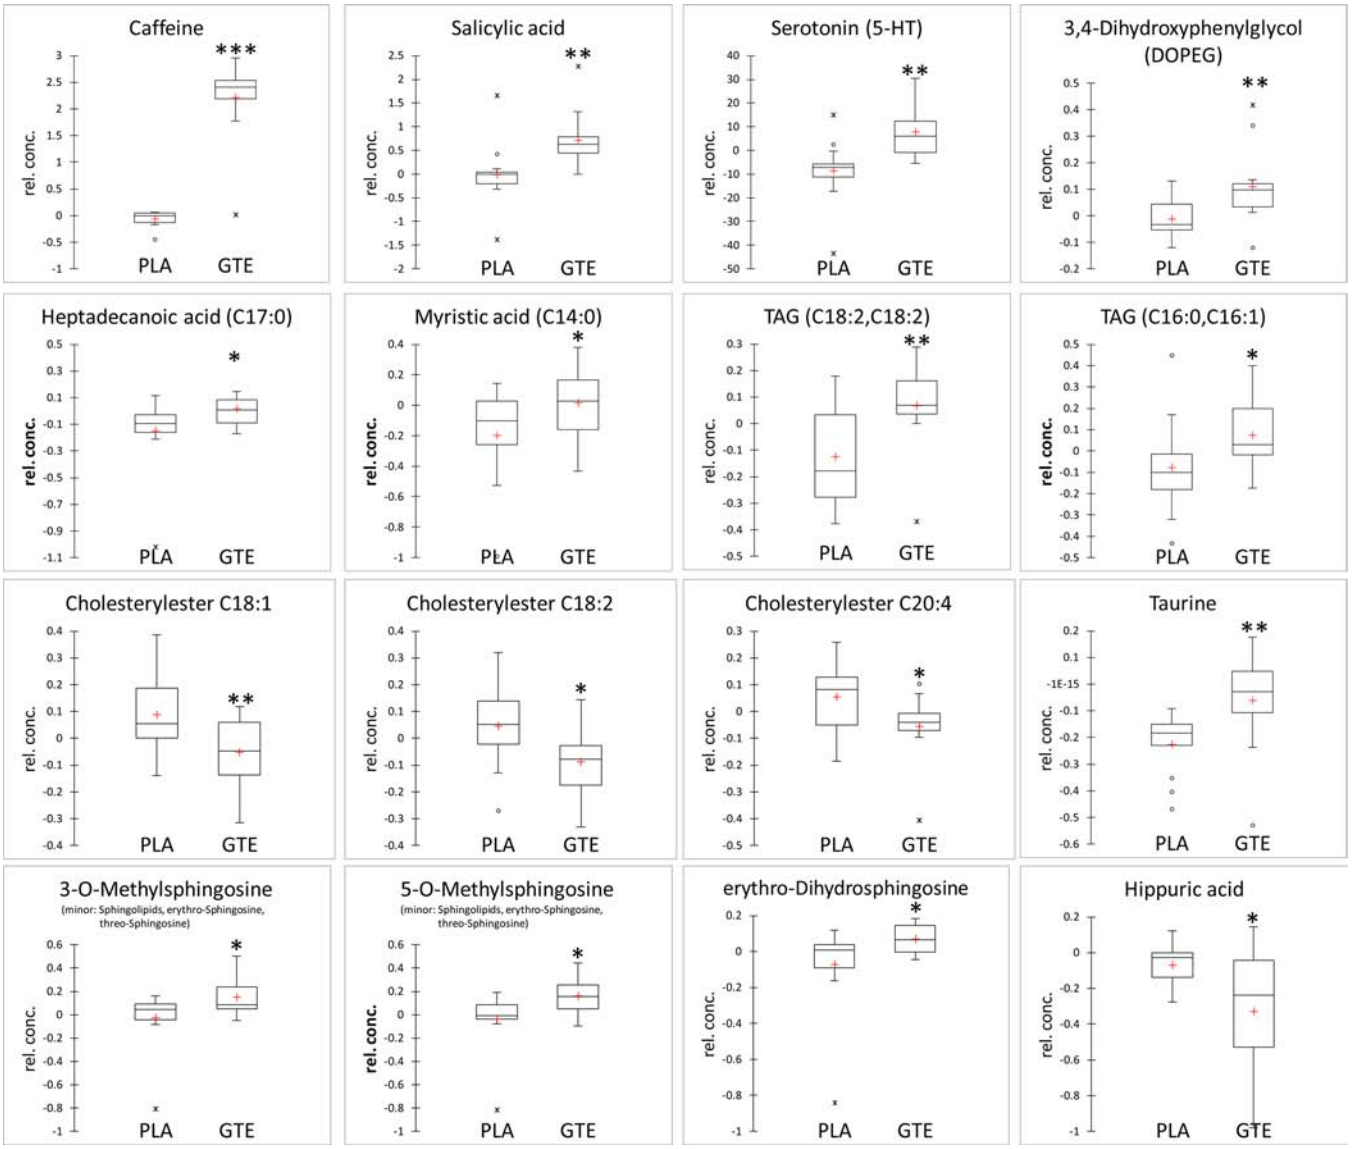

Figure 4. Box plots of the most important metabolites that contribute to the PLS-DA discrimination between the GTE7 and PLA supplementation. (* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$). The boxplots were calculated on the differences between relative concentrations measured on D8 at time point $t = 120$ min and $t = 0$ min.

1-day GTE supplementation, which is in line with a recent study also showing high levels of ECG in fasting plasma after chronic consumption.[16] We estimated that only 0.48% of total ingested catechins reached the circulation within 3 h after tea consumption suggesting poor bioavailability, which has also been proposed by others.[28] EGCG, as previously shown,[28] had the highest c_{max} when compared to the other catechins. Interestingly, C and GC were found at lower concentrations in the circulation, while ECG/CG and EC were present at higher concentrations in plasma when compared to their relative concentrations in the GTE supplement. The relatively better absorbance of ECG is in agreement with a recent study.[16] In contrast, a higher relative bioavailability of EGC compared with that of EGCG as shown in other studies[25,47,48] could not be confirmed in this study. However, it is well-known that variations in the plasma concentrations of the individual catechins depend on the dose, the composition of the green tea, the food format, and the study population.[14,48] Further, catechins were also converted by gut microbiota to 3,4-diOH-VL and 3MeO-4-OH-VL in the colon, with 3,4-diOH-VL being the more abundant metabolite. Both microbial metabolites appeared later in the plasma when compared to catechins with an onset at 120 min. These results are in agreement with the previous findings.[49,50]

While the bioconversion of catechins to their conjugated metabolites in vivo is well understood, fewer studies[15,16,25,51,52] have assessed the plasma concentrations of free catechins that may display different biological activity when compared to their glucuronides and sulphates.[53] The free catechins are those that escape phase II metabolism and appear in the circulation.[28] We found that 68−70% of all catechins appeared in the conjugated form. In agreement with other studies,[15,25,54,55] the catechins C, EGC, and EC were predominantly in the conjugated form, contributing 90%, 88%, and 97% to total catechin concentration, respectively. In contrast, the gallated catechins EGCG, ECG/CG, GC, and GCG underwent less conjugation, possibly because of their higher polarity and/or steric hindrance. Other studies[16,25,28] have found larger percentages of free catechins

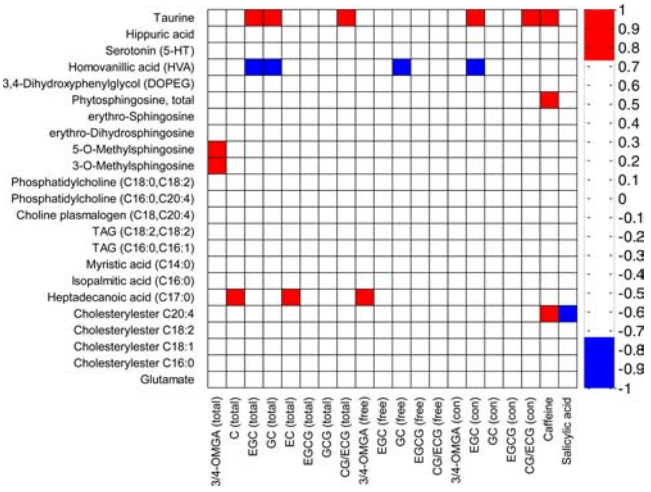

Figure 5. Pearson correlation matrix of total, free, and conjugated (conj = total − free) catechin/metabolites and endogenous metabolites that were most significantly affected by the consumption of a single bolus drink of GTE on D8. Only correlations $R > 0.72$ or $R < -0.72$ corresponding to $p < 0.01$ are displayed (red and blue colors for positive and negative values, respectively).

[ref 28: EGCG (100%); ref 16: EGCG (100%), EGC (30%), and ECG (75%); ref 25: EGCG (77%), EGC (31%), and EC (21%)] when compared to our study [EGCG (57%) ECG: (33%), EGC (12%), EC (3%)]. In contrast, Kotani et al.[51] have found GCG to be mostly (91%) present in the conjugated form, while we found GC and GCG to be present mostly in the free (53% and 78%, respectively) form. Further investigations are needed to explain these inconsistent results.

Metabolite Changes Following Acute GTE Intake. In addition to the metabolism of GTE catechins already being well understood, we explored the effects on the endogenous metabolism at a time point when the catechin/metabolites were at their maximum concentrations in plasma. Significant changes in 16 metabolites were found when comparing the concentrations of 163 metabolites 2 h after the intake of a single bolus of GTE or PLA (Figures 3 and 4).

As expected, caffeine was increased, because the GTE contained 120 mg of caffeine. Caffeine has been shown to peak 1 h following intake.[18] Furthermore, salicylic acid was found to be significantly increased in plasma following the single bolus intake of GTE, which has not been documented to date. Salicylic acid has been identified in green tea infusion[56] and thus may be considered as exogenous metabolite. Salicylic acid also is a hydrolysis product of acetyl salicylic acid (ASA), otherwise known as aspirin. The metabolic effects of salicylic acid in vivo are largely unknown. Salicylic acid is capable of yielding hydrogen peroxide, which in vitro has been shown to activate numerous signaling molecules that are associated with mitochondrial biogenesis, namely, sirtuin 1 (SIRT1) and proliferator-activated receptor-gamma coactivator-1-α (PGC1-α).[57] The up-regulation of these signaling pathways in the skeletal muscle over time (through pharmaceutical, exercise, and nutritional interventions[58,59]) causes mitochondrial biogenesis, fiber type transformation, and greater capacity to oxidize fat.[60] Similarly, chronic GTE has also been suggested to regulate the signaling pathways that regulate mitochondrial content and substrate metabolism in vitro[61] and in animals at rest[62] and in combination with endurance exercise training.[63] In contrast, Deschamps et al.[64] have shown that a single dose of salicylic acid fed to mice at high concentrations led to significant reductions in long chain fatty acid oxidation. The authors also showed that hepatic triglyceride concentrations was significantly increased following salicylic acid, which may provide indirect evidence for the elevated TAG concentration (TAG C16:0, C16:1; TAG C18:2, C18:2) observed in the current study (Figure 4).

Interestingly, we found significant reductions in several cholesterylesters (C16:0, C18:1, C18:2, 20:4) 2 h after the GTE intake, which is in line with the hypocholesterolemic effect of tea catechins suggested earlier based on a study in rats.[65] A more in-depth investigation has attributed the hypocholesterolemic effect to the inhibition of intestinal cholesterol absorption and specifically to gallated tea catechins.[39] Further evidence has been provided by an in vitro study showing that gallated catechins are potent and selective inhibitors of rat squalene epoxidase, a rate-limiting enzyme of cholesterol biogenesis.[66] It has also been shown that EGCG but no other green tea catechins reduced the activity of an ileal transporter, namely, apical sodium-dependent bile acid transporter (ASBT), which is responsible for reabsorption of bile acids.[67] Alternatively or in addition, a decrease in intestinal lipid absorption by GTE catchins, especially EGCG,[68] may be due to the inhibition of pancreatic phospholipase A_2, an important enzyme interfering with the intestinal hydrolysis of phosphaditylcholines, which has been demonstrated in an animal study.[69] Interestingly, two phosphatidylcholines (C16:0, C20:4; C18:2, C18:2) were also reduced in the current study upon the consumption of a single bolus GTE drink. The acute effects on the cholesterylesters and phosphaditylcholines found in the current study are most likely transient, because these effects were not retained after 7-day supplementation.[43] However, it remains unclear whether the cholesterol lowering effects observed after long-term supplementation of green tea[70] may at least partially be explained by reduced lipid absorption.

In the current study we also observed that the intake of a single bolus GTE induced a significant increase in taurine when compared to PLA. Taurine has important metabolic roles in health and disease, for example, leading to improved insulin sensitivity,[71] cholesterol metabolism,[72] and fat metabolism.[73] Yet, taurine adopts many diverse biological functions such as conjugation of bile acids, membrane stabilization, osmoregulation, and neurotransmission, and therefore the implication of our finding is unclear. Similarly, serotonin is a polyfunctional signaling molecule acting, inter alia, as neurotransmitter and vasoconstrictor. The increase in serotonin found in the current study may thus entail effects on blood pressure, mood, appetite, and sleep. Remarkably, several sphingosines were increased upon acute GTE intake. Sphingosine can be produced from ceramides and further phosphorylated to potent signaling lipids. Although the functions of individual spingosines are largely unknown, it has already been suggested that alterations in sphingolipid biology play a pivotal role in regulation of vascular function.[74]

Identification of Potential Bioactive GTE Catechin/Metabolites. To date the bioactivity of specific catechins in vivo has lacked research. Furthermore, while in vitro evidence provides insight into the bioactivity of specific catechins in various cell lines, many investigations have used supra-physiological concentrations of catechins in the free form (5−50 times greater than in human plasma). These studies therefore provide an unrealistic physiological environment to what would be seen in human plasma, let alone in human

dx.doi.org/10.1021/jf404872y | J. Agric. Food Chem. 2014, 62, 1198−1208

cells.[75] Therefore in an attempt to provide new insights into the bioactivity of specific catechins in humans, we examined the in vivo association between the transient increases in GTE catechins and those significant metabolite changes (Figure 5). Besides a few consistent correlations, namely, the correlations between total and conjugated EGC and ECG/CG and taurine, only scattered correlations and no clear patterns were observed, suggesting that there is no straightforward relation between exogenous and endogenous metabolites in plasma. Interestingly, a clear superiority of EGCG or gallated catechins did not become apparent, although EGCG has been identified as the most pharmacologically active catechin[76] and gallated catechins are considered to be more potent at inducing the metabolic effects in vitro.[31,39] Considering that metabolite concentrations in plasma represent the spillover of many effects occurring in diverse tissues and cells, clearer relationships may be found in specific cells and tissues where catechin/metabolites exert their bioactivity. Another limitation of the correlation analysis is that associations do not necessarily imply causations. Nevertheless, the current study highlights the need for future studies to examine the metabolic effects of specific catechins, especially in vivo or alternatively in vitro using physiological doses and forms of catechins found in vivo.

In conclusion, this study confirms and extends our current knowledge regarding the transient increases in 10 catechin/metabolites in plasma following acute GTE intake. In particular, the concentrations provided in both the free and total (conjugated and free) form delivered deeper insight into the different species circulating in blood. This information can still be refined by identifying the conjugation pattern of the catechin/metabolites similar to a study by Stalmach et al., who have already quantified 16 different methylated, sulphated, and glucuronidated conjugates of (epi)catechin and (epi)-gallocatechins.[52] This list still is incomplete, in particular with respect to gut microbial metabolites. This warrants further investigations including study designs with longer sampling periods and using sensitive high-resolution mass spectrometers that are capable of covering in an untargeted manner a wider range of the catechin/metabolites.

Furthermore, the current study demonstrates that a single bolus dose of GTE intake induced significant acute effects on diverse endogenous metabolites when compared to PLA. These acute effects differed from the metabolic effects observed after 7-day supplementation of GTE,[43] suggesting that the acute metabolic effects may be subject to different mechanisms or that long-term GTE supplementation is required for progressive regulation of various proteins and enzymes at certain sites in the body leading to systemic shifts on the endogenous metabolites. The diversity of these metabolites possibly indicates that GTE catechin/metabolites target different pathways. The changes in cholesterylesters and phosphatidylcholines may point toward changes in lipid metabolism. Other changes, such as those in sphingosines, sertonine, and salicylic acid may be related to vascular function. Overall, however, there is still too little known about the importance of specific metabolite changes in plasma to physiology. In addition, as many of the observed effects were subtle, the present results should be confirmed in further studies, as an initial step toward building systematic hypotheses on structure-physiology relationships.

IMPLICATIONS

Applications for the future of food and agriculture are exciting to consider, but a look at the current literature reveals a precautionary note struck by researchers. Implications involve risks for both the environment and organisms within that environment (including humans). Researchers in this area are studying hazards by examining the harm done when nanomaterials reach the nanobio interface. They are also studying exposure by determining how ENMs transport in the environment, how ENMs might accumulate, the types and quantities of ENMs we are currently exposed to through products we already consume, and what the fate of those materials might be in our digestive tracts.

Researchers have asked the following questions: How do we measure the ecotoxicity of these emerging technologies? How do we make these technologies safe/ How do we make these technologies sustainable?

Reviews of econanotoxicology found in this ACS Select describe the challenge of quantifying the hazards of ENMs that vary in size, shape, surface area, and coating to a wide variety of organisms ranging over several trophic levels. The researchers' goal is to understand how to make these ENMs more sustainable before full-scale release to the environment. Zhu et al. summarize the current understanding of the cellular uptake, intracellular fate, and transformation as affected by the physicochemical properties of ENMs and suggest that the advancement of research in this field along with better analytical capabilities and in silico simulation may lead to safe-by-design ENMs.[7] Mauer-Jones et al. discuss three grand challenges for chemists involved in econanotoxicity work: functional level toxicity assessment; detecting ENMs and distinguishing them from the background particles; and particle characterization in complex environments.[8] In addition, Kahru et al. review the econanotoxicological research done on aquatic species concluding that although computational methods such as quantitative structure−activity relationships (QSARs) are attractive for solving the problem, too many material types and too many organism types make these relationships difficult to apply due to lack of quality experimental data.[9] As a new approach to this problem, in their review Holden et al. propose high-throughput screening integrated with dynamic energy budget models.[10]

Whether nanoparticles are intentionally applied during agricultural processes or they are present as contaminants, it is important to understand what effects they will have on plants and more specifically plants grown for food. To investigate this question, Dimpka et al. amended sand with silver nanoparticles and grew wheat plants, disrupting the growth of shoots and roots in a dose-dependent manner.[11]

Ma et al. performed a similar study utilizing *Arabidopsis thaliana* and either CeO_2 or In_2O_3 nanoparticles. The physiological and molecular responses were different between the two particles, with CeO_2 inhibiting root and shoot growth in a dose-dependent manner (concentrations ranged from 0 to 2000 ppm).[12] Reviewing the direct and indirect effects of many different types of ENMs on algae, a species at the bottom of the ocean food web, Quigg et al. noted that the presence of exopolymeric substances produced by the organisms play a major role in the toxicity demonstrated by the particles.[13] In addition, they discuss how little is known about the biological uptake mechanisms and toxicity of nanoparticles in general.

Nanomaterial fate in the environment is discussed by Bately et al., who suggest that currently there is low risk of exposure, that the concentrations reaching the nanobio interface will be very low, and that work needs to be continued on studying toxicity under real environmental conditions to define no-effect concentrations.[14]

Although environmental concentrations may be low, there is a risk that these materials will accumulate in certain receptors and compartments, resulting in much higher concentrations. Three studies found in this ACS Select examine the potential for bioaccumulation. Metallic and metal oxide ENMs can be measured in samples taken from plants using X-ray fluorescence; using this technique, Hernandez-Viezcas and coauthors examined whether soil contaminated with zinc oxide and cerium oxide ENMs results in a bioaccumulation of particles in soybean crops.[15] Their results indicate that changing particle types will alter how they interact with the plant and whether or not they will accumulate. Using a transmission electron microscopy approach, Wang et al. demonstrated that copper oxides will bioaccumulate in maize plants translocating from the roots to the shoots and back again.[16] Another important process that is just beginning to be studied is trophic transfer, the movement of pollutants up the food chain. A simulated transfer of soil contaminated with gold nanoparticles to earthworms and subsequently to bullfrogs undertaken by Unrine and coauthors showed that this transfer does occur, but concentrations decrease by 2 orders of magnitude with each step.[17]

Humans are exposed to ENMs through food consumption. What is the current level of exposure? How are we processing them once they enter our digestive systems? Two research papers highlighted in this ACS Select ask these questions by examining the titanium dioxide found in food products already on the market and performing an in vitro study designed to simulate digestion of products containing a silica nanoparticle additive. Analysis by Weir et al. showed that children may have the highest exposure level to titanium dioxide in food because candy products contain a relatively high concentration of the material.[18] When silica ENMs enter our digestive systems, Peters and coauthors showed nanoscale particles could appear in the gut epithelium after digestion in the stomach, cause for concern and further research.[19]

Scientists agree that although nanoscale technology is promising for food and agriculture, the development must be done in a sustainable manner. Governments, through existing regulations, will play a large part of this development. It was through this lens that Bergeson examined if existing laws are sufficient to govern ENM development in a sustainable manner; because the state of knowledge is still playing catchup, development entities involved in regulation must adapt new procedures to promote sustainability.[20]

Despite the fact that the environmental health and safety of some ENMs have been extensively studied in the past decade, as evident in this issue of ACS Select, knowledge gaps still widely exist in many aspects including

- measurement and metrology of ENMs in complex matrixes;
- environmental fates and transformation of currently known ENMs and ever-increasing number of new ENMs;
- nanobio interface between ENMs with human body and ecosystem species;

- exposure and full life cycle assessment;
- risk assessment and management of diverse uses of ENMs;
- safety by design; and
- sustainable nanomaterials and nanomanufacturing.

Predictive models for the effects of nanomaterials on cells/living tissues have shown promise but still have a long way to go to be fully useful. High-throughput and high-content screening approaches using model biological species may be used to more effectively reveal mechanisms of nanomaterials safety. Nanoinformatics for nanomaterials design, data integration, and communication is an emerging field of study. In addition, risk governance of nanotechnology for societal benefit is still in a formative stage.

CONCLUSION

Nanoscale science is an exciting scientific frontier focusing on the length scale of approximately 1−100 nm. Advancement of analytical instrumentation has tremendously enhanced our ability to observe physical and biological worlds at the nanoscale and lead to creation of numerous new materials and functions at this length scale. Emergence of novel concepts and discovery of unexpected properties stimulate new approaches in traditional scientific disciplines. Combining these developments with the need to feed a predicted 9 billion people by 2050 establishes the intersection of nanotechnology, food, and agriculture as a research priority in the coming years.

Many applications of nanotechnology have been explored across the whole spectrum of national economic sectors, including agriculture, food, forest, and the environment, with demonstrated societal benefits. In the vast literature of nanoscale science, engineering, and technology, the majority is of discovery and application nature, whereas a relatively small portion, one estimate at <15%, in implication. Nanotechnology has been an essential megatrend in science and engineering worldwide and will continue its exponential growth in R&D as the primary science and technology platform in the years ahead. Given that nanotechnology is still in its formative stage in many regards, it is anticipated that fundamental and application-related publications will dominate the literature, whereas implication-related papers will continue to grow to fill knowledge gaps and become more effective supports to regulation and policy development for the safety and health of consumers and ecosystem. We invite researchers to continue submitting their works to ACS journals and reading the excellent works of their colleagues. A bright future through exploration and exploitation of nanoscale science, engineering, and technology indeed lies ahead for the benefit of a sustainable society.

tion,[16] the molecular mechanism of atherosclerotic modulation in balloon injury is unclear. The first aim of this study is that we will elucidate the effect of EGCG on balloon injuries and angiotensin II-induced aortic VSMCs and also investigate the aortic lumen, neointimal formation, and molecular modulation.

The therapeutic approach for controlling atherosclerotic formation, compared with conventional angioplasty or agents, is adjunctive intervention using natural phytochemicals. The second aim of this study is that we investigate the effects of EGCG potential phytochemicals on attenuation of the atheroma progression. Results from the molecular mechanisms of EGCG identified in the aortic neointimal formations of rats, and VSMC culture studies, strongly support our findings regarding the control of human cardiovascular diseases.

MATERIALS AND METHODS

Chemical Reagents. (−)-Epigallocatechin gallate (EGCG) with high purity (>98%) was purchased from Wako Pure Chemical Industry (Osaka, Japan). Dulbecco's modified Eagle's medium (DMEM) was purchased from GIBCO (Invitrogen Co., Grand Island, NY, USA). Angiotensin II (Ang II) was obtained from CytoLab Ltd. (Rehovot, Israel), and trysolol (aprotinin) was purchased from Bayer CropScience Co. Ltd. (Leverkusen, Germany). Dimethyl sulfoxide (DMSO), penicillin, and streptomycin were obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Matrigel basement membrane matrix was acquired from Becton Dickinson (Bedford, MA, USA). Antibodies were purchased from R&D Systems (Minneapolis, MN, USA), Cell Signaling Technology, Inc. (Beverly, MA, USA), or Santa Cruz Biotechnology, Inc. (CA, USA). SP600125 (a potent, cell-permeant, selective and reversible inhibitor of JNK, 25 μmol/L), SB203580 (a highly specific cell-permeant inhibitor of p38 MAPK, 3 μmol/L), and PD98059 (extracellular-signal-regulated kinase, ERK, 50 μmol/L) were purchased from Calbiochem (Merck, Darmstadt, Germany). EGCG was dissolved with DMSO, and the DMSO concentration was below one thousand.

Small Interfering RNA (siRNA) Design. The rat leptin mRNA was designed by siRNA duplexes targeting (GenBank accession no. NM144741). The most effective siRNA duplexes were initially screened, and then the 25-nucleotide RNAs were synthesized by in vitro transcription (Invitrogen). Further experiments were evaluated with the most efficient siRNA duplex. No significant similarities to any genes other than leptin were found using BLAST against the rat reference sequence database.

Vascular Smooth Muscle Cell (VSMC) Culture. Primary cultures of VSMCs were incubated by the explant technique from the thoracic aorta of 220−260 g male Wistar rats, as documented previously.[13] The animal experiments approved and carried out in accordance with the Guide for the Care and Use of Laboratory Animals published by the U.S. National Institute of Health (NIH Publication no. 85-23, revised 1996). Adult Wistar rats were anaesthetized with isoflurane (3%) and subjected to a balloon catheter injury of the right carotid artery as described previously.[17] To test the effect of (−)-epigallocatechin gallate (EGCG) on vessel remodeling after balloon injury, EGCG at 50 mg/kg of body weight was given by oral gavage for 2 weeks after balloon injury.

Immunohistochemical Analysis. The carotid artery was harvested, and fixed in 10% formaldehyde and sliced into 5-μm-thick paraffin sections. Immunohistochemical staining analysis was performed as previously described. [18]

Migration Assay. The migration assay was performed as previously described.[19] Briefly, 250 μL of Matrigel was coated onto each well of a 24-well multiple-plate Boyden chamber (BW 200s; Neuroprobe, Cain John, MD, USA) with polycarbonate filters (pore size, 8 μm) and then incubated at 37 °C for 30 min. Then, 5×10^4 VSMCs were implanted onto each of the upper Boyden chamber's wells, and EGCG-, leptin siRNA-, SP600125-, SB203580-, and PD98059-treated medium was filled in the lower chamber to a total volume of 1 mL. After 18 h of incubation at 37 °C and 5% CO_2, the Matrigel was removed. Then, cells that had migrated to the reverse side of the filter (upper chamber) were stained with Liu's stain solution (Handsel Technologies, Inc., Taipei, Taiwan). Following a photograph of four randomized visual fields, the percentage of cell migration was measured by counting the number of VSMCs that had migrated through the membrane. The data is presented as percentages of control.

Proliferation Assay. The VSMCs proliferation was determined using the [^{3}H]-thymidine incorporation assay. Vascular smooth muscle cells were seeded on a ViewPlate (Packard Instrument) for 60 min at a density of 5×10^3 cells per well in serum-free medium and incubated overnight. Angiotensin II (Ang II), EGCG, leptin siRNA, SP600125, SB203580, PD98059, and DMSO were then added to the plates. Thymidine uptake was measured by the addition of 500 nCi/ml [^{3}H]-thymidine (Perkin-Elmer, Boston, MA). The detailed procedure was performed as previously described. [18]

Electrophoretic Mobility Shift Assay (EMSA). Oligonucleotide sequences included the AP-1 (activating factor 1) consensus binding region (5′-CGCTTGATGACTCAGCCGGAA-3′) and the AP-1 mutant oligonucleotide sequence (5′-CGCTTGATGACTTGGCCG-GAA-3′). After annealing, these double-stranded oligonucleotides were labeled with (γ-^{32}P)-ATP probes by T4 polynucleotide kinase (Mission Biotech Company, Taipei, Taiwan). In each case, controls were performed in which mutant oligonucleotides competed with the labeled sequence. The detailed procedure was performed as described previously.[19]

Quantification of Leptin Protein. Leptin antibodies were purchased from Oncogene (San Diego, CA, USA). VSMCs were grown to confluence and subsequently stimulated with or without Ang II. Western blot analyses were performed as previously documented.[18]

RNA Isolation and Reverse Transcription. RNA was isolated from cells using the single-step acid guanidinium thiocyanate/phenol/chloroform extraction method. RNA isolation and reverse transcription were performed as previously described.[18]

Statistical Analysis. The data were expressed as the mean ± SD of three replicates from four separate experiments. Statistical significance was determined by analysis of variance (GraphPad Software Inc., San Diego, CA, USA). The Dunnett's test was used to compare multiple groups to a single control group. The Tukey−Kramer comparison test was used for pairwise comparisons between multiple groups after the ANOVA. A value of $P < 0.05$ was considered to be statistically significant.

RESULTS

EGCG and Leptin siRNA Attenuates Intimal Thickening and Increases Lumen Size after Carotid Artery Balloon Injury. Carotid artery balloon injury sustained for 14 days significantly increased the thickness of the intimal area and narrowed the vascular lumen, compared with the uninjured control group (Figure 2A, left panel). Leptin siRNA and (−)-epigallocatechin gallate (EGCG) treatment significantly attenuated the thickness of the intimal area after balloon injury. The thickness of the intimal area decreased 53.4% with leptin siRNA delivery and 40.7% with administering EGCG treatment (Figure 2B). The control siRNA (scrambled siRNA) did not reduce the thickness of intimal area induced by balloon injury. Leptin siRNA delivery and EGCG treatment similarly and both significantly increased the vessel lumen size after balloon injury. The lumen size increased 85.4% after delivering leptin siRNA, and 70.7% after administrating EGCG treatment (Figure 2C). The control siRNA did not change the lumen size after balloon injury. Immunohistochemical double staining demonstrated strongly leptin-positive labeled cells 14 days after carotid injury, whereas the intimal layer in the sham group did not express leptin (Figure 2A, right panel). Leptin siRNA and EGCG diminished the leptin and CD68 labeling signal intensity after carotid artery balloon injury (Figure 2D). Scrambled siRNA did

not alter the expression of leptin labeling after carotid artery injury.

Inhibitory Effect of Leptin siRNA, EGCG, and the JNK Inhibitor on VSMC Migration Induced by Ang II. We performed a cell migration assay to evaluate the effects of leptin siRNA, EGCG, and the JNK inhibitor on phenotypic alterations of VSMCs induced by Ang II. Ang II (10 ng/mL) treatment significantly augmented the migratory activity of the VSMCs. However, pretreatment with leptin siRNA, EGCG (100 μM), or SP600125 (JNK inhibitor) diminished the migratory activity of VSMCs induced by Ang II (Figure 3A,B).

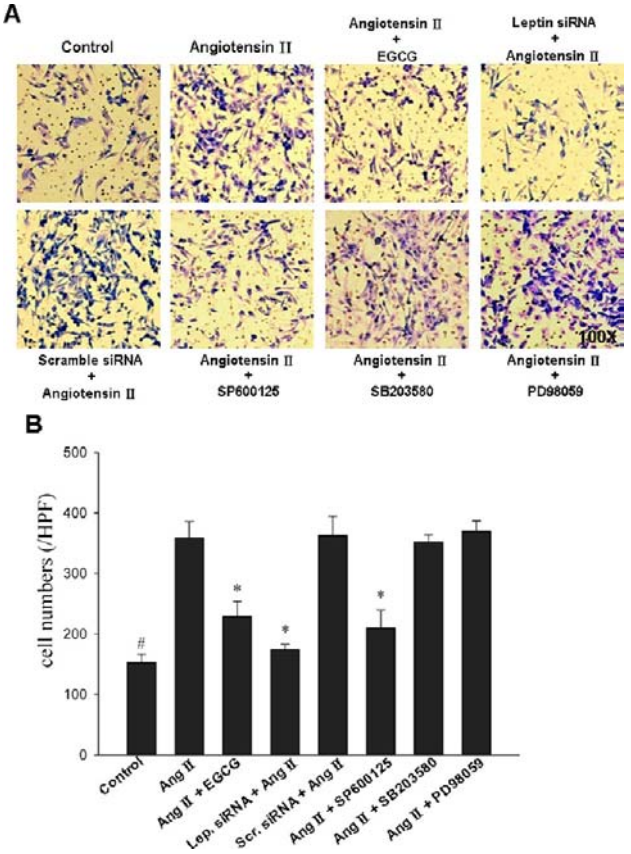

Figure 3. Effects of EGCG and leptin siRNA on migration activity of Ang II-induced vascular smooth muscle cells (VSMCs). Panel A: VSMCs migrated through Boyden chamber filters were stained. Panel B: Quantitative analysis of migration of VSMCs. VSMCs were treated with different agents for 18 h, and the migrating cells were then quantified (n = 4 per group). The assay was performed in triplicate. *, $P < 0.05$ when compared to the Ang II induced group. #, $P < 0.05$ when comparing the control group to the Ang II-induced VSMC (Wilcoxon rank sum test).

Attenuated Proliferation Effects of Leptin siRNA, EGCG, and SP600125 on VSMCs. We performed a [^{3}H]-thymidine incorporation assay to investigate the effects of leptin siRNA and EGCG on the Ang II-induced proliferation of VSMCs. Figure 4 presented that Ang II (10 ng/mL) treatment significantly increased the VSMCs proliferation. Pretreatment with leptin siRNA, EGCG (100 μM), or SP600125 attenuated the of VSMC proliferation induced by Ang II (Figure 4).

Suppressive Effects of EGCG on Balloon-Injury-Induced AP-1 Binding Activity, and the c-Jun Mediated Leptin-JNK Pathway. As shown in Figure 5, the EMSA indicted that balloon injury increased AP-1 DNA−protein

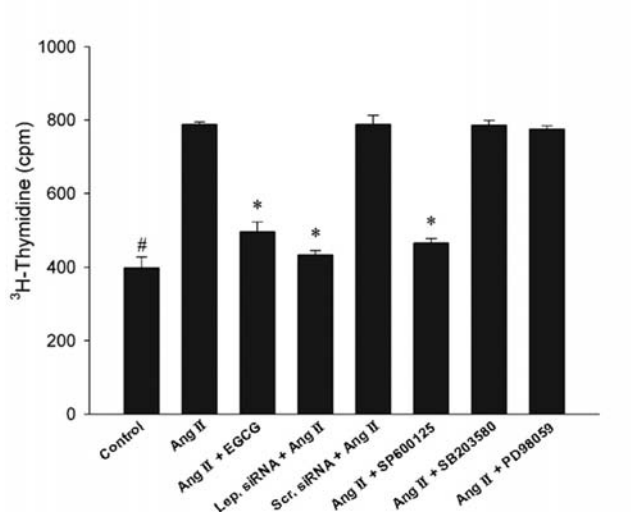

Figure 4. Attenuated proliferation of EGCG-treated VSMCs after Ang II induction. Representative [^{3}H]-thymidine incorporation assays showing the proliferation of VSMCs after Ang II (10 ng/mL) induction in the presence or absence of EGCG (100 μM), leptin siRNA, or JNK inhibitor SP600125 (n = 5 per group). The assay was performed in triplicate. *, $P < 0.05$ when compared to the Ang II induced group. #, $P < 0.05$ when comparing the control group to the Ang II-induced VSMC (Wilcoxon rank sum test).

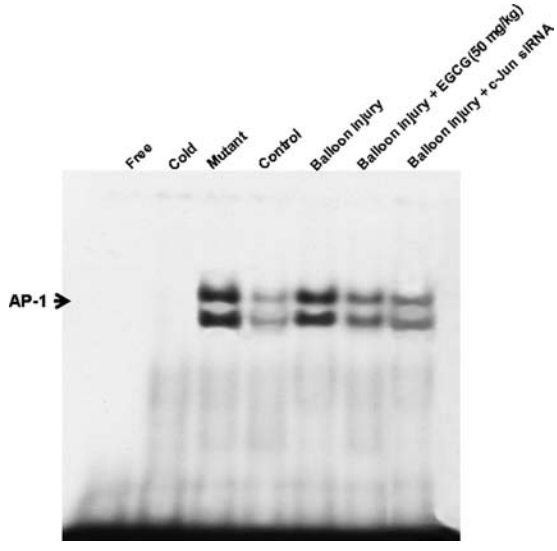

Figure 5. Balloon injury enhanced the AP-1-binding activity, and EGCG inhibited the AP-1-binding activity through JNK. Representative EMSA showing protein binding to the AP-1 oligonucleotide in nuclear extracts of VSMCs after carotid balloon injury sustained for 14 days. The assay was performed in triplicate.

binding activity, which reached its peak after 1 h. When an excess amount of the unlabeled probe with the AP-1 binding site competed with the isotope labeled probe, the binding activity decreased. An excess of the labeled probe with a 2-bp substitution at the AP-1 binding site did not reduce the AP-1 binding when competing with a nonmutated probe. The addition of EGCG (50 mg/kg) abolished the DNA−protein binding activity induced by balloon injury. The production of DNA-binding complexes induced by balloon injury can be supershifted by a monoclonal AP-1 antibody, indicating the presence of this protein in these complexes. These results

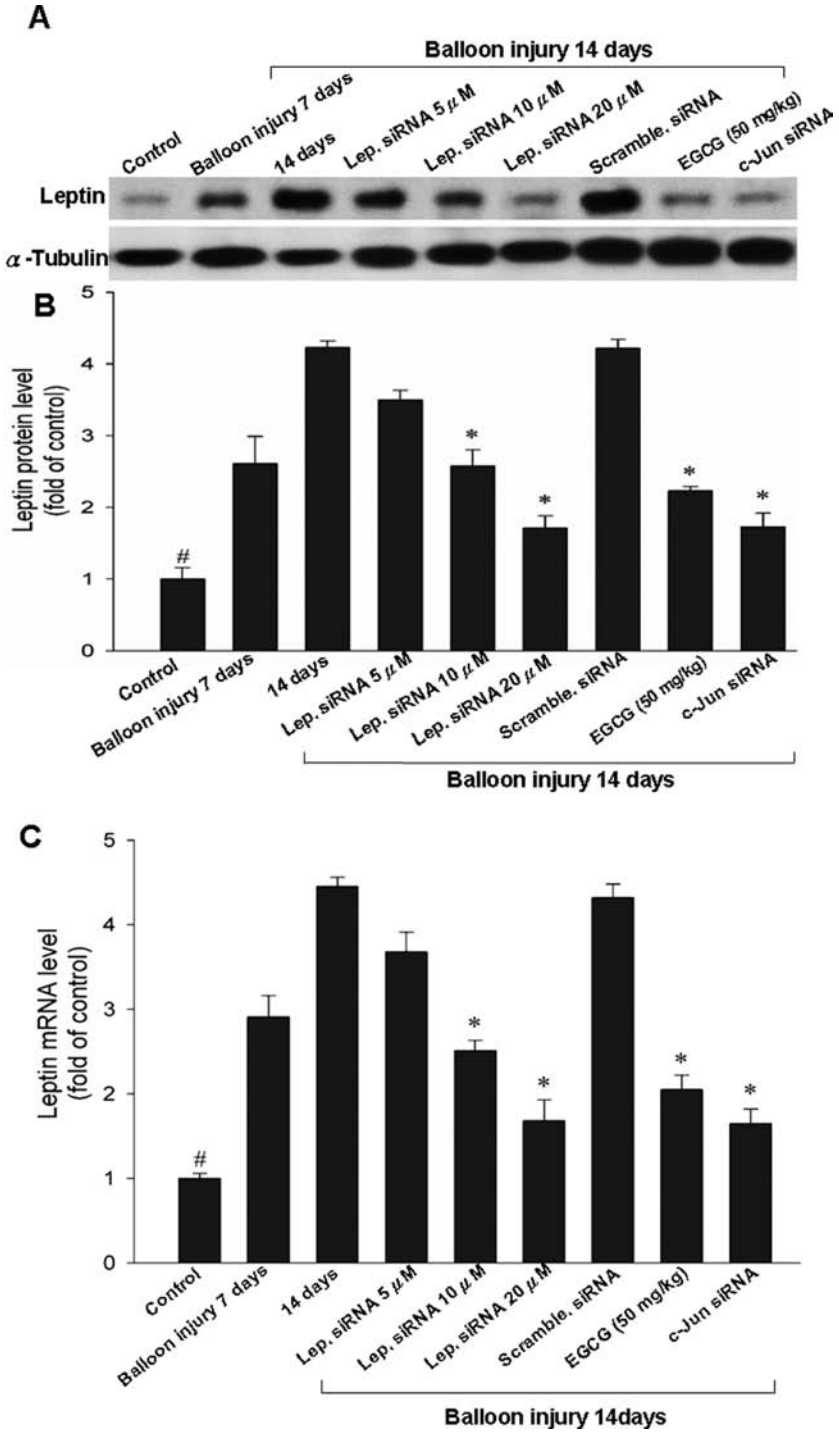

Figure 6. Effects of EGCG, leptin siRNA, and c-Jun siRNA on carotid artery leptin protein expression. Panel A: Representative Western blot for leptin in the injured carotid artery for 14 days with different doses of leptin siRNA. Panel B: Quantitative analysis of leptin protein levels. Panel C: Quantitative analysis of leptin mRNA by real-time PCR. The assay was performed in triplicate. *, $P < 0.05$ when compared to the balloon injury induced group. #, $P < 0.05$ when comparing the control group to the balloon injury group (Wilcoxon rank sum test; $n = 5$ per group).

suggested that the AP-1 binding site in the c-Jun is critical for transcriptional regulation by balloon injury and that EGCG regulates c-Jun activity through the JNK/AP-1 pathway.

EGCG-Induced Leptin Reduction through JNK. To demonstrate the efficiency of siRNA delivery into the carotid artery through electric pulses, control siRNA was labeled with Cy3 (cyanine 3) at the 5′-side (Invitrogen). The carotid artery was transfected with siRNA by using electric pulses, and successful transfection was evidenced by green staining observed under the fluorescence microscope at the area of intimal thickening 14 days after balloon injury (data not shown). After 7 and 14 days of balloon injury, leptin protein expression was significantly induced compared with the control group (Figure 6). Delivering leptin siRNA into the carotid artery after balloon injury reduced leptin protein expression in a dose-dependent manner. The most potent dose of leptin siRNA that reduced leptin protein expression after balloon injury was 20 μM (Figure 6A). No inhibitory effect of

dx.doi.org/10.1021/jf404479x | J. Agric. Food Chem. 2014, 62, 1213−1220

scrambled leptin siRNA on leptin protein expression was observed in the concentration-dependent manners. Daily EGCG treatment with 50 mg/kg of body weight significantly inhibited the leptin protein expression induced by carotid artery injury. Leptin mRNA expression was similar to leptin protein expression. Leptin siRNA and EGCG significantly reduced the leptin mRNA expression induced by balloon injury (Figure 6B).

DISCUSSION

EGCG was isolated from green tea, of which is the main polyphenolic constituent of green tea. Green tea has been used as a health-promoting remedy for thousands of years in China, and has rarely exhibited adverse effects during administration in both animals and humans. Recent studies have suggested that EGCG produces nutraceutical and medicinal benefits.[20,21] Increasing evidence from these investigations supports that EGCG has an antiatherosclerosis through the modulation of inflammatory pathways in various cells, such as EGCG supplemented olive oil improved endothelial dysfunction in early atherosclerosis and reduced leukocytes,[22] and the effect of EGCG on reduction of plasma IL-6 level, and NF-kappaB/AP-1 pathway in myocardial ischemia reperfusion injury in rats.[23] Compared with the model of EGCG-treated cardiovascular diseases, our balloon injury-induced model was used to mimic the pathphysiologic condition in the percutaneous angioplasty of vascular atherosclerosis. These studies have proved that EGCG inhibited neointimal formation through leptin modulation in cell cultures. However, the influence of EGCG on the expression of leptin and the molecular pathway is still unclear. Our study is the first to examine the effect of EGCG on intimal thickening and its molecular mechanism. Trovati et al. reported that leptin promotes atherogenesis through intracellular signaling molecules including JAK/STAT, PI3K/Akt, ERK 1/2, and p38 MAPK.[24] Tao et al. documented that perivisceral aortic leptin in ApoE(−/−) mice induced local aortic medial degeneration and augmented angiotensin II-induced aneurysm.[25] Our in vitro model is consistent with the existence of angiotensin II/leptin modulation in aorta or vascular smooth muscle cells.

EGCG has been reported to attenuate atherogenic regulation in both human aortic smooth muscle cells and macrophages through IL-6/MCP-1 and anti-inflammatory ROS systems.[26,27] Comparison with Won's study, pretreatment with EGCG inhibited the Ang II-induced phosphorylation of ERK 1/2, JNK 1/2, or p38 MAPK, and the presentation of c-jun or c-fos mRNA.[28] We investigated the effect of EGCG on attenuating rat aortic leptin expression, neointimal formation, Ang II-induced VSMCs and the molecular modulation of cell proliferation and migration. In our study, treatment with EGCG inhibited the selective JNK/AP-1 pathway (Figure 4A) but did not inhibit the MAPK, P38, or PI3K pathways. The novel presentation revealed that EGCG exhibited antiatherosclerosis in the carotid balloon injury model, the modulating mechanism suggested through the attenuation of inflammation. Furthermore, polyphenol resveratrol and quercetin interacted to inhibit neointimal hyperplasia in mice with carotid injury as well as VSMC proliferation and macrophage chemotaxis.[29] Polyphenol EGCG was reported to reduce evolving atherosclerotic lesions in apolipoprotein E−null mice.[30] When compared with these previous studies, our data displayed that EGCG attenuated significantly the neointimal formation and reduced aortic lumen narrowing after carotid balloon injury in rats.

A significant relationship between leptin and atherosclerosis has been reported, whereby modulated signaling is involved in endothelial function and smooth muscle cells, regulating numerous pathological processes, including vascular calcification and Ang II-induced VSMC activation and vasoconstriction.[13,31,32] Rapidly accumulating evidence has also revealed that leptin acts as a key cytokine in processing atherosclerosis in various cells. In previous studies, the daily administration of leptin to ob/ob mice after carotid artery injury with ferric chloride markedly increased neointimal thickness and the severity of luminal stenosis.[33] EGCG was used to treat atherosclerosis, whereas aortic leptin attenuation was not documented. We used EMSA to determine that EGCG inhibited the expression of leptin after balloon injury in a concentration-dependent manner (Figure 5). Additionally, in the cell migration/thymidine incorporation assay and molecular signaling analysis, the addition of EGCG, leptin siRNA, and the SB600125 inhibitor in Ang II-induced VSMCs showed that leptin contributed to the atherogenic process. The results of antimigration and signaling studies indicated that EGCG might particulate in crucial anti-inflammatory activity through the Ang II/leptin/JNK pathway.

Obesity accelerates vascular diseases; thus, the regulation of Ang II-induced leptin expression has been studied to focus on cellular molecular modulation.[34,35] Herbs, such as extracts of Chinese herb "Danshen" and Ginkgo biloba, have been shown to prevent atherosclerosis and restenosis in altering aortic lumen phenotypes after balloon injury.[36,37] In a previous plant study, the habitual consumption of green tea beverages reduced the incidences of cardiovascular events and reduced surrogate markers of atherosclerosis and lipid peroxidation.[38] Regarding dose, Chyu et al. reported that daily treatment with intraperitoneal injections of EGCG (10 mg/kg) reduced evolving atherosclerotic lesions without affecting the size of aortic sinus plaque or the aortic plaque size in apolipoprotein E−null mice.[30] In our study, EGCG (50 mg/kg) treatment eliminated atheroma formation, caused the experimental group to exhibit a similar aortic lumen size with the control group, and attenuated neointimal formation after carotid balloon injury in rats. The neointimal formation discrepancy between our data and previous studies on EGCG-treated aortic balloon injuries assumed to result from a concentration-dependent effect.

The data demonstrated that EGCG attenuated vascular smooth muscle cell (VSMC) migration and proliferation through the Ang II/leptin/JNK pathway by regulating the activation of transcription factor AP-1, thereby suppressing neointimal formation. Our study adds evidence to the claim that EGCG has therapeutic potential for preventing and controlling of atherosclerosis in future clinical applications.

(Millipore, Bedford, MA) water purification system. All other solvents and reagents used in the present study were of HPLC grade or analytical grade.

Preparation of Standard Solutions. A stock standard solution containing thiabendazole was prepared by weighing the analytical standard and dissolving it in methanol. One set of working standard solutions (0.01, 0.02, 0.1, 1, 2, and 5 mg/L) were prepared by diluting the stock solution or a working solution using methanol. All standard solutions were maintained in amber bottles at 4 °C.

Trials for Uptake Study. The application of thiabendazole was carried out by either spraying the pesticide directly on substrates (spraying treatment) or premixing thiabendazole with the substrates (premixing treatment). The substrates for shimeji and king oyster mushrooms consisted of cotton seed hulls (50%), corn cob (30%), rice bran (10%), and wheat bran (10%), and the amount of water was approximately 65%. The substrate for oyster mushroom consisted of cotton seed hulls (50%), corn cob (30%), rice bran (10%), and sawdust (10%), and the amount of water was approximately 70%.[17] Both nonsterilized and sterilized substrates were used in the study. The sterilization was carried out at 120 °C and 0.1 MPa for 2 h. Five substrates, i.e., one nonsterilized substrate and the four sterilized substrates, were treated with thiabendazole by either premixing or spraying treatment. In the spraying treatment, the suspension concentrate formulation containing 50% (w/v) of thiabendazole was sprayed on the substrates at the rate of 0.75 g a.i./m^2 using the JACTO-HD sprayer. In the premixing treatment, thiabendazole was premixed with the substrate at the ratio of 1:2500 (active ingredient:substrate, w/w). Then three edible fungi of mycelia were inoculated to the sterilized substrates which were treated with thiabendazole. Each experiment was carried out in a plot of 10 m^2.

The treated substrate samples were collected from each plot on days 0, 1, 3, 5, 7, 10, 14, 21, 28, 35, and 42 days after the application. The edible fungi were collected from each plot on days 3, 5, and 7 after producing mushroom. Based on the OCED guidelines,[18] the substrate sample was randomly collected from a minimum of 12 separate spots and the collected samples (total approximately 0.5 kg) were composted. In the mature stage, edible fungi samples (including pileus, stipe, and volva) were collected. Then, each of the three treated edible fungi samples (approximately 0.5 kg each) were separated into pileus, stipe, and volva, respectively. All samples were stored in individual polyethylene bags and stored a refrigerator at −20 °C until being analyzed.

Extraction and Cleanup. The analytical method for determination of the thiabendazole residues in the edible fungi parts and substrates was derived from the reference methods using the QuEChERS technique,[19−21] followed by LC−MS/MS analysis.

Extraction. Samples including fungus parts and the substrates were ground with dry ice before extraction. After the dry ice was sublimated, the ground sample (5.00 g) was weighted into an Erlenmeyer flask. Forty-five (45.0) mL of acetonitrile was added. The sample mixture was macerated using the homogenizer for 1 min. The probe of the homogenizer was rinsed with a portion of 5.0 mL of the extraction solvent (acetonitrile), and the rinsate was added to the extraction flask. The sample was transferred into a centrifuge tube containing anhydrous magnesium sulfate and mixed. The mixture was centrifuged at 10000*g* for 5 min. Then, a portion (5 mL) of the supernatant was transferred to a 15 mL plastic centrifuge tube for cleanup.

Cleanup. A QuEChERS packet containing 100 mg of PSA and 100 mg of ODS-C18 was added to the sample extract (5 mL of the supernatant). The sample mixture was vortexed for 2 min. After centrifugation (5 min, 10000*g*), a portion of the supernatant (1 mL) was transferred to another centrifuge tube and dried at 40 °C on the N-EVAP under a stream of nitrogen. The thiabendazole residues were dissolved in 1 mL of methanol. The extract was filtered through a 0.22 μm nylon filter into an autosampler vial. The sample was analyzed using LC−MS/MS.

LC−MS/MS Analysis. The LC−MS/MS analysis was carried out using the Agilent LC−MS/MS. The parameters used were as follows: mobile phase A, water containing 0.1% of formic acid (v/v); mobile phase B, methanol containing 0.1% of formic acid (v/v); injection volume 5 μL; flow rate 1.0 mL/min; mobile phase gradients of binary pump, 20% B (0−0.50 min), 50%-95% B (ramp, 0.51−2.00 min), 95% B (2.01−6.00 min), and 10% B (6.01−7.00 min); electrospray positive ionization (ESI+); gas flow 10 L/min; gas temperature 350 °C; nebulizer pressure 40 psi; capillary voltage 2800 V. The multiple reaction monitoring (MRM) transitions were 202 > 175 (collision energy, CE = 27) and 202 > 131 (CE = 35 V). Transition 202 > 131 was for quantitation. The retention time was 2.3 min.

Per the SANCO/10684/2009 Guideline,[22] calibration curves were obtained by plotting the concentrations of thiabendazole standards injected versus peak areas. The concentrations of thiabendazole in the samples were calculated using the peak areas obtained against the calibration curves.

RESULTS AND DISCUSSION

Method Validation. *Calibration, LOD, and LOQ.* The 6-point calibration curves were obtained ranging from 0.01 mg/L to 5 mg/L. The calibration curves showed good linearity with a typical correlation coefficient (R^2 > 0.990). These were used to calculate the concentrations of thiabendazole residues in edible fungi and substrates. The limit of quantitation (LOQ) was set to be the lowest fortification level at which acceptable recovery data (between 70% and 120%) were obtained.[23] Three fortification levels (0.01, 0.1, and 1.0 mg/kg) were analyzed for thiabendazole, and LOQ was set to 0.01 mg/kg for all matrices. The limit of detection (LOD) is defined as the lowest calibration standard used whose signal−noise ratio is found to be greater than 3.[23] In this work, the lowest calibration standard used was 0.01 mg/L and injection volume of 10 μL. Thus, LOD = 0.01 mg/L × 5 μL = 0.05 ng.

Table 1. Recoveries of Thiabendazole (n = 3)

matrix	spike level (mg/kg)	recovery (%)	RSD (%)
shimeji mushroom (*H. marmoreus*)	0.01	104.3	4.4
	0.1	87.9	13.1
	1.0	96.9	3.4
king oyster mushroom (*P. eryngii*)	0.01	84.8	4.9
	0.1	92.4	9.7
	1.0	78.6	8.5
oyster mushroom (*P. ostreatus*)	0.01	91.3	10.9
	0.1	86.2	4.1
	1.0	105.7	7.8
substrate	0.01	82.5	8.9
	0.1	76.2	11.1
	1.0	93.7	7.1

Accuracy and Precision. The accuracy was evaluated by determining the spike recoveries at various levels in a complex matrix. The precision of the method can be evaluated in terms of the relative standard deviation (RSD) of the spike recoveries. In this study, samples were prepared with a modified QuEChERS method. Acetonitrile was selected as the extraction solvent and then cleaned up with PSA and ODS-C18 sorbents. A total of three replicate measurements were performed for each fortification level and for each matrix. The data of spike recoveries are given in Table 1. The average recoveries ranged from 76.2% to 105.7% for thiabendazole in four different matrices, and the relative standard deviations (RSD) ranged from 3.4% to 13.1%. The recovery and precision results are acceptable according to China's National Standard.[23]

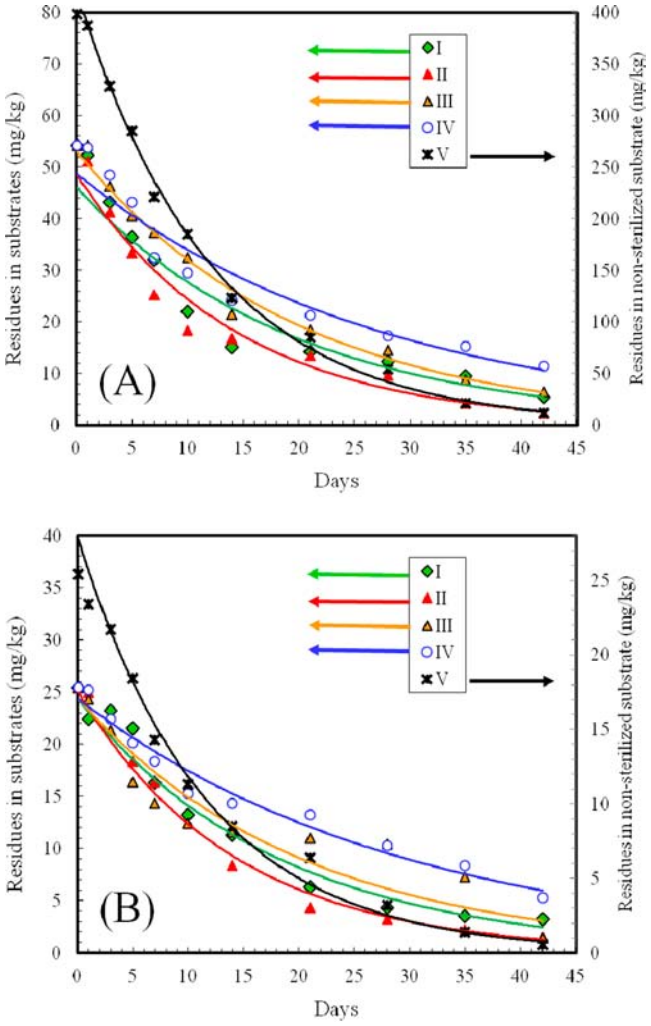

Figure 1. Degradation trends of thiabendazole in 5 different substrates for (A) premixing treatment and (B) spraying treatment. The substrates are as follows: (I) substrates with shimeji mushroom (*H. marmoreus*); (II) substrates with king oyster mushroom (*P. eryngii*); (III) substrates with oyster mushroom (*P. ostreatus*); (IV) sterilized substrates without mycelium; and (V) nonsterilized substrates. Left vertical axis for curves I, II, III, and IV; right vertical axis for curves V.

Degradation of Thiabendazole in Substrates. The degradation of thiabendazole in different substrates is modeled by a first-order equation,

$$C_t = C_0\, e^{-rt}$$

where C_t is the thiabendazole concentration at time t (days) after treatment, C_0 the initial concentration, and r the first-order rate constant (1/day). The degradation half-life ($t_{1/2}$) of thiabendazole is calculated by $t_{1/2} = \ln(2)/r$ in each experiment.[24−26] The degradation trends of thiabendazole in different substrates are shown in Figure 1. The data of half-lives and first-order equations are given in Table 2.

Premixing and Spraying Treatments. For premixing, the trends of degradation of thiabendazole in different substrates are shown in Figure 1A. In the five substrates, half-lives of thiabendazole were found to be 13.6 days for shimeji mushroom (*H. marmoreus*), 10.0 days for king oyster mushroom (*P. eryngii*), 13.7 days for oyster mushroom (*P. ostreatus*), 19.1 days for sterilized substrate, and 8.4 days for nonsterilized substrate, respectively, Table 2. The data indicate that sterilization at high temperature (120 °C) and high pressure (0.1 MPa) kill most of the microbials and thus a longer half-life for sterilized substrate was observed. However, the half-lives were 10−13.7 days in the substrates with the three fungi, indicating that the decrease in thiabendazole residue was due to either degradation resulting from the enzymes generated by the mushrooms or uptake by the edible fungi. The order of the half-lives is king oyster < shimeji mushroom ≈ oyster mushroom, suggesting that king oyster has the most effect on thiabendazole residues on the substrates.

For spraying, the half-lives and the trends of degradation are shown in Table 2 and Figure 1B, respectively. As can be seen in Table 2, the half-life data are consistent with those in the premixing treatment. Thus, the longest and shortest half-lives were found to be 19.5 and 8.1 days for the nonsterilized and sterilized substrates, respectively. Also, the order of the half-lives is nonsterilized < king oyster < shimeji mushroom ≈ oyster mushroom < sterilized.

The spraying treatment leads to higher residue concentration on the surfaces of the substrates while premixing is expected to generate homogeneous concentrations of thiabendazole in the substrates. The data suggest that the degradation of thiabendazole in substrates is not affected significantly by the means of pesticide treatments. It was reported that microorganism in mushroom substrates influenced the degradation of pesticide in the substrates.[27,28] Thus, spent mushroom substrates have been used as biofuel, for animal feeding, mushroom recultivation, soil bioremediation, and biodegradation of organic pollutants, as a soil conditioner, amendment, and fertilizer, for remediation of acidic mine wastewater, and as a sorbent for various heavy metals and organic pollutants.[27,28]

Thiabendazole Residues in Edible Fungi Parts. The thiabendazole residues in three edible fungi's parts (pileus, stipe, and volva) are listed in Table 3. For both spraying and premixing treatments, the highest residues of thiabendazole were found in volva and the lowest in stipe for all three mushrooms. This can probably be ascribed to the fact that the volva is a cuplike structure at the base of the mushroom and is often partially buried in the substrate, and therefore, more

Table 2. First-Order Kinetic Equations and Half-Lives of Thiabendazole

[a]Days are the number of days after producing of mushroom. [b]P + S = residues (pileus) × weight percent (pileus) + residues (stipe) × weight percent (stipe). The weight ratios (P:S, pileus to stipe) for *H. marmoreus*, *P. eryngii*, and *P. ostreatus* were 25:75, 5:95, and 50:50, respectively.

pesticide residues are taken by the volva part.[29,30] The spraying treatment results in higher residues of thiabendazole in three fungi (and their mushrooms' parts) than premixing treatment. The residues increase with increasing the number of growing days, except king oyster mushroom (*P. eryngii*) by spraying treatment. This can be understood as, when the fungi are cultivated longer, more thiabendazole residues are taken up from the substrate by the fungi. The highest residue was found in the oyster mushroom (*P. eryngii*) and day 5, however, the residue data of the oyster mushroom of days 3, 5, and 7 were identical within the experimental errors. The results indicate that the king oyster mushroom (*P. eryngii*) has the greater uptake ability of thiabendazole from substrates.

Typically, pileus and stipe are the edible parts of the mushrooms. The total residues (P + S) in the edible mushrooms are calculated by combining pesticide residues in the edible parts (pileus and stipe). Thus,

$$\mathrm{P + S} = \sum [(\text{residue}) \times (\text{weight percent})]$$

$$= (\text{residue in pileus}) \times (\%\text{pileus}) + (\text{residue in stipe}) \times (\%\text{stipe})$$

where the weight ratios (pileus to stipe) in the three different fungi (i.e., *H. marmoreus*, *P. eryngii*, and *P. ostreatus*) are 25:75, 5:95, and 50:50, respectively. Based on the mass balance, the total mass of extractable thiabendazole in the system decreased with the incubation time extended, since the residues in mushroom parts are increased slightly while those in the substrates decreased more rapidly. This indicates that the loss of thiabendazole in the substrates is due to the uptake by the mushrooms, degradation, and volatilization. The change in thiabendazole residues in the mushrooms may be caused by combined effects of mushrooms' uptake (increase residues), degradation by metabolism (decreasing residues), and dilution (growth, decreasing residues).[27,28,30]

The residues in edible fungi are important to human health and the environment. Compared with the existing maximum residue limits (MRLs) on mushroom in different countries and organizations, i.e., 5 mg/kg in China (preharvest interval is 14 days),[31] 40 mg/kg in the USA,[32] 60 mg/kg in Codex Alimentarius Commission,[33] and 10 mg/kg in the EU,[34] the thiabendazole residues in three mushrooms were found to be below 5 mg/kg, which is less than these established MRLs.

Plant uptake and distribution have been shown to be dependent on the physicochemical properties of the chemicals, the characteristics of the cultivation, and the plant species and physiology, including properties, such as lipid, enzymes, or water contents and transpiration rates.[30,35,36] It has been demonstrated that an aqueous extract of *P. pulmonarius* carpophores is able to reduce 89.8% of chlorothalonil concentration in a 1 h reaction. The fact is that this degradation rate was lower than the one observed with the spent mushroom substrates (100% in 45 min), indicating that microorganisms and enzymes other than *P. pulmonarius* were present in the spent substrate and contributed to degrade the insecticide faster.[37] Spent compost of oyster mushroom (*P. pulmonarius*) provides an integrated system of biosorption and biodegradation to remove pentachlorophenol. Spent mushroom substrates offer a nutrient source and an attachment substratum for a consortium of micro-organisms. In addition, it offers a solid support to the immobilized enzymes secreted by the mushroom during growth and fruiting.[38]

The study demonstrates that the thiabendazole residues in mushroom media (substrates) by spraying and premixing are readily taken up by three selected edible fungi and subsequently translocated as a function of time. The degradation rate of thiabendazole in nonsterilized substrates was the fastest and in sterilized substrates was the slowest, respectively, without mycelia present in the substrates. The thiabendazole residues in substrates show different degradation rates with edible fungus mycelia. These results also suggest that the thiabendazole uptake ability by *P. eryngii* is stronger than that of the other two fungi. Further research is needed to characterize the ability of the enzymatic system and the mycelia of edible fungi involved in the degradation of thiabendazole and other pesticides.

transplanted to the field. Plants were visually screened for red coloration phenotype. Target *RG* mutant had the inflorescence bagged upon emergence for self-pollination. *RG* M_{1-3} lines were bagged and followed by single-seed descent and progeny phenotypically scored for leaf coloration.

Morphological Characterization of *RG*. Phenotype was examined over the course of three generations. Three discrete zones are defined in the *RG* leaf, the green zone (no red), the transition zone where green and red tissues are present, and the red zone, which comprises the red area of the leaf (no green, phase 3). Chlorophyll content was measured[12] (n = 4 leaf disks per leaf from n = 10 plants).

Spectrophotometric Analyses. Extraction and pigment quantification were carried out on fully expanded *RG* and wild type leaves (dried for 2 days at 37 °C). Each biological sample comprised the same physiological and ontological leaf type from multiple plants (n = 10), and four biological pool replicates were used. For the analysis of total pigments, sample (10 mg) was extracted in acidified methanol (1 mL HCl/100 mL) and centrifuged, and supernatant absorbance measured at 480 nm as previously described.[7] 3-Deoxyanthocyanin content was estimated as luteolinidin equivalents (ε = 31000), because it was the dominant pigment in the samples. Total phenolic were measured as ferulic acid equivalents as previously described.[13] Condensed tannins were estimated using the vanillin−HCl method described by Butler et al.[14] Chlorogenic acid was determined as described.[15]

HPLC and LC-MS Analysis. Analysis of 3-deoxyanthocyanidin composition in sorghum leaf tissue was performed using a HPLC-DAD (Agilent 1200 system) as previously described.[8] A Kinetex C18 75 × 4.6 mm i.d. column (Phenomenex, Torrance, CA, USA) thermostated at 40 °C was used; UV−vis spectra were collected between 200 and 700 nm. LC-MS analysis was performed by a reverse phase quadrupole time-of-flight (Q-TOF) mass spectrometer equipped with an Agilent Jet Stream electrospray ionization (ESI) ion source with continuous introduction of reference mass compounds: 121.050873, 922.009798 (positive ion mode) (QTOF MS/MS) on an Agilent 1200 LC stack interfaced with an Agilent 6530A (Agilent Technologies, Santa Clara, CA, USA). Samples (5 μL) were separated using an Acquity BEH Shield RP-18 analytical column (1.7 μm 2.1 × 150 mm, Waters Corp., Milford, MA, USA) maintained at 40 °C. Sample analysis was triplicated. The MS/MS data were used to infer the anthocyanidin species. Quantification of the 3-deoxyanthocyanins was achieved by comparing HPLC peak areas at 480 nm to those obtained using pure standards (apigeninidin, luteolinidin, 7-*O*-methylluteolinidin, 7-*O*-methylapigeninidin, 5-*O*-methylapigeninidin, 5,7-*O*-dimethylluteolinidin, and 5,7-*O*-dimethylapigeninidin). The 3-deoxyanthocyanin standards were purchased from AlsaChim (Strasbourg, France); all standards were at least 97% pure.

Dihydroflavonolreductase (DFR) Activity. Plant samples were homogenized in liquid N_2 and total protein extracted.[16] Protein concentration was measured and standardized between samples using the Bradford method; the DFR activity was measured according to the method in ref 17. The absorbance due to cyanidin in the butanol solvent at 550 nm (absorption coefficient = 34.7)[18] was normalized for the 550 nm absorbance due to chlorophyll at 600 nm (absorbance at 550 nm − absorbance at 600 nm). Control used heat-inactivated enzyme. (n = 3 biological pooled samples each comprising five leaves.)

Statistical Analysis. Statistical analyses consisted of Student's t test or one-way ANOVA with a post hoc Tukey test and performed using PRISM4 (Graphpad, La Jolla, CA, USA) (significance established at $P < 0.05$).

RESULTS

Identification of *REDforGREEN* (*RG*). Within an M_1 generation of chemically mutagenized *S. bicolor* L. var. Della, the *RG* mutant was identified from approximately 12000 M_1 individuals on the basis of distinct red coloration of lamina tissue throughout development, which carried through to subsequent M_2 and M_3 generations. Self-pollination of the M_1 *RG* selection resulted in 761 M_2 generation individuals. These inherited the trait in a nearly 3:1 ratio of red coloration of lamina (*RG*) to wild type (green lamina) (567:194, χ^2 = 0.05573, df = 1, P = 0.4067), which would be expected for a dominant allele. Furthermore, the single wild type segregant failed to inherit the trait in subsequent generations. Two subsequent backcrosses were made between the red coloration mutant *RG* and wild type *S. bicolor* L. var. Della (referred to throughout as wild type). Each backcross was carried through to the M_2 generation and the inheritance examined. Interestingly, the heterozygous individuals failed to carry lighter lamina pigmentation than homozygous *RG*, suggesting the *RG* allele in the heterozygote was fully penetrant. The progeny of the M_2 were examined to determine homozygosity of the allele and the homozygote used in the third backcross. Both rounds of backcrossing resulted in 3:1 red versus green lamina coloration, consistent with single gene dominant inheritance of the target allele. The third backcross *RG* line was used during mutant characterization.

Between 3 and 5 days post-germination *RG* displayed no distinguishable difference from the sorghum wild type seedling. Onset of pigmentation was evident from the cotyledon and each true leaf lamina thereafter (Figure 1). Upon the leaf completing expansion, light-driven pigment accumulation initiated at the leaf apex and progressed to the base, termed basipetal accumulation (Figure 1A−N). Subsequent basipetal progression of red coloration occurred in all lamina during the plant life cycle (Figure 1). Visual examination indicated that coloration was predominantly interveinal (Figure 1B,C). As a general trend, basipetal red/purple coloration of lamina began after cellular expansion had plateaued. The red/purple coloration therefore progressed in a hierarchical manner (with the earliest emerged leaves being fully red, and newly emerged and expanding leaves being green). This phenotype led to a continuum of green terminal leaves and red fully expanded leaves. Red/purple leaf coloration extended partially into the leaf sheath (shown in Figure 1L−N). The process of complete red/purple coloration of the lamina took progressively longer (2 days for leaves 1−3 to 21 days for leaves subtending the inflorescence).

Spectrophotometric Determination of Pigment and Related Polyphenols. To estimate the pigment accumulation, we spectrophotometrically quantified (as luteolinidin equivalents, LUTe)[7] pigments in whole lamina at various temporal points during leaf development (leaves 1−2, 3, 5, and 7; Figure 2A). Fully pigmented *RG* leaves were compared with leaves from a wild type plant at the identical spatial and temporal ontology. Results demonstrated (1) that pigments accumulated until reaching a plateau level (Figure 2A) and (2) a >20-fold LUTe increase in the *RG* leaf material compared with wild type, with a maximum value of 10.05 mg g^{-1} db LUTe in *RG* (Figure 2A). The LUTe levels observed in the *RG* leaves were much higher than those reported for high-pigment black sorghum grains[7] and are economically relevant when current anthocyanin pigment yield from commercial sources, such as red cabbage, are considered.[19]

Measurements of total phenolics, condensed tannins, and chlorogenic acid content were also completed in *RG* and wild type leaves (Figure 2B−D). Results showed that the *RG* accumulated between 2- and 6-fold greater total phenolics than wild type ($P < 0.05$; Figure 2B). Condensed tannins also were up to 4-fold higher in the *RG* leaf material when compared with wild type leaf ($P < 0.05$; Figure 2C). As a general trend, total phenolics and tannins positively correlated with the LUTe

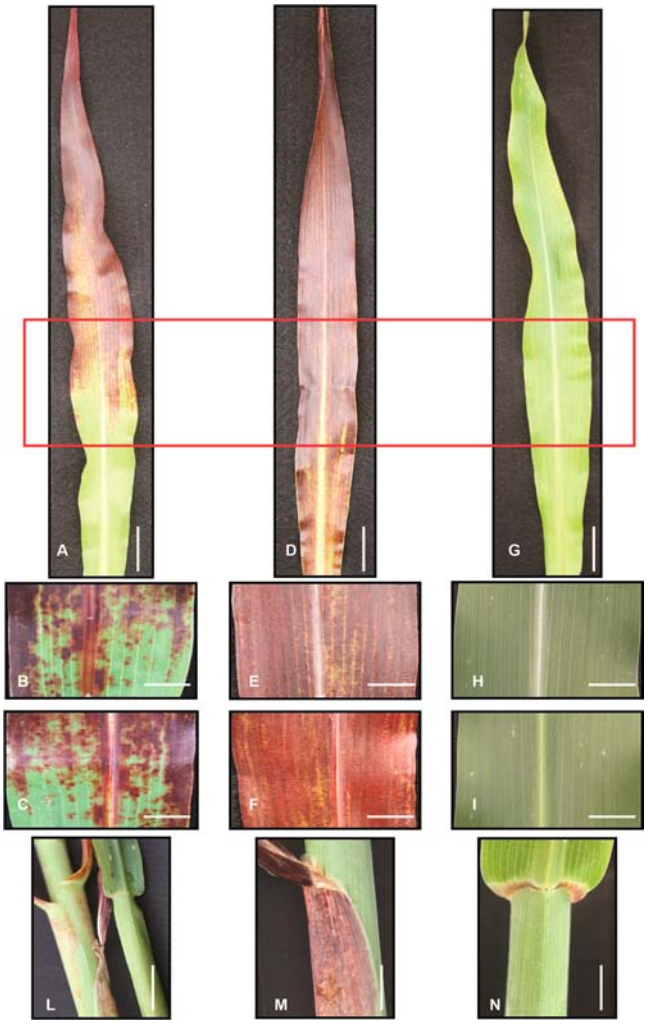

Figure 1. *RG* phenotype development (basipetal progression of pigment accumulation in *RG* leaves): (A, D) full-length leaves of *RG* partially and fully pigmented; (G) wild type leaf with no pigment (scale bar = 2 cm); (B, E, H) detailed image of the abaxial leaf surface with evidence of transition from red to green (B), completed accumulation and no green tissue (E), and all green tissue in WT (H); (C, F, I) detailed view of the adaxial leaf surface; (L, M, N) leaf sheath displaying pigment accumulation for *RG* but not for the wild type (scale bar = 1 cm); (A) 2-week-old plantlet with evidence of pigment accumulation (scale bar = 1 cm); (B) comparison and progression of pigment accumulation on cotyledon, first and second leaf of *RG*, and WT (scale bar = 1 cm).

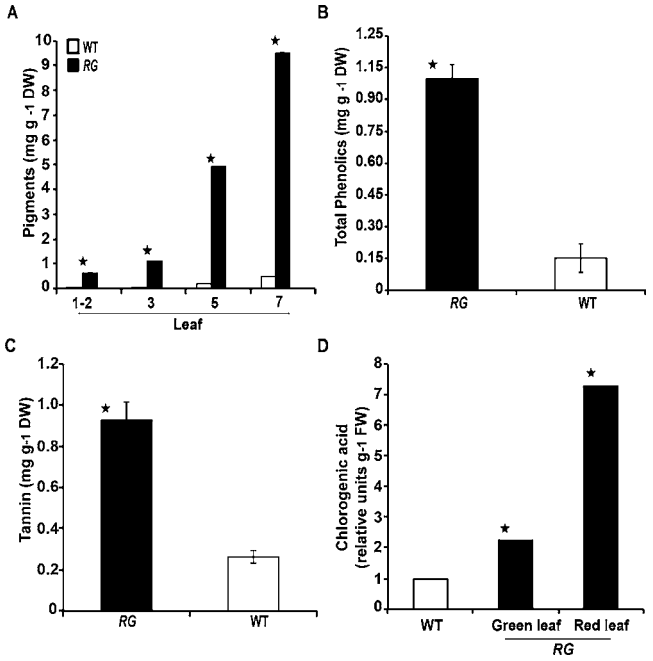

Figure 2. Metabolite analyses for the *RG* and WT leaf tissues: (A) pigment evaluation across a developmental gradient (leaves 1−7); (B) total phenolics estimation; (C) soluble tannin quantification; (D) chlorogenic acid evaluation on wild type (WT) and *RG* green and red leaf tissue (expressed as a relative unit per gram of fresh weight (FW)). (n = 4 biological pooled sample each containing 10 leaves.) Significance ($P < 0.05$) is indicated by a star (★). DW, dry weight.

pigments, thus suggesting a coordinated metabolic response in the *RG* mutant leaves. In agreement with this trend, chlorogenic acid content was also higher in the *RG* mutant versus the wild type, with the red leaf being up to 7-fold greater and the *RG*-green being up to 2-fold greater than the wild type (Figure 2D). The presence of other polyphenols generally helps to stabilize the pigments via condensation reactions or copigmentation;[20,21] thus, the coaccumulation of the non-pigmented polyphenols may improve functionality of the 3-deoxyanthocyanins from the leaf tissue. Additionally, there is a potential for the *RG* leaves to serve as a source of bioactive dietary polyphenols.

Chemical Characterization of Pigment Composition. The specific composition of accumulated pigments was investigated using HPLC and LC-MS. We identified LUT as the dominant 3-deoxyanthocyanidin compound in the *RG* leaf, accounting for 68% of resolved 3-deoxyanthocyanin peaks, followed by apigeninidin (APG) (16%), and 7-*O*-methyl-luteolinidin (13%) (Table 1; Figure 3). Results demonstrated 1768 μg g^{-1} db LUT was present in RG leaves compared to trace amounts in wild type (Table 1). Low levels of 7-*O*- and 5-*O*-glucosides and diglycosides of LUT and APG, as well as 7-*O*- and 5-*O*-glucosides and diglycosides of *O*-methyl derivatives of LUT and APG, were also detected (Figure 3). In addition, dimers of LUT and its 7-*O*-methyl derivative were also detected at low levels (Figure 3); such dimers (apigenin- or luteolin-flavene dimer) were recently reported as highly stable compared to the monomeric 3-deoxyanthocyanins.[8] In general, LUT and its derivatives accounted for >80% of total 3-deoxyanthocyanins, whereas APG and its derivatives accounted for the rest (Table 1). The 3-deoxyanthocyanin composition of the *RG* was generally comparable to the typical composition observed in sorghum grains derived from purple plant phenotypes.[22] Thus, the potential performance of these pigments as natural food colorants should be equivalent to those previously reported.[7−23]

LC-MS data revealed the presence of significant quantities of various mono- and diglycosides of the flavones luteolin and apigenin (Table 2). These flavones are common components of sorghum grain and tissue;[24] however, the extensive degree of glycosylation with glucose, galactose, and rhamnose observed in this study is not typically reported for sorghum. Interestingly, the relative proportions of the glycosides of luteolin and apigenin seemed to match the relative proportions of LUT and APG pigments, yet the luteolin glycosides were much more predominant. The higher proportion of LUT family pigments and corresponding luteolin-based flavones compared to APG/

apigenin family of compounds has been reported for purple sorghum plant phenotype.[22] Red plant sorghum phenotypes, on the other hand, express the opposite effect, with the APG/apigenin compounds dominating.[22,24] In general, accumulations of most of these compounds were much higher in the *RG* compared to wild type, following the overall trend observed for the other phenolics.

Quantification of Seed Bran Pigments. The sorghum seed bran accumulates 3-deoxyanthocyanidins in the red, brown, and black varieties.[7−25] *S. bicolor* Della is a "brown" variety displaying accumulation of 3-deoxyanthocyanidin. However, no increase in the pigment content or in total phenolics was observed between the seed bran of *RG* and wild type (pigments: *RG*, 48 ± 8.6 μg g^{-1} seed; WT, 51 ± 6.2 μg g^{-1} seed), consistent with visual observations and the *RG* leaf specific accumulation of anthocyanins in the broad sense.

DFR Activity Supports Accumulation of 3-Deoxyanthocyanidins in *RG*. DFR catalyzes the reduction of dihydroflavonols to leucoanthocyanidins[26] and the conversion of naringenin to apiferol.[27] The DFR products are substrates for downstream steps in both branches of the PPP that lead to 3-deoxyanthocyanidins and 3-hydroxyflavonoids. Consistent with greater LUT and APG accumulations in *RG* (Tables 1 and 2), DFR activity (Figure 4) was significantly higher in the

dx.doi.org/10.1021/jf405324j | J. Agric. Food Chem. 2014, 62, 1227−1232

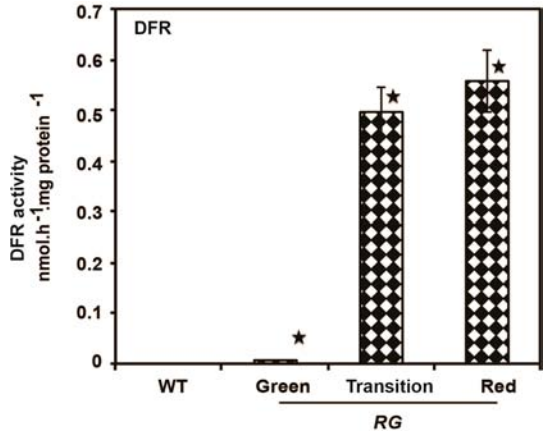

Figure 4. Estimation of the dihydroflavonolreductase (DFR) activity in *RG* leaves. The DFR activity was determined in green and red leaf tissues and compared to the wild type (WT) green tissues. (n = 3 biological pooled sample each containing 5 leaves.) Significance (P < 0.05) is indicated by a star (★).

RG red leaf tissue than in wild type (0.36 nmol h^{-1} mg $protein^{-1}$). Notably, despite a lack of anthocyanin in the green zone of *RG*, detectable DFR activity was observed, which was not the case for wild type leaves, suggesting early onset of precursor accumulation (Figure 4).

Pigment Progression Is Paralleled by Total Chlorophyll Reduction. The large and progressive increase in 3-deoxyanthocyanidins in the *RG* mutant led us to ask if in parallel there was an alteration in the chlorophyll content. It was found that no significant changes in total chlorophyll occurred in the green and transition zone, but a significant reduction in total chlorophyll was evident in the red zone (Figure 5A). A lower proportion of chlorophyll *a* versus chlorophyll *b* was observed (Figure 5B,C). Thus, total chlorophyll levels were not impeded in *RG* until the fully red leaf stage.

DISCUSSION

The suitability of sorghum 3-deoxyanthocyanin pigments as potential natural food colorants has been established in prior studies (pH stability and antioxidant).[23,28] Prior work has identified dark bran sorghum lines as possible sources for natural food colorants,[9] but the bran yield remains low relative to other parts of the plant. In this work we have sought to identify a sorghum plant (via mutagenesis-assisted breeding) with increased concentration of 3-deoxyanthocyanin in leaf tissue. Leaves are vastly more abundant than bran and can be easily stored and harvested using existing technology. *RG* displayed intense red/purple coloration of the normally green lamina tissue (Figure 1). The *RG* mutant accumulated a >1000-fold increase in 3-deoxyanthocyanidin structures LUT and AP (and variants thereof, Figure 3) in leaves. In addition, we identified by LC-MS/MS a range of glycosylated flavones, which also contribute to the complex phenolic fingerprint of the sorghum *RG* leaf. The *RG* mutant also caused an antithetic leaf-stem accumulation−depletion of lignin.[29] Increased aglycosylated flavones, 3-deoxyanthocyanin, and lignin suggest that the *RG* locus simultaneously influenced multiple branches in the phenylpropanoid pathway.

In our measurements, *RG* leaf material contained up to 10.1 mg of pigment per gram of dry leaf tissue. This concentration compares favorably to popular commercial sources of anthocyanin pigments, such as red cabbage, on a dry weight basis.[19] Because most commercial sources of anthocyanin colorants are succulent tissues high in moisture and enzyme activity, and thus having poor storability (e.g., purple carrots, sweet potatoes, and red cabbage), the opportunity to add sorghum leaf tissue to the mix seems interesting. Moreover, sorghum leaves are very thin and easy to dehydrate for transportation and/or long-term storage.

Many variables would influence the production of pigment from the *RG* mutant, and the agronomic appropriateness of the crop was not part of the current work scope. However, drawing rough estimates from agronomic data such as density of planting (typically, between 20000 nonirrigated and 60000 irrigated plants per acre), leaf yield (approximately 70:30 to 50:50 ratio of stem to leaf), and biomass per acre (between 6 and 13 tons per acre), the yield of pigment would be approximately between 27 and 45 kg/acre (or 67−111 kg/ha). This again compares favorably to pigment yield from, for example, red cabbage, of 17−98 kg/ha.[19] Additional advantages of using a high pigment accumulating sorghum variety (*RG*) to obtain 3-deoxyanthocyanins are that it displays C4 photosynthesis, which confers drought tolerance. A row crop alternative may also offer cost-effective planting and harvesting compared with below-ground crops (purple-fleshed sweet potato and carrots, which are limited to water and soil type constraints). However, it is important to note that the 3-deoxyanthocyanins are not replacements for anthocyanins, but are complementary to them, because each class of pigments displays distinctly

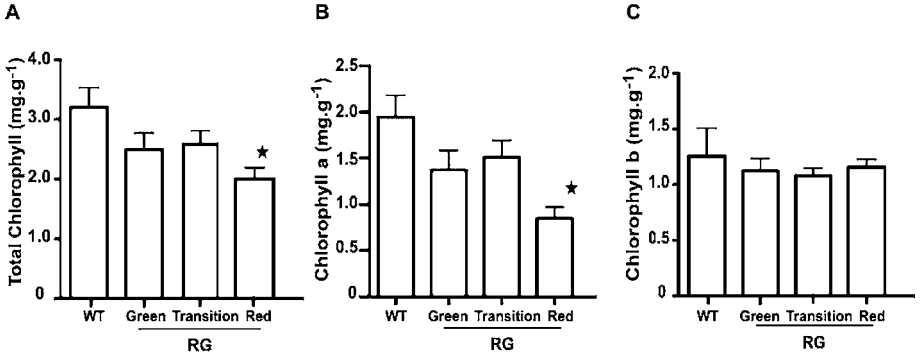

Figure 5. Chlorophyll estimation in *RG* and WT leaves: (A) total chlorophyll content for the *RG*, measurements made on red, green, and transition zone and compared to WT leaves at an equal developmental stage; (B, C) chlorophylls *a* and *b* were estimated as in (A). A star (★) indicates significant difference between the columns (four leaf disks for each leaf, leaf number = 6). (P < 0.05, ANOVA with a post hoc Tukey test.)

dx.doi.org/10.1021/jf405324j | J. Agric. Food Chem. 2014, 62, 1227−1232

different hues and would thus work in different applications or as blends to achieve expanded hues for water-soluble plant-based food colorants.

interaction with the origin of TMV RNA (oriRNA), exhibiting its virus inhibition by binding to oriRNA and interfering with virus assembly initiation.[19] Moreover, structure−activity relationship (SAR) studies showed that most compounds of the phenanthroindolizidine-based library with structural diversity exhibited antiviral effect against TMV.

In previous work, the SAR studies mainly focused on (1) substituted patterns of methoxyl group on the phenanthrene ring, (2) the number of methoxyl groups on the phenanthrene ring, (3) derivatation at the C-14 position, and (4) D ring opened derivatives.[20,21] However, there is no investigation on the variation of basic skeletons of phenanthroindo/quinolizines, which will largely change the conformation of the molecules. To study the influence of the variation of basic skeletons and conformations of these phenanthroindo/quinolizidine alkaloids, two types of structurally novel phenanthroindo/quinolizidine alkaloid analogues were designed, synthesized, and evaluated for their antiviral activity against TMV. The SAR study of these compounds against TMV is also discussed.

MATERIALS AND METHODS

Instruments. ^{1}H NMR spectra were obtained at 400 MHz using a Bruker AC-P 400. Chemical shift values (δ) were given in parts per million and were downfield from internal tetramethylsilane. High-resolution mass spectra (HRMS) were recorded on an FT-ICR MS (Ionspec, 7.0 T). Melting points were determined on an X-4 binocular microscope melting point apparatus (Beijing Tech Instruments Co., Beijing, China) and were uncorrected. Reagents were purchased from commercial sources and were used as received. All anhydrous solvents were dried and purified according to standard techniques just before use.

1-(2,3,6,7-Tetramethoxyphenanthren-9-yl)ethanone 3. To a solution of phenanthryl carboxylic acid (6.84 g, 20 mmol) in THF (100 mL) was added MeLi (28.8 mL, 1.6 M, 46 mmol) dropwise via a syringe at −78 °C under an atmosphere of nitrogen. The reaction mixture was stirred at this temperature for 30 min and then warmed to room temperature. Two hours later, saturated aqueous NH_4Cl (10 mL) was added to quench the reaction. After evaporation of THF, the aqueous layer was extracted with CH_2Cl_2 (80 mL × 3). The combined organic phase was washed sequentially with diluted aqueous HCl, water, and brine, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. Crude product was recrystallized from MeOH to give compound **3** (5.2 g, 77%) as a white solid: mp 214−215 °C; ^{1}H NMR (400 MHz, DMSO) δ 8.44 (s, 1H), 8.41 (s, 1H), 7.98 (s, 1H), 7.95 (s, 1H), 7.53 (s, 1H), 4.07 (s, 3H), 4.04 (s, 3H), 3.94 (s, 3H), 3.89 (s, 3H), 2.77 (s, 3H); ^{13}C NMR (100 MHz, DMSO) δ 201.0, 151.2, 148.9, 148.8, 148.8, 130.3, 129.5, 126.5, 124.9, 124.0, 122.4, 109.6, 106.8, 103.7, 103.3, 55.9, 55.7, 55.4, 55.1, 29.5; HRMS (ESI) calcd for $C_{20}H_{20}NO_5Na$ $(M + H)^+$ 363.1203, found 263.1205.

***tert*-Butyl 2-(2-Oxo-2-(2,3,6,7-tetramethoxyphenanthren-9-yl)ethyl)pyrrolidine-1-carboxylate 5a.** To a solution of compound **3** (0.68 g, 2.0 mmol) and i-Pr_2NEt (0.38 g, 3.0 mmol) in CH_2Cl_2 (50 mL) was added TMSOTf (0.53 g, 2.4 mmol) in CH_2Cl_2 (10 mL) dropwise. The reaction mixture was stirred at room temperature for 4 h and then quenched with water (30 mL). After separation, the organic phase was washed sequentially with water and brine, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. Crude product **4** was dissolved in CH_2Cl_2 (50 mL) without further purification, and then compound **2** (0.44 g, 2.18 mmol) was added. $BF_3{\cdot}Et_2O$ (3.0 mL, 30%) in CH_2Cl_2 (10 mL) was added dropwise at −78 °C. The reaction mixture was stirred at this temperature for 1 h, warmed to room temperature, and then quenched with diluted aqueous NaOH. After separation, the organic phase was washed with water and brine, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel to give compound **5a** (0.73 g, 72%) as a light yellow solid: mp 147−149 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.51 (s, 1H), 8.33 (s, 1H), 7.80 (s, 1H), 7.77 (s, 1H), 7.32 (s, 1H), 4.44 (br, 1H), 4.15 (s, 3H), 4.13(s, 3H), 4.06 (s, 6H), 3.86 (d, J = 14.8 Hz, 1H), 3.40 (br, 2H), 3.10−2.98 (m, 1H), 2.13 (br, 1H), 1.89 (br, 3H), 1.48 (s, 9H); ^{13}C NMR (100 MHz) δ 199.2, 156.7, 152.2, 151.0, 150.4, 149.0, 130.3, 130.14 126.0, 125.1, 124.9, 123.5, 109.5, 107.2, 105.9, 102.6, 81.2, 56.1, 56.0, 55.9, 55.8, 46.0, 44.3, 33.1, 28.6, 24.9; HRMS (ESI) calcd for $C_{29}H_{36}NO_7$ $(M + H)^+$ 510.2486, found 510.2490.

2-(2-(2,3,6,7-Tetramethoxyphenanthren-9-yl)ethyl)-pyrrolidine 6a. To a solution of compound **5a** (0.37 g, 0.73 mmol) in EtOH (50 mL) was added $NaBH_4$ (0.1 g, 2.6 mmol). The reaction mixture was stirred at room temperature for 2 h and then quenched with water. After evaporation, the aqueous layer was extracted with CH_2Cl_2 (30 mL × 3). The combined organic phase was washed with brine, dried over Na_2SO_4, and concentrated under reduced pressure. Crude product was dissolved in CH_2Cl_2 (50 mL) without further purification, and then Et_3SiH (0.18 mL, 1.13 mmol) and CF_3COOH (0.33 mL, 4.4 mmol) were added. The reaction mixture was stirred at room temperature overnight and then quenched with diluted aqueous NaOH. After separation, the organic layer was washed with brine, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel to give compound **6a** (0.27 g, 93%) as a white solid: mp 224−226 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.63 (s, 1H), 7.56 (s, 1H), 7.30 (s, 1H), 7.23 (s, 1H), 7.04 (s, 1H), 4.08 (s, 6H), 4.02 (s, 3H), 3.97 (s, 3H), 3.40−3.30 (m, 1H), 3.28−3.22 (m, 1H), 3.19−3.05 (m, 2H), 2.99−2.88 (m, 1H), 2.22−2.17 (m, 1H), 2.11−1.90 (m, 3H), 1.89−1.76 (m, 1H), 1.57−1.52 (m, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 148.4, 148.4, 148.3, 130.9, 125.9, 124.7, 124.5, 123.2, 122.9, 107.9, 104.1, 102.9, 102.2, 60.6, 56.2, 55.8, 55.8, 44.5, 31.9, 30.8, 30.3, 23.6; HRMS (ESI) calcd for $C_{24}H_{30}NO_4$ $(M + H)^+$ 396.2169, found 396.2168.

2,3,6,7-Tetramethoxy-11,12,13,13a,14,15-hexahydro-9*H*-phenanthro[9,10-e]pyrrolo[1,2-*a*]azepine 7a. To a solution of compound **6a** (0.2 g, 0.51 mmol) in toluene (20 mL) were added formaldehyde (1.0 mL, 30%) and CF_3COOH (0.5 mL, 6.7 mmol). A Dean−Stark trap topped with a reflux condenser was attached to the reaction vessel, and the reaction mixture was heated at reflux. Seven hours later, the solvent was evaporated under reduced pressure, and then aqueous NaOH was added to the residue. The aqueous solution was extracted with CH_2Cl_2 (30 mL × 3), and the combined organic phase was washed with brine, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel to give compound **7a** (0.18 g, 87%) as a light yellow solid: mp 178−180 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.84 (s, 2H), 7.53 (s, 2H), 4.69 (s, 1H), 4.12 (s, 3H), 4.11 (s, 3H), 4.06 (s, 3H), 4.05(s, 3H), 3.88−3.83 (m, 1H), 3.65 (dd, J = 15.0, 7.5 Hz, 1H), 3.21 (s, 1H), 3.09 (t, J = 12.0 Hz, 1H), 2.69 (s, 2H), 2.22−2.10 (m, 1H), 2.00 (s, 1H), 1.78 (s, 2H), 1.57−1.40 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 148.0, 147.8, 147.7, 147.5, 133.9, 127.4, 124.3, 123.8, 123.7, 122.9, 103.5, 103.2, 102.4, 102.3, 76.3, 76.0, 75.7, 55.0, 54.9, 54.8, 49.3, 30.2, 29.8, 28.7, 25.4, 19.9; HRMS (ESI) calcd for $C_{29}H_{30}NO_4$ $(M + H)^+$ 408.2169, found 408.2169.

2-(2,3,6,7-Tetramethoxyphenanthren-9-yl)acetonitrile 9. To a solution of compound **8** (7.2 g, 18.4 mmol) in DMF (150 mL) was added NaCN (1.0 g, 20.4 mmol). The reaction was stirred at room temperature for 5 h, and then solvent was evaporated under reduced pressure. Water and CH_2Cl_2 were added to the residue, and, after separation, the aqueous layer was extracted with CH_2Cl_2. The combined organic phase was washed with brine, dried over Na_2SO_4, filtered, and concentrated in vacuo. The residue was purified by column chromatography on silica gel to give compound **9** (4.2 g, 68%) as a white solid: mp 198−200 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.86 (s, 1H), 7.77 (s, 1H), 7.70 (s, 1H), 7.23 (s, 1H), 7.14 (s, 1H), 4.14 (s, 3H), 4.13 (s, 3H), 4.12 (s, 2H), 4.07 (s, 3H), 4.05 (s, 3H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 148.7, 148.3, 148.1, 148.0, 124.6, 123.9, 123.6, 123.4, 122.7, 120.3, 116.7, 107.2, 102.6, 102.3, 101.6, 55.1, 55.0, 54.9, 21.3; HRMS (ESI) calcd for $C_{20}H_{23}N_2O_4$ $(M + NH_4)^+$ 499.2551, found499.2552.

2-(2,3,6,7-Tetramethoxyphenanthren-9-yl)ethanamine 10. To a solution of compound **9** (0.3 g, 0.89 mmol) in THF (30 mL) was added BH_3 (2.7 mL, 1 M in THF) at 0 °C under an atmosphere of

nitrogen. Then, the reaction was heated at reflux for 3 h. After the mixture had cooled to room temperature, diluted aqueous HCl was added to quench the reaction. The mixture was heated at reflux for an additional 0.5 h and then was cooled to room temperature. The mixture was extracted with EtOAc, and the aqueous layer was basified by aqueous NaOH to pH >7. The aqueous layer was extracted with EtOAc and then washed with brine, dried over Na_2SO_4, filtered, and concentrated under reduced pressure to give compound **10** (0.25 g, 67%) as a white solid: mp 148−149 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.82 (s, 1H), 7.75 (s, 1H), 7.44 (s, 1H), 7.38 (s, 1H), 7.17 (s, 1H), 4.11 (s, 3H), 4.09 (s, 3H), 4.05 (s, 3H), 4.02 (s, 3H), 3.21 (m, 4H), 2.2 (br, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 148.9, 148.8, 148.6, 130.8, 126.2, 125.3, 125.0, 124.6, 123.7, 107.9, 104.6, 103.4, 102.7, 56.1, 56.0, 55.9, 55.8, 41.8, 37.1; HRMS (ESI) calcd for $C_{20}H_{24}NO_4$ $(M + H)^+$ 342.1700, found 342.1702.

4-Oxo-4-((2-(2,3,6,7-tetramethoxyphenanthren-9-yl)ethyl)-amino)butanoic Acid 12a. To a solution of amine **10** (0.4 g, 1.17 mmol) in $CHCl_3$ (30 mL) was added dihydrofuran-2,5-dione (0.23 g, 2.34 mmol). The reaction was stirred at room temperature for 2 h, and then water (30 mL) was added and stirred for an additional 1 h. After separation, the aqueous layer was extracted with $CHCl_3$ (30 mL × 3). The combined organic phase was dried over Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel to give compound **12a** (0.46 g, 89%) as a white solid: mp 203−204 °C; ^{1}H NMR (400 MHz, DMSO) δ 8.16 (t, J = 5.2 Hz, 1H), 8.03 (s, 1H), 7.97 (s, 1H), 7.65 (s, 1H), 7.47 (s, 1H), 7.33 (s, 1H), 4.03 (s, 3H), 4.01 (s, 3H), 3.98 (s, 3H), 3.89 (s, 3H), 3.42−3.36 (m, 2H), 3.13 (t, J = 8 Hz, 2H), 2.46 (d, J = 6.4 Hz, 2H), 2.35 (t, J = 6.8 Hz, 2H); ^{13}C NMR (100 MHz, DMSO) δ 173.6, 171.1, 148.8, 148.7, 148.6, 148.5, 130.6, 125.8, 124.9, 124.5, 124.1, 123.3, 108.1, 105.0, 104.3, 103.7, 55.9, 55.8, 55.5, 55.3, 33.5, 30.1, 29.2; HRMS (ESI) calcd for $C_{24}H_{28}NO_7$ $(M + H)^+$ 442.1860, found 442.1866.

1-(2-(2,3,6,7-Tetramethoxyphenanthren-9-yl)ethyl)-pyrrolidine-2,5-dione 13a. To a solution of compound **12a** (0.46 g, 1.04 mmol) in Ac_2O (20 mL) was added AcONa (0.1 g). The reaction was stirred at 70 °C for 2 h and then cooled to room temperature. The reaction was quenched with water and stirred for an additional 1 h. After separation, the aqueous phase was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic phase was dried over Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel to give compound **13a** (0.43 g, 98%) as a white solid: mp 262−263 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.82 (s, 1H), 7.76 (s, 1H), 7.75 (s, 1H), 7.50 (s, 1H), 7.17 (s, 1H), 4.18 (s, 3H), 4.13 (s, 3H), 4.11 (s, 3H), 4.02 (s, 3H), 3.83 (t, J = 8.6 Hz, 2H), 3.25 (t, J = 8.6 Hz, 2H), 2.74 (s, 4H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 177.2, 149.02, 148.9, 129.4, 126.21, 125.2, 124.8, 124.0, 107.9, 104.7, 103.3, 102.8, 77.3, 77.0, 76.7, 56.2, 56.1, 56.0, 55.9, 39.2, 32.1, 28.2; HRMS (ESI) calcd for $C_{24}H_{26}NO_6$ $(M + H)^+$ 424.1755, found 424.1754.

5-Hydroxy-1-(2-(2,3,6,7-tetramethoxyphenanthren-9-yl)-ethyl)pyrrolidin-2-one 14a. To a solution of compound **13a** (0.48 g, 1.13 mmol) in CH_2Cl_2 (20 mL) was added $LiEt_3BH$ (1 M, 2.2 mL) at −60 °C. The reaction mixture was stirred for 2 h and then quenched with water. After separation, the aqueous layer was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic phase was dried over Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel to give compound **14a** (0.44 g, 92%) as a white solid: mp 187−188 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.81 (s, 1H), 7.75 (s, 1H), 7.68 (s, 1H), 7.44 (s, 1H), 7.13 (s, 1H), 4.99 (s, 1H), 4.12 (s, 3H), 4.11(s, 3H), 4.10 (s, 3H), 4.06−4.02 (m, 1H), 4.00 (s, 3H), 3.82−3.72 (m, 1H), 3.67−3.63 (m, 1H), 3.39−3.29 (m, 2H), 2.63−2.52 (m, 1H), 2.37−2.19 (m, 2H), 1.82−1.77 (m, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 173.6, 148.1, 148.0, 147.9, 129.7, 125.2, 123.7, 122.9, 106.8, 103.9, 102.1, 101.8, 83.2, 55.2, 55.1, 55.0, 54.9, 40.7, 31.4, 27.9, 27.8; HRMS (ESI) calcd for $C_{24}H_{28}NO_6$ $(M + H)^+$ 426.1911, found 426.1913.

2,3,12,13-Tetramethoxy-5,6,10,10a-tetrahydrodibenzo[*f*,*h*]-pyrrolo[2,1-*a*]isoquinolin-8(9*H*)-one 15a. To a solution of compound **14a** (0.4 g, 0.94 mmol) in CH_2Cl_2 (20 mL) was added TMSI (0.44 g, 2.1 mmol) at −55 °C. The reaction was stirred for 1 h and then quenched with diluted aqueous NaOH. After separation, the aqueous layer was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic phase was dried over Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel to give compound **15a** (0.3 g, 80%) as a light yellow solid: mp 222−224 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.86 (s, 1H), 7.83 (s, 1H), 7.29 (s, 1H), 7.25 (s, 1H), 5.45 (br, 1H), 4.66 (d, J = 11.7 Hz, 1H), 4.13 (s, 6H), 4.06 (s, 3H), 4.05 (s, 3H), 3.18 (br, 2H), 3.14−2.98 (m, 2H), 2.71 (br, 1H), 2.48 (br, 1H), 1.80 (br, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 149.1, 148.7, 148.6, 128.9, 125.9, 125.5, 124.3, 123.7, 123.2, 123.1, 104.6, 104.2, 103.7, 103.3, 56.2, 56.1, 56.0, 36.6, 29.7, 29.1, 26.6; HRMS (ESI) calcd for $C_{24}H_{26}NO_5$ $(M + H)^+$ 408.1805, found 408.1805.

2,3,12,13-Tetramethoxy-5,6,8,9,10,10a-hexahydrodibenzo-[*f*,*h*]pyrrolo[2,1-*a*]isoquinoline 16a. To a solution of compound **15a** (0.29 g, 0.71 mmol) in THF (30 mL) was added $LiAlH_4$ (50.0 mg, 1.3 mmol). The reaction mixture was heated at reflux for 2 h and then quenched with diluted aqueous NaOH after cooling to room temperature. After separation, the aqueous layer was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic phase was dried over Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel to give compound **16a** (0.23 g, 82%) as a light yellow solid: mp 155−158 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.83 (s, 1H), 7.83 (s, 1H), 7.35 (s, 1H), 7.30 (s, 1H), 4.66 (t, J = 8.1 Hz, 1H), 4.12 (s, 6H), 4.05 (s, 6H), 3.25−3.16 (m, 2H), 3.15−3.04 (m, 4H), 2.73−2.69 (m, 1H), 2.04−1.92 (m, 2H), 1.84−1.72 (m, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 147.8, 147.5, 147.3, 147.2, 129.3, 124.5, 124.2, 123.5, 122.9, 122.4, 104.1, 103.2, 102.4, 102.3, 58.8, 55.1, 55.0, 54.9, 54.8, 51.9, 44.2, 31.2, 23.4, 22.4; HRMS (ESI) calcd for $C_{24}H_{28}NO_4$ $(M + H)^+$ 394.2013, found 394.2018.

2-(Piperidin-2-yl)-1-(2,3,6,7-tetramethoxyphenanthren-9-yl)ethanone 5b. The synthetic procedure was similar to that of compound **5a**, and compound **5b** was obtained as a light yellow solid (73%): mp 203−205 °C; ^{1}H NMR (400 MHz, DMSO) δ 8.55 (s, 1H), 8.45 (s, 1H), 8.07 (s, 1H), 8.03 (s, 1H), 7.64 (s, 1H), 4.09 (s, 3H), 4.06 (s, 3H), 3.95 (s, 3H), 3.90 (s, 3H), 3.85−3.77 (m, 1H), 3.69 (s, 1H), 3.57−3.55 (m, 1H), 3.26 (s, 2H), 2.97 (s, 1H), 1.94−1.91 (m, 1H), 1.77−1.75 (m, 4H); ^{13}C NMR (100 MHz, DMSO) δ 200.1, 151.5, 149.1, 149.0, 148.8, 130.0, 128.9, 126.7, 125.0, 123.9, 122.3, 109.7, 106.7, 103.8, 103.4, 56.0, 55.8, 55.5, 55.2, 52.6, 44.3, 28.9, 22.6, 22.2, 14.0; HRMS (ESI) calcd for $C_{25}H_{30}NO_5$ $(M + H)^+$ 424.2118, found 424.2123.

2-(2-(2,3,6,7-Tetramethoxyphenanthren-9-yl)ethyl)-piperidine 6b. The synthetic procedure was similar to that of compound **6a**, and compound **6b** was obtained as a white solid (88%): mp 175−176 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.83 (s, 1H), 7.76 (s, 1H), 7.41 (s, 1H), 7.40 (s, 1H), 7.16 (s, 1H), 4.11 (s, 6H), 4.05 (s, 3H), 4.03 (s, 3H), 3.09 (t, J = 8.0 Hz, 3H), 2.71−2.59 (m, 2H), 1.89−1.82 (m, 4H), 1.64−1.61 (m, 2H), 1.52−1.32 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 148.7, 148.5, 134.0, 126.4, 125.4, 124.9, 123.5, 107.9, 104.8, 103.4, 102.8, 77.3, 77.0, 76.7, 56.9, 56.1, 56.0, 55.9, 55.8, 47.2, 37.8, 33.0, 29.8, 26.7, 24.8; HRMS (ESI) calcd for $C_{25}H_{32}NO_4$ $(M + H)^+$ 410.2326, found 410.2331.

2,3,6,7-Tetramethoxy-9,11,12,13,14,14a,15,16-octahydrophenanthro[9,10-*e*]pyrido[1,2-*a*]azepine 7b. The synthetic procedure was similar to that of compound **7a**, and compound **7b** was obtained as a white solid (68%): mp 216−218 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.83 (s, 2H), 7.50 (s, 1H), 7.45 (s, 1H), 4.37 (d, J = 14.9 Hz, 1H), 4.16−4.02 (m, 13H), 3.56−3.53 (m, 1H), 3.30−3.19 (m, 1H), 3.06−3.04 (m, 1H), 2.60−2.41 (m, 2H), 2.01 (s, 1H), 1.68−1.60 (m, 5H), 1.49 (s, 1H), 1.34−1.31 (m, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 148.7, 148.6, 148.5, 148.3, 125.7, 124.2, 123.7, 104.6, 104.3, 103.4, 103.3, 94.5, 77.3, 77.0, 76.7, 56.8, 56.0, 55.9, 55.8, 55.7, 33.9, 33.5, 26.8, 26.5, 23.8; HRMS (ESI) calcd for $C_{26}H_{32}NO_4$ $(M + H)^+$ 422.2326, found 422.2332.

5-Oxo-5-((2-(2,3,6,7-tetramethoxyphenanthren-9-yl)ethyl)-amino)pentanoic acid 12b. The synthetic procedure was similar to that of compound **12a**, and compound **12b** was obtained as a white

15b was obtained as a white solid (80%): mp 153−155 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.85 (s, 1H), 7.82 (s, 1H), 7.32 (s, 1H), 7.21 (s, 1H), 5.35 (d, J = 10.8 Hz, 1H), 5.18 (dd, J = 12.4, 3.2 Hz, 1H), 4.13 (s, 6H), 4.05 (s, 3H), 4.04 (s, 3H), 3.19 (t, J = 16.0 Hz, 1H), 3.14−3.03 (m, 1H), 2.85−2.75 (m, 1H), 2.76−2.66 (m, 2H), 2.60−2.48 (m, 1H), 2.09−1.93 (m, 2H), 1.40−1.35 (m, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 169.8, 149.2, 148.6, 148.53, 128.2, 127.6, 125.5, 124.5, 123.5, 123.3, 104.2, 104.1, 103.8, 103.3, 56.2, 56.1, 56.1, 56.0, 56.9, 38.0, 32.1, 31.6, 26.8, 20.0, 14.2; HRMS (ESI) calcd for $C_{25}H_{27}NO_5$ $(M + H)^+$ 422.1962, found 422.1959.

2,3,13,14-Tetramethoxy-6,8,9,10,11,11a-hexahydro-5*H*-dibenzo[*f*,*h*]pyrido[2,1-*a*]isoquinoline 16b. The synthetic procedure was similar to that of compound **16a**, and compound **16b** was obtained as a white solid (60%): mp 89−92 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.83 (s, 1H), 7.82 (s, 1H),7.32 (s, 1H), 7.25 (s, 1H), 4.26 (d, J = 9.7 Hz, 1H), 4.11 (s, 6H), 4.04 (s, 3H), 4.03 (s, 3H), 3.47−3.39 (m, 1H), 3.28−3.25 (m, 1H), 3.21−3.13 (m, 2H), 2.93−2.87 (m, 1H), 2.21 (d, J = 11.9 Hz, 1H), 1.96−1.63 (m, 6H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 149.5, 149.3, 148.8, 131.1, 126.6, 126.5, 124.7, 124.5, 124.2, 105.4, 104.8, 104.3, 103.9, 60.5, 56.8, 56.7, 56.6, 56.5, 46.3, 29.2, 28.5, 26.6, 22.5; HRMS (ESI) calcd for $C_{25}H_{30}NO_4$ $(M + H)^+$ 408.2169, found 408.2170.

Antiviral Biological Assay. The procedure of purifying TMV and the method to test the anti-TMV activity of the synthesized compounds were the same with those reported previously in the literature.[22]

RESULTS AND DISCUSSION

Chemistry. The synthesis of D-ring expanded phenanthroindo/quinolizidine alkaloid analogues **7a** and **7b** is shown in Scheme 1, which features a Mukaiyama−Aldol reaction and a Pictet−Spengler cyclization. The precursors **2** of the Mukaiyama−Aldol reaction were prepared from commercially available lactams through literature protocols.[23] Silylenol ether **4** was synthesized from acetophenanthrone **3**, which was obtained from readily available phenanthryl acid.[24] After extensive reaction screening, it was found that boron trifluoride was the optimal Lewis acid for the desired Mukaiyama−Aldol reactions, giving compounds **5** in good yields. Ketones **5** were reduced to alcohols by sodium borohydride, followed by deprotection and further reduction of the benzylic hydroxyl by triethylsilicane under acidic conditions, furnishing amines **6** efficiently. It is worth noting that the following Pictet−Spengler cyclization did not occur when concentrated hydrochloric acid was used as catalyst in ethanol, which may be due to the energy of the seven-membered ring transition state being too high. When the reaction was performed in a high boiling point solvent (toluene) using much stronger acid CF_3COOH as catalyst, the desired cyclized products **7** were obtained in good yields.

The synthesis of the isomerized phenanthroindo/quinolizidine analogues **16a** and **16b** is shown in Scheme 2, featuring a Bischler−Napieralski cyclization. Using readily available phenanthryl bromide **8** as starting material,[25] intermediate **10** could be easily be prepared via sequential nucleophilic substitution and reduction. With the phenanthrylethylamine **10** in hand, we initially attempted to construct the pentacyclic skeleton through Pictet−Spengler cyclization/condensation sequence. Unfortunately, although much effort was devoted to the screening of reaction conditions, including catalysts, solvents, and reaction temperature, all attempts to perform the desired Pictet−Spengler cyclization failed. The main difficulty was proposed to be the Pictet−Spengler cyclization, presumably because reactivity of the key intermediate formed through condensation of amine and aldehyde was so slow that self-condensation of the aldehyde occurred quickly. To improve the reactivity of the intermediate of the cyclization, we turned to an alternative Bischler−Napieralski cyclization approach, which employed highly reactive acyl iminium as key intermediate. Imides **13** prepared from amine **10** and corresponding anhydride were subjected to partial reduction, affording compounds **14**. The subsequent Bischler−Napieralski cyclization went smoothly when trimethyliodosilane was employed. After reduction, isomerized phenanthroindo/quinolizidine alkaloid analogues **16** were obtained in good yields.

Antiviral Activity. To make a judgment of the designed structurally novel phenanthroindo/quinolizidine alkaloid analogues **7a**, **7b**, **16a**, and **16b**, two commercially available antiviral agents were used as control. To further investigate the influence of the variation of the basic skeletons of the natural alkaloids on the antiviral effects, corresponding tylophorine **I** and phenanthroquinolizidine **II** (Figure 1) were also used for comparison, which were synthesized using methods reported previously by our group.[24] The in vitro and in vivo (protection, inactivation, and curative effect) antiviral results against TMV of phenanthroindo/quinolizidine alkaloids **I** and **II**, analogues **7a**, **7b**, **16a**, and **16b**, ribavirin, and ningnanmycin are listed in Table 1. All of the compounds were tested at both 500 and 100 μg/mL.

Table 1. In Vitro and in Vivo Antiviral Activity of Compounds 7a, 7b, 16a, and 16b against TMV

		inhibition rate (%)			
compd	concn (μg/mL)	in vitro effect	protection effect	inactivation effect	curative effect
I	500	38.5	40.4	45.2	42.6
	100	15.3	18.2	17.5	13.1
7a	500	43.8	46.5	47.3	42.5
	100	20	21.6	20.3	10.6
16a	500	60	54.1	55.8	58.6
	100	30.6	24.1	26.7	30
II	500	67.5	65.8	64.2	68.9
	100	32.4	32.1	30	34.7
7b	500	54.7	48.3	52.6	50.7
	100	27.6	26.9	28.9	21.7
16b	500	37.7	42.9	41.7	39.5
	100	10	17.5	18.3	12.4
ribavirin	500	41.3	38.9	37.2	39.4
	100	18.5	15.6	11.9	14.7
ningnanmycin	500	69.3	57.9	54.2	58.7
	100	26.8	38.4	20.0	23.1

The first in vitro anti-TMV bioassay demonstrated that all of the synthesized sturcturally novel analogues except for **16b** exhibted higher activity than ribavirin at both high (500 μg/mL) and low (100 μg/mL) concentrations. Especially, although compounds **16a** and **7b** showed only comparable inhibitory effect with that of ningnanmycin at 500 μg/mL, they exhibited higher antiviral activity at 100 μg/mL. Further in vivo anti-

dx.doi.org/10.1021/jf405562r | J. Agric. Food Chem. 2014, 62, 1233−1239

TMV bioassay indicated that all of the newly designed analogues displayed protection and inactivation effects superior to those of ribavirin at both concentrations, and all of them also showed preferable curative effects except for **7a** and **16b** at 100 μg/mL. Compared with ningnanmycin, perhaps the most effective commercial plant virucide, analogue **16a** can also exhibit higher inactivation effect at both concentrations, and **7b** and **16a** showed inactivation and curative effects superior to those of ningnanmycin at 100 μg/mL.

The SARs demonstrated that phenanthroindolizidine analogue **7a** with the six-membered D-ring of natural alkaloid expanded to seven-membered ring that showed higher in vitro, protection, and inactivation effects than tylophorine **I** at both concentrations. The isomerized analogue **16a** also displayed preferable antiviral effects both in vitro and in vivo relative to its precursor **I** at both high and low concentrations. Then, we can conclude that for natural phenanthroindolizidine alkaloid **I**, no matter how the six-membered D-ring was expanded to seven-membered or the fused pattern of D/E rings was changed, analogues **7a** and **16a** showed superior antiviral activity to that of the precursor **I**, which indicated that the original conformation of the phenanthroindolizidine was not optimal and deserved further optimization. However, no matter how the D-ring was expanded from six-membered to seven-membered or the fused pattern of D/E rings was changed, both phenanthroquinolizidine analogues **7b** and **16b** exhibited inferior inhibitory effects against TMV, indicating that the original conformation of the phenanthroquinolizidine was a relatively preferential conformation. Another interesting result was that although six-membered E ring compound **7b** showed higher activity than five-membered E ring compound **7a**, their corresponding counterparts **16b** and **16a** displayed reverse bioactive results, which suggested that the fused pattern of D/E rings of phenanthroquinolizidine alkaloid also has a great effect on its activity, and the original fused pattern is relatively optimal.

In summary, two types of structurally totally novel analogues of phenanthroindo/quinolizidines were synthesized and evaluated for their antiviral activities aganist TMV for the first time. The bioassay results indicated that most of the four designed structural analogues showed good to excellent in vivo anti-TMV activity, among which analogue **16a** dispalyed comparable activity with that of one of the most successful commercial antiviral agents, ningnanmycin, thus emerging as a potential inhibitor of plant virus. Further structure−activity relationships demonstrated for the first time that the original skeleton of the pentacyclic structure of phenanthroindolizidine is not optimal, and further optimization for preferential conformation is needed, whereas changes of the original skeleton of the phenanthroquinolizidine descreased its antiviral activity, indicating that the original conformation is a relative preferential conformation. Further investigations on structual optimization and mode of action are currently underway in our laboratories.

and silica, were of interest as a sorbent trap to extract nitrosamines from the liquid extract of frankfurter sausage after SWE. Because PS−DVB and P-DVB possess high hydrophobicity and thermal stability, they are likely to absorb fat and nonpolar matrix. Silica was chosen because it was successfully used as a fat retainer[20] and also provides a high thermal stability.

EXPERIMENTAL SECTION

Chemicals and Sample. For polymer-based monolith capillary synthesis, γ-(trimethoxysilyl)propyl methacrylate (98.0%) obtained from Acros (Morris Plains, NJ) and glacial acetic acid from BDH (Poole, U.K.) were used as silanization solutions. Styrene monomer (99.0%) was purchased from Fluka (Buchs, Switzerland), and divinylbenzene monomer (80.0%) was from Sigma-Aldrich (Steinheim, Germany). Decanol (99.0%) from Acros (Morris Plains, NJ), tetrahydrofuran (99.9%) from Fisher (Loughborough, U.K.), and dodecanol (>99.5%) from Fluka (Buchs, Switzerland) were used as porogenic agents. Dibenzoyl peroxide (75%) from Acros (Morris Plains, NJ) was employed as an initiator. For silica-based monolith capillary synthesis, polyethylene glycol [MW of 10 000 g/mol; analytical reagent (AR) grade] was bought from Sigma-Aldrich (Steinheim, Germany), while urea of analytical grade and tetramethoxysilane (98.0%) were obtained from Merck (Darmstadt, Germany). Both polymeric and silica-based monoliths were synthesized inside a 0.32 mm inner diameter × 10 m bare fused silica capillary tubing with polyimide coating purchased from SGE (SGE Analytical Science, Melbourne, Victoria, Australia).

Standard nitrosamines, namely, *N*-nitrosodiethylamine or NDEA (99.0%) from Fluka (Buchs, Switzerland), *N*-nitrosopiperidine or NPIP (99.0%) and *N*-nitrosopyrrolidine or NPYR (99.0%) from Sigma-Aldrich (Milwaukee, WI), and *N*-nitrosomorpholine or NMOR (5.0 mg/mL in methanol) from Supelco (Bellafonte, PA) were used in this study. Each 1.0 mg/mL standard stock solution was prepared in methanol. *N*-Nitroso-di-*n*-propylamine or NDPA from Supelco (Bellafonte, PA) was used as an internal standard for quantification. Other chemicals were of analytical grade.

Frankfurter sausages from a local supermarket in Bangkok were chopped and homogenized. A 1.0 g sample was fortified with 100 μg of each nitrosamine, rehomogenized, and left at room temperature for 10 min.

Monolith Capillary Preparation. *Silanization of the Inner Wall of the Capillary.* The silanization method described by Coufal et al. was used. In brief, silanization solution was prepared from 1.817 g of glacial acetic acid mixed with 20 μL of γ-(trimethoxysilyl)propyl methacrylate in a 5.00 mL volumetric flask and adjusted to the volume by decanol. The solution was filled into a 0.32-mm inner diameter × 100 cm bare fused silica capillary, where both ends of the capillary were subsequently sealed with a septum. The sealed capillary was then incubated in an oven at 60 °C for 20 h. After cooling to room temperature, it was rinsed with acetone to remove the silanizing solution, dried with a gentle flow of nitrogen gas for 1 h, and finally cut into 10.0 cm pieces.

PS−DVB and P-DVB Monolith Capillary. A PS−DVB polymerization mixture consisted of 200 μL of styrene monomer, 200 μL of divinylbenzene, 520 μL of decanol, 80 μL of tetrahydrofuran porogen, and 10 mg/mL dibenzoyl peroxide initiator. The formulation of the PS−DVB polymerization solution used the method by Premstaller et al.[21,22] The P-DVB polymerization solution was a mixture of 400 μL of divinylbenzene monomer, 520 μL of dodecanol, 80 μL of toluene, and 10 mg/mL dibenzoyl peroxide, and its formulation was from the method by Svec and Kurganov.[18] Either polymerization solution was filled in the 10 cm silanized capillary for about 5 cm. The capillary was sealed at both ends and kept at 70 °C for 24 and 20 h for PS−DVB and P-DVB synthesis, respectively. To remove the porogen and monomeric residues, the fabricated monolith in capillary was flushed with either acetonitrile or methanol at a flow rate of 10 μL/min for 3 h and then dried with nitrogen gas flow.

Silica Monolith Capillary. A fabrication method for silica monolith capillary was adapted from one previously reported by Tanaka et al.[9] In brief, a 0.32 mm. inner diameter × 100 cm bare fused silica capillary was pretreated with 1 M NaOH, and both ends were tightly sealed with a septum. The filled tubing was kept at 40 °C for 6 h, rinsed with deionized water, and dried with nitrogen gas. The sol−gel solution for silica monolith synthesis was a mixture of 400 μL of tetramethoxysilane, 0.088 g of polyethylene glycol, and 0.09 g of urea in 0.01 M acetic acid. The solution was stirred in an ice bath for 45 min and then filled into the pretreated capillary that was subsequently heated at 40 °C for 24 h. The temperature was then raised to 120 °C for 6 h. After cooling, the monolith in capillary was washed with methanol and then dried with nitrogen gas. The fabricated PS−DVB, P-DVB, and silica monolith capillaries were cut perpendicular to the cross-section into 0.50 cm long pieces, and the specimens were subjected to scanning electron microscopy (SEM) using a JSM-5600 SEM microscope (JEOL, Japan) at 20 kV.

SWE. The SWE system was similar to the one described previously.[6,23] In brief, degassed double-deionized water was delivered by a ConstraMetric 3200 HPLC pump (LDC Analytical, Riviera Beach, FL) passing through a 1 m × 0.51 mm inner diameter stainless-steel preheating coil (Alltech Chromatography, Columbia, MD) to a 15 cm × 4.6 mm inner diameter stainless-steel extraction cell containing 1.0 g of fortified frankfurter sausage sample. Glass wool was put at both ends of the cell, where 2 μm stainless-steel frits and screw caps were subsequently mounted. Both the preheating coil and extraction cell were heated in an oven at 140 °C for 5 min of static time. The end of the outlet tubing was crimped to control pressure to more than 300 psi. After that, the water was reflowed and the aqueous extract was cooled using a stainless-steel cooling coil wrapped with aluminum fins. The aqueous extract was collected for 10 mL in a vial containing 2 g of NaCl and 2 mL of dichloromethane (DCM). The cloudy mixture in the vial was transferred to centrifuge at 1100 rpm for 7 min, and the DCM layer was filtered and dried with anhydrous Na_2SO_4. To preconcentrate, the organic phase was purged with nitrogen gas and then adjusted to 100 μL with the solvent.

Monolith Capillary GC Setup. A 1 μL sample of the organic extract was subjected to extraction, separation, and quantification by coupling a fabricated monolith sorbent with GC. To set up the connection, a 0.32 mm inner diameter × 5.0 cm bare fused silica tubing was connected with an injection port of a HP5890 series II gas chromatograph (Hewlett-Packard, Palo Alto, CA) at one end and the other end was connected with a fabricated monolith capillary, where a glass connector led to a 0.32 mm inner diameter × 0.52 μm film thickness × 25 m HP-5 column (Hewlett-Packard, Polo Alto, CA). The temperature program was started by ramping from 40 to 80 °C at 7 °C/min, held for 8 min, then increased to 200 °C at 15 °C/min, and maintained for 5 min. Either a flame ionization detector (FID) or HP 5989B mass spectrometer (MS, Hewlett-Packard, Polo Alto, CA) in an electron impact mode was employed as a detector. The injector and FID temperatures were maintained at 250 and 280 °C, respectively. The temperatures of the ion source and quadrupole mass analyzer were 200 and 100 °C, respectively. During optimization of the monolith sorbent capillary, the FID was operated with nitrogen carrier gas and the split ratio at the injection port was 1:15. For quantification by using GC−MS, the operation was in splitless mode and nitrogen was replaced with helium carrier gas.

RESULTS AND DISCUSSION

Optimization of Monolith. The types of primarily studied monolith for fat adsorbent were chosen from two individual properties, namely, polarity and thermal stability. The monolith should be adequately nonpolar to retain fat while releasing the polar analytes. It must also have sufficiently high thermal stability to tolerate heat in the oven during the desorption step. When the monolith capillary was connected to the analytical column, the column head pressure increased, particularly for the polymeric monolith. The pressure was measured from the

column head pressure gauge in the front panel of the GC instrument. The maximum scale of the gauge corresponded to 40 psi. Although a high surface area was obtained with a long monolith capillary, the longer the monolith, the higher the column head pressure, and the gas flow stopped at the maximum allowed length for different types of monoliths. At high carrier gas flow through the column, increased resistance occurred, and as a consequence, a higher pressure was needed to drive gas through both the monolith capillary and analytical column to obtain the required column flow rate. The maximum pressure was restricted to 40 psi because of a limitation of the GC instrument. Figure 1 shows the average column head

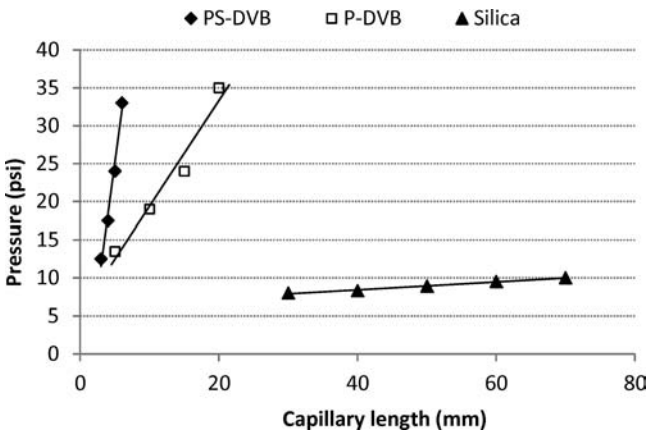

Figure 1. Average column head pressure for the GC column connected with different types of synthesized monolith capillary.

pressure when connected with each type of monolith with the flow of 1.4 mL/min. No flow occurred for PS−DVB and P-DVB monoliths of more than 6 and 20 mm, respectively.

With the coupling of the PS−DVB monolith to the analytical column, nitrosamines did not separate well. For the 5−6 mm long monoliths, baseline drift occurred and all compounds gave broad and tailing peaks, presumably as a result of their strong interaction with the polymeric phase. Besides, NDPA and NPYR peaks were completely overlapped. For 4.0 and 3.0 mm monoliths, a better peak shape was obtained but NDPA and NPYR peaks remained completely overlapped (Figure 2). Because of thermal stability and hydrophobic properties similar to those of PS−DVB, P-DVB was investigated as a nonpolar monolith sorbent trap. After varying the length of polymer monolith from 5 to 20 mm, the best separation in this experiment occurred using a 5 mm P-DVB monolith. Despite the higher column permeability and effective surface area than those of PS−DVB, an improved peak shape was obtained but the separation of NPYR and NDPA was still not possible. It was then concluded that both polymer monoliths gave rather poor performance in retaining fat. According to our previous study[6] in which silica sorbent was primarily used as a lipid retainer, a silica monolith was then synthesized and studied, despite the fact that it has rather high polarity. A scanning electron micrograph of the silica monolith in the capillary showed a skeleton with large through pores, and the microglobule diameter was on average 1 μm. The specific surface area was 32−43 m^2/g determined by inverse size-exclusion chromatography.[24] Because of large macropores, silica monoliths provide several times higher column permeability than the two polymer monoliths and permeability of silica monolith was not affected by the capillary length. The flow was almost constant when

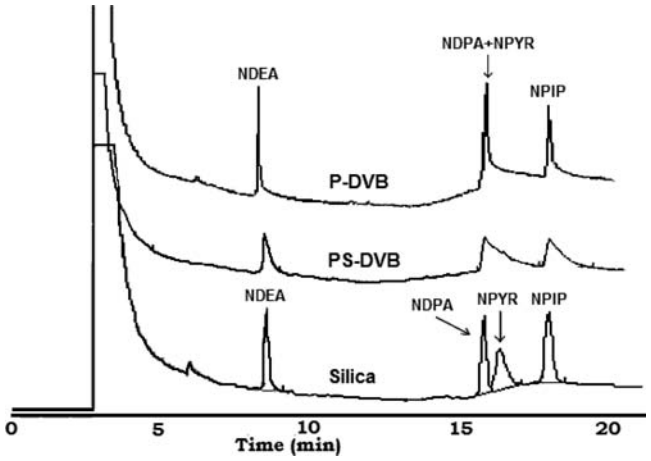

Figure 2. Separation of nitrosamines on a HP-5 column coupled with online sorbent of 5 mm P-DVB and 3 mm PS−DVB and 30 mm silica monolith sorbent. Temperature program: 60−100 °C at 7 °C/min, maintained for 8 min, then raised to 120 °C at 7 °C/min, and maintained for 5 min.

increasing the capillary length. This led to the feasibility of using a very long silica capillary. Better separation of nitrosamines was obtained with a short silica monolith, owing to the lower interaction of nitrosamines with silica sorbent. Separation of all nitrosamines was achieved for the silica monolith, although the NPYR peak was rather broad. Gradually reducing the monolith length from 70 to 60, 50, and 40 mm improved both the peak shape and separation. A 30 mm long monolith gave the most favorable separation, and the chromatogram is shown in Figure 2. Further reducing sorbent capillary length likely caused poor nonpolar matrix trapping, thus affecting the separation efficiency of nitrosamines.

Capability and reusability of a silica monolith capillary as a nonpolar sorbent trap was studied to investigate the feasibility of multiple use before disposal. Figure 3 shows the chromato-

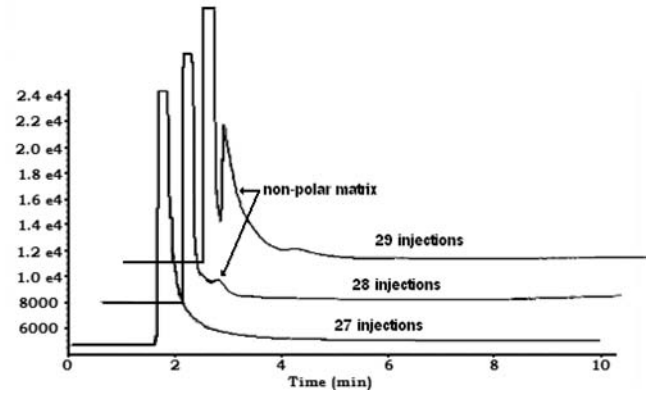

Figure 3. GC chromatograms obtained from different numbers of repeated injections of unfortified frankfurter extract on 30 mm silica monolith connected with a HP-5 column.

gram of the nonpolar matrix of frankfurter sausage. The extract was repeatedly injected onto the monolith coupled with the HP-5 column, the peak area of the nonpolar matrix was observed after 27 injections for a 30 mm long silica monolith (Figure 3). The number of repeated injections was also dependent upon the amount of contaminating fat, and for our sample, the fat content from the frankfurter sausage package

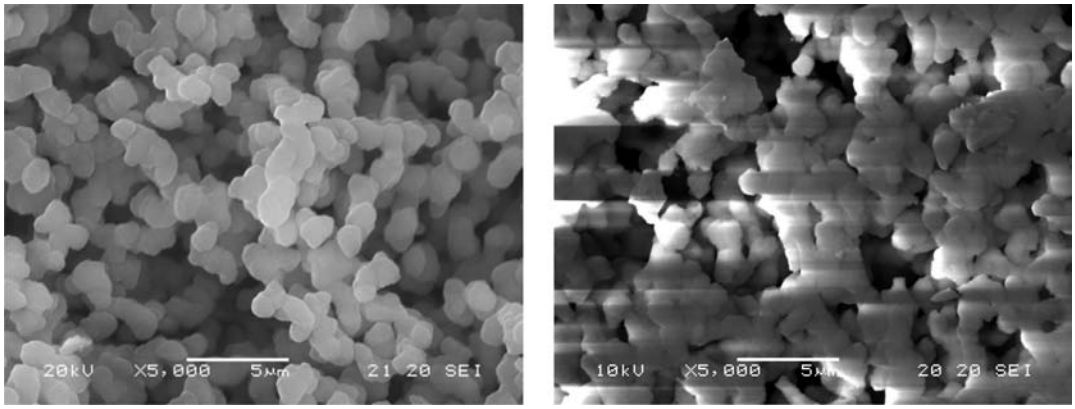

Figure 4. Scanning electron micrograph of silica monolith (a) before and (b) after use as a sorbent trap for frankfurter extract.

label was 30% by weight. The sample of absorbed fat on the monolith after 30 injections was also subjected to SEM (Figure 4), confirming that the deposit of fat and other nonpolar matrix covered the monolithic skeleton. The deposition might occur from both condensation and adsorption of the volatile fat and other nonpolar components onto the silica surface, because the operating temperature was lower than the smoke point of lard (188 °C). It was then concluded that the reusability of a 30 mm fabricated silica monolith capillary as a sorbent trap for a fat matrix was up to 27 times. In practice, for prevention of fat leachate reaching an analytical column, the number of reuses should be reduced by a quarter or to about 20.

Application to Real Samples. When the silica monolith trap was connected to the HP-5 analytical column, the elution order of NPYR and NPDA was obviously swapped, in comparison to the one without the silica monolith. NPYR changed the retention with the silica trap, and its peak shape was quite broad. The phenomenon possibly occurred from an increased dipole−(induced) dipole interaction of NPYR to the silica surface, because NPYR is more polar than the other chosen nitrosamines. However, the interaction that caused the broad peak was traded off by better separation between the NPYR and NDPA peaks, giving benefits to the overall nitrosamine separation.

A two-tailed *t*-test also revealed no significant difference in the average peak area of each nitrosamine obtained from its separation on the analytical column with and without the silica monolith trap. The $|t|$ values of NDEA, NPYR, NPIP, and NDPA were 0.1532, 0.5815, 0.6317, and 0.2820, respectively, lower than the *t*-critical value of 4.30 at the 95% confidence limit. A 20 μg/g fortified sausage extract was repeatedly injected onto the same capillary and different capillaries to show the reliability of the method for each nitrosamine. The percent relative standard deviations (%RSDs) of an average area ratio of each analyte to the internal standard showed very good precision for injection−injection (0.79−1.46%) and reasonably good precision for capillary−capillary (2.4−6.0%) experiments, and %RSDs of average retention time of both comparison tests were very good (0.09−0.22%). Such results confirm that fat adsorption on the silica monolith did not significantly affect either the quantification or retention of nitrosamines.

Efficiency of the extraction and determination method was assessed by an investigation of detection limits and percent recovery of all analytes. The detection limits of nitrosamine were found to lie in a range of 2.1−5.4 ng injected for all components. The detection limits of all analytes obtained was not as low as expected, probably because of the small amount of sausage packed in the extraction cell and an insufficiently high sensitivity of the HP 5989B mass spectrometric detector used in the work. It was then postulated that the detection limits could be reduced using more sensitive and selective detectors, such as a tandem mass spectrometric detector (tandem MS) and thermal energy analyzer (TEA).

The recoveries of nitrosamine extraction from frankfurter sausage using SWE coupled with monolith sorbent capillary were compared to SWE−conventional SPE in our previous study[6] and determined by GC−MS analysis. The recovery of nitrosamines was in a range of 74.7−88.4%, which lies within the acceptable range, and precision of the coupling method was satisfactory, varying between 2.09 and 3.85%. Although the results showed the same trend for both methods, the recovery obtained from SWE−conventional SPE was slightly higher than those from SWE−silica monolith: about 7% for NPYR, 10% for NDEA, and 18% for NPIP. Silica monolith has obviously proven to be the most optimal monolith absorbent for our purpose. No additional ions of significant relative abundance were detected in those spectra measured with the silica monolith capillary coupled to the HP-5, indicating that the method was very clean with no interference with similar retention and fragmented mass.

The coupling method of SWE with a silica monolith capillary for nitrosamine determination from frankfurter sausage in our present work was compared to other extraction methods and our previous work for several meat products, as shown in Table 1. Although the extraction efficiency, represented by percent recovery, of the proposed method was close to those of other methods,[2,25,26] this method gave more advantages by reducing solvent consumption, amount of sample, and analysis time. For example, in the method by Byun et al.,[3] up to 600 mL of DCM was consumed per sample for additional extraction after distillation. The necessary organic solvent volume for the methods by Yurchenko et al.[25,26] and our previous classical SPE[6] were 52, 72, and 30 mL, respectively. The total volume of extracting organic solvent used in this work was significantly reduced at less than 3 mL, related to a fast preconcentration step, compared to those methods. The required amount of sample was also significantly reduced in this work. Only 1 g of food sample was subjected to the overall preconcentration and cleanup process, while the amount was 2−200-fold larger for the other techniques.[2,27−35]

Some reference methods require several steps of sample preparation and are therefore time-consuming. For example,

Table 1. Method Comparison for Determination of Nitrosamine from Different Meat Matrices (Adapted from Ref 6)

sample matrix	preparation method	analytical method	sample mass (g)	percent recovery (%)	detection limit	reference
pork luncheon meat, pig liver	steam distillation (alkali and acid), electrochemical reduction, and amine derivative method	HPLC	200	42−77 yield of derivative	1−10 μg/kg	27
frankfurter sausage	supercritical CO_2 coupled with SPE (Florisil)	GC−TEA	2.5	84.3−104.8		30
sausages	two-step SPE with Extrelut and Florisil	GC−TEA	6.0	40−100	0.3 ppb	31
fresh and preserved food	liquid−liquid extraction with DCM and SPE with basic alumina	GC−TEA	10.0	60−90	0.1−0.5 μg/kg	32
cured ham, bacon, and sausage	flow-injection method (on the basis of photochemical cleavage of the N−NO bond) and then nitrite was detected	DAD	2.0	91.6−105.8	6.0 ng/mL	28
meat products	steam distillation, extraction with DCM, and denitrosation	HPLC with fluorescence	80−100	72−76	0.7−2.2 ng	2
canned sausage	steam distillation (rotary vacuum evaporator) and SPE with active carbon	MEKC	150	38.2−55.0		29
dried seafood	steam distillation and extraction with DCM	GC−TEA	25	83.2−102.2	0.1 μg/kg	38
fermented sausage	steam distillation on a steam generator and extraction with DCM	GC−TEA	20	87−93	0.1 μg/kg	3
sausage	headspace solid-phase microextraction	GC−TEA	2.5	105−110	3 μg/kg	33
fish sample	two-step SPE with Extrelut and Florisil	GC−MS	6.0	79−88	0.10 μg/kg	25
sausage	supercritical fluid CO_2 coupled with SPE (Florisil)	MEKC	0.2	21−82		39
meats	two-step SPE with Extrelut and Florisil	GC−MS	6.0	79−88	0.09 μg/g	26
meat products	two-step SPE with Extrelut and Florisil	GC × GC−NCD	6.0		1.66−3.86 μg/g	34
meat sample	two-step SPE with Extrelut and Florisil	GC × GC−NCD	6.0	83.1−89.8	1.54−1.86 pg	35
meat products	microwave-assisted extraction (MAE) and dispersive liquid−liquid microextraction (DLLME)	GC−MS	0.25	36−74	0.003−0.014 ng/mL for NPIP and NMEA	40
frankfurter	SWE and LLE couple with SPE (Florisil)	GC−MS	1.0	81−106	0.47−1.48 ng	6
frankfurter	SWE and LLE couple with silica monolith capillary	GC−MS	1.0	74.7−88.4	2.10−5.40 ng injected/g	proposed method

dx.doi.org/10.1021/jf4036645 | J. Agric. Food Chem. 2014, 62, 1240−1246

the AOAC reference method using vacuum distillation takes about 75 min per sample followed by a second step of DCM extraction of the distillate.[36] The total sample preparation time is approximately 2 h. A cleaning and preconcentration process using a conventional SPE took about 1 h in the work by Yurchenko et al.,[26] but it was reduced to less than 10 min for separation of those components using a coupling technique of monolith capillary with GC after 20 min of extraction with superheated water. In addition, one monolith capillary could be reused with the liquid extract more than 20 times (corresponding to 20 samples).

Many significant benefits were obtained for the determination of nitrosamines in sausage by coupling of SWE with a silica monolith capillary and GC. The detection limits results were, however, not as low as expected. To improve the sensitivity, additional steps, such as denitrosation,[37] could be introduced prior to detection. Specific detectors, namely, a TEA or highly sensitive tandem MS, can enhance the detection efficiency. Furthermore, the monolith capillary can also be adapted to couple with other methods of extraction for further preconcentration and purification of a wide range of analytes prior to chromatographic analysis. This method investigated here has also been proven to be a green technique with environmental advantages, because it greatly reduced solvent consumption and minimized analysis time and costs associated with obtaining reproducible results.

and randomly chosen. A portion of each item was minced three times with a meat grinder, packed into polyethylene bags, frozen, and stored at −20 °C until it was submitted to the specific sample preparation procedure preceding the assay. All commercial food labels were maintained and their data collected; food labeling in Italy is enforced by Council Directive 2000/13/EC on labeling: in the European Union the list of ingredients is compulsory on the labeling of food products, where under the term "Ingredient" there should be the list of any substance, including additives, used in the manufacture or preparation of a food and present in the final product, even in altered form. In this investigation, after examining the label information, we divided cooked ham items into three different groups that were characterized by a different use of P-containing ingredients and additives during the production processes. We classified them as follows: "regular", when no evidence of P-containing ingredients and additives was present on the package label (n = 8); "enhanced with P-containing additives" (EWP), when the words "containing polyphosphates" or the coding "E338−E341, E450−452" was used on the package labelling (n = 8); "enhanced with P-containing ingredients and additives" (EWPIA), when the words "containing polyphosphates" or the coding "E338−E341, E450−452" together with the key words "milk proteins", "plant protein extracts", "soy protein isolates", "wine" were mentioned on the package labeling (n = 8).

Chemicals, Reagents, and Certified Reference Materials. Potassium dihydrogen phosphate (KH_2PO_4), sodium hydroxide (NaOH), sulfuric acid 96% (H_2SO_4), sodium sulfate (Na_2SO_4), trichloroacetic acid 99%, chloroform, and methanol were used as analytical grade and provided by Sigma-Aldrich (St. Louis, MO, USA). Ammonium heptamolybdate tetrahydrate ($(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$), hydrogen peroxide solution 30% (H_2O_2), and L-ascorbic acid were purchased from Carlo Erba (Milano, Italy). KH_2PO_4 and Na_2SO_4 were dried in an oven (110 °C for 2 h) and cooled in a desiccator overnight before use. Meat reference material, lyophilized pork muscle powder (ERM-BB384), was supplied by LGC Standards (Teddington, UK), whereas a 1 g/L phosphorus standard solution (Certified Reference Material, CRM) was supplied by Carlo Erba. Calibrated class A glassware and bidistilled water (specific conductivity < 18 mS) were used in the preparation of all solutions. In particular, the following solutions were prepared: 4 M sulfuric acid, 100 g/L trichloroacetic acid solution, P working standard solution at a concentration of 5 mg/L by using the 1 g/L P standard solution, 18 g/L ammonium molibdate solution by dissolving ammonium heptamolybdate tetrahydrate and 25 g/L ascorbic acid, these latter freshly prepared.

Instrumentation. Absorbance was measured by a UV−visible spectrophotometer (CP/2300, CGA Strumenti Scientifici, Firenze, Italy) in a 1 cm quartz cell, against reagent blank. Mineralization of samples and solutions was performed using a heating digester with programmable temperature controller (DK 20/26, Velp Scientifica Ertec, Poland). Samples were centrifuged by a laboratory centrifuge (4235A, ALC, Milano, Italy) with an angle rotor (maximum speed 6000 rpm, RCF 4800g, angle 45°, Falcon tubes 50 mL). Minced samples were obtained by using a manual meat grinder having a plate with 3 mm diameter holes. Homogenization of samples and solutions was performed using an Ultra-Turrax T 25 homogenizer with an S25N-18G dispersing tool (IKA-Werke GmbH, Staufen, Germany). For solvent evaporation a Rotavapor R-114 (Büchi Labortechnik AG, Flawil, Switzerland) with a water bath B-480 (Büchi Labortechnik AG) was used.

Total and Different Subtypes of Phosphorus. Total P, inorganic P, P from phospholipids, and P from phosphoproteins were detected by molybdenum blue method on wet ashing samples, preceded by a specific sample preparation.

Total Phosphorus (TP): Sample Preparation Method and Wet Ashing Procedure. Total P was determined as previously described.[11] In brief, the sample (0.4 g fresh mass, fm) was wet mineralized with 96% sulfuric acid and 30% hydrogen peroxide by using the temperature digestion program shown in Table 1. The cool digest was then transferred to a 100 mL volumetric flask and made up to the mark with bidistilled water, and it underwent a final measurement of P by using the P quantification procedure.

Table 1. Wet Digestion Program for TP, IP, PL, and PP Measurement Analyses

step	temperature (°C)	digestion time (min)
1	120	45
2	260	60
3	320	90
4[a]	420	180

[a]PP and PL sometimes needed an extra 60 min at step 4.

Inorganic Phosphorus (IP): Sample Preparation Method and Wet Ashing Procedure. Soluble phosphate ions, which usually include either natural or, to a greater extent, added inorganic P, were extracted according to the method described by Jastrzębska et al. modified in our laboratory: the samples (5 g fm) were extracted with 10 mL of 1 mM NaOH, using an orbital shaker for 60 min.[6,12] The extracts were separated by centrifugation at 6000 rpm (RCF 4800g) for 30 min, and supernatant was filtered under vacuum with a Whatman no. 1 filter paper. Filtrate was transferred to a 50 mL volumetric flask, where it was made up to the mark with bidistilled water. Afterward, a 5 mL aliquot of the sample solution was moved to a 125 mL digestion flask where, after the addition of 5 mL of 96% sulfuric acid and 5 mL of 30% H_2O_2, it was digested until the mixture was clear, by using the temperature program reported in Table 1. The so-obtained cool digest was transferred to a 100 mL volumetric flask and made up to the mark with bidistilled water, and it underwent a final measurement of P by using the P quantification procedure.

Phosphorus from Phospholipids (PL): Sample Preparation Method and Wet Ashing Procedure. P derived from phospholipid content was determined in the polar lipid extract of samples. On the basis of the results reported by Pérez-Palacios et al., lipid extraction was performed according to the method of Folch.[13,14] In practice, the samples (2 g fm) were mixed with 20 mL of a chloroform/methanol (2:1, v/v) mixture and immediately homogenized for 2 min at medium speed (motor speed set to 13500 rpm) in an Ultra-Turrax homogenizer. The apparatus was rinsed twice with 5 mL of the above-mentioned chloroform/methanol mixture, and the extracts were then combined. The pooled extract was centrifuged (10 min, 4000 rpm, RCF 2000g) and filtered through Whatman no. 1 filter paper. The residue in the filter paper was washed with 5 mL of chloroform/methanol (2:1, v/v), and all of the filtrates were then combined. Subsequently, 4 mL of bidistilled water was added, and the new mixture was shaken vigorously. The final biphasic system was separated by centrifugation (10 min, 4000 rpm, RCF 2000g). The upper aqueous layer was eliminated, 1 g of anhydrous sodium sulfate was added to the organic phase, and the mixture was shaken vigorously. The chloroform phase was filtered by Whatman no. 1 filter paper and collected. The residue in the filter paper was washed with 5 mL of chloroform, and the filtrates were then combined. The solvent was further evaporated with a rotary evaporator under vacuum and, finally, the glass vessels with the residue, which contained the lipids, were dried in an oven (100 °C for 30 min). Cool lipid extract content was then weighed, and half of it (from 40 to 80 mg) was then placed into a 125 mL digestion flask, to which 5 mL of 96% sulfuric acid and 5 mL of 30% H_2O_2 were added, and digested until the mixture was clear by using the temperature program reported in Table 1. The cool digest was transferred to a 100 mL volumetric flask and made up to the mark with bidistilled water, and it underwent a final measurement of phosphorus by using the phosphorus quantification procedure.

Phosphorus from Phosphoprotein (PP): Sample Preparation Method and Wet Ashing Procedure. The quantification method for P from phosphoprotein was strictly derived from that published by Dušek et al.:[9] samples (1.5 g fm) were homogenized in 36.5 mL of bidistilled water for 2 min at medium speed (motor speed set to 13500 rpm) by an Ultra-Turrax homogenizer. The apparatus was rinsed with 1 mL of bidistilled water, and the solutions were then combined. The so-obtained mixture was boiled for 30 min on a hot plate. After cooling, 10 mL of a 100 g/L trichloroacetic acid solution was added. The precipitate was filtered through Whatman no. 1 filter paper and

dried in an oven (100 °C for 30 min). After cooling, the filter was weighed, and about 50% of it (equivalent to 0.75 g fm) was placed in a 125 mL digestion flask and digested as described above. The cool digest was transferred to a 100 mL volumetric flask and made up to the mark with bidistilled water, and it underwent a final measurement of phosphorus by using the P quantification procedure.

Phosphorus Quantification Procedure: Molybdenum Blue Method on Wet Ashing Sample. Orthophosphate ions contained in wet mineralized sample solutions from TP, IP, PP, and PL were determined by using the Molybdenum Blue method according to Soderberg[15] and Italian Dairy Product Official Methods of Analysis. In brief, the mineralized sample solutions (800 μL) were transferred to a 10 mL volumetric flask and then were added the following reagents: 7 mL of bidistilled water, 390 μL of 4 M sulfuric acid solution, 400 μL of an 18 g/L ammonium molibdate solution, and 400 μL of a 25 g/L ascorbic acid solution. Each flask was gently swirled and finally placed in boiling water for 30 min to form characteristic molybdenum blue species. The solutions were then cooled to room temperature and made up to the mark with bidistilled water, and absorbance was measured by spectrophotometry at 650 nm against a blank.

Reference Samples. The TP method was tested by the ERM-BB384 Certified Reference Material (lyophilized pork muscle), the mean value and expanded uncertainty of which were provided by the certificate of analysis.

For IP analysis, one of the regular samples was spiked at two different levels: 100 mg P/100 g fresh sample or 150 mg P/100 g fresh sample. Because hydrolysis of polyphosphates leads to orthophosphate anions,[12] 443.8 and 665.7 mg of KH_2PO_4 were respectively added to 100 g of minced cooked ham, which was then passed twice through a meat grinder. Spiked samples were stored at −20 °C until assayed. The measurement uncertainty in spiked samples was calculated by type B evaluation of uncertainty. For PP and PL methods suitable meat certified reference materials were not available on the market; hence, in-house reference samples were prepared from "regular" cooked ham samples as reported below.

The PP in-house reference sample was obtained using the following procedure. Bidistilled water was added to a cooked ham sample and homogenized. The mixture thus obtained was boiled on a hot plate and, after cooling, trichloracetic acid was added. The precipitate was filtered and then was dried in a laboratory oven and allowed to cool in a desiccator overnight. Amounts of this dried filtrate were used as reference samples for PP analysis.

The PL in-house reference sample was prepared using the method developed by Folch.[14] In brief, the sample of cooked ham was mixed with a solution of chloroform/methanol (2:1, v/v) and homogenized. The extract was centrifuged and filtered. Bidistilled water was added to the filtrate and was shaken vigorously. The final biphasic system was allowed to separate by centrifugation. The upper aqueous phase was discharged, and anhydrous sodium sulfate (about 2 g) was added to the mixture to dry the organic phase. Then the chloroformic phase was filtered, the solvent was further evaporated under vacuum, and, finally, the glass vessel with the residue, which contained phospholipids, was dried in a laboratory oven. Cool lipid extract content was stored at −20 °C until assayed.

Reference values of P in-house reference samples of PP and PL were determined by the TP method as the averages of 10 measurements spread over three weeks. The standard deviations of average divided by the square root of the number of measurements were used as estimation of uncertainty of measurements. Coverage factors k, accordingly based on Student's test to a level of confidence of 95%, were applied to calculate the expanded uncertainties from the uncertainties of in-house reference samples used in PP and PL methods and of two spiked levels in IP method.

Calibration Curve. The linearity of the calibration curve was established for the concentration range of 0.1−1.2 mg P/L. The calibration curve was built using nine calibrators obtained by appropriate dilution of the 5 mg P/L working standard solution by bidistilled water. Their concentration values were 0.10−0.20−0.30−0.40−0.65−0.90−1.00−1.10−1.20 mg P/L. Calibration solutions underwent a P quantification procedure, after adjustment of the H_2SO_4 concentration by adding 190 μL of 4 M H_2SO_4, as required by the Molybdenum Blue quantitation method.[16,17] Notably, the amount of H_2SO_4 added to the calibrators was for matching its concentration in the samples from wet ashing. The instrumental limit of detection (LOD) and limit of quantification (LOQ) were calculated by the formulas $(y + 3s_{y/x})/b$ and $(10s_{y/x})/b$, respectively, where y is the intercept of the calibration line, $s_{y/x}$ is the standard deviation in the y-direction of the calibration line, and b is the slope of the calibration line.[18] Both values were expressed as mg P/L.

Analytical Performances of TP, IP, PP, and PL Measurement Methods. Precision and bias of TP, PP, and PL methods were estimated by using both Certified Reference Material ERM-BB384 and in-house reference standards. Sample spiking at two P addition levels, as previously described, was used for the IP method. Results were calculated as an average of five measurements spread over three weeks. All data were expressed as a mean value ± μ (confidence interval, p = 95%). Intermediate precisions were evaluated as the between-day coefficient of variation (CV) and the standard error of the mean (M). Measurement bias of each TP, IP, PP, and PL analytical procedure was determined by evaluating the deviation between the average value obtained from a series of measurements and the theoretical reference value. It includes the percent method recovery (REC), calculated as 100(obtained concentration/theoretical concentration).[19] Each method's LOD and LOQ, expressed as mg P/100 g fm, were calculated from instrumental LOD and LOQ values taking into account weights, dilutions, and percent method recovery.

Assay Quality Control in Cooked Ham Analysis. Each sample batch of cooked ham samples for the quantification of TP, PP, or PL included two reference (certified or in-house) samples, whereas two spiked and two unspiked samples were used for the IP determinations. Set measurements were rejected and repeated when the absolute difference between measured average values and reference (certified, in-house, or spiked) values were outside the range ± expanded uncertainty reported in the certificate of analysis for CRM and ± estimation of expanded uncertainty for in-house or spiked values. All sample analyses were performed in duplicate. Notably, food label nutritional content was blinded to all laboratory technicians to have no influence on the final results.

Statistical Analysis. Two relationships, the first between the concentration of P and absorbance at 650 nm in the calibration curve and the second between TP and the total differential P (DfP), which was the sum of the subtypes of sample P in form of IP plus PP and PL (DfP = IP + PP + PL) in cooked ham samples, were evaluated by paired t test for the significance of the Pearson product−moment correlation coefficient. The experimental t test value (t_{exp}) was compared to its tabulated value (t_{crit}). A linear relationship between variables was accepted at a significance level of $p < 0.001$. The unbiased measurement of any TP, IP, PL, and PP methods was verified with Student's paired test, when REC was not significantly different from 100 at a significance level of $p < 0.01$. Differences in P values from TP, IP, PL, and PP in each group of cooked ham were compared by one-way ANOVA post hoc tests. The null hypothesis was rejected at a significance level of $p < 0.05$. When a significant effect was detected, the comparison of means was done using Fisher's least significant difference (LSD) test.

RESULTS AND DISCUSSION

Calibration Curve of TP, IP, PP, and PL. The regression parameters of the calibration curve are shown in Table 2. The calibration line exhibits both a coefficient of determination close to 1 and a nearly 0 intercept, which suggests a satisfactory linearity. The calculated experimental t test value (t_{exp}) was higher than the theoretical values (t_{crit}), indicating that there was a significant linear relationship ($p < 0.001$) between the concentration of P and absorbance at 650 nm in the selected calibration solution range. The standard deviations (SD) of either slope and intercept were 1.3×10^{-3} and 9×10^{-4}, respectively. Instrumental LOD and LOQ values were 41 and

118 μg P/mL, respectively. In our study instrumental LOQ value was a few units higher than the lowest concentration of standard solutions. These data were in agreement with the data in the literature for P determination by phosphomolybdic acid with different reducing agents methods.[20−22]

Analytical Performances of the Proposed Procedures for TP, IP, PP, and PL. The amounts of TP, PL, and PP, as an average of the five replicates above-mentioned (certificate and in-house references), are reported in Table 3. The estimated amounts of IP in two spiked samples, in five replicates, are reported in Table 4. In the TP analysis, REC, between-day CV, and *M* were 100.7%, 1.3%, and 5.1, respectively. For the assessment of the TP method performance, the measured value of CRM lyophilized pork muscle was compared to the certified value, confirming that no significant difference ($p < 0.05$) was present and REC was not significantly different from 100 at a significance level of $p < 0.01$. Therefore, the TP method showed a satisfactory precision and was unbiased. A previous study comparing several spectrophotometric procedures for total P determination in meat samples reported between-day CV from 0.34 to 1.48%, *M* from 0.11 to 0.66, and REC in the range of 99.6−101.5% by using Standard Meat Reference Material.[22] Indeed, the present study provides analytical performances for TP method in agreement with those reported in the paper by Jastrzębska.[22] In addition, LOD and LOQ values were 13 and 37 mg P/100 g fm, respectively.

For the assessment of the IP method performance, the measured REC values for the two spiked levels were compared by using Student's paired test, and no significant difference ($p < 0.01$) was present, thus indicating that REC was stable in the range of 100−150 mg P added to 100 g of cooked ham samples (Table 4). Lower between-day CV and *M* in the 100 mg P spiking level with respect to those measured in the 150 mg P spiking level showed that the IP method precision worsens when the inorganic phosphate content is increased. The measured values of IP spiked samples were compared to the reference values, and significant differences ($p > 0.05$) were present. Values of between-day CV and *M* ranged from 0.4 to 2.6% and from 0.2 to 1.6, respectively, and thus indicate satisfactory precision; data from REC showed an acceptable method bias. Therefore, these results are in agreement with data present in the literature. In particular, Lee et al.[23] reported within-day relative standard error (RSD) values of 2.39 and 9.49% in raw and cooked beef meats, respectively, and Jastrzębska et al.[12] a within-day RSD of 9.9% in fresh pork meat and a within-day RSD ranging form 6.01 to 11.7% in polyphosphate-spiked fresh pork meat, whereas Jastrzębska et al.[24] reported between-day CV and REC ranging from 2.22 to 4.25% and from 95 to 97%, respectively, in polyphosphate-spiked pork meat. LOD and LOQ values for IP were 11 and 33 mg P/100 g fm, respectively.

Table 4. Results of Phosphorus Determination in Spiked Sample IP Methods (Number of Samples = 5)

		level 1	level 2
spiked sample	av (mg P/100 g sample)	100	150

[a]Expanded uncertainty reference value. [b]Measured average phosphorus content with the confidence limits for $p = 95\%$. [c]Average % recoveries with standard deviations. [d]LOD, LOQ from calibration curve.

In the PP analysis, REC, between-day CV, and *M* were 97.5%, 1.2%, and 0.7, respectively. For the assessment of the PP method performance, the measured value of PP in-house reference samples was compared to the reference values, and a significant difference ($p > 0.05$) was present. Therefore, the PP method showed a satisfactory precision and an acceptable method bias. In addition, LOD and LOQ values were 2 and 20 mg P/100 g fm, respectively. To the best of the authors' knowledge, no data about the analytical performance of the PP method are present in the literature.

In the PL analysis, REC, between-day CV, and *M* were 93.1%, 1.2%, and 2.1, respectively. For the assessment of the PL

method performance, the measured value of PL in-house reference samples was compared to the reference values, and a significant difference ($p < 0.05$) was present. Therefore, the PL method showed a satisfactory precision and an acceptable method bias. In addition, LOD and LOQ values were 6 and 16 mg P/100 g fm, respectively. Quantification of phospholipids by using total P content in lipid extracts from biological samples is currently used, but only a few data regarding the validation of these procedures are reported in the literature.[25−29] In particular, Kirkpatrick et al.[17] reported a recovery range from 95 to 101% and a relative standard deviation of 1.7% by using organophosphate and phosphonate pure standards, and Xi et al.[30] found recoveries within 93−103% and CV from 0.6 to 6.1% by using phospholipid pure standards. The present study provides analytical performances for the PL method in agreement with those published in the literature.

In conclusion, the analytical performances of the proposed procedures for differential measurement of TP, IP, PP, and PL prove their suitability for routine analyses. Whereas our innovative measurements are derived from well-known methods and make use of instrumentations present in routine analytical laboratories, our novel combinations and refinements of these techniques enable accurate and differential quantification of the different types of P more practical and hence more attractive.

Determinations of Phosphorus Type and Content in Different Brands of Cooked Ham Samples. The proposed analytical methods were applied to cooked ham samples of 24 different brands. Table 5 shows the results obtained for TP, IP, PP, and PL, as well as DfP.

TP average content and value range were 251 and 174−331 mg P/100 g fm, respectively. These results are in agreement with data present in the literature. In particular, Dušek et al.[9] reported values from cooked hams with listed phosphorus-containing additives ranging in the interval 204−366 mg P/100 g fm and Hrynczyszyn et al.[31] values between 141 and 197 mg P/100 g fm from tinned pork foods, between 106 and 111 mg P/100 g fm from luncheon pork meats, and 100 mg P/100 g fm from a single smoked pork ham sample, whereas Jastrzębska[7] reported values of 222 and 286 mg P/100 g fm, respectively, from single samples of cooked ham and smoked ham with a reported content of orthophosphate additives. Moreover, the obtained values for TP content in cooked ham samples were in close agreement with both previously published results[6] and data reported in the Food Composition Table of the National Research Institute for Food and Nutrition, Italy.[32]

IP average content and value ranges were 154 and 87−238 mg P/100 g fm, respectively. These results are in agreement with data present in the literature. In particular, Dušek et al.[9] reported an average content of 212 mg P/100 g fm and values ranging in the interval of 136−292 mg P/100 g fm from cooked hams with listed phosphorus-containing additives and Hrynczyszyn et al.[31] values between 124 and 173 mg P/100 g fm from tinned pork foods, between 73 and 88 mg P/100 g fm from luncheon pork meats, and 75 mg P/100 g fm from a single smoked pork ham sample.

PP average content and value ranges were 39 and 22−67 mg P/100 g fm, respectively. To the best of our knowledge, no data about PP contents in meat products were present in the literature. Only Dušek et al.[9] reported values ranging in the interval of 22−43 mg P/100 g fm in fresh meat from different species.

DfP average content and value ranges were 229 and 155−311 mg P/100 g fm, respectively. In our series of experiments the average DfP value was slightly lower than the measured average TP (229 vs 251 mg/100 g), indicating that we succeeded in measuring 91% of the constituents of the TP accurately. This gap of approximately 9%, by TP with respect to DfP, may be due to the technical difficulties of completely extracting the inorganic P from the food matrix, as reported by Jastrzębska et al.,[12] or due to yet other unmeasured types of P present in cooked ham items. Figure 1 shows the scatter plot of

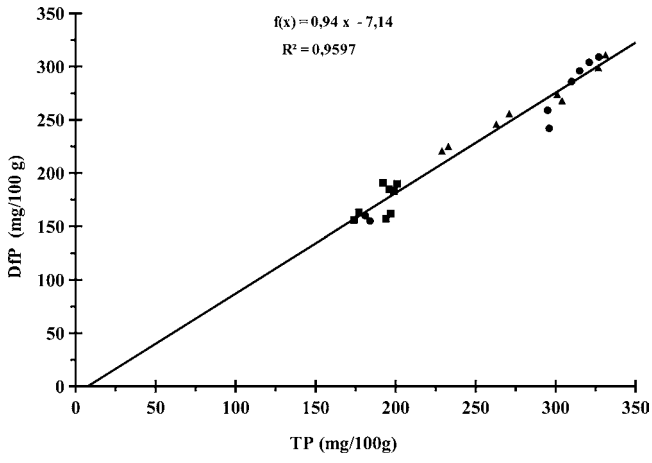

Figure 1. Scatter plot of the correlation between the sum of the subtypes of sample P and the measured total P: EWPIA (▲), EWP (●), and regular (■).

the correlation between the measured TP (X axis) and DfP (Y axis). The relationship between DfP and TP was evaluated by t test for the significance of the Pearson product−moment correlation coefficient. The calculated experimental t test value (t_{exp}) was higher than the theoretical values (t_{crit}), indicating that there was a significant linear relationship (Figure 1) for all intervals of TP measured (174−331 mg P/100 g) that include both EWPIA and EWP regular cooked ham items. Large RSD values in TP as well as in IP, PL, and PP content in cooked ham (ranged from 23 to 43%) demonstrate a wide variability in P contents. To explain this, we classified TP, IP, PL, and PP contents into three different groups of cooked ham items: EWPIA, EWP, and regular. Table 6 shows the results of TP as

dx.doi.org/10.1021/jf404187n | J. Agric. Food Chem. 2014, 62, 1247−1253

Table 6. Results of Phosphorus Determination into Three Different Groups of Cooked Ham Brands (mg P/100 g Fresh Samples; Number of Samples = 8)

group	TP	IP	PP	PL	DfP
EWPIA $(w \pm \sigma)^a$	282 ± 40	159 ± 18	55 ± 7	48 ± 11	263 ± 32
EWP $(w \pm \sigma)^a$	279 ± 60	199 ± 50	27 ± 4	25 ± 14	251 ± 62
regular $(w \pm \sigma)^a$	191 ± 10	103 ± 12	35 ± 8	36 ± 13	173 ± 15

[a]Average phosphorus content with standard deviations.

well as IP, PP, and PL contents classified into the three groups of cooked ham items. As expected, TP content was significantly higher in EWPIA and EWP than regular but no significant difference was observed for EWPIA with respect to EWP. Differences in inorganic phosphorus content were found not only between the regular group as compared to both EWPIA and EWP, but also in IP content, being higher in the EWP group than in regular products. Therefore, obtained results of TP and IP contents showed that the addition of P-containing ingredients, such as milk proteins and plant protein extracts or isolates, decreased the amount of functional additives, such as polyphosphates and phosphate salts, used in the production processes of EWPIA with respect to EWP.

PP content was higher in EWPIA than in EWP and regular samples, and no significant difference was observed for EWP with respect to regular, although the average value of PP content of EWP was lower with respect to those of regular. The key reason for higher measured PP contents in EWPIA with respect to EWP and regular was the addition of ingredients, such as milk proteins and plant protein extracts or isolates, in which there was a large increase of P from phosphoprotein with respect to total phosphorus content.

PL content was higher in EWPIA than EWP, and no significant difference was observed from EWP with respect to regular, although the average value of PL content of EWP was lower with respect to those of regular items. The dilution effect due to inclusion of water in ingredients (reported on the package label) of each EWPIA and EWP with respect to regular (in which water was not listed on the product label) may explain even lower PL and PP values measured in EWP with respect to those of regular items.

contamination have been reported in shellfish samples collected from different regions,[28−30] an effective method for on-site detecting OA in shellfishes is required. Therefore, this study produced a mAb against OA and successfully applied it to an ultrasensitive ELISA and gold nanoparticle immunochromatographic strip for detecting OA in shellfish samples.

MATERIALS AND METHODS

Materials. Okadaic acid (OA) and dinophysistoxin-1 (Figure 1) were obtained from Taiwan Algal Science Co. (Taiwan). An analytical

	R^1	R^2	R^3	R^4
OA	CH_3	H	H	H
DTX-1	CH_3	CH_3	H	H

Figure 1. Structures of okadaic acid (OA) and dinophysistoxin-1 (DTX-1).

standard solution of OA at 20 μg/mL was a product from Calbiochem (San Diego, CA). Bovine serum albumin (BSA), γ-globulin, gelatin, ovalbumin (OVA), ammonium biocarbonate, Tween 20, dimethyl sulfoxide (DMSO), 1,1′-carbonyldiimidazole (CDI), 1-ethyl-3-[3-dimethylaminopropyl]-carbodimide (EDC), and *N*-hydroxysuccinimide (NHS) were purchased from Sigma (MO, USA). Keyhole limpet hemocyanin (KLH) and antimouse−peroxidase conjugate from goat were purchased from Pierce (IL, USA). Horseradish peroxidase (HRP), BM Condimed H1 Hybridoma Cloning Supplement (BMH1), and the mouse mAb isotyping kit were from Roche (Mannheim, Germany). TMB (3,3′,5,5′-tetramethylbenzidine) is a substrate solution of HRP from Neogen Corp (KY, USA). Acetonitrile (HPLC grade), methanol (HPLC grade), ammonium sulfate, and absolute ethanol were obtained from Merck (Darmstadt, Germany). Polyethylene glycol (PEG 1500), hypoxanthine (H), aminopterin (A), and thymidine (T) were purchased from Boehringer Mannheim Biochemicals (IN, USA). Microtiter plates and strips with various protein binding abilities were obtained from Nunc (Roskilde, Demark). The fetal calf serum and penicillin−streptomycin were obtained from GIBCO Laboratories (Grand Island, NY). Gold nanoparticles with diameters of 20 and 40 nm were obtained from BB International (Cardiff, United Kingdom). The murine myeloma cell line P3/NS-1/1-AG4-1 (NS-1) was obtained from Bioresources Collection and Research Center in Taiwan, and virus-free BALB/c mice (9 to 10-week-old, female) were ordered from National Animal Research Center (Taipei, Taiwan).

Preparation of Different OA Conjugates. *Conjugation of OA to γ-Globulin.* OA was conjugated to γ-globulin in the presence of EDC.[31] The EDC and NHS solutions (1.0 mg of EDC and 1.0 mg of NHS in 0.04 mL of DMSO) were freshly prepared and then mixed with an OA solution containing 1.0 mg of OA in 0.2 mL of DMSO. The mixture (0.24 mL) was added slowly into 0.4 mL of γ-globulin solution (2.0 mg in 0.1 M carbonate buffer, pH 9.6), and then the reaction was conducted at room temperature for 2 h. Continuously, the mixture was dialyzed against 0.01 M phosphate buffer containing 0.15 M NaCl (PBS, pH 7.5) for three constitutive days with two exchanges of PBS. Final products were lyophilized for storage at −20 °C.

OA-KLH/OVA Conjugation. As a solid-phase antigen for indirect competitive ELISA, OA was conjugated to KLH or OVA by the EDC and NHS method.[31] Generally, 0.5 mg of OA in 0.1 mL of DMSO was added with 0.5 mL mg of KLH or OVA (2.5 mg in 0.1 M carbonate buffer, pH 9.6) first, and then EDC and NHS solutions (1.0 mg of EDC and 0.75 mg of NHS in 0.04 mL of DMSO) were added to the mixed solution at room temperature with a constant stirring for 2 h. The final product was dialyzed against PBS for three days and then lyophilized for storage.

Preparation of OA−Peroxidase. Conjugation of OA to HRP was achieved by the EDC and NHS method.[26,31] Briefly, 0.2 mg of OA in 0.1 mL of DMSO was mixed with 0.6 mg of EDC and 0.4 mg of NHS, and then an HRP solution (0.8 mg of HRP in 0.3 mL of 0.1 M carbonate buffer, pH 9.6) was added. After being stirred at room temperature for 2 h, the mixture was dialyzed against PBS for 72 h and then lyophilized.

Monoclonal Antibody (mAb) Production. *Immunization.* Female BALB/c mice (9−10 weeks of age) were intraperitoneally (ip) injected with 40 μg of OA-γ-globulin in 0.1 mL of PBS solution, which had been emulsified with 0.1 mL of Freund's complete adjuvant. Four weeks after the first injection, sequential boosters were conducted weekly with 40 μg of immunogen in 0.1 mL of PBS without adjuvant. After each booster, blood samples were collected from the tail vein of each mouse, and serum was isolated by centrifugation. The antibody specificity was determined by a competitive indirect ELISA (ciELISA) as described below.

Fusion and Cloning. The mouse showing the highest antibody specificity, 9 weeks after the initial immunization, was chosen for further fusion reaction. The selected mouse was primed with a total of 50 μg of OA-γ-globulin four days before fusion, and then the mouse was euthanized on the fusion day. The entire spleen was removed aseptically, mashed with a glass pestle, and then passed through a sieve-tissue grinder kit equipped with mesh 80 (CD-1, Sigma). Spleen cell suspension at a single-cell stage was mixed with 1×10^7 of myeloma cells. The cells were centrifuged and suspended in 0.2 mL of HT medium, and then 1 mL of PEG 1500 was dropped into the cell pellet within one minute. To dilute the PEG1500, 15 mL of HT medium was added gradually within 10 min. After centrifugation at 300*g* for 5 min, the pelleted cells were resuspended in the HAT medium containing hypoxanthine, aminopterin, and thymidine plus BMH1 (final concentration 10%) and plated into 96-well tissue culture plates. The plates were fed with freshly prepared HAT medium every five days. When the cell colonies reached at least half-confluence in the well, ciELISA was applied to screen hybridomas secreting specific antibodies against OA. Finally, hybridoma cells from three wells were found to be positive and were further cloned by the limiting dilution method.[32]

Ascites Fluid Generation. Female BALB/c mice, 10 weeks old, were injected with pristine (0.5 mL, ip); seven days later, 2×10^6 hybridoma cells suspended in DMEM were injected (ip). Three weeks after the injection, ascites were collected every other day and centrifuged at room temperature for 5 min. IgG antibodies in the supernatant fluid were precipitated with 50% of ammonium sulfate solution twice. Purified antibodies were stored at −70 °C for future usage.

Characterization of Monoclonal Antibodies. *Determination of the mAb Isotype.* Identification of specific immunoglobulin was carried out by a mouse mAb isotyping kit (Roche, Germany) according to the manufacturer's protocol.

Competitive Indirect ELISA (ciELISA). The process of ciELISA was conducted primarily according to Yu et al.[31] with a slight modification. OA−OVA (0.1 mL) was coated on each well of a microtiter plate which then was kept at 4 °C overnight. After the plate had been washed four times with Tween−PBS, 0.17 mL of gelatin−PBS (0.17 mL per well; 0.1% gelatin in PBS) was poured into the wells and incubated at 37 °C for 30 min. The plate was washed again, and 0.05 mL of OA standard with concentrations from 0.01 to 100 ng/mL in PBS or extracted sample solutions were added to each well. Then the anti-OA mAb (25 ng/mL in PBS, 0.05 mL per well) was added to all wells and incubated at 37 °C for 50 min. The plate was washed again, and 0.1 mL of goat antimouse IgG−HRP conjugate (1:20 000 dilution) was added and incubated at 37 °C for 45 min. The plate was washed, and 0.1 mL of TMB substrate solution (Neogen Corp) was added and waited the color development for 10 min. Then hydrochloric acid (0.1 mL, 1 N) was added to stop the reaction. A

Vmax ELISA reader (Molecular Devices Co.; Menlo Park, CA) was used to determine the absorbance value at 450 nm.

cdELISA. The process of cdELISA was conducted primarily according to Liu et al.[26] with a slight modification. The anti-OA mAb from ascites in PBS (1:10 000 dilution; 1 μg/mL) was used to coat the plate (0.1 mL/well). After a series of washing and blocking steps, OA standards (concentrations from 0.01 to 100 ng/mL) or samples together with the OA-HRP conjugate (10 ng/mL in PBSl) were added and incubated at 37 °C for 50 min. The plate was washed with PBS−Tween and incubated with TMB solution (Neogen Corp) at room temperature in the dark for 10 min. The absorbance at 450 nm was determined in the Vmax automatic ELISA reader

cdELISA of Shellfish Samples Contaminated with OA. Twenty shellfish samples, including clam, scallop, mussel, and oyster, were obtained from local stores for OA level determination. Briefly, 5 g of each sample (whole body) was homogenized with 20 mL of extraction solvent (methanol/water, 80/20, v/v) for 5 min[24,33] and then centrifuged at 14 000*g* for 10 min. An amount of 1 mL of supernatant fluid was mixed with 1 mL of hexane by vortex for 1 min, and then 3 mL of chloroform was added. After centrifugation for 5 min, the lower chloroform layer was aspirated and dried under a rotary vacuum evaporator. The dried sample was reconstituted with 1 mL of PBS buffer for cdELISA analysis or for the immunostrip assay.

Preparation of the Antibody-Gold Nanoparticle Probe. For conjugation, OA mAbs were dialyzed in boric acid−borax buffer (pH 8) for 24 h at 4 °C, and the gold nanoparticle solution was adjusted to pH 9.0 with 0.1 M K_2CO_3 (pH 11.5).[27,28] An amount of 5 μL of anti-OA mAb (1 μg/μL) was added dropwise to 2 mL of gold nanoparticle solution with gentle stirring. After 1 h reaction at room temperature, 10% (w/v) filtered BSA was added to block the reaction for 30 min and then centrifuged at 19 000*g* for 30 min at 4 °C. The pellets containing an OA mAb−gold nanoparticle conjugate were resuspended in 450 μL of 20 mM Tris-buffered saline (pH 8.0) containing 1% BSA and 0.1% sodium azide and stored at 4 °C for further usage.

Preparation of Immunochromatographic Strip. An Easypack Developer's Kit composed of three pads (sample, conjugate release, and absorbent pads), glass fiber, cover tape, and nitrocellulose (NC) membrane plates (pore sizes of 5 and 15 μM) are purchased from Advanced Microdevices P. Ltd. (Ambala Cantt, India). With the aid of a Double Axes Programmable Control Printer (model P-602 from Troy Technology, Taiwan), the test and control zones of the NC membrane were drawn with 0.5 μL of OA−KLH (0.8 mg/mL) conjugate and 0.5 μL of rabbit−antimouse IgG antibody (1 mg/mL), respectively, and then dried for 10 min at room temperature. Subsequently, the OA mAb−gold nanoparticle conjugate (5 μL/strip) was added to the conjugate release pad and dried at 37 °C for 5−10 min. The release pad was first pasted on the plate by overcrossing 4 mm with the NC membrane. Then, the sample pad was further pasted on the plate by overcrossing 6 mm with the release pad. Finally, the top of the membrane sheet was pasted on an absorbent pad. The whole assembled sheet was cut lengthways with an automatic cutter and divided into strips (5 mm × 75 mm).[27,28]

Assay of OA in Shellfish Samples with an Immunochromatographic Strip. Three hundred microliters of sample extract solutions as mentioned above or various concentrations of OA analytical standard (0−50 ng/mL) were poured into the wells of a microtiter plate. Subsequently, one immunochromatographic strip was dipped per well vertically. The extracted samples or OA standard solution migrated upward the membrane by capillary action. Ten minutes after color development, test results on the strip were determined visually.

RESULTS

Monoclonal Antibody Production. Mice were injected with OA-γ-globulin and boosted 4 times with the same antigen, and the mouse with serum that had the highest affinity for OA was sacrificed for a hybridoma screening. Following the NS-1/spleen cell fusion and growing, the ciELISA with OA−OVA as a coated reagent was used for screening the hybridoma cells, which secreted mAbs specific to OA. In the about 500 examined wells, three clones displayed strong positive color results in the ciELISA; of these, the clone 6B1 had the highest affinity for OA. Therefore, the clone 6B1 culture was aspirated from the fusion well and subjected to limiting dilution for a single hybridoma selection. After limiting dilution and ciELISA screening, clone 6B1A3, which showed the highest affinity for OA, was used to generate culture supernatant and ascites fluid.

Antibody Characterization. *Isotype Determination.* The isotype of the mAb, secreted from the hybridoma cell line 6B1A3, was identified as immunoglobulin G1, κ-light chain.

Competitive Direct and Indirect ELISA. The specificity of 6B1A3 mAb was measured by both cdELISA and ciELISA. As shown in Figure 2A, the concentrations causing 50% inhibition

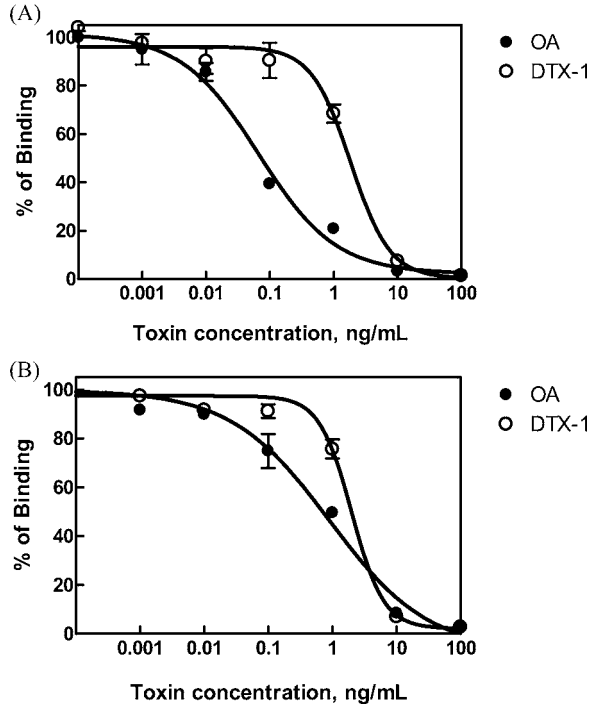

Figure 2. (A) Cross-reactivity of anti-OA antibodies with OA (●) and DTX-1 (○) in a cdELISA. (B) Cross-reactivity of anti-OTA antibodies with OA (●) and DTX-1 (○) as determined by a ciELISA. All data were obtained based on the average of three sets of experiments. The absorbance of the control, A0, with no toxin present, was 2.0.

(IC_{50}) of binding of OA−HRP to the mAb by OA and DTX-1 were calculated to be 0.077 and 1.870 ng/mL, respectively, in cdELISA. The ciELISA revealed similar results for OA−OVA coated onto the microplate wells to serve as a solid-phase antigen. The IC_{50} values for mAb binding to OA−OVA by free OA and DTX-1 were 0.58 and 2.0 ng/mL, respectively (Figure 2B). However, other phycotoxins such as domoic acid and saxitoxin, even at concentrations as high as 10 μg/mL, did not inhibit the mAb binding to the OA-enzyme/protein conjugates (OA−HRP or OA−OVA) in either ELISA system.

Assay of OA in Shellfishes with mAb-Based cdELISA. Twenty shellfish samples were purchased from local supermarkets and subjected to cdELISA to measure OA contamination; Table 1 presents the measurement results. The proposed detection system revealed that ten of the twenty examined samples were OA-positive. Sample 7 showed the highest OA levels (0.517 ng/mL; 2.068 ng/g). The OA levels

[a]Each sample was extracted twice, and each extract was analyzed in triplicate. [b]1 mL of extract solution contains 0.25 g of shellfish samples. [c]ND, not detectable.

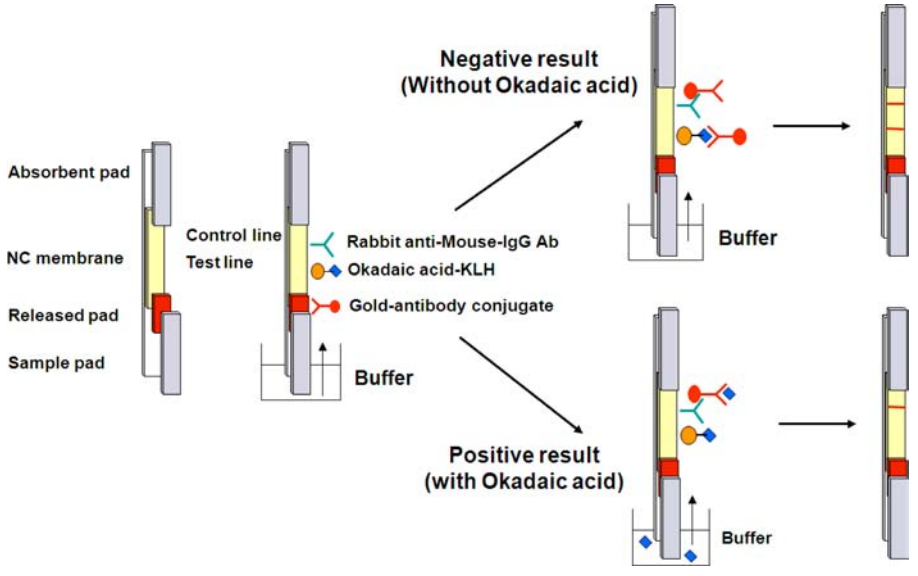

Figure 3. Schematic illustration of the immunochromatographic strip for OA. C, control zone (rabbit antimouse IgG); T, test zone (OA−KLH).

of samples 9 and 13 are also higher than 1.0 ng/g. The OA levels in the other seven positive samples were lower than 1.0 ng/g. However, all the oyster samples are free of OA contamination.

Assembly of the Immunochromatographic Strip. The mAb−gold nanoparticle conjugates were used to fabricate an immunochromatographic strip, in which OA in the sample solution competes with the OA−KLH conjugate on the membrane for the antibody−gold nanoparticle label. Figure 3 is a schematic description of the immunochromatographic strip test format. A sufficient OA level in the sample solution occupied all the antibody binding sites of the antibody−gold nanoparticle conjugates, which prevented the limited antibody−gold nanoparticle conjugates from binding with the OA−KLH conjugate in the test zone. The absence of the red line in the test zone indicated a positive result (Figure 3). In contrast, when OA is absent in sample solution, the antibody−gold nanoparticle conjugate trapped and bound by the OA−KLH conjugate to form a red line in the test zone indicated a negative result (Figure 3). The control zone was designed with rabbit-antimouse secondary antibody to confirm that the assay had been performed properly; regardless of the presence of OA, the control zone on the membrane will show one red line (Figure 3).

Characterizaion of Immunochromatographic Strip for OA. Different concentrations of OA analytical standard solution (0−50 ng/mL) were subjected to an immunochromatographic strip test. This assay required no more than 10

dx.doi.org/10.1021/jf404827s | J. Agric. Food Chem. 2014, 62, 1254−1260

min, and the detection limit of the strip test for OA approached 5 ng/mL (Figure 4). At least five measurements were examined

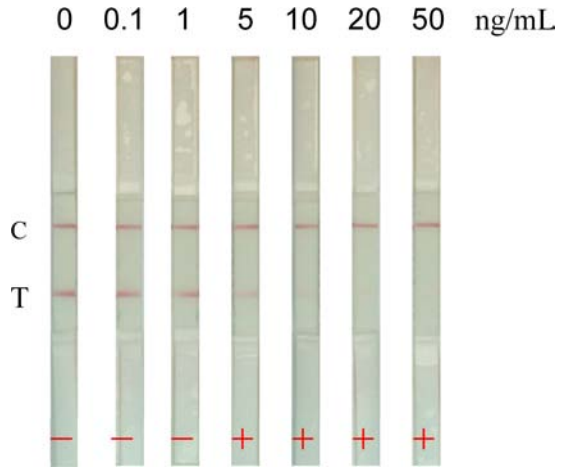

Figure 4. Detection limit of OA with immunochromatographic strip. A series of dilutions (0−50 ng/mL) of certificated standard OA was dissolved in PBS. A concentration higher than 5 ng/mL of OA caused a disappearance of a red line at the test zone.

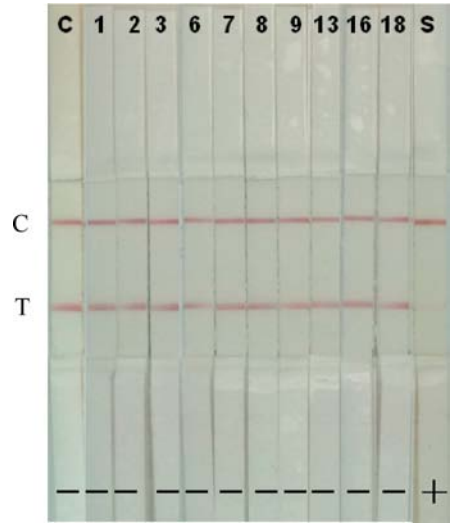

Figure 5. Detection of OA with immunochromatographic strip in control (C), spiked (S), and 10 shellfish samples. A spiked strip containing 5 ng/mL of OA in shellfish extract indicates that a red line disappeared in the test zone, verifying that it is OA positive. All samples containing OA lower than 5 ng/mL showed two red lines on the membrane indicating that they are OA negative.

by the strip detection system to define the cutoff level for each selected concentration. When OA levels are higher than 5 ng/mL, all antibody−gold nanoparticle conjugates were bound by free OA, which restricted the antibody−gold nanoparticle conjugates to bind with the OA−KLH in the test zone of the membrane. Finally, rabbit antimouse secondary antibody captured antibody−gold nanoparticle conjugates in the control zone which resulted in only one red line on the membrane.

Analysis of OA in Shellfish Samples by Immunochromatographic Strip Assay. The strip was further applied to examine OA contamination shellfishes. Table 1 shows the analytical results. Ten contaminated shellfish samples with OA levels ranging from 0.051 to 0.517 ng/mL, according to cdELISA results (Table 1), had two red lines on the immunostrip membranes, which indicated a negative outcome (Figure 5). However, in one spiked sample (S) containing 5.0 ng/mL of OA in shellfish extract, one red line disappeared in the test zone, which indicated that the sample was OA-positive (Figure 5).

DISCUSSION

Since OA is a nonimmunogenic phycotoxin with low molecular weight, conjugating OA to a protein carrier is needed to contribute to its immunogenicity. Our laboratory has successfully produced a polyclonal antibody for OA using the OA−γ-globulin conjugate as an antigen and established a sensitive ELISA for detecting OA. Since this study obtained a hybridoma clone secreting mAb specific to OA, the supply of mAb for OA is theoretically unlimited. Both mAbs produced from culture supernatant and mouse ascites could be adopted in the cdELISA. However, the rabbit-antimouse Fc secondary antibody must be coated onto the microplate before adding the supernatant. In contrast, cdELISA can be run by directly coating the microplate with mAb purified from ascites.

The mAb obtained from 6B1A3 showed a better affinity (IC50 value) for OA compared to DTX-1 in both cd- and ciELISA systems. The IC50 value of the mAb-based cdELISA for OA was 0.077 ng/mL, and the detection limit of OA in PBS solution in the cdELISA approximated 0.004 ng/mL based on a 90% confidence interval at 10% of inhibition of binding of the OA−HRP conjugate. Therefore, the proposed ELISA method is about 2 orders of magnitude higher than that of the mAb-based ELISA reported by Lu et al.[16] (IC50 and detection limits of 4.4 and 0.45 ng/mL, respectively) and that of Kreuzer et al.[14] with an IC50 of 100 ng/mL.

After using a combination of water/methanol (20:80, v/v) to extract OA from shellfishes, 1 mL of clear supernatant solution was diluted with 9 mL before cdELISA analysis. The analytical results showed that all examined samples were slightly OA positive because the matrix components caused interference in the cdELISA. Therefore, a cleanup procedure was incorporated into the sample preparation procedure. Washing the methanolic sample extracts with hexane effectively eliminated the lipid in the extract solution to avoid the matrix interference.[24] The cdELISA analysis of shellfishes demonstrated that 10 of the 20 shellfish samples had a low-level contamination with OA (Table 1). In all samples, OA was lower than 2.068 ng/g, which was approximately 80-fold below the regulatory limit of EU which is 160 ng/g of OA in shellfish samples.[7] This concentration is consistent with a previous report by Lee et al.[29] that gastropod samples collected in Korea had OA concentrations up to 21.5 ng/g but is lower than that reported by Ciminiello et al.[28] with OA concentrations of 100−200 ng/g.

To establish an assay that could be broadly used for field detection of OA-contaminated shellfish samples, this study further developed an mAb-based rapid immunochromatographic strip for faster and simpler screening compared to cdELISA. The mAb-based immunochromatographic strip established in this study for on-site OA determination had a limit of detection of about 5.0 ng/mL. In Lu et al.,[17] a lateral flow assay developed for OA analysis had a detection limit of 30−50 ng/mL, which may not be sensitive enough for a practical sample test. Several factors also correlated with the effectiveness of an immunochromatographic strip include the size of the gold nanoparticles, the membrane pore size, and the test line of OA−protein conjugates. Therefore, both 20 and 40

nm gold particles were adopted to prepare mAb−gold particle conjugates. On the nitrocellulose membrane, the 40 nm particles provided better visibility compared to the 20 nm gold particles, probably due to their optimal size and their lower steric hindrance between conjugation of 40 nm gold particles and antibody. To test the effectiveness of 5 and 15 μm membrane pore size, in the membrane pore size of 15 μm, the red gold nanoparticles provided a more obvious visual effect and also a faster migration during the process. Finally, 15 μm membrane pore size and 40 nm gold particles were selected for all immunochromatographic strips. Either OA−KLH or OA−OVA is drawn onto the membrane test zone to compare their effectiveness in binding OA in the sample with the antibody−gold nanoparticle conjugate. Compared to OA−OVA, the OA−KLH proved to be a suitable protein conjugate because coating OA−KLH onto the test zone of a strip obtained a stronger red color line in the strips and also had a lower detection limit of 5 ng/mL compared with 20 ng/mL in which it was coated with OA−OVA onto the test line (data not shown).

Results of sample analysis acquired by the immunochromatographic strip were in good agreement with those acquired by ELISA (Table 1). The test strip can be directly immersed into 300 μL of sample extraction solution, and the test can be performed in 10 min. Therefore, the strip test is effective for on-site OA detection not only in terms of accuracy and sensitivity but also in terms of labor and speed. This study obtained a novel hybridoma cell line for secreting mAb against OA and successfully applied it to an ultrasensitive ELISA and gold nanoparticle immunostrip for detecting OA in shellfish. The IC_{50} value of ELISA was 0.077 ng/mL, and the gold nanoparticle immunostrip had a visual detection limit of 5.0 ng/mL. The OA immunostrip is a semiquantitative, rapid, and visual assay that uses gold nanoparticles as a color tracer to provide visual indication to examine OA in shellfish samples within 10 min. This strip will be conceivably applicable for on-site detection of OA in the seafood industry.

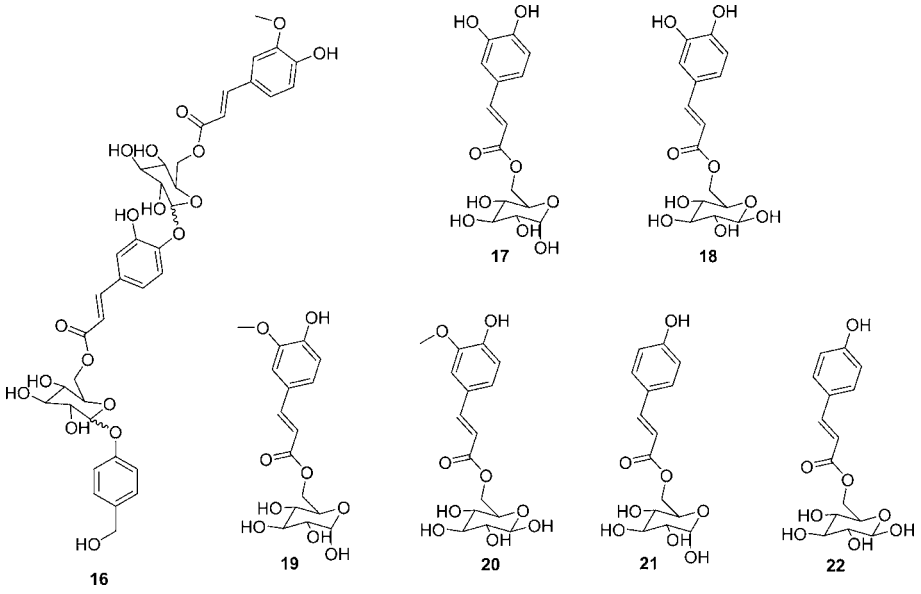

Figure 1. Representative structures of *Lagenaria siceraria* Stand. phenolic glycosides.

loop, and a DAD detector with a light-pipe flow cell (recording at 254, 280, and 320 nm and scanning from 200 to 600 nm). This was interfaced with an ion-trap mass spectrometer fitted with an ESI source (Bruker Daltonics HCT Ultra, Bremen, Germany) operating in full-scan, auto-MS^n mode to obtain fragment ion m/z. Tandem mass spectra were acquired in auto-MS^n mode (smart fragmentation) using a ramping of the collision energy. The maximum fragmentation amplitude was set to 1 V, starting at 30% and ending at 200%. MS operating conditions (negative mode) had been optimized using 5-*O*-caffeoylquinic acid with a capillary temperature of 365 °C, a dry gas flow rate of 10 L/min, and a nebulizer pressure of 10 psi. High-resolution LC−MS was performed using the same HPLC instrument equipped with a MicrOTOF mass spectrometer (Bruker Daltonics, Bremen, Germany) fitted with an ESI source, and internal calibration was achieved with 10 mL of 0.1 M sodium formate solution injected through a six-port valve prior to each chromatographic run. Calibration was done using the enhanced quadratic mode.

HPLC Coupled to MS. Separation was achieved on a 250 × 3 mm i.d. column containing diphenyl 5 μm, with a 5 mm × 3 mm i.d. guard column (Varian, Darmstadt, Germany). Solvent A was water/formic acid (1000:0.05, v/v), and solvent B was methanol. Solvents were delivered at a total flow rate of 500 μL/min. The gradient profile was from 10% B to 70% B linearly in 70 min followed by isocratic conditions for 10 min and a return to 10% B at 90 and isocratic conditions for 10 min to re-equilibrate.

Base Hydrolysis. A 10 mg sample of plant extract was dissolved in 2 mL of 0.5 M NaOH solution and the resulting solution stirred at room temperature for 2 h. The reaction mixture was neutralized by adding 1 g of acidic resin (Amberlite IR-120, H^+). The reaction mixture was filtered, washed with water (2 mL), and directly used for HPLC−MS^n.

NMR. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL-ECX 400 spectrometer operating at 400 MHz for ^{1}H NMR and 100 MHz for ^{13}C NMR at room temperature in acetone-d_6 or methanol-d_4 using a 5 mm probe. The chemical shifts (δ) are reported in parts per million and were referenced to the residual solvent peak. The coupling constants (J) are quoted in hertz.

Synthesis of 6-*O*-Caffeoylglucoses 17 and 18. To a solution of 1,2-*O*-isopropylidene-α-D-glucofuranose (1.00 g, 4.54 mmol) and DMAP (200 mg, 1.63 mmol) in DCM (50 mL) were added pyridine (5 mL, 62 mmol) and 3,4-di-*O*-allylcaffeoyl chloride (1.58 g, 5.70 mmol)[22] at room temperature. The reaction mixture was stirred for 24 h at room temperature and acidified (pH ≈ 3) with 2 M HCl. The layers were separated, and the aqueous phase was extracted with DCM (3 × 50 mL). The combined organic layers were dried over sodium sulfate and filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate−petroleum ether, 30−50%) to give 6-*O*-(3,4-di-*O*-allylcaffeoyl)-1,2-*O*-isopropylidene-α-D-glucofuranose (80%): δ_H (acetone-d_6) 7.62 (1H, d, J = 15.6, $C_{Ar}CH$), 7.32 (1H, dd, J = 1.8, $C_{Ar}H$), 7.17 (1H, dd, J = 8.7, 2.3 $C_{Ar}H$), 6.99 (1H, d, J = 8.2, $C_{Ar}H$), 6.41 (1H, d, J = 16.0, $C_{Ar}CH$═CH), 6.08 (2H, m, CH_2═CH), 5.85 (1H, d, J = 3.6, *H*-3), 5.43 (2H, m, CHH═CH), 5.23 (2H, m, CH*H*═CH), 4.65 (4H, m, $C_{Ar}OCH_2$), 4.49 (1H, d, J = 3.7, *H*-2), 4.31 (2H, m, *H*-6a, *H*-6b), 4.12 (2H, m, *H*-4, *H*-5), 1.39 (3H, s, OCH_3), 1.24 (3H, s, OCH_3); δ_C (acetone-d_6) 166.6 (−COOC), 150.9 ($C_{Ar}OCH_2$), 148.9 ($C_{Ar}OCH_2$), 144.5 ($C_{Ar}CH$), 133.9 (CH_2═CH), 133.5 (CH_2═CH), 127.7 ($C_{Ar}CH$), 122.9 (C_{Ar}), 116.9 (CH_2═CH), 116.5 (CHCOO), 115.7 (C_{Ar}), 113.7 (C_{Ar}), 112.6 ($H_3COCOCH_3$), 111.2 ($H_3COCOCH_3$), 105.0 (*C*-3), 85.3 (*C*-6), 80.4 (*C*-1), 74.4 (*C*-2), 69.4 (*C*-4), 69.2 ($C_{Ar}OCH_2$), 67.1 ($C_{Ar}OCH_2$), 66.8 (*C*-5), 26.4 (OCH_3), 25.6 (OCH_3).

To a solution of 6-*O*-(3,4-di-*O*-allylcaffeoyl)-1,2-*O*-isopropylidene-α-D-glucofuranose (1.00 g, 2.23 mmol) and *p*-TsOH (50 mg) in methanol−water (9:1, 50 mL) was added 10% Pd/C (350 mg) at room temperature. The reaction mixture was heated at 70 °C for 48 h, cooled to room temperature, and filtered, and methanol was removed in vacuo. The aqueous reaction mixture was extracted with ethyl acetate (3 × 50 mL). The combined organic layers were dried over sodium sulfate and filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate−petroleum ether, 50−95%) to give 6-*O*-caffeoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (62%). The resulting ester 6-*O*-caffeoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (400 mg, 1.10 mmol) was dissolved in a mixture of 20 mL of TFA and water (8:2) at room temperature and the resulting solution stirred for 1 h. The solvents were removed in vacuo to obtain the resulting esters 6-*O*-caffeoylglucoses **17** and **18** in quantitative yield: δ_H (methanol-d_3) 7.54 (1H, d, J = 16.0, $C_{Ar}CH$), 7.02 (1H, d, J = 2.2, $C_{Ar}H$), 6.92 (1H, dd, J = 8.2, 1.4, $C_{Ar}H$), 6.75 (1H, d, J = 8.2, $C_{Ar}H$), 6.25 (1H, J = 16.5, $C_{Ar}CH$═CH), 5.10 (1H, d, J = 3.7, gluc *H*-1), 4.45 (1H, m, gluc *H*-6a), 4.30 (1H, m, gluc *H*-6b), 4.05 (1H, m, gluc *H*-4), 3.28−3.37 (2H, m, gluc *H*-2, gluc *H*-5); δ_C (methanol-d_3) 167.9 (COOC), 148.3 (C_{Ar}), 145.8 ($C_{Ar}CH$), 145.5 (C_{Ar}), 126.4 (C_{Ar}), 123.6 (C_{Ar}), 121.6 (C_{Ar}), 115.2 (CH_2═CH), 113.7 (CHCOO), 113.6 (CH_2═CH), 96.8 (β-gluc *C*-1), 92.6 (α-gluc *C*-1), 76.7 (β-gluc *C*-3), 74.9 (β-gluc *C*-2), 74.1 (β-gluc *C*-5), 73.5 (α-gluc *C*-3), 72.2 (α-gluc *C*-2), 71.6 (α-gluc *C*-5), 70.4 (α-gluc *C*-4), 69.6 (β-gluc *C*-4), 63.6 (β-gluc *C*-6), 63.5 (α-gluc *C*-6).

RESULTS AND DISCUSSION

For all the compounds the high-resolution mass data were in good agreement with the theoretical molecular formulas, all displaying a mass error of below 5 ppm, thus confirming their elemental composition. In general, peak identities were consistent both within and between analyses. However, when the mass spectrum for a particular substance included two ions of similar mean intensities, within-analysis experimental error dictated that in some individual MS scans one would be more intense while for other scans the reverse would be true. This phenomenon was encountered primarily when the signal intensity was lower, that is, with quantitatively minor components and/or higher order spectra. For example, one of the phenolics (**21**) produces MS^2 ions at m/z 235 and 265 which were essentially coequal in some spectra. However, in this particular case the higher mass ion was assigned consistently as the base peak. Fragment ions with intensities <5% of that of the base peak were reported only when they were needed for comparison. The phenolic glycosides were positively identified by their typical UV absorptions at 254, 280, and 320 nm. From the literature[37,38] it is known that bottle gourd fruit contains 3,4-dihydroxybenzyl alcohol and 4-hydroxybenzyl alcohol glucosides. In these glucosides the glucosyl unit (C-1′ of glucosyl) is connected with the C-4 of the phenolic hydroxyl of 3,4-dihydroxybenzyl alcohol and 4-hydroxybenzyl alcohol by an ether linkage while the cinnamic acids are connected with the glucosyl hydroxyl (C-6′) by an ester linkage (Figure 1). In this study we also observed 6-*O*-caffeoyl-, 6-*O*-feruloyl-, and 6-*O*-*p*-coumaroylglucoses in bottle gourd fruit. For the confirmation of ester linkages we used base hydrolysis, which gave the hydrolysis products 4-hydroxybenzyl alcohol−glucose, 3,4-dihydroxybenzyl alcohol−glucose, caffeic acid, ferulic acid, and *p*-coumaric acid. To confirm the *cis*−*trans* isomers of the caffeoyl residue in a molecule, we performed a photochemical experiment as reported previously.[21,33,34]

Characterization of 4-*O*-Glucosyl-3,4-dihydroxybenzyl Alcohol (M_r = 302), 4-*O*-Glucosyl-4-hydroxybenzoic Acid (M_r = 300), and 4-*O*-Glucosyl-4-hydroxybenzyl Alcohol (M_r = 286). One peak was detected at m/z 301 which produced the MS^2 base peak at m/z 139 ([3,4-dihydroxybenzyl alcohol − H^+]$^-$) by the loss of a glucosyl residue (162 Da) (Figure 2 and Table 1). It produced the MS^3 base peak at m/z 121 ([3,4-dihydroxybenzyl alcohol − H_2O − H^+]$^-$) by the loss of H_2O and a secondary peak at m/z 93 ([3,4-dihydroxybenzyl alcohol − CO − H_2O − H^+]$^-$) by the loss of CO and H_2O (Figure 2 and Table 1). In MS^3 it is possible to lose a CO molecule from a 1,2-benzoquinone moiety (Figure 2). On the basis of the fragmentation pattern and the HRMS data, this isomer was assigned as calleryanin, 4-*O*-glucosyl-3,4-dihydroxybenzyl alcohol (**1**). Calleryanin was previously reported in *Prunus lusitanica* (Rosaceae).[39]

One peak was detected at m/z 299 which produced the MS^2 base peak at m/z 137 ([4-hydroxybenzoic acid − H^+]$^-$) by the loss of a glucosyl residue (162 Da) (Figure 2 and Table 1). It produced the MS^3 base peak at m/z 93 ([4-hydroxybenzoic acid − CO_2 − H^+]$^-$) by the loss of CO_2 (Figure 2 and Table 1). From this it was clear that the loss of CO_2 was only possible from an acid. On the basis of the fragmentation pattern and the HRMS data, this isomer was assigned as 4-*O*-glucosyl-4-hydroxybenzoic acid (**2**).

One peak was detected at m/z 285 which produced the MS^2 base peak at m/z 123 ([4-hydroxybenzyl alcohol − H^+]$^-$) by the loss of a glucosyl residue (162 Da) and secondary peaks at m/z 161 ([glucose − H_2O − H^+]$^-$) by the loss of the 4-hydroxybenzyl alcohol moiety and at m/z 207 ([M − 78 Da − H^+]$^-$) (Figure 2 and Table 1). It produced the MS^3 base peak at m/z 105 ([4-hydroxybenzyl alcohol − H_2O − H^+]$^-$) by the loss of H_2O (Figure 2 and Table 1). On the basis of the fragmentation pattern and the HRMS data, this isomer was assigned as 4-*O*-glucosyl-4-hydroxybenzyl alcohol (**3**).

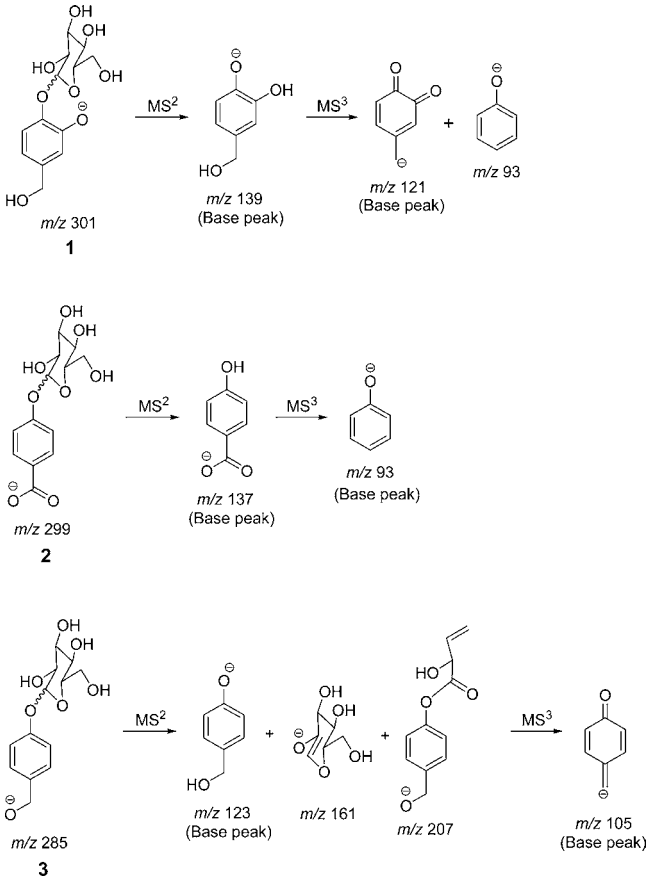

Figure 2. Fragmentation pathway of 4-*O*-glucosyl-3,4-dihydroxybenzyl alcohol (**1**), 4-*O*-glucosyl-4-hydroxybenzoic acid (**2**), and 4-*O*-glucosyl-4-hydroxybenzyl alcohol (**3**) in negative ion mode.

Characterization of 4-*O*-(6′-*O*-Glucosylcaffeoyl)-4-hydroxybenzyl Alcohol (M_r = 448). One peak was detected at m/z 447 which produced the MS^2 base peak at m/z 323 ([caffeoylglucose − H_2O − H^+]$^-$) by the loss of the 4-hydroxybenzyl alcohol moiety (124 Da). It produced secondary peaks at m/z 179 ([caffeic acid − H^+]$^-$) by the loss of the 4-*O*-glucosyl-4-hydroxybenzyl alcohol residue (268 Da), at m/z 161 ([caffeic acid − H_2O − H^+]$^-$) by the loss of the 4-*O*-glucosyl-4-hydroxybenzyl alcohol moiety (286 Da), at m/z 221 ([caffeoylglucose − hydroxybenzyl alcohol − 120 Da − H^+]$^-$), at m/z 251 ([caffeoylglucose − hydroxybenzyl alcohol − 90 Da − H^+]$^-$), and at m/z 263 ([caffeoylglucose − hydroxybenzyl alcohol − 78 Da − H^+]$^-$) by the loss of the 4-hydroxybenzyl residue (106 Da) and 78 Da (Figure 3 and Table 1). It produced the MS^3 base peak at m/z 179 ([caffeic acid − H^+]$^-$) by the loss of the glucosyl residue. It produced secondary peaks at m/z 161 ([caffeic acid − H_2O − H^+]$^-$) by the loss of the glucosyl residue (162 Da), at m/z 221 ([caffeoylglucose − 120 Da − H^+]$^-$), at m/z 251 ([caffeoylglucose − 90 Da − H^+]$^-$), and at m/z 263

19	6-*O*-feruloyl-*α*-glucose	26.3	355	MS^2 → 265 (100), 337 (5), 295 (96), 247 (7), 235 (73), 217 (7), 193 (30); MS^3 → 193 (100), 217 (6)
20	6-*O*-feruloyl-*β*-glucose	23.9	355	MS^2 → 265 (100), 337 (5), 295 (99), 247 (7), 235 (72), 217 (5), 193 (31); MS^3 → 193 (100), 217 (5)
21	6-*O*-*p*-coumaroyl-*α*-glucose	25.1	325	MS^2 → 265 (100), 307 (6), 235 (99), 205 (12), 163 (14); MS^3 → 205 (100), 247 (6), 187 (13), 163 (56), 145 (11), 119 (13); MS^4 → 161 (100), 133 (5)
22	6-*O*-*p*-coumaroyl-*β*-glucose	22.5	325	MS^2 → 265 (100), 307 (5), 235 (99), 205 (10), 163 (17); MS^3 → 205 (100), 247 (5), 187 (11), 163 (56), 145 (7), 119 (11); MS^4 → 161 (100), 133 (6)

([caffeoylglucose − 78 Da − H^+]$^-$) (Figure 3 and Table 1). The MS^2 secondary peaks at *m/z* 323, 221, 203, 251, and 263 suggested that caffeic acid (C-9″) was connected with the glucosyl residue by an ester linkage (C-6′). In a recent study Mohan et al.[17] isolated 4-*O*-(6′-*O*-glucosylcaffeoyl)-4-hydroxybenzyl alcohol (**4**) from bottle gourd fruit. On the basis of the above points, this compound was tentatively assigned as 4-*O*-(6′-*O*-glucosylcaffeoyl)-4-hydroxybenzyl alcohol (**4**).

Characterization of 4-*O*-(6′-*O*-Glucosylcaffeoyl)-3,4-dihydroxybenzyl Alcohol (M_r = 464). One peak was detected at *m/z* 463 and produced the MS^2 base peak at *m/z* 323 ([caffeoylglucose − H_2O − H^+]$^-$) by the loss of the 3,4-dihydroxybenzyl alcohol moiety (140 Da). It produced secondary peaks at *m/z* 179 ([caffeic acid − H^+]$^-$) by the loss of the 4-*O*-glucosyl-3,4-dihydroxybenzyl alcohol residue (284 Da), at *m/z* 161 ([caffeic acid − H_2O − H^+]$^-$) by the loss of the 4-*O*-glucosyl benzyl alcohol moiety (302 Da), at *m/z* 221 ([caffeoylglucose − dihydroxybenzyl alcohol − 120 Da − H^+]$^-$), at *m/z* 301 ([M − caffeoyl − H^+]$^-$), and at *m/z* 135 ([caffeic acid − CO_2 − H^+]$^-$) by the loss of the 4-*O*-glucosyl-3,4-dihydroxybenzyl alcohol residue (284 Da) and CO_2 (Figure 4 and Table 1). It produced the MS^3 base peak at *m/z* 179 ([caffeic acid − H^+]$^-$) by the loss of the glucosyl residue. It produced secondary peaks at *m/z* 161 ([caffeic acid − H_2O − H^+]$^-$) by the loss of the glucosyl residue (162 Da), at *m/z* 221 ([caffeoyl glucose − 120 Da − H^+]$^-$), at *m/z* 251 ([caffeoyl glucose − 90 Da − H^+]$^-$), and at *m/z* 263 ([caffeoyl glucose − 78 Da − H^+]$^-$) (Figure 4 and Table 1). The MS^2 secondary peaks at *m/z* 323, 221, 203, 251, and 263 suggested that caffeic acid (C-9″) was connected with the glucosyl residue by an ester linkage (C-6′).

An MRM (multi-reaction monitoring) of *m/z* 301 produced ions at *m/z* 139 by the loss of the glucosyl residue and *m/z* 121 by the loss of the glucosyl residue and H_2O. The absence of the MRM ions generated by the caffeoyl moiety at *m/z* 179, 161, and 135 suggested that the glucosyl residue (C-1′) was connected at C-4 by an ether linkage. In a recent study Mohan et al. [17] also isolated 4-*O*-(6′-*O*-glucosylcaffeoyl)-3,4-dihydroxybenzyl alcohol (**5**) from bottle gourd fruit. On the basis of the

dx.doi.org/10.1021/jf4053989 | J. Agric. Food Chem. 2014, 62, 1261−1271

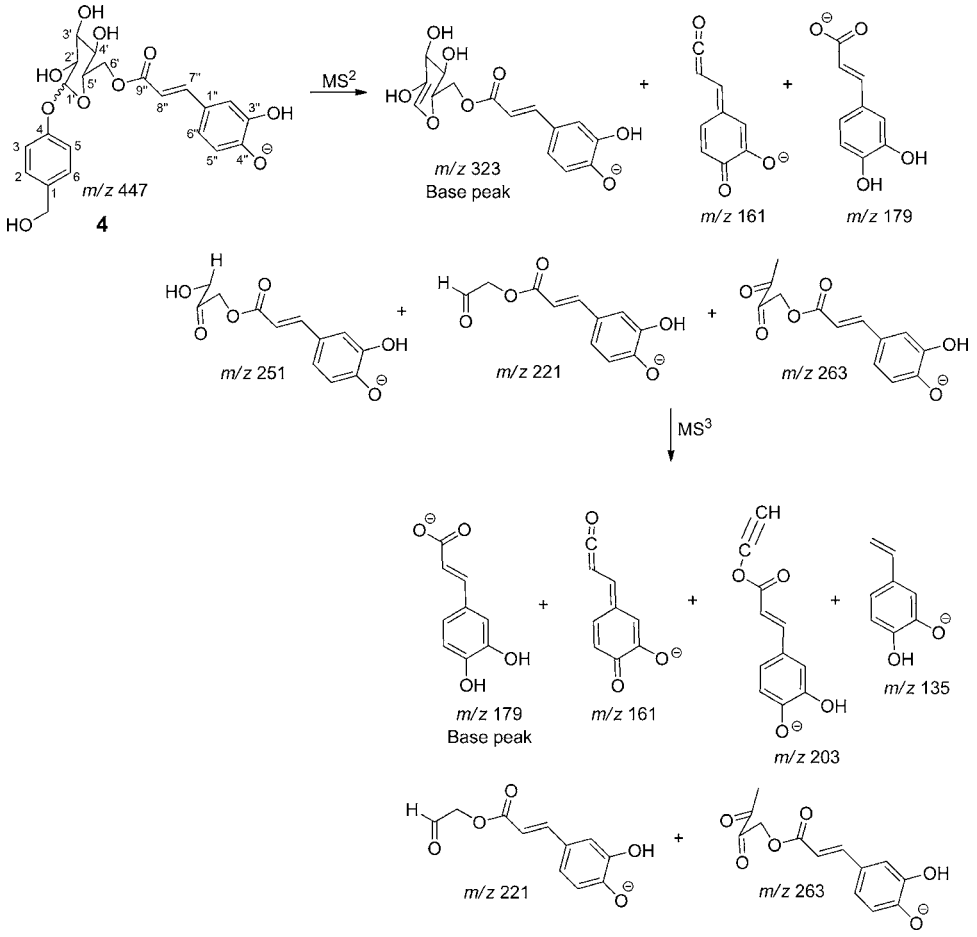

Figure 3. Fragmentation pathway of 4-*O*-(6′-*O*-glucosylcaffeoyl)-4-hydroxybenzyl alcohol (**4**) at *m*/*z* 447 in negative ion mode.

above points, this compound was tentatively assigned as 4-*O*-(6′-*O*-glucosylcaffeoyl)-3,4-dihydroxybenzyl alcohol (**5**).

Characterization of 4-*O*-(6′-*O*-Glucosyl-*p*-coumaroyl)-4-hydroxybenzyl Alcohol (M_r = 432). One peak was detected at *m*/*z* 431 which produced the MS^2 base peak at *m*/*z* 307 ([*p*-coumarylglucose − H_2O − H^+]$^-$) by the loss of the 4-hydroxybenzyl alcohol moiety (124 Da) and a secondary peak at *m*/*z* 145 ([*p*-coumaric acid − H_2O − H^+]$^-$) by the loss of the 4-*O*-glucosyl-4-hydroxybenzyl alcohol residue (268 Da) and H_2O (Figure 5 and Table 1). It produced the MS^3 base peak at *m*/*z* 145 ([*p*-coumaric acid − H_2O − H^+]$^-$) by the loss of the glucosyl residue. It produced secondary peaks at *m*/*z* 163 ([*p*-coumaric acid − H^+]$^-$) by the loss of the glucosyl residue (162 Da), at *m*/*z* 187 ([*p*-coumaroylglucose − 138 Da − H^+]$^-$) by the loss of $C_4H_{10}O_5$, at *m*/*z* 205 ([*p*-coumaroylglucose − 120 Da − H^+]$^-$) by the loss of $C_4H_8O_4$, and at *m*/*z* 247 ([*p*-coumaroylglucose − 78 Da − H^+]$^-$) by the loss of $C_2H_6O_3$ (Figure 5 and Table 1). The MS^2 and MS^3 peaks at *m*/*z* 305, 187, 205, and 247 suggested that *p*-coumaric acid (C-9″) was connected with the glucosyl residue by an ester linkage (C-6′). This compound showed an MS fragmentation analogy with compound **4** and was tentatively assigned as 4-*O*-(6′-*O*-glucosyl-*p*-coumaroyl)-4-hydroxybenzyl alcohol (**6**) (Figures 3 and 5 and Table 1).

Characterization of 4-*O*-(6′-*O*-Glucosyl-4″-hydroxybenzoyl)-4-hydroxybenzyl Alcohol (M_r = 406). One peak was detected at *m*/*z* 405 which produced the MS^2 base peak at *m*/*z* 281 ([(hydroxybenzoyl)glucose − H_2O − H^+]$^-$) by the loss of the 4-hydroxybenzyl alcohol moiety (124 Da) and a secondary peak at *m*/*z* 137 ([hydroxybenzoic acid − H^+]$^-$) by the loss of the 4-*O*-glucosyl-4-hydroxybenzyl alcohol residue (268 Da) (Figure 5 and Table 1). It produced the MS^3 base peak at *m*/*z* 137 ([hydroxybenzoic acid − H^+]$^-$) by the loss of the glucosyl residue and a secondary peak at *m*/*z* 93 ([hydroxybenzoic acid − CO_2 − H^+]) by the loss of glucosyl residue and CO_2 (Figure 5 and Table 1). The MS^2 and MS^3 peaks at *m*/*z* 281, 137, and 93 suggested that 4-hydroxybenzoic acid (C-7″) was connected with the glucosyl residue by an ester linkage (C-6′). This compound showed an MS fragmentation analogy with compounds **4** and **6** and was tentatively assigned as 4-*O*-(6′-*O*-glucosyl-4″-hydroxybenzoyl)-4-hydroxybenzyl alcohol (**7**) (Figures 4 and 5 and Table 1).

Characterization of 4-*O*-(6′-*O*-Glucosylcaffeoyl)-4-hydroxybenzoic Acid and 4-*O*-(6′-*O*-Glucosylferuloyl)-4-hydroxybenzyl Alcohol (M_r = 462). Two peaks were detected at *m*/*z* 461 and were tentatively assigned as 4-*O*-(6′-*O*-glucosylcaffeoyl)-4-hydroxybenzoic acid (**8**) and 4-*O*-(6′-*O*-glucosylferuloyl)-4-hydroxybenzyl alcohol (**9**). Isomer **8** produced the MS^2 base peak at *m*/*z* 323 ([caffeoylglucose − H_2O − H^+]$^-$) by the loss of the 4-hydroxybenzoic acid moiety (138 Da). It produced secondary peaks at *m*/*z* 179 ([caffeic acid − H^+]$^-$) by the loss of the 4-*O*-glucosyl-4-hydroxybenzoic acid residue (282 Da), at *m*/*z* 221 ([caffeoylglucose − 120 Da − H^+]$^-$) by the loss of $C_4H_8O_4$, and at *m*/*z* 403 ([M − 58 Da − H^+]$^-$) by the loss of $C_2H_2O_2$ (Figure 5 and Table 1). It produced the MS^3 base peak at *m*/*z* 221 ([caffeoylglucose −

dx.doi.org/10.1021/jf4053989 | J. Agric. Food Chem. 2014, 62, 1261−1271

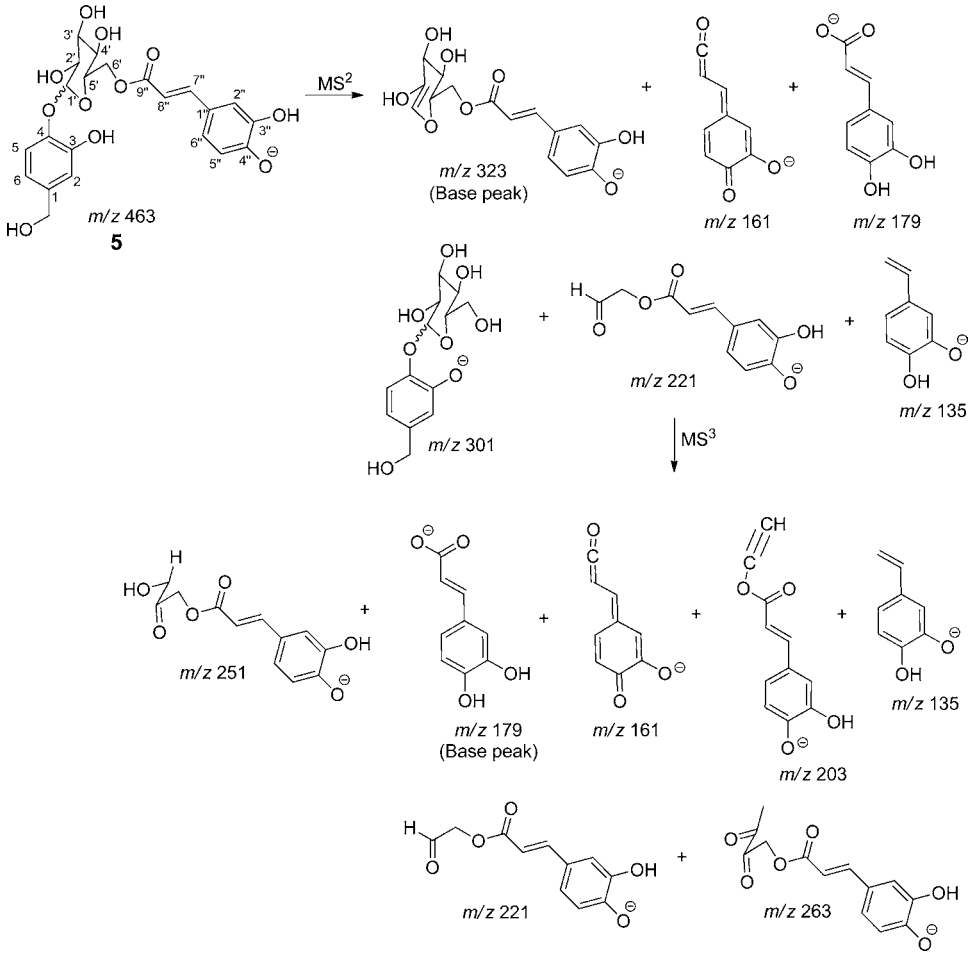

Figure 4. Fragmentation pathway of 4-*O*-(6′-*O*-glucosylcaffeoyl)-3,4-dihydroxybenzyl alcohol (**5**) at *m*/*z* 463 in negative ion mode.

120 Da − H^+]$^-$) by the loss of $C_4H_8O_4$. It produced secondary peaks at *m*/*z* 179 ([caffeic acid − H^+]$^-$) by the loss of the glucosyl residue (144 Da), at *m*/*z* 161 ([caffeic acid − H_2O − H^+]$^-$) by the loss of the glucosyl residue (162 Da), at *m*/*z* 203 ([caffeoylglucose − 120 Da − H_2O − H^+]$^-$) by the loss of $C_4H_8O_4$, and at *m*/*z* 263 ([caffeoylglucose − 60 Da − H_2O − H^+]$^-$) by the loss of $C_2H_4O_2$ (Figure 5 and Table 1). The MS^2 and MS^3 secondary peaks at *m*/*z* 323, 221, 203, and 263 suggested that caffeic acid (C-9″) was connected with the glucosyl residue by an ester linkage (C-6′). Hydrolysis experiments confirmed the presence of 4-hydroxybenzoic acid, which is connected with C-1′ of the glucose moiety by an ether linkage (C-4). On the basis of the above points, isomer **8** was assigned as 4-*O*-(6′-*O*-glucosylcaffeoyl)-4-hydroxybenzoic acid.

Isomer **9** produced the MS^2 base peak at *m*/*z* 337 ([feruloylglucose − H_2O − H^+]$^-$) by the loss of the 4-hydroxybenzyl alcohol moiety (124 Da). It produced secondary peaks at *m*/*z* 193 ([ferulic acid − H^+]$^-$) by the loss of the 4-*O*-glucosyl-4-hydroxybenzyl alcohol residue (268 Da) and at *m*/*z* 175 ([ferulic acid − H_2O − H^+]$^-$) by the loss of 4-*O*-glucosyl-4-hydroxybenzyl alcohol (Figure 5 and Table 1). It produced the MS^3 base peak at *m*/*z* 175 ([ferulic acid − H_2O − H^+]$^-$) by the loss of the glucosyl residue (162 Da). It produced secondary peaks at *m*/*z* 193 ([ferulic acid − H^+]$^-$) by the loss of the glucosyl residue (144 Da), at *m*/*z* 235 ([feruloylglucose − 120 Da − H^+]$^-$) by the loss of $C_4H_6O_3$, at *m*/*z* 134 ([ferulic acid − CO_2 − CH_3 − H^+]$^-$) by the loss of the glucosyl residue (144 Da), CO_2, and a CH_3 residue, at *m*/*z* 217 ([feruloylglucose − 120 Da − H_2O − H^+]$^-$) by the loss of $C_4H_8O_4$, and at *m*/*z* 277 ([caffeoylglucose − 60 Da − H_2O − H^+]$^-$) by the loss of $C_2H_4O_2$ (Figure 5 and Table 1). The MS^2 and MS^3 peaks at *m*/*z* 337, 217, 235, and 277 suggested that ferulic acid (C-9″) was connected with the glucosyl residue by an ester linkage (C-6′). Isomer **9** showed a fragmentation analogy with compounds **4**−**7** (Figures 3−5 and Table 1) and was assigned as 4-*O*-(6′-*O*-glucosylferuloyl)-4-hydroxybenzyl alcohol.

Characterization of 4-*O*-(6′-*O*-Glucosylcaffeoyl)-3,4-dihydroxybenzoic Acid and 4-*O*-(6′-*O*-Glucosylferuloyl)-3,4-dihydroxybenzyl alcohol (M_r = 478). Two peaks were detected at *m*/*z* 477 and were tentatively assigned as 4-*O*-(6′-*O*-glucosylcaffeoyl)-3,4-dihydroxybenzoic acid (**10**) and 4-*O*-(6′-*O*-glucosylferuloyl)-3,4-dihydroxybenzyl alcohol (**11**). These isomers showed a fragmentation analogy with compounds **8** and **9**, respectively (Figures 5 and 6 and Table 1).

Characterization of 4-*O*-(6′-*O*-Glucosylcaffeoylglucosyl)-4-hydroxybenzyl Alcohol (M_r = 610) and 4-*O*-(6′-*O*-Glucosylcaffeoylglucosylcaffeoyl)-4-hydroxybenzyl Alcohol (M_r = 772). One peak was detected at *m*/*z* 609 and was tentatively assigned as 4-*O*-(6′-*O*-glucosylcaffeoylglucosyl)-4-hydroxybenzyl alcohol (**12**). It produced MS^n spectra identical to MS^{n-1} spectra of compound **4** (Figures 3 and 6 and Table 1).

One peak was detected at *m*/*z* 771 and was tentatively assigned as 4-*O*-(6′-*O*-glucosylcaffeoylglucosylcaffeoyl)-4-hy-

dx.doi.org/10.1021/jf4053989 | J. Agric. Food Chem. 2014, 62, 1261−1271

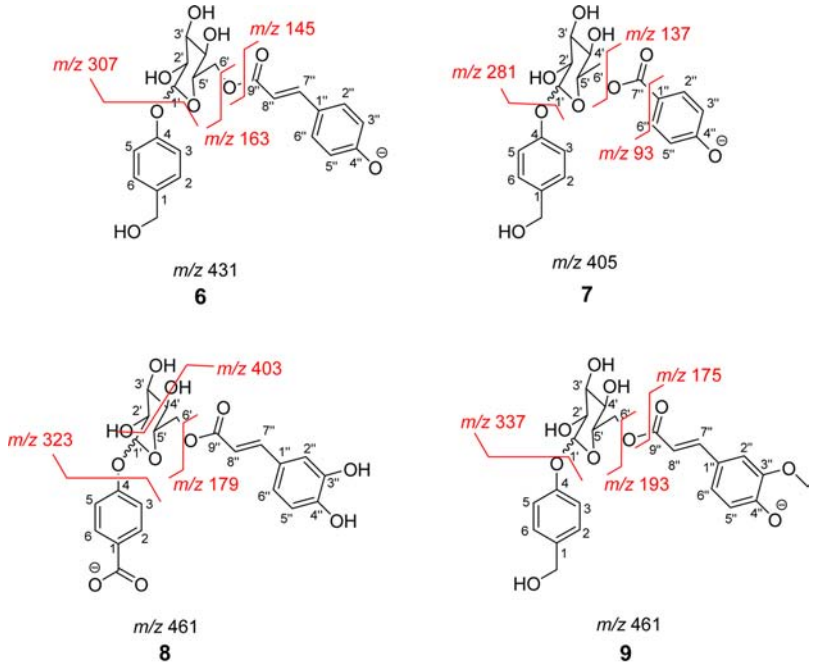

Figure 5. Fragmentation pathways of 4-*O*-(6′-*O*-glucosyl-*p*-coumaroyl)-4-hydroxybenzyl alcohol (**6**), 4-*O*-(6′-*O*-glucosyl-4″-hydroxybenzoyl)-4-hydroxybenzyl alcohol (**7**), 4-*O*-(6′-*O*-glucosylcaffeoyl)-4-hydroxybenzoic acid (**8**), and 4-*O*-(6′-*O*-glucosylferuloyl)-4-hydroxybenzyl alcohol (**9**) in negative ion mode.

droxybenzyl alcohol (**13**). It produced MS^n spectra identical to MS^{n-1} spectra of compound **12** (Figure 6 and Table 1). MRM of the MS^2 ion at m/z 771 produced ions similar to those of compound **12** (Figure 6 and Table 1).

Characterization of 4-*O*-(6′-*O*-Glucosylcaffeoylglucosyl-*p*-coumaroyl)-4-hydroxybenzyl Alcohol (M_r = 756), 4-*O*-(6′-*O*-Glucosylferuloylglucosylcaffeoyl)-4-hydroxybenzyl Alcohol, and 4-*O*-(6′-*O*-Glucosylcaffeoylglucosylferuloyl)-4-hydroxybenzyl Alcohol (M_r = 786). One peak was detected at m/z 755 and was tentatively assigned as 4-*O*-(6′-*O*-glucosylcaffeoylglucosyl-*p*-coumaroyl)-4-hydroxybenzoic acid (**14**). This isomer showed a fragmentation analogy with compound **13** (Figures 6 and 7 and Table 1).

Two peaks were detected at m/z 785 and were tentatively assigned as 4-*O*-(6′-*O*-glucosylferuloylglucosylcaffeoyl)-4-hydroxybenzyl alcohol (**15**) and 4-*O*-(6′-*O*-glucosylcaffeoylglucosylferuloyl)-4-hydroxybenzyl alcohol (**16**). These isomers showed a fragmentation analogy with compounds **13** and **14** (Figures 6 and 7 and Table 1).

Characterization of 6-*O*-Caffeoylglucoses (M_r = 342), 6-*O*-Feruloylglucoses (M_r = 356), and 6-*O*-*p*-Coumaroylglucoses (M_r = 326). Two peaks were detected at m/z 341 in the extracted ion chromatogram (λ_{max} = 320 nm) and were tentatively assigned as caffeoyl glucoses (**17** and **18**). They produced the MS^2 base peak at m/z 281 ($[M - H^+ - 60\ Da]^-$) by the loss of $C_2H_4O_2$ and secondary peaks at m/z 251 ($[M - H^+ - 90\ Da]^-$) by the loss of $C_3H_6O_3$, at m/z 221 ($[M - H^+ - 120\ Da]^-$) by the loss of $C_4H_8O_4$, and at m/z 179 ([caffeic acid $- H^+]^-$) by the loss of a glucosyl residue ($C_6H_{10}O_5$) (Figure 8 and Table 1). Isomers **17** and **18** produced the ions $[M - H^+ - 60\ Da]^-$, $[M - H^+ - 90\ Da]^-$, and $[M - H^+ - 120\ Da]^-$, which are characteristic of glycosides.

Further evidence for the assignment of the caffeoylglucoses came from an independent synthesis of 6-*O*-caffeoyl-α-glucose (**17**) and 6-*O*-caffeoyl-β-glucose (**18**). A β stereochemistry was assigned on the basis of the characteristic $^3J_{HCCH}$ coupling constant between the anomeric hydrogen and the hydrogen at C-2 of glucose, with 6-*O*-caffeoyl-α-glucose (**17**) showing values between 3 and 4 Hz and 6-*O*-caffeoyl-β-glucose (**18**) showing values between 7 and 8 Hz. On standing in methanol-d_3, the mixture of 6-*O*-caffeoylglucoses equilibrated to yield after one day exclusively the β-anomers. The retention times and fragmentation patterns of synthetic 6-*O*-caffeoylglucoses **17** and **18** were identical to those of isomers **17** and **18** present in *L. siceraria*. On the basis of these arguments, the first eluting isomer was assigned as 6-*O*-caffeoyl-β-glucose (**18**) and the later eluting isomer as 6-*O*-caffeoyl-α-glucose (**17**).

Two peaks were detected at m/z 355 in the extracted ion chromatogram (λ_{max} = 320 nm) and were tentatively assigned as feruloylglucoses **19** and **20**. They produced the MS^2 base peak at m/z 295 ($[M - H^+ - 60\ Da]^-$) by the loss of $C_2H_4O_2$ and secondary peaks at m/z 265 ($[M - H^+ - 90\ Da]^-$) by the loss of $C_3H_6O_3$, at m/z 235 ($[M - H^+ - 120\ Da]^-$) by the loss of $C_4H_8O_4$, and at m/z 193 ([ferulic acid $- H^+]^-$) by the loss of a glucosyl residue ($C_6H_{10}O_5$) (Figure 8 and Table 1). Compounds **19** and **20** showed a fragmentation analogy to compounds **17** and **18** (Figure 8 and Table 1). On the basis of these arguments, isomer **20** was assigned as 6-*O*-feruloyl-β-glucose and isomer **19** as 6-*O*-feruloyl-α-glucose.

Two peaks were detected at m/z 325 in the extracted ion chromatogram (λ_{max} = 320 nm) and were tentatively assigned as *p*-coumaroylglucoses **21** and **22**. They produced the MS^2 base peak at m/z 265 ($[M - H^+ - 60\ Da]^-$) by the loss of $C_2H_4O_2$ and secondary peaks at m/z 235 ($[M - H^+ - 90\ Da]^-$) by the loss of $C_3H_6O_3$, at m/z 205 ($[M - H^+ - 120\ Da]^-$) by the loss of $C_4H_8O_4$, and at m/z 163 ([*p*-coumaric acid $- H^+]^-$) by the loss of a glucosyl residue ($C_6H_{10}O_5$) (Figure 8 and Table 1). Compounds **21** and **22** showed a fragmentation

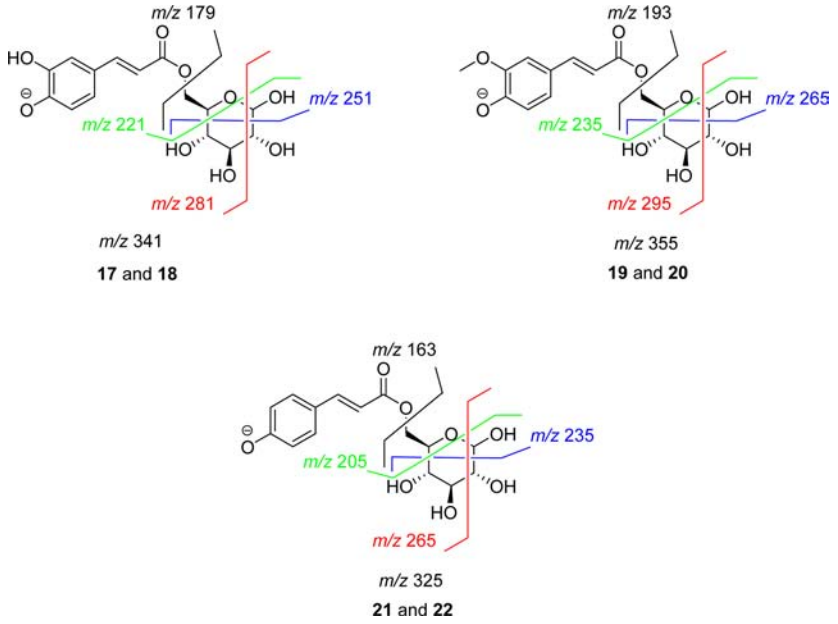

Figure 8. Fragmentation pathways of 6-*O*-caffeoylglucoses **17** and **18**, 6-*O*-feruloylglucoses **19** and **20**, and 6-*O*-*p*-coumaroylglucoses **21** and **22** in negative ion mode.

analogy to compounds **17**−**20** (Figure 8 and Table 1). On the basis of these arguments, isomer **22** was assigned as 6-*O*-*p*-coumaroyl-*β*-glucose and isomer **21** as 6-*O*-*p*-coumaroyl-*α*-glucose.

In this study we showed that bottle gourd is a rich source of phenolic glucosides which are not commonly present in fruits and vegetables. During this study we were able to identify and characterize the phenolics of bottle gourd (*L. siceraria*). We also developed a tandem mass spectrometric method for the positive identification of the phenolic glucosides. This tandem MS method can be applied for the rapid identification and characterization of new analogous compounds and their derivatives. The phenolic acids caffeic acid, dimethoxycinnamic acid, 3,4-dihydroxybenzoic acid, and gallic acid have been reported in bottle gourd,[17] but in the present study we did not observe them.

the analysis of food-borne toxicants such as acrolein,[9] acrylamide,[39] furan,[40] or glycidamide.[41] However, to the best of my knowledge, no further method for the quantitation of crotonaldehyde using a stable isotopically labeled internal standard has been reported yet (after submission of this paper, I became aware of a similar approach of a Belgian group, which is not yet published), except our recently presented preliminary studies using synthesized deuterium or ^{13}C-labeled crotonaldehyde.[42,43]

Because it is a common trend in high-temperature cooking to use vegetable oils with a high degree of unsaturation, the aims of the present study were (i) to develop a stable isotope dilution analysis using a ^{13}C-labeled internal standard for the quantitation of crotonaldehyde, which also enables the simultaneous determination of acrolein using [$^{13}C_3$]-acrolein, (ii) to compare the data obtained by three different techniques, namely, a direct headspace GC−MS analysis (method I) and two indirect analyses using liquid−liquid extraction combined with a high-vacuum distillation after derivatization by means of GC−MS (with pentafluorophenylhydrazine, method II) and LC−MS/MS (with 2,4-dinitrophenylhydrazine, method III), and (iii) to apply these methods on thermally treated oils differing in their fatty acid composition as well as on fried foods.

MATERIALS AND METHODS

Safety. Acrolein, [$^{13}C_3$]-acrolein, crotonaldehyde, and [$^{13}C_4$]-crotonaldehyde are hazardous and must be handled carefully.

Food Samples. Potatoes, wheat flour, eggs, whole milk, sugar, and vegetable fats and oils (coconut oil, extra virgin olive oil, rapeseed oil, safflower oil, and linseed oil) were purchased at local supermarkets.

Chemicals. [$^{13}C_2$]-Acetaldehyde (99%), crotonaldehyde, 2,4-DNPH (99% purity, stabilized with 50% water), and PFPH (97%) were obtained from Sigma-Aldrich (Steinheim, Germany). Acrolein and sodium methylate were from Fluka (Steinheim). [$^{13}C_3$]-Acrolein (99%) was obtained from Isotec (Ohio, IL). All other reagents were of analytical grade.

Synthesis of the Stable Isotopically Labeled Standard [$^{13}C_4$]-Crotonaldehyde. To a solution (8 mL) of [$^{13}C_2$]-acetaldehyde in dichloromethane (500 mg in 8 mL) were added, first, a solution (8 mL) of pyrrolidine in dichloromethane (48.3 mg in 10 mL) under stirring at 4 °C and, second, a solution (8 mL) of pure acetic acid in dichloromethane (81.5 mg in 10 mL) using a dropping funnel. After a reaction time of 30 min, the mixture was extracted with a solution (2 × 15 mL) of saturated sodium hydrogen carbonate, and the organic phase was dried over anhydrous sodium sulfate. For purification, the solution was first subjected to high-vacuum distillation, and then the solvent was distilled off using a Vigreux column (60 cm × 1 cm i.d.). The residue was dissolved in pentane (1.5 mL), and the obtained solution was applied onto a silica gel column (water-cooled, 45 g of silica gel 60 (0.040−0.063 mm) containing 7% water) using the following elution: pentane (P)/diethyl ether (E) = 100/0 (v/v; 100 mL, fraction 1), P/E = 90/10 (v/v; 100 mL, fraction 2), P/E = 80/20 (v/v; 100 mL, fraction 3), and P/E = 70/30 (v/v; 100 mL, fraction 4). The target compound [$^{13}C_4$]-crotonaldehyde (isotopic purity >97%) was obtained in fraction 4. The concentration of [$^{13}C_4$]-crotonaldehyde was determined using methyl octanoate as the internal standard using a response factor of 0.90 calculated from data obtained by GC-FID analysis of a mixture of unlabeled crotonaldehyde and methyl octanoate.

Fatty Acid Composition Analysis. The fatty acid composition was determined by GC-FID after transesterification with methanol/sodium methylate to obtain the corresponding fatty acid methyl esters closely following the IUPAC standard method.[44]

Aliquots of the oil (100 mg) were accurately weighed into screw-capped centrifuge tubes, and tetrahydrofuran (1 mL) was added. After the oil was dissolved by shaking, sodium methylate (2 mL, 0.5 mol/L) was added, and the solution was heated for 1 h at 50 °C. Then, water (5 mL) and hexane (5 mL) were added, the suspension was mixed using a vortexer (1 min), and the organic layer was separated and, finally, dried over anhydrous sodium sulfate. Aliquots (2 μL) of the solutions were analyzed by means of a Thermo Quest gas chromatograph (Thermo Finnigan, Egelsbach, Germany), equipped with a fused silica DB-5 column (30 m × 0.25 mm i.d., 0.25 μm film thickness) (J&W Scientific, Agilent Technologies, Köln, Germany) using the cold-on-column technique at 60 °C. After 2 min, the temperature was raised at 10 °C/min to 240 °C and, finally, held for 10 min isothermally. The flow of the carrier gas helium was 2.5 mL/min. A flame ionization detector was used at 250 °C. Identification was carried out using a reference mixture of fatty acid methyl esters.

Sample Preparation. To check possible matrix effects during the quantitation of crotonaldehyde by headspace analysis of fats and oils, first, either crotonaldehyde or [$^{13}C_4$]-crotonaldehyde (100 ng each, dissolved in pentane/diethyl ether (70/30, v/v)) was added to unheated extra virgin olive oil (1 g in 20 mL vials), which did not contain crotonaldehyde above the detection limit. After 20 min of continuous stirring at room temperature, the samples were subjected to mass spectrometric analysis as described below.

Oil Heating Process. Oil samples (5 g) were weighed into glass tubes (200 mm × 15 mm i.d.) covered with aluminum foil and were heated in a metal block. Heating was controlled by a thermocouple placed inside the oil. Samples were singly heated at 100, 140, 180 (regular deep-frying temperature), and 220 °C for 24 h each. In a further series of experiments, the samples were heated at 180 °C for 2, 4, 8, 16, 24, and 55 h. Immediately after the samples were cooled to room temperature, [$^{13}C_4$]-crotonaldehyde (0.5−150 μg, dissolved in pentane/diethyl ether (70/30, v/v), depending on the amounts determined in preliminary experiments) and [$^{13}C_3$]-acrolein (0.5−250 μg) were added, the glass tubes were closed and kept at −20 °C prior to analysis.

Preparation of Deep-Fried Food. *Dough Recipe for Donuts.* After the yeast (42 g) was dissolved in warm water, wheat flour (500 g), whole milk (150 mL), sugar (50 g), eggs (100 g), and water (25 mL) were mixed until a homogeneous dough was obtained. The dough was then divided into pieces of about 50 g and incubated at 30 °C for 2 h. Deep-frying (4 min at 180 °C) was performed as mentioned below for potatoes.

Deep-Frying of Potatoes. Thin slices (peeled, 1.5 mm cross section) were fried for 2.5 min at 180 °C in an electrical deep-fryer (Kenwood DF320, Heusenstamm, Germany) containing 2.3 L of oil, which was preheated for 10 min prior to frying. The potato-to-oil mass ratio was about 1:7. After the potatoes were cooled to room temperature, an aliquot (10 g) of the chips was weighed into a headspace vial (20 mL), [$^{13}C_4$]-crotonaldehyde and [$^{13}C_3$]-acrolein (each 150 ng) were added, and the mixture was stirred for equilibration (15 min). To provide the most similar conditions, the first five batches of the respective fried food were rejected, and only the sixth batch was used for analysis.

Quantitation of Crotonaldehyde by Headspace High-Resolution Gas Chromatography−Mass Spectrometry (HRGC−MS) (Method I). Aliquots (250−2000 μL) of the headspace volume were injected into the hot PPKD injector (Thermo Finnigan) of a Trace 2000 series gas chromatograph (Thermo Finnigan) using a Combi Pal autosampler (CTC Analytics, Zwingen, Switzerland) held at 20 °C and equipped with a 2 mL gastight syringe (SGE Analytic Science, Darmstadt, Germany). After each injection, a possible carry-over into the syringe was eliminated by an automatic syringe flush (helium). The headspace autosampler conditions were set as follows: incubation temperature, 30 °C; syringe temperature, 35 °C; syringe injection volume, 2 mL; syringe injection speed, 0.1 mL/s. The effluent was quantitatively transferred into a cold trap (initial temperature, −150 °C for 0.1 min; heating rate, 15 °C/s; final temperature, 240 °C for 3 min) (SGE Analytic Science) using a moving column stream switching system (Thermo Finnigan). After the cooling was turned off, the trapped compounds were transferred onto a fused silica DB-5 MS column (30 m × 0.25 mm i.d., 1.0 μm film thickness) (J&W Scientific). The oven was heated from 10 °C to 60 °C at 6 °C/min and then to 220 °C at 10 °C/min. The effluent was monitored by an ion trap mass spectrometer, Saturn 2000 (Varian, Darmstadt), running in the chemical ionization mode (70 eV ionization energy) with methanol as the reagent gas. Crotonaldehyde and [$^{13}C_4$]-crotonaldehyde were

located by means of their molecular masses obtained in the full scan mode (the mass range from m/z 50 to m/z 250 was recorded; m/z 71 for the analyte and m/z 75 for the labeled standard were used for determination) and by means of their retention indices. Crotonaldehyde concentrations were calculated from the area counts obtained from the mass chromatograms using the following equation:

$$m(\text{crotonaldehyde}) = R_f \times \frac{A(\text{crotonaldehyde}) \times m([^{13}C_4]\text{-crotonaldehyde})}{A([^{13}C_4]\text{-crotonaldehyde})}$$

where A(crotonaldehyde) is the area of unlabeled crotonaldehyde, $A([^{13}C_4]$-crotonaldehyde) is the area of $[^{13}C_4]$-crotonaldehyde, and $m([^{13}C_4]$-crotonaldehyde) is the amount of added $[^{13}C_4]$-crotonaldehyde. The response factor (R_f) was determined by analysis of defined mixtures of crotonaldehyde and $[^{13}C_4]$-crotonaldehyde (10:1, 5:1, 3:1, 1:1, 1:3, 1:5, and 1:10, w/w) as described below using the resulting response curve showing a very good linearity (coefficient of determination (R^2) of 0.99). Applied concentration ranges varied from 0.2 to 200 μg of crotonaldehyde depending on the amounts determined in preliminary experiments.

Quantitation of Acrolein by Headspace HRGC−MS. Quantitation of acrolein was performed by headspace high-resolution gas chromatography−mass spectrometry using $[^{13}C_3]$-acrolein as the internal standard as previously described.[9]

Quantitation of Crotonaldehyde by HRGC−MS after Derivatization with PFPH (Method II) or by High-Performance Liquid Chromatography−Tandem Mass Spectrometry (HPLC−MS/MS) after Derivatization with 2,4-DNPH (Method III). *Preparation of Reference Substances.* First, the reference derivatives of both crotonaldehyde and labeled crotonaldehyde were made up by adding these aldehydes into olive oil to consider possible matrix interferences, which might also occur during the analysis of real samples. Therefore, unheated extra virgin olive oil (10 g) was spiked singly either with crotonaldehyde or with $[^{13}C_4]$-crotonaldehyde (5 μg each, dissolved in pentane/diethyl ether (70/30, v/v)). After the addition of PFPH solution (0.5 mL; 2 mg of PFPH were dissolved in 1 mL of 0.1 mol/L HCl, method II) or 2,4-DNPH solution (1 mL; first, 100 mg of 2,4-DNPH were dissolved in 10 mL of 2.0 mol/L HCl using an ultrasonic bath and, then, diluted with 90 mL of methanol, method III), the mixture was stirred for 60 min (PFPH) or for 180 min (2,4-DNPH) at room temperature using a magnetic stirrer. In the same way, acrolein and $[^{13}C_3]$-acrolein were derivatized with PFPH[9] or 2,4-DNPH.

Then, the water-in-oil emulsion was extracted with dichloromethane (50 mL) by continuous liquid−liquid extraction. The PFPH derivatives as well as the 2,4-DNPH derivatives of crotonaldehyde and $[^{13}C_4]$-crotonaldehyde were separated from the bulk of the fat by the solvent-assisted flavor evaporation (SAFE) technique[45] at 48 °C under vacuum (5×10^{-3} Pa). The distillate was dried over anhydrous sodium sulfate and concentrated to a final volume of ∼1 mL using a Vigreux column (100 cm × 3 cm i.d.) at 48 °C. Aliquots (2 μL) of the solution were analyzed by GC−MS or LC−MS/MS as described below.

Analyses of Oil Samples. Oil samples were prepared as described above for the oil-heating process. To aliquots (approximately 5 g) was added PFPH (method II) or 2,4-DNPH (method III) solution, and the mixture was stirred for 20 min at room temperature. Further workup was done as described above for the reference substances.

Instrumental Conditions for HRGC−MS (Method II). Using a Combi Pal autosampler (CTC Analytics), an aliquot (2 μL) of the sample was injected into the hot PPKD injector of a Trace 2000 series gas chromatograph and transferred onto a DB-1701 column (30 m × 0.25 mm i.d., 0.25 μm film thickness) (J&W Scientific). The following temperature program was used: 40 °C for 2 min and then at 8 °C/min to 230 °C for 10 min. The effluent was monitored using an ion trap mass spectrometer Saturn 2000 running in the chemical ionization mode (70 eV ionization energy) with methanol as the reagent gas.

The derivatives of crotonaldehyde and $[^{13}C_4]$-crotonaldehyde were characterized by means of their molecular masses obtained in the full scan mode (the mass range from m/z 50 to m/z 300 was recorded; m/z 251 (analyte) and m/z 255 (labeled standard) for the PFPH derivatives were used for determination) and by means of their retention indices.

Instrumental Conditions for HPLC−MS/MS (Method III). Mass spectra were recorded by means of a triple-quadrupole tandem mass spectrometer (TSQ Quantum Discovery) (Thermo Electron, Dreieich, Germany) coupled to a Surveyor high-performance liquid chromatography system (Thermo Finnigan) equipped with a thermostated (20 °C) autosampler and an 120 mm × 2.0 mm i.d., 3 μm Nucleosil C18 120 Å HPLC column (Macherey-Nagel, Düren, Germany) kept at 30 °C connected to a 4 mm × 2.0 mm i.d. C18 precolumn (Phenomenex, Aschaffenburg, Germany). The solvent system was composed of formic acid in water (0.1% by weight; solvent A) and formic acid in acetonitrile (0.1% by weight; solvent B). A linear gradient was applied by increasing the concentration of solvent B from 30% to 100% within 15 min. Separation was performed at a flow rate of 0.2 mL/min. For quantitation, mass spectrometry was performed with positive electrospray ionization (ESI^+) in multiple reaction monitoring (MRM) mode with a spray needle voltage of 3.3 kV. The temperature of the capillary was 300 °C. The sheath gas and auxiliary gas (nitrogen) were adjusted to 35 and 10 arbitrary units, respectively. The collision cell was operated at a collision gas (argon) pressure of 0.20 Pa.

First, the derivatives of crotonaldehyde and $[^{13}C_4]$-crotonaldehyde were characterized by means of their molecular masses obtained in the full-scan mode. Clear molecular ions were obtained $[M + H]^+$: m/z 251 for derivatized crotonaldehyde and m/z 255 for derivatized $[^{13}C_4]$-crotonaldehyde. These were then subjected to MS/MS (collision energy 20 V). First, the most intense transitions of the precursor ions were determined, and second, the yields of the product ions were optimized by performing a series of runs with different collision energies and flow rates of the sheath gas and auxiliary gas. Finally, the mass transitions m/z 251 to m/z 234 and m/z 251 to m/z 157 for crotonaldehyde as well as m/z 255 to m/z 238 and m/z 255 to m/z 161 for $[^{13}C_4]$-crotonaldehyde were selected for quantitation, including the signal-to-noise ratio in oil samples as criteria.

Next, the 2,4-DNPH derivatives of acrolein and $[^{13}C_3]$-acrolein were characterized by means of their molecular masses obtained in the full-scan mode. Again, clear molecular ions were obtained $[M + H]^+$: m/z 237 for derivatized acrolein and m/z 240 for derivatized $[^{13}C_3]$-acrolein. These were then subjected to MS/MS (collision energy 20 V). First, the most intense transitions of the precursor ions were determined, and second, the yields of the product ions were optimized by performing a series of runs with different collision energies and flow rates of the sheath gas and auxiliary gas. Finally, the mass transitions m/z 237 to m/z 220 and m/z 237 to m/z 143 for acrolein as well as m/z 240 to m/z 223 and m/z 240 to m/z 146 for $[^{13}C_3]$-acrolein were selected for quantitation, including the signal-to-noise ratio in oil samples as criteria.

On both mass filter quadrupoles, the resolution setting was 0.8 full width at half-maximum, the scan time for each transition and single reaction monitoring (SRM) was 0.20 s, the scan width was 0.8 amu, and the source collision-induced dissociation (CID) voltage was 12 V.

Quantitation of Acrolein by HRGC−MS after Derivatization with PFPH. Quantitation of acrolein after derivatization with PFPH was performed by high-resolution gas chromatography−mass spectrometry using $[^{13}C_3]$-acrolein as the internal standard as previously described.[9]

Calibration Curves. For calibration, seven mixtures of crotonaldehyde and $[^{13}C_4]$-crotonaldehyde as well as of acrolein and $[^{13}C_3]$-acrolein in defined concentrations (molar ratios 10:1 to 1:10) were analyzed for all methods as described above, and the response factors were calculated from the results as previously described.[41] Calibration was always performed prior to sample measurement.

Limit of Detection (LoD) and Limit of Quantitation (LoQ). Calculation of the LoD and LoQ was carried out on the basis of a correlation between the intensity of the respective ions and the background noise with a minimum ratio of 3:1. Unheated oil samples were spiked with known amounts of crotonaldehyde (or acrolein for method III) in decreasing concentrations (100, 50, 25, 20, 15, 10, 5, 2.5, 1.25, and 0.5 μg/kg) and were analyzed in triplicate using all three methods. A control run without addition of crotonaldehyde and $[^{13}C_4]$-

crotonaldehyde (or acrolein and [$^{13}C_3$]-acrolein) was performed to ensure the absence of the respective mass signals in the oil samples.

HRGC−Sector Field Mass Spectrometry. To obtain mass spectra in electron impact (EI) as well as in chemical ionization (CI) mode for the PFPH derivatives of crotonaldehyde and [$^{13}C_4$]-crotonaldehyde, HRGC−MS analyses were performed by means of a Hewlett-Packard gas chromatograph, type 5890 series II (Hewlett-Packard, Waldbronn, Germany), coupled to a sector field mass spectrometer, type MAT 95 S (Finnigan MAT, Bremen, Germany), running either in EI mode (70 eV ionization energy) or in CI mode using isobutane as the reagent gas (115 eV ionization energy). The samples were injected by the cold on-column technique at 40 °C onto a DB-FFAP fused silica capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness) (J&W Scientific). The oven temperature was held for 2 min isothermally and then raised by 8 °C/min to 230 °C for 10 min.

RESULTS AND DISCUSSION

Synthesis of the Stable Isotopically Labeled Internal Standard [$^{13}C_4$]-Crotonaldehyde. Due to the fact that the deuterated labeled standard, which was used in preliminary trials,[42] showed a heterogeneous labeling pattern ([$^2H_{3-4}$]-crotonaldehyde), first, a new ^{13}C-labeled standard was synthesized using [$^{13}C_2$]-acetaldehyde. By Aldol condensation, 4-fold-labeled [$^{13}C_4$]-crotonaldehyde was obtained (Figure 1),

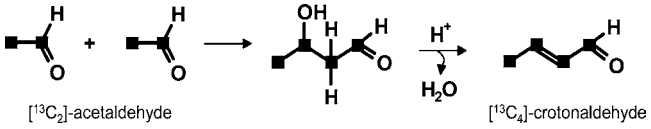

Figure 1. Reaction scheme for the synthesis of the internal standard [$^{13}C_4$]-crotonaldehyde. The symbol "■" indicates ^{13}C-labeling.

revealing a ratio between [$^{13}C_4$]-(*E*)-2-butenal (=[$^{13}C_4$]-crotonaldehyde) and [$^{13}C_4$]-(*Z*)-2-butenal of 95:5. Stereochemistry was confirmed by comparison of the retention index using commercially available (*E*)-2-butenal. Mass spectrometry experiments in the EI and CI modes have proven the successful incorporation of the labeling into the internal standard [$^{13}C_4$]-crotonaldehyde. The isotopic purity of [$^{13}C_4$]-crotonaldehyde was >97% (data not shown).

Development of the Analytical Procedure. *Method I (Headspace GC−MS).* In the first experiment, crotonaldehyde and [$^{13}C_4$]-crotonaldehyde (2 μg, dissolved in pentane/diethyl ether (70/30, v/v)) were singly placed into two 20 mL headspace vials, and after 20 min of equilibration, the solutions were analyzed by headspace GC−MS. The mass chromatogram of crotonaldehyde obtained by chemical ionization showed a clear peak at *m/z* 71. At the same retention index, the labeled isotopologue revealed a peak at *m/z* 75. Next, either crotonaldehyde or [$^{13}C_4$]-crotonaldehyde (100 ng each, dissolved in pentane/diethyl ether (70/30, v/v)) was singly added to unheated extra virgin olive oil (1 g in 20 mL vials). The analyte and the labeled analogue were characterized by selected ion monitoring at *m/z* 71 (for crotonaldehyde) and *m/z* 75 (for [$^{13}C_4$]-crotonaldehyde) as well as by their retention indices. The results showed that the fatty matrix neither contained coeluting compounds showing a signal either at *m/z* 71 or at *m/z* 75 at the respective retention index nor contained crotonaldehyde above the detection limit.

Method II (GC-MS after Derivatization) and Method III (LC−MS/MS after Derivatization). The crucial factor in headspace analysis of low molecular weight compounds such as crotonaldehyde is, however, the low specificity of the mass traces. This prompted us to develop two additional methods to confirm the reliability of the results obtained by the headspace method similar to the development of a derivatization method using 2-mercaptobenzoic acid for the quantitation of acrylamide,[39] also having an *m/z* signal of 72 (MS-CI) with a low specificity, or using pentafluorophenylhydrazine (PFPH) for the quantitation of acrolein (*m/z* 57, MS-CI).[9]

Preliminary trials showed a good conversion of crotonaldehyde by derivatization with the nucleophiles PFPH or 2,4-DNPH, and the respective adducts were analyzed. Both hydrazines were found to convert crotonaldehyde within 60 min (PFPH) or 180 min (2,4-DNPH) (120 min for acrolein using 2,4-DNPH) with high yields into stable hydrazones, which were detected either by GC−MS (PFPH) or by LC−MS/MS (2,4-DNPH).

For method development, first, the derivatives were synthesized by reacting crotonaldehyde as well as [$^{13}C_4$]-crotonaldehyde singly with either PFPH (Figure 2A) or 2,4-DNPH (Figure 2B) to obtain stable derivatives. Samples were analyzed by GC−MS (CI mode) or by LC−MS/MS (ESI$^+$ mode).

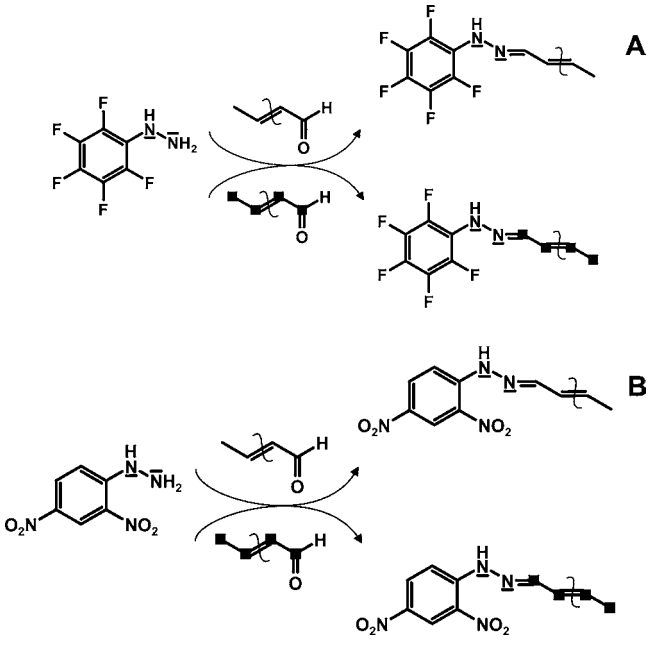

Figure 2. Derivatization scheme used for the conversion of crotonaldehyde (analyte) and [$^{13}C_4$]-crotonaldehyde (internal standard) into stable pentafluorophenylhydrazones (method II, A) or 2,4-dinitrophenylhydrazones (method III, B) prior to analysis. The symbol "■" indicates ^{13}C-labeling.

PFPH Derivatives of Crotonaldehyde and [$^{13}C_4$]-Crotonaldehyde (Method II, GC−MS). As PFPH itself has a lower retention time compared to the crotonaldehyde derivatives, the MS detector was switched off during its elution to avoid any contamination of the ion trap. The mass spectra (EI mode) of the PFPH derivatives of crotonaldehyde and [$^{13}C_4$]-crotonaldehyde are given in Figure 3A and 3B. Various ions were obtained, which are postulated to be [C_5F_3]$^+$, [C_5F_4]$^+$, [C_5F_5]$^+$, and [$C_6F_5NH_2$]$^+$.[9] The fragment *m/z* 183 in the spectrum is attributable to the cleavage of the hydrazone bond between both nitrogen atoms, whereas the fragments *m/z* 155, 136, and 117 may be formed by rearrangement of the aromatic ring. Intense [M]$^+$ ions of the unlabeled (*m/z* 250) and the labeled (*m/z* 254)

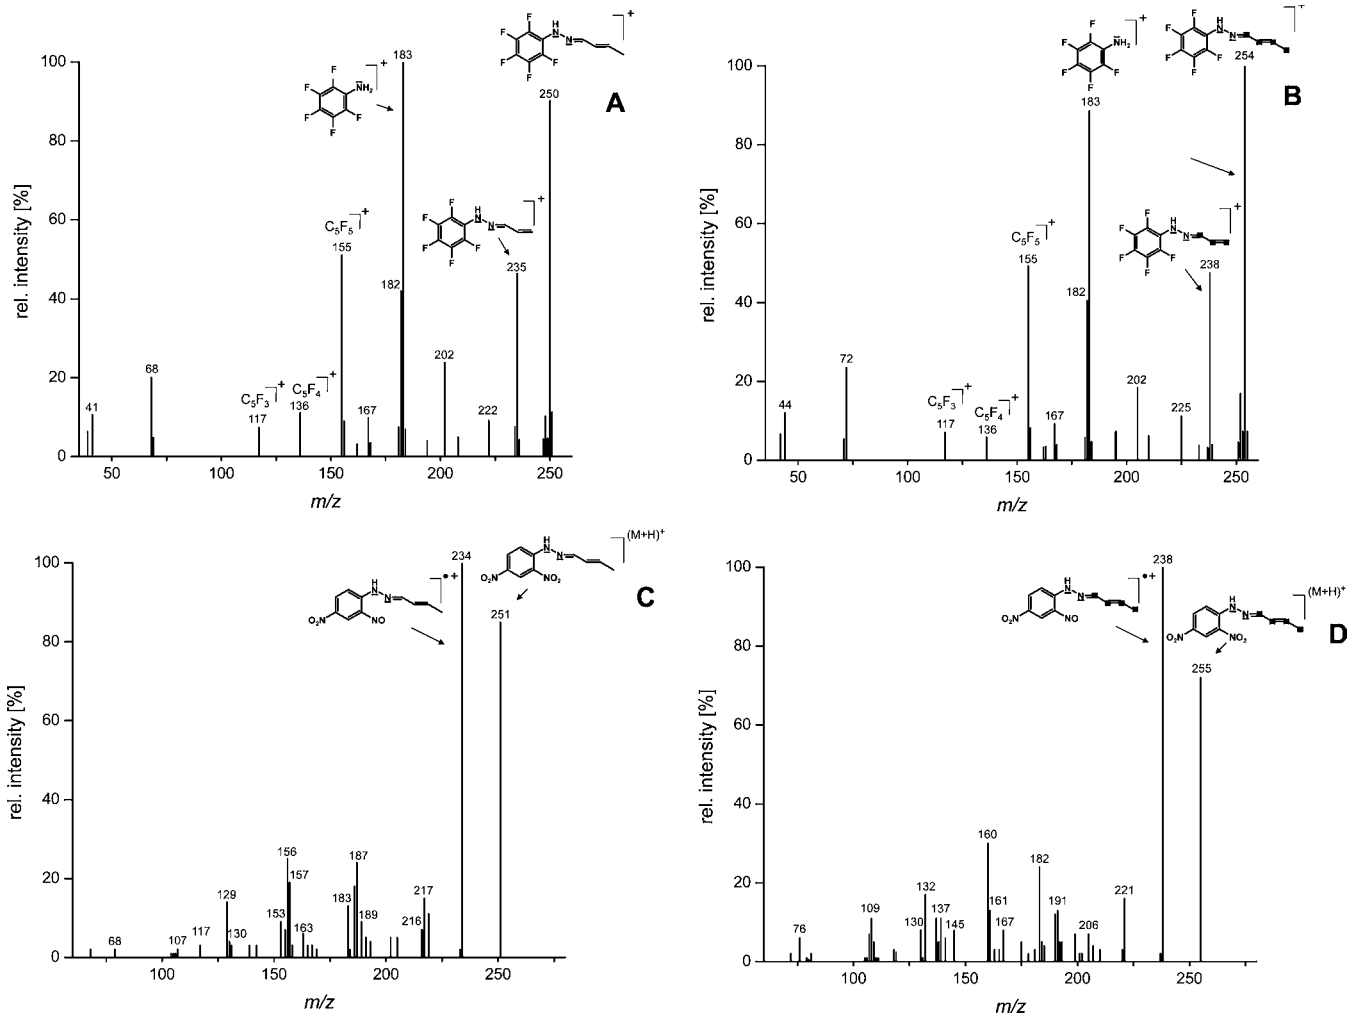

Figure 3. Mass spectra (GC−MS, EI) of the PFPH derivatives of crotonaldehyde (A) and [$^{13}C_4$]-crotonaldehyde (B) as well as mass spectra (LC−MS/MS, ESI$^+$) of the 2,4-DNPH derivatives of crotonaldehyde (C) and [$^{13}C_4$]-crotonaldehyde (D). The symbol "■" indicates ^{13}C-labeling.

crotonaldehyde derivatives confirmed the successful derivatization reactions of crotonaldehyde and its isotopologue using PFPH. In contrast to the assumption that two peaks (syn and anti forms of the enamine) might be generated, double peaks were not detected in the chromatogram, probably because the two isomers did not separate on the stationary phase used (Figure 4).

Next, unheated oil samples (10 g) were spiked with crotonaldehyde and [$^{13}C_4$]-crotonaldehyde (each 5 μg, dissolved in pentane/diethyl ether (70/30, v/v)), and the solutions were derivatized with PFPH. The best results to remove interfering compounds from the derivatives were obtained by high-vacuum distillation, the so-called SAFE technique.[45] Thus, mass spectra were obtained for the oil extracts identical to those shown in Figure 3A and 3B obtained from the model solutions, proving the workup procedure to be suitable for the quantitation of crotonaldehyde. Last, similar to the development of method I, unheated extra virgin olive oil was analyzed without addition of either crotonaldehyde or [$^{13}C_4$]-crotonaldehyde. Again, no signals for m/z 251 and m/z 255 (both MS-CI) were detected in the respective unspiked samples, revealing again that crotonaldehyde is, if at all, only present below its detection limit and that [$^{13}C_4$]-crotonaldehyde is an appropriate internal standard.

2,4-DNPH Derivatives of Crotonaldehyde and [$^{13}C_4$]-Crotonaldehyde (Method III, LC−MS/MS). The mass spectra (ESI$^+$, full scan mode) of the 2,4-DNPH derivatives of crotonaldehyde and [$^{13}C_4$]-crotonaldehyde are shown in Figure 3C and 3D. The following molecular ions were obtained [M + H]$^+$: m/z 251 for derivatized crotonaldehyde and m/z 255 for derivatized [$^{13}C_4$]-crotonaldehyde. Subjection to MS/MS revealed the following mass transitions, which were used for quantitation: m/z 251 to m/z 234 and m/z 251 to m/z 157 (crotonaldehyde) as well as m/z 255 to m/z 238 and m/z 255 to m/z 161 ([$^{13}C_4$]-crotonaldehyde). Even if m/z 157 and m/z 161 did not reveal the highest intensities, they showed the best signal-to-noise ratios in real samples besides m/z 234 and m/z 238.

2,4-DNPH Derivatives of Acrolein and [$^{13}C_3$]-Acrolein (Method III, LC−MS/MS). Next, the 2,4-DNPH derivatives of acrolein and [$^{13}C_3$]-acrolein were characterized by means of their molecular masses obtained in the full scan mode, revealing the following molecular ions [M + H]$^+$: m/z 237 for derivatized acrolein and m/z 240 for derivatized [$^{13}C_3$]-acrolein (data not shown). Subjection to MS/MS resulted in the following mass transitions for quantitation: m/z 237 to m/z 220 and m/z 237 to m/z 143 (acrolein) as well as m/z 240 to m/z 223 and m/z 240 to m/z 146 ([$^{13}C_3$]-acrolein).

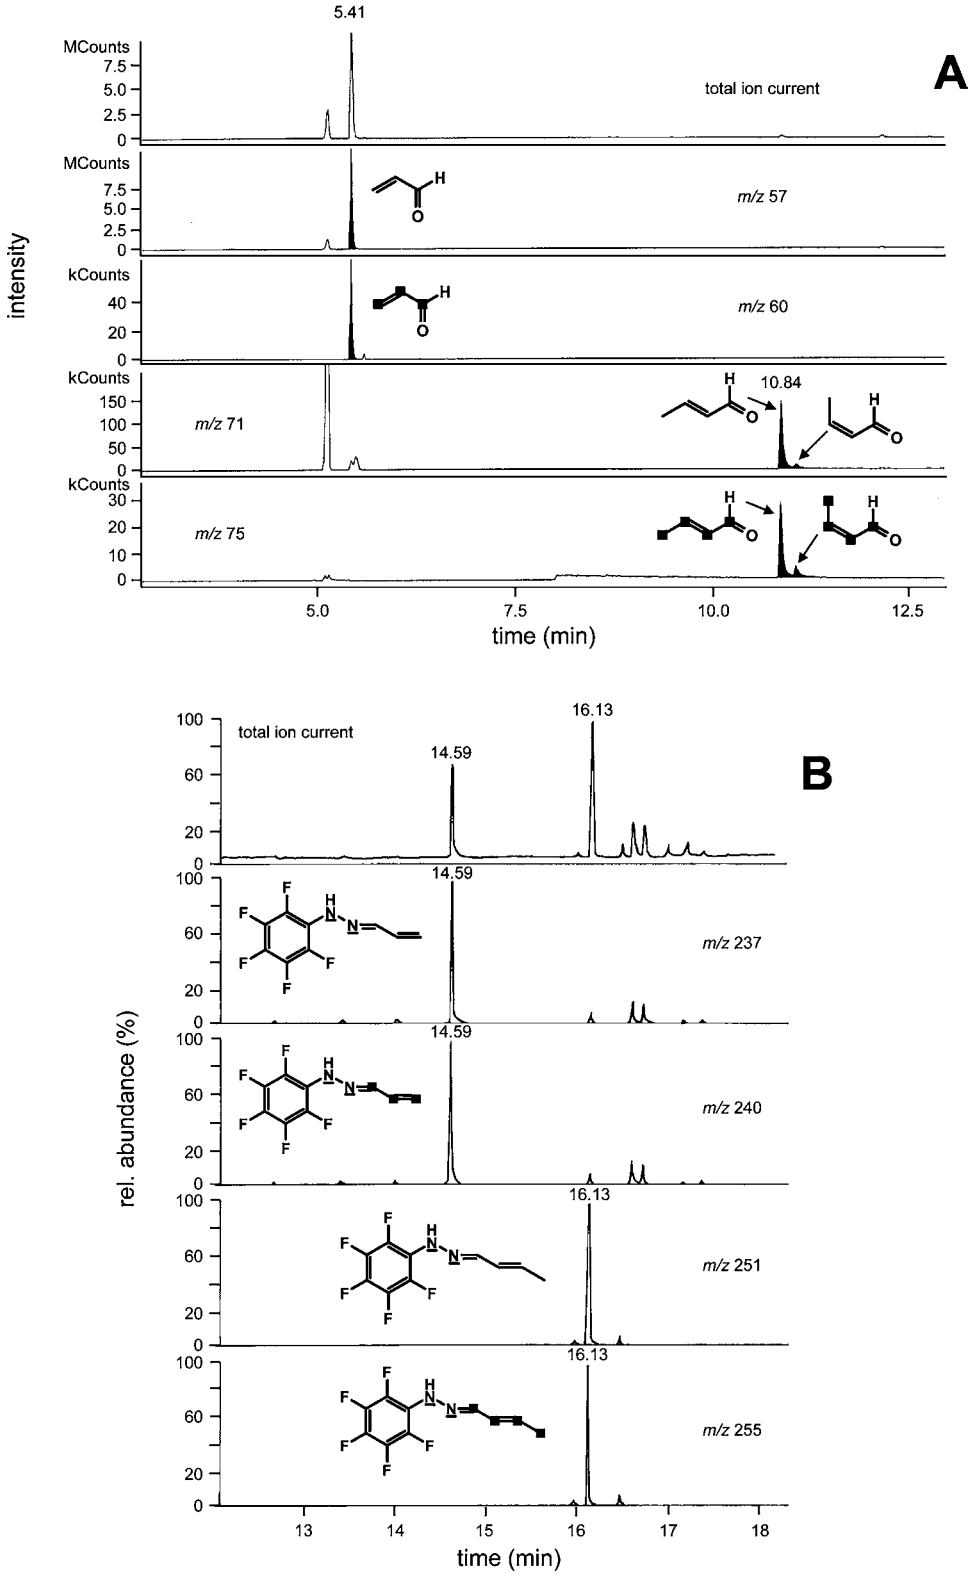

Figure 4. Extracts of GC−mass chromatograms (MS-CI) obtained for the analysis of crotonaldehyde (about 0.1 mg/kg) and acrolein (about 0.3 mg/kg) in a heat-processed olive oil sample using method I (without derivatization, A) and method II (derivatization with PFPH, B), respectively. The symbol "■" indicates ^{13}C-labeling.

Again, unheated oil samples (10 g) were spiked with crotonaldehyde and [$^{13}C_4$]-crotonaldehyde (each 5 μg, dissolved in pentane/diethyl ether (70/30, v/v)) as well as with acrolein and [$^{13}C_3$]-acrolein (each 5 μg, dissolved in methanol/dichloromethane (50/50, v/v)). Then, the solutions were derivatized with 2,4-DNPH and subjected to SAFE distillation.[45] In this way, mass spectra were obtained for the oil extracts identical to those of the reference compounds from the model solutions, proving the workup procedure to be suitable for the quantitation of crotonaldehyde and acrolein.

dx.doi.org/10.1021/jf404902m | J. Agric. Food Chem. 2014, 62, 1272−1282

Last, similar to the development of methods I and II, unheated extra virgin olive oil was analyzed without addition of crotonaldehyde, [$^{13}C_4$]-crotonaldehyde, acrolein, or [$^{13}C_3$]-acrolein. Again, no signals for m/z 251, 255, 237, or 240 were detected in the respective unspiked samples, revealing again that crotonaldehyde and acrolein are, if at all, only present below their detection limits and that [$^{13}C_4$]-crotonaldehyde and [$^{13}C_3$]-acrolein are appropriate internal standards.

Calibration Curves, LoDs, and LoQs. A calibration curve was generated for each method by analyzing seven model mixtures in unheated extra virgin olive oil containing defined amounts of labeled and unlabeled crotonaldehyde in different molar ratios (10:1 to 1:10). The mixtures were worked up for each method as described above and were analyzed by headspace GC−MS (method I), GC−MS (method II), or LC−MS/MS (method III). The $[M + H]^+$ mass ratios of the area counts of the analyte (m/z 71 for method I and m/z 251 for methods II and III) and the labeled standard (m/z 75 for method I and m/z 255 for methods II and III) were plotted against the concentration ratios. From these data, three response curves were obtained showing a good linearity ($R^2 > 0.99$).

For all three methods, limits of detection were calculated on the basis of a signal-to-noise ratio of 3:1. For this purpose, unheated extra virgin olive oil samples were spiked with different amounts of crotonaldehyde and acrolein (each 0.5−100 μg/kg, methods I−III), worked up, and measured by headspace GC−MS, GC−MS, or LC−MS/MS. The results allowed the calculation of LoDs for crotonaldehyde of 3 μg/kg for method I, 2 μg/kg for method II, and 1.5 μg/kg for method III as well as LoQs of 9 μg/kg for method I, 6 μg/kg for method II, and 4.5 μg/kg for method III. Interestingly, all three methods revealed nearly the same LoDs, pointing out method III as the most sensitive one due to MS/MS detection. For acrolein, LoDs were determined to be 3 μg/kg for method I and 2 μg/kg for methods II and III and LoQs to be 9 μg/kg for method I and 6 μg/kg for methods II and III. Thus, the main goal of this method development, using selective quantifier fragments of m/z 251 (analyte) and m/z 255 (internal standard) to check the correctness of the results obtained by the headspace GC−MS method (method I) using less selective quantifier signals of m/z 71 (analyte) and m/z 75 (internal standard), was achieved.

Generation of Acrolein and Crotonaldehyde during Thermal Processing of Oils. To estimate the influence of the fatty acid composition on the amounts of crotonaldehyde formed after heating, five different oil samples varying in their fatty acid compositions were heated at 180 °C for 24 h, and analyses were carried out using all three methods. First, the fatty acid composition of the fat and oil samples was determined (Table 1). In agreement with the literature, coconut oil was dominated by lauric and myristic acid, while olive oil mainly consisted of oleic acid. Also in rapeseed oil, oleic acid was the most prominent fatty acid, while safflower oil showed the highest amount of linoleic acid, and linseed oil was highest in linolenic acid. To check the influence of heat-processing on the fatty acid composition, the five fats were heated for various times (up to 96 h) at 180 °C and were analyzed again, revealing only marginal decreases, particularly for the unsaturated fatty acids (data not shown).

Typical chromatograms of heated oil samples obtained by method I (Figure 4A), method II (Figure 4B), and method III (Figure 5) are exemplarily shown for a thermally processed olive oil sample, showing clear peaks for acrolein and crotonaldehyde and their respective internal standards, [$^{13}C_3$]-acrolein and

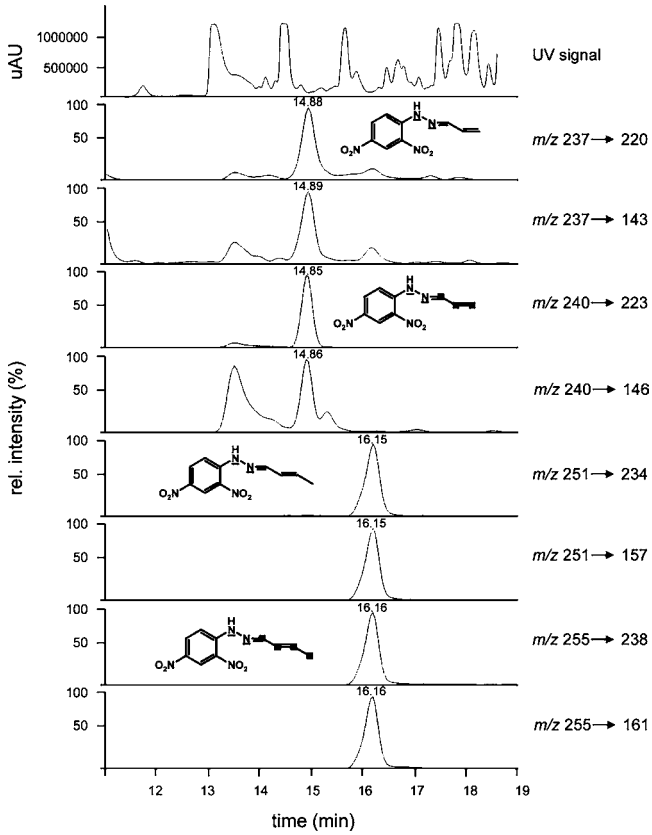

Figure 5. Extract of an LC−MS/MS chromatogram (ESI^+) obtained for the analysis of crotonaldehyde (about 0.1 mg/kg) and acrolein (about 0.3 mg/kg) in a heat-processed olive oil sample using method III (derivatization with 2,4-DNPH). The symbol "■" indicates ^{13}C-labeling.

[$^{13}C_4$]-crotonaldehyde. Interestingly, the separation of crotonaldehyde ((*E*)-2-butenal) from its stereo isomer (*Z*)-2-butenal was only achieved using method I, which can be explained by the use of a thick film capillary (Figure 4A).

The quantitative results obtained for the five different oils by all three methods are summarized in Table 2. A first observation was that all three methods resulted in very similar data, proving that the quick direct headspace GC−MS measurement, which does not require any time-consuming workup steps, can be used without any interference of coeluting compounds (m/z 71 for crotonaldehyde and m/z 75 for [$^{13}C_4$]-crotonaldehyde, MS-CI). Thereby, both derivatization methods using the same type of conversion by forming stable hydrazones, but different

separation (GC, method II; LC, method III) and detection (MS-CI, method II; MS/MS-ESI$^+$, method III) techniques, revealed nearly the same results in comparison to headspace GC−MS-CI (method I). Thus, the small amount of (*Z*)-2-butenal (not separated by methods II and III) present in the [$^{13}C_4$]-crotonaldehyde standard solution (cf. Figure 4A) did not significantly influence the quantitative data of crotonaldehyde.

At first glance, it seems that heat-processing of oils with higher amounts of unsaturated fatty acids, in particular linolenic acid, generated higher amounts of crotonaldehyde: linseed oil revealed about 34 mg/kg and rapeseed oil about 12 mg/kg in comparison to coconut oil with only 0.3 mg/kg (cf. Tables 1 and 2). This result is in good accordance with previous studies about the formation of acrolein upon heat-processing of oils depending on the fatty acid composition.[9]

To have the possibility of a direct comparison of the formation of crotonaldehyde and acrolein, the amounts of acrolein were determined in parallel in this study, especially due to the fact that a different model system was used for heat-processing compared to the method of Ewert et al.[9] Although another model was applied in the present study and, therefore, different concentrations of acrolein were generated, the tendency was clearly the same. Again, safflower oil, containing by far more linoleic acid compared to, e.g., rapeseed oil, showed remarkably lower contents of both crotonaldehyde and acrolein. Although its mean fatty acid is linoleic acid, safflower oil commonly contains a high level of antioxidants, e.g., tocopherols, which might explain its higher stability and, thus, the lowered formation of 2-alkenals. Since saturated or monounsaturated fatty acids are more stable during thermal oxidation, this may be the reason for the significantly lower generation of crotonaldehyde and acrolein from coconut and olive oil, respectively (Tables 2 and 3).

To study the influence of the temperature on crotonaldehyde formation, the five oil samples were analyzed after being heated at four different temperatures using headspace GC−MS (method I). With the exception of coconut oil and safflower oil, an increase of the temperature from 100 to 180 °C led first to a clear increase in crotonaldehyde formation, followed by a decrease from 180 to 220 °C after 24 h of heating (Table 3). Probably, at this quite high temperature, crotonaldehyde already undergoes reactions with other degradation products of these oils. In contrast, coconut oil and safflower oil did not show a maximum of crotonaldehyde formation up to 220 °C, and the amounts were much lower as compared to those of linseed oil and rapeseed oil. Exactly the same tendency, but in much higher concentrations compared to that of crotonaldehyde, was obtained for the formation of acrolein, with the only exception that safflower oil showed the same decrease in acrolein content from 180 to 220 °C as linseed oil, rapeseed oil, and olive oil (Table 3). These results confirmed that obviously the content of linolenic acid is crucial for the formation of both crotonaldehyde and acrolein during heating of oils. Furthermore, the data confirmed the findings of previous studies on acrolein formation[9] and acrolein release into the air[46,47] during frying of foods in different oils.

In a further series of experiments, the influence of the heating time on crotonaldehyde and acrolein formation was studied using again the headspace GC−MS method. For this purpose, the oil samples were heated at 180 °C, applying different heating times from 2 to 55 h. Thereby, linseed oil and rapeseed oil showed quite high amounts of crotonaldehyde and acrolein already after 2 h (Table 4). With increasing heating time, all analyzed oil samples revealed increasing amounts of both crotonaldehyde and acrolein, whereat normally the acrolein concentration dominates, except for olive oil, for which the formed amounts of both 2-alkenals are very similar after a heating time of >4 h. For coconut oil and rapeseed oil, crotonaldehyde concentrations increase until 16 h, followed by a decrease from 16 to 24 h and, finally, a further increase from 24 to 55 h. In contrast, olive oil and safflower oil had their maxima already after 8 h of heating, and linseed oil showed no maximum at all, still showing an increase of crotonaldehyde up to 55 h. Interestingly, the highest amounts of formed acrolein were determined already after 4 or 8 h for all oils. Thus, the results indicated the presence of different precursors, of different amounts of precursors, or at least of different conversion rates into crotonaldehyde or acrolein in the analyzed oils (Table 4).

Due to the fact that most of the available quantitative data for crotonaldehyde in different foods are more than 20 years old,[13−18] finally, the three newly developed quantitation methods for crotonaldehyde and acrolein were applied on self-prepared potato chips as well as on donuts. Therefore, thin slices of potatoes and donut dough were deep-fried in rapeseed oil and

in olive oil at 180 °C for 2.5 and 4 min, respectively. As shown in Table 5, crotonaldehyde and acrolein were detected in all samples, but in order of magnitude lower concentrations compared to those in the heated oils. Similar results were obtained for all three methods, again proving the possible use of the quick headspace GC−MS method for both matrixes.

Interestingly, crotonaldehyde concentrations differed both in the heat-processed oils and in the final food (potato chips and donuts) depending on the oil used (e.g., olive oil and rapeseed oil). In contrast, acrolein concentrations were very similar in both potato chips and donuts without reflecting the different oils used for processing (cf. Tables 2−5). A possible explanation for these results might be the higher reactivity of acrolein, reported to be 150-fold higher with the thiol group in glutathione using in vitro systems compared to that of crotonaldehyde.[48] Thus, the differences in acrolein concentrations originally occurring in the various frying media and, consequently, being transferred into the food during the frying process cannot be found in the final products due to a quick formation of acrolein adducts with different food constituents. These data may confirm recent findings by Watzek et al., who recovered higher amounts of acrolein mercapturic acids in human urine after consumption of potato crisps than expected compared to the before analyzed amounts of free acrolein in the crisps.[49] In contrast, for crotonaldehyde, showing less reactivity, these differences seem still to be analyzable in the respective foods (Table 5). In addition, also the generally higher amounts of acrolein formed in all types of frying media in comparison to those of crotonaldehyde were not reflected in the final products.

In summary, the results showed that all three newly developed methods on the basis of stable isotope dilution assays can be used for a simultaneous quantitation of crotonaldehyde and acrolein in frying oils as well as in food. Furthermore, the data suggested that linolenic acid might be an important precursor not only for acrolein but also for crotonaldehyde formation during heat-processing of oils. Thus, oils containing higher amounts of linolenic acid should be more carefully recommended for, e.g., frying purposes. Further studies on the formation pathway of crotonaldehyde are under way.

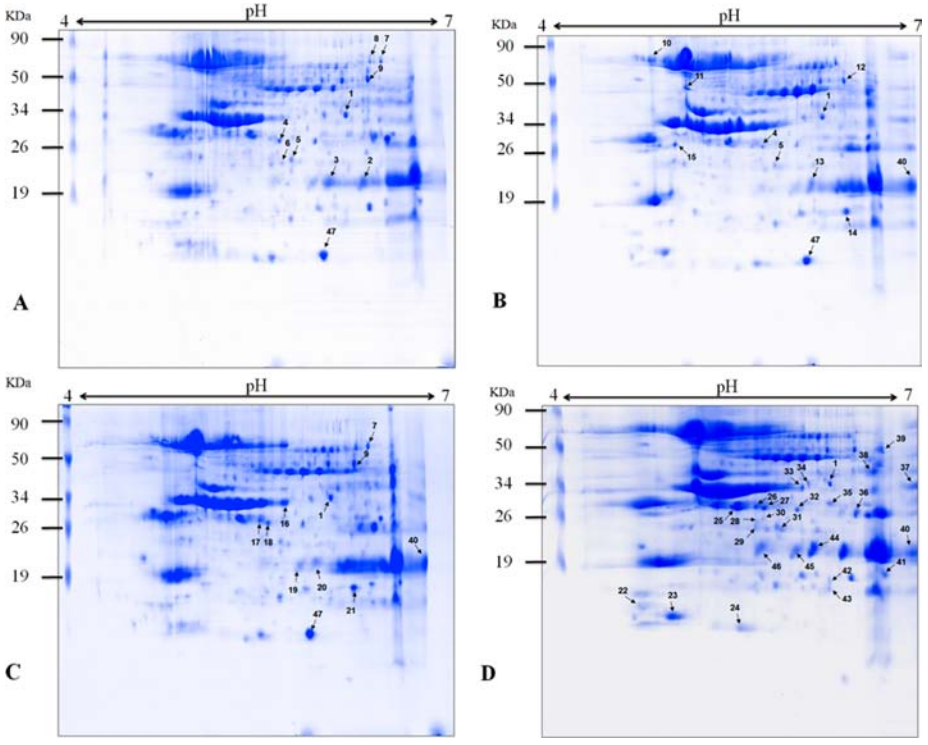

Figure 1. Two-dimensional electrophoresis was carried out using a narrow-range 18 cm IPG strip of pH 4−7: analyses of the proteins extracted using a thiourea/urea protocol from *Glycine max* cultivars (A) BRS 257, (B) BRS 258, (C) Embrapa 48, and (D) BRS 267. Identical numbers refer to the same spots, and distinct numbers correspond to differential spots present in each cultivar. The sizes of the protein markers in kilodaltons (kDa) are shown at the left of the images.

administration of these proteins in hypercholesterolemic rats.[18] Zhang et al.[19] demonstrated that hydrolyzed soybean proteins reduced the plasma level of very low-density lipoproteins cholesterol and triglycerides in mice. Additionally, the 11S globulin has hypotensive effects that are attributed to its ability to inhibit the angiotensin I-converting enzyme.[20] Peptides derived from the 7S globulin can act as blockers of fatty acid synthase, an enzyme present in large quantities in diseases such as cancer, obesity, and other metabolic disorders.[21]

Because of their health benefits, especially in the prevention and treatment of noncommunicable diseases, soybean proteins are the only proteins to offer benefits for cardiovascular disease that are certified by the American Dietetic Association (ADA).[22] According to the ADA, soybean products that provide 6.25 g of soy protein per serving are allowed to state on the label that "25 g of soy protein a day as part of a diet low in saturated fat and cholesterol may reduce the risk of coronary heart disease". The consumption of 3−4 tablespoons of soybeans (56−67 g of grains) each day meets the FDA requirements regarding the ingestion of 25 g of protein.

Despite the nutritional and functional properties mentioned above, the consumption of soybeans in Brazil is limited due to the characteristic flavor caused by lipoxygenases, which oxidize lipids and cause a beany flavor. In addition, gastrointestinal distress may be caused by the presence of oligosaccharides, raffinose, stachyose, phytic acid, and protease inhibitors.[23] *Embrapa-Soja*, *Empresa Brasileira de Pesquisa Agropecuária*, developed conventional cultivars in 2008 to stimulate consumption.[24] These cultivars were obtained by crossing different varieties to mitigate flavor and improve nutritional value. This process resulted in lipoxygenase-free grains with higher levels of carbohydrates and improved protein content.

The use of proteomics in nutrition is diverse and offers different possibilities for nutritional interventions of great value. The proteome study represents an important tool when associated with nutrigenomics as it provides insights into promises of future dietary approaches.[25] One proteomic strategy is the separation of proteins by polyacrylamide gel electrophoresis (in one or two dimensions), followed by the analysis and identification of proteins by mass spectrometry.[26] Another approach is a combination of liquid chromatography and mass spectrometry, which has become a powerful approach for the identification of proteins and peptides occurring in complex mixtures.[27]

The production of conventional plants with improved sensory qualities and nutritional characteristics is an important strategy to increase soybean consumption. However, the impact of these changes and the soybean improvements should be investigated by methods such as comparative analysis of protein expression profiles. This analysis will allow for the determination of the legume proteins that interfere with the nutritional and functional properties. We analyzed the protein profiles of four conventional soybean seeds (BRS 257, BRS 258, Embrapa 48, and BRS 267) using proteomic tools.

MATERIALS AND METHODS

Plant Materials. *G. max* seeds were kindly donated by the *Empresa Brasileira de Pesquisa Agropecuária* (EMBRAPA - Soja, Londrina, PR, Brazil). The cultivars used in this study were the following: BRS 257, BRS 258, EMBRAPA 48, and BRS 267. The grains of these four cultivars were ground in a mechanical mill (Retsch ZM 1) using a metallic sieve with a pore size of 0.5 mm until a fine powder was obtained. The samples were stored at −20 °C until analysis.

Extraction of Proteins from Seeds. The samples were delipidated with hexane until a colorless supernatant was obtained and then

[a]Number of spot identified. [b]Proteins identified by MALDI-TOF-TOF. [c]Molecular weight (MW) and isoelectric point (p*I*). [d]"+" indicates the presence of a spot and "−" the absence of a spot in the soybean cultivar. Protein spot data for this analysis were recorded (Supporting Information).

lyophilized. A 50 mg lyophilized sample was added to 495 μL of buffer containing 5 M urea, 2 M thiourea, 4% CHAPS, 65 mM DTT, 0.8% ampholytes at either pH 3−10 or pH 4−7, and 0.002% bromophenol blue. A 5 μL aliquot of a protease inhibitor cocktail (made up of 104 mM benzenesulfonyl fluoride hydrochloride, 80 μM aprotinin, 4 mM bestatin hydrochloride, 1.4 mM E-64, 2 mM leupeptin, and 1.5 mM pepstatin A) was added. After sonication for 20 min, the samples were centrifuged at 13000*g* for 15 min at room temperature, and supernatants were stored at −80 °C according to the methodology described by Herman et al.[28] with modifications. The protein content was determined using the protocol described by Peterson.[29]

One-Dimensional Gel Electrophoresis (1D SDS-PAGE). For 1D analysis, 90 μg of protein from each cultivar that had been previously extracted using a thiourea/urea method was applied to three lanes (30 μg in each lane) of a 12% SDS-PAGE gel (8.3 × 7.3 cm dimensions). The gels were fixed and stained with CBB G-250. One-dimensional separation was performed following the method described by Laemmli.[30] The experiments were performed with biological triplicates. After the image analysis, each lane was arbitrarily divided into approximately 2.5 mm slices and subjected to in-gel proteolysis with trypsin.

Two-Dimensional Gel Electrophoresis (2D SDS-PAGE). One milligram of soybean protein that had been extracted using a thiourea/urea method was applied to 18 cm IPG strips. The first dimension (isoelectric focusing) was performed using linear IPG strips that covered a pH range of 4.0−7.0 in an Ettan IPGphor (Amersham Biosciences) with the following program: 12 V for 12 h (rehydration), 200 V for 1 h, 500 V for 1 h, 1000 V for 1 h, 4000 V for 0.5 h, and 75067 V for 9.38 h. For the second dimension, the IPG strips were incubated with 50 mM Tris-HCl (pH 8.8), 6 M urea, 30% glycerol, 2% SDS, 0.002% bromophenol blue, and 65 mM DTT for 15 min. The strips were alkylated with iodoacetamide (25 mg/mL) and subsequently placed onto 15% polyacrylamide gels. The gels were run in a DALTsix system (GE Healthcare) at 2.5 W/gel for 30 min followed by 100 W for six gels until the end of the run. The reference gel was obtained after the analysis of biological triplicates. The experiments were performed in technical triplicates.

Gel Staining, Scanning, and Image Analysis. After 2D gel electrophoresis, gels were kept for 20 min in a fixation solution (2% orthophosphoric acid and 30% ethanol), washed with 2% orthophosphoric acid, and stained with a solution containing 2% orthophosphoric acid, 15% ammonium sulfate, 18% ethanol, and 0.002% CBB G-250. Direct scanning and image analysis were performed using an ImageScanner with ImageMaster 2D Platinum software (GE Healthcare). For MALDI-TOF/TOF mass spectrometry analysis, the presence or absence of spots in each cultivar was considered.

In-Gel Digestion. Each 1D gel band or 2D gel spot was excised, cut into smaller pieces, and destained overnight with a solution of 25 mM NH_4HCO_3 and 50% acetonitrile (ACN) at pH 8.0. For 1D gels, protein

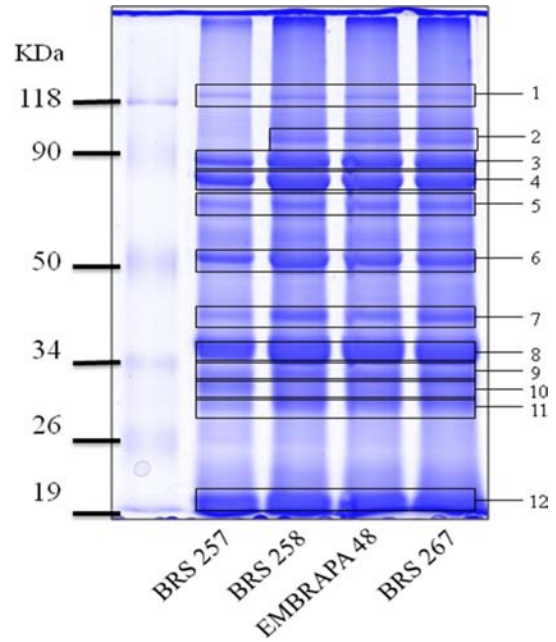

Figure 2. 1D SDS-PAGE analysis of protein extracts suitable for 2D SDS-PAGE from BRS 257, BRS 258, Embrapa 48, and BRS 267. Excised bands are identified at the right of the gel (numbered 1−12). The sizes of the protein markers in kilodaltons (kDa) are shown at the left of the figure.

disulfide bonds were reduced with 10 mM DTT in 25 mM NH_4HCO_3 at 56 °C for 1 h. The supernatant was then removed, and the gel pieces were incubated with 55 mM iodoacetamide for 30 min at room temperature in the dark. The pieces were washed with 25 mM NH_4HCO_3 to remove excess reagent. Finally, the 1D and 2D gel pieces were dehydrated with 100% ACN for 5 min and dried completely using a Speed-Vac system. The excised spots and bands were then rehydrated in 15 μL of digestion buffer containing 10 ng/μL of trypsin (Promega, modified sequencing grade) in 25 mM NH_4HCO_3 in an ice-cold bath for 10 min. The digestion was performed at 37 °C for 20 h. Following the incubation, the microcentrifuge tubes containing the samples were centrifuged, and 4 μL of 1% formic acid was added. The liquid from each gel piece was transferred into a clean microcentrifuge tube. The peptides were extracted from the gel pieces twice by incubation with 50% ACN in 5% trifluoroacetic acid (TFA) for 30 min. The resulting solutions from the two extractions were pooled together and concentrated to near dryness using a Speed-Vac system. Each sample was then solubilized in 20 μL of deionized water. Prior to mass spectrometry, peptides were

[a]Number of band identified. [b]Proteins identified by ESI-Q-TOF mass spectrometry. [c]Molecular weight (MW) and isoelectric point (p*I*). [d]"+" indicates the presence of a protein and "−" the absence of a protein in the soybean cultivar band. Protein band data for this analysis were recorded (Supporting Information).

desalted using a mini-reverse phase column PerfectPure C-18 Tip (Eppendorf). The tips were conditioned in 100% acetonitrile and washed three times with water. The peptide solution was aspirated and expelled from the tips 10 times. After three washings of the tip with water, the peptides were eluted with 50% ACN. The samples were dried using a Speed-Vac system and resuspended in solution of 0.1% formic acid and 3% ACN.

MALDI-TOF/TOF Mass Spectrometry Analysis. The mass spectrometry (MS) and tandem mass spectrometry (MS/MS) experiments were performed using a 5800 Proteomics Analyzer (Applied Biosystems, Foster City, CA). Approximately 0.6 μL of the extracted peptide solution was mixed with an equal volume of α-cyano-4-hydroxycinnamic acid matrix solution (Aldrich, Milwaukee, WI, USA) at 10 mg/mL in 50% ACN/0.1% TFA. Samples were placed on the target plate and allowed to dry at room temperature. Both MS and MS/MS data were acquired with a neodymium-doped yttrium aluminum garnet (Nd:YAG) laser with a 200 Hz repetition rate. Typically, 1600 shots were accumulated for spectra in the MS mode and 2400 shots were accumulated for spectra in the MS/MS mode. MS and MS/MS spectra were acquired in reflector mode. Up to eight of the most intense ion signals with signal-to-noise ratios above 30 were selected as precursors for MS/MS acquisition. The external calibration in MS mode was performed using a mixture of the following four peptides: des-Arg1-bradykinin (m/z 904.468), angiotensin I (m/z 1296.685), Glu1-fibrinopeptide B (m/z 1570.677), and adrenocorticotropic hormone (18−39) (m/z 2465.199). MS/MS spectra were externally calibrated using known fragment ion masses observed in the MS/MS spectrum of angiotensin I.

ESI-Q-TOF Mass Spectrometry Analysis. The peptides extracted from the 1D gel slices were desalted and fractionated by liquid chromatography (LC) coupled online with an electrospray ionization quadrupole time-of-flight mass spectrometer (ESI-Q-TOF). A 7.5 μL aliquot of the sample was loaded on a Waters nanoACQUITY UPLC System (Waters, Milford, MA, USA) with a Waters symmetry C18 trap column coupled to a Q-Tof MicroMass spectrometer. Afterward, the peptides were fractioned by a nanoEase BEH 130 C18 100 mm × 100 μm column (Waters) at a flow rate of 0.5 μL/min and eluted with a linear acetonitrile gradient (from 10 to 40%) of 0.1% formic acid. The ESI voltage was set at 3.5 kV using a metal needle. The source temperature was 80 °C, and the cone voltage was 40 V. Instrument control and data acquisition were conducted using a MassLynx data system (version 4.1, Waters). The experiments were performed by scanning a mass-to-charge ratio (m/z) of 300−2000 using a scan time of 1 s during the entire chromatographic process. A maximum of three ions with charge states of 2, 3, or 4 were selected for MS/MS from a single MS survey. Collision-induced dissociation (CID) MS/MS spectra were obtained using argon as the collision gas at a pressure of 1 bar. The collision voltage varied between 22 and 60 eV depending on the mass and charge of the precursor. The reference ion used was the monocharged ion m/z 588.8692 of phosphoric acid. Mass spectra corresponding to each signal from the total ion current (TIC) chromatogram were averaged, allowing for an accurate molecular mass determination. Exact mass MS/MS was automatically determined using the LockSpray source (Waters).

The acquired peak lists were analyzed by searching the National Center for Biotechnology Information (NCBI) database using the MASCOT search engine (www.matrixscience.com) for identification based on the MS/MS ions. Under standard thresholds (mass error tolerance, ±50 ppm for MALDI-TOF-MS and 0.2 Da for ESI-Q-TOF mass spectrometry analysis; MS/MS tolerance, ±0.2 Da for MALDI-TOF-MS and ESI-Q-TOF mass spectrometry analysis; fixed modifications, Cys-carbamidomethylation; variable modifications, methionine oxidation; one tolerated missed cleavage), proteins with a MOWSE score of at least 54 were considered as significantly identified. The functional classification of the identified proteins was performed by searching the http://www.ncbi.nlm.nih.gov, http://www.uniprot.org, and www.genome.jp/kegg databases.

Statistical Analysis. The statistical analysis was performed using the program GraphPad Prism 5.0 for Windows. A one-way ANOVA was applied followed by Tukey's test ($p \leq 0.05$).

RESULTS AND DISCUSSION

Plant breeding is one of the strategies used to enhance the sensory characteristics and increase the nutritional properties of foods. However, the impact of this technique on both environmental and human health should be monitored. In this study, we investigated the proteome profiles of four new soybean varieties (BRS 257, BRS 258, Embrapa 48, and BRS 267) and the relationships between the protein expression profiles and the nutritional properties of these cultivars.

Alves et al.[31] showed that BRS 258 has higher protein content than BRS 257, Embrapa 48, and BRS 267. Such a finding is in accordance with our results. The thiourea/urea method of protein extraction provided the following amounts of protein (μg/g dry matter ± SD): BRS 257 had a protein content of 144000 ± 10324, BRS 258 had a protein content of 168700 ± 12587, Embrapa 48 had a protein content of 153400 ± 46528, and BRS 267 had a protein content of 138450 ± 46315.

Comparative Analysis of Soybean Seed Proteomes by 2D SDS-PAGE. Proteins from four soybean cultivars were extracted using a urea/thiourea protocol. These proteins were then separated by 2D SDS-PAGE (Figure 1), followed by protein identification using mass spectrometry (Table 1).

The image data from the triplicate 2D gel experiment were analyzed for each cultivar. The numbers of proteins spots (±SD) detected for BRS 257, BRS 258, Embrapa 48, and BRS 267 were 102 ± 22, 124 ± 5, 113 ± 32, and 99 ± 23, respectively. After this analysis, the differentially expressed protein spots were identified using MALDI-TOF-TOF mass spectrometry (Figure 1). A total of 47 protein spots were identified (Table 1).

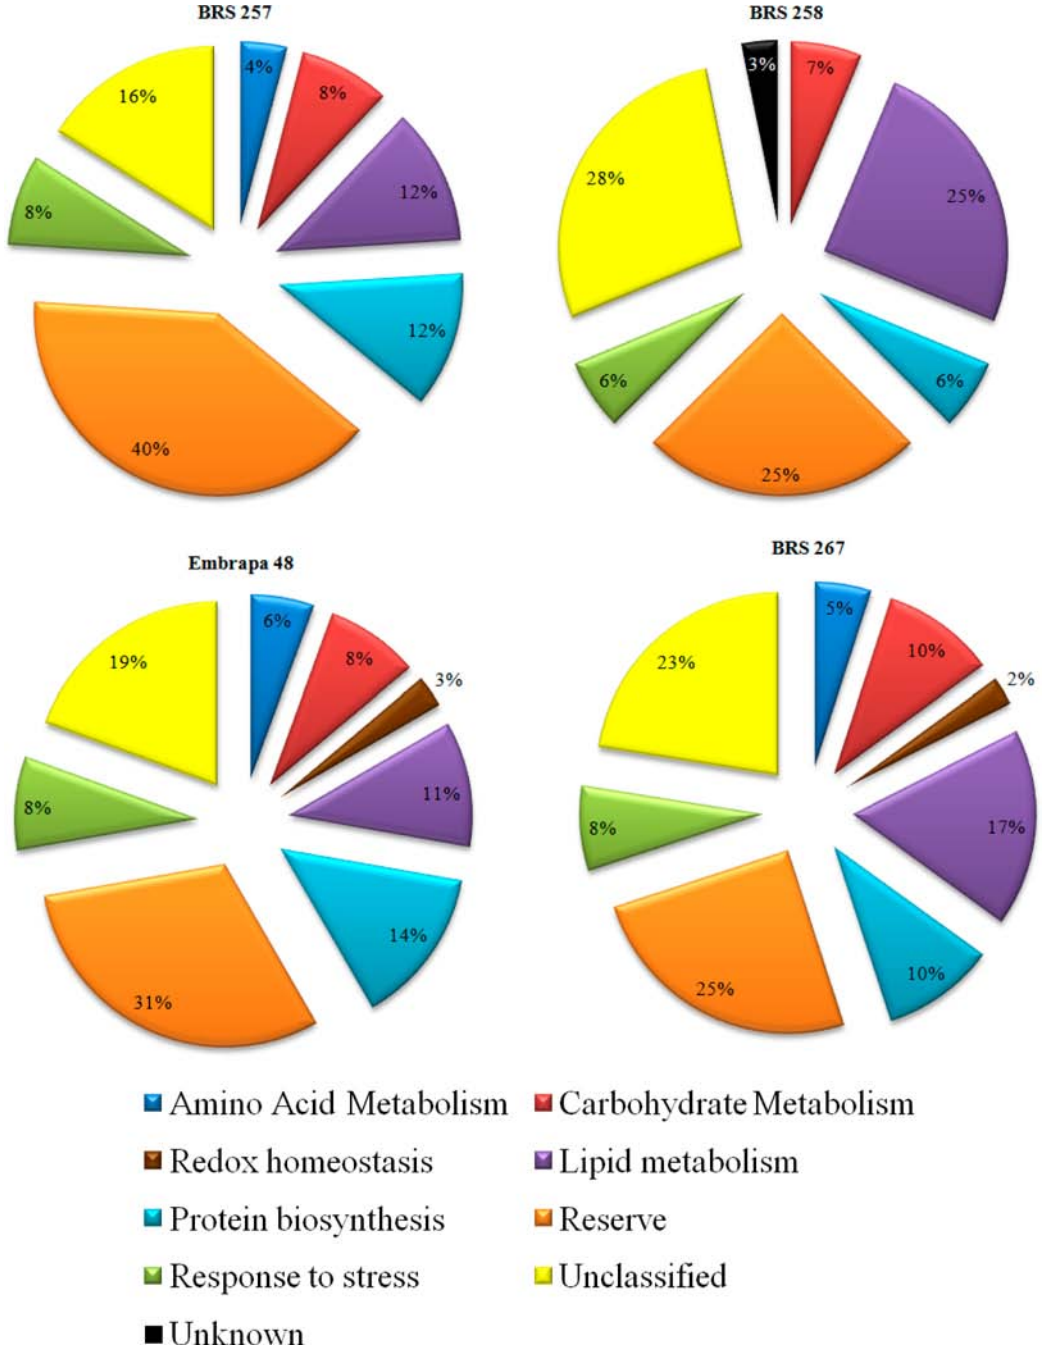

Figure 3. Functional classification of the soybean proteins isolated from BRS 257, BRS 258, Embrapa 48, and BRS 267 identified by 1D gel electrophoresis followed by ESI-Q-TOF mass spectrometry.

It has been reported that various soybean seeds may have different protein profiles due to genetic variability.[32,33] Among the analyzed spots, we found storage, allergenic, maturation, and agglutinin proteins as well as trypsin inhibitors. The comparative study of the 2D gels showed that the cultivar BRS 267 had the highest diversity for the identified spots (approximately 53%); this cultivar also had a greater number of spots corresponding to allergenic proteins and antinutrients, such as lectin and Kunitz inhibitor.

Eighteen glycinin and β-conglycinin spots were detected in the four soybean seeds. As the data show, these protein spots are distributed over a wide p*I* range in the same MW region. This pattern suggests the presence of isoforms or post-translational modifications of glycinin that occur during seed development, such as dissociation and reassembly.[12] Conversely, some authors attribute the occurrence of different spots for the same protein to the natural variation among different cultivars.[34]

Comparative Analysis of the Soybean Seed Proteomes by 1D SDS-PAGE. A 1D SDS-PAGE (Figure 2) analysis was performed using a protein extract suitable for 2D separation. The gels were stained with CBB, and proteins were identified by ESI-Q-TOF mass spectrometry. After image analysis, each intense Coomassie staining lane of the gel was divided into approximately 2.5 mm slices; the slices were then subjected to in-gel proteolysis with trypsin. A total of 117 proteins were identified from 12 bands in the 1D SDS-PAGE gel of soybean seed proteins.

dx.doi.org/10.1021/jf404351g | *J. Agric. Food Chem.* 2014, 62, 1283−1293

Distinct differences between the cultivars were found. Table 2 shows a comparative scheme indicating the presence or absence of the proteins identified in each cultivar.

Band 1 is the result of proteolysis. Lipoxygenase was detected in this band only in the BRS 267 cultivar. BRS 257 contains the lipid storage P24 oleosin isoforms A and B in this band, whereas only the α-subunit of β-conglycinin was identified in Embrapa 48.

These data confirm that BRS 257 is a cultivar without lipoxygenase, which is in accordance with information from Embrapa-soja.[24] Scientists have recently verified that a soybean seed lacking lipoxygenase had higher contents of calcium, magnesium, glucosides, and the aglycone forms of isoflavones and phytate compared to cultivars containing lipoxygenase.[35]

Other proteins were found only in the BRS 267 cultivar, including the following: 2S albumin precursor (band 12 and spot 24), cytosolic malate dehydrogenase (band 7), and hydroxysteroid 11-β-dehydrogenase 1-like protein-like (band 7). A 24 kDa oleosin isoform was found in BRS 257. The antinutrients lectin and Kunitz trypsin inhibitor were present in all soybean seeds.

The analyses of band 11 of BRS 257 and band 12 of BRS 258 were not reliable in any replicate. It is possible that some form of contamination occurred.

Functional Classification of the Identified Soybean Proteins. Classification according to the biological function of the proteins identified for each cultivar is illustrated in Figure 3. The proteins identified by ESI-Q-TOF-MS from the 1D SDS-PAGE analysis were grouped into nine categories according to their possible biological functions, based on molecular function, using the Universal Protein Knowledgebase (UniprotKB) and NCBI databases.

Comparison of the four soybean cultivars revealed similar protein function profiles. The distribution of proteins from the cultivars BRS 257 and BRS 258 had greater differentiation between categories than was observed in BRS 267 and Embrapa 48. Cultivars BRS 267 and Embrapa 48 had similar distributions of proteins between the categories; among the four cultivars, BRS 267 and Embrapa 48 had the greatest amounts of total sugar. These cultivars are described in the literature as having similar characteristics and as containing more sucrose.[36]

The highest percentage of storage proteins was found in BRS 257 (40%), followed by Embrapa 48 (31%), BRS 258 (25%), and BRS 267 (25%). The second largest protein group was unclassified proteins, which ranged from 16 to 28% of the total protein content.

The third major group of proteins observed was related to lipid metabolism (11−25%). Although BRS 257 does not possess lipoxygenases, lipid metabolism proteins represented 12% of the total protein content. Other observed protein categories were protein biosynthesis (6−14%) and stress response proteins (6−8%). Protein disulfide isomerase, a redox homeostasis enzyme, was observed only in the cultivars Embrapa 48 and BRS 267. Amino acid metabolism proteins were not observed in BRS 258.

According to the literature, BRS 258 is a soybean cultivar with a milder flavor and high protein content,[31] which is in agreement with our finding of a higher extraction yield of protein, although the values found were similar to those of other cultivars. Another distinctive feature of this cultivar is the significant percentage of proteins related to lipid metabolism.

An investigation of the proteomics of seed filling in soybean was reported by Hajduch et al.[37] The authors demonstrated that the largest functional class was unclassified proteins (28%), followed by metabolic proteins (22%; mainly lipid and sterol metabolism) and protein destination and storage proteins (10%). We noted that the maximal percentages in our study were similar for unclassified proteins and those associated with lipid metabolism. It must be noted that the protein profile is changed during seed filling; there is a decrease in lipid and sterol metabolism proteins and an increase in storage proteins.

Asakura et al.[38] characterized the gene expression patterns of developing soybeans. This group demonstrated that gene expression changes according to the stages of seed development. These changes could contribute to the differences in protein content. Kottapalli et al.[39] identified variations between four peanut cultivars. Proteins such as storage proteins, antinutritive proteins, and allergens were present in some peanut cultivars and absent in others. According to their study, the expression of some identified protein spots was cultivar specific.

According to Embrapa-soja,[24] BRS 257, BRS 258, Embrapa 48, and BRS 267, are promising options for human nutrition due to their elevated levels of carbohydrates and the high quality of the proteins. The diversity of proteins among the four soybean seeds in this study suggests that there are significant differences in the functional and nutritional properties of these seeds. Nevertheless, little is known about the protein composition of new conventional soybean varieties. The results obtained in this study indicate which cultivars are most suitable for human consumption and can direct the development of new cultivars with consideration of the protein composition.

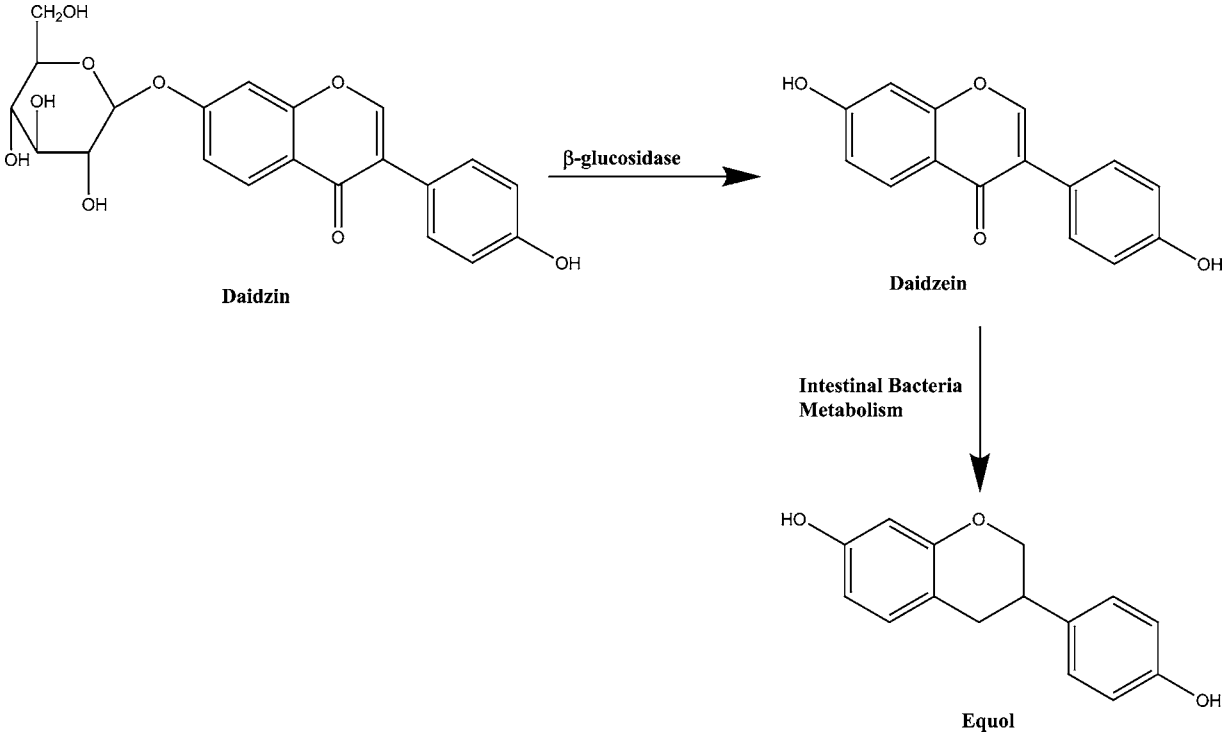

Figure 1. Schematic of equol production from intestinal bacteria metabolism of daidzein.

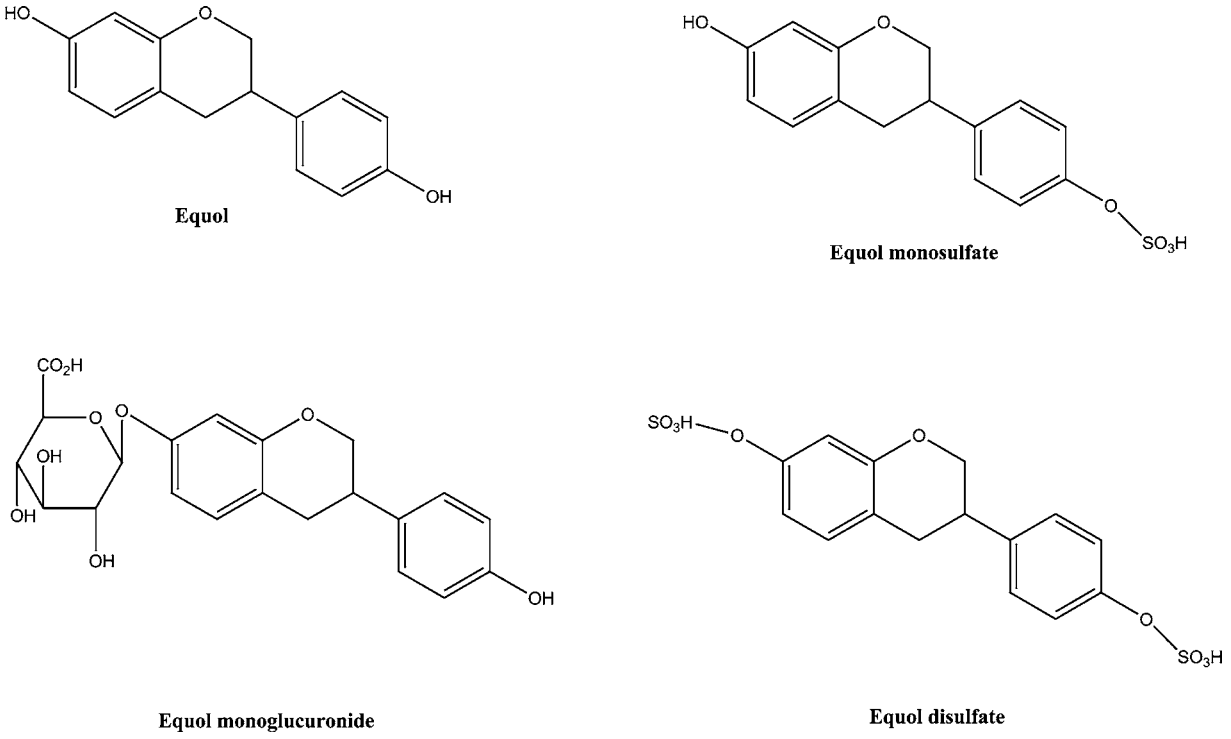

Figure 2. Chemical structures of equol and its conjugates.

MATERIALS AND METHODS

Animal Procedures. Three-month-old female Sprague−Dawley rats were purchased from Harlan (Indianapolis, IN, USA) and underwent ovariectomy (OVX) surgery. Rats were maintained on an AIN-93 M diet[32] with corn oil replacing soybean oil (to eliminate the potential presence of phytoestrogens in diet) for 1 week before undergoing pharmacokinetics. Animals were housed in individual cages in temperature- and humidity-controlled rooms with a 12 h−12 h on−off light cycle. After a 2 day acclimation period, animals were grouped into pairs and divided into two treatment groups: dietary daidzein (n = 6 pairs) and dietary equol (n = 6 pairs). Animals were matched on the basis of body weight, and pairs were selected to ensure similar body weight average across treatment groups.

Chemicals. Daidzein was obtained from a commercial source (Indofine Chemical Co., Hillsborough, NJ, USA). Racemic equol (50% *R*-equol, 50% *S*-equol) as well as equol sulfate conjugates (equol monosulfate and disulfate) were generously provided by the Helferich

dx.doi.org/10.1021/jf400097m | *J. Agric. Food Chem.* 2014, 62, 1294−1300

Table 1. Equol Metabolites Detected in Plasma of Ovarectiomized Rats Fed a Single Oral Dose of Dietary Daidzein (n = 4 Pairs, 10 mg/mL) or Equol (n = 5 Pairs, 2 mg/mL)

metabolite	retention time (min)	m/z transition
equol	10.8	241/119
equol disulfate	8.83	401/321
equol glucuronide	8.72	417/241
equol monosulfate	9.76	321/121

(Division of Nutritional Sciences, University of Illinois, Urbana, IL, USA) and Botting laboratories (Department of Chemistry, St. Andrew's University, Fife, UK), respectively. Synthesis details including purity for racemic equol[33] and equol conjugates[34] are described in earlier work. All other reagents were obtained from Sigma-Aldrich (St. Louis, MO, USA).

Materials. For formulation of oral gavage solutions, both daidzein and equol were suspended in 4.5% starch solution for single oral doses of 10 and 2 mg/mL, respectively. The oral equol dose represents a daily intake of 200 mg racemic equol/kg diet based on a physiologically relevant level for dietary racemic equol seen in earlier research in our laboratory.[35] The oral daidzein dose (1000 mg daidzein/kg diet) was selected due to the fact it produced similar circulating equol levels as seen with the dietary dose of 200 mg racemic equol/kg diet.

Pharmacokinetics. Animals were implanted with jugular catheters for blood collection 2 days before pharmacokinetics. Animals received a single oral gavage solution (2 mL) of dietary daidzein (10 mg/mL) or dietary equol (2 mg/mL). Blood (0.2 mL) was drawn via jugular catheter from each rat at the following time points: 0, 0.5, 1, 2, 3, 4, 6, 8, 12, 16, 20, and 24 h. For each pair of animals, blood was pooled at each time point (total of 0.4 mL). Animals weighed between 200 and 250 g. To replenish animals from blood loss, fluids (50:50, saline/5% dextrose, 2 mL) were given after the 3 h time point. After the last blood collection, animals were euthanized by CO_2 inhalation. All procedures were approved by the Purdue University Animal Care and Use Committee (Protocol 08-112).

Sample Preparation, Extraction and Analysis. Plasma samples were processed through two separate sample preparations to determine total aglycone and equol conjugate concentrations. To determine total plasma aglycone equol, samples underwent enzymatic hydrolysis as described previously.[36] In brief, two conjugates, phenolphthalein β-glucuronide (PHG) and 4-methylumbelliferone sulfate (4-MUS), were added to all samples as markers of effective hydrolysis along with an internal standard, chrysin (CHYS). Isoflavones were recovered by diethyl ether extraction. The ether extracts were evaporated under a stream of nitrogen and reconstituted with 100 μL of an 80% aqueous methanol solution for analysis.

To determine circulating levels of free equol and equol sulfate conjugates, plasma samples (200 μL) underwent protein precipitation. Methanol containing 1% acetic acid solution and a mixed set of internal standards (10 μM 4-MUS−PHG−CHYS) were added to each sample in a ratio of 4:1. Samples were centrifuged for 10 min at 3000g and 4 °C. The supernatants were used for analysis.

Total unconjugated equol, free equol, equol monosulfate, and equol disulfate concentrations were identified and quantified using a highly sensitive and specific electrospray ionization liquid chromatography−multiple reaction ion monitoring (MRM) mass spectrometry method

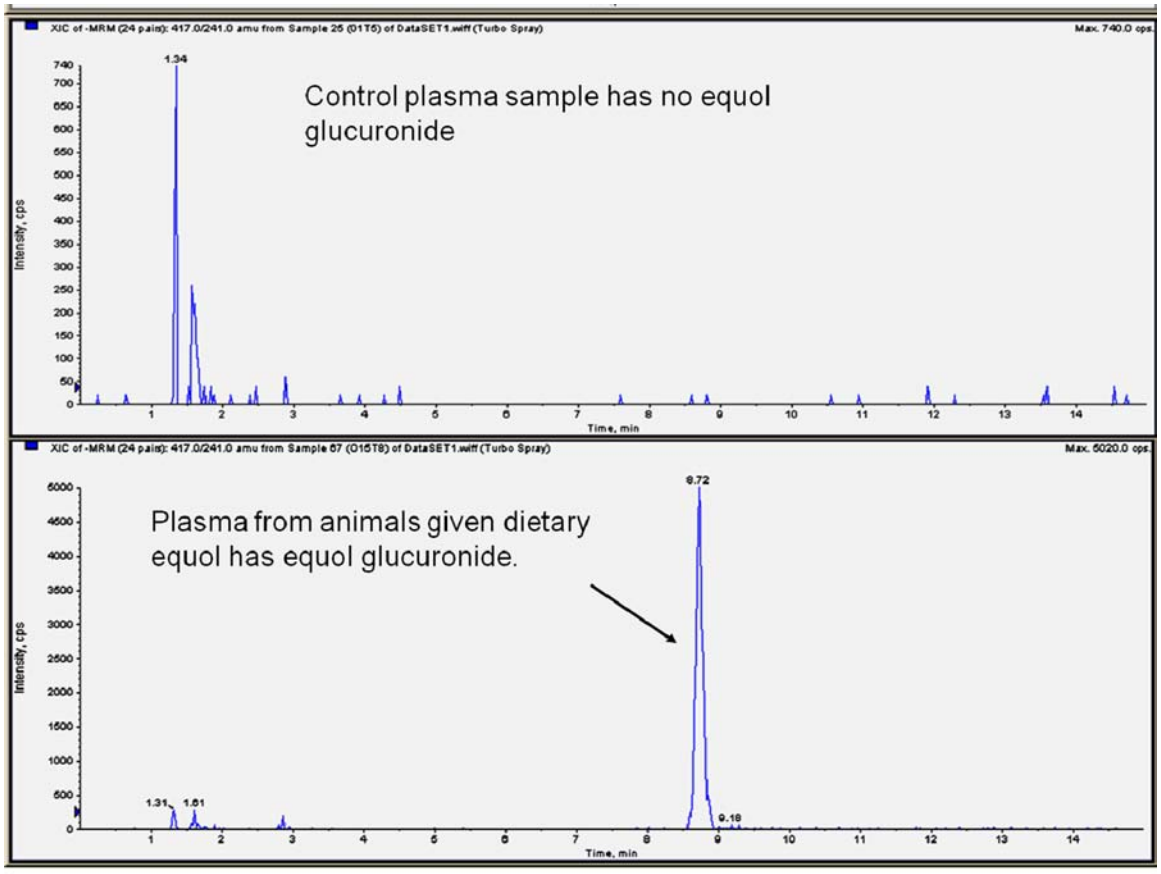

Figure 3. MS/MS chromatogram of control sample and product ion mass spectra of plasma samples from rats fed dietary equol (2 mg/mL). The presence of equol glucuronides was determined by monitoring the m/z 417/241 transition using a triple-quadrupole mass spectrometer (4000 QTRAP, ABSCIEX, Framingham, MA, USA) with chromatography details described previously.[35]

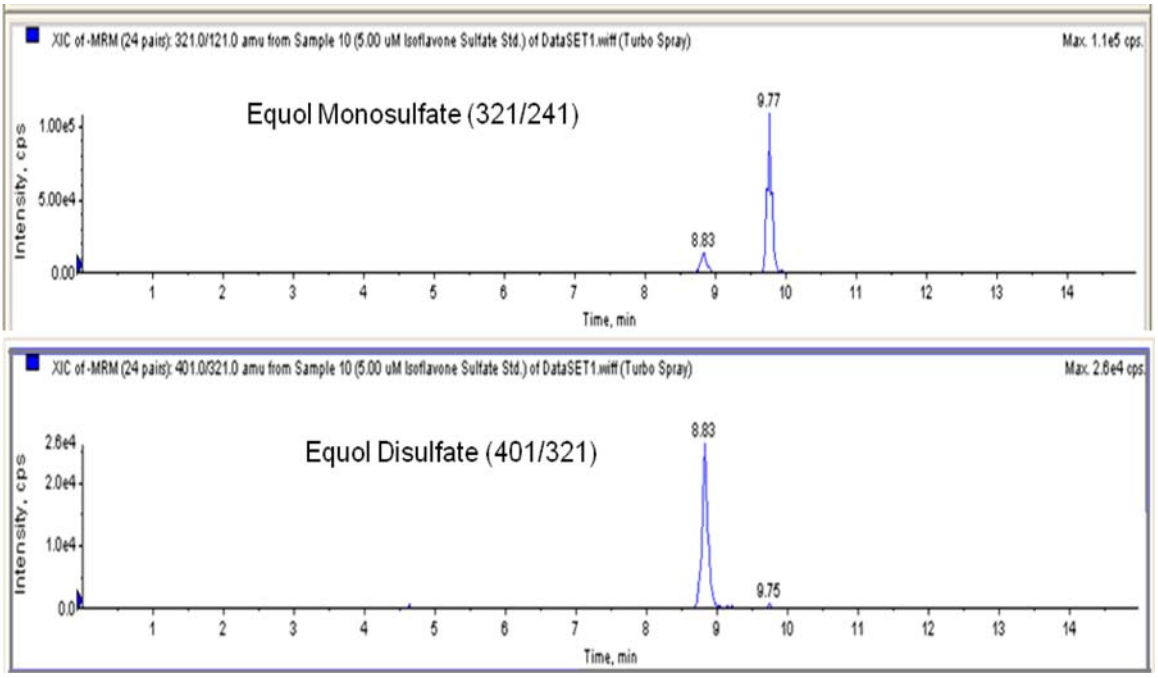

Figure 4. Representative MS/MS chromatogram of a 5 μM isoflavone sulfate standard containing equol monosulfate and disulfate.

as previously described[37] with chromatography conditions detailed in earlier work[35] and with the following modifications: equol monosulfate and disulfate were detected using their precursor to product ion transitions of m/z 321/121 and m/z 401/321, respectively. Identification and quantitation of equol and its sulfate conjugates were determined on the basis of comparison of MS/MS fragmentation pattern and retention time to reference material. LC-MS/MS method did not distinguish between *R*- and *S*-equol enantiomers. Due to limited availability of known standard for equol glucuronide, it was identified by its m/z 417/241 transition, and concentrations were determined using the following equation, which assumes that only equol sulfate and glucuronide conjugates are present:

$$\begin{aligned}&\text{equol glucuronide conjugates (nM)}\\&\quad = \text{total aglycone equol (nM)} - \text{free equol (nM)}\\&\qquad - \text{equol sulfate conjugates (nM)}\end{aligned} \quad (1)$$

The limit of detection for all analytes of interest was 5 nM. All parameters for metabolite identification including retention times and m/z transitions are listed in Table 1. To validate calculation for equol glucuronide conjugates and ensure no other metabolites were present, a control plasma sample was analyzed along with a sample from the dietary equol group. All pertinent m/z transitions were monitored. Representative chromatograms of equol glucuronide and equol sulfates are shown in Figures 3 and 4.

Pharmacokinetic Parameters. The following pharmacokinetic parameters were determined using noncompartmental methods (WinNonlin Pro version 4.01, Pharsight Corp., Mountain View, CA, USA): C_{max} (maximum concentration), HL (elimination half-life), t_{max} (time of maximum concentration), AUC_{0-24} (area under plasma concentration time curve from 0 to 24h), CL/F (clearance rate), and V/F (volume of distribution).

RESULTS AND DISCUSSION

Pharmacokinetic parameters for equol metabolites from dietary daidzein and racemic equol are detailed in Tables 2 and 3. There were higher levels of equol glucuronides than equol monosulfate for both dietary daidzein and racemic equol groups. There were no detectable levels of equol disulfate.

Table 2. Pharmacokinetic Parameters of Equol Metabolites from a Single Oral Gavage of Dietary Daidzein Administered to Ovariectomized Rats (n = 4−6 Pairs)[a]

metabolite	t_{max} (h)	C_{max} (nM)	AUC_{0-24} (nM·h)
total equol	20.67 ± 4.67	3682 ± 2675	24346 ± 8778
unconjugated equol	20.00 ± 4.90	1.21 ± 0.64	9.34 ± 8.43
equol monosulfate	20.00 ± 3.27	3.15 ± 3.04	19.16 ± 17.76
equol glucuronides	20.67 ± 4.67	3349 ± 2799	22438 ± 9907

[a]Values are means ± SD. Pharmacokinetic parameters: t_{max} (time of maximum concentration), C_{max} (maximum concentration), AUC_{0-24} (area under plasma concentration time curve from 0 to 24 h).

There were significantly higher maximum concentrations of all equol metabolites from dietary racemic equol compared to *S*-equol produced from dietary daidzein. Plasma concentrations of equol metabolites peaked around 2−3 h for dietary racemic equol and appeared in large levels at 8−13 h for dietary daidzein. The late appearance of equol metabolites with dietary daidzein was expected due to time required for bacterial conversion of daidzein to equol in the large intestine and therefore is a measure of intestinal transit.

Dietary equol led to rises in circulating equol and equol conjugates at 1, 4−5, and 8−9 h (Figure 5). The initial rise at 1 h is attributed to its rapid absorption in the small intestine, which is also seen in both in vitro[27] and in vivo[30] studies of equol metabolism. The second and third peaks at 4−5 and 8−9 h may be indicators of enterohepatic recycling and additional absorption occurring in the large intestine, respectively. Increases in equol metabolite levels during 16−24 h could also reflect enterohepatic recirculation, as previously reported with other isoflavones.[18] Small rises in equol metabolite levels could also be due to high biological variation. Additional studies with greater animals are needed to confirm if plasma increases are significant. Equol conjugates had lower clearance rates (CL/F) than unconjugated equol, which is unexpected due to polarity of conjugates, and warrants further investigation.

Table 3. Pharmacokinetic Parameters of Equol Metabolites from a Single Oral Gavage of Dietary Equol Administered to Ovariectomized Rats (n = 5−6 Pairs)[a]

metabolite	HL (h)	t_{max} (h)	C_{max} (nmol/L)	AUC_{0-24} (nmol/L·*h)	CL/F (L/h)	V/F (L)
total equol	21.9 ± 8.02	2.17 ± 2.91	8815 ± 2988	104337 ± 20531	0.08 ± 0.03	2.32 ± 0.26
unconjugated equol	9.41 ± 3.93	4.42 ± 4.50	9.46 ± 3.56	96.0 ± 41.9	179 ± 138	1,937 ± 692
equol monosulfate	14.4 ± 9.26	3.20 ± 2.95	23.9 ± 8.54	234 ± 97	43.7 ± 11.7	912 ± 703
equol glucuronides	23.0 ± 2.91	2.17 ± 2.91	8775 ± 2976	104082 ± 20516	0.08 ± 0.03	2.38 ± 0.50

[a]Values are means ± SD. Pharmacokinetic parameters: HL (elimination half-life), t_{max} (time of maximum concentration), C_{max} (maximum concentration), AUC_{0-24} (area under plasma concentration time curve from 0 to 24 h), CL/F (clearance rate) = D/AUC_{0-24}, V/F (volume of distribution)

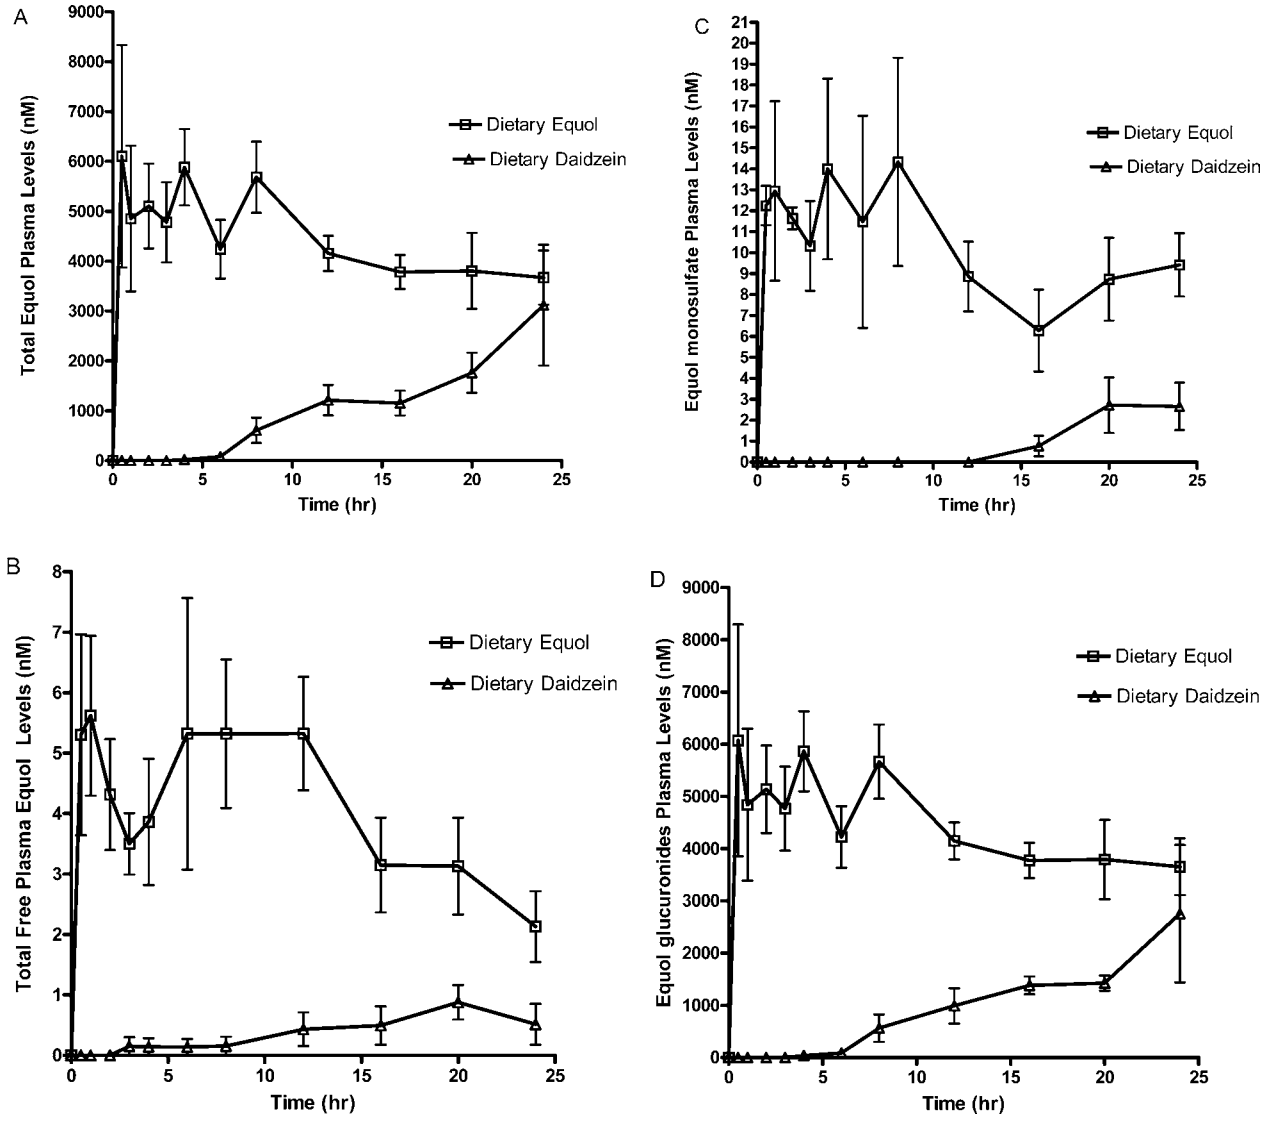

Figure 5. Pharmacokinetic curves over a 24 h period in ovarectiomized rats after a single oral dose of dietary daidzein (n = 6 pairs) (10 mg/mL) or equol (n = 6 pairs) (2 mg/mL) for plasma (A) total aglycone equol, (B) unconjugated or free equol, (C) equol monosulfate, and (D) equol glucuronides. The equol glucuronide was calculated as the difference between the total plasma equol concentration and the sum of the plasma unconjugated and sulfated equol.

The first appearance of equol metabolites (total equol and equol glucuronides) after administration of dietary daidzein occurred around 7−8 h (Figure 5A,D). This corresponds to findings from previous studies.[15,17,38] In the dietary daidzein treatment group, total equol, unconjugated equol, and equol glucuronide levels from dietary daidzein rose between 8 and 13 h and all metabolites peaked between 20 and 24 h, consistent with earlier work assessing the bioavailability of daidzein and genistein conjugates in rats.[15] None of the equol metabolites reached a plateau after 24 h (Figure 5). There were few data to accurately assess HL, CL/F, and V/F of equol metabolite produced from dietary daidzein. Both findings suggest that a longer time frame is needed to adequately assess the pharmacokinetic profile of equol metabolites from daidzein consumption.

Our results indicate there were higher levels of circulating equol metabolites with dietary racemic equol compared to equol produced from dietary daidzein in ovariectomized rats. We also observed poor clearance of equol metabolites as well as high enterohepatic recirculation as seen previously with other soy isoflavones.[18] Most of the circulating equol was conjugated equol, specifically equol glucuronides, which agrees with findings from other in vivo studies. Pharmacokinetics studies of *S*-equol in various species (rat, monkey, human) show similar metabolism including rapid absorption.[12,29,30] Future studies could utilize animal models to determine mechanisms of action for various forms of equol. More elucidation on the impact of the forms of equol (various enantiomers, dietary vs intestinal production) as well as the effect of equol conjugates on health benefits of equol is needed.

Preparations of Ovalbumin−Dextran (O−D) Conjugates. Ovalbumin (250 mg) and an equal amount of dextran were mixed and dissolved in 100 mL of water. The pH of the solution was adjusted to pH 8.0 using a 0.1 N NaOH. Afterward, this solution was lyophilized to form a fine powder. The dry powder was heated at 60 °C with 79% relative humidity in a desiccator containing saturated KBr solution for 2 days to form the O−D conjugates. The conjugates were stored at −20 °C and used without any further purification.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE) Analysis of O−D Conjugates. The formation of O−D conjugates was confirmed using SDS-PAGE on a gel electrophoresis apparatus to detect the molecular weight distributions of ovalbumin and the O−D conjugates. Proteins were separated on gels made of 10% acrylamide and 0.1% SDS. Stacking gel made of 5% acrylamide and 0.1% SDS was used to load the samples. Samples were treated with 100 mM dithiothreitol and boiled for 5 min before loading. After electrophoresis, the gel was stained for protein and carbohydrate using Coomassie Blue R-250 and Fuchsin solution, respectively. The protein and carbohydrate stain were destained with 10% acetic acid (v/v) containing 10% methanol (v/v) and 7.5% acetic acid (v/v) water solution, respectively. The ovalbumin content reacted with dextran was analyzed using UN-SCAN-IT gel analysis software (version 6.1, Silk Scientific, Inc., Orem, UT, USA).

Preparations of EGCG O−D Conjugate Nanoparticles and Cross-Linked EGCG O−D Conjugate Nanoparticles. Briefly, 50 mg of O−D conjugate and 25 mg of EGCG were dissolved in 10 mL of deionized water (mass ratio of ovalbumin to EGCG was 1:1). After adjustment of the pH to 5.2, the solution was incubated at 80 °C for 60 min to form EGCG O−D conjugate nanoparticles. The resulting nanoparticle suspension was stored at 4 °C before analysis.

Cross-linked EGCG O−D conjugate nanoparticles were prepared by adding 5 μL of glutaraldehyde to 1 mL of nanoparticle suspension. The cross-linking process was carried out at room temperature for 24 h under a stirring speed of 750 rpm.

Particle Size and Particle Morphology. Particle size was measured in aqueous suspension. One milliliter of EGCG O−D conjugate nanoparticles or cross-linked nanoparticles was centrifuged at 13300 rpm for 5 min, and the sediments were resuspended in 5 mL of deionized water. Mean particle size (number-weighted distribution) was measured using dynamic light scattering (DLS) on Zetatrac (Microtrac Inc., Largo, FL, USA). Samples were measured in four replicates at 25 °C to calculate the average particle size.

The morphology of dry EGCG O−D conjugate nanoparticles and cross-linked nanoparticles was measured using a field emission scanning electron microscope (model JSM-633OF, JEOL Ltd., Tokyo, Japan).

Loading Efficiency and Loading Capacity Assessments. The nanoparticle suspensions were centrifuged at 13300 rpm for 5 min to collect the supernatant. The supernatant was analyzed using HPLC for EGCG content. The loading efficiency and the loading capacity were calculated using the following equations:

$$\text{loading efficiency} = (\text{EGCG amount used for nanoparticle fabrication} - \text{EGCG amount in supernatant}) / \text{EGCG amount used for nanoparticle fabrication} \times 100\%$$

$$\text{loading capacity} = (\text{EGCG amount used for nanoparticle fabrication} - \text{EGCG amount in supernatant}) / \text{dry nanoparticle amount} \times 100\%$$

Nanoparticle Characterization under Different pH Conditions. Briefly, 1 mL of EGCG O−D conjugate nanoparticles or cross-linked EGCG O−D conjugate nanoparticles was centrifuged at 13300 rpm for 5 min, and the sediments were resuspended in 5 mL of deionized water. The pH of the suspension was adjusted to 2.5, 3.0, 4.0, 5.0, 6.0, 7.0, and 7.5 using a diluted HCl or NaOH solution. Mean particle size (number-weighted distribution) and zeta-potential were immediately measured on Zetatrac (Microtrac Inc.). Samples were measured in duplicates at 25 °C to calculate the average particle size and zeta-potential.

Nanoparticle Stability in Simulated Gastric or Intestinal Fluid. One milliliter of EGCG O−D conjugate or cross-linked EGCG O−D conjugate nanoparticles was centrifuged at 13300 rpm for 5 min, and the sediments were resuspended in 5 mL of SGF (pH 4.0, fed state) or SIF (pH 6.0) at 37 °C for 0.5, 1, 1.5, and 2 h. At each time point, particle size (number-weighted distribution) was measured on Zetatrac (Microtrac Inc.). Samples were measured in duplicates to calculate the average particle size.

Release of EGCG in Simulated Digestive Fluids. The cumulative release of EGCG in the nanoparticles was measured in SGF without or with pepsin and in SIF without or with pancreatin.[19] Briefly, after centrifugation, nanoparticles were resuspended in deionized water and then lyophilized. The dry nanoparticles were suspended in 5 mL of SGF (pH 4.0) with or without 0.1% pepsin (w/v) and incubated at 37 °C for 0.5 h. Subsequently, 1 mL of the sample was centrifuged at 13300 rpm for 5 min. Supernatant was measured on HPLC for EGCG content. The nanoparticles were suspended in 5 mL of SIF (pH 6.0) with or without 1.0% pancreatin (w/v) and incubated at 37 °C for 2 h. Then, 1 mL of sample was centrifuged at 13300 rpm for 5 min. The supernatant obtained was measured by HPLC analysis. Samples were measured in four replicates. An Agilent Zorbax SB C18 column (4.6 mm × 250 mm) was used to analyze EGCG. The binary mobile phase consisted of 0.04% acetic acid/water (A) and acetonitrile (B). A 22 min gradient was used as follows: 0−20 min, 10−30% B linear; 20−22 min, 30−10% B linear; followed by 2 min of re-equilibration of the column before the next run. The detection wavelength on the diode array detector was 280 nm. The injection volume was 5 μL with a flow rate at 1 mL/min. The cumulative EGCG release was calculated using the following equation:

$$\text{cumulative EGCG release (\%)} = (\text{EGCG amount in supernatant}/\text{EGCG amount in dry nanoparticles}) \times 100\%$$

EGCG Absorption on Caco-2 Cell Monolayers. Caco-2 cells were seeded in 6-well transwell plates with an internal diameter of 24 mm and a membrane growth area of 4.67 cm^2 (Corning Inc., Lowell, MA, USA). The cells were cultured using Dulbecco's modified Eagle media containing 20% fetal bovine serum, 1% penicillin−streptomycin, and 1% nonessential amino acids. The cells were grown to confluence and allowed to mature for 17 days at 37 °C and 5% CO_2. The cell culture media were changed every 1−2 days. The permeability study was carried out in triplicate after the transepithelial electrical resistance (TEER) was 500−600 Ω × cm^2, measured using an epithelial volt-ohm meter (Millicell ERS-2, Millipore Corp., Billerica, MA, USA). The permeability study followed a published paper with minor modifications.[29] EGCG or EGCG O−D conjugate nanoparticles were added into Hank's balanced salt solution (HBSS, pH adjusted to 6.0) to control EGCG concentration at 0.025 mg/mL. HBSS buffer was used as a blank. One and a half milliliters of each sample was transferred to the apical chamber of the transwells, and 2.6 mL of the fresh buffer was added to the basolateral chamber. After incubation at 37 °C for 30, 60, 90, and 120 min, the TEER was measured. Subsequently, 0.5 mL of the samples was taken from the basolateral chamber, acidified with ascorbic acid solution to adjust the pH to 2.5 and stored in −80 °C until analyses. The fresh buffer (0.5 mL) was refilled in the basolateral chamber. The samples were analyzed by HPLC-ESI-MS^n using a published method with minor modifications.[29] An Agilent Zorbax SB C18 column (4.6 mm × 250 mm) was used for compound separation. The binary mobile phase consisted of 0.04% acetic acid/water (A) and acetonitrile (B). A 22 min gradient was as follows: 0−20 min, 10−30% B linear; 20−22 min, 30−10% B linear; followed by 2 min of re-equilibration of the column before the next run. The injection volume was 20 μL with a flow rate at 1 mL/min. Electrospray ionization in negative mode was performed using a nebulizer at 65 psi, drying gas at 11 L/min, drying temperature of 350

°C, and capillary at 4000 V. The MRM was used to monitor the transition of deprotonated EGCG m/z 457 $[M - H]^-$ to the product ion m/z 169. EGCG was used as an external standard. Quantification was conducted using QuantAnalysis (version 2.0, Bruker Daltonics Inc., Billerica, MA, USA). The apparent permeability coefficient (P_{app}) of EGCG was calculated using the equation

$$P_{app} = (dQ/dt) \times (1/AC_0)$$

where dQ/dt is the permeability rate (μg/s), C_0 is the initial concentration in the apical chamber (μg/mL), and A is the surface area of the filter (cm^2), which was 4.67 cm^2 in this study.

Statistical Analyses. Data were expressed as the mean ± standard deviation. Student's t test was used to compare mean values between two groups using JMP software (version 8.0, SAS Institute Inc., Cary, NC, USA). A difference with $p \leq 0.05$ was considered significant.

RESULTS

Synthesis and Characterization of O−D Conjugates. Natural ovalbumin showed a single band (45 kDa), whereas dextran did not show any bands on electrophoresis gel (Figure 1A). The ovalbumin/dextran physical mixture showed the same band as the ovalbumin sample, indicating that no reaction took place between ovalbumin and dextran. After the ovalbumin and dextran mixture was incubated at 60 °C under a relative humidity of 79% for 2 days, a new smear band (80−230 kDa) appeared, and the ovalbumin single band became smaller. In Figure 1B, the ovalbumin and ovalbumin/dextran physical mixture showed a single band in carbohydrate stained gel. This was because ovalbumin itself is a glycoprotein. No band appeared on dextran samples because dextran could not enter the gel. However, O−D conjugate samples showed a smear band and the ovalbumin band was weaker, which further confirmed that dextran was covalently conjugated with ovalbumin. Gel analysis using UN-SCAN-IT software showed that about 27% of ovalbumin reacted with dextran to form conjugates.

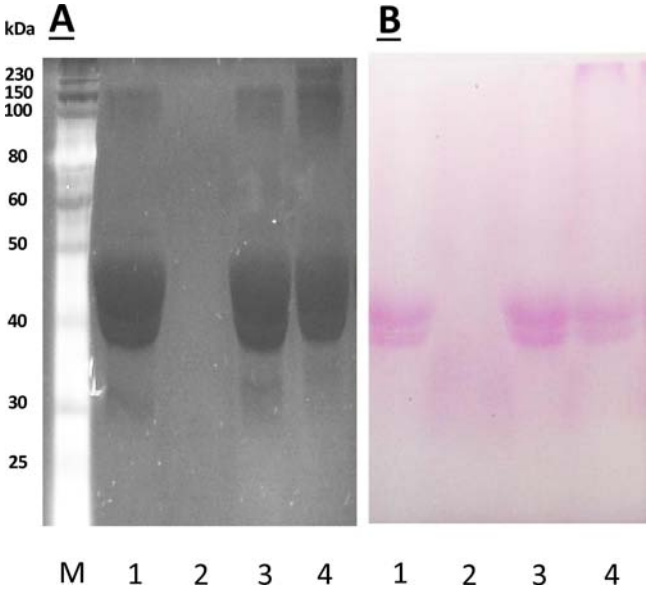

Figure 1. SDS-PAGE analysis of ovalbumin, dextran, ovalbumin/dextran physical mixture, and O−D conjugates: (A) protein stain; (B) carbohydrate stain. Lanes: M, molecular weight marker; 1, 2, 3, and 4, ovalbumin, dextran, ovalbumin/dextran physical mixture, and O−D conjugates, respectively. The amount of ovalbumin in each lane was 22 μg. The amount of dextran was 22 μg.

Particle Size, Morphology, EGCG Loading Efficiency, and Loading Capacity. After nanoparticles were resuspended in water, EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles showed average particle sizes of 285 and 339 nm, respectively (Figure 2A1,A2). Both dry EGCG O−D conjugate nanoparticles and cross-linked nanoparticles showed spherical morphology, visualized by SEM (Figure 2B1,B2).The sizes measured by Zetatrac were larger than those measured by SEM because dry particles were used in the SEM assessment.[13] The loading efficiencies of EGCG in EGCG O−D conjugate nanoparticles and cross-linked nanoparticles were 23.4 and 30.0%, respectively (Table 1). The loading capacities of EGCG in the nanoparticles were 19.6 and 20.9%, respectively. No significant differences were observed in either loading efficiency or loading capacity between EGCG O−D conjugate nanoparticles and cross-linked nanoparticles.

Nanoparticle Characterization under Different pH Conditions. EGCG O−D conjugate nanoparticles showed a particle size of 210 nm in aqueous suspension at pH 2.5, and size remained at 323 and 308 nm when the pH was adjusted to 3.0 and 4.0, respectively (Figure 3A). Particle size increased to 634 nm when the pH of EGCG O−D conjugate nanoparticle suspension was 5.0 and then decreased to between 168 and 211 nm in the pH range from 6.0 to 7.5. Cross-linked EGCG O−D conjugate nanoparticles showed particle sizes of 173, 336, and 347 nm at pH 2.5, 3.0, and 4.0, respectively. When the pH of the nanoparticle suspension was adjusted to 5.0, cross-linked EGCG O−D conjugate nanoparticles had a size of 325 nm, and particle sizes remained between 244 and 340 nm in a pH range of 6.0−7.5.

EGCG O−D conjugate nanoparticles and cross-linked nanoparticles had comparable zeta-potentials in a pH range from 2.5 to 7.5 (Figure 3B). Both EGCG O−D conjugate nanoparticles and cross-linked nanoparticles showed a zeta-potential of around 10 mV at pH 2.5 and 3.0. Decreased zeta-potentials were observed in EGCG O−D conjugate nanoparticles (between 6.71 and −1.37 mV) and cross-linked nanoparticles (between 1.45 and −6.07 mV) in a pH range of 4.0−6.0. This was because such a pH range was close to the isoelectric point of ovalbumin (around 4.5−4.8). When the pH was above 7, both of the nanoparticles had a zeta-potential around −10 mV.

Stability of Nanoparticles in Simulated Digestive Fluids. The initial particle sizes of EGCG O−D conjugate nanoparticles and cross-linked nanoparticles resuspended in SGF were 261 and 380 nm, respectively (Figure 4A). Incubating these two types of nanoparticles in SGF at 37 °C for 2 h did not cause a significant change in particle size. The particle sizes of EGCG O−D conjugate nanoparticles were 183, 349, 294, and 299 nm at 0.5, 1, 1.5, and 2 h, respectively. Similarly, cross-linked EGCG O−D conjugate nanoparticles showed average particles sizes of 478, 294, 527, and 439 nm after 0.5, 1, 1.5, and 2 h of incubation, respectively.

Both EGCG O−D conjugate nanoparticles and cross-linked nanoparticles appeared stable in the SIF at 37 °C for 2 h (Figure 4B). After EGCG O−D conjugate nanoparticles and cross-linked nanoparticles were resuspended in SIF, particle sizes were 232 and 206 nm, respectively. After 0.5 h of incubation, the particle sizes of these two nanoparticles were 217 and 280 nm, and the size remained at 291 and 265 nm for 2 h.

EGCG Release from Nanoparticles in Simulated Digestive Fluids. After incubation of the nanoparticles in

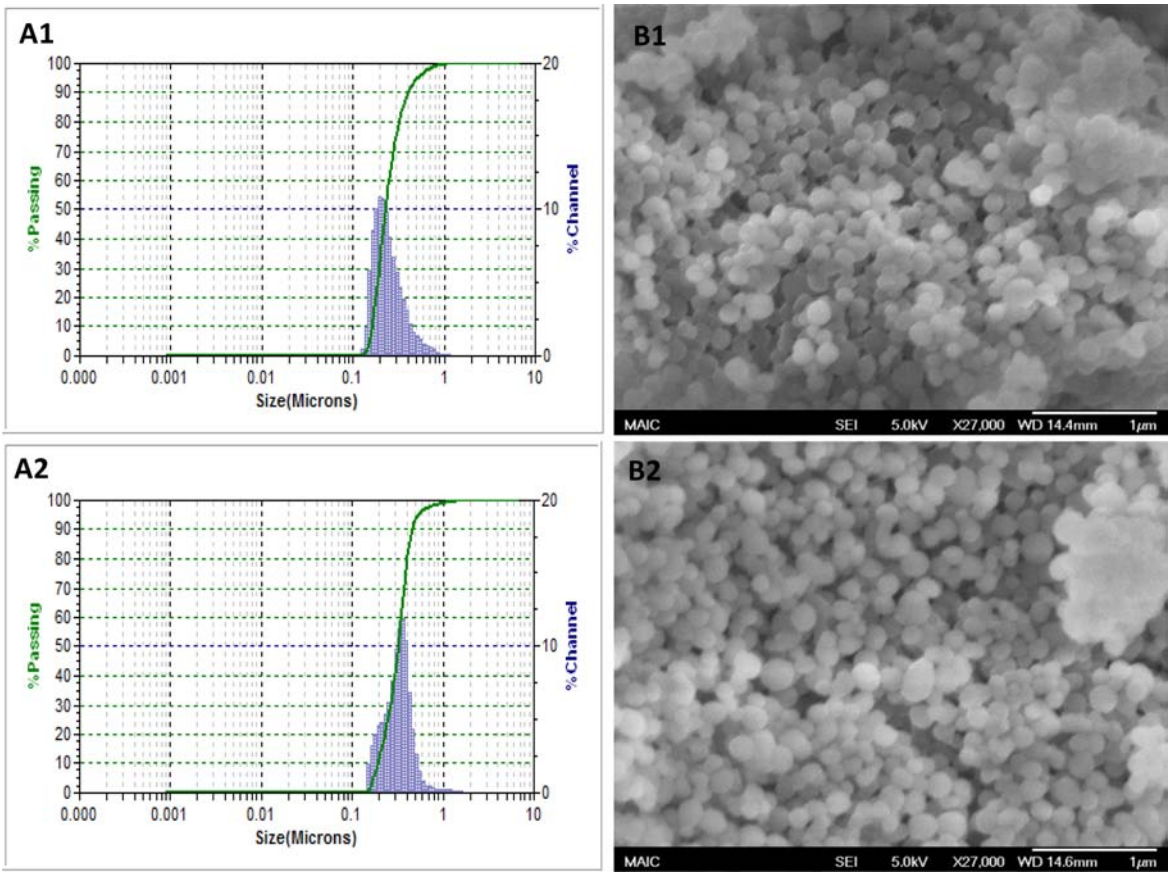

Figure 2. Particle size of (A1) EGCG O−D conjugate nanoparticles and (A2) cross-linked EGCG O−D conjugate nanoparticles measured in aqueous suspension and morphology of (B1) EGCG O−D conjugate nanoparticles and (B2) cross-linked EGCG O−D conjugate nanoparticles measured by scanning electron microscopy (SEM), respectively.

Table 1. Loading Efficiency and Loading Capacity of EGCG in EGCG O−D Conjugate Nanoparticles and Cross-Linked EGCG O−D Conjugate Nanoparticles[a]

nanoparticles	loading efficiency (%)	loading capacity (w/w %)
EGCG O−D conjugate	23.4 ± 2.9	19.6 ± 3.2
cross-linked EGCG O−D conjugate	30.0 ± 4.9	20.9 ± 3.8

[a]Data are the mean ± standard deviation of four replicates. No significant differences are observed between samples using Student's t test at $p \leq 0.05$.

SGF for 0.5 h, 12.3 and 8.3% of EGCG was released from EGCG O−D conjugate nanoparticles and cross-linked nanoparticles, respectively (Figure 5A). Introducing pepsin into the SGF significantly increased release of EGCG to 17.2 and 14.9%, respectively. Similarly, 27.1 and 21.9% of EGCG was released from EGCG O−D conjugate nanoparticles and cross-linked nanoparticles in SIF at 2 h, respectively (Figure 5B). Adding pancreatin in SIF significantly increased EGCG release to 37.9 and 32.5% of EGCG, respectively. Cross-linking of ovalbumin in the nanoparticles retarded the EGCG release in SIF with or without pancreatin.

EGCG Transport on Caco-2 Monolayers. Cross-linking using glutaraldehyde did not show significant advantages compared with non-cross-linked ones, except for a slight reduction of accumulated release in simulated intestinal fluids. Such minor benefit did not warrant the cross-linking step using toxic glutaraldehyde. Therefore, EGCG O−D conjugate nanoparticles were used on a permeability study. The TEER percentage of Caco-2 monolayers treated by HBSS buffer (blank) dropped to 100.6, 95.6, 94.1, and 89.9% of initial value at 30, 60, 90, and 120 min, respectively (Figure 6A). TEER percentages of Caco-2 monolayers treated by EGCG were 98.1, 95.1, 91.7, and 85.0% of the initial value at different incubation periods. EGCG O−D conjugate nanoparticles caused theTEER to decrease to 95.2, 90.9, 89.3, and 79.8% of the initial value at 30, 60, 90, and 120 min, respectively. However, there were no significant differences of TEER percentage among Caco-2 monolayers treated by the nanoparticles, EGCG, or buffer.

The apparent permeability coefficient (P_{app}) of EGCG from the apical to the basolateral side on Caco-2 monolayers was investigated after incubation of EGCG solution or EGCG O−D conjugate nanoparticles with Caco-2 monolayers for up to 120 min (Figure 6B). The P_{app} of EGCG in EGCG solution was between 0.28 and 0.42 × 10^{-6} cm/s during the incubation period. However, the P_{app} of EGCG in the nanoparticles was between 0.52 and 0.78 × 10^{-6} cm/s, and significantly higher than those of EGCG solution.

DISCUSSION

The Maillard reaction forms covalent bonds between carbonyl groups and amino groups.[26] The O−D conjugates were generated by controlling the Maillard reaction at an early stage, the Amadori rearrangements.[27,28,30]

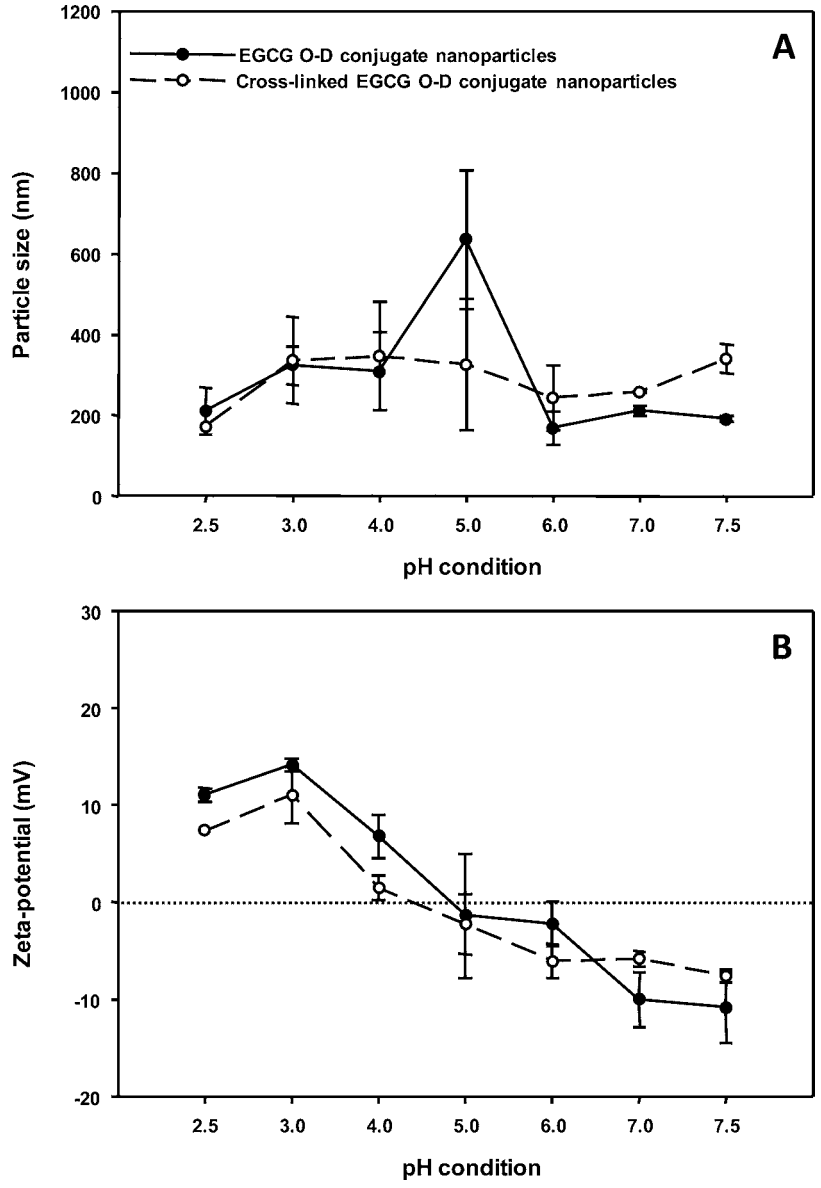

Figure 3. (A) Particle size and (B) zeta-potential of EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles in the pH range from 2.5 to 7.5.

After the O−D conjugates had been mixed with EGCG and the pH of the solution had been adjusted to 5.2, heating the mixture at 80 °C for 60 min caused the formation of a white milky suspension. The heating step induced the gelation of ovalbumin, which led to the heat-induced unfolding of ovalbumin.[31] The protein−protein interactions (hydrogen bonding, electrostatic and hydrophobic interactions, and disulfide−sulfhydryl interchange) and protein−EGCG interactions (hydrogen bonding and hydrophobic interactions) caused the self-assembly of EGCG and O−D conjugates. This resulted in encapsulation of EGCG in the nanoparticles.[13,15,31] Conjugation of ovalbumin with dextran increased the hydrophilic property of O−D conjugates, which helped to stabilize the nanoparticles in aqueous suspension. Glutaraldehyde was added to the nanoparticle suspension to cross-link the ovalbumin proteins, which further stabilized the structure of EGCG O−D conjugate nanoparticles. The loading efficiency and the loading capacity of EGCG in EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles were not affected by additional cross-linking because glutaraldehyde was used after the heating step (Table 1). The formation of EGCG O−D conjugate nanoparticles is illustrated in Figure 7. We hypothesized that the core of the nanoparticles was formed by the hydrophobic peptides of ovalbumin and that the hydrophilic dextran was on the surface of the nanoparticles as the shell. Our data showed that the heating process degraded about 2.4% EGCG. Therefore, the degradation of EGCG was not a concern.

The pH in the human gastrointestinal tract varies drastically in different segments, such as pH 6.5−7.0 in the mouth, 1.5 (fast state)−5.0 (fed state) in the stomach, 5.0−7.0 in the small intestine, and 7.0−7.4 in the large intestine.[10,11] The size and surface charge of protein-based nanoparticles depend on pH conditions. Weakened repulsion among the nanoparticles caused particle precipitation when the pH was around the isoelectric point of the selected proteins.[16] Therefore, it is important to understand the change of particle size and zeta-potential under different pH conditions. In the present study,

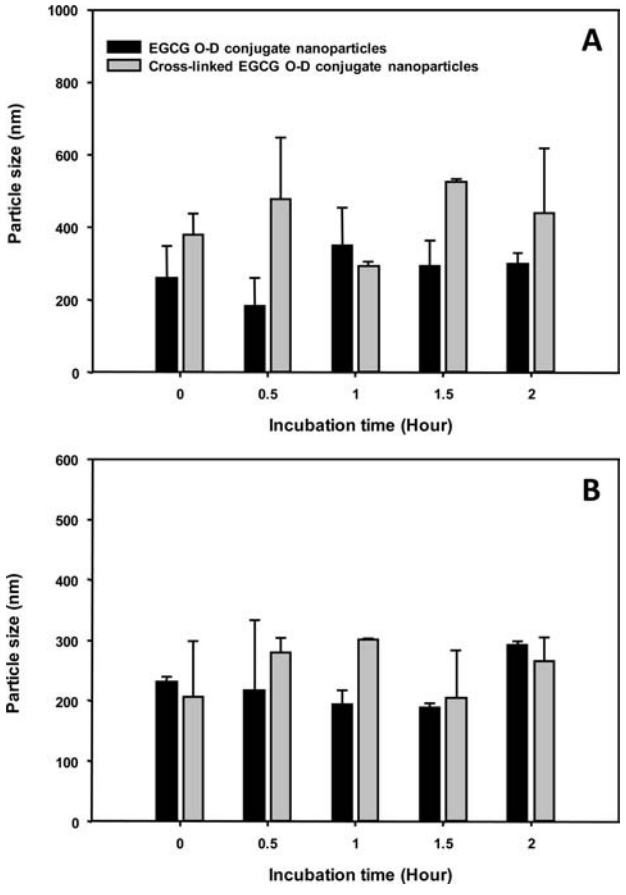

Figure 4. Particle size of EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles in (A) simulated gastric fluid (SGF, pH 4.0) and (B) simulated intestinal fluid (SIF, pH 6.0) at 37 °C for 0, 0.5, 1, 1.5, and 2 h.

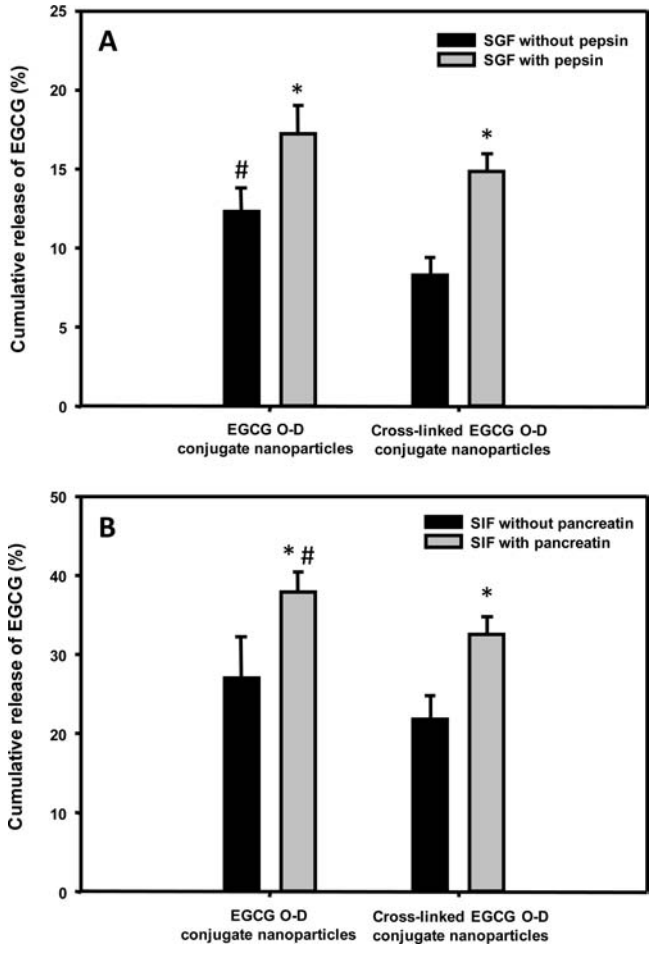

Figure 5. Cumulative release of EGCG from EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles in (A) simulated gastric fluid (SGF, pH 4.0) without or with pepsin for 0.5 h and (B) simulated intestinal fluid (SIF, pH 6.0) without or with pancreatin for 2 h at 37 °C. ∗ indicates significant differences between simulated fluid without enzyme and fluid with enzyme. # indicates significant differences between EGCG O−D conjugate nanoparticles and cross-linked nanoparticles.

both EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles remained nanosized in a pH range from 2.5 to 7.5 (Figure 3). Dextran has been reported to enhance colloidal stability.[23,32,33] Thus, hydrophilic dextran on the surface of the nanoparticles may retard the aggregation of ovalbumin proteins. The zeta-potential of nanoparticles is primarily determined by protein, and zeta-potential varies according to pH conditions. Both EGCG O−D conjugate and cross-linked nanoparticles showed positive zeta-potentials in a pH range from 2.5 to 3.0, whereas negative charges were observed when the pH was adjusted above 7.0. Both types of nanoparticles showed weakened zeta-potentials (−6.07 to 6.76 mV) at pH 4.0−6.0. Mucus layers in the small intestine possess negative charges and serve as a barrier between drugs and intestinal epithelia.[34] Thus, nanoparticles with strong negative or positive charges may be repulsed or adsorbed by mucus layers to hinder contact with epithelial cells, whereas weakly charged nanoparticles may readily penetrate the mucus layers.[34,35] EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles had weak zeta-potentials at pH 5.0−6.0, which may enhance the penetration of nanoparticles through the mucus layers to reach epithelial cells in the upper portion of the small intestine.

It takes about 0.5−2 and 2−4 h for ingested food to pass through the stomach and small intestine, respectively.[10,11] Thus, the stability of nanoparticles in the stomach and small intestine is critical. The majority of ingested nanoparticles should maintain nanosize to enhance the absorption of loaded drugs. In SGF (pH 4.0, fed state) for 2 h, EGCG O−D conjugate nanoparticles showed an average particle size between 183 and 349 nm, whereas the sizes of cross-linked EGCG O−D conjugate nanoparticles were between 294 and 527 nm. More importantly, both types of nanoparticles showed particle sizes of below 300 nm in SIF (pH 6.0, upper portion of the small intestine) for up to 2 h. This was explained by the capacity of dextran to stabilize nanoparticles in the gastrointestinal tract with high salt concentration and pH conditions.[33] Nanoparticles with better stability in the gastrointestinal tract may increase permeation of EGCG in the small intestine.

Release of bioactive compounds from nanoparticles in the gastrointestinal tract is attributed to the diffusion of bioactive compounds in gastrointestinal fluid. More importantly, degradation of nanoparticles by digestive enzymes in the gastrointestinal tract may cause the burst release of bioactive compounds.[19,36] For example, pepsin in the stomach and trypsin, chymotrypsin, elastase, and carboxypeptidases A and B in the small intestine can hydrolyze protein to amino acids, whereas α-amylase can hydrolyze 1,4-α-D-glucosidic linkages in

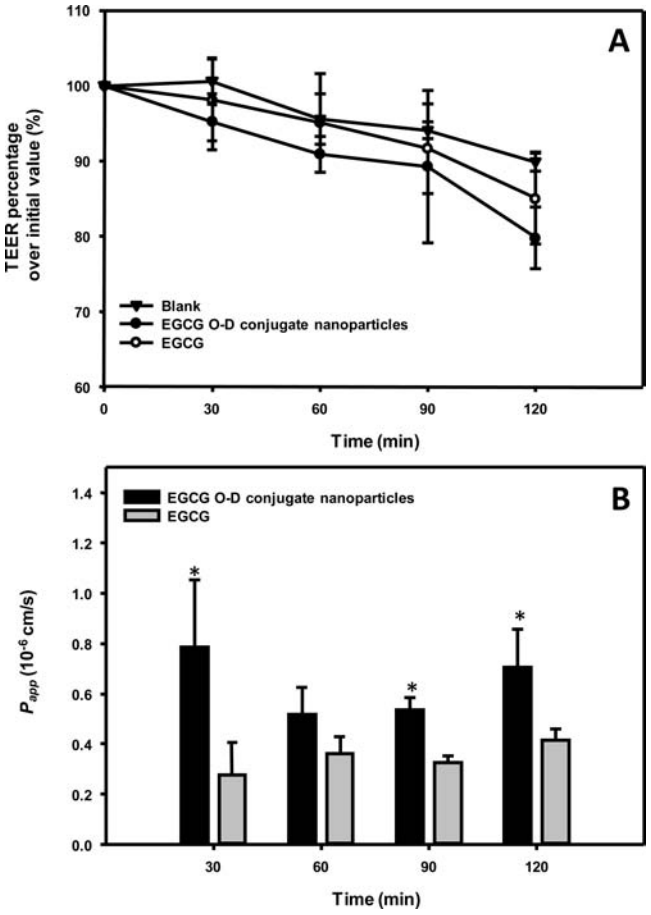

Figure 6. (A) Transepithelial electric resistance (TEER) and (B) apparent permeability coefficient (P_{app}) of EGCG in solution and EGCG O−D conjugate nanoparticles at 37 °C for 30, 60, 90, and 120 min. ∗ indicates significant differences between nanoparticles and solutions at $p \leq 0.05$.

polysaccharides. Dextran consists of the straight chains with α-1,6 glycosidic linkages between glucoses and branches with α-1,3 linkage. This structure makes dextran resistant to hydrolysis by amylase in the gastrointestinal tract.[25] In the present study, the release of EGCG from both types of nanoparticles in simulated fluids with digestive enzymes was higher than that without digestive enzymes. This suggests that ovalbumin was hydrolyzed by proteinases in both SGF and SIF. It should be noted that EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles showed similar EGCG release percentages in the simulated fluid with digestive enzymes. This may be explained by dextran on the surface of the nanoparticles, which protected the proteins from digestion by hindering contact between ovalbumin and proteinase. Also, ovalbumin was reported to be resistant to pepsin digestion in the stomach at fed state, and the conformational change of ovalbumin after thermal process provided resistance against trypsin, chymotrypsin, and elastase in the small intestine.[20,21,37] Furthermore, cross-linking ovalbumin in nanoparticles decreased EGCG release in simulated fluids with or without digestive enzymes, which suggested that protein cross-linking further improved the stability of nanoparticles in the presence of proteinases.

Caco-2 cell monolayers have been widely used to estimate the permeability of phenolic compounds in vitro.[38,39] Monolayers were formed after the TEER value of Caco-2 cells was between 150 and 1600 Ω × cm^2.[40] The TEER value of Caco-2 monolayers in the present study was 500−600 Ω × cm^2. A significant decrease of TEER indicated that the tight junctions of the monolayers were disrupted or monolayer integrity was compromised. Nanoparticles with a size <20 nm have the capacity to reversibly open tight junctions among cells and facilitate the permeation of loaded drugs via the paracellular pathway.[10] In this study, TEER values of Caco-2 monolayers were similar among the blank, EGCG solution, and EGCG O−D conjugate nanoparticles. This suggested that the concentration of EGCG had little adverse effect on the integrity of the monolayer, and nanoparticles did not open tight junctions of the monolayers to facilitate the permeation of EGCG by the paracellular pathway.

The main mechanism for nanoparticles to enhance the permeability of bioactive compounds was the cellular uptake of the nanoparticles via endocytosis, including clathrin- and/or caveolae-mediated endocytosis.[10,11,41] It has been proposed that clathrin-mediated endocytosis allowed nanoparticles with an average size below 300 nm to penetrate the cell membrane, whereas nanoparticles with a size below 500 nm could be internalized into cells by caveolae-mediated endocytosis.[42] Upon internalization, nanoparticles can either be delivered into endo/lysosome for release of bioactive compounds by

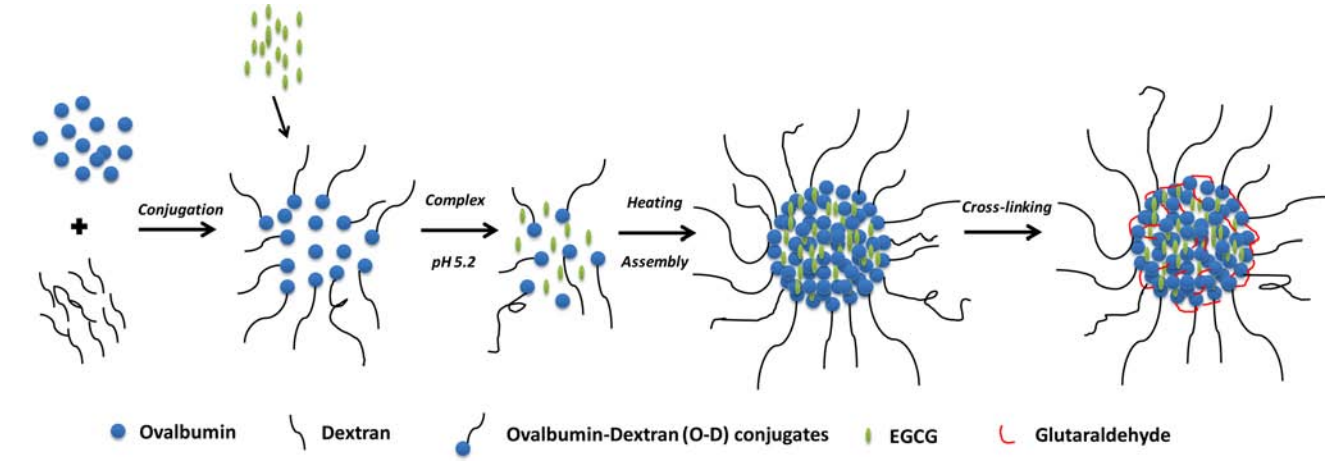

Figure 7. Hypothetical illustration of formation of EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles.

degradation or escape the endo/lysosome to arrive at the basolateral side by exocytosis.[10,11] In the present study, the P_{app} of EGCG in EGCG solution was (0.28−0.42) × 10^{-6} cm/s, which was in accordance with previous studies.[29,43] EGCG O−D conjugate nanoparticles significantly increased the P_{app} of EGCG to (0.54−0.78) × 10^{-6} cm/s. We hypothesized that the P_{app} increase of EGCG using EGCG O−D conjugate nanoparticles was mainly attributed to the cellular uptake of nanoparticles by Caco-2 cells.

In conclusion, ovalbumin and dextran were conjugated using the Maillard reaction. EGCG O−D conjugate nanoparticles and cross-linked EGCG O−D conjugate nanoparticles were formed using a heat-induced self-assembly. These particles showed a spherical morphology and had sizes of 285 and 339 nm in aqueous suspension. The loading efficiencies of EGCG in these conjugate nanoparticles were 23.4 and 30.0%, whereas the loading capacities were 19.6 and 20.9%, respectively. EGCG O−D conjugate nanoparticles and cross-linked nanoparticles remained nanosized in a pH range from 2.5 to 7.5, and the size remained stable in SGF and SIF. EGCG in EGCG O−D conjugate nanoparticles showed higher apparent permeability coefficient (P_{app}) on Caco-2 monolayers compared to EGCG solution.

oxidative stress-induced cell death *in vitro* by using RGC-5 cells, a transformed retinal ganglion cell line. We also report neuroprotective properties *in vivo* against retinal damage following optic nerve crush (ONC) in mice.

MATERIALS AND METHODS

Chemicals. First grade solvents were used for extraction fractionation, and column chromatography. Kiesel gel 60 (70−230 mesh, Art, 7734 Merck) was used as the column packing material. Kiesel 60 F_{254} (precoated plate, Art. 5559, Merck) was used for thin layer chromatography (TLC). Iodine vapor and 10% H_2SO_4 were used for TLC detection. Hoechst 33342 and propidium iodide (PI) were from Molecular Probes (Eugene, OR). Antipoly (ADP-ribose) polymerase (PARP) and anticleaved caspase-3 were purchased from Cell Signaling Technology (Beverly, MA). All other chemicals and reagents were purchased from Sigma-Aldrich (St Louis, MO).

Animals. All animal studies were carried out in a pathogen-free barrier zone at the KIST Gangneung Institute and were done in accordance with the procedure outlined in the Association for Research in Vision and Ophthalmology (ARVO) Statement for the Use of Animals in Ophthalmic and Vision Research. Procedures used in this study were approved by the Animal Care and Use Committee of KIST.

In the present study, male adult Sprague−Dawley rats weighing between 250 and 300 g (8 weeks of age) and male ICR mice weighing between 30 and 35 g (8 weeks of age) were used for the protective effects on NMDA and ONC induced retinal damage, and were acclimated for one week, caged in groups of five for mice and two for rat, and were fed with a diet of animal chow and water *ad lib.* They were housed at 23 ± 0.5 °C and 10% humidity with a 12 h light−dark cycle.

Plant Material and Isolation of Compounds. The *C. denticulatum* samples were collected in the vicinity of Gangneung, Korea, and the voucher specimen (Voucher No. D-043) was deposited at the Herbarium of Functional Food Center, KIST Gangneung Institute, Korea. The dried aerial section of deposited sample (10.0 kg) was extracted three times with hot 94% EtOH (57.0 L) for 4 h. This residue was evaporated *in vacuo* to yield the total extract (1.4 kg).

Dried plants (1.0 kg) were extracted three times by sonication with 94% ethanol for 4 h at room temperature. The residue was evaporated to yield ethanol extract of *C. denticulatum* (EECD, 70 g) under reduced pressure. High-performance liquid chromatography (HPLC)−ultraviolet chromatograms of EECD were obtained as follows. The HPLC system was equipped with an Agilent (Palo Alto, CA) series 1200 liquid chromatograph and a Shiseido MG II C_{18} column packed with 5 μm particles (4.6 mm × 250 mm, film thickness 4 μm) (Shiseido Inc., Japan). The temperature of the column oven was 35 °C, and the injection volume was 10 μL. Separations and simultaneous determination were performed using a mixture of acetonitrile and 0.3% formic acid in water (18:82) as a mobile phase. The flow rate was 1.0 mL/min, and UV detection was performed at 330 nm.

EECD (2.0 g) was chromatographed on a Sephadex LH-20 column (2.5 cm × 65 cm, 100% methanol) to yield fractions 1−9. Chicoric acid was isolated by semipreparative HPLC using the YMC Hydrosphere C_{18} column (20 mm × 250 mm, film thickness 5 μm) with acetonitrile containing 0.1% trifluoroacetic acid in an aqueous gradient (20−30% acetonitrile for 40 min, 10 mL/min) from fraction 4. 3,5-Dicaffeoylquinic acid (3,5-DCQA) was purified using semi-preparative HPLC (acetonitrile containing 0.1% trifluoroacetic acid in aqueous isocratic 25% acetonitrile for 40 min at a flow rate of 2 mL/min, using the YMC Hydrosphere C_{18} column [10 mm × 250 mm, film thickness 5 μm]) from fraction 5. Chemical structures were confirmed by ^1H and ^{13}C nuclear magnetic resonance spectroscopy and compared with the literature.[22−24]

The contents of chicoric acid and 3,5-DCQA in 1 g of EECD were found to be 12.44 mg/g ± 0.25 and 3.80 mg/g ± 0.10, respectively.

Culture of RGC-5 Cells and Cell Viability. RGC-5 cells were used in this study, which have been previously shown to express ganglion cell markers and exhibit ganglion cell-like behavior in culture.[25] In previous report, RGC-5 cells have been proven to be mice origin.[26]

There were 5.0 × 10^3 cells seeded in 96 well plates for 24 h for incubation, and they were then exposed to DMEM containing 1% FBS plus samples or plus vehicle. After 1 h pretreatment with samples, 1-buthionine-(*S*,*R*)-sulfoximine (BSO) (0.5 mM) plus glutamate (10 mM) (glutamate/BSO) was added to cultures. To test cell viability, MTT was added to the cells in 96-well plates at a final concentration of 0.5 mg/mL for 1 h at 37 °C. Optical density of the solubilized formazan product in each well was measured using a spectrophotometer (BioTek Instruments, VT) with a 570 nm test wavelength and a 690 nm reference wavelength.[27]

Microscopic Analysis of Cell Viability by PI and Hoechst 33342 Double Staining. The cells were stained with 8 μM of Hoechst 33342 with or without 1.5 μM of PI for 30 min at 37 °C in order to determine apoptotic or necrotic cell death caused by glutamate/BSO.[13] After being washed twice with serum free media, the cells were imaged using a fluorescence microscope (Olympus, Tokyo, Japan).

Assessment of ROS. Intracellular ROS was quantified using the dye, dichlorodihydrofluorescein diacetate (DCFH-DA), as a radical probe.[28,29] The RGC-5 cells were seeded at a density of 5.0 × 10^3 cells per well into 96-well plates, and 24 h later, the cell-culture medium was replaced with DMEM containing 1% FBS. The cells were loaded with the radical probe DCFH-DA (10 μM) through incubation for 20 min at 37 °C. Then, the cell-culture medium was replaced to remove the extra probe. To generate the radical species, we added H_2O_2 at 1 mM (H_2O_2 radical), H_2O_2 at 1 mM plus 100 μM of iron(II) perchlorate hexahydrate ($^{\bullet}OH$) or KO_2 at 1 mM ($O_2^{\bullet-}$), to the radical probe loading-medium. Fluorescence was then measured after ROS-generating compounds had been present for various time-periods, using excitation/emission wavelengths of 485/535 nm (luminescence spectrometer LS50B, Perkin-Elmer Ltd., England).

Superoxide radicals were assessed using the dye dihydroethidium (DHE) according to previous methods.[30,31] Red fluorescence was detected using a laser scanning confocal microscope (model Leica TCS SP5; Leica, Germany). Excitation wavelength was set at 514 nm and emissions filters at 590 nm. Quantifying of images was analyzed with Leica Application Suite 2.02 software using four representative fields from each well, and images of four wells were sampled per group (n = 16 in each group).

Protein Extraction and Western Blot Analysis. After the pretreatment with different concentrations of EECD for 1 h in RGC-5 cells, the cells were treated with glutamate/BSO for 24 h. For Western blot analysis using retina in rat or mice, four animals (4 retinas) were used from three independent experiments. After cells were washed with cold D-PBS, the cells were scraped using a cell scraper and centrifuged at 14 000 × *g* for 10 min. The cell pellets were resuspended in cell lysis buffer (1 M Tris pH 7.4, 2 M NaCl, 1 M EDTA, 10% NP40, 1 × protease inhibitors, 1 mM PMSF) and then incubated on ice for 10 min. After centrifuging at 14 000 × *g* for 30 min at 4 °C, the supernatant was sonicated, and the total protein concentration was determined using a Bio-Rad Protein Assay kit (Bio-Rad Laboratories, Hercules, CA). A 10 μg sample of protein from the retina homogenates was loaded per lane on a 10% polyacrylamide gel and then transferred to a polyvinylidenedifluoride (PVDF) membrane (Hybond-P; Amersham Biosciences, GE Healthcare, U.K.).

Western blot analysis was performed with the primary antibodies including anti-PARP, anticleaved caspase-3 (1:1000, Cell Signaling Technology, Beverly, MA), and secondary antibodies (1:3000, Santa Cruz Biotechnology, CA). Immunoreactive bands were detected using the enhanced chemiluminescence reagents (Amersham Bioscience, GE Healthcare, U.K.) and were measured *via* densitometry using a LAS-4000 image reader and Multi Gauge 3.1 software (Fuji Photo Film, Japan)

Quantification of mRNA Using Real-Time RT-PCR. Total RNA was extracted from RGC-5 cells using the RNeasy minikit (Qiagen, Valencia, CA) according to the manufacturer's protocol. After quantification, total RNA (1 μg) was used to synthesize cDNA by

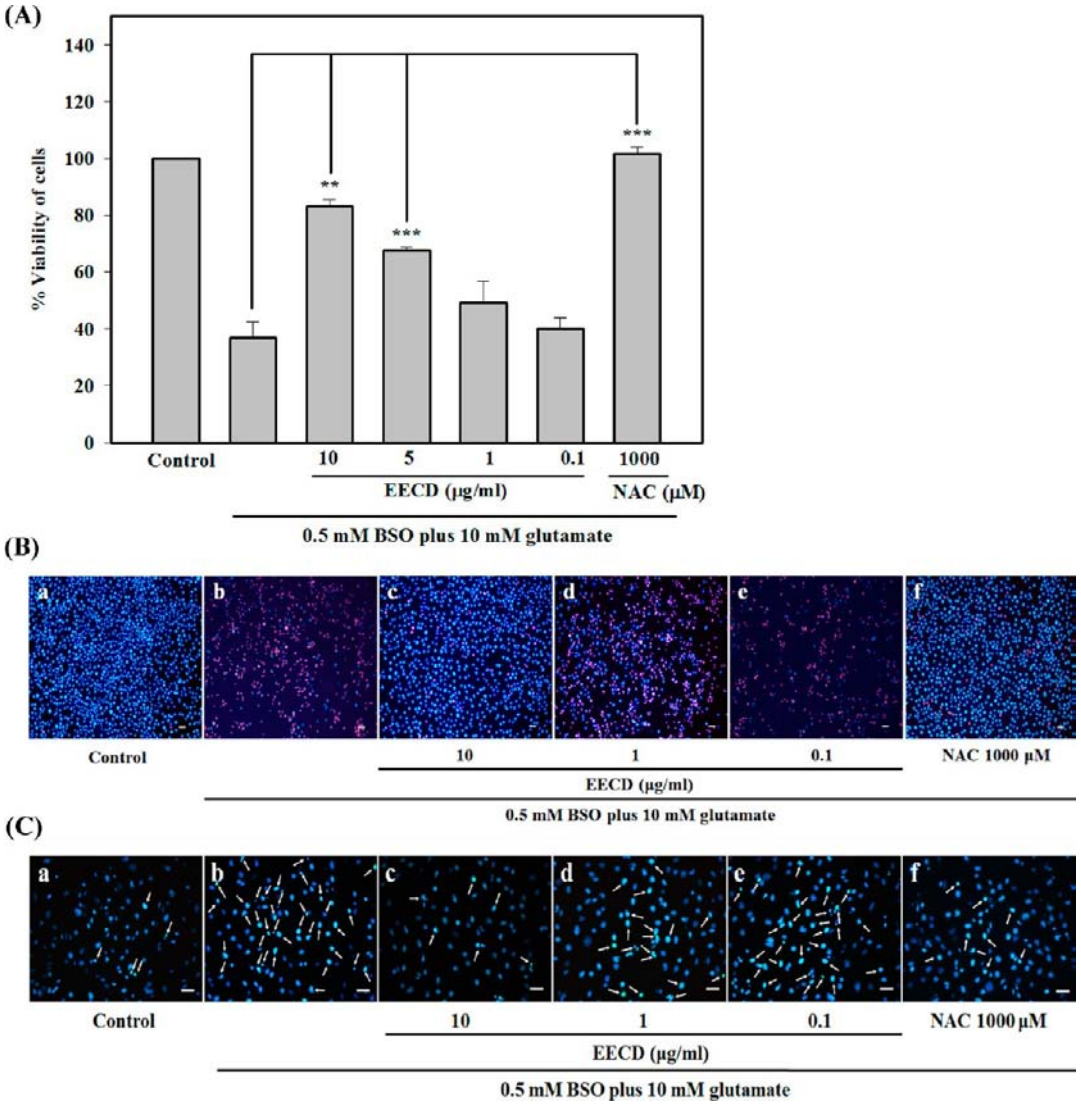

Figure 1. (A) Effect of EECD on the viability of RGC-5 cells exposed to 10 mM glutamate plus 0.5 mM BSO for 24 h as measured by the MTT assay. 1 mM *N*-acetyl-L-cysteine (NAC) was used as a positive control. The results are mean values with error bars indicating ± SEM where $n = 6$ independent experiment (** $p < 0.01$, *** $p < 0.001$). (B) Representative fluorescence microscopy of PI (red) and Hoechst 33342 (blue) staining. (a) Control RGC-5 cells in culture. (b) 10 mM glutamate plus 0.5 mM BSO treated RGC-5 cells in culture. reverse transcription with the Omniscript reverse transcription kit and the T7-$(dT)_{24}$ primer (Qiagen). Quantitative real-time RT-PCR was performed to evaluate mRNA expression for PARP and caspase-3 with the Light-Cycler Real-Time PCR System (Roche, Manheim, Germany). The primers for PARP were 5′-AGGCCGCCT-ACTCTATCCTC-3′ (sense) and 5′-GATTCACTG-CTGCCTTGAGA-3′ (antisense). The primers for caspase-3 were 5′-GAGGCTGACTTCCTGTATGCTT-3′ (sense) and 5′-AACCACGACCCGTCCTTT-3′ (antisense). The primers for GAPDH as control were 5′-AGGCAAAAGACACCGTCAAG-3′ (sense) and 5′-CACAAGAAGATGCGGCTGT-3′ (antisense). Analysis was based on the results of three independent experiments.

Lipid Peroxidation Assay. Lipid peroxidation was tested for the amount of formation for thiobarbituric acid reactive species (TBARS) as described in previous studies.[13,32] The rat brain was homogenized in ice-cold 0.9% saline, centrifuged at 1000 × *g* for 10 min at 4 °C, and the supernatant was used for the lipid peroxidation assays. The lipid peroxidation in rat homogenate was evaluated using the TBARS method as described previously.[33] Absorbance of the samples was measured at 532 nm, and the amount of TBARS was determined using a standard curve of the malondialdehyde (MDA) derivative 1,1,3,3-tetraethoxypropane (0.63−100 μM). Protein concentration was determined using a Bio-Rad protein assay kit (Bio-Rad, Richmond, CA) using bovine serum albumin as the standard.

NMDA-Induced Retinal Damage and Histological Analysis. Retinal damage caused by NMDA was determined according to previous methods.[14] Rats ($n = 7$) were put under anesthesia with a Zoletil (1.6 μg/g, Verbac Laboratories 06515, France) and Rompun (0.05 μL/g, Bayer) mixture, and retinal damage was induced using an injection (2 μL/eye) of NMDA (2.5 mM dissolved in 0.01 M PBS) to the left eye using a 30 gauge Hamilton syringe (final concentration 5 nmol/eye).[34] Seven days after the injection, the eyeballs were enucleated for histological analysis. Previous study has shown that 18 h after an NMDA injection into a rabbit retina, typical apoptotic

features in degenerative cells in the retinal ganglion cell layer (GCL) and the inner nuclear layer (INL) were noted by electron microscopy. TUNEL positive nuclei were detected in these layers as early as 4 h showing maximal numbers at 18 h.[35,36] For this reason, the animals were killed 18 h after the NMDA injection and fixed for the TUNEL assay, and 7 days after the NMDA injection they were fixed for histological analysis.

The enucleated eyes were fixed in 10% formalin for 24 h, embedded in paraffin, and sectioned through an equatorial plane at 4 μm thickness using a HM340E microtome (Walldof, Germany). Four sections (n = 4) were used for analysis.

Hematoxylin solution was added to the retina section (0.1% hematoxylin, 10% ammonium) for 8 min. The sections were then washed three times with distilled water. Bluing reagent (0.2% lithium carbonate solution) was added to the section for 1 min. The sections were quickly rinsed in 95% alcohol, and 1% Eosin Y solution was added to the sections for 1 min. Eosin Y was washed off with 95% alcohol three times, and the sections were coverslipped with a mounting medium and observed under a light-microscope (Olympus, Tokyo, Japan).

TUNEL Staining. To analyze TUNEL-positive cells, the sections were submitted to enzymatic digested with 20 μg/mL of proteinase K for 15 min, then washed with PBS and incubated with 3% hydrogen peroxide in PBS for 5 min at room temperature, and twice rinsed in PBS. They were then immersed, incubated with a stock solution of terminal deoxynucleotidyl transferase (TdT) reaction enzyme in a humidified chamber at 37 °C for 1 h, and then washed three times in PBS for 1 min. The sections were subsequently incubated with antidigoxygenin peroxidase conjugate and peroxidase substrate to detect signs of apoptosis, which appear brown.

The histological aspect of apoptosis was observed using a light microscope (Olympus, Tokyo, Japan).

Optic Nerve Crush (ONC) and Quantification of Retinal Ganglion Cells. Mice (n = 8) were put under anesthesia by

dx.doi.org/10.1021/jf4046232 | J. Agric. Food Chem. 2014, 62, 1310−1323

intraperitoneal injection of Zoletil (1.6 μg/g, Verbac Laboratories 06515, France) and Rompun (0.05 μL/g, Bayer) mixture, and retinal damage was induced using optic nerve crush.[37] The optic nerve of the left eye was exposed by opening the meninges of the optic nerve with the sharp tips of a forceps, followed by blunt dissection. ONC was crushed 2 mm behind the globe for 7 s with a cross-action calibrated forceps. The samples were injected intravitreally 1 h before ONC, and the animals were killed 7 days after the ONC and the eyeballs enucleated immediately after sacrifice. The eyeballs were fixed for retrograde label of RGCs.

RGC Labeling and Retinal Flat Mount Preparation. Mice were anesthetized by intraperitoneal administration of a mixture of Zoletil (1.6 μg/g, Verbac Laboratories 06515, France) and Rompun (0.05 μL/g, Bayer), and to the superior colliculi in mice was applied 5% solution of the neurotracer dye Fluorogold (Invitrogen, NY) by a piece of soaked gelfoam. Skull openings were then sealed with a petrolatum based antibiotic ointment. The overlying skin was sutured and antibiotic ointment applied externally.

Seven days after the application of Fluorogold, eyes were enucleated, and the retinas were detached at the ora serrata and cut with a trephine around the optic nerve head. Four radial relaxing incisions were made and the retinas prepared as flattened whole mounts on silane-coated microscope slides.[38]

Statistical Analysis. The data are expressed as a mean percentage of the control value plus standard error of the mean (SEM). Statistical comparisons were made using a one-way ANOVA followed by a Dunnett's test. Statistical analyses were conducted using GraphPad Prism (version 4.0) (GraphPad, San Diego, CA). $p < 0.05$ was considered significant.

RESULTS

Effect of EECD on the Apoptotic Cell Death Caused by an Insult of Glutamate/BSO. Figure 1 shows the protective effects of EECD against oxidative stress-induced RGC-5 cell death (Figure 1). When glutamate/BSO was added to RGC-5 cells for 24 h, cell viability was significantly decreased by 36.7%. However, this decrease in cell viability was significantly attenuated by EECD in a concentration-dependent manner (Figure 1A).

The protective effect of EECD caused by oxidative stress was confirmed by microscopic analysis using a Hoechst 33342/PI double staining method for DNA (Figure 1B).

Hoechst 33342 is a blue fluorescent dye that is permeable to live or fixed cells, while PI is a red membrane-impermeant dye and is, therefore, commonly used to identify dead cells.[13]

As shown in Figure 1B, there were few red-stained nuclei in cells under basal conditions. However, cells treated with glutamate/BSO showed numerous red-stained nuclei. Pretreatment with EECD attenuated red-stained nuclei and chromatin condensation in a concentration-dependent manner (Figure 1B,C).

To determine whether EECD's protective effects on oxidative stress-induced RGC-5 cell death were due to antiapoptotic activities, Western blot analysis was performed to evaluate the change in apoptotic protein levels for cleaved PARP and cleaved caspase-3 (Figure 2). Exposure to glutamate/BSO resulted in the up-regulation of protein levels for cleaved PARP and cleaved caspase-3; however, EECD significantly reduced this up-regulation in a concentration-dependent manner (Figure 2A). Moreover, EECD significantly reduced the mRNA expression of PARP and caspase-3 caused by glutamate/BSO in a concentration-dependent manner (Figure 2B).

Effect of EECD on the Intracellular Levels of ROS. Inhibitory effects of EECD on ROS production were determined by DCFH-DA as a ROS fluorescence probe. ROS was induced by different oxidative insults including H_2O_2, $O_2^{\bullet-}$, and $^{\bullet}OH$.

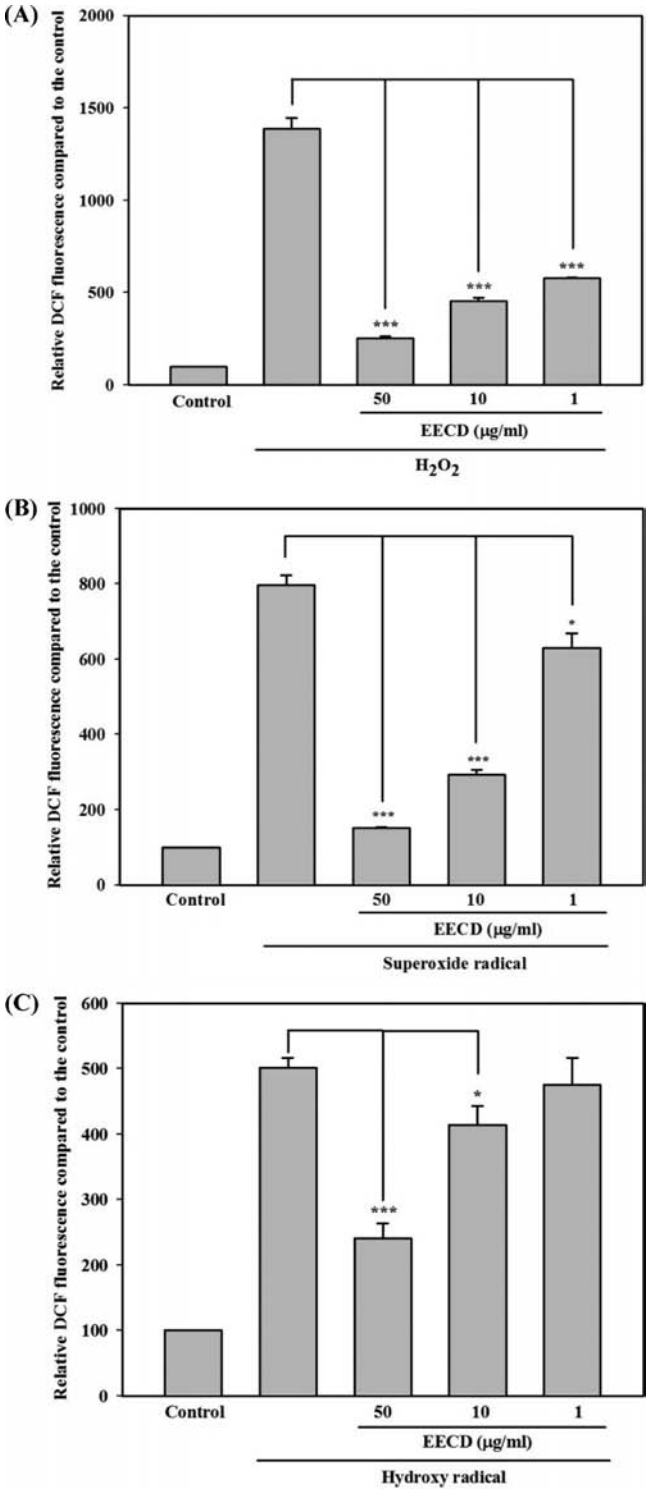

Figure 3. Radical scavenging capacities of EECD against the production of three radical species (H_2O_2, $O_2^{\bullet-}$, and $^{\bullet}OH$) in RGC-5. ROS production was stimulated with H_2O_2 at 1 mM, or with KO_2 at 1 mM, or with H_2O_2 at 1 mM plus ferrous perchlorate(II) at 100 μM. (A) H_2O_2-induced oxidation of DCFH in RGC-5, (B) $O_2^{\bullet-}$-induced oxidation of DCFH in RGC-5, and (C) $^{\bullet}OH$-induced oxidation of DCFH in RGC-5. Results are mean values with error bars indicating ± SEM where $n = 3$ (* $p < 0.05$, *** $p < 0.001$).

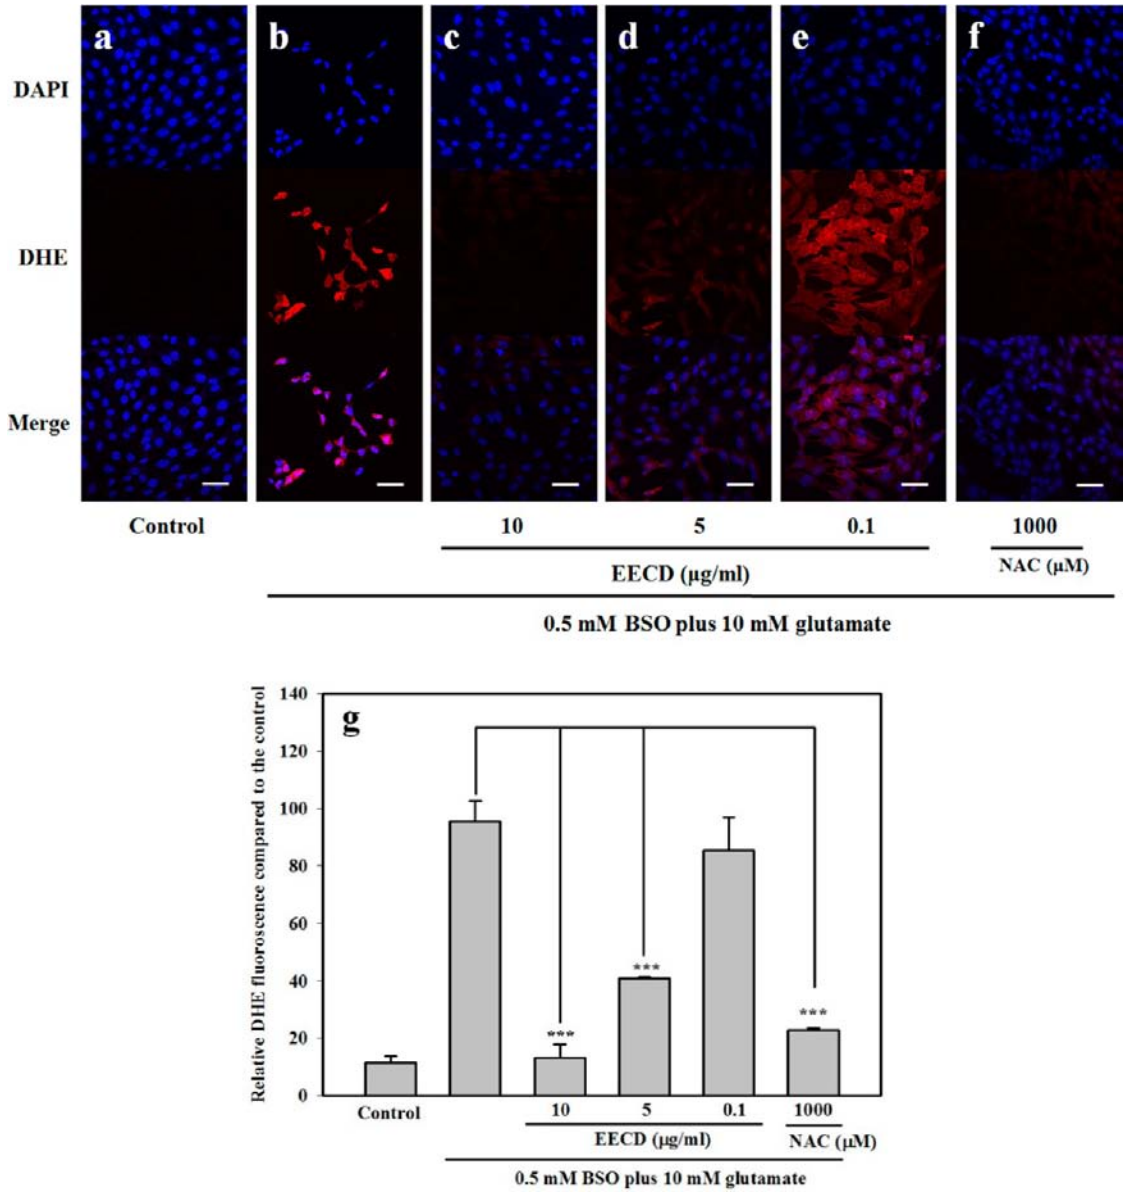

Figure 4. Effect of EECD on ROS levels in RGC-5 cells subjected to oxidative stress induced by 10 mM glutamate plus 0.5 mM BSO for 24 h. DHE assay was used to demonstrate the intensity of intracellular ROS generated by oxidative stress. Images were obtained by confocal microscopy (400×). DAPI was used to demonstrate live cells. (a) Control RGC-5 cells in culture. (b) 10 mM glutamate plus 0.5 mM BSO treated RGC-5 cells in culture. (c–e) Pretreatment of EECD (0.1–10 μg/mL concentration) with 10 mM glutamate plus 0.5 mM BSO. (f) Pretreatment of NAC (1 mM concentration) with 10 mM glutamate plus 0.5 mM BSO. (g) Quantification of DHE fluorescence was analyzed with Leica Application Suite 2.02 software (Leica, Germany) using four representative fields from each well, and images of four wells were sampled per group (n = 16 in each group). Scale bar = 50 μm. The results are mean values with error bars indicating ± SEM (*** $p < 0.001$).

ROS activity was increased more than 13 times when the RGC-5 cells were exposed to H_2O_2 at 1 mM, from the basal level of 100.63 ± 27.36 to 1343.13 ± 103.27 (Figure 3A). However, pretreatment with EECD markedly inhibited ROS production in a concentration-dependent manner (Figure 3A). Moreover, EECD also scavenged $O_2^{\bullet-}$ and $^{\bullet}OH$ radicals in a similar manner (Figure 3B,C).

To test the ability of EECD to inhibit the superoxide production caused by glutamate/BSO, DHE staining was used, and the results are shown in Figure 4. DHE fluorescence is blue in the cell cytoplasm, but is converted to red fluorescence by ROS production upon DNA intercalation. DAPI staining was used to verify the DHE staining of live cells because DAPI is able to penetrate live cell membranes and to bind double-stranded DNA in the nucleus, and to dye live cells (Figure 4).

When the cells were exposed to glutamate/BSO, the number of live cells decreased while red fluorescence increased by approximately 9-fold (relative DHE fluorescence 97.3 ± 8.2) compared to control. However, enhancement of this red fluorescence was clearly attenuated in a concentration-dependent manner by pretreatment of EECD, with 10 μg/mL showing the highest potency (DHE fluorescence 10.8 ± 5.2 relative to control) (Figure 4).

EECD Inhibition of Sodium Nitropruside (SNP)-Induced Lipid Peroxidation in Rat Forebrain Homogenates. Malondialdehyde (MDA) is the final product of lipid peroxidation and a marker for oxidative stress-induced injury.

dx.doi.org/10.1021/jf4046232 | J. Agric. Food Chem. 2014, 62, 1310–1323

Table 1. Effect of EECD on Inhibition of Lipid Peroxidation Induced by Sodium Nitroprusside (SNP) in Rat Forebrain Homogenates[a]

	lipid peroxidation		
sample	conc (μg mL)	inhibition (%)	IC_{50} (μg mL)
EECD	2.5	57.78 ± 16.41	1.72
EECD	1.25	42.93 ± 13.84	1.72
EECD	0.625	33.19 ± 10.59	1.72
EECD	0.3125	27.22 ± 11.20	1.72
EGCG	0.23	63.06 ± 7.48	0.12

EGCG	0.028 75	27.53 ± 12.67	0.12

[a]SNP at a concentration of 20 μM caused a submaximum stimulation of TBARS in a previous study; therefore, this SNP concentration was used to determine the inhibitory effects in the samples. Different concentrations of EECD were preincubated with brain homogenates at 37 °C for 5 min. SNP was then added at the concentrations indicated, and the homogenates were incubated for a further 10 min. Results are means values ± SEM of three independent experiments.

The TBARS method was used to assess the production of MDA in rat brains. As shown in Table 1, MDA levels were increased following SNP (20 μM) stimulation in rat forebrain homogenates as compared to the control group. However, pretreatment with EECD inhibited the production of MDA in a concentration-dependent manner, with an IC_{50} value of 1.72 μg/mL (Table 1). EGCG as a positive control inhibited the stimulation of TBARS induced by SNP, with an IC_{50} value of 0.12 μg/mL (Table 1).

Effect of EECD on NMDA-Induced Retinal Damage. To determine whether EECD had neuroprotective effects *in vivo*, the changes in ganglion cell numbers and IPL thickness caused by the intravitreal injection of NMDA into rat retinas were determined. After intravitreal injection of NMDA, significant thinning of the IPL was observed (compare Figure 5b to Figure 5a). However, this IPL thinning was attenuated by treatment with EECD (2 μg/mL, intravitreal injection) (Figure 5c,e).

The antiapoptotic properties of EECD against NMDA-induced damage to ganglion cells were tested using TUNEL staining (Figure 6). There were few TUNEL-positive cells in the normal control (Figure 6a,e). At 24 h after the intravitreal injection of NMDA, prominent TUNEL-positive cells were found in the GCL as shown in Figure 6b,e. After pretreatment with 2 μg/mL of EECD, the number of TUNEL-positive cells was decreased as shown in Figure 6c–e.

Effect of EECD on Optic Nerve Crush (ONC)-Induced Retinal Damage. The neuroprotective effect of EECD was tested following ONC in mice by injecting the fluorescent retrograde tracer Fluorogold into the superior colliculus.

RGC death was observed in mice after ONC by the loss of fluorescent Fluorogold-labeled RGCs (Figure 7b,e,h), as compared with the normal control (Figure 7a,d,g). However, the degeneration of RGCs caused by ONC was significantly attenuated by pretreatment with EECD (Figure 7c,f,i).

Major Compounds in EECD and Their Protective Effects on Oxidative Stress-Induced RGC-5 Cells and

Optic Nerve Crush (ONC)-Induced Retinal Damage. As shown in Figure 8, the HPLC profile of EECD was recorded at 330 nm. Matching the compounds isolated from EECD with HPLC data indicated that the major constituents of EECD were chicoric acid and 3,5-DCQA.

It has also reported from our laboratory that 3,5-DCQA isolated from *Gymnaster koraiensis* can protect RGCs *in vitro* and *in vivo*;[14] thus, we have focused on the effects of chicoric acid in this study.

Chicoric acid showed protective effects against glutamate/BSO-induced RGC-5 cell death in a concentration-dependent manner (Figure 9A). This was confirmed by the Western blot analysis, and chicoric acid significantly reduced this up-regulation of protein levels for cleaved PARP and cleaved caspase-3 in a concentration-dependent manner (Figure 9B). Moreover, chicoric acid significantly reduced the mRNA expression of PARP and caspase-3 caused by glutamate/BSO (Figure 9C).

From the ONC model, RGCs death caused by ONC was also significantly attenuated by pretreatment with 5 nmol/eye (Figure 9Dc,g,E) and 25 nmol/eye chicoric acid (Figure 9Cd,h), as compared with vehicle group (Figure 9Db,f,E), although the attenuation by 5 nmol/eye chicoric acid-treated group was not statistically significant (Figure 9E).

■ DISCUSSION

In this study, we presented *in vitro* and *in vivo* evidence that EECD and its isolated compounds protects against retinal degeneration.

Using quantitative analysis of cell death, our *in vitro* studies showed a concentration-dependent effect of EECD to protect against the retinal degeneration caused by glutamate/BSO-induced oxidative stress (Figure 1).

It has been shown that glutamate/BSO can induce apoptosis in RGC-5 cells and up-regulate cleaved caspase-3 and cleaved PARP proteins.[39] We confirmed these observations in our study and also found that pretreatment with EECD inhibited in a concentration-dependent manner this up-regulation of apoptotic proteins and mRNA level (Figure 2). This suggests that EECD protects against the retinal degeneration from antiapoptotic effects by inhibiting the activation of apoptotic proteins.

Retinal degeneration may occur by various mechanisms including neurotrophic factor deprivation, ischemia, glial cell activation, glutamate excitotoxicity, and abnormal immune response.[40]

These mechanisms can induce oxidative stress caused by imbalance the production of ROS and have been recognized as critical mediators in RGC death.[41]

Increased levels of ROS cause significant molecular damage within cells, which can lead to neuronal death by several mechanisms including protein modification and DNA damage.[42] In addition, accumulating evidence from experimental models indicates that oxidative stress, including oxidative damage in the trabecular meshwork and retina, is implicated in glaucoma.[43,44]

It is therefore proposed that antioxidants that regulate oxidative imbalance may be therapeutic strategies for retinal degeneration. Furthermore, natural antioxidants may be

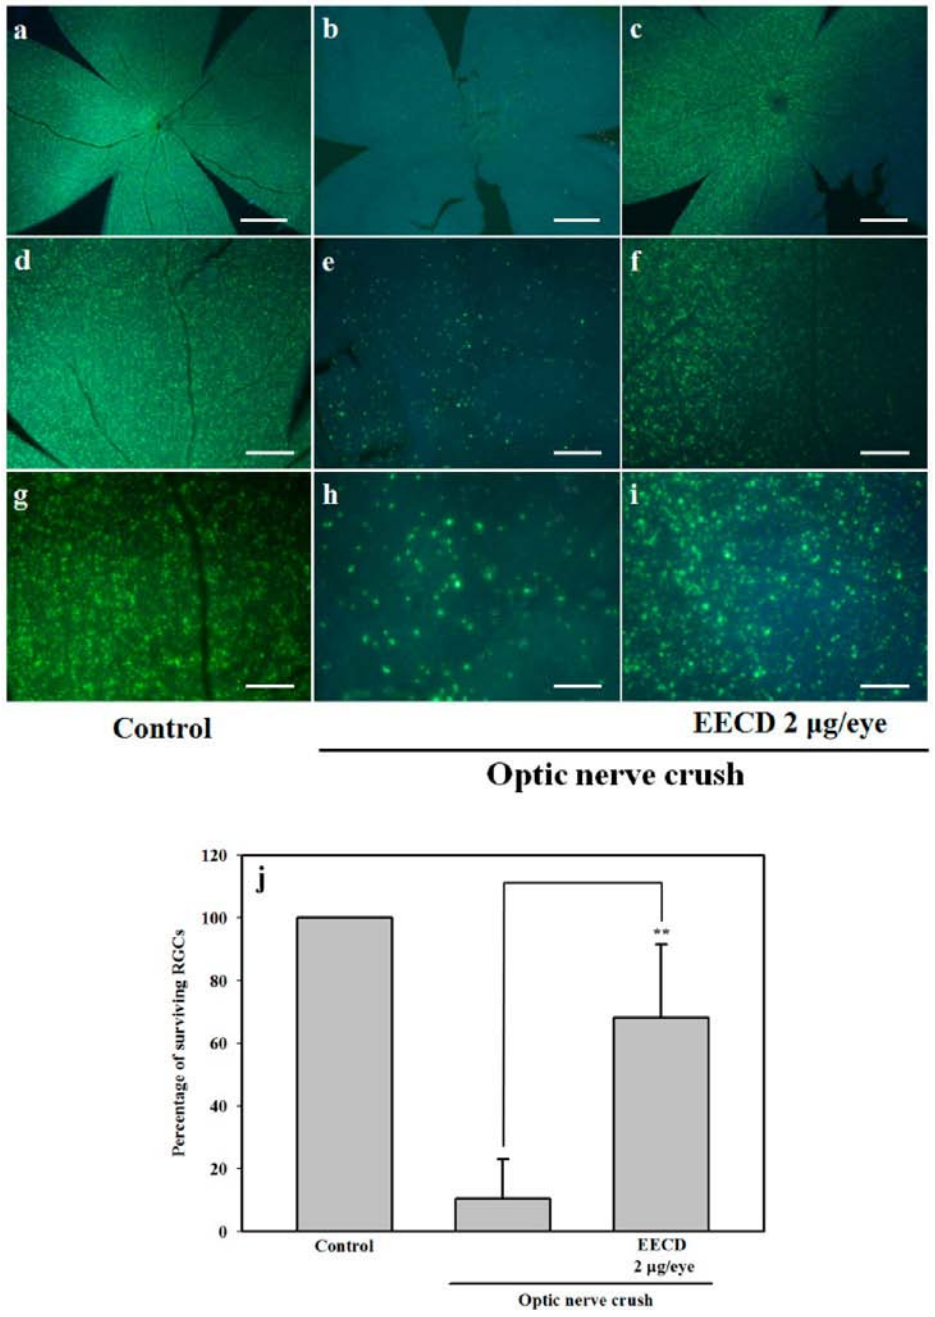

Figure 7. Fluorogold labeled RGCs in the mouse 1 week after optic nerve crush (ONC). Retrogradely labeled RGCs of mice with uninjured and injured optic nerves. RGCs were labeled by injecting 3% Fluorogold into the superior colliculi of the brain. The figure shows representative micrographs of normal retina (a) and damaged retina 1 week after ONC with (c) or without EECD (b). Scale bars in parts a–c represent 500 μm. Low-magnification (×100) images of labeled RGCs in a–c are shown in d–f. Scale bars in d–f represent 100 μm. High magnification (×200) images of a–c are shown in g–i. Scale bars in g–i represent 50 μm. The results showed a significant increase in RGC survival after EECD treatment compared with vehicle treatment (j). Experimental values are expressed as percentage of surviving RGCs with error bars indicating ± SEM from three independent experiments (** $p < 0.01$).

putative agents for treating or preventing retinal degeneration such as in glaucoma.[45] In view of the roles of oxidative stress in the retinal degeneration, we have shown that in RGC-5 cells EECD ameliorates the effects of the ROS production induced by H_2O_2, $O_2^{\bullet-}$, or $^{\bullet}OH$ by scavenging radicals (Figure 3). Moreover, the inhibitory effects of EECD on ROS were clearly confirmed by using the DHE assay, which directly measures intracellular $O_2^{\bullet-}$ (Figure 4).[46]

Lipid peroxidation can be referred to as oxidative degeneration of lipids, and it has been shown that lipid peroxidation is implicated in glaucoma.[47] In a study using UV-spectrophotometry and fluorescent analysis of lipid extracts from lenses, aqueous humor, and blocks containing trabecular and Schlemms canal tissues in primary open-angle glaucoma (POAG), significant changes of lipid peroxidation in comparison with the control were observed.[48]

MDA is final product of lipid peroxidation, and MDA levels were estimated in rat brain homogenates after induction by SNP using a TBARS assay.[13] In our hands, treatment with EECD clearly inhibited lipid peroxidation in a concentration-

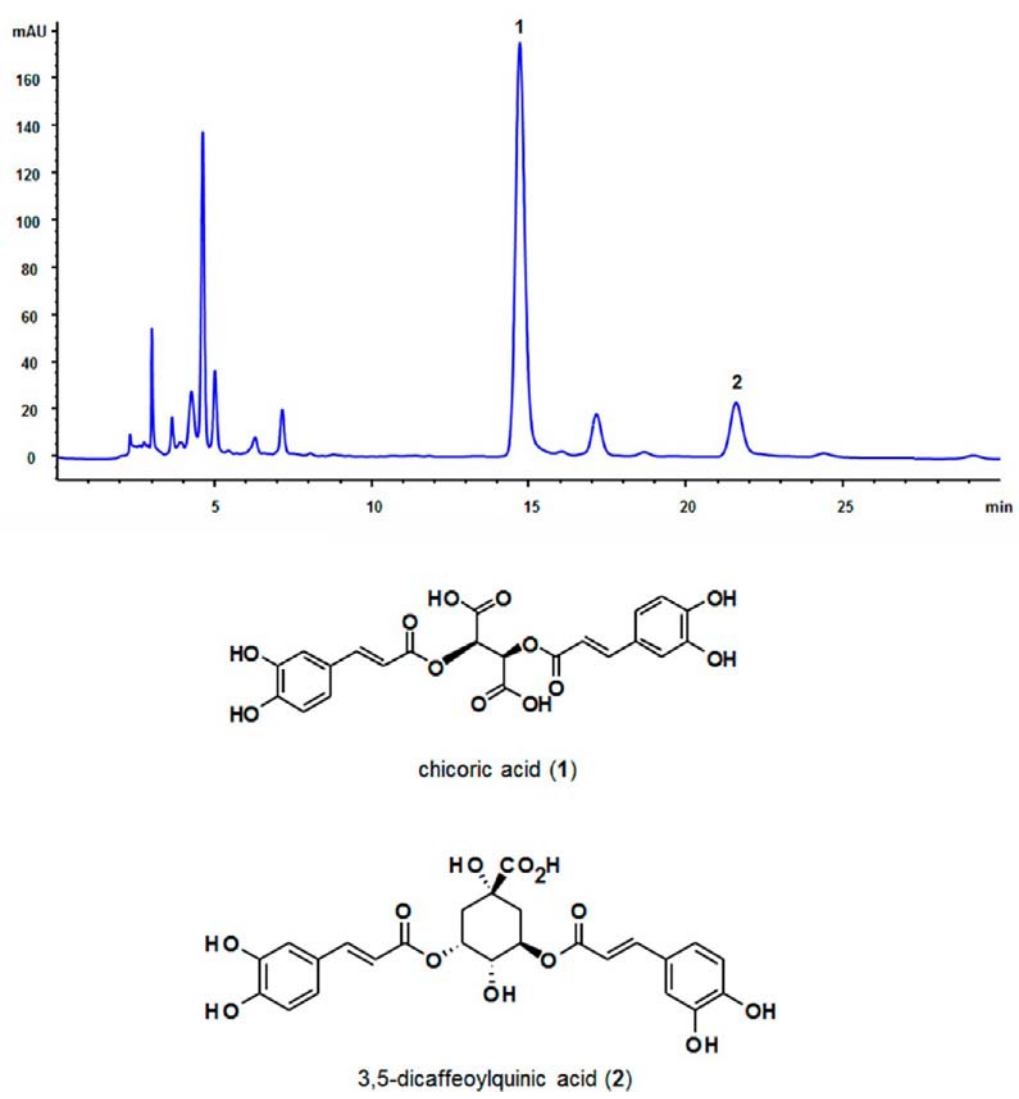

Figure 8. Chromatogram of the HPLC profile for EECD at 330 nm. Peaks: (1) chicoric acid, (2) 3,5-dicaffeoylquinic acid.

dependent manner (Table 1). Thus, taken together, our results suggest that the neuroprotective effects of EECD *in vitro* occur through antiapoptotic and antioxidative mechanisms.

In order to confirm the neuroprotective effects of EECD, we examined the number of TUNEL-positive cells in the GCL and the thickness of IPL following a single intravitreal injection of NMDA because excessive activation of the excitatory amino acid glutamate has been implicated in retinal neuronal cell death and in the pathogenesis of glaucoma.[49] NMDA receptors have been identified on RGC and amacrine cells, and NMDA-receptor activation causes apoptosis *via* ROS production through intracellular Ca^{2+} influx.[50] It was previously reported that NMDA administered in rat eye caused cell death in the GCL and reduction of IPL thickness, and that the blockade of excessive glutamate could be a possible strategy for development of neuroprotective agents.[51−53] Moreover, IPL thicknesses are well correlated with retinal nerve fiber layer thickness and visual field sensitivity, and the IPL thickness can provide the index of INL damage after retinal injury.[54] The present study showed that EECD attenuated the detrimental effects caused by NMDA (Figures 5 and 6).

These results indicate that, in addition to its direct inhibition of oxidative stress, EECD protection of RGC may be due to blockade of the downstream signaling pathways involved in NMDA-induced excitotoxicity.

We also determined whether EECD was effective in optic nerves to protect RGC following optic nerve crush (ONC) (Figure 7).

ONC is a common experimental model of chronic glaucoma in which the optic nerve is surgically exposed and clamped for several seconds.[55] There are several possible mechanisms for the degeneration of RGCs by ONC, including blockade of axonal transport resulting in inadequate supply of neurotrophic factors, disturbances of intracellular calcium homeostasis, activation of cell death genes, and local excitotoxicity due to uncontrolled activation of NMDA receptors.[56,57] Another mechanism of degeneration may be through ROS production, which causes the slow, chronic, and synchronous death of RGCs.[58] In our study the density of RGCs was decreased by ONC; however, pretreatment with EECD significantly reduced the loss of RGCs (Figure 7).

Our HPLC results identified the major components in EECD as chicoric acid and 3,5-DCQA (Figure 8).

Previous studies have shown that 3,5-DCQA from propolis extracts have neuroprotective effects on oxidative stress induced retinal damage.[8] It was also reported that 3,5-DCQA isolated

from *Gymnaster koraiensis* can protect RGCs from oxidative stress *in vitro* and from NMDA-induced excitotoxicity *in vivo*.[14]

We have proven that 3,5-DCQA has protective effects on retinal degeneration in previous research, thus focused on the effects of chicoric acid in this study.

Our present study supported that chicoric acid, the major phenolic compound of EECD, has protective effects both *in vitro* and *in vivo* (Figure 9), which could be postulated that chicoric acid and 3,5-DCQA are active compounds for the RGCs protective effects of EECD.

This is the first report of the presence of chicoric acid in *C. denticulatum* and the potential value in retinal degeneration.

Variations in food matrices and/or phenolic composition can contribute to having a major influence on intestinal bioavailability, since there are controversial results by observing the oral bioavailability of hydroxycinnamic acids intake.[59] Thus, further study will be needed for the bioavailability of chicoric acid and 3,5-DCQA with the *C. denticulatum* as food matrices. This is supported by another report that chicoric acid strengthens the anti-inflammatory activity of luteolin through NF-κB attenuation.[60]

In conclusion, the present study demonstrated that EECD and its isolated compound of chicoric acid can ameliorate RGC degeneration caused by oxidative stress both *in vitro* and *in vivo*, and that this protective effect may be mediated by its antioxidative and antiapoptotic effects.

Taken together, these findings support EECD as a potential bioactive wild vegetable that could be used as functional food for the prevention of neurodegenerative diseases such as glaucoma and age-related macular degeneration. Moreover, chicoric acid and 3,5-DCQA isolated from *C. denticulatum* are suggested to be offered as mark compounds for the standardization in the development of functional food.

peroxidation and tumor cell proliferation.[12] Betalains are more effective than tea catechins in protecting against the oxidation of human low-density lipoprotein and metmyoglobin.[13] Beetroot extracts showed a significant inhibitory effect against skin and lung cancer in mice.[14] An investigation into the differences between the chemical structures and activity of various betaxanthins and betacyanins with respect to their free radical-scavenging capacities was also suggested.[15]

Betaine is a modified amino acid commonly known as trimethylglycine or glycinebetaine. It is distributed widely in animals, plants, and microorganisms, and the rich dietary sources of betaine include many foods such as wheat germ or bran (≈1% or 1339 mg), spinach (≈0.7% or 600−645 mg), and sugar beets (0.2−0.3% or 117−297 mg/100 g fresh weight).[16,17]

Betaine was first discovered in the juice of sugar beets (*B. vulgaris*) in the 19th century and subsequently found in several other organisms.[16] It is naturally found in the body due to the breakdown of choline. The principal role of betaine in plants is thought to be the protection of cells against osmotic inactivation by adjusting the osmotic balance inside the plant cells and tissues.[18] By this natural defense mechanism, betaine helps the plants to overcome the environmental stress caused by salinity,[19,20] water stress,[21,22] and cold stress.[23] For example, the betaine content increased significantly in spinach grown in saline soil, up to 3% of the fresh weight.[20] Red beetroot grown under saline conditions also showed an increase in betaine in the tissue, indicating its ability to synthesize and regulate betaine production.[18]

In addition to the osmotic functions resulting from environmental stress, betaine has been used as a dietary supplement in animal nutrition for the purpose of promoting overall health.[16] Red beetroot is a rich source of betaine, although it is often overlooked as a food source.[24] Betaine has the biological properties of lowering blood homocysteine levels,[25,26] regulating osmolyte function in the kidney,[27] and protecting the liver from toxins such as chloroform.[28] Betaine is believed to be the most active naturally occurring osmoprotectant molecule for bacteria, and dimethylthetin has been suggested as a useful model for the development of antibacterial agents.[29] The betaine content of foods has been found to vary greatly when different individual food sources were analyzed and different cooking methods were used; for example, boiling led to the greatest loss of betaine.[24]

In this study, we investigated the distribution of betalains and betaine in various beetroot cultivars grown in a greenhouse or in the field, and we also evaluated the cytotoxic activities of betanin and betaine in human cancer cells. The objectives of this study were (1) to separate and quantify the individual betalains and betaine from beetroots, (2) to compare the contents of betalains and betaine among nine beetroot cultivars, (3) to test the environmental effects on the composition of both compounds between the greenhouse and field, and (4) to examine the cytotoxicity of betanin and betaine to HepG2 cells to promote the health benefits of beetroots.

MATERIALS AND METHODS

Chemical Reagents and Plant Materials. All chemicals and solvents were purchased from Sigma-Aldrich (St. Louis, MO, USA) or Fisher Scientific (Pittsburgh, PA, USA). All other chemicals used were of analytical grade. Authentic betanin (red beetroot extract diluted with dextrin) was purchased from TCI (Tokyo Chemical Industry Co., Tokyo, Japan), and betaine was obtained from Sigma-Aldrich. The seeds of beetroot cultivars were obtained from Burpee (Warminster, PA, USA) (Table 1). Yellow-red Swiss chard, red-violet portulaca, and red cactus pear fruit were purchased from local markets.

Table 1. Cultivars, Root Colors, and Sample Identification Codes of Beetroots (*Beta vulgaris* L.)

cultivar	root color	identification code
Little Chicago hybrid	red	I
Detroit King	red	II
Red Heart hybrid	red	III
Red Cloud hybrid	red	IV
Scarlet Prince	red	V
Bull's Blood	red	VI
Burpee's Red Ball	red	VII
Detroit Supreme	red	VIII
Burpee's Golden Globe	yellow-gold	IX

Production of Beetroots. Beetroots were cultivated in a field in Weslaco (26° 15′ N, 97° 98′ W) in the Rio Grande Valley of southern Texas and in the greenhouse at College Station (30° 36′ N, 96° 18′W) at Texas A&M University. The soils were clay or loam types, with a pH ranging from 7.4 to 8.2. Average soil sulfur levels were 120−150 ppm. In the greenhouse, beetroots were planted in a 7- L pot filled with Sunshine mix 1 (Sun Grow Horticulture, Agwam, MA, USA), and the plants were watered with a modified fertilizer solution,[30] as necessary. The plants were managed by commercial standard cultural practices.

Beetroots were harvested at a stage of commercial harvest maturity from each location and transported to the labortory. Harvested beetroots were washed, and approximately 100 g was cut from the midsection of the root. The root sample was chopped into small pieces, placed into a plastic bag, and stored at −20 °C until analysis.

Preparation of Crude Betalain Extracts. Approximately 50 g of the frozen tissue was pulverized with a rubber mallet and mixed thoroughly while the tissue remained frozen. Five grams of tissues was homogenized with 30 mL of 80% aqueous methanol and 0.1% ascorbic acid using a homogenizer (model PT 10-35, Brinkmann, Westbury, NY, USA). The homogenates were centrifuged at 10000*g* for 20 min, and the supernatants were filtered. All extracts were stored at 4 °C until HPLC analysis.

In addition to beetroot extracts, we analyzed and compared betalains extracted from different plant sources for use as references to identify betalains because betalains are abundant in cactus fruit (*Opuntia* spp.),[9,31] portulaca flowers,[32] and Swiss chard.[4] They were processed as mentioned above.

Analysis of Betalains. Betalains were separated and quantified using a Perkin-Elmer HPLC system (Shelton, CT, USA) equipped with a series 200 pump, autosampler, and diode array detector (DAD). An analytical column (Spherisorb ODS2, Waters, 4.6 × 250 mm, 5 μm) was used with a guard cartridge. Solvents A and B were water and methanol, both containing 0.01% acetic acid, respectively. The solvent gradient was programmed as follows: from 0 to 60% solvent B over 45 min at a flow rate of 1.0 mL/min, then changed to 100% solvent B (0% A) for 5 min to flush the column. The calibration standards and sample extracts were injected via a 20 μL sample loop. Chromatographic detection was set at 480 nm for betaxanthins and at 540 nm for betacyanins. Spectral data were simultaneously collected between 200 and 700 nm.

Purification of Betalains. Betalains were purified by a semipreparative HPLC method. A semipreparative column (Waters Spherisorb ODS2, 20 × 250 mm) was used, and 1 mL of crude betalain extracts was injected using a manual injector. The solvents were water and methanol (40:60, v/v) at a flow rate of 4 mL/min. Peak fractions of column eluates were repeatedly collected, combined, and lyophilized for use as betalain standard compounds. The purity of the compounds was tested on the basis of the peak areas detected by the analytical HPLC method.

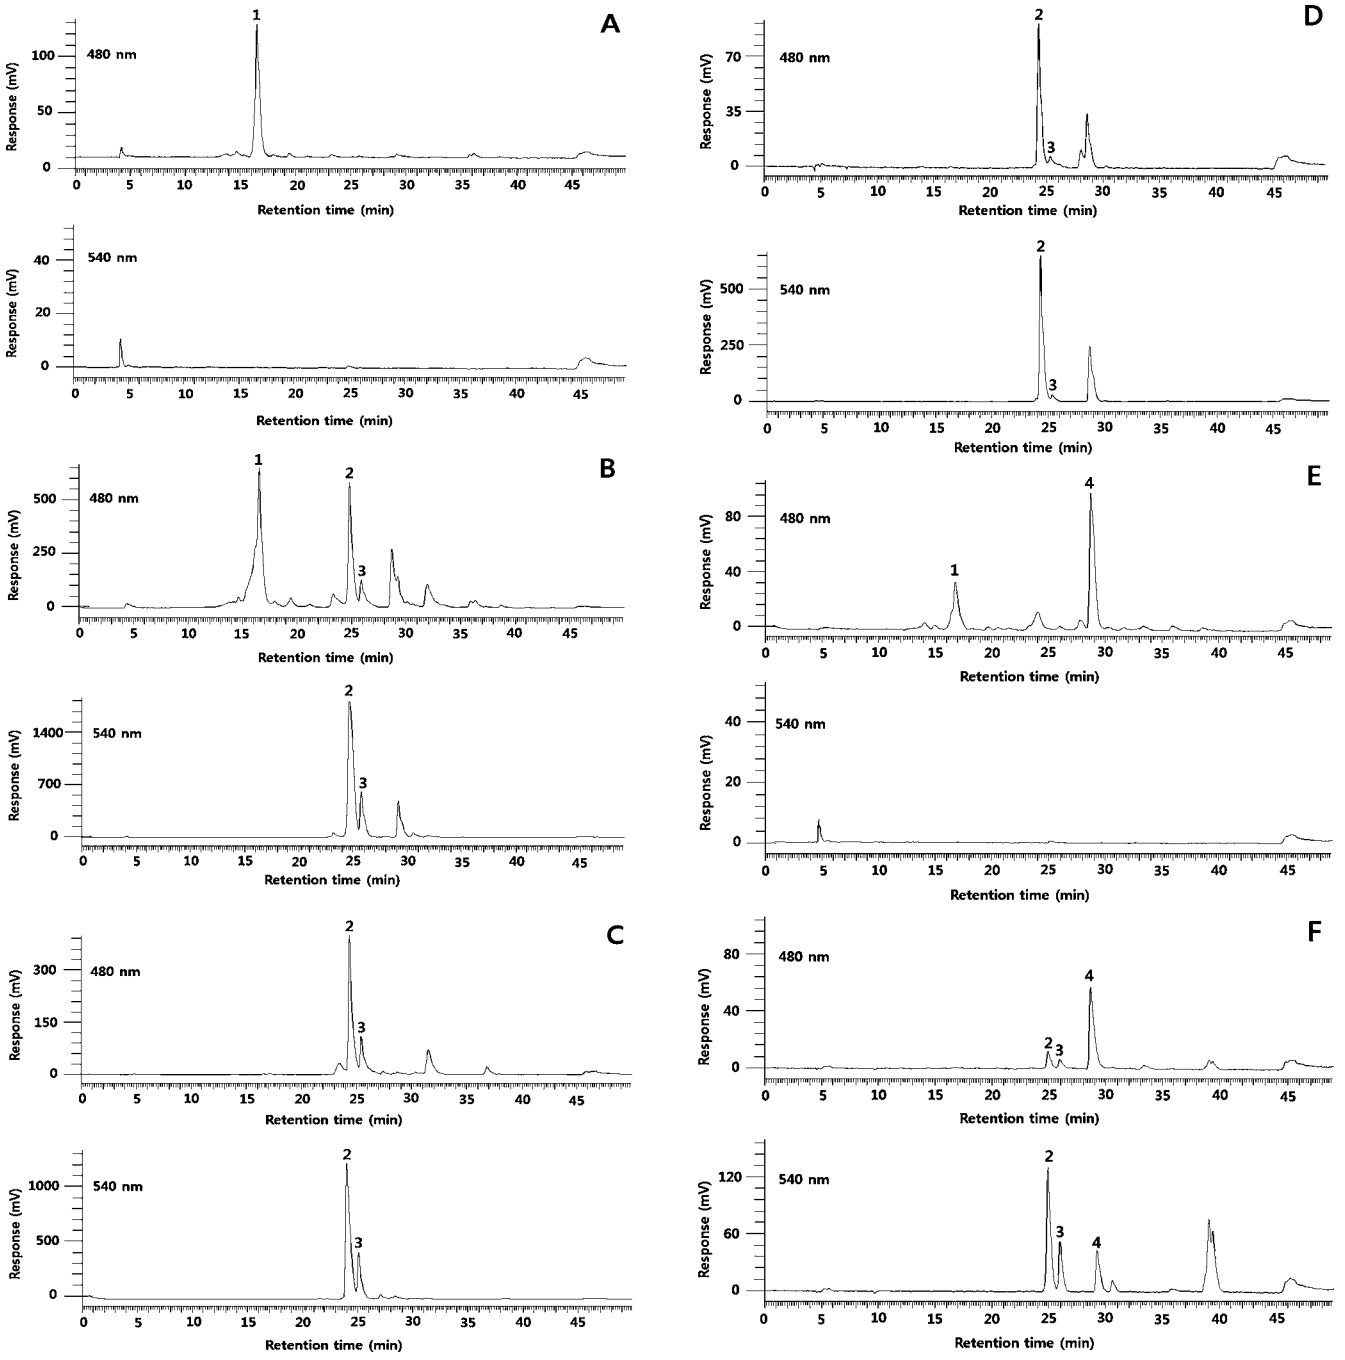

Figure 1. HPLC chromatograms of betalains extracted from different plants: yellow beetroot (A); red beetroot (B); red cactus pear (C); petals of red-violet portulaca (D); petioles of yellow Swiss chard (E); petioles of red Swiss chard (F). Elution was monitored at 480 nm for betaxanthin (A) and at 540 nm for betacyanin (B). The numbers on the peaks refer to the betalains listed in Table 1.

Identification of Betalains. Electrospray ionization in positive ion mode was carried out by applying 4.5 kV at the spray needle to create positive ions. Sheath gas and auxiliary gas flow rates were 50 and 10 arbitrary units, respectively. The transfer capillary temperature was maintained at 250 °C. The Xcalibur 2.0 software package (ThermoFinnigan) was used to control the LC-MS system and for data acquisition and processing. Identities were also determined by comparing the experimental data with previously reported HPLC-MS data from a betanin standard using the analytical HPLC method, as described above, and by spectral analysis.[4,31−34]

Quantification of Betalains. The concentrations of individual betacyanins (betanin and isobetanin) and betaxanthins (vulgaxanthin I and miraxanthin V) were calculated using extinction coefficient values ($E^{1cm}_{1\%}$) of 1120 at 537 nm and 750 at 480 nm with their respective absorption maxima, respectively.[35,36] The total betacyanins and betaxanthins of beetroots were expressed as betanin equivalents or vulgaxanthin equivalents, respectively, because they were the predominant compounds in beetroots. The total betalain content was calculated by summing the total betacyanin and betaxanthin contents.

Extraction and Analysis of Betaine. Three grams of tissues obtained from the pulverized sample was homogenized in 30 mL of 80% ethanol. Homogenates were filtered and 20 μL samples were injected into an HPLC system with a refractive index detector and a 700 CH carbohydrate column (Alltech, Deerfield, IL, USA) with a guard cartridge. A betaine standard was dissolved in 80% ethanol, and the concentrations were calculated using standard curves between 0 and 10 mg/mL.

Table 2. HPLC, HPLC-MS, and Purity of Isolated Betalains from Beetroots and Petioles of Swiss Chard

peak	retention time (min)	λ_{max} (nm)	m/z $[M + H]^+$	purity (%)	name	source
1	16.8	470	340	97	vulgaxanthin I	yellow beetroot
2	24.8	534	551	92	betanin	red beetroot
3	25.3	534	551	76	isobetanin	red beetroot
4	29.1	461	347	95	miraxanthin V	yellow Swiss chard

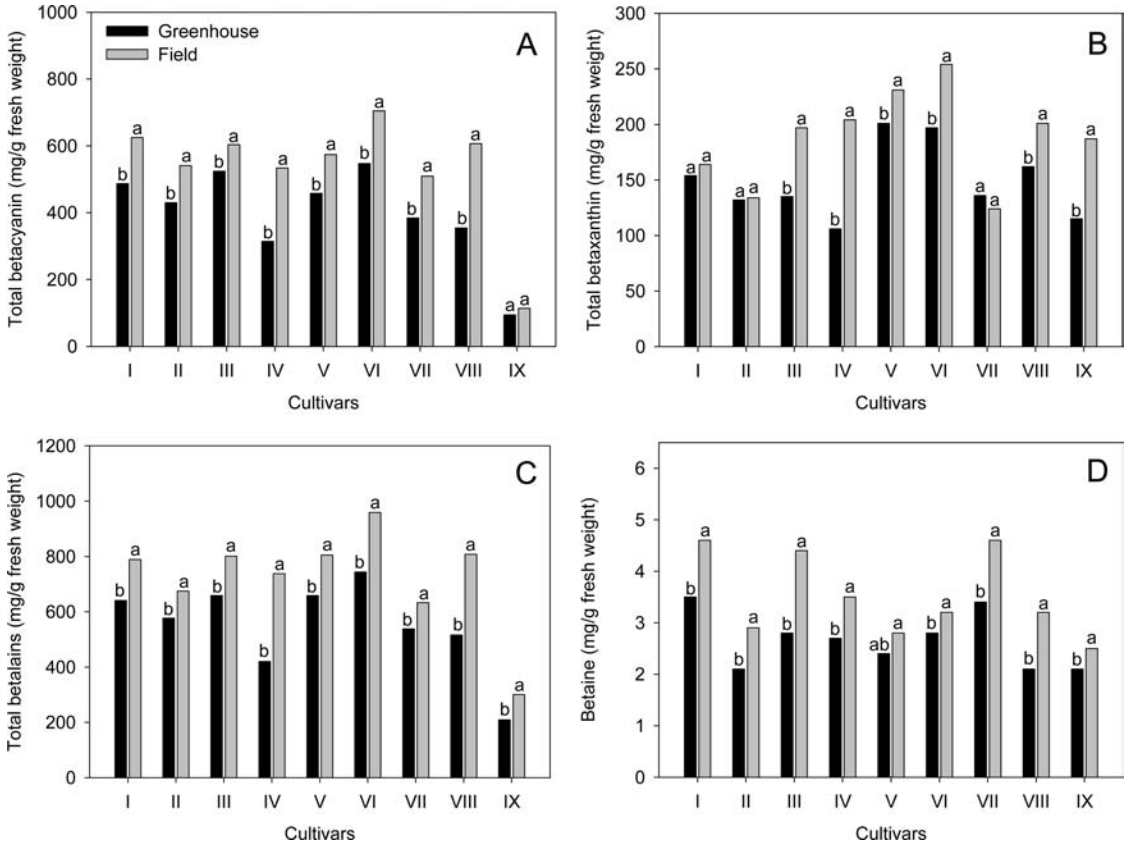

Figure 2. Total betacyanins (A), betaxanthin (B), betalains (C), and betaine (D) contents of various beetroot cultivars grown in a greenhouse or in the field. Beetroot cultivars are listed in Table 1. Means in each cultivar with different letters are significantly different according to Duncan's multiple-range test at $P < 0.05$.

Cell Culture and MTT Assay. HepG2 cells (ATCC) were cultured in Dulbecco's modified Eagle medium (DMEM) containing 10% fetal bovine serum at 37 °C in a 5% CO_2 incubator. Betanin isolated from beetroot extracts and standard betaine were used for cytotoxicity assay. The cancer cell proliferation inhibitory activity of betanin and betaine was determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) staining method.[37] A total of 0.8×10^4 HepG2 cells in DMEM was placed in each well of a 96-well plate and incubated to stabilize for 12 h. The growth medium was removed, and media containing increasing concentrations of betanin (0, 25, 50, 100, 200, and 400 μg/mL) and betaine (0, 25, 50, 100, 200, 400, and 800 μg/mL) were added to the cells for 48 h, with media being refreshed every 12 h. The cell proliferation was determined using the colorimetric MTT assay. After 4 h of incubation with a thiazolyl blu,e tetrazolium bromide dissolved in sodium perborate at 5 mg/mL, the media, MTT reagents, and dead cells were aspirated. Dimethyl sulfoxide (100 μL) was added to all wells and mixed thoroughly for 2 h to dissolve the purple formazan crystals. After verification that all crystals were dissolved, the MTT absorbance was measured at 570 nm using a multidetection microplate reader (SpectraMax M2e, Molecular Devices, Sunnyvale, CA, USA).

Data Analysis. Experiments were conducted using a randomized block design with three replicates and determined using SAS 9.0 for Windows (SAS Institute, Cary, NC, USA). Each replicate included five beetroots. The means were separated using Duncan's multiple-range test at $P < 0.05$.

RESULTS AND DISCUSSION

HPLC Chromatograms and Identification of Betalains. The HPLC chromatograms of betalains from the extracts of different plant sources, monitored at 480 nm (betaxanthins) and 540 nm (betacyanins), are shown in Figure 1. Information regarding the identified individual betalains is presented in Table 2.

Figure 1 shows the different betalain patterns of differently colored plants. Betanin (peak 2) was a major compound in red cactus pear (C), petals of red-violet portulaca (D), and petioles of red Swiss chard (F); however, miraxanthin V (peak 4), known as dopamine-betaxanthin, was the major betaxanthin in the petioles of yellow Swiss chard (E). It was eluted at 29.1 min and showed its maximum absorbance at 461 nm. We could obtain the compound at a high purity of 95% from the yellow petioles of Swiss chard (Table 2). It was reported that miraxanthin V and vulgaxanthin I accounted for 37 and 34% of the whole peak area of all identified betaxanthins at 470 nm in yellow-colored Swiss chard petioles, and they also accounted

dx.doi.org/10.1021/jf404648u | J. Agric. Food Chem. 2014, 62, 1324−1331

for up to 55 and 25% in red-purple petioles, respectively.[4] As shown in Figure 1, however, vulgaxanthin I (peak 1) was not detected in the red petioles of Swiss chard (F) and miraxanthin V (peak 4) was identified in extracts of both the yellow (E) and red (F) petioles of Swiss chard.

In this study, we identified and isolated only four predominant betalains, which were two betacyanins (betanin and isobetanin) and two betaxanthins (vulgaxanthin I and miraxanthin V), because they comprised >90% of betalains detected in our samples and analysis system. Individual betalains identified and listed according to their retention times during analysis are vulgaxanthin I (peak 1), betanin (peak 2), isobetanin (peak 3), and miraxanthin V (peak 4) (Table 2). Vulgaxanthin I was isolated from yellow beetroot extracts with a purity of 97% and showed a retention time of 16.8 min and a maximum absorbance at 470 nm (Table 2). As shown in Figure 1A, vulgaxanthin I (peak 1) is only one major betaxanthin identified in yellow beetroot extract, along with other trace compounds that were not identified. Other betaxanthins, such as indicaxanthin, vulgaxanthin IV, and miraxanthin V, were analyzed in yellow beetroot, but they have been detected only in suspension cultures of yellow beetroot due to their low concentrations.[8] Betacyanins were completely absent in extracts from yellow beetroot in our study. The two main betacyanin peaks in red beetroot extract were identified as betanin (peak 2) and isobetanin (peak 3) (Figure 1B), according to their absorption maxima and protonated molecular ions (m/z 551) (Table 2). Both molecules differ only in the absolute configuration of their C15 chiral center[38] and were eluted at very close retention times, 24.8 and 25.3 min, respectively. Due to this difficulty, we were able to obtain purities of 92 and 76% for betanin and isobetanin from red beetroot extract, respectively (Table 2). Vulgaxanthin I (peak 1) is the third major compound, together with betanin and isobetanin. Trace amounts of other unknown compounds were also detected at 480 and 540 nm, although we did not identify them.

Quantification of Betalains. To compare the betalain contents of various beetroot cultivars produced in the field or a greenhouse, we cultivated a total of nine beetroot cultivars, consisting of eight red-colored (I–VIII) and one yellow-colored (IX) beetroot (Table 1). The total betacyanins and betaxanthins were calculated by the spectrophotometric method and are shown in Figure 2. Additionally, the analysis of individual betalains of the two cultivars, 'Bull's Blood' (A) and 'Burpee's Golden Globe' (B), which were obtained from the field, was performed by DAD-HPLC, and the concentrations of individual betalains are presented in Figure 3.

Figure 2A shows the results obtained for the total betacyanin contents, expressed as betanin equivalents, in beetroots grown in the greenhouse or in the field. All beetroot cultivars (Table 1) grown in field conditions showed higher contents of total betacyanins compared with those from the greenhouse, except for the 'Burpee's Golden Globe' cultivar (IX), which was yellow in color. The total betaxanthins of each cultivar from the field were relatively higher or similar to the total betaxanthin contents of beetroots from the greenhouse (Figure 2B). Consequently, the total betalains of beetroots produced in the field were between 650 and 800 μg/g fresh weight, showing >25% higher total betalain content than those from the greenhouse (Figure 2C). The total betalains of the 'Burpee's Golden Globe' cultivar (IX) were 301 μg/g fresh weight, the sum of 114 μg/g for betacyanins and 187 μg/g for betaxanthins.

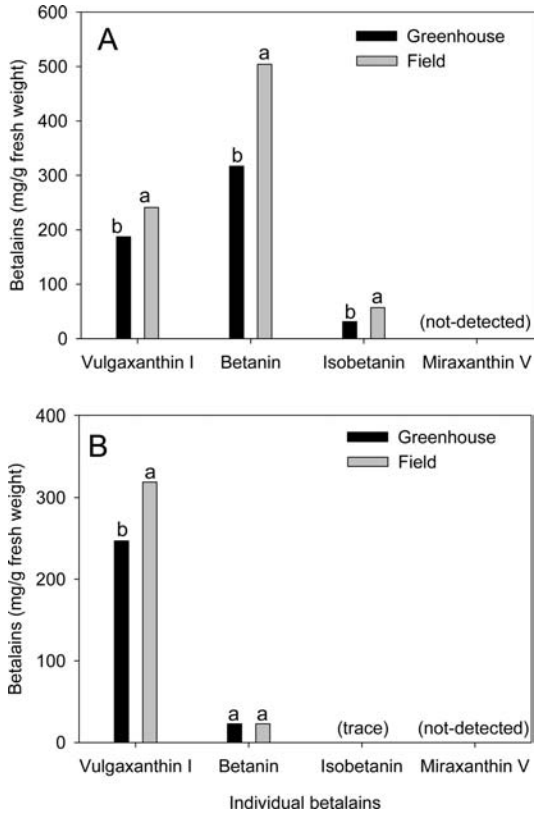

Figure 3. Individual betalains content of beetroot 'Bull's Blood' (A) and 'Burpee's Golden Globe' (B) cultivars grown in a greenhouse or in the field. Means in each cultivar with different letters are significantly different according to Duncan's multiple-range test at $P < 0.05$.

The content of betalains differed greatly among cultivars as well as growing conditions.

The compositions of the four individual betalains for the 'Bull's Blood' (A) and 'Burpee's Golden Globe' cultivars (B) are presented in Figure 3. Betanin is one of the major betacyanins of red beetroots, comprising >60% of the total pigments, followed by vulgaxanthin I and isobetanin. Miraxanthin V was not detected in our analysis due to its low concentration in red and yellow beetroots. However, vulgaxanthin I was the most abundant betaxanthins in the yellow 'Burpee's Golden Globe' cultivar, whereas betanin was a minor compound and isobetanin was detected in trace amounts. Similar results were reported in other previous studies.[9,39]

It has been well-known that light is a physical factor that can affect metabolite production. A positive correlation between increasing light intensity and levels of betalains has been reported.[40,41] Light enhances betalain production in red beetroots[42,43] and portulaca[40,44] by increasing tyrosinase activity, catalyzing the formation of both L-(3,4-dihydroxyphenyl)alanine (DOPA) and *cyclo*-DOPA, which are precursors in betalain biosynthesis in higher plant.[45] In addition, blue light was more effective for the production of betalains than other lights.[40]

The signal transduction pathway of light-induced betacyanin and anthocyanin synthesis may be similar to the light quality- and quantity-influenced betacyanin synthesis of *Suaeda salsa* calli.[46] Most studies of light-induced betalain biosynthesis have been focused and conducted on cultured cells. Little is known about the mechanism of light-induced betalain biosynthesis of beetroots grown under field or greenhouse conditions.

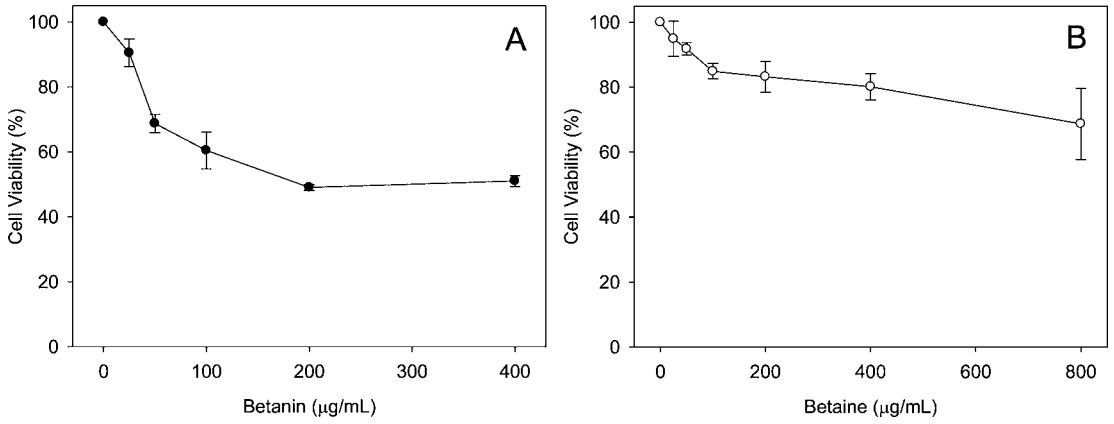

Figure 4. Cytotoxicity on HepG2 cells after their exposure to betanin (A) and betaine (B) for 48 h at 37 °C. Vertical bars represent the standard errors.

However, we could assume that sufficient or high light intensity from natural sunlight promoted betalain biosynthesis, resulting in high levels of betalain accumulation in beetroots grown in the field. In greenhouse studies, the light quantity was deficient and/or the quality of light was insufficient, probably due to the significantly reduced levels of UV light passing through the cover plastic, resulting in betalain contents lower than in the field.

In addition to stimulus by light, plants might be exposed to other environmental factors that aid in the accumulation of betalain pigments in cells. Thus, it is of interest to explore whether betalain biosynthesis can be induced by common stimuli, such as soil conditions, high temperatures, or growing practices from conventional, organic, or integrated farming systems, as aspects of promoting the health benefits of beetroots.

Quantification of Betaine. Figure 2D shows that beetroots grown under field conditions accumulated more betaine, regardless of the cultivar. There was also great variation in betaine concentrations among cultivars. It has been reported that betaine is synthesized in response to abiotic stress, especially to water or salt stress.[19−21] Under our growing conditions, the water capacities of soil in the field and the greenhouse were completely different. The plants had different water supplies in the greenhouse (automatic irrigation to obtain ∼60% water capacity) and in the field (automatic irrigation to obtain ∼30% water capacity). Thus, we could assume that betaine was increased significantly in beetroots grown in the field as a consequence of a long-term or frequent drought in Texas. In addition, soil sulfur levels of >100 ppm in Texas fields[47−49] and high temperature extremes might influence betaine biosynthesis in beetroots during field cultivation as sources of abiotic stress, but it has not yet been scientifically reported in beetroots.

In Vitro Inhibition of HepG2 Cell Proliferation. The MTT test was carried out to evaluate the effect of betanin and betaine, which are major dietary compounds for human health in beetroots, on HepG2 cell inhibition after 48 h of incubation. As shown in Figure 4A, treatment with betanin exhibited dose-dependent inhibition of HepG2 cell proliferation at concentrations between 0 and 200 μg/mL. However, the HepG2 cells were inhibited by 25% when treated with a betaine concentration of 800 μg/mL (Figure 4B). The addition of betaine at a concentration of 1600 μg/mL showed a similar level of cell cytotoxicity (data not shown). Although betanin was more effective in reducing cell viability than betaine in this study, an overall reduction of cell viability was observed in the MTT assay.

The free radical-scavenging and biological activities of betanin or betalains as extracts of beetroots against human cancer as well as some other diseases have been reported.[12,50,51] In vitro HepG2 cell cytotoxicity by betalains extracted from *Rivina humilis* berries[50] and *Tamarindus indica* fruit pulp[52] was also confirmed. Similarly, our results showed that betanin obtained from beetroots has anticancer activity (49% proliferation inhibition) especially against HepG2 cells at relatively high concentration of betanin (200 μg/mL). Although betaine has been shown to protect the liver in animals[16,53] and act as an antimicrobial agent,[29] there was a slight effect with respect to HepG2 cell cytotoxicity in our study.

METHODS AND MATERIALS

***In Vitro* Fermentation Using Human Fecal Inoculums.** Potential human fecal sample donors were recruited on the University of Minnesota campus. Subjects were screened using a questionnaire. Inclusion criteria were self-reported absence of disease ("healthy"), consumption of a nonspecific western diet, and no antibiotic use for three months prior to the study. Fecal samples were collected using a Commode Specimen Collection System (Sage, IL) lined with a 2 mm thickness plastic bag. Samples were immediately placed into an anaerobic bag (Remel, Lenexa, KS) containing an AnaeroPouch anaerobic sachet (Mitsubishi Gas Company, Tokyo Japan), sealed with a Pouch Clip (Remel, Lenexa, KS) and placed on ice in an insulated container to maintain microbial viability and ensure standardized sample preparation. Fecal samples were delivered to the laboratory and processed within 2 h.

Fiber samples were provided by Nestle Health Science S.A. (Lutry, Switzerland) in coded pouches, and investigators were blinded to the treatments. The fibers tested were fructo-oligosaccharides (FOS, Beneo, Morris Plains NJ), inulin (Beneo, Morris Plains NJ), gum acacia (Nexira, Somerville NJ), outer pea fiber (Nutri-Pea Limited, Manitoba Canada), and a 50:50 soluble/insoluble blend of FOS, inulin, gum acacia, and outer pea fiber. Half a gram (0.5 g) of each fiber or blend was weighed and placed into sterilized 100 mL serum bottles. Forty milliliters of sterile trypticase peptone fermentation media was added to each bottle and fibers were allowed to hydrate for 12 h at 4 °C.[18] The fiber/media slurry was heated to 37 °C and 10 mL of fecal inoculum was added to each bottle along with 0.8 mL of oxyrase (Oxyrase Inc., Mansfield, OH) to remove oxygen from the environment. Fecal inoculum was prepared by pooling three fecal samples with phosphate buffer solution (1:6 w/v) and then mixing two parts reducing solution (950 mL of distilled water, 6.25 g of cysteine hydrochloride, 40 mL 1 M sodium hydroxide, 6.25 g of sodium sulfide nonahydrate) to 15 parts diluted fecal inoculum (v/v).[19] Bottles were flushed with carbon dioxide and sealed. Sealed bottles were placed in a 37 °C shaking water bath and allowed to ferment for 0, 4, 8, 12, and 24 h (triplicate bottles for each time point).

***In Vitro* pH, Gas Volume, and SCFA.** At each time point, aliquots were taken for measurement of pH, gas volume, and SCFAs. Gas volume was measured by piercing the rubber cap of the sealed fermentation bottle with a 50 or 100 mL glass syringe fitted with a stainless steel needle and allowing the gas to fill the syringe.[20] The pH of the fermented treatments was measured with a calibrated pH probe, and following pH measurement, 1 mL of copper sulfate (200 g/L) was added into the serum bottles to inhibit further fermentation. A 2-mL aliquot was removed from each triplicate for SCFA measurement and frozen at −20 °C until subsequent analysis.

Enteral Nutrition Human Feeding Study. *Subjects and Subject Protocol.* For a full description of the subject inclusion/exclusion criteria and the subject protocol, please refer to ref 21. Briefly, healthy adult men and women were recruited on the University of Minnesota campus. Written informed consent was obtained from each subject and the study was approved by the University of Minnesota Institutional Review Board for Human Research Protection Program (IRB Number 1103M96878). Each subject completed the randomized, double-blind, crossover protocol. Subjects consecutively consumed habitual diet for 14 days, enteral diet 1 for 14 days, habitual diet for 28 days, and enteral diet 2 for 14 days. During each period, subjects recorded diet records, and anaerobically collected a fecal sample on day 14 (as described in the *in vitro* section). Subjects exclusively consumed (orally) formula during the enteral periods and were provided with formula in excess of their total energy needs as calculated by the Harris-Benedict equation and adjusting with physical activity factors.[22] Subjects were withdrawn from the study if their intake was below 75% of the target volume for two consecutive days. Formula was provided in 250 mL cans that were identically labeled with the exception of four different product codes (to ensure blinding).

Enteral Formula and Diet Measurements. Enteral formulas were nutritionally complete and identical in composition except for fiber content. Base formula contained 1500 kcal/L, 67.6 g protein/L, 64.8 g fat/L, and 168 g carbohydrate/L. The formula contained casein as the sole protein source. Fiber containing formula was base supplemented with 15 g/L of fiber blend. The fiber blend was composed of a 50:50 insoluble/soluble mixture of FOS, pea hull fiber, gum acacia, and inulin.

Enteral formula energy and protein intake was calculated from 14 day diet records during the formula periods. Enteral formula fiber intake was calculated from 14 day diet records during the fiber formula period. Habitual diet reports were generated by entering the diet records into Nutrition Data System for Research (University of Minnesota, Version 2011). Habitual diet energy, fiber, and protein intake values were averaged from the 2-day diet records recorded during the run-in and washout phases.

Human Subject Fecal Sample Preparation. Anaerobically packaged fecal samples were kneaded for 2 min to homogenize. A 10 g aliquot of fecal sample was diluted 1:10 (w/w) in phosphate buffered saline (PBS, 0.1 M, pH 7.2). The fecal/PBS mixture was homogenized in a stomacher for 2 min and the slurry was aliquoted for SCFA. The remaining sample was used for pH measurement via calibrated pH probe.

***In Vitro* and Human Subject Short Chain Fatty Acid Measurement.** SCFA were completed in triplicate using a modified Schneider method.[23] *In vitro* fermentation liquid aliquots were thawed at 4 °C. To the fermentation liquid, 1.6 mL of distilled water and 0.4 mL 50% sulfuric acid were added and vortex mixed. Two milliliters of diethyl ether and 2 μL of 2-ethylbutyric acid (99%, internal standard) were added to each tube. Tubes were sealed, vortex mixed and orbitally shaken at 300 rpm for 45 min. Samples were centrifuged at 2060*g* for 5 min and the supernatant was transferred to a test tube containing solid calcium chloride to remove residual water. The final sample was filtered through a 0.2 μm nylon filter, placed into a 2 mL glass gas chromatography vial and sealed.

For the human subjects samples, approximately 2 mL of PBS/stool slurry was centrifuged at 9300*g* for 10 min. To 1 mL of fecal supernatant were added 0.4 mL of 50% sulfuric acid and 2 mL of ether containing 1 μL/mL of 2-ethyl butyric acid (99%, internal standard). The sample was sealed, vortex mixed for 10 s and shaken at 300 rpm for 45 min. The ether was retained, excess water removed with calcium chloride, and the final sample placed into a 2 mL glass gas chromatography vial and sealed.

All SCFA samples were analyzed using a HP 5890 gas chromatograph (in split mode) equipped with a 30 m × 0.53 mm × 1 μm film thickness Stabilwax-DA (Restek Corporation, Bellefonte PA) column. The injection port temperature was 220 °C, the detector 240 °C, and oven program 110 °C for 0.5 min followed by 10 °C/min to 180 °C and then 50 °C/min to 240 °C, hold 3 min. Acetate, propionate, and butyrate were quantified for *in vitro* samples. Acetate, propionate, isobutyrate, butyrate, isovalerate, and valerate were quantified for *in vivo* samples. All quantification was performed using standard curves generated from known amounts of acids and internal standard.

Statistical Analysis. All data analysis was performed in SAS (Version 9.2). *In vitro* longitudinal repeated measurements were compared between fibers using a mixed-effects linear model, with a random intercept to model within-fiber correlation. Gas volume was log transformed before analysis. To adjust for multiple comparisons, Bonferroni correction for multiple comparisons was used: differences were considered significant at the $P < 0.05/10 = P < 0.005$ since there were 10 comparisons among treatments.

Baseline characteristics of human subject data were compared using a *t* test. All other human subject data was compared using longitudinal regression models with random subject effect to model the within-subject correlation. For each outcome, period, gender and unequal carryover effects were tested for. Data collected during the initial habitual diet and washout periods were combined and adjusted for period effects. Differences were considered significant at $P < 0.05$.

Table 1. Gas Volume Produced during 24 h Batch *in Vitro* Fermentation of Fibers[a]

	gas volume (mL)			
fiber	4 h	8 h	12 h	24 h

[a]Values are means (SEM). Total SCFA reflects the sum of acetate, propionate, and butyrate. Means with no letters in common were significantly different at the 0.05 level after Bonferroni correction within each time point. [b]FOS: Fructo-oligosaccharides.

RESULTS

***In Vitro* Fermentation Study.** Three volunteers (aged 24–32; one male, two female) provided fecal samples for the fermentation. Samples were pooled and used in the fermentation.

All fiber/fecal slurries produced more than 3 mL of gas during the 24 h fermentation except the negative control and pea fiber (Table 1). At 4 h, gas production was the highest for inulin followed by 10 times less gas for FOS and gum acacia and essentially no gas from the fiber blend. By 8 h, inulin and FOS produced approximately 20 times more gas than the fiber blend. At 12 h, inulin and FOS continued to have the highest gas production (and statistically similar) that was three times higher than the gum acacia and five times more than the fiber blend. At the final 24 h time point, FOS and inulin produced the most (and statistically similar) amount of gas, followed by gum acacia (which was similar to FOS levels). The blend produced intermediate amounts at approximately a quarter of that produced by inulin and FOS.

Due to the fermentation media used, the initial pH of the system was approximately 9, and no statistical differences were found between any fibers at time 0 (Table 2). At 4 h, the FOS and inulin both had dropped approximately 3 pH units from baseline (time 0) and were significantly lower than all other fibers. Statistically different, but somewhat higher than FOS and inulin was the fiber blend (pH 6.5), followed by approximately pH neutral values for the outer pea, gum acacia and control. At 8 h, the inulin and FOS continued to have the lowest (and statistically similar) pH, followed by (in increasing pH) fiber blend and gum acacia. Outer pea and control remained approximately pH neutral. By 12 h, FOS and inulin had the lowest (and statistically similar) pH at approximately 5.9 with increased and similar values for the fiber blend and gum acacia (~pH 6.5), followed by the pH neutral outer pea and control. At the end of the 24 h fermentation, the control continued to remain approximately neutral followed by (highest to lowest) outer pea, fiber blend, inulin and gum acacia and FOS.

Total SCFA production (sum of acetate, propionate, and butyrate) from the *in vitro* fermentation is shown in Table 3. At baseline, all fiber samples had similar SCFA values except fiber blend that was 7–10 mmol/L lower than the rest. At 4 h, FOS and inulin had the highest (and similar) SCFA values, whereas gum acacia and outer pea had intermediate concentrations and the control and outer pea fiber had the lowest values. By 8 h, inulin had the highest production that was statistically different from all other fibers. FOS, fiber blend, gum acacia and outer pea had intermediate values with the control the lowest. At 12 h

inulin continued to have the highest SCFA followed by (in decreasing concentration) FOS, gum acacia, fiber blend, control and outer pea. At the conclusion of the fermentation, inulin produced the highest SCFA, but was statistically similar to FOS. Gum acacia produced similar amounts of SCFA as FOS and these were not statistically distinguishable from fiber blend, pea fiber or control.

Proportions of the short chain fatty acids from the *in vitro* fermentation of the fiber blend are presented in Table 4.

Table 4. 24 h Batch *in Vitro* Fermentation of a Blend of Inulin, FOS, gum Acacia, and Pea Fiber: Proportions of Acetate, Propionate, and Butyrate[a,b]

	fiber blend		
time	acetate %	propionate %	butyrate %
0 h	36.2 (0.4) a	32.8 (0.5) a	30.9 (0.4) a
4 h	41.1 (0.4) b	34.9 (0.5) ad	24.0 (0.4) bd
8 h	33.5 (0.4) c	47.1 (0.5) b	19.4 (0.4) c
12 h	33.9 (0.4) ace	42.5 (0.5) c	23.6 (0.4) d
24 h	31.9 (0.4) de	37.4 (0.5) d	30.7 (0.4) a

[a]Values are means (SEM). Acid proportions were compared between time points (within column comparison). Means with no letters in common were significantly different at the 0.05 level after Bonferroni correction. [b]FOS: Fructo-oligosaccharides.

Acetate increased approximately 5% by 4 h but decreased to significantly lower than initial concentrations by 24 h. Propionate increased significantly by almost 15% by 8 h, steadily decreased until 24 h, but still remained above initial values. Butyrate significantly decreased by 10% from 0 to 8 h but increased to levels similar to the initial value by 24 h.

Enteral Nutrition Human Feeding Study. Twenty-four subjects were enrolled, and 20 subjects (10 men, 10 women) completed the study. The mean age, BMI, and habitual diet energy and fiber intake of the women and men did not statistically differ. Overall mean subject age was 25.8 (±9.9 SD) with a BMI of 25.8 (±2.5 SD). Age, BMI and habitual diet energy and fiber intake of the two sequence groups (fiber blend-fiber free vs fiber free-fiber blend) were also compared, and no statistical differences were found. Subject dietary intake is listed in Table 5.

Fecal Acids. Human samples were analyzed for both SCFA and BCFA. Total SCFA refers to total amounts of acetate, propionate, and butyrate. Total BCFA refers to amounts of isobutyrate, isovalerate and valerate. SCFA and BCFA are reported per milliliter of fecal water. Human subject fecal acid content is reported in Table 6.

Total SCFA were approximately 2 times higher during the habitual diet phase than during the formula phases ($p < 0.0001$). Between the formula periods, SCFA on the fiber blend was 1.1% higher than the fiber free formula ($p = 0.029$). Individual SCFA also differed; butyrate proportion was approximately 1.6 times higher in the habitual diet compared to both formulas (both $p < 0.0001$), and 1% higher in the fiber free formula compared to the fiber formula ($p = 0.041$). Propionate was in a lower proportion in habitual diet than both formula diets (both $p < 0.03$), but did not differ between formulas. Acetate was also in a lower proportion during habitual diet than both formulas (both $p < 0.0001$) and did not differ between formulas. Total BCFA were 1% higher in habitual diet compared to the fiber blend formula ($p = 0.046$), but fiber free did not statistically differ from habitual diet or fiber blend formula.

Table 6. Fecal SCFA and BCFA of Human Subjects Consuming Formula and Habitual Diets[a]

	habitual diet	fiber free formula	fiber blend formula
Total SCFA (mmol/L)	80.9 (2.7) a	39.7 (2.3) b	43.5 (2.3) c
Acetate %	39.5 (0.6) a	49.2 (1.0) b	50.2 (0.9) b
Propionate %	29.7 (1.1) a	31.6 (1.3) b	31.5 (1.3) b
Butyrate %	30.7 (1.1) a	19.2 (0.8) b	18.3 (0.8) c
Total BCFA (mmol/L)	11.5 (1.2) a	10.5 (1.1) ab	10.1 (1.1) b

[a]Values are means (SEM). Means with no letters in common were significantly different at $P < 0.05$ within each outcome.

DISCUSSION

Fiber source and structure, as well as the bacterial populations present, affect fiber fermentation patterns in both *in vitro* and *in vivo* models.[2,24] Fermentation leads to the production of acids, which are considered to be a beneficial product of fermentation, but also gas that can lead to reduced tolerance of fiber *in vivo*. Greater gas volume is perceived more in the proximal bowel compared to the distal colon, so rapidly fermented fibers would be expected to cause more gastrointestinal intolerance than those that are more slowly fermented.[25] Human studies have found that dietary supplementation with short chain fibers such as FOS and inulin lead to increased side effects.[26−28] In contrast, complex molecules, such as gum acacia are tolerated at doses up to 40 g/day, and a 1:1 combination of gum acacia and FOS fed to humans led to reduced gastrointestinal side effects than FOS alone.[29,30] Others have reported the use of fiber blends of varying chain length to attenuate gas production *in vitro*.[5,31]

Our results demonstrate similar trends in gas production. Fermentation of soluble shorter chain, single fibers (FOS and inulin) typically led to higher gas production at earlier time points (4 and 8 h). In contrast, gas production was almost

Table 5. Human Subject Diet Characteristics[a]

	fiber (g/day)		protein (g/day)		
	habitual diet[b]	fiber blend formula[c]	habitual diet[b]	fiber blend formula[d]	no fiber formula[d]
Women	16.8 (4.2)	16.2 (1.9)	71.5 (21.4)	73.2 (9.1)	72.4 (9.7)
Men	15.1 (6.5)[e]	21.6 (3.8)[e]	102.4 (27.9)	98.1 (16.3)	102.5 (15.5)
Total	16.0 (5.3)	18.9 (4.0)	89.6 (29.2)	85.6 (18.1)	87.4 (19.9)

[a]Values are means (SD). [b]Habitual diet values were averaged from the 2-day diet records recorded during the run-in and washout periods. Values were generated by entering the diet records into Nutrition Data System for Research (University of Minnesota, Version 2011). [c]Enteral formula fiber intake was calculated from 14-day diet records during the fiber formula period. [d]Enteral formula protein intake was calculated from 14-day diet records during each of the formula periods. [e]In men, fiber intake on habitual diet is different from formula diet ($p = 0.0153$).

undetectable at these time points for the larger and more complex soluble gum acacia, insoluble pea fiber and fiber blend. Pea fiber has been shown to be poorly fermented and would be expected to contribute minimally to gas production.[32] While the fiber blend contains inulin, FOS, and gum acacia that are known to be fermentable, it also contains pea fiber that changed the fermentation pattern as a whole and resulted in delayed gas production until 12 and 24 h. The slower fermentation could lead to improved tolerance *in vivo*, as gas is perceived more in the proximal bowel.[25] The results of the human feeding study were parallel to the *in vitro* gas production from the fiber blend. As published in our previous article,[21] no differences in gas and bloating were detected between any diets. This result suggests that the fiber blend did not induce symptoms beyond subject's normal levels and was well tolerated at the dose delivered.

In general, *in vitro* pH changes were consistent with changes in gas production. pH values were lower at earlier time points for substrates comprised entirely of rapidly fermented, short chain fructans (FOS, inulin). A similar *in vitro* study found the greatest decrease in pH for FOS and inulin after 8 h fermentation, which is consistent with our results.[31] In agreement with a more gradual fermentation, the addition of higher molecular weight molecules resulted in a delayed decrease in pH. As a single source, gum acacia maintained a relatively high pH until 24 h, after which it decreased to values lower than other single fiber treatments. Similarly, the blend had a significantly lower pH than the control and pea fiber that can be attributed to delayed fermentation of the gum acacia fraction of the blend. For reference, fecal pH of the human samples was statistically lower during habitual diet period (pH 6.5) than both formula periods (pH 7.5).[21]

In vitro total SCFA production followed a similar pattern as gas and pH, although significant differences between treatments were more difficult to detect due to high standard errors. Among the single fiber treatments, total SCFA levels were higher at early time points for inulin and FOS compared to gum acacia and pea fiber. Later in the fermentation, total levels were difficult to statistically distinguish, but inulin produced the greatest SCFA levels overall. Since SCFAs are a product of fermentation, these results are consistent with rapid fermentation of short chain molecules, and more gradual fermentation of fibers with higher molecule weight.[32] More gradual fermentation may translate into increased SCFA production throughout the entire colon, which may have additional health benefits.[33]

In vivo SCFA are more complex. Absorption of SCFA is thought to occur via ionic exchange and nonionic diffusion and in human rectal studies, absorption rates can be manipulated by changing electrolyte composition.[34] Furthermore, in an animal model, acetate absorption rates increased with increasing concentration.[35] Fecal SCFA, then, reflect residual SCFA after both production and absorption with potentially differing rates depending on concentration. Fecal SCFA of the subjects on habitual diet was approximately 2 times higher than both of the formulas, although it should be noted that the whole gut transit times were approximately 1.5 times longer on the formula diet versus the habitual diet (data not shown). Longer transit times may influence SCFA and water absorption.[36] Furthermore, the types of fiber from habitual diet likely differed from the fiber blend. Between formulas, the fiber blend formula may have had increased SCFA concentration compared to the fiber free formula due to more substrate present, but because concentration may influence absorption, it is difficult to make a conclusion. Similarly, it is difficult to draw conclusions regarding the proportions of SCFA measured in the fecal samples since differences may be due to production or absorption.

Differences also existed between the *in vitro* and *in vivo* SCFA proportions for the fiber blend. *In vivo* proportions of SCFA on the fiber blend formula yielded much higher concentrations of acetate (50%) and low butyrate (18%), whereas after a 24 h fermentation of the fiber blend in the *in vitro* system, propionate was the highest (37%) with other acid concentrations in similar concentrations (varying from propionate by approximately 6%). Differences may be due to different *in vitro* vs *in vivo* fecal donors as well as the absorption in the *in vivo* study. A more clear comparison would have been possible with the same donors for both portions, although varying absorption and transit times would confound the comparison.

BCFA, although not directly detrimental, reflect a process that also produces undesirable metabolites. Measured levels of BCFA were the highest on habitual diet despite similar protein intakes between the habitual and formula diets. Between the two formulas, it was surprising that the fiber free formula diet did not have higher BCFA since the diet was devoid of fiber and the only substrates reaching the colon would be undigested formula, endogenous mucus, sloughed off cells, and digestive secretions.[2] Although these substances would also be present during the fiber containing formula, carbohydrate fermentation is preferred over protein and it was hypothesized that BCFA would be found in lower amounts.[3] A possible explanation is that the SCFA and BCFA produced were almost completely absorbed and the residual amounts reflected equilibrium concentrations. Whether residual values are useful in evaluating *in vivo* fermentation is unclear.

Overall, the fermentation of fibers with a range of physicochemical properties yielded differing profiles of pH, gas and SCFA. By blending insoluble and soluble fibers, an intermediate fermentation profile was observed when fed to healthy human subjects. During the human intervention study, fecal SCFA was increased on the fiber containing formula compared to the fiber free that may have indicated increased fermentation in the gut. Although not directly comparable, *in vitro* and *in vivo* models provide complementary information on fermentation in the gut.

MATERIALS AND METHODS

General Apparatus and Chemicals. NMR spectra were recorded on a Bruker AM500 instrument (^{1}H NMR at 500 MHz, ^{13}C NMR at 125 MHz, Billerica, Massachusetts, U.S.A.). Electron ionization (EI) and EI-high resolution (HR) mass spectra were obtained on a JEOL JMS-700 instrument (JEOL Ltd., Tokyo, Japan). Optical rotations were measured on a Perkin-Elmer 343 polarimeter (Perkin-Elmer, Bridgeport, U.S.A.). Melting points were measured on a Thomas Scientific Capillary Melting Point Apparatus and are uncorrected. Column chromatography was performed on RP-18 (ODS-AQ, 25 and 10 μm, YMC, Kyoto, Japan). Thin layer chromatography (TLC) was done on precoated TLC plates with silica gel 60 F_{254} (0.25 mm, normal phase, Darmstadt, Merck). These were visualized using a UVGL-58 254 nm Hand-held UV lamp (UVP, Cambridge, U.K.) or by spraying with 10% H_2SO_4 in ethanol followed by heating. CD_3OD, acetone-d_6, and $CDCl_3$ were purchased from Cambridge Isotope Lab. Inc., (MA, U.S.A.). CH_3CN (HPLC grade) and water were purchased from J.T. Baker (U.S.A.). Equine serum BChE (esBChE), *Electrophorus electricus* AChE (eeAChE), human erythrocyte AChE (hAChE), acetylthiocholine iodide (AtCh), butyrylthiocholine iodide (BtCh), 5-5′-dithiobis(2-nitrobenzoic acid) (DTNB), NaH_2PO_4, Na_2HPO_4, and DMSO were purchased from Sigma-Aldrich Co., U.S.A. All solvents were distilled before use.

Plant Materials. *G. mangostana* (Clusiaceae) [imported from Vietnam, as permitted by Korea Food and Drug Administration (KFDA)] was purchased from LanSea Food Co., Ltd. (www.lansea.co.kr, Seoul, Korea).

UPLC-PDA-QTOF-MS Analysis. The chloroform extracts were analyzed by UPLC PDA QTOF-MS. Chromatographic separations were performed on a 2.1 × 100 mm, 1.7 μm ACQUITY BEH C18 chromatography column. The column temperature was maintained at 35 °C, and the mobile phases A and B were water with 0.1% formic acid and acetonitrile with 0.1% formic acid, respectively. The gradient duration program was as follows: 0−1 min, 10% B; 1−12 min, 10−98% B; wash to 13.5 min with 98% B; and a 1.5 min recycle time. The flow rate was 0.4 mL/min.

The mass spectrometer was operated in positive ion mode. N_2 was used as the desolvation gas. The desolvation temperature was set to 350 °C at a flow rate of 500 L/h and source temperature of 100 °C. The capillary and cone voltages were set to 2300 and 35 V, respectively. The Q-TOF premier was operated in the more sensitive "V" mode with 9000 mass resolving power. The data were collected for each test sample from 100 to 1500 Da with a 0.25 s scan time and a 0.01 s interscan delay over a 15 min analysis time. Leucine-enkephalin was used as the reference compound (m/z 554.2615 in the negative mode) and an infusion flow rate of 1 μL/min.

Enzyme Binding Affinity of Cholinesterase. To 75 μL of 100 mM sodium phosphate buffer was added 5 μL cholinesterase (100 U/mL in 100 mM sodium phosphate buffer) and 20 μL of 5 mg/mL $CHCl_3$ extract in MeOH subsequently. The final concentration of extract was adjusted to 1000 ppm. The mixture was incubated for 30 min at 37 °C on a plate shaker. Then, the sample was centrifuged at 12 000 rpm for 10 min and the supernatant was collected for analysis. The supernatant solution was filtered through a membrane (PTFE 0.2 μm, hydrophobic, Advantec, Japan), and 2 μL solutions were injected for UPLC-PDA-QTOF-MS analysis. Control experiment was carried out with the same procedure without enzyme.[16,18]

Cholinesterase Inhibitory Activity. The *in vitro* inhibition assays of BChE (EC 3.1.1.8, 0.05 U/mL) from equine serum, AChE (EC 3.1.1.7, 0.05 U/mL) from electric eel, and human AChE (0.25 U/mL) were run in sodium phosphate buffer 100 mM, pH 8.0 (reaction buffer). AtCh and BtCh were used, respectively, as substrates, and DTNB was used as the chromophoric reagent.[19] Inhibition assays were carried out on a SpectraMax M2Multi-Mode Microplate Reader (Molecular Devices, CA, U.S.A.) equipped with a 10.0 mm quartz cell (or plate) and a thermostatted bath. Solutions of tested compounds were prepared starting from 10 mM stock solutions in DMSO, which were diluted into aqueous assay medium to give a final content of organic solvent lower than 1%. hAChE inhibitory activity was determined in a reaction mixture containing 2 μL of a solution of hAChE (0.25 U/mL in 100 mM sodium phosphate buffer, pH 8.0), 30 μL of a 3.3 mM solution of DTNB in 100 mM sodium phosphate buffer (pH 8.0), 10 μL of a solution of the inhibitor (5−10 concentrations ranging from 0.1 to 200 μM), and 138 μL of reaction buffer. After incubation for 10 min at 37 °C, ACh (20 μL of 1 mM aqueous solution) was added as the substrate, and hAChE-catalyzed hydrolysis was followed by measuring the increase of

absorbance at 412 nm for 5.0 min at 37 °C. The concentration of compound that caused 50% inhibition of the hAChE activity (IC_{50}) was calculated by nonlinear regression of the response/log (concentration) curve, using Sigma Plot, version 10.0 (SPCC Inc., Chicago, IL). eeAChE and esBChE inhibitory activities were assessed similarly using acetylthiocholine iodide as the substrate. Kinetic parameters were determined using the Lineweaver−Burk double-reciprocal-plot method at increasing concentrations of substrates and inhibitors.[20] The inhibitor, eserine (Sigma-Aldrich, St. Louis, MO), was used in the assays for comparison.

Fluorescence Quenching Measurements. All fluorescence spectra were measured on a SpectraMax M2Multi-Mode Microplate Reader (Molecular Devices, CA, U.S.A.) equipped with a 10.0 mm quartz cell and a thermostatted bath. In a typical fluorescence measurement, 2 μL of hAChE solution (100 mM sodium phosphate buffer, pH 8.0), 0.25 U/mL, was added to the quartz cell and addition of inhibitor solution (10 μL) to attain final concentrations. Fluorescence spectra of hAChE-xanthone mixture were recorded in the range from 300 to 400 nm. Both slits of excitation and emission were 2 nm with an excitation wavelength at 276 nm.[21−23]

Extraction and Isolation of the Inhibitors from *G. mangostana*. The seedcases of *G. mangostana* (1 kg) were extracted by chloroform for 3 days at room temperature to give crude extract (40 g). Crude extract (10 g) was submitted to MPLC (LC-Forte/R, YMC Korea Co. LTD) reversed phase silica gel (YMC ODS-AQ, 25 μm, 120 g) using a stepwise MeOH−H_2O gradient (10−100% methanol, 10 mL/min, 120 min) to give 60 fractions. This MPLC procedure was repeated four times using the same conditions before further isolation. The bioactive constituents from each MPLC column were eluted as a single, UV-absorbing band and pooled. Fractions 18−25 (8.0 g) were chromatographed on a Sephadex LH-20 column eluted with MeOH and isolated by preparative (prep)-HPLC using a reversed-phase column (1.9 × 25 cm, YMC ODS-AQ, 10 μm particle size), eluted with ACN−H_2O gradient (5−70% ACN, 14 mL/min, 60 min) by repeated injection of 10 mg/mL MeOH dilutions to yield pure **2** (82 mg) and **3** (65 mg). Fractions 26−37 (980 mg) were chromatographed on a Sephadex LH-20 column eluted with MeOH and isolated by prep-HPLC using a reversed-phase column (2.0 × 25 cm, YMC ODS-AQ, 10 μm, 120 g), eluted with MeOH−H_2O gradient (10−80% methanol, 10 mL/min, 60 min) by repeated injection of 10 mg/mL MeOH dilutions to yield pure **5** (11 mg) and a mixture of **6** and **7** (Fr. 26−37-B). Fractions 26−37-B (118 mg) were chromatographed by prep-HPLC using a reversed-phase column [Waters Atlantis T3 column (1.9 × 25 cm, 5 μm particle size), eluted with MeOH−H_2O gradient (5−70% methanol, 60 min) by repeated injection of 10 mg/mL MeOH dilutions to yield pure **6** (48 mg) and **7** (38 mg). Fractions 39−49 (8.7 g), enriched with compound **8**, were purified over a silica gel (10 × 50 cm, 230−400 mesh, 300 g) column using the solvent system hexane−acetone (10−90% acetone, 10 mL/min, 60 min) to afford **8** (1730 mg). All isolated compounds were identified on the basis of the following spectroscopic data (Supporting Information).

Statistical Analysis. All the measurements were made in triplicate. The results were subject to variance analysis using Sigma plot. Differences were considered significant at $p < 0.05$.

RESULTS AND DISCUSSION

The extracts from different polar solvents ($CHCl_3$, EtOH, and H_2O) were tested for enzymatic inhibitory activities against ChEs. The high potency of the chloroform extract (IC_{50} = 2.7 μg/μL, hAChE) encouraged us to identify the compounds responsible for its ChEs inhibition. Protein binding affinity can be used to identify inhibitors of a particular enzyme. This is because, for inhibition to occur, an enzyme inhibitor complex

(Inset) Insets I and II represent the secondary plot of the slope and the intercept of the straight lines versus concentration of compounds (**6** and 7), respectively.

must form. Herein small molecules within the extracts of mangosteen seedcases that bind to cholinesterase were identified by assessing which compounds were lost from the crude extract upon incubation with the enzyme. The binding event was assessed using an experimental set up involving an initial incubation step (1000 ppm extracts with 0.5 U enzyme), followed by centrifugation, and finally analysis of the flow through (i.e., fraction not bound by the enzyme) using UPLC-

dx.doi.org/10.1021/jf405072e | J. Agric. Food Chem. 2014, 62, 1338−1343

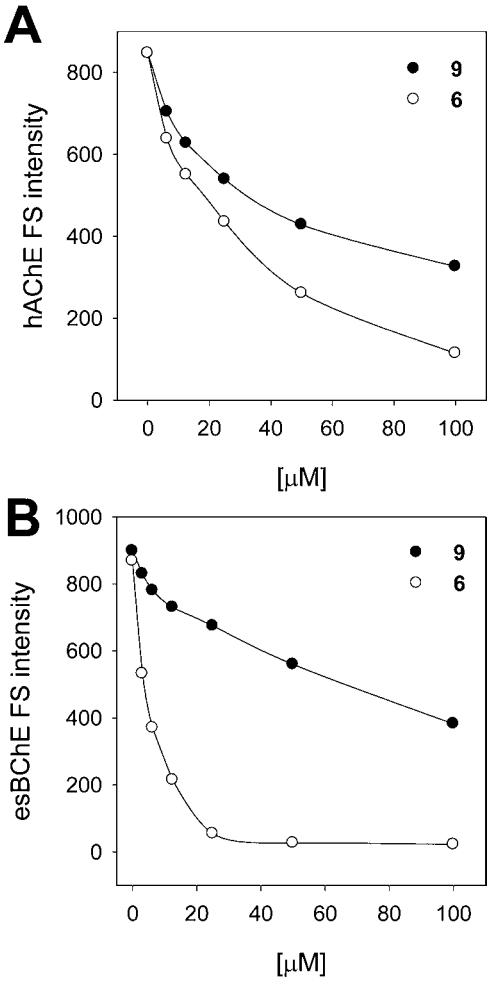

Figure 4. (A, B) Effect of compounds **6** and **9** on intrinsic fluorescence of hAChE. Measurement conditions: xanthonoids (**6** and **9**) concentrations were at 0, 6.25, 12.5, 25, 50, and 100 μM, respectively. [hAChE] = 0.25 units, [esBChE] = 0.05 units, pH 8.0, at 37 °C, λ_{ex} = 276 nm, λ_{em} = 305 nm.

PDA-QTOF-MS. By comparing the UPLC traces from experiments carried out in the presence and absence of enzyme, peaks that were reduced when the enzyme was present were correlated with compounds that bind the enzyme. Representative UPLC-PDA chromatograms of extracts are shown in Figure 1A. The peak areas of six compounds (**2**, **3**, and **5**−**8**) within the chloroform extract of mangosteen were significantly reduced upon treatment with hAChE (blue) and esBChE (red). This result indicates that six compounds, corresponding to peaks (**2**, **3**, and **5**−**8**) have significant interaction with both ChEs. Importantly, the extent to which the peak areas were reduced did not correlate with peak size (for instance **1** and **2** have similar sizes but **2** was reduced by approximately 100% whereas **1** had a very small depletion). This indicates binding is dictated by affinity rather than bulk concentration.

UPLC-PDA-QTOF-MS analyses were carried out using a C18 column with a linear gradient of acetonitile/water. As presented in Figure 1A, complete chromatographic separation of xanthonoids (**1**−**10**) was achieved within 15 min. Each peak was characterized using MS. The exact molecular ions $[M+H]^+$ of peaks (**1**−**10**) were 425, 427, 425, 409, 327, 397, 381, 411, 409, and 425. Table 1 shows UV−vis absorption maxima, retention times, and mass spectral data of molecular ions of xanthonoids in comparison with previously published data.[11,12,24] Thus, peaks (**1**−**10**) were identified as mangostingone (**1**, peak 1), mangostanol (**2**, peak 2), allznxanthone E (**3**, peak 3), mangostenone F (**4**, peak 4), gudraxanthone (**5**, peak 5), γ-mangostin (**6**, peak 6), 8-deoxygartanin (**7**, peak 7), α-mangostin (**8**, peak 8), 9-hydroxycalabaxanthone (**9**, peak 9), and β-mangostin (**10**, peak 10). We next isolated the six active compounds using chromatography over octadecyl-functionalized silica gel. The isolated compounds were fully characterized with spectroscopic data including 2D-NMR. The representative xanthone **6** was obtained as a yellowish powder having molecular formula $C_{23}H_{24}O_7$ and 12 degrees of unsaturation, as established by high-resolution electrospray ionization mass spectrometry (HRESIMS) (m/z 397.1637 $[M+H]^+$, calcd for $C_{23}H_{25}O_6$, 397.1573). ^{1}H and ^{13}C NMR data in combination with molecular formula indicated a tricyclic skeleton with two aromatic rings, corresponding to a xanthone. Two prenyl appendages were identified by successive connectivities in the COSY spectrum. HMBC correlations of H-11 (δ_H 3.21) with C-2 (δ_C 112.6) and of H-16 (δ_H 4.03) with C-8 (δ_C 129.5) unveiled that these prenyl chemotypes were situated on C-2 and C-8 (Supporting Information). Thus, compound **6** was confirmed to be γ-mangostin (Figure 1B).

The purified compounds were next assayed for inhibition of hAChE. Eserine, a known ChE inhibitor, was used as a positive control.[25] Xanthonoids (**2**, **3**, and **5**−**8**) showed dose-dependent inhibitory effects against hAChE, with IC_{50} values ranging between 5.4 and 15.0 μM (Table 2). Consistent with the amount of reduction of intensity in the UPLC assay, there was a significant difference in inhibitory potencies of the strong binding compound set (**2**, **3**, and **5**−**8**, IC_{50}s = 5.4−15.0 μM) and the weaker binding compound **9** (peak 9, IC_{50} > 100). This indicates that hAChE binding affinity facilitates ranking of inhibitors of hAChE in a complex mixture. Our compounds feature at least one prenyl group. According to a previous study, parent compound, 1,3,5,6-tetrahydroxyxanthone, showed very low efficacy (IC_{50} > 200 μM) toward AChE.[26] Thus, prenyl appendages within the isolated active compounds appear to play a pivotal role in the inhibition of cholinesterase. All inhibitors showed a similar relationship between enzyme activity and concentration. The inhibition of hAChE (K_m = 0.1 mM) by compound **6**, the most potent inhibitor (K_i = 5.1 μM) is illustrated in Figure 2, representatively. Increasing the inhibitor concentration resulted in lowering of the slope of the line (Figure 2A). The plots of residual enzyme activity versus enzyme concentration at different concentrations of compound **6** gave a family of straight lines with a y-axis intercept indicating that **6** is a reversible inhibitor (Figure 2B). The enzyme inhibitory properties of target compound **6** were modeled using double reciprocal plots (Lineweaver−Burk and Dixon analysis). The results show a family of lines with common intercept on the left of the vertical axis and above the horizontal axis (Figure 2C and D). This implies that increasing inhibitor concentration leads to a decrease in V_{max} and an increase in K_m, indicating that compound **6** was a mixed-type inhibitor.[20] The K_i values of all compounds were measured by Dixon plot (Table 2). On the other hand, as illustrated in Table 2, the isolated six xanthones (**2**, **3**, and **5**−**8**) were found to exhibit a significant degree of esBChE inhibition with IC_{50} values ranging between 0.7−11.0 μM. These compounds were also mixed inhibitors of this enzyme (Figure 2C and D, and Figure 3).

The binding affinities of the purified inhibitors to ChEs were measured by monitoring quenching of intrinsic protein

fluorescence. hAChE has high intrinsic fluorescence arising from 14 Trp, 17 Tyr, and 30 Phe.[21] The quenching of the intrinsic fluorescence of hAChE by compounds **6** and **9** is displayed in Figure 4. A dramatic difference in fluorescence quenching was observed between **6** and **9**: hAChE **6** (IC_{50} = 5.4 μM) versus **9** (IC_{50} > 100 μM); esBChE **6** (IC_{50} = 0.7 μM) versus **9** (IC_{50} = 86.3 μM). This is in agreement with the affinity difference between both compounds observed in the UPLC-PDA chromatogram (Figure 1, peaks 6 and 9).

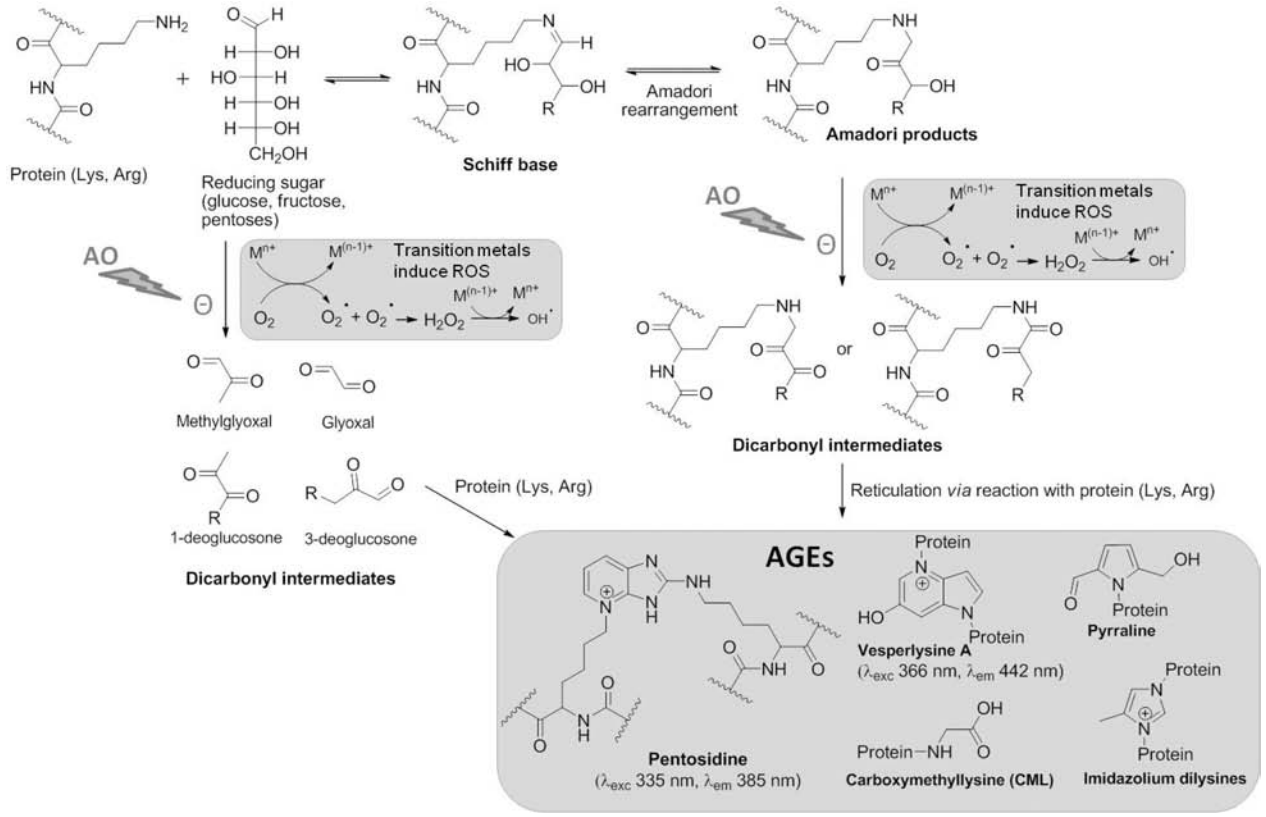

Figure 1. Schematic formation of AGEs. AGEs inhibitors may follow different inhibition pathways in order to prevent AGEs formation. For exemple, they can prevent glycation via reaction with free amino groups in proteins or carbonyl groups on reducing sugars. In addition, compounds with antioxidant (AO) properties (free radical scavengers or transition metal chelators) may reduce reactive oxygen species (ROS). Finally, they can also scavenge α,β-dicarbonyl intermediates or break them (AGEs breakers) [adapted from Ahmed, 2005[8]].

from different places in France (Figure 2) were homogeneously mixed to undergo this study. For the same reason, various

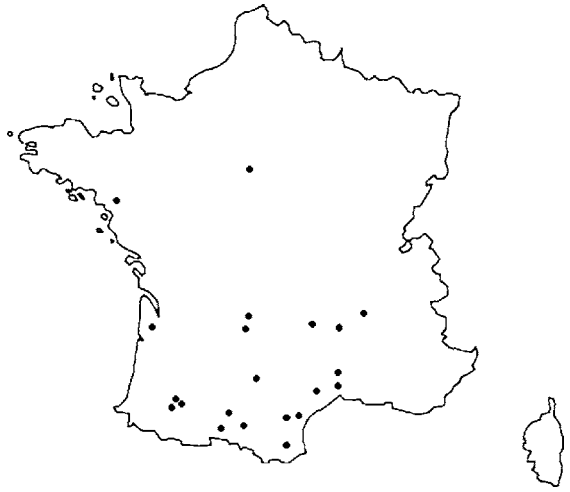

Figure 2. Collection sites of French propolis samples.

extracts using different solvents or mixtures of solvents were prepared in order to find the more appropriate extraction conditions.

MATERIALS AND METHODS

Chemicals. 1,1-Diphenyl-2-picrylhydrazyl (DPPH), aluminum chloride hexahydrate, Folin−Ciocalteu reagent, potassium acetate, 2,4-dinitrophenylhydrazine, formic acid, gallic acid, quercetin, naringenin, *p*-coumaric acid, ferulic acid, isoferulic acid, 3,4-dimethoxycinnamic acid, prenyl caffeate, bovine serum albumin (BSA, fraction V), potassium phosphate monobasic, potassium phosphate dibasic trihydrate, sodium azide, aminoguanidine hydrochloride, all of analytical grade, were purchased from Sigma-Aldrich (St Quentin Fallavier, France). 2,2′-Azobis (2-methylpropionamidine) dihydrochloride (AAPH), fluorescein (FL), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 5′-caffeoylquinic acid (chlorogenic acid), caffeic acid, and chrysin were obtained from Acros Organics (Geel, Belgium). Ribose was from Alfa Aesar (Schiltigheim, France). Galangin was purchased from Extrasynthese (Genay, France), and caffeic acid phenylethyl ester was purchased from Tocris biosciences (Bristol, United Kingdom). Pinocembrin, pinobanksin-3-acetate, and pinostrobin were isolated from the DCM extract of propolis.

Propolis Batch. A batch (240 g) corresponding to 24 propolis samples (10 g of each), collected in 2010 and 2011 in apiaries originating from different regions of France was used for this study. This batch was provided by the "Ballot-Flurin Apiculteurs" company, specialized in organic beekeeping. The different collection sites of propolis samples are given in Figure 2.

Instrumentation. NMR spectra (1D and 2D) were recorded on a Bruker (Wissembourg France) Avance spectrometer at 500 MHz for ^{1}H and 125 MHz for ^{13}C. Absorbances were obtained from a Tecan (Lyon, France) Infinite M200 microplate spectrophotometer.

dx.doi.org/10.1021/jf4053397 | J. Agric. Food Chem. 2014, 62, 1344−1351

Extractions. The propolis batch was homogeneously pulverized in the presence of liquid nitrogen and divided into 1 g samples. Four different extractions were then carried out on 1 g samples with water (E1), 95% EtOH (E2), 70% EtOH (E3), and MeOH (E4). Then, two extractions, preceded by a cyclohexane wax elimination, were independently performed on 1 g samples with DCM (E5) and a mixture of DCM, MeOH, and H_2O (31/19/4) (E6). For E1, a decoction of 1 g of propolis powder was boiled in 20 mL H_2O at 100 °C for 15 min. After the samples were cooled, the solidified wax and the residue were removed by filtration, and the filtrate was concentrated. For other solvents, 1 g of propolis powder (or of residue issued from a previous extraction) was macerated in 3 × 20 mL of solvent. After stirring for 3 × 2 h at room temperature, the mixture was filtered. The filtrates were gathered and evaporated under vacuum.

Total Polyphenol Content. Total polyphenol content was determined according to the Folin−Ciocalteu colorimetric method.[15] Briefly, 20 μL of extract solution (2.5 mg/mL in MeOH) were mixed with 280 μL of distilled water and 100 μL of Folin−Ciocalteu's phenol reagent. After 3 min, 1200 μL of distilled water and 400 μL of 20% aqueous sodium carbonate solution were added. Aliquots (200 μL) of each solution were distributed in a 96-well microtiter plate. The absorbance was measured at 760 nm after 30 min in the dark at room temperature. A blank was prepared in the same way by using MeOH instead of the extract solution. Gallic acid was used to calculate the calibration curve (0.4−1.2 mg/mL; $y = 0.5800x$; $r^2 = 0.9941$), and total polyphenol contents were expressed in terms of gallic acid equivalent (mg) per gram of extract (mg GAE/g). All measurements were performed in triplicate.

Flavone and Flavonol Content. Flavone and flavonol content was determined according to the aluminum chloride colorimetric method described by Woisky and Salantino.[16] Three hundred microliters of 95% EtOH was mixed with 100 μL of extract solution (1.5 mg/mL in EtOH 80%), 20 μL of 10% aqueous aluminum chloride solution, 20 μL of 1 M potassium acetate aqueous solution, and 560 μL of distilled water. Two hundred microliters of each solution was put into the 96-well microtiter plate. After the samples were incubated at room temperature for 30 min, the absorbance was measured at 415 nm. The amount of 10% aqueous aluminum chloride solution was replaced by the same amount of distilled water in blank for each extract solution. Quercetin, used as standard, was prepared at concentrations of 25−200 μg/mL to build the calibration curve ($y = 2.7677x$; $r^2 = 0.9988$). Flavone and flavonol content were expressed as mg QE/g (quercetin equivalent per gram of extract). All assays were performed in triplicate.

Flavanone and Dihydroflavonol Content. The modified method described by Nagy and Grancai[17] was used to determine flavanone and dihydroflavonol content. Briefly, 500 μL of extract solution (2.5 mg/mL in MeOH) was reacted with 250 μL of MeOH and 500 μL of 1% 2,4-dinitrophenylhydrazine (DNP) solution (500 mg of DNP mixed with 1 mL of 96% sulfuric acid and diluted to 50 mL with MeOH) at 50 °C for 50 min. After the solution was cooled, 500 μL of the solution were mixed with 500 μL of 20% potassium hydroxide in 70% EtOH and then centrifuged at 4000 rpm for 10 min to remove the precipitate. Twenty microliters of the supernatant was collected, put into the 96-well microtiter plate, and mixed with 180 μL of 1% potassium hydroxide methanolic solution. Absorbance was measured at 495 nm. A blank was prepared using the same amount of MeOH instead of the extract solution. Standard solutions of (+)-naringenin (0.25−2.00 mg/mL in MeOH) were used to build the calibration curve ($y = 0.2053x$; $r^2 = 0.9945$). Flavanone and dihydroflavonol content was calculated as mg NE/g (naringenin equivalent per gram of extract). All measurements were performed in triplicate.

HPLC-DAD and HPLC-MS Procedures. Five milligrams of propolis extracts dissolved in 1 mL of MeOH were centrifuged at 13000 rpm for 10 min and filtered through a 0.2 μm nylon-membrane syringe filter prior to injection (10 μL). Analytical HPLC was run on a 2695 Waters (Guyancourt, France) separation module equipped with a diode array detector 2996 Waters. Separation was achieved on a Phenomenex (Le Pecq, France) Luna column 3 μm C18 100A (150 × 4.6 mm i.d., 3 μm) protected with a Phenomenex SecurityGuard cartridge C18 (4 × 3 mm i.d.) at a flow rate of 0.4 mL/min. The mobile phase consisted of 0.1% formic acid in water (solvent A) and 0.1% formic acid in MeOH (solvent B). The separation was performed using the following gradient: 40% B (0−10 min), 40−50% B (10−25 min), 50−60% B (25−55 min), 60−90% B (55−70 min), 90% B (70−80 min). UV detection and quantification were achieved at two wavelengths: 254 and 280 nm. The mass analyses were performed on a Bruker (Bremen, Germany) ESI/APCI Ion Trap Esquire 3000+ in both, positive and negative modes, with the conditions as follows: collision gas, He; collision energy amplitude, 1.3 V; nebulizer and drying gas, N2, 7 L/min; pressure of nebulizer gas, 30 psi; dry temperature, 340 °C; flow rate, 1.0 mL/min; solvent split ratio 1:9; scan range, m/z 100−1000.

Quantification of 12 Compounds by HPLC/DAD. MeOH stock solutions of 12 major compounds chosen as markers for this quantification analysis were prepared as follows: caffeic acid (0.5 mg/mL), *p*-coumaric acid (0.5 mg/mL), ferulic acid (0.3 mg/mL), isoferulic acid (0.3 mg/mL), 3,4-dimethoxycinnamic acid (0.3 mg/mL), pinocembrin (0.8 mg/mL), pinobanksin-3-acetate (1.0 mg/mL), prenyl caffeate (0.4 mg/mL), chrysin (0.8 mg/mL), caffeic acid phenylethyl ester (CAPE) (0.3 mg/mL), galangin (0.6 mg/mL) and pinostrobin (0.2 mg/mL). Stock solutions were diluted (3/4, 1/2, 1/4, 1/8, 1/16) and used to determine the calibration curves of the 12 markers ($n = 2$): caffeic acid ($y = 78{,}027x$; $r^2 = 0.9999$), *p*-coumaric acid ($y = 113{,}20x$; $r^2 = 0.9999$), ferulic acid ($y = 78{,}364x$; $r^2 = 0.9999$), isoferulic acid ($y = 103{,}68x$; $r^2 = 0.9998$), 3,4-dimethoxycinnamic acid ($y = 77{,}748x$; $r^2 = 0.9998$), pinocembrin ($y = 54{,}982x$; $r^2 = 0.9998$), pinobanksin-3-acetate ($y = 49{,}022x$; $r^2 = 0.9994$), prenyl caffeate ($y = 60{,}462x$; $r^2 = 0.9987$), chrysin ($y = 100{,}4x$; $r^2 = 0.9998$), CAPE ($y = 43{,}434x$; $r^2 = 0.9996$), galangin ($y = 48{,}653x$; $r^2 = 0.9984$) and pinostrobin ($y = 93{,}633x$; $r^2 = 0.9995$). All propolis extracts (E1 to E6) were analyzed in triplicate.

Fractionation by Flash Chromatography. Fifty grams of the propolis mixture was extracted with cyclohexane (3 × 200 mL, 2 h, room temperature) to remove beewax. Then, the residue was extracted with DCM (5 × 200 mL, 2 h, room temperature), filtered, and concentrated to give 25.0 g of DCM extract (50% yield). Twenty-one grams of DCM extract was dissolved in 200 mL of DCM, mixed with 42 g of silica gel (extract/silica gel: 1/2), and concentrated to obtain a dry thin powder. Fractionation was performed using a CombiFlash Teledyne ISCO (Lincoln, NE, U.S.A.) apparatus, on a prepacked silica gel column (Interchim PF-50SI HC/300g, 50 μm, 20 bar) at a flow rate of 100 mL/min with the following gradient: 100% C_6H_{12} (2.0 L), C_6H_{12}:EtOAc 90:10 (1.7 L),

Table 1. Extraction Yield, Total Polyphenol (TP), Flavone/Flavonol (FF), and Flavanone/Dihydroflavonol (FD) Contents of French Propolis Extracts (E1−E6)

extract	solvent	extraction yield (%)	TP[a] (mg GAE/g)	FF[b] (mg QE/g)	FD[c] (mg NE/g)
E1	H_2O	6.9 ± 0.4	292.1 ± 13.1	20.5 ± 1.2	76.6 ± 7.7
E2	EtOH	68.4 ± 0.8	253.6 ± 5.1	67.0 ± 2.6	153.1 ± 2.5
E3	70% EtOH	65.3 ± 1.5	246.3 ± 10.6	69.3 ± 3.7	158.6 ± 8.5
E4	MeOH	67.3 ± 0.4	238.6 ± 13.3	66.4 ± 4.9	156.8 ± 3.1
E5	DCM	50.3 ± 0.5	273.5 ± 6.8	78.6 ± 2.7	176.0 ± 9.9
E6	mixed solvents	58.6 ± 0.7	281.0 ± 7.1	80.0 ± 1.2	156.0 ± 10.2

[a]Total polyphenol contents were determined by the Folin−Ciocalteu method. The results are expressed as milligram of gallic acid equivalent per gram of extract. [b]Flavone/flavonol contents were determined by $AlCl_3$ coloration. The results are expressed as milligram of quercetin equivalent per gram of extract. [c]Flavanone/dihydroflavonol contents were determined by the DNP method. The results are expressed as milligram of naringenin equivalent per gram of extract. For all, each value is the mean ± standard deviation (n = 3).

C_6H_{12}:EtOAc 90:10 to 80:20 (2.2 L), C_6H_{12}:EtOAc 80:20 to 70:30 (2.5 L), C_6H_{12}:EtOAc 70:30 to 60:40 (2.2 L), C_6H_{12}:EtOAc 60:40 to 50:50 (3.0 L), and at last DCM:MeOH 96:4 (2.2 L). UV detection, achieved at 254 and 280 nm, allowed us to separate 21 fractions.

Scavenging of DPPH Radicals. The diphenyl-picrylhydrazyl (DPPH) radical scavenging evaluations of propolis extracts were carried out using a modified previously established methodology.[18] Tested compounds and standards were diluted in absolute EtOH at 0.02 mg/mL from stock solutions at 1 mg/mL in DMSO. Aliquots (100 μL) of these diluted solutions were placed in 96-well plates in triplicates. The reaction was initiated by adding 25 μL of freshly prepared DPPH solution (1 mM) and 75 μL of absolute EtOH using the microplate reader's injector (Infinite 200, Tecan, France) to obtain a final volume of 200 μL per well. After 30 min in the dark and at room temperature, the absorbance was determined at 517 nm. EtOH was used as a blank, whereas 10, 25, 50, and 75 μM solutions of Trolox (hydrophilic α-tocopherol analog) were used for the calibration curve. A sample of chlorogenic acid ethanolic solution (0.02 mg/mL) was used as the quality control standard. Results were expressed in terms of Trolox equivalents (micromoles of TE per gram of extract).

Measurement of Oxygen Radical Absorbance Capacity (ORAC). ORAC assays were carried out according to the method described by Huang et al.[19] with some modifications. The assay was performed in a 96-well plate. The reaction mixture contained 100 μL of 75 mM phosphate buffer (pH 7.4), 100 μL of freshly prepared fluorescein (FL) solution (0.1 μM in phosphate buffer), 50 μL of freshly prepared 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH) solution (51.6 mg/mL in phosphate buffer), and 20 μL of sample per well. Samples were analyzed in triplicate and diluted in phosphate buffer at different concentrations (25, 12.5, 6.25, and 3.12 μg/mL) from stock solutions at 1 mg/mL in DMSO. FL, phosphate buffer, and samples were preincubated at 37 °C for 10 min. The reaction was started by the addition of AAPH using the microplate reader's injector (Infinite 200, Tecan, France). Fluorescence was then measured and recorded during 40 min (λ_{exc} 485 nm, λ_{em} 520 nm). The 75 mM phosphate buffer was used as a blank, and 12.5, 25, 50, and 75 μM solutions of Trolox were used as calibration solutions. A chlorogenic acid solution in phosphate buffer (8.8 μM) was used as quality control standard. The final ORAC values were calculated using a regression equation between the Trolox concentration, and the net area under the FL decay curve and were expressed as micromole of Trolox equivalents per gram of dry matter. Areas under curves were calculated using Magellan data analysis software (Tecan, France).

Determination of Sample Concentrations Inhibiting 50% of AGEs Formation. IC_{50} values were determined using a previously described method[20] with slight modifications. Briefly, BSA (10 mg/mL) was incubated with D-ribose (0.5 M) together with the tested compound (3 μM to 3 mM) or extract (1 μg to 1 mg) in 50 mM phosphate buffer at pH 7.4 (NaN_3, 0.02%). Solutions were incubated in 96-well microtiter plates at 37 °C for 24 h in a closed system before AGE fluorescence measurement. Fluorescence resulting from the incubation, under the same BSA (10 mg/mL) and tested compound (3 μM to 3 mM) or extract (1 μg to 1 mg) conditions, was subtracted for each measurement. A control (i.e., no inhibition of AGEs formation) consisted of wells with BSA (10 mg/mL) and D-ribose (0.5 M). A blank control (i.e., 100% inhibition of AGEs formation) consisted of wells with only BSA. The final assay volume was 100 μL. Pentosidine-like (λ_{exc} 335 nm, λ_{em} 385 nm) AGEs fluorescence was measured using a microplate spectrofluorometer. In this type of automation, a single analysis is sufficient for an accurate IC_{50} determination.[20,21] The percentage of AGEs formation was calculated as follows for each compound/extract concentration:

$$\text{AGEs}(\%) = \frac{\text{fluorescence intensity(sample)} - \text{fluorescence intensity(blank of sample)}}{\text{fluorescence intensity(control)} - \text{fluorescence intensity(blank of control)}} 100$$

Dose−effect curves were best fitted with a sigmoidal dose−response equation using Sigma Plot 12.0 software, which enabled calculation of the IC_{50} values.

RESULTS AND DISCUSSION

Extraction Yield. As shown in Table 1, the extraction yield of E1 was very low (6.9%), whereas those of the alcoholic extracts E2−E4 were much higher (65−69%). Those of E5 and E6 were, respectively, 50.3 and 58.6% after a prior cyclohexanic extraction, to remove waxes, which exhibited a 33.0% yield. Thus, yields of E2−E4 were higher than those of EtOH extracts of propolis (EEP) collected in Greece and Cyprus (23.9 to 61.2%).[22] These yields were also higher than those observed for 70% EtOH propolis extracts from Bulgaria (58%), Albania (41%), Egypt (18%), Brazil (12−55%)[5], and a MeOH propolis extract from Mexico (40%).[23]

Figure 3. [a]Each value is the mean of triplicate analyses ± standard deviation. N.D. = not detected.

Total Polyphenol Content. Total polyphenol (TP) contents (Table 1) were high for E1−E6, in a range of 238.6 to 292.1 mg GAE/g. This is in accordance with values observed for European and Asian poplar-type propolis (≈200−300 mg GAE/g).[1] Best TP contents were observed for E1, E5, and E6. E2 (253.6 mg GAE/g) had a similar value to EEP from Ukraine (255 mg GAE/g) and United States (256 mg GAE/g) but higher than the ones found in Hungary (242 mg GAE/g), Bulgaria (220 mg GAE/g), Argentina (212 mg GAE/g), Uzbekistan (174 mg GAE/g), Brazil (120 mg GAE/g), South Africa (100 mg GAE/g), and Thailand (31 mg GAE/g).[1]

Flavone/Flavonol and Flavanone/Dihydroflavonol Contents. As indicated in Table 1, E1 showed the lowest flavone/flavonol (FF) and flavanone/dihydroflavonol (FD) contents (respectively, 21 mg QE/g and 77 mg NE/g), whereas FF contents of the other extracts were in a range of 66−80 mg QE/g and FD contents in a range of 153−176 mg NE/g, E5 and E6 showing the best values. For all extracts, FD was superior to FF contents. Alcoholic extracts E2−E4 had similar values (66−69 mg QE/g for FF and 153−159 mg NE/g for FD contents), which appeared superior to those of propolis from Northeastern Spain (≈48.2 mg/g for FF and 78.8 mg/g for FD).[2] They seem closer to those of EEP from Pueblo de Alamos in Northwestern Mexico (57.8 mg/g for FF and 150.6 mg/g for FD content.[24] Nevertheless, FF and FD contents of E2−E4 differed from those of Italian and Swiss 70% EtOH propolis extracts where FF > FD.[25]

Identification of Components by HPLC Analysis with DAD and MS Detection. Figure 3 shows the HPLC chromatograms of E1 and E5, the profiles of E2−E4 and E6

Table 3. Antioxidant and Anti-AGEs Activities of Propolis Extracts (E1−E6)

extract/compd	solvent	DPPH[a] (μmol TE/g)	ORAC[a] (μmol TE/g)	anti-AGEs[b] IC_{50} (mg/mL)
E1	H_2O	1731 ± 28	9722 ± 273	0.34
E2	EtOH	1605 ± 26	8155 ± 114	0.05
E3	70% EtOH	1650 ± 149	9890 ± 480	0.03
E4	MeOH	1386 ± 171	7769 ± 360	0.03
E5	DCM	1437 ± 105	9242 ± 739	0.03

propolis (Greece)[c]	EtOH	1110 ± 70	N.D.	N.D.
propolis (Colombia)[d]	EtOH	190	1965	N.D.
E392[e]	EtOH	591 ± 20	2433 ± 88	0.60
S. japonicum[f]	EtOH	1714 ± 68	7896 ± 711	0.09
chlorogenic acid		2740 ± 64	11289 ± 531	0.04
quercetin		6723 ± 66	13907 ± 662	0.06

[a]DPPH and ORAC results are expressed as micromoles of Trolox equivalent per gram of extract. For both, each value is the mean ± standard deviation ($n = 3$). [b]Anti-AGEs activity is evaluated by the half maximal inhibitory concentration (IC_{50}) expressed as milligram per milliliter (mg/mL) ($n = 1$). [c](Kalogeropoulos et al., 2009). [d](Rodríguez et al., 2012). [e]*Rosmarinus officinalis*. [f]*Styphnolobium japonicum*. N.D. = not determined.

(not shown) being very similar to E5. As expected with differences in solvent polarities, we observed two profile types: the aqueous type with retention times ranging from 6 to 33 min and the organic one, with retention times of most compounds ranging from 10 to 72 min. Chemical profiling was achieved by comparison with literature data (UV/MS), using pure standards or, when needed, after isolation through ^1H and ^{13}C (1D and 2D) NMR analysis. These studies allowed us to identify 40 compounds as benzaldehyde, benzoic, and cinnamic acid derivatives and their ester, glycerols, and different classes of flavonoids (flavones, flavonols, flavanones, and dihydroflavonols). E1 contained benzaldehyde and benzoic acid derivatives (**1**, **3**−**5**, **9**), cinnamic acid derivatives (**2**, **6**−**8**, **10**, **12**, **13**) and some flavanones/dihydroflavonols (**11**, **14**, **15**). E5 exhibited the same compounds, in less quantities, added with cinnamylidene acetic acid **19**, cinnamic ester derivatives (**23**, **24**, **27**, **29**, **31**, **32**, **34**, **35**, **38**−**40**), glycerol derivatives (**16**, **25**), and other flavonoids, as flavanones/dihydroflavonols (**21**, **22**, **26**, **33**, **36**), flavones/flavonols (**17**, **18**, **20**, **28**, **30**, **37**). So, mainly exhibiting cinnamic acid derivatives (caffeic and *p*-coumaric acids...) and their esters (prenyl caffeate, CAPE...), and flavonoids (pinocembrin, pinobanksin-3-acetate, chrysin, galangin...), this French propolis clearly belongs to the poplar type with polyphenols originating from *Populus* spp. of section *Aigeiros* and especially *P. nigra* L.[7,26]

Quantification of 12 Major Compounds. Results of the quantitative analysis of E1−E6 are given in Table 2. As already outlined in Figure 2a, E1 contained mainly phenolic acids with a majority of caffeic **2** and *p*-coumaric **6** acids with 76.9 ± 0.6 and 61.4 ± 0.3 mg/g, respectively. In E2−E6, pinobanksin-3-acetate **28** appeared as the major component, followed by pinocembrin **25**, chrysin **32**, galangin **34**, and prenyl caffeate **29**. Taken as a whole, the higher cumulative amount of these 12 components was observed for E5 with 271.6 ± 3.5 mg/g, whereas the lowest indexes were associated with E4 and E1 (186 and 185.3 mg/g, respectively). For the aqueous extract (E1), it can be noticed that this amount corresponded to only five detectable markers (phenolic acids). Therefore, the quantification results were in accordance with our total polyphenol and flavonoid contents (Table 1). The same three major compounds were also observed in different proportions with poplar type propolis from China (chrysin ≫ pinocembrin > pinobanksin-3-acetate), Hungary (chrysin ≫ pinobanksin-3-acetate > pinocembrin), and Uruguay (pinobanksin-3-acetate > chrysin > pinocembrin).[1]

Antioxidant and Anti-AGEs Activities. AO and anti-AGEs activities observed for E1−E6 are shown in Table 3. E1−E6 are compared with specific references (extract or pure compounds) on the one hand and literature data on the other hand. E392 is an ethanolic rosemary extract used as an AO food additive in Europe (Official Journal of European Union, Directive 2010/67/UE, L 277/17). It should be noticed that, at least in our survey, E392 only showed very weak activities. As expected, E1 exhibited good AO activities but, lacking flavonoids, no real antiglycation potential. At the opposite, E6 showed very good overall activities due to a comprehensive polyphenol extraction. However, as far as anti-AGEs activity was concerned, similar results were obtained with E3−E5. Therefore, from a food additive point of view, a mother tincture such as E3, exhibiting fair AO activities associated with a true anti-AGEs potential, appears as quite interesting. According to its very good anti-AGEs activity (IC_{50} = 0.03 mg/mL), combined with the best cumulative content of the 12 quantified markers (272 mg/g), E5 was chosen for a bioguided fractionation by Flash chromatography.

Anti-AGEs Guided Fractionation of E5. Among 21 fractions (F) issued from the flash chromatography, F1−F5 did not exhibit any activity (IC_{50} > 1 mg/mL), whereas the IC_{50} values for F6−21 were in a range of 0.01 to 0.13 mg/mL. Eight fractions showing $IC_{50} \leq 0.04$ mg/mL (namely, F8−F12 and F16−F18, i.e., F8:0.02; F9:0.04; F10:0.01; F11:0.03; F12:0.03; F16:0.03; F17:0.03 and F18:0.04 mg/mL) were then selected for a chemical profiling, and the anti-AGEs activities of purified components were finally achieved (Table 4). The 16 analyzed compounds can be divided into three groups. The first one contained the most active components in our assay, with $IC_{50} \leq$ 0.10 mM (i.e., in decreasing order, pinobanksin-3-acetate **26**, 2-acetyl-1,3-dicoumaroylglycerol **25**, pinobanksin **14**, prenyl caffeate **27** and pinobanksin-5-methyl ether **11**) The second group was composed of moderately anti-AGEs compounds ($0.2 \leq IC_{50} \leq 1.6$ mM) like naringenin **15**, caffeates **24**, **38** and **29**, ferulic and isoferulic acids **7** and **8**, and ester **34**. The last group exibited non active molecules (IC_{50} > 3 mM) like *p*-coumaric and cinnamic acids **6** and **12** as well as chrysin **28**. Thus, among the most active components, three of them were pinobanksin derivatives (flavanones **26**, **14**, and **11**). Besides, a trisubstituted

dx.doi.org/10.1021/jf4053397 | J. Agric. Food Chem. 2014, 62, 1344−1351

Table 4. Anti-AGEs Activities of Compounds Present in the Eight Selected Fractions (with $IC_{50} \leq 0.04$ mg/mL)

compd (no.)	anti-AGEs[a] IC_{50} (mM)	fraction
pinobanksin-3-acetate (**26**)	0.06	F8
2-acetyl-1,3-dicoumaroylglycerol (**25**)	0.07	F17
pinobanksin (**14**)	0.08	F9
prenyl caffeate (**27**)	0.09	F10
pinobanksin-5-methyl ether (**11**)	0.10	F18
naringenin (**15**)	0.2	F11−F12
benzyl caffeate (**24**)	0.4	F11
cinnamyl caffeate (**38**)	0.5	F11
cinnamyl isoferulate (**34**)	0.6	F8
ferulic acid (**7**)	0.7	F16
isoferulic acid (**8**)	0.9	F18
CAPE (**29**)	1.6	F11
p-coumaric acid (**6**)	>3	F16
cinnamic acid (**12**)	>3	F9
chrysin (**28**)	>3	F9

[a]The anti-AGEs activity was evaluated by the means of the half maximal inhibitory concentration (IC_{50}) expressed as millimole of compound per liter (mM) (n = 1). Reference: quercetin IC_{50} = 0.2 mM.

glycerol (**25**) and a prenylated caffeate (**27**) also appeared as good glycation inhibitors.

There is nowadays a growing interest in compounds exhibiting antiglycation combined with antioxidant properties. However, if a fair anti-AGEs activity is expected from any AO compound (Figure 1), the measured effect may be deceptive, at least because glycation spontaneously occurs so that AO must exhibit long lifetimes. Indeed, whereas coincubation of methylglyoxal (MGO) and reduced glutathione or Trolox totally prevents ROS production, it only partially prevents the MGO-induced decrease of brain cell viability.[27] A contrario, an AO synthetic compound such as aminosalicylic acid proved in vitro more effective than aminoguanidine in reducing the antiproliferative effects of both high glucose and BSA-issued AGEs.[28] One may then turn to natural AO, especially in the search for compounds exhibiting low toxicities. As a food ingredient used from ancient times with very high AO activity, it was therefore of great interest to evaluate the antiglycation potential of our propolis batch. Our study actually demonstrates that a mother tincture of propolis such as E3 represents a very good candidate for further food development.

Bioactive compound may also act by blocking the interaction between AGEs and their specific receptors (i.e., RAGEs). As far as neurodegeneration is concerned, it was recently demonstrated that inhibiting the upregulation of RAGEs transcripts, pinocembrin (**22**), a major component in E2−E6 extracts, truly improved cognitive function, preserved the ultrastructural neuropil, and decreased the neurodegeneration of the cerebral cortex in amyloid-β-peptide-treated mice.[29] All in all, a poplar type propolis like this French batch have therefore great potential to be used as food additive to prevent glycoxidation.

aggressive type of lung cancer, and it is unclear whether these properties are conserved in more aggressive lung cancers such as small lung cancer cell types. Additionally, while several mechanisms of action of 6S have been identified, no study has considered the contribution of M2 to the mechanisms of action of 6S in cancer cells. Also, the mechanism of action of 6S *in vivo* remains largely unexplained, especially in light of its quick metabolism. In the present study, we test the hypothesis that the M2 metabolite can account for all or most of 6S bioactivity by activating similar molecular pathways in a determined sequence. We further correlate our findings on both compounds *in vivo* using a mouse xenograft model. Overall, this work describes for the first time that 6S and M2 can activate a similar cascade of pathways, ultimately leading to cancer cell apoptosis. It also demonstrates that the cysteine-conjugated metabolite has a superior *in vivo* cancer chemopreventive potential, in addition to its ability to discriminate between cancer and normal cells.

MATERIALS AND METHODS

Cell Culture and Reagents. A549 cells were cultured in F12K medium (Corning, NY) supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin (Gemini Bio-Products, West Sacramento, CA). Protease and phosphatase inhibitor mix was from Thermo Scientific (Waltham, MA). Antibodies for Western blotting were from Cell Signaling (Danvers, MA). Protein concentrations were determined from cell lysates using a Pierce BCA kit (Thermo Fisher Scientific, Rockford, IL). BrdU (5-bromo-2-deoxyuridine) was from Sigma-Aldrich (St. Louis, MO). Apoptag plus Peroxydase In Situ Apoptosis Detection Kit was from Millipore (Billerica, MA), and the BrdU Immunohistochemistry Kit was from Chemicon International (Temecula, CA).

6S was purified from ginger extract in our laboratory.[12] M2 was synthesized in our laboratory, as previously reported.[29] HPLC-grade solvents and other reagents were obtained from VWR International (South Plainfield, NJ). LC/MS (liquid chromatography/mass spectrometry) grade solvents and other reagents were obtained from Thermo Fisher Scientific (Rockford, IL). Glutathione, sulfatase from *Aerobacter aerogenes*, and β-glucuronidase from *Helix aspersa* were obtained from Sigma Aldrich (St. Louis, MO).

Metabolism of 6S and M2 in A549 and IMR90 Cells. A549 or IMR90 cells (1.0×10^6) were plated in 6-well culture plates and allowed to attach for 24 h at 37 °C in 5% CO_2 incubator. 6S or M2 (in DMSO) was then added to culture media to reach a final concentration of 10 or 20 μM, respectively. At different time points (0, 30, 1, 2, 4, 8 min, and 24 h), 190 μL samples of supernatant were taken and transferred to vials containing 10 μL of 0.2% acetic acid to stabilize 6S, M2, and their respective metabolites. To extract compounds from the culture media, an equal volume of acetonitrile was added to the supernatant samples and these mixtures were centrifuged. The supernatant was harvested and the samples were analyzed by HPLC-ECD as described by us previously.[14]

Determination of Cell Viability. A549 cell viability was determined by a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) colorimetric assay.[30] A549 cells (6000 cells/well) were plated in 96-well microtiter plates and allowed to attach for 24 h at 37 °C and 5% CO_2. 6S or M2 (in DMSO) were added to cell culture medium to desired final concentrations (0−80 μM; final DMSO concentrations for control and treatments were 0.1%). After the cells were cultured for 24 h, the medium was aspirated and the cells were treated with 2.41 mM MTT in fresh media. After incubation for 3 h at 37 °C, the medium containing MTT was removed, 100 μL of DMSO was added to the wells, and the plates were shaken gently for an hour at room temperature. Absorbance values were derived from the plate reading at 550 nm on a Biotek Synergy 2 plate reader (Winooski, VT). The experiment was repeated independently to confirm the results.

Determination of Apoptosis. We used the Cell Death Detection ELISA (Enzyme-linked immunoabsorbant assay) Plus kit from Roche (Mannheim, Germany). A549 cells (10 000 cells/well) were plated in 96-well microtiter plates and allowed to attach for 24 h at 37 °C and 5% CO_2. 6S or M2 (in DMSO) was added to cell culture medium to desired final concentrations (10 or 20 μM; final DMSO concentration for control and treatments was 0.1%). After 24 h, the microplate was centrifuged for 10 min at 1200 rpm, and the supernatant was removed. Then, 200 μL of the lysis buffer was added in each well and the microplate was incubated for 30 min at room temperature. The plate was then centrifuged for 10 min at 1200 rpm and 20 μL of the supernatant was transferred to streptavidin-coated microwells. ELISA assay was performed according to manufacturer's instruction. Absorbance in each well was measured at 405 nm in absorbance units (AU), and the enrichment factor (EF) in small nucleosomes was calculated with the formula $EF = AU_{(treated)}/AU_{(DMSO)}$. The experiment was repeated independently to confirm the results.

Intracellular Glutathione (GSH) Measurement. The total GSH content was measured using a HT Glutathione Assay kit (Trevigen, Galthersburg, MD). Briefly, A549 cells were plated in 60 × 15 mm culture plates and were allowed to attach overnight at 37 °C. Cells were treated with 10 μM M2 and incubated for 0, 2, 4, 8, or 24 h. Cells were harvested and proteins were precipitated with 5% (w/v) metaphosphoric acid. Samples were then processed following the manufacturer's instructions. The measurement of the absorbance of 5-thio-2-nitrobenzoic acid (TNB) at 405 nm was used to quantify glutathione levels in each sample, which was then compared to the standard curve and corrected for protein concentration. The experiment was repeated independently to confirm the results.

For measurement of oxidized glutathione (Glutathione Disulfide or GSSG), samples and GSSG standards were treated with 2 M 4-vinylpyridine (1 μL/50 μL sample) at room temperature for 1 h. 4-Vinylpyridine (Sigma Aldrich, St. Louis, MO) blocks free thiols present in the reaction, consequentially blocking the formation of new GSSG by GSH. The 2 M solution was freshly prepared by diluting 4-vinylpyridine in ethanol in a ratio of approximately 1:3:6. After incubation, samples were processed using the Trevigen kit's protocol and absorbance was measured at 405 nm as described above.

The quantity of reduced cellular glutathione (or GSH) is obtained by subtracting the oxidized samples values from the total glutathione values or: $GSH_{(reduced)} = GSH_{(total)} - GSSG_{(oxidized)}$. Ratios of reduced to oxidized glutathione are shown to further represent cellular redox status after treatment with 6S or M2. The experiment was repeated independently to confirm the results.

Western Blotting. Cell extracts were prepared by incubating cells for 5 min on ice with RIPA (Radio-Immunoprecipitation Assay) buffer (Thermo Fisher Scientific, Rockford, IL) supplemented with a protease and phosphatase inhibitor mix. Cell lysate was then centrifuged at 13 000 rpm at 4 °C for 20 min, and supernatant was harvested for Western blot analysis. Briefly, 30−60 μg of protein extract was separated on a 10−16% polyacrylamide gel and transferred on PVDF (polyvinylidene difluoride) membrane (Biorad, Hercules, CA). Membrane was blocked using a 1% casein solution in Tris-buffered saline-Tween 20 (TBS-T). Primary rabbit antibodies were diluted in blocking solution and incubated with the membrane overnight at 4 °C. After the membrane was washed with 3 changes of TBS-T, secondary Horse Radish Peroxydase (HRP)-conjugated anti-rabbit antibody was diluted 1:3000 in blocking solution and incubated with PVDF membrane for 1 h at room temperature. Signal was then revealed using FEMTO chemoluminescent substrate (Thermo Scientific, Waltham, MA) and by exposing the membrane to photosensitive photographic films for various times. Films were developed using a SRX-101A Konica Minolta developer (Tokyo, Japan).The experiment was repeated independently twice to confirm the results. Fold-induction of proteins was calculated by normalizing the band of interest to the loading control (β-actin), and this adjusted intensity was compared to the control (DMSO) sample.

GSH Rescue Assay. A549 cells were plated on 60 mm culture dishes, at 0.5×10^6 density. After 24 h, DMSO, 6S or M2 (10, 20, 40, 80, 120 μM) were added to the cells and incubated with or without the

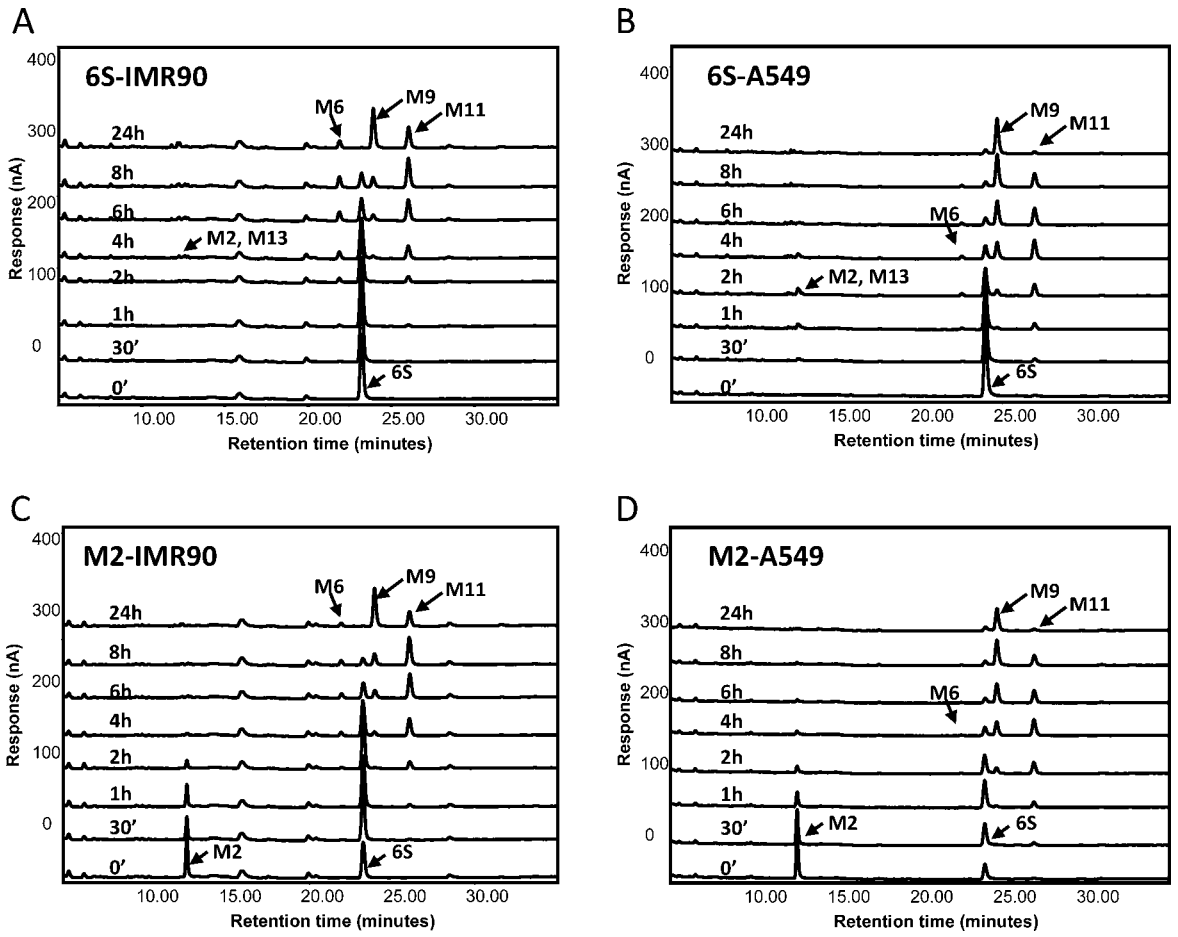

Figure 1. HPLC metabolic profile of IMR90 (A and C) or A549 (B and D) cells exposed to 10 μM of 6S (A and B) or M2 (C and D) after 0, 0.5, 1, 2, 4, 6, 8, and 24 h.

addition of 5 mM GSH in the culture media. After 24 h, toxicity was assessed using the MTT assay and using the method described above. The experiment was repeated independently to confirm the results.

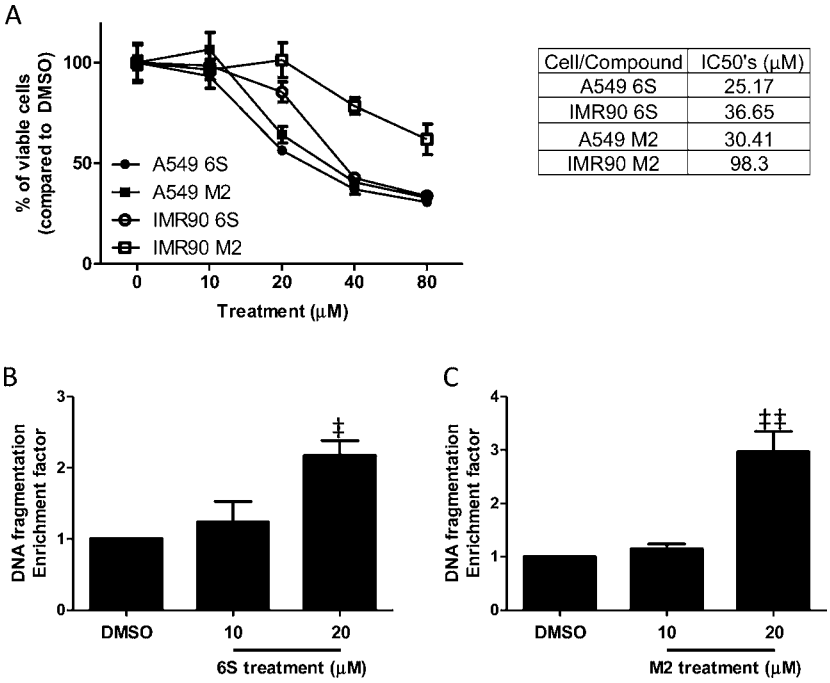
Animal Experiments. Experiments with mice were carried out according to protocol approved by the Institutional Review Board for the Animal Care and Facilities Committee at North Carolina Research Campus and North Carolina Agricultural and Technical State University. Nu/J nude mice were obtained from Jackson Laboratories (Bar Harbor, ME). Animals were randomized into 4 groups. A549 cells (5×10^6 cells) were implanted in both flanks of 8-weeks old Nu/J mice. One week after implantation, animals were given 100 μL of the following treatments through oral gavage 5 times/week: DMSO 0.25 mL/kg (control; $n = 4$); 6S 10 mg/kg ($n = 4$); 6S 30 mg/kg ($n = 4$) or M2 30 mg/kg ($n = 5$). Compounds were diluted in a solution of 5% DMSO in corn oil. Animal body weight and tumor volume were recorded for the duration of the experiment. Tumor volume was calculated by measuring the length and width of the tumors using a digital caliper and using the formula (Length × Width^2)/2. One hour before sacrifice, mice were given one last treatment dose as well as one intraperitoneal injection of BrdU (7.5 mg/kg in 100 μL PBS). After 7 weeks, tumor tissues were harvested and weighed. A portion of the tumors was snap frozen in liquid nitrogen and another portion was placed in a histology cassette and immersed in formalin solution.

Immunohistochemistry. Formalin-fixed tissues were sent to Precision Histology Lab (Oklahoma City, OK) for embedding in paraffin blocks. Paraffin blocks were then processed into 3–4 μm sections that were then put on microscope slides. Sections were then deparaffinized by using a succession of 3 baths of xylene (5 min each), 2 baths of absolute ethanol (5 min each), 95% ethanol for 3 min, 70% ethanol for 3 min, and rinsed in PBS. Immunostaining with TUNEL (terminal deoxynucleotidyl transferase dUTP nick end labeling) and BrdU staining kits was performed following manufacturer's recommendation. For staining quantification, sequential high-power field pictures of tumors were taken (10 pictures per tumor) using an A1 Zeiss microscope (Oberkochen, Germany). Images were processed using the Image J software,[31,32] which was used to count positive, brown-colored cells in each field. Average number per tumor was calculated by averaging the number obtained for each field, and the average number of positive cells per group was obtained by averaging the values of each tumor belonging to the experimental group.

Statistics. Statistics were calculated using either a two-tailed Student t test, or ANOVA followed by Bonferroni's post-test. Results were considered significant when $p < 0.05$.

RESULTS

6S and M2 Are Similarly Metabolized by IMR90 and A549 Cells. We recently published that 6S is metabolized in cancer cells and that its bioactivity -i.e. selective toxicity- can be attributed to some of its metabolites, notably M2.[28,29] For this study, we first needed to determine if 6S or M2 are similarly metabolized in our model of small cell lung cancer A549 human cells as well as in IMR90 human normal lung cells. After exposing A549 or IMR90 cells to 10 μM of 6S or M2, we analyzed the metabolic profiles obtained from the culture supernatants at different time points using HPLC-ECD. We confirmed that 6S is metabolized by IMR90 or A549 cells (Figure 1, panel A or B, respectively), with an initial conversion into mostly the metabolites named M2, M13 and M11, while in later time points, most of 6S has been metabolized into M9.[29] The structures of all metabolites were confirmed using LC/MS



Cell/Compound	IC50's (μM)
A549 6S	25.17
IMR90 6S	36.65
A549 M2	30.41
IMR90 M2	98.3

Figure 2. (A) 6S and M2 toxicity in A549 cancer cells and IMR90 normal lung cells using MTT assay, with the corresponding IC_{50} values on the right side table. (B) Apoptosis measured by ELISA assay in A549 cells after 24 h treatment with 10 or 20 μM of 6S. (C) Apoptosis measured by ELISA assay in A549 cells after 24 h treatment with 10 or 20 μM of M2. *Bars*, SEM; ‡, $p < 0.05$; ‡‡, $p < 0.01$ using one-way ANOVA followed by Bonferroni's post-test.

analysis (data not shown). As initially reported in HCT-116 and H-1299 cells,[28] M2 metabolism in IMR90 (Figure 1C) or A549 cells (Figure 1D) was also characterized by an initial conversion of this cysteine-conjugated metabolite back into 6S, which is then metabolized in a similar pattern than described above for 6S. These results show that normal lung IMR90 and lung cancer A549 cells can quickly metabolize 6S and M2 in a similar pattern, which correlates with the observations in other cell models.[28]

M2 Toxicity Can Selectively Target Cancer Cells Compared to 6S. Our results show that M2 can quickly revert back to 6S native form when metabolized by A549 cells. We wanted to determine if that reversion led to a distinct bioactivity or if the parent compound and M2 shared the same bioactivity. We used an MTT assay to compare the bioactivity of 6S and M2 in A549 cells as well as in IMR90 human, noncancerous lung cells. The results are summarized in Figure 2A. When treated with increased concentration of 6S or M2, we detected an increase in toxicity in A549 cells with IC_{50}'s of 25.2 and 30.4 μM, respectively. In IMR90 cells, the IC_{50} was 36.6 and 98.3 μM for 6S and M2, respectively. In other words, in normal cells the IC_{50} value was 45.6% higher for 6S and 223.2% higher for M2 when compared to A549 cells. These results show that 6S and M2 exert similar toxicity toward A549 cells. However, M2 toxicity is greatly diminished against non-cancerous cells compared to that of 6S.

6S and M2 Activate the Apoptosis and p53 Pathways. Since our results show that 6S and M2 are bioactive against A549 cancer cells, we tried to determine the potential mechanisms of activation by looking at apoptosis, since it is one of the major pathways that can be specifically activated by the exposure to environmental stressors, and that ultimately leads to cell death. We used an ELISA assay that quantified the release of cytoplasmic histone-associated DNA fragments in A549 cells exposed to 6S or M2 for 24 h. Figure 2B shows that after 24 h these apoptotic markers were significantly higher (enrichment factor of 2.2) for cells treated with 20 μM of 6S. We also detected a significant increase in apoptotic markers (about 3-fold enrichment) after treatment with 20 μM M2 (Figure 2C).

To confirm these results, we performed Western blot analysis on extracts of A549 cells treated with 20 or 40 μM of 6S or M2 for 2 or 24 h. The results are summarized in Figure 3. For both concentrations of 6S or M2, we found that the pro-apoptotic markers cytochrome C, cleaved caspases 3 and 9 were markedly elevated after 2 h. Only cleaved caspases 3 and 9 levels remained elevated after 24 h, especially at the 40 μM concentration. Consistently, we could detect a small increase of caspases 3 and 9 after 2 h of exposure, and these levels were lower after 24 h. Markers of the mitochondrial apoptotic pathway Bax, Bak and Bcl-2 were all slightly elevated after 2 h of exposure to the test compound, but their levels were close to that of DMSO-treated cells after 24 h.

Since we could not detect any meaningful changes in the mitochondrial apoptotic pathway associated with the release of cytochrome C and subsequent caspase cascade activation,[33] we looked into the p53 pathway since it is responsive to oxidative stress and capable of triggering apoptosis.[34] Indeed, our results showed an increase in p53 levels after 2 and 24 h treatment with 6S or M2. It correlated with an increase of one of its downstream targets PUMA (p53 upregulated modulator of apoptosis), which was most evident after 24 h (Figure 3, top lines). These results show that both 6S and M2 can activate the p53 and the apoptosis pathways.

Excess GSH Can Rescue A549 Cells from 6S and M2 Toxicity and Suppress p53 Activation. Recent studies in our group showed that 6S can modulate GSH levels in HCT-116 colon cancer cells,[14] and we wanted to determine if that

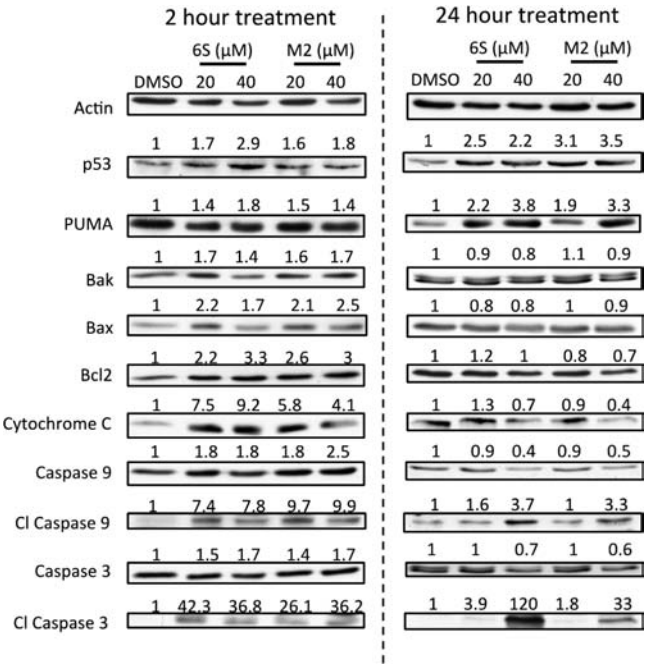

Figure 3. Western blot analysis of cell extracts after treatment with DMSO (control), 20 or 40 μM of 6S or M2 for 2 and 24 h. Markers are indicated on the left. Fold induction for each marker compared to DMSO is indicated over the corresponding line and was calculated as indicated in Material and Methods section.

effect was also present in the A549 small lung cancer cells model using 6S and M2. Figure 4A,B shows that GSH levels are significantly depleted as early as 2 h after exposure to 10 μM of 6S or M2. This depletion further continues after 4 h. After 8 h, GSH levels were still significantly lower in 6S treated cells, and significantly higher in M2 treated cells. After 24 h, GSH levels were significantly increased after exposure to both compounds compared to baseline. While changes of GSH levels are not as large as those of 6S in the case of M2, it is nonetheless significant for all tested time points.

When cells are exposed to increased levels of oxidative stress, GSSG will accumulate and the ratio of GSH to GSSG will decrease.[35] The results of a GSH/GSSG assay are presented in Figures 4C (for 6S) and 4D (for M2). This experiment shows that after 2 h the GSH/GSSG ratio is significantly lower for 6S-treated (10 μM) cells but not for M2-treated (10 μM) cells. After 4 h of exposure to 6S or M2, the GSH/GSSG ratio is significantly lower and after 24 h of exposure it is significantly higher. Collectively, these results show that both 6S and M2 can deplete GSH levels and induce oxidative stress in A549 cells in a similar fashion.

We demonstrated that 6S and M2 can modify GSH levels, but it is unclear whether this effect can be directly linked to their apoptotic activity. We wanted to verify the link between GSH modulation and apoptosis by conducting a GSH rescue assay in which excess GSH in the culture medium essentially prevented any fluctuation in GSH level after treatment with the test compounds. Excess GSH in the culture media completely rescued A549 cells from both 6S and M2 toxicity, with modified IC_{50}'s over 80 μM (Figure 5A). Western blot analysis showed that in the presence of excess GSH, there was no change in p53 expression in the 24 h extracts of cells treated with 40 μM 6S or M2 (Figure 5B). These results show that the changes in GSH levels induced by both 6S and M2 in A549 cells are necessary to induce toxicity and the p53 pathway.

The p53 Pathway Is Involved in 6S and M2-induced Toxicity and Apoptosis. We further investigated the involvement of p53 pathway in 6S or M2-induced toxicity and apoptosis by using the p53-specific inhibitor pifithrin μ

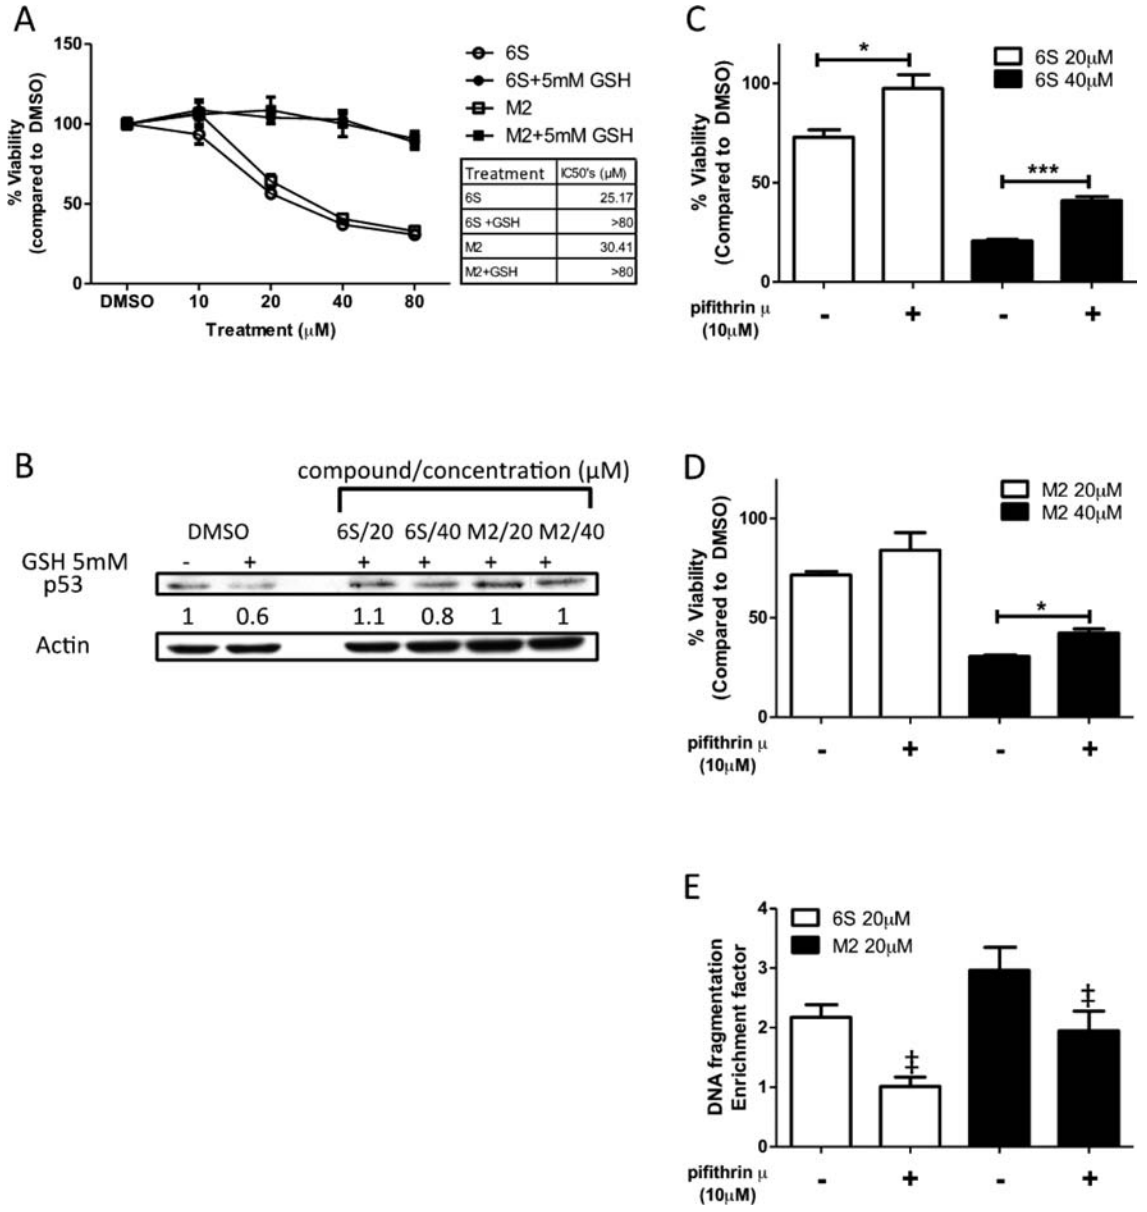

Figure 5. (A) GSH rescue assay in A549 cells. Cells were treated for 24 h with 0, 10, 20, 40, or 80 μM of 6S or M2 in the presence or absence of 5 mM GSH. The associated table indicates the IC_{50} values for each treatment. (B) Western blotting analysis of cell extracts treated with DMSO, 20 or 40 μM of 6S or M2 for 24 h with or without 5 mM of GSH. Fold induction for each marker compared to DMSO is indicated under the corresponding line and was calculated as indicated in Material and Methods section. (C) Effect of pft treatment on A549 cell death after treatment with 20 or 40 μM of 6S for 24 h. (D) Effect of pft treatment on A549 cell death after treatment with 20 or 40 μM of M2 for 24 h. (E) Effect of pft treatment on A549 cell apoptosis after treatment with 20 μM of 6S or M2 for 24 h. *Bars*, SEM *, $p < 0.05$; ***, $p < 0.001$ using a paired Student's *t* test; ‡, $p < 0.05$ using one-way ANOVA followed by Bonferroni's post-test.

(pft). This inhibitor can block the direct interaction and mitochondrial relocation of p53 with members of the Bcl-2 family.[37]

Treatment of A549 cells with pft in addition to 6S was very effective in reducing the toxic effect of both 6S (Figure 5C) and M2 (Figure 5D). When treated with 20 μM of 6S or M2 for 24 h, the percentage of viable cells was close to 100% for 6S and 84.2% for M2. Without pft to block p53 interaction with Bcl-2 family members, the percentage of viable cells was only around 72% in both cases. This effect was also observed at a higher dose of compound (40 μM). In the case of 6S, the percentage of viable cells was significantly higher (20.6% of viable cells without pft and 41% of viable cells with pft). For 40 μM M2, the effect was similar, with 30.6% of viable cells without pft and 42.4% of viable cells with pft. These results show that interfering with p53 signaling can at least partially rescue cells from 6S and M2-induced toxicity.

Since pft directly interferes with p53 signaling toward the mitochondria, we also tried to determine the effect of pft on apoptosis induction in A549 cells. For this experiment, a 20 μM dose was used since we established it to be the most effective dose for this assay (Figure 3B,C). The treatment with pft reduces the enrichment factor in small nucleosomes by a factor of 1 for both 6S and M2 (Figure 5E): in the case of 6S, the presence of pft significantly returned the enrichment factor to baseline (about 1), while in the case of M2, the enrichment factor is significantly down to 2 with pft from 3 without pft. Altogether these results show that 6S and M2 induce cell

apoptosis through the modulation of GSH levels and the activation of a p53 pathway.

6S and M2 Can Reduce Tumor Burden in Nu/J Mice. It is always uncertain how an observed anticancer bioactivity of a given natural compound translates *in vivo*, mainly due to the fast turnover and degradation of the compounds.[16,27] To ascertain the bioactivity of 6S and M2 *in vivo*, we studied their effect on the development of A549 tumors in a mouse xenograft model.

Exposure of animals to a daily oral gavage for up to 7 weeks did not induce any significant changes in body weight between groups (data not shown). Tumor volume in the control group grew exponentially, tumors from the groups receiving 6S 10 mg/kg, 6S 30 mg/kg or M2 30 mg/kg grew markedly slower, with tumors from the M2 group being significantly different by week 7 (Figure 6A). After 7 weeks, tumor weight was significantly lower in both 6S 30 mg/kg (minus 40.8% compared to DMSO-treated control) and M2 30 mg/kg (minus 53.7% compared to DMSO-treated control). Tumor weight was also markedly lower in the 6S 10 mg/kg group (minus 25.6%), albeit not significantly (Figure 6B). Taken altogether, both treatments were sufficient to lower the tumor burden of A549 engrafted cells at a 30 mg/kg body weight. Interestingly M2 appeared to be the most active compound *in vivo*, albeit not significantly when compared to the 6S 30 mg/kg treatment.

6S and M2 Induce Apoptosis and Reduce Cell Proliferation in A549 Xenografts. Next we sought to investigate the mechanisms by which 6S and M2 can reduce tumor burden in A549 xenografts tissues. TUNEL staining of tumor tissues (Figure 6C) showed a marked increase of apoptotic bodies in the animals treated with 6S 10 mg/kg body wt (27.8 TUNEL+ cells/field) compared to control (about 15.5 TUNEL+ cells/field). This trend became significant in the tumors from animals treated with 6S 30 mg/kg, with an average of 32.6 TUNEL+ cells/field. In the case of the animals treated with M2 30 mg/kg, we also observed the same trend (28.6 TUNEL+ cells/field) that was very close to being significant ($p = 0.0669$). BrdU staining of tumor tissues (Figure 6D) showed a significant reduction of cell proliferation in the animals treated with 6S 30 mg/kg body wt (3.4 BrdU+ cells/field) compared to control (about 6.3 BrdU+ cells/field). We also detected a marked reduction of cell proliferation in the 6S 10 mg/kg group (4.7 BrdU+ cells/field) that was very close to significance ($p = 0.0678$ by unpaired *t* test compared to control). While there was also a slight decrease in the M2 30 mg/kg group (4.3 BrdU+ cells/field), it was also very close to significance ($p = 0.0558$ by unpaired *t* test compared to control). These results

dx.doi.org/10.1021/jf405573e | J. Agric. Food Chem. 2014, 62, 1352−1362

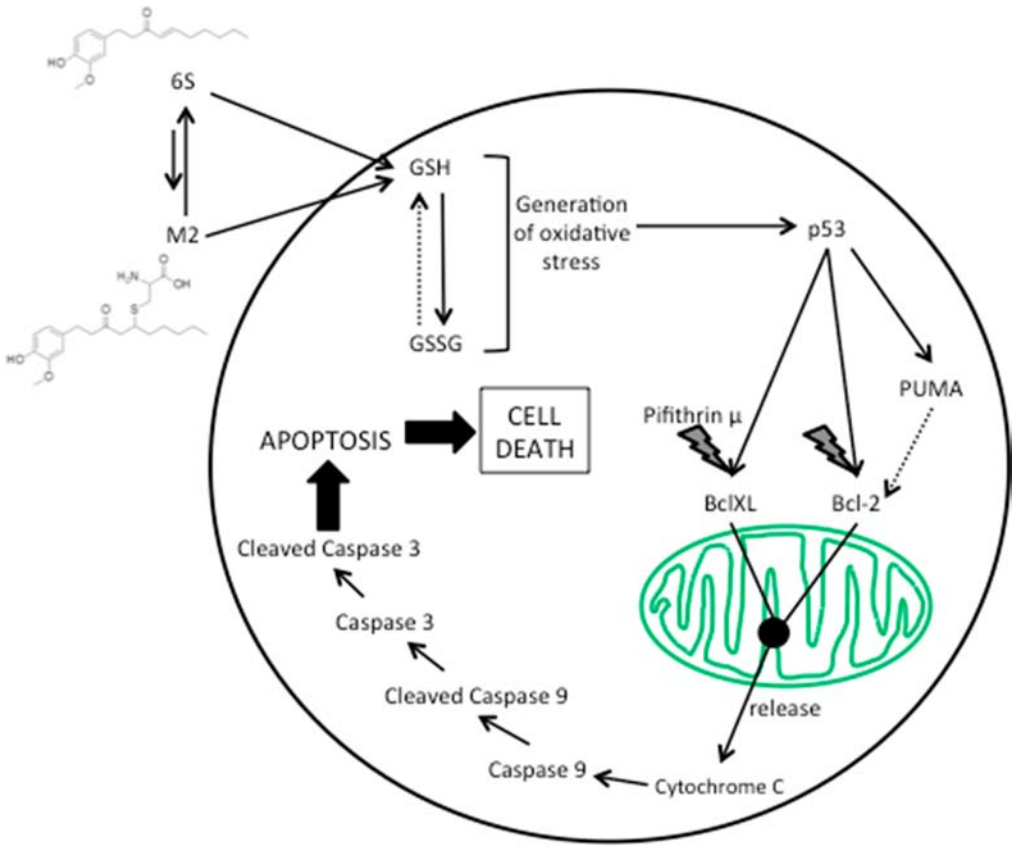

Figure 7. Schematic representation of the proposed mechanism of apoptosis activation in A549 cells by 6S and its cysteine-conjugated metabolite M2. Dotted arrows: possible interactions. Plain arrows: proposed interactions.

show that the reduction in tumor burden *in vivo* can be correlated to the induction of apoptosis for 6S and M2. In the case of 6S, it can also be associated to others molecular mechanisms such as cell proliferation.

■ DISCUSSION

Dietary intervention is a well-accepted mean of reducing cancer events. Cohort studies show that increased intake of fruits, vegetables and spices are indeed inversely correlated with the risk of various cancers.[3,4] While a full explanation for these observations is still heavily investigated, there is no doubt that dietary compounds can have long-term health benefits in terms of cancer prevention despite their fast metabolisms. Our lab showed that 6S, the major component of dried ginger, can be rapidly metabolized in colon and nonsmall cell lung cancer cells.[28] This proved to be also true in the human lung cancer cell model A549 (Figure 1), which is of the more aggressive type of lung cancer.

We initially assessed the bioactivity of 6S and M2 in A549 using an MTT assay. While both compounds displayed a significant toxicity toward cancer cells, it was remarkable that M2 was significantly less toxic toward noncancerous cells. 6S did not possess this property, suggesting that the cysteine-conjugation of 6S allowed discrimination between cancerous and normal human lung cells. This result validated its usefulness as a superior anticancer compound compared to 6S, and justified further investigation of M2. While the noncancerous lung cell line IMR-90 is from a different embryonic origin than A549, there is no perfect normal cell line that is currently available *in vitro*. In consequence, further *in vivo* toxicity study of 6S and M2 is warranted.

We then tried to gain insight into the mechanism of action of both compounds. Our laboratory previously demonstrated in others models that 6S and several other metabolites were able to trigger apoptosis,[16,29] a mechanism of programmed cell death that is often impaired in cancer cells. We determined that 6S and its metabolite M2 could also activate the apoptosis pathway in A549 cells. This was demonstrated by the detection of cytoplasmic histone-associated-DNA-fragments in A549 cells upon treatment with 6S or M2 for 24 h. Notably, we demonstrated that while the IC_{50} of M2 is higher than 6S, its capacity to specifically induce apoptosis was superior (as shown in Figure 2). Additionally, we showed the activation of the apoptosis pathway by demonstrating the modulation of final apoptotic markers such as cytochrome C, capases 3 and 9 and their cleaved isoforms. Caspase 9 was also slightly elevated after 2 h of exposure, but it could be the result of newly synthesized protein to reinforce the already activated apoptotic pathway. These markers are part of the mitochondrial apoptotic pathways, but interestingly the traditionally associated markers of the Bcl-2 family (Bak, Bax) were not affected. Bcl-2 showed a small increase after 2 h, but the increase did not appear to be concentration-dependent and was very modest compared to the others markers, which suggest a very limited influence. On the other hand, we were able to detect a very early increase in p53 and PUMA, two major actors in the transmission of cellular changes such as (but not limited to) oxidative stress. Indeed, as was previously described in other cell lines, treatment of A549 cells with 6S and M2 led to a clear disturbance in GSH

dx.doi.org/10.1021/jf405573e | J. Agric. Food Chem. 2014, 62, 1352−1362

homeostasis, which would explain the generation of oxidative stress. This disturbance has been observed before and can be explained by the property of dietary electrophiles to activate the transcription factor Nrf2:[38] after the initial depletion of GSH to detoxify electrophiles compounds, the cellular GSH levels can be restored and even enhanced by the subsequent Nrf2-mediated signal and GSSG recycling. This mechanism exists in order to maintain cell equilibrium, and rescuing it from oxidative damage or others carcinogens. However, GSH variation, if too great, can also be interpreted by cellular components as irreparable damage, which requires the cell to engage into the apoptotic pathway.

The next question was to determine the mechanism of transition from oxidative stress to apoptosis. p53 is known to be able to trigger apoptosis through interaction with members of the Bcl-2 family such as Bax, Bcl-2 or Bcl-XL to trigger apoptosis without modifying their level of transcription.[39,40] Using the chemical inhibitor pft, we show here that the interaction between Bcl-2 or Bcl-XL and p53 might be disrupted, as evidenced by a reduced toxicity of both 6S and M2 (Figure 5C,D), as well as the induction of apoptosis (Figure 5E). It has been reported that pft is also a known inhibitor of hsp70.[36] Whether hsp70 is also a target of 6S or M2 is a topic for future study. Nevertheless, our results suggest a direct relationship between the propagation of a mitochondrial apoptotic signal and an induction of p53 expression, which could explain the lack of variation in the Bcl-2 family markers expression. The proposed pathway of cancer cell apoptosis induction is summarized in Figure 7. It is interesting to note, however, that while apoptosis could be almost completely abolished by pft in lower doses of compounds, the cell viability could never be completely rescued. We also observed a marked increase in PUMA expression, especially after 24 h of exposure to both 6S and M2 (Figure 3). PUMA is another molecule that can mediate the p53 apoptotic message through its interaction with members of the Bcl-2 family.[41] This suggests that apoptosis is in part accountable for the death of A549 cells, and that multiple mechanisms inducing apoptosis and/or toxicity in cancer cell might be acting together.

While we determined that both 6S and its metabolite M2 can trigger similar biological responses and mechanisms in A549 cells, it was unclear if this would still be true *in vivo*. This was a concern especially when taking into account the short half-life of these compounds due to their quick metabolisms, as our previous studies reported.[14] To this end, we carried out a xenograft experiment where A549 tumor growth was significantly delayed by both 6S and M2. Additionally, M2-treated animals showed a further reduction in tumor burden compared to the animals treated with 6S at an equivalent dose of 30 mg/kg body wt (Figure 6B). As demonstrated by TUNEL staining of tumor tissues, 6S could significantly induce apoptosis *in vivo*, while M2 was very close to also having a significant effect. However, there was still a clear trend and it is probable that the number of animals used was not sufficient and that an increased number would allow for the detection of a significant induction of apoptosis even by M2 (Figure 6C). We also demonstrated that both 6S and M2 can decrease cell proliferation (Figure 6D). Similarly to what we observed by TUNEL staining, only 6S at the higher dose was shown to have a significant effect, while M2 was close to having a significant effect. As described above, this is expected since we showed that blocking of the apoptotic pathway through chemical methods *in vitro* could only partially rescue cells from the toxicity of 6S and M2. Similarly, the percentage of apoptotic cells detected by ELISA could not be entirely restored to DMSO (control)-treated levels, especially at the higher concentration (40 μM) of the compounds, when treated with pft. The fact that the exposure to our compounds results in an increase of the multiacting molecule p53 can also explain the activation of multiples pathways. The p53 pathway has been demonstrated to have multiple effects, and is a major regulator of the cell cycle.[42] In this light, it is not surprising that cell proliferation would be affected by the exposure to compounds that can increase p53 expression. It is particularly interesting in terms of cancer prevention since p53 expression is lost in most late-stage cancers but can still be active in early stage cancers or even aggressive cancers, such as in A549 cells. 6S and its metabolites could exert their activity in an optimal manner in these conditions, while M2 could also exert this activity and being harmless against normal cells.

Altogether, this study shows that the traditional model of bioactivity by natural compounds can be challenged and that the products of degradation of the parent compound can be responsible for the observed bioactivity. This would also explain how dietary compounds can exert a long-term effect despite being quickly metabolized. Finally, there is evidence that drug conjugation using cysteine can be an effective tool to deliver drugs to its target, as in the case of antibody-drug conjugates.[43,44] Our lab previously suggested that M2 could act as a carrier for 6S to prolong or enhance its activity,[28] and the current study clearly reinforces this hypothesis. The cysteine group can be hydrolyzed out of M2 to form 6S in both A549 human lung cancer cells and IMR90 human normal lung cells. It appears that natural modifications of dietary compounds through metabolism, such as cysteine addition, can be a fertile source for the discovery of novel bioactive molecules and the identification of novel targets and strategies for cancer prevention and treatment.

pid–protein monolayers by phospholipase A_2 using similar model systems and simple intestinal conditions.[20]

In this study, we aimed at elucidating the interactions between bile salts and milk phospholipids occurring at the oil–water interface of milk fat globules and liposomes during the early stages of digestion in the small intestine using a simplified model system (not including free fatty acids from lipolysis and pancreatic lipases). We extracted phospholipids from whey buttermilk, a rich source of MFGM. As others have shown that the composition of the interface has an impact on digestion[2,21] and mostly adsorption of bile salts onto the interface at the early stages of digestion,[22] and that MFGM contains proteins, we also aimed to characterize the impact of the presence of proteins at the interface. Due to the lack of commercially available MFGM proteins and the difficulty in purifying them, we used two widely studied milk proteins known to interact with the MFGM during milk processing and commonly used as emulsifiers but with different conformation at the interface.[18] To investigate the effect of bile composition on milk phospholipid layer systems, a mixture of bile salts and a crude bile extract were used.

MATERIALS AND METHODS

Samples and Reagents. The phospholipid extract was obtained from whey buttermilk processed as described by Costa et al.[23] Total lipids were extracted using the modified Mojonnier ether extraction method,[24] and the phospholipids were recovered by solid-phase extraction according to the method of Bitman et al.[25] The phospholipid extract was analyzed by HPLC according to the method of Rombaut et al.[26] and contained 57.1 ± 12.4% of phosphatidylethanolamine (PE), 22.0 ± 3.7% of phosphatidylcholine (PC), 11.0 ± 1.7% of phosphatidylserine (PS), 6.2 ± 1.2% of sphingomyelin (SM), and 3.7 ± 2.0% of phosphatidylinositol (PI). Bovine milk β-casein (*Bio*Ultra, ≥98% from PAGE analysis) and bovine milk β-lactoglobulin (≥90% from PAGE analysis) were purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA) and stored at −20 °C. A mixture of negatively charged bile salts (Fluka, 50% sodium cholate (430.55 Da) and 50% sodium deoxycholate (414.55 Da)) and a crude bovine bile extract from ox gall (including glycocholic acid, glycodeoxycholic acid, taurocholic acid, taurodeoxycholic acid, and cholic acid (60% w/w) from TLC analysis) were purchased from Sigma-Aldrich Corp. and stored at 4 °C. A detailed composition of the bile extract is given elsewhere.[27] As a crude bile extract, it is likely to also contain phospholipids, cholesterol, bilirubin, and electrolytes.[3] All solvents (Fisher Scientific, Pittsburgh, PA, USA) were of HPLC grade. The fluorescent headgroup-labeled phospholipid analogue Texas Red 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt (Tx-Red-DHPE, 0.1 mL/mL in chloroform, Invitrogen, Molecular Probes (Carlsbad, CA, USA)) allows the detection of phase coexistence within phospholipid monolayers under an epifluorescence microscope. Milli-Q water (18 MΩ cm, pH 5.5–6.5) was used to prepare buffers and was purified by means of a Millipore filtration device (Millipore Corp., Bedford, MA, USA). For AFM imaging, AC 240 TS cantilevers (Asylum Research, Santa Barbara, CA, USA) were used for alternating current (AC) mode imaging.

Langmuir Isotherms. A Minitrough Langmuir film balance (KSV Instruments, Helsinki, Finland) with a platinum Wilhelmy plate and mounted on an Olympus BX60 microscope, equipped with an Olympus QColorA mercury lamp, was used to acquire Langmuir isotherms and fluorescent images of phospholipid and phospholipid–protein monolayers before and after addition of bile salts or extract. All glassware was thoroughly cleaned with detergent, rinsed with Milli-Q water and then with ethanol, and dried in a 100 °C oven. Tx-Red-DHPE was added to the phospholipid extract at a concentration of 2% by mass, which is low enough to avoid introducing significant perturbations to the membrane system.[28] The phospholipid extract was dissolved in chloroform to a concentration of 1 mg mL^{-1}, β-casein and β-lactoglobulin were prepared fresh daily and diluted to 1 mg mL^{-1} in PBS buffer (pH 7.45), and stock solutions (120 or 60 mM) of bile salts and bile extract were prepared with simulated intestinal fluid (SIF, 150 mM NaCl, 10 mM $CaCl_2$, pH 7.0). SIF was used as the subphase simulating the ionic strength and the pH found in the small intestine. At pH 7, both proteins carry a negative net charge.[13,17] The aqueous surface was cleaned before and between experiments until a surface pressure of <0.1 mN m^{-1} was reached after full compression of the symmetric barriers.

Forty microliters of phospholipid extract was carefully spread onto the surface with a gastight microsyringe, and the solvent was allowed to evaporate over 5 min. The phospholipid monolayer was then compressed to 15 or 25 mN m^{-1} or to 6 mN m^{-1} if β-casein or β-lactoglobulin was added to the subphase with a gastight microsyringe. If not specified, the phospholipid/protein ratio was 1:1 (w/w). The surface pressure stabilized after 30 min of addition of the protein, and the phospholipid–protein monolayer was then compressed to 15 or 25 mN m^{-1}. A surface pressure of 15 mN m^{-1} was chosen as it is lower than the collapse pressure of the proteins but high enough so that phase coexistence occurred. A surface pressure of 25 mN m^{-1} was found at the oil–water interface of emulsions.[16] Bile salts or bile extract were then added gently in a single injection to the subphase with a gastight syringe from the stock solution, to a final subphase concentration of 0.22 or 4.4 mM. A concentration of 4.4 mM is physiologically relevant.[27] The surface pressure was recorded at constant area, and fluorescence images were acquired every 5 min. Different ratios of phospholipid/protein (1:2 and 2:1, w/w) were also used. All isotherm experiments were conducted in duplicate at 20.0 ± 0.5 and 37.0 ± 0.5 °C, and all imaging experiments were performed at 20.0 ± 0.5 °C. The experiments were carried out at least in duplicates to confirm the reproducibility of the experiment.

As a control, bile salts and bile extract were added to the subphase on a clean air–water interface at 20 and 37 °C and the surface pressure was recorded at constant area.

Langmuir–Blodgett Films and Atomic Force Microscopy. Imaging on the trough was not possible at 37 °C due to condensation on the objective lens; thus, the preparation of the Langmuir–Blodgett films to be imaged with an atomic force microscope (AFM) was performed at 20 °C. All LB films were prepared by equilibrating the phospholipid and phospholipid–protein monolayers at a surface pressure of 25 mN m^{-1} for 5 min before addition of bile salts or bile extract. The phospholipid and phospholipid–protein monolayer films spread at 20 °C on Milli-Q water at pH 7 before and 5 min after addition of bile salts or bile extract were transferred to a clean glass microscope slide, as described previously,[12,13] forming LB films. The addition of salt in the subphase can lead to the formation of salt crystals on the glass slide, making the imaging with an AFM difficult.

To obtain higher resolution images of the monolayers, an MFP-3D AFM (Asylum Research) was used to image the LB films in air and with tapping mode as described elsewhere.[13]

RESULTS AND DISCUSSION

Effect of Temperature and Ionic Strength. Figure 1 presents the compression isotherms of milk phospholipids spread at 20 or 37 °C on Milli-Q water or SIF. All three isotherms showed similar features. The lift-off of the isotherm represents the transition from a gas phase to a liquid-ordered/liquid-disordered coexisting phases, as observed in our previous work.[12] This phase coexistence exists during the monotonous increase in surface pressure, which plateaus at the collapse of the monolayer, denoting the transition to a solid-like phase. Milli-Q water is slightly acidic, and SIF has a pH of 7.0 and contains sodium, calcium, and chloride ions. The slight difference in pH and ionic strength did not affect the compression isotherms of phospholipids. Phospholipid monolayers spread at 20 °C on Milli-Q water or SIF collapsed at about 45 mN m^{-1}. However, the increase in temperature led to an earlier liftup (end of the gas phase) of the compression

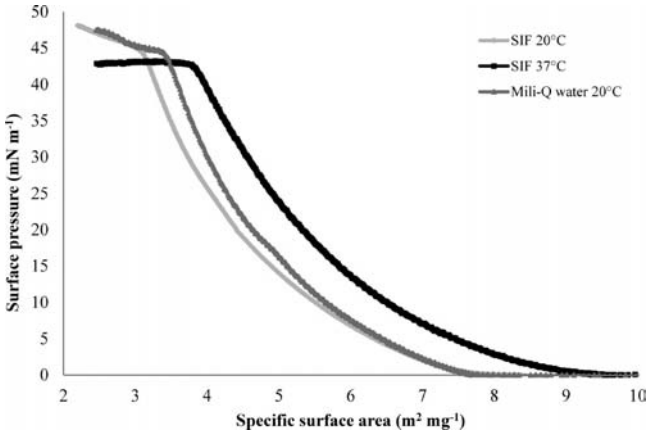

Figure 1. Lateral compression surface pressure−area isotherms of milk phospholipids at 20 °C spread on Milli-Q water (dark gray) or SIF (light gray) and at 37 °C spread on SIF (black).

isotherm. The effects of temperature, pH, and ionic strength on phospholipid−β-casein (1:1, w/w) and phospholipid−β-lactoglobulin (1:1, w/w) monolayers were similar.

Interfacial Properties of Bile Salts and Bile Extract. The addition of bile salts (Figure 2) and bile extract (results not shown) to a clean air−water interface gave similar final surface pressures at 20 and 37 °C. Upon injection of 0.22 mM bile salts (Figure 2), the surface pressure increased rapidly to about 27 mN m^{-1} and equilibrated after 5−10 min at 22−23 mN m^{-1}, whereas upon addition of a physiologically relevant concentration of bile salts, 4.4 mM, the surface pressure equilibrated within <1 min at 30 mN m^{-1}. For comparison with data reported in the literature and with the available equipment, it was not possible to stir the subphase. However, Brownian motion is quite effective in distributing salts in solution, as observed with the rapid increase in surface pressure after injection of bile salts or bile extract.

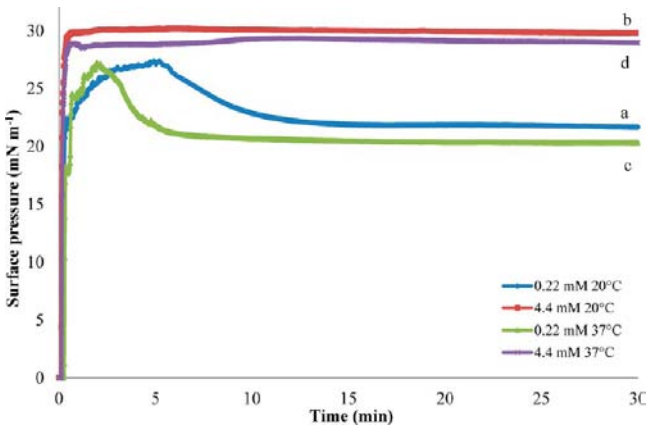

Figure 2. Surface pressure change of the clean air−water interface upon single addition of 0.22 mM (blue (a) and green (c)) or 4.4 mM (red (b) and purple (d)) bile salts at 20 °C (blue (a) and red (b)) or 37 °C (green (c) and purple (d)) to the SIF subphase.

The contrast between the monotonous increase in surface pressure to a plateau at a bile salt concentration of 4.4 mM and the increase in surface pressure followed by a decrease at a concentration of 0.22 mM may suggest a rearrangement or solubilization of bile salts at lower concentrations and a rapid saturation of the interface at higher concentrations. Bile salts adsorb rapidly due to a strong affinity for oil−water and air−water interfaces.[4] Their behavior at both surfaces is similar,[29] and they decrease the interfacial tension or increase the surface pressure with increasing concentration up to a limiting value.[22] Similar values of maximal surface pressure reached by physiological concentrations of bile salts have been reported in the literature; Maldonado-Valderrama et al.[30] reported a surface pressure value of <30 mN m^{-1}, even at concentration above the critical micellar concentration, and Chu et al.[16] found a surface pressure of 25 mN m^{-1} reached by 9.7 mM of a mixture of two conjugated bile salts. The final surface pressure is not the result of a synergism between two bile salts but the ratio of the surface pressure reached by each pure bile salt.[17]

Upon injection of 0.22 or 4.4 mM bile extract to a clean air−water interface, the final surface pressure equilibrated at 40 mN m^{-1} within 5 min (results not shown). As a crude product, bile extract is likely to contain negatively charged (at physiological pH) conjugated bile salts, phospholipids (mostly PC), and cholesterol.[3] Thus, the higher surface pressure found for bile extract is likely due to the presence of the other molecules, such as cholesterol.

Interactions of Bile Salts and Bile Extract with Phospholipid and Phospholipid−Protein Monolayers. The effect of a single injection of 0.22 mM bile salts on the surface pressure of a monolayer of phospholipids and β-lactoglobulin at different ratios, spread at 20 or 37 °C and after 5 min of equilibration at either 15 or 25 mN m^{-1}, is reported in Figure 3. The addition of bile salts to a phospholipid−β-lactoglobulin (1:1, w/w) monolayer stabilized at 15 mN m^{-1} at 37 °C led to an increase in surface pressure up to 20 mN m^{-1} within 5 min (Figure 3). Similar results were obtained with phospholipid and phospholipid−β-casein monolayers (Table 1). The surface pressure increase found by Chu et al.[16] after addition of a 0.144 mM bile salt mixture at 37 °C was higher for dipalmitoylphosphatidylcholine (DPPC) monolayers but lower for digalactosyldiacylglycerol (DGDG) monolayers. Welzel and Cammenga[5] added 0.47 mM sodium cholate to a dimyristoylphosphatidylcholine monolayer stabilized at 20 °C at 15

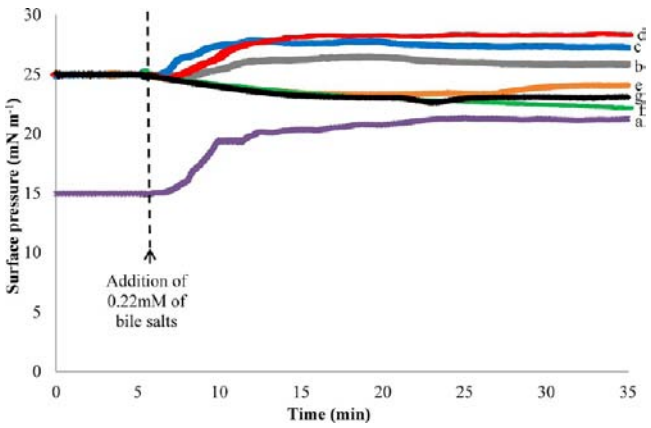

Figure 3. Surface pressure change upon single addition of 0.22 mM bile salts to phospholipid−β-lactoglobulin monolayers on SIF subphase at 20 °C (orange (e), green (f), and black (g)) or 37 °C (purple (a), gray (b), blue (c), and red (d)). The phospholipid/β-lactoglobulin ratios (w/w) are 1:1 (purple (a), gray (b), and orange (e)), 2:1 (blue (c) and green (f)), and 1:2 (red (d) and black (g)). The initial surface pressures of the monolayers before addition of bile salts are 15 mN m^{-1} (purple (a)) and 25 mN m^{-1} (all others).

Table 1. Surface Pressure Change (mN m^{-1}) upon Single Addition of 0.22 mM Bile Salts to Phospholipid, Phospholipid−β-Casein, and Phospholipid−β-Lactoglobulin Monolayers on SIF Subphase at 20 or 37 °C[a]

	phospholipid	phospholipid−β-casein	phospholipid−β-lactoglobulin
37 °C native surface pressure = 15 mN m^{-1}	22.5	21.4 (1:1)	21.2 (1:1)
20 °C native surface pressure = 15 mN m^{-1}	19.4	20.2 (1:1)	20.9 (1:1)
37 °C native surface pressure = 25 mN m^{-1}	27.1	26.2 (1:1)	25.8 (1:1)
		28.2 (1:2)	28.3 (1:2)
		28.5 (2:1)	27.6 (2:1)
20 °C native surface pressure = 25 mN m^{-1}	24.5	22.8 (1:1)	24.1 (1:1)
		24.2 (1:2)	23.1 (1:2)
		23.9 (2:1)	22.2 (2:1)

[a]The phospholipid/protein ratios (w/w) are indicated in parentheses. The initial surface pressures of the monolayers before addition of bile salts are 15 or 25 mN m^{-1}.

mN m^{-1}, which led to an increase in surface pressure to 35 mN m^{-1}, and addition at 25 mN m^{-1} led to an increase to 39 mN m^{-1}. Thus, bile salts adsorbed less onto milk phospholipid monolayers than onto pure phospholipid monolayers but more than onto DGDG monolayers.

The addition of bile salts to a phospholipid−β-lactoglobulin (1:1, 1:2, or 2:1, w/w) monolayer previously stabilized at 25 mN m^{-1} at 20 °C led to a decrease in surface pressure to 21−23 mN m^{-1} (Figure 3), which is similar to the surface pressure reached by a bile salt system only (Figure 2) but different from the increase found by Welzel and Cammenga,[5] whereas at 37 °C it led to an increase in surface pressure to 26−28 mN m^{-1} (Figure 3), which is higher than the surface pressure reached by a bile salt system only (Figure 2). Similar results were observed for phospholipid and phospholipid−β-casein monolayers (Table 1). When 4.4 mM bile salts were added to a phospholipid monolayer stabilized at 25 mN m^{-1} at 37 °C, the surface pressure increased and stabilized at 27.5 mN m^{-1} (results not shown).

When 0.22 mM bile extract was added to phospholipid and phospholipid−protein monolayers stabilized at 15 or 25 mN m^{-1} at 20 °C (results not shown), the surface pressure reached the same values as those after addition of 0.22 mM bile salts (Figure 3). When bile extract was added at a concentration of 0.22 or 4.4 mM to a phospholipid, phospholipid−β-casein or phospholipid−β-lactoglobulin monolayer stabilized at 15 or 25 mN m^{-1} at 37 °C, the surface pressure increased to 40 mN m^{-1} (results not shown), which is the surface pressure reached when bile extract was added to a clean interface (Figure 2). This suggests that displacement by bile extract may be more efficient than that by bile salts. As the lipid packing, and thus the phase coexistence, of milk phospholipids is affected by temperature,[12] the interaction of bile salts with the monolayer molecules is likely to be affected by the temperature of the system.

Bile salts are known to lie parallel, thus flat, onto phospholipid membranes.[31] The hydrophilic part faces the water side, and the hydrophobic part interacts with the phospholipid polar head groups and condenses the hydrocarbon chains of phospholipids.[4] The adsorption of bile salts improves the stability of phospholipid monolayers,[32] as observed in Figure 3 where the surface pressure of the phospholipid−bile salt monolayers stabilize rapidly at constant area. As negatively charged molecules at physiological pH, bile salts bring a negative charge to the surface, whereas calcium ions decrease the electrostatic repulsions between phospholipid headgroups. Steric and electrostatic effects govern the adsorption of phospholipids and bile salts at the oil−water interface.[33] Bile salt adsorption is affected by micellar state;[31] thus, the increase in surface pressure at 37 °C and decrease in surface pressure at 20 °C after injection of bile salts may be due to different micellar state, but also different lipid packing, at different temperatures. Indeed, the critical micellar concentration of bile salts increases with increasing temperature,[34] and phospholipid monolayers are less fluid at 20 °C than at 37 °C and thus likely more resistant to penetration by bile salts. The increase in surface pressure at 37 °C is likely due to a synergism between bile salts and phospholipids and possible remaining proteins. The decrease in surface pressure at 20 °C indicates a solubilization of phospholipids (and proteins) with the possible formation of mixed bile salt−phospholipid vesicles and micelles in the subphase. Unlike here, the displacement of protein monolayers by bile salts was reported to be similar at 37 °C and at room temperature and the adsorption of bile salts into protein monolayers was slower, on the order of 20 min.[17]

Microstructural Changes upon Addition of Bile Salts or Bile Extract. Morphological insights into the formation of domains upon compression of monolayers and phase coexistence changes upon addition of surfactants can be obtained using epifluorescence microscopy and appropriate fluorescent probe. The microstructure of the phospholipid, phospholipid−β-casein, or phospholipid−β-lactoglobulin monolayers stabilized at 20 °C at 15 or 25 mN m^{-1} and 30 min after the addition of 0.22 mM bile salts or bile extract was investigated with an epifluorescence microscope (Figure 4). In our previous study,[12] the fluorescent phospholipid analogue, Tx-Red-DHPE, was shown to be located preferentially in the liquid-disordered phase, leaving the tightly packed liquid-ordered phase, likely rich in SM, dark. The native phospholipid, phospholipid−β-casein, or phospholipid−β-lactoglobulin monolayers presented "snowflake"-shaped liquid-ordered domains; the largest ones were observed in phospholipid−β-casein monolayers, and the domains increased in size and number from 15 to 25 mN m^{-1} (Figure 4). As proteins were not labeled, it was not possible to locate them.

The addition of bile salts and bile extract to all monolayers led to microstructural changes within a few minutes and the

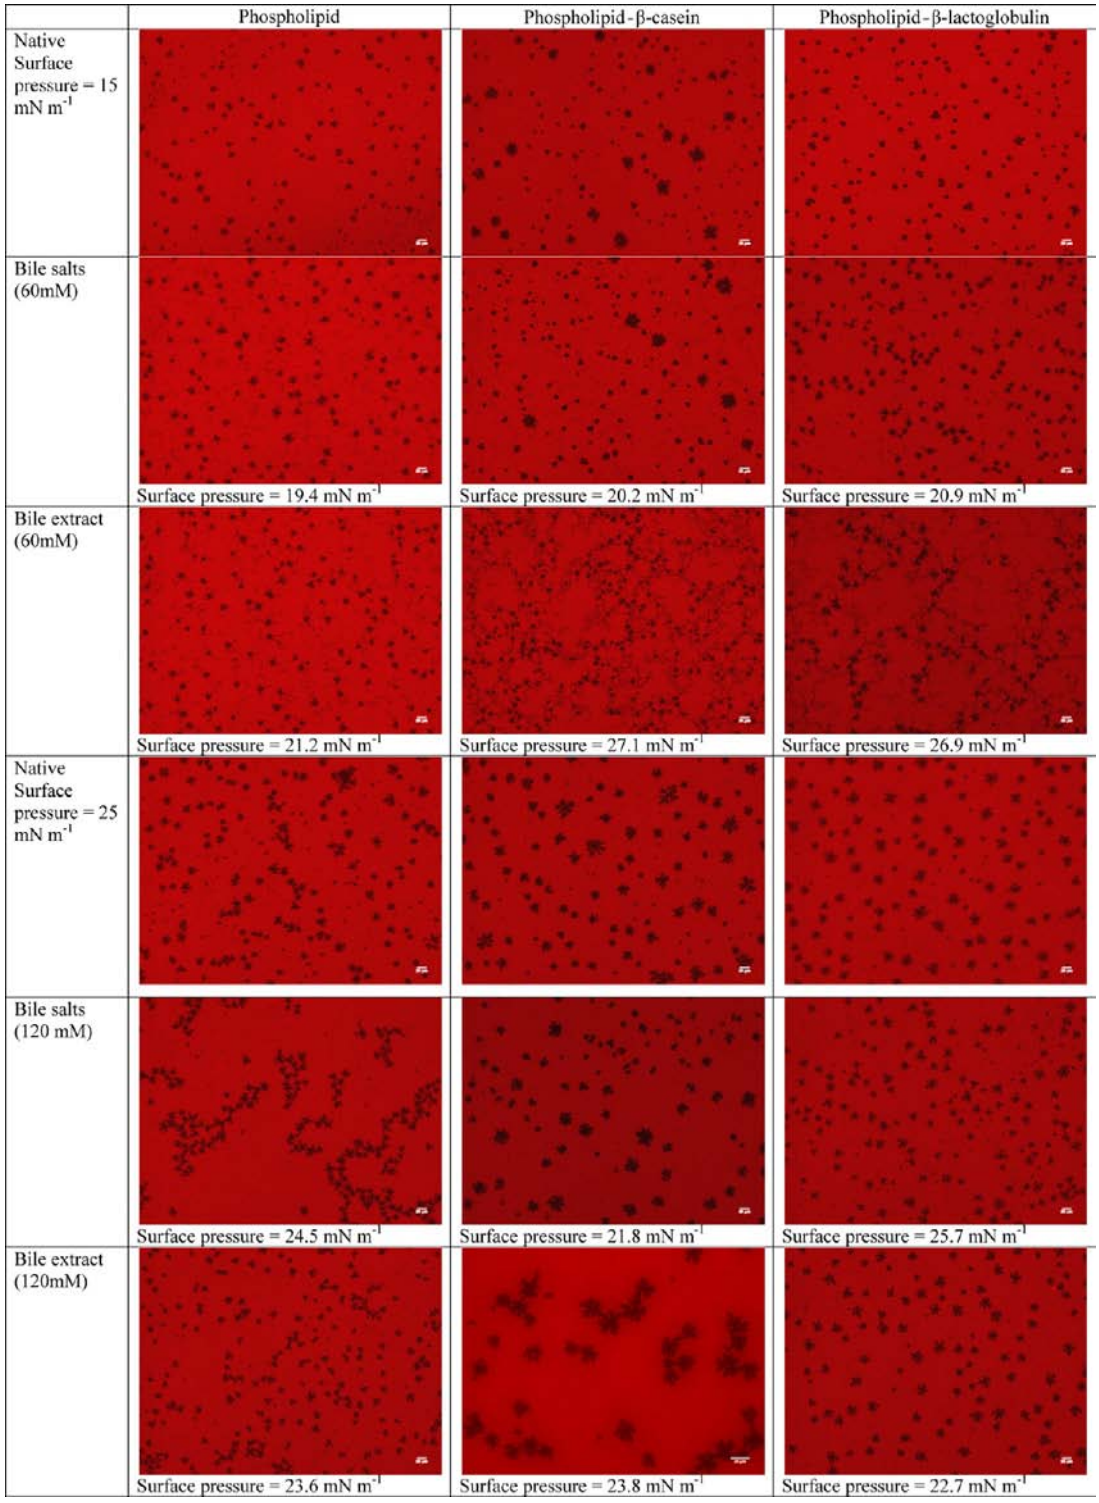

Figure 4. Epifluorescence microscopic images of phospholipid, phospholipid–β-casein (1:1, w/w), and phospholipid–β-lactoglobulin (1:1, w/w) monolayers spread on SIF at 20 °C before (native) and after the addition (30 min) of 0.22 mM bile salts or bile extract from a 60 or 120 mM stock solution. The bile salts or bile extract was added after the monolayers had been stabilized for 5 min at either 15 or 25 mN m^{-1}. Scale bar = 20 μm.

formation of mixed bile salt–phospholipid films. It was not possible to conclude whether or not the addition of bile salts caused the displacement of proteins. The main changes were seen when bile salts and bile extract were added from a 60 mM stock solution to a monolayer previously stabilized at 15 mN m^{-1} (Figure 4). Some gray thin linear network, another phase domain where a small amount of fluorescent phospholipid analogue is dissolved, was observed within the liquid-disordered phase 30 min after the addition of bile salts. The network was more evident after the addition of bile extract, and the network was stretching out from the branches of the "snowflake"-shaped domains. The network formed very quickly, within 5 min in phospholipid monolayers and within 7–10 min for phospholipid–protein monolayers (results not shown). Similar

dx.doi.org/10.1021/jf404448d | J. Agric. Food Chem. 2014, 62, 1363–1372

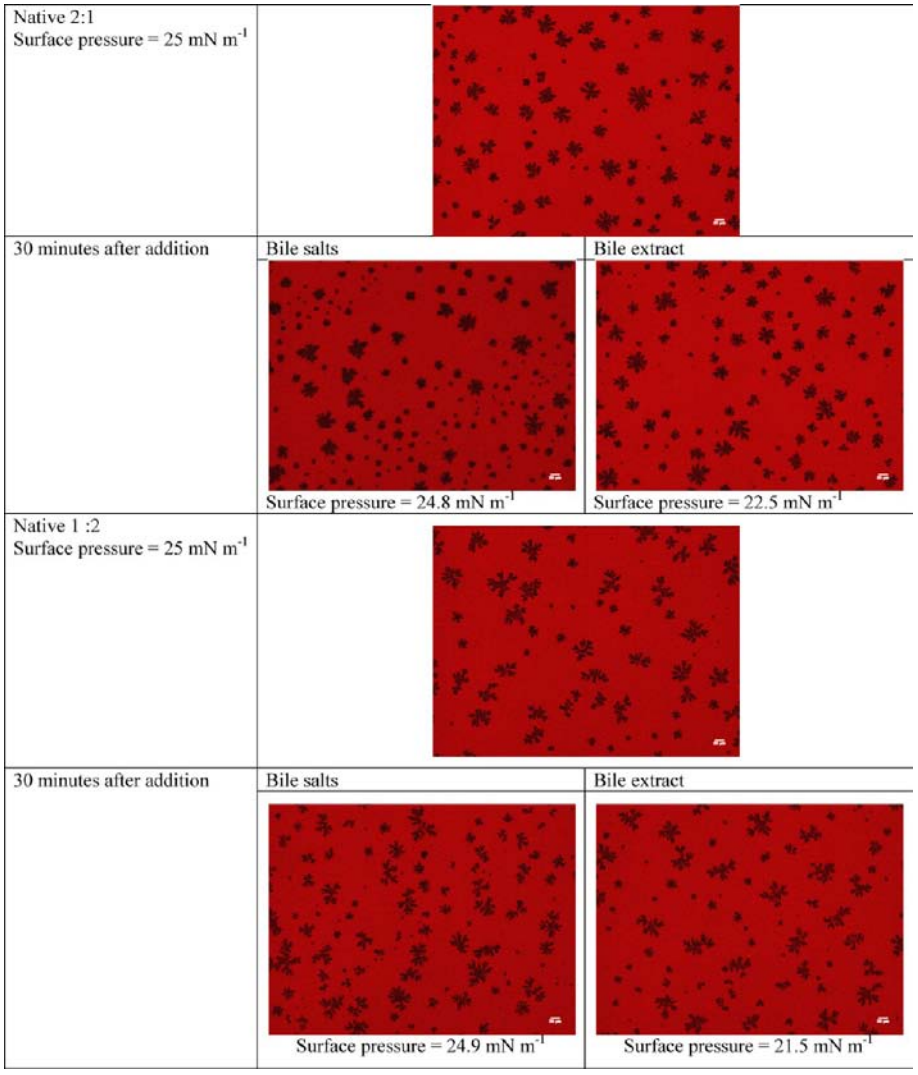

Figure 5. Epifluorescence microscopic images of phospholipid–β-lactoglobulin (2:1 or 1:2, w/w) monolayers spread on SIF at 20 °C before (native) and after the addition (30 min) of 0.22 mM bile salts or bile extract from a 120 mM stock solution. The bile salts or bile extract was added after the monolayers had been stabilized for 5 min at 25 mN m^{-1}. Scale bar = 20 μm.

branching was observed by Nagadome et al.[35] studying a system of cholesterol and bile acids at the air–water interface. The branching segments were identified as bile acids and were more pronounced in the presence of cholesterol. Thus, here, bile salts were likely responsible for the network (Figure 4) within the liquid-disordered phase, which could be accentuated in the presence of cholesterol from the bile extract. The cholesterol molecules were likely to interact with the liquid-ordered domains because of the preference of cholesterol for saturated SM.[12] The "thinning" of the branches of the "snowflake"-shaped domains was probably due to cholesterol molecules reducing the line tension at the liquid-ordered–liquid-disordered interface.[36]

When bile salts and bile extract were added from a 120 mM solution to a phospholipid, phospholipid–β-casein, or phospholipid–β-lactoglobulin monolayer stabilized at 15 mN m^{-1}, the network was less distinct but the liquid-ordered domains were clustered linearly, and additional small round black domains were seen within the liquid-disordered phase 30 min after the addition of bile salts (results not shown). The rate of addition of bile salts to phospholipid membranes affects the bile salt/phospholipid molar ratio related to the micellar state.[37] A slow rate of addition will allow time for structural reorganization of the bile salt/phospholipid membranes. When bile salts are added rapidly, an inhomogeneous or micellar morphological rearrangement takes place. This could explain the difference in partitioning of bile salts in phospholipid and phospholipid–protein monolayers when added from a 60 or 120 mM stock solution. The clustering of liquid-ordered domains is likely due to a reduction of the electrostatic forces between domains in the presence of bile components.[38]

When bile salts were added from a 120 mM stock solution after stabilization of the monolayers at 25 mN m^{-1}, lateral microstructural changes were observed only in phospholipid monolayers with linear clustering of a few liquid-ordered domains, whereas when bile extract was added, linear clustering of liquid-ordered domains was also observed in phospholipid–β-casein monolayers (Figure 4). It is possible that bile salts penetrate the monolayers more easily when the latter are compressed at 15 mN m^{-1} than at 25 mN m^{-1}, as phase separation (presence of liquid-ordered domains) was more pronounced at 25 mN m^{-1}, as seen in Figure 4.

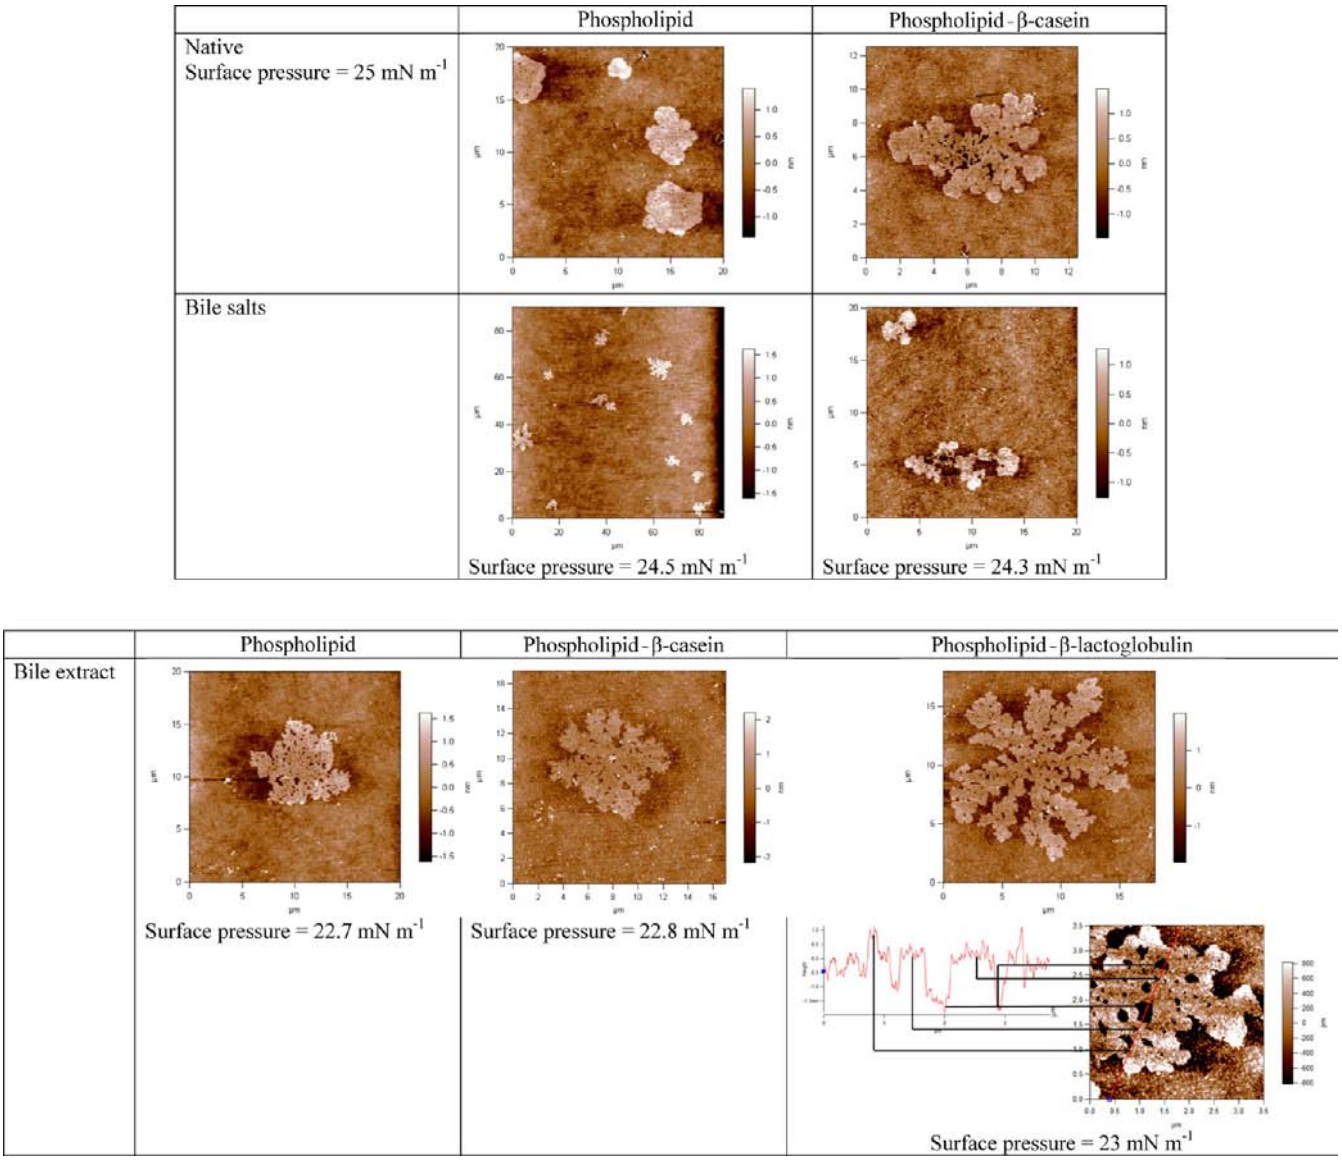

Figure 6. Atomic force microscopic height images of phospholipid, phospholipid−*β*-casein (1:1, w/w), and phospholipid−*β*-lactoglobulin (1:1, w/w) monolayers spread on SIF at 20 °C before (native) and after the addition (5 min) of 0.22 mM bile salts or bile extract from a 120 mM stock solution. The bile salts or bile extract was added after the monolayers had been stabilized for 5 min at 25 mN m^{-1}. The height measurement corresponds to the red line on the zoomed height image.

Figure 5 presents the effect of adding 0.22 mM bile salts or bile extract on the lateral microstructure of a phospholipid−*β*-lactoglobulin (2:1 or 1:2, w/w) monolayer previously stabilized at 25 mN m^{-1} and observed with an epifluorescence microscope. No change in microstructure of the native monolayers was observed using either phospholipid/*β*-lactoglobulin ratio, suggesting that under these conditions (surface pressure higher than the equilibrium surface pressure of the protein) phospholipids dominated the interface. The addition of bile salts or bile extract to phospholipid−*β*-lactoglobulin (2:1 or 1:2, w/w) monolayers did not induce any microstructural changes (Figure 5). The displacement of proteins by bile salts depends on the native structure of the proteins and the concentration of the bile salts.[31] *β*-Lactoglobulin is a compact globular protein, and its displacement may be incomplete due to the presence of intramolecular disulfide bonds. This may explain the absence of branching and clustering of the liquid-ordered domains. In addition, the surface pressure may also play a role as, at 25 mN m^{-1}, which is higher than the collapse pressure of *β*-lactoglobulin, no change in the morphology of the phospholipid−*β*-lactoglobulin monolayers was observed after addition of bile salts or bile extract (Figures 4 and 5).

The interactions between phospholipids and *β*-casein are weak at neutral pH at the air−water interface, allowing for the displacement of the protein by the phospholipids.[39] In addition, phospholipids dominate the air−water interface at high phospholipid/protein ratios. At surface pressures higher than the collapse pressure of *β*-casein, in this study 25 mN m^{-1}, *β*-casein and phospholipids interact to some extent. Thus, the displacement of the remaining proteins or weakly associated proteins by bile salts and cholesterol may be facilitated in the presence of phospholipids and at 25 mN m^{-1}.

The effect of the addition of bile salts and bile extract to phospholipid, phospholipid−*β*-casein, or phospholipid−*β*-lactoglobulin monolayers previously stabilized at 25 mN m^{-1}

dx.doi.org/10.1021/jf404448d | J. Agric. Food Chem. 2014, 62, 1363−1372

at 20 °C was studied with an atomic force microscope (Figure 6). Five minutes was sufficient to reach the final surface pressure after the addition of bile salts (Figure 3) or bile extract (results not shown). The native monolayers presented liquid-ordered domains with round edges (Figure 6). As seen in Figures 4 and 5, the addition of bile salts and bile extract led to a stretching of the branches of the "snowflake"-shaped domains (Figure 6). The shape of fractal-like or "snowflake"-like domains is governed by electrostatic repulsive forces, which maximize the intermolecular distance within a domain.[40] Thus, the increase of negative charges at the surface from the adsorbed bile salts is likely responsible for the change of the domain shape. The use of AFM revealed extra features within the liquid-ordered domains. The interactions of the bile salts and bile extract with the monolayers led to the formation of small platforms within the "snowflake"-shaped domains (Figure 6). As seen from the height measurement on the zoomed height image, the liquid-ordered domains were 1 nm higher than the liquid-disordered phase and the platforms were between 1.5 and 2 nm lower than the liquid-ordered domains (Figure 6).

Bile salts tend to form clusters at the oil−water interface.[31] The platforms within the liquid-ordered domains (Figure 6) are thus likely to be bile salt-rich areas. Bile salts may be able to disturb the order of the hydrocarbons chains of SM and insert themselves into defects present in the liquid-ordered domains or at the borders between the liquid-disordered and liquid-ordered phases. At the domain boundaries, the line tensions are lower, facilitating the insertion of bile salts into the monolayers. This could explain the clustering of liquid-ordered domains upon adsorption of bile salts seen in Figures 4 and 5. In DPPC monolayers, the liquid-condensed phase was solubilized into a liquid-expended phase upon association of bile salts with DPPC head groups.[30] However, SM and cholesterol molecules are solubilized at higher concentration of bile salts;[41] thus, liquid-ordered domains are still present here after the addition of 0.22 mM bile salts and bile extract.

The MFGM acts as a barrier against lipolysis by inhibiting the access of the triglyceride core to the pancreatic lipase.[14] Chu et al.[16] found that the pancreatic colipase−lipase complex adsorbed preferentially onto the mixed bile salt−DPPC regions rather than onto the liquid-condensed phase of monolayers. As the liquid-ordered domains are tightly packed, the colipase−lipase complex is likely to adsorb onto the bile salt-rich platforms within the liquid-ordered domains and in the liquid-disordered phase, where there is more space between molecules allowing the adsorption of the colipase−lipase complex.

Most often, studies are carried out at 20−27 °C,[5,29,37] which is not physiologically relevant, but there are some technical difficulties associated with working at 37 °C such as evaporation of the aqueous subphase and condensation on the optical lens. However, some AFM work was performed at 37 °C[16] or the adsorption experiment was performed at 37 °C but the LB films were prepared at 20 °C.[18] It is important to keep in mind that lipid packing is affected by temperature.[12,42] Thus, performing the adsorption experiment at 37 °C and then decreasing the temperature to 20 °C before the preparation of LB films was not possible in this study.

Using a physiological concentration of conjugated bile salts, Patton et al.[43] investigated the release of MFGM to understand the intestinal lipolysis of fat globules from different species. After addition of up to 1 mM bile salts to washed milk fat globules, MFGM fragments were recovered as a pellet after centrifugation. Above a bile salt concentration of 1 mM, most phospholipids were recovered in the subnatant, likely associated with bile salts. Thus, depending on the temperature and concentration of bile salts, either a solubilization or an interaction phenomenon takes place between bile salts and phospholipids. It is likely that, at a physiological concentration of 4.4 mM bile salts, phospholipids are solubilized.

This study showed that the adsorption of bile salts to phospholipid and phospholipid−protein monolayers was affected by the temperature, the surface pressure, and the addition rate, concentration, and composition of bile. The presence of β-casein did not seem to affect the adsorption of bile salts, whereas β-lactoglobulin seemed to play a role in maintaining some of the microstructural features of native phospholipid−β-lactoglobulin monolayer films. The surface pressure of the phospholipid and phospholipid−protein monolayers before the addition of bile salts and bile extract was also a determining factor of resistance to penetration by bile components. The formation of bile salt-rich platforms within the liquid-ordered domains might play a role in the adsorption of pancreatic lipase and colipase at the surface of the milk fat globules and milk phospholipid liposomes in the duodenum.

applications in winemaking. Among them, as a consequence of its high content in GSH, g-IDYs have been claimed to preserve wine aroma and color during wine storage. Although, as has been recently stated,[17] no literature could be found on the industrial preparation of g-IDYs[15] and it is still not clear whether exogenous GSH enrichment is allowed during the manufacturing process, the release of reduced GSH (the form active against oxidation) into the wines has been recently proven.[18,19] However, the effectiveness of the GSH released by these preparations on wine oxidation inhibition has not yet been investigated. Andujar-Ortíz and collaborators[20] recently revealed significant differences between rosé Grenache wines produced by using a g-IDY preparation and nontreated wines in some sensory aroma attributes but only after 9 months of wine aging. This effect could be attributable to the GSH released from IDY or the stimulating effect of amino acids and other peptides from the IDY on GSH synthesis by yeast under winemaking conditions.[18,19]

Considering the current interest of the wine industry in the use of g-IDY preparations to preserve the aroma of wines and the lack of published literature on this topic, the aim of this work was to evaluate the effect of a g-IDY preparation on some typical and desirable wine aroma compounds (linalool, α-terpineol, β-citronellol, and nerol) by using model wines submitted to accelerated oxidative conditions. The effect of a second type of IDY preparation with a different claim (fermentative nutrient) and the effect of commercial GSH were also evaluated. To further understand the role of GSH from the IDY formulations, the wines were spiked with the low molecular weight fraction (<3 kDa) obtained by cold ultracentrifugation, avoiding the interaction of other yeast components (glycoproteins) with the aroma compounds.[21,22] To conclude, chemical characterization of both IDY permeates (<3 kDa fraction) was carried out by using targeted and nontargeted metabolomic approaches using Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR-MS) and capillary electrophoresis−mass spectrometry (CE-MS) analytical platforms.

MATERIALS AND METHODS

IDY Samples. Two types of enological IDY preparations were selected for being representative of the current preparations in the enological market and because they are widely used in winemaking: a GSH-enriched IDY (g-IDY) recommended to reduce the oxidation of wine aroma compounds because of the presence of higher amounts of GSH, and an IDY preparation commonly used as fermentation nutrient (n-IDY). The comparison between both types of IDYs (with and without GSH in their composition) should better provide evidence about the role of GSH released by IDY in wine aroma oxidation.

Isolation of <3 kDa Fraction from the IDY Preparations by Ultrafiltration. Four grams of each IDY powder was weighed into 50 mL centrifuge tubes. Samples were extracted with 50 mL of water/ethanol solution (87:13, v/v) in an ultrasonic bath (3 cycles, 5 min each) at 4 °C. The mixture was then centrifuged (15 min at 5000*g* and 10 °C), and the supernatant was ultrafiltered using a Centricon device (Amicon Inc., Beverly, MA, USA) with a 10 kDa cutoff membrane. The obtained permeates were submitted to a second ultrafiltration step through a 3 kDa cutoff membrane Centricon (Amicon Inc.). Both ultrafiltration steps were carried out at cold temperature (below 10 °C). The obtained <3 kDa permeates from each IDY preparation were freeze-dried and kept at −20 °C until use. Prior to chemical characterization, permeates were reconstituted with water to 100 mg/mL dry residue. Only for FT-ICR-MS analysis were reconstituted samples dialyzed by using a Float-a-Lyzer G2 device with a 0.1−0.5 kDa cutoff membrane from Spectrum (Breda, The Netherlands) to remove salts.

Model Wine Solutions under Accelerated Aging Conditions. Model wine solutions (50 mL) were prepared in 100 mL vials by adding ethanol (VWR, Leuven, Belgium) at 120 mL/L and 4 g/L tartaric acid (Panreac, Barcelona, Spain). The pH was adjusted at 3.5 using a 5 M NaOH solution (Panreac). Model wines were spiked with single terpene compounds (nerol, β-citronellol, α-terpineol, and linalool) from Sigma (Stenheim, Germany) at a final concentration of 25 mg/L each. Finally, 100 μL of the reconstituted <3 kDa fractions isolated from g-IDY or n-IDY at 100 mg/mL was added. In addition, another set of model wines were individually aromatized with the four aroma compounds and spiked with commercial GSH (Sigma) to a final concentration of 10 mg/L. Finally, four control model wines, one with each aroma compound but without addition of the IDY fractions or commercial GSH, were also prepared. Two vials of the model wines containing each terpene compound were analyzed at the beginning of the experiment (t = 0 days). The different model wine mixtures were submitted to an accelerated oxidation process during 3 weeks at 25 °C, saturating the headspace of the vials with oxygen (t = 21 daus). All of the preparations were carried out in duplicate.

HS-SPME-GC/MS Analysis. Model wine aroma analysis was performed before (t = 0 days) and after (t = 21 days) model wine oxidation process. It was carried out by headspace solid-phase microextraction coupled to gas chromatography−mass spectrometry (HS-SPME-GC-MS). Model wine samples (8 mL), 2.3 g of NaCl, and 40 μL of an internal standards solution (400 mg/L 3,4-dimethylphenol and 2.5 mg/L methyl nonanoate) were added to a 20 mL SPME vial. The SPME procedure and chromatographic conditions were detailed in a previous work.[23] Briefly, the extraction procedure was automatically performed using a CombiPal system (CTC Analytics AG, Zwingen, Switzerland) with a 50/30 μm DVB/CAR/PDMS fiber of 2 cm length from Supelco (Bellefonte, PA, USA). Samples were preincubated for 10 min at 50 °C, and extraction was performed in the headspace of each vial for 30 min at 50 °C. Desorption was performed in the injector of the GC system in splitless mode for 1.5 min at 270 °C. After each injection, the fiber was cleaned for 20 min to avoid any memory effect. The chromatographic separation was performed in a GC-MS instrument (Agilent 6890GC, Agilent 5973 N MS) equipped with a Supra-Wax fused silica capillary column (60 m × 0.25 mm i.d. × 0.50 μm film thickness) from Konik (Barcelona, Spain). Helium was used as the carrier gas at a flow rate of 1 mL/min. The oven temperature was initially held at 40 °C for 5 min, then increased at 4 °C/min to 240 °C, and held at 240 °C for 20 min. The acquisitions were performed in scan (from 35 to 350 amu) and electronic impact mode (70 eV). Other MS conditions were 270, 150, and 230 °C for the transfer line, quadrupole, and ion source, respectively. The signal corresponding to a specific ion of quantification (m/z 93, 59, 69, and 69 for linalool, α-terpineol, β-citronellol, and nerol, respectively) was calculated by the data system. Compound identification was carried out by comparison of retention times and mass spectra of the reference compounds with those reported in the mass spectrum library NIST 2.0. Data were obtained by calculating the relative peak area (RPA) in relation to that of the corresponding internal standard (3,4-dimethylphenol, for all of the aroma compounds except for nerol, which was methyl nonanoate).

Analysis of Reduced Glutathione (GSH), Total Glutathione, and γ-Glutamylcysteine (γ-glu-cys) by RP-HPLC-FL. Reversed-phase HPLC using a liquid chromatograph consisting of a Waters 600 Controller programmable solvent module (Waters, Milford, MA, USA), a WISP 710B autosampler (Waters), and a HP 104-A fluorescence detector (Hewlett-Packard, Palo Alto, CA, USA) was used following the procedure previously optimized and validated.[18] The mobile phase was composed of methanol (Lab-Scan, Sowinskiego, Poland) and an aqueous solution of phosphate buffer (10 mM $NaH_2PO_4 \cdot 12H_2O$ at pH 8.5) with a ratio of 15:85 (v/v). The sample (30 μL) was placed in a 1 mL vial (by using an insert), and the precolumn derivatization was automatically made in the autosampler at 12 °C as follows: to a sample vial were added 105 μL from the dithiotreitol (Sigma-Aldrich) solution vial [5 mM and 0.5 mM in

borate buffer (0.2 M H_3BO_4, pH 9.2) to determine total GSH or reduced GSH, respectively] and 15 μL of 2,3-naphthalenedialdehyde (NDA) (Sigma-Aldrich) solution (5 mg mL^{-1} in ethanol); then, two mixture cycles of the total content of the insert were carried out, and 100 μL was injected in the chromatographic system. Separation was carried out on a Nova Pack C18 (150 mm × 3.9 mm i.d., 60 A, 4 μm) column (Waters) in isocratic mode (flow at 1 mL min^{-1}), and detection was performed by fluorescence ($\lambda_{excitation}$ = 467 nm, $\lambda_{emission}$ = 525 nm). The derivatization conditions for the determination of γ-glu-cys were the same as previously described. Calibrations were carried out by using pure standard compound solutions of GSH and γ-glu-cys. The analysis of the samples was made in duplicate.

ORAC-Fluorescein (ORAC-FL) Assay. The antioxidant capacity of IDY permeates and GSH was measured by ORAC-FL assay based on that proposed previously.[24] Briefly, the reaction was carried out at 37 °C in 75 mM phosphate buffer (pH 7.4), and the final assay mixture (200 μL) contained FL (70 nM), AAPH (12 mM), and antioxidant [Trolox (1−8 μM) or sample at different concentration]. The plate was automatically shaken before the first reading, and the fluorescence was recorded every minute for 80 min. A polestar Galaxy plate reader (BMG Labtechnologies GmbH, Offemburg, Germany) with 485-P excitation and 520-P emission filters was used. The equipment was controlled by Fluostar Galaxy software (version 4.11-0) for fluorescence measurement. Black 96-microwell microplates (96F untreated, Nunc, Denmark) were used. AAPH and Trolox solutions were prepared daily, and FL was diluted from a stock solution (1.17 mM in 75 mM phosphate at pH 7.4). Fluorescence measurements were normalized to the curve of the blank (no antioxidant). From the normalized curves, the area under the fluorescence decay curve (AUC) was calculated. The regression equation between net AUC and antioxidant concentration was calculated, and the slope of the equation was used to calculate the ORAC-FL value by using the Trolox curve obtained for each assay. Final ORAC-FL values were expressed as micromoles of Trolox equivalent per milligram of dry permeate (for the <3 kDa permeates from g-IDY and n-IDY) and in micromoles of Trolox equivalent per milligram of pure compound for commercial GSH.

Total Free Amino Acids and Peptides. Free amino acids and peptides in model wine were determined according to the protocols proposed by Doi and co-workers.[25] Free amino acids were determined by the reaction of ninhydrin/Cd with the free amino group by measuring the absorbance at 507 nm (method 5).[25] On the other hand, free amino acids plus peptides were determined by the reaction of the amino group with ninhydrin/Sn by measuring the absorbance at 570 nm (method 1).[25] A DU 70 spectrophotometer from Beckman Coulter (Fullerton, CA, USA) was used. Quantification was carried out on the basis of the standard curve of leucine, and results were expressed as milligrams N/L. All of the model wine samples were analyzed in duplicate.

Analysis of Amino Acids by RP-HPLC-FL. Amino acids were analyzed in duplicate by reversed-phase HPLC using a liquid chromatograph as described under Analysis of Reduced Glutathione (GSH), Total Glutathione, and γ-Glutamylcysteine (γ-glu-cys) by RP-HPLC-FL. Samples were submitted to automatic precolumn derivatization with *o*-phthaldehyde (OPA) in the presence of 2-mercaptoethanol following the method described by Moreno-Arribas and collaborators.[26] Separation was carried out on a Waters Nova Pack C18 (150 × 3.9 mm i.d., 60 A, 4 μm) column and the same type of precolumn. Detection was performed by fluorescence ($\lambda_{excitation}$ = 340 nm, $\lambda_{emission}$ = 425 nm).

Analysis of Sulfur-Containing Metabolites by CE-MS. CE analyses were carried out in a P/ACE 5500 CE apparatus from Beckman Coulter. The CE system was coupled to a TOF MS instrument from Bruker Daltonics (Bremen, Germany) through an orthogonal ESI interface model G1607A from Agilent Technologies (Palo Alto, CA, USA). Electrical contact at the ESI needle tip was established via a sheath liquid delivered by a 74900-00-05 Cole Palmer syringe pump (Vernon Hills, IL, USA). The electrophoretic separation was carried out using an uncoated fused-silica capillary (50 μm internal diameter, 363 μm outside diameter, and 80 cm total length) from Composite Metal Services (Worcester, UK). Before first use, the separation capillary was conditioned by rinsing with 1 M NaOH for 10 min, followed by 20 min with water, both using pressurized N_2 at 20 psi (1380 mbar). After each run, the capillary was conditioned with water during 2 min, followed by BGE during 4 min. Injections were made at the anodic end using N_2 pressure at 0.5 psi (34.5 mbar) for 80 s. Electrophoretic separation was achieved by applying +25 kV at room temperature in a BGE composed of 3 M formic acid. Electrical contact at the ESI needle tip was established via a sheath liquid based on isopropanol/water (50:50, v/v) and delivered at a flow rate of 0.24 mL/min. The mass spectrometer operated in the positive ion mode. The nebulizer and drying gas conditions were 0.4 bar N_2 and 4 L/min N_2, respectively, and the ESI chamber temperature was maintained at 250 °C. Spectra were acquired in the m/z 50−700 range every 90 ms. External and internal calibration of the TOF MS instrument was performed by introducing a 10 mM sodium formate solution through the separation capillary. The ions used for the calibration of the TOF MS instrument were next: m/z 90.9766, 158.9641, 226.9515, 294.9389, 362.9263, 430.9138, 498.9012, and 566.8886. TOF MS provided a high mass resolution and high mass accuracy with errors usually below 10 ppm. Selected mass spectra were processed through the software DataAnalysis (Bruker Daltonics), which provided a list of possible elemental formulas by using the Generate-Molecular Formula Editor (Bruker Daltonics), which provided standard functionalities such as minimum/maximum elemental range, electron configuration, and ring-plus double bond equivalents, as well as a comparison between the theoretical and experimental isotopic pattern (Sigma-Value) for increased confidence in the theoretical molecular formula assignment.

Nontargeted Metabolomic Analysis by FT-ICR MS. FT-ICR MS was used to obtain ultrahigh-resolution (>100,000) mass spectra. Separation and identification of the metabolites were possible without the need of chromatography or derivatization due to the ultrahigh mass accuracy. Commercial beer maltooligosaccharides were used as mass calibrants and tuning standards in both the positive and negative ion modes.[27] The maximum mass error achieved was below 2 ppm.

Experiments were performed on a hybrid triple-quadruple-FT-ICR instrument Varian 920 MS provided with a 7.0 T actively shielded superconducting magnet and equipped with an electrospray ionization (ESI) source. The conditions in the electrospray were as follows: In positive mode the potential in the needle was set at 4.5 kV and 600 V in the shield. The capillary potential to pass the ions from the source to the skimmer was set in a range between 40 and 60 V. Nitrogen was employed as nebulizer gas, and its pressure was 50 psi. The pressure for drying gas was set at 18 psi and the temperature at 300 °C. The flow rate of the sample was kept at 15 μL/min and injected by direct infusion. In negative mode MS parameters were as follows: −3.5 kV, 600 V, from −70 to −90 V in the capillary, 18 psi, and 300 °C. Sample flow rate was 15 μL/min. Air was used instead of nitrogen as nebulizer gas. The spectra were acquired in full scan mode, defining a mass range from m/z 100 to 1000. The internal detection signal in the cell detector of the FT-ICR was optimized for a mass of m/z 500.

Monoisotopic mass and isotope cluster profiles were extracted from the raw data by using Varian MS Peak Hunter software version 4.1.89. These two parameters were used by the same software to get the elemental composition following the next criteria: error was set at 2 ppm, and only chemical formulas containing C, H, N, O, P, and S were allowed. The spectra were exported to mzXML format and applied against XCMS[28] online METLIN database. When the results from the METLIN database were in good agreement in accordance with the chemical formula found in Varian MS Peak Hunter, the metabolite was given as a good result.

Statistical Analysis. Data from the analysis of aroma compounds (RPAs) from the model wine experiments were submitted to one-way ANOVA and LSD to test the effect of wine treatment.

RESULTS AND DISCUSSION

Effect of the Addition of GSH and the <3 kDa Permeates Isolated from IDYs on Specific Wine

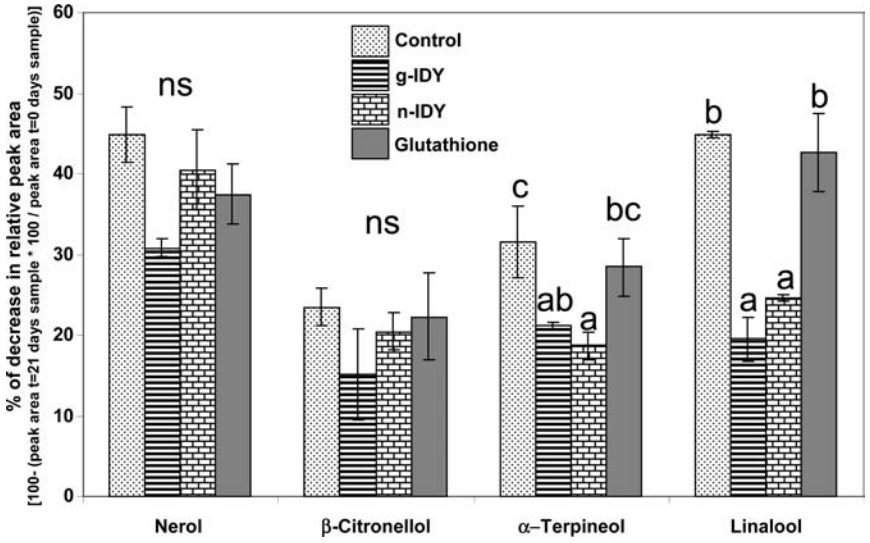

Figure 1. Percentage of decrease in the relative peak area of the aroma compounds in the model wines submitted to accelerated aging conditions (wines supplemented with the <3 kDa permeates isolated from g-IDY and n-IDY, wines with added 10 mg/L of commercial glutathione, and control wines without any treatment) compared to the original model wines (0 days). Results of ANOVA and LSD test are indicated with different letters (a–c). ns: no significant differences.

Terpenes in Model Wines under Accelerated Aging Conditions. To determine the effect of GSH-enriched IDY preparations on the evolution of aroma compounds during aging and whether the GSH released from IDYs into the wines might have a role in the behavior of aroma compounds during aging, the <3 kDa permeate from a g-IDY preparation was isolated by ultracentrifugation and spiked into model wines, as described under IDY Samples. Model wines spiked with this permeate were coded g-IDY-W. Ultrafiltration ensured the removal of glycoproteins (with molecular masses >3 kDa) from the IDY preparations that might interact with volatiles,[21,22] masking the potential action of GSH on the aroma compounds, which was the main objective of this study. In addition, to compare the effect of a different type of IDY preparation currently commercialized as a fermentation nutrient (without any claim on wine aroma protection), the <3 kDa permeate was also isolated and added to model wines (n-IDY-W). In addition, two other types of model wines with added commercial GSH (10 mg/L) referred to as glut-W and control model wines, without any addition (cont-W), were also prepared. To avoid chemical transformations due to the high reactivity of terpene compounds,[3] each model wine solution was individually aromatized with a single aroma compound (nerol, β-citronellol, α-terpineol, and linalool). These aromas were selected because they are characteristic of young wines providing pleasant floral-fruity nuances and are very sensitive to the oxidation phenomena.[3,29,30] The behavior of the four terpene compounds was evaluated in all of the model wines at the beginning of the experiment (t = 0 days), corresponding to nonoxidized model wines, and after 3 weeks of accelerated aging conditions (t = 21 days). Figure 1 shows the percentage of decrease in relative peak area (RPA) between the initial wine sample (nonoxidized) and the wines after 21 days of aging for each aroma compound and wine type. As can be seen, there was a general decrease in RPAs for all of the aromas during aging, which ranged from 24 to 45%, therefore confirming the outstanding effect of aging on the loss produced in these types of aroma compounds,[2,3,14] which can be attributable to oxidation phenomena.[3,29,30] Interestingly, compared to the control wine solution, α-terpineol and linalool showed a lower reduction in RPAs in the model wines supplemented with the <3k Da permeate isolated from either of both preparations (g-IDY or n-IDY). In the case of nerol, a slightly lower reduction in RPAs was also observed in the g-IDY model wine, although this effect was not statistically significant. β-Citronellol did not show a significant effect either. These results seemed to indicate a protective effect of these preparations on some specific aroma compounds, which is in agreement with the aroma sensory differences recently found between control rosé wines (without IDY added) and rosé wines produced in cellar conditions with the same type of g-IDY after 9 months of aging.[20]

However, the addition of commercial GSH to the model wine solutions did not have a significant effect under the essayed conditions. Different published works have shown an inhibition of the decline of certain aroma compounds when using GSH at a similar or even lower dosage in wines or model wine systems.[4,6−9] Nonetheless, it is well-known that the main effect of GSH in wines is its ability to react with *o*-quinones produced by oxidation of caftaric acid (and other polyphenols) to give grape reaction product (GRP) by the action of polyphenol oxidases blocking the subsequent steps in which polyphenols are involved (polymerization) and responsible for browning.[4,6,17] Moreover, *o*-diphenols can be directly oxidized in the presence of oxygen and some cations (iron, copper) to *o*-quinones and hydrogen peroxide, which might be involved in subsequent aroma oxidation.[4] In our experimental conditions this action mechanism was limited because of the absence of polyphenols to react with GSH in the model wine, which seems to explain the absence of a noticeable effect of GSH on aroma protection in the model wines supplemented with commercial GSH. However, GSH presents scavenging hydroperoxide and hydroxyl radical properties, which might have allowed it to act as an antioxidant by other mechanisms different from its capacity to interact with *o*-quinones in polyphenol-free systems.[10,11] Nonetheless, on the basis of our results, this mechanism did not seem as significant in our experimental conditions. Despite this, it is important to highlight that this model system allowed us to uncover the potential role of other

yeast components, different from GSH and contained in the <3 kDa fraction, which seemed to be related to the protection of some terpenes in model wines submitted to accelerated aging conditions.

Following this rationale, to find out if the observed reduction in peak areas for some of the terpenes employed in our study was effectively related to an antioxidant effect exerted by the IDY permeates, the radical scavenging activity of both of them was calculated by using the ORAC-FL method. The ORAC values were 0.33 and 0.22 μmol TE/mg dry permeate for g-IDY and n-IDY permeates, respectively, showing that the two permeates had a positive and similar antioxidant capacity. These results are in agreement with the previous experiment, in which g-IDY-W and n-IDY-W wines showed a similar reduction in the corresponding peak areas for the same aroma compounds (linalool and α-terpineol). In addition, to confirm the antioxidant activity of the commercial GSH employed in this experiment, the ORAC value for the pure compound was also calculated; this is 10.7 μmol TE/mg pure compound, thus corroborating its high antioxidant capacity, comparable to other important wine antioxidants such as polyphenols. As an example, for a representative set of pure polyphenolic compounds, the calculated ORAC values ranged between 2.35 and 18.16 μmol TE/mg pure compound determined for myricetin and caffeic acid, respectively.[31] Nevertheless, and as previously stated, despite the high antioxidant activity determined for GSH, this compound did not exert a noticeable effect in preventing aroma oxidation in a model wine in the absence of polyphenols, as used in the present work. However, these results confirmed the antioxidant properties of both IDY permeates in agreement with the better preservation of some terpenes observed in the model wines supplemented with them. However, this effect, at least in the g-IDY wines, might have been a consequence of the higher amount of GSH contained in the g-IDY permeate compared to that added into the wines by using commercial GSH (10 mg/L), which on the basis of its radical scavenging properties might be responsible for the lower aroma loss in g-IDY wines. Therefore, a quantitative determination of GSH, total GSH, and the precursor γ-glutamylcysteine, was carried out.

Determination of GSH, Total GSH, and γ-Glutamylcysteine. Reduced GSH, total GSH, and the precursor γ-glutamylcysteine were analyzed by using a previously optimized RP-HPLC-FL method.[18] These results are shown in Table 1. As can be seen, only the g-IDY permeate presented detectable levels of GSH (1293 mg/L) and γ-glutamyl-cysteine (873 mg/L). The amount of total GSH was higher (3147 mg/L), meaning that only 41% of glutathione was in its reduced form (GSH) and available to act as a potential antioxidant. However, in the n-IDY permeate, there were traces of GSH or GSH-related compounds. This is in agreement with some previously published works in which in a screening of commercial enological IDY preparations, only those claimed to be GSH-enriched IDY preparations released reduced GSH into synthetic wines.[18] With the amount of each permeate added into the model wines (100 μL) taken into consideration, the final amounts of reduced and total GSH in g-IDY-W model wines were 2.6 and 6.3 mg/L, respectively, which are very close to the amounts determined in model wines when using IDYs at the recommended wine dosage (0.3 g IDYs/L), which has been established to be between 1 and 2.5 mg/L.[18,19] Considering that no GSH (or other GSH-related compounds) was detected in n-IDY-W model wine and that the amount of GSH determined in g-IDY-W was lower than the amount of commercial GSH employed in the GSH-W model wine (10 mg/L), it could be concluded that the observed antioxidant effect of these preparations on the reduction of aroma loss during wine aging did not seem to be linked to the sole antioxidant action of GSH but could be due to other compounds or to the combined action of GSH and other antioxidant compounds from yeast origin present in the permeates (at least in n-IDY-W model wine). In the attempt to elucidate these compounds, a comprehensive chemical characterization of both g-IDY and n-IDY permeates was carried out.

Table 1. Concentration of Total GSH, Reduced GSH, and γ-Glutamyl-cysteine Determined in the <3 kDa Permeates Isolated from g-IDY and n-IDY Preparations

IDY preparation	total GSH (mg/L)	reduced GSH (mg/L)	γ-glutamyl-cysteine (mg/L)
g-IDY	3147 ± 118	1293 ± 76	873 ± 63
n-IDY	nd[a]	nd	nd

[a]nd, not detected.

Analysis of Other Sulfur-Containing Compounds by CE-MS. In addition to GSH, other biological sulfur-containing compounds have been said to present antioxidant properties.[32] Thus, the analysis of other low molecular weight sulfur-containing compounds in the <3 kDa permeates from both g-IDY and n-IDY samples was performed by using CE-MS. This targeted analysis was carried out on the basis of the presence of at least one S atom in the molecular structure. The existence of sulfur in the molecule requires the presence in the mass spectra of an isotopic peak 2 Da higher than the molecular ion and at least 4% in intensity per sulfur. After further inspection of n-IDY and g-IDY CE-MS profiles, besides the 2 sulfur-containing amino acids methionine and cysteine, another 14 highly abundant sulfur-containing compounds were found in the permeate from the g-IDY sample. In Figure 2, extracted ion electropherograms (EIEs) from these two amino acids and the most abundant sulfur-containing compounds are represented (continuous and dotted lines for g-IDY and n-IDY samples, respectively). The electropherogram from n-IDY showed, however, only three major peaks (compounds **1**, **3**, and **5**), and methionine and cysteine were not detected either. Detailed information about the identity of these compounds is shown in Table 2. As can be seen in this table, 8 of 14 compounds could be tentatively identified. Most of them corresponded to glutathione derivatives (compounds **7**, **8**, **10**, **11**, and **14**) and, in general, the rest of the identified compounds were compounds related to the amino acids cysteine and methionine. Many sulfur compounds, including the sulfur-containing amino acids, have been shown to exhibit antioxidant properties in vivo and in vitro,[32,33] and all of them are synthesized from methionine.[29,33] Therefore, the absence of this amino acid in the n-IDY permeate is in agreement with the lack of sulfur-containing compounds in this sample. In synthetic wines, Papadopoulou and Roussis[8] showed that some sulfur-containing compounds, such as *N*-acetylcysteine, are effective at decreasing the rate of reduction of some aroma compounds (including terpenes) during wine aging. On the basis of existent literature and the chemical structure of the sulfur-containing compounds identified in g-IDY, the involvement of these compounds in the antioxidant activity determined in the model

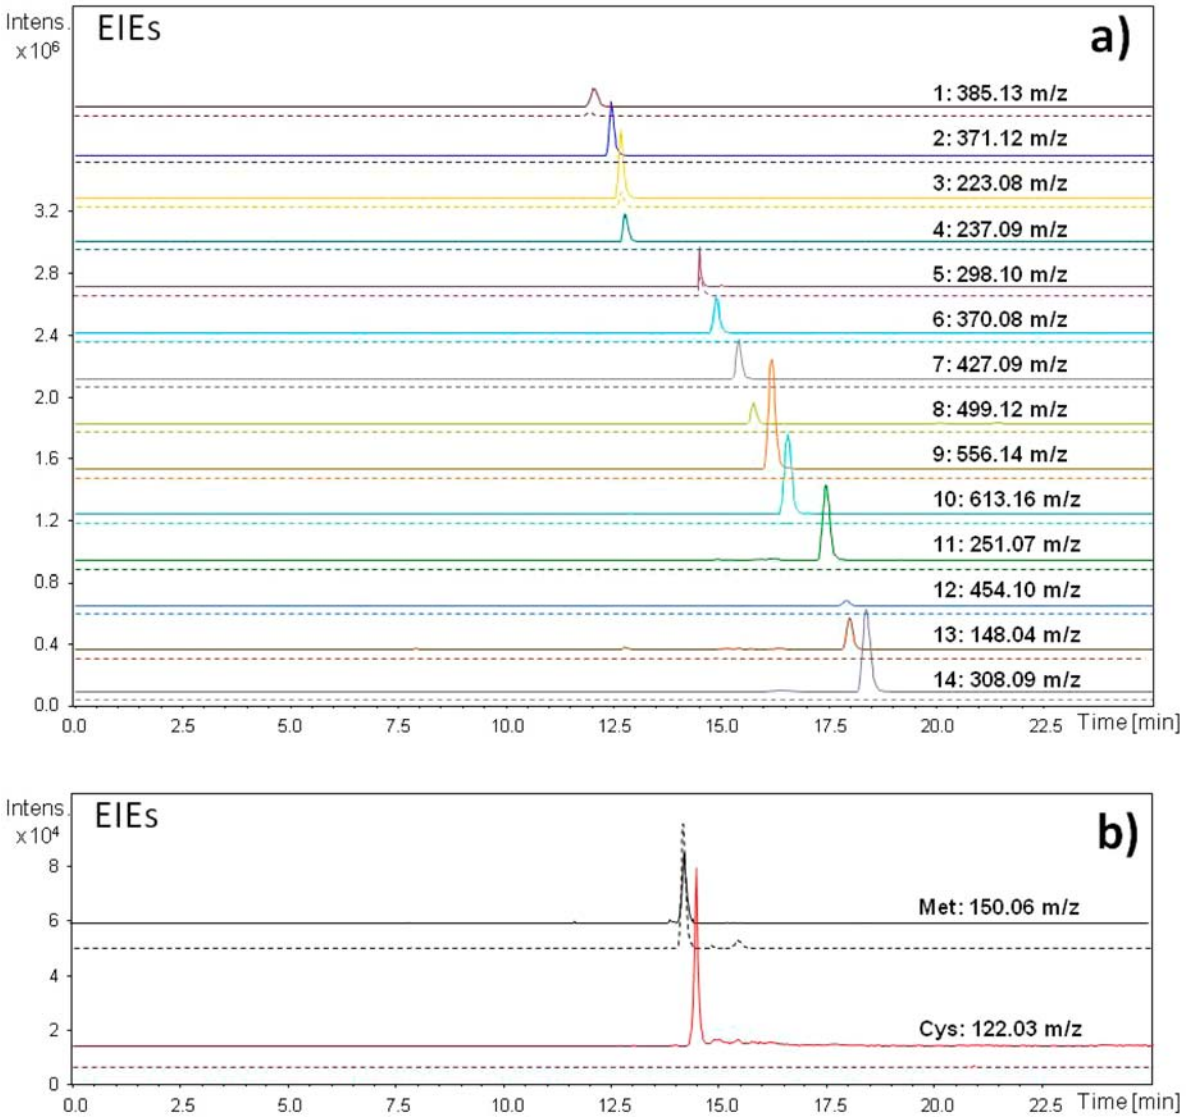

Figure 2. CE-TOF-MS extracted ion electropherograms (EIEs) of (a) the 14 most abundant sulfur-containing compounds and (b) methionine and cysteine from g-IDY and n-IDY samples. A continuous line for g-IDY permeate and a dotted line for n-IDY permeate are used. See Analysis of Sulfur-Containing Metabolites by CE-MS for experimental conditions.

wines spiked with the g-IDY permeate seems plausible. However, the absence of sulfur-containing compounds in the n-IDY permeate might indicate that the antioxidant effect determined in n-IDY-W model wines should be due to compounds from a different nature.

Analysis of Nitrogen-Containing Compounds. Previous works have already shown that free amino acids represent the greatest nitrogen fraction released by IDYs into model wines, the specific composition of which depends on the type of IDYs.[22] In addition, the antioxidant effect exerted by different types of nitrogen compounds such as peptides and amino acids (other than sulfur-containing amino acids) has also been described.[34,35] Therefore, to determine which other chemicals might be responsible for the antioxidant effect found in both permeates, their nitrogen composition was determined. Table 3 shows the content of total free amino acids, free amino acids and peptides, and individual amino acids determined by RP-HPLC-FL. As can be seen, both permeates exhibited important qualitative and quantitative differences. First, the content of free amino acids was clearly higher in the g-IDY permeate (2964 mg N/L) than in the n-IDY permeate (1248 mg N/L). However, the n-IDY permeate was richer in N from peptides. Besides, the amino acid profile showed important differences between IDYs. For instance, the major amino acids in g-IDY permeate were glutamic acid (62.2 mg/L), threonine (56.27 mg/L), and β-alanine (45.82 mg/L), whereas histidine (56.39 mg/L), glycine (33.15 mg/L), and lysine (21.99 mg/L) were most abundant in the permeate from n-IDY. Some amino acids have been associated with relatively important radical scavenging activities in the order tryptophan > tyrosine > methionine > cysteine > phenylalanine.[34] In this sense, only tyrosine was detected in the free form in both permeates, although in relatively low concentrations (5.6 and 1.05 mg/L for g-IDY and n-IDY permeates, respectively), whereas phenylalanine and tryptophan were not detected in any of the samples. Corroborating the previous results obtained by CE-MS, methionine was identified only in the g-IDY permeate (1.55 mg/L). However, the analytical method employed did not allow the detection of cysteine, although its sole presence in the g-IDY permeate was previously confirmed by CE-MS analysis. Therefore, consider-

ing the amino acidic profile, the contribution of free amino acids to the total antioxidant activity of g-IDY and n-IDY permeates did not seem very relevant, meaning that there were still other compounds which should be more related to this activity.

Nontargeted Metabolomic ESI FT-ICR MS Analysis. Direct infusion ESI-FT-ICR-MS was further employed to gain insight into the chemical metabolites responsible for the antioxidant effect exerted by the two permeates. This technique has been proposed as one of the best techniques to directly investigate complex natural mixtures[36] due to the high mass resolving power and mass accuracy. It has also been recently applied to food materials such as coffee[37] and other metabolomic studies of natural products.[38]

Panels a and b of Figure 3 show the ESI-FT-ICR-MS spectra from g-IDY and n-IDY permeates, respectively. Although they were acquired in the positive and negative ion mode, Figure 3 depicts only the MS from the positive mode. Visually, it is possible to see that both MS profiles were substantially different. This is in good agreement with the more thorough ion identification study that was performed and summarized in Table 4. Using positive and negative ionization modes, it was possible to tentatively identify a total of 10 compounds, 8 of which were detected in the g-IDY permeate and only 4 in the n-IDY permeate. Some of the identified compounds were sulfur-containing compounds, such as *S*-glutathionyl-L-cyteine, γ-glutamyl-cystine, and oxidized glutathione, which were already identified by CE-MS in the g-IDY sample. In addition, the ion *m/z* 556.1379 was identified as a biotinil-5-AMP, an intermediary in the synthesis of biotin.[39] This compound was already detected but not identified by CE-MS in the g-IDY permeate. In any case, in agreement with the results obtained from other analytical techniques (HPLC-FL, CE-MS), there were non-sulfur-containing compounds in the n-IDY permeate. However, a very interesting finding was the detection in both samples of some small peptides, specifically tripeptides. Two of them were found in both permeates and were tentatively identified as histidine/cysteine/lysine- and methionine/lysine/histidine-containing peptides. Their MS and chemical structures are shown in Figure 4. Because of their low concentration in the sample, it was not possible to confirm their sequence. Even more interestingly was the finding of another two peptides only in the n-IDY permeate containing methionine/aspartic/tryptophane and tyrosine/histidine/methionine (Figure 4). It is worth mentioning that the antioxidant properties of small peptides, mainly contained in fermented food, have been

extensively documented.[35] As was previously commented, small peptides containing tryptophan, tyrosine, methionine, cysteine, and phenylalanine have been described to exhibit a high antioxidant activity.[34] In the present study, from the two peptides detected in the permeates from g-IDY and n-IDY, only one (histidine/cysteine/lysine) had an amino acid (cysteine) that could be involved in the antioxidant properties. However, the two peptides exclusively identified in the n-IDY permeate (methionine/aspartic acid/tryptophan and tyrosine/histidine/methionine) contained two of these amino acids each. In addition, both peptides contained tryptophan and tyrosine, the two most highly antioxidant amino acids. Previously published works have already described the biological activities (antioxidant, antihypertensive) of peptides from yeast origin found in synthetic wines submitted to autolytic conditions[40] and in red wines,[41,42] although their chemical structures remained unresolved. Moreover, considering these results, the preservation of aroma and reduction of aroma loss in wines aged on lees that has been linked to the GSH released by yeast autolysis[6] might also be attributable to other types of small peptides, which could have even greater antioxidant properties than GSH.

In conclusion, it has been proven that the use of IDY preparations (with or without GSH) reduces the loss of certain terpenes during the accelerated aging of model wines. It has also been shown that g-IDY preparations do in fact contain GSH in their reduced state, which can contribute to the aroma preservation in model wines, but they also contain other sulfur compounds of yeast origin that might also act as antioxidants. In addition, both g-IDY and n-IDY contained small peptides (tripeptides) with methionine, tryptophan, and tyrosine, which seem to be involved in the antioxidant properties determined in the permeates isolated from both IDYs, also being effective in the preservation of some terpenes during model wine aging. Because of the instability of GSH in wines (easily oxidized, fast combination with polyphenols, etc.), this finding could be of technological interest, assuming the higher stability of these antioxidant peptides when used, for example, after wine bottling. Subsequent work will be directed to unequivocally identify the sequence of these compounds, and further studies are needed to confirm the antioxidant effect of these peptides in closer winemaking conditions. Undoubtedly, this will be interesting for the wine and biotechnological industry to redirect the formulation of IDY preparations to achieve specific and effective winemaking applications.

comprehensive quality assessments of commercial products. Potential new HPLC−UV conditions for improving the chromatography of steviol glycosides have been reported, including the use of gradient elution with C18 columns or the use of HILIC columns with isocratic elution, but none have been sufficiently evaluated or validated for use as standardized methods.[2,10]

The new chromatographic method presented here not only shows an improved and acceptable chromatographic performance but also features significant improvements of three other analytical elements of current HPLC analysis standards for steviol glycosides. Included are the addition of system suitability tests, the HPLC peak identification approach, and the use of modern and efficient quantitation approaches for measuring individual glycosides. System suitability tests are used to verify whether a chromatography system is fit for the analysis it will undertake on the day of analysis for critical parameters such as precision and resolution.[11] Such tests are missing in current standardized methods of analysis for steviol glycosides and are critical and essential to ensure their reliable use in quality control laboratories. Peak identification in the current HPLC method established by JECFA uses a mixed standard solution prepared with nine individual standards.[1] This approach is not practical for routine analysis, given the current cost of purchasing high-purity reference materials. Quantitation of individual steviol glycosides in the current JECFA methods is conducted using a quantitative stevioside reference standard and molecular weight correction factors.[1] This approach assumes that all nine measured steviol glycosides have equal molar UV absorptivities. Reports supporting the validity of this assumption are lacking and are necessary to ensure the accuracy of the approach. The relative response factor approach is a well-established quantitative approach and was established for this method.[12]

In this work, a reversed-phase HPLC−UV method with acceptable selectivity for typical steviol glycoside products was developed and validated, and optimal separation of the critical pair rebaudioside A and stevioside was established. The versatility of the method was demonstrated by evaluating forced degradation samples of rebaudioside A, a primary component in commercial samples. Additionally, reference standards and criterion-based system suitability tests were developed for the HPLC method to ensure efficient and reliable performance for quantitative measurements. Finally, the research provides validation data for establishing the linearity, accuracy, precision, and ruggedness of the developed HPLC method.

MATERIALS AND METHODS

Reagents and Chemicals. Reagent-grade potassium dihydrogen phosphate (KH_2PO_4), 85% phosphoric acid (H_3PO_4), concentrated hydrochloric acid (HCl, 12.1 M), a sodium hydroxide (NaOH) solution [50% (w/w) in water], and pH 2.00 and 4.00 buffer solutions were purchased from Fisher-Scientific (Pittsburgh, PA). A pH 4.01 buffer solution was also obtained from Thermo-Scientific (Waltham, MA). HPLC-grade acetonitrile (ACN) was obtained from Merck KGaA (Darmstadt, Germany) and Fisher Scientific. Water (H_2O) was purified using the Millipore (Billerica, MA) Advantage A10 system. A peroxide (H_2O_2) solution (30% in H_2O) was purchased from Sigma-Aldrich (St. Louis, MO). Karl Fisher reagents Hydranol solvent and Titrant 5 were purchased from Fluka (Trademark of Sigma-Aldrich). United States Pharmacopeia (USP, Rockville, MD) primary reference standards were used for rebaudioside A, B, and D, rubusoside, stevioside, and steviolbioside. Reference standards for rebaudioside C and F, dulcoside A, isosteviolmonoside, steviol, and isosteviol were purchased from ChromaDex (Irvine, CA). A USP system suitability reference standard containing the nine steviol glycosides (Figure 1) to be measured with this method was used for performing system suitability checks. Four commercial samples of high-purity steviol glycoside ingredients used in this study were generous donations from three different suppliers.

Standard and Sample Solutions. Potassium phosphate buffer (5 mM, pH 3.0) was prepared by dissolving KH_2PO_4 in H_2O, and the pH was adjusted to 3.0 using H_3PO_4 on a Thermo-Scientific Orion 3 Star benchtop pH meter. The buffer solution was vacuum filtered by being passed through a filter membrane with a 0.45 μm pore size. The diluent solution was prepared by mixing 5 mM potassium phosphate buffer (pH 3.0) with ACN in a 65:35 (v/v) ratio. For quantitative measurements, standard and sample materials were equilibrated at ambient temperature for ≥24 h because of their hygroscopic nature. The moisture (H_2O) content was determined by Karl Fisher titration using a Mettler-Toledo (Columbus, OH) DL38 titrator. Materials were accurately weighed on a Mettler-Toledo analytical balance (AT201), and solutions were routinely prepared in volumetric flasks. A brief sonication step (2−5 min) was used to dissolve materials.

Rebaudioside A Forced Degradation Studies. Sample solutions of rebaudioside A (5 mM) were tested following several different types of degrading paradigms to test system stability and specificity. A 5.0 mL aliquot of a rebaudioside A solution (10 mM in diluent) was mixed with 5.0 mL of NaOH in one experiment, and HCl solutions (500 mM in H_2O) in a separate experiment, both conducted at ambient temperature. The monitored reaction times were 2, 7, and 24 h. The reaction mixtures were neutralized with an equal molar ratio of acid or base and diluted 10-fold for analysis (0.5 mM rebaudioside

dx.doi.org/10.1021/jf4047557 | J. Agric. Food Chem. 2014, 62, 1384−1389

A). A 5.0 mL aliquot of a rebaudioside A solution (10 mM in diluent) was incubated with 5.0 mL of 30% H_2O_2 at ambient temperature. After incubation for 2 h, 1 day, and 5 days, 1.0 mL aliquots of the reaction mixture were removed and diluted as described above for analysis. Control reaction mixtures containing all components except degradant were analyzed, along with chromatographic controls containing all components except rebaudioside A. Rebaudioside A powder was exposed to UV (total of 1958 W h^{-1} m^{-2}) and white light (total of 2302 klx/h) using a Caron (Marietta, OH) photostability chamber (model 6545-2). Light stability studies were conducted for up to 72 h, and samples were removed at 24, 48, and 72 h for analysis at a concentration of 1.2 mg/mL. Similarly, rebaudioside A powder was incubated at 60 °C in a Yamato (Santa Clara, CA) vacuum oven for up to 8 days. Customarily, photodiode array (PDA) peak purity analysis of rebaudioside A was attempted to provide evidence of the spectral purity of the main peak after forced degradation. Because of a lack of a unique UV spectrum for the main component (λ_{max} = 210 nm), peak purity analysis could not be applied to identify a co-elution. However, mass balance to control reactions was evaluated to determine the amount or lack of significant degradation.

Chromatographic Conditions. Agilent (Wilmington, DE) 1200 and Waters (Milford, MA) Alliance 2965 HPLC systems consisting of a degasser, a quaternary pump, an autosampler, a column compartment, and a PDA detector were used for analysis. Both of the HPLC systems were controlled using Waters Empower 2 software. The method used a YMC (Kyoto, Japan) ODS-AQ column (250 mm × 4.6 mm, 5 μm) and mobile phase consisting of solvent A [5 mM potassium dihydrogen phosphate buffer (pH 3.0)] and solvent B (ACN). Two step gradients with ACN were used to elute analytes of interest as follows: 10 to 35% solvent B over 10 min, held for 15 min at 35% solvent B, 35 to 75% solvent B over 10 min, and held for 15 min at 75% solvent B. The column was re-equilibrated to the starting condition of 10% solvent B and 90% solvent A for 15 min. The column was maintained at 32 °C with a flow rate of 0.5 mL/min. The injection volume was 15 μL for both sample and standard solutions, which were kept under ambient conditions in the autosampler. UV detection at 210 nm with a 4 nm bandwidth was used for analysis. Other tested columns for method development purposes included Shiseido (Tokyo, Japan) Capcell Pak C18 MGII (250 mm × 4.6 mm, 5 μm, JECFA, 2010) and Imtakt USA (Philadelphia, PA) Scherzo SM-C18 (250 mm × 4.6 mm, 3 μm) columns.

System Suitability Tests. A solution of the *USP* system suitability reference standard was prepared at a concentration of 1.2 mg/mL, and five replicate injections of the solution were performed to assess the HPLC system performance in terms of critical pair separation, system precision, and detector sensitivity. The following acceptance criteria were defined per *USP* general chapter ⟨621⟩[11] and intended use of method: a resolution of rebaudioside A and stevioside of ≥1.5, a percent relative standard deviation (%RSD) of the rebaudioside A peak area responses for the five injections of ≤1.5%, and %RSD of the rubusoside peak responses of ≤2.5%.

Total Assay Determination. Standard solutions of rebaudioside A were prepared at concentrations of 0.5 mg/mL (S1) and 0.03 mg/mL (S2) to quantify major and minor analyte peaks in samples. The standard solutions were prepared in duplicate and confirmed to have weight-corrected UV responses (response factors) within 2.5% of each other. The nominal concentration for sample solutions was established at 1.2 mg/mL, which provided adequate detection of major and minor peaks. Separately, equal volumes of sample solutions at the nominal concentration were injected. The chromatograms from the system suitability solutions were used to identify the nine steviol glycosides in the samples. The percentages of each component in the sample were calculated as follows:

$$\%\ \text{assay} = (r_U/r_S) \times (C_S/C_U) \times (1/F) \times 100$$

where r_U is the peak area for the analyte in the sample, r_S is the peak area for rebaudioside A in S1 or S2, C_S is the concentration of USP rebaudioside A RS in S1 or S2 corrected for water and purity, C_U is the concentration in the sample solution corrected for water content, and F is the relative response factor (RRF) (see Table 2).

Note solution S1 was used to quantify rebaudioside A and stevioside, which were the two major components, and solution S2 was used to quantify all other minor components. It is noteworthy that if r_U for rebaudioside A or stevioside was less than 12% of r_S in solution S1, then solution S2 was used for a more accurate quantification. The sum of percentages of the nine measured steviol glycosides was determined as the total assay.

Method Validation. The *USP* general chapter ⟨1225⟩ validation of compendial procedures was used to design validation experiments.[13] The validation was limited to the nine named steviol glycosides in the JECFA monograph because of their established significance as components of the food ingredient.[1] The linearity range for the procedure was evaluated at a concentration level of 0.01−1.2 mg/mL for the two major components, rebaudioside A and stevioside. The range for the seven minor components was 0.01−0.06 mg/mL, except for rebaudioside C, which was evaluated up to 0.25 mg/mL because of its higher natural abundance in evaluated commercial samples. Linear regression analysis was performed to determine the correlation coefficient. The RRF values for each of the eight steviol glycosides with reference to rebaudioside A were determined at a single concentration (0.05−0.08 mg/mL) with duplicate preparations.

The accuracy of the method was assessed by conducting the total assay determinations at the 80, 100, and 120% levels of the nominal assay concentration using a commercial product with an established assay value determined using an alternative procedure. Triplicate samples at each level were prepared and analyzed (n = 9). The precision of the method was determined by evaluating the %RSD of assay measurements with six sample preparations (n = 6) at the nominal concentration. The intermediate precision (ruggedness) was examined by performing assay determinations with six sample preparations by a different analyst using a different column and HPLC system, on a different day. The difference of the means was determined at the 90% confidence interval. The robustness of the method was evaluated by introducing small deliberate changes to key chromatographic conditions and assessing the effect upon critical pair separation and system precision. The modifications included the monitored wavelength at ±3 nm, a column temperature of ±2 °C, and a relative change of ±10% of the initial ACN content and flow rate.

RESULTS AND DISCUSSION

Method Development. A reversed-phase HPLC−UV method with acceptable selectivity for typical steviol glycoside products was developed for its ease and widespread use of methodology. The method was also capable of the separation and identification of steviol and isosteviol, the 2-unglycosylated aromatic aglycons, and a rarely occurring monoglycosylated structure known as isosteviolmonoside. Figure 2 shows a chromatogram of a solution composed of individual reference standards for each analyte combined at the concentration listed in Table 1. The analytes were eluted with an ACN gradient that was the key parameter affecting the selectivity of the method

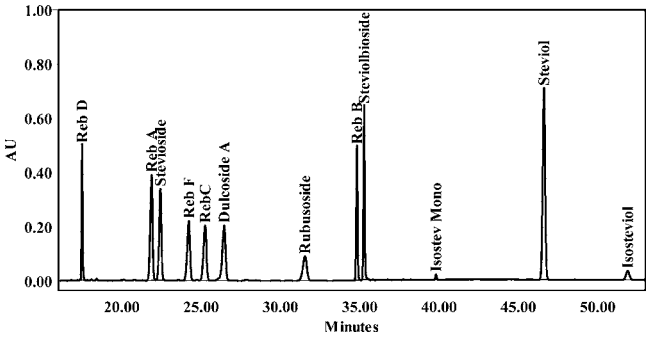

Figure 2. Representative chromatogram of a mixture of several reference standards of steviol glycosides in solution.

Table 1. Elution Profile of Steviol Glycosides[a]

peak name	concn (mg/mL)	RT (min)	RT (% RSD)	resolution (*R*)
rebaudioside D	0.6	17.5	0.1	–
rebaudioside A	0.9	21.9	0.2	20.3
stevioside	0.6	22.4	0.2	2.0
rebaudioside F	0.7	24.2	0.2	5.9
rebaudioside C	0.6	25.2	0.2	3.0
dulcoside A	0.6	26.4	0.2	3.3
rubusoside	0.8	31.5	0.2	11.9
rebaudioside B	0.6	34.8	0.1	10.4
steviolbioside	0.6	35.3	0.0	3.0
isosteviolmonoside	0.2	39.8	0.0	28.2
steviol	0.6	46.6	0.0	29.4
isosteviol	0.6	51.9	0.0	15.0

[a]Individual characteristics of reference standards in solution tested in Figure 2.

under reversed-phase conditions. Two step gradients were introduced; the first served to resolve the hydrophilic components at an acceptable resolution [*R* of ≥2.0 (Table 1)], and the second one allowed for efficient elution of the hydrophobic diterpenoids. The %RSD for retention time [RT (Table 1)] was obtained from five replicate injections of the mixture solution from three independent experiments on different days, which showed minimal shifts in retention time (%RSD, ≤0.2%), and well-resolved peaks ($R \geq 2.0$) were consistently achieved.

The optimal separation of the critical pair rebaudioside A and stevioside was also established by evaluating up to 10 commercial samples with various ratios of the critical pair that demonstrated *R* values in the range of 1.7−2.2. The worst-case scenario (*R* of 1.7) was observed for a commercial product containing 95% rebaudioside A and 1% stevioside. In addition, aside from the primary column, C18 columns from two other manufacturers with slight differences in particle packing and size were tested that provided *R* of ≥1.9 for the critical pair.

The stability-indicating capability of the newly developed method was determined by conducting forced degradation studies of rebaudioside A. As shown in Figure 3, a sample solution of rebaudioside A (5 mM) was tested following several different types of degrading paradigms to test system stability and specificity. Solutions depicted were subjected to degradation in the following conditions: base (250 mM NaOH, 2 h), peroxide (15% in H_2O_2, 5 days), acid (250 mM HCl, 7 h), heat (60 °C, 8 days), and UV and white light (1958 W h^{-1} m^{-2} and 2302 klx/h, 72 h). Heat exposure and UV and white light exposure were used for rebaudiside A powder, while base, peroxide, and acid incubations were used in solution.

Hydrolysis of the ester-linked sugar leading to rebaudioside B was observed within 2 h of incubation in a strong base [RT = 34.8 min (Figure 3)]. In addition, an unknown peak at a RT of 20.3 min appeared to be well-resolved (*R* = 5.9) from rebaudioside A and rebaudioside D. An acid-induced degradant eluted near rebaudioside A within 7 h of incubation (RT = 22.7; *R* = 3.3). As shown in Figure 3, several minor unknown peaks that eluted close to rebaudioside D were also observed during the prolonged oxidative condition (5 days). Rebaudioside D, however, was resolved from the degradation peaks at *R* values of ≥1.7. Rebaudioside A powder exposed to UV and white light for up to 72 h and incubation at 60 °C for up to 8 days did not lead to known or unknown structures as compared to an unexposed sample. Stability-indicating HPLC methods provided the ability to discover compromises to product quality more efficiently.

System Suitability Tests. Validation of the system suitability criteria was obtained via five independent experiments conducted on different days, by two different analysts, and on two different HPLC instrument setups. The assessments established that the resolution of the critical pair, rebaudioside A and stevioside, was observed at 1.8−2.1 with a criterion of ≥1.5. The system precision was monitored by evaluating the %RSD of the rebaudioside A peak area response from five replicate injections, which was determined at 0.12−0.46% with a criterion of ≤1.5%. The %RSD of the rubusoside peak response was used to evaluate detector sensitivity as the smallest peak (0.004 AU) in the mixture. The variation in peak area response was detected at a %RSD of 1.3−1.8% with a criterion of ≤2.5%. The acceptable performance of the HPLC method against the evaluated system suitability criteria

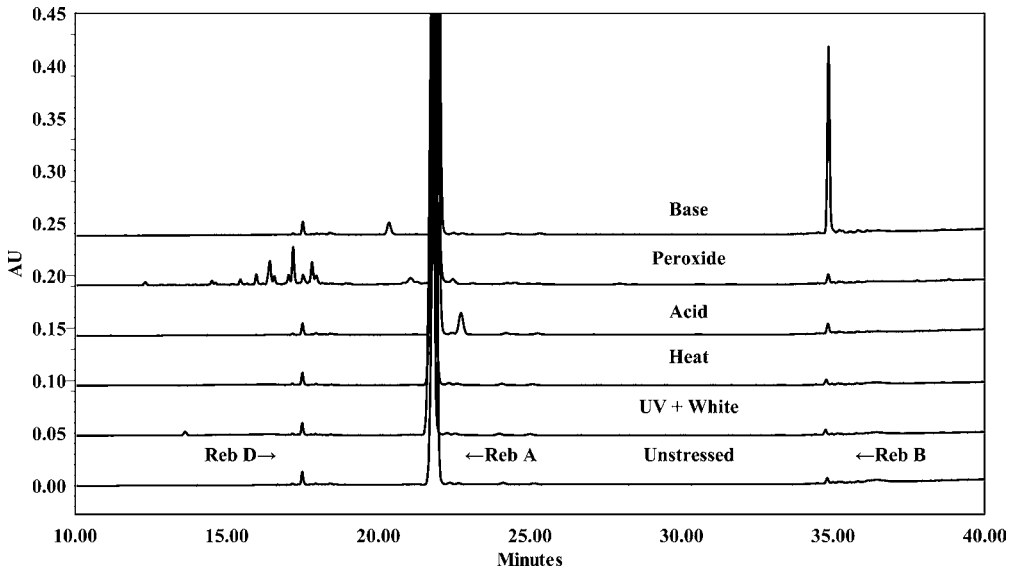

Figure 3. Overlaid chromatograms of degraded sample solutions of rebaudiside A (Reb A).

dx.doi.org/10.1021/jf4047557 | J. Agric. Food Chem. 2014, 62, 1384−1389

established that the method was suitable for quantitative measurements.

Method Validation. The linearity of the UV response for each of the analytes of interest was evaluated independently at concentration ranges commonly observed in commercial samples. Results of the study established the linearity of the method at a correlation coefficient of 1.000 with a negligible intercept (≤2%). The limit of quantification was determined to be 1% of the nominal concentration of 1.2 mg/mL (~0.01 mg/mL) established as the lowest concentration point of the linearity curve for each of the glycosides. RRF values were determined at a single concentration level with duplicate preparations within the linear range for all analytes. In addition, the ratio of the slopes from the linear regression studies provided equivalent values. Table 2 lists the RRF values and relative retention times (RRTs) determined for the eight other steviol glycosides with reference to rebaudioside A in the USP system suitability reference standard solution. The RRF values were intended to correct for intrinsic differences in the UV response among steviol glycosides.[12] This was especially important for assay determinations, where rebaudioside A was used for quantification of all other related analytes in uncharacterized samples. Similarly, the RRT values served to easily identify analytes in uncharacterized samples. *USP* resolution values are defined in *USP* General Chapter ⟨621⟩[11] and are used to demonstrate the acceptable separation of neighboring peaks.

Table 2. Chromatographic Profile of Steviol Glycosides with Respect to Rebaudioside A

name	relative retention time (RRT)	USP resolution	relative response factor (RRF)
rebaudioside D	0.80	not available	0.83
rebaudioside A	1.00	21.3	1.00
stevioside	1.03	2.1	1.22
rebaudioside F	1.10	5.6	1.02
rebaudioside C	1.15	3.1	0.98
dulcoside A	1.21	3.5	1.16
rubusoside	1.44	8.6	1.06
rebaudioside B	1.59	12.2	1.07
steviolbioside	1.61	3.0	1.38

Average method accuracy values were 99.1, 99.9, and 100.9% at 80, 100, and 120%, respectively, of the nominal concentration of 1.2 mg/mL. The %RSD for six independent assay determinations at the nominal concentration was 1.0%. A second analyst repeated the precision experiment with a different HPLC system and column, on a different day. The difference of means at the 90% confidence interval was within 2.0%, which was deemed an acceptable equivalence for the intended purpose.

The method was determined to be robust for minor changes in column temperature, initial ACN content, and flow rate. A significant difference in the peak area response was observed when the detection wavelength changed ±3 nm. Specifically, a 40% decline in the peak area response was measured at 213 nm for rebaudioside A and rubusoside during system suitability evaluations. However, the %RSD for the two affected analyte peaks and the resolution of the critical pair met the established acceptance criteria, indicating a negligible impact on analysis.

The validation results met the established acceptance criteria for linearity, accuracy, precision, and ruggedness. The acceptance criteria for the validation experiments were developed using industry-accepted guidance[14,15] and were based on the intended use of the method for quantification of steviol glycosides within JECFA's monograph specification of ≥95.0%.

Total Assay Determinations. Standard solutions of rebaudioside A were prepared at concentrations of 0.5 mg/mL (S1) and 0.03 mg/mL (S2) to generate a two-point calibration curve. Duplicate preparations of standard solutions showed response factors in the range of −0.1 to 2.2% throughout the validation experiments. Figure 4 illustrates profiles of select commercial samples, which showed the major components to be rebaudioside A and stevioside, with rebaudioside C observed at 3−8%. The other minor components were observed at 0.8−1.8% of the total assay. Assay determinations of individual and total steviol glycosides for commercial purposes were in close agreement with the manufacturer's certificate of analysis (data available in Table S1 of the Supporting Information) and within the JECFA Steviol Glycosides monograph specification of ≥95.0% (JECFA, 2010). The acceptable results of the analysis added further evidence to

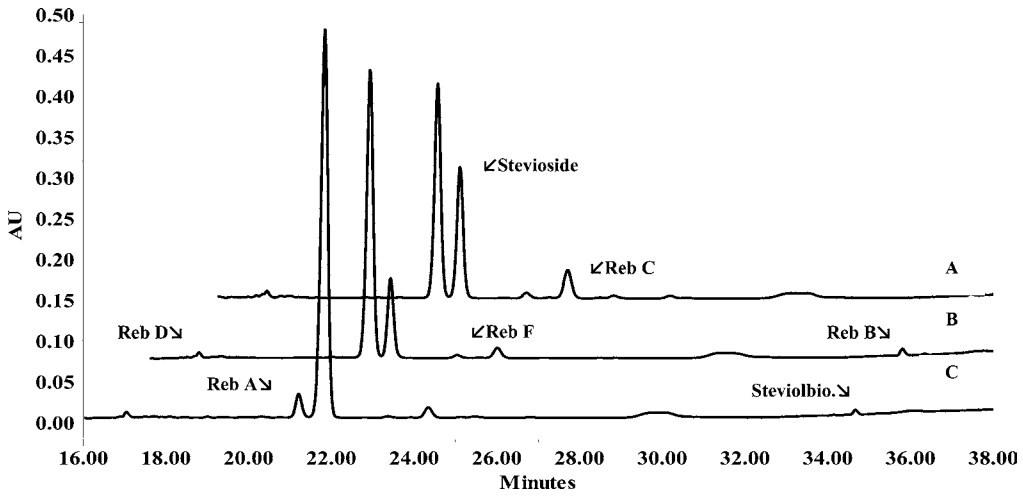

Figure 4. Overlaid chromatograms of sample analysis that illustrate the varying ratios of the critical pair rebaudioside A and stevioside in commercial samples. Traces are offset to illustrate peak differences.

the utility of the method for quality and strength determinations of commercial steviol glycoside products.

Advantages. Steviol glycoside products are known to contain a mixture of highly hydrophilic analytes carrying multiple sugar moieties, whereas other compounds in the mixture exhibit the hydrophobic nature of the diterpenoid backbone common to all of the glycosides. The developed reversed-phase HPLC method was capable of separating the nine related structures known to be components of steviol glycoside products with exceptional reproducibility. In addition, the method was able to identify the 2-diterpenoid backbones found in the glycosylated structures and a rarely occurring glycoside. Moreover, the rebaudioside A forced degradation studies provided solid evidence that the developed reversed-phase HPLC method could resolve known and unknown structures that may arise from extreme stress conditions of these products. The method validation results met the established acceptance criteria for linearity, accuracy, precision, and ruggedness. The method was also found to be robust for minor changes to LC parameters that may arise during routine analysis. The validated HPLC method was found to be suitable for quality and strength assessments and is to be included by USP in the *Food Chemicals Codex* compendial standard for steviol glycosides.

induced resistance responses using NO donor sodium nitroprusside (SNP) and SNP plus U0126.

MATERIALS AND METHODS

Fruit Materials and Treatments. Cherry tomato (*Lycopersicon esculentum* Mill. cv. Qian-xi) fruits were harvested at the mature green stage in Guangxi, China, and immediately transported to the laboratory. The fruits were selected based on the uniform size and shape without physical injuries or infections. The fruits were then surface-disinfected with 2% (v/v) sodium hypochlorite for 2 min, washed with distilled water, and air-dried at room temperature. The fruits were infiltrated in either (1) water (the control), (2) 10 μM U0126 (LC Laboratories, Woburn, MA, USA), (3) 0.2 mM NO donor sodium nitroprusside (SNP, Sigma-Aldrich, St Louis, MO, USA), or (4) 0.2 mM SNP plus 10 μM U0126 solutions under a pressure of −35 kPa for 0.5 min, then kept in the solution under air pressure for 2 min and then air-dried. All fruits were stored at 25 ± 1 °C with 85−90% relative humidity (RH). The fruits were divided into four treatment groups of 265 fruits each. Then, each treatment group of fruits was divided into two further categories. One category was used in the inoculation experiment (45 fruits); the other category was sampled at 0 h, 0.5 h, 1 h, 4 h, 8 h, 16 h, 24 h, 2 d, 4 d, 6 d, and 8 d for measurements of *LeMAPK1/2/3* gene expression, NO content, nitric oxide synthase (NOS) activity, and defense enzyme activities. Pericarp tissues from the fruits equatorial region were cut into small pieces, frozen in liquid nitrogen and stored at −80 °C until analysis.

Pathogen Inoculation and Disease Symptom Measurement. *B. cinerea* (ACCC 36028) was purchased from Agricultural Culture Collection of China (Haidian, Beijing). *B. cinerea* was incubated on potato dextrose agar medium, at 25 °C for 7−10 d. Spore suspensions (2×10^6 conidia mL^{-1}) were prepared by brushing the surface of the plates and suspending them in sterile distilled water containing 0.01% Tween-80. After being treated for 24 h, the inoculations were carried out. Forty-five fruits were sterilized with 75% ethanol before inoculation. A 2 mm wide × 4 mm deep wound was cut with a sterile nail on the equator of the fruits. Then 10 μL of spore suspension of *B. cinerea* was injected into the wound with a pipet and the fruits were stored at 25 ± 1 °C and 90−95% relative humidity (RH).

Decay development was monitored daily after inoculation. Disease incidence was expressed as the percentage of fruits showing disease symptoms. Lesion area = 3.14 × (lesion diameter/2)^2.

Measurement of NO Accumulation and NOS Activity. Frozen fruit samples (3 g) were ground with a mortar and pestle in a 3-mL ice-cold extraction buffer [50 mM phosphate buffer saline (PBS, pH 7.4) containing 1 mM dithiothreitol, 1 mM $MgCl_2$].[23] After centrifugation at 12 000*g* for 20 min at 4 °C, supernatant was collected and used for NO determination. NO content was determined according to the instruction of the nitric oxide assay kit (Nanjing Jiancheng Bioengineering Institute, Jiangsu, China). Briefly, NO reacts with oxygen to form a variety of end products, including nitrite (NO_2^-) and nitrate (NO_3^-). The reduction of NO_3^- to NO_2^- was then achieved using nitrate reductase. The determination of NO_2^- was based on the Griess reaction. NO content was expressed as $\mu M \cdot g^{-1}$ fresh weight (FW).

Frozen fruit samples (3 g) were homogenized in a 3-mL extraction buffer (50 mM HEPES, pH 7.4, containing 0.1 mM NADPH, 10 nM CaM, 30 μL BH_4, 1.25 mM $CaCl_2$, and 1 mM EGTA). After centrifugation at 12 000*g* for 15 min, the supernatant was collected and recentrifuged at 12 000*g* for 15 min at 4 °C. The supernatant was then used for NOS determination. We used the conversion of L-arginine to NO to determine NOS activity as described.[24]

Determination of Defense Enzyme Activities. To determine activities of defense enzymes, 1 g of frozen fruit sample was extracted with a 5-mL extraction buffer (100 mM PBS (pH 6.8) for PPO; 0.2 mM boric acid buffer pH 8.8, containing 10% (w/v) polyvinyl pyrrolidone and 1 mM EDTA for PAL; 100 mM acetic acid buffer (pH 5.2) for CHI and GLU) and centrifuged at 12 000*g* for 15 min at 4 °C. The supernatant was collected and used for defense enzyme determination.

CHI (EC 3.2.1.14) (Chitinase) activity was measured according to the method of Boller, et al.[25] with some modifications. The reaction mixture contained 0.5 mL of crude enzyme extract and 0.5 mL of colloidal chitin. It was incubated at 37 °C for 1 h. After the addition of 0.1 mL of 3% desalted snailase, the mixture was incubated at 37 °C for 1 h. The reaction was stopped by the addition of 0.3 mL of 0.6 M potassium tetraborate and was boiled at 100 °C for 5 min. After the samples were cooled immediately in ice, 2 mL of 20 $g \cdot L^{-1}$ 4-(dimethylamino) benzaldehyde reagent diluted with glacial acetic acid:HCl (39:1 v/v) was added and the mixture was incubated at 37 °C for 40 min. The absorbance was measured at 585 nm. A control was also included by measuring the fluorescence of the reaction mixture without the enzyme extract. CHI activity was expressed as $U \cdot g^{-1}$ FW, and one unit of CHI activity was defined as the amount of 10^{-9} mol *N*-acetyl-D-glucosamine being produced per hour.

GLU (EC 3.2.1.39) (β-1,3-glucanase) activity was measured according to the methods of Boller et al.[26] and Hinton and Pressey[27] with some modifications. The reaction mixture contained 100 μL of crude enzyme extract and 50 μL of 0.4% laminarin. Incubation was carried out at 37 °C for 40 min with shaking. The reaction was stopped by the addition of 1.8 mL of H_2O and 1.5 mL of 3.5-dinitrosalicylic and was boiled at 100 °C for 3 min. The mixture was then cooled immediately in ice and added to 25 mL of distilled water. The absorbance was measured at 540 nm. Quantification was carried out with a standard curve using the solutions of glucose with different concentrations. GLU activity was expressed as $U \cdot g^{-1}$ FW, based on glucose reducing equivalents from laminarin, and one unit of GLU activity was defined as the formation of 1 μmol of glucose per hour.

PPO (EC 1.10.3.2) (polyphenol oxidase) activity was measured according to the method of Liu et al.[28] with some modifications. The enzyme solution (0.5 mL) was rapidly reacted with 2 mL of PBS buffer (100 mM, pH 6.8) and 1 mL of 100 mM catechol. The change in absorbance at 420 nm was recorded over 2 min. PPO activity was expressed as $U \cdot g^{-1}$ FW, and one unit of PPO activity was defined as the amount of enzyme that caused a change of 1 in absorbance per minute.

PAL (EC 4.3.1.5) (phenylalanine ammonia-lyase) activity was measured according to the method of Koukol and Conn[29] with some modifications. The reaction mixture contained 0.5 mL of crude enzyme extract, 1 mL of 20 mM L-phenylalanine, and 2 mL of boric acid buffer (200 mM, pH 8.8). Incubation was carried out at 37 °C for 1 h. PAL activity was expressed as $U \cdot g^{-1}$ FW, and one unit of PAL activity was defined as the amount of enzyme that caused an increase in absorbance of 1 at 290 nm per hour.

Quantitative Real-Time PCR. Trizol reagent (Invitrogen, Carlsbad, CA, USA) was used to extract total RNA from 2 g of frozen fruit samples. Any remaining genomic DNA was removed by digestion with RNase-free DNase I (Promega, Madison, WI, USA), according to the manufacturer's instructions. Reverse transcription was completed to synthesize the first-strand of cDNA with 2 g of total RNA according to the manufacturer's protocol from Promega. The oligo $(dT)_{18}$ was used as a primer and the reverse transcription reaction was incubated at 42 °C for 60 min in a total volume of 25 μL.

Real-time PCR was performed using the Chromo4 Real-Time PCR Detection System (Biorad, Hercules, CA, USA). Specific primers used for PCR were designed, including *LeMAPK1* (GenBank accession AJ535702), 5′-CTTTACCGTCGACAATCATTTACTG-3′ and 5′-TGGTATTCAGGATTAAATGCAATCG-3′; *LeMAPK2* (GenBank accession AY261513), 5′-CTTTACCGTCGACAATCATTTGTC-3′, and 5′-TGGTATTCGGGATTAAATGCAAGAC-3′; *LeMAPK3* (GenBank accession AY261514), 5′-AGCATTAGCTCATCCCTACCTC-3′ and 5′-GCTCTTCTCCTATCCCTTGTTG-3′. The PCR reaction contained a total volume of 25 μL, containing 1 μL of cDNA template, 1 μL of specific primer, and 12.5 μL of 2 × SYBR GREEN I MasterMix (Toyobo, Osaka, Japan). PCR was performed with an initial step of 2 min at 94 °C followed by 40 cycles of 15 s at 94 °C, 20 s at 60 °C, and 45 s at 72 °C. The gene transcript levels for

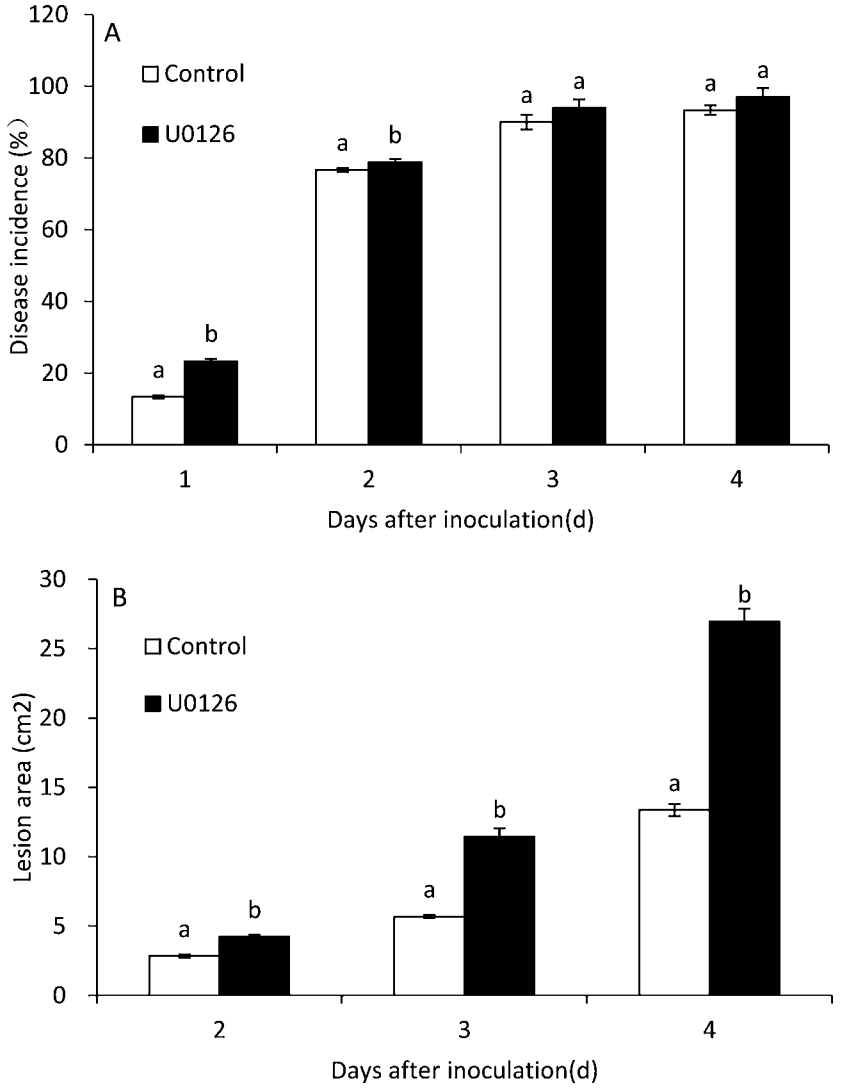

Figure 1. Effects of 10 μM U0126 on disease incidence (A) and lesion area (B) in 'Qian-xi' cherry tomato fruit inoculated with *Botrytis cinerea*. Tomato fruits were inoculated with *Botrytis cinerea* (2×10^6 conidia mL^{-1}) 1 d after treatment and incubated at 25 ± 1 °C and relative humidity (RH) of 90–95%. Disease symptoms on each fruit were recorded on days 1, 2, 3, and 4 after inoculation. Data with different lowercase letters in each column are significantly different at $P < 0.05$. Data are expressed as mean ± SD of triplicate assays.

each sample were normalized to Ubi3 Ct value and calculated using the formula $2^{-\Delta\Delta Ct}$.

Statistical Analysis. All data were presented as the mean ± standard deviation (SD). One-way analysis of variance (ANOVA) and Duncan's multiple range tests were carried out to determine significant differences ($p < 0.05$) between the means by the statistical software SPSS 18.0 (IBM Corp., Armonk, NY).

RESULTS

Effects of U0126 on Disease Incidence and Lesion Area. Treatment with U0126 increased the disease symptoms to different degrees (Figure 1). This observation suggests that the existence of MAPKs is important for the tomato fruit to resist pathogen infection in common physiological processes. Disease incidence in the U0126-treated fruits was increased by 75.0%, 2.8%, 4.4%, and 3.9% on day 1, 2, 3, and 4 after inoculation, respectively (Figure 1A). The lesion areas in the U0126-treated fruits increased by 48.6%, 103.0%, and 101.7% with respect to those of control fruits, respectively (Figure 1B, $P < 0.01$). After inoculation with *B. cinerea*, significant differences of disease incidence were only observed on day 1 and 2. However, lesion areas increased significantly as days go on after inoculation. It may be owing to that MAPKs mainly role in postinfection than in preinfection in tomato fruits. The results support the idea that MAPKs are necessary for the defense response against the invasion and expansion of *B. cinerea*.

Effects of SNP and SNP+U0126 on Disease Incidence and Lesion Area. Disease symptoms appeared on the third day after inoculation and increased with storage time (Figure 2). Treatment with SNP reduced disease symptoms in the tomato fruits after inoculation with *B. cinerea*. Disease incidence in the SNP-treated fruits was inhibited by 11.5%, 15.4%, 4.1%, and 1.5% on day 3, 4, 5, and 6 after inoculation, respectively. In contrast, SNP + U0126 treatment accelerated the increase in the incidence of disease compared to the control fruits ($P < 0.01$). Lesion areas were significantly smaller in SNP-treated fruits than those of the control fruits on day 4, 5, and 6 ($P < 0.01$). However, treatment with the MAPK pathway inhibitor U0126 weakened the effect of NO. Fruits treated with SNP showed smaller lesion areas than control fruits. In contrast, the lesion areas in (SNP + U0126)-treated fruits were 1.9, 1.6, and

dx.doi.org/10.1021/jf404870d | J. Agric. Food Chem. 2014, 62, 1390–1396

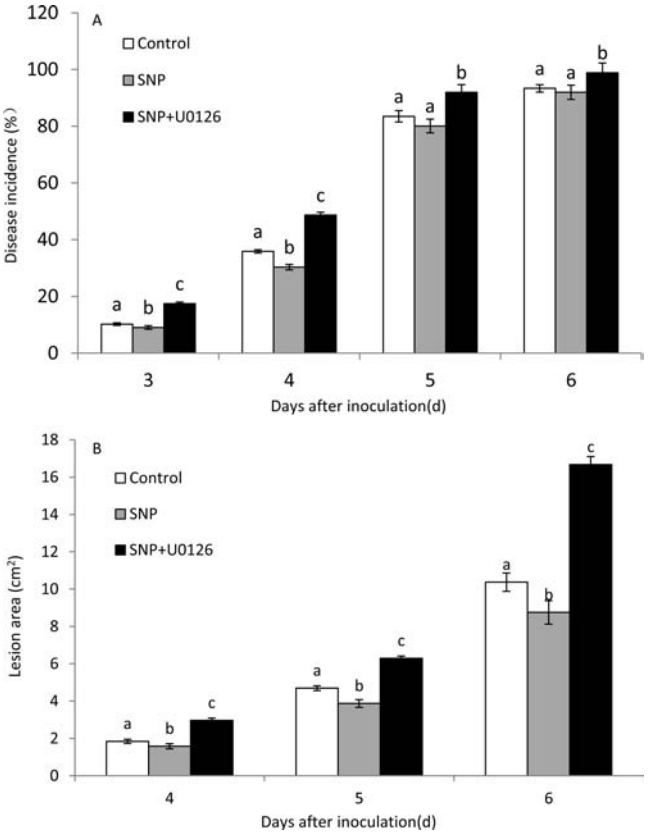

Figure 2. Effects of SNP and SNP+U0126 treatments on disease incidence (A) and lesion area (B) in 'Qian-xi' cherry tomato fruit inoculated with *Botrytis cinerea*. Tomato fruits were inoculated with *Botrytis cinerea* (2×10^6 conidia mL^{-1}) 1 d after treatment and incubated at 25 ± 1 °C and relative humidity (RH) of 90−95%. Disease symptoms on each fruit were recorded on days 3, 4, 5, and 6 after inoculation. Data with different lowercase letters in each column are significantly different at $P < 0.05$. Data are expressed as mean ± SD of triplicate assays.

1.9 times higher than those in SNP-treated fruits. The results commit to the idea that MAPKs are necessary for the NO-induced defense response against invasion and expansion of *B. cinerea*.

Effects of SNP and SNP+U0126 on NO Content and NOS Activity. NOS activity is significantly increased in SNP-treated fruits than in control fruits during the whole storage period except for the fourth hour ($P < 0.01$, Figure 3A). However, treatment with a MAPK pathway inhibitor U0126 weakened the effect of NO treatment on NOS activity. NOS activities in (SNP + U0126)-treated fruits were lower than those in SNP-treated fruits during storage. NO content in SNP-treated fruits was higher than in the control fruits (Figure 3B). NO content in SNP-treated fruits increased rapidly and reached a maximum of 14.66 $\mu M \cdot g^{-1}$ FW at 8 h, and then slowly fell after this rise, but still remained higher than that in the control. (SNP + U0126)-treated fruits shared a trend similar to the SNP-treated fruits. However, the NO content of (SNP + U0126)-treated fruits remained at a higher level throughout the storage period than that of the control fruits; the peak value was 1.36-fold higher compared to the control fruits.

Effects of SNP and SNP+U0126 on CHI, GLU, PPO, and PAL Activities. CHI activity showed a fluctuating increase in SNP treatment (Figure 4A). During the whole storage period, CHI activity in SNP-treated fruits was significantly higher ($P <$

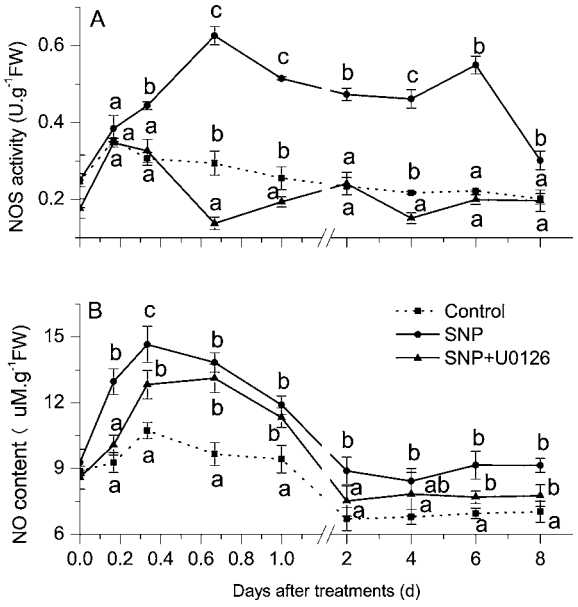

Figure 3. Effects of SNP and SNP+U0126 treatments on NOS activity (A) and NO concentration (B). The sampling time courses of treated tomato fruits are 0, 4, 8, 16, and 24 h, and 2, 4, 6, and 8 days. Values followed by different letters are significantly different according to Duncan's multiple range test at $P < 0.05$. Data are expressed as mean ± SD of triplicate assays.

0.05) than that in the control fruits. Treatment with a MAPK pathway inhibitor U0126 influenced the effect of NO-improved accumulation of defense enzymes. CHI activity in the (SNP + U0126)-treated fruits was significantly lower ($P < 0.05$) than in the SNP-treated fruits except for the fourth hour, but SNP + U0126 treatment had less effect on CHI activity than in the control during most of the storage period.

SNP treatment increased the activity of GLU. Two peaks of GLU activity in SNP-treated fruits were observed at 16 h and 6 d (Figure 4B) during the whole storage period. However, the GLU activity in (SNP+U0126)-treated fruits remained at a low level throughout the storage period.

SNP-treated tomato fruits exhibited a marked increase in PPO activity and reached a maximum of 1.03 $U \cdot g^{-1}$ FW at 8 h (Figure 4C). SNP treatment maintained a higher PPO activity compared with the control during the storage period. However, (SNP + U0126)-treated fruits showed significantly lower ($P <$ 0.05) PPO activity than the control during storage except for days 4 and 6.

PAL activity was induced rapidly by NO during the early stages of storage and peaked at the eighth hour of 4.33 $U \cdot g^{-1}$ FW (Figure 4D), then declined with some fluctuation. Treatment with U0126 inhibited the effect of NO on PAL activity. A significant decrease was found in (SNP + U0126)-treated fruits ($P < 0.05$) compared with SNP-treated fruits.

LeMAPK1/2/3 Relative Expression Analysis with Real-Time PCR. NO significantly enhanced the expression levels of *LeMAPK1*, *LeMAPK2* and *LeMAPK3* genes in the tomato fruits ($P < 0.05$). The expression patterns of *LeMAPK1* and *LeMAPK2* were similar in the SNP-treated fruits. NO-induced expression of *LeMAPK1* and *LeMAPK2* reached a peak at 8 h, then declined (Figure 5A and B). The expression of *LeMAPK3* was induced rapidly by NO and reached the maximum expression at 1 h (Figure 5C). However, treatment with U0126 weakened the effect of NO. The expression of

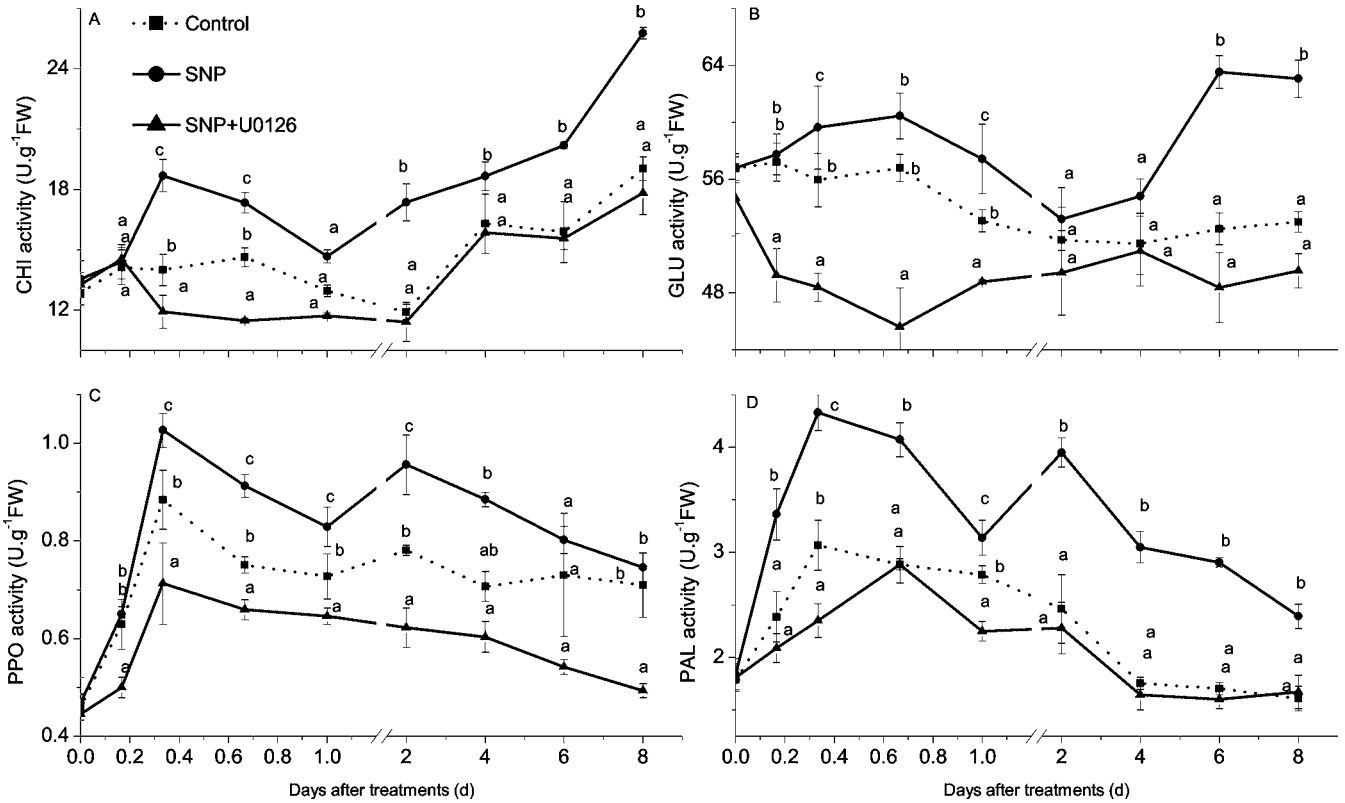

Figure 4. Effects of SNP and SNP+U0126 treatments on the activities of defense enzymes: (A) chitinase; (B) β-1,3-glucanase; (C) polyphenol oxidase; and (D) phenylalanine ammonia-lyase. The sampling time courses of treated tomato fruits are 0, 4, 8, 16, and 24 h, and 2, 4, 6, and 8 days. Values followed by different letters are significantly different according to Duncan's multiple range test at $P < 0.05$. Data are expressed as mean ± SD of triplicate assays.

LeMAPK1, *LeMAPK2*, and *LeMAPK3* in (SNP + U0126)-treated fruits was significantly lower than that in the SNP-treated fruits ($P < 0.05$).

■ DISCUSSION

NO is known to have a critical role in both regulating defense responses and inducing resistance to fungal pathogens. Exogenous NO treatment has been shown to result in lower decay incidence and improved disease resistance in several fruits.[30,31] No generation was induced by conditional activation of MAPK cascades in *Nicotiana benthamiana* leaves.[32] Plant MAPK cascades play pivotal roles in signaling plant defense against pathogen attack.[14,15,18,33] However, most of the supporting experimental data focuses on the level of disease prevention by NO, while little is known about how durable the disease prevention is and how it interacts with other signaling molecules.[34] This study investigated the interaction between NO and *LeMAPK1/2/3* in the defense response to the pathogen *B. cinerea* in postharvest tomato fruits. These findings further extend our understanding on the functions of *LeMAPK1/2/3* in defense response. We found that U0126 could significantly increase the disease symptoms caused by *B. cinerea* in the tomato fruits (Figure 1), while exogenous SNP treatment could reduce the disease incidence and lesion area. The MAPKs inhibitor weakened NO-induced resistance to pathogen invasion and development (Figure 2). This indicated that MAPKs play a crucial role in the postharvest tomato fruits defense response induced by NO.

Previous studies indicate that NOS is closely related to NO production in plants.[35] Recently, Zheng et al.[36] also found that NOS is a key enzyme regulating NO production in induced resistance in tomatoes. In adipose tissue, MAPKs are implicated in the regulation of NOS activity. Catherine et al.[37] reported that MAPKs inhibitor (U0126) could abolish NOS activity stimulated by insulin. In the present investigation, NO treatment resulted in an increase in NOS activity, but the MAPKs inhibitor (U0126) abolished NOS activity resulted by NO (Figure 3A). These results in part suggest that the MAPKs participated in the action of NO. NO burst is considered an early event during resistance response.[38] This conclusion is also supported by our results from the SNP and SNP + U0126 treatment. However, effects of the MAPKs inhibitor on NO content were not obvious, possibly owing to the fact that NO rapid bursts and MAPK cascades are the downstream signal molecule of NO.[39]

GLU, CHI, PPO, and PAL have been categorized as primary defense systems against fungal pathogens. Both GLU and CHI are well-known as pathogenesis-related (PR) proteins, belonging to the PR-2 and PR-3 families, respectively. These enzymes are involved in plant defense mechanisms against fungal infection and are currently used as markers for innate immunity.[40] PPO, which catalyzes the O_2-dependent oxidation of phenolic compounds to form quinines, has been proposed as a component of plant defense mechanisms, and is associated with induced defense responses in plants.[41] PAL is a key, rate-limiting enzyme in plant secondary metabolism, especially in the phenylpropanoid pathway and is established as an enzyme downstream of NO action.[42] Thus, the variation of these enzyme activities can indirectly reflect plant disease resistance. There is a close relationship between the change of disease

dx.doi.org/10.1021/jf404870d | J. Agric. Food Chem. 2014, 62, 1390−1396

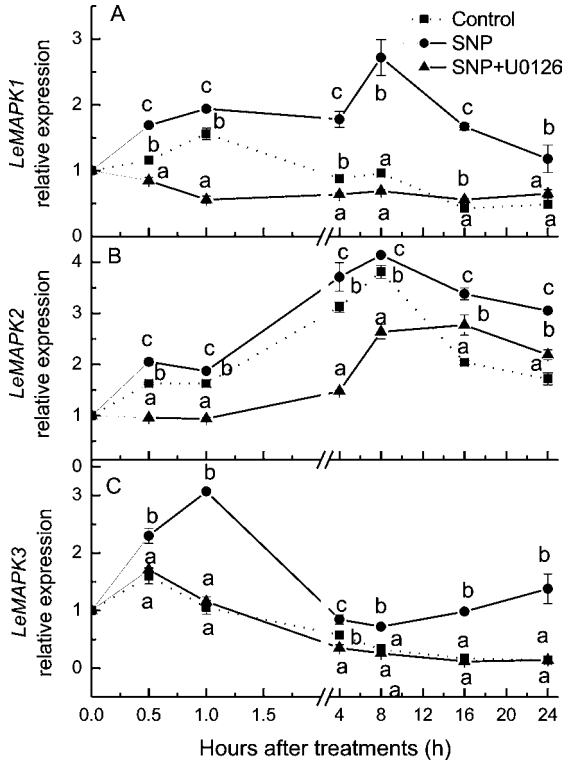

Figure 5. Effects of SNP and SNP+U0126 treatments on the relative expression of *LeMAPK1/2/3* in tomato fruits. The sampling time courses of treated-tomato fruits are 0, 0.5, 1, 4, 8, 16, and 24 h. The expression levels of *LeMAPK1/2/3* were evaluated by quantitative real-time PCR, normalized to the host *Ubis3* gene, and set relative to control sample from day 0 according to the $2^{-\Delta\Delta Ct}$ method. Values followed by different letters are significantly different according to Duncan's multiple range test at $P < 0.05$. Data are expressed as mean ± SD of triplicate assays.

incidence and the activities of defense enzymes (Figures 2A and 4).The present results showed NO induces higher activities of GLU, CHI, PPO, and PAL in tomato fruits compared with the control. Meanwhile, NO inhibits disease incidence after inoculation with *B. cinerea*. However, the MAPKs inhibitor weakened the effects of NO on defense enzymes (Figure 4) which further supposed the participation of MAPKs in the action of NO. These results suggest an intermediate role of MAPKs in NO-induced disease resistance in harvested tomato fruits.

Specific virus-induced gene silencing (VIGS) of *LeMAPK1*, *LeMAPK2* and *LeMAPK3* resulted in the reduction of defense gene expression and defense response against herbivorous insects.[15,22] In our study, the levels of *LeMAPK1* and *LeMAPK2* expression increased rapidly in response to SNP vapor treatment and peaked at 8 h. Besides, a quick increase in the expression of *LeMAPK1*, *LeMAPK2*, and *LeMAPK3* was seen in the control fruits, which may be attributable to the wound response caused by the vacuum infiltration method adopted in our study.[43] Meanwhile, NO content (Figure 3B), PPO activity, and PAL activity (Figure 4C and D) reached a peak value at 8 h. These results suggest that the expression of *LeMAPK1*, *LeMAPK2*, and *LeMAPK3* was positively correlated with NO content, PPO activity, and PAL activity. The expression of *LeMAPK3* induced by NO seemed to be somewhat different from *LeMAPK1* and *LeMAPK2*. The expression of *LeMAPK3* reached a maximum value at 1 h and a minimum value at 8 h. However, the expression levels of *LeMAPK1*, *LeMAPK2*, and *LeMAPK3* in SNP-treated fruits were all higher than that in the control fruits. The MAPKs inhibitor significantly decreased the expression of *LeMAPK1*, *LeMAPK2*, and *LeMAPK3*. These were accompanied by an obvious decrease in defense enzymes in fruits treated with SNP + U0126 throughout the storage period. These data indicated that (i) *LeMAPK1*, *LeMAPK2*, and *LeMAPK3* played a critical role in tomato disease resistance, and (ii) *LeMAPK1*, *LeMAPK2*, and *LeMAPK3* mediated the NO-induced defense response against *B. cinerea*. These results should be useful in the integrated control of postharvest diseases of fruit. Recently, Zheng et al.[44] indicated that preharvest L-arginine (the precursor of NO) treatment may be a promising measure for controlling postharvest decays on a commercial scale.

Another area of controversy is the acceptability of hard cheeses in the diet management of galactosemia. Bacterial fermentation and aging of some cheeses substantially reduces the galactose content.[16] Negligible amounts of lactose and galactose were found in European sources of Gruyere, Emmentaler, Jarlsberg, grated and block Italian Parmesan (Parmigiano Reggiano, Grana Padona), and Cheddar cheese aged for >1 year produced by the UK West Country Farmhouse Cheese Makers Association in England.[16] Minibel Emmental (Laughing Cow), a mild processed Emmentaler cheese produced in France, did contain various amounts of residual lactose, with an average of 6 mg galactose/100 g.[17] A study of 30 8−12-month-aged Cheddar cheeses reported undetectable concentrations of lactose and galactose using HPLC with refractive index detection,[18] whereas others have reported variable amounts of galactose in hard cheeses.[19−22] Analysis of additional sources of these cheeses has not been completed in recent years; thus, it is not known whether these aged cheeses can be universally recommended for those with galactosemia. In addition, caseinates may contain negligible galactose and need to be further evaluated.[23] Understandably, addition of milk-based products has been especially difficult to accept by families who are hesitant to include these foods without adequate assurance regarding their safety. Thus, a second aim of this current study is to determine the galactose content of these same hard cheeses produced in the United States and Canada and to analyze sources of food-grade caseinates to provide additional data to help establish dietary recommendations for classic galactosemia.

MATERIALS AND METHODS

Various types of cheeses (n = 19) and sodium and calcium caseinate (n = 6) were purchased between June and August 2011 in different locations in North America. These products were analyzed at a commercial food analysis laboratory (Covance, Inc., Madison, WI, USA). Each sample was ground to ensure consistent composition, and a 2 g aliquot was extracted with room temperature water. The sample was shaken for ∼1 min with 10 volumes of chloroform to remove lipids and then centrifuged for 5 min. The aqueous fraction was filtered through a 0.45 μm filter. The quality control sample used for the analysis was a cereal product that had ranges determined on 60 replicates of the material.

Total galactose content was determined from both lactose and galactose quantitated by a high-performance anion exchange chromatograph equipped with a pulsed amperometric detector (HPAEC-PAD).[24] Each standard curve had an r^2 > 0.995. The individual standard concentrations for each analyte were within 10% of the theoretical concentrations. For any sample containing lactose, 53% of total lactose was considered galactose, on the basis of the molecular weights of 342 for lactose and 180 for galactose. All galactose concentrations are expressed as milligrams per 100 g product. For dairy products, a galactose content <5.1 mg/100 g product was considered below quantitation limits. The published method reported carbohydrate recoveries of 94.9−105% and a coefficient of variation of 3.3%.[24]

For legume analysis, commercially canned garbanzo beans (kabuli chickpeas), black beans, red kidney beans, and pinto beans were selected. One can of three national brands of each product were purchased in Madison, WI, USA, in December 2012. From each sample can, liquid was drained and weighed, and beans were briefly rinsed with distilled water to ensure that all canning liquid was collected. Whole beans were macerated in a food processor, and both the liquid (38−51 g sample) and beans (61−82 g sample) were freeze-dried separately. Sugar extraction and analysis were completed in Food, Nutrition and Health at the University of British Columbia in Vancouver using the method of Sanchez-Mata et al.[25] with an extraction temperature of 60 °C. Duplicates of each freeze-dried bean and liquid sample were extracted in 80% ethanol before analysis of galactose and galacto-oligosaccharides using an Agilent 1100 series HPLC system with an aminopropyl Zorbax carbohydrate column (4.6 × 250 mm, 5 μm particle size, 30 °C). Sugars were detected using an Agilent 1200 series refractive index detector (Agilent Technologies, Canada, Inc., Mississauga, ON, Canada) regulated at 35 °C. The isocratic mobile phase was premixed 75:25 acetonitrile/water, at 2.0 mL/min. Sample aliquots of 100 μL were injected. Total galactose, free galactose, melibiose, raffinose, ciceritol, and stachyose were quantitated and expressed in milligrams sugar per 100 g product. Commercial standards for all compounds except ciceritol were used to construct standard curves for quantitation (r^2 > 0.99). The galactose, melibiose, and stachyose standards were purchased from Sigma-Aldrich Canada (Oakville, ON, Canada), and raffinose was purchased from Fisher Scientific Canada (Ottawa, ON, Canada). All sugar standards were of 98% purity or higher. Ciceritol concentrations were estimated using the raffinose standard curve with a correction for the molecular weight.

RESULTS AND DISCUSSION

Addressing the galactose content of caseinates, hard cheeses, and legumes will provide further data to address the inclusion or restriction of these foods and ingredients in the diet for classic galactosemia.

Caseins, a complex group of proteins comprising α_{s1}, α_{s2}, β, and κ gene products, are present in milk in the range of 2.4−2.9 g/100 mL.[27] The isolated proteins, termed caseinates, are used as food ingredients in a wide range of products for emulsification, stabilizing, water binding, film formation, and nutritional purposes. Therefore, restricting caseinate in the galactosemia diet eliminates many foods that could add dietary and nutritional variety.

Caseinates can be manufactured via acid precipitation or enzymatic (chymosin) precipitation. After precipitation, the caseinate is washed and dewatered. The isolated caseinate is subsequently solubilized by the addition of an alkali or polyphosphates and dried.[26] Because of the removal of whey via precipitation and extensive washing of the precipitated protein, the concentration of lactose, and therefore galactose, remaining in the final caseinate is expected to be low. Analysis of food grade caseinates in this study confirmed this observation. Residual lactose was detected in three of six caseinate samples with equivalent galactose contents ranging from 40 to 96 mg/100 g powder (Table 1). Typically, the amount of caseinates added to various foods ranges from 1 to

Table 1. Galactose Content of Sodium and Calcium Caseinate[a]

	country of origin	galactose (mg/100 g)
sodium caseinate	USA (Wisconsin)	95.5
	New Zealand	62.0
	The Netherlands	<5.1
	mean ± SD	54.2 ± 45.7
calcium caseinate	USA (Wisconsin)	<5.1
	New Zealand	40.3
	The Netherlands	<5.1
	mean ± SD	16.8 ± 20.4
	total mean ± SD	35.5 ± 37.7

[a]Values reported are from a single analysis.

25% by weight,[27] which suggests that foods containing caseinates are an insignificant dietary source of galactose.

Cheesemaking is a complex process, and there are multiple factors that may affect the residual galactose concentration in the final product. Reports of residual galactose in cheese vary within the same type of cheese and can be attributed to minor variations in the milk itself[28] but, more importantly, to the specific starter and the nonstarter (secondary) cultures, the processing steps used to separate the curd from the lactose-rich whey, and the conditions used for cheese aging.[29] Hard cheeses that are aged for extended periods of time may be expected to have lower residual galactose content due to the metabolic activity of the secondary cultures[30,31] and, in some cases, persistence of the starter culture.[32]

For all analyzed cheese samples, only one sample contained both residual lactose and galactose. For all other cheeses, lactose was below quantitation limits and only galactose was measurable. The data confirm that Gruyere, Emmentaler, and brick Parmesan cheeses produced in U.S. dairies contain negligible lactose or galactose, similar to results reported for these cheese varieties produced in Europe.[16] The galactose content was below quantitation limits in Emmentaler and Gruyere cheeses produced in Switzerland and Wisconsin (Table 2). In North America, Emmentaler cheese may be called "Swiss" cheese; one sample of Swiss cheese contained 7.4 mg galactose/100 g. Another study also reported the absence of lactose and galactose, determined enzymatically, for Swiss cheese manufactured in the United States.[33] The specific bacterial starter culture used may contribute to differences in the residual galactose in Emmentaler cheese. For example, *Streptococcus salivarius* subsp. *thermophilus* and *Lactobacillus helveticus* are thermophilic starter species typically used for Emmentaler or Swiss cheese production. The presence of *L. helveticus* is essential to produce a low-galactose cheese, as only a fraction of *S. thermophilus* strains are able to metabolize galactose;[34] however, *L. helveticus* strains vary in their ability to deplete galactose during the initial stages of cheesemaking.[35]

One sample of block Parmesan cheese aged for >10 months contained galactose below quantitation limits (Table 2). Unlike grated Parmesan cheese from Italy found to contain negligible galactose by enzymatic analysis,[16,36] a commercial brand of grated cheese from the United States contained 23.6 mg galactose/100 g. Similarly, using HPLC-PAD, eight New Zealand-produced Parmesan cheese samples varying in age from 6 to 19 months were found to contain an average of 38 ± 21 mg galactose/100 g, whereas two samples aged for 7 and 20 months contained 378 and 156 mg galactose/100 g, respectively[22] As with Emmentaler cheese, the growth and metabolic activity of the specific *Lactobacillus* species in the starter culture and during aging may affect residual galactose. Together, the data suggest that Parmesan cheese produced using traditional methods and aging are likely to have the lowest free galactose content.

Cheddar cheese is classified by the length of aging; mild Cheddar is aged for 2−3 months, medium Cheddar for 4−6 months, and sharp Cheddar, for >9 months. Nine samples of sharp Cheddar cheese were analyzed, averaging 28.9 mg galactose/100 g. One sample of medium Cheddar cheese and two samples of mild Cheddar cheese contained negligible galactose. Interestingly, sharp Cheddar cheeses produced in smaller regional dairies contained 7.8 ± 4.0 mg/100 g compared to 55.4 ± 37.2 mg/100g found in sharp Cheeses produced by a larger multinational producer (Kraft Foods Global, Northfield, IL, USA). This suggests that a more consistent product may be produced in smaller dairies. A similar conclusion was reached in analysis of sharp cheeses produced in England; cheeses produced at the UK West Country Farmhouse Cheese Makers Association contained negligible amounts of galactose determined enzymatically, whereas less consistency was found from other manufacturers.[16,17] It may be speculated that smaller producers are more consistent in the use of a traditional Cheddar process, whereas larger plants may adapt various modifications to reduce costs and/or increase efficiency of the operation. For example, high residual galactose concentrations were reported in a Cheddar cheese made using a 42 °C cook temperature to decrease production time.[30] Cheddar cheese is usually made with mesophilic *Lactococcus lactis* subsp. *cremoris* and/or *lactis* starter culture and a cook temperature of 38 °C. However, at the higher temperature, *L. lactis* was not effective in metabolizing galactose and was not active during cheese ripening due to a high salt sensitivity and extensive autolysis. In these experimental Cheddar cheeses, lactose was undetectable after 3−5 months of aging, but galactose was slower to decrease and was present in some samples at approximately 170 mg/100 g cheese after 6 months.[30]

Table 2. Galactose Content of Various Types of Cheese[a]

type	brand/manufacturer	galactose (mg/100 g)
Cheddar, sharp		
sharp, aged 1 year	Brennan's Cellars/Brennan's, New Glarus, WI	6.6

			16.3–34.7	28.1–81.7		250.7–622.5	304.6–738.8

[a]Values are the average and range of three analyses. Carbohydrate values are in milligrams per 100 g beans or 100 mL liquid. [b]ND, not detected.

Free galactose is toxic to plant cells and is highly regulated, so it is a very minor component of most plants and often not reported.[37] Instead, the major source of galactose in legumes is galacto-oligosaccharides, which are thought to aid in seed tolerance to desiccation and to serve as an energy reserve for germination.[38,39] The most common linear oligosaccharides include raffinose, stachyose, and verbascose, with one, two, or three galactosyl residues, respectively, linked α-1−6 to the glucose residue of sucrose and α-1−6 to each other. Galactose can also be linked to inositols; for example, ciceritol, found in garbanzo beans, is the α-digalactoside of pinitol (α-D-galactopyranosyl-(1→6)-α-D-galactopyranosyl-(1→2)-4-*O*-methyl-*chiro*-inositol).

The effect of various legume preparation methods on galacto-oligosaccharides has been reported;[15,40−43] however, there is almost no information on the effect of these treatments on free galactose concentrations. Although soaking and cooking reduce the oligosaccharide content, it is not clear whether these compounds are simply lost from the tissue or whether they are subject to enzymatic or thermal degradation, which may release free galactose.

The galactose content of various commercially canned legumes and canning liquid is shown in Table 3 Free galactose was highest in garbanzo beans (24.6 ± 26.4 mg/100 g whole beans and 39.5 ± 26.5 mg/100 mL canning liquid) compared to the other varieties examined. Free galactose was also found in black beans (5.3 ± 9.2 mg/100 g) but was not detected in whole red kidney beans or pinto beans; however, free galactose was detected in the canning liquid of kidney beans (17.7 ± 15.5 mg/100 mL). Stachyose contributed the greatest amount of bound galactose in pinto, black, and kidney beans, whereas ciceritol was the highest source of bound galactose in garbanzo beans.

Free galactose found in the canned garbanzo beans and the canning liquid is equivalent to approximately 180 mg/100 g bean dry weight (calculated accounting for the weight of each portion). This value is substantially lower than the 444 mg/100 g reported by Acosta and Gross,[7] but similar to concentrations of 184, 110, and 80 mg/100 g reported by others.[44−46] The high concentration reported by Acosta and Gross may be due in part to a different variety of garbanzo bean or the different analytical technique used for quantitation. Although similar extraction methods were used in all studies, Acosta and Gross reduced and derivatized the sugars to alditol acetates for analysis by gas chromatography, which would exaggerate the galactitol peak with any galactitol naturally present in the beans. As well, the difference may be related to the bean preparation method. Soaking beans at room temperature prior to cooking as done by Acosta and Gross would initiate germination, which, in turn, initiates hydrolysis of galacto-oligosaccharides by α-galactosidase with possible liberation of free galactose.[47]

In addition, the higher free galactose concentration found in the canning liquid indicates that the free galactose content associated with the consumption of canned legumes can be significantly reduced if the canning or cooking liquid is discarded and any residual liquid on the legumes is removed by rinsing.

Although the maximum amount of dietary galactose safely tolerated by those with classic galactosemia remains unknown,[3,48] results from this study find that the galactose content of specific cheeses, caseinates, and legumes are within those found in currently allowed foods and ingredients and are low enough to be acceptable in the diet for classic galactosemia. Allowing some previously restricted foods in the diet could improve both adherence and nutrient intake of individuals who require chronic galactose restriction. These analytical findings may have important implications for patients with galactosemia and support a review of current dietary recommendations for classic galactosemia.

intended use as possible, i.e., in contact with the food that they are intended to be used with, while maintaining storage times and temperatures consistent with consumer practices. Alternatively, exaggerated conditions can be used to assess a worst-case scenario, so that measures can be taken to protect even the most careless consumer. Where possible, the food that the intended food packaging material is to be used with should be used in the migration tests because the nexus of interrelationships, such as water availability and viscosity, is not accounted for when using food simulants.

Simulation models can be a valuable resource in risk assessment, particularly in migration[9] and exposure assessments.[10] Simulation models can be used as an initial screening tool to provide a range of values likely to result from a given scenario, reducing the need for expensive, time-consuming migration tests. Simulation models can also provide guidance on expected migration ranges, hence guiding the selection of sensitive analytical techniques. Model design inherently involves the incorporation of multiple factors that affect the overall system and the collation of variability and uncertainty of all known factors that contribute to the models output. For example, a migration model requires inputs; these inputs should account for all of the attributes that affect migration in a packaging−food system. Often existing interrelations between input factors can be found in the literature,[11] and these can be useful as a starting framework. By reviewing the literature on existing knowledge regarding mass-transfer phenomena, these systems can be mathematically simulated to calculate potential nanoparticle migration for a particular scenario. When the necessary data are available, exposure assessments are a logical progression from migration testing, particularly when dealing with migration into real foodstuffs. Exposure assessments can improve our understanding of the risks associated with migration. They can make migration results more tangible as the migration figures are combined with likely consumption levels of the particular food in question while also considering the relative body weight of an individual. Hence, the objective of this study was to analytically assess the migration of silver and copper nanoparticles from polyethylene (PE) matrices into a food matrix and to use known interrelationships reported in the literature to create a simulation model to predict likely migration levels. The migration results were also used for an exposure assessment, focusing on the oral route of exposure, following the ingestion of chicken meat packaged with a nanopolymer.

MATERIALS AND METHODS

Experimental Procedure. *Nanoparticle Synthesis.* To make the silver nanoparticles, an $AgNO_3$ solution (0.1 M) was prepared in ethanol at 45 °C to make 10 nm nanoparticles. An equal amount of 0.1 M polyvinylpyrrolidone (PVP) solution in ethanol was then added to this at a rate of 0.667 mL min^{-1}. The solution was stirred for 2 h (800 rpm), until the solution had turned a stable orange−brown color. Silver nanoparticles were separated from solution by the addition of acetone at a volume ratio of approximately 1:4. The solution was sonicated for 10 min and centrifuged at 6000 rpm for 15 min. The supernatant was discarded; the pellet was redispersed in ethanol; and the separation step was repeated. The pellet was dried in an oven overnight at 60 °C and crushed to a powder; this procedure was adapted from Chen et al.[12] Scanning electron microscopy (SEM) images were taken of the particles (Figure 1)

To make the copper nanoparticles, CuCl (99% minimum), sodium formaldehyde sulfoxylate (SFS), and sodium citrate were purchased from Sigma-Aldrich. The concentration of all solutions was 0.5 M, and they were prepared in deionized water. Sodium citrate solution was added dropwise to CuCl solution under stirring at a 2:1 volume ratio, at 60 °C. The mixture was stirred for 30 min, before SFS solution was added dropwise. The mixture was stirred for a further 60 min. A brown precipitate was formed. The supernatant was discarded, and the precipitate was washed. The supernatant was again discarded, and the brown precipitate was dried at 60 °C. This procedure was adapted from Khanna et al.[13]

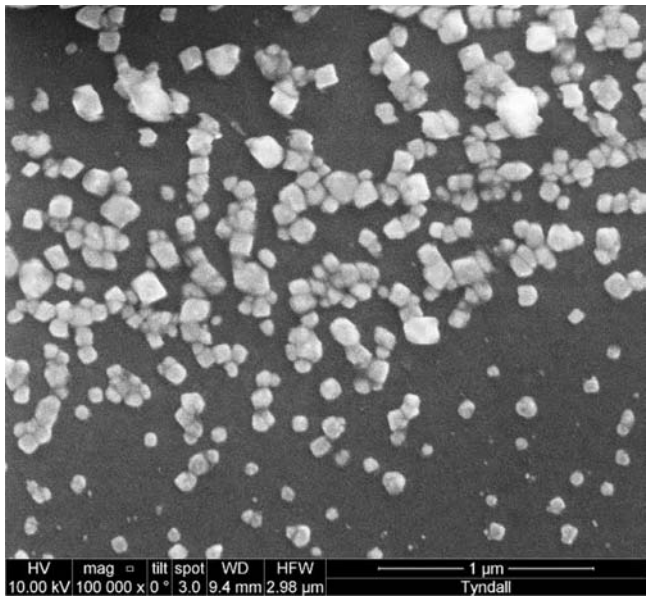

Figure 1. SEM images of silver nanoparticles that were incorporated into PE.

Composite Manufacture. PE-based composites were manufactured via extrusion in a micro 27 lab-scale twin screw extruder (Leistritz, Nuernberg, Germany) with a 27 mm screw diameter and a 38:1 length/diameter ratio, using the screw geometry as outlined by Gunning et al.[14] PE pellets (melt flow rate of 0.33 g/10 min and density of 921 kg/m^3) were supplied by Boxmore Plastics Co., Cavan, Ireland. In the compounding process, the temperature profile was increased from 160 °C at the hopper to 200 °C at the die with a screw speed of 120 rpm. Two PE nanocomposites were designed containing 0.5% (w/w) of the nanocomponent (properties of the PE used can be found in Table 1). The silver nanocomposite incorporated nanosilver with a logistic size distribution with a mean of 1.01×10^{-8} m and a standard deviation of 6.4×10^{-10} m (Figure 1). The copper nanocomposite incorporated nanocopper with a logistic size distribution with a mean of 1.14×10^{-8} and a standard deviation of 6.8×10^{-10} m. Skinless, boneless chicken breasts (samples) were sourced from an Irish supplier, and 32 samples were wrapped in 120 cm^2 of one of the prepared nanocomposites ($n = 16$ for both silver and copper). The packaging did not overlap. Aluminum foil was wrapped around these to eliminate any possible variation that light may impart.[15] Oxidation of silver nanoparticles because of ultraviolet (UV) radiation is known to facilitate silver dissolution.[16]

Each sample (nanocomposite and foiled unit) was then vacuum-packed in standard, heat-sealable, clear, PE vacuum packing bags to ensure maximum, consistent contact between the active nanocomposite and the samples. For such active packaging materials, sharing a common interface or physical contact with the food surface is essential for the desired effect to be observed.[17] Each unit was performed in quadruplicate. Also, eight control units were prepared, where samples were in contact with a PE packaging that did not contain added nanosilver or nanocopper.

Units were kept in constant temperature rooms for the duration of the experiment (t): either 1.1 or 3.1 days. The time periods chosen for the migration tests were thought to represent likely and unfavorable (however, possible) storage periods for chicken.

Table 1. Inputs, Constants, and Outputs of the Simulation Model

	name	subdivision	value	unit	symbol	equation	reference
			Inputs				
PE	dynamic viscosity	viscosity[a]	uniform (200,[b] 2300)	Pa s	$\eta(p)$		29
		temperature	uniform (473, 487.87[b])	K	x		29

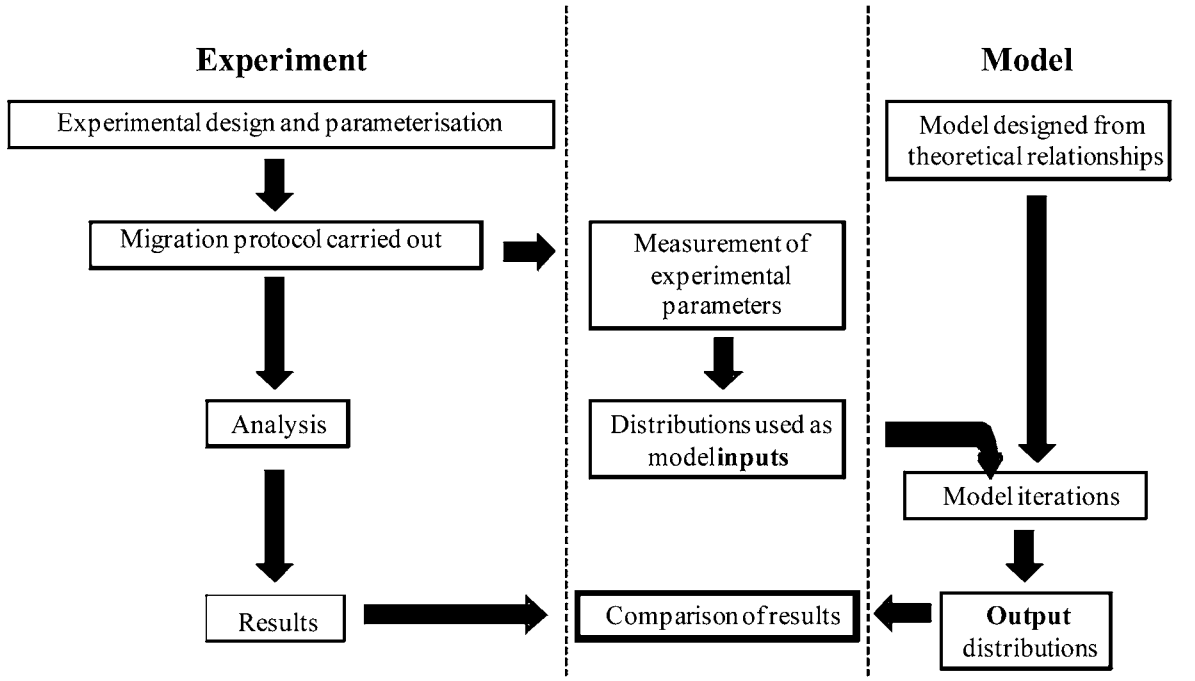

Figure 3. Study framework showing experimental procedures, modeling tasks, and their interrelationships culminating in the comparison of the two results to assess the performance of the migration model.

chosen to represent the conditions of a poorly performing/overcrowded refrigerator and ambient storage. The two levels of temperatures were set and then logged during the migration tests. The means ± standard deviations of the distributions T1 and T2 were 8.13 ± 0.48 and 21.80 ± 0.64 °C, respectively.

Following the migration tests, all packaging was removed from the samples. Each chicken breast sample was homogenized, and 2 g of it was added to a Teflon microwave vessel. A total of 10 mL of concentrated nitric acid (Fisher Scientific) was added to the vessel. The sample was digested using microwave-assisted acid dissolution at 200 °C (microwave unit from Mars Xpress supplied by CEM). The extract produced was diluted to 50 mL with deionized water. Digests were analyzed using inductively coupled plasma−mass spectrometry (ICP−MS, Agilent 7500 ICP−MS) according to the protocol assigned the ISO number DIN EN ISO 17294-2-E29. Standards were derived from stock solutions from Spectrosol.

Mathematical Model. A migration model was designed, and its validity was assessed by comparing migration predictions to the results of the laboratory migration tests, given the same set of conditions (time and temperature). Migratability and subsequent migratables were intermediate outputs that were also generated by the mathematical model. The equations to follow are applicable to polyolefins and not to non-amorphous polymers. The Williams−Landel−Ferry equation for time−temperature superposition was used with the dynamic viscosity of the polymer to obtain the viscosity at the glass transition temperature of the polymer, as used by Šimon et al.[11] and defined as

$$\eta(T_g) = \frac{\eta(T)}{\left(\exp\left(\frac{-1(C_1(T-T_g))}{C_2+T-T_g}\right)\right)} \quad (1)$$

where η is the viscosity, T_g is the glass transition temperature, T is the experimental temperature (as mentioned above; in this case, the dynamic viscosity information of the polymer was used), and C_1 and C_2 are constants with values of 17.44 and 51.6 K, respectively.

As seen from eq 2, the Williams−Landel−Ferry equation is also used for the subsequent calculation of the viscosity at a particular temperature. During validation, experimental temperatures were used as inputs.

$$\eta(T) = \eta(T_g)\exp\left(\frac{-1(C_1(T-T_g))}{C_2+T-T_g}\right) \quad (2)$$

Migratability (M) is a value of the likelihood of particles migrating from a given system and is defined as

Table 3. Inputs and Outputs of the Model of Nanosilver and Nanocopper Concentrations in the Nanocomposites

	value	symbol	unit	equation
	Inputs			
quantity of PE in the nanocomposite	triangular (99.48, 99.5, 99.52)	b	%, w/w	
quantity of silver in the nanocomposite	triangular (0.48, 0.5, 0.52)	d	%, w/w	
PE density	921	$\rho(p)$	kg/m^3	
silver density	10490	$\rho(n)_s$	kg/m^3	
copper density	8940	$\rho(n)_c$	kg/m^3	
	Outputs for Nanosilver Nanocomposite			
volume of PE	distribution with a mean of 1.08×10^{-3} and σ of 8.86×10^{-8}	f	m^3	$b/\rho(p)$
volume of silver	distribution with a mean of 4.76×10^{-7} and σ of 7.78×10^{-9}	g	m^3	$d/\rho(n)$
volume of 1 kg of nanocomposite	distribution with a mean of 1.08×10^{-3} and σ of 8.09×10^{-8}	h	m^3	$f + g$
weight of 1 m^3 of nanocomposite	distribution with a mean of 925 and σ of 0.07	j	kg/m^3	$1/h$
weight of nanosilver in 1 m^3 of nanocomposite	distribution with a mean of 1.53×10^{-5} and σ of 1.45×10^{-6}	c	kg/m^3	$j \times d$
	Outputs for Nanocopper Nanocomposite			
volume of PE	distribution with a mean of 1.08×10^{-3} and σ of 8.86×10^{-8}	f	m^3	$b/\rho(p)$
volume of copper	distribution with a mean of 4.76×10^{-7} and σ of 7.78×10^{-9}	g	m^3	$d/\rho(n)$
volume of 1 kg of nanocomposite	distribution with a mean of 1.08×10^{-3} and σ of 8.09×10^{-8}	h	m^3	$f + g$
weight of 1 m^3 of nanocomposite	distribution with a mean of 925 and σ of 0.07	j	kg/m^3	$1/h$
weight of nanocopper in 1 m^3 of nanocomposite	distribution with a mean of 1.53×10^{-5} and σ of 1.45×10^{-6}	c	mg/m^3	$j \times d \times 10^6$

$$M = \sqrt{\left(\frac{k_B T t}{24(\pi^2)\eta r}\right)} \quad (3)$$

where k_B is the Boltzmann constant ($k_B = 1.3807 \times 10^{-23}$ J K^{-1}), t is the time in seconds, and r is the radius of the particles. Migratables (N_{mg}) is the quantity of nanoparticles migrating from the polymer matrix[11] and is calculated as given in eq 4

$$N_{mg} = Mac \quad (4)$$

where a is the area of the nanocomposite−food interface and c is the initial concentration of nanoparticles in the nanocomposite assuming homogeneous distribution. The final migration level (Q) must consider background levels of the metal (eq 5). In this study, the background level of each metal was estimated using measurements taken from the control samples. This was particularly important in the case of the samples in contact with the copper nanocomposites because chicken breasts have naturally occurring background levels of copper (BL), which are highly variable relative to likely copper migration levels. A dimensionless uncertainty factor (e) is also included in the migration model to take into account the model uncertainty (eq 5). It was calculated by optimizing the representations of the experimental data of the models.

$$Q = (N_{mg} + \mathrm{BL})e \quad (5)$$

A Monte Carlo simulation was used so that inherent variability of the input parameters can be considered. The inputs, constants, and outputs of the model are given in Table 1. The @RISK 5.5 software (Palisade, Middlesex, U.K.), a package specifically used for risk assessment, was used as an add in in Microsoft Excel (Microsoft Office 2007). The model was run for 10 000 iterations, giving a final simulated output probability density distribution for the level of nanosilver and nanocopper likely to migrate into the food matrix.

Model−Experimental Synchronization. The conditions of the experiments were used as inputs in the model (Table 2). Scenario 1 used a time (t) of 1.1 days and a temperature (T) of 8.13 ± 0.48 °C. Scenario 2 used a time of 1.1 days and a temperature of 21.80 ± 0.64 °C. Scenario 3 was for a time of 3.1 days and a temperature of 8.13 ± 0.48 °C. Scenario 4 was for a time of 3.1 days and a temperature of 21.80 ± 0.64 °C. This allowed for the direct comparison of the model outputs to the experimental results. This framework is explained diagrammatically in Figure 3. The input variable of the concentration was converted from %, w/w (given in the Experimental Procedure above) to kg/m^3 to allow for comparison to model outputs (Table 3).

Exposure Model. If migration occurs, likely exposure arising from the migration can be calculated by an exposure assessment. In doing so, it was assumed that all silver was in its most harmful form, i.e., unagglomerated nanoparticles, because it is not known how readily silver nanoparticles produce silver ions or in what ratios they coexist. In addition, both processes are likely to vary according to pH, temperature, and/or time.[10] Any agglomeration of the nanoparticles is likely to reduce the active particle surface area and, hence, reduce toxicity, and therefore, the model assumed no agglomeration throughout the process. A mathematical model were created to generate probability distributions of human exposure to silver and copper nanoparticles as a result of the consumption of chicken after contact with the nanosilver PE nanocomposite and the nanocopper PE nanocomposite used in the migration tests. The results of the migration experiments fed into the exposure assessment as an input variable.[10] Monte Carlo simulation (10 000 iterations) was used so that the inherent uncertainty and variability of input parameters were considered. Risk analysis software (@Risk 5.5, Palisade, Middlesex, U.K.) was used to generate a predicted exposure estimate from the series of input distributions using eq 6

$$E_x = (y_x z)/\mathrm{bw} \quad (6)$$

where E is exposure in mg kg$_{bw}^{-1}$ day^{-1} and x is the particular migrant particle (in this case, nanosilver or nanocopper). The term y is migration in mg/kg into the particular food, chicken breast meat in this case. The term z is the consumption of that food in kg/day in a given population. The term bw refers to the body weight of an individual in kilograms in the given population. Chicken consumption data for Ireland,[18] for those who consumed chicken (67%; n = 1500), took account of "... all chicken eaten as meat only, chicken on the bone, chicken skin and chicken meat extracted from composite meals by way of an arbitrary percentage of 66.7%." The data provided was fit to a log-normal distribution (with a mean of 62.01 g/day and a standard deviation of 43.84 g/day) using @Risk 5.5 software to represent consumption (z). Irish adult body weight data[18] (bw) was fit to a normal distribution (with a mean of 77.48 kg and a standard deviation of 16.18 kg) using @Risk 5.5 software.

RESULTS AND DISCUSSION

Experimental Migration. The results of the experiments are presented in Table 2. All four scenarios were conducted at temperatures above the recommended storage temperature of a perishable food product (>5 °C); this is an important consideration when comparing the migration of nanosilver in this study to other studies or ingestion limits.

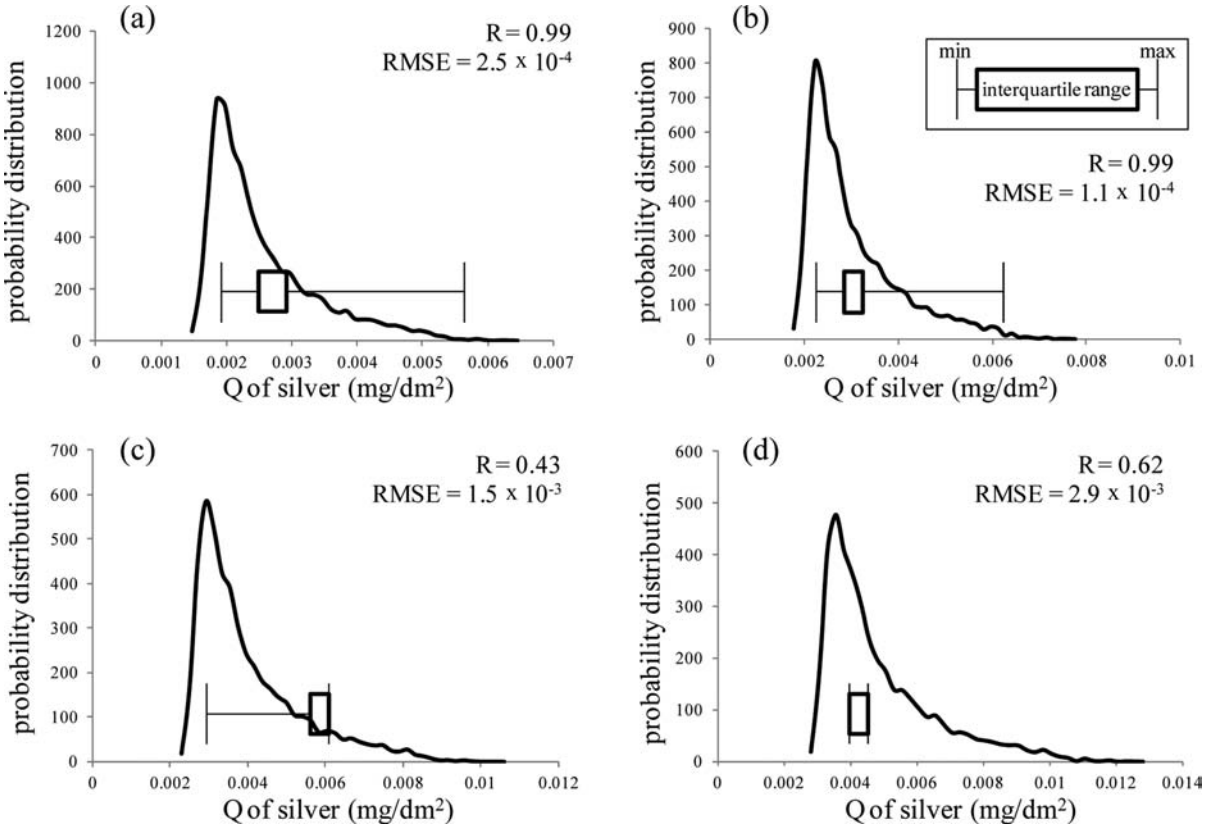

Figure 4. Probability density distribution of the final migration level (Q) of silver in chicken and the minimum, maximum, and interquartile range of the corresponding experimental values, following simulations and migration tests of the following conditions: (a) scenario 1, (b) scenario 2, (c) scenario 3, and (d) scenario 4.

SAS 9.1 was used to establish if there were any effects of time and temperature on the migration of silver or copper from the nanocomposites. No significant effects of time or temperature were observed in the samples analyzed for copper or silver ($p > 0.1$). In the case of both time and temperature, it is suggested that migration levels may have already plateaued over the time period studied, and hence, no significant effect in the migration results was observed. This is supported by the fact that recent research, which focused on a shorter time period, reported a reduction in the migration rate within the first day of contact.[19] It is likely that both of these time periods used in the migration tests of this study are beyond the point of the migration−time relationship, where an increase in time brings about an increase in silver levels. Silver ion release from a polyester matrix into liquid simulant reached a maximum in less than 5 min in another study,[20] but corresponding SEM imagery seemed to confirm that this was due to the dissolution of particles on the surface or very near the surface of the polyester matrix in which they were bound.

The quantities of silver in samples that had been in contact with the nanosilver PE composite (with a mean of 0.0041 mg/dm^2; $n = 16$) were significantly different from the control samples (with a mean of 0.001 mg/dm^2; $n = 8$) ($p < 0.001$). The samples in contact with the nanocopper PE composite had significantly higher copper levels (with a mean of 0.037 mg/dm^2; $n = 16$) than the control samples (with a mean of 0.0157 mg/dm^2; $n = 8$) ($p < 0.05$) but to a different level of significance than the silver experiments. This may be explained by the presence of copper in chicken meat as a naturally occurring biological mineral.

It should be noted that the levels of migration observed in this study are from a pilot bench-scale nanocomposite developed in a laboratory for experimental uses only. Commercially, it would be unlikely that nanocomposites containing 0.5% (w/w) fill of nanosilver or nanocopper would be produced because novel effects are observed at much lower levels.[19] This is particularly important because the level of nanoparticulate fill was identified as the most significant parameter in a recent study[10] influencing migration compared to other parameters of time, temperature, and nanoparticle size. Hence, it is feasible to engineer a functional antimicrobial nanocomposite, with a lower nanofiller percentage and which will potentially result in less migration.

Model Validation. It is shown in Figure 4 that the model proved to be reliable in predicting the migration results for nanosilver over a range of storage conditions with coefficients of correlation (R) of 0.99, 0.99, 0.943, and 0.62 and root-mean-square error (RMSE) values of 2.5×10^{-4}, 1.1×10^{-4}, 1.5×10^{-3}, and 2.9×10^{-3} for scenarios 1, 2, 3, and 4, respectively. In general, the model was slightly less accurate in predicting the levels of copper in the chicken samples, with R values of 0.65, 0.97, 0.99, and 0.66 and RMSE values of 9.6×10^{-3}, 3.4×10^{-2}, 1.4×10^{-2}, and 2.1×10^{-2} for scenarios 1, 2, 3, and 4, respectively, as shown in Figure 5. This suggests that the model may be a useful tool in the design and engineering of new nanopackaging materials that are likely to come on stream in the coming years as the fruits of the recent surge of nanotechnological research mature. The main appeal of this model to industry is that it reduces the need for expensive and time-consuming migration tests, thus also reducing costs.

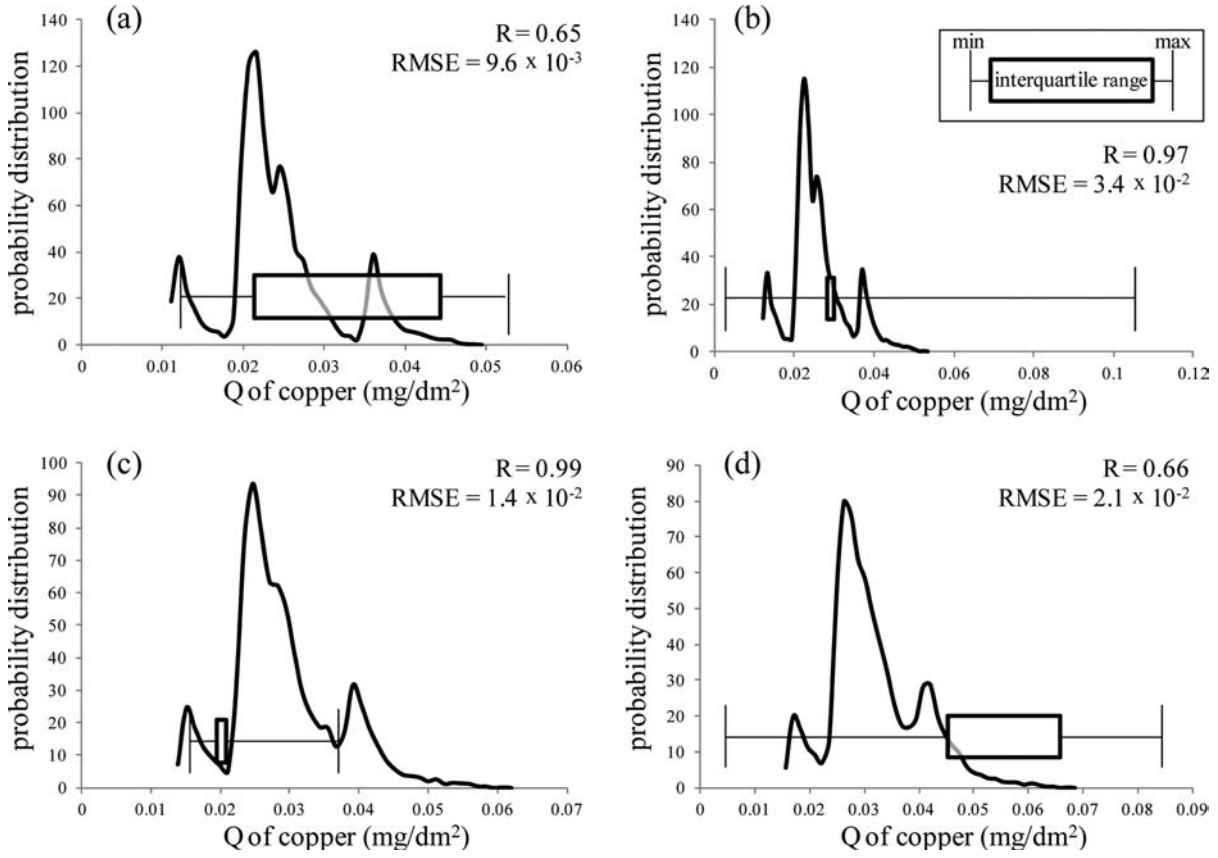

Figure 5. Probability density distribution of the final migration level (Q) of copper in chicken and the minimum, maximum, and interquartile range of the corresponding experimental values, following simulations and migration tests of the following conditions: (a) scenario 1, (b) scenario 2, (c) scenario 3, and (d) scenario 4.

The model, which took into account background levels (BL) in the food material in mg/dm^2, generated from control values, and a model error (e) of 0.32, had mean predicted migration levels (Q) ranging from 2.61×10^{-3} to 5.01×10^{-3} mg/dm^2 for silver (Table 2). The model for copper migration, which also included BL and an e of 1.1, had Q values ranging from 3.82×10^{-2} to 4.75×10^{-2} mg/dm^2 (Table 2). It can be seen from the R and RMSE values (Figures 4 and 5) that the model more accurately predicted the levels of silver in the samples than the levels of copper in the samples. It is likely that the highly variable BL for copper with a mean of 12.6×10^{-2} mg/kg and a standard deviation of 4.76×10^{-2} mg/kg (n = 8) makes it difficult to capture the true treatment effect. Therefore, the use of a food simulant rather than a real food may be more suited to studying nanoparticles that share a common element with food substances.

This study assesses the migration in a nanocomposite−food system not only from nanocomposites with a high nanoparticle fill level but at relatively high temperatures for the storage of perishable goods. An additive to the extreme conditions is the vacuum packaging procedure applied to the individual units. This maximized the contact surface area in the experiments. Hence, the study represents a pessimistic evaluation of potential commercial use and poor storage practices. The predicted migration values increased with time and temperature; this trend corresponds to results where a broader temperature range and longer time periods were studied.[11]

Exposure Assessment. The exposure model generated probability distributions describing the likely human exposure to nanoparticles, following the consumption of chicken wrapped in nancomposites based on the laboratory migration results and current population data. Because of the extreme nature of the migration testing conditions, the exposure must also be viewed as extreme. The 95th percentiles of human exposure to silver (as shown in Table 2) were 5.89×10^{-5}, 7.06×10^{-5}, 8.9×10^{-5}, and 7.97×10^{-5} mg kg_{bw}^{-1} day^{-1}, for scenarios 1, 2, 3, and 4, respectively. The 95th percentiles of human exposure to copper (as shown in Table 2) were 2.26×10^{-5}, 5.67×10^{-5}, 4.24×10^{-5}, and 1.17×10^{-4} mg kg_{bw}^{-1} day^{-1} for scenarios 1, 2, 3, and 4, respectively. Putting these values into context in terms of their potential to cause adverse effects is difficult because research on toxicity is sparse. However, a provisional ingestion limit (PIL) for silver nanoparticles of 0.084 mg kg_{bw}^{-1} day^{-1} was calculated for silver nanoparticles with a diameter of 10 nm[10] based on principles outlined by O'Brien and Cummins,[21] which, in turn, were derived from a nanosilver exposure study.[22] The exposure to silver nanoparticles calculated in this study ranged from 7.01×10^{-4} to 1.06×10^{-3}% of that PIL. In the study by Cushen et al. for similar sized silver nanoparticles migrating from a polyvinyl chloride (PVC) composite into chicken breasts stored at 5 °C for 4 days, 16.02% of the same PIL was reached. A crucial factor in the migration levels seen in the PVC study and the subsequent exposure values was the fill level. The fill level in this current study at 0.5% is 10 times less than that of the comparable study,[10] and migration and subsequent exposure levels are far lower because of this.

dx.doi.org/10.1021/jf404038y | J. Agric. Food Chem. 2014, 62, 1403−1411

No such nanocopper exposure studies exist, and therefore, a PIL cannot be calculated. However, the levels of migration measured in this study are not likely to lead to adverse effects because the simulated exposure levels in this experiment (with approximately half attributed to BL of copper in chicken), with the highest being 1.37×10^{-4} mg kg_{bw}^{-1} day^{-1}, are very low compared to the average dietary intake of copper. These were found to have averages of 1.42×10^{-2} and 1.9×10^{-2} mg kg_{bw}^{-1} day^{-1} for women and men, respectively [calculated using the Irish Universities Nutrition Alliance (IUNA) adult body weight distribution[18] and U.S.A. population values expressed in mg/day[23,24]].

It can be concluded that, if the effect of silver or copper nanoparticles incorporated into PE is optimally effective against the microbial spoilage profile of a particular food (and in line with properties and conditions investigated in this study), then their use may be recommended, because the migration and subsequent exposure (resulting for materials investigated in this study and representing pessimistic scenarios) did not exceed the safety limitation sourced from scientific literature. Having said this, the limits used to assess the safety of silver migration vary hugely,[2,10] and safety assessments are highly dependent upon the levels to which they are compared. The limit of 0.01 mg/kg (unauthorized substances) from European legislation that was used to assess the migration from the nanosilver−PE composites and Agion−PE composites to food simulants by Cushen et al.[2] is very restrictive. This precautionary approach is due to the lack of appropriate toxicity research available, and it is understandable that the European Commission cannot base permissible migration levels on the results of an insufficient number of toxicity studies. Until more research in this area becomes available, a ban has been imposed on nanomaterials being used in food contact materials,[9] unless specifically listed in the Union List of EU 10/2011.[9] Neither nanosilver nor nanocopper is mentioned on this list.

It is likely that the full antimicrobial potential (by ion release or the particles in nanoform) of nanosilver and nanocopper is excessive for delaying food spoilage at the fill rates tested in this study. The antimicrobial profile (including intensity and longevity) that is required to offset food spoilage should be defined and an antimicrobial system should be designed accordingly, including percentage fill rate, antimicrobial release mechanism, and recommended storage conditions. Such a development could see antimicrobial packaging systems becoming more food-specific, which is justifiable given the effect of food pH observed.[2] Because of the association between silver release, antimicrobial potential, and toxicity,[25−28] it can be deduced that composites that are excessively antimicrobial are more likely to lead to high exposure levels. Although the effect of both silver nanoparticles and silver ions on humans is largely unknown, recent initial studies into their effects on model organisms suggest that nanoparticles are more toxic than ions.[26−28] Considering this, antimicrobial potential and, therefore, fill rate should be minimized within the limits that allow for an acceptable antimicrobial effect.

The widespread use of antimicrobials in food packaging depends upon their active behavior, but any commercial success relies on how they perform in migration tests. It can be concluded that this study demonstrates the potential for nanosilver and nanocopper for use in food contact materials, with low migration levels observed in all scenarios tested. The migration and exposure models can be used by industry to study the migration behavior of nanosilver and nanocopper composites under varying conditions. It is acknowledged that there is still considerable uncertainty regarding the toxicity of materials at the nanoscale; hence, exposure estimates should be re-evaluated when more toxicity data become available.

MATERIALS AND METHODS

Chemicals. Acetonitrile was purchased from Fisher Scientific (Fair Lawn, NJ, USA). Water was purified to 18.1 MΩ·cm using a Barnstead E-Pure System (Barnstead International, Dubuque, IA, USA). Methanol was purchased from EMD Millipore Corporation (Billerica, MA, USA). Formic acid (98−100% purity) was purchased from EMD Chemicals (Gibbstown, NJ, USA). Met-Arg-Phe-Ala (MRFA) was purchased from Research Plus, Inc. (Barnegat, NJ, USA) and taurocholic acid sodium salt hydrate from Sigma-Aldrich (St. Louis, MO, USA) were used as internal standards.

Plant Material. Fifty genetically diverse non-GM commercial maize hybrids from DuPont Pioneer were planted at six different locations. Five of the locations were in the U.S. (Illinois, Kansas, Minnesota, Nebraska, and Texas) and the sixth location was in Ontario, Canada. Planting locations for the hybrids were selected based on days to maturity such that each location had 20 unique genotypes. At every location, each genotype was planted in three randomized blocks (three blocks and two replicate plots per block). Each block was separated by an alley at least 36 in. wide and surrounded on each end by two-row borders. Details and a pictorial representation are shown elsewhere.[10] Agronomic practices such as irrigation, fertilization, and herbicide and pesticide applications were applied uniformly across locations and were consistent with the normally acceptable practices for maize production. From the 50 genotypes, a core subset of five that were grown at all six locations were used for LC/MS analysis.

Two forage samples were collected from three plants after flowering for each genotype and block and placed immediately on dry ice. Each forage sample represented the pooled aerial portions of three entire plants. Collected frozen samples were stored temporally at less than or equal to −10 °C for less than 10 min. Each grain sample was collected at maturity from five hand pollinated ears from each genotype and block. For each sample, the resulting grain from five shelled ears were pooled and immediately placed on dry ice until transferred to a less than or equal to −10 °C freezer for temporary storage. The same harvesting protocol was adopted in all locations. Samples were shipped frozen to the DuPont Pioneer Regulatory Science processing laboratory in Ankeny, Iowa, where they were lyophilized and ground. Lyophilized forage and grain samples were then shipped on dry ice to the DuPont Pioneer metabolomics laboratory in Johnston, Iowa, where they were stored at −80 °C until analyzed.

Sample Preparation. For forage samples, metabolites were extracted from lyophilized tissue with a mean dry weight of 6.7 mg. Metabolites were extracted from grain samples with a mean dry weight of 29.9 mg. Five hundred microliters of cold extraction solvent (80% methanol/20% water) containing 10 mg/mL Met-Arg-Phe-Ala (MRFA) and 5 mg/mL taurocholate as internal standards for positive and negative electrospray, respectively, were added to each sample and reference sample in a 1.1 mL polypropylene microtube containing two 5/32 in. stainless steel ball bearings. Samples were homogenized in a 2000 Geno/Grinder ball mill (SPEX CertiPrep, Inc., Metuchen, NJ) at a setting of 1650 rpm for 1 min and then rotated on an end-over-end mixer (Glas-Col, LLC, Terre Haute, IN) at 4 °C for 30 min. Samples were then centrifuged at 1454*g* at 4 °C for 15 min. The supernatant of each sample was transferred to 0.2 μM (VWR International LLC, Radnor, PA) spin filter and centrifuged at 800*g*. Solution was transferred to a limited volume autosampler vial.

Forage and grain samples were rearranged into 10 analytical batches separately. Each batch contained samples from every genotype and location to minimize analytical errors and system bias in the acquired data. We prepared four quality control (QC) samples for each batch by pooling extract aliquots from each individual sample within the batch. In addition, we ran three reference samples in each batch that were prepared from pooled grain or forage material. The reference samples were sourced from grain or forage originating from all locations and containing all genotypes. Both QC and reference samples were placed at regular intervals within each batch.

Liquid Chromatography−Mass Spectrometry. Analyses were performed on an Accela ultra high pressure liquid chromatograph (uHPLC) system coupled to a LTQ-FT hybrid mass spectrometer (Thermo Scientific, West Palm Beach, FL, USA) via an electrospray ionization (ESI) interface. Sample extracts were separated via reversed phase on a Thermo Scientific Hypersil Gold C18 column (2.1 × 200 mm × 1.9 μm). The mobile phase consisted of water/0.1% formic acid (A) and acetonitrile/0.1% formic acid (B) and flow rate was set to 0.5 mL/min. A linear gradient was used beginning with 10% B at 0.98 min, reaching 100% B at 18 min, 100% B at 35 min, then recovered to initial condition within 30 s where it was held for 4.5 min. Injection volume and column temperature were 25 μL and 40 °C, respectively. The optimized parameters for positive and negative ion electrospray were set as follows: capillary temperature 250 °C; sheath gas flow rate 70 arbitrary units, sweep gas flow rate 5 arbitrary units. The instrument was tuned prior to each batch run. Metabolites were detected using the linear ion trap detector collecting full-scan data from 150 to 975 m/z. Automatic gain control were set at 30 000 for both positive and negative ionization modes. The source voltage was set at 2.5 kV for positive mode and 4 kV for negative mode. Xcalibur version 2.1.0 SP1 software (Thermo Scientific) was used for data acquisition.

Data Pretreatment. Xcalibur raw files were imported to Genedata Expressionist Refiner MS version 6.1 (Basel, Switzerland) for chromatogram gridding, aligning, chemical noise subtraction, peak detection, isotope clustering, adduct detection, and signal clustering. Preprocessed data consisted of intensities for each m/z value and retention time combination or peak. For a peak to be valid and retained, it had to be present in at least 50% of the samples in addition to being detected in all QC samples. The data matrix was exported to Genedata Expressionist Analyst version 2.2 for normalization by both internal standard signal and the sample dry weight. To further minimize unwanted variation in our data set due to within batch run order drift or across batch variability, we performed QC and reference sample normalizations in addition to internal standard and weight normalizations. QC samples normalization was used to minimize and correct for within batch variation. QC sample normalization was performed by dividing the relative abundance of each sample peak by the mean of that for the two bracketing QC samples within a batch. Reference sample normalization was used to correct for and minimize variability across batches. Reference sample normalization was performed after QC normalization by dividing the relative abundance of each sample peak by the mean of that peak in all reference samples within a batch. Fully normalized data were exported to Matlab or Excel 2007 for further data analysis. We used the LC/MS data individually and in combination with GC/MS data for statistical analyses. GC/MS data were obtained from the same samples and were processed in the same way as described elsewhere[10] prior to combining the two data sets.

Data Analysis. *Univariate Analysis.* To measure of the variance in metabolomics data due to different genotypes and environments, we calculated the coefficient of variation (CV) for each metabolite. The mean CV for all metabolites grown in all location was used to quantify the effect of the environment. The mean CV for all metabolites from each genotype using samples grown in each location was used to evaluate the effect of genotype. To investigate the effects of both environment and genotype, a paired student's t test for each metabolite was applied. The p-value was calculated for each metabolite and used to determine those metabolites that were significantly altered (p-value < 0.01). To determine effect of environment, the p-values of each metabolite from one location were compared to metabolites in other locations. To evaluate effect of genotype, p-values of every metabolite for a given genotype were compared to those from the other genotypes at the same location.

To further determine the consistency of those metabolites that were altered due to environment or genotype, we first identified those metabolites that were statistically significant from one location compared to the other five (total of 15 comparisons were made). We then calculated the number of paired comparisons (locations) in which the abundances of each of those metabolites were significantly altered (p-value < 0.01), for example, if a metabolite was altered between Kansas and Illinois, was it also altered in Kansas vs Texas, etc. A similar exercise was performed to identify those metabolites that

Table 1. Mean Percent CV of Metabolomics Data from Different Locations in (a) Forage and (b) Grain Samples Using LC/MS Data Set Alone and in Combination with GC/MS Data Set

locations	# of samples	LC/+ESI/MS	LC/−ESI/MS	LC/±ESI/MS	GC/MS and LC/MS
			(a)

Texas	29	43.77	53.11	45.95	49.37

were altered due to genotype. For each location, we first determined the number of genotype paired comparisons in which a particular metabolite exhibited a significantly altered abundance (a total of 10 comparisons were made for every location). Comparisons across different locations asked the same question, for example, if metabolite X was altered between entries 1 vs 2 in Kansas was it also altered in other locations? Finally, those metabolites that were altered by both the environment and genotype were identified.

Multivariate Analysis. Principal component analysis (PCA) was performed by using Matlab version R2010b (Mathworks) installed with the PLS toolbox version 6.0.1 (eigenvector Research Inc., Wenatchee, WA). All data sets were normalized and autoscaled prior to modeling. R statistical package (version 2.12.1) was used for hierarchical cluster analysis (HCA) to generate dendrograms and heat maps and calculate correlations between metabolites.

RESULTS AND DISCUSSION

Data Variability in Grain and Forage (Coefficient of Variance Analysis). To evaluate the effect of the environment, we compared the mean percent CV of all metabolites detected using samples grown at different locations (Table 1). The mean percent CV for all metabolites in forage samples was lower than for grain samples grown at the same locations, with the exception of Texas. Similar trends were observed in the mean percent CV using LC/MS data acquired in positive or negative ionization mode analyzed independently, although more metabolites were detected in the positive mode (866 metabolites) compared to the negative mode (277 metabolites) as shown in Supporting Information Table S1. This result was also consistent with what we observed using GC/MS data, in which grain samples had the higher mean percent CV compared to forage samples originating from the same location.

To investigate the effect of different genotypes on data variability, we compared mean percent CV of all metabolites from different genotypes grown at different locations, as shown in Table 2. The number of samples per genotype and location is shown in Supporting Information Table S2. These results allowed for the comparison of the mean percent CV of one genotype to another within and across different environments. We did not observe any differences in mean percent CV across different locations for any genotype, indicative of good reproducibility across different locations. In addition, mean percent CV values for different genotypes at the same location were very similar to those for the same genotype at different locations with the exception of few cases. For example, grain samples from Minnesota had higher mean percent CV values compared to forage samples.

Univariate Analysis, Effect of Environment. To determine the number of metabolites detected by LC/MS that were affected by the environment (location), we calculated and compared *p*-values for the relative amount of each metabolite from one location to another in both grain and forage samples. Unless stated otherwise, herein and hereafter, LC/MS data sets were comprised of combined positive and negative ionization mode data. Table 3a,b shows the percentage of metabolites with statistically significant altered levels (*p*-values <0.01) between different locations in forage and grain samples, respectively. A total of 15 paired comparisons were made for each of 1143 metabolites. For forage, samples from Kansas versus Ontario had the highest percentage (47.17%) of metabolites altered between the two locations, while Nebraska versus Texas show the lowest percentage (21.49%) of metabolites altered. In general, more metabolites were altered in forage samples compared to grain samples for the same location to location comparisons. For example, only 8% of the metabolites detected in grain were altered between Illinois and Nebraska compared to 31.45% in forage samples. More metabolites were detected in forage samples than in grain samples. Similar results were obtained using LC/MS positive and negative ionization mode data analyzed independently (Supplemental Table S3, Supporting Information). The LC/

MS results for forage agree very well with our previous findings with the same samples using metabolites detected by GC/MS where on average about 50% of the metabolites altered from one location to another.

Univariate Analysis, Effect of Genotype. To evaluate the effect of genotype on the metabolome, we eliminated the influence of the environment by comparing only samples grown at the same location. Table 4a,b shows the percentage of metabolites with statistically significant altered levels (p-values <0.01) between genotypes using LC/MS data sets from Illinois's forage and grain samples, respectively, as an example. In total, 10 paired comparison were done for each of the six locations and each of the 1143 metabolites. The percentage of metabolites that were altered between genotypes was very low compared to those that were altered due to the environment. In some cases, less than 1% of the metabolites were altered from one genotype to another. For example, only 0.45% of all metabolites detected in forage samples were altered between genotype 3 and 4. Similar results were obtained using samples from other locations as shown in Supplemental Tables S4 and S5, Supporting Information. With forage samples, the percentage number of metabolites altered between different genotypes was very similar across different locations. However, for grain samples, a higher percentage of metabolites were altered between genotype 5 and any of the other genotypes at all locations.

Multivariate Analysis, Effect of Environment. To evaluate the effect of the environment, visualization of the metabolomic profiles of forage samples from all locations was done using unsupervised PCA. Figure 1a,b shows PCA scores plots from forage samples using LC/MS data set and the combined LC/MS and GC/MS data sets, respectively. Forage samples from Illinois and Kansas were separated completely from samples from other locations along PC1 that accounted for about 17% of the total variance in the both the LC/MS data set (Figure 1a) and combined LC/MS and GC/MS data set (Figure 1b). The same pattern was observed using data sets of positive and negative ionization mode of LC/MS separately as shown in Supplemental Figure S1, Supporting Information. PCA scores plots show a strong environment effect in that samples are clustered based on where they were grown. The circles in the PCA score plots represent 95% confidence level. Quality control samples and reference samples were tightly clustered in the middle of the PCA score plot indicative of very good reproducibility and stability of our instrument during the run. This result also indicates that technical error is lower than environmental variability.

To further evaluate the effect of the environment on the plants' metabolomes, the same data were subjected to unsupervised HCA. Figure 1c,d shows heat maps and dendrograms obtained using LC/MS data sets and combined LC/MS and GC/MS data sets, respectively. HCA allowed for visualization of sample similarity across different locations. HCA results were also consistent with our PCA results where by samples from Kansas and Illinois clustered together, indicating that their metabolomes were very similar Figure 1c,d. In addition, samples from Minnesota and Ontario clustered together, indicative of substantial similarity of their metabolome profiles.

Unsupervised PCA was used to visualize the metabolomic profiles of grain samples from all locations. Figure 2a,b shows PCA scores plots for grain samples using LC/MS and the combined LC/MS and GC/MS data sets, respectively. Separation was observed based on where the samples were grown. For example, samples from Ontario and Minnesota separated along PC2 with LC/MS the only data set (Figure 2a) and along PC1 for LC/MS and GC/MS combined data sets (Figure 2b). The first two principle components accounted for 30.8% and 26.9% of total variance in grain using LC/MS only

and LC/MS plus GC/MS data sets, respectively. Figure 2c,d shows HCA from grain samples collected from LC/MS data set and the combined LC/MS and GC/MS data sets, respectively. Grain samples from Minnesota and Kansas were clustered together as were those from Nebraska and Illinois. Therefore, we expect coclustered metabolomes to be very similar.

Multivariate Analysis: Effect of Genotype. To investigate the effect of genotype, metabolomics data derived from grain and forage samples collected from each location were subjected to unsupervised PCA separately. Figure 3a,b shows PCA scores plots using LC/MS and LC/MS plus GC/MS data sets from forage. No genotype could be classified separately; that is, samples from different genotypes were all clustered together. The same pattern was observed for grain samples with different genotypes as shown in Figure 3c,d, again from LC/MS and combined LC/MS and GC/MS data sets. In both cases (panels c and d), the total variance explained by PC1 and PC2 was about 30%. LC/MS positive and negative ionization mode data sets were subjected independently to unsupervised PCA as shown in Supplemental Figure S2, Supporting Information. Similar results were obtained, whereby no separation was observed among different genotypes.

Effect of Genotype × Environment Interaction (G × E). To investigate the genotype by environment interaction and understand the contribution of each to the measured metabolome, we first calculated the mean of each metabolite for each genotype from every location. The resulting data matrices were represented by 30 hybrids × 286 metabolites and 30 hybrids × 857 metabolites for grain and forage samples, respectively. These data sets were subjected to HCA separately.

dx.doi.org/10.1021/jf404702g | J. Agric. Food Chem. 2014, 62, 1412−1422

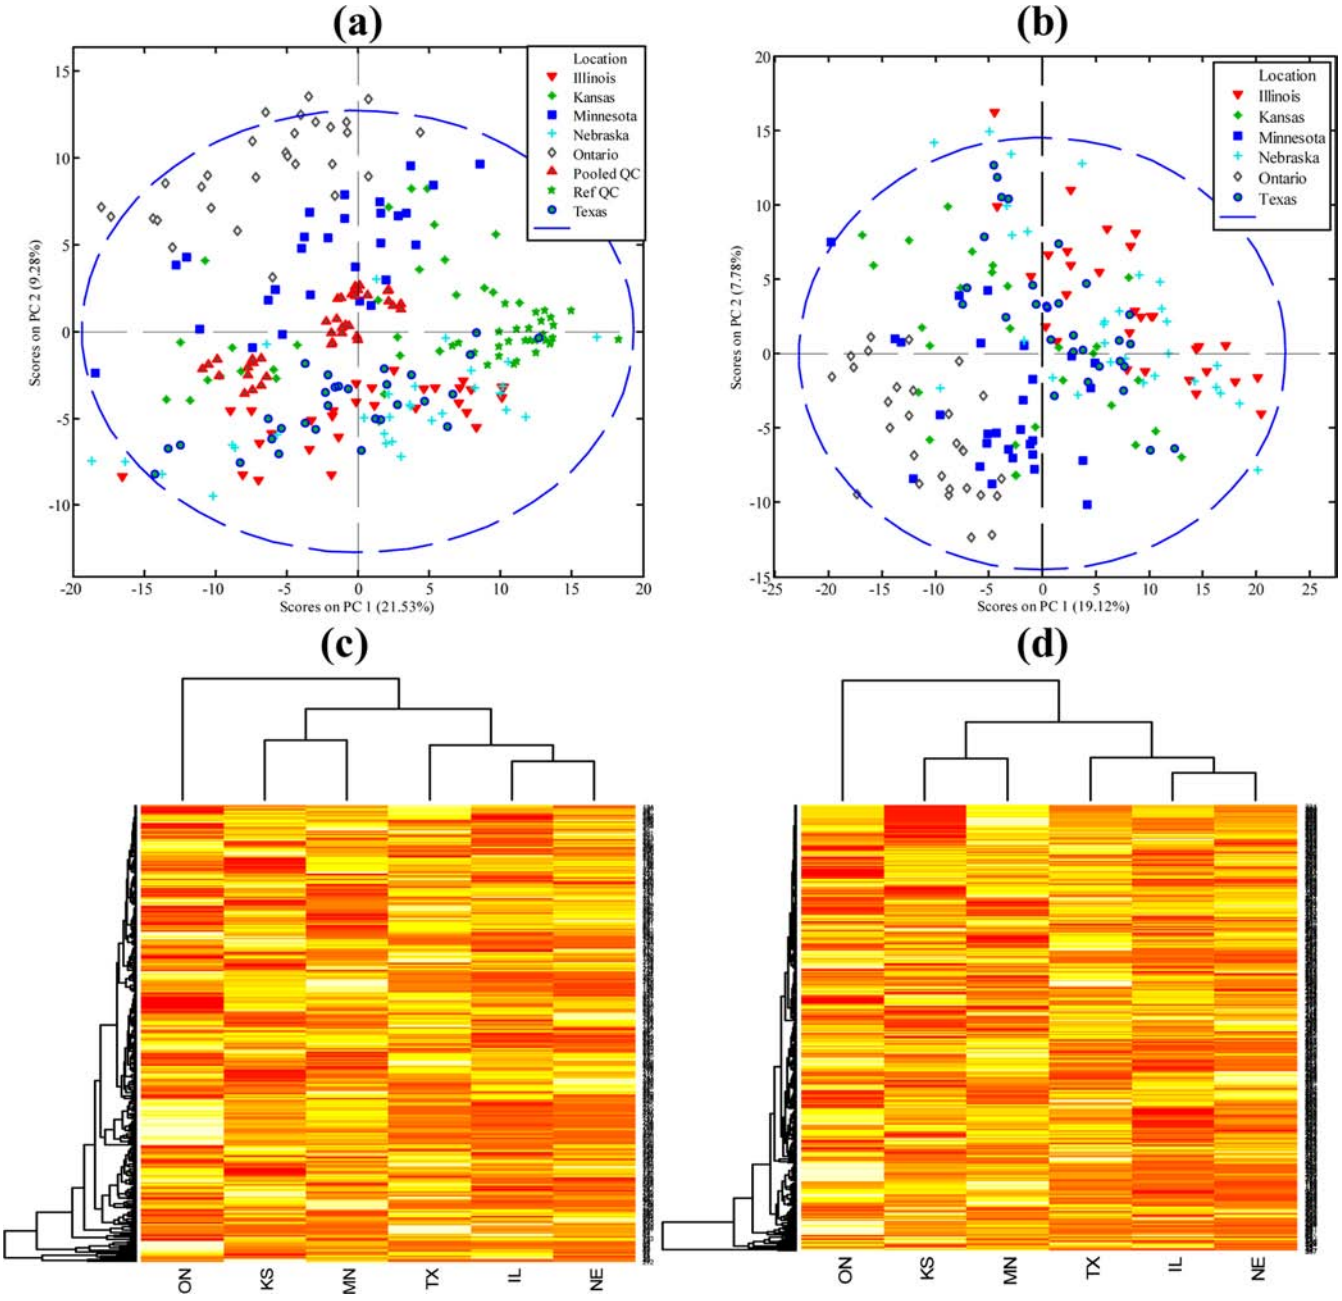

Figure 2. PCA scores plots showing the effect of environment on the metabolome in grain samples using (a) LC/MS data set and (b) combined LC/MS and GC/MS data sets. HCA and heat maps showing effect of environment using (c) LC/MS and (d) combined LC/MS and GC/MS data sets.

We reasoned that if the environment had a strong effect, we would expect to see samples from the same location clustered together regardless of genotype, and if the genotype had a strong effect, we would expect samples from the same genetic background cluster together regardless of where they were grown. Figure 4a,b shows dendrograms using the LC/MS data set and a combination of LC/MS and GC/MS data sets, respectively, from forage samples. The HCA from forage samples revealed a strong environmental effect, especially for samples from Illinois and Kansas. Figure 4c,d shows the analogous dendrograms from grain samples. These HCA did not show any strong clustering of samples based on the where they were grown or their genotype, except for samples from Ontario (Figure 4d). This finding is consistent with the results we obtained from the PCA analysis (see Figure 2a) with which samples originating from Ontario were slightly separated from the rest of the samples. Grain samples from genotype 5 were clustered together regardless of where the samples were grown. However, this finding was not the case for forage samples where the environment effect was very strong.

Figure 5a,b shows the percentage of metabolites that were significantly altered due to environment or genotype based on the number of paired comparisons in forage and grain samples. Those metabolites that were not altered at any location are represented by zero percent. From Figure 5a, it is evident that the relative amounts of approximately 40% of all metabolites detected in forage samples were not altered at all due to genotype, compared to only 20% not altered due to

dx.doi.org/10.1021/jf404702g | J. Agric. Food Chem. 2014, 62, 1412−1422

environment. In grain samples, approximately 30% of the metabolites detected were not altered due to environment or genotype, as shown in Figure 5b. Figure 5c,d shows the cumulative percentage of metabolites that were altered based on paired comparisons due to environment and genotype, respectively. The percentage of metabolites altered due to environment or genotype in grain or forage decreased significantly as the number of paired comparisons increased. More metabolites were altered due to environment in forage samples compared to grain samples as shown in Figure 5c. For example, approximately 57% of the metabolites were significantly altered in five paired comparisons with forage compared to only 37% with grain. These results are consistent with what we present in Table 3. However, more metabolites were altered in grain samples due to genotype compared to forage samples, as shown in Figure 5d. For example, less than 2% of all metabolites detected in forage samples were altered in five paired comparisons compared to about 28% in grain samples. We determined those metabolites that were altered by both the environment and genotype based on the number of paired comparisons, as shown in Supporting Information Table S6a,b. Initially, a higher number of metabolites were altered by both the environment and genotype in less than five paired comparisons with both grain and forage; however, as the number of paired comparisons increased, very few metabolites were significantly altered.

In this study, LC/MS metabolomics method was applied to investigate the effect of environment, genotype, or both on

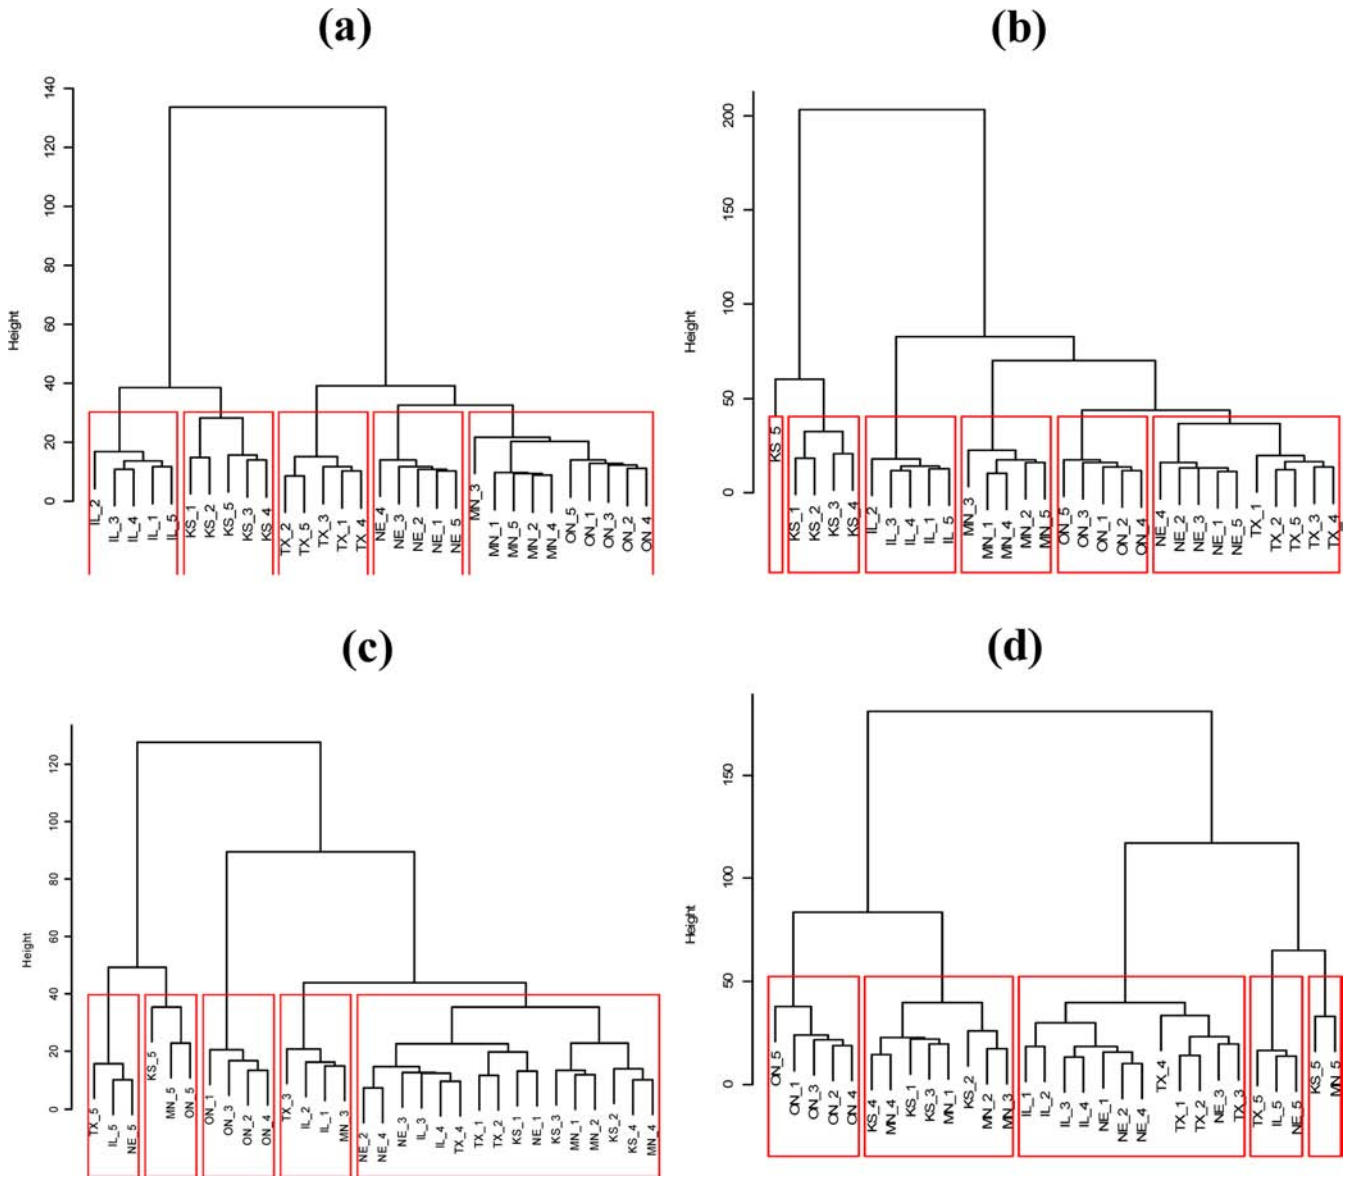

Figure 4. HCA showing effect of G × E in forage samples using (a) LC/MS data set, (b) combined LC/MS and GC/MS and grain samples using (c) LC/MS and (d) combined LC/MS and GCMS data sets.

variation of many metabolites in commercial maize. The effect of environment and genotype on forage and grain metabolomes was investigated individually using samples collected from five genetically diverse non-GMO DuPont Pioneer commercial hybrids grown at six North American locations. HCA was employed to visualize metabolic differences associated with genotype and environment in both tissue types. Our results obtained from either LC/MS, or a combination of LC/MS and GC/MS, show that the environment or growing location had the highest impact on the relative amounts of metabolites in both grain and forage. These finding are in an agreement with Frank et al. who reported that environment had a greater effect on the metabolite profiles in maize than either Bt or Roundup Ready genetic modifications.[18] Our LC/MS results showed more variability in grain compared to forage regardless of where the samples were grown or their genetics. These results are in agreement with our previous report using GC/MS for the same sample set that exhibited more variability in grain compared to forage.[10] Higher variability of grain metabolites has been reported previously.[38−41]

Our current research using LC/MS shows that the environment exerts a greater effect on the metabolomes of both grain and forage samples than genotype, consistent with previous research on other crops such as wheat, rice, and maize.[11,16,42] Previous research reported that amounts of macromolecule nutrients such as protein, fiber, and fat are very variable in grain samples.[39,40,43] Although we did not measure these constituents per se, we found that the concentrations of metabolites in grain samples were lower compared to those in forage samples. This finding is also consistent with the number of metabolites that we detected in our forage and grain samples. We detected generally more metabolites in forage than in grain.

This study not only confirmed our previous finding and what others have reported in the literature but also allowed us to probe other classes of metabolites that are not detected by GC/MS alone. By running LC/MS in the positive ionization mode,

dx.doi.org/10.1021/jf404702g | J. Agric. Food Chem. 2014, 62, 1412−1422

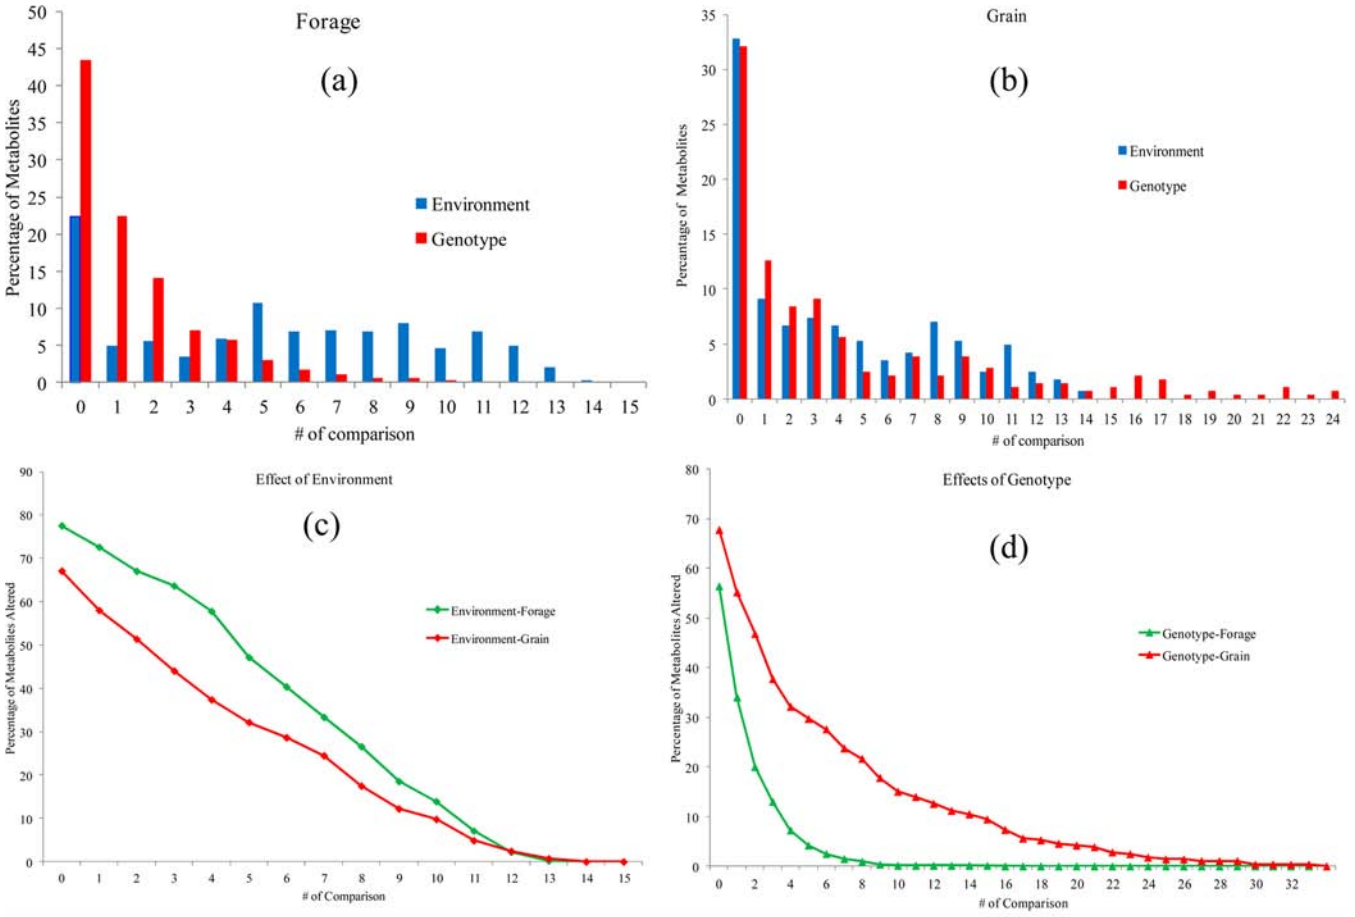

Figure 5. Percentage of metabolites that were significantly altered based on the number of paired comparisons done in (a) forage (b) grain samples and cumulative percentage of metabolites that were altered based on paired comparisons due to (c) environment and (d) genotype using LC/MS data sets.

we were able to detect 647 and 219 metabolites consistently in forage and grain, respectively, while the negative ionization mode presented 210 and 67 metabolites consistently in forage and grain, respectively. There were undoubtedly a number of metabolites detected in both positive and negative modes. In this study, those metabolites associated with differences due to genotype, environment, or both were not identified. Using untargeted metabolomics that generates a large number of variables and thus is especially susceptible to false discoveries, the emphasis should be on differences among samples rather than individual metabolites.

Although GM varieties were not included in this study, there is need to have a clear understanding of the biological variability of many metabolites in non-GMO crops before comparisons can be made with GM counterparts. We show clearly that although a metabolite can be significantly altered between two locations, it is very important to consider several locations before drawing broad conclusions. The same consideration should be made for differences due to genotype, since it is very important to determine if metabolome differences between two genotypes occur at more than one location. This approach helps eliminate any bias that might occur at a particular location that is unrelated to the genotype. There is also the need to consider more geographical locations, multiple years, and different growing environments before concluding if particular metabolites are altered by environment, genotype, or both.

In conclusion, LC/MS metabolomics was used to investigate the effect of environment, genotype, or both on the variation of many metabolites in commercial maize. Data reproducibility was satisfactory and metabolic differences caused by the environment and genotype were investigated using positive and/or negative ESI LC/MS data alone or in combination with previously acquired GC/MS data acquired from the same samples. Multivariate statistical analysis was used to determine the degree of metabolic difference caused by genotype and environment. Our results obtained from LC/MS or the combination of LC/MS and GC/MS show that environment had a greater impact on forage metabolites than those in grain. However, in both tissues, the metabolomic changes caused by genotype were minor.

elaborated by Moncrief in 1961; he worked on material coatings that would enable discrimination between simple and complex aromas such as polychloride vinyl, gelatin, and plant fat. Moncrief proved that the electronic system containing an array of six sensors with different coatings is capable of detecting a large number of odors.[13,14] In 1964, Wilkens and Hartman developed another system for artificial smell detection, which was based on electrochemical reactions taking place on the electrodes as a result of stimulation with odorants. Wilkens and Hartman concluded that transformation of the sensor output in response to the chemical reaction is possible; in other words, the transformation of a chemical signal into an electrical signal is possible.[7,11] In the following 20 years, new sensors were designed, including MOSFET (metal oxide semiconductor field-effect transistor), BAW (bulk acoustic wave), ion exchange membrane, potentiometric biosensor, ISFET (ion sensitive field-effect transistor), PdMOS (palladium metal oxide semicoductor), and SAW (surface acoustic wave). In 1982, at the University of Manchester, Persaud and Dodd constructed the first electronic nose, which consisted of three metal oxide sensors and was capable of identifying 20 odorants. A detailed definition of an electronic nose was introduced by Gardner in 1988.[15] In 1985, Otto and Thomas presented the first system for liquid phase analysis by using a multisensor array.[16] Seven years later, at the University of Kyusho, the taste sensor was constructed by Toko; it consisted of ion-selective lipid membranes immobilized in PCV polymer.[17,18] In 1995, as a result of cooperation between Russia and Italy, the concept of an electronic tongue was presented; it was based on an inorganic chalgogenide glass sensor, which enables both qualitative and quantitative analysis.[19]

The history of the computer system for image analysis started in the 1960s. In 1964, Minsky began to realize the project that involved coupling a camera to a computer as well as the interpretation of the obtained image.[20] Five years later, Boyle and Smith received the Noble Prize for developing the CCD (charge coupled device) array used to register images in a videophone.[21] In 1970, attempts to better understand the methods for image edge extraction were made, which has resulted in the construction of 3D images.[22] At the same time, such algorithms as line labeling, articulated body model, and optical flow became popular. In 1982, David Marr proposed three levels of information (image) processing, that is, computational theory, representations and algorithms, and hardware implementation.[23] Since 1980 the research has focused on sophisticated mathematical techniques for the segmentation and modeling of shapes and contours. This phenomenon has given rise to the analysis of moving objects, the so-called tracking, which is presently applied on production lines. In 1989, the CMOS (complementary metal oxide semiconductor) array was developed, having principles of operation that are similar to those of the CCD array.[24,25]

Structure and the Principles of Operation of an Electronic Nose. An electronic nose is the analytical device used for the fast detection and identification of mixtures of odorants, which mimics the principles of operation of human smell. Specific chemical sensors are used in the device, which generates a characteristic odor profile, a so-called fingerprint, in response to the interaction with a gaseous mixture; identification of the mixture components is made by comparing the obtained odor profile with odor standards.[26] The electronic nose is similar to the human nose because it is based on the same principles of operation. The volatile components in the investigated sample are analyzed by chemical sensors that mimic olfactory cells present in the nose. Then the signal is sent to the data recognition system, which simulates brain functions.[17,27]

Usually, an electronic nose is composed of a set of sensors, electronic components, pumps, a flowmeter, and software, which is necessary for data processing and statistical analysis.[7] A sample dispensing system is the first element of the device. Sampling can be conducted in different ways, for example, by collecting a headspace sample, by using diffusion methods, and via prior sample enrichment. Commercially available electronic noses have two or more separate chambers, that is, a sample dispensing chamber and a sensor chamber. Temperature and humidity are measured in each chamber to determine the influence of these two factors on the conducted analysis. The sample dispensing chamber should be made of nonflammable and nonreactive materials to avoid the effect of "wall memory"; it should also be adjusted to the sample size.[28] Moreover, a thermostat is required to increase the amount of volatile components in the headspace for the volatile fraction analysis. Air or an inert gas in introduced into the sample chamber. A special system of pumps and tubes made of plastic or stainless steel delivers the gas together with the volatile sample components to the chamber where the second element of the electronic nose, that is, a set of sensors is located.[29] The sample injection step should be preceded by passing the clean and dry air through both chambers. Such a procedure should stabilize the signal at the baseline level and purge the remnants of sample that had been analyzed earlier.[30,31] Due to the contact between odorants and the active material, the electric properties of sensors change; for example, the conductivity changes, which results in an electric signal.[32] The strength of the response signal depends on the type and concentration of odorant. It is important to stabilize the sensors by heating them for two or three days prior to measurement. The time required to receive a sensor output is called a response time, whereas the time required for a sensor to return to baseline after a response is defined as a recovery time[33] (Figure 1). Depending on the application of an electronic nose, different numbers and types of sensors are used.

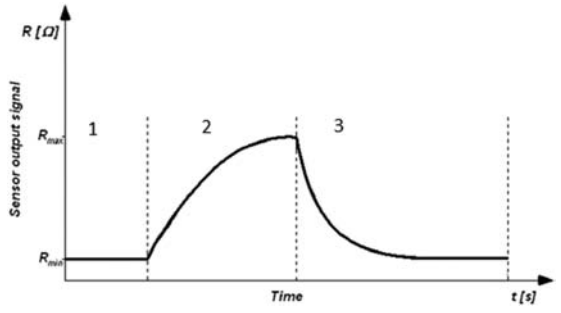

Figure 1. Response characteristics of a semiconductor-based electronic nose: R_{min}, baseline; R_{max}, resistance; 1, gas flow; 2, response time; 3, recovery time.

Structure and Principles of Operation of an Electronic Tongue. An electronic tongue, also known as an artificial tongue, or taste sensor, is the analytical device mainly used to classify the tastes of various chemical substances in liquid phase samples. Its mode of operation is based on the human sense of taste (Figure 2). An electronic tongue can be used to identify, classify, and analyze in a qualitative and quantitative way the

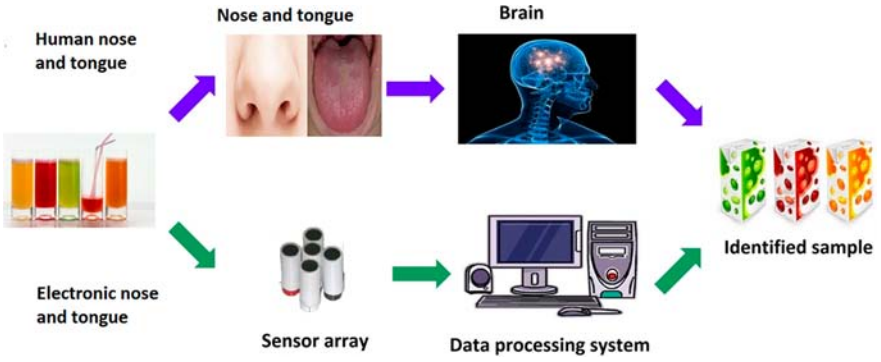

Figure 2. Comparison of the principles of operation of the senses of taste and smell and electronic tongue and electronic nose.

multicomponent mixtures by applying a fingerprint method, that is, by comparing the mixture profiles with those of standards.[31,32] An electronic tongue consists of three elements, that is, the sample-dispensing chamber or automatic sample dispenser (it is not necessary), an array of sensors of different selectivities, and software for data processing (image recognition system, which mimics brain functions).[34] The analysis of liquid phase samples is performed directly; solid phase samples have to be dissolved prior to analysis. An artificial tongue is most commonly used to evaluate food and pharmaceutical products.[35]

An electronic tongue consists of two chambers; the first chamber is used to analyze the sample, whereas the second one cleans the array of sensors after each analysis. A thermostat enables continuous monitoring of the sample temperature during analysis, which results in the repeatability of measurements. Two mechanized flow analysis techniques are used in artificial tongues, that is, flow injection analysis (FIA) and sequential injection analysis (SIA). The first-generation equipment (FIA), designed by Ruzik and Hanser in 1975, consists of a pump, injection valve, solenoid, and detector. In 1995, Ruzick and Marshal elaborated the second-generation apparatus (SIA) consisting of a single-channel duct, two-way pump, solenoid, multiposition valve, and flow sensor. Both techniques are commonly used; however, SIA has more advantages, including the capability to perform a larger number of analyses and a significantly lower use of reagents. The mechanized sample injection allows for decreasing analysis time and improving repeatability. The injected sample reaches the array of chemical sensors.[34] These sensors are characterized by low selectivity and generate information about a wide concentration range of different substances present in the mixture. The sensor response, which is a function of the concentration of components in the liquid, is presented via image recognition module. The signal from the chemical sensors is transformed into a data matrix. The identification and classification are based on a comparison of standard images and the image of the analyzed sample.[36] Depending on the application of an electronic tongue, sensors with different modes of operation are used.

Structure and Principles of Operation of Computer Image Processing. Computer image analysis system, called, "computer vision", includes subjects such as acquisition, processing, and analysis of images.[37] The main reason for creating the system was to understand the mode of operation of human vision. In general, the computer system consists of five elements, that is, lighting, a camera (in the case of an analog camera, a frame grabber is necessary, which allows for analog-to-digital signal conversion), a computer with software, and a high-resolution monitor[38,39] (Figure 3). The application of an

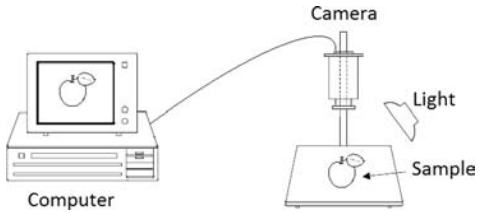

Figure 3. Schematic structure of an image analysis system.

image analysis system is very broad, particularly in the food industry. It is a fast, precise, and noninvasive way of evaluating the product quality already at the production step. Moreover, the system enables detection of imperfections, for example, in meat structure, and the onset of food deterioration, which are both invisible to the human eye.[40]

As in the case of the human eye, the operation of vision systems depends on the intensity of lighting. Properly designed lighting can improve the precision of analysis and decrease analysis time. Fluorescent and incandescent bulbs are the most frequently used light sources. Luminescent electric diodes (LED), quartz halogen lamps, metal halide lamps (applied in microscopy), and high-pressure sodium lamps (best suited for lighting large industrial buildings) are also used. However, due to more uniform and intensive light at specific wavelengths, fluorescent lamps are the most popular. There are two types of lamp arrangements, that is, a circular system used with flat samples and a scattered system for lighting ball-shaped samples. An X-ray tube is used to perform a detailed evaluation of the quality and ripeness of food products; the penetration of X-rays depends on the emitted energy, absorption coefficient, and density and thickness of the analyzed objects.[41] On the other hand, fluorescent spectroscopy is applied to monitor stress in plants.[42] Another part of the image analysis system is a still camera, movie camera, or scanner; its purpose is to record a photograph of a given object. There are two types of cameras, that is, analog and digital cameras, which are equipped with CCD or CMOS sensor arrays.[43] In an analog camera, the recorded image is transformed into the analog signal and then transferred to a frame grabber (in the form of a card), which transforms the analog signal into a digital data stream and sends it to the computer memory. In digital cameras, a frame grabber is not needed because the analog signal is sent directly to the computer via a USB or FireWire adapter.[38,41]

SENSORS USED IN ELECTRONIC SENSES

Sensors are the most important element of electronic senses; their task is to collect information about the parameters measured.[27,29,43] During this process, the input signal, which occurs as some form of energy, is transformed into the output signal in a different energy form, for example, electric, magnetic, chemical, thermal, or radiation energy.[44] Sensors are divided into five groups: piezoelectric; electrochemical (potentiometric, voltammetric, amperometric, conductometric, and impedimetric) and colorimetric sensors; biosensors; and sensors based on gas chromatography and mass spectrometry.[7,34,36,45]

Conductometric Sensors. The mode of operation of a conductometric sensor is based on the changes in conductivity. These changes result from the interactions with the volatile odorants, which leads to the changes in the sensor's electrical resistance; the underlying mechanism differs depending on the material used. Despite the fact that various materials are used, the construction and distribution of specific elements in conductometric sensors are, in principle, the same. There are three types of conductometric sensors that are most commonly used in electronic noses; they are conductive polymer (CP) sensors, metal oxide semiconductors (MOS), and metal oxide semiconductor field-effect transistors (MOSFET). In addition, the conductometric sensors are divided into cold and hot sensors, the latter being capable of performing at higher temperatures.[7,30] Publications on the use of conductometric sensors in an electronic tongue are very scarce.[46]

The advantages of CP sensors are a low price and fast response, whereas susceptibility to humidity is the main disadvantage.[32] These sensors have been used in an electronic nose to, among others, identify stages of wine fermentation,[47] monitor decomposition in Atlantic salmon during its storage at different temperatures,[48,49] and detect spoiled vacuum-packed beef.[50] Cyranose 320, Aroma Scan A32/50S, and Bloodhound BH114 are commercially available electronic noses that employ CP sensors. MOS sensors are also inexpensive, stable, easy to use, and highly sensitive.[7,48] They require a high working temperature, which is a disadvantage.[51] These sensors are used in electronic noses to monitor red wine spoilage[52] and the dehydration process in tomatoes;[53] for the quality control of Atlantic salmon;[54] to determine the freshness of meat;[55] to classify fruits on the basis of their ripeness;[56,57] and to detect aflatoxins in corn.[58] The commercially available electronic noses that employ MOS type sensors are, among others, i-PEN, i-PEN3, PEN-2, PEN3, FOX 2000, 3000, 4000, 5000, FishNose (GEMINI), KAMINA, EOS^{835}, and FF-2A. Compared to the above-mentioned, the MOSET sensors are small and inexpensive; however, their main disadvantage is low sensitivity to ammonia and carbon dioxide and drifting baseline.[13] These sensors have been employed in electronic noses that are used to evaluate the oxidation level of olive oil stored under various conditions;[59] to detect the presence of fungi, bacteria, and ergosterol in grain samples;[60] to monitor fermentation in sausages;[61] and to determine the freshness of shrimp and cod roe.[62] NST 3210, NST 3220, and NST 3320 are the commercial electronic noses that employ MOSET type sensors.

Amperometric/Voltammetric Sensors. Measurements by means of these sensors are based on the electric current reading between the working and reference electrode in an electrochemical cell as a function of analyte concentration.[63] The main disadvantage of such sensors is the lack of selectivity. This type of sensor in electronic noses is used to assign the correct class to wheat samples in accordance with the quality classification,[64] whereas in the electronic tongue it is used to evaluate different conditions under which olive oil is stored,[59] to identify white wines with regard to the type of grape and geographical origin,[65] and to discriminate among various blends of fruit juices.[66] Additionally, similarly to potentiometric sensors, these sensors are used to monitor the aging phase of wine,[67] to monitor beer fermentation,[68] to control the freshness of milk stored at room temperature,[69] to detect chemically adulterated red wine,[70] and to identify rice wine with regard to its age.[71]

Potentiometric Sensors. Potentiometric sensors are based on the voltage measurement at null current, which is usually needed to retain the balance of electrochemical process.[7] Potentiometric sensors have the following positive properties: well-known principles of operation, low cost, ease of commercial production, the possibility of obtaining selective sensors, and the highest degree of similarity with the mechanism of molecular recognition. Their disadvantages are the dependence of the measured value on temperature and adsorption of the solution components onto the electrodes, which influences the changes in potential.[32,34,36] Potentiometric sensors are most frequently found in electronic tongues, which are used to monitor cheese fermentation;[72] to evaluate the impact of micro-oxygenation and oak chip maceration on wine composition, in particular, on the presence of phenol compounds;[73] to monitor changes during beer brewing;[74] and to identify the botanical origin of honey.[75]

Impedimetric Sensors. The principle of operation of impedimetric sensors is based on measuring the impedance at one constant frequency or for a frequency spectrum by means of impedance spectroscopy.[34] They could be employed in an electronic tongue; however, in practice, this happens only sporadically. This sensor was used, for example, to discriminate brands in red wines in an electronic tongue.[76]

Piezoelectric Sensors. The operation of piezoelectric sensors is based on a piezoelectric phenomenon. As a result of sensor exposure to odorants, a change in mass occurs due to the adsorption or absorption of odorants by the sensor, which, in turn, causes changes in the sensor resonance. Consequently, the electric current also changes, which is the output signal. The main advantages of piezoelectric sensors are high sensitivity, real-time measurements, small size, durability, low cost, and the principle of detecting analytes on the basis of the universal change in mass.[77] A quartz crystal microbalance (QMB) is an example of the application of a piezoelectric sensor.[7,29] Piezoelectric sensors are more commonly used in electronic noses (e.g., to determine the optimal time for harvesting apples[78] and to evaluate the quality of tomatoes[79]) than in electronic tongues. It seems, however, that their wider use in electronic tongues is just a question of time.[32]

Colorimetric Sensors. Colorimetric sensors are devices mostly based on the interaction of electromagnetic radiation with matter. Colorimetric sensors can be based on different phenomena such as fluorescence, reflection, and absorbance. These sensors consist of an indicator, detector, and light source, the latter set at a specific wavelength to maximize selectivity. Due to the interaction with an analyte, the properties of an indicator change, which influences the membrane absorbance or fluorescence. The changes are monitored via a detector, which converts the signal from optical into electric form.[32] There is a great variety of colorimetric sensors; therefore, they are characterized by low cost, simple procedure, and high

selectivity.[7] Thanks to the use of colorimetric sensors, it is possible to detect substances that are not electrochemically active and therefore cannot be detected by an electrochemical sensor. Colorimetric sensors have some disadvantages that significantly limit their application, for example, sensor durability and output signal distortion.[32] These sensors have been employed in electronic noses to discriminate commercial drinks[80] and in electronic tongues to evaluate the quality of beer brands[81] and discriminate wines with regard to wine age and grape variety.[82]

Electronic Noses Based on Gas Chromatography and Mass Spectrometry. In the electronic nose technology, it is possible to use the technique of fast gas chromatography. A fast gas chromatograph is a stationary device that requires a short time for analyzing samples; it simulates the work of a system consisting of hundreds of orthogonal sensors, which allows for precise separation of volatile components in the investigated sample. There are also electronic noses employing a mass spectrometer;[52,83−85] the mass spectra of particular substances are then used as the output signal from the sensor. However, due to the high cost of such devices, their application is relatively rare.[7,51] A mass spectrometer was used, for example, to predict the shelf life of pasteurized and homogenized low-fat milk in an electronic nose[86,87] and to discriminate bacterial strains and monitor the smell intensity during fermentation of milk and cheeses.[83]

Biosensors. A biosensor consists of a biological measuring element, which is located close to the transducer to achieve high sensitivity to the target analytes (Figure 4).[31] A biosensor-based electronic tongue is often called a bioelectronic tongue. Such a device can be described as an analytical system made of a number of biosensors that are sensitive to particular compounds present in a solution; the system is connected to the properly selected chemometric tool for data processing.[88] Until now, different principles of operation of bioelectonic tongues have been proposed, including voltammetric, amperometric, and potentiometric principle. Biosensor arrays display high selectivity due to enzyme−substrate interactions. Moreover, the biosensor efficiency can be improved by the introduction of electron mediators, which facilitate the transfer of electrons from the enzyme to the electrode.[89] Such sensors have been used to, among others, monitor changes occurring during the aging process in beer.[90]

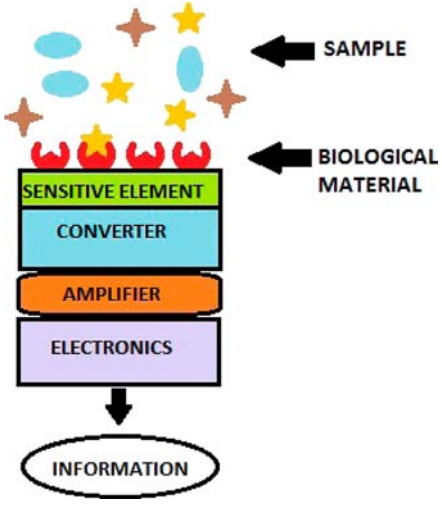

Figure 4. Exemplary structure of a biosensor.

Arrays in Still Cameras. *CCD Array.* A charge coupled device (CCD) array consists of hundreds of thousands of light-sensitive elements, or semiconductor sensors, which are called pixels. The creation and storage of the electric charge originating in the presence of light is one of the sensor's functions. The task of the whole array is to sample the image, be light-sensitive, and store and transport the created charges. CCD sensors are made of light and fragile materials; they can be in the form of diodes and a MOS capacitor stacked in rows. Light, upon reaching the array covered with a crystal silicon plate, ejects electrons from particular pixels. The number of ejected electrons is proportional to light intensity at a given pixel. A CCD array has two working modes, that is, passive and active. In passive mode, different numbers of electrons are gathered depending on light intensity, whereas in active mode the pixel readout takes place, where charges from higher levels are transferred one pixel lower. This process is repeated until all pixels have been read. Next, the content of consecutive rows ends up in the shift register, a so-called output register, where a conversion of charge into a voltage occurs at the output (Figure 5).[41]

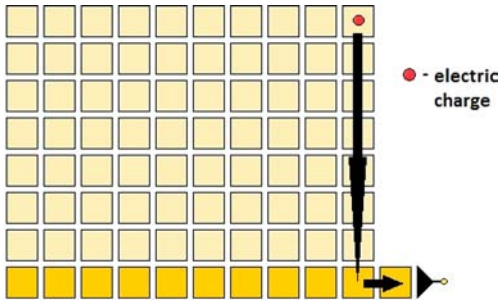

Figure 5. Simplified schematic representation of a CCD array.

Color Sensors. The most commonly used color sensors are a Bayer sensor and a device called 3CCD. The Bayer sensor is employed as an RGB (red, green, blue) filter in CCD sensors of digital cameras. It is a chess board-like grid having a filter pattern that is 50% green, 25% red, and 25% blue. Such an arrangement of colors results from the fact that a human eye is most sensitive to green color. Unfortunately, the filter transmits only a part of the spectrum; therefore, some information does not reach the sensor. Additional information is created by using a demosaicing algorithm. The 3CCD sensor has better color resolution because it contains three independent image sensors and dichroic prisms, which split light into red, green, and blue beams. This sensor is characterized by better light sensitivity as it absorbs the whole beam of light, whereas sensors covered with a Bayer filter absorb only 33%.[41]

CMOS Array. A complementary metal oxide semiconductor (CMOS) array is based on the same principle as a CCD array. Light absorbed by silicon crystals generates electric charges. The CMOS sensors differ from the CCD sensors with regard to distribution and structure (Figure 6). The basic difference is that each so-called active pixel has its own voltage transducer. As a result, the coefficient of a transformation of electric charge to voltage is almost the same for each pixel. Consequently, it is necessary to calibrate the CMOS array with regard to differences between pixels by using digital camera software. Contrary to the CCD array, the CMOS pixels can be read in

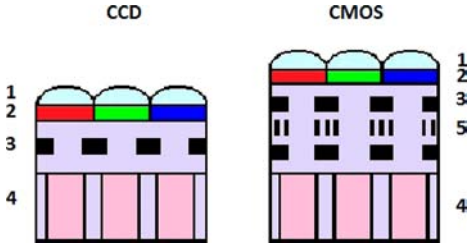

Figure 6. Comparison of the CMOS and CCD arrays: 1, microlenses; 2, color filter; 3, signal transmission path; 4, photodiodes; 5, transistors and amplifiers.

any order. The main advantages of the CMOS array are low energy use and the possibility to miniaturize the camera.[41,91,92]

METHODS OF SIGNAL ANALYSIS USED IN ELECTRONIC SENSES

A measurement performed by means of electronic senses generates a vast volume of data; therefore, it is necessary to apply methods of data analysis which allow for data classification. The simplest method is the graphical representation of data in the form of a histogram or circle diagram. Both of these graph types are used to determine the sample components that significantly differ from the others. Another method of signal analysis is based on statistical analysis or multidimensional data analysis. Besides the aforementioned methods, artificial neural networks can also be applied.

Artificial Neural Networks (ANN). An artificial neural network mimics a biological neural network, which collects and transfers signals to the central nervous system, processes the data, and makes specific decisions depending on the identified objects. The basic elements of ANN are artificial neurons. The most important parts of a neuron are the nucleus, dendrites, synapses, axon hillock, and axon. The nucleus is the computing center of the neuron. Dendrites are entrance gates of the neuron through which the input signals enter, whereas a synapse is the end part of dendrites and a so-called exit gate of the neuron. The input signal at a synapse undergoes a preliminary modification; that is, it is either amplified or attenuated. As in a dendrite, the axon is the exit gate from the neuron, whereas the axon hillock is the so-called neuron's exit.

In an axon, the neuron's exit is intertwined with the dendrites of other neurons (i.e., entrances), which enables further transfer of the signal. An artificial neuron has been designed to simulate its biological counterpart. The entrances, or more specifically the signals passing through them, correspond to dendrites. Weights are digital analogues of changes made in the signals at a synapse. The summation function block corresponds to a nucleus, the activation function block corresponds to the axon hillock, and the exit is analogous to the axon. Signal processing by an artificial neuron can be presented in a generalized way as follows. Signals delivered by the entrance gates are multiplied by weights. The multiplied signals are then summed using a summation function block, which results in the signal called a membrane potential. This signal is passed through an activation block, which can be described by different activation functions depending on the requirements. The value of a activation function is the neuron's output signal, which is transferred to the neurons in the next layer. The activation function can have one of three forms: step function (a so-called threshold function), linear function, and nonlinear function. Neurons are usually distributed in layers. The first neuron layer is called an input layer and is responsible for inputting data into the network. The number of neurons in this layer equals the number of values that are concurrently being fed into the network. The last neuron layer, a so-called output layer, is used to generate the output values. Hidden layers can be present between the input and output layers. Neurons assigned to specific hidden layers process the input information into the output information. Neurons in adjacent layers are connected, which results in a system of paths used for information transfer; these connections can be of a one-way or two-way type. One of the main advantages of neural networks compared to other methods of data processing is the learning process, which enables the proper reaction to signals that have not been foreseen by the constructor. Contrary to mathematical methods and algorithms, a neural network can be used for many different models without significant alterations. The aforementioned advantages are available only when a proper learning algorithm is employed. The most commonly used methods of training ANN include error back-propagation (BPNN) and its modified versions.[93−95] We can identify different types of ANN used in the analysis of data obtained through electronic senses: radial basis function (RBF), counterpropagation−artificial neural network (CP-ANN), generalized regression neural network (GRNN), time delay neural networks (TDNN), probabilistic neural networks (PNN), self-organizing maps (SOM), and neural networks of learning vector quantization (LVQ) type.

***k*-Nearest Neighbor (kNN) Algorithm.** The kNN algorithm belongs to the group of algorithms in which the description of the classifier's target function is not performed during the classifier's training, but at the stage of assigning an object to the specific classes. The underlying principle of the classifier's operation is that the object belonging to a specific class has in its close proximity other objects belonging to the same class. Classification is performed by comparing the fitted object to all objects stored in the training set and then choosing from among them k objects that are most alike. To estimate how similar the two feature vectors are, the Euclidean distance is commonly used; the objects that are separated by the shortest Euclidean distance are considered similar. The object is assigned to the class represented by the highest number of objects from among k selected neighbors. When more than one class is represented by the same number of neighbors, the class consisting of the closest neighbors is chosen. Parameter k is selected experimentally to obtain the best classification for a given data set.[96,97]

Hierarchical Cluster Analysis (HCA): Czekanowski's Method. Czekanowski's method/diagram is mainly used to cluster territorial units into homogeneous regions. The starting point of Czekanowski's method is the matrix of distances between the objects, $D[dii']$, which are defined on the basis of any distance type. The distance measures in the D matrix are divided into similarity classes of objects, and the appropriate graphical symbols are assigned to these classes. In this way, an unorganized Czekanowski's diagram is created, which allows for a visual evaluation of the object classification. Object sorting is performed by organizing the diagram, that is, by rearranging its rows and the corresponding columns to align the graphical symbols that code the shortest possible distances along the main diagonal. As the distance from the main diagonal increases, the symbols corresponding to larger distances appear. The sequence in which objects are organized is defined by the sequence of the corresponding rows (columns).[98]

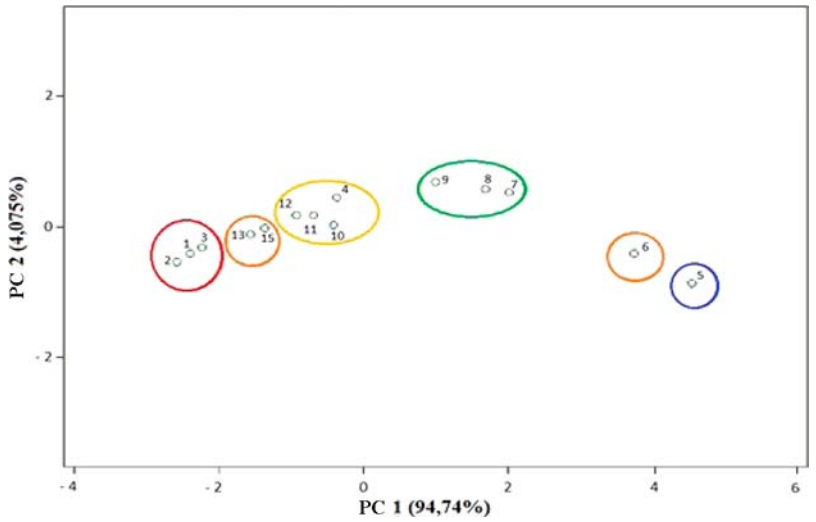

Figure 7. Example of a PCA plot for the varieties of Polish honey.

Cluster Analysis (CA). CA is a method that allows for grouping elements described by more than one feature into relatively homogeneous classes. The most important part of CA is the formation of clusters, that is, the sets of objects for which the similarity between any two objects from the same set is higher than that between any object from the same set and any object not belonging to the set. The clusters do not overlap; that is, none of the objects can belong to more than one class. The clusters are separated by a precisely determined distance, which can be defined in a number of ways. There are two types of clustering methods, that is, hierarchical methods that allow for generating a hierarchy of clusters depending on the distance between the clusters and nonhierarchical methods based on relocating objects from one cluster to another in the search for the most suitable scheme according to the desired criterion. Agglomeration and *k*-means clustering are considered hierarchical and nonhierarchical methods, respectively.[99,100]

Discriminant Function Analysis (DFA). DFA is used when the assumptions of a linear regression are met. The cases are classified into groups using a discriminant prediction equation to examine differences between or among groups. It allows for the rejection of variables that are little related to group distinctions and to determine the fastest way to distinguish groups of elements. Discriminant analysis is carried out in two stages. The first stage, the *F* test, is used to check whether the discriminant model as a whole is significant. The second step is carried out when the *F* test shows significance. The individual independent variables are evaluated to see which differ significantly in mean by the group, and they are used to classify the dependent variable.[101]

Principal Component Analysis (PCA). PCA is mainly used to model, compress, and visualize multivariate data (Figure 7). The aim of PCA is to present the data set *X*, with *m* objects and *n* variables, in the form of a product of two new matrices T $(m \times f)$ and P $(n \times f)$, where $f \ll n$; matrices T and P contain the object coordinates and parameters that lie on the first new coordinate (first principal component), which is the direction of maximum variance. The PCA model can be described by the equation

$$X_{[m,n]} = T_{[m,f]}P_{[f,n]}{}^{T} + E_{[m,n]}$$

where E is the matrix of residues for the PCA model with f principal components. The columns of matrices T and P contain the object coordinates and parameters that are assigned to new variables called principal components. The principal components are derived by iteration in such a way as to maximize the data variance. Each consecutive principal component explains the variance that has not been accounted for by the earlier principal components; therefore, the variance assigned to it decreases. Each principal component has an associated value, a so-called eigenvalue, v_i, which is computed by summing the squares of results for a specific principal component. Eigenvalues quantitatively describe the variance associated with the consecutive principal components. Principal components form a new coordinate system in which the Euclidean distances between the objects remain the same; that is, new distances are identical with the original distances in the data space. Each object has coordinates defined by specific results.[102]

Support Vector Machine (SVM). SVM is a mathematical model described by the supervised learning algorithm that is capable of making predictions. Similarly to ANN, the assignment of objects to specific classes by the SVM method is realized with the use of a training set. SVM is a great alternative to ANN because of better classification compared to the latter, for example. The underlying principle of SVM is the creation of an optimal hyperplane that would separate the data belonging to the opposite classes, with the highest possible confident margin. The SVM algorithm assumes that a maximum-margin hyperplane separates the two classes of data sets in the best way. The margin is a distance between the hyperplane and the support vectors. The support vectors are hyperplanes that separate two classes of data points and are supported by these data sets. Besides the standard support vector machine, different modifications of this method exist such as support vector regression (SVR) and least-squares support vector regression (LSSVR).[103]

Partial Least Squares (PLS). Partial least squares regression (PLSR) is a technique commonly used in data analysis. PLSR is a variant of PCA; a number of linear combinations of the predictors, which predict the response variable in a satisfactory way and are orthogonal, is sought. In the case of the PLSR method, the new explanatory variables should not only explain the variability of the original data but

also be correlated with the response variable. This method is used when one analyzes a relationship between one response variable and many explanatory variables. PLSR is particularly useful when the number of variables is larger than the number of data points. For these reasons, the method is frequently applied in chemometry. The multiple-regression methods, for example, PLS, can also be used to construct discriminant analysis models (PLSDA).[104]

Principal Component Regression (PCR). In PCR the model is composed of principal components instead of the original variables. The principal components are derived via iteration by decomposing the original data matrix X into the result matrix T and the weight matrix P. The role of principal components is to maximize the data variance. In general, a PCR model with f factors that allows for the prediction of dependent variables can be described by the following set of equations:

$$X_{[m,n]} = T_{[m,f]}P^{T}_{[f,n]} + E_{[m,n]}$$

$$Y_{[m,k]} = T_{[m,f]}Q^{T}_{[f,k]} + G_{[m,k]}$$

The coefficients of the regression model Q are estimated by the least-squares method, as follows:

$$Q_{[f,k]} = (T^{T}_{[f,m]}T_{[m,f]})^{-1}T^{T}_{[f,m]}Y_{[m,k]}$$

The principal components used for the construction of the PCR model are orthogonal. This property allows for the calculation of regression coefficients by applying the least-squares method. Moreover, a part of the experimental error of data set X is reduced after a couple of principal components have been chosen. The number of columns in matrix T, that is, the number of principal components used in the constructed model, defines the model's complexity. Matrices E and G contain this part of variance of X and Y, which has not been accounted for by the fitted model.[104]

Soft Independent Modeling of Class Analogies (SIMCA) Classifier. In the SIMCA method, a separate model is constructed for each class, which is based on the principal component approach. Next, a so-called confidence envelope (i.e., a certain volume or hypervolume) is created around the model, which should contain all elements belonging to the specific class with a given probability. For each class, the number of significant principal components in the model is individually chosen in accordance with the commonly used methods. In the case when only one principal component is significant for a given class, the component mean and the vector associated with this component become the model of the class. For two significant components, the model is defined by the location of class center and the plane determined by the component vectors. The remaining models are constructed in a similar way.[97]

Analysis of Variance (ANOVA). ANOVA is a parametric tool that allows for comparing more than two groups that had been categorized on the basis of one variable (one-way ANOVA). The underlying idea is to compare the variance of dependent variables within the groups that had been created on the basis of the values of independent variables. To apply ANOVA, the following assumptions must be fulfilled: the dependent variable is normally distributed; between-group variance is homogeneous; the dependent variable must be measured at least on an interval scale; and the analyzed groups should contain equal numbers of objects.[105,106]

Linear Discriminant Analysis (LDA). The aim of LDA is to construct linear discriminant functions for the samples in the model set that belong to specific groups. The constructed discriminant functions are used to classify new samples. The underlying idea of the method is to reduce the dimension of the data set and, at the same time, retain the value of the T^2 statistic, which is used to evaluate the hypothesis about the equality of means in a multidimensional space. As a result of LDA, a space is created having a dimension that had been reduced to $k - 1$ at best (k is the number of classes). For normal multidimensional distributions of the analyzed data in such a space, the discriminatory features remain intact. To properly apply LDA, a number of assumptions has to be fulfilled, that is, the distribution of objects in each group should be approximately normal; the groups should be linearly separable; variance−covariance matrices of each group should be linearly separable; and the total number of objects has to be at least 3 times larger than the number of variables. There are three variants of LDA, stepwise linear discriminant analysis (SLDA) being an example of one of them.[104,107]

Fisher Discriminant Analysis (FDA). FDA assumes that data vectors occupy p-dimensional space $X \times {}^{1}/_{2}R^{p}$, whereas its aim is to obtain a discrimination rule based on a linear function. For $g = 2$ (g is the number of classes), the rule determines the direction a in X that separates the two training sets in the best possible way and, at the same time, creates a distance measure between the classes that includes a within-group variability. A within-group dispersion should be characterized by appropriate covariance matrices that are based on suitable data. FDA requires that the information about classes, to which new observations are assigned, should be categorized by using the indicators of location and dispersion of g subsets in the training set.[108]

Quadratic Discriminant Analysis (QDA). QDA is also considered a statistical method however, of a more sophisticated type than LDA. In QDA, the data set is subdivided by using quadratic curves. This method is applied when variance−covariance matrices significantly differ. In the case of QDA, the boundaries between the groups are nonlinear.[107,108]

Multiple Linear Regression (MLR). The aim of MLR is to determine the relationships between many independent (explanatory) variables and the dependent (response) variable. In the regression analysis, the parameters of a theoretical model are estimated to reflect the true relationship in the best possible way, as illustrated by the plot of real and theoretical values of the response variable.

The basic regression models assume the existence of linear relationships between the response variable and the explanatory variables.[104]

Complex Data Analysis (CDA). CDA is based on the assumption that data consist of x vectors containing non-negative elements x_1, ..., x_D, which form a specific unity:

$$x_1 + ... + x_D = 1$$

The variables in the aforementioned equation are not independent because they sum to 1; such data are called closed data.

Information contained in the vectors is connected to the relative content of a component. Therefore, the relationships between the components can be expressed in the form of proportions. A transformation of the component vector spaces (simplex) into a Euclidean space can be performed by applying

logarithmic transformations. The characteristic feature of a complex data set is that each row in the data matrix corresponds to only one sample, whereas each matrix column corresponds to one component. Moreover, each matrix element is non-negative, and all matrix rows sum to 1 (e.g., proportions) or 100 (e.g., percentage shares).[108]

Canonical Correlation Analysis (CCA). CCA allows one to find points (variables) in the new coordinate system and points (objects) in the same coordinate system.

In this way, a relationship between the variables and objects under observation can be defined. The analysis of relationships between the variables and objects is conducted directly, which is contrary to the indirect analysis via relationships among the variables and factors, as in other factor-based methods. The rows of matrix X, that is, the input data matrix, can be interpreted geometrically as the coordinates of data points of the variables in n-dimensional object space R_n, whereas the matrix columns as the coordinates of points (objects) in m-dimensional variable space R_m. The input variables are made uniform by applying a canonical transformation. The standardization process in CCA aims at homogenizing the columns and rows of the relative frequency matrix. This type of standardization is performed by scaling the coordinates after matrix columns and matrix rows had been standardized.[109]

Color Image Analysis. *RGB Model.* The most popular method of color image analysis is the RGB model based on three components, that is, red (R), green (G), and blue (B). The RGB color space can be depicted in the form of a cube with three perpendicular axes R, G, and B, each with the axis range from 0 to 255,[25,110] as presented in Figure 8.

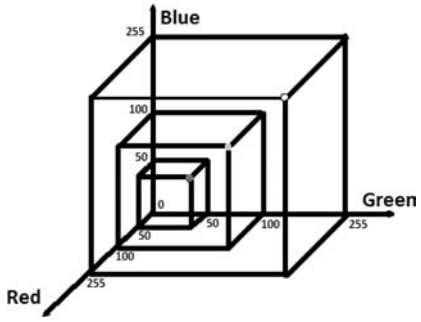

Figure 8. 3D volume of RGB model in a Cartesian coordinate system.

For $R = G = B = 0$, no light is present; therefore, such assignment indicates the color black. In the case when all components assume maximum values, white color is the outcome. Points with different hues of gray color, which lie along the achromatic axis of the RGB cube, are also shown in the figure. The achromatic axis has been defined as a set of points lying on the main diagonal of RGB cube between the points $[R_{min}\ G_{min}\ B_{min}] = [0,0,0]$ and $[R_{max}\ G_{max}\ B_{max}] = [255,255,255]$. The RGB model is called an additive color model because a broad spectrum of colors is obtained by adding beams of primary colors in space.[25,110]

CIE XYZ Model. The CIE XYZ, or CIE 1931 color space, is the first mathematically defined color space model. It is considered a standard and reference point for CIE $L^*a^*b^*$ and CIE $L^*u^*v^*$ color spaces. The abbreviation CIE stands for the International Commission on Illumination (Comission Internationale de I'Eclairage). The tristimulus values XYZ correspond to the percentage shares of primary colors in the RGB model.[111]

*CIE L*a*b* and CIE L*u*v**. Unfortunately, the CIE XYZ model has numerous flaws, for example, the lack of uniform color perception; that is, similar differences among colors are not separated by the same Euclidean distances in the color space. As a result of mathematical transformation of the CIE XYZ model, two models are produced: CIE $L^*a^*b^*$ and CIE $L^*u^*v^*$.[25,112] Colors in the CIE $L^*a^*b^*$ model are defined by three components: L^*, which is luminance, an achromatic property in the range between black and white; a^*, which is a chromatic component in the range between green and magenta; and b^*, another chromatic component in the range between blue and yellow.[111,112]

Contrary to the CIE L^*a^*b model, the CIE $L^*u^*v^*$ model is characterized by a simpler calculation required to transform the CIE XYZ model, which does not involve so many cube root operations. However, the transformation requires intermediate parameters, u^* and v^*. As in the previous model, the symbol L^* stands for luminance, whereas u^* is a chromatic component in the range between green and red and v^* is a chromatic component in the range between blue and yellow.[111,112]

HSV, HSL, and HSI Models. HSV, HSL, and HSI are other color space models; each letter codes a specific model component, that is, hue, saturation, value, lightness, and intensity. These models are modified versions of the RGB space that more precisely reflect the perception of a human eye and, at the same time, retain the simplicity of calculation.[41,113−115] Figure 9 shows a comparison of the three aforementioned models.

The HSV model has the shape of a pyramid, whereas the HSL and HSI models are a double pyramid and a cylinder, respectively. The HSV model is based on the cube that has resulted from the RGB model. The analogy is also visible in the HSL model. The HSI model has a different shape; saturation is expressed as a distance from the cylinder center, and intensity is defined as the axis height. As all color models, the HSV, HSL, and HSI models have certain flaws, for example, unspecified H value for $S = 0$. In the HSI model, intensity contains information that is tightly connected to the other system components. In the case when intensity is close to 0, the analysis of hue and saturation is pointless because of the possible occurrence of large errors.[113]

Analysis of Image Properties. An image has basic properties such as resolution, dimension, the number of discrete intensity levels for each pixel, color space, and the signal-to-noise ratio.[38,116] The processing of a raw image consists of many graphical operations, which enable the improvement of image quality by removing specific flaws, for example, geometric distortions, inappropriate sharpness, uneven lighting, and camera movement. Image analysis is mostly based on the discrimination between a given object and its background. There are three levels of image processing: low, medium, and high.[38,110] In low-level image processing, simple corrections can be introduced to the image by using geometrical operations such as moving, rotating, and scaling to correlate the image with the coordinate system. The consecutive processes that improve image quality are arithmetic operations; they allow for increasing the contrast and adjusting the brightness to increase the differences between the object and the background.[117] Image filtering is one of the possible operations where the intensity at pixel location is recalculated on the basis of the pixel intensity and the intensity of

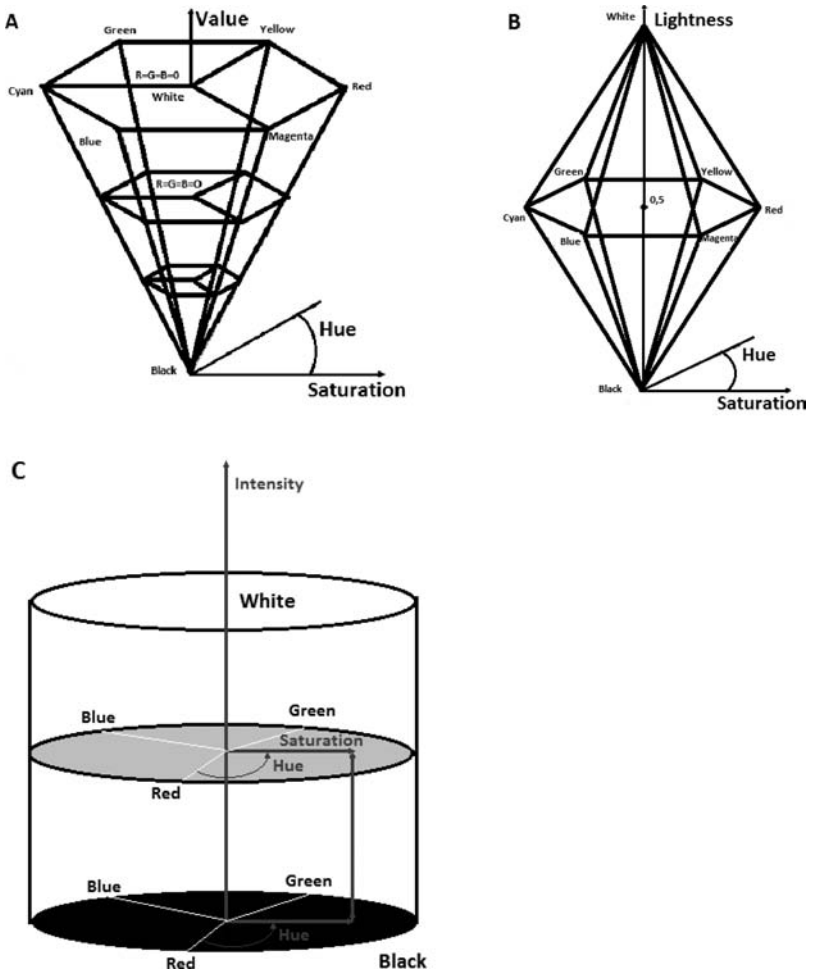

Figure 9. Three color models: (A) HSV; (B) HSL; (C) HSI.

neighboring pixels. Due to the use of filters, it is possible to improve image quality by removing the sensor noise or by correcting the nonuniformly lit image. Moreover, filtering enables the sharpness correction of edges and boundaries between the objects. Segmentation, which is considered a medium-level image processing, is one of the most important methods of image analysis. In this method, the previously filtered image is partitioned into fragments that correspond to specific objects. This allows delineation of image areas that fulfill the homogeneity criterion with regard to color, brightness, and texture.[38,118] A high-level image processing is based on image recognition and interpretation by using statistical classification, neural networks, and fuzzy logic. This stage of image processing supplies information that is necessary for quality control, sorting operations, and object classification on the production lines in food-processing plants.[38,119]

APPLICATION OF ARTIFICIAL SENSES TO FOOD ANALYSIS

At first, an electronic nose was used only to analyze the mixtures of volatile air contaminants that had already been detected by olfaction. At present, the application of this device is much broader and includes the analysis of liquids and oxygen-free gas mixtures. The use of electronic nose encompasses environmental monitoring (detection of air pollution, tracking of pollution pathways, and efficiency assessment of wastewater and waste gas treatment), medical sciences (identification of selected diseases, including tumors, based on odorants excreted by the infected cells and organs), the perfume industry (authentication of perfumes), the pharmaceutical industry (production control of medicines), forensic operations, and the food-processing industry.[7]

An electronic tongue is used to analyze liquid samples. This device enables a parallel analysis of multiple components present in the investigated liquid. The artificial tongue is applied in environmental monitoring (detection of contaminants in samples of water and wastewater), medical sciences (detection of pathogens in liquid samples), and the food-processing industry.[120]

On the other hand, computer vision is used in the food-processing industry for quality control. The system is commonly employed on the production lines for sorting and discriminating specific products.

Milk and Dairy Products. Dairy products are a very diverse group due to the fact that they comprise many types of yogurt, cheese, and milk, each of these foods being broadly diversified as well. Dairy products are made in various ways by using a wide spectrum of fermentation techniques, microorganisms, and food additives. This scenario stimulates the search for analytical tools that would allow for the discrimination of products and their quality evaluation. The electronic nose and tongue are used to monitor food processing, evaluate food freshness, authenticate products, and determine the shelf life of foods. This allows for reducing

the number of poisonings and allergic reactions in human. The electronic eye is employed to monitor visual changes in cheese during the pizza-baking process.[121]

In the case of food process monitoring, the electronic nose and tongue have been used to monitor fermentation in milk and cheese.[72,83] The application of artificial senses assures product quality at the very start of the food production line.

The monitoring of food freshness and product quality during storage is the foremost application of the electronic nose and tongue.[69,87,122−126] This allows the exclusion of spoiled products from the market as well as the determination of appropriate shelf times and storage conditions for milk and cheese to avoid financial losses by the dairy industry.

Another important application of electronic senses is product authentication. Thanks to this procedure, falsified products are excluded from the market; therefore, consumers can purchase merchandise of quality precisely specified by the manufacturer. In the case of dairy products, the conducted studies were aimed at discriminating the brands of milk and yogurt[127−130] and identifying hydrogen peroxide in cow's milk.[131] The determination of age, geographical origin, type, and maturation level in cheeses is also very important; such studies were conducted on a broad variety of cheeses by means of an electronic nose.[132−139] It is necessary to perform this type of research because the investigated parameters influence the cheese quality and therefore the price of specific cheese varieties.

Meat Products. Chemical analyses of meat products are mainly performed via an electronic nose; the use of an electronic tongue in this case is less suitable because it requires a more complex preparation of samples. On the other hand, an electronic eye can be employed to evaluate the freshness of different meat types,[140−145] the medical condition of meat,[146] and the influence of storage conditions on meat quality to determine an expiration date[147,148] based on color and shape. Computer image analysis was used to evaluate the freshness of beef,[140,142] pork,[141,144,147] and poultry.[144,146] The electronic tongue was applied to analyze ground meat to predict the level of chlorides, nitrates, and nitrites.[149] Actually, it is the electronic nose that has found a broader application in the field of meat product analysis. This device is used to, among others, monitor the curing process in Iberian ham to detect spoilage;[150] this allows exclusion of a production batch that could possibly pose a health risk to consumers. Moreover, the electronic nose is frequently used to detect spoilage, evaluate freshness,[55] and determine the storage time of meat. Until now, the conducted studies were aimed at discriminating between fresh and spoiled meat in samples of beef,[50,151,152] turkey meat,[153] sheep meat,[151] and sausages.[61] Another field of application of electronic senses is the freshness evaluation in meat during storage, which is aimed at determining the optimal storage time and conditions to avoid meat spoilage.[154] On the basis of freshness evaluation studies, different freshness categories of meat products can be defined. Research on the influence of storage time on meat quality was conducted on samples of veal,[155] beef,[156] lamb,[157] and meat products used in pizza production.[158] The meat price depends on the animal species from which meat is produced. Therefore, it is specifically important to avoid falsified or misidentified meat. The electronic nose was used to discriminate llama meat from alpaca meat,[159] identify the meat of Iberian pigs among other pork meat,[160] discriminate among hams and sausages on the basis of their type and quality,[161,162] and discriminate meats on the basis of the meat preparation.[163]

Fish and Shellfish. The electronic senses are employed in the fish-processing industry to mainly evaluate the freshness of fish and shellfish. The electronic nose has been used to perform such analysis in sardines,[164−166] shrimp and cod roe,[62] and Atlantic salmon,[54] whereas the electronic tongue has been used on samples of bream.[167] The electronic eye was employed to analyze the freshness of shrimp,[145,168] sturgeon fillets,[148] and salmon fillets.[143] The duration and conditions of storage have a great influence on the freshness of fish and shellfish. To protect consumers from the purchase of old fish, studies on the relationship between the duration and conditions of storage and product freshness were conducted by means of an electronic nose on cod fillets,[169] fresh and frozen Atlantic salmon,[48,49] tilapia,[170] Argentine hake,[171] and oysters.[172,173] Similar investigations were performed on gilt-head bream[174,175] and tench fillets[176] by employing an electronic tongue; in the case of gilt-head bream, the analysis aimed at predicting the biochemical and chemical parameters of spoilage.[175] Another aspect of the application of artificial senses is discrimination between fish species. The electronic tongue was used to discriminate between freshwater and marine fish species.[177] Similar studies were conducted by using an electronic eye.[176] Moreover, the electronic nose was applied to discriminate shrimp on the basis of the presence of phosphates, sulfates, and bleaching agents due to processing.[178]

Fruits and Vegetables. An electronic nose is mainly used to analyze fruits and vegetables. The application of this device is related to the monitoring of food processing and the evaluation of freshness, shelf life, and authenticity of food. On the other hand, the electronic tongue has been mostly used to classify cultivars (e.g., discrimination between onion and shallot),[179] tomatoes on the basis of various parameters,[180,181] apples,[182] and apricots, the latter being also discriminated on the basis of storage duration.[183] The electronic eye is employed to determine the quality of product by using shape and size parameters;[38,119,184−187] to identify the presence of unwanted objects, for example, twigs and leaves;[119,188] to establish the relationship between storage time and product condition on the basis of color analysis;[189−192] and to identify bruising.[191,193] The following fruits and vegetables have been investigated so far: bananas, apples, pears, oranges, strawberries, broccoli, potatoes, and carrots. The electronic nose was used to monitor dehydration in tomatoes[53] and grapes[194,195] to determine the optimal storage time. Studies aimed at evaluating the freshness of fruits and vegetables were conducted to determine the optimal harvest time (apples[78]), the ripeness level (bananas[56] and mandarins[57]), and quality (tomatoes,[79] tomato puree,[155] peaches,[196,197] and apricots[198]). Some products were analyzed to determine their shelf life and classify the ripeness levels (apples,[199−202] tomatoes,[203−205] peaches,[202,206] mandarins,[207] and pears[202]). The electronic nose has also become a useful tool for discriminating among the varieties of, among others, apricots,[208] mangoes,[209] and apples.[210,211] Yet another application of this device was the determination of selected parameters that influence the quality of fruits and vegetables such as oranges, apples,[212] peaches, nectarines,[213] pears,[214,215] and onions.[216] It has also been confirmed that the e-nose can be used for monitoring diseases in cucumbers, paprika, and tomatoes.[167]

Oils, Sauces, Vinegars, and Spices. Among this group of products, olive oil is most frequently analyzed because attempts to adulterate more expensive olive oil with its cheaper alternative are very common.[217] Therefore, the electronic

Table 1. Examples of the Application of an Electronic Nose to Food Analysis

application	sample	object of investigation	type of e-nose	method of data analysis	ref
food process monitoring	grape wine	discrimination of the sequential stages of fermentation	AromaScan A32S: 32 CP	PCA	47

tongue and nose were both used to discriminate among olive oils on the basis of oil geographic origin[218−220] and type and quality.[59,221−223] In the case of olive oil, the conducted studies were also aimed at determining rancidity[224] and the relationship between storage time and oil quality.[59] Also, other plant oils were analyzed via an electronic tongue[89,219] and an electronic nose,[225,226] whereas soy sauces,[227] Chinese vinegars,[228] and selected spices[229] were analyzed by using an e-nose. As mentioned before, in the case of luxury and traditional products, it is of utmost importance to authenticate such merchandise to protect the consumer from purchasing substandard goods. The electronic nose was used to authenticate the balsamic vinegar of Modena[230] and sesame seed oil.[231]

Grains and Grain Products. In the case of grains and grain products, quality evaluation and authentication are important (wheat,[64,232−234] rice,[235] barley and oats,[233,234] and corn[186]); however, the critical issue for consumers is the evaluation of possible health risks of such products by means of electronic senses. Possible health risks are related to grain diseases, which often go unnoticed due to the fact that they are not visible to the naked eye. Mycotoxin contamination of grain, which also includes contamination with aflatoxins, and various diseases caused by fungi and bacteria are such risks. Studies on the subject of disease detection were performed on samples of corn[58] and oats, rye, and barley.[60] The electronic nose was used on samples of bread,[236] whereas an electronic eye was used on samples of rice[237] and corn.[238,239] The artificial senses allowed exclusion of samples that could have caused the development of a disease in consumers.

Teas, Coffees, and Herbal Infusions. Coffees, teas, and herbal infusions are mainly analyzed to distinguish among specific types, quality levels, and brands. This is due to the fact that these products are highly variable. Products of low and high quality are frequently mixed together to lower the overall production costs and then sold as top-quality merchandise. Coffees were discriminated on the basis of the quality,[220] brand,[45,177,240−242] and ripening period,[243] whereas teas were evaluated in relation to quality,[244−247] brand,[248−250] geographical origin,[251,252] and content of flavoring substances such as coumarin[253] and theaflavin.[254] Moreover, the electronic nose was used to monitor the fermentation process in black tea and to determine the optimal time for producing tea with the best flavor.[255]

Nonalcoholic Beverages. The analysis of alcohol-free beverages is among many applications of electronic senses. Until now, studies aimed at identifying brands and quality of such beverages were conducted in, for example, cola type drinks,[256] other commercial beverages,[80] mineral water,[257−260] and fruit juices and fruit juice-based drinks.[66,130,240,257,261,262] The beverages were analyzed by means of an electronic eye to determine the quality of orange juice on the basis of its color and color saturation.[263] Another example of the application of electronic senses is the identification of geographical origin in juices[263−265] as well as discrimination of juices on the basis of fruit type.[266]

Alcoholic Beverages. Alcoholic beverages are among the products that have been most frequently analyzed by means of electronic senses. Process monitoring in alcohol production requires fast analytical tools that can detect substandard products, discriminate among products, and authenticate products in real time. Wine and beer are mostly subjected to such type of monitoring because both beverages undergo fermentation that results in a release of specific compounds influencing the taste and aroma of the final product. The artificial senses monitored the processes of fermentation,[68] brewing,[74] and aging[90] in beer. In the case of wine, these devices were employed to control the aging process, to determine the influence of wooden barrels on aging and maceration,[67,73,267] and to monitor grape fermentation.[47] Authentication of alcohols is aimed not only at detecting adulterated products with substandard characteristics but also at identifying falsified products that can be potentially harmful to the consumer's health. Until now, the electronic nose was used to, among others, discriminate among vodkas,[268,269] spirits,[270] whiskeys,[268,269] wines,[268,269] tequilas,[268,269] beers,[269,271] and sorghum-based drinks.[272] The most widely researched group of alcoholic beverages is wines, which have been discriminated on the basis of geographical origin,[273,274] grape variety,[275] and type of maturation and aging process[276−281] as well as analyzed to detect cases of product adulteration.[282,283] The electronic tongue was applied to detect falsified vodkas,[284] whiskeys,[285] and wines; to determine the amount of ethanol in alcohols;[286] and to discriminate among beers on the basis of beer type[287−290] and quality.[81] Similarly to the electronic nose, the electronic tongue was used to analyze wines in relation to their geographical[65,259,291−294] and botanical origin,[65,71,82,294,295] brand,[293] and product adulteration,[70] as well as discrimination based on flavor, for example, bitterness level[296−298] and age.[82,295,299] The electronic eye was employed to monitor aging in wine on the basis of the color analysis.[300]

Others. Besides the aforementioned applications, the electronic nose has been used to, amont others, evaluate egg freshness,[301,302] discriminate honey on the basis of botanical[303,304] and geographical origin,[305] discriminate lyophilized mushroom species,[306] and detect pathogens in food.[307] The electronic tongue has been applied to discriminate honey on the basis of geographical[308] and botanical origin.[75,308−311] On the other hand, the electronic eye has been used to evaluate the quality of pizza,[312] corn tortillas,[313] potato fries,[314] and popular potato chips[315] on the basis of food appearance.

Examples of the application of e-nose, e-tongue, and computer image processing in food analysis are presented in Tables 1, 2, and 3, respectively.

SUMMARY

Due to growing consumer awareness, the need for safe and high-quality food increases. At present, consumers are willing to

Table 2. Examples of the Application of an Electronic Tongue to Food Analysis

application	sample	object of investigation	type of e-tongue	method of data analysis	ref
food process monitoring	bacterial cultures used in cheese production	monitoring of the fermentation process	30 potentiometric sensors	PLS	72

	pizza	quality control based on color and size	image segmentation algorithms	312
	Cheddar and mozzarella cheese	comparison of cheese properties during cooking and baking	image processing algorithms	39

pay more for products that, beyond any doubt, have better quality and are naturally processed. Therefore, the companies that specialize in the processing, transport, and sale of food are put under increasing pressure to find new solutions that would parallel a sensory evaluation of food products. Sensory analysis is performed by testers; therefore, it is a subjective method that does not always reflects the true condition of a given product. Chromatographic techniques such as comprehensive two-dimensional chromatography coupled with detection by olfactometry require a long analysis time, and they often yield unreliable results mainly due to the complexity of the sample matrix. In the case of companies that process and sort food, time and reliability are the most significant and most valued parameters in relation to food quality evaluation. The equipment used until now is frequently being replaced with electronic senses, which, despite their many faults (e.g., complicated calibration, poor selectivity of sensors, and complicated data analysis), are promising alternatives. At present, electronic noses are widely applied to food evaluation with regard to both liquid and solid phase samples. Sample preparation is simple, and the analysis is noninvasive; therefore, different types of meat (e.g., veal, beef, and poultry) as well as different fruits and vegetables, alcoholic and nonalcoholic beverages, dairy products, etc., can be evaluated by means of an electronic nose. The conducted evaluations are also aimed at authenticating luxury products such as traditional balsamic vinegar of Modena and extra-virgin olive oil, detecting falsified wines, and determining the quality, freshness, and shelf life of food products. An electronic tongue has been used for similar purposes, although this device is mainly applied to evaluate liquid samples, for example, alcoholic and nonalcoholic beverages, oils, vinegars, and milk. It has been mostly used for product authentication and freshness evaluation. A computer image analysis system has found wide application

in production plants for sorting foods such as fruits, vegetables, meat, and fish and to discriminate packaging in which food is packed. The evaluated features are color, shape, size, morphology, discoloration, and color intensity. These parameters allow for excluding faulty or substandard products. It is an increasing trend to combine all artificial senses into a quality evaluation system that encompasses the evaluation of appearance, taste, and smell and most closely simulates the sensory analysis by testers. At the same time, such a system is much more sensitive, precise, and reliable. Projects dealing with the improvement of electronic senses via the search for better sensors create the opportunity to widen the range of applications of these devices in food analysis.

current evidence strongly supports that hydroxytyrosol may also provide an indirect protection on the body through increasing the endogenous defense systems.[9] It was reported that the antioxidants of an extra virgin olive oil rich in phenolics concentrated on pancreatic islets and liver in the mice fed with a nonpurified diet.[10] The concentration of plasma hydroxytyrosol was greater in the mice fed with olive oil than in the control mice. The oxidized glutathione and the antioxidant capacity in plasma of the former were higher than those of the latter, and the glucose-stimulated insulin secretion became greater in the olive oil mice. It is concluded that the protective effects of extra virgin olive oil against oxidative stress occur mainly through a direct antioxidant action and an indirect mechanism involved in higher expressions of certain enzymes with antioxidant activities.

Anticancer Potential. Several epidemiological and animal research studies suggested that polyphenols might have a protective effect against some chronic degenerative diseases such as cancer. Dietary hydroxytyrosol has recently received particular attention because of its antioxidant, antiproliferative, proapoptotic, and anti-inflammatory activities, which can specifically counteract all cancer hallmarks.[11]

Investigations have shown that the incidence of various cancers is much lower in the Mediterranean area compared to other countries. Besides the chemopreventive ability, the antitumor effects of olive oil phenols with high antioxidant activity have been in-depth studied because of their capacities of inhibiting proliferation and promoting apoptosis.[12,13]

Growing experimental evidence has suggested that, in addition to antioxidant and anti-inflammatory abilities, hydroxytyrosol and other olive oil phenols exert anticancer effects through the activation of molecular signaling pathways, leading to cell apoptosis and growth arrest in several tumor cell lines in vitro.[14,15]

Cardioprotective Capacity. Hydroxytyrosol would be an effective dietary supplement for preventive therapy of cardiovascular diseases related to insulin decrease, and the reduction of hypertension risk. Among other healthy properties promoted by hydroxytyrosol, olive oil has beneficial effects on cardiovascular risk for its ability to reduce blood pressure and improve lipid profile.[16]

Health efficacy of olive oil intake on cardiovascular disease is greatly attributed to phenolic compounds such as hydroxytyrosol. A study involving 200 healthy male volunteers indicated that the intake of different kinds of virgin olive oil with various phenolic contents reduced lipid oxidative damage and increased HDL-cholesterol.[17]

EFSA endorsed the health claim that the consumption of olive oil polyphenols contributes to the protection of blood lipids on oxidative damage. Besides the ability to prevent LDL oxidation, hydroxytyrosol shows a beneficial effect on platelet function. Hydroxytyrosol derived from olive oil can inhibit platelet aggregation and production of eicosanoids in vitro, and olive derivatives share the same biological activities.[18,19]

A study involving the hyperlipidemic rabbits fed with hydroxytyrosol suggested an improvement of the antioxidant status and the reduction of the size of atherosclerotic lesions.[20] In order to examine the effect of extra virgin olive oil phenolic compounds on homocysteine-induced endothelial dysfunction, the structurally related compounds had been assayed for their ability to reduce homocysteine-induced monocyte adhesion as well as the expression of intercellular adhesion molecule-1 (ICAM-1) in EA.hy.926 cells.[21] All of the tested compounds, including hydroxytyrosol, significantly reduce the expression homocysteine-induced cell adhesion and ICAM-1. In addition, synergy of olive oil phenolic compounds in the modulation of the Hcy-induced ICAM-1 expression was investigated, and no synergistic effect has been observed when hydroxytyrosol and tyrosol are tested for their protective effects on ICAM-1 expression induced by TNFα.

Diabetes Treatment. *Olea europaea* leaves have been used in folk medicine to treat diabetes for many years. Supplementation with phenolic compounds of olive leaf, containing 51.1 mg of oleuropein and 9.7 mg of hydroxytyrosol per day for 12 weeks, improved the glucose regulation of insulin action and secretion in middle-aged overweight men. Insulin sensitivity and pancreatic β-cell secretory capacity were significantly improved in the people at risk of developing the metabolic syndrome.[22]

It was hypothesized that dietary antioxidants could reduce the risk of diabetes since oxidative stress plays a role in the pathogenesis of insulin resistance. Specific dietary strategies may be helpful in the prevention of this disease by improving glucose homeostasis.

Hydroxytyrosol supplementation to surviving diabetic rats greatly decreased the activities of intestinal lactase, lipase, maltase, and sucrose and enhanced the activities of superoxide dismutase, catalase, and glutathione peroxidase.[23] Moreover, significant decreases were observed in the level of thiobarbituric acid reactive substances and the activity of lactate dehydrogenase in diabetic rat pancreas after hydroxytyrosol administration. In addition, hydroxytyrosol increased lipid profile in diabetic rats through lowering the content of LDL-cholesterol and triglycerides and increasing HDL-cholesterol content. These properties of hydroxytyrosol are valuable when it is used as a therapeutic agent, especially as anti-hypocholesterolemic and diabetic drugs in biotechnological applications.

A long period of oxidative stress and inflammatory responses will cause many diseases. A proinflammatory cytokine plays an important role in the pathogenesis of chronic and autoimmune diseases. Some data shows that the intake of polyphenols such as oleuropein and hydroxytyrosol can affect the formation of advanced glycation end products and their interaction with respective receptors, and modulate chronic inflammatory diseases, for example, type II diabetes, rheumatoid arthritis, and inflammatory bowel disease.[24]

Neuroprotective Activity. As a major component of the Mediterranean diet, olive oil is very important to counteract neurodegenerative diseases such as Alzheimer's and Parkinson's diseases. Dietary hydroxytyrosol intake may have beneficial effects on neuroprotection.

Elevated oxidative and nitrosative stress can impair the integrity and function of brain tissue. The efficacy of a hydroxytyrosol-rich extract in diminishing NO-induced cytotoxicity in murine-dissociated brain cells was investigated. The addition of either Fe^{2+} or SNP (an NO donor) could cause a marked depolarization in mitochondrial membrane and a severe loss of cellular ATP, confirming the promising cytoprotection on brain cells by hydroxytyrosol-rich olive mill wastewater extract in different stressor paradigms.[25] Furthermore, correlation analyses revealed that the observed cytoprotective effects on PC-12 cells were likely due to the presence of hydroxytyrosol in the extract. Additionally, some evidence suggesting a physiological function of hydroxytyrosol, which is affected by ethanol consumption, warrants further investigation into the potential of intake of hydroxytyrosol extracts to exert a

Table 1. Potential Therapeutic Effects of Hydroxytyrosol

type of activity	protective effects and mechanisms	conditions	levels	ref
antioxidant activity	increasing CAT and SOD activities	in rats fed a cholesterol-rich diet	in vivo	36
	inhibiting the activities of 12-lipoxygenase and 5-lipoxygenase; reducing leukotriene B4 production	in rat platelets and rat polymorphonuclear leukocytes	in vitro	37
antiatherosclerosis and cardioprotection activity	preventing platelet aggregation and eicosanoid formation; inhibiting thromboxane B2 production	in platelet rich plasma	in vitro	19
	inhibiting thromboxane B2 production	in patients with uncomplicated type I diabetes	in vivo	38
	inhibiting leukotriene B4 generation; inhibiting 5-lipoxygenase	in rat peritoneal leukocytes	in vitro	39
	reducing monocytoid cell adhesion to stimulated endothelium; decreasing VCAM-1 mRNA and protein	in human umbilical vein endothelial cells	in vitro	40
	lowering serum TC and LDL-C; slowing the lipid peroxidation process	in rats fed a cholesterol-rich diet	in vivo	36
neuroprotective effect	attenuating Fe^{2+} and NO-induced cytotoxicity; increasing cellular ATP; reducing lipid peroxidation; hyperpolarizing basal mitochondrial membrane	in murine-dissociated brain cells and mice	in vitro ex vivo	25
	inhibiting lactate dehydrogenase (LDH) efflux in a concentration-dependent manner	in a model of hypoxia−reoxygenation in rat brain slices	in vivo	28
anticarcinogenic activity	inhibiting cell proliferation; inducing apoptosis by arresting the cells in the G0/G1 phase with a concomitant decrease in the cell percentage in the S and G2/M phases	in human promyelocytic leukemia cells HL60	in vitro	15
	a dose dependent growth inhibition of MCF-7 cells; inducing apoptosis by arresting the cells in the G0/G1 phase	in MCF-7 breast cancer cells	in vitro	12
	inhibiting cell proliferation through the inhibition of estrogen-dependent rapid signals involved in uncontrolled tumor cell growth; not be involved in estrogen receptor alpha-mediated regulation of gene expression	in MCF-7 breast cancer cells	in vitro	13
antibacterial activity	antimycoplasmal activity against *M. pneumoniae*, *M. hominis*, and *M. fermentans*	in mycoplasma	in vitro	34
diabetes treatment	decreasing considerably intestinal maltase, lactase, sucrose, and lipase activities and enhancing the superoxide dismutase, catalase, and glutathione peroxidase activities; decrease in the level of thiobarbituric acid reactive substances and lactate dehydrogenase activity; improving lipid profile by lowering LDL-cholesterol and triglycerides and increasing HDL-cholesterol content	in diabetic rats	in vivo	23

dx.doi.org/10.1021/jf405820v | J. Agric. Food Chem. 2014, 62, 1449−1455

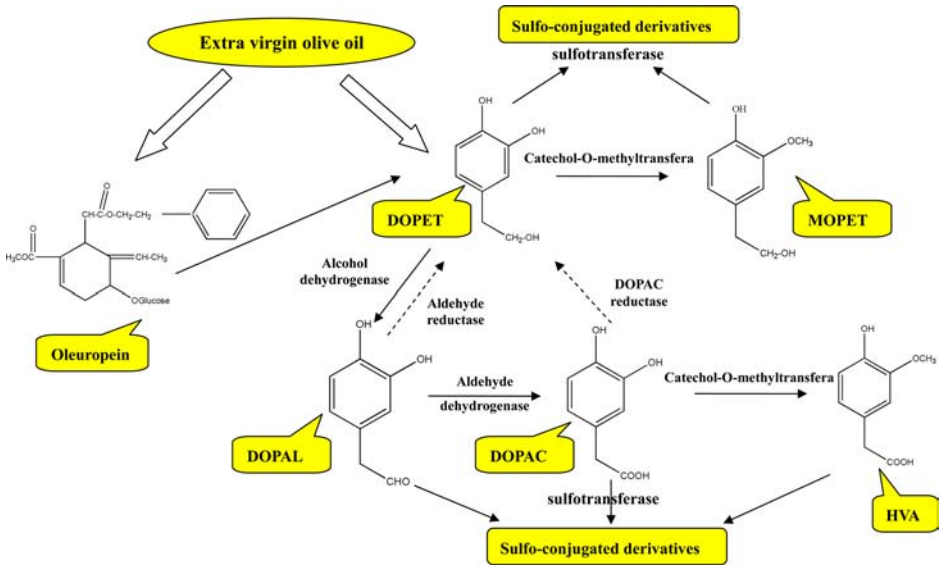

Figure 1. Pharmacokinetic analysis and metabolism pathways of exogenously administered hydroxytyparosol in rats. DOPET is hydroxytyparosol; MOPET is 4-hydroxy-3-methoxy-phenylethanol; DOPAL is 3,4-dihydroxy-phenylacetaldeyde; DOPAC is 3,4-dihydroxy-phenylacetic acid; HVA is 4-hydroxy-3-methoxy-phenylacetic acid.

beneficial effect on the body.[26] Hydroxytyrosol significantly attenuated the cytotoxic effect of stressors. In vivo data have provided evidence of neuroprotective effects of oral hydroxytyrosol intake. Both in vivo and in vitro data have identified that the mitochondria are among the preventive targets of hydroxytyrosol in the brain.

Oleuropein had shown neuroprotective activity by forming noncovalent complexes with the beta amyloid peptide, which is the major protein component of senile plaques formed in several neurodegenerative diseases such as Alzheimer's and Parkinson's diseases. Therefore, as the primary degradation product of oleuropein, hydroxytyrosol has been speculated to be a potential neuroprotective compound.[27]

The possible neuroprotective effect of hydroxytyrosol was tested using a model of hypoxia−reoxygenation in rat brain slices. Lactate dehydrogenase (LDH) was measured as a marker of brain cell death. Hydroxytyrosol significantly inhibited LDH efflux, providing an initial basis for further study of hydroxytyrosol as a potential neuroprotective compound.[28]

Modulation of Enzymes. The activities of enzymes potentially sensitive to phenolic compounds were tested in a variety of cellular models, such as platelets, leukocytes, and macrophages. Hydroxytyrosol was tested for enzyme-modulating activities, such as in vitro effects on the platelet function, where hydroxytyrosol inhibited chemically induced aggregation, the accumulation of proaggregant thromboxane in human serum, and the production of proinflammatory leukotrienes by activated human leukocytes.[29]

Hydroxytyrosol is able to regulate several enzymatic activities associated with cardiovascular disease. Its inhibitions on the inducible form of nitric oxide synthase, platelet aggregation, and proinflammatory enzymes such as 5-lipoxygenase have been demonstrated in vitro. The vasomodulating effects of olive leaf extracts have been demonstrated in a rabbit model, although the human relevance of these findings needs further investigation.[30]

Other Effects. Hydroxytyrosol also has many other significant activities. It could control and prevent various pathological changes caused by smoking. A low dose of hydroxytyrosol, administered through olive mill wastewater, reduced the consequences of sidestream smoke-induced oxidative stress in rats.[31] Data indicate that hydroxytyrosol is able to completely prevent artery and renal oxidative stress induced by cyclosporine A, and it has only a minor effect on the associated tubular injury and interstitial fibrosis without affecting the arteriolopathy.[32] Hydroxytyrosol significantly reduced the DNA strand breaks caused by *o*-phenylphenol (OPP) and effectively suppressed the formation of OPP-induced reactive oxygen species. The antioxidant activity of hydroxytyrosol may play an important role in attenuating the DNA damage of OPP.[33] In addition, growing experimental evidence suggested that hydroxytyrosol exerts antibacterial effects.[34] Moreover, hydroxytyrosol is a potent genotoxic compound and used as fungicides and antibacterial agents for pest control in agriculture.[35] Table 1 shows the main biological activities and potential therapeutic effects of hydroxytyrosol.

IN VIVO ABSORPTION AND METABOLIZATION

Bioavailability studies have demonstrated that hydroxytyrosol is dose dependently absorbed in animals and humans after olive oil ingestion, and systemically exerts biological effects.[41,42]

Absorption studies with olive oil and phenolic extracts derived from olive oil indicated that hydroxytyrosol is absorbed, while other phenolic components undergo metabolism in the small and large intestine.[43,44] Especially, oleuropein is not absorbed in the small intestine, and undergoes rapid degradation in the large intestine to yield hydroxytyrosol (Figure 1).

D'Angelo et al.[45] evaluated the toxicity of hydroxytyrosol and investigated its molecular pharmacokinetics. When orally administered to rats, hydroxytyrosol does not show appreciable toxicity up to 2 g/kg BW. To identify and quantify its metabolites, ^{14}C-hydroxytyrosol was synthesized and intravenously injected into rats. The pharmacokinetic analysis indicated a fast and extensive uptake of hydroxytyrosol by the organs and tissues with a preferential renal uptake. Moreover, 90% of the administered radioactivity was excreted in urine collected up to 5 h after injection, and about 5% was detectable

in feces and gastrointestinal content. The characterization of the labeled metabolites, extracted from the organs and urine, was performed by HPLC analysis, which showed that hydroxytyrosol was enzymatically converted in four oxidized and/or methylated derivatives. Moreover, a significant fraction of total radioactivity is associated with the sulfoconjugated forms, which also represent the major urinary excretion products.

Corona et al.[46] conducted an investigation into the absorption, metabolism, and microflora-dependent transformation of hydroxytyrosol, tyrosol, and their conjugated forms, which underwent rapid hydrolysis under gastric conditions, leading to significant increases of free hydroxytyrosol and tyrosol entering the small intestine. Both hydroxytyrosol and tyrosol transferred across rat segments of jejunum and ileum and human Caco-2 cell monolayers, and were subject to classic phase I/II biotransformation. The major metabolites identified were glucuronides of hydroxytyrosol, O-methylated derivative of hydroxytyrosol and tyrosol, and a novel glutathionylated conjugate of hydroxytyrosol. In contrast, there was no absorption of oleuropein in both models. However, oleuropein was rapidly degraded by the colonic microflora resulting in the formation of hydroxytyrosol. This study provided additional information regarding the breakdown of complex olive oil polyphenols in the GI tract, in particular the stomach and the large intestine.

Visioli et al. were the first to elucidate the metabolism of hydroxytyrosol.[47] Soon afterward they further studied the difference of metabolism and urinary excretion of hydroxytyrosol between rats and humans by evaluating excretion of hydroxytyrosol and its major metabolite. The results showed that the urinary excretion of hydroxytyrosol was greater in humans than in rats, suggesting that the rat is not the appropriate model for the study of hydroxytyrosol metabolism and that hydroxytyrosol-containing functional foods should be carefully formulated.[48] To date, the only study on human was conducted by González-Santiago et al., in which the absorption of high amounts of purified hydroxytyrosol administered as an aqueous solution is very low and produces a large number of metabolites.[49] The transient association with low-density lipoproteins observed in plasma may have physiological implications, but further research is needed using larger intervention trials with different hydroxytyrosol and formulations that render hydroxytyrosol more bioavailable before any conclusion can be made.

Administration of hydroxytyrosol in animal studies has been carried out as part of an extra virgin olive oil, using an olive oil mill wastewater extract or an aqueous solution as a drug for daily animal consumption. A study on the stability of hydroxytyrosol in aqueous solutions by varying its concentration, the temperature, and the ionic content showed that the storage of hydroxytyrosol is best at −20 °C where no significant degradation occurred for one week.[50] Hydroxytyrosol in lower concentrations was more prone to degrade than the higher ones. The results were of high relevance for future studies to predict the stability of potential liquid food samples containing hydroxytyrosol and perform quantitative determinations of hydroxytyrosol in biological fluids.

There may be some synergy effects between natural antioxidants. Evidence indicated that the cancer-preventive activity of olive oil could be mediated by the presence of minor components, such as antioxidant phenolic compounds. Hydroxytyrosol is one of the main olive oil phenols with a very strong antioxidant activity. Although it has not been reported yet, we believe that there will be a certain synergistic effect between hydroxytyrosol and other olive oil phenols or natural antioxidants, such as oleuropein, tyrosol, tea polyphenol, Vc, lycopene, and so on, when they act together. Zhang et al. studied the antagonistic effect of hydroxytyrosol on male reproductive toxicity induced by perfluorooctane sulfonate (PFOS).[51] Male mice were randomly divided into five groups: control group, PFOS group, PFOS plus low-dose hydroxytyrosol, PFOS plus midium-dose hydroxytyrosol, and PFOS plus high-dose hydroxytyrosol groups. After animals were fed with deionized water supplemented with PFOS and/or hydroxytyrosol for a month, the number of sperm in the rat groups with low, medium, and high dose of hydroxytyrosol increased significantly compared with that of PFOS exposure groups. At present, there is little research on the synergetic effects, which is worth being further researched.

SAFETY

The safety profile of hydroxytyrosol appears to be excellent; no untoward effects have been demonstrated even at very high doses.[52−54] An olive mill wastewater nutraceutical, i.e., Hidrox, containing 6% of hydroxytyrosol has been granted the GRAS status. In terms of safety profile, hydroxytyrosol has been investigated as the predominant part of raw olive mill wastewater extracts due to the previous unavailability of appropriate quantities of the pure compound. A toxicological evaluation on hydroxytyrosol was reported by Auñon-Calles et al., and they finally proposed a No Observed Adverse Effects Level (NOAEL) of 500 mg/kg/d based on the results.[55] In addition, their other research indicated that hydroxytyrosol is non-genotoxic and non-mutagenic at concentrations that far exceed those attainable after intake.[56]

Due to its variety of biological activities, hydroxytyrosol is currently one of the most actively investigated natural phenols in synthesis. Given its excellent safety profile, future availability as a health food supplement might be conceivable. Moreover, EFSA has endorsed the health claim that "on the basis of the data presented, the Panel concludes that a cause and effect relationship has been established between the consumption of olive oil polyphenols (standardized by the content of hydroxytyrosol and its derivatives) and protection of LDL particles from oxidative damage. The Panel considers that in order to bear the claim, 5 mg of hydroxytyrosol and its derivatives (e.g., oleuropein complex and tyrosol) in olive oil should be consumed daily."

In conclusion, hydroxytyrosol is being exploited as a potential peculiar supplement in the nutraceutical and food industry. It is noteworthy that there are a large number of patents on hydroxytyrosol and other olive phenols, and the number is in continuous increase.[30] Several industrial applications of hydroxytyrosol are being envisioned. In addition, hydroxytyrosol has been heavily exploited for the treatment and the prevention of heart disease, carcinogenesis, cerebral hemorrhage, atherosclerosis, and many other traditional therapeutic uses. It can be expected that, with the continuous accumulation of data in various areas of human health, other products in the fields of cosmetology or food science might be launched in the near future. Furthermore, new derivatives of hydroxytyrosol can be tested and developed for the purpose of potential applications.

With the demand for healthy organic food, the nutrition market exploring the potential health benefits of products from

olive and extra virgin olive oil is expanding. It is obvious that hydroxytyrosol from olive oil has significant bioactivity, which suggests its good potentiality for the development of dietary supplements. Further studies are needed to elaborate its physiological and pharmacological mechanisms to provide the theoretical basis for its use as health supplements.

bioindicators because <1% of microorganisms can be isolated from soil.[12]

Among soil enzymes, phosphatase is one of the most important enzymes. It is involved in nutrient cycling, mineralization, and plant nutrition and provides soil organic phosphorus (P).[13] The description of the action of these enzymes on P cycling is fully described in the literature.[14−17] Both acid and alkaline phosphomonoesterases can be found in soils according to the pH medium. Because phosphatases are involved in P cycling, which is essential for plant nutrition and soil fertility, the maintenance, preservation, and understanding of the behavior and the factors affecting these enzymes on soil are very important to ensure soil quality, plant growth, and agricultural productivity.

The aim of this study was to evaluate the effect of OM and CM on acid phosphomonoesterase (AcP) and alkaline phosphomonoesterase (AkP) and which factors within these soils would contribute the most with the variation on this enzyme activity on soil. For that, AcP and AkP activities were measured in soils under OM and CM, and the results were compared with those found for the native soil (NS), without any agricultural practices. The main physicochemical characteristics of soils that may affect AcP activity were also assayed.

MATERIALS AND METHODS

Materials. *p*-Nitrophenyl disodium phosphate was purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). All other reagents were of analytical reagent grade and were used without further purification unless otherwise specified. Solutions were prepared with distilled deionized water.

Site Description and Soil Sampling. Soil samples were collected from areas under OM and CM sugar cane crop and NS field in Goiás, Brazil. Samples of up to 15 cm of soil were collected on December 13, 2011. This region is under tropical climate. For the season of November 2011, the rainfall precipitation was 279.4 mm; on average, the temperature was minimum 20 °C and maximum 30.8 °C.

There were three replications per land use type, and each replication was composed of three soil sample cores. Fresh samples were sieved (<2 mm) after removal of debris and stored at −8 °C for AcP assay. The geographical coordinates for CM replications were as follows: CM 1, 18.06806° S and 49.71139° W; CM 2, 18.06383° S and 49.71093° W; CM 3, 18.06384° S and 49.70392° W. For OM, the coordinates were as follows: OM 1, 18.07656° S and 49.67653° W; OM 2, 18.07394° S and 49.67653° W; OM 3, 18.07455° S and 49.68620° W. The coordinates for NS were as follows: NS 1, 18.07710° S and 49.67603° W; NS 2, 18.07912° S and 49.68508° W; NS 3, 18.08009° S and 49.68508° W.

To standardize the amount of soil weighed in each test, moisture was determined from weight loss after the samples had been dried at 105 °C for 48 h.

The area under OM has been treated with this management for 10 years. The cultivated area was fertigated with vinasse (average of 436 m^3/ha per year) and received 29.1 ton/ha of an organic compound that includes sugar cane bagasse and filter cake.

The area under CM has been treated with this management for more than 10 years. This area was fertigated with vinasse (average 306 m^3/ha per year). In addition, this area was also treated with commercial pesticides and fertilizers. In the past three years, the chemical compounds used in CM were amonium nitrate, amonium phosphate, (*RS*)-5-amino-1-(2,6-dichloro-α,α,α-trifluoro-*p*-tolyl)-4-trifluoromethylsulfinylpyrazole-3-carbonitrile, 3-(3,4-dichlorophenyl)-1,1-dimethylurea, 3-cyclohexyl-6-dimethylamino-1-methyl-1,3,5-triazine-2,4(1*H*,3*H*)-2′,4′-dichloro-5-(4-difluoromethyl-4,5-dihydro-3-methyl-5-oxo-1*H*-1,2,4-triazol-1-yl)methanesulfonanilide, limestone, gypsum, and a herbicide of the organoarsenic family.

The area under NS is a preserved Cerrado area in the sugar cane mill property, presenting the features of the vegetation of this biome, and has not been explored for any agriculture or livestock.

All of the managements in the study area were under rotation with *Crotalaria juncea* every 5 years.

Physicochemical Analyses. Physicochemical analyses were performed at the Laboratory of Soil Analysis of the School of Agronomy at Universidade Federal de Goiás according to methodology described by EMBRAPA.[18]

The analyses included the determination of clay, silt, and sand percentage (soil granulometry), soil organic matter (SOM), pH using $CaCl_2$ determined by potenciometer, saturation of acids (M %), saturation of alkalis (V %), potential acidity total (H^++Al^{3+} $cmol_c/dm^3$) determined by Schoemaker, McLean, and Pratt buffer (SMP),[19] aluminum (Al^{3+} $cmol_c/dm^3$) extracted with 1 mol/L KCl and determined by volumetric titration, inorganic phosphorus (P^+ $cmol_c/dm^3$, extracted by Mehlich 1 and determined by colorimetry), potassium (K^+ $cmol_c/dm^3$) extracted by a Mehlich 1 extractor and determined by flame photometry, magnesium (Mg^{2+} $cmol_c/dm^3$) and calcium (Ca^{2+} $cmol_c/dm^3$) extracted with 1 mol/L KCl and determined by atomic absorption spectrophotometry, and cation exchangeable capacity (CEC), Ca/K, Ca/Mg, Mg/K, Ca/CEC, K/CEC, and Mg/CEC.

All tests were carried out in triplicates and are shown as the mean ± standard deviation.

Optimum pH and Enzyme Assay. To determine the optimum pH for the measurement of enzyme activity, the reaction was performed at pH 2.0, 3.0, and 4.0 (0.1 M glycin buffer), pH 5.0 and 5.5 (0.1 M acetate buffer), pH 6.0 (0.1 M sodium citrate buffer), pH 7.0 and 8.0 (0.1 M TRIS buffer), and pH 9.0 and 11.0 (0.1 M glycin buffer) using samples from NS because it presents the natural conditions for native phosphatases from Cerrado.

The assay was performed following the standard methodology for phosphatase measurement described by Eivazi and Tabatabai[15] with modifications. The reaction was conducted using 16 mg of soil, 0.4 mL of the respective buffer, and 0.1 mL of 2.5 mM *p*-nitrophenyl disodium phosphate. The mixture reacted at 55 °C for 1 h. Then, 0.1 mL of 0.5 M Na_2CO_3 was added followed by the addition of 0.4 mL of 0.1 M NaOH to stop the reaction. The mixture was centrifuged and the supernatant measured at 400 nm using a UV−vis spectrophotometer. A control was performed by adding NaOH followed by Na_2CO_3 to stop the reaction immediately after addition of the substrate. One enzyme unit (U) was defined as the amount of enzyme that released 1 mg of *p*-nitrophenol (pNP) after 1 h of reaction per gram of soil.

After determination of the optimum pH for acid (AcP) and alkaline (AkP) phosphomonoesterase, the enzyme activity was tested in the different soil samples according to the description above. AcP was measured using 0.1 M acetate buffer, pH 5.0, for all samples or with 0.1 M citrate buffer, pH 5.6 for CM and pH 5.7 for OM. AkP was measured in pH 8.0 using 0.1 M TRIS buffer, pH 8.0.

Statistical Analyses. All experiments were conducted at least in triplicate, and the results were processed by central tendency (mean) and dispersion (standard deviation) measurements. Statistica software 7.0 (StatSoft Inc., Tulsa, OK, USA) was used to perform multivariate analysis (ANOVA) followed by correlation, as well as Tukey's test, to determine the significant differences among the means. The *p* level of significance used was 0.05.

Principal component analysis (PCA) was performed to evaluate the variables that would interfere in AcP activity according to soil management. Only principal components with eigen values that explain 10% of the total variance were retained. A Varimax rotation was performed to enhance the interpretability of the unrelated components.[20]

RESULTS

Physicochemical Characteristics. In regard to clay, silt, and sand, there were differences in the particle size distribution in the soils (Table 1). Even though Cerrado soils present a high percentage of sand (CM 37%; OM 54%; NS 44%), they are

Table 1. Amounts of Clay, Silt, Sand, and SOM and pH in the Cropped and Native Soils[a]

	management		
	conventional	organic	native soil
clay %	39a ± 1.4	34b ± 2.8	35ab ± 2.8
silt %	25a ± 0.9	16b ± 1.4	17b ± 1.1
sand %	37b ± 1.2	54a ± 1.1	44b ± 7.6
SOM %	2.9a ± 0.5	2.9a ± 0.6	3.0a ± 0.5
pH	5.6a ± 0.1	5.7a ± 0.2	4.9b ± 0.1

[a]Results are means ± standard deviation of three determinations. Data followed by the same letters in the same rwo are not significantly different ($p > 0.05$).

considered loamy.[18] The amounts of clay in the soils tested were CM 39%, OM 34%, and NS 35%.

Physicochemical analysis showed that there were no statistical differences in the SOM content among the samples tested ($p > 0.05$) (CM 2.9%; OM 2.9%; NS 3.0%).

Except for Mg^{2+}, there was significant difference of K^+ and inorganic P^+ contents (Table 2). The results showed higher K^+ and inorganic P^+ in OM (K^+ 0.25 $cmol_c/dm^3$; P^+ 11.3×10^{-3} $cmol_c/dm^3$) than in CM (K^+ 0.13 $cmol_c/dm^3$, P^+ 1.2×10^{-3} $cmol_c/dm^3$) and NS (K^+ 0.17 $cmol_c/dm^3$; P^+ 3×10^{-3} $cmol_c/dm^3$). The amount of Ca^{2+} was also different in all tested soils, with higher values in OM (2.6 $cmol_c/dm^3$).

The saturation of alkaline ions (V %) represents the capacity of a soil to exchange alkaline cations such as K^+, Mg^{2+}, and Ca^{2+}. The amounts of K^+, Mg^{2+}, and Ca^{2+} adsorbed on clay were higher in OM (71%) and CM (54%) (Table 2). This means that soils used in agriculture present more cations with exchangeable capacity than NS (35%), which is a consequence of management practices such as fertilizer addition in OM and CM.

The results showed that soil pH values in the cultivated areas (5.6 in CM and 5.7 in OM) were higher than in the NS (4.9). This pH variation among the studied soils occurred as a consequence of liming, which is also the reason for the higher amount of Ca^{2+} in cultivated soils.

Cerrado soils are known for presenting a high amount of aluminum, which is toxic for many plants by causing plasmolysis on plant roots. This problem is overcome by the precipitation of Al^{3+} by addition of limestone, which is converted in the soil into $Ca(OH)_2$, causing the precipitation of Al^{3+} by the formation of $Al(OH)_3$. The results showed the presence of Al^{3+} in NS (0.7 $cmol_c/dm^3$) and its absence in the cultivated soils.

Optimum pH. Figure 1 depicts the activity of phosphomonoesterases in NS expressed as U (mg^{-1} g^{-1} h^{-1}). The figure

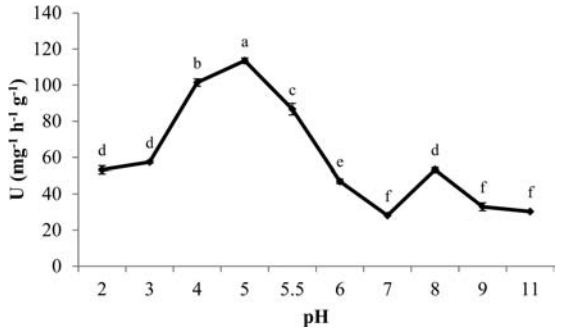

Figure 1. Effect of pH on the activity of phosphomonoesterase from native soil.

shows AcP presented a considerably higher activity than AkP and that the optimum pH values for AcP and AkP activity were pH 5 (113.5 U) and pH 8 (53.3 U), respectively.

Acid and Alkaline Phosphomonoesterase Activity in NS, OM, and CM. There was no difference in the AkP activity between the cultivated areas and NS, considering most of the samples (average of activity in CM 33.5 U, OM 31.5 U, and NS 39 U) (Figure 2). This result implies that sugar cane

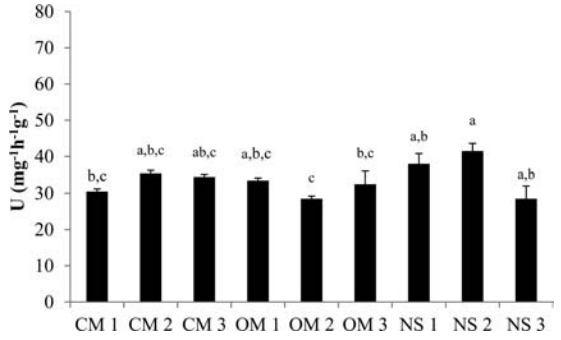

Figure 2. Alkaline phosphomonoesterase activity in cropped (organic and conventional management) and native soils.

management did not affect AkP activity. On the other hand, AcP activity is quite different among cultivated areas and NS (Figure 3). The activity observed in the NS (average of 96 U) was considerably higher than in the soils with sugar cane agriculture (average of CM 47.3 U and OM 45.6 U). In the original pH of soil, CM presented an average enzyme activity of 61.6 U and OM, 49 U.

Effects of Soil Physicochemical Characteristics on Acid Phosphomonoesterase Activity. An additional approach to estimate the relationship among physicochemical

factors and AcP activity and to allow the distinction concerning these data, PCA was carried (Figure 4). PCA often reveals previously unexpected associations among variables and thereby allows interpretation that would not be possible otherwise.[21]

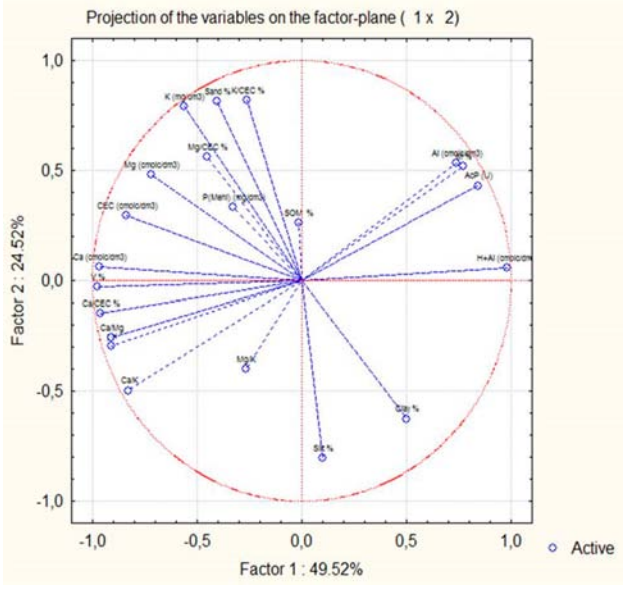

Figure 4. Principal component analysis of the soil physicochemical characteristics and acid phosphomonoesterase activity from organic and conventional management and native soils.

PCA (Table 3) showed that there were two factors explaining the variance of the data. Factor 1 explained 49.5% of the total of variance. The total of variance of this factor is defined by AcP, pH, Ca^{2+} ($cmol_c/dm^3$), Mg^{2+} ($cmol_c/dm^3$), H+Al, Al^{3+} ($cmol_c/dm^3$), CEC ($cmol_c/dm^3$), M %, and V %. Factor 2 explained 24.5% and is defined by silt %, sand %, and

K^+ (mg/dm^3). Factor 1 is related to pH and CEC, and factor 2 is related to the soil's granulometry.

From the results of PCA (Figure 4), for AcP activity, it can be seen that this enzyme presentd a greater relationship with NS than with OM and CM and that the main factors related to AcP were those influencing soil pH, which is demonstrated by the high values and proximity of the loadings of aluminum and H^++Al^{3+}.

The correlation matrix showed positive correlations between AcP and H+Al (r = 0.8), Al^{3+} (r = 0.9), and M % (r = 0.9). However, negative correlations with AcP were found for pH (r = −0.8), Ca^{2+} (r = −0.8), and V % (r = −0.8).

According to PCA, granulometry also seems to be related to AcP activity. In fact, Table 1 shows a higher amount of sand in OM than in CM and NS and clay appears to be more related to AcP.

DISCUSSION

Soil Physicochemical Characteristics and Acid Phosphomonoesterase Activity. Cerrado soils present color variations from red to yellow and are classified as haplustox dystrophic.[18] They are deep and well-drained during the major part of the year, making them vulnerable to leaching, contributing to their low CEC (Table 1). This characteristic is related to the granulometry of soil particles, especially the sand content (Table 1). Even though Cerrado soils present a high percentage of sand, they are considered loamy because clay appears in a percentage >20% (Table 1). Loamy soils are

dx.doi.org/10.1021/jf403141w | J. Agric. Food Chem. 2014, 62, 1456−1463

generally considered fertile; however, Cerrado soils present low active clay, 1:1 of minerals proportion, making them less fertile soils.

It is important to consider a soil's granulometry when soil enzymes are studied, because they are often immobilized onto these particles. Several authors reported that enzyme immobilization on soil particles provides stability to this biocatalyst against unfavorable soil environment.[22,23] Then, the smaller the particle size, the higher the area available for enzyme immobilization. Indeed, considering that Cerrado soils present a high amount of clay, it is possible to assume that these soils constitute a favorable environment for soil enzymes. AcP produced by *Heloma cylindrosporum* and *Suillus collinitus* strains presented more affinity for clay than the other soil size fractions.[24] In addition, it has also been reported that clay with 1:1 minerals was able to retain more enzymes catalytically active.[25]

In fact, results from PCA showed a relationship between AcP activity and soil granulometry. Sand and silt are explained by factor 2 and are more related with OM and CM. Indeed, Table 1 shows a higher amount of sand on OM and a higher amount of silt on CM.

This result means that, apparently, the reduction of AcP activity on these soils is also affected by the size of the soil's granulometry because the support for enzyme immobilization is responsible for protecting enzymes against denaturation factors and conditions.[26−28] Several authors reported the influence of soil granulometry on enzyme activity. They report that soil granulometry can affect enzymes in distinct ways.[10,25,29,30]

This finding is important because knowledge of how managements affect biochemical characteristics on soil may allow agricultural techniques that reduce management impact on soil quality. In fact, the amount of sand and silt in agricultural soil is indicative of the possible reduction of AcP activity.

Not only clay but also the SOM content is important to soil quality, because it also acts as a support for enzyme immobilization and can influence enzyme activity and stability.

However, there was no statistical difference ($p > 0.05$) of SOM content in the studied soils, suggesting that this parameter is not the most relevant factor affecting AcP activity. This is an interesting result considering that the quality of the organic matter is expected to change according to organic and conventional managements.[31,32] In this sense, despite the probable difference in the quality of SOM in the studied soils, this parameter did not significantly affect AcP activity. Different amounts of SOM were reported by several authors according to different locations, management, cover, and soil type.

It is well-known that soils from Cerrado are acid, present aluminum toxicity, and are poor in essential nutrients such as calcium, magnesium, potassium, and some micronutrients. In this sense, these soils require amendments to allow sugar cane agriculture. The quantification of K^+ and inorganic P^+ among the tested soils showed that OM presented higher amounts of these cations (Table 2).

This result indicates one of the effects of the application of vinasse, a residue from the fractional distillation of sugar cane, in OM and CM because this residue is rich in organic matter and nutrients, especially K^+.[33] The application of vinasse was more frequent in OM than in CM, because there were applications in 2008 (572 m^3/ha) and 2010 (300 m^3/ha), whereas in CM there was application only in 2010 (306 m^3/ha).

The higher amount of vinasse applied in OM might be due to OM requirements, because only the addition of organic fertilizers is allowed, and it would also be an attempt to overcome the lower productivity of OM due to the presence of high amounts of nutrients in this residue. In addition, filter cake, another organic residue from the industrial processing of sugar cane, is also added to OM soil as fertilizer. This residue is rich in P^+, which contributes to its higher amount in OM. Then, the residual effect of vinasse and filter cake application over the years explains the high amount of some nutrients in soil, mainly K^+ and P^+.

Potassium is a very important macronutrient for sugar cane and is the most required nutrient by this culture. Among the functions of K^+ in sugar cane is the productivity effect. An adequate amount of K^+ is important to the conversion of sugars in sucrose,[34] to increase the amount of carbohydrates, oils, and proteins, and to promote sugar and starch storage. It also regulates water use in plants and increases resistance during dry periods. Additionally, an abundant amount of K^+ may interfere in the absorption of Ca^{2+} and Mg^{2+} by the plant.[35] The correlation matrix showed a positive correlation between K^+ and Ca^{2+} ($r = 0.6$) and between K^+ and Mg^{2+} ($r = 0.7$).

As can be observed in Table 2, the amount of potassium was higher in OM, and there was no statistical difference in the amount of K^+ between CM and NS ($p > 0.05$). Cerrado soil is poor in macronutrients such as potassium, and its vegetation is adapted to this condition. Haridasan[36] observed a low amount of potassium content in the biomass of Cerrado vegetal species, corroborating this adaptive mechanism. On the other hand, sugar cane presents a high demand for potassium, and it is added to the soil by different fertilization strategies used in OM and CM.

Shaviv et al.[37] reported that continuous addition of fertilizers in cultivated soils may cause a saturation effect, which may reduce its ability to fix the potassium added by fertilization. Therefore, the addition of fertilizers does not solve the problem of low nutrient content in soils because other factors in the composition must be considered.

In this scenario, the importance of soil particles is demonstrated by PCA. There was a positive correlation between K^+ and sand ($r = 0.9$) and a negative correlation between K^+ and clay ($r = -0.7$) and between K^+ and silt ($r = -0.7$). Murashkina et al.[38] studied the fixation of potassium in different soil size particles and reported that in soils with a predominant proportion of sand, this is the most important particle in the fixation of potassium. Because Cerrado soils present a high proportion of sand, especially in OM, this may be the explanation for the higher amount of potassium in this soil management.

This result indicates that the presence of nutrients in soils depends on the characteristics of the cover, management, biochemical factors, and proportion of soil size particles.

In regard to the amount of Ca^{2+}, liming is the main factor that contributes to the increased amount of this ion in the managed soils. OM presented the higher values among the tested soils. The effect of liming is also observed in the values of soil pH, which were higher in the cultivated areas (5.6 in CM and 5.7 in OM) than in the NS (4.9). This result explains part of the reduction on AcP activity in the cultivated soil (Figure 3). Liming is the agricultural practice responsible for increasing soil pH, and it explains the negative correlation between AcP activity and Ca^{2+}.

The saturation of alkaline ions (V %) represents the capacity of a soil to exchange alkaline cations such as K^+, Mg^{2+}, and Ca^{2+}. Soil with V % >50% is considered rich in nutrients or eutrophic, whereas V % <50% is poor in nutrients.[39] The amounts of K^+, Mg^{2+}, and Ca^{2+} adsorbed on clay were higher in OM and CM (Table 2). This means that managed soils present greater capacity of exchanging cations than NS.

However, it is important to point out that the value of V % alone does not guarantee soil quality, as it does not reflect the biochemical conditions of soil. Indeed, this result indicates that even though there are nutrients in soil, they may not be absorbed by plant nor perform their functions, because nutrient availability in soils depends not only on the presence of such nutrients but also on other soil conditions such as enzyme activities.

Moreover, these applications include nutrients ready for plant absorption. Then, if they do not aggregate with other soil fractions, they only attenuate the problem of nutrient losses by the agriculture practices and do not contribute to the maintenance and preservations of soil structure, biological, and biochemical characteristics that are important to preserve soil fertility.

Considering NS, the low value of V % is a consequence of the higher amount of H^+ and Al^{3+} sorbed on clay than the alkaline cations, which is characteristic of acid soils.

The acidity of soils influences the amount of Al^{3+} in it and affects its availability because an acid environment allows dissolution of Al^{3+} present in the clay structure. This process occurs especially in clay type 1:1 of minerals and the Al^{3+} released is toxic to plants, mainly to the Poaceae family. The addition of limestone to these soils decreases the Al^{3+} availability by the formation and precipitation of $Al(OH)_3$, which is not soluble in pH >5.5.[40,41]

Optimum pH. The optimum pH of a soil enzyme is not necessarily the same as the soil's. Nevertheless, enzyme activity is dependent on soil pH, because it affects the proper ionization, expression, enzyme stability, and release by soil microorganisms.[13] In this sense, it is important to assay the optimum pH for enzyme activity to establish the best catalysis conditions and to identify if the soil offers proper conditions for enzymatic catalysis.

Aiming to evaluate the effect of pH on phosphomonoesterase activity, tests were conducted on NS with pH ranging from 2 to 11 (Figure 1).

The presence of phosphatase activity is observed in both acid and alkaline ranges, with optimum at pH 5.0 and 8.0 for AcP and AkP, respectively. Despite the acid character of Cerrado soil, AkP were found in these samples. However, the AkP activity is remarkably lower (53.3 U) than that in AcP (113.5 U).

It is important to note that although most reports in the literature affirm that the optimum pH for assaying AcPs from soils is 6.5 or close to neutral[15,42] acid phosphatases from Cerrado soil did not follow the same profile. The optimum pH for AcP found in this study was 5.0, which is almost the same pH of the NS (pH 4.9).

Acid and Alkaline Phosphomonoesterase Activity in NS, OM, and CM. Another important result is that there was no difference of AkP activity between the cultivated areas and NS. This result implies that management does not affect AkP activity. The presence of AkP in acid soils such as soils from Cerrado is mainly from cell lyses of microorganisms and small animals and was adsorbed on clay or other solid component of soil that preserved its activity.

The lower activity of AkP is also explained because the expression of acid and alkaline phophomonoesterases is influenced by pH. Considering the acid pH of the soil samples, the microbial expression of AcP was induced in the tested soils, contributing to the higher amount of this enzyme compared to AkP. Therefore, AkP is not an effective enzyme to be used as a bioindicator of soil quality in acid soils.

Samples from the NS showed markedly higher AcP activity when compared to OM and CM. Moreover, it is noticeable that there was no difference between the two management practices, demonstrating that whatever the management is chosen, the enzyme activity is considerably affected.

Previous studies showed that agricultural practices affected biomass composition, enzyme activities, and organic and biomass C and that phosphatase activity was significantly greater in undisturbed soils compared to conventional agriculture.[43,44] Previous studies stated that a decrease in organic soil disturbance could improve microbial activity and it, consequently, would increase the synthesis and secretion of enzymes and that there were variations on enzyme activity due to different groundcover crops and soil tillage, demonstrating that enzymes are sensitive to soil disturbance.[41,45]

The activity found for AcP in NS from Cerrado (average of 96 U g^{-1}) was considerabley higher than that reported in the literature. In the best conditions for AcP catalysis, the maximum activity was 249 U kg^{-1} in a Kenyon loam soil (fine-loamy, mixed, mesic Typic Hapludoll) from Iowa,[46] USA. In a study about the effect of permanent cover crop from sandy Ultisol soil (Paraná, Brazil), the activity of AcP varied from 87 to 176 U kg^{-1}.[41] AcP had its activity affected in different management practices with activity varying from 200 to 300 U kg^{-1}; in addition, in this study organic C also influenced AcP with a maximum activity of 600 U^1 kg^{-1} in the presence of 3% of organic C.[43] Note that in these data, enzyme activity is given in U kg^{-1} and in this study AcP activity is expressed in U g^{-1} because of the high amount of this enzyme in Cerrado soils (NS).

The most important finding of this study is that OM affected AcP activity as well as CM. Some reports in the literature showed that OM presented better chemical, biochemical, and biological parameters compared to CM. Other studies have already observed that organic C was higher in OM than in CM. They also showed that OM presented higher mineralized C, potentially mineralized C, and basal respiration than CM.[1] However, soil microbial biomass and mineralized C per microorganism biomass unity showed no difference between OM and CM. Moreover, biological parameters such as the presence of arthropods sensitive to agriculture process was higher in CM than in OM.[45]

Another important observation is that the managed soils OM and CM did not favor any of the phosphatase forms (AcP and AkP) because the soil pH of OM and CM is higher than the optimum pH for AcP and lower than the optimum pH for AkP, compromising enzyme synthesis in these soils.

Conclusions. All of the results presented showed the importance of the identification of the physicochemical characteristic changes by the sugar cane management affecting soil enzymes. Reduction of AcP activity in both management practices, OM and CM, was observed. However, AkP activity was not affected by management.

Our results demonstrated that AcP is affected by soil pH and soil particle size. This enzyme showed higher activity in lower pH with optimum pH 5.0. Despite the acid characteristic of Cerrado soils, AkP was also found in the tested soil and presented optimum pH 8.0. This finding highlights the importance of research in soils because this ecosystem is still not well studied, especially with regard to the biological and biochemical characteristics, which are highly influenced and have particular characteristics according to the region, agricultural practice, and cultivated crop.

The presence of AkP in the tested soils demonstrated also the importance of the soil particle size for AcP and AkP, because according to PCA clay size particles are closely related with the enzyme activity because these particles support enzyme immobilization, contributing to the maintenance and protection of enzyme structure and activity, which also explains the presence of AkP on these soils becausse they do not offer favorable pH conditions for its secretion and hydrolysis.

[a]The chromosome numbers assignments to linkage group based on SoyBase and the Soybean Breeder's Toolbox (http://soybase.org/LG2Xsome.php.

Soybean breeders need more QTL from different mapping populations with different genetic backgrounds and from multiple environments. Thus, the objective of this study was to identify additional QTL associated with daidzein, genistein, glycitein, and total isoflavone concentrations in a population of RILs of MD 96-5722 by Spencer. A genome-wide genetic map in a single population was used in identifying QTL associated with isoflavone content.

MATERIALS AND METHODS

Plant Material and Seed Analysis of Isoflavones. In this study, 92 $F_{5:8}$ RIL lines developed by crossing line MD 96-5722 with line Spencer were used for QTL analysis. The population was grown at Fayettvile State University campus, Fayetteville, in 2012. Plant to plant distance was 25 cm, and no additional fertilizer or insecticide was used. Seeds were harvested from the mature plants and were analyzed for isoflavone concentrations using a near-infrared reflectance (NIR) diode array feed analyzer (Perten, Springfield, IL, USA) following methodology previously reported.[25−27] Calibration equations were initially developed by the University of Minnesota using Thermo Galactic Grams PLS IQ from Perten. Twenty-five grams of seed from each line was ground using a Laboratory Mill 3600 (Perten), and the analysis was performed on a dry matter basis. Total isoflavones were calculated by adding the concentration of the three main isoflavones, daidzein, genistein, and glycitein.[25,28]

Genetic Map and QTL Detection. The MD 96-5722 by Spencer genetic linkage map[29] was constructed using JoinMap 4 (Kyazma BV, Wageningen, The Netherlands)[30] using 5376 SNPs from SoySNP6K BeadChip. Composite interval mapping (CIM) was used to detect QTL associated seed isoflavones using phenotypic data by running WinQTLCart 2.5 software (http://statgen.ncsu.edu/qtlcart/WQTLCart.htm).[31] Model 6 of WinQTLCart with four parameters for forward and backward stepwise regression, 10 cM window size, 1 cM step size, and five control markers was chosen.[30] The threshold was determined by permutations of 1000 times.

RESULTS

Phenotypic analysis shows the wide variation of seed daidzein, genistein, glycitein, and total isoflavone concentrations among the 92 RILs (Table 1). Variations among RIL lines were 6.51, 10.68, 6.21, and 6.88% for daidzein, glycitein, genistein, and total isoflavones, respectively. Among the two parents, the mean values of genistein, glycitein, and total isoflavones were higher for Spencer than for MD 96-5722; however, the mean values were lower for daidzein. Individual or total isoflavone means of RILs suggested that the segregation of these traits fits a normal distribution model as both the skewness and kurtosis values for these traits were <1.0 (Table 1). Mean values of daidzein were higher in RILs than in the parent MD 96-5722. However, glycitein content was lower than the parental means, genistein content was higher than the parental means, and total isoflavone content was lower than parental means.

A total of three QTL for seed isoflavone concentrations were identified on three different linkage groups (LGs) (Table 2; Figure 1). One QTL for seed daidzein concentration (*qDaid001*) was identified on LG A1 or chromosome (Chr) 5 at 11.70 cM position with a LOD score of 4.55. Two other QTL were identified for glycitein, *qGly001* and *qGly002* located on LG K (Chr 9) and LG B2 (Chr 14), respectively. LOD scores of these two QTL were 2.66 (*qGly001*) and 2.97 (*qGly002*).

DISCUSSION

Soybean isoflavone has been increasingly demanded by consumers because of its several beneficial health effects in humans as food ingredients, medicines, and cosmetics.[32] Therefore, breeders are interested in improving seed isoflavone concentration in soybean cultivars. The range of total isoflavones in these RIL populations was 1266−1776 μg g^{-1}. Wang and Murphy[33] also found a similar range for total isoflavone concentration in a cultivar from 1176 to 1749 μg g^{-1} among locations within the same year. Choi et al.[34] reported that total isoflavone concentration ranged from 458 to 2317 μg g^{-1} among cultivars in a single year. The variability observed in our recent study in 'PI438489B' by 'Hamilton' RIL population

dx.doi.org/10.1021/jf4040173 | J. Agric. Food Chem. 2014, 62, 1464−1468

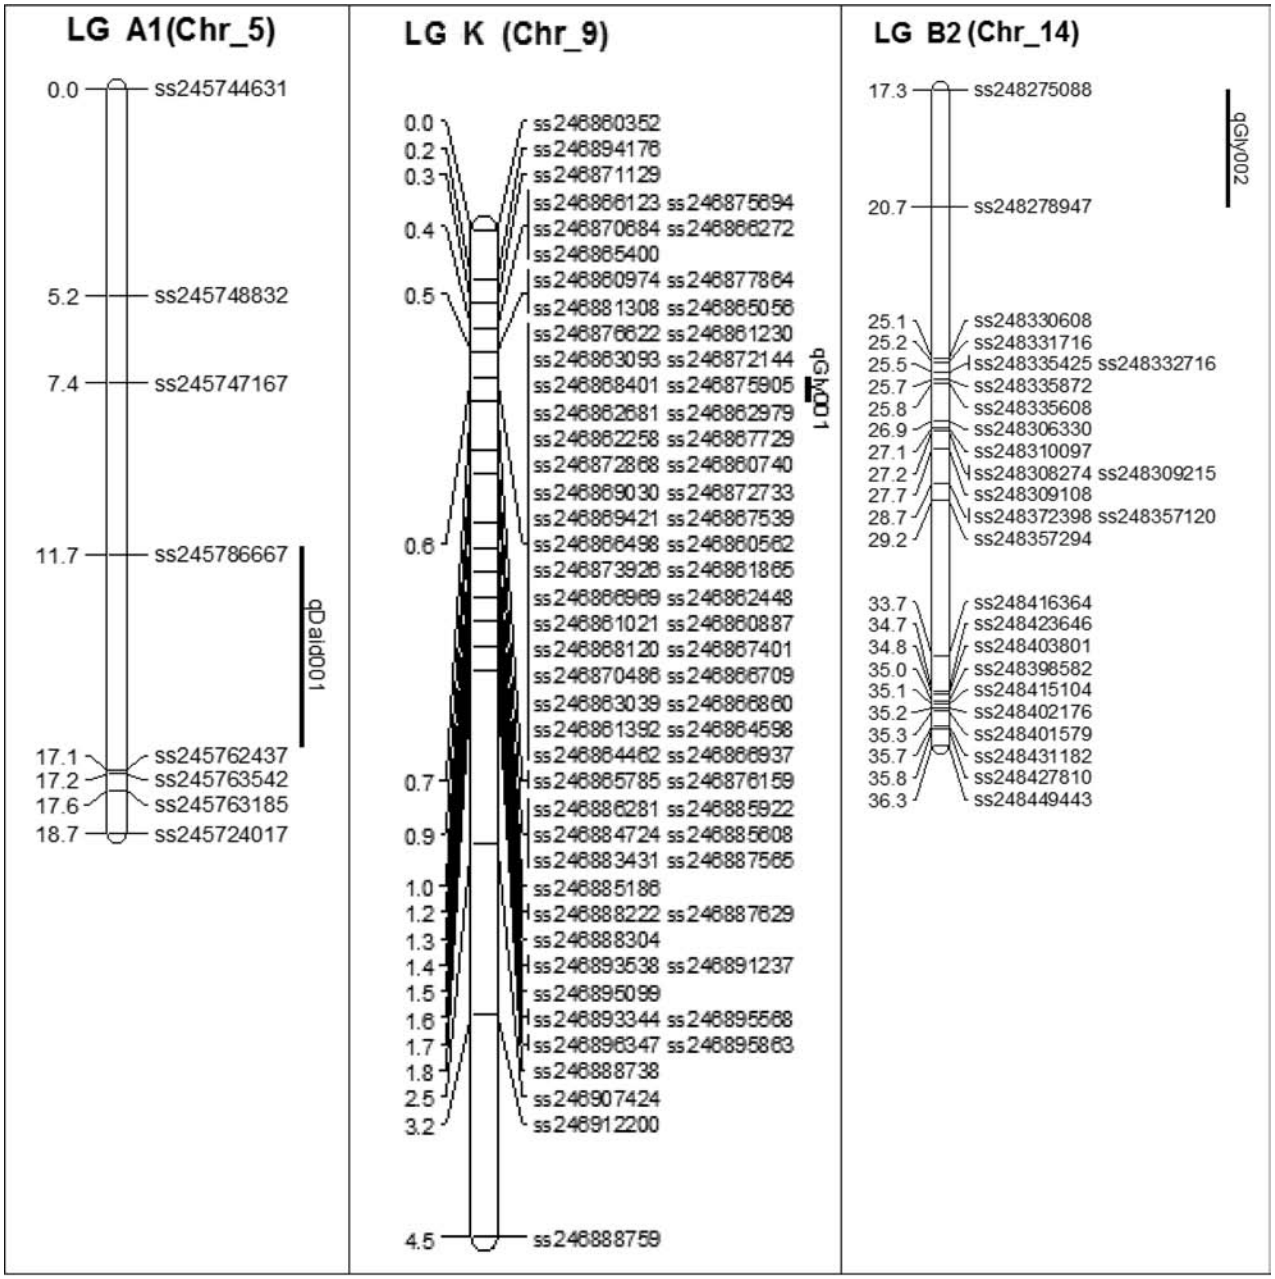

Figure 1. Locations of SNP markers and the QTL that underlie soybean seed daidzein (*qDaid001*) and glycitein (*qGly001* and *qGly002*) concentrations in the MD 96-5722 by Spencer RIL populations. LGs/Chr were drawn using MapChart[41] according to the 'Maryland' by 'Spencer' genetic linkage map.

for seed isoflavone concentration suggested that the control or accumulation of individual isoflavones was influenced by genotype, growing season/growing site, and their interactions. However, previous studies[10,34−36] showed that the main genotypic effects of total and individual isoflavones were effective in cultivar improvement.

A total of three QTL for seed isoflavone concentration have been identified in three different LGs or Chr. A QTL that controls daidzein (*qDaid001*) has been identified on LG A1 (Chr 5). Several other studies used different mapping populations and identified QTLs for daidzein concentrations in the same or different LGs. Smallwood[37] identified five QTL for daidzein in an 'Essex' × 'Williams 82' population; among those QTL was one on Chr 5 and the rest were on Chr 6, 9, 13, and 19. Gutierrez-Gonzalez et al.[37] identified six QTL for daidzein in Chr 5 (dai-A1), 8 (dai-A2), 2 (dai-D1b), 7 (dai-M), 12 (dai-H), and 19 (dai-L), although the QTL they identified for daidzein on Chr 5 (dai-A1) was located in a different position. Very recently, we identified four QTL for daidzein in the 'PI438489B' by 'Hamilton' RIL population on Chr 6, 7, 13m and 17 (unpublished data). Several other QTL were identified in different genetic regions on Chr 6, 9, and 13.[9,22,24,39]

Glycitein is the most variable individual isoflavone concentration among RILs of soybean MD 96-5722 by Spencer (Table 1). Two QTL have been identified for glycetein; *qGly001* and *qGly002* were identified on LG K (Chr 9) and LG B2 (Chr 14), respectively. Gutierrez-Gonzalez et al.[38] found a QTL for glycitein on LG K (Chr 9), and the QTL they reported for glycitein (*q*gly-K) is very apart from the QTL we

dx.doi.org/10.1021/jf4040173 | J. Agric. Food Chem. 2014, 62, 1464−1468

identified in this study. They also reported another five QTL for glycitein concentration on LG C2 (gly-C2), LG E (*q*gly-E), LG C2 (gly-C2), LG D2 (gly-D2_1 and gly-D2_2), and LG G (gly-G). Later, Gutierrez-Gonzalez et al.[40] also reported QTL for the glycitein QTL on LG C2 (Chr 6). Smallwood[37] identified three QTL for glycitein in an 'Essex' × 'Williams 82' population on LG C2 (Chr 6), LG K (Chr 9), and LG I (Chr 20). Interestingly, both of the above-mentioned studies[36,37] identified QTL for glycitein on LG K (Chr 9). Primomo et al.[9] identified QTL for daidzein and glycitein on LG M (Chr 7) using an 'AC756' by 'RCAT Angora' RIL population. However, previous studies have reported QTL for genistein, glycitein, daidzein, and total isoflavones on LG C2 (Chr 6) and LG L (Chr 19).[9,24,38−40] Very recently, we identified four QTL for glycitein in the 'PI438489B' by 'Hamilton' RIL population (unpublished data), and neither of those identified QTL were on LG K (Chr 9) or LG B2 (Chr 14). However, so far no study has yet identified the QTL for glycitein on LG B2 (Chr 14) that we identified in this study.

The additional three new QTL for daidzein and glycitein added to the existing QTL for isoflavones may increase the understanding of the genetic regions controlling isoflavone accumulation. Therefore, the QTL identified in this study represent a valuable resource for studying the genetic basis underlying isoflavone biosynthesis in soybean.

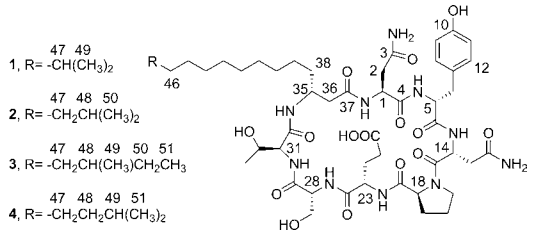

Figure 1. Structures of compounds **1**−**4**.

Bruker Avance II 800US2, Bruker Avance II 600, and Bruker DRX500 systems (Bruker Daltonics, Billerica, MA, USA). The spectra for compounds **1**−**4** were acquired in pyridine-d_5 (δ_H 7.19; δ_C 123.5) at room temperature. HR-ESI-MS spectra were obtained with a Waters Micromass LCT Premier XE (Waters, Milford, MA, USA), and HR-FAB-MS spectra were obtained with a JEOL JMS-700 spectrometer (JEOL, Tokyo, Japan). Preparative HPLC and HPLC analyses were performed with a Waters Alliance system.

Microorganisms. Soil samples collected in Ibaraki prefecture, Japan, were suspended in sterilized water and vortexed. The supernatants were serially diluted with sterilized water and spread on nutrient agar plates (15 × 90 mm). The plates were incubated at 30 °C for 48 h in darkness, and 500 colonies were transferred to other nutrient agar plates. Bacteria thus isolated were tested for their antifungal activity against a phytopathogenic fungus, *Botrytis cinerea* Persoon MAFF 744071. PCR amplification of the 16S rRNA gene of strain SD-32 with universal forward (5′-AGAGTTTGATCCTGG-CTCAG-3′) and reverse (5′-GGCTACCTTGTTACGACTT-3′) primers was carried out. The 16S sequence for SD-32 was deposited in GenBank (accession no. AB853319).

Isolation of Compounds 1−4. Strain SD-32 was grown at 30 °C with 150 rpm shaking for 64 h in 500 mL flasks containing liquid medium (50 mL/flask, total 800 mL) composed of maltose (80 g/L), soybean powder (80 g/L; J-OIL Mills, Tokyo, Japan), yeast extract (10 g/L; Becton, Dickinson and Co., Franklin Lakes, NJ, USA), $MgSO_4·7H_2O$ (2 g/L), $CaCl_2$ (2 g/L), K_2HPO_4 (1 g/L), $FeSO_4·7H_2O$ (0.1 g/L), $MnSO_4·5H_2O$ (0.1 g/L), and H_2O adjusted to pH 7.0 by Na_2CO_3. Antifungal metabolites were extracted from the culture filtrate (750 mL) with 1 L of EtOAc three times after adjustment of the pH to 4.0 with HCl. The EtOAc solution was dehydrated over anhydrous Na_2SO_4 and concentrated to dryness to afford an extract (3.8 g). The extract was dissolved in H_2O, and the pH of the solution was adjusted to 7.0. The solution was purified with solid-phase extraction (Oasis HLB 35 cc LP extraction cartridge, Waters) eluted stepwise with 50 mL each of 0, 20, 40, 60, 80, and 100% (v/v) MeOH in H_2O. The antifungal activity of each fraction was determined by the paper-disk method using *B. cinerea* as the test organism on a potato dextrose agar (PDA, Becton, Dickinson and Co.) plate at 20 °C for 3 days. The active fractions eluted with 60−80% MeOH in H_2O were combined and concentrated to dryness. The concentrate was subjected to Sephadex LH-20 column chromatography with MeOH. The active fractions were pooled and evaporated to dryness to afford a residue (0.80 g). The residue was further purified by preparative HPLC (XBridge C18, 250 × 10 mm) and eluted with 45% (v/v) CH_3CN−H_2O containing 0.1% TFA at a flow rate of 4.7 mL/min at 40 °C, and absorbance at 205 nm was measured to afford the active compounds **1** (23 mg), **2** (92 mg), **3** (120 mg), and **4** (56 mg).

Amino Acid Analysis. Compound **3** (1 mg) was hydrolyzed with 6 N HCl at 110 °C for 18 h, and the hydrolysate was dried with N_2. The amino acids were analyzed using the Shimadzu Prominence Amino Acid Analysis System (Shimadzu Corp., Tokyo, Japan) by postcolumn fluorescence derivatization with *o*-phthalaldehyde (OPA)/*N*-acetylcysteine as the reaction reagent.

***N*-Bromosuccinimide Cleavage and Edman Degradation.** Compound **3** (2.5 mg) was dissolved in 0.5 mL of 70% aqueous AcOH. *N*-Bromosuccinimide[19] (2.5 mg) was added, and the solution was allowed to stand for 1 h at room temperature. Three drops of formic acid were added to the solution to terminate the reaction. The open-up fragment of compound **3** was purified by preparative HPLC (XBridge C18, 250 × 4.6 mm) and eluted with 50% (v/v) CH_3CN−H_2O containing 0.1% TFA at a flow rate of 1.0 mL/min at 40 °C, and absorbance at 205 nm was measured. The N-terminal amino acid sequence of the fragment was determined by Edman degradation using Shimadzu Protein Sequencer PPSQ-23A.

Matrix-Associated Laser Desorption Ionization Time of Flight (MALDI-TOF) MS/MS Analysis. MALDI-TOF MS/MS was recorded by the Shimadzu AXIMA Resonance using a 337.1 nm nitrogen laser for desorption and ionization. 2,5-Dihydroxybenzoic acid (10 mg/mL) in 50% (v/v) CH_3CN−H_2O containing 0.1% TFA was used as the matrix solution. Positive-ion detection and reflectron mode were used.

Absolute Configuration of α-Amino Acid. Compound **3** (1 mg) was hydrolyzed with 0.5 mL of 6 N HCl at 110 °C for 18 h and dried with N_2. To the hydrolysate was added 100 μL of H_2O, 200 μL of 1% FDAA (Marfey's reagent)[20] in acetone, and 40 μL of 1 M $NaHCO_3$. The mixture was kept at 40 °C for 1 h, and 20 μL of 2 M HCl was added to terminate the reaction. The reaction mixture was analyzed by HPLC equipped with a reverse-phase column (XBridge C18, 250 × 4.6 mm) and eluted with a linear gradient of 10−50% (v/v) CH_3CN−H_2O containing 0.1% TFA in 45 min at a flow rate of 1.0 mL/min, 40 °C, and absorbance at 340 nm was measured. Derivatives of standard L- and D-amino acids were co-injected. To determine the absolute configuration of Asn1 and Asn2, two tripeptides, NH_2-L-Asp-D-Tyr-D-Asp and NH_2-D-Asp-D-Tyr-L-Asp, were used as standard peptides (Sigma-Aldrich). Compound **3** (3 mg) was hydrolyzed in 0.5 mL of 3 N HCl at 105 °C for 1 h and dried with N_2. To the hydrolysate was added 100 μL of H_2O, and the hydrolysate solution was analyzed by HPLC equipped with a phenyl column (XBridge Phenyl, 250 × 4.6 mm) and eluted with 5% (v/v) CH_3CN−H_2O containing 0.1% TFA at a flow rate of 1.0 mL/min, 40 °C, and absorbance at 280 nm was measured. Two standard tripeptides, NH_2-L-Asp-D-Tyr-D-Asp and NH_2-D-Asp-D-Tyr-L-Asp, were eluted at 8.2 and 7.3 min, respectively.

Absolute Configuration of β-Amino Fatty Acid. A β-amino fatty acid of compound **3** was produced by the hydrolysis (1 mL of 6 N HCl, 110 °C, 24 h) of compound **3** (10 mg) and extraction with chloroform. Dinitrophenylation of the β-amino fatty acid was carried out according to Sanger's procedure.[21] The Dnp derivative thus obtained was treated with *p*-methoxyaniline, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, and 1-hydroxybenzotriazole in methylene chloride. The reaction products were purified by preparative HPLC using a column (XBridge C18, 250 × 4.6 mm) eluted with 90% (v/v) CH_3CN−H_2O containing 0.1% TFA at a flow rate of 1.0 mL/min at 40 °C, and absorbance at 340 nm was measured to yield the dinitrophenyl-*p*-methoxyaniline derivative (<1.0 mg). The structure was confirmed by mass ($[M + H]^+$, 557.4) and ^1H NMR ($CDCl_3$) spectra. The amount of the derivative was determined to be 0.41 mg by a calculation based on ε value at A_{347} in the literature.[22] The CD spectrum of the derivative was compared to that in the literature.[22] CD (c 8.4 × 10^{-5} M, MeOH) λ_{max} (Δ ε) 262 (+4.29), 300 (+0.54), 330 (+0.77), 400 (−1.82) nm.

In Vitro Assay against Plant Pathogens. We obtained the following from the National Institute of Agrobiological Science, Tsukuba, Japan: *Botrytis cinerea* Persoon MAFF 744071, *Rhizoctonia solani* J. G. Kuehn MAFF 305219, *Fusarium oxysporum* Schlechtendahl MAFF 410171, *Pyricularia grisea* (Cooke) Saccardo MAFF 101583, *Alternaria alternata* (Fries) Keissler MAFF 731001, *Botryosphaeria berengeriana* De Notaris f. sp. *pyricola* Koganezawa et Sakuma MAFF 645002, *Didymella bryoniae* (Fuckel) Rehm MAFF 235932, and *Pythium aphanidermatum* (Edson) Fitzpatrick MAFF 239200. The following strains were obtained from Biological Resource Center (NBRC), National Institute of Technology and Evaluation, Chiba, Japan: *Colletotrichum acutatum* Simmonds NBRC 32849, *Monilinia fructicola* (Winter) Honey NBRC 30451, *Penicillium expansum* Link ex S.F. Gray NBRC 5453, and *Sclerotinia sclerotiorum* (Libert) de Bary NBRC 4876. *Fusarium graminearum* Schwabe ARC 2075-1 was supplied from NARO Agricultural Research Center, Tsukuba, Japan. The DMSO solution (60 μL) of the each compound was added to

6 mL of PDA held at 50 °C. The agar medium was poured onto a 60 mm plate. Each compound was tested at concentrations of 2.5, 5.0, 10, 20, 40, and 80 μg/mL. A PDA disk (5 mm in diameter) with mycelia of each test pathogen was placed on each plate containing a compound. The pathogens were incubated at 22 °C for 1.5 days (*B. cinerea*, *D. bryoniae*, and *S. sclerotiorum*), 2 days (*R. solani*, *P. aphanidermatum*, *F. graminearum*, *B. berengeriana*, and *M. fructicola*), 2.5 days (*F. oxysporum*), 3 days (*P. expansum* and *C. acutatum*), 4 days (*A. alternata*), and 5 days (*P. grisea*). The pathogens growing on PDA (6 mL) containing 60 μL of DMSO were used as controls. All experiments were performed in triplicate. IC_{50} values (median inhibitory concentrations) were calculated using the inhibition rate of mycelial growth. That rate was calculated as

$$\text{inhibition rate of mycelial growth (\%)} = (1 - D_a/D_b) \times 100$$

where D_a is the diameter of the pathogen colony in the plate containing a test compound and D_b is the diameter of the colony in the control plate. The results were expressed as IC_{50} (mean ± SD, μM).

Leaf Disk Assay Using Cucumber Cotyledon and *Botrytis cinerea*. Cucumber seeds (*Cucumis stativus* L., Sagami-Hanjiro) were planted in 12 cm pots containing artificial soil and grown in the greenhouse at 16−23 °C without supplemental lighting. The cotyledons were collected from 3-week-old plants. The test compound was dissolved in an appropriate amount of phosphate buffer (40 mM, pH 7.2), and 50 μL of the solution was applied to a paper disk (8 mm in diameter, thick type, Advantec Toyo Kaisha, Ltd., Tokyo, Japan) on the cucumber cotyledon. For the control, only phosphate buffer was applied. Then the paper disks on the leaves were inoculated with 50 μL of *B. cinerea* spore suspension (2×10^4/mL) containing 0.2% (w/v) yeast extract and 2% (w/v) sucrose. Each compound was tested at final concentrations of 10, 20, 30, 40, 60, and 80 μM. The leaves were kept in a humidity chamber (relative humidity > 95%) at 20 °C for 4 days in darkness. The experiment was repeated four times. The inhibition rate of *B. cinerea* infection was calculated as

$$\text{inhibition rate of infection (\%)} = (1 - D_c/D_d) \times 100$$

where D_c is the diameter of the infection zone in the leaf with a test compound and D_d is the diameter of the infection zone in the control leaf. The results were expressed as inhibition rate (mean % ± SD).

RESULTS AND DISCUSSION

Isolation of Compounds 1−4 from *Bacillus amyloliquefaciens* SD-32. In our screening search, SD-32, a bacterium isolated from soil, was found to have strong antifungal activity against plant pathogen *Botrytis cinerea*. The PCR product of its 16S rRNA gene was sequenced to give a 1472 bp sequence followed by a BLAST similarity search; it was identified as *Bacillus amyloliquefaciens*. SD-32 was cultured in a medium (800 mL) composed of maltose, soybean powder, yeast extract, and some minerals at 30 °C for 64 h. Antifungal activity-guided purification of the EtOAc extract of the culture filtrate with solid-phase extraction, gel filtration, and preparative HPLC afforded compounds **1** (23 mg), **2** (92 mg), **3** (120 mg), and **4** (56 mg) as white amorphous powders. The HPLC profile at the final step of purification is shown in Figure 2.

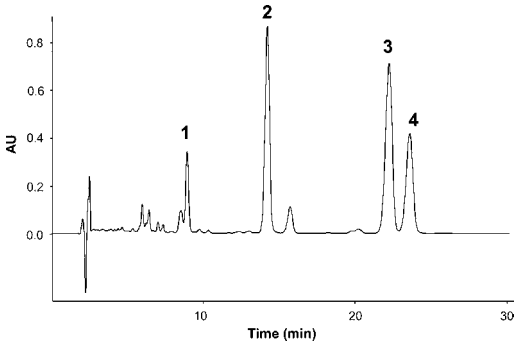

Figure 2. Preparative HPLC of compounds **1**−**4** in the active fractions after Sephadex LH-20 column chromatography.

Structures of Compounds 1−4. Compound **3** was most abundant in the culture broth, so we elucidated its structure first. Compound **3** gave an $[M + H]^+$ peak at m/z 1073.5902 (calcd for $C_{51}H_{81}N_{10}O_{15}$, 1073.5883) in HR-ESI-MS. Six α-amino acids, Asp, Tyr, Glu, Pro, Ser, and Thr, were found in a 2:1:1:1:1:1 ratio in an amino acid analysis of the hydrolysate. Because the ^{1}H NMR spectrum of compound **3** in DMSO-d_6 showed peaks due to a couple of conformers in the solution, pyridine-d_5 was used as NMR solvent. The ^{1}H NMR data for compound **3** (Table 1) indicated the presence of 11 amide protons (δ_H 9.66−7.80) and 7 α-protons (δ_H 5.39−4.72, partially overlapped) of amino acid residues of a peptide, a *p*-substituted benzene ring (δ_H 7.47 d, 7.06 d, 2H each), a long methylene chain (δ_H 1.20−1.15), and three terminal methyl groups (δ_H 1.34 d, 0.82 t, and 0.82 d, each 3H). The ^{13}C NMR data for compound **3** (Table 2) exhibited 49 signals, including 11 carbonyl groups (δ_C 175.5−171.1), a *p*-substituted benzene (δ_C 157.5, 1C; 131.3, 2C; 128.6, 1C; 116.1, 2C), methylene carbons (δ_C 63.5−26.1), and three methyl carbons (δ_C 20.8, 19.3, and 11.5). We deduced that compound **3** was *anteiso*-C_{17} bacillomycin D, a cyclic lipopeptide consisting of two Asn, one Tyr, one Pro, one Glu, one Ser, and one Thr residues and a β-amino acid with a $-(CH_2)_{10}CH(CH_3)CH_2CH_3$ group as a side chain from the ^{1}H−^{1}H COSY, HMBC, and NOESY data shown in Figure 3 and also by considering the molecular formula. To confirm this, we conducted chemical analysis and MALDI-TOF MS/MS analysis as follows. Compound **3** was cleaved at the C-terminus of the Tyr residue by *N*-bromosuccinimide,[19] and the cleaved product (oxidized form of Tyr with 2 mol of Br, molecular mass 1246) was purified by preparative HPLC. The fragment was analyzed by Edman degradation and yielded the following sequence: NH_2-Asn-Pro-Glu-Ser-Thr-X (Figure 4A). Compound **3** was also analyzed by MALDI-TOF MS/MS to afford the sequence information as shown in Figure 4B. These results confirmed that the structure of compound **3** was *anteiso*-C_{17} bacillomycin D.

The absolute configurations of α-amino acids in compound **3** were determined by treatment of the hydrolysate with Marfey's reagent[20] and HPLC analysis of the derivatives. The hydrolysates were shown to contain L-Asp, D-Tyr, D-Asp, L-Pro, L-Glu, D-Ser, and L-Thr. There is no ambiguity in the absolute configuration of the five amino acids other than Asn (in the form of the corresponding Asp). The absolute configurations of the two Asn were determined by HPLC comparison of the tripeptide in the partial hydrolysate of compound **3** with two synthesized tripeptides, NH_2-L-Asp-D-Tyr-D-Asp and NH_2-D-Asp-D-Tyr-L-Asp. The existence of NH_2-L-Asp-D-Tyr-D-Asp in the hydrolysate finally allowed us to establish the amino acid sequence, NH_2-L-Asn-D-Tyr-D-Asn-L-Pro-L-Glu-D-Ser-L-Thr of compound **3**.

To determine the absolute configuration of C3 in the β-amino fatty acid, the β-amino fatty acid was isolated from the hydrolysate of compound **3** and modified with dinitrofluorobenzene and *p*-methoxyaniline (Figure 4C). The CD spectrum of the dinitrophenyl-*p*-methoxyaniline derivative was similar to that of the derivative of iturinic acid,[22] indicating apparently that the β-amino fatty acid of compound **3** had an *R*-configuration, the same as iturinic acid.

The HRMS of compounds **1**, **2**, and **4** showed their $[M + H]^+$ ion peaks at m/z 1045.5552 (HR-FAB-MS; calcd for

[a]Compound **1**, 500 MHz; **2**, 600 MHz; **3** and **4**, 800 MHz. [b,c,d,e,f,g]Overlapped in each column.

$C_{49}H_{77}N_{10}O_{15}$, 1045.5570), 1059.5756 (HR-ESI-MS; calcd for $C_{50}H_{79}N_{10}O_{15}$, 1059.5726), and 1073.5876 (HR-ESI-MS; calcd for $C_{51}H_{81}N_{10}O_{15}$, 1073.5883), respectively. A series of NMR spectral analyses revealed that compounds **1**, **2**, and **4** had the same amino acid sequence as compound **3**, except for the side-chain structures of the β-amino fatty acids. The ^{1}H NMR and ^{13}C NMR spectra of compounds **1**, **2**, and **4** showed the presence of the $-(CH_2)_9CH(CH_3)_2$, $-(CH_2)_{10}CH(CH_3)_2$, and $-(CH_2)_{11}CH(CH_3)_2$ groups, respectively. Thus, we concluded that compounds **1**, **2**, and **4** were *iso*-C_{15}, *iso*-C_{16}, and *iso*-C_{17} bacillomycin D, respectively.

[a]Compound **1**, 125 MHz; **2**, 150 MHz; **3** and **4**, 200 MHz. [b,c,d]Assignments may be interchanged in each column.

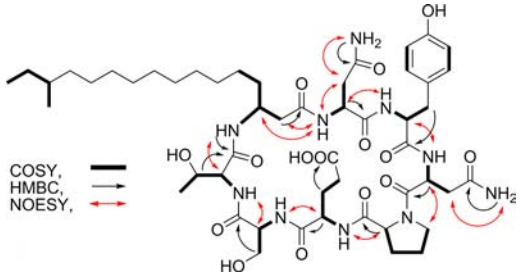

Figure 3. Key COSY, HMBC, and NOESY correlations detected for compound **3**.

Compounds **1** and **2** are known,[7] and compounds **3** and **4** are new. Compounds **3** and **4** have *anteiso*- and *iso*-C_{17} β-amino fatty acids and seven α-amino acids with the same chiral sequence, LDDLLDL, as the iturin family. This is the first study to establish the absolute structure of bacillomycin D. The metabolites assumed to be *anteiso*-C_{17} and *iso*-C_{17} bacillomycin D (**3** and **4**) were previously detected in mass spectrometric analyses of extracts from *Bacillus* species by Koumoutsi et al.,[23] Ramarathnam et al.,[24] Athukorala et al.,[25] and Liu et al.,[26] although their chemical structures were not determined. The lipid moieties of compounds **3** (*anteiso*-C_{17}) and **4** (*iso*-C_{17}) were previously reported in iturin A,[27,28] bacillomycin F,[8] and mycosubtilin,[11] and the reported contents of C_{17} homologues in iturin A, bacillomycin F, and mycosubtilin were 3, 39, and 61%, respectively. In the case of bacillomycin D, Peypoux et al.[7] reported percentages of each homologue (C_{14}, C_{15}, and C_{16}) in bacillomycin D were 48, 35, and 12%, respectively, and did not mention C_{17} homologues. Hourdou et al.[29] showed contents of each homologue (C_{14}, C_{15}, C_{16}, and C_{17}) in bacillomycin D were 48, 30, 22, and 0%, respectively. It is noteworthy that the content of the C_{17} bacillomycin D homologues was very high (60%) in the present study.

Activities of Compounds 1−4 against Plant Pathogens. The activities of compounds **1**−**4** were evaluated against 13 plant pathogens in PDA medium, and the results are shown in Table 3. The table reveals that the activities of compounds **3** and **4** (*anteiso*- and *iso*-C_{17}) were almost the same against all fungi tested and were stronger than those of compounds **1** and **2**; compound **1** was the weakest. Compounds **2**−**4** inhibited the growth of all fungi tested, and *B. berengeriana*, *B. cinerea*, *P. grisea*, *D. bryoniae*, *S. sclerotiorum*, and *M. fructicola* were the most sensitive to the compounds. By contrast, the oomycete *P. aphanidermatum* was not inhibited at all by any of the compounds. The activity of iturin family lipopeptides is attributed to their membrane-disruptive property through a direct lipopeptide−sterols interaction.[30] However, oomycetes do not synthesize sterols[31] and thus are assumed to be insensitive to bacillomycin D homologues.

The structure−antifungal activity relationships of iturin A,[32] bacillomycin Lc,[9] and bacillopeptins[10] have been studied. The activity of iturin A is directly related to the lipophilic side chain of its β-amino fatty acid; the activity increased with the number of carbon atoms in the β-amino fatty acid (C_{16} > C_{15} > C_{14}).

Table 4. Leaf-Disk Assay Using Cucumber Cotyledon and *Botrytis cinerea*

compd	inhibition rate (%) ± SD (n = 4)					
	10 μM	20 μM	30 μM	40 μM	60 μM	80 μM
1	3.8 ± 9.0	15.9 ± 12.5	7.5 ± 26.6	−14.2 ± 11.0	19.5 ± 19.6	100
2	18.3 ± 12.3	29.1 ± 25.8	77.2 ± 22.9	100	100	100
3	3.8 ± 15.2	19.5 ± 21.3	100	100	100	100
4	21.9 ± 28.9	20.7 ± 5.4	100	100	100	100

The same results were obtained for bacillomycin Lc and bacillopeptins. Recently, Tabbene et al.[33] investigated bacillomycin D-like compounds and showed that their anti-*Candida* activity increased in the order of the side-chain length: C_{16} > C_{15} > C_{14}. Our result for bacillomycin D showed that the order of activity against plant pathogens was C_{17} > C_{16} > C_{15}; the activity of bacillomycin D increased with side-chain length until C_{17}. Recently, it was reported that mycosubtilin interacts preferentially with ergosterol compared to the other classes of lipids and that the presence of ergosterol makes it easier to insert the lipopeptide into the membrane.[34] The *β*-amino fatty acid with 17 carbon atoms in bacillomycin D is assumed to be the best-fitting molecule for hydrophobic interactions with the sterols in the membrane.

dx.doi.org/10.1021/jf404531t | J. Agric. Food Chem. 2014, 62, 1469−1476

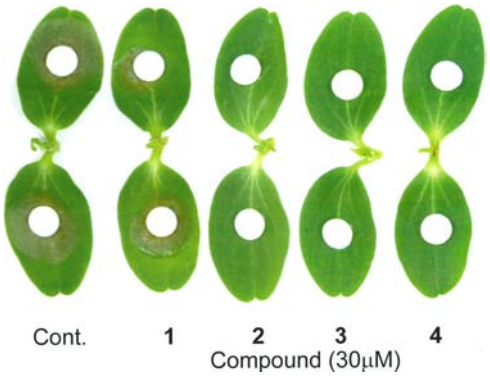

Figure 5. Leaf-disk assay using cucumber cotyledon and *Botrytis cinerea*.

Finally, to clarify the potential effect of bacillomycin D against gray mold disease, we conducted a leaf-disk assay using cucumber cotyledon and *B. cinerea*. The result is shown in Table 4 and Figure 5. Compounds **1**−**4** at concentrations of 80, 40, 30, and 30 μM, respectively, inhibited completely the *B. cinerea* infection in the cucumber leaf.

The present study demonstrates that strain SD-32 is unique because it produced higher contents of the C_{17} bacillomycin D homologues than other strains reported previously. Our result also showed that the activities of C_{17} bacillomycin D homologues are much stronger than the known C_{15} and C_{16} homologues, and from the cucumber leaf-disk assay the C_{17} bacillomycin D homologues can control gray mold disease. These indicate that this unique strain, SD-32, must be a potential promising resource for the biological control of plant disease, and experiments to assess its effect in fields are now being arranged.

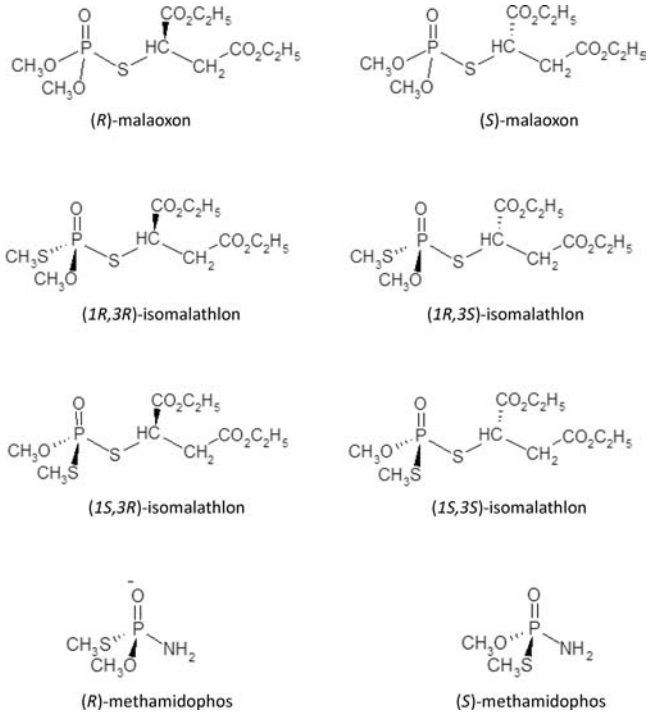

Figure 1. Enantiomers of malaoxon, isomalathion, and methamidophos. *, chiral center. Asymmetric phosphorus and carbon atoms of isomalathion were designated at positions 1 and 3, respectively.

13−29-fold.[15,16] Methamidophos (*O*,*S*-dimethyl phosphoramidothioate) is a highly toxic and widely used OP, which has an asymmetric center at the phosphorus atom and hence contains one pair of enantiomers (Figure 1).[17] The inhibitory potency of (*S*)-methamidophos was approximately 8.0−12.4 times stronger than that of (*R*)-methamidophos for AChE. It was noted that many studies had been conducted on postinhibitory reactions of AChE inactivated by enantiomers of isoparathion-methyl, malaoxon, and stereoisomers of isomalathion, and the results indicated that AChE inhibited by isomalathion stereoisomers with (1*S*)-configuration could not undergo a reactivation. The structural difference of inhibited AChE was thought to be responsible for the observation, that is, *S*-diethyl thiosuccinyl-*O*-methyl phosphorylated AChE incapable of reactivation was formed in the inhibition processes by (1*S*)-isomalathions due to the loss of thiomethyl as the primary leaving group, whereas inhibition of AChE by (1*R*)-isomalathions and enantiomers of isoparathion and malaoxon produced *O*,*O*-methyl or *O*,*S*-methyl phosphorylated AChEs, which were readily reactivated.[18]

The toxic effect of OPs has been observed for broad-spectrum plants and crops.[19−21] Previous studies showed that a variety of OPs could inhibit the activity of acid α-naphthyl acetate esterase, which is present in extracts from wheat.[22] The enantioselectivity in the inhibition was observed for malaoxon and isomalathion. The half-inhibition concentration (IC_{50}) values indicated (*R*)-malaoxon was 1.3 times stronger than its (*S*)-configuration, and the decreasing order of potency against ANAE was (1*R*,3*R*) > (1*R*,3*S*) > (1*S*,3*R*) > (1*S*,3*S*), with a 4.7-fold difference between (1*R*,3*R*) and (1*S*,3*S*).[9] However, selective inhibition kinetics and postinhibitory reactions, which were intensively studied in the inhibition of AChE by chiral OPs, were not included in those studies.

In an attempt to get the more detailed information on enantioselective reaction of ANAE with chiral OPs, we investigated enantioselective inhibition kinetics and post-inhibitory reactions of ANAE by chiral OPs and the difference in mechanism of ANAE inactivation between enantiomers of OPs.

EXPERIMENTAL PROCEDURES

Chemicals. Racemic isomalathion and malaoxon (purity > 99.5%) were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Analytical standard of racemic methamidophos (purity > 99.0%) was purchased from Kefa New Technology Development Co. (Shengyang, China).The four resolved stereoisomers of isomalathion, two enantiomers of malaoxon, and two enantiomers of methamidophos were collected at the outlet of a high-performance liquid chromatograph (HPLC) with chiral columns and circular dichroism detectors during the observed responses.[17] The absolute configuration was determined according to the elution order of enantiomers on chiral columns described in a previous study.[23] Fast Blue B, α-naphthyl acetate, and α-naphthol were purchased from National Physic Chemical Co. (Shanghai, China). Other solvents or chemicals were of HPLC or analytical grade.

Preparation of ANAE. ANAE was extracted from wheat flour by using the process employed in our previous study.[9] Briefly, homogenized wheat flour and deionized water were gently mixed for 15 h at 4 °C and then centrifuged for 20 min at 5000 rpm. The supernatant containing ANAE was obtained and stored at 4 °C until use. Working solutions of the enzymes were prepared in 0.2 M potassium phosphate buffer (pH 6.38), in which the hydrolysis rates of plant enzyme were approximately 0.05−0.10 absorbance unit/min.

Assay for ANAE Inhibition. The extent of ANAE inhibition was evaluated by the bimolecular reaction constant (k_i), dissociation constant (K_d), and phosphorylation constant (k_p), which were determined according to the method from inhibition of AChE by OPs.[10,11,24] All kinetic assays depend on the ANAE-catalyzed hydrolysis of α-naphthyl acetate and the estimation of diazonium dye produced.[22] The remaining ANAE activity after incubation of the enzyme with a progression of inhibitor concentrations was measured to calculate the kinetic components K_d and k_p.[11] Briefly, ANAE solution (180 μL) was treated with 20 μL each of a progression of inhibitor concentrations. At predetermined time intervals, 20 μL of the enzyme-inhibitor solution was taken to measure the residual activity of enzyme. The line regression between ($-\ln(E_t/E_0)$) and t will give k_{app}, where E_0 is the initial activity of AChE, E_t is the remaining activity at the time of measurement, and t is the reaction time.

$$k_{app} = -\ln(E_t/E_0)/t \quad (1)$$

The kinetic parameters were then obtained by plots of 1/[I] versus 1/k_{app} (at the individual inhibitor concentration) using the following equation.

$$1/k_{app} = 1/k_p + K_d/(k_p[I]) \quad (2)$$

[I] is the concentration of inhibitor.

k_i is calculated by the following equation:

$$k_i = k_p/K_d \quad (3)$$

Spontaneous Reactivation of ANAE Inhibited. ANAE solution (180 μL) was added to vessels A and B, and then 20 μL of phosphate buffer (pH 6.38) and 20 μL of an inhibitor solution that caused 90% inhibition were added to vessel A as a control and B as a test, respectively. Following a 30 min incubation at 35 °C, an aliquot of 100 μL of ANAE inhibitor (or phosphate buffer) solution was drawn and diluted in vessel C, which contained 1.9 mL of phosphate buffer to halt further inhibition, and the enzyme activity was determined following a brief temperature equilibration. At predetermined time intervals, including a time point immediately following dilution (t = 0), 20 μL aliquots from vessel C were transferred to a well containing α-naphthyl acetate solution (100 mg/80 mL, 23 μL) and Fast Blue B solution

(125 mg/80 mL, 207 μL). Returned enzyme activity was followed for 50 min by measuring the increase in absorbance at 550 nm. The rate constants of spontaneous reactivation (k_3) were calculated from the linear portion of the slopes according to eq 4

$$\ln[100(A_0 - A_t')/(A_0 - A_0')] = -k_3 t \quad (4)$$

where A_0 is the ANAE activity without inhibitor at time = 0, A_t' is the ANAE activity of inhibited ANAE at time = t, and A_0' is the ANAE activity of inhibited ANAE at time = 0.

Statistical Analysis. At least four separate experiments were used to calculate all values, and the results were expressed as the mean ± standard deviation (SD). Significance of differences between means was determined by one-way ANOVA ($\alpha = 0.05$) or t tests ($p < 0.05$). All statistics and regressions were performed using Origin version 8.0 for Windows. An F test was employed to determine whether slopes of regression lines of reactivation plots were significantly different from zero ($p < 0.05$).

RESULTS AND DISCUSSION

The line regressions between $(-\ln(E_t/E_0))$ and t and between $1/[I]$ and $1/k_{app}$ for (R)-malaoxon are shown in Figure 2, and those for other compounds can be found in Figures SI1−7 in the Supporting Information; the kinetic parameters are given in Table 1.

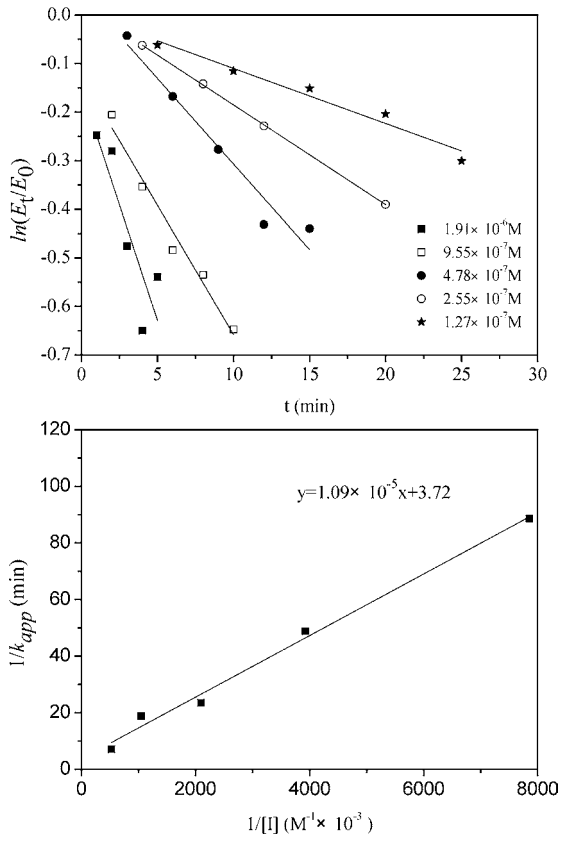

Figure 2. Typical plots for the determination of k_{app} and k_i for (R)-malaoxon.

Enantioselective Inhibition of ANAE by Malaoxon. The enantioselectivity of malaoxon in inhibition of AChE has been demonstrated by the difference for k_i values between (R)- and (S)-malaoxon. (R)-Malaoxon was always a more potent inhibitor of AChE than (S)-malaoxon with R/S ratios of 4.4−22.5. Similar to the enantioselective inhibition order of malaoxon to AChE, (R)-malaoxon was also a more potent inhibitor of ANAE than (S)-malaoxon as shown in Table 1. However, the difference of k_i values between (R)- and (S)-malaoxon for ANAE was less than that for AChE, indicating that ANAE was less preferential in enantioeselective recognition toward enantiomers of malaoxon than AChE. A further study was carried out to compare K_d and k_p values for ANAE with those for AChE, indicating that K_d and k_p values of enantiomers of malaoxon for ANAE were in the same order as those for AChE. Namely, (S)-malaoxon had higher K_d values for both ANAE and AChE than (R)-malaoxon, whereas k_p values of R-malaoxon were always higher than those of (S)-malaoxon for both ANAE and AChE. These results suggested that enantioselective interactions between the enzyme and malaoxon were similar for ANAE and AChE.

Table 1. Kinetic Constants for Enantiomers of Malaoxon, Isomalathion and Methamidophos against ANAE

	k_i	k_p	K_d
Malaoxon			
(R)-malaoxon	4.83 ± 0.10	0.27 ± 0.01	0.06 ± 0.00
(S)-malaoxon	3.78 ± 0.10	1.31 ± 0.03	0.08 ± 0.01
Isomalathion			
(1R,3R)-isomalathion	31.90 ± 1.01	0.55 ± 0.02	0.02 ± 0.00
(1R,3S)-isomalathion	20.42 ± 0.87	0.58 ± 0.01	0.03 ± 0.00
(1S,3R)-isomalathion	13.71 ± 0.55	0.15 ± 0.01	0.01 ± 0.00
(1S,3S)-isomalathion	8.49 ± 0.33	0.69 ± 0.02	0.08 ± 0.01
Methamidophos			
(R)-methamidophos	0.27 ± 0.01	0.20 ± 0.01	0.75 ± 0.02
(S)-methamidophos	1.18 ± 0.02	0.06 ± 0.00	0.05 ± 0.00

Enantioselective Inhibition of ANAE by Isomalathion. Previous studies found that the inactivation of AChE by isomalathion stereoisomers was in the order (1R,3R) > (1R,3S) > (1S,3R) >(1S,3S) according to k_i values, and chirality at both the phosphorus and carbon atoms influenced the rate of the inhibitory reaction of isomalathion with AChE.[15,16] The same order of k_i values and effect of chiral center on the rate of the inhibitory reaction were observed in the inhibition of ANAE by isomalathion stereoisomers as shown in Table 1. Additionally, changing the stereochemistry at the phosphorus atom could result in bigger k_i ratios than changing the stereochemistry at the carbon atom in the inhibition of AChE by isomalathion;[25] such results were also observed in the inhibition of ANAE by isomalathion. The observations indicated that stereoselective interactions between ANAE and isomalathion were similar to that between AChE and isomalathion.

Enantioselective Inhibition of ANAE by Methamidophos. Methamidophos exhibited significant enantioselectivity on the inhibition of AChE with the S/R ratios of 8.0−12.4.[17] The inhibitory potency of (S)-methamidophos was 4.4 times stronger than that of (R)-methamidophos for ANAE, indicating the active site of ANAE was less discriminatory toward enantiomers of methamidophos than that of AChE. However, the enantiomers of methamidophos were in the same order of potency in inhibiting ANAE as observed for AChE. This showed ANAE and AChE were similar in enantioselective interactions with methamidophos.

Although the enantioselectivity of ANAE is less potent toward malaoxon, isomalathion, and methamidophos than that of AChE, the orders of k_i values of malaoxon, isomalathion, and methamidophos enantiomers for ANAE are exactly the same as those for AChE.

Postinhibitory Reactions of ANAE Inhibited by Chiral OPs. The spontaneous reactivation of ANAE inhibited by chiral OPs is shown in Figure 3. The rate constants of spontaneous reactivation (k_3) were calculated from the linear portion of the slopes in Figure 3 and are given in Table 2. The measured k_3 values indicated that spontaneous reactivation of ANAE inhibited by (*R*)-malaoxon was not different from that of ANAE inhibited by (*S*)-malaoxon (Table 2), implying that the two enantiomers generated the same organophosphorylated enzyme with identical stereochemistry in the malaoxon moiety that is covalently bonded to the active site. ANAE inhibited by (1*R*)-isomalathion can readily undergo a reactivation, whereas the enzyme inactivated by the (1*S*)-isomers was refractory toward reactivation. A >3-fold difference was observed in k_3 values for ANAE modified by (1*R*)- versus (1*S*)-isomalathion (Table 2). The results were very similar to those observed in spontaneous reactivation of inhibited AChE by isomalathions.[26] A pronounced difference in spontaneous reactivation was observed for ANAE inactivated by enantiomers of methamidophos; namely, ANAE inhibited by (*S*)-methamidophos spontaneously reactivated at a remarkable k_3 value, whereas spontaneous reactivation could not be detected for ANAE modified by (*R*)-methamidophos, which is indicated by a nearly zero value of k_3 (Table 2), suggesting the mechanism of ANAE inactivation was different between (*S*)- and (*R*)-methamidophos. The spontaneous reactivation of AChE inhibited by enantiomers of methamidophos has not received examination to date. Thus, the comparison of enantioselectivity in spontaneous reactivation between ANAE and AChE cannot be made. However, the primary leaving group in the inhibition of ANAE by methamidophos can be predicted as methoxy for (*S*)-methamidophos and as thiomethyl for (*R*)-methamidophos according to the similarity of spontaneous reactivation of ANAE inhibited by isomalathion stereoisomers and methamidophos enantiomers.

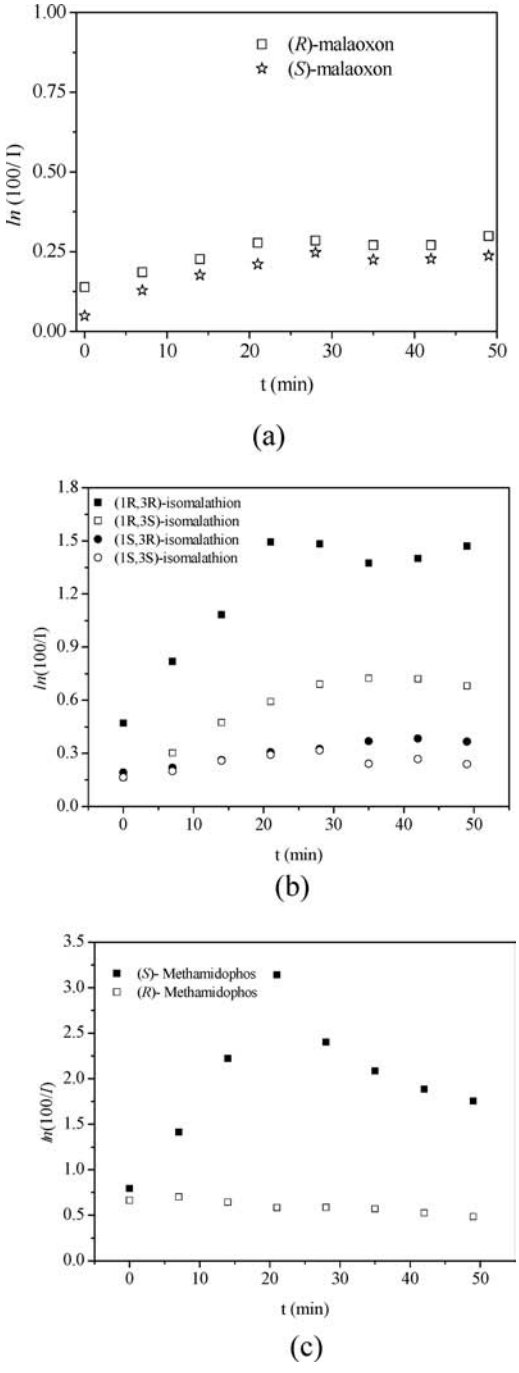

Figure 3. Representative plots of reactivation for ANAE inhibited by chiral organophosphorus insecticide enantiomers (a, malaoxon; b, isomalathion; c, methamidophos). The slopes of the initial linear portion of each serial represent k_3 (min^{-1}).

Table 2. Rate Constants of Spontaneous Reactivation (k_3) of ANAE Inhibited by the Enantiomers of Chiral Organophosphorus Insecticides

compound	$k_3 \times 10^3$ (min^{-1})
Malaoxon	
(*R*)-malaoxon	6.5 ± 0.33
(*S*)-malaoxon	5.6 ± 0.31
Isomalathion	
(1*R*,3*R*)-isomalathion	47.5 ± 1.8
(1*S*,3*R*)-isomalathion	5.1 ± 0.27
(1*S*,3*S*)-isomalathion	5.7 ± 0.23
(1*R*,3*S*)-isomalathion	19.1 ± 0.61
Methamidophos	
(*R*)-methamidophos	0 ± 0.01
(*S*)-methamidophos	112.0 ± 5.2

Overall, cholinesterase and ANAE are identified as the only enzymes that can be inhibited by OPs at the present. Furthermore, the enantioselectivity demonstrated to occur for inhibition of AChE by malaoxon, isomalathion, and methamidophos is conserved for ANAE. Thus, it can be concluded that ANAE and AChE had similar selective inhibition kinetics and postinhibitory reactions in reaction with chiral OPs. The results extend the knowledge on the enantioselective toxicity of chiral OPs.

different drying methods. The use of both mature and immature maize kernels was to identify the effects of kernel drying in the field.

EXPERIMENTAL SECTION

Materials. Maize cobs from different maturity stages of plants were selected from a local farm (Warwick, QLD, Australia) by visual observation (late R4 and early R6 plants, as described by WeedSOFT decision support system, available at http://weedsoft.unl.edu/documents/growthstagesmodule/corn/corn. htm) and designated as immature maize (IM) and mature maize (MM), respectively. The kernels were manually scraped from the cobs using a knife for determination of moisture content and isolation of starch granules. The moisture contents of IM and MM kernels averaged from six cobs were 66.8% and 37.6%, respectively, with standard deviations of 4.1% and 2.5%, respectively. Potato tubers (PTs) of similar sizes (70 ± 6 g) were also collected from a local farm (Killarney, QLD, Australia). Canna tubers (CTs) were collected from a local garden in St. Lucia, QLD, Australia. Gelose 50 (G50) and Gelose 80 (G80) starches were obtained from Penford Australia Ltd. (now Ingredion Pty. Ltd., Lane Cove, NSW, Australia), and both are high-amylose maize starches.

Porcine pancreatin and fluorescein isothiocyanate conjugate tagged dextran (FITC-dextran, molar mass 20 kDa) were obtained from Sigma-Aldrich Pty. Ltd. (Castle Hill, NSW, Australia), and amyloglucosidase from *Aspergillus niger* (EC 3.2.1.3, 3260 U/mL) was obtained from Megazyme International Ltd. (Bray, Co., Wicklow, Ireland). The pancreatin had 4 times the activity specified by United States Pharmacopeia (USP), that is, at least 100 USP units of amylase and protease and at least 8 USP units of lipase per milligram of product.

Starch Isolation and Drying Processes. Brushed and washed PTs were peeled manually, diced, and stored in 0.1 M NaCl solution before starch isolation. Similarly, maize kernels were stored in 0.1 M NaCl solution. Starch granules were isolated from the maize kernels and PTs using the method of Whistler et al.,[8] and the purified starch granules were kept in 0.025% sodium azide solution until being used for further analyses or subjected to various drying methods. The apparent amylose contents of IM, MM, and PT starches, determined by an iodine colorimetric method,[9] were 20.2%, 25.3%, and 30.3%, respectively. The purified starches from IM, MM, and PT were dehydrated using three methods: oven, freeze, and ethanol drying. For oven drying (OD), wet starch granules were dried in an oven at 40 °C for 48 h, manually ground, and passed through a sieve with openings of 125 μm. For freeze-drying (FD), wet starch granules were frozen in a liquid nitrogen bath (from −210 to −196 °C) and dried using a freeze-dryer (VirTis Benchtop 4K, SP Industries, Inc., Warminster, PA), ground, and sieved in the same way as the OD starch samples. For ethanol drying (ED), wet starch granules were washed using absolute ethanol, centrifuged, and dried in a fume hood at ambient temperature under a flow of N_2. To separate the effects of freezing and drying steps during FD, starch granules were also frozen in a liquid nitrogen bath and then thawed at room temperature (frozen−thawed, FT). The wet (W) controls were starch granules that had never been dried.

CT starch granules were isolated in a same way as the PT starch granules and subjected to ED and FD processes. The G50 and G80 starch granules were dried commercially by the manufacturer and were dispersed in water before being subjected to ED and FD processes.

In Vitro Starch Digestion. Starch was digested following the method of Dhital et al.[10] with slight modifications. Starch granules (~50 mg, dry basis) were suspended in 15 mL of sodium acetate buffer (0.2 M, pH 6.0). Freshly prepared enzyme solution (500 μL) containing pancreatin (2 mg/mL) and amyloglucosidase (28 U/mL) was added to the starch suspension, and the mixture was incubated in a water bath at 37 °C with shaking. Aliquots (0.3 mL) were removed at specific time intervals, mixed with absolute ethanol (0.9 mL), and centrifuged at 4000*g* for 10 min. The undigested starch residues collected as precipitates after centrifugation were freeze-dried for further microscopic analysis. The concentration of glucose in the supernatant was determined using an enzymatic glucose reagent (TR 15104, Thermo Scientific, Noble Park, VIC, Australia), and the absorbance was measured at 505 nm. The glucose release (%) was calculated as

$$\text{glucose release (\%)} = \frac{\text{total weight of glucose in supernatant} \times 0.9}{\text{dry weight of starch}} \times 100 \quad (1)$$

where 0.9 is the molar mass conversion from glucose to anhydroglucose (the starch monomer unit). The glucose profile or digestogram was then fitted to a first-order equation[11] for the kinetics of starch digestion as follows

$$C = 1 - e^{-kt} \quad (2)$$

where t is the digestion time (min), C is the fraction of digested starch at digestion time t, and k is the digestion rate constant (min^{-1}). The value of k can be obtained from the slope of a linear-least-squares fit of a plot of $\ln(1 - C)$ against t.

Scanning Electron Microscopy. Starch granules were thinly spread onto a circular metal stub covered with a double-sided adhesive carbon tape. The starch granules were then coated with platinum to approximately 10-nm thickness using a sputter coater (Eiko IB3, Mito, Japan) for 3 min at 15 mA in an argon-gas environment. Images of the starch granules were acquired using a Philips XL30 scanning electron microscope (SEM, Philips, Eindhoven, The Netherlands) under an accelerating voltage of 5 kV and at several magnifications; 4000× and 1500× magnifications were used to obtain representative images for maize (IM and MM) and PT starches, respectively.

Confocal Laser Scanning Microscopy. Starch granules (~1 mg) were dispersed in 500 μL of FITC-dextran solution (2 mg/mL) in a microcentrifuge tube and mixed at 300 rpm overnight at room temperature in a thermomixer (Eppendorf, Hamburg, Germany).[12] The mixture was spread onto a glass slide and covered with a glass slip and observed using an LSM 700 confocal laser scanning microscope (CLSM, Zeiss, Oberkochen, Germany). The excitation wavelength of the argon-ion laser was set at 488 nm and was operating at 2% of capacity power, and the emission light was detected at 492−600 nm. The images of optical sections of granules were recorded with ZEN 2011 software (Zeiss, Oberkochen, Germany).

Differential Scanning Calorimetry. A differential scanning calorimeter (DSC, DSC 1, Mettler Toledo, Schwerzenbach, Switzerland) with an intracooler was used to analyze the gelatinization properties of starch, following the method of Zhang et al.[13] Starch granules (~5 mg) were mixed with deionized water (~12 mL) by a needle and hermetically sealed in an aluminum pan. The pan was held at 10 °C for 1 min and then heated to 95 °C at 10 °C/min. The enthalpy change (ΔH) and the onset (T_o), peak (T_p), and conclusion (T_c) temperature of starch gelatinization were calculated from the DSC endotherm using STARe software (Mettler Toledo, Schwerzenbach, Switzerland).

Wide-Angle X-ray Diffractometry. Starch granules were equilibrated in a chamber with 44% relative humidity at 20 °C for 48 h, to give a moisture content of ~11% w/w. X-ray diffraction analysis was performed with an X'Pert Pro powder X-ray diffractometer (PANalytical, Almelo, The Netherlands) operating at 40 kV and 30 mA with Cu Kα radiation (λ) at 0.15405 nm. The scanning region was set from 3° to 40° of the diffraction angle 2θ, which covers all of the significant diffraction peaks of starch crystallites. A step interval of 0.02° and a scan rate of 0.5°/min were employed for all samples. The percentages of crystalline and amorphous starch from the total scattering and the relative degree of crystallinity were determined following the fitting method of Dhital et al.[14]

Fourier Transform Infrared Spectroscopy. Fourier transform infrared (FTIR) spectra of starch granules were obtained using a Spectrum 100 FTIR spectrometer (Perkin-Elmer, Norwalk, CT) with an attenuated-total-reflectance (ATR) single-reflectance cell with a diamond crystal. For each spectrum, 32 scans were recorded over the range of 1200−800 cm^{-1} at a resolution of 4 cm^{-1}. A single-beam

dx.doi.org/10.1021/jf405196m | J. Agric. Food Chem. 2014, 62, 1482−1491

spectrum of the clean crystal was obtained as the background. The ratio of absorbance at 1045 cm^{-1} to that at 1022 cm^{-1} was calculated to represent the short-range ordered structure of starch.[15]

Solid-State Nuclear Magnetic Resonance Spectroscopy. Starch samples were analyzed by solid-state ^{13}C cross-polarized magic-angle-spinning (CP/MAS) nuclear magnetic resonance (NMR) spectroscopy using a Bruker MSL-300 spectrometer (Bruker, Billerica, MA) at a frequency of 75.46 MHz. Approximately 200 mg of starch was packed in a 4-mm-diameter, cylindrical PSZ (partially stabilized zirconium oxide) rotor with a Kel-F end cap. The rotor was spun at 5 kHz at the magic angle (54.7°). The 90° pulse width at 5 μs and a contact time of 1 ms were used for all starches with a recycle delay of 3 s. The spectral width was 38 kHz, the acquisition time was 50 ms, the number of time domain points was 2 k, the transform size was 4 k, and the line broadening was 20 Hz. At least 1000 scans were accumulated for each spectrum. The spectral acquisition and interpretation methodologies as described by Tan et al.[16] were used to quantify the double helices, single helices, and amorphous conformational features.

Statistical Analysis. Results are expressed as means with standard deviations of at least duplicate measurements. In the case of XRD and NMR spectroscopy, only one measurement was performed. The standard deviations of XRD and NMR measurements are typically within 2%.[17] Analysis of variance (ANOVA) was used to determine the least significance at $p < 0.05$ using Minitab 16 (Minitab Inc., State College, PA), and correlation coefficients were determined using Microsoft Office Excel 2011.

RESULTS AND DISCUSSION

Dehydration Effects on Starch Digestion Kinetics. Although in vitro methods oversimplify the digestion mechanisms in human and animal digestive tracts, such studies are still useful for comparing the digestion rates/extents among starches with different structures. Granular starches follow a "side-by-side" digestion process involving the apparently simultaneous digestion of crystalline and amorphous regions. As model studies consistently report that amorphous starch is digested more rapidly than crystalline starch, this suggests that the digestions of the molecular and crystalline structures are not the rate-limiting steps for either in vitro or in vivo digestion.[18−20] The digestograms of PT, MM, and IM starch granules subjected to different drying methods are shown in Figure 1. All samples show increasing trends of glucose release within 6 h of digestion time without reaching a plateau. All digestograms follow first-order behavior with R^2 values above 0.99, and the digestion rate coefficients (k) are summarized in Table 1. The k values of MM and IM starches were ca. 2 times higher than those of PT starch, which agrees with the results reported by others.[10,21]

There are no significant differences among the k values of OD, ED, and W samples of each type of starch (PT, MM, and IM) (Table 1), and they show similar digestograms (Figure 1). Therefore, the OD and ED methods do not seem to influence the digestion properties of PT, MM, and IM starches.

The PT-FD starch, on the other hand, shows greater glucose release under the same in vitro digestion method with a significantly higher k value than the other PT samples (Figure 1A and Table 1). The FD (or lyophilization) process consists of two steps: the formation of ice (freezing) and the sublimation of the ice as water molecules under vacuum (drying). To identify which step, freezing or sublimation, is critical for the increased starch digestion rate, the digestion kinetics of PT-FT (i.e., PT sample with the freezing step only) was determined. There are no significant differences between the k values of the PT-FT and PT-W samples (Table 1), suggesting that the rapid

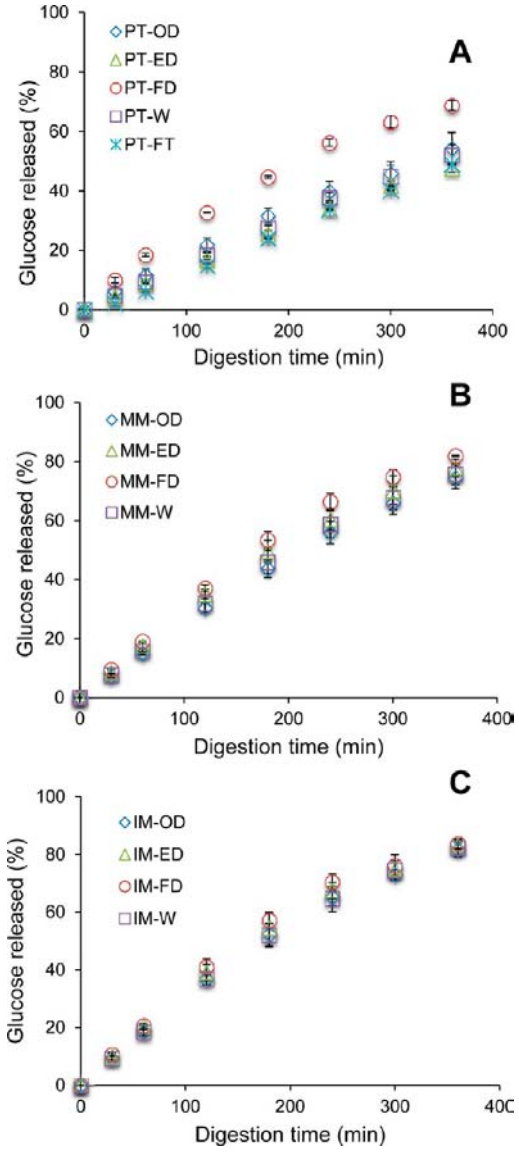

Figure 1. Digestion kinetic profiles of potato tuber (PT), mature maize (MM), and immature maize (IM) starch granules subjected to oven drying (OD), ethanol drying (ED), and freeze-drying (FD), as well as PT starch granules after freezing and immediate thawing (FT), compared with wet/never dried controls (W).

formation of ice crystals in the liquid nitrogen bath does not alter the digestion properties of PT starch granules. This is consistent with the observation of Waigh et al.[22] that some structural disorder of starch granules occurring at subzero temperatures is reversible. Therefore, the differences between the k values of the PT-FD and PT-W samples are likely caused by the sublimation step, including the external mass transfer of water vapor near the surface and the internal mass transfer from the inside of the PT starch granules.[23] This phenomenon, however, was not observed with MM and IM starches, where FD treatment does not significantly increase the k values of the starch granules compared with the W control counterparts and those from other drying methods (OD and ED). Thus, at least two hypotheses can be raised for the increased digestion rate of PT-FD starch: (1) FD breaks the smooth surface organization of potato starch granules that otherwise act as a barrier preventing the diffusion of enzymes into the inside or hilum of

the granules and/or (2) starch molecular features, namely, starch crystallinity and molecular order, are disrupted during FD, leading to higher accessibility of enzymes to bind with starch molecules.

Surface Architecture of Granular and Partly Digested Starches. Electron micrographs of PT, MM, and IM starch granules subjected to various drying methods are shown in Figure 2. MM and IM starch granules have either round or irregular shapes with diameters of 5−30 μm, whereas PT starch granules have either ellipsoidal or round shapes with a wide range of granule sizes (5−100 μm). The variations in granule shape and size within each starch sample are likely due to the termination of starch granule synthesis at different growth stages and/or the synthesis of starch granules at different grain developmental stages. In general, maize starch granules show the presence of pores on the granule surface, whereas potato starch granules have smooth surfaces lacking pores.[24] The high k values of MM and IM starch granules compared with those of PT starch granules can be related to the surface pores linking the hilum and surface through interior channels, facilitating "inside-out" digestion from the hilum to the surface of the granules.[25,26] On the other hand, the smooth surface structure of PT starch granules limits the enzyme diffusion, and hence, the digestion takes place from the surface (exocorrosion).

PT-FD starch granules exhibit relatively more wrinkles or scratches on their surface than PT-OD and PT-ED starch

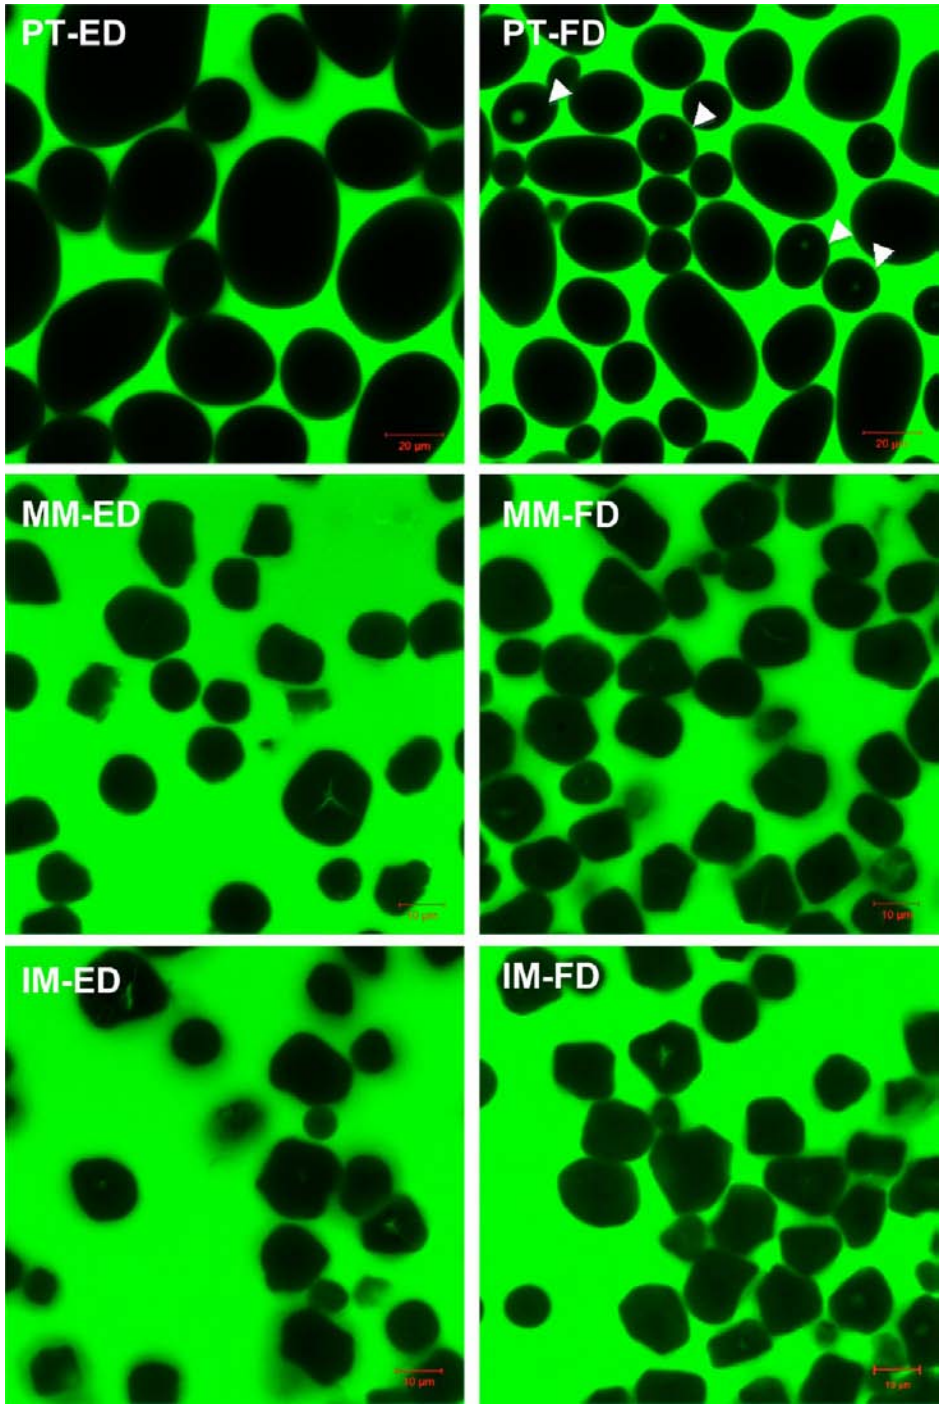

Figure 3. CLSM micrographs of ethanol- and freeze-dried starch granules suspended overnight in FITC-dextran solution (PT, potato tuber; MM, mature maize; IM, immature maize; ED, ethanol-dried; FD, freeze-dried).

granules, which show similar smooth surface structures (Figure 2). The scratches and roughness are likely caused by the forced distortion of starch granules due to local explosive release of water vapor from the builtup pressure inside the rigid granules, as the water molecules try to escape through the solid internal structure and smooth surface structure under the vacuum conditions. The presence of pores and channels on the surface and inside the MM and IM starch granules, respectively, facilitates the escape of water molecules during FD, resulting in no apparent changes to the granular structure when compared with the W controls and those after OD and ED processes.

Some micropores might be generated during FD but would not be easily observed by SEM, because the pores could be covered by the platinum sputter coating (at least 10-nm thickness) used in the sample preparation. To assess the possible generation of micropores, a fluorescent FITC-dextran probe (molar mass 20 kDa, $R_h \approx 3.3$ nm) was used, and its diffusion into starch granules was observed using CLSM.[12] The size of the FITC-dextran probe is similar to that of α-amylase, the rate-determining enzyme during granular starch digestion;[21] therefore, the diffusion of this probe can be used to identify the ability of α-amylase to diffuse into starch granules. CLSM

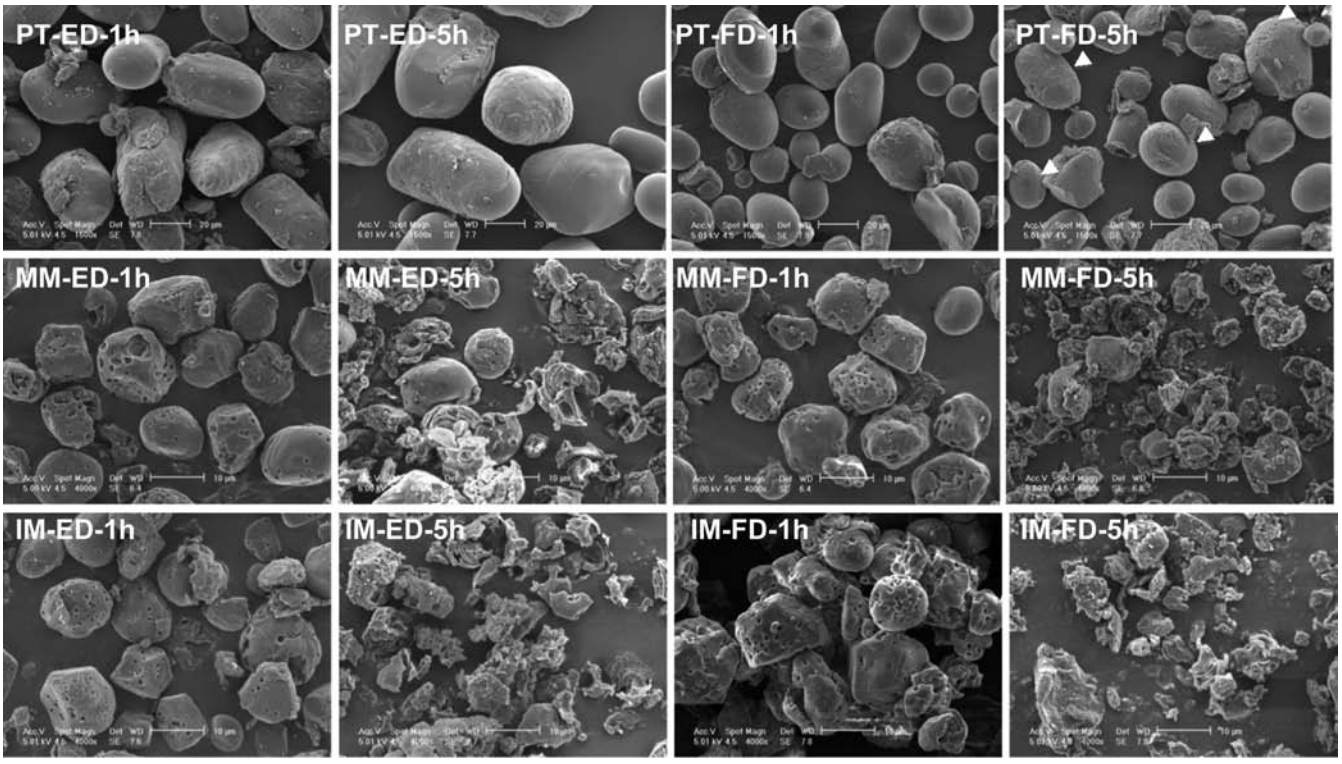

Figure 4. Morphologies of ethanol- and freeze-dried starch granules/fragments after 1- and 5-h in vitro digestion (PT, potato tuber; MM, mature maize; IM, immature maize; ED, ethanol-dried; FD, freeze-dried).

micrographs of PT, MM, and IM starch granules in the FITC-dextran solution are presented in Figure 3. No qualitative differences are observed in the internal structures of MM-ED, MM-FD, IM-ED, and IM-FD starch granules, which show the characteristic central cavity and extended channels of various sizes. There are, however, apparent differences between the internal structures of PT-ED and PT-FD starch granules. No internal fluorescence can be detected within PT-ED starch granules, especially at the hilum, after they had been exposed to the FITC-dextran probe, suggesting that the surface of PT starch granules was not greatly damaged by the ED process and that it was impermeable to the enzyme-sized FITC-dextran because of the effective barrier of tightly packed starch molecules.[27] The FITC-dextran probe, on the other hand, can diffuse into the hilum of the PT-FD starch granules under the same diffusion conditions as for the PT-ED starch granules. This clear distinction suggests that the surface of the PT-FD starch granules is more porous than those of the PT-OD and PT-ED starch granules.

After 1 h of in vitro digestion, the surface pores of maize starch granules (MM-ED, MM-FD, IM-ED, and IM-FD) became larger (Figure 4). The maize starch granules were broken into smaller fragments and debris, sometimes with visible growth rings after 5 h of in vitro digestion. The hydrolytic pattern of the amylolytic enzymes on starch granules is not random, with the surface pores and internal channels being rapidly attacked in the beginning of the digestion. The apparent diameter of these internal channels ranges from 0.007 to 0.1 μm, whereas that of the surface pores is larger, varying between 0.1 and 0.3 μm.[24,28,29] The presence of surface pores and internal channels in maize starch granules enables the diffusion of enzymes, namely, α-amylase (3−4 nm diameter) and amyloglucosidase (8−10 nm diameter), into the hilum of starch granules during digestion,[25,29,30] allowing the internal corrosion or inside-out digestion pattern.[18] After prolonged digestion, the internal structure of starch granules becomes hollow, which can then be easily broken into smaller fragments or debris. There are no qualitative differences among MM-ED, MM-FD, IM-ED, and IM-FD starch granules, consistent with their insignificantly different k values.

On the other hand, the granule surfaces of PT-ED and PT-FD starch granules were roughened, sometimes with visible scratches, after 1 h of in vitro digestion (Figure 4). A further increase in surface roughness, sometimes with deep cracks, is observed on some granules after 5 h of in vitro digestion. Potato starch granules lack surface pores and internal channels, and thus, they are slowly digested because the enzymes have to break through the dense molecular packing at the surface of starch granules to diffuse into the hilum ("exocorrosion" digestion pattern).[10] Furthermore, some pinholes can be observed on the surface of the PT-FD starch granules, but not the PT-ED starch granules, after 5 h of in vitro digestion. The SEM images of digested PT-FD starch granules are consistent with the higher porosity of undigested PT-FD starch granules deduced from CLSM micrographs (Figure 3). However, the drying process does not change the overall starch digestion pattern: inside-out pattern for maize starch granules and exocorrosion pattern for potato starch granules.

Gelatinization Properties. Starch gelatinization is an endothermic transition corresponding to the dissociation of amylopectin double helices from a semicrystalline structure to an amorphous conformation.[31] The gelatinization properties of starch granules dried using different methods are summarized in Table 2. The gelatinization temperatures of maize (IM and MM) and PT starch granules, except PT-FD starch granules, range from 64 to 78 °C, which are within the range reported by

Table 2. Gelatinization Properties (Measured by DSC) of Potato and Maize Starches under Different Drying Conditions[a]

[b]PT, potato tuber; MM, mature maize; IM, immature maize; OD, oven-dried; ED, ethanol-dried; FD, freeze-dried; W, wet/not dried.

others.[32] The gelatinization temperatures and ΔH values of MM starch granules are slightly higher than those of IM starch granules, which is likely due to the annealing of starch granules during field drying of MM.[33] All dehydrated starch granule samples show lower gelatinization temperatures and ΔH values than their W control counterparts. The FD process significantly decreases ($p < 0.05$) both the gelatinization temperatures and ΔH values of all starch granule samples, especially the PT starch granules. Other drying methods (OD and ED), in comparison, result in only slightly lower gelatinization temperatures and ΔH values, suggesting that OD and ED induce fewer structural changes than FD and/or the W controls are annealed during storage in the solution. The gelatinization temperature reflects the heat stability of the crystallites, whereas the ΔH value is associated with the amount of molecular order and crystallinity.[31] Therefore, the disruption of the crystalline arrangement (long-range ordered structures) and/or the reduction in the amount of double helices (short-range ordered structures) might have occurred during the FD process. To further understand the differences in the starch gelatinization properties after drying processes, the crystallinity and molecular conformation of starch after drying were analyzed and compared.

Starch Crystallinity and Molecular Order. XRD was used to study the type and level of starch crystallinity or long-range order. X-ray diffractograms of PT, MM, and IM starch granule samples are shown in Figure 5A. Maize starch granules, irrespective of the drying method or stage of maturity, exhibit the A-type polymorph (major peaks at ~15°, 17°, 18°, and 23° 2θ) with similar peak heights and widths. The percentages of crystallinity, calculated from the ratio of the total peak area to the total diffraction area, are similar for all maize starch granules (Table 3). On the other hand, PT starch granules show the B-type polymorphic pattern (major peaks at ~5°, 17°, 22°, and 24° 2θ) with marked differences observed in the type and level of crystallinity between the PT-OD/ED and PT-FD starch granules, where the peaks in the diffractogram of the PT-FD starch granules are lower and broader (less sharp) than those in the diffractogram of their OD/ED counterparts. Furthermore,

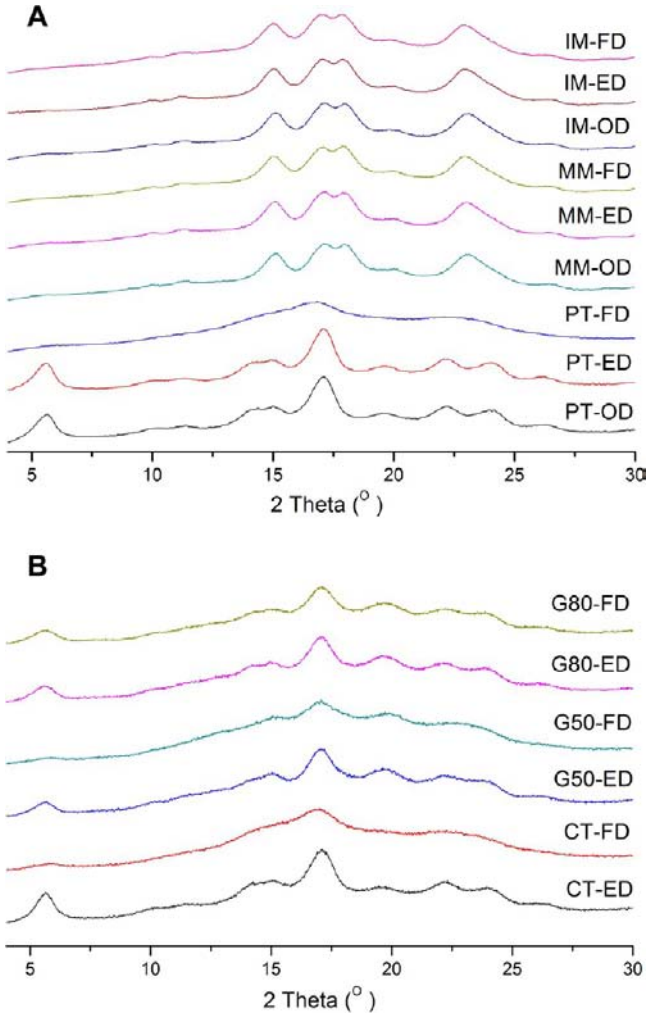

Figure 5. X-ray diffractograms of oven-, ethanol-, and freeze-dried starch granules (PT, potato tuber; MM, mature maize; IM, immature maize; CT, canna tuber; G50, Gelose 50; G80, Gelose 80; OD, oven-dried; ED, ethanol-dried; FD, freeze-dried).

the percentage crystallinity of the PT-FD starch granules is about 50% of that for those of the PT-OD and PT-ED starch granules. The results indicate that FD significantly alters the crystalline structure of the PT starch granules.

Solid-state NMR spectroscopy was used to determine whether the changes observed in long-range crystalline order are consistent with the changes in short-range molecular order; NMR spectra are shown in Figure 6. All maize starch granules, irrespective of drying method and stage of maturity, display similar spectra with a triplet in the C1 region at 101.6, 100.4, and 99.3 ppm, typical of the A-type double-helical conformation.[34] The PT-OD and PT-ED starch granule samples display a doublet in the C1 region with distinctive signals at 110.79 and 99.72 ppm, expected for the B-type polymorphic starch.[35−37] However, the intensity of this doublet is greatly reduced in PT-FD starch granules, where it is no longer visible in the NMR spectrum. To calculate the degree of molecular order in the starch granule samples, gelatinized maize starch was used as an amorphous standard, and its intensity at 84 ppm was matched to those in the NMR spectra of the starch granule samples.[16] Subtraction of the sample NMR spectrum from the amorphous standard spectrum reveals a doublet or a triplet in the C1 region for the double helix and a smaller peak around

103 ppm for the V-type single helix.[36] Calculating the areas of these peaks gives the percentages of double-helical, single-helical, and amorphous starch shown in Table 3. The results of molecular order from NMR analysis are similar for all maize starch granule samples, in a good agreement with the degree of crystallinity from XRD, indicating that both the long-range crystallinity and the short-range molecular order are conserved under the three drying methods. A similar phenomenon was observed for the PT-OD and PT-ED starch granule samples; however, a notable difference of a ~40% reduction in double-helical order was observed for the PT-FD starch granule sample, which is slightly lower than the loss of crystalline order (~50%) analyzed by XRD. It was reported in a previous study[31] that the amount of double helices is higher than the degree of crystallinity and, thus, not all double helices participate in the crystalline structure in native starch granules. The results suggest that FD causes slightly greater disruption to the long-range crystalline packing of PT starch granules than the short-range molecular order, that is, the misalignment or disruption of crystallites with less unwinding of the double helices.

The ratios of absorbance at 1045 and 1022 cm^{-1} from the FTIR spectra have been associated with ordered (organized) and amorphous (less organized) structures of starch, and their absorbance ratio can be used as an index to characterize the short-range alignment of double helices.[15] The absorbance ratios for all maize starch granule samples are similar (Table 3), irrespective of their drying method and stage of maturity, whereas that of the PT-FD starch granule sample is significantly lower than those of the PT-OD and PT-ED starch granule samples. The FTIR results are in good agreement with the XRD and NMR results, indicating that a decrease in the molecular order of PT starch granules by FD, which is likely to be associated with the disruption of double helices. As observed from the gelatinization properties of PT starch granule samples (Table 2), the PT-FD starch granules have considerably lower T_o and ΔH values, whereas these values are almost conserved for other drying methods compared with the PT-W control. The current results corroborate previous reports that showed a reduction in the ΔH and gelatinization temperatures of potato starch granules but not wheat starch granules after freeze-drying.[38−40]

From previous reports and the current findings, it is evident that freeze-drying has less of an effect on the structure and molecular packing of A-type polymorphic cereal starches (wheat and maize) than those of potato starch granules. This raises an interesting question as to the effects of drying methods on other B-type polymorphic starches from both cereals and tubers, which have not yet been reported but which would be useful for understanding the mechanism behind the alteration of molecular packing of freeze-dried starches. In a recent report, Zhang et al.[41] reported an increase in the crystallinity of starch granules isolated from freeze-dried Chinese yam; however, this does not represent the freeze-dried isolated starch granules.

The X-ray diffractograms of additional B-type polymorphic starches (CT, G50, and G80) after being subjected to ED and FD processes are presented in Figure 5B. Similarly to the PT starch granules, the diffraction peaks of CT and G50 starch granules are shorter and broader after the FD process than after the ED process, confirming the ability of FD to alter the molecular packing of B-type polymorphic starches. The decrease in crystallinity or increase in amorphous character results in an increase in the enzymatic hydrolysis rate of CT and G50 starches after FD (Table 1). However, the effects of FD are less apparent for G80 starch granules, probably because of the high amylose content and/or very small granular size of G80, which needs further investigation.

Apart from changes in surface morphology, the increased digestion rate of FD starches could be due to differences of molecular order in starch granules, related to the starch polymorphism rather than the botanical sources, for example, cereal grains versus tubers. At least two molecular-level hypotheses can be proposed to explain the alteration of short- and long-range molecular order after FD (but not FT treatment) in B-polymorphic starches. First, the higher amount of intracrystalline water in B-type polymorphic starch might distort the helical organization of amylopectin molecules by sublimation. However, this hypothesis should also apply to OD

samples, which do not show the effect. Alternatively, B-polymorphic starches with more stable intermolecular structures compared to A-polymorphic starches, due to more longer branch chains, might hinder the passage of subliming water, ultimately increasing internal pressure and destabilizing the helical structure and molecular order under high vacuum. In contrast, because of the lower and more scattered intercrystalline water and loosely packed internal structure caused by a larger population of short amylopectin branches, the subliming water molecules can escape A-polymorphic starch granules more easily, exerting lesser internal pressure. A key difference between the OD and FD methods is the effect of temperature on starch chain mobility. The greater rigidity of starch chains during FD compared with OD means that, although both processes involve removal of vapor-phase water, the lower temperature involved in freeze-drying is more likely to result in local fracture and structure disorganization events as a result of water removal. We therefore propose that the effect of freeze-drying on B-type polymorphic starches is due to a combination of local (crystalline packing, long branches) and larger-scale (lack of pores and channels) effects, resulting in structural disorganization from nanometer to micrometer length scales.

In summary, oven and ethanol drying are mild dehydration methods that do not significantly affect the digestion, thermal, or structural properties of starches compared with their counterparts that have never been dried. However, freeze-drying can result in a marked increase in the digestion rate of B-type polymorphic starches, but not that of A-type polymorphic starches. Freeze-drying not only generates some micropores on the surface of potato starch granules, but also disrupts both crystallinity and molecular order, each of which can cause an increase in the digestion rate.

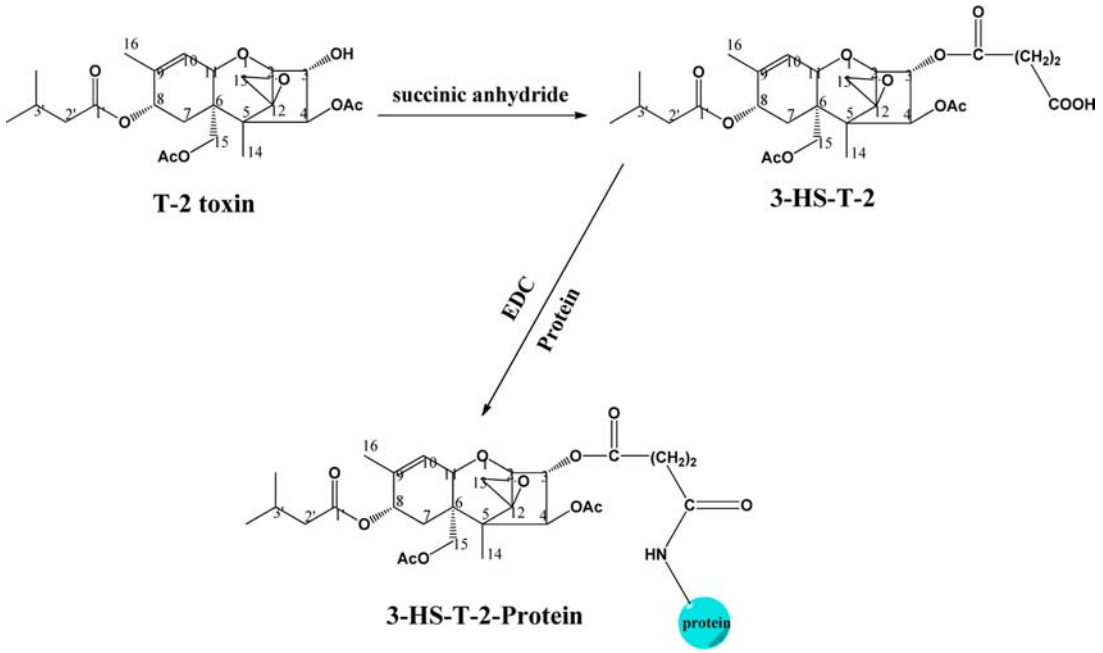

Figure 1. Synthesis of T-2 toxin immunogen and coating antigen.

assay (ELISA) is a very mature and well-applied technology for T-2 toxin monitoring.[29] For the screening of T-2 toxin, the ELISA method generally based on a competitive assay format by using a specific anti-T-2 toxin antibody. Moreover, compared with instrumental analytical methods, ELISA method does not need complicated sample preparation, and could be applied for T-2 toxin screening.[31]

Most antibodies used in the previously reported immunoassays cannot distinguish T-2 toxin and HT-2 toxin (a metabolite of T-2 toxin) in the ELISA method due to their similar structure (Supporting Information, SI, Figure S1).[31−33] When an ELISA method gave a positive result, it was difficult to make sure whether the contaminants were T-2 toxin, HT-2 toxin, or both. For this reason, a specific anti-T-2 toxin monoclonal antibody (mAb) was produced and characterized, which could only bind to T-2 toxin with negligible CR value to most mycotoxins, including HT-2 toxin. Using this specific antibody, an ELISA method for the determination of T-2 toxin in rice was developed. And this developed protocol was confirmed by UPLC-MS/MS (ultrahigh performance liquid chromatography-tandem mass spectrometry). To the best of our knowledge, this is the first time that T-2 toxin specific antibody was produced, and this developed ELISA method could specially recognize T-2 toxin rather than the combination of T-2 toxin and HT-2 toxin.

MATERIALS AND METHODS

Chemicals and Reagents. T-2 toxin, HT-2 toxin, 3-acetyl-deoxynivalenol (3-AcDON), 15-acetyl-deoxynivalenol (15-AcDON), deoxynivalenol (DON), neosolaniol (NEO), and nivalenol (NIV) standard were obtained from Fermentek biotechnology, Israel. BSA (bovine serum albumin), DOM-1 (SI Figure S1), OVA (ovalbumin), T-2-triol, and T-2-tetraol were obtained from Sigma-Aldrich (St. Louis. MO, U.S.). Peroxidase-conjugated goat antimouse IgG was obtained from Jackson ImmunoResearch Laboratories, Inc. (West Grove, Pa, U.S.). Water was purified using a Milli-Q Synthesis system from Millipore (Bedford, MA, U.S.). HPLC grade acetonitrile was purchased from Dima Technology (Muskegon, MI, U.S.). Other reagents were analytical grade obtained from Beijing Reagent Corp. (Beijing, China)

Apparatus. 96-Well polystyrene microtiter wells were purchased from Costar (Costar Inc., Milpitas, CA, U.S.). Waters Acquity UPLC system, Acquity BEH C18 column (50 × 2.1 mm^2 I.D., 1.7 μm particle size), and Micromass Quattro Premier XE triple quadrupole mass spectrometer were from Waters (MA, U.S.). Spectra Max M5 microplate reader (Molecular Devices, Sunnyvale, CA, U.S.) was obtained for this study.

Monoclonal Antibody (mAb) Production. The structure of T-2 toxin is shown in Figure 1. Hapten (3-HS-T-2) was prepared by esterification at the C3 position. Briefly, 10 mg of T-2 toxin was dissolved in 0.4 mL pyridine. Then 210 mg of succinic anhydride was added and stirred for 4 h in a boiling water bath. Dry pyridine and the residues were redissolved using 5 mL of chloroform. Five mL of deionized water was added for washing, and then the water was removed with centrifugation at 3000*g* for 5 min. The washing step was repeated 4 times. Then the chloroform was dried to obtain hapten 3-HS-T-2 under a gentle stream of nitrogen at 60 °C.

This hapten was used to prepare the immunogen (3-HS-T-2-BSA) and coating antigen (3-HS-T-2-OVA). Briefly, solution A was prepared by dissolving the hapten in 1 mL of DMF, while Solution B was prepared by adding 25 mg BSA (OVA) and 15 mg EDC in 5 mL PBS (0.1 M, pH 8.0). Then,solutions A and B were mixed and stirred for 24 h at room temperature. After that, the mixture was dialyzed in PBS (pH7.4, 0.01 M) for 3 d to obtain immunogen and coating antigen (the synthesis protocol shown in Figure 1).

The preparation procedure for anti-T-2 toxin mAb and immunoglobulin were performed as previously described.[34] Briefly, immunize ten female BALB/c mice subcutaneously with immunogen emulsified in Freund's complete adjuvant (FCA). For booster immunization, each mouse was immunized subcutaneously with immunogen in Freund's incomplete adjuvant (FICA) every four weeks for four times (immune procedure was shown in SI Table S1). In order to select the optimum mouse for the subsequent fusion, the serum of each mouse was collected and the titer was monitored by the ELISA method ten days after the last injection. The mouse was boost immunized with immnogen without adjuvants four days before fusion. The splenocytes were fused SP2/0 myelome cells with the help of PEG 1500, and the hybridomas were cultured in 96-well plates. Select and screen the culture supernatant to make sure the hybridomas which excreted the highest affinity anti-T-2 toxin mAb. The cultured

dx.doi.org/10.1021/jf404818r | J. Agric. Food Chem. 2014, 62, 1492−1497

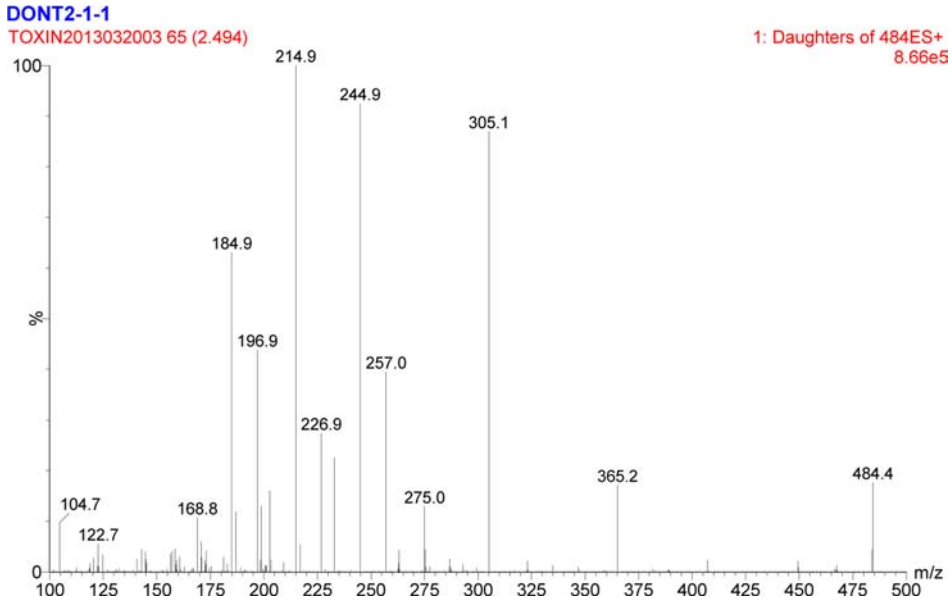

Figure 2. MS/MS spectrum of T-2 toxin $[M + NH_4]^+$.

hybrioma cells ($5-10 \times 10^6$ cell) were injected intraperitoneally into a mouse, and the anti-T-2 toxin mAb was prepared from the ascites fluid.

Principle and the Procedure of ELISA. The ELISA procedure for T-2 toxin determination was performed previously described.[31] 3-HS-T-2-OVA was performed as the coating antigen and the anti-T-2 toxin mAb working solution was prepared at a dilution of 1/6000 in PBS. Each well was individually analyzed, and the values were plotted to yield the calibration curve.

Calibration curves were prepared at 11 concentration levels with the initial concentration at 10 000 ng/mL. The following concentrations were one-third of the previous in turn. Each concentration was run in triplicate, and standard curves were fitted with a four-parameter logistic equation by using Origin version 7.0 (OriginLab, Northampton, MA, U.S.).

Sample Preparaton for ELISA Analysis. Two grams of rice samples were weighed into 50 mL polypropylene centrifuge tubes. After that, 20 mL of ethyl acetate was added for extraction. Then the mixture was vortexed for 3 min and centrifuged at 5000 rpm for 15 min at 4 °C. Ten milliliter aliquots of the supernatant of each sample were drawn to other centrifuge tubes and dried under a gentle stream of nitrogen at 60 °C. The residue was redissolved by 1 mL of 10% methanol and filtered through a 0.22 μm membrane. Fifty microliter aliquots of the supernatant of each sample were added to a 96-well plate for ELISA analysis.

Accuracy and Precision. Negative rice samples, which were previously confirmed by UPLC-MS/MS analyses, were spiked with T-2 toxin at concentrations 40, 200, and 1000 μg/kg. Analysis was performed according to the developed protocol with five replicates each (n = 5), and accuracy and precision were calculated on the basis of the standard curve.

UPLC-MS/MS Method. Results obtained from the developed ELISA protocol were verified and confirmed by an UPLC-MS/MS method. An Acquity BEH C18 column was applied in a Waters Acquity UPLC system for T-2 toxin separation, with the oven temperature maintained at 30 °C. A Micromass Quattro Premier XE triple quadrupole mass spectrometer detector was coupled to the UPLC system via an ESI interface. The analysis was performed in positive ionization mode. The optimized chromatographic conditions were as follows: Mobile phase, 0.005 mM ammonia−water/acetonitrile (40:60, v/v); isocratic elution with the flow rate, 0.3 mL/min; and injection volume, 10 μL.

For monitoring T-2 toxin, Multiple Reaction Monitoring mode was adopted. Quadrupoles 1 and 2 were set to transmit the precursor molecular ion ($[M + NH_4]^+$) of T-2 toxin (m/z 484) and the product ions, respectively. In this research, we choose m/z 484 as the precursor ion and m/z 214.9 and m/z 244.9 as the product ions (Figure 2).

RESULTS AND DISCUSSION

mAb Preparation and Characterization. In this research, the anti-T-2 toxin mAb produced in this research showed high titer with a low LOD value. In order to characterize the specificity of the mAb, another 9 mycotoxins (SI Figure S1) were determined by this developed ELISA protocol. The cross-reactivity (CR) values were calculated using the following equation.

$$\mathrm{CR}(\%) = \frac{\mathrm{IC50\ of\ T\text{-}2\ toxin}}{\mathrm{IC50\ of\ analogue}} \times 100\%$$

where IC_{50} is half maximal inhibitory concentration of a substance.

The selectivity of T-2 toxin and its analogues is shown in Table 1. It can be concluded that mAb shows a negligible CR value to most of the mycotoxins investigated in this research, including HT-2 toxin. The CR value and IC_{50} value of HT-2 toxin was 3.08% and 717 ng/mL, respectively. Considering the negligible CR value for other mycotoxins, this developed mAb could specially recognize T-2 toxin.

Table 1. IC50 and Cross-Reactivity (CR) Value of T-2 Toxin Analogues

no.	analogue	IC50 (ng/mL)	CR (%)
1	T-2	22.09	100
2	HT-2	717	3.08
3	T-2 triol	14 000	<0.1
4	T-2 tetraol	>100 000	<0.01
5	NEO	>100 000	<0.01
6	NIV	>100 000	<0.01
7	DON	>100 000	<0.01
8	DOM-1	>100 000	<0.01
9	3-AcDON	>100 000	<0.01
10	15-AcDON	>100 000	<0.01

dx.doi.org/10.1021/jf404818r | J. Agric. Food Chem. 2014, 62, 1492−1497

Sample Pretreatment. The extract efficiency from a complicated biological matrix depends on the structure of the target analyte. In the previous researches, acetonitrile/water (85:15, v/v) was the most common extraction solvent for T-2 toxin extraction.[24,35,36] Besides, dichloromethane, ethyl acetate, methanol, and PBS have been adopted as the extraction solvent.[37−40] On the basis of the previous research, ethyl acetate with high volatility and low toxicity was adopted as the extraction solvent in this research. On the basis of the previous report, ethyl acetate was adopted as the extraction solvent because of its high volatility and low toxicity. Then the supernatant was condensed in order to wipe off the organic solvent and get a lower LOD (limit of detection).

Sensitivity. To evaluate to sensitivity of the proposed ELISA protocol, IC_{50} and LOD (measured by IC_{10}) were obtained from the sigmoidal standard curve (Figure 3). LOD

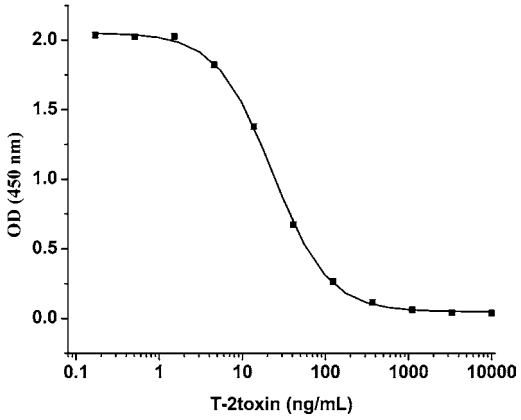

Figure 3. Standard curve of ELISA for T-2 toxin.

for T-2 toxin was 5.8 μg/kg, while IC50 was 23 μg/kg. Compared to the published colorimetric ELISA methods,[31] this research exhibited a higher sensitivity for T-2 toxin. Besides, published immunoassays for T-2 toxin mainly focused on the sum of T-2 toxin and HT-2 toxin. This is mainly due to the similar structure between T-2 toxin and HT-2 toxin, and the broad specificity mAb used in those methods could not distinguish one from another.[41−46] In this research, a high specific antibody was produced, which could recognize T-2 toxin specifically. The developed ELISA using this mAb could detect T-2 toxin in rice specifically, rather than the sum of T-2 toxin and HT-2 toxin.

Accuracy and Precision. Recoveries of T-2 toxin in fortified samples were calculated, and accuracy and precision were evaluated with five replicates each on three validation days. The fortified levels were 40, 200, and 1000 μg/kg. The mean recovery of T-2 toxin in spiked samples ranged from 72.0% to 108.5% for rice samples, and the intraday and interday variation were less than 16.8 and 13.7%, respectively (Table 2).

Table 2. Accuracy and Precision of T-2 Toxin in Rice with Five Replicates Each (n = 5) on Three Validation Days (n = 3)

matrix	analyte	spiked level (μg/kg)	recovery (%)	interday RSD (%)	intraday RSD (%)
rice	T-2 toxin	40	74.8−91.9	1.27−8.97	8.16
		200	77.9−108.5	3.15−16.8	13.7
		1000	72.0−100.7	1.73−10.8	12.4

Comparison of the ELISA and UPLC-MS/MS Analyses. Figure 4 demonstrates the correlation between the developed

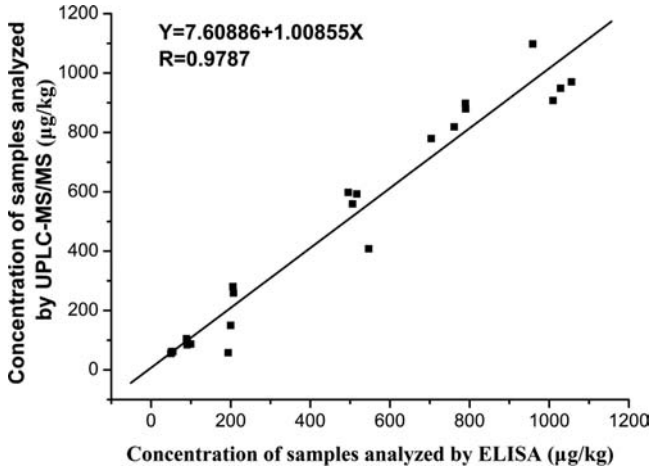

Figure 4. Correlation of T-2 toxin assay between the confirmatory UPLC-MS/MS and the ELISA method in rice samples obtained from T-2 toxin spiked at levels of 50, 100, 200, 500, 750, and 1000 μg/kg (n = 4).

ELISA protocol and the confirmatory UPLC-MS/MS method. Rice samples were prepared with T-2 toxin spiked levels of 50, 100, 200, 500, 750, and 1000 μg/kg with four replicates each concentration. The linear regression equation between the two methods was Y = 7.60886 + 1.00855X. The two methods exhibited significant correlation at the various fortified levels with the correlation at 0.9787.

Analysis of T-2 Toxin in Commercial Rice Samples. Commercial rice samples were purchased from local supermarkets in order to verify the applicability of this developed ELISA method. Samples were processed and analyzed according to the established ELISA protocol as well as the UPLC-MS/MS procedure. From all 20 commercial rice samples, 5 were detected with trace amount of T-2 toxin (Table 3). It is well-known that UPLC-MS/MS is a confirmatory method for quantification. The results in Table 3 showed a good correlation between this developed ELISA method and the UPLC-MS/MS method. It can be concluded that these specific ELISA methods could be applied for T-2 toxin detection in rice.

In conclusion, a specific anti-T-2 toxin mAb was produced and characterized in the present study. By the use of this mAb, an ELISA method was developed for the determination of T-2 toxin in rice. The results of the analysis were confirmed by UPLC-MS/MS, and significant correlation was obtained between the two methods. The proposed format offers the advantage of simplicity, rapidity, and cost-effectiveness. With respect to its overall sensitivity and specificity, the method is superior to most reported immunoassays for T-2 toxin in rice. What's more important is that this developed protocol could be specifically applied for T-2 toxin detection rather than the sum of T-2 toxin and HT-2 toxin. This newly developed procedure could be a suitable tool for specific, rapid, semiquantitative, and quantitative detection of T-2 toxin in rice, which will contribute to the control of contamination by this fungal toxin.

were among the earliest to discuss EMA and allergen labeling concerns in 1989 and apply ELISA, SDS−PAGE, and fast protein liquid chromatography (LC) to detect soy proteins in bovine milk.[30,31] Detection limits ranged from 1 to 5%. Cattaneo et al. spiked cheese with soy protein, extracted samples with tetraborate-EDTA buffer, and performed analyses using gel-permeation chromatography, isoelectric focusing, and SDS−PAGE.[32] The respective limits of detection (LODs) were 0.6, 3, and 0.06% soy by weight. Lopez-Tapia et al. determined the LOD of soy and pea protein in milk powder to be 1% in an interlaboratory SDS−CE assay validation study.[10,33] The Lopez-Tapia study confirmed observations by Cattaneo et al. that tetraborate-EDTA buffer efficiently extracts soy proteins from milk proteins.[32,33] The outstanding selectivity of this buffer was also used to concentrate soy and pea proteins from milk for LC−MS/MS analysis in an experimental EMA model.[13,34] In an interlaboratory ELISA study, where tetraborate-EDTA extraction buffer was not used, soy, pea, and wheat proteins spiked in milk were detected at the 1% level.[11] The detection of plant proteins in milk products using HPLC−UV, NIR, SPR, perfusion chromatography, and flow cytometry have also been reported without using tetraborate-EDTA buffer.[5,9,12,35−38] These studies commonly accept 1% by weight as a nominal level above which EMA is practical. However, dilution of adulterated products during blending in complex distribution chains may require even more sensitive assays.

These methods may be useful for detecting specific foreign proteins or authenticating food samples, but none of them are especially well suited to performing low cost screening to detect the economically motivated adulteration of SMP with a variety of inexpensive plant proteins. Long electrophoretic or chromatographic separation times, the complicating effects of food processing and matrices on immunochemical assay and chemometric model performance, requirements for multiple different antibodies, and in some cases, expensive instrumentation contribute to this problem. However, the selectivity of tetraborate-EDTA buffer for extracting plant proteins from milk can be put to use in another way to address this problem. In this work, we demonstrate a rapid screening assay using tetraborate-EDTA buffer to prepare SMP for the turbidimetric detection of insoluble plant proteins. It is based on an intrinsic property of normal milk powder, namely, the absence of a visible precipitate upon extraction.

EXPERIMENTAL PROCEDURES

Materials. Reference samples were donated by the USP (Rockville, MD, USA), and their names are followed by USP-assigned identification codes: medium heat SMP (S085), soy protein isolate (A027), pea protein isolate (A011), rice protein isolate (A019), wheat protein isolate (A028), whey (A044), egg whites (A045), high molecular weight fish gelatin (A013), chitosan (A035), sorbitol (A122). Liquid and powdered soy milk products and powdered partially hydrolyzed (bovine whey) infant formula were purchased at a local market. Sequencing grade trypsin was purchased from Promega. Lo-bind microcentrifuge tubes (2 mL) were purchased from Eppendorf. "Fisherbrand" nonsterile, clear, flat-bottom polystyrene 96-well plates were used.

Methods. *Preparation of SMP Samples Containing Plant Proteins.* Plant protein isolate (PI) powders were individually dry blended with SMP to yield mixtures containing 0.03, 0.10, 0.30, 1.00 and 3.00% PI/SMP by weight. SMP and SMP/PI blends were brought up in buffer (30 mM sodium tetraborate/40 mM EDTA/pH 8.3) to 300 mg/mL. Individual PI solutions, without SMP, were prepared in buffer at 15 mg/mL.

Extraction and Turbidimetric Analysis in 96-Well Plates. Immediately after vortex mixing, SMP solution and PI/SMP suspensions in buffer (300 μL, 300 mg/mL) were loaded in 96-well plate column 1 wells, rows B−G, using a multichannel pipettor to deliver 90 mg of SMP test sample and progressively diluted 2-fold with buffer (150 μL) in columns 2−3, to respectively deliver 45 and 22.5 mg of each SMP test sample. Rows B through G were respectively loaded with test samples containing 0−3% PI/SMP. A schematic of the 96-well plate sample layout is provided as Supplemental Figure S1 in the Supporting Information. Wells in columns 4−6, 7−9, and 10−12 were similarly used to prepare replicates of samples prepared in columns 1−3 (rows B−G). Row A was used to prepare duplicate standard curves using only the plant PI without any SMP. Immediately after vortexing, PI solution (300 μL, 15 mg/mL) was deposited in wells A1 and A7. These test portions were progressively diluted 3-fold with buffer in columns A2−6 and A8−12. Buffer was added to produce a final volume of 300 μL in all wells. Solvent blank wells in row H were filled with 300 μL of buffer. Two 96-well plates were prepared for each type of PI/SMP mixture to provide 8 data points at each spike level and 4 data points at each PI (alone) concentration. Plates were centrifuged (Sorvall Evolution RC, Thermo Electron Corporation) at 1,500 rpm (466*g*) for 5 min at 20 °C in a swinging microplate carrier. Supernatants were removed taking care not to disturb sample pellets. Pellets were resuspended in fresh buffer (150 μL) by pipetting them up and down three times using aerosol barrier pipet tips. Samples were centrifuged again, and the supernatants were removed. This washing process was repeated three times. Pellets were finally resuspended in fresh buffer (150 μL), and the absorbance (360 ± 2 nm) was promptly measured, without shaking, for 1 s per well using a VERSAmax microplate reader (Molecular Devices, Sunnyvale, CA) at 20 °C.

Plant Protein Isolate Turbidimetric Standard Curves. Individual plant PI powders without SMP were suspended in buffer (5 mg/mL) and serially diluted 2-fold in 96-well plates so that 300 μL aliquots delivered 0−1.5 mg (dry powder weight). Four technical replicate wells were prepared at 12 concentrations. Test portions were not extracted before measuring the absorbance. Standard curves were prepared by linear regression of the baseline corrected absorbance data, limited to values approximately less than 1 OD unit. The LOD was estimated as three times the ratio of the standard error of the absorbance divided by the slope. The limit of quantitation (LOQ) was estimated as ten times this ratio. Standard curves were used to estimate the recovery of adulterants from samples extracted with tetraborate-EDTA buffer.

Fourier Transform Infrared Spectroscopy. Transmission Fourier transform infrared (FT-IR) measurements were carried out on an Agilent Technologies Inc. (Wilmington, DE; formerly Varian, Randolph, MA) FTS 7000e IR spectrometer operating with Resolution Pro 4.0 software. The optical bench included a Michelson interferometer with an air bearing moving mirror, a KBr substrate beam splitter, and a linearized mercury cadmium telluride liquid N_2 cooled detector. In the absence of a test sample, a 3 min data collection at 4 cm^{-1} resolution from 2200 to 2000 cm^{-1} yielded a peak-to-peak noise level <0.0005 OD. Test samples (~2 mg) were measured as KBr pellets. Test sample single-beam spectra were measured relative to an open beam (air). Spectra were collected from 4000 to 700 cm^{-1} at a resolution of 4 cm^{-1} and 32 scans were coadded and signal averaged.

SDS−PAGE. Pellets extracted from SMP containing 0 and 3% (w/w) protein isolate were suspended in Laemmli buffer containing 5 mM β-mercaptoethanol, heated (100 °C) in a steam bath (10 min), and cooled on ice. Precision Plus Protein Dual Xtra (Bio-Rad, Hercules, CA) protein ladder and samples were loaded onto a 4−20% SDS−PAGE gel (Bio-Rad, precast Criterion), and run in pH 8.3 Tris (89 mM)/Borate (89 mM)/EDTA (2 mM) buffer at 180 V for 60 min. Gels were stained with Gel Code Blue (Thermo Fisher Scientific). Gel images were acquired using a Syngene G:Box (Synoptic Group, Frederick, MD).

Reduction, Alkylation, and Digestion of Proteins. Solvent (200 μL: 94.9% water, 5% CH_3CN, 0.1% HCOOH) was added to single wells containing pellets from extracted SMP, plant protein isolate, or

plant protein adulterant in SMP from a 96-well plate loaded with 90 mg of test sample. Resuspended pellets were diluted with 50 mM ammonium bicarbonate containing 5 mM dithiothreitol (DTT) and heated (100 °C) in a steam bath for 10 min. After rapid cooling on ice, iodoacetamide (IAA) was added to a final concentration of 14 mM and samples were incubated in the dark for 30 min. DTT was added in 1.3-fold stoichiometric excess to IAA, and test portions were incubated in the dark for 15 min. Alkylated test samples were digested with trypsin at 37 °C overnight at a 1:50 (w/w) ratio. Digestions were acidified to a final 0.1% HCOOH by the addition of 10% HCOOH.

nLC–MS/MS Analysis. Digested samples (~125–200 ng) were analyzed using an LTQ-XL (Thermo Fisher Corp.) equipped with a CaptiveSpray (Bruker) electrospray source operated in the positive ionization mode. Collision-induced dissociation (CID) spectra were acquired in a data-dependent mode from the most abundant nine ions detected in survey scans. Chromatographic conditions: nano-Acquity LC system (Waters Corp., Milford, MA, USA), loop volume = 5 μL, C18 MAGIC column (0.1 × 50 mm, Bruker), flow rate = 1 μL/min, sample compartment temperature = 4 °C, column temperature 20 °C, run time = 60 min; mobile phases, A = 99.9% H_2O/0.1% HCOOH, B = 99.9% CH_3CN/0.1% HCOOH; gradient conditions started at 5% B and were held for 30 s, then linear gradient to 10% B at 1 min, then linear gradient to 60% B at 46 min, then linear gradient to 80% at 46 min and hold for 2 min, then linearly return to 5% B at 48 min and hold for 12 min.

Peptide Identification. LTQ-XL mass spectrometer .raw data files were converted to .mgf files using ProteoWizard's freely available software program MSConvert.[39] MASCOT search engine (2.3.02) was used to query .mgf files against the SwissProt database 20110214 (525,997 sequences, 185E6 residues) using the following parameters: mass values = monoisotopic; protein mass = unrestricted; enzyme = trypsin; max. missed cleavages = 2; variable modifications = oxidation (M), carbamidomethyl (C), Gln > pyro-Glu (N-terminal Q), Glu > pyro-Glu (N-terminal E); peptide charge = +2, +3; peptide and MS/MS tol. = ±0.8 Da; instrument type = ESI-trap. Individual proteins were inferred to be present if at least two different peptide sequences exceeding the critical peptide MASCOT score were detected.

RESULTS AND DISCUSSION

Soy, pea, rice, and wheat protein isolates extracted from SMP/PI suspensions in 96-well plates were turbidimetrically detected using a semitargeted technique for the rapid screening of milk powder for EMA with insoluble foreign proteins. Because previous reports described adulterant concentration as a percentage of the total sample weight, soy data are initially presented using this metric to facilitate comparison with published work.[5,13,33] Extracted sample absorbance in Figure 1 linearly increased with the addition of soy adulterant to SMP from ~0.1–1.0 OD units. Liquid and soy beverage powder added to SMP at 5% by weight yielded strong positive results with absorbance values ranging from 0.4 to 1.2 OD (data not shown). By contrast, negative control samples extracted from 5% sorbitol, chitosan, gelatin, whey, egg protein, and infant formula containing partially hydrolyzed whey in SMP were turbidimetrically and visually indistinguishable from the SMP blank. The observed lack of a pellet in these samples demonstrates that the extraction method is to some degree selective for plant proteins over other sources of added protein, polysaccharides, or monosaccharides potentially encountered in EMA schemes. Instead of longer visible wavelengths often used in turbidimetric assays, 360 nm was used because it was empirically found to yield the strongest signal.

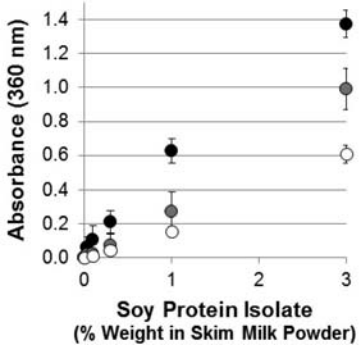

Figure 1. Turbidimetric detection of soy protein isolate extracted from skim milk powder in 96-well plates. Powder sample weight loaded: 22.5 mg (open circles), 45 mg (shaded circles), 90 mg (filled circles). Data points represent the mean (n = 8) ± one sample standard deviation.

It is more direct to specify the weight of spiked adulterant, instead of a weight percentage, because different SMP sample weights were used to explore the assay's dynamic range. The spiked adulterant weight and extracted sample absorbance data for soy in Figure 1 are replotted in Figure 2, along with pea, rice, and wheat protein isolate data. In Figure 2, absorbance begins to exhibit nonlinearity with increases in the theoretical amount of plant protein deposited above ~900 μg (assuming 100% extraction efficiency). This parallels the onset of nonlinearity in Figure 1 above 1% soy in 90 mg SMP samples.

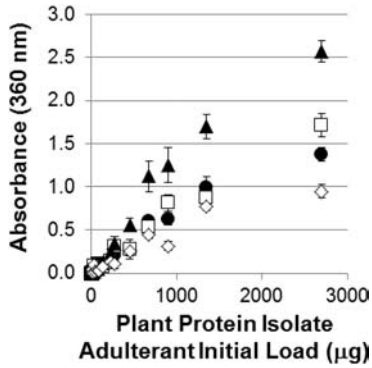

Figure 2. Turbidimetric detection of soy, pea, rice, and wheat protein isolates extracted from 22.5 to 90 mg of skim milk powder samples spiked with 0–3% plant protein isolate by weight. Data points represent the mean (n = 8) ± one sample standard deviation. Protein isolate symbol legend: rice (triangles), pea (squares), soy (closed circles), wheat (diamonds).

Extraction Efficiency. Plant protein extraction efficiency and gel formation can be affected by intra- and intermolecular protein interactions.[40–42] Changes in the resuspended particle size distribution could affect turbidimetric responses because light scattering is a function of particle size.[43] To survey for the influence of these effects and measure extraction efficiencies, absorbance differences between nonextracted and extracted plant adulterant standards alone (without SMP) and extracted adulterant-spiked SMP (Figure 2) were compared. Linear regression of adulterant weight versus absorbance data was performed from 0.1 to 1.0 OD. The extracted to nonextracted sample linear regression slope ratio was multiplied by 100 to calculate adulterant extraction efficiency in the presence and absence of SMP. Linear regression, LOD, LOQ, and extraction efficiency results are presented in Table 1. Recovery estimates were constrained to absorbance values nominally equal to the LOD (~200 μg of plant protein isolate). LODs were similar for

Table 1. Turbidimetric Assay Performance Metrics for Detection of Protein Isolates

protein isolate	slope (OD 360 nm/mg)	*Y*-intercept (OD)	R^2	LOD[a] (% wt)	LOD (μg)	LOQ (μg)	recovery (%) with SMP	recovery (%) without SMP
soy	0.7	0.0020	0.9829	0.2	190	575	50	65
rice	1.6	−0.0472	0.9728	0.1	115	350	100	96
wheat	0.6	0.0015	0.9296	0.2	191	580	25	47
pea	0.7	0.014	0.9525	0.2	204	618	90	46

[a]90 mg powder sample basis.

all isolates, ranging from 0.1 to 0.2% by weight (for 90 mg SMP load), and corresponded to 115−205 μg of spiked protein (independently of SMP load). This analytical sensitivity is comparable to or better than that offered by other reported ELISA, SDS−PAGE, and CE assays for detecting dairy product EMA with plant proteins and is achieved more rapidly using less equipment.[30−33,44] The extraction efficiencies of soy and rice proteins were not substantially affected by presence of SMP matrix in Table 1. However, wheat and pea protein extraction efficiencies were respectively decreased and increased by 50% in the presence of SMP. Soy extraction efficiency independence from SMP is consistent with HPLC−fluorescence data reported by Luykx, but, for unknown reasons, the dependency of pea extraction is not.[13] The 96-well plate assay format detected adulteration of 90 mg SMP samples spiked with ∼200 μg of plant protein isolate, a level (0.2% by weight) generally considered satisfactory for EMA detection. If adulterated samples are blended in complex supply chains, detection at even lower concentrations may be required.

A Larger Capacity Microcentrifuge Assay Format. Linear relationships between the protein spike concentration and absorbance in Figure 1 indicate that even lower amounts of adulterant, on a percentage of sample weight basis, could be detected by extracting larger amounts of sample. However, the maximum amount of SMP that could be precisely loaded in a single 96-well plate well was limited by three factors: solution viscosity, bubble formation, and well volume. The viscosity of nonspiked SMP solutions exceeding ∼600 mg/mL interfered with pipetting, and these samples formed bubbles. Aerosolization occurred when bubbles burst during pipetting of even lower concentration samples and gradually led to deposit accumulation inside the pipettor. The use of aerosol barrier pipet tips eliminated this problem. Because sensitivity is limited by the amount of SMP loaded in a well, a microcentrifuge tube assay format was briefly examined to increase the maximum sample load from 90 mg (300 μL of 300 mg of solids/mL) in the 96-plate format to 540 mg (1.8 mL × 300 mg of solids/mL). Photographs of pellets extracted using the 96-well plate and microcentrifuge tube assay formats are provided as Supplemental Figures S2 and S3 in the Supporting Information. Resuspended microcentrifuge pellet aliquots were transferred to 96-well plates to measure absorbance. The same linear dependence of absorbance on the amount of protein isolate spiked was observed in the microcentrifuge tube assay format without change in the SMP baseline signal. LODs in the microcentrifuge tube format ranged from 100 to 200 μg as was observed in the 96-well plate assay format in Figure 1. The microcentrifuge tube format is useful for detecting adulteration at low percent weight concentrations due to the more readily visible pellet obtained from larger samples. This enables spot tests to be performed if a microplate reader is not available. Although not explored here, larger samples could be used to achieve LODs at even lower % spike concentrations. Changes in extraction efficiency, baseline absorbance of SMP, and the optimal number of pellet washes need to be investigated to extend analyses to lower adulterant concentrations.

Effects Extraction Buffer Composition on Pellet Washing. The sequential extraction of storage proteins from plant sources by adjusting salt concentrations, pH, and organic solvent composition, known as Osborne fractionation, has been extensively studied, but mechanism(s) are not known through which EDTA-tetraborate buffer selectively precipitates plant proteins from dairy samples.[13,32,42] The formation of insoluble protein−boronate complexes via carbohydrate modified plant proteins and dissociation of casein micelles by EDTA may be involved.[45,46] On the basis of HPLC−fluorescence analysis of soy and pea protein isolate extracted from SMP, storage protein hydrophobicity may also be responsible.[13] Studies of protein extraction from soybean meal do not support isoelectric precipitation as being involved at pH 8.3.[47] To determine the optimal number of pellet washes and the effect of extraction buffer composition during assay development, SMP samples (n = 4) spiked with 0 and 2.5% soy protein isolate were extracted with water, EDTA (40 mM, pH 8.3), tetraborate (30 mM, pH 8.3), or EDTA (40 mM)/tetraborate (30 mM)/pH 8.3. The average resuspended pellet absorbance (n = 4) after each of five successive washes is presented in Supplemental Figure S4 in the Supporting Information. Water alone failed to yield differences between SMP and spiked sample absorbance after five washes. Tetraborate alone failed to yield significant ($p < 0.05$) differences between SMP and spiked test samples until the third wash. The absorbance of both samples continued to decrease in the fifth wash. EDTA alone and EDTA-tetraborate buffer were both very effective for extracting plant proteins and worked equally well. Large stable differences between SMP and spiked samples were apparent after the first wash. No changes occurred after the third wash, where absorbance of SMP-only samples decreased to 0.10 ± 0.00 OD (average ± SD). Three washes also produced optimal results in SMP samples spiked with pea protein isolate (data not shown). The insolubility of soy protein isolate at pH 8.3 in 30−40 mM salt solutions due to hydrophobicity, instead of boronate−plant protein complex insolubility, appears to more significantly contribute to the effectiveness of this extraction technique.[41] SMP solutions prepared in water exhibit a characteristic milky white appearance, but addition of EDTA under conditions of the assay produces transparent colorless solutions. Collapse of milk casein micelles due to EDTA chelation of Ca^{2+} minimizes light scattering, produces transparent SMP solutions, and enables the visual and turbidimetric detection of insoluble material that is otherwise obscured.[48] Detailed EDTA−SMP titration studies were not performed, but this process can be saturated by SMP to produce samples of varying turbidity in the absence of plant proteins, unless EDTA is maintained at some undetermined stoichiometric excess of Ca^{2+}. This is important if the amount of SMP loaded in the assay is increased.

Other Analytical Tools. To determine the composition of pellets detected in the turbidimetric assay and demonstrate a general work-flow for characterization of EMA with insoluble foreign proteins, additional SDS−PAGE, FT-IR, and LC−MS/MS analyses were performed. SDS−PAGE gel images of SMP and spiked (3% by weight) SMP test samples before and after extraction are presented in Figure 3. Nonextracted samples

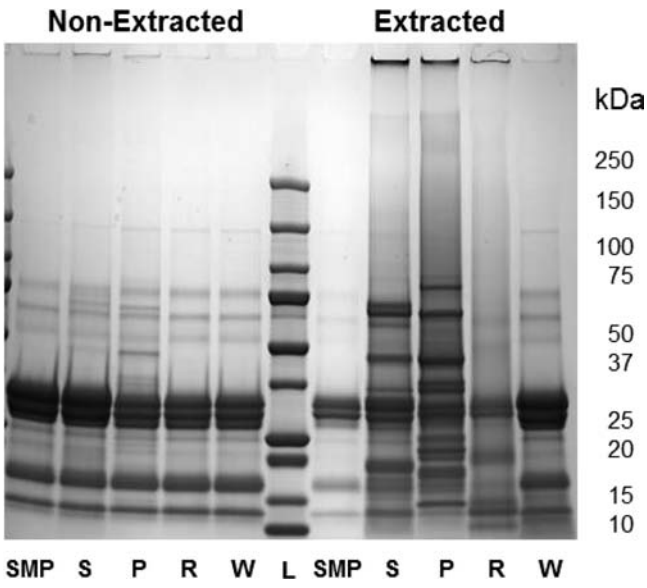

Figure 3. Reducing SDS−PAGE analysis of skim milk powder samples spiked with 3% plant protein isolate by weight before and after extraction with tetraborate-EDTA buffer. SMP = skim milk powder. Plant protein isolates: soy (S), pea (P), rice (R), wheat (W), molecular weight ladder (L).

(lanes 1−5) are dominated by intense bands (25−37 kDa) that correspond to milk proteins (α-S1, α-S2, and β-caseins) known to comprise ∼72% of normal milk protein. All nonextracted samples also exhibit bands (10−20 kDa) corresponding to β-lactoglobulin and α-lactalbumin that normally contribute a total of ∼15% to all milk protein. Nonextracted soy and pea spiked SMP samples (lanes 2 and 3) exhibit additional faint bands (50−75 kDa) that are also observed in extracted spiked samples (lanes 8 and 9) and the corresponding individual protein isolate standards analyzed without SMP (Supplemental Figure S5 in the Supporting Information). These bands are interpreted as being plant protein-specific proteins and are indicative of the protein isolate spike. This contrasts with nonextracted rice and wheat (lanes 4 and 5) where there are no clear differences from nonspiked SMP (lane 1). Comparison of nonextracted (lanes 1−5) and extracted (lanes 7−10) samples in Figure 3 shows that extraction produces distinct banding pattern changes and enables discrimination of spiked from nonspiked samples. The appearance of Figure 3 is consistent with previously reported SDS−PAGE data for soy and pea samples prepared using tetraborate-EDTA precipitation.[13]

Transmission FT-IR of Extracted SMP. Rapid screening of SMP using mid- and near-IR spectroscopy and chemometrics to detect EMA with low and high molecular weight compounds (e.g., melamine and soy protein isolate) is an active research area.[5,6] This is an appealing strategy because the NIR analysis of dry powder does not require samples to be dissolved or extracted. This lends itself to high sample throughput and automation. However, if seasonal or other manufacturing related factors (e.g., heat treatment, storage time) yield sufficiently large SMP matrix variability and compromise chemometric detection models, sample processing may be required to improve adulterant detection. Removal of milk components and concentration of plant proteins via tetraborate-EDTA extraction is expected to simplify IR spectra and facilitate the detection of insoluble foreign proteins but at the cost of lowering assay throughput. The FT-IR spectra of SMP, soy protein isolate, and extracted soy protein isolate are presented in Figure 4. Extracted protein isolate pellets exhibit

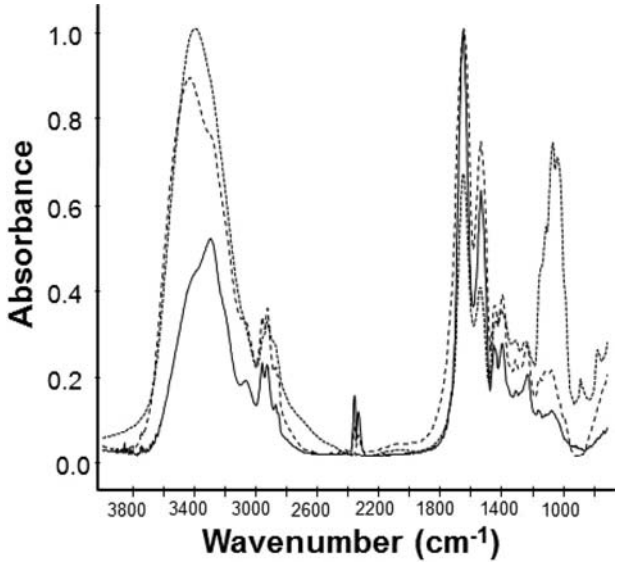

Figure 4. FT-IR KBr pellet transmission spectra of nonextracted skim milk powder and soy protein isolate reference samples, and a pellet extracted from skim milk powder spiked with soy protein isolate at 0.1% by weight. The atmospheric CO_2 stretching band (2360 cm^{-1}) appears as an artifact of the analyte to background single-beam normalization process. Nonextracted reference samples: skim milk powder (top dotted line), soy protein isolate (middle dashed line). Extracted pellet: skim milk powder spiked with soy protein isolate (bottom solid line).

strong amide I (1600−1700 cm^{-1}) and amide II (1500−1600 cm^{-1}) bands and the loss of the intense C−O stretching bands (1000−1200 cm^{-1}) that are uniquely characteristic of milk lactose and detected only in nonextracted SMP. The corresponding pea and rice data are provided as Supplemental Figures S6 and S7 in the Supporting Information. Subtle differences in protein bands between extracted soy, pea, and rice pellets were observed. These data principally indicate that extraction removes soluble lactose and milk proteins and yields pellets from spiked samples that exhibit IR spectra confirming the presence of insoluble proteins. The analysis of pellets using SDS−PAGE and LC−MS/MS, discussed below and in related work by Luykx et al., further indicates that these characteristic amide absorbance bands do not substantially arise from coprecipitated milk proteins.[13] The spectrum of nonextracted SMP in Figure 4 is similar to a published spectrum.[49]

LC−MS/MS Identification of Peptides and Detection of Proteins. To identify peptides and detect proteins in extracted pellets, trypsin digested samples were analyzed by nLC−MS/MS and protein database searching. Table 2 presents a list of proteins detected in the pellet obtained from SMP spiked with soy protein isolate. These soy storage proteins account for ∼70% of all seed protein.[27] Virtually identical lists

Table 2. Proteins Detected in Pellets Isolated from SMP Spiked with Soy Protein Isolate

of soy proteins were previously reported in tetraborate-EDTA extracted pellets from different soy isolate samples, except that α-S1-casein and β-lactoglobulin were not detected in the present study.[13,34] This is presumably due to more extensive washing of the pellet in the 96-well plate assay format presented here. The corresponding protein detection data for pea and rice isolate-spiked SMP samples are presented in Supplemental Tables SI and SII in the Supporting Information. A corresponding abundance of pea and rice storage proteins were detected in these pellets, and the pea list matched those reported in earlier studies.[13,34] The detection of extracted soy, pea, and rice storage proteins amid little to no milk protein confirms the selectivity of tetraborate-EDTA buffer reported in this and previous studies. MASCOT search results for extracted soy, pea, and rice spiked SMP pellets are provided as Supplemental Data Files in the Supporting Information. Analysis of pellets from SMP spiked with wheat protein isolate failed to identify wheat peptides. The addition of glutamine and asparagine deamidation as variable modifications to protein database searches did not improve search results. Wheat storage proteins are generally less soluble in low salt aqueous conditions than soy, pea, and rice and contain many fewer trypsin cleavage sites. The use of more effective organic solvent (alcohol) and endoproteases (e.g., chymotrypsin) that yield a larger number of wheat peptide sequences for MS detection may be required to address this problem in future studies.

Turbidimetric detection of plant proteins extracted from SMP samples offers an inexpensive, fast, and simple procedure to detect a class of foreign proteins suspected of being used in EMA schemes. This is a semitargeted screening approach in that it is not plant-specific and relies on an intrinsic property of SMP, namely, the failure to form a precipitate under assay conditions. It does not require chemometric treatment of data, special equipment, or expertise. It exploits the use of EDTA to render adulterated opaque milk solutions transparent and the insolubility of plant protein isolates to rapidly produce samples for measurement by optical absorbance. The assay is scalable in that different amounts of SMP can be used to achieve different LODs on a percent weight basis. Other plant protein (e.g., zein, lupin, sorghum, millet) sources are expected to yield comparable turbidimetric results due to chemical similarities among storage proteins. Although SMP was studied, other imported high dairy protein concentration products such as milk protein concentrate, whey protein concentrate, and caseinates along with high value finished products such as quark, skyr, and greek yogurt are of special interest. Even without the use of a 96-well plate reader, the addition of as little as 0.1−0.2% by weight of plant protein isolate to SMP was visually detected. These features potentially make the assay useful for performing spot tests in resource poor environments. Very small, portable and inexpensive centrifuges that accommodate 2 mL sample tubes can be purchased for less than $300 (US). Hand-held spectrophotometers suitable for field deployment can be purchased for less than ~$2000 (US). Although data reported here were acquired in a laboratory, the simplicity of the assay should make it possible to obtain comparable results using these less expensive tools in field applications. Given the ubiquitous presence of smart phones, their adaptation to enable even lower cost absorbance measurements in the field is expected.[50] It has been pointed out that it is not possible to "test your way to absolute food safety."[3] However the selective application of this simple assay to the riskiest high protein dairy products may act as a deterrent and mitigate EMA risk imposed by insoluble and potentially allergenic proteins.

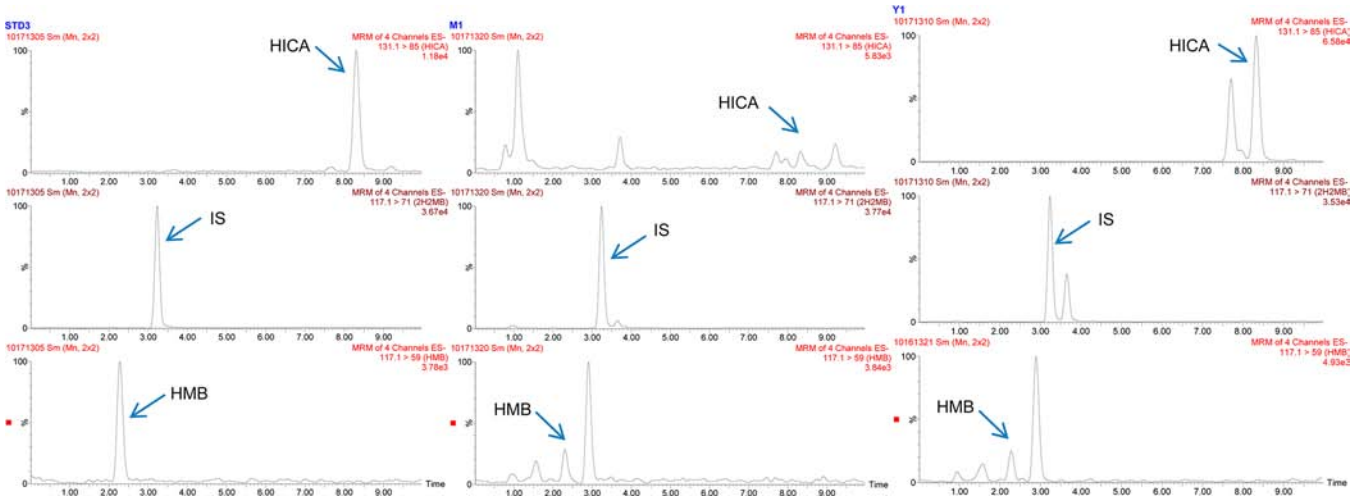

Figure 2. Multiple reaction monitoring (MRM) chromatograms of HMB, IS, and HICA in neat standard (left), whole milk (center), and yogurt (right).

Besides some early reports of qualitative identification of HICA in certain fermented foods (reviewed by Mero et al.[26]), analytical methods for HICA in various biological fluids, e.g., plasma and serum,[36−38] urine,[39,40] amniotic fluid,[41] and in cell culture[42] have been reported in the literature. These analyses were based on GC/MS after derivatization,[36−40] ammonia chemical ionization GC/MS without derivatization,[41] or preparative column chromatography with ultraviolet detection.[42] Some of these methods[36−38] have employed an in-house synthesized stable isotope labeled internal standard. Stable isotope labeled internal standards for HMB and HICA are not available commercially.

The presence of naturally occurring levels of HMB and HICA in milk and fermented dairy products has not been reported to date. Because milk and fermented dairy products are widely consumed, they are potentially suitable media for fortification with HMB and/or HICA in order to deliver the above-described physiological benefits.

This paper describes the development and comprehensive validation of a quantitative and confirmatory method based on liquid chromatography−mass spectrometry for both HMB and HICA in bovine whole milk and fermented dairy products such as yogurt. The method's applicability was demonstrated by analyzing a set of commercial bovine whole milk and yogurt samples for HMB and HICA.

MATERIALS AND METHODS

Safety. Solvents (methanol, acetonitrile) and acids (formic, hydrochloric) should be dispensed in a hood, and appropriate laboratory safety glasses, coat, and gloves should be worn.

Chemicals and Reagents. β-Hydroxy-β-methylbutyric acid (aka β-hydroxyisovaleric acid) (≥95%), α-hydroxyisocaproic acid (aka 2-hydroxyisocaproic acid) (99%), α-hydroxy-α-methylbutyric acid (aka 2-hydroxy-2-methylbutyric acid) (98%), and formic acid (≥96%) were purchased from Sigma-Aldrich Corp. (St. Louis, MO). The purity of β-hydroxy-β-methylbutyric acid was determined by the method of Baxter et al.[35] and was found to be 93.2%. Methanol (LC/MS grade) and hydrochloric acid (34−37% HCl) were purchased from Fisher Scientific (Fair Lawn, NJ). Acetonitrile (LC/MS grade) was from Honeywell Burdick & Jackson (Muskegon, MI).

Stock Solutions and Calibration Standards. Individual stock solutions of β-hydroxy-β-methylbutyric acid (HMB), α-hydroxyisocaproic acid (HICA), and α-hydroxy-α-methylbutyric acid (internal standard, IS) were prepared at concentrations of 2000, 400, and 400 mg/L, respectively, in 0.1 M HCl in 90/10 (v/v) water−acetonitrile. Stock solutions were prepared fresh every two weeks and were determined to be stable when stored at +5 °C during this time period. A mixed intermediate stock solution containing 1 mg/L of HMB and 0.25 mg/L of HICA was prepared in 0.1 M HCl in 90/10 (v/v) water−acetonitrile. A 4 mg/L intermediate stock solution of IS was also prepared in 0.1 M HCl in 90/10 (v/v) water−acetonitrile. Mixed calibration standards containing, respectively, 1, 2, 5, 10, 50, and 100 μg/L of HMB, 0.25, 0.5, 1.25, 2.5, 12.5, and 25 μg/L of HICA, and 10 μg/L each of IS were prepared in 0.1 M HCl in 90/10 (v/v) water−acetonitrile.

Samples. Bovine whole milk (3.3% fat) and plain, low-fat (1−2% fat) yogurt was purchased from supermarkets in the Columbus, OH, metropolitan area.

Sample Preparation. Yogurt was mixed well with a spatula prior to sampling. One-half milliliter (0.5 mL) of whole milk (undiluted) or yogurt (undiluted or 50-fold diluted with water) or water (for method blanks) was pipetted into a 2 mL Eppendorf centrifuge tube. Appropriate aliquots of spiking solution were added (for QC accuracy determination), followed by 25 μL of the 4 mg/L solution of internal standard. After brief vortexing, 1 mL of 0.15 M HCl in acetonitrile was added. The tube was capped, shaken for 30 s, and centrifuged at 3000 rpm for 5 min at ambient temperature. A 150 μL portion of the supernatant was transferred to a clean 2 mL Eppendorf centrifuge tube, followed by addition of 850 μL of 0.1 M HCl in water. The tube was vortexed briefly, and its content was filtered through a 0.2 μm pore size PTFE syringe filter into a 2 mL autosampler vial.

For confirmatory analysis on a hydrophilic interaction chromatography (HILIC) column, 900 μL of acetonitrile were added to a 2 mL Eppendorf centrifuge tube, followed by 100 μL of whole milk or 50-fold yogurt dilution. The tube was capped and shaken briefly, and its content was filtered through a 0.2 μm pore size PTFE syringe filter into a 2 mL autosampler vial.

Instrumentation. Analysis was performed on a Waters ACQUITY Ultra Performance LC coupled to a Xevo-TQS triple quadrupole mass spectrometer. Chromatographic separation was carried out on a Waters ACQUITY UPLC BEH C18 column (1.7 μm, 2.1 mm × 100 mm) maintained at 40 °C, according to the following gradient program: 0−2 min 90% A, switch to 85% A and maintain between 2−10 min, switch to 0% A and maintain between 10−12.5 min, and finally switch to 90% A and maintain between 12.5−16 min (A = 0.1% formic acid in water, B = 0.1% formic acid in methanol). Flow rate was 0.3 mL/min. Injection volume was 10 μL.

The mass spectrometer was operated in the negative electrospray (ESI−) mode with both quadrupoles tuned for unit resolution. Selected operating parameters were: capillary voltage 3.5 kV, desolvation temperature 350 °C, desolvation gas (N_2) 800 L/h,

[a]Retention time. [b]Internal standard.

cone gas (N_2) 250 L/h, collision gas (Ar) (0.15 mL/min). One multiple reaction monitoring (MRM) transition was recorded for each compound as follows: HMB 117.1 > 59.0, IS 117.1 > 71.0, and HICA 131.1 > 85.0. Cone voltage and collision energy were 20 V and 10 eV, respectively, for all transitions. Dwell times were 0.2 s for HMB and IS and 0.4 s for HICA. The solvent flow was diverted to waste between 10 and 16 min of each run.

For confirmatory analysis, a Waters ACQUITY UPLC HILIC column (1.7 μm, 2.1 mm × 150 mm) was used. Mobile phase was 10 mM ammonium acetate in 85.5/14.5 acetonitrile–water (isocratic) at 0.3 mL/min and 40 °C. Mass spectrometer conditions were as described above (the flow diversion valve was not used).

RESULTS AND DISCUSSION

Method Development. Sample preparation consisted of a two-step dilute-and-shoot approach, i.e., protein precipitation with acetonitrile, followed by further dilution to achieve compatibility with the starting mobile phase composition. Hydrochloric acid was used in both steps at a concentration of 0.1 M in order to ensure complete dissociation of the calcium salt of HMB which could be potentially present, as described previously.[35] The injection solvent for both sample extracts and calibration standards was 0.1 M HCl in 90/10 (v/v) water–acetonitrile.

The internal standard α-hydroxy-α-methylbutyric acid was selected based on structural similarity with HMB and HICA. Whole milk and yogurt samples were first screened for the presence of a peak at the expected retention time of the internal standard. A small peak was indeed present; however, its intensity was <5% of the intensity of the internal standard peak at the concentration used (200 μg/L) and hence it did not adversely affect quantitation.

Chromatography was carried out on a sub-2 μ reverse phase column with a water–methanol (0.1% formic acid) mobile phase system. It was found that isocratic programming was necessary to resolve both HMB and HICA from closely eluting matrix peaks. HMB was eluted at ca. 2.3 min with 10% methanol in the mobile phase, at which point the percentage of methanol was increased to 15% to speed up elution of HICA at ca. 8.3 min. Finally, the column was flushed with 100% methanol and re-equilibrated to the starting conditions. The internal standard was eluted at ca. 3.2 min. A matrix peak was

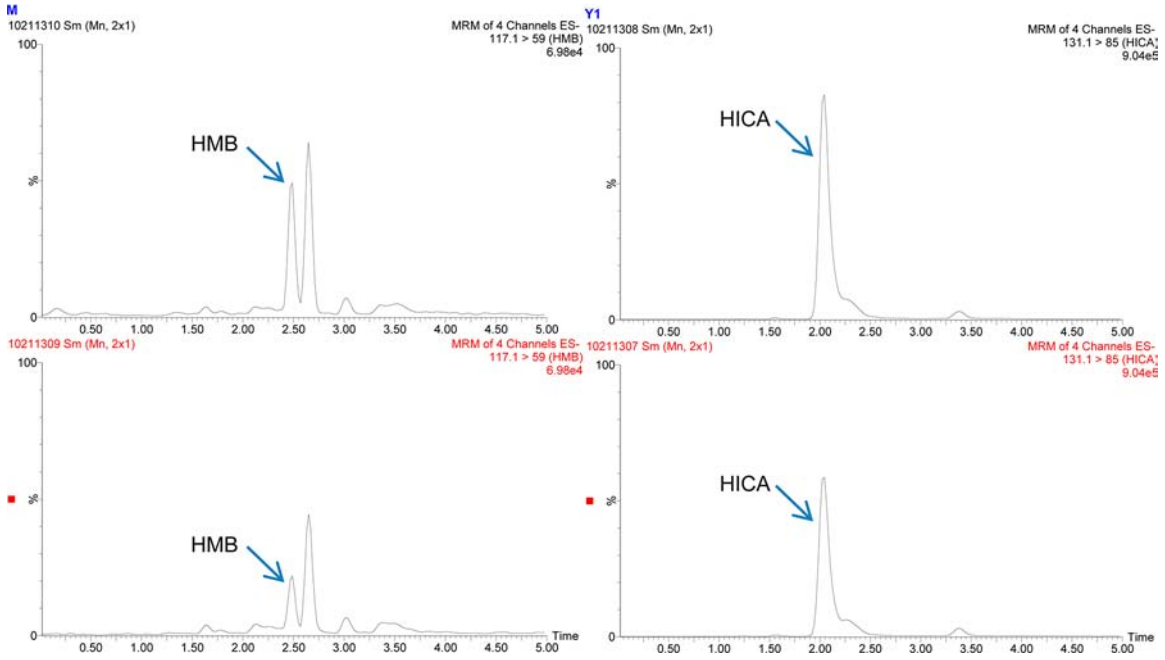

Figure 3. Confirmation of HMB in whole milk and HICA in yogurt (50-fold dilution) on a hydrophilic interaction (HILIC) column (bottom, sample extracts; top, sample extracts spiked with 20 μg/L HMB and 100 μg/L HICA, respectively).

present in the immediate vicinity of the internal standard peak in yogurt samples; however, the two peaks were fully resolved (Figure 2).

Both HMB and HICA are low molecular weight carboxylic acids (118 and 132 Da, respectively), which are amenable for detection in the negative electrospray ion mode. Because of limited fragmentation pathways associated with such low molecular weights, only one multiple reaction monitoring (MRM) transition could be monitored for each compound. Given the limited specificity of MRM transitions used and the expected presence of numerous amino acid metabolites with structures similar to HMB and HICA in milk, the presence of matrix peaks in the chromatograms is not surprising.

Method Validation. Three validation runs consisting of six replicates each at four QC spiking levels were conducted on three separate days. Calibration standards were analyzed at the beginning and at the end of each run. A linear regression model (1/x-weighted) was used for both HMB and HICA. Coefficients of determination (R^2) were ≥0.99. Residuals were ≤20% at the lowest calibration level and ≤15% at all other levels. Up to 25% of all calibration points could be rejected as needed while ensuring that at least one is maintained at each level.

A blank whole milk matrix in which both HMB and HICA were absent could not be found. Most samples of whole milk which were screened contained HMB at quantifiable levels. A small nonquantifiable peak at the retention time of HICA was also present (Figure 2).

The QC1 level for HMB was the incurred concentration (no spike) and for HICA the limit of quantitation (5 μg/L). The QC2, QC3, and QC4 spiking levels are listed in Table 1. All QC data points were within 80−120% of expected values (sum of incurred and spiked concentrations), with one single exception for HICA at the QC4 level. The latter data point was rejected. Mean accuracy, within-day precision, between-day precision, and total precision were calculated as described in ref 43 and are summarized in Table 1. Mean accuracy was 90−110% for HMB and 85−115% for HICA at all QC levels. Total precision for both HMB and HICA was <10% RSD at all QC levels with the exception of HMB at the QC1 level (<20% RSD). The consistent performance of the method over three validation runs established its ruggedness. Method ruggedness parameters are summarized in Table 2.

Limits of quantitation (LOQ) for HMB and HICA in whole milk were 20 and 5 μg/L, respectively. These concentrations corresponded to the lowest calibration levels used for each compound after accounting for the 20-fold dilution incurred during sample preparation.

Process stability was determined by reanalyzing an entire validation run after maintaining the samples on the autosampler tray for 48 h at ambient temperature. The run met accuracy and precision criteria outlined above.

Survey of HMB and HICA in Commercial Bovine Whole Milk and Yogurt. Fourteen samples of bovine whole milk and four samples of commercial plain yogurt were analyzed for their HMB and HICA content by the above-described validated method. Results of this survey (averages of duplicate analyses) are summarized in Tables 3 and 4.

All samples of whole milk contained a trace of HMB ranging from <LOQ (20 μg/L) to 29 μg/L. HICA was not present other than a small nonquantifiable peak and is being reported as <LOQ (5 μg/L) in all samples. A serendipitous finding was the progressive formation of HICA in certain samples of whole milk which were stored in the refrigerator (+5 °C) past their expiration dates. This is not entirely surprising because HICA has been reported previously in fermented foods (reviewed by Mero et al.[26]).

The above finding prompted further investigation of the potential presence of HICA in fermented dairy products such as yogurt. Samples of yogurt which were subjected to analysis contained significant concentrations of HICA between 3.0 and 15.2 mg/L. A 50-fold dilution of yogurt with water prior to analysis was necessary in order to bring concentrations of HICA within the method's quantitative range. Samples of

dx.doi.org/10.1021/jf500026s | J. Agric. Food Chem. 2014, 62, 1506−1511

yogurt were also analyzed for HMB (without dilution). Concentrations of HMB in yogurt were between 32 and 37 μg/L, slightly higher than in whole milk.

Confirmatory Analysis of HMB and HICA by Orthogonal Chromatography. Given that only one multiple reaction monitoring (MRM) transition was available for both HMB and HICA and the limited specificity of these transitions (as evidenced from the presence of matrix peaks in the chromatograms), further confirmation of the positive findings for HMB in whole milk and HICA in yogurt was undertaken. Hydrophilic interaction chromatography (HILIC) which is orthogonal to reversed phase chromatography was employed for this purpose. Both HMB in whole milk and HICA in yogurt have been confirmed by their respective retention times at 2.5 and 2.0 min, respectively (Figure 3). Because the internal standard α-hydroxy-α-methylbutyric acid did not show acceptable retention behavior on the HILIC column, and superior peak shape and retention were achieved for both HMB and HICA on the reversed phase column, the latter was retained for method validation and routine analysis.

In conclusion, a rugged, quantitative, and confirmatory method based on liquid chromatography−mass spectrometry was developed and comprehensively validated for the analysis of HMB and HICA in bovine whole milk and yogurt. The method was successfully applied to survey the concentrations of HMB and HICA in commercial samples of bovine whole milk and yogurt. To our knowledge, this is the first report in the scientific literature of naturally occurring (endogenous) concentrations of HMB in bovine whole milk and yogurt and of HICA in yogurt and also the first report of a quantitative and confirmatory analytical method for HICA in foods. On the basis of existing clinical studies and largely musculoskeletal outcome measures, the endogenous concentrations of HMB and HICA found by this study are insufficient by large margins to deliver any physiological benefits. Hence the opportunity arises for the fortification of milk, milk-based nutritional products, and fermented dairy products with HMB and/or HICA.

Spectral inspection indicates that there is a considerable number of interfering compounds that absorb in the UV−vis region. These compounds make it difficult to confirm the identical nature of the individual pigment peaks.

Anthocyanins are able to capture free radicals by donation of phenolic hydrogen atoms.[10,11] Acylation of the anthocyanin molecule improves their stability through intramolecular and/or intermolecular copigmentation and self-association reactions. Therefore, sources of acylated anthocyanins of the *S. scabrum* and *S. burbankii* berries may ensure the desirable stability for food applications. The anthocyanins with acylating substituents are more stable during processing and storage than the unacylated pigments.

The antioxidative activity of phenolic compounds, especially anthocyanin, was studied by different chemical methods. The Folin−Ciocalteu method, the oxygen radical absorbance capacity (ORAC) assay, and the Trolox equivalent antioxidant capacity (TEAC) assay are the most considered methods. Kilmartin et al.[13] developed an electrochemical method for the characterization of the antioxidant properties of wine and wine phenolics. Recently, Janeiro et al.[14] studied the redox behavior of anthocyanins by voltammetric techniques and found that all the phenolic hydroxyl groups can be oxidized electrochemically. Also differences in electroactive substituents on analogous structures can lead to characteristic differences in their voltammetric behavior.[15] Pereira at al.[16] studied the effects of substitution for the hydroxyl group at position C4′ in the B-ring of the flavylium cation, which indicated that the para-position of the ring B is important for the increase in the delocalization of π-electrons in the chromophore. Electrochemical studies reveal general trends in the electron-donating abilities of flavonoids. Cren-Olivé at al.[17] shown the importance the catechol group in the B-ring, which is more easily oxidizable than the resorcinol group in the A-ring. They indicated that the 4′-OH is the group that deprotonates preferentially in the flavylium cation of cyanidin and cyanidin-3-*O*-glucoside.[17]

The purpose of this research was to tentatively identify and quantify phenolic compounds, main flavonoids, phenolic acids, and anthocyanins for better characterization of *S. scabrum* and *S. burbankii* berries. Additionally, the study was aimed at monitoring the changes in the antioxidant activity by spectrometric methods (ABTS and FRAP assay) and an electrochemical technique, cyclic voltammetry. These rapid analytical techniques are very useful in determining the antioxidant activity, which is a consequence of the ability of an antioxidant to donate electrons around the potential of the anodic wave.

MATERIALS AND METHODS

Reagents and Standard. Acetonitrile and methanol for UPLC and LC/MS purity, formic acid, leucine enkephalin, 2,2-azinobis(3-ethylbenzothiazoline-6-sulfonic acid (ABTS), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 2,4,6-tri(2-pyridyl)-*s*-triazine (TPTZ), ammonium formate, and methanol were purchased from Sigma-Aldrich (Steinheim, Germany). Quercetin-3-*O*-glucoside and -3-*O*-rutinoside; peonidin, delphinidin and petunidin aglycon; *p*-coumaric acid; and sinapic acid were purchased from Extrasynthese (Lyon, France). Chlorogenic acid, neochlorogenic acid, and cryptochlorogenic acid were purchased from TRANS MIT GmbH (Giessen, Germany).

UPLC-grade water, prepared by using an HLP SMART 1000s system (Hydrolab, Gdańsk, Poland), was additionally filtered through a 0.22 μm membrane filter immediately before use.

Plant Material. *S. scabrum* and *S. burbankii* berries were collected in 2011 from the Garden of Medicinal Plants herbarium at the Medical University in Wroclaw, Poland, by cultivation in the University's experimental field. The fruits were harvest successively during 10 days and after harvest, the berries (100 g per day, finally 1 kg) were immediately frozen and stored at −20 °C until used for analysis.

Extraction Procedure. The extraction procedure of polyphenols was carried out as described previously by Oszmiański et al.[18] The frozen berries were quick thawed in a microwave oven and heated only to 20 °C and then directly crushed in a laboratory mill (IKA A11). This extraction procedure was applied because use of the microwave oven was previously found to be the best extraction method when berries were exposed for 1 min. Polyphenols were isolated from berries by maceration with water containing 200 mg/L SO_2 and subsequently extracted in a ultrasonic bath at 20 °C for 15 min. The ratio of this solvent to berries was 10:1 (v/v). The homogenized mixture was then centrifuged for 5 min (4000 rpm; MPW 360R; Warsaw, Poland), and the extraction was repeated twice. The experiment were performed in triplicate.

Four milliliters of the extract was passed through a C18 Sep-Pak cartridge (360 mg/0.7 mL; Waters) preconditioned with 5 mL of ethyl acetate, 5 mL of methanol, and 5 mL of 0.01 N HCl. The loaded cartridge was washed with 3 mL of 0.01% HCl and then the cartridge was dried with a flow of nitrogen gas for 3 min. Phenolic compounds other than anthocyanins were eluted with 20 mL of ethyl acetate. The solvent was removed using a rotary vacuum evaporator at 20 °C, and the phenolic residue was dissolved in 20% acetonitrile for UPLC-PDA−MS analysis. Anthocyanins adsorbed in the Sep-Pak C18 were eluted with methanol containing 0.5% HCOOH, and the anthocyanin fraction was analyzed by the UPLC-PDA−MS method.

Absorption Spectra of Berry Extracts. Berry extract was used for measurement of absorption spectra, which were recorded in the visible wavelength range from 450 to 600 nm. These spectra were measured using a PC 2401 UV−vis spectrophotometer (Shimadzu; Tokyo, Japan) in a 10-mm path length cell, with buffer solutions as a reference. Buffer solutions of two different pH values (pH 2.5 and 7.5) were prepared by mixing 50 mM ammonium formate with acetonitrile (50/50; v/v). pH was adjusted with ammonium hydroxide. All experiments were repeated in triplicate.

Identification of Polyphenols by the UPLC-PDA−Q/TOF-MS Method. Identification of polyphenol of *S. scabrum* and *S. burbankii* berry extracts was carried out using an ACQUITY ultra-performance LC system (UPLC) with binary solvent manager (Waters Corp.; Milford, MA) and a Micromass Q-Tof Micro mass spectrometer (Waters; Manchester, UK) equipped with an electrospray ionization (ESI) source operating in negative and positive mode. Separations of individual polyphenols were carried out using a UPLC BEH C18 column (1.7 μm, 2.1 × 100 mm, Waters Corp.; Milford, MA) at 30 °C. Samples (10 μL) were injected, and elution was completed in 15 min with a sequence of linear gradients and isocratic flow rates of 0.45 mL min^{-1}. The mobile phase was composed of solvent A (4.5% formic acid, v/v) and solvent B (100% acetonitrile). The program began with isocratic elution with 99% A (0−1 min), and then a linear gradient was used until 12 min, lowering A to 0%; from 12.5 to 13.5 min, the initial composition (99% A) was used and then held constant to re-equilibrate the column. Analysis was carried out using full scan, data-dependent MS scanning from m/z 100 to 1500. Leucine enkephalin was used as the internal reference compound during ESI-MS accurate mass experiments and was permanently introduced via the LockSpray channel using a Hamilton pump. The lock mass correction was ±1.000 for the mass window. All quadrupole time-of-flight mass spectrometry (Q/TOF-MS) chromatograms are displayed as base peak intensity (BPI) chromatograms and scaled to 12 400 counts per second (cps) (=100%). The effluent was led directly to an electrospray source with a source block temperature of 130 °C, desolvation temperature of 350 °C, capillary voltage of 2.5 kV, and cone voltage of 30 V. Nitrogen was used as desolvation gas at flow rate 300 L h^{-1}.

The characterization of the single components was carried out via the retention time and the accurate molecular masses. Each compound was optimized to its estimated molecular mass $[M - H]^-$ in the

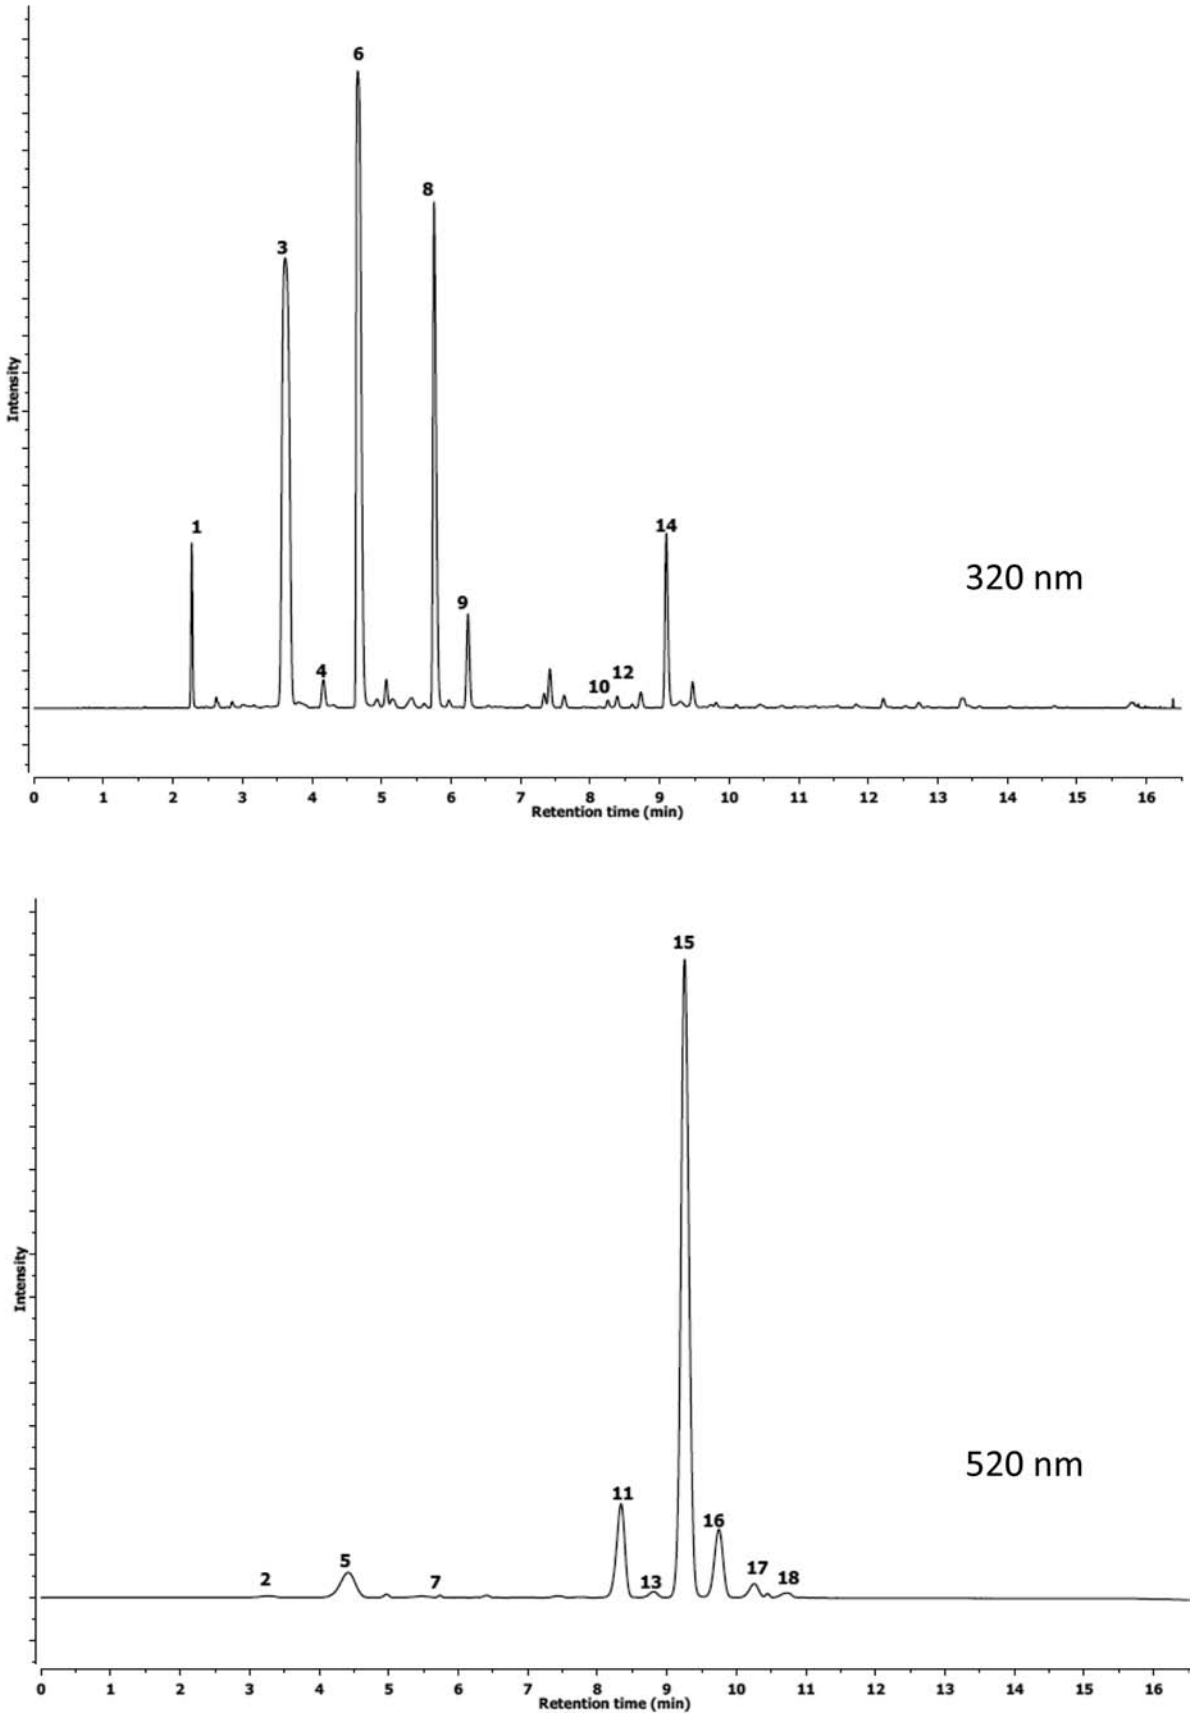

Figure 1. UPLC profile at 320 nm (phenolic acid and quercetin derivative) and 520 nm (anthocyanins) of *Solanum* berry extracts. For abbreviations of the peak labels, see Table 1

dx.doi.org/10.1021/jf4045233 | *J. Agric. Food Chem.* 2014, 62, 1512−1519

negative and positive mode before and after fragmentation. The data obtained from UPLC/MS were subsequently entered into the MassLynx 4.0 ChromaLynx Application Manager software. On the basis of these data, the software is able to scan different samples for the characterized substances.

The runs were monitored at the following wavelengths: hydroxycinnamates at 320 nm, flavonol glycosides at 360 nm, and anthocyanins at 520 nm. Photodiode detector (PDA) spectra were measured over the wavelength range 200−600 nm in steps of 2 nm. Retention times and spectra were compared with those of pure standards within 200−600 nm. Calibration curves were run for the external standards 3-, 4-, and 5-*O*-caffeoylquinic acids, *p*-coumaric acid, quercetin-3-*O*-rutinoside and -3-*O*-glucoside, peonidin-3-*O*-rutinoside, delphinidin-3-*O*-rutinoside, and petunidin-3-*O*-rutinoside at concentrations ranging from 0.05 to 5 mg/mL. Amounts of 3-, 4-, and 5-*O*-caffeoylquinic acids were calculated for the quantification of the neochlorogenic, cryptochlorogenic, and chlorogenic acids and their isomers. The concentrations of *p*-coumaric and sinapic acid containing compounds were calculated by using *p*-coumaric and sinapic acid, respectively. The concentrations of delphinidin-, petunidin-, and malvidin-containing compounds were calculated by using delphinidin, petunidin, and malvidin aglycons, respectively. Obtained results was express as milligrams per 100 g of dry matter (dm).

Analysis of Antioxidant Activity. The protocols for analysis were prepared as described previously by Wojdyło et al.[19] The $ABTS^{\bullet+}$ activity of the sample was used for measurement of antioxidant activity. The total antioxidant potential of the sample was determined using a ferric reducing ability of plasma (FRAP) assay. For all analyses, a standard curve was prepared using different concentrations of Trolox. All determinations were performed in triplicate using a Shimadzu UV-2401 PC spectrophotometer (Kyoto, Japan). The results were corrected for dilution and are expressed in millimole of Trolox per 100 g dm.

Cyclic Voltammograms. The mixture of 50 mM ammonium formate (pH 7.4) and acetonitrile (50/50, v/v) was prepared as the supporting electrolyte. All experiments were performed on a ROXY EC system (Antec; Zoeterwoude, The Netherlands). Electrochemical conversions were accomplished in an electrochemical thin-layer cell (ReactorCell, Antec). The reactor cell consisted of a three-electrode arrangement including a working electrode, an auxiliary electrode, and a reference electrode. Glassy carbon was used as working electrode material. The accessible area of the working electrode was 15.1 mm^2. The inlet block of the cell was employed as auxiliary electrode and the HyREF (Antec) electrode was used as reference electrode. The working electrode and the auxiliary electrode inlet block were separated by a 50-μm spacer, giving a cell volume of approximately 750 nL. Potentials (0−3000 mV) were applied using a purposive potentiostat (ROXY potentiostat, Antec). Shredded *S. scabrum* and *S. burbankii* berry extracts (~2.5 g) were mixed with 3 mL of ammonium formate and then centrifuged for 10 min at 15 000 rpm (20.878*g*; MPW-360R; Warsaw, Poland). Prior to each run, the surface of the glassy carbon electrode was freshly abraded with 12 μm flattening plate and rinsed with redistilled water and methanol. The scan was taken in the potential range between 0 and 3000 mV with a scan rate 50 mVs^{-1}. Samples were pumped through the cell at a flow rate of 5 μL/min by a syringe pump model 74900 (Cole Parmer; Vernon Hills, IL). Cyclic voltammograms were also recorded for 0.25 mM cyanidin, malvidin, and pelargonidin aglycon standards solutions.

RESULTS AND DISCUSSION

Characterization and Quantification of Phenolic Compounds. The data for retention times (t_R), wavelengths of maximum absorbance (λ_{max}), protonated/deprotonated molecules ($[M + H]^+/[M - H]^-$), diagnostic fragments, and identification for each peak of the phenolic compound detected in the *S. scabrum* and *S. burbankii* berry extracts are listed in Table 1. The compounds were characterized according to their retention time at 320 nm for phenolic acid derivatives, 360 nm for quercetin derivatives, and at 520 nm for anthocyanins and are shown in Figure 1, respectively.

Eighteen phenolic acid derivatives and flavonoids were detected in the *S. scabrum* and *S. burbankii* berry extracts. Among them, there were three nonacylated anthocyanin hexosides and six acylated anthocyanin hexosides.

Nine compounds other than antocyanin phenolic ones were tentatively identified in the *S. scabrum* and *S. burbankii* berry extracts for the first time. Among them, there were seven phenolic acid derivatives and two flavonol hexosides.

Chlorogenic acid (5-caffeoylquinic acid, compound **1**) and its isomers were found at different t_R, showing the deprotonated molecule $[M - H]^-$ (m/z 353) and the ion corresponding to the deprotonated quinic acid (m/z 191) in the full scan mode. Reference substances neochlorogenic acid (3-caffeoylquinic acid, compound **3**) and cryptochlorogenic (4-caffeoylquinic acid, compounds **4**) were confirmed by injection of standards and the subfractions in neutral loss of m/z 162, which also corresponds to the loss of a caffeic acid unit. Several isomers of chlorogenic acid have been found in other plant sources.[20,21]

Compounds **6** and **8** possessing two malonyl-caffeoylquinic acid derivatives were detected in full-scan experiments showing m/z 439, 191, and 173 at the t_R of 4.66 and 5.76 min in decreasing concentrations. The mass spectra of the peaks in full scan mode showed the typical fragmentation of the malonyl acid and quinic acid of chlorogenic acid derivatives at m/z 86 and 191, respectively.

Acetylo-*p*-coumaroylquinic acid (**9**) and sinapoyl-malic acid (**14**) were found in the analyzed berries as well. The compound **9** (t_R 6.24 min, λ_{max} 310 nm) produced the parent ion at m/z 163 and compound **14** (t_R 9.10 min, λ_{max} 328 nm) produced an ion at m/z 233, corresponding to *p*-coumaric acid and sinapic acid, respectively. The chemical nature of the nonphenolic acid side chains was established using high resolution in source fragmentation experiments in a negative ion mode showing fragment ions with the neutral losses of 60 amu (m/z 379 − 60 = 319) and 116 amu (m/z 339 − 116 = 223) for the acetyl and maloyl residues, respectively (Table 1).

Two glucosides of quercetin, namely, quercetin-3-*O*-rutinoside (**10**, rutin) and quercetin-3-*O*-glucoside (**12**, isoquercitrin), were identified. Quercetin-3-*O*-rutinoside was detected at the t_R of 8.30 min, whereas quercetin-3-*O*-glucoside was found at the t_R of 8.44 min, both of them exhibiting a mass spectrum in full-scan mode with m/z 609 and 463, respectively, and a precursor ion scan m/z 301 as quercetin aglycon. Comparison of the mass spectra and t_R with those of the respective standards confirmed the occurrence of these glycosylated flavonols in the *S. scabrum* and *S. burbankii* berry extracts. The fragmentation pathway of *O*-glycosylated flavonoids starts with the cleavage of the glycosydic bonds and elimination of the sugar moieties with charge retention on the aglycon. In compounds containing two or more sugars at the same aglycon carbon, ions arising from the cleavage of the glycosidic bonds between sugar units are weak. Compounds such as quercetin-3-*O*-glucosyl-rutinoside and quercetin-3-*O*-rutinoside were typical for the Solanaceae family and have been previously reported in potato.[22] Quercetin, a major representative of the flavonol subclass found at high concentrations in fruit and vegetables, has recently received considerable attention. This flavonoid displays the ability to prevent the oxidation of LDL by scavenging free radicals and chelating transition metal ions. As a result, quercetin may aid in the prevention of certain diseases, such as cancer, atherosclerosis, and chronic inflammation by

retarding oxidative degradation and inducing enzymes that detoxify carcinogens and also by blocking cancer formation by deactivating at least 30 types of potentially carcinogenic agents.[23,24]

The UPLC method was applied for short run times combined with a photodiode array detector (PDA), and a quadrupole/time-of-flight mass spectrometer (Q/TOF-MS) enables better characterization of individual compounds, especially with high molecular mass, i.e., acetylated anthocyanins. Three nonacylated anthocyanins were presented as delphinidin-*O*-3-rutinoside-*O*-5-glucoside (**2**; *m*/*z* 773, $[M + H]^+$), petunidin-3-*O*-rutinoside-5-*O*-glucoside (**5**; *m*/*z* 787, $[M + H]^+$), and malvidin-3-*O*-rutinoside-5-*O*-glucoside (**7**; *m*/*z* 801, $[M + H]^+$). Malvidin-3-*O*-rutinoside-5-*O*-glucoside was detected only in *S. burbankii* berry extract. The ESI mass spectrum of pigments showed fragment ions at $[M - 162 (glucose)]^+$ corresponding *m*/*z* 611, 625, and 639, respectively, and the next fragment ions at $[M - 146 (hexoside, probably rhamnoside)]^+$ *m*/*z* 465, 479, and 493, respectively. The last fragment ions at $[M - 162 (hexoside, probably glucoside)]^+$ *m*/*z* 303 (dephinidin), 317 (petunidin) and 331 (malvidin) were aglycons, as listed in Table 1. Seven other compounds **11** and **13**−**18** (t_R 8.37−10.78 min; molecular weights *m*/*z* 918−976 amu) were also clearly detected in *Solanum* berry extracts (Table 1). Acylated anthocyanin glycosides were easily identified on the basis of the increase in the mass of the parent ions and the wavelength maxima (330−336 nm) of their UV−vis spectra. Thus, peaks with the t_R at 8.37, 8.89, 9.30, 9.82, 10.28, and 10.75 min were identified as 3-*O*-*p*-coumaroyl-hexoside-5-*O*-hexoside (**11**) and 3-*O*-feruoyl-hexoside-5-*O*-hexoside (**13**) of delphinidin, 3-*O*-*p*-coumaroyl-hexoside-5-*O*-hexoside (**15**) and 3-*O*-feruoyl-hexoside-5-*O*-hexoside (**16**) of petunidin, and 3-*O*-*p*-coumaroyl-hexoside-5-*O*-hexoside (**17**) and 3-*O*-feruoyl-hexoside-5-*O*-hexoside (**18**) of malvidin, respectively. The ESI mass spectrum of the acylated pigment compound **11** showed a flavylium cation at *m*/*z* 919 $[M + H]^+$ together with a fragment ion at *m*/*z* 757 $[M - 162 (glucose)]^+$. On the basis of observations of two additional fragment ions at *m*/*z* 465 [M − 292 (the presence of hexoside, probably rhamnose, and *p*-coumaric acid)], and *m*/*z* 303 derived from successive losses of 162 amu, the presence of glucose moiety was confirmed, for structural elucidation. Similar fragmentation ions were observed for the remaining acetylated anthocyanins (Table 1). Although these compounds have already been presented in earlier works,[1,2] to enable their complete identification, their structures should be fully elucidated by means of NMR or by comparison with authentic compounds, if existing.

In addition, nonacylated anthocyanins were shown to be the most abundant compounds in wild species of berry and other fruits.[25,26] The presence of acylated anthocyanins is typical of grapes, blueberry, blackberry, and some vegetables, i.e., red cabbage, radish, and red-fleshed potato.[27]

Recent research has shown that anthocyanins with acylating substituents are more stable during processing and storage than other natural pigments.[6,9,27] Brouillard et al.[28] explain that the effect of the improved stabilization of the acylated anthocyanins has been attributed to the stacking of the acyl groups with the pyrylium ring of the flavylium cation, thereby reducing the susceptibility of a nucleophile attack of water and subsequent formation of intramolecular copigmentation of a pseudobase or a chalcone.

The concentrations of low molecular weight flavonols (quercetin) and hydroxycinnamic acid conjugates (caffeic, *p*-coumaric and sinapic acid) were higher in the *S. burbankii* berries (78.89 mg/100 g) than in the *S. scabrum* berries (33.13 mg/100 g) (Table 1). In both berries, 3-caffeoylquinic acid was dominant, and the concentration of 5-caffeoylquinic acid was higher than that of 4-caffeoylquinic acid. The content of acylated derivatives of anthocyanins showed the largest differences between the investigated berries. *S. scabrum* berries were much more richer sources of anthocyanins (206.22 mg/100 g) than *S. burbankii* berries (82.06 mg/100 g). Price et al.[2] found more anthocyanin compounds in *S. scabrum* berries (350 mg/100 g). The concentration of acylated antocyanins was higher than that of the nonacylated antocyanins in *Solanum* berries. Petunidin-3-*O*-*p*-coumaroyl-rutinoside-5-*O*-glucoside was the dominant acylated antocyanin in the investigated berries.

Figure 2 shows the spectral character of *S. scabrum* (A) and *S. burbankii* (B) berry extracts at pH 2.5 and 7.5, indicating that

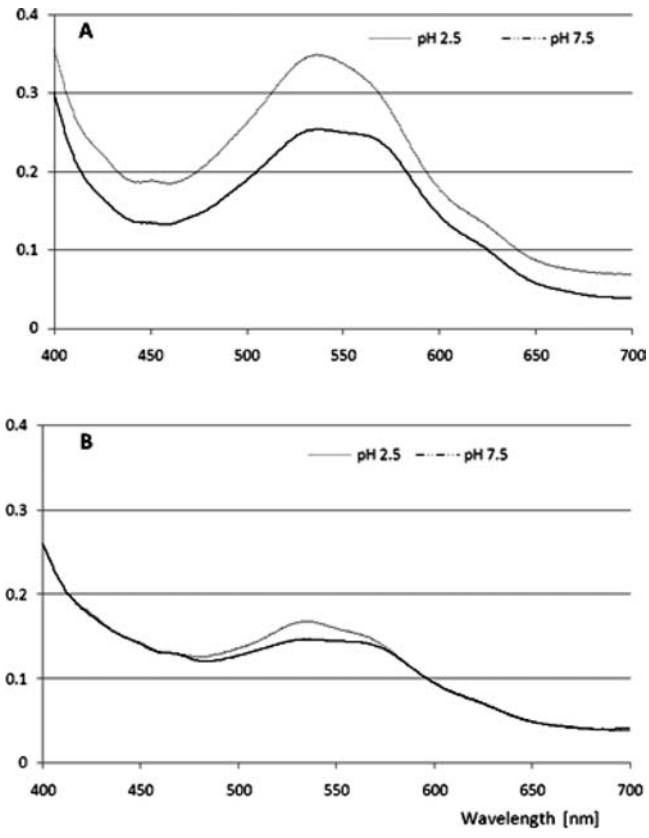

Figure 2. Spectral character of *S. scabrum* (A) and *S. burbankii* (B) berry extracts at pH 2.5 and 7.5.

these berries contain acylated anthocyanin. Changing the pH from 2.5 to 7.5 did not result in any significant reduction in absorbance at a wavelength of 530 nm, as is observed in the case of nonacylated anthocyanins. The variation of pH values influences anthocyanin properties, such as color, stability, spectral shape, and absorption peak.[29] In our research, it could be observed from Figure 2 that the anthocyanin extracts from *S. scabrum* (A) and *S. burbankii* (B) berries had the maximum absorption around 530 nm at pH 2.5 and 7.5. Anthocyanin solutions, at both pH values, exhibited bright red-violet color, and their absorbances at 530 nm varied slightly. Acylated

anthocyanins are also more resistant to color fading with increased pH than their unacylated analogs. Unacylated anthocyanins are only stable at pH values where the flavylium cation dominates. Cevallos-Casals et al.[6] showed that vegetables such as sweet potato and purple carrot, which contain acylated anthocyanins, were more resistant to the solution pH than red grape rich, which is in unacylated anthocyanins. Other researchers confirmed the unusual stability of acylated anthocyanins at pH >5.0.[7,8]

Antioxidant Activity and Cyclic Voltammetry of Solanum Berries. The antioxidant activity of *S. scabrum* (a) and *S. burbankii* (b) berries was tested by measuring their activity to scavenge radical (Table 2). The ABTS radical

Table 2. Antioxidant Activity (mmol Trolox/100 g dm) of *Solanum* Fruits

	S. scabrum	*S. burbankii*
ABTS	2.89 ± 0.37	2.07 ± 0.42
FRAP	1.65 ± 0.09	0.71 ± 0.06

Mean values with standard deviation of $n = 3$.

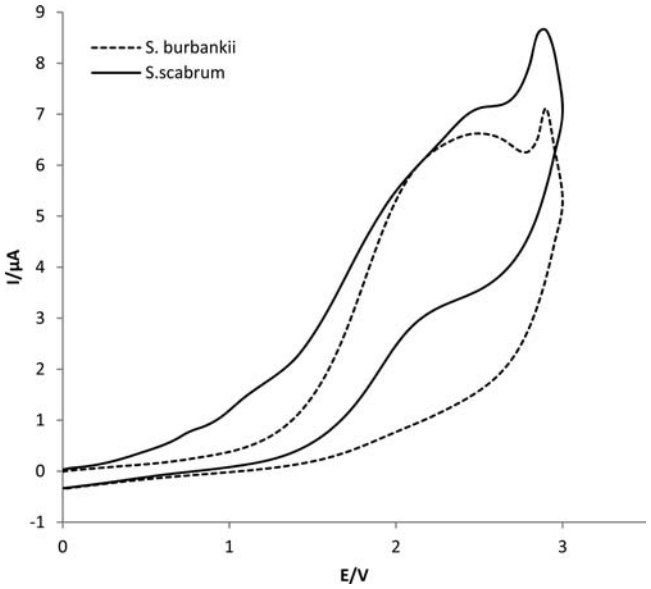

Figure 3. Cyclic voltammograms of *S. burbankii* and *S. scabrum*.

scavenging activity was higher in *S. scabrum* berry extract [2.89 mmol Trolox equiv (TE)/100 g dm] than in *S. burbankii* berry extract (2.07 mmol TE/100 g dm). After comparing the $ABTS^{\bullet+}$ activity of the *Solanum* berries with that of known food products we found that they exhibited a lower antioxidant activity than that of blueberries (4.59 mmol TE/100g dm), which constitute one of the richest reported sources of antioxidants.[30] But, still, *S. scabrum* berry extract had a higher antioxidant activity than *Rubus* species (0−2.53 mmol TE/100 g dm), which have been recommended as improving the nutritive value due to its high antioxidant activities.[31] In regard to the FRAP activity, *S. scabrum* had 1.65 mmol TE/100 g dm and *S. burbankii* had 0.71 mmol TE/100g dm, respectively. The differences in polyphenols between *Solanum* varieties could be preliminarily attributed to their different contents of antioxidant activity. *S. scabrum* berry extract contained much more phenolic compounds than *S. burbankii* berry extract.

The cyclic voltammetric technique (CV) was employed to study the electrochemical behavior of *S. scabrum* and *S. burbankii* berry polyphenol extracts, and results are presented in Figure 3. The major current peak appears at approximately 2.4 V for *S. scabrum* and at 2.1 V for *S. burbankii*. According to literature data, this peak may be attributed to powerful, low formal potential phenolics characterized by an *o*-hydroxyphenol or di- or trihydroxyphenol group. Petuninidin and delphinidin anthocyanin derivatives were the main compounds of *Solanum* berry, but higher contents of these compounds were determined in *S. scabrum*. These anthocyanins possess three and two catechol groups on the B-ring. Cevallos-Casals at al.[6] explained that oxidation of phenolic compounds involved the formation of a stable quinone, which can be reduced in the reverse scan, this process appearing as a cathodic peak of the current response. In the return scan, the electrochemical behavior of *S. burbankii* extract is irreversible. Yakovleva et al.[32] present the irreversible oxidation of some phenolic acids and flavones in plants. However Tamura et al.[12] found that anthocyanins acylated by *p*-coumaric acid are much better antioxidants than α-tocopherol or (+)-catechin. Besides the color and antioxidant activity, anthocyanins have free radical scavenging activity. The anthocyanin radical is more stable than other radicals generated in the human body; hence the duration of this radical is longer.[12]

In both cultivars, the major compound was found to be the anthocyanin petunidin-3-(*p*-coumaroyl-rutinoside)-5-glucoside. Eight additional anthocyanins in *S. burbankii* berries and 11 in *S. scabrum* berries were identified as petunidin, delphinidin, and malvidin with the same glycosidic substitution pattern as the major pigment and varying degrees of acylation with *p*-coumaric and ferulic acids. The presence of seven phenolic acid mainly caffeoylquinic derivatives and two quercetin derivatives was reported for the first time. *S. scabrum* extracts are richer in anthocyanins but have less phenolic acid than *S. burbankii*. This study demonstrated the usability of fast and effective electrochemical measurements and a spectrophotometric technique for determination of the phenolic content as well as antioxidant activity of *Solanum* berry extracts. *S. scabrum* exhibited the highest TEAC values according to both CV and ABTS and FRAP assay.

From the consumers' point of view, the analyzed fruits are good sources of bioactive compounds and colorants to be used in the food industry.

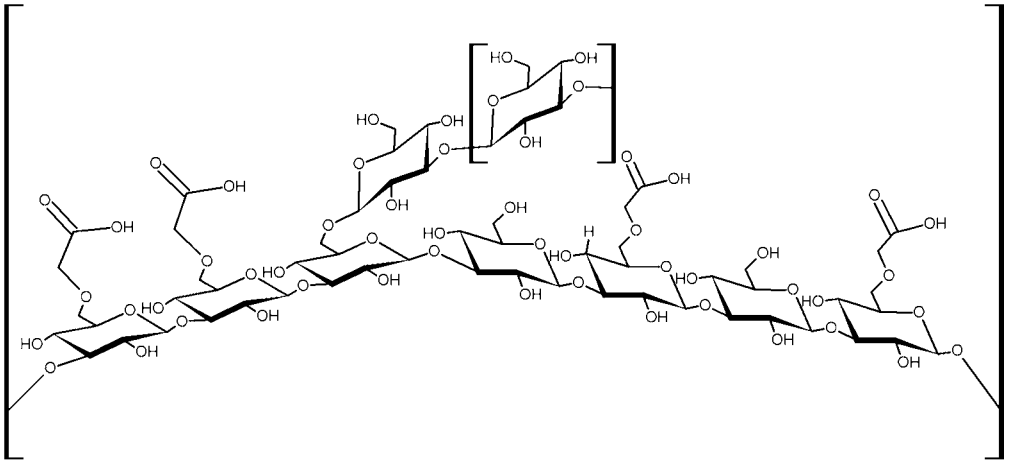

Figure 2. Carboxymethylated-(1,3/1,6)-β-D-Glucan chemical structure.

storage stability under wet and light stresses within 10 days. Furthermore, the authors demonstrated that no chemical modification occurs on resveratrol, which retains unaltered antioxidant and physicochemical properties following encapsulation in yeasts.

In this paper we aimed at studying a new association of resveratrol with a high molecular weight polysaccharide, the carboxymethylated (1,3/1,6)-β-D-glucan (CM-glucan), to be used in liquid formulations (Figure 2). β-Glucans are a class of natural polysaccharides that are endowed with well-known pharmacological activities and are increasingly utilized in pharmaceutical applications and in the food industry.[13] The term β-glucans indicates noncellulosic polymers of β-glucose, with glycosidic bonds in position $\beta(1\rightarrow3)$ and with a significant portion of $\beta(1\rightarrow6)$-bound glucose molecules. They are isolated from fungi, cereals, bacteria, or seaweeds.[14−16] The most important quality of β-glucans, and the reason so much attention has been devoted to these compounds, is that they are typical biological response modifiers with pronounced immunomodulating activity, which confer anticancer, antioxidant, antiviral, and wound-healing capacities to these molecules.[13,17] These biopolymers are also widely utilized in view of their structural and drug delivery properties for the nanoencapsulation of lipophilic pharmaceutical compounds and for poorly bioavailable drugs.[18,19]

However, despite their very interesting pharmaceutical and pharmacological profile, β-glucans have limited applications in liquid formulations due to their poor water solubility. Hence, for our aims we opted for the use of the carboxymethylated derivative of β-glucan, CM-glucan, showing a higher degree of solubility in water due to the presence of the easily ionizable carboxyl residues (Figure 2).[20] This chemical modification does not affect the pharmaceutical and pharmacological properties of the product, which still exerts outstanding anticancer and antioxidant properties.[21,22]

The purpose of the present investigation was to evaluate the effect of CM-glucan on the long-term stability and solubility of resveratrol in aqueous solutions. To this purpose, we have developed a liquid formulation in which resveratrol is complexed with CM-glucan and resuspended in a buffered saline solution. The stability and antioxidant activity of resveratrol were further confirmed with spectroscopic methods.

MATERIALS AND METHODS

Reagents. *trans*-Resveratrol was purchased from Shanghai Novanat Co., Ltd. (Shanghai, China) and CM-glucan from Nutraceutica s.r.l. (Bologna, Italy). 2,2-Diphenyl-1-picrylhydrazyl (DPPH) and benzalkonium chloride were purchased from Sigma-Aldrich (Milan, Italy). Gradient grade solvents used for chromatographic analyses were purchased from Carlo Erba Reagents (Milan, Italy). All other reagents were analytical grade products from Sigma-Aldrich.

Sample Preparation. Samples for the stability study were prepared by dissolving resveratrol at a final concentration of 0.05% in different aqueous solvents (0.9% NaCl or phosphate-buffered saline (PBS)) containing 0.1% CM-glucan. Sonication or extensive magnetic stirring was employed for evenly dispersing the preparations. The samples were prepared in triplicate and then split in two aliquots, one of which was maintained at 25 °C and the other at 40 °C for accelerated stability determinations. Samples were stored in the dark at over a relative humidity (RH) range of 40−45%. At different times, an aliquot of each sample was taken and analyzed for resveratrol content. In a similar manner, control solutions were prepared without CM-glucan to evaluate the stability of 0.05% resveratrol, which was brought in solution by using surfactant agents, such as 0.5% PEG and 0.1% Tween-20. Benzalkonium chloride (0.04%) was employed as a preserving agent to inhibit microbial growth during long-term storage in stability analyses both in samples and in controls. For specific purposes, such as for spectrofluorometric measurements, samples were centrifuged at 12000*g* for 10 min before analysis.

HPLC Determination and Quantification of Resveratrol. The HPLC consisted of a Waters apparatus equipped with a 600 pump and pump controller, a Waters autosampler model 717, a Symmetry C18 column (reversed phase, 3.9 × 150 mm, 5 μm particle size, with a 10 mm guard column of the same material matrix), and a UV−visible photodiode array detector model 2996. Solvent A was 10% acetic acid in water, and solvent B was acetonitrile. The elution was performed in isocratic conditions at a flow rate of 1 mL/min at 25 °C with 80% A and 20% B. Resveratrol had a retention time of ≃7.0 min, and its quantitation was performed by automatic peak area integration using dedicated software (*Millennium*,[32] Waters). Before the analysis, each sample was resuspended, diluted in mobile phase 1:10, and filtered onto 0.2 μm filters, and then 50 μL was injected onto the column.

Stock solutions of resveratrol were freshly prepared immediately before use in DMSO at a concentration of 20 mM. Working solutions were prepared by diluting stock resveratrol solutions to the desired concentration in appropriate solvents. Calibration curves in the range of 1−12 nmol were prepared by replicate autosampler injections of different volumes of a standard solution of 0.219 mM resveratrol. The curves (six data points, in duplicate) were linear with R^2 values of ≃1.00. Peak detection was carried out at 306 nm, and the purity of the peak was checked with the diode array detector to verify the characteristic absorption spectrum of the polyphenol. The limit of

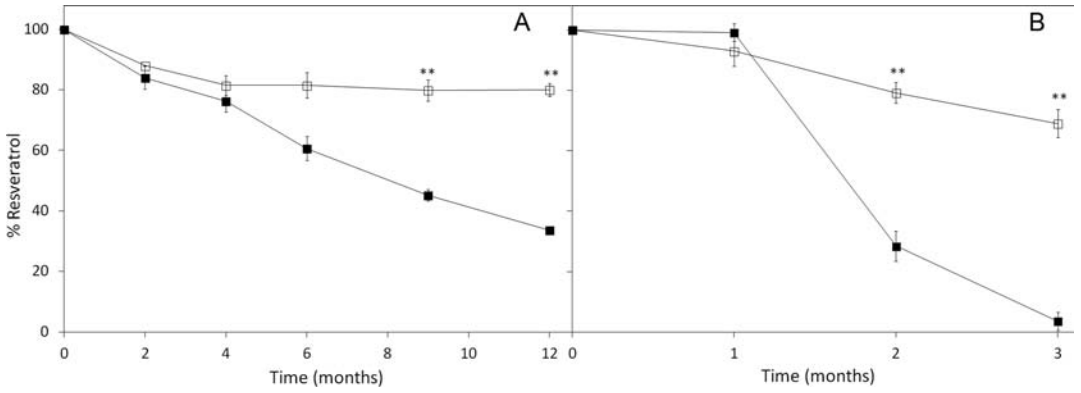

Figure 3. Stability analyses of the resveratrol/CM-glucan suspension. (A) Long-term stability at 25 °C: 0.05% resveratrol was resuspended in aqueous solutions in the presence (white squares) or in the absence (black squares) of 0.1% CM-glucan. Data points at 9 and 12 months are significantly different between resveratrol and resveratrol with CM-glucan (** = $p < 0.01$). (B) Accelerated stability at 40 °C: 0.05% resveratrol was resuspended in aqueous solutions in the presence (white squares) or in the absence (black squares) of 0.1% CM-glucan. Data points at 2 and 3 months are significantly different between resveratrol and resveratrol with CM-glucan (** = $p < 0.01$).

detection (4 pmol) was calculated as the analyte concentration giving a signal 3 times higher than the baseline value.

Fourier Transform Infrared Spectroscopy (FT-IR). FT-IR spectra were measured with a Nicolet Magna 760 (Thermo Scientific, Waltham, MA, USA) infrared spectrometer equipped with an ARK attenuated total reflectance device. The internal reflection element was ZnSe. Spectra were recorded at 4 cm^{-1} resolution with a DTGS detector. Samples were evaporated onto the ATR crystal by N_2 stream. The IR spectrum of the preserving agent utilized in the long-term measurements (i.e., benzalkonium chloride) was subtracted from spectrum of each sample analyzed.

Spectrofluorometric Analyses. Fluorescence emission spectra were recorded on a SPEX-Fluoromax spectrofluorometer (Horiba Scientific, Horiba Ltd., Kyoto, Japan) from 360 to 500 nm with excitation at 350 nm using a 0.1 cm path length quartz cuvette, under continuous stirring. The excitation and emission slits were both set to 5 nm, and scan speed was 120 nm/min.

Free Radical Scavenging Assay. Samples were tested for their free radical scavenging capacity by using the DPPH• test. DPPH•, a stable nitrogen-centered free radical, shows an absorption maximum at 517 nm, which decreases in the presence of H-donor molecules. Ten microliters of each sample was added to 1 mL of 30 μM DPPH• in ethanol, vortexed, and left for 15 min in the dark. Absorbance was measured at 517 nm on a Hitachi U-2000 spectrophotometer (Hitachi Ltd., Tokyo, Japan). The DPPH radical scavenging activity was estimated as described by Shi et al.[12]

Statistical Analyses. Experiments were repeated at least in triplicate, and all of the results are expressed as the mean value ± standard deviation (SD). Statistical comparison between groups was made using Student's t test. p values <0.05 were regarded as significant.

RESULTS

Long-Term and Accelerated Stability Analyses. To assess whether CM-glucan is able to stabilize resveratrol, we analyzed the shelf life of this compound in aqueous solutions in various storage conditions and at different times.

Data obtained from HPLC analyses of 0.05% resveratrol dissolved in PBS or in 0.9% NaCl solutions containing 0.1% CM-glucan show that the stability of this polyphenol is highly improved, with respect to the samples in which resveratrol is dispersed in saline solutions without CM-glucan. In the former case the loss of resveratrol is about 20% within 12 months; in the latter. this compound quickly undergoes oxidative and degradation processes with a loss of about 70% within 12 months (Figure 3A). Accelerated stability measurements at 40 °C confirm these data, indicating that in aqueous solutions without CM-glucan, resveratrol undergoes a rapid degradation and that this phenomenon is counteracted by CM-glucan (Figure 3B).

Further evidence of the stabilizing effect of CM-glucan on resveratrol is supported by the analysis of the absorbance spectra of the resveratrol peak (t_r = 7 min), as obtained by photodiode array detector. The results show that when resveratrol is in association with CM-glucan, it maintains its characteristic absorbance spectrum after 12 months at 25 °C, with a maximum at 306 nm and a shoulder around 320 nm, whereas preparations containing only resveratrol in aqueous solution show a peak at 270 nm and a shoulder at 305 nm, the absorbance of which is markedly lower than that of the unmodified compound (Figure 4).

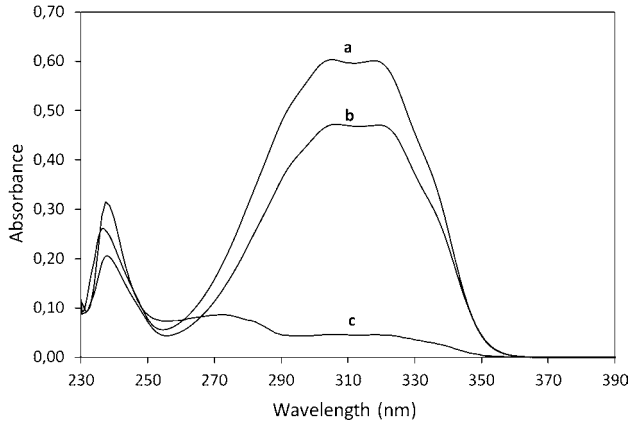

Figure 4. UV−visible spectra of the resveratrol peak (retention time = 7 min) isolated by HPLC from various samples: (a) freshly prepared 0.05% resveratrol in aqueous solution; (b) 0.05% resveratrol in 0.1% CM-glucan after 12 months at 25 °C; (c) 0.05% resveratrol in aqueous solutions after 12 months at 25 °C.

FT-IR. The spectra of resveratrol, CM-glucan, and their association were analyzed by FT-IR immediately after sample preparation and after 1 year of storage at room temperature to ascertain the concordances or the differences and to eventually verify the integrity or the degradation of resveratrol. As shown in Figure 5, the spectrum of isolated CM-Glucan (a) shows absorption bands at 1600, 1421, 1328, and 1047 cm^{-1} corresponding to the asymmetrical stretch of COOH, the

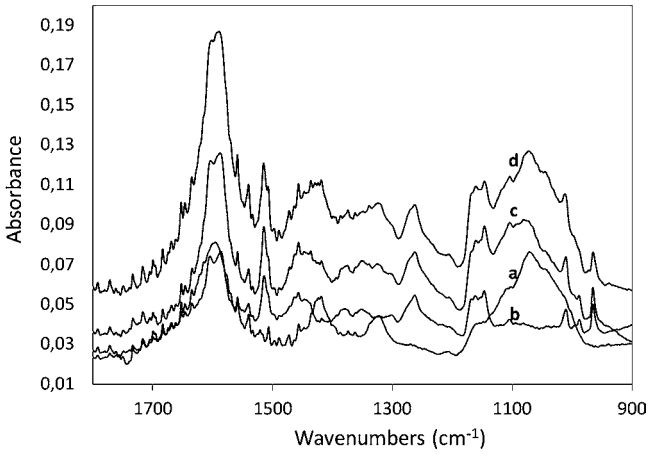

Figure 5. FT-IR spectra of resveratrol within the CM-glucan matrix. FT-IR-ATR spectra of 0.05% resveratrol embedded within 0.1% CM-glucan matrix are reported immediately after preparation (d) and after 12 months at 25 °C (c), in the region from 1800 to 900 cm^{-1}. Spectra of freshly prepared resveratrol (a) and CM-glucan (b) are also reported. All spectra were recorded at 25 °C, as thin layers over a ZnSe ATR reflection element.

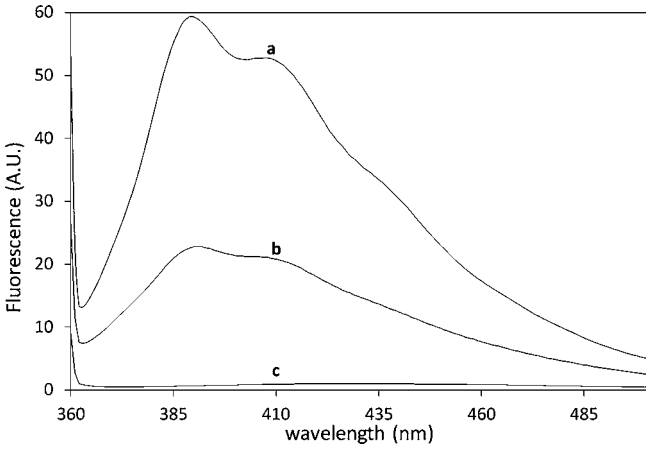

Figure 6. Fluorescence spectra of resveratrol or resveratrol/CM-glucan suspension. Resveratrol (0.05%) resuspended in aqueous solutions in the presence (b) or in the absence (a) of 0.1% CM-glucan was excited at 350 nm. Fluorescence spectra were recorded between 360 and 500 nm. CM-glucan in water (0.1%) (c) was used as a blank.

symmetrical stretch of COOH, and C−O and C−C stretches, respectively.[20] The resveratrol spectrum (b) shows a typical aromatic stretch at 1614 cm^{-1} that overlaps with asymmetrical COOH stretching of the CM-glucan. Resveratrol has also characteristic absorption bands at 1270 and 1150 cm^{-1} in the fingerprint region, corresponding to the in plane aromatic bending. Additional resveratrol bands occur at 1010, 988, and 966 cm^{-1}, corresponding to the three phenolic C−O stretches of the three hydroxyl groups on the aromatic rings. The same features observed in the isolated compounds are also present when resveratrol is complexed with CM-glucan. Interestingly, the spectrum of the mixture, recorded after 12 months at 25 °C (c), shows that there are no differences with respect to the spectrum of the freshly prepared solution (d).

Fluorescence Spectroscopy Analyses. To analyze whether resveratrol is able to interact with CM-glucan, we carried out spectrofluorometric analyses. When excited at 350 nm, resveratrol shows an emission spectrum with a maximum at 390 nm and a shoulder at 410 nm (Figure 6).[23] No significant spectral shift was noticed in the fluorescence spectrum of resveratrol after the addition of CM-glucan; however, a quenching effect was evident. The quenching effect on resveratrol by CM-glucan was calculated using the equation

$$Q\% = (1 - F/F_0) \times 100\%$$

where $Q\%$ represents the quenching fraction (%) and F_0 and F are the fluorescence intensities read at emission maximum of resveratrol (390 nm) in the absence or in the presence of CM-glucan, respectively. In our experimental conditions, CM-glucan is able to quench resveratrol intrinsic fluorescence by about 65−70%.

DPPH Radical Quenching by Resveratrol. DPPH• radical scavenging activity is widely used by many authors to measure the antioxidant activity of phenolic compounds.[24−26] This method was used to assess the radical scavenging activity of resveratrol solutions, either freshly prepared or aged in the presence or absence of CM-glucan.

The results of the radical scavenging capacity are expressed as percent of scavenging activity versus the intrinsic scavenging activity of the freshly prepared resveratrol samples (Figure 7). The higher the inhibition rate, the greater the hydrogen-donating ability and thus the higher the antioxidant activity. In our experimental conditions the association of resveratrol and CM-glucan has the same DPPH• scavenging activity with respect to freshly prepared resveratrol, and this activity is maintained after 12 months of storage at 25 °C, with only a partial loss of activity. On the contrary, aged resveratrol samples without CM-glucan or samples of CM-glucan have no significant antioxidant activity.

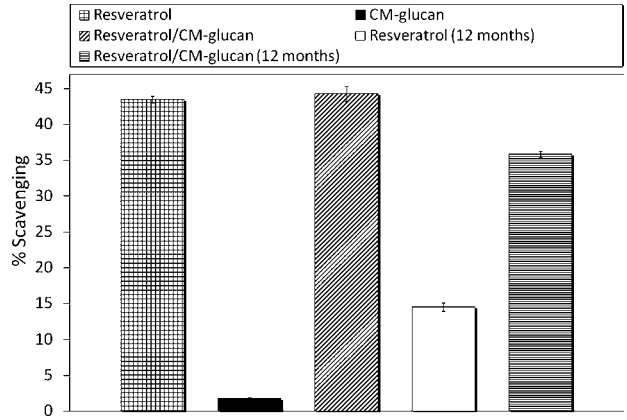

Figure 7. DPPH radical scavenging activity of resveratrol or resveratrol/CM-glucan suspension. DPPH scavenging activity was measured by determining the decrease in absorbance at 517 nm of a DPPH ethanolic solution taken as 100%.

DISCUSSION

Despite great interest in resveratrol and its multiple pharmacological properties, to date no pharmaceutical preparations are available on the market except for various food supplements or nutraceuticals. Resveratrol is unstable in aqueous solutions, and therefore the development of a liquid formulation useful for pharmacological applications is a significant challenge. The goal of our work was to develop a new liquid formulation by combining resveratrol with a

dx.doi.org/10.1021/jf404155e | J. Agric. Food Chem. 2014, 62, 1520−1525

polysaccharide able to stabilize this polyphenol over the long term.

One of the most interesting properties of CM-glucan is its structure-forming capacity, which, combined with its pharmacological activity, makes this compound ideal for the formulation of pharmaceutical preparations, which simultaneously take advantage of both properties. Gao and co-workers successfully encapsulated the anticancer drug Epirubicin in carboxymethyl Curdlan (a polysaccharide having a structure very similar to that of glucan) and demonstrated that compared with the free drug, Epirubicin-loaded Curdlan particles showed a higher anticancer activity.[27]

The evidence that glucan biopolymers may simultaneously act as a carrier of insoluble compounds and exert immunomodulatory and antioxidant activities prompted us to develop a new formulation in which resveratrol was combined with CM-glucan. This latter compound could act in synergistic action with resveratrol against a variety of pathogens (virus, bacteria) and could counteract its degradation in aqueous solutions. Recently, a combination of resveratrol and β-glucan has been described by Vetvika and co-workers in a number of publications in which the authors tested the synergistic effect of these two components in different model systems.[28−30] However, they did not aim at developing a new formulation or at assessing its shelf life.

Long-term stability studies, up to 12 months at 25 °C, demonstrated that the association with CM-glucan protected resveratrol from the fast degradation in aqueous medium. However, within the first 3 months the stability of resveratrol is only slightly affected by CM-glucan presence and is quite similar to the control sample, most probably because not all of the resveratrol molecules are bound to CM-glucan. The accelerated stability analyses at 40 °C further confirmed that the combination of resveratrol and CM-glucan shows a higher stability compared to resveratrol alone in solution.

In long-term stability analyses in the absence of CM-glucan, resveratrol shows a shift in its absorption spectrum, from 306 to 270 nm. This spectral feature can be correlated to the degradation or the oxidation of resveratrol[31] and cannot be attributed to the formation of *cis*-resveratrol, which has a λ_{max} of 284 nm and a retention time of 11.5 min in our experimental conditions.

HPLC analysis and the FT-IR spectra support the idea of a stable complex formation, as no modification of the UV−vis and IR spectra are observed during storage time. FT-IR, spectrophotometric, and stability data are in good agreement and overall clearly indicate that the CM-glucan matrix exerts a strong stabilizing effect on the polyphenolic molecule.

Furthermore, in our experiments, we observed that resveratrol stabilization by CM-glucan was independent of the method utilized for resuspension; that is, the mechanical dissolution by vortexing gave similar results compared to sonication or extensive magnetic stirring (data not shown). This indicates that the interaction between CM-glucan and resveratrol is of a chemical nature and independent of any physical or mechanical action that may favor the interaction of these two molecules.

The evaluation of the antioxidant potential of resveratrol by the DPPH assay further supports the HPLC and FT-IR data, as the CM-glucan completely prevents the loss of antioxidant activity of resveratrol due to prolonged storage of the preparations. In our experimental conditions the association of resveratrol and CM-glucan has the same $DPPH^{\bullet}$ scavenging activity with respect to resveratrol control samples, and this activity is maintained after 12 months of storage at 25 °C, even though there is a partial loss of activity, which exactly matches the 20% reduction in resveratrol amount observed by HPLC. On the contrary, CM-glucan alone or aged solutions of resveratrol have a low antioxidant activity in contrast to freshly prepared resveratrol samples.

As widely described in the literature, resveratrol is an extremely unstable molecule, easily undergoing oxidative and degradative processes when solubilized in water. The stabilization of the polyphenolic molecule by CM-glucan may be due to various factors. First, CM-glucan may exert a physical barrier by encapsulating resveratrol and protecting it from the environment, acting with a β-cyclodextrin-like mechanism.[6] This hypothesis is supported by spectrofluorometric measurements, in which we observed a quenching of resveratrol fluorescence without any significant modification of the emission spectrum or spectral shift. These data indicate that CM-glucan does not induce any obvious changes in resveratrol conformation, most likely due to a dynamic interaction. The decrease of fluorescence may indicate that the microenvironment of resveratrol molecules was altered due to the interaction with the biopolymer. These data suggest that the chemical environment created by CM-glucan can protect the polyphenol from degradation processes. It can be hypothesized that CM-glucan can establish a weak electrostatic interaction with resveratrol, contributing to the stabilization of the molecule by counteracting oxidative processes of hydroxyl groups and hampering the formation of quinonoid species. Indeed, another possible mechanism by which CM-glucan may exert a stabilizing effect on resveratrol may be due to its antioxidant activity, which can limit resveratrol autoxidation in solution, thereby hampering the formation of oxidation and degradation products of this compound. CM-glucan antioxidant activity was extensively studied by many authors, and this compound is largely utilized in many cosmetic preparations as it protects skin cells against ultraviolet A (UV-A) irradiation and promotes keratinocytes growth, thus enhancing the renewal rate of the stratum corneum.[21,32−34] In our experimental conditions CM-glucan shows a low antioxidant activity, most likely due to the low amount of sample used to highlight the differences in the scavenging activity of resveratrol among the various samples.

At present, a search of the clinicaltrials.gov database reveals that there are a total of 68 studies on resveratrol, of which 28 are ongoing trials. This is strong evidence of the great interest of the scientific community in this molecule; however, there is compelling evidence for the need of improved and more suitable formulations to get better clinical outcomes and reach clinical effectiveness. Our data provide evidence of the possibility to formulate resveratrol in liquid suspensions, overcoming its chemical instability and the consequent loss of biological activity and pharmacological efficacy.

the TLRs, TLR2 is known to recognize several molecules from Gram-positive bacteria and mycobacteria, such as lipoteichoic acid, lipopeptides, and peptidoglycan,[11] whereas TLR4 is a transmembrane protein that plays an essential role in the recognition of LPS, which is the main component of the outer membrane of Gram-negative bacteria.[12] Both of these receptors have been demonstrated to play important roles in recognition of mushroom compounds that possess bioactive properties and active TLR-mediated signaling pathways that enhance the immune response.[13,14]

In the present study, a novel immune-activating protein, *T. fuciformis* immunomodulatory protein (TFP), which was isolated from the dried fruiting bodies of *T. fuciformis*, was demonstrated to induce macrophage activation. We demonstrated that TFP induces macrophage activation through NF-κB. Furthermore, our data revealed that TFP enhances proinflammatory gene expression and induces M1-type polarization of macrophages through a TLR4-dependent pathway.

MATERIALS AND METHODS

Mice. BALB/c and C57BL6 mice that were 8−10 weeks of age were purchased from the National Laboratory Animal Center, Taipei, Taiwan. TLR4-deficient mice ($TLR4^{-/-}$, strain C57BL/10ScN) were purchased from Jackson Laboratory (Bar Harbor, ME) and maintained in our animal facility under specific pathogen-free conditions. All mice were fed a standard mice diet (LabDiet, Richmond, IN). All experimental procedures were approved by the Institutional Animal Care and Use Committee of National Taiwan University (NTU-IACUC-95-139).

Cell Preparation. Peritoneal macrophages were obtained from BABL/c, C57BL/6J, and $TLR4^{-/-}$ mice 3 days after i.p. injection of 1.8 mL of sterile 3% thioglycollate (Sigma, St. Louis, MO). Macrophages were harvested by sacrificing mice and flushing ∼6 mL of cold phosphate-buffered saline (PBS) into the mouse peritoneal cavity twice. The fluid containing the macrophages was centrifuged and resuspended in Dulbecco's modified Eagle's medium (DMEM) (Hyclone, Logan, UT) with 10% (v/v) fetal bovine serum (FBS) (Life Technologies, Grand Island, NY). The cells were counted, plated in 24-well (2×10^6 cells/well) or 12-well (4×10^6 cells/well) flat-bottom culture plates (Costar, Cambridge, MA), and incubated for 2 h in a humidified atmosphere of 5% CO_2 at 37 °C. After the incubation, the supernatants were removed, and the cells were washed with warm PBS to remove nonadherent cells. The cells were further incubated in DMEM containing 10% FBS before and during all experiments.

Purification of TFP. One kilogram of weighed dried fruiting bodies of *T. fuciformis* that were obtained from a local market were soaked in water for 2 h for rehydration and then soaked in a 5% (v/v) acetic acid solution containing 50 mM 2-mercaptoethanol at 4 °C overnight. After soaking, the fruiting bodies were homogenized and centrifuged at 8500*g* for 50 min. The soluble proteins in the supernatant were precipitated by adding ammonium sulfate from 60% saturation and centrifuging at 8500*g* for 50 min to collect the precipitates. The precipitates were dialyzed in 20 mM Tris-HCl buffer (pH 8.2) for 96 h with at least eight changes of the dialysis buffer. The main active fractions in the dialysate, which was capable of increasing TNF-α production by RAW 264.7 macrophages, were fractionated and purified using a fast protein liquid chromatography (FPLC) system with a Resource-Q anion exchange column (GE Healthcare, Uppsala, Sweden) in 10 mM Tris-HCl buffer containing 0.5 M NaCl (pH 8.0). Each fraction was analyzed with denaturing sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), and the fraction containing a single 24 kDa protein was chosen for activity analysis. The 24 kDa protein that could induce RAW264.7 macrophages to produce TNF-α was our target protein, TFP. The fraction containing TFP was further dialyzed and concentrated optimally for the subsequent analysis and in vitro experiments.

Molecular Weight Determination and Amino Acid Sequencing. The purity and molecular weight of TFP were analyzed by SDS-PAGE using a Bio-Rad mini protein III gel apparatus (Bio-Rad Laboratories, Hercules, CA). The gels were stained with Coomassie brilliant blue R250 or periodic acid-Schiff reagent (Sigma). The molecular mass of the protein was compared with those of standard proteins in the range of 10−170 kDa (Fermentas Life Sciences, Glen Burnie, MD). The molecular weight of TFP was further estimated using an FPLC system with a Superdex gel filtration column (GE Healthcare), equilibrated, and eluted with 50 mM phosphate buffer (pH 7.0) containing 0.15 M NaCl. The column was calibrated using the same parameters with protein standards (Amersham Biosciences, Uppsala, Sweden) consisting of ovalbumin, carbonic anhydrase, trypsin inhibitor, and lysozyme (Supplemental Figure 1 in the Supporting Information). The TFP sample was separated by SDS-PAGE and electrotransferred onto a poly(vinylidene difluoride) (PVDF) Immobilon P membrane (Millipore, Billerica, MA) using a Trans-Blot cell system (Bio-Rad) with transfer buffer. The TFP protein band was cut out from the membrane, and its N-terminal peptide sequence was determined using automated Edman degradation and sequence analysis (Mission, Taipei, Taiwan).

Molecular Cloning of the Gene and cDNA Encoding TFP. The total RNA of *T. fuciformis* fruiting bodies was extracted using an RNeasy Plant Mini Kit (Qiagen, Germantown, MD) according to the manufacturer's protocol. First-strand cDNA was synthesized from total RNA by reverse-transcription polymerase chain reaction (RT-PCR) using a Thermoscript RT-PCR system (Invitrogen, Carlsbad, CA) with a 3′-SMART RACE cDNA Amplification Kit (Clontech, Mountain View, CA). The 3′-RACE TFP primer and the TFP-specific forward degenerate primer 3T36, which was designed on the basis of the partial N-terminal amino acid sequence with the lowest degeneracy of the genetic code, were paired for PCR amplification of the *tfp* gene. The resulting 600 bp PCR product (3T36-600) was ligated into the pGEM-T easy vector (Promega, Madison, WI), transformed into *Escherichia coli*, and sequenced. The 5′ end of TFP was obtained by using a 5′-SMART RACE cDNA Amplification Kit (Clontech). The 5′-RACE TFP primer was paired with the reverse primer Fru5T1, which is specific for the 3T36-600 fragment, for PCR amplification. A 400 bp PCR product (Fru5T1-400 fragment) was sequenced by the same method. The full-length sequence of TFP cDNA was obtained by alignment of the 3T36-600 and Fru5T1-400 fragments. After synthesis of cDNA from the total RNA of *T. fuciformis* fruiting bodies as the template, the sequence was confirmed via PCR amplification with gene-specific primer pairs that were designed on the basis of the full-length sequence of TFP.

Expression and Purification of Recombinant TFP. The cDNA synthesized from the total RNA of *T. fuciformis* fruiting bodies was used to amplify the TFP gene for expression. The primers used for PCR amplification of TFP were 5′-CCATGGTCGTCCAGAGGGATGACACA-3′ and 5′-CTCGAGATCAAACGCCTAGTCGAACTC-3′. After purification, the PCR products were digested with *Nco*I and *Xho*I (New England Biolabs, Beverly, MA). Double-digested PCR products were ligated into pET30a(+) vector and transformed into *E. coli* BL-21 competent cells (Bioman, Taipei, Taiwan) for protein expression. A single BL-21 colony containing the pET30-TFP vector was inoculated into LB/ampicillin medium overnight and then induced with 1 mM IPTG for 3 h at 37 °C. The cultures were centrifuged at 6500 rpm for 30 min and rinsed twice with PBS. After collection, the bacteria were sonicated for 30 min and then centrifuged at 6500 rpm for 30 min. The supernatants were collected for FPLC purification with a HiTrap chelating HP column (GE Healthcare). Before loading of the supernatants, the 1 mL Hitrap chelating column was prepared according to the manufacturer's instructions and equilibrated with binding buffer (0.02 M sodium phosphate, 0.5 M NaCl, 5 mM imidazole, pH 7.4) by washing with five column volumes. The column was loaded with supernatants containing His-tagged TFP protein and washed with five column volumes of binding buffer to remove nonbinding protein. His-tagged TFP protein was eluted with elution buffer (0.02 M sodium phosphate, 0.5 M NaCl, 0.5 M imidazole, pH 7.4) in the final fractions. The purities of the fractions containing His-tagged TFP protein were identified by SDS-PAGE and Western blotting analysis with monoclonal antibodies (mAbs) specific

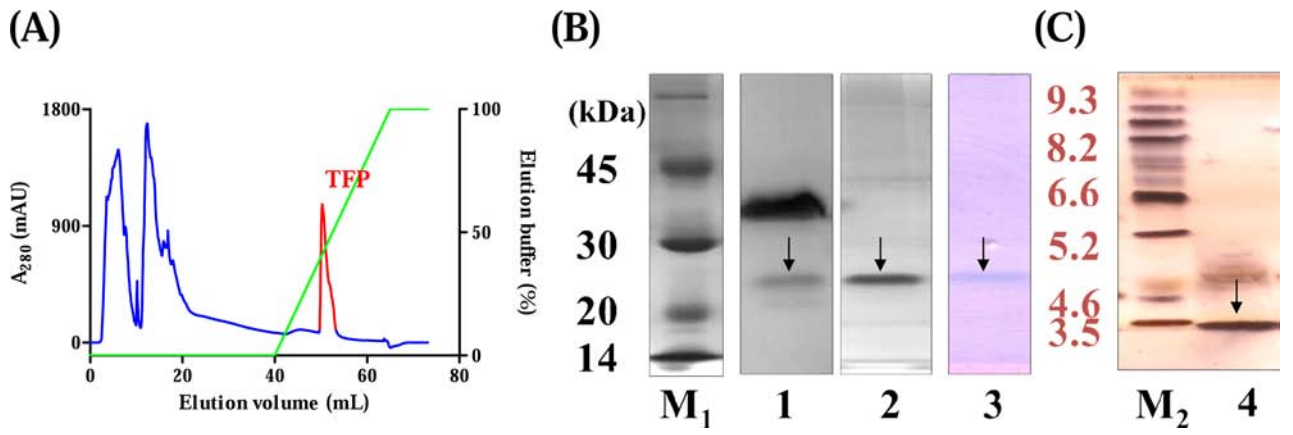

Figure 1. Chromatographic purification and electrophoretic analysis of native TFP. (A) The elution profile of the ammonium sulfate precipitates of a *T. fuciformis* dried fruiting body from FPLC using a Resource Q column displayed a single peak of TFP. (B) SDS-PAGE analysis of the crude protein from *T. fuciformis* (lane 1), purified TFP (lane 2), and purified TFP with periodic acid/Schiff's staining (lane 3) indicated that TFP had a mobility similar to that of a 24 kDa protein that did not contain carbohydrates. (C) Isoelectric focusing analysis (lane 4) indicated that the pI of TFP is 3.45.

for TFP and the His tag. The His tag was removed from the recombinant His-tagged TFP protein using EKMax enterokinase (Invitrogen) to yield recombinant TFP. All of the proteins were dialyzed with PBS and further concentrated optimally for the subsequent analysis.

Determination of Cytokine Production. The production of the cytokines TNF-α, IL-1β, IL-10, and IL-12p70 in cell-culture supernatants was determined by sandwich enzyme-linked immunosorbent assay (ELISA) using mouse TNF-α, IL-1β, and IL-10 ELISA kits (eBioscience, San Diego, CA) and a DuoSet mouse IL-12p70 ELISA Kit (R&D Systems, Minneapolis, MN) according to each manufacturer's protocols.

Quantitative Real-Time PCR. The cells were lysed using TRIzol reagent (Invitrogen), and the total RNA was extracted from the cell lysate according to the manufacturer's protocols. The quality and concentration of RNA were determined using a NanoDrop ND-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE). The total RNA was used as a template to synthesize the first-strand cDNA with a ThermoScript RT-PCR system (Invitrogen) for evaluation of the expression of genes implicated in TFP-induced activation in macrophages. The expression differences of individual genes were measured using real-time PCR. The primers were based on macrophage-specific cytokines, chemokines, and transcription factor sequences from NCBI and designed for SYBR green probes with Probe Design software (Roche, Mannheim, Germany) (Supplemental Table 1). Gene amplifications were normalized to the β-actin housekeeping gene. Real-time PCR was performed using a Bio-Rad MyiQ single-color detection system (Bio-Rad). The expression level of the individual target genes was quantified with the relative levels of the specific mRNA using cycling threshold (Ct) analysis. The relative expression value of significantly different expression in the gene should be higher than 4-fold relative to the 0 h control.

Electrophoretic Mobility Shift Assay. The DNA−protein interaction was determined using a LightShift Chemiluminescent EMSA kit (Pierce, Rockford, IL) according to the manufacturer's protocol. The nuclear protein extracts were prepared using NE-PER nuclear and cytoplasmic extraction reagents (Pierce) and incubated with biotinylated double-stranded NF-κB probes. The DNA−protein complexes were analyzed using a native 6% polyacrylamide gel and electrotransferred onto nylon membranes. When the transfer was completed, the biotinylated NF-κB−DNA complexes were detected using a chemiluminescent substrate kit (Pierce) with peroxidase-conjugated streptavidin.

Fluorescence-Activated Cell Sorting (FACS) Analysis. The expressions of surface CD80, CD86, and MHC-II on mouse peritoneal macrophages that were cultured with TFP for 24 h were detected using a FACScan flow cytometer (BD Biosciences, Franklin Lakes, NJ) with fluorescein isothiocyanate (FITC)-conjugated antibodies specific for mouse CD80, CD86, and MHC-II (eBioscience). The cells were harvested with PBS, centrifuged at 1500*g*, and resuspended with PBS containing 2% bovine serum albumin and 0.1% sodium azide (FACS buffer). Antibody was added to the cell suspensions, which were then incubated at 4 °C for 30 min. After the treatments, the cells were washed with FACS buffer to remove the unbound antibodies.

For phagocytosis experiments, the cells were incubated with TFP for 24 h, collected, centrifuged, and resuspended in FACS buffer. The phagocytosis ability of macrophages was analyzed using a Vybrant Phagocytosis Assay Kit (Molecular Probes) according to the manufacturer's protocol. After addition of the fluorescent *E. coli* BioParticles, cells (10^6 cells/mL) were incubated at 4 °C as a negative control and for 37 °C for 1 h. Antibody-stained or *E. coli*-treated cells were analyzed to determine the mean fluorescence intensity (MFI) and percentage of positive fluorescent cells using a FACScan flow cytometer with CellQuest software (BD Biosciences). The peak fluorescence intensities of the control and experiment groups were compared.

Statistical Analysis. All data are presented as means ± standard deviations of three independent experiments (n = 3) performed in triplicate. The statistical comparisons were executed by analysis of variance (ANOVA). When the P value was below 0.05 (i.e., $P < 0.05$), the differences were considered to be statistically significant.

RESULTS

Purification of TFP. To isolate the bioactive protein from *T. fuciformis*, the crude protein of the dry fruiting body that was obtained from homogenization and ammonium sulfate precipitation was subjected to FPLC using a Resource Q anion exchange column with a linear gradient of sodium chloride (0−0.5 M in 20 mM Tris-HCl buffer, pH 8.2). Measuring absorbance at 280 nm revealed a remarkable peak in the elution profile (Figure 1A). With this procedure, we were able to collect around 61 mg of this purified protein from 100 g of the dry fruiting bodies. The protein of this peak was then collected, and its activity was investigated by coculturing with RAW 264.7 macrophages. Significant TNF-α production was observed in the supernatant of RAW 264.7 cells that were cultured with the peak fraction (Supplemental Figure 2). This active fraction was analyzed with SDS-PAGE and displayed a single protein with an observed molecular mass of approximately 24 kDa (Figure 1B). This bioactive protein was designated TFP. The endotoxin level in the TFP sample which as determined with a ToxinSensor Chromogenic LAL Endotoxin Assay Kit was around 0.14 EU/μg (data not

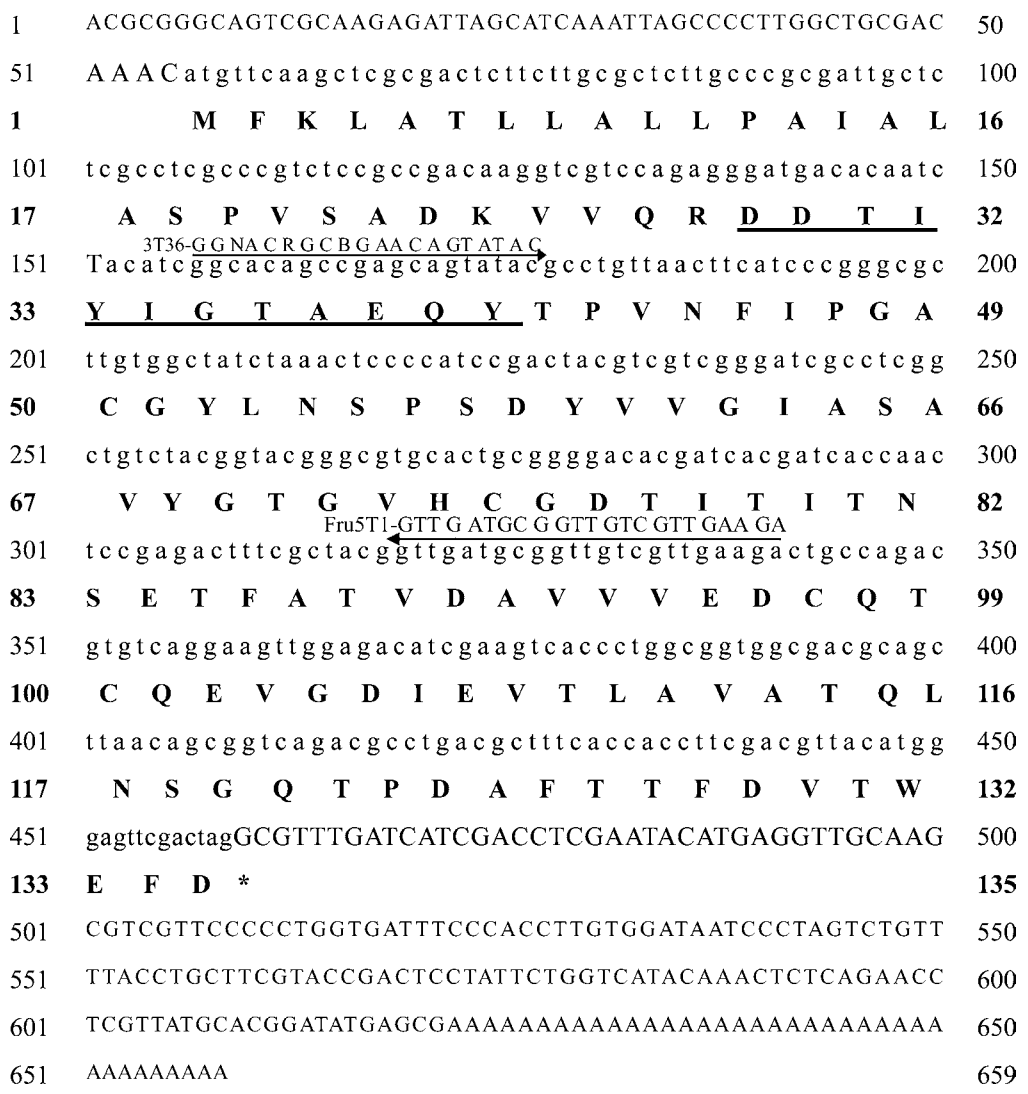

Figure 2. Nucleotide and translated amino acid sequence of TFP. The N-terminal amino acid sequence obtained by Edman degradation is underlined, and the signal peptide of TFP is shown in bold. The forward degenerate primer (3T36) based on the TFP N-terminal sequence (GTAEQY) and used in 3′-RACE PCR is indicated above the right-pointing arrow. The DNA sequence of the reverse degenerate primer (Fru5T1) used in 5′-RACE with the 3′-RACE product sequence (VDACCCED) is shown above the left-pointing arrow. The full-length sequence of TFP reported in this paper has been deposited in the GenBank database (accession number EF152774).

shown). To further analyze the biochemical characteristics of TFP, we used carbohydrate staining and isoelectric focusing electrophoresis to determine that TFP was not a glycoprotein (Figure 1B and Supplemental Figure 3) and that its pI value was 3.45 (Figure 1C), respectively.

Cloning of TFP. To clone the full-length cDNA sequence of TFP, we used N-terminal amino acid analysis and RACE by RT-PCR. First, the TFP after electrophoretic analysis with SDS-PAGE was immobilized onto a PVDF membrane and then subjected to N-terminal amino acid analysis. The sequence of the 15 N-terminal amino acid residues, DDTIYIGTAEQYTPV, was obtained from Edman degradation and analysis. This sequence exhibited low similarity to any known protein based on an NCBI database search with BLASTP. Next, we designed degenerate primers for RACE according to the TFP N-terminal amino acid sequence. The full-length DNA sequence was determined by a combination of RT-PCR and 3′/5′-RACE PCR with degenerate oligonucleotide primers. The 3′-RACE primer was designed by selecting the codon with the highest frequency based on the NCBI codon usage table of the *Tremella encephala* β-tubulin (tub2) gene. We obtained a 600 bp sequence of the 3′-RACE product (3T36-600), and its translated amino acid sequence was highly similar to the N-terminal sequence of TFP. On the basis of this 3′-RACE product, the primer Fru5T1 was then designed and used for the 5′-RACE PCR, which further generated a 400 bp fragment, Fru5T1-400, that encoded the same starting amino residues (DDTIYIGTAEQYTPV) as native TFP. By merging the two open reading frames of 3T36-600 and Fru5T1-400, we obtained the full-length sequence of TFP (GenBank accession number EF152774). A conceptual translation and analysis of the 336 bp open reading frames of the 408 bp TFP transcript suggested that this gene encodes a 112 aa protein with a predicted molecular mass of 11.34337 kDa (Figure 2).

Native TFP Exists as a Homodimer. According to the gene sequence of TFP, its predicted molecular mass (11 kDa) is approximately half of the mass of native TFP from the SDS-PAGE (24 kDa) (Figure 1B, lane 2). To clarify the conflict in the values of the molecular mass from the prediction and the SDS-PAGE observations, we determined the mobility of

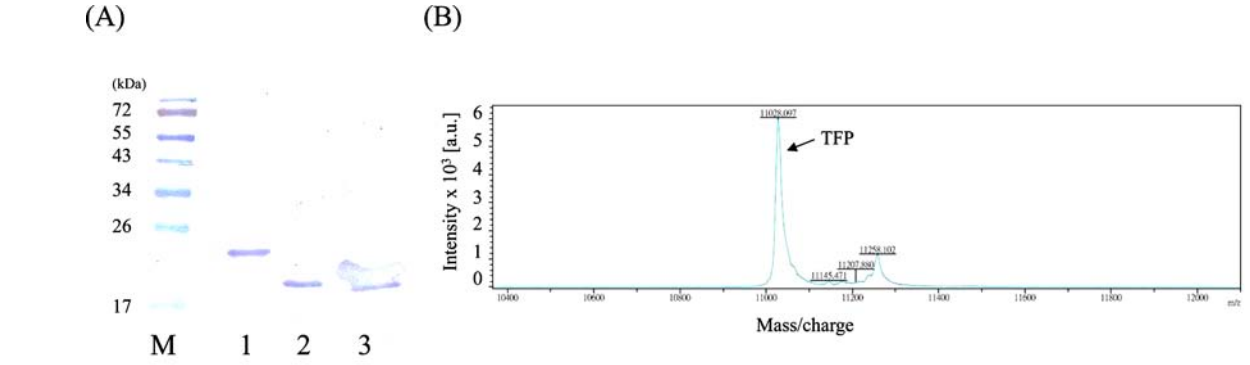

Figure 3. TFP is a homodimer protein. (A) Western blotting using an mAb against recombinant His-tagged TFP (lane 1), the enterokinase-digested product of His-tagged TFP (lane 2), and native TFP (lane 3). (B) The MALDI-TOF MS spectrum obtained from a purified TFP sample indicated a protein mass/charge ratio of between 10 400 and 12 000. The TFP peak is marked.

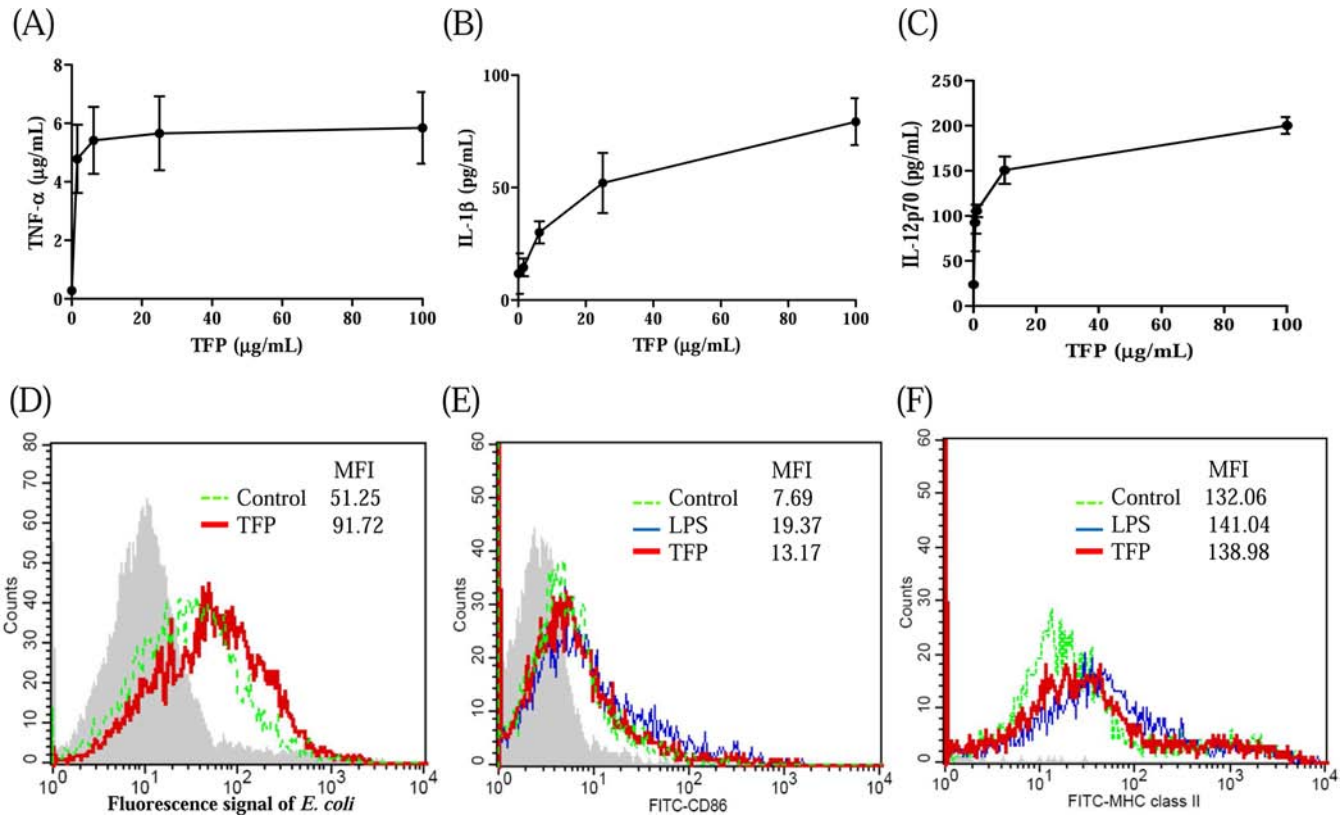

Figure 4. Effect of TFP on cytokine production and activation in mouse peritoneal macrophages. (A–C) Peritoneal macrophages freshly prepared from BALB/c mice were cultured in the presence of TFP at the indicated concentrations for 24 h. TFP induced (A) TNF-α, (B) IL-1β, and (C) IL-12p70 production. (D–F) Peritoneal macrophages stimulated with TFP (6 μg/mL) or LPS (1 μg/mL) for 24 h were analyzed, and the TFP-stimulated cells displayed enhanced (D) phagocytosis activity, (E) CD86 expression, (F) and MHC class II expression. The shaded areas indicate unstained controls, the green dotted lines indicate cells without stimulation, the thin blue solid lines indicate LPS-stimulated cells, and the thick red lines indicate TFP-stimulated cells.

recombinant TFP (rTFP) and its mass spectrum. To produce rTFP, the cDNA sequence encoding TFP from Asp[25] to the stop codon, containing 110 amino acids, was cloned into a pET-30a(+) vector and then transformed into the bacteria host *E. coli* BL21 with the constructed plasmid. Interestingly, transformant-expressed rTFP exhibited the mobility of a 24 kDa protein even though the inserted gene was predicted to translate an 11 kDa protein (Figure 3A), implying that TFP from the fruiting body of *T. fuciformis* could natively form a homodimer. Furthermore, to establish the molecular mass of TFP, the protein was analyzed with MALDI-TOF mass spectrometry. As shown in Figure 3B, TFP had a molecular mass of 11 033 Da, which is approximately the same as the predicted molecular mass from the TFP gene analysis. In addition, in the presence of a high percentage of β-mercaptoethanol, the mobility of TFP in SDS-PAGE still equaled that of a 24 kDa protein in the SDS-PAGE (Supplemental Figure 4). According to these results, we assume that the TFP dimer results not from disulfide bonds but rather from other protein interactions. Furthermore, we

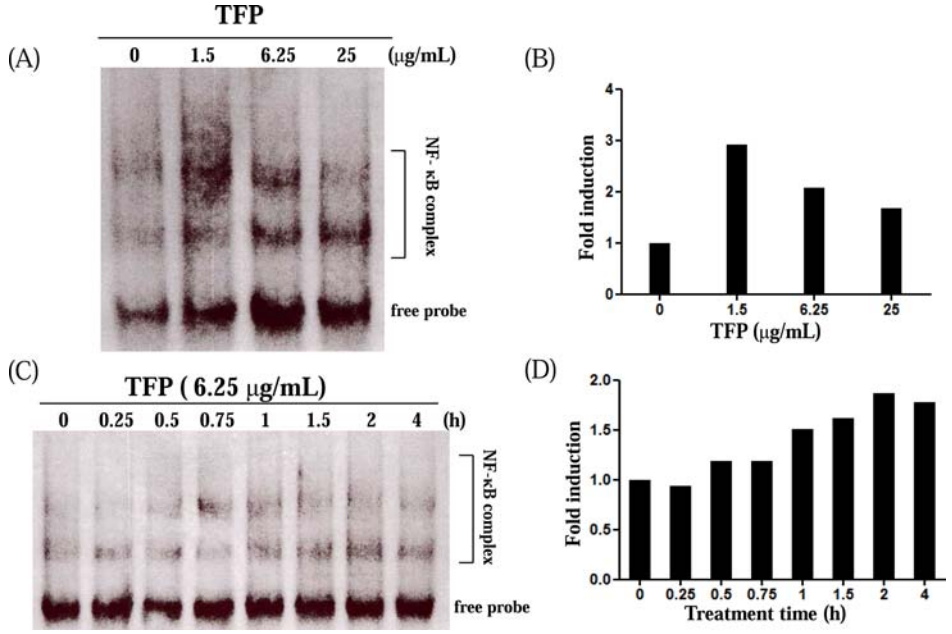

Figure 5. Effect of TFP on NF-κB activity in peritoneal macrophages. TFP-induced nuclear NF-κB DNA binding in mouse peritoneal macrophages occurred in a dose- and time-dependent manner. Nuclear NF-κB activity was determined by EMSA after the binding of nuclear extract to the labeled oligonucleotide corresponding to the NF-κB binding site. The biotin-labeled NF-κB DNA binding complex was visualized using chemiluminescence detection. (A) TFP-induced NF-κB DNA binding varied with the treatment concentration. The cells were cultured with the indicated concentration of TFP for 1.5 h, collected for nuclear protein extraction, and analyzed with EMSA. (B) The results of the densitometry analyses were compared with that for untreated cells (0 μg/mL TFP). (C) TFP initiated nuclear NF-κB DNA binding after 1 h of TFP treatment. The cells were treated by TFP (6.25 μg/mL) for the indicated times. (D) The results of the densitometry analyses were compared with that for the untreated time point (0 h).

used the COTH software,[15] a web service for protein complex structure prediction, to identify the complex structure of TFP from its primary amino acid sequence (Supplemental Figure 5). Taken together, these data suggest that the observed TFP is an 11 kDa protein and that it mostly forms natural homodimers.

TFP Activates the NF-κB Pathway in Mouse Peritoneal Macrophages. We then investigated the influence of TFP on cytokine production in mouse peritoneal macrophages to explore the activating capability of TFP in innate immune systemic cells. The peritoneal macrophages were cultured with medium that contained TFP at different concentrations ranging from 1.5 to 100 μg/mL. The supernatants were harvested to analyze the production of TNF-α, IL-1β, and IL-12p70. The macrophages cultured in the presence of TFP displayed dose-dependent upregulation of TNF-α, IL-1β, and IL-12p70 (Figure 4A−C). In addition, we investigated the effects of TFP on the phagocytic activity and activation marker expression in macrophages with flow cytometry. In the phagocytic activity assay, TFP significantly enhanced the phagocytosis of mouse peritoneal macrophages (Figure 4D). The MFI value of the TFP-induced cells (91.72; red thick line) was significantly higher ($P < 0.05$) than that of the control cells (51.25; green dotted line). Similarly, the cells cultured in the presence of TFP expressed more CD86 and MHC class II molecules than the control cells (Figure 4E,F). However, TFP treatment did not induce CD80 expression in the macrophages (Supplemental Figure 6). These results suggest that TFP can activate the phagocytic and antigen-presentation capabilities of mouse macrophage cells.

NF-κB, one of the most essential transcription factors in the generation of host defense and the innate immune system, has an important role in the induction of TNF-α and IL-12p40 gene expression in macrophages.[16] In the present study, we investigated whether TFP induces the activation of NF-κB, resulting in upregulation of the production of the previously described cytokines. As shown in Figure 5A,B, TFP directly induced an increase of NF-κB in the cell nucleus, and stimulation with different concentrations of TFP could enhance the NF-κB activation. In addition, the activation of NF-κB displayed a time-dependent pattern with the TFP treatment (Figure 5C,D). These results reveal that TFP can induce NF-κB activation and further modulate cellular immune responses.

TFP Induces M1-Type Polarization in Mouse Peritoneal Macrophages. Polarization is an important method of differentiation of function and phenotype in macrophages and has been broadly classified into types M1 and M2 on the basis of functional property differences.[17] Given the high levels of pro-inflammatory cytokine expression in TFP-induced mouse peritoneal macrophages, we examined some of the known markers of activated M1 macrophages.[18,19] We performed real-time PCR assays to determine the cytokine gene expression in macrophages that were treated with 6.25 μg/mL TFP for 8 h. As shown in Figure 6, TFP treatment increased the mRNA expression of TNF-α, IL-1β, IL-6, and IL-12p35, all of which are M1-type cytokines, but not IL-10, which is an M2-type cytokine. In addition, we observed that TFP-induced cells displayed enhanced mRNA expression of M1-type chemokines, including CCL3 and CXCL10 (Figure 7A,D). The CCL4 and CCL5 expression levels were unaffected (Figure 7B,C). However, the mRNA expression levels of CCL17 and CCL24, which are M2-type chemokines, were not changed during 8 h of 6.25 μg/mL TFP treatment (Figure 7E,F). These results indicate that TFP might upregulate the expression of M1-type cytokines and chemokine mRNA expression and therefore may induce M1 polarization of mouse macrophages.

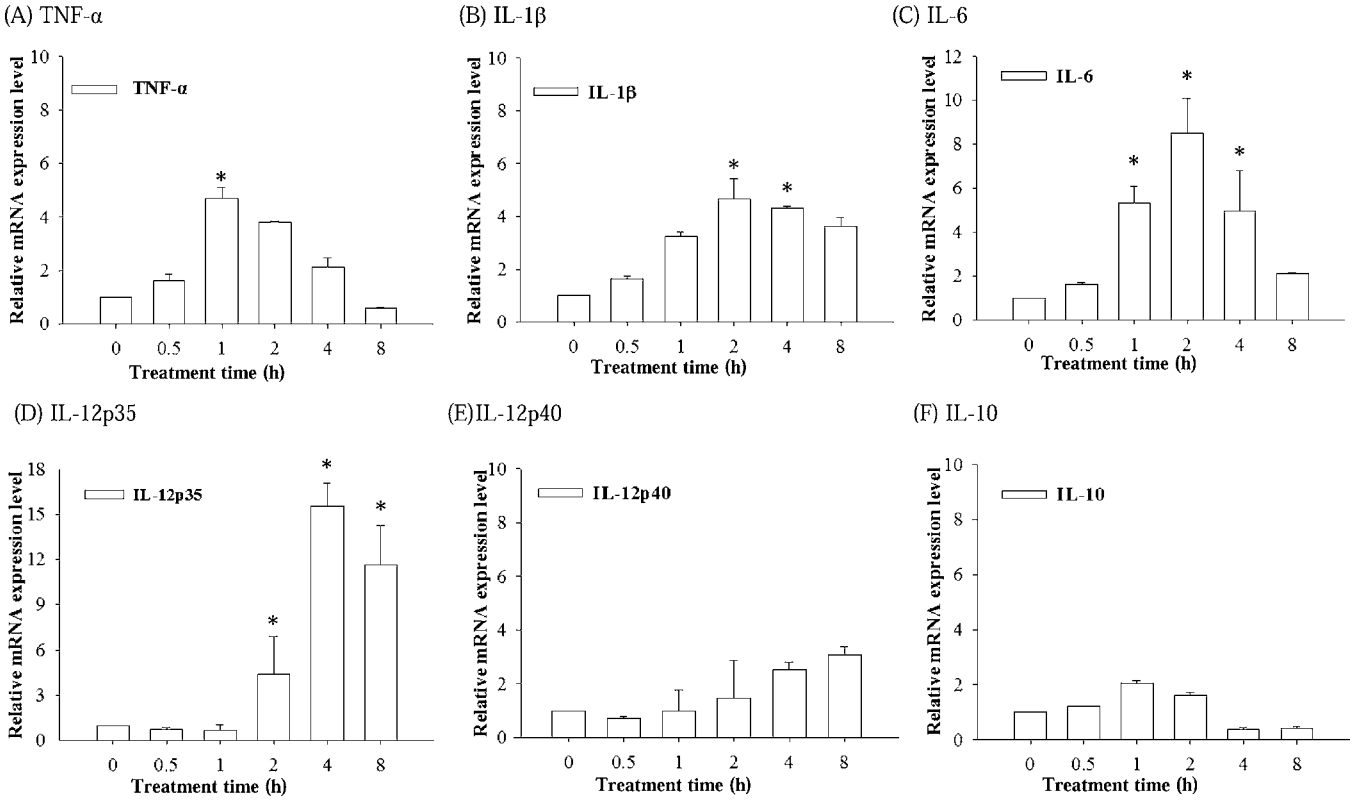

Figure 6. Effect of TFP on cytokine gene expression in peritoneal macrophages. A time course evaluation of cytokine mRNA expression in TFP-induced macrophages is shown. The cells were cultured in the presence of TFP (6.25 μg/mL) for the indicated times and collected for total RNA extraction. The expression of (A) TNF-α, (B) IL-1β, (C) IL-6, (D) IL-12p40, (E) IL-12p35, and (F) IL-10 mRNA was analyzed with quantitative real-time PCR. The mRNA expression level in each case was calculated on the basis of the Ct value and is shown as the ratio of the product to β-actin expression level. The relative mRNA expression of each time event is presented as the fold change relative to the 0 h time point. Asterisks indicate that the mRNA expression was 4-fold higher than that of the 0 h control.

TLR4 Is Associated with the Stimulation of TFP in Macrophages. The activation of TLR4 is believed to promote a Th1 response and induce the production of Th1-associated cytokines, specifically IL-12p70.[20] Therefore, we investigated whether TFP promotes activation through TLR4 in mouse peritoneal macrophages. Preliminary experiments were performed by using the anti-mouse TLR4 mAb to neutralize the TLR4-related activation in the cells. The TFP-induced TNF-α production was inhibited in the TLR4-neutralized cells (Figure 8A). To further confirm this result, we measured the TNF-α production in TFP-treated macrophages from TLR4-deficient mice (TLR4$^{-/-}$, C57BL/10ScN). As expected, the TNF-α secretion in wild-type (WT) macrophages was not observed in TLR4$^{-/-}$ cells (Figure 8B). On the basis of these results, we concluded that TLR4 is involved in TFP-mediated activation in mouse peritoneal macrophages.

DISCUSSION

In this work, we first identified that TFP, an immune-activating protein from *T. fuciformis*, is capable of enhancing Th1 cytokine secretion, phagocytic activity, co-stimulatory molecule expression, and M1 polarization of macrophages via the TLR4 signaling pathway. The cloned TFP cDNA sequence was dissimilar to those of other fungi or any other species (Supplemental Table 2). After biochemical and genetic analysis, we demonstrated that TFP consists of 112 amino acid residues (Figure 2) and lacks a glycosylation in *T. fuciformis* (Figure 1). In addition, TFP might lack a carbohydrate moiety linking the polypeptide through O- and N-glycosylation according to the predictions using NetNGlyc 1.0 and DictyOGlyc 1.1 software (Supplemental Figures 7 and 8).

Moreover, we found that TFP exists as a homodimeric molecule in the experiments. Dimerization of proteins could be related to many biological functions and could be a key process in the control a variety of cellular actions.[21] For the previously mentioned proteins, the formation of the homodimer through the N-terminal α-A-helix is necessary for recognition by their receptors on the cell surface and their immunomodulatory activities.[22−24] The method of Garnier[25] was used to predict the secondary structure of TFP, and the TFP was determined not to contain the N-terminal α-A-helix structure (Supplemental Figure 9), which differed from fungal immunomodulatory proteins (FIPs). Many proteins that have been purified from edible mushrooms have been classified as lectins and FIPs on the basis of their biochemical activities and conserved amino acid sequences.[23,24,26,27] Fip-*vvo* was classed as a lectin because of its hemagglutination and cell proliferation activity.[24] Lectins, known as carbohydrate-binding proteins, can agglutinate red blood cells and can recognize a wide variety of pathogens, and they consequently play an important role in innate immunity.[9,27] As shown in Supplemental Figure 10, the purified TFP (0.03125−1 mg/mL) lacked the ability to agglutinate mouse red blood cells. Moreover, the amino acid sequence of TFP exhibited low homology to any known FIP that has been classified as lectin (Supplemental Figure 11). Taken together,

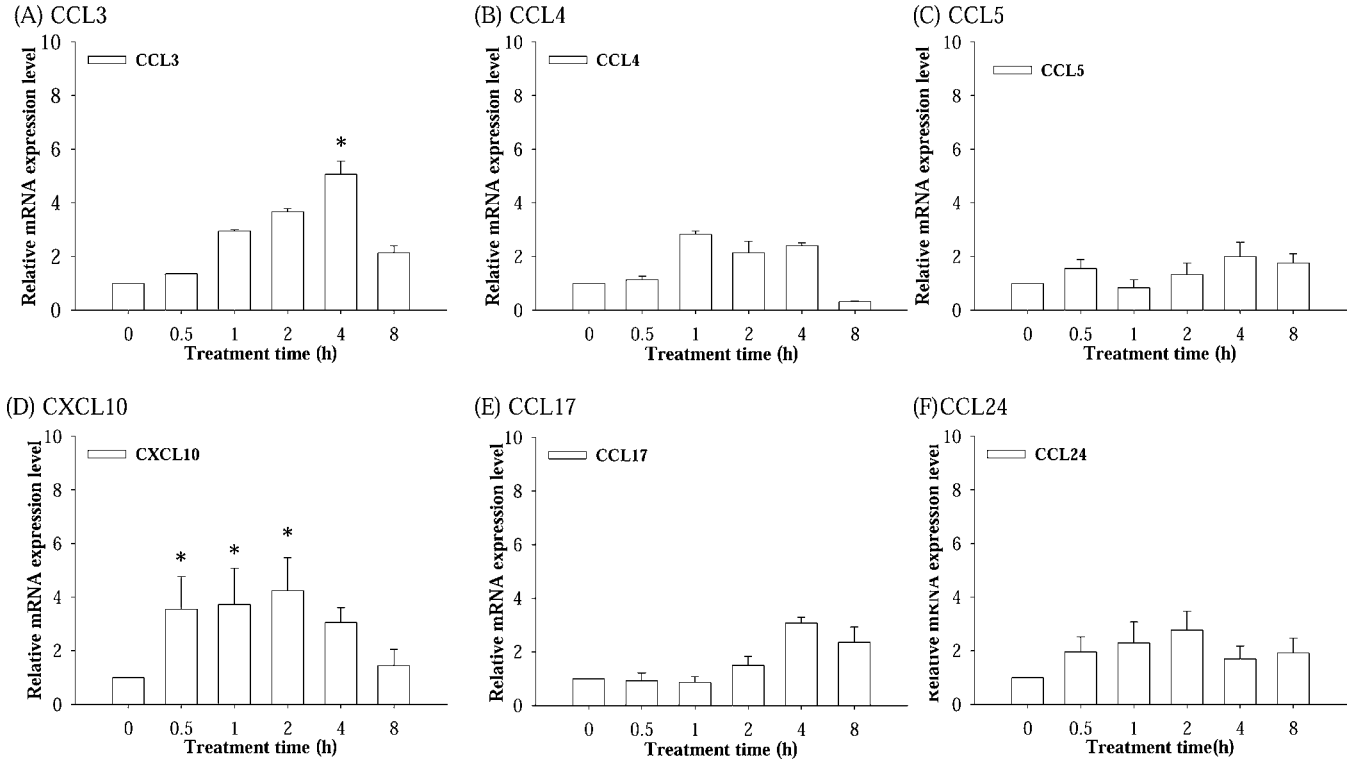

Figure 7. Time course evaluation of chemokine mRNA expression in TFP-induced macrophages. The cells were cultured in the presence of TFP (6.25 μg/mL) for the indicated times and collected for total RNA extraction. The expression of (A) CCL3, (B) CCL4, (C) CCL5, (D) CXCL10, (E) CCL17, and (F) CCL24 mRNA was analyzed with quantitative real-time PCR. The mRNA expression level in each case was calculated on the basis of the Ct value and is shown as the ratio of the product to the β-actin expression level. The relative mRNA expression of each time event is presented as the fold change relative to the 0 h time point. Asterisks indicate that the mRNA expression was 4-fold higher than that of the 0 h control.

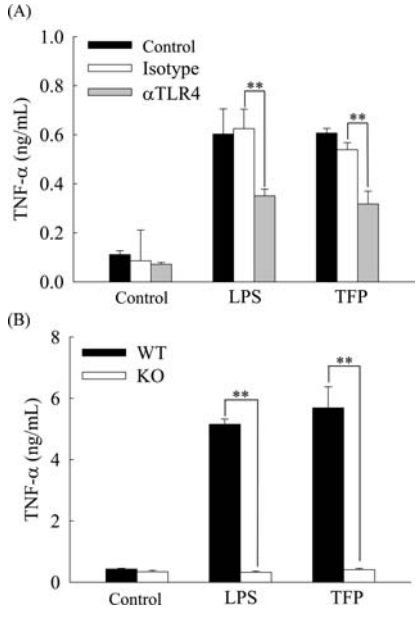

Figure 8. TFP-mediated activation of mouse peritoneal macrophages involves TLR4. (A) WT macrophages were pretreated with control (isotype) or anti-TLR4 mAb 30 min before incubation with 1 μg/mL ultrapurified LPS or 6.25 μg/mL TFP for 18 h. (B) TLR4$^{-/-}$ macrophages were incubated with 1 μg/mL ultrapurified LPS or 6.25 μg/mL TFP for 24 h. The supernatants were collected to determine the TNF-α production by macrophages using ELISA. **, $P < 0.01$ vs the isotype control.

these results show that TFP is different from those FIPs in regard to amino acid composition and biological activity.

As shown in Supplemental Table 2, the two known proteins identified in mushroom-forming fungi that are most similar to TFP, according to the NCBI nr database, are the noncatalytic module family EXPN protein (expressed by the wood-degrading fungus *Schizophyllum commune*)[28] and an expansin family protein (secreted by the ectomycorrhizal fungus *Laccaria bicolor*).[29] The noncatalytic module family EXPN proteins with high similarity (max identity >50%) from *S. commune* and *L. bicolor* are both classified as expansin superfamily proteins.[28,29] Expansins, the plant cell-wall-loosening proteins involved in plant cell growth processes, are not only found in plants but also secreted by mycorrhizal fungi, which develop symbiotic tissues in plant root tissues by using expansins to induce extension in the cell wall of roots.[30] As *T. fuciformis* is a wood-degrading fungus, the role of TFP may be associated with wood digestion and fungi development. As shown in Supplemental Figure 12, one of the TFP-similar proteins (max identity 37%) that is distinct from the expansins was found in *L. bicolor*, a riboflavin-aldehyde-forming enzyme that functions as an upregulator of the expanding sporophores.[31] It is possible that TFP plays an important role in the growth and development of *T. fuciformis*. Nevertheless, *T. fuciformis* genomics data remain sparse, and the physiological function of TFP in *T. fuciformis* remains unclear and requires further investigation.

TFP directly activates macrophages accompanying the enhanced macrophage immune functions in the innate immune responses as an immune modulator. It is well-known that

dx.doi.org/10.1021/jf403835c | J. Agric. Food Chem. 2014, 62, 1526−1535

macrophages rely on phagocytosis to eliminate exogenous pathogens and the production of cytokines to further improve the differentiation of T cells in adaptive immunity.[32−34] We demonstrated that TFP-activated macrophages display an increased phagocytosis ability and secrete a high level of TNF-α, IL-1β, and IL-12. TNF-α can promote the M1 polarization of macrophages, which leads to the tissue macrophages giving rise to classically activated macrophages. Subsequently, those macrophages produced more IL-12, which enhanced Th1 cell development.[32,33] Furthermore, we observed that TFP can induce the expression of M1 chemokines such as CCL3, CCL4, and CXCL10 but not M2 chemokines such as CCL17 and CCL24. These results suggest that TFP-mediated macrophage activation is associated with M1 polarization, which could further upregulate the Th1-response-integrated macrophages that are involved in type I inflammation, resulting in the killing of intracellular microorganisms and tumor resistance.[19] The TFP-activated macrophages exposed to TFP increased the expression of CD86, which is a well-known activation marker of macrophages and a considerable T cell co-stimulatory molecule involved in proliferation, cytokine production, and cytotoxic T lymphocyte generation during adaptive immune responses.[35] Therefore, we theorize that TFP might be a potent macrophage activator that drives the activation and M1 polarization of macrophages to promote innate immune responses.

TLRs are critical for the recognition of pathogen components and play important roles in eliciting innate immune responses, especially TLR4.[16,19] TLR4 has been reported to be capable of recognizing several pathogen molecules, including LPS from bacteria and mycobacteria, glycoinositolphospholipids from parasites, mannan from fungus, and structural proteins from viruses.[16] Using an anti-TLR4 mAb neutralization experiment and TLR4-deficient mice ($TLR4^{-/-}$), we demonstrated that TLR4 could be a major TFP-recognition receptor for macrophages and that blocking TLR4 causes macrophages to decrease TNF-α secretion. In addition, it is known that MyD88 and TIR-domain-containing adaptor protein (TIRAP) play necessary roles in the production of inflammatory cytokines such as TNF-α and IL-12p40 after the stimulation of TLR4.[10,36] Through the TLR4-mediated MyD88-dependent signaling pathway, recruited IRAK activates TRAF6 to trigger the activation of the IκB kinase (IKK) complex, leading to the translocation of NF-κB and expression of inflammatory cytokines.[10,36] We observed that TFP-mediated macrophage activation is related to the activation of NF-κB. This observation suggests that TFP regulates macrophage activation via the TLR4-NF-κB signaling pathway. Furthermore, NF-κB regulates the transcriptional program of inflammatory-response-related gene expression as the mediator of innate responses and promotes specific gene expression involving the recruitment and survival of leukocytes as an initiator of adaptive immune responses.[37,38] It was demonstrated previously that TFP induces the production of IL-12p70 and the expression of IL-12p35 and IL-12p40, which have been reported as bridges between the innate and adaptive immune responses.[37] It has also been reported that IL-12 has the ability to induce the production of IFN-γ, the differentiation of Th1 and NK cells, and the generation of cytotoxic T lymphocytes and LAK cells.[38] Taken together, these data suggest that TFP might utilize the TLR4-NF-κB signaling pathway to stimulate macrophages that have the potential to enhance the adaptive immune response.

In conclusion, TFP is a novel immune-activating protein and may be an important bioactive molecule from *T. fuciformis*. The current study is the first to provide evidence that TFP activates mouse macrophages (promoting M1-type polarization) via the TLR4-NF-κB pathway and might promote a further Th1 response. This research has revealed the potential for the use of TFP in the development of health foods and pharmaceutical products.

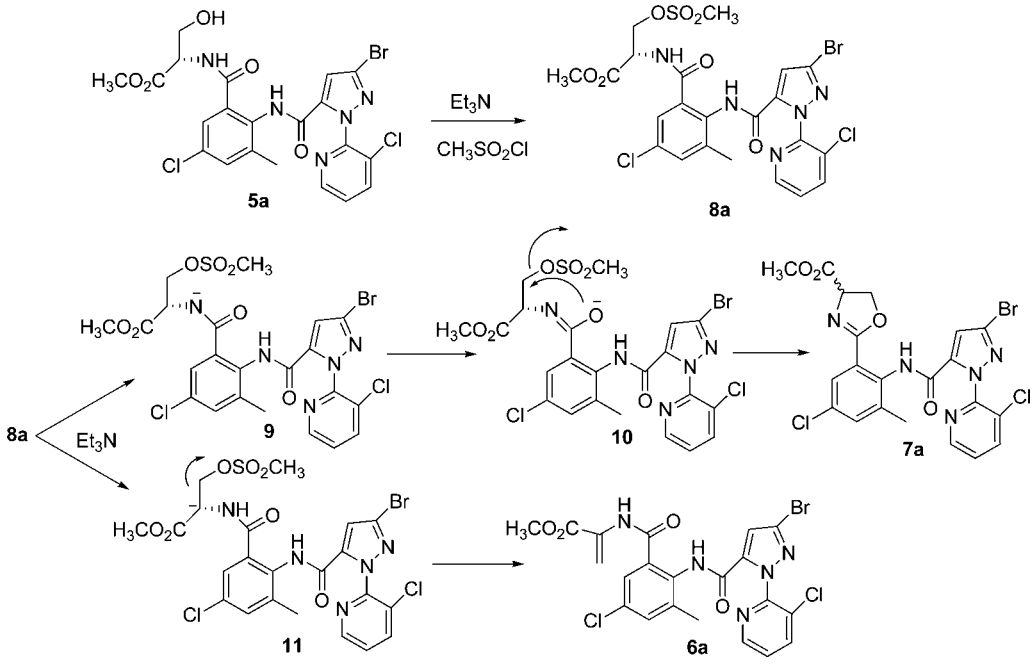
Scheme 2. Proposed Formation of 6a, 7a, and 8a



MATERIALS AND METHODS

Instruments. The measurement of melting points was conducted on a Yanaco MP-500 micromelting point apparatus without calibration. ^{1}H NMR spectra were recorded on a Bruker AC-400 instrument in $CDCl_3$ as solvent and Me_4Si as internal standard. Chemical shifts were reported as δ values in parts per million (ppm). Elemental analysis was performed on a Yanaco CHN Corder MF-3 automatic elemental analyzer. All chemical reagents and solvents were of analytical grade.

Compounds **1a−c** were synthesized according to the method reported by our previous work.[15−17] 2-Amino-5-substuituted-3-methylbenzoic acids (**2a−c**) were prepared by referring to the known procedure.[15,16] The intermediates **3a−h** were synthesized according to the literature.[18] The title compounds were prepared as shown in Scheme 1.

General Procedure for the Synthesis of Compounds 4 and 5.[19] L-Cysteine methyl ester hydrochloride (1.0 mmol) was added to 20 mL of acetonitrile under stirring, followed by the addition of triethylamine (1.2 mmol). After stirring for 0.5 h at room temperature, **3a** (1.0 mmol) was added and the resulting mixture was refluxed for a further 12 h (monitored by TLC). After completion of the reaction, the solvent was evaporated in vacuum and the residue was purified on silica gel, eluting with petroleum/ethyl acetate (v/v, 1:1), and **4a** was obtained.

Compounds **5a−f** were prepared following the same procedures described in the preparation of compound **4a** using L-serine methyl ester hydrochloride instead of L-cysteine methyl ester hydrochloride.

General Procedure for the Synthesis of Compounds 6−8.[20] To an ice-cold solution of **5** (1 mmol) in 20 mL of dichloromethane were added successively triethylamine (3 mmol) and methanesulfonyl chloride (1.5 mmol) with stirring. Then the reaction mixture was allowed to warm to room temperature and stirred until the reaction completed, monitored by TLC. After completion, the mixture was then washed with dilute hydrochloric acid solution and brine and dried with magnesium sulfate. The solvent was evaporated in a vacuum, the residue was purified on silica gel with petroleum/ethyl acetate (v/v, 4:1), and **6a**, **7a**, and **8a** were obtained.

Compound **5** (1 mmol) was dissolved in 20 mL of tetrahydrofuran and cooled in an ice bath. With constant agitation, thionyl chloride (2 mmol) was added dropwise, and the reaction mixture was stirred at 0 °C until the reaction completed, monitored by TLC. After the reaction, saturated sodium bicarbonate solution (30 mL) was then added to quench the excess amount of thionyl chloride. The resulting mixture was extracted with ethyl acetate (3 × 20 mL), and then the combined organic extracts were washed with brine and dried with magnesium sulfate. The solvent was evaporated in a vacuum, and the residue was purified on silica gel with petroleum/ethyl acetate (v/v, 4:1) to give **6a**.[21]

X-ray Diffraction. The crystal structure of compound **6g** was determined, and X-ray intensity data were recorded on a Bruker SMART 1000 CCD diffraction meter using graphite monochromated Mo Kα radiation (λ = 0.71073 Å). All calculations were refined anisotropically. All hydrogen atoms were located from a difference Fourier map and were placed at calculated positions and were included in the refinements in the riding mode with isotropic thermal parameters.

Biological Assay. Insecticidal activities against oriental armyworm (*Mythimna separata*) and diamondback moth (*Plutella xylostella*) were performed on test organisms reared in a greenhouse. The bioassay was replicated at 25 ± 1 °C according to statistical requirements. Assessments were made on a dead/alive basis, and mortality rates were corrected applying Abbott's formula.[22] Evaluation was based on a percentage scale of 0−100, where 0 equals no activity and 100 equals total kill. Error of the experiments was 5%. For comparative purposes, chlorantraniliprole was tested as control under the same conditions.

Larvicidal Activity against Oriental Armyworm (*M. separata*). The insecticidal activities of compounds **4a−8a** and chlorantraniliprole were evaluated using the reported procedure.[23] For the foliar armyworm tests, individual corn leaves were placed on moistened pieces of filter paper in Petri dishes. The leaves were then sprayed with the test solution and allowed to dry. The dishes were infested with 10 fourth-instar oriental armyworm larvae. Percentage mortalities were evaluated 2 days after treatment. Each treatment was performed three times.

Larvicidal Activity against Diamondback Moth (*P. xylostella*). The larvicidal activities of compounds **4a−8a** and chlorantraniliprole were tested by the leafdip method. First, a solution of each test sample in DMSO (AR, purchased from Alfa Aesar) at a concentration of 200 mg/L was prepared and then diluted to the required concentration with water (distilled). Leaf disks (6 cm × 2 cm) were cut from fresh cabbage leaves and then were sprayed with the test solution for 3 s and allowed to dry. The resulting leaf disks were placed individually into glass tubes. Each disk was infested with 30 second-

dx.doi.org/10.1021/jf500003d | J. Agric. Food Chem. 2014, 62, 1536−1542

instar diamondback moth larvae. Percentage mortalities were evaluated 2 days after treatment. Each treatment was performed in triplicate.

Calcium Imaging. Calibration of the fluorescence signal was obtained using the procedure of Iakahashi et al. with minor modifications.[24,25] The attached neurons were rinsed in standard physiological saline [(mM) 150 NaCl, 4 KCl, 2 $MgCl_2$, 2 $CaCl_2$, 10 HEPES, buffered to pH 7.0] and then incubated in the dark at 28 °C in standard external saline containing the dye Fluo-3 AM (Sigma, 10 μM). After dye loading, cells were again rinsed in physiological saline twice.

To block IP3Rs, cells were incubated with heparin for 10 min. Calcium ratio imaging studies were conducted using the imaging system coupled to an inverted fluorescence microscope with a Fluor 40× oil immersion objective (Olympus IX71). Cells excited at 488 and 530 nm under fluorescence emission were acquired by using a CCD (Image Pri-6.0).

Each experiment was replicated at least six times. The data were analyzed by using SPSS Inc., version 17.0, and Microcal Origin, version 8.0 (Origin Lab Corp., Northampton, MA, USA). Results were expressed as the mean ± SD (n = number of cells). Statistical significance was determined by Student's paired or unpaired t test. Fluorescence values were expressed as F/F_0, with F_0 being the resting (or baseline) fluorescence and F the change in fluorescence from baseline after drug application.[26]

RESULTS AND DISCUSSION

Chemistry. Compounds **5a**–**h** were prepared by treating compounds **3a**–**h** with L-serine methyl ester hydrochloride using triethylamine as alkali in acetonitrile, affording the desired product in good yields. Compound **4a** was prepared following the same procedures described in the preparation of compounds **5a**–**h** using L-cysteine methyl ester hydrochloride instead of L-serine methyl ester hydrochloride.

In the initial step,[20] we attempted to treat **5a** with methanesulfonyl chloride in the presence of triethylamine to prepare **7a**. Surprisingly, the elimination product **6a** was obtained as the main product, together with compounds **7a** and **8a** in low yields as shown in Scheme 1. On the basis of the literature previously reported, a mechanism that can possibly explain the formation of **6a**, **7a**, and **8a** was proposed and is illustrated in Scheme 2. In the presence of methanesulfonyl chloride in dichoromethane, compound **5a** first undergoes initial mesylation to give the intermediate **8a** and then generates nitrogen anion **9** and carbanion **11**. The nitrogen anion **9** subsequent isomerizes to **10**, which undergoes intramolecular nucleophilic attack to form the oxazoline ring closure compound **7a**, whereas compound **6a** is obtained by elimination of **11**.

Due to the low insecticidal activities of **7a**, the synthesis of this derivative was not further processed. Another alternative synthetic route was explored to prepare the target compound **6a**[21] by using thionyl chloride in tetrahydrofuran at 0 °C, which resulted in high yields and purity of **6a**.

Crystal Structure Analysis. Compound **6g** was recrystallized from a mixture of dichloromethane and petroleum ether (60–90 °C) to give colorless crystals (0.22 mm × 0.14 mm × 0.12 mm) suitable for X-ray single crystal diffraction as shown in Figure 2 with the following crystallographic parameters: a = 15.005(2) Å, b = 15.005(2) Å, c = 21.630 (4) Å, α = 90°, β = 90°, γ = 120°, V = 4217.8 (12) Å^3, Z = 6, D_c = 1.553 g cm^{-3}, μ = 0.486 mm^{-1}, $F(000)$ = 2004, R = 0.0498, T = 113 (2) K, wR = 0.0988, final R factor = 4.63%.

Structure–Activity Relationship (SAR). The larvicidal activity of compounds **4a**–**8a** against oriental armyworms is summarized in Table 1. The bioassay results indicated that

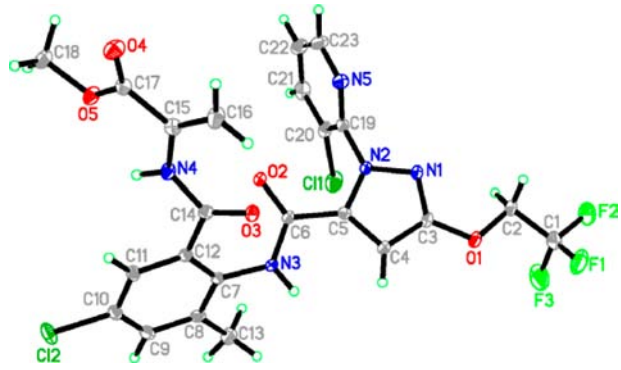


Figure 2. Crystal structure of compound **6g**.

some compounds have excellent larvicidal activities against oriental armyworm. Compounds **4a** and **5a**–**h** containing an amino acid methyl ester displayed moderate activities against oriental armyworm; the insecticidal activities were below 100% at 100 mg/L except for compound **4a**, which showed 60% at 50 mg/L. Compound **7a** containing oxazoline-4-carboxylate also showed low larvicidal activity against oriental armyworm; the mortality was only 60% at 200 mg/L. The larvicidal activity of mesylation product **8a** at a concentration of 10 mg L^{-1} was 50%, much higher than that of **5a**, indicating that the introduction of a mesyl in the hydroxyl group has a positive effect on larvicidal activities. The elimination products containing methyl acrylate substructure **6a**–**h** showed excellent insecticidal activities against oriental armyworm, especially compounds **6g** and **6h**, which showed 100% larvicidal activities at the concentration of 2.5 mg/L. Activities varied significantly depending upon the types of substituents on the 3-position of pyrazole. Compared with 3-Br and 3-CF_3 in pyrazole, compounds with 3-OCH_2CF_3 substituents showed higher insecticidal activities against oriental armyworm, which suggests that the introduction of the 2,2,2-trifluoroethoxy groups in the 3-position of pyrazole has a positive effect on the larvicidal activities. The substituents on the aromatic ring showed no significant effect on the activity.

The larvicidal activity of compounds **6a**–**h** against diamondback moth was evaluated as shown in Table 2. Most of them had excellent larvicidal activity against diamondback moth; all of the compounds showed 100% activity at 1 mg/L. Compounds with 3-Br substituents on the 3-position of pyrazole showed higher insecticidal activities against diamondback moth, which was different from the activities against oriental armyworm. For instance, the larvicidal activities of **6a**–**c** at 0.01 mg/L were 100, 57, and 43%, respectively, whereas **6d**–**h** had no more than 43% at the same dosage. In particular, compound **6a** had 100% mortality at the concentration of 0.005 mg/L, equal to that of chlorantraniliprole, but its LC_{50} was 0.0008 mg/mL, still higher than that of chlorantraniliprole (0.00009 mg/mL, Table 3).

Previously, the neurons of *S. exigua* were used for studying the mechanism of diamide insecticides, and we also found the increase of $[Ca^{2+}]_i$ was positive for the insecticidal activity against oriental armyworm. To determine whether compounds **6a**–**h** might be involved in calcium signaling transduction, we examined the effects of several novel compounds on the central neurons of *S. exigua* on the calcium homeostasis with calcium imaging technique after neuron loading with Fluo-3 AM. Figure 3 shows the change of $[Ca^{2+}]_i$ versus recording time when the neurons were treated with compounds **6a**, **6d**, **6g**, and **6h** in the

absence of extracellular calcium. Application of 1000 mg/L compound **6** and chlorantraniliprole to isolated *S. exigua* neurons caused an increase in the cytosolic calcium concentration. The peak of $[Ca^{2+}]_i$ was increased to 104.13 ± 2.88% (n = 9), 103.6 ± 3.10% (n = 16), 106.00 ± 2.17% (n = 12), 106.59 ± 2.41% (n = 15), and 115.42 ± 2.37% (n = 12) of the initial value after the neurons were treated with compounds **6a**, **6d**, **6g**, and **6h** for <10 s, respectively. Thus, calcium released from the calcium store elevated the cytosolic calcium levels. The calcium concentration in the neurons elevated by compounds **6a** and **6h** (Figure 4) is in a concentration-dependent manner, the same as previously reported for diamide insecticides by our research group.

When external Ca^{2+} was free, IP3 receptors were blocked by using heparin, and the increase of $[Ca^{2+}]_i$ was only attributed to the release by RyRs. Preincubated by heparin, the effect of compound **6h** on F/F_0 was reduced to 103.63 ± 2.04% (n =

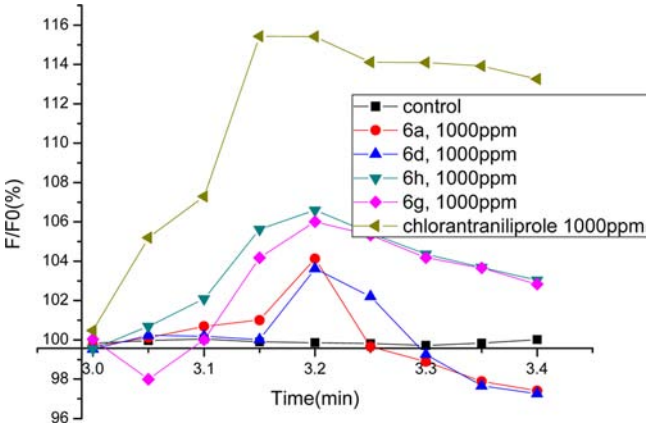

Figure 3. Effects of different concentrations of compounds **6a**, **6d**, **6g**, and **6h** on $[Ca^{2+}]_i$ in the central neurons of *S. exigua* when extracellular Ca^{2+} was absent (EGTA replaced Ca^{2+}). The central neurons of *S. exigua* third-instar larvae were dyed by loading with Fluo-3 AM.

13) (Figure 5). Inhibiting IP3Rs with heparin can activate the RyRs, meaning that using heparin can actually cause an increase in calcium. Figure 5 demonstrates compound **6h** could activate IP3Rs and RyRs, so it is elucidated that these compounds have

dx.doi.org/10.1021/jf500003d | J. Agric. Food Chem. 2014, 62, 1536–1542

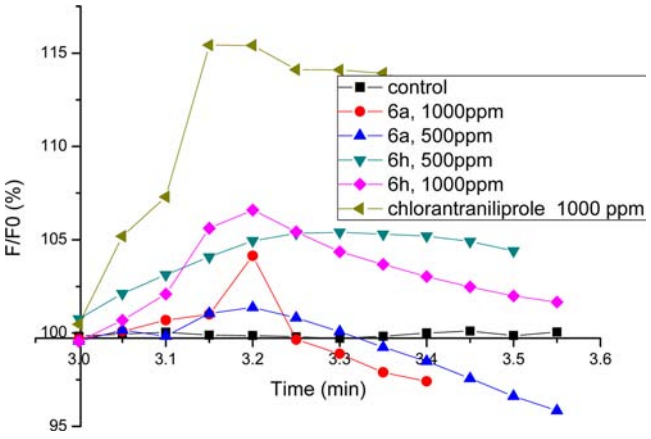

Figure 4. Effects of different concentrations of compounds **6a** and **6h** on $[Ca^{2+}]_i$ in the central neurons of *S. exigua* when extracellular Ca^{2+} was absent (EGTA replaced Ca^{2+}). The central neurons of *S. exigua* third-instar larvae were dyed by loading with Fluo-3 AM.

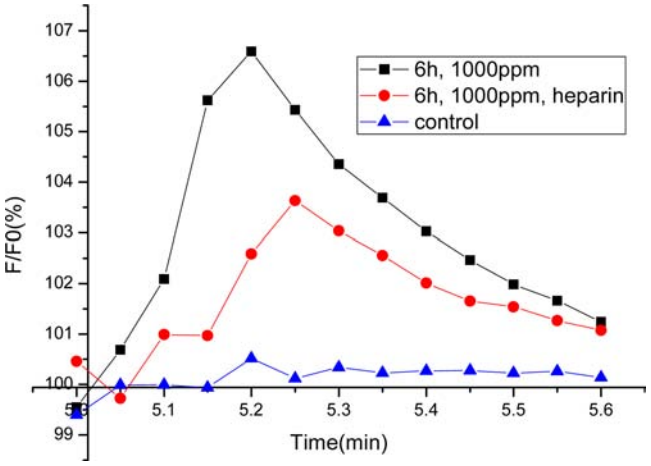

Figure 5. Effects of **6h** on $[Ca^{2+}]_i$ in the central neurons of *S. exigua* when the neurons were preincubated by heparin and thapsigargin. The central neurons of *S. exigua* third-instar larvae were dyed by loading with Fluo-3 AM.

a different mechanism from chlorantraniliprole, and we speculate that this difference affected the insecticidal activity.

In conclusion, a series of novel *N*-pyridylpyrazolecarboxamides containing an amino acid methyl ester and analogous substructures in the *ortho*-position were designed and synthesized. The bioassays showed that compounds **6** containing methyl acrylate substructure exhibited excellent insecticidal activities against oriental armyworm (*M. separata*) and diamondback moth (*P. xylostella*). Especially, compound **6a** showed 100% larvicidal activity against *P. xylostella* at the concentration of 0.005 mg/L, whereas the activities of compounds **6g** and **6h** against *M. separata* were 100% at 2.5 mg/L. More importantly, we concluded that the different mechanism of these novel compounds may decrease the insecticidal activity against Lepidoptera pests.

Therefore, we studied, using an in vitro model simulating human gastrointestinal digestion, the bioaccessibility of phenolic compounds, vitamins, and total antioxidant capacity in durum wheat bran fractions rich in aleurone layer obtained by micronization. Moreover, the ultramicronization was applied to the fractions in order to investigate the effect of the particle size reduction as a possible way to further improve the bioaccessibility of these compounds.

MATERIALS AND METHODS

Chemicals. Ferulic acid, *p*-hydroxybenzoic acid, *p*-coumaric acid, caffeic acid, sinapic acid, nicotinic acid, thiamine, pepsin from porcine gastric mucosa, pancreatin from porcine pancreas (3xUSP), and taka diastase from *Aspergillus oryzae* were purchased from Sigma-Aldrich (Steinheim, Germany). Spectra/Por dialysis membrane tubes were from Spectrum Laboratories Inc. (Rancho Dominguez, CA, USA). All chemicals used in the study were of analytical grade. Ultrapure water from a Milli-Q system (Millipore, Bedford, MA, USA) was used throughout the experiments.

Wheat Bran Fractions. The durum wheat bran fractions were provided by Barilla G. e R. F.lli, Parma, Italy. Durum wheat (*Triticum turgidum* L. subsp. *durum*) grains underwent three subsequent steps of debranning (DECO 420R from TAE, Italy) in an industrial durum mill (capacity 13 ton/h, traditional milling by roller-millers, plansichters, and purifiers). The material produced from the third debranning step was processed through a micronization technique (Micronizer KMX-875, Separ Microsystem, Italy), followed by an air separation step (Air Separator SX-1.000, Separ Microsystem, Italy) to obtain two different bran fractions: the IN sample (the inner part of aleurone, Barilla Aleurone A) and the OUT sample (the outer part of aleurone, containing also a residue of tissue cells coming from the outer layer close to the aleurone, Barilla Aleurone B). The extraction yield of IN and OUT samples was 0.75% and 1.25% of wheat, respectively. The IN (particle sizes <100 μm) and OUT (particle sizes ranging 300−425 μm) fractions were subsequently ultramicronized by jet milling (Fluid Jet Mill Plant J-125, Tecnologia Meccanica Srl, Italy) to obtain the IN ultramicronized (IN-M) (particle sizes <20 μm) and the OUT ultramicronized (OUT-M) (particle sizes <100 μm) fractions, respectively.

Moreover, a standard wheat bran fraction (BRAN) (particle sizes 100−600 μm) was used as a control in this work. The BRAN was produced with a standard milling process (capacity 10 ton/h, traditional milling by roller-miller, plansichter, and purifiers).

Proximate Composition of Wheat Bran Fractions. All fractions were analyzed for starch (%, AOAC method 996.11), protein (% N × 5.70, AOAC method 992.23), lipid (%, AOAC method 922.06), fiber (%, AOAC method 985.29), and ash content (%, AOAC method 923.03).

For the analysis of minerals, samples were digested using a closed-vessel microwave digestion system (Milestone ETHOS PLUS with HPR-1000/10S high-pressure rotor). Raw and retained samples were weighted to proper Teflon digestion vessels. A mixture of concentrated nitric acid and hydrogen peroxide was carefully added, vessels were properly closed and introduced into the microwave oven. Vessels were thereafter cooled to room temperature and digested samples were diluted with deionized water for subsequent determination of minerals. An inductively coupled plasma atomic emission spectrometer (ULTIMA 2 ICP-AES HORIBA Jobin Yvon, France) with a radial configuration was used for Fe, Cu, Zn, and Mg determinations. Measurements were performed at the following emission lines (nm): Zn 213.856, Cu 324.754, Fe 259.940, Zn 213.856, and Mg 280.270.

In Vitro Digestion. All in vitro digestions were performed in triplicate for each wheat bran fraction, following the method described by Amrein et al.[8] with some modifications. Prior to digestion, the wheat fractions were mixed with water to obtain a mixture with ≈40% moisture, obtaining a homogeneous dough. The in vitro gastrointestinal model was set up as follows: 8 g of humidified samples was suspended in phosphate buffer (20 mmol L^{-1}) and incubated at 37 °C stepwise with human saliva for 2 min at pH 6.9, and porcine pepsin (2500 U) for 2 h at pH 2.0−2.5. Each sample was then transferred into 20-cm dialysis tubing strips (12 000 Da molecular weight cutoff) with 100 mg of pancreatin from porcine pancreas (3xUSP), sealed with plastic clamps, and incubated for 24 h at pH 6.9 into 1000-mL sealed containers containing 500 mL of phosphate buffer.

The dialyzed and retained solutions were collected after dialysis and the volumes were carefully measured. The dialyzed solution contained free low molecular weight compounds that are potentially absorbed during digestion, whereas the solution retained within the dialysis tube contained the portion of sample that is ideally not fully digested and absorbed in the upper gastrointestinal tract. The bioaccessibility of a specific compound was calculated considering the quantity of compound dialyzed with respect to the initial quantity in the sample before digestion (100%).

The analyses of total antioxidant capacity, phenolic acids, and vitamins were carried out in triplicate on the undigested, retained, and dialyzed solutions of all wheat bran fractions.

Extraction of Antioxidant Compounds and Phenolic Acids. For the preparation of soluble extracts, 50 mg of raw sample was extracted with 6 mL of water under agitation for 20 min at room temperature, followed by centrifugation at 9200*g* for 10 min, and the supernatant was collected. For the extraction of the bound phenolic compounds, the residue was further hydrolyzed with 1.5 mL of 2 mol L^{-1} sodium hydroxide at room temperature for 1 h. After alkaline hydrolysis, the pH of the mixture was adjusted to 3 by adding 1.35 mL of 3 mol L^{-1} citric acid. The bound phenolic samples were then extracted with 6 mL of ethyl acetate. The ethyl acetate extracts were evaporated to dryness under a stream of nitrogen at room temperature and the residue was dissolved in methanol. Retained samples were centrifuged at 9200*g* for 10 min, and the supernatant was collected and treated as soluble extract. The residue underwent the extraction of bound phenolic compounds as reported for raw samples. Dialyzed samples did not undergo extraction. Soluble and bound extracts and dialyzed samples were kept at −20 °C in the dark and filtered (0.45-μm nylon filters) prior to analysis.

Extraction of Vitamins. For the extraction of vitamins in undigested (i.e., raw samples) and retained fractions, about 1 g of undigested samples and 5−9.4 g of retained fractions (according to moisture of the sample) corresponding to 1 g of dried sample were extracted with 20 mL of water in the presence of 300 mg of taka diastase at pH 4.5 for 1 h at 37 °C, followed by centrifugation at 9200*g* for 10 min, and the supernatant was collected. The extraction was performed following the method described in a specific kit for vitamin analysis in cereal products (VitaFast Vitamin B3, VitaFast Vitamin B1, R-Biopharm, Italy).

Total Antioxidant Capacity (TAC). The total antioxidant capacity was measured by ferric reducing antioxidant power (FRAP) assay.[13]

LC-MS^n Analyses. Phenolic acids, thiamine and nicotinic acid in wheat bran fractions, dialyzed and retained solutions were analyzed using an Accela UHPLC 1250 equipped with linear ion-trap-mass spectrometer (LTQ XL, Thermo Fisher Scientific Inc., San Jose, CA, USA) fitted with a heated-electrospray ionization probe (H-ESI-II; Thermo Fisher Scientific Inc.). The separation was performed using a Hypersil Gold column (50 × 2.1 mm), 1.9 μm particle size (Thermo Fisher Scientific Inc.).

Phenolic Acids. The phenolic acids analysis was carried out in negative ionization mode, using the following conditions. The MS worked with a capillary temperature equal to 275 °C, while the source heather temperature was set to 45 °C. The sheath gas flow was 40 units, while auxiliary and sweep gases were set to 5 and 2 units, respectively. The source voltage was 4 kV. The capillary voltage and tube lens were −21.00 and −57.71 V, respectively. For separation of the analytes, phase A was aqueous formic acid (0.1% v/v) and phase B was methanol/water (98:2 v/v). The mobile phase, pumped at a flow rate of 0.3 mL/min, was kept for 10 min in linear gradient of 7% to 40% of B. Analyses were carried out using Selected Reaction Monitoring; *p*-hydroxybenzoic acid (m/z 137) was fragmented using a pure helium (99.999%) collision-induced dissociation (CID) of 36, generating a fragment ion with m/z 93; *p*-coumaric acid (m/z 163) was fragmented with CID 30, generating the corresponding fragment ion at m/z 119; caffeic acid (m/z 179)

yielded the corresponding fragment ion at m/z 135, using a CID of 29; ferulic acid (m/z 193) generated three daughter ions at m/z 134, 149, and 178, using a CID of 28; sinapic acid (m/z 223) generated three fragment ions at m/z 164, 179, and 208, with a CID of 25. The quantification of each phenolic acid was performed through a calibration curve with the respective commercial standard. The R^2 of the curves of standard compounds ranged from 0.992 to 0.998.

Thiamine and Nicotinic Acid. The analysis of thiamine and nicotinic acid was carried out in positive ionization mode, using the following conditions. The MS worked with capillary temperature equal to 275 °C, while the source heather temperature was set to 200 °C. The sheath gas flow was 40 units, while auxiliary gas was set to 5 units. The source voltage was 3.5 kV. The capillary voltage and tube lens were 24 and 85 V, respectively. For the separation of the analytes, phase A was aqueous formic acid (0.1% v/v) and phase B was acetonitrile in 0.1% formic acid (v/v). The mobile phase, pumped at a flow rate of 0.2 mL/min, was kept at 100% phase A up to 2 min, and then from 2 to 6 min linear gradient to 40% phase B. The analysis of nicotinic acid (m/z 124) was carried out using Selected Reaction Monitoring (SRM), with CID 55, generating the corresponding fragment ions at m/z 78, 80, 94, 96, 106. Thiamine (m/z 265) was analyzed by Consecutive Reaction Monitoring, with CID equal to 18, generating the corresponding fragment ion at m/z 122. This fragment was further fragmented with a CID of 42, generating fragment ions at m/z 81, 95, 105. The quantification of each vitamin was performed through a calibration curve with the respective commercial standards.

Statistical Analysis. All experiments were performed in triplicate. Means and standard deviations (SD) were calculated with SPSS Version 19.0 statistical software (SPSS Inc., Chicago, IL, USA). One-way analysis of variance followed by LSD posthoc test ($p < 0.05$) was used to identify differences among different fractions.

RESULTS

Proximate Composition and Analyses of Wheat Bran Fractions. *Macro- and Micronutrients.* The composition in macro- and micronutrients of the different wheat fractions is reported in Table 1. The OUT fraction was characterized by a higher fiber content, equal to 55%, with respect to 15 and 36% in the IN and BRAN samples, respectively. The IN fractions showed a higher content in starch, proteins, lipids, and ash. Regarding minerals, we limited the analysis to iron, copper, zinc, and magnesium because of their reported relevant concentration in wheat. The distribution among the fractions was similar for all the analyzed minerals, with slightly higher levels observed in the IN and IN-M fractions. Thiamine was higher in the IN and IN-M fractions, whereas the distribution of niacin was uniform.

Total Antioxidant Capacity. The TAC of the wheat bran fractions is reported in Figure 1. The OUT fractions showed the highest total antioxidant capacity values (11.69 and 11.04 mmol Fe^{2+}/100 g for OUT and OUT-M, respectively), followed by BRAN (8.73 mmol Fe^{2+}/100 g). The IN fractions showed the lowest TAC values (5.27 and 5.07 mmol Fe^{2+}/100 g in IN and IN-M, respectively). The ultramicronized and regular-sized samples showed comparable TAC values. The main TAC contributors to the OUT and OUT-M fractions TAC were bound compounds (88% and 84% of the global TAC, respectively), whereas the IN and IN-M fractions presented a high proportion of antioxidant capacity related to free compounds (≈ 50%).

Phenolic Acids. Figure 1 reports the phenolic acid profile of the wheat fractions. In each fraction, five phenolic acids were detected and quantified: ferulic, *p*-coumaric, sinapic, caffeic, and *p*-hydroxybenzoic acids. Ferulic acid was the main phenolic acid, with a concentration ranging between 50.2 and 210.4 mg/100 g, whereas *p*-coumaric, sinapic, caffeic and *p*-hydroxybenzoic acids were present in the different fractions in the range of 3.4−8.7,

Table 1. Macro- and Micronutrient Composition of Wheat Bran Fractions[a]

	starch	protein	lipid	fiber	ash	iron	copper	zinc	magnesium	thiamine	niacin

[a]Values are presented as means ± SD and are expressed on dry weight basis. Data of starch, protein, lipid, fiber, and ash are expressed as g/100 g, and those of minerals and vitamins are expressed as mg/100 g.

dx.doi.org/10.1021/jf404522a | J. Agric. Food Chem. 2014, 62, 1543−1549

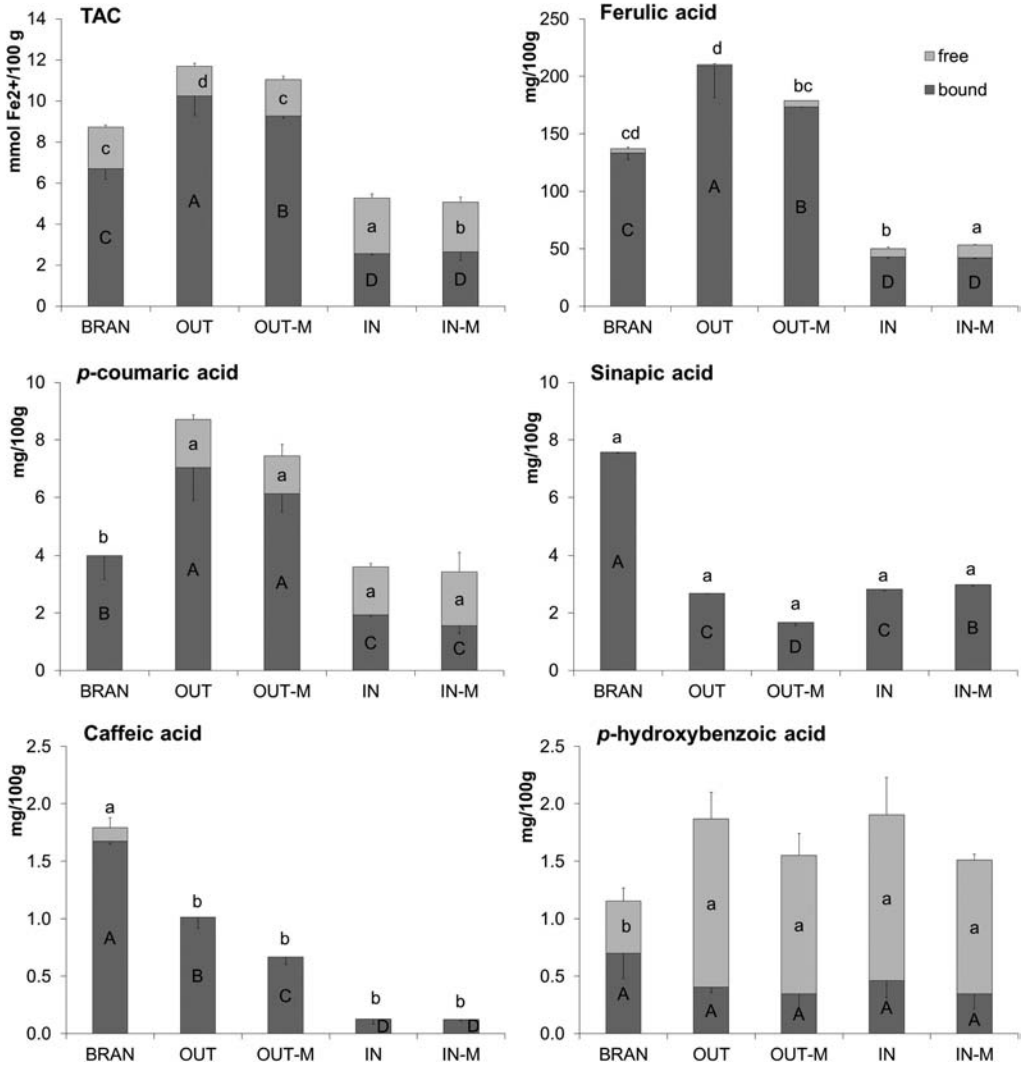

Figure 1. Total antioxidant capacity (mmol Fe^{2+}/100 g dry weight) and phenolic acids content (mg/100 g dry weight) of the wheat bran fractions. Different lowercase letters in the same panel correspond to significant ($p < 0.05$) differences in soluble portion among the fractions. Different capital letters in the same panel correspond to significant ($p < 0.05$) differences in bound portion among the fractions.

1.7−7.6, 0.1−1.8, and 1.2−1.9 mg/100 g dry weight, respectively. Ferulic, sinapic, and caffeic acids were present almost completely bound to the fiber fraction. Peculiarly, *p*-coumaric acid was present mainly in the bound form in BRAN, OUT, and OUT-M fractions, but its free form was close to the 50% in the IN and IN-M samples. Finally, *p*-hydroxybenzoic acid showed to be prevalently free in all samples.

Bioaccessibility of the Wheat Bran Fractions. *Total Antioxidant Capacity.* Figure 2 reports the percentage of absorbed TAC calculated as the amount of TAC found in the dialyzed solution divided by the initial TAC value of each wheat bran fractions. Antioxidant compounds contributing to the TAC were more bioaccessible in the IN and IN-M fractions, with bioaccessibility values of 60 and 65%, respectively, whereas the relative bioaccessibility in the other fractions was lower (≈ 20% in the OUT and OUT-M and 33% in BRAN), and not significantly different among these fractions. TAC values in retained and dialyzed samples are reported in Table 2. The retained samples of BRAN, OUT, and OUT-M, representing the non-bioaccessible components, showed a higher TAC level, mainly attributable to bound antioxidant compounds, than that of the dialyzed solutions. Conversely, the IN and IN-M fractions showed the lowest TAC in retained, unabsorbable portion, with a complementary high TAC of the dialyzed solution.

Phenolic Acids. The bioaccessibility of phenolic acids after digestion is reported in Figure 2. The percentage of absorbed compounds was different for the five phenolic acids and among fractions. Ferulic acid absorption did not show any significant difference among fractions, with values ranging from 32 to 51%. In addition, ferulic acid content in retained and dialyzed samples is presented in Table 2. Compared with the other fractions, IN and IN-M showed a lower content in dialyzed and retained ferulic acid, in accordance with their lower original content. Among the minor acids, *p*-hydroxybenzoic presented the highest percentage of absorption (84−99%), whereas for *p*-coumaric, sinapic, and caffeic acids the bioaccessibility was widely variable among the fractions.

Vitamins. Vitamin content in the retained fractions and bioaccessibility values are described in Table 3. Thiamine was extremely bioaccessible, with IN and IN-M fractions reaching the highest values (≈ 99%), followed by OUT-M, OUT, and BRAN. On the contrary, niacin was highly retained within the dialysis membrane, with slightly higher bioaccessibility values for the IN and IN-M fractions.

[a]Values are presented as means ± SD. Data of TAC are expressed as mmol Fe^{2+}/100 g of undigested fraction on dry weight basis. Data of ferulic acid are expressed as mg/100 g of undigested fraction on dry weight basis. Different letters in column correspond to significantly ($p < 0.05$) different samples.

DISCUSSION

The present work aimed to study the nutritional characteristics of two innovative wheat aleurone fractions, in order to evaluate their potential use as functional ingredients in cereal-based foods. In particular, the bioaccessibility of vitamins, antioxidants, and phenolic compounds was evaluated in different wheat bran fractions by means of an in vitro digestive process, and in function of an ultramicronization treatment influencing their particle size. The aleurone fractions were obtained through an industrial process and do not correspond to a specific histological separation, making this work novel, and the results hardly comparable with those obtained with aleurone fractions obtained with different milling techniques analyzed in other studies.[14,15]

The compositional analysis of the investigated samples showed that the outer aleurone fraction is for a great extent fibrous, whereas the inner aleurone is mainly composed of intracellular material, containing more starch, proteins, and lipids. The higher mineral and vitamin content in the latter fraction might be explained by their compartmentalization within the cells.[7]

[a]Values are presented as means ± SD and are expressed on dry weight basis. The content in retained is expressed as mg/100 g of undigested fraction on dry weight basis, the bioaccessibility is expressed as %. Different letters in column correspond to significantly ($p < 0.05$) different samples.

In accordance with the literature,[16,17] the most relevant contribution to the TAC was attributable to bound compounds, with the OUT fraction showing the highest bound and overall TAC, and the IN fraction showing the lowest, in good agreement with their content of fiber. This was expected, as fiber-bound phenolics represent the major TAC contributors in cereals.[14]

Ferulic acid was the predominant phenolic compound measured in the bran and aleurone fractions, as already reported.[10] This phenolic compound has been previously identified as the main contributor to aleurone TAC[14] and it constitutes a structural component of the cell wall. It is mostly esterified to arabinoxylans, as previously described by Beaugrand et al.,[18] who reported a strong correlation between arabinoxylans and ferulic acid content in wheat bran. In agreement with these observations, ferulic acid, together with *p*-coumaric acid, was present in a greater extent in the OUT fraction, which is richer in cell wall fiber. Conversely, *p*-hydroxybenzoic and sinapic acids contents were comparable in inner and outer aleurone layers, as they are mainly located in the aleurone intracellular compartment.[12]

The ultramicronized samples showed a TAC value comparable with their respective regular size fractions. Moreover, such process did not cause significant modifications to phenolic acid composition, with the only exception of a slight but significant increase in free ferulic acid. Conversely, previous works[19,20] observed that the ultrafine grinding increased the antioxidant capacity of wheat bran. These different results might be linked to the different analytical methods used for analyzing samples, as Zhou et al.[19] measured only free antioxidant compounds, whereas Rosa et al.[20] measured TAC with a direct method,[21] in which the reduction of particle size leads to a higher exposure of cell wall phenolic acids.

After the in vitro digestion, the inner aleurone layers showed the highest bioaccessibility and the highest in vitro absorbed TAC values. A higher antioxidant capacity of the bioaccessible aleurone fraction with respect to bran has been already reported by Mateo Anson et al.[15] Interestingly, in the present study, despite the inner aleurone fraction containing less antioxidant compounds, its TAC was released more efficiently during digestion, possibly because phenolics were present in large proportion in the free and more bioaccessible form. Actually, Adam et al.[22] observed that the rate of release of the esterified ferulic acid from a complex matrix within the digestive tract appears dependent on the nature of the fibers to which it is linked, with nonstarch polysaccharides in endosperm cell walls being more extensively broken down than their pericarp counterparts. Therefore, phenolic compounds bound to endosperm arabinoxylans might be more easily released with respect to phenolics linked to the pericarp or the outer aleurone layer.

In the present study, phenolic acids were differently released during digestion among the fractions. In particular, *p*-hydroxybenzoic acid presented the highest bioaccessibility in all the fractions, likely because of its predominant free form in the undigested fractions. The previous studies regarding the bioaccessibility of phenolic acids in cereals and cereal products have shown a very low bioavailability of ferulic acid from cereals in humans, with figures as low as 3%.[23] Mateo Anson et al.[24] reported that in a dynamic in vitro system the bioaccessibility of this compound from bran and aleurone was lower than 1%, assuming that the sole free fraction is a significant contributor. In the present study, the bioaccessibility of ferulic acid measured by an in vitro digestive model was observed to be higher, with all the free form absorbed, but also with a relevant percentage of the bound fraction able to become available for absorption after digestion. The micronization process could have partially improved the bioaccessibility of phenolic compounds.

The bioaccessibility of thiamine resulted high in all the fractions, as previously suggested by Roth-Maier and colleagues,[25] reporting a high prececal bioavailability of thiamine from wheat bran (92%) in pigs. Yu and Kies[26] observed that particle size is able to influence thiamine absorption. In the present study, the proportion of absorbed thiamine was BRAN < OUT < IN, with ultramicronized samples showing slightly higher values.

Niacin was less bioaccessible than thiamine, with values ranging between 10 and 55% in OUT-M and IN-M, respectively. In good agreement to this observation, in a study conducted on pigs treated with ileo-rectal anastomosis and fed wheat, the prececal digestibility of niacin was nearly 50−60%.[27] In aleurone, niacin forms inclusions with proteins, which can influence its bioaccessibility.

There is growing evidence indicating that the consumption of wholemeal cereals and wholemeal cereal-based products with respect to refined ones contributes to the prevention of chronic diseases. For this reason, the 2010 Dietary Guidelines for Americans recommended a consumption of at least 3 ounce-equivalents of wholemeal cereals per day.[28] In many western countries, the consumption of wholegrain products is estimated to be low, under the recommended intake; indeed, on average, Americans eat less than 1 ounce-equivalent per day of wholegrain products.[28] One barrier to a major consumption probably is the expected low sensory quality. The isolation and use of selected fractions in the formulation of new cereal based products could be a strategy for improving the offer of wholegrain products. In particular, aleurone fractions can be promising in replacing a part of the flour in the formulation of new products with wholegrain nutritional characteristics and that look and taste like a refined grain product. Moreover, the utilization of these fractions allows to valorize the milling byproducts, and to reduce wastes.

On the basis of the present results, wheat aleurone fractions analyzed in this study could represent a nutritionally relevant ingredient in the preparation of wheat-based products, bringing

together a high fiber content and an excellent bioaccessibility of vitamins and minor phytochemicals generally associated with nutritional benefits. Moreover, these nutritional characteristics are present in inner and outer aleurone layer fractions also without any further ultramicronization treatment, permitting obtaining nutritionally interesting ingredients without additional processing costs. In particular, IN fraction presented the most interesting characteristics among the analyzed fractions, suggesting that it can be used in the formulation of new wheat-based products. These promising results obtained with an in vitro model suggest proceeding with a human study to evaluate the bioaccessibility and bioavailability of aleurone-enriched foods.

pulverized using a mortar and pestle. The resulting powders were then stored at −80 °C for 5 months until use.

Extraction of Pistachio Bioactives. Free carotenoids, chlorophylls, and tocols in 0.1 g of pulverized whole pistachios, nutmeat, and skins (0.1 g) were extracted twice for 24 h at 4 °C with 5 mL of methanol, hexane, or acetone/methanol (75:25) with or without 0.5 g of Na_2CO_3. After centrifugation for 5 min at 3000 rpm (1200*g*), the supernatants were transferred and combined. Aliquots of the supernatants were dried under N_2 air and reconstituted for HPLC analyses. The solid residues yielded after the extractions of free lipophilic constituents were saponified with 5 mL of methanol containing 0.5 mol/L KOH for 15 min at 60 °C, 30 min at 60 °C, 45 min at 60 °C, 60 min at 60 °C, 60 min at 70 °C, 60 min at 80 °C, or 24 h at 4 °C. After the saponification, the released carotenoids, chlorophylls, and tocols were extracted twice for 24 h at 4 °C with three solutions separately to find the optimal extract solvent: (1) 2 mL of H_2O and 5 mL of hexane, (2) 7 mL of methyl *tert*-butyl ether (MTBE), and (3) 7 mL of diethyl ether. After centrifugation for 5 min at 3000 rpm (1200*g*), organic supernatants were transferred, combined, dried under N_2 air, and reconstituted for HPLC analyses. In order to simplify the extraction, the effect of combining the organic solvent supernatant of these two steps on the extraction efficiency of bioactives in pistachios was also investigated. The concentration of bioactives in extracts obtained using different extraction methods was calculated using standard curves constructed with authentic standards. Subsequently, the best extraction method was selected on the basis of the concentration of determined bioactives. All samples were analyzed in triplicate.

Phenolics, including phenolic acids and flavonoids (excluding anthocyanins), were determined according to the method of Bolling et al. with slight modifications.[12] Briefly, bioactives in 0.2 g of pulverized sample (whole pistachios, nutmeat, and skins) were extracted sequentially twice with 5 mL acidified methanol (50% methanol, 3.7% acetic acid) at 4 °C for ≥18 h. After centrifugation, the combined supernatant was aliquoted, dried under N_2 air, and reconstituted for HPLC analysis. The dry residue was incubated with 50% methanol containing 0.1 M HCl for 2 h at 90 °C to cleave conjugated glycosidic moieties of flavonoids,[13] followed by centrifugation, solvent removal, and reconstitution for HPLC analysis. All extractions were performed in triplicate.

The extraction of anthocyanins was performed according to the method of de Rosso and Mercadante with slight modifications.[14] Briefly, anthocyanins in 0.1 g of pulverized sample (whole pistachios, nutmeat, and skins) were extracted sequentially twice for 24 h at 4 °C with 5 mL of methanol containing 1% HCl. After centrifugation, the resulting supernatant was transferred, combined, dried under N_2 gas, and reconstituted for LC−MS/MS analysis. All the extractions were performed in triplicate.

Bioaccessibility of Pistachio Bioactives. The bioaccessibility of pistachio bioactives was assessed using the gastrointestinal mimic (GI) protocol of Chen and Blumberg.[15] Briefly, bioactives in 0.2 g of pulverized sample (whole pistachios, nutmeat, and skins) were mixed first with 18 mL of saline buffer and then acidified to pH 2 with HCl. After the addition of 500 μL pepsin solution, the resulting mixture was incubated at 37 °C for 1 h. At the end of the first gastric incubation, pH was titrated to pH 6.9 using $NaHCO_3$, followed by the addition of 2.5 mL of pancreatin-bile solution and incubation at 37 °C for 2 h. Subsequently, 500 μL of GI extract was mixed with 500 μL of 100% methanol. After centrifugation, 800 μL of supernatant was transferred, dried under N_2 gas, and reconstituted for HPLC analyses. All the extractions were performed in triplicate.

Quantification of Pistachio Bioactives. Lipophilic compounds were determined using a reversed-phase HPLC method according Cho et al. with slight modifications.[16] The HPLC system includes two Waters 515 pumps (Waters, Milford, MA), a Waters 717 plus autosampler, a Waters 2996 UV/visible detector, and a ProntoSIL 200-3-C30 column (3 μm, 4.6 mm × 150 mm, Leonberg, Germany). Lipophilic constituents in the extracts were separated with a gradient elution mode at a flow rate of 1 mL/min. The composition of mobile phases was 0.3 g of ammonium acetate dissolved in 830 mL of methanol, 150 mL of MTBE, and 20 mL of HPLC water for mobile phase A and 0.2 g of ammonium acetate in 80 mL of methanol, 900 mL of MTBE, and 20 mL of HPLC water for mobile phase B. The following gradient profile was used (percent mobile phase B): 0% (0−1 min), 0−30% (1−8 min), 30% (8−13 min), 30−55% (13−22 min), 55% (22−24 min), 55−95% (24−34 min), 95% (34−38 min), 95−0% (38−40 min), 0% (40−62 min). Tocols and lutein were monitored at 290 and 450 nm, respectively. Their concentration in the unknown samples was calculated on the basis of standard curves constructed with authentic standards. All samples were analyzed in triplicate.

The contents of phenolic acids and flavonoids were detected using an HPLC system equipped with an electrochemical detector (ECD) (ESA Inc., Chelmsford, MA) and an Agilent ZORBAX SB-C18 column (5 μm, 4.6 mm × 250 mm, Santa Clara, CA), according to the method of Chen et al.[17] Concentrations of phenolic acids and flavonoids in the unknown samples were calculated on the basis of the standard curves constructed with authentic standards. All samples were analyzed in triplicate.

Anthocyanins were quantified according to the LC−MS/MS method of Milbury et al. with slight modifications.[18] Briefly, anthocyanins in the extracts were eluted in a Phenomenex Synergy Max-RP C18 analytical column (4 μm, 250 × 4.6 mm, Torrance, CA) with 0.1% formic acid (mobile phase A) and 0.1% formic acid in acetonitrile (mobile phase B) at a flow rate of 0.3 mL/min in a gradient mode. The following gradient profile was used (percent mobile phase B): 5−10% (0−12 min), 10−15% (12−27 min), 15−100% (27−29 min), and 100−5% (29−40 min). Anthocyanins were monitored with an electrospray interface operated in the positive ion mode with their concentrations calculated on the basis of standard curves of authentic anthocyanin standards. The samples were determined in triplicate.

Statistical Analysis. The results are expressed as mean ± SD. One-way analysis of variance (ANOVA) was performed to evaluate differences between extraction methods, followed by the HSD Tukey's test. All statistical tests were performed using SPSS (v 16.0 program). $P < 0.05$ value was considered statistically significant.

RESULTS

Optimization of extraction method. *Solvent Selection for Free Lipophilic Bioactives.* Hexane, acetone/methanol, and methanol were employed to test extraction efficiency for dominant tocols, carotenoids, and chlorophylls (Figure 1). While methanol and hexane displayed comparable extraction efficiency for lutein, methanol was the most effective solvent for the extraction of free γ-tocopherol and chlorophylls, followed by acetone/methanol. Methanol extracted 114, 32, and 29% more γ-tocopherol, chlorophyll *a*, and chlorophyll *b* than acetone/methanol, respectively ($P < 0.05$)

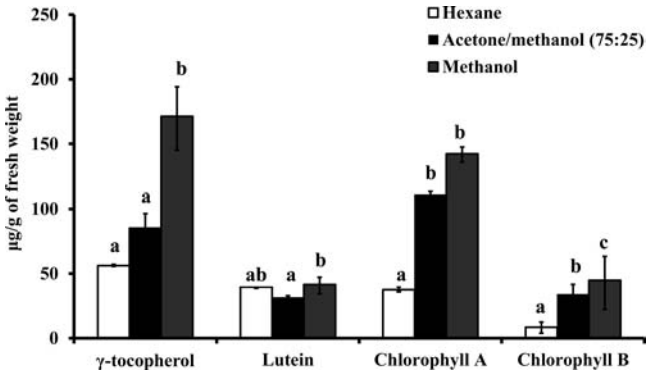

Figure 1. The effect of solvent on the extraction efficiency of lipophilic bioactives. Means bearing different letters within each nutrient differ ($n = 3$); $P < 0.05$, tested by one-way ANOVA, followed by the HSD Tukey's test.

dx.doi.org/10.1021/jf4046864 | J. Agric. Food Chem. 2014, 62, 1550−1556

Saponification and Extraction of Esterified Lipophilic Bioactives. Saponification was tested under seven conditions with different combinations of temperature (4, 60, 70, 80 °C) and duration (15, 30, 45, and 60 min and 24 h). As α-tocopherol and β-carotene exist mostly in an esterified form in pistachios (Supporting Information, Supplemental Table 1), we assessed the effect of saponification on their de-esterification (Figure 2). We found the optimal saponification condition was

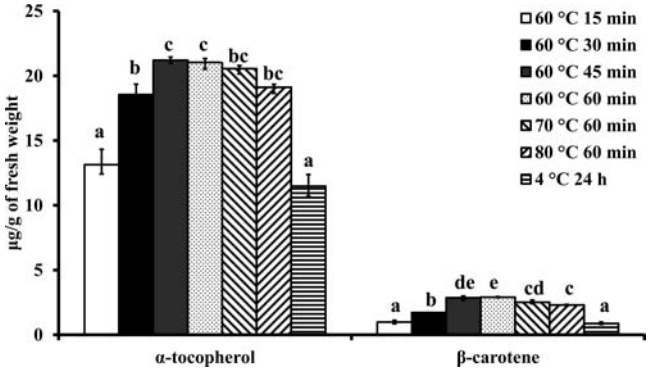

Figure 2. The effect of saponification conditions (temperature and duration) on the release of the esterified lipophilic bioactives. Means bearing different letters within each nutrient differ (n = 3); P < 0.05, tested by one-way ANOVA, followed by the HSD Tukey's test.

the incubation for 45−60 min at 60 °C (P < 0.05). Two conditions, 24 h at 4 °C and 15 min at 60 °C, were the least effective in de-estertifying α-tocopherol and β-carotene (P < 0.05). Saponification at 60 °C and 45 min was employed in the study.

Hexane, MTBE, and diethyl ether were selected to assess the efficiency for the extraction of de-esterified α-tocopherol and β-carotene (Figure 3). Both hexane and diethyl ether exhibited a

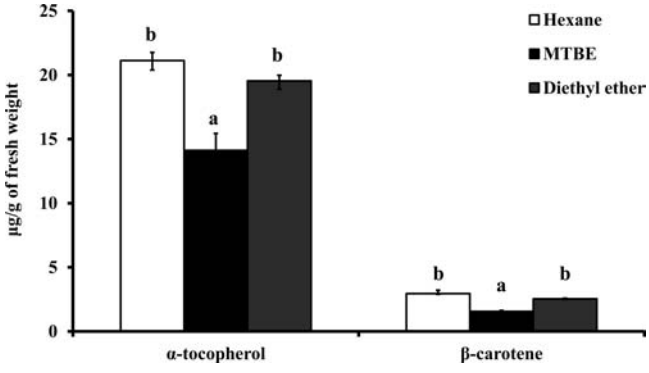

Figure 3. The effect of solvent on the extraction efficiency of esterified lipophilic bioactives. Means bearing different letter within each nutrient differ (n = 3); P < 0.05, tested by one-way ANOVA, followed by the HSD Tukey's test.

comparable efficiency and were ≥38.5 and 62.7% larger than MTBE, respectively (P < 0.05). As hexane extracted slightly more of these two compounds than diethyl ether, hexane was selected for the study.

Optimal Extraction Condition for Chlorophylls. Anhydrous Na_2CO_3 has been employed in the extraction of chlorophylls to prevent their conversion to pheophytins.[19] The addition of Na_2CO_3 to methanol decreased the amount of extractable chlorophylls as compared to methanol alone (Figure 4A,B)

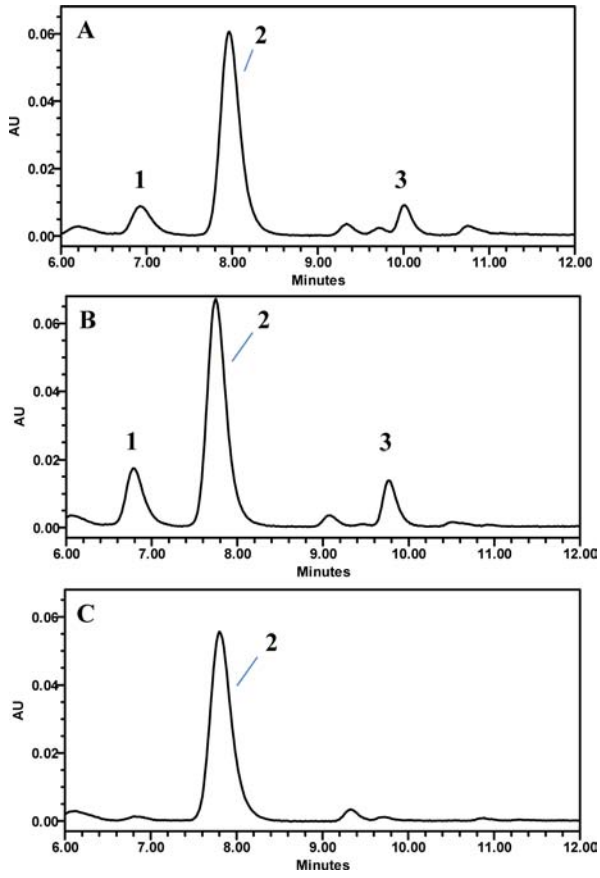

Figure 4. The effect of the alkaline condition as a result of the addition of Na_2CO_3 or KOH used in the saponification of recovery rate of chlorophyll a (peak 1), lutein (peak 2), and chlorophyll b (peak 3), as shown in the chromatographic 450 nm trace: (A) the addition of Na_2CO_3 to the extraction solvent, methanol; (B) methanol; and (C) the combination of methanol and saponification extracts.

with the area under the curve value of chlorophyll a and b being 42.6 and 36.0% smaller. Similarly, this method decreased the amount of extractable lutein by 15.3% (Figure 4C). Thus, the final extraction protocol for lipophilic nutrients in pistachios did not employ Na_2CO_3. The concentrations of the lipophilic bioactives in methanol and saponified extracts were quantified in two separated HPLC runs. The total content of each lipophilic compound in pistachios was obtained as the calculated sum of free and esterified forms.

Quantification of Lipophilic Compounds in Pistachios. A total of nine lipophilic compounds were quantified in pistachio skins, nutmeat, and whole pistachios (Table 1). Whole pistachios were comprised of 6% skin and 94% nutmeat by weight. The dominant carotenoid was lutein, chlorophyll was chlorophyll a, and tocol was γ-tocopherol. The content of the nine compounds in whole pistachios ranked as γ-tocopherol > chlorophyll a > chlorophyll b > lutein > α-tocopherol > γ-tocotrienol > β-carotene > zeaxanthin > α-carotene. The concentration of α-tocopherol and γ-tocotrienol were at least 81% lower than that of γ-tocopherol. While all nine compounds were detected in pistachio skins, their contribution to whole pistachios was minimal, ranging from 5.3% for α-carotene to 0.1% for chlorophyll A. The calculated sum of each lipophilic compound in the skin (6%) and the nutmeat (94%) was 21 ± 8% lower than the value obtained in whole pistachios, ranging from 4% (α-carotene) to 31% (chlorophyll a).

[a]Results are expressed as mean ± SD, $n = 3$. Means bearing different letters within a row differ; $P < 0.05$, tested by one-way ANOVA, followed by the HSD Tukey's test. [b]GI: gastrointestinal digestion mimic. [c]ND: not detected. [d]The percent contribution of the bioactives in the skin to those in whole nuts was calculated on the basis of the following equation: (amount of bioactives in skin × 0.06)/[(amount of bioactives in nutmeat × 0.94) + (the amount of bioactives in skin ×0.06)] × 100%. [e]M: Concentration obtained after acidified methanol extraction. [f]H: Concentration obtained after acid hydrolysis treatment.

We employed the in vitro GI mimic digestion mimic to estimate the bioaccessibility of the lipophilic nutrients. As the efficiency of the extraction appeared low for lipophilic compounds, these nutrients were not detected in the skin. Only lutein and γ-tocopherol were quantifiable in the GI mimic extract of nutmeat and whole pistachios. Their concentrations were 93 and 95% lower than those quantified after the extraction using the organic solvents described above.

Quantification of Phenolics in Pistachios. Eleven phenolic compounds were detected and quantified in pistachios (Table 2). All 11 compounds were detected in the skin, but only 6 were found in the nutmeat. The dominant phenolics in the skins with the concentration ≥100 μg/g FW were catechin, cyanidin-3-galactoside, epicatechin, cyanidin-3-glucoside, gallic acid, and quercetin, in descending order. The nutmeat was rich in luteolin and myricetin, with concentrations ≥140 μg/g. The percentage contribution of the phenolics in the skins to whole pistachios ranged from 2% for luteolin to 100% for epicatechin, rutin, eriodictyol, cyanidin-3-galactoside, and cyanidin-3-glucoside. The glycon form of quercetin, luteolin, and myricetin was quantified after the acidified hydrolysis. Myricetin was present exclusively as the glycone form in the skins and nutmeat. Quercetin and luteolin were found in the glycon form in the nutmeat and were present as the glycon and aglycon in the skins. The calculated sum of each nonanthocyanin compound in the skins (6%) and the nutmeat (94%) was 40 ± 24% lower than the value in whole pistachios, ranging from 1% (myricetin) to 86% (eriodictyol). The calculated sum of cyanidin-3-galactoside and cyanidin-3-glucoside was 37 and 39% larger than their value obtained in whole pistachios, respectively.

With the in vitro GI mimic digestion, only gallic and protocatechuic acids were detected, with their concentration ≤1 μg/g in the nutmeat. In the skins, except for luteolin and myricetin, the other nine compounds were all detected with their concentration being 30−94% lower than the corresponding value found in the acidified methanol extract. Only seven

dx.doi.org/10.1021/jf4046864 | J. Agric. Food Chem. 2014, 62, 1550−1556

compounds were detected in whole pistachios after the GI mimic extraction. Their total content were ≤10% that obtained from the acidified methanol extraction. Gallic and protocatechuic acids and catechin were the main compounds liberated from whole pistachios during the GI mimic digestion.

DISCUSSION

A variety of low-polarity solvents has been employed for extraction of carotenoids, chlorophylls, and tocols in pistachios. Mandalari et al., Bellomo and Fallico, and Ballistreri et al. used hexane for carotenoids and tocopherols.[9,19,20] Bellomo and Fallico employed acetone/methanol (75:25) for extraction of chlorophylls in pistachios, as compared to the study of Henriques et al. showing that methanol was the most suitable solvent for chlorophylls in marine microalga.[19,21] Contrary to Mandalari et al., Bellomo and Fallico, and Ballistreri et al.,[9,19,20] we found that methanol was superior to hexane and acetone/methanol (75:25) for the extraction of chlorophylls and nonesterified γ-tocopherol. While hexane and methanol displayed comparable extraction efficiency for lutein in our study, Craft and Soares indicated that lutein was the least soluble in hexane among all tested organic solvents.[22] As lutein is the dominant carotenoid in pistachios, we suggest that methanol is the most suitable solvent for extraction of nonesterified carotenoids and tocols and chlorophylls in pistachios.

Anhydrous Na_2CO_3 has been added to the extraction solvents with the intention of preventing the conversion of chlorophylls to pheophytins.[19] However, our results do not support the use of Na_2CO_3, in contrast to the reports from Bellomo et al. (for Italian pistachios) and Fuke et al. (for Kiwi fruit).[19,23] In addition to the reduction in the extracted chlorophyll contents, Na_2CO_3 resulted in a lower recovery rate of lutein. Thus, the use of Na_2CO_3 for the maximum extraction efficiency for chlorophylls may depend on climate, soil, or genetic conditions of the cultivars.

An adequate de-esterifying protocol is necessary to liberate esterified lipophilic bioactives to their free counterparts. On the basis of our results (data not shown), 62% of α-tocopherol in pistachios was present in the esterified form, as well as all α- and β-carotene. The effectiveness of saponification to de-esterify bioactives depends on incubation temperature and duration when the KOH concentration in methanol is fixed. There is a diversity of saponification conditions described in the literature, e.g., 30 min at 80 °C for 10 different nuts (including pistachios),[24] 10 min at 85 °C for soybeans,[25] and 5 min at 50 °C for sausages,[26] and 30 min at 70 °C for human serum and rat liver.[27] We found that saponification at 60 °C for 30 min appears optimal for tocols and carotenoids in pistachios, which is slightly different from the conditions employed by Kornsteiner et al. for their analysis of nuts.[24] Hexane, MTBE, and diethyl ether are usually employed as the extraction solvent of choice after the saponification.[24,28,29] However, we found that hexane is the most suitable one for tocols and carotenoids.

The phytochemical composition of pistachios has not been comprehensively examined for over 30 years,[30] even though such information is important to understanding the mechanisms of action by which pistachio consumption may reduce the risk of cardiovascular disease.[31] Consistent with the work of Tomaino et al.,[32] we found that most lipophilic compounds exist in the nutmeat, while most hydrophilic compounds are present in the skins. The dominant compounds characterized in our study include γ-tocopherol, chlorophylls *a* and *b*, lutein, cyanidin-3-galactoside, catechin, quercetin, luteolin, and myricetin, with their content being ≥38 μg/g FW. Interestingly, the calculated sum of each compound in the skins and nutmeat was generally lower than that quantified in whole pistachios. We speculate the difference was attributed to the reciprocal protection of antioxidants in pistachios against degradation during the extraction and the storage before analysis.

γ-Tocopherol is the dominant tocol in pistachios.[3,9,24] Consistent to the literature, we found γ-tocopherol is the main tocol in California pistachios, followed by α-tocopherol and γ-tocotrienol. Kornsteiner et al. reported that δ-tocopherol was detected at a concentration of 5 μg/g FW, while α-tocopherol was not detected.[24] However, Mandalari et al. found all three forms.[9] The α- and γ-tocopherol content of pistachios has been reported to range from 0 to 11 and 105 to 293 μg/g FW, respectively.[2,9,24] The content of γ-tocopherol [182.2 μg/g fresh weight (FW)] found in our study is within this range, while α-tocopherol (34.3 μg/g FW) is about 2-fold larger. The well-appreciated factors determining phytochemical contents, including cultivar, harvest season, cultivation practice, irrigation, growing region, soil, maturity level, and postharvest processing, may all contribute to the difference in the tocol contents of pistachios, as well as other phytochemicals.

Carotenoids are found in pistachios and other tree nuts with the exception of Brazil nuts and macadamias.[33] We found α- and β-carotene, lutein, and zeaxanthin mainly in the nutmeat of pistachios, as compared to lutein, violaxanthin, neoxanthin, luteoxanthin, and β-carotene reported by Giuffrida et al.[34] The other three studies of pistachios reported only the presence of lutein and/or β-carotene.[9,24,30] The reported content of β-carotene and lutein in pistachios ranges from 0 to 7 μg/g and 17 to 52 μg/g FW, respectively.[2,9,24,30,34] The content of β-carotene (2.94 μg/g) and lutein (42.35 μg/g) found in this study are within these ranges.

Chlorophylls are a conjugated tetrapyrrole ring that allows them to absorb light, thereby contributing to photosynthesis, color, and oxidative stability of plants.[34] Chlorophylls may also play a role in human health due to their antioxidant and antimutagenic activities.[35,36] Pistachios and pine nuts are the only two tree nuts containing chlorophylls.[33] Chlorophyll *a* and *b* in pistachios harvested in Italy, Turkey, Greece, and Iran ranged from 18.3 to 150.6 and 7.1 to 49.7 μg/g, respectively.[19,34] We found similar concentrations of chlorophyll in California pistachios. It is worth noting that Na_2CO_3 was employed in the extraction of chlorophylls in the studies by Bellomo and Fallico and Giuffrida et al.[19,34] Our results establish an adverse effect of Na_2CO_3 on chlorophylls during extraction. Further, methanol is proved a better extraction solvent than the hexane and acetone/methanol (75:25) solvents used in these two studies, respectively.[19,34] Thus, the chlorophyll contents reported in these studies might be underestimated.

Pistachios contain a variety of phenolic compounds, e.g., anthocyanins, flavonols, and isoflavones.[33] Consistent with a general understanding,[30] we found pistachio phenolics are mainly present in the skins, with cyanidin-3-galactoside, catechin, quercetin, luteolin, and myricetin being the main compounds. According to the USDA flavonoid database, pistachios contain 68.5 μg/g flavanols, 14.6 μg/g flavonols, and 60.6 μg/g anthocyanins. While the content of anthocyanins in pistachios found in this study are 22% lower than the USDA value, the contents of flavanols and flavonols are 1.3- and 16.6-fold larger. The main difference in flavonols is attributed to the

presence of myricetin. The wide variation is not unexpected, because phenolic contents in plant foods are subject to influence by growing location, season, cultivar, and food processing.[6,9,10,20,32]

In this study, we also tested in vitro bioaccessibility of pistachio bioactives in whole nuts using an upper GI mimic digestion protocol. It is worth noting that this protocol cannot fully reflect the mechanic and biochemical processes during human digestion. We observed that, as compared to the acidified methanol extraction, most phenolics found in pistachios were not readily accessible during the mimic digestion, with 5% phenolics being released, except protocatechuic and gallic acids. It is interesting to note that quercetin glycosides dominantly present in the skins were not released during the mimic digestion. As expected, fat-soluble nutrients in pistachios were not readily released to the aqueous GI mimic solvents, and only lutein and γ-tocopherol were found to be <7% in the GI mimic extract. Our data appear inconsistent with the Mandalari et al. study[9] in which gallic and procatechuic acids, luteolin, eriodyctiol, tocols, and lutein were >90% accessible during an in vitro digestion using a more sophisticated system. Kay et al. reported in a dose−response trial that consumption of diets containing 10% (32−63 g/d) or 20% (64−126 g/d) daily calories from California pistachios for 4 weeks increased circulating β-carotene, lutein, and γ-tocopherol in hypercholesterolemic adults, suggesting bioavailability of the lipophilic bioactives. Thus, more clinical studies are needed to validate the bioaccessibility and bioavailability of other pistachio bioactives.[37]

Lipophilic bioactives, including four carotenoids, two chlorophylls, and three tocols, in California pistachios were methodically characterized, as their quantification was performed after extraction protocols were optimized with solvents, saponification condition, and Na_2CO_3 addition. Further, 11 hydrophilic bioactives (2 phenolic acids, 9 flavonoids) were characterized. The most dominant bioactives were lutein, chlorophyll *a*, γ-tocopherol, catechins, luteolin, myricetin, and cyanidin-3-galactose in each nutrient category. γ-Tocotrienol, zeaxanthin, α-carotene, and myricetin were quantified in pistachios for the first time.

California pistachios are good source of antioxidants, e.g., tocols, carotenoids, and phenolics. Thus, pistachios incorporated into healthy diets shall help enhance health by prevention of cancers and cardiovascular diseases. Bioactive contents in pistachios and other nuts shall be systematically assessed so that health benefits of nut consumption can be fully appreciated.

oxygen species (ROS) production, and in modifying redox-sensitive molecular pathways.

MATERIALS AND METHODS

Chemicals. Tomatoes (*Solanum lycopersicum* L.) were obtained from a local market. Methanol (MeOH), methyl *tert*-butyl ether (MTBE), tetrahydrofuran (THF), and all others solvents used were of HPLC grade. A Millipore Milli-Q purification system (Millipore GmbH, Schwalbach, Germany) was used to obtain HPLC-grade water (18 MΩ). Carotenoids used were obtained from CaroteNature (Ostermundigen, Switzerland). Di(acetoxymethyl ester) analogue (C-2938) 6-carboxy-2′,7′-dichlorodihydrofluorescein diacetate (DCF) (Molecular Probes, Inc., Eugene, OR). Ethylene diamine tetraacetic acid (EDTA), DL-dithiothreitol (DTT), poly(deoxyinosinic-deoxycytidylic) acid (Poly(dI-dC)), and T4 polynucleotide kinase were obtained from Sigma-Aldrich at highest quality available (95−99%). Buffer salts and all other chemicals were of analytical grade. The concentrations of the carotenoid standard solutions were determined using standard spectrophotometric methods.[24]

Dry Tomato Peel (DTP) Preparation. Tomato peel was separated from the pulp using a tomato processing machine after cleaning with fresh water, then peel was freeze-dried in a Virtis lyophilizer (model FM12XL). DTP were grounded with a mill (particle size 0.025−0.05 mm) and stored in darkness at −30 °C until use.

Tomato Powder (TP) Preparation. Tomatoes were cleaned, ground, and centrifuged at 6000 *g* by 10 min at 5 °C. Supernatant was eliminated, and the pellet was dried in a Virtis lyophilizer (model FM12XL). The TP was ground with a mill (0.025−0.05 mm particle size) and stored in darkness at −30 °C until use.

E-Beam Treatment. Both tomato products were packed (1 g weigh) into laminated bags of low permeability (35 cm^3/24 h m^2 bar for oxygen, 150 cm^3/24 h m^2 bar for CO_2), vacuum-packaged, and transported in refrigeration to the irradiation plant (IONISOS Ibérica SA, Tarancón, Spain). This type of film is industrially used to manufacture vacuum packaged foods and guarantee the vacuum during storage of our samples. The treatment was performed with an electron accelerator which operated at 10 MeV. Doses of 4 kGy were applied which have been found to be effective to ensure spoilage and pathogen microbiota control.[22,23] Cellulose triacetate dosimeters were used to check the actual dose absorbed.[25] Experiments were made in triplicate and at a temperature of 15−18 °C. The temperature increased in the product less than 2 °C during E-beam treatment. DTP and TP were always protected from the light.

The samples were under refrigerated conditions (4 °C) during transport, and subsequently they were stored at −30 °C until analysis. Both irradiated and nonirradiated samples were analyzed as follows.

Analysis of Lycopene Composition and Quantification. Lycopene isomer composition as well as contents of lycopene were analyzed using a gradient C30-HPLC method using a Merck−Hitachi HPLC system (Darmstadt, Germany) and a Jetstream Plus column oven (JASCO, Groß-Umstadt, Germany).[25] For quantification of lycopene, a sample extract of 500 mg was diluted in 25 mL of methanol/methyl *tert*-butyl ether (MTBE) (20/80 v/v). *β*-apo-8-Carotenal was used as internal standard. A C_{30} column Trentec Stability 100 C30 PEEK (250 mm × 4.6 mm, 5 μm) (Trentec, Rutesheim, Germany), preceded by a C_{18} ProntoSil 120−5-C18 H (10 mm × 4.0 mm, 5 μm) column (Bischoff, Leonberg, Germany) was used. As mobile phase (1.0 mL/min), a gradient procedure consisting of MeOH (solvent A) and MTBE (solvent B) was used. Column temperature was 10 ± 1 °C and detection wavelength 470 nm. Lycopene contents were quantified using (*all-E*)-lycopene as external standard. For lycopene isomers, a different HPLC method was used: mobile phase (1.0 mL/min), MTBE/methanol/ethylacetate (50/45/5 v/v/v); column, polymeric C30 (250 mm × 4.6 mm, 5 μm) column (YMC Europe, Dinslaken, Germany); column temperature, 32 ± 1 °C; detection wavelength, 470 nm. Retention time of (*Z*)-isomer) in relation to that of (*all-E*)-lycopene was used to identify lycopene isomers. As only very low amounts of samples were available for HPLC of lycopene isomers, peak areas were used to calculate isomer ratios. Thus, exact contents of different lycopene isomers were not determined.

Cell Culture. RAT-1 fibroblasts have been used because they are a cellular line successfully used to study the antioxidant activity of lycopene.[26] The RAT-1 fibroblasts (American Type Culture Collection, Rockville, MD) were grown in Minimun Essential Medium Eagle (MEM) with streptomycin 100 μg/mL, penicillin 100 μg/mL, and supplemented with 10% fetal calf serum and 2 mM glutamine. Cells were maintained in log phase by seeding twice a week at density of 3×10^5 cells/mL at 3 °C under 5% CO_2 air atmosphere.

One milliliter of tetrahydrofuran (THF) was added to DTP and TP (0.5 g), and 2 μL of these solutions were added per 1 mL of MEM medium containing 10^6 cells for 24 h, and ROS production was measured after 30 and 60 min of incubation in the absence or in the presence of 100 μM H_2O_2. The solutions with THF were prepared immediately before each experiment in order to avoid lost of lycopene. After the addition of tomato extracts, the medium was not further replaced throughout the experiments. Control cultures received an equal amount of solvent (THF) but without tomato extracts. Experiments were routinely carried out on triplicate cultures. Intracellular radical species were detected by measuring the fluorescence intensity values due to oxidation of DCF (see below).

Measurement of ROS. Cells were harvested to evaluate the ROS production using the di(acetoxymethyl ester) analogue (C-2938) of 6-carboxy-2′,7′-dichlorodihydrofluorescein diacetate.[27] Before the addition of the fluorescent probes, 2×10^6 cells were washed to eliminate the amount of tomato products not cell-associated. Fluorescent units were measured in each well after 30 min incubation with DCF (10 μM) by use of a Cytofluor 2300/2350 fluorescence measurement system (Millipore Corp., Bedford, MA). Tomato products did not alter the basal fluorescence of DCF. Then cells were treated with 100 μM H_2O_2 for 30−60 min in order to amplify ROS production.

Western Blot Analysis of p38 and p-p38, ERK1/2, pERK1/2, JNK, p-JNK, Nox-4, and Cox-2 Expression. Cells (10×10^6) were harvested, lysed, and centrifuged. The supernatants were used for Western blot analysis.[28] The anti-p38 (clone C-20, catalogue no. SC-535), anti p-p38 (clone D-8, catalogue no. 7973), anti-ERK1/2 (clone K-23, catalogue no. SC-94), anti p-ERK1/2 (clone E-4, catalogue no. SC-7383), anti-JNK (clone C-17, catalogue no. SC-474), anti-p-JNK (clone G-7, catalogue no. SC-6254), anti-Nox-4 (clone N-15, catalogue no. sc-21860), and anti-Cox-2 (clone C-20, catalogue no. 1745) monoclonal antibodies, and the antihsp 70 (clone K-20, catalogue no. sc-1060) and the anti-hsp90*α* (clone C-20, catalogue no. sc-8262 goat) polyclonal antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). The blots were washed and exposed to horseradish peroxidase-labeled secondary antibodies (Amersham Pharmacia Biotech, Arlington Heights, IL) for 45 min at room temperature. The immunocomplexes were visualized by the enhanced chemiluminescence detection system and quantified by densitometric scanning.

Electrophoretic Mobility Shift Assay. Frozen cell pellets were processed to obtain nuclear extracts. The pellet was treated as previously indicated by Joo et al.[29] Binding reactions containing 5 μg of nuclear extracts, 10 mM Tris-HCl (pH 7.6), 5% glycerol, 1 mM EDTA, 1 mM DTT, 50 mM NaCl, and 3 mg poly(dI-dC) were incubated for 30 min with 5000 cpm of α-^{32}P-end-labeled double-stranded oligonucleotide in a total volume of 20 μL. The probe was 5′-AGTTGAGGGGACTTTCCCAGGC3′. Labeling of the probe was obtained by incubating 5 pmol of oligonucleotide with 10 pmol [α-^{32}P] ATP and 3U T4 polynucleotide kinase for 30 min at 37 °C. The probe was then purified with MicroBIO-Spin P-30 columns. Complexes were separated on 60 g/L polyacrylamide gels with 45 mM Tris-borate, 1 mM EDTA, pH 8, buffer. After drying under vacuum, gels were exposed on phosphor screens which were then analyzed by phosphor/fluorescence imager STORM 840 (Molecular Dynamics, Sunnyvale, CA). The intensity of the revealed bands were directly quantified by Image QuaNT software (Molecular Dynamics, Sunnyvale, CA).

Table 1. Lycopene Isomers in Dry Tomato Peel (DTP) Tomato Powder (TP) Following Irradiation[a]

	ratios of (*all-E*)-lycopene to the different (*Z*) isomers			
	DTP	irradiated DTP	TP	irradiated TP
all-E/5*Z*	14.4 ± 0.5[a]	7.3 ± 0.4[b]	12.5 ± 0.8[c]	10.7 ± 0.5[d]
all-E/5*Z*,9*Z*	42.8 ± 1.2[a]	32.3 ± 1.3[b]	30.2 ± 0.7[c]	26.9 ± 1.4[d]
all-E/5*Z*,9′*Z*	728.0 ± 2.1[c]	317.0 ± 1.5[d]	1360.0 ± 1.6[a]	1051.0 ± 2.5[b]
all-E/9*Z*	57.8 ± 0.9[a]	33.4 ± 2.1[d]	61.4 ± 1.5[b]	56.0 ± 1.9[c]
all-E/13*Z*	4.6 ± 0.7[c]	3.0 ± 0.3[d]	10.6 ± 0.6[a]	8.8 ± 0.3[b]

[a]Values not sharing the same letter were significantly different ($P < 0.05$, Fisher's test).

Analysis of p65 Protein. Nuclear extracts, 25−30 μg of protein, were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis with 40−120 g/L Bis-Tris gels (NOVEX, San Diego, CA) and transferred to Immobilon-P membranes (Millipore Corp, Bedford, MA) with the use of a semidry system. Membranes were blocked overnight at 4 °C in 50 g/L dried milk in PBS, pH 7.4, plus 0.05% Tween 20. Blots were incubated with polyclonal primary antibodies to p65 (Santa Cruz, Biotechnology, CA, clone 49.Ser 311, catalogue no. SC-135769) in PBS plus 0.05% Tween 20 for 1−2 h at room temperature. The blots were visualized as described in Western blotting assay.

Statistical Analysis. Values were presented as means ± standard error of the mean (SEM). One-way ANOVA was used to determine differences between different treatments (control and irradiated and nonirradiated tomato samples) in ROS production (Figure 1), MAPK expression (Figure 3) in NF-κB activation (Figure 4), and Cox-2 and Nox-4 expression (Figure 5). A posthoc comparison of means was made, using Fisher's test, when significant values ($P < 0.05$) were found. Multifactorial two-way analysis of variance (ANOVA) was adopted to assess any differences among the treatments and the doses (Figure 2). A posthoc comparison of means was made, using the Tukey's Honestly Significant Differences test, when significant values ($P < 0.05$) were found. Differences were analyzed using Minitab Software (Minitab, Inc., State College, PA).

RESULTS AND DISCUSSION

Influence of irradiation on lycopene concentration was measured. The dry tomato peel showed almost double lycopene content (0.2 ± 0.02 mM) compared to tomato powder (0.1 ± 0.01 mM). Irradiation exposure consumed the carotenoid by almost 50% for both extracts (0.10 ± 0.01 and 0.06 ± 0.01 mM to DTP and TP, respectively). A decrease in lycopene content by E-beam irradiation has been reported in grapefruit;[30] these authors discussed evidence that lycopene levels decreased as the E-beam dose increased.

The HPLC analyses revealed a reduction of (*all-E*)-lycopene with increasing peaks of lycopene (*Z*)-isomers following irradiation (Table 1). This effect was significantly stronger in the DTP samples than in TP. Lycopene has 11 conjugated double bonds, and each of them could be either in an *E* or *Z* configuration. *all-E*-Lycopene is the predominant isomer in plants, representing about 80−97% of total lycopene in tomatoes and related products.[31] In the human body fluids and tissues such as plasma, breast milk, prostate, testis, and skin, 25−70% of lycopene is found in various *Z* forms.[32,33] Shi and Le Maguer[31] indicated that the biological potency of *Z*-lycopene isomers is different from that of the *all-E* form. In terms of bioefficacy, some *Z*-isomers had a stronger in vitro antioxidant activity than the *all-E* form.[34] These data may be particularly interesting in view of the high concentrations of *Z*-isomers in vivo.

The antioxidant activity of DTP and TP extracts, before and after irradiation, was analyzed in RAT-1 fibroblasts in the absence and in the presence of the well-known prooxidant agent H_2O_2. Antioxidant tomato efficiency was evaluated as inhibition of intracellular reactive oxygen species (ROS) production induced spontaneously or in the presence of the prooxidant (Figure 1). In the absence of the prooxidant, a very

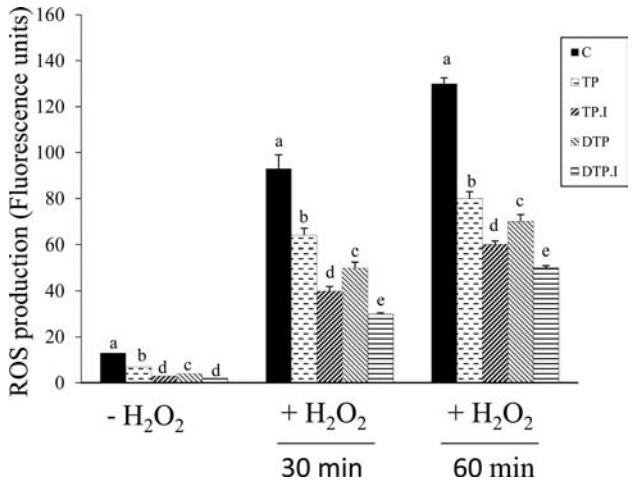

Figure 1. ROS production in RAT-1 fibroblasts incubated, without tomato products (C), tomato powder (TP), and dry tomato peel (DTP), pretreated (I) or untreated with E-beam, as indicated in Materials and Methods section. Spontaneous ($-H_2O_2$) and H_2O_2-induced ROS production in control cells and in treated cells, exposed, as indicated, to 100 μM H_2O_2 for 30−60 min. Values were the means ± SEM of three experiments. The treatment interaction was significant ($P < 0.05$). Values not sharing the same letter were significantly different ($P < 0.005$, Tukey's test).

small amount of ROS production was observed but it increased significantly in the presence of H_2O_2. Treatment of RAT-1 fibroblasts with the different tomato extracts caused a significant decrease in ROS production with respect to control cells (C), which was remarkably evidenced during the incubation with H_2O_2. A weak, but significant inhibition of ROS production in the absence of H_2O_2 was also observed following tomato extracts treatment. Such an effect was more remarkable for DTP than for TP extracts and more evident for irradiated samples than for unirradiated ones. Such effects were specific for both extracts because cells treated with H_2O_2 and THF alone as a vehicle did not differ in ROS expression from cells treated with H_2O_2 alone (data not shown).

The antioxidant effects of tomato extracts were clearly dose-dependent as can be observed by the progressive decrease of H_2O_2-induced ROS production after the addition of increasing concentrations of the different tomato extracts to RAT-1 fibroblasts (Figure 2).

The possible modulation of the MAPK cascade was analyzed in macrophages pretreated with the different tomato extracts to investigate intracellular redox signal transduction in RAT-1 cells

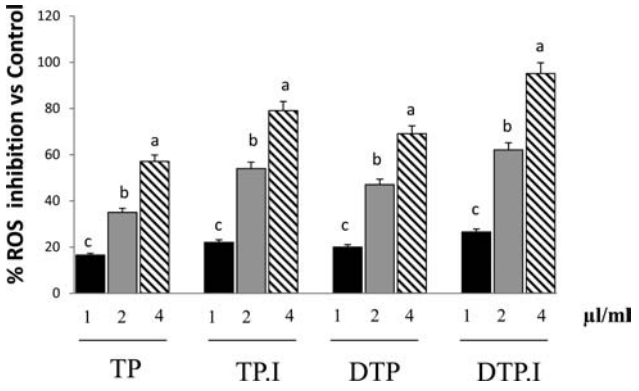

Figure 2. H_2O_2-induced ROS production in the presence of varying concentrations (1−4 μL/mL) of tomato powder (TP) and dry tomato peel (DTP) or without tomato products (C), pretreated (I) or untreated with E-beam, as indicated in Materials and Methods section. RAT-1 fibroblasts were exposed to 100 μM H_2O_2 for 60 min. Values were the means ± SEM of three experiments. The treatment/dose interaction was significant ($P < 0.05$). Values were the means ± SEM of three experiments. Values not sharing the same letter were significantly different ($P < 0.002$, Tukey's test).

(Figure 3). These kinases have been reported to be activated by various stress stimuli, including an overproduction of ROS, and they have been also implicated in the modulation of several intracellular redox functions. Remarkable levels of the phosphorylated forms of ERK1/2 (p-ERK1/2) (Figure 3A, B), JNK (p-JNK) (Figure 3C, D), and p-38 (p-p38) (Figure 3E, F) were observed in control cells after 3 h. Such levels were all decreased significantly by the addition of the different tomato extracts. Such inhibitions were more remarkable for DTP than for TP and more evident for irradiated samples than for unirradiated ones.

These data are not surprising in view of evidence showing that lycopene is a powerful in vitro antioxidant. Among naturally occurring carotenoids, lycopene has shown to possess ability in scavenging free radicals and in interacting with ROS, preventing ROS-induced cell damage.[35] Accordingly, several epidemiological studies have evaluated the role of lycopene and tomato products as potential in vivo antioxidants. Although the data are sometimes controversial, using tomatoes or tomato products, numerous studies have demonstrated decreased DNA damage,[36] decreased susceptibility to oxidative stress in lymphocytes,[37] and decreased LDL oxidation[5] or lipid peroxidation.[38] Moreover, tomato extracts acted in this study as a potent inhibitor of the phosphorylation of MAPKs, which are reported to be activated by ROS. These data are in agreement with previous observations showing that lycopene, alone or in combination with other natural products, modulate MAPK phosphorylation.[39] In particular, the carotenoid was reported to attenuate the phenotypic and functional maturation of murine bone marrow dendritic cells, especially in lipopolysaccharide (LPS)-induced DC maturation.[40] The carotenoid was also able to inhibit platelet derived growth factor (PDGF)-BB-induced signaling and migration in human fibroblasts by inhibiting the activation of extracellular signal-regulated kinase (ERK)1/2, p38, and jun N-terminal kinase (JNK).[41]

In view of recent studies suggesting that NF-κB plays an important role in regulating redox signaling, the involvement of this redox-sensitive transcription factor in THP-1 macrophages following the different tomato extracts was investigated (Figure 4A). In control cells, a net enhancement of nuclear trans-

Values not sharing the same letter were significantly different ($P < 0.05$, Fisher's test).

location was evident at 3 h treatment. However, the up-regulation of NF-κB nuclear binding was prevented by the addition of the different tomato extracts. In agreement with the previous results, the reductions were significantly higher for DTP extract than for TP extract and more evident for irradiated samples than for unirradiated ones. Similar results were found when nuclear extracts were prepared from fibroblasts treated with the different tomato extracts and nuclear translocation of the NF-κB p65 subunit was detected by Western blotting (Figure 4B, C). In control cells, a nuclear translocation of the NF-κB subunit p65 was evidenced within 3 h. Such an effect was inhibited by the addition of the different tomato extracts and, once again, the inhibition was significantly greater for DTP than for TP extract and also was significantly affected by irradiation.

dx.doi.org/10.1021/jf4048012 | J. Agric. Food Chem. 2014, 62, 1557−1563

In recent studies from our laboratory, lycopene suppressed both MAPK phosphorylation and NF-κB activation in oxysterol-stimulated macrophages as well as in prostatic cancer cells.[42] In addition, in this study, tomato extracts also inhibited H_2O_2-induced NF-κB activation, which has been reported to be the first eukaryotic transcription factor shown to respond directly to oxidative stress.[43] It has been found that lycopene inhibited the binding activity of NF-κB in human hepatoma cells[44] and in THP-1 cells exposed to cigarette smoke extract.[45] Such inhibition was mediated by the down-regulation of IκB phosphorylation, NF-κB expression, and NF-κB p65 subunit translocation from cytosol to nucleus.[46] Moreover, tomato lycopene extract prevented LPS-induced pro-inflammatory gene expression by blocking NF-κB signaling.[29]

Because it has been reported that cyclooxygenase-2 (Cox-2) and nicotinamide adenine dinucleotide phosphate oxidase (Nox) are proteins involved in oxidative stress, the expression of both of them in RAT-1 fibroblasts following the different tomato extracts was measured (Figure 5). The addition of all tomato extracts decreased significantly the expression of both Cox-2 and Nox-4 with respect to untreated control cells. The inhibition was significantly greater for DTP than for TP extract, and a significant influence of irradiation was observed showing irradiated samples a greater inhibition.

Tomato extracts inhibited the expression of proteins involved in stress signaling, such as Nox-4, one of the homologues of NADPH oxidase, and Cox-2. These results confirming those obtained in THP-1 cells[47] and in RAW 264.7 macrophages.[48]

The obtained results demonstrate that DTP had significantly ($p < 0.05$) higher concentration of total lycopene than TP. The higher lycopene content of DTP compared to the TP could probably explain its better antioxidant activity in our cell model. These results are not surprising because it has been reported that tomato peel can contain up to 5 times more lycopene than the whole tomato.[49]

Our study confirms the potency of tomato extracts containing lycopene in inhibiting oxidative stress in a cell model. In fact, all the extracts studied were able to counteract the effects of H_2O_2 on ROS formation and on redox-sensitive molecular targets involved in cell signaling, including MAPK and NF-κB, and on the expression of redox-sensitive proteins, including Nox-4 and Cox-2. All these events occurred in a range of carotenoid concentrations which can be reached in vivo after lycopene or tomato supplementation.[36]

The present study shows that E-beam treatment increased the antioxidant ability of both DTP and TP in inhibiting H_2O_2-induced oxidative stress. Concomitantly, it reduced the content of *all-E*-lycopene and increased the levels of *Z*-lycopene. The addition of the two irradiated tomato products (DTP or TP) could be suitable to manufacture meat functional products, improving their antioxidant capacity.

Anchovy (*Engraulis japonicus*) is a schooling marine fish of the family *Engraulidae*. The estimated annual harvest of this fish in China is 700−800 t.[19]Anchovies are rich in proteins and oil, but because of their small bodies and rapid autolysis and spoilage soon after capture induced by endogenous protease, this species is underutilized.[20] Boiled-dried anchovies are a traditional Chinese seafood known as "haiyan". They are a potentially untapped source of bioactive peptides and value-added food production because of their high protein content and the digestive proteolytic enzymes that are distributed in the fish intestine. AMPs derived from boiled-dried anchovies might be natural and safe antimicrobial agents.

In this work, a new antibacterial peptide was rapidly purified from boiled-dried anchovies through immobilized bacterial membrane liposome chromatography (IBMLC) based on the peptide−membrane interaction. In addition, the attributes of the peptide including antimicrobial spectrum, hemolysis effect, and membrane permeability activity of the peptide were also studied.

MATERIALS AND METHODS

Materials. Boiled-dried anchovies (*Engraulis japonicus*) were purchased from a local aquatic wholesale market (Qingdao, China) and stored at −20 °C until use. Calcein, propidium iodide (PI), melittin (≥85%), acetonitrile (ACN), formic acid, and trifluoroacetic acid (TFA) for HPLC were purchased from Sigma (St. Louis, MO). Macroporous spherical silica (particle diameter 5 μm, pore diameter 120 Å) was supplied by Sepax Technologies (Suzhou, China). All other chemicals and reagents used were of analytical grade.

Bacterial Strains and Cultivation Conditions. *Escherichia coli* ATCC 25922, *Shigella dysenteriae* ATCC 51302, *Pseudomonas aeruginosa* ATCC 27853, *Salmonella typhimurium* ATCC 50013, *Staphylococcus aureus* ATCC 25923, *Bacillus subtilis* ATCC 9372, and *Streptococcus pneumoniae* ATCC 49619 were provided by Wuxi Center for Disease Prevention and Control (Wuxi, China). *E. coli* ATCC 25922 was cultured in Luria−Bertani (LB) agar at 37 °C unless otherwise specified. Other strains were cultured in nutrient agar at 37 °C. All tested strains were maintained at −80 °C in 20% (v/v) glycerol. Throughout the experiments, the strains were subcultured every 2 weeks on agar media to keep the microorganisms viable and kept at 4 °C. The cultures were propagated twice in liquid media overnight before use.

Peptide Extraction from Boiled-Dried Anchovies. Peptides were extracted from boiled-dried anchovies according to the method of Zhu et al. with some modifications.[21] Boiled-dried anchovies (20 g) were ground to uniformity with 100 mL of 0.01 M HCl and centrifuged at 10000*g* for 20 min at 4 °C. The supernatant was filtered by 0.45-μm membrane and then added to 3 volumes of ethanol to remove the protein fraction. The sample was kept for 20 min at 4 °C and then centrifuged at 10000*g* for 20 min at 4 °C. The supernatant was dialyzed against Milli-Q water using a 100-Da cutoff membrane (Spectrum, Spectra/Por cellulose acetate membrane, Los Angeles, CA), concentrated in a rotatory evaporator, and lyophilized.

Total Lipid Extraction of *E. coli* Membranes. Total lipid extraction of membranes of *E. coli* was conducted according to the method of Dennison et al. with some modifications.[22] *E. coli* ATCC 25922 was grown in LB broth at 37 °C to produce an inoculum population of about 10^9 colony-forming units per milliliter (CFU/mL). About 10 g of wet cells was harvested from 2.5 L of the medium by centrifugation (3000*g*, 5 min). The obtained cell pellets were then resuspended in 60 mL of Tris buffer (25 mM, pH 7.5), and then, 180 mL of a 1:2 (v/v) chloroform/methanol mixture was added to the cell suspension. The cell/solvent sample was then stirred for 90 min. After stirring, an additional 60 mL of chloroform and 60 mL of distilled water were added, and the whole mixture was vortexed for 20 min. The chloroform phase was separated, and then the solvent was removed in a rotary evaporator under a vacuum.

Preparation of Immobilized Bacterial Membrane Liposome Chromatography (IBMLC) Stationary Phase. Macroporous spherical silica was activated with 20% (v/v) hydrochloric acid for 6 h by reflux. It was then washed with deionized water to neutrality, dried at 120 °C, and kept dry until use. The lipid film was dissolved in chloroform/methanol (19:1, v/v). Activated silica (3.5 g) was added to the solution and shaken for 45 min at 4 °C. Then, the solvent was removed by rotary evaporation. The dried material was treated with nitrogen and kept under a vacuum overnight to remove the remaining solvent. The bacterial lipid film coated porous silica gel was swollen in Tris buffer (10 mM, pH 7.2) for 6 h to form liposome. The supernatant was removed by centrifugation (1000*g*, 5 min). To remove nonimmobilized bacterial lipid, the silica gel was washed with Tris buffer until no phosphorus was detected in the supernatant. Phosphorus was determined by Fiske and SubbaRow reagent according to the method of Bartlett.[23]

Calcein Fluorescence Release from IBMLC Stationary Phase. Ten milliliters of calcein (1 μg/mL) and 0.5 g of lyophilized IBMLC stationary phase were added to a centrifuge tube and incubated overnight at ambient temperature. Then, the supernatant was removed by centrifugation (10000*g*, 5 min), and the precipitate was repeatedly washed with Tris buffer with the same volume (10 mL). Each washing was followed by centrifugation at 10000*g* for 5 min. The supernatant after each centrifugation was collected and analyzed by a fluorescence spectrophotometer (F-7000 FL Spectrophotometer, Hitachi, Tokyo, Japan) at excitation and emission wavelengths of 490 and 515 nm, respectively. The stationary phase was washed until no fluorescence was detected. After that, 500 μL of methanol was injected into the centrifuge tube containing stationary phase. The procedures of washing with buffer and fluorescence determination were then repeated.

IBMLC of Anchovy Antimicrobial Peptide. The obtained IBMLC stationary phase was packed into a stainless steel column with dimensions of 250 mm × 4.6 mm i.d. using the slurry packing method. The column was equilibrated with phosphate-buffered saline (PBS; 10 mM, pH 7.2) containing 50 mM NaCl. Anchovy peptide sample (5 mg/mL, 60 μL) was run on the column at a flow rate of 0.5 mL/min. The eluate absorbance was monitored at 215 nm with a diode-array UV/vis detector (Agilent 1260 series, Agilent Technologies, Santa Clara, CA, USA). PBS (10 mM, pH 7.2) containing 50 mM NaCl was used as the mobile phase for an isocratic elution system with a fraction volume of 0.5 mL at 25 ± 2 °C. Thirty repeated injections were conducted to obtain sufficient quantities of the sample for analysis. The peaks were collected, lyophilized, and evaluated for their antibacterial activities against *E. coli* ATCC 25922 at identical concentrations. The peptide concentration was determined by monitoring its UV absorbance at 215 and 225 nm using the equation concentration (mg/mL) = $(A_{215} - A_{225}) \times 0.144$.[9,24] The same concentration of different fractions was obtained by dilution. The fraction with the highest activity was rechromatographed to RP-HPLC (Symmetry C18 column, 250 × 4.6 mm, 5 μm, Waters, Dublin, Ireland). The eluents were (A) 0.05% (v/v) trifluoroacetic acid (TFA) and (B) 100% acetonitrile. The elution program consisted of a gradient system (5−100% B in 40 min) at a flow rate of 0.5 mL/min at 30 ± 2 °C.

Analysis of Amino Acid Sequence of Anchovy Antimicrobial Peptide. The molecular mass and amino acid sequence of the purified peptide from IBMLC were analyzed by ultraperformance liquid chromatography tandem matrix-assisted laser desorption/ionization quadrupole time-of-flight mass spectrometry (UPLC MALDI Q-TOF MS) coupled with an electrospray ionization (ESI) source. UPLC was performed on an ACQUITY UPLCTM system (Waters, Milford, MA) using a reverse-phase column (BEH C18 2.1 × 150 mm, 1.7 μm, Waters, Milford, MA). The gradient elution was performed at a flow rate of 0.3 mL/min with eluent A as 100% ACN and eluent B as 0.1% formic acid. The flow gradient was as follows: 0−0.1 min, 100% B; 0.1−15 min, 100−60% B; 15−20 min, 60−0% B. The column temperature was maintained at 45 °C. Positive ion pattern (ESI+) was employed for ionization in TOF MS. In the experiments, the following parameters were used: capillary voltage, 3.5 kV; cone voltage, 40 V; source block temperature, 100 °C; desolvation temperature, 300 °C;

desolvation gas flow, 300 L/h; cone gas flow, 500 L/h; collision energy, 6 eV; detector voltage, 1700 V.

Peptide Synthesis. The analyzed peptide and nisin A were chemically synthesized on a model 432A peptide synthesizer (Applied Biosystems, Foster City, CA) using the standard 9-fluorenylmethyloxycarbonyl (FMOC) strategy. The purification of the crude peptides was conducted by RP-HPLC on a C18 column, and then the molecular mass and sequence of the purified peptide (>98% homogeneity) were confirmed by mass spectroscopy analysis.

Assay of Antimicrobial Activity. The antimicrobial activity during peptide purification was examined by liquid growth inhibition assay according to the method of Xiao and Zhang.[13] The antimicrobial activity was calculated using the equation antimicrobial activity (%) = $(A_0 - A)/A_0 \times 100$, where A and A_0 represent the absorbance of the sample and control, respectively. *E. coli* ATCC 25922 was used as the test organism throughout the peptide purification procedure.

Minimum inhibitory concentrations (MICs) were determined by microdilution assays. Briefly, microorganisms were collected during their midlogarithmic phase and resuspended in PBS (pH 7.2, 10 mM) to obtain a final microbial density of about 10^5 CFU/mL. Then, 100 μL of the cell suspension was placed in sterile flat-bottomed 96-well plates, after which 50 μL of peptides serially diluted 2-fold in the same buffer and 100 μL of media were added. The samples were then incubated at 37 °C for 18 h. MICs of the peptide against reference microorganisms were obtained by measuring the optical density at 600 nm (OD600) using a microplate reader (Multiskan MK3, Thermo Fisher Scientific, Waltham, MA). The lowest peptide concentration that completely inhibited the growth of bacteria was defined as the MIC. [25]

Assay of Hemolysis Activity. Hemolytic activity of the peptide was measured on C57BL/6 mouse red blood cells (MRBc).[26] Serial dilutions of the peptide were used to incubate with MRBc suspension for 30 min at 37 °C. Then the sample was centrifugated for 10 min at 400*g* to remove the cells. The absorbance of the supernatants was assessed at 595 nm. PBS (10 mM, pH 7.2) and 0.1% Triton X-100 were used as the negative and positive controls, respectively. The experiments were performed in triplicate.

Analysis of Nucleotide Leakage. The midlogarithmic *E. coli* ATCC 25922 cells grown in M9 minimal medium were adjusted to a final density of 10^7 CFU/mL with the same medium. Then the cells were incubated with the peptide at 2 × MIC for 0.5, 1.0, 2.0, 4.0, 6.0, 8.0, and 10.0 h. The cells incubated in M9 minimal medium without the peptide were used as the control. The cultures were centrifugated at 10000*g* for 1 min. Then the supernatant was filtered through a 0.22-μm membrane to remove the bacteria cells. The filtrate was diluted appropriately, and the OD value at 260 nm was recorded (UV-2800, Unico) at room temperature.[27] The experiments were performed in triplicate.

Scanning Electron Microscopy (SEM). The effect of the purified antimicrobial peptide on the morphology of *E. coli* ATCC 25922 cell was assessed by SEM (SU1510, Hitachi, Tokyo, Japan). The cells were prepared as follows: Midlogarithmic cells were obtained by centrifugation and then washed twice with PBS (10 mM, pH 7.2). The pellet was resuspended with PBS (10 mM, pH 7.2) and incubated with the active peptide (1 × MIC) at 37 °C for 30 min. Then the cells were washed twice with PBS (10 mM, pH 7.2), fixed with 2.5% glutaraldehyde for 4 h, and washed again with PBS. The fixed cells were dehydrated in ethanol gradients (30% × 10 min, 50% × 10 min, 70% × 10 min, 85% × 10 min, 90% × 10 min, and twice with 100% × 10 min, respectively). Dried cells were coated with gold and visualized by SEM. The control was performed in a similar manner except that the cells were incubated with PBS instead of the peptide.

Confocal Laser Scanning Microscopy (CLSM) Image Analysis. For the CLSM assay, *E. coli* ATCC 25922 cell suspensions were adjusted to (1−2) × 10^9 CFU/mL. The peptide-treated cells suspension (200 μL, 1 × MIC) was incubated with 50 μL of PI (final concentration of 50 μg/mL) for 30 min at 4 °C in darkness and then washed twice with 10 mM PBS (pH 7.2) and resuspended in the same buffer. Control cells were not treated with the peptide. Then 20 μL of the cell suspension was pipetted into glass bottom dishes. Images were captured on a LSM 710 confocal microscope (Carl Zeiss, Oberkochen, Germany) with ZEN 2011 software (Carl Zeiss, Oberkochen, Germany).

Statistical Analysis. The data were analyzed using SPSS 18.0 statistical software. The results are expressed as mean ± standard deviation (SD). The MALDI Q-TOF MS results were input into Mass Lynx4.1 software (Waters, Milford, MA) to obtain accurate molecular masses and amino acid sequences of the peptides. The matched peptides were verified manually. Peptide amino acid sequence homology search and analysis of biochemical properties were performed in the Antimicrobial Peptide Database (APD, http://aps.unmc.edu/AP/main.html) and NCBI database (http://www.ncbi.nlm.nih.gov/).

RESULTS AND DISCUSSION

Calcein Fluorescence Release. The content of phosphorus bound to the silica was determined to be 6.8 μM/g of silica. The bilayer structure of the liposome formed on the silica was further confirmed by calcein fluorescence leakage. Fluorescent calcein preferentially partitions into the hydrophobic environment. Therefore, the liposome with its characteristic bilayer structure can encapsulate calcein. However, when the liposome is disrupted by destructing reagent, calcein is released, and the fluorescent signal can be detected. The IBMLC stationary phase incubating with calcein was first washed repeatedly until no fluorescent signal was detected. However, the fluorescence intensity of the eluent substantially increased to 3514 fluorescence units after methanol was injected (Figure 1). This result

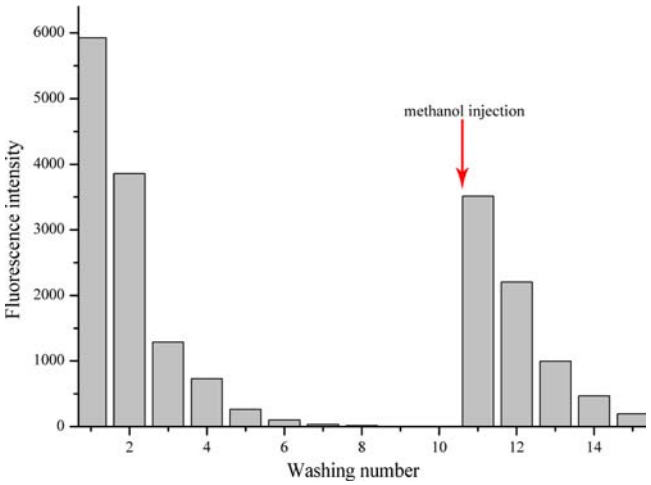

Figure 1. Fluorescence intensity change of the eluent of the calcein-entrapped IBMLC stationary phase induced by the injection of 500 μL of methanol. The fluorescent signal was monitored with excitation at 490 nm and emission at 515 nm.

indicates that the liposome with the lipid bilayer was formed on the silica. Yang et al. also confirmed the integrity of the bilayers of immobilized liposomes by determination of the release of liposome-entrapped calcein.[28]

Isolation of Antibacterial Peptide by IBMLC. Extracts of boiled-dried anchovies were fractionated (F1−6) by IBMLC, and the fractions were assayed for antimicrobial activity against *E. coli* at the same concentration (14.9 μg/mL). As shown in Figure 2, fractions eluting after 15 min exhibited antimicrobial activity, whereas those eluting before 15 min promoted the growth of the microorganism. The nitrogenous matter and phosphates in these fractions might provide further nutrients available for the growth. F6, which had the longest retention time, showed the highest antimicrobial activity among all of the fractions. A longer retention time suggests a greater interaction

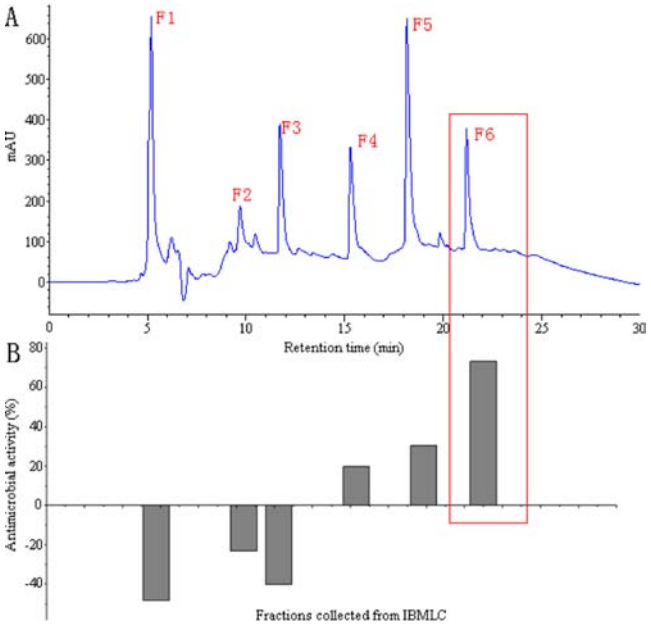

Figure 2. (A) Separation of antimicrobial peptide from boiled-dried anchovies by IBMLC. The column was equilibrated with PBS (10 mM, pH 7.2) containing 50 mM NaCl. Peptides were eluted with an isocratic elution at 25 ± 2 °C. The flow rate was 0.5 mL/min, the fraction volume was 0.5 mL, and the injection number was 60 μL. The peaks were combined and lyophilized. (B) Antimicrobial activities against *E. coli* of the fractions (14.9 μg/mL) obtained by IBMLC. The activity was evaluated according to a liquid growth inhibition assay.

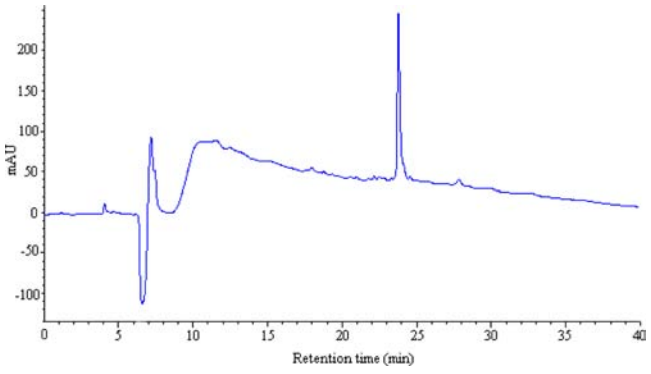

Figure 3. RP-HPLC of F6 from IBMLC. The sample was applied to an Agilent 1260 HPLC system (Symmetry C18 column, 250 × 4.6 mm, 5 μm, Waters, Dublin, Ireland). Elution was carried out using a gradient system [A, 0.05% (v/v) trifluoroacetic acid; B, 100% acetonitrile; 5−100% B in 40 min] at a flow rate of 0.5 mL/min at 30 ± 2 °C.

between the stationary phase and the solute.[29] This result indicates that the retention of a peptide in the IBMLC stationary phase might have a certain relationship with its activity because of the interaction with the bacterial membrane liposome, which is driven by electrostatics and hydrophobicity.[30] The reproducibility of the separation of the sample by IBMLC was also tested. The mean value and relative standard deviation (RSD) of the retention time of each peak were calculated. The RSD of the retention time of each peak was less than 1% (n = 6). F6 was pooled and further applied to RP-HPLC. A major single peak of absorbance at 215 nm was observed (Figure 3). As this method involved only one-step chromatography, it might be more time-saving and cost-effective than other AMP screening protocols that include multiple-step chromatography. The retention behavior of the AMP in the IBMLC reflects the interaction between the AMP and the bacterial cell membrane.

Identification of Antibacterial Peptides by MALDI Q-TOF MS. The fraction of F6 with the highest antimicrobial activity was collected and subjected to MALDI Q-TOF MS coupled with an ESI source to identify the molecular mass and amino acid sequence. m/z 974.12 was selected as the precursor ion for further analysis (Figure 4). The molecular mass of the peptide was 973.11 Da according to the analysis by Mass Lynx4.1, and the amino acid sequence was determined to be GLARCLAGTL (Gly-Leu-Ala-Arg-Cys-Leu-Ala-Gly-Thr-Leu) (Figure 5). The targeted antimicrobial peptide is a cationic decapeptide, with a total net charge of 1+ and a total hydrophobic ratio of 60%. The theoretical pI is 8.25. The prediction of Apep10 in APD showed that it might form α-helices and had at least five residues on the same hydrophobic surface. These features facilitate its affinity binding to the negatively charged bacterial cell membrane surface.[9] The results further support the previous conclusion that most antimicrobial peptides are hydrophobic and less than 10 kDa in molecular weight, with an overall net positive charge.[1] Searches in the APD and NCBI

Table 1. Minimal Inhibitory Concentrations (MICs) of Antimicrobial Peptide Apep10

species	Gram staining	MIC (μg/mL)
Escherichia coli ATCC 25922	−	8
Shigella dysenteriae ATCC 51302	−	16
Pseudomonas aeruginosa ATCC 27853	−	8
Salmonella typhimurium ATCC 50013	−	16
Staphylococcus aureus ATCC 25923	+	64
Bacillus subtilis ATCC 9372	+	8
Streptococcus pneumoniae ATCC 49619	+	16

databases found no match, suggesting that it is a novel peptide, which we have named "Apep10".

Antimicrobial Activity. Apep10 extracted from boiled-dried anchovies was found to have antimicrobial activity against all of the tested bacteria, with MIC values ranging from 8 to 64 μg/mL (Table 1). The synthetic peptide was equally active against the tested strains. These bacteria are common pathogens or food-spoilage-related bacteria, suggesting a promising strategy to control some harmful strains by Apep10. The most susceptible bacteria were *E. coli*, *P. aeruginosa*, and *B. subtilis*, with a

dx.doi.org/10.1021/jf4052286 | J. Agric. Food Chem. 2014, 62, 1564−1571

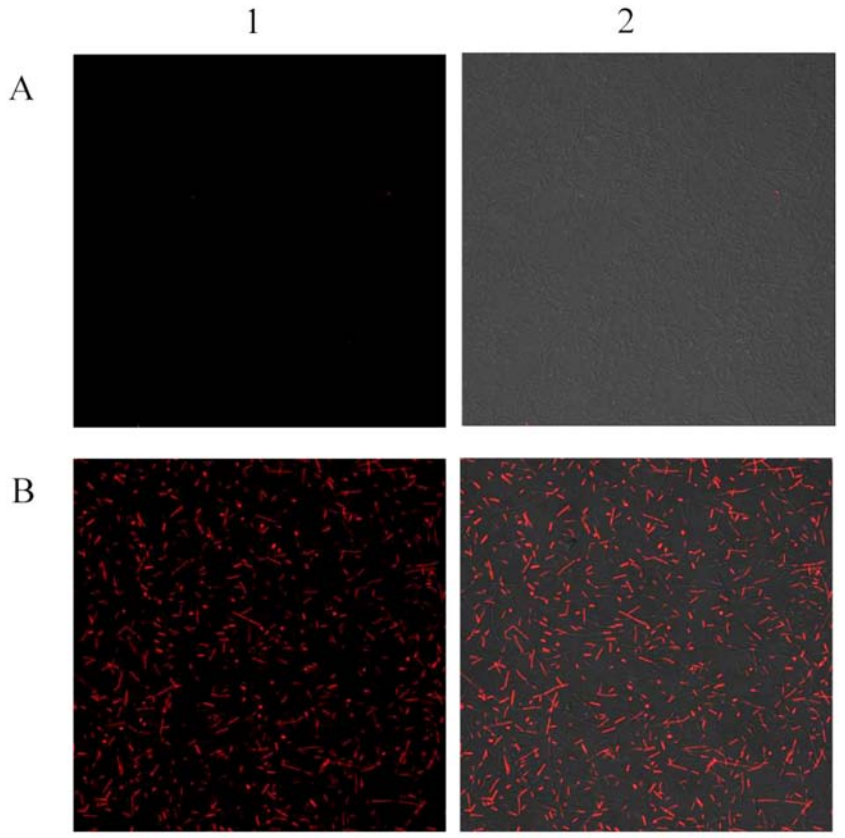

Figure 9. Confocal laser scanning microscopy images of Apep10-treated *E. coli*: (A) control *E. coli* cells, (B) *E. coli* cells treated with Apep10 (1 × MIC) for 60 min at 37 °C; (1) fluorescence images obtained by fluorescent field microscopy, (2) images obtained by fluorescent-field and bright-field micrososcopy.

MIC of 8 μg/mL. Although the liposome used to screen Apep10 was constructed from *E. coli*, Apep10 exhibited antibacterial activity against both Gram-negative (*E. coli*, *S. dysenteria*, *P. aeruginosa*, and *S. typhimurium*) and Gram-positive bacteria (*S. aureus*, *B. subtilis*, and *S. pneumoniae*). This might be because it could interact with the cell envelope of both Gram-negative and Gram-positive bacteria by electrostatic and hydrophobic interactions.[31] In addition to the negatively charged phospholipids, negatively charged teichoic acids (for Gram-positive bacteria) on the outer surface of the peptidoglycan and the negatively charged lipid A of lipopolysacharide (for Gram-negative bacteria) in the real bacteria might also contribute to the electrostatic interaction.[9] In addition, the peptide could interact with the bacterial membrane, with the hydrophobic face toward the lipid components and the polar residues binding to the phospholipid head. The differences in activity against the tested bacteria might be due to the diversity of lipids and other components among the microorganisms.

Hemolytic Activity. Typically, antibacterial peptides exhibiting no/low hemolytic activity can be considered for application in practice. The hemolytic activities of Apep10, nisin, and melittin against C57BL/6 mouse erythrocytes following 30 min of incubation were compared (Figure 6). Following a 30-min exposure to concentrations of 10 and 20 μg/mL, nisin A showed <2.0% hemolysis, and Apep10 exhibited <0.52% hemolysis, in contrast to the hemolysis of more than 50% for melittin at the same concentrations. When the concentrations were higher than 30 μg/mL, Apep10 induced a higher percentage of hemolysis than nisin A. For melittin, almost complete hemolysis was observed at concentrations higher than 30 μg/mL. It can be concluded that Apep 10 almost did not exert a cytotoxic effect against mouse erythrocytes below 20 μg/mL, a concentration higher than most MICs of the tested bacteria in Table 1 (except *S. aureus*). These results suggest that Apep10 might be a promising candidate for food preservative and antimicrobial drug.

Activity on Membrane Permeability. Membrane binding is thought to be the first step in the interaction between antimicrobial peptides and bacterial membranes.[32] Previous work has also indicated that membrane permeability is a key step in the antimicrobial mechanism of cationic peptides.[33,34] In this work, a membrane permeability assay was conducted to explore whether the permeabilization occurred when the peptide bound to the cell membrane. Nucleotides can release from the cells when the plasma membrane is permeable. As nucleotides have strong UV absorption at 260 nm, OD260 was used to determine the membrane permeability. As shown in Figure 7, the total nucleotide leakage content from *E. coli* cells induced by Apep10 was time-dependent. Compared with the control, a fast increase to 0.172 of OD260 in the first 4 h was observed. Slight change was observed afterward. However, the control showed very little increase in OD 260 in 10 h. The results indicate that Apep10 could cause membrane permeabilization and result in nucleotide leakage.

Typical SEM images of the effects of Apep10 on the morphology of *E. coli* are shown in Figure 8. The control *E. coli* cells (not incubated with Apep10) had a rodlike shape with a regular, intact, and smooth surface (Figure 8A). After treatment with Apep10, the *E. coli* cells exhibited significant abnormalities,

dx.doi.org/10.1021/jf4052286 | J. Agric. Food Chem. 2014, 62, 1564−1571

including noticeable holes or wrinkles on their surfaces, the collapse of the cell structure, and a ghostlike appearance in which the cells seemed transparent and looked empty (Figure 8B). These cell abnormalities suggest that the peptide might have caused pore formation and induced the release of cytoplasmic components. This result indicates that Apep10 can directly interact with the bacterial membrane and damage its integrity. This type of morphological effect on microorganisms has previously been shown for other antimicrobial peptides. Some researchers observed morphological changes such as a shrunken appearance on the surface of *Klebsiella pneumoniae* treated with cecropin B and its analogues.[35] Park et al. found that *Pseudomonas aeruginosa* treated with P5 and melittin showed cell surface disruption.[36] Tomasinsig et al. also observed that incubation with BMAP-28 caused extensive surface blebbing on *Prototheca wickerhamii* cells, with release of intracellular material.[37]

For more precise observation of the cytoplasmic-membrane-perturbing activity of Apep10, PI was used as a fluorescent probe in combination with CLSM. PI has been proposed in previous research as an appropriate probe in the assessment of membrane permeabilization, as it is supposed to penetrate cells and stain them only when the membrane is disrupted.[38,39] Indeed, when *E. coli* cells were incubated with the probe without pretreatment with Apep10, no appreciable fluorescent signal was observed, as visualized by comparing bright-field and fluorescence microscopy images (Figure 9A), suggesting that the intact membrane of the control *E. coli* prevented the uptake of PI. In contrast, the cells emitted a red fluorescence after exposure to 1 × MIC Apep10 as the result of PI uptake (Figure 9B), indicating that the peptide increased the permeability of the bacterial membrane. This finding was confirmed by SEM images (Figure 8). These results together demonstrate that Apep10 can interact with a bacterial membrane, which is the basis of IBMLC.

The present data demonstrate that immobilized bacterial membrane liposome chromatography can be employed to screen AMPs, which is much faster than conventional protocols using multiple-step chromatography. In addition, the activity on the bacterial membrane permeability of the peptide provides further insight into the interaction between AMPs and bacterial membranes.

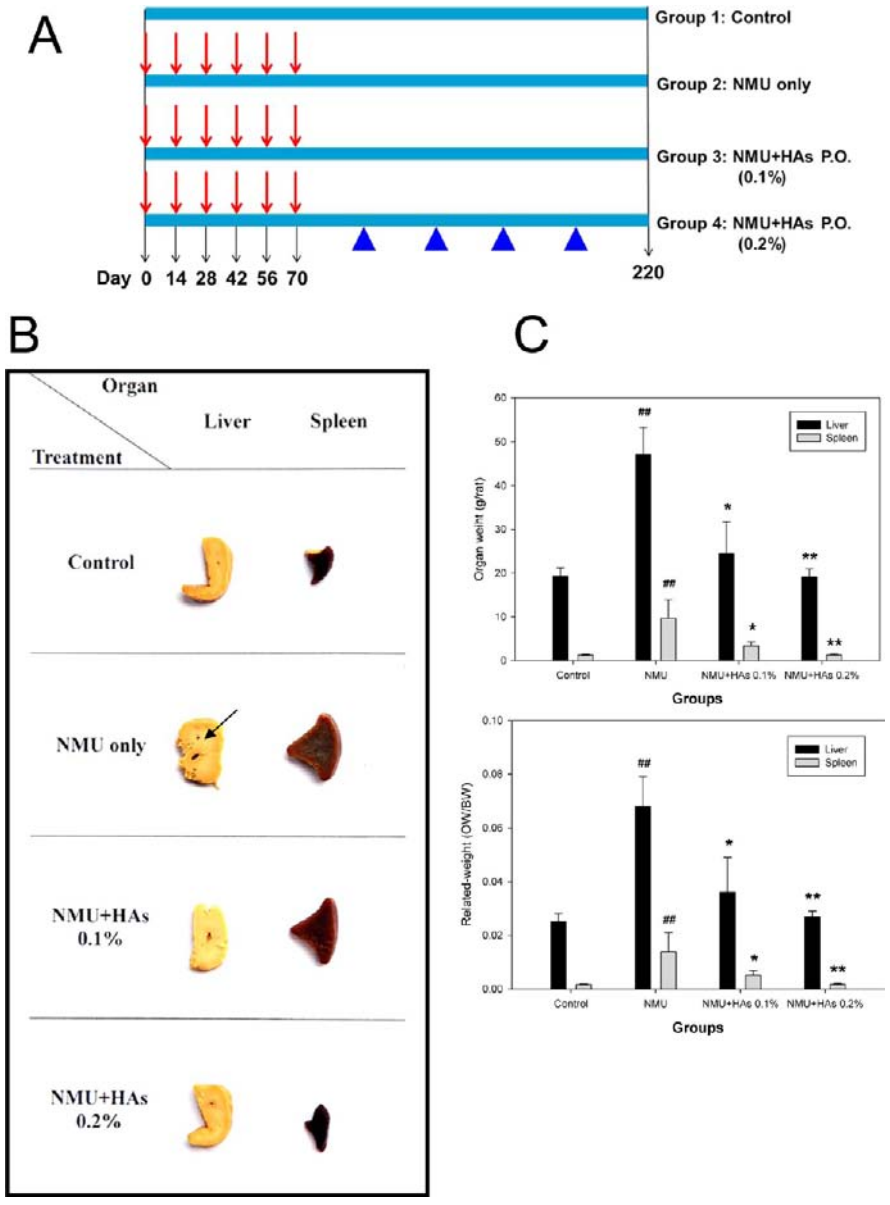

Figure 1. Effect of HAs on gross appearance and organ weight of NMU-treated rats. (A) Protocol of the animal model (experimental design). Rats were injected with NMU every 2 weeks for 6 times (arrow). The day of the first injection is designated day 0. HAs were given orally at day 0 every day until sacrifice. NMU at 35 mg/kg iv and animals after iv injection were monitored for blood data every 30−40 days from the caudal vein (triangle). The details were as described under Materials and Methods. (B) All of the animals were sacrificed, and the livers and spleens were immediately fixed in 6% formaldehyde for specimen preparation. The arrows indicate cancer cell invasion in liver tissue shown with a gray-white hyalinized look. (C) Data represented as net weight of organ (liver or spleen)/body weight (OW/BW). The indicated days are counted after iv NMU and recorded once about 30−40 days. These values were expressed as the mean ± SD, $n = 12$. (#) $p < 0.01$ and (##) $p < 0.001$, compared with control group. (∗) $p < 0.05$ and (∗∗) $p < 0.005$, compared with NMU-treated group.

acid (a phenolic acid extract from roselle) was reported to inhibit LDL oxidation induced by copper or a NO donor.[16] (ii) Antihyperlipidemia and antiatherosclerosis effects of roselle extract reduced foam cell formation, reduced smooth muscle cell migration, and lowered calcification in the blood vessels of treated rabbits.[17] HAs markedly inhibited oxidation of oxLDL by $CuSO_4$, perhaps by CD36 down-regulation in vitro.[18,19] (iii) Hepatoprotection effect of roselle extract was shown to exert the hypolipidemic effect via inhibiting lipogenesis and promoting hepatic lipid clearance.[20] (iv) Anticancer inhibitory effect of roselle extracts on carcinogenesis demonstrated that it possesses potential as a cancer chemopreventive agent against apoptosis evasion, insensitivity to antigrowth signals, tissue invasion, and metastasis.[21,22] (v) Antidiabetes effects roselle extracts are worthy of further investigation toward development as an adjunct therapy for diabetes or metabolic syndromes.[23,24] (vi) Other activities of *H. sabdariffa* polyphenols (HPE) give them potential as anti-inflammatory agents.[25] Recently, Pen et al. and Lee et al. illustrated the anti-insulin resistance properties of HPE and its effect on hypoglycemia, hypolipidemia, and antioxidation.[26,27] The demonstration of the beneficial effects of dietary polyphenols on health is becoming an important issue. Although most cellular studies have proven their biological effects at the in vitro level, the correlation between the in vivo observed effects and the presence of the responsible metabolites is still unclear. Therefore, the aim of this study

dx.doi.org/10.1021/jf405235j | J. Agric. Food Chem. 2014, 62, 1572−1580

was to characterize the antileukemia effect of the methanol extract of roselle, especially anthocyanins (HAs), using an animal model.

MATERIALS AND METHODS

Reagents. MPO (n1578), LSAB2 System-HRP, and the liquid DAB substrate chromogen system were purchased from Dako Corp. (Carpinteria, CA, USA). *N*-Methyl-*N*-nitrosourea (NMU) was purchased from Sigma (St. Louis, MO, USA). NMU was stored in a refrigerator at 4 °C. NMU solution (0.5 g/100 mL) was freshly prepared, dissolved immediately before use in physiologic saline. The PD-10 column was purchased from Amersham Biosciences (Uppsala, Sweden).

Preparation of HAs. The extraction of HAs was performed as previously described.[28] Briefly, 20 g of the dried flower *H. sabdariffa* L. with methanol (2 L) containing 1% HCl was kept for 1 day at 4 °C. The extract was filtered and concentrated; then, the precipitate was collected and stood on an Amberlife Diaion HP-20 resin column for 24 h. After that, distilled water (5 L) containing 0.1% HCl solution was used to clean, and the components of interest were eluted with methanol. The filtrate was collected and then lyophilized to obtain approximately 2 g of HAs and stored at −20 °C before use. A stock solution of HAs in ddH_2O at a concentration of 100 mg/mL was prepared and protected from light and stored at 4 °C.

Animal Treatment. The experimental design is presented in Figure 1A Male Sprague−Dawley rats (at 7 weeks old) were purchased from the National Laboratory Animal Breeding Research Center (Taipei, Taiwan) and acclimatized for 1 week. These animals were housed in an environmentally controlled animal room (at 25 °C with a 12 h light−dark cycle). Animal food (basal diet CE2) and water were provided ad libitum. The current study was approved by the Chung Shan Medical University Institutional Animal Care and Use Committee (IACUC, CSMU). Animals were randomly housed 3 per cage and divided into four experimental groups of 12 rats each. The first group served as control (untreated), and the second group received intravenous (iv) administration of NMU. Group 1: control, Sprague−Dawley rats fed the standard diet, without any treatment. Group 2: NMU only, iv injected with 35 mg/kg of NMU, fed the standard diet. Group 3: NMU+HAs oral administration (per os, po) (0.1%), fed 0.1 g/kg/day HAs in the standard diet and iv injected with 35 mg/kg NMU. Group 4: NMU+HAs po (0.2%), fed 0.2 g/kg/day HAs in the standard diet and iv injected with 35 mg/kg NMU. HAs extract been mixed with the feed, and the animals were dosed each day for 220 days. The dose of HAs was the amount of lyophilized powder per kilogram of body weight. A total of 12 rats (NMU group) were given a series of six iv injection of NMU, at 35 mg/kg of body weight, at biweekly intervals as described by Huggins et al.[29] with some modification. NMU was injected in a caudal vein; the day of the first injection was designated day 0, and HAs was administered orally to each assigned group at the same time. After carcinogen treatment, they were kept on basal diet and water ad libitum until sacrifice at 220 days of the experiment. The animals were individually observed daily for mortality and weekly for clinical signs throughout the study period. Body weights were measured weekly. Blood samples were collected in blood tubes every 30−40 days before sacrifice. The hepatic and splenic tissues were immediately fixed in 6% formaldehyde for specimen preparation and histochemical staining analysis.

Hematology and Blood Biochemistry. Blood was freshly obtained for hematological examination at intervals of 30−40 days after final NMU administration; 0.5−1.0 mL of blood was drawn on occasion without foaming or hemolysis. The lateral tail vein is usually used, and 0.1−2 mL of blood can be obtained per sample depending on the size of the rat. Whole blood samples were collected in tubes coated with an anticoagulant, 0.3 M EDTA-2K (ethylenediaminetetraacetic acid). Complete blood count (CBC) analysis included WBC (white blood cell) count, RBC (red blood cell) count, PLT (platelet) count, Hb (hemoglobin) concentration, and WBC differential count. Measurements were carried out by a fully automated hematology analyzer (model XE-2100, Sysmex). Blood smears were stained with Liu and Papanicolaou stain for cytological examination.

Biochemical Data Measurement. Analyses of all biochemical parameters in serum were examined with an autoanalyzer (Olympus AU2700, Olympus) using commercial reagent kits. The aspartate aminotransferase (AST/GOT), alanine aminotransferase (ALT/GPT), and uric acid were measured by enzymatic methods (AST, ALT, kinetic UV test; and UA, enzymatic color test).

Pathological Examination. Biopsies of liver and spleen were immediately obtained after the animals were sacrificed (day 220). A portion of them was fixed in 10% formalin solution, processed using routine histology procedures, embedded in paraffin, cut in 5 μm sections, and placed on a glass microscope slide for analysis. The samples were stained with hematoxylin and eosin (H&E) for morphological evaluation and then examined microscopically.

Immunohistochemistry. Immunohistochemical investigations were carried out on paraffin-embedded sections. Sections were dried in an oven at 50 °C overnight, deparaffinized in xylene, rehydrated in a graded alcohol series, immersed in citrate buffer (pH 6.0), and incubated in an autoclave for 25 min. Sections were then removed, allowed to cool at room temperature for 20 min, and rinsed with running water and distilled water for a total of 10 min. They were then blocked for the endogenous peroxidase measurement by incubating in a solution of 3% hydrogen peroxide (H_2O_2) for 10 min. Tissue sections were washed with PBS and then immunostained with primary antibodies for 30 min. The antigen−antibody complex was visualized by an avidin−biotin−peroxidase complex method followed by diaminobenzidine tetrahydrochloride (DAB) as a chromogen. After washing, sections were counterstained with Gill's hematoxylin, washed with tap water, mounted with Permount (Merck, Darmstadt, Germany), and examined by light microscopy. For confirmation that the immunocystochemical procedure was performing correctly, antibodies against MPO were tested.

Statistical Analysis. All data are presented as means ± SD. The statistically significant differences compared with the untreated control group or NMU group were calculated by Student's *t* test. Differences with probability value <0.05 were considered significant.

RESULTS

Anthocyanin Content in *H. sabdariffa* L. Extract. Our previous yield of HAs was approximately 2 g.[28] Spectrophotometer analysis of HAs showed that the purity of HAs was approximately 85−95%. According to calibration standards, the major components of HAs were delphinidin (3.7%) and cyanidin (0.9%) as analyzed by HPLC.[18] The phytochemical profile and HPLC analysis of the calyx extract of *H. sabdariffa* L. were previously performed by another research group.[30,31] The HPLC chromatogram shows the presence of several unidentified peaks.

Effect of HAs on Weights of Visceral Organs. Several papers have indicated that NMU can induce thymic lymphoma and myelogenous leukemia.[32,33] We first observed the gross evaluation of these four groups in Sprague−Dawley rats. Each group had 12 individuals. Normal spleens appeared dark brown in color, but the enlarged spleens with infiltrative tumors induced by NMU appeared paler. NMU-treated livers showed a gray-white hyalinized appearance with the presence of cancer cells. Invaded cells are indicated with arrows in Figure 1B. Gross visual examination of the livers and spleens from the NMU-exposed rats revealed that these organs were abnormally enlarged in appearance, whereas both organs appeared nearly normal upon administration of HAs (Figure 1B).

The effects of HAs on body weight and relative weights of liver and spleen of NMU-exposed rats were analyzed. The body weight gain of each rat was determined every day by comparing the current weight with the weight on day 0. The four groups of

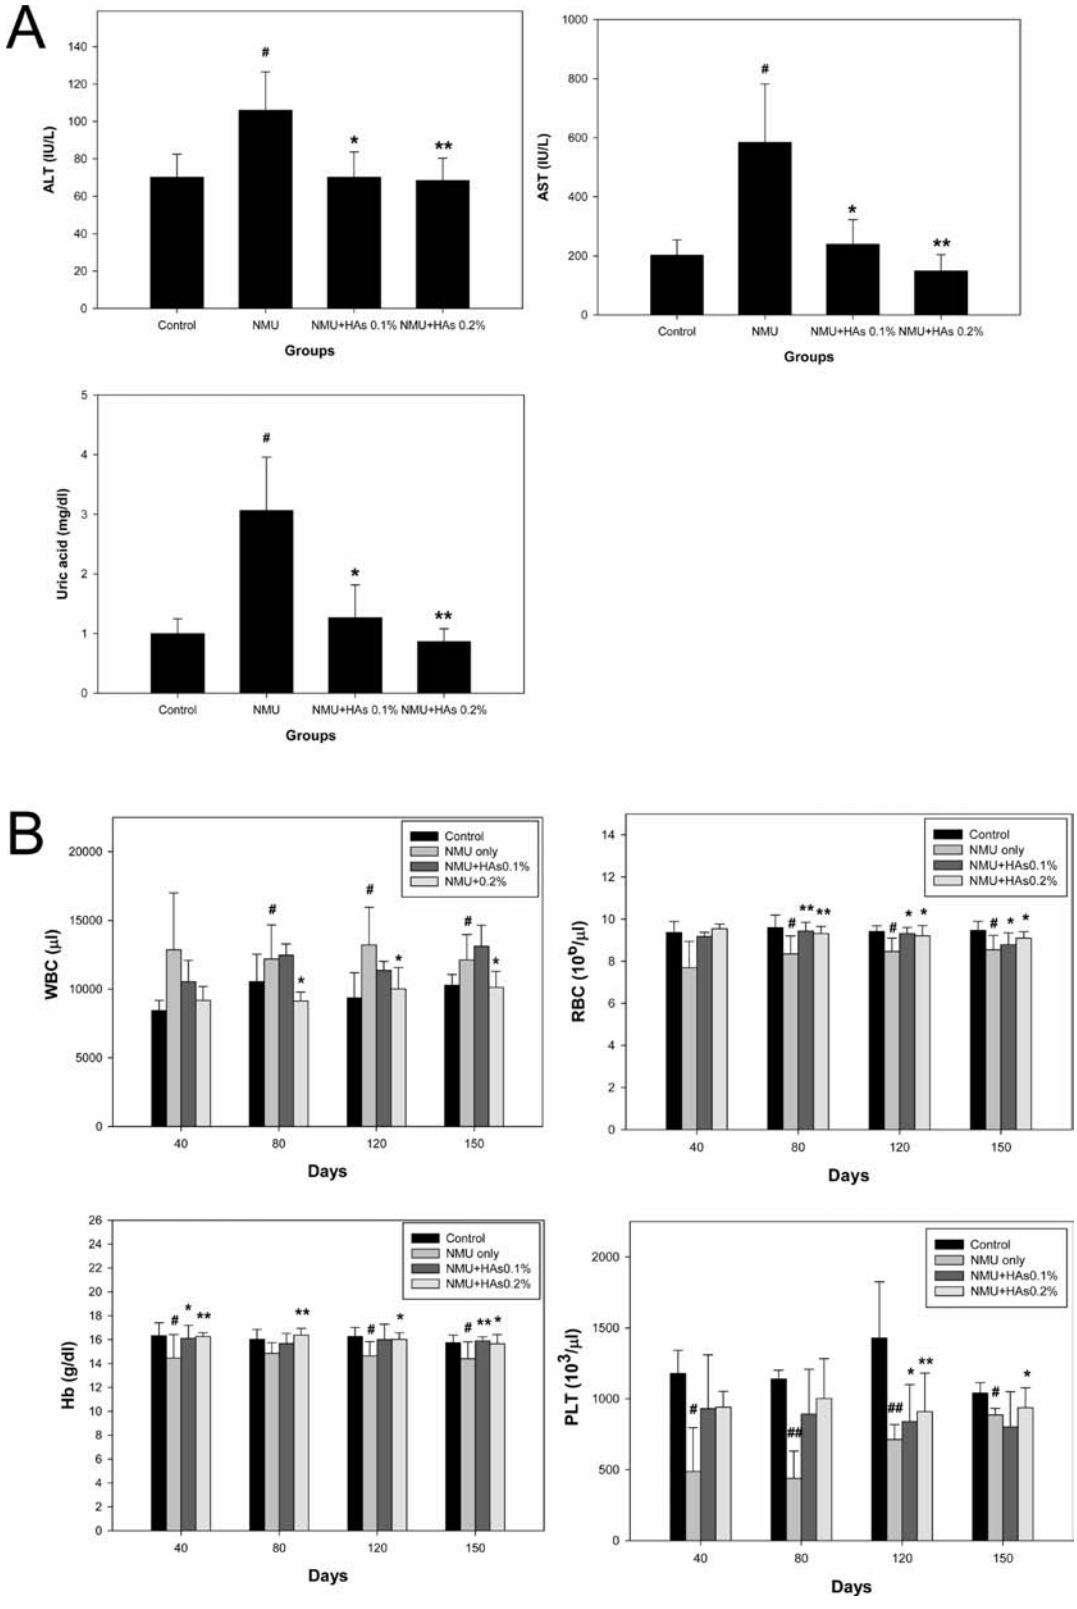

Figure 2. Effect of HAs on the serum biochemical analysis and complete blood count in Sprague−Dawley rats: (A) levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), and uric acid; (B) count of white blood cell (WBC), red blood cell (RBC), hemoglobin (Hb), and platelet (PLT). The indicated days are counted after iv NMU and recorded once about 30−40 days. Values are expressed as the mean ± SD, $n = 12$. (#) $p < 0.05$ and (##) $p < 0.005$, compared with control group. (∗) $p < 0.05$ and (∗∗) $p < 0.005$, compared with NMU-treated group.

rats had an average body weight gain during the whole experimental period. There was a remarkable increase (more than untreated group) in liver and spleen weight of NMU-induced leukemia rats. After oral treatment with HAs at two different doses (0.1 and 0.2%), the liver and spleen weights were significantly reduced dose dependently compared to the

dx.doi.org/10.1021/jf405235j | J. Agric. Food Chem. 2014, 62, 1572−1580

NMU group (Figure 1C). The mean liver and spleen weights in the 0.2% HAs groups were 19.11 ± 1.89 and 1.25 ± 0.27 g, respectively (*, $p < 0.05$; **, $p < 0.005$). Furthermore, the weights of liver and spleen, relative to body weight of rats after HAs administration, were also found to be significantly reduced, compared with rats in the NMU-treated group (Figure 1C). In the 0.2% HAs group, the mean values of relative liver and relative spleen weights were 0.027 ± 0.002 and 0.0017 ± 0.00040 g, respectively (*, $p < 0.05$; **, $p < 0.005$). Figure 1 illustrates that HAs treatment attenuated the elevated liver and spleen weight values in NMU-exposed rats.

Effect of HAs on Serum Biochemical Analyses. The effects of HAs on aspartate aminotransferase (AST), alanine aminotransferase (ALT), and uric acid level in the plasma of NMU-exposed rats are presented in Figure 2A. The hepatic function test was used to evaluate the liver for injury, infection, inflammation, or abdominal swelling. Increased permeability of the hepatocellular membrane caused by injury or disease results in a release of serum transaminase (ALT and AST). A high level of the soluble enzymes released into the bloodstream may be a sign of liver damage, cancer, or other diseases. Thus, the degree of liver cell damage can be estimated from the level of serum ALT and AST. Activities of ALT and AST enzymes were increased after NMU administration in rats as compared with the untreated control group (approximately 110 and 600 IU/L, respectively). Treatment with HAs (0.2%) resulted in significant inhibition of ALT (approximately 70 IU/L) and AST (approximately 180 IU/L), as compared with rats treated with NMU (Figure 2A). In addition, uric acid (UA) is the end product of purine nucleotide metabolism in humans. Determining the level of serum uric acid is useful in detecting hyperuricemia and in diagnosing leukemia,[34] gout, polycythemia, and renal dysfunction. Treatment of HAs at two tested concentrations caused significant decreases in the levels of uric acid compared to NMU treatment only (Figure 2A). HAs at 0.2% decreased from 3.07 ± 0.89 to 0.87 ± 0.22 mg/dL at the end of the study, which shows a decrease of 70%. These results confirmed that taking HAs can significantly diminish serum ALT and AST as well as uric acid level in rats exposed to NMU.

Effect of HAs on Complete Blood Count. Leukemia is a malignant disorder of the blood that is sometimes discovered during a routine blood test in an asymptomatic individual. More often, patients have constitutional complaints arising from leukocytosis (or neutropenia), anemia, or thrombocytopenia. The values of RBC and Hb decreased in the NMU-treated group, indicating a tendency to anemia; likewise, low platelet count of blood was considered as thrombocytopenia. WBC count was elevated significantly in the NMU-treated group, as compared with the control group, indicating the production of leukemia blasts induced by NMU in rats. On the other hand, the WBC count was decreased significantly after HAs (0.2%) treatment as compared with NMU ($10 \times 10^3/\mu L$ versus $13 \times 10^3/\mu L$) (Figure 2B). In contrast, other hematological data of HAs-treated rats were higher (mean of $9.6 \times 10^6/\mu L$ for RBC counts; $938 \times 10^3/\mu L$ for PLT counts; and 16.8 g/dL for Hb concentration at 0.2%) when compared to NMU-exposed rats ($7.5 \times 10^6/\mu L$, $613 \times 10^3/\mu L$, and 14.5 g/dL, respectively) (Figure 2B). In this study, we observed that the RBC, Hb, and PLT values were lower, whereas WBC values were higher in the HAs-treated group compared to the NMU-induced group (*, $p < 0.05$; **, $p < 0.005$). These data imply that HAs may improve anemia, leukocytosis, or thrombocytopenia. Hence, these results suggest that the administration of HAs decreased the NMU-induced increases in WBC counts.

Effect of HAs on Cytological Morphology Features. Figure 3 shows that Liu-stained smears in the NMU-induced group were cellular and revealed a markedly polymorphous mixture of small to large cells. A greater proportion of large, dark staining, blast-like promyelocytes and metamyelocytes, and dysplastic granulocytes were present in NMU-treated rats. The smaller cells were mature neutrophils. Most neutrophils were normal or occasionally dysplastic in the progression of the leukemia. The large cells were primitive and had abnormal nuclear maturation. The overall cytomorphological picture posed serious difficulties in differentiating this condition from those of the peripheral blood smear. In addition, the original staining procedure was developed by Papanicolaou to visualize

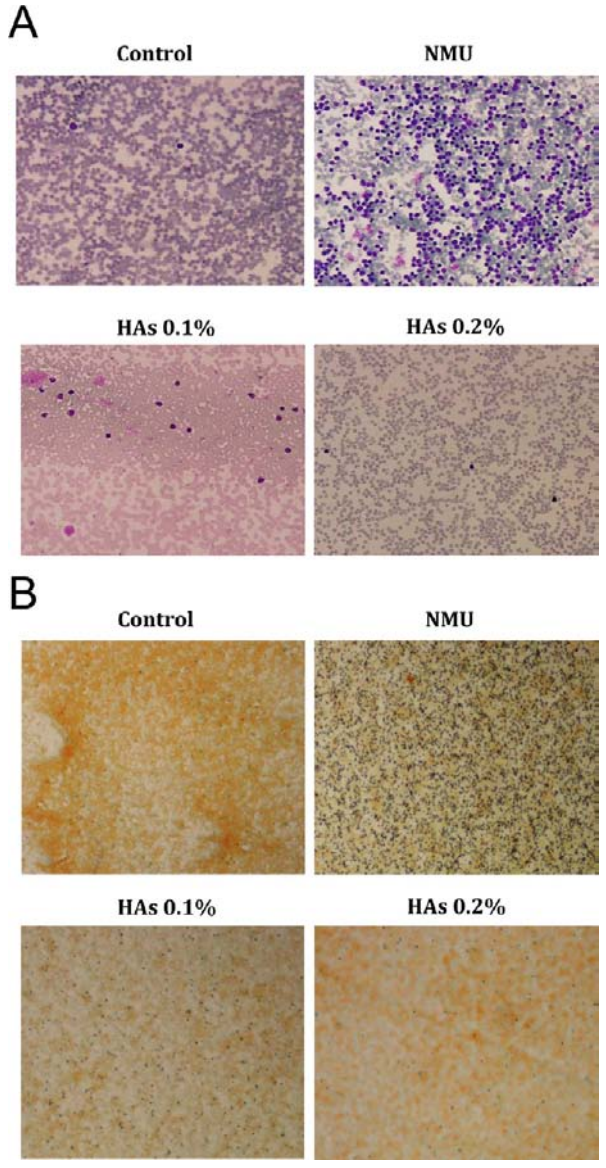

Figure 3. Hematology analysis for whole blood cells by Liu (A) and Papanicolaou (B) staining. After animals were treated with NMU alone (35 mg/kg) for 220 days or with HAs (0.1 and 0.2%) given orally for at least 150 days, animals were killed and blood was collected, which showed fewer malignant cells. All experiments were done in duplicate, and photographs were taken at 100× magnification.

dx.doi.org/10.1021/jf405235j | J. Agric. Food Chem. 2014, 62, 1572−1580

cancer cells, for example, cervical cancer. Papanicolaou's is the most important staining method in cytology because it enhances differentiation between malignant and nonmalignant cells and also allows critical examination of nuclei and cytoplasmic components. The Papanicolaou stain method revealed more atypical single cells in the NMU group than in the control group (Figure 3B). These atypical cells were round, dark blue in color, and approximately 2−3 times the size of lymphocytes. Abnormal leukemia cells equivalent to immature white blood cells were verified in smears from the NMU-induced group. Remarkably, the smears showed normal number and shape of blood cells in HAs administration (0.2% HAs group of Figure 3). These results show that HAs given orally to rats at a dose of 0.2% exhibited a potent antileukemia activity in all of the treated animals.

Effect of HAs on Histopathological Features. The effect of HAs on NMU-induced leukemia was evaluated. Liver and spleen samples of NMU-injected and HAs-fed rats were submitted for routine histological analysis to characterize their morphological aspects. Panels A and B of Figure 4 show the histological findings using H&E stain on the different organs. The spleen and liver were frequently enlarged in all cases (NMU group) and showed leukemic cell infiltration. Because the portal vein brought much more blood to the liver, cancer cells (arrows) infiltrated the portal area and sinusoids in the NMU-induced group (Figure 4A). In the spleen, the normal architecture of red and white pulp was destroyed in NMU-treated rats with a massive spread of undifferentiated cells (Figure 4B). The spleen showed marked red/white pulp diffusely infiltrated by leukemic cells induced by NMU. HAs effectively abrogated NMU-induced leukemic cell infiltration and subsequent tissue damage (0.2% HAs group of Figure 4A,B). Histopathological examination revealed 91.7% leukemia incidence by NMU. In the HAs groups (especially at the high dose of 0.2%), the incidence of leukemia was reduced by 33.3% (Table 1). Also, at the end of the experiment, the number of dead rats was 0 (0/12), 6 (6/12), 3 (3/12), and 1 (1/12) for control (rats with no manipulation), rats treated with NMU, and rats treated with HAs of 0.1 and 0.2%, respectively. It is clear that the mortality rate of rats that were given a high dosage of HAs was less than the mortality in the NMU group. In the 0.2% HAs-treated rats, four developed leukemia and one died. All control rats that were not given leukemia cells were still alive at the end of the study. HAs treatment reduced NMU-induced liver and spleen injury in a dose-dependent manner.

Effect of HAs on Immunohistochemical Analysis. The myeloperoxidase (MPO) stain distinguishes the immature cells in acute myeloblastic leukemia (cells stain positive) from those in acute lymphoblastic leukemia (cells stain negative).[35] In rat liver sections, immunohistochemical staining of MPO showed that there was a dark purple reaction product in NMU-exposed rats, indicating that this is a myeloid leukemia. Weak MPO expression was observed in control and HAs-treated groups (Figure 4C). These findings suggest that myeloperoxidase activity was increased in NMU-induced blast cells. Treatment with HAs may have had an anti-inflammatory effect consistent with no staining or weak staining.

DISCUSSION

Leukemia is cancer of the blood or bone marrow. It begins in the bone marrow and is characterized by an abnormal increase of immature white blood cells (called blasts). Cases of leukemia are classified into different types mainly on the basis of the kind

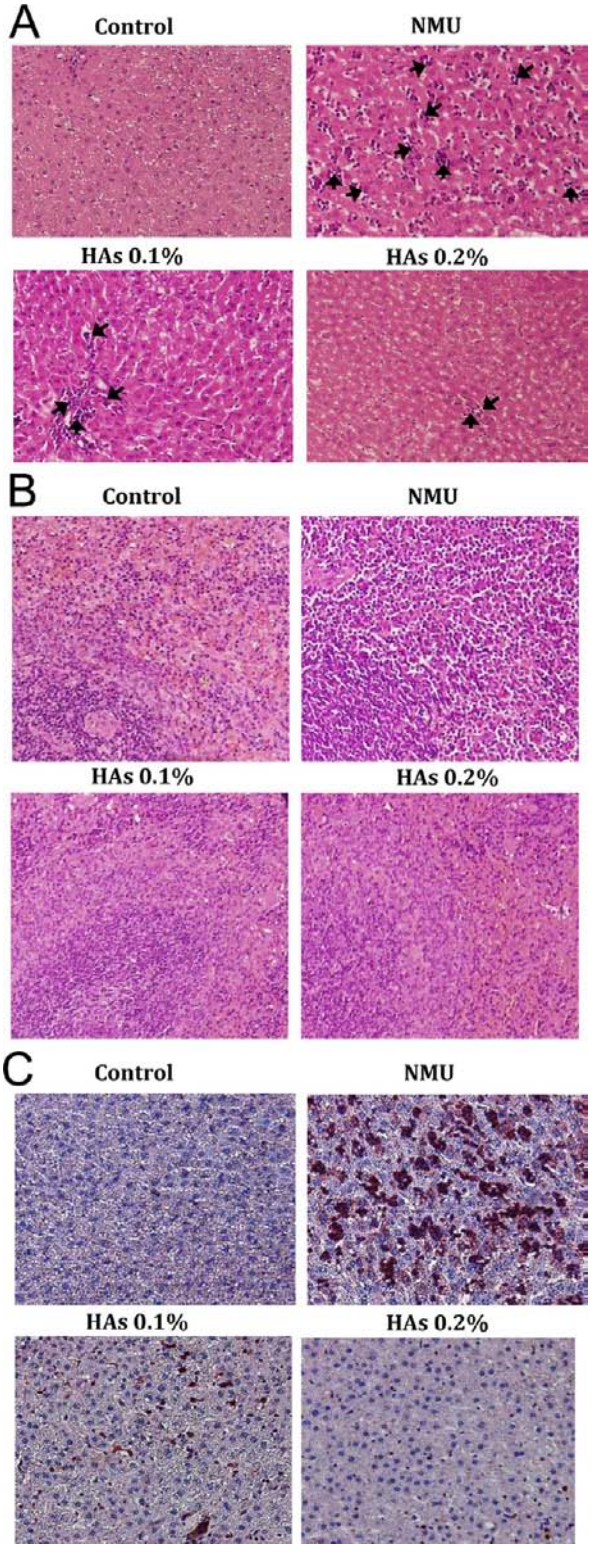

Figure 4. Histopathological examinations of organs in Sprague−Dawley rats. Paraffin-embedded sections of representative liver tissues (A) and spleen tissues (B) were stained by H&E staining. (C) The liver tissues were stained by MPO staining (immunohistochemical analysis). Animals were treated with NMU alone (35 mg/kg), which showed marked infiltrative cells in the NMU group. HAs (0.1 and 0.2%) were given orally for at least 150 days, which showed fewer infiltrative cells in the HAs-treated group. The arrows indicate malignant cells. All experiments were done in duplicate, and photographs were taken at 100× magnification.

Table 1. Inhibitory Effects of HAs on NMU-Induced Rats Tumorigenesis

treatment[a]	leukemia tumor incidence[b] (%)	ratio of death
control	0/12 (0%)	0/12 (0%)
NMU only	11/12 (91.7%)	6/12 (50%)
NMU + HAs 0.1%	7/12 (58.3%)	3/12 (25%)
NMU + HAs 0.2%	4/12 (33.3%)	1/12 (8.3%)

[a]First time iv NMU and treated various concentrations of HAs (0.1 and 0.2%) on the same day. [b]Tumor incidence is equal to the number of dead rats that had leukemia combined with the number of tumor rats.

of progression. Leukemia can be divided into four common types: chronic lymphocytic leukemia (CLL), chronic myeloid leukemia (CML), acute lymphocytic leukemia (ALL), and acute myeloid leukemia (AML). *N*-Methyl-*N*-nitrosourea (NMU), a DNA alkylating agent, acts as a potent carcinogen and mutagen to various tissues. O^6-Methylguanine adducts have been proposed to be the critical lesion in a variety of NMU-induced tumors. In particular, Huggins et al. found that NMU specifically elicited a high incidence of leukemia in Sprague–Dawley rats.[36] Therefore, NMU is a broad-spectrum carcinogen capable of inducing tumors in various target organs, including leukemia. According to a previous paper, blood samples were collected and used to evaluate cytological examination (through Liu and Papanicolaou stains) and morphological changes of rat livers and spleens by histological evaluation (through H&E staining) and to classify the leukemia of poorly differentiated blasts (through an immunohistochemical analysis).[37] The results showed that the NMU-induced group was positive for MPO, but negative for CD3, CD15, CD20, and CD34. NMU-induced leukemogenesis in a S-D rat suggests a more definite way to classify leukemia M3 (APL, acute promyelocytic leukemia). NMU characteristically induces an early and high incidence of leukemia and malignant lymphomas in young rats when provided at relatively high doses, resulting in a high mortality rate of the animals and limiting the conduct of long-term experimental studies.[38] In this study, we used the animal model of NMU-induced leukemia to detect the influence of HAs. Mortality rates varied from 50% in the NMU-only group to 8.3% with the HAs 0.2% group through the whole course (Table 1). NMU-related macroscopic observations included pale liver, heart, kidney, and bone marrow and enlargement of the spleen, thymus, and mandibular and mesenteric lymph nodes, which correlated with the diagnosis of lesions of the hematopoietic system.[39] Figure 1B shows that the livers and spleens from the NMU-exposed rats were abnormally enlarged, but with treatment of HAs both organs were significantly restored to nearly normal. Subsequently, we detected the count of ALT, AST, WBC, RBC, PLT, and Hb levels in the blood. These results display that HAs can significantly diminish elevated serum ALT and AST as well as complete blood count levels in rats exposed to NMU (Figure 2). Finally, we investigated the presence of leukemic cells in the peripheral smear using Liu and Papanicolaou stains; in addition, the severity of tissue injury resulting from leukemic cell infiltration was also assessed by histological detection (H&E and MPO assay). We found HAs can effectively abrogate NMU-induced leukemic cell infiltration and subsequent tissue damage (Figures 3 and 4). Thus, evaluation of the protective effect of anthocyanin extract of roselle on leukemia might shed light on drug discovery or alternative therapy.

Anthocyanins are a large group of polyphenols widely distributed in our diet. The intake of anthocyanins has been estimated at >180 mg/day in humans.[40] Anthocyanins have received considerable attention because of their wide range of potential health-promoting properties,[41] including cancer-prevention effects.[42] Indeed, intact anthocyanin forms (glycosides) have been detected in rat and human plasma as well as in urine after oral administration.[43] However, low bioavailability of anthocyanins, much less than 0.1% of intake, was suggested by the low concentration measured in plasma and urine after anthocyanin ingestion in some short-term studies.[44] Therefore, we wanted to ensure a sufficiently high intake and, thus, selected a daily dose of HAs of 100–200 mg/kg (approximately equal to 0.1–0.2%). On the other hand, our purpose was to assess the influence of HAs in rats fed an anthocyanin-rich diet for a relatively long period. This study was to evaluate the potential chemoinhibitory effects of HAs on leukemia. In this 220 day study we observed that dietary supplementation of 0.1 and 0.2% HAs decreased the WBC counts and uric acid levels by 30–70% in a dose-dependent manner. Our data demonstrate that an anthocyanin-rich diet (HAs) in fact is sufficient to enhance the antileukemia response, which is consistent with other studies. For instance, anthocyanin-rich berry extract significantly inhibits leukemia cell proliferation at 10–100 μg/mL, which corresponds to anthocyanin concentrations between 10^{-6} and 10^{-5} M.[45] There is some controversy about its bioavailabilty, but recent evidence indicates that despite low bioavailability, plasma concentrations of anthocyanins appear sufficient to induce changes in gene expression and signal transduction in vivo[46] in a manner suggesting a positive role in physiological functions and health outcomes. Several in vivo studies have provided evidence that plant foods have a notable impact on the absorption and metabolism of anthocyanins. In view of the above lower bioavailability of anthocyanins in patients, this was ascribed to the plasma or urinary recovery. For example, Harada et al. and Oki et al. found that 0.01–0.03% of purple sweet potato anthocyanins given by oral administration can be absorbed into plasma of both rat and human.[47,48] Ohnishi et al. pointed out that the recovery of administered cranberry juice anthocyanins in the urine of humans was estimated as 5%,[49] whereas other researchers recovered between 1.8 and 2% of strawberry anthocyanins.[50] Moreover, a previous study of 15 patients with coronary artery disease tested for total urinary recovery of administered cranberry juice anthocyanins. The recovery was in the range of 0.078–3.2% among the volunteers.[46] Although anthocyanin bioavailability appears low, it could have been underestimated, because the metabolites and breakdown products of anthocyanins have not yet been identified.[44] In addition, some research is needed to determine if anthocyanins alone or from their synergistic interactions with other phenolic compounds play a role in the inhibition of cancer. We believe such questions will be answered through continuing investigations in future decades.

The present results demonstrated that the HAs induced significant anticancer activity in a NMU-induced rat leukemia model. Although a cancer cell killing mechanism for HAs in human leukemia (HL-60) cells has been suggested,[9,28,51,52] clinical trials evaluating the use of roselle as a chemopreventive or therapeutic agent are lacking. Separation of the phenolic compounds of the roselle extract and in vivo experiments to determine whether HAs could be an effective anticancer agent for leukemia are important. Hence, this is the first report of the

antileukemic activity of HAs in vivo. Although further studies are needed to examine the mechanisms in detail, this study supports the contention that dietary intake of bioactive food compounds such as HAs may prevent cancer and reduce cancer risk.

two diverse pathways. The extrinsic pathway is initiated by the interaction of the ligands with their death receptors, which lead to activate caspase-8 and -3. The intrinsic pathway for programmed cell death requires the destabilization of the mitochondrial membrane and release of related apoptotic proteins like cytochrome *c*. Cytosolic cytochrome *c* together with Apaf-1 activates caspase-9, and the latter then activates caspase-3, resulting in apoptosis.[19] This process is controlled by the Bcl-2 family of proteins, which regulate the permeability of mitochondrial membrane. [20] According to previous studies, the effects of natural polysaccharide on apoptosis are likely to be through the intrinsic pathway. Currently, the importance of the mitochondrial pathway in cancer is being investigated.

To further identify the bioactivity and molecular mechanism of PSG-1, we analyzed the abilities of PSG-1 to inhibit tumor growth in CT26-bearing mice and activate immune responses. In addition, the molecular mechanism of PSG-1 inhibited tumor growth was elucidated. We found that PSG-1 could induce the apoptosis of CT26 colon carcinoma cells through an intrinsic apoptotic pathway and enhance the host antitumor immune response. These findings suggest the possibility of PSG-1 to be a promising drug candidate or functional food, and supply a theoretical basis for further exploring.

MATERALS AND METHODS

Materials. *G. atrum* was cultivated and gathered in Ganzhou, Jiangxi Province, China. The species identification was carried out by Prof. Zhihong Fu, from Jiangxi University of Chinese Medicine. PSG-1 was purified according to a previously published protocol.[13] 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) and 5-fluorouracil (5-Fu) were products of Sigma-Aldrich (St. Louis, MO, USA). Annexin V-FITC/PI assay kit was purchased from KeyGEN Biotech (Nanjing, China). Caspase-3 and -9 activity assay kits, Rhodamine 123 (Rh123), and reactive oxygen species assay kits were products of Beyotime Biotech (Jiangsu, China). The antibodies against Bcl-2, Bax, and cytochrome *c* were from Cell Signaling Technology (Danvers, MA). Anti-voltage-dependent anion channel (VDAC) 1 and anti-α-tubulin antibodies were purchased from Abcam (Cambridge, MA). Cytokine (TNF-α, IL-2, and IFN-γ) ELISA kits were from R & D Systems (Minneapolis, MN, USA).

Cells and Animals. CT26.WT mouse colon cell line was provided by Type Culture Collection of Chinese Academy of Sciences, Shanghai, China. The cells were cultured in RPMI-1640, 10% fetal bovine serum (FBS), and 1% P/S (100 units/mL penicillin and 100 units/mL streptomycin) under 37 °C, 5% CO_2 humidified conditions. BALB/c mice (male, 18−22 g) aged 6−8 weeks (SPF Certificate; No. SCXK (jing) 2009−0004, Beijing, China), were provided by Beijing HFK Biotechnology Company (Beijing, China). The animals were kept according to the Guide for the Care and Use of Laboratory Animals (NRC 2011), and all experimental protocols were in accordance with Nanchang University Medical College Animal Care Review Committee guidelines.

Cell Proliferation Assay. CT26 cells (2×10^4 cells/well) were plated into culture plates (Costar, Corning, NY) and incubated for 48 h in the absence or presence of different concentrations (0−320 μg/mL) of PSG-1. Then 20 μL MTT (5 mg/mL) solutions were added to each well. After incubation for 4 h, the optical density was measured at 570 nm in each well by using a microplate reader (Thermo, Shanghai, China) following removal of the medium and dissolution of the formazan crystals in the DMSO. Triplicate experiments were performed in a parallel manner for each concentration.

In Vivo Antitumor Activity. Mouse model of CT26 was established by inoculating 0.2 mL 5×10^6 cells/mL into the right hind groin of each mouse. After 24 h, the mice were divided into five groups (eight mice in each group) at random. The three groups of PSG-1-treated mice received different dosages (50, 100, and 200 mg/kg body weight), respectively. The positive control group was treated with 5-Fu (20 mg/kg), and the model control group was administered 0.9% saline solution. PSG-1 or saline solution was administered by using intragastric perfusion, and 5-Fu was administered by intraperitoneal injection once daily. On the 15th day, the mice were weighed and sacrificed by cervical dislocation. The spleen, tumor, and thymus were immediately excised and weighed. Thymus and spleen indexes were calculated as the weight of thymus and spleen relative to body weight. The inhibition rate was expressed as follows:

$$\text{tumor inhibitory rate}\ (\%) = (W_{\text{control}} - W_{\text{treated}})/W_{\text{control}} \times 100\%$$

W_{treated} and W_{control} were the average tumor weight of the treated and control mice, respectively.

The blood samples of mice in each group were centrifuged at 3,500 rpm for 10 min, and the serum was collected to detect the levels of TNF-α, IFN-γ, and IL-2 using commercial ELISA kits (R & D, Minneapolis, MN, USA). The absorbance was measured in an automatic ELISA plate reader (Thermo, Shanghai, China) at 450 nm.

Analysis of Apoptotic Cells. Flow cytometry can be used to quantitatively measure the apoptotic rate. The tumor tissue was isolated from CT26-bearing mice and chopped into small pieces with sterile scissors. Single cell suspension was prepared with a sterile filter screen. The suspension was washed twice and adjusted to the concentration of 1×10^6 cells/mL with cold PBS. Then the Annexin V-FITC and propidium iodide (PI) were added and incubated for 10−15 min away from light. Ten thousand events were collected for each sample. Stained cells were analyzed by flow cytometry (FACSCalibur, Becton Dickinson, Franklin Lakes, NJ, USA) in the FL1-H and FL2-H channels.

Determination of Mitochondrial Transmembrane Potential ($\Delta\Psi_m$). $\Delta\Psi_m$ was assessed by Rhodamine 123 (Rh123) probe (Beyotime Biotech, Jiangsu, China). Cells were collected and adjusted to a density of 0.5×10^6 cells/mL with RPMI 1640 medium and then incubated with 2 μM Rh123 at 37 °C for 20 min. The relative fluorescence intensities were measured by flow cytometry (FACSCalibur, Becton Dickinson) assay with the excitation and emission wavelengths of 488 and 530 nm, respectively.

Western Blot Analysis. The fresh tumor tissues were collected from tumor-bearing mice and fractionated into mitochondrial and cytoplasmic compartments with a Mitochondrial/Cytosol Fractionation Kit (Biovision, Mountain View, CA). Equal protein concentrations of lysate (containing 50 μg of proteins) were separated by SDS−PAGE in 12% gels, and then the proteins were electrotransferred to 0.22 μm nitrocellulose membranes. Membranes were preincubated with TBS buffer containing 5% BSA and 0.05% Tween 20 (TBST) for 2 h at room temperature and then incubated with anti-p53, anti-cytochrome *c*, anti-Bcl-2, or anti-Bax antibody (Cell Signaling Technology, Beverly, MA, USA) overnight at 4 °C. Immunoreactive bands were then incubated with peroxidase-conjugated secondary antibodies (ZSGB-Bio, Beijing, China) and detected by an enhanced chemiluninescence detection kit (ECL, Beyotime Biotech). β-Actin, α-tubulin, and VDAC1 were used as loading controls.

Assay for Caspase Activity. The activities of caspase-3 and -9 in cells were detected using caspase activity assay kits (Beyotime Biotech, Jiangsu, China) according to the manufacturer's protocols. The equal amounts of cells (1×10^5 cells/mL) from each sample were preincubated with cell lysis buffer for 10 min on ice and centrifuged for 8 min in a microcentrifuge at 10000*g*. The supernatant (100 μg of protein) was incubated with each caspase substrate (LEHD-AFC for caspase-9 and DEVD-AFC for caspase-3) at 37 °C for 1.5 h. Formation of ρ-nitroanilide was measured by ELISA Microplate Reader (Thermo, Shanghai, China) at 405 nm.

Intracellular Reactive Oxygen Species (ROS) Analysis. The intracellular levels of reactive oxygen species were monitored using the fluorescent probe DCFH-DA. 1×10^6 CT26 cells were isolated from tumor tissue, seeded in a 6-well plate, and then directly treated with 10 μM DCFH-DA dissolved in RPMI 1640 (1 mL) without FBS at 37 °C for 20 min. After the cells were washed with medium, the fluorescence intensity was measured with excitation wavelength at 488 nm and emission wavelength at 525 nm.

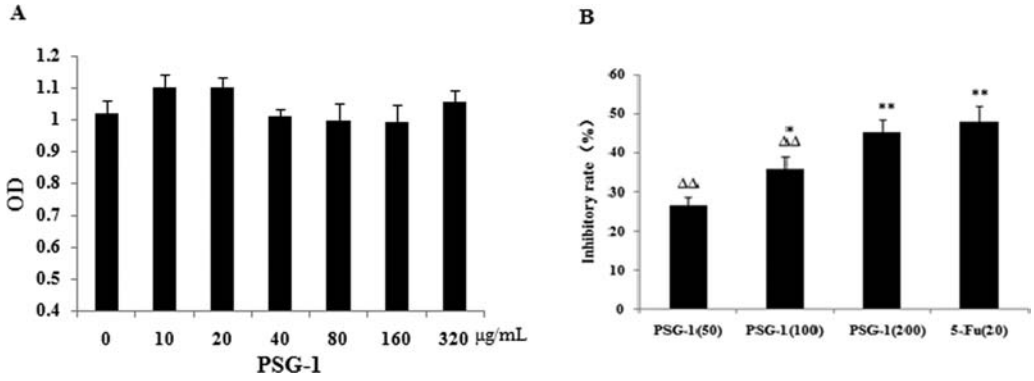

Figure 1. Antitumor effects of PSG-1 in vitro and in vivo. (A) Growth inhibitory effect of PSG-1 on CT26 cells. The effects of PSG-1 on the growth of CT26 cells were determined by the MTT method. The data presented are averages derived from at least triplicate experiments. (B) The tumor growth inhibitory rates of 5-Fu (20 mg/kg) and PSG-1 (50, 100, and 200 mg/kg) treated groups. Each data point is the average from 8 mice ($n = 8$). $^{*}P < 0.05$ and $^{**}P < 0.01$ vs control group; $\Delta\Delta$ $P < 0.01$ vs 5-Fu group.

Splenocyte Proliferation. Splenocytes were collected from tissue by homogenizing spleens; and then separated mononuclear cells were suspended in RPMI 1640 medium. The splenocytes were set up into the 96-well microplates at a density of 5×10^5 cells/well in RPMI 1640 medium, and then Con A (final concentration, 5 μg/mL) or LPS (final concentration, 10 μg/mL) was added to the wells. Plates were kept for 48 h at 37 °C with 5% CO_2. Cell proliferation was measured by MTT assay. The absorbance of each well was measured with an automatic microplate reader (Thermo, Shanghai, China) at 570 nm wavelength filter.

Statistical Analysis. All results were analyzed by one-way ANOVA using SPSS to determine the significance of differences between treatment groups and presented as the mean ± SEM. P values more than 0.05 were considered to be statistically insignificant.

Table 1. Effects of PSG-1 on Thymus Index and Spleen Index in CT26-Bearing Mice[a]

group	concn (mg/kg)	thymus index (mg/g)	spleen index (mg/g)
CT26 control		$1.341 \pm 0.263^{\Delta\Delta}$	$7.362 \pm 1.523^{\Delta\Delta}$
5-Fu	20	$0.421 \pm 0.114^{**}$	$3.982 \pm 1.375^{**}$

	100	$1.892 \pm 0.341^{**\Delta\Delta}$	$9.884 \pm 2.061^{**\Delta\Delta}$
	200	$2.746 \pm 0.385^{**\Delta\Delta}$	$10.253 \pm 3.226^{**\Delta\Delta}$

[a]Data are expressed as mean ± SEM of eight mice. $^{*}P < 0.05$, $^{**}P < 0.01$ vs CT26 control group. $^{\Delta}P < 0.05$, $^{\Delta\Delta}P < 0.01$ vs 5-Fu group.

RESULTS

Effect of PSG-1 on the Proliferation of CT26 Cells in Vitro. To investigate the effects of PSG-1 on the proliferation of CT26 cells, the cells were cultivated with different concentrations of PSG-1. MTT assays showed that PSG-1 exhibited no growth inhibitory activity on CT26 cells at concentrations of 20−320 μg/mL (Figure 1A).

PSG-1 Inhibited the Growth of Transplantable Tumors. After the 14 day treatment, PSG-1 (50, 100, and 200 mg/kg) and 5-Fu (20 mg/kg) had significant inhibitory effects on the growth of inoculated CT26 in mice. Figure 1B shows the inhibition ratio of tumor growth for different treatments in tumor-bearing mice. The data suggested that PSG-1 could inhibit the tumor growth in vivo.

Effect of PSG-1 Treatment on Thymus and Spleen Indexes. As shown in Table 1, after the treatment of PSG-1, the thymus and spleen indexes were significantly raised in CT26-bearing mice compared with the control group.

PSG-1 Promoted Apoptosis of CT26 Cells in Vivo. To investigate whether the inhibition of tumor growth may be caused by induced apoptosis in vivo, CT26 cells were prepared and then analyzed using Annexin V-FITC/PI double-straining. The results showed that the number of both necrotic cells and apoptotic cells was dramatically increased in the tumor administered with PSG-1 compared with control group (Figure 2). After treatment with PSG-1 for 2 weeks, the early and median apoptotic cells (lower right section of the fluorocytogram) were upregulated from 1.48% to 3.16%, 3.92%, and 5.01%, respectively. The late and apoptotic and necrotic cells (upper right section of the fluorocytogram) were also improved markedly (from 1.2% to 2.97%, 5.25%, and 8.51%). These data confirmed that PSG-1 induced the apoptosis of tumor cells of CT26-bearing mice.

Effect of PSG-1 on the Mitochondrial Transmembrane Potential ($\Delta\Psi_m$) in the Tumor of CT26-Bearing Mice. The disruption of mitochondrial integrity is an initial and irreversible event that occurs following induction of apoptosis through the mitochondrial pathway. To assess whether PSG-1 affects the function of mitochondria, the mitochondrial transmembrane potential were investigated by using the mitochondria probe, Rhodamine 123. With the increase of PGS-1 concentration, a remarkable attenuation of $\Delta\Psi_m$ was observed (Figure 3A,B). PSG-1 administration led to the $\Delta\Psi_m$ collapse.

PSG-1 Increased Release of Cytochrome *c* and Apoptosis-Associated Protein Expression in the Tumor of CT26-Bearing Mice. A critical step in the intrinsic apoptotic pathway is the liberation of mitochondrial intermembrane proteins into the cytosol, most notably cytochrome *c*, which plays a pivotal role in the activation of the caspase cascade.[21] Western-blotting results revealed that the level of cytosolic cytochrome *c* protein was unregulated dose-dependently (Figure 4B). In contrast, PSG-1 caused a slight decrease in protein level of cytochrome *c* in the mitochondrial fraction in 100 and 200 mg/kg body weight treated mice. These results indicated that PSG-1 led to the release of cytochrome *c* from the mitochondria to the cytosol.

The p53 is a potent tumor suppressor, which plays an important role in apoptosis signaling. A great many stress signals converge on p53, which responds to them by triggering cell cycle arrest and/or cell death by apoptosis.[22] The p53 directly binds to and inhibits antiapoptotic protein Bcl-2, and

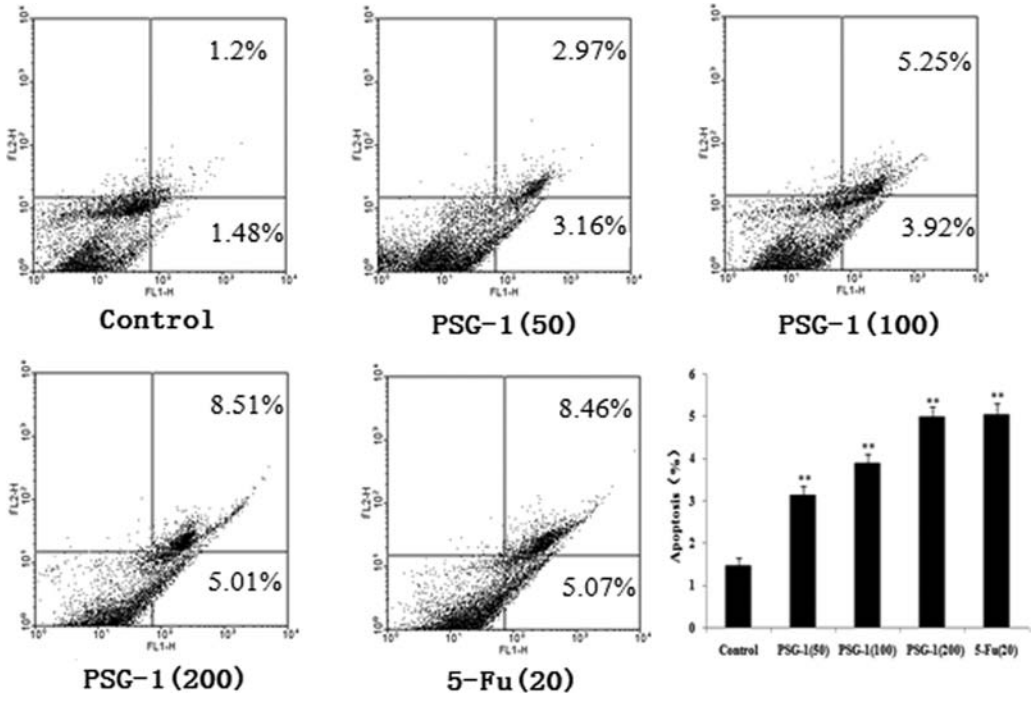

Figure 2. PSG-1 induced apoptosis in CT26 cells from CT26-bearing mice. CT26 tumor cells stained with AnnexinV-FITC and PI labeling and analyzed by flow cytometry.

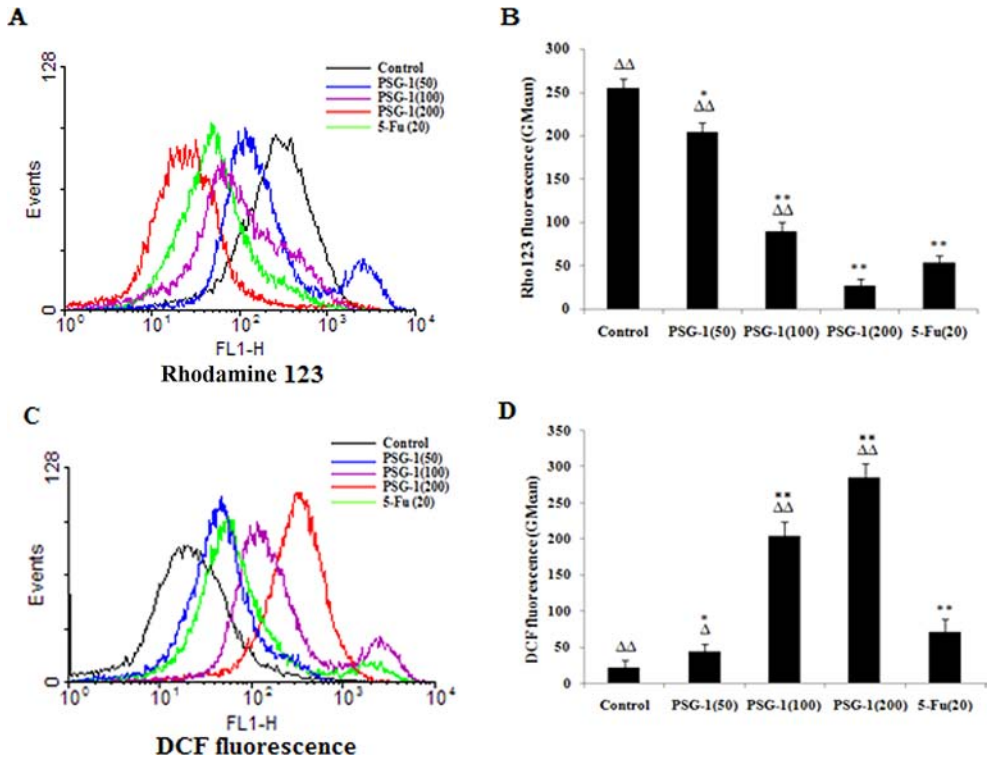

Figure 3. Effects of PSG-1 on the loss of $\Delta\Psi_m$ and generation of ROS. (A) The loss of $\Delta\Psi_m$ was evaluated by Rh123 staining. (B) Column chart of cell fluorescence for Rh123. (C) Intracellular ROS levels were measured by flow cytometry using an oxidation-sensitive fluorescent probe, DCFH-DA, which is oxidized to DCF in the presence of ROS. (D) Column chart of cell fluorescence for DCF. Values are mean ± SEM of eight mice. *P < 0.05 and **P < 0.01 vs control group; Δ P < 0.05 and ΔΔ P < 0.01 vs 5-Fu group.

also can trigger oligomerization of proapoptotic protein Bax, which are necessary for the disruption of mitochondria and release of cytochrome *c* from mitochondria into cytosol, stirring up the activation of the mitochondria-dependent apoptotic signaling pathway.[23] The Bcl-2 family members are important regulators of the mitochondrial apoptotic pathway. In order to clarify the mechanism of PSG-1-induced apoptosis, this study examined the expression of p53, Bax, and Bcl-2 proteins. Western blotting testing revealed that protein levels of both Bax and p53 increased dramatically in the 100 and 200 mg/kg PSG-

dx.doi.org/10.1021/jf4053012 | J. Agric. Food Chem. 2014, 62, 1581−1589

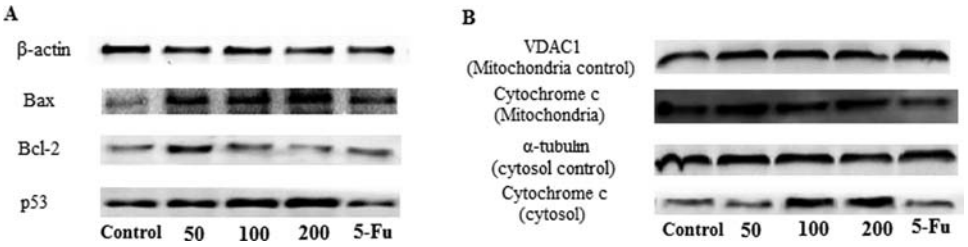

Figure 4. Western blot analysis of cytochrome *c* release and the expression of Bcl-2 family in tumor. (A) Total protein extracts were prepared and then analyzed by Western blotting with antibodies to p53, Bax, Bcl-2, and *β*-actin. (B) The cytosolic and mitochondrial proteins were analyzed by Western blotting with anti-cytochrome *c*, anti-VDAC1, and anti-*α*-tubulin antibodies. Western blots were representative of three independent experiments.

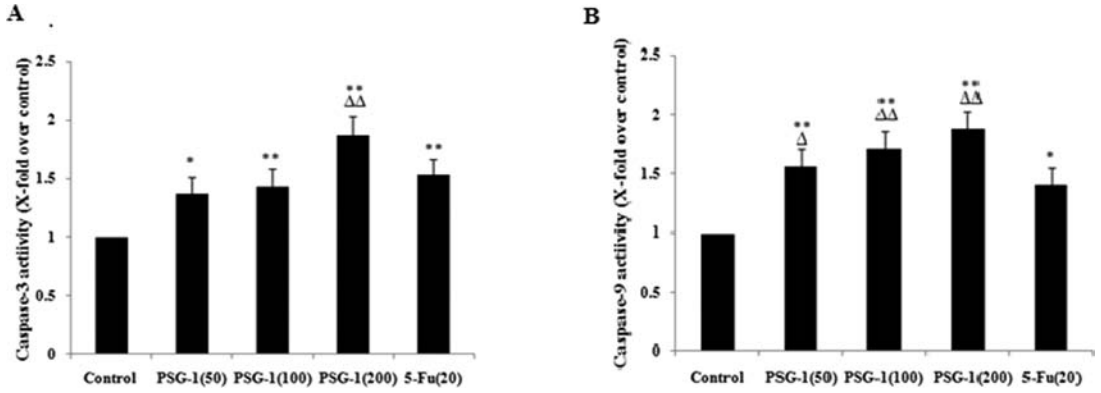

Figure 5. Effects of PSG-1 on the activation of caspase in the tumor of CT26-bearing mice. Quantitative analysis of caspase-3 and -9 activities in the tumor cells of CT26-bearing mice. Values are mean ± SEM of eight mice. $^{*}P < 0.05$, $^{**}P < 0.01$ vs control group; $^{\Delta}P < 0.05$ and $^{\Delta\Delta}P < 0.01$ vs 5-Fu group.

1-treated tumor-bearing groups, compared with control group, whereas the protein expression level of Bcl-2 was decreased in a dose-dependent manner (Figure 4A).

Effect of PSG-1 on Caspase Activity in the Tumor of CT26-Bearing Mice. Caspases are at the core of apoptotic machinery and play essential roles in the execution of apoptosis. According to the results of apoptosis assay, we hypothesized that PSG-1 might promote the activation of the caspase-dependent cell apoptosis pathway. We therefore set out to analyze the ability of PSG-1 to modulate caspase-3 and caspase-9 activities. Both caspase-3 and caspase-9 activities were elevated by treatment of PSG-1 in the CT26-bearing mice (Figure 5A,B). Taken together, all these lines of evidence suggested that PSG-1 could activate caspase-3 and caspase-9, and induce caspase-dependent apoptosis in the tumor of CT26-bearing mice.

Effect of PSG-1 on ROS Production in the Tumor of CT26-Bearing Mice. ROS generation are closely related to mitochondrial depolarization and apoptosis induction.[24] The level of ROS was detected to test whether oxidative stress went into effect in PSG-1-induced apoptosis in the tumor of CT26-bearing mice. As shown in Figure 3C,D, PSG-1 led to a remarkable increase in intracellular ROS level compared with control group. Therefore, the elevation of ROS production may be a major cause of PSG-1-induced apoptosis.

Effect of PSG-1 on Lymphocyte Proliferation and Cytokine Production in Serum of CT26-Bearing Mice. A wide variety of polysaccharides hold up antitumor activities and are side-effect-free in vivo. Most studies proved that fungus polysaccharides could exert the antitumor function through stimulating the immune response of the host organism. Furthermore, many mushroom polysaccharides were regarded as biological response modifiers. In this study, the normal murine lymphocyte proliferation rate induced by Con A or LPS was investigated. As shown in Table 2, there was a marked increase in the Con A- or LPS-induced proliferation of splenic cells in PSG-1 treated groups. As shown in Figure 6, TNF-*α*, IL-2, and IFN-*γ* concentrations in serum of 5-Fu treated CT26-bearing mice were lower than in control group. In contrast, administration of PSG-1 significantly increased TNF-*α*, IL-2, and IFN-*γ* levels in serum of tumor-bearing mice.

Table 2. Effects of PSG-1 on Immunomodulatory Activity in CT26-Bearing Mice[a]

group	concn (mg/kg)	A_{570} (OD) Con A	A_{570} (OD) LPS
CT26 control		$0.735 \pm 0.034^{\Delta}$	$0.699 \pm 0.023^{\Delta}$

DISCUSSION

Bioactive polysaccharides have been found in a large number of natural resources, including plants, fungi, and bacteria, and have attracted more and more attention in the biochemistry and medical areas. Among them, the antitumor activity of polysaccharides from medical fungi were most attractive owing to their low cytotoxicity to normal cells and no obvious

side effects in patients.[25] Lentinan from *Lentinus edodes* and PS-K/PS-P from *Coriolus versicolor* and *G. lucidum* polysaccharide are the most efficient and powerful fungal polysaccharides that have been extensively employed in antitumor action.[26] Recently, many kinds of polysaccharides displaying cyctoxic activity on tumor cells have been revealed, and some of these bioactive polysaccharides were possessed of potent apoptosis-inducing activities.

PSG-1 is a novel fungal polysaccharide purified from *G. atrum* and possesses excellent inhibitory activities against the proliferation of many kinds of tumor cells in vivo. Our previous studies have demonstrated that PSG-1 could inhibit S180 tumor growth, and improve immune system function through the TLR4 mediated-NF-κB and MAPKs signaling pathway.[27] Moreover, oral administration of PSG-1 could significantly prevent and inhibit CT26 solid tumor formation in BALB/c mice via TLR4-dependent signaling pathway.[15] In this study, we further assessed the apoptosis-inducing effect of PSG-1 on CT26 cells, and investigated the mechanism of tumor growth inhibition by PSG-1.

Apoptosis is always considered as the main pathway by which cytotoxic drugs induce tumor cell death and also a critical process that makes a contribution to both drug sensitivity and resistance in tumor cells.[28] Defective apoptosis would promote carcinogenesis and tumor progression as many antitumor therapies work by inducing apoptosis in tumor cells. In the present study, the results showed that PSG-1 induced CT26 cells apoptosis in vivo. We further explored the possible mechanism of apoptosis induced by PSG-1. The apoptotic process is often considered to be mediated by two separate mechanisms, mitochondrial and nonmitochondrial pathways. Mitochondrial outer membrane permeabilization is a decisive event in apoptosis which is mediated by Bcl-2 family proteins.[19,29] At present, existing data demonstrate that elimination of potentially malignant cells often relays on mitochondria apoptotic pathway.[30] Moreover, our previous study also found that the mitochondrial apoptotic pathway was closely related to the antitumor effect of (−)-epigallocatechin-3-gallate (EGCG) on human hepatoma cells.[31] Thus, we detected several apoptosis associated parameters of mitochondrial apoptotic pathway in our research.

$\Delta\Psi_m$, the loss of mitochondrial membrane potential, is one of the crucial parameters of mitochondrial dysfunction and could lead to an irreversible event during the process of cell apoptosis.[32] The disruption of $\Delta\Psi_m$ could result in the release of some apoptogenic proteins, activating the cascade of events that lead to the activation of caspases in the mitochondrial dependent apoptotic pathway.[33] In the present study, a very significant depletion of $\Delta\Psi_m$ was revealed by flow cytometry in PSG-1 treated groups. As could be judged from the loss of $\Delta\Psi_m$, PSG-1 is most likely to elicit marked changes in these mitochondrial functions.

The disruption of $\Delta\Psi_m$ in mitochondria could cause not only an uncoupling of the respiratory chain but also the efflux of some proteins as well as small molecules (e.g., cytochrome *c* and calcium). When cytochrome *c* is released into the cytosol, cytochrome *c* would bind to Apaf-1 to produce apoptosome accelerating the activation of caspase-9 and then caspase-3 for caspase-dependent apoptosis.[34] The dissipation of $\Delta\Psi_m$ prompted us to investigate the effect of PSG-1 on the release of cytochrome *c*. In the present study, we revealed that PSG-1 was able to induced the release of cytochrome *c*. Caspases are a

ubiquitous family of cysteine proteases that modulate the apoptotic response. Particularly, the activation of caspase-3 is one of the most common involvements in the apoptosis of various cell types.[35] Caspase-3, which might be activated by caspase-9, typically functions in the downstream of other caspases and directly activates enzymes that are responsible for DNA fragmentation in the mitochondrial apoptosis pathway. Lots of microtubule inhibitors such as vincristine, paclitaxel, colchicines, and vinblastine induce growth arrest, subsequent inactivation of Bcl-2, and finally apoptotic cell death through the caspase-9-dependent pathway.[36] Our current results were consistent with previous studies that the activities of caspase-9 and caspase-3 were markedly elevated in the PSG-1 treated group. These results suggested that PSG-1 exhibited the antitumor effect via induction of apoptosis mediated by mitochondrial pathways.

In cancer cells, ROS have been broadly reported to play a crucial part in apoptosis induction in both pathological and physiological processes. It has been detected as an early signal that initiates and mediates cellular apoptosis.[37] Interestingly enough, mitochondria are both the major source of and target of ROS. It could lead to the breakdown of membrane phospholipids, inactivation of enzymes, and destruction of mitochondrial function, which contribute to the intermembrane proteins, such as cytochrome *c*, to be released out of the mitochondria and eventually initiate caspase-3 activation. Recent evidence suggested that another cause of PSG-1-induced apoptosis may be ROS overproduction. The production of ROS in CT26 cells from CT26-bearing mice was determined by the oxidation-sensitive fluorescence dye, DCFH-DA. The data showed that PSG-1 elevated the level of ROS generation, suggesting that ROS production is relevant to PSG-1-induced mitochondria-mediated apoptosis.

The mitochondria-mediated apoptotic pathway was under the control of multiple layers of regulation, one of the most important players being members of Bcl-2 family.[38] Two most important members of Bcl-2 family, the antiapoptotic protein Bcl-2 and the proapoptotic protein Bax, are key regulators of this progress. The main function of them is to control mithochondrial permeability. Bax can promote cell death. Conversely, Bcl-2 proteins cause resistance to chemotherapeutic agents and radiation therapy, while reducing Bcl-2 expression could promote apoptotic responses to antitumor agents.[39] Triterpene extract was found to be able to modulate the expression of Bcl-2 and Bax in many types of tumor cell lines.[40] In addition, tumor suppressor p53 has been identified as an effector of apoptosis signals. Reactivating p53 provides a general strategy in conquering cancer specifically.[41] It is a regulator of cell cycle arrest progression and the mediator of apoptosis in various cases. To further analyze the possible mechanism underlying the PSG-1-induced apoptosis, we assessed the expression of these proteins. The results revealed that Bcl-2 expression was downregulated while Bax and p53 expression levels were strikingly increased, suggesting that upregulation of p53 and Bcl-2 family proteins might be another important mechanism contributing to mitochondrial pathway of apoptosis induced by PSG-1.

Taken together, our results suggest that PSG-1 may induce tumor apoptosis through mitochondrial death pathways. Downregulation of the death antagonist Bcl-2 and upregulation of p53 and the death agonist Bax, which lead to the collapse of $\Delta\Psi_m$, may promote the mitochondria-related cytochrome *c* release and lead to the activation of caspase-9, followed by caspase-3, thus paving the way for PSG-1-induced apoptosis.

To the best of our knowledge, PSG-1 is also a good immune-regulated agent. It could increase macrophage phagocytosis and the levels of cytokines and nitride oxide and elicit its antitumor effect by improving immune system functions through TLR4 mediated-NF-κB and MAPK signaling pathway. The inhibition rate of PSG-1 on S180-bearing mice is about 46.52%.[27] In the present research, PSG-1 showed a better antitumor effect on the CT26-bearing mice, reaching up to 47.83%. We supposed that PSG-1 not only induced the tumor apoptosis through mitochondrial pathway but also stimulated the host immune system. To support this hypothesis, we evaluated the immunomodulatory activity of PSG-1 on CT26-bearing mice. Many effects of polysaccharides are related to the potentiation of precursor T cells after recognition of malignant cells.[42] The occurrence, development, and prognosis of tumor has a close relationship to the immune condition of the cancer patients. So we further investigated the effect of PSG-1 on immune function in CT26-bearing mice. PSG-1 was found to cause an increase in the thymus and spleen indexes dramatically. Protective immunity against tumor can be separated into two branches: cellular and humoral immunity. Immune responses play a key role in eliminating the locally growing and circulating tumor cells and, hence, lead to the suppression of growth and metastasis of tumors. In this research, cell-mediated immune defense was likely to be mediated specifically by T- and B-cells. The results of the present study suggested that PSG-1 significantly enhanced spleen lymphocyte proliferation.

In addition to the action on immune cells, another crucial function of polysaccharides is the augmentation of the cytokine level. Cytokines play a vital role in mediating the host defense, and regulate communication between antigen-presenting cells (APCs), lymphocytes, and other host effector cells during the immune response. The data of the present study clearly indicated that PSG-1 was a potent inducer of the cytokines, TNF-α, IL-2, and IFN-γ. It might also explain the enhancement of cytotoxicity of splenocytes by PSG-1 administration. Therefore, it is suggested that PSG-1 might elicit its antitumor effect by promoting immunity and killer activities.

In conclusion, PSG-1 has been shown to exhibit prominent antitumor activity in vivo, at least in part by inducing apoptosis through the mitochondrial pathway and enhancement of host immune system function. To the best of our knowledge, our results have provided new evidence to support clinical trials of PSG-1 in cancer patients in the future. PSG-1 could be a safe and effective antitumor bioactive agent or food material.

MATERIALS AND METHODS

Ethical Approval. The animal protocol followed in this study was reviewed and approved by the Bioethical Committee of our University, and guidelines for the use and care of laboratory animals of the University were followed.

Animals and Experimental Design. Virgin female Wistar rats (Charles River Laboratories Spain, SA, Barcelona, Spain), housed at 22 °C with a period of light/dark of 12 h each (lights on from 08:00 to 20:00) and with free access to food and water, were mated with male rats. The day of conception (day 0 of pregnancy) was determined by examination of vaginal smears for the presence of sperm, and then female rats were single caged. Pregnant rats were supplemented with 30% of the normal caloric intake of a group of dams fed ad libitum in the form of different fat sources (refined olive oil, margarine, or butter) during late pregnancy and lactation (from day 14 of pregnancy to day 21 of lactation), as previously described.[19] The fatty acid profile of the different fat sources has been previously described[20] and is shown in Table 1. Supplementation of the different fat sources was carried out by gavage once a day. As described,[19] no differences were observed in the total amount of kilocalories ingested by dams during the supplementation period among fat-supplemented groups. Thus, different outcomes observed in the offspring may be attributed to the different fat sources of maternal supplementation and not to the intake of different amount of calories. The offspring of these animals are referred to as olive oil, margarine, and butter groups, respectively. The offspring of dams fed ad libitum (control group) were also followed. At day 1 after delivery, excess pups in each litter were removed to keep 10 pups per dam.

Table 1. Fatty Acid Composition of Fat Sources Used in the Experimental Design[19,a]

fatty acid	olive oil	margarine	butter

[a]Data are the means of three different measurements expressed as a percentage of total fat. SFAs = saturated fatty acids, MUFAs = monounsaturated fatty acids, PUFAs = polyunsaturated fatty acids, and nd = nondetectable levels. The bold numbers indicate the total of each category of fatty acid in each fat source.

At weaning animals were fed a standard diet until the age of 4 months; then they were divided into two groups: one group continued under a normal-fat (NF) diet (standard diet containing 3.2 kcal/g, with 8% calories from fat), and the other group was exposed to a high-fat (HF) diet (containing 4.7 kcal/g, with 45% calories from fat, Research Diets, Inc., New Brunswick, NJ). The HF diet contained 5.5% calories from soybean oil and 39.5% from lard. Body mass and food intake were followed until the age of 6 months. At this age, the body fat content (by EchoMRI-700, Echo Medical Systems, LLC, Houston, TX) was recorded and blood samples were collected (in heparinized containers) from the saphenous vein, under fasting—animals deprived of food for 12 h. All groups include at least seven animals (n = 7−12).

At the age of 6 months, the animals were killed by decapitation under fed conditions, during the first 2 h of the beginning of the light cycle. The liver and various WAT depots—gonadal, retroperitoneal, mesenteric, and inguinal—were rapidly removed. All samples were weighed, immediately frozen in liquid nitrogen, and stored at −70 °C. The retroperitoneal was the depot selected as representative of the WAT to perform mRNA expression. Blood was also collected and centrifuged at 1000g for 10 min to collect the plasma, which was stored at −20 °C until analysis.

Quantification of Insulin and Glucose Concentration and Calculation of the Homeostatic Model Assessment for Insulin Resistance. The blood glucose concentration was measured with an Accu-Chek glucometer (Roche Diagnostics, Barcelona, Spain). The plasma insulin concentration was measured using a rat insulin enzyme-linked immunosorbent assay (ELISA) kit (Mercodia AB, Uppsala, Sweden) following standard procedures.

The homeostatic model assessment for insulin resistance (HOMA-IR) was used to assess insulin resistance. It was calculated from the fasting insulin and glucose concentrations using the formula of Matthews et al.:[21] HOMA-IR = [fasting glucose concentration (mmol/L) × fasting insulin concentration (mU/L)]/22.5.

Quantification of Plasma Levels of Triglycerides, Nonesterified (or Free) Fatty Acids, and β-Hydroxybutyrate and Hepatic Lipid Content. Commercial enzymatic colorimetric kits were used for the determination of plasma triglyceride (Sigma, Madrid, Spain), nonesterified (or free) fatty acids (NEFAs) (Wako Chemicals GmbH, Neuss, Germany), and 3-hydroxybutyrate (BEN S.r.l.-Biochemical enterprise) levels. Total lipids were extracted from about 600 mg of hepatic tissue and quantified by the method of Folch et al.[22]

Histological Studies. A histological study was performed on the liver. A piece of fresh dissected liver (n = 6) was fixed by immersion in 4% paraformaldehyde in 0.1 M phosphate buffer (pH 7.4) overnight at 4 °C. The samples were then washed in phosphate buffer and dehydrated in a graded series of ethanol, cleared in xylene, and embedded in paraffin blocks. Sections of the tissues 5 μm thick were stained with hematoxylin and eosin. Liver sections were classified into four grades depending on fat accumulation following the Burnt et al. classification.[23] Grade 0 was assigned when no fat accumulation was found in the liver, grade 1 when fat vacuoles were seen in less than 33% of hepatocytes, grade 2 when 33−66% of hepatocytes were affected by fat vacuoles, and grade 3 when fat vacuoles were found in more than 66% of hepatocytes. Liver images from light microscopy were digitalized and analyzed using Axio Vision software (Carl Zeiss Imaging Solutions).

RNA Extraction. Total RNA was extracted from the liver and retroperitoneal WAT by an E.Z.N.A. RNA purification system (Omega Biotek, Inc., Norcross, GA) according to the manufacturer's instructions. Isolated RNA was quantified using the NanoDrop ND-1000 spectrophotometer (NadroDrop Technologies Wilmington, DE) and its integrity confirmed using agarose gel electrophoresis.

RT-qPCR Analysis. Real-time polymerase chain reaction was used to measure mRNA expression levels of selected genes in the liver and retroperitoneal WAT in the offspring of the different groups of animals at the age of 6 months: specifically, CD36, sterol regulatory element binding protein 1c (SREBP1c), fatty acid synthase (FAS), stearoyl coenzyme A desaturase 1 (SCD1), peroxisome proliferator activated receptor α (PPARα), fibroblast growth factor 21 (FGF21), liver carnitine palmitoyltransferase 1a (CPT1L), pyruvate dehydrogenase kinase 4 (PDK4), glucokinase (GK), pyruvate kinase 4 (PK), insulin

Table 2. Body Mass, Fat Content, and Mass of Different WAT Depots and Liver of 6 Month Old Male Offspring of Dams Supplemented with 30% of the Normal Caloric Intake with Different Fat Sources (Olive Oil, Margarine, or Butter) during Late Pregnancy and Lactation[a]

		Control	Olive oil	Margarine	Butter	ANOVA
Body weight (g)	NF	450 ± 12	442 ± 10	439 ± 9	462 ± 14	D

	HF	13.8 ± 0.7	14.7 ± 0.9	13.3 ± 0.3	14.2 ± 0.6	

[a]Animals were fed a standard NF diet until the age of 4 months and then an NF or HF diet until the age of 6 months. The double vertical line indicates that the ANOVA analysis was assessed without the control group. Data are means ± SEM (n = 7−12). Statistics: D, effect of diet (NF or HF); T, effect of maternal supplementation ($p < 0.05$, two-way ANOVA). a ≠ b, LSD post hoc analysis. Key: *, different from their respective NF-diet-fed group ($p < 0.05$, Student's t test); ↑, different versus the control ($p < 0.05$, Student's t test).

receptor (INSR), and insulin receptor substrate 1 (IRS1) in the liver and lipoprotein lipase (LPL), CD36, muscle CPT1, adipose triglyceride lipase (ATGL), glucose transporter 4 (GLUT4), hexokinase II (HK), PPARγ2, SREBP1c, FAS, acetyl coenzyme A carboxylase (ACC), glycerol-3-phosphate acyltransferase (GPAT), and InsR in WAT. 18S (in liver) and β-actin (in WAT) were used as reference genes.

A 0.25 μg of total RNA (in a final volume of 5 μL) was denatured at 65 °C for 10 min and then reverse transcribed to cDNA using MuLV reverse transcriptase (Applied Biosystems, Madrid, Spain) at 20 °C for 15 min and 42 °C for 30 min with a final step of 5 min at 95 °C in an Applied Biosystems 2720 thermal cycler (Madrid, Spain). Each polymerase chain reaction (PCR) was performed from diluted (1/20) cDNA template, forward and reverse primers (1 μM each), and Power SYBER Green PCR Master Mix (Applied Biosystems, Foster City, CA). Primers, obtained from Sigma (Madrid, Spain), for the different genes are described in ref 24. Real-time PCR was performed using the Applied Biosystems StepOnePlus real-time PCR system with the following profile: 10 min at 95 °C, followed by a total of 40 two-temperature cycles (15 s at 95 °C and 1 min at 60 °C). To verify the purity of the products, a melting curve was produced after each run according to the manufacturer's instructions. The threshold cycle (Ct) was calculated by the instrument's software (StepOne Software v2.0), and the relative expression of each mRNA was calculated as previously described.[25]

Western Blot Analysis of ATGL in Retroperitoneal WAT. The amount of ATGL in retroperitoneal WAT was determined by Western blot. This protein was chosen because it is considered to be the main triacylglycerol lipase in adipose tissue and catalyzes the first step of lipid hydrolysis.[26] Briefly, tissue was homogenized at 4 °C in 1:5 (w/v) in RIPA buffer containing Halt protease and phosphatase inhibitor cocktail (Thermo Fisher, Rockford, IL). Western blot was performed in a 4−15% Criterion TGX precast gel (BioRad, Madrid, Spain), transferred to a nitrocellulose membrane. ATGL antibody was obtained from Cayman Chemical (Ann Arbor, MI). Membranes were also incubated with anti-β-actin antibody (Cell Signaling, Inc., Hercules, CA) to ensure the equal loading. Specific infrared (IR)-dyed secondary anti-IgG antibodies (LI-COR Biosciences, Lincoln, NE) were used. For IR detection, membranes were scanned in an Odyssey imager (LI-COR); the bands were quantified using the software Odyssey v3.0 (LI-COR).

Statistical Analysis. All data are expressed as the mean ± SEM (n = 7−12). Multiple comparisons were assessed by repeated measures ANOVA and two-way ANOVA to determine the effects of different factors (maternal fatty acid source supplementation and type of diet). Differences between groups were assessed by one-way ANOVA followed by least significant difference (LSD) post hoc comparison to assess statistical differences between the groups. Single comparisons were assessed by Student's t test or pair t test analysis. Principal component analysis (PCA) was performed to assess relationships between the adiposity of the animals, the lipid content in the liver, and the expression levels of the genes measured in the liver and WAT (a total of 27 variables). Two PCA models were constructed, one for all samples receiving the NF diet and another for all those receiving the HF diet. The score plot of PC1 versus PC2 was used to examine the potential contribution of these components to discriminate the four groups of animals (control, olive oil, margarine, and butter). The analyses were performed with SPSS for Windows (SPSS, Chicago, IL). The threshold of significance was defined at $p < 0.05$.

RESULTS

Body Mass, Body Fat, and Hepatic Lipid Content. As previously described for the same cohort of animals,[19] no significant differences were found regarding the body mass of

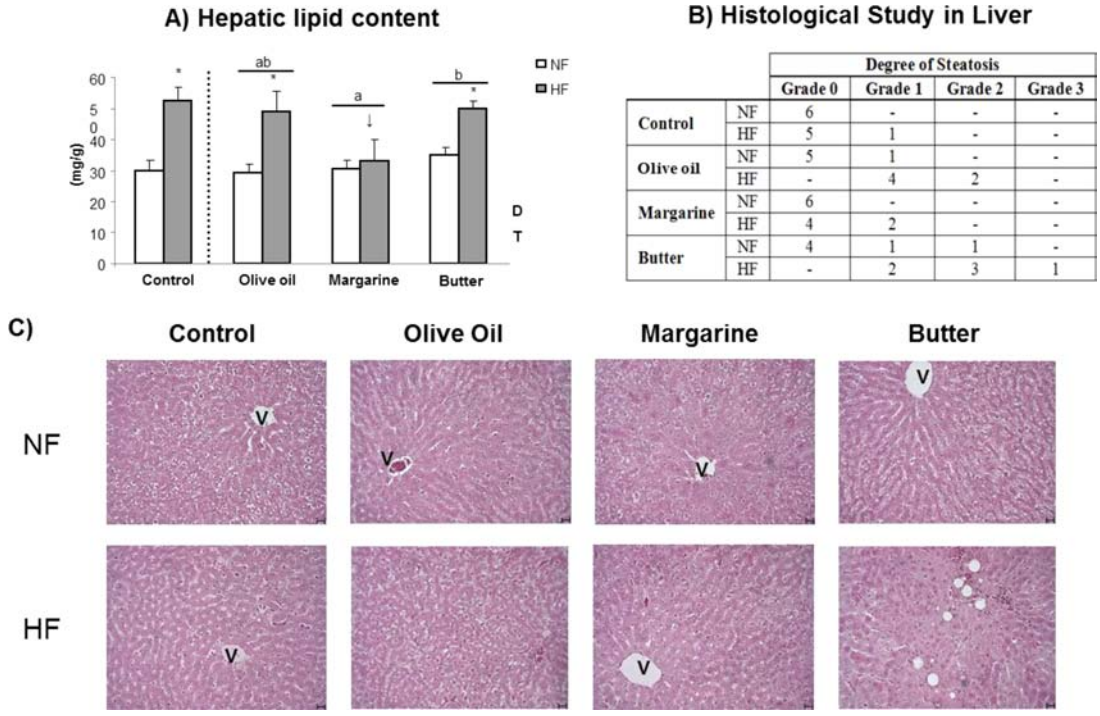

Figure 1. (A) Hepatic lipid content, (B) numerical grading of NASH in liver biopsies, and (C) representative hematoxylin and eosin staining of histological liver samples from 6 month old male offspring of dams supplemented with 30% of the normal caloric intake with different fat sources (olive oil, margarine, or butter) during late pregnancy and lactation. Animals were fed a standard NF diet until the age of 4 months and then an NF or HF diet until the age of 6 months. Scale bar = 20 μm. V = terminal hepatic venule. The dotted line indicates that the ANOVA analysis was assessed without the control group. Data are the mean ± SEM (n = 7−12). Statistics: D, effect of diet (NF or HF); T, effect of maternal supplementation ($p < 0.05$, two-way ANOVA). a ≠ b, LSD post hoc analysis. Key: *, different from their respective NF-diet-fed group ($p < 0.05$, Student's t test); ↓, different versus the control ($p < 0.05$, Student's t test).

Table 3. Circulating Glucose, Insulin, Nonesterified Fatty Acid (NEFA), Triglyceride, and β-Hydroxybutyrate Levels and HOMA-IR in Male Offspring of Dams Supplemented with 30% of the Normal Caloric Intake with Different Fat Sources (Olive Oil, Margarine, or Butter) during Late Pregnancy and Lactation, at 6 months of Age under ad Libitum Feeding Conditions, and after 12 h of Fasting[a]

	Control		Olive oil		Margarine		Butter
